**Release Studies.** *Release Assay in Food Simulants.* Ferulic acid-imprinted polymers were cut in pieces of 1 × 1 cm$^2$. These polymer samples were placed in 60 mL amber flasks in contact with 50 mL of the selected simulants and substitutes (10% EtOH (v/v), 20% EtOH (v/v), 50% EtOH (v/v), 3% acetic acid (w/v), 95% EtOH (v/v), and isooctane), representatives of the main foods that may be intended this antioxidant. All assays were done in triplicate. Likewise, the migration tests in vegetable oil were performed by total immersion.

The time−temperature conditions for each simulant are presented in Table 2. The kinetics release of ferulic acid into 20% EtOH (v/v) and 3% acetic acid (w/v) was only conducted at 25 °C. Aliquots of 0.5 mL were removed at selected time intervals. In the case of isooctane, it was evaporated under a nitrogen vapor stream, and then the residue was dissolved in 0.5 mL of MeOH. After that, all samples were filtered through a 0.45 $\mu$m PTFE membrane filter (Advanted, Toyo Roshi Kaisha, Ltd., Japan).

*Release Assay in Food Samples.* Chicken samples were halved in two pieces, one of them containing the stuffing and the other one the chicken breast. Ferulic acid-imprinted polymers were cut in pieces of 0.5 × 3 cm$^2$. All of them, food samples and the polymeric materials, were accurately weighed. In each piece of chicken, a precise incision was done in the most homogeneous area and ferulic acid-imprinted polymer MIP was incorporated in it. Then, the set was wrapped in aluminum foil, packed in plastic bags, and sealed.

**Table 2. Time−Temperature Conditions for Migration Assays in Food Simulants and Real Food**

| food simulant/real food | temperature (°C) | time (h) |
|---|---|---|
| 10% EtOH (v/v) | 4 | 3, 6, 9, 12, 24, 48, 72, 144, 192, 240, 312, 384, 480, 528, 576, 672, 840 |
| | 20 | 3, 6, 9, 12, 24, 48, 72, 144, 192, 240, 312, 384, 480, 528, 576, 672, 840 |
| 3% acetic acid (w/v) | 25 | 1, 7, 17, 41, 53, 70, 91, 114, 138, 158, 264, 370, 476, |
| 20% EtOH (v/v) | 25 | 1.8, 7.8, −, −, 53.8, 70.8, 91.8, 114.8, −, 158.8, 264.8, 370.8, 476.8 |
| 50% EtOH(v/v) | 4 | 3, 6, 9, 12, 24, 48, 72, 144, 192, 240, 312, 384, 480, 528, 576, 672, 840 |
| | 20 | 3, 6, 9, 12, 24, 48, 72, 144, 192, 240, 312, 384, 480, 528, 576, 672, 840 |
| 95% EtOH (v/v) | 4 | 3, 6, 9, 12, 24, 48, 72, 96, 168, 240, 336, 528 |
| | 20 | 3, 6, 9, 12, 24, 48, 72, 96, 168, 240, 336, 528 |
| isooctane | 4 | 3, 6, 9, 12, 24, 48, 72, 96, 168, 240, 336, 528 |
| | 20 | 3, 6, 9, 12, 24, 48, 72, 96, 168, 240, 336, 528 |
| chicken roti | 4 | 24, 48, 120, 168, 216, 312, 360, 504, 576, 660 |

The samples were stored at 4 °C, and at each selected time the samples were withdrawn. Packages were carefully unwrapped, and the polymeric material was removed, cleaned, and extracted. The time−temperature conditions for the assay are presented in Table 2.

*Extraction Procedure of Ferulic Acid from the Polymeric Materials.* Ferulic acid was extracted from MIPs by placing them in amber flasks of 60 mL hermetically closed with 50 mL of pure MeOH. Then, they were stored at 40 °C during 24 h. After the extraction time, an aliquot was taken, filtered through a 0.45 μm PTFE membrane filter (Advanted, Toyo Roshi Kaisha, Ltd., Japan), and analyzed by HPLC.

In migration studies, the quantification of migrants transferred is usually measured in the food. However, due to the fact that foods are complex matrices, the extraction processes are difficult and lead to very laborious and time-consuming methods and losses related to the existence of several steps. For this reason, to avoid all of these problems, instead of determining the quantity of migrants in the foodstuff, the migrant that remained in the polymer was determined and it was assumed that all of the missing migrant was in the food.

In this case, the concentration of the ferulic acid released was indirectly calculated as the difference between the initial concentration and the concentrations at selected time intervals in the polymer.

To verify if the extraction had been complete, the MIP hydrogel was cleaned with MeOH to remove any remaining migrant that came from the methanolic extraction solution, and it was submitted to a second extraction under the same conditions.

**Equipment and Chromatographic Conditions.** *HPLC-DAD.* Chromatographic analyses were performed on a HP1100 system (Hewlett-Packard, Waldbronn, Germany) consisting of a quaternary pump, a degassing device, an autosampler, a column thermostating system, a diode array detector (DAD), and an Agilent Chemstation for LC and LC/MS system software. A Kromasil ODS (C18) (150 × 3.20 mm i.d., 5 μm) column thermostated at 35 °C was used. The mobile phases consisted of A (MeOH) and B (0.1% acetic acid (v/v) water). The gradient elution program was as follows: 0−2 min, mobile phase isocratic at 10% A; 2−10 min, linear gradient from 10 to 100% A followed by washing (10−18 min 100% A); and finally re-equilibration of the column. The flow rate was 0.5 mL/min and the injection volume 20 μL. The ferulic acid retention time was ($t_R$ = 9.343 min). Chromatograms were registered at 325 nm.

Identification of ferulic acid was made by comparison of the retention time and UV spectrum with those of a pure standard.

Quantification was performed on the basis of linear calibration plots of peak area against concentration. A calibration line was constructed based on six concentration levels of standard solutions within the 0.1−10 mg/L range, and it was fitted to a linear equation $y = 214.88x - 9.6896$ ($R^2 = 0.99995$).

The limits of detection and quantification (defined as a signal 3 and 10 times, respectively, the height of the noise level), determined in accordance with American Chemical Society (ACS) guidelines,[32] were 0.05 and 0.1 mg/L, respectively.

*HPLC-MS as a Confirmatory Technique.* For confirmation purposes a LC-MS/MS system comprising an Accela autosampler and an Accela 1250 pump fitted with a degasser and a column oven coupled to a triple-quadrupole mass spectrometer TSQ Quantum Access max controlled by Xcalibur was used (Thermo Fisher Scientific, San Jose, CA, USA). Mass data were acquired in the negative ion mode employing electrospray ionization (ESI). Mass spectra were monitored in the mass range $m/z$ 150−225. Nitrogen was used as sheath gas (pressure = 35 psi) and as auxiliary gas (pressure = 10 arbitrary units), and argon was used as the collision gas (1.5 mTorr). Optimized MS/MS detector settings were as follows: spray voltage, 2500 V; vaporizer temperature, 340 °C; and capillary temperature, 350 °C.

With regard to LC-MS chromatographic conditions, the mobile phase consisted of A (MeOH) and B (Milli-Q water), whereas the column and the gradient elution system were the same as for HPLC-DAD analysis.

*Identification of Monomers by GC-MS.* The monomers and starting substances used in the fabrication of MIPs were identified by GC-MS (FisonsGC8000 series gas chromatograph, mass selective detector MD800, Manchester, UK). Briefly, approximately 300 mg of material was place in a glass container with 20 mL of methanol and extracted for 24 h at 40 °C. After that, the material was separated from the solution, and an aliquot of 1 μL was removed, filtered, and injected into the GC-MS. A ZB-5 MS (Zebron Capillary GC column from Phenomenex, USA) (30 m × 0.25 mm i.d. × 1 μm film thickness) column was used. Helium was used as carrier gas at a flow rate of 1 mL/min. The ramp temperature was initially set at 40 °C for 4 min, then raised at the rate of 15 °C/min to 150 °C, then increased at 30 °C/min until 200 °C, and held for 10 min. The injector temperature and the split ratio were 175 °C and 1:30, respectively. The MS detector was operated in the full scan mode with an acquisition range of $m/z$ 33−300.

**Mathematical Model.** *Calculation of Partition Coefficients MIP/Food (Food Simulant/Substitute) ($K_{P/S}$).* Partition coefficients between MIP and food or food simulants were calculated according to the equation

$$K_{P/S} = \frac{C_P}{C_S}$$

where $K_{P/S}$ is the partition coefficient between the MIP and the food, food simulant, or substitute. $C_P$ is the concentration of substance in the MIP at equilibrium, in μg/g. $C_S$ is the concentration of substance in the simulant at equilibrium, in μg/g.

*Calculation of Diffusion Coefficients.* A mathematical model based on Fick's second law to assess ferulic acid release from MIPs into the food and food simulants was employed.

$$\frac{\partial C_P}{\partial t} = D\frac{\partial^2 C_P}{\partial x^2}$$

$C_p$ is the concentration of the migrant in the polymer at time $t$ (s) and position $x$, and $D$ is the diffusion coefficient in P ($cm^2/s$).

An analytical solution of this differential equation, proposed by Crank,[33] is usually employed to determine the diffusion coefficient; after a small modification, it can be expressed by the equation[34]

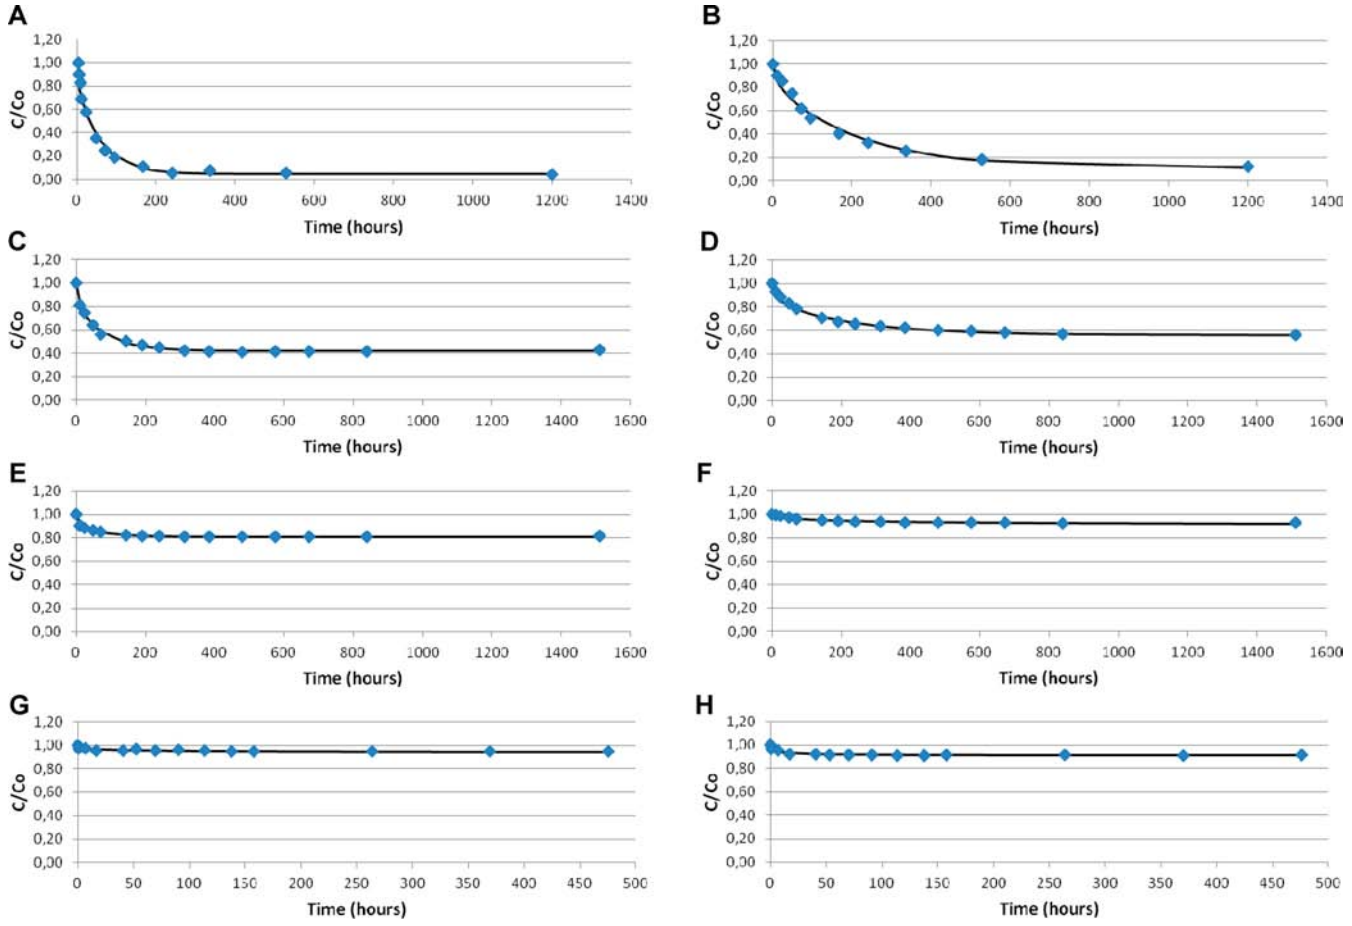

**Figure 1.** Diffusion of ferulic acid from MIP into 95% EtOH (v/v) food substitute at 20 °C (A), into 95% EtOH (v/v) food substitute at 4 °C (B), into 50% EtOH (v/v) food simulant at 20 °C (C), into 50% EtOH (v/v) food simulant at 4 °C (D), into 10% EtOH (v/v) food simulant at 20 °C (E), into 10% EtOH (v/v) food simulant at 4 °C (F), into 20% EtOH (v/v) food simulant at 25 °C (G), and into 3% acetic acid (w/v) food simulant at 25 °C (H).

$$\frac{m_{F,t}}{A} = C_{P,0}\rho_P d_P\left(\frac{\alpha}{1+\alpha}\right)\times\left[1-\sum_{n=1}^{\alpha}\frac{2\alpha(1+\alpha)}{1+\alpha+\alpha^2 q_n^2}\exp\left(-D_P t\frac{q_n^2}{d_P^2}\right)\right]$$

$$\alpha = \frac{1}{K_{P/F}}\frac{V_F}{V_P}$$

where $m_{F,t}$ is the mass of the migrant transferred from P into F after time $t$ ($\mu$g); $A$ is the area of P in contact with F (cm$^2$); $C_{P,0}$ is the initial concentration of the migrant in P (mg/kg); $\rho_P$ is the density of P (g/cm$^3$); $t$ is the migration time (s); $d_P$ is the thickness of P (cm); $V_P$ is the volume of P (cm$^3$); $V_F$ is the volume of F (cm$^3$); $q_n$ is the positive roots of the equation $\tan q_n = -\alpha q_n$; $D_P$ is the diffusion coefficient of the migrant in the polymer (cm$^2$/s); and $K_{P/F}$ is the partition coefficient of the migrant between P and F.

## RESULTS AND DISCUSSION

Ferulic acid molecularly imprinted polymers (MIPs) were developed as a novel controlled release system to be applied as an active food packaging.

To assess the safety and suitability of the active materials developed for use as food contact materials, overall migration tests were conducted. The overall migration assays evaluate the total amount of nonvolatile substances released from the material into food simulants. The migration tests were performed under the time−temperature conditions that represent the worst possible scenario for the intended applications, namely, any long-term storage at room temperature or below. After migration tests, no physical changes were observed in the materials, and all overall migration results were lower than the limit (<10 mg/dm$^2$) established by Commission Regulation (EU) No. 10/2011;[31] thus, the ferulic acid-imprinted polymers (MIPs) comply with food contact materials legislation regarding this limit.

The release behavior of ferulic acid from the new active system into food simulants and food was investigated. High-performance liquid chromatography with diode array detector (HPLC-DAD) was used to quantify ferulic acid. HPLC-MS was used for confirmatory purposes, and the characteristic mass corresponding to the deprotonated molecular ion $[M-H]^-$ was detected.

The monomers used in the molecularly imprinted hydrogel preparation were successfully identified by GC-MS by means of comparison of their mass spectra with the Wiley mass spectrum library.

For these release studies it is crucial to establish the initial concentration of the active compound that is present in the developed material. Thus, the determined concentration of the antioxidant in the developed MIPs before the release studies was 30.8 mg/g (RSD 5%, $n$ = 6).

Table 3. Diffusion and Partition Coefficients and RMSE Values for the Food Simulants and Real Food Samples

| food simulant/real food | temperature (°C) | $K_{P/F}$ exp | $K_{P/F}$ est | $D$ ($cm^2/s$) | RMSE % |
|---|---|---|---|---|---|
| 10% EtOH (v/v) | 4 | $4.2 \times 10^3$ | $3.2 \times 10^3$ | $1.8 \times 10^{-11}$ | 0.60 |
| | 20 | $2.1 \times 10^3$ | $1.5 \times 10^3$ | $8.0 \times 10^{-10}$ | 0.28 |
| 50% EtOH (v/v) | 4 | $3.4 \times 10^2$ | $4.4 \times 10^2$ | $5.0 \times 10^{-10}$ | 1.33 |
| | 20 | $1.9 \times 10^2$ | $2.5 \times 10^2$ | $1.8 \times 10^{-9}$ | 1.10 |
| 95% EtOH (v/v) | 4 | $3.6 \times 10^1$ | $4.4 \times 10^1$ | $9.3 \times 10^{-10}$ | 3.93 |
| | 20 | $1.4 \times 10^1$ | $3.5 \times 10^1$ | $4.2 \times 10^{-9}$ | 1.37 |
| 20% EtOH (v/v) | 25 | | $1.9 \times 10^3$ | $1.6 \times 10^{-10}$ | 0.43 |
| 3% acetic acid (w/v) | 25 | | $1.1 \times 10^3$ | $8.7 \times 10^{-10}$ | 0.47 |
| chicken roti | 4 | $6.1 \times 10^1$ | $1.0 \times 10^2$ | $5.1 \times 10^{-10}$ | 8.6 |

With regard to the release studies, Figure 1A−G shows the relative amount ($C/C_0$) of ferulic acid in the ethanolic food simulants at different temperatures. For the ferulic acid MIP−95% EtOH (v/v) system, the percentages of release at 4 and 20 °C were 82.0 and 85.9%, respectively, after equilibrium was reached.

In general, a decrease in the EtOH content in food simulants resulted in lower amounts of the antioxidant released; thus, in the food simulant 50% EtOH (v/v), the release of ferulic acid was 38.6 and 44.9% at 4 and 20 °C, respectively. In the case of 10% EtOH (v/v), the percentages of release were 6.5% at 4 °C and 10% at 20 °C. For the 20% EtOH (v/v) the delivery kinetics was only carried out at 25 °C.

The delivery of ferulic acid into the food simulant 3% acetic acid (w/v) at 25 °C is illustrated in Figure 1H. The percentage of release (8.7%) was higher than that obtained in simulant EtOH (20% v/v) at the same temperature.

No release of the antioxidant was observed at the quantification level in the vegetable oil and isooctane (LOQ = 0.1 μg/mL). This fact could be explained because of the scarce solubility of ferulic acid in these food simulants.

To characterize the kinetic release process, the partition coefficient ($K_{P/F}$) and the diffusion coefficient ($D$) were determined.

The partition coefficient ($K_{P/F}$) indicates the relative solubility of the active compound between the MIP and the food simulant or food when the equilibrium is reached. Values of $K_{P/F} > 1$ indicate that the active compound is found in greater concentration in the polymer (MIP) than in the food or food simulant.[35−40] The experimental and estimated $K_{P/F}$ values of ferulic acid in food simulants are presented in Table 3. The lower values at the temperatures studied correspond with the food simulant 95% EtOH (v/v), which are in good agreement with the higher percentages the release of the antioxidant. On the contrary, the highest values correspond to 10% EtOH (v/v), indicating the tendency of ferulic acid to remain in the polymer (MIP) rather than be delivered into the food simulant. As can be seen in Table 3 there was a good correlation between the $K_{P/F}$ values calculated from experimental data and those theoretically estimated. The diffusion coefficients of ferulic acid determined in the MIP−food simulant systems are presented in Table 3. The values obtained ranged between $1.8 \times 10^{-11}$ and $4.2 \times 10^{-9}$ $cm^2/s$. As expected, $D$ increased with the temperature, and for the ethanolic simulants $D$ also increased with the percentage of EtOH in the food simulant; therefore, the faster diffusion occurred in 95% EtOH (v/v). Because no migration occurred in isooctane and vegetable oil, $D$ was not calculated.

López-de-Dicastillo et al.[41] found values within the range from $1 \times 10^{-14}$ to $1 \times 10^{-13}$ for the diffusion of ferulic acid from an active antioxidant packaging films based on an ethylene vinyl alcohol copolymer (EVOH) matrix into water, 10% EtOH, and 95% EtOH at 37 °C.

When compared to the diffusion of other antioxidants, the $D$ values obtained in the present work were within the same range as those obtained in a study conducted by Ortiz-Vázquez et al.,[42] in which they investigated the release of BHT from poly(lactic acid) (PLA) films into 95% EtOH at different temperatures ($(0.295−19.04) \times 10^{-10}$ $cm^2/s$). Manzanarez-López et al.[43] studied the migration kinetics of α-tocopherol from PLA films in EtOH and reported values between $3.16 \times 10^{-11}$ and $38.00 \times 10^{-11}$ $cm^2/s$. Lower $D$ values ($4.60 \times 10^{-10}$−$6.58 \times 10^{-12}$ $cm^2/s$) for α-tocopherol in a low-density polyethylene (LDPE)/polypropylene blend films−95% EtOH system were reported by Zhu et al.[44]

Iñiguez-Franco et al.[35] determined the diffusion of two polyphenols, catechin and epicatechin, from PLA films into different ethanolic simulants; the $D$ values obtained were between $0.49 \times 10^{-11}$ and $51.2 \times 10^{-11}$ $cm^2/s$. Higher $D$ values were found for resveratrol from PLA films into EtOH ($(3.06−82.60) \times 10^{-11}$ $cm^2/s$[45]). These values were in general lower than those obtained in this study for ferulic acid.

The results indicate that using MIP hydrogels as active packaging systems enables controlled release through extended periods (4−6 days) compared with EVOH films,[41] so it is possible to prolong the shelf life of the food over more time. This advantage is related to the strong binding of the FA toward the active sites of the MIP films, which is in concordance with the higher binding properties that MIP polymers display.[30]

A wide range of diffusivities ($(0.19−176.1) \times 10^{-10} cm^2/s$) were reported by Jamshidian et al.,[46] who evaluated the release of synthetic phenolic antioxidants from extruded poly(lactic acid) (PLA) films into food simulants at 20 and 40 °C. Similar values of diffusivity were obtained for solvent-cast PLA films.[47]

The release kinetics of ferulic acid from the active system developed in real samples was also studied; for that purpose a stuffed chicken roast was selected as foodstuff. The release tests were conducted as described under Materials and Methods. As has been pointed out earlier, the ferulic acid remaining in the MIP was quantified instead of the antioxidant delivered into the food to avoid the analytical problems associated with the extraction of the compound in the food matrix. Figure 2 illustrates the delivery of ferulic acid from the MIP into the food sample; the percentage of release was 98% at equilibrium. The key parameters of the release process and partition and diffusion coefficients are listed in Table 3. A middle rate of release was obtained, so the active system developed could be useful for the intermediate-term protection of packed foods against lipid oxidation and consequently extend their shelf life.

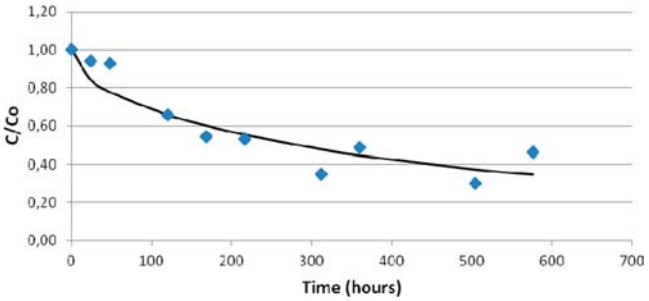

**Figure 2.** Diffusion of ferulic acid from MIP into chicken roti.

For the ferulic acid release studies, the food simulant that represents most appropriately the behavior of stuffed chicken roast samples seems to be 50% ethanol (v/v).

The Arrhenius equation was used to study the effect of the temperature on the diffusion of ferulic acid from the MIP into ethanolic food simulants.

$$D = D_0\, e^{-E_A/RT}$$

$D$ is the diffusion coefficient ($cm^2/s$), $D_0$ is the preexponential factor ($cm^2/s$), $E_A$ is the activation energy (kJ/mol), $R$ is the gas constant (kJ/mol K), and $T$ is the temperature (K).

The $E_A$ was determined from the slope by representing the $1/T$ versus the logarithm of $D$. The determination was performed using the data obtained in this work (two temperatures) and assuming a linear behavior within this range. The $E_A$ is the energy necessary for a given compound to move through the polymeric matrix.[48,49] The $E_A$ and $D_0$ values for the systems studied are presented in Table 4. Higher values

**Table 4. $E_A$ and $D_0$ Values for the Systems Studied**

| food simulant | $D_0$ | $E_A$ |
|---|---|---|
| 10% EtOH (v/v) | $2.23 \times 10^{19}$ | 159.6 |
| 50% EtOH (v/v) | 8.23 | 54.20 |
| 95% EtOH (v/v) | $7.58 \times 10^{2}$ | 63.20 |

of $E_A$, 175−177 and 164.7 ± 27.7 kJ/mol, were obtained for other antioxidants (resveratrol and butylated hydroxytoluene (BHT)) incorporated into poly(lactic acid) matrices[42,45]). This indicates that less energy is required for the diffusion of ferulic acid from the MIP hydrogels into the food simulants studied compared to resveratrol and BHT from PLA into EtOH.

With the aim of measuring the fit between the experimental and estimated data, the root of mean-square error percent (RMSE (%)) was calculated according the following equation:

$$\text{RMSE (\%)} = \frac{1}{M_{P,0}}\sqrt{\frac{1}{n}\sum_{i=1}^{n}((M_{F,t})_{exp,i} - (M_{F,t})_{pred,i})^2} \times 100$$

$n$ is the number of experimental points per migration/release curve, $i$ is the number of observations, and $M_{P,0}$ is the initial amount of the migrant in the polymer ($\mu g$).

RMSE (%) values <4 were obtained in all food simulants, indicating that there was a very good fit between the experimental and estimated data. A low RMSE value (8.6%) was also obtained for the real food chicken roti. This means that this model can be used to predict the release of ferulic acid into food simulants and food matrices.

In brief, an active system based on molecularly imprinted polymers for the sustained delivery of ferulic acid was developed. The release kinetics of ferulic acid into food simulants and one real sample were studied. The diffusion coefficients were calculated by using a mathematical model based on Fick's second law, and the values obtained ranged between $1.8 \times 10^{-11}$ and $4.2 \times 10^{-9}$ $cm^2/s$. Both the temperature and the percentage of EtOH of the simulant affected the diffusion. The proposed system could be used as an antioxidant controlled release packaging to inhibit or delay lipid oxidation.

Table 1. Mineral Concentrations in Wheat Samples[a]

| wheat fractions | minerals (mg/100 g dry weight) | | | | | |
|---|---|---|---|---|---|---|
| | Fe | Mn | Zn | Ca | Mg | Cu |
| aleurone | 14.0 ± 0.36 | 9.50 ± 0.29 | 10.02 ± 0.29 | 102 ± 1.13 | 792 ± 6.7 | 1.53 ± 0.11 |
| aleurone (micromilled) | 12.7 ± 0.05 | 6.81 ± 0.11 | 8.15 ± 0.18 | 91.0 ± 0.09 | 660.1 ± 0.41 | 1.30 ± 0.04 |
| whole wheat | 3.5 ± 0.05 | 4.71 ± 0.55 | 3.18 ± 0.09 | 40.4 ± 0.47 | 139.6 ± 3.4 | 0.47 ± 0.02 |
| whole wheat (micromilled) | 3.5 ± 0.10 | 4.02 ± 0.07 | 2.99 ± 0.03 | 39.5 ± 0.63 | 129.3 ± 2.2 | 0.36 ± 0.04 |

[a]Values are means ± SEM ($n$ = 4).

charred over a Bunsen burner flame at a low heat to eliminate smoke before placing in a muffle furnace at 525 °C for 3 h hours during which all the organic matter was oxidized leaving remnants of clean white ash. Samples were oven-dried for 48 h, cooled in a desiccator, and reweighed. Fe, Mg, Zn, Ca, and Mn concentrations in the samples were analyzed using inductively coupled plasma optical emission spectrometry (ICP-OES, Thermo-Fisher). Plasma parameters and sample aspiration methods were performed according to the manufacturer's recommendations. Mineral concentrations were extrapolated from the standard curve in the range of 0.1−10 μg/mL. The internal standard, yttrium (Merck Millipore), was added to each sample according to manufacturer's specification to correct for sample losses due to volatility and evaporation.

**In Vitro Peptic−Pancreatic Digestion.** Samples were digested by simulated peptic−pancreatic digestion.[13] Enzymes and bile extract were demineralized with Chelex-100 (Bio-Rad Laboratories Ltd., Hercules, CA) before performing the experiments. The weight of samples used for experiment was calculated according to iron content in different samples to ensure that equal amounts of iron (150 μg) were used for digestion experiments. Following this, known weights of samples (in quadruplicate) were added to 10 mL of isotonic saline solution (140 mM NaCl and 5 mM KCl) and were adjusted to pH 2.0 with HCl (1 M). During peptic digestion, 0.5 mL pepsin (16 mg/mL) was added, and the mixture was incubated at 37 °C for 75 min followed by pH adjustment to 5.5 with $NaHCO_3$ (1 M) to stop peptic digestion. Afterward, 2.5 mL of bile−pancreatin extract (8.5 mg/mL bile extract and 1.4 mg/mL pancreatin) was added and pH was adjusted to 7.0 with $NaHCO_3$ (1 M) to start pancreatin−bile digestion. The volume was brought to 15 mL by adding isotonic saline solution, and the mixture was incubated at 37 °C for 120 min. Following digestion, tubes were centrifuged at 3000$g$ for 5 min and of the digests supernatant of digests was retained for experiment.

**Cell Culture.** Caco-2 cells (ATCC; HTB-37) at passage 28 were used for the experiments. Cells were grown in Dulbecco's modified Eagle's medium (DMEM, Gibco, Life Technologies, U.K.), which contained 1% antibiotic/antimycotic solution, 25 mM HEPES, and 10% fetal bovine serum. For the experiment, cells were trypsinized and seeded into 6-well plates at a density of 50 000 cells in 2.5 mL of DMEM. Cells were incubated at 37 °C with 5% $CO_2$ and 95% air for 14 days while the medium was changed every 2 days.

The day before experiments, DMEM was replaced with minimum essential medium (MEM, Gibco Life Technologies, U.K.) containing 10 mmol/L PIPES, 1% penicillin and streptomycin, 11 μM dexamethasone, and 0.87 μM insulin, and the cells were incubated at 37 °C for 24 h. Afterward fresh MEM (2 mL) was added to the cells. An amount of 1.5 mL of each digest was pipetted into cellulose dialysis tubing (15 000 Da molecular weight cutoff dialysis membranes (Tubing Spectra/Por 7 dialysis membrane, Fisher Scientific) that were exposed to the medium bathing the cells. Cells were then incubated at 37 °C for 2 h for iron uptake. The baseline control was incubated with only MEM medium. Following that, the digest was removed, 1 mL of supplemented MEM was added to the cells, and these were incubated for a further 22 h. Following this incubation period, cells were washed with PBS and lysed with mammalian protein extraction reagent (MPER, Thermo Fisher Scientific, Cramlington, U.K.). The cell lysate was centrifuged (5 min, 16 000$g$) to remove cell debris, and the supernatant used for ferritin and protein analysis. Thereafter, cells were harvested in 200 mL of PER protein lysate solution (Thermo Scientific) and analyzed for ferritin content using a commercially available ELISA (Ramco Laboratories, TX, U.S.A.). Experiments were carried out in triplicate and data expressed as nanograms of ferritin per milligram of cell protein.

**In Vitro Digestion with Driselase.** Wholegrain wheat flour was digested with Driselase (EC286-055-3), an enzyme mixture containing laminarinase, xylanase, and cellulase activity that hydrolyses cell walls of plants. Two milliliters of enzyme solution (1 unit/mL) was made by mixing 100 μL of 2% Driselase (w/v) with 1.9 mL of buffer (1.33 mL of 50 mM sodium acetate and 0.57 mL of 50 mM acetic acid, pH 2.5). An amount of 100 mg of wholegrain wheat flour was added to 2 mL of enzyme solution, and this was incubated at 37 °C for 6 h. The control group was incubated with the buffer without Driselase. After digestion, tubes were centrifuged at 3000$g$ for 5 min and the supernatant was saved for measurement of soluble iron afterward.

**Iron Solubility from Wheat Samples.** The amount of soluble iron was analyzed using the ferrozine assay.[14] The blank solution consisted of enzymes without the wheat samples. One milliliter of supernatant from each of the digests, the blank, and the standards was added to microfuge tubes (Figure 2). To this was added 0.1 mL of solution containing 10% HCl (v/v) and 5% hydroxylamine hydrochloride (w/v), mixed, and incubated at room temperature for 30 min. Afterward, 0.1 mL of a solution containing 5 mg/mL ferrozine and 1 M 4-(2-hydroxyethyl)-1-piperazineethanesulfonic acid (HEPES) buffer was added, mixed, and allowed to stand at room temperature for 1 h. Finally, the absorbance of the solutions was measured in a spectrophotometer (Camspec M330 UV−vis) at 562 nm. Standard solutions containing 0.015−0.5 μg/mL $FeCl_3$ were prepared and treated as with the samples.

**Microscopic Localization of Iron in Wheat Aleurone Layer.** The localization of iron and the structure of AL observed under the microscope after staining with Perl's Prussian blue according to a protocol described by Wang and Cuschieri.[15] The stain used was a mixture of 2.5% potassium ferrocyanide (w/v) in 2.5% HCl (v/v). Approximately 50 mg of wheat sample and 500 μL of Perl's Prussian blue solution were placed in 1.5 mL microfuge tubes and incubated at room temperature for 30 min before examination with a light microscope (Axioskop 2 mot plus, Car-Zeiss, U.K.) to reveal tissue structure and iron deposits in the AL.

**Animal Studies.** Changes to the structure of AL and the iron content of the aleurone cells in different regions of the gastrointestinal tract and in feces were also determined. Eight male 6 weeks old C57BL/6 mice (Charles Rivers, Kent, U.K.) were used for the studies. Mice were fasted overnight and then fed in two groups of four mice, wholegrain wheat flour or aleurone flour ad libitum for 24 h to allow complete transit through the gastrointestinal tract. Mice were housed in a light- and temperature-controlled room with ad libitum access to deionized water.

Following the feeding of flour for 24 h, mice were anaesthetized, and sacrificed by cervical dislocation and contents of the stomach, duodenum, jejunum, ileum, and colon contents as well as feces from the mice were removed and placed in tubes for microscopic examination. Perl's Prussian blue staining and light microscopic examination in each sample was performed as described above. All procedures were conducted in accordance with methods approved by the United Kingdom Animals (Scientific Procedures) Act 1986.

**Statistical Analysis.** Data were analyzed with Microsoft Office Excel 2010 and SPSS software 20.0.0 (SPSS Inc., U.S.A.). Data are shown as mean ± SEM. Comparison of means was analyzed either by Student's unpaired $t$ test or one-way analysis of variance (ANOVA)

with Turkey's post-test for multiple comparisons. Significant differences were considered at $P < 0.05$.

## RESULTS

**Mineral Analysis in Wheat Samples.** Table 1 shows the mineral content of wholegrain wheat and aleurone samples. Mineral concentrations were significantly enriched in the aleurone fraction compared with the whole wheat samples, with iron in particular being some 3−4-fold enriched. The mineral content of wholegrain and aleurone flour was not significantly altered following micromilling.

**Microscopic Localization of Iron in Wheat Products.** Light microscopy revealed the localization of iron in the aleurone layer of whole wheat (Figure 1). Aleurone cells were largely resistant to in vivo digestion during transit along the gastrointestinal tract. Microscopic examination of digests from mice that were fed aleurone flour overnight revealed iron-stained globules encased within aleurone cells obtained from different regions of the gastrointestinal tract (Figure 2A−E) and also in fecal contents (Figure 2F).

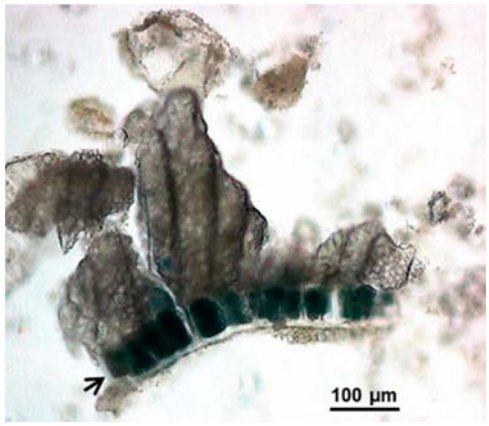

**Figure 1.** Localization of iron in the aleurone layer of whole grain wheat flour. Wheat flour treated with Perl's Prussian blue solution and visualized under the microscope revealed a single blue-stained aleurone layer (arrow).

**In Vitro Iron Solubility from Aleurone Samples.** The aleurone cell walls were disrupted by enzymatic digestion with Driselase (Figure 3, parts A and B) and by micromilling (Figure 3, parts C and D). Next we investigated whether enzymatic or mechanical disruption of aleurone cells would alter bioaccessibility of iron. Following Driselase treatment (Figure 4A) and mechanical disruption through micromilling there was a significant increase in iron solubility in aleurone and whole wheat samples (Figure 4B).

**Micromilling and Iron Availability in Wheat Aleurone.** To determine whether mechanical disruption of the aleurone cell layer increased iron solubility and in turn led to increased iron bioaccessibility, we employed a model of in vitro digestion/cell iron uptake.[13] Micromilling of purified aleurone flour and wholegrain wheat flour (Figure 5) significantly enhanced iron bioaccessibility after peptic−pancreatin digestion of the samples and iron uptake in Caco-2 cells, using cell ferritin protein content as a surrogate marker.

## DISCUSSION

Fortification of staple crops with iron is recommended for alleviation of the high prevalence of ID and IDA in population groups in many countries.[16] Well-established strategies employ ferrous (II) salts, ferric (III) salts, ferric (III) chelates, or elemental Fe powders as the primary fortificants.[17] Moreover, iron supplementation poses inherently difficult issues such as solubility, bioavailability, toxicity, or tolerability in the gastrointestinal (GI) tract.[18,19] Consequently, transgenic transformation of cereals and other food crops became an attractive option for improving iron nutrition in human populations.[20,21] Plants have been genetically modified to yield grains that express ferritin,[22] phytase,[23,24] hemoglobin,[25,26] or coexpression of ferritin and phytase in an attempt to improve iron nutrition.[27] Biofortification is still in its developmental phase and is beset by numerous challenges both technical and emotive. Thus, if a simple food processing technique could increase iron bioaccessibility, or a naturally iron-rich food component could be modified to provide a bioaccessible and bioavailable source of iron for food fortification, this would represent a major advance in human nutrition.

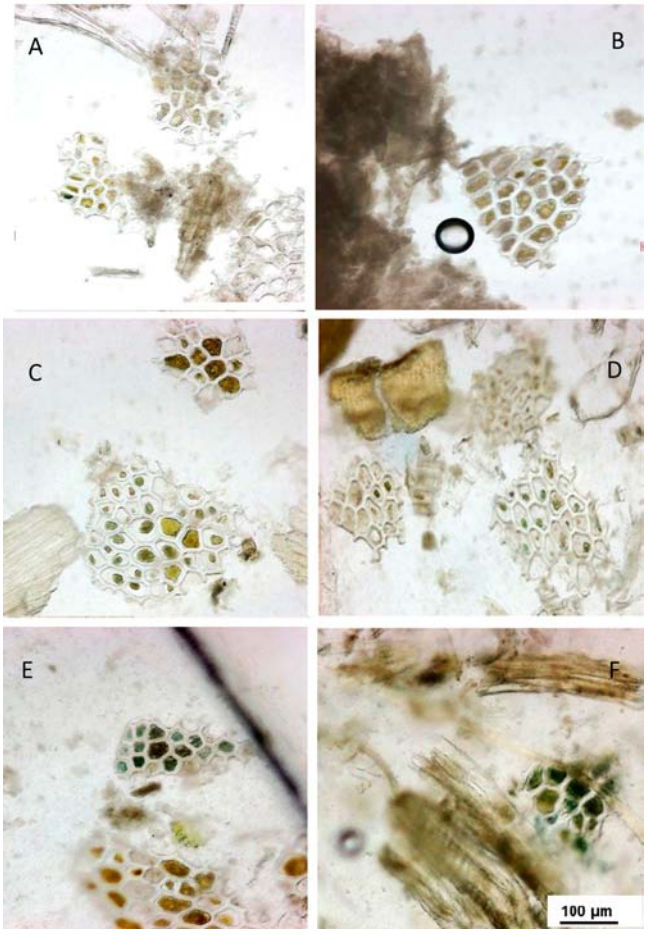

**Figure 2.** Structure and localization of iron in aleurone flour after passing through gastrointestinal tract of mice. Mice were fed aleurone flour overnight, and food contents were obtained from different parts of the gastrointestinal (GI) tract for microscopic observation. Samples were obtained from stomach (A), duodenum (B), jejunum (C), ileum (D), colon (E), and feces (F).

Here we have investigated whether wheat aleurone might provide a bioaccessible source of iron. One immediate obstacle to the use of aleurone is that the cell walls, which are composed of mainly nonstarch polysaccharides (dietary fiber), are highly resistant to digestion in the upper GI tract of humans and many experimental animals. Microscopic examination of the lumenal

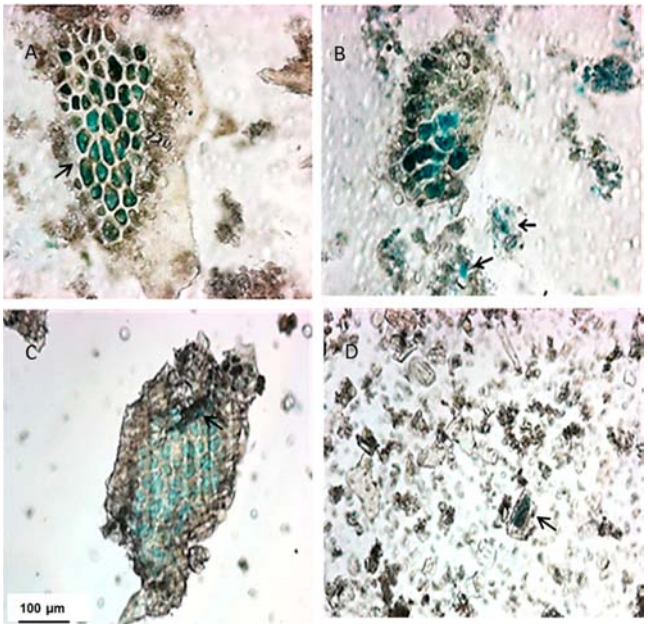

**Figure 3.** Location of iron in wheat flour before (A) and after (B) digestion by Driselase. Wholegrain wheat flour was digested by Driselase (final concentration of 0.1%) at 37 °C for 6 h. Structure and localization of iron in whole aleurone flour (C) and micromilled aleurone flour (D). Samples were treated with Perl's Prussian blue solution and observed under microscope. Iron staining in intact aleurone in wholegrain and aleurone flour and in diffuse particle globules in digested wholegrain and micromilled aleurone (arrows).

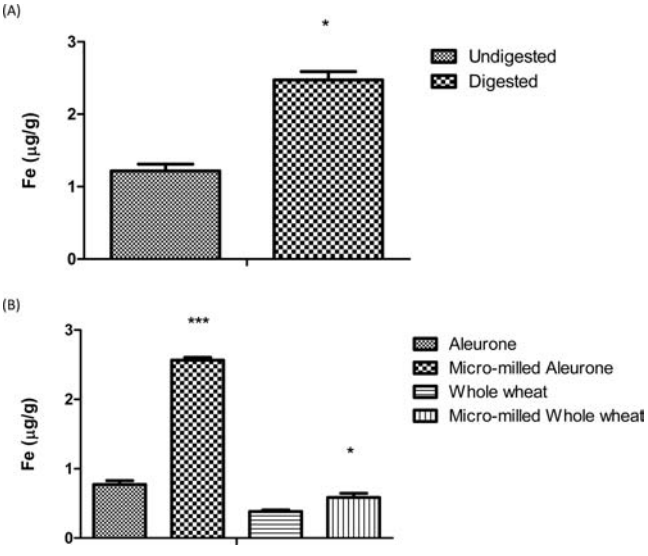

**Figure 4.** Iron solubility in whole grain wheat flour after digestion with Driselase (A). Iron solubility from standard and micromilled aleurone and whole grain wheat flour (B). Data are means ± SEM, $n$ = 4−6. Comparison of means was analyzed by Student's $t$ test. * $P < 0.0001$ (aleurone), and $P < 0.05$ (whole grain wheat).

contents from different segments of mouse (GI) tract and even from fecal samples revealed encapsulated iron in intact aleurone cells (Figure 2). This suggests that iron in aleurone cells is partly inaccessible even after transit throughout the entire length of the GI tract. It has been reported that plant cell walls are resistant to digestion in the upper GI tract of humans[28] with only 60% of the aleurone cell walls degraded in this region in the pig.[29] Colonic fermentation could lead to further

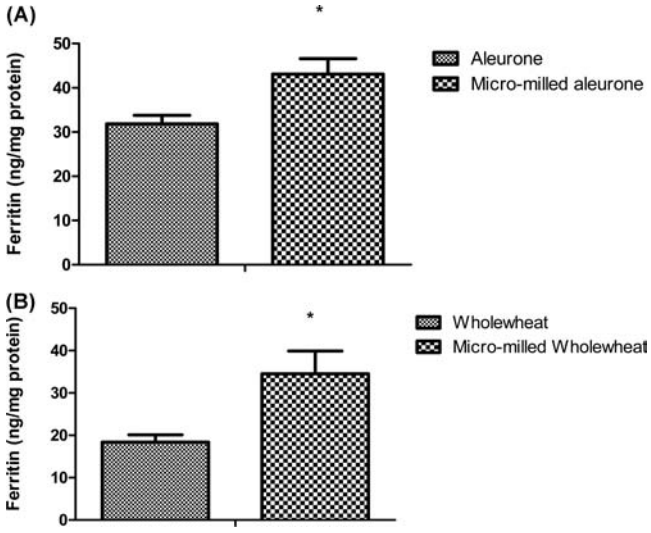

**Figure 5.** Iron bioaccessibility from standard and micromilled aleurone flour (A) and whole grain wheat flour (B) expressed in terms of Caco-2 cell ferritin synthesis. Data are means ± SEM, $n$ = 6. Comparison of means was analyzed using Student's $t$ test. * $P < 0.01$.

degradation of cell walls and the release of nutrients in the distal segment of the GI tract. A study using animal models demonstrated that 45% and 24% of aleurone was degraded during fermentation in the colon of rats and cockerels, respectively.[30] Moreover, partial degradation of the aleurone cell walls was evident in fecal samples from rats[31] fed wheat fractions. However, for iron at least, little or no absorption takes place in the colon.[32,33]

Clearly to be of use as a food fortificant the aleurone cell walls would need to be disrupted to provide increased access to the iron contained within. Our first approach was to use an enzymatic digest with Driselase. Following a 6 h digest with Driselase there was a significant increase in the release of soluble iron (Figure 4A). While this approach increases iron release from aleurone cells, its use would be limited to situations where predigested aleurone could be added as a food fortificant. We therefore also used a nonenzymatic approach by mechanically disrupting aleurone through micromilling. Micromilling of the AL was found to significantly increase iron solubility and bioaccessibility (Figures 4B and 5). The increase in bioaccessibility might be due to increased digestibility and degradability by grinding, which in ruminants increases the surface area of the samples for enhanced enzymatic digestion.[34] Furthermore, there is evidence that phytic acid, a resident component of the AL, is decreased during ball milling.[35] Phytic acid is a potent inhibitor of non-heme iron bioavailability.[13,36] It is possible that changes in phytate species and concentration as a result of micromilling may influence iron bioaccessibility from aleurone flour, and this is currently under investigation. Moreover, particle size reduction increased redistribution of cellulose-rich fiber fractions (another potent resident inhibitor of iron absorption) in favor of water-soluble fiber components as well as increased gastrointestinal function.[37]

An advantage of the mechanical approach to iron release from wheat aleurone is that the bioaccessibility of the endogenous aleurone iron reservoir could be increased through modified food processing technique. Potentially this could enhance the bioaccessibility of iron from wholegrain flour. Furthermore, micromilled aleurone could offer a natural, stable,

bioavailable iron fortificant or complement in foods. While our study has focused on iron, micromilled aleurone could potentially provide a bioavailable source of a number of other minerals (e.g., calcium) and vitamins (e.g., thiamine, nicotinic acid, and folate), all of which are commonly added as fortificants to white wheat flour.[38−40] Indeed, aleurone has been studied previously as a potential folate source for incorporation into bread. This approach would also be feasible for iron fortification. Published data already shows that wheat bread made with white flour enriched with 20% aleurone has a flavor similar to standard white bread and contains comparable levels of nutrients to wholegrain bread.[41] Subsequent studies will address the optimal particle size and relative proportions of micromilled aleurone enrichment required to achieve comparable or improved iron absorption efficacy to standard inorganic iron fortificants. This strategy might contribute to an improvement of the management of iron status in vulnerable groups in different countries. While our in vitro data support the notion that micromilled aleurone might be useful as an iron fortificant, it will be important to validate our findings in vivo by assessing the bioavailability of iron from aleurone-enriched wheat products in human volunteers, both in single-meal studies and also as part of more complex diets.

content, antioxidant activity, phenolic profile (HPLC-DAD-ESI-$MS^n$), and sensory acceptability.

## MATERIALS AND METHODS

Dry-blanched peanut skin (cv. Runner IAC 886) samples were kindly donated by CAP—Agroindustrial, Dumont, São Paulo, Brazil. White sugar, vanilla, wheat flour, baking powder, margarine, eggs, salt, brown sugar, oatmeal, sodium bicarbonate, and bittersweet chocolate were procured from a local market in São Paulo, Brazil. Folin—Ciocalteu's reagent, DPPH, ABTS, mono- and dibasic potassium phosphates, hydrogen peroxide, 5,5-dimethyl-1-pyrroline-*N*-oxide (DMPO), ferrous sulfate, protocatechuic acid, *p*-coumaric acid, (+)-catechin, and (−)-epicatechin were purchased from Sigma-Aldrich Canada (Oakville, ON, Canada). Sodium carbonate, sodium hydroxide, potassium persulfate, hexane, methanol, acetonitrile, formic acid, and sodium hydroxide were purchased from Fisher Scientific (Ottawa, ON, Canada).

**Cookie Making.** The cookie formulation was developed by our research group. Control and fortified formulations are shown in Table 1.

**Table 1. Formulation of Control and Fortified Cookies**

| ingredient | wet basis (%) | | | |
|---|---|---|---|---|
| white sugar | 8.96 | 8.84 | 8.80 | 8.73 |
| vanilla | 0.15 | 0.15 | 0.15 | 0.15 |
| wheat flour | 22.5 | 22.2 | 22.1 | 21.9 |
| baking powder | 0.15 | 0.15 | 0.15 | 0.15 |
| margarine | 8.96 | 8.84 | 8.80 | 8.73 |
| eggs | 6.41 | 6.33 | 6.29 | 6.25 |
| salt | 0.15 | 0.15 | 0.15 | 0.15 |
| brown sugar | 7.72 | 7.62 | 7.58 | 7.53 |
| oatmeal | 12.8 | 12.7 | 12.6 | 12.5 |
| sodium bicarbonate | 0.15 | 0.15 | 0.15 | 0.15 |
| bittersweet chocolate | 32.0 | 31.6 | 31.5 | 31.2 |
| peanut skins | | 1.30 | 1.80 | 2.50 |

The process was carried out in two steps. In a first bowl, margarine, brown sugar, and white sugar were homogenized in a mixer (Mondial, Barueri, SP, Brazil), which was followed by the addition of eggs and vanilla, a further mixing step for 5 min, and the addition of wheat flour. In a second bowl, oatmeal, salt, baking powder, and sodium bicarbonate were homogenized. Both mixtures were then blended with chocolate chips and fractionated in four parts to which different amounts of peanut skins (excluding control) were mixed. Each cookie weighed 32 g. Cookies were baked for 15 min at 280 °C using an Esmaltec oven (Esmaltec, Fortaleza, CE, Brazil). The samples were stored at room temperature (25 °C) until checked for their microbiological safety (within 2 days) followed by sensory analyses on the third day. The remaining samples (chemical analyses) were immediately frozen (−20 °C) for further analysis, within 1 month.

**Proximate Composition.** The ash, lipid, protein, and fiber contents of the sample were determined using AOAC[14] methods. Total carbohydrates were calculated by difference, and results are reported as percentage of the sample on a dry weight basis.

**Extraction of Phenolic Compounds.** Cookies were ground using a coffee bean grinder (model CBG5 series, Black & Decker Canada Inc., Brockville, ON, Canada), and the powder so obtained was passed through a mesh 16 (sieve opening 1 mm, Tyler test sieve, Mentor, OH, USA) sieve. The samples were defatted three times using hexane (solid/solvent, 1:5, w/v) in a Waring blender (model 33BL73, Waring Products Division Dynamics Co. of America, New Hartford, CT, USA). Defatted samples were immediately used for the extraction of phenolic compounds.

Defatted cookies were extracted with 70% acetone in a gyratory water bath shaker (model G76, New Brunswick Scientific Co. Inc., New Brunswick, NJ, USA) at 30 °C for 20 min, at a solid to solvent ratio of 2.5% (w/v). After centrifugation at 4000*g* (IEC Centra MP4, International Equipament Co., Needham Heights, MA, USA), the upper layer was collected and extraction was repeated twice. The combined supernatant was evaporated to remove the organic solvent in vacuo at 40 °C (Buchi, Flawil, Switzerland), and the residue containing soluble phenolics (free plus soluble esters) was stored at −20 °C until used for further analysis, within 1 month.

**Total Phenolic Contents (TPC).** TPC were evaluated using the Folin—Ciocalteu method[15] with minor modifications.[16] Phenolic extracts were diluted to 5 mg/mL, and the solution so obtained (0.5 mL) was mixed with distilled water (4.0 mL) and Folin—Ciocalteu reagent (2.5 mL). After 3 min, 1 mL of a saturated solution (30%, w/v) of $Na_2CO_3$ was added, and the mixture was kept in the dark at room temperature (23 °C) for 2 h. The absorbance was read at 760 nm using an Agilent UV—visible spectrophotometer (Agilent 8453, Agilent Technologies, Palo Alto, CA, USA). The results were expressed as milligram catechin equivalents (CE) per gram dry weight of cookies.

**DPPH Radical Scavenging Activity.** The DPPH assay was carried out using a slightly modified version of the method previously explained.[17,18] The phenolic extracts were diluted in methanol (20 mg/mL), and 1 mL of the solution so obtained was mixed with 250 $\mu$L of a methanolic solution of DPPH (0.5 mM). The mixture was kept in the dark at room temperature (23 °C) for 10 min, after which it was injected onto the capillary tubing that guides the sample through the sample cavity of a Bruker e-scan EPR spectrophotometer (Bruker E-Scan, Bruker Biospin Co., Billercia, MA, USA). The spectrum was recorded with the following parameters: $5.02 \times 10^2$ receiver gain, 1.93 G modulation amplitude, 2.62 s sweep time, 8 scans, 100.000 G sweep width, 3495.258 G center field, 5.12 ms time constant, 9.793220 GHz microwave frequency, and 86.00 kHz modulation frequency. The DPPH scavenging activity of the extracts was calculated using the equation

$$\text{DPPH scavenging activity (\%)} = [(\text{EPR}_{\text{control}} - \text{EPR}_{\text{sample}})/(\text{EPR}_{\text{control}})] \times 100$$

where $\text{EPR}_{\text{control}}$ is the signal intensity of DPPH radical + methanol and $\text{EPR}_{\text{sample}}$ is the signal intensity of DPPH radical + phenolic extract or catechin. The results were expressed as catechin equivalents per gram dry weight of cookies.

**ABTS Radical Cation Scavenging Activity.** The ABTS assay[19] was performed using a modified version of the method described by de Camargo et al.[16] The ABTS radical (7.00 mM) was generated in 100 mM phosphate buffer saline solution (PBS) (pH 7.4, 0.15 M sodium chloride) via potassium persulfate oxidation (2.45 mM). Prior to analysis, the stock solution of ABTS was diluted with PBS to reach an absorbance value of 0.70 (734 nm). Phenolic extracts were diluted in PBS (30 mg/mL), and 20 $\mu$L of the extract so obtained was added to 2 mL of the ABTS radical cation solution. The absorbance was read at 734 nm after 6 min using an Agilent UV—visible spectrophotometer (Agilent 8453). ABTS radical cation scavenging activity was calculated using the equation

$$\text{ABTS radical scavenging activity (\%)} = [(\text{Abs}_{\text{control}} - \text{Abs}_{\text{sample}})/(\text{Abs}_{\text{control}})] \times 100$$

where $\text{Abs}_{\text{control}}$ is the absorbance of the ABTS radical + PBS and $\text{Abs}_{\text{sample}}$ is the absorbance of ABTS radical cation + phenolic extract or trolox. The results were expressed as micromoles of trolox equivalent (TE) per gram dry weight of cookies.

**Hydrogen Peroxide Scavenging Activity.** The hydrogen peroxide scavenging activity of phenolic extracts was evaluated as previously explained.[20] Phenolic extracts (10 mg/mL) and 0.4 mM hydrogen peroxide solution were prepared in 0.1 M phosphate buffer (pH 7.4). The extracts (0.4 mL) were mixed with hydrogen peroxide solution (0.6 mL), and the final volume was made to 2.0 mL with the same buffer. The samples were kept in a gyrotory water bath shaker (model G76, New Brunswick Scientific Co. Inc.) for 40 min, and the absorbance was read at 230 nm in an Agilent UV—visible spectrophotometer (Agilent 8453). Blanks devoid of hydrogen peroxide (in phosphate buffer) were prepared for background corrections. The hydrogen peroxide scavenging activity was calculated using the equation

Table 2. Proximate Composition Cookies with Different Levels of Peanut Skins[a]

| component | control | 1.3% | 1.8% | 2.5% | peanut skins |
|---|---|---|---|---|---|
| ash | 1.78 ± 0.01b | 2.08 ± 0.09b | 1.89 ± 0.35b | 1.92 ± 0.06b | 2.89 ± 0.38a |
| lipid | 19.1 ± 1.28a | 21.3 ± 1.11a | 20.7 ± 1.26a | 21.6 ± 0.76a | 11.2 ± 0.31b |
| protein | 4.10 ± 0.05b | 4.21 ± 0.01b | 4.19 ± 0.11b | 4.30 ± 0.04b | 4.66 ± 0.04a |
| insoluble fiber | 6.40 ± 0.91c | 7.54 ± 0.04bc | 7.81 ± 0.88bc | 9.70 ± 0.96b | 76.6 ± 1.48a |
| soluble fiber | 2.17 ± 0.30b | 1.99 ± 0.03b | 2.43 ± 0.10b | 2.00 ± 0.33b | 4.11 ± 0.25a |
| carbohydrate | 66.3 | 63.3 | 63.2 | 60.0 | 0.31 |

[a]Data represent mean values for each sample ± standard deviation ($n = 3$). Means with the same letters within a row are not statistically ($p > 0.05$) different. Carbohydrates were calculated by difference. Results are expressed on a dry weight basis of cookies.

$$\text{hydrogen peroxide scavenging activity (\%)} = [(\text{Abs}_{\text{control}} - \text{Abs}_{\text{sample}})/(\text{Abs}_{\text{control}})] \times 100$$

where $\text{Abs}_{\text{control}}$ is the absorbance of $H_2O_2$ + phosphate buffer and $\text{Abs}_{\text{sample}}$ is the absorbance of $H_2O_2$ + phenolic extract or catechin. The results were expressed as catechin equivalents per gram dry weight of cookies.

**Reducing Power.** The reducing power assay was performed according to a method described by Alasalvar et al.[21] The extracts (6 mg/mL) were prepared in phosphate buffer (pH 6.6, 0.2 mM). Extracts (1.0 mL) were then mixed with phosphate buffer (2.5 mL) and 1% (w/v) potassium ferricyanide solution (2.5 mL), followed by their incubation at 50 °C for 20 min in a gyrotory water bath shaker (model G76, New Brunswick Scientific Co. Inc.), and subsequently a 10% (w/v) solution of trichloroacetic acid (2.5 mL) was added to it. The mixture was centrifuged at 1750*g* for 10 min, and the supernatant (2.5 mL) was added to distilled water (2.5 mL) and 0.1% (w/v) ferric chloride solution (0.5 mL). The absorbance was read at 700 nm, as before. The results were expressed as micromoles of trolox equivalents per gram dry weight of cookies.

**Hydroxyl Radical Scavenging Activity.** The ability of phenolic compounds in scavenging hydroxyl radicals generated by Fenton reaction was evaluated by electron paramagnetic resonance (EPR) spectroscopy using a slightly modified version of a method previously reported.[20] Extracts were prepared in 0.1 M phosphate buffer (pH 7.4). A 0.2 mL portion of the solution so obtained was mixed with 0.2 mL of $H_2O_2$ (10 mM), 0.4 mL of 17.6 mM DMPO, and 0.2 mL of $FeSO_4$ (10 mM). After 3 min, the EPR spectrum was recorded using a Bruker e-scan EPR spectrophotometer (Bruker E-Scan, Bruker Biospin Co.) The spectrum was recorded with the same parameters as for DPPH. The hydroxyl radical scavenging activity of the extracts was calculated using the equation

$$\text{hydroxyl radical scavenging activity (\%)} = [(\text{EPR}_{\text{control}} - \text{EPR}_{\text{sample}})/(\text{EPR}_{\text{control}})] \times 100$$

where $\text{EPR}_{\text{control}}$ is the signal intensity of hydroxyl radical + phosphate buffer and $\text{EPR}_{\text{sample}}$ is the signal intensity of hydroxyl radical + phenolic extract or catechin. The results were expressed as micromoles of catechin equivalents per gram dry weight of cookies.

**HPLC-DAD-ESI- $MS^n$ Analysis.** The identification of the major soluble phenolics (free plus soluble esters) was performed using an Agilent 1100 system (Agilent) equipped with a G1311A quaternary pump, a G1379A degasser, a G1329A ALS automatic sampler, a G1130B ALS Therm, a G1316 Colcom column compartment, a G1315B diode array detector, and a system controller linked to Chem Station Data handling system (Agilent). Separations were performed with a SUPELCOSIL LC-18 column (4.6 × 250 mm × 5 μm, Merck, Darmstadt, Germany). The binary mobile phase consisted of 0.1% formic acid (A) and 0.1% formic acid in acetonitrile (B). The flow rate of mobile phase was 0.5 mL/min, and the elution gradient used was as follows: 0 min, 100% A; 5 min, 90% A; 35 min, 85% A; 45 min, 60% A; held at 60% A from 45 to 50 min; afterward, mobile phase A was increased to 100% at 55 min, followed by column equilibration from 55 to 65 min. The compounds were detected at 280 nm, and the samples were filtered before injection using a 0.45 μm PTFE membrane syringe filter (Thermo Scientific, Rockwood, TN, USA).

HPLC-ESI-$MS^n$ analysis was carried out using the same conditions as described above in an Agilent 1100 series capillary liquid chromatography−mass selective detector (LC-MSD) ion trap system in electrospray ionization (ESI) in the negative mode. The data were acquired and analyzed with Agilent LC-MSD software (Agilent). The scan range was from $m/z$ 50 to 1200, using smart parameter setting, drying nitrogen gas at 350 °C, flow 12 L/min, and nebulizer gas pressure of 70 psi. Protocatechuic acid, (+)-catechin, and (−)-epicatechin were identified by comparing their retention times and ion fragmentation with coded and authentic standard and the same conditions as the samples. Dimers, trimers, and tetramers of proanthocyanidins were tentatively identified using tandem mass spectrometry ($MS^n$), UV spectral, and literature data.[8]

**Sensory Evaluation.** The present study was approved by the ethics committee of "Luiz de Queiroz" College of Agriculture, University of São Paulo, Brazil. Sensory analyses were performed using the acceptability test. Sixty volunteers, students and employees, from "Luiz de Queiroz" College of Agriculture (ESALQ/USP), aged between 18 and 60 years, participated in the acceptability test. The panel was composed by 72% women, with no history of allergy to peanuts or other ingredients of the formulation. Samples were placed in white ceramic plates coded with three-digit random numbers and delivered to the panel. The members received a set of four samples (control and cookies with added 1.3, 1.8, and 2.5% peanut skins) and water (25 °C). Participants were requested to rinse their mouths between each sample and evaluate color, odor, taste, texture, and overall impression. Scores were recorded on a paper ballot using a five-point hedonic scale (5 = extremely like, 4 = like, 3 = neither like nor dislike, 2 = dislike, and 1 = extremely dislike). Acceptable scores were ≥3 points.

**Statistical Analysis.** Unless stated otherwise, the experimental design was randomized with three replications, and the results were analyzed using Tukey's test ($p < 0.05$) and SAS software.

## RESULTS AND DISCUSSION

**Proximate Composition.** A cookie formulation (Table 1) was developed by a gastronomy professional from our research group for different addition levels of peanut skins. Such concentrations were decided on the basis of the saturation point, at which an increase in peanut skin concentration would result in a loss of pasting properties. Chocolate flavor was chosen to avoid or mask potential bitterness and astringent mouthfeel due to the presence of peanut skins, which was reported by the sensory panel in a first formulation developed (data not shown).

The proximate composition of the cookies and peanut skins, reported on a dry weight basis, is summarized in Table 2. The moisture content is shown in Figure 1. Industrial and homemade cookies have several differences, and one of them is the moisture content. Homemade cookies tend to be softer, mainly because of the moisture content and freshness. In the present study, the addition of peanut skins increased the moisture retention of cookies in a concentration-dependent manner upon addition of up to 1.8% peanut skins, from which no difference was found,

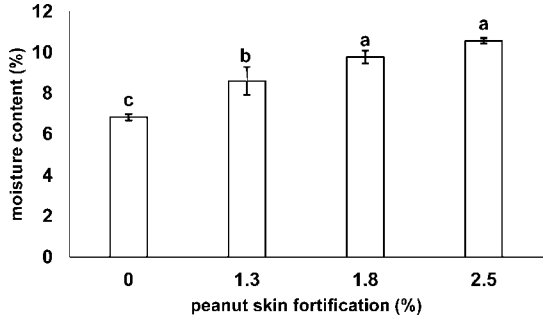

**Figure 1.** Moisture content of cookies fortified with peanut skins. Data represent the mean ± standard deviation of each sample ($n = 3$). Means with different letters indicate significant differences ($p < 0.05$).

suggesting that the saturation point for moisture retention was achieved.

The addition of 2.5% peanut skins resulted in a 50% increase of insoluble fiber content. These data are supported by the high content of insoluble fiber in peanut skins. Dietary fiber intake has been recognized for the reduction of cardiovascular disease risk and colorectal cancer,[22,23] management of diabetes, and body weight gain.[24,25] The insoluble fiber increase is in good agreement with a previous study reporting the use of peanut skins to fortify peanut butter.[9] A negative correlation existed between the addition of peanut skins and the carbohydrate content ($r = -0.9663$); a 10% reduction in total carbohydrates was noted. According to a randomized intervention study,[26] a low-carbohydrate Mediterranean diet improved cardiovascular disease risk factors and diabetes control in overweight patients with type 2 diabetes mellitus. In the present study, the addition of peanut skins to cookies increased the content of insoluble fiber and moisture retention and decreased the total carbohydrate content.

**Total Phenolic Content.** Phenolic compounds are secondary metabolites found in nuts, vegetables, cereals, legumes, and certain vegetable oils as well as in alcoholic and nonalcoholic beverages.[17,27−31] The TPC of peanut skins used in the present study as well as their contribution to the TPC of whole peanuts has already been reported.[16,32] Although their contribution as a weight percentage of peanuts was very low, around 2.6%,[33] the same does not apply for their contribution to the TPC in whole peanuts as their removal during the blanching process induced a reduction of 45% in TPC.[32]

Most peanuts for industrial purposes, such as production of candies, chocolates, and stuffing, are subjected to a blanching process that removes their skins, and these become a byproduct. In the current study, cookies were fortified with peanut skins, and their contribution to the TPC is summarized in Table 3. Food ingredients such as wheat flour, oatmeal, and chocolate, which have been used in the present study, also have polyphenols;[34−36] however, they have a different qualitative and quantitative polyphenol composition when compared to peanut skins. The addition of 2.5% peanut skins to cookies increased the TPC of the product by almost 50%. Although no recommended daily intake has been established for polyphenols, the extensive literature available lends support for the consumption of dietary sources of polyphenols.

**DPPH Radical Scavenging Activity Using Electron Paramagnetic Resonance (EPR).** The radical scavenging activity results are given in Table 3 and Figure 2A, showing a decrease of the EPR signal. Although TPC displayed an increase of around 50%, DPPH radical scavenging activity increased by up to 250% upon addition of peanut skins. The increase of both TPC and DPPH scavenging activity demonstrates the potential enhancement of beneficial health effect of the product due to increase in the content of bioactives present. Furthermore, the data suggest that the heating process did not have any detrimental effect on either TPC or scavenging activity. In fact, the phenolic content and antioxidant activity of food products may be increased upon heating.[18]

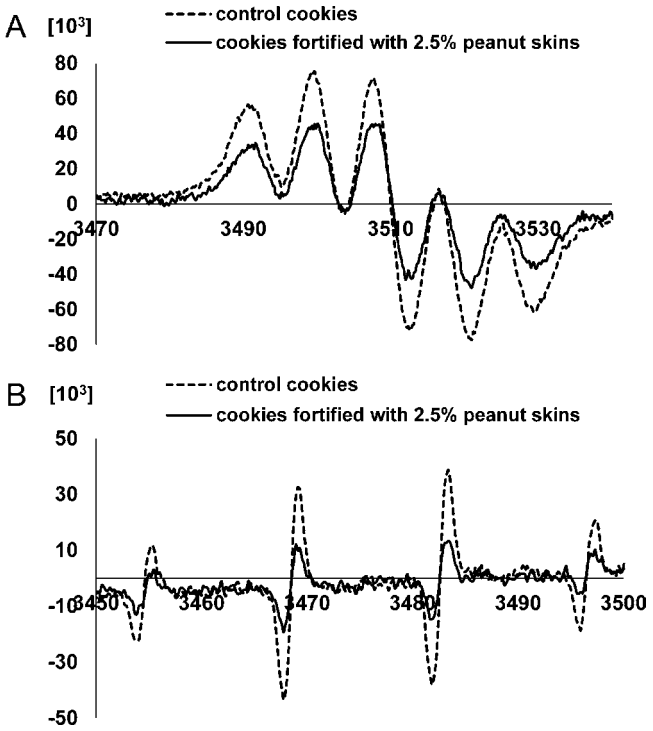

**Figure 2.** Electron paramagnetic resonance signals of phenolics of control cookies and cookies fortified with 2.5% peanut skins as evaluated by DPPH (A) and DMPO-OH (B) assays.

**Table 3. Total Phenolic Content (TPC), Antioxidant Activity, and Reducing Power (RP) of Cookies Fortified with Peanut Skins[a]**

| addition level (%) | TPC (mg CE/g) | DPPH (μmol CE/g) | ABTS (μmol TE/g) | $H_2O_2$ (μmol CE/g) | RP (μmol TE/g) | HRSA (μmol CE/g) |
|---|---|---|---|---|---|---|
| control, 0 | 61.2 ± 3.1d | 1028 ± 119d | 1119 ± 81.0c | 372.0 ± 14.3d | 57.14 ± 5.34d | 563 ± 46c |
| 1.3 | 68.5 ± 1.2c | 1715 ± 13.2c | 1769 ± 40.3b | 520.6 ± 19.8c | 97.18 ± 7.59c | 657 ± 6.7b |
| 1.8 | 78.5 ± 2.8b | 2437 ± 190b | 1986 ± 229b | 692.3 ± 12.3b | 113.3 ± 5.23b | 706 ± 2.9ab |
| 2.5 | 91.4 ± 2.0a | 3607 ± 169a | 2579 ± 176a | 997.5 ± 22.4a | 134.9 ± 3.25a | 766 ± 6.8a |

[a]Data represent mean values for each sample ± standard deviation ($n = 3$). Means followed by the same letters within a column are not significantly ($p > 0.05$) different. CE, catechin equivalents; TE, trolox equivalents. HRSA, hydroxyl radical scavenging activity. Results are expressed on a dry weight basis of cookies.

Table 4. Content of Soluble Polyphenols (Micrograms per Gram Dry Weight) of Cookies Fortified with Peanut Skins[a,b]

| compound | addition level | | | |
|---|---|---|---|---|
| phenolic compounds | control, 0% | 1.3% | 1.8% | 2.5% |
| protocatechuic acid[c] | 56.94 ± 2.03a | 55.96 ± 0.83a | 56.61 ± 0.25a | 58.14 ± 1.69a |
| (+)-catechin[c] | 219.2 ± 3.78a | 219.2 ± 8.90a | 220.1 ± 16.8a | 241.7 ± 13.3a |
| (−)-epicatechin[c] | 340.3 ± 19.4b | 355.6 ± 11.1ab | 385.1 ± 4.78ab | 426.0 ± 58.4a |
| procyanidin dimer A[d] | 118.5 ± 2.05b | 131.8 ± 2.23a | 129.6 ± 2.56a | 132.7 ± 2.43a |
| procyanidin dimer B[d] | 2708 ± 64.4bc | 2688 ± 35.0c | 2826 ± 33.2ab | 2859 ± 68.0a |
| procyanidin trimer A[d] | nd | 108.3 ± 1.33c | 318.9 ± 6.36b | 601.4 ± 22.7a |
| procyanidin tetramer A[d] | nd | 42.48 ± 0.44c | 55.97 ± 4.94b | 173.0 ± 4.98a |
| total | 3443 | 3601 | 3992 | 4492 |

[a]Data represent mean values for each sample ± standard deviation ($n = 3$). Means followed by the same letters within a row are not significantly ($p > 0.05$) different. [b]The contents (μg/g) of soluble phenolics in the original peanut skins were 118.9 ± 1.09 (protocatechuic acid); 1211 ± 49.0 ((+)-catechin); 450.7 ± 15.5 ((−)-epicatechin); 3623 ± 60.1 (procyanidin dimer A); 1477 ± 27.5 (procyanidin dimer B); 6494 ± 296 (procyanidin trimer A); 827.6 ± 51.7 (procyanidin tetramer A). [c]Identified with authentic standards. [d]Values are given as catechin equivalents.

**ABTS Radical Cation Scavenging Activity.** The antioxidant evaluation carried out using the ABTS method demonstrated the same trend as that from the DPPH assay (Table 3). The total antioxidant activity, which comprises hydrophilic and lipophilic antioxidants, was increased from 1119 to 2579 μmol TE/g. As demonstrated by the proximate composition, peanut skins still have a lipid content of 11%. Tocopherol, which is found in the lipid fraction of peanuts,[37] renders antioxidant properties. However, in the present study, the samples were defatted prior to the analysis for phenolics and antioxidant activity; thus, tocopherol is not affecting the assay results. According to Francisco and Resurreccion,[10] infusions prepared with Runner type peanut skins had the highest antioxidant activity as evaluated by the ABTS assay when compared to other preparations using Virginia or Spanish cultivars. It is interesting to note that peanut skins have been reported to possess a higher antioxidant activity than green tea.[38]

**Hydrogen Peroxide Scavenging Activity.** Hydrogen peroxide in the presence of ferrous ion generates hydroxyl radicals via Fenton's reaction, which makes the hydrogen peroxide scavenging assay a biologically relevant one. Hydroxyl radicals are highly reactive, leading to changes in DNA[39] and inactivating enzymes.[40] Furthermore, hydrogen peroxide induces cell damage.[41] Data from the present study (Table 3) demonstrated that control cookies already had scavenging activity against hydrogen peroxide, which, as mentioned before, is due to the presence of antioxidant compounds from its ingredients such as wheat flour, oatmeal, and chocolate. Furthermore, the baking process generates Maillard reaction products; these are produced in the presence of reducing sugars and amino acids. Such compounds also have antioxidant properties and may influence the evaluation. However, there was a clear concentration-dependent increase in the ability of phenolic groups in scavenging hydrogen peroxide, which was significant upon addition of peanut skins at 1.3, 1.8, and 2.5%.

**Reducing Power.** The reducing power measures the ability of phenolic compounds to reduce ferric to ferrous ion. As already mentioned, ferrous ions participate in Fenton's reaction, as well as in the oxidation of proteins and lipids. Phenolic compounds demonstrated the ability to scavenge hydrogen peroxide to different extents. Thus, evaluating the ability of phenolic compounds in preventing oxidative damages through other mechanisms provides useful information to anticipate additional protective effects of the bioactive compounds.

The reducing power of cookies fortified with 2.5% peanut skins rose by 136% (Table 3). The reducing power has been correlated with the degree of hydroxylation and conjugation in the phenolic compounds.[42] Peanut skins have a high content of proanthocyanidins, which possess several hydroxyl groups; this may explain the increase in reducing power despite the low addition level of peanut skins. The addition of 2.5% peanut skins in peanut butter[9] induced an increase of 747% in reducing power as evaluated by ferric reducing antioxidant power assay (FRAP); however, a direct comparison with the present study is not possible due to the different starting material (peanut butter) and method used by these authors. Whereas the FRAP assay is evaluated in acidic medium (pH 3.6), the method applied in the present study was carried out at pH 6.6. In fact, the antioxidant/reducing power of phenolic compounds has been demonstrated to be dependent on the pH of the medium.[43]

**Hydroxyl Radical Scavenging Activity.** Reactive oxygen species (ROS) are involved in several pathologies and the aging process; among them, hydroxyl radicals are of special concern and, although short-lived, they play an important role in the development of chronic diseases. They can be produced by Fenton's reaction in the presence of ferrous ions, via decomposition of hydroperoxides, which are intermediate in lipid oxidation process, and UV light. In the present study, the Fenton's reaction was carried out to produce hydroxyl radicals, and DMPO was used in the reaction medium as a spin trap to enable the study of scavenging activity of phenolics as evaluated by EPR.

The addition of peanut skins increased the hydroxyl scavenging activity of cookies (Table 3), which can also be seen by the decrease in the intensity of the EPR signals (Figure 2B). As monomeric flavonoids and proanthocyanidins are the major phenolic compounds in peanut skins, the results were expressed as catechin equivalents. No difference was found between 1.8 and 2.5% addition levels; however, in other experiments, a significant difference was observed, which suggests that the addition of 2.5% would provide more potential health benefits to consumers.

The control cookies and those fortified with 2.5% peanut skins had scavenging activities in the range of 563 and 766 μmol CE/g, respectively. Peanut butter fortified with peanut skins also exhibited higher ORAC values. According to Ma et al.,[9] peanut butter fortified with dry-blanched peanut skins was more effective in neutralizing peroxyl radicals than that fortified with roasted peanut skins. Another study[11] reported similar results

**Table 5. Sensory Acceptability of Cookies Fortified with Peanut Skins**[a]

| addition level (%) | color | odor | taste | texture | overall impression |
|---|---|---|---|---|---|
| control, 0 | 3.7 ± 1.0a | 3.9 ± 0.9a | 4.1 ± 1.0a | 3.9 ± 1.1a | 4.0 ± 1.1a |
| 1.3 | 4.1 ± 0.8a | 4.0 ± 0.9a | 4.2 ± 1.0a | 3.9 ± 1.0a | 4.1 ± 0.8a |
| 1.8 | 3.9 ± 0.7a | 4.0 ± 0.9a | 4.1 ± 0.8a | 4.0 ± 0.9a | 4.2 ± 1.0a |
| 2.5 | 4.2 ± 0.8a | 3.9 ± 1.0a | 3.9 ± 1.1a | 3.6 ± 1.0a | 3.9 ± 1.0a |

[a]Data represent the mean scores for each sample ± standard deviation ($n$ = 60); means with the same letters within a row are not significantly ($p$ > 0.05) different from each other; 5 = extremely liked, 4 = liked, 3 = neither liked nor disliked, 2 = disliked, and 1 = extremely disliked). Acceptable scores were ≥3 points.

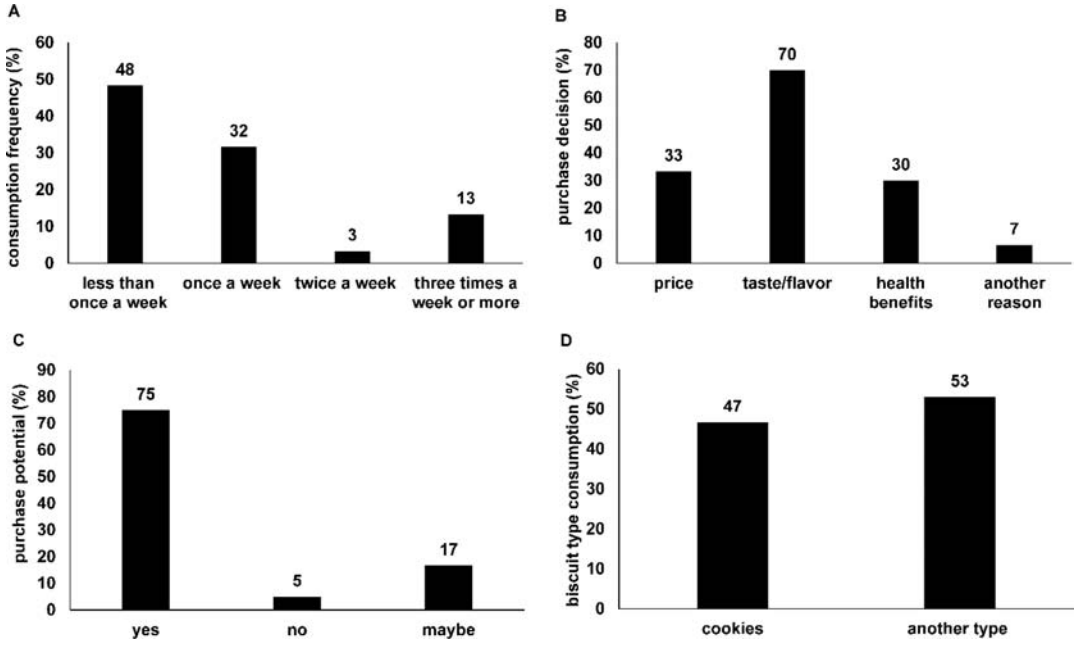

**Figure 3.** Complementary information collected during sensory evaluation of cookies fortified with peanut skins: (A) how often do you consume cookies? (B) what influences your cookie purchase decision? (C) would you increase your cookie consumption in the case of having additional health benefits?; (D) which kind of cookie do you consume more often?

using the ORAC assay for peanut butter and peanut paste with added peanut skins. The present study demonstrated increases in the antioxidant activity of cookies in the range of 36−251%, depending on the assay, and all results were statistically significant ($p$ < 0.05), which suggests that cookies with added peanut skins have potential health benefits, yet to be fully substantiated and exploited.

**HPLC-DAD-ESI-MS$^n$ Analysis.** The data presented so far have evidenced improvement in the potential health benefits of cookies fortified with peanut skins. Peanut skins have several phenolic compounds, namely, phenolic acids, stilbenes, monomeric flavonoids, and dimeric to oligomeric proanthocyanidins. However, in the present study the major phenolic compounds were evaluated as biomarkers to explain the potential functionality of cookies with added peanut skins (Table 4).

Here, we also focused only on the soluble phenolic as they accounted for >90% of total phenolic compounds in peanut skins (data not shown). Protocatechuic acid was positively identified by comparison of its retention time and fragmentation pattern with those of authentic standard. The MS and MS$^2$ spectra of protocatechuic acid gave ions at $m/z$ 153 and 109, respectively. The deprotonated molecular ion $[M - H]^-$ of both (+)-catechin and (−)-epicatechin exhibited an $m/z$ signal at 289 and MS$^2$ spectra at $m/z$ 245, and their identities were confirmed according to their different retention times by comparison with those of authentic standards. In accordance with the literature,[17,28] protocatechuic acid, (+)-catechin, and (−)-epicatechin showed loss of $CO_2$, giving $[M - H - 44]^-$ as their characteristic ion in MS$^2$. The major procyanidins, which consist exclusively of (epi)catechin units, were tentatively identified according to the literature.[8,44] Procyanidin dimer A showed a deprotonated molecular ion at $m/z$ 575 and at $m/z$ 449, 423, 407, 289, and 285 in MS$^2$. Procyanidin dimer B exhibited an $m/z$ at 577 and in MS$^2$ at $m/z$ 451, 425, 407, 289, and 287. The MS fragmentation of procyanidin trimer A gave deprotonated ion at $m/z$ 863 and at $m/z$ 737, 711, 693, 575, 559, and 449 in MS$^2$. Procyanidin tetramer A showed an $m/z$ signal at 1149 in MS and at $m/z$ 861, 737, and 575 in MS$^2$. The mass spectra of the most representative compound tentatively identified as procyanidin dimer B is provided as Supporting Information. Prodelphinidins, which have (epi)gallocatechin in their structures, were also present in peanut skins; however, their concentration was very low and had no effect on their concentration in cookies fortified with peanut skins.

Protocatechuic acid and (+)-catechin did not show any significant increase ($p$ > 0.05). Protocatechuic acid and (+)-catechin were present at less than 1 and 2% in the free nonconjugated phenolic fraction of peanut skins in the present study (data not shown), which may explain the lack of increase for such compounds in cookies fortified with peanut skins. On the other hand, the content of (−)-epicatechin increased upon

addition of peanut skins, and a small, but significant, increase was found for procyanidin dimers A and B.

The formulation used in the present study included a high proportion of chocolate, which also has a high content of (−)-epicatechin and procyanidins;[36] this may explain why the threshold for the increase of (−)-epicatechin and procyanidins B was achieved only with 2.5 and 1.8%, respectively, in comparison with the control. However, procyanidin dimer A, which is the major one in peanut skins, also increased with the lowest addition (1.3%). Furthermore, procyanidin trimers and tetramers were not found in the control sample, but were gradually increased with increasing addition levels of peanut skins.

The addition of peanut skins to cookies rendered an increase of up to 30% in major phenolics as evaluated by HPLC-DAD-ESI-MS$^n$. Data from the present study demonstrated that proanthocyanidins accounted for the highest increase in phenolics of cookies fortified with peanut skins. The degree of polymerization of proanthocyanidins has an effect on their absorption. According to Ou and Gu,[45] proanthocyanidins with a degree of polymerization of <5 are absorbable, which lends support to the potential health benefits of the product formulated in this study.

**Sensory Evaluation.** To ensure the safety of cookies prepared here, coagulase-positive *Staphylococcus aureus*, yeasts and molds, *Salmonella* spp., total coliform, *Escherichia coli*, and aflatoxins were investigated (data not shown). The heating process and storage may influence the color of polyphenol-rich source material, which has been demonstrated by sensory evaluation. An unexpected food color may be the first attribute related to consumers' rejection. The peanut skins used in the present study were a byproduct of the dry blanching process, which involved heating at 70−90 °C for 2 h. This process and long-term storage may have some influence on the color of the skins. Furthermore, the peanut skin color might change the final color of the peanut skins fortified cookie. However, the present study revealed no humanly perceptible changes in the final product (Table 5). The color of dry-blanched peanut skins (cv. Runner IAC 886) is light brown. The combination of this color, low peanut skin concentration, and the chocolate flavor of the cookie produced here may be the reason for imperceptible color changes. Furthermore, no change in the remaining sensory attributes were found among samples (Table 5), all of which received scores ≥3, which was considered acceptable. Figure 3 shows additional results collected during the sensory evaluation. Results from the consumption frequency demonstrate a potential to be exploited for increasing cookie consumption by 48% as noted by the volunteers that consumed cookies only once a week or less. Taste/flavor is a factor that mainly influences their purchase decision (70%). This demonstrates the importance of sensory evaluation in the development of new products. According to their responses, a cookie with higher health benefit would have a positive impact on their future purchase decision. Additionally, 47% of the panel mentioned cookies as the most consumed kind of biscuits, which demonstrates their preference for this kind of biscuit in comparison with others available on the market.

In summary, physical and chemical properties of cookies were influenced by the addition of peanut skins. Carbohydrate content decreased, whereas the contents of insoluble fiber, moisture, total polyphenol, and antioxidant activity increased. Protocatechuic acid and (+)-catechin were identified and quantified, but only the contents of (−)-epicatechin and procyanidin dimers A and B increased. Procyanidin trimers and tetramers, which were not found in the control samples, were also increased. Sensory evaluation demonstrated no significant difference among the control and the remaining samples; thus, cookies fortified with peanut skins offer promise for possible commercialization.

[a]Volatiles were identified in freshly roasted almonds and in stored almonds after roasting. DB-Wax was used as the analytical column. [b]$t_R$, retention time. [c]KI, Kovats' index; and values were obtained from http://flavornet.org or www.pherobase.com. [d]Extracted ion from total ion scan used for quantitation. [e]Compounds verified with authentic standards.

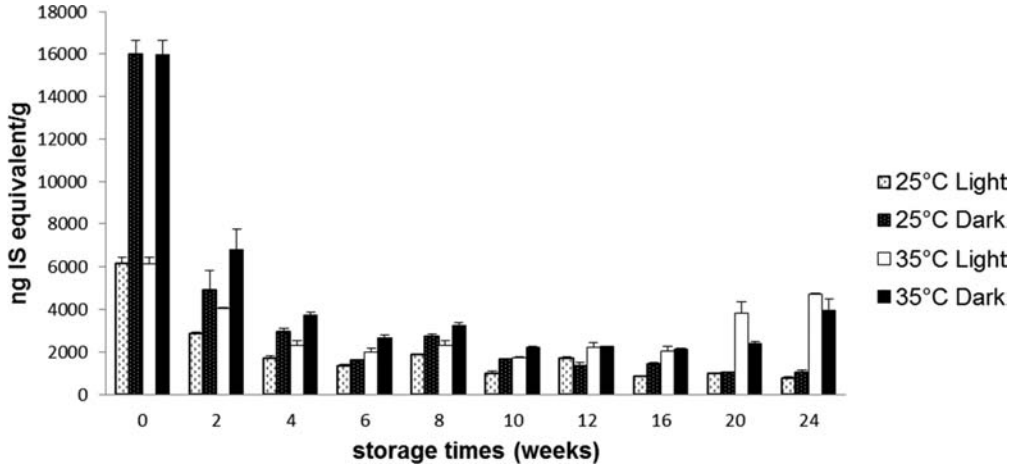

**Figure 1.** Sum of almond volatile compounds for different roastings, storage temperatures, and storage times.

are not static, and moderate values may reflect depletion rather than low levels of oxidation. The TBA assay can be used to monitor the formation of malondialdehyde, a product of lipid oxidation.[13] However, low TBA values are not absolute indicators of oxidation as malondialdehyde may not be a good marker for other lipid-derived aldehydes and artifacts can easily form during the analysis procedure.[13] Hexanal, the most commonly used marker of lipid oxidation, exists in raw almonds and is generated during heat processing.[14,15] During the initial stages of storage, the hexanal, formed during thermal processing, volatilizes, and levels decrease.[16] As lipids oxidize during storage, the levels of hexanal increase.[17]

Numerous volatile compounds are generated through the Maillard reaction and via lipid oxidation during roasting and are important to flavor.[18,19] These include ketones, aldehydes, pyrazines, alcohols, aromatic hydrocarbons, furans, and pyrroles. Pyrazines, furans, and pyrroles are key components of toasted almond aroma.[18] Pyrazines, which have nutty and roasted aromas, are formed during heating via Maillard sugar–amine reactions and Strecker degradation.[20] The thermal degradation of sugars such as fructose and glucose produce furan-containing compounds (e.g., furfural).[18] Linoleic acid is a precursor to many aldehydes and alcohols[21] including (*E*)-2-heptenal and nonanal.[22] (*E*)-2-Heptenal is responsible for pungent and green aromas,[18] and nonanal is responsible for tallow and fruity aromas.[23] Thermal decomposition of methyl linoleate hydroperoxide generates 1-octen-3-ol,[22] which contributes to an herbaceous aroma in almonds.[18] The oxidation of linolenic acid produces (*Z*)-3-hexen-1-ol (a green leaf aroma)[24] and 1-butanol (an unripe apple aroma).[22,25] Other lipid oxidation volatiles such as lactones, including butyrolactone, contribute to milky and creamy aromas in foods[26]

Roasted almonds often display inconsistent shelf life stability and can develop rancidity during storage, which is usually detected only after nuts develop considerable off-flavors. The inconsistent identification of the presence and extent of rancidity leads to considerable product loss. At the same time, the levels of the desirable aromas that arise from roasting tend to decrease during storage. To address this, we used HS-SPME GC-MS to (1) evaluate changes in volatile profiles of roasted almonds during 6 months of storage, (2) identify possible early markers of rancidity development in roasted almonds, and (3) gain a better understanding of the time line

**Table 2. Volatiles Detected in Almond Samples: Raw, Freshly Roasted, or Stored Roasted at 35 °C for 24 Weeks (Nanograms per Gram)**

for fading of aromas and the point when oxidation products start to dominate volatile profiles.

## MATERIALS AND METHODS

**Reagents.** C7−C40 saturated alkanes standard (1000 μg/mL in hexane), ethanol (HPLC/spectrophotometric grade), and 36 other standards were purchased from either Sigma-Aldrich (St. Louis, MO, USA) or Fisher Scientific (Pittsburgh, PA, USA) (Table 1). The exceptions were decanal (Eastman, Rochester, NY, USA), 2-ethylthioethanol (Alfa Aesar, Ward Hill, MA, USA), 3-hydroxybutan-2-one (Supelco, Bellefonte, PA, USA), and 1-methylthio-2-propanol (Ryan Scientific, Inc., Mount Pleasant, SC, USA). Octanal-$d_{16}$, 2-methylpyrazine-$d_6$, and *n*-hexyl-$d_{13}$ alcohol were purchased from C/D/N Isotopes Inc. (Quebec, Canada). The stable isotopes were used as stable isotope internal standards for three major categories of identified compounds (i.e., aldehydes, pyrazines, and alcohols).

**Almond Samples and Roasting.** Raw almond kernels (cv. Butte/Padre) were obtained from Hughson Nut Co. (Hughson, CA, USA) and had been in storage at ambient warehouse temperatures for 7 months since harvest. Kernels were commercially dry roasted using a Revent baking rotary roaster (Ready Roast, Madera, CA, USA). Almonds were roasted in triplicate batches (4.5−5.4 kg each) at 138 °C using different roasting times to achieve light (28 min) and dark roast (38 min). The almonds were stored in two E7/2 Conviron chambers (Manitoba, Canada) with controlled environments of 25 or 35 °C and at 65% relative humidity. The almonds were placed in a single layer on trays in the dark by covering the trays with aluminum foil to simulate dark storage. All almonds were evaluated at 0, 2, 4, 6, 8, 10, 12, 16, 20, and 24 weeks of storage.

To prepare samples for analysis, a random 50 g sample was removed from each tray and ground for 5 s at low speed with a Waring laboratory blender (Torrington, CT, USA). The ground samples were passed through a Tyler standard sieve (16 mesh; Mentor, OH, USA) to collect almond powder of a uniform particle size. For HS-SPME analysis, 5 g (±1%) of the powder was transferred into a 22.5 × 75 mm (20 mL) glass headspace vial (Sigma-Aldrich). Samples were prepared in duplicate ($n$ = 2).

**HS-SPME Sampling and Gas Chromatography Analysis.** Volatile extraction was carried out as described previously.[27] Briefly, a 1 cm 50/30 μm SPME fiber assembly coated with divinylbenzene/carboxen/polydimethylsiloxane (Supelco, Inc.) was used for headspace analyses of almond sample volatiles. A mixed internal standard solution (octanal-$d_{16}$, 2-methylpyrazine-$d_6$, and *n*-hexyl-$d_{13}$ alcohol) was added to each headspace vial containing a 5 g sample of ground almond (10 ng/g). Equilibration time was 40 min, and the SPME fiber extraction time was 30 min in the headspace of the vials at room temperature (24 ± 1 °C). Following headspace extraction, SPME fibers were injected into the GC and remained in the GC inlet for 10 min.

**GC-MS Analysis.** Volatile analysis was determined using GC-MS analysis on an HP 6890 coupled to an Agilent 5973 mass selective detector (Agilent, Palo Alto, CA, USA) as previously described.[27] Compounds were separated on a DB-Wax column (30 m × 0.25 mm i.d., 0.25 μm film thickness, Agilent Technologies) by applying 35 °C for 1 min, 5 °C/min to 100 °C, and 20 °C/min to a final temperature of 250 °C, with a final holding time of 5 min. The injection was performed in splitless mode (0.7 mm splitless inlet liner, Supelco), and the injector temperature was 220 °C. The purge valve was opened at 0.5 min at a 50 mL/min flow rate. Carrier gas was helium (99.999%) with a constant starting flow rate at 0.7 mL/min. The detector was fitted with an electron impact ionization source set at 230 °C. The quadrupole temperature was set to 150 °C, and the transfer line temperature was kept at 250 °C. The solvent delay was set to 3 min. Total ion chromatograms were collected by scanning from $m/z$ 30 to 150 at a rate of 3.06 scans/s.

**Identification and Relative Quantification of Volatile Compounds.** Volatile compounds were identified by comparison of their mass spectra and retention times with those of authentic standards. Volatile compounds without authentic standards were tentatively identified by comparing the Kovats' retention indices (KI) and/or mass spectrum with those reported in the NIST Mass Spectral Search Program (version 2.0 a) with <80% as a cutoff to match compounds. The KIs were calculated from the retention times of $C_6$−$C_{40}$ *n*-alkanes.

The full spectrum was scanned in total ion chromatogram (TIC) mode. Relative quantification of each volatile compound was performed using a unique extracted ion peak area at its respective retention time and comparing to the extracted ion peak area of one of three internal standards (i.e., octanal-$d_{16}$, 2-methylpyrazine-$d_6$, and *n*-hexyl-$d_{13}$ alcohol, for aldehydes, pyrazines, and alcohols, respectively) as described previously.[27] Concentration was calculated using the following equation according to Baek and Cadwallader:[28]

$$\text{concentration}\left(\frac{\text{ng}}{\text{g}}\right) = \frac{\text{extracted ion peak area}}{\text{extracted ion peak area of IS}} \times \left(\text{IS} \times \frac{10\ \text{ng}}{\text{g}}\right)$$

The peak area of each extracted ion for each analyte was divided by the peak area of extracted ion for the respective internal standard. The area ratio obtained was subsequently converted to relative

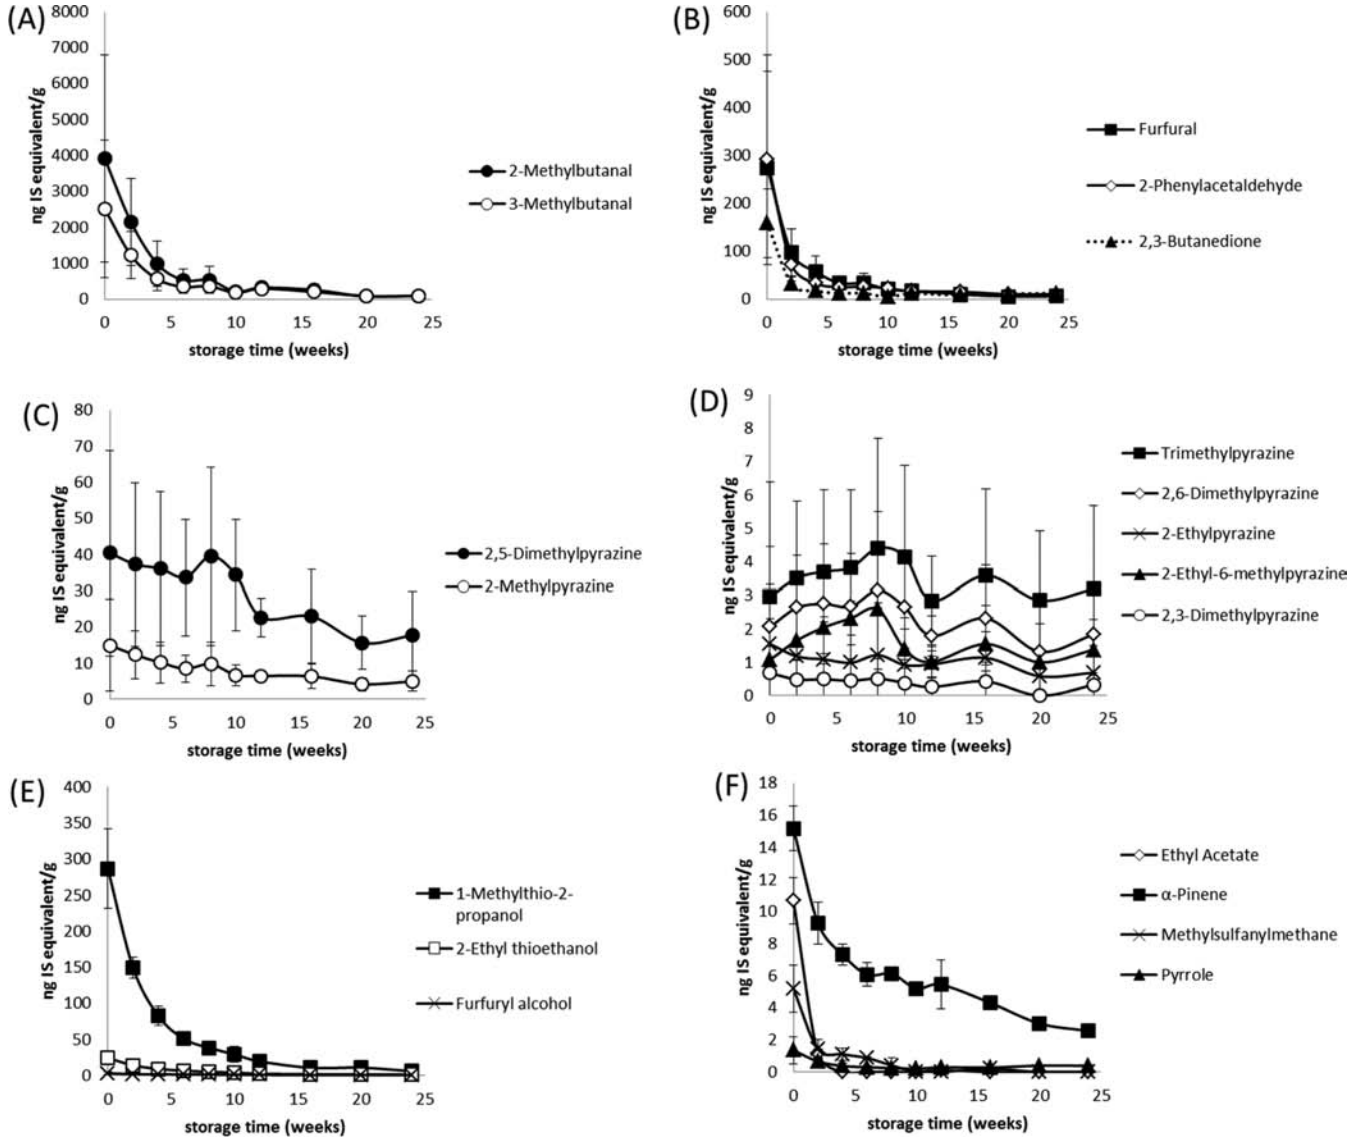

**Figure 2.** Roasted almond volatile compounds that decreased during almond storage: (A, B) carbonyls; (C, D) pyrazines; (E) alcohols; (F) additional volatiles. Concentrations are the average concentrations across the roasting treatments evaluated (i.e., light- and dark-roasted samples) and stored at 35 °C over 24 weeks.

concentration of the analyte in a 5 g sample based on the concentration of the appropriate IS (10 ng IS/g almond). The obtained relative concentration was used to compare the difference in volatile profiles among raw and roasted almonds.

**Statistical Analysis.** Principal component analysis (PCA) was performed to visualize clustering formation of different conditions (roasting time and storage time) and the relationship between volatile compounds and samples. Before PCA was performed, a one-way analysis of variance (ANOVA) was used to determine the volatile compounds significantly different in volatile concentrations across the whole data set. XLSTAT (version 2013.05.06) was employed for this analysis. The data were then normalized by log transformation for normal distribution and autoscaling for unit scaling. MetaboAnalyst (www.metaboanalyst.ca) was used for PCA.

## ■ RESULTS AND DISCUSSION

Seventy-one volatile compounds were identified using NIST libraries and the Kovats index, in freshly roasted and roasted stored almonds.[27] These include 28 aldehydes and ketones, 7 pyrazines, 18 alcohols, and 18 additional compounds (Table 1). The identities of 38 of these compounds were confirmed with authentic standards. Raw almonds contained the fewest volatiles, whereas levels increased in freshly roasted and roasted stored almonds. Some volatiles were specifically unique to the raw,[27] roasted, or roasted stored almonds (Table 1). Seventeen new volatiles were formed during storage and include ketones (2-octanone, 2-nonanone, 3-octen-2-one, and 2-decanone), aldehydes ((*E*)-2-decenal, 2,4-nonadienal, and 2-undecenal), alcohols (1-octen-3-ol and nonanol), oxiranes (pentyl oxirane and hexyl oxirane), and short-chain acids (acetic acid, pentanoic acid, heptanoic acid, and octanoic acid). Higher levels of 1-octen-3-ol, acetic acid, and pentanoic acid were found in the dark-roast almonds as compared to the light-roast almonds. Lower levels of 3-oceten-2-one, 2-decanone, (*E*)-2-decenal, 2,4-nonadienal, and 2-undecenal were found in the dark-roast almonds as compared to the light-roast almonds.

The roasted almonds were stored in dark controlled environments at 25 or 35 °C with 65% relative humidity. Storage studies evaluated the influence of storage temperature and storage time on total volatile compounds in light- and dark-roast almonds over 24 weeks. The dark-roast almonds had

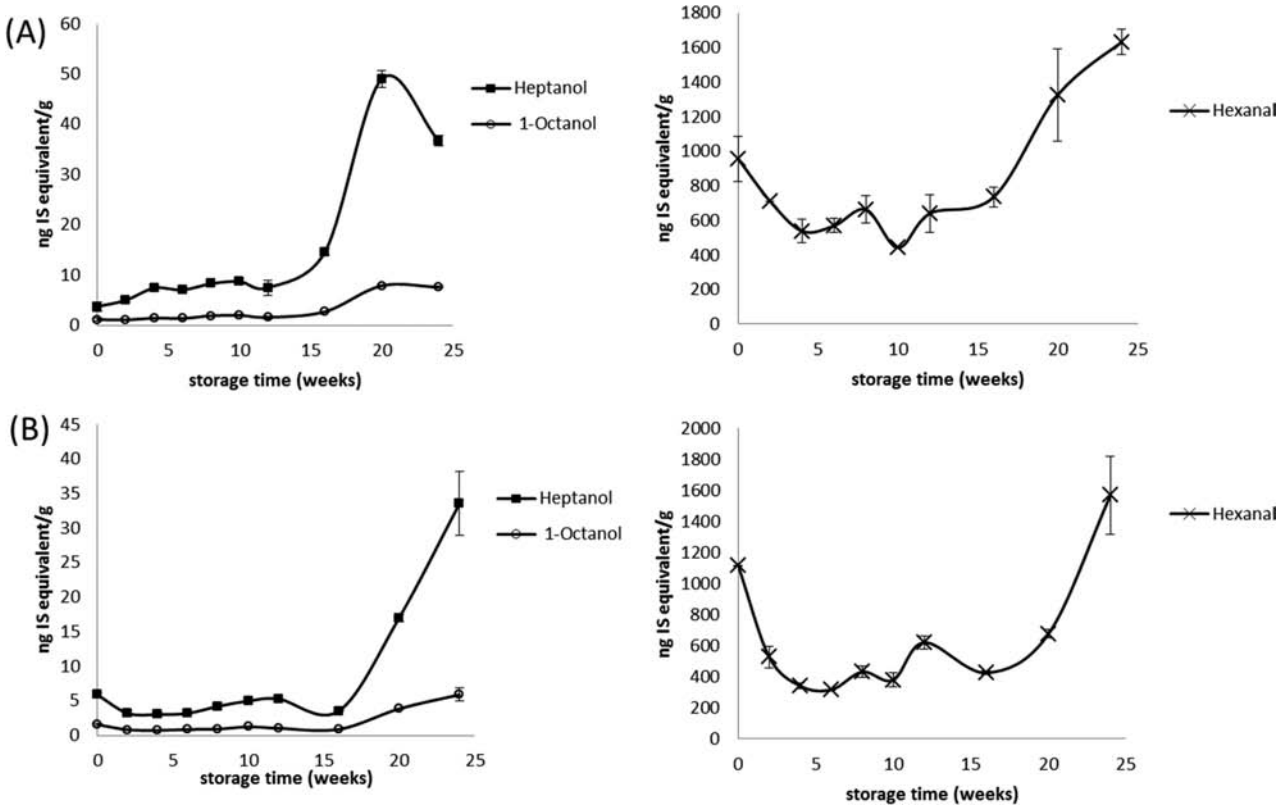

**Figure 3.** Roasted almond volatile compounds that increased with storage time: 1-heptanol, 1-octanol, and hexanal (a traditional indicator for oxidation in almonds) in (A) light-roasted and (B) dark-roasted samples stored at 35 °C over 24 weeks.

[a]ND, not detected.

higher levels of total volatiles as compared to the light-roast almonds (Figure 1). Regardless of the degree of roasting or storage temperature, total volatiles decreased significantly during the first 4 weeks of storage. Volatiles continued to decrease at a slower rate between 6 and 24 weeks. The decrease in total volatiles was due to the loss of volatile compounds that were formed during the roasting process (Table 2). The almonds stored at 35 °C demonstrated increases in total volatiles after 20 weeks of storage, whereas no increases were observed in almonds stored at 25 °C.

The decreases in volatile compounds in the light- and dark-roast almonds stored at 25 or 35 °C were similar. In general, roasting increases the concentration of branch-chain aldehydes, alcohols, pyrazines, heterocyclic, and sulfur-containing compounds.[27] Herein, we found that the majority of these compounds decreased significantly with storage and could not be detected after 8−10 weeks of storage.

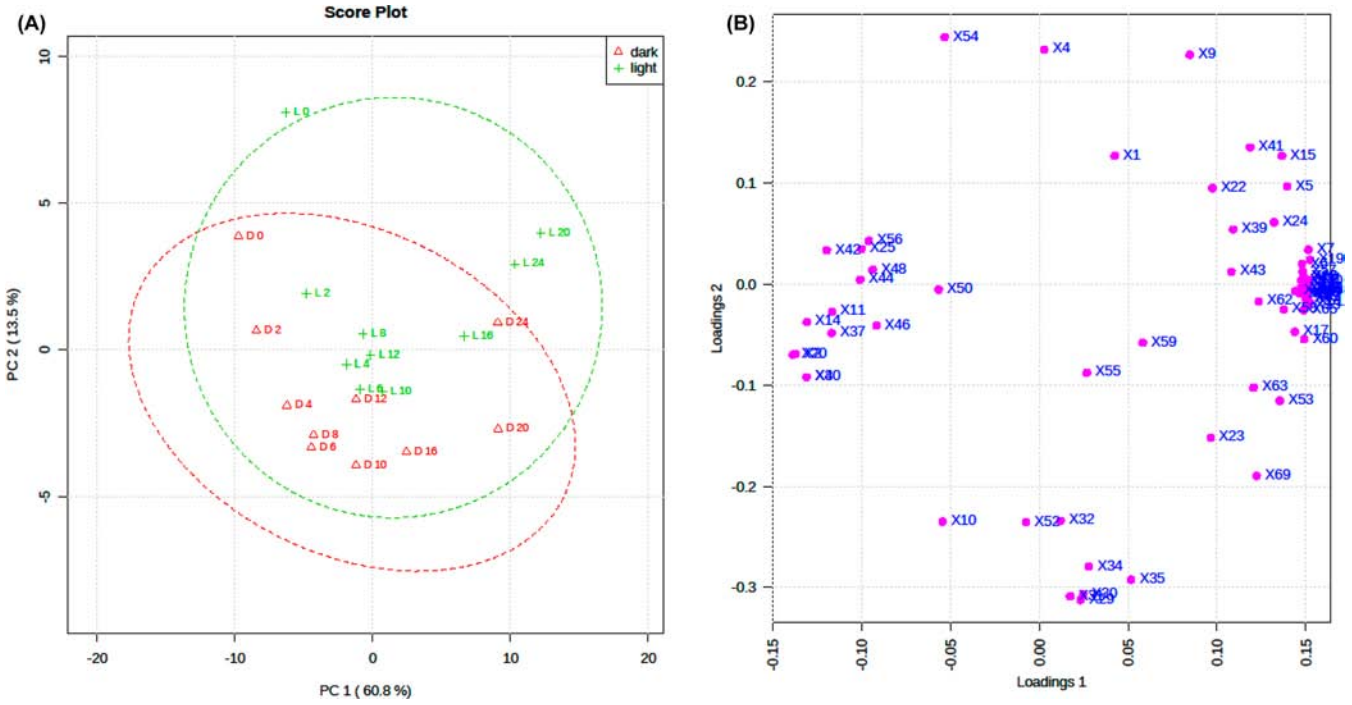

**Figure 4.** Principal component analysis on 68 volatile compounds determined by HS-SPME-GC-MS for different roasting and storage times: (A) PCA score plot with sample labeling; (B) PCA loading plot with compound codes. Compound codes are explained in Table 1.

The volatile carbonyl compounds detected in roasted almonds include 2-methylbutanal, 3-methylbutanal (Figure 2A), 2,3-butanedione, furfural, and 2-phenylacetaladehyde (Figure 2B). The concentrations of these volatiles decreased by 75−89% in the first month of storage and remained low through the remainder of the 6 month study. 2-Methylbutanal and 2-phenylacetaldehyde are produced through the Strecker reaction.[29] The concentration of these compounds decreased by 45−75% in the first 2 weeks of storage and remained low through the remainder of the 24 week study.

Pyrazines are key components of toasted almond aroma[18] and are formed in almonds during roasting.[27] Herein, most pyrazines did not show significant decrease during storage ($p < 0.05$) (Figure 2C,D). This result is consistent with Warner et al.'s study on roasted peanuts.[30] By 24 weeks of storage the concentrations of trimethylpyrazine and 2,6-dimethylpyrazine remained at initial levels (Figure 2D).

Roasting promoted the formation of Maillard reaction products including furfuryl alcohol and two branched-chain ketones (1-hydroxypropan-2-one and 3-hydroxybutan-2-one). These volatiles decreased significantly (>90%) by 10 weeks of storage regardless of the degree of roast (Table 2). The two sulfur-containing volatiles (1-methylthio-2-propanol and 2-ethylthio-ethanol) formed during roasting decreased significantly with storage time (Figure 2E). The majority of additional volatiles that were detected, such as ethyl acetate, $\alpha$-pinene, methylsulfanylmethane, and pyrrole, also decreased during storage (Figure 2F).

Levels of straight-chain aldehydes (e.g., butanal, pentanal, hexanal, heptanal, octanal, and nonanal) were significantly higher in the roasted almonds immediately after roasting. Straight-chain aldehydes and alcohols are products of lipid oxidation, generated in response to thermal processing.[18,27] The levels of straight-chain aldehydes decreased over the first 6−10 weeks of storage. After 20 weeks of storage, the levels of these aldehydes increased again, reflecting lipid oxidation (Table 2). The levels of heptanal increased 2−4-fold as compared to its original concentration after 24 weeks of storage. Heptanal is a common oxidation product of oleic acid.[31] The levels of caproic acid (hexanoic acid) began to increase at ∼16 weeks, increasing by 7-fold at 24 weeks. Caporic acid can be generated by the oxidation of lipids.[32]

Hexanal is commonly used as a volatile marker of oxidation in foods.[12] Hexanal is an abundant oxidation product and therefore is more easily detected than are other oxidation products.[12] However, the concentration of hexanal in nuts is affected by numerous factors including kernel maturity,[33] roasting conditions,[15] fat content,[12] and variety.[8] Significant oxidation has generally occurred when substantial increases in hexanal are measurable, and the quality of the almonds may no longer be acceptable.

During initial stages of storage, we found that the levels of hexanal decreased. Levels then increased at ∼20−24 weeks of storage regardless of the degree of roasting (Figure 3A,B). This is similar to results shown by García-Llatas et al.[16] The levels of 1-heptanol increased more significantly between 16 and 20 weeks of storage regardless of the degree of roast (Figure 3A,B), and the response was more sensitive than the response of hexanal. Additionally, unlike hexanal, the levels of 1-heptanol did not show a decrease during the initial 16 weeks of storage. A similar trend was observed for 1-octanol; however, the response of 1-octanol was not as sensitive as that of 1-heptanol.

Additional potential markers of oxidative events include compounds that were initially absent in the roasted almonds but detectable ∼16−20 weeks of storage (i.e., 2-octanone, 2-nonanone, 3-octen-2-one, 2-decanone, (*E*)-2-decenal, 2,4-nonadienal, 2-undecenal, 1-octen-3-ol, nonanol, pentyl oxirane, hexyl oxirane, acetic acid, vinyl hexanoate, pentanoic acid, heptanoic acid, octanoic acid, and nonanoic acid). At 16 weeks of storage, the levels of 2-octanone, 3-octen-2-one, and acetic

acid showed significant increases (Table 3), whereas hexanal levels (the traditional marker) were not significantly increased. At 24 weeks of storage, 2-octanone, 3-octen-2-one, and acetic acid levels increased between 1.2- and 5.3-fold as compared with their levels at 16 weeks. Thus, 2-octanone, 3-octen-2-one, and acetic acid may be more sensitive indicators of early oxidation development in roasted almonds than hexanal.

A PCA was performed on the data. ANOVA indicated that 2,3-dimethylpyrazine, 2-methyl-1-propanol, and 2-propenol were not significant compounds ($p < 0.001$), and so these compounds were excluded from the PCA. In the PCA score plot, 74.3% of the variance could be explained within the first two dimensions (Figure 4A). Almond samples were separated on the basis of storage periods; volatile profiles in late storage periods (16−24 weeks) separated from volitle profiles from early storage periods (0−12 weeks). PC1 explains 60.8% of the total variance. Along the PC1, early storage periods clustered on the left side, whereas late storage periods clustered on the right side. PC2 explains 13.5% of the total variance. Light-roast samples clustered in the bottom right quadrant, whereas dark-roast samples clustered in the top right.

The PCA loading plot (Figure 4B) indicates that compounds formed during storage drive the separation (i.e., 2-octanone (X12), 2-nonanone (X16), 3-octen-2-one (X18), 2-decanone (X21), (*E*)-2-decenal (X26), 2,4-nonadienal (X27), 2-undecenal (X28), 1-octen-3-ol (X45), nonanol (X51), pentyl oxirane (X57), hexyl oxirane (X58), acetic acid (X61), vinyl hexanoate (X64), pentanoic acid (X66), heptanoic acid (X68), octanoic acid (X70), and nonanoic acid (X71)).

In conclusion, improved sensitivity of oxidation may be achieved by evaluating the levels of two groups of volatile compounds. The first are those that are absent from raw and freshly roasted almonds but detectable around 16 weeks of storage and include certain oxiranes, carbonyls, and short-chain acids. The second includes heptanol and 1-octanol as these correlate to early stages of oxidation and are observed before hexanal levels rise. Together these markers can be used to probe early changes in product quality, improve the sensitivity of detection for oxidation, and help to prevent the loss from significant oxidation in almonds at later stages.

In addition, we found significant decreases in roasting-related aroma volatiles at 4 weeks of storage, independent of the degree of roast or storage temperature. In general, a low volatile stage occurs around the fourth week of storage. This is followed by increasing levels of volatiles associated with lipid oxidation. At a storage temperature of 35 °C, oxidation-related volatiles begin to dominate the volatile profile at 20 weeks.

droplets.[21] Furthermore, it has been reported that the storage stability of emulsions stabilized by nonionic surfactants is strongly dependent upon their PIT,[22−24] which depends on salt concentration. Many previous studies on the impact of salt on nanoemulsion formation have utilized simple organic solvents or liquids as the oil phase. In this study, we utilized an oil phase that is more representative of those that might be used in the food industry, that is, vitamin E acetate dissolved in medium-chain triglycerides (MCT).

Recently, we demonstrated that stable vitamin E-enriched emulsions containing very fine droplets ($d$ < 60 nm) could be produced by spontaneous emulsification.[25] We also showed that addition of cosolvents to the aqueous phase of these emulsions had an appreciable influence on their formation and stability.[26,27] The purpose of the present study was to investigate the influence of two salts commonly used in industrial applications (NaCl and $CaCl_2$) on the formation and stability of vitamin E emulsions produced using spontaneous emulsification. The knowledge gained from this study will be useful for the successful incorporation of emulsion-based delivery systems into commercial products.

## MATERIALS AND METHODS

**Materials.** Vitamin E acetate (VE) was kindly donated by BASF (Ludwigshafen, Germany). MCT oil (MIGLYOL 812) was purchased from Warner Graham Co. (Sasol Germany GmbH). Nonionic surfactant (Tween 80), sodium chloride, calcium chloride anhydrous, citric acid, and sodium benzoate were purchased from Sigma-Aldrich Co. (St. Louis, MO, USA). Double-distilled water was used in the preparation of all solutions and emulsions.

**Emulsion Preparation.** Emulsion formation was carried out using the spontaneous emulsification procedure described in our previous study.[27] In brief, spontaneous emulsification was performed by the addition of an organic phase to an aqueous phase with constant magnetic stirring (600 rpm) at 25 °C. The organic phase consisted of VE, MCT, and surfactant, whereas the aqueous phase consisted of a buffer solution containing 0.8 wt % citric acid, 0.08 wt % sodium benzoate, and different levels of NaCl or $CaCl_2$ (pH 3.0). On the basis of the results of our previous studies, we prepared emulsions with the following composition: 8% vitamin E acetate; 2% MCT; 10% Tween 80; and 80% buffer solution (pH 3). The oil (8 g VE + 2 g MCT) and surfactant (10 g) were first mixed together to form an organic phase, which was then slowly poured into 80 g of aqueous phase over a 15 min period with continuous stirring.

Emulsions were diluted in three different ways to contain final systems with different droplet concentrations and aqueous phase compositions: (i) with buffer solution (pH 3); (ii) with salt solutions (NaCl or $CaCl_2$) with similar salt concentrations as the emulsions (pH 3); and (iii) with salt solutions containing various salt concentrations.

**Particle Size Measurements.** Particle size distributions were measured using a dynamic light scattering instrument (Zetasizer Nano ZS, Malvern Instruments, Malvern, UK). This instrument determines the particle size from intensity−time fluctuations of a laser beam (633 nm) scattered from a sample at an angle of 173°. Each individual measurement was an average of 13 runs. To avoid multiple scattering effects, samples were diluted (500 times) before the particle size measurements using buffer solution (pH 3.0). The mean droplet radius ($Z$-average) was calculated from the particle size distribution. All measurements were conducted at ambient temperature.

**Turbidity Measurements and Cloud Point Calculation.** The influence of temperature on emulsion turbidity was determined using a UV−visible spectrophotometer with temperature scanning capabilities (Evolution Array, Thermo Scientific). The absorbance ($A$) at 600 nm was measured as the temperature was increased from 20 to 95 °C at 1 °C/min. The cloud point was empirically defined as the temperature at which the slope of the turbidity−temperature profile ($d\tau/dT$) first reached a maximum value during heating.

**Statistical Analysis.** All experiments were carried out two or three times using two freshly prepared samples, and the results are reported as the calculated mean and standard deviation of these measurements. Differences between group means were determined by analysis of variance (ANOVA) using statistical software (version 12.0; SPSS, Inc., Chicago, IL, USA). Means were subjected to Duncan's test, and a $P$ value of <0.05 was considered statistically significant.

## RESULTS AND DISCUSSION

**Effect of Salts on Initial Particle Size.** Initially, the influence of salt type and concentration on the size of the oil droplets formed in vitamin E emulsions produced by spontaneous emulsification was determined. The oil phase contained 80% vitamin E and 20% MCT. This composition produced the smallest particle size as shown in a previous study,[25] and so we used this oil phase composition in the present study. The aqueous phase contained either 0−1 N NaCl or 0−0.5 N $CaCl_2$. The influence of different salt concentrations on the initial mean droplet diameter of the emulsions was measured. The mean droplet diameter remained relatively constant at all salt levels used: ≈52 nm from 0 to 1 N NaCl and ≈51 nm from 0 to 0.5 N $CaCl_2$. Therefore, the addition of salt did not have an appreciable effect on the mean droplet diameter of the emulsions at any of the levels tested. The particle size distributions of all these emulsions were also similar, that is,, monomodal with similar modes and widths (data not shown).

In principle, one might expect the presence of salts to affect the size of the droplets produced by spontaneous emulsification by altering the bulk physicochemical properties of the aqueous phase (e.g., density, refractive index, viscosity, and interfacial tension) or by altering its molecular properties (e.g., structural organization). Changes in the viscosity of an aqueous solution would be expected to affect the mass transport kinetics of surfactant and oil molecules at the boundary between the organic and aqueous phases, which could influence the spontaneous formation of small droplets at the phase boundary.[28] Changes in oil/water interfacial tension would also be expected to influence spontaneous droplet formation by altering the dynamics of the phase boundary. Having said this, the addition of NaCl and $CaCl_2$ to aqueous solutions at the highest levels used in this study (1 and 0.5 N, respectively) should only slightly increase their interfacial tension, viscosity, density, and refractive index (Table 1). Consequently, the influence of salts on the physicochemical properties of the

**Table 1. Effect of Salt Concentration (N Salts in Aqueous Phase) on the Relative Viscosity, Refractive Index, Relative Density, and Excess Interfacial Tension**

| | relative viscosity $\eta/\eta_o$[a] | refractive index | relative density (kg/L) | excess interfacial tension[b] (mN/m) |
|---|---|---|---|---|
| water | 1.000[c] | 1.333[c] | 1.000[c] | 0.0[e] |
| NaCl solution (1 N) | 1.090[c] | 1.343[c] | 1.038[c] | 0.9[e] |
| $CaCl_2$ solution (0.5 N) | 1.070[d] | 1.346[c] | 1.044[c] | 1.9[e] |

[a]Ratio of the absolute viscosity of solution at 20 °C to the ratio of the absolute viscosity of water at 20 °C. [b]Excess interfacial tension is defined as the difference between interfacial tension of hydrocarbon/salts solution and interfacial tension of hydrocarbon/water. [c]Reference 50. [d]Reference 51. [e]Reference 52.

aqueous phase might be expected to be relatively small. Previous studies have shown that changes in the solubility and optimum curvature of surfactants in surfactant−oil−water (SOW) mixtures play a crucial role in the spontaneous formation of oil droplets using low-energy methods.[8,29,30] The fact that we observed no influence of salts on the initial particle size in this study (Table 1 and Figure 1) suggests that the salts did not have an appreciable influence on surfactant solubility or optimum curvature under the conditions used. Nevertheless, this is likely to be highly dependent on the nature of the surfactant used to form the emulsions.

**Effect of Salts on Thermal Stability.** Emulsion-based delivery systems are usually exposed to elevated temperatures during their manufacture, storage, or utilization, for example, hot filling, pasteurization, or cooking. Therefore, information about the thermal stability of emulsions is of particular importance for many commercial applications. We therefore investigated the impact of salt type and concentration on the thermal stability of the vitamin E emulsions using a spectrophotometric method. The turbidity of emulsions containing different NaCl and $CaCl_2$ concentrations was measured as they were subjected to a temperature increase from 20 to 95 °C. The turbidity profiles in the presence of NaCl and $CaCl_2$ were qualitatively similar, and therefore we show only the results for the emulsion containing NaCl (Figure 1a).

The turbidity of the emulsions remained relatively low and constant during heating from 0 to 75 °C in the absence of NaCl, then increased sharply around 75−80 °C, and then remained high upon further heating from 80 to 95 °C (Figure 1a). This steep rise in turbidity can be ascribed to an increase in droplet size during heating. As the temperature increased, there would be progressive dehydration of the polar headgroups of the nonionic surfactant molecules (Tween 80), which would reduce the hydration repulsion between the droplets, thereby promoting droplet coalescence.[31,32] Furthermore, dehydration of the surfactant headgroups changes the optimum curvature of the surfactant monolayer toward unity, which favors ultralow interfacial tension, high interfacial flexibility, and droplet coalescence.[3,33] The turbidity−temperature profiles of emulsions containing salt were more complex than those containing no salt (Figure 1a). For instance, for the emulsions containing 0.15 N NaCl, the turbidity remained low and constant from 20 to 74 °C, increased steeply from 74 to 78 °C, and remained high from 78 to 88 °C, which was qualitatively similar as the turbidity−temperature profile measured in the absence of salt. However, upon increasing the temperature further, there was a sharp drop in the turbidity from 88 to 90 °C, followed by another steep increase from 90 to 93 °C, after which the turbidity remained high from 93 to 95 °C (Figure 1a). The turbidity−temperature profiles observed for the emulsions containing salt can be related to a transitional phase inversion of the SOW system around the PIT. The phase inversion temperature is governed by changes in the optimum curvature and relative solubility of nonionic surfactants with temperature.[29,34] The molecular geometry of a surfactant can be defined by a packing parameter, $p$[35]

$$p = \frac{a_T}{a_H}$$

where $a_T$ and $a_H$ are the cross-sectional areas of the lipophilic tail-group and hydrophilic headgroup, respectively. Initially, the emulsions had relatively low turbidities at room temperature

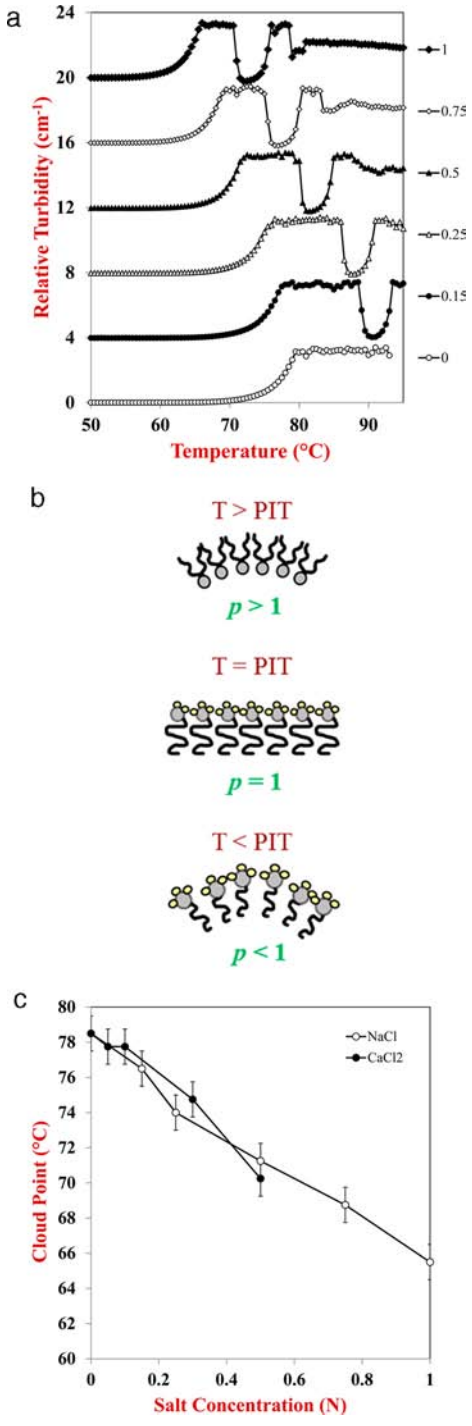

**Figure 1.** (a) Influence of temperature on the relative turbidity of vitamin E-enriched mini-emulsion produced using 10% oil phase (vitamin E/MCT, 8:2), 10% surfactant phase (Tween 80), and 80% aqueous phase with different concentrations (N) of NaCl. To prevent overlap of the graphs, the unit values of 4, 8, 12, 16, and 20 were added to the turbidity data obtained for the emulsion with aqueous phase containing 0.15, 0.25, 0.5, 0.75, and 1 N NaCl, respectively, and the corresponding turbidities were reported as relative turbidity. (b) Packing parameter ($p$) and optimum curvature of Tween 80 at different temperatures. (c) Influence of salt concentration on the cloud point of vitamin E-enriched mini-emulsion produced using 10% oil phase (vitamin E/MCT, 8:2), 10% surfactant phase (Tween 80), and 80% aqueous phase.

because they contained very small droplets that did not scatter light strongly.[36] At these low temperatures the surfactant is relatively hydrophilic, and the corresponding optimum curvature ($p < 1$) favors the formation of oil-in-water emulsions. As temperature increases, the headgroup of the nonionic surfactant (Tween 80) undergoes progressive dehydration, causing the packing parameter to increase (Figure 1b). As a result, the rate of droplet coalescence increases because of the reduced hydration repulsion between droplets and the increase in interfacial flexibility, and so there is a corresponding increase in turbidity. However, when the temperature reaches the PIT, the surfactant monolayer has zero curvature, the packing parameter is close to unity ($p = 1$), and the interfacial tension becomes ultralow (Figure 1b). These changes favor the formation of a bicontinuous microemulsion phase containing very small structures that do not scatter light strongly, thereby leading to a reduction in turbidity. Increasing the temperature above the PIT further dehydrates the headgroups of the surfactant molecules, which increases their lipophilicity, increases the packing parameter ($p > 1$), and changes the optimum curvature so that it favors the formation of water-in-oil emulsions (Figure 1b). The water droplets in the water-in-oil emulsions formed above the PIT are relatively large and therefore scatter light strongly, leading to increased turbidity.[3,29]

The impact of salt on the turbidity−temperature profiles of the emulsions can be attributed to the fact that salt decreases the PIT of the emulsions. In the absence of salt, the PIT is relatively high, and therefore we observed only the initial droplet coalescence regimen. In the presence of sufficient salt, the PIT moved into the experimental temperature range, and we could observe droplet coalescence, microemulsion formation, and phase inversion. A similar behavior was observed in the turbidity−temperature profiles of vitamin E-enriched emulsions in the absence and presence of glycerol; that is, glycerol reduced the PIT.[26]

The turbidity versus temperature profiles were used to determine the cloud points of the emulsions so that we could establish the influence of salt type and concentration on their thermal behavior. The cloud point of the emulsions decreased from around 78 to 65 °C when the NaCl concentration was increased from 0 to 1 M and decreased from around 78 to 70 °C when the $CaCl_2$ concentration was increased from 0 to 0.5 N (Figure 1c). The ability of NaCl[14,15,20,37] and $CaCl_2$[14,15,37] to decrease the cloud points of nonionic surfactant has been reported previously. Our results are also in agreement with previous studies that have reported that the cloud point and/or PIT of nonionic surfactants is a linear function of their salt concentration.[15,38,39] The decrease in thermal stability (cloud point) of emulsions in the presence of NaCl and $CaCl_2$ can be attributed to the effect of these salts on the solubility and packing characteristics of nonionic surfactants.

Specific anionic[19,40,41] and cationic[12,16,19,40] salt ions may either increase (salting in) or decrease (salting out) the solubility of nonionic surfactants due to their effects on the structural organization of water molecules. Ions can be classified as either "structure-makers" (salting out) or "structure-breakers" (salting in) according to their position in the Hofmeister series.[42,43] The presence of mineral ions in an aqueous solution may alter the PIT of a nonionic surfactant by altering the solubility and packing characteristics of the surfactant molecules. In particular, salts may affect the optimum curvature of the surfactants by altering the hydration of their hydrophilic headgroups. In this study, we found that both NaCl and $CaCl_2$ reduced the PIT of the emulsions, which suggests that they increased the packing parameter ($p$) by promoting headgroup dehydration. Previously, this affect has been attributed to the fact that these ions promote structure formation of bulk water around the ions, thereby reducing the amount of water molecules available to hydrate the surfactant headgroups.[18] In an alternative interpretation of the Hofmeister series, Kabalnov et al.[44] suggested that the salting-in and salting-out phenomena have an interfacial origin driven by preferential adsorption/desorption of salt ions at the hydrophilic headgroup of the nonionic surfactant monolayers. Adding NaCl as a nonadsorbing salt dehydrates the hydrophilic headgroups through an osmotic effect associated with preferential ion exclusion, [44] thereby altering the optimum curvature and decreasing the PIT.

The fact that salt addition did not strongly influence the size of droplets during emulsion formation, but did influence their thermal stability (Figure 2), may have been due to their influence on the dehydration of the hydrophilic headgroups at different temperatures. Emulsion formation was carried out at low (room) temperature, and therefore the surfactant molecules would have been highly hydrated. Presumably, headgroup hydration was still sufficient in the presence of salt to generate a strong steric repulsion between the droplets and to have a high surfactant curvature. However, once the emulsions were heated, the effects of salts became more pronounced because the surfactants were already partially dehydrated, and any further change due to salt addition was sufficient to promote instability.

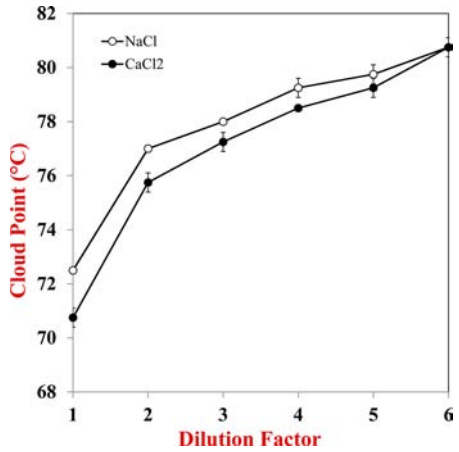

**Figure 2.** Influence of dilution on the cloud point of vitamin E-enriched mini-emulsion produced using 10% oil phase (vitamin E/MCT, 8:2), 10% surfactant phase (Tween 80), and 80% aqueous phase (0.5 M salt). Oil phase concentrations were 10, 5, 3.33, 2.5, and 1.67, and salt concentrations were 0.4, 0.2, 0.13, 0.1, 0.08, and 0.067 N for the emulsion diluted with dilution factors of 1, 2, 3, 4, 5, and 6, respectively.

**Influence of Dilution on Thermal Stability.** Emulsions are diluted when they are incorporated into functional food and beverage products. Our previous studies have shown that emulsion dilution may have an appreciable influence on emulsion thermal stability.[26,27,45] We therefore examined the influence of dilution with buffer solution on the thermal stability of vitamin E emulsions initially containing 0.5 N NaCl or $CaCl_2$ in the aqueous phase. Qualitatively, all of the diluted

emulsions had similar turbidity−temperature profiles as the undiluted emulsions (Figure 1a): upon increasing the temperature from 20 to 95 °C, the turbidity initially remained low, then steeply increased, then sharply decreased to a minimum, then steeply increased again, and then remained high (data not shown). The cloud points determined from these profiles increased from 73 to 81 °C for NaCl and from 70 to 81 °C $CaCl_2$ as the emulsion dilution factor (DF) increased from 1 to 6 (Figure 2). As these samples were diluted with buffer solution, the observed results may have been due to a decrease in salt concentration in the aqueous phase or due to a decrease in oil droplet concentration.

We therefore carried out additional experiments in which the emulsions were diluted with various salt solutions so as to obtain samples where (i) the droplet concentration was kept constant, but the salt concentration varied (Figure 3) or (ii) the droplet concentration varied, but the salt concentration was kept constant (Figure 4). In the diluted emulsions with fixed droplet concentration, the cloud point increased from around 73 to 77 °C for NaCl and from around 72 to 77 °C for $CaCl_2$ as the salt content decreased from 0.4 to 0.2 N, respectively (Figure 3). These results suggest that at least part of the increase in cloud point observed upon emulsion dilution (Figure 2) was related to a reduction in salt concentration in the aqueous phase. In the diluted emulsions with fixed salt concentration, the cloud point initially increased and then decreased as the droplet content was reduced from 10 to 1% (Figure 4a). This effect may have been an artifact of the cloud point measurement at high droplet concentration. As the droplet concentration increased, there was an increase in the overall turbidity of the samples due to an increase in light scattering by the droplets (Figure 4b). In the emulsions with the highest droplet concentrations, the turbidity was so great (>3 $cm^{-1}$) that it was not possible to observe the entire region where rapid droplet coalescence occurred. Consequently, it was not possible to accurately measure the cloud points for these samples. In the more dilute emulsions (≤3% oil), the cloud point decreased with increasing dilution (decreasing droplet concentration), which may have been due to changes in the nature of the microemulsion phase formed around the PIT when the SOW ratio was changed. Taken together, these results suggest that the increase in cloud point observed when salt-containing emulsions were diluted with buffer solution was primarily due to the reduced salt concentration in the aqueous phase, rather than the reduced droplet concentration.

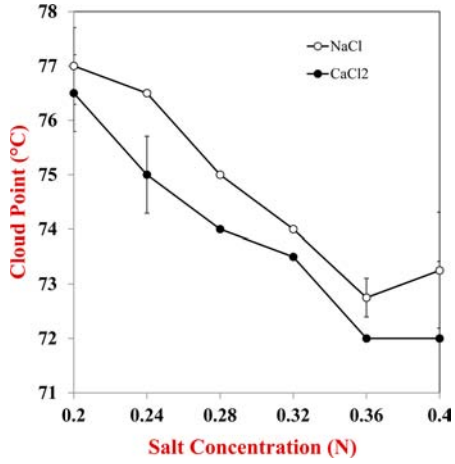

**Figure 3.** Influence of salt concentration on the cloud point of vitamin E-enriched mini-emulsions containing 5% oil phase. The initial emulsion was produced using 10% oil phase (vitamin E/MCT, 8:2), 10% surfactant phase (Tween 80), and 0.4 N salt.

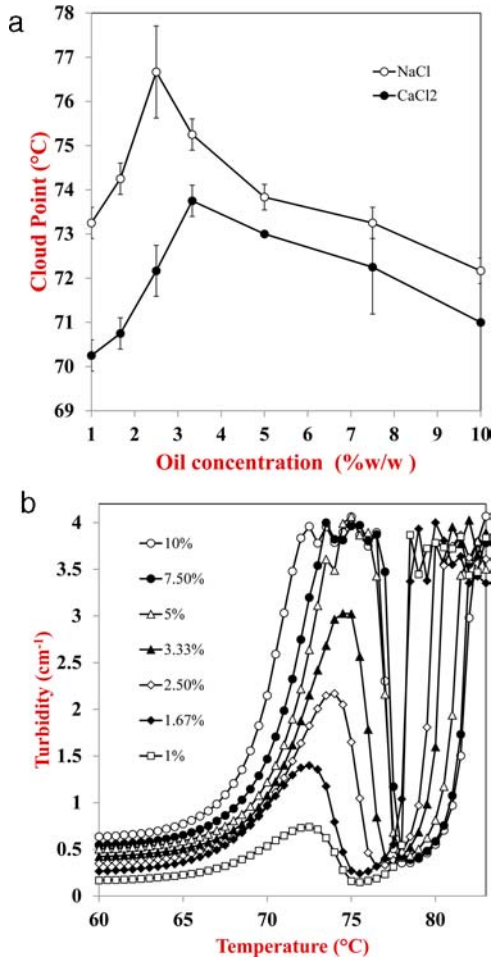

**Figure 4.** (a) Influence of oil phase concentration on the cloud point of diluted vitamin E-enriched mini-emulsions containing 0.4 N salts. The initial emulsion was produced using 10% oil phase (vitamin E/MCT, 8:2), 10% surfactant phase (Tween 80), and 0.4 N NaCl. (b) Influence of temperature on the turbidity of vitamin E-enriched miniemulsions containing 0.4 N $CaCl_2$ and different oil phase concentrations. The initial emulsion was produced using 10% oil phase (vitamin E/MCT, 8/2), 10% surfactant phase (Tween 80), and 0.4 N $CaCl_2$.

**Influence of Salts and Dilution on Isothermal Stability.** Physical stability of emulsion-based delivery systems during storage, transport, and utilization is required for most commercial applications. Emulsions may become unstable through a number of different physicochemical processes, including flocculation, coalescence, Ostwald ripening, and gravitational separation.[10,33] The mechanism and rate of breakdown depend on emulsion composition and microstructure, as well as the environmental conditions experienced during its lifetime. We therefore examined the influence of salt addition and dilution on the storage stability of vitamin E emulsions. A series of emulsions was fabricated with different droplet concentrations (2.5 or 10 wt %) and salt concentrations (0, 0.2, and 0.4 N NaCl or $CaCl_2$) by diluting an initial emulsion with different types and amounts of salt solution. After preparation, the resulting emulsions were stored for 1

month at three storage temperatures representing refrigeration conditions (5 °C), ambient storage in mild climates (20 °C), and ambient storage in hot climates (37 °C).

The initial emulsion formed by spontaneous emulsification contained 0% salt and 10% oil and was therefore designated "0/10". The extent of droplet growth in this emulsion after 1 month of storage was appreciable and increased with increasing storage temperature: ~15% at 5 °C, 19% at 20 °C, and 54% at 37 °C (Figure 5). The droplet size distribution of these

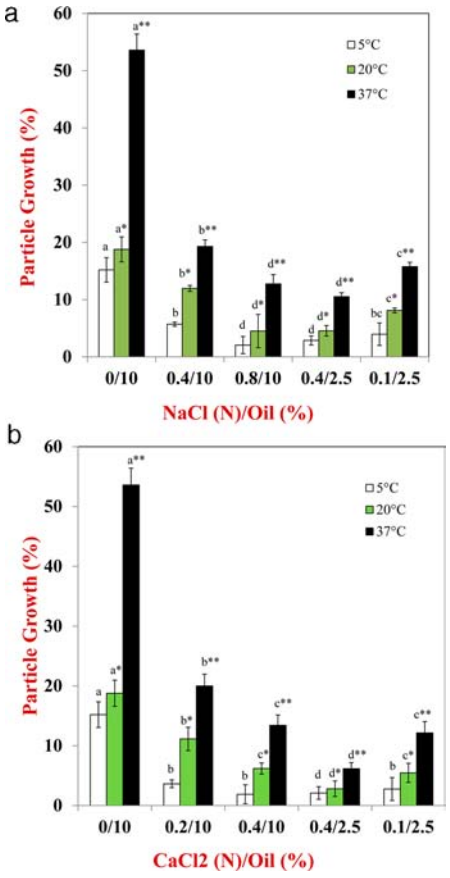

**Figure 5.** (a) Influence of storage time and temperature on the particle growth (%) of vitamin E-enriched mini-emulsions containing different ratios of NaCl (N)/oil phase. The initial emulsions were produced using 10% oil phase (vitamin E/MCT, 8:2), 10% surfactant phase (Tween 80), and different NaCl concentrations (0, 0.4, and 0.8 N). Means within different letters and the same number of stars are significantly ($P < 0.05$) different. (b) Influence of storage time and temperature on the particle growth (%) of vitamin E-enriched mini-emulsions containing different ratios of $CaCl_2$ (M)/oil phase. The initial emulsions were produced using 10% oil phase (vitamin E/MCT, 8:2), 10% surfactant phase (Tween 80), and different $CaCl_2$ concentrations (0, 0.2, and 0.4 N). Means within different letters and the same number of stars are significantly ($P < 0.05$) different.

emulsions remained monomodal throughout storage at all temperatures (data not shown). The stability of the emulsions to droplet growth improved significantly ($P < 0.05$) as the level of NaCl or $CaCl_2$ added was increased, especially at the elevated temperatures (Figure 5). In addition, reducing the droplet concentration from 10 to 2.5% also led to a significant ($P < 0.05$) inhibition of droplet growth for emulsions containing both types of salt (Figure 5). Overall, these results suggest that the addition of NaCl or $CaCl_2$ improved the isothermal storage stability of the emulsions, even though it decreased their thermal stability by reducing the cloud point (Figure 2). This independence of thermal and isothermal stability of vitamin E emulsions has also been reported upon posthomogenization addition of cosurfactants.[46]

There are a number of possible mechanisms that might be responsible for the observed instability of the emulsions during storage: flocculation, coalescence, and Ostwald ripening.[4,33] We do not believe that flocculation played an important role in emulsion instability as we did not observe any flocs using an optical microscope. We therefore postulated that the observed instability was due to either coalescence or Oswald ripening. It is often difficult to distinguish between these two mechanisms because they both lead to a net increase in mean droplet diameter over time.[33,47] An increase in droplet growth rate with increasing temperature could be attributed to the effects of temperature on coalescence and/or Ostwald ripening. Increasing temperature can dehydrate the surfactant headgroups and thereby increase droplet coalescence by (i) decreasing the hydration repulsion between droplets and (ii) by changing the optimum curvature of the surfactant monolayer toward unity.[3,31,48] A temperature rise may also increase the rate of Ostwald ripening by increasing the diffusion rate or solubility of the oil molecules in the aqueous phase.[49]

Inorganic salts might influence the isothermal storage stability of oil-in-water emulsions stabilized by nonionic surfactant through a number of mechanisms:

*Effect of Salts on Surfactant Headgroup Dehydration.* Previous studies have reported that salts that decrease the cloud point of emulsions stabilized by nonionic surfactant also increase droplet coalescence.[11,20] This effect was attributed to the ability of the salts to promote dehydration of the surfactant headgroup, thereby reducing the hydration repulsion between droplets and altering the surfactant monolayer curvature. However, the fact that we actually observed a decrease in droplet growth during storage in the presence of NaCl and $CaCl_2$ suggested that this mechanism was not prominent under the conditions used.

*Effect of Salts on van der Waals Interactions.* van der Waals interactions are attractive forces that almost always act between oil droplets suspended in water and, therefore, promote droplet aggregation. The addition of salts to an aqueous solution appreciably decreases the magnitude of the van der Waals interaction due to an electrostatic screening effect.[33] This mechanism may therefore account for the increased storage stability of the emulsions in the presence of salt, because there would have been a reduction in the attractive forces acting between the oil droplets. It should be noted that salt can also decrease the electrostatic interaction between the droplets through electrostatic screening, thereby increasing droplet coalescence.

*Effect of Salts on Oil Solubility.* One of the major factors influencing the rate of Ostwald ripening in oil-in-water emulsions is the solubility of the oil phase in the aqueous phase.[33] The addition of salts to the aqueous phase changes the structural organization of the water molecules, which will alter the equilibrium solubility of oil molecules. Salt addition causes an increase in interfacial tension (Table 1), which would increase the free energy associated with introducing a nonpolar molecule into water, thereby decreasing its water solubility. Consequently, addition of salt to the emulsions may have reduced the rate of Ostwald ripening, which is consistent with the reduction in droplet growth rate observed in the presence of salt observed in this study.

In summary, the addition of salt may have improved the storage stability of the emulsions by decreasing the attractive interactions between them (thereby decreasing coalescence) or by reducing the water solubility of the oil phase (thereby decreasing Ostwald ripening). Further studies are required to establish the relative importance of these two different physicochemical mechanisms. The improved stability of the emulsions to droplet growth when the droplet concentration was reduced can simply be attributed to the reduction in droplet collision frequency in the more dilute system.

**Conclusions.** In this study, we examined the influence of salts on the formation, properties, and stability of vitamin E-enriched emulsions prepared by spontaneous emulsification. We have shown that the addition of salts (NaCl and $CaCl_2$) to the aqueous phase of the emulsions did not change the initial droplet size produced. However, the ability of salts to modulate surfactant properties had an appreciable effect on their thermal stability: the cloud point decreased with increasing salt concentration. This effect was attributed to the ability of salts to promote dehydration of the surfactant headgroup, which alters the optimum curvature of the surfactant monolayer. The isothermal stability of the emulsions was influenced by storage temperature, with the droplet growth rate increasing with increasing temperature. This effect was attributed to the impact of temperature on the rate of droplet coalescence and Ostwald ripening. Addition of salts to the emulsions decreased the rate of droplet growth during isothermal storage. This effect was attributed to the ability of salts to reduce the attractive van der Waals interactions between droplets (thereby reducing coalescence) or to reduce the solubility of the oil molecules in water (thereby reducing Ostwald ripening). These results have important implications for the development of emulsion-based delivery systems for application in products containing salts.

between the central region and the surrounding subaleurone layer.[22] However, it is not clear whether these heterogeneous starch granules have different structures.

In this study, heterogeneous starch granules were separated from the kernels of TRS, and their structures were investigated. The objective of this study was to compare the structures of heterogeneous starch granules from high-amylose rice. The results could add to our understanding of the structures of different morphology starch granules from high-amylose cereal crops.

## MATERIALS AND METHODS

**Plant Materials.** An *indica* rice cultivar Te-qing (TQ) and its transgenic resistant starch rice line (TRS) with high amylose content were used in this study. TRS was generated from TQ after transgenic inhibition of both SBE I and SBE IIb through an antisense RNA technique and was homozygous for the transgene.[13] TQ and TRS were cultivated in the transgenic close experiment field of Yangzhou University, Yangzhou, China. Mature kernels were used to isolate starches.

**Total Starch Isolation.** Total starches were isolated from TQ and TRS mature kernels according to the method of Wei et al.[21] with some modifications. Brown kernels were steeped in deionized water overnight at 4 °C, and homogenized with ice-cold water in a home blender. The homogenate was squeezed through five layers of cotton cloth. The residue was homogenized and squeezed twice more in a mortar with a pestle to facilitate the release of starch granules. The combined extract was filtered with 150, 75, and 38 $\mu$m sieves and centrifuged at 5000*g* for 10 min. The yellow gel-like layer on top of the packed white starch precipitate was carefully scraped off and discarded. The process of centrifugation separation was repeated several times until no dirty material existed. The precipitated starch was dehydrated with anhydrous ethanol two times, dried at 40 °C, ground into powders, and passed through a 38 $\mu$m sieve.

**Separation of Heterogeneous Starch Granules.** TRS polygonal, aggregate, elongated, and hollow starch granules were separated from the different regions of the mature kernels referring to the methods of Ao et al.,[2] Peng et al.,[23] Naguleswarana et al.,[24] and Dhital et al.,[25] and combining with the regional distribution of heterogeneous starch granules in endosperm. The detailed separation methods were as described below.

**Separation of TRS Polygonal Starch Granules.** The central regions of the kernels were cut with a stainless razor blade, and used to isolate the crude starch as total starch isolation from kernels. The crude starch was suspended in deionized water and centrifuged at 100*g* for 5 min. The precipitate was repeatedly suspended and centrifuged ten times. Finally, the precipitate was again suspended with 40 mL of deionized water in a 50 mL centrifuge tube and settled for 1 h. The upper 30 mL of starch suspension was collected, and the residual starch suspension was repeatedly made up to 40 mL with deionized water and settled ten times. After that, the collected starch suspension was centrifuged at 5000*g* for 10 min, and the starch precipitate was dehydrated and dried to obtain the TRS polygonal starch granules.

**Separation of TRS Hollow Starch Granules.** The kernels were steeped in deionized water overnight at 4 °C. The peripheral regions (about 0.3 mm thickness) of kernels were cut with a stainless razor blade and used to isolate the crude starch as total starch isolation from kernels. The crude starch was suspended in 50% (v/v) glycerol aqueous solution and centrifuged at 100*g* for 5 min. The supernatant was collected, and the precipitate was repeatedly suspended and centrifuged ten times. After that, the collected supernatant was centrifuged at 5000*g* for 10 min to obtain the starch precipitate. The starch precipitate was suspended in 30% (v/v) glycerol aqueous solution and centrifuged at 100*g* for 5 min. The starch precipitate was repeatedly suspended and centrifuged ten times. Finally, the starch precipitate was washed with deionized water three times to remove the glycerol, dehydrated, and dried to obtain the TRS hollow starch granules.

**Separation of TRS Elongated and Aggregate Starch Granules.** The middle regions between the central region and the surrounding subaleurone layer of the kernels were cut with a stainless razor blade and used to isolate the crude starch as total starch isolation from kernels. The crude starch was suspended in deionized water and centrifuged at 100*g* for 5 min. The precipitate was repeatedly suspended and centrifuged ten times. After that, the precipitate was suspended in 30% (v/v) glycerol aqueous solution and centrifuged at 100*g* for 5 min. The supernatant was collected, and the precipitate was repeatedly suspended and centrifuged ten times. The collected supernatant was centrifuged at 5000*g* for 10 min, and the starch precipitate was washed with deionized water three times, dehydrated, and dried to obtain the TRS elongated starch granules. The precipitate obtained from starch suspension in 30% glycerol was again suspended with 40 mL of deionized water in a 50 mL centrifuge tube and settled for 30 min. The supernatant was discarded, and the starch precipitate was repeatedly suspended and settled ten times. Finally, the starch precipitate was dehydrated and dried to obtain the TRS aggregate starch granules.

**Morphology Observation.** A starch suspension (1%, w/v) was prepared with 50% glycerol aqueous solution. Ten microliters of starch suspension was placed on the microscope slide and covered with a coverslip. The starch granule morphology and Maltese cross were viewed under an Olympus BX 53 polarizing microscope equipped with a CCD camera.

**Measurements of Iodine Absorption Spectrum, Iodine Blue Value, and Amylose Content.** Iodine absorption spectrum, iodine blue value, and amylose content of starch were determined according to the method of Man et al.[26] with some modifications. Ten milligrams of dry starch was dispersed in 5 mL of dimethyl sulfoxide (DMSO) containing 10% 6.0 M urea. Dissolution was obtained by incubating the mixture at 95 °C for 1 h with intermittent vortexing. A 1.0 mL aliquot of the starch−DMSO solution was then placed in a 50 mL volumetric flask along with 45 mL of deionized water, and 1.0 mL of iodine solution (0.2% $I_2$ and 2% KI, w/v) was added. The mixture was made up to 50 mL with deionized water, mixed immediately, and placed in darkness for 20 min. Control solution was made in the same way but without sample. All samples were scanned from 400 to 900 nm with a spectrophotometer (Ultrospec 6300 pro, Amershan Biosciences). The $\lambda_{max}$ was the wavelength (in nm) at which the absorbance was the highest over the range of the wavelengths. Iodine blue value was measured at 680 nm under the above experimental conditions. Apparent amylose content (AAC) was evaluated from absorbance at 620 nm. The recorded values were converted to percent of amylose by reference to a standard curve prepared with amylopectin from corn (Sigma-Aldrich 10120) and amylose from potato. The experiments were performed in triplicate.

**Gel-Permeation Chromatography (GPC) Analysis.** Starch was deproteinized with protease and sodium bisulfite, and debranched with isoamylase following the methods of Tran et al.[27] and Li et al.[28] The molecular weight distribution of debranched starch was analyzed using a PL-GPC 220 high temperature chromatograph (Agilent Technologies UK Limited, Shropshire, U.K.) with three columns (PL110-6100, 6300, 6525) and a differential refractive index detector according to the method of Cai et al.[29] The areas of peaks were integrated, and their relative peak area was expressed as a percentage of the total area of all peaks. The experiments were performed two times.

**X-ray Powder Diffraction (XRD) Analysis.** XRD analysis of starch was carried out on an XRD (D8, Bruker, Germany) as described by Wei et al.[30] All the specimens were stored in a desiccator where a saturated solution of NaCl maintained a constant humidity for 1 week before measurements. The relative crystallinity (%) was measured following the method of Wei et al.[30] A smooth curve that connected peak baselines was computer-plotted on the diffractogram. The areas of peaks at 5.6°, 15°, 17°, 18°, 20°, and 23° at 2$\theta$ above the smooth curve were taken as the crystalline portion. The ratio of diffraction peak area to total diffraction area over the diffraction angle 4−30° at 2$\theta$ was taken as the relative crystallinity. The relative crystallinity was quantitatively analyzed three times.

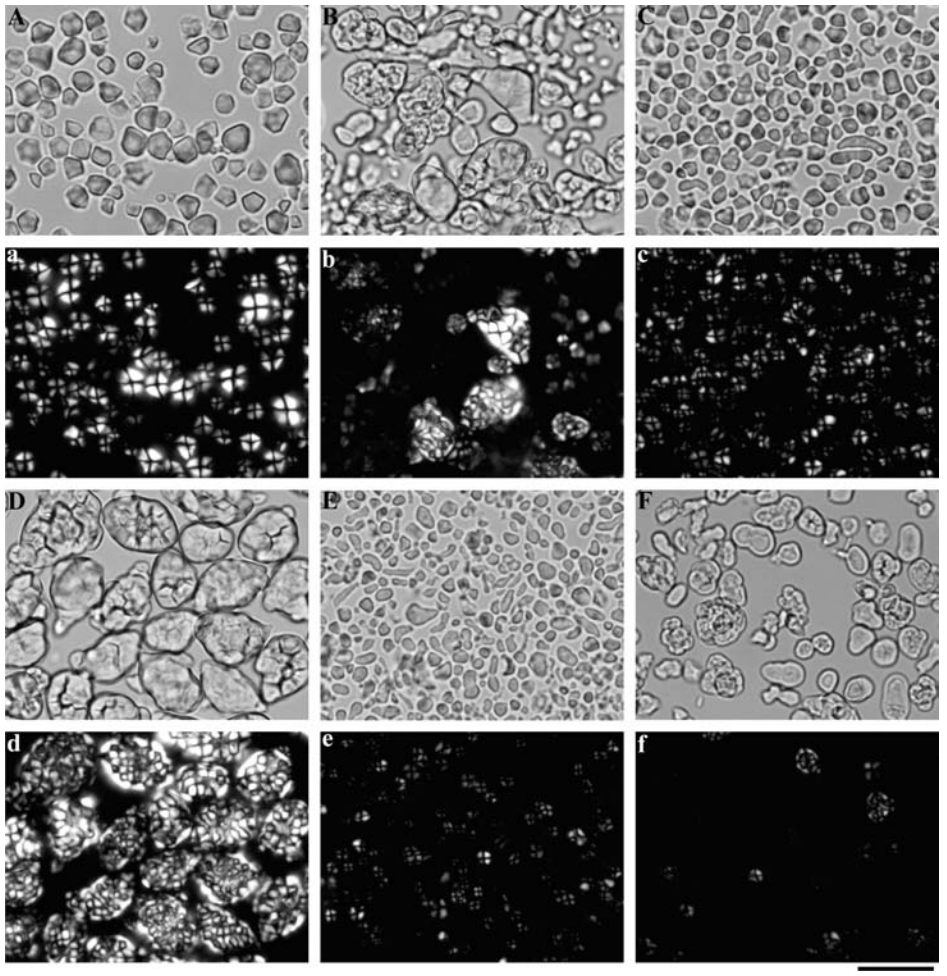

**Figure 1.** Microphotographs of starch granules under normal light (A–F) and polarizing light (a–f). (A, a), TQ total starch granules; (B, b), TRS total starch granules; (C, c), TRS polygonal starch granules; (D, d), TRS aggregate starch granules; (E, e), TRS elongated starch granules; (F, f), TRS hollow starch granules. Scale bar = 20 $\mu$m.

**Attenuated Total Reflectance Fourier Transform Infrared (ATR-FTIR) Analysis.** ATR-FTIR analysis of starch was carried out on a Varian 7000 FTIR spectrometer with a DTGS detector equipped with an ATR single-reflectance cell containing a germanium crystal (45° incidence angle) (PIKE Technologies, USA) as previously described by Wei et al.[30] The spectra were quantitatively analyzed three times.

**Solid-State $^{13}$C Cross-Polarization Magic-Angle Spinning Nuclear Magnetic Resonance ($^{13}$C CP/MAS NMR) Analysis.** High-resolution solid-state $^{13}$C CP/MAS NMR analysis of starch was carried out at B0 = 9.4 T on a Bruker AVANCE III 400 WB spectrometer as previously described by Man et al.[31] Amorphous starch was prepared by gelatinizing native starch following the method of Wei et al.[30] The spectrum of amorphous starch was matched to the intensity of native starch at 84 ppm and subtracted to produce the ordered subspectrum. The $^{13}$C CP/MAS NMR original spectrum and ordered subspectrum were peak fitted by using PeakFit version 4.12. The quantitative analyses of double-helix, single-helix, and amorphous conformational features within starch were carried out according to the method described by Tan et al.[32] The spectra were quantitatively analyzed three times.

**Small-Angle X-ray Scattering (SAXS) Analysis.** SAXS measurement of starch was carried out on a Bruker NanoStar SAXS instrument equipped with Vantec 2000 detector and pinhole collimation for point focus geometry as previously described by Cai et al.[33] SAXS data sets were analyzed using DIFFRAC$^{plus}$ NanoFit software. Parameters of the SAXS spectrum were determined according to the simple graphical method.[33] The experiments were performed two times.

**Differential Scanning Calorimetry (DSC) Analysis.** The thermal properties of starch were determined using DSC (200-F3, Netzsch, Germany). Three milligrams of starch was mixed with 9 $\mu$L of deionized water and hermetically sealed in an aluminum pan overnight at 4 °C. After equilibrating for 1 h at room temperature, the sample was scanned against a blank (empty pan) at a heating rate of 10 °C/min from 25 to 130 °C. The major parameters of the DSC profile were described as onset temperature ($T_o$), peak temperature ($T_p$), conclusion temperature ($T_c$), gelatinization range ($\Delta T$), and gelatinization enthalpy ($\Delta H$). The experiments were performed two times.

**Statistical Analysis.** The data reported in all of the tables were mean values and standard deviation. One-way analysis of variance (ANOVA) and Tukey's test ($p < 0.05$) were evaluated using the SPSS 16.0 Statistical Software Program.

## RESULTS AND DISCUSSION

**Separations and Morphologies of TRS Heterogeneous Starch Granules.** TRS starch contained heterogeneous starch granules.[16] These heterogeneous granules were distributed in different regions of the endosperm.[22] According to the distribution regions of heterogeneous starch granules, we separated these heterogeneous starch granules using different methods in this study. Figure 1 showed the morphology and the separation effectiveness of heterogeneous starch granules. TQ total starch granules isolated from kernels were homogeneous in morphological structure, showed polygonal

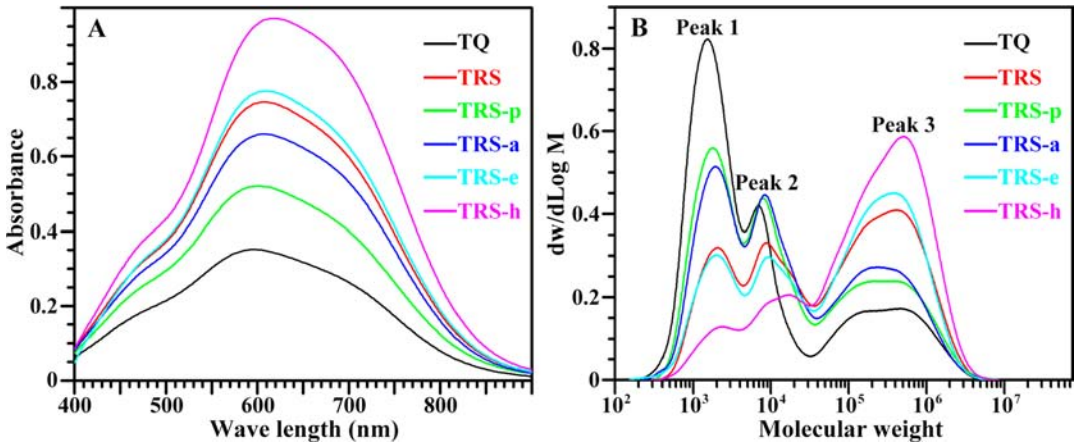

**Figure 2.** Absorbance spectra of starch–iodine complex (A) and GPC profiles of isoamylase-debranched starches (B). TQ, TRS, TRS-p, TRS-a, TRS-e, and TRS-h are TQ total starch, TRS total starch, TRS polygonal starch granules, TRS aggregate starch granules, TRS elongated starch granules, and TRS hollow starch granules, respectively.

morphology, and had a typical Maltese cross in one granule (Figures 1A, 1a). Normal rice starch is compound starch, which means that many starch granules individually form and develop in one amyloplast. These separate starch granules (in fact they are subgranules of compound starch) are freely released from the amyloplast when starch is isolated from mature endosperm.[16,34] TRS total starch granules isolated from kernels were significantly heterogeneous in morphological structures and birefringent patterns (Figures 1B, 1b). These heterogeneous starch granules could be classified into four types: polygonal, aggregate, elongated, and hollow starch granules according to their morphological structures and birefringent patterns. TRS polygonal starch granules showed polygonal morphology, had a typical Maltese cross in one granule, and were essentially similar to the TQ polygonal starch granule (Figures 1 C, 1c). According to the morphological structure of TRS polygonal starch granule, we thought that it was compound starch. TRS aggregate starch granules consisted of many subgranules, showed large voluminous, nonangular rounded bodies, and had many Maltese crosses in one granule. In fact, each subgranule of aggregate starch had only one Maltese cross. There was a thick band or wall encircling the entire exterior of the aggregate starch granule (Figures 1D, 1d). The morphological structure of TRS aggregate starch had been reported in high-amylose rice by Kim et al.[12] and Wei et al.,[16] and the exterior band or wall prevented the release of subgranules during starch isolation.[12,16] That meant that the isolated starch was still the aggregate body of many subgranules, and was therefore designated as aggregate starch. At the early stage of TRS aggregate starch development, starch subgranules individually form and develop in one amyloplast. At the middle stage of starch development, adjacent subgranules start fusion. At the late stage of starch development, the subgranules located at the periphery of the aggregate starch fuse together and form a continuous outer band or wall.[34] Starch granule is considered as elongated granule when the ratio of long axis and short axis is larger than 1.3.[8,35] TRS elongated starch granules contained some small spherical granules. The spherical granule had one typical Maltese cross, and the elongated granule consisted of several small granules and showed very weak Maltese cross (Figures 1E, 1e). The elongated starch granules in high-amylose maize are formed from fusion of several small granules.[35] TRS hollow starch granules were similar to TRS aggregate starch granule in surface shape, but their interiors lacked subgranules and had no birefringence (Figures 1F, 1f). The hollow starch granule has been reported in high-amylose wheat and barley endosperm,[9−11] but its formation is not unclear until now. Among the four types of heterogeneous starch granules, the purity of aggregate starch granules was the highest (Figures 1D, 1d), but the polygonal starch granules contained some small spherical and elongated starch granules (Figures 1C, 1c), the elongated starch granules had some polygonal and small aggregate starch granules (Figures 1E, 1e), and the hollow starch granules contaminated some small aggregate starch granules (Figures 1F, 1f).

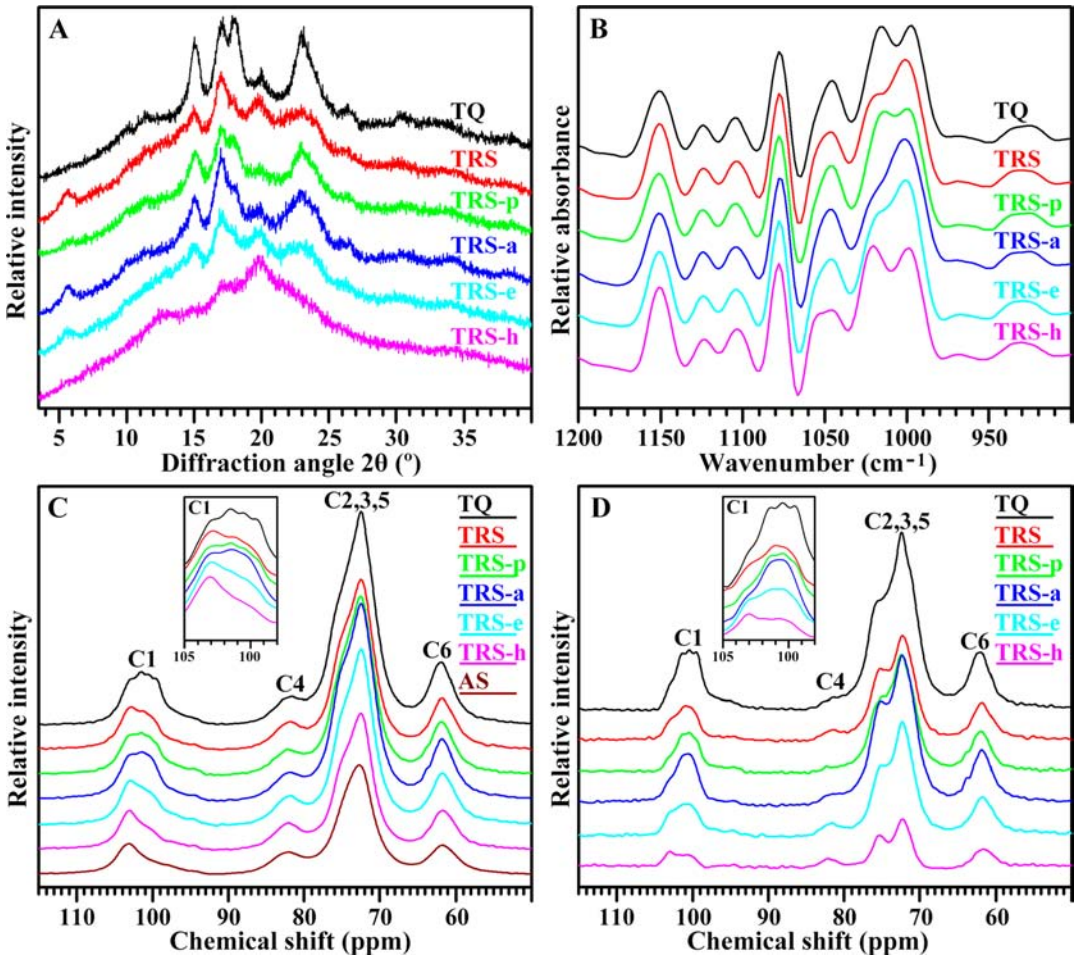

**Figure 3.** XRD spectra (A), ATR-FTIR spectra (B), and $^{13}C$ CP/MAS NMR original spectra (C) and ordered subspectra (D) of starches. AS is amorphous starch. TQ, TRS, TRS-p, TRS-a, TRS-e, and TRS-h are TQ total starch, TRS total starch, TRS polygonal starch granules, TRS aggregate starch granules, TRS elongated starch granules, and TRS hollow starch granules, respectively.

**Iodine Absorption Spectra and Amylose Contents of TRS Heterogeneous Starch Granules.** The iodine absorption spectra of TQ total starch, TRS total starch, and TRS heterogeneous starch granules are presented in Figure 2A, and they showed significant difference. The maximum absorption wavelength ($\lambda_{max}$), iodine blue value (BV), and AAC of starch were summarized in Table 1. The $\lambda_{max}$, BV, and AAC of starches had significantly positive relationships for each other. The correlation coefficients were 0.989, 0.983, and 0.999 between $\lambda_{max}$ and BV, $\lambda_{max}$ and AAC, and BV and AAC, respectively ($P < 0.001$). The AAC of TRS total starch was 60.0%, and was markedly higher than that of TQ total starch (25.5%), which was in agreement with the previous report.[21] TRS heterogeneous starch granules showed significantly different AAC. The hollow starch granules had the highest AAC (80.2%), and the polygonal starch granules showed the lowest AAC (39.8%). The significantly different AACs of TRS heterogeneous starch granules indicated that these heterogeneous starch granules significantly differed in not only the morphology but also the structure.

**Molecular Weight Distributions of TRS Heterogeneous Starch Granules.** The molecular weight distributions of isoamylase-debranched starches as determined by GPC are shown in Figure 2B. A trimodal distribution of low, middle, and high molecular weight peaks, designated peak 1, peak 2, and peak 3, respectively, was observed. Peak 1 and peak 2 consist of short (A and short B chains) and long (long B chains) branch-chains of amylopectin, respectively. The area ratio of peak 1 to peak 2 might be used as an index of the extent of branching of amylopectin; the higher the ratio, the higher the branching degree.[36] Peak 3 mainly includes amylose.[37] The GPC parameters are summarized in Table 1. The AC determined based on iodine and starch affinity is described as AAC, which overestimates AC if there are branched molecules with long side chains that bind iodine.[38] The present results showed that the ACs of TRS total starch and TRS heterogeneous starch granules determined by GPC were significantly lower than AACs obtained by iodine colorimetric method (Table 1), which was in agreement with the report of Shi et al.[38] and indicated that the intermediate chain and amylopectin long branch-chain could bind iodine to increase the value of AAC. In the present study, the correlation coefficient between AAC obtained by iodine colorimetric method and AC determined by GPC was 0.963 ($P < 0.002$), indicating that the AAC and AC had a significantly positive relationship though the AC was lower than the AAC. The molecular weight distributions and the branching degrees were significantly different among TRS heterogeneous starch granules, indicating that these heterogeneous starch granules had different molecular structures.

**XRD Patterns of TRS Heterogeneous Starch Granules.** Native starches can be divided into A-, B-, and C-type crystallinity according to their XRD patterns.[39] XRD patterns of

Table 2. Relative Crystallinity, IR Ratio, and the Proportions of Single Helix, Double Helix, and Amorphous Conformation of Starch[a]

[a]Data are means ± standard deviations, $n = 3$. Values in the same column with different letters are significantly different ($P < 0.05$). [b]Relative crystallinity determined by XRD. [c]IR ratio determined by ATR-FTIR. [d]Relative proportion determined by $^{13}C$ CP/MAS NMR.

TQ total starch, TRS total starch, and TRS heterogeneous starch granules are presented in Figure 3A, and their relative crystallinities are shown in Table 2. TQ total starch showed strong reflection at about 15° and 23° 2$\theta$ and an unresolved doublet at 17° and 18° 2$\theta$, indicating that it had a typical A-type XRD pattern, and was similar to that of normal cereal starches.[39] TRS total starch showed strong reflection at about 15°, 17°, and 23° 2$\theta$ and a small peak at about 5.6° 2$\theta$, indicating that TRS total starch was C-type crystallinity, which was in agreement with our previous report.[21] It was very interesting that TRS heterogeneous starch granules had different XRD patterns. The polygonal starch granules exhibited A-type crystallinity, the aggregate and elongated starch granules showed C-type crystallinity, and the hollow starch granules had no crystallinity. The different crystalline structures might result from the different ACs. Cheetham and Tao[39] thought that the crystalline type of maize starch could be varied from A- to B- via C-type when AC increased. The TQ total starch had the highest relative crystallinity, which was in agreement with the lowest amylose content. The elongated starch granules had very low crystalline peak intensities, resulting in low relative crystallinity. The hollow starch granules did not show birefringence under polarizing light, which was in agreement with an absence of crystallinity measured by XRD. The absence of crystallinity has also been reported in wheat hollow starch granules.[40]

**ATR-FTIR Spectra of TRS Heterogeneous Starch Granules.** The ATR-FTIR spectrum of starch is sensitive to the short-range ordered structure. The variations in spectra among different starches can be interpreted in terms of the short-range ordered structure present in the external region of starch granule.[41] The ATR-FTIR spectra of TQ total starch, TRS total starch, and TRS heterogeneous starch granules in the 1200−900 $cm^{-1}$ region are shown in Figure 3B. The bands at 1045 and 1022 $cm^{-1}$ are associated with ordered/crystalline and amorphous regions in starch, respectively. The ratio of absorbance 1045/1022 $cm^{-1}$ is used to quantify the degree of order, and that of 1022/995 $cm^{-1}$ can be used as a measure of the proportion of amorphous to ordered carbohydrate structure in the starch.[41] The ratios for 1045/1022 and 1022/995 $cm^{-1}$ of TQ total starch, TRS total starch, and TRS heterogeneous starch granules are shown in Table 2. On the basis of both the spectra and calculated data, the ATR-FTIR characteristics were significantly different among TRS heterogeneous starch granules, indicating that TRS heterogeneous starch granules had different short-range ordered structures in the external region of granule.

**$^{13}C$ CP/MAS NMR Spectra of TRS Heterogeneous Starch Granules.** The solid-state $^{13}C$ CP/MAS NMR spectra of TQ total starch, TRS total starch, and TRS heterogeneous starch granules are shown in Figure 3C. The resonances at different ppm were assigned according to the data reported in the literature.[42,43] The C1 resonance, which gives information about both the crystalline nature and the noncrystalline (but rigid) chains, has been used to examine the crystallinity of starches. A-type starch is a triplet at the C1 region; B-type starch shows a doublet. C-type starch has an inconspicuous triplet or doublet according to the proportions of A- and B-type allomorph.[42,43] Amorphous starch has one peak at 103 ppm, which arises from the amorphous domain for C1, and the peak intensity is positively relative with AC.[32] TQ total starch had a clear triplet at 99.5, 100.5, and 101.5 ppm, and TRS total starch showed an inconspicuous doublet at the C1 region and a strong peak at 103 ppm, indicating that TQ total starch had A-type crystallinity, and TRS total starch had C-type crystallinity and high AC. This result was in agreement with our previous report.[21] TRS polygonal starch granules showed a triplet at the C1 region, TRS aggregate and elongated starch granules had an inconspicuous doublet, and TRS hollow starch granules exhibited no peak except the amorphous peak at 103 ppm. These results indicated that TRS polygonal starch granules had A-type crystallinity, TRS aggregate and elongated starch granules had C-type crystallinity, and TRS hollow starch granules had no crystallinity, and were in agreement with the XRD patterns of TRS heterogeneous starch granules.

Figure 3D shows the ordered subspectra of starches. In this analysis, the standard amorphous starch spectrum was subtracted from the test spectrum until there was no residual intensity at 84 ppm (a region of the spectrum with intensity due solely to amorphous conformations).[32] The ordered subspectra were similar to the original spectra, but they had clearer crystalline peaks of C1 resonances than the original spectra. The ordered subspectra were peak-fitted. A combination (50/50) of Lorentzian and Gaussian profiles gave an acceptable fit (data not shown). The proportions of single helixes, double helixes, and amorphous components are listed in Table 2, and showed significant difference among TRS heterogeneous starch granules. The amylopectin side chains can form two types of helices in starch granule. Helices that are packed in the short-range order are defined as the double helical order, and helices that are packed in long-range order are related to the packing of double helices forming crystallinity. That means that the double helices at a short-range level would be prerequisite for occurrence of the crystallinity but the crystallinity would not necessarily be present when short-range order exists.[41] The double helices in the short- and long-range distance can both be detected by $^{13}C$ CP/MAS NMR, but only the double helices in the long-range

distance can be detected by XRD.[42] Therefore, the double helix content of starch was generally higher than its relative crystallinity, especially for high-amylose starch (Table 2). In the present study, the double helix contents of the elongated and hollow starch granules were markedly higher than their relative crystallinities, indicating that most of the double helices did not form the crystallinity in these starches, which was in agreement with their very high amylose contents (Table 1).

**SAXS Spectra of TRS Heterogeneous Starch Granules.** A comparison of the SAXS spectra of starches is shown in Figure 4. All starches were scaled to equal intensity at high $q$ ($q$ = 0.2 Å$^{-1}$) to account for variations in sample concentrations.[44] The SAXS patterns were at the same relative scale and therefore directly comparable. The well-resolved main scattering peak around scattering vector ($q_0$) of about 0.07 Å$^{-1}$ is thought to arise from the periodic arrangement of alternating crystalline and amorphous lamellae of amylopectin, and corresponds to the lamellar repeat distance or Bragg spacing. The peak intensity depends mainly on the degree of order in semicrystalline regions.[45] The parameters of the SAXS peak were determined using the simple graphical method[33] and are presented in Table 3. The peak position and Bragg spacing were not significantly different among TQ total starch, TRS total starch, and TRS heterogeneous starch granules. However, the scattering peak intensity and peak full width at half-maximum were significantly different among TRS heterogeneous starch granules. The scattering peak could not be detected in TRS hollow starch granules, which might result from the high AC and was in agreement with the finding that no crystallinity was detected by XRD and NMR. In native starches, the intensity of the scattering peak decreases with increasing AC, which might result from the decrease in the electron density difference between crystalline and amorphous regions of the lamellae.[45] This in turn may be caused by several factors: cocrystallization of amylose macromolecules with amylopectin side chains within crystalline lamellae, accumulation of amylose chains oriented transverse to the lamellar stack within amorphous lamellae, and accumulation of amylose tie-chains inside both crystalline and amorphous lamellae.[45,46]

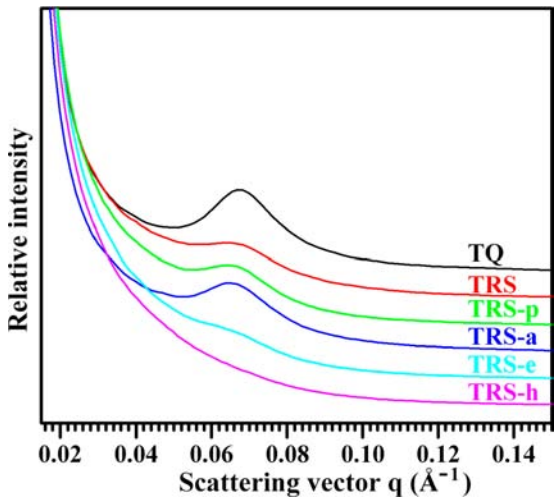

**Figure 4.** SAXS patterns of starches. TQ, TRS, TRS-p, TRS-a, TRS-e, and TRS-h are TQ total starch, TRS total starch, TRS polygonal starch granules, TRS aggregate starch granules, TRS elongated starch granules, and TRS hollow starch granules, respectively.

**Thermal Properties of TRS Heterogeneous Starch Granules.** DSC thermograms of TQ total starch, TRS total starch, and TRS heterogeneous starch granules are shown in Figure 5, and the thermal properties are summarized in Table 4.

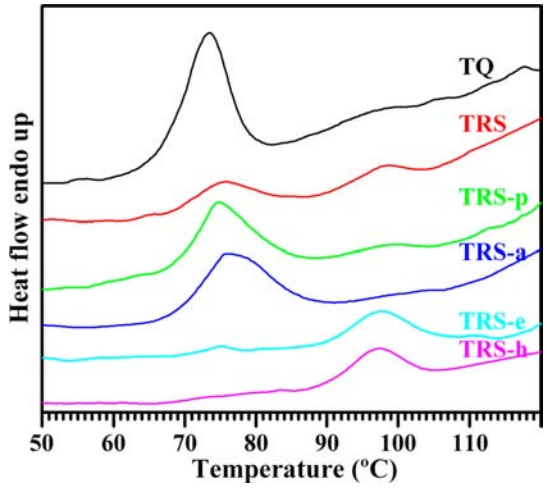

**Figure 5.** DSC thermograms of starches. TQ, TRS, TRS-p, TRS-a, TRS-e, and TRS-h are TQ total starch, TRS total starch, TRS polygonal starch granules, TRS aggregate starch granules, TRS elongated starch granules, and TRS hollow starch granules, respectively.

TRS total starch had significantly higher gelatinization temperature and lower gelatinization enthalpy than TQ total starch, which might result from the high AC in TRS total starch and was in agreement with our previous report.[47] TRS heterogeneous starch granules showed significantly different thermal properties. TQ total starch, TRS polygonal starch granules, and TRS aggregate starch granules had one clear peak with $T_p$ from 73.6 to 76.2 °C. TRS total starch and TRS elongated starch granules had two peaks with $T_p$ at about 76 and 98 °C, but the first peak was very weak in TRS elongated

starch granules. TRS hollow starch granules had one clear peak with $T_p$ at 98 °C. After immediate rescan of the gelatinized TRS total starch, elongated starch, and hollow starch, the peaks with $T_p$ at about 76 °C disappeared, but the peaks with $T_p$ at about 98 °C still existed on rescanned DSC thermograms (data not shown). The peaks with $T_p$ at about 98 °C disappeared after removal of lipids from high-amylose maize starch.[48] Therefore, the peak with $T_p$ from 73.6 to 76.3 °C was due to the dissociation of double-helical crystallites of the amylopectin molecules, and the peaks with $T_p$ at about 98 °C corresponded to the melting of the amorphous amylose−lipid complex, which had a lower thermal transition temperature than the crystalline amylose−lipid complex ($T_p$, about 120 °C).[48] In the present study, no V-type crystalline pattern was found in TQ total starch, TRS total starch, and TRS heterogeneous starch granules. Therefore, the peaks with $T_p$ at 98 °C were the melting of the amorphous amylose−lipid complex. It was noteworthy that TQ total starch, TRS polygonal granules, and TRS aggregate granules also had very weak amylose−lipid dissociation peak for their low amylose contents. This result was in agreement with XRD patterns that the amylose−lipid complex diffraction peak of $2\theta$ 20° was very prominent in TRS total starch, TRS elongated starch granules, and TRS hollow starch granules, especially for TRS hollow starch granules. The low relative crystallinity and double helix content and weak birefringence in TRS elongated starch granules were in agreement with the weak DSC peak of melting double-helical crystallites of the amylopectin molecules. The very low relative crystallinity and double helix content, no birefringence, and very high proportion of amorphous conformation in TRS hollow starch granules were also in agreement with the only DSC peak of melting the amorphous amylose−lipid complex. Though TRS total starch had similar double helix content to TRS elongated granules, their DSC parameters were significantly different. The main reason might be attributed to the difference in amylose content, granule morphology and size distribution, crystalline type, and molecular ordered structure in short- and long-range distance.[49] In addition, TRS total starch was a mixture of polygonal, aggregate, elongated, and hollow granules, which added the complication of analyzing DSC parameters for TRS total starch.

In conclusion, TRS polygonal, aggregate, elongated, and hollow starch granules were separated from the different regions of the mature kernels of high-amylose rice. These heterogeneous starch granules were essentially different in structures, including morphology, birefringence, iodine maximum absorption wavelength, iodine blue value, AC, molecular weight distribution, crystalline type, relative crystallinity, short-range ordered structure, relative proportions of single helix, double helix, and amorphous conformation, and scattering peak intensity and peak full width at half-maximum of SAXS. The different structures of TRS heterogeneous starch granules resulted in significantly different thermal properties.

[a]The acidity of all solutions was pH 3.6 and was set using citric acid−sodium phosphate buffer prepared according to the method of Ruzin.[20] Abbreviations: BA, benzoic acid; C3G, cyanidin-3-glucoside; Fru, fructose; Glu, glucose; P3G, pelargonidin-3-glucoside; RebA, rebaudioside A; Ste, stevioside; Suc, sucrose.

carbonated drinks,[11−14] dairy products and pastries,[15,16] and hot beverages, model solutions, and solid sweetener.[9,10] All of the cited publications show that the stability of glycosides decreases with increasing acidity (significant decomposition at room temperature occurred only in solutions with a pH <2). The thermal degradation of sweetener in solutions and solid form occurred above 80 and 140 °C, respectively.

The present study reports the interactions between steviol glycosides and selected food antioxidants: vitamin C and anthocyanins. These compounds can be found mainly in fruits and fruit products, accounting for their health-promoting properties and, in the case of anthocyanins, their sensory quality. The impact on the stability of steviol glycosides during storage was also determined, and the results were compared to those obtained by other research teams. All of the tests were performed on model solutions in conditions similar to those prevailing in fruit juices and beverages.

## MATERIALS AND METHODS

**Materials.** Highly purified steviol glycosides, rebaudioside A (RebA, 96.2%) and stevioside (Ste, 98.5%), were obtained from ChromaDex (Irvine, CA, USA). Certified standards of anthocyanins, cyanidin-3-*O*-glucoside (C3G, 98.79%) and pelargonidin-3-*O*-glucoside (P3G, 99.22%), were purchased from Extrasynthese (Genay, France). L-Ascorbic acid (99%) was obtained from POCh (Gliwice, Poland). Acetonitrile for chromatography (HPLC grade) was acquired from Sigma-Aldrich (St. Louis, MO, USA). Other chemicals were of analytical grade and came from various suppliers.

**Instrumentation.** All chromatographic analyses were performed using Waters (Milford, MA, USA) equipment: 2695 Separations Module, 2995 Photodiode Array Detector, and 2414 Refractive Index Detector. During preparation of the sample an ME235S analytical balance (Sartorius AG, Göttingen, Germany) and an HI 211 pH meter (Hanna Instruments, Woonsocket, RI, USA) were used.

**Analytical Methods.** Steviol glycosides were determined using a method proposed by Bergs et al. with modifications.[17] For the analysis a Sunfire C8, 5 $\mu$m, 4.6 mm × 250 mm analytical column with a Sunfire C8 Sentry guard cartridge, 5 $\mu$m, 4.6 mm × 20 mm (both Waters) was used. Separation of the 10 $\mu$L samples was performed within 12 min at a flow rate of 1 mL $min^{-1}$ and a column temperature of 40 °C. Samples were eluted using a gradient of 1.8 mM hydrochloric acid (solvent A) and acetonitrile (solvent B), as follows (time, corresponding composition): 0 min, 65% A; 3 min, 65% A; 5 min, 60% A; 7 min, 60% A; 9 min, 65% A; 12 min, 65% A. Compounds were quantified using UV absorption at 210 nm.

The L-ascorbic (AA) and L-dehydroascorbic acid (DHAA) contents were measured according to the a method proposed by Odriozola-Serrano et al.[18] Before analysis, 1 mL of the sample was diluted with 1 mL of 0.01% phosphoric acid (determination of AA) or 1 mL of 1 g $L^{-1}$ solution of dithiothreitol (DTT) in 0.01% phosphoric acid (determination of AA and DHAA sum). The samples with DTT were kept in the cold (4 °C) for at least 1 h before injection. Separation was done on a Sunfire C18, 5 $\mu$m, 4.6 mm × 250 mm analytical column with a Sunfire C18 Sentry guard cartridge, 5 $\mu$m, 4.6 mm × 20 mm (both Waters). Analysis of the 10 $\mu$L samples was performed within 10 min at a flow rate 1 mL $min^{-1}$ and a column temperature of 25 °C. The samples were eluted isocratically using 0.01% phosphoric acid. The compounds were quantified using UV absorption at 245 nm.

Anthocyanin concentrations were determined using a method proposed by Oszmiański[19] using the same analytical column and guard column as described above. Separation of the 10 $\mu$L samples was performed within 26 min at a flow rate of 1 mL $min^{-1}$ and a column temperature of 25 °C. The samples were eluted using a gradient of 80% solution of acetonitrile in 4.5% formic acid (solvent A) and 4.5% formic acid (solvent B), as follows (time, corresponding composition): 0 min, 0% A; 7 min, 15% A; 15 min, 15% A; 21 min, 100% A; 26 min, 0% A. Compounds were quantified using vis absorption at 520 nm.

Glucose, fructose, and sucrose were determined according to EN 12630:1999 standard. For the analysis a Sugar-Pak I, 10 $\mu$m, 6.5 mm × 300 mm analytical column with a Sugar-Pak Guard-Pak insert, 10 $\mu$m (both Waters), was used. Separation of the 10 $\mu$L samples was performed within 18 min at a flow rate 0.5 mL $min^{-1}$ and a column temperature of 90 °C. Samples were eluted isocratically using 0.1 mM calcium disodium EDTA. The compounds were quantified using a refractive index detector.

**Model Solutions.** During research work, two series of experiments were conducted. The first investigated the interactions between steviol glycosides and two anthocyanins, cyanidin-3-glucoside and pelargoni-

din-3-glucoside (Table 1); the second series investigated interactions between stevioside and ascorbic acid (Table 2). The component

[a]The acidity of solutions has been set using citric acid−sodium phosphate buffers prepared according to the method of Ruzin.[20] Abbreviations: AA, ascorbic acid; BA, benzoic acid; Ste, stevioside; Suc, sucrose.

concentrations and pH were set taking into account the values typical for fruit juices and the legal requirements for steviol glycoside concentration in beverages (applicable in the European Union).[21] Samples were kept in the dark at ambient temperature for up to 60 and 7 days for the first and second series, respectively.

**Statistical Analysis.** Data were analyzed using Statistica 7.1 software (StatSoft, Tulsa, OK, USA). The statistical significance of the differences in mean values was determined using an ANOVA test at $\alpha = 0.05$, and when significant differences existed, a Tukey test was performed. The kinetic parameters of degradation reactions were found using linear (C3G, P3G, AA) and nonlinear regression (DHAA). All of the results were obtained from duplicate analyses of two independent samples.

## RESULTS AND DISCUSSION

**Stability of Steviol Glycosides.** Concentrations of stevioside and rebaudioside in all of the model solutions investigated in the study were measured on the first and last days of each experiment (data not shown). The Tukey test did not reveal statistically significant differences between the initial and final concentrations of glycosides in any sample. These results are consistent with previous studies. Chang and Cook[11] found that steviol glycosides in carbonated drinks are stable at room temperature. These results were later confirmed by many authors examining various food matrices.[9,10,12−16]

**Kinetics of Anthocyanin Degradation.** Anthocyanins are a group of flavylium cation based glycosides that act as pigments and antioxidants in plant tissues. The main route of their degradation leads through deglycosylation and cleavage to aldehyde and benzoic acid derivatives.[22,23] The kinetics of anthocyanin (ACN) decrease is often described as a first-order reaction with results expressed as half-life time values (eq 1−3).[24−27]

$$\mathrm{ACN} \xrightarrow{k_1} \text{product} \quad (1)$$

$$c_{\mathrm{ACN}} = c_{\mathrm{ACN},0} \exp(-k_1 t) \quad (2)$$

$$t_{1/2} = \ln 2/k_1 \quad (3)$$

$c_{\mathrm{ACN}}$ = concentration of ACN, $c_{\mathrm{ACN},0}$ = initial concentration of ACN, $k_1$ = rate of reaction, $t$ = time, and $t_{1/2}$ = half-life time.

The rates of this reaction were determined using linear regression. The influence of the type of sweetener and its concentration on the C3G and P3G half-life time is shown in Figure 1. Detailed data can be found in Table S1 in the Supporting Information.

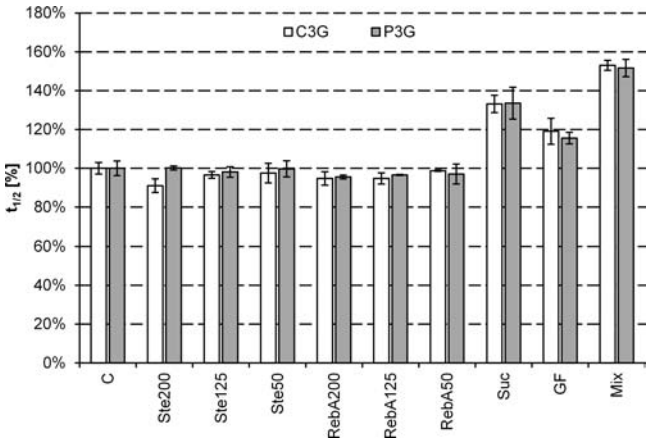

**Figure 1.** Influence of sweetener type and concentration on anthocyanin half-life times. Symbols and composition of model solutions are described in Table 1. Error bars represent standard deviation. Results were obtained from a duplicate analysis of two independent samples.

The addition of steviol glycosides, even at the highest concentration of 200 mg $L^{-1}$, did not affect the anthocyanin degradation rate. Regardless of the glycoside used and its concentration, the differences between the sample and control were statistically insignificant. The addition of sugars at a concentration of 100 g $L^{-1}$ significantly increased the stability of both anthocyanins by ca. 15% for a glucose−fructose mixture and by ca. 33% for sucrose. The simultaneous use of both sucrose and steviol glycosides turned out to be optimal with respect to anthocyanin stabilization: the half-life values of C3G and P3G were >50% higher than those observed in the control samples. Pelargonidin-3-glucoside was more stable than cyanidin-3-glucoside. This fact is consistent with the principle that increased hydroxylation of the flavylium cation decreases the stability of anthocyanins.[28] The effect of sweeteners was similar for both anthocyanins.

The influence of sugar on the stability of anthocyanin in water solutions is dependent to a large extent on the temperature, concentration, and type of sugar. Low concentrations, below 20%, of most carbohydrates stabilize pigments during storage in cold and ambient temperatures; an exception is fructose, which shows a destabilizing effect.[29−31] The results obtained in this study are consistent with these conclusions: anthocyanins were more stable in solutions containing sugars, and sucrose was also a better stabilizer than a mixture of glucose and fructose. Steviol glycosides did not affect the stability of anthocyanins, although they enhanced the protective properties of carbohydrates. The mechanism of this process is not yet known and should be examined in further research.

**Kinetics of Vitamin C Degradation.** The mechanism of AA degradation is specific, as it depends on several factors, whether it follows an aerobic or anaerobic pathway. The first

step of both pathways leads to the formation of DHAA, through ascorbic radical as intermediate in the anaerobic pathway or the multistage aerobic pathway catalyzed by metal ions. The second step is the irreversible hydrolysis to 2,3-diketogulonic acid (DKGA). DHAA retains part of the antioxidant and health-promoting activities of AA, although DKGA and further metabolites do not have such properites.[32]

Reduction of DHAA to AA occurs in the presence of reducing agents or enzymes such as dehydroascorbate reductase. Lack of such compounds in model solutions allows the above-mentioned reaction to be considered irreversible, so the degradation of ascorbic acid can be regarded as two consecutive first-order reactions (eq 4).[33]

$$\mathrm{AA} \xrightarrow{k_1} \mathrm{DHAA} \xrightarrow{k_2} \mathrm{DKGA} \tag{4}$$

Changes in the concentration of compounds can be described with differential equations. Their solutions (eqs 5 and 6) can be used to determine the kinetic parameters of the reaction.

$$c_{\mathrm{AA}} = c_{\mathrm{AA},0} \exp(-k_1 t) \tag{5}$$

$$c_{\mathrm{DHAA}} = \frac{k_1 c_{\mathrm{AA},0}}{k_2 - k_1}[\exp(-k_1 t) - \exp(-k_2 t)] \tag{6}$$

$c_{\mathrm{AA}}$ = concentration of AA, $c_{\mathrm{AA},0}$ = initial concentration of AA, $c_{\mathrm{DHAA}}$ = concentration of DHAA, $k_1$ = rate of first reaction, $k_2$ = rate of second reaction, and $t$ = time.

Rates of reaction were found using linear (AA) and nonlinear regression (DHAA). The fit of the model kinetics to experimental data is shown in Figure 2. The experimental data are highly consistent with the assumed model of the kinetics; for each sample the coefficient of determination was >0.95 (significant at $\alpha = 0.05$).

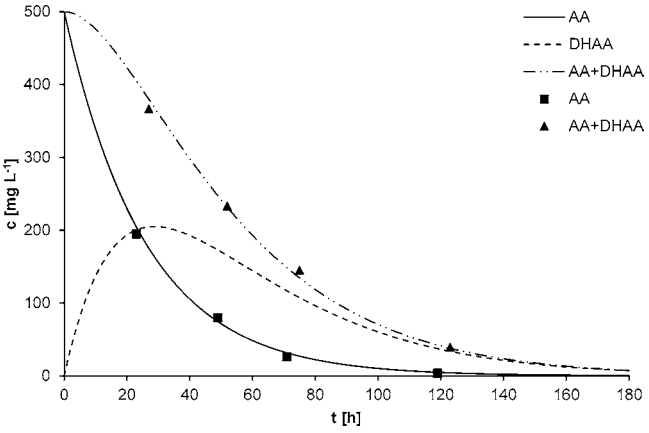

**Figure 2.** Fit between changes of ascorbic (AA) and dehydroascorbic (DHAA) acid concentration computed using kinetic equations (eqs 5 and 6; lines) and experimental data (dots) in sample pH4.0/Ste200 (composition of sample in Table 2).

A graphical representation of the influence of the type of sweetener and its concentration on the stability of vitamin C (AA and DHAA) at various pH values is shown in Figure 3 (AA) and Figure 4 (DHAA). Detailed data can be found in Table S2 in the Supporting Information.

The addition of steviol glycosides significantly increased the stability of both ascorbic and dehydroascorbic acid. The rate of degradation of ascorbic acid decreased by 4.0−22.3%, depending on the conditions. In the case of DHAA the protective

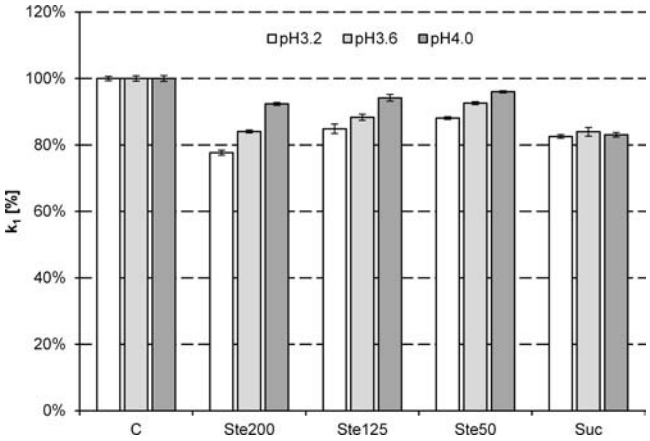

**Figure 3.** Influence of sweetener type, concentration, and acidity of solution on ascorbic acid degradation rate. Symbols and composition of model solutions are described in Table 2. Error bars represent standard deviation. Results were obtained from a duplicate analysis of two independent samples.

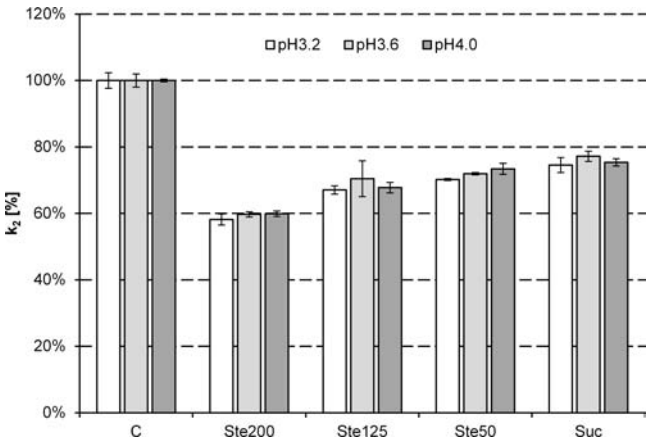

**Figure 4.** Influence of sweetener type, concentration, and acidity of solution on dehydroascorbic acid degradation rate. Symbols and composition of model solutions are described in Table 2. Error bars represent standard deviation. Results were obtained from a duplicate analysis of two independent samples.

effect was stronger: the rate of degradation was 26.6−41.9% lower than in the control sample. Higher concentrations of sweetener strengthened the protective effect; however, this relationship was not linearly proportional.

The acidity of the solution influenced the stability of vitamin C and the stabilizing effect of glycosides from *S. rebaudiana*. Higher acidity of the solutions significantly improved the protective effect of steviol glycosides on AA stability and, to a lesser extent, on DHAA stability. In general, ascorbic acid degradation is fastest in a pH close to 4.0 due to the maximum occurrence of hydrogen ascorbate ions.[32,34]

Control samples containing sucrose (100 g $L^{-1}$) were also examined. The protective effect of this carbohydrate was observed. Its strength did not depend on the acidity of the solution.

The protective effect of steviol glycosides on the stability of ascorbic acid was observed by Kroyer; however, his experiments were very limited.[9,10] Our research confirmed and expanded these results: the protective effect applied to both vitamin C forms, and it depended on the concentration of the sweetener

and acidity of the sample. The protective effect of sucrose on ascorbic acid is consistent with earlier publications.[35,36]

To our best knowledge this is the first study concerning the influence of steviol glycosides on anthocyanin stability. It also considerably expanded earlier experiments regarding interactions between stevioside and vitamin C.

The presented data demonstrate that the addition of glycosides from *S. rebaudiana* can increase the stability of vitamin C in water solutions of an acidic pH to a greater extent than sucrose used in sensory equivalent amounts. The addition of steviol glycosides also enhanced the protective effect of sucrose on anthocyanins. This fact may be of practical importance, indicating the additional benefits of using this natural noncaloric sweetener for fruit beverages.

Our research was conducted on model solutions, which, on the one hand, simplifies following the changes occurring in the sample, but, on the other hand, eliminates the influence of other constituents of real matrices, for example, radicals and metal ions, which might significantly change the degradation pattern through Fenton or Haber−Weiss reactions. The observed phenomena should be further investigated in complex food samples.[37]

milk after 12 weeks are highly important for further understanding of the shelf life of lactose-hydrolyzed UHT milk.

## MATERIAL AND METHODS

**Chemical Reagents.** Bis-Tris, $D_2O$ containing 0.025% sodium trimethylsilyl-[2,2,3,3-$_2H_4$]-1-propionate (TSP), 1,4-dithioerythritol, guanidine hydrochloride, sodium citrate dehydrate, and trifluoroacetic acid were obtained from Sigma-Aldrich Inc. (Steinheim, Germany). Acetonitrile was purchased from Mikrolab RA 1016 (Rathburn Chemicals, Ltd. Walkerburn, UK).

**Milk Samples.** Four types of milk (conventional indirect UHT, lactose-hydrolyzed direct UHT, lactose-hydrolyzed indirect UHT, and filtered (lactose-reduced) indirect UHT) were produced at a commercial Danish dairy plant (Arla Foods, Esbjerg, Denmark) (Table 1). The milk contained 1.5% (w/w) fat and 3.5% (w/w) protein. All milks were UHT heated using indirect heat treatment, where a tubular heat exchanger was used to heat the milk, followed by cooling with a plate heat exchanger.[16] An additional lactose-hydrolyzed milk batch was heat-treated using direct heat treatment, where steam was injected into the milk, followed by flash cooling.[16] The UHT temperature range is 140−145 °C for 4−6 s, and the direct heating temperature is generally 2−3 °C higher than the indirect heating temperature; however, the overall heat load is considerably lower.[16] Ultra- and nanofiltrations (cutoff was 10000 and 250 Da for the UF and NF filters, respectively)[17] were applied to reduce the lactose content to approximately 60% in the lactose-hydrolyzed and the filtered milk before heat treatment. The remaining lactose was enzymatically hydrolyzed after heat treatment, by addition of $\beta$-galactosidase (Maxilact LAG 5000, DSM, Heerlen, The Netherlands). The enzyme was dosed in an appropriate concentration to obtain total lactose hydrolysis (<1% of original lactose level) after 7 days of storage at 21 °C. All milk samples were packaged aseptically in 1 L Tetra Brik cartons. The milk samples were stored in an air-conditioned room at 22 °C. After 14, 21, 28, 45, 60, 90, 120, 150, 180, 210, 240, and 270 days of storage, one carton of each milk type was opened for analyses. Milk samples for $^1$H NMR spectroscopic analysis were filtered using Amicon Ultra 0.5 mL 10 kDa (Millipore, Bedford, MA, USA) spin filters at 10000*g* for 15 min, and the supernatant was subsequently frozen at −80 °C in 2 mL tubes. Milk samples for RP-HPLC-MS analysis were skimmed by centrifugation (Sorvall RC 5B plus, Thermo, Waltham, MA, USA) at 12800*g* for 30 min at 4 °C, and the skim milk was subsequently frozen at −80 °C in 2 mL tubes.

**Table 1. Overview of Milk Types, Heat Treatment, and Lactose Level Included in the Study[a]**

| milk | enzymatic hydrolysis | heat treatment | filtration | level of lactose (% of original level) | amount of lactose (% w/w) |
|---|---|---|---|---|---|
| conventional indirect UHT | − | indirect | − | 100 | 5 |
| lactose-hydrolyzed direct UHT | + | direct | + | <1 | 0.01 |
| lactose-hydrolyzed indirect UHT | + | indirect | + | <1 | 0.01 |
| filtered indirect UHT | − | indirect | + | 60 | 3 |

[a]All milk contained 1.5% (w/w) fat and 3.5% (w/w) protein.

**Aroma Profiling by Dynamic Headspace Sampling (DHS) and GC-MS.** DHS GC-MS was used to extract and analyze the volatile compounds in the fresh, unfrozen milk according to the procedure described by Jansson et al.[18] Adsorbent traps (Tenax TA, 200 g Tenax TA, 35/60 mesh, Markes International Limited, Llantrisant, UK) were used to isolate the volatile compounds, which were then desorbed (250 °C, 15 min) onto a cold trap (U-TIIGCP, Markes International Limited) using a thermal desorption system (ultra-UNITY, Markes International Limited). Subsequently, the volatiles were injected into a gas chromatograph (Finnigan trace GC ultra, Thermo, Waltham, MA, USA) and separated using a CP-Wax 52CB column (50 m × 0.25 mm, film thickness 0.25 $\mu$m, Varian, Palo Alto, CA, USA). The separated volatile compounds were detected using a single-quadrupole mass spectrometer (Finnigan Trace dual-stage quadrupole (DSQ), Thermo). The mass spectrometer scanned over a mass to charge ($m/z$) range of 45−650 (4.46 scans/s) in TIC mode. In total, 28 compounds were identified using the NIST mass spectral library (NIST MS search 2.0, 2011) and external standards. Dimethyl disulfide (DMDS), dimethyl trisulfide (DMTS), 2-ethylfuran, and 2-pentylfuran were quantified using external standard curves as previously described.[1]

**Metabolite Profiling by $^1$H NMR Spectroscopy.** Prior to proton nuclear magnetic resonance ($^1$H NMR) spectroscopy, the milk filtrates were thawed in randomized order and analyzed as described previously by Jansson et al.:[1] Four hundred microliters of milk was mixed with 200 $\mu$L of $D_2O$ containing 0.025% TSP as an internal standard. The samples were analyzed on a Bruker Avance III 600 spectrometer (Bruker Biospin, Rheinstetten, Germany) equipped with a 5 mm triple-resonance (TXI) probe. From a single 90° pulse experiment with a relaxation delay of 5 s standard one-dimensional spectra were obtained. The water peak was suppressed by irradiation during the relaxation delay, and a total of 64 scans were collected into 32K data points, scanning with a spectral width of 12.15 ppm. The data were multiplied by a 0.3 Hz line-broadening function and subsequently Fourier transformed. The TSP signal at 0 ppm was used as a reference, and all of the $^1$H spectra were manually baseline and phase corrected using Topspin 3.2 (Bruker Biospin). The sugar regions at 5.29−5.22, 5.0−4.49, and 4.11−3.32 ppm and the region with citrate at 2.74−2.47 ppm were removed from the data to facilitate the interpretation of the other metabolites. Metabolite concentrations were calculated for alanine, isoleucine, leucine, lysine, methionine, tryptophan, tyrosine, valine, formate lactose, glucose, and galactose, using Chenomx NMR suite 7.7 (Chenomx, Edmonton, Canada).

**Protein Profiling and Determination of Glycation by RP-HPLC-MS.** The RP-HPLC-MS procedure used in the present study was modified according to Jensen et al., and the procedures for sample preparation, settings for the HPLC, ESI source, and the mass selective detector were as described by Frederiksen et al.[19,20] Proteins were separated by reversed phase chromatography using an Agilent 1100 system (Agilent Technologies, Santa Clara, CA, USA) with a Jupiter C4 column (250 mm × 2 mm, 5 $\mu$M particle size, 300 Å pores; Phenomenex, Torrance, CA, USA) operated at 40 °C and a G1315A diode array detector with ultraviolet (UV) detection at 214 nm coupled to a mass selective detector for identification and relative quantification. The ESI source and the mass selective detector settings were as follows: ion mode was positive, the capillary exit voltage for the fragmentor was 200 V, the capillary voltage was 4500 V, and the nitrogen drying gas flow and temperature were 10 mL/min and 300 °C, respectively. Average molecular masses ($M_w$) of the milk proteins were obtained using the deconvolution algorithm of the ChemStation software (rev. B.04.01 SP [650], Agilent Technologies). All milk samples were analyzed in technical duplicates. The relative protein content of the intact milk proteins was calculated as the integrated area of each intact protein normalized with total integrated peak area in each LC chromatogram (Figure 2). "Total CN" comprised the sum of relative amounts of $\alpha_{s1}$-CN, $\alpha_{s2}$-CN, $\beta$-CN, and $\kappa$-CN.

**Statistical Analysis.** Prior to multivariate data analysis, $^1$H NMR spectroscopic data were mean-centered and Pareto-scaled. Principal component analysis (PCA) was applied to the centered and scaled data to elucidate differences between the milk types. A partial least-squares (PLS) regression model was used to predict the storage time, and a corresponding variable important in projection (VIP) plot was applied to identify the metabolites correlating strongest with the storage-induced changes. The PLS model was cross-validated (CV) using segmented CV with nine splits, where it was ensured that each sample replicate was in the same split. The root-mean-square error of cross-validation (RMSECV) was used as a measure of model performance. PCA was performed using SIMCA P+ 13.0 (Umetrics,

Umeå, Sweden) and PLS was performed using PLS Toolbox 6.71 (eigenvector Research Inc. Wenatchee, WA, USA) in MATLAB 7.11 (Mathworks, Natick, MA, USA).

To test the effect of milk type and storage time on the quantified proteins, amino acids, formate, carbohydrates, and the Strecker degradation compound linear mixed models (LME), least-squares means (LSMEANS), and Tukey's honest significant differences test ($\alpha$ = 0.05) were calculated in R (version 3.0.2, R Foundation for Statistical Computing, Vienna, Austria).

## RESULTS

Chemical changes in UHT-heated milk stored at 22 °C were followed over a period of 9 months. $^1$H NMR spectroscopy was applied to follow proteolysis through the detection of free amino acids. In total, nine free amino acids could be quantified (Table 2), and most of them increased significantly in the lactose-hydrolyzed milk during storage, for example, isoleucine (Figure 1), whereas they remained constant or were not

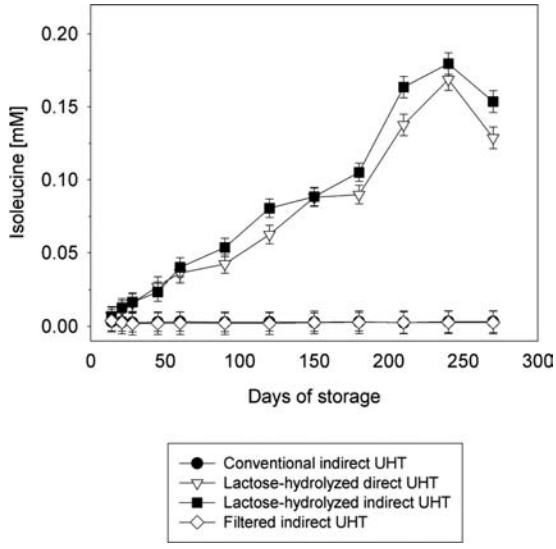

**Figure 1.** Concentration of isoleucine in conventional, lactose-hydrolyzed, and filtered UHT milk, quantified by $^1$H NMR spectroscopy.

detected (phenylalanine, tryptophan, and tyrosine) in the filtered and conventional UHT milk (Figure 1; Table 2). The only exceptions were methionine, which was constant throughout the storage period, and lysine, which increased in all milk types.

To investigate which proteins gave rise to the increased level of amino acids in the lactose-hydrolyzed UHT milk, the intact proteins in the milk were separated using RP-HPLC and detected with an UV detector at 214 nm, resulting in the chromatogram shown in Figure 2. Proteolysis was measured as a decrease in content of intact protein, and proteolysis was observed for all proteins in all milk types during storage. However, the level of proteolysis was significantly higher in the lactose-hydrolyzed UHT milk compared to the filtered and conventional UHT milk (Table 2). The relative amount of total intact CN was reduced by 56% for lactose-hydrolyzed indirect UHT-heated milk and by 61% for lactose-hydrolyzed direct UHT-heated milk during the storage period, as compared to 15% for conventional and filtered indirect UHT-heated milk (Table 2). The two most extensively hydrolyzed proteins during storage were $\beta$-CN and $\alpha_{s1}$-CN (Figure 3), which were reduced by approximately 80 and 45%, respectively (Table 2),

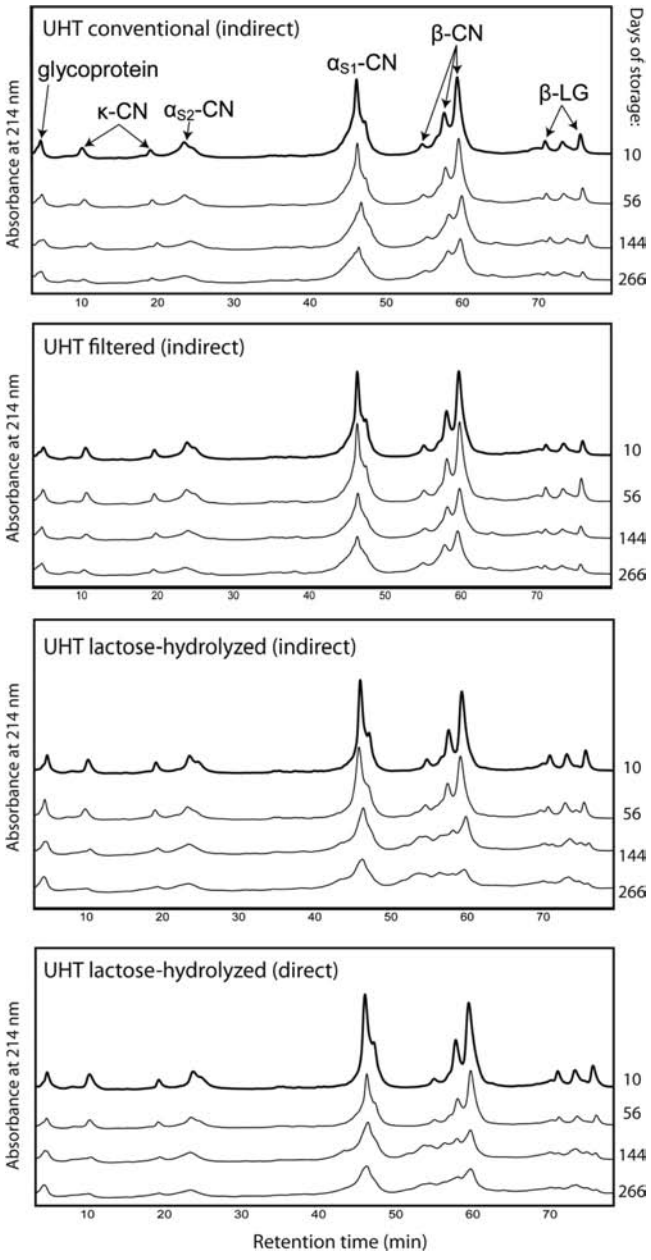

**Figure 2.** RP-HPLC chromatogram with UV detection at 214 nm of proteins in conventional, filtered, and lactose-hydrolyzed UHT milk at four storage times.

in lactose-hydrolyzed milk compared to a more moderate reduction for conventional and filtered milk. The content of intact $\kappa$-CN and intact $\beta$-LG decreased in all milk types, (Table 2), whereas $\alpha_{s2}$-CN content decreased only in the filtered and lactose-hydrolyzed UHT milk.

The identified amino acids and their involvement in Strecker degradation product formation are summarized in the Supporting Information. Five putative Strecker degradation products were identified; however, no clear connection between the volatile compounds and the increased levels of free amino acids could be observed. Likewise, no clear effects of lactose hydrolysis, filtration, or heat treatment on volatile compound formation were revealed (Table 2).

Exploring the MS, we detected glycation of all major milk proteins in the four milk types at all storage times as N-linked glycans with mass addition of 162 and 324 Da, indicating that

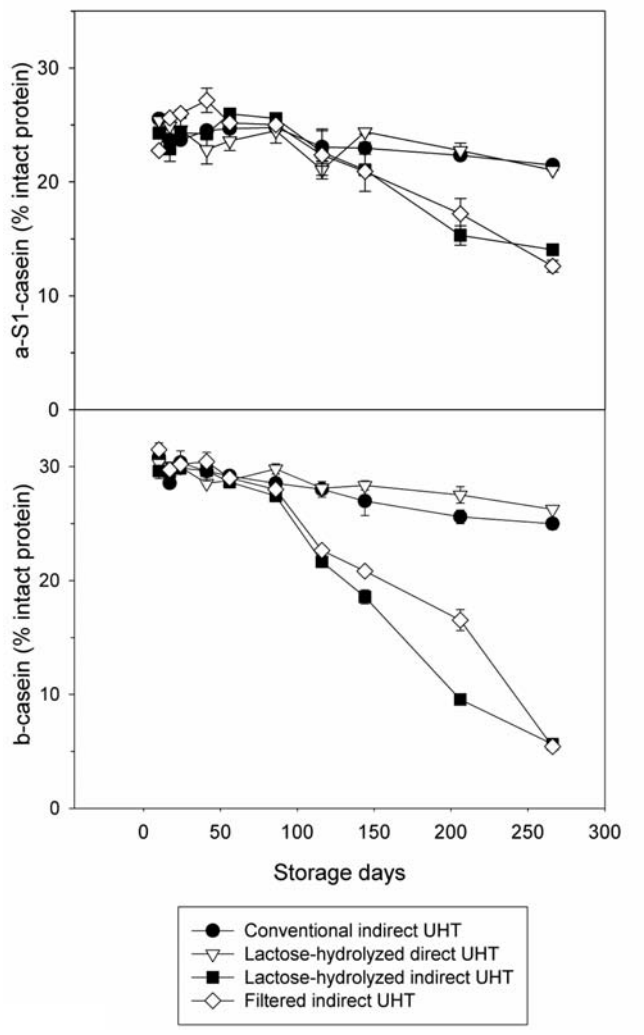

**Figure 3.** Relative quantification of $\alpha_{s1}$-casein and $\beta$-casein in conventional, lactose-hydrolyzed, and filtered UHT milk as a function of storage.

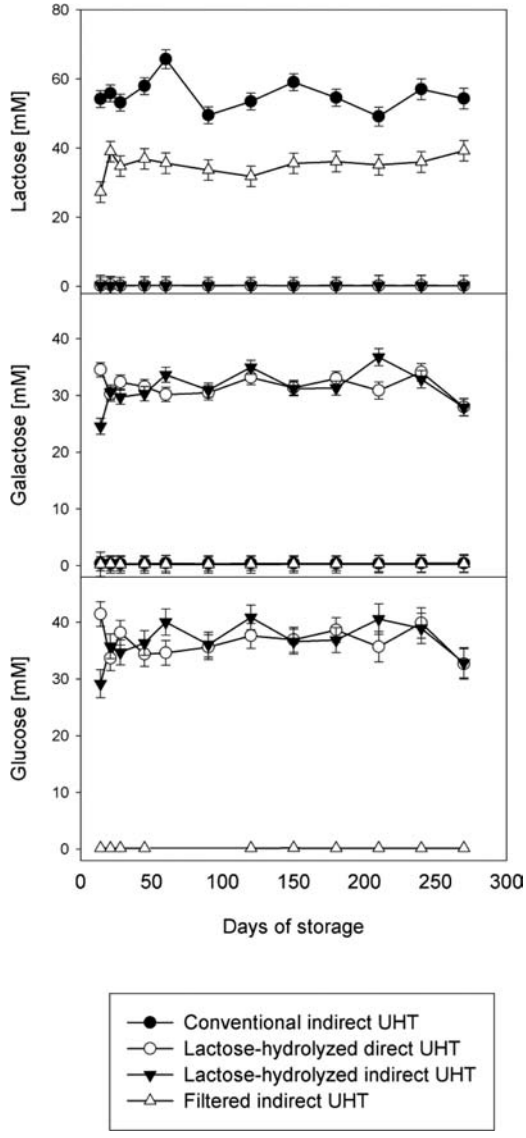

**Figure 4.** Concentration of lactose, galactose, and glucose in conventional, lactose-hydrolyzed, and filtered UHT milk, quantified by $^1$H NMR spectroscopy.

hexose and lactose molecules, respectively, were attached to the proteins. The level and type of glycation could not be revealed from the method used. Furthermore, another indicator for protein glycation is the hydrophilic protein fraction in the UV chromatograms, denoted glycoproteins, identified as the first peak eluting from the RP-HPLC column (Figure 2). The glycoprotein has previously been identified as glycosylated $\kappa$-CN and must also be considered to contain glycated peptides.[19] This peak increased significantly during storage in all milk samples, although being significantly highest in indirect heated lactose-hydrolyzed milk (Table 2). Even though protein glycation was observed, the level of free carbohydrates analyzed with $^1$H NMR spectroscopy was constant during the storage time, although after 240 days of storage, a decrease in glucose and galactose content was observed in all lactose-hydrolyzed milk samples (Figure 4), which is consistent with a decrease in the concentration of free amino acids, as shown in Figure 1 for isoleucine.

Finally, formate can be formed from the deoxyosones and may therefore be an indicator of the Maillard reaction. It was found that initial formate concentrations were highest in conventional milk; however, during storage similar formation rates were observed for all milk types, except for the filtered milk (Table 2).

Furthermore, the $^1$H NMR spectroscopic data were analyzed using an untargeted approach to elucidate how storage affected overall metabolite composition. In Figure 5 a PCA of $^1$H NMR spectroscopic data showed a separation along PC1 and PC2 between the lactose-removed (lactose-hydrolyzed and filtered UHT milk) and non-lactose-removed (conventional UHT milk) samples, probably due to the dilution (removal of 40% lactose) occurring in this step. In fresh samples (<50 days old), no clear separation between lactose-hydrolyzed milk and filtered milk could be observed. On the other hand, along PC1 a pronounced effect of storage was observed for lactose-hydrolyzed milk, whereas for the conventional and filtered milks the storage effect was much smaller. A PLS regression model with $^1$H NMR spectroscopic variables as $X$ and storage time as $Y$ was generated for each milk type (Figure 6A,C,E). The models revealed that the storage time of lactose-hydrolyzed and filtered milk could be predicted within a variance of 11 days ($R^2$ CV was 0.99 and 0.98, respectively;

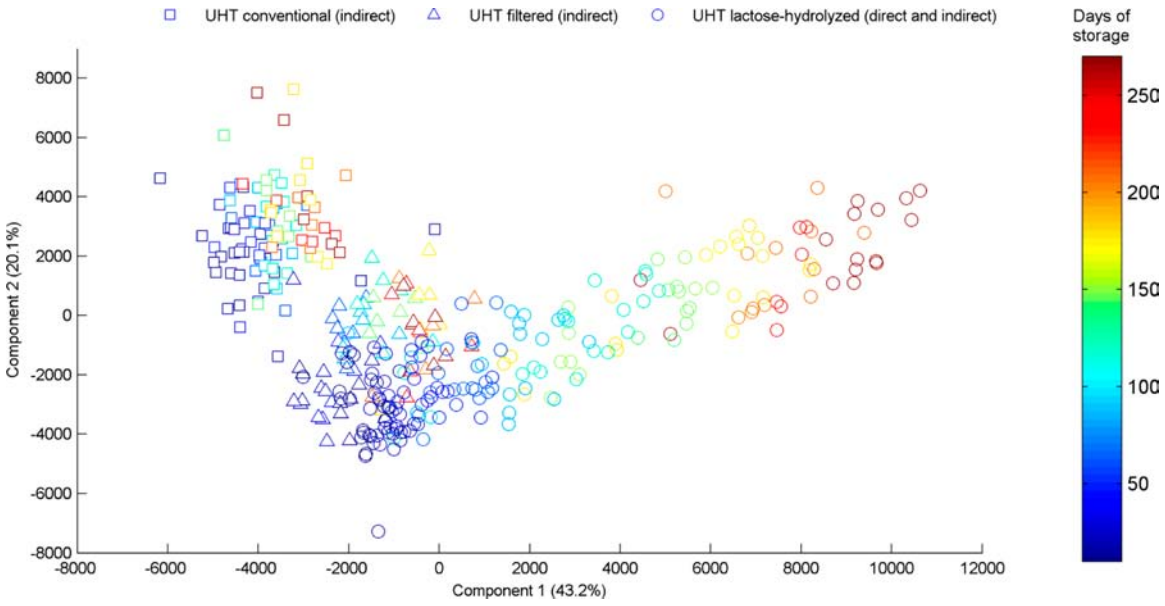

**Figure 5.** PCA score plot of $^{1}$H NMR spectroscopic data of conventional, filtered, and lactose-hydrolyzed UHT milk during storage. Samples are colored according to days of storage. The first principal component explains 43.2% of the variation, and the second principal component explains 20.1% of the variation.

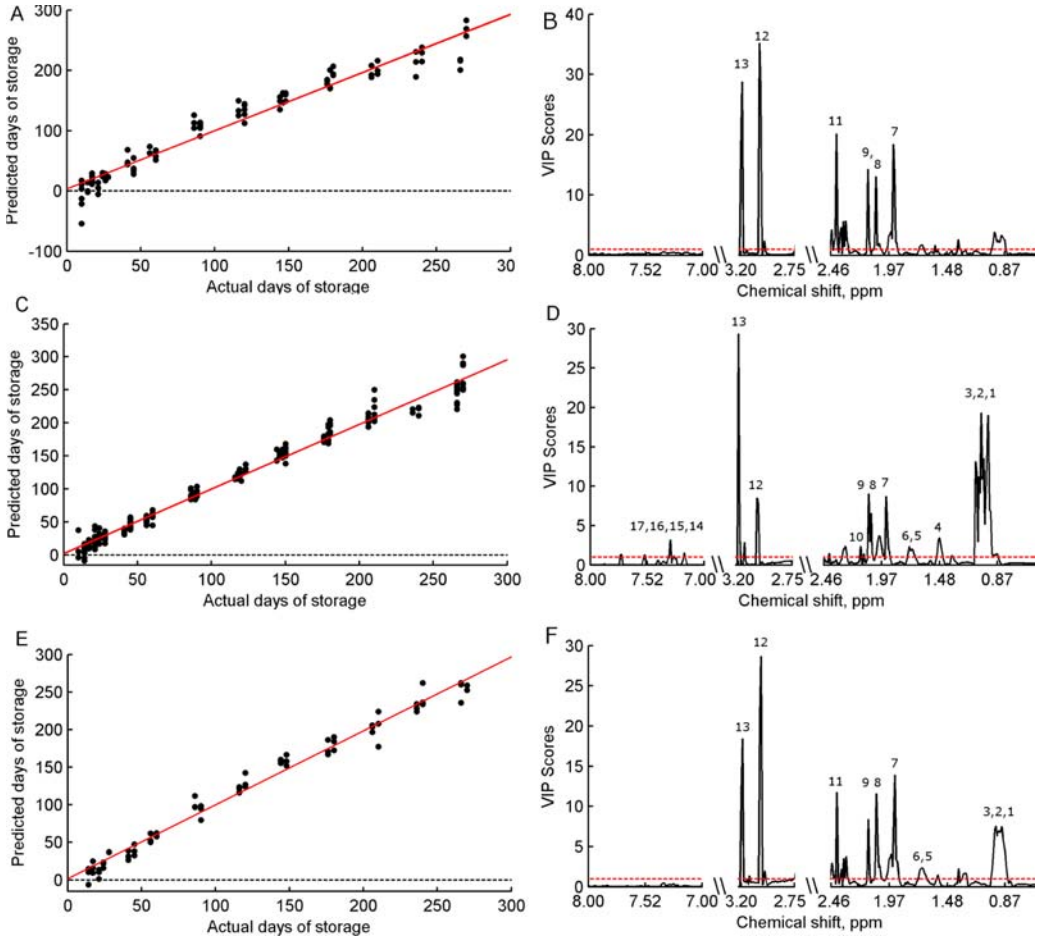

**Figure 6.** PLS regression plots from $^{1}$H NMR spectroscopic data with predicted versus actual and corresponding VIP plot for model based on (A, B) conventional UHT milk ($n$ = 33), $R^2$ CV = 0.95, RMSECV = 18.59 days; (C, D) lactose-hydrolyzed UHT milk ($n$ = 65), $R^2$ CV = 0.98, RMSECV = 11.23 days; and (E, F) filtered UHT milk ($n$ = 23), $R^2$ CV = 0.98, RMSECV = 11.45 days. Peak numbers indicate the metabolites important for the regression: 1, 2, 3, leucine, isoleucine, valine; 4, alanine; 5, 6, lysine, leucine; 7, acetate; 8, *N*-acetyl carbohydrates; 9, 10, methionine; 11, not identified; 12, 13, creatine/creatinine, choline; 14, 15, 16, 17, hippurate, tyrosine, tryptophan, phenylalanine.

dx.doi.org/10.1021/jf504104q | *J. Agric. Food Chem.* 2014, 62, 11270−11278

RMSECV was 11.23 and 11.45 days, respectively), and the storage time of conventional milk could be predicted within a variance of 19 days ($R^2$ CV was 0.95 and RMSECV was 18.59 days). To find the metabolites responsible for the changes during storage, VIP scores were plotted for each PLS model (Figure 6B,D,F). Choline was significant in all milk types, whereas amino acids (leucine, isoleucine, valine, alanine, phenylalanine), as expected, were much more important in lactose-hydrolyzed milk as compared to the other milk types. In the unhydrolyzed milk samples hippurate, creatine/creatinine, *N*-acetyl carbohydrates, and acetate were identified as significant.

## DISCUSSION

Storage stability is of importance in UHT milk to maintain consumer acceptability of the milk. In the present study, chemical changes that could be detrimental to milk quality were investigated in UHT milk produced with and without lactose hydrolysis during a storage period of 9 months. Furthermore, filtered indirectly heated UHT milk was included to follow the effect of the $\beta$-galactosidase added to the milk. The two different heat treatments (direct and indirect) applied to the lactose-hydrolyzed milk were included to investigate the effect of severity of heat treatment. The indirect lactose-hydrolyzed UHT milk had a significantly higher level of glycoprotein compared to the direct lactose-hydrolyzed UHT milk. However, the type of heat treatment did not have any effect on volatile compounds, metabolite profile, or proteolytic activity, and therefore the term lactose-hydrolyzed milk refers to both milk types.

**Proteolysis Has Major Effect in Lactose-Hydrolyzed Milk.** $^1$H NMR spectroscopy was used to identify metabolites in the milk, and PCA of $^1$H NMR spectroscopic data revealed much more severe storage-induced changes in lactose-hydrolyzed milk than in the conventional and filtered UHT milk (Figure 5). This result shows that major chemical changes are not induced by the filtration but rather they can be attributed to the addition of the $\beta$-galactosidase preparation. The PLS models calculated (Figure 6) could predict the time of storage of each milk with a high precision, as reflected in the low RMSECV values (11−19 days). However, the prediction was considerably better for lactose-hydrolyzed UHT milk than conventional UHT milk, which supports the more severe storage-induced changes in the lactose-hydrolyzed UHT milk shown in the PCA. In the present study proteolysis was the major chemical change observed. Lysine was the only amino acid that increased in all milk types during storage; however, the increase was only significant in the lactose-hydrolyzed milk, which likely can be ascribed to the presence of heat-stable endogenous proteases that cleave proteins after lysine and arginine (Lys or Arg in $P^1$ position).[21−24] A decrease in lysine could be expected due to its involvement in the Maillard reaction. However, the binding of carbohydrates to lysine seems to be of minor importance compared to the proteolytic activity. No significant changes were observed in methionine during storage, which is different from a previous study[1] in which a decrease of methionine was observed during storage in the conventional and lactose-hydrolyzed UHT milk. This difference suggests that methionine is affected by batch variations.[18]

The increased proteolytic activity was further elucidated by RP HPLS-MS by investigating the content of intact protein during storage. Our study showed that the caseins present in the lactose-hydrolyzed UHT milk were considerably affected by the proteolytic activity, whereas in the conventional UHT milk only a moderate proteolytic activity could be observed during storage. The proteolytic activity in the filtered milk did not deviate from the conventional UHT milk, which indicates that no proteolysis originated from the filtration step. The most hydrolyzed proteins in the lactose-hydrolyzed UHT milk were $\beta$-CN and $\alpha_{s1}$-CN, which significantly decreased after 90 days of storage (Table 2; Figure 2). This was an important pattern depicting differences between the lactose-hydrolyzed and conventional UHT milks during storage. The results are in agreement with the results from Tossavainen and Kallioinen, who investigated lactose-hydrolyzed and conventional UHT milks stored at different temperatures (5, 22, 30, and 45 °C) for 12 weeks.[6] In addition, Tossavainen and Kallioinen found that the $\alpha_{s1}$-, $\alpha_{s2}$-, and $\beta$-CN were the most extensively degraded proteins, whereas $\beta$-LG, $\alpha$-LA, and $\kappa$-casein were less affected.[14] Another interesting observation was that the free amino acids increased immediately during storage, whereas the reduction in $\beta$-CN and $\alpha_{s1}$-CN was not observed until after 90 days in the lactose-hydrolyzed milk. These findings could indicate that a low degree of hydrolysis of proteins gives rise to an increase in the level of free amino acids but does not affect the proteins sufficiently to be detectable by RP HPLC-MS.

The decrease in $\beta$-CN and $\alpha_{s1}$-CN after approximately 90 days of storage (Figure 2) seems to relate to the development of an off-flavor, which typically develops after 90 days. Casein contains a high amount of hydrophobic amino acids, which are highly correlated to bitterness,[25,26] and a proteolysis of casein and especially $\beta$-CN and $\alpha_{s1}$-CN would consequently result in a bitter taste.[27−30] McKellar et al. investigated proteolysis and bitterness in UHT milk during 8 months storage at ambient temperature and observed a high correlation between storage time, proteolysis, and bitterness.[8]

**Maillard Reaction in the Lactose-Hydrolyzed Milk.** The Maillard reaction is dependent on the reaction between amines (primarily protein-bound lysine and N-terminals) and reducing carbohydrates, and the type and concentration of these substrates are highly important for the level of Maillard reaction product formation.[1,2] In the present study protein glycation, formate, and Strecker degradation product formation were investigated in filtered, lactose-hydrolyzed, and conventional UHT milks. The relative estimate of identified glycopeptides and -protein increased during storage for all milk types (Table 2), although the absolute degree of glycation could not be quantified on the basis of the RP HPLC-MS method applied. This is in contrast to the study by Carulli et al., who observed a higher degree of glycation of $\alpha$-LA and $\beta$-LG in the presence of glucose and galactose compared to lactose.[5] Likewise, we were not able to detect a significant difference in the degree of formate or in the Strecker degradation product formation analyzed (2-pentylfuran, 2-methylfuran, DMDS, DMTS, and benzaldehyde) during storage.

Strecker aldehydes have been shown to affect the milk aroma,[31,32] and both lactose hydrolysis and proteolysis were expected to promote the formation of Strecker aldehydes in lactose-hydrolyzed milk as compared to conventional UHT milk. However, the lack of significant differences could indicate that the Maillard reaction may not be the most important pathway for their formation.[33,34] For instance, benzaldehyde was observed in all milk types, whereas its precursor, phenylalanine,[35] was detected only in lactose-hydrolyzed milk (Table 2). Valero et al. observed an increase of benzaldehyde in

skim milk during storage.[34] However, the present study could not support this observation.

We previously observed a striking correlation between 2-methylbutanal, isoleucine, and furosine formation in lactose-hydrolyzed UHT milk after approximately 90 days of storage.[1] This seems to be closely connected to the decrease in intact casein concentrations observed here. Hence, a possible link between proteolysis, glycation, and Strecker aldehyde formation seems likely, although we cannot prove causality.

A final aspect that might affect the quality of lactose-hydrolyzed milk is the dilution that occurs during the filtration step; thus, the lactose-hydrolyzed and filtered UHT milk were heat-treated with a 40% lower level of lactose compared to the conventional milk. This was reflected by a lower formate level in fresh lactose-hydrolyzed and filtered milk (Table 2), but did not result in different rates of formate formation during storage. The most significant pathway for formate generation is through $\alpha$-dicarbonyls generated in the Maillard reaction,[36,37] but our results indicate that the type of sugar and proteolysis are not decisive factors for the formation of formate in milk. However, a lower level of lactose during heating could be reflected in the lower initial concentration of the Maillard reaction compounds furosine and 2-methylbutanal in the lactose-hydrolyzed milk compared to the conventional milk in a previous study by Jansson et al.[1] In addition, the type of sugar was decisive for the formation rate of furosine and 2-methylbutanal in the lactose-hydrolyzed UHT milk.

The present study shows that the side effects of the added $\beta$-galactosidase are highly relevant for the chemical reactions taking place in the lactose-hydrolyzed milk during storage. Tossavainen and Kallioinen[6] investigated how heat treatment before and after the addition of $\beta$-galactosidase to lactose-hydrolyzed milk affects the proteolytic activity, but no significant difference was observed between the different enzymatic treatments. In milk hydrolyzed prior to the heat treatment, a higher concentration of $\beta$-galactosidase is added compared to the milk hydrolyzed after the heat treatment to obtain the same hydrolytic effect. However, the implication of higher enzyme addition may be additional enzyme activity after heat treatment as a result of an incomplete inactivation during heating. Although an increased heating temperature would increase inactivation of enzyme activity, it would also affect the nutritional value of the milk.[6]

The generation of free amino acids during storage of lactose-hydrolyzed milk originates most likely from either enzymatic impurity in the used $\beta$-galactosidase preparation and/or side activities of the $\beta$-galactosidase. Higher levels of proteolytic activity contribute to the flavor of the milk through formation of flavor-active amino acids/peptides and/or through formation of additional Maillard reaction products, for example, Strecker aldehydes. The reactivity of glucose and galactose determines the rate of the Maillard reaction. In addition, our results indicate that a sufficient level of free amino acids is required to accelerate the Maillard reaction. To gain an improved understanding of the chemical changes observed in lactose-hydrolyzed milk, it would be relevant to focus on the proteins $\beta$-CN and $\alpha_{s1}$-CN, which are most affected by the proteolytic activity.

concentrations required for protection (i.e., dose-dependency of the phenolic antioxidants) are a critical issue. It has been suggested that protein-to-protein radical transfer may occur at a faster rate than protein-to-phenol radical transfer, especially when the antioxidant concentration is low.[9] In a model system with 1% phenol relative to protein (w/w), Jongberg, Lund, Østdal, and Skibsted[22] demonstrated that a green tea extract could limit radical transfer from perferrylmyoglobin to myosin by scavenging the hypervalent myoglobin species.

In the present study the dose-dependent reduction of perferrylmyoglobin radicals by myofibrillar proteins (MPI) and bovine serum albumin (BSA), plant extracts from green tea (GTE), maté (ME), and rosemary (RE), and three phenolic compounds characteristic of those extracts, namely catechin, caffeic acid, and carnosic acid, has been investigated. The reduction of perferrylmyoglobin radical by these proteins, plant extracts, and phenols was monitored directly by electron paramagnetic resonance (EPR) spectroscopy to obtain quantitative information on the concentrations of well-defined phenols and plant extracts required to afford protection against protein oxidation. The role of thiols in perferrylmyoglobin radical reduction was also investigated for MPI and BSA using *N*-ethylmaleimide, a modifying agent with a high degree of specificity for thiols.[23]

## MATERIALS AND METHODS

**Chemicals and reagents.** Myoglobin from equine heart (MbFe(III)) of >90% purity and bovine serum albumin (BSA) of >96% purity were obtained from Sigma-Aldrich, Steinheim, Germany. Guardian Green Tea extract 20 M (GTE) and Guardian Rosemary extract 202 (RE) were obtained from DuPont Nutrition and Biosciences ApS (formerly Danisco A/S), Brabrand, Denmark. Dried maté leaves (*Ilex paraguariensis*) of the Brazilian trade mark Tertúlia (Ervateria Marca Ltd.a., Jaborá, Santa Catarina) were obtained from a local market in Brasilia, Brazil. Carnosic acid, caffeic acid, and catechin were obtained from Sigma-Aldrich, St. Louis, MO. All other reagents were of analytical grade. Double-deionized water (Milipore, Bedford, MA) was used throughout.

**Extraction of phenolics from maté leaves.** An aliquot of 0.5 g maté leaves was mixed with 50 mL of double-deionized water in an ultrasonic bath for 15 min, centrifuged for 10 min at 936 g, and filtered through Whatman 589/3 filter paper (GE Healthcare Life Sciences, Buckinghamshire, UK). These extracts were used on the day of preparation. The phenolic concentration was determined by Folin Ciocalteu's method as described by Singleton and Rossi.[24] In brief, maté extract was dissolved in double-deionized water and left to react with Folin–Ciocalteu phenol reagent for 8 min. Subsequently, 20% sodium carbonate was added and the reaction mixture was left to incubate at 20 °C for 2 h. The phenol concentration was determined spectrophotometrically at 765 nm against a standard curve prepared from gallic acid. The concentrations are given in gallic acid equivalents (g/100 g dry extract; % w/w), $n = 5$.

**Isolation of myofibrillar proteins.** Myofibrillar protein isolates (MPI) were prepared from pork *Longissimus dorsi* muscle according to Park and Xiong[25] with slight modifications as described by Koutina, Jongberg, and Skibsted.[26]

**Protein identification by gel-electrophoresis (SDS-page).** Freeze-dried MPI was mixed with 0.1 M Tris buffer (pH 7.4, $I = 1.0$) and stirred for 30 min at 20 °C. The protein suspension was centrifuged at 12100*g* for 1 min, and the supernatant was collected. Total protein concentration was determined spectrophotometrically by measuring absorbance at 280 nm. The molar extinction coefficient of myosin, $A_{280(1g/l)}$ 0.496 and the molar mass of myosin (520000) were used to calculate the molar concentration of MPI in μM myosin equivalents. Dissolved MPI was analyzed with or without prior addition of 5% SDS by SDS-PAGE using NuPAGE Novex 3–8% TRIS-Acetate Gels with or without addition of dithiotreitol (DTT) as reducing agent (Invitrogen, Carlsbad, CA) as described by Jongberg et al.[22]

**Blocking of protein thiol groups with NEM.** Thiol groups in 10 mg/mL MPI or BSA were blocked by reaction with 100 μM *N*-ethylmaleimide (NEM) in 0.1 M Tris buffer (pH 7.4, $I = 1.0$) for 90 min at 4 °C.[12] NEM-blocked samples (MPI-NEM, BSA-NEM) were used on the day of preparation.

**Quantification of thiol groups.** Protein thiols were quantified by reaction with 5,5′-dithiobis(2-nitrobenzoic acid) (DTNB)[27] according to Jongberg, Terkelsen, Miklos, Lund[28] with slight modifications. In brief, an aliquot of 835 μL of dissolved protein (MPI, MPI-NEM, BSA, or BSA-NEM) was mixed with 165 μL of 10 mM DTNB dissolved in 0.10 M Tris buffer (pH 7.4, $I = 1.0$) and left to react for 30 min, protected from light at 20 °C. The absorbance at 412 nm was obtained before ($ABS_{412\text{-before}}$) and after reaction with DTNB ($ABS_{412\text{-after}}$) for both samples and blanks containing Tris buffer. Thiol concentrations were calculated based on a 5-point standard curve (0.4–83.3 μM) of L-cysteine diluted in Tris buffer. Thiol concentrations are reported as nmol thiol/mg protein.

**Preparation of freeze-quenched samples.** Myoglobin (30 mg) was dissolved in 1.0 mL of 0.1 M Tris buffer (pH 7.4, $I = 1.0$) and purified on a Sephadex PD10 column preconditioned with 25 mL of 0.1 M Tris buffer. Myoglobin concentrations were determined spectrophotometrically at 525 nm using $\varepsilon = 7.700\ M^{-1}\ cm^{-1}$.[29] Myoglobin (100 μM final concentration) was mixed with proteins, phenols, or plant extracts (for concentrations see text and figure legends) in a total volume of 270 μL in a 1.5 mL Eppendorf tube and transferred to an EPR tube (5 mm outside diameter, 227 mm length (Wilmad, NJ) using a syringe with a needle and long plastic tubing. Thirty microliters of $H_2O_2$ (100 μM final concentration) was then added in a similar manner, and the samples were vortex mixed and frozen in liquid nitrogen 15 s after $H_2O_2$ addition. BSA was dissolved in Tris buffer, and MPI was applied as a suspension in Tris buffer. A stock solution of RE (120 mg/mL) was dissolved in ethanol and subsequently diluted in Tris buffer. GTE and ME were dissolved and diluted directly in Tris buffer. Aqueous stock solutions of caffeic acid (61 mM) and catechin (55 mM) were prepared in Tris buffer/ethanol (1:1, v/v). Stock solutions of carnosic acid (107 mM) were made up in acetonitrile and subsequently diluted with Tris buffer.

**Radical detection by Electron Paramagnetic Resonance (EPR) spectroscopy.** Freeze-quenched samples were mounted in the cavity of an ECS 106 or EMX X-band spectrometer (Bruker, Rheinstetten, Germany) equipped with a quartz liquid nitrogen finger dewar flask filled with liquid nitrogen. Radical spectra were obtained using identical settings with four acquisitions averaged. The peak intensity (PI) of the Trp-radical signal was determined by the maximum intensity of the detected peak after baseline subtraction using WINEPR software.

$$PI_{Sample} = Intensity_{max.peak} - Intensity_{Baseline}$$

The peak intensity was normalized to gain the relative peak intensity (Rel.PI) by using the mean PI of the control samples without any oxidation substrate, indicated as the peak intensity normalization factor ($PI_{Norm}$).

$$Rel.PI = \frac{PI_{Sample}}{PI_{Norm}} \times 100\%$$

**Dose–response analysis and calculation of $IC_{50}$ values.** Dose–response analysis was performed by calculating the $IC_{50}$ values (concentration of reductant to obtain 50% inhibition of the perferrylmyoglobin radical signal) using Origin Pro 9.1.0 (OriginLab Coperation, Northampton, MA).[30] The relative peak intensity was fitted as a function of the logarithm of molecular concentration using Sigmoidal fitting and the DoseResp function.

$$y = A1 + \frac{A2 - A1}{1 + 10^{(\log x0 - x)p}}$$

The $x$ values are the logarithm of dose, and the log$x$0 is the center of the curve, meaning the concentration for half response. Global fit

was used to fix the upper (A2) and lower (A1) limits to 100 and 0%, respectively.

**Statistical data analysis.** All experiments were conducted in triplicates as a minimum unless otherwise stated, and data are expressed as mean ± standard deviation (sd). Statistical analysis were performed using R version 2.12.1, The R Foundation for Statistical Computing (ISBN 3-900051-07-0). Data were analyzed by analysis of variance (ANOVA) using a linear model with mixed effects, where replicates were included as random effects and concentration was included as a systematic effect. Student's $t$ test using Microsoft Excel was applied for statistical analysis of the $IC_{50}$ values and variation in relative peak intensity. Significance for all data analysis was assumed at $P < 0.05$

## RESULTS

**Characterization of protein radicals.** MPI was isolated from pork *longissimus dorsi* muscle, and the proteins were identified by the molecular mass after separation by SDS-PAGE (Figure 1). MPI consists of primarily myosin heavy chain

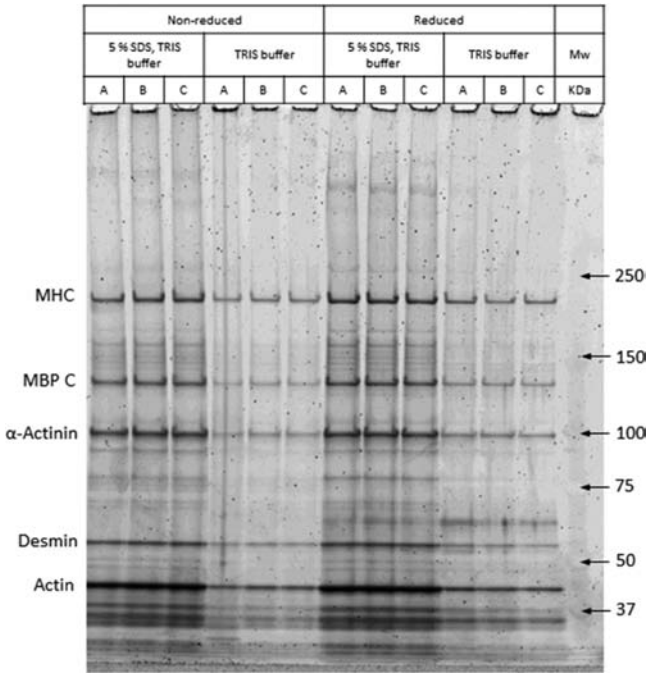

**Figure 1.** SDS-PAGE analysis of porcine myofibrillar protein isolate (MPI) suspended in 0.1 M Tris buffer (pH 7.4, $I$ = 1.0) with or without addition of 5% sodium dodecyl sulfate (SDS). Reduced samples were treated with dithiothreitol (DTT) prior to running the gel. A, B, and C represent triplicate suspensions, and $M_w$ indicates a mixed protein standard with known molecular masses indicated on the figure. Myosin heavy chain (MHC), myosin binding protein C (MBP C), α-actinin, desmin, and actin were identified based on their molecular masses.

(MHC, ~220 kDa), myosin binding protein C (MBP C, ~130 kDa), α-actinin (~100 kDa), desmin (~55 kDa), and actin (~42 kDa) according to Lametsch et al.[31] These proteins were found to dissolve in the 0.1 M Tris buffer (pH 7.4, $I$ = 1.0) both with and without 5% SDS. Although the presence of SDS increased protein solubility, as indicated by the increased protein band intensities, the protein compositions of the solutions with and without SDS were the same, and Tris buffer without SDS was therefore used throughout the study.

Reaction between MbFe(III) and hydrogen peroxide (1:1 molar ratio) for 15 s before freeze-quenching in liquid nitrogen at 77 K resulted in the detection of a protein radical by EPR spectroscopy (Figure 2, upper spectra in A, B, C, and D). No signals were observed when any one of the components of the reaction mixture was omitted (data not shown). The observed spectra are interpreted in terms of the presence of a mixture of Trp-derived peroxyl and Tyr-derived phenoxyl radicals with hyperfine coupling constant and $g$-values as reported previously,[9] with the major EPR absorptions of each species indicated by TRP and TYR.

The presence of increasing concentrations of MPI in the reaction mixture of MbFe(III) and hydrogen peroxide reduced the intensity of the features assigned to the Trp-peroxyl radical, with this being most noticeable with the low field component (i.e., the left-hand feature) due to the presence of significant overlap of the other components of this signal with features from the Tyr phenoxyl radical. The Trp-peroxyl radical was almost fully extinguished with a concentration of MPI of 14.8 μM (Figure 2A). The intensity of the EPR absorptions assigned to the Tyr-phenoxyl radical also decreased in the presence of increasing concentrations of MPI (Figure 2A). These data are interpreted in terms of subsequent reaction of the Mb-derived Trp and Tyr radicals with the MPI protein, rather than interference with the initial formation of these species on the Mb protein.

In order to assess whether this process was specific to MPI, similar experiments were carried out in which increasing concentrations of BSA were added to the Mb/hydrogen peroxide system. This resulted in a concentration-dependent decrease in the Trp-peroxyl radical signal (Figure 2B). Modification of the Mb-derived Tyr-radical signal was also detected, with increasing concentrations of BSA resulting in the detection of a broad signal with increased intensity at an identical $g$ value. This change is interpreted in terms of radical transfer from the perferrylmyglobin species to BSA, with the formation of a mixture of different radical species on the BSA; these are likely to be predominantly Tyr-derived phenoxyl radicals (as the $g$ value remains unchanged) in different environments, with the latter resulting in the loss of spectral resolution (i.e., a broad absorption envelope rather than distinct spectral features).[32] As no additional protein radicals were observed in the experiments in which MPI was added to the reaction mixture, it is proposed that the radicals formed on the MPI must be located on residues/sites which do not give rise to EPR-detectable absorptions, or are too short-lived to be detected under the conditions employed. As one potential target residue on the MPI with which the Mb-derived radicals might react is the Cys residues (cf. previous reports on the reaction of Mb-derived radicals with thiols),[9] further experiments were carried out with MPI and BSA with blocked Cys residues.

**Role of Cys residues on MPI and BSA and concentration dependency in perferrylmyoglobin radical transfer.** The average number of thiol groups per molecule present in the MPI preparations was found to be 15 (Table 1). As MHC contains 16 Cys residues, whereas other myofibrillar proteins contain fewer (e.g., 6 in actin), this value represents a mean thiol concentration of all proteins combined in the MPI. In contrast, the average number of thiol groups was found to be 0.2 for BSA (Table 1). The sequence of native BSA contains one free Cys, but it is well established that a considerable proportion of these residues are present in modified or derivatized forms in plasma,[33] so this value of <1 is not surprising. The protein thiol groups of MPI and BSA

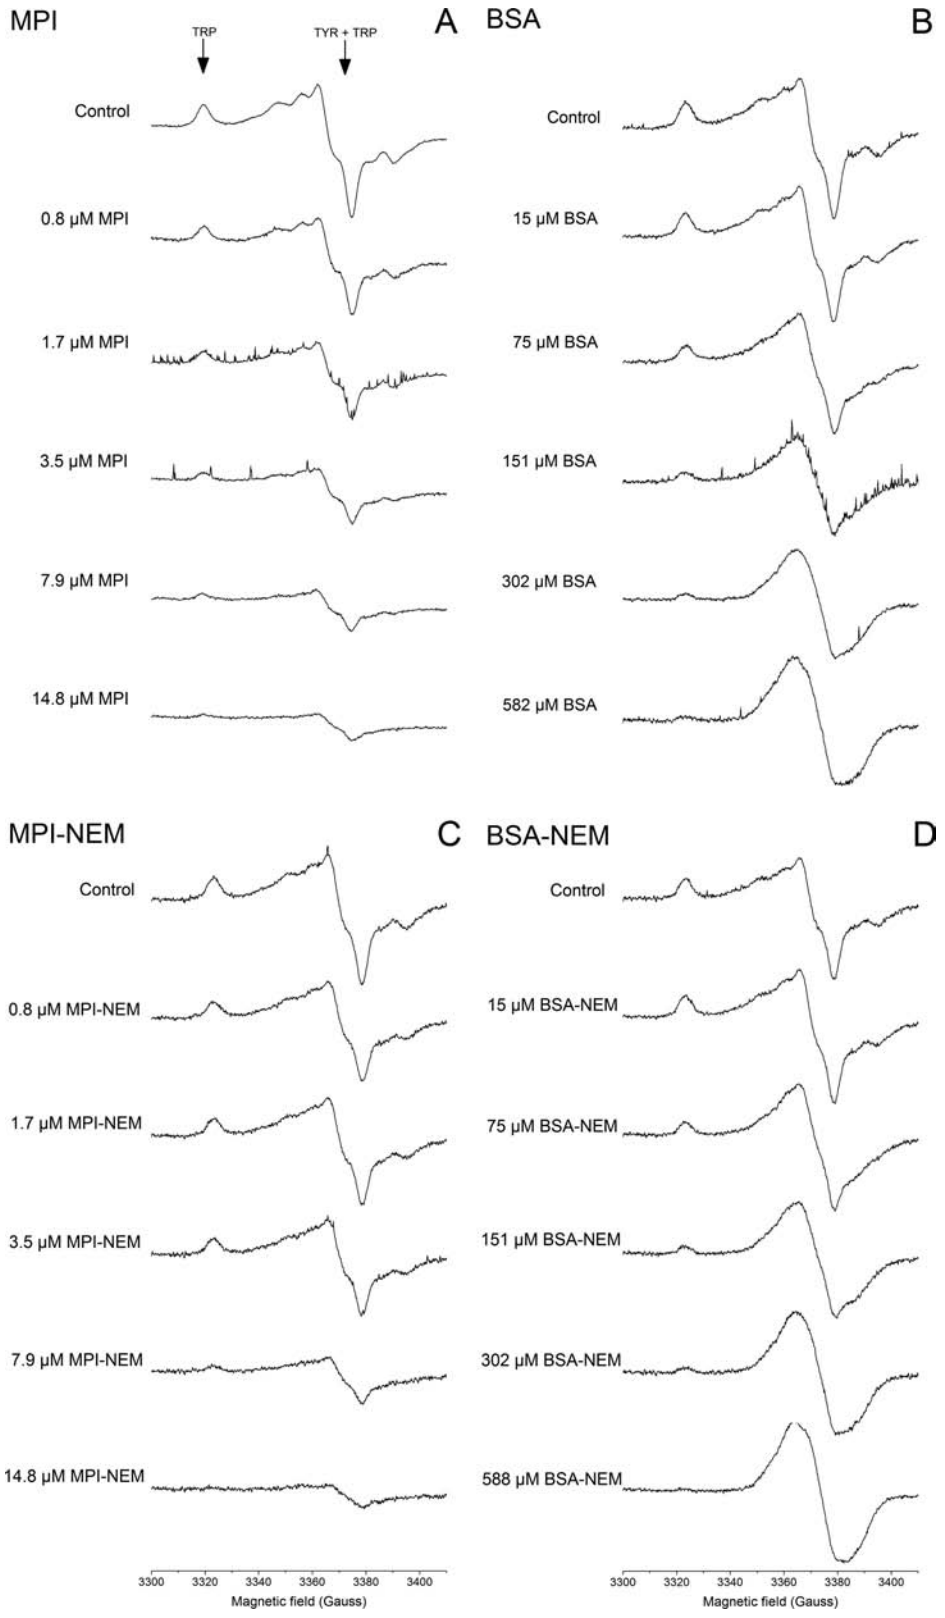

**Figure 2.** EPR spectra of perferrylmyoglobin radicals generated by reaction with hydrogen peroxide in a 1:1 molar ratio (100 $\mu$M) alone or in the presence of (A) MPI, (B) BSA, (C) MPI-NEM, or (D) BSA-NEM in increasing concentrations. The signals assigned to the Trp-peroxyl radical and the Tyr-phenoxyl radical are indicated by arrows in the Control−MPI EPR spectra (upper left panel). The spiking observed on some spectra is experimental artifacts caused by gas bubbles.

were blocked by *N*-ethylmaleimide (NEM) as described in the Materials and Methods to obtain MPI-NEM and BSA-NEM. The efficiency of thiol-blocking was calculated to be 90 and 75% for MPI and BSA, respectively (Table 1). The low blocking percentage for BSA may be ascribed to the constrained location of the Cys-34 residue in a cleft in the

**Table 1. Concentration of Thiol Groups in Proteins Presented as Mean ± sd ($n$ = 3) and Efficiency of Thiol-Blocking by *N*-Ethylmaleimide (NEM)**

| protein | [thiols] nmol/mg protein | thiols per protein molecule[a] | efficiency of thiol blocking |
|---|---|---|---|
| MPI | 29.0 ± 2.8 | 15.1 ± 1.2 | |
| MPI-NEM | 3.1 ± 0.9 | 1.6 ± 0.4 | 90% |
| BSA | 3.6 ± 1.0 | 0.2 ± 0.1 | |
| BSA-NEM | 0.9 ± 1.0 | 0.1 ± 0.1 | 75% |

[a]Thiols per molecule are calculated from the concentration of thiols divided by the molecular mass of BSA or MPI using myosin as reference.

BSA structure. Higher concentrations of NEM which might result in a greater extent of reaction at the Cys-34 residue were not employed, in order to avoid reaction at other (less reactive, nucleophilic) sites such as Lys residues.[23]

These NEM-blocked proteins were subsequently employed in EPR experiments as outlined above for the nonblocked proteins. While blocking of the Cys-34 residues on BSA did not give rise to any noticeable effect on the EPR spectra obtained for the BSA system (Figure 2D), increasing concentrations of MPI-NEM resulted in the detection of EPR signals from the Mb-derived radicals of diminished intensity (Figure 2C). These data are interpreted in terms of a key role for the Cys residues of MPI in reaction with the perferrylmyglobin radicals, with subsequent formation of thiyl radicals on the MPI proteins when the Cys residues are not blocked.

Dose−response curves were generated by plotting the relative peak intensity of the Trp-peroxyl radical signal against the concentration of MPI, BSA, or their NEM-blocked counterparts as a function of their molecular (primary $x$-axis) or mass-based (secondary $x$-axis) concentrations (Figure 3). As the half-life of the perferrylmyoglobin radical is short, reactions were stopped after 15 s by freeze-quenching, such that the reactions did not reach equilibrium. The same concentrations of myoglobin and hydrogen peroxide were used in all experiments. Hence, the dose−response curves represent titration curves of the Mb-derived Trp-peroxyl radical by the added reactive agents, which provide information on the stoichiometry of these reactions.

The dose−response curve for native MPI was found to be steeper than that for MPI-NEM (Figure 3), and the relative peak intensity at 3.5 $\mu$M MPI or MPI-NEM was found to be significantly ($P$ = 0.014) different. This confirms that blocking the Cys thiol groups dramatically affects the rate of reaction of MPI with the Mb-derived Trp-peroxyl radicals. In contrast, the effect of blocking the Cys-34 residue of BSA observed in these dose−response curves was less dramatic. This may arise from steric interactions due to the partly buried nature of the BSA Cys-34 residue.

$IC_{50}$ values were estimated for comparison of the titration data obtained with MPI and BSA, and they indicate that 114 $\mu$M BSA is required to reduce the Trp-signal by 50% whereas only 1.1 $\mu$M is required for MPI (Table 2). This suggests that

**Table 2. $IC_{50}$ Values for the Reduction of Perferrylmyoglobin Radical by Proteins, Extracts, and Phenols Presented as Mean ± sd ($n \geq 3$)[a]**

| sample | $IC_{50}$ ($\mu$M) |

MPI is a 100-fold more efficient reducing agent compared to BSA based on the molecular concentration. When considering the size of the protein and comparing by mass-based concentrations, only a ∼10-fold higher BSA concentration was necessary to reduce the Trp-signal by 50% as compared to MPI. This indicates that the amino acid composition of the

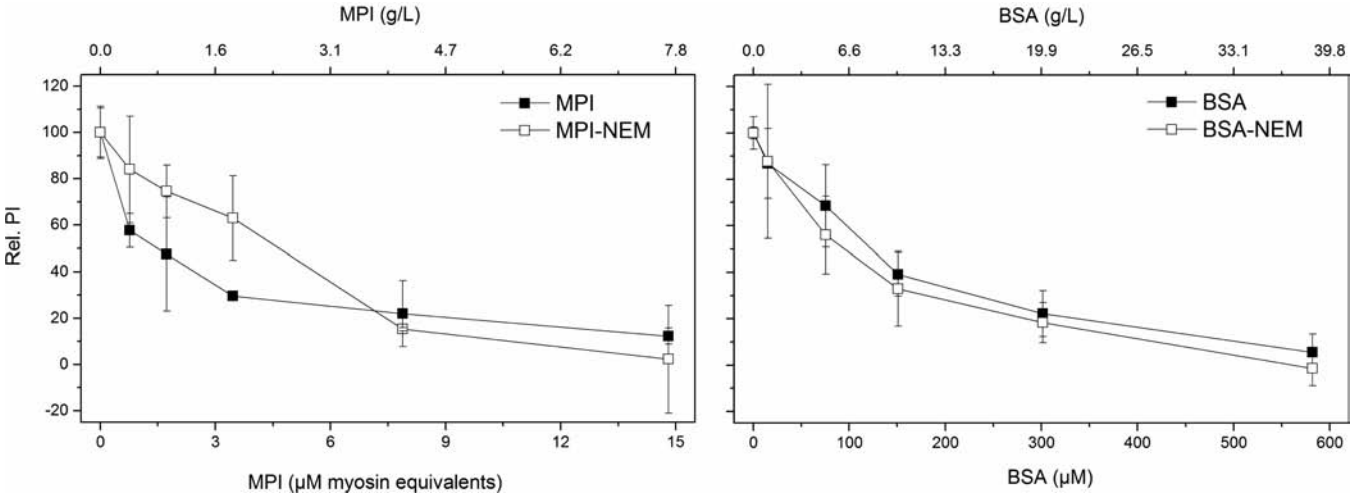

**Figure 3.** Dose−response curves of the relative peak intensity (Rel.PI, mean ± standard deviation, $n \geq 3$) of the Trp-peroxyl radical as a function of the molar concentrations of MPI and MPI-NEM (left panel), and BSA and BSA-NEM (right panel). The secondary (top) $x$-axis presents the mass-based concentration of the proteins.

target protein is a major factor in the observed reducing capacity. Expressing the $IC_{50}$ value of MPI or BSA based on the thiol concentration in each protein gives 17 ± 3 or 23 ± 3 μM thiols, respectively (calculated e.g. for MPI as 15.1 thiols per molecule × 1.1 ± 0.2 μM MPI). As the two numbers are not significantly different, this indicates that the thiol reactivities of the two proteins are comparable despite the steric hindrance for the BSA thiol. This may arise from the different reaction times used for the two proteins.

**Characterization of green tea, maté, and rosemary extracts.** The total phenolic content of the three plant extracts from green tea (GTE), maté (ME), and rosemary (RE) varied with the highest concentration (determined in gallic acid equivalents by the Folin−Ciocalteau assay) for GTE followed by ME and then RE (Table 3). The total phenolic content determined for ME corresponds well with the average total phenolic content of 8.4 g/100 g dry matter reported for three commercial maté brands.[34]

**Table 3. Total Phenolic Content in Extracts Presented as Mean ± sd ($n$ = 3)**

| extract | total phenolic content (% w/w)[a] |
|---|---|
| Green tea extract | 23.8 ± 1.3[b] |
| Maté extract | 7.7 ± 0.9 |
| Rosemary extract | 4.8 ± 0.1[b] |

[a]g of gallic acid equivalents/100 g of extract. [b]Jongberg, Lund, Østdal, and Skibsted.[23]

The phenolic composition of green tea (*Camellia sinensis*) extract consists primarily of flavonoids, such as catechin, epicatechin, epicatechin gallate, epigallocatechin gallate, and quercetin, with lower levels of hydrocinnamic acids, caffeic, coumaric, and ferulic acid.[35] Maté (*Ilex paraguariensis*) extract consists primarily of caffeoyl derivatives, including caffeic acid, chlorogenic acid, 3,4-dicaffeoylquinic acid, 3,5-dicaffeoylquinic acid, and 4,5-dicaffeoylquinic acid.[36] Rosemary (*Rosemarinus officialis*) extract consists primarily of phenolic diterpenes, such as carnosic acid, carnosol, rosmanol, rosmadial, 12-methoxycarnosic acid, epi- and iso-rosmanol, and the phenolic acids rosmarinic and caffeic acid.[35]

**Perferrylmyoglobin radical scavenging by green tea, maté, and rosemary extracts.** Addition of the plant extracts to the reaction mixture of MbFe(III) and hydrogen peroxide showed that all plant extracts were able to reduce the perferrylmyoglobin radicals (Figure 4). The EPR spectra demonstrated that both the Tyr-phenoxyl and Trp-peroxyl radicals were reduced in the presence of increasing concentrations of these extracts. This is presumed to result in the generation of phenoxyl-/catechol-derived radicals on the phenols present in the extracts, though these transients were not detected. The absence of EPR signals from such extract-derived radicals is not surprising, as both a number of species are likely to be formed from such complex mixtures and these species are likely to undergo rapid subsequent reaction (dimerization or disproportionation) due to their low molecular mass and unhindered nature.

The relative capability of the different extracts to reduce the Mb Trp-peroxyl radical was examined by determining dose−response curves based on the concentration of gallic acid equivalents in the extracts (Figure 4, left lower panel) or the mass of extract used (Figure 4, right lower panel). Full reduction of the Trp-peroxyl radical signal was detected with each extract, and there was no significant difference in the gallic acid equivalents between the three extracts required to achieve this (Figure 4, left lower panel). In contrast, when the reducing capacity of the extracts was assessed based on the amount of extract added, much lower levels of GTE (∼10 mg/L) were necessary to reduce the radical signal by 50% compared to ME and RE, where ∼40 mg/L and ∼60 mg/L, respectively, were necessary (Figure 4, right lower panel). These data indicate that the total phenolic content has a more marked impact on the reducing capacity of these extracts against the perferrylmyoglobin radicals than the specific composition of the phenolic compounds present in each extract.

**Perferrylmyoglobin radical scavenging by catechin, caffeic acid, and carnosic acid.** In light of the above data, further experiments were carried out with a number of specific phenolic compounds (catechin, caffeic acid, and carnosic acid) to determine their relative efficacies with regard to reaction with Mb radicals. The EPR spectra obtained from reaction mixtures containing these three phenolic compounds showed that all of them were able to scavenge perferrylmyoglobin radicals (Figure 5). The spectra obtained indicate that no additional phenoxyl radicals from the added compounds were formed as a result of radical transfer, as no additional EPR signals were observed. However, significant reductions in the intensity of the Mb-derived radicals were observed, indicating that reaction had occurred. Even at the highest phenol concentrations, a weak residual signal was detected (Figure 5, upper panels). However, as identical signals were observed at elevated concentrations (up to 100 μM catechin, data not shown), the modifications are more likely to be an artifact rather than a secondary phenoxyl radical.[9,37]

Dose−response curves obtained for increasing concentrations of these plant phenols, presented in molar concentration of the phenolic compounds, showed that the phenols had markedly different reducing capacities (Figure 5, lower panel). Caffeic acid was a far more efficient scavenger of the perferrylmyoglobin radicals as compared to catechin, and carnosic acid was least efficient. These phenols were selected as representatives of the extracts, GTE, MA, and RE, as they are the dominant phenol in each extract. However, while the reducing capacity of the extracts was shown to be primarily dependent on the total phenolic content, and showed little variation with regard to phenol composition, these phenols when present alone showed marked variations.

## DISCUSSION

**Protection against meat protein oxidation by phenol-rich extracts.** The reducing capacity of the proteins, plant extracts, and phenols was quantified by their $IC_{50}$ values (Table 2) and may be used to predict whether a specific phenol-rich extract may protect against protein oxidation. Comparing the $IC_{50}$ values between the two proteins showed that the proteins in the MPI are ∼100-fold more efficient as compared to BSA, and after blocking the thiol groups by NEM this ratio dropped to ∼20, indicating that the thiol groups are highly significant for the reducing capacity. No significant differences were observed between the plant extracts, indicating that the exact phenolic composition of these extracts is not the most important factor with regard to the overall reducing capacity and that the total amount of phenol is important for these extracts where several phenols are present in mixtures. In fact, other constituents of the extracts, such as fillers or fibers, may be of higher importance, facilitating radical transfer processes in the extract.

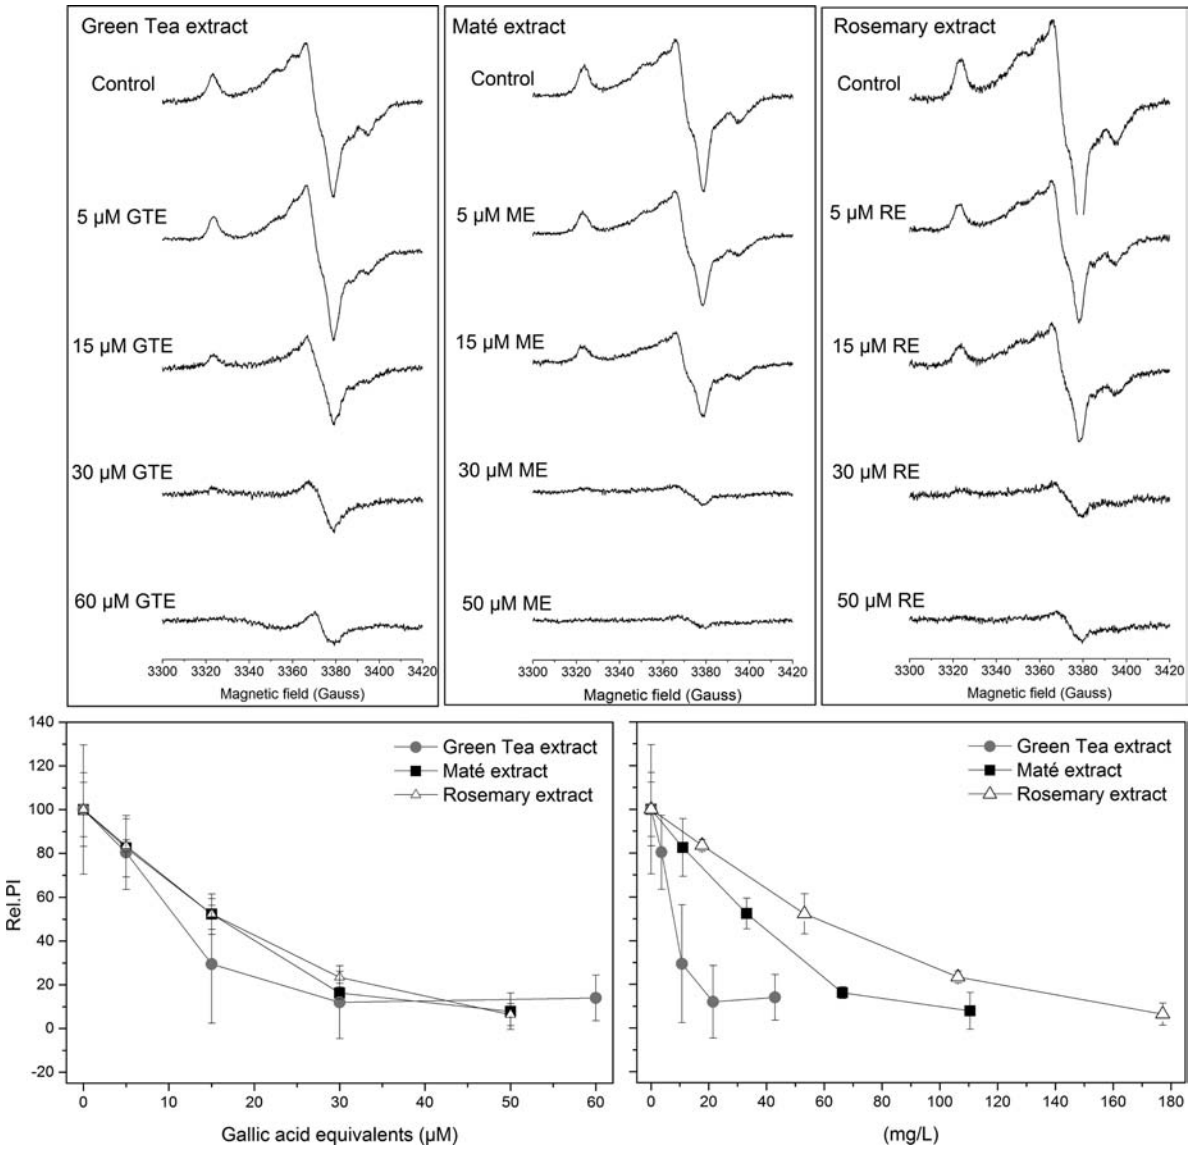

**Figure 4.** Upper panels: EPR spectra of perferrylmyoglobin radicals generated by reaction with hydrogen peroxide in a 1:1 molar ratio (100 $\mu$M) alone or in the presence of green tea (GTE), maté (ME), or rosemary (RE) extracts in increasing concentrations. Lower panels: Dose−response curves of the relative peak intensity (Rel.PI, mean ± standard deviation, $n \geq 3$) of the Trp-peroxyl radical as a function of the molar- (left panel) or mass-based (right) concentrations of green tea, maté, or rosemary extract.

A study including the same GTE and RE extracts was recently presented by Jongberg et al.[22] Phenoxyl radicals are stabilized when coordinated to divalent metal ions, such as $Zn^{2+}$, hereby preventing the dimerization reaction and enhancing the radical signals.[38,39] The results of Jongberg et al.[22] showed increased phenoxyl radical intensities of RE as compared to GTE after reaction with the perferrylmyglobin radical in the presence of Zn(II), and this increase was explained by more efficient radical-derived polymerization reaction of the phenols contained in the GTE as compared to the RE. This is of major significance for the application of such extracts to foods, as the addition of "antioxidative" ingredients may add flavors or aromas to the given food product. In order to minimize any off-flavors derived from the extract, a high total phenolic content and high ability to terminate radical processes by polymerization is beneficial, and radical transfer processes in the extract are of importance in this respect.

In the present study, it was shown that with the isolated, specific phenols there is considerable variation in $IC_{50}$ values, with caffeic acid being significantly more efficient than catechin, which in turn was significantly more efficient than carnosic acid. All three phenols examined contain catechol moieties (Figure 6), which are important for their radical scavenging activity.[35] Caffeic acid, which contains a single catechol moiety with two hydroxyl groups, showed the most efficient reducing capacity toward perferrylmyoglobin radicals when compared with catechin, which contains four hydroxyl groups. Hence, the *number* of hydroxyl groups in the aromatic structure may not be the most significant contributor to the reducing capacity observed, and other properties may be important for effective Mb radical scavenging. The carboxylate groups of caffeic and carnosic acids are powerful electron delocalizing groups that affect the $pK_a$ values of the neighboring phenolic hydroxyl groups. The carboxylic acids are deprotonated in the reaction mixture (pH 7.4), as the $pK_{a1c}$ values of caffeic acid and

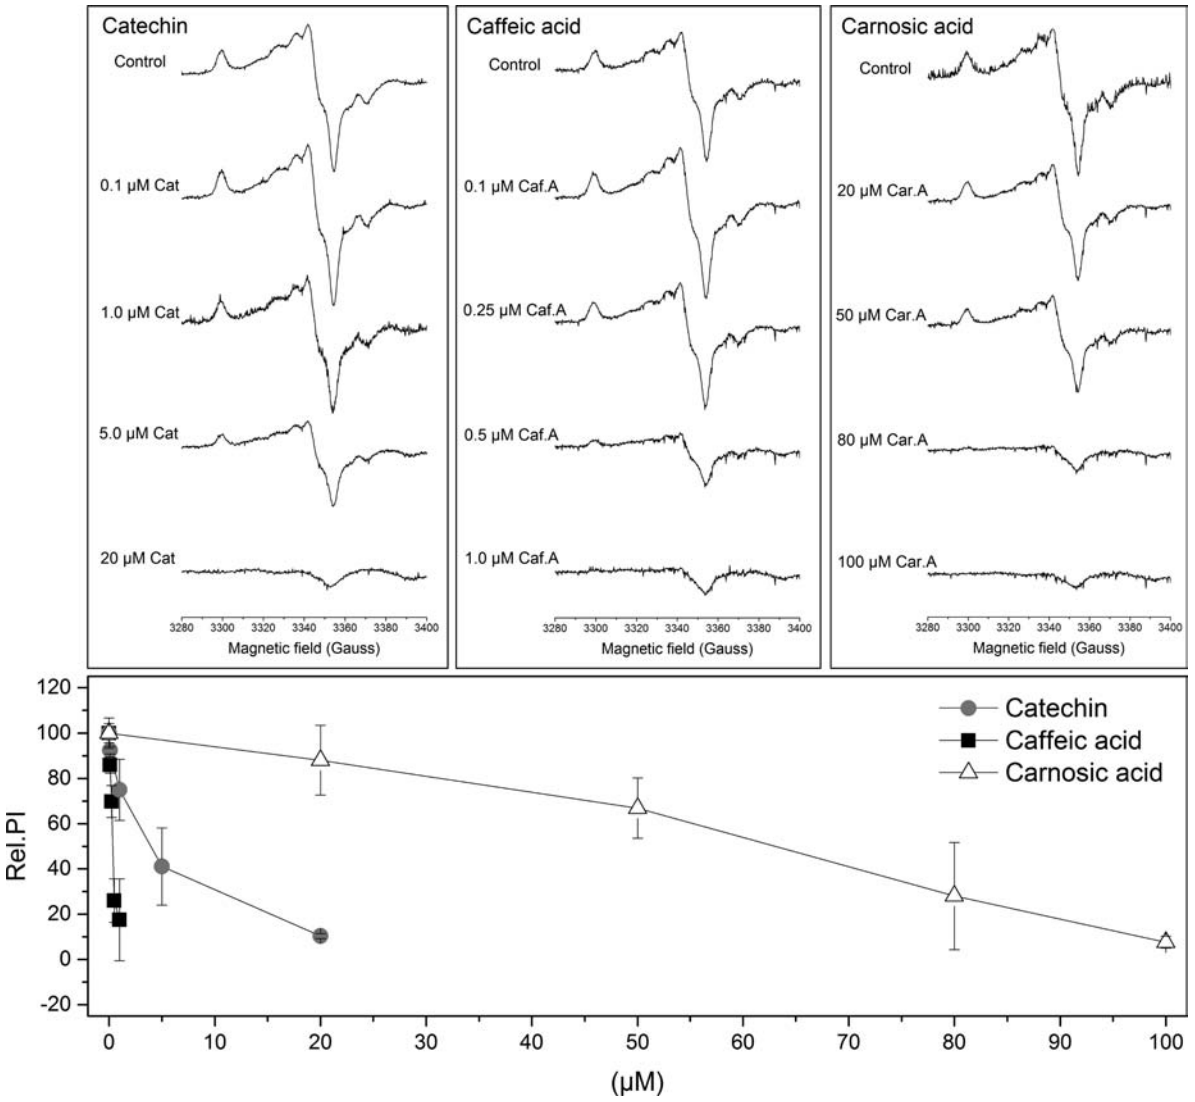

**Figure 5.** Upper panels: EPR spectra of perferrylmyoglobin radicals generated by reaction with hydrogen peroxide in a 1:1 molar ratio (100 $\mu$M) alone or in the presence of catechin (Cat), caffeic acid (Caf.A), or carnosic caid (Car.A) in increasing concentrations. Lower panel: Dose–response curves of relative peak intensity (Re.PI, mean ± standard deviation, $n \geq 3$) of the Trp-peroxyl radical as a function of the molar concentration of catechin, caffeic acid, or carnosic acid.

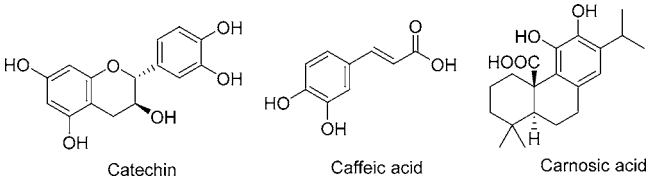

**Figure 6.** Chemical structures of catechin, caffeic acid, and carnosic acid.

carnosic acid are 4.36 and 4.9, respectively.[40,41] In contrast, catechin is protonated in the reaction mixture, as the p$K_a$ values of the most acidic groups, the catechol and phloroglucinol moieties, are 8.7 and 9.7 for the B-ring and A-ring, respectively.[42] The presence of the ionized form of the phenol enhanced the reducing capacity, as an increased electron density enhances the ability of the molecule to donate electrons. Nevertheless, Silva et al.[40] found that structural modification of the ethylenic side-chain on the aromatic ring of caffeic acid to yield alkyl esters actually increased the radical scavenging activity toward DPPH$^{\bullet}$ (2,2-diphenyl-1-picrylhydrazyl radical). The same authors concluded that no relationship between the radical scavenging activity and p$K_a$ exists, and they suggested that other physicochemical properties, such as the redox potential, could be of major importance for the radical scavenging capacities.[40]

A third factor to consider with regard to the reducing capacity is the size and three-dimensional structure of the phenols (Figure 6). Caffeic acid has a planar structure, which may allow it to react at protein sites that are inaccessible to larger more bulky molecules. An example of this could be catechin, in which the C-ring allows the B-ring to be in the pseudoaxial position, which may decrease the reactivity of the phenol with the protein radical due to steric hindrance. Similarly, the carboxylic group of carnosic acid is also in an axial position, and this may reduce the reactivity toward the protein radicals. A final factor to consider is the radical–radical interactions resulting in the polymerization of phenolic compounds that terminate radicals and regenerate the hydroxyl groups to regenerate their radical scavenging activity. Carnosic acid contains only one unsubstituted carbon atom in the

aromatic ring and may not polymerize to the same extent as catechin and caffeic acid, which both contain multiple unsubstituted carbons. Hence, the low reducing capacity of carnosic acid may be due to the limited ability to regenerate the phenolic moiety. However, in extracts multiple components are present and other radical transfer mechanisms may be active.

Overall, the results based on the $IC_{50}$ values indicate that MPI is 15-fold more efficient as a scavenger of the perferrylmyoglobin radical as compared to GTE or RE based on the molecular concentration of the components. This may reflect the different chemical reactivity of a thiol compared to a phenol, and it suggests that the molar ratio between GTE and MPI needs to be >15 in order to obtain efficient protection against protein-to-protein radical transfer.

Polyphenols have been shown, based on kinetic experiments and modeling, to protect lipids against oxidation by meat pigments in the gastric tract.[43] In other complex systems, such as meat emulsions, 100 ppm GTE, corresponding to 1.6% GTE per MPI, has been found to protect against protein thiol loss.[28] In the present study, the mass-based concentrations of MPI and GTE needed to reduce the Trp-radical signal by 50% were 0.6 g/L (Figure 3) and 8 mg/L (Figure 4), respectively. Calculation of the mass to mass percentage of GTE per MPI gives 1.3%, which is within the concentration range of GTE per MPI in the meat emulsion study mentioned above. This indicates that the model system applied may allow an effective preliminary evaluation of the amounts of plant extracts needed to inhibit protein oxidation in meat and meat products.

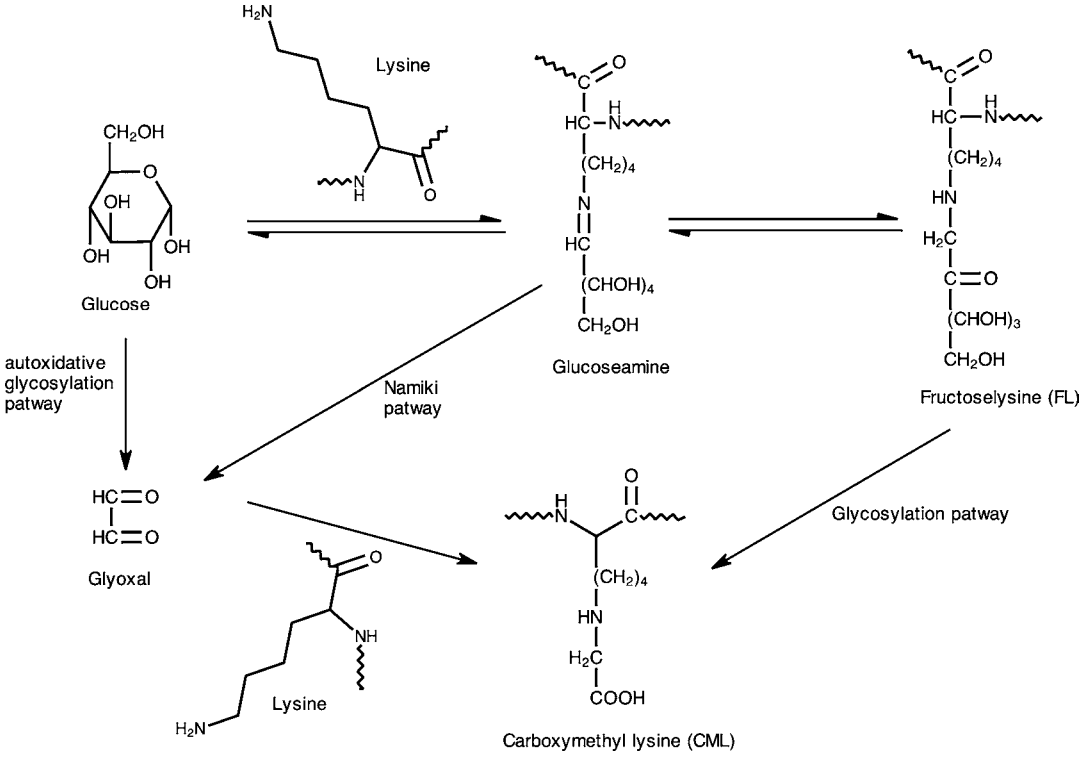

**Figure 1.** Pathways of CML formation (adapted from Han et al.[30]).

was interacted with calcium chloride and epicatechin to form casein−calcium and casein−epicatechin complexes. These complexes were heated in the presence of glucose at temperatures ranging from 70 to 150 °C, covering food processing conditions. FL and CML were determined in the heated mixtures as early and advanced glycation products, respectively.

## MATERIALS AND METHODS

**Chemicals.** Casein from bovine milk, glucose, (−)-epicatechin, sodium borohydride (Fluka), and CML standard were purchased from Sigma-Aldrich Chemie Gmbh (Germany), whereas calcium chloride, disodium hydrogen phosphate, potassium dihydrogen phosphate, and boric acid were from Merck (Germany). Furosine standard was purchased from Neosystem Laboratoire (Strasbourg, France). Hydrochloric acid and formic acid were also purchased from Sigma-Aldrich (Germany) and were of HPLC grade.

**Consumables.** Syringe filters (nylon, 0.45 μm), Oasis HLB (1 mL, 30 mg) solid-phase extraction cartridges, Acquity UPLC HSS T3 column (4.6 × 150 mm, 3 μm), and Atlantis dC18 column (250 × 4.6 mm, 5 μm) were supplied by Waters (Millford, MA).

**Preparation of Casein Complexes.** Casein was suspended in 50 mM phosphate buffer (pH 6.8) at a concentration of 5%. The suspension was continuously stirred for 20 min using a magnetic stirrer. Next, 0.1% of calcium chloride was added to promote ionic interaction between casein molecules and calcium ions, or 0.1% of epicatechin was added to promote hydrophobic interaction between casein and epicatechin molecules. The contents were continuously stirred for 20 min to maintain the casein−calcium or casein−epicatechin complexes. Afterward, 5% of glucose was added onto these complexes and stirred for further 20 min to obtain final mixtures of casein−glucose−calcium (CN-G-Ca) and casein−glucose−epicatechin (CN-G-EC). The control (CN-G) was a mixture of 5% casein and 5% glucose. Finally, the mixtures were glycated in solution state or in dry state after freeze-drying. The glycation reactions were performed in tightly closed test tubes containing the mixtures (in solution or dry states) prepared as described above. The tubes were placed in an oil bath and heated at 70, 90, 110, 130, and 150 °C for 10 min. A set of samples was also heated at 70 °C for 6 h.

To see the effect of protein conformation on glycation potential of casein, high shear microfluidization was applied to cause physical modification of the casein micelles. The casein suspension (5%) was treated under 30 000 psi for 5 min using a high-shear microfluidizer device (M110P, Microfluidics, Newton, MA). High-shear treated casein was dried by freeze-drying and kept at −20 °C. It was used to prepare the mixtures of high-shear treated casein−glucose−calcium (hsCN-G-Ca) and high-shear treated casein−glucose−epicatechin (hsCN-G-EC) complexes as described above. In this case, the control (hsCN-G) was a mixture of 5% high-shear treated casein and 5% glucose. The mixtures were glycated in dry state after freeze-drying by heating at 70 °C for 6 h.

The concentrations of FL and CML were determined as early and advanced glycation products in the heated mixtures. To see the effect of storage on the concentrations of FL and CML concentrations, the samples were incubated at 37 °C for 7 days after heat treatment.

**Analysis of Furosine by HPLC.** Analysis of furosine was performed according to Gökmen et al.[17] 30 mg of sample was weighed into a glass tube, and 10 mL of hydrochloric acid (8 N) was added. The tubes were flushed with nitrogen and tightly closed. They were hydrolyzed for 23 h at 110 °C. The hydrolyzates were filtered through filter paper, and then 100 μL was put into a glass vial. It was evaporated to dryness under nitrogen gas. The content then was washed with 1 mL of deionized water and passed through OASIS HLB cartridges. Ten microliters was injected into the HPLC system. Chromatographic separation was performed on an Atlantis HILIC column (250 × 4.6 mm, 5 μm) at 40 °C with a mobile phase of 1% formic acid at a flow rate of 1 mL/min. Data acquisition was performed acquiring chromatograms at the detection wavelength of 280 nm. Quantification was based on the calibration curve prepared using calibration solutions of furosine (1−10 mg/L), and was expressed as mg/g protein.

**Analysis of CML by LC−MS/MS.** Analysis of CML was performed according to Palermo et al.[18] with some modifications. A total of 20 mg of sample was mixed with 100 μL of deionized water in a glass tube. 450 μL of sodium borate buffer (0.2 M, pH 9.2) and 500

μL of sodium borohydride (1 M solution prepared in 0.1 M NaOH) were added. They were incubated at room temperature for 4 h to reduce fructoselysine into hexitol lysine. Afterward, 2 mL of hydrochloric acid (8 N) was added, and the tubes were closed under nitrogen flush. They were hydrolyzed for 24 h at 110 °C. Twenty microliters of hydrolyzate was evaporated with nitrogen. After the content was washed with 1 mL of deionized water, it was passed through a preconditioned Oasis HLB cartridge for cleanup. The first 8 drops of the eluent were discarded, and the rest was collected and diluted properly prior to LC−MS/MS analysis. The sample was injected into an Acquity UPLC HSS T3 column (4.6 × 150 mm, 3 μm) at 40 °C coupled to a Waters LC−MS/MS system operated in positive ionization mode using the following interface parameters: source temperature of 120 °C, desolvation temperature of 450 °C, collision gas flow of 0.20 mL/min, desolvation gas flow of 900 L/min, capillary voltage of 3 kV, cone voltage of 25 V, and extractor voltage of 2 V. Chromatographic separation was performed by using a mobile phase consisting of 0.1% formic acid in water:0.1% formic acid in acetonitrile (90:10, v/v) at a flow rate of 0.50 mL/min. Acquisition was performed by monitoring $m/z$ ratio of 205.10 for CML, 84.10 and 130.10 for its product ions. Quantification was performed by means of a matrix-matched calibration curve. Hydrolyzate of unheated protein was used as blank matrix. Calibration solutions of CML were prepared in the blank matrix at concentrations of 0, 1, 2.5, 5.0, and 10 μg/mL. They then were subjected to the lengthy extraction procedure that was used for actual samples, and analyzed as described above.

**Statistical Analysis.** The samples were analyzed at least in triplicate. Statistical analyses were performed by using IBM SPSS Statistics 19. Differences between mean values of samples were evaluated by analysis of variance (ANOVA), and the Duncan test was applied to determine significant differences at $p < 0.05$ level. Determination of significant differences between samples before and after incubation was performed with independent samples $t$ test.

## RESULTS AND DISCUSSION

**Effects of Complex Formation on Glycation of Casein.** Exogenous glycation of proteins that takes place during food processing may occur in a wide range of temperatures. In this study, glycation behavior of casein was investigated by forming hydrophobic or ionic interactions prior to heating. In the presence of glucose, casein−calcium and casein−epicatechin complexes were heated at temperatures of 70, 90, 110, 130, and 150 °C for 10 min to monitor glycation under aqueous and dry conditions.

Furosine is a good marker of early glycation especially for monitoring modification of proteins rich in lysine like casein. Figure 2 shows furosine concentrations of casein complexes heated at different temperatures in solution and dry state conditions. In solution state, furosine concentrations of all samples gradually increased as the temperature increased from 70 to 130 °C during heating. Further increase of temperature from 130 to 150 °C did not cause a remarkable increase in furosine concentrations. There were statistically significant differences ($p < 0.05$) in furosine concentrations of the samples heated at 70, 90, 110, and 130 °C. In comparison to the control, there were no significant differences ($p > 0.05$) in furosine levels for casein complexes formed with calcium and epicatechin at all temperatures studied except 130 and 150 °C.

The effect of temperature on furosine concentrations was different for the samples heated in dry state than in solution state. Furosine levels increased when the temperature was raised from 70 to 110 °C. With an exception for 150 °C, furosine concentrations of the samples glycated in dry state were higher than those of the samples glycated in solution state at all temperatures studied. This indicates a higher glycation potential of casein in dry conditions. It is known that the first

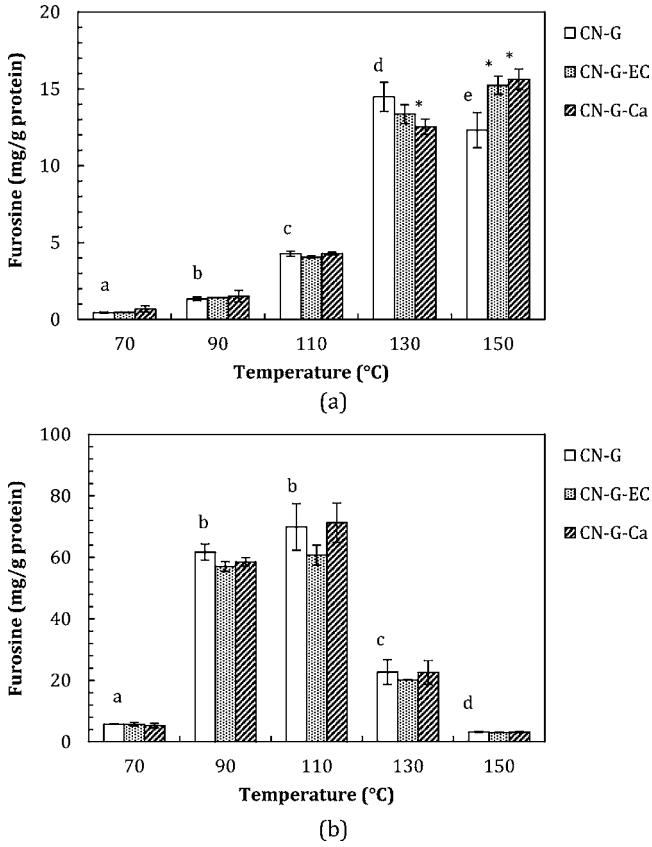

**Figure 2.** Effects of complex formation on furosine concentration of samples heated at different temperatures in (a) solution state, and (b) dry state. Bars with different letters indicate significant difference for control (CN-G) at $p < 0.05$ level. Bars with an asterisk indicate significant differences of complexes from control (CN-G) within the same temperature ($p < 0.05$).

stage of the glycation reaction is a condensation between the amino group of casein and the carbonyl group of glucose, yielding one molecule of water. Hence, the presence of water in the medium might be suppressing the reaction.

The peak levels of furosine were observed for the samples heated at 110 °C for 10 min in dry state that were significantly higher ($p < 0.05$) than the levels observed for the samples heated in solution state. Increasing the temperature in the dry state from 110 to 130 and to 150 °C caused a gradual decrease in furosine levels. It is a fact that furosine, an acid derivative of FL, is the indicator of early glycation. As an intermediate compound, FL can be converted faster to advanced glycation products at higher temperatures. So, the furosine concentration decreases as glycation progresses. FL is considered as the main precursor of CML.[19] It was shown that decomposition of FL leads to formation of CML.[20] Similar to the results observed in solution state, there were no significant differences ($p > 0.05$) in furosine levels for casein complexes formed with calcium and epicatechin.

Figure 3 shows CML concentrations of casein complexes heated at different temperatures in solution and dry state conditions. In solution state, there was a gradual increase in CML concentrations of the samples as the temperature increased from 70 to 150 °C (Figure 3a). For the control (CN-G), the CML level increased by a factor of 114 when the temperature was increased from 70 to 150 °C during heating. However, this increase was limited to 39 and 60 times for

dx.doi.org/10.1021/jf5038954 | J. Agric. Food Chem. 2014, 62, 11289−11295

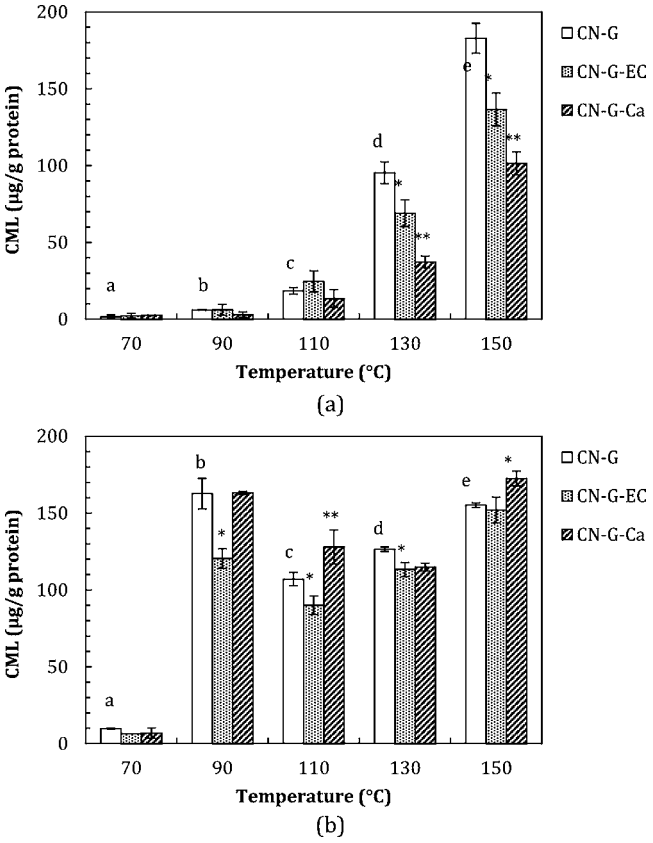

**Figure 3.** Effects of complex formation on CML concentration of samples heated at different temperatures in (a) solution state, and (b) dry state. Bars with different letters indicate significant difference for control (CN-G) at $p < 0.05$ level. Bars with an asterisk indicate significant differences of complexes from control (CN-G) within the same temperature ($p < 0.05$).

casein complexes formed with calcium and epicatechin, respectively. This revealed that formation of casein−calcium and casein−epicatechin complexes before heat treatment has a potential to limit the formation of advanced glycation end products during heating under certain conditions. At 130 and 150 °C, the amounts of CML formed during heating in the samples of casein complexes (CN-G-Ca and CN-G-EC) were found significantly lower ($p < 0.05$) than those formed in the control (CN-G). It is known that calcium ions act as a cross-linker forming bridges between casein micelles.[21] Formation of the casein−calcium complex through ionic interaction makes it difficult for glucose to bind amine groups of casein. On the other hand, there are different possible mechanisms for epicatechin to limit glycation. Protein−phenol interactions are known so far by taking place between hydrophobic residues of protein and polyphenols, mainly flavonoids. Noncovalent interaction between protein molecules and polyphenols results in bridges that make protein molecules hold together.[22] Hence, the first mechanism of epicatechin is to form a complex with casein, which is sterically hindered for glucose molecules. Because polyphenols are known to have carbonyl-trapping activity,[23,24] the second mechanism of epicatechin might be trapping glucose derived dicarbonyl compounds like glyoxal. CML may be formed from FL or from the reaction between glyoxal and lysine residues of protein (Figure 1). Hence, the decreased CML level besides the undiminished FL level indicates that epicatechin may have trapped glyoxal, and therefore have inhibited advanced glycation of casein. In our experiments, epicatechin did not cause a significant reduction in early glycation as stated earlier; however, the CML level significantly decreased ($p < 0.05$). There is another potential mechanism for epicatechin to limit glycation; Yin et al.[25] reported that epicatechin inhibited formation of intermediary radicals during the Maillard reaction. It was explained that autoxidation of epicatechin yielded formation of quinones that reacted with lysine through either a Michael-type addition or a Strecker-like reaction. There is additional evidence that supports such a reaction happening at 110 °C in semi dry mixtures; the reaction of glycine and the oxidized form of catechin leads to the formation of single- and double-addition products.[26] However, that kind of mechanism is favorable at alkaline conditions in which polyphenols may readily oxidize to respective quinones.[27] Therefore, this mechanism should occur to a limited extent at the conditions applied in this study.

In dry state, there was a remarkable increase in the amounts of CML formed in the samples when the temperature was increased from 70 to 90 °C (Figure 3b). In general, the CML levels were comparable to each other for all samples heated at 90, 110, 130, and 150 °C. In detail, the casein−epicatechin complex had significantly lower amounts of CML during heating at 90, 110, and 130 °C ($p < 0.05$). The casein−calcium complex had a lower amount of CML during heating only at 130 °C ($p < 0.05$). It is thought that the thermal impact suppressed molecular interactions because the treatment was harsh during heating casein complexes in dry state. Calcium ion accelerates dehydration of sugar molecules as do all mono-, di-, and trivalent cations.[28] Dehydration of glucose causes ian ncrease in the formation of CML through the glyoxal pathway, as explained in Figure 1. This is the most probable reason for higher amounts of CML found in heated casein−calcium complexes in dry state.

**Effects of Protein Conformation on Glycation of Casein.** In the second part, the complexes were formed using high-shear treated casein to understand the effects of physical modifications on the glycation tendency of casein. High-shear application was performed by treatment of casein suspension using a microfluidizer at 30 000 psi for 5 min.

As mentioned before, formation of casein complexes with calcium and epicatechin before heat treatment did not cause a change in the formation of early glycation products measured as furosine in the samples (Figure 4). However, heating the complexes prepared from high-shear treated casein formed lower amounts of furosine than the complexes prepared from native casein ($p < 0.05$). This indicated that physical modification has an effect on complex formation, and therefore on protein glycation. Among others, high-shear treated casein−epicatechin complex (hsCN-G-EC) had the lowest amount of furosine ($p < 0.05$).

It is thought that more hydrophobic and ionic interaction sites might become available for epicatechin and calcium to bind when casein micelle was dissociated. This consequence could have yielded a decrease in glycation reaction. Altuner et al.[29] showed that high hydrostatic pressure affected noncovalent interactions and especially hydrophobic bonds in milk. It was reported that as the pressure applied increased, the casein micelles decomposed into submicelles and the embedded hydrophobic areas inside the micelles repositioned in such a way that they readily interfered with the fluorescent marker, 1,8-naphthaleresulfonic acid (ANS).

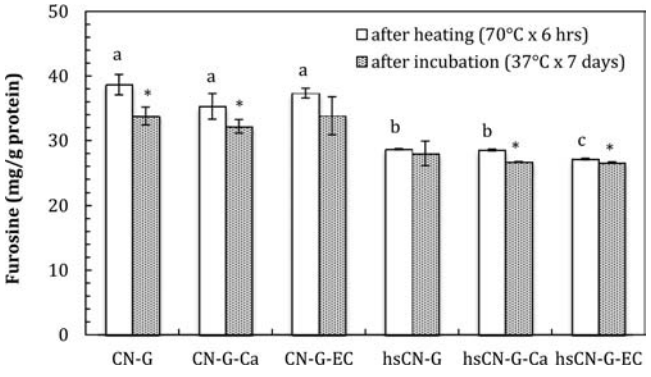

**Figure 4.** Furosine levels of native and high-shear treated casein complexes heated at 70 °C for 6 h. Bars with different letters indicate significant difference between complexes at $p < 0.05$ level. Bars with an asterisk indicate significant differences between samples before and after incubation ($p < 0.05$).

To see the progression of glycation during storage, the heated mixtures of casein complexes were incubated at 37 °C for 7 days. As shown in Figure 4, furosine concentrations decreased slightly during incubation. This is not surprising because FL being an intermediate compound formed in the Maillard reaction would decrease as glycation further developed under the stated conditions. Ahmed et al.[20] reported that FL content decreased during 15 days of reaction at 37 °C. Also, Han et al.[30] reported a decrease in FL and its simultaneous conversion to CML in the lysine−glucose−lipid model system during 4 h of incubation at 100 °C.

Figure 5 shows the amounts of CML formed in the mixtures of native and high-shear treated casein complexes during

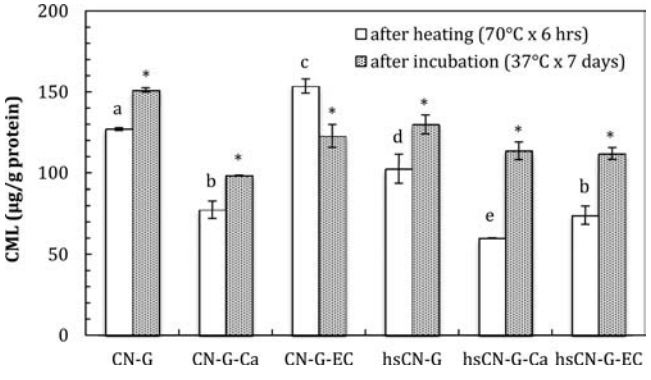

**Figure 5.** CML levels of native and high-shear treated casein complexes heated at 70 °C for 6 h. Bars with different letters indicate significant difference between complexes at $p < 0.05$ level. Bars with an asterisk indicate significant differences between samples before and after incubation ($p < 0.05$).

heating at 70 °C for 6 h. Interestingly, the presence of calcium ions showed a distinct antiglycation effect on native casein in terms of the formation of CML as the indicator of advanced glycation, whereas epicatechin caused an increase in CML level during heating. During incubation at 37 °C for 7 days, CML levels increased in all samples with an exception for the heated mixture of casein−epicatechin complex (CN-G-EC). It is a fact that calcium ions act as a cross-linking agent, forming bridges between casein micelles.[21] The results of the present study bring evidence that forming casein−calcium complex makes it difficult for glucose to bind amine groups of casein. There are conflicting reports about epicatechin; some reported an antiglycation effect,[23−26,31] while others reported an increased glycation.[32,33] Epicatechin was found to be an effective agent for the inhibition of thermally developed Maillard reaction products and reduced the cooked flavor in UHT milk.[31] Some reported antiglycation effect of epicatechin by carbonyl trapping,[23,24] while others explained the mechanism through quinone formation reacting with amines[25,26] as mentioned above. Also, Zhang et al.[34] reported that polyphenols reduce glyoxal generation by inhibiting lipid peroxidation. However, in a recent review, it was stated that epicatechin could both inhibit and enhance glycation.[33] It was explained by Fujiwara et al.[32] that catechol group containing polyphenols generates hydrogen peroxide during autoxidation of catechol structure, then hydrogen peroxide may generate hydroxyl radicals, and finally CML is generated by the reaction of hydroxyl radicals and Amadori products. So, the increased CML level of the complex prepared from the native casein in this study could be explained by the oxidation triggering effect of epicatechin. However, the CML level could be decreased if the complex was prepared using high-shear treated casein (Figure 5). It is thought that epicatechin can bind to casein structure more easily when it is treated using high-shear microfluidizer because the hidden hydrophobic sites within intact protein are exposed to interaction. Epicatechin has the ability to make weak hydrophobic interactions through hydrophobic amino acids of protein such as proline, tryptophan, tyrosine, and phenylalanine.[35]

So far, several methods have been proposed to inhibit protein glycation during food processing. The main thought is the blockage of carbonyl attachment to proteins, preventing oxidative stress or breaking down formed AGE cross-links. As exemplified for casein, this study proposes ionic and weak hydrophobic interactions as a strategy to limit advanced glycation of proteins during heating in a wide range of temperatures in both solution and dry states. It is certain that epicatechin or calcium ions do not block free amine groups of proteins, but they form steric hindrance that makes it difficult for carbonyl compounds to bind to amine groups on protein molecule. Casein micelle has a hydrophobic core and a hydrophilic surface. High shear treatment of casein allows more interaction sites, causing exposure of embedded hydrophobic regions within the intact molecule. So if the hydrophobic complex is to be formed to reduce glycation, physical modification of protein prior to complexation seems advantageous. Under the stated conditions, antiglycation effects of epicatechin molecules and calcium ions as hydrophobic and ionic interaction agents are remarkable in the advanced state. However, these interactions do not make significant differences in the early stage of glycation.

In conclusion, calcium ions and epicatechin molecules may inhibit the glycation of casein during heating under aqueous and dry conditions as follows:

- In aqueous solution state, calcium ions act as cross-linking agent forming bridges between casein micelles that make it difficult for carbonyl compounds to bind to glycation sites on protein.
- In dry state, calcium ions accelerate dehydration of glucose that may enhance advanced glycation of casein through the formation of glyoxal at high temperatures.
- Epicatechin forms a complex with casein through a well-known protein−phenolic interaction phenomenon that

may cause reduction in the accessibility of glycation sites on protein.

- Epicatechin may limit early glycation of protein through the formation of quinones that further react with amine residues on protein. However, this effect is more favorable under strong alkaline and oxidizing conditions.
- Epicatechin may limit advanced glycation by trapping glyoxal formed from the degradation of glucose. The reduced CML concentrations despite undiminished furosine levels indicate that mechanism is dominating in our experimental conditions.

The above-mentioned effects of calcium and epicatechin observed in the model system can be useful to prevent casein glycation in actual food systems such as pasteurized or sterilized milk and spray dried milk powder. Inhibition of Maillard reaction during milk processing not only improves the nutritional value of milk products, but also brings some sensorial advantages such as prevention of off-flavor. However, it should be kept in mind that the ingredient profile has substantial effects on advanced glycation.

Aldrich, MO, U.S.A.) by CYP2C9, respectively, were measured by the Waters AQCUITY UPLC H-Class system (MA, U.S.A.) with an ACQUITY UPLC BEH C18 column (Waters, MA, U.S.A.) at a flow rate of 0.4 mL/min at 40 °C. (±)-4′-Hydroxymephenytoin, a metabolite of (*S*)-mephenytoin (BD Gentest, MA, U.S.A.) by CYP2C19, was measured using the above UPLC system as described above at a flow rate of 0.5 mL/min at 40 °C. Dextromethorphan, a metabolite of dextrorphan (Wako Pure Chemicals Industries Ltd., Osaka, Japan) by CYP2D6, was measured by the Shimadzu LC Solution system (Kyoto, Japan) with an Ascentis Express C18 column (Sigma-Aldrich, MO, U.S.A.) at a flow rate of 0.8 mL/min at 40 °C. 6$\beta$-Hydroxytestosterone, a metabolite of testosterone (Nacalai Tesque Inc., Kyoto, Japan) by CYP3A4, was measured by the Waters Alliance HPLC system (Waters, MA, U.S.A.) with an Ascentis Express C18 column (Sigma-Aldrich, MO, U.S.A.) at a flow rate of 0.8 mL/min at 40 °C. Other analytical conditions such as mobile phase, gradient condition, and detected wavelength are presented in Table 2.

First, the inhibitory effects of EEP-B55 on the various enzymatic activities of CYPs were examined, and the $IC_{50}$ values for each CYP activity were calculated using GraphPad Prism software version 5.02 (Graphpad Software, Inc., La Jolla, U.S.A.). The test concentrations ($\mu$g/mL) of EEP-B55 used in each CYP enzyme assay were as follows: 0.8 to 67.2 for CYP1A2, 0.105 to 65.6 for CYP2C9, 0.617 to 50.0 for CYP2C19, 4.06 to 130.0 for CYP2D6, and 0.794 to 193.0 for CYP3A4. Each assay was performed in duplicate. Second, the inhibitory effects of the major ingredients of EEP-B55, the quantities of which are shown in Table 3, on the enzymatic activities of CYP were measured at a concentration of 50 $\mu$M in screening. Each assay was performed in duplicate. Then, the relative contributions of artepillin C, baccharin, kaempferide, dihydrokaempferide, isosakuranetin, and kaempferol to the inhibitory effect of EEP-B55 on each CYP activity were obtained in duplicate. In this study, the test concentrations of these compounds were individually determined by calculating the quantities of them in EEP-B55 that caused 70% inhibition for each of 5 CYP enzymatic activities. Artepillin C, kaempferide, dihydrokaempferide, isosakuranetin, and kaempferol, the contributions of which were each more than 5%, were further evaluated by calculating their $IC_{50}$ values in each CYP enzyme assay. This assay was performed in triplicate.

**Table 3. Major Ingredients and Their Respective Contents in EEP-B55**

| ingredients | ($\mu$g/mg of solid content) |
|---|---|
| artepillin C | 170.4 |
| baccharin | 50.3 |
| kaempferide | 29.4 |
| drupanin | 25.3 |
| *p*-coumaric acid | 19.3 |
| dihydrokaempferide | 16.5 |
| betuletol | 15.6 |
| isosakuranetin | 3.7 |
| kaempferol | 1.2 |

**In Vivo Assay.** Male Wistar/ST rats (7 weeks old) were purchased from Japan SLC Inc. (Shizuoka, Japan), fed on a standard diet (CE-2; Clea Japan Inc., Tokyo, Japan) ad libitum, and allowed free access to tap water. After acclimatization for 7 days, the animals were orally administered EEP-B55 at 100 mg/kg or 250 mg/kg (20 mL/kg) under fasting conditions for approximately 16 h. EEP-B55 was mixed with dextrin to prepare a powder formulation comprising 40% EEP-B55 content and suspended in a 0.5% methylcellulose solution. Blood samples were collected from the jugular vein under ether anesthesia before and at 10, 20, 30, and 60 min after administration. After a 2-week wash out period, blood samples were collected from the portal vein at 10 min after administration of the same dose of EEP-B55 as described above. After centrifugation at 1118*g* for 10 min at 4 °C, serum samples were collected, deproteinized by adding an equal volume of methanol/acetonitrile mixed solution containing 2% acetic acid, and then centrifuged at 6439*g* for 10 min at 4 °C. The supernatant was collected and filtered, and it was used for measuring the concentrations of artepillin C detected at 315 nm, kaempferide at 360 nm, dihydrokaempferide at 290 nm,

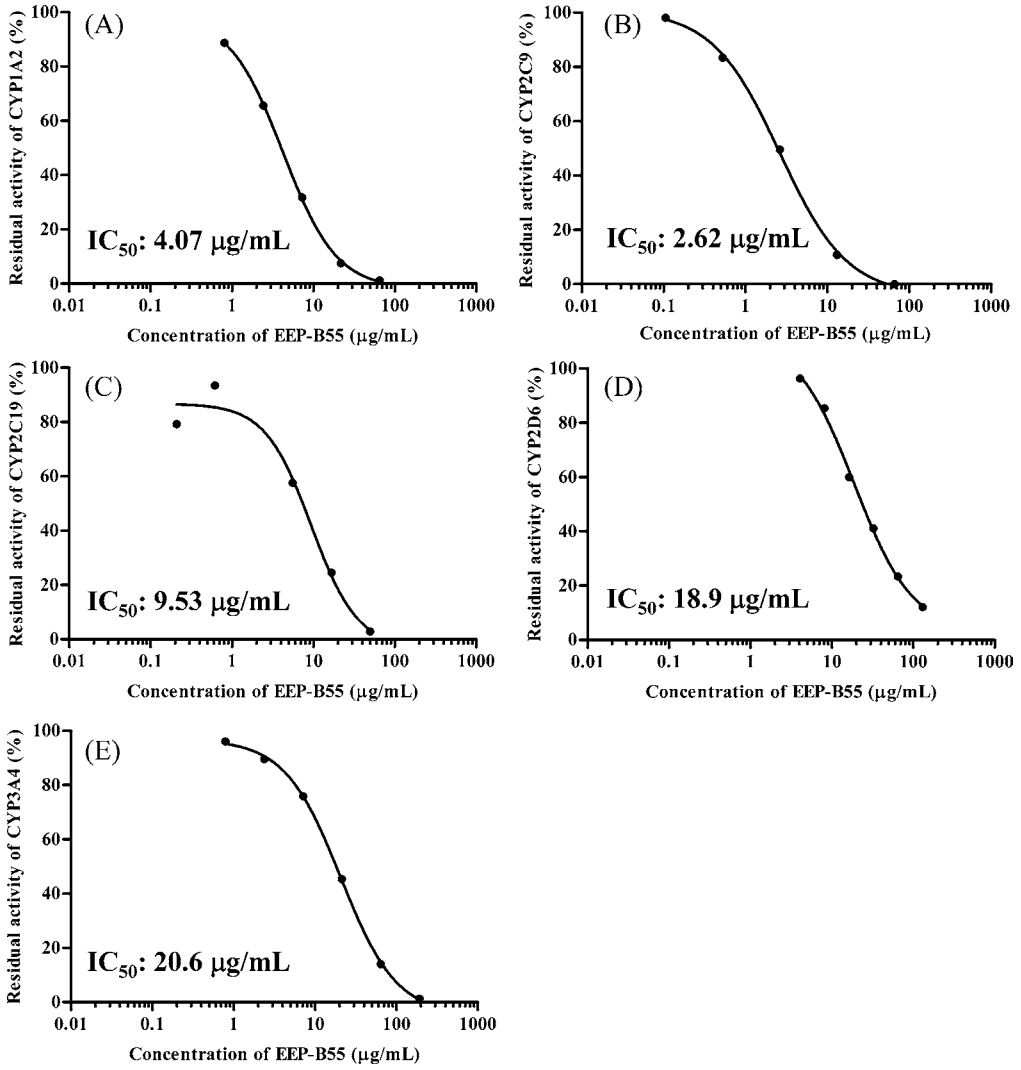

**Figure 1.** Effects of EEP-B55 on the activity of (A) CYP1A2, (B) CYP2C9, (C) CYP2C19, (D) CYP2D6, and (E) CYP3A4. Each value represents the average of duplicate assays, and the $IC_{50}$ values were calculated by nonlinear regression analysis using the GraphPad Prism software version 5.02.

**Table 4. Inhibition Ratio (%) of Major Ingredients of EEP-B55 at a Concentration of 50 $\mu$M**

| ingredients | CYP1A2 | CYP2C9 | CYP2C19 | CYP2D6 | CYP3A4 |
|---|---|---|---|---|---|
| artepillin C | 86.3 | 50.7 | 60.4 | 13.3 | 31.2 |
| baccharin | 17.4 | 60.7 | 13.9 | 0.6 | 30.9 |
| kaempferide[a] | 60.7 | 28.0 | 9.8 | 19.0 | 12.7 |
| drupanin | 16.7 | 7.6 | 3.1 | 1.2 | 7.1 |
| *p*-coumaric acid | 1.8 | 0.0 | 0.0 | 0.7 | 1.9 |
| dihydrokaempferide | 28.2 | 0.0 | 96.7 | 10.7 | 88.9 |
| betuletol[a] | 3.1 | 1.4 | 1.0 | 0.9 | 5.7 |
| isosakuranetin | 86.6 | 94.9 | 100.0 | 30.3 | 91.8 |
| kaempferol | 100.0 | 83.7 | 77.9 | 37.7 | 82.4 |

[a]Kaempferide and betuletol were each dissolved in the reaction buffer at 50 $\mu$M.

isosakuranetin at 290 nm, and kaempferol at 360 nm by a Shimadzu LC Solution system with photodiode array detector. These compounds were separated with an Ascentis Express C18 column using ultrapure water with 0.1% trifluoroacetic acid (TFA, solvent A) and methanol with 0.1% TFA (solvent B) and linear gradient conditions at 40−90% of solvent B for 50 min with a flow rate of 0.5 mL/min at 40 °C. The animal study was handled according to our company's regulations based on the Standards Relating to the Care and Management of Laboratory Animals and Relief of Pain (Notice No. 88 of the Ministry of Environment dated April 28, 2006), and the protocol of the animal study was approved by the Animal Ethics Committee of API Co., Ltd. (protocol 41-010).

## RESULTS

**Effect of EEP-B55 on the Activity of Human Recombinant CYPs.** First, we found that EEP-B55 inhibited all the CYP enzymatic activities tested in a concentration-

dependent manner (Figure 1). Second, in screening of EEP-B55's ingredients at a concentration of 50 $\mu$M, the following ingredients exhibited the inhibition ratio of 50% or more: artepillin C for CYP1A2, CYP2C9, and CYP2C19, baccharin for CYP2C9, kaempferide for CYP1A2, dihydrokaempferide for CYP2C19 and CYP3A4, isosakuranetin for CYP1A2, CYP2C9, CYP2C19, and CYP3A4, and kaempferol for CYP1A2, CYP2C9, CYP2C19, and CYP3A4. No ingredients inhibited CYP2D6 enzyme activity by more than 50%. Conversely, drupanin, *p*-coumaric acid, and betuletol did not cause the inhibition of more than 20% for all the CYP enzymes tested (Table 4). We examined a contribution of EEP-B55 ingredients to inhibition of each CYP activity and found that artepillin C, kaempferide, and isosakuranetin were effective for CYP1A2 activity; artepillin C was for CYP2C9 activity; artepillin C, dihydrokaempferide, isosakuranetin, and kaempferol were for CYP2C19 activity; artepillin C and kaempferide were for CYP2D6 activity; and artepillin C, dihydrokaempferide, and isosakuranetin were for CYP3A4 activity (Table 5). In addition, the $IC_{50}$ values of these ingredients were as follows: 16.1 $\mu$M for artepillin C, 6.0 $\mu$M for kaempferide, and 15.9 $\mu$M for isosakuranetin in the CYP1A2 enzyme assay; 34.9 $\mu$M for artepillin C in the CYP2C9 enzyme assay; 37.0 $\mu$M for artepillin C, 2.0 $\mu$M for dihydrokaempferide, 1.7 $\mu$M for isosakuranetin, and 31.9 $\mu$M for kaempferol in the CYP2C19 enzyme assay; 427.4 $\mu$M for artepillin C and 14.6 $\mu$M for kaempferide in the CYP2D6 enzyme assay; and 268.9 $\mu$M for artepillin C, 10.5 $\mu$M for dihydrokaempferide, and 4.3 $\mu$M for isosakuranetin in the CYP3A4 enzyme assay (Table 5).

**Pharmacokinetic Study on EEP-B55 Ingredients in Rats.** In the peripheral blood, maximum serum concentrations (Cmax; mean ± SD) of artepillin C reached 415 ± 360 nM and 487 ± 307 nM at doses of 100 mg/kg and 250 mg/kg, respectively, at 10 min (Tmax) after administration. The area under the curve (AUC; mean ± SD) of artepillin C was 9551 ± 6729 nmol·min/L and 9991 ± 4037 nmol·min/L at doses of 100 mg/kg and 250 mg/kg, respectively. At 10 min after administration, serum concentrations (mean ± SD) of artepillin C in portal blood were 2794 ± 955 nM and 7142 ± 5044 nM at doses of 100 mg/kg and 250 mg/kg, respectively. In contrast, kaempferide, dihydrokaempferide, isosakuranetin, and kaempferol in serum were not detected and their lower limits of detection (LLD) were as follows: 4.97, 7.15, 4.87, and 5.97 nM, respectively.

**Table 5. Relative Contribution and $IC_{50}$ Values of Major Ingredients of EEP-B55**

| | contribution ratio[a] (%) | $IC_{50}$ values[b] ($\mu$M) |
|---|---|---|
| **CYP1A2** | | |
| artepillin C | 55.3 | 16.1 |
| kaempferide | 47.1 | 6.0 |
| isosakuranetin | 5.1 | 15.9 |
| kaempferol | 1.9 | – |
| **CYP2C9** | | |
| artepillin C | 58.6 | 34.9 |

| isosakuranetin | 23.0 | 4.3 |
| kaempferol | 0.0 | – |

[a]The final concentrations of the test materials were as follows: EEP-B55 16.9 $\mu$g/mL, artepillin C 9.6 $\mu$M, kaempferide 1.7 $\mu$M, isosakuranetin 0.22 $\mu$M, and kaempferol 0.07 $\mu$M in the CYP1A2 assay; EEP-B55 5.3 $\mu$g/mL, artepillin C 3.0 $\mu$M, baccharin 0.74 $\mu$M, isosakuranetin 0.069 $\mu$M, and kaempferol 0.022 $\mu$M in the CYP2C9 assay; EEP-B55 12.8 $\mu$g/mL, artepillin C 7.3 $\mu$M, dihydrokaempferide 0.7 $\mu$M, isosakuranetin 0.17 $\mu$M, and kaempferol 0.053 $\mu$M in the CYP2C19 assay; EEP-B55 36.9 $\mu$g/mL, artepillin C 20.9 $\mu$M, kaempferide 3.6 $\mu$M, isosakuranetin 0.48 $\mu$M, and kaempferol 0.15 $\mu$M in the CYP2D6 assay; EEP-B55 34.6 $\mu$g/mL, artepillin C 19.6 $\mu$M, dihydrokaempferide 1.9 $\mu$M, isosakuranetin 0.45 $\mu$M, and kaempferol 0.14 $\mu$M in the CYP3A4 assay. [b]Artepillin C, kaempferide, and isosakuranetin were tested at concentrations of 0.78 to 100.0 $\mu$M, 0.063 to 16.0 $\mu$M, and 0.78 to 100.0 $\mu$M, respectively, in the CYP1A2 assay. Artepillin C was tested at concentrations of 0.66 to 1000.0 $\mu$M in the CYP2C9 assay. Artepillin C, dihydrokaempferide, isosakuranetin, and kaempferol were tested at concentrations of 0.33 to 200.0 $\mu$M, 0.046 to 100.0 $\mu$M, 0.082 to 50.0 $\mu$M, and 0.016 to 100.0 $\mu$M, respectively, in the CYP2C19 assay. Artepillin C and kaempferide were tested at concentrations of 39.0 to 1000.0 $\mu$M and 0.62 to 16.0 $\mu$M, respectively, in the CYP2D6 assay. Artepillin C, dihydrokaempferide, and isosakuranetin were tested at concentrations of 15.6 to 1000.0 $\mu$M, 0.78 to 100.0 $\mu$M, and 0.16 to 100.0 $\mu$M, respectively, in the CYP3A4 assay.

## DISCUSSION

In general, changes in pharmacokinetics and pharmacodynamic responses are thought to be caused by drug–drug or drug–food interactions. In pharmacokinetic interactions, approximately 65% of drug–drug interactions occur in metabolic sites, and drug metabolic enzymes are considered to be the most important interactive sites.[18] A large number of drugs are metabolized by CYP enzymes in the liver, and more than 90% of drug–drug interactions occur at the CYP-catalyzed step.[18] Similarly, supplement–drug interactions involving CYP activity are occasionally found to cause considerable adverse events. For these reasons, we evaluated the effects of an ethanol extract of Brazilian green propolis and its major ingredients on the activity of CYP enzymes in vitro. We selected CYP isoforms CYP1A2, CYP2C9, CYP2C19, CYP2D6, and CYP3A4 because more than 90% of drugs are known to be metabolized by these 5 CYP enzymes.[19] In addition, CYP2 and CYP3 families are known to be largely different between human and rat in genome sequences.[20] We therefore used human recombinant CYPs in the present study.

It is difficult to estimate the risk of interactions between drugs and a natural product such as propolis extract because natural products include multiple chemical substances. In the present study, we tried to estimate the risk of an interaction with EEP-B55 in the following steps. First, we evaluated the effects of EEP-B55 and its major ingredients on the activities of CYP enzymes, and calculated the $IC_{50}$ value of each ingredient showing a contribution of more than 5% in vitro CYP enzyme assays. Second, to extrapolate the risk of a propolis–drug

interaction in humans, we measured blood concentrations of the ingredients after oral administration of EEP-B55 in rats and compared them with their $IC_{50}$ values obtained in the in vitro assay.

EEP-B55 reduced the activity of CYP1A2, CYP2C9, CYP2C19, CYP2D6, and CYP3A4 in a concentration-dependent manner, and it was shown that artepillin C, kaempferide, dihydrokaempferide, isosakuranetin, and kaempferol made a major contribution to the inhibitory activity of EEP-B55. Among these compounds, kaempferol, a flavonoid found in fruits and vegetables, is known to inhibit CYP1A2,[21,22] CYP2C9,[23,24] and CYP3A/CYP3A4[25−27] activities in vitro and in vivo. In accordance with the previous reports, kaempferol was found to inhibit these CYP enzyme activities by more than 80% at a concentration of 50 $\mu$M in our in vitro assay (Table 4).

Recently, the number of adverse events caused by the interaction of dietary supplements with drugs has increased, and it has generally been reported that dietary supplements ingredients which possibly cause the interaction with drugs exhibit the $IC_{50}$ values almost less than 50 $\mu$M for CYP enzyme inhibition in vitro. This is the reason for the concentration of 50 $\mu$M used in the in vitro screening test. For example, black cohosh (*Actaea racemosa L.*) has been reported to inhibit CYP2D6 activity in a clinical trial,[28] and the ingredients of black cohosh, fukinolic acid ($IC_{50}$ value: 5.4 $\mu$M), cimicifugic acid A ($IC_{50}$ value: 9.0 $\mu$M), and cimicifugic acid B ($IC_{50}$ value: 12.6 $\mu$M) have been suggested to be responsible for this clinical event in vitro.[29,30] Goldenseal (*Hydrastis Canadensis L.*) exhibits inhibition of human CYP2D6 and CYP3A4 activities,[28,31,32] and these activities are affected by its ingredients of berberine ($IC_{50}$ value: 45 $\mu$M) and hydrastine isomer ($IC_{50}$ values: (+) isomer is 25 $\mu$M and (−) isomer is 30 $\mu$M), respectively, in vitro.[33] Piperine, a major ingredient of black pepper (*Piper nigrum L.*), inhibits human CYP2C9 and CYP1A2 activities in clinical trial,[34,35] and $IC_{50}$ values of piperine were 40.7 $\mu$M and 29.8 $\mu$M for CYP2C9 and CYP1A2, respectively, in vitro.[36] Thus, the $IC_{50}$ value of effective ingredients in a supplement which has been reported the interaction with drug in clinical are always below 50 $\mu$M for the inhibition of CYP enzyme activity. In our in vitro assay, artepillin C was found to reduce all 5 tested CYP enzyme activities, whereas its $IC_{50}$ values for CYP2D6 and CYP3A4 enzymes were greater than 200 $\mu$M, suggesting that the inhibitory activity of artepillin C against these CYPs is relatively weak.

To inhibit CYP enzyme activity in vivo, artepillin C, kaempferide, dihydrokaempferide, isosakuranetin, and/or kaempferol need to be absorbed after ingestion of EEP-B55, and the CYP enzymes in hepatocytes need to be exposed to them at the concentration of their $IC_{50}$ value or more. When EEP-B55 was orally administered at doses of 100 mg/kg and 250 mg/kg in rats, artepillin C was detected in peripheral blood as well as in portal blood. However, the other compounds (i.e., kaempferide, dihydrokaempferide, isosakuranetin, and kaempferol) were not detected in either the peripheral or portal blood even at a dose of 250 mg/kg. The dose of 250 mg/kg is estimated to be equivalent to 5-fold of the recommended daily intake, 500 mg/day, when converting animal doses to human equivalent doses based on their body surface area. This dose corresponds to a dose of 42.5 mg/kg for artepillin C. The bioavailability of artepillin C is known to be low, and the reason is thought to be clearance by the liver.[37] When a free-form compound in blood permeates the cell membrane in the liver by transcellular passive diffusion, its concentration is held in equilibrium between the blood and the hepatocytes. Because artepillin C is transported by transcellular passive diffusion,[38] the concentration of this compound in hepatocytes is thought to be equal to that in peripheral blood. Shimizu et al. have indicated that artepillin C is absorbed as a free-form through the intestinal tract and approximately 5% of them are incorporated into hepatocytes in vitro experiments using Caco-2 and HepG2 cells.[39] The concentration of artepillin C was 7142 ± 5044 nM in portal blood at 10 min after a single oral administration of EEP-B55 (250 mg/kg), and its exposure concentration on hepatocytes is roughly estimated at 400 nM. This predicted concentration is similar to the peripheral blood concentration (Cmax: 487 ± 307 nM). The $IC_{50}$ values of artepillin C for CYP1A2, CYP2C9, and CYP2C19 were approximately 33-, 70-, and 75-fold, respectively, higher than the Cmax value in peripheral blood. The blood concentrations of the other potent compounds, kaempferide, dihydrokaempferide, isosakuranetin, and kaempferol, were below their LLD concentration, and their minimum $IC_{50}$ values (Table 5) for the CYP enzymes tested were 1200-, 280-, 350-, and 5300-fold, respectively, higher than the concentration of their LLD. Thus, it is conceivable that the activities of liver CYP enzymes are not markedly affected by artepillin C at the recommended daily intake of EEP-B55.

An inhibitory effect of a given compound on CYP's enzymatic activity in vitro is not necessarily related to its influence on the pharmacokinetics of drugs in human. For example, silybin, an active constituent of milk thistle (*Silybum marianum L.*), has been found to be a potent mechanism-based inhibitor of CYP3A4 and CYP2C9 enzymes[40] but not to cause a clinically significant interaction with drugs because there are large differences between the blood silybin concentration after ingestion of silybin-containing supplements and its $IC_{50}$ values for CYP activities.[41,42] It has also been reported that kavalactones, active ingredients in kavakava (*Piper methysticum G.*), inhibit the activity of CYP1A2 and CYP3A4[43] but do not induce a clinically significant interaction with drugs for the same reason as described for silybin.[28] These findings seem to support our conclusion that EEP-B55 hardly affects interactions with drugs in the case of the recommended daily intake even though compounds such as artepillin C have inhibitory effects on CYP enzymes in vitro. However, it is necessary to consider species differences between rats and humans in the pharmacokinetics of drugs. Oral absorption is often more rapid, and the hepatic first-pass effect is also often greater in rodents than in humans. Thus, the blood concentrations of major EEP-B55 ingredients will be much higher in humans than in rats. In general, the extent of absorption is thought not to differ substantially because the diffusion of drugs through the small intestine epithelium is similar in most species.[44] It is therefore likely that the concentration of artepillin C found in rat portal blood corresponds to the human blood concentration of it after oral ingestion of EEP-B55. If so, the $IC_{50}$ value of artepillin C for CYP1A2, which was the lowest such value, was approximately 2.3-fold higher than the concentration in rat portal blood (16.1 $\mu$M vs 7.14 $\mu$M) after oral administration of EEP-B55 at a dose of 250 mg/kg, which is estimated to be equivalent to 5-fold the amount of the recommended daily intake. Poor bioavailability of flavonoids is well-known in human[45] and also in rat.[46] The present study also showed extremely low blood concentrations (blow LLD) of the inhibitory flavonoids, kaempferide, dihydrokaempferide, iso-

sakuranetin, and kaempferol, after oral administration of EEP-B55.

This is the first report on an investigation of the interaction of propolis extract with drugs, and the present results indicate that ethanol extract of Brazilian green propolis is unlikely to attenuate the hepatic metabolism of drugs under dosing condition comparable to daily intake. This expectation can be supported by the fact that no undesirable interactions between propolis extracts and drugs have been reported. Meanwhile, further investigations on whether administration of EEP-B55 alter expression of CYP enzymes would give us valuable information regarding the interactions of EEP-B55 with drugs because induction of drug metabolizing enzyme reduces the efficacy of drugs.

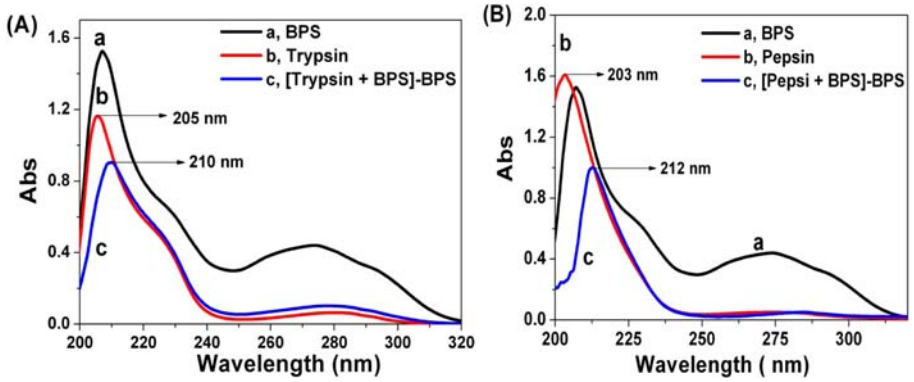

**Figure 1.** (A) Absorption spectra of trypsin, BPS, and trypsin−BPS. (B) Absorption spectra of pepsin, BPS, and pepsin−BPS. The concentrations of trypsin and pepsin were $2.0 \times 10^{-5}$ mol·L$^{-1}$; the concentrations of BPS were $4.0 \times 10^{-5}$ mol·L$^{-1}$.

BPS enters the human digestive system such as stomach and duodenum, digestive proteases may be the indirect binding targets. Both pepsin and trypsin are principal protein-degrading or proteolytic enzymes in the digestive system. The former is released by the chief cells in the stomach, while the latter is produced in the pancreas as the inactive proenzyme trypsinogen in the duodenum. During the process of digestion, each of these two enzymes is specialized in cleaving links between particular types of amino acids, leading to the breakdown of dietary proteins into their components.[15,16] Due to the importance of pepsin and trypsin in the digestive system of human, they are often selected as binding model proteins to investigate the effects on their activities and conformational structures of small molecules that are found in food and medicinal herbs.[17−26] However, little is known about the binding interactions of BPS with pepsin and trypsin and the effects of BPS on their activities.

Herein, pepsin and trypsin were selected as the investigated digestion enzyme models to study the binding interactions of BPS. The effects of BPS on the activities and conformations of pepsin and trypsin were investigated by means of multispectroscopic techniques and molecular modeling method in order to cast some light on the future study of the toxicity of BPS.

## MATERIALS AND METHODS

**Materials.** Trypsin (from porcine pancreas), pepsin (from porcine stomach mucosa), bovine hemoglobin (from bovine erythrocyte), and *N*-benzoyl-D,L-arginine-*p*-nitroanilide (BApNA) were purchased from Sigma-Aldrich Company (St. Louis, MO) and were used without further purification. Analytical standard of BPS (≥98%) was obtained from Aladdin Industrial Corporation (Kaplan Ave, City of Industry, CA). The other reagents were all of analytical purity. Pepsin solution was prepared in pH 2.00 citric acid buffer (0.025 M, 0.1 M NaCl). Trypsin solution was prepared in a phosphate buffer (0.01 M) of pH 7.40. The 0.5 wt % solution of bovine hemoglobin was prepared in pH 2.00 citric acid buffer. Muriatic acid (reagent grade, 37%) was used to adjust the pH of buffer solution. The 10% of trichloroacetic acid was prepared in water. BApNA (3.0 mM) was dissolved in DMSO and was stored at 0−4 °C. Water was purified with a Milli-Q purification system (Barnstead, Dubuque, IA, USA).

**UV−Vis Spectroscopy.** A SPECORD S600 (Germany, Jena) equipped with 1.0 cm quartz cells was used to record the UV−vis spectra of trypsin or pepsin in the absence and presence of BPS. During the assay of enzyme activity, BApNA and bovine hemoglobin were used as substrates for trypsin and pepsin, respectively.[27,28] Each experiment was repeated three times in order to take the mean. The activity of trypsin was determined by BApNA degradation into *p*-nitroaniline, which is detected by spectrophotometer based on the increase in absorbance at 410 nm in a phosphate buffer (pH 7.40, 0.01 M$^{-1}$) in the absence and presence of trypsin ($5.0 \times 10^{-6}$ mol·L$^{-1}$). In addition, the Anson method was used to detect pepsin activity.[28] First, 1 mL of pepsin (30.0 $\mu$M) and different volumes of BPS were mixed in a 10 mL centrifuge tube, and then different volumes of citric acid buffer were dropped into the above solution and made up to a constant volume of 3 mL. Second, the pepsin−BPS systems were set at 37 °C for 20 min, and then 2 mL of bovine hemoglobin (0.5 wt %) solution was added to the above solution. Third, 2 mL of 10% trichloroacetic acid was used to terminate the above reactions after 20 min. The supernatant was obtained by centrifuging at 12,000 rpm for 20 min twice and was measured via OD 275 nm. The original activity of pepsin is 3000 NFU/mg, and the activity of pepsin in the presence of BPS was obtained by eq 1:

$$\text{activity}/_{(\text{NFU/mg})} = 3000 \times \frac{\text{OD275(pepsin−BPS)}}{\text{OD275(original pepsin)}} \quad (1)$$

**Fluorescence Spectroscopy.** An LS-50B spectrofluorimeter (Waltham, MA, USA) equipped with 1.0 cm quartz cells and a thermostat bath was used to record the steady-state fluorescence and synchronous fluorescence spectra of trypsin ($2 \times 10^{-5}$ mol·L$^{-1}$) and pepsin ($2 \times 10^{-5}$ mol·L$^{-1}$) in the absence and presence of BPS (from 0 to $5.0 \times 10^{-5}$ mol·L$^{-1}$). As for steady-state fluorescence spectral experiments, the excitation wavelength was selected as 280 nm and the scan range of emission wavelengths was from 300 to 500 nm. The scan speed and the slit widths of emission and excitation were set at 500 nm/min, 5.0 nm, and 5.0 nm, respectively. In addition, the wavelength intervals $\Delta\lambda$ ($\lambda_{em} - \lambda_{ex}$) were set at 15 and 60 nm to obtain the synchronous fluorescence spectra of trypsin and pepsin in the same experimental conditions as the steady-state fluorescence emission spectra.

**Circular Dichroism Spectroscopy.** A Chirascan spectrometer (Applied Photophyysics Ltd., Leatherhead, Surrey, U.K.) equipped with a temperature control quantum were used to measure the circular dichroism (CD) spectra of trypsin ($2.5 \times 10^{-5}$ mol·L$^{-1}$) and pepsin ($2.5 \times 10^{-5}$ mol·L$^{-1}$) in the absence and presence of BPS. The CD spectra were recorded from 190 to 260 nm with a scan speed of 20 nm/min and a bandwidth of 1 nm using 0.1 cm quartz cells.

**Molecular Modeling.** The molecular docking program Autodock 4.2.3 and Autodock tools v 1.5.4 were used to study the binding models of trypsin and pepsin with BPS at the molecular level.[29] The geometry of BPS was optimized using density functional theory (DFT) at the level of B3LYP/6-311G by the program Gaussian 09.[30] The molecular structures of trypsin (PDB ID 2ZQ1) and pepsin (PDB ID 5PEP) were obtained from RCSB Protein Data Bank, http://www.rcsb.org/pdb.[31,32] During molecular calculation studies, all water molecules and ligands were removed from the molecular structures of trypsin and pepsin, and essential hydrogen atoms, Kollman united atom type charges, and salvation parameters were also added in the protein model.[19,33] The Gasteiger partial charges were added to atoms

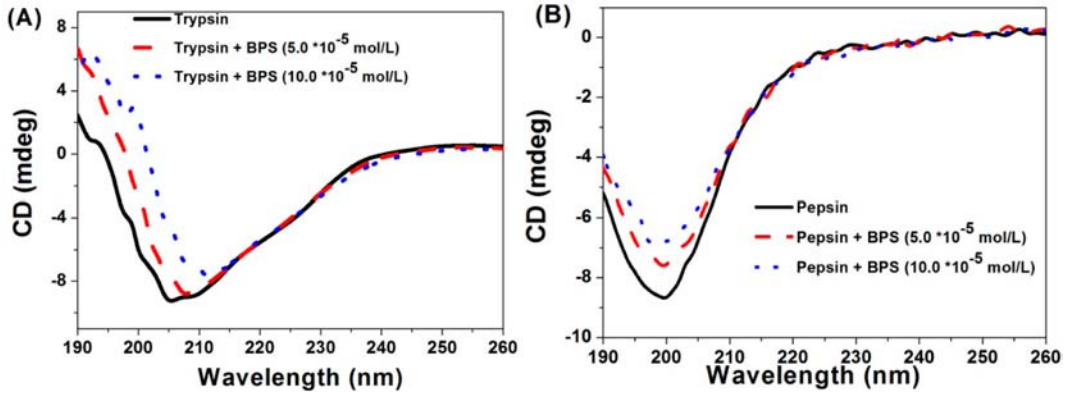

**Figure 2.** Far-UV CD spectra of trypsin (A) and pepsin (B) ($2.5 \times 10^{-5}$ mol·L$^{-1}$) in the absence and presence of BPS.

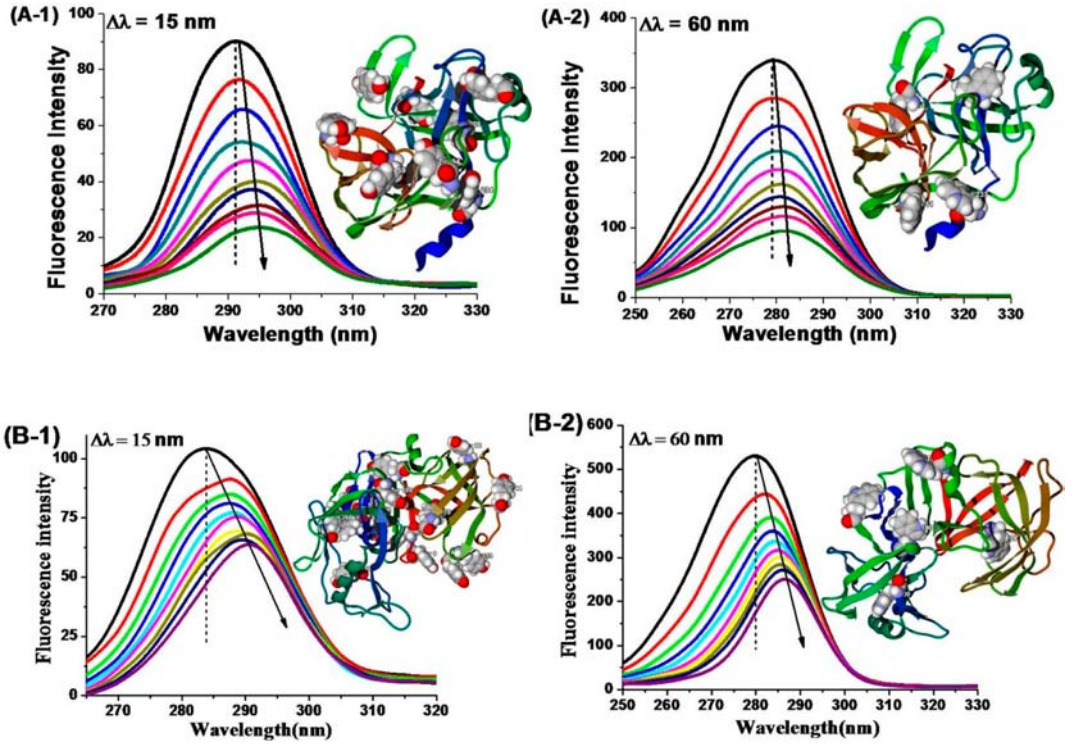

**Figure 3.** Effects of BPS on the synchronous fluorescence spectra of trypsin (A) and pepsin (B), $c$ (trypsin) = $c$ (pepsin) = $2.0 \times 10^{-5}$ mol·L$^{-1}$. $c$ (BPS) ($\times 10^{-5}$ mol·L$^{-1}$) (from top to bottom), 0, 0.5, 1.0, 1.5, 2.0, 2.5, 3.0, 3.5, 4.0, and 5.0, respectively. The insets show the positions of Trp residues and Tyr residues in the three-dimensional structures of trypsin and pepsin.

of BPS, and rotatable bonds were defined. In addition, the grid box sizes of BPS−trypsin/pepsin systems were 126 Å × 126 Å × 126 Å, with grid spacing of 0.375 Å, while the GA population size was set at 150, the maximum number of energy evaluation was set at 2500000, the number of GA runs was set at 100, and others used were default parameters. When the docking calculation finished, Molegro Molecular Viewer software (Molegro—A CLC bio company, Aarhus, Denmark) was used to analyze the predicted binding mode with the lowest binding free energy and the hydrogen bond interactions of BPS with trypsin and pepsin.[34]

## RESULTS AND DISCUSSION

**Effect of BPS on the Secondary Structure of Trypsin and Pepsin.** Absorption spectroscopy is a simple and excellent technique for determining the conformational transitions in proteins, which are presented by the changes of wavelength of absorption and the strength of their absorbance.[35] The UV−vis absorption spectra of trypsin and pepsin in the absence and presence of BPS are shown in Figure 1A,B. Both trypsin and pepsin show two main absorption bands. The strong one is from 200 to 230 nm and reflects the secondary structures of trypsin and pepsin.[36] The weak one between 260 and 290 nm is caused by the absorbance of the main two aromatic amino acids tryptophan (Trp) and tyrosine (Tyr) and indicates the transformation of the microenvironment of their chromophores.[37] It can be seen from Figure 1A,B that the absorbance intensities of the former peak decrease with a red shift in the presence of BPS. This peak that comes from the n−$\pi^*$ transitions reflects the conformations of protein backbone.[36] Upon BPS binding, the peak was red-shifted by 5 and 9 nm for trypsin and pepsin, respectively. These changes are related to the alterations in the secondary structures of trypsin and pepsin.[36,38] In addition, the absorption spectra of the aromatic amino acids in trypsin and pepsin also change. The absorbance intensity at about 278 nm of trypsin increases in the presence of

BPS, indicating that the unfolding of trypsin induced by BPS results in exposing aromatic amino acids to the aqueous solvent. For pepsin, the maximum of the absorption of aromatic amino acids is shifted to long wavelength. Therefore, the binding interactions of BPS with trypsin and pepsin not only induce the secondary structure changes of these two enzymes but also partly affect the tertiary structure of enzymes.

The far-UV CD spectra from 190 to 260 nm coming from electronic transitions between molecular orbitals in ground and excited states of proteins provide another well-studied method for determining the secondary structure of proteins.[39] Herein, the influences of BPS on the CD spectra of trypsin and pepsin are shown in Figure 2A,B. It is observed that a strong negative band at about 200 nm coming from the n−$\pi^*$ transitions is changed obviously. First, the intensities of CD spectra of trypsin and pepsin display obvious decreases in the presence of BPS, indicating the significant variations of the secondary structural components of enzymes. In addition, the red shift of maximum peak also implies that the interactions of BPS with trypsin and pepsin induce a change of the proteins' secondary structure and loosen the skeleton of trypsin and pepsin.[40] These results are consistent with the above conclusion of UV−vis measurement.

**Effect of BPS on the Tertiary Structure of Trypsin and Pepsin.** There are multiple Trp residues and Tyr residues in trypsin and pepsin. The intrinsic fluorescence of these two kinds of aromatic amino acid residues was used to evaluate the changes in the tertiary structure of trypsin and pepsin caused by BPS.[41] As shown in the insets of Figure 3A-1,A-2, there are ten Tyr residues (Tyr-20, 29, 39, 59, 94, 151, 172, 184, 228, 234) and four Trp residues (Trp-51, 141, 215, 237) in trypsin.[42] In addition, it can be seen from the insets of Figure 3B-1,B-2 that pepsin contains 13 Tyr residues (Tyr-9, 14, 44, 75, 86, 113, 114, 175, 189, 268, 275, 310, 311) and five Trp residues (Trp-39, 141, 181, 190, 300).[43] Herein, the synchronous fluorescence spectroscopy was used to evaluate the effects of BPS on the microenvironment of Trp and Tyr residues of trypsin and pepsin. When $\Delta\lambda$ is fixed at 15 and 60 nm, the synchronous fluorescence can give spectral information on Tyr residues and Trp residues, respectively.[44] Figure 3A,B shows the effects of BPS on the synchronous fluorescence spectra of trypsin and pepsin. As shown in Figure 3, the addition of BPS in enzyme solution resulted in strong fluorescence quenching of Trp residues and Tyr residues in trypsin and pepsin. The polarity of their microenvironment can be presented by the $\lambda_{max}$ of Tyr and Trp residues.[45] Figure 3A-1,A-2 shows, upon the gradual addition of BPS to trypsin, red shifts around 4 and 2 nm of the maximum emission wavelength of Tyr and Trp residues, indicating that the conformation of trypsin changed, BPS binding resulted in a more polar environment for Tyr residues and Trp residues, and the fluorophores of enzymes have easy contact with solvent molecules. The vicinities of Trp residues and Tyr residues are rearranged. In addition, the results of Figure 3B-1,B-2 show that the interactions of BPS with pepsin induce more obvious changes of the environment of Trp residues and Tyr residues than those of trypsin, since the maximum emission wavelength of Tyr and Trp residues in pepsin shifted 7 and 8 nm, respectively. In a word, the tertiary structure of pepsin is more easily changed by BPS binding than that of trypsin.

**Effects of BPS on the Activities of Trypsin and Pepsin.** According to the UV−vis, CD, and fluorescence spectral results, it was found that BPS not only affected the secondary structure of these two enzymes but also partly affected their tertiary structure. Therefore, it is necessary to study the effects of BPS on the enzymatic activities of trypsin and pepsin. The activity of trypsin or pepsin in the presence of BPS was obtained by setting the relative activity of trypsin or pepsin as 100% in the absence of BPS. As shown in Figure 4, the activity

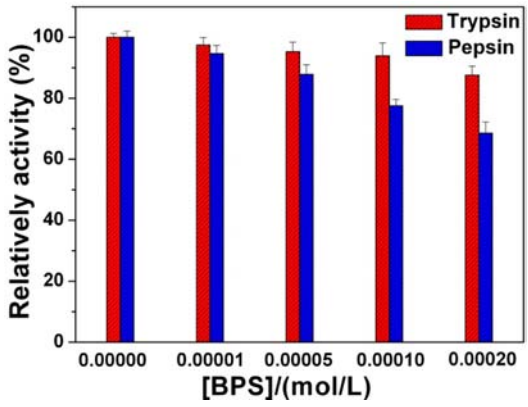

**Figure 4.** Trypsin and pepsin activities in the absence and presence of BPS at different concentrations, $c$ (trypsin) = $c$ (pepsin) = $1.0 \times 10^{-5}$ mol·L$^{-1}$.

of pepsin decreases obviously with the increasing concentration of BPS, while the activity of trypsin does not change remarkably. The interaction probably occurs near the active site of pepsin. Therefore, these results indicated that when BPS enters human stomach and duodenum, it can probably inhibit pepsin activity, but not trypsin activity. Using these activity experiments, it is difficult to obtain information about the binding sites of BPS in pepsin or trypsin. The binding nature of BPS with these two enzymes should be further investigated.

**The Putative Binding Sites of BPS in Trypsin and Pepsin.** Herein, molecular docking-based calculation was used to find the preferable binding sites of BPS in trypsin and pepsin. If BPS enters the active pocket of trypsin or pepsin and locates near the key amino acids, it may affect the enzyme activity. In trypsin, His-57, Asp-102, and Ser-195 are mainly catalytic residues.[45] In addition, Asp-189, Ser-190, and Gly-219 can play important roles in the trypsin activity.[46] As for pepsin, Asp-32 and Asp-215 are the main two catalytic residues.[47] The predicted binding models of BPS with trypsin and pepsin with the lowest docking energy are shown in Figure 5A,B. It was indicated that there were many amino acid residues taking part in the binding interactions of enzymes with BPS. As for trypsin, Asn-97, 100, Gln-175, Gly-174, 216, 219, Ile-176, Leu-99, Met-180, Ser-214, Thr-98, 177, Trp-215, and Val-227 form the binding pocket of BPS; while in pepsin, Asp-32, 215, Asn-37, Ala-130, Gly-34, 76, 217, Ile-73, 128, Ser-35, 36, 129, Thr-74, 218, and Tyr-75, 189 take part in binding with BPS. It can be seen in Figure 5A that there are no directly binding interactions between BPS and catalytic residues (His-57, Asp-102, and Ser-195) of trypsin. On the contrary, for pepsin it can be seen from Figure 5B that hydrogen bonding interactions exist between the two catalytic residues (Asp-32 and Asp-215) of pepsin and BPS. Therefore, it is deduced that BPS binds into the primary substrate-binding pocket and occupyies the active site of pepsin, leading to the enzyme inhibition. These calculation results well explained the in vitro data that BPS binding affected the activity of pepsin and did not obviously affect that of trypsin. Besides the conformation changes induced by BPS

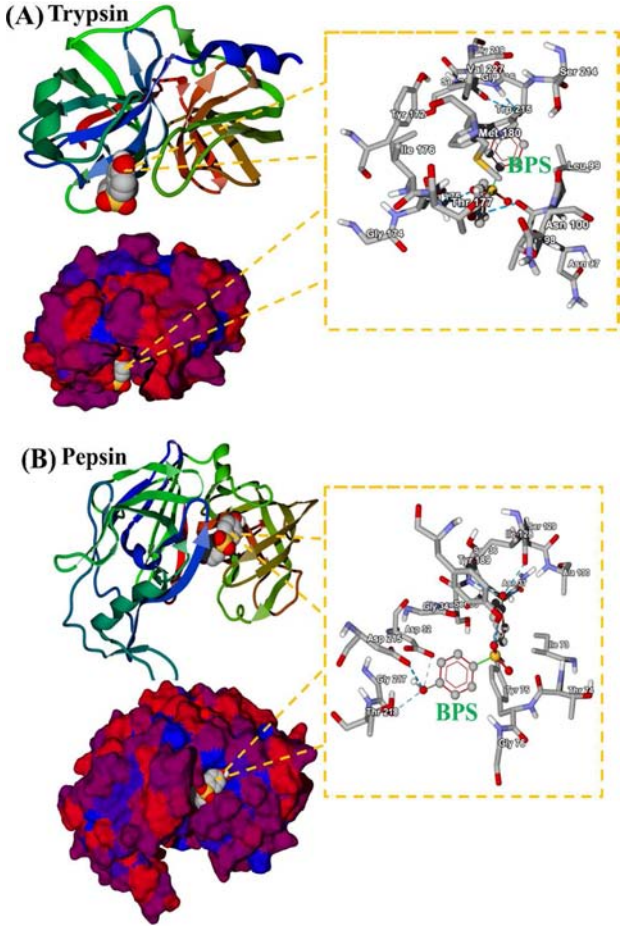

**Figure 5.** Predicted orientations of the lowest docking energy conformations of BPS with trypsin (A) and pepsin (B).

binding, the direct interactions between BPS and catalytic amino acid residues were another main reason resulting in the decrease of enzyme activity.

**Binding Nature of BPS with Trypsin and Pepsin.** Seen from the molecular docking-based calculations, the interactions of BPS with trypsin and pepsin are not presumed to be only one kind of force. First, many hydrogen bonding interactions exist in their binding processes. There are four hydrogen bonds (Gln-175, −S═O, 2.802 Å; Ile-176, −OH, 2.739 Å; Gly-216, −OH, 2.675 Å, 3.024 Å) in the binding interaction of BPS with trypsin. In addition, seven hydrogen bonds (Asp-215, −OH, 3.067 Å; Asp-32, −OH, 3.446 Å; Gly-217, −OH, 2.954 Å; Asn-37, −OH, 2.908 Å; Ile-128, −OH, 3.249 Å; Ser-36, −OH, 3.510 Å; Tyr-189, −S═O, 2.665 Å) exist between BPS and pepsin. Therefore, hydrogen bonding interactions play a key role in stabilizing BPS−trypsin/pepsin complexes. Second, many polar and nonpolar amino acid residues take part in the binding of trypsin and pepsin with BPS, so other binding forces including hydrophobic and electrostatic forces should not be excluded.

In order to provide convincing evidence for the binding energies of BPS with trypsin and pepsin, the best binding site with minimum binding energy is selected from the minimum energy conformers from 100 runs. The results given are in the form of the estimated free energy of binding, $E_{\text{intermol}}$ (the final intermolecular energy), $E_{\text{VHD}}$ (VDW + Hbond + desolvo energy), $E_{\text{elec}}$ (the electrostatic energy), $E_{\text{total}}$ (the final total internal energy), and $E_{\text{torsional}}$ (the torsional free energy). The docking summaries of BPS−trypsin and BPS−pepsin are listed in Tables 1 and 2, respectively. As data show, the negative values of the estimated free energy of binding indicate the spontaneity of the binding of trypsin and pepsin with BPS. In addition, $E_{\text{VHD}}$ energy including van der Waals energy ($E_{\text{VDW}}$), $E_{\text{Hbond}}$, and $E_{\text{desolvo}}$ are the main part of binding free energy, which imply that hydrogen bonds along with hydrophobic interactions play a crucial role in complexation processes of BPS with trypsin and pepsin. Although $E_{\text{elec}}$ force is also involved in the binding interactions of BPS with trypsin and pepsin, it is not the mainly driving force.

Apart from the molecular modeling, the fluorescence quenching method was also used to obtain the binding parameters including fluorescence quenching mechanism, binding constants, binding sites, and thermodynamic parameters ($\Delta H^\circ$, $\Delta G^\circ$, $\Delta S^\circ$). The fluorescence emission spectra of trypsin and pepsin in the absence and presence of BPS are shown in Figure 6A,B.

When excited at 280 nm, trypsin and pepsin produced their fluorescence spectra in the wavelength range of 300−500 nm with the emission maxima at 337 and 345 nm, respectively, which come from Trp and Tyr residues. At the same concentration, the fluorescence emission intensity of pepsin was stronger than that of trypsin. The main reason is that the number of Trp and Tyr residues in pepsin is more than that of trypsin. In addition, the difference in the emission maximum of trypsin and pepsin implies that the microenvironment of Trp and Tyr residues in trypsin is more hydrophobic than for those residues in pepsin, which probably affects their ability in binding with BPS. As the data show, additions of BPS result in fluorescence quenching of the intrinsic fluorescence of trypsin and pepsin. The fluorescence quenching intensity of trypsin induced by BPS was stronger than that of pepsin. In addition, the fluorescence quenching data were analyzed by the Stern−Volmer eq 2:[48]

$$\frac{F_0}{F_{\text{cor}}} = 1 + K_{\text{sv}}[Q] \tag{2}$$

where $F_0$ and $F_{\text{cor}}$ are the corrected fluorescence intensities of trypsin and pepsin in the absence and presence of BPS, respectively.[49] $K_{\text{sv}}$ is the Stern−Volmer dynamic quenching constant, and $[Q]$ is the concentration of BPS. Figure 7A,B displayed the Stern−Volmer plots for the fluorescence quenching of teypsin and pepsin by BPS at 298 and 310 K. The nature of the fluorescence quenching process can be determined by evaluating its dependence on temperature. Dynamic quenching is increased with an increase of system temperature; on the contrary, static quenching decreases at higher temperature.[50] Thus, it can be seen from Figure 7A,B that the rise in temperature did decrease the $K_{\text{sv}}$ values, indicating that the fluorescence quenching of trypsin and pepsin induced by BPS was not initiated from dynamic collision but from the complex formation between BPS and trypsin or pepsin. In addition, the UV−vis spectral changes of trypsin and pepsin induced by BPS binding also confirmed that the fluorescence quenching of trypsin and pepsin by BPS was static quenching because the UV−vis spectra of trypsin and pepsin would have no detectable changes if the quenching was a dynamic mechanism.[51]

Results from fluorescence quenching data can also be used to estimate the binding constants ($K_{\text{A}}$) and binding sites ($n$) of the BPS−trypsin/pepsin system by eq 3.[52,54]

$$\log \frac{F_0 - F_{cor}}{F_{cor}} = n \log K_A - n \log\left(\frac{1}{[Q_t] - (F_0 - F_{cor})[P_t]/F_0}\right) \quad (3)$$

where $F_0$ and $F_{cor}$ are the corrected fluorescence intensities of enzymes in the absence and presence of BPS, respectively.[49] $[P_t]$ and $[Q_t]$ are the total concentration of enzymes and BPS, respectively. $K_A$ is the binding constant, and $n$ is the number of binding sites. According to eq 3, the plots of $\log[(F_0 - F_{cor})/F_{cor}]$ vs $\log(1/([Q_t] - (F_0 - F_{cor})[P_t]/F_0))$ are shown in Figure 8A,B. As depicted in Figure 8A,B, the plots give straight lines. The values of $n$ and $K_A$ are summarized in Table 3. The computed binding site ($n$) values clearly indicate the existence

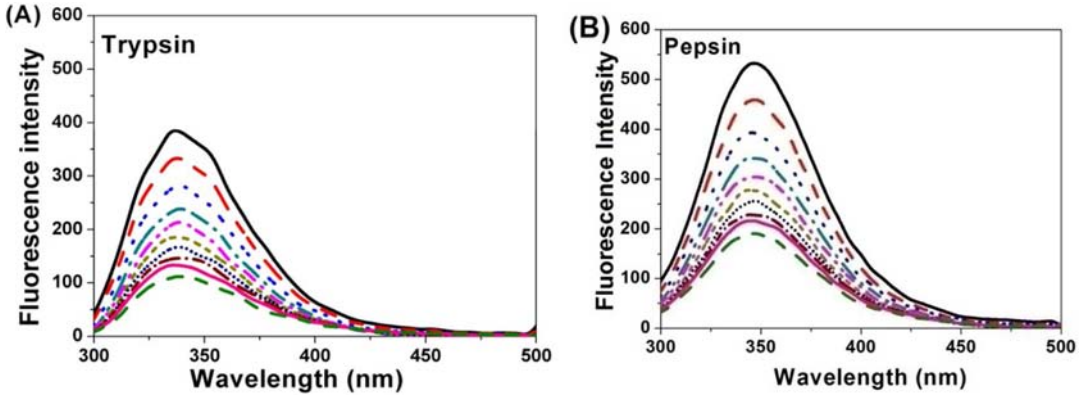

**Figure 6.** Fluorescence emission spectra of trypsin (A) and pepsin (B) in the absence and presence of BPS, $c$ (trypsin) = $c$ (pepsin) = $2.0 \times 10^{-5}$ mol·L$^{-1}$. $c$ (BPS) ($\times 10^{-5}$ mol·L$^{-1}$) (from top to bottom), 0, 0.5, 1.0, 1.5, 2.0, 2.5, 3.0, 3.5, 4.0, and 5.0, respectively.

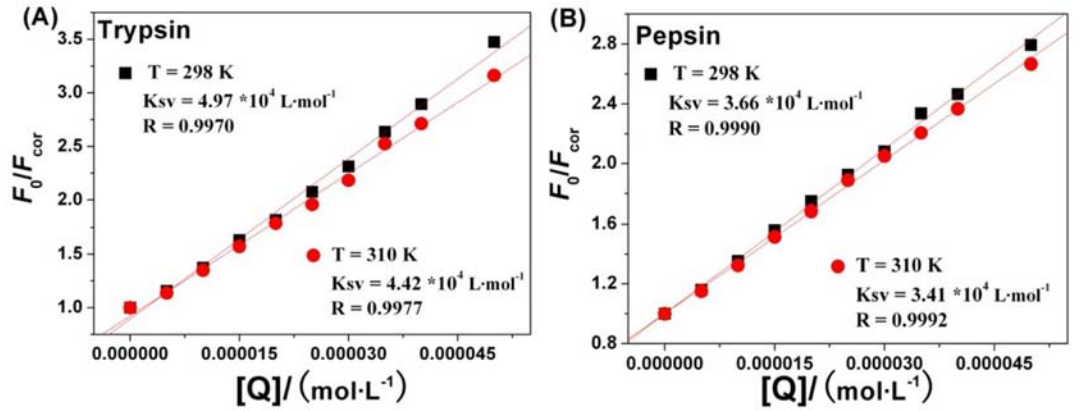

**Figure 7.** Stern–Volmer plots for the quenching of trypsin (A) and pepsin (B) by BPS. $\lambda_{ex}$ = 280 nm, $\lambda_{em}$ (trypsin) = 336 nm, $\lambda_{em}$ (pepsin) = 345 nm.

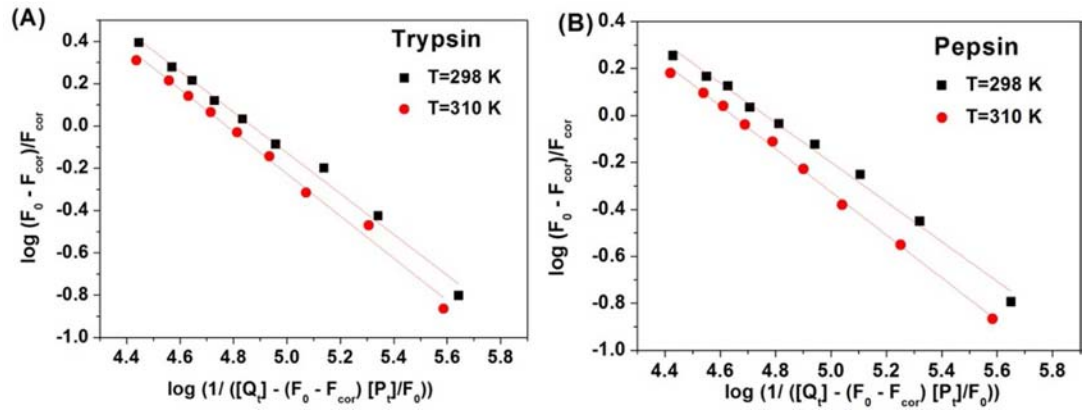

**Figure 8.** Plots of $\log(F_0 - F_{cor})/F_{cor}$ as a function of $\log(1/([Q_t] - (F_0 - F_{cor})[P_t]/F_0))$ of BPS with trypsin (A) and pepsin (B). $\lambda_{ex}$ = 280 nm, $\lambda_{em}$ (trypsin) = 336 nm, $\lambda_{em}$ (pepsin) = 345 nm.

**Table 3. Association Parameters of Trypsin and Pepsin with BPS at Different Temperatures**

| enzyme | $T$ (K) | $K_A$ (L·mol$^{-1}$) | $n$ | $\Delta H°$ (kJ·mol$^{-1}$) | $\Delta G°$ (kJ·mol$^{-1}$) | $\Delta S°$ (J·mol$^{-1}$·K$^{-1}$) |
|---|---|---|---|---|---|---|
| trypsin | 298 | $7.42 \times 10^4$ | 0.96 | −14.56 | −27.78 | 44.36 |
| | 310 | $5.91 \times 10^4$ | 0.99 | | −28.32 | |
| pepsin | 298 | $5.78 \times 10^4$ | 0.85 | −16.88 | −27.16 | 34.50 |
| | 310 | $4.44 \times 10^4$ | 0.91 | | −27.58 | |

of mainly one kind of binding site for trypsin and pepsin with BPS and the formation of the molar ratio 1:1 complex, respectively. In addition, the factor of the order of binding constants of BPS with trypsin and pepsin is $10^4$, which is lower than that of antibody–antigen complex ($10^9$–$10^{10}$).[55] These results imply that the binding of BPS with these two enzymes is

dx.doi.org/10.1021/jf504347w | J. Agric. Food Chem. 2014, 62, 11303–11311

of moderate intensity. Except for the binding constant $K_A$ and the number of binding sites $n$, thermodynamic parameters ($\Delta H^\circ$, $\Delta G^\circ$, $\Delta S^\circ$) are also obtained by using eqs 4−6.

$$\ln \frac{(K_A)_2}{(K_A)_1} = \frac{\Delta H^\circ}{R}\left(\frac{1}{T_1} - \frac{1}{T_2}\right) \quad (4)$$

$$\Delta G^\circ = -RT \ln K_A \quad (5)$$

$$\Delta S = \frac{\Delta H^\circ - \Delta G^\circ}{T} \quad (6)$$

As shown in Table 3, $\Delta G^\circ < 0$, $\Delta H^\circ < 0$, and $\Delta S^\circ > 0$ of BPS−trypsin and BPS−pepsin systems. As for trypsin and pepsin binding BPS, there are many similarities. First, the negative values of $\Delta G^\circ$ indicated the spontaneity of the binding of trypsin and pepsin with BPS. Second, the positive values of $\Delta S^\circ$ are 44.36 J·mol$^{-1}$·K$^{-1}$ and 34.50 J·mol$^{-1}$·K$^{-1}$ for trypsin and pepsin, indicating that hydrophobic forces are involved in the BPS−trypsin and BPS−pepsin binding processes.[53] Third, the values of $\Delta H^\circ$ are negative and are not about zero, which indicate that hydrogen bonds also play important roles in their binding processes. Analyzing from the molecular structure of BPS, the benzene rings of BPS having hydrophobic property enhance the possibility of their hydrophobic interactions with the hydrophobic amino acid residues in trypsin and pepsin. The $\pi-\pi$ stacking interactions of BPS with aromatic amino acids of enzymes might be involved. The two −OH on aromatic rings and −S═O linking two benzene rings might make BPS bind with trypsin and pepsin by hydrogen bonds. In addition, the molecular modeling results also support the above conclusion that hydrophobic and hydrogen bonding forces are the main driving forces stabilizing BPS−trypsin/pepsin complex.

**Conclusions.** This is the first study that offers a detailed binding mechanism of BPS with trypsin and pepsin and its effects on the structures and activities of these two digestion enzymes. The results showed that the binding interactions existed between BPS and enzymes. The secondary and tertiary structures of trypsin and pepsin are affected upon BPS binding. Moreover, the binding of BPS to pepsin did cause an obvious decrease of enzyme activity. However, the interaction of BPS with trypsin did not inhibit the activity remarkably. The present study could provide some important biophysical insights on the binding mechanisms of bisphenol analogues with digestive proteases from the point of view of food security.

two hybrids, FxCh77 and FxCh90 (fourth week of February), in 2009. In all cases, three biological replicates per genotype were obtained, all representing at least four different fruits each. Juice was obtained using a hand extractor to avoid squeezing the flavedo and to prevent juice becoming contaminated with peel components. Juice samples of 10 mL aliquots each were placed in 22 mL crimp cap headspace vials and kept frozen at −20 °C until analyzed. Two 10 mL aliquots corresponding to technical replicates of each sample were analyzed. The total number of analysis was 24 (3 biological samples × 2 technical replicates for all 4 genotypes).

Eleven fruit quality traits were also evaluated, as usual, in the *Citrus* breeding program: fruit weight (FW, g); fruit diameter (FD, mm), measured in the transversal section including flavedo and albedo; rind thickness (RT, mm), including albedo; juice volume (JV, mL), quantified as the volume of juice without pulp; number of seeds per fruit (SN); juice content (JC) as JV% of FW; total soluble solids (TSS, degrees Brix), measured with a digital refractometer (PR-101$\alpha$; Palette, Atago; Tokyo, Japan); acidity (*A*), determined by titration with 0.4 N NaOH and a phenolphthalein indicator; maturation index as the ratio between TSS and *A* (Brix/*A*); and color of rind and juice (Rcol and Jcol, respectively), evaluated by visual comparisons with the chromatic circle (from red, 1, to yellow, 20). All of these traits were used for the principal component analysis (see Figure 2).

**HS-SPME Extraction Conditions.** Immediately before the analysis, samples were thawed at 20 °C for 10 min and were then subjected to headspace solid phase microextraction (HS-SPME). Extraction was carried out using 10 mL of sample placed into a 22 mL crimp cap headspace vial. A 50/30 $\mu$m DVB/CAR/PDMS (Supelco, Bellefonte, PA, USA) fiber was used in all cases. Samples were preincubated for 10 min at 50 °C, and volatiles were extracted from the vial headspace for an additional 20 min period at the same temperature, as previously described.[13] Desorption was performed for 1 min at 250 °C in the splitless mode.

**Gas Chromatography−Mass Spectrometry Conditions.** VOCs were analyzed by GC-MS using a COMBI-PAL autosampler (CTC Analytics, Zwingen, Switzerland), and a 6890N gas chromatograph coupled to a 5975B mass spectrometer (Agilent Technologies, Santa Clara, CA, USA), equipped with a J&W Scientific DB-5 ms fused silica capillary column (5−95 phenyl−dimethylpolysiloxane as the stationary phase; 60 m length; 0.25 mm i.d.; 1 $\mu$m film thickness) (Folsom, CA, USA). Oven temperature conditions were 40 °C for 2 min, with 5 °C/min ramp until 250 °C, and were then held isothermally at 250 °C for 5 min. Helium was used as the carrier gas at 1.2 mL/min constant flow. Detection was performed by an Agilent mass spectrometer in the EI mode (ionization energy, 70 eV; source temperature, 230 °C). Acquisition was performed in the scan mode (mass range, $m/z$ 35−220; 7 scans/s). Considering that the molecular weight of the identified compound with the highest mass (nootkatone) was 218 Da, a wider $m/z$ range was not necessary. Chromatograms and spectra were recorded and processed using the Enhanced ChemStation for GC-MS software (Agilent). For the unequivocal identification of volatile compounds, both standards and samples were also injected into a 6890N gas chromatograph (Agilent) coupled to a Pegasus 4D time-of-flight (TOF) mass spectrometer (LECO, St. Joseph, MI, USA) under the following chromatographic conditions: BPX35 column (30 m, 0.32 mm, 0.25 $\mu$m), helium (1.5 mL/min) constant flow, and the same oven temperature ramp as previously described. Ionization was performed by EI (ionization energy, 70 eV; source temperature, 200 °C), and acquisition was performed within the mass range $m/z$ 35−300.

**Compound Identification.** Compound identification in each sample was based on the comparison of both mass spectrum and retention time in two columns of different polarity with those of pure standards. The retention times of the identified compounds in each column are detailed in Supporting Information (SI) Table S1. From 113 compounds, 103 compounds were identified in the *Citrus* samples when analyzed with each of the two columns. The other 10 volatiles were overlapped by more abundant compounds in the BPX35 column chromatograms, and therefore their identity could not be confirmed. The identification of these 10 compounds was based on the similarity of mass spectrum and retention time in only one column, and should therefore be considered tentative, as indicated in Table 1. The compounds used as a reference were of analytical grade and purchased from Sigma-Aldrich Química (Madrid, Spain), except for 2-carene, which was obtained from Extrasynthese (Genay, France). In addition to the commercial compounds, four esters (ethyl heptanoate, methyl octanoate, methyl nonanoate, and ethyl nonanoate) were synthesized by acid-catalyzed esterification, according to González-Mas et al.[13] For relative quantification, one specific ion for each compound was selected, and the corresponding peak from the extracted ion chromatogram was integrated. The ion selected for the integration of each peak was that with the highest signal-to-noise ratio and one that was specific enough to provide good peak integration for that particular region of the chromatogram. An admixture reference sample was prepared by mixing equal amounts of each sample corresponding to the four analyzed genotypes. This admixture was aliquoted (10 mL in 22 mL headspace vials), stored, and further treated as any other sample. This admixture contained all of the compounds identified in any of the samples at an intermediate concentration between those in the individual samples. The admixture aliquots were injected regularly (one admixture for every five to six samples) as part of the injection series and were used as a reference to normalize for temporal variation and fiber aging. All of the samples were analyzed using the same SPME fiber. Finally, the normalized results (corrected for temporal variation and fiber aging) for each compound were expressed as the relative levels to the average levels present in the Chandler juice. If a compound was not detected in Chandler, the ratio was calculated to the levels in a genotype that contained it, as indicated (Table 1).

**Statistical Analysis.** A principal component analysis (PCA) and a hierarchical cluster analysis (HCA) were done to analyze the volatile data set, which included all of the replicates and samples. In them both, the ratio of the levels of each volatile in a sample to the average of the four genotypes was $\log_2$-transformed. For the PCA, SIMCA-P version 11 (Umetrics, Umea, Sweden) was used with Pareto normalization. For the HCA, Acuity 4.0 (Axon Instruments, Union City, CA, USA) was used with the distance metrics based on the Pearson correlation.

To represent the phenotypic traits (either volatile levels or quality traits) that were intermediate or significantly under or over the parental levels, the *Z*-scores of the average values for each genotype were calculated. Data were expressed as the values relative to the corresponding level in Chandler, $\log_2$-transformed ($\log R_{Fortune}$ or $\log R_{hybrid}$), and then *Z*-score standardization was performed for each metabolite in all the samples. To calculate the fold change between hybrids and Fortune, the *Z*-score for the difference was calculated using $ZD = \log R_{hybrid} - \log R_{Fortune}/(SE^2_{hybrid} + SE^2_{Fortune})^{1/2}$, where $SE^2$ is the squared standard error of the mean. The *Z*-score for each phenotypic trait (volatile level or other) in both of the two hybrids was plotted against the corresponding *Z*-scores in Fortune (Figure 1 and SI Figure S2). The between, under, or over parental sectors were defined by the *X* and *Y* axes, and the slope 1 diagonal, where the phenotypic traits with the *Z*-score hybrid > 0 ($y > 0$) and ZD > 0 were in the *overparent* sector and the phenotypic traits with the *Z*-score hybrid < 0 and ZD < 0 in the *underparent* sector. To determine the significance of the differences relating to both Chandler and Fortune, the *p*-value associated with each *Z*-score and ZD was calculated. The metabolites and physiological parameters in each sector were considered statistically significant with a *p*-value < 0.05 (SI Table S2).

## RESULTS AND DISCUSSION

Table 1 lists the VOCs detected by the HS-SPME-GC-MS technique and the relative volatile levels in hybrids FxCh90 and FxCh77 as compared to those in the parental genotypes: Fortune mandarin and Chandler pummelo. In all, 113 compounds were identified: 31 esters (22 aliphatic and 9 monoterpene acetates), 23 aldehydes (18 aliphatic, 4 monoterpene, and 1 norisoprenoid), 20 alcohols (11 aliphatic and 9 monoterpene), 14 monoterpene hydrocarbons, 13

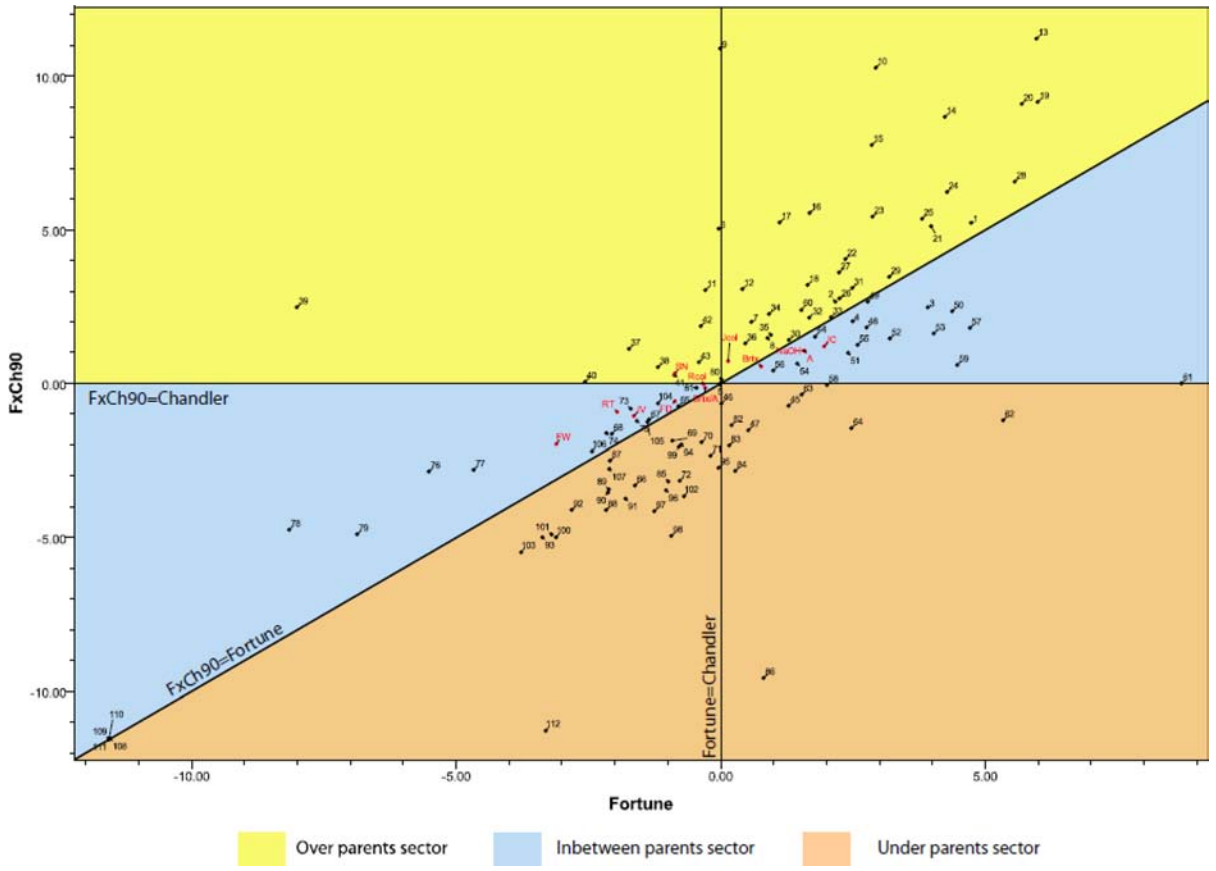

**Figure 1.** Values for the different metabolites and phenotype traits in hybrid FxCh90 in relation to the values in Fortune. Values are expressed as standardized *Z*-score values of $\log_2$ relative to Chandler (value = 0). The blue sector defines those traits whose value in the hybrid fell between the values of the parents. The pale orange and pale yellow sectors correspond to the *underparent* sector and the *overparent* sector, respectively. Volatile compounds are represented in black; phenotypic traits are represented in red.

ketones (7 aliphatic, 2 norisoprenoid, 3 monoterpene, and 1 sesquiterpene), 4 sesquiterpene hydrocarbons, 3 monoterpene cyclic ethers, 4 furans, and 1 aromatic hydrocarbon. Although more than 300 VOCs have been reported in other *Citrus* juice,[9,15,17−19] some were identified only tentatively.[9,11,20−22] To assign chemical names to our data set, in this work we used the actual compounds to verify the identification of the VOCs analyzed by confirming and expanding the power of our volatile profiling platform.[13] All of these compounds were unequivocally identified based on the coincidence of both mass spectrum and retention time with those of pure standards in two capillary columns of different polarity, with the only exception of 10 compounds not identified in the second column (Table 1). A representative chromatogram is shown in SI Figure S1.

The majority of the identified compounds were described in our previous *Citrus* juice studies, which included Chandler pummelo, Fortune and Clemenules mandarins, and Powell orange.[13] In this work, eight new compounds were identified in hybrids FxCh90 and FxCh77 and their parental genotypes: (*E*)-2-decenal (*m* 56), isobornyl acetate (*m* 81), dihydrocarvone (*m* 52), hexyl butanoate (*m* 73), butyl hexanoate (*m* 75), hexyl hexanoate (*m* 74), 3-octanone (*m* 93), and 2-nonanone (*m* 96). The first four compounds have been previously identified in other *Citrus* genotypes: (*E*)-2-decenal in tangerine hybrids juices and in pummelo, lime, orange, and tangerine peel oils,[9,23,24] isobornyl acetate in pummelo peel,[25] dihydrocarvone in orange and mandarin juices,[9,20,26] and hexyl butanoate in orange and tangerine hybrids juices and mandarin peel.[9,11,27] The other four compounds are described here for the first time in the juice of a *Citrus* species (Table 1). Hexyl butanoate and butyl hexanoate are typical apple fruit volatile compounds that can be used as a maturity index in this fruit; butyl hexanoate is also an insect attractant.[28,29] Regarding 3-octanone, it has been described as having a mushroom odor, similar to 1-octen-3-one, this being another aliphatic ketone identified frequently in *Citrus* juice.[3,9,30] The other new ketone, 2-nonanone, has been identified in several matrixes such as kiwifruit juices, in the essential oil of several Rutaceae species, in yellowfin tuna, or even as a component of cheese aroma.[31−35] The compound 2-nonanone has been described to have nematicidal and antifungal properties.[36,37] In fact an active packaging system based on the release of 2-nonanone is used to increase the postharvest shelf life of fresh wild strawberries in the marketing stage; excessive levels of this volatile can, however, affect the taste of berries and lead consumers to reject the product.[38]

As seen in Table 1, almost all of the identified compounds were detected in the four genotypes. Only four compounds were identified exclusively in the Chandler parental genotype ((*Z*)-ocimene, (*E*,*E*)-2,4-nonadienal, (*E*)-linalool oxide, and γ-dodecalactone; *m* 109, *m* 110, *m* 111, and *m* 113, respectively). Similarly, propyl acetate (*m* 60) and ethyl 2-methylbutanoate (*m* 61) were compounds identified exclusively in the parental Fortune genotype. Regarding hybrids, β-citronellal (*m* 5) was the only exclusive compound identified in the FxCh77 hybrid,

while no exclusive compound was detected in the FxCh90 hybrid.

The relative levels of each compound for all of the genotypes are shown in relation to the level of each compound in the Chandler genotype, because this is the genotype where the largest number of compounds was identified (107 compounds, with γ-dodecalactone, *m* 113, only detected in trace amounts). The relative levels of those compounds not detected in Chandler are expressed in relation to a genotype containing it (Table 1). Although very few qualitative differences were observed in any of the four genotypes, differences in the levels of accumulation were observed for almost all of the compounds, indicating that the characteristic volatile profile of each genotype relies on quantitative rather than qualitative differences.

Although it seemed reasonable to expect that hybrids would show that the levels of most volatiles are intermediate between those of the two parents, the results revealed that 56 of the 113 compounds were present at transgressive levels in at least one of the hybrids. Indeed, 40 compounds in the hybrids presented significantly higher levels than in any of their parents, and 16 compounds were present at statistically significantly lower levels. The remaining 57 volatiles were present at levels that were either intermediate or not significantly different from one of the parentals. The most extreme behavior was shown by ester compounds hexyl acetate (*m* 6), α-terpinyl acetate (*m* 13), or linalyl acetate (*m* 15), present in hybrid FxCh90 at levels of 30-fold or higher than in any of their parentals. Compounds such as ethyl heptanoate (*m* 86), 6-methyl-5-hepten-2-one (*m* 100), and 1-pentanol (*m* 101), which were present at different levels well above the threshold levels in both parentals, were not be detected in at least one of the hybrids, while 2,3-pentanedione (*m* 98) was reduced 17-fold in the hybrids (Table 1). This transgressive behavior can be observed graphically for FxCh90 and FxCh77 in Figure 1 and SI Figure S2, respectively, where the volatiles that over- or underaccumulated in the hybrids if compared to their parents are shown in the three defined areas (overaccumulating zone, underaccumulating zone, and interparents zone). The statistical significance of these differences is shown in Table 1 and SI Figure S3. However, the transgressive behavior described for the levels of volatile compounds in these hybrids was not observed for other fruit quality traits (see those traits in the interparental zone in the plots, in Figure 2 and in SI Figure S4). A similar transgressive behavior in the volatile profile has been observed in a number of peach siblings derived from a cross also involving one hybrid as a parent[39] and also in apple,[40] which probably indicates that volatile traits are especially prone to this type of transgressive behavior.

To globally verify whether the volatile profiles can be used to differentiate both hybrids from the parental genotypes and to identify the volatiles that contributed the most to the separation between the new materials generated by breeding and the parental genotypes, a PCA was performed using the complete data set. Based on the volatile profile, Figure 3 shows that all four genotypes are completely separated from each other. Principal component 1 accounts for the majority of total variance (53.6% of variance), and mainly separates the parent Chandler pummelo from the other three genotypes, and also the parent Fortune from their derived hybrids to a lesser extent. The relative position of the samples in the PCA space is not consistent with any of the hybrids, with a volatile phenotype intermediate shown between the two parentals. In fact,

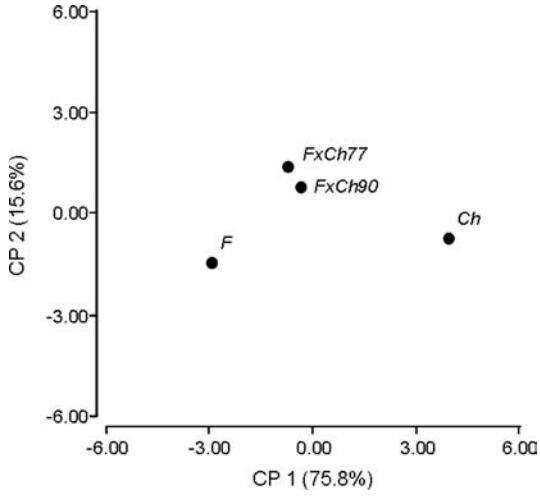

**Figure 2.** Principal component analysis score plot based on a data set of 11 fruit quality traits. Principal components 1 and 2 are represented.

principal component 1 confirmed that both hybrids showed rather transgressive behavior, with a volatile profile opposed to that of the male parental Chandler pummelo, which was even more distant to Chandler than the other parental, Fortune mandarin. Of the two hybrids, FxCh90 was seen to be slightly more transgressive than FxCh77. An analysis of the loading plot revealed the compounds to be responsible for the separation between samples (Figure 4). The volatile compounds that most contributed to the first component were a group of monoterpenoid compounds (*p*-cymene, (*Z*)-ocimene, (*E*)-linalool oxide, 2-carene; *m* 108, *m* 109, *m* 111, *m* 112, respectively) and (*E,E*)-2,4-nonadienal (*m* 110), which are almost exclusive of Chandler pummelo. This group of compounds also differentiated Chandler pummelo from Clemenules mandarin and Powell orange, as previously reported,[13] and some have also been identified in the other few pummelo juice and flavedo studies.[14,15,25,41] According to the literature, 2-carene has never been detected in orange and mandarin aroma juices, and (*Z*)-ocimene, linalool oxides, and (*E,E*)-2,4-nonadienal have been detected only very occasionally.[1,11,14,21,22,42] In contrast, *p*-cymene has been frequently isolated in these juices.[6,9,11,12,18,19,43] Fortune mandarin, and the two hybrids in particular, show higher levels of acetic esters octyl acetate (*m* 19), nonyl acetate (*m* 14), decyl acetate (*m* 20), α-terpinyl acetate (*m* 13), linalyl acetate (*m* 15), geranyl acetate (*m* 25), and citronellyl acetate (*m* 28), the monoterpene alcohol linalool (*m* 1), and long-chain lipid derivatives 1-decanol (*m* 10) and dodecanal (*m* 24).

Principal component 2 explained about 22.4% of variance and clearly separated Fortune from the other three genotypes (SI Figure S5). What differentiated Fortune from the rest was mainly the higher levels of propyl acetate (*m* 60) and a series of ethyl esters: ethyl 2-methylbutanoate (*m* 61), ethyl acetate (*m* 62), ethyl propanoate (*m* 59), ethyl butanoate (*m* 57), and ethyl nonanoate (*m* 64) (SI Figure S6). Principal component 3, accounting for only 10.2% of variance, revealed that it is possible to distinguish the two hybrids from each another in accordance with specific volatiles (Figure 3). According to the loading plot corresponding to PC3, hybrid FxCh90 was characterized by higher levels of acetate compounds heptyl acetate (*m* 9), octyl acetate (*m* 19), nonyl acetate (*m* 14), decyl acetate (*m* 20), methyl decanoate (*m* 18), α-terpinyl acetate (*m* 13) and (*E*)-carvyl acetate (*m* 23), and also long-chain lipid

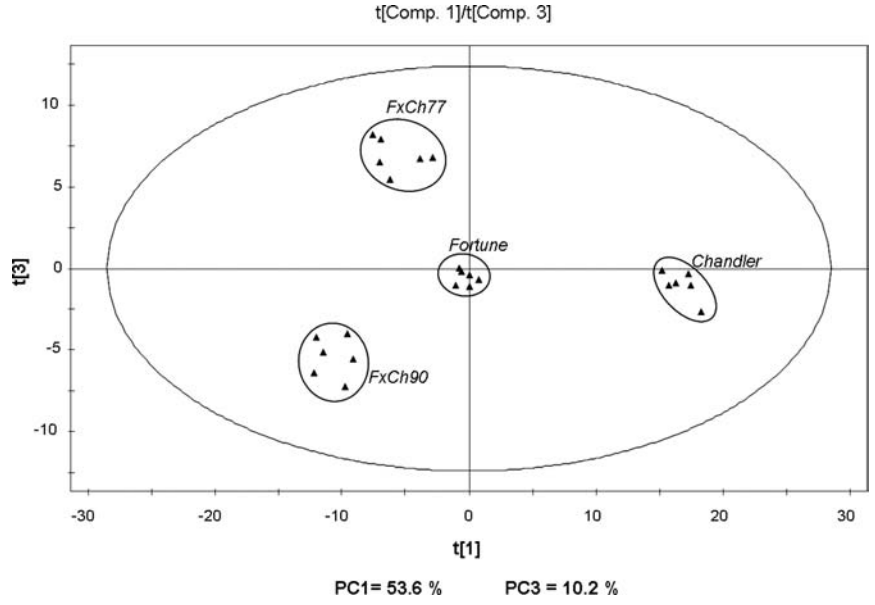

**Figure 3.** Principal component analysis score plot based on 113 volatile compounds. Principal components 1 and 3 are represented.

derivatives 1-octanol (*m* 17), decanal (*m* 42), and undecanal (*m* 43) (Figure 4). Hybrid FxCh77, however, was characterized by lower levels of these compounds, together with higher levels of monoterpenoids linalool (*m* 1), *β*-citronellol (*m* 2), perillaldehyde (*m* 3), *α*-terpineol (*m* 4), *β*-citronellal (*m* 5), geraniol (*m* 7), (*Z*)- and (*E*)-limonene oxides (*m* 44 and *m* 48, respectively), and geranial (*m* 67), norisoprenoids geranylacetone (*m* 65), and *β*-ionone (*m* 71), $C_5$ and $C_6$ lipid derivatives 1-penten-3-one (*m* 45), (*E*)-2-pentenal (*m* 47), 3-pentanone (*m* 72), and (*Z*)-3-hexen-1-ol (*m* 66) (Figure 4).

When the complete data set of fruit quality traits was used (Figure 2), the PCA showed that both hybrids displayed mostly an intermediate behavior between their parental genotypes for these traits, as revealed by principal component 1, which accounted for most of the total variability (75.8%).

The HCA done over the same volatile data set confirmed that FxCh90 and FxCh77 shared the most similar volatile profile (Figure 5). Consistently with the PCA results, the volatile profile of the Fortune genotype in HCA clustering also fell between Chandler and the hybrids. HCA also allowed us to analyze the compounds to check if clustering revealed any

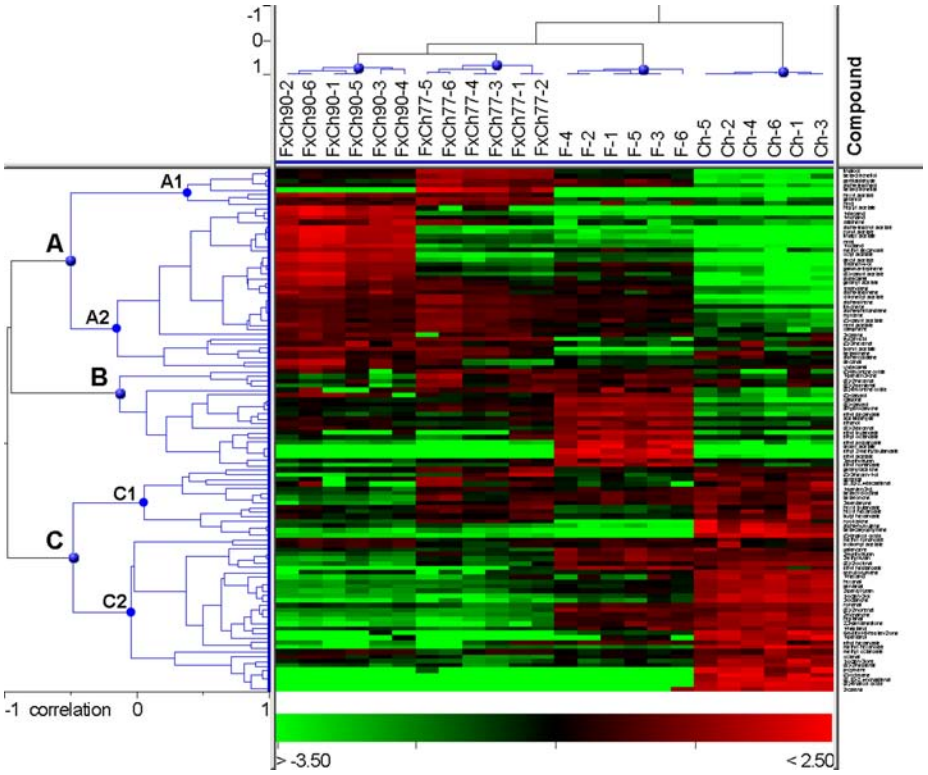

**Figure 5.** Hierarchical cluster analysis of both samples and volatile compounds. Samples grouped according to varieties: Ch, Chandler; F, Fortune; FxCh90 and FxCh77 hybrids. Volatiles grouped into clusters A, B, and C, and subclusters A1, A2, C1, and C2. Colors in the heatmap are related to fold change, in accordance with the scale shown at the bottom: red for higher levels; green for lower levels.

underlying relationship between them. Compounds were organized by HCA into three clusters, namely, A, B, and C, with some subclusters (named A1, A2, C1, and C2), as shown in Table 1. The compounds in cluster A were generally present with higher values in the hybrids than in their parentals. All of these compounds have been generally described in *Citrus* juices.[13,18] Subcluster A1 included the compounds generally present at the highest levels in hybrid FxCh77. These compounds are principally several monoterpene alcohols such as linalool (*m* 1), *β*-citronellol (*m* 2), or geraniol (*m* 7), and monoterpene aldehydes such as *β*-citronellal (*m* 5). Actually this latter compound is exclusive for the FxCh77 genotype and has been identified only in very few mandarins, orange, or hybrids juices.[13,19,43,44] Subcluster A2 mainly included the compounds that accumulated preferentially in the FxCh90 genotype and included *α*-terpinyl acetate (*m* 13), nonyl acetate (*m* 14), neral (*m* 16), *α*-terpinene (*m* 27), 3-carene (*m* 36), or decanal (*m* 42). Interestingly, most of these compounds are aliphatic and monoterpene acetates and monoterpene hydrocarbons. The results from the compounds in cluster A indicated that the two hybrids showed higher levels than their parental genotypes of many monoterpenoid compounds, such as linalool (*m* 1), *β*-citronellol (*m* 2), geraniol (*m* 7), citronelly acetate (*m* 28), or *α*-phellandrene (*m* 31). The odor of these last compounds has been described as floral, fruity, or citrus,[15] which are positive aromatic notes that can make these two hybrids more appealing to consumers. Nevertheless, a taste panel will be necessary to confirm this term.

Cluster B was defined principally by the compounds found more abundantly in Fortune than in the other three genotypes. These include compounds such as propyl acetate (*m* 60), which has never been described in other *Citrus* genotypes in the literature,[13] (*E*)-2-decenal (*m* 56), 3-methylfuran (*m* 63), and ketones carvone (*m* 50) and dihydrocarvone (*m* 52). Seven ethyl esters, e.g., ethyl octanoate (*m* 58), ethyl 2-methylbutanoate (*m* 61), or ethyl acetate (*m* 62), were more abundant in the Fortune genotype, which is consistent with the results of the loading plots for PC2. According to the literature, these ethyl esters have been frequently identified in many *Citrus* juices.[3,11,17,18,20,24,45] It should be noted that the Fortune samples analyzed herein were relatively rich in ethanol as compared to the other genotypes. This observation might explain the high levels of ethyl esters as they can be produced by esterification of ethanol with the acyl groups derived from fatty acid and amino acid metabolism.[46]

Finally, cluster C included the compounds that were more abundant in Chandler than in the other three genotypes. Subcluster C1 included the compounds found more abundantly in Chandler but also in hybrid FxCh77 (the most similar hybrid to Chandler), such as geranylacetone (*m* 65) or geranial (*m* 67). Subcluster C2 included the compounds that were more abundant in the Chandler genotype than in the other three genotypes. A number of aliphatic aldehydes (pentanal to nonanal, *m* 90, *m* 89, *m* 97, *m* 105, and *m* 94, respectively) and olefins (*E*)-2-heptenal, (*E*)-2-octenal, and (*E*,*E*)-2,4-nonadienal; *m* 107, *m* 85, and *m* 110, respectively), several aliphatic alcohols (1-pentanol, 1-hexanol, 1-heptanol, and 1-octen-3-ol; *m* 101, *m* 88, *m* 99, and *m* 92, respectively), and some aliphatic ketones (3-octanone, 2-nonanone, 2,3-pentanedione, 6-methyl-5-hepten-2-one, and 1-octen-3-one; *m* 93, *m* 96, *m* 98, *m* 100, and *m* 106, respectively) abounded in this genotype if compared to the other three genotypes. The higher levels of aliphatic aldehydes (octanal, nonanal) can, in part, be responsible for peely and fatty notes of pummelo juices.[15]

The higher levels of both 3-octanone and 1-octen-3-one can confer a hint of mushroom to the characteristic pummelo juice aroma.[30] These compounds were detected in Fortune and in hybrids FxCh90 and FxCh77 at almost trace levels. Several esters, such as some alkyl hexanoates (*m* 74, *m* 103), and compound 2-pentylfuran (*m* 91), were also present in larger quantities in Chandler than in Fortune or the hybrids. Moreover, as we noted in the analysis of the loading plots, some monoterpene compounds, such as *p*-cymene (*m* 108), (*Z*)-ocimene (*m* 109), 2-carene (*m* 112), or (*Z*)- and (*E*)-linalool oxide (*m* 79 and *m* 111, respectively), were also more abundant in Chandler juices, and some were not even detected in the hybrids. Nevertheless, Chandler juice generally showed lower levels of monoterpene compounds than the other three genotypes. Regarding sesquiterpenes, α-humulene (*m* 77) and β-caryophyllene (*m* 78) (subcluster C1) were much more profuse in the Chandler genotype than in any of the other three genotypes here studied or in Powell orange and Clemenules mandarin, according to a previous study.[13] However, sesquiterpene compounds α-copaene (*m* 41) and nootkatone (*m* 76), which served to differentiate Chandler from Powell orange, Clemenules mandarin, or Fortune juices in a previous study,[13] were herein found at similar levels in their hybrids FxCh90 and FxCh77. Therefore, these compounds are unsuitable to differentiate Chandler from their hybrids. The differential terpene profile can explain, at least partially, why pummelo juices exhibit the most differential volatile profile as compared to orange and mandarine juices, and a more similar profile to that of grapefruit.[13,25,41] It is interesting to note that some volatile compounds described in the only other previous study into pummelo juice[15] were not detected in our study (2-ethylhexanol, dimethylsulfone, and (*E*)-2-dodecenal). This might be due to biological variability, differences in growth conditions, or the chemical nature of the fiber used for volatile extraction, among other causes.

This study basically indicates that the differences in the volatile profile between the juice of the two *Citrus* parental genotypes (Chandler pummelo and Fortune mandarin) and their two hybrids are mainly quantitative. Each genotype exhibited a specific volatile profile that can be used for classification or identification purposes. As also noted in our previous study into *Citrus* aroma, there seems to be only a small number of *Citrus* genotype-specific compounds.[13] Most remarkably, the two hybrids characterized herein showed a transgressive (i.e., not intermediate) volatile profile when compared to those of the parents, which completely differed from that of Chandler pummelo and was more similar to that of Fortune mandarin. FxCh90 is especially rich in aliphatic and monoterpene acetates, while FxCh77 contains higher levels of monoterpene hydrocarbons and monoterpene alcohols than any of their parents. In our case the most characteristic VOCs of the Fortune genotype are 3-methylfuran (*m* 63), (*E*)-2-decenal (*m* 56), carvone (*m* 50), and dihydrocarvone (*m* 52), and some ethyl esters (*m* 53, *m* 57, *m* 58, *m* 59, *m* 61, *m* 62, and *m* 64). Finally, the juice of the Chandler genotype is more abundant in aliphatic compounds (aldehydes, alcohols, and ketones), some monoterpene hydrocarbons (*p*-cymene, (*Z*)-ocimene, and 2-carene; *m* 108, *m* 109, and *m* 112, respectively), and sesquiterpenes, such as α-humulene (*m* 77) and β-caryophyllene (*m* 78).

In conclusion, the volatile analysis platform used has allowed us to identify genotypes with differences in the aromatic profile that either enhance or inhibit some of the volatile characteristics of their parents, which the genetic analysis neither predicted nor anticipated. The HS-SPME-GC-MS analysis of *Citrus* juice has proven to be a tool that allows genotype differentiation that can be used in the assessment of *Citrus* breeding programs.

## NOTE ADDED AFTER ASAP PUBLICATION

An additional Supporting Information file has posted for this paper on November 10, 2014.

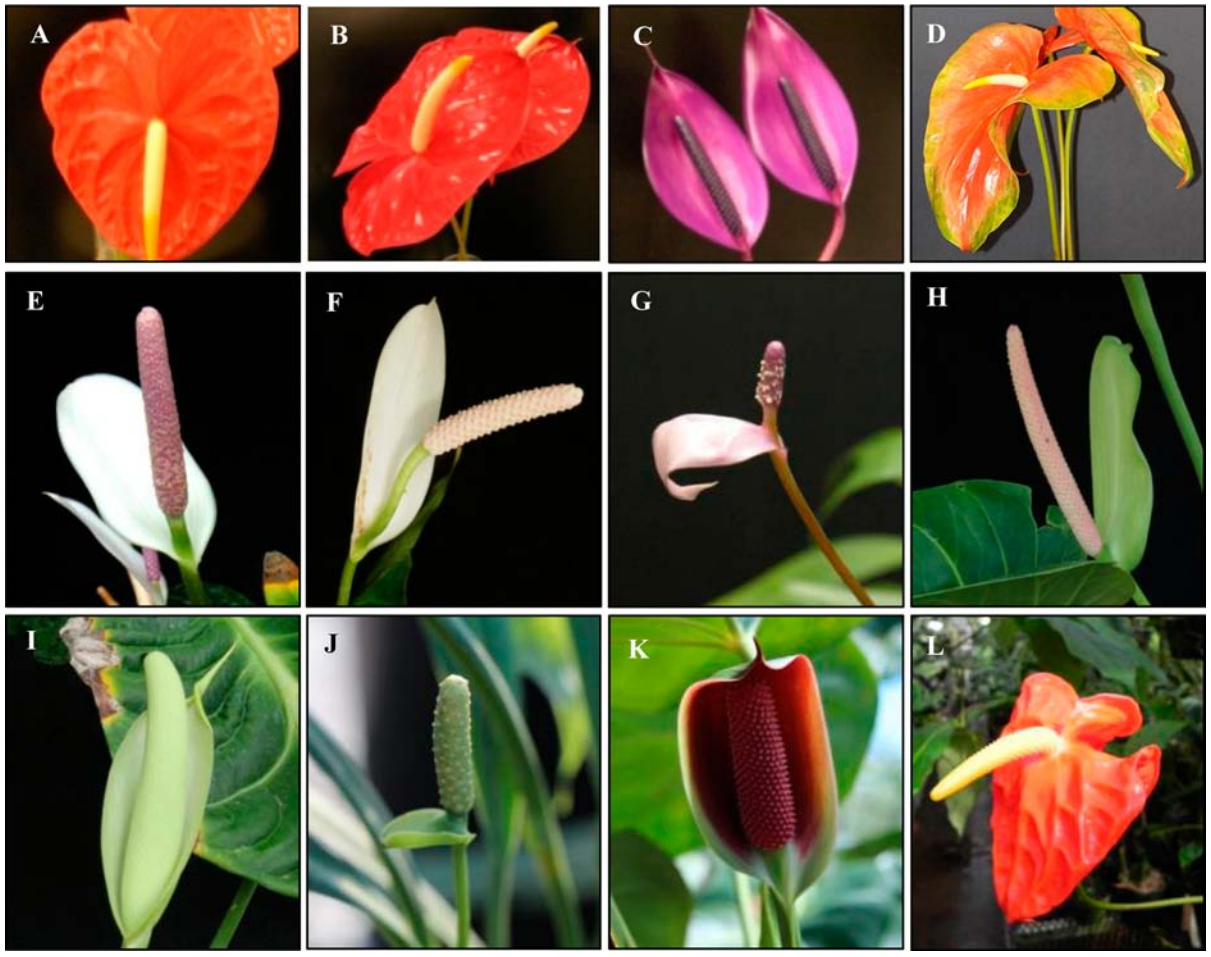

**Figure 1.** *Anthurium* spathes from commercial varieties (A–D) and species (E–L): (A) standard commercial cultivar 'Nitta', (B) standard commercial cultivar 'New Pahoa Red', (C) tulip commercial cultivar 'ARCS', (D) Obake commercial cultivar 'Tropic Sunrise', (E) *A. antioquiense*, (F) *A. armeniense*, (G) *A. amnicola*, (H) *A. hoffmannii*, (I) *A. veitchii*, (J) *A. bakeri*, (K) *A. kamemotoanum*, and (L) *A. andraeanum*.

larger study of the Araceae.[5] Iwata et al.[4] noted the presence of a major flavone component in several commercial *Anthurium* cultivars, which they suggested might be an acacetin derivative, but the structure was not determined. A 2001 study described the isolation of four new flavone C-glycosides from an *Anthurium versicolor* sample,[13] while in 2012 three additional examples were reported from the commercial *Anthurium* cultivar 'New Pahoa Red'.[14] Contemporary with this study, additional flavonoids from a range of commercial *Anthurium* cultivars were identified, largely on the basis of MS/MS data.[15]

Flavonoids have proved useful as chemotaxonomic markers in a range of agriculturally important plants, being used to categorize plants as diverse as plums,[16] grapes,[17] nettles,[18] and yew (*Taxus* spp.).[19] Modern analytical methods, in particular hyphenated mass spectrometry techniques combined with high-performance liquid chromatography (HPLC-MS) and gas chromatography (GC-MS), have proved invaluable in carrying out chemotaxonomic analyses. These methods have the capability to monitor and quantitate hundreds or even thousands of metabolites, while simultaneously providing high-resolution mass or fragmentation data that can be used to identify key compounds, allowing a much more rigorous analysis of the total metabolite content of the organism. Statistical techniques such as principal component analysis (PCA), hierarchical cluster analysis (HCA), and partial least squares discriminant analysis (PLS-DA) can be used to simplify the dimensionality of the data and compare different samples and classes.

In this study, we performed HPLC-MS analysis of the flavonoid components of 28 commercial cultivars of *Anthurium* grown in Hawaii, in addition to eight species sampled from living collections. Analysis of these data by HCA, PCA, and PLS-DA revealed distinctive differences in the various commercial cultivars and identified key anthocyanins (**1**–**3**), flavone glycosides (**4**–**8**), and other phenolics (**9**) that can be used in differentiating the cultivars and their ancestry.

## MATERIALS AND METHODS

**General Experimental Procedures.** NMR spectra were recorded on an Avance DRX 400 (Bruker, Billerica, MA) with the solvent used as an internal standard; MS analyses were conducted on an Accurate Mass 6530 qTOF HPLC-MS (Agilent, Santa Clara, CA) attached to an 1260 Infinity HPLC system (Agilent, Santa Clara, CA); preparative HPLC separations were carried out on a Dionex Ultimate 3000 HPLC system (Thermo-Fisher, Waltham, MA). All solvents were HPLC-grade and used without further purification.

**Biological Material.** Plant tissues of commercial cultivars of *Anthurium* were provided by Grayson Inouye, Keaau, HI, member of the Hawaiian Anthurium Industry Association; by *Anthurium* breeder and grower Stanley Oishi, Pahoa, HI; or from cultivars maintained at the greenhouses of Daniel K. Inouye U.S. Pacific Basin Agricultural Research Center facilities in Hilo, HI. Fresh, fully expanded spathes of anthurium cut flowers harvested at marketable stage were used in

these analyses. Anthuriums are market-ready when the tiny flowers on the spadix, which mature from the bottom up, have begun to open, associated with a change of color and appearance. Market-ready anthuriums have at least one-quarter but less than one-third of the flowers on the distal tip of the spadix tightly closed, typically with a contrasting color to the remainder of the spadix. The "nose" of the spadix is approximately $^1/_2$ to $^3/_4$ in. long. The spathe tissue from bicolored (Obake) cultivars was separated by color and processed separately. All commercial cultivars and most species were analyzed in triplicate, with the exception of *A. andraeanum* ABG 19931433, *A. armeniense*, and *Anthurium veitchii* (two spathes each), in addition to *A. andraeanum* ABG19911368, *A. amnicola* Selby 1976-0053-002, and *A. amnicola* MBG Croat 84952 (one spathe each); peak areas shown are average values. Species sampled were obtained from the University of Hawaii at Manoa (*Anthurium bakeri* and *A. kamemotoanum*), the Atlanta Botanical Garden (*A. amnicola* and *A. andraeanum*), Marie Selby Botanical Gardens (*A. amnicola*, *A. antioquiense*, *A. armeniense*, *A. hoffmannii*, and *A. veitchii*) and the Missouri Botanical Garden (*A. amnicola*). Pedigree data for some commercial cultivars were available from historical records: these included 'ARCS',[1] 'Lavender Lady',[1] 'Lady Jane',[1] 'Tropic Sunrise',[20] 'Hokuloa',[21] 'Centennial',[22] 'Tropic Mist',[23] 'Kalapana',[23] 'Tropic Fire',[24] 'Jasmine',[25] 'Marian Seefurth',[26] 'Tropic Lime' (T. Amore, personal communication), and 'Princess Aiko'.[27]

**Analytical HPLC-MS.** Spathes (spadix was not included) were chopped and extracted in methanol−HCl (0.5%) overnight at room temperature at a ratio of 10 mL of solvent per 1 g of tissue. An Inertsil ODS-4 150 mm × 2.1 mm i.d., 3 μm column (GL Sciences) was used for all analytical HPLC separations, and 0.5% formic acid was added to both solvents in order to improve peak shape for anthocyanin components. A complex gradient was employed with a flow rate of 0.4 mL/min, starting at 100% $H_2O$ and ramping to 9% acetonitrile (MeCN) over 10 min, holding for 20 min, before ramping to 24% MeCN over 30 min, holding for 5 min, then ramping to 40% over 13 min. The column was then ramped to 100% MeCN over 5 min, before reverting to initial conditions for the next analysis. Peak areas were obtained for each compound at either 525 nm (anthocyanins), 330 nm (flavones), or 280 nm (other phenolics). In total, 315 compounds were analyzed.

An Agilent Jetstream source in positive mode was used for mass analysis, with a capillary voltage of 3500 V and a fragmenter voltage of 175 V. Gas temperature was 300 °C at a flow rate of 8 L/min; sheath gas was at 350 °C at 11 L/min. Masses were detected from $m/z$ 100 to 2000, with internal calibration carried out by use of internal standards at $m/z$ 121.0509 and 922.0098.

**Statistical and Multivariate Data Analyses.** Statistical analysis was conducted by use of Massprofiler Professional software (Agilent, Santa Clara, CA). Three sample sets were used for statistical analyses. For initial hierarchical clustering analysis (HCA) and the first principal component analysis (PCA), the full set of 28 commerical cultivars and eight species was used, with a total of 315 metabolites. For the second PCA and PLS-DA analyses, a reduced sample set of 27 commercial cultivars and four species was used, with a total of 196 metabolites. Finally, for the Heatmap analysis, a reduced sample set of 27 cultivars and four species was used, with 42 metabolites (Tables 2 and 3) used for analysis. For HCA, Euclidean distances were used with complete clustering. For PCA, raw compound integration values were baselined to the median across all samples. They were transformed via log2 prior to analysis, and eight principal components were used. For PLS-DA analysis, two components were used, with auto-scaling and 3-fold validation. Validation with confusion matrices confirmed the assigned groupings.

**Large-Scale Extractions and Isolation of Selected Metabolites.** Spathes from the 'ARCS' cultivar (40 g) were extracted twice with methanol−HCl (0.1%, 400 mL) at room temperature. The crude extract was reduced under vacuum, dissolved in methanol, and passed through Amberlite XAD-4 resin (50 g) to remove nonpolar metabolites. This extract was then fractionated by reversed-phase (RP) HPLC on a 250 × 20 mm i.d., 5 μm, Sunrise C-18 column (Shimadzu) under isocratic conditions (20% MeCN−$H_2O$, 10 mL/min), with peaks monitored by online UV detection, to yield compound **7** (18.7 mg). High-resolution mass spectrometry data were consistent with the proposed structure, and NMR data matched well with literature values.[29]

The isolation of flavonoids **4**−**6** has been reported previously.[14] Neobudofficide **8** and epicatechin **9** were isolated from the same extraction. Briefly, leaves (39 g) from the 'New Pahoa Red' cultivar of *A. andraeanum* were obtained from Pacific Floral Exchange (Keaau, HI) and extracted and passed through a resin as described above. This extract was then fractionated by reversed-phase HPLC on a 250 × 20 mm i.d., 5 μm, Sunrise C-18 column (Shimadzu), under isocratic conditions (18% MeCN−$H_2O$, 10 mL/min), to yield **8** (11.1 mg) and **9** (14.6 mg). High-resolution electrospray ionization (ESI) MS data were consistent with the proposed structures, and NMR data matched well with literature values.[30,31]

## RESULTS AND DISCUSSION

**General.** Twenty-eight Hawaiian *Anthurium* cultivars were selected for analysis, including a variety of colors and encompassing standard-shaped, tulip-shaped, and Obake cultivars. In addition, in order to provide a baseline against which to compare the commercial cultivars, a small suite of species were sampled from living collections (Table 1). Specimens were extracted with methanol−HCl and the extracts were analyzed via HPLC-MS (Figure 2). Analyses were carried out at three wavelengths, 525, 330, and 280 nm, and peak areas for a total of 315 compounds were obtained. Compounds absorbing at 525 nm possessed UV/vis spectra consistent with anthocyanin pigments, while compounds absorbing at 330 nm had UV/vis spectra characteristic of flavonols, with mass spectrometry data suggesting that most were present as glycosides or similarly decorated species. Compounds absorbing primarily at 280 nm were more heterogeneous, but UV and MS data suggested the presence of other phenolic metabolites. While 315 compounds were detected overall, only 161 were found in commercial cultivars; the remaining metabolites were found only in *Anthurium* species. Of the 161 compounds detected in commercial cultivars, 12 were exclusive to the standard varieties and 70 to tulip varieties, with the remaining 79 metabolites found in both standard and tulip-shaped cultivars.

Positive identifications were not made for the majority of metabolites; however, several key compounds (Figure 3) were identified by comparison with standards, including the pelargonidin, cyanidin, and peonidin 3-rutinosides (**1**−**3**). Previous analyses conducted by thin-layer chromatography (TLC) had detected only peonidin 3-rutinoside (**3**) in purple cultivars such as 'ARCS';[6,7] however, using HPLC-MS, we were able to detect **3** in a number of red-spathed cultivars, as also reported in a 2013 study on anthurium spathe color.[15] When detected, peonidin 3-rutinoside (**3**) always co-occurred with cyanidin 3-rutinoside (**2**), a biosynthetic precursor (Tables 2 and 3). In purple spathes, the ratios of peak areas (525 nm) of peonidin to cyanidin rutinosides were much higher than those in red cultivars. For example, 'ARCS' and *A. amnicola* had percentage ratios of 19.1% and 19.8%, respectively, while the bright red cultivars 'Kozohara' and 'New Pahoa Red', despite containing significant quantities of **3**, possessed much lower ratios of **3**:**2** (0.3% and 2.9%, respectively). Thus, we propose that this ratio is a contributing factor in determining the observed color of the spathe, though other factors such as vacuolar pH and the presence of copigments may also have an effect.[8]

Accessions of *A. amnicola* and *A. kamemotoanum* species sampled (Figures 1G,K) accumulated higher levels of cyanidin rutinosides compared to pelargonidin 3-rutinoside, **1**, as did

Table 1. *Anthurium* Cultivars and Species Used for Analysis[a]

[a]UH accession numbers are given where known. [b]For Obake cultivars, the colored portion is indicated by a rectangular icon and the green portion with an oval icon. [c]'Snowball' and 'Tropic Fire' possess intermediate shapes; chemically they are closer to standard varieties and have been classified as such.

red-spathed standard and tulip cultivars. In comparison, both accessions of the *A. andraeanum* species (Figure 1L) examined displayed lower cyanidin rutinoside levels (compared to pelargonidin rutinoside) and no peonidin rutinoside, a pattern also found in commercial orange-spathed cultivars. Kamemoto and Kuehnle[1] previously described the wild-type *A. andraeanum* spathe as "orange-red". Thus, it is interesting to speculate that factors increasing cyanidin levels in modern cultivars, including activity of the flavonoid 3′-hydroxylase,[9,10,12] may have been acquired through hybridization with other species.

In addition to anthocyanins, a number of other flavonoid components were identified: embinin (**4**) and its two derivatives 4‴-(3,4-dimethoxycinnamoyl)embinin (**5**) and 4‴-ferruloylembinin (**6**);[14] two additional flavone glycosides, isocytisoside 7-glucoside (**7**)[28] and neobudofficide (**8**);[29] and the flavanol epicatechin (**9**),[30] which were isolated by HPLC and characterized by standard spectroscopic techniques. Peak areas for a selection of metabolites from commercial cultivars and species are given in Tables 2 and 3, respectively.

In their 2013 report, Li et al.[15] characterized several flavonoid components of commercial *Anthurium* cultivars on the basis of MS/MS data. Of particular interest was a metabolite designated f11, which gave a strong $[M + H]^+$ ion at $m/z$ 607.1 and was identified by the authors as methyleucalyptin (benzoyl)glucoside. Given the prominence of embinin (**4**) in all of the standard *Anthurium* cultivars that were analyzed, it seemed possible that this had been misidentified in the prior study, as **4** also gives a strong pseudomolecular ion at $m/z$ 607. Literature MS/MS data for compound f11 showed fragments at $m/z$ 461, 443, 395, 365, and 341. MS/MS analysis was conducted on an authentic sample of embinin, revealing a very similar fragmentation pattern to those reported by Li et al.;[15] these match well with those of other flavonoid C-glycosides.[31,32] As such, we suggest that compound f11 reported by Li et al. was instead embinin (**4**). Likewise, the reported metabolites f5 and f4, which have pseudomolecular ions at $m/z$ 593 and 579 (both $[M + H]^+$), respectively, and possess very similar fragmentation patterns, are most likely demethylated embinin derivatives.

**Hierarchical Cluster Analysis.** The data were subjected to hierarchical cluster analysis, revealing a wide range of different chemotypes that we have separated into nine classes (Figure 4). All standard (including Obake) cultivars fell into a single

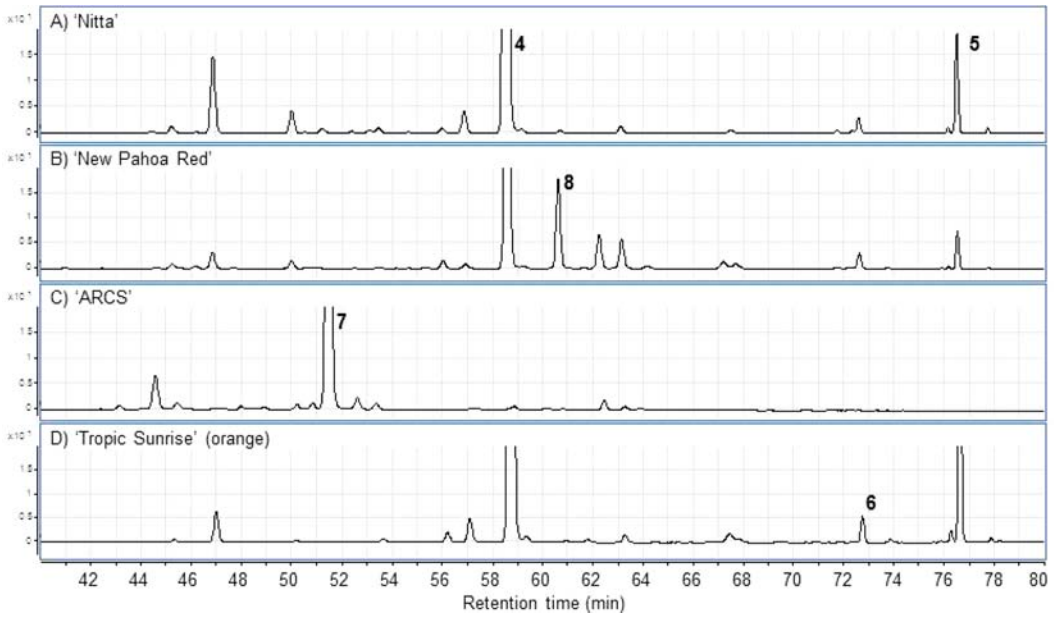

**Figure 2.** HPLC-MS analysis of representative *Anthurium* cultivars. UV absorbance at 330 nm is shown. (A) Standard commercial cultivar 'Nitta'; (B) 'New Pahoa' cultivar Standard, 'New Pahoa Red'; (C) Tulip-shaped commercial cultivar 'ARCS'; (D) Obake cultivar 'Tropic Sunrise' (orange portion). Numbered peaks reference flavonols described in Tables 2 and 3 and illustrated in Figure 3.

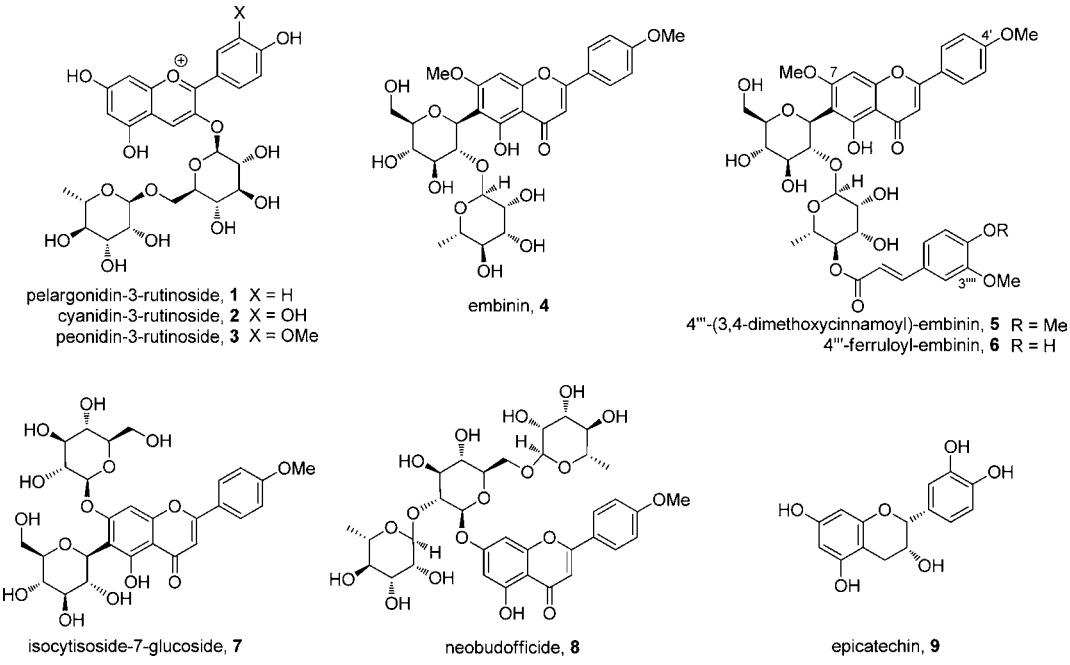

**Figure 3.** Compounds identified from commercial *Anthurium* cultivars.

supergroup, designated D. This low chemical diversity is probably due to the fact that most commercial standard cultivars derive primarily from *A. andraeanum*, with less if any genetic contributions from other *Anthurium* species. For ease of analysis we have separated them into three separate subcategories: D1, 'New Pahoa' cultivars; D2; and D3, which included both accessions of *A. andraeanum*. Of particular interest were the relationships between the recently developed 'New Pahoa' cultivars. These 'New Pahoa' cultivars derive from sports that arose from tissue culture clones, and they possess vibrant colors and a long vase life (S. Oishi, personal communication). The cultivars cluster very tightly together; 'New Pahoa' cultivars are extremely similar chemically, and changes in pigment levels are one of the very few changes observed among them, a finding that supports their clonal origins.

In contrast, tulip-shaped cultivars exhibited a much greater range of chemical diversity, separating into seven chemotypes (Figure 4). The irregularly-shaped *A. bakeri* was the single member of chemotype A and is distantly related phylogenetically to all other species and cultivars used in this study.[2] Chemotype B consisted of the 'Tropic Lime' and 'Princess Aiko' cultivars, while chemotype C consisted of 'Hokuloa', 'Lady Jane', 'Ami', and the intermediate-shaped 'Snowball' cultivar.

[a]Compounds **1**−**9** correspond to structures **1**−**9** in Figure 3. Numbers **10**−**42** are numerical designations only.

*A. armeniense* is the sole member of chemotype E, while *A. kamemotoanum* and 'Calypso' are likewise the sole members of chemotypes F and G. Chemotype H consisted of *A. hoffmannii*, *A. veitchii*, and the commercial 'Centennial' cultivar. Finally, chemotype I contained the species *A. antioquiense* and *A. amnicola* in addition to the 'ARCS' and 'Lavender Lady' cultivars, which share *A. amnicola* as pollen parent. The multiple accessions sampled of *A. amnicola* and *A. andraeanum* clustered together in chemotypes I and D, respectively.

The greater heterogeneity among the tulip samples was expected, given that while all of the standard samples analyzed have been bred largely from *A. andraeanum*, tulip cultivars have a much wider range of ancestry, including *A. amnicola*, *A. antioquiense*, *A. armeniense*, *A. hoffmannii*, *A. formosum*, and *A. kamemotoanum*, as well as others not tested in this study such as *A. lindenianum* and *A. nymphaeifolium*. Relationships between the species analyzed were similar to those obtained by genetic analysis,[2] indicating that chemometric analysis may be a valid tool for investigating the phylogenetic relationships among these species.

**Principal Component Analysis.** HCA offers a powerful tool for analysis and differentiation of *Anthurium* species. However, for commercial cultivars, particularly hybrid cultivars that have ancestry from multiple species, complicating factors can arise. Such cultivars may contain flavonoids derived from the biosynthetic pathways of multiple ancestral species, and as

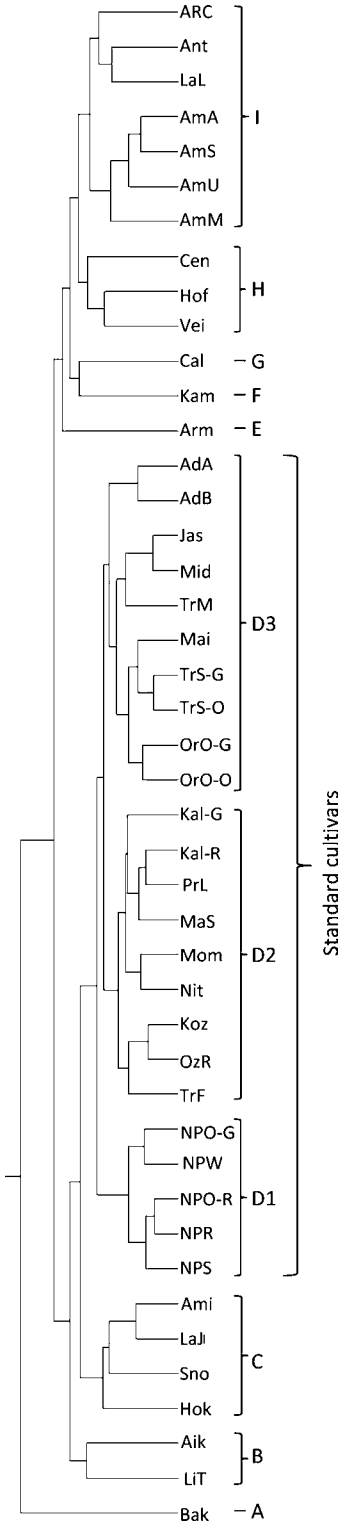

**Figure 4.** Hierarchical cluster analysis of *Anthurium* cultivars and species. Cultivars have been categorized into nine chemotypes (A–I), as indicated, with chemotype D (standard cultivars) further subdivided.

such the position of such cultivars in the dendrogram can change dramatically, depending on the specific quantities of flavonoid components and the clustering algorithm and distance measures used in the analysis. Principal component analysis (PCA) offers a multidimensional display of results, which can reveal additional differentiating factors and better separate cultivars with multiple species in their ancestry; PCA was used to expand upon the results obtained through HCA.

Initial PCA of commercial *Anthurium* cultivars and species showed separation of the various commercial cultivars based on spathe shape, with standard (including Obake) samples scoring higher in PC2 than tulip cultivars (Figure 5). However, while

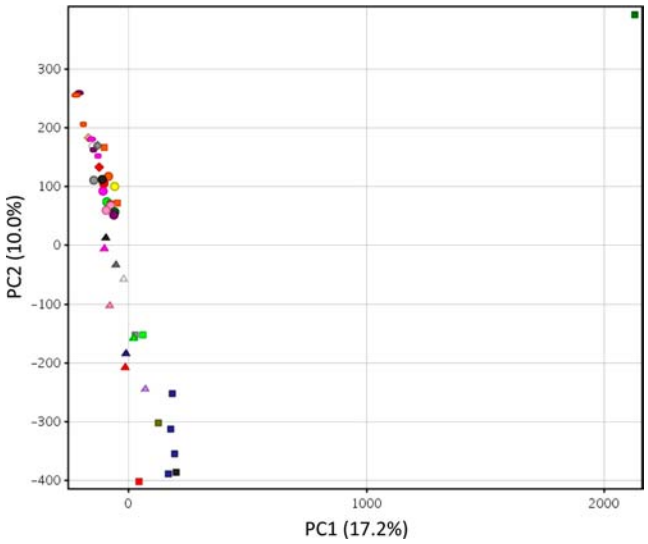

**Figure 5.** Principal component analysis of commercial *Anthurium* cultivars and species, displaying principal components 1 and 2. Full set of samples and 315 metabolites were used. Contribution to overall variation were PC1 17.2% and PC2 10.0%. See Table 1 for cultivar identities. *A. bakeri* can be seen as an outlier at the top right.

some separation was observed along PC2, the majority of the remaining principal components were not useful for the differentiation of commercial cultivars, as they were dominated by the more outlying species and cultivars, in particular *A. bakeri* and *A. kamemotoanum*, but also *A. armeniense* and *A. veitchii*. The chemical profiles of these four species are very different from most of the commercially available *Anthurium* cultivars and they share only a few chemical constituents in common. Likewise, the commercial cultivar 'Calypso' is also chemically very distinct from most of the other commercial varieties. Inclusion of such outlying varieties leads to reduced differentiation of the cultivars of interest and requires the use of large number of principal components to account for the observed differences. In order to focus more specifically on the majority of commercial cultivars, the analysis was repeated with 'Calypso' and the outlying species listed above omitted, with a total of 196 metabolites used.

For this new analysis, eight principal components were used, which accounted for a total of 63% of the total variation in the samples. The requirement for such a large number of components may be due to the very high chemical diversity and degree of variation between the samples. PC1 accounted for 18.7% of the observed variance between the species and cultivars analyzed, separating standard cultivars from tulip-shaped cultivars and species (Figure 6A). PC2 (9.5%) separated the majority of commercial cultivars from *A. amnicola*, which scored very high in this component, and from *A. antioquiense* and the commercial varieties 'Tropic Lime' and 'Princess Aiko', which had very low PC2 scores. Principal component 3 (6.9%) differentiated 'Tropic Lime', 'Lavender Lady', and *A. antioquiense* from others. 'New Pahoa' and Obake cultivars clustered close to

dx.doi.org/10.1021/jf502187c | J. Agric. Food Chem. 2014, 62, 11323−11334

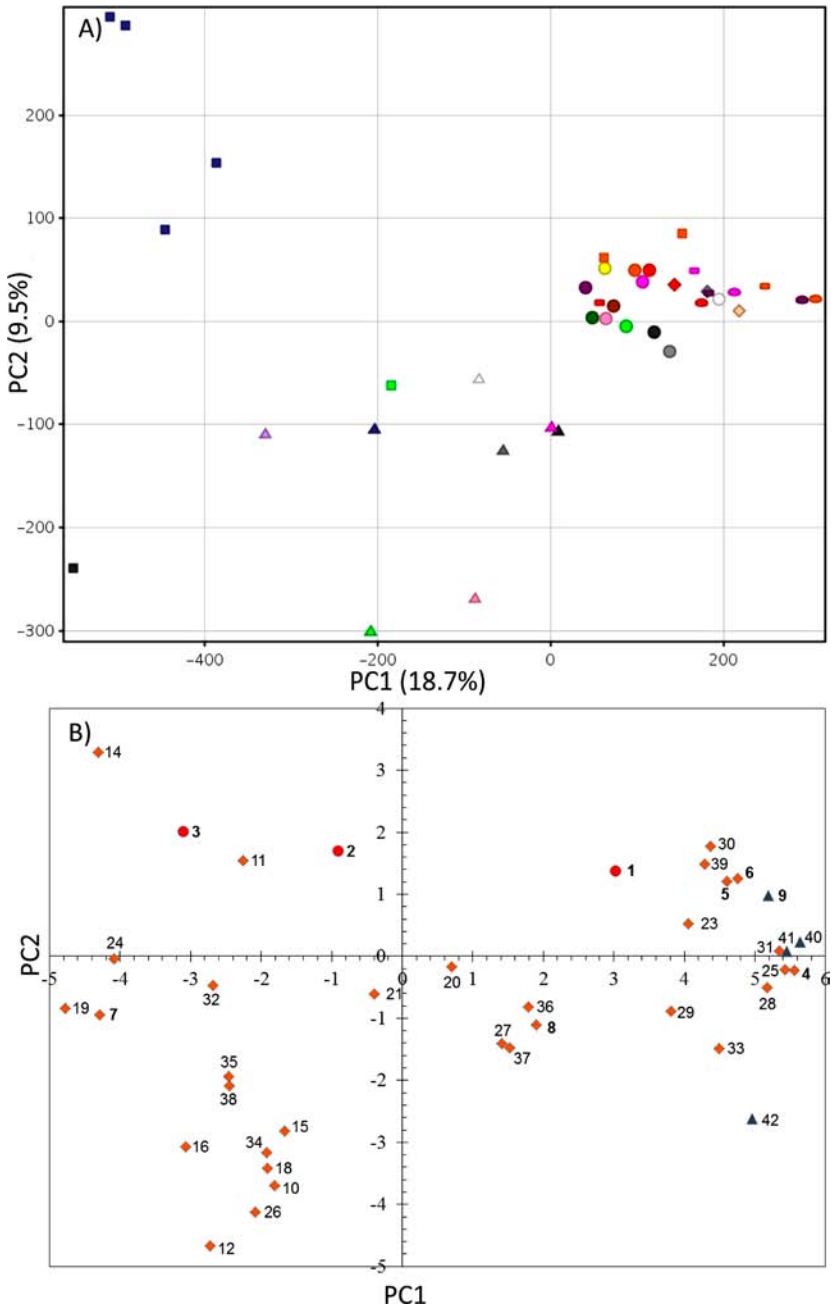

**Figure 6.** Principal component analysis of selected *Anthurium* cultivars for reduced sample set of 196 metabolites. Contribution to overall variation: PC1, 17.2%; PC2, 10.0%; PC3, 8.1%; PC4, 6.5%; PC5, 6.0%; PC6, 5.4%; PC7, 4.9%; and PC8, 4.0%. (A) Score plot of PC1 and PC2 scores; see Table 1 for cultivar identities. (B) Loading plot for selected metabolites contributing to PC1 and PC2. Red circles indicate anthocyanins, orange diamonds show flavones, and gray triangles represent other phenolics. Labels correspond to metabolites as defined in Tables 2 and 3.

the other standard varieties, with characteristic high values in PC1 and moderate values in PC2. Commercial tulip cultivars clustered less tightly, but tended to low PC2 values and moderate PC1 values (Figure 6A). The 'Tropic Fire' and 'Snowball' cultivars have a shape intermediate between a classic standard and tulip shape; these clustered with standard cultivars, suggestive of a pedigree with significant contributions from *A. andraeanum*. Another characteristic pattern was the predictable difference observed between the green and colored portions of the bicolored Obake spathes, with the green portion of all Obake spathes scoring higher in PC1, which may be associated with reduced concentrations of pelargonidin 3-rutinoside (**1**) in green tissue.

These results mirrored those from the HCA and highlighted the difference between standard and tulip cultivars. Analysis of the loading plot (Figure 6B) highlighted key metabolites responsible for differentiation of principal components. Several of these metabolites could be found in the species sampled; their presence in commercial cultivars may reflect the presence of a particular species in their pedigree. Metabolites with high loading values for PC1 were found in the majority of standard cultivars. In particular, **6**, **25**, **28**, and **39** were found in all commercial standard cultivars and also in the parent species *A. andraeanum*, consistent with ancestry from this species. The modified embinin derivatives **5** and **6** were found in particularly

dx.doi.org/10.1021/jf502187c | *J. Agric. Food Chem.* 2014, 62, 11323−11334

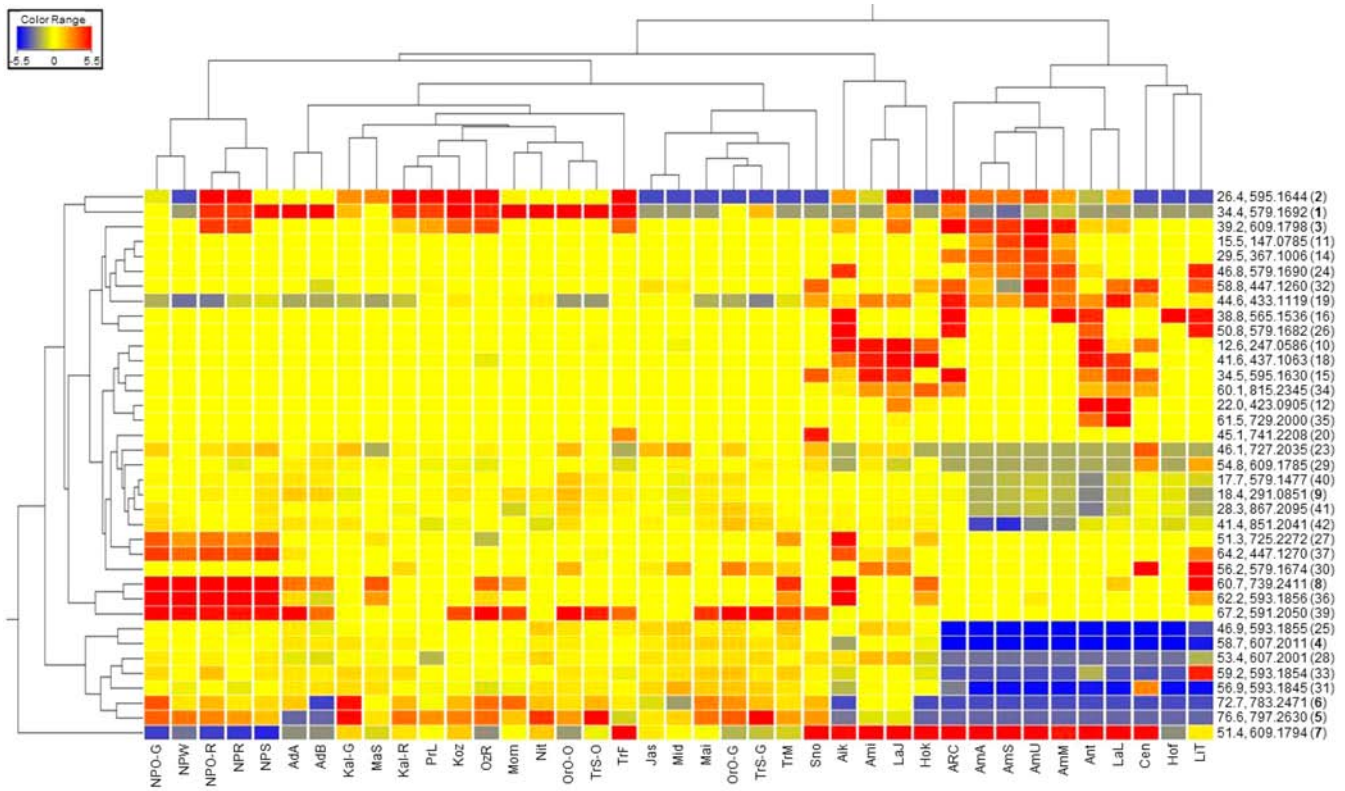

**Figure 7.** Heatmap from hierarchical cluster analysis of *Anthurium* species and commercial cultivars, using metabolites listed in Tables 2 and 3. The dendrogram at the top shows clustering of cultivars, while the dendrogram at the left displays clustering of individual compounds, with Euclidean distances and complete clustering. Normalized levels of selected metabolites are shown in the central portion of the figure.

high levels in both 'New Pahoa' and Obake cultivars. Additionally, the phenolic compounds **9**, **40**, **41**, and **42** had very high loading values for PC1: while these metabolites were found in all *Anthurium* cultivars and species, the levels were much higher in standard than in tulip cultivars.

Several metabolites scoring low in PC1 and high in PC2 (e.g., **11** and **14**) (Figure 6B) were characteristic of *A. amnicola* but were found only in the species itself and not in any commercial cultivars, while peonidin 3-rutinoside (**3**) was also found in *A. kamemotoanum* and in all red and purple commercial cultivars. In contrast, compounds scoring low in PC1 and moderately in PC2 were found in both *A. amnicola* and a range of commercial cultivars. Compound **32** proved a particularly useful marker: it was found in the commercial cultivars 'ARCS', 'Centennial', and 'Lavender Lady', and all three have confirmed pedigrees including *A. amnicola*. However, the 'Tropic Lime' cultivar, which lacks any known *A. amnicola* ancestry, also contains this metabolite. We suggest that in 'Tropic Lime' this metabolite may derive from the contribution of *A. lindenianum* to the pedigree, though we were unable to obtain samples of this species for analysis. Two additional metabolites scoring low in PC1 and moderately in PC2, **7** and **19**, were found in both *A. amnicola* and *A. antioquiense*, with the latter also found in *A. kamemotoanum*, and could represent ancestry from any of these species. All surveyed commercial tulip cultivars, except for 'Calypso' and 'Tropic Lime', contained high levels of isocytisoside 7-glucoside (**7**). A subset of tulip cultivars, including 'Tropic Fire', 'Lady Jane', 'Ami', 'Snowball', and 'Hokuloa', contained significant quantities of both embinin (**4**) and isocytisoside 7-glucoside (**7**), reflecting their known or probable ('Ami' and 'Snowball') mixed pedigrees from *A. andraeanum* as well as *A. amnicola* and/or *A. antioquiense*, the latter two being closely related tulip species.[1]

Similarly, compounds scoring low in PC2 and low to moderate in PC1 were indicative of *A. antioquiense* ancestry (Figure 6B). Two in particular were good markers for *A. antioquiense* ancestry in commercial cultivars. Compound **10** was present in high abundance in 'Princess Aiko', 'Centennial', and 'Hokuloa', all of which have confirmed *A. antioquiense* ancestry, and in 'Lady Jane' or 'Ami' with probable *A. antioquiense* ancestry; while **18** was present in all of these except 'Centennial'. On the other hand, 'Tropic Fire', which also has *A. antioquiense* ancestry, does not contain either of these metabolites. Thus, while the presence of a metabolite may be indicative of a particular *Anthurium* species in the lineage of a given commercial cultivar, the absence of such a metabolite does not necessarily indicate that the species is not a progenitor, as cultivar development involves selecting for and excluding traits over multiple generations of selective breeding. Compound **16** was similarly widespread in these cultivars, but as it is also found in *A. hoffmannii*, and some accessions of *A. amnicola*, this metabolite was not a unique marker of *A. antioquiense* ancestry.

Similar analyses were conducted for other species, but characteristic metabolites indicating ancestry from *A. kamemotoanum*, *A. hoffmannii*, *A. bakeri*, or *A. veitchii* could not be identified. The latter two species are not commonly used in breeding commercial *Anthurium* cultivars in Hawaii, but *A. kamemotoanum* is an ancestor of both 'ARCS' and 'Lavender Lady'. As discussed earlier, *A. kamemotoanum* shares several metabolites in common with *A. amnicola*, including **19** and **3**.

Both of these species are involved in the pedigree of 'ARCS' and 'Lavender Lady', which may be why unique identifying metabolites cannot be identified for *A. kamemotoanum*.

Additional clustering analysis was conducted on the reduced sample list, using the metabolites displayed in Tables 2 and 3, and the results are displayed as a heatmap (Figure 7). This analysis displays cultivar clustering horizontally and metabolite clustering vertically, while the central portion of the figure displays normalized metabolite quantities. Metabolites that cluster closely together likely share a common ancestry and/or biochemical origin and thus can suggest metabolic pathways associated with complex compound mixtures. For example, the anthocyanins pelargonidin 3-rutinoside (**1**) and cyanidin 3-rutinoside (**2**) cluster tightly together, consistent with their production from precursors originating from a common biosynthetic pathway. Likewise, embinin (**4**) clustered tightly with the two derivatives **5** and **6**, in addition to the two unidentified compounds **25** and **33**. On the basis of this tight clustering, we propose that these two unidentified metabolites are biosynthetically related to embinin **4**. They possess masses of 593.1855 and 593.1854 respectively, consistent with a molecular formula of $C_{28}H_{32}O_{14}$, and as such we suggest that they are demethylated embinin derivatives. Clustering was also observed between **3**, **11**, **14**, **19**, and **32**, described previously as compounds found in species *A. amnicola*, *A. antioquiense*, or *A. kamemotoanum*, among others.

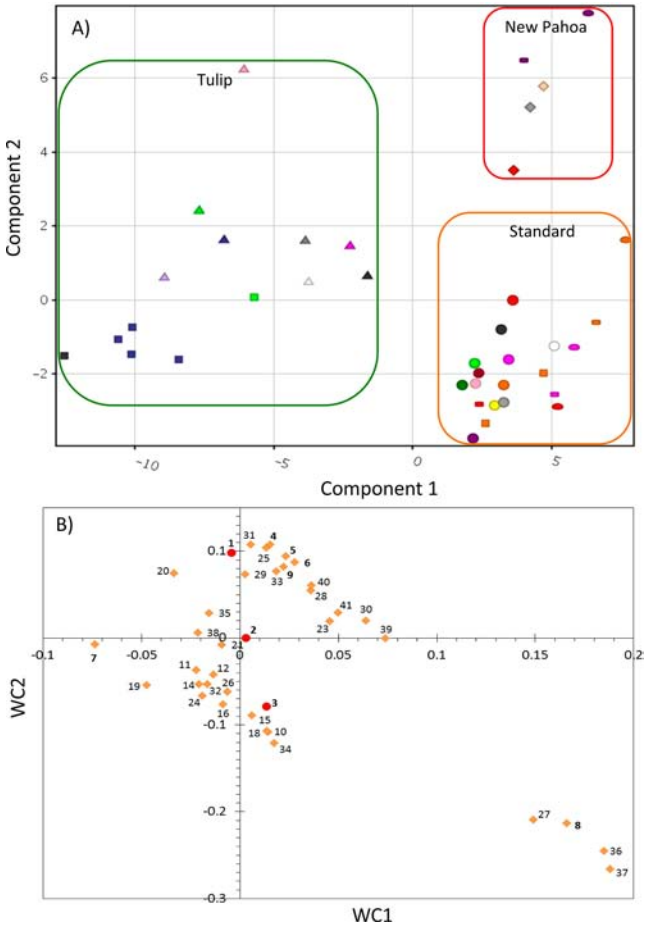

**Figure 8.** Partial least squares discriminant analysis (PLS-DA) of selected *Anthurium* cultivars for a reduced sample set of 196 metabolites. (A) Score plot of component 1 and component 2 scores; see Table 1 for cultivar identities. Highlighting around classes is for clarity only. (B) Loading plot for selected metabolites that contribute to classifying 'New Pahoa' (WC0) and "standard" (WC1) cultivars. Red circles indicate anthocyanins, orange diamonds show flavones, and gray triangles represent other flavonoids. Labels correspond to metabolites as defined in Tables 2 and 3.

Partial least squares discriminant analysis (PLS-DA) was conducted on the reduced data set in order to confirm the results obtained by PCA. PLS-DA offers an excellent tool for discrimination of classes in analyses requiring dimensional reduction.[33] PLS-DA was carried out for three designated classes: standard, tulip, and 'New Pahoa' cultivars. Visualization by use of components 1 and 2 (Figure 8A), showed clear differentiation between the three classes. As this PLS-DA analysis had been optimized to differentiate between 'New Pahoa' and other standard (including Obake) cultivars, it gave much better separation between these two categories than the PCA. In contrast to other standard cultivars, 'New Pahoa' cultivars all scored very highly in component 2, highlighting the fact that there are characteristic chemical differences between the two groups. Analysis of loading plots for the data revealed key metabolites involved in discrimination of 'New Pahoa' from other standard varieties (Figure 8B). Two of these metabolites, **36** and **37**, were characteristic of 'New Pahoa' cultivars, though they were also found in 'Princess Aiko' and in *A. armeniense* (Tables 2 and 3). This may indicate that 'New Pahoa' and 'Princess Aiko' cultivars contain *A. armeniense*, or a closely related species, in their pedigrees. However, ancestry data for 'New Pahoa' varieties is not publicly available, and only the immediate progenitors for 'Princess Aiko' are known.[28] Co-occurrence of these metabolites in different cultivars might also be due to interaction of biosynthetic pathways contributed by multiple ancestral species or to variations arising de novo during cultivar development.

Overall, this research displays the utility of chemotaxonomic analysis in classification of the *Anthurium* genus, both for species and for commercial cultivars. This study lays the groundwork for future work on the identification of key metabolites indicative of a particular ancestry and for identification of the key biosynthetic pathways involved in their biosynthesis.

| 79 | thiabendazole | $C_{10}H_7N_3S$ | pesticide |
| 80 | thiacloprid | $C_{10}H_9ClN_4S$ | pesticide |
| 81 | thiamethoxam | $C_8H_{10}ClN_5O_3S$ | pesticide |
| 82 | trifloxystrobin | $C_{20}H_{19}F_3N_2O_4$ | pesticide |
| 83 | trimethoprim | $C_{14}H_{18}N_4O_3$ | antibiotic |

HCD in the LTQ/Orbitrap) or by resonance (radial excitation with LTQ and SORI-CID Qh/ICR). Although the recorded CID spectra are instrument-dependent, they are a very useful tool for confirming metabolite structure, especially when the product ions from CID are analyzed under high-resolution conditions yielding their respective elemental composition.[27]

Beside improvements brought in the fields of screening and multiplexed quantification of pollutants in various matrices, LC-HRMS methods have also been coupled to untargeted data processing approaches[28] or to effect directed analysis studies[29] to highlight untargeted chemical contaminants in wastewater effluents and river sediments. Furthermore, HRMS is nowadays the tool most used for metabolomics, which deals with the large-scale detection and quantification of metabolites in biological media. Metabolomics is an interdisciplinary approach,[30] which combines analytical chemistry, mathematics, statistics, and bioinformatics. In this context, the main objective of the present study is to demonstrate that LC-HRMS combined with a metabolomics data treatment workflow, which is mostly used for systems biology and biomarker discovery studies, is highly relevant to the field of food control by enabling the monitoring and identification of emerging pollutants and also by improving the chemical characterization of food matrices.

We chose to focus on the analysis of honey as a proof-of-concept study. Honey is a complex matrix obtained from bees during the harvest of nectar and pollen. Bees also play a major role in biodiversity as well as in the pollination[31,32] of plants, which is very important in agriculture. However, they are exposed to pesticides sprayed on fields and fruit trees. The European Union has established maximum residue levels (MRLs) for some pesticides in honey, the lowest of them being 10 $\mu$g/kg.[33] Three types of collateral damage may occur: (i) pollution of harvests and hence honey; (ii) poisoning of the

bees and decimation of their colonies; and (iii) chronic intoxication of consumers. The decline in the number of bee colonies in Europe in general and France in particular has considerably reduced honey production, whereas consumption has remained stable. As a consequence, most of the honey consumed in France is imported from around the world, and advanced methods are required to improve the chemical characterization of honey to highlight adulteration or contamination.

We report here the development, validation, and application of an LC-HRMS approach enabling the detection of 83 pollutants known to occur in honey samples and indicating whether or not their concentrations are above or below regulatory limits. We show that the same raw data can be processed using metabolomics like workflow, including automatic peak detection and alignment software, data mining, and multivariate statistical analysis tools to highlight untargeted and unknown chlorinated chemical contaminants and also to discriminate honey samples according to their floral origin.

## MATERIALS AND METHODS

**Chemicals and Reagents.** All standards (see Table 1, 28 antibiotics and 55 pesticides, >95% purity), magnesium sulfate salt ($MgSO_4$, >99%), sodium acetate ($CH_3COONa$, >97%), and glycine (>99% purity) were from Sigma-Aldrich (Saint-Quentin Fallavier, France). HPLC grade acetonitrile (ACN), formic acid (HCOOH, content >99%), dichloromethane ($CH_2Cl_2$), methyl *tert*-butyl ether (MTBE), sterile Falcon tubes (50 mL), and propylene tubes (5 mL) were from VWR International (Fontenay-sous-Bois, France). HPLC grade methanol (MeOH) was from Carlo Erba reagents (Val de Reuil, France). HPLC grade water was obtained by purifying demineralized water in a Milli-Q system (Millipore, Molsheim, France). The standard mixtures used for the external calibration of the MS instrument (Calmix-positive, for the positive ion mode, consisting of caffeine, L-methionylarginyl-phenylalanyl-alanine acetate, and Ultramark 1621; and Calmix-negative, for the negative ion mode, consisting of the same mixture plus sodium dodecyl sulfate and sodium taurocholate) were from Thermo Fisher Scientific (Les Ulis, France).

**Preparation of Stock Solutions.** Stock solution (1 mg/mL when possible) of each standard was prepared by dissolving 1 mg of each substance in 1 mL of an appropriate solvent consisting of $H_2O$, ACN, MeOH, $H_2O$/ACN, or $H_2O$/MeOH (50:50, v/v. containing or not 0.1% formic acid). A working mixed standard solution (1 $\mu$g/mL) was prepared by diluting each standard stock solution by a factor of 1000 with water. To minimize degradation of standards, stock and working standard solutions were stored at −20 °C immediately after preparation.

**Honey Samples.** A panel of 76 honeys was purchased by Institut National de la Consommation (INC, which is the French national institute for consumer protection) from different stores in the Paris region (France). These honeys were produced from around the world and from different types of flowers (multifloral, lavender, acacia, mountain, orange tree, and eucalyptus). They were of various prices and quality, ranging from discount, private label, handmade, to luxury, and of different kinds of label (i.e., none, organic farming, red label, and protected environmental indication (IGP)).

**Sample Preparation.** Honey samples were processed by liquid−liquid extraction with acetonitrile solvent, by adapting the protocol developed by Pizzuti et al.[34] to extract pesticides from soybeans to honey samples. Each honey sample (5 g) was weighed into a 50 mL polypropylene Falcon tube with a screw cap, and 4 mL of water was added to homogenize the samples of various consistencies (liquid, solid, or creamy). Each sample was then prepared in six replicates. Three of six replicates were spiked with an appropriate volume of working solution (1 $\mu$g/mL) to obtain a concentration of 10 ng/g for each targeted pollutant. Samples were then extracted with 10 mL of ACN with 2 g of magnesium sulfate and 2.5 g of sodium acetate added. The 50 mL Falcon tubes were rotated end-over-end for 1 h. After centrifugation at 3500 rpm for 5 min, an aliquot of 4 mL of the upper layer extract (acetonitrile) was transferred into a 5 mL propylene tube. The eluents were evaporated to dryness under nitrogen. Samples were then reconstituted to 200 $\mu$L of $H_2O$/ACN (95:5, v/v) before injection into the LC-HRMS system.

**Liquid Chromatography and Mass Spectrometry.** Analyses were performed using a Nexera LC-30AD liquid chromatographic system (Shimadzu, Marne-la-Vallée, France) coupled to an Exactive mass spectrometer (Thermo Fisher Scientific, Les Ulis, France) fitted with an electrospray source operated in the positive ionization mode. The software interface was Xcalibur (version 2.1) (Thermo Fisher Scientific). To ensure the accuracy of the mass measurements, the instrument was calibrated every week in both polarities with a homemade modified Calmix solution (Thermo Fisher Scientific) with the addition of 100 $\mu$L of glycine solution (10 $\mu$g/mL) to 150 $\mu$L of Calmix. For singly charged ions, the mass resolution power of the analyzer was set to 25 000 ($m/\Delta m$, full width at half-maximum at $m/z$ 200) and the mass accuracy over the range of $m/z$ 70−1000 was below 5 ppm. The AGC target and the maximum injection time were set to $10^6$ and 50 ms, respectively. The high-performance liquid chromatographic (HPLC) separation was performed on an Xterra C18 (5 $\mu$m, 150 mm × 2.1 mm) column (Waters, Guyancourt, France) with a Javelin column filter 0.5 $\mu$m (Thermo Fisher Scientific). The mobile phases were composed of water (A) and acetonitrile (B), both containing 0.1% formic acid. The elution consisted of an isocratic step of 2 min at 5% phase B, followed by a linear gradient from 5 to 100% of phase B from 2 to 22 min. These proportions were kept constant for 4 min before returning to 5% B from 26.1 to 30 min. The flow rate of the mobile phase was 0.3 mL/min, and the injection volume was 10 $\mu$L. The column and the automatic sample injector were kept at 30 and 4 °C, respectively. For the ESI source, the capillary voltage was set to 4800 V. For droplet evaporation, the sheath and auxiliary gas ($N_2$) flows were fixed at 28 and 9 arbitrary units, respectively. The capillary temperature was set to 280 °C. For MS/MS experiments, a Q-Exactive (Thermo Fisher Scientific) was used with the same source parameters and chromatography conditions as previously described. Two scan events were used: (i) an MS scan with a mass resolution power, AGC target, and maximum injection time set to 70 000 ($m/\Delta m$, full width at half-maximum at 200 u), $10^6$, and 50 ms, respectively; and (ii) an MS/MS scan (in HCD mode without LMCO limit) at normalized collision energies of 20 and 40%, with a mass resolution power, AGC target, maximum injection time, isolation width set to 17500 ($m/\Delta m$, full width at half-maximum at 200 u), $10^6$, 250 ms, and 0.4 $m/z$, respectively.

**Experimental Design.** Samples were randomized and analyzed in three batches of 152 samples (76 spiked and nonspiked samples). Within each batch, nonspiked samples were injected first. A blank and a pool of the 83 compounds of interest (in buffer at 100 ng/mL) were injected every 5 and 10 biological samples, respectively.

**Data Processing.** *Targeted Data Processing.* All raw data were processed with two application managers of Xcalibur 2.1 software: Qualbrowser (for peak detection) and Quanbrowser (for peak integration). The identification of the xenobiotics of interest from raw data was based on four criteria: (1) retention time of the expected molecule compared with the retention time of standard compound in a time window of ±0.15 min; (2) accurate mass measurement of the analyte (mass tolerance ±5 ppm); (3) reliability of the isotopic pattern compared with that of the reference compound; and (4) increase of the chromatographic peaks area in honey spiked with xenobiotics.

*Data Processing for the Nontargeted Approach.* Peak detection, alignment, and integration were performed with the XCMS software package. Raw files were first converted to mzXML format with MSconvert (ProteoWizard[35]). Data were processed using XCMS version 1.30.3 running under R version 3.0.0. The R software was installed on a Lenovo ThinkStation C20X 24 core Intel Xeon E5645 2.4 GHz with 24 Go RAM running Linux (Centos release 6.4 Final x86_64). The CentWave algorithm was used.[36] The list of the parameters used is available as Supporting Information (Table 3s). The resulting peak table was then processed as described below. First,

features were quantile normalized.[37] Features were then kept if they were detected with the same trend (i.e., present or absent) in the three replicates of 90% of honeys, with a coefficient of variation below 30% and with a sample to blank concentration ratio above a factor of 10. Finally, features were annotated by matching their mass accurate measured mass at ±10 ppm with theoretical ones contained in the KEGG,[38] HMDB,[39] and Metlin[40] databases by using an informatics tool developed in R language.

*Identification of Chlorinated Xenobiotics in Honey Samples.* A script was written in R language to highlight the chlorinated molecules thanks to the specific isotopic patterns provided by chlorine atoms. This script uses the peak table generated by XCMS. It groups two variables with the same retention time (±5 s) and differing by 1.9970 ± 0.0010 $m/z$, which corresponds to the accurate $m/z$ difference between the two natural chlorine isotope masses (i.e., $^{35}Cl$ and $^{37}Cl$).

*Statistical Analyses. (a) Multivariate Statistical Analyses.* The data resulting from the XCMS process were mean-centered and logarithm-scaled and then analyzed using SIMCA-P11 software (Umetrics, Umea, Sweden) for multivariate analyses using principal component analysis (PCA) and projection to latent structure discriminant analysis (PLS-DA). This software returns a variable importance in projection (VIP) score, which reflects the contribution of the variables to the model. A variable is considered as important for the model when its VIP is above 1. The PLS-DA models were validated using the cross-validation function of SIMCA-P11 and by permutation tests ($k$ = 100).

*(b) Univariate Statistical Analyses.* For each VIP feature, the normality assumption was checked (Shapiro–Wilk test, $\alpha$ = 5%). Then, the Wilcoxon test was used with $\alpha$ = 5% to determine the significance ($p$ value) between the two groups.

## RESULTS AND DISCUSSION

**Screening of Emerging Pollutants in Honey Samples Using a Targeted Approach.** *Method Development and Validation.* An HRMS-based metabolomic approach was first developed and implemented with honey samples as a proof-of-concept study. A list of 83 pollutants (55 pesticides and 28 antibiotics) of interest was drawn up (Table 1). A liquid–liquid extraction method and a UHPLC-HRMS method were developed and validated to (i) detect these 83 pollutants, (ii) indicate whether their concentrations in honeys are above or below regulatory limits, and (iii) detect a wide range of chemicals present in honeys.

Method development and validation are detailed in the Supporting Information. Briefly, a spectral database including chromatographic retention times and MS information (i.e., protonated, adduct, isotope, and in-source fragment ions for each molecule of interest) was built to select the ions to be extracted from raw data. Table 1s displays retention times and ions used for detection and quantification. Metabolite extraction from honey samples was achieved using acetonitrile supplemented with magnesium sulfate and sodium acetate (please refer to Materials and Methods for additional information), and an LC-HRMS method was optimized to achieve chromatographic separation of the 83 xenobiotics of interest within 30 min. This method was validated by studies of linearity, matrix effect, and intra-assay precision and by determination of the limit of detection (LOD), which corresponds in our case to the lowest concentration for which the coefficient of variation of the areas of triplicates was <15%. Intra-assay precision was satisfactory with RSD below 15%. Linearity was evaluated in the range from 0.01 to 1000 $\mu$g/kg and the determination coefficient ($r^2$) was >0.99 for all compounds. LOD values ranged from 0.1 to 10 $\mu$g/kg.

Finally, the sensitivity achieved with our method is comparable to[12] or even better[1,34] than that achieved with triple-quadrupole instruments operated in the MRM mode. In addition, all LOD values determined are below the regulatory values imposed by the European Union, when available (Table 2s).

*Targeted Analysis of Honey Samples.* Seventy-six honey samples from different countries and of different floral origins were selected. The results of the targeted analysis indicate that 74 of 76 honeys are contaminated with at least one molecule of the 83 selected xenobiotics. Figure 1a displays the number of molecules detected in each honey. A bimodal distribution seems to emerge with maximum points corresponding to two and seven molecules per honey. Classifications of the number of molecules per honey were made by country, floral origin, and organic farming, but did not show significant correlation (data not shown). Two honeys, in which no pollutants were found, came from organic farming in Australia and Mexico.

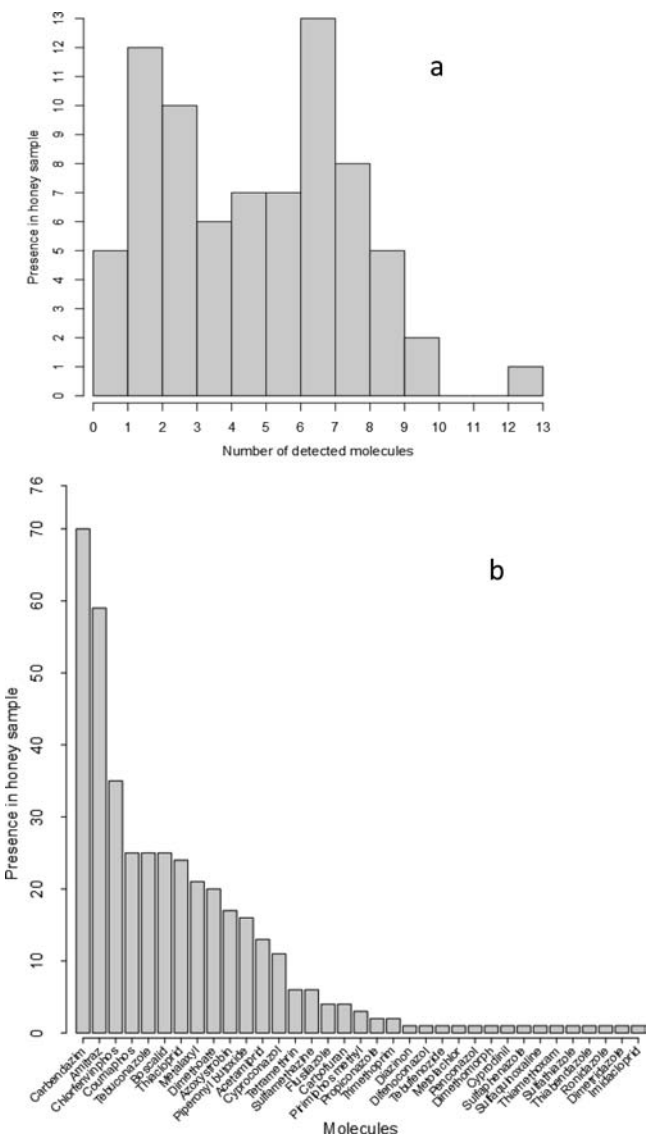

**Figure 1.** Targeted analysis of xenobiotics in honey samples: (a) histogram representing the number of molecules found in honey; (b) representation of the number of honey samples in which each molecule was found.

Figure 1b displays the number of xenobiotics detected and their presence in honey samples. It indicates that 35 of 83

**Table 2. Xenobiotics Detected in Honey Samples**

| ID | *m/z* | RT (min) | interpretation | occurrence in honey samples (floral origin) | ID status[a] |
|---|---|---|---|---|---|
| 1 | 189.9817 | 7.9 | 2,6-dichlorobenzamide ($C_7H_5ONCl_2$) | 6 (lavender) | identified (a, b, c) |

[a]a, elemental composition; b, retention times matching with that of a standard; c, MS/MS matching with that of a standard; d, MS/MS matching with a structural hypothesis; e, MS/MS experiment available. [b]Structural hypothesis obtained from the Scifinder database (elemental composition).

targeted molecules were detected. The three most frequently recovered compounds were carbendazim, amitraz, and chlorfenvinphos (i.e., 70, 59, and 35 times in 76). Carbendazim is a fungicide belonging to the carbamate family, which is commonly used in cereal and fruit crops. It has been banned in the European Union (EU) since 2009.[41] Amitraz is an acaricide belonging to the family of formamidines. It is commonly used by beekeepers to protect their hives against the parasite *Varroa destructor*.[42] Finally, chlorfenvinphos is an insecticide and an acaricide belonging to the family of organophosphates. It was mainly used against fly larvae in farmed chicken or beef.[43] Because of its toxicity, it was banned in the EU in 2007. Some beekeepers may still use it to combat *Varroa* because it is more effective than amitraz.[44] However, our results, which provide an order of magnitude of concentration, indicate that no xenobiotics were found at concentrations above the regulatory threshold levels of the EU.

**Data Mining from LC-HRMS Fingerprints.** Unlike data acquired on a triple-quadrupole mass spectrometer operated in the MRM mode, HRMS-based data can be subjected to subsequent data mining procedures to highlight unanticipated information, as already performed with metabolomics in systems biology or for biomarker discovery. Proof-of-concept studies detailed below emphasize the relevance of such an approach for the detection of unexpected xenobiotics and for an improved chemical characterization of honeys.

To this end, raw data were processed using XCMS software, a collection of algorithms written in R language for the detection and alignment of peaks. XCMS output is a data matrix that can thus be processed by data mining algorithms and can also be subjected to multivariate statistical analyses.

*Detection of Unexpected Xenobiotics.* How to discriminate between signals related to metabolites (i.e., all organic substances naturally occurring from the metabolism of the living organism studied) or xenobiotics and contained in LC-HRMS fingerprints is a key question. It was addressed at the beginning of the 2000s by chemoinformatic analysis that describes metabolites present in the *Escherichia coli* bacteria listed in the EcoCyc and KEGG databases in terms of fragment-based fingerprints and descriptors based on physicochemical properties.[45] Other studies, such as those of Gupta et al.,[46] Dobson et al.,[47] and Peironcely et al.,[48] were subsequently published. Peironcely et al., for example, found some discrimination trends between metabolites and nonmetabolites on a PCA score plot on the basis that metabolites tend to have a higher water solubility, lower molecular mass, fewer C, N, and S atoms, and a lower number of cycles and rotatable bonds than nonmetabolites.[48]

However, from the analysis of these studies, it is difficult to establish rules to discriminate between signals related to either metabolites or xenobiotics in LC-HRMS data sets. The fact that xenobiotics can be metabolized by living organisms or degraded by the environment, and also the difficulty of automatically generating relevant elemental compositions from accurate measured mass despite the availability of chemical and empirical rules,[49] further complicates this task. Thus, we decided to focus on chlorine-containing compounds for this proof-of-concept study.

As chlorine atoms mainly occur in biological media as sodium chloride, chlorine-containing organic compounds are assumed to be, or at least to come from, xenobiotics produced by human industrial activity. Note that 35% of our 83 targeted xenobiotics contain at least one chlorine atom. In addition, chlorinated compounds can be easily and selectively detected in biological media using HRMS-based instruments thanks to their particular natural isotopic signature consisting of two stable isotopes, $^{35}Cl$ and $^{37}Cl$, the latter having a relative abundance of 33% of the first one and these two isotope masses being separated by 1.9970 u. We therefore developed an algorithm written in R language that highlights features differing by 1.9970 ± 0.0010 u (for singly charged ions) and occurring at the same retention time (±5 s) from peak tables produced by an automatic peak detection and alignment software.

First, 76 XCMS peak tables (see Supporting Information for the XCMS parameters, Table 3s) were produced on triplicates of each honey sample to improve the accuracy of RT and measured masses when compared with a single peak table containing 228 samples. These peak tables were then annotated with public databases (see Materials and Methods) and processed by our algorithm. Features highlighted by this algorithm in all 76 peak tables were then merged, leading to a

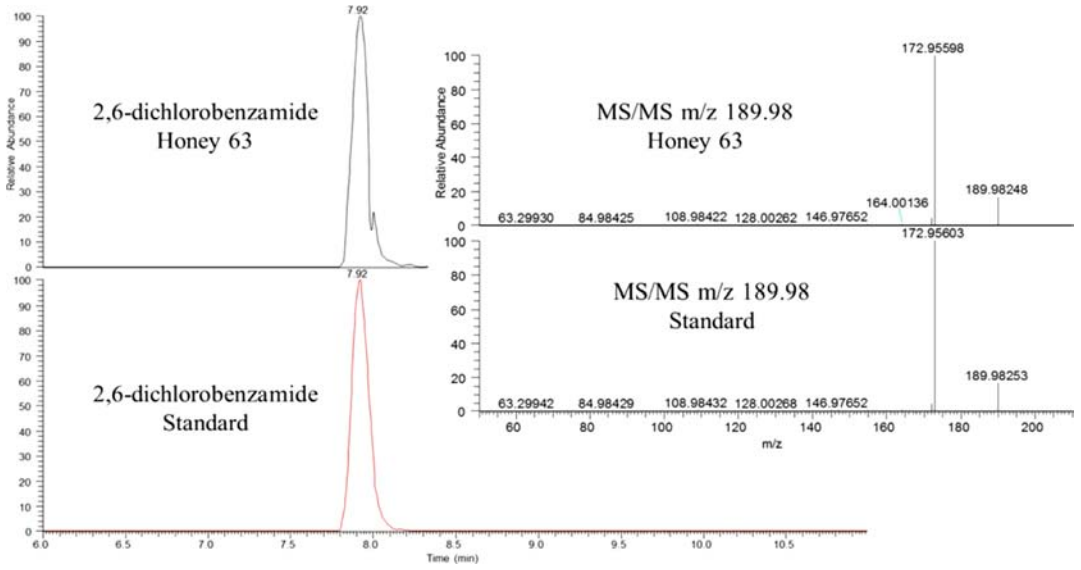

**Figure 2.** Identification of 2,6-dichlorobenzamide in honey ($[M + H]^+$ = 189.9821, $m/z \pm 8$ ppm).

peak table containing 25000 features. First, it is of note that 97% of the chlorinated molecules previously monitored in the course of the targeted approach were present in this peak table. Then, due to the high number of features, manual inspection was limited to the 1300 most represented features, which were sorted by increasing $m/z$ values. Features corresponding to a unique molecule were then merged in 143 clusters corresponding to couples of potential $^{35}$Cl- and $^{37}$Cl-containing ions and which were manually inspected. Only 28 of them were confirmed to correspond to chlorinated ions, among which 13 chlorinated compounds were detected in honeys (i.e., the others features were artifacts generated by the automatic peak detection process). The inspection of a fraction of the peak table shows that too many false positives are selected using only the criteria retention time and $m/z$ difference.

Additional criteria were then applied: (i) the relative abundance the $^{37}$Cl ion had to be between 20 and 120% of the $^{35}$Cl, which ensures the detection of ions bearing one to four chlorine atoms; (ii) the retention time had to be above 90 s (to avoid false positives due to the huge number of molecules present in the void volume); (iii) the area of the chromatographic peak related to the monoisotopic ion should be above $10^6$ AU; and (iv) sample (i.e., mean of the three replicates per honey) to blank concentration ratio should be above a factor of 3. By these means, only 4 chlorinated molecules of 35 previously detected in the targeted analysis (i.e., thiacloprid, imidacloprid, cyproconazole, tebuconazole) were detected, but the number of clusters generated was much smaller, thus allowing manual inspection. Moreover, this led to the detection of 18 new chlorinated compounds that are present in at least one honey sample, in addition to the 4 chlorinated compounds that were part of our list.

An XCMS peak table including the 228 samples (i.e., 76 honeys analyzed in triplicate) was generated without any specific criteria (see the Supporting Information for the XCMS parameters, Table 4s) to confirm the presence of these new chlorinated compounds. This led to the confirmation of 12 chlorinated molecules of the 18 initial ones, and 10 of them were present in at least 10 kinds of honey samples (Table 2).

MS/MS information, elemental composition, and isotope pattern regarding the number of Cl atoms were obtained successfully for these 12 compounds. However, only two structures were proposed on the basis of the MS/MS interpretation. The CID spectrum of compound **15** matched with U50488, a compound present in the Scifinder database (Table 2), whereas compound **1** was identified as 2,6-dichlorobenzamide by matching its retention time, accurate measured mass, isotopic pattern, and CID spectrum to those of the purchased compound (Figure 2), and it was found in 6 of 11 French lavender honeys (Table 2). Interestingly, this molecule is the metabolite of dichlobenil, a herbicide that was not part on our list of xenobiotics and which was widely used in lavender and lavendin plantations until it was banned in France in 2010.

*Honey Typing.* Besides the detection of chemical contaminants and/or their metabolites, we would also like to show that LC-HRMS and associated data mining could be relevant to improving the chemical characterization of honey samples. Here we focus on the discovery of biomarkers of floral origin that could help to detect fraud and provide a preliminary experiment. To this end, we used the XCMS peak table previously produced on the 76 kinds of honey samples (see Table 4s for XCMS parameters). This peak table contained 121,000 features and 300 samples (i.e., 76 honeys analyzed in triplicate and 72 analytical blanks). It was filtered out (see Materials and Methods for more detail), and 42500 analytically relevant signals were kept for multivariate statistical analyses.

The PCA score plot displayed in Figure 3a shows a clear discrimination between single-flower (acacia, lavender and orange) and multifloral (multiple flowers and mountain) honeys, except for eucalyptus honey samples for which the sampling was too small (four honey samples only). It also indicates that acacia honey samples are well separated of orange and lavender honey samples. We then focused on the discrimination between single and multifloral honey samples and used PLS-DA, the score plot of which is shown in Figure 3b, to confirm these results. This PLS-DA model was validated using the cross-validation function of the SIMCA P11 software and by permutation tests ($k$ = 500), which dramatically reduced the performances of the model, thus confirming its validity (Figure 3c).

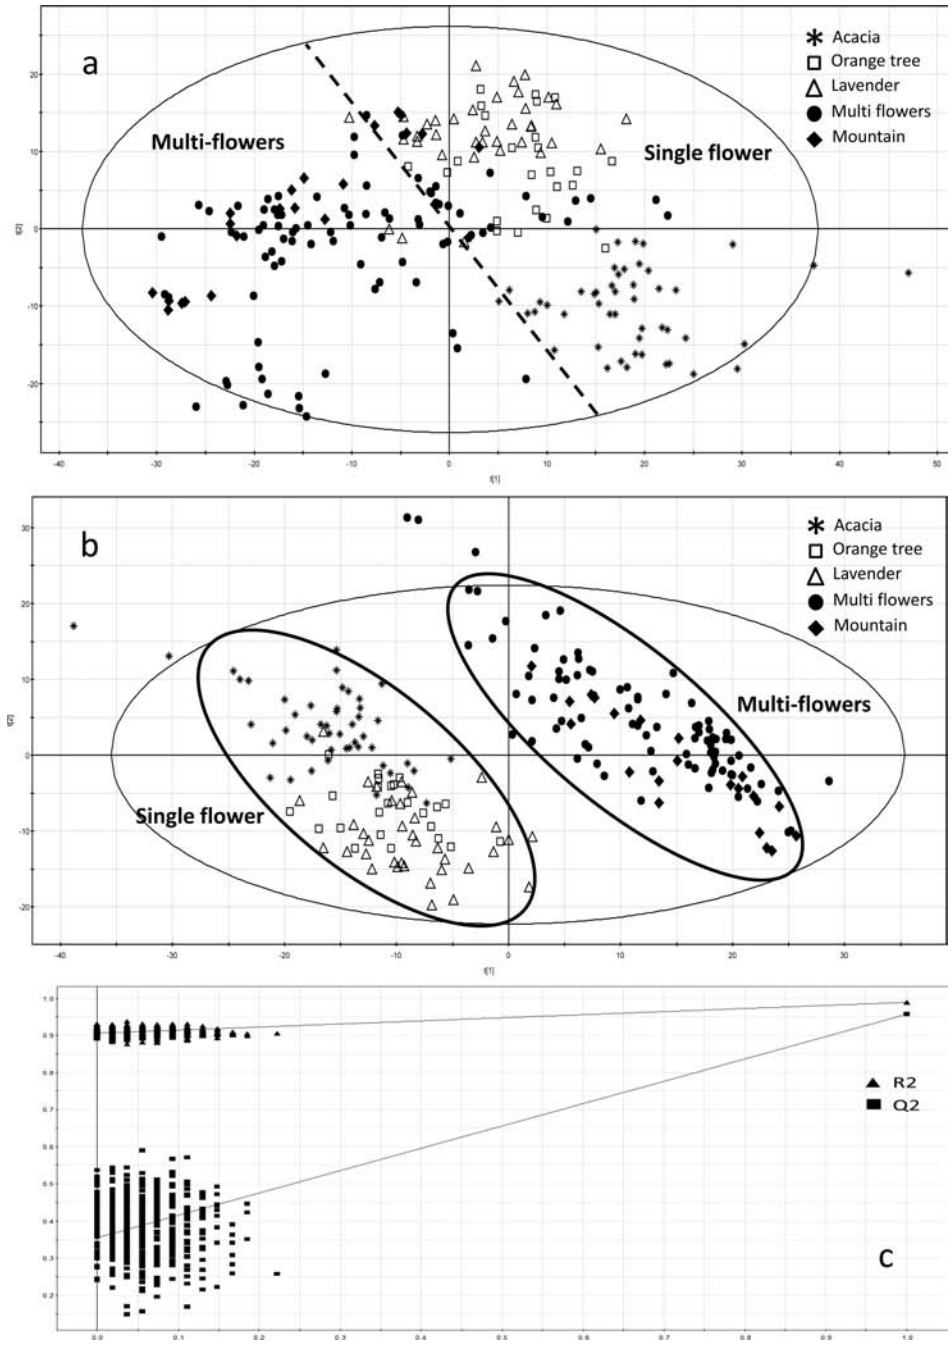

**Figure 3.** Multivariate statistical analyses of the data set of 76 honey samples. Multifloral (●), mountain (◆), acacia (*), orange tree (□), and lavender (△) honey samples. (a) PCA score plot of honey samples (excluding eucalyptus). Data were log-transformed and centered before multivariate statistical analysis. (b) PLSDA score plot of honey samples. (c) Validation model of PLSDA by permutation tests ($k$ = 500) on the first component. R2(Y) corresponds to the proportion of the variance of the response variable that is explained by the model, and Q2 (cum) expresses the cumulative proportion of the variance of the variables that can be predicted by the model. Permutation of data from multifloral samples related to data from single-flower samples dramatically decreased the performance of the model, thus confirming its validity.

Variables exhibiting a VIP score (please refer to the Materials and Methods for more details) above a value of 2 were then annotated using public databases such as KEGG,[38] HMDB,[39] and METLIN.[40] Six of the most significant annotated variables (VIP > 2) were selected. Their significance was confirmed by the Wilcoxon test with $\alpha$ = 5% (after verification of the normality assumption with the Shapiro−Wilk test; see Materials and Methods for more details), and their box and whisker plots are displayed in Figure 4.

Five of these six variables were putatively identified and exhibited MS spectra compatible with the proposed structure; a flavone-like structure was proposed for the last one (Table 3). CID spectra (in HCD mode) are available as Supporting Information. Figure 5 displays CID spectra of $m/z$ 438 (i.e., X84952) and a proposed fragmentation scheme suggesting that the precursor ion could be lunarine, an alkaloid occurring in plants of the *Lunaria* genus, native to central and southern Europe. A complete fragmentation scheme of lunarine is provided as Supporting Information (Figure 6s).

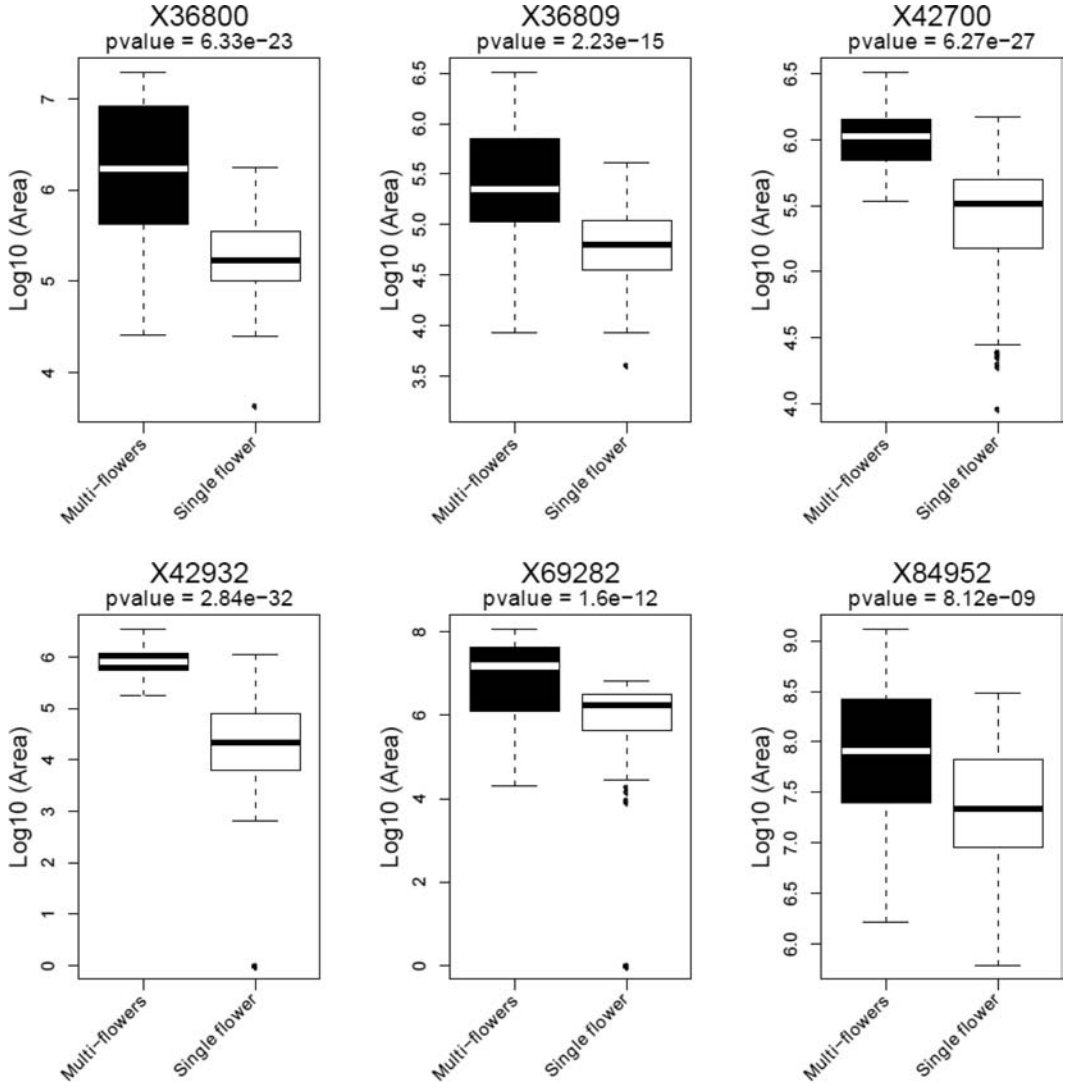

**Figure 4.** Box-plot of the six features of the most significance from PLS-DA. The thick line corresponds to the median. The box corresponds to the first and third quartiles. The whiskers represent 1.5 times the interquartile range. The outliers are marked by dots. Names of molecules putatively identified: X36800, methyl 2-(2-ethoxyacetamido)-4-methylpentanoate; X36809, methyl 2-(2-ethoxyacetamido)-2-methylpentanoate; X42700, *N*-D-glucosylarylamine; X42932, piscidic acid; X69282, flavone with ramification C18H16O8; X84952, lunarine.

**Table 3. Significant Features for the Discrimination between Single-Flower and Multifloral Honey Samples**

| feature | *m/z* | RT (min) | interpretation | ID status[a] |
|---|---|---|---|---|
| X36800 | 232.15433 | 5.5 | methyl 2-(2-ethoxyacetamido)-2-methylpentanoate or methyl 2-(2-ethoxyacetamido)-4-methylpentanoate | a, d |
| X36809 | 232.15433 | 5.7 | methyl 2-(2-ethoxyacetamido)-2-methylpentanoate or methyl 2-(2-ethoxyacetamido)-4-methylpentanoate | a, d |
| X42700 | 256.11795 | 1.6 | *N*-D-glucosylarylamine | a, d |
| X42932 | 257.0654 | 3.8 | piscidic acid | a, d |
| X69282 | 361.09179 | 11 | flavone with ramification $C_{18}H_{16}O_8$ | a, d |
| X84952 | 438.23873 | 7.9 | lunarine | a, d |

These molecules enable discrimination between multifloral and single-flower honeys and could be used for fraud detection (i.e., selling of multifloral honeys instead of single-flower honeys) after confirmation studies. Indeed, these are preliminary results based on information indicated on labels. Additional data mining procedures should be developed to improve these results, and confirmatory studies have to be undertaken, based on confirmation of floral origins of honey by melissopalinological, sensory, or chemical analyses.

In conclusion, this study demonstrates that LC-HRMS and LC-HRMS/MS associated with "metabolomics like" data mining tools are versatile tools allowing both target and global analyses for a better characterization of food matrices by enabling (i) conventional multiplexed and targeted analyses of xenobiotics, (ii) the detection of untargeted and unknown chemical contaminants, and (iii) the detection of metabolites useful for the characterization of food matrices. This was achieved by performing a proof-of-concept study on honey samples. Our results for a panel of 76 honeys showed that at least 1 of the 83 targeted pollutants was detected in 74 of the 76 honeys and that an average of 5 xenobiotics were found per

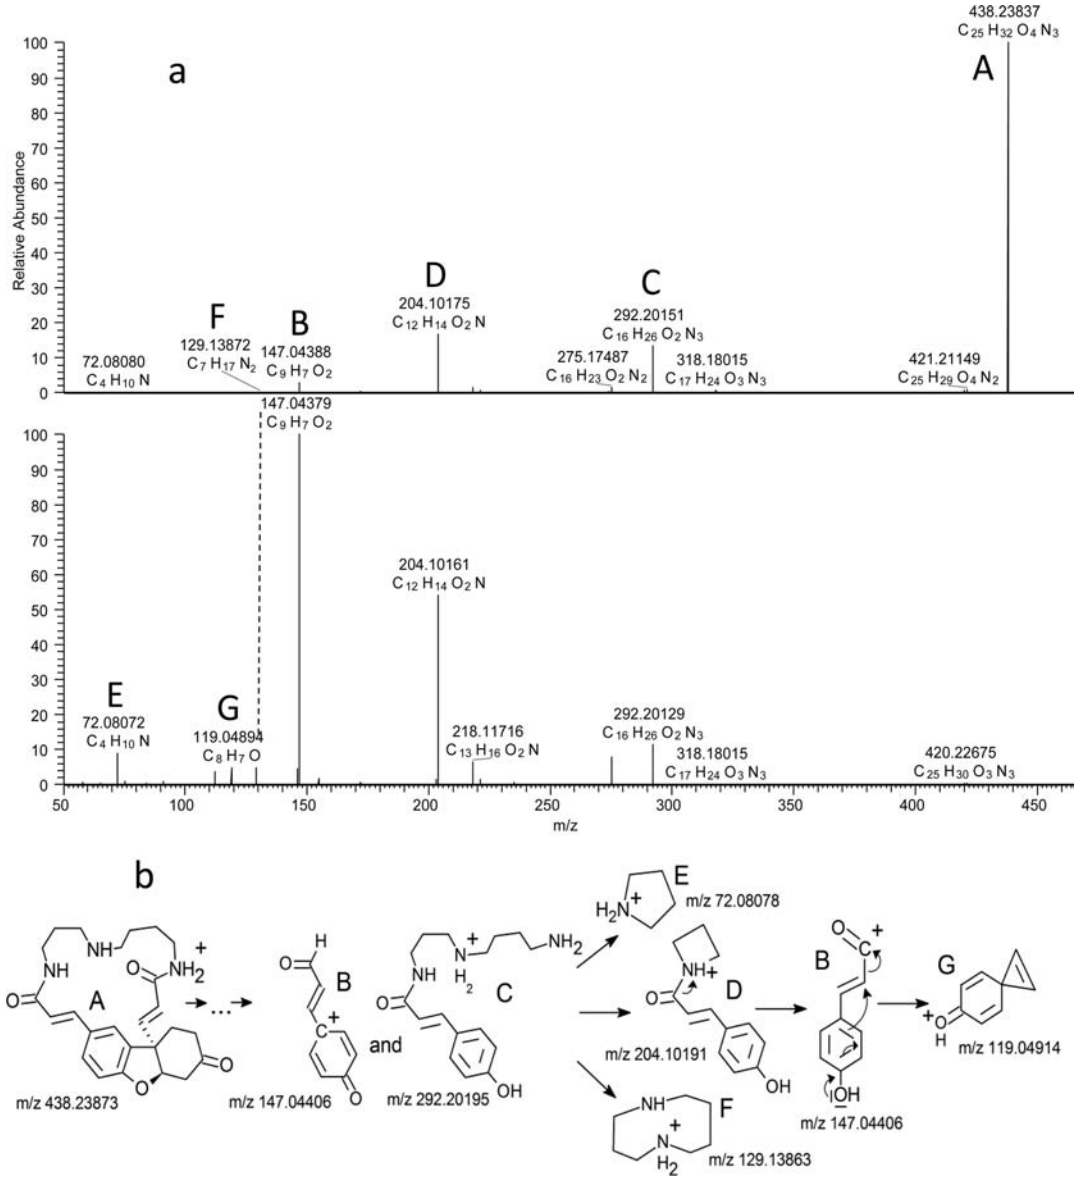

**Figure 5.** Characterization of lunarine from a honey sample: (a) CID spectrum of protonated variable X84952 annotated as lunarine recorded in HCD mode under (a) 20% and (b) 40% normalized collision energies; (b) summary of the proposed formal mechanism of fragmentations for lunarine (a complete scheme is available as Supporting Information, Figure 6s).

honey, with concentrations below the regulatory limits. Multivariate statistical analyses performed on analytically relevant features discriminated honey samples according to their floral origin. The data mining procedure also highlighted the presence of 12 unknown chlorinated chemicals in honey samples. One of these compounds was present in 4 lavender honeys and was formally identified as 2,6-dichlorobenzamide (a metabolite of dichlobenil, a herbicide that was widely used in lavender plantations before 2010).

Such an approach could be applied to any other food matrix to build (i) spectral databases of metabolites and pollutants to improve data set annotation and compound identification and (ii) metabolite fingerprint databases related to any given food matrix that could be coupled with data mining tools to highlight the presence of unexpected compounds. However, this requires the development of standardization and normalization tools to handle batch-to-batch variations of signal intensities and chromatographic retention times and also the analysis of a large number of samples to build a robust model. Furthermore, and as emphasized by our results, the characterization of untargeted and unknown chemicals by using MS and CID information remains highly challenging, but informatics tools such as in silico fragmenters and software for fragment ion prediction[50−53] that could be combined with other physical−chemical properties such as retention time index or octanol−water partitioning coefficients[54] could be of value to address this issue.

The products selected to implement the pesticide impurities detection program in Greece include both solid and liquid formulations. Initial screening of formulated pesticide products revealed the presence of carbaryl in copper oxide formulation. Carbaryl (1-naphthyl-*N*-methylcarbamate) is a widely used highly effective carbamate insecticide, with both agricultural and residential/domestic uses. However, it poses a potential hazard for health due to its relatively high acute toxicity.[12]

For the quantitative determination of carbaryl residues in plant matrices, soil, and water, several sample preparation methods have been developed, depending on the matrix used. For pesticide formulations liquid−liquid extraction (LLE) is the easiest and most common procedure followed by many pesticide laboratories. Conventional high-performance liquid chromatographic methods (HPLC) using reversed phase C18 columns have been extensively used with aqueous−organic mobile phases containing various proportions of acetonitrile, methanol, and methanol/acetonitrile in isocratic or gradient elution and UV, electrochemical, and fluorescence detection. Liquid chromatography with ion trap mass spectrometry and GC-MS were also used in multiresidue methods for quantitation of carbaryl in fresh fruit and vegetable samples. The typical limits of detection achieved were 0.01−0.02 mg/kg in plant matrices,[13,14] 0.2−5 μg/L in water,[15−17] and 0.15−0.64 μg/kg in soil[18−20]

Nowadays, the online combination of high-performance liquid chromatography and mass spectrometry (LC-MS) or tandem mass spectrometry (LC-MS/MS) holds a significant position in the analysis of contaminants and pesticides, in particular, because these methods provide unambiguous identification of thermally labile and polar pesticides at trace levels. Interfaces for LC-MS such as electrospray ionization (ESI) and atmospheric pressure chemical ionization (APCI) have been important tools in environmental analytical chemistry, especially in the area of pesticide analyses in soil and water. Recent developments in instrumentation made more readily available the high-resolution mass spectrometer (e.g., QTOF-UHPLC systems) with ≥10000 resolution. These instruments are ideal for the detection and identification of unknown substances and will have wide application in pesticide formulation control in the future.

Thus, a logical strategy is first to inject a diluted solution of the pesticide formulation to the GC-MS system, because the number of peaks eluting from the system can be assessed and possibly identified with existing libraries and then ideally confirmed. The next step is to use HPLC analysis coupled with mass spectrometry to incorporate thermally labile compounds that are not stable under GC conditions.

The aim of this work is to illustrate our testing strategy using as an example the determination of a trace amount of carbaryl (organic contaminant) in copper oxychloride solid pesticide formulation including the development and full validation of the method based on HPLC-DAD and confirmation of the identity of the compound with HPLC-PDA-ESI-MS.

## MATERIALS AND METHODS

**Working Standard Solutions and Sample Preparation.** An analytical standard of carbaryl (99.8%) was purchased from Sigma-Aldrich (Steinheim, Germany). HPLC grade water, acetone, and methanol were obtained from Fischer Scientific (USA) and LC-MS water and methanol from Merck (Germany). The stock solution of carbaryl (1000 μg/mL) was prepared in acetone. For GC-MS all solutions used for verification purposes were prepared in acetone as well. All working solutions used for method validation in the HPLC part were prepared in methanol (HPLC grade). Samples of two different inorganic copper oxychlorides formulated as wettable powder were obtained from the Greek market.

The GC-MS analysis was performed on a Chromtech Evolution MS/MS triple-quadrupole mass spectrometer built on an Agilent 5975 B inert XL EI/CI MSD system. Samples were injected with a Gerstel MPS-2 autosampler using a 10 μL syringe. Separations were performed on a DB-5MS 30 m × 0.25 mm × 1.0 μm column (J&W, Folsom, CA, USA). Helium was used as the carrier gas at a flow rate of 1.2 mL $min^{-1}$. Briefly, the oven temperature was initially programmed to 45 °C. The temperature was increased to 130 °C at 25 °C/min and held for 2 min. The temperature was further increased to 180 °C at 12 °C/min, to 240 °C at 7 °C/min, and finally to 320 °C at 10 °C/min, which was held for 2 min. The injector, MS transfer line, and MS heater temperatures were maintained at 250 °C. The mass spectrometer was operated in the full scan data acquisition mode. The transfer line, manifold, and source of ionization temperatures were 250, 40, and 230 °C, respectively. The electron multiplier voltage was set at 2000 V. The total GC analysis time was 44.85 min, and carbaryl eluted at 11.05 min.

For the HPLC-DAD method 10 matrix-matched solutions were freshly prepared by spiking copper formulation product (with no organic impurities present at the retention time of carbaryl) performed in such way to obtain concentrations of 0.2, 0.4, 1, 2, 4, 8, 12, 16, 20, and 200 μg/g formulated product. A similar 10 solutions were prepared for the HPLC-MS method, at a concentration range from 0.1 to 20 μg/g formulated product.

A representative pesticide formulation subsample of 5 g was placed into a 100 mL glass volumetric flask with methanol. The sample was pretreated in an ultrasonic bath, to ensure complete dissolution of organic components, for 15 min. The sample solution was filtered through a 0.45 μm nylon filter membrane and/or centrifuged (Heraeus Labofuge 400R Thermo Electron Corp., 5 min, 2000 rpm) prior to injection of the solution into the HPLC column.

**High-Performance Liquid Chromatography.** The HPLC system used was a Shimadzu UFLC instrument, equipped with a column oven (CTO-20A), a diode array detection system (SPD-M20A), a degasser (DGU-20As), and an autosampler (Sil-20AC) and connected to a reverse-phase Nucleosil C18 column (250 mm × 4 mm × 5 μm, Macherey-Nagel). The analysis was carried out using, as mobile phase, an isocratic mixture of methanol/water 70:30. The mobile phase was filtered and degassed prior to use. The detection wavelength was set at 220 nm. The flow rate of the mobile phase was maintained at 1.0 mL $min^{-1}$, which provided a pressure of 148 bar. System control and data analysis were carried out using LC LabSolution software (Shimadzu). The temperature of the column was maintained at 40 °C during all runs, and the injection volume was 10 μL. The total run time was 10 min. The retention time of carbaryl was 4.9 min.

**Liquid Chromatography Coupled with Diode Array and Mass Spectrometry.** Carbaryl presence was confirmed using HPLC-DAD-ESI-MS. A Shimadzu LCMS-2010 EV liquid chromatograph−mass spectrometer together with a SIL-20A prominence autosampler and an SPD-M20A diode array detector was used with LC-MS solution version 3.0 software. The latter was coupled in series with a mass selective detector equipped with an atmospheric pressure ionization source usable as either ESI interface. The LC separation was achieved on a Shim-Pack XR-ODS 2.2 μm, 100 × 4.6 mm i.d.. chromatographic column using the isocratic mobile phase of methanol/water 70:30 with the addition of formic acid (0.1%) in the aqueous phase to promote ionization of carbaryl molecule. The flow rate was 0.5 mL $min^{-1}$. The identification of carbaryl (4.20 min, retention time) was achieved by the HPLC-ESI-MS system functioning in the positive ionization mode. Full scan and selected ion monitoring mode (SIM mode) were applied, and the characteristic ions at 145 and 202 amu were observed (Figure 2).

## RESULTS AND DISCUSSION

In the presented work, the first step of the screening procedure revealed the presence of carbaryl in the copper oxychloride formulation (see full scan MS chromatogram, Figure 1).

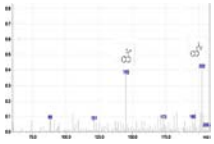

**Figure 1.** Full scan mass spectrum peak eluting at 4.2 min attributed to carbaryl (diluted pesticide formulation).

Because carbaryl is thermally labile[21] and decomposes to α-naphthol either in the injector or additionally during elution, it was decided to determine its concentration in the formulations by HPLC under the conditions described above (Figures 2−4). Additionally, maximum information was gained through the use of HPLC coupled with mass spectrometry (Figures 5 and 6) and PDA (Figure 7).

If a potential carbaryl peak was detected in the copper oxide pesticide formulations analyzed with the optimum chromatographic conditions described under High-Performance Liquid Chromatography (Figure 1), that peak was then identified by full scan mass spectrometry with HPLC-PDA-ESI-MS (Figures 5 and 7) and further quantified with the use of both techniques.

The only peak that was assessed with regard to its mass spectrometry profile was the peak eluting at 4.9 min in the HPLC (or at 4.2 min in LC-MS method) because the other two eluting peaks (1.6 and 2.3 min) are lower than the 2.91 min void time of the column.

With regard to the sample preparation step and its impact on analyte retention, the critical step is purification of the sample prior to injection. In this context both nylon filtering and centrifugation showed similar GC-MS chromatograms, indicating that for GC-amenable compounds no significant alteration of their composition was evidenced.

**Validation of the HPLC LC-PDA-ESI-MS Procedure.** For the validation of the method, the following parameters were determined: linearity, repeatability, reproducibility, limit of detection (LOD) and limit of quantification (LOQ), recoveries, and matrix-dependent variations as is established by the EU guidelines for HPLC-UV and LC-MS methods.[22,23] Linearity and matrix effect were assessed by analyzing standard solutions and matrix-matched standards to cover the expected range of carbaryl concentrations as an impurity in commercial formulations. The results are presented in Table 1. Both HPLC and HPLC-MS provided linear responses over the mentioned concentration ranges with excellent correlation coefficient ($r^2$) values. No matrix effect was observed.

Accuracy was assessed after performing a recovery study with both methods. Recoveries and repeatability relative standard deviations ($RSD_r$) with the HPLC method were, respectively, in the range of 89.2−102.1% and 5.10, 3.13, and 2.45% at the three concentration levels of 2, 16, and 200 μg/kg. In the case of LC-MS the recoveries and RSD values were in the range of 91.1−102.9% and 3.12, 4.11, and 4.77%, respectively, at 0.4, 4, and 16 μg/g spike levels. The Dixon test revealed that there was no outlier in the recovery values obtained by both methods.

For reproducibility studies with both methods, five replicate determinations were performed on five different days at three standard concentration levels (2, 16, and 200 μg/g, HPLC method and 0.4, 4, and 16 μg/g, LC-MS method) on one pesticide lot. The $RSD_r$ values for reproducibility were 2.38, 4.1, and 4.34%, respectively. In the LC-MS method, the $RSD_r$ values for reproducibility were 4.05, 3.65, and 2.48%, respectively. To calculate the homogeneity of the variances of the repeatability and reproducibility RSDs, the Cochran test was applied, which indicated no outliers. The LOD and LOQ were determined as 3 times the standard deviation of the blank (matrix without analyte) and 10 times the standard deviation of the blank (formulation sample not containing carbaryl). LOD and LOQ values are presented in Table 1, and the respective chromatograms at LOQ level are shown in Figures 4 and 6.

The above results demonstrate the reliability and accuracy of the measurement of carbaryl in commercial pesticide formulations and indicate an absence of systematic error.

**Chromatographic Peak Confirmation.** It is important to point out that the same sample solutions were used for both HPLC-DAD and LC-PDA-MS systems, simultaneously, to ensure the presence of carbaryl in the samples analyzed.

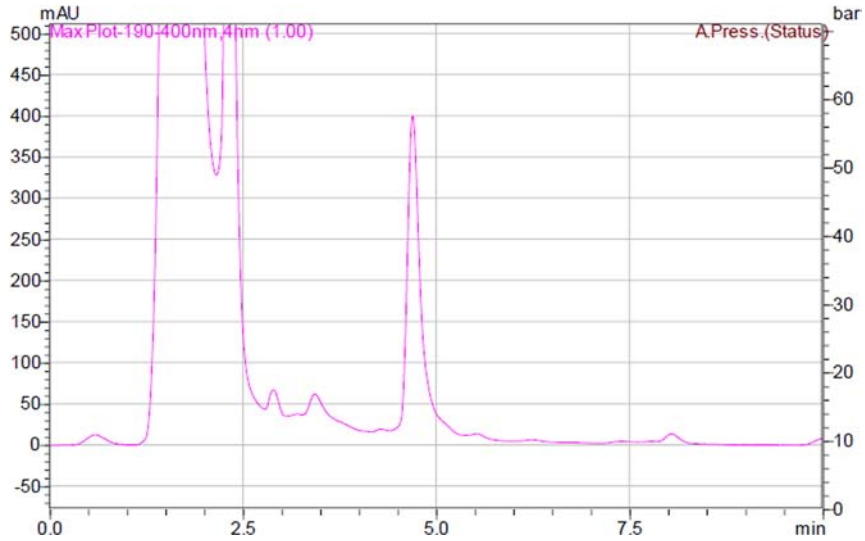

**Figure 2.** HPLC-PDA maximum plot chromatogram of the diluted pesticide formulation.

dx.doi.org/10.1021/jf504729g | J. Agric. Food Chem. 2014, 62, 11347−11352

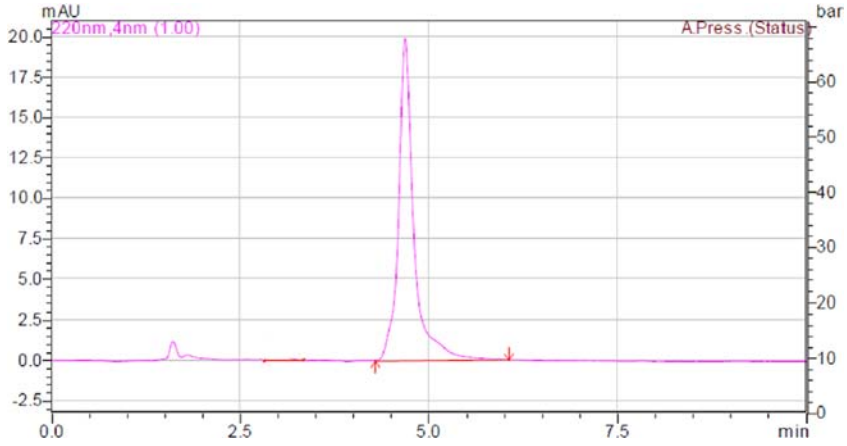

**Figure 3.** HPLC-UV chromatogram of carbaryl analytical standard.

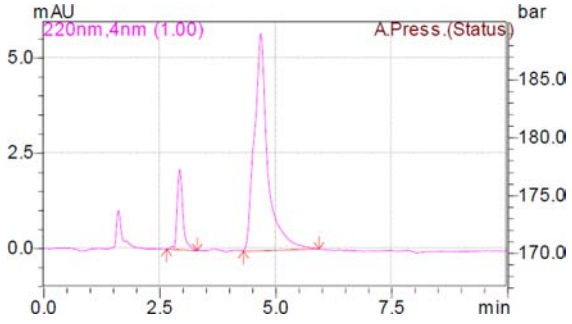

**Figure 4.** HPLC-UV chromatogram of carbaryl in a sample extract spiked at LOQ level.

Specificity is a measurement of the degree of interference in the analysis of pesticide formulation. The chromatographic peak was identified/confirmed according to molecular masses obtained by LC-ESI-MS in the positive ionization mode. The SIM chromatogram at 4.2 min verified the presence of two specific anions that characterize the molecule.

The ions obtained by this method are typical and previously reported by other research teams.[13,24] Thus, $m/z$ 202 corresponds to $[M + H]^+$, whereas $m/z$ 145 corresponds to $[M - 56]^+$.

**Comparison with Other Analytical Studies.** The advantage of the proposed methodology is the quantitative and sensitive determination of carbaryl in pesticide formulations. The extraction of the analyte from a formulation product assisted with ultrasonication resulted in repeatable and reproducible results. Considering the need to test for organic impurities in inorganic formulations, the presented method is an efficient solution for the analysis of carbaryl in such formulations. The principle of the stepwise procedure developed can be applied for testing other formulations as well.

Another sensitive and selective way to detect carbaryl would be using a fluorescence detector. An indicative work in this field was published in 2011.[18] However, the fluorescence method

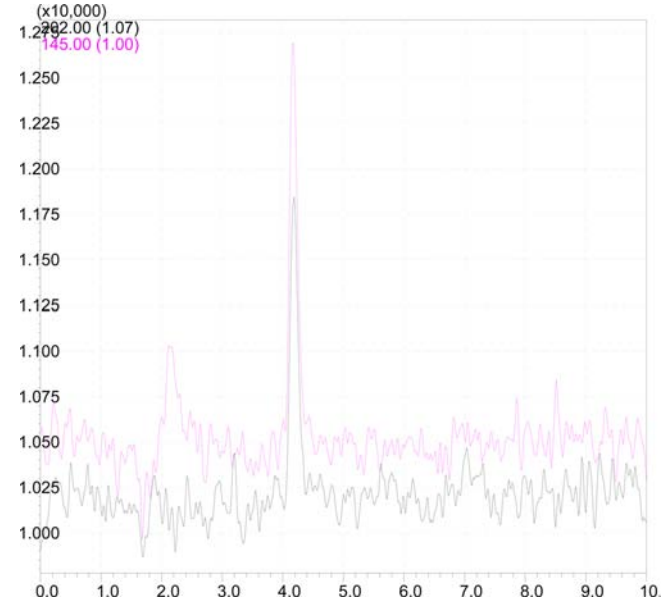

**Figure 6.** SIM chromatogram of carbaryl in sample extract spiked at LOQ level.

dx.doi.org/10.1021/jf504729g | J. Agric. Food Chem. 2014, 62, 11347−11352

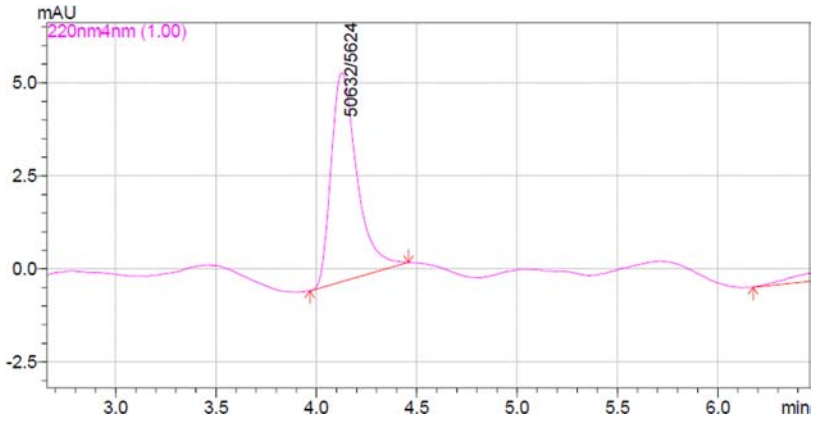

**Figure 7.** UV chromatogram of carbaryl of sample extract spiked at 220 nm using LC-PDA-ESI-MS.

**Table 1. Analytical Performance of HPLC and HPLC-MS Methods**

| method | linear range ($\mu g/g_{form}$) | LOD ($\mu g/g_{form}$) | LOQ ($\mu g/g_{form}$) | calibration equation | correlation coefficient, $r^2$ |
|---|---|---|---|---|---|
| HPLC-DAD | 0.2−200 | 0.13 | 0.42 | $y = 211948x + 47423$ | 0.9974 |
| HPLC-ESI-MS | 0.1−20 | 0.05 | 0.18 | $y = 371278x - 1921.1$ | 0.9995 |

has some drawbacks related to (1) time-consuming postcolumn derivatization, (2) time-consuming sample preparation, and (3) the lack of confirmatory information from the analytical results.

The testing strategy proposed in this paper is a novel and logical combination of existing chromatographic techniques, which were fully validated for this particular purpose. Therefore, it could be used to monitor the purity profile of pesticide formulations.

**Contamination of Real Samples and Preliminary Risk Assessment.** Our procedure was applied for the determination of the concentration of carbaryl in formulations. Specifically, two formulations of copper oxychloride from the Greek market were received and analyzed for the presence of carbaryl, and one of them contained carbaryl at a concentration of 12.4 mg/kg formulation. This concentration clearly demonstrates that cross-contamination occurred probably in the production−assembly line, because it is far below the usual concentration of carbaryl in formulations with copper oxychloride.[25]

In the presented case carbaryl's concentration was determined at 12.4 mg/kg formulation. The MRL of carbaryl varies between 0.01 and 0.8 mg/kg.[26] Assuming the worst scenario of copper oxychloride being applied at double the suggested rate (8 kg/ha) and all pesticide being deposited on grape bunches harvested with a yield of 10 tons/ha on the day of treatment, the resulting carbaryl residue would be 0.0012 mg/kg. It would not be detectable and would not cause any risk for consumers or result in MRL violation. However, there might be some adverse health effects for the pesticide applicators. The latter scenario is of importance considering that users of plant protection products tend to be less careful with inorganic pesticides, and thus unintended exposure to an acute toxic substance (carbaryl in this case) could take place.

In this case study the presence of carbaryl was verified in an inorganic pesticide formulation, indicating cross-contamination in the production. In this regard, it is evident that the combination of various chromatographic techniques and detection methods should be employed in the portfolio of analytical laboratories aiming to detect impurities and ensure the quality of pesticide products.

Unexpected impurities or contaminations in pesticides might constitute a hazardous threat to the environment and human health. In this regard authorities should encompass regular monitoring applying specific techniques to detect the presence of harmful impurities. It is expected that the presented procedure will be used as a routine approach in laboratories involved in pesticide formulation analyses. This strategy will be strengthened by a complementary LC-MS screening approach that is currently being pursued in our laboratories. Regular monitoring of contaminants in pesticide formulations followed by appropriate regulatory actions could ideally prevent or substantially reduce counterfeiting and would ensure proper quality of plant protection products, minimize the risk for pesticide applicators and residents, and protect human health and the environment.

## RESULTS AND DISCUSSION

**Photoisomerization with Various Sensitizers.** To isomerize (*all-E*)-carotenoids to *Z*-isomers, heat treatment has been the typical method used so far.[3,7,11] Very recently, we reported a detailed study on the thermal isomerization of high-purity (*all-E*)-lycopene (≥99%), which showed that heating (*all-E*)-lycopene at 50 °C in hexane produced ca. 30% (5*Z*)-lycopene as a main product, whereas the use of benzene generated ca. 20% (13*Z*)-lycopene.[12] On the other hand, there are some reports on the photosensitized *E*/*Z* isomerization of carotenoids, an alternative method to thermal processing, which has been confined to (*all-E*)-*β*-carotene.[13,14] Under these circumstances, we performed the photoisomerization of (*all-E*)-lycopene to the corresponding *Z*-forms in acetone in the presence of four kinds of sensitizers using filtered light. After irradiation with 480−600 nm light for 60 min, the concentrations of undecomposed lycopene remaining in solution were determined to be $1.5 \times 10^{-5}$ mol/L (with MB), $1.7 \times 10^{-5}$ mol/L (with chlorophyll *a*), and $1.7 \times 10^{-5}$ mol/L (without sensitizer) under ≥600 nm light irradiation; $0.7 \times 10^{-5}$ mol/L (with erythrosine), $1.0 \times 10^{-5}$ mol/L (with RB), and $1.9 \times 10^{-5}$ mol/L (without sensitizer) by the HPLC analysis; typical chromatograms are shown in Figure 1. The total amounts of *Z*-isomers relative to the remaining lycopene after the reaction were 57.4, 51.3, 47.7, and 46.4% with MB, chlorophyll *a*, erythrosine, and RB, respectively (Table 1). On the other hand, the blank tests irradiated at the light regions more than 600 nm and between 480 and 600 nm without sensitizer resulted in *Z*-isomer contents of only 7.4 and 7.7%, respectively. To the best of our knowledge, photoisomerization of (*all-E*)-lycopene was previously conducted by Stahl et al.[15] and Lee and Chen.[16] However, Stahl et al.[15] performed the iodine-catalyzed isomerization; the iodine is inedible, and the reaction mechanism would contain a radical process principally.[17] Then, Lee and Chen[16] carried out the isomerization of (*all-E*)-lycopene by direct light irradiation for 60 min, obtaining only a few percent of *Z*-isomers. Our results obviously indicated that the use of sensitizer and filtered light resulted in an accelerated isomerization of (*all-E*)-lycopene to *Z*-isomers. MB was the most efficient sensitizer for the isomerization among the reagents tested; however, it is not approved for use in food processing. In contrast, chlorophyll *a*, erythrosine, and RB are usable in such industrial fields, and therefore erythrosine appears to be the most suitable sensitizer for (*all-E*)-lycopene isomerization.

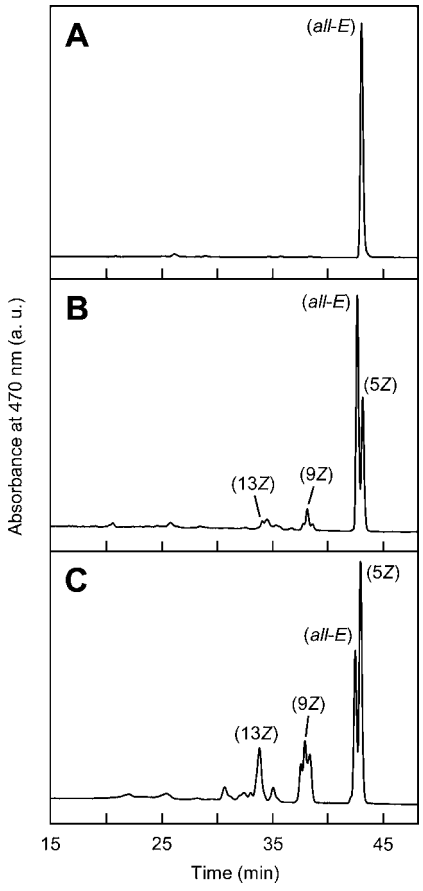

**Figure 1.** Reversed-phase HPLC charts of (A) (*all-E*)-lycopene and photoirradiated lycopene with rose bengal (RB) as a sensitizer in (B) acetone and (C) hexane at 32 °C for 60 min. Unidentified peaks contain multi-(*Z*)-isomers as well as other mono-(*Z*)-isomers.

As for the individual *Z*-isomers generated, several *Z*-isomers of lycopene were observed in the HPLC chart in addition to (5*Z*)-, (9*Z*)-, and (13*Z*)-lycopene (Figure 1B), which are predominantly contained in processed food.[7] In all cases with the above sensitizers after 60 min of irradiation, (5*Z*)-lycopene showed the greatest increases to 39.9, 31.7, 37.7, and 29.9% relative to the remaining lycopene with MB, chlorophyll *a*, erythrosine, and RB, respectively (Table 1). On the other hand, (9*Z*)-, (13*Z*)-, and other *Z*-isomers increased to <10% with each sensitizer under the same irradiation duration. (5*Z*)-Lycopene exhibits higher bioavailability[7] and antioxidant activity[10] compared to (*all-E*)-lycopene and possibly to (9*Z*)- and (13*Z*)-lycopene. In addition, (5*Z*)-lycopene is estimated to be thermodynamically more stable than (9*Z*)- and (13*Z*)-lycopene according to the results of quantum chemistry calculations.[18] Therefore, we believe that photosensitized isomerization is an effective method to produce lycopene isomers with sophisticated functionalities and greater storage stability among the *Z*-isomers.

**Time Course of the Photosensitized Isomerization of Lycopene and Solvent Effects on the Content of *Z*-Isomers.** To determine the optimum conditions for photosensitized isomerization of (*all-E*)-lycopene, the sensitizers erythrosine and RB, which are approved for use in food processing and have good isomerization efficiency, as mentioned above, were used. The time course examinations of photosensitized isomerization of lycopene were carried out with the sensitizers in acetone (Figure 2A,B). The total amount of *Z*-isomers of lycopene with erythrosine was slightly greater than with RB, and (5*Z*)-lycopene constituted the majority of *Z*-isomers with both sensitizers. Using erythrosine, (9*Z*)-lycopene, a kinetically preferable isomer, initially emerged and likely reversed to the (*all-E*)-form with time.

Next, solvent effects on isomerization with the two sensitizers were investigated using ethyl acetate (Figure 2C,D) and hexane (Figure 2E,F), both of which are approved for use in the food, drink, and dietary supplement manufacturing industries. After irradiation in ethyl acetate for 60 min, the concentrations of lycopene remaining in solutions were $0.6 \times 10^{-5}$ mol/L with both erythrosine and RB; on the other hand, relatively higher levels of lycopene were obtained in hexane: $1.7 \times 10^{-5}$ mol/L with erythrosine and $1.4 \times 10^{-5}$ mol/L with RB. The total amounts of *Z*-isomers relative to the remaining lycopene after 60 min irradiation were 80.4, 67.6, and 47.7% in hexane, ethyl

**Table 1. Photoisomerization of (*all-E*)-Lycopene to Individual *Z*-Isomers with Methylene Blue (MB), Chlorophyll *a*, Erythrosine, and Rose Bengal (RB) as Sensitizers**

| | | content[a] (%) | | | | |
|---|---|---|---|---|---|---|
| sensitizer | irradiation (nm) | total *Z*-isomers[b] | 5*Z* | 9*Z* | 13*Z* | other *Z*[c] |
| MB | ≥600 | 57.4 ± 3.8 | 39.9 ± 3.3 | 7.1 ± 0.6 | 3.6 ± 0.2 | 6.8 ± 1.3 |
| chlorophyll *a* | ≥600 | 51.3 ± 5.9 | 31.7 ± 2.8 | 7.1 ± 1.3 | 3.4 ± 0.6 | 9.1 ± 3.8 |

[b]Total amount of *Z*-isomers of lycopene. [c]Sum of *Z*-isomers of lycopene other than (5*Z*)-, (9*Z*)-, and (13*Z*)-forms. [d]Not detected.

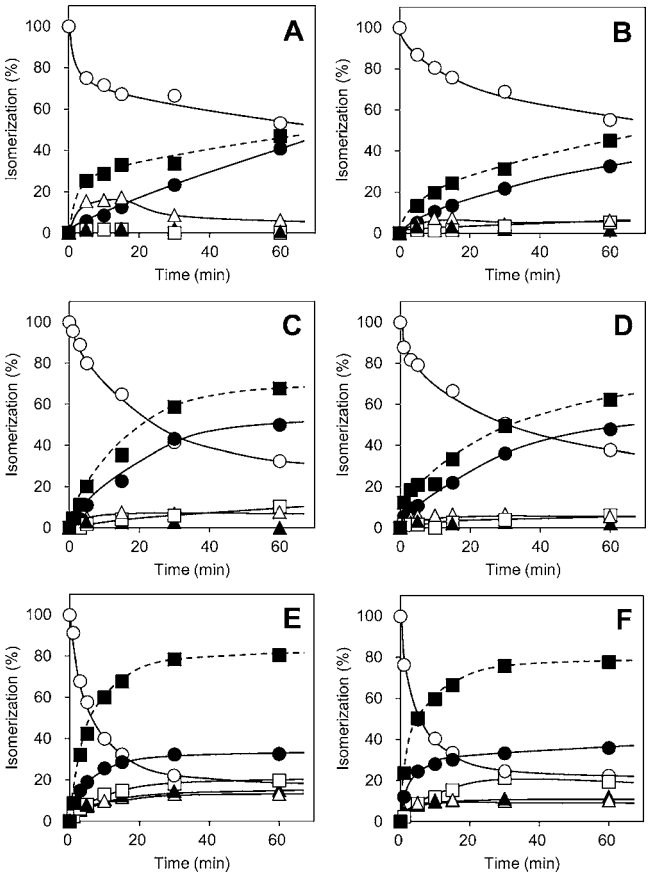

**Figure 2.** Photoisomerization of (*all-E*)-lycopene to individual *Z*-isomers in (A, B) acetone, (C, D) ethyl acetate, and (E, F) hexane with (A, C, E) erythrosine and (B, D, F) RB as a sensitizer under 480−600 nm light irradiation. Changes in the isomer content are presented relative to the total amount of lycopene isomers at each sampling point: (○) (*all-E*)-lycopene; (●) (5*Z*)-lycopene; (△ (9*Z*)-lycopene; (▲) (13*Z*)-lycopene; (□) other *Z*-isomers including those unidentified; (■) total amount of *Z*-isomers.

acetate, and acetone, respectively (Figure 2E,C,A), and a similar tendency was also observed with RB (Figure 2F,D,B). As for the individual *Z*-isomers, (5*Z*)-lycopene was again predominantly produced in each condition and both (9*Z*)-lycopene and (13*Z*)-lycopene exceeded 10% by content after 60 min of irradiation with erythrosine (Figure 2E) or RB (Figures 1C and 2F) in hexane. In addition, the total amount of other *Z*-isomers except for (5*Z*)-, (9*Z*)- and (13*Z*)-lycopenes was also markedly increased in hexane, 19.7 and 19.4% with erythrosine and RB, respectively. These results demonstrate that the use of a less polar solvent not only accelerated *Z*-isomerization but also was effective in suppressing the degradation of lycopene. To explain the higher rate of the photosensitized isomerization of (*all-E*)-lycopene to the *Z*-isomers, it could be reasonable to investigate the energy gap between the photosensitizer in an excited triplet state and the (*all-E*)-lycopene in a triplet state.[13,14,19]

In conclusion, the photoisomerization of (*all-E*)-lycopene to *Z*-isomers with sensitizer and filtered light has proven to be more effective than thermal isomerization. In particular, the reaction condition with erythrosine in hexane under 60 min of irradiation at wavelengths between 480 and 600 nm was the best method to enrich the content of *Z*-isomers and suppress the degradation of lycopene. These findings will contribute to the development of facile isomerization of (*all-E*)-lycopene to *Z*-isomers in the fields of food, drink, and dietary supplement manufacturing.

obsogenic nature of the foods.[8] To reduce the high calorie content, researchers have been trying to develop water-in-oil (cocoa butter) emulsion gels.[9] These emulsion gels can be used as chocolates or suppositories. Gelatin is a good emulsifying and gelling agent, often used in the preparation of emulsion gels. Gelatin improves the processing of the emulsion when low fat or high aqueous phase volume is needed.[10] Gelatin improves the stability of the emulsions by preventing coalescence of the dispersed aqueous phase. In addition to these properties, gelatin gel has a similar "melt in the mouth" behavior (melting point of ~32 °C) as that of fats.[10] Yet limited research has been carried using gelatin-based cocoa butter emulsion gels.[10,11] On the other hand, to the best of our knowledge, gelatin-based mango butter-based emulsion gels as the cocoa butter equivalents have not been investigated.

The aim of this work is to check the usage of mango butter emulsion gels as cocoa butter equivalents. The emulsion gels were critically evaluated by performing microscopy, XRD, DSC, and mechanical studies.

## MATERIALS AND METHODS

**Materials.** Cocoa butter and mango butter were procured from NV Organics (P) Ltd., New Delhi, India. Span 80 (Sorbitan monooleate) was purchased from Himedia, Mumbai, India. Metronidazole (MZ) was a kind gift from Aarthi drugs, Mumbai, India. Double distilled water (DW) was used throughout the study. All of the experiments were performed in triplicate.

**Preparation of Emulsion Gels.** Emulsions of cocoa butter and mango butter were prepared by the hot emulsification method.[12] Span 80 was chosen as the emulsifier as it is a FDA (Food and Drug Administration, US) approved nonionic and biocompatible surfac-

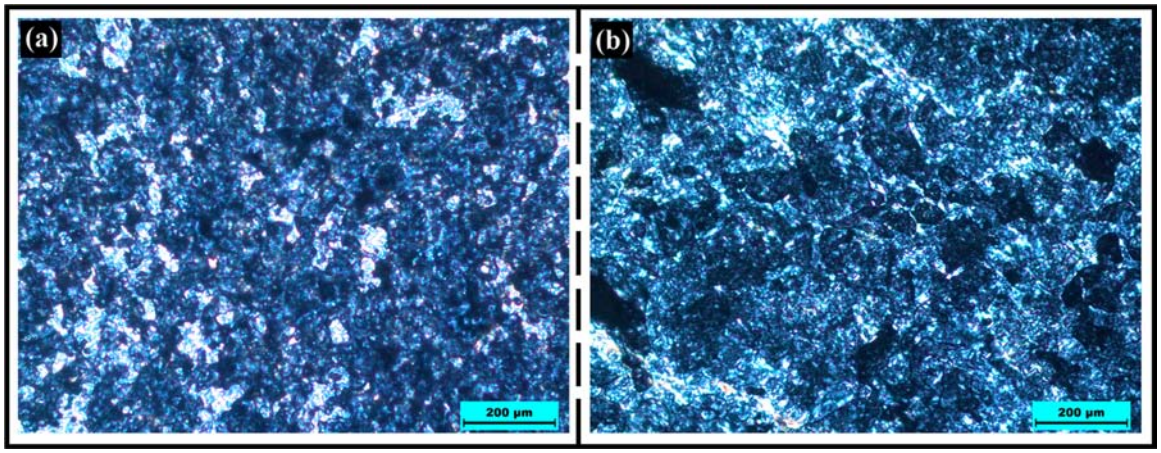

**Figure 2.** Polarized micrographs of (a) CG10 and (b) MG10.

tant.[13] Accurately weighed cocoa butter and span 80 were melted at 45 °C using a temperature-controlled water bath. The above mixture was homogenized for 5 min at 1200 rpm (45 °C) using an overhead stirrer (RQ-126/D, Remi Motors Ltd., India). Gelatin solution (20% w/w, 45 °C) was added drop-by-drop to the mixture and homogenized for another 15 min at the same temperature. The hot homogenized emulsion was poured into culture bottles (10 mL) and incubated at room temperature (25 °C) for 30 min to induce gelation. Mango butter-based formulations were also prepared in a similar fashion.

**Microscopic Studies.** Microstructure of the emulsion gels was observed using an upright bright-field microscope (Leica DM750 equipped with ICC50 HD camera, Germany) and polarized microscope (Leica DMLP attached with Leica DFC 295 camera, Germany). For bright field microscopy, molten emulsion gels were taken on a glass slide and visualized under the microscope. On the other hand, emulsion gels were made into a thin smear and visualized under the polarized microscope. Size distribution of the emulsion droplets was performed by image processing using National instrument vision assistant (NI vision assistant-2010, US) software.

**XRD Studies.** The physical nature of the emulsion gels was studied by X-ray diffraction (XRD) studies. A Philips X-ray diffractometer (Pananalytical, X-Pert Pro; Almelo, Netherlands) was used to study the polymorphism of the emulsion gels in their native state. Gels were spread over a glass plate and then subjected to X-ray analysis. X-rays of 1.54 Å were generated by a Cu K$\alpha$ source. The diffraction was measured in the 2$\theta$ range of 5−50°.

**DSC Studies.** The thermal properties, solid fat content (SFC), and crystallization behavior of the emulsion gels were examined by DSC studies using a differential scanning calorimeter (DSC-200 F3MAIA, Netzsch, Germany). Accurately weighed 10−15 mg of the formulations was taken in pure aluminum (Al) crucibles and hermetically sealed with pierced Al lids. The formulations were heated from 20 to 60 °C at 2 K/min and kept at 60 °C for 10 min to remove the crystal memory. The formulations then were cooled from 60 to 10 °C at 2 K/min, and the formulations were incubated at 10 °C for 1.0 h to allow isothermal crystallization. The analysis was performed under inert atmosphere using $N_2$ gas. The results were analyzed using the Netzsch-proteus software.

**Mechanical Analysis.** Mechanical properties of the emulsion gels were determined using a static mechanical tester (Stable Micro-systems, TA-HD plus, U.K.). To determine the strength, viscoelastic nature, and spreadability of the emulsion gels, uniaxial compression, stress relaxation, and spreadability experiments were conducted, respectively. Supporting Information Table S1 summarizes the details of the mechanical studies.

## ■ RESULTS AND DISCUSSION

**Preparation of the Emulsion Gels.** The molten fats appeared as pale yellow translucent liquids. Addition of gelatin solution resulted in the formation of milky white emulsions. Appearance of milky white color without any phase separation is an indication to the formation of emulsions.[14] After incubation at room temperature, the emulsions that failed to flow under gravity, upon inversion of the vials, were regarded as emulsion gels.[15] The stability of the emulsion gels was dependent on the type of the vegetable fat used. During preparation, cocoa butter emulsion gels were able to accommodate 70% (w/w) aqueous gelatin solution. On the other hand, only 35% (w/w) gelatin solution was accommodated within the mango butter-based emulsion gels. An increase in the aqueous proportion beyond 70% and 35% for cocoa butter and mango butter formulations, respectively, resulted in the phase separation. The pictographs of the cocoa butter and mango butter emulsion gels have been shown in Supporting Information Figures S1 and S2, respectively. The difference in the gelation properties of the vegetable fats can be attributed to the variation in the fatty acid compositions. The total unsaturated fatty acid content in cocoa butter is in the range of 36−43%, whereas in mango butter it is in the range of 43−59%.[6] Literature suggests that the crystallization efficiency of the fats depends on the proportion of the unsaturated fatty acids present.[16] This may be associated with the molecular geometry of the fatty acids. The tetrahedran bond angles of carbon enable the saturated fatty acids to arrange in linear and stack-wise fashion. On the other hand, the presence of double bonds (unsaturation) in carbon linkages leads to the bending of the fatty acyl molecules.[16] These molecules do not stack well and lead to weak intermolecular interactions, which, in turn, affect the crystallization process. As mango butter possesses a higher amount of unsaturated fatty acids than cocoa butter, the crystallization efficiency was found to be lower. The emulsion gels were stored at 4 °C and were stable for more than 12 months. Because mango butter formed stable emulsion gels up to MG35, we chose CG10, MG10, CG35, and MG35 as the representative formulations for further characterization.

**Microscopic Studies.** The microstructure of the emulsion gels showed evenly dispersed circular droplets of aqueous phase in the fat matrix (Figure 1). An increase in the droplet size was noticed with increase in the aqueous phase. Prevention of the droplets coalescence was responsible for the formation of such spatially arranged distinct droplets. Similar kinds of microstructures have been previously reported.[11,17] At higher water to fat ratio in cocoa butter emulsion gels (>70% (w/w) aqueous phase) and mango butter emulsion gels (>35% (w/w)

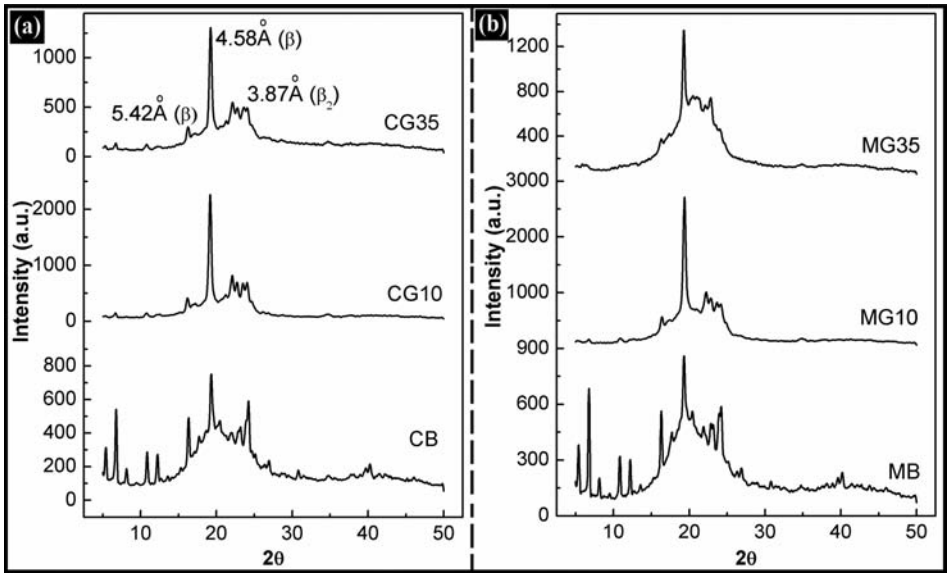

**Figure 3.** XRD profiles of (a) CB, CB-based gels and (b) MB, MB-based gels.

aqueous phase), crystallization of fats was not sufficient to prevent droplet coalescence. Hence, larger and nonuniform droplets were observed in the unstable emulsion gels (Supporting Information Figure S3). Formation of water-in-oil emulsion was confirmed by dilution test.[18] Both kinds of emulsion gels showed uniform dispersion within the oil phase and showed phase separation in water (Supporting Information Figure S4). This indicated the formation of water-in-oil type of emulsions.

Polarized light micrographs of the emulsion gels showed the presence of continuous crystalline network (Figure 2). Aqueous phase was dispersed as dark circles in the bright colored fat matrices of CG10 and MG10 (representative emulsion gels). The continuous crystalline network stabilized the emulsion by physically locking the dispersed phase.[11,18] Bright field micrographs of the molten emulsion gels showed dispersed water droplets within the fat continuous phase (Figure 1). Light micrographs of cocoa butter emulsions showed by Norton et al. (2012) also contained a similar kind of microstructure.[10] The presence of fat around the water droplets imparts microbiological and physical stability to the emulsion gels. The probability of microbial growth within the water droplets is minimized by completely isolating the aqueous phase from the environment. This helps in imparting microbial stability to the emulsion gels. The presence of emulsifiers affects the network crystallization. Hence, a high percentage of gelatin (20% (w/w)) solution was used in the study. High gelatin concentration enhances the rate of adsorption of the gelatin at the newly formed fat−droplet interface. Rapid gelatin adsorption enhances the gelatin membrane formation, thereby resulting in the decrease of the interfacial tension.[9] Lower interfacial tension prevented the coalescence of the droplets during the homogenization process and resulted in the formation of smaller droplets. In general, a narrow size distribution was observed in the formulations with lower aqueous proportion as compared to the formulations with higher proportions of the aqueous phase (Figure 1e). CG10 and MG10 had a narrow size distribution as compared to CG35 and MG35, respectively. The mean size of the droplets ($d_{32}$) was calculated using the following equation:

$$d_{32} = \sum n_i d_i^3 / \sum n_i d_i^2 \quad (1)$$

where $n_i$ is the number of droplets with diameter $d_i$.

The mean size of the droplets varied in the order of CG10 (15.2 $\mu$m) < CG35 (17.5 $\mu$m) < MG10 (19.63 $\mu$m) < MG35 (41.05 $\mu$m). The differences in the mean droplet size of the emulsion gels with the same water to fat ratio can be explained by the differences in the fatty acid composition of cocoa butter and mango butter. In general, long chain saturated fatty acids behave as solid at the fat−droplet interface, and the unsaturated fatty acids behave as liquid. Because the rate of crystallization of the unsaturated fatty acids at the fat−droplet interface is slower as compared to the rate of crystallization of the saturated fatty acids,[19] coalescence of the droplets might have led to the formation of the larger droplets in mango butter-based emulsion gels. Stearic hindrances associated with the unsaturated fatty acids slows the crystallization rate.[19] The average diameter ($d_{avg}$) of the droplets was calculated from Figure 1f (shown as dotted lines). The diameter of the 50% population of the droplets was considered as $d_{avg}$. The $d_{avg}$ values were in close proximity of the $d_{32}$ values.

**XRD Studies.** The XRD profiles of the emulsion gels and the vegetable fats have been shown in Figure 3. Literature suggests that cocoa butter and mango butter exist in four to six polymorphic forms.[6,20] The characteristic peaks ($d$-values: 3.79, 4.2 Å) corresponding to $\alpha$ polymeric state were not found in the XRD profiles of the vegetable fats and their corresponding emulsion gels.[21] Four characteristic $d$-values (3.7, 3.94, 4.58, and 5.42 Å), corresponding to the $\beta$ polymorphic state of the fatty acids, were observed both in the vegetable fats and in their emulsion gels.[21] Peaks at 19.3° and 16.3° 2$\theta$ corresponded to the $d$-values of 4.58 and 5.42 Å, respectively.[21,22] These peaks were conserved in both kinds of emulsion gels. This indicated that the stable polymorphic state ($\beta$) was retained by the emulsion gels. But their peak intensity was lowered as compared to the peaks of pure cocoa butter and mango butter. This suggested that the number of fatty acids present in $\beta$ polymorphic state might have been reduced and transformed to the other polymorphic states. The presence of a peak at 2$\theta$ 23.2° ($d$-value: 3.83 Å) indicated the presence of $\beta'_2$ and $\beta'_1$ polymorphic forms.[21] These peaks were retained in all of the

emulsion gels, and their intensity was not significantly changed. In general, $\beta'_2$ and $\beta'_1$ polymorphic states are intermediary polymorphic states during the conversion of $\alpha$ polymorphic fatty acids to the stable $\beta$ polymorphic fatty acids.[23,24] Because wide-angle X-ray scattering was performed, the peaks below 5° 2$\theta$ were not observed. Hence, confirmation for the existence of $\alpha$ polymorphic state could not be established. In general, tempering of the fats at high temperature leads to the polymorphic transition.[25] Keeping this in mind, emulsion gels were prepared by melting the fats at 45 °C, so as to minimize the tempering effects. As a result, minimal changes in the polymorphic state of the emulsion gels were observed.

Although the position of the peaks and the $d$-value of the $\beta$ polymorphic state were not significantly changed, the full width half-maximum (FWHM) values of the emulsion gels were altered (Table 2). The change in the fwhm values can be correlated to the change in the crystallinity of the emulsion gels. The change in the crystallinity was determined by calculating the crystal size ($D$) using the Debye−Scherrer equation:[26]

**Table 2. XRD Parameters of the Cocoa Butter, Mango Butter, and Emulsion Gels**

| sample | FWHM of peak at 19.3° 2$\theta$ | crystal size ($D$), nm |
|---|---|---|
| cocoa butter | 0.14 | 61.11 |
| CG10 | 0.22 | 38.9 |
| CG35 | 0.25 | 33.68 |
| mango butter | 0.16 | 53.5 |
| MG10 | 0.22 | 38.9 |
| MG35 | 0.26 | 32.71 |

$$D = \frac{K\lambda}{\beta \cos\theta} \tag{2}$$

where $K$ is the Scherrer constant or shape factor, 0.89 (as shape of the crystallite is unknown); $\lambda$ is the Cu K$\alpha$ wavelength, that is, 1.54 Å; $\beta$ is the full width at half-maximum (fwhm) of the diffraction peak in radians; and $\theta$ is the Braggs diffraction angle.

The crystal size was determined using the $\beta$ polymorphic peak (19.3° 2$\theta$), because it had the maximum intensity. The crystal size of cocoa butter was reduced with the incorporation of gelatin solution within the emulsion gels (Table 2). The decrease in the crystal size can be attributed to the presence of a heterogeneous system (fat and water mixture) within the emulsion gels.[27] During crystallization, the crystal growth of cocoa butter might have been hindered by the presence of a heterogeneous system.[27] This led to the formation of smaller crystal sizes in the emulsion gels. The changes in crystal size suggested that the crystallinity of the emulsion gels was also changed. XRD patterns of the cocoa butter, mango butter, and their corresponding emulsion gels (hump-like structures at ∼20°) suggested predominantly amorphous nature. Amorphousity of the emulsion gels was dependent on the proportion of the aqueous gelatin solution and liquid triacylglycerols. Change in the crystal size of the fats can be correlated to the amorphousity of the gels.[28] Crystallinity of the cocoa butter and the mango butter gels was found to be in the order of cocoa butter > CG10 > CG35 and mango butter > MG10 > MG35, respectively. Higher crystallinity of the cocoa butter-based emulsion gels was due to the presence of a higher amount of saturated fatty acids in cocoa butter as compared to mango butter.

**DSC Studies.** Heating DSC curves showed four and five endotherms in cocoa butter and mango butter-based emulsion gels over the temperature range of 10−40 °C, respectively (Figure 4a and b). The presence of more than one endotherm indicated the existence of the fats in different polymorphic states. Pure cocoa butter and mango butter yielded a sharp endotherm at 36.7 and 38.4 °C, respectively, corresponding to the $\beta$ polymorphic state.[29] The peak intensity of the $\beta$ state's endotherm was decreased with the addition of aqueous phase. Simultaneously, considerable enhancement in the peak intensities of the other polymorphic forms ($\alpha$ and $\beta'$) was noticed. The presence of peaks at ∼20 °C indicated the existence of $\alpha$ polymorphic state of triacylglycerols in the emulsion gels.[29] Next to the $\alpha$-polymorphic peaks, a peak corresponding to the $\beta'$ polymorphism was observed. Pure fats showed a broad endotherm of $\beta'$ polymorphic triacylglycerols with two overlapping endothermic peaks ($\beta'_2$ and $\beta'_1$ states) (indicated by arrows in Figure 4a and b).[21] Incorporation of water showed distinct endothermic $\beta'_2$ and $\beta'_1$ polymorphic peaks in the emulsion gels. This indicated that the presence of water might have slowed the polymorphic transformation (from $\alpha$ to $\beta$) of fats. The extent of overlapping of $\beta'_2$ and $\beta'_1$ states was higher in cocoa butter-based emulsion gels, whereas separate endotherms were noticed in mango butter-based emulsion gels. Thermal profiles of CG10 and CG35 showed overlapping endotherms of $\beta'_2$ and $\beta'_1$ (as that of cocoa butter) and an extra peak of $\alpha$ polymorphic state (unlike cocoa butter). On the contrary, MG10 and MG35 showed separate endotherms of $\alpha$, $\beta'_2$, and $\beta'_1$ polymorphic states (unlike mango butter). The melting endotherm of $\beta$ was not prominent in the emulsion gels as compared to the pure fats. In addition to the aforementioned peaks (corresponding to $\alpha$, $\beta'$, and $\beta$ polymorphic states), an additional peak at very low temperatures (<15 °C) was noticed in pure mango butter and its corresponding emulsion gels. This peak was due to the sub-$\alpha$ or $\gamma$ polymorphic triacylglycerols.[21] The cocoa butter-based emulsion gels did not show any such a peak. This may be explained by the merging of the endotherms of $\gamma$ and $\alpha$ polymorphic triacylglycerols.

Because different polymorphic states were existing, the amount of fat (cocoa butter and mango butter) present in those forms was calculated as solid fat content (SFC) in the emulsion gels.[6]

$$\%\mathrm{SFC} = \frac{\Delta H_t}{\Delta H_m} * 100 \tag{3}$$

where $\Delta H_t$ is the change in enthalpy at time $t$ and $\Delta H_m$ is the change in enthalpy during total melting.

The change in the enthalpy during the endothermic events was calculated by integrating the area under the peak.[30,31] The peak temperatures ($T$) of the endotherms, change in enthalpies ($\Delta H$), and SFC associated with the corresponding endotherms (polymorphic states) have been tabulated in Table 3. SFC of the $\beta$ polymorphic state was higher in pure cocoa butter and mango butter, whereas SFC of the $\alpha$ and $\beta'$ polymorphic states was increased in the emulsion gels. Figure 4c shows the SFC profiles of the emulsion gels at different temperatures. Melting points of $\alpha$ and $\beta'$ polymorphic states of mango butter were found to be lower than that of cocoa butter, whereas the melting point of the $\beta$ polymorphic state was found to be higher than that of cocoa butter. This suggested that the pure mango butter was softer than cocoa butter at low temperatures

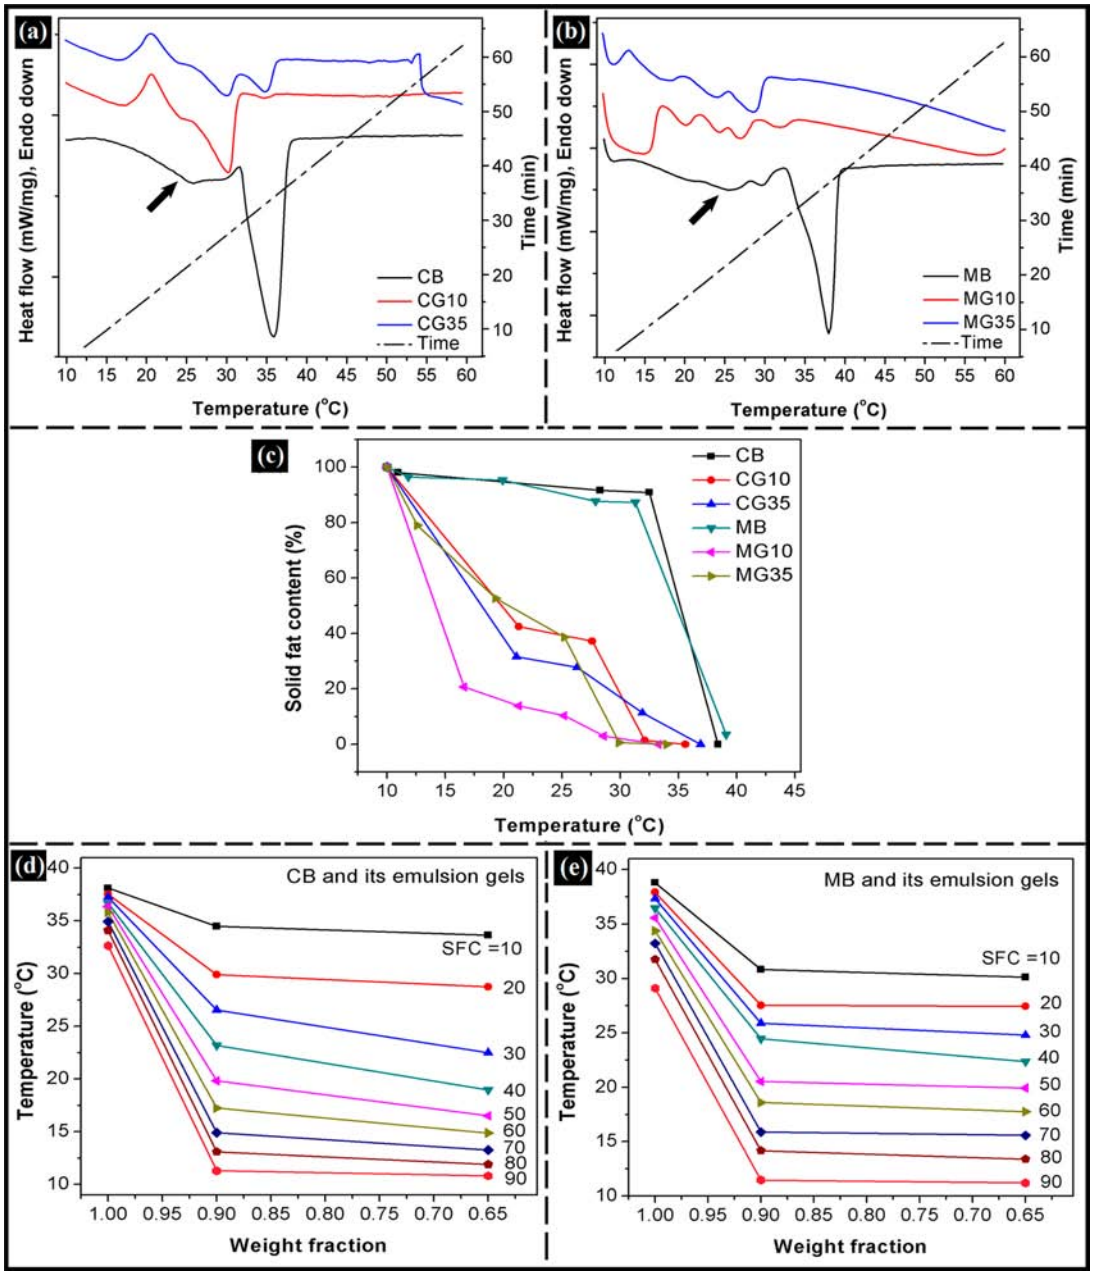

**Figure 4.** Melting endotherms of (a) CB, CB emulsion gels and (b) MB, MB emulsion gels; (c) SFC of the emulsion gels; and isosolid diagrams of (d) CB, CB emulsion gels and (e) MB, MB emulsion gels.

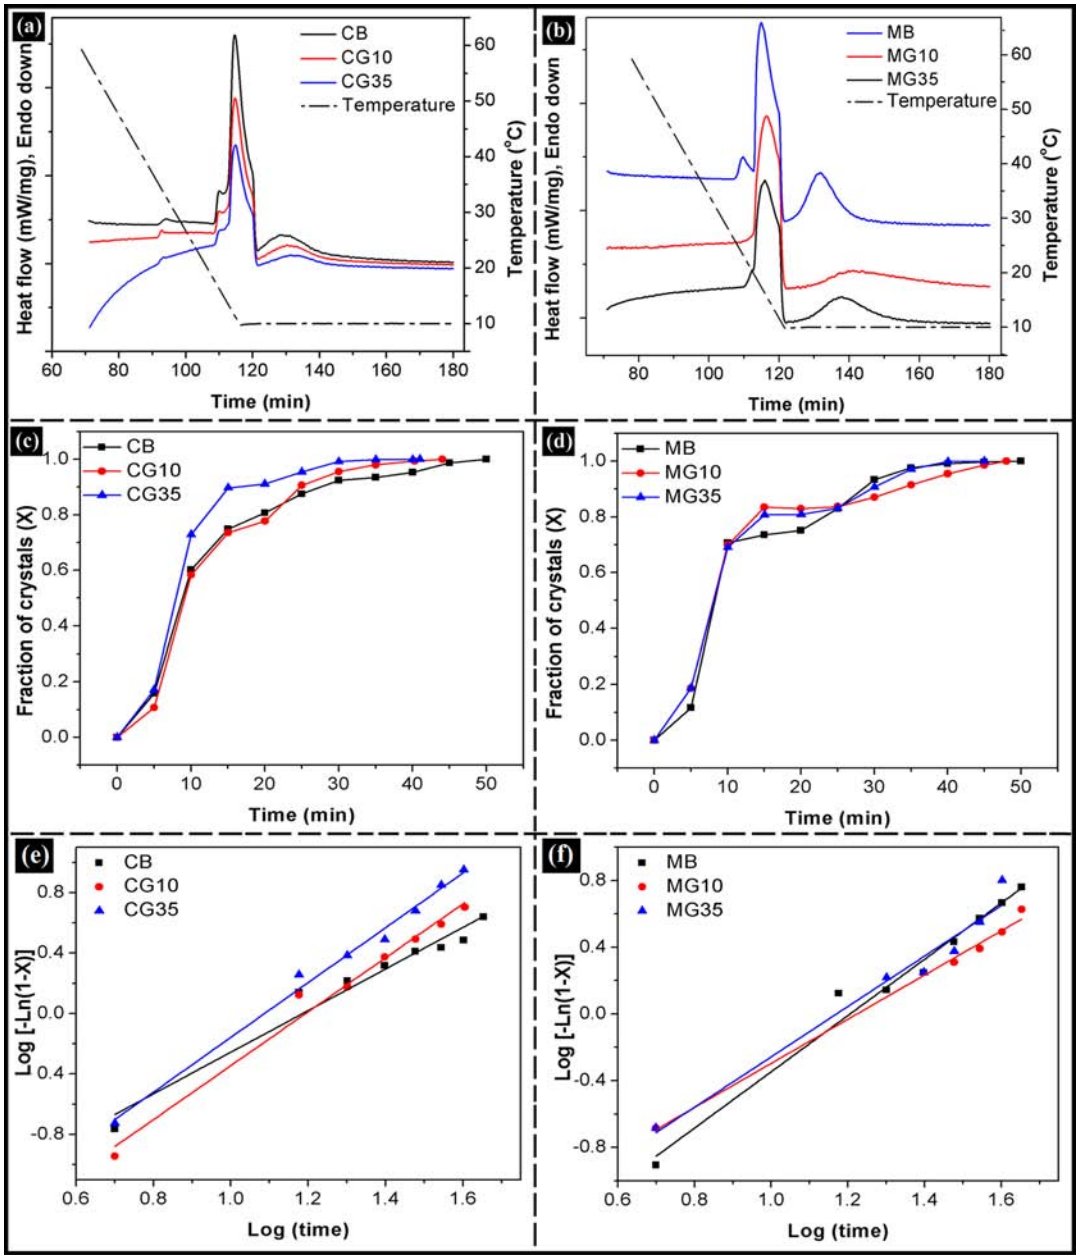

**Figure 5.** Crystallization exotherms of (a) CB, CB emulsion gels and (b) MB, MB emulsion gels; crystal fraction of (c) CB, CB emulsion gels and (d) MB, MB emulsion gels; and Avrami analysis of (e) CB, CB emulsion gels and (f) MB, MB emulsion gels.

but retained a higher number of solids at higher temperatures. This was due to the presence of the higher oleic acid content, which might have a "dilution effect" on the saturated fatty acids, thereby increasing the softness of mango butter.[6] On the other hand, mango butter contains longer chain fatty acids such as behenic and lignoceric acids. These fatty acids contributed to the induction of the stable $\beta$ polymorphic state, which resulted in the higher melting point of mango butter.

SFC content of cocoa butter and mango butter was drastically decreased when water was added. There was no significant difference in the rate of decrease in SFC of CG10 and CG35, but it was significant in MG10 and MG35. MG35 lost almost ~80% of the SFC below 15 °C. This may be the reason that mango butter could not form stable emulsion gels beyond 35% (w/w) aqueous phase. This indicated that the emulsion gels became softer than the pure fats and their thermal stability was greatly influenced. To measure the compatibility of the emulsion gel components and their effects on the gel softening, isosolid diagrams were drawn (Figure 4d and e).

In general, isosolid diagrams links the points of different samples with equal solid content in weight fraction−temperature graphs. As a matter of fact, if the isosolid lines are parallel and approximately horizontal to each other, then the components are said to be compatible with each other.[6] Isosolid diagrams suggested that the mango butter emulsion gels were softer than the cocoa butter emulsion gels. This may be explained by the lower melting points of the mango butter emulsion gels than the cocoa butter emulsion gels at the equal SFC. A sudden decrease in the melting points of the isosolid lines was observed when 10% (w/w) of gelatin solution was added to either cocoa butter or mango butter. The decrease in

dx.doi.org/10.1021/jf502658y | J. Agric. Food Chem. 2014, 62, 11357−11368

the melting temperature indicated softening of the emulsion gels. The results suggested that the softening effect was more pronounced when 10% (w/w) aqueous phase was added to cocoa butter and mango butter. Upon further addition of aqueous phase (35% w/w), no significant softening effect was observed, which resulted in almost parallel lines. The isosolid lines of the mango butter emulsion gels were more parallel to each other than the cocoa butter emulsion gels. This indicated that the softening was continuing in cocoa butter emulsion gels, but a plateau phase was reached in mango butter emulsion gels. Because the isosolid lines were not horizontal and parallel to each other up to the 90% solid fraction, the gel components (butter and gelatin solution) seemed to be not compatible with each other. Yet the compatibility was improved when the aqueous portion was raised to 35% (w/w). 100% compatibility among the fat (cocoa butter and mango butter) and aqueous phase cannot be expected due to the thermodynamic instability among them. Yet the compatibility of the fat and the aqueous phase was improved when a higher amount of gelatin (20% w/w) solution was added. Comparatively, the components of the mango butter emulsion gels were more compatible than the cocoa butter emulsion gels. This can be explained by the fact that the isosolid lines were more parallel and horizontal to each other in mango butter emulsion gels. This may be due to the presence of the higher amount of unsaturated fatty acids in mango butter. Disordered packing of unsaturated fatty acids might have allowed the incorporation of the aqueous phase in the emulsion gels and subsequent improvement of the compatibility of the fat and the aqueous phases.

**Crystallization Studies.** Isothermal crystallization studies of the emulsion gels were performed by holding them at 60 °C for 10 min (to eliminate the crystal memory of the fats) and subsequently cooling to 10 °C at 1 °C/min, followed by holding at 10 °C for 1 h. The crystallization exotherms of cocoa butter and mango butter emulsion gels can be divided into three exothermal events (Figure 5a and b). The first exotherm (~19 °C) was not distinctly separated but exists as a shoulder peak of the second exotherm at ~22.5 °C. The intensity of the shoulder peak was reduced when water was added to the fats. The third exotherm was recorded during the isothermal stage that spans over a wide time range. These kind of exothermic events were similar to the fat mixtures of cocoa butter.[29,31] Crystallization of the fats started at 22.5 °C and continued up to 10 °C, leading to a broad exotherm. Evolution of this kind of exotherm is a characteristic feature of hexagonal packing of triacylglycerol chains in $\alpha$ form.[29] Literature suggests that the progressive crystallization of triacylglycerides arranges from liquid crystalline to double-chain length ($2L$) organization in $\alpha$ form.[29] The first exothermic peak (shoulder peak) corresponded to the crystallization of the high-melting saturated fatty acids.[29] The second (major) exothermic event was due to the transformation of monounsaturated fatty acids.[29] During crystallization, a steep increase of the second exotherm at 15.4 and 15.1 °C was noticed in cocoa butter and mango butter emulsion gels, respectively. On the basis of these events, it can be inferred that the saturated fatty acids acted like seed crystals for the transformation of the liquid crystalline fat. Because the crystal growth of the saturated fatty acids was coinciding with the transformation of the unsaturated fatty acids, the first exotherm in DSC thermogram existed as the shoulder peak. The transformation of the fatty acids continued even during the isothermal stage. Crystallization at 10 °C suggested the transformation of the liquid crystalline fatty acids into $\alpha$ polymorphic state.[21] Because the crystallization at 10 °C resulted in a broad exotherm, it was expected that some of the $\alpha$ polymorphic fatty acids might have converted to $\beta'$ polymorphic state (found in DSC melting and XRD profiles as well).[21,29] Overall, the peak positions did not change, but the enthalpies associated with the exotherms of emulsion gels were changed due to the difference in the peak intensities. The overall crystallization enthalpies of the pure fats and the emulsion gels have been provided in Table 4. On the basis of the difference in crystallization enthalpies, the Avrami equation (eq 4) was used to predict the nucleation and crystal growth in emulsion gels.[30]

**Table 4. Avrami Analysis of the DSC Exotherms**

| sample | $\Delta H_c$ (J/g) | $n$ | $k \times 10^{-3}$ (min) | $t_{1/2}$ (min) |
|---|---|---|---|---|
| cocoa butter | 2.28 | 0.94 | 103.0 | 7.56 |
| CG10 | 1.55 | 1.26 | 42.7 | 9.10 |
| CG35 | 0.96 | 1.63 | 19.5 | 8.88 |
| mango butter | 1.94 | 1.05 | 82.0 | 7.65 |
| MG10 | 1.41 | 1.32 | 24.1 | 12.68 |
| MG35 | 0.94 | 1.45 | 17.1 | 12.85 |

$$\ln[\ln(1/(1 - X_t))] = \ln k + n \ln t \quad (4)$$

where $X$ is the fraction of the crystals formed at time $t$ during crystallization, $k$ is the crystallization rate constant (measure of crystallization), which depends on the crystallization temperature, and $n$ is the Avrami exponent. The Avrami exponent determines the dimensionality of crystallization. Crystal fraction ($X$) at a given time was calculated by the ratio of partial enthalpy ($\Delta H_x$) to the total crystallization enthalpy ($\Delta H_c$).

Figure 5c and d indicates that the crystal formation was very rapid during the early stages of the crystallization. Subsequently, the rate of formation was slowed and ultimately reached a stationary phase. The shape of the curves ($X$ vs $t$) illustrates the crystallization mechanism of the substance.[32] The shape of the curves did not change, indicating that the crystallization mechanism was not affected by the incorporation of the aqueous phase.[32] To better understand the crystallization mechanism, the crystal fraction ($X$) was used to calculate the Avrami parameters ($n$ and $k$). Crystallization data of the emulsion gels showed good fitting ($R^2 > 0.95$) to the Avrami equation (Figure 5e and f). The Avrami parameters calculated from the fit curves have been given in Table 4. $n$ values were found to be in the range of 0.9−1.5. This suggested the occurrence of instantaneous nucleation during the crystallization process.[21] $n$ values below 2 suggest that the nucleation rate was very rapid at the beginning, but decreased as the time progressed (as predicted by $X$ vs $t$ curves).[30] $n$ values indicated needle-like growth of the crystals along one or two dimensions. Formation of the spherulitic crystals was reported by the growth of the small needle like crystals during suspension crystallization with agitation.[33] Because static crystallization (no agitation) was studied in DSC, needle-like crystals might have not aggregated to spherulites.

On the other hand, high $k$ values (Table 4) suggested rapid crystallization in cocoa butter, followed by mango butter and the emulsion gels, respectively. The rate of crystallization was influenced by the presence of water. CG10 and MG10 had a higher rate of crystallization as compared to CG35 and MG35, respectively. The presence of aqueous phase might have prevented the growth of the crystals in quick time. Increase

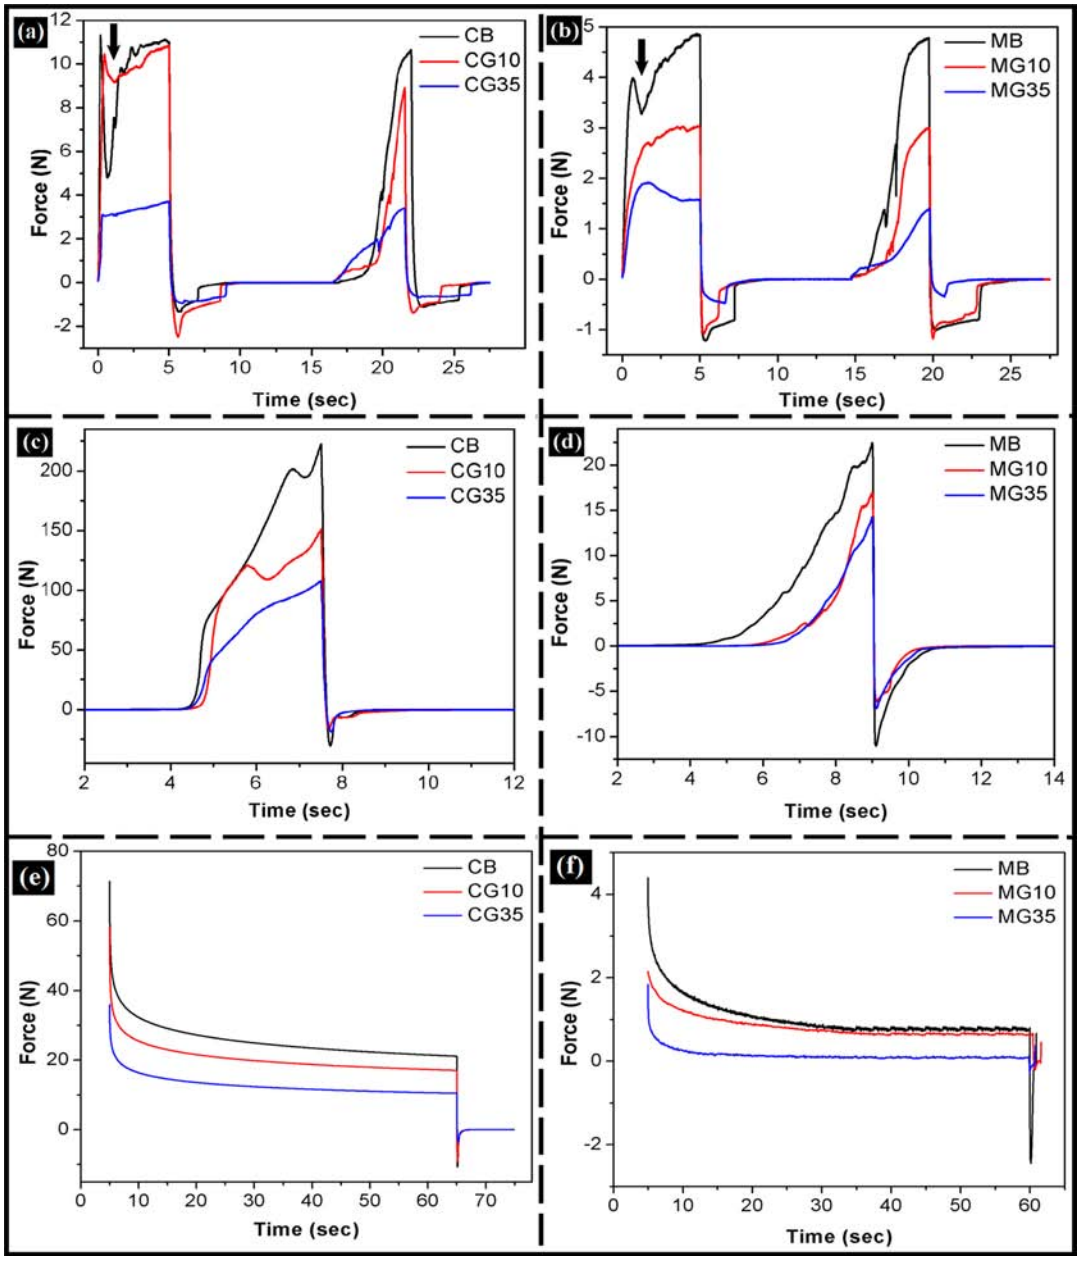

**Figure 6.** Mechanical analysis of the emulsion gels. Compression studies of (a) CB, CB emulsion gels and (b) MB, MB emulsion gels; stress relaxation studies of (c) CB, CB emulsion gels and (d) MB, MB emulsion gels; and spreadability of (e) CB, CB emulsion gels and (f) MB, MB emulsion gels.

in the crystallization time might also have led to the change in dimensionality of the growing crystals.[30] Hence, $n$ values suggested the possibility of two-dimensional growth of the crystals. Change in the crystallization times was determined by calculating the half-time of the crystallization ($t_{1/2}$). Because $k$ is dependent on nucleation, crystal growth, and temperature, it can be directly related to the half-time of crystallization ($t_{1/2}$).

$$(t_{1/2})^n = 0.693/k \quad (5)$$

$t_{1/2}$ is a function of both $n$ and $k$. It provides information about the time taken to form 50% of the crystals. The $t_{1/2}$ values were lower in pure fats as compared to the emulsion gels (Table 4). This indicated that the rate of crystallization was highest in cocoa butter and mango butter followed by CG10, CG35, MG10, and MG35 under the experimental conditions. As the rate of fat crystallization was slower in emulsion gels with higher water proportions, water droplets coalescence has led to the formation of unstable emulsion gels. Higher crystallization rates in cocoa butter emulsion gels facilitated the cocoa butter to tolerate high amounts of water. Because the rate of crystallization was slower in mango butter emulsion gels, the water droplets might have coalesced prior to the fat crystallization. Hence, stable cocoa butter emulsion gels were formed even at high proportion of water (70% (w/w)) as compared to the mango butter emulsion gels (35% (w/w)).

**Mechanical Analysis.** During the two-cycle uniaxial compression test, fracturing of pure cocoa butter and mango butter (shown by an arrow in Figure 6a and b) indicated the brittle nature of the pure fats. Fracture points were also seen during the second cycle of compression in the pure fats. Emulsion gels, except CG10, did not show fracture points. This

indicated a decrease in the brittleness with the addition of the aqueous phase. Higher brittleness can be attributed to the higher cohesive strength of the pure fats (Supporting Information Table S2). The triacylglycerols in pure fats are tightly packed either in double or in triple chain length structures.[34] This kind of orientation favors ordered arrangement of the triacylglycerols and imparts higher cohesive strength.[34] The presence of aqueous phase might have disturbed the orientation of the triacylglycerols, which resulted in the decrease in the cohesiveness, hardness, and gumminess of the emulsion gels (Supporting Information Table S2). This indicated that the emulsion gels became softer with the incorporation of the aqueous phase (as predicted during melting studies). Increase in the softness might have enhanced the adhesive nature and spreadability of the emulsion gels. Interestingly, adhesiveness of the cocoa butter and mango butter emulsion gels was enhanced when a lower amount of aqueous phase was added, but a reverse trend was observed when a higher amount of aqueous phase was added. The presence of gelatin in the aqueous phase might be responsible for the enhancement in the adhesive nature of the emulsion gels, but at higher amounts of gelatin, the intermolecular attraction (cohesive interactions) between the gelatin molecules might have dominated the adhesive forces.[35] Increase in the spreadable nature of the emulsion gels was confirmed by spreadability studies (Figure 6c and d). Application of force during the spreadability test did not result in the syneresis of water. Because the water droplets were physically locked within the fat continuous phase (evident from the microscopic studies), syneresis did not occur, which in turn imparted physical stability to the emulsion gels. CG35 and MG35 showed higher spreadability than CG10, MG10 followed by cocoa butter and mango butter. Increase in the softness may be associated with the spreadability of the emulsion gels. During cyclic compression studies, springiness of the emulsion gels did not vary significantly. This suggested that the elastic nature of the pure fats was not altered in the emulsion gels. To confirm this and to critically evaluate the viscoelastic properties of the emulsion gels, stress relaxation studies were conducted.

The stress relaxation profiles of the emulsion gels have been shown in Figure 6e and f. The firmness ($F_0$) and the residual force ($F_r$) were higher in cocoa butter and mango butter as compared to the emulsion gels. $F_0$ and $F_r$ decreased with the increase in the aqueous phase. This was due to the decrease in the SFC of the emulsion gels. The stress relaxation profiles of the emulsion gels followed an exponential decay function. The force decay with respect to time ($F(t)$) during the relaxation of the emulsion gels was analyzed by fitting the data in modified Peleg's equation.[36]

$$\frac{(F_0 - F(t))t}{F_0} = k_1 + k_2 t \tag{6}$$

where $F_0$ is the maximum force attained after loading; $k_1$ and $k_2$ represent the initial rate and extent of the relaxation, respectively.

Normalized stress relaxation data from modified Peleg's equation yielded a straight line with good fitting ($R^2 > 0.995$) (Supporting Information Figure S5). Curve analysis indicated that the initial rate of relaxation ($k_1$) was decreased with the increase in the proportion of the aqueous phase, but the extent of relaxation ($k_2$) did not vary significantly in both kinds of emulsion gels (Table 5). Although $k_2$ (slope) represents the total relaxation behavior of the formulations, almost similar values were obtained. To find the viscoelastic nature and to know the stress relaxation behavior, asymptotic residual force was calculated from the stress relaxation curve ($F^*$):[37]

**Table 5. Viscoelastic Parameters of CB, MB, and Emulsion Gels from Stress Relaxation Studies**

| samples | $F_0$ (N) | $F_r$ (N) | $k_1$ | $k_2$ | $F^*$ | % relaxation |
|---|---|---|---|---|---|---|
| CB | 71.37 | 21.09 | 0.036 | 0.001 | 0.29 | 70.45 |
| CG10 | 58.17 | 15.03 | 0.031 | 0.016 | 0.26 | 74.16 |
| CG35 | 35.98 | 8.42 | 0.015 | 0.001 | 0.24 | 76.60 |
| MB | 4.39 | 0.74 | 0.041 | 0.017 | 0.17 | 83.14 |
| MG10 | 2.15 | 0.26 | 0.013 | 0.017 | 0.12 | 87.90 |
| MG35 | 1.85 | 0.08 | 0.005 | 0.017 | 0.04 | 95.67 |

$$F^* = \frac{F_r}{F_0} \tag{7}$$

where $F_r$ is the residual force after relaxation and $F_0$ is the maximum force attained prior to the relaxation.

For viscoelastic materials, $F^*$ lies in the range of 0−1. "$F^*$" value close to 1.0 indicates that the material is an elastic material. There was a reduction in the $F^*$ values with the decrease in the SFC of the emulsion gels. This indicated that the elastic nature of the cocoa butter and mango butter decreased with the increase in the aqueous phase. Cocoa butter and mango butter emulsion gels have shown $F^*$ values in the range of 0−1, suggesting that the developed emulsion gels were viscoelastic in nature. % relaxation was calculated using eq 8:

$$\%\text{relaxation} = \left(\frac{F_0 - F_r}{F_0}\right)*100 \tag{8}$$

Mango butter emulsion gels showed more relaxation than cocoa butter emulsion gels (Table 5). Because mango butter emulsion gels were more amorphous than the cocoa butter emulsion gels (as per XRD studies), relaxation of the mango butter emulsion gels was more than that of the cocoa butter emulsion gels.

In conclusion, this study is intended to develop mango butter emulsion gels as the cocoa butter equivalents. Stable gelatin-based cocoa butter and mango butter emulsion gels were formed by a simple hot emulsification method. Cocoa butter incorporated high amounts of aqueous fraction (70% (w/w)) as compared to mango butter (35% (w/w)). The water droplets were dispersed within the fat continuous matrix. In general, physical and microbiological stabilities are the major concerns in the usage of water containing products in confectionaries. The presence of fat around the water droplets imparted physical stability to the emulsion gels. Because water droplets were locked within the crystallized fats, microbial contamination can be arrested. Avrami analysis indicated that the rate of fat crystallization was higher in cocoa butter and it was decreasing with the increase in water proportion. A high fat crystallization rate in cocoa butter might be responsible for the high tolerance capacity of the water as compared to mango butter. X-ray diffractograms indicated the fats present in the emulsion gels had a stable $\beta$ polymorphic state even after tempering. The effect of tempering was lowered as the emulsion gels were prepared by melting the fats at lower temperature (45 °C). DSC results suggested that the emulsion gels showed a high percentage of SFC as $\beta$ polymorphic form and intermediary polymorphic forms ($\beta'_1$ and $\beta'_2$). As $\beta'_1$ and

$\beta'_2$ possess the melting point at ~30 °C, the emulsion gels may have high chances of consumer acceptance if employed in the preparation of chocolates and/or other confectionaries. Increase in softness and spreading nature of the emulsion gels with respect to the pure fats also will favor the consumer acceptance. Mango butter emulsion gels are found to be softer than the cocoa butter emulsion gels, which may be due to the presence of high amounts of liquid-like unsaturated fatty acids. On the basis of the observations, it was suggested that the mango butter emulsion gels may have potential to be used as cocoa butter equivalents in food and pharmaceutical industries. Yet, prior to the use of mango butter emulsion gels as the cocoa butter equivalents, the emulsion gels need to be tested for the microsafety issues and compared to the existing marketed formulations.

[a]GB1, GB2, GB3, GB4, and GB5 were used to amplify the full-length DNA sequence of the *Waxy* gene. [b]Position in the amplified region refers to the nucleotide sequence Genbank X07931.

are relatively fewer than those on wheat, rice, and maize, but some molecular information could be documented. Barley *Waxy* gene consists of 12 exons and 11 introns and codes 603 amino acids with a transit peptide of 72 amino acid residues.[19] A high level of variations is also found in the barley *Waxy* gene sequence, and some important nucleotide changes can greatly affect the amylose synthesis and further alter starch properties. It has been demonstrated that a 400 bp (approximately) deletion in the 5′ untranslated region (5′UTR) led to a significant decrease of the mRNA transcript level and the GBSS I protein level and thus low-amylose trait.[20−24] Three SNP mutations in the *Waxy* gene produce amylose-free traits.[20,22,25] Like wheat or rice, low-amylose or amylose-free barley has special starch properties and thus can expand the use of barley grain. However, in previous studies, investigations of the full-length sequence of the *Waxy* gene were conducted only on several barley accessions,[20,25,26] and only a few studies were carried out with the combination of nucleotide differences, the mRNA expression level, the GBSS I protein level, the amylose content, and starch properties.[20,25,26] Therefore, further comprehensive study on the *Waxy* locus with a larger population should be useful for understanding the genes controlling amylose synthesis and starch properties and improving barley starch quality.

Hull-less barley is also called naked barley and has advantages over hulled barley, such as easy processing and higher content of functional components. The Qinghai-Tibet plateau (QTB) in China has the most abundant hull-less barley resources in the world and is also the only region where hull-less barley serves as the first food crop, accounting for 60% of total crop planting area and 55% of tonnage harvested.[27] Hull-less barley is respectfully called "Qingke" by Tibetans and is always an important economic and cultural carrier for the Tibetan people. To date, hull-less barley has attracted more and more attention in the world due to its potential health benefits.[28−30] Barley flour, alone or as a mixture with wheat, has been processed into various types of food products, such as biscuits, noodles, steam buns, and breads. With the increase of processed products of hull-less barley, more and more attention has been paid to starch properties and the screening of germplasm resources for starch traits. We have determined the amylose content of about 300 hull-less barley accessions mainly from QTB in China and found the amylose content was widely variable with a range of 0−40%. This indicates the *Waxy* gene responsible for amylose synthesis may have rich variations, and a further study of the *Waxy* gene in hull-less barley from QTB could be useful for producing various types of barley with more variable amylose contents. Therefore, in this study, we selected 34 of 300 barley accessions that we had analyzed before, with different amylose contents from QTB in China, to conduct the characterization of DNA sequence variations of the full length of the *Waxy* gene and to determine the expression differences of *Waxy* alleles at both RNA and protein levels and to characterize the starch properties to understand how sequence polymorphisms in the *Waxy* gene affect amylose synthesis and starch properties in hull-less barley from QTB in China.

## MATERIALS AND METHODS

**Plant Material.** A total of 34 hull-less barley (*Hordeum vulgare* L. var. *nudum* Hook. F.) accessions with different amylose contents were used in this study, comprising 13 indigenous varieties and 21 cultivars or breeding lines. Among these accessions, breeding lines Z999, Z1191, and Z1979 were derived from the crosses of local varieties × overseas introduced lines. All barley accessions were collected from QTB in China and planted in Shuangliu, Chengdu, Sichuan, China. All accessions and breeding lines were planted as three replicates in three blocks in the same field. Within each block, each of the accessions and breeding lines was planted in one plot using a randomized block design. Barley grains from the same accession or breeding line were mixed at an equal grain number or weight from three plots in three blocks. The mixed samples were used to conduct further analyses.

**Determination of Amylose Content, Swelling Power, and Starch Pasting Properties.** Starch was isolated with a proteinase extraction method.[31] Amylose content was measured using an iodine adsorption method.[7] Swelling power was measured according to the method reported by Konik-Rose et al.[32] Pasting properties were

[a]A superscript "M" indicates the alteration of the amino acid residue in the mature protein region. Nucleotides and amino acids bolded and underlined are newly identified nucleotide sequence variations. The sequence of the 187 insertion was TGCATACACGTTTCTGTTTCCA-ACCAAGCCTTTGATTCTATGCAATTCCAAAAAAAAACATTTCATATTTTTGTCATGGAATTCGACTGCACGCTACAAGAAAAACA-CCAGTATGGAGTATATTTTACCCTCACTGCAGTTCCCCCTCTGTACACGCGATTTAACCGACTGTTTTGCTACTACCCGTAC. [b]Position refers to the nucleotide position in Genbank accession no. X07931.

measured by using a Micro Visco-Amylo-Graph (A. W. Brabender Instruments, South Hackensack, NJ, USA) and followed the procedure given: starch (10 g) was suspended with distilled water (98 mL) and 10% (m/v) $AgNO_3$ (2 mL), then the starch suspension was heated from 50 to 92 °C at the rate of 7.5 °C/min, held at 92 °C for 5 min, cooled to 50 °C at 7.5 °C/min, and held at 50 °C for 1 min, and the rotation speed was 250 rpm. All determinations were performed in triplicate with the mixed grains (equal weight of grains) of three plots from three blocks for each accession.

**PCR and Sequencing.** DNA was extracted from young hull-less barley leaves according to the CTAB procedure.[33] Five primer pairs[23,26] were used to amplify the full length of *Waxy* genes (Table 1). The PCR was carried out in a 20 μL volume containing 100 ng of DNA template, 0.1 μM of each primer, 200 μM of each dNTP, 1.5 mM $MgCl_2$, 1× PCR reaction buffer, and 1 unit of Taq DNA polymerase (TaKaRa Inc., Dalian, China). The PCR procedure consisted of a pre-incubation at 94 °C for 4 min, followed by 35 cycles of 94 °C for 40 s, 60 or 55 °C for 50 s, 72 °C for 50 s, and a final extension at 72 °C for 6 min.

PCR products were separated with 1% agarose gels, and the target band was purified with a Universal DNA Purification Kit (Tiangen, China). The purified band was then ligated into the pMD19-T vector (TaKaRa Inc.) and transformed into the competent cells of *Escherichia coli* (JM109). Purified plasmid DNAs from at least three colonies from each PCR DNA band were sequenced by Invitrogen (Shanghai, China).

**Transcript Level Analysis Using Q-PCR.** Total RNA was extracted from developing endosperms, which were obtained from the 8th, 13th, 18th, 23rd, and 28th day post anthesis (dpa) using RNAiso Plus (TaKaRa Inc.) and Fruit-mate purification kits (TaKaRa Inc.). A total of 15 endosperms from three plots (randomly collected five endosperms from each plot) were mixed and ground and then used for RNA extraction for each developmental stage of each accession. cDNA was synthesized from total RNAs using oligo $(dT)_{18}$ primer and M-MLV reverse transcriptase (TaKaRa Inc.). The gene-specific Q-PCR primer (C5) was designed according to a barley *Waxy* mRNA sequence (X07932). The Q-PCR procedure consisted of a pre-incubation at 94 °C for 5 min, followed by 40 cycles of 95 °C for 15 s, 60 °C for 15 s, and extension at 72 °C for 15 s. All reactions were performed in the Chromo4 real-time PCR detector system (Bio-Rad, Hercules, CA, USA) using iQ SYBR green supermix (Bio-Rad). To normalize the cDNA templates, a housekeeping gene encoding elongation factor 1α (EF) was co-amplified as a control.[34] All primers (Table 1) were synthesized by Invitrogen. Each accession was analyzed with three replicates.

**Separation of GBSS I Protein by SDS-PAGE.** Extraction of GBSS I protein was mainly based on the reports by Pan et al.[35] and Yamamori et al.[36] The developing endosperms without pericarp and embryo were collected at the 8th, 13th, 18th, 23rd, and 28th dpa, then homogenized in washing extraction buffer (55 mmol $L^{-1}$ Tris-HCl, pH 6.8; 23 g $L^{-1}$ SDS; 5% (v/v) β-mercaptoethanol; and 10% (v/v) glycerol) with a mortar. The extraction of GBSS I protein was performed from mixed endosperms of 15 seeds from three plots for each developmental stage of each barley accession or breeding line. The mixture was incubated at 25 °C with shaking at a speed of 150 rpm for 2 h and then centrifuged (CP100-WX; Hitachi, Japan) at 12000 rpm for 4 min. The supernatant was discarded, and the sediment was washed twice with each of the SDS washing buffer, distilled water, and acetone, and finally dried overnight. GBSS I protein was released by boiling starch (5 mg) in 400 μL of protein extraction buffer (containing 62 mmol $L^{-1}$ Tris-HCl, pH 6.8; 23 g $L^{-1}$ SDS; 5% (v/v) β-mercaptoethanol; 10% (v/v) glycerol; 0.05 g $L^{-1}$ bromophenol blue) for 15 min and centrifuged (with CP100-WX) at 12000 rpm for 10 min at 4 °C. Protein supernatant (20 μL) was separated with 10% SDS-PAGE gels, which contained acrylamide/Bis at a ratio of 30:0.135, and protein gels were then stained with silver staining solutions.

**Data Analysis.** The deduced amino acid sequence of GBSS I protein was predicted using BioEdit. Multiple alignments of nucleotide and amino acid sequences were performed by Clustalx1.83 and further adjusted manually. A phylogenetic tree based on nucleotide sequence differences was constructed by MEGA 4.0 with the UPGMA method. Cis-acting regulatory DNA elements were searched using Plant Care[37] and PLACE.[38] Transcript levels of *Waxy* gene were calculated using Gene Expression Analysis for iCycler iQ Real-Time PCR Detection System. Significant difference was determined by the least significant difference (LSD) test using Tukey's test (SPSS package, version 17.0).

## RESULTS

**DNA Sequence Variations of the Barley *Waxy* Gene.** A total of 116 polymorphic variations were detected in the 34 barley accessions; 39 of them were not reported in previous studies. These 116 polymorphic variations comprised 4 simple sequence repeats (SSRs), 18 insertions and deletions (INDELs), and 94 single-nucleotide polymorphisms (SNPs) (Table 2). Furthermore, these polymorphic sites were mainly distributed in 5′UTR (untranslated region), intron 1, and exons 1 and 2. No polymorphic variations were found in exons 3, 6, 9, 11, and 12, and only 33 polymorphic variations were located in coding regions.

A phylogenetic tree (Figure 1) was constructed on the basis of the multiple alignment of *Waxy* gene sequences of a total of 42 barley accessions, including the 34 accessions in this study, plus another 8 sequences downloaded from NCBI. All accessions were divided into two DNA groups: the *Waxy* I DNA group containing 25 barley accessions and the *Waxy* II DNA group containing another 17 accessions. Considering the 34 accessions sequenced in this study, *Waxy* I and *Waxy* II DNA groups can be further classified into six (HP I-1−I-6) and five (HP II-1−II-5) haplotypes, respectively. Haplotype (HP) I-4, including 13 accessions, was the representative haplotype for the *Waxy* I DNA group, and HP II-4 with 9 accessions was the major haplotype for the *Waxy* II DNA group. Detailed sequence variations among haplotypes are listed in Table 2 and Figure 2A. The *Waxy* I DNA group was different from the *Waxy* II DNA group mainly because the *Waxy* I DNA group had an insertion of about 190 bp in the first intron 1 and a 15 bp insertion within the second exon. Among the *Waxy* I DNA group, HP I-1 and I-2 were distinguished from the others mainly due to a newly found 187 bp insertion in intron 1 instead of the specific 191 bp insertion. In addition, HP I-1 and I-2 contained a transversion of a C-to-T base, which was first identified in the second exon of barley *Waxy* gene. HP I-3 (Z1979) was peculiar due to a large deletion of a 403 bp in the promoter region. In the phylogenetic tree, GU599883, GSHO 1828, MMD, and GSHO 908C and HP I-3 were clustered into a small single clade because all of them had the 403 bp fragment deletion in the promoter region. HP I-5 was similar to I-4 except for the substitution of a T for $C^{2453}$ base in the fifth exon that was also identified in barley cv. SH97 and Yon M Kei. HP I-6 was also the same as I-4, with the exception of a T instead of $C^{3077}$, a T instead of $C^{3078}$, and a C instead of $T^{3118}$ in the seventh exon, and all three of these SNPs were first identified in barley *Waxy* gene. For the *Waxy* II DNA group, HP II-2 was almost identical to II-1 except for the substitution of a T for $G^{3935}$ in the 10th exon. HP II-3 formed a single clade in the phylogenetic tree because it contained some unique SSRs and many other newly found SNPs in introns and 5′UTR. HP II-5 was the same as II-4 with the exception of a single base change of a C to a T between positions 882 and 883 in 5′UTR.

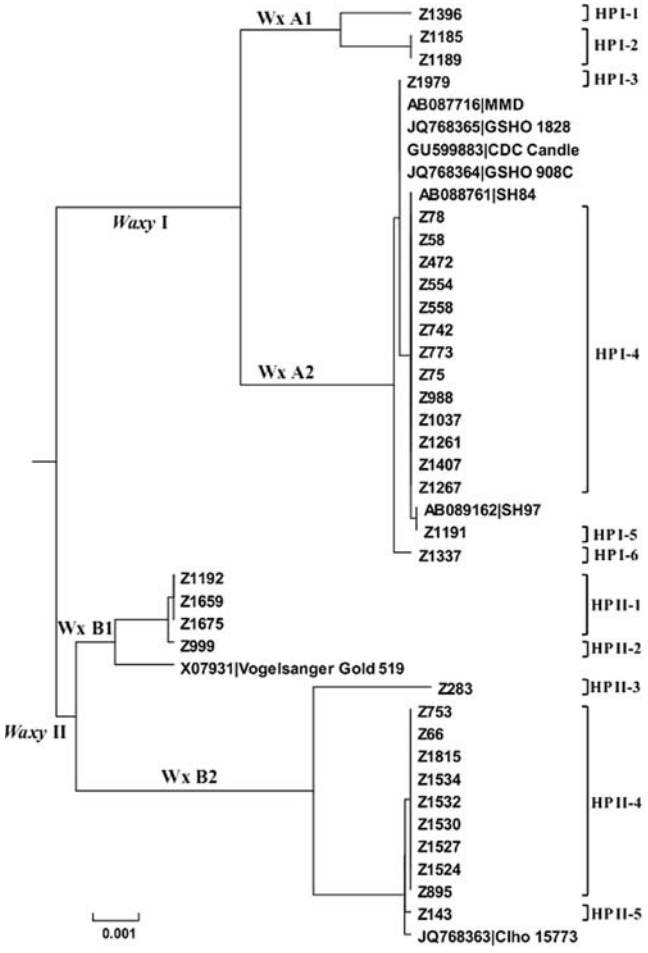

**Figure 1.** Phylogenetic tree of barley *Waxy* gene nucleotide sequences constructed using the multiple alignment. Nucleotide sequences were from 34 QTB barley accessions and breeding lines and 8 down-loaded sequences. HP is the abbreviation of haplotype. Genomic DNA sequences (AB087716|MMD, AB088761|SH84, GU599883|CDC Candle, JQ768365|GSHO 1828, JQ768364|GSHO 908C, AB089162|SH97, JQ768363|CIho 15773, X07931|Vogelsanger Gold519) were downloaded from NCBI. The format is Genbank number|Strain.

**Differential Expression of mRNA Transcripts of *Waxy* Gene.** To investigate mRNA differential transcript expression among haplotypes, a total of 26 of the 34 barley accessions, representing different haplotypes, were used for analysis. To reduce the number of samples, six and two accessions, belonging to HP I-4 and II-4, respectively, were randomly excluded, due to more accessions being present within HP I-4 and HP II-4. As shown in Figure 3A, the transcript level of the barley *Waxy* gene generally showed a wide range of variations during endosperm development, starting with a very low level at the 8th dpa, increasing rapidly, and peaking at the 13th or 18th dpa, then declining. Moreover, significant difference of transcript level was observed among *Waxy* DNA groups or haplotypes. The average transcript level of the *Waxy* I DNA group or HP I-4 was significantly higher than that of the *Waxy* II DNA group or HP II-4 haplotype (Figure 3B). Among different haplotypes, the order sorted by the average transcript level was HP II-2 > I-4 > I-6 > I-1 > II-4 > II-3 > I-2 > II-1 > II-5 > I-3 > I-5. Additionally, attention was paid to some special accessions. The transcript level of Z773 in HP I-4 was the highest and that of Z1191 in HP I-5 was the lowest, which contained a single nucleotide change in the fifth exon compared to Z773. The level of the differential transcript expression between them was up to 99-fold. HP I-3 with a 403 bp deletion also had an extremely low transcript level. However, HP I-6 with three base substitutions in the seventh exon, displayed a normal level of *Waxy* gene transcript, and HP II-2 with a single base mutation in the 10th exon had relatively higher transcript level.

**Analysis of Cis-Acting Regulatory DNA Elements in 5′UTR.** The number of putative cis-acting regulatory DNA

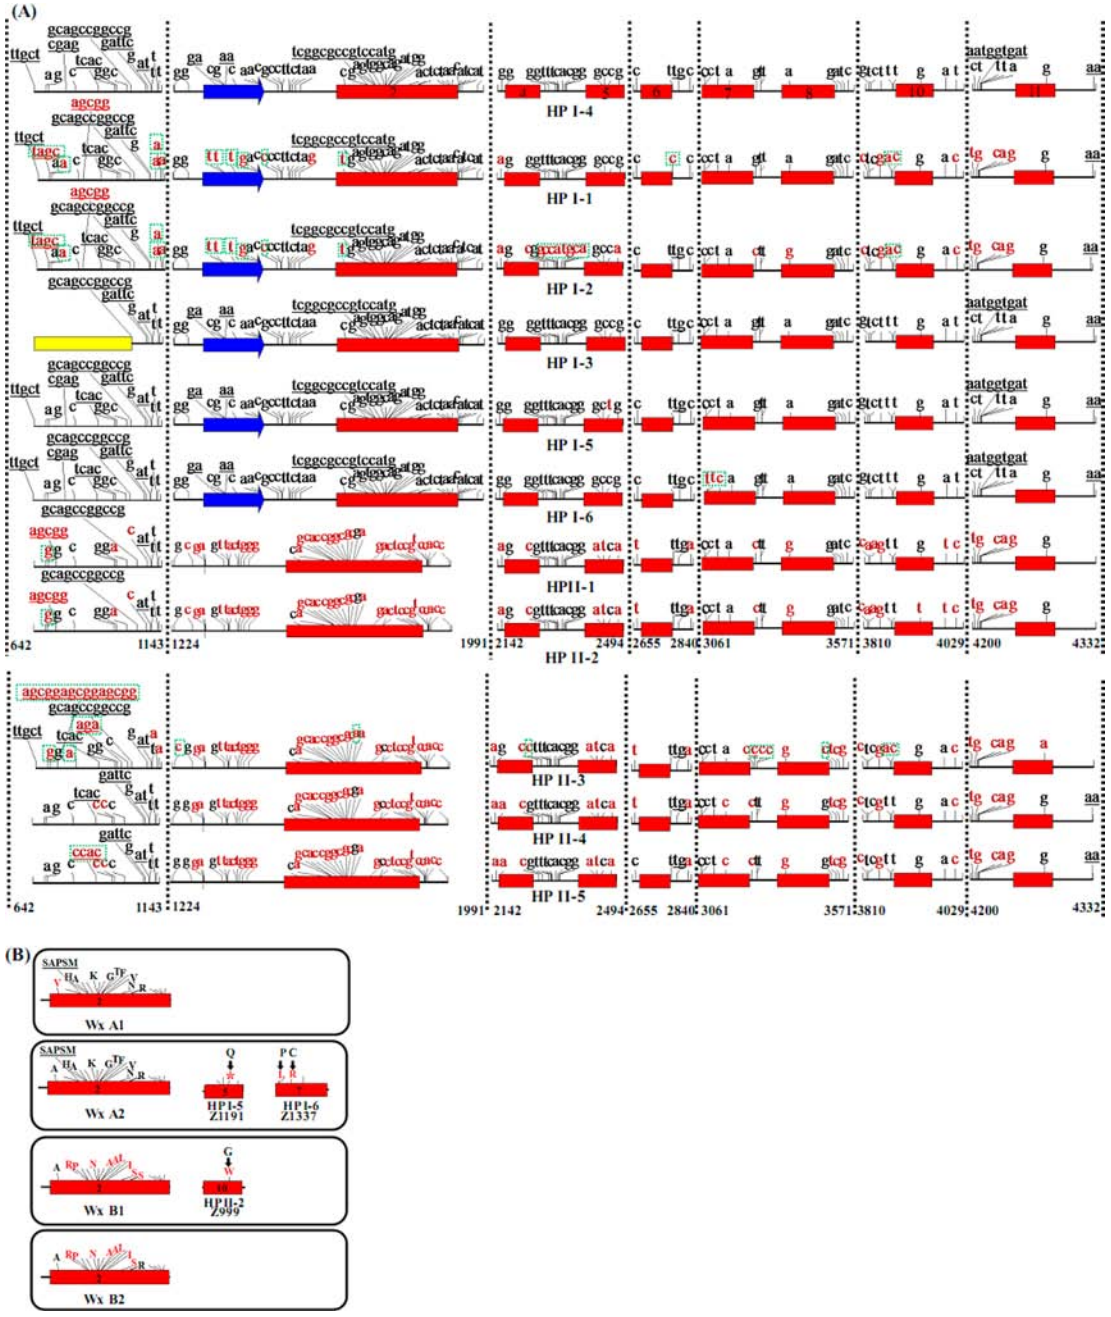

**Figure 2.** Variations of DNA and amino acid sequences of the *Waxy* gene among barley haplotypes and *Waxy* DNA groups. Red boxes represent exons. Lines between exons represent introns. SNPs underlined represent insertion. (A) Variations of DNA sequences of the waxy gene among barley haplotypes. The numbers at the bottom of the figure indicate the nucleotide positions referred to the nucleotide sequence Genbank No. X07931. The blue arrow represents the 191 or 187 bp insertion in intron 1. The yellow box represents the 403 bp deletion. The red bases mean different nucleotides from those accessions compared to HP I-4 at the same position. The green boxes represent the locations of newly identified SNPs. The DNA sequence variations of 11 haplotypes were distributed among seven nucleotide sequence regions, indicated as 642−1143, 1224−1991, 2142−2494, 2655−2840, 3061−3571, 3810−4029, and 4200−4332 at the bottom of the figure. (B) Variations of deduced amino acid sequences of the *Waxy* gene among four haplotypes and the altered amino acid residues within four Wx types labeled with one-letter amino acid abbreviations. Synonymous mutation is not shown. Amino acids are listed at the same position corresponding to nucleotides. ∗ represents the stop codon. The red SNPs indicate different SNPs from those haplotypes compared to the type of Wx A2 at the same position. The numbers inside the red boxes are exon numbers.

elements was different in 5′UTRs of the *Waxy* gene among 11 haplotypes with differential transcript expression. We tried to identify putative cis-acting regulatory DNA elements in the 5′UTRs to understand whether regulatory element divergences were associated with the transcription efficiency of *Waxy* genes. Up to 174 DNA regulatory elements were found in HP I-4, I-5, and I-6. In contrast, HP I-3 contained only 73 DNA regulatory elements because of the 403 bp deletion. The 403 bp deletion contained −300 element, RYREPEAT motif, and some other elements required for seed- and endosperm-specific expression.[24] Meanwhile, there might be about 49 cis-acting motifs in the 191 bp (187 bp) insertion, and most of them might be

dx.doi.org/10.1021/jf5026746 | J. Agric. Food Chem. 2014, 62, 11369−11385

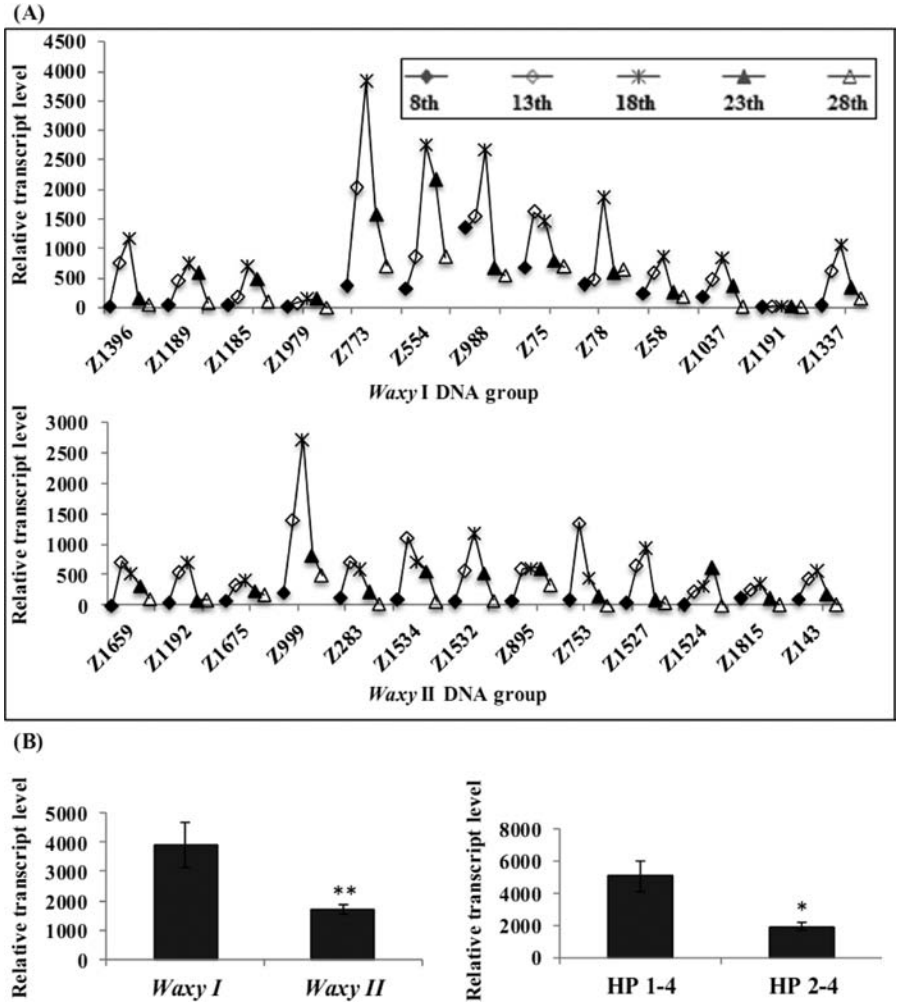

**Figure 3.** mRNA expression pattern of the barley *Waxy* gene: (A) relative transcript levels during five endosperm development stages of 26 barley accessions; (B) average transcript levels of barley *Waxy* DNA groups and haplotypes. Average transcript levels were calculated by total values of five endosperm development stages for each *Waxy* DNA group or haplotype divided by the number of accessions used for each *Waxy* DNA group or haplotype. (∗) Difference is significant at the $p < 0.05$ level; (∗∗) difference is significant at the $p < 0.01$ level.

involved in light responsiveness and stress tolerance.[24] In addition, we found the *Waxy* gene in HP I-1, I-2, I-3, II-1, and II-3, with relatively lower mRNA levels, also lacked either seven or eight RYREPEAT elements due to the single-base substitution of $A^{684}$ or $G^{698}$ (Table 3). RYREPEAT elements were believed to be involved in seed-specific regulation.[39] In addition, by comparison with HP II-4, the single base-substitution of T to C between positions 882 and 883 in HP II-5 resulted in the absence of putative SORLIP5AT that was thought to be involved in light responsiveness (Table 3).

**Variation of Deduced GBSS I Protein Sequences.** Fifteen amino acid alterations were identified in the deduced GBSS I protein sequences, due to a total of 33 polymorphic sites in coding regions, including 11 amino acid changes in the transit peptide and 4 of them within the mature protein regions.

According to these variations in the transit peptide, the 34 accessions in this study could be obviously divided into four protein groups of Wx A1, Wx A2, Wx B1, and Wx B2. As shown in Figure 1, except that HP I-1 and I-2 belonged to Wx A1, the rest of the accessions in the *Waxy* I DNA group were classified into protein group Wx A2. The difference among the four protein groups Wx A1, Wx A2, Wx B1, and Wx B2 was that Wx A1 and Wx A2 contained a five amino acid insertion of serine (Ser)−alanine (Ala)−proline (Pro)−Ser−methionine (Met) and some other amino acid alterations in the transit peptide (Table 2 and Figure 2B). Protein group Wx B1 was completely identical with Wx B2 except for the substitution of Ser for the 70th Arg (Table 2 and Figure 2B) that was caused by one SNP in the second exon.

The sequences of mature protein within the four protein groups were identical with the exceptions of HP I-5 (Z1191) and HP I-6 (Z1337) of protein group Wx A2 and HP II-2 (Z999) of group Wx B1. For Z1191, the 189th glutamine (Gln) was mutated to a stop codon because of the substitution of T for $C^{2453}$ in the 5th exon (Table 2 and Figure 2B). For Z1337, the 321th Pro and the 335th cysteine (Cys) were replaced by a leucine (Leu) and an arginine (Arg), respectively, because of the three newly found SNPs in the 7th exon (Table 2 and Figure 2B). As shown in Figure 4A, the two amino acids substituted were conserved in most cereal crops. For Z999, a tryptophan (Trp) was substituted for the 513th glycine (Gly) due to the mutation of $G^{3935}$ to T in the 10th exon (Table 2 and Figure 2B). From the result of a CDD Search on NCBI, the 513th Gly was highly conserved in the GBSS I protein of the grass family and even in glycogen synthase of various bacteria (Figure 4B).

Table 3. Variations of Cis-Acting Regulatory Elements of the *Waxy* Gene among Barley Haplotypes

| position[b] | nucleotide | haplotype and DNA group | cis-acting DNA regulatory element[a] | |
|---|---|---|---|---|
| | | | name | function |
| 589−590 | AGC | II-1, II-2 | ANAERO2CONSENSUS[a] | fermentative pathway |
| 621−1023 | 403 deletion | I-3 | total of 101 regulatory elements | |
| 636−637 | —— | I-3, II-1, II-2, II-4, II-5 | DOFCOREZM | binding of Dof proteins |
| 684 | G | II-1, II-2, II-3, I-3 | INTRONLOWER | 3′ intron−exon splice junctions |
| | | | total of 6 RY-REPEAT elements | seed-specific expression |
| 698 | A | I-1, I-2 | total of 8 RY-REPEAT elements | seed-specific expression |
| 794 | A | II-1 | MYBCOREATCYCB1 | cell cycle phase-independent activation |
| 882−883 | —— | II-1, II-2 | SORLIP5AT | light-induced expression |
| | | | SORLIP5AT(−) | light-induced expression |
| | | | GTGANTG10 | pollen gene expression |
| | | | CACTFTPPCA1 | mesophyll-specific and phosphoenolpyruvate carboxylase expression |
| | CCAC | II-5 | SORLIP5AT | light-induced expression |
| 1007 | A | II-1, II-2 | WBOXNTERF3[a] | stress resistance |
| | | | WRKY71OS*α* | stress resistance |
| 1084−1085 | —— | II-1, II-2, II-3 | ARR1AT | environmental stimuli |
| 1087 | C | II-1, II-2 | CURECORECR | coordinate copper and oxygen-responsive expression |
| 1102−1103 | —— | I-1, I-2 | P1BS | phosphate starvation |
| | | | P1BS(−) | phosphate starvation |
| 1109 | A | I-1, I-2 | GATABOX | light regulation and tissue-specific expression |
| | | | MYBST1 | core motif of MybSt1 binding site |
| | | | REBETALGLHCB21 | phytochrome regulation |
| 1132 | A | I-1, I-2, II-3 | CACTFTPPCA1 | mesophyll-specific and phosphoenolpyruvate carboxylase expression |
| 1325−1326 | 187 bp insertion | I-1, I-2 | total of 49 regulatory elements | |
| | 191 bp insertion | I-3, I-4, I-5, I-6 | total of 41 regulatory elements | |
| 1326 | A | *Waxy* I DNA group | POLLEN1LELAT52 | pollen-specific activation |
| | | | GT1CONSENSUS | light regulation |
| 1390 | C | *Waxy* I DNA group | HDZIP2ATATHB2 | light regulation |
| 1392 | T | *Waxy* I DNA group | POLASIG3 | plant polyadenylation signal |
| 1415 | T | *Waxy* I DNA group | POLLEN1LELAT52*α* | pollen-specific activation |
| | C | *Waxy* II DNA group | GT1CONSENSUS[a] | light regulation |

| 1446 | G | I-1, I-2, *Waxy* II DNA group | MYB1AT | responsible for dehydration |

[a]Cis-acting DNA regulatory elements without a superscript "a" indicated that they were missing because of nucleotide variations of haplotypes listed in this table. [b]Position refers to the nucleotide position in Genbank accession no. X07931. "(-)" means this regulatory element is located in the antisense strand.

**Differing Levels of GBSS I Protein among Haplotypes.** GBSS I protein was also extracted from the developing endosperms at the 8th, 13th, 18th, 23rd, and 28th dpa and separated by SDS-PAGE. The level of GBSS I protein was estimated visually. As shown in Figure 5, GBSS I was detected as a band of about 60 kDa by SDS-PAGE analysis of proteins extracted from starch granules and identified on the basis of the known molecular markers. The level of GBSS I protein expressed was related to the variations at DNA and transcript levels. GBSS I protein expressed with a very low level at the 8th dpa and then remained stable with a high level from the 13th dpa (Figure 5). It was found that the GBSS I protein concentration for each barley accession was largely consistent with the level of total mRNA expression (Figure 6). Additionally, special attention was paid to HP I-5, I-6, and II-2 because there were some mutations in their mature GBSS I protein. Hardly any GBSS I protein was detected for HP I-5, which carried a stop codon to terminate the extending polypeptide chain. The GBSS I protein level of HP I-6, with two amino acid alterations, was moderate and did not change sharply in comparison with normal types of barley accessions. HP II-2 presented a relatively high GBSS I protein level. We also focused our attention on HP I-3, because it contained a 403 bp deletion in the 5′UTR. HP I-3 had a very low level of GBSS I protein during the entire development of the endosperm.

**Difference in Starch Properties.** The starch properties, including amylose content, swelling power, and pasting properties, were determined. Tables 4 and 5 show the results of statistical analysis for the starch properties of different *Waxy*

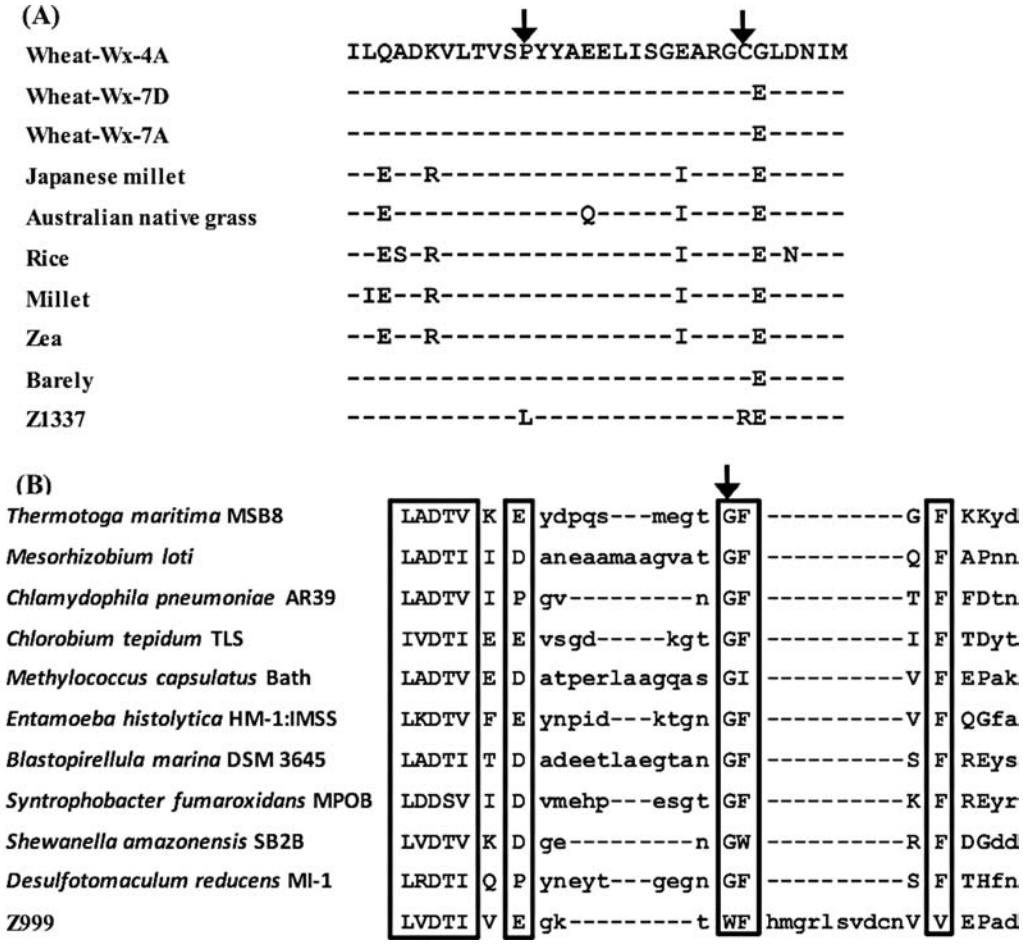

**Figure 4.** Conservation of amino acid residues of *Waxy* proteins and glycogen synthases. (A) Conservation of the amino acid residues at the 321th Pro and the 335th Cys in the GBSS I protein of most cereal crops. These two conserved amino acids at similar positions are indicated by arrows on the top of the figure. Short-dash lines indicate the same residues as that of wheat-Wx-4A. Genbank accession numbers of these crops are listed in order as BAA88509, BAA88512, HQ338724, BAM38099, EF600044, EF600036, NP_001267750, HQ423234, and X07931. (B) Conservation of the amino acid residues at the 513th Gly in GBSS I proteins or glycogen synthases. The top 10 most diverse members from the cluster of sequences are used to create a domain model. Short-dash lines indicate the deletion of amino acid residues; lower case letter indicates unconserved amino acid residues. The boxed residues indicate that they are highly conserved. The 513th Gly at a similar position is pointed out by arrows. Genbank accession numbers in order are AAD35976, AAK58596, NP_445448, NP_662888, YP_113933, XP_653076, ZP_01093037, YP_846231, YP_928323, and ZP_01665840.

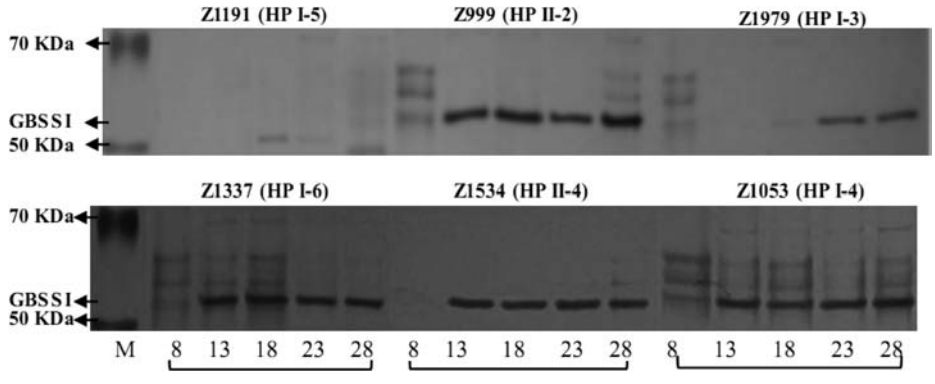

**Figure 5.** Separation of GBSS I proteins during five endosperm developmental stages of barley by SDS-PAGE. M, marker, ProteinRuler IV (Trans). Numbers 8, 13, 18, 23, and 28 represent the developmental endosperms at the 8th, 13th, 18th, 23rd, and 28th dpa, respectively. The GBSS I protein band of hull-less barley (about 60 kDa) and molecular markers are indicated on the left side.

DNA groups or haplotypes. Significant differences in some starch properties were found between HP I-4 and II-4, the representative types for *Waxy* I and *Waxy* II DNA groups, respectively. Amylose content, pasting temperature, time to peak viscosity, peak temperature, final viscosity, and setback viscosity of HP I-4 were significantly higher than those of HP II-4, but HP I-4 showed significantly lower swelling power, lower peak viscosity, and lower breakdown viscosity compared

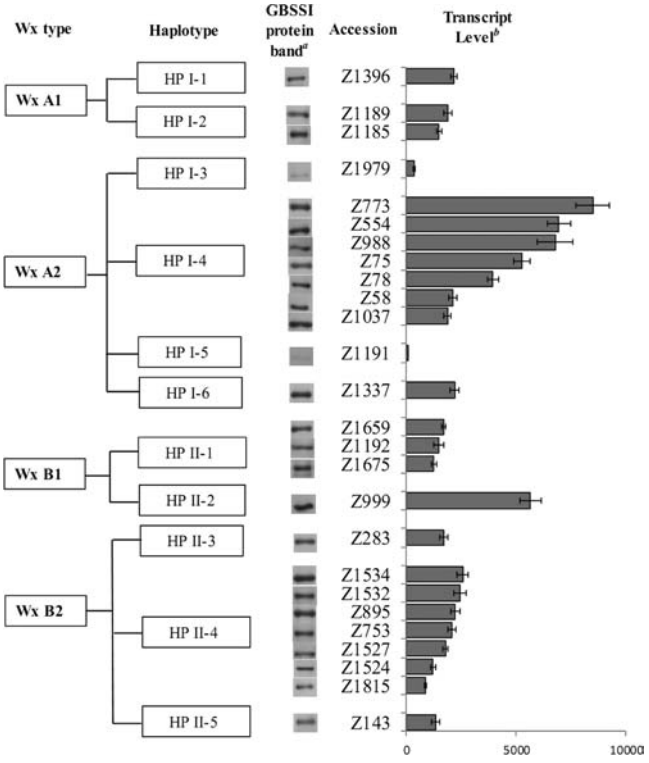

**Figure 6.** Alignment of deduced amino acid sequence types (Wx), expression levels of GBSS I proteins, and their transcript levels from different barley haplotypes. [a]Protein bands show GBSS I level of endosperm developmental stage at the 28th dpa. The GBSS I protein band of barley was about 60 kDa. [b]Total transcript level contains transcript levels from all five endosperm developmental stages.

to HP II-4. These results indicated that HP I-4 had lower hot-pasting stability, higher cold-pasting viscosity, and better gel-forming performance than those of HP II-4. Except for three low-amylose or amylose-free haplotypes (HP I-3, I-5, and II-2), the difference in starch properties between *Waxy* I and *Waxy* II DNA groups resembled the difference between HP I-4 and II-4. In addition, significant differences for trough viscosity were observed between *Waxy* I and *Waxy* II DNA groups. The starch properties of low-amylose and amylose-free accessions and Z1337 (HP I-6) containing mutations in mature protein regions are highlighted in Figure 7 and Table 6. HP I-6 (Z1337), with two amino acid mutations in the mature protein region, showed higher peak time and lower breakdown viscosity value (Figure 7 and Table 6). HP I-5 (Z1191), HP II-2 (Z999), and HP I-3 (Z1979) were of low or zero amylose content, and they had much higher swelling power value (about 20) than the representative types (Tables 4 and 6). Their starch also presented the typical pasting characteristics of lower pasting temperature, shorter peak time, higher peak viscosity, lower peak temperature, lower final viscosity, and higher breakdown viscosity than other types (Figure 7 and Table 6), which was consistent with previous findings.[40] To a large extent, the change in starch pasting properties and swelling power values was derived from the alteration of amylose/amylopectin ratio, and low amylose content usually caused high swelling power value, high peak pasting viscosity, and low peak temperature.[4,40,41] The differences in starch properties presented in this study were consistent with the differences in amylose content.

**Table 4. Difference in Starch Properties between HP I-4 and HP II-4[a]**

| type | no. of accessions | AC[b] (%) | SP[c] | PT[c] (°C) | TTP[c] (min) | PV[c] (BU) | PVT[b] (°C) | FV[b] (BU) | BD[b] (BU) | SB[b] (BU) |

[c]Difference is significant at the 0.01 level.

## DISCUSSION

**Wide Variations of DNA Sequences of the *Waxy* Alleles Have Different Effects on Amylose Content in Barley.** Tibet is the center of Oriental barley,[42] and barley accessions collected from QTB are indeed highly variable.[27,43,44] In this study, a total of 116 polymorphic sites were identified from the *Waxy* genes of the 34 barley accessions. Particularly, 39 new nucleotide variations were found for the first time. For example, a 187 bp instead of a 191 bp insertion was found in intron 1 of HP I-1 and HP I-2 haplotypes, and three SNPs were found in HP 1-6 (Z1337), resulting in two amino acid residue alterations within the mature protein region. All accessions were obviously divided into two DNA groups or 11 haplotypes according to the sequence differences. These results indicate that the *Waxy* genes from different hull-less barley accessions from QTB are highly variable in genetic backgrounds, which may be a major factor responsible for the wide range of amylose content of QTB barley accessions used in this study. Although the deficiency of SSIIa or SBE activity has also been proven to greatly elevate the amylose content of the induced cereal crop grains,[2,4,8,45] SSIIa and SBE were not candidate enzymes in the determination of amylose content change for those 34 barley accessions because no obvious changes in the intensity of SSIIa and SBE on the SDS-PAGE gel were observed in our work. Extensive genetic diversity of the *Waxy* gene may be due to the wide range of geographic origin of these accessions as well as the low level of domestic selection of these indigenous barley accessions. Due to the wide variations of the *Waxy* gene nucleotide sequences, significant differences in the expression of *Waxy* gene transcripts and GBSS I proteins and in some starch properties were observed among different *Waxy* DNA groups or haplotypes. The *Waxy* I DNA group had an average transcript level significantly higher than that of the *Waxy* II DNA group and had significantly different starch properties. HP I-5 with a SNP, a T for $C^{2453}$ change in the fifth exon, presented very low transcript level and undetectable GBSS I protein on SDS-PAGE gel and the amylose-free type. HP II-2 with a T for $G^{3935}$ change in the 10th exon, had relatively high transcript level and normal GBSS I protein level on the SDS-PAGE gel, but showed no amylose content. HP I-3 with a 403 bp deletion gave an extremely low level of *Waxy* transcript, undetectable GBSS I protein, and low amylose content. These differences in the amylose content correspond to the variation of the *Waxy* gene at the nucleotide level. The changes of nucleotides in the coding and noncoding regions greatly influence the expression of the *Waxy* gene.

**Effect of Polymorphic Sites in the Coding Region on the Function of *Waxy* Gene.** Four amino acid alterations were identified in the mature protein region of the *Waxy* protein due to five SNPs. One SNP, a T for $G^{3935}$ in the 10th exon, was identified only in Z999 (HP II-2) and resulted in the change of $Gly^{513}$ to Trp in the mature region of GBSS I protein and was the only difference of both nucleotides and deduced amino acids of *Waxy* gene between HP II-1 and II-2. However, the expression of *Waxy* gene and starch properties of Z999 (HP II-2) presented significant differences from that of HP II-1. The level of transcript and GBSS I protein in accession Z999 was obviously higher than that of HP II-1. Interestingly, accession Z999 with high GBSS I protein level displayed amylose-free phenotype and the resulting special starch pasting characteristics, whereas HP II-1 showed normal transcription, amylose content, and starch properties. The 513th Gly was located in

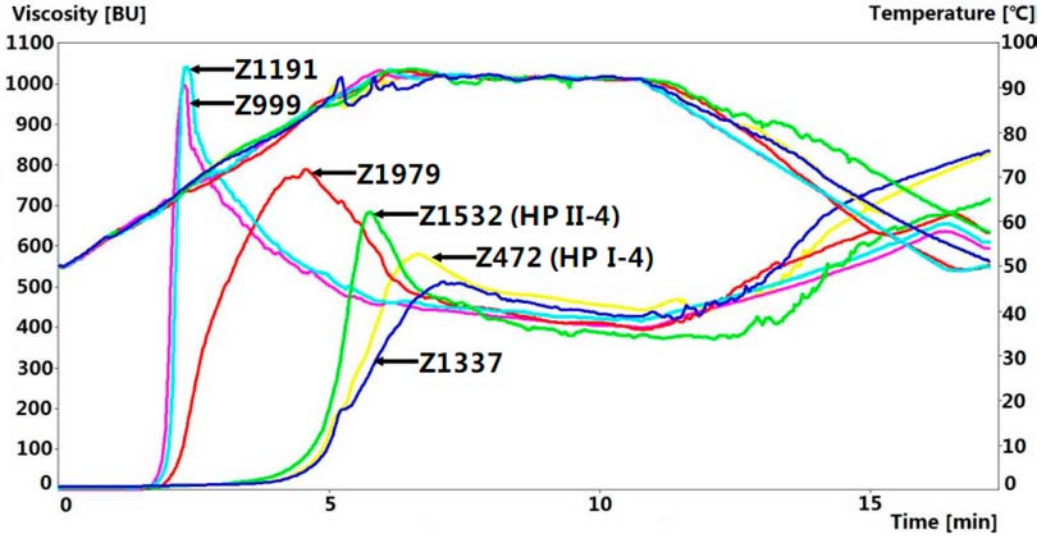

**Figure 7.** Starch pasting profiles of selected barley accessions. Z1191 (HP 1-5) and Z999 (HP 2-2) are amylose-free barley, Z1979 (HP 1-3) is a low-amylose barley, Z1337 (HP I-6) contains two amino acid mutations in the mature protein region. Z1532 (HP II-4) and Z472 (HP I-4) are used as controls due to their normal starch properties compared with anylose-free or low-amylose ones.

the conserved glycosyltranferase domain (GT-1) that transfers UDP-, ADP-, GDP-, or CMP-linked sugars to fructose-6-phosphate, glycogen, and many other substrates.[46] The 513th Gly was not located within the region of conserved motifs I–VIII or not involved in the formation of $\alpha$-helices and $\beta$-sheets.[46] However, multiple alignment analysis found the 513th Gly was highly conserved in GBSS I proteins of cereal crops and even in glycogen synthases of various bacteria. Therefore, a single amino acid residue substitution may completely deactivate the function of the GBSS I protein, which causes amylose-free characteristics. This demonstrates that the 513th Gly may be a very critical site for maintaining the functional activity of the GBSS I protein. The similar high expression pattern of the *Waxy* gene coexisting with no amylose characteristic was also reported in another amylose-free barley cultivar, CDC Alamo,[47] which contained the substitution of Val for the 287th Asp, an essential conserved amino acid in the conserved starch catalytic domain (GT-5) within the catalytic core, which was found in many starch synthases and glycosyltransferases that use only ADPglucose as substrate.[46,47] Moreover, the 287th Asp participates in the formation of 380s loop,[48,49] which was important in determining the specificity of many starch synthases.[46] However, it is still hard to explain why a single amino acid change occurring in these two special sites would increase the transcript level to a large extent. Possibly, the enhancers located further upstream of the *Waxy* gene or other genes affect the transcription of the *Waxy* gene.

The other SNP alteration of $C^{2453}$ to T in the fifth exon was detected in accession Z1191 (HP I-5). This SNP was also the only difference between accessions HP I-5 and HP I-4 that was one of the major haplotypes of QTB hull-less barley, but the expression level of *Waxy* transcript and amylose content of Z1191 (HP I-5) was almost undetected, whereas HP I-4 presented a much higher mRNA transcript level and amylose content. These results indicate the alteration of $C^{2453}$ to T in the fifth exon of barley *Waxy* gene can greatly affect the function of the *Waxy* gene. Actually, the same SNP mutation was earlier reported in barley cultivars SH97 and Yon M Kei.[20,22] Similarly, both of them also presented undetectable GBSS I protein and amylose-free characteristics. The alteration of $C^{2453}$ to T in the fifth exon of barley *Waxy* gene brings about a pre-existing terminator in extending the polypeptide chain and probably results in premature termination of the GBSS I protein or limits the combination of amyloplast to incomplete peptide, thus blocking amylose synthesis. However, Yon M Kei showed slightly normal transcript level,[22] which was inconsistent with the result of HP I-5 haplotype. We aligned the *Waxy* gene sequences from these two accessions and found they were not completely identical. Therefore, other base alterations in the *Waxy* sequence may cause different levels of transcription, or different genetic background changed the mRNA expression profiles even if both of them contained the same critical mutation site.

In this study, another three SNPs were identified for the first time, and all of them were located in the seventh exon of Z1337 (HP I-6), an indigenous hull-less QTB barley. The three SNPs resulted in Leu and Arg instead of the 321st Pro and the 335th Cys. The two substituted residues were located in the starch catalytic domain (GT-5) within the catalytic core, and the 321st Pro was in motif II and located between an $\alpha$-helix and a $\beta$-sheet.[46] Both the 321st Pro and the 335th Cys were very conserved in most cereal crops. Except for the lowest breakdown value of starch viscosity and higher peak time, Z1337 showed no obvious changes for the transcription of the *Waxy* gene, GBSS I protein level, and most of the starch properties. This indicates that the change of these amino acid residues has little effect on the function of *Waxy* gene.

High conservation in the mature region of the *Waxy* protein is essential for ensuring the normal function of the GBSS I protein. Compared with only 4 amino acid alterations in the mature protein region, a total of 11 mutations were found in the transit peptide. In particular, a 15 bp insertion in the second exon resulted in five additional residues in the transit peptides, which classified barley accessions in this study into Wx A1, Wx A2, Wx B1, and Wx B2 protein groups. Significant difference in GBSS I protein level among Wx A1, Wx A2, Wx B1, and Wx B2 protein groups (except for a few accessions) could not be observed visually on SDS-PAGE gel, but transcript level and starch properties of Wx A1, Wx A2, Wx B1, and Wx B2 protein groups displayed significant differences. Therefore, it was

Table 6. Difference in Starch Properties among Four Special Accessions and Normal Barley Accessions[a]

| type | AC (%) | SP | PT (°C) | TTP (min) | PV (BU) | PVT (°C) | TV (BU) | FV (BU) | BD (BU) | SB (BU) |

[a]AC, amylose content; SP, swelling power; PT, pasting temperature; TTP, time to peak viscosity; PV, peak viscosity; PVT, peak temperature; TV, trough viscosity; FV, final viscosity; BD, breakdown viscosity; SB, setback viscosity. Z472 (HPI-4) and Z1532 (HP II-4) were served as control, here we defined them as normal types because of their common starch properties.

thought that the 15 bp insertion might have an impact on GBSS I protein level and starch properties.

**Effect of Polymorphic Sites in Noncoding Region on the Function of Barley *Waxy* Gene.** The effects of variations in the noncoding region on gene expression have attracted more and more attention. Especially, the variations in the 5′UTR usually play an important role in the transcription level. A number of cis-acting DNA regulatory elements and trans-acting protein impacting transcription have been characterized in the 5′UTR of the *Waxy* gene.[50−58] Fragment deletion or just a single SNP could disturb the combination of cis-acting motif and protein and, thus, drastically influence the expression level of transcripts. It has been reported that a large deletion in the 5′UTR had a negative effect on the transcription of the *Waxy* gene. For example, a 140 bp deletion in 5′UTR of the *Waxy* gene significantly decreased the transcript level, GBSS I activity, and amylose content in potato.[59] In this study, a total of 84 polymorphic sites were found in the noncoding region, making up nearly 77% of all polymorphisms. First, we analyzed the effect of two large fragment deletions on the function of the *Waxy* gene. The 403 bp deletion in 5′UTR was found in accession Z1979 (HP I-3), including the transcription start site, TATA box, exon 1 and partial intron 1. Z1979 also had low transcript level, low GBSS I protein content and low amylose content, which was consistent with previous studies. This suggests that the large deletion in the 5′UTR negatively affects transcription of the *Waxy* gene. It was further found that there might be up to about 100 cis-acting regulatory DNA elements in the 403 bp deleted fragment, many of which are involved in seed-specific regulation and light responsiveness.[24]

All accessions in this study were divided into two *Waxy* DNA groups mainly according to the 191 bp insertion in intron 1 within the 5′UTR: the *Waxy* I DNA group containing such an insertion and the *Waxy* II DNA group without the corresponding insertion. The average transcript level of the *Waxy* I DNA group (or haplotype I-4) was significantly higher than that of the *Waxy* II DNA group (or haplotype II-4), and the amylose content of the *Waxy* I DNA group (or haplotype I-4) was significantly higher than that of the *Waxy* II DNA group (or haplotype II-4). This result indicates that the 191 bp insertion probably has a positive effect on the function of barley *Waxy* gene. It has been reported that cis-acting motifs in the first intron within the 5′UTR of rice *Waxy* gene usually play a positive role in the transcript level.[60] A total of 49 additional putative cis-acting motifs were found in the 191 bp insertion, most of them involved in light responsiveness and stress tolerance and some responsible for embryo-specific expression.[24] Therefore, these additional cis-acting motifs might have positive effects on enhancing the *Waxy* gene transcription, which finally affects amylose content, swelling power, and starch pasting characteristics of hull-less barley. The insertion of approximately 190 bp has been reported previously; however, its role was always neglected due to two possible reasons. First, this insertion was found in both waxy and wild phenotypes, which make its role less obvious. Second, it was difficult to assess its role when the studies were carried out on only several barley accessions.[20,22] Our study investigated a population of 34 barley accessions and breeding lines, making it possible to compare the groups with a number of accessions having the presence/absence of the 191 bp fragment.

Besides such large fragments as 403 bp or 191 bp INDELs, some other SNPs, SSRs, and short INDELs were found in 5′UTR, which may affect DNA regulatory elements, which

finally affect the function of barley *Waxy* gene. HP I-1, I-2, II-1, and II-3 expressed relatively low transcript level, possibly due to the lack of seven or eight putative RYREPEAT elements that were conserved in many seed-specific promoters. It has been reported that increasing the copy number of a cis-acting element likely improved the gene expression level.[61,62] Therefore, the reduction of RYREPEAT copies was probably relevant to the decrease in *Waxy* gene expression. Likewise, the transcript level of HP II-5 was much lower than the average transcript level of the HP II-4 haplotype, probably because HP II-5 lacked the putative SORLIP5AT, which was involved in light responsiveness, due to the single base difference.

**Effect of GBSS I on the Starch Properties of Hull-less Barley from QTB.** This study particularly indicates that the specific variations of the *Waxy* genes of hull-less barley from Qinghai-Tibet play an important role on amylose synthesis, and the starch properties are strongly influenced by the change of amylose content. Actually, starch biosynthesis and the resulting starch properties are influenced by multiple concerted biosynthetic enzymes, rather than a single biosynthetic enzyme. Amylose contents in cereal grains were not only changed by the *Waxy* gene but also highly elevated when the activity of SBE or SSIIa was drastically reduced.[2,4,8,45] However, to our knowledge, in a normal case, when other starch biosynthetic enzymes do not suffer from significant change, GBSS I is the main target enzyme responsible for amylose formation.[9−13,63] As the genes encoding those starch biosynthetic enzymes locate on different chromosomes in cereals, it is unlikely that the changed activities of those enzymes cosegregated with the *Waxy* gene in a large population. In this study, the hull-less population was mainly composed of indigenous varieties or breeding lines through crossing among indigenous varieties, so GBSS I should be the target enzyme controlling amylose content.

Except for the amylose content, starch properties were also modified with the alteration of amylopectin properties.[64] The high percentage of long chains (degree of polymerization > 35) in amylopectin displayed elevated swelling power.[65] GBSS I was also thought to be responsible for the synthesis of the extra-long-chain fraction of amylopectin.[14,15] However, previous studies on waxy rice and wheat showed that when GBSS I was deactivated, carbon was mainly allocated to amylopectin, and thus low-amylose or amylose-free mutants were produced, whereas no significant changes were observed for chain length distribution of amylopectin and starch granules.[14,66−68] Therefore, it is indicated that amylose content change might be the main cause of alterations in starch properties of the accessions in this study.

## NOTE ADDED AFTER ASAP PUBLICATION

This article published November 7, 2014 with errors in the amino acids columns of Table 2. The corrected version posted November 14, 2014.

**Table 1. Fertilizer Treatments and Application Rates**

| | application rate | |
|---|---|---|
| treatments ($n$ = 3) | low dose (75 kg N ha$^{-1}$) | high dose (150 kg N ha$^{-1}$) |
| composted chicken manure | 18.7 g/pot (coded L−M) | 37.4 g/pot (coded H−M) |
| chemical fertilizer | urea 0.72 g, $Ca(H_2PO_4)_2{\cdot}H_2O$ 1.39 g, $K_2SO_4$ 0.33g/pot (coded L−C) | urea 1.45 g, $Ca(H_2PO_4)_2{\cdot}H_2O$ 2.78 g, $K_2SO_4$ 0.67 g/pot (coded H−C) |
| compost−chemical fertilizer (1:1) | chicken manure 9.35 g + urea 0.36 g, $Ca(H_2PO_4)_2{\cdot}H_2O$ 0.70 g, $K_2SO_4$ 0.16 g/pot (coded L−M+C) | chicken manure 18.7 g + urea 0.72 g, $Ca(H_2PO_4)_2{\cdot}H_2O$ 1.39 g, $K_2SO_4$ 0.33 g/pot (coded H−M+C) |
| control | no fertilizer application (coded CK) | |

had different N isotope ratios, with a range from −3.9‰ to 0.5‰ for synthetic fertilizers, 5.3‰ to 7.2‰ for animal manure, and 9.3‰ to 20.9‰ for compost manure,[12] and the mean value of $\delta^{15}$N was 0.2‰ for synthetic fertilizers and 8‰ for organic manure.[13] The $\delta^{15}$N value of plants is affected by many factors such as the timing of application and the chemical form of synthetic fertilizer,[14] form of manure,[15,16] growth stages,[14,17] and irrigation water.[13]

The $\delta^{15}$N values in different plants were significantly different between organic and conventional production and may vary with growth periods. The mean $\delta^{15}$N values of products from organic and conventional agriculture vary with mean values 8.1‰ and −0.1‰ for tomatoes, 7.6‰ and 2.9‰ for lettuces, and 5.1‰ and 4.7‰ for carrots.[18] The $\delta^{15}$N values of leaves and grains of maize grown with composted pig manure were also significantly ($P < 0.05$) higher than those grown with urea even after 70 days of growth,[14] and the $\delta^{15}$N of maize increased for urea or decreased for composted manure with time, probably because of isotope fractionation accompanied by N losses and an increased uptake of soil-derived N by the maize.[14] Cabbage treated with compost had a higher $\delta^{15}$N value (>9.0%) than that treated with urea (<1.0%). Further, specific $\delta^{15}$N signals of basal N inputs were detected in the outer parts of cabbage formed in the early growth stage, while those of additional N inputs were detected in the inner parts of cabbage formed in the latter growth stage.[19] Different parts of the plant also had different $\delta^{15}$N values, such as roots, stems, leaves, and grains for maize;[14] root, shoot, unpolished grain, and polished grain for rice;[20] and fruits and leaves for cucumber.[21] Thus, for these reasons it could be difficult to identify a certain value to discriminate organic food from conventional ones.

Although some reports indicated that the $\delta^{15}$N of vegetables or crops differed between organic and conventional agriculture, the conclusions were drawn either from the results of a single cultivating experiment for carrots, tomatoes, lettuces,[13,22,23] maize,[14] Chinese cabbage,[19,22] cabbage, and onions,[22] or from statistical data on commercial products such as paprika,[22] tomatoes,[18,22] lettuces, and carrots,[18] or from a crop rotation experiment for canola, barley, and wheat for four years[15] and lettuces, onions, and cabbages for three years.[24] Particularly, as far as we know, no study has been published on investigating the variations of the $\delta^{15}$N value of a single crop in different seasons.

The $\delta^{15}$N values between organic crops and conventional crops overlapped, most probably due to $^{15}$N enrichment of plant-available N derived from synthetic fertilizer through N loss via $NH_3$ volatilization and denitrification with time after fertilization in soil.[17,18,22,23] In our previous study, the overlapped $\delta^{15}$N values were observed in *Brassica campestris* with combined application of organic and synthetic fertilizers.[17] Some reports drew a conclusion that $^{15}$N isotope analysis could only be used to determine whether chemical fertilizer had been singly applied.[18,23] The chemical fertilizer combined with composted manure as the basal application was very common in practice, but there are relatively limited reports on the application of $^{15}$N isotope analysis to identify the use of synthetic fertilizers in organic farming, so the $^{15}$N technique is worth being further studied under the fact that there are currently no other better and reliable techniques available.

Because of the increasing demand on food in China, natural soils such as pasture and forest are converting to agricultural soils. Up to now, most of the relevant studies have been conducted with agricultural soils cultivated for a long time with chemical fertilization, which may have severe effects on the $\delta^{15}$N of plants. It is very common for conventional agriculture to apply chemical fertilizer and composted manure as basal fertilizer, which could increase the $\delta^{15}$N of plant.[17] It is difficult to discriminate if a vegetable with a high $\delta^{15}$N value was really organic, because chemical fertilizer could be used during 2 years of organic conversion. Through a well-schemed experiment, the purpose of this study is to investigate the dynamics of the $\delta^{15}$N value in a single crop with Chinese cabbage (*B. chinensis*) in different seasons with different fertilizer treatments in an uncultivated soil. This result would explore the potential of applying $^{15}$N isotope analysis to discriminate the authenticity of organic food, and further contribute to the $\delta^{15}$N database developed.

## MATERIALS AND METHODS

**Soil and Fertilizers.** A brown soil without any fertilization history was collected from a site of Laoshan Mountain, China (120°53′13″ E, 36°22′10″ N), with temperate marine climate. The soil has a pH in distilled water (1:1) of 6.8, soil organic matter of 7.4 g kg$^{-1}$, total N of 0.676 g kg$^{-1}$, available N of 65.4 mg kg$^{-1}$, available P of 8.9 mg kg$^{-1}$, available K of 75.0 mg kg$^{-1}$, and a total $\delta^{15}$N value of 6.9‰. Because there is no available standard for NPK content evaluation in organic soil in China, instead we referred to the Green food standard−Environmental quality for production area issued by Ministry of Agriculture, China, for the evaluation.[28] The result showed that the NPK content of the soil is low (high, median, and low).

Two types of fertilizer were chosen for this experiment. The organic fertilizer was chicken manure with high-temperature compost treatment (total N of 20.4 g kg$^{-1}$, $P_2O_5$ of 40.0 g kg$^{-1}$, $K_2O$ of 24 g kg$^{-1}$, $\delta^{15}$N of 13.0‰). The chemical fertilizers contained urea (total N of 460 g kg$^{-1}$, $\delta^{15}$N of −1.2‰), calcium superphosphate ($P_2O_5$ of 120 g kg$^{-1}$) and potassium sulfate ($K_2O$ of 500 g kg$^{-1}$).

**Pot Experiment.** A pot experiment with *B. chinensis*, which has a short and fast growing period and can be planted for 2−3 seasons with continual harvest during its entire growing process, was successively conducted in the spring of 2011, the autumn of 2011,and the spring of 2012 at an erimental field of Qingdao Academy of Agricultural Sciences, China. Three treatments with two levels were conducted: for organic treatment, composted chicken manure (code L−M for low dose and H−M for high dose); for chemical treatment, urea application combined with calcium superphosphate and potassium sulfate (N/P/K = 2:1:1) (code L−C for low dose and H−C for high

dose); for compost−chemical treatment, equal parts organic N, chemical N, and potassium sulfate (code L−M+C for low dose and H−M+C for high dose). The control was given no additional fertilizer (code CK). Fertilizer applications equivalent to 75 and 150 kg N $ha^{-1}$ were made for each fertilizer type. Three treatments were employed in a completely randomized factorial design in triplicate.

The spring experiments of 2011 and 2012 were conducted according to the application rates shown in Table 1. After the spring experiment, the autumn experiment of 2011 was conducted in the same pot without any further application to explore the effect of previously added fertilizer in the soil. The soil was air-dried and griddled through a 50 mm sieve, and then 10 kg was thoroughly mixed with fertilizer as a basal application then placed into each plastic pot (200 mm bottom diameter × 300 mm top diameter × 220 mm height, ∼44 L in volume). Sixty-three pots were prepared 5 days before the spring and autumn experiments of 2011 and the spring experiment of 2012, and 20 seeds were planted in each pot on May 23 and August 25, 2011, and May 8, 2012. During the experiment, the vegetables were watered on demand with tap water containing $NO_3^-$ of 33.0 mg $L^{-1}$.

**Sample Collection and Preparation.** Composted chicken manure sample and chemical fertilizer sample were taken before the start of the experiment. The above-ground parts of *B. chinensis* of each treatment were sampled from three pots at the seedling stage (∼20 plants per pot), middle stage (∼10 plants), and terminal stage (∼6 plants), which were conducted on the dates of June 14 (25 days after seeding, DAS 25), June 23 (DAS 31), and June 30 (DAS 38) for the spring experiment of 2011; September 19 (DAS 26), September 29 (DAS 36), and October 9 (DAS 46) for the autumn experiment of 2011; and June 4 (DAS 26), June 15 (DAS 37), and June 27 (DAS 49) for the spring experiment of 2012, respectively. To investigate the relationship between $\delta^{15}N$ of soil and plant, a portion of the soil sample was collected during the spring experiment of 2011 as the vegetable sampling time.

The urea fertilizer sample was directly crushed into powder and sieved. The compost sample was first dried at 60 °C in an oven and then crushed and sieved. The soil samples were air-dried and then homogenized and passed through a 100-mesh sieve. The *B. chinensis* samples were heated at 105 °C in an oven for 30 min to inactivate all enzymes and then dried at 70 °C, homogenized, and passed through a 100-mesh sieve. All the prepared samples were kept in desiccators before analysis.

**Analytical Procedures.** Samples of fertilizer or vegetable containing ∼200−400 μg of N were weighed into tin capsules and then automatically analyzed for their $\delta^{15}N$ and %N values using elemental analyzer−isotope ratio mass spectrometry (EA-IRMS, Elementar Vario PYRO cube equipped with Isoprime100, Isoprime Ltd., England). The EA-IRMS conditions were as follows: the temperature of the oxidation furnace and the reduction furnace were set at 1020 and 650 °C, respectively, and the rate of carrier gas flow was set at 230 mL $min^{-1}$. The nitrogen isotope composition was calculated as

$$\delta^{15}N_{sample}\ (‰) = [(R_{sample}/R_{standard}) - 1] \times 1000 \quad (1)$$

where $R$ is the ratio of $^{15}N/^{14}N$ and standard refers to the ratio for atmospheric $N_2$. Pure $N_2$ ($\delta^{15}N$ = 0‰) served as the reference gas. IAEA-$N_1$ (ammonium sulfate, $\delta^{15}N$ = 0.4‰ ± 0.2‰) was used as the standard reference material. The analytical precision and reproducibility of the measurements for $\delta^{15}N$ were better than ±0.2‰.

**Statistical Analysis.** For statistical analysis, data were first tested for homogeneity of variance and normality of distribution. Analysis of variance (ANOVA) was performed on all experimental variables using the general linear models procedure of the SPSS 10.0 package (SPSS Inc., Chicago, IL, USA) to assess treatment effects. When treatment effects were significant, means were separated by Duncan's multiple range test.

## RESULTS AND DISCUSSION

**Variations in $\delta^{15}N$ Value of *B. chinensis* with Different N Source and Rate in Spring of 2011.** For the spring experiment of 2011 (as shown in Figure 1), the $\delta^{15}N$ values of

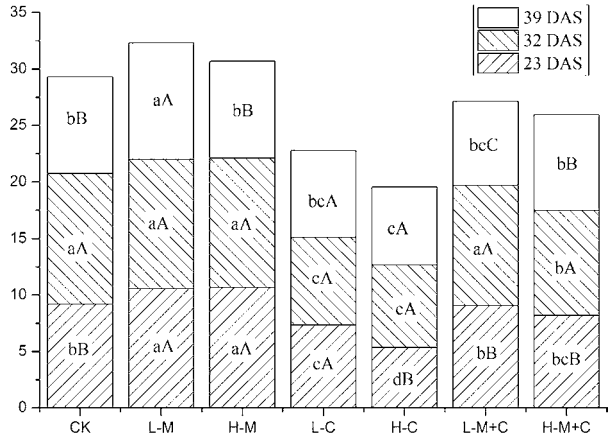

**Figure 1.** Variation in $\delta^{15}N$ of *B. chinensis* for the spring experiment of 2011. Treatment codes are described in Table 1. The same lowercase letter in the bars indicate no significant difference between different treatments at the same stage, and the same capital letters indicate no significant difference between different stages for the same treatment ($\alpha$ = 0.05 level).

*B. chinensis* receiving compost manure at 23 DAS were 10.6‰−10.7‰, significantly higher ($p < 0.05$) than that of the treatment L−C and H−C (5.4‰−7.4‰), L−M+C and H−M+C (8.2‰−9.1‰), and CK (9.2‰), which reflected the $\delta^{15}N$ of chicken compost manure (13.0‰), chemical fertilizer (−1.2‰), and soil N of CK (2.5‰). Temporal variations of $\delta^{15}N$ in the plant could be partially attributed to changes in the concentration and $\delta^{15}N$ value of soil inorganic N that is available for plant uptake. Figure 1 shows that the $\delta^{15}N$ values of *B. chinensis* became higher at DAS 32 for compost treatment (14.4‰), for chemical treatment (7.3‰−7.7‰), for compost−chemical treatment (9.3‰−10.6‰), and for CK (11.5‰). The $\delta^{15}N$ value of the vegetable increased during the later stage of growth, attributable to a decrease in the availability of the synthetic fertilizer over time and an increasing contribution of natural soil nitrogen to plant total nitrogen.[13] However, the value became lower at 39 DAS for compost treatment (8.6‰−10.3‰), for chemical treatment (6.9‰−7.7‰), for compost−chemical treatment (7.4‰−8.5‰), and for CK (8.6‰). There was also a similar report that the $\delta^{15}N$ value of *Brassica campestris* became lower at harvest time (60 DAT) for all treatments except for split additional manure.[19] A previous report also indicated the trend that the $\delta^{15}N$ of corn growing from 30 to 70 days varied from 7.7‰ to 6.7‰ for compost treatment, from 1.0 to 6.0‰ for chemical treatment, and from 4.5‰ to 6.1‰ for compost−chemical treatment.[14] A possible reason for this was that $NO_3^-$ is the most abundant N for plant uptake when compost with enriched $^{15}N$ was added in upland soils,[25] and more $^{15}N$-enriched $NH_4^+$ and $NO_3^-$ produced by nitrification were assimilated with time.[19] The $\delta^{15}N$ values of *B. chinensis* for the same treatment generally did not significantly differ between the low and high doses. The possible reasons for this were that when excess compost or chemical fertilizers were added in the soil, the mineralized N would be the dominant source for plant-N. It is possible that

this source exceeds the uptake ability of the plant, so the $\delta^{15}$N would not be changed even though more N was still available for the plant.[26] However, we also observed exceptions for L−C (mean value of 7.4‰) and H−C (5.4‰) at 23 DAS, L−M+C (10.6‰) and H−M+C (9.3‰) at 32 DAS, and L−M (10.3‰) and H−M (8.6‰) at 39 DAS, and the $\delta^{15}$N of *B. chinensis* for the compost−chemical treatment (8.2‰−9.1‰) was similar to that of CK. Reasons for this could be that the varied microbial immobilization ability of N leads to different mineralizations of fertilizers in soil, but this hypothesis needs to be further studied. There was a significant difference ($p < 0.05$) between the composted manure and the chemical fertilizer for three growth times with the exception of H−M and L−C at 39 DAS; the reasons could be that more N was lost and mineralization at 39 DAS resulted in the small difference of $\delta^{15}$N between H−M and L−C. The difference of different treatments was large at 23 DAS but became smaller at 39 DAS, which is a trend that was similar to the previous reports.[14,19,20,23,26] The results of this experiment indicated that the $\delta^{15}$N values of *B. chinensis* were affected by the addition of fertilizers, and that *B. chinesis* has a higher $\delta^{15}$N value than that of the N source for chemical treatment and for CK but not for compost treatment.

There was an overlap value without a significant difference between H−M (11.4‰) or L−M (11.4‰) and L−M+C (10.6‰) at 32 DAS, and between H−M (8.6‰) and L−M+C (7.4‰) or L−M+C(8.5‰) at 39 DAS, which was also confirmed by the previous reports for vegetables of *Brassica campestris*,[17] tomatoes,[18] lettuces,[18,22,23] onions, cabbages, and Chinese cabbages.[22] Thus, $\delta^{15}$N value could be used as a rough organic marker only in the case of single fertilizer application.[23] It is necessary to employ a statistical methodology to classify a randomly analyzed "off the shelf" sample as organic/conventional.[22]

**Variations in $\delta^{15}$N of *B. chinensis* without Fertilizer Application in Autumn of 2011.** In the autumn experiment of 2011, no additional fertilizer was applied to any pot after the spring experiment. Although the $\delta^{15}$N of the crop may be more affected by the presence of fertilizers, the value could also increase without the addition of fertilizer due to fractionation of N in previous fertilizers.[15] Compared with the results of the spring experiment of 2011, the $\delta^{15}$N value of *B. chinensis* rose especially for CK, L−C, H−C, and H−M+C due to more N mineralized dominantly in soil with a similar amount of $\delta^{15}$N for plant uptake. However, no significant difference was observed between the compost treatment and the chemical treatment (shown in Figure 2). For the autumn experiment of 2011, the $\delta^{15}$N mean value for CK increased significantly to 13.4‰ at 26 DAS, which was higher than that of the spring experiment of 2011 with a 45.6% increase. The $\delta^{15}$N mean values for the L−C (11.5‰), H−C (10.7‰), and H−M+C (10.6‰) were also higher than those of the same treatment in spring 2011 with increases of 55.4%, 98.1%, and 51.4%, respectively. However, the $\delta^{15}$N mean values for L−M (11.2‰), H−M (13.4‰), and L−M+C (11.9‰) at 26 DAS increased slightly with increases of 6.7%, 25.2%, and 14.4%, respectively. Our result was in agreement with the previously reported canola case, where the $\delta^{15}$N of canola was about 5.5‰ in the first year, 6.6‰ in the third year with hog manure, and 8.5‰ in the fourth year without hog manure application.[15] This could be explained by the fact that more $^{15}$N were enriched due to N lost or fractionation in soil after the spring

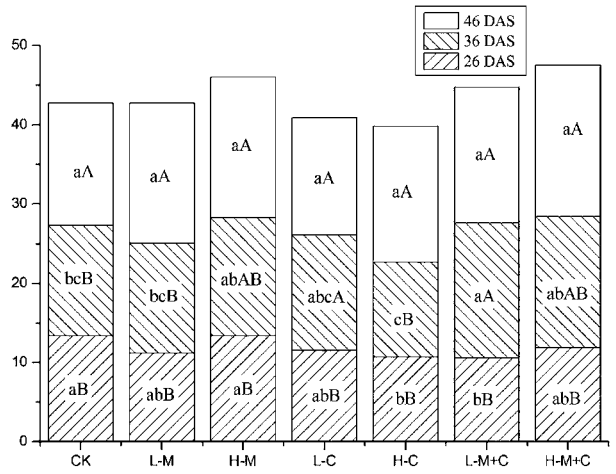

**Figure 2.** Variation in $\delta^{15}$N of *B. chinensis* for the autumn experiment of 2011. Treatment codes are described in Table 1. The same lowercase letter in the bars indicate no significant difference between different treatments at the same stage, and the same capital letters indicate no significant difference between different stages for the same treatment ($\alpha$ = 0.05 level).

experiment and were absorbed by the vegetable in the autumn experiment.

With the growth of *B. chinensis*, the $\delta^{15}$N mean value continued to be higher and was maintained at a high level with a range of 12.0−17.0‰ at 36 DAS and 14.8‰−19.1‰ at 46 DAS for all treatments (shown in Figure 2) due to high uptake of $\delta^{15}$N with the help of microbial nitrification effects. The maximum value of $\delta^{15}$N in *B. chinensis* was 17.7‰ for H−M, which was higher than that of organic tomato (16.6‰), lettuce (17.2‰), carrot (11.2‰),[12,17] cabbage (16.0‰),[18] and rice at harvest (<9.0‰),[19] as well as lettuce (<9.0‰),[22] and it extended the known database of the $\delta^{15}$N value in organic food. The large variation of $\delta^{15}$N in *B. chinensis* for most treatments between the terminal stage (46 DAS) and the seedling stage (26 DAS) was also observed, which was >6.0‰ for the treatment of L−M, H−C, L−M+C, and H−M+C. The mean values of $\delta^{15}$N for the treatments L−C and H−C were lower than those of the treatments L−M and H−M at the terminal stage (46 DAS). However, there were no significant differences among the various treatments, except for H−C (12.0‰) compared with L−M+C (17.0‰) and H−M+C (16.5‰). These findings indicated that the $\delta^{15}$N value of *B. chinensis* without chemical fertilizer application (such as in organic conversion) may also be higher than that of organic vegetable as other studies reported and proved that the vegetable with chemical fertilizer history within organic conversion would possibly be mislabeled as "organic food" if only judging on its high $\delta^{15}$N value.

**Variations in $\delta^{15}$N Values of *B. chinensis* with Further Fertilizer Application in Spring of 2012.** For the spring experiment of 2012, the same dose fertilizer as the 2011 spring experiment was employed to the corresponding treatment after the autumn experiment. As shown in Figure 3, the $\delta^{15}$N values for *B. chinensis* at 26 DAS decreased compared with that of the autumn experiment. Compared with the 2011 autumn experiment, we observed a sharp decrease in chemical fertilizer treatment. The mean $\delta^{15}$N values of L−C and H−C were significantly lower at 72.2% and 72.9%, respectively. This finding could result from additional urea-N application with more available $^{14}$N to plants, and it is in good agreement with

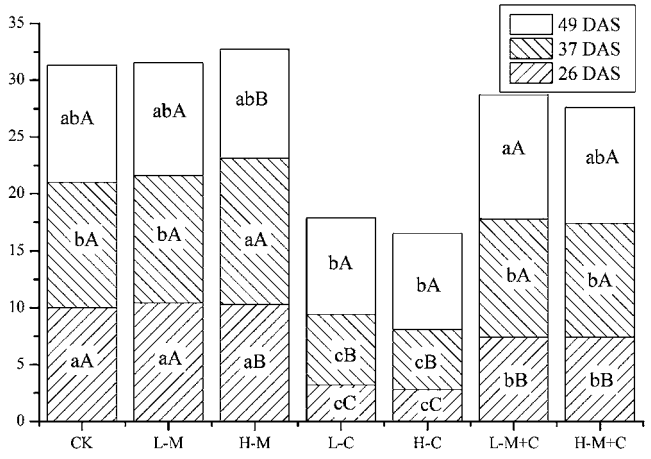

**Figure 3.** Variation in $\delta^{15}$N of *B. chinensis* for the spring experiment of 2012. Treatment codes are described in Table 1. The same lowercase letter in the bars indicate no significant difference between different treatments at the same stage, and the same capital letters indicate no significant difference between different stages for the same treatment ($\alpha$ = 0.05 level).

previous reports depicting the fast response and sharp decline in $\delta^{15}$N values with additional chemical fertilization in Chinese cabbage[19] and lettuce.[23] The results in the 2012 experiment at 26 DAS had a similar trend as those from the spring experiment of 2011, with the range of 10.0‰ for CK, 10.3‰−10.4 ‰ for L−M and H−M, 2.8‰−3.2‰ for L−C and H−C, and 7.4‰ for L−M+C and H−M+C. The values observed in this experiment for the treatment L−C and H−C were also lower than those of the 2011 spring experiment at 55.4% and 48.1%, respectively, which may result from two applications of urea-N. The $\delta^{15}$N value of the vegetable reflected the isotopic composition and historical fertilization of N sources and changed remarkably when isotopically different N sources were added.[19] For treatments of L−M+C and H−M+C, the mean $\delta^{15}$N values were much lower than those of the autumn experiment at 29.2% and 37.3%, respectively. The results were slightly lower than those from the 2011 spring experiment at 17.6% and 9.8%, respectively. However, results from treatments of CK, L−M, and H−M were similar to those of the spring experiment and lower than those of the autumn experiment in 2011. These results indicated that the types of fertilizers directly affected the $\delta^{15}$N value of the vegetable as previously reported.[14] Different manures may have different temporal effect patterns, for instance, the grain $\delta^{15}$N of barley in hog manure plots showed an increase tendency with time, but the phenomenon was not observed in the cattle manure treatment.[15] In our study, there was also a tendency observed that the $\delta^{15}$N values of *B. chinensis* receiving chemical fertilizer treatment were significantly lower ($p$ < 0.05) than those receiving compost manure at the early growth stages. The difference became narrower during the later stage, possibly due to a decrease in the availability of the chemical fertilizer over time (plant uptake, loss and immobilization, etc.) and contribution of natural soil nitrogen to plant total $\delta^{15}$N.[13] At 49 DAS, the $\delta^{15}$N value for L−M and H−M decreased compared with that at 37 DAS, from 11.2 to 9.9‰ and from 12.8‰ to +9.6‰, respectively, which may be explained by uptake of mineralized N from the organic pool decreasing the value during the later period.[14] The $\delta^{15}$N value for treatment H−C (8.4‰) has significant differences ($p$ < 0.05) with that of CK (10.3‰) and L−M+C (10.9‰), and there were no significant differences observed among other treatments. Although the $\delta^{15}$N of *B. chinensis* may be increased by compost application or decreased by chemical application, the results of this season experiment also showed that no significant differences ($p$ > 0.05) were observed between high dose and low dose for the same treatment, except for L−M and H−M at 37 DAS. This result corroborated that fertilizer quantity was not a key factor effecting $\delta^{15}$N of carrot[13] and cabbage.[26] The $\delta^{15}$N value of the vegetable may vary depending on the vegetable variety and the fertilizer type. The $\delta^{15}$N values of *B. chinensis* observed in this experiment were different from those for cabbage that were 7.7‰ for CK, 3.2‰ for urea, and 11.9−13.2‰ for liquid manure-A and 13.0‰−14.9‰ for liquid manure-B.[16] Another example was that the $\delta^{15}$N values for strawberry fruits grown in the presence of inorganic and organic fertilizers were −0.4 ± 1.5‰ and 9.2 ± 1.7‰, respectively.[27] This may be because of different manures with different $\delta^{15}$N values and variations in the uptake rates of different vegetables.

As a summary of the pot experiments of three continuous seasons at middle stage, the $\delta^{15}$N value of *B. chinensis* for the spring experiment of 2011 at 32 DAS has a similar value to that of 2012 at 37 DAS (shown in Figure 4), which was mostly

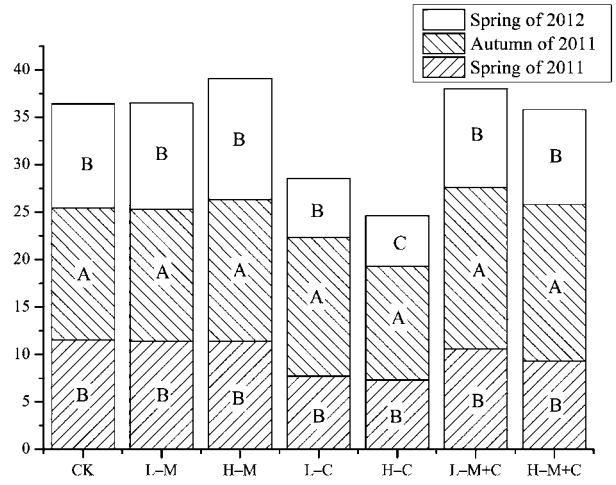

**Figure 4.** Variation in $\delta^{15}$N of *B. chinensis* for the middle stage of three experiments. Treatment codes are described in Table 1. The same capital letter in the bars indicate no significant difference between different seasons at the middle stage ($\alpha$ = 0.05 level).

affected by the types of fertilizers. Both experiments had a similar tendency, which is that there was a significant difference between the compost treatment and the chemical treatment. However, there was an apparent overlap in $\delta^{15}$N value for the combined application of chemical and compost fertilizer. The $\delta^{15}$N value of *B. chinensis* for the autumn of 2011 without any additional fertilizer at 36 DAS increased (shown in Figure 2), and was higher than those of the spring of 2011 and 2012, but there was no significant difference between the compost treatment and the chemical treatment.

**Variation in $\delta^{15}$N Value of Soil with Different N Source and Rate.** The total $\delta^{15}$N of soil was determined only for the spring experiment of 2011 to investigate the variation in $\delta^{15}$N of soil affected by different fertilizers and the relationship of $\delta^{15}$N between soil and plant. The $\delta^{15}$N mean value of soil (no fertilizer application) before this experiment was 6.9‰, which

was very close to the previous report[20] with 6.4‰. After fertilization and uptake by vegetables, the $\delta^{15}$N mean value range of soil at 23 DAS was 2.5‰ for CK, 5.3‰−6.3‰ for L−M and H−M, 2.2‰−2.4‰ for H−C and L−C, and 2.7‰−4.5‰ for L−M+C and H−M+C, as shown in Figure 5. The

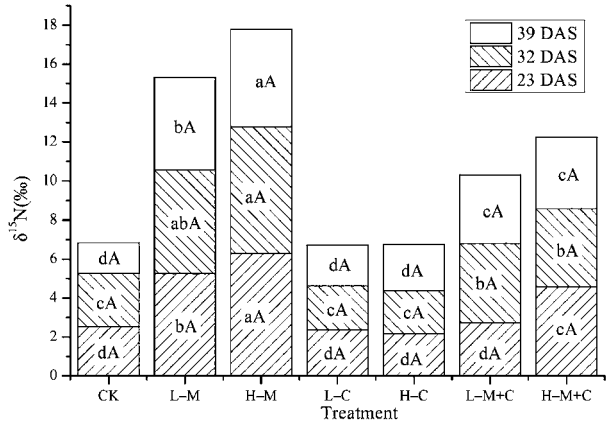

**Figure 5.** Variation in $\delta^{15}$N of soil for the spring experiment of 2011. Treatment codes are described in Table 1. The same lowercase letter in the bars indicate no significant difference between different treatments at the same stage, and the same capital letters indicate no significant difference between different stages for the same treatment ($\alpha$ = 0.05 level).

total $\delta^{15}$N mean value of soil was lower for chemical treatment than that for compost treatment, which may be explained by the fact that the $\delta^{15}$N of soil was more affected by the chemical fertilizer than by the compost fertilizer. There was a significant difference ($p < 0.05$) between the compost treatment (L−M, H−M) and CK as well as other treatments. There was also a report[25] that the total $\delta^{15}$N value of soil was significantly higher for compost-applied (8.8‰) than for fertilizer-applied (5.9‰), which corroborated that the $\delta^{15}$N value of upland-grown plants receiving compost would be higher than those treated with chemical fertilizer because $NO_3^-$ is the most abundant N for plant uptake. However, another report showed that there was no difference between the organic production and the integrated production for total $\delta^{15}$N of soil, because the quantity of fertilizer application added was only ∼1/100 of the total soil N-pool.[24] As shown in Figure 5, the $\delta^{15}$N mean value of soil from 32 DAS to 39 DAS varied over time from 2.7‰ to 1.6‰ for CK, and also had a tendency to go from higher to lower for other treatments. Although the total $\delta^{15}$N values slightly varied with the growing stage for all treatments, there were no significant differences ($p > 0.05$) among three stages. The total $\delta^{15}$N values of the treatment L−M (5.3‰) and H−M (6.3‰) were higher than those of L−C (2.4‰) and H−C (2.2‰) at 23 DAS, which were also significantly different ($p < 0.05$) at 32 DAS and 39 DAS. The $\delta^{15}$N values of soil were affected by the different fertilizer treatments found in this experiment, and the $\delta^{15}$N values of *B. chinensis* were also affected by that of soil, as per the previous report that the $\delta^{15}$N of upland-grown plants receiving compost would be higher than for those treated with chemical fertilizer.[16]

Figure 6 shows that the $\delta^{15}$N of *B. chinensis* were all higher than that of soil during the spring experiment of 2011, which has a positive correlation to that of soil at the seedling stage ($R^2$ = 0.537, $p$ = 0.0656). As *B. chinensis* grew, the positive correlation became minor at the middle stage ($R^2$ = 0.485, $p$ =

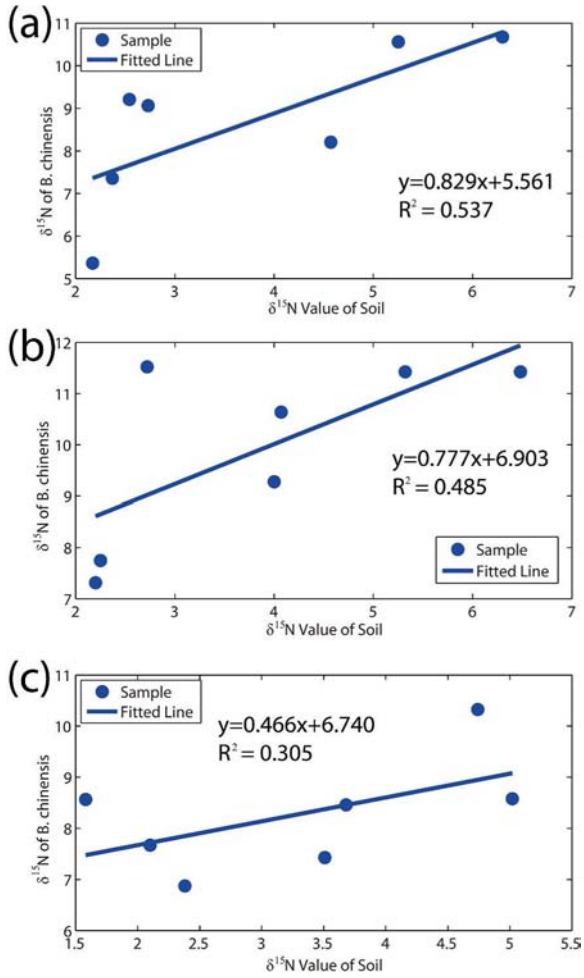

**Figure 6.** Relationship of $\delta^{15}$N between *B. chinensis* and soil in the spring experiment of 2011 at the seedling stage (a), the middle stage (b), or the terminal stage (c).

0.0848) and the terminal stage ($R^2$ = 0.305, $p$ = 0.2102). The results also confirmed that total $\delta^{15}$N value of *B. chinensis* was greatly affected by N derived from compost or fertilizer rather than indigenous soil-N during the early growth season as previously reported.[25] The results demonstrate that there was no strong correlation ($p > 0.05$) between *B. chinensis* and soil in terms of $\delta^{15}$N value, which was in agreement with the previous study.[25]

Finally, the results of this experiment confirmed that the $\delta^{15}$N value of *B. chinensis* increased when organic manure fertilizer was applied and was significantly different fromthose for manure treatment and chemical treatment. With the growth, the $\delta^{15}$N value of *B. chinensis* varied depending on the fertilizer application. There was no fixed cutoff value for $\delta^{15}$N in organic discrimination. The $\delta^{15}$N value of *B. chinensis* in the autumn of 2011 without any fertilizer application was higher than those for the spring experiments of 2011 and 2012. This may be the result of the fact that more soil-$^{15}$N from N lost or fractionation in soil after the spring experiment was absorbed by the vegetable, which confirmed that using uncultivated soil in the pot experiment could eliminate the effect of background interference on the $\delta^{15}$N of plant. The $\delta^{15}$N value of soil was slightly affected by fertilizers and varied without significant difference among three growing stages of *B. chinensis*. Thus, the $\delta^{15}$N value may be useful to discriminate whether a particular

dx.doi.org/10.1021/jf502627c | J. Agric. Food Chem. 2014, 62, 11386−11392

vegetable was grown in the presence of a chemical fertilizer (a low value, ~3.0‰) or in the presence of compost manure or a chemical−compost fertilizer (a high value, ~10.0‰). Once again, it was difficult to discriminate if a labeled organic vegetable was really grown without chemical fertilizer just using the $\delta^{15}$N value, especially for the overlap value of those planted with chemical−compost fertilizer. However, the results also indicated that the $\delta^{15}$N value of *B. chinensis* grown with compost manure or chemical−compost treatment has a higher value compared to vegetables previously reported, which could be useful for the development of the $\delta^{15}$N value database for organic food discrimination.

relationship between N availability and flavonol or total phenolic concentrations in leaf mustard (*Brassica juncea*), tomato (*Lycopersicon esculentum*), and *Arabidopsis thaliana*.[26,27] Moreover, a report on eight different field-grown curly kale cultivars showed relatively high flavonoid concentrations in traditional old cultivars in contrast to lower concentrations in hybrids.[5]

However, the influence of the genetic variation on flavonoid glycoside and GLS concentrations associated with fertilizer strategies, agronomic characteristic, and biomass allocation in traditional and F1 hybrid cultivars of curly kale has not been reported. Trials conducted under field growth conditions with less control over biogeochemical environments compared to, for example, greenhouse experiments are necessary in the testing of agronomic practices, particularly when a crop stand is examined with relevance to growers and consumers.

On the basis of testing genetic variation between traditional and F1 hybrid kale cultivars to optimize fertilizer management based on genotype, the objectives of this study were as follows: (i) investigate whether GLS and flavonoid glycoside concentration and composition differed markedly among cultivars; (ii) determine if varying N supplies in relationship to agronomic characteristic and biomass allocation modified GLS and flavonoid glycoside composition and concentration; and (iii) investigate field S and N application effects on GLS concentration and composition.

## MATERIALS AND METHODS

**Chemicals.** Glucoiberin, progoitrin, glucoraphanin, gluconapin, sinigrin, 4-hydroxyglucobrassicin, glucobrassicin, 4-methoxyglucobrassicin, and neoglucobrassicin were obtained from C2 Bioengineering ApS (Karlslunde, Denmark); glucotropaeolin was from PhytoLab GmbH & Co. KG (Vestenbergsgreuth, Germany); and acetic acid, barium acetate, calcium glycerophosphate hydrate, methanol, sulfatase, and sodium hydroxide were obtained from Sigma-Aldrich (Steinheim, Germany).

**Field Experiment.** The field site was located at the Department of Food Science in Aarslev, Denmark (55°18′N, 10°27′E) on a sandy loam (Typic Agrudalf) soil containing 1.35% organic C, 33% coarse sand, 38.8% fine sand, 12.6% silt, and 13.4% clay. Inorganic N and S levels in the field before planting were 10 and <4 kg ha$^{-1}$, respectively. Seeds of the F1 hybrid 'Reflex' (SeedCom A/S, Denmark) and the traditional cultivars 'Halvhøj Ekstra Moskruset Tiara' (TIARA) accession 1833 and 'Høj Amager Toftø' (HAT) accession 4085 (both NordGen germplasm collection)[28] were sown on April 4, 2011, and propagated in an unheated greenhouse. Plants were transferred to the field on May 5, 2011, with a row/plant distance of 50/60 cm, respectively. Plots of 3 × 5 m$^2$ with the two outermost rows as guard rows to eliminate border effects were arranged in a complete randomized block design with three replication of plots ($n = 3$) per fertilizer level and cultivar (see below). An insect net was applied over the plots and used for pest management to reduce herbivory until August 16, 2011. Weeding was conducted manually and mechanically once during the experimental trial. The trials included two separate experimental regimes. Experiments were performed as follows: In experiment I, Reflex, HAT, and TIARA were grown under 30 kg S ha$^{-1}$ with 90, 135, 185, or 230 kg N ha$^{-1}$ available in the field (36 plots in total with 30 kg S and 185 kg N ha$^{-1}$ being standard conditions); and under experiment II, Reflex had either 4 or 30 kg S ha$^{-1}$ available combined with 90, 135, or 185 kg N ha$^{-1}$ accessible in the field (18 plots in total). Fertilizer levels applied were adjusted according to the levels in the field measured before planting. S fertilizer was dispersed just prior to planting, and approximately half the total N fertilizer dose was distributed just after planting. The other half was given 6 weeks later. Granulate kieserite ($MgSO_4$, 20% S, K+S Kali GmbH, Germany) and granulate calcium ammonium nitrate ($NH_4NO_3$+Ca, 27% N, Hydro Agri Danmark A/S, Denmark) were used as S and N sources, respectively. On October 10, 2011, 10 plants from each replicate plot were harvested, including the entire stalk and leaves (corresponding to 3.1 m$^2$), and total yield was assessed. Four of 10 plants from each plot were evaluated with respect to stalk height from plant base at soil surface to the plant top. Yield characteristics were estimated as follows: edible yield as usable leaf weight (stem diameter < 7 mm) and stalk weight without leaves, stems, and top. Entire plants were maintained at a temperature of 1 °C and 100% relative humidity in black plastic bags until further analysis within 4 days. The plants were handled carefully to avoid tissue disruption and thereby loss of GLSs. The described experiments correspond to analyses 2, 3, and 4 reported by Jensen et al.[10] from which sensory evaluation of the different fertilization approaches was assessed.

**Plant Analyses.** Representative samples of approximately 200 g of separated leaves and stalks from each plot were oven-dried at 80 °C to a constant weight, and dry matter content (DM) was calculated. Total leaf and stalk N and S concentrations were analyzed from the oven-dried material. VDLUFA methods were used to determine plant N and S.[29,30]

**Glucosinolate Analysis.** Three of the 10 harvested plants per replication plot ($n$ = 3) were randomly selected, and nine evenly distributed leaves per plant with a stem width at the widest point of approximately 7 mm were removed from the primary stem. Curly kale leaves were rinsed in cold tap water, chopped fine, immediately frozen in liquid nitrogen, and stored at −24 °C until freeze-drying in a CHRIST freeze-dryer, Gamma 1-20 (Osterode am Harz, Germany). After freeze-drying, the samples were ground in an Ultra Centrifugal Mill, ZM 200 (Retsch, Haan, Germany). GLS concentration was determined as described by Beck et al.[31]

**Flavonoid Glycoside and Hydroxycinnamic Acid Analysis.** Twenty milligrams of the freeze-dried ground leaves was extracted with 600 μL of 60% methanol (MeOH) (Roth, Karlsruhe, Germany) and shaken for 40 min in a Thermomixer (Eppendorf, Thermo Fischer Scientific Inc., Wesseling-Berzdorf, Germany) at 1400 rpm and 20 °C. Hereafter, extracts were centrifuged at 12000 rpm for 10 min. The supernatant was transferred to a new sterile test tube. The procedure was repeated twice with 400 μL of 60% MeOH, for 20 min, and with 200 μL of 60% MeOH, for 10 min. The combined supernatants were filtered through a Spin-X (Sigma-Aldrich Chemical Co., St. Louis, MO, USA) tube by centrifugation at 3000 rpm for 5 min and dry evaporated in a vacuum centrifuge. The residue was dissolved in 200 μL of distilled water. Flavonoid glycosides and hydroxycinnamic acid derivatives were qualified by HPLC-DAD-MS$^n$ according to their parent ions and fragmentation patterns as described by Schmidt et al.[23] and quantified as equivalents of caffoylquinic acid and 3-*O*-glycosides of quercetin, kaempferol, and isorhamnetin as described by Neugart et al.[32] Analyses were done for experiment I but not experiment II as influences of S on flavonoid glycosides and hydroxycinnamic acid derivatives were not expected.

**Statistical Analyses.** All univariate statistical analyses were performed in SAS (SAS Institute Inc., Cary, NC, USA; release 9.2, 2000). The general linear model and general linear mixed model procedures were applied for comparison of least-squares (LS) means ($p \leq 0.05$). GLS, flavonoid glycoside, and hydroxycinnamic acid derivative analyses (this study) and sensory analyses (reported in Jensen et al.[10]) were made from all treatments in experiment I except HAT grown under 135 and 185 kg N ha$^{-1}$. Therefore, each of the 10 cultivar and N level combinations in experiment I were grouped as one factor to compare data analysis results using statistical contrasts. All linear relationships were investigated using a simple linear regression.

## RESULTS AND DISCUSSION

**Agronomic Characteristics and Glucosinolate Concentrations.** *Experiment I: N Level and Cultivar Effects.* The three cultivars showed distinct differences in agronomic characteristic parameters, which consisted of total and edible yield, stalk weight and height, and leaf and stalk N and S content as well as total N and S uptake. The HAT cultivar exhibited the highest total yield, but Reflex generated the highest edible yield (Table 1). The shift in highest total and edible yield between HAT and Reflex, respectively, corresponded to stalk data. Likewise, higher leaf S and stalk N and S concentrations corresponded to lower yields of TIARA, opposite Reflex. Similar to our findings, Padilla et al.[33] identified different morphologic and agronomic traits of 148 kale landraces (*acephala* group) resulting in 5 clusters based on these trait differences. The higher stalk N concentration in TIARA indicated that TIARA growth was not limited by N availability at increased N applications, which was consistent with the capacity of cabbage to take up more N than required for growth.[34] Total S uptake did not respond to increased application of N, whereas total N uptake increased continuously from 90 to 230 kg N ha$^{-1}$ applied (Table 1). This result does not support the close association in plant N and S assimilation, where adenosine 5′-phosphosulfate (APS) plays a special role in relationship to S assimilation[35] and APS reductase activity, which is controlled by N availability.[36] Possibly *B. oleracea*, with the capacity to accumulate nitrate, does not apply strictly to this hypothesis as similar findings of less N and S interaction in relation to plant N and S concentration have been reported in other field studies.[14,15,34] Thus, increasing N application resulted in increased edible yield of Reflex, whereas TIARA showed no response in biomass despite elevated stalk N concentrations (Table 1). The response of HAT to N was mainly found in increased stalk biomass and total yield.

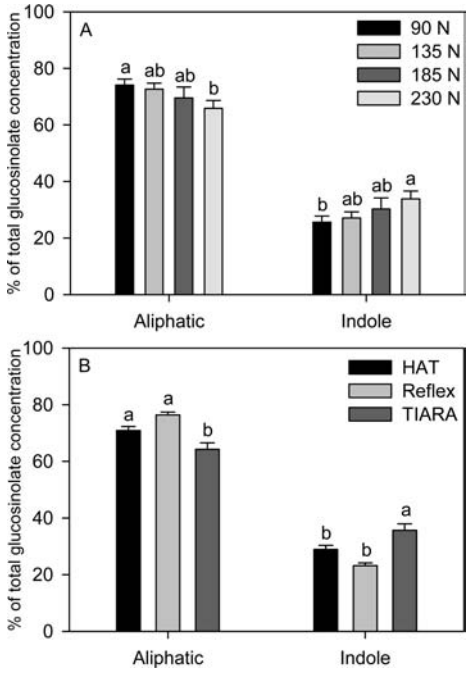

**Figure 1.** Effects of available nitrogen (kg ha$^{-1}$) on aliphatic and indole percentage of total GLS concentration in curly kale cultivars HAT, Reflex, and TIARA. Different letters indicate significant differences ($p \leq 0.05$) among cultivars or N levels ($n$ = 3) within the glucosinolate groups. There were no statistical interactions between N and cultivar. Bars represent standard errors.

Different agronomic characteristics were associated with a diverse GLS composition observed among the three cultivars. The following GLSs were identified: the aliphatic GLSs, including glucoiberin (3-methylsulfinylpropyl GLS), sinigrin (2-propenyl GLS), glucoraphanin (4-methylsulfinylbutyl GLS), gluconapin (3-butenyl GLS), and progoitrin ((*R*)-2-hydroxy-3-butenyl GLS); the indole GLSs, including glucobrassicin (3-indolymethyl GLS), 4-hydroxy glucobrassicin (4-hydroxy-3-indolylmethyl GLS), 4-methoxy glucobrassicin (4-methoxy-3-indolylmethyl GLS), and neoglucobrassicin (1-methoxy-3-indolylmethyl GLS); and the aromatic gluconasturtiin (2-phenylethyl GLS). Cultivars differed in total GLS concentration (TIARA, 3503 μg g$^{-1}$ DM; HAT, 2799 μg g$^{-1}$ DM; Reflex, 2454 μg g$^{-1}$ DM; cultivar, $p < 0.01$; N × cultivar, not significant). Increased N application resulted in a decreased percentage of the aliphatic GLS group and a corresponding increase in indole GLS percentage (Figure 1A, $p < 0.0001$). Studies in broccoli and green cabbage were congruent with our results, but the present study is the first documented in field-grown curly kale.[13−15] However, wild-type Col-0 *Arabidopsis* studies found $NO_3^-$ addition repressed the shikimate pathway, responsible for the synthesis of flavonols and the indole GLS amino acid precursor tryptophan.[19,37] A negative linear relationship was detected for Reflex, between edible yield and aliphatic or total GLS concentration, respectively ($p$ = 0.0193, $R^2$ = 0.44; and $p$ =

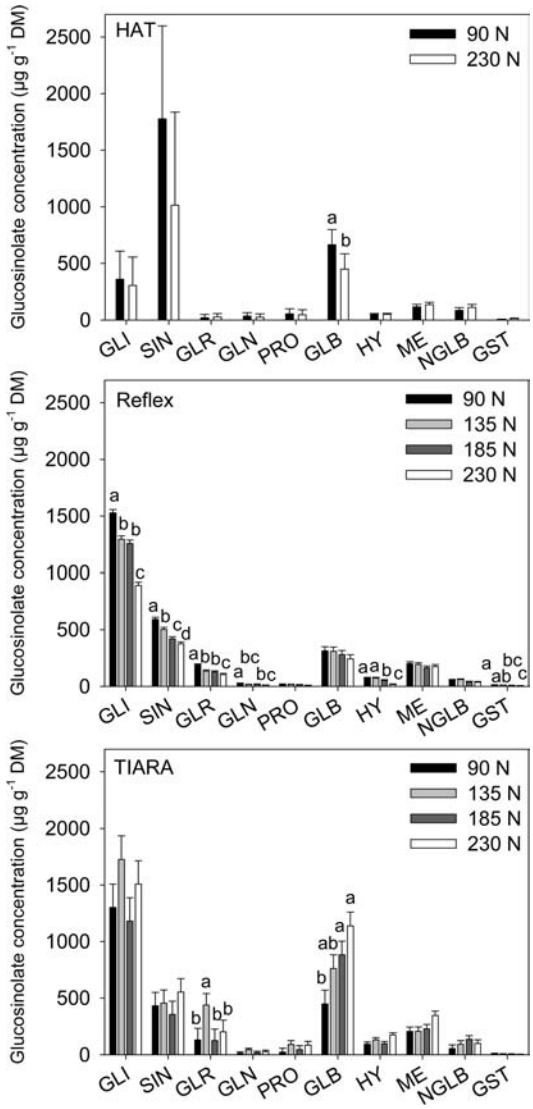

**Figure 2.** Effects of nitrogen (N) available (kg $ha^{-1}$) on individual glucosinolate concentrations ($\mu g\ g^{-1}$ DM) in the edible plant material of curly kale cultivars HAT, Reflex, and TIARA. Different letters indicate significant differences ($p \leq 0.05$) in a general linear mixed model among N level means ($n = 3$) within glucosinolate. Bars represent standard errors. GLI, glucoiberin; SIN, sinigrin; GLR, glucoraphanin; GLN, gluconapin; PRO, progoitrin; GLB, glucobrassicin; HY, 4-hydroxyglucobrassicin; ME, 4-methoxyglucobrassicin; NGLB, neoglucobrassicin; GST, gluconasturtiin.

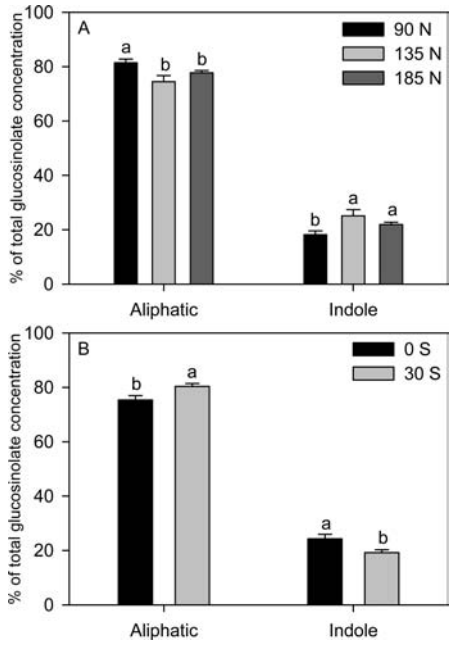

**Figure 3.** Effects of nitrogen and sulfur available (kg $ha^{-1}$) on aliphatic and indole percentages of the total GLS concentration in the edible plant material of curly kale cultivar Reflex. Different letters indicate significant differences ($p \leq 0.05$) between N or S level means ($n = 3$) within the glucosinolate group. Bars represent standard errors.

0.0023, $R^2 = 0.62$, respectively), while TIARA showed a positive linear relationship between indole GLS concentration and edible yield ($p = 0.0395$, $R^2 = 0.36$). Suggestions on increased biosynthesis of C-, N-, and S-containing phytochemicals in cases of limited availability to one or more of the compounds have been put forward.[18−20] For example, increased N availability under normal $CO_2$ conditions might increase N-containing phytochemicals such as GLSs as C limits growth. Likewise, growth limitation by less N availability might shift to metabolism of phytochemicals containing much C, such as flavonoids. Partly contradicting our results, studies on GLS content of Chinese kale (*Brassica alboglabra* L.) grown under increasing N levels showed reduced aliphatic GLS but enhanced indole GLS concentrations with both ambient and elevated $CO_2$ levels.[38] In this study the increased indole GLS concentration response in TIARA reflected limited growth by factors other than N and, to some extent, aliphatic and total GLS decrease in Reflex, where N but not C was presumably scarce. However, GLSs also contain C, and the biosynthetic pathways for N- and C-containing phytochemicals cannot be fully distinguished, as indicated above. This was further documented by Sønderby et al.,[39] who reported an epistatic effect of aliphatic myeloblastosis (MYB) transcription factor on total indole GLS concentration. Moreover, aliphatic GLSs also contain N, although less than indole GLSs. Controlled crop improvement is very often aimed at higher yield, which was demonstrated in our results, where the modern F1 hybrid Reflex showed increased edible yield (Table 1). Therefore, reduced growth and higher N concentration in TIARA might be associated with increased indole GLS percentage, and total GLS concentration, compared with HAT and Reflex, which exhibited higher yield, lower N concentrations, and variable ratios between leaf and stalk growth.

Notable differences between individual GLS concentrations of the cultivars were detected (Figure 2). These differences reflected the diverse growing patterns as a result of increasing N application where the homomethionine-derived aliphatic GLSs glucoiberin and sinigrin concentrations decreased in Reflex opposite no response in TIARA. Further cultivar differences were revealed for the dihomomethionine-derived aliphatic GLSs glucoraphanin and gluconapin with concentration decreases in Reflex in contrast to an optimum of glucoraphanin concentration at 135 kg N $ha^{-1}$ in TIARA. Possibly the activity of methylthioalkylmalate synthase 1 (MAM) and MAM3, which catalyzes condensations in the chain elongation process of homomethionine- and dihomomethionine-derived aliphatic GLSs,[37] responds differently to N and S, dependent on the cultivar. A S-dependent response in MAM activity due to more substrate in the chain elongation process has previously been suggested,[40] whereas our results propose genetically determined diverse N sensitivity. N effects on the indole glucobrassicin

differed between all cultivars with increasing concentrations in TIARA and no response in Reflex. Furthermore, a trend of more glucobrassicin hydroxylation and methoxylation with increasing N application in TIARA is suggested. Higher susceptibility of indole GLSs to environmental influences[11] supports the diverse responses of indole GLSs among cultivars in contrast to uniform and possibly genetically determined responses to N of aliphatic GLSs within cultivar. In a study of 148 kale landraces (*acephala* group), 5 clusters based on morphologic and agronomic traits differed in total GLS concentration and all individual GLSs except sinigrin.[4] Calculated from the agronomic traits described, the cluster with the highest edible yield contained the highest total GLS concentration, opposite TIARA in our study. The cluster constituted by the tallest plants and lower edible yields had lowest total GLS concentration but highest concentration of glucoiberin. The results suggested a similar relationship between agronomic traits and GLS content, but the agronomic characteristics and GLS concentrations were not comparable. Stalk S status might be important to GLS concentration; internal sulfate pools in *Arabidopsis thaliana* have been documented mobile under S deficiencies due to high vacuolar transporter expression.[41] However, the three cultivars showed no visible signs of S deficiency, that is, uniform chlorosis, and stalk S concentration level was positively related to leaf GLS

concentration level rather than exhibiting an inverse relationship. These results indicated the necessity to examine agronomic characteristic and biomass allocation of traditional and F1 hybrid curly kale cultivars to assess altered GLS composition in future research.

*Experiment II: N and S Level Effects.* The GLSs identified were similar to those resolved in experiment I. S application increased the total GLS concentration substantially, besides the percentage of the aliphatic GLS group within total GLS concentration, and decreased indole GLS percentage correspondingly (Figure 3B, $p = 0.00911$; Table 2). Similarly, Stavridou et al.[14] and Rosen et al.[15] showed a comparable response to S fertilization in field studies of broccoli and cabbage, but diverse effects were observed from N supplies. In the current study, an interaction between N and S levels was only found for gluconasturtiin (Table 2). Earlier investigations in other *Brassica* species grown in pots have demonstrated higher level interactions between N and S applications in relationship to GLS concentration.[12,17] Our results obtained under less constricted field conditions showed relatively higher total N uptake at low N fertilizer levels and total S uptake in experiment II (40 kg S $ha^{-1}$ on average when no S was applied; data not included). This reflects influence from other soil properties under field conditions contra, for example, pots or hydroponics, such as N and S mineralization of soil organic matter. These observations might explain the reduced number of interactions between N and S as the N and S soil pool is influenced by other factors in addition to fertilizers applied.[15] They emphasize the challenges in transfer of management methods to manipulate GLS biosynthesis from highly controlled environments to large-scale production under field conditions. Closely related N and S assimilation in plants often causes an interaction between N and S fertilizers in relationship to plant N and S concentrations. APS reductase regulates the balance between S partitioning in primary or secondary metabolism and controls 90% of the primary sulfate reduction, which leads to cysteine and glutathione, which both donate S in core GLS biosynthesis.[37,42] However, Mugford et al.[20] reported that even though APS reductase capacity was reduced and resulted in sulfate accumulation, the GLS pathway end-products showed no decrease in a mutant *Arabidopsis thaliana*. Therefore, although a close relationship existed between N and S assimilation and between primary and secondary S metabolism with respect to GLS biosynthesis, enzyme and substrate levels were under more complex regulation,[20] which was consolidated by multifaceted soil properties in the present study.

**Agronomic Characteristics, Flavonoid Glycosides, and Hydroxycinnamic Acid Derivatives.** *Experiment I: N Level and Cultivar Effects.* Schmidt et al.[23] and Neugart et al.[32] identified 71 flavonoid glycosides and 3 main hydroxycinnamic acid derivatives, which were also detected in HAT, Reflex, and TIARA. We selected 19 structurally different flavonoid glycosides, including the main flavonol glycosides and related structures in kale, and the three main hydroxycinnamic acid derivatives to examine cultivar and N level effects on these phytochemicals (Figure 4; Table 3). Kaempferol glycosides were the main constituent in the three kale cultivars, followed by hydroxycinnamic acid derivatives, and quercetin glycosides (Table 4). Quercetin and total flavonoid glycosides decreased with increasing N application in Reflex. This was in line with the results of Stewart et al.,[26] who found decreasing concentrations of quercetin and total flavonoid aglycones as well as kaempferol and isorhamnetin in *Arabidopsis thaliana* when increasing N levels were applied. Furthermore, another *Arabidopsis* study revealed a broad and clear coordinated response to $NO_3^-$ addition in genes controlling phenylpropanoid and flavonoid metabolism, as well as primary metabolism, suggesting a shift away from C-rich phytochemicals, such as flavonols.[19] This corresponded to the balance between N and C in relationship to primary and secondary metabolism as discussed in connection to GLSs.

Higher quercetin glycoside and lower isorhamnetin glycoside concentrations in Reflex, as compared to HAT ($p < 0.0001$ and $p < 0.01$, respectively), indicated decreased quercetin to isorhamnetin conversion in Reflex, possibly due to the reduced activity of the responsible enzyme, quercetin-3-*O*-methyltransferase, which is suggested not to be affected by N concentration.[40] Cultivar differences in our study do not support this as Reflex seemed to be more responsive to N fertilization with respect to phytochemical modulation as well as biomass production. A study on two F1 kale hybrids revealed no changes

[a] ± standard deviation. [b] *, $p \leq 0.05$; **, $p < 0.01$; ***, $p < 0.001$ in a general linear model among N level and cultivar means ($n = 3$) within chemical group. NS, not significant.

in phenolic compound concentrations when application of N increased, although yield increased in one of the cultivars.[43] Kaempferol is a precursor to quercetin, and isorhamnetin is a methylated product of quercetin; therefore, the lack of response of kaempferol and isorhamnetin to increased N levels might be due to the absence of a catechol structure in the B-ring and, consequently, a lower antioxidant activity.[44] However, both increases and decreases in concentrations of individual kaempferol flavonoids were revealed in tronchuda cabbage (*B. oleracea* L. var. *costata* DC.) grown under moderate and high N levels.[45] Variations were due to harvest time and plant part, with no consistency, suggesting additional ontogenetic and environmental influences. The above-mentioned indicates that the F1 hybrid Reflex was more responsive to N fertilization compared to TIARA and HAT. This could be explained by breeding focusing on increased biomass production, which strictly relates to N responsiveness and possibly corresponds to the clear response to N fertilization as the agronomic characteristics revealed in the present study.

N level had no effect on total hydroxycinnamic acid derivatives (Table 4). TIARA had the highest concentration of hydroxycinnamic acid derivatives, as well as isorhamnetin glycosides compared to Reflex ($p < 0.0001$). This might reflect different cultivar yields, like for the GLSs. However, cinnamic acid is the flavonoid and hydroxycinnamic acid precursor, and its biosynthesis is controlled by phenylalanine ammonia-lyase (PAL) activity, which is responsible for phenylalanine conversion into cinnamic acid in flavonol biosynthesis.[46] Increased N levels have been found to reduce PAL activity.[47] Therefore, elevated N concentration in TIARA does not support our results. Furthermore, high N concentration and reduced plant growth might shift secondary metabolism toward N-containing phytochemicals, as argued earlier. Simple linear regression results between flavonoid glycoside groups or total hydroxycinnamic acid derivatives and either leaf N concentration or total N uptake revealed no relationships between these parameters for any of the cultivars (data not included). Inconsistent with our results, Fallovo et al.[40] found a negative linear relationship between quercetin and kaempferol as well as total flavonoids and N concentration in *Brassica rapa* and *Brassica juncea* leaves. However, in Reflex a negative linear relationship between edible yield and kaempferol, quercetin, and total flavonoid glycosides was detected ($p = 0.0345$, $R^2 = 0.18$; $p < 0.0001$, $R^2 = 0.52$ and $p < 0.0001$, $R^2 = 0.58$, respectively). These results support the effects of N application and agronomic characteristic on flavonoid glycosides and hydroxycinnamic acid derivatives if we assume Reflex was N but not C limited at high edible yield levels.

Distinct agronomic characteristics among the three kale cultivars were associated with a diverse non-, mono-, and diacylated mono-, di-, or tetraglycosylated flavonoid composition ($p < 0.001$). Whereas the nonacylated monoglycoside (isorhamnetin-3-*O*-D-glucoside) was detected only in HAT, the nonacylated diglycosides were comparable in the traditional cultivars HAT and TIARA. Lower concentrations were resolved in the F1 hybrid Reflex ($p < 0.001$), possibly due to higher edible yield. The main kale flavonoid glycosides, the monoacylated tri- and tetraglycosides, decreased in concentration with increasing N application in Reflex (Figure 5). Likewise, the minor monoacylated diglycosides decreased in TIARA. Schmidt et al.[5] reported similar cultivar effects on flavonoid glycosides in kale as a response to changing temperature and radiation. The different responses to N application of Reflex and TIARA might therefore explain the variable effects on monoacylated diglycosides and monoacylated tri- and tetraglycosides. A study in cauliflower showed a higher kaempferol-3-diglucoside-7-diglucoside concentration with mineral fertilizer application containing less total N due to a high share of compost compared to the other cultivation methods.[48] Diacylated tetraglycoside concentrations in TIARA seemed to follow elevated leaf N level patterns at 135 and 230 kg N $ha^{-1}$ applications. This was inconsistent with the results of Scheible et al.,[19] suggesting less C-rich phytochemicals under high $NO_3^-$ levels. We propose a different response to excess N uptake in TIARA, because glucose molecules, as a result of primary metabolism, possibly lead to glycosylation resulting in

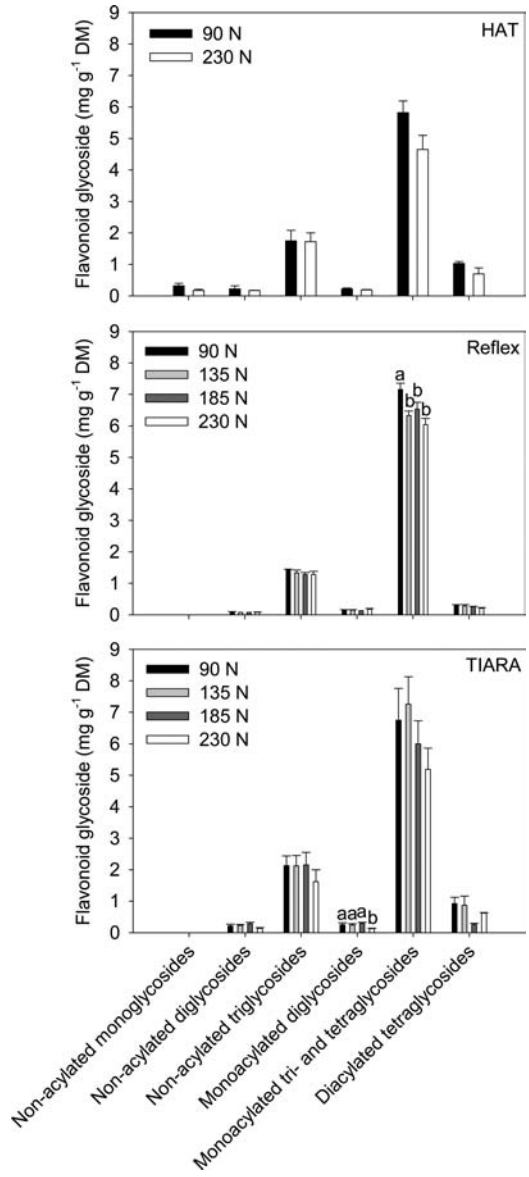

**Figure 5.** Effects of nitrogen (N) available (kg $ha^{-1}$) on flavonoid glycoside concentration (mg $g^{-1}$ DM) in the edible plant material of curly kale cultivars HAT, Reflex, and TIARA. Different letters indicate significant differences ($p \leq 0.05$) in a general linear model among N level means ($n = 3$) within flavonoid glycoside group. Bars represent standard errors.

higher diacylated tetraglycoside concentrations. Fritz et al.[49] found elevated glucose concentration in N-replete compared to N-deficient tobacco plants (*Nicotiana tabacum* L.), supporting our suggestion. Results did not reveal differences in free glucose levels among cultivars and N levels (0.82 mg $g^{-1}$ DM on average, data not included), which indicates all cultivars had the same threshold for free glucose, in contrast to the moiety levels in GLS or flavonoid glycoside molecules, which differed between cultivars. In summary, monoacylated diglycosides and monoacylated tri- and tetraglycosides decreased with increasing N application in TIARA and Reflex, respectively. The main kale glycosides, that is, nonacylated triglycosides, were not affected.

In conclusion, genetic differences between traditional and F1 hybrid cultivars were reflected in cultivar agronomic characteristics and N responses and could be associated with phytochemical composition and concentration. Our results emphasize that N and S fertilizer management and cultivar selection can be used as a tool for optimization of GLS and flavonoid concentrations as well as edible yield. However, the target of interest subsequently defines the choice of cultivar and fertilizer strategy. Furthermore, it points to the positive perspective of reintroduction of traditional kale cultivars with health beneficial compounds and, additionally, the potential role of phytochemicals related to sensory properties, as reported by Jensen et al.[10]

**Table 1. Characteristics of Compounds Used in the Study**

| Code | Commercial name | Active ingredient (concentration) | | General use | Concentration used* |
|---|---|---|---|---|---|
| A | Aliette® Flash | Fosetyl-Aluminium (80% w/w) |  | Fungicide and/or PRI | 3 g/L |
| B | Amid Thin® W | 1-Naphthaleneacetamide (8.4% w/w) | | Thinning agent | 0.6 g/L |
| C | Bion® 50 WG | Acibenzolar-*S*-methyl (50% w/w) | | PRI | 0.4 g/L |
| D | Iodus®2 CS | Laminarin (4.5% w/v) |  | PRI | 7.5 mL/L |
| E | MaxCel® | 6-benzyladenine (1.9% w/v) |  | Thinning agent | 7.5 mL/L |
| F | PRM 12® RP | Etephon (12% w/v) |  | Thinning agent | 3 mL/L |
| G | Regalis® | Prohexadione-Ca (10% w/w) | | Growth regulator | 2.5 g/L |
| H | Rhodofix® | Naphthalene acetic acid (1% w/w) | | Thinning agent | 1.5 g/L |
| I | Stifenia® | Fen 560 (Fenugrec 100% w/w) | | PRI | 10 g/L |
| J | V-Plaask® | Organic mixture, K, Ca, Mg, B + salicylic acid derivatives (concentration not given) | | Fertilizer + PRI | 10 mL/L |
| K | Agrimycin® 17 | Streptomycin (17% w/w) | | Bactericide | 0.1 g/L |

*Concentration of commercial product.

costly in terms of time and price. Protection assays in field conditions also require infrastructures and regulatory agreements to manipulate pathogen inocula or rely on natural infections that may fluctuate from year to year. In addition, the number of candidate preparations regularly increases, and recent results suggest that new PRIs will soon be identified with the design of miniaturized cultivation systems involving the model plant *Arabidopsis* to test many compounds in <2 days.[16,17] However, because of the specificity of plant responsiveness to a given compound, it is obvious that ultimate assays must use the pathosystem of interest. In addition, it is noteworthy that the cuticle, a physical barrier that may prevent foliar-sprayed PRIs from reaching cellular targets, differs in thickness and composition between plant species.

In the present study we developed a methodology for the upstream screening of PRIs against the causative agent of fire blight, *Erwinia amylovora*, on young apple (*Malus* × *domestica*) plants. Fire blight is a devastating disease affecting apples, pears, and more generally members of the *Malinae* (ex *Maloideae*) tribe of the family *Rosaceae*.[18] Its control is far from optimal due to the limited number of efficient bactericidal chemicals and because it occurs very sporadically, with outbreaks difficult to forecast. Furthermore, the obvious long-term breeding programs for resistance do not allow quick response to spatiotemporally limited attacks.[18] All of these specificities explain why fire blight is still expanding around the world with regular outbreaks[19] and why it has been classified as a quarantine disease in most countries. The use of PRIs to confer protection against *E. amylovora* is an attractive strategy to prevent or reduce incidence of fire blight to an acceptable level. Our methodology to screen PRIs relies on the ability of a given PRI to trigger activation of defenses in conditions that favor resistance development without the use of the pathogen even for the evaluation of priming agents. It includes (i) the foliar spraying of candidate preparations on plantlets in greenhouse assays, (ii) the possible subsequent foliar spraying of hydrogen peroxide ($H_2O_2$) to simulate a pathogen attack and to discriminate compounds that directly activate defense genes from those that prime immunity, and (iii) the monitoring of transcription levels of 28 carefully selected defense genes that are part of the plant defense system[4] including PR-proteins, secondary metabolic pathways, cell wall modifications, antioxidant mechanisms, and signaling pathways in apple tissue after PRI application. The 28 defense genes were chosen to represent the widest diversity of known defense mechanisms but in a user-friendly format (96-well qPCR). Using this methodology, we compared the ability of several PRI candidates and plant growth regulators to induce apple defenses as well as to protect against fire blight in semicontrolled conditions. Our aim

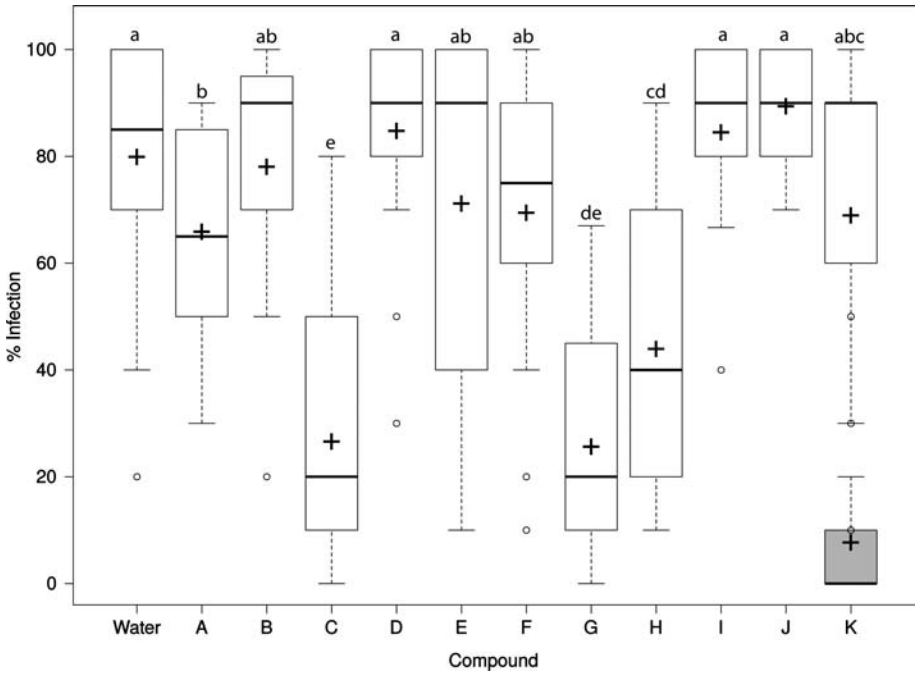

**Figure 1.** Efficacy of 10 candidate PRIs (A–J) against fire blight on apple seedlings. PRIs were applied 4 days before leaf inoculation with *E. amylovora*. Water (applied 4 days before inoculation) and product K (applied 4 days before inoculation, white box) were used as negative controls. Product K applied 4 h before inoculation (gray box) was used as a positive biocidal control. Data are percentages of plants exhibiting a progressive necrosis on stem per plot of 10 plants ($n \geq 15$, i.e., 3 plots per experiment × 5 independent experiments at least). Medians are represented by black horizontal segments in each box and means by "+" symbols. Boxes with the same letters represent means that are not significantly different.

was to demonstrate that monitoring the expression of a few genes may be of great usefulness to discriminate active from nonactive compounds on apple tissues and reduce their number included in further tests.

## MATERIAL AND METHODS

**Materials and General Methodologies.** Experiments were conducted on apple seedlings (4–6 leaves) from open-pollinated cv. Golden Delicious grown in a greenhouse under semicontrolled conditions (natural photoperiod supplemented with artificial light if needed, 17 °C night, 23–30 °C day, according to the sunlight). A virulent French standard strain CFBP1430 of *E. amylovora* was used for the inoculations.[20] Bacteria were grown for 24 h at 27 °C on King's medium B, allowing bacterial cells to reach the exponential growth phase.[21] Bacterial suspensions were prepared in reverse osmosis water to yield a concentration of $10^8$ colony-forming units (CFU)/mL and sprayed on entire seedlings to runoff with the help of a pressurized hand sprayer. The compounds tested in this study were the following: (A) Aliette Flash (Bayer CropScience, France), (B) Amid Thin W (Nufarm SAS, France), (C) Bion 50 WG (Syngenta, Switzerland), (D) Iodus 2 CS (Goëmar, France), (E) MaxCel (Philagro, France), (F) PRM 12 RP (Bayer CropScience, France), (G) Regalis (BASF, Germany), (H) Rhodofix (Nufarm SAS, France), (I) Stifenia (SOFT, France), (J) V-Plaask (Plaaskem, Italy), and (K) Agrimycin 17 (Nufarm SAS, France). Their known characteristics are given in Table 1. They were prepared in reverse osmosis water and sprayed on entire seedlings to runoff with the help of an electric airless spray painter.

**Testing of the Protective Efficiency.** In each experiment, the experimental design was a randomized block of 3 plots of 10 seedlings per treatment. Compounds (or water) were sprayed 4 days before inoculation. On the morning of the day of inoculation, the youngest nearly expanded leaf of each plant was wounded by a double incision perpendicular to the midrib near the petiole, and the bacterial suspension was sprayed 4 h later. As biocidal control, untreated plants were sprayed with product K immediately after wounding and allowed to dry for 4 h before inoculation. Symptoms were assessed 3 weeks later. Disease incidence (DI), that is, the percentage of plants exhibiting a progressive necrosis on stem, was calculated per plot. The protection rate in each plot $X$ was also set as follows: % protection = $[(\mu DI_{water} - DI_X)/\mu DI_{water})] \times 100$, where $\mu DI_{water}$ is the mean of DI of the three plots of water control and where negative values are treated as if they were zero. Each treatment was repeated in five independent biological experiments at least, and all experiments contained the two controls, water, and the biocidal reference.

**Defenses Analyses.** The experimental design was a randomized block of 5 plots of 5 seedlings per treatment. One day after application of compounds, the five youngest expanded leaves of one plot per block were collected, pooled, frozen in liquid nitrogen, and kept at −80 °C until extraction. Then 2 of the 4 remaining plots per block were sprayed with 40 mM $H_2O_2$ to runoff with a trigger sprayer. The five youngest expanded leaves per plot (treated with $H_2O_2$ or not) were sampled on days 2 and 3 as on day 1. RNA extraction, reverse-transcription, and quantitative real-time PCR were performed as previously described,[22] using the same set of primers of 28 defense genes and of 3 reference genes.[23] Relative changes in defense gene expression were calculated using the $2^{-\Delta\Delta Ct}$ method[24] and the 3 internal reference genes for normalization[25] and relative to water control plants at every sampling date. Three independent biological experiments were performed.

**Data Analyses.** The statistical programming environment R[26] was used for all data analyses. To compare protection efficiency, a nonparametric rank-based statistical test was used. Means of disease incidence were pairwise compared with a Wilcoxon test, and corresponding $p$ values were adjusted using the Benjamini–Hochberg correction. Treatments were declared to significantly differ for a corrected $p$ value <0.05. Clustering of gene expression in the heatmap representation was performed using dissimilarity distance (1 − cor($X$,$Y$)). In the principal component analysis (PCA), plots and correlation coefficients of each variable (gene) versus each dimension were obtained using the FactoMineR R package.[27] Statistical evaluation of treatment effects on defense response was done with multivariate ANOVA.

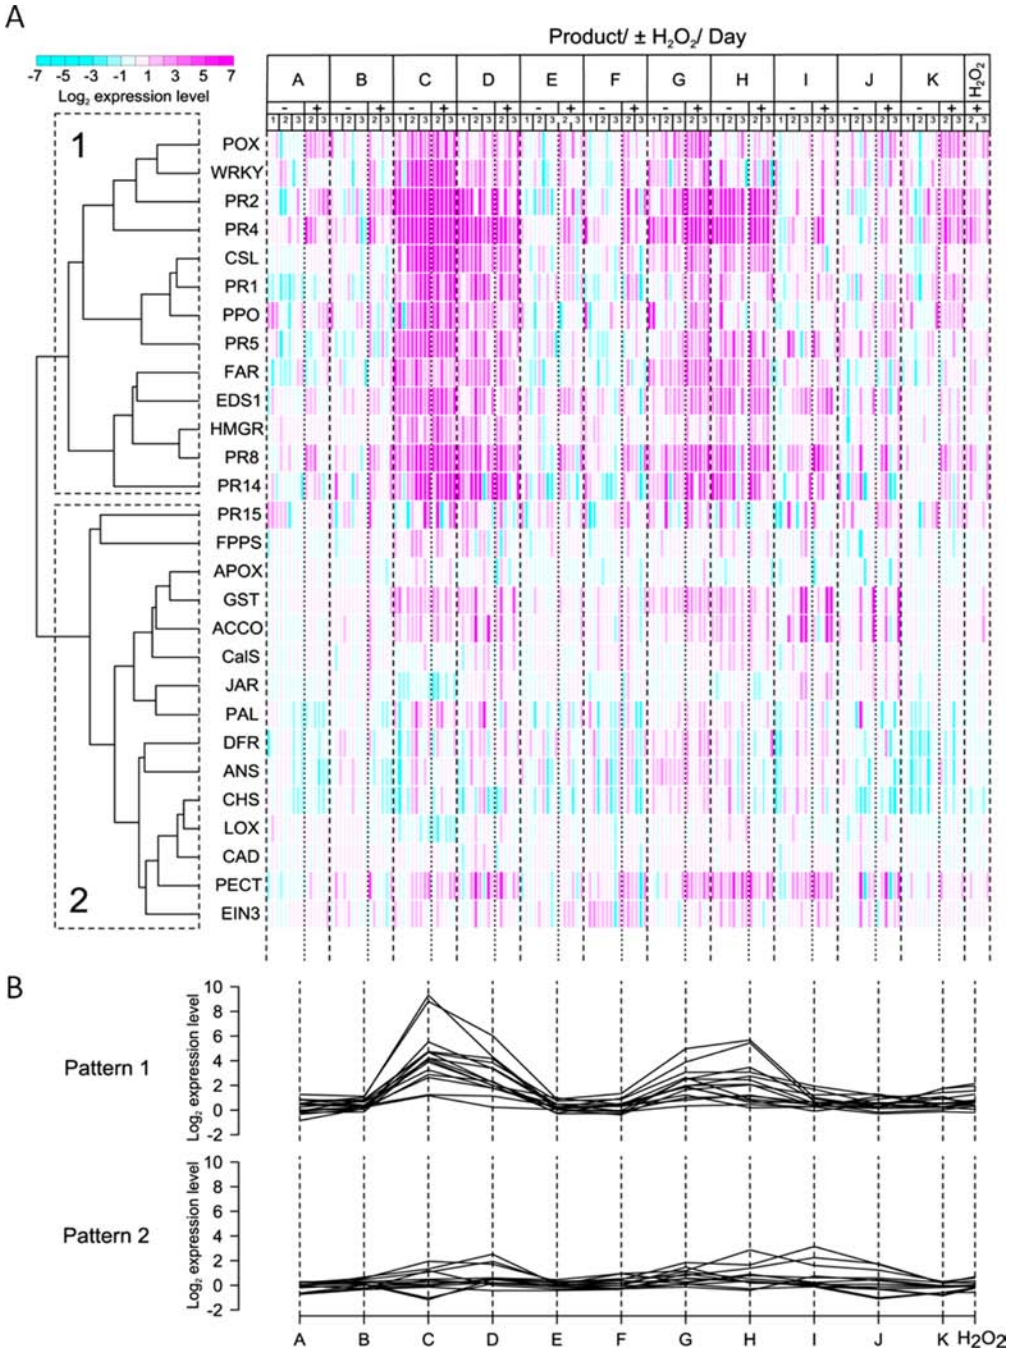

**Figure 2.** Defense gene expression profiles obtained after product application on apple seedlings. (A) Heatmap profiling across all experimental conditions (product, day, ± $H_2O_2$) with hierarchical clustering of genes: ACCO, 1-aminocyclopropene-1-carboxylate oxidase; ANS, anthocyanidin synthase; APOX, ascorbate peroxidase; CalS, callose synthase; CHS, chalcone synthase; CAD, cinnamyl-alcohol dehydrogenase; CSL, cysteine sulfoxide lyase; DFR, dihydroflavonol reductase; EIN3, EIN3-binding F box protein 1; EDS1, enhanced disease susceptibility 1; Far, (*E*,*E*)-α-farnesene synthase; FPPS, farnesyl pyrophosphate synthase; GST, glutathione *S*-transferase; HMGR, hydroxymethyl glutarate-CoA reductase; JAR, jasmonate resistant 1; LOX, 13-lipoxygenase; PAL, phenylalanine ammonia-lyase; Pect, pectin methyl esterase; PR, pathogenesis-related protein; PPO, polyphenol oxidase; POX, peroxidase; WRKY, WRKY transcription factor 30. (B) Expression patterns of genes from the two main clusters and for each compound averaged over all experimental conditions ($n$ = 15, i.e., 5 experimental conditions (days and ± $H_2O_2$) × 3 independent experiments).

## RESULTS AND DISCUSSION

**Protective Efficiency against *E. amylovora*.** The 10 commercially released products (Table 1) were first tested for their protective efficiency against *E. amylovora* when applied 4 days before inoculation (Figure 1). They were compared to water applied also 4 days before inoculation and to product K (biocidal reference) applied 4 days or 4 h before inoculation. Disease incidence obtained with water control shows that a stringent testing procedure was applied. However, great differences in disease incidence after the different treatments were observed.

Resulting values of protection rate ranging from >70% for compounds C and G to <10% for compounds A, B, D, E, F, I, and J and the biocide K applied 4 days before inoculation were observed (Figure 1). Those values are in the range of a previous observation with PRIs.[5] Compound H displayed intermediate-to-high protection efficiency. Although not as efficient as the

**Figure 3.** Principal component analysis (PCA) of gene expression among experimental conditions. (A) Variables (genes) projected on the dimension 1/dimension 2 map and list of most correlated variables (genes) ($r^2 > 0.5$) with each of the two dimensions. All correlation coefficient ($r^2$) were significant at $p < 10^{-15}$. Dim, dimension; ACCO, 1-aminocyclopropene-1-carboxylate oxidase; ANS, anthocyanidin synthase; APOX, ascorbate peroxidase; CalS, callose synthase; CHS, chalcone synthase; CAD, cinnamyl-alcohol dehydrogenase; CSL, cysteine sulfoxide lyase; DFR, dihydroflavonol reductase; EIN3, EIN3-binding F box protein 1; EDS1, enhanced disease susceptibility 1; Far, (*E*,*E*)-α-farnesene synthase; FPPS, farnesyl pyrophosphate synthase; GST, glutathione *S*-transferase; HMGR, hydroxymethyl glutarate-CoA reductase; JAR, jasmonate resistant 1; LOX, 13-lipoxygenase; PAL, phenylalanine ammonia-lyase; Pect, pectin methyl esterase; PR, pathogenesis-related protein; PPO, polyphenol oxidase; POX, peroxidase; WRKY, WRKY transcription factor 30. (B) Coordinates of samples on dimension 1. Different sampling days are indicated by circles of increasing size: white dots, no $H_2O_2$ application; black dots, $H_2O_2$ application. A small amount of jittering was added to improve visualization. The horizontal line indicates the position of the calibrator sample (water treatment at each sampling date, the expression levels of which set the 0 value). (Bottom) Result of a linear model constructed with the dimension 1 coordinates as the response vector and the factors day/$H_2O_2$ treatment showing significant differences between a given compound and water treatment (one-way ANOVA; ∗, $p < 0.05$; ∗∗, $p < 0.01$; ∗∗∗, $p < 0.001$). na, not applicable.

biocide K applied 4 h before inoculation, the three compounds C, G, and H allowed significant protection when compared to water control and all other products. The lack of effectiveness with product K applied 4 days before inoculation highly suggests that

dx.doi.org/10.1021/jf504221x | J. Agric. Food Chem. 2014, 62, 11403−11411

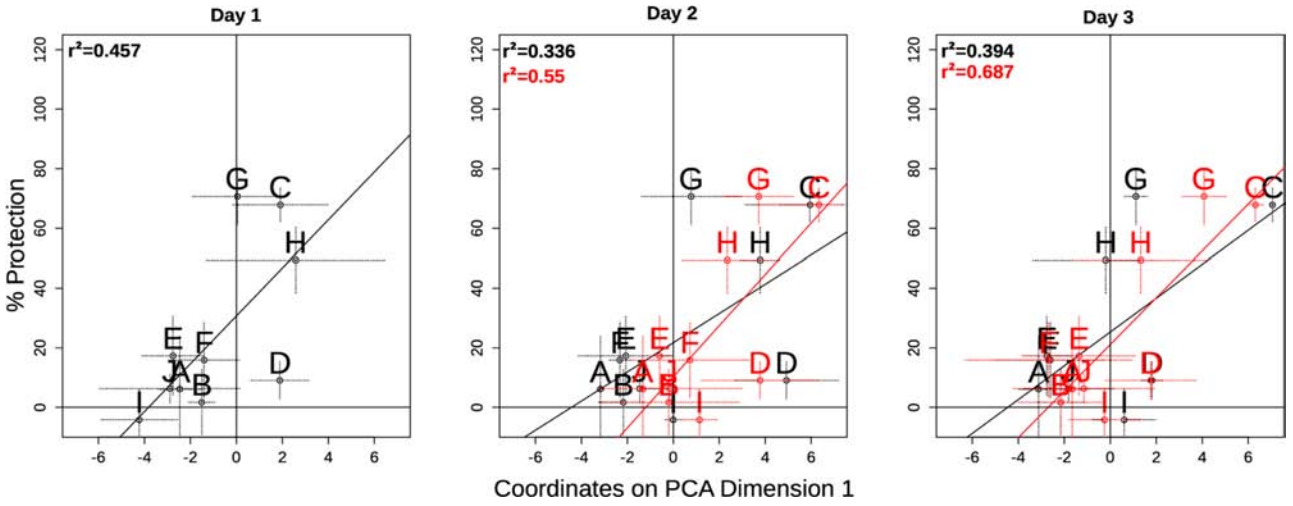

**Figure 4.** Relationships between defense gene expression and protective effects at each analysis date. Coordinates on dimension 1 of the previous PCA averaged across biological replicates were used as a measure of gene expression induction activity. $H_2O_2$ application for priming activity assay: black, without; red, with. Bars correspond to standard deviation ($n = 3$ for PCA coordinates and $n \geq 15$ for the protection assays). Correlation coefficients of linear models are indicated in each plot.

reduction of disease incidence with compounds C, G, and H is unlikely to be due to a bactericidal effect. Lack of direct antibacterial activity was therefore verified in vitro (data not shown) and allows us to assume that the high protection efficiency of these three compounds indeed relies on a PRI effect. In addition, applying these candidate PRIs only 4 h before inoculation was less efficient in protection, especially for G and H (Supporting Information Figure s1).

These results indicate that time is needed for the plant to activate its defense system. This is in accordance with previous works; for example, 3 days were described to be necessary for acibenzolar-*S*-methyl-treated tomato seedlings to develop a successful resistance against *Clavibacter michiganensis* ssp. *michiganensis*.[28] Next we focused on the defense stimulating activities of these compounds to determine how much induction of a given set of defense genes and the protection efficiency are correlated.

**Defense Gene Expression Monitoring.** As protective effects were mostly observed when inoculation was performed 4 days after candidate treatments, activation of defense responses at the transcriptional level is expected to be visible within 3 days following product application. Expressions of 28 marker genes[22,23] were therefore monitored 1, 2, and 3 days after spraying. Global overview of the data set clearly indicated a differential ability of the compounds to modulate gene expression (Figure 2). Clustering the genes according to their expression levels gave two main patterns. The first one included genes encoding PR-proteins, terpenoid biosynthetic enzymes, and salicylic acid-related markers, and those were strongly up-regulated in several samples (C, D, G, and H) but not in the others. The remaining genes including flavonoid and jasmonic acid marker genes were found to be weakly influenced by treatments. Contrasted activation of salicylate and jasmonate pathways probably relies on the common antagonism reported between these two pathways.[8] However, given the diversity of compounds assayed here, it was quite unexpected to mobilize only salicylate-related defenses.

A PCA performed using genes as variables and samples as individuals (Figure 3) revealed that the first dimension (35% of the initial variation) was the only one to correctly separate the samples while coherently taking into account the strength of biological measurements ($r^2 > 0.6$, $p < 10^{-6}$ between biological repeats). Dimension 1 clearly clustered two groups of genes, and those that strongly correlated with it ($r^2 > 0.5$, $p < 10^{-15}$) (Figure 3A) corresponded to those having the first expression pattern described above (Figure 2B). This indicated that the data set could be correctly summarized by using dimension 1 as a new variable. By comparing values of samples projected on this dimension, we observed three intensities of gene induction, according to the product applied, ranging from high (compound C) to intermediate (D, G, H, I) and low (A, B, E, F, J, K) (Figure 3B). For this last group of compounds, gene expression levels did not significantly change in most cases in comparison to water treatment. The expression pattern for compound C, which contained acibenzolar-*S*-methyl, a well-known SAR inducer,[6,29] was expected. In addition, previous studies already reported the induction of PR-protein encoding genes by acibenzolar-*S*-methyl in apple trees.[13,30] Concerning compounds that efficiently activate apple defenses, we found a strong interactive effect between compound and day factors (MANOVA, $p < 10^{-7}$). Only four compounds, C, D, G, and H, significantly activated expression of genes belonging to the first cluster 1 day after application (smaller symbols) (Figure 3B). Significant inductions at day 2 were observed for compounds C and D, as well as G, H, and I to a lesser extent ($p < 0.05$). A transient effect could be attributed to compounds D and H because intensities at 2 days were always stronger than at 3 days. Interestingly, laminarin (compound D) was reported to induce both salicylic acid- and jasmonic acid-related defenses in grapevine and tobacco,[31,32] whereas in apple only salicylic acid-related markers were induced. This difference of results might reveal specificities in the perception/signaling systems between plant species; however, both previous studies dealt with cell suspension cultures and favored laminarin in reaching its targets. Our data also showed that compound G triggered a priming effect, because expression levels of pattern 1 genes without $H_2O_2$ application were significantly lower (Student's *t* test, $p < 0.05$) than after $H_2O_2$ application on days 2 and 3 (Figure 3B). Our results are in agreement with a previous study on prohexadione-Ca (compound G), which reported stronger activation of defense genes in

prohexadione-Ca-treated apple trees challenged with *Venturia inaequalis*, the causative agent of apple scab.[33] Interestingly, this study also indicated that defense genes primed with prohexadione-Ca were related to salicylic acid signaling, as observed here. Another study showed that this plant growth regulator altered flavonoid metabolism by activation of the expression of genes encoding chalcone synthase (CHS) and flavanone 3-hydroxylase (FHT).[34,35] However, in our conditions, this compound only slightly induced the expression of the flavonoid related genes *CHS*, *DFR* (dihydroflavonol reductase), and *ANS* (anthocyanidin synthase), in comparison to genes encoding PR-proteins. It was quite surprising that PRIs, which triggered defense activation in our study, did not display specificities in the set of induced genes, as has been previously shown for other plant species. For example, acibenzolar-*S*-methyl, the active molecule of product C, and chitosan triggered specific responses in strawberry, in particular concerning the flavonoid biosynthetic pathway.[35]

In the light of the present results and data found in the literature, it seems that the same PRI is able to trigger specific responses in distinct hosts. Although differences in treatment application (time, concentration, method of spraying, plant material) could be the source of such discrepancies, this specificity could also reflect specific abilities of plant species to respond to elicitors.

**Correlation between Intensity of Gene Induction and Protection Efficiency.** We next investigated to what extent the protective effect was correlated with defense induction levels (estimated with values of projected individuals on dimension 1) for the apple/*E. amylovora* pathosystem. To establish such a correlation, we plotted at each analysis date the protection data obtained for compounds applied 4 days before inoculation (data resulting from Figure 1) vs PCA abscissa (Figure 3B).

On the whole, positive correlations between protection efficiency and defense induction were obtained at the three sampling dates, although not always significant ($p$ values of 0.03, 0.07, and 0.05 for days 1, 2, and 3, respectively) (Figure 4). However, correlations were stronger and more significant with samples corresponding to $H_2O_2$-treated leaves ($r^2 = 0.55$, $p = 0.01$; and $r^2 = 0.687$, $p = 0.003$ at days 2 and 3, respectively). This increase could be explained by the priming effect of compound G, which therefore contributed more to the model when defense induction was revealed by spraying $H_2O_2$. Our results show that the higher the coordinates were on dimension 1, the higher the protective effect, with the exception of compound D. Using coordinates on dimension 2 (which represented only 14% of the initial variance) in a similar way gave only low correlation coefficients (Supporting Information Figure s2). This reinforces that defense genes represented by this dimension are not related to active defense against *E. amylovora*. Taken together, our results were able to discriminate compounds with no effects by testing a relatively low number of genes.

It is noteworthy that the most efficient products (C, G, and H) displaying protective effects together with defense elicitation are synthetic inputs dealing with phytohormone signaling pathway. Although the effects of product C (acibenzolar-*S*-methyl) and G (prohexadione-Ca) were expected,[13,36] the activity of product H gave interesting prospects. This preparation is an auxin analogue (naphthaleneacetic acid) used as a thinning agent in apple orchards. Its effect contrasted with the antagonistic interactions between the salicylic acid and auxin signaling pathways usually reported.[37] Indeed, those three compounds, C, G, and H, triggered similar responses in our case. The fact that compound H had a high protection efficiency together with high induction activity suggests that new disease managements could take into account the property of particular growth regulators to induce plant defenses. Activities of compounds D and H displayed contrasting profiles. Whereas both triggered moderate and transient activation of defenses in a similar way, their protection efficacies strongly differed. Indeed, compound H was able to confer a significant protection against *E. amylovora*, whereas compound D did not. Our hypothesis is that compound H may either induce the expression of defenses not assayed here or alter plant development in a way that reduces susceptibility of treated plants to *E. amylovora*. However, no particular macroscopic phenotype was seen on our apple seedlings during the time of experiment. Synergism between auxin and jasmonate signaling pathways has been reported several times.[38] Because methyl jasmonate treatments were shown to protect apple seedlings against *E. amylovora*,[39] it is possible that a set of defense commonly regulated by auxin and jasmonates is involved in the responses of apple to this bacterial pathogen. As far as compound D is concerned, it could be interesting to try to correlate the transient defense induction with a protective effect 2 days after spraying. However, and from a practical point of view, the lack of protective effectiveness observed 4 days after treatment would suggest a difficult integration in orchard disease management with the requirement of a high treatment frequency.

It is interesting to point out that product A does not protect against *E. amylovora* or stimulate defense responses in our experimental conditions. This product belongs to the phosphite family and is registered for the control of various diseases including fire blight on apple and pear. Its mode of action is known to be complex with both direct and indirect effects.[5] According to our results, it does not appear to be a PRI in apple. However, for this compound as well as for other inactive compounds in our experimental conditions, we cannot exclude dose rate effects, which were not tested here and which have been reported in several works.[32,40,41]

Another interesting finding to further improve the use of PRIs is that strong marker genes among the 28 assayed here were identified. In particular, PR-protein encoding genes and several secondary metabolism genes strongly responded to PRI treatments. It is known that field-grown plants often exhibit high expression levels of PR-proteins.[5] However, an appropriate combination of those markers might help to uncover how plants respond to PRIs and, for example, to determine periods or organs of maximum responsiveness.

Taken together, our results show that compounds failing to activate specific defense genes (and with no direct antimicrobial activity) are most unlikely to confer protection against *E. amylovora*. The molecular tool and the associated methodology developed in this work could therefore be proposed to agribusiness to facilitate the screening of PRIs, which are efficient against fire blight without the difficult handling of the pathogen. The strong marker genes highlighted by the screening may also be further used to test the influence of different experimental factors on PRI activity and to improve their integration into disease management programs.

lignin moieties, found at 56, 124, 148, and 153 ppm, as well as to COOH groups at 174 ppm.[22]

Complementary molecular characterization of complex matrices may be obtained by the combination of NMR spectra with structural information provided by thermally assisted hydrolysis and methylation reactions (thermochemolysis) followed by gas chromatography−mass spectrometry (GC-MS).[24,25] Pyrolysis in the presence of tetramethylammonium hydroxide involves the controlled partial cleavage of chemical bonds with the simultaneous solvolysis and methylation of ester and ether bonds present in natural organic materials, thereby enhancing both thermal stability and chromatographic detection of different polar functional groups.[26] Moreover, the off-line technique allows the analysis of large quantities of solid material and thus a more representative sample and more effective qualitative and quantitative measurements of structural components and their relationship with biological activity.[27] The aim of this study was to evaluate by $^{13}C$ NMR spectroscopy and thermochemolysis the molecular characteristics of HAs isolated from five mature vermicomposts of different composition and to measure their bioactivity by the emergence of lateral roots in maize seedlings.

## MATERIALS AND METHODS

**Preparation of Vermicomposts.** Five different vermicomposts were prepared using the following different substrates: (1) cattle manure; (2) cattle manure and sugar cane bagasse (1:1 w/w as dry mass); (3) cattle manure and sunflower cake (1:1 w/w as dry mass); (4) cattle manure, sugar cane bagasse, and sunflower cake (1:1:1 w/w/w as dry mass); and (5) filter cake from a sugar cane factory. Each organic residue was placed on a concrete cylinder (100 cm internal diameter) with a 150 L capacity using two replicates (two cylinders per treatment). The humidity was maintained at 65−70% by weekly addition of water followed by mixing. After approximately 1 month of composting, the earthworm *Eisenia fetida* was introduced at a ratio of 5 kg of worms per cubic meter of organic residue. At the end of the transformation process, the worms were removed by attracting them to a pile of fresh organic residue (cattle manure) in a corner of the container. The VCs were air-dried, powdered with a ball mill, and sieved through a 500 $\mu$m mesh. Total organic carbon (OC) and total nitrogen (TN) contents were determined by dry combustion using an automatic CHN analyzer (PerkinElmer 2400 series, Norwalk, CT, USA).

**Extraction of Humic Acids.** The humic acids were extracted and purified as reported previously.[5] Briefly, 10 volumes of 0.5 M NaOH was mixed with 1 volume of earthworm compost under a $N_2$ atmosphere and shaken overnight. After 12 h, the suspension was centrifuged at 5000*g* and acidified (pH 1.5) using 6 M HCl. This suspension was allowed to settle overnight, the precipitated humic acids were recovered by centrifugation at 5000*g*, resolubilized in 0.5 M NaOH, and precipitated by acidification (pH 1.5) with 6 M HCl, and the resulting pellet after centrifugation at 5000*g* was mixed with 10 volumes of a 0.1 M HCl and 0.3 M HF. After centrifugation at 5000*g* for 15 min, the precipitate was repeatedly washed with water until a negative test against $AgNO_3$ was obtained. The pH of the final suspension was adjusted to pH 7.0 with 0.01 M KOH and then dialyzed against deionized water using a 1 kDa cutoff membrane (Thomas Scientific, Swedesboro, NJ, USA), and lyophilized. Five humic acids (HA1, HA2, HA3, HA4, and HA5) were obtained from the respective vermicomposts (1−5) described above.

**Characterization of HA.** *Offline Thermochemolysis and GC-MS Analysis.* About 100 mg of purified humic acid was placed in a quartz boat and moistened with 0.5 mL of tetramethylammonium hydroxide (25% in methanol) solution. After the mixture had dried under a gentle stream of nitrogen for about 10 min, the sample was introduced into a Pyrex tubular reactor (50 cm × 3.5 cm i.d.) and heated at 400 °C for 30 min in a furnace. The products released by thermochemolysis were continuously transferred by a flow of helium (20 mL/min) into two successive chloroform (50 mL) traps kept in an iced salt bath. The chloroform solutions were combined in a round flask and concentrated by rotoevaporation under reduced pressure. The residue was redissolved in 1 mL of chloroform and transferred to a glass vial for GC-MS analysis. Two thermochemolysis replicates were carried out for each humic acid sample. The products of thermochemolysis were analyzed by GC-MS. Chromatographic separations were carried out with a GC-MS QP2010 Plus instrument (Shimadzu, Tokyo, Japan). The column used was a 30 m × 0.25 mm id, 0.25 $\mu$m, Rtx-5MS WCOT. Chromatographic separation was achieved with the following temperature program: 60 °C for 1 min (isothermal), raised at 7 °C/min to 100 °C and then at 4 °C/min to 320 °C, followed by 10 min at 320 °C (isothermal). The carrier gas was helium at 1.90 mL/min, the injector temperature was 250 °C, and the split injection mode had a split flow at 30 mL/min. Mass spectra were obtained in EI mode (70 eV), and scanning was in the range $m/z$ 45−850 with a cycle time of 1 s. Compound identification was based on comparison of mass spectra with the NIST library database, published spectra, and real standards. For quantitative analysis, due to the large variety of detected compounds with different chromatographic responses, external calibration curves were built by mixing methyl esters and/or methyl ethers of the following molecular standards: tridecanoic acid, octadecanol, 16-hydroxyhexadecanoic acid, docosanoic acid, $\beta$-sitosterol, and cinnamic acid. Increasing amounts of standard mixtures were placed in a quartz boat and moistened with 0.5 mL of tetramethylammonium hydroxide (25% in methanol) solution. The same thermochemolysis conditions as for compost samples were applied to the standards. The lignin transformation was estimated using specific thermochemolysis products in the following indices:[26,28]

**Ad/AlP** (P6/P4): benzoic acid, 4-methoxy-, methyl ester/benzaldehyde, 4-methoxy

**Ad/AlS** (S6/S4): benzoic acid, 3,4,5-trimethoxy-, methyl ester/benzaldehyde, 3,4,5-trimethoxy

**Ad/AlG** (G6/G4): benzoic acid, 3, 4-dimethoxy-, methyl ester/benzaldehyde, 3,4-dimethoxy

$\Gamma_G$ [G6/(G14 + G15)]: benzoic acid, 3,4-dimethoxy-, methyl ester/1,2-dimethoxy-4(1,2,3-trimethoxypropyl)benzene

*Solid-State CP-MAS $^{13}C$ NMR Spectroscopy.* The C functionality distributions of the humic acid samples were determined by solid-state CP-MAS $^{13}C$ NMR spectroscopy. The spectra were acquired with an Avance 500 MHz (Bruker, Karlsruhe, Germany) spectrometer equipped with a 4 mm wide-bore MAS probe and operating at $^{13}C$ and $^{1}H$ frequencies of 125 and 500 MHz, respectively. The samples (100−200 mg) were packed in 4 mm zirconia rotors with Kel−F caps, which were spun at 13 ± 1 kHz. The spectra were acquired by the ramped CP-MAS method, with linear amplitude variation of the $^{1}H$ pulse. The experiments were carried out using a cross-polarization time of 1.0 ms, an acquisition time of 25 ms, a cycle delay of 2 s, and a high-power two-pulse phase modulation (TPPM) proton decoupling of 70 kHz. Bruker Topspin 1.3 software (Bruker Biospin, Karlsruhe, Germany) was used to collect and process the spectra. All of the free induction decays (FIDs) were transformed by applying a 4K zero filling and a line broadening of 75 Hz. The spectra were normalized by area and integrated in the following $^{13}C$ chemical shift intervals: 190−160 ppm (carbonyls of ketones, quinones, aldehydes, and carboxyls), 160−140 ppm (phenols and O-substituted aromatic C), 140−110 ppm (unsubstituted aromatic C and olefinic C), 110−95 ppm (anomeric C), 95−65 ppm (O-alkyl systems), 65−45 ppm (methoxy substituent; *N*-alkyl groups), and 45−0 ppm (alkyl C, mainly $CH_2$ and $CH_3$). The relative areas of the alkyl (45−0 ppm) and aromatic (160−110 ppm) components were summed to represent the proportion of hydrophobic C in the humic samples (degree of hydrophobicity, HB). Similarly, the summation of the relative areas in intervals related to polar groups (190−160 and 110−45 ppm) indicates the degree of C hydrophilicity (HI); the HB/HI ratio was then calculated. The ratio between the signal areas in the 45−65 ppm interval (methoxyl-C) over those in the 140−160 ppm range (O-aromatic-C), denoted the lignin ratio, was used to discriminate the contribution of lignin components.[21]

*Bioactivity of HA.* Detailed experimental protocols for lateral root emergence and acidification of the growth medium for the maize seedling have been reported.[21] Briefly, maize seedlings with homogeneous root length (1 ± 0.2 cm) were treated or not (control) for 48 h with different humic acids applied at a concentration of 2 mM C and adjusted to pH 7.00 with diluted HCl or NaOH. Next, seedlings were washed abundantly with deionized water and transferred to a 2 mM $CaCl_2$ solution at pH 7.00 ± 0.01. After 48 h, the seedlings were collected. Then, the seedling roots were digitized, and the number of lateral roots was counted. We used five pots as replicates ($n$ = 5) with five seedlings in each pot.

## RESULTS AND DISCUSSION

The total ion chromatograms derived from the thermochemolysis products obtained from the different humic acids extracted from the vermicomposted plant biomass residues and from cattle manure are shown in Figures 1 and 2.

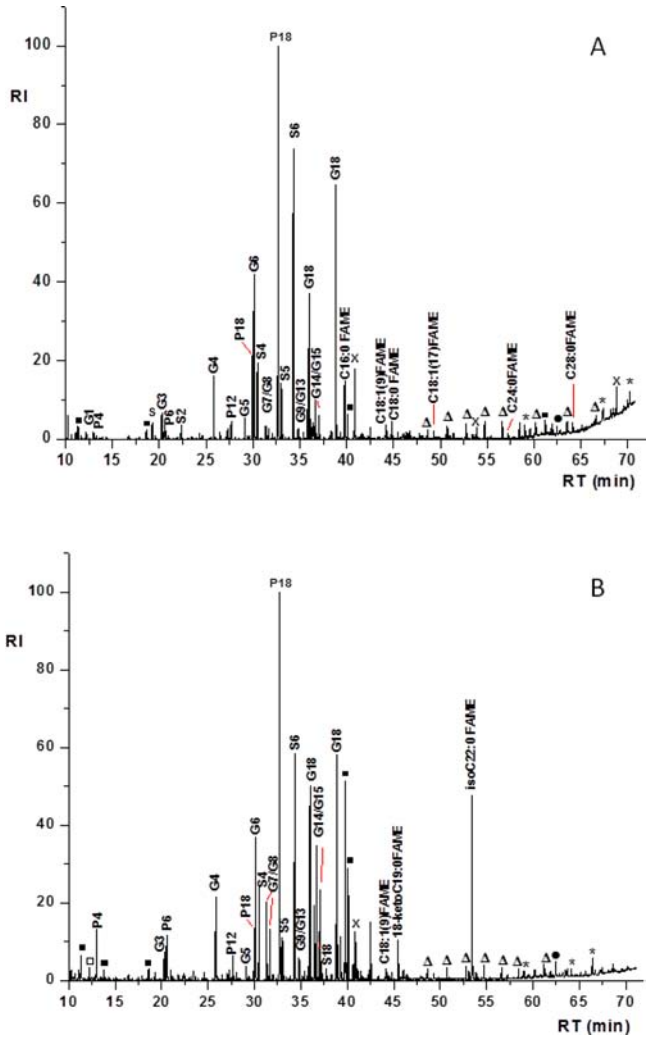

**Figure 1.** Total ion current (TIC) obtained from offline pyrolysis GC-MS of humic acids isolated from vermicompost of (A) cattle manure and (B) sugar cane bagasse.

Thermochemolysis of humic acids released more than 200 different molecules, which were identified as methyl ethers and esters of natural compounds. The list of compounds identified in different pyrograms is shown in the Supporting Information, whereas the data in Table 1 summarize the amount and distribution of the major compound classes. Most of the humic

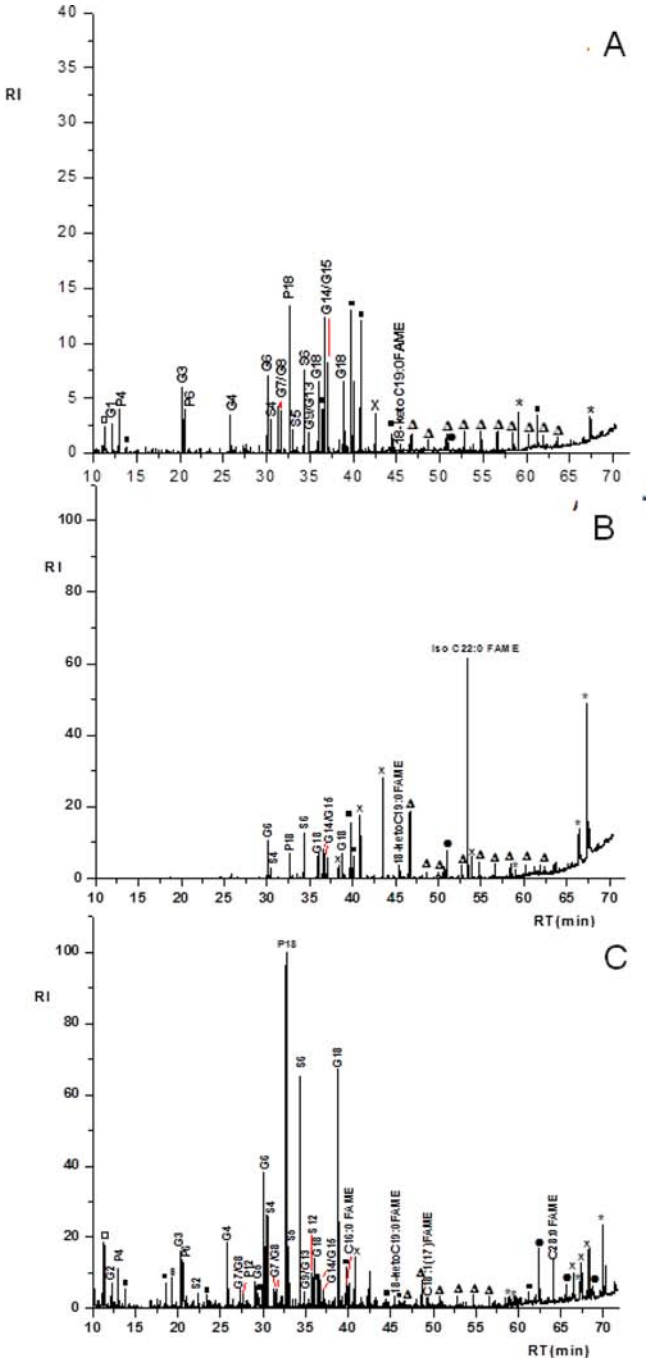

**Figure 2.** Total ion current (TIC) obtained from offline pyrolysis GC-MS of humic acids isolated from vermicompost of (A) sunflower cake, (B) a mixture of cattle manure, sugar cane bagasse, and sunflower cake, and (C) sugar cane filter cake.

components originated from higher plant residues that had been biostabilized by microbial activity and were represented by lignin, alkyl biopolymers, nitrogenous compounds, terpenes, and sterol products. The thermochemolysis revealed noticeable differences in humic acid composition, presumably reflecting the variable sources of organic residues for vermicompost production. HA2 and HA3 showed the largest amount of lignins and nitrogenous compounds, whereas HA1 and HA4 were characterized by a large presence of C-alkyl compounds, and HA5 was characterized by terpenes and sterol derivatives.

[a]P, *p*-hydroxyphenyl; G, guaiacyl; S, syringyl; P6/P4, G6/G4, S6/S4, and $\Gamma_G$ are indices to evaluate lignin transformation using specific thermochemolysis products as described under Materials and Methods. The values represent the means from two chromatograms followed by standard deviation. [b]HA1, HA2, HA3, HA4, and HA5 are the humic acids isolated from vermicomposts produced with cattle manure, sugar cane bagasse, sunflower cake, a mixture of cattle manure, bagasse, and sunflower cake, and sugar cane filter cake residue, respectively.

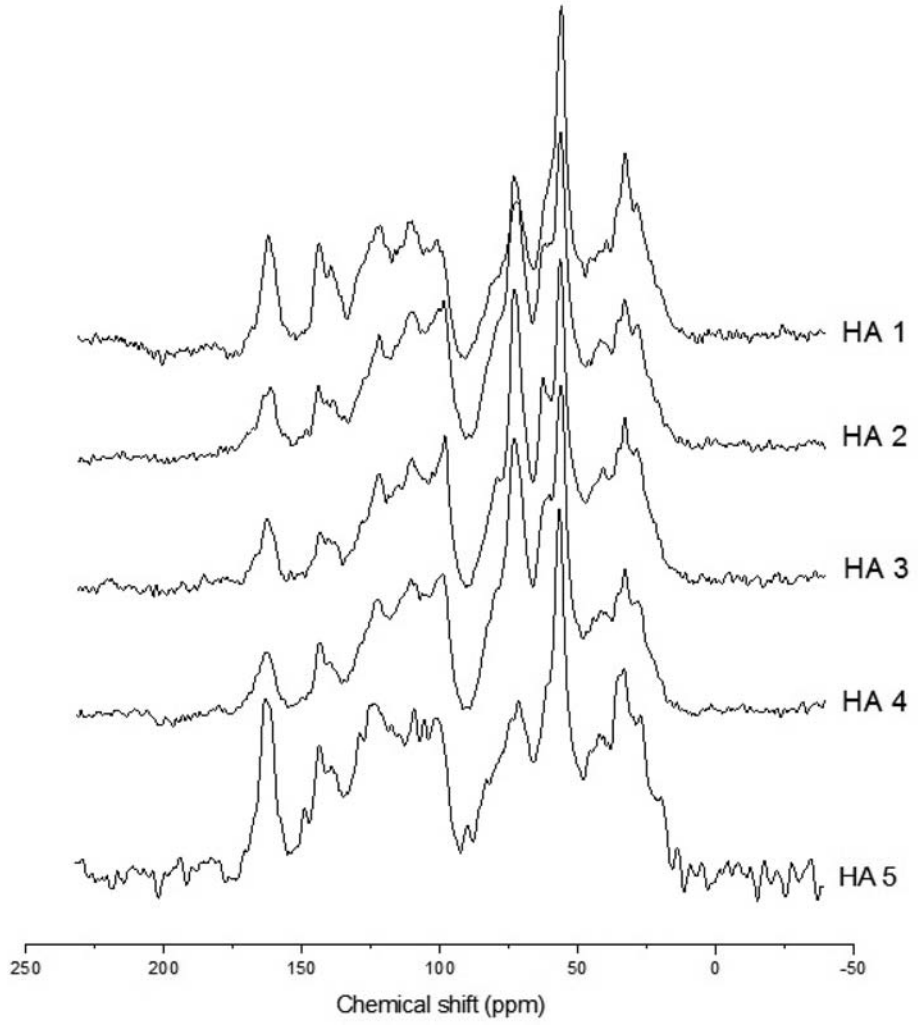

**Figure 3.** CP-MAS $^{13}C$ NMR spectra of humic acids from different vermicomposts: (HA1) cattle manure; (HA2) sugar cane bagasse; (HA3) sunflower cake; (HA4) mixture of cattle manure, sugar cane bagasse, and sunflower cake; (HA5) sugar cane filter cake.

The various lignin components released by thermochemolysis from humic acids were associated with the current symbolism for basic lignin structures used in thermochemolysis analysis: P, *p*-hydroxyphenyl; G, guaiacyl (3-methoxy-4-hydroxyphenyl); and S, syringyl (3,5-dimethoxy-4-hydroxyphenyl).[26] As expected, the most representative lignin

compound found among the pyrolyzed products for all humic acids was a propenoic acid derivative (2-propenoic acid, 3-(4-methoxyphenyl)-methyl ester, P18), which is a basic component of lignified tissues of herbaceous crops and grasses. The lignin compounds decrease in the following manner: HA2 > HA5 > HA1 > HA3 > HA4. HA2 obtained from sugar cane bagasse and cattle manure showed 65.7 times more lignin than HA4 obtained from the mixture of bagasse, cattle manure, and sunflower cake (Table 1). A large range of methylated guaiacyl derivatives were found in all HAs, although at lower concentration with respect to the propenoic acid monomer, whereas limited distribution and lower abundance were shown by syringyl units. Useful specific components found in all humic extracts may be associated with the presence of either microbially processed organic materials or undecomposed plant debris. The extent of lignin decomposition may be estimated by structural indices that are based on the relative amount of specific thermochemolysis products.[26−28] Whereas the aldehydic (G4 and S4) and acidic (G6 and S6) forms of lignin structures result from progressive degradation of lignin polymer, involving the ongoing oxidation of propyl chain, the corresponding homologues with integral hydroxylated side chains (G14/15, S14/15) are indicative of unaltered lignin components, which retain the typical $\beta$-O-4 ether intermolecular linkages. Therefore, the indices are obtained (Table 1) by dividing the amount found for the acidic structures by that of, respectively, G4 and S4 aldehydes (Ad/AlG = G6/G4, Ad/AlS = S6/S4) and for the global yield of threo/erythro isomers (ΓG = G6/[G14 + G15]) currently used as indicators of the bio-oxidative transformation of lignin polymers. The larger the values of dimensionless indices, the wider the decomposition process of lignin substrates. The largest amount of fatty acids identified as methyl ester derivatives was observed in HA2 isolated from sugar cane bagasse followed by HA5 from filter cake. However, a larger diversity of methyl esters of fatty acids was found in HA1. The main methyl ester derivatives were even- and odd-numbered long chains from plant and bacterial origin, respectively. HA5 was characterized by the presence of docosanol, a long-chain alcohol from carbohydrate enzymatic reactions. Squalene was found in all humic acids, whereas 15-hydroxydehydroabietic acid was found only in HA2 and $\beta$-sitosterol only in HA3. Large amounts of cholest-7-ene-3-ol acetate were found in HA5 and lanost-8-ene-3,7-dione in HA2.

The most common nitrogenous compounds found in all humic acids, and in larger amounts in HA3, were 2,4-dimethoxyphenylamine, *N*-methoxycarbonyl, and benzenamine. Proline derivatives were found only in HA1 and HA5, whereas pyrrolidone and pyrimidone derivatives were found only in HA2 and HA3. Few compounds derived directly from carbohydrates were found in the samples and only as furan derivatives.

The $^{13}C$ NMR spectra were characterized by a sharp resonance in the 45−65 ppm range for all humic acids (Figure 3). The main signal centered around 55 ppm, associated with the methoxy substituents in the aromatic ring of guaiacyl and syringyl components of lignified tissues of plants, which clearly indicate the incorporation of lignin derivatives in mature vermicomposts. The broad and strong signals found in the alkyl-C region (0−45 ppm) region revealed the large incorporation of alkyl chains pertaining to different components. The peaks at 16 and 23 ppm may be derived mainly from $CH_3-$ and $CH_2-$ groups of various lipid compounds, such as waxes, polyesters, and phospholipids. In addition to the peaks between 0 and 30 ppm, many distinct signals were shown in the broad alkyl-C region around 30−45 ppm with signals at 30, 32, 39, and 44 ppm, which indicate the simultaneous presence of different alkyl chains from linear and branched fatty acid and peptide derivatives. The inclusion of N-containing organic compounds was stressed by the peaks positioned at 40−44 ppm, which were assigned to both $C_\alpha$ and $C_\beta$ in amino acids.[20] Moreover, a different preservation of nitrogen components in the humic extracts was also suggested by the comparison of the intense peak at 55 ppm, with a less pronounced intensity of the O-aromatic functional groups in the 140−160 ppm interval, found in the $^{13}C$ NMR spectra of HA2, HA3, and HA4 (Figure 3 and Table 2). Besides the lignin structures, the signals included in the 45−60 ppm chemical shift range may also result from the C−N bonds in amino acid moieties. In this respect the comparison of signal intensity in the 45−60 ppm interval over that in the 140−160 ppm range may be helpful for a more accurate assignment of methoxyl and phenolic resonances. This dimensionless index, hereby denoted the lignin ratio, has been used to improve discrimination between signals from lignin units characteristic of other phenolic components or peptidic moieties.[20] Whereas a sharply lower ratio of <1 is usually associated with the inclusion of tannin and polyphenol constituents to the global O-aromatic-C signals, the opposite prevalence of the upper fractional part indicates the contribution of C−N bonds in the 45−60 ppm area. Therefore, the discrepancy between methoxyl-C and phenolic-C signals, summarized by the larger lignin ratio found in HA2, HA3, and HA4 humic extracts (Table 2), suggests a greater incorporation of peptidic moieties and a lesser preservation of lignin derivatives in the stabilized organic fractions of sugar cane bagasse, sunflower cake, and mixed mature vermicompost.

The different resonances in the O-alkyl-C region (65−110 ppm) are currently assigned to monomeric units in oligo- and polysaccharide chains of plant tissue. The intense signal around 72 ppm corresponds to the overlapping resonances of carbons 2, 3, and 5 in the pyranoside structure in cellulose and some hemicelluloses, whereas the signal at 104 ppm is assigned to the anomeric carbon 1 of the glucose unit in cellulose. The

shoulders localized around 62−65 and 84−88 ppm result from carbons 6 and 4 of monomeric units, respectively. The low-field resonances (higher chemical shift) of each couple indicate the presence of crystalline forms of cellulose, whereas the high-field resonances are assigned to either amorphous cellulose or hemicellulose structures. Besides the signals usually assigned to cellulose, the spectra of different HAs revealed three additional resonances around 93, 106, and 110 ppm. These signals may be related, respectively, to the di-O-alkyl-C of monomeric units of simple carbohydrates and to the C1 of either hemicellulose or pectic polysaccharides chains contained in cell walls of plants, such as $\alpha$-1,5 arabinan, $\beta$-1,4 galactan, and $\alpha$-1,4 galacturonan.

In the aromatic/olefinic-C region (110−145 ppm), the different resonances around 120 and 123 ppm are related to unsubstituted and C-substituted aryl carbon pertaining to both lignin monomers and ring components of polyphenols. The signal intensity shown by the specific O-aromatic region (145−160 ppm) in HAs confirms the incorporation of O-substituted ring carbon derived from different lignin structures. The evident resonances shown at 152 (sharp) and 158 ppm chemical shift ranges are usually assigned to carbons 3, 4, and 5 in the aromatic ring of lignin components, with carbon 3 and 5 being coupled to the corresponding methoxyl substituents. Finally, the intense signal in the carbonyl region (160−190 ppm) at 174 ppm suggests the contribution of carbonyl groups of peptide bonds of amino acid moieties in all of the humic materials. The relative distribution of organic functional groups and the hydrophobic index indicate that the HAs from cattle manure and filter cake underwent a more advanced humification process, with a final large preservation of recalcitrant hydrophobic components. Conversely, the lignin ratio and the larger amount of polysaccharides found in HA2, HA3, and HA4 (Figure 3) revealed a steady maintenance of biolabile compounds in the final mature vermicompost, with the mixed vermicompost showing a lower hydrophobic character (Table 2).

The results of the root growth biological assay represented by humic acid application are shown in Figure 4. All of the humic acids from mature vermicomposts showed an improvement in the number of lateral roots ranging from 36 to 135% with respect to control plants. However, HA4 showed no significant differences related to the control by the mean test applied. The lowest and no significant effect was found for HA4 extracted from the mixture of cattle manure, bagasse, and sunflower cake. Among those humic acids that produced significant bioactivity effect, we have humic acids re-isolated from bagasse (HA2) and sunflower cake (HA3), which enhanced the emergence of lateral roots in a very similar range from 51 to 58%, respectively. HA1 extracted from cattle manure revealed an increase of 98%, whereas the larger promotion was associated with HA5 from filter cake vermicompost.

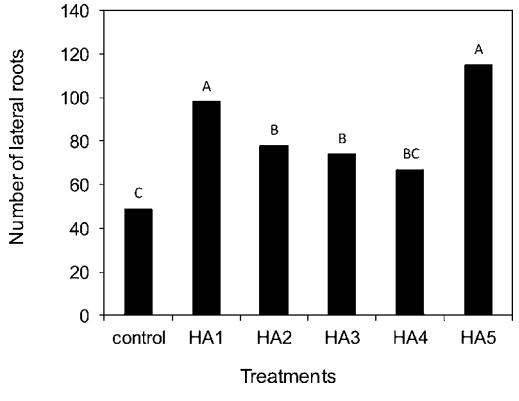

**Figure 4.** Number of lateral roots in maize seedlings treated with humic acids from different vermicomposts: (HA1) cattle manure; (HA2) sugar cane bagasse; (HA3) sunflower cake; (HA4) mixture of cattle manure, sugar cane bagasse, and sunflower cake; (HA5) sugar cane filter cake. Different letters represent a significant difference by means of Duncan's test ($p < 0.01$). The coefficient of variation was 13.37%.

Vermicomposting technology, using earthworms as versatile natural bioreactors for effective recycling of organic wastes to the soil, is an environmentally suitable method to convert residual biomass into nutrient-rich composts for crop production.[29] Considerable work has been carried out on vermicomposting processes of various organic materials such as animal manures, agricultural wastes, forestry wastes, city leaf litter and food residues, sewage sludge, and industrial wastes such as paper pulp and distillery wastes. Vermicomposting represents an important environmental service for waste recycling coupled with the generation of valuable products.[29] The results of $^{13}$C NMR spectroscopy and offline thermochemolysis GC-MS indicate that despite the intense biochemical transformation process of accelerated humification by earthworms, the final humic products retained the chemical features inherited from the original organic source. Contrary to the indications of $^{13}$C NMR spectra, a relatively low yield of carbohydrates was detected among the pyrolysis products. The lack of polysaccharide compounds was already noted in applications of thermochemolysis on plant woody tissues and soil organic matter.[24,26] These authors pointed out that the large amount of thermally unstable hydroxyl functional groups in polysaccharide chains makes the pyrolysis technique less suitable for the effective detection of carbohydrates in complex geochemical matrices. It is thus conceivable that for compost samples the setup of thermochemolysis parameters may be highly selective for lignin and alkyl components and may reduce the simultaneous identification of carbohydrate units from cellulose. Such selective detection reinforces the use of different approaches for a more complete compound inventory associated with the supramolecular structure of humic substances.

The different humic acids showed a variable effect on the emergence of lateral roots (Figure 4) and were characterized by an uneven incorporation of alkyl and aromatic hydrophobic components (Tables 1 and 2). To date, the most hydrophobic humic acids were isolated from cattle manure and filter cake biomasses, and they provided the best stimulation of lateral root emergence (Figure 4). In contrast, the root biostimulation effect was decreased by humic acids from sugar cane bagasse, sunflower cake, and mixed materials, which were characterized by the progressive lowering of hydrophobic character (Table 2). These results are consistent with the previous findings that humic fractions with a larger hydrophobicity provide a steady and high bioactivity, and the presence of aromatic and aliphatic components, such as lignin compounds and methyl esteres derivatives, is closely related to the ability of humic acids to induce lateral root emergence.[23,27,30,31] An apparent inconsistency with these previous findings was presented in the current thermochemolysis results, which showed that the largest lignin content was for HAs from sugar cane bagasse (Table 1). However, the most abundant aromatic monomers

found in the pyrograms of HA2 were 3-(4-methoxyphenyl)-2-propenoic (P18) and 3-(4,5-dimethoxyphenyl)-2-propenoic (G18) derivatives, which accounted for about 40% of the total lignin content (Table 1). These molecules originated either from the side-chain oxidation of lignin units or from the aromatic domains of plant biopolymers, the important relative contribution of which in herbaceous plants may have exaggerated the total content of lignin in the HAs from sugar cane, compared to those from cattle manure and filter cake. Moreover, the higher values of lignin structural index found in the pyrograms of HA2 and HA5 (Table 1) suggest the occurrence of an intense decomposition process of lignin biopolymers in the humic fraction from cattle manure and filter cake. Therefore, the most advanced humification may have promoted a preferential accumulation of small and active aromatic fragments bound to the supramolecular humic acids structure, which should allow a more prompt physiological response compared to the partial undecomposed and rigid lignin residues.[16]

In addition to the content of specific molecules, the ratio of hydrophobic to hydrophilic moieties is considered an important characteristic for the bioactivity of humic extracts. The role of humic hydrophobicity may be explained by the selective preservation, in humic recalcitrant compartments, of active biofragments that may be successively released by conformational changes of humic associations in solution.[8,19,21] The reduced microbial and enzymatic activity provided by the hydrophobic domains is assumed to contribute to the protection of biolabile hydrophilic compounds, which may become available to the plant root system by means of cell exudation in the rhizosphere.[28,32] For example, plants treated with humic substances showed enhanced exudation of organic acids, thereby leading to a modification of structural arrangement and to a release of active molecules in the rhizosphere.[22]

The present results confirm that mature vermicompost is a viable way to recycle agricultural biomass and to demonstrate that, acting as a source of bioactivity, humic extracts represent an additional valuable biological product for a wide range of agricultural practices.[18] Notwithstanding the modification by the composting processes, the final humic substances retained a chemical composition strongly related to the composition of the initial biomass. Although the role of hydrophobic humic components needs further evaluation to gain a deeper insight into the structure−activity relationship, the association of detailed molecular characterization and bioactivity assays are unavoidable requirements for a more accurate and valuable utilization of humic material as plant growth promoters and for a comprehensive understanding of the interaction between plant and soil organic matter.

release in functional foods, for example, low-fat, low-sugar food. Previous studies either on pure gels (e.g., pectin gels, protein gels, carrageenan gels) or mixed gels (e.g., starch-carrageenan gels, pectin-gelatin gels) have shown that the gel structure affects volatile release from food,[14,16−18] and gels with stronger texture had weakened volatile profile.[14] In EFP gels, oil droplets are immobilized in a viscoelastic gel network, with slowed rates of diffusion and mass transfer of volatile molecules. When the gel network collapses under mechanical forces (e.g., chewing), volatile release can be accelerated.[17] Therefore, EFP gels can behave as volatile carriers to control volatile release and target delivery. Although biopolymer gels have long been used as delivery systems for bioactives, they differ from EFP gels in physicochemical properties and functional values. Among the few studies conducted, Lee et al.[19] reported that volatile retention ranged from 60 to 100% in EFP gels and from 5 to 25% in emulsions when stored at 37 °C for 72 h.

In the current study, cold-set EFP gels were prepared through acidification by glucono-$\delta$-lactone (GDL), and different volatile compounds were incorporated into the gels. The main objective of the study was to understand the release behavior of volatiles in EFP gels with different rheological properties by adjusting the protein and oil content. Because protein gels are sometimes used as fat replacers in food,[20] another goal was to explore the possibility of slowing volatile release in oil-reduced systems by creating stronger EFP gels.

## MATERIALS AND METHODS

**Materials.** WPI (BiPro), which contained >90% w/w total protein (5% moisture, 1% fat, 3% ash, 1% lactose), was bought from Davisco Food International (Le Sueur, MN, USA). Sunflower oil was purchased from a local supermarket and used without further purification.

**Chemicals.** Glucono-$\delta$-lactone (GDL), sodium azide, 1-propanol (>99.5% purity), diacetyl (>99.5% purity), 2-pentanone (>99% purity), hexanal (>99% purity), 2-heptanone (>99% purity), Nile red, and fast green were all products of Sigma-Aldrich (St. Louis, MO, USA).

**Preparation of EFP Gels.** EFP gels were prepared following the method described by Sok Line et al.[21] with some modifications. Briefly, WPI suspension was prepared by dispersing the powdered WPI in deionized water, and the mixture was stirred overnight to ensure complete dissolution. Sodium azide (0.01% w/w) was added to inhibit microbial growth. The solution was then heated at 85 °C for 30 min in a water bath, followed by rapid cooling to room temperature (~23 °C) with an ice−water mixture. An oil-in-water emulsion was prepared by mixing the heated WPI solution and sunflower oil at 10 000 rpm for 1 min using an Ultra-Turrax (IKA, Staufen, Germany), followed by high-pressure homogenization (M110-EH Microfluidizer, Microfluidics International Corp., Newton, MA, USA) at 50 MPa for three passes. The emulsions were immediately cooled to room temperature (~23 °C) with tap water and stored in an incubator for further use. The droplet sizes of the emulsions were determined by dynamic light scattering using a Zetasizer Nano-ZS90 (Malvern Instruments Ltd., Malvern, UK) at a fixed detector angle of 90°. The refractive indices of the particle and water were set at 1.45 and 1.33, respectively. To minimize multiple scattering effects, emulsions were diluted with deionized water to an oil concentration of ~0.005% w/w prior to each measurement. The intensity mean diameter (nm) based on three repeats was reported.

To induce cold gelation, GDL (0.5% w/w) was added into the emulsions and incubated at 25 °C for 16 h. The evolution of the pH of the emulsions during gelation was recorded by Cinac (Ysebaert Dairy Division, Frepillon, France). In the measurement, the sample tubes with one pH probe in each tube were kept in a water bath (25 °C), and the pH values of the samples were recorded every 5 min for 16 h.

For comparison purposes, an ungelled emulsion (no GDL, 20% oil, 5% WPI, w/w) and an emulsion with unheated WPI solution (20% oil, 5% WPI, 0.5% GDL, w/w) were also prepared using the above method.

**Characterization of EFP Gels.** *Viscoelastic Properties.* After the addition of GDL, emulsions (~15 mL) were allowed to form gels in a AR 2000ex rheometer (TA Instruments, Crawley, UK) using a concentric cylinder geometry (cup radius = 15 mm, rotor radius = 14 mm). To avoid water evaporation, a thin layer of tetradecane oil was added to the surface of the samples. The samples were oscillated at a strain of 0.5% and a frequency of 1 Hz to ensure the linear behavior and measurements were taken every 10 s for 16 h. The measurement was performed at 25 ± 0.05 °C, controlled by a Grant GD 120 stirred thermostatic circulator (Grant Instruments, Cambridge, UK). The evolution of the storage and loss moduli ($G'$ and $G''$) of the samples during oscillation was recorded. Dynamic strain sweep measurement (strain 0.1−300%, frequency 1 Hz) was previously carried out to determine the linear viscoelastic range of the gels. Gelation time ($T_{gel}$), defined as the time point at which the $G'$ time curve and $G''$ time curve crossed over, was also reported. The pH value of the emulsions at $T_{gel}$ was defined as gelation pH ($pH_{gel}$).

*Mechanical Properties.* A large deformation rheological test was applied to evaluate the mechanical properties of EFP gels. The gels were formed in cylindrical plastic beakers (20 mm internal diameter × 35 mm height) for 16 h at 25 °C. The test was performed on a TA-HDi Texture Analyzer (Stable Micro System, Godalming, UK) with a cylindrical plunger (diameter = 5 mm) and a 5 kg load, operating at a test speed of 1 mm/s to a total penetration distance of 10 mm. Three parameters were recorded: force at breaking (N), defined as the first significant inflection point in the force−distance curve; strain at breaking (mm), defined as the penetration distance at which the force at breaking was recorded; and stiffness (N/mm), defined as the initial slope of the force−distance curve.[22] The reported results were the mean value of eight replicates.

*Water-Holding Capacity (WHC).* For WHC determination, EFP gels were formed in Nalgene centrifuge tubes (Sigma-Aldrich). The gels were centrifuged at 20 000$g$ (Sorval RC 5B Plus, DuPont Instruments, Connecticut, US) for 30 min at 4 °C, and the water released was then drained, and the amount of water was calculated. WHC was determined as

$$\mathrm{WHC} = \frac{W_T - W_F}{W_T} \times 100\%$$

where $W_T$ was the total amount (g) of water in the gel and $W_F$ was the quantity of water (g) released. The mean of three repeats was reported.[23]

*Microstructure.* Confocal scanning laser microscopy was used to observe the microstructure of the EFP gels. A thin layer (~2 mm) of the gel was transferred to a glass slide and stained with a mixture of Nile red (0.1%, w/v, in distilled water) and fast green (0.1%, w/v, in distilled water) at a ratio of 3:1. Confocal observation was performed after 5 h of labeling using a Leica TCS SP5 microscope (Leica Microsystems GmbH, Wetzlar, Germany). Images of representative areas of each sample were taken using a 63× oil immersion objective (numerical aperture = 1.4) at an excitation wavelength of 633 nm, provided by a He−Ne laser.

**Emulsion Flavoring.** Emulsion flavoring was achieved before the addition of GDL, and the procedure was described in a previous study.[27] Briefly, a volatile-ethanol solution (5% v/v for each volatile) was added into emulsions in gastight glass vials (20 mL, silicone/PTFE seals) (La-pha-pack GmbH, Langerwehe, Germany) to reach a concentration of 500 mg/L for each volatile, and the solution was equilibrated for 1 h. Two grams of the flavored emulsion was rapidly transferred to a headspace vial (20 mL, silicone/PTFE seals) (La-pha-pack GmbH) containing 0.01 g of GDL. The vials were stored at 25 °C for 16 h before GC headspace analysis.

**GC Headspace Analysis.** Headspace concentrations of the volatiles at different time points (0.5,1, 2, 4, 6, 10, 20 min) were measured using a Varian CP-3800 gas chromatograph (Varian Inc.,

Palo Alto, CA, USA) equipped with a ZB-5MSi capillary column (60 m, 0.25 mm i.d., film thickness = 0.25 $\mu$m) and coupled with a FID detector. Headspace vials containing EFP gels were incubated at 37 °C for different times in a Combi PAL autosampler (CTC Analytics AG, Switzerland). Injections of the headspace (1 mL) were performed using a preheated (42 °C) 2.5 mL thermostated gastight syringe (Hamilton, Switzerland) under split mode (1:10). Only one sampling was made in each vial. Injector and FID temperatures were 225 and 230 °C, respectively. The helium carrier gas flow rate was 1 mL/min. The temperature program was as follows: 50 °C (4 min), 200 °C at 10 °C/min rate, 240 °C at 40 °C/min rate (2 min).

To quantify the concentrations of the volatiles in the headspace, calibration curves of the tested five volatiles were plotted using peak areas obtained from GC analysis against six known concentrations of each volatile in ethanol. The completely vaporized volatile-ethanol solution (2.0 $\mu$L solution in a 20 mL vial, incubated at 37 °C for 1 h) was analyzed according to the above GC methods. Results were based on triple analysis.[24]

**Statistical Analysis.** Statistical analysis was performed using OriginPro 7.5. All of the measurements were repeated at least three times. A one-way analysis of variance (ANOVA), followed by Tukey's test, was applied to determine significant differences between the mean values of each test. A significance level of $p < 0.05$ was used throughout the study.

## RESULTS AND DISCUSSION

**Characterization of EFP Gels.** Storage modulus ($G'$) is an indicator of the energy reserved every cycle of deformation, and its value reflects the elastic or solid-like properties of the tested sample, whereas loss modulus ($G''$) is a measure of the energy dissipated by the sample and is connected with the viscous or liquid-like properties of the sample. Figure 1 shows the evolution of $G'$ and $G''$ as the gelation process went on after the addition of GDL. A change in the pH of the emulsion was also recorded. As the graph indicates, when the pH of the emulsion decreased to about pH 5.9, $G'$ and $G''$ increased dramatically, and the $G'$ value dominated the $G''$ value thereafter, indicating onset of gelation in the emulsion.[12] The $G'$ values increased further with a decrease in the pH of the emulsion, reaching a plateau at around pH 4.7, indicating the formation of an elastic gel at pH values below pH 5. The increase in the $G'$ over time was attributed to structure rearrangements within the emulsion, and a compact gel network was gradually formed.[25] The gelation process took place mainly in the first 16 h, as the storage modulus increased slowly after that.

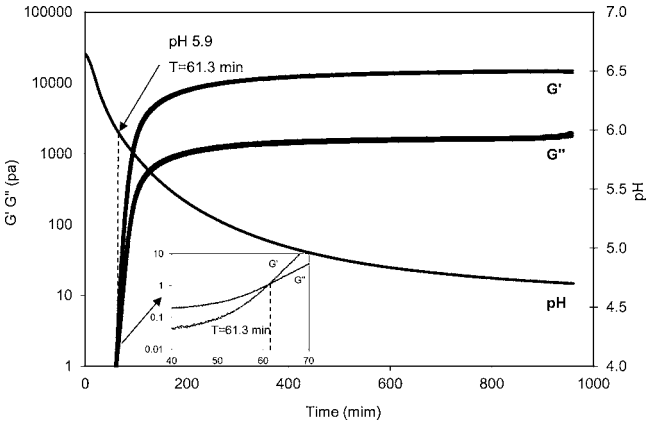

**Figure 1.** Evolution of storage modulus ($G'$), loss modulus ($G''$), and pH during the cold-gelation of emulsion filled protein gel (5% WPI, 20% oil, 0.5% GDL, w/w). The protein solution was preheated at 85 °C for 30 min. The inset image highlights the intersection of $G'$ and $G''$.

WPI contributed to the majority of the gel network, and the change in the WPI content allowed great variation in the physicochemical properties of the EFP gels. Particle size analysis showed that the increase in the WPI content coincided with an increase in the droplet size, and all the emulsions had droplet sizes < 300 nm, with a fine droplet distribution. The size difference could be attributed to depletion flocculation and bridge flocculation induced by the denatured protein in the continuous phase.[26] No significant difference in $T_{gel}$ was observed in gels with a WPI content from 4 to 6%. Because the evolution of the pH was induced by GDL, all of the emulsions started gelation at the same $pH_{gel}$ ($p > 0.05$) (Table 1). During gelation, the presence of GDL allowed a pH decrease to a value below the isoelectric point of the WPI, which resulted in a reduced repulsion force between protein aggregates and then association of the aggregates through noncovalent interactions.[27] In gels with a higher WPI content, protein interactions and the packing density increased, leading to a strengthened gel matrix with a higher $G'$ (Figure 2). It was also observed that an increase in the WPI content from 3 to 6% led to ~3-fold enhancement of the storage modulus. The relationship between the protein concentration and the gel storage modulus follows a power law, $G' = f(c^x)$,[28] and the exponent $x$ is calculated from the slope of the log−log relationship between the storage modulus and the protein concentration. The exponent is dependent on the gel microstructure and gelation conditions (e.g., pH, salt composition).[28,29] For heat-set protein gels (WPI 0.1−10% w/w), the constant could reach >4.[30,31] In the current cold-set EFP gels with 20% oil, the power law constant decreased to 2.6. This change indicated that in EFP gels, the contribution of the protein concentration to the storage modulus was reduced, which could be a sign of the active role of oil droplets in the gel.[31]

Visual observation found that the gel with 3% WPI was pourable, reflecting a weak network. Gels with higher WPI content presented soft solid-like properties with a smooth surface and homogeneous cross section. The mechanical properties of the gels were determined by a texture analyzer under a penetration test. For all of the gels, an increase in the WPI content induced an increase in both the force and the strain at breaking, suggesting that more rigid gels were formed with a higher WPI content (Table 1). This finding was in agreement with published data for cold-set protein gels.[32] The resistance against the deformation of a protein network and dispersed oil droplets was measured as a force.[8] In the more rigid gels, a closer proximity among the protein chains allowed a more even distribution of applied force against breaking down of the gel network. It was also found that the force increased more than proportionally with the strain value with an increase in the WPI content, suggesting that the gels with a higher WPI content became more strain-hardening.[8] Stiffness calculation reconfirmed the findings because the value increased with the WPI content. In line with the visual observation, the gel with 3% WPI presented poor mechanical properties (the lowest force at breaking and stiffness). Determination of the WHC showed that a higher WPI content also contributed to a higher WHC, although only a slight difference was found for gels with WPI ≥ 4%. In the gel with 3% WPI, about 1/3 of the water was lost after a centrifuge test, suggesting a weak water−protein gel interaction and a less compact gel structure. The above result

[a]Gelation was induced with the addition of 0.5% w/w GDL. Within each row, values with different letters are significantly different ($p < 0.05$). [b]WHC, water holding capacity.

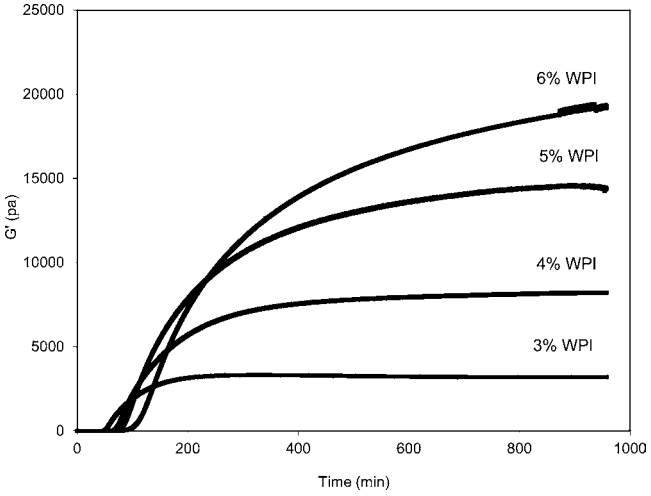

Figure 2. Effect of WPI content (w/w) on the evolution of the storage modulus ($G'$) during the cold-gelation of emulsion-filled protein gels (20% oil, 0.5% GDL, w/w). The protein solution was preheated at 85 °C for 30 min.

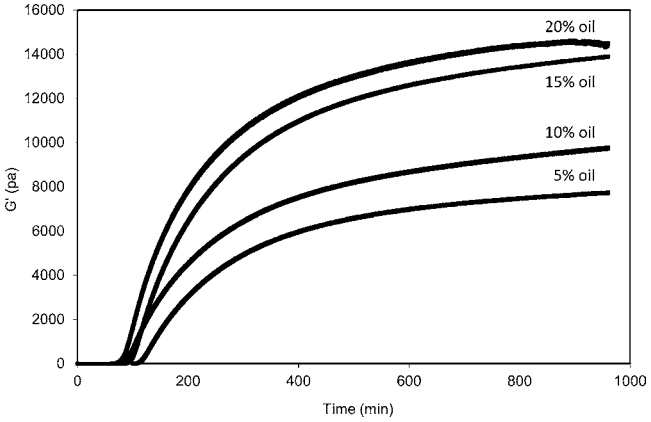

Figure 3. Effect of oil content (w/w) on the evolution of storage modulus ($G'$) during the cold gelation of emulsion-filled protein gels (5% WPI, 0.5% GDL, w/w). Protein solution was preheated at 85 °C for 30 min.

also showed that WPI content ≥4% was essential to obtain gels with suitable mechanical properties.

Because oil droplets behaved as active fillers in EFP gels, the oil content showed large effects on the gel properties (Table 2). First, a higher oil content greatly shortened the gelation process. For example, with 5% oil, the gelation took place 104.3 min after the addition of GDL, but with 20% oil, the gelation was observed much earlier (61.3 min after GDL addition) (Table 2). In gels with a higher oil droplet concentration, more droplet−droplet and droplet−matrix interactions were expected, and the emulsion presented elastic properties ($G' > G''$) at a much earlier stage.

Second, the maximum rate of increase in $G'$ and the final $G'$ were higher for gels with a higher oil content (Figure 3). Similar results were reported by Sok Line et al.,[21] who found that the presence of 30% oil in the protein network enhanced about 10-fold of the storage modulus. The findings reconfirmed that oil droplets were acting as space fillers in the gels, and they helped to build a gel matrix structure through the interaction between the protein covering the droplets and the protein in the bulk phase.[11]

Third, gels with a higher oil content had a higher value of force at breaking and stiffness, although the effect was much smaller than that of the WPI content. According to Kim et al.,[8] the increase in the force at breaking with the oil content was more significant in gels containing smaller droplets. However, such an increase in force was not observed in the current study, probably because of the slight deviation in the droplet size of emulsions with different oil contents. Furthermore, the increased WPI concentration in the water phase (reduced water content due to the increase in the oil content) could also contribute to the enhancement of the gel texture. The decrease in the strain at breaking indicated that the gels became more

brittle with the increase in the oil content. The finding was also reported in previous studies.[8,32,33] The minor effect of the oil content on the WHC was probably due to the fact that the water was mostly bound to the protein, and the slight increase in the rigidity or compactness of the gel did not present a profound enhancement of the WHC.

From a theoretical point of view, an increase in the oil content would result in a decrease in both the force and strain at breaking for gels with foreign droplets , as a result of stress concentration. Stress concentration can be induced by structure defects in the structure, for example, oil droplets in the protein gel network. Becauise of the inhomogeneity in the gel, the gel between droplets is deformed at a higher level than the gel at the surface of the droplets under large deformation. The stress concentration between droplets triggers gel fracture due to dissociation of gel from the droplets or fracture of the gel matrix.[34,35] Therefore, protein gels with a higher oil content were more likely to break down at lower stress and strain. However, a slight increase rather than a decrease in the breaking force with the oil content was observed in the current study, which could be attributed to the viscous properties of the EFP gels. In these gels, viscous flow arose as a result of local yielding in the area where the stress was concentrated, and energy was dissipated. Furthermore, the viscous nature of the interfacial layer of the oil droplets in the gels can dissipate energy, as well.[11] Therefore, more force was required to break the EFP gels with the higher oil content. Another possible reason responsible for the slight increase in the breaking force was that the slip between droplets and the gel matrix took place at the expense of additional force.[36]

Figure 4 shows representative confocal microscopy images of EFP gels with different WPI contents and oil contents. As the pictures indicate, all of the oil droplets (green) had a regular spherical shape, and they were evenly distributed, with no clear droplet aggregation being observed. The images did not present large difference in droplet size of different systems, and the droplet size obtained was in good agreement with that determined by dynamic light scattering, suggesting that little or no coalescence occurred upon gelation. Careful observation of the protein network (red) showed variation in gel structures in gels with different compositions. Gel A (5% WPI, 20% oil) presented a continuous network with evenly distributed small pores, whereas in gel B (5% WPI, 10% oil), the pores became rather big, and they broke the network. By contrast, gel C (3% WPI, 20% oil) did not show a typical gel network but, rather, a network containing only some protein clumps, and individual oil droplets were observed. This observation supported the previous finding that both WPI and oil contributed to form the gel network, and increase in WPI content or oil content could result in gels with higher compactness.

**Volatile Release from EFP Gels.** Five volatile compounds, that is, propanol (C3), diacetyl (C4), pentanone (C5), hexanal (C6), and heptanone (C7), were incorporated into the EFP gels, and their release behaviors were evaluated. The selection of these compounds was mostly based on the carbon numbers and polarity of the different compounds. Diacetyl is the most hydrophilic one (log $P$ = −1.43), whereas heptanone is the most lipophilic one (log $P$ = 1.98), with propanol (log $P$ = 0.25), pentanone (log $P$ = 0.91), and hexanal (log $P$ = 1.78) in between them.[37] Volatile release from food is mainly controlled by two factors: the volatility of volatile compounds (thermodynamic factor) and the resistance to mass transfer from a food matrix to the air phase (kinetic factor).[38] The

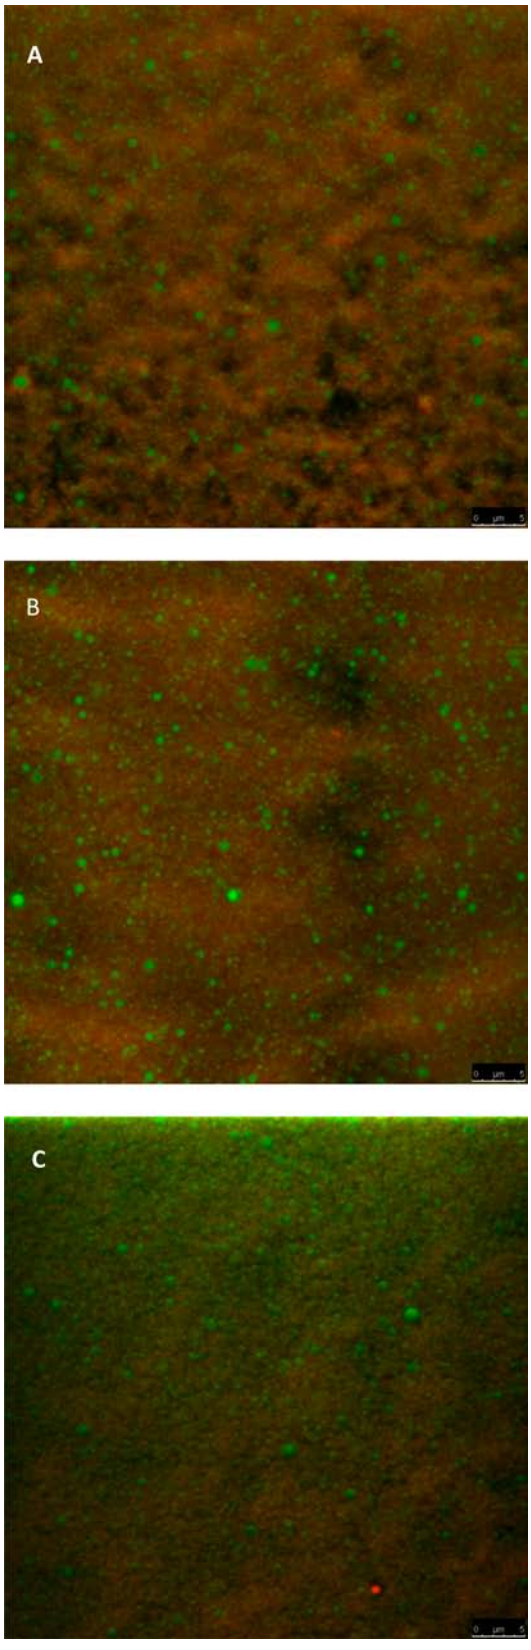

**Figure 4.** Confocal microscopy images of cold-set emulsion filled protein gels with different WPI contents and oil contents: A (5% WPI, 20% oil, w/w), B (5% WPI, 10% oil, w/w), and C (3% WPI, 20% oil, w/w). Green represents the oil; red, the protein. Gelation was induced with the addition of 0.5% w/w GDL. Gels were labeled for 5 h before confocal observation. The bars indicate 5 $\mu$m in length.

thermodynamic factor determines the retention or partition of volatiles in the matrix at equilibrium, and the kinetic factor mainly affects the release rate of volatiles from the foods. The rationale of encapsulating emulsion droplets within a protein gel network was to reduce the rate of volatile diffusion from oil droplets to the continuous phase and to the external environment (e.g., headspace, saliva) and mass transfer inside aqueous phase by creating physical barriers in the oil–water interface and aqueous phase. Pre-experiments (using the same GC method described in Material and Methods) indicated that volatile compounds had linear releases ($r^2$ ranging from 0.96 to 0.99) in the initial stage from 0.5 to 6 or 10 min, and release equilibrium was reached within 20 min. The slope of the linear curve was regarded as the release rate of each volatile compound. Headspace concentrations at equilibrium were used to calculate partition coefficients $K_{A/E}$ ($K_{A/E} = C_A/C_E$, $C_A$, $C_E$ were the volatile concentrations in the headspace and bulk emulsions, respectively).

Figure 5 shows the release rates of the volatile compounds in EFP gels (with GDL) or ungelled emulsions (no GDL). In the

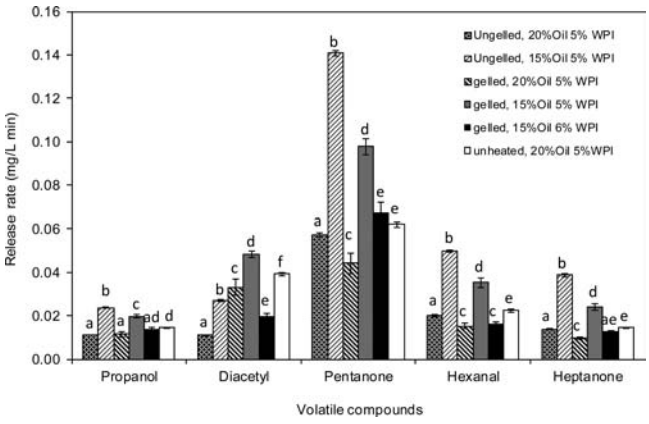

**Figure 5.** Release rates of the volatiles in EFP gels (with GDL) and ungelled emulsions (no GDL) varying in WPI content (w/w), oil content (w/w), and in the emulsion with unheated WPI solution (with 0.5% w/w GDL). Gelation was induced with the addition of 0.5% w/w GDL. Samples were incubated at 37 °C before each measuring point.

systems with 20 or 15% oil, most volatiles had lower release rates in EFP gels than those in the corresponding ungelled emulsions. For example, in the EFP gel with 15% oil and 5% WPI, pentanone had a release rate of 0.098 ± 0.004 mg/L min, whereas in the ungelled emulsion, the release rate was 0.141 ± 0.001 mg/L min. Similarly, most volatile compounds had a lower $K_{A/E}$ in the EFP gels than in the ungelled counterparts (Table 3). Therefore, in the EFP gels, volatile release was at a lower rate and of lower intensity. Similar findings were also reported in other gel systems. Boland et al.[14] compared volatile release from gelatin gel, pectin gel, and starch gel and found that increasing gel hardness could reduce the amount of volatiles released to the headspace. Guinard and Marty[39] reported that firm gels made with gelatin and carrageenan had volatiles released with a lower intensity than soft gels made with the same gelling agents.

The effect of the gel network on the volatile release could work through two different mechanisms. One was the physical entrapment of volatile compounds in the gel matrix. It was reported that the presence of an entangled polymer network in a gel system could inhibit diffusion and reduce the mobility of small molecules, for example, volatile compounds.[40] One may argue that the open space in the gel network (e.g., pores) could provide channels for the movement of small molecules, and the release of volatiles may not be blocked by the gel. In fact, Juteau-Vigier et al.[16] concluded in their study that the structure level of carrageenan gel did not show a big influence (<20%) on diffusion properties of ethyl hexanoate, but they admitted that the mobility of the volatile compounds was limited by the matrix organization. In the same study, it was also observed that addition of 1% carrageenan induced a 5.3-fold reduction in the diffusion coefficient of the volatiles. In EFP gels, volatile compounds, especially the more hydrophobic ones, were mostly distributed inside oil droplets, which were covered by compact protein films. The movement of volatiles across the interface could be inhibited to a higher level when the protein film gelled and cross-linked with the gel matrix. The gel matrix may provide additional force to retard the movement of both hydrophobic and hydrophilic compounds.

The second mechanism involved interactions between volatile compounds and gel components, which was also responsible for the reduced partition coefficients of ethyl hexanoate in the study conducted by Juteau-Vigier et al.[16] The interactions between the volatiles and protein in the current system could be due to adsorption, complexation, and entrapment.[15] WPI (or β-lactoglobulin) can attract ketones and esters through hydrophobic interaction or covalent binding.[41,42] The former attraction occurs in the hydrophobic pocket (the central calyx) of the protein,[41] whereas the latter could happen at a protein surface.[43]

According to Harrison and Hills,[44] binding reduced the concentration of free volatile compounds in the aqueous phase and, consequently, the released volatiles into the headspace. Protein adsorbed at the interface can act as a barrier to slow mass transfer of volatiles, leading to reduced release rate.[45] For example, the presence of β-lactoglobulin at the miglyol–water interface increased resistance to the transfer of benzaldehyde across the lipid layer.[46] In EFP gels, the interaction between the volatiles and protein was strengthened when the protein was

**Table 3. Air–Gel Partition Coefficients ($K_{A/E} \times 10^4$) of the Volatiles in EFP Gels (with GDL) and Ungelled Emulsions (no GDL) Varying in WPI Content (w/w), Oil Content (w/w), and in the Emulsion with Unheated WPI Solution (with GDL)[a]**

heat-denatured. It was reported that in the heating stage, the selected temperature and time must yield >95% of the protein to be aggregated so as to produce a gel with appropriate mechanical properties.[47] Therefore, in EFP gels, more hydrophobic sites could be present,[3,4] and they were able to bind volatile compounds. In an emulsion with unheated protein (with GDL, weak gel), the release rates and partition coefficients of the volatiles were significantly higher than those in the EFP gel and the ungelled emulsion (heat-treated protein, no GDL) with the same compositions (Table 3). This finding could be associated with the newly exposed hydrophobic area in the protein structure during heat treatment, which provides additional binding sites for the hydrophobic volatile compounds. This deduction contradicted the conclusion made by O'Neill and Kinsella,[48] who argued that unfolding of the protein structure (chemically modified by urea, sulfate, or ethanol) would result in a reduced binding affinity for hydrophobic compounds. The disagreement could be due to the different denaturation methods applied. In fact, O'Neill and Kinsella[48] found that the number of binding sites remained unchanged during denaturation, whereas the binding sites were believed to increase in the current study. For the more hydrophilic compounds, interaction with the protein was induced mainly by hydrogen bonding.

It is well accepted that a reduction in the oil content can accelerate the release of hydrophobic volatile compounds.[49] In the gelled system, the acceleration was of a much lower level than that in the ungelled system (Figure 5). For example, the release rate of heptanone increased from 0.0138 ± 0.0002 to 0.0388 ± 0.0008 mg/L min in the ungelled systems (181% increase) by reducing the oil content from 20 to 15%, whereas it increased from 0.0097 ± 0.0006 to 0.0239 ± 0.0014 mg/L min in the gelled systems (146% increase). Therefore, the EFP gel has the potential to slow the volatile release in an oil-reduced system. To verify this hypothesis, an EFP gel with a lower oil content (15% oil) but stronger gel network (higher WPI content, 6%) was made. Static headspace analysis revealed that four out of five volatiles in the low-oil content gel had either a lower or an unaffected release rate in comparison with those in the high-oil content gel system (20% oil, 5% WPI) (Figure 5). In terms of partition coefficients, a similar conclusion was made. Propanol and pentanone had unchanged $K_{A/E}$ values as those in the high-oil content gel, and diacetyl and hexanal had lower $K_{A/E}$ values (Table 3).

To better correlate the gel structure and volatile release, further studies were conducted on the effects of the WPI and oil contents on volatile release in EFP gels. Figure 6 shows the release rates of volatiles in EFP gels with different WPI contents. The expected decrease in the release rate with the increase in the WPI content was observed when the WPI content was ≥4%, and in the 3% WPI EFP gel, the volatiles presented lower release rates than those in the 4% WPI EFP gel. The effect of the WPI content on the partition coefficients of the volatiles followed a similar trend (Table 4), as reduced

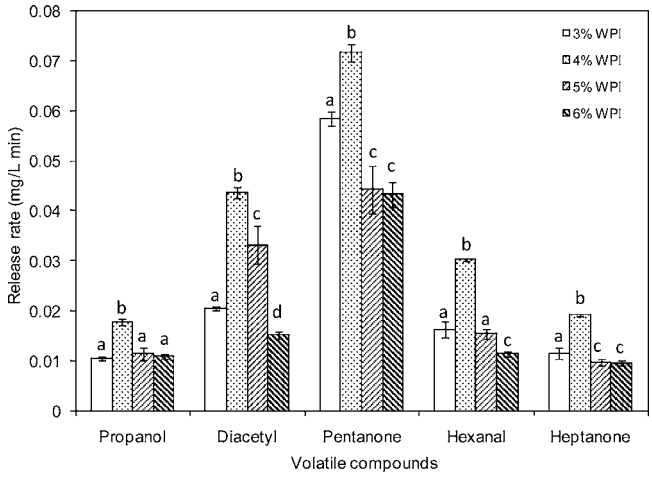

Figure 6. Release rates of the volatiles in EFP gels varying in WPI content (20% w/w oil).Gelation was induced with the addition of 0.5% w/w GDL. Samples were incubated at 37 °C before each measuring point.

$K_{A/E}$ values were obtained with the increase in the WPI content from 4 to 5 and 6%. Similar results were reported in gelatin gels and pectin gels, in which the increase in the gelling agent concentration resulted in more rigid gels and lower partition coefficients of the volatiles.[14]

Along with the strengthened volatile-protein interaction, the gel with the higher protein content provided a more compact network and smaller pores to slow volatile release. Spotti et al.[50] found that an increase in the WPI content from 12 to 16% could reduce the pore size of the WPI gel from 157 to 63 nm; however, only a slight or no significant difference in the $K_{A/E}$ values was observed for volatiles in gels containing 3 and 4% WPI. The relatively lower release of volatile in the 3% WPI system could be the result of the earlier commencement of the gelation (Table 1), and more volatiles were trapped in the gel network before headspace analysis. Although volatiles in the EFP gel with 6% WPI showed the lowest release rates and partition coefficients, the difference was rather small compared with the release in the 5% WPI system. The result indicated that both the steric hindrance and volatile-protein bindings in the EFP gels reached a maximum level in the 5% WPI system, and they were not linearly increased with a further increase in the WPI content. An exception to the above discussion was diacetyl, whose release was significantly inhibited in the 6% WPI system. It could be related to its high hydrophilic characteristic, and it was mostly distributed in the continuous aqueous phase. In a system with a higher protein content, almost all the water was trapped in the network.

Oils can act as volatile precursors, as solvents for volatile compounds, and as volatile release modulators. Changes in oil property or oil content can lead to a significantly different volatile releasing profile.[49] The result obtained in this study was

in agreement with previous findings that an increase in the oil content can result in a decreased release of lipophilic volatile compounds[49] because volatiles would have reduced concentration in the oil droplets. In EFP gels, increased stiffness with a higher oil content in the gels also contributed to inhibit volatile release. Significantly reduced partition coefficients of pentanone, hexanal, and heptanone with an increase in the oil content were observed in the current gels (Table 5). However, the effect on the release rates of pentanone and hexanal was rather small or even insignificant when the oil content was reduced to 5−15% (Figure 7). The finding suggested that the barrier function of the gel network worked better in a low-oil-content system, but in gels with a higher oil content, the slowed release by the gel network could not compensate the quick release induced by a reduction in the oil content. The decreased release rate of heptanone could be due to its high lipophilic characteristic (log $P$ = 1.98), and it had a strong affinity for the oil phase. For the hydrophilic volatile compounds, that is, propanol and diacetyl, a change in the oil content did not show a consistent effect on the release rates and partition coefficients, and sometimes the effect was insignificant.

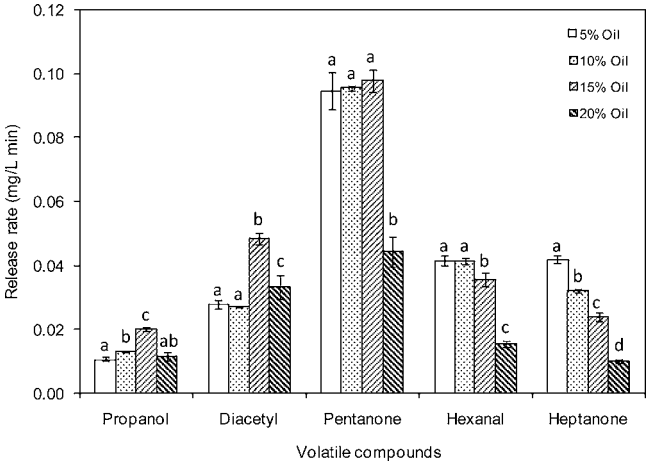

**Figure 7.** Release rates of the volatiles in EFP gels varying in oil content (5% w/w WPI). Gelation was induced with the addition of 0.5% w/w GDL. Samples were incubated at 37 °C before each measuring point.

This work presents the application of EFP gels as delivery systems for volatile compounds. The results have demonstrated that EFP gels can slow volatile release from the gels and reduce the air−gel partition coefficients at equilibrium. Because WPI content showed a dominant effect on the rheological properties (both small deformation and large deformation properties) of EFP gels, and oil content gave a bigger effect on volatile release, producing more rigid EFP gels by increasing the WPI content provided a novel means to inhibit volatile release in oil-reduced gels. Therefore, EFP gels could find applications in fat-reduced foods with improved flavor profile. However, flavor perception is influenced not only by the released volatile but also by the food texture, and both of them vary significantly during oral processing. To better apply EFP gels to real food systems, further attempts can be made to understand the effect of gel breakdown on volatile release and volatile−texture interaction on flavor perception, either in vivo or in vitro.

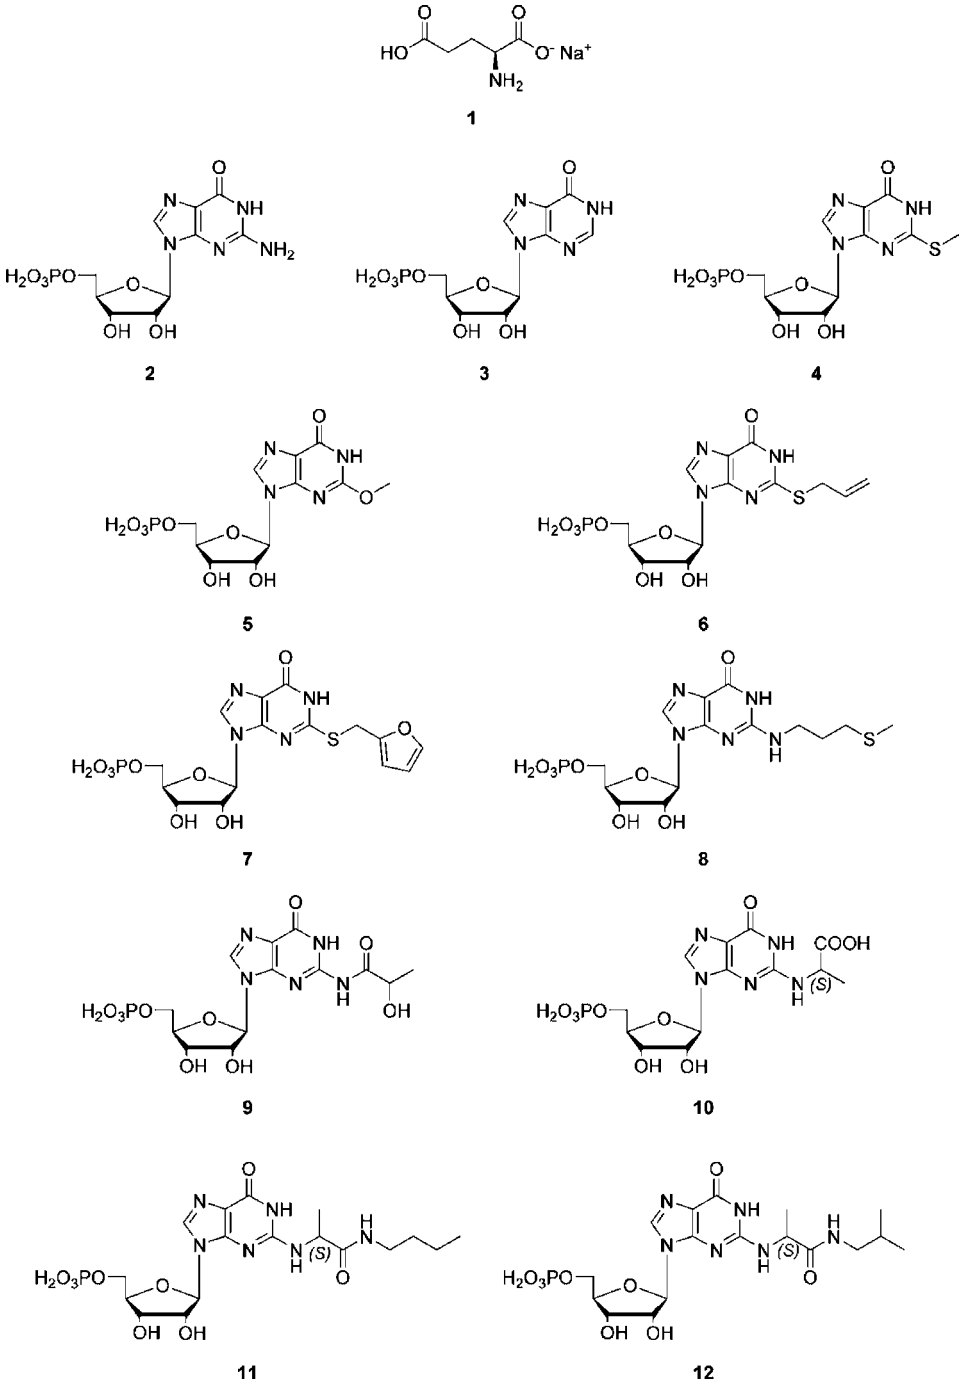

**Figure 1.** Chemical structures of umami-tasting and umami-modulating molecules: monosodium L-glutamate (**1**), guanosine 5′-monophosphate (**2**), inosine 5′-monophosphate (**3**), 2-methylthioinosine 5′-monophosphate (**4**), 2-methoxyinosine 5′-monophosphate (**5**), 2-allylthioinosine 5′-monophosphate (**6**), 2-furfurylthioinosine 5′-monophosphate (**7**), $N^2$-(3-methylthiopropyl)guanosine 5′-monophosphate (**8**), $N^2$-lactoylguanosine 5′-monophosphate (**9**), (*S*)-$N^2$-(1-carboxyethyl)guanosine 5′-monophosphate (**10**), (*S*)-$N^2$-{[1-(*N*-butylamino)carbonyl]ethyl}guanosine 5′-monophosphate (**11**), and (*S*)-$N^2$-{[1-(*N*-isobutylamino)carbonyl]ethyl}guanosine 5′-monophosphate (**12**).

Despite these achievements in the synthesis of umami taste-enhancing nucleotides, the growing aversion of alienated consumers toward nonnatural chemicals added to foods is creating an increasing request for flavor molecules of biological origin or made by "greener" or "kitchen-type" chemistry.[4] This inspired initiatives targeting the discovery of previously unknown, naturally occurring chemosensorica in processed food. Among those sharing a guanosine 5′-monophosphate scaffold, $N^2$-lactoylguanosine 5′-monophosphate, **9** (Figure 1), has been identified in fermented tuna fish, while (*S*)-$N^2$-(1-carboxyethyl)guanosine 5′-phosphate (**10**) was isolated from yeast extracts.[11,12] Accompanied by its corresponding (*R*)-configured isomer, the latter nucleotide has been reported to be generated by Maillard-type reactions of nucleotide **2** with dihydroxyacetone, glyceraldehyde, and hexoses, respectively.[12] Intriguingly, only the (*S*)-configured nucleotide **10** showed a high $\beta$-value of 7.0 while the corresponding (*R*)-isomer showed only marginal sensory activity,[12] again demonstrating that small structural changes impact on the umami taste-enhancing activity of this molecule. To further widen the portfolio of

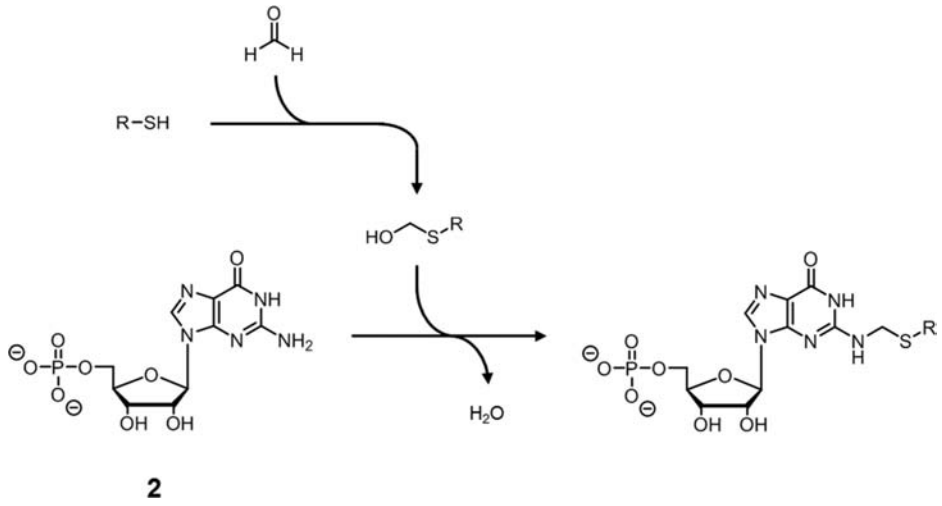

**Figure 2.** $N^2$-Alkyl- and $N^2$-arylthiomethylation of guanosine 5′-monophosphates by Maillard-type reaction of guanosine 5′-monophosphate (**2**), formaldehyde, and organic thiols.

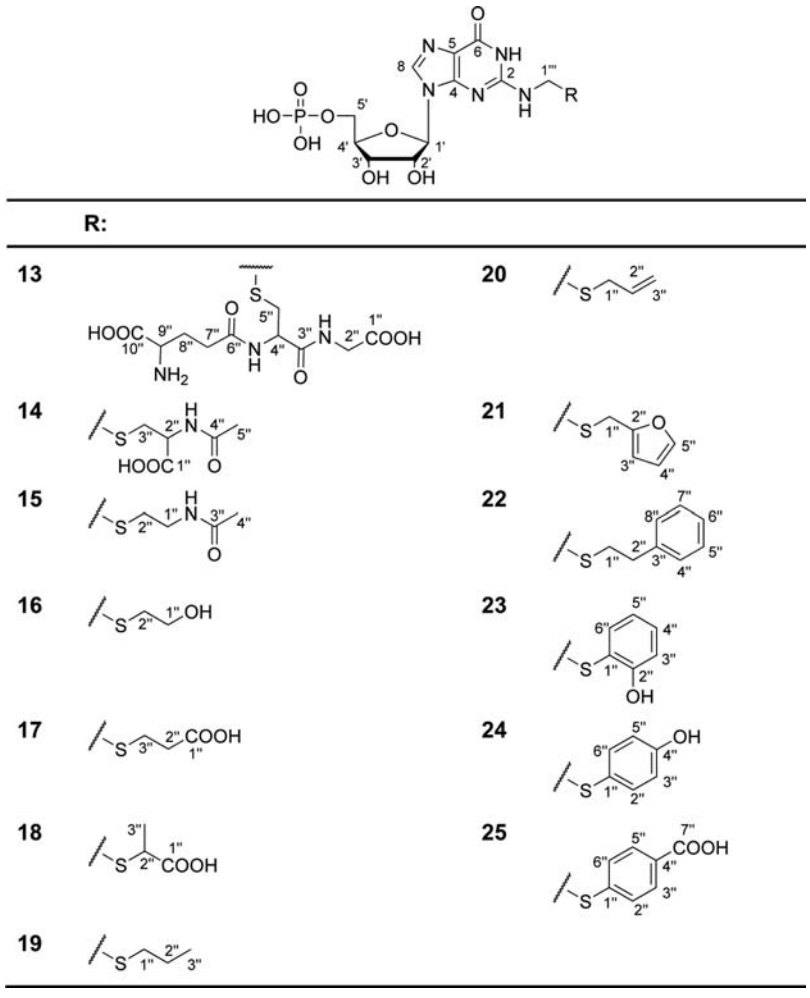

**Figure 3.** Chemical structures of $N^2$-(alkylthiomethyl)guanosine 5′-monophosphates **13**−**20** and $N^2$-(arylthiomethyl)guanosine 5′-monophosphates **21**−**25**.

Maillard-type modified derivatives of nucleotide **2**, the $N^2$-(1-carboxyethyl)guanosine 5′-phosphate scaffold was further altered by amidation of the side chain's carboxy group, thus leading to butylated (**11**) and isobutylated ribonucleotides (**12**) with an increased $\beta$-value of 7.6.[13,14] These results were verified both by human psychophysical as well as cell-based T1R1/T1R3 receptor assays.[14]

Inspired by the reported beneficial effect of a sulfur atom in $N^2$-alkylated ribonucleotides,[9] the objective of the present study was to prepare sulfur-containing guanosine 5′-monophosphates

dx.doi.org/10.1021/jf504686s | J. Agric. Food Chem. 2014, 62, 11429−11440

by means of Maillard-type reactions of nucleotide **2** with glycine's Strecker aldehyde formaldehyde and organic thiols, as depicted in Figure 2, and to evaluate their umami taste-enhancing potential of these chemosensorica in vivo by means of human sensory studies and in vitro by means of T1R1/T1R3 taste receptor experiments.

## MATERIALS AND METHODS

**Chemicals and Materials.** The following chemicals were obtained commercially: dipotassium hydrogen phosphate, formic acid, glycine, mercaptoethanol, monosodium L-glutamate monohydrate, orthophosphoric acid, potassium dihydrogen phosphate, and 1-propanethiol (Merck KGaA, Darmstadt, Germany); formaldehyde, D-glucose, L-glutathione (reduced), and 2-propen-1-thiol (Fluka, Buchs, Switzerland); 2-furanmethanethiol, inosine 5′-monophosphate disodium salt, 2-mercaptophenol, 2-mercaptobenzoic acid, 2-mercaptopropionic acid, 3-mercaptopropionic acid, 4-mercaptophenol, *N*-acetylcysteamine, and *N*-acetyl-L-cysteine (Sigma−Aldrich, Steinheim, Germany); guanosine 5′-monophosphate disodium salt and 2-phenethylthiol (Acros Organics, Geel, Belgium); and HPLC-grade solvents (J. T. Baker, Deventer, Netherlands). Deionized water used for chromatography was purified by means of a Milli-Q gradient A10 system (Millipore, Molsheim, France). Deuterated solvents and 3-trimethylsilyl-2,2,3,3-$d_4$-propionic acid sodium salt were supplied by Euriso-Top (Gif-Sur-Yvette, France). For medium-pressure liquid chromatography, RP-18-bulk material (LiChroprep RP-18, 25−40 μm, Merck KGaA, Darmstadt, Germany) was used. Sensory analyses were performed with Evian bottled water (Danone Waters Deutschland, Frankfurt, Germany).

**Preparation of $N^2$-(Alkylthiomethyl)guanosine and $N^2$-(Arythiomethyl)guanosine 5′-Monophosphate Derivatives.** Following a literature protocol[15] with some modifications, formaldehyde (2 mmol; 50 μL of a 36% solution in water) was added to a solution of potassium phosphate buffer (40 mL, pH 7.0; 30 mmol/L) containing one of the mercaptans (15 mmol/L), namely, L-glutathione, *N*-acetyl-L-cysteine, *N*-acetylcysteamine, 2-mercaptophenol, 2- and 3-mercaptopropionic acid, 1-propanethiol, 2-propen-1-thiol, 2-furanmethanethiol, 2-phenethylthiol, 2- and 4-mercaptophenol, and 2-mercaptobenzoic acid, respectively. After the mixture was stirred for 4 h at 40 °C in a closed vessel, guanosine 5′-monophosphate (0.6 mmol) was added and stirring was continued at 40 °C for another 16 h. Subsequently, the reaction product was isolated by means of reversed-phase medium-pressure liquid chromatography (RP-MPLC) on a Buechi-Sepacore system (Flawil, Switzerland) equipped with a 150 × 40 mm column filled with 25−40 μm LiChroprep RP-18 material (Merck KGaA Darmstadt, Germany). The effluent was monitored at 260 nm, and chromatography was performed at a flow rate of 40 mL/min with 1% aqueous formic acid (solvent A) and methanol (solvent B) as eluents. *S*-[1-($N^2$-guanosinyl)methyl]-glutathione 5′-monophosphate, **13** (Figure 3), $N^2$-(2-acetylaminoethylthiomethyl)guanosine 5′-monophosphate (**15**), and $N^2$-(phenethylthiomethyl)guanosine 5′-monophosphate (**22**) were isolated by eluting with 100% solvent A for 2 min, then increasing solvent B from 0 to 40% within 3 min, and finally increasing to 100% solvent B within an additional 16 min. 100% organic solvent was maintained for an additional 5 min. For isolation of nucleotide derivatives $N^2$-(2-hydroxyethylthiomethyl)guanosine 5′-monophosphate (**16**), $N^2$-(2-carboxyethylthiomethyl)guanosine 5′-monophosphate (**17**), $N^2$-(1-carboxyethylthiomethyl)guanosine 5′-monophosphate (**18**), $N^2$-(furfurylthiomethyl)guanosine 5′-monophosphate (**21**), $N^2$-(2-hydroxyphenylthiomethyl)guanosine 5′-monophosphate (**23**), $N^2$-(4-hydroxyphenylthiomethyl)guanosine 5′-monophosphate (**24**), and $N^2$-(4-carboxyphenylthiomethyl)guanosine 5′-monophosphate (**25**), elution was started isocratically with 100% solvent A for 5 min, and then the content of solvent B was linearly increased to 100% during 35 min and maintained for an additional 5 min. Purification of $N^2$-(propylthiomethyl)guanosine 5′-monophosphate (**19**) and $N^2$-(prop-2-enylthiomethyl)guanosine 5′-monophosphate (**20**) was achieved by isocratic elution with 100% eluent A for 2 min and then increasing the content of eluent B to 45% within 8 min, to 80% in 20 min, and finally to 100% in 1 min. Elution with 100% solvent B was continued for 5 min. $N^2$-[(2-Acetylamino-2-carboxyethyl)thiomethyl]-guanosine 5′-monophosphate (**14**) was isolated by increasing the content of solvent B from 0% to 15% within 10 min, then to 30% within 20 min, and finally within 10 min to 100%, with continued elution with 100% organic solvent for 5 min. Fractions showing UV absorbance at 260 nm were collected individually with an automated fraction collector, freed from organic solvents in vacuum, and lyophilized three times.

**Hydrolytic Stability of Nucleotide 21 in Aqueous Solution.** A solution of $N^2$-(furfurylthiomethyl)guanosine 5′-monophosphate (**21**; 1.0 mg) in potassium phosphate buffer (1 mL, pH 4.0/6.0/8.0) was stored at 22 °C and analyzed by means of RP-HPLC with diode array detection (DAD) after 7 h. To evaluate the stability over a longer period of time, the samples dissolved at pH 6.0 and 8.0 were stored at room temperature and analyzed daily by RP-HPLC-DAD.

**Sensory Analyses.** *Precautions Taken for Sensory Analysis.* Prior to sensory analysis, the isolated compounds were suspended in water and, after removal of volatiles in high vacuum (<5 mPa), were freeze-dried three times and analytically confirmed to be essentially free of solvents and buffer compounds used. Formic acid, which is considered "generally recognized as safe" (GRAS) as a flavoring agent for food and feed applications, was used to adjust the pH value of solutions that should be sensorially analyzed to pH 6.0, because trace amounts of this acid do not influence the sensory profile of the test solution. In order to minimize the ingestion of test compounds, the "sip and spit" method was applied, meaning that the test solutions were expectorated. During sensory analyses, the oral cavity was frequently rinsed with water.

*Training of the Sensory Panel.* Thirteen subjects (8 women and 5 men, aged 22−30 years), who gave informed consent to participate in the sensory tests of the present investigation and have no history of known taste disorders, were trained to evaluate the taste of aqueous solutions of the following standard taste compounds in bottled water (pH 6.0): sucrose (50 mmol/L) for sweet taste, lactic acid (20 mmol/L) for sour taste, NaCl (20 mmol/L) for salty taste, caffeine (1 mmol/L) for bitter taste, and monosodium L-glutamate (3 mmol/L) for umami taste. Additionally, the panel was familiarized to differentiate several umami taste qualities by tasting solutions of monosodium L-glutamate (3 mmol/L), a binary mixture of monosodium L-glutamate (3 mmol/L) and guanosine 5′-monophosphate (0.1 mmol/L), and a disodium succinate solution (5 mmol/L). The assessors had participated earlier at regular intervals for at least 18 months in sensory experiments (triangle tests, isointensity testings, scale training) and were, therefore, familiar with the techniques applied. To prevent any cross-modal interactions with olfactory inputs, the panelists wore nose clips.

*Determination of Taste-Enhancing Activity and Calculation of $\beta$-Values.* To evaluate the taste-enhancing potential of nucleotide derivatives, a paired comparison test was performed as reported earlier.[6,12] Briefly, a solution of the test nucleotide (50 $\mu$mol/L) was compared to solutions containing ascending concentrations (in 30% steps) of inosine 5′-monophosphate (**3**), all compounds being dissolved in an aqueous monosodium L-glutamate matrix (3 mmol/L; pH 6). The solutions were presented to the panel in randomly coded cups in a series of five duo tests. Under forced-choice conditions, panelists were asked to determine the sample possessing the stronger umami taste. Subsequently, the percentage of panelists rating the solution containing the test nucleotide to exhibit a more intense umami taste was calculated, subjected to a Probit transformation, and plotted against the logarithm of the corresponding inosine 5′-monophosphate concentrations. By means of linear regression, the inosine 5′-monophosphate concentration was calculated at which panelists were unable to distinguish between test and reference solution. The $\beta$-value of the test compound was calculated according to $v = \beta v'$, wherein $v$ represents the inosine 5′-monophosphate concentration at the point of umami taste equality (micromoles per liter) and $v'$ is the concentration of the test nucleotide (micromoles per liter).

**Cell-Based hT1R1/rT1r3 Umami Taste Receptor Experiments.** Functional experiments were carried out in the human embryonic kidney cell line PEAK$^{Rapid}$ (American Type Culture Collection, Manassas, VA) stably expressing the umami receptor subunit hTAS1R1 and the G protein subunit mG$\alpha$15. Cells were cultured under regular conditions at 37 °C, 5% $CO_2$, and 95% humidity in Dulbecco's modified Eagle medium (D-MEM) high-glucose GlutaMAX (Invitrogen, Karlsruhe, Germany) supplied with fetal calf serum (FCS; 10%, tetracycline-free), penicillin G (10 000 units/mL), and streptomycin (10 mg/mL) and selected for stable expression of hT1R1 and mG$\alpha$15 with G418 (50 $\mu$g/mL), zeocin (100 $\mu$g/$\mu$L), hygromycin (100 $\mu$g/mL, all Invitrogen), and puromycin (1.0 $\mu$g/mL, Sigma−Aldrich, Schnelldorf, Germany).

For functional experiments, cells were seeded into 96-well plates (Greiner Bio-One, Frickenhausen, Germany) coated with poly-D-lysine (10 $\mu$g/mL) to improve cell adhesion. To enable expression of a functional umami receptor, cells were transfected with rTas1r3 (in pcDNA3, Invitrogen) by use of Lipofectamine2000 (Invitrogen) in serum-free D-MEM low-glucose GlutaMAX (Invitrogen). After transfection, cells were cultured in D-MEM low-glucose GlutaMAX with dialyzed FCS for about 24 h. Prior to the experiment, cells were incubated for 1 h with Fluo4-AM (2 $\mu$mol/L, Molecular Probes) in serum-free D-MEM low-glucose GlutaMAX containing 2.5 mM probenecide to block leakage of the fluorescent dye. Cells were washed with bath solution [130 mmol/L NaCl, 5 mmol/L KCl, 10 mmol/L $N$-(2-hydroxyethyl)piperazine-$N'$-ethanesulfonic acid (HEPES), 2 mmol/L $CaCl_2$, and 10 mmol/L glucose, pH 7.4] three times and incubated at room temperature for ∼40 min to allow complete de-esterification of the fluorescent dye. Test substances were dissolved in bath solution. For coapplication experiments, the individual substances were premixed prior to application. Intracellular calcium levels were recorded during automated application of test solutions on a fluorometric imaging plate reader (FLIPR$^{384}$, Molecular Devices, Munich, Germany). To control for cell number and vitality, isoproterenol was applied subsequent to test compounds. Cells transfected with empty vector stimulated with the same test solution served as control for unspecific responses of the cellular background. Data were collected from two independent experiments carried out in quadruplicate. Raw fluorescence signals of hT1R1/rT1r3-expressing cells were corrected for fluorescence signals of mock-transfected cells (software FLIPR$^{384}$, Molecular Devices, Munich, Germany) and normalized to baseline fluorescence ($\Delta F/F$, SigmaPlot 9.01, Systat Software GmbH, Erkrath, Germany).

Fluorescence signals after coapplication of test compounds with L-glutamic acid were analyzed for statistical significance compared to those induced by sole application of L-glutamic acid in the presence and absence of the allosteric enhancer inosine 5′-monophosphate by one-way analysis of variance followed by a Tukey's posthoc means comparison test with 5% $\alpha$-risk level (GraphPad Prism 4.03, GraphPad Software, Inc., La Jolla, CA).

**Generation of $N^2$-(Propylthiomethyl)guanosine 5′-Monophosphate (19) by Maillard Reaction from Guanosine 5′-Monophosphate (2), Glucose, Glycine, and 1-Propylthiol.** Ternary solutions of glucose (0.1, 1.0, 10, 100, 200, 500, or 1000 mmol/L), glycine (1 mol/L), and 1-propanethiol (5, 10, 20, or 50 mmol/L) in potassium phosphate buffer (2 mL, 2 mol/L, pH 7) were heated at 40 °C for 4 h. Then a solution (400 $\mu$L) of a guanosine 5′-monophosphate (25 mmol/L) in potassium phosphate buffer (2 mol/L, pH 7) was added, and incubation was continued for additional 16 h at 40 °C. The reaction solutions were made up to 10 mL with 1% aqueous formic acid and directly used for HPLC-MS/MS analysis of $N^2$-(propylthiomethyl)guanosine 5′-monophosphate (**19**). Quantitation was performed by six-point external calibration using an analyte-free matrix solution of glucose and glycine treated like the ternary reaction systems described above but in the absence of **2**. Solutions containing defined amounts of **19** in concentrations ranging from 0.005 to 0.170 $\mu$mol/L were prepared. The calibration curve, obtained

by linear regression analysis of the peak area versus concentration, showed a linear response with a correlation coefficient of $R^2 > 0.99$.

**Medium-Pressure Liquid Chromatography.** Medium-pressure liquid chromatography (MPLC) was performed on a Sepacore chromatography system (Buechi, Flawil, Switzerland) consisting of two C-605 pumps with C-615 pump manager, manual rheodyne injection port (20 mL loop), C-635 UV/vis detector, and C-660 fraction collector. Chromatography was performed at a flow rate of 40 mL/min on a self-packed 150 × 40 mm i.d. polypropylene cartridge filled with 25−40 μm LiChroprep RP-18 Material (Merck KGaA, Darmstadt, Germany).

**High-Performance Liquid Chromatography.** Analytical HPLC was carried out on an HPLC apparatus (Jasco, Groß-Umstadt, Germany), consisting of two PU-2087 Plus pumps, M800 gradient mixer, DG-2080−53 degasser, auto sampler (AS-2055 Plus) and diode array detector (MD-2010 Plus). Chrompass software was used for data acquisition. With a flow rate of 0.8 mL/min, chromatography was performed on a 250 × 4.6 mm i.d., 5 μm, Microsorb-MW 100−5 C18 column (Varian, Darmstadt, Germany). The output was monitored at 220 and 260 nm; 1% aqueous formic acid (solvent A) and methanol (solvent B) were used as eluents. After sample injection (10 μL), isocratic elution with 100% solvent A was performed for 5 min. Subsequently, the content of organic solvent was linearly increased to 100% within 25 min, and 100% solvent B was maintained for an additional 5 min.

**High-Performance Liquid Chromatography/Tandem Mass Spectroscopy.** For HPLC-ESI-MS/MS analysis, a Dionex UHPLC UltiMate 3000 HPLC system (Dionex, Idstein), consisting of HPG-3400SD type binary pump, SRD-3400 type degasser, WSP-3000TSL type autosampler, and TCC-3000SD type column compartment and operated with the DC MS Link 2.8.0.2633 software, was linked to an API 4000 QTRAP mass spectrometer (AB Sciex Instruments, Darmstadt, Germany), which was equipped with an electrospray ionization (ESI) source and operated in negative ionization mode. Nitrogen served as nebulizer gas (50 psi), and heated at 400 °C as turbo gas for solvent drying (60 psi). Nitrogen also served as curtain (20 psi) and collision gas ($4.5 \times 10^{-5}$ Torr). For the detection of **19**, the following transition reactions were optimized prior to analyses and monitored for a duration of 100 ms each. Declustering potential (DP), collision energy (CE), and collision cell exit potential (CXP) are given in parentheses: $m/z$ 450 → 374 (DP −65 V, CE −24 V, CXP −11 V), $m/z$ 450 → 161 (DP −65 V, CE −50 V, CXP −11 V), and $m/z$ 450 → 374 (DP −65 V, CE −36 V, CXP −1 V). Both quadrupoles were set at unit resolution.

For HPLC-ESI-MS/MS analysis, data acquisition and integration were carried out with Analyst 1.5.1 software (Applied Biosystems). After sample injection (5 μL), chromatographic separation was performed on a 150 × 2.0 mm i.d., 3 μm, Phenomenex Luna PFP column (Phenomenex, Aschaffenburg, Germany) by use of a linear binary gradient with a flow rate of 200 μL/min. Eluent A was 1% formic acid in acetonitrile, and eluent B was 1% formic acid in water. Chromatographic separation was performed as follows: After isocratic elution with 100% solvent B for 5 min, the content of solvent A increased to 50% within 10 min and then to 100% within 2 min. The organic solvent was finally maintained at 100% for an additional 5 min. With help of a Valco valve, the effluent was directed into the mass spectrometer during minutes 12 and 22 of each chromatographic run, while the remaining effluent was split into the waste. To determine the effect of matrix components on the LC-MS/MS analysis, 5 μL of analyte-free matrix solutions were injected into the LC-MS/MS system described above, but in addition, a constant flow (10 μL/min) of a solution of **19** (0.19 μmol/L) was introduced by means of a PHD 4400 Hpsi type syringe pump (Harvard Apparatus, Holliston, MA) connected to the solvent flow via a three-way valve.

**Ultraperformance Liquid Chromatography/Time-of-Flight Mass Spectrometry.** Mass spectra of the compounds were measured on a Waters Synapt G2 HDMS mass spectrometer (Waters, Manchester, U.K.) coupled to an Acquity UPLC core system (Waters) consisting of a binary solvent manager, sample manager and column oven. The compounds were dissolved in 1 mL of methanol ,and aliquots (1−5 μL) were injected into the UPLC-TOF-MS system equipped with a 150 × 2 mm, 1.7 μm, BEH C18 column (Waters). Operated with a flow rate of 0.3 mL/min at a temperature of 40 °C, the following gradient was used for chromatography: starting with a mixture (5/95 v/v) of acetonitrile and aqueous formic acid (0.1%, pH 2.5), the acetonitrile content was increased to 95% within 3 min and held at 95% for 1 min. Calibration of the Synapt G2 was performed with a solution of sodium formate (0.5 mmol/L) in 2-propanol/water (9/1 v/v). Data were processed by use of MassLynx 4.1 (Waters) and the tool elemental composition. All data were lock mass (leucine enkephalin) corrected ($[M + H]^+$, $m/z$ 556.2771, $[M - H]^-$, $m/z$ 554.2615). Measurements were performed with negative ESI and the resolution mode consisting of the following parameters: capillary voltage (+2.5 or −3.0 kV), sampling cone (30 V), extraction cone (4.0 V), source temperature (150 °C), desolvation temperature (450 °C), cone gas (30 L/h), and desolvation gas (850 L/h).

**Nuclear Magnetic Resonance Spectroscopy.** The $^1$H, $^{13}$C, and two-dimensional (2D) NMR spectroscopic experiments were performed on a 500 MHz Avance III NMR spectrometer from Bruker (Rheinstetten, Germany), equipped with a TCI cryoprobe and operating at 500 and 125 MHz for $^1$H and $^{13}$C, respectively. Unless stated otherwise, all experiments were performed at 300 K. Samples were dissolved in $D_2O$ with 3-(trimethylsilyl)propionic-2,2,3,3-$d_4$ acid sodium salt (TMSP) used as reference. In methanol-$d_4$, tetramethylsilane (TMS) served as reference. For accurate NMR signal assignment, correlation (COSY), heteronuclear single quantum coherence (HSQC), and heteronuclear multiple-bond correlation (HMBC) spectroscopic experiments were carried out by use of pulse sequences from the Bruker software library. While data processing was performed with Topspin version 1.3 (Bruker, Rheinstetten, Germany), the individual data interpretation was done with MestReNova 5.1.0−2940 (Mestrelab Research S.L., Santiago de Compostela, Spain).

## RESULTS AND DISCUSSION

Recent investigations revealed that $N^2$-1-carboxyalkylation of guanosine 5′-monophosphate by Maillard-type reactions with reducing carbohydrates increased the umami-enhancing potential of the nucleotide; for example, (*S*)-$N^2$-(1-carboxyethyl)guanosine 5′-phosphate (**10**) was isolated as a high-potency umami enhancer from yeast extracts.[12,13] Furthermore, amidation of the side chain's carboxy group induced a further increase of sensory activity of **10**; for example, butylation revealed the high-potency umami enhancer **11**.[14] Since the presence of sulfur atoms in synthetic $N^2$-alkylated nucleotides was described to be beneficial for sensory activity,[6−10] the following experiments targeted the substitution of the exocyclic amino function of guanosine 5′-monophosphate (**2**) with formaldehyde, the Strecker aldehyde of glycine, and alkyl- and arylmercaptans, respectively, by means of Maillard-type reaction chemistry following the scheme depicted in Figure 2.

**Preparation of $N^2$-(Alkylthiomethyl)guanosine and $N^2$-(Arylthiomethyl)guanosine 5′-Monophosphates 13−25.** In a first set of experiments, the umami-enhancing guanosine 5′-monophosphate (**2**) was reacted for 16 h at 40 °C with a binary mixture of formaldehyde and the kokumi-active glutathione, which was preincubated for 4 h at the same temperature. Reaction product **13** was isolated by means of RP-MPLC in a purity of >98% [$^1$H NMR, HPLC with evaporative light-scattering detector (ELSD)] and its structure was determined by means of UPLC-TOF-MS and 1D/2D-NMR experiments. UPLC-TOF-MS revealed $m/z$ 681.1357 as a pseudo-molecular ion ($[M - H]^-$), which is in accordance with the calculated mass of 681.1340 ($C_{21}H_{30}N_8O_{14}PS$). COSY, HSQC, and HMBC spectra allowed us to assign the proton signals at 2.05, 2.43, and 3.80 ppm to H−C(8″), H−C(7″), and

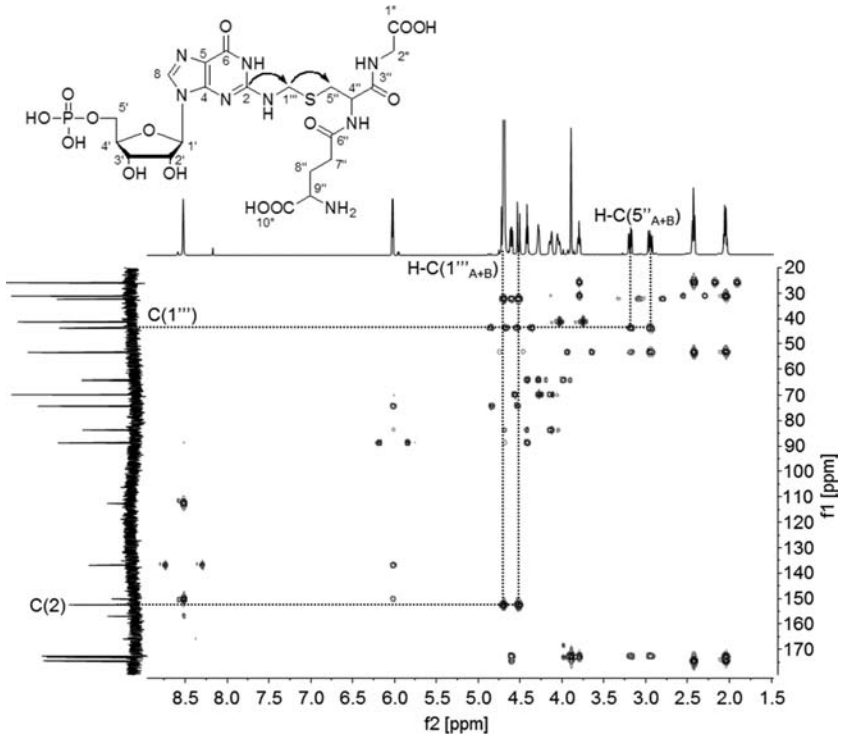

**Figure 4.** Excerpt of HMBC spectrum (500 MHz, $D_2O$) of *S*-[1-($N^2$-guanosinyl)methyl]glutathione 5′-monophosphate (**13**) generated from guanosine 5′-monophosphate (**2**), formaldehyde, and glutathione.

H−C(9″) of the glutamyl residue. $^1J_{C,H}$ couplings observed in the HSQC spectrum identified carbon signals resonating at 25.8, 30.8, and 53.2 parts per million (ppm) to correspond to the carbon atoms C(8″), C(7″), and C(9″), respectively. The two quaternary carbon atoms C(10″) and C(6″) resonated at 172.6 and 174.8 ppm and showed the expected $^{2,3}J_{C,H}$-couplings in the HMBC spectrum. The cysteine moiety showed proton signals at 2.95 [H−C(5″$_A$)], 3.07 [H−C(5″$_B$)], and 4.62 ppm [H−C(4″))] and the corresponding carbon resonances at 32.3 [C(5″)] and 53.1 ppm [C(4″)]. The signal at 172.8 ppm was assigned to the carbon atom C(3″), showing heteronuclear $^{2,3}J$-coupling with the protons H−C(2″), H−C(4″), and H−C(5″). The singlet at 3.89 ppm in the $^1$H NMR spectrum and at 41.2 ppm in the $^{13}$C NMR spectrum were attributed to methylene group of the glycine moiety. In addition, the HMBC experiment led to the identification of the carbon signal at 173.0 ppm as the glycine carboxy carbon C(1″). Moreover, the singlet at 8.52 ppm in the $^1$H NMR spectrum and the signal at 137.0 ppm in the $^{13}$C NMR spectrum were assigned to position C(8) of the purine scaffold. Due to heteronuclear $^3J$- and $^4J$-coupling detectable in the HMBC, the signals resonating at 112.4, 150.2, and 156.4 ppm were assigned as the quaternary carbon atoms C(5), C(4), and C(6) of the nucleotide moiety. The proton signals at 4.05, 4.13, 4.30, 4.41, 4.70, and 6.02 ppm in the $^1$H NMR spectrum and at 64.0, 83.8, 69.8, 74.3, and 88.6 ppm in the $^{13}$C NMR spectrum were attributed to the positions 5′$_{A+B}$, 4′, 3′, 2′, and 1′ of the nucleotide's ribose moiety. The presence of the phosphate group in the molecule was confirmed by coupling of the $^{31}$P nucleus with the carbon atoms C(5′) and C(4′); for example, coupling constants of 4.3 and 8.7 Hz were observed for $^2J$- and $^3J$-coupling of the phosphate group with C(5′) and C(4′), respectively. Two doublets recorded in the $^1$H NMR spectrum at 4.51 and 4.71 ppm were assigned as protons of the methylene group C(1‴), and with help of the HSQC spectrum, the carbon atom resonating at 43.5 ppm was assigned to this methylene group. This carbon atom showed heteronuclear $^3J$-coupling with diastereotopic methylene protons H−C(5″$_{A+B}$) of the cysteine residue. Connection to the nucleotide scaffold was verified by heteronuclear $^3J$-coupling of the quaternary carbon atom C(2) at 152.7 ppm to two proton signals of the methylene group H−C(1‴) (Figure 4). With all these spectroscopic data taken into consideration, the reaction product **13** was unequivocally identified as *S*-[1-($N^2$-guanosinyl)methyl]glutathione 5′-monophosphate (Figure 3).

By a straightforward synthetic approach, a series of $N^2$-(alkylthiomethyl)guanosine and $N^2$-(arylthiomethyl)guanosine 5′-monophosphates, **14**−**25**, was successfully generated by reacting guanosine 5′-monophosphate (**2**) with formaldehyde and *N*-acetyl-L-cysteine, *N*-acetylcysteamine, 2-mercaptophenol, 2- and 3-mercaptopropionic acid, 1-propanethiol, 2-propen-1-thiol, 2-furanmethanethiol, 2-phenethylthiol, 2- and 4-mercaptophenol, and 2-mercaptobenzoic acid, respectively (Figure 3).

To investigate the hydrolytic stability of such $N^2$-(alkylthiomethyl)guanosine 5′-monophosphates in aqueous solution, solutions of **21** in phosphate buffer were kept at pH 4.0, 6.0, and 8.0 at room temperature and repeatedly analyzed by RP-HPLC-DAD. While the target nucleotide remained rather stable at pH 4.0 and 6.0, storage under alkaline conditions induced rapid degradation with a half-life time of 8 days (data not shown).

**Sensory Evaluation of $N^2$-(Alkylthiomethyl)guanosine and $N^2$-(Arylthiomethyl)guanosine 5′-Monophosphates.** In order to study the umami taste-enhancing properties of ribonucleotides **13**−**25**, the highly purified substances were presented to a panel of trained assessors in a series of forced-choice comparison tests described earlier (Table 1).[6,13] To evaluate the umami taste synergism between L-glutamic acid

**Table 1. Umami-Enhancing Activity ($\beta$-Value) of Reference Nucleotides (2 and 3) and $N^2$-(Methylene-*S*-alkyl/aryl)guanosine 5′-Monophosphate Derivatives (13−25)**

| nucleotide derivative[a] | $\beta$-value |
|---|---|
| inosine 5′-monophosphate, disodium salt (**3**) | 1.0 |
| guanosine 5′-monophosphate, disodium salt (**2**) | 2.4 |
| *S*-[1-($N^2$-guanosinyl)methyl]glutathione 5′-monophosphate (**13**) | 1.1 |
| $N^2$-[(2-acetylamino-2-carboxyethyl)thiomethyl]guanosine 5′-monophosphate (**14**) | 2.3 |
| $N^2$-(2-acetylaminoethylthiomethyl)guanosine 5′-monophosphate (**15**) | 2.8 |
| $N^2$-(2-hydroxyethylthiomethyl)guanosine 5′-monophosphate (**16**) | 2.8 |
| $N^2$-(2-carboxyethylthiomethyl)guanosine 5′-monophosphate (**17**) | 2.5 |
| $N^2$-(1-carboxyethylthiomethyl)guanosine 5′-monophosphate (**18**) | 3.1 |
| $N^2$-(propylthiomethyl)guanosine 5′-monophosphate (**19**) | 5.1 |
| $N^2$-(prop-2-enylthiomethyl)guanosine 5′-monophosphate (**20**) | 4.1 |
| $N^2$-(furfurylthiomethyl)guanosine 5′-monophosphate (**21**) | 3.1 |
| $N^2$-(phenethylthiomethyl)guanosine 5′-monophosphate (**22**) | 2.7 |
| $N^2$-(2-hydroxyphenylthiomethyl)guanosine 5′-monophosphate (**23**) | 2.1 |
| $N^2$-(4-hydroxyphenylthiomethyl)guanosine 5′-monophosphate (**24**) | 3.0 |
| $N^2$-(4-carboxyphenylthiomethyl)guanosine 5′-monophosphate (**25**) | 3.6 |

[a]Chemical structures and numbering of the compounds refer to Figures 1 and 4.

and ribonucleotides, each target ribonucleotide (50 $\mu$mol/L) was dissolved in a matrix of monosodium glutamate (3 mmol/L; pH 6). In five duo tests, panelists had to evaluate this solution for umami taste intensity in comparison with reference solutions containing increasing concentrations (in 30% steps) of inosine 5′-monophosphate (**3**) dissolved in the monosodium glutamate matrix. The percent of panelists judging the test solution to exhibit more intense umami taste was calculated and, after Probit transformation, related to the logarithm of the corresponding inosine 5′-monophosphate reference solutions. By means of linear regression, the concentration of inosine 5′-monophosphate was calculated at which panelists were unable to distinguish between test and reference solutions. Subsequently, the $\beta$-value was calculated as the ratio of the inosine 5′-monophosphate concentration perceived as isointense to test solution and the concentration of the target ribonucleotide applied in this sensory test. Reference nucleotide **2** was evaluated with a $\beta$-value of 2.4, thus being well in line with literature data.[6,13]

Sensory analysis of the 5′-GMP/glutathione conjugate **13** revealed umami enhancement with a $\beta$-value of 1.1, which is close to that of the reference inosine 5′-monophosphate, **3** (Table 1). To evaluate the influence of mercaptan structure on the taste-enhancing properties of the nucleotide conjugate, the tripeptide glutathione was substituted by *N*-acetylcysteine to give nucleotide **14**. Sensory evaluation revealed a $\beta$-value of 2.3, thus demonstrating that ribonucleotide **14** possessed taste-modifying properties equivalent to its mother nucleotide **3**. Removal of the carboxy group from the *N*-acetylcysteine moiety showed an additional increase of the umami-enhancing potential ($\beta$-value 2.8) of the *N*-acetylcysteamine conjugate **15**, while substituting the acetylated amino by an hydroxyl group to give **16** did not alter the sensory properties of the target nucleotide. Removal of the *N*-acetylamino group from *N*-acetylcysteine revealed a slightly lower $\beta$-value of 2.5 for the corresponding 3-mercaptopropionic acid conjugate **17**. Shifting the carboxyl group from the $\alpha$- into the $\beta$-position induced an increase in sensory activity from a $\beta$-value of 2.5 (**17**) to 3.1 (**18**). Complete absence of all functional groups in the mercaptan structure revealed the 5′-GMP/propanethiol conjugate **19** with a remarkably higher taste-enhancing potential ($\beta$-value 5.1) than the molecules evaluated before. Substitution of the propyl residue in **19** by an allyl residue (**20**) slightly decreased the $\beta$-value of the nucleotide to 4.1. These data confirm earlier observations,[13,14] that the incorporation of small and nonpolar *N*-substituents in **2** evoke more pronounced umami-enhancement activity than large and hydrophilic substituents.

A second set of experiments focused on the activity of $N^2$-(arylthiomethyl)guanosine 5′-monophosphates, exhibiting an

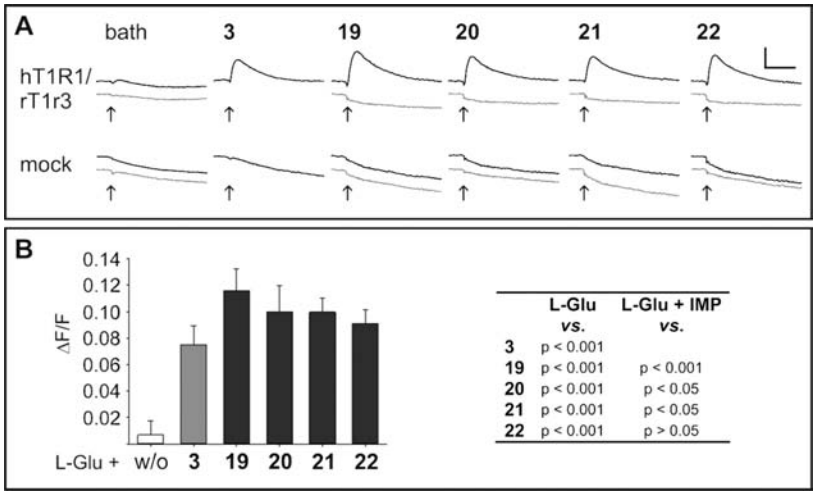

**Figure 5.** Umami-enhancing activity of selected $N^2$-(alkylthiomethyl)guanosine 5′-monophosphates (**19**, **20**) and $N^2$-(arylthiomethyl)guanosine 5′-monophosphates (**21**, **22**) assessed in umami receptor assay. (A) Calcium fluorescence traces from PEAK Rapid/G$\alpha$15 cells expressing the umami receptor heteromer hT1R1/rT1r3 (upper row) and control cells (lower row) to application (↑) of **19** (0.05 mmol/L), **20** (0.05 mol/L), **21** (0.05 mmol/L), **22** (0.05 mol/L), and 5′-IMP (**3**; 0.5 mmol/L), in the absence (gray) and presence (black) of L-glutamate (0.5 mM). Control cells were transfected with empty vector. Scale: *y*-axis, 1050 counts; *x*-axis, 2 min. (B) Fluorescence ratios of cells expressing hT1R1/rT1r3 to L-glutamate (0.5 mM) in the absence (white bar) and presence of 5′-IMP (**3**; 0.5 mM; light gray bar) and nucleotides **19**−**22** (each 0.05 mmol/L; dark gray bars) ($N$ = 2).

aromatic ring in the mercaptan moiety. Conjugates of guanosine 5′-monophosphate with the key food odorants 2-furfurylthiol and 2-phenethylthiol,[16] respectively, showed only slightly increased umami-enhancement activity with $\beta$-values of 3.1 (**21**) and 2.7 (**22**) when compared to the reference nucleotide **2** (Table 1). While $N^2$-(2-hydroxyphenylthiomethyl)guanosine 5′-monophosphate (**23**) showed an even lower $\beta$-value of 2.1, shifting the hydroxy group at the phenyl ring from the ortho into the para position resulted in ribonucleotide **24**, evaluated with an increased $\beta$-value of 3.0. However, replacement of the hydroxyl group in **24** by a carboxy function induced a further increase in the taste-enhancing potential of the target nucleotide **25** to reach a $\beta$-value of 3.6. Intriguingly, substitution of the exocyclic amino group of **3** with $N^2$-(arylthiomethyl) groups followed a different structure–activity relationship than substitution with $N^2$-(alkylthiomethyl) groups. The sensory activity of $N^2$-(arylthiomethyl) derivatives seems to depend on the substitution pattern of the aromatic moiety rather than on the size of the substituent.

**Enhancing Effect of Nucleotides on Functionally Expressed hT1R1/rT1r3 Umami Receptor.** Although the candidate umami taste receptors in humans were identified almost a decade ago,[4] only a few studies have combined human psychophysical experiments with functional expression of T1 receptors so far.[14,17] As the human sensory data obtained for $N^2$-(alkylthiomethyl)guanosine and $N^2$-(arylthiomethyl)-guanosine 5′-monophosphates implied high chemoselectivity of the umami receptor binding site, the enhancing effect of the most efficient compounds **19**–**22** on the L-glutamate-induced response of functionally expressed T1R1/T1r3 umami receptor was investigated (Figure 5).

In human embryonic kidney PEAK$^{Rapid}$ cells that stably express the G protein subunit mG$\alpha$15, activation of the heteromeric umami receptor combination of hT1R1 and rT1r3 is coupled to release of calcium from the endoplasmatic reticulum that can be detected by fluorescent dyes. Since L-glutamate and nucleotide enhancer are known to interact with the T1R1 subunit of the umami receptor heteromer, the functional expression system is likely to resemble the detection of umami compounds in human taste receptor cells.[5,14,18] With regard to its sensitivity to L-glutamate, the pharmacological characteristics of our umami functional expression system were well in accordance with previously published in vitro data.[5]

Calcium traces of T1R1/T1r3-expressing cells and mock-transfected cells (control) upon bath application of $N^2$-(alkylthiomethyl)guanosine 5′-monophosphates (**19** and **20**; 0.05 mmol/L each), $N^2$-(arylthiomethyl)guanosine 5′-monophosphates (**21** and **22**; 0.05 mmol/L each), and reference nucleotide **3** (0.5 mmol/L each) in the presence or absence of L-glutamic acid (0.5 mmol/L) are depicted in Figure 5A. In the absence of L-glutamate, none of the compounds elicited calcium fluorescence responses from T1R1/R3-expressing cells nor from mock-transfected cells (Figure 5A, gray traces). These data propose that the $N^2$-(alkylthiomethyl)guanosine and $N^2$-(arylthiomethyl)guanosine 5′-monophosphates do not exhibit intrinsic umami taste activity. However, the receptor-dependent fluorescence signal to L-glutamate (0.5 mmol/L) was strongly enhanced by 0.05 mM **19**, **20**, **21**, and **22** (Figure 5A, black traces).

Each of the tested ribonucleotides **19**–**22** increased receptor responses in a more pronounced manner than 5′-IMP did (**3**), thus confirming the human sensory data shown above. The average normalized fluorescence ratios of T1R1/R3-expressing cells upon coapplication of L-glutamate (0.5 mM) and the target compounds **19**, **20**, and **21** (0.05 mM), respectively, significantly exceeded those induced by L-glutamate (0.5 mM) and 5′-IMP (**3**), even though **3** was employed at a 10-fold higher concentration (Figure 5B).

Interestingly, the rank order of the compound's in vitro efficacy in modulating the T1R1/R3 receptor (**19** > **20** = **21** > **22**) resembles that of the human sensory data, although the differences were less pronounced at the cellular level. For example, **19** ($\beta$-value 5.1) showed almost twice the activity of **22** ($\beta$ value 2.7) in the human sensory experiment, but the fluorescence ratio of 0.116 ± 0.017 measured for **19** elicited an only 27% higher signal than **22** (0.091 ± 0.010). These differences between human sensory and taste receptor data may be explained either by response differences of the cells expressing the hT1R1-rT1r3 receptor construct when compared to human umami taste receptor cells or by assuming that the umami-enhancing activity of the modified nucleotides is only partially mediated by the T1R1/R3 umami receptor.

**Maillard-type Generation of $N^2$-(Propylthiomethyl)-guanosine 5′-monophosphate (19).** Apart from the formation of volatile odorants,[16] the generation of taste modulators by the Maillard reaction gained increasing attention during recent decades.[12−14,19−25] As the Strecker aldehyde formaldehyde is released from the amino acid glycine upon thermal processing in the presence of reducing carbohydrates, the following experiments were done to investigate the generation of target nucleotide **19** by food-related Maillard-type reactions involving glycine, glucose, and 1-propanethiol, known as a key odorant released from freshly cut onions.[26] After thermal reaction in phosphate buffer (pH 7.0), the reaction mixture was analyzed by means of HPLC-MS/MS (ESI$^-$) analysis in the multiple reaction monitoring (MRM) mode. As depicted in Figure 6, the target molecule **19**, eluted after 14.1 min, was detected at the same retention time in the Maillard reaction system and was further verified by means of cochromatography. External quantitation of **19** by means of HPLC-MS/MS in reaction systems varying the molar carbohydrate/amino acid ratio between 1 and 1000 revealed that the generation of **19** went through a maximum of 6.5 $\mu$g/

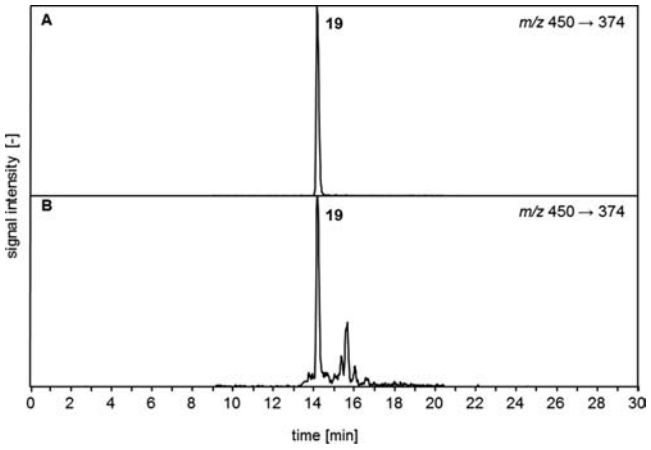

**Figure 6.** HPLC-MS/MS (ESI$^-$) analysis of (A) purified sample of $N^2$-(propylthiomethyl)guanosine 5′-monophosphate (**19**) and (B) nucleotide **19** in a Maillard-type reaction mixture of guanosine 5′-monophosphate (**2**), glucose, glycine, and 1-propanethiol. Signal intensity of the mass chromatograms is normalized.

100 mL at a glucose/glycine ratio of 10 (Figure 7). Furthermore, varying the amount of 1-propanethiol between

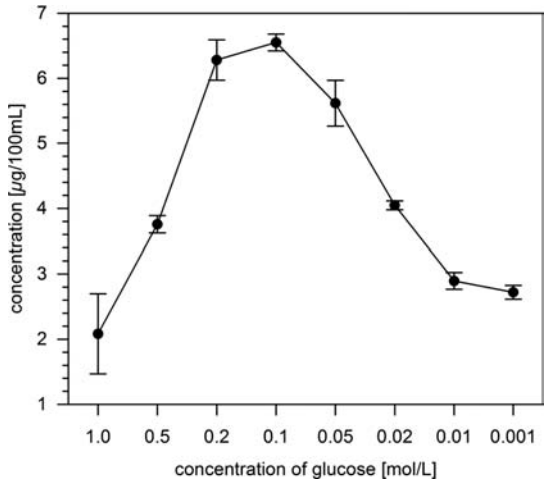

**Figure 7.** Influence of glucose (0.001−1.0 mmol/L) on the formation of $N^2$-(propylthiomethyl)guanosine 5′-monophosphate (**19**) from **2** (25 mmol/L), glycine (1 mol/L), and 1-propanethiol (5 mmol/L) in potassium phosphate buffer (2 mol/L, pH 7).

5 and 50 mmol/L at a glucose/glycine ratio of 10 revealed almost the same concentration of **19** varying between 5.8 and 7.1 µg/100 mL (data not shown), thus demonstrating the presence of formaldehyde rather than the thiol to be a limiting factor in the generation of **19**.

In summary, structurally versatile $N^2$-(alkylthiomethyl)-guanosine and $N^2$-(arylthiomethyl)guanosine 5′-monophosphates were preparatively generated and evaluated in their activity to enhance the umami taste of monosodium L-glutamate in vivo (human sensory experiments) and in vitro (T1R1/T1r3 taste receptor assay). The most active umami enhancer, $N^2$-(propylthiomethyl)guanosine 5′-monophosphate (**19**), showing a $\beta$-value of 5.1, was generated by Maillard-type reactions from guanosine 5′-monophosphate (**2**), glucose, glycine, and 1-propanethiol. Future studies are needed to fully exploit the potential of the exocyclic amino group of guanosine 5′-monophosphate as an effective anchor group to chemically fix small and hydrophobic food-derived molecules. This strategy opens a valuable avenue to produce high-potential chemosensorica from food-derived natural products by kitchen-type chemistry.

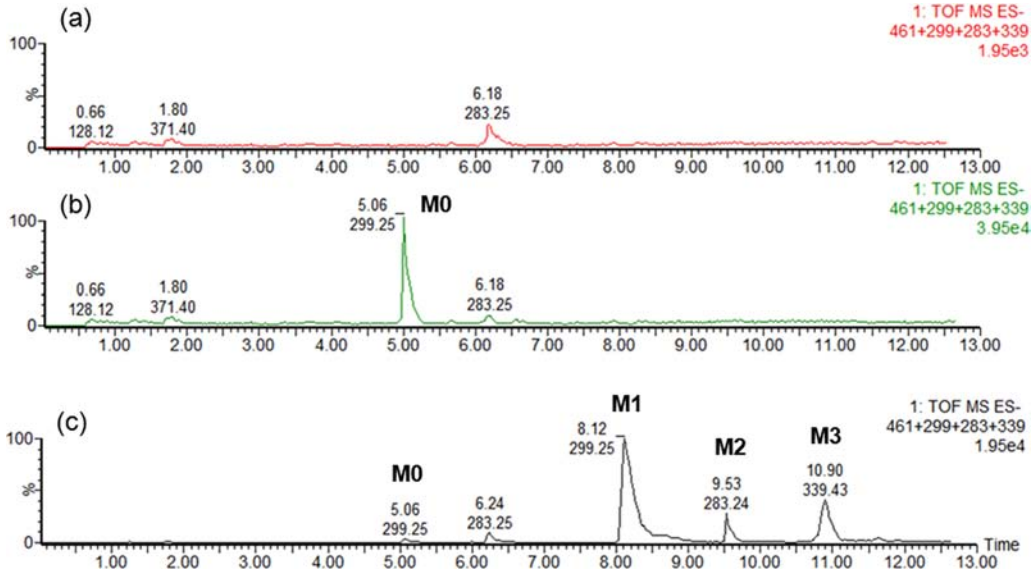

**Figure 1.** UPLC-MS chromatograms of diosmetin-7-*O*-glucoside and its metabolites: (a) blank sample (containing GAM only); (b) GAM with standard solution of diosmetin-7-*O*-glucoside sample; (c) *Escherichia* sp. 4 sample.

## MATERIALS AND METHODS

**Chemicals and Media.** The HPLC grade acetonitrile was purchased from TEDIA Co. Inc. (Fairfield, OH, USA). The distilled water was purified by an EPED super purification system (Nanjing, China). The formic acid was obtained from Merck KGaA (Darmstadt, Germany). Other reagents were all of analytical grade. AnaeroPack rectangular jars were purchased from Mitsubishi Gas Chemical Co. Inc. (Japan). Diosmetin-7-*O*-glucoside, diosmetin, and acacetin standard substances (purity > 98%) were purchased from Chengdu Preferred Biotechnology Co., Ltd. (Chengdu, China).

The general anaerobic medium (GAM) used in the fermentation experiment contained the following compounds per liter: 5.0 g of yeast extract, 3.0 g of glucose, 2.2 g of beef extract, 2.5 g of $KH_2PO_4$, 0.3 g of sodium thioglycolate, 13.5 g fo digestive serum powder, 10.0 g of proteose peptone, 3.0 g of soy peptone, 10.0 g of tryptone, 5.0 g of soluble starch, 1.2 g of beef liver extract powder, 3.0 g of NaCl, 0.3 g of L-cysteine hydrochloride, and about 1000 mL of distilled water. After the above were well mixed, the pH was adjusted to approximately 7.3 with NaOH aqueous solution. Then, the GAM was autoclaved at 121 °C for 20 min.

**Collection and Incubation of Fecal Samples.** Fresh human feces (4.0 g) were weighed and suspended in a centrifuge tube covered with 20 mL of sterile physiological saline and then homogenized adequately by a vortex-mixer. The mixture was centrifuged at 2000*g* for 10 min, and the suspension was used as the bacterial mixture.

The bacterial mixture was diluted serially in sterile water, and each of the dilutions was spread on the GAM agar plates, which were incubated under anaerobic condition in anaerobic jars for 48 h at 37 °C. Each bacterium picked up from the GAM agar plate was inoculated into 1.0 mL of GAM broth and anaerobically incubated at 37 °C for 24 h.

**16S rRNA Gene Sequencing and Phylogenetic Analysis.** The bacterial genomic DNA was extracted from the isolates using a Karroten Genomic DNA Purification Kit (Beijing, China). Their 16S rRNA sequences were amplified with two universal primers. The Gram-negative bacteria were 16S-2F (CATGCAAGTCGARCG) and 16S-2R (GGTGTGACGGGCGGT), whereas the Gram-positive bacteria were 16S-1F (AGAGTTTGATCCTGGCTCAG) and 16S-1R (AGAAAGGAGGTGATCC). The polymerase chain reaction (PCR) program used for amplification was as follows: 94 °C for 1 min, followed by 29 cycles consisting of 94 °C for 30 s, 55 °C for 30 s, and 72 °C for 2 min, and a single final extension step consisting of 72 °C for 10 min. The PCR products were purified from the agarose gel using a Karroten gel purification kit. Sequencing of the 16S rRNA fragments was performed by Majorbio (Shanghai, China). The homology search of the 16S rRNA gene sequence was performed by EzBioCloud server. The phylogenetic tree was constructed using the neighbor-joining method of the CLUSTAL W program and MEGA (ver 5.0) software.[26]

**Sample Preparation for Analysis.** The diosmetin-7-*O*-glucoside standard solution was prepared by dissolving accurately diosmetin-7-*O*-glucoside in methanol to give a final concentration of 3.0 mg/mL. The 0.1 mM standard solution was inoculated into 0.9 mL of GAM broth with 0.1 mL of precultured bacteria prepared from the culture stock and then anaerobically incubated at 37 °C for 24 h. The samples were extracted three times with ethyl acetate, and the ethyl acetate layer was dried under vacuum. Before UPLC-MS analysis, the samples were dissolved with 0.3 mL of methanol and centrifuged at 12000*g* for 10 min, and then the supernatant was filtered through a 0.22 μm membrane. To exclude the deviation deriving from one time test, each bacterial strain was prepared to be three samples for incubation with the diosmetin-7-*O*-glucoside standard, and the processed sample was tested three times.

**UPLC-MS Analysis.** The flavonoids were separated on a Waters Acquity UPLC system (Waters Corp., Milford, MA, USA) fitted with a Syncronis C 18 column (100 mm × 2.1 mm i.d., 1.7 μm; Thermo,

**Table 2. Diosmetin-7-*O*-glucoside and Its Metabolites Identified in Different Human Intestinal Bacterial Samples Using UPLC-MS/MS**

| peak | $t_R$[a](min) | exptl mass ($m/z$) | formula | $MS^2$ fragment ions | mass change | formula change |
|---|---|---|---|---|---|---|
| M0 | 5.06 | 462.1162 | $C_{22}H_{22}O_{11}$ | 461, 299, 284, 255, 151 | 0 | null |
| M1 | 8.10 | 300.0634 | $C_{16}H_{12}O_6$ | 299, 284, 256, 151 | −162.0528 | -Glc |

| M3 | 10.90 | 340.0947 | $C_{19}H_{16}O_6$ | 339, 283, 268, 240, 151 | −122.0215 | -Glc − OH + $CH_3$ + $C_2H_2O$ |

[a] $t_R$, retention time.

USA) by gradient elution using acetonitrile (solvent A) and 0.1% formic acid in distilled water (solvent B). The gradient profile was as follows: 0−7.5 min, from 10 to 30% solvent A; 10 min, 70% solvent A; 11 min, 95% solvent A; held for 1 min. The gradient was recycled back to 10% in 1 min for the next run. The injection volume was 5 μL. The temperature of the column oven was set to 35 °C.

Mass spectrometry was carried out using a Waters Acquity Synapt mass spectrometer (Waters Corp., Manchester, UK) connected to the UPLC system via an electrospray ionization (ESI) interface. Ionization took place in the negative ion mode. The conditions for the MS analysis were designed as follows: capillary voltage, 3.0 kV; cone gas flow rate, 50 L/h; source temperature, 120 °C; desolvation gas flow rate, 60 L/h at a temperature of 350 °C. All data in the centroid mode were acquired by using Masslynx$^{NT4.1}$ software (Waters Corp., Milford, MA, USA).

## RESULTS

**Characterization of the Human Intestinal Bacteria.** On the basis of the colony morphology, micromorphology, and comparative 16S rRNA gene sequence analysis, 67 *Escherichia*, 16 *Enterococcus*, and 16 *Bacillus* strains were identified. Due to the stronger bioconversion ability (Table 1), Gram-negative strain 4 was picked as a representative example for analysis. The PCR amplified 16S rRNA of strain 4 was 1298 bp, and its nucleotide sequence has been registered in GenBank under accession no. KC819112. After comparison of the 16S rRNA gene sequence with the CLUSTAL W program, the phylogenetic affiliation of strain 4 was determined. The phylogenetic tree also showed that the isolated strain 4 was in the same cluster with *Escherichia* species. It is closely related to *Escherichia coli* O157 EC4115 CP001164 with 99.15% similarity. Thus, we identified it as one species of the genus *Escherichia* and named it *Escherichia* sp. 4.

**Metabolic Profile of Diosmetin-7-*O*-glucoside by the Different Human Intestinal Bacteria.** According to the retention behaviors, changes of molecular weights and MS/MS fragment patterns, the prototype, and its metabolites could be tentatively identified. Compared with blank sample (Figure 1 and Table 2), parent compound diosmetin-7-*O*-glucoside (M0) and its three metabolites were detected in different human intestinal bacterial samples. Three metabolites were likely to be diosmetin-7-*O*-glucoside aglycone diosmetin (M1), acacetin (M2), and methylated and acetylated acacetin (M3). Considerable amounts of M1 and minor amounts of M2 were produced by the majority of the isolated intestinal bacterial strains such as *Escherichia* sp. 4. A small amount of M3 existed in the minority of the bacterial samples.

**Identification of the Diosmetin-7-*O*-glucoside Metabolites.** The retention time of diosmetin-7-*O*-glucoside (M0) was at 5.06 min, and its fragment ion was at $m/z$ 461 (Figure 2a). The precursor ion $[M - H]^-$ $m/z$ 461 afforded the diosmetin product ion at $m/z$ 299 by loss of the glucuronide group. Then, the $m/z$ 299 lost $CH_3$ to be $m/z$ 284. The $m/z$ 255 was generated from $m/z$ 284 by elimination of CO. The product ion at $m/z$ 151 was formed from the aglycone at $m/z$ 299 by the retro-Diels−Alder (RDA) cleavage (Figure 3a).

Metabolite M1 was detected as deprotonated molecular ion $[M - H]^-$ at $m/z$ 299 with the retention time at 8.10 min, which was 162 Da lower than that of M0 diosmetin-7-*O*-glucoside. It gave signals at $m/z$ 299, 284, 256, and 151. In the MS/MS spectrum of M1 are displayed similar product ions as M0 diosmetin-7-*O*-glucoside (Figure 2b). According to the MS/MS spectrum and the fragmentation regularity with standard diosmetin (Figure 3b), M1 was identified as the aglycone of diosmetin-7-*O*-glucoside, diosmetin.

The fragment ion of M2 (retention time, 9.53 min) was at $m/z$ 283 $[M - H]^-$. As illustrated in Figures 2c and 3c, the $m/z$ 283 lost $CH_3$ to give $m/z$ 268. The $m/z$ 268 was further fragmented to be $m/z$ 240 by the loss of CO. The $m/z$ 151 was obtained from $m/z$ 283 by RDA cleavage. Becausee M1 was 16 Da higher than M2, M2 was tentatively identified as dehydroxylated aglycone. Additionally, M2 was confirmed on the basis of its retention time and MS/MS spectrum compared with the standard of acacetin. Therefore, we concluded M2 was acacetin.

The characteristic fragment ion of M3 (Figure 2d) was at $m/z$ 339 $[M - H]^-$, which was 56 Da higher than that of M2, indicating the chemical structure of M3 could be the methylated and acetylated product of M2. According to the fragmentation pathway (Figure 3d), M3 lost $CH_2$ and $C_2H_2O$ to form $m/z$ 283. Then, $m/z$ 268 and 240 were obtained from $m/z$ 283 by the loss of $CH_3$ and $C_2H_3O$, respectively. The $m/z$ 151 was also obtained by RDA cleavage from $m/z$ 283. Thus, M3 was identified as the methylated and acetylated acacetin.

## DISCUSSION

The commercially available UPLC has proved to be one of the most promising recent developments in fast chromatographic separations. There has been substantial focus on UPLC separations with the objective of reducing analysis times while maintaining good efficiency. Additionally, the UPLC-Q-TOF/MS plays a crucial role in the study of drug metabolism because it can not only provide accurate masses of ions but also give valuable structural information from the MS/MS spectra.[24,25] According to the retention behaviors, changes of molecular weights, and MS/MS fragment patterns, the prototype and its metabolites can be tentatively identified.[27,28] Compared with the HPLC-MS technology, UPLC-MS significantly improves the repeatability and reliability of quantitative analysis as well as the accuracy of qualitative analysis.

On the basis of our experimental results, the metabolic pathways of diosmetin-7-*O*-glucoside by the isolated *Enterococci*, *Escherichia*, and *Bacillus* strains in vitro were proposed as shown in Figure 4. Diosmetin-7-*O*-glucoside in the human intestine might initially be involved in deglycosylation of the flavonoid glycoside by intestinal bacteria with β-D-glucosidase,

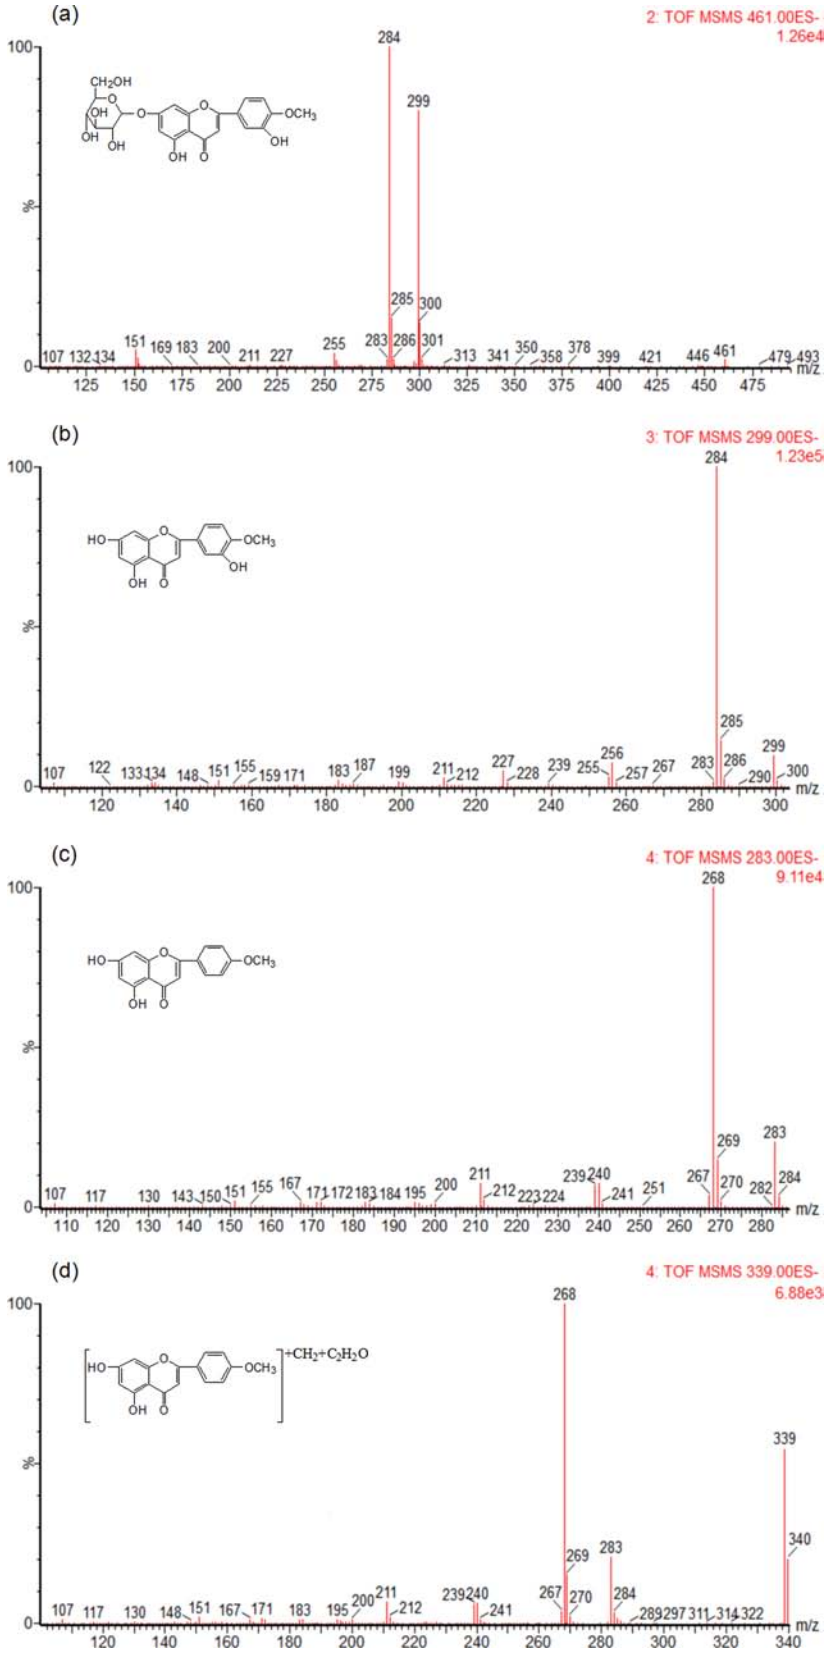

**Figure 2.** UPLC-MS/MS spectra: (a) M0 (*m*/*z* 461); (b) M1 (*m*/*z* 299); (c) M2 (*m*/*z* 283); (d) M3 (*m*/*z* 339).

and it was almost totally bioconverted to diosmetin, which thereafter could be further biocoverted to acacetin (M2). However, only a few intestinal bacteria such as *Escherichia* sp. 4 could produce methylated and acetylated acacetin (M3). An early study indicated that diosmetin could be reduced to its flavanone analogue hesperetin through reduction of the 2,3 double bond of the C-ring by intestinal bacterial enzymes.[29] However, the course of polyphenol degradation depended on

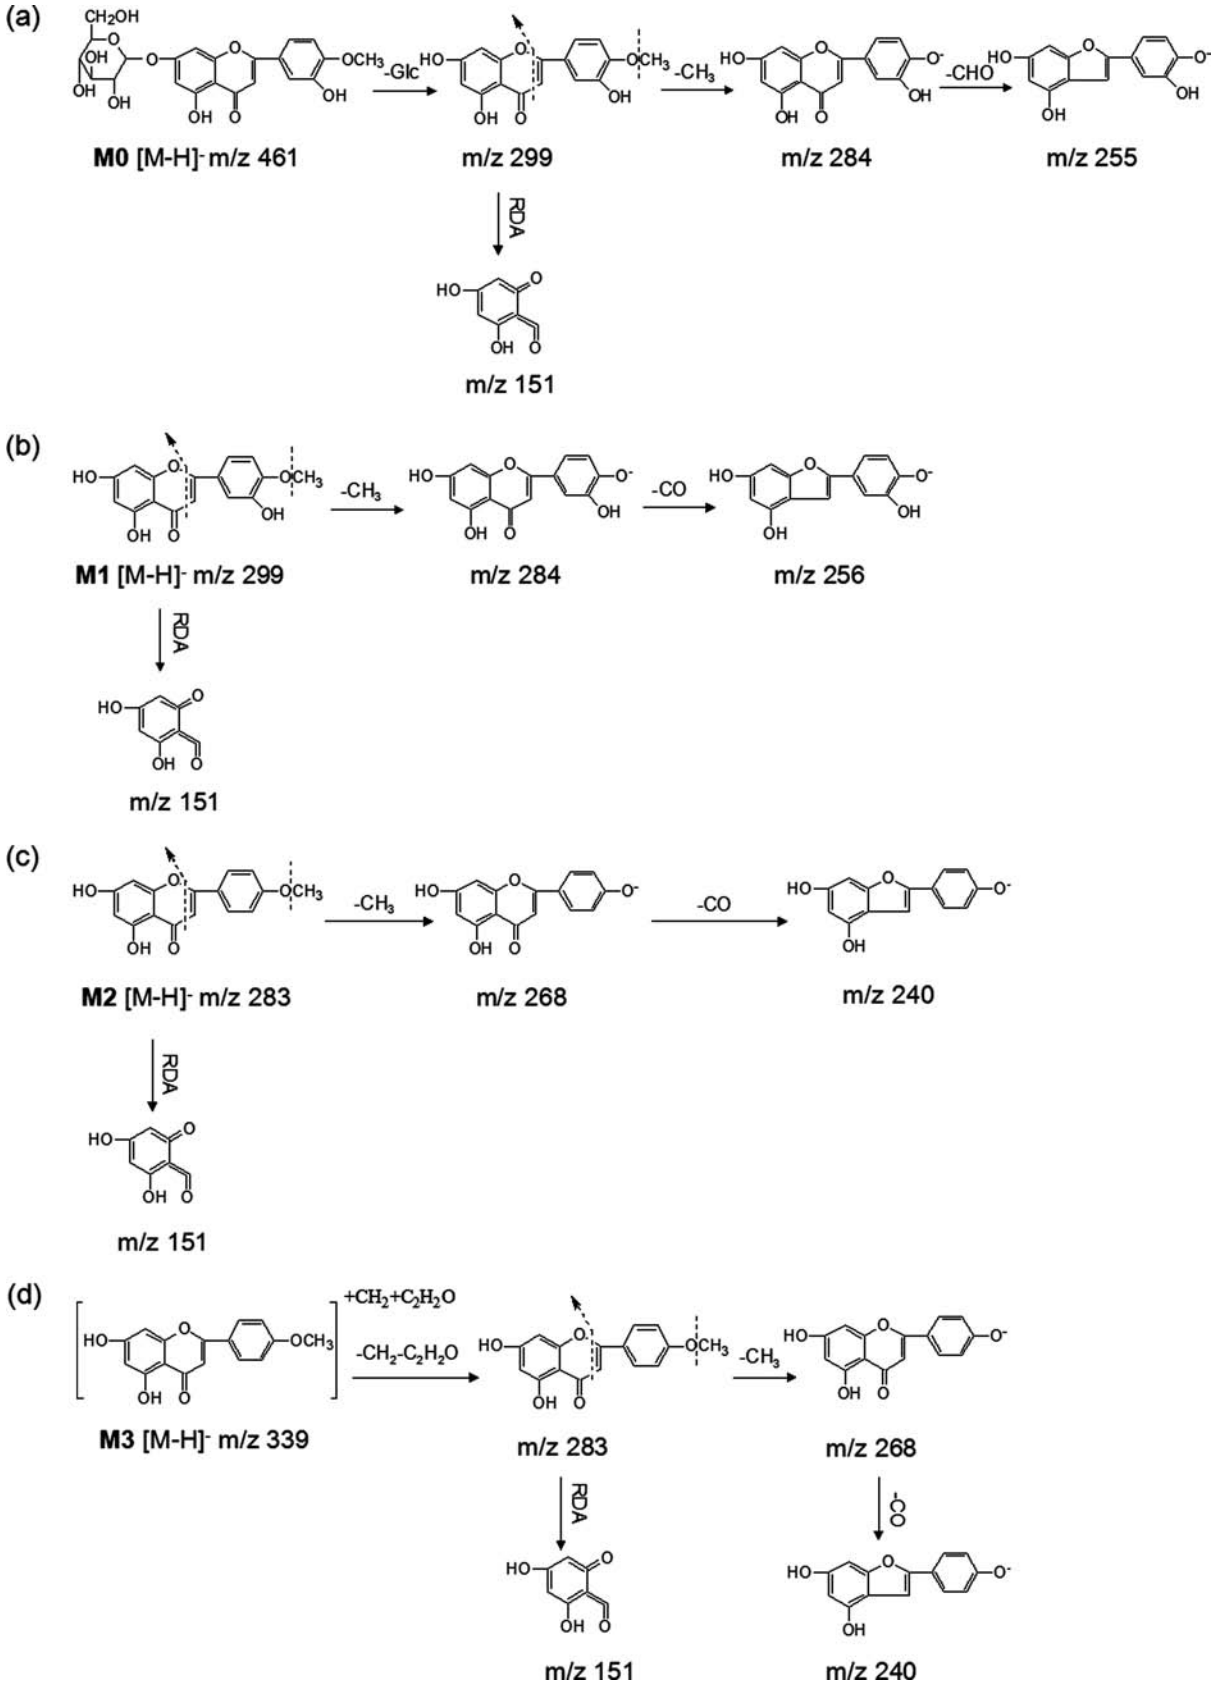

**Figure 3.** Proposed fragmentation pathways of M0−M3.

the type of bacteria in the gut,[30] and hydrogenation might not be a general feature of the intestinal microflora even though the bacteria were from the same strain. For example, quercetin could be hydrogenated to taxifolin by a *Clostridium orbiscindens* strain.[31] *Escherichia coli* HGH21 could bioconvert the isoflavone daidzin to daidzein and further metabolize the

dx.doi.org/10.1021/jf502676j | *J. Agric. Food Chem.* 2014, 62, 11441−11448

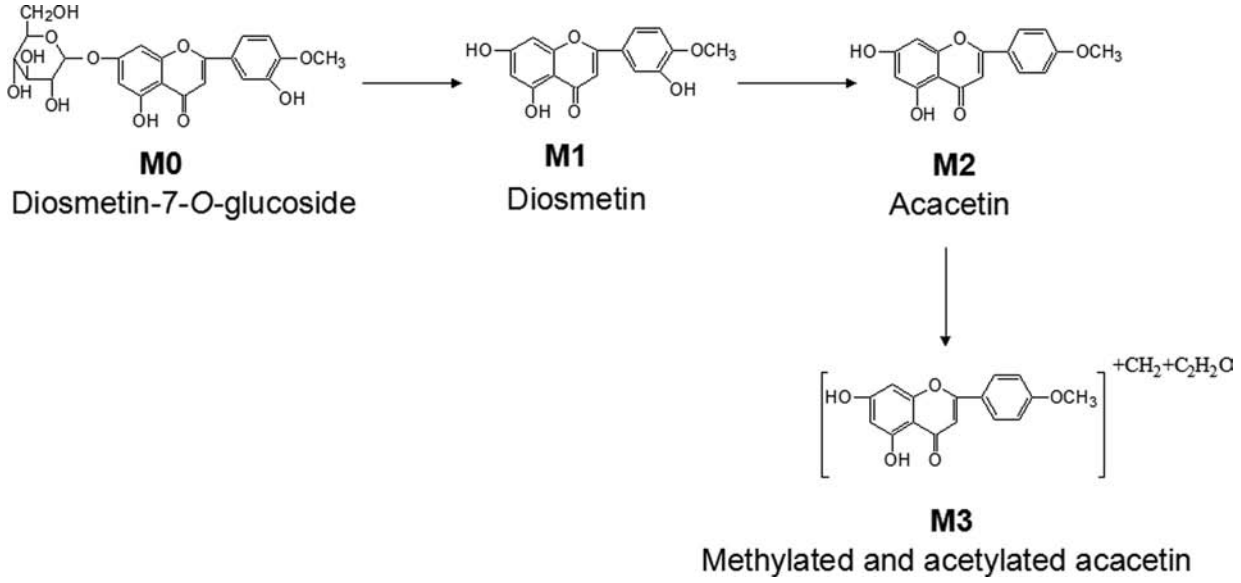

**Figure 4.** Proposed metabolic pathways of diosmetin-7-*O*-glucoside by the human intestinal bacteria.

isoflavone daidzein to dihydrodaidzein.[32] However, *Escherichia coli* JCM5491 did not convert daidzin to daidzein.[33] Therefore, it was speculated that the release of diosmetin improved diosmetin-7-*O*-glucoside bioavailability for absorption by colonic mucosa and/or further biotransformation to hesperetin by other human intestinal microorganisms. The removal of hydroxyl groups from aromatic rings and the acetylation of phenolic compounds might be exceptional metabolic activities. However, the conversion of phenolic compounds has been widely described in recent years.[34,35]

The human intestinal bacteria, classified as resident and transient flora, comprise a diversity of bacterial species and have excellent enzymatic systems contributing to their enormous catalytic and hydrolytic potential.[36] The factors influencing the flavonoids absorption in the gastrointestinal tract include deglycosylation before absorption, conjugation in the small intestine through glucuronidation, sulpfation or methylation, etc., and metabolism and degradation in the colon to smaller phenolic molecules by intestinal bacteria. The forms in which they circulate in vivo will influence their polarity and, thus, their localization and bioactivities.[37] Diosmetin commonly occurs in citrus species and olive leaves, shows significant antibacterial activity against drug-resistant *Staphylococcus aureus*,[38,39] and has the potential to suppress stem cell factor-/ultraviolet B-induced melanogenesis. Thus, it can be developed as an antipigmentation agent.[40] Diosmetin exhibits anticancer activity. It can inhibit tumor growth and protect tumor-induced apoptosis of the thymus[41] and shows significant cytotoxicities against colon cancer cell Colo205.[42] Additionally, diosmetin slightly inhibits superoxide anion generation or elastase release by human neutrophils, indicating moderate anti-inflammatory activity.[43] It can induce osteoblastic differentiation and is a promising agent for treating osteoporosis.[44] Diosmetin is one of the main active ingredients of some medications.[45] The metabolite acacetin can exert anti-inflammatory, anticancer, and antihypertension activities.[46,47] Deglycosylation is an important step in the absorption and metabolism of glycosides.[48−53] The absorption rate of aglycones is higher than that of their corresponding glycosides due to their higher lipophilicities and smaller molecular sizes.[54−56] Hence, the human intestinal bacteria play an important role in the pharmacological effects of diosmetin-7-*O*-glucoside in vivo.

As we know, the polarity of a compound might significantly affect its bioavailability. The polarity of flavonoid aglycones highly depends on the substitution of the three rings in their chemical structures. Flavonoids with methoxy groups on ring A or B are relatively nonpolar, which can protect them from extensive bacterial degradation.[57] The methoxy group is beneficial for the absorption if the dissolution is satisfactory.[58] Because the other intestinal bacteria might be also able to demeth(ox)ylate phenolic compunds, we speculated that the clinical effects of diosmetin-7-*O*-glucoside mainly resulted from diosmetin, which displayed stronger bioactivities and higher absorption rate than those of the parent compound in vivo. Although the metabolism results from our work might not fully reflect the interaction between human intestinal bacteria and medicines, it still could provide a good reference to study and understand the mechanism of the interaction.

efficiency, smaller volume of organic solvents, simplicity of operation, simple and convenient equipment, and low cost per sample.[14] In recent years, modified QuEChERS methods for sample preparation with LC−MS/MS or GC−MS detection obtained high recoveries and reproducibility.[1,5,15−17] The above methods were approved and mainly employed in governments, food industry, and related laboratories, and much time was consumed because of complex procedures as well as the expensive cost. In the case of vegetables, the pesticide residue analysis was more different and difficult, corresponding to complex components in the matrix, and the pesticides sprayed were unknown during cultivation.

In this paper, different cleanup methods [primary secondary amine (PSA), multi-walled carbon nanotubes (MWCNTs), and polystyrene (PLS) as sorbents] based on QuEChERS sample preparation were evaluated for Chinese cabbage and cucumber. The analysis was carried out by tandem mass spectrometry within 10 min. The aim of this study was to develop rapid and robust analytical methods for the simultaneous extraction and determination of 238 pesticides in Chinese cabbage and cucumber.

## MATERIALS AND METHODS

**Chemicals and Reagents.** Most of the pesticide standards used in this work were purchased from Dr. Ehrenstorfer (Augsburg, Germany), Chem Service (West Chester, PA), and Fluka (Buchs, Germany), with the highest available purity. Some pesticide standards were generously provided by the Korean Food and Drug Administration. HPLC-grade acetonitrile, acetone, and methanol were obtained from Honeywell (Morristown, NJ). LC−MS-grade formic acid and ammonium formate were ordered from Fluka (Buchs, Germany). The DisQuE QuEChERS pouch as in the EN method 15662 sample preparation kit, was acquired from Waters (Milford, MA) and contained 4 g of anhydrous $MgSO_4$, 1 g of NaCl, 1.5 g of sodium citrate dehydrate, and 0.5 g of disodium citrate sesquihydrate. Dispersive solid-phase extraction (D-SPE) 5982-5021 was purchased from Agilent Technologies (Santa Clara, CA) and contained 25 mg of PSA and 150 mg of anhydrous $MgSO_4$. The 30 mg PSA cartridge column and 20 mg PLS cartridge column were purchased from Aisti Science (Wakayama, Japan). MWCNTs (15−20 nm) were purchased from Hanwha Nanotech (Seoul, Korea).

**Preparation of Standard Solutions.** Individual standard solutions were prepared in acetone, acetonitrile, or methanol with a concentration of approximately 1000 mg/L and stored at −20 °C. A working standard mixture was prepared by diluting each individual standard solution with methanol, to obtain a concentration of 10 mg/L for each compound. The linearity in the response was studied with standard solution prepared in both blank matrix extra and acetonitrile solvent.

**Sample Preparation.** Chinese cabbage (*Brassica rapa*) and cucumber (*Cucumis sativus*) were obtained as organic products from a Seoul local market in Korea, and no pesticide residue was detected in the vegetables. An approximately 200 g portion of sample was weighed and homogenized at 10 000 rpm for 1 min. A 10 g sample of homogenized Chinese cabbage (or cucumber) was weighed into a 50 mL Teflon centrifuge tube, followed by the addition of 10 mL of acetonitrile, and the tube was vigorously shaken for 1 min manually. A DisQuE QuEChERS pouch was added to each sample, which was then shaken again. The tube was centrifuged at 3500 rpm for 5 min at 4 °C after cooling on ice. Finally, the acetonitrile layer was prepared for the cleanup step.

**Sample Purification.** A total of 1 mL of the acetonitrile layer was transferred to a 2 mL microcentrifuge tube containing different sorbents, including D-SPE 5982-5021 containing 25 mg of PSA and 150 mg of $MgSO_4$ for method "A". A total of 2.5 mg of MWCNTs was added to the sorbent of method "A" as method "B". Only 10 mg of MWCNTs was used as the cleanup sorbent with D-SPE for method "C". The mixture was shaken vigorously for 2 min and centrifuged at 13 000 rpm for 2 min. Then, 400 μL of supernatant was transferred to an autosampler vial, followed by the addition of 100 μL of acetonitrile [0.5% (v/v) formic acid], and this was then filtered through a 0.2 μm polytetrafluoroethylene (PTFE) filter.

Moreover, the 30 mg PSA mini-cartridge column for method "D" and the 20 mg PLS mini-cartridge column for method "E" were also used for sample purification. The columns were preconditioned with 2 mL of acetone and activated with 2 mL of acetonitrile. After loading 1 mL of acetonitrile layer, the column was eluted with 1 mL of methanol [0.1% (v/v) formic acid] as the elution solvent. Then, the sample was dissolved in 1 mL of acetonitrile after evaporating the methanol, and 400 μL of solution was transferred to an autosample vial, to which 100 μL of acetonitrile [containing 0.5% (v/v) formic acid] was added for analysis.

**LC−MS/MS Analysis.** Triple quadrupole LC−MS/MS was a Shimadzu LCMS-8030 (Japan) equipped with an electrospray ionization (ESI) source, operating in positive and negative ionization modes. LC was carried out with two Shimadzu LC-30AD pumps (Japan), a Sil-30AC autosampler, a CTO-30AC column oven, and a CBM-20A controller. A Phenomenex Kinetex $C_{18}$ column (Phenomenex, Torrance, CA), 2.6 μm, 100 × 2.1 mm, was used. Nitrogen was used in the ion source and as the collision gas.

The LC−MS/MS system parameters were set as follows: flow rate, 0.5 mL/min; interface voltage, 4.5 kV; desolvation line temperature, 250 °C; nebulizing gas flow, 3 L/min; heat block temperature, 400 °C; performed gas flow, 15 L/min; and collision-induced ionization (CID) gas, 230 kPa. The temperature of the column was 40 °C, and a 10 μL amount of the sample extract was injected in each run.

**Mobile Phase.** Mobile phase A was water, and mobile phase B was methanol, both containing 5 mM ammonium formate and 0.1% (v/v) formic acid. The gradient program was as follows: 100% A (0% B) for 0.5 min from the start, ramped to 55% B linearly for 0.5 min, followed by a linear gradient up to 95% B over 7 min, and maintained for 2 min at 95% B. A constant flow rate of 0.5 mL/min was used, and the total running time was 10 min.

**Optimization of MS/MS Parameters.** The optimization of MS conditions was performed for each pesticide by introducing individual standard solutions directly into MS. The two most intense precursor ion−fragment ion transitions of each pesticide were chosen, and the optimal MS/MS parameters for all transitions were recorded. The final method was constructed on the basis of these data (see Table S1 of the Supporting Information).

**Matrix Effect Study.** Change of ionization efficiency in the presence of other compounds is call the matrix effect. An average matrix effect exceeding 25% is generally considered to significantly affect quantitative analytical results,[17,18] depending upon the relative standard deviation (RSD) values.

To an aliquot of blank extract in methanol, a pesticide mixture, 78% of the extract volume, was added. Matrix effect values were calculated for all samples using matrix-matched calibration and a methanol calibration slope with the following formula: ME (%) = $100 \times ((S_m/S_s) - 1)$, where ME is the matrix effect and $S_m$ and $S_s$ are the slopes of the calibration curves obtained in the matrix and methanol, respectively.

**Recovery Experiments.** A recovery study was performed by spiking each sample with a mixture of a working standard solution (10 mg/L) containing 238 pesticides to reach a final concentration of 8 and 40 μg/kg, and each spike level was repeated 3 times.

## RESULTS AND DISCUSSION

**LC−MS/MS Method Validation Using Standard Solutions.** The linearity of each pesticide in Chinese cabbage and cucumber samples was studied in the range of 1−200 μg/L with seven calibration points (1, 5, 10, 20, 50, 100, and 200 μg/L) by a matrix-matched standard calibration. Summary results are presented in Table S1 of the Supporting Information. These data indicated that the LC−MS/MS procedure had good linearity and high sensitivity. Approximately 96% of the

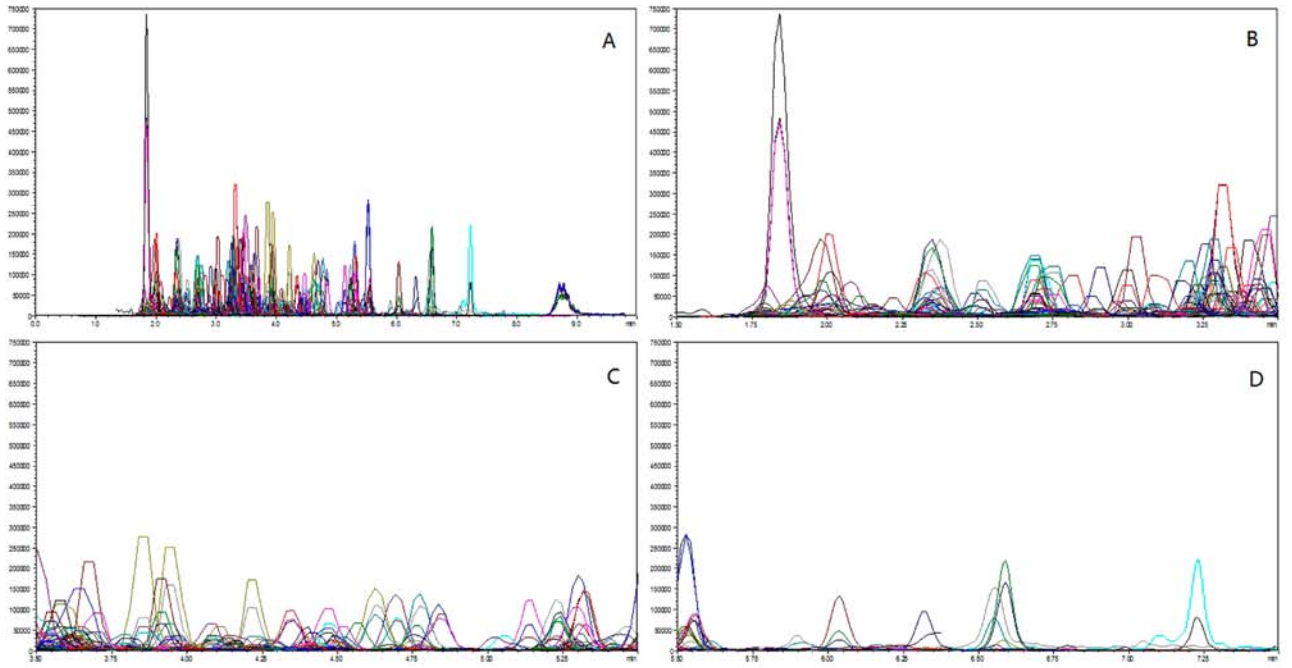

**Figure 1.** Chromatogram of 238 pesticides at a spiked level of 8 μg/kg in Chinese cabbage samples. The original chromatogram (A) was divided into panels B (1.5−3.5 min), C (3.5−5.5 min), and D (5.5−7.5 min) by running time.

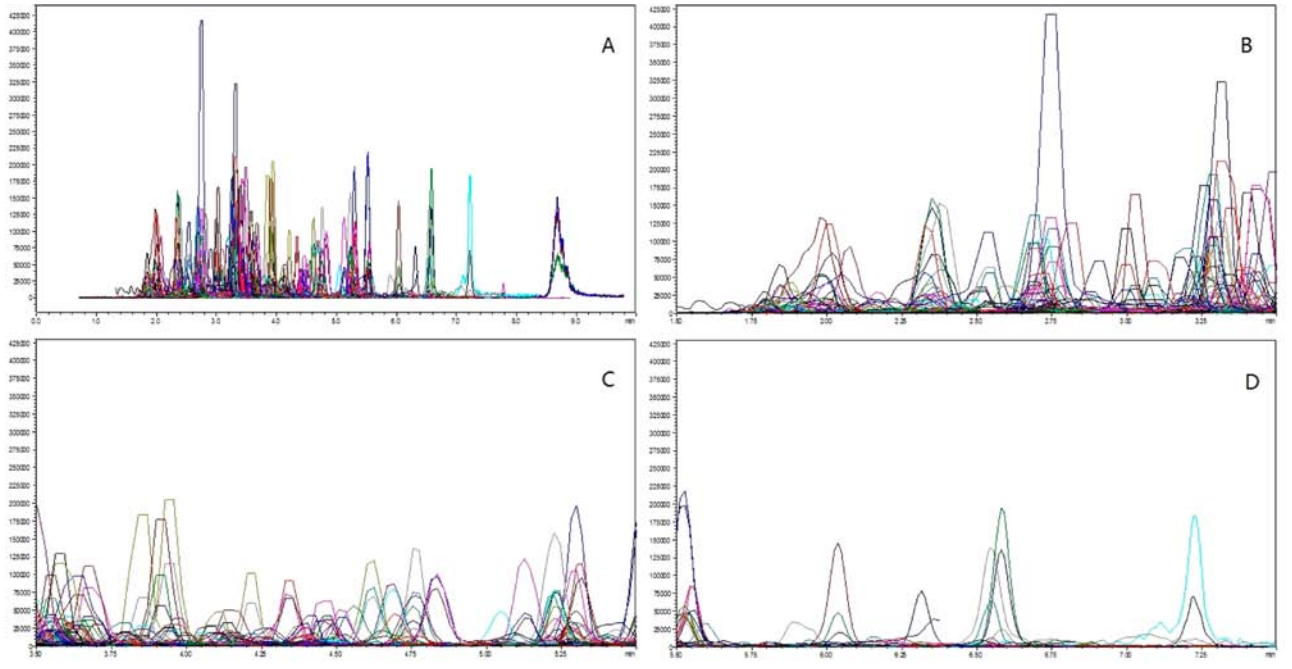

**Figure 2.** Chromatogram of 238 pesticides at a spiked level of 8 μg/kg in cucumber samples. The original chromatogram (A) was divided into panels B (1.5−3.5 min), C (3.5−5.5 min), and D (5.5−7.5 min) by running time.

pesticides (238 pesticides), in either the methanol or the matrix, analyzed by ESI in positive or negative mode, exhibited $r^2 \geq 0.99$ and a linear range from 1 to 200 μg/kg. For three pesticides, bentazone, fluoroxypyr, and trichlorfon, $r^2$ was less than 0.99 in both the methanol standard solution and the matrix solution. Seven pesticides, including boscalid, bromacil, cyazofamid, diafenthiuron, formothion, terbuthylazine, and triflumuron, showed $r^2 < 0.99$ in the Chinese cabbage matrix solution. In cucumber, seven pesticides, including bromacil, clothianidin, diafenthiuron, ethoxyquin, fludioxonil, formothion, and isoprothidane, had $r^2 < 0.99$ in the cucumber matrix solution.

In Chinese cabbage (see Table S2 of the Supporting Information), the limits of detection (LODs) for 211 of 238 pesticides were below 1 μg/kg, the LODs for 20 pesticides ranged between 1 and 2 μg/kg, and seven pesticides had LOD values above 2 μg/kg, including benthiavalicarb-isopropyl (2.15 μg/kg), fenpiclnoil (2.02 μg/kg), hexythiazox (2.92 μg/kg), malathion (2.02 μg/kg), orthosulfamuron (2.40 μg/kg), pyrazosulfuron-ethyl (2.00 μg/kg), and pyrazoxyfen (3.06 μg/

dx.doi.org/10.1021/jf504570b | J. Agric. Food Chem. 2014, 62, 11449−11456

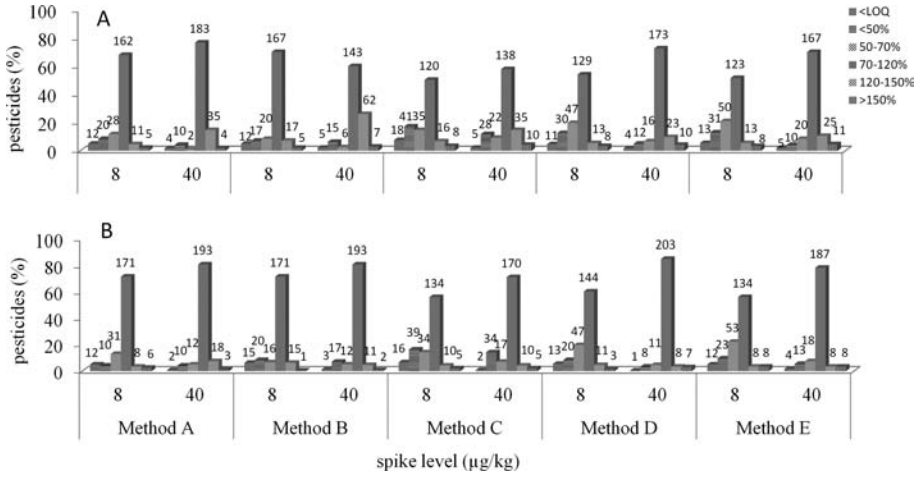

**Figure 3.** Percentage of pesticides within each recovery range with four different cleanup procedures by LC−MS/MS for the (A) Chinese cabbage and (B) cucumber samples. The number of pesticides is depicted above the bars.

kg). In the case of cucumber (see Table S3 of the Supporting Information), the LODs for 209 of 238 pesticides were below 1 μg/kg, the LODs for 17 pesticides ranged between 1 and 2 μg/kg, and 12 pesticides had LOD values above 2 μg/kg, containing bifenazate (4.69 μg/kg), boscalid (2.15 μg/kg), carbaryl (2.36 μg/kg), famoxadone (2.02 μg/kg), fipronil (2.30 μg/kg), hexythiazox (2.75 μg/kg), MCPA (2.04 μg/kg), mecarbam (2.02 μg/kg), metconazole (3.34 μg/kg), pyrazosulfuron-ethyl (4.04 μg/kg), tebuconazole (3.76 μg/kg), and triflumuron (6.32 μg/kg). There were no significant differences among the estimated instrument LOD values, which were calculated from the results obtained with standard solutions prepared with the matrix extract and solvent.

**Matrix Effect.** The matrix effect is very compound-dependent, often probably because of co-eluting matrix components, which interact with the pesticide in the ionization step in the interface.[6] Decreasing or increasing of the ion amount formed results in a corresponding positive or negative matrix effect, respectively.

The matrix effects were determined for 238 pesticides in two vegetables using five different cleanup methods at two concentration levels (8 and 40 μg/kg). The observed matrix effect values are presented in Table S1 of the Supporting Information. It could be concluded that the mean values of the matrix effect for 238 pesticides were 14.89 and 20.5% in Chinese cabbage and cucumber, respectively, which were less than 25%. However, 92 and 42 pesticides of the matrix effect values were still greater than 25% in two vegetables; it meant that there was a significant influence on quantitative detection that could not be ignored. Therefore, matrix-matched calibration curves were used for decreasing the influence of the matrix.

**Optimization of the Purification Procedure.** The recoveries and repeatability of the spiking experiments at the spiked levels of 8 and 40 μg/kg are listed in Tables S1 and S2 of the Supporting Information. The chromatograms are presented in Figures 1 and 2. Relevant histograms by five different cleanup steps with LC−MS/MS are shown in Figure 3.

Considerably higher recoveries were obtained when PSA D-SPE was applied in method "A". Recoveries of 183 and 193 of pesticides were in the range of 70−120% at a spiked level of 40 μg/kg in Chinese cabbage and cucumber, respectively (Table 1). The results were consistent with those presented in a former study, in which adequate recoveries were reported with the use of this method.[5,19−22] When PSA mini-cartridge column (method "D") replaced PSA D-SPE, as observed, the performance of method "D" reached the highest recoveries in cucumber; there was 203 pesticide recoveries in range of 70−120% (Table 2). In the case of Chinese cabbage, recoveries of method "D" were lower than those obtained in method "A"; 173 pesticide recoveries were in the range of 70−120% at a spiked level of 40 μg/kg.

The effect of MWCNTs (methods "B" and "C") for cleanup was investigated in target vegetables. 143 and 138 pesticide recoveries ranged from 70 to 120% at a spiked level of 40 μg/kg for Chinese cabbage, whereas 193 and 170 pesticide recoveries ranged from 70 to 120% at the same spiked level for cucumber. It meant that the lowest recoveries were achieved in method "C" (PSA sorbent was excluded) at a spiked level of 40 μg/kg in Chinese cabbage. Less acceptable recoveries were obtained using a PLS mini-cartridge column (method "E"); just 167 and 187 of the detected pesticide recoveries were in the acceptable range (70−120%) at a spiked level of 40 μg/kg in Chinese cabbage and cucumber, respectively.

On the basis of the above results in the recovery test, it could be concluded that the PSA D-SPE was the most suitable for Chinese cabbage and the PSA-mini cartridge column was the most suitable for cucumber out of the five investigated methods.

**Accuracy and Reproducibility Using Spiked Samples.** Both retention time and the presence of all ions in the correct ratio were necessary (see Table S1 of the Supporting Information)[23] for identification. In this study, there was no interference observed; the retention time and ion ratio should correspond to those obtained from a standard; and it showed good stability of relative selected reaction monitoring (SRM) responses.

From the recovery study, PSA D-SPE and PSA mini-cartridge column were selected as the best methods for matrix purification of Chinese cabbage and cucumber, respectively. The RSD results demonstrated that the methods were repeatable. In Chinese cabbage, 162 and 183 of the 238 pesticides in method "A" had recoveries in the range of 70−120% at the spiked levels of 8 and 40 μg/kg; the number of RSDs less than or equal to 10% was 84 and 139 pesticides; and

RSDs between 10 and 20% were 70 and 44 pesticides at the two spiked levels (Figure 4).

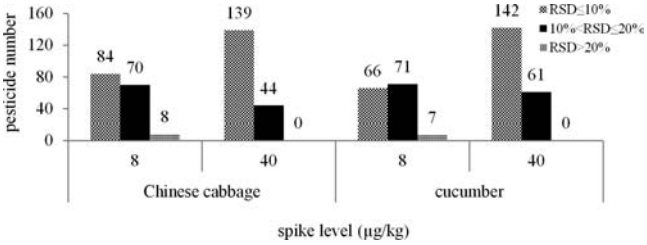

**Figure 4.** Repeatability of the optimization methods with a recovery in the range of 70−120%.

In the case of cucumber, 144 and 203 pesticides had acceptable recoveries at the spiked levels of 8 and 40 μg/kg in method "D", respectively, in which RSDs were less than or equal to 10% for 66 and 142 pesticides and RSDs of ≤20% were 137 and 203 pesticides at the two spiked levels. The results were satisfied with the selected purification method.

The limit of quantitation (LOQ), which is the lowest validated spike level with acceptable precision and sensitivity for all ions chosen for quantitation and identification, was between 0.16 and 10.20 μg/kg in Chinese cabbage and between 0.06 and 21.06 μg/kg in cucumber for the 238 pesticides.

The suitable methods were developed and validated using standards dissolved in methanol and proven to be rugged using matrix-matched standards of two samples. In general, Chinese cabbage and cucumber provided high matrix effects, showing greater dependence upon the cleanup procedure. During validation, the matrix effects were remarkable, although they could be compensated by the use of the matrix-matched calibration curves. In the case of Chinese cabbage, acceptable recoveries were achieved, except the methods containing MWCNTs. D-SPE using PSA removes acidic components, certain pigments, and to some extent sugars.[12,24] At the same time, freezing out removes most of the lipids, waxes, and sugars as well as other components with low solubility in acetonitrile that may negatively affect the robustness of the LC analysis.[12]

With regard to recovery values, the method containing excess MWCNTs (10 g) provided the lowest results. It can be ascertained that this sorbent combination was less efficient for the extraction of the selected pesticides from the investigated matrices. MWCNTs were used as the sorbent and obtained good results contributed to its high surface area, mechanical strength, and chemical stability.[25,26] The sorbent could adsorb many matrix components, such as primarily chlorophyll. It not only adsorbed the co-extractive matrix components but also the pesticides, especially those exhibiting planar ring structures. Therefore, when the matrix contained little pigment, MWCNTs could adsorb more analytes, resulting in low recoveries.

In cucumber, the percentage of pesticides ranging between 70 and 120% was higher than that in Chinese cabbage. It may be attributed to the different fatty acid contents of the vegetable, and the content of pigment in Chinese cabbage was more than that in cucumber.

In Chinese cabbage, method "A" was the best sorbent for purification, while method "D" was the most efficient for cucumber matrix purification. The validation results have shown acceptable recoveries and precision (RSDs of ≤20%) for most pesticides in the study. In general, when many pesticides were mixed together, they would influence each other and reduce the sensitivity. In this study, 238 pesticides were mixed, and acceptable results were obtained at a spiked level of 8 μg/kg, which was lower than others.[27,28] In recent years, pesticide residue limits were lower; the selected methods could meet the requirement of low multi-residue pesticide determination; and the high-resolution capacity of LC combined with the extremely short analysis time (10 min) offered a significant benefit for the determination of pesticide residues in vegetables.

The establishment of rapid and high-throughput detection methods for multi-residue pesticides in Chinese cabbage and cucumber samples solved the problem of complex pretreatment for grouping hundreds of pesticides and analyzing with different instruments; the procedure of sample preparation was reduced as well as the time and cost.

**Application of Real Chinese Cabbage and Cucumber Samples.** The developed methods were applied in routine analysis to Chinese cabbage and cucumber samples collected from local markets in Seoul. Among 15 Chinese cabbage samples, 3 have been proven to be chlorantraniliprole, of which the content was 0.21−0.31 mg/kg; methoxyfenozide was detected in 2 samples with the concentration ranging from 0.14 to 0.23 mg/kg; and iprovalicarb (0.22−0.36 mg/kg) and fluopicolide (0.04−0.12 mg/kg) were detected in 5 Chinese cabbage samples, as shown in Table 3. Among 14 cucumber samples, 2 have been proven to be thiacloprid, of which the content was 0.11−0.19 mg/kg, and ethaboxam was detected in 3 samples with the concentration ranging from 0.24 to 0.65 mg/kg (Table 3). Six of the detected pesticides, which were registered in Korea, were lower than their regulatory levels.

Two rapid and simple methods have been developed for the analyses of 238 pesticides in Chinese cabbage and cucumber prior to LC−MS/MS performance. Best recoveries were achieved with PSA D-SPE for cleanup in Chinese cabbage,

**Table 3. Analytical Results of Chinese Cabbage and Cucumber Real Samples**

| pesticide | number of samples | concentration range (mg/kg) | | LOD (μg/kg) | maximum residue limit (MRL) (mg/kg) |
|---|---|---|---|---|---|
| | | minimum | maximum | | |
| | | | Chinese Cabbage | | |
| chlorantraniliprole | 3 | 0.21 | 0.31 | 0.76 | 1.0 |
| methoxyfenozide | 2 | 0.14 | 0.23 | 0.36 | 2.0 |
| iprovalicarb | 2 | 0.22 | 0.36 | 0.19 | 0.7 |
| fluopicolide | 3 | 0.04 | 0.12 | 0.44 | 0.3 |
| | | | Cucumber | | |
| thiacloprid | 2 | 0.11 | 0.19 | 0.25 | 0.3 |
| ethaboxam | 3 | 0.24 | 0.65 | 0.42 | 2.0 |

and acceptable results were obtained by PSA mini-cartridge column in cucumber. The proposed methods have the advantage of detecting a large amount of pesticides in one single extraction and detection system, which is suitable for routine analysis and monitoring pesticides in Chinese cabbage and cucumber samples.

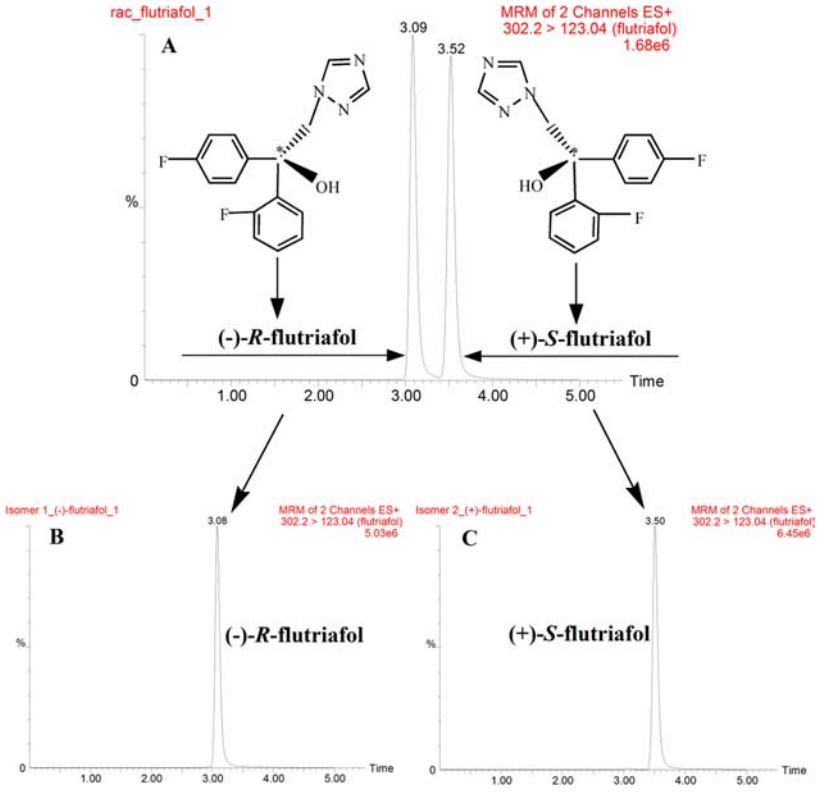

**Figure 1.** SFC-MS/MS chromatograms for the separation of flutriafol enantiomers on an IA-3 chiral column: (A) structures of the enantiomers of flutriafol and chromatogram of racemic flutriafol; (B) SFC-MS/MS chromatogram of (−)-*R*-flutriafol; (C) SFC-MS/MS chromatogram of (+)-*S*-flutriafol. ∗, chiral center.

residue analytical method for the accurate monitoring of trace information on flutriafol at the enantiomer level.

In this paper, the supercritical fluid (carbon dioxide, $CO_2$), which is nontoxic and nonreactive, exhibits various advantages. Featured by its low viscosity and high diffusivity, $CO_2$ contributes greatly to improve the separation efficiency, shorten the analysis time, and save labor cost. Moreover, the study adopted a postcolumn polar solvent compensation technology, which turned out to be a good solution to low ionization efficiency existing in the combination of supercritical fluid chromatography (SFC) with mass spectrometry (MS). Meanwhile, the influences of different parameters on the resolution and sensitivity were investigated and optimized. Besides, the adoption of QuEChERS (quick, easy, cheap, effective, rugged, and safe) methodology greatly simplified the sample preparation procedure. Therefore, a green, rapid, and sensitive analytical method for the determination of flutriafol enantiomers in vegetables, fruits, and soil was successfully established based on the SFC-MS/MS technique. In comparison with a previous paper,[23] the established method exerted obvious advantages in terms of solvent consumption, analysis time, and sensitivity. Furthermore, it had been used for the determination of flutriafol enantiomers in authentic samples. The result confirms that the proposed effective analytical method is environmentally friendly, convenient, and reliable in the detection of flutriafol enantiomers in food and environmental samples, which will facilitate further studies on the difference of individual enantiomers in toxicity, metabolism, and environmental fate.

## MATERIALS AND METHODS

**Chemicals and Reagents.** Racemic flutriafol (98.2% purity) was obtained from China Standard Material Center (Beijing, China). HPLC grade acetonitrile (ACN) was purchased from Sigma-Aldrich (Steinheim, Germany). Analytical grade NaCl, $MgSO_4$, and ACN were purchased from Beihua Fine-Chemicals Co. (Beijing, China). Ultrapure water was obtained from a Milli-Q system (Bedford, MA, USA). Sorbents including PSA (40 μm), C18 (40 μm), and GCB (40 μm) were obtained from Agela Technologies Inc. (Beijing, China). The mobile phase solvents were distilled and filtered through a 0.22 μm pore size filter membrane (Tengda, Tianjin, China) before use.

Standard stock solutions (100 mg/L) of racemic flutriafol were prepared in pure ACN and serially diluted to 5, 10, 50, 100, 500, and 1000 μg/L for flutriafol (2.5, 5, 25, 50, 250, and 500 μg/L of each enantiomer) with ACN. All solutions were wrapped with aluminum foil and stored in a refrigerator in the dark at −20 °C. The working standard solutions underwent no degradation for 3 months.

**SFC-MS/MS.** A Waters Acquity UPC$^2$ system (Milford, MA, USA) consisting of the Acquity UPC$^2$ binary solvent manager, the Acquity UPC$^2$ sample manager, the Acquity UPC$^2$ PDA detector, the auto back pressure regulator (ABPR), and the Waters compensation pump, was used for the separation of analytes. A Chiralpak IA-3 (150 mm × 4.6 mm i.d., Daicel, Japan) column with 3 μm particle size was used for the separation of the enantiomers of chiral flutriafol.

The enantiomeric analysis of flutriafol was performed using the Chiralpak IA-3 column after injection of a 1 μL volume standard working solution. The separation was carried out isocratically using solvent A ($CO_2$) and solvent B (methanol) in an 88:12 (v/v) ratio and at a 2.2 mL/min flow rate for 5 min. The temperatures of the column and sample manager were kept at 30 and 25 °C, respectively. The ABPR 2200 psi was selected, and the flow rate of compensation solution was 0.1 mL/min.

The parameters, including capacity factor ($k$), separation factor ($\alpha$), and resolution (Rs), were calculated from the formula $k = (t - t_0)/t_0$, $\alpha = k_2/k_1$, Rs $= 2(t_2 - t_1)/(W_1 + W_2)$, where $t_0$ is the void time at

dx.doi.org/10.1021/jf504324t | J. Agric. Food Chem. 2014, 62, 11457−11464

given conditions ($t_0$ = 0.85 min, determined using 1,3,5-yri*tert*-butylbenzene), $t$ is the retention time, $k$ is the retention factor, and $W$ is the baseline peak width.

The qualitative and quantitative analysis of flutriafol was conducted on a Xevo triple-quadrupole (Xevo-TQD) mass spectrometer (Waters Corp.) equipped with an electrospray ionization (ESI) source. The analyses were performed in the positive mode with a 3.5 kV capillary voltage, 150 °C source temperature, and 500 °C desolvation temperature. A 50 L/h cone gas flow and a 900 L/h desolvation gas flow were used. The nebulizer gas was 99.95% nitrogen, and the collision gas was 99.99% argon with a pressure of $2 \times 10^{-3}$ mbar in the T-Wave cell. MassLynx NT v. 4.1 (Waters, USA) software was used to collect and analyze the data obtained.

MS analyses were performed in the multiple reaction monitoring (MRM) mode, measuring the fragmentation of the protonated pseudomolecular ions of flutriafol. The monitoring conditions were optimized for flutriafol. A dwell time of 130 ms per ion pair was used to maintain the high sensitivity of the analysis, and a number of data points across the chromatographic peak were required. Typical conditions were as follows: the cone voltage of flutriafol was 24 V; $m/z$ 302.2 was selected as the precursor ion for flutriafol, $m/z$ 123.04 for its product quantitative ion, and $m/z$ 70.05 for its qualitative ion when the collision energy was set at 28 and 58 V. Under the conditions above, the retention times of (−)-*R*-flutriafol and (+)-*S*-flutriafol were approximately 3.08 and 3.50 min, respectively (Figure 1). These settings were utilized for all subsequent studies.

**Sample Preparation.** Tomato, cucumber, apple, grape, and soil (sandy loam) samples from trial plots were obtained from the Institute of Plant Protection (Haidian region, Beijing). These five matrices were not contaminated by the target analyte. The food samples were placed in polyethylene bags, then transported to the laboratory and stored in the dark at −20 °C until analysis. The soil samples were collected at depths of 0−30 cm at 15 randomly selected points. Afterward, the soil samples were air-dried at room temperature, homogenized, and passed through a 2 mm sieve. The treated samples were kept in the dark until analysis.

Approximately 300 g of blank samples (tomato, cucumber, apple, and grape) were homogenized in an Ultra-Turrax homogenizer (IKA-Werke, Staufen, Germany). Next, 10 g aliquots of the homogenized samples including soil (dry weight) were placed into 50 mL polypropylene centrifuge tubes with screw caps. Appropriate amounts of the working standard solutions were added to the blank samples to perform recovery studies. Then the samples were vortexed for 30 s and allowed to stand for 2 h at room temperature to be evenly distributed. Afterward, 10 mL of ACN (additional 5 mL $H_2O$ for soil) was added. After the tubes were vortexed for 3 min, 1 g of NaCl and 4 g of anhydrous $MgSO_4$ were added to the mixtures. These mixtures were vortexed for another 3 min. Subsequently, the tubes were centrifuged for 5 min at a relative centrifugal force (RCF) of 2811*g* with an effective radius of 13.5 cm. Then, 1.5 mL of the upper layer (ACN) was transferred to a single-use centrifuge tube containing 40 mg of PSA and 10 mg of GCB (whereas a single sorbent of 50 mg of C18 was used for the soil matrix) and 150 mg of anhydrous $MgSO_4$. The tubes were vortexed again for 30 s and centrifuged for 5 min at RCF of 2400*g* with an effective radius of 6.5 cm. The resulting supernatant was filtered using a 0.22 μm nylon syringe filter into an autosampler vial for chromatography injection. The comparative analysis of different sorbents will be discussed in a later section.

**Method Validation.** The developed method was validated according to a conventional validation procedure that included the following parameters: specificity, linearity, limits of detection (LODs) and quantification (LOQs), matrix effect, accuracy, precision, and stability.

For each matrix, 10 g of the blank samples was extracted and analyzed to verify the absence of any interfering species at retention times similar to the target analytes. The standard solutions and different matrix-matched standard solutions were analyzed in triplicate with the concentrations ranging from 5.0 to 1000 μg/L to determine the linearity of the method. The parameters of the linear regression equations, including the slopes, intercepts, standard deviations, and correlation coefficients ($R^2$), were calculated. The matrix-induced signal suppression/enhancement (SSE) was expressed as the slope ratio of the matrix-matched calibration curve/pure solvent calibration curve.

The LODs and LOQs were defined as the concentrations that produced signal-to-noise (S/N) ratios of 3 and 10, respectively. The matrix-dependent LOD and LOQ of the developed method were estimated using spiked samples (tomato, cucumber, apple, grape, and soil) at the lowest fortification level (10 μg/kg).

The accuracy and precision of the method were investigated by performing recovery assays. Five replicates of the spiked samples (tomato, cucumber, apple, grape, and soil) at three levels (10, 100, and 500 μg/kg) were prepared on three different days. The precision in the repeatability and reproducibility, expressed as the relative standard deviation (RSD), were determined from the intraday and interday assays.

The stability of the stock solutions (both in the solvent and in the matrix) was determined monthly by injecting a freshly prepared working solution. The stabilities of the spiked samples (100 μg/kg) with flutriafol were evaluated monthly. All of the samples used for stability detection were stored at −20 °C. The results of the stability tests were compared with those obtained from the freshly prepared sample using Student's $t$ test ($P < 0.05$).

## RESULTS AND DISCUSSION

**Optimization of Enantioseparation Conditions.** *Composition of the Mobile Phase.* To achieve excellent separation for flutriafol enantiomers on the IA-3 chiral column, different compositions of mobile phases were investigated. Comparative analysis assays were conducted, selecting methanol, ACN, 2-propanol, and mixtures of ACN and 2-propanol in varied proportions as modifier. Results showed that flutriafol enantiomers gave worse peak shape when ACN was selected as modifier, whereas the retention times for flutriafol enantiomers were all delayed, the first peak exceeding 5.5 min with the existence of 2-propanol. The reason is that methanol is a hydrogen-bond donor and acceptor, but ACN is just a weak hydrogen-bond acceptor. The chiral recognition process might be the joint interactions including hydrogen bonding between −OH on flutriafol and −NH on chiral stationary phase (CSP);[5,22] thus, with methanol as modifier, it exhibited stronger interactions and better peak shape than ACN. As for 2-propanol, there might be two aspects accounting for the delay of retention of flutriafol enantiomers. On the one hand, the polarity of 2-propanol is less than that of methanol, so the latter has stronger interactions with the polar action sites on CSP and was more easily recognized by CSP. On the other hand, 2-propanol possesses larger spatial volume than methanol, which is frustrated in the process of being recognized by CSP. Comparatively, methanol was more capable of separating flutriafol enantiomers. The effects of percentage of methanol on the retention and resolution are shown in Table 1. When methanol content increased from 6 to 15%, the retention time (RT) of flutriafol enantiomers was gradually shortened, and Rs was gradually decreased, whereas $\alpha$ remained almost unchanged. Thus, $CO_2$/methanol (88:12, v/v) was chosen as the mobile phase because of the relatively better resolution (2.40) and shorter retention (2.95, 3.32 min) (Figure 2). It exhibits an approximately 6-fold reduction in the retention time compared with a previous study.[23]

*Flow Rate of the Mobile Phase.* On the basis of the mobile phase of $CO_2$/methanol (88:12, v/v), the effects of flow rate of the mobile phase became another consideration. It was found that different flow rates of mobile phase gave rise to the change of retention time and resolution. As shown in Figure 2A, the

**Table 1. Effects of Percentage of $CO_2$ and Methanol on the Enantioseparation of Flutriafol, Concerning the Retention Time (RT), Separation Factor ($\alpha$), and Resolution (Rs)[a]**

| percentage in mobile phase (%) | | | RT | | | |
|---|---|---|---|---|---|---|
| $CO_2$ | methanol | total | (−)-*R*-flutriafol | (+)-*S*-flutriafol | $\alpha$ | Rs |
| 85 | 15 | 100 | 2.37 | 2.65 | 1.18 | 2.06 |
| 88 | 12 | 100 | 2.95 | 3.32 | 1.18 | 2.40 |
| 90 | 10 | 100 | 3.50 | 3.98 | 1.18 | 2.61 |
| 92 | 8 | 100 | 4.61 | | | |
| 94 | 6 | 100 | | | | |

[a]Flow rate, 2.2 mL/min; temperature, 30 °C; ABPR, 2200 psi; flow rate of compensation solvent (1% formic acid/methanol), 0.1 mL/min.

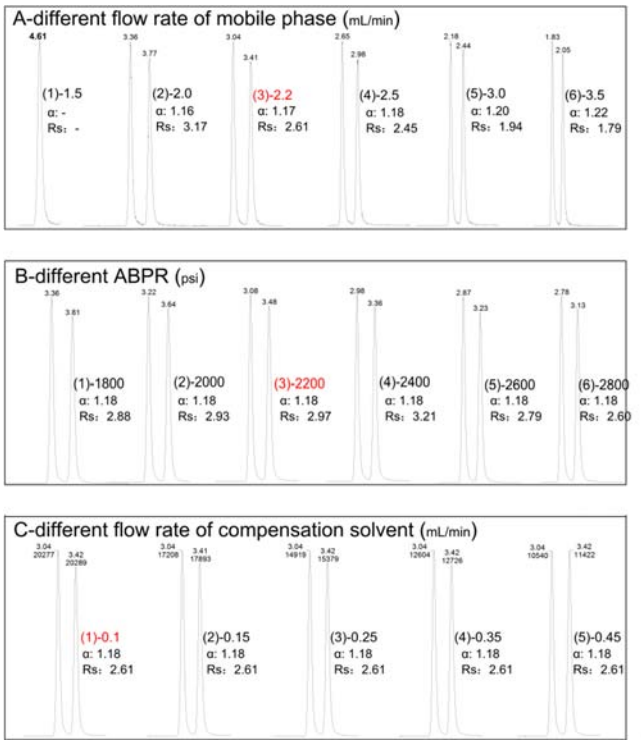

**Figure 2.** Comparison of effects of different parameters (A, flow rate of mobile phase; B, ABPR; and C, flow rate of compensation solvent) on the enantioseparation of flutriafol enantiomers, concerning the retention time (RT), separation factor ($\alpha$), resolution (Rs), and peak areas.

RT for flutriafol enantiomers was gradually shortened; meanwhile, Rs was lowered as the flow rate of the mobile phase increased from 1.5 to 3.5 mL/min. The effect of the flow rate of the mobile phase on resolution is due to changes in efficiency. That is relatively complicated in the SFC system because of the density gradient of the mobile phase along the column, which changes a lot as the flow rate varies. With better resolution (2.61) and relatively centered retention time (3.04, 3.41 min), the flow rate of 2.2 mL/min was selected for further study.

*ABPR Pressure.* The ABPR settings affect retention time by changing the density of the mobile phase before the release of pressure. To evaluate the effect of pressure on chromatographic separation for flutriafol enantiomers, ABPR was stepwise increased from 1800 (124 bar) to 2800 psi (193 bar) with 200 psi increments. The increase in ABPR resulted in a decrease in retention time and an increase in resolution, especially when it was below 2400 psi, but it had no impact on separation factor (Figure 2B). However, higher pressure is of no benefit to the usage lifetime of the chiral columns according to the instructions. Comprehensive consideration, 2200 psi, resulting in shorter retention and better resolution, was selected.

*Flow Rate of the Compensation Pump Solvent.* The pump was provided with compensation solution, commonly used 1% formic acid/methanol, which could improve ionization intensity to some extent. Efforts were made to investigate the effects of different flow rates of the compensation pump solvent in the range of 0.1−0.45 mL/min on resolution, retention, and peak area. Figure 2C shows that an increase in the flow rate had no influence on the retention and resolution of flutriafol enantiomers, but the peak areas for flutriafol enantiomers gradually decreased as the flow rate increased. That is because increased flow rate of compensation solvent results in a decrease of the amount of active ingredients that entered into the mass spectrum. Hence, for those compounds with low sensitivity, it is better to appropriately lower the flow rate to obtain higher signal response values. Less organic solvent and higher peak area made 0.1 mL/min the obvious choice in this experiment.

*Column Temperature.* Column temperature has been one of the important factors for optimization of chiral separations.[5,22,24,25] In this study, the chiral separation for flutriafol enantiomers was conducted with stepwise increases of column temperature from 30 to 40 °C under supercritical fluid state with 5 °C increments. The influence of temperature on the chiral separation of flutriafol enantiomers was relatively slight. It turned out that an increase in column temperature resulted in long retention and better resolution, which is the opposite of what was found in a previous HPLC study.[26] That is ascribed to the fact that as the column temperature increases, followed by decreases in the mobile phase density and reductions in the solvating power of mobile phase, the retention of analytes increases.[27] Therefore, the supercritical fluid can never be treated as normal state, such as liquid or gas, and should be given further investigation in later study. Considering the short retention time and relatively better separation, 30 °C was selected as the optimal temperature in this experiment.

**Elution Order of Flutriafol Enantiomers.** The two optically pure isomers of flutriafol were methodically collected by preparative chromatography. Then optical rotation of each isomer was determined on the basis of the same instrument conditions as in a previous study.[22] Each single isomer and racemic flutriafol were individually subjected to SFC-MS/MS determination under the same chromatographic conditions as mentioned in the above section. It turned out that the elution order of flutriafol was (−)-*R*-flutriafol and (+)-*S*-flutriafol in this study, respectively (Figure 1), which is exactly the same as in previous research using normal-phase liquid chromatography (NPLC).[8]

**Optimization of Cleanup Sorbents.** QuEChERS methodology, involving a streamlined procedure prior to sample analysis, has been widely employed because of its outstanding merits including simplicity, high throughput, and lower costs.[28−31] In this work, the effects of different types of sorbents on recovery and purification in different matrices were evaluated. Five types of sorbents for vegetables and fruits were investigated, including PSA (50 mg), C18 (50 mg), GCB (30 mg), and two kinds of sorbent mixtures (40 mg of PSA + 10

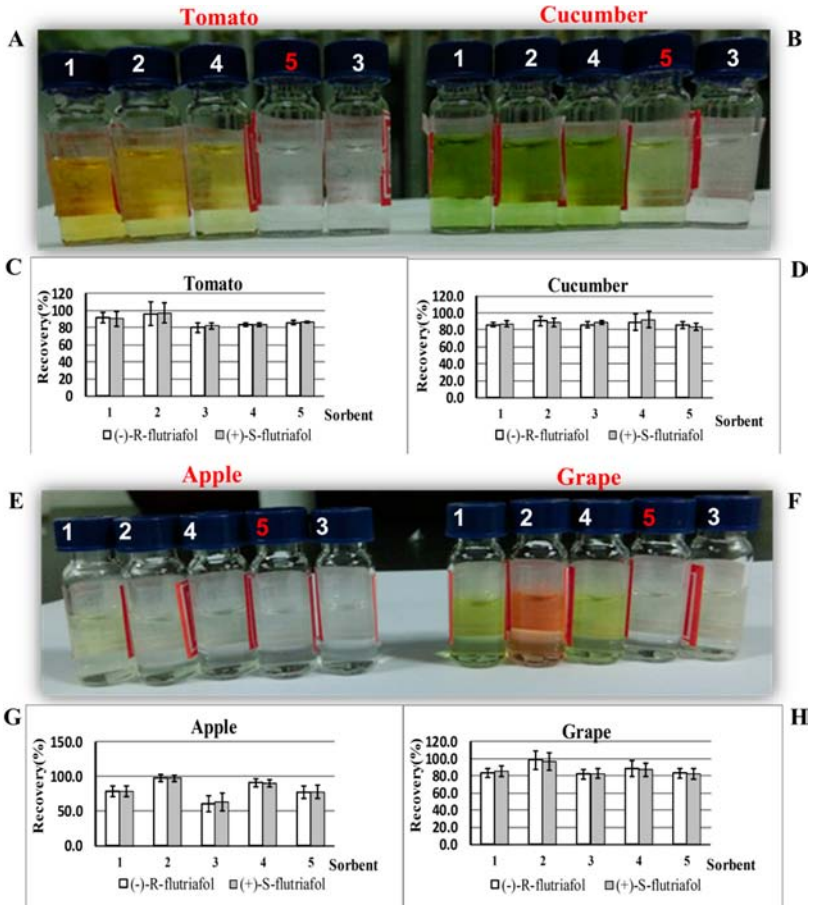

**Figure 3.** Effects of different sorbents on recoveries for flutriafol enantiomers (C, tomato; D, cucumber; G, apple; and H, grape) and purification performances in different matrices (A, tomato; B, cucumber; E, apple; and F, grape) at 100 $\mu$g/kg level ($n$ = 5). Sorbents 1, 2, 3, 4, 5, and 6 refer to 50 mg of PSA, 50 mg of C18, 30 mg of GCB, 40 mg of PSA + 10 mg of C18, and 40 mg of PSA + 10 mg of GCB, respectively. The number on the cap of each vial represents the corresponding sorbent.

[a]Slope ratio = matrix/ACN. [b]Matrix effect (%) = ((slope matrix − slope solvent)/slope solvent) × 100.

mg of C18 and 40 mg of PSA + 10 mg of GCB). Considering the particular characteristics of soil, four types of sorbents were made for a comparison, 40 mg PSA, 50 mg PSA, 50 mg C18, and 20 mg GCB. The influence of different sorbents on recoveries for flutriafol enantiomers and purification effects is shown in Figure 3.

As illustrated in Figure 3C,D,G,H, for vegetables and fruits, almost all tested types of sorbents exhibited satisfactory recoveries except for sorbent 3 (30 mg of GCB) applied to apple (G) with a recovery of approximately 60%. However, from Figure 3A,B,E,F, the purifying performance visually observed by the color varied with sorbents, and sorbents 5 (40 mg of PSA + 10 mg of GCB) and 3 (30 mg of GCB) exerted better cleanup effects compared with other sorbents for tomato, cucumber, and grape. Although treatment with sorbent 2 showed best recoveries, the purifying performance was not so

good. Sorbent 3 exhibited an excellent cleanup effect, but poor recovery appeared in the treatment of apple matrix. Taking all of the factors into consideration, sorbent 5 (both satisfactory recoveries and purifying effect) was selected for vegetables and fruits. As for soil, all four tested types of sorbents exhibited satisfactory recoveries (78.9−95.8%). Comparatively, 50 mg of C18, the cheapest one, was chosen as the optimal sorbent. Compared with a previous paper,[23] it exhibits an approximately 6-fold reduction in terms of organic solvent consumption in the sample pretreatment procedure.

**Method Validation.** *Specificity and Linearity.* Blank samples of different matrices were applied to evaluate the specificity of the presented method, and no interference occurred at the retention time. Linear regression analysis was performed with the concentration range at 2.5−500 $\mu$g/L for each enantiomer. The standard solution and matrix-matched calibration curves (acetonitrile, tomato, cucumber, apple, grape, and soil) for each enantiomer are summarized in Table 2, including the slopes, intercepts, and coefficients of determination ($R^2$). Excellent linearities were observed for two enantiomers ($R^2 \geq 0.9990$ in all cases).

*LODs, LOQs, and Matrix Effect.* In this work, the LODs for both enantiomers were estimated at 0.12−0.35 $\mu$g/kg, whereas the corresponding LOQs were 0.41−1.18 $\mu$g/kg based on five replicated extractions and analyses of five spiked samples at low concentration levels. More than 40-fold sensitivity enhancement of the method was obtained compared with a previous study.[23] As is well-known, the occurrence of matrix effects is regarded as a major drawback in the analysis of pesticide residues in complex samples by liquid chromatography−mass spectrometry (LC-MS).[32] In the present study, the matrix effect was investigated in tomato, cucumber, apple, grape, and soil by comparing the standards in the solvent with the matrix-matched standards. It was considered to be a strong effect of signal suppression or enhancement when the values of matrix effects were below −50% or above +50%.[33] Data in Table 2 indicate strong signal enhancement for flutriafol enantiomers in five matrices with the slope ratios of matrix/ACN in a range of 1.62−2.07, and the matrix effects were between 61.8 and 107.1%. In this study, a calibration was performed for flutriafol enantiomers using external matrix-matched standards to eliminate the matrix effect to obtain more accurate and realistic results for all samples.

*Accuracy, Precision, and Stability.* Each blank sample matrix was spiked with racemic flutriafol at three concentration levels (10, 100, and 500 $\mu$g/kg) and then analyzed in quintuplicate. The precision and accuracy were expressed by the RSD (%) and the recovery (%) of spiked samples, respectively. The repeatability RSD[a] was calculated by comparing the standard deviation of recoveries of spiked samples injected on the same day (intraday). The reproducibility RSD[b] was measured by analyzing the standard deviation of recoveries of spiked samples injected on three different days (interday). As shown in Table 3, the method presented satisfactory recoveries (77.2−98.9%) and precision, with all RSDs below 9.6% at the three spiked concentration levels. For (+)-*S*-flutriafol, the intraday and interday recoveries for all five samples were 77.8−92.7 and 78.0−90.8%, with 0.9−9.5% RSD[a] (intraday RSD) and 1.6−8.6% RSD[b] (interday RSD), respectively, whereas they were 77.2−91.8% with 2.0−9.6% RSD[a] (intraday RSD) and 81.8−98.9% with 2.3−12.6% RSD[b] (interday) for (−)-*R*-flutriafol. In general, RSD[a] ($n$ = 5) ranged from 0.9 to 9.6% and RSD[b] ($n$ = 3) from 1.6 to 8.2%. Therefore, it is concluded that the proposed method and the SFC-MS/MS enantioselective analysis can achieve satisfactory accuracy and precision for the enantiomeric analysis in tomato, cucumber, apple, grape, and soil.

The stability of the stock solutions was tested monthly by injection of a newly prepared working standard solution. The spiked samples (tomato, cucumber, apple, grape, and soil, 100 $\mu$g/kg) for flutriafol were evaluated monthly, and all of the samples used in the stability test were stored at −20 °C. The

final results of the stability tests showed that no significant difference was observed ($P > 0.05$) during the solvent and matrix storage treatment as described under Materials and Methods.

*Application to Real Samples.* To ascertain its applicability, the validated SFC-MS/MS method was applied to analyze five kinds of matrix samples obtained from our residual trial field (Langfang, China, collected at 2 h after spaying commercial flutriafol formulation (25% flutriafol suspending agent at the dose of 225 g ai/hm$^2$) and local market (Beijing, China). Neither enantiomer of flutriafol was detected in all samples from the local market. (−)-*R*-Flutriafol and (+)-*S*-flutriafol in tomato, cucumber, apple, grape, and soil samples from the trial field were detected in the concentrations of 56.3 ± 3.1 and 57.4 ± 4.0, 86.5 ± 5.2 and 86.8 ± 3.9, 101.2 ± 6.7 and 102.1 ± 5.9, 130.4 ± 9.0 and 131.1 ± 8.4, and 109.8 ± 8.6 and 109.3 ± 7.8 μg/kg, respectively.

In this work, upon the primary evaluation of the SFC-MS/MS technique, a novel and rapid quantitative method for flutriafol enantiomers in tomato, cucumber, apple, grape, and soil has been established and validated. On the basis of the QuEChERS method, target compounds were extracted and purified and then analyzed using the chiral SFC-MS/MS in the ESI$^+$ mode. This work provides a novel and green chiral analytical method for the determination of flutriafol enantiomers in plants and environmental matrices. Importantly, the combination of SFC with MS greatly improves the sensitivity compared with previous research on flutriafol enantiomers. With good mean recoveries, excellent linearities, and satisfactory accuracy and precision, it could be selected as a suitable qualitative and quantitative alternative compared to existing complex and time-consuming methods. This rapid method facilitates further studies of the environmental behavior of each enantiomer of flutriafol and will finally help minimize the risks posed by this fungicide to humans, animals, and the environment.

oxidase-A inhibitors,[11] antioxidants,[12−14] fungal membrane $H^+$ ATPase inhibitors,[15] and α-glucosidase inhibitors[16,17] direct from crude extracts of medicinal plants, endophytic fungi, and food.

For high-resolution α-amylase inhibition profiling of plant extracts, a sensitive, stable, and cheap assay that can be performed in microplates is needed. Most studies reported so far have been based on colorimetric measurements of reducing sugars by reaction with dinitrosalicylic acid (DNS method) or blue starch−iodine complexes formed between iodine and starch polymers.[18,19] Both methods use cheap reagents but are experimentally time-consuming and rely on secondary chemical processes to occur (i.e., reaction with DNS and formation of starch−iodine complexes). Direct assessment of α-amylase activity can be performed by colorimetric measurement of the formation of chromophores like 2-chloro-4-nitrophenolate and *p*-nitrophenolate by cleavage of substrates like 2-chloro-4-nitrophenyl-α-maltotrioside (CNP-G3) and *p*-nitrophenyl-α-D-maltoheptaoside (PNP-G7), respectively.[19,20] The 2-chloro-4-nitrophenyl chromophore hydrolyzes 10 times faster than the corresponding 4-nitrophenyl group, and α-amylase assays based on the former are therefore more sensitive.[20,21] In this work the development of a high-resolution microplate-based α-amylase inhibition assay using 2-chloro-4-nitrophenyl-α-D-maltotrioside as substrate is described. The aim is to implement a stable, cheap, and sensitive α-amylase assay suitable for fast and efficient high-resolution α-amylase profiling in combination with HPLC−SPE−NMR for analysis of α-amylase inhibitors in plant extracts with presumed anti-diabetic effect.

## EXPERIMENTAL SECTION

**Chemicals.** α-Amylase type VI-B (E.C. 3.2.1.1, from porcine pancreas, lyophilized powder), 2-chloro-4-nitrophenyl-α-D-maltotrioside (CNP-G3), sodium chloride, sodium azide, dimethyl sulfoxide (DMSO, ≥99.5%), acarbose, (−)-epicatechin, brucine, luteolin, myricetin, coumarin, trolox, and HPLC-grade acetonitrile were purchased from Sigma-Aldrich (St. Louis, MO). Calcium acetate and formic acid were purchased from Merck (Darmstadt, Germany), HPLC-grade methanol for extraction of cinnamon was from Fischer Scientific (Leicester, UK), and methanol-$d_4$ (99.80% D, less than 0.03% water) was from Euriso-top (Saint-Aubin Cedex, France). Cinnamon (*Cinnamomum verum* Presl) was purchased from Urtekram (Mariager, Denmark). Water was purified by 0.22 μm membrane filtration and deionization (Millipore, Billerica, MA).

**Extraction and Sample Preparation.** The stock solution of the artificial mixture consisted of 5 g/L brucine, 5 g/L coumarin, 2.5 g/L trolox, 0.875 g/L luteolin, 0.875 g/L myricetin, and 1.25 g/L (−)-epicatechin in a 1:1 mixture of HPLC solvents A and B, *vide infra*. Crude methanol extract of cinnamon was prepared by extracting 1 g of ground material with 10 mL of solvent at room temperature overnight. The extract was filtered (45 μm filter fitted to a 10 mL syringe) and evaporated to dryness. The dry extracts were reconstituted in phosphate buffer (pH 6.0) containing 10% DMSO to a concentration of 20 mg/mL. Ten-fold dilutions were performed 12 times for $IC_{50}$ determinations.

**Development of α-Amylase Assay.** The α-amylase assay was performed in 96-well microplates using a final volume of 200 μL. Unless otherwise stated, experiments were performed with phosphate buffer (0.1 mM) containing 0.02% $NaN_3$ and adjusted to pH 6.0 with 2.0 M phosphoric acid. Stock solutions of α-amylase and CNP-G3 in phosphate buffer were prepared at concentrations of 2.0 U/mL and 10.0 mM, respectively. To all wells were added 175 μL of buffer and 5 μL of enzyme solution (final well concentration 0.05 U/mL), and the microplate was subsequently incubated for 10 min. The reaction was started by addition of 20 μL of substrate solution (final well concentration 1.0 mM), whereafter the absorbance was measured at 405 nm every third minute for 30 min. Preincubation, incubation, and absorbance measurements were performed with a Multiscan FC microplate photometer with built-in incubator (Thermo Scientific, Waltham, MA) coupled to SkanIt version 2.5.1 software for data acquisition. Cleavage rates were obtained by plotting the absorbance values as a function of time using Microsoft Excel 2010 for slope calculations. Optimal concentrations of $Ca^{2+}$, $Cl^-$, and DMSO as well as optimal pH and temperature were assessed by measuring enzyme activities for the following array of parameter changes (in addition to above-described protocol): sodium chloride = 0, 10, 20, 30, 40, 50, 60, 70, 80, 90, and 100 mM; calcium acetate (using 60 mM sodium chloride) = 0, 0.5, 1.0, 2.0, and 2.5 mM; DMSO (using 60 mM sodium chloride and 1 mM calcium acetate) = 0, 2, 4, 6, 8, 10, 12, 14, 16, 18, and 20% v/v; temperature = 25, 28, 31, 34, 37, and 40 °C; pH = 5.0, 5.5, 5.7, 6.0, 6.3, 6.7, 7.0, and 7.5 (using 2.0 M phosphoric acid or 2.0 M NaOH for adjustment of buffer). Stability of the α-amylase enzyme was assessed for a period of 8 weeks. Stock solution of 20 U/mL enzyme in buffer (60 mM sodium chloride, 1 mM calcium acetate, pH 6.0) was dispersed in 600 μL aliquots and stored at −18 °C. The first measurement at day 0 was performed on a non-frozen enzyme solution; the remaining measurements were performed using thawed stock solutions diluted to 2.0 U/mL as above. Enzymatic activity of α-amylase was subsequently assessed three times per week for 2 weeks and then once a week for an additional 6 weeks. For comparison of kinetic vs end point measurements (using 5% DMSO, 60 mM sodium chloride, 1 mM calcium acetate, and pH 6.0), absorbance was measured at 405 nm every third minute for 30 min after addition of substrate. Subsequently the pH was adjusted to 12 by addition of 13 μL of 4 M NaOH solution, and the absorbance was measured for an additional 30 min.

**HPLC Separations and High-Resolution α-Amylase Inhibition Chromatograms.** HPLC separations were performed on an Aglient 1200 series instrument (Santa Clara, CA) consisting of a G1311A quaternary pump, a G1322A degasser, a G1316A thermostated column compartment, a G1315C photodiode-array detector, a G1367C high-performance auto sampler, and a G1364C fraction collector, all controlled by Agilent ChemStation version B.03.02 software. Analyses were performed at 40 °C on a 150 × 4.6 mm i.d. Phenomenex Luna $C_{18}(2)$ reversed-phase column (3 μm particle size, 100 Å pore size) with a flow rate of 0.5 mL/min. HPLC solvent A consisted of water−acetonitrile 95:5 added 0.1% formic acid, and solvent B consisted of acetonitrile−water 95:5 added 0.1% formic acid. For high-resolution α-amylase inhibition profiling, 10 μL of the artificial mixture was separated using the following gradient elution profile: 0 min, 5% B; 20 min, 70% B; 23 min, 70% B; 24 min, 5% B; 35 min, 5% B. The column eluate from 7.5 to 20 min was fractionated into one 96-well microplate (Sterilin Limited, Aberbargoed Caerphilly, United Kingdom) using the eight wells in column 12 as blank controls, yielding a resolution of 7 points per min. The microplates were subsequently evaporated to dryness using a SPD121P Savant SpeedVac concentrator (Thermo Scientific, Waltham, MA) equipped with an OFP400 oil-free pump and a RVT400 refrigerated vapor trap. α-Amylase cleavage rates (kinetic measurements) were measured for each well as described above (using 10% DMSO, 60 mM sodium chloride, 1 mM calcium acetate, pH 6.0), and inhibition was calculated using the formula

$$\%\ \text{inhibition} = \left(\frac{\text{slope}_{\text{blank}} - \text{slope}_{\text{sample}}}{\text{slope}_{\text{blank}}}\right) \times 100\%$$

Inhibition for each well was plotted at its respective retention time as an α-amylase inhibition profile underneath the HPLC chromatogram.

**Validation of HPLC Method for Separation of Artificial Mixture.** The HPLC method described above was used for the quantification of individual constituents in the artificial mixture and validation of linearity, sensitivity (limit of detection, LOD, and limit of quantification, LOQ), and precision (intra- and inter-day). The linearity was assessed using regression analysis of standard curves (254 nm) obtained from injection of 10 μL of a complex mixture containing brucine, coumarin, trolox, luteolin, myricetin, and epicatechin. Thus, a

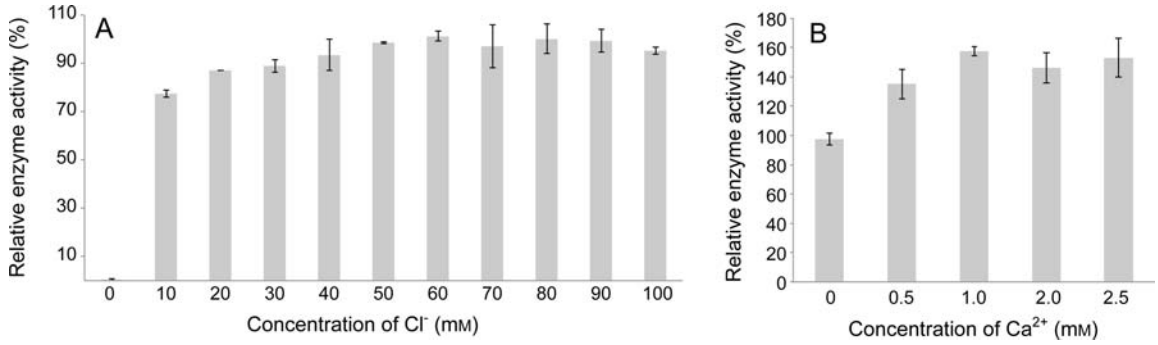

**Figure 1.** (A) Relative enzyme activity at different chloride ion concentrations. The enzyme activity in buffer containing 60 mM $Cl^-$ is normalized to 100%. (B) Relative enzyme activities at calcium ion concentrations in the range 0−2.5 mM. Data represent mean ± standard deviation of three replicate measurements.

stock solution containing 5 g/L brucine, 5 g/L coumarin, 2.5 g/L trolox, 0.875 g/L luteolin, 0.875 g/L myricetin, and 1.25 g/L (−)-epicatechin in a 1:1 mixture of HPLC solvents A and B was diluted two-fold 12 times with the same solvent mixture. The HPLC calibration curves were constructed by plotting the peak area ($A$) against the concentration of each standard solution ($c$) of each compound. The data were used for determining LOD (S/N = 3) and LOQ (S/N = 10). Precision of the method was determined after injection of 10 $\mu$L of the artificial mixture containing 200, 150, and 100 mg/L of each compound. The analysis was performed in quadruplicate on day 1 (intra-day precision) and for five additional days (inter-day precision). Results are expressed in %RSD (= SD/average) of the instruments.

**HPLC−HRMS−SPE−NMR Analysis.** Chromatographic separation of a 19.8 mg/mL solution of crude extract of cinnamon was performed using an Agilent 1200 system (Santa Clara, CA) comprising a photodiode-array detector, an autosampler, a quaternary pump, a degasser, and a thermostated column compartment, using the same column, solvent composition, temperature, and gradient profile as described above. A small proportion (1%) of the HPLC eluate was directed to a micrOTOF-Q II mass spectrometer (Bruker Daltonik GmbH, Bremen, Germany) equipped with an electrospray ionization interface. Mass spectra were acquired in positive-ion mode, using a drying temperature of 200 °C, capillary voltage of 4100 V, nebulizer pressure of 2.0 bar, and drying gas flow of 7 L/min. A solution of sodium formate clusters was automatically injected at the beginning of each run to enable internal mass calibration. The rest of the HPLC eluate was directed to the photodiode array detector and subsequently to a Prospekt 2 SPE unit (Spark Holland, Emmen, The Netherlands). Cumulative SPE trappings of individual analytes were performed for five consecutive injections (10 $\mu$L/injection) using absorption threshold at 254 nm to trigger analyte trapping. Chromatography, peak trapping, and analyte transfer from the SPE unit were controlled with HyStar version 3.2 software (Bruker Biospin GmbH, Rheinstetten, Germany). The HPLC eluate was diluted with Milli-Q water at a flow rate of 1.0 mL/min prior to trapping on 10 × 2 mm i.d. resin GP (general purpose, 5−15 $\mu$m, spherical shape, polydivinylbenzene phase) SPE cartridges from Spark Holland (Emmen, The Netherlands). After being dried for 45 min with pressurized nitrogen gas, analytes were automatically eluted into 1.7 mm o.d. NMR tubes (96 position tube racks) with methanol-$d_4$ using a Gilson liquid handler controlled by PrepGilson version 1.2 software (Bruker Biospin). NMR experiments were performed with a Bruker Avance III system ($^1$H operating frequency of 600.13 MHz) equipped with a Bruker SampleJet sample changer and a cryogenically cooled gradient inverse triple-resonance 1.7 mm TCI probe-head (Bruker Biospin) optimized for $^1$H and $^{13}$C observation. Icon NMR version 4.2 software (Bruker Biospin) was used for controlling automated acquisition of NMR data, and processing of NMR data was performed using Topspin version 3.0 software (Bruker Biospin). All NMR spectra were recorded in methanol-$d_4$ at 300 K. $^1$H and $^{13}$C chemical shifts were referenced to the residual solvent signal ($\delta$ 3.31 and $\delta$ 49.00, respectively). A one-dimensional $^1$H NMR spectrum was acquired in automation (temperature equilibration to 300 K, optimization of lock parameters, gradient shimming, and setting of receiver gain) with 30° pulses, 3.66 s inter-pulse intervals, 64k data points, and multiplied with an exponential function corresponding to line-broadening of 0.3 Hz prior to Fourier transform. Phase-sensitive DQF-COSY and NOESY spectra were recorded using a gradient-based pulse sequence with a 20 ppm spectral width and 2k × 512 data points (processed with forward linear prediction to 1k data points). A multiplicity-edited HSQC spectrum was acquired with the following parameters: spectral width 20 ppm for $^1$H and 200 ppm for $^{13}$C, 2k × 256 data points (processed with forward linear prediction to 1k data points), and 1.0 s relaxation delay. HMBC spectrum was optimized for $^nJ_{C,H}$ = 8 Hz and acquired using the following parameters: spectral width 20 ppm for $^1$H and 240 ppm for $^{13}$C, 2k × 128 data points (processed with forward linear prediction to 1k data points), and 1.0 s relaxation delay.

## RESULTS AND DISCUSSION

This work describes development and optimization of a direct colorimetric $\alpha$-amylase inhibitory assay based on cleavage of 2-chloro-4-nitrophenyl-$\alpha$-D-maltotrioside (CNP-G3), its implementation in microplates for high-resolution inhibition profiling, and its combination with HPLC−HRMS−SPE−NMR for fast and efficient identification of $\alpha$-amylase inhibitors in medicinal plant and functional food extracts with a presumed anti-diabetic effect. Porcine pancreatic $\alpha$-amylase and CNP-G3 were chosen as enzyme and substrate, respectively, in the current work because they are relatively cheap compared to human $\alpha$-amylase and maltopentaoside/maltoheptaoside substrates—an important factor for the use of high-resolution $\alpha$-amylase inhibition assays as a routine method in natural products and functional food research.

**Development and Optimization of $\alpha$-Amylase Bioassay with 2-Chloro-4-nitrophenyl-$\alpha$-D-maltotrioside Substrate.** Development and optimization of the $\alpha$-amylase inhibition assay using 2-chloro-4-nitrophenyl-$\alpha$-D-maltotrioside as substrate were based on the assay previously described.[20,21] The optimization and microplate-based adaptation ensure a sensitive, robust, and reproducible setup that is suitable for high-resolution $\alpha$-amylase inhibition profiling and further coupling with HPLC−HRMS−SPE−NMR. Initial experiments were performed with 0.1 mM phosphate buffer (pH 6.0) containing 0.02% $NaN_3$ and 0.05 U/mL $\alpha$-amylase (final well concentration). $NaN_3$ was added as a preservative it has been reported that $NaN_3$ in the buffer contributes to improvement of the enzyme activity as well.[20] After 10 min incubation, CNP-G3 (1.0 mM) was added to start the reaction, whereafter the absorbance was measured at 405 nm every third minute for 30

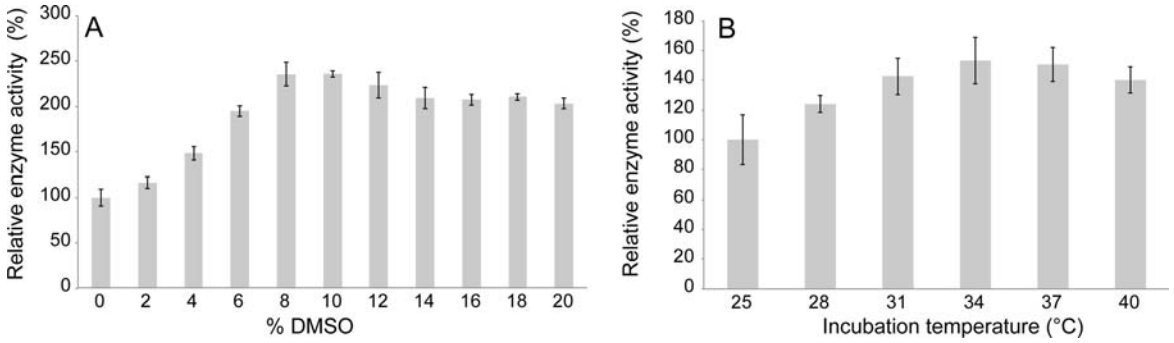

**Figure 2.** (A) Relative enzyme activities at different DMSO concentrations. The enzyme activity in buffer containing 0% DMSO is normalized to 100%. (B) Relative enzyme activities at different temperatures. The enzyme activity at 25 °C normalized to 100%. Data represent mean ± standard deviation of three replicate measurements.

**Table 1. Parameters for Validation of the HPLC Method for the Reference Compounds**

| | | precision (%RSD)[a] | | | sensitivity ($\mu$g) | |
|---|---|---|---|---|---|---|
| compound | amount on-column ($\mu$g) | intra-day | inter-day | linearity[b] | LOD | LOQ |

[a] $n = 4$. [b] $A$ = peak area; $c$ = concentration of reference compound; $r$ = correlation coefficient.

min to obtain cleavage rates. Chloride ions are necessary for activation of the enzyme's hydrolyzing property,[22] and sodium chloride was therefore added to the phosphate buffer in concentrations of 0−100 mM. As seen in Figure 1A, the maximal enzyme activity was reached at 60 mM NaCl, and no further increase in enzyme activity was observed at higher concentrations. Likewise, calcium is required to stabilize and activate the enzyme,[23] and therefore calcium acetate was added to the buffer in concentrations of 0−2.5 mM. As seen in Figure 1B, maximal enzyme activity was achieved at a calcium acetate concentration of 1.0 mM. Thus, further experiments were performed with 0.1 mM phosphate buffer containing 60 mM sodium chloride, 1.0 mM calcium acetate, and 0.02% $NaN_3$.

The microplate-based $\alpha$-amylase inhibition assay used in a HPLC microfractionation setting requires subsequent evaporation of the HPLC solvent to allow use of high amount of organic solvent in the elution solvent. Subsequent dissolution in the above-described buffer containing DMSO improves dissolution of lipophilic constituents, but high amounts of DMSO are known to interfere with enzymes. Thus, the activity of $\alpha$-amylase was assessed with DMSO concentrations in the range 0−20%, as seen in Figure 2A. Maximum enzyme activity was achieved at 10% DMSO, i.e., a 2-fold increase in activity compared to that with no DMSO in the buffer DMSO did not decrease enzyme activity of porcine pancreatic $\alpha$-amylase dramatically at the tested concentrations. This confirms the robustness of porcine pancreatic $\alpha$-amylase in the presence of DMSO as previously described.[24]

The enzyme activities at different temperatures were assessed to determine the optimal incubation temperature, but also to

ensure enzyme stability during preincubation as well as incubation. As seen in Figure 2B, enzyme activity increased significantly from 25 to 34 °C, with only a slight decrease at 37 and 40 °C. The enzymatic cleavage rate at 37 °C remained constant during the 30 min of incubation, and 37 °C was therefore chosen as the optimal temperature for all further experiments.

The highest cleavage rate of CNP-G3 with porcine α-amylase was observed at pH 6 (Figure S1, Supporting Information), which is comparable with previous findings of pH optimum for pancreatic and salivary human α-amylase.[20] All results are based on cleavage rates, i.e., the slopes of the absorbance values plotted against measurement times, which (i) makes it possible to monitor the linearity of the reaction during the entire incubation time, and (ii) prevents the need for subtracting background absorbance for analytes that absorbs at 405 nm. However, we also explored the use of end point measurements after 30 min, especially because the increased absorbance of 2-chlorophenol under alkaline conditions might increase the sensitivity of the assay. In Figure S2 in the Supporting Information, the end point measurements at pH 5−7.5, i.e., absorbance measurements at 30 min, are compared with absorbance measurements after basifying all wells to pH 12 after 30 min. It is clear that adjusting the pH to 12 yields an increase in absorbance, with the relative increase being highest at incubation performed at low pH values. For pH 6 the adjustment to pH 12 gives an increase of approximately 20%, but given the potential problems with background absorbance of analytes from HPLC microfractionation, the use of cleavage rates is preferred, and that is what we used for the remainder of this work. A further warning about using end point measurements after adjusting to pH 12 is the autohydrolysis of CNP-G3, as shown in Figure S3 in the Supporting Information. Finally, the stability of α-amylase stored at −18 °C as ready-to-use aliquots of enzyme solution was assessed as a means of avoiding repeated freeze−thaw cycles of crude enzyme. Thus, aliquots corresponding to the amount of enzyme needed for one 96-well microplate were prepared, and the enzyme activity of each of these aliquots was measured for 8 weeks. Figure S4 in the Supporting Information shows that the enzyme had maximum activity within the first 2 weeks, whereafter the enzyme activity decreased. Thus, it is unfortunately not advisable to store porcine α-amylase in solution. With the above-described conditions, (−)-epicatechin, myricetin, and luteolin showed $IC_{50}$ values of 2300 ± 45, 37 ± 4.7, and 33 ± 8.9 μM, respectively.

**Validation of HPLC Method.** A mixture of three compounds with α-amylase inhibitory activity, i.e., (−)-epicatechin (**2**), myricetin (**3**), and luteolin (**4**), and three compounds without α-amylase inhibitory activity, i.e., brucine (**1**), coumarin (**5**), and trolox (**6**), was prepared. A reversed-phase HPLC separation that allowed baseline separation of **1**−**6** in the retention time ($R_t$) range 7.5−20 min was developed. The HPLC method was validated by determining linearity, sensitivity (LOD and LOQ), and precision (intra- and inter-day). The data are given in Table 1 and demonstrate a satisfactory performance of the HPLC method to be used for high-resolution α-amylase inhibition profiling.

**Microplate-Based High-Resolution α-Amylase Inhibition Profiles: Proof-of-Concept with Artificial Mixture.** Using the above-described HPLC method for separation of **1**−**6** (see Figure 3), the HPLC eluate from 7.5 to 20 min was fractionated into 88 wells of a 96-well microplate. The HPLC

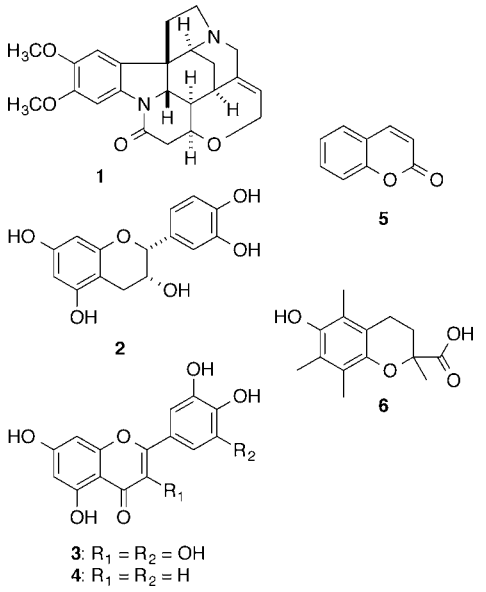

**Figure 3.** Structures of α-amylase inhibitors (−)-epicatechin (**2**), myricetin (**3**), and luteolin (**4**), and inactive constituents brucine (**1**), coumarin (**5**), and trolox (**6**), used for proof-of-concept of the microplate-based high-resolution α-amylase inhibition profiling developed in this work.

solvent was subsequently evaporated, and the α-amylase inhibition assay was performed for all wells as described above. The α-amylase cleavage rate of each well was calculated as percent inhibition (using the average of the last column of the microplate as blank control), and the results were plotted underneath the HPLC trace at 254 nm as well as the trace at 230 nm. The resulting high-resolution biochromatogram with a resolution of 7 data points per minute is shown in Figure 4.

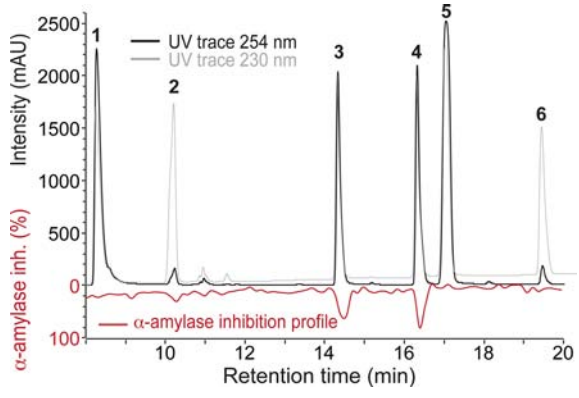

**Figure 4.** High-resolution biochromatogram of α-amylase inhibitors (−)-epicatechin (**2**), myricetin (**3**), and luteolin (**4**), as well as inactive constituents brucine (**1**), coumarin (**5**), and trolox (**6**). Black line: UV trace at 254 nm. Gray line: UV trace at 230 nm. Red line: high-resolution α-amylase inhibition profile.

From the figure it is evident that there is a perfect retention time match between the peaks of (−)-epicatechin (**2**), myricetin (**3**), and luteolin (**4**) in the HPLC chromatogram and the bioactivity peaks in the high-resolution α-amylase inhibition profile—in agreement with these compounds possessing α-amylase inhibitory activity. The weak peak for (−)-epicatechin in the biochromatogram is in agreement with the high $IC_{50}$ value of 2300 μM for **2** compared to the $IC_{50}$

dx.doi.org/10.1021/jf5047283 | J. Agric. Food Chem. 2014, 62, 11465−11471

values of 37 and 33 $\mu$M for **3** and **4**, respectively. Likewise, there are no observable bioactivity peaks corresponding with peaks for brucine (**1**), coumarin (**5**), and trolox (**6**) in the HPLC chromatogram. Thus, this proof-of-concept experiment shows that the high-resolution $\alpha$-amylase inhibition profile is an excellent tool for pinpointing individual constituents with $\alpha$-amylase inhibitory activity—and thereby focusing subsequent dereplication or full-structure elucidation on only the bioactive peaks. The peaks in the high-resolution $\alpha$-amylase inhibition profile are marginally broader than the corresponding peaks in the HPLC chromatogram, which might cause problems with closely eluting peaks. However, if needed, the resolution of the biochromatogram can be increased by fractionating into two 96-well plates and subsequently combining the results from $\alpha$-amylase inhibition assaying of both microplates. However, one should be aware of the lower sensitivity of the $\alpha$-amylase inhibition assay that evidently will follow from fractionating one HPLC peak into more wells in the microplate.

**High-Resolution $\alpha$-Amylase Inhibition Coupled with HPLC−HRMS−SPE−NMR for Analysis of Cinnamon Extract.** Cinnamon has previously been shown to reduce serum glucose, triglyceride, LDL cholesterol, and total cholesterol for type 2 diabetics,[25] and successive extraction with polar to nonpolar solvent showed 50% inhibition of the relative activity of porcine pancreatic $\alpha$-amylase *in vitro* at a concentration of 0.06 mg/mL isopropanol extract.[26] The fractionation might, however, concentrate the active constituent(s), and we therefore wanted to investigate crude extract of cinnamon. A crude methanol extract was prepared, and the $IC_{50}$ value of the crude extract was 0.200 ± 0.061 mg/mL. A total of 25 $\mu$g of crude methanol extract was subjected to analytical-scale reversed-phase HPLC, and the eluate from 11 to 27 min was fractionated into 88 wells (resolution = 5.5 data points per minute). After evaporation to dryness, the $\alpha$-amylase inhibition of each well was determined and plotted at their respective retention times to give the high-resolution biochromatogram shown in Figure 5. It is clearly seen that only the major peak at $R_t$ = 22 min showed $\alpha$-amylase inhibitory activity. Subsequent HPLC−HRMS−SPE−NMR analysis showed the major peak to be cinnamaldehyde (see Supporting Information Table S1 for $^1$H NMR data assignment and Figure S5−S10 for annotated MS, $^1$H NMR, and 2D COSY, NOESY, HSQC, and HMBC spectra obtained in the HPLC−HRMS−SPE−NMR mode).

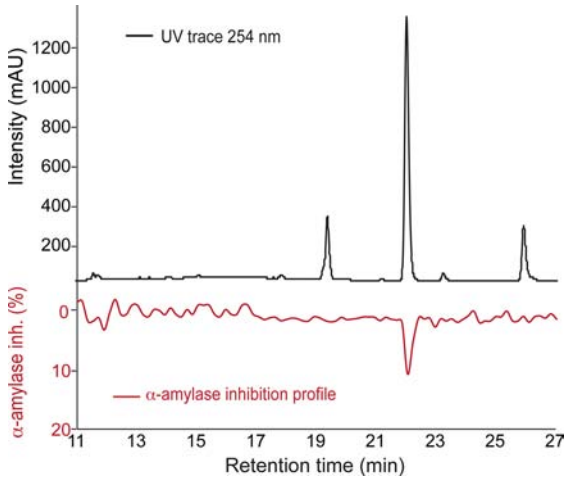

**Figure 5.** High-resolution biochromatogram of crude methanol extract of cinnamon. Black line: UV trace at 254 nm. Red line: high-resolution $\alpha$-amylase inhibition profile.

In conclusion, a microplate-based high-resolution $\alpha$-amylase inhibition assay that is compatible with HPLC−HRMS−SPE−NMR was developed. The proof-of-concept study with an artificial mixture as well as the investigation of crude methanol extract allowed direct identification of $\alpha$-amylase inhibitors by observing correlations between peaks in the high-resolution $\alpha$-amylase inhibition profile and the HPLC chromatogram.

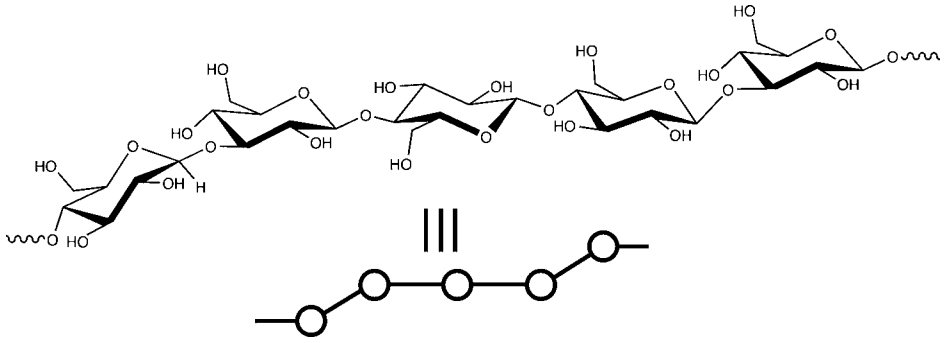

**Figure 1.** Schematic representation of (1→3)(1→4)-$\beta$-glucan with horizontal lines indicating $\beta$(1→4) linkages and diagonal lines indicating $\beta$(1→3) linkages.

stronger at pH 5.3 than at pH 6.5. The data are consistent with a stabilization of bile salt micelles in the presence of $\beta$-glucan due to a stronger multivalent binding of the $\beta$-glucan to bile salt micelles than to the monomers. $^{1}H-^{13}C$ NMR assays thus provide a rapid means for probing interactions between $\beta$-glucan and bile salts with atomic-level resolution.

## EXPERIMENTAL SECTION

**Materials.** Low and medium viscosity barley $\beta$-glucans (Figure 1) were obtained from Megazyme International Ltd. (Bray, Ireland), and these samples have previously been characterized by various physicochemical methods.[13] Briefly, low viscosity $\beta$-glucan had a molecular mass of 140 kDa as determined by high performance size-exclusion chromatography and a calibration curve using five $\beta$-glucan molar mass standard samples. Upon extensive hydrolysis with lichenase, a block structure ($\beta$-(1→4) linked glucopyranoses between $\beta$-(1→3) branches) of approximately 77% DP3, 19% DP4, and 3% DP5 (molar ratio) was derived. Medium viscosity $\beta$-glucan had a molecular mass of 200 kDa and a block structure of approximately 76% DP3, 19% DP4, and 4% DP5. Samples contained less than 1% each of protein or starch. Low viscosity barley $\beta$-glucan was chosen for the experiments monitoring $\beta$-glucan signals in order to improve spectral quality at lower sample viscosity (at high viscosity molecular tumbling rates decrease and NMR signals might become broad due to rapid relaxation). Signal appearance is less of an issue when monitoring the bile salt sample due to the higher achievable concentration, and medium viscosity barley $\beta$-glucan was used in these experiments due to the reportedly higher retention of bile salts by $\beta$-glucan of higher viscosity.[14] Bile salts, glycolate (GC) and taurochenodeoxycholate (TCDC) (Figure 2), along with buffer materials, sodium phosphate and sodium acetate, were obtained from Sigma-Aldrich (St. Louis, MO, USA). Buffers prepared at 100 mM concentration were sodium phosphate buffer of pH 6.5 and sodium acetate buffer of pH 5.3. Buffers were lyophilized and redissolved in $D_2O$ (Cambridge Isotope Laboratories, Tewksbury, MA, USA).

**Sample Preparation.** Low viscosity and medium viscosity barley $\beta$-glucan were dissolved in buffer to concentrations of 0.5, 1, 1.5, or 2% (w/v) and hydrated at 80 °C for 30 min. Stock solutions of bile salt were prepared in buffer, and bile salt was added to $\beta$-glucan samples at the concentrations indicated (3, 7, 10, 14, or 28 mM). Samples containing $\beta$-glucan and bile salts were incubated at 37 °C for 120 min under continuous shaking, and pure bile salt and $\beta$-glucan reference samples, in the absence of the potential interaction partner, were treated identically.

**NMR Spectroscopy.** Upon incubation at 37 °C for 120 min, the samples were directly transferred to 5 mm NMR sample tubes and analyzed by sensitivity-enhanced $^{1}H-^{13}C$ heteronuclear single-quantum correlation[15] (HSQC) experiments with a spectral width in the indirect ($^{13}C$) dimension that was reduced to permit rapid sampling of the $^{13}C$ dimension at high resolution. Experiments treating $\beta$-glucan as the host were recorded with a spectral width of 5 ppm and an offset in the $^{13}C$ dimension of 80 ppm. A total of 75 complex points

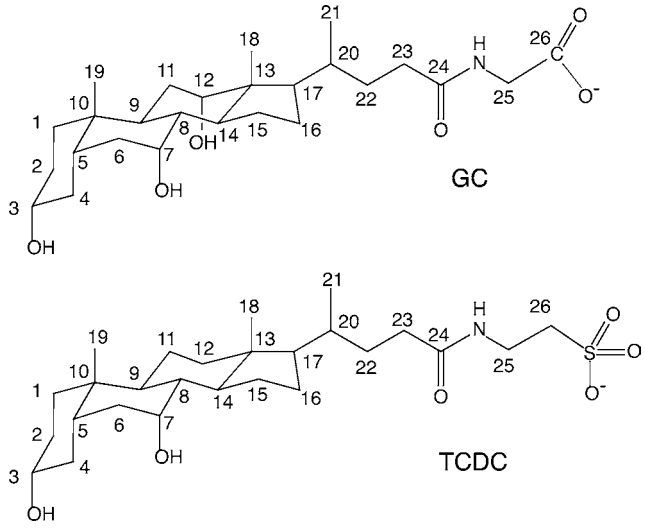

**Figure 2.** Structure of the bile salt molecules glycocholate (GC) and taurochendeoxycholate (TCDC) including their atom numbering.

were recorded in the $^{13}C$ dimension to sample an indirect acquisition time of 75 ms. Experiments treating bile salt as the host were recorded with a spectral width of 20 ppm centered around a spectral offset of 32 ppm. A total of 400 complex points were recorded in the $^{13}C$ dimension to sample an indirect acquisition time of 100 ms. The proton dimension was sampled with 1024 complex data points sampling 160 ms in both instances. Experiment times were 25 min for $^{1}H-^{13}C$ HSQC experiments with $\beta$-glucan as the host and 16 min for $^{1}H-^{13}C$ HSQC experiments with bile salt as the host. A recycle delay of 1 s was employed in each instance. For reference samples of bile salts and $\beta$-glucan, additional $^{1}H-^{13}C$ HSQC experiments were recorded sampling 60 ppm to yield the chemical shift values of the aliased spectral signals. All NMR spectra were recorded on an 800 MHz Bruker (Fällanden, Switzerland) Avance spectrometer equipped with a TCI Z-gradient CryoProbe and an 18.7 T magnet (Oxford Magnet Technology, Oxford, U.K.).

**Data Processing, Assignments, and Analysis.** All spectra were processed in Topspin 2.1 (Bruker) with extensive zero filling in both dimensions. Projections of $^{1}H-^{13}C$ HSQC experiments onto the $^{13}C$ dimension were created as projected spectra between $^{1}H$ chemical shifts of 3.4 and 3.8 ppm. Spectral assignments were obtained from the literature as full chemical shift assignments have been previously reported both for bile salts and for $\beta$-glucan.[16,17] In the fitting of titrations, the NMR signal changes in $\beta$-glucan upon addition of bile salt were treated as a chemical shift difference between individual $\beta$-glucan signals as shown in Figure 4. This treatment provides an internal reference and renders very small chemical shift changes detectable without the need for adding potentially interfering reference compounds. Due to the plethora of equivalent potential binding sites

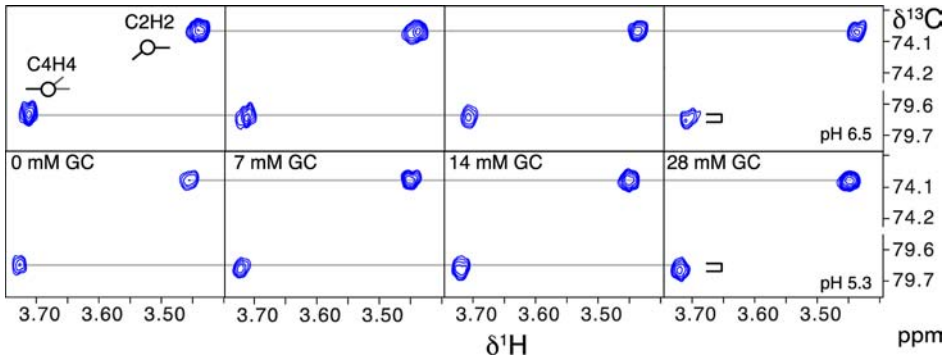

**Figure 3.** $^{1}H-^{13}C$ HSQC spectral region of 2% (w/v) low viscosity $\beta$-glucan (140 kDa) in the presence of increasing concentrations of glycocholate in 100 mM sodium phosphate buffer of pH 6.5 (top) and 100 mM sodium acetate buffer of pH 5.3 (bottom). The two resonances are of a C4H4 in a glycosidic bond and of a C2H2 in a glucopyranosyl unit that has a glycosidic bond at $O_3$. Chemical shift changes are highlighted by horizontal lines.

in $\beta$-glucan, adsorption of bile salts to $\beta$-glucan was treated as a Langmuir adsorption isotherm according to

$$\Delta\delta = \Delta\delta_0 + \Delta\Delta\delta_{max}\frac{c}{K_d + c} \quad (1)$$

where $\Delta\delta$ is the chemical shift difference between two select $\beta$-glucan signals, $\Delta\delta_0$ is the given chemical shift difference in the absence of bile salt, $\Delta\Delta\delta_{max}$ is the maximum change in this chemical shift difference upon saturation with bile salt, $c$ is the concentration of the bile salt, and $K_d$ is the dissociation constant. Fitting to the Langmuir adsorption isotherm was used to qualitatively probe the effect of weakly acidic pH on interactions between $\beta$-glucan and bile salt.

## RESULTS

In the current study, we attempt to probe interactions between $\beta$-glucan (Figure 1) and bile salts (using GC and TCDC as examples, see Figure 2) by $^{1}H-^{13}C$ NMR spectroscopic experiments on the time scale of minutes. The current study is thus aimed at establishing rapid binding assays for polysaccharide–host interactions and at improving the molecular understanding of interactions between $\beta$-glucans and bile salts.

In vitro binding assays were conducted using low viscosity $\beta$-glucan at a concentration of 2% (w/v) as the host and adding glycocholate of varying concentrations (0, 7, 14, and 28 mM). The detection of molecular interactions by probing carbohydrate signals has remained somewhat underexplored, presumably due to the congestion of carbohydrate signals in the $^{1}H$ dimension and the poor sensitivity of $^{13}C$ NMR spectroscopy at natural abundance. This sensitivity restriction is ameliorated by recent generations of NMR spectrometers employing cryogenically cooled detection electronics, by rapid pulsing techniques, or by $^{1}H$ homodecoupling.[18,19] Highly resolved $^{1}H-^{13}C$ spectra of carbohydrates can thus be obtained even at low millimolar concentrations on time scales of minutes or even seconds, especially when using narrow sweep widths in the $^{13}C$ dimension.[20−22] Resultant $\beta$-glucan $^{1}H-^{13}C$ HSQC spectra provided a signal-to-noise ratio above 20 for 2% (w/v) $\beta$-glucan samples within 25 min of experiment time. This signal-to-noise ratio proves sufficient for accurate measurements of $\beta$-glucan signal positions during the titrations with bile salts (Figure 3).

Titration of low viscosity $\beta$-glucan with bile salts yields systematic signal changes in the $\beta$-glucan $^{1}H-^{13}C$ HSQC spectra. Two well-separated signals showing different systematic changes were monitored to probe the interaction of $\beta$-glucan with bile salts (Figures 3, 4). Differences in chemical shift were obtained by peak picking of signals in the two-

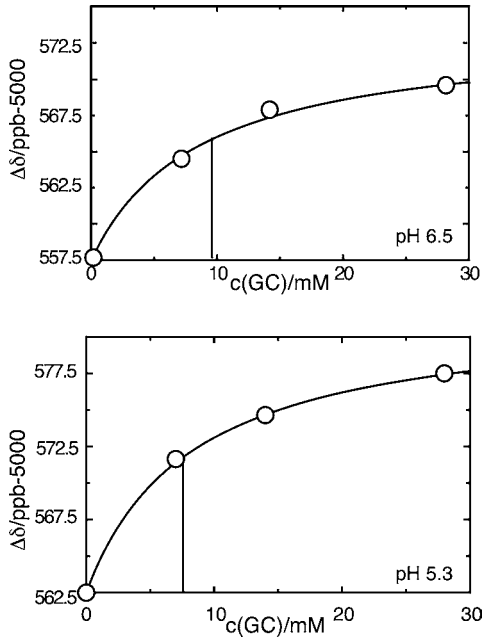

**Figure 4.** Chemical shift change ($\Delta\delta$) between the two $\beta$-glucan resonances displayed in Figure 3 upon addition of increasing glycocholate (GC) concentrations (0, 7, 14, 28 mM) at pH 6.5 (top) and pH 5.3 (bottom). Similar chemical shift trends at pH 5.3 and 6.5 indicate systematic and titration-responsive effects on the $\beta$-glucan signals upon addition of glycocholate. The chemical shift changes are consistent with a lower $K_d$ at pH 5.3.

dimensional experiments. In order to exclude systematic effects due to instabilities of the deuterium lock signal or temperature, the anticipated small chemical shift changes in the titration were measured as the chemical shift difference ($\Delta\delta$) between the two $\beta$-glucan signals. Changes in $\Delta\delta$ up to 15 parts per billion (3 Hz at a $^{13}C$ frequency of 201 MHz) were detected in experiments of 25 min duration. Titrations were conducted at 2 different pH values, 6.5 and 5.3 (Figure 4). Similar trends are observed in the titrations conducted at different pH values, and NMR determinations are consistent with previous in vitro studies with HPLC analysis indicating that the retention of bile salts by $\beta$-glucan-rich oat extrudates is higher near pH 5 than near pH 6.5.[23]

$^{1}H-^{13}C$ HSQC supports the notion of interactions between bile salts and $\beta$-glucan using reasonably rapid assays. The observation of the carbohydrate signal in monitoring guest

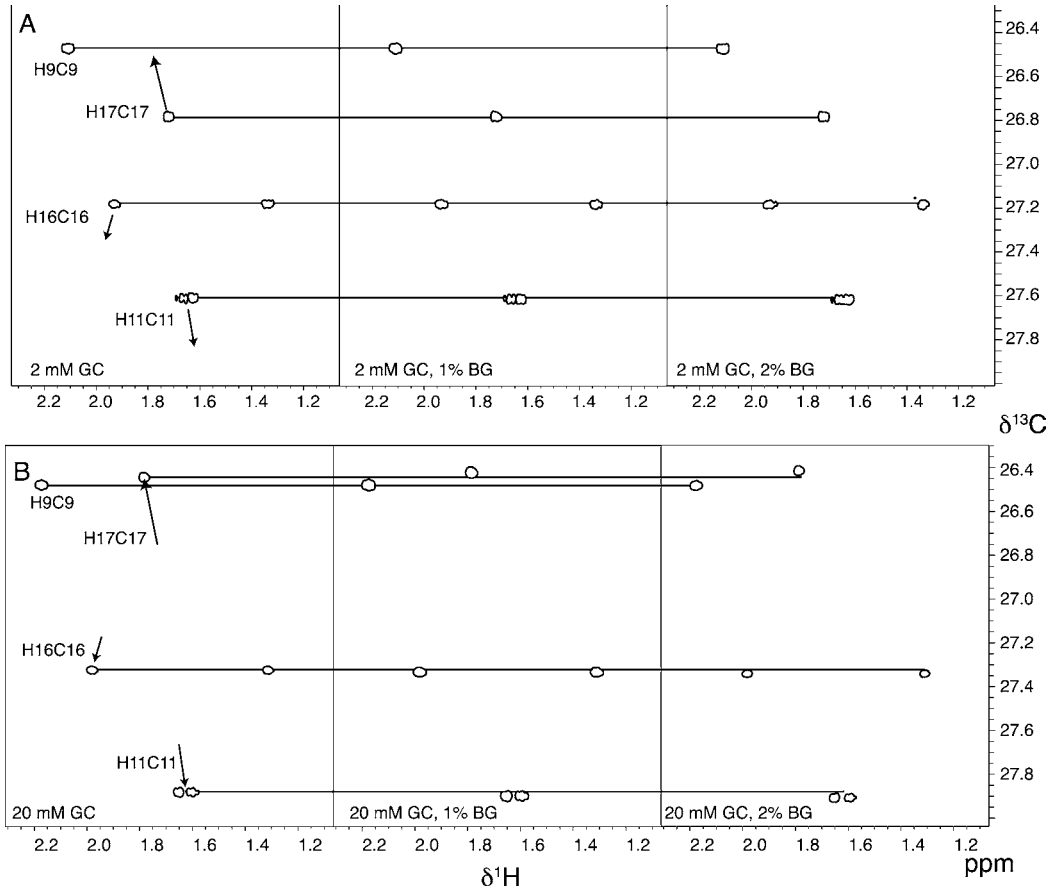

**Figure 5.** $^{1}H-^{13}C$ HSQC spectral region of glycocholate (2 mM in A and 20 mM in B) in the presence of increasing concentrations of medium viscosity $\beta$-glucan (200 kDa). Arrows indicate the change in GC signal when increasing the concentration from 2 mM to 20 mM. The addition of $\beta$-glucan induces small chemical shift changes of bile salt signals with the same trend as chemical shift changes upon the addition of bile salt itself. In the displayed spectral region, H11C11 and H16C16 resonances experience $^{13}C$ signal changes toward higher chemical shift, upon addition of $\beta$-glucan and of bile salt, while the H9C9 resonance remains unchanged and H17C17 shows a $^{13}C$ resonance change toward lower chemical shift, upon addition of $\beta$-glucan and of bile salt. These changes are more pronounced at 20 mM GC, above the critical micelle concentration of GC (7−11 mM).[28]

absorption onto functional polysaccharides or onto fragments thereof has practical advantages. The polysaccharide signals are intrinsically more robust to inaccuracies in sample pH or concentration, for instance due to the absence of easily ionizable groups in carbohydrates. Interactions between the bile salt and $\beta$-glucan were likewise probed by titrating medium viscosity $\beta$-glucan into samples containing a constant bile salt concentration, as previously described.[9] Chemical shift changes were monitored using $^{1}H-^{13}C$ HSQC experiments of 16 min duration, to yield the titration of glycocholate with $\beta$-glucan shown in Figure 5. Notably, rapid $^{1}H-^{13}C$ HSQC experiments can be conducted at concentrations near or below the critical micelle concentration of bile salts (low millimolar). Consequently, binding of $\beta$-glucan to glycocholate was monitored at 2 mM and at 20 mM bile salt concentration. Due to the aggregation into micelles, the glycocholate signals are strongly concentration dependent. Addition of up to 2% (w/v) medium viscosity $\beta$-glucan induces only small chemical shift changes at 2 mM bile salt and more pronounced chemical shift changes at 20 mM bile salt concentration. The bile salt signals are generally found to move upon $\beta$-glucan addition into the same direction that results from a concentration increase of the bile salt itself (Figure 5, Figure S1 in the Supporting Information). The presence of $\beta$-glucan therefore appears to stabilize micelle formation or lateral self-aggregation in the bile salt. Changes in bile salt signals themselves could be a consequence of increased local bile salt concentrations through confinement or excluded volume effects, thus underlining the usefulness of detecting signal changes in the binding partner to validate interactions.

Even using high-resolution spectroscopy, the chemical shift changes are at the edge of what is detectable. Hence, experiments were repeated using a different bile salt, taurochenodeoxycholate (TCDC) in order to validate the above findings. As for the titration with glycocholate, a downfield shift of the $^{13}C4$ signal in a glycosidic bond is detected upon addition of 7, 14, and 28 mM TCDC (Figure 6A). A titration of TCDC with $\beta$-glucan was conducted at a TCDC concentration of 3 mM to validate the viability of rapid $^{1}H-^{13}C$ HSQC assays at low millimolar bile salt concentrations. Chemical shift changes are again consistent with a stabilization of bile salt aggregation in the presence of $\beta$-glucan, as the addition of $\beta$-glucan consistently induces chemical shift changes in the bile salt that resemble chemical shift changes due to an increase in bile salt concentration (Figure 6B).

## ■ DISCUSSION

Polysaccharides play central roles as functional components of supramolecular assemblies in biology and technology. We find that $^{1}H-^{13}C$ HSQC NMR spectroscopy provides sufficient

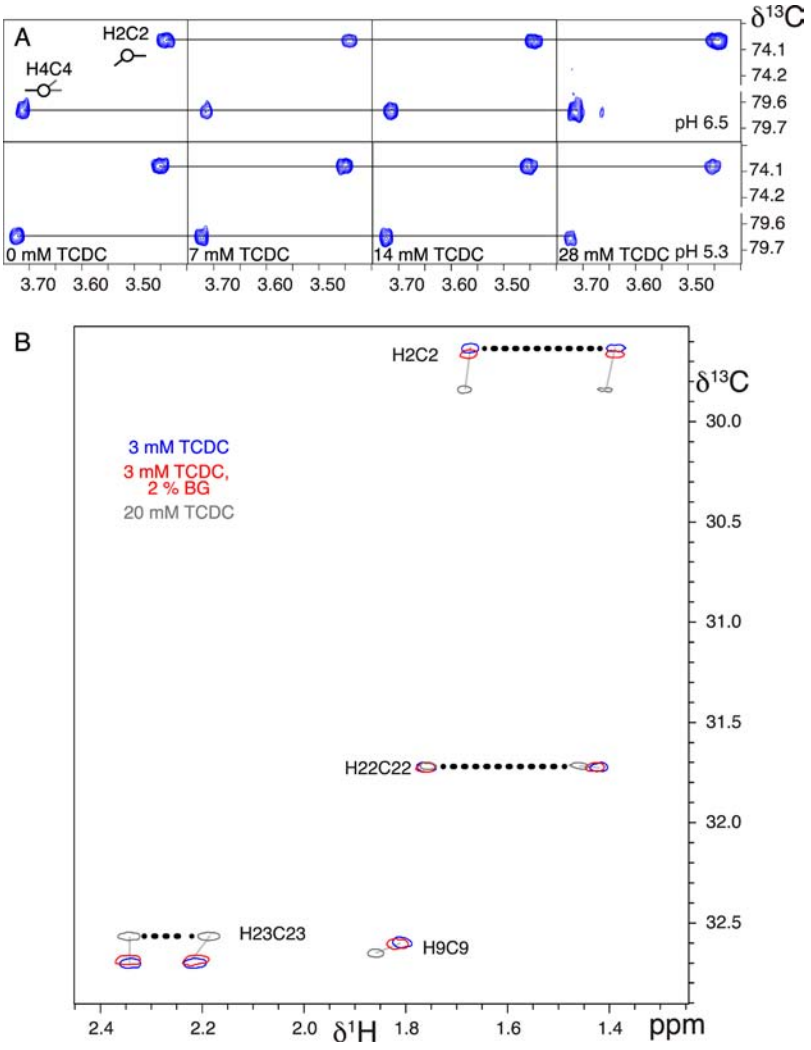

**Figure 6.** Titrations of $\beta$-glucan with TCDC (A; top pH 6.5, bottom pH 5.3) and of TCDC with $\beta$-glucan (B) support small chemical shift changes in the $\beta$-glucan and signal changes in the bile salt consistent with a stabilization of the micellar form.

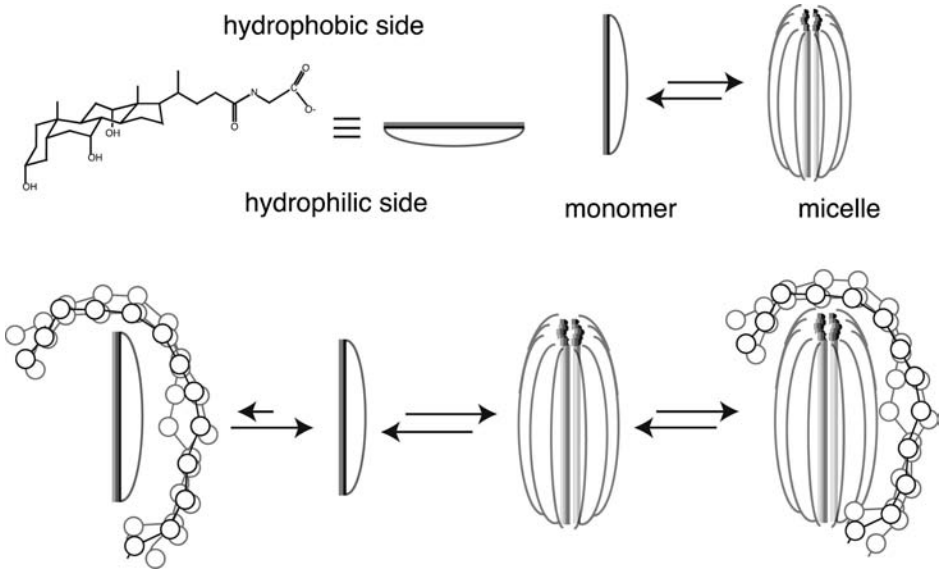

**Figure 7.** Model of $\beta$-glucan interaction with bile salts. The higher affinity between multivalent host and guest favors binding of $\beta$-glucan to the bile salt micelle relative to the monomer, thus stabilizing the micellar form, overall.

dx.doi.org/10.1021/jf504352w | J. Agric. Food Chem. 2014, 62, 11472−11478

sensitivity to enable rapid observations of molecular interactions involving polysaccharides and guest molecules at molecular detail. Such observations are feasible for probing interactions of β-glucan and bile salts, even though the interactions are dynamic and result in chemical shift changes in viscous polysaccharide solutions on the order of only 0.01 ppm. Interactions involving carbohydrates are commonly probed by NMR spectroscopy through the detection of signals from the non-carbohydrate binding partner,[9,24−26] as the carbohydrate $^{1}H$ spectral region usually is crowded and overlaps with the water signal. The observation of well-separated carbohydrate signals in aliased $^{1}H-^{13}C$ HSQC spectra enables the use of both binding partners as host and guest molecules in titrations. The detection of chemical shift changes in both binding partners then supports direct interactions with the carbohydrate.

Many attempts have been made to clarify how β-glucans might interact with bile salts in the small intestine, preventing their reabsorption and leading to excess excretion via the feces. Collectively, there are three main hypotheses: (a) increase, by β-glucans, of the intestinal viscosity whereby reabsorption of bile salts may be prevented by a potential β-glucan barrier layer; (b) entrapment of bile salt micelles in β-glucan molecular networks or aggregates; and (c) binding of bile salt monomers or micelles to β-glucans at a molecular level.[5,10] Here, we obtain $^{1}H-^{13}C$ HSQC titrations of bile salts and β-glucan that are consistent with direct molecular interactions between bile salts and all used β-glucans. The interaction results in a stabilization of bile salt micelles in the presence of β-glucan, presumably due to a stronger interaction of the β-glucan with the micelle than with the bile salt monomer (Figure 7), and influences β-glucan signals, primarily at the sites of glycosidic linkages (Figure S3 in the Supporting Information). An increased interaction between bile salt micelles and β-glucan is not surprising given the repetitive structure of the β-glucan and the resultant possibility for multivalent interactions between micelle and polymer. The minute chemical shift changes observed in the β-glucan argue against a cooperative structural transition of β-glucans upon addition of the bile salt host and against highly specific binding, opposite to the formation of hydrophobic inclusion complexes between amphiphilic hosts and α(1−4)-glucans.[24] Notably, the use of $^{1}H-^{13}C$ HSQC NMR at high magnetic field provides sufficient selectivity and sensitivity to examine polysaccharide−guest interactions within a time frame of minutes, making the screening of various host and guest molecules practical. We finally note that cholic acid based receptors have been devised as biomimetic receptors for carbohydrates, including β-glucosides.[27] These receptors exhibit multivalent interactions between the carbohydrate and the hydrophilic face of the cholic acid building blocks, thus exploiting similar interactions as those indicated in the model of Figure 7.

In conclusion, this study shows that $^{1}H-^{13}C$ NMR assays on the time scale of minutes detect signal changes in both bile salts and β-glucans, thus arguing for direct dynamic interactions, without inducing cooperative conformational changes in the β-glucans. Titrations are consistent with stronger interactions at pH 5.3 than at pH 6.5 in this in vitro assay. The changes in bile salt and β-glucan signals suggest a stabilization of bile salt micelles through transient, multivalent interactions with β-glucans.

## ■ ASSOCIATED CONTENT

### Supporting Information

An overview figure of bile acid signal changes upon concentration increase of the bile acid itself and upon addition of β-glucan is provided. These changes are mapped onto the bile acid structure. Interaction studies using laminaribiose as a model saccharide are demonstrated, indicating transient interactions with low specificity and weak effect on molecular tumbling, but exerting some small changes in glycosidic linkage conformation. This material is available free of charge via the Internet at http://pubs.acs.org.

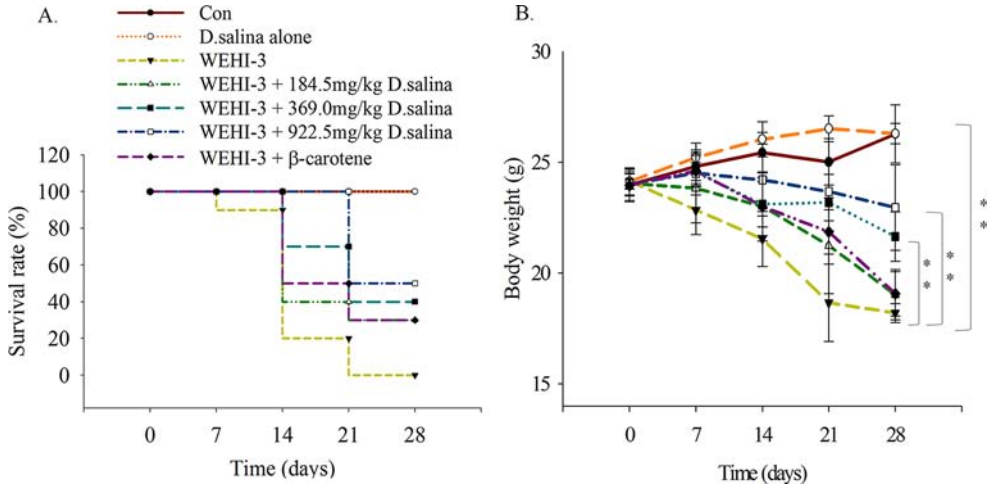

**Figure 1.** Effects of *D. salina* on survival rate and body weight. BALB/c mice were iv injected with WEHI-3 cells ($1 \times 10^5$ cells/mice) and treated with *D. salina* by oral administration for 4 weeks. ($n = 10$, mean ± SD.) *, **, and *** indicate significant difference between two groups at $p < 0.05$, $p < 0.01$, and $p < 0.001$, respectively.

contents in the *D. salina* of *all-trans*-*β*-carotene, 9- or 9′-*cis*-*β*-carotene, *all-trans*-zeaxanthin, *all-trans*-lutein, 13- or 13′-*cis*-*β*-carotene, *all-trans*-*α*-carotene, and 9- or 9′-*cis*-*β*-carotene were 138.25, 124.65, 11.27, 6.55, 4.95, 2.69, and 2.41 mg/g algae, respectively, measured by HPLC as described previously.[5,15] The ratio of *all-trans*- and *cis*-*β*-carotene, the major carotenoids in the algae, was 53:47. RPMI-1640 medium was obtained from Hyclone (South Logan, UT, USA). Fetal bovine serum (FBS) was obtained from Biological Industries (Kibbutz Beit Haemek, Israel). Penicillin−streptomycin and glutamine were obtain from Gibco BRL (Grrand Island, NY, USA). *β*-Carotene was obtained from Sigma (St. Louis, MO, USA).

**Animals.** A total of 140 male BALB/c mice, each at the age of 6 weeks and about 22−28 g in weight, were purchased from the Animal Department of BioLASCO Taiwan Co., Ltd. (Taipei City, Taiwan, ROC). The animals were maintained under a 12 h light/dark cycle in a humidity- and temperature-controlled room under standard laboratory conditions. Mice were housed five in each cage and allowed food and water ad libitum. They were acclimated and quarantined for a week prior to experimentation. The protocol for the animal study was approved by the Institutional Animal Care and Committee (IACUC no. 1074), and all mice were cared for following the institutional ethical guideline.[6,16]

**Cell Culture.** The WEHI-3 murine myelomonocytic leukemia cell line and YAC-1 murine lymphoma cell line were purchased from the Bioresource Collection and Research Center (Hsinchu, Taiwan). The cells were cultured onto 10 $cm^2$ dishes and maintained in RPMI-1640 medium supplemented with 10% fetal bovine serum, 100 $\mu$g/mL streptomycin, 100 U/mL penicillin, and 2 mM L-glutamine at 37 °C in a 5% $CO_2$ incubator.

**Experimental Designs.** The experiment was made up of two parts. In part I, over a period of 4 weeks, the effect of *D. salina* on the survival rate in WEHI-3 leukemic mice was investigated. In part II, over a period of 2 weeks, the immunomodulatory effects of *D. salina* on WEHI-3 leukemic mice were investigated. Seventy BALB/c mice were randomly divided into 7 groups with 10 animals in each group. *D. salina* was suspended in distilled water before use and administered by oral gauge. The dosages of *D. salina* used in this study were calculated from the commercial product's suggestion for daily intake (i.e., 15 mg/kg bw/human equals 184.5 mg/kg bw/mice). Group I was the control and group II was treated with *D. salina* only. Groups III−VII were intravenously injected via the tail vein with WEHI-3 cells ($1 \times 10^5$ cells/100 $\mu$L PBS) only. Group IV−VI were cotreated with *D. salina* at doses of 184.5, 369, and 922.5 mg/kg, respectively. Group VII was cotreated with 922.5 mg/kg *β*-carotene as the positive control.

**Cell Surface Markers Examination.** The mice were euthanized by $CO_2$, and whole blood was collected via heart puncture after injection of WEHI-3 cells for 2 weeks. The blood samples were immediately lysed with BD Pharm Lyse (BD Biosciences) and then centrifuged at 1500 rpm (1000*g*) for 15 min at 4 °C. The collected white blood cells evaluated for cell surface markers including T-cells, B-cells, monocytes, and macrophages were respectively stained with anti-CD3-FITC, anti-CD19-PE, anti-CD11b-PE, and anti-Mac-3-FITC antibodies (SouthernBiotech Inc.) and then were analyzed by flow cytometry (FACS Calibur, Becton Dickinson, NJ, USA) as previously described.[20]

**Organ Weight and Pathological Examination.** A necropsy was performed on each mouse, and the spleen was weighed after dissection. Then, it was examined grossly and fixed in 10% formalin buffer. A transverse section in the hilus was made at the largest extension of the spleen; red and white pulps of spleen were trimmed and embedded in paraffin, sectioned to a thickness of 2 $\mu$m, and stained with hematoxylin and eosin for the microscopic examination. For semiquantitative grading, the severity of the lesions was graded on the basis of the criteria of Shackelford et al.[21] with five grades of severity of lesions specified: 1 = minimal (<1%); 2 = slight (2−25%); 3 = moderate (26−50%); 4 = moderate/severe (51−75%); and 5 = severe/high (76−100%).

**Splenocyte Proliferation Examination.** About $1 \times 10^5$ splenocytes/mL isolated from the spleen in each group were individually cultured with RPMI-1640 medium in 24-well culture plates. Con A (5 $\mu$g/mL) and LPS (5 $\mu$g/mL) were added to activate T- and B-cells, respectively. The treated and untreated cells were incubated for 72 h in a $CO_2$ incubator. The proliferation of T- and B-cells was determined by MTT assay.[17]

**Cytokine Examination.** About $2 \times 10^5$ splenocytes/mL isolated from the spleen in each group were individually cultured with RPMI-1640 medium in 24-well culture plates. After stimulation of splenocytes with Con A (5 $\mu$g/mL) and incubating for 24 h, the plates were centrifuged for 4 min at 500*g*, and the supernatants were collected before use.[17,22] The contents of IFN-*γ*, IL-2, IL4, and IL-10 were quantified using commercial ELISA kits (Enzo Life Sciences, Vinci-Biochem, Vinci, Firenze, Italy). The procedurse followed in accordance with the manufacturer's protocols.

**Phagocytosis Examination.** The phagocytosis of macrophages in the PBMCs was measured by using the Phagotest kit (Orpegen Pharma, Heidelberg, Germany). The assay procedures followed in accordance with the manufacturer's instructions. Briefly, isolated cells from each mouse were individually incubated with the FITC-labeled *Escherichia coli* bacteria (20 $\mu$L) at 37 °C for 1 h. Next, 100 $\mu$L of ice-cold quenching solution was added to stop the reaction. Then, the macrophages/monocytes were fixed and stained with PI solution. The samples were analyzed by using a flow cytometer with Cellquest software.[22,23]

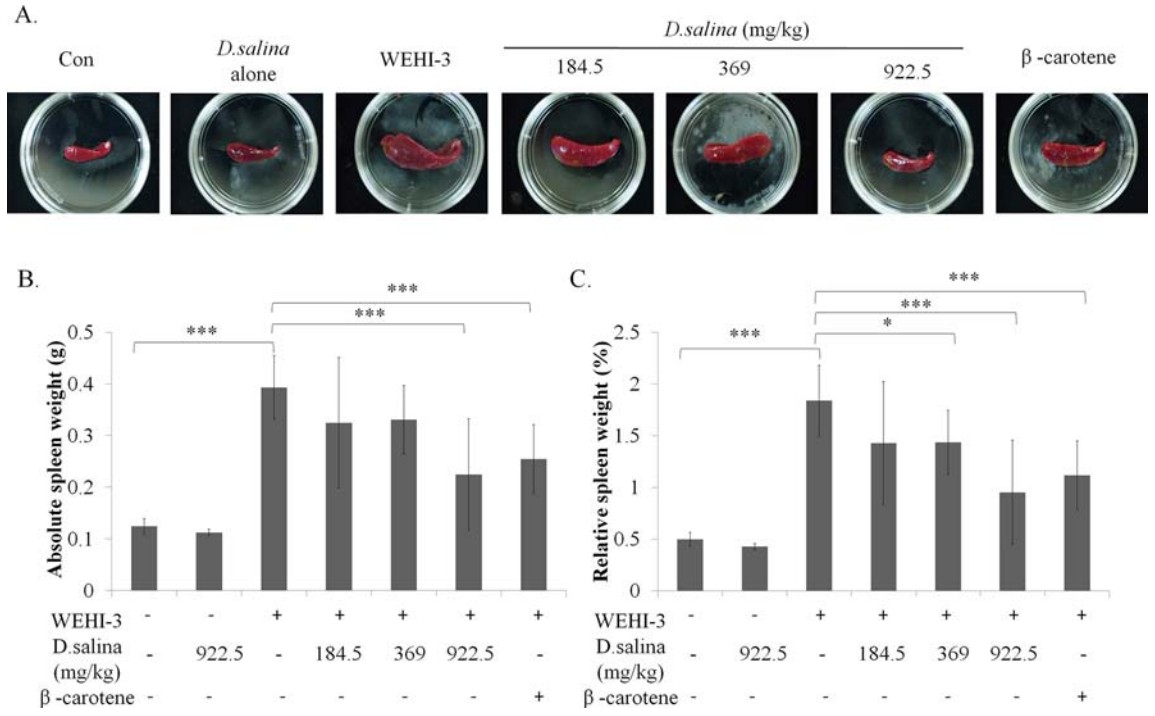

**Figure 2.** Change of spleen in the WEHI-3-induced leukemic mice. BALB/c mice were iv injected with WEHI-3 cells ($1 \times 10^5$ cells/mice) and treated with *D. salina* by oral administration for 2 weeks. Animals were sacrificed for examinations of gross (A) and spleen weights (B). ($n$ = 10, mean ± SD.) ∗, ∗∗, and ∗∗∗ indicate significant difference between two groups at $p < 0.05$, $p < 0.01$, and $p < 0.001$, respectively.

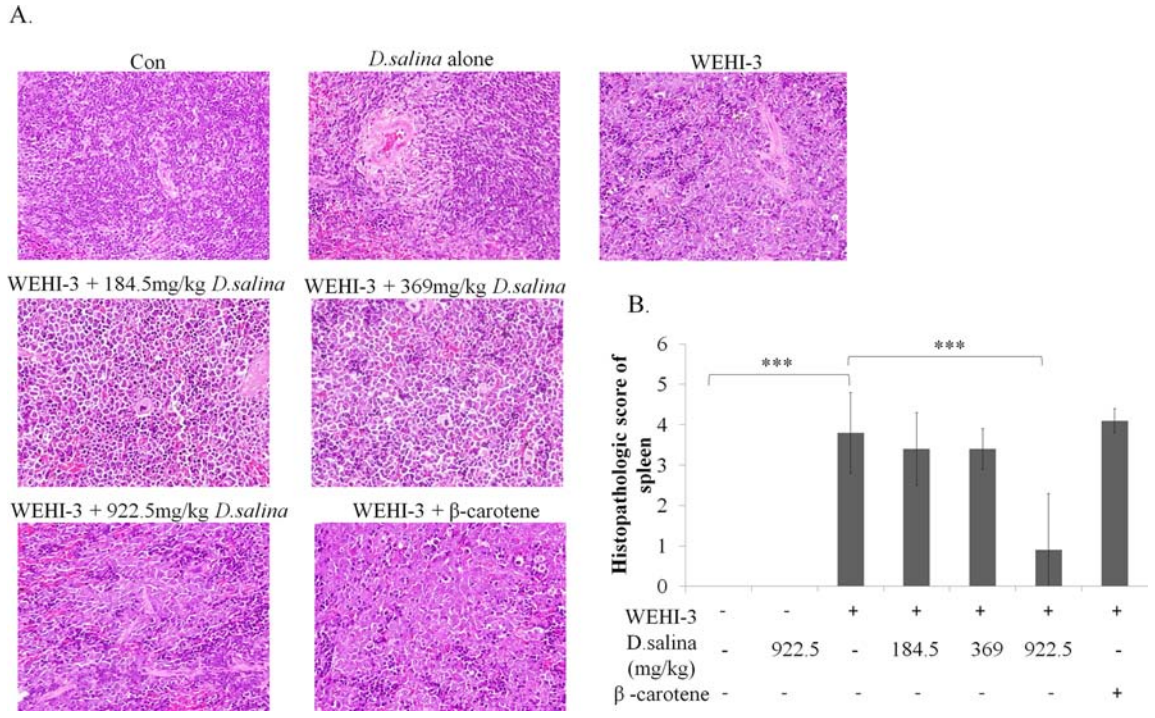

**Figure 3.** Hisopathological photographs and scores of spleen in the WEHI-3-induced leukemic mice. BALB/c mice were iv injected with WEHI-3 cells ($1 \times 10^5$ cells/mice) and treated with *D. salina* for 2 weeks. Spleens were sectioned, stained with hematoxylin eosin (400×) (A) and scored (B). The severity of the lesions was graded with five grades of severity of lesions specified: 1 = minimal (<1%); 2 = slight (2−25%); 3 = moderate (26−50%); 4 = moderate/severe (51−75%); and 5 = severe high (76−100%). ($n$ = 10, mean ± SD.) ∗, ∗∗, and ∗∗∗ indicate significant difference between two groups at $p < 0.05$, $p < 0.01$, and $p < 0.001$, respectively.

**NK Cell Cytotoxicity Examination.** Splenocytes isolated from spleens in each group were used as effector cells. YAC-1 cells sensitized to NK cell cytotoxicity were used as target cells. Target cell killing was determined with a lactic dehydrogenase (LDH) release assay by using the LDH-Cytotoxicity Assay Kit II (Biovision, Inc.). YAC-1 ($1 \times 10^5$) was cocultured with splenocytes at a final effector/target (E:T) ratio of 50:1 and incubated in 24-well culture plates for 6 h in an incubator. Ten microliters of supernatants was transferred into

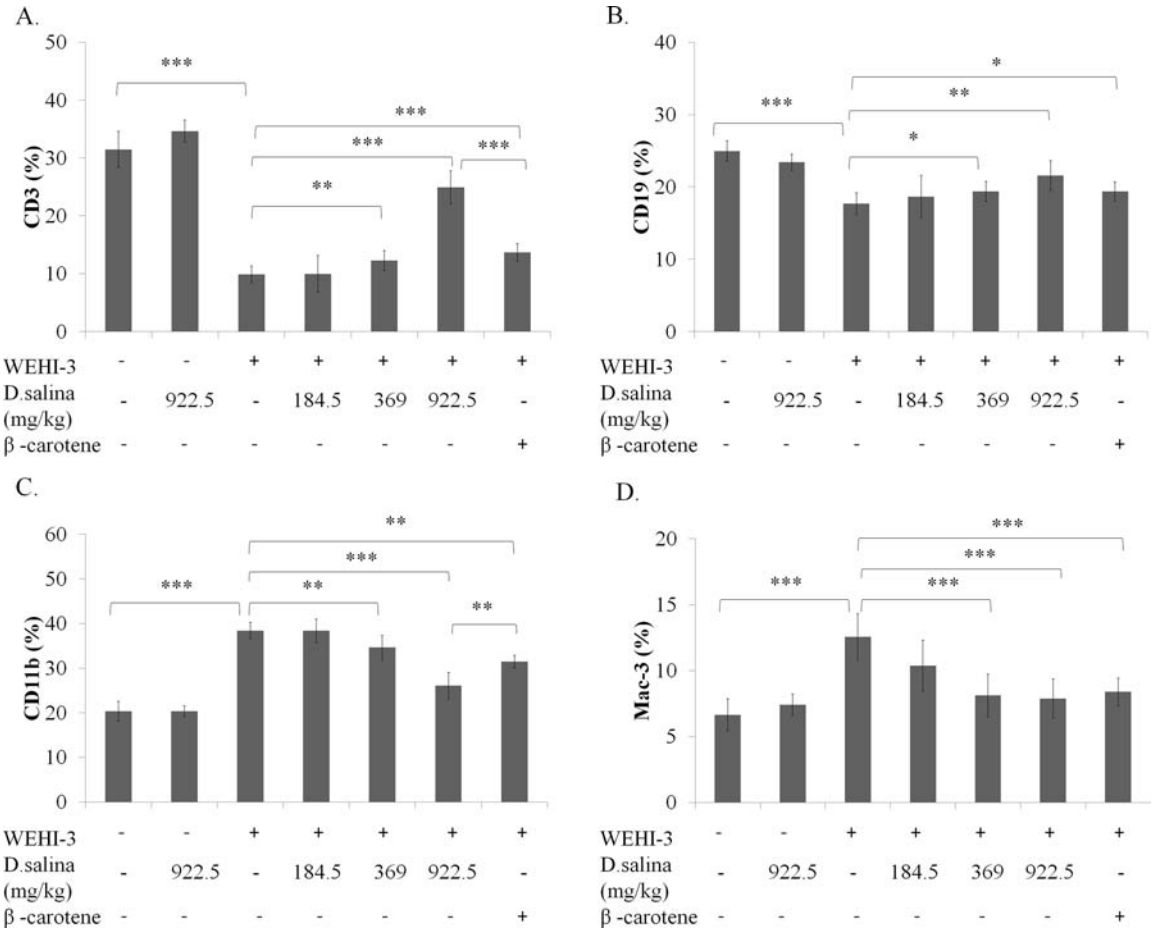

**Figure 4.** Effect of *D. salina* on cell markers of white blood cells from BALB/c mice. BALB/c mice were injected with WEHI-3 cells ($1 \times 10^5$ cells/mice) and treated with *D. salina* for 2 weeks. Blood was collected from individual animals and analyzed for cell markers (A) CD3, (B) CD19, (C) CD11b, and (D) Mac-3 by flow cytometry. ($n = 10$, mean ± SD.) *, **, and *** indicate significant difference between two groups at $p < 0.05$, $p < 0.01$, and $p < 0.001$, respectively.

a 96-well plate, followed by centrifuging for 4 min at 500*g*. One hundred microliters of LDH of substrate was added and incubated at room temperature. After 20 min, 10 $\mu$L of stop solution was added immediately, and then the absorbance was measured by microplate reader at OD450 nm. The NK cell cytotoxicity was calculated using the formula cytotoxicity % = (experimental OD − effector cell spontaneous OD − target cell spontaneous OD)/(target cell lysis OD − target cell spontaneous OD) × 100.[24]

**Statistical Analysis.** The data were expressed as mean ± SD, and the differences between any two groups were performed using one-way analysis of variance (ANOVA) followed by Dunnett's multiple-comparison tests using the statistical software SPSS (DR Marketing Co., Ltd., New Taipei City, Taiwan, ROC). Values of $p < 0.05$, $p < 0.01$, and $p < 0.001$ were used as the levels of significance.

## RESULTS

**Survival Rate and Body Weight Change in WEHI-3 Leukemic Mice.** Over a period of 4 weeks, the effects of *D. salina* on the survival rate and body weight in mice were recorded. As shown in Figure 1A, there was no significant difference between control and *D. salina* only treated group on the survival rate. *D. salina* (184.5, 369, and 922.5 mg/kg) prolonged the survival rate in WEHI-3 leukemic mice in a dose-dependent manner. Treatment with $\beta$-carotene, as a positive control group, showed the 30% survival rate when compared to the WEHI-3 only group at the fourth week. As shown in Figure 1B, *D. salina* (369 and 922.5 mg/kg) significantly restored the body weight when compared to WEHI-3 only group during 4

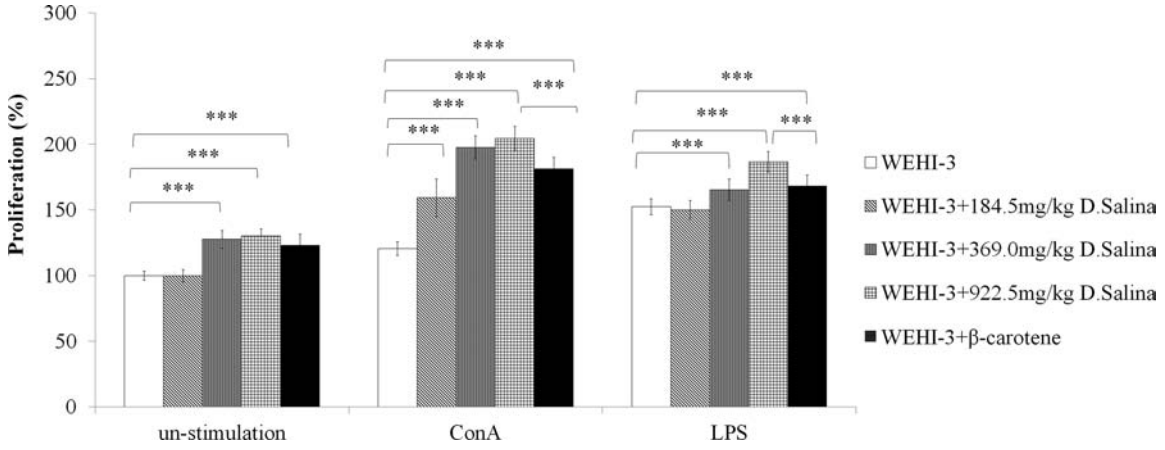

**Figure 5.** Effect of *D. salina* on the proliferation of T- and B-cells from BALB/c mice. Splenocytes were isolated from each group of BALB/c mice following *D. salina* treatment and then Con A and LPS stimulated for 3 days for examinations of T- and B-cell proliferation, respectively. ($n$ = 10, mean ± SD.) ∗, ∗∗, and ∗∗∗ indicate significant difference between two groups at $p < 0.05$, $p < 0.01$, and $p < 0.001$, respectively.

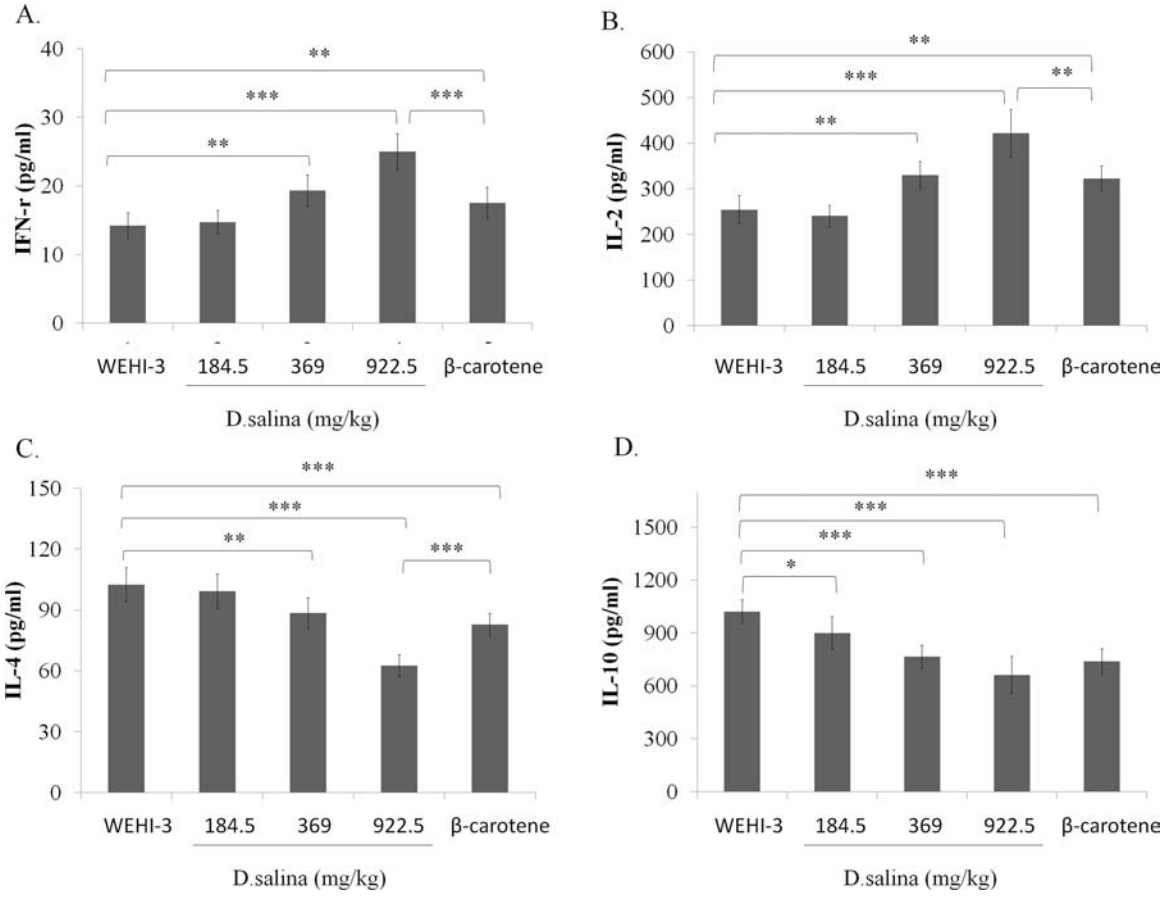

**Figure 6.** Effect of *D. salina* on the levels of cytokine after Con A stimulation of splenocytes from BALB/c mice. About $2 \times 10^5$ splenocyte cells in medium from WEHI-3 cells were injected into BALB/c mice following *D. salina* treatment for 2 weeks and then were stimulated with Con A (5 μg/mL). Levels of IFN-γ (A), IL-2 (B), IL-4 (C), and IL-10 (D) were determined by ELISA kit. ($n$ = 10, mean ± SD.) ∗, ∗∗, and ∗∗∗ indicate significant difference between two groups at $p < 0.05$, $p < 0.01$, and $p < 0.001$, respectively.

weeks ($p < 0.01$). *D. salina* treatment showed more beneficial effects than β-carotene in both the survival rate and body weight.

**Change of Spleen Weight in WEHI-3 Leukemic Mice.** Over a period of 2 weeks, the animals were euthanized, whole blood was collected, and spleen was isolated and weighed. The spleen size and weight are presented in Figure 2. There was no significant difference between control and *D. salina* only treated groups (Figure 2A). The treatment of WEHI-3 cells in group III had increased the absolute and relative organ weights ($p < 0.001$) (Figure 2B,C). The high dose of *D. salina* (922.5 mg/kg) and β-carotene treatment significantly decreased the absolute and relative weights of spleen when compared to the WEHI-3 only group ($p < 0.001$).

**Histopathological Examination of Spleen in WEHI-3 Leukemic Mice.** As shown in Figure 3A, no significant

dx.doi.org/10.1021/jf503564b | J. Agric. Food Chem. 2014, 62, 11479−11487

changes of spleen were found in the control and *D. salina* only group. However, numerous leukemia cells had infiltrated into the spleen of the WEHI-3 leukemic mice. The neoplastic cells showed round with enlarged nuclei, high nucleonic/cytoplasm ratios with highly mitosis, and increased megakaryocytes in the red pulp area of the spleen. The treatment of WEHI-3 cells in group III has increased the leukemia score in spleen ($p < 0.001$) (Figure 3B). The high dose of *D. salina* (922.5 mg/kg) group had significantly decreased leukemia scores of spleen when compared to the WEHI-3 only group ($p < 0.001$). None of the above effect was found in the $\beta$-carotene group.

**Hematology and Cell Surface Markers in WEHI-3 Leukemic Mice.** The results of hematological analysis in BALB/c mice following *D. salina* treatment are presented in Table 1. *D. salina* groups (369 and 922.5 mg/kg) showed decreased levels of WBC compared to the WEHI-3 only group ($p < 0.05$). There was no significant difference between the $\beta$-carotene and WEHI-3 only groups ($p > 0.05$). The cell surface markers of WBC from BALB/c mice following *D. salina* treatment are presented in Figure 4, which indicated that *D. salina* (369 and 922.5 mg/kg) and $\beta$-carotene increased the percentages of CD3 (Figure 4A) and CD19 (Figure 4B) compared to the WEHI-3 only group in a dose-dependent manner but decreased the percentages of CD11b (Figure 4C) and Mac-3 (Figure 4D).

**Proliferation of Splenocytes in WEHI-3 Leukemic Mice.** Splenic lymphocyte proliferation was stimulated by Con A and LPS in vitro as methods to evaluate T- and B-lymphocyte activities, respectively.[25] As shown in Figure 5, *D. salina* (369 and 922.5 mg/kg) enhanced the significant proliferation of splenocytes under untreated Con A and LPS conditions ($p < 0.001$). Especially, Con A-induced T-cell proliferation was significantly enhanced by *D. salina* (184.5, 369, and 922.5 mg/kg) ($p < 0.001$), and the proliferation rates of the treatment groups were increased nearly 38, 77, and 84% as compared with the WEHI-3 only group. Similarly, LPS-induced B-cell proliferation was significantly enhanced by *D. salina* (369 and 922.5 mg/kg), increasing nearly 13 and 34% as compared with the WEHI-3 only group. Also, both Con A- and LPS-induced T- and B-cell proliferations in the *D.salina*-treated group were higher than those of the $\beta$-carotene-treated group ($p < 0.001$).

**Levels of Cytokine after Con A Stimulation of Splenocytes in WEHI-3 Leukemic Mice.** The splenocytes from mice following Con A treatment were separated, and the levels of IFN-$\gamma$, IL-2, IL-4, and IL-10 were determined. As shown in Figure 6, *D. salina* significantly increased the levels of IFN-$\gamma$ (Figure 6A) and IL-2 (Figure 6B) in a dose-dependent manner. However, *D. salina* significantly reduced the levels of IL-4 (Figure 6C) and IL-10 (Figure 6D) when compared to the WEHI-3 only group. Additionally, *D. salina* (922.5 mg/kg) significantly enhanced the levels of IFN-$\gamma$ and IL-2 but decreased the level of IL-4 when compared to the $\beta$-carotene-treated group ($p < 0.01$).

**Activity of NK Cells in WEHI-3 Leukemic Mice.** YAC-1 as target cells could be killed by NK cells isolated from spleens of the mice at an effector/target ratio of 50:1. As shown in Figure 7, treatment with *D. salina* alone increased the activity of NK cells when compared to the control group ($p < 0.05$). However, there was significantly reduced NK cell activity in the WEHI-3 only group ($p < 0.001$). As compared to the WEHI-3 only group, the doses of 369 and 922.5 mg/kg *D. salina* treatment exhibited high activity of NK cells. Additionally, *D. salina* (922.5 mg/kg) treatment showed better activity than $\beta$-carotene treatment ($p < 0.0.5$).

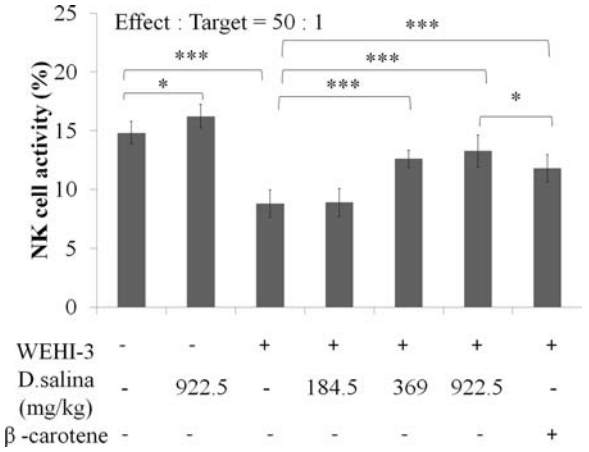

**Figure 7.** Effect of *D. salina* on the natural killer (NK) cell cytotoxic activity from BALB/c leukemic mice. The effects of *D. salina* on the YAC-1 target cells which were killed by NK cells from the mice following *D. salina* treatment in target cell ratio of 50:1 were analyzed for NK cell cytotoxic activity by LDH assay kit. ($n = 10$, mean ± SD.) *, **, and *** indicate significant difference between two groups at $p < 0.05$, $p < 0.01$, and $p < 0.001$, respectively.

**Macrophage Activity in WEHI-3 Leukemic Mice.** The phagocytosis from PBMC of the control and treated groups is presented in Figure 8. Treatment with *D. salina* alone increased

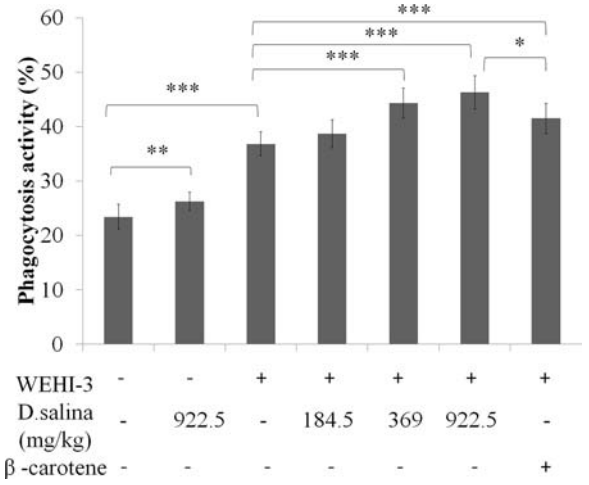

**Figure 8.** Effect of *D. salina* on the phagocytic activity by macrophages in WEHI-3-induced leukemic mice. Mice were injected without or with WEHI-3 cells ($1 \times 10^5$ cells/mice) and then orally treated with or without *D. salina* for 2 weeks. Cells were collected from animals of PBMC, and they were analyzed for phagocytic activity by flow cytometry. ($n = 10$, mean ± SD.) *, **, and *** indicate significant difference between two groups at $p < 0.05$, $p < 0.01$, and $p < 0.001$, respectively.

the phagocytosis rate when compared to the control group ($p < 0.01$) *D. salina* elevated the phagocytic rate compared to the WEHI-3 only group in a dose-dependent manner. At doses of 369 and 922.5 mg/kg, the effects enhanced the value from 36.8 to 44.3 and 46.3%, whereas increasing the dose to 184.5 mg/kg showed very little additional effect when compared to the WEHI-3 only group. These results indicated *D. salina*

promoted the activities of phagocytosis and showed stronger activity than that in mice treated by $\beta$-carotene ($p < 0.05$).

## DISCUSSION

In recent years, immunomodulation has become a promising direction in health food development in complementary and alternative medicine, especially for cancer. As $\beta$-carotene induced cytotoxicity in leukemia cells in vitro[10] and our pilot studies showed that *D. salina* inhibited the proliferation of leukemia cell lines including HL-60, KG-1, MOLT-4 and Jurkat cells, these raised the possibility that *D. salina* could be useful in complementary and alternative medicine against human leukemia. Thus, in the present study, we investigated the potential of *D. salina* in leukemia therapy in vivo. Our results showed that *D. salina* increased NK cell activity and phagocytosis and expression levels of IFN-$\gamma$ and IL-2 but reduced the levels of IL-4 and IL-10. These results provided strong support that the antileukemia immunity of *D. salina* was important in anti-WEHI3 leukemia in mice.

*D. salina*, which contains significant amounts of *all-trans*-$\beta$-carotene and 9- or 9′-*cis*-$\beta$-carotene, has excellent antioxidant activity. Also, 9- or 9′-*cis*-$\beta$-carotene has been implied to have better potential against the development of cardiovascular disease and malignant cancer as compared with the *all-trans* isomer.[5,13,26] This finding had been confirmed in our earlier studies, which suggested that *D. salina* enhanced the antioxidant enzyme activities against $CCl_4$- and UV-B-induced hepatotoxicity and corneal oxidative damage in mice.[6,16] Also, previous studies in vivo demonstrated that *D. salina* induced antioxidant enzyme activities against carcinogen-induced fibrosarcoma in rats as well as cisplatin combined vitamin E treatment[11] and that *D. bardawile* promoted the normal cell growth, but suppressed the tumor progression in mice.[12] Additionally, *D. salina* reduced LPS-induced inflammation via NF-$\kappa$B and MAPK pathways.[15] In the current study, *D. salina* promoted the immune response against leukemia in mice, therefore indicating that *D. salina* exhibited multiple biological functions including antioxidation, anti-inflammation, immunomodulation, and anticancer properties in vitro and in vivo.

The well-established WEHI-3 leukemic murine model has been used to show the increase in immature WBC, which consequently metastasized to the spleen, resulting in infiltration and enlargement.[20,27−29] The present study showed that *D. salina* (922.5 mg/kg) inhibited splenic tumor growth in leukemic mice (Figures 2 and 3). Results similar to ours can be found in combined treatment with chemotherapeutic drugs, arsenic trioxide, and *all-trans*-retinoic acid, which revealed that neoplastic cells appeared less in the splenic red pulp in leukemic mice following the drug treatment.[27]

In the current study, treatment with *D. salina* alone increased WBC (Table 1), with the increase still within the normal range. Also, the treatment showed no significant adverse effect (Figure 3). Following WEHI-3 cell injection, there was a significant increase in WBC, indicating that the increase was from the leukemia cells. This could be confirmed through the spleen pathology, indicating that leukemic cells were metastasized to the spleen tissue. This study showed *D. salina* caused an inhibitory effect on WEHI-3-induced WBC increase, which was probably due to *D. salina* inducing cell cycle arrest and apoptosis in neoplastic cells but not in normal cells.[8,9,12,30] In terms of lymphocyte population, there were similarity and corroboration between the significant increase in percentages of T- and B-cells in the blood by *D. salina* (Figure 4A,B) with the proliferation of T- and B- cells stimulated by Con A and LPS in the splenocytes (Figure 5). On the basis of the increment of T- and B-cells, it is suggested that the effects of *D. salina* in leukemic mice may involve activating a cascade of cellular and humoral immune responses.

IFN-$\gamma$, IL-2, IL-4, and IL-10 are immunity-related cytokines. Th1 cytokines such as IFN-$\gamma$ and IL-2 stimulate lymphocytes and macrophages to destroy pathogens and activate NK cells against viruses and tumors.[19] IL-4 can regulate Th2 cell differentiation and antibody formation. IL-4 not only suppresses Th1 and Th17 cell response via inducing IFN-$\gamma$ production, it also promotes tumor metastasis.[18] There is cross-inhibition between Th1 and Th2 cells. IL-10 is an immunosuppressive cytokine, which is produced and released from tumor cells and tumor-associated macrophages. Also, IL-10 is involved in STAT-mediated tumor progression.[31] Therefore, as the cytokines play a vital role in the development of immune response and antitumor property, we investigated the effects of *D. salina* on those targets. The results revealed that the levels of IFN-$\gamma$ and IL-2 were significantly increased, whereas the levels of IL-4 and IL-10 were significantly decreased following *D. salina* treatment compared with those of leukemic mice (Figure 6). This implied that the antileukemia property of *D. salina* might be achieved by regulating the Th1/Th2 balance and blocking STAT-mediated signal cascades, which attracted pro-inflammation to tumor development.

NK cells can release many kinds of cytokines and chemokines, which have a direct effect on tumors.[32] NK cells are known to be an early source of IFN-$\gamma$, which can decrease tumor proliferation and suppress angiogenesis.[32,33] Also, NF-$\kappa$B can induce target cell apoptosis via granule exocytosis and the death receptor activation.[34] It had been reported that spirulina increased the activity of tumoricidal NK cells via MyD88 signal transduction. Also, when cotreated with BCG-cell wall skeleton in melanoma, spirulina exerted a synergistic antitumor activity.[35] The present study revealed that *D. salina* treatment promoted NK cell activity when compared to the leukemia group (Figures 6A and 7), implying that *D. salina* might elicit MyD88 signal cascades to activate NK cell cytotoxicity.

Tumor-associated macrophages have been considered as an important source of tumor-promoting inflammation, and they consistently promote tumor growth and metastasis.[18] The present study revealed that WEHI-3 cell injection resulted in myelomonocytic leukemia, which had the characteristic of elevated monocytes coupled with increased macrophage population leading to splenic metastasis. Following *D. salina* treatment these effects, especially macrophage toward pro-inflammation induced by leukemia, could be inhibited (Figures 4D and 6D). This suggested that *D. salina* could prevent carcinogenesis via anti-inflammation by reducing macrophage production. Moreover, the proportions of phagocytosis by macrophage were significantly enhanced following *D. salina* treatment in leukemic mice (Figure 8). Phagocytosis is a process with antigen presentation for digesting dead cells and debris and killing microbes by phagocytes such as macrophages and dendritic cells. This indicated that *D. salina* might initiate an anticancer immune response resulting in phagocytosis of cancer by macrophages.

It is noted that following WEHI-3 cell injection, there were significant increases in the population and activity of macrophages (Figures 4D and 8), indicating that the increase stemmed from the leukemia cells. *D. salina* decreased the percentages of CD11b and Mac-3 cells in the blood, but the

phagocytosis of macrophage activity increased from PBMC in WEHI-3 leukemic mice. This suggested that *D. salina* probably induced differentiation, apoptosis, and anti-inflammation in leukemia cells and activated phagocytosis in normal cells. This could be confirmed through the increase of WBC and phagocytosis when treated with *D. salina* alone, as compared to control animals. Thus, *D. salina* could not only increase the immune response via promoting T- and B-cells proliferation and enhancing NK cells and macrophages activities but also induce cancer cell death via promoting differentiation, apoptosis, and altering tumor microenvironment, especially following *D. salina* treatment in leukemic mice.

The mechanisms of antileukemia include oxidative stress, inflammation, cell cycle arrest, apoptosis, autophagy, differentiation, immunomodulation, etc.[7,20,31,32] Previous studies showed that *D. salina* had antioxidative and anti-inflammatory activities via NF-$\kappa$B and JNK inactivation in vitro and in vivo[5,6,14,15] and that it induced cancer cell death coupled with cell cycle G0/G1 arrest and apoptosis through p53 and p21 up-regulation of Fas and FasL expression.[8,9] Three doses of *D. salina* were used in this study, and the results in the survival rate indicated the beneficial effects of these three doses. However, only one or two doses were found to have beneficial effects in the other experiments. From the above evidence, it is suggested that the modulating immune responses induced by *D. salina* might exert partial contribution in prolonging the biological life in leukemic mice.

Additionally, unlike *D. salina*, $\beta$-carotene did not show significant beneficial effects on body weight and splenic infiltration. This suggested that the efficacy of $\beta$-carotene in chemical synthesis was not as evident as in biological production. In support of this finding, previous studies revealed that the carotenoids extracted from *D. salina* showed more antioxidant enzyme activities against $CCl_4$-induced hepatotoxicity in rat[36] and induced higher apoptotic rate in prostate cancer cell line[8] as compared to synthetic $\beta$-carotene. In the current study, *D. salina* promoted the immune response against leukemia in mice better than $\beta$-carotene. It was also proposed that the combined antioxidant supplementation could be a useful chemopreventive approach against oxidative damage and carcinogenesis.[5,9,37] As *D. salina* has been a commercial product that contains *all-trans*-$\beta$-carotene, 9- or 9′-*cis*-$\beta$-carotene, and other carotenoids, the whole alga should show more powerful antileukemic effects as compared to those specific materials from *D. salina* itself.

In conclusion, the results showed that *D. salina* prolonged the survival rate and reduced the enlargement of the spleen in the leukemic mice. *D. salina* increased the population of T- and B-cells but decreased the population of monocytes and macrophages in the blood. *D. salina* improved immunomodulation by increasing the proliferation of T- and B-cells, enhancing the cytotoxicity of NK cells, and activating the phagocytosis of macrophages in leukemic mice. Therefore, we suggest that *D. salina* might be able to promote antileukemic properties partially through modulating immune responses in leukemic mice. However, these mechanisms of immunomodulation for antileukemic activity need to be clarified.

extracts obtained by conventional extraction protocols are usually resuspended in acidified water (e.g., pH 2 with HCl), and the released free phenolic compounds are amassed with an organic solvent such as diethyl ether. Alkaline hydrolysis of phenolic extracts with NaOH under a nitrogen headspace yields phenolic compounds liberated from soluble esters, if present, whereas phenolic compounds bound to sugars are released by a subsequent acid hydrolysis involving 6 M HCl.[10−12] The liberated aglycones are easily identified by HPLC with UV diode array detection (DAD). For instance, Krygier et al.[13] successfully extracted free and soluble esterified phenolic acids in oilseeds from a methanol/acetone/water (7:7:6, v/v/v) extraction supernate. Their fractionation involved extracting the free phenolic compounds from an acidified aqueous suspension (pH 2 with HCl) of the supernate into a solvent mixture of diethyl ether and ethyl acetate. The aqueous residue was then subjected to alkaline hydrolysis to liberate soluble esterified phenolic compounds.

The determination of individual flavonoid glycosides present in foods is a formidable task, due to the numerous varieties that exist.[14] Therefore, to simply the situation, flavonoids are often analyzed after hydrolysis of their glycosides. The resulting aglycones are typically then separated by HPLC and identified using UV DAD detection or mass spectrometry.[5,14,15] Hertog et al.[14] acidified methanolic fruit and vegetable extracts with 6 M HCl, and the hydrolysis of flavonoid glycosides was performed under nitrogen at 90 °C for 2 h. The resultant aglycones were then identified by HPLC. Wang's research group[16] described the HPLC analysis of flavonoids in peanuts and other legume seeds with acid hydrolysis, in which the extraction was conducted on mixed ground seeds using 80% $CH_3OH$ containing 1.2 M HCl.

A certain percentage of phenolics, including some PACs, are "unextractable" or "insoluble" because, as aforementioned, they are bound to cell-wall material such as polysaccharides via covalent and hydrogen bonds as well as hydrophobic interactions.[3,7,8] Consequently, the phenolics content in any analytical determination is underestimated because of the bound phenolic cell-wall material that is not released by normal extraction protocols. To liberate bound phenolic derivatives, acid or base hydrolysis is applied to the plant sample prior to conventional extraction or to residual sediments resulting from conventional extraction procedures. According to Krygier et al.,[13] the residues from a methanol/acetone/water (7:7:6, v/v/v) extraction were hydrolyzed with alkali, and this effectively released insoluble bound phenolics. Similarly, Arranz et al.[7] treated a methanol/water extraction residue with $CH_3OH$/$H_2SO_4$ 90:10 (v/v) at 80 °C for 20 h to unfetter bound polyphenols, whereas the unextractable PACs were then released by mixing the aqueous acetonic residue with butanol/HCl (97.5:2.5, v/v) and $FeCl_3$ at 100 °C for 1 h. Furthermore, to liberate bound PAC derivatives, base hydrolysis was employed to treat cranberry pomace prior to conventional extraction protocols.[8] Caution must be exercised because severe alkaline conditions can, nonetheless, lead to cleavage of C−C interflavan bonds between the monomeric flavan-3-ol constituents. This may explain why alkaline-hydrolyzed PACs typically exist as monomers, dimers, trimers, and other low-molecular-weight oligomers. The A-ring of flavan-3-ols can also be broken by prolonged alkaline treatment.[8]

As previously reported, phenolic compounds of PS include simple phenolic acids (e.g., caffeic, ferulic, and coumaric acids), flavan-3-ols (e.g., (epi)catechin, epigallocatechin, catechin gallate, and epicatechin gallate), stilbenes (e.g., *trans*-resveratrol), and polymerized PACs,[17−19] but limited information is available concerning the soluble esterified and glycoside-bound phenolics and PACs of PS. Therefore, the objectives of this study were to liberate such soluble phenolic compounds from dry-blanched peanut skins (PS) extracts using alkaline and acid hydrolyses and then to characterize them by RP-HPLC-ESI-$MS^n$.

## MATERIALS AND METHODS

**Materials.** In a peanut processing plant, dry blanching of raw peanuts was performed to remove the seed coat (i.e., testa) from the kernel by transporting redskin peanuts on a conveyer belt through a low-temperature heating zone (at a maximum of 96 °C) for ∼45 min. The resultant dry-blanched PS were provided for this study by Universal Blanchers, LLC (Sylvester, GA, USA). After receipt of the PS, they were placed in a 4 °C refrigerator and analyzed within a month. All solvents and reagents were of analytical (ACS) grade, unless otherwise specified. Methanol, ethanol (95%), and hexanes were purchased from VWR International (Suwanee, GA, USA). (−)-Epiafzelechin was acquired from BOC Science (Shirley, NJ, USA), whereas all other phenolic standards were bought from either VWR International or the Sigma-Aldrich Chemical Co. (St. Louis, MO, USA).

**Phenolic Extraction.** Extraction of phenolics from PS was carried out in triplicate according to the method of Amarowicz et al.[20] with slight modifications. In brief, samples were first placed in Whatman cellulose extraction thimbles (43 mm i.d. × 123 mm e.l., VWR International), covered with a plug of glass wool, and defatted in a Soxhlet extraction apparatus under reflux for 12 h with hexanes. Defatted PS were transferred to 125 mL Erlenmeyer flasks at a mass-to-solvent ratio of 1:10 (w/v) with 80% (v/v) acetone. Extractions were performed in a gyrotary water bath shaker (model G76, New Brunswick Scientific Co., Inc., New Brunswick, NJ, USA) set at 150 rpm and a temperature of 45 °C for 30 min. The slurry was then filtered by gravity through fluted P8 filter paper (Fisher Scientific). The extraction process was repeated two more times as described above. All filtrates were pooled, and acetone was evaporated with a Büchi Rotavapor R-210 using a V-700 vacuum pump connected to a V-850 vacuum controller (Büchi Corp., New Castle, DE, USA) at 45 °C. The aqueous residue was frozen and then lyophilized in a FreeZone 2.5 L benchtop freeze-dryer (Labconco Corp., Kansas City, MO, USA) to ensure all traces of moisture were removed. The powder obtained was referred to as CE and stored in amber glass bottles at −20 °C until further analyzed.

**Hydrolysis of Phenolic Compounds from Crude Extracts.** Phenolic compounds from the acetonic PS extracts were fractionated into three classes (i.e., free, esterified, and glycoside-bound) from the acetonic PS extracts according to the method described by Dr. Amarowicz's laboratory[10,11] with slight modifications. Briefly, a 400 mg portion of each crude extract was dissolved in 20 mL of deionized water followed by acidification to pH 2 with 6 M HCl. Using a separatory funnel, free phenolic compounds were then extracted into 20 mL of diethyl ether. The extraction process was repeated four more times; the ether layers were transferred intermittently to a 100 mL round-bottom flask and the solvent was removed with a Büchi Rotavapor R-210 using a V-700 vacuum pump connected to a V-850 vacuum controller (Büchi Corp.) at 30 °C. Traces of water, when present, were removed from the contents in the round-bottom flask by a nitrogen evaporator (N-EVAP 111 with an aluminum bead dry bath set at ∼50 °C, Organomation Associates, Inc., Berlin, MA, USA). This sediment is referred to as F1 and was characterized by Ma et al.[19] The aqueous-phase residue in the separatory funnel was then mixed with 20 mL of 2 M NaOH, hydrolyzed under a $N_2$ atmosphere for 4 h at room temperature, and then acidified to pH 2 with 6 M HCl. Using 30 mL aliquots of diethyl ether, liberated phenolic compounds from soluble esters were extracted a total of five times. The ether layers were

[a]A represents an A-type bond with both (C4→C8) and (C2→O→C7) linkages or (C4→C6) and (C2→O→C7) linkages; B represents a B-type bond, which can be (C4→C8) or (C4→C6) linkage; (E)C represents (epi)catechin. [b]Retention times ($t_R$) of the total ion chromatograms. [c]The most abundant ions observed in the mass spectra are indicated in bold; quinone methide (QM) fission diagnostic ions are underlined.

transferred intermittently to a 100 mL round-bottom flask and the solvent was removed with the Rotavapor. Traces of water, when present, were removed from the contents in the round-bottom flask by the N-EVAP. This sediment is referred to as F2. The aqueous-phase residue was then finally combined with 15 mL of 6 M HCl and hydrolyzed under a $N_2$ atmosphere for 1 h at 100 °C in a forced-air convection oven. Using 45 mL aliquots of diethyl ether, liberated phenolic compounds from soluble glycosides were extracted a total of five times. The ether layers were transferred intermittently to a 100 mL round-bottom flask and the solvent was removed with the Rotavapor. Traces of water, when present, were removed from the contents in the round-bottom flask by the N-EVAP. This sediment is referred to as F3.

**Reversed-Phase High-Performance Liquid Chromatography–Electrospray Ionization Mass Spectrometry (RP-HPLC-ESI-MS$^n$).** An Agilent 1200 series HPLC system consisting of a quaternary pump with a degasser, autosampler, thermostated column compartment, UV–vis diode array detection with standard flow cell, and 3D ChemStation software (Agilent Technologies, Santa Clara, CA, USA) was employed for the chromatography. A reversed-phase Luna $C_{18}(2)$ column (4.6 × 250 mm, 5 μm particle size; Phenomenex, Torrance, CA, USA) was utilized. A gradient elution consisting of mobile phase A ($H_2O/CH_3CN/CH_3COOH$, 93:5:2, v/v/v) and mobile phase B ($H_2O/CH_3CN/CH_3COOH$, 58:40:2, v/v/v) from 0 to 100% B over a 50 min period at a flow rate of 1 mL/min was employed. Before subsequent injections, the system was re-equilibrated for 30 min using 100% A. A 10 mg portion of the PS CE, F2, and F3, were dissolved in 5, 4, and 2 mL of 80% (v/v) methanol, respectively, and then passed through a Phenex-RC, 15 mm, nonsterile, 0.2 μm syringe filter (Phenomenex Inc.) before determination of their phenolics; the injection volume was 20 μL. Detection wavelengths employed were $\lambda$ = 255 and 260 nm (hydroxybenzoic acids, as well as ellagic acid and ellagic acid derivatives), 280 nm ((+)-catechin, (−)-epicatechin, and PACs), 320 nm (phenolic acids notably of the *trans*-cinnamic acid family), and 360 nm (flavonols and general flavonoids). Tentative identification of separated components was made by matching UV–vis spectra and retention time ($t_R$) mapping with commercial standards. For quantification, calibration curves were constructed for each standard to confirm linearity on the basis of the UV–vis signal as well as for the determination of response factors.

RP-HPLC-ESI-MS$^n$ analyses of the phenolics were performed on an Agilent 1100 HPLC system, with the same chromatography conditions as described above, coupled with a Bruker Esquire 3000$^{plus}$ ion-trap mass spectrometer (Bruker Daltonics Inc., Billerica, MA, USA), which was equipped with an ESI source. Instrument control and data acquisition were performed with Bruker Daltonics Esquire 5.3 software. The HPLC eluent flowed directly into the mass spectrometer via a flow splitter delivering roughly 100 μL/min. Mass spectra were acquired in the negative-ion mode with smart settings for a target mass at an $m/z$ of 800, compound stability at 100%, and trap drive level at 100%. The voltage applied to the capillary was 4.0 kV with an end plate offset of −500 V. Nitrogen was used as the nebulizing gas at a pressure of 10 psi, a dry gas flow rate of 6 L/min, and a dry gas temperature of 280 °C. The phenolic compounds were fragmented using the auto-MS$^2$ mode with the following precursor-ion selection

parameters: two precursor ions, threshold absorbance of 10000, threshold relativity of 5.0%, ion excluded after two spectra, and exclusion release after 0.5 min. All collision-induced dissociation mass spectra were obtained with He as the collision gas at a fragmentation voltage of 1 V after isolation of the desired precursor ion. A full scan was performed over the mass range of $m/z$ 100−1000 at a rate of $m/z$ 13000 per second under standard−normal scan mode. The ion current control target was 50000 with a maximum accumulation time of 50 ms. Each mass spectrum generated was based on an average of 10 scans. Precursor ions of interest were further subjected to auto-$MS^n$ under the same conditions as described above.

**Statistical Analysis.** For each quantified phenolic compound, the mean and standard deviation were calculated from the measurements of triplicate extractions.

## RESULTS AND DISCUSSION

Alkaline and acid hydrolyses of the PS crude extracts were performed prior to chromatographic analysis to liberate phenolic aglycones from soluble esters and glycosides, respectively. Even though the HPLC profile of hydrolyzed samples may not reflect the actual structure of each phenolic ester and glycoside present in PS, hydrolysis does simplify the identification of phenolic compounds and provides important information concerning the profile of the individual aglycones. Moreover, it allowed further compounds to be detected via chromatography. In the present study few phenolic species were isolated from the PS crude phenolic extracts (Table 1), unlike those first liberated via base and acid hydrolyses followed by RP-HPLC separation and detection by ESI-$MS^n$ (Tables 2 and 3).

**Identification of Phenolic Compounds Using RP-HPLC-ESI-$MS^n$.** Only PACs and rutin were detectable in the PS crude phenolic extracts. However, many phenolics were identified in the free phenolics fraction (F1) after acidification of the extract and then extraction of these compounds with ether. Characterization of F1 is reported elsewhere.[19] A large variety of phenolic compounds, including PACs (monomer to pentamer), hydroxybenzoic acids, *trans*-cinnamic acids, stilbenes, and flavonoids, were eluted in fractions F2 (i.e., phenolics liberated from soluble esters) and F3 (i.e., phenolics liberated from soluble glycosides). Noteworthy is that flavonoids were liberated primarily from glycosides and recovered in F3.

Phenolic acids and flavonoids show characteristic UV range absorbance patterns from 190 to 380 nm.[9,15] From UV−vis DAD, four groups of phenolic compounds were characterized, namely, hydroxybenzoic acids (255 and 260 nm), (+)-catechin, (−)-epicatechin, and their polymers (280 nm), hydroxycinnamic acids (320 nm), and flavonols (360 nm). These compounds was subsequently introduced to the ESI mass spectrometer and analyzed on the basis of their $m/z$ values. Tentative identification of separated compounds was based on mass spectrometry alone; positive identification was achieved by the matching of $t_R$ values and spectral data with those of commercial standards, when available. Possible misinterpretations of spectra are due to the presence of stereoisomers, which are impossible to distinguish by mass spectra. Typically, the cleavage of a distinctive moiety from a compound in $MS^n$ analysis brings about a corresponding change in mass. To illustrate, rutinoside possesses a characteristic mass of 308 Da, so loss of 18 and 15 Da typically indicates the cleavage of a $H_2O$ molecule and a $CH_3^\bullet$ group, respectively. A-type PACs ($m/z$ 575, 861, 863, 1151, 1149, 1437, 1725, etc.) display a 2 Da difference in $[M - H]^-$ from B-type polymers ($m/z$ 577, 865, 1153, 1441, 1729, etc.). Quinone methide fission (QM), retro-Diels−Alder fission (RDA), and heterocyclic ring fission (HRF) are three major fragmentation routes of PACs well-described in the literature.[21]

$^{ij}A^-$ and $^{ij}B^-$ ions are diagnostic fragments for flavonoid identification and produced by the RDA cleavage in the C-ring. $A^-$ and $B^-$ are product ions in the negative-ion mode consisting of intact A- and B-rings, whereas the superscript *i* and *j* indicate the positions in the C-ring where two C−C bonds have been broken. Besides RDA cleavage in the C-ring, losses of neutral molecules such as $H_2O$ (18 Da), CO (28 Da), $CO_2$ (44 Da), $C_2H_2O$ (42 Da), and $C_3O_2$ (68 Da) can be characteristic in the negative-ion mode. The fragmentations of flavone, flavonol, and flavanone aglycones in the negative-ion mode by ESI trap mass spectrometry are well-demonstrated by Fabre et al.[22] The successive loss of $CH_3^\bullet$ and then CO (28 Da) or $CHO^\bullet$ (29 Da) were characteristic in methoxylated flavonoids.[23] However, the position of the methoxy group must be identified by the comparison with standards or by NMR analysis.[24] A similar nomenclature of fragmentation was adopted as for flavonoids. $^{ij}A^-$ and $^{ij}B^-$ ions are RDA fragments produced by cleavage of two C−C bonds in the C-ring. The flavonoid having a C-ring attached to the A-ring of the other flavonoid is denoted "part I", and the other flavonoid is referred to as "part II". Identification of compounds detected in both PS crude extracts and each base- and acid-hydrolytic fraction is discussed as follows.

**PS Crude Extracts.** *Proanthocyanidins (PACs).* Compounds providing a molecular ion $[M - H]^-$ at $m/z$ 575 (compounds **CE-1-13**, **-17**, **-21**, **-24**, **-26**, and **-27**) and 577 (compounds **CE-1-6** and **-10**) are likely PAC A- and B-type dimers, respectively. In the negative-ion mode, A-type dimers yield product ions at $m/z$ 449 $[M - H - 126\ (C_6H_6O_3)]^-$ and 423 $[M - H - 152\ (C_8H_8O_3)]^-$ via HRF fragmentation at the top unit and RDA fragmentation at the base unit, respectively. Generally, the top unit is the favored site for RDA, but fission can occur at the base unit when blocked by A-type bonds.[21] QM ions were present at $m/z$ 289 $[M_T - H\ (290 - H)]^-$ (QM cleavage at the terminal (T) unit) and $m/z$ 285 $[M_E - 5H\ (290 - 5H)]^-$ (QM cleavage at the extension (E) unit). Likewise, product ions at $m/z$ 451 $[M - H - 126\ (C_6H_6O_3)]^-$, 425 $[M - H - 152\ (C_8H_8O_3)]^-$, 289 $[M_T - H\ (290 - H)]^-$, and 287 $[M_E - 3H\ (290 - 3H)]^-$ were present in the $MS^2$ fragmentation of B-type dimers. The fragment ion at $m/z$ 407 was generated by further loss of a $-H_2O$ moiety from the ion at $m/z$ 425. These data and characteristic MS fragmentation patterns are consistent with the findings of previous studies.[21,25,26]

Molecular ions present at $m/z$ 863 (compounds **CE-1-1**, **-3**, **-4**, **-7**, **-8**, **-9**, **-11**, **-12**, **-18**, **-19**, **-22**, and **-23**) and 865 (compound **CE-1-2**) were likely produced by PAC A- and B-type trimers, respectively. Theoretically, PAC trimers dissociate in a similar way to dimers: there are two types of A-type trimers both possessing a molecular ion at $m/z$ 863, but with different QM diagnostic ions caused by varied positions of the A-bond. QM cleavage between the top and middle units produced ions at $m/z$ 575 $[M_T - H\ (576 - H)]^-$ and 287 $[M_E - 3H\ (290 - 3H)]^-$, indicating that the A-type linkage is located between the middle and base units (compounds **CE-1-1**, **-3**, **-7**, **-11**, **-18**, and **-22**). The HRF and RDA fragmentation of the top unit yielded product ions at $m/z$ 737 $[M - H - 126\ (C_6H_6O_3)]^-$ and 711 $[M - H - 152\ (C_8H_8O_3)]^-$, respectively. The HRF fragmentation of the middle unit gave a product ion at $m/z$

| **F-2-48** | prodelphinidin A-type tetramer [(E)C→A→(E)GC→A→(E)C→A→(E)C] | 234, 280 | 37.4 | 1163 | 581 | 877, 873, 751, 575, 449, 411, 289, 285 |

[a]A represents an A-type bond with both (C4→C8) and (C2→O→C7) linkages or (C4→C6) and (C2→O→C7) linkages; B represents a B-type bond which can be (C4→C8) or (C4→C6) linkage; (E)C represents (epi)catechin, (E)GC represents (epi)gallocatechin, (E)CG represents (epi)catechin gallate, and (E)Afz represents (epi)afzelechin. [b]sh, shoulder in the spectrum. [c]Retention times ($t_R$) of the total ion chromatograms. [d]The most abundant ions observed in the mass spectra are indicated in bold; quinone methide (QM) fission diagnostic ions are underlined.

449. When the A-type linkage is located between the top and middle units (compounds **CE-1-4**, **-8**, **-9**, **-12**, **-19**, and **-23**), QM cleavage ions are present at $m/z$ 573 $[M_E - 3H\ (576 - 3H)]^-$ and 289 $[M_T - H\ (290 - H)]^-$. In this case, the product ion at $m/z$ 711 was formed by RDA fragmentation of the middle unit. The HRF fragmentation of the middle unit yielded product ions at $m/z$ 451 and 411. However, these two types of trimer, containing the same number of A-type bonds, were not well resolved by HPLC. Two series of fragments were observed in one mass spectrum. HRF and RDA fragmentation of the B-type trimer gave rise to dissociation ions at $m/z$ 739 $[M - H - 126\ (C_6H_6O_3)]^-$ and 713 $[M - H - 152\ (C_8H_8O_3)]^-$, respectively. The HRF fragmentation of the middle unit resulted in a product ion at $m/z$ 451. The prominent fragment ion at $m/z$ 695 was generated by further loss of a $-H_2O$ moiety from the RDA ion at $m/z$ 713. QM diagnostic ions were present at $m/z$ 577 $[M_T - H\ (578 - H)]^-$, 575 $[M_E - 3H\ (578 - 3H)]^-$, and 287 $[M_E - 3H\ (290 - 3H)]^-$.

$[M - 2H]^{2-}$ at $m/z$ 719 (compounds **CE-1-5**, **-14**, and **-15**) and 574 (compounds **CE-1-16** and **-20**) are doubly charged ions generated from a PAC A-type pentamer ($m/z$ 1439) and a PAC A-type tetramer ($m/z$ 1149), respectively. Apropos the pentamer (**CE-1-5** and **-14**), the diagnostic QM ions present at $m/z$ 863 $[M_T - H\ (864 - H)]^-$, 575 $[M_E - 3H\ (578 - 3H)]^-$, and 573 $[M_E - 3H\ (576 - 3H)]^-$ indicate a connection sequence such as (epi)catechin→B→(epi)catechin→B→(epi)-catechin→A→(epi)catechin→B→(epi)catechin, where A and B represent A- and B-type linkages, respectively. The A-type pentamer (**CE-1-15**) gave rise to QM cleavage fragments at $m/z$ 861 $[M_E - 3H\ (864 - 3H)]^-$, 577 $[M_T - H\ (578 - H)]^-$, and 575 $[M_T - H\ (576 - H)]^-$, being assigned to a sequence such as (epi)catechin→B→(epi)catechin→A→(epi)catechin→B→(epi)catechin→B→(epi)catechin. Vis-à-vis the tetramer, the QM fragment at $m/z$ 859 $[M_E - 3H\ (862 - 3H)]^-$ were observed when the B-type linkage is located between the base and its upper unit (**CE-1-16**). The production of a QM fragment at $m/z$ 861 $[M_T - H\ (862 - H)]^-$ indicates that the B-type linkage is located between the top and its subsequent unit, whereas the remaining units are linked by A-type bonds (compound **CE-1-20**).

*Flavonoid.* A 316 Da *O*-methylated flavonoid with a rutinoside attached was determined as compound **CE-1-25**. It yielded a $[M - H]^-$ at $m/z$ 623 and fragment ions at $m/z$ 315 $[M - H - 308]^-$ by loss of a rutinoside moiety and $m/z$ 300 $[M - H - 308 - 15]^-$ by further loss of a $CH_3^\bullet$ group from the deprotonated flavonoid aglycone. Although there is a wide range of candidates for 316 Da *O*-methylated flavonoids such as rhamnetin, isorhamnetin, tamarixetin, and neptin, the compound is likely to be isorhamnetin according to an NMR study reported by Lou's group.[27]

**Esterified Phenolics.** *Phenylacetic Acid.* Compound **F-2-3** yielded a molecular ion at $m/z$ 167 and a fragment ion at $m/z$ 123 by loss of a $-CO_2$ group from the carboxylic acid moiety. Among several candidates such as 3,4-dihydroxyphenylacetic acid (DOPAC), vanillic acid, orsellinic acid, and homogentisic acid, the most likely compound is DOPAC, as evidenced by $t_R$ matching with a commercial standard. Compound **F-2-6** is likely a derivative of DOPAC because of the fragment ion at $m/z$ 167 corresponding to the deprotonated form of DOPAC and its decarboxylated ion at $m/z$ 123.

*Hydroxycinnamic Acids.* Compound **F-2-11** yielded a molecular ion at $m/z$ 179 and its decarboxylated ion at $m/z$

[a] A represents an A-type bond with both (C4→C8) and (C2→O→C7) linkages or (C4→C6) and (C2→O→C7) linkages; B represents a B-type bond which can be (C4→C8) or (C4→C6) linkage; (E)C represents (epi)catechin, (E)GC represents (epi)gallocatechin, and (E)Afz represents (epi)afzelechin. [b] sh, shoulder in the spectrum. [c] Retention times ($t_R$) of the total ion chromatograms. [d] The most abundant ions observed in mass spectra are indicated in bold; quinone methide (QM) fission diagnostic ions are underlined.

135. It is further confirmed as *trans*-caffeic acid by $t_R$ matching with a commercial standard. Compound **F-2-22** was identified as *p*-coumaric acid by the standard ($\lambda_{max}$ = 310 nm), resulting in a $[M - H]^-$ at *m/z* 163 and a classic fragment at *m/z* 119 through neutral loss of $CO_2$. Compound **F-2-25** displayed a maximum UV absorption band at 322 nm and was further confirmed as ferulic acid by a commercial standard. It gave a $[M - H]^-$ at *m/z* 193 together with fragment ions at *m/z* 178 $[M - H - 15\ (CH_3)]^{\bullet -}$, 149 $[M - H - 44\ (CO_2)]^-$, and 134 $[M - H - 44\ (CO_2) - 15\ (CH_3)]^{\bullet -}$.

*Hydroxybenzoic Acids, Their Esters, and Phenyllactic Acid.* Compounds **F-2-4** and **-7** both yielded a molecular ion at *m/z* 181. Further dissociation ions of compound **F-2-4** were present at *m/z* 163 $[M - H - 18\ (H_2O)]^-$, 153 $[M - H - 28\ (CH_2CH_2)]^-$, 137 $[M - H - 44\ (C_2H_4O)]^-$, and 109 $[M - H - 72\ (COOCH_2CH_2)]^-$. The tentative candidate was ethyl protocatechuate. This compound in peanut seed testa was identified by NMR analysis performed by Huang et al.[28] Compound **F-2-7** gave fragment ions at *m/z* 163 $[M - H - 18\ (H_2O)]^-$ and 137 $[M - H - 44\ (CO_2)]^-$ and is likely DL-3-(4-hydroxyphenyl)lactic acid. Compound **F-2-5** was confirmed by a commercial standard to be protocatechuic acid ($\lambda_{max}$ = 260 nm), producing a molecular ion at *m/z* 153 and a fragment ion at *m/z* 109 by loss of $CO_2$ from the carboxylic acid moiety. *p*-Hydroxybenzoic acid (compound **F-2-9**) was recovered in F2 and showed a molecular ion at *m/z* 137. Although no significant $MS^2$ fragments were observed, this compound's identity was further confirmed by $t_R$ matching with a commercial standard.

*Procyanidins (Monomers to Tetramers).* Compounds **F-2-1** and **-2** are likely gallocatechin and a derivative, respectively. The molecular ion $[M - H]^-$ of gallocatechin was present at *m/z* 305, which further fragmented to product ions at *m/z* 261 $[M - H - 44]^-$ by loss of a $-CH_2-CHOH-$ group or neutral loss of $CO_2$, 219 $[M - H - 86]^-$ by loss of a $C_4H_4O_2$ from the A-ring plus 2H, and 179 $[M - H - 126]^-$ attributed to a $^{1,4}B^-$ ion. The conjugate $^{1,4}A^-$ fragment at *m/z* 125 represents the intact A-ring with two phenolic groups and is formed through a pathway as demonstrated by Miketova et al.[29] Compounds **F-2-8**, **-10**, and **-12** are stereoisomers with the same molecular ions at *m/z* 289. Classic fragments were observed at *m/z* 245 $[M - H - 44]^-$ by loss of a $-CH_2-CHOH-$ group or neutral loss of $CO_2$, 205 $[M - H - 84]^-$ by loss of $C_4H_4O_2$ from the A-ring, and 179 $[M - H - 110]^-$ by loss of $C_6H_6O_2$ (B-ring). The

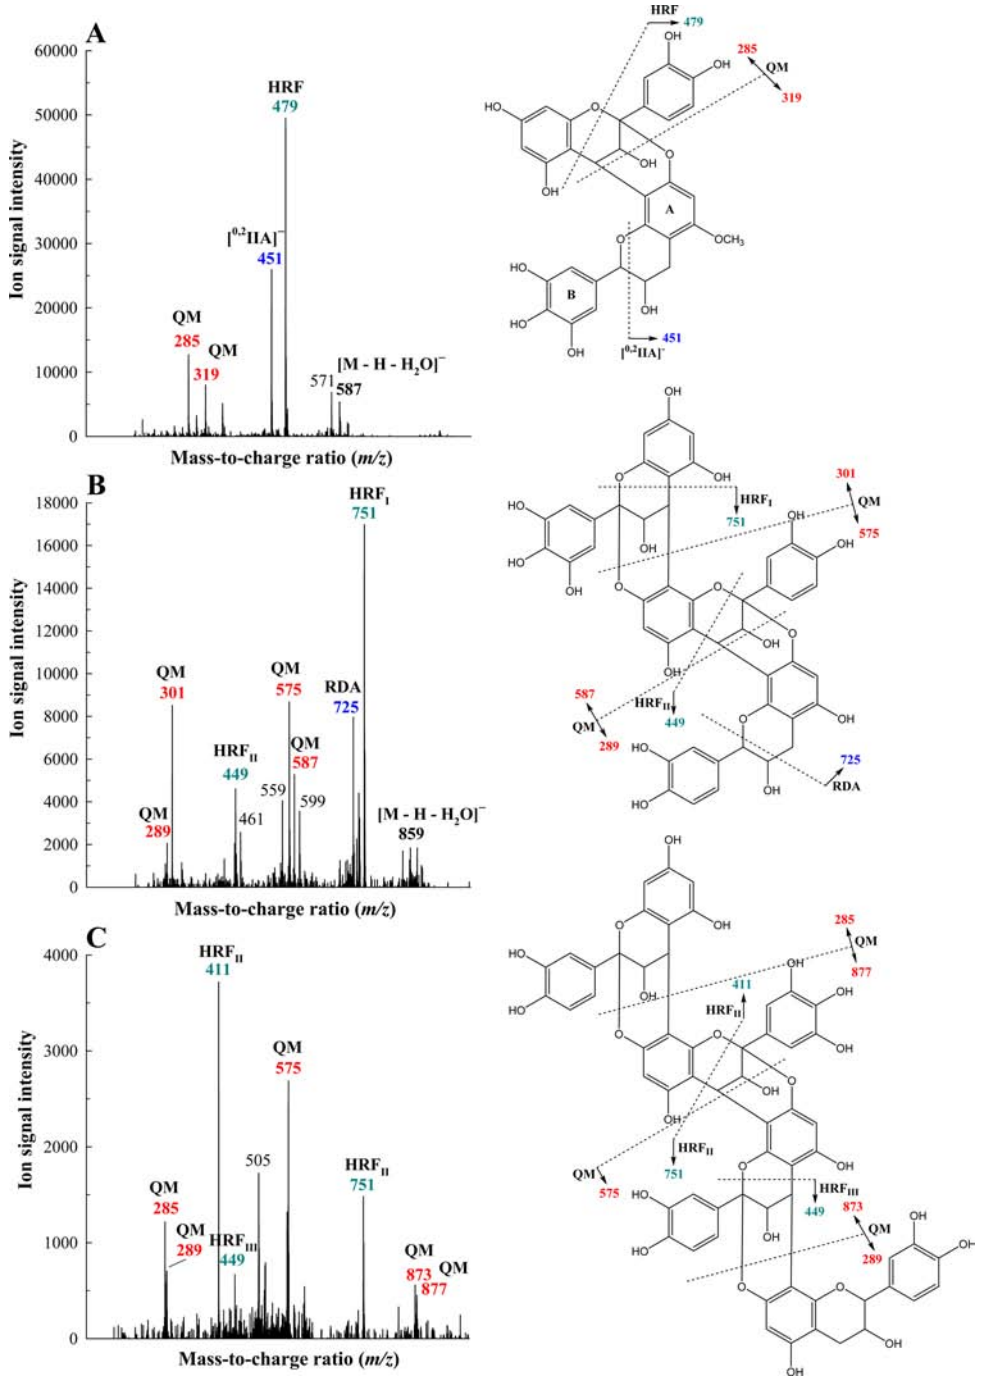

**Figure 1.** Tentative structures and fragmentation schemes of (A) prodelphinidin A-type dimer [(E)C→A→6-*O*-methyl (E)GC] (**F-2-18**, *m/z* 605), (B) prodelphinidin A-type trimer [(E)GC→A→(E)C→A→(E)C] (**F-2-34**, *m/z* 877), and (C) prodelphinidin A-type tetramer [(E)C→A→(E)GC→A→(E)C→A→(E)C] (**F-2-48**, *m/z* 1163). See Table 3 for formal designations.

fragmentation mechanisms of (epi)catechin were described by Bravo et al.[30] The compounds were further confirmed by standards as (−)-catechin (compound **F-2-8**), (+)-catechin (compound **F-2-10**), and (−)-epicatechin (compound **F-2-12**), respectively. Compound **F-2-13** was found to be (−)-epiafzelechin with a $[M - H]^-$ at *m/z* 273, which dissociated further into ions at *m/z* 229 $[M - H - 44]^-$ by loss of a $-CH_2-CHOH-$ group or neutral loss of $CO_2$, 187 $[M - H - 86]^-$ by loss of $C_4H_4O_2$ from the A-ring plus 2H, and 137 $[M - H - 136]^-$ attributed to a $^{1,3}A^-$ ion. The identification was confirmed by $t_R$ matching with a commercial standard.

Compounds **F-2-19**, **-21**, **-26**, **-27**, **-28**, **-30**, and **-31** are probably PAC A-type dimers, yielding molecular ions at *m/z* 575, whereas compound **F-2-20** is likely a PAC B-type dimer with a $[M - H]^-$ at *m/z* 577. As aforementioned, PAC A-type trimers (*m/z* 863) can further be divided into two categories according to the location of the A-bond. Compounds **F-2-14**, **-29**, **-33**, **-36**, and **-44** are likely PAC A-type trimers with an A-type linkage between the middle and bottom units. Trimers with an A-type linkage between the top and middle units are candidates for compounds **F-2-15** and **-45**. Compound **F-2-42**, yielding a $[M - H]^-$ at *m/z* 861, is likely a PAC trimer with

dx.doi.org/10.1021/jf503836n | J. Agric. Food Chem. 2014, 62, 11488−11504

two A-type linkages. The HRF fragment ions of the top unit were present at $m/z$ 735, whereas the RDA fragmentation of the base unit generated an ion at $m/z$ 709. The QM cleavage between the top and middle units gave ions at $m/z$ 575 $[M_T - H\ (576 - H)]^-$ and 285 $[M_E - 5H\ (290 - 5H)]^-$. The QM cleavage between the middle and base units produced ions at $m/z$ 289 $[M_T - H\ (290 - H)]^-$ and 571 $[M_E - 5H\ (576 - 5H)]^-$. The fragment at $m/z$ 449 was generated by fragmentation of the QM ion at $m/z$ 575 and HRF ion at $m/z$ 735 via the mechanism of HRF.[21]

Compounds **F-2-32**, **-38**, **-39**, **-43**, and **-46** are PAC A-type tetramers, displaying doubly charged ions $[M - 2H]^{2-}$ at $m/z$ 574. Noteworthy is that no significant fragments were observed for the determination of the flavan-3-ol connection sequence. Compound **F-2-47** yielded a $[M - 2H]^{2-}$ at $m/z$ 507. Although no significant $MS^2$ fragments were evident, the proposed candidate is a PAC A-type trimer with (epi)catechin gallate as its base unit.

*Propelargonidin.* Compound **F-2-35** ($m/z$ 559) is tentatively identified as a propelargonidin A-type dimer with (epi)afzelechin as its base unit. HRF fragmentation of the (epi)catechin top unit and the RDA fragmentation of the (epi)afzelechin base unit gave product ions at $m/z$ 433 $[M - H - 126\ (C_6H_6O_3)]^-$ and 423 $[M - H - 136\ (C_8H_8O_2)]^-$, respectively. Diagnostic ions at $m/z$ 273 $[M_T - H\ (274 - H)]^-$ and 285 $[M_E - 5H\ (290 - 5H)]^-$ were produced by QM fission. The fragmentation pathways of a similar propelargonidin A-type dimer, only with an (epi)afzelechin as its top unit, was well described by Appeldoorn et al.[25]

*Prodelphinidins.* Compound **F-2-16** is likely a prodelphinidin dimer containing a B-bond linked to (epi)gallocatechin (top) and (epi)catechin (base) units. It yielded a $[M - H]^-$ of $m/z$ 593 and further fragments at $m/z$ 467 $[M - H - 126\ (C_6H_6O_3)]^-$ by HRF at the top unit, 425 $[M - H - 168\ (C_8H_8O_4)]^-$ by RDA at the top unit, 303 $[M_E - 3H\ (306 - 3H)]^-$, and 289 $[M_T - H\ (290 - H)]^-$. The fragmentation scheme of this B-type prodelphinidin dimer has been documented.[31] Compound **F-2-17** showed a $[M - H]^-$ at $m/z$ 591 and is tentatively identified as a prodelphinidin dimer containing an A-bond linked to (epi)gallocatechin (top) and (epi)catechin (base) units. The HRF fragmentation of the (epi)gallocatechin unit and RDA fragmentation of the (epi)-catechin unit yielded product ions at $m/z$ 465 $[M - H - 126\ (C_6H_6O_3)]^-$ and 439 $[M - H - 152\ (C_8H_8O_3)]^-$, respectively. The QM cleavage ions were present at $m/z$ 289 $[M_T - H\ (290 - H)]^-$ and 301 $[M_E - 5H\ (306 - 5H)]^-$. On the other hand, compound **F-2-23** is a similar A-type prodelphinidin dimer but with (epi)catechin as its top unit and (epi)gallocatechin as its base unit. QM diagnostic ions were present at $m/z$ 305 $[M_T - H\ (306 - H)]^-$ and 285 $[M_E - 5H\ (289 - 5H)]^-$. A product ion at $m/z$ 423 $[M - H - 168\ (C_8H_8O_4)]^-$ was generated by the RDA fragment of the base (epi)gallocatechin unit.

A molecular ion $[M - H]^-$ at $m/z$ 605 was provided by compound **F-2-18**. It is likely a prodelphinidin A-type dimer with a (epi)catechin top unit connected to a 5-*O*-methyl (epi)gallocatechin. The HRF fragmentation of top (epi)-catechin unit gave an anion at $m/z$ 479 $[M - H - 126\ (C_6H_6O_3)]^-$. The $^{0,2}IIA^-$ fragment from the base methyl (epi)gallocatechin was present at $m/z$ 451 $[M - H - 154\ (C_7H_6O_4)]^-$, which indicates that the methoxy group is attached to the 5-position on the A-ring. QM diagnostic ions were found at $m/z$ 319 $[M_T - H\ (320 - H)]^-$ and 285 $[M_E - 5H\ (290 - 5H)]^-$. The tentative structure and fragmentation pathways for compound **F-2-18** are depicted in Figure 1A. Similarly, the proposed candidates for compound **F-2-41**, which yielded a $[M - H]^-$ at $m/z$ 607, are a prodelphinidin B-type dimer containing an (epi)catechin unit and a methyl (epi)-gallocatechin unit or a prodelphinidin A-type dimer with two (epi)gallocatechin units. Unfortunately, the identification cannot be unequivocally assigned because of the lack of significant $MS^2$ fragments.

Compound **F-2-34** yielded a $[M - H]^-$ at $m/z$ 877, which was tentatively identified as a prodelphinidin trimer with a connection sequence of (epi)gallocatechin→A→(epi)-catechin→A→(epi)catechin; here, A represents an A-type linkage. The HRF fragment from the (epi)gallocatechin top unit and the RDA fragment from the base (epi)catechin unit were present at $m/z$ 751 $[M - H - 126\ (C_6H_6O_3)]^-$ and 725 $[M - H - 152\ (C_8H_8O_3)]^-$, respectively. An ion at $m/z$ 599 was generated by RDA fragmentation of the HRF ion at $m/z$ 751. QM diagnostic ions were present at $m/z$ 575 $[M_T - H\ (576 - H)]^-$, 289 $[M_T - H\ (290 - H)]^-$, 301 $[M_E - 5H\ (306 - 5H)]^-$, and 587 $[M_E - H\ (592 - 5H)]^-$. HRF fragmentation of QM cleavage ions at $m/z$ 587 and 575 yielded anions at $m/z$ 461 and 449, respectively. The tentative structure and fragmentation pathways for compound **F-2-34** are depicted in Figure 1B. The tentative candidate for compound **F-2-40** is likely a prodelphinidin trimer containing a luteolin or kaempferol base unit. Further fragmentation of $[M - H]^-$ at $m/z$ 875 yielded ions at $m/z$ 749 $[M - H - 126\ (C_6H_6O_3)]^-$ and 723 $[M - H - 152\ (C_8H_8O_3)]^-$ by HRF and RDA fragmentation, respectively, indicating a top (epi)catechin unit with a B-type linkage to the following (epi)gallocatechin unit. Unfortunately, no significant diagnostic QM ions were observed in the mass spectra to further support the assignment. The $[M - 2H]^{2-}$ at $m/z$ 581 (compound **F-2-48**) was a doubly charged ion yielded by a prodelphinidin tetramer with a molecular mass of 1164 Da. The diagnostic QM fragments were present at $m/z$ 877 $[M_T - H\ (878 - H)]^-$, 575 $[M_T - H\ (576 - H)]^-$, 289 $[M_T - H\ (290 - H)]^-$, 873 $[M_E - 5H\ (878 - 5H)]^-$, and 285 $[M_E - 5H\ (290 - 5H)]^-$, indicating a connection sequence of (epi)catechin→A→(epi)-gallocatechin→A→(epi)catechin→A→(epi)catechin. HRF fragmentation of the QM ions at $m/z$ 877 and 575 gave further dissociation ions at $m/z$ 751 and 449, respectively. The proposed structure and fragmentation pathways for compound **F-2-48** are shown in Figure 1C.

*Flavonoid.* The proposed candidate for compound **F-2-37** is myricetin, which was further confirmed by $t_R$ matching with a commercial standard. Its $[M - H]^-$ at $m/z$ 317 dissociated into fragments at $m/z$ 271 $[M - H - 18\ (H_2O) - 28\ (CO)]^-$, 243 $[M - H - 18\ (H_2O) - 56\ (2CO)]^-$, and 227 $[M - H - 18\ (H_2O) - 28\ (CO) - 44\ (CO_2)]^-$. RDA diagnostic ions at $m/z$ 179, 151, and 137 were noted as $^{1,2}A^-$, $^{1,3}A^-$, and $^{1,2}B^-$, respectively.

*Stilbene.* Compound **F-2-24** was tentatively identified as *trans*-piceatannol by a molecular ion $[M - H]^-$ at $m/z$ 243. Further fragment ions were present at $m/z$ 225 $[M - H - 18\ (H_2O)]^-$, 201 $[M - H - 42\ (CHCOH)]^-$, 199 $[M - H - 42\ (CHCOH) - 2H]^-$, 175 $[M - H - 68\ (C_3O_2)]^-$, 173 $[M - H - 42\ (CHCOH) - 28\ (CO)]^-$, and 159 $[M - H - 42\ (CHCOH) - 42\ (C_2H_2O)$ or $M - H - 42\ (CHCOH) - 2H - 40\ (C_2O)]^-$. This is the CID fragmentation of $[M - H]^-$ when the deprotonation reaction occurs on the catechol moiety of *trans*-piceatannol. These fragmentation mechanisms have been elucidated and described by Stella et al.[32] Similar $MS^2$

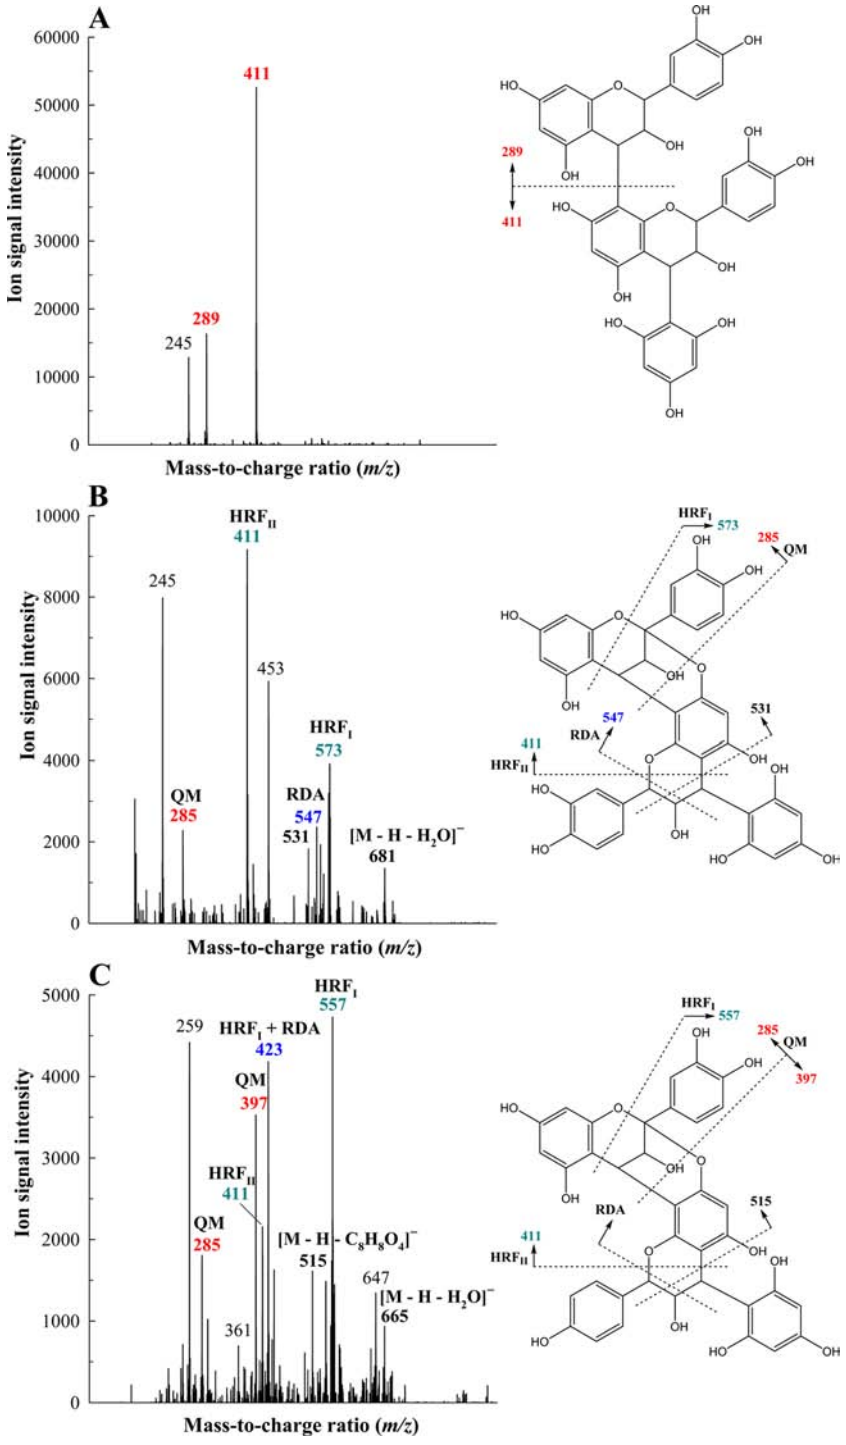

**Figure 2.** Tentative structures and fragmentation schemes of (A) PAC B-type dimer [(E)C→B→(E)C→phloroglucinol] (**F-3-13**, **-16**, and **-19**, *m/z* 701); (B) PAC A-type dimer [(E)C→A→(E)C→phloroglucinol] (**F-3-10**, **-12**, **-15**, **-17**, **-18**, **-20**, **-25**, **-26**, and **-38**, *m/z* 699); and (C) PAC A-type dimer [(E)C→A→(E)Afz→phloroglucinol] (**F-3-34** and **-43**, *m/z* 683). See Table 3 for formal designations.

fragments for *trans*-piceatannol in peanuts were reported by Ku et al.[33]

**Glycoside-Bound Phenolics.** *Phenolic Acids.* Compound **F-3-3** with a molecular ion $[M - H]^-$ at *m/z* 167 and a fragment ion at *m/z* 123 is likely DOPAC, as discussed for F2. Compound **F-3-5** was identified as protocatechuic acid by its $[M - H]^-$ at *m/z* 153 and the decarboxylated ion at *m/z* 109 $[M - H - 44\ (CO_2)]^-$. Compound **F-3-6** may be a protocatechuic acid derivative: it yielded a $[M - H]^-$ at *m/z* 233 and a prominent fragment ion at *m/z* 153, corresponding to deprotonated protocatechuic acid. Compound **F-3-8**, giving a molecular ion at *m/z* 137, was identified as *p*-hydroxybenzoic acid by UV spectra ($\lambda_{max}$ = 256 nm) and $t_R$ matching with a commercial standard.

Compound **F-3-11** is confirmed as vanillic acid by UV spectra ($\lambda_{max}$ = 260 nm) and $t_R$ matching with a commercial standard. It yielded a $[M - H]^-$ at *m/z* 167 and a fragment ion at *m/z* 123 by loss of $CO_2$ from the carboxylic acid moiety.

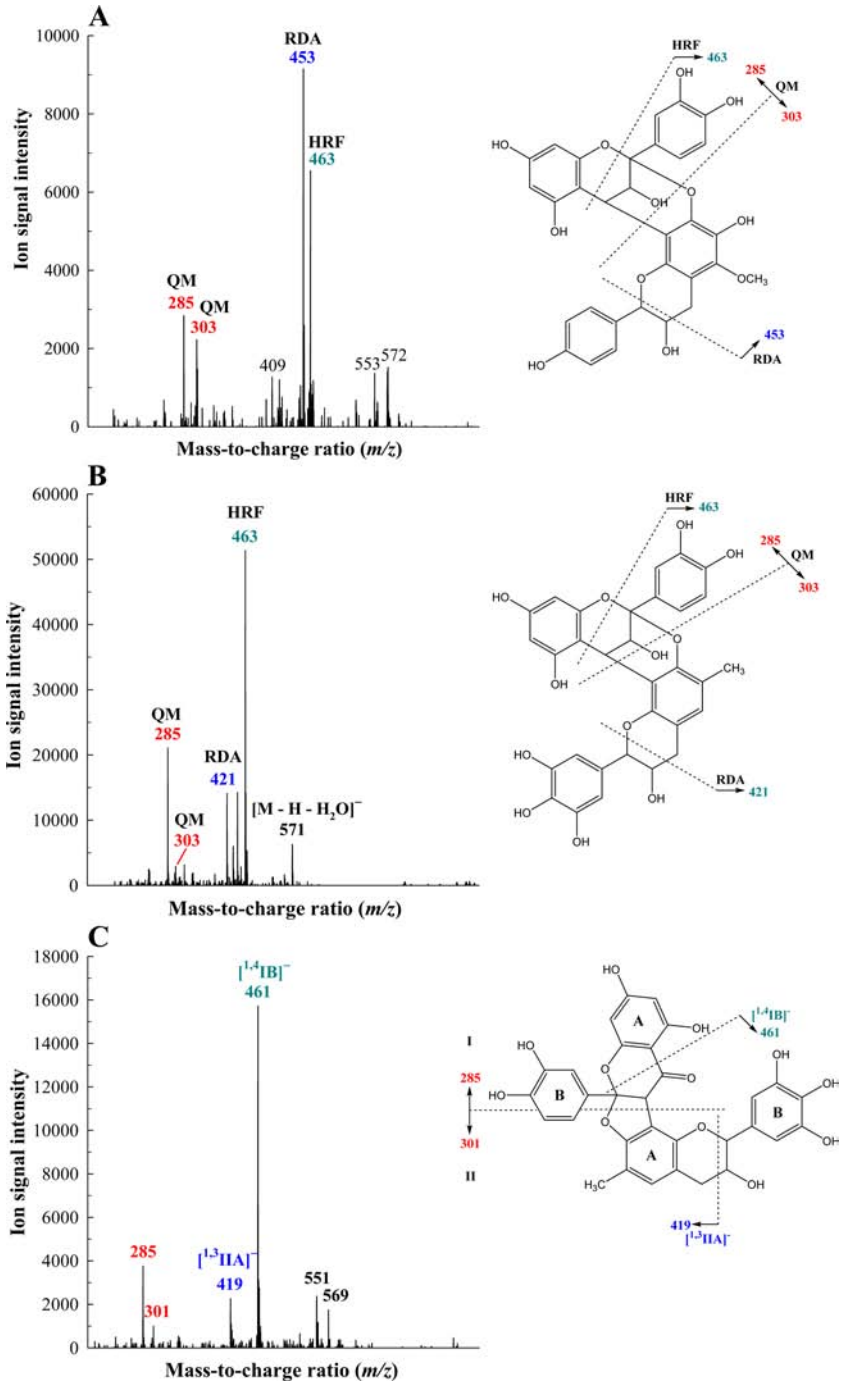

**Figure 3.** Tentative structures and fragmentation schemes of (A) PAC A-type dimer [(E)C→A→dihydroscutellarein] (**F-3-39**, *m/z* 589), (B) prorobinetidin A-type dimer [(E)C→A→C-methyl (epi)robinetinidol] (**F-3-56**, **-62**, **-64**, and **-68**, *m/z* 589), and (C) biflavanoid [eriodictyol→C-methyl robinetinidol] (**F-3-48**, **-57** and **-67**, *m/z* 587). See Table 3 for formal designations.

Other dissociation ions were present at *m/z* 152 [M − H − 15 $(CH_3)$]$^{\bullet-}$ and 108 [M − H − 44 $(CO_2)$ − 15 $(CH_3)$]$^{\bullet-}$. **F-3-22** is likely homovanillic acid with a [M − H]$^-$ at *m/z* 181, which dissociated further into fragments at *m/z* 137 [M − H − 44 $(CO_2)$]$^-$ and 122 [M − H − 44 $(CO_2)$ − 15 $(CH_3)$]$^{\bullet-}$.

*Procyanidins (Monomers to Dimers).* Compounds **F-3-1** and **F-3-2** are identified as gallocatechin and a derivative, as in F2. Compound **F-3-4** is likely methyl gallate, yielding a [M − H]$^-$ at *m/z* 183 and a fragment ion at 124 [M − H − 44 $(CO_2)$ − 15 $(CH_3)$]$^{\bullet-}$. Compounds **F-3-9** and **F-3-14** are (+)-catechin and (−)-epicatechin, respectively, as described for F2 and further confirmed by $t_R$ matching with commercial standards. Compounds **F-3-21**, **-23**, **-27**, **-32**, **-35**, **-36**, and **-40** are likely PAC A-type dimers with molecular ions at *m/z* 575 and QM ions at *m/z* 289 [$M_T$ − H (290 − H)]$^-$ and 285 [$M_E$ − 5H (290 − 5H)]$^-$.

*Propelargonidins.* Compound **F-3-24** (*m/z* 847) is likely a propelargonidin A-type trimer with an (epi)afzelechin middle unit. QM cleavage ions were present at *m/z* 289 [$M_T$ − H (290 − H)]$^-$ and 557 [$M_E$ − 3H (560 − 3H)]$^-$, indicating the presence of a B-type linkage between the middle (epi)-afzelechin unit and the base (epi)catechin unit. Compound **F-**

dx.doi.org/10.1021/jf503836n | *J. Agric. Food Chem.* 2014, 62, 11488−11504

**3-52** yielded a $[M - H]^-$ at *m/z* 845 and was tentatively identified as a propelargonidin trimer with one (epi)afzelechin top unit and two A-type linkages. QM cleavage of this trimer resulted in fragments at *m/z* 289 $[M_T - H\ (290 - H)]^-$, 575 $[M_T - H\ (576 - H)]^-$, and 269 $[M_E - 5H\ (273 - 5H)]^-$, 555 $[M_E - 5H\ (560 - 5H)]^-$. The fragmentation pathways for these two propelargonidin oligomers are well documented.[21,25]

*Proanthocyanidins (PACs) Containing an Additional Phloroglucinol Unit.* Compounds **F-3-10**, **-12**, **-15**, **-17**, **-18**, **-20**, **-25**, **-26**, and **-37** are likely A-type PAC dimers containing an additional phloroglucinol unit, which was reported in cranberry by Foo et al.[34] These compounds yielded molecular ions at *m/z* 699, which dissociated further into fragments at *m/z* 573 $[M - H - 126]^-$ by losing a phloroglucinol moiety ($C_6H_6O_3$) from the top (epi)catechin unit via the HRF function, 547 $[M - H - 152]^-$ by losing $C_8H_8O_3$ from the base (epi)catechin-phloroglucinol unit via the RDA function, and 531 $[M - H - 168]^-$ by losing $C_8H_8O_4$ from the base (epi)catechin-phloroglucinol unit. Product ions at *m/z* 411 and 287 were generated by HRF fragmentation at the base (epi)catechin-phloroglucinol unit. A QM diagnostic ion was present at *m/z* 285 $[M_E - 5H\ (290 - 5H)]^-$. It is interesting that the conjugate ion at *m/z* 413 was not observed. Our identification is further supported by the $MS^3$ experiment. Compounds **F-3-28**, **-29**, and **-31** (*m/z* 657) appear to be generated by losing a $C_2H_2O$ group (42 Da) from the additional phloroglucinol unit of the above-described PAC dimers. Compounds **F-3-33** and **-50** (*m/z* 547) are also likely fragments from the aforementioned dimers by RDA at the base (epi)catechin-phloroglucinol unit. Furthermore, compounds **F-3-39**, **-44**, **-48**, and **-51** (*m/z* 531) are tentatively identified as fragments from this dimer after loss of $C_8H_8O_4$ from the base (epi)catechin-phloroglucinol unit. Such cleavages can be induced by heat or acid hydrolysis applied to release phenolics bound to glycosides.

Compounds **F-3-13**, **-16**, and **-19** are tentatively identified as a similar PAC dimer, but the top (epi)catechin and the base (epi)catechin-phloroglucinol units are connected by a B-type linkage. The $[M - H]^-$ was present at *m/z* 701. Diagnostic ions were evident at *m/z* 289 $[M_T - H\ (290 - H)]^-$ and 411 $[M_B - 3H\ (414 - 3H)]^-$, indicating a fragmentation pathway as described by Sarnoski et al.[26] whereby QM cleavage is blocked by a carbonyl group on the C-ring of the base luteolin or kaempferol group. In the present study, the presence of an additional phloroglucinol unit, which is connected to the C-ring of the base (epi)catechin unit, inhibits QM fission. Our identification is further supported by the $MS^3$ experiment. Compounds **F-3-42** and **-47** (*m/z* 549) are likely fragments from the aforementioned B-type dimers by RDA at the base (epi)catechin-phloroglucinol unit.

The proposed candidate for compounds **F-3-34** and **-41** (*m/z* 683) is a PAC dimer with an (epi)catechin unit connected to an (epi)afzelechin-phloroglucinol unit through an A-type bond. HRF fragmentation ions of this dimer were present at *m/z* 557 $[M - H - 126\ (C_6H_6O_3)]^-$ and 411 $[M - H - 272\ (C_{15}H_{12}O_5)]^-$, which were assigned to HRF at the top (epi)catechin unit and the base (epi)afzelechin-phloroglucinol unit, respectively. Other product ions were observed at *m/z* 515 $[M - H - 168]^-$ by loss of $C_8H_8O_4$ from the base (epi)afzelechin-phloroglucinol unit and 423 $[M - H - 126\ (C_6H_6O_3) - 136\ (C_8H_8O_2)]^- + 2H$ by combination of HRF (at the top (epi)catechin unit) and RDA (at the base (epi)afzelechin-phloroglucinol unit) fragmentations. QM fission resulted in fragments at *m/z* 397 $[M_T - H\ (398 - H)]^-$ and 285 $[M_E - 5H\ (290 - 5H)]^-$. Our assignment is further supported by the $MS^3$ experiment. Compounds **F-3-45**, **-66**, and **-69** (*m/z* 557) are likely fragments from the aforementioned dimers by HRF at the top (epi)catechin unit. Further dissociation ions were present at *m/z* 431 $[M - H - 126\ (C_6H_6O_3)]^-$ by loss of the additional phloroglucinol group, 389 $[M - H - 168\ (C_8H_8O_4)]^-$, and 285 $[M - H - 272\ (C_{15}H_{12}O_5)]^-$ by HRF at the base (epi)afzelechin-phloroglucinol unit. These types of fragments can be caused by heat or acid applied in deglycosylation. The proposed structures and fragmentation pathways of the above three types of PACs containing an additional phloroglucinol unit are depicted in Figure 2, panels A, B, and C, respectively.

*Proanthocyanidin (PAC) Containing a Novel Flavan-3-ol Unit.* Compound **F-3-38** is likely a PAC dimer with a catechin connected to a novel flavan-3-ol unit through an A-type linkage. It yielded a $[M - H]^-$ at *m/z* 589, which further dissociated into ions at *m/z* 463 $[M - H - 126\ (C_6H_6O_3)]^-$ by HRF at the top catechin unit and 453 $[M - H - 136\ (C_8H_8O_2)]^-$ by RDA at the base unit. QM diagnostic ions were present at *m/z* 303 $[M_T - H\ (304 - H)]^-$ and 285 $[M_E - 5H\ (290 - 5H)]^-$. Our identification is further supported by the $MS^3$ experiment; nevertheless, further analyses are necessary to support the assignment. The tentative structure and fragmentation scheme are shown in Figure 3A. Compound **F-3-73** is probably a PAC derivative due to the product ions at *m/z* 441 and 285, which can be assigned to an HRF and a QM ion, respectively.

*Prorobinetidin and Prodelphinidin.* As shown in Figure 3B, compounds **F-3-55**, **-57**, **-62**, **-64**, and **-68** (*m/z* 589) are tentatively identified as a prorobinetidin dimer with a base unit most likely being a C-methyl (epi)robinetinidol A-linked to an (epi)catechin top unit. The HRF fragment ion of the (epi)catechin unit and RDA fragment ion of the C-methyl (epi)robinetinidol unit were present at *m/z* 463 $[M - H - 126\ (C_6H_6O_3)]^-$ and 421 $[M - H - 168\ (C_8H_8O_4)]^-$, respectively. QM cleavage gave rise to diagnostic ions at *m/z* 303 $[M_T - H\ (304 - H)]^-$ and 285 $[M_E - H\ (290 - 5H)]^-$, corresponding to C-methyl (epi)robinetinidol and (epi)catechin units, respectively. Our identification was further supported by the $MS^3$ experiment. The proposed candidate for compound **F-3-58** is a prodelphinidin dimer, as discussed in F2.

*Flavonols and Flavanonols.* Compound **F-3-7** yielded a molecular ion $[M - H]^-$ at *m/z* 301 and fragments at *m/z* 283 $[M - H - 18\ (H_2O)]^-$, 257 $[M - H - 44\ (CO_2)]^-$, and 229 $[M - H - 44\ (CO_2) - 28\ (CO)]^-$. $^{1,2}B^-$ and $^{1,2}A^-$ ions were present at *m/z* 163 and 137, respectively. The likely candidate is robinetin. Compound **F-3-78** yielded a $[M - H]^-$ at *m/z* 343, which further dissociated into ions at *m/z* 328 $[M - H - 15\ (CH_3)]^{\bullet -}$, 313 $[M - H - 30\ (2CH_3)]^-$, 299 $[M - H - 15\ (CH_3) - 29\ (HCO)]^-$, 285 $[M - H - 30\ (2CH_3) - 28\ (CO)]^-$, and 135 attributed to a $^{1,3}A^-$ fragment. The proposed candidate is 3′,4′,5′-trimethylrobinetin.

Compound **F-3-63** is identified as quercetin with a $[M - H]^-$ at *m/z* 301 that fragmented into ions at *m/z* 273 $[M - H - 28\ (CO)]^-$, 257 $[M - H - 44\ (CO_2)]^-$, and 229 $[M - H - 44\ (CO_2) - 28\ (CO)]^-$. The $^{1,2}A^-$ ion at *m/z* 179 further yielded ions at *m/z* 151 noted as $^{1,2}A^- - CO$ and 107 noted as $^{1,2}A^- - CO - CO_2$. This compound was further confirmed by UV spectra ($\lambda_{max}$ = 256 and 370 nm) and $t_R$ matching with a commercial standard. Compound **F-3-77** is likely a quercetin methyl ether such as isorhamnetin with a molecular ion $[M - H]^-$ at *m/z* 315 and a fragment at *m/z* 300 $[M - H - 15$

Table 4. Content of Selected Phenolics Quantified[a] in Dry-Blanched Peanut Skins by $C_{18}$ RP-HPLC

| phenolic compound | quantification UV $\lambda$ (nm) | content[b] (mg/100 g) |
|---|---|---|
| **esterified** | | |
| protocatechuic acid | 260 | 41.4 ± 1.72 |
| (+)-catechin | 280 | 52.0 ± 2.66 |
| (−)-epicatechin | 280 | 8.33 ± 0.40 |
| prodelphinidin A-type dimer [(E)C→A→5-*O*-methyl (E)GC] | 280 | 22.2 ± 0.58 |
| PAC A-type dimer [(E)C→A→(E)C] | 280 | 74.9 ± 2.84 |
| *p*-coumaric acid | 320 | 6.88 ± 0.22 |
| ferulic acid | 320 | 2.03 ± 0.12 |
| PAC A-type dimer [(E)C→A→(E)C] | 280 | 44.3 ± 3.32 |
| PAC A-type dimer [(E)C→A→(E)C] | 280 | 152 ± 7.09 |
| PAC A-type dimer [(E)C→A→(E)C] | 280 | 81.2 ± 1.74 |

| diosmetin | 360 | 0.46 ± 0.00 |
| isorhamnetin | 360 | 1.29 ± 0.00 |

[a]PACs are quantified as (+)-catechin equivalents. Fisetin, genkwanin, isorhamnetin, and diosmetin are quantified using corresponding flavonoid aglycone equivalents. [b]Values are means of triplicate analyses ± standard deviation. Findings are reported as mg respective phenolic/100 g dry weight (dw) of dry-blanched peanut skins.

$(CH_3)]^{\bullet-}$. The $MS^3$ fragments of the ion at $m/z$ 315 were present at $m/z$ 300 $[M - H - 15\ (CH_3)]^{\bullet-}$, 271 $[M - H - 15\ (CH_3) - 29\ (HCO)]^-$, and 256 $[M - H - 44\ (CO_2) - 15\ (CH_3)]^{\bullet-}$. The $^{1,3}A^-$ ion at $m/z$ 151 is a diagnostic ion observed in CID fragmentation of isorhamnetin by ESI-MS.[23,35]

Compound **F-3-75** is kaempferol, which gave a $[M - H]^-$ at $m/z$ 285 and fragments at $m/z$ 257 $[M - H - 28\ (CO)]^-$, 241 $[M - H - 44\ (CO_2)]^-$, 229 $[M - H - 56\ (2CO)]^-$, 213 $[M - H - 44\ (CO_2) - 28\ (CO)]^-$, 199 $[M - H - 42\ (C_2H_2O) - 44\ (CO_2)]^-$, and 151 assigned to a $^{1,3}A^-$ fragment. Identification of kaempferol was confirmed by its UV absorption spectrum and $t_R$ matching with a commercial standard. Fabre et al.[22] described the fragmentation pathways of kaempferol by ESI-MS. Compound **F-3-43** is tentatively identified as fisetin. Fragments produced from $[M - H]^-$ at $m/z$ 285 were present at $m/z$ 257 $[M - H - 28\ (CO)]^-$, 241 $[M - H - 44\ (CO_2)]^-$, 229 $[M - H - 56\ (2CO)]^-$, 213 $[M - H - 44\ (CO_2) - 28\ (CO)]^-$, and 177 $[M - H - \text{ring B}]^-$. RDA cleavage at the 1/2-position on the C-ring generated ions $^{1,2}A^-$ ($m/z$ 163) and $^{1,2}B^-$ ($m/z$ 121), which are highly consistent with the dissociation routes described by Fabre et al.[22] The loss of a CO molecule from $^{1,2}A^-$ ion leads to a fragment at $m/z$ 135 noted as $^{1,2}A^- - CO$. Compound **F-3-49** yielded a $[M - H]^-$ at $m/z$ 317 and was identified as myricetin as described in F2.

Compound **F-3-30** yielded a $[M - H]^-$ at $m/z$ 303 that further fragmented into ions at $m/z$ 285 $[M - H - 18\ (H_2O)]^-$, 259 $[M - H - 44\ (CO_2)]^-$, 241 $[M - H - 18\ (H_2O) - 44\ (CO_2)]^-$, and 217 $[M - H - 18\ (H_2O) - 68\ (C_3O_2)]^-$. RDA cleavage at the 1/4-position on the C-ring gave rise to ions $^{1,4}B^-$ ($m/z$ 177) and $^{1,4}A^-$ ($m/z$ 125). The proposed candidate is taxifolin.

*Flavanones, Flavones, and Isoflavones.* Compound **F-3-65** is tentatively identified as hesperetin. It yielded a $[M - H]^-$ at $m/z$ 301 and further dissociation fragments at $m/z$ 286 $[M - H - 15\ (CH_3)]^{\bullet-}$, 283 $[M - H - 18\ (H_2O)]^-$, 257 $[M - H - 15\ (CH_3) - 29\ (HCO)]^-$, 242 $[M - H - 44\ (CO_2) - 15\ (CH_3)]^{\bullet-}$, and 215 $[M - H - 42\ (C_2H_2O) - 44\ (CO_2)]^-$. RDA diagnostic ions were present at $m/z$ 164, 151, and 125, which were ascribed to $^{1,2}A^-$, $^{1,3}A^-$, and $^{1,4}A^-$, respectively. Further loss of $CO_2$ from $^{1,3}A^-$ generated an ion at $m/z$ 107, noted as $^{1,3}A^- - CO_2$. It undergoes the similar fragmentation route of hesperetin as reported by Justesen.[35] Compound **F-3-71** ($m/z$ 301) is likely homoeriodictyol, producing RDA diagnostic ions at $m/z$ 151 assigned to $^{1,3}A^-$. Compound **F-3-**

**61** is likely isosakuranetin with a $[M - H]^-$ at $m/z$ 285 and further dissociation ions at $m/z$ 270 $[M - H - 15\ (CH_3)]^{\bullet -}$, 243 $[M - H - 42\ (C_2H_2O)]^-$, 226 $[M - H - 44\ (CO_2) - 15\ (CH_3)]^{\bullet -}$, and 199 $[M - H - 42\ (C_2H_2O) - 44\ (CO_2)]^-$. RDA cleavage at the 0/4-position of the C-ring after loss of $CH_3^{\bullet}$ gave a diagnostic ion at $m/z$ 164. This $-CH_3{}^{0,4}B^{\bullet -}$ ion lost a further CO molecule, leading to a fragment noted as $-CH_3{}^{0,4}B^{\bullet -} - CO$ ($m/z$ 136).

The proposed candidate of compound **F-3-53** is 3′,4′,5,6-tetrahydroxy-7-methoxyflavone. It yielded a $[M - H]^-$ at $m/z$ 315 that dissociated further into fragments at 300 $[M - H - 15\ (CH_3)]^{\bullet -}$ and 191 $[M - H - 109\ (B\text{-ring}) - 15\ (CH_3)]^{\bullet -}$. Compound **F-3-74** is likely a flavone dimethyl ether such as 3′,5,6-trihydroxy-4′,7-dimethoxyflavone, which gave a $[M - H]^-$ at $m/z$ 329. It dissociated further into fragments at $m/z$ 314 $[M - H - 15\ (CH_3)]^{\bullet -}$, 299 $[M - H - 30\ (2CH_3)]^-$, and 191 $[M - H - 15\ (CH_3) - 123\ (B\text{-ring})]^-$. Unfortunately, the actual position of the methoxy group for the above two compounds can not be confirmed without a commercial standard or NMR analysis. Compound **F-3-54** yielded a $[M - H]^-$ at $m/z$ 283 and a prominent fragment at $m/z$ 268 $[M - H - 15\ (CH_3)]^{\bullet -}$. The proposed candidate is genkwanin. An RDA diagnostic ion $-CH_3{}^{1,3}A^{\bullet -}$ was present at $m/z$ 151, with the identification being further confirmed by a UV $\lambda_{max}$ at 338 nm.[36] Compound **F-3-76** is likely a luteolin methyl ether such as diosmetin with a $[M - H]^-$ at $m/z$ 299 and a prominent fragment $m/z$ 284 $[M - H - 15\ (CH_3)]^{\bullet -}$. $MS^3$ [299→284] fragments were observed at $m/z$ 256 $[M - H - 15\ (CH_3) - 28\ (CO)]^{\bullet -}$, 240 $[M - H - 15\ (CH_3) - 44\ (CO_2)]^{\bullet -}$, 216 $[M - H - 15\ (CH_3) - 68\ (C_3O_2)]^{\bullet -}$, and 151 attributed to a $^{1,3}A^-$ fragment. The identification is supported by its UV spectra of 254(sh), 266, and 348 nm.[37] The fragmentation pathways for diosmetin were described by Justesen.[23]

Compound **F-3-60** is likely biochanin A. It yielded a $[M - H]^-$ at $m/z$ 283 and a prominent fragment at $m/z$ 268 $[M - H - 15\ (CH_3)]^{\bullet -}$. Further $MS^3$ [283→268] fragmentation generated ions at $m/z$ 267 $[M - H - 15\ (CH_3) - H]^{\bullet -}$, 239 $[M - H - 15\ (CH_3) - H - 28\ (CO)]^-$, 224 $[M - H - 15\ (CH_3) - H - 44\ (CO_2)]^-$, and 135 [A-ring fragment]$^-$, which are consistent with the $MS^3$ spectra of biochanin A obtained by Kang et al.[38] Biochanin A is an *O*-methylated isoflavone, and it has long been reported in peanuts.[39] Compound **F-3-72** exhibited a $[M - H]^-$ at $m/z$ 299. Further fragment ions were observed at $m/z$ 284 $[M - H - 15\ (CH_3)]^{\bullet -}$, 255 $[M - H - 15\ (CH_3) - 29\ (CHO)]^-$, 177 $[M - H - B\text{-ring}]^-$, and 151 attributed to a $^{1,3}A^-$ ion. The proposed candidate is pratensein, that is, 3′,5,7-trihydroxyisoflavone-4′-methoxy-3′-*O*-*β*-glucopyranoside, which has been found in peanut skin according to NMR.[27]

*Biflavonoids.* Compounds **F-3-46**, **-56**, **-59**, and **-67** are likely daphnodorin H-type biflavonoids composed of eriodictyol (part I) and C-methyl (epi)robinetinidol (part II) units. They gave a $[M - H]^-$ at $m/z$ 587 and fragment ions at $m/z$ 569 $[M - H - 18\ (H_2O)]^-$, 461 assigned to a $^{1,4}IB^-$ fragment, and 419 attributed to a $^{1,3}IIA^-$ fragment. The direct cleavage of the interflavan bond generated fragments at $m/z$ 285 [eriodictyol unit $(288 - 3H)]^-$ and 301 [C-methyl (epi)-robinetinidol unit $(304 - 3H)]^-$. This identification is further supported by the $MS^3$ experiment; however, NMR analysis is required to support the assignment. The tentative structure and fragmentation are present in Figure 3C.

*Stilbene.* Compound **F-3-70** is tentatively identified as *trans*-3,3′,5,5′-tetrahydroxy-4′-methoxystilbene. It yielded a $[M - H]^-$ at $m/z$ 273 and further dissociation ions at $m/z$ 258 $[M - H - 15\ (CH_3)]^{\bullet -}$, 163 $[M - H - 68\ (C_3O_2) - 42\ (C_2H_2O)]^-$, 136 $[M - H - 137\ (C_7H_5O_3)]^-$, and 109 $[M - H - 165\ (C_9H_9O_3)]^-$.

**Quantification.** Phenolic compounds were quantified on the basis of peak areas of the observed UV signals from the HPLC chromatograms and calibration curves of commercial standards. Mean phenolic contents for the identified compounds are reported in Table 4. All values are expressed in milligrams of respective phenolic compound per 100 g of dry weight (dw) of PS.

Protocatechuic acid was determined to be the most dominant in the non-PAC phenolics profile and comprised 6.62 and 6.48% of the esterified and glycoside-bound phenolic compounds, respectively. Kaempferol, fisetin, quercetin, isorhamnetin (flavonols), genkwanin, and dosmetin (flavones) are quantifiable flavonoid aglycones liberated from glycosides and account for 1.54% of the total glycoside-bound phenolic compounds. Quercetin and its methyl ether (isorhamnetin) are primary flavonoid aglycones and constituted 57.1% of the total recovered flavonoid aglycones. As aforementioned, PACs possess the lion's share of the phenolics in PS[19] and are the major phenolics released from esters and glycosides. PAC monomers ((+)-catechin and (−)-epicatechin), dimers, trimers, and tetramers constituted 9.65, 60.0, 6.38, and 15.9% of esterified phenolic compounds, respectively. The PAC monomer ((+)-catechin) and dimers are primary phenolics released from glycosides and account for 31.7 and 59.1% of total glycoside-bound phenolic compounds.

It should be noted that the quantification can be easily affected by many factors involved in the details of the extraction and fractionation protocols selected. As for flavonoids, strong acid hydrolysis may degrade unstable aglycones, whereas, on the other hand, some of the cell wall-bound glycosides may not be hydrolyzed completely, yielding inconsistent results.[14,40] The cleavage of the C−C interflavan bond between monomeric flavan-3-ol constituents can result from severe alkaline conditions.[8] This may possibly explain why a large portion of PAC monomers and dimers were found in the profile of esterified and glycoside-bound phenolic compounds. According to our MS data, there are also a number of fragments resulting from PACs containing an additional phloroglucinol unit due to heat or acid treatment, which would lead to underestimation of their quantity. PACs can be modified by thermal treatment. Yu et al.[18] reported a significant influence of the skin removal methods on the PACs content of PS. Dry heat, like that imparted during blanching of redskin peanuts, would increase A-type dimers and B-type trimers compared to directly peeled PS due to monomeric polymerization or the degradation of trimers and tetramers.

In conclusion, analysis of the crude extract gave a simple-looking HPLC chromatogram where only PACs and rutin were determined. In contrast, a large variety of soluble phenolic compounds were liberated from esters and glycosides in PS. They were further separated and detected by HPLC-ESI-$MS^n$. Compounds identified included PACs (monomers to tetramers), free phenolic acids (e.g., hydroxybenzoic acids and *trans*-cinnamic acids), stilbenes, and flavonoids. Free phenolic acids such as *p*-coumaric acid, ferulic acid, and caffeic acid were most likely released from their tartaric acid esters, which were revealed in our previous study.[19] Epicatechin was liberated from the soluble esters, whereas catechin was released from both soluble esters and glycosides. The increased sums of

phenolic aglycones (e.g., *p*-coumaric acid and catechin) was also quantified due to such liberation from esters and glycosides. To our knowledge this is the first report of PACs in PS containing an additional phloroglucinol unit. Although further analytical techniques are required for the final confirmation of some of the compounds identified, our data enrich the phenolic database of PS and perhaps provide a justification as to why PS might be considered as a valuable functional food ingredient.

## MATERIALS AND METHODS

**Materials.** 10-Undecenoic acid was obtained from Jayant Oil Mills (Mumbai, India). Methanol, propan-2-ol, butan-1-ol, 2-methylpropan-1-ol, hexan-1-ol, 2-ethylhexan-1-ol, hexane, and ethyl acetate were procured from Qualigens Fine Chemicals (Mumbai, India). Dichloromethane, *m*-chloroperbenzoic acid (m-CPBA), aniline, butylated hydroxytoluene (BHT), paraffin oil, ammonium thiocyanate, 1-methylimidazole, and HBf4 were purchased from Sigma-Aldrich (St. Louis, MO, USA). Hydrogen peroxide (30% aqueous solution), xylene, and *p*-toluenesulfonic acid (p-TSA) were purchased from M/s sd fine-chem Ltd., Mumbai, India. Formic acid solution (85%) and sulfuric acid (AR grade) were purchased from M/s Rankhem, New Delhi, India. Sebacic acid was procured from Sisco Research Laboratories (Mumbai, India). Jatropha oil was obtained from a local company. LZ 1359 and tricresyl phosphate (TCP) was used as control in antiwear and extreme pressure analyses, respectively. All of the chemicals were of analytical reagent grade and used as received.

**Methods.** The analytical determinations of the sebacic acid and jatropha oil derivatives were accomplished according to the official methods of the American Oil Chemists' Society (AOCS) as follows: acid value (AOCS Cd 63), iodine value (IV, AOCS Da 15-48), and oxirane value (OO, AOCS Cd 9-57). The base oil lubricant properties such as density, viscosity, and viscosity index were evaluated per methods described previously.[20] $^1$H NMR and $^{13}$C NMR spectra were recorded on Bruker AR X 400 spectrometer (400 MHz) and a Varian spectrometer at 75 MHz, respectively, and TMS was used as an internal standard. IR spectra were recorded in chloroform on a PerkinElmer Fourier transform (model Spectrum BX; Shelton, CT, USA) FT-IR spectrometer neat as thin film. The spectrum was recorded in absorbance mode.

A gas chromatograph Agilent 6890N series was employed to analyze the fatty acid composition using an HP-1 column (30 m × 0.25 mm × 0.5 $\mu$m). The flame ionization detector and injector were at 300 °C. The oven temperature was programmed at 150 °C for 2 min and then increased to 300 °C at 10 °C/min. The carrier gas used was nitrogen at a flow rate of 1.5 mL/min. The GC-MS analysis was carried out using an Agilent 6890 gas chromatograph connected to an Agilent 5973 mass spectrophotometer at 70 eV ($m/z$ 50−600; source at 230 °C and quadruple at 150 °C) in the EI mode using an HP-1 MS capillary column (30 m × 0.25 mm × 0.5 $\mu$m). The oven temperature was programmed at 150 °C for 2 min, 10 °C/min to 300 °C, and 20 min at 300 °C. The carrier gas used was helium at a flow rate of 1.0 mL/min.

The antioxidant activity of the synthesized epithio derivatives in three base oils was evaluated using a differential scanning calorimeter (DSC Q 2000, TA Instruments) under oxygen atmosphere. The oxidative onset temperature (OOT) was measured for base oils with and without added additives in dynamic mode. The temperature programming was set at 25−300 °C, ramped at 10 °C/min, and purified oxygen was passed through the sample enclosure at 50 mL/min. The oxidative onset temperature was determined from the start of the exothermic reaction peak in the DSC thermogram.

The load-carrying capacity and antiwear properties of synthesized additives were investigated using a Stanhope SETA four-ball tester. All of the wear tests were conducted at a rotating speed of 1200 rpm under a load of 40 kg, with a duration of 60 min. An optical microscope was used to determine the wear scar diameters (WSD) of the three lower balls with an accuracy of ±0.01 mm, and these diameters were averaged and cited as the WSD reported in this paper. The extreme pressure tests were run at 1475 rpm, ambient temperature at variable load, and test duration for 1 min or until the balls welded, whichever occurred first. The extreme pressure properties of three base oils with and without added additive at different concentrations were evaluated as weld point loads and are reproducible to within one loading increment (±10 kg for 10 kg loading increments).

The surface analysis of wear scar developed on the steel balls during the antiwear analysis was studied using a Hitachi S-3000N scanning electron microscope (SEM) with energy/wavelength dispersion, at a voltage of 20 kV.

**Synthesis of Di-2-ethylhexyl Sebacate.** Sebacic acid (200 g, 0.99 mol), 2-ethylhexanol (465 mL, 2.97 mol), *p*-toluenesulfonic acid (2 g, 1 wt % of KFA), and xylene, 100 mL, were taken in a four-necked round-bottom flask and stirred at 130−140 °C for a period of 8 h. The reaction was monitored by TLC. The crude product was distilled at 180 °C temperature and 5 mmHg to remove excess alcohol and xylene. The distilled product was extracted with hexane and washed with water until it was acid free, passed through $Na_2SO_4$, concentrated, and dried under vacuum. The product was further purified using basic alumina column chromatography by elution with hexane to obtain di-2-ethylhexyl sebacate with an acid value of <0.1. The yield of the product was found to be 95%. The structure of the product was characterized by FT-IR, EI-MS, and $^1$H NMR spectral studies.

**Synthesis of Epoxy Jatropha Fatty Acid *n*-Butyl Esters (EJB).** *n*-Butyl esters of jatropha fatty acids[21] (125 g, 0.385 mol), formic acid (26.6 g, 0.577 mol), and sulfuric acid (1.7 mL, 2 wt % of HCOOH and hydrogen peroxide) were taken in a three-necked round-bottom flask equipped with an overhead stirrer. A 30% aqueous hydrogen peroxide solution (117.9 mL, 1.155 mol) was added slowly to the contents under strong mechanical stirring at 15−20 °C over a duration of 1 h. After addition, the temperature was raised to 55−60 °C for 5 h. The product was extracted with ethyl acetate and washed with water until it was acid free, then passed through anhydrous sodium sulfate, and dried under reduced pressure to yield the product with oxirane oxygen content of 4.4%. The yield of the epoxy jatropha fatty acid *n*-butyl esters was found to be 95%. The structure of the product was characterized by FT-IR and $^1$H NMR spectral studies.

$^1$H NMR (400 MHz, $CDCl_3$) $\delta$ 0.85−0.95 (t, $-CH_2-CH_3$), 1.2−1.4 (m, $-CH_2-CH_3$), 1.4−1.5 (m, $CH_2-CHOCH-$), 1.6−1.7 (m, $CH_2-CH_2-CO-$), 2.8−3.1 (m, $-CHOCH-$), 2.3 (t, $-CH_2-C=O$), 4.05 (t, $-CH_2-O-C=O$); IR (neat, cm$^{-1}$) 2927 (C—H), 1740 (C=O), 826 (epoxy ring), 1172 (C—C (=O)—O).

**Preparation of Ionic Liquid [HMIM]$BF_4$.** 1-Methylimidazole (6 g, 0.0738 mol) was taken into a three-necked round-bottom flask. The temperature of the medium was sustained at 0 °C, and 48% tetrafluoroboric acid (9.54 mL, 0.0738 mol) was added slowly to it for 40 min, and then the reaction was further continued at room temperature for 2 h. After completion of the reaction, the contents were kept under high vacuum to remove moisture at 80−90 °C. The product was subjected to ethyl acetate washings to remove excess imidazole followed by drying under reduced pressure to obtain a light yellow viscous liquid.

**Synthesis of Alkyl 10-Undecenoates (2a-f).** 10-Undecenoic acid was esterified with different alcohols, namely, methanol, propan-2-ol, butan-1-ol, 2-methylpropan-1-ol, hexan-1-ol, and 2-ethylhexan-1-ol, in the presence of p-TSA (1 wt % of the acid) for a duration of 4−5 h to yield alkyl 10-undecenoates **2a−f**). The synthetic procedure is reported elsewhere.[22]

**Synthesis of Alkyl 10-Epoxyundecanoates (3a−f).** Alkyl 10-undecenoates were epoxidized using *m*-chloroperbenzoic acid to yield alkyl epoxy undecanoates. The synthetic procedure is reported elsewhere.[22]

**Typical Procedure for the Preparation of Butyl 10-Epithioundecanoate (4a−f).** *n*-Butyl 10-epoxyundecanoate (2 g, 0.0078 mol) and ammonium thiocyanate (0.594 g, 0.0078 mol) were taken into a round-bottom flask. Ionic liquid [HMIM]$BF_4$ (4 g) and water (2 g) in a 2:1 ratio were added to the contents, and the resultant reaction mixture was stirred at 60 °C for a period of 23 h. The progress of the reaction was monitored by TLC using hexane/ethyl acetate (90:10 v/v). After completion of the reaction, the crude product was extracted using ether, and the ethereal solution was washed with water and dried over sodium sulfate. The combined ether extracts were concentrated using a rotary evaporator. The structure of the product was established by GC-MS and GC (90%). The crude product was purified using silica gel column chromatography using hexane and ethyl acetate (80/20) to afford *n*-butyl 10-epithioundecanoate (1.44 g, 68% of isolated yield). The product was characterized by $^1$H NMR, IR, GC, and GC-MS spectral data.

**Methyl 10-Epithioundecanoate (ESUME, 4a):** 1.29 g, 60%; $^1$H NMR (400 MHz, $CDCl_3$) $\delta$ (TMS) 1.2−1.40 (m, 12 H, $-CH_2$), 1.4−1.65 (m, 2H, $CH2-CH2-C=O$), 1.75−1.85 (m, 2H, $H_2CSCH-CH_2$), 2.15−2.18 (d, 2H, $H_2CSCH$), 2.25−2.35 (t, 2H, $-CO-CH_2$),

dx.doi.org/10.1021/jf5033558 | J. Agric. Food Chem. 2014, 62, 11505−11511

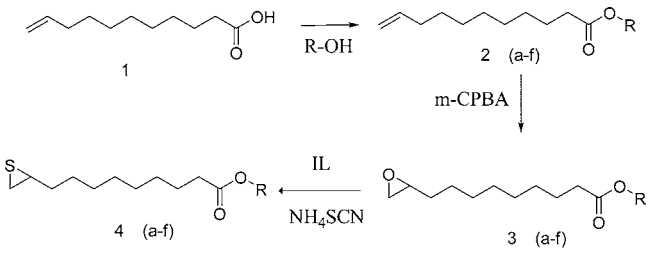
## RESULTS AND DISCUSSION

In the present study epithio undecanoates were synthesized from epoxy undecanoates in a green reaction medium, ionic liquid. The use of ionic liquid for the synthesis of epithio compounds helps in carrying out the reaction under mild and neutral conditions to afford epithio undecanoates in high yields. The performance of the epithio derivative as multifunctional additives was evaluated in three base oils: epoxy jatropha *n*-butyl esters (EJB), di-2-ethylhexyl sebacate (DOS), and paraffin (S-105) base oil.

The epoxy undecanoates were used as starting material to synthesize epithio undecanoates using ammonium thiocyanate in stoichiometric ratio (Scheme 1). All of the reactions were

**Scheme 1. Synthesis of Epithio Undecanoates**



R= a, -$CH_3$; b, -CH-($CH_3$)$_2$; c, -$CH_2$-CH-($CH_3$)$_2$; d, -($CH_2$)$_3$-$CH_3$; e, -($CH_2$)$_5$-$CH_3$; f, -($CH_2$)$_5$-CH-($CH_3$)$_2$.

completed within 20−24 h, affording high yields of alkyl 10-epithioundecanoates as revealed by GC analysis (85−96%). The products were purified using silica gel column chromatography using hexane and ethyl acetate (80:20) to afford pure alkyl 10-epithioundecanoates with an isolated yield of 60−68%. The FT-IR spectra of the epoxy undecanoate derivatives are characterized by a stretching vibration frequency at 835 $cm^{-1}$, which is attributable to the epoxy stretching vibration frequency and asymmetric ring deformation at 916 $cm^{-1}$. In contrast, the IR spectral feature observed in epithio derivatives is the disappearance of these peaks, indicating complete conversion of epoxy to epithio group in the synthesized products. Two new peaks appeared at 619 and 1011 $cm^{-1}$, which are attributable to the symmetric and asymmetric epithio ring deformation,[23−25] proving the successful conversion of epoxide to epithio group. The FT-IR spectra also exhibited the characteristic absorptions of aliphatic carbons around 2987 and 2865 $cm^{-1}$ and an ester group (−COO−) around 1735 $cm^{-1}$.

In $^1$H NMR spectra of alkyl 10-epithioundecanoates, signals at 2.2 and 2.5 ppm corresponding to methylene and methine protons, respectively, confirmed the epithio ring introduction into the molecule, respectively. In epithio undecanoate derivatives the disappearance of peaks at 2.8−2.9 ppm corresponding to −CH− protons of the epoxy carbon confirmed the epithio ring formation. Both the infrared spectra and NMR spectra of these epithio derivatives indicated the absence of an epoxy group in the epithio derivatives. The GC-MS and GC chromatograms also indicated the absence of an epoxy group, indicating complete conversion into an epithio group. Signals in $^{13}$C NMR at 31.0 and 26.0 ppm confirm the presence of an epithio ring in the synthesized products. The adjacent methylene group of the epithio system was shifted to 36.0 ppm due to a β effect from the sulfur atom, also confirming the product formation.

**Performance Evaluation of the Epithio Derivatives as Antioxidants.** The antioxidant activity of the synthesized epithio derivatives and commercial antioxidant BHT were

dx.doi.org/10.1021/jf5033558 | J. Agric. Food Chem. 2014, 62, 11505−11511

evaluated using three base oils, EJB, DOS, and S-105. The oxidative onset temperature (OOT) of the pure base oils was found to be 164.4, 180.2, and 193.6 °C, respectively. The fatty acid composition of synthesized biolubricant base oil EJB revealed that almost all of the unsaturation converted to epoxy group as follows: C18:1 epoxy, 44.1%; C18:2 mono epoxy, 3%; and C18:2 di epoxy, 26%. The basic lubricant properties such as viscosity, viscosity index, and density exhibited by the three base oils are shown in Table 1. The additive percentage in base oils

**Table 1. Physicochemical Properties of Base Oils**

| property | | EJB | DOS | S-105 |
|---|---|---|---|---|
| density 15 °C (g/cm$^3$) | | 0.915 | 0.920 | 0.835 |
| viscosity | 40 °C, cSt | 11.15 | 12.38 | 10.28 |
| | 100 °C, cSt | 3.09 | 3.26 | 3.36 |
| viscosity index | | 126 | 126 | 117 |

was optimized using base oil (DOS) spiked with additive butyl 10-epithioundecanoate (**4d**) ranging from 0.5 to 4% and their OOTs are 181.8, 188.1, 229.2, 230.5, and 232.5 °C, respectively. The maximum antioxidant activity was observed at 2 wt % concentration, and even though the additive dosage was increased to 3 and 4%, a negligible increase in antioxidant activity was observed. Hence, the antioxidant efficacies of synthesized epithio derivatives and commercial antioxidant, BHT, were evaluated at 2 wt % concentration in the base oils. All of the epithio undecanoates exhibited superior performance compared to BHT in DOS base oil, whereas **4d** exhibited comparable performance with BHT in EJB and S-105 base oils. The nature of the ester alkyl group of the epithio undecanoate derivatives displayed different antioxidant activities in the three base oils tested. Products prepared from short-chain alcohols (methyl and *n*-butyl) exhibited better performance, and as the chain length increased (2-ethylhexyl), the antioxidant activity decreased. There is a clear effect of the length of the alkyl chain of the ester moiety of epithio derivatives on antioxidant potency, resulting in products (**4a** and **4d**) with greater antioxidant ability to stabilize base oil than their corresponding epithio derivative, **4e**. Similar results have been published earlier for ether derivatives of hydroxytyrosol and amino alcohols,[21,25] and in which the shorter alkyl side chains improved the scavenger activity and the reducing ability of hydroxytyrosol, and the presence of longer linear chains ($C_7$−$C_9$) decreased such antioxidant effects.[26] A cutoff effect in the antioxidant efficacy in relation to the alkyl chain length was also reported by Sorensen et al. on alkyl ferulates. The most efficient alkyl ferulates were methyl and butyl ferulate, whereas octyl ferulate was pro-oxidative, and the pro-oxidative effect increased further with an increment in the alkyl chain length from $C_8$ to $C_{12}$. Further elongation of the alkyl chain length to $C_{16}$ and $C_{20}$ resulted in weak pro-oxidative effects to weak antioxidative effects.[27] This might be also due to readily available sites for oxidation, making them more sensitive to cleavage than shorter ester chain lengths.[28−31] The three epithio derivatives prepared with iso alkyl epoxy undecanoates exhibited less antioxidant activity compared to straight-chain epithio derivatives. This could be related to the steric effect of side chains present in the ester chain of isoalkyl epithio derivatives.

Epithio derivatives with methyl and butyl ester chain lengths exhibited comparable antioxidant activities in base oil EJB. The same trend was observed in DOS and S-105 base oils, and the results are summarized in Table 2. The optimum chain length $C_4$ exhibited superior OOT of 229 °C among the synthesized

**Table 2. Antioxidant Property of the Synthesized Additives (2 wt %) in Three Lubricant Base Stocks**

additives in DOS base oil. In the case of S-105 base oil, as the chain length increased from $C_1$ to $C_4$, an increase in activity, and on further increase in chain length ($C_8$), a decrease in activity were observed. Butyl 10-epithioundecanoate exhibited excellent antioxidant activity among all of the synthesized additives in the three base oils EJB, DOS, and S-105 with OOTs of 180.6, 229.2, and 242 °C, respectively, followed by **4a**. A typical dynamic DSC curve is given in Figure 1, showing the dynamic curve of a base oil without any additive and of a base oil with **4d** at 2 wt % concentration in EJB and S-105 base oil.

**Performance Evaluation of the Synthesized Epithio Derivatives as Extreme Pressure Additives.** The weld point (WP) in extreme pressure property can be defined as the load at which welding of the balls due to the friction between the stationary three balls and the rotating top ball is high enough to weld. The WP of a test sample can be evaluated within ±10 kg by increasing the smaller load close to the weld point. Higher WP indicates the better EP properties of the test sample. Compounds containing certain elements such as sulfur, phosphorus, and halogens are known to be capable of participating in tribochemical reactions with the friction surfaces and generating in situ tribofilms that reduce friction under extreme pressure conditions.[32] Therefore, the synthesized alkyl epithio undecanoates were evaluated for their EP activity using three base oils, EJB, DOS, and S-105, and the results were compared with those of commercial EP additive, TCP. In the absence of EP additives the three base oils displayed weld points of 160, 120, and 120 kg, respectively. The base oil doped with the additives was stirred under magnetic stirring for 30 min at 40 °C to attain the homogeneity of the sample. Butyl epithio undecanoate and base oil DOS were used for optimization of additive concentration. The improvement in weld point of the base oil was analyzed at different concentrations ranging from 0.5 to 4%, and their weld points were 130, 140, 170, 160, and 150 kg, respectively. From the results 2 wt % was the optimum concentration at which the maximum weld point was observed. Even though the concentration was increased further to 3 and 4%, a decrease in weld point was observed. The blending of EP additives with the base oils resulted in increased weld point of three base oils as shown in Table 3. As the chain length of the ester moiety of the episulfide undecanoate increased from $C_1$ to $C_4$, the weld point of the base oil EJB increased from 160 to 210 kg. Surprisingly, methyl and butyl ester chains of episulfide undecanoate exhibited similar weld points of 210 kg. In the case of the 2-ethyhexyl ester of episulfide undecanoate the decrease in weld load of 180 kg was observed. The same trend was observed in base oils DOS and

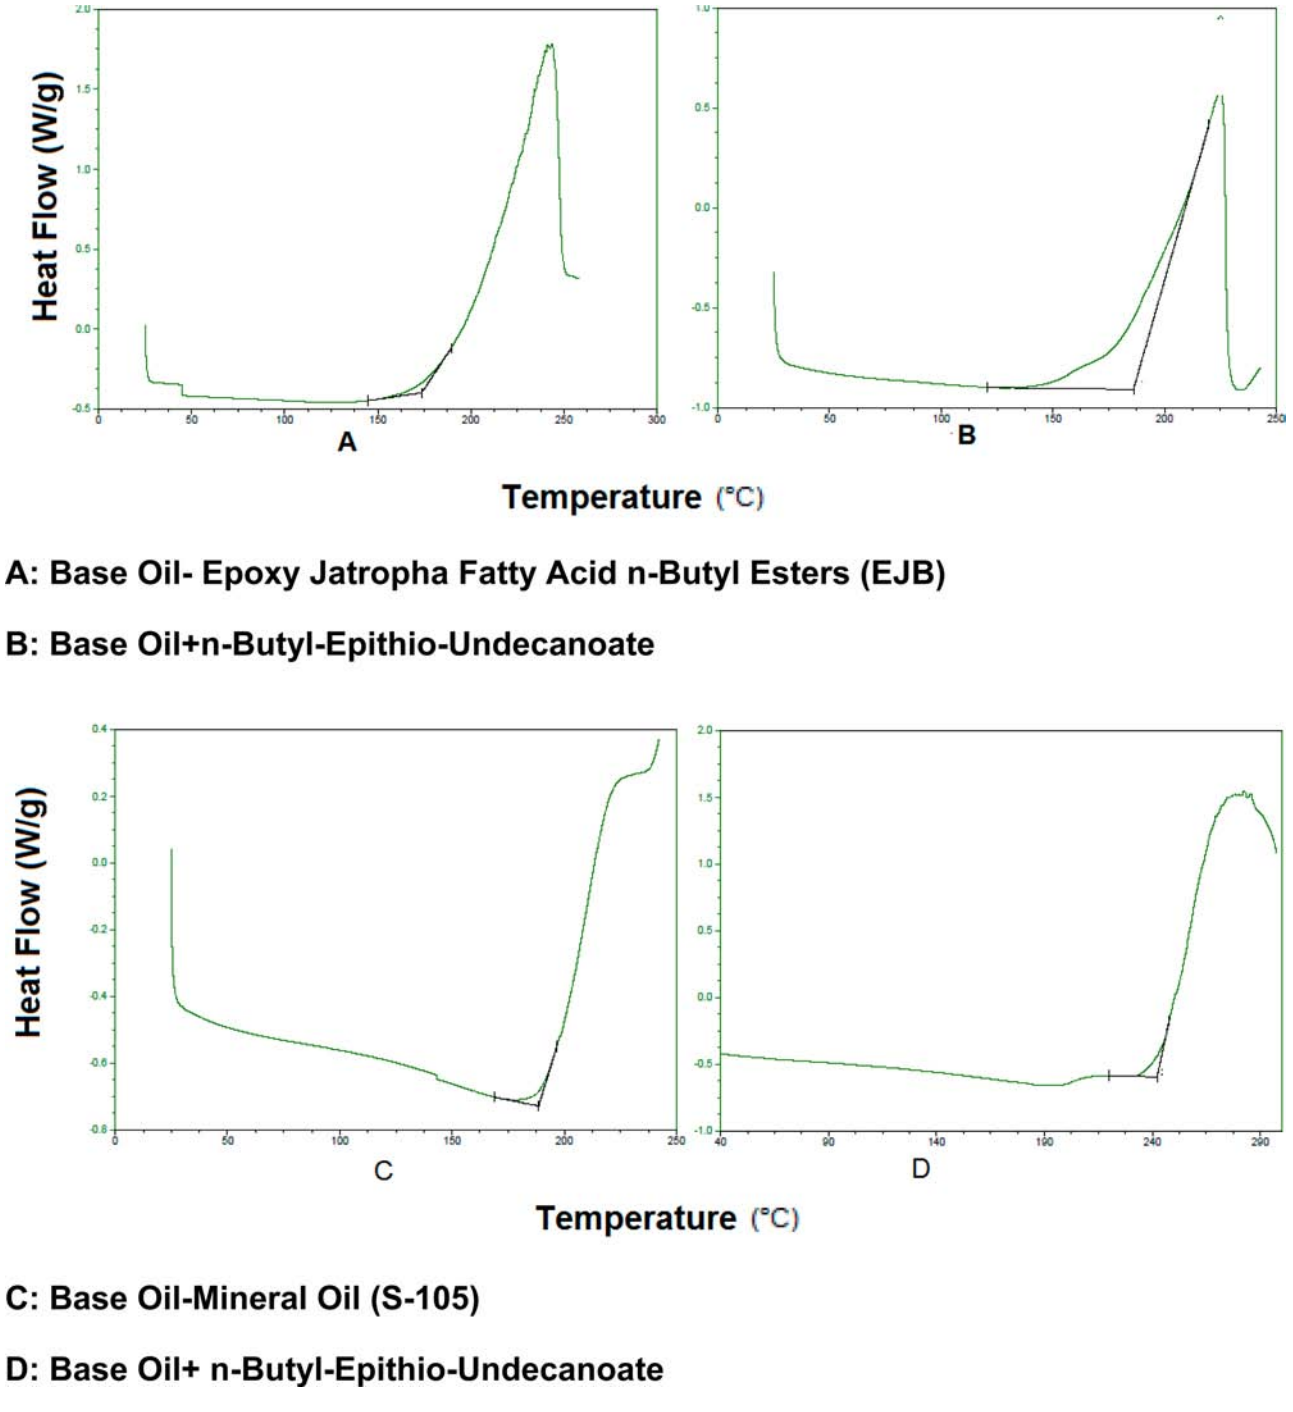

**Figure 1.** Nonisothermal DSC curves of base oil with and without antioxidant.

S-105. This shows a decrease in load-carrying capacity with increasing chain length of the alcohol moiety of the fatty acid ester of epithio derivatives. These results demonstrate the effects of molecular structure on lubricity property. This is in good agreement with the general observation that shorter chain lengths reduce molecular interactions and decrease the temperature stability of a protective lubricant film.[33] *n*-Butyl 10-epithioundecanoate exhibited comparable performance with commercial additive TCP in both base oils EJB and DOS and inferior performance in S-105. The synthesized additives exhibited better compatibility with biolubricant base oil (EJB) and synthetic ester (DOS) compared to mineral base oil (S-105), which indicates a better synergistic effect of the epithio derivatives with these two oils than with mineral oil. Similar enhancements of load-carrying capacity in biobased base stocks relative to mineral oil have been reported.[34] Results indicate that the prepared compounds exhibited improved EP activity, and they can be effectively used as EP additives for biobased lubricant basestocks.

**Performance Evaluation of Epithio Derivatives as Antiwear Additives.** The investigation of the antiwear ability of methyl and butyl epithio undecanoates was done by varying their concentration in base oil DOS. Figure 2 shows the variation of the WSD of the lower steel balls with different additive concentrations. It is observed from the figure that the addition of additives in base stock, even at small concentrations, can

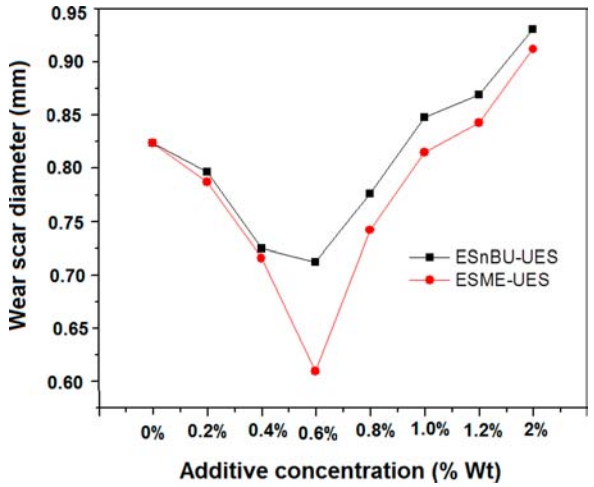

**Figure 2.** Wear scar diameter of the synthesized antiwear additive at different concentrations. ESnBU-UES, butyl epithio undecanoate; ESME-UES, methyl epithio undecanoate.

significantly reduce the WSD of the system. In particular, the introduction of 0.6 wt % methyl epithio undecanoate led to a decrease of the WSD by >26%. The addition of commercial antiwear additive LZ1359 also improved the AW property of the base fluid by 30%. The WSD decreased gradually with further increase of the additive concentration, implying that the AW property of the additive is dependent on its concentration in the base stock. When the additive concentration was below 0.6%, the WSD was smaller, indicating that additives demonstrated better AW property at a low concentration of 0.6%. This may be attributed to the formation of a more effective AW film by the additives through competing adsorption with base oil at a low concentration. The slight increase in the WSD with increasing additive concentration has also been reported in the literature.[35,36] This might be ascribed to corrosion of metal caused by the sulfur element present in the additives.

**Worn Surface Analysis.** Figure 3 shows the SEM images of the worn surface of steel balls lubricated with base oil DOS alone and with **4a** added oil at 0.6% concentration. The wear scar obtained from the test lubricated with base oil alone exhibited more scratches and deeper furrows compared with the scar produced with base oil with 0.6 wt % epithio derivative (**4a**). It can also be observed that the worn surface of steel balls lubricated by base oil with **4a** is shallower and smoother than that lubricated by base oil alone. This result further verifies that **4a** possesses good AW ability.

In conclusion, we have synthesized a series of novel epithio derivatives from 10-undecenoic acid. The addition of epithio derivatives as multifunctional additives to the base oils resulted in the enhancement of antioxidant, extreme pressure, and antiwear properties. Among the reported products, butyl 10-epithioundecanoate exhibited superior antioxidant and extreme pressure properties.

obstacle to improving the final amount of yields of cellulose hydrolysis.[13] Besides, previous studies showed that addition of BG during enzymatic hydrolysis of cellulose could promote the sugar yield effectively and reduce inhibition of cellobiose on CBH or EG.[13] Research also indicated that BG in hydrolysate having better glucose tolerance through directed mutation could also promote the yield of cellulose saccharification.[14]

A novel cellulytic strain, *Hypocrea orientalis*, has been isolated for enzymatic degradation of agricultural residues and production of bioethanol. Research found that the cellulase activity secreted by *H. orientalis* was obviously higher than that of *H. jecorina*, *T. koningii*, *P. decumbens*, and *A. niger*, and especially, *H. orientalis* secreted a relatively balanced cellulase system,[15] which showed good application of *H. orientalis* enzymes in the bioethanol industry. In recent work, BG of *H. orientalis* has been purified and the inhibition mechanism of glucose on BG was investigated. This study provided the basis for directed mutation of BG to improve the glucose tolerance of *H. orientalis* BG.

## MATERIALS AND METHODS

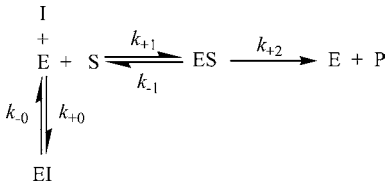
**Cassava Residues, Enzymes, and Reagents.** Cassava residues were generated in a local factory following starch production, and residual starch was stripped for the next process. The analysis of cassava residues was carried out according to the protocols of NREL.[16] *H. orientalis* strain was cultured in modified MS medium (1% cassava residues as carbon source).[7] Crude enzyme was prepared from the culture with centrifugation at 10000 rpm for 15 min at 4 °C. Homogeneous BG was isolated from the fermentation liquid sequentially through ammonium sulfate precipitation, DEAE chromatography, and Sephacryl S200 filtration. *p*-Nitrophenyl-*β*-D-glucopyranoside (pNPG) was from Sigma (St. Louis, MO, USA). Cellulase DF was purchased from Lizhudongfeng Biotechnology Co., Shanghai, China, and Cellulase R-10 was a product of Yakult in Japan. All other chemicals were local products of analytical grade.

**Enzymatic Activity and Hydrolysis of Cassava Residues.** Cassava residues were pretreated with NaOH for 30 min at 121 °C in an autoclave. After cooling, the residues was filtered and washed to neutral pH. Then the cassava residues were dried in an oven and chopped for hydrolysis. The hydrolysis reactions were run in 100 mL of 50 mM sodium acetate buffer (pH 5.0) containing 1.5% (w/v) residues and 0.1 mg/mL enzymes with incubation in a shaking water bath (160 rpm) for up to 24 h at the given temperature. Samples of hydrolysate were taken periodically and centrifuged (5000*g*, 5 min) for quantification of reducing sugars by DNS assay.[17] An Aminex HPX-87H column was used to determine the composition and quantity of the products with 5 mM $H_2SO_4$ as flow phase and pure glucose, cellobiose, and xylose as standards. Activities of CMCase, CBH, xylase and amylase were determined according to the method given in ref 15. One unit (U) of enzyme activity was defined as the amount of enzyme liberating 1 *μ*mol of glucose, xylose, *p*-nitrophenol, or maltose from the appropriate substrates per minute per milliliter of crude filtrate under assay conditions.

**Glucose Inhibition Assays.** *β*-Glucosidase activity was measured by adding 40 *μ*L of enzyme (0.03 *μ*g) into 960 *μ*L of substrate solution containing 0.16 mM pNPG and 50 mM NaAc buffer at pH 5.0. The mixture was incubated in a 60 °C water bath for 15 min, and then 2 mL of 0.5 M NaOH was added to stop the reaction; the adsorption at 405 nm of the reaction solution was measured by using a Beckman DU800 to determine the amount of liberated *p*-nitrophenolate using a standard curve. To determine the effect of D-glucose on BG, activity was measured in substrate solution containing different concentrations of glucose.

**Determination of Microscopic Inhibition Rate Constants.** The progress-of-substrate-reaction method described by Tsou[17] was used to study the inhibitory kinetics of BG by glucose. In this method, 40 *μ*L of enzyme was added to 1.0 mL of assay system 0.16 mM pNPG in the presence of different concentrations of glucose.

The substrate reaction progress curve was analyzed to obtain the reaction rate constants as detailed below. The results showed that the inhibition was a reversible reaction with fractional residual enzyme activity. This catalytic reaction can be written as where E, S, I, and P



denote enzyme, substrate, inhibitor (glucose), and product, respectively. EI and ES are the respective compounds. $k_{+0}$ and $k_{-0}$ are the microscopic rate constants for the forward and reverse reactions of EI, respectively. As a rule, $[S] \gg [E_0]$ and $[I] \gg [E_0]$, and the product formation can be written as

$$[P]_t = \frac{vB}{(A[I] + B)} \times t + \frac{A[I]}{(A[I] + B)^2} - \frac{A[I]}{(A[I] + B)^2} \times e^{-(A[I]+B)t} \quad (1)$$

$$A = \frac{k_{+0} \times K_m}{K_m + [S]} \quad (2)$$

$$B = k_{-0} \quad (3)$$

where $[P]_t$ is the concentration of the product formed at time $t$, which is the reaction time; $A$ and $B$ are the apparent rate constants of inhibition; $[S]$ and $[I]$ are the concentrations of the substrate and inhibitor, respectively; $v$ is the initial rate of reaction in the absence of the inhibitor, where $v = (V_m \times [S])/(K_m + [S])$. When $t$ is sufficiently large, the curves become straight lines and the product concentration is written as $[P]_{calcd}$:

$$[P]_{calcd} = \frac{Bv}{A[I] + B} \times t + \frac{A[I]}{(A[I] + B)^2} \quad (4)$$

Combining eqs 1 and 4 yields

$$[P]_{calcd} - [P]_t = \frac{A[I]}{(A[I] + B)^2} \times e^{-(A[I]+B)t} \quad (5)$$

$$\ln([P]_{calcd} - [P]_t) = \text{constant} - (A[I] + B) \times t \quad (6)$$

where $[P]_{calcd}$ is the product concentration to be expected from the straight-line portions of the curves as calculated from eq 4 and $[P]_t$ is the product concentration actually observed at time $t$. Plots of $\ln([P]_{calcd} - [P]_t)$ versus $t$ give a series of straight lines at different concentrations of inhibitor ($[I]$) with slopes of $-(A[I] + B)$. A secondary plot of the slopes versus $[I]$ gives a straight line. The apparent forward and reverse rate constants, $A$ and $B$, can be obtained from the slope and intercept of this straight line. The value of $B$ directly gives the reverse rate constant $k_{-0}$.

From eq 2 and the Michaelis–Menten equation we can get

$$\frac{A}{v} = \frac{K_m \times k_{+0}}{V_m} \times \frac{1}{[S]} \quad (7)$$

A plot of $A/v$ versus $1/[S]$ gives a straight line with $(k_{+0} \times K_m/V_m)$ as the slope of the straight line; as $K_m$ and $V_m$ are obtained from measurement of the substrate reaction in the absence of glucose at different substrate concentrations, the rate constant $k_{+0}$ can be easily determined from the slope of the straight line.

## RESULTS AND DISCUSSION

**Enzymatic Hydrolysis of Cassava Residues.** The composition of cassava residue enzymes secreted by *H. orientalis* was previously determined to ensure what enzyme could be used for the hydrolysis (Tables 1 and 2). The optimum conditions for

**Table 1. Main Components of Cassava Residues**[a]

| NaOH for pretreatment | cellulose | hemicellulose | lignin | starch | ash | reducing sugars |
|---|---|---|---|---|---|---|

[a]The values are average of the results of four independent tests. [b]Not detected.

saccharification yields of cassava residues were studied with 0.1 mg/mL enzymes and 1.5% matter. The results in Figure 1A show that, at pH 5.0, highest sugar yield (9.7 mg/mL) of enzymatic saccharification was obtained for 24 h of reaction.

The hydrolysis yields at different temperatures are presented in Figure 1B. As seen from the reaction curves, the highest yield of reducing sugar was obtained 10 mg/mL for 24 h of hydrolysis at 50 °C. Reaction kinetic study (data not shown) found that although enzymatic hydrolysis at 55 and 60 °C released sugars more quickly and more sugars were obtained at the initial stage, much less sugars were produced finally than at other temperatures due to thermo-inactivation of enzymes, which was in accordance with a previous study.[7] Effects of different concentrations of NaOH on sugar yields were determined. The results in Figure 1C indicate that alkali pretreatment can effectively and obviously improve yields of cellulase hydrolysis of cassava residues. Enzymatic hydrolysis of cassava residues pretreated with 0.5% (w/v) NaOH yielded 3-fold the amount of sugar of 0% NaOH pretreated residues (curve 3, from 2.5 to 7.5 mg/mL). However, there is a less significant increase in the amount of released sugar even alkaline up to 4%, showing the performances of NaOH above 0.5% were similar on removal of lignin of cassava residues.

Hydrolysis products were then separated and identified through Aminex HPX-87H (Figure 1D) chromatography. Major glucose (8.74 min) was found far more than xylose (9.36 min) and cellobiose (7.20 min), and the concentrations of the three sugars were 7.6, 0.75, and 0.34 mg/mL, respectively. Meanwhile, in a later phase of hydrolysis, a small amount of cellobiose emerged due to inhibition on β-glucosidase by accumulated glucose, with the yield of saccharification of cassava residues maintained but not increased.

**Hydrolysis of Cassava Residues by Different Enzymes.** Two resources of cellulases were used to hydrolyze cassava residues as compared with *H. orientalis* cellulase. Enzyme compositions of these three cellulases are presented in Table 2. It can be easily seen from the data that cellulase R-10 occupied the highest activity of each enzyme activity and that the BG activity of cellulase DF was lower much than those of the other two enzymes. The CMCase activity of *H. orientalis* was relatively small. When hydrolyzing cassava residues, CMCases of enzymes were all adjusted to 15 U/mL in the hydrolysis systems (pH 5.0, 50 °C). The yields of 24 h of hydrolysis catalyzed by *H. orientalis* enzyme and cellulase R-10 (Figure 2, curves 1 and 2) were close (9 mg/mL) and greater than that of cellulase DF (curve 5), which may be due to relatively small

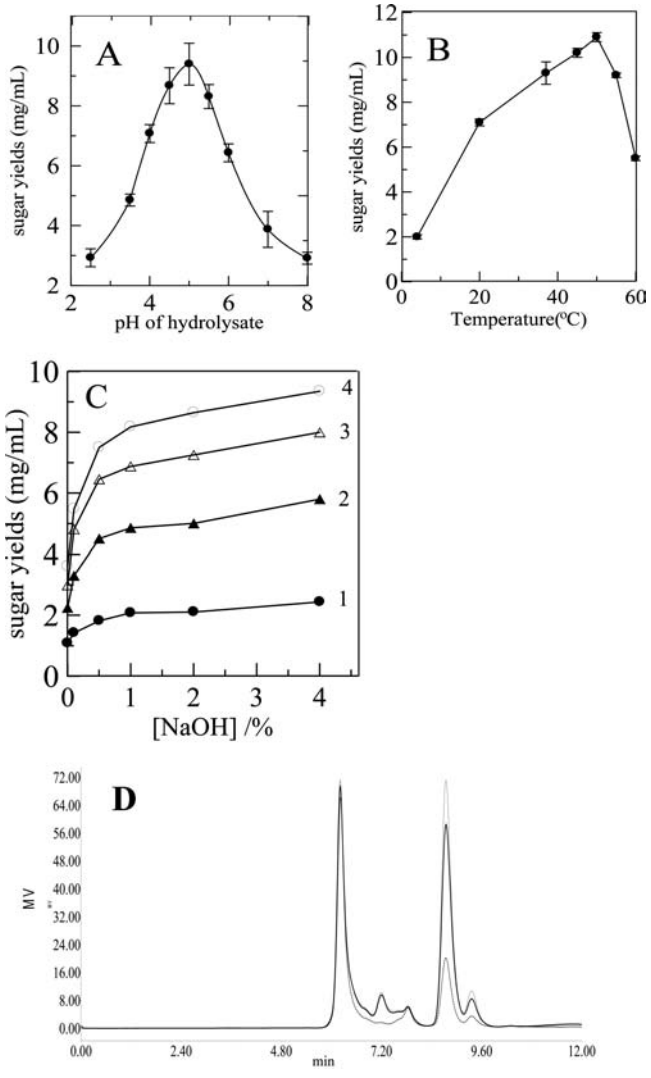

**Figure 1.** Enzymatic hydrolysis yield of pretreated cassava residues at different pH values (A) and temperatures (B) for 24 h of incubation at 50 °C with 0.1 mg/mL cellulase and 1.5% residues. (C) Enzymatic hydrolysis of cassava residues pretreated by different doses of NaOH. The hydrolysis times for curves 1−4 were 0.5, 2, 9, and 12 h, respectively. The values were means of duplicated experiments. (D) HPLC spectra of hydrolysate at three different hydrolysis times, 0.5 (dashed line), 9, and 12 h, respectively. The products were released from hydrolysis of 4% NaOH treated residues.

dx.doi.org/10.1021/jf5039663 | J. Agric. Food Chem. 2014, 62, 11512−11518

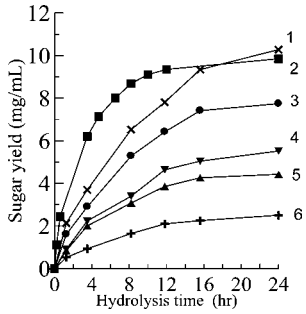

**Figure 2.** Enzymatic hydrolysis of cassava residues by different enzymes (50 °C, pH 5.0). The hydrolyzed residues were pretreated by 4% NaOH. Curves: 1, cellulase R-10 at 15 U/mL CMCase; 2, *H. orientalis* enzymes at 15 U/mL CMCase; 3, cellulase R-10 at 15 U/mL CMCase; 4, 2 U/mL CMCase *H. orientalis* enzymes with 7.5 U/mL cellulase R-10; 5, cellulase DF at 15 U/mL CMCase; 6, *H. orientalis* enzymes at 2 U/mL CMCase. The values are the average of three replicates.

activities of BG and xylase. Meanwhile, hydrolysis by *H. orientalis* enzyme reached the maximum yield faster than the other two enzymes, which could effectively and remarkably reduce the production costs.

To determine whether BG promotes the enzymatic hydrolysis, different enzyme blends were made to hydrolyze the residues. *H. orientalis* enzymes at 2 U/mL CMCase was respectively mixed with cellulase DF and cellulase R-10, both at 7.5 U/mL CMCase (total 9.5 U/mL CMCase with similar activity of xylase). Hydrolyses by the enzyme blends were run in the same conditions as above, respectively. The yields are shown in Figure 2 (curves 3 and 4) compared with respective enzymes. Results presented in the figure suggested that the sugar yields of the blends containing cellulase R-10 decreased significantly more than that of cellulase R-10 hydrolysis due to lower EG activity than that of cellulase R-10, whereas another enzyme blend containing *H. orientalis* enzymes and cellulase DF yielded a similar amount of sugars as that of cellulase DF, even though CMCase was relatively smaller. This result was in accordance with previous studies, which pointed out that adding BG could promote the yield of cellulose hydrolysis.[18,19]

**Hydrolysis of Various Residues by *H. orientalis* Enzymes.** Various resources of agricultural lignocelluloses producing sugars catalytically with *H. orientalis* cellulase (0.1 mg/mL enzymes loaded) were also studied. These cellulosic substrates were prepared from wheat grass, sugar cane bagasse, waste papers, peanut hulls, and stem dregs of swainsona salsula taubert (*Sphaerophysa salsula*, Chinese traditional medicine), respectively, which were all treated with 4% NaOH. Stems of swainsona salsula taubert were processed for extraction of flavonoids before this work. Hydrolysis yields of these materials are shown in Figure 3. The results showed that, without pretreatment, saccharification of cassava residues can produce more sugars than the other cellulose materials due to residual starch. With 4% NaOH pretreatment, sugar cane bagasse, wheat grass, and cassava residues produced similar amounts of sugars far greater than that of waste papers, peanut hulls, and stems of swainsona salsula taubert. Due to condensed lignin cortex, peanut hulls and stems of swainsona salsula taubert cannot release significant amounts of sugars by *H. orientalis* cellulase hydrolysis, whether 4% NaOH pretreated or not, and other effective treatment methods and enzymes were required for that saccharification.

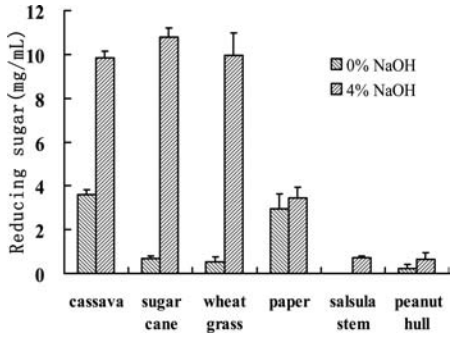

**Figure 3.** Enzymatic hydrolysis yields of pretreated wastes for 24 h of incubation at 50 °C and pH 5.0 with 0.1 mg/mL cellulase and 1.5% dry matter.

On the basis of the results above, with pretreatment, each gram of nonstarch cassava residues hydrolyzed by 0.1 mg/mL cellulase at 50 °C, pH 5.0, for 24 h can release the highest amount of 660 mg of reducing sugars, equal to that of bagasse and wheat grass. *H. orientalis* secreted enzymes were deficient to degrade peanut hulls and stems of swainsona salsula efficiently. The yield was similar to that of cellulase R-10.

**Glucose Gave Reversible and Competitive Inhibition on BG.** The relationship between the activity of *H. orientalis* BG and the concentrations of glucose is shown in Figure 4A.

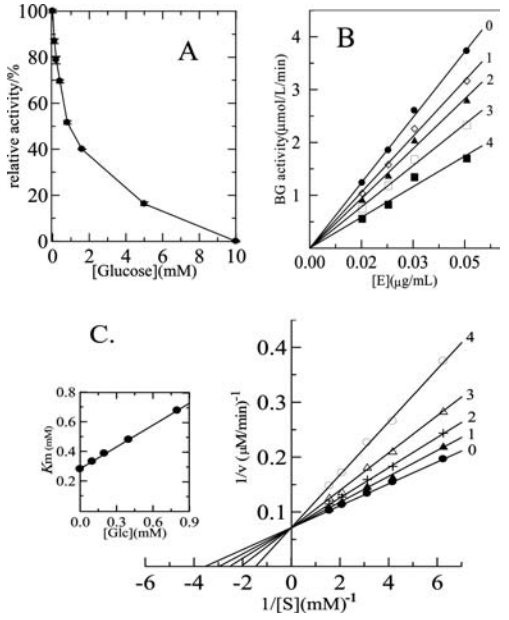

**Figure 4.** Inhibition of BG by glucose. Methods were described in the text. (A) Relative activity of BG at different concentrations of glucose. (B) Effects of BG concentrations on activity for the hydrolysis of pNPG with different concentrations of glucose. The concentrations of glucose for curves 0–4 were 0, 0.1, 0.2, 0.4, and 0.8 mM, respectively. (C) Lineweaver–Burk plots for the hydrolysis of pNPG catalyzed by BG in the presence of different concentrations of glucose. The glucose concentrations for lines 0–4 were 0, 0.1, 0.2, 0.4, and 0.8 mM, respectively. (Inset) Plot of $K_m$ versus glucose concentrations to determine the inhibition constant.

The effect of glucose on BG was dose-dependent inhibition, and the activity of BG was sharply reduced to 20% following the increase of glucose to 5 mM (0.9 mg/mL); the $IC_{50}$ value of glucose was estimated to be 0.87 ± 0.1 mM in the presence of 0.16 mM pNPG.

dx.doi.org/10.1021/jf5039663 | J. Agric. Food Chem. 2014, 62, 11512–11518

Plots of BG activity versus enzyme concentrations under various doses of glucose gave a family of straight lines all passing through the origin (Figure 4B), indicating that D-glucose was a reversible inhibitor of *H. orientalis* BG. Meanwhile, Lineweaver–Burk plots of $1/v$ versus $1/[S]$ under different concentrations of glucose gave a family of lines on a common intercept with slopes ascending along with the increase of glucose (Figure 4C), showing glucose can competitively inhibit BG activity in the progress of cellulose hydrolysis. The results indicated that adding enough enzymes or substrates can effectively reduce depression by glucose products during cellulose saccharification. From curve 0, values of $K_m$ and $V_m$ for pNPG hydrolysis in the absence of inhibitor were determined as 0.28 mM and 14.92 $\mu$M/min, respectively. The inhibition constant ($K_I$) of glucose was calculated to be 0.56 mM from the plot of $K_m$ versus concentrations of glucose as presented in the inset of Figure 4C, which was higher than BG from *P. purpurogenum*, *T. harzianum* C-4, *Daldinia eschscholzii* but lower than another six *Aspergillus* species.[20−25]

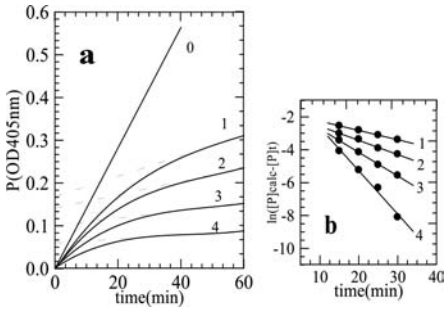

**Figure 5.** Courses of substrate reaction of BG in the presence of different concentrations of glucose. The substrate concentration was 0.16 mM in 0.1 M NaAc buffer (pH 5.0). (a) Substrate reaction course. The concentrations of glucose for curves 0−4 were 0, 0.1, 0.2, 0.4, and 0.8 mM, respectively. (b) Semilogrithmic plots of ln $([P]_{calcd} - [P]_t)$ against time. Data were taken from curves 0−4 in panel a.

**Determination of Microscopic Rate Constants of Glucose Inhibition on BG.** Reaction kinetics hydrolysis of pNPG by BG in the presence of different concentrations of D-glucose was measured as shown in Figure 5a. The results indicated that the reaction rate at each concentration of glucose decreased with increasing time until a straight line (identical with dash line) was approached. Plots of $\ln([P]_{calcd} - [P]_t)$ versus $t$ at different concentrations of glucose are shown in Figure 5b with slopes of $-(A[I] + B)$.

Time courses of the reaction at different concentrations of pNPG are shown in Figure 6a in the presence of 0.1 mM glucose. Plots of $\ln([P]_{calcd} - [P]_t)$ versus $t$ in Figure 6b gave a family of straight lines with slopes of $-(A[I] + B)$. The kinetic curves of substrate reaction at other concentrations of glucose can also be obtained with the same method.

With the presence of various substrate concentrations, plots of the values of $(A[I] + B)$ versus concentrations of glucose presented a series of straight lines with slopes of $A$, respectively, and had a common intercept on the ordinate (Figure 7A). The value of the apparent reverse rate constant $B$ was obtained from

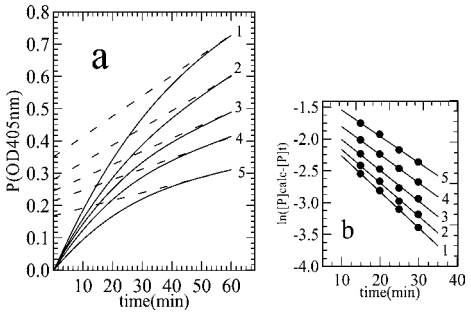

**Figure 6.** Courses of substrate reaction of BG in the presence of 0.1 mM glucose with different concentrations of pNPG. (A) Substrate reaction course. The concentrations of pNPG for curves 1−5 were 0.16, 0.24, 0.32, 0.48, and 0.64 mM, respectively. (B) Semilogrithmic plots of ln $([P]_{calcd} - [P]_t)$ against time. Data were taken from curves 1−5 in panel a.

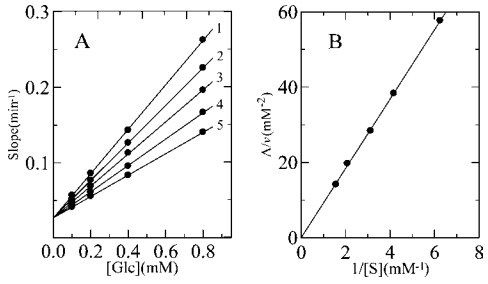

**Figure 7.** Determination of microscopic inhibition rate constants of BG by glucose. (A) Secondary plots of the slopes versus glucose concentrations for a series of fixed substrate concentrations. The concentrations pNPG for lines 1−5 were 0.16, 0.24, 0.32, 0.48, and 0.64 mM, respectively. (B) Plot of $A/v$ versus $1/[S]$. The $A$ value was calculated from the slopes of the straight lines in panel A.

the ordinate intercept, equal to the microscopic rate constant $k_{-0}$. Then, the plot of $A/v$ versus $1/[S]$ was obtained, a straight line that passed through the origin (Figure 7B) with the slope of $(K_m k_{+0}/V_m)$. The microscopic forward rate constant $k_{+0}$ was obtained according to eq 7. The results are summarized in Table 3.

**Relative BG Activities with Different Monosaccharides.** Effects of some monosaccharides (derivatives or isomers of glucose) on BG activity were studied as compared with glucose. Residual activities of BG at different concentrations of monosaccharides were assayed as described previously. It can be seen from the results (Table 4) that, within low concentrations of monosaccharides, BG was far more sensitive to D-glucose than to the other sugars. Meanwhile, the inhibitory effect of L-glucose, a chiral isomer of D-glucose, declined evidently with $IC_{50}$ to >5 mM. Moreover, mannose showed lower $IC_{50}$ than galactose, perhaps because the 2′-OH in the sugar molecule was more accessible to BG active residues than 3′-OH to block the catalytic site. Additionally, a 20% loss of BG activity caused by aminoglucose was detected at 200 mM, and no significant loss of BG activity was found in the presence of *N*-acetylglucose or fructose at a range below 200 mM.

Some of these sugars are components of many agricultural and food wastes,[12] which can be hydrolyzed catalytically

**Table 3. Inhibition Equilibrium Constants and Microscopic Rate Constants for BG by D-Glucose**

| $IC_{50}$ | $K_I$ | $k_{+0}$ | $k_{-0}$ |
|---|---|---|---|
| 0.87 ± 0.1 mM | 0.56 ± 0.02 mM | $4.88 \times 10^{-4}$ (mM· s)$^{-1}$ | $2.7 \times 10^{-4}$ s$^{-1}$ |

accompanied with cellulosic materials for production of biofuels or other chemicals. This work provides theoretical support for that application. Furthermore, comparisons of effects on BG by these saccharides proved that the combination between the active site and chemicals required strict structural specificity, which guided molecular modification to improve sugar tolerance of cellulase.[14]

M82.[15] The *S. pennellii* ILs were used to map several QTLs associated with characters related to tomato fruit quality.[17,18] By using these lines, in our laboratory two QTLs increasing fruit phenolics and AsA content were detected on tomato chromosomes 7 and 12.[19−21] In a subsequent study, these QTLs were pyramided in the genetic background of the cultivated line M82 using marker-assisted selection. The efficacy of pyramiding to improve tomato traits has been previously reported. For example, Gur et al.[22] developed genotypes carrying three independent yield-promoting genomic regions introduced from *S. pennellii* that resulted in a hybrid with 50% higher yields than leading commercial varieties in multiple environments and irrigation regimens. Moreover, introgressions originating from *S. pennellii* were introduced into lines of processing tomato, and the resulting hybrid, AB2, is presently a leading variety in California.[23] In our case, IL 7-3 and IL 12-4 were crossed, and four genotypes of the $F_3$ progenies were selected that carry both introgressions 7-3 and 12-4 at the homozygous condition (DHO).[24] Because the combined effect of these QTLs is unpredictable, here we evaluated the nutritional quality of the four genotypes obtained by QTL pyramiding. We analyzed the amount of phytochemicals associated with antioxidant activity in the cultivated line M82, in the two introgression lines IL 7-3 and IL 12-4 and in the DHO genotypes. In particular, the hydrophilic and lipophilic antioxidant activity and contents of AsA, total phenolics, flavonoids, phenolic acids, total carotenoids, lycopene, and $\beta$-carotene were investigated. In addition, to assess the nutraceutical potential of the DHO lines, we tested the activity of tomato fruit extracts on the proliferation of human normal and cancer cell lines.

## MATERIALS AND METHODS

**Chemicals and Reagents.** Ascorbic acid, Trolox, gallic acid, ferulic acid, quercetin, and kampferol were purchased from Sigma (St. Louis, MO, USA). All solvents used (water, methanol, chloroform) were obtained from Fluka (Swizerland), whereas HPLC grade formic acid was purchased from Aldrich Chemical Co. (Milwaukee, WI, USA). Folin−Ciocalteu's phenol was purchased by AppliChem (Darmstadt, Germany). $FeCl_3$, trichloroacetic acid (TCA), $Na_2CO_3$, $NaH_2PO_4$, $Na_2HPO_4$, 2,2′-dipyridil, $CH_3COOH$, 2,4,6-tripyridyl-*s*-triazine (TPTZ), 2,2′-azinobis(3-ethylbenzothiazoline-6-sulfonic acid) (ABTS), and $K_2S_2O_8$ were obtained from Sigma-Aldrich, $Na_2HPO_4$ and $H_3PO_4$ were obtained from J. T. Baker (Germany), and HCl was obtained from Riedel-deHaën (Germany). Deionized water was obtained from a Milli-Q water purification system (Millipore, Bedford, MA, USA). Chromatographic solvents were degassed for 20 min using a Branson 5200 (Branson Ultrasonic Corp., USA) ultrasonic bath.

**Plant Material and Growth Conditions.** Seeds from IL 12-4 (LA4102), IL 7-3 (LA4066), and their parental line M82 (LA3475) were kindly provided by the Tomato Genetics Resource Centre (TGRC) (http://tgrc.ucdavis.edu/).[25] Genotypes carrying introgressions IL 7-3 and IL 12-4 at the homozygous condition (DHO) were obtained using marker-assisted selection as described in Sacco et al.[24] During the year 2013, the double-homozygous plants of the $F_4$ progenies and their parents were grown according to a completely randomized design with three replicates (10 plants/replicate), in an experimental field located in Acerra (Naples, Italy). Samples of about 20 full mature red fruits per plot were collected.

Tomato fruits were chopped, ground in liquid nitrogen by a blender (FRI150, Fimar) to a fine powder, and kept at −80 °C until the analyses.

**Chemical Extractions.** For the biochemical analyses, each tomato fruit sample consisted of 20 pooled fruits per plot. The extraction of hydrophilic fraction was carried out according to the procedure reported by Choi et al.[26] with minor changes. Briefly, frozen powder (2 g) was weighed, placed into a 50 mL Falcon tube, and extracted with 25 mL of 80% methanol into an ultrasonic bath (Branson 5200 Ultrasonic Corp.) for 60 min at 30 °C. The mixture was centrifuged at 14000 rpm for 10 min at 4 °C, and the supernatant was stored at −20 °C until analysis of total phenolic compounds and hydrophilic antioxidant activity (HAA). The pellet was extracted with 10 mL of chloroform (100%) with the aid of a pestle and was centrifuged at 4000 rpm for 5 min at 4 °C according to the method reported by Wellburn[27] with some modifications. This procedure was repeated five consecutive times, and supernatants were collected and stored at −20 °C until analysis of carotenoids and lipophilic antioxidant activity (LAA).

**Carotenoid Determination.** The evaluation of total carotenoids was carried out according to the method reported by Wellburn,[27] whereas lycopene and $\beta$-carotene were determined according the method reported by Zouari et al.[28] with slight modifications. All biological replicates of samples were analyzed in triplicate. Results were expressed as milligrams per 100 g fresh weight (FW).

**Ascorbic Acid Determination.** AsA quantification was carried out according to the method reported by Stevens et al.[18] with slight modifications. Briefly, frozen powder (500 mg) was placed in a 2 mL eppendorf tube, and 300 $\mu$L of ice-cold 6% TCA was added. The mixture was vortexed for 10 s, incubated for 15 min on ice, and centrifuged at 14000 rpm for 20 min at 4 °C. Then, 20 $\mu$L of supernatant for each assay was transferred in a 1.5 mL eppendorf tube with 20 $\mu$L of 0.4 M phosphate buffer (pH 7.4) and 10 $\mu$L of double-distilled (dd) $H_2O$. Then, 80 $\mu$L of color reagent solution was prepared immediately before assay by mixing solution A (31% $H_3PO_4$, 4.6% (w/v) TCA, and 0.6% (w/v) $FeCl_3$) with solution B (4% 2,2′-dipyridil (w/v) made up in 70% ethanol) at a proportion of 2.75:1 v/v. The mixture was vortexed and incubated at 37 °C for 40 min prior to measurement at 525 nm by a NanoPhotometer (Implen) using 6% TCA as reference. Three separated biological replicates for each sample and three technical assays for each biological repetition were measured. The concentration was expressed in nanomoles of AsA according to the standard curve, designed over a range of 0−70 nmol; then the values were converted into milligrams per 100 g FW.

**Total Phenolic Compounds Determination.** Total polyphenolic amount was evaluated by using Folin−Ciocalteu's assay as reported by Singleton et al.[29] with some modifications. In an eppendorf tube (1.5 mL) 62.5 $\mu$L of methanolic extract, 62.5 $\mu$L of Folin−Ciocalteu's phenol reagent, and 250 $\mu$L of dd $H_2O$ were added and shaken. After 6 min, 625 $\mu$L of 7% $Na_2CO_3$ solution was added to the mixture. The solution was diluted with 500 $\mu$L of dd $H_2O$ and mixed. After incubation for 90 min at room temperature, the absorbance against prepared reagent blank was determined at 760 nm by a NanoPhotometer (Implen). All biological replicates of samples were analyzed in triplicate. Total phenolic content of tomato fruits was expressed as milligrams of gallic acid equivalents (GAE) per 100 g FW.

**Identification and Quantification of Individual Phenolic Compounds.** An aliquot (1 mL) of the methanolic extract was passed through a 0.45 $\mu$m Millipore nylon filter (Bedford, MA, USA) before HPLC analysis. Free phenolic acids and flavonoids were separated and quantified by using a HPLC (Spectra System SCM 1000) fitted with an UV−visible detector. Separation of compounds was carried out on a reversed phase C18 Prodigy column (Phenomenex, 250 × 4.6 mm; particle size = 5 $\mu$m), preceded by a guard column (Phenomenex, 4 × 3.0 mm) of the same stationary phase. A gradient of water acidified with 5% formic acid (A) and methanol (B) at a flow rate of 1 mL/min was applied with the following modes: A = 60% (0 min), 40% (3−18 min), 0% (23−28 min), and 60% (30 min) according to the method reported by Ferracane et al.[30] with minor modifications. To determine total flavonoids and total phenolic acids concentration, the sum of all peaks present in the chromatogram was considered at two characteristic wavelengths of 365 and 287 nm, respectively. Each sample was analyzed by HPLC in triplicate. The quantification was carried out using the calibration curves of quercetin, gallic acid and ferulic acid in the ranges of 1−100, 0.5−10, and 0.01−1 $\mu$g/mL, respectively. The amount of phenolic compounds was expressed as milligrams of

quercetin equivalents (QE) per kilogram FW for quercetin and total flavonoids, as milligrams of GAE per kilogram FW for gallic acid and total phenolic acids, and as milligrams of ferulic acid (FA) per kilogram FW for ferulic acid.

**Antioxidant Activity Determination.** HAA was evaluated in the water-soluble fraction using two different methods, the ferric reducing/antioxidant power (FRAP) method[31] and the 2,2′-azinobis-(3-ethylbenzothiazoline-6-sulfonic acid) (ABTS) method[32] with slight modifications.

The FRAP assay was carried out by adding in a vial (3 mL) 2.5 mL of acetate buffer, pH 3.6, 0.25 mL of TPTZ solution (10 mM) in 40 mM HCl, 0.25 mL of $FeCl_3 \cdot 6H_2O$ solution (12 mM), and 150 $\mu$L of methanolic extract. The mixture was incubated for 30 min in the dark, and then readings of the colored product (ferrous tripyridyltriazine complex) were taken at 593 nm using the spectrophotometer against a blank constituted by a mixture of reaction and 150 $\mu$L of extracting solution ($CH_3OH/H_2O$ 80:20 v/v). The standard curve was linear between 20 and 800 $\mu$M Trolox. Results were expressed as micromoles of Trolox equivalents (TE) per 100 g FW.

The ABTS assay was based on the reduction of the $ABTS^{\bullet+}$ radical action by the antioxidants present in the sample. A solution constituted by 7.4 mM $ABTS^{\bullet+}$ (5 mL) mixed with 140 mM $K_2S_2O_8$ (88 $\mu$L) was prepared and stabilized for 12 h at 4 °C in the dark. This mixture was then diluted by mixing $ABTS^{\bullet+}$ solution with ethanol (1:88) to obtain an absorbance of 0.70 ± 0.10 unit at 734 nm using a spectrophotometer. Methanolic extracts (100 $\mu$L) were allowed to react with 1 mL of diluted $ABTS^{\bullet+}$ solution for 2.5 min, and then the absorbance was taken at 734 nm using a spectrophotometer against a blank constituted by $ABTS^{\bullet+}$ solution added with 100 $\mu$L of ethanol. The standard curve was linear between 0 and 20 $\mu$M Trolox.

LAA determination was carried out according to the ABTS assay, using the extract in chloroform. All biological replicates of samples were analyzed in triplicate. Results were expressed as micromoles of TE per 100 g FW.

The percentage of the variations of quantitative parameters among genotypes was calculated by using the following formula: % increase and/or decrease = (value in genotype 1 − value in genotype 2)/value in genotype 2) × 100. Total antioxidant activity (TAA) was calculated by adding LAA to HAA obtained by using the ABTS test. HAA contribution to TAA was evaluated by dividing HAA value obtained by using the ABTS test by TAA.

**MTT Test Procedure.** Human renal cortical epithelial cells HRCE (Innoprot, Biscay, Spain) were cultured in basal medium, supplemented with 2% fetal bovine serum, epithelial cell growth supplement, and antibiotics, all from Innoprot. Human HeLa adenocarcinoma cells, human renal epithelial cells (Hek 293), and murine BALB/3T3 and SV-T2 fibroblasts (ATCC) were cultured in Dulbecco's modified Eagle's medium (Sigma-Aldrich), supplemented with 10% fetal bovine serum (HyClone, Logan, UT, USA), 2 mM L-glutamine, and antibiotics. Cells were grown in a 5% $CO_2$ humidified atmosphere at 37 °C. Cells were seeded in 96-well plates (100 $\mu$L/well) at a density of $5 \times 10^3$/well. Methanolic tomato extracts, obtained as reported above, were dried by rotovapor (R-210, Buchi), redissolved in dimethyl sulfoxide (DMSO) 5% in PBS, and then added to the cells 24 h after seeding for dose-dependent cytotoxicity assays. At the end of incubation, cell viability was assessed by the MTT assay. The MTT reagent, dissolved in DMEM in the absence of phenol red (Sigma-Aldrich), was added to the cells (100 $\mu$L/well) to a final concentration of 0.5 mg/mL. Following an incubation of 4 h at 37 °C, the culture medium was removed, and the resulting formazan salts were dissolved by adding isopropanol containing 0.1 N HCl (100 $\mu$L/well). Absorbance values of blue formazan were determined at 570 nm using an automatic plate reader (Microbeta Wallac 1420, PerkinElmer). The decrease in absorbance in the assay measures the extent of decrease in the number of viable cells following exposure to the test substances calculated by using the following formula: % inhibition of cells = $(A_{control} - A_{test\ substance})/A_{control} \times 100$. Three separate analyses were carried out with each extract. Control experiments were performed either by growing cells in the absence of the extract and by supplementing the cell cultures with identical volumes of extract buffer (5% DMSO in PBS). The method used avoids any possibility of a DMSO effect on the results.

**Statistical Analyses.** Quantitative results were expressed as the mean value ± SD for three replicates. Differences among genotypes for each evaluated parameter were determined by using SPSS (Statistical Package for Social Sciences) Package 6, version 15.0. Significance was determined by comparing mean values of DHOs to the common controls M82, IL 7-3, and IL 12-4 through a factorial analysis of variance (one-way ANOVA) with LSD post hoc test at a significance level of 0.05. Principal component analysis (PCA) was carried out using the same version of SPSS. For the MTT test all of the data are representative of at least three independent experiments (with comparable results). Statistical significance of the data was evaluated by *t* test analyses.

## RESULTS AND DISCUSSION

Tomato plants represent one of the major sources of antioxidants and other bioactive compounds that benefit nutrition and human health. It is well-known that carotenoids, phenolics, and AsA alone are not responsible for tomato functional effect, but they act synergistically.[12] In this study we report the characterization of novel tomato lines obtained by QTL pyramiding to combine different wild chromosomal regions and the evaluation of their phytochemical parameters in comparison with parental lines.

**Carotenoids.** In Table 1 the levels of total carotenoids, lycopene, and $\beta$-carotene in M82, the ILs, and DHO lines are reported. The cultivated line M82 showed a mean value of carotenoids of 11.10 ± 0.41 mg/100 g FW. The genotype IL 7-3 exhibited a significant ($p < 0.05$) increase (22.19%) of total carotenoids content compared to the cultivated line M82. On the contrary, IL 12-4 showed a significant decrease of total carotenoids content (35.6%) compared to M82. The DHO genotypes were characterized by an amount of carotenoids significantly lower than in M82, with a decrease ranging between 31.42 and 43.30% and comparable to the amount calculated in IL 12-4. In all of the genotypes lycopene constituted about 90−94% of total carotenoids, whereas $\beta$-carotene represented about 4−6% of total carotenoids. The reduction of carotenoids in the DHO lines and in IL 12-4 compared to the control M82 could be explained by taking into consideration the detection and fine-mapping of one major QTL (*lyc12.1*) for lycopene content in the chromosomal region 12-4.[33,34] In fact, wild alleles of the region 12-4 influenced negatively the levels of these metabolites in the tomato fruits of the DHO lines, even contrasting and overcoming the positive influence of the wild alleles located on the region 7-3 that may contribute increasing carotenoids levels. Therefore, we can

**Table 1. Lycopene, $\beta$-Carotene, and Total Carotenoids Contents in the Tomato Lines Analyzed[a]**

| genotype | lycopene (mg/100 g FW) | $\beta$-carotene (mg/100 g FW) | total carotenoids (mg/100 g FW) |
|---|---|---|---|
| M82 | 10.09 ± 0.38a | 0.67 ± 0.03a | 11.10 ± 0.41a |
| IL 12-4 | 6.66 ± 0.14b | 0.41 ± 0.01b | 7.15 ± 0.09b |
| IL 7-3 | 12.70 ± 0.20c | 0.58 ± 0.01c | 13.56 ± 0.22c |
| DHO1 | 6.15 ± 0.241b | 0.40 ± 0.02b | 6.78 ± 0.261b |
| DHO2 | 5.73 ± 0.64bd | 0.39 ± 0.05b | 6.40 ± 0.72bd |
| DHO3 | 5.75 ± 0.23bd | 0.33 ± 0.03bd | 6.29 ± 0.18bd |
| DHO4 | 6.85 ± 0.20b | 0.42 ± 0.01b | 7.61 ± 0.21b |

[a]Values are means ± SD ($n = 9$). Values with different letters are significantly different ($p < 0.05$).

speculate that a negative interaction exists between genes and/or transcription factors located in the *S. pennellii* regions 12-4 and 7-3. However, it is noteworthy that the amount of these metabolites calculated in the DHO lines and in IL 12-4 are comparable to those found in some cultivated tomato lines.[2,35−37]

**Ascorbic Acid.** The average AsA concentration in red ripe fruit of M82 was 14.27 ± 1.30 mg/100 g FW. Genotypes IL 12-4 and IL 7-3 showed significant increases (40 and 45%, respectively) compared to the cultivated genotype (Figure 1).

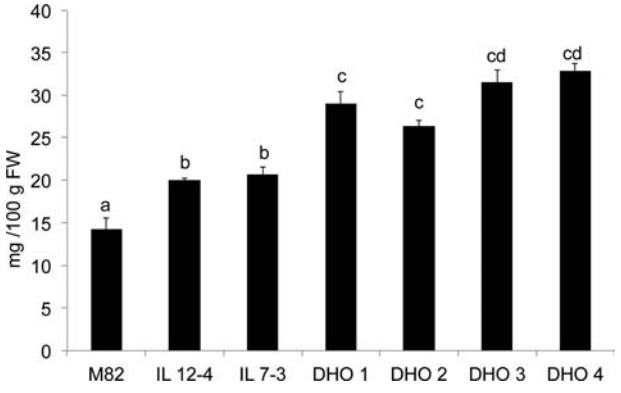

**Figure 1.** Ascorbic acid content (mg/100 g FW) in tomato lines analyzed. Values are means ± SD ($n$ = 9). Values with different letters are significantly different ($p$ < 0.05).

The amount of AsA calculated in M82 and in the IL lines is in agreement with the presence of QTLs for high AsA content previously identified in the 12-4 and 7-3 introgressed regions.[19,24] The mean value of ascorbic acid calculated in the DHO lines was between 28.99 and 32.84 mg/100 g FW. The DHO genotypes showed a significant increase of AsA content ranging between 84 and 130% compared to M82. Interestingly, the DHO genotypes also showed a significant mean increase of AsA content of 50% compared with IL 12-4 and of 45% compared to IL 7-3, indicating that in this case QTL pyramiding is effective in increasing AsA content. In addition, the DHO lines analyzed showed a higher AsA level compared to common commercial varieties,[2] for which a value of 20 mg/100 g FW was established as normal.[38] The high levels of AsA in DHOs may not only increase the nutritional value of these genotypes but might also have an effect on plant health, because AsA biosynthesis has been related to resistance to biotic and abiotic stresses.[39] Finally, the increase of AsA levels in the DHO lines compared to M82, but mostly compared to the two ILs, demonstrated that it is possible to have a positive interaction of the two wild chromosomal regions 7-3 and 12-4 on the level of this metabolite in tomato fruit.

**Phenolic Compounds.** The levels of total phenolic compounds were calculated in M82, ILs, and DHO lines. Results obtained from Folin−Ciocalteu's assay are reported in Figure 2. The cultivated line M82 showed a mean value of 18.12 ± 0.91 mg GAE/100 g FW. IL 12-4 did not exhibit a significant variation compared to M82, whereas IL 7-3 showed a significant increase (35.43%) compared to the cultivated genotype. The data obtained in the present study are in agreement with the levels reported for M82, IL 12-4, and IL 7-3 by Sacco et al.[24] Therefore, we could confirm the presence of a major QTL for fruit phenolic accumulation mapping to the introgressed region 3 of chromosome 7. DHO lines showed a

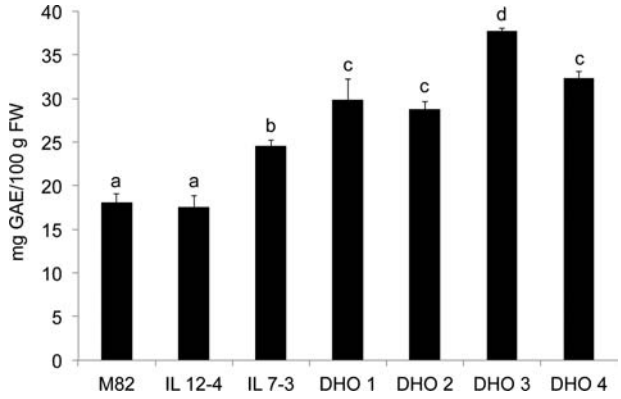

**Figure 2.** Total phenolics content (mg GAE/100 g FW) in tomato lines analyzed. Values are means ± SD ($n$ = 9). Values with different letters are significantly different ($p$ < 0.05).

significant increase of phenolics compared to the control M82 (ranging between 59.09 and 107.92%) and to IL 12-4 (ranging between 64.24 and 114.65%), but, interestingly, also compared to IL 7-3 (ranging between 17.46 and 53.52%). In the DHO lines the calculated amount of phenolic compounds ranged between 30 and 38 mg/GAE 100 g FW. These values are comparable with those observed by García-Valverde et al.[36] and by Martínez-Valverde et al.[40] in some tomato cultivated lines and higher than those reported by George et al.[35] and Hernández et al.[41]

Phenolic acids and flavonoids were also detected by HPLC (Table 2). Quercetin and gallic acid represent the majority of detected phenolics, whereas kampferol was not detected in any analyzed lines. These results are not in line with those reported by Slimestad et al.,[42] who observed that chlorogenic acid was the major phenolic acid and rutin the major flavonoid together with naringenin. This variability can be attributed mainly to the diverse genetic sources adopted in the different studies.[43] In particular, in our case quercetin was present in M82 at the mean level of 25.70 ± 4.26 mg QE/kg FW, and in IL lines it did not show significant variations compared to M82. By contrast, in DHOs a significant decrease ranging between 67.00 and 76.00% was found. Despite this decrease, values found for quercetin in the pyramided lines were higher than those reported by Vallverdú-Queralt et al.[44] in cultivated tomatoes. The same trend observed for quercetin in tested lines was observed for total flavonoids. The amount of total flavonoids in pyramided lines is comparable to that reported by Slimestad et al.[42] in different cultivars of tomato.

Total phenolic acids were significantly higher in IL 7-3 and DHO lines compared to M82 and IL 12-4. In particular, DHO genotypes showed an increase ranging between 94.11 and 154.16% compared to M82 and between 77.39 and 132.27% compared to IL 12-4. Interestingly, the DHO genotypes also showed a significant mean increase of total phenolic acid content up to 50.64% compared to IL 7-3. Frusciante et al.[2] established an optimum concentration of these compounds in tomato of 53.6 mg/kg FW. Therefore, the amount of total phenolic acid calculated in M82 in this study exceeded the recommended concentration of 53%, whereas in DHOs it exceeded this value of 197−288%.

There was also an increase in the level of gallic acid in the DHO genotypes compared to M82 and IL 12-4. These results are noteworthy because it has been demonstrated that gallic acid exerts a protective effect on diabetes due to its

Table 2. Flavonoids, Ferulic Acid, Gallic Acid, and Total Phenolic Acids Evaluated by HPLC[a]

[a]Values are means ± SD ($n$ = 9). Values with different letters are significantly different ($p < 0.05$).

antihyperglycemic and antilipid peroxidative capacity as well as its strong antioxidant power.[45] In addition, a significant increase in the level of ferulic acid in the DHO lines compared to the cultivated line and IL 12-4 was detected. Also, the increase of ferulic acid in the DHO lines is significant from a nutritional point of view, because a positive effect derived from the combination of ferulic acid with AsA, in particular associated with the protection of the myocardium, has been demonstrated.[46]

Taken together, the data obtained from two independent assay procedures (Folin−Ciocalteau and phenolics estimation by HPLC-UV procedure) clearly indicated that the amount of phenolic compounds, in particular of phenolic acids, was increased in DHOs compared to ILs and M82, and above all compared to IL 7-3. This suggested that on the region 12-4 there are wild alleles that synergistically interact with those mapping to the 7-3 region, resulting in increased phenolic levels. On the contrary, the decrease of total flavonoid in the DHO lines must be due to negative interactions between the two wild regions. These findings highlight that detailed information regarding the interaction effects between detected QTLs and between QTLs and the recipient background genotype are necessary to design an efficient pyramiding strategy for increasing tomato nutritional quality.

**Antioxidant Activity.** Results regarding lipophilic (LAA), hydrophilic (HAA), and total antioxidant activity (TAA) of genotypes analyzed are reported in Table 3. In the cultivated M82 line, the LAA antioxidant activity showed a mean level of 104.79 ± 3.38 μmol TE/100 g FW. A significant 20% lower value of LAA was calculated in genotype IL 12-4 compared to the cultivated line, whereas in IL 7-3 the mean value of LAA (112.05 ± 3.27 μmol TE/100 g FW) was comparable to the value obtained in M82. In DHO lines, the detected values were not significantly different from those of IL 12-4 and showed a decrease compared to M82 ranging between 15.30 and 23.88%. Our LAA results confirmed the data obtained for carotenoids that constitute the major fraction of lipophilic compounds in tomato fruit. Nevertheless, the LAA decrease in the DHO lines and in IL 12-4 (estimated by ABTS) was lower than the decrease calculated for total carotenoids and lycopene. This is probably due to the presence of other lipophilic compounds such as tocopherol and lipophilic phenolics, as well as to the synergic effect of compounds contributing to LAA.[47]

The HAA determined by FRAP and ABTS tests in M82 showed values of 115.36 ± 11.89 and 131.61 ± 13.34 μmol TE/100 g FW, respectively. The parental lines IL 7-3 and IL 12-4 showed increased values of HAA compared to the cultivated line. Values calculated in DHO lines were significantly different from M82, with a mean increase of 96% by FRAP test and 80% by ABTS test. Compared to IL 12-4, DHO genotypes revealed significant mean increases of 46.63 and 54.46% according to FRAP and ABTS tests, respectively, and compared to IL 7-3 mean increases of 57.43 and 62.72% in the two assays. The mean contribution of HAA to TAA was estimated to be 55.67% in M82, 64.78% in IL 12-4, and 56.48% in IL 7-3, whereas in DHOs these percentages were between 68.63 and 75.52%. Overall, the TAA in DHOs revealed significant increased values in comparison to the cultivated M82 and IL lines, and this increase was attributed mostly to a higher contribution of HAA to TAA. Our data on HAA and TAA were comparable to those reported by Cano et al.,[48] and the contribution of HAA to TAA was comparable to that found by Kotíková et al[3] and Arnao et al.[49]

Comprehensively, our data demonstrated that there is a positive interaction between the two wild regions 7-3 and 12-4 that caused an increment of HAA. On the contrary, there is a negative influence of the wild alleles of the region 12-4 on LAA. Therefore, the improvement of the nutritional quality in DHO lines can be attributed mostly to the increment of the hydrophilic fraction that includes the majority of tomato phytochemicals, despite a general decrease of the lipophilic fraction.

Accordingly, by the PCA we observed that the separation of DHOs from M82 and from the two ILs is mainly due to the

hydrophilic fraction (Figure 3). Indeed, PC1 explained 71.92% of the variation in the data and was associated positively with

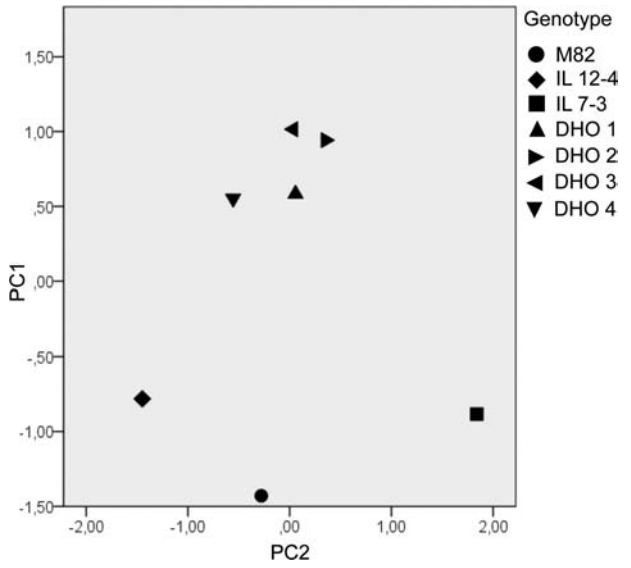

**Figure 3.** Principal component analysis (PCA) of metabolic profiles of analyzed genotypes.

AsA, phenolic acids, gallic acid, ferulic acid, total phenolics, total flavonoids, quercetin, hydrophilic ABTS, and FRAP (loading values > 0.60). PC2 explained 18.09% of the variation in the data and was associated positively with total carotenoids, lycopene, $\beta$-carotene, and lipophilic ABTS (loading values > 0.60). The PCA output shows an evident separation of both IL 12-4 and IL 7-3 from M82, mainly attributable to PC2 that included the lipophilic compounds and their contribution to the antioxidant activity. DHOs were well separated from the parental lines for both PC1 and PC2 and from M82 mainly for PC1, which represented the hydrophilic fraction of the analyzed metabolites and their relative antioxidant activity.

**Effects of Tomato Extracts on Cell Viability.** Finally, the biological activity of extracts from M82, IL 7-3, IL 12-4, and DHO has been tested in our study by using two normal cell lines (Figure 4): a primary human cell line derived from kidney (HRCE) and an immortalized murine fibroblast cell line (BALB/3T3). The viability of cells treated for 48 h with increasing amounts of tomato extracts was tested by the MTT reduction assay, as an indicator of metabolically active cells. In Figure 4 the results of dose−response experiments are shown. The values are the average of three independent experiments, each carried out with triplicate determinations. We observed that M82, IL 7-3, and IL 12-4 extracts had a cytotoxic effect on the HRCE cells and on the BALB/3T3 cells, which was very evident at the highest concentration tested. On the contrary, DHO extracts had no effect, independent of the concentration used on primary cells (HRCE cells), and small effects only at the highest concentration used (24 mg/mL) on immortalized normal cells (BALB/3T3 cells). The cytotoxic effect of M82, IL 7-3, and IL 12-4 extracts could be due to the presence in these genotypes of higher levels of compounds with reported antiproliferative activity such as flavonoids[50] compared with the lower levels observed in the DHO lines (Table 2). In fact, it has been demonstrated that exposure to high levels of flavonoids may potentially damage cells.[51] To test the anticarcinogenic potential of the tomato genotypes, we performed the same experiments using cancer cell lines of the same anatomical origin of normal cells (Figure 5). We examined the inhibition of the rapidly proliferating human cancer cell lines (HeLa cells), of BALB/3T3 murine fibroblasts transformed with SV40 virus, and of human renal cancer cell lines (Hek293). As shown in Figure 5, we observed a strong and selective cytotoxic effect of DHO extracts, particularly evident at the highest concentration used on all of the cancer cell lines tested. Generally, a lower cytotoxic effect was observed with the M82, IL 7-3, and IL 12-4 extracts. The effects of DHO extracts on cancer cells could be also dependent on the content of total phenolic acids[54] and on the presence of gallic acid, a compound known to have a selective cytotoxic effect on cancer cells.[55] The mechanism for the known selective effects of plant phenolics on cancer cell growth is still under debate and may also involve differences in gene expression between normal and tumor cell lines.[50] At low concentrations all of the tomato extracts caused an initial increase in HeLa and SV-T2 cell growth followed by inhibition of growth at higher concentration. This result was not observed on Hek293 cells. The proliferative effect here observed has been reported for several plant extracts used at low concentration on different cancer cells.[26,52,53] This could be due to the fact that cancer cells are actively proliferating; thus, the presence of nutrients in the plant extracts in combination with low levels and/or low

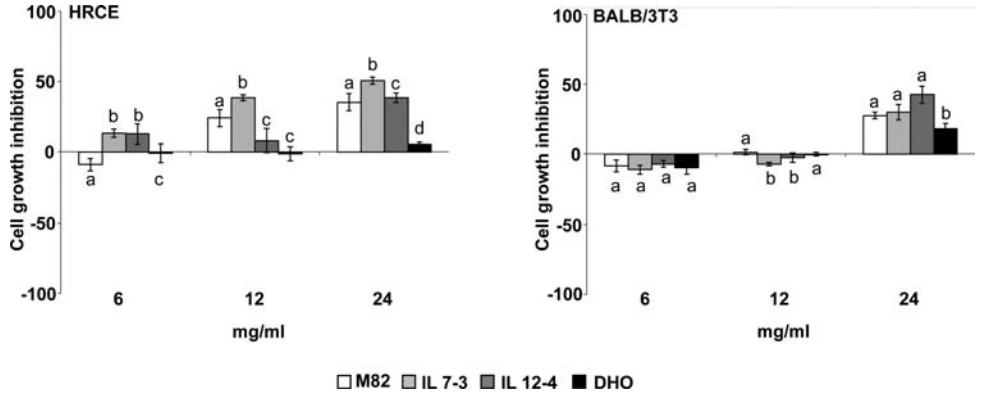

**Figure 4.** Dose−response curves obtained upon treatment of HRCE and BALB/3T3 cells with extracts from M82, IL 7-3, IL 12-4, or DHO after 48 h. Cell growth inhibition was assessed by the MTT assay and expressed as described under Materials and Methods. All values are given as means ± SD ($n \geq 3$). Within each treatment, values with different letters are significantly different ($p < 0.05$).

susceptibility to active compounds may have a positive effect on cell growth, as suggested by Choi et al.[26]

In conclusion, the combination of multiple QTLs, QTL pyramiding, offers a straightforward and useful way for improving target traits in crop plants.[56] Here we demonstrated that it is possible to incorporate favorable wild-species QTLs in the same genetic background to obtain genotypes with a reproducibly higher nutritional value. In particular, we have shown that QTL pyramiding resulted in genotypes with higher AsA and phenolics and increased the total antioxidant power. In addition, crude extracts from the pyramided genotypes showed antiproliferative activity only on human cancer cells, whereas they did not affect the growth of normal cells. On the contrary, extracts from the cultivated genotypes and the ILs did not show the same selective cytotoxic effect but inhibited proliferation of normal cells. The pyramided QTLs should now be transferred in cultivated genetic backgrounds different from M82 to verify that they might exert the same increase of the total antioxidant activity and the same selective cytotoxic effect on aggressive cancer cells. In particular, because compounds such as vitamin C (that are increased in DHO lines) are heat-labile, the pyramiding strategy here used to increase tomato nutritional value could be applied to varieties that are used for fresh consumption.

Consequently, these novel genotypes could be used as genetic material for breeding schemes aimed at generating new hybrids or improved varieties with higher nutritional levels. However, to use these DHO lines as breeding materials, it will be important to understand if introgressed wild regions determine taste alterations and/or allergenic effects. Finally, further studies aimed at dissecting the introgressed region into sublines, as well as in-depth analyses of candidate genes, will be necessary to elucidate the underlying mechanisms of the selected QTLs. These studies will help also to disrupt the linkage between the genes that promote AsA content and those that contribute to low carotenoid levels in region 4 of chromosome 12, thus facilitating the use of IL 12-4 as a source of favorable alleles for higher AsA.

effect, in most experiments, the juice pH was modified using citrate buffer salts at a constant ionic strength. Given the possible role of double-layer interactions between particles on cloud stability, juice ionic strength could well be an important parameter in clarification rates.

Through research presented in this paper, we examine particle interactions as a function of pH, via static light scattering, turbidity, and $\zeta$ potential, and discuss the role of interparticle energy barriers in the observed cloud stability. We seek to elucidate cloud stability in low-acid carrot juice, which may have inherent properties different from those of juices previously studied that are naturally more acidic.

## MATERIALS AND METHODS

**Material Sourcing.** Refrigerated fresh carrot juice ("ready to drink"), commercially produced in Bakersfield, CA, was purchased from the local grocery store and used for all experiments. Juices prepared by us in the laboratory could not replicate the qualitative features and consistency of the particle size distributions of purchased fresh carrot juices, and thus, a study on commercial juice was preferred. According to the manufacturer, the juice was produced from finely ground fresh carrots that were separated into juice and pomace; the juice was then pasteurized, packed, stored, and distributed under refrigeration. There were no added ingredients, and the juice was not acidified. As indicated by the manufacturer, the average total solids of the commercial juice was 10−20% and the soluble solids was 5−6%. The weight fraction of all solids in carrot juice was estimated in our laboratory to be 0.09 g/g, by drying the juice in a 56 °C oven and weighing the residual. From this concentration, the amount of soluble solids in carrot juice was subtracted, to give a value of ∼0.04 g of insoluble solids/g of juice.[18] Turbidity of the juice was measured in our laboratory using ultraviolet (UV) absorption at 660 nm to be 14 $cm^{-1}$. The range of pH for carrots used by the manufacturer was reported to be 5.85−6.45, and the pH of the unbuffered juice was measured by us to be 6.2.

Citric acid monohydrate, sodium citrate, sodium chloride, and calcium chloride were obtained from Fisher Scientific (Fair Lawn, NJ).

**Acidification.** Citric acid and sodium citrate were added directly to commercial carrot juice to obtain seven samples of carrot juice with 0.1 M buffer concentrations and pH values spanning 3.5−6.1. Buffer salts were directly added to the carrot juice to ensure consistent ionic concentrations between the samples. All measurements were taken on the same day after 3 days of storage at 7 °C to ensure that particle flocculation was complete.

Certain juice samples were acidified by adding various small volumes of 2 M citric acid solution to commercial carrot juice, to achieve the desired pH value.

To explore the effect of neutralizing acidified juice back to its natural pH (6.2), 40 mL aliquots of juice were acidified with 2 M citric acid to pH 3.0 and left to sit for 1 day to allow for flocculation to occur. The juice was then neutralized back to pH 6.2 using 2 M NaOH.

**Relative Sediment Height.** Relative sediment height, also known as the sedimentation test, is a measure of the quantity of visible settling that occurs in the juice.[7,19] It is the height ($H_{sediment}$) of the cloud sediment divided by the total height ($H_{total}$) of the juice in a vial.

Roughly 5 mL of each juice sample was placed in a 7 mL glass vial with a screw cap and allowed to remain undisturbed, except for gentle transportation of the vials from the refrigerator to the laboratory bench for measurements. The height of the liquid in the vials was between 25 and 30 mm. A caliper was used to make height measurements in triplicate.

**Relative Turbidity.** Relative turbidity is a spectrophotometric method to determine cloud stability by comparing the turbidity in a juice sample before and after centrifugation.[3,5,7,12,20] For the carrot juices examined here, absorbance at 660 nm was used as the measure of juice turbidity. At this wavelength, absorbance is predominantly determined by the scattering as a result of the particles rather than specific chemical absorption.[21] Relative turbidities were determined by measuring the absorbance values for the homogeneously mixed whole juice and for the supernatants obtained after centrifugation (4200$g$ for 15 min at 20 °C). When absorbance values measured in standard 1 cm cuvettes were unacceptably high, shorter path length cuvettes (0.5 mm for whole juice and 5.0 mm for juice supernatants) were used. The absorbance of the whole commercial juice was determined to be 0.68, and the supernatant was 0.81. Turbidity ($\tau$) was calculated as the absorbance divided by the path length used for measurement. Relative turbidities (expressed as a percentage) were calculated as $\tau_{super}/\tau_{total} \times 100$, with $\tau_{super}$ obtained from the centrifuged supernatant layer and $\tau_{total}$ obtained from the uncentrifuged whole juice. Measurements were performed in triplicate.

**Particle Size Determination.** Static light scattering was used to measure the average particle size.[3−5,7,11,22] Measurements were performed using a Microtrac S3500 (Montgomeryville, PA). Results were obtained as the volume fraction of particles contained within a discrete size range (bin). The mean diameter was determined as a volume average:

$$D_{4,3} = \frac{\sum_i n_i d_i^4}{\sum_i n_i d_i^3} \quad (1)$$

where $D_{4,3}$ is the volume mean diameter, $n_i$ is the number of particles in bin $i$, and $d_i$ is their diameter. Carrot juice was inverted gently 10 times to ensure even distribution of particles and then added to the instrument sample port, which was operated at a flow rate of 15% of the maximum. Particles were assumed to be irregular in shape and absorbing, and a refractive index value for water of 1.333 was used. Three replicates were measured for each sample.

**$\zeta$ Potential.** Using a Malvern Zetasizer (Westborough, PA), the $\zeta$ potential ($\zeta$) of the cloud particles was determined by measuring the electrophoretic mobility ($\mu$) of the particles in the presence of an electric field. Carrot juice was diluted 1:40 with deionized water to ensure that it was in the appropriate concentration range for measurements, which in our experiments corresponded to a signal intensity of ∼100 kcps. The dielectric constant and viscosity of the continuous phase were set to 78.3 F/m and 0.8903 mPa s, respectively, at 25 °C. A minimum of 10 analysis runs were performed for each sample, the values for which were averaged together and analyzed via Smoluchowski's equation, $\zeta = \varepsilon\mu/\eta$, where $\varepsilon$ is the dielectric constant and $\eta$ is the viscosity of the continuous phase. This model requires the diffuse double layer to be thin compared to the particle radius. Three replicates were taken for each sample.

## RESULTS AND DISCUSSION

**Relative Sediment Height and Relative Turbidity.** Cloud stability decreased as juice pH was lowered by the use of citrate buffer. After 3 days of refrigerated storage, there was almost no precipitate in the buffered control juice (pH 6.1) nor in the juices at the two next highest pH values, whereas a separate sediment layer was seen in more acidified juices (Figure 1). The extent of the separation was quantified by

**Figure 1.** Cloud sedimentation in buffered commercial carrot juice after 3 days in refrigerated storage. pH 6.1 is the control buffered juice.

measuring the height of the sediment layer relative to the total juice height (Figure 2). This relative height increased with decreasing pH. These results were consistent with turbidity measurements of the supernatant before and after centrifugation (Figure 2). With a reduction in juice pH, the relative turbidity decreased monotonically, indicating that, most likely because of particle aggregation, particles sedimented more readily in lower pH samples upon centrifugation. The agreement between the results of relative sediment height and relative turbidity demonstrate that either method would be an appropriate way to measure the cloud instability in carrot juice. Results in Figure 1 also demonstrate that, as previously noted by Reiter et al.,[5] formation of a sediment in this experiment was not accompanied by the loss of visible turbidity in the supernatant, except to a small extent at the two lowest pH values.

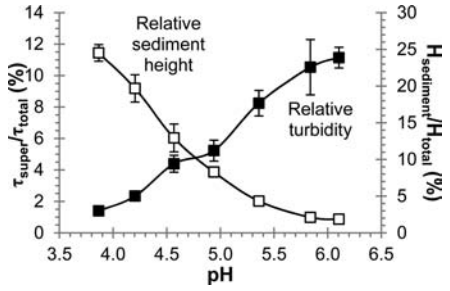

**Figure 2.** (■) Relative turbidity ($\tau_{super}/\tau_{total}$) and (□) relative sediment height ($H_{sediment}/H_{total}$) as a function of pH of commercial carrot juice with buffer salts added.

**Particle Size Distributions.** Particle size distributions were measured for the unbuffered juice at pH 6.2 (Figure 3a) as well as the samples with added buffers (panels b–h of Figure 3).

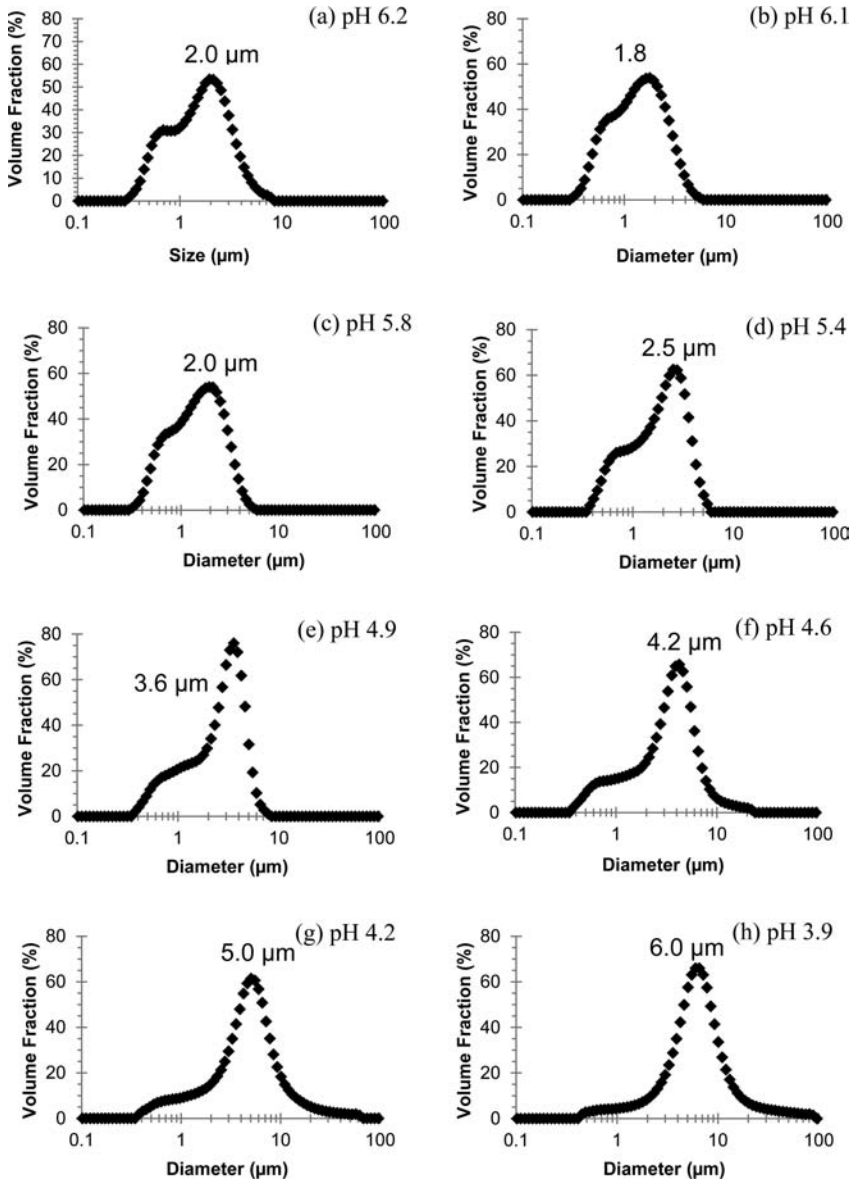

**Figure 3.** Particle size distribution graphs showing the volume fraction with the associated particle diameter (±0.04 μm) of (a) control unbuffered juice (pH 6.2) and (b–h) juices with added buffer salts at (b) pH 6.1, (c) pH 5.8, (d) pH 5.4, (e) pH 4.9, (f) pH 4.6, (g) pH 4.2, and (h) pH 3.9. The particle diameter at the maximum volume fraction is indicated above the main peak.

The distribution for the control buffered juice (Figure 3b, pH 6.1), shows evidence of two overlapping modes: one with particle sizes of a few micrometers and the other with sub-micrometer sizes. Particles of diameters less than 10 $\mu$m only were observed in the control juices, in contrast to typical juices analyzed by Reiter et al.,[5] which had particle sizes ranging from 0.1 to 700 $\mu$m. Thus, we did not observe a "coarse particle" fraction (defined as containing particles with a diameter of >10 $\mu$m),[5] and effects of acidification on fine particles (<10 $\mu$m) could be monitored directly (Figure 3). The average particle size ($D_{4,3}$) of the control juice (pH 6.1) was approximately 2 $\mu$m.

Juices with buffer at high pH levels, i.e., close to the natural juice pH, had particle distributions that were similar to the control (Figure 3c). As pH decreased, the main peak shifted toward larger particle sizes and increased in height. These particle distributions also exhibited a shoulder to the left of the main peak, and this mode decreased in height as the pH decreased (panels d–h of Figure 3). The rightward shift in the main peak with decreasing pH corresponded to only a moderate increase in the modal diameter (values marked in Figure 3), with this mode remaining below 10 $\mu$m for all pH conditions. Thus, it seems likely that, upon acidification, cloud particles of various sizes (sub-micrometer and micrometer) flocculated together to form clusters with just a few members, resulting in fewer sub-micrometer particles in the cloud and an accompanying growth in the size of the larger main mode. In addition, for pH values of ≤4.6, a new mode developed at larger particle sizes above 10 $\mu$m (panels f–h of Figure 3). The size of particles in this mode dramatically increased as the juice became more acidic. In contrast to particles in the main peak, it is clear that these largest particles are clusters with a large number of subparticles. These latter findings, in particular, are consistent with the work by Reiter et al.,[3] who observed that acidification of carrot juice to pH 4.4 increased the average diameter of the particles above 10 $\mu$m.

Overall, a monotonic increase in the average droplet size was observed with decreasing pH, as shown in Figure 4.

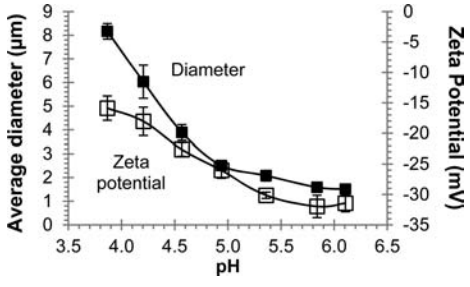

**Figure 4.** (■) Average particle size $D_{4,3}$ and (□) $\zeta$ potential of commercial carrot juice samples with added buffer.

Acidification caused particles to form aggregates that more rapidly sedimented and created an unstable cloud (Figures 1 and 2). The average particle size also increased in juices acidified by a method that was closer to industrial practice: by adding concentrated (2 M) citric acid in increasing amounts to the original juice. Measured results for the average diameter in the entire juice under these conditions are shown in Figure 5a.

Particle sizes in the supernatant and sediment of acidified (unbuffered) juices were also measured, with results in Figure 5a indicating that particles increased in size in both layers as the juices were acidified. During sedimentation of a monodisperse dispersion of particles, the vertical concentration profile exhibits three regions (Figure 5b): a stationary, concentrated region at the bottom of the container (the "sediment"), a region of intermediate concentration, which still falls toward the sediment layer, and above that, a particle-free region. In a polydisperse mixture, such as carrot juice cloud, these three distinct regions will occur simultaneously for different particle size fractions,[23] as shown schematically for a bidisperse suspension in Figure 5c. The "supernatant" region observable above the sediment layer in Figure 1 therefore comprises a mixture of different particle sizes, in sedimenting layers progressing toward the bottom, stationary layer. The influence of pH on the particle size in the supernatant is, thus, complex, because it results from opposing effects to the rate of particle settling and the size distribution remaining within the sedimenting supernatant regions. At high pH (pH ≥ 5.0), little sedimentation occurred over the 3 days of the experiment, and therefore, average sizes in the supernatant and sediment are the same as for the overall juice (Figure 5a). Under more acidic conditions, sedimentation partially separated the large and small particles, yielding smaller averages in the supernatant and larger averages in the sediment. However, because the sedimentation process was incomplete, the supernatant contained the still settling aggregates created at lower pH, and its average particle diameter is therefore larger than that measured at higher pH.

The process of particle separation described above depends upon not only the particle size but also the strength of the forces exerted on the particles. Thus, we expect differences in the extent of particle separation in juices sedimenting as a result of gravity (Figures 1 and 5a) and juices subjected to centrifugation. After centrifugation for 15 min at 4200*g*, control and acidified carrot juices studied by Reiter et al.[3] formed supernatants that displayed very similar particle size distributions. Large particles with diameters of > ~5 $\mu$m that were present in the intact juices were mainly absent from the supernatant in all cases, leading the authors to conclude that acidification causes only coarse particles to aggregate.[3] However, it is also possible that the centrifugation is effectively removing aggregates and other coarser particle fractions from all of the sample supernatants, regardless of the origins of those aggregates. In our results at lower pH values, we find that supernatants created by sedimentation of commercial carrot juice retained clear evidence of aggregates formed from fine particles.

**Aggregate Formation and Reversibility.** The effects of neutralizing acidified carrot juice back to its initial pH were also examined. Juice was acidified with 2 M citric acid to pH 3.0, causing the average particle size in the total juice to increase from 1.9 $\mu$m at the natural pH of carrot juice (6.2) to 13 $\mu$m at pH 3.0 (Figure 5). This aggregate growth led to almost complete clarification upon centrifugation, with a relative turbidity of 5.2% (data not shown). The juice at pH 3.0 was then neutralized back to pH 6.2 with the addition of 2 M NaOH. At 1 day after neutralization, the average particle size had decreased from 13 to 2.6 $\mu$m and the relative turbidity increased to 14%, although it did not recover fully to the initial value of 39%.

This partial recovery of cloud properties upon neutralization likely indicates that the aggregation of the particles at lower pH is reversible. These results are qualitatively similar to that seen in work performed on the more acidic apple and orange juices. In these systems, adjusting the juices to pH 7 retarded

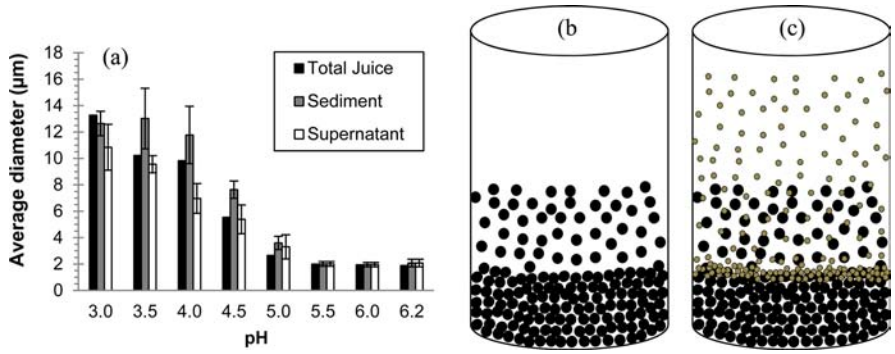

**Figure 5.** Effect of gravitational separation and pH on particle size: (a) $D_{4,3}$ measured in the entire juice (black bar), in the sediment (gray bar), and in the supernatant (white bar) in commercial juice acidified with 2 M citric acid and allowed to separate for 3 days, (b) particle layers in a monodisperse suspension during settling, and (c) particle layers in a bidisperse suspension during settling.

clarification and bringing the pH back down to the natural pH accelerated clarification.[24,25] Ellerbee and Wicker[11] also observed particle association and dissociation in orange juice aggregates at a fixed pH, which suggests formation of weak flocs. Likewise, carrot particles may flocculate at low pH, because of protonation and neutralization of the negatively charged pectin groups at the surface of the particles, which reduces repulsion sufficiently to allow for particles to be trapped together because of an attractive potential well, as discussed previously for orange juice.[24] When base is added and those groups are again deprotonated, the negative charges of the pectin become exposed again and the particles repel one another. This apparently reverses flocculation, decreasing the particle size. In this study, full recovery of the initial particle size may not have occurred because the attractive energy minimum between particles remained sufficiently large compared to thermal energy to allow for complete cluster separation. The protonation/deprotonation equilibrium of acid or base groups may also be altered within the cluster.

The growth in particle size with acidification can be seen more directly by viewing the particles under a light microscope at 20× magnification (Figure 6). A substantial increase in particle size between pH 4.9 and 4.6 was particularly visible. At pH values above 4.6, the aggregates appeared to consist of small rather symmetric clusters, whereas at the lower pH values, the clusters appeared to become more irregular and elongated. In addition, the dispersions at the lowest pH displayed some very large aggregates, approaching 100 $\mu$m in size, consistent with results in panels f–h of Figure 3.

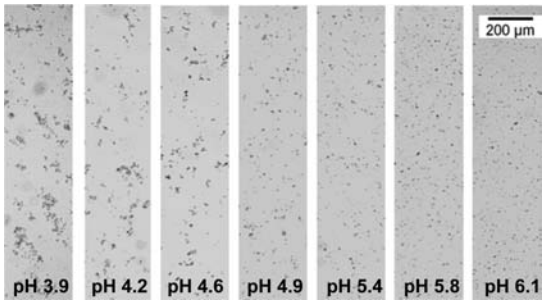

**Figure 6.** Optical micrographs with 20× magnification of carrot juice cloud particles at different pH values created by acidification of the juice.

**ζ Potential.** The $\zeta$ potential decreased in magnitude, from −31 to −15 mV, as pH decreased from 6.1 to 3.9. The average particle size increased over this same range (Figure 4). Below pH 4.6, the particle size increased and the magnitude of the potential decreased more steeply; this change corresponded to conditions where the large particle mode (diameter > 10 $\mu$m) appeared and grew on the size distribution graphs (Figure 3) and in the micrographs (Figure 6). From these results, a clear correlation between $\zeta$ potential and particle size increase is apparent.

Similar trends have been seen previously in apple and orange juices, which are naturally more acidic than carrot juice. Croak and Corredig[4] found that, when they adjusted the pH of orange juice over the range of pH 2.5–6.0, the most negative $\zeta$ potential existed when the pH was 6.0 and its magnitude decreased steeply until it nearly reached 0 mV at pH 2.5. Ellerbee and Wicker[11] also report a more negative $\zeta$ potential for pH 5.5 orange juice compared to that at the natural pH of 4.0. Larger average particle sizes and increased clarification were also observed at the lower pH condition. In apple juice, Benítez et al.[26] measured $\zeta$ potential and turbidity in diafiltered apple juice after allowing 1 h for sedimentation, comparing the control juice (pH 4.5) to those acidified with HCl to lower pH. Turbidity was the greatest, and thus, the cloud was most stable at the highest pH of 4.5, where the $\zeta$ potential was also most negative. The $\zeta$ potential for carrot juice at pH 4 was found to be only slightly more negative (−17 mV) than the value (−19 mV) published for the fruit juices; this difference may reflect the lower DM for carrot pectin.

For all three types of juice, decreasing the pH decreased the magnitude of the negative charge on the particle, and this change likely reduced the energy barrier between the particles. Thus, particle flocculation and cloud instability were enhanced at lower pH in these three types of juice. Interestingly, Mensah-Wilson et al.[7] demonstrated in a very different way the connection between the particle charge and cloud stability, by measuring the effects of adding pectin to pineapple juice and passion fruit nectar. The fruit particles were initially very weakly (positively) charged and would flocculate and separate but became negatively charged and stabilized upon the addition of pectin.

**Acidification and Ionic Strength Effects.** The practice of acidification by the addition of different amounts of strong acid to the juice modifies both the concentration and ionic strength of the juice, in addition to its pH. Modification of pH by the addition of 2 M citric acid required adding no more than 3% by volume of the concentrated acid, and thus, the dilution factor was insignificant. However, concentrations of the citric acid in

the final juice ranged up to 0.062 M at the lowest pH, and this would increase the juice ionic strength by up to ~0.04 M at pH values below 5.5.

These acidified juices can then be compared to those in which buffer salts were added directly to keep the ionic strength uniform between samples. The relative turbidity results from Figure 2, in which citric acid/sodium citrate buffers were used to alter pH, are replotted and compared in Figure 7 to carrot

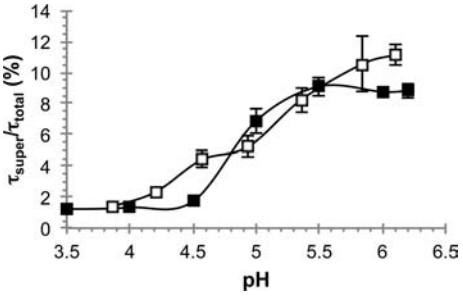

**Figure 7.** Relative turbidity ($\tau_{super}/\tau_{total}$) as a function of pH of commercial carrot juice with (■) 2 M citric acid solution or (□) buffer salts added. Buffer salts contributed 0.1 M to the ionic strength at all pH values.

juice to which 2 M citric acid was added to decrease pH. Juices acidified using citrate buffer salts (prepared at a constant ionic strength of 0.1 M) showed a smoother increase in turbidity over the entire pH range, while the turbidity data of the juice acidified with 2 M citric acid displayed a more sigmoidal shape. The latter juices were slightly less stable at high and low pH than the juices containing buffer salts. This result is somewhat surprising, because the higher ionic strength in the buffer salt-containing mixtures might be expected to promote flocculation by decreasing the Debye length and lowering the energy barrier between particles.[10,13]

To probe this effect further, the extent of clarification of juices was compared when sodium chloride versus calcium chloride was added in specific amounts to unbuffered commercial carrot juice at pH 6.2 (Figure 8). The juices

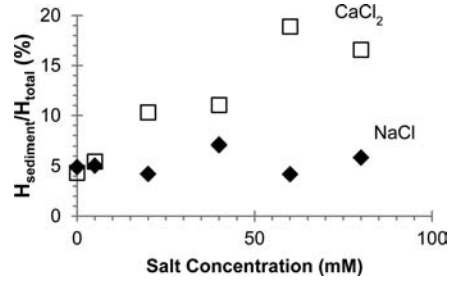

**Figure 8.** Relative sediment height ($H_{sediment}/H_{total}$) in commercial carrot juice (no acidification) after 3 days of storage at 4 °C, with added (□) $CaCl_2$ or (◆) NaCl.

were stored at 4 °C for 6 days, undisturbed, before relative sediment height was measured. The results in Figure 8 indicate that $CaCl_2$ significantly induced clarification, in contrast to NaCl, which had little effect on the cloud stability. Results with the sodium salt are consistent with those in Figure 7 and indicate that any effect of $Na^+$ on the particle diffuse double layer thicknesses does not seem to impact the particle stability.

Benítez et al.[10] explored the effect of the ionic strength on apple juice cloud stability, by first separating apple juice cloud particles from the juice serum and reconstituting them in aqueous solutions containing potassium chloride concentrations between $10^{-4}$ and $10^{-1}$ M. Turbidity and, hence, cloud stability were greatest at the lowest ionic strength, as expected.

A key difference between the results in Figure 8 and those by Benítez et al.[10] is that, in the latter study, the contributions of the native juice serum have been removed. To account for the surprisingly weak effect of ionic strength on our carrot juice cloud results, it is important to recognize that the native carrot juice serum will itself contain ions that contribute to the overall ionic strength. Data from the United States Department of Agriculture (USDA) National Nutrient Database[27] as well as measurements of electrolyte concentrations in other types of juices[28−32] suggest that native ionic strength values of the order of 20−100 mM[10] are likely. At such concentrations, the diffuse double layer is already less than 1−2 nm and further thinning upon addition of further ions may not have a large effect on modifying interparticle repulsion. In addition, with such small Debye lengths, electrostatic repulsion may occur over length scales comparable to short-range forces, such as steric interactions, giving the latter an important contributing role.[33] Benítez et al.[26] found that, even at very low pH values, where the $\zeta$ potential of isolated cloudy apple juice particles was close to zero, particles remained significantly stable because of a short-range repulsion. Ackerley and Wicker[24] also concluded that, at high pH values (pH 7), steric stabilization as a result of a hydrated pectin layer accompanies repulsive forces in preventing aggregation and clarification of orange juice. Thus, despite the high pH and high negative charge in the native carrot juice, such short-range interactions may be playing a significant role in carrot juice cloud stability, relative to the longer range double-layer interactions.

Results in Figure 8 also indicate an important contribution because of specific ion effects. Previous research has demonstrated that the presence of divalent cations increases fruit juice cloud instability, consistent with our results for carrot juice.[11,34−36] Calcium bridging of pectin is an important mechanism in the clarification of orange juice.[37] Such particle destabilization has been attributed to the formation of junction zones, in which divalent cations, such as calcium, induce pectin chain association.[34] Consequently, one explanation for the greater stability of the juices modified with buffer salts (Figure 7), despite their higher ionic strength, is that the higher concentration of sodium ions in the system competes with native calcium for binding to pectin. This would make calcium-induced flocculation less likely in these samples compared to juices acidified with citric acid.

**pH Threshold for Carrot Cloud Instability.** In summary, results from this study demonstrated that acidification of carrot juice caused clarification of the cloud because of particle flocculation. The growth in particle size was attributed to the particle $\zeta$ potential becoming less negative, which reduced the repulsion between particles and allowed them to approach one another and aggregate. Effects on $\zeta$ potential and particle clustering were observed over the entire pH of 3−6; however, the impact on cloud stability became more marked for pH values below 5. At these lower pH values, particle clusters between 10 and 100 $\mu$m developed as a significant portion of the size distribution. As the $\zeta$ potential increases more strongly below pH 5, these larger clusters may be promoted by a reduction in the energy barrier below a threshold value. However, the attractive interactions between particles in the cluster also appear quite weak, because the aggregation process

was at least partially reversible upon returning the juice to neutral pH.

However, salts had a complex effect on cloud stability. Small differences were only seen between juices acidified with buffer salts at a constant ionic strength versus those acidified by the addition of various amounts of concentrated citric acid; surprisingly, the juices at higher ionic strength were slightly more stable. The addition of monovalent sodium chloride to the juice had no clear influence on the stability, whereas the addition of divalent calcium chloride promoted clarification, likely because of its ability to bind to pectin and form bridges between different pectin molecules. Further work is needed to elucidate the types and concentrations of ions present in carrot juice, to understand how these ions influence interparticle interactions. Factors (such as chelators) that reduce the contribution of these ions in the juice as well as factors enhancing the negative charge of the particles could push the threshold pH for cloud stability lower and promote carrot juice stability in the presence of acidification.

removed by decorticating sorghum cultivars prior to food use.[10] Soaking of sorghum grains decreases the content of phenolic compounds only moderately,[11] but the content and composition of phenolic compounds changes substantially during malting and spontaneous fermentation.[12] Hydrolysis of phenolic acid esters and flavonoid glycosides during sorghum fermentation with defined lactic starter cultures has been attributed to cereal enzymes.[4] Strain-specific esterase, glucosidase, phenolic acid decarboxylase, and phenolic acid reductase activities of lactobacilli contribute to the conversion of phenolic compounds in sorghum sourdoughs.[4,13]

Yeast metabolites that are produced during wine maturation, particularly pyruvate, acetoacetic acid, and acetaldehyde, have been shown to react with grape anthocyanins to form a multitude of pyranoanthocyanins.[14] Vinyl derivatives that are produced by enzymatic decarboxylation of hydroxycinnamic acids were also suggested to generate pyranoanthocyanidins.[15,16] Microbial metabolism of caffeic and coumaric acids in sorghum sourdoughs is known to yield vinylcatechol and vinylphenol, respectively;[4,13] however, the effect of these vinylaromatics on the fate of 3-deoxyanthocyanidins during sorghum fermentations has not been elucidated. It was, therefore, the aim of this study to determine the conversion of 3-deoxyanthocyanidins during fermentation of sorghum sourdoughs. Pure cultivar sorghum flour was fermented with defined strains of lactobacilli; 3-deoxyanthocyanidins and their derivatives formed during fermentation were identified with qualitative spectroscopic techniques including mass spectrometry and $^1$H nuclear magnetic resonance (NMR) spectroscopy.

## MATERIALS AND METHODS

**Chemicals and Reagents.** Apigeninidin and luteolinidin were purchased from Extrasynthése (Genay, France). High-performance liquid chromatography (HPLC)-grade acetonitrile, water, and formic acid (95%) were purchased from Fisher Scientific (Ottawa, ON, Canada). Deuterium oxide, methanol-$d_4$, and trifluoroacetic acid (TFA) were obtained from Sigma-Aldrich (Mississauga, ON, Canada). Solid-phase extraction (SPE) cartridges containing either 200 mg or 1 g of $C_{18}$ sorbent were obtained from Waters Corporation (Elstree, U.K.).

**Bacterial Strains and Culture Conditions.** *Lactobacillus plantarum* FUA 3171 and *Lactobacillus casei* FUA 3166 were isolated from ting, a fermented sorghum porridge.[9] Strains were grown on modified MRS (mMRS) agar for 24 h at 34 °C in modified atmosphere (1% $O_2$, 5% $CO_2$, 10% $H_2$, and balance $N_2$) and subcultured in mMRS broth for 24 h at 34 °C. The mMRS broth had the following composition per liter: 5.0 g of fructose, 5.0 g of glucose, 10.0 g of maltose, 10.0 g of tryptone, 5.0 g of beef extract, 5.0 g of yeast extract, 2.6 g of $H_2KPO_4$, 4.0 g of $HK_2PO_4$, 3.0 g of $NH_4Cl$, 0.5 g of L-cysteine HCl, 0.2 g of $MgSO_4$, 0.05 g of $MnSO_4$, 1.0 g of Tween 80, and 1.0 mL of vitamin mix (B12, B1, B2, B6, folic acid, and pantothenic acid). Solid media additionally contained 15 g·L$^{-1}$ agar.

**Fermentation of Sorghum Sourdough.** Pure cultivar *Sorghum bicolor* var. Town, a high-tannin red variety, was obtained from the Food Technology Research Centre, Kanye, Botswana. Grains were ground in an Ultra Centrifugal Mill ZM 200 (Retsch, Burlington, Canada) to a size of 0.5 mm, and the whole-grain flour was stored at −18 °C for less than 4 weeks until use. Starter cultures were prepared by harvesting cells from overnight cultures by centrifugation, washing with peptone saline solution (8.5 g·L$^{-1}$ sodium chloride and 1 g·L$^{-1}$ peptone), and resuspending the cells in an equal volume of sterile tap water. Sorghum sourdoughs were prepared by mixing 10 g of flour with 5 mL of each cell suspension of *L. plantarum* and *L. casei*, or by mixing with 10 mL of cell suspension of individual strains. Sourdoughs were fermented for 48 h at 34 °C. To account for modifications of 3-deoxyanthocyanidins in the absence of microbial activity, chemically acidified sorghum doughs were prepared with 10 g of ground sorghum and 10 mL of sterile tap water, acidified with 0.4 mL of 90% lactic acid and glacial acetic acid in a 4:1 ratio (v/v), and fermented for 48 h at 34 °C. The chemically acidified control had a pH of 3.8, comparable to the pH of sorghum sourdoughs. Fermentations were carried out in duplicate independent experiments. Before and after fermentation, samples were taken for the determination of cell counts and pH as described,[9] as well as for extraction of 3-deoxyanthocyanidins as described later.

**Table 1. Retention Times and Mass Spectra of 3-Deoxyanthocyanidins in Sorghum, Sorghum Sourdoughs, and Chemically Acidified Controls; Compounds That Were Observed Exclusively in Sorghum Sourdoughs but Were Absent in Unfermented Sorghum or Chemically Acidified Controls Are Shown in Bold Font**

[a]Dimeric 3-deoxyanthocyanidin pigments. [b]Tentative identification as pyrano-3-deoxyanthocyanidin based on matching molecular mass.[24] [c]Apigeninidin−flavene dimer has previously been identified.[22]

**Extraction of 3-Deoxyanthocyanidins.** Ground sorghum (10 g), sorghum sourdoughs, or chemically acidified doughs were mixed with 50 mL of 70% (v/v) aqueous methanol for 1 h and then processed with high-intensity ultrasound for 20 min. After filtering, the residues were extracted again as described. Methanol was evaporated under vacuum at 40 °C (Rotavapor RE 21, Büchi, Flawil, Switzerland). Ethyl acetate (40 mL) was added, the organic phase was removed, and the liquid−liquid extraction was repeated. The ethyl acetate phases were combined and evaporated under vacuum at 30 °C. Solids were redissolved in 2 mL of methanol and filtered through a 0.22 μm filter prior to LC-DAD-MS (DAD, diode array detector) analysis. To concentrate 3-deoxyanthocyanidins, the methanol solution (1.5 mL) was diluted with water (9 mL) and loaded on a SPE C18 end-capped cartridge (1 g). The SPE cartridges were eluted with 30%, 45%, and 70% (v/v) aqueous

methanol. The fraction eluting with 70% aqueous methanol was collected and concentrated 10-fold prior to LC-DAD-MS analysis.

**Identification and Relative Quantitation of 3-Deoxyanthocyanidins by LC-MS/MS.** Analytes were separated using a Shimadzu UFLC system consisting of a degasser, binary pump, autosampler, thermostated column compartment, and SPD-M20A Prominence diode array detector (DAD). The LC was connected to a 4000 Q TRAP LC-MS/MS system (MDS SCIEX, Applied Biosystems, Streetville, ON, Canada). Phenolic compounds were separated on a Luna C18 HPLC column (5 $\mu$m, 250 × 4.6 mm, Phenomenex, Torrance, CA) and detected by diode array scanning from 190 to 800 nm; 3-deoxyanthocyanidins were monitored at 480 nm. Mobile phase A consisted of 1% (v/v) formic acid in water, and mobile phase B consisted of 1% (v/v) formic acid in water and acetonitrile (50:50, v/v) of HPLC grade (Fisher Scientific). Samples were eluted with the following gradient: 0−8 min, 10% B; 10−15 min, 10−20% B; 15−22 min, 20% B; 22−30 min, 20−30% B; 30−38 min, 30% B; 38−45 min, 30−40% B; 45−52 min, 40% B; 52−60 min, 40−50% B; 60−62 min, 50% B; 62−67 min, 50−60% B; 67−70 min, 60−65% B; 70−80 min, 65−65% B; 80−90 min, 65−68% B; 90−105 min, 68−100% B; 105−110 min, 100% B; 110−116 min, 100−10% B; 116−120 min, 10% B. The injection volume was 10 $\mu$L, and the flow rate was 0.8 mL·min$^{-1}$ at 35 °C.

Mass spectra were recorded in the positive-ion mode; the values of operating parameters were as follows: spray voltage, 5000 V in positive mode; source temperature, 600 °C; nebulizing gas (GS1), 55 psi; heating gas (GS2), 45 psi; and curtain gas, 15 psi. An information-dependent acquisition (IDA) method using enhanced MS, enhanced product ion, precursor ion scan modes, and MS$^3$ was used to tentatively identify 3-deoxyanthocyanidins. Both Q1 and Q3 were operated at unit mass resolution. The spectra were obtained over a range from $m/z$ 100 to 1000 in 0.8 s. The linear ion trap (LIT) fill time was set at 20 ms. The IDA threshold was set at 500 cps, above which enhanced product ion (EPI) spectra were collected from the three most intense peaks. The EPI scan rate was 4000 amu·s$^{-1}$. Collision-induced dissociation (CID) spectra were acquired using nitrogen as the collision gas under Rolling collision energy (CE) (CE = 0.008 × ($m/z$) + 37.75 for positive-ion mode). The data analysis was performed by Analyst 1.5 (Applied Biosystems).

**Isolation of Novel 3-Deoxyanthocyanidin Adducts from Sourdough.** Sterile tap water (3 L) was added to ground sorghum (3 kg), inoculated with 10 mL of a cell suspension of *L. plantarum*, and fermented for 48 h at 34 °C. After fermentation, doughs were extracted twice by mixing with 3 L of methanol for 1 h and processing with high-intensity ultrasound for 20 min. Extracts were combined and methanol was evaporated under vacuum at 40 °C. Ethyl acetate (3 L) was added to the water phase, and the liquid−liquid extraction was repeated as described. The ethyl acetate phase was combined and evaporated under vacuum at 30 °C. The solids were redissolved in 15 mL of methanol and filtered through a 0.45 $\mu$m nylon syringe filter (Fisher Scientific) prior to preliminary separation by preparative LC.

The resulting crude sample (3 mL) was passed through a PREP LC column (4 $\mu$m, 250 × 21.20 mm, Phenomenex) preequilibrated with 1% (v/v) formic acid in water and acetonitrile (60:40, v/v) of HPLC grade. The PREP LC column was eluted with the same solvent at a flow rate of 15 mL·min$^{-1}$. Fifty fractions (7.5 mL each) were collected. Fractions from 5 runs were combined; fractions containing deoxyanthocyanidins were identified on the basis of their color, and acetonitrile was removed by evaporation. SPE columns (1 g) were used to enrich each peak and to store pure compounds after separation on a Luna C18 RP-HPLC.[17] The separation on the analytical C18 column was repeated if necessary to obtain seven purified compounds. To reduce degradation the purified 3-deoxyanthocyanidin adducts were concentrated by SPE C18 end-capped cartridges (200 mg) for subsequent structure elucidation by $^1$H NMR, offline electrospray ionization−tandem mass spectrometry (ESI-MS/MS), and hydrogen/deuterium (H/D) exchange techniques for offline ESI-MS/MS.

**$^1$H NMR to Identify New 3-Deoxyanthocyanidins.** $^1$H NMR spectra were recorded on a Varian Inova 500 or 600 MHz spectrometer. For $^1$H NMR spectra, $\delta$ values were referenced to the solvent residual peak ($CHD_2OD$, 3.31 ppm). Samples were dissolved in a 1% TFA solution of $CD_3OD$ and analyzed immediately.

**Chemical Synthesis of Apigeninidin.** Apigeninidin was prepared from 2,4,6-triacetoxybenzaldehyde according to a previously published methodology[18,19] with the following modifications: 2,4,6-triacetoxybenzaldehyde (0.223 g) was cooled to 0 °C and a solution of hydrogen chloride in dioxane (4 M, 10.0 mL) and 4-hydroxyacetophenone (0.762 g, 7.00 equiv) was added. The solution was removed from ice and stirred for 1 h at room temperature, at which point dry methanol (7.5 mL) was added. After a further 30 min at room temperature, the solvents were removed under reduced pressure. Diethyl ether (25 mL) was then added to the dry residue to dissolve unreacted 4-hydroxyacetophenone, and the red insoluble fraction was collected by filtration (0.205 g). This solid proved to be a mixture of apigeninidin and aldehyde impurities. Attempts to purify apigeninidin by published methods[18,19] were unsuccessful. Instead, 110 mg of the crude apigeninidin chloride was divided into 25 mg segments, dissolved in 5 mL of 1:1 methanol/water, and purified via preparative HPLC on a Phenomenex Luna 5 $\mu$m C18(2) column with a gradient of 0.1% TFA in water (A) and 0.1% TFA in acetonitrile (B) as follows: 0 min, 5% B; 5 min, 5% B; 40 min, 24% B; 60 min, 40% B; 70 min, 64% B; 72 min, 95% B; followed by reequilibration to 5% B. Apigeninidin eluted as a single peak at 51.3 min, with strong absorbance at 254 and 480 nm. Fractions containing apigeninidin were pooled, partially concentrated under reduced pressure to remove acetonitrile, and stored wet on a Phenomenex Strata C18-E solid-phase extraction column (Phenomenex, U.S.A.) at 4 °C (1 mM HCl as the final wash). Elution with methanol provided pure apigeninidin triflate (0.0333 g, 21%). The NMR spectra and MS data were consistent with the structure and literature values.[20] Once it was purified via HPLC we found that concentration of apigeninidin chloride or triflate in the absence of C18 silica led to rapid degradation, as evidenced by a sharp decrease in methanol and water solubility. Storage in acidic methanol also led to degradation over time; apigeninidin and the apigeninidin adducts were thus stored on wet Phenomenex Strata C18-E columns at 4 °C.[17]

**Small-Scale Apigeninidin Adduct Synthesis.** To a solution of apigeninidin in methanol (0.50 mL at 1.0 mg/mL, 1.8 $\mu$mol) was added 1 mM hydrochloric acid (2 mL) and either a 10% solution of 4-vinylphenol in propylene glycol (5.10 $\mu$L, 3.25 equiv) or 4-coumaric acid (*p*-coumaric acid) (2.45 mg, 11.0 equiv). The solution was stirred for 24 h and then purified via HPLC on a Phenomenex Luna 5 $\mu$m C18(2) column as described above for the synthesis of apigeninidin. Samples were eluted at a flow of 1.0 mL min$^{-1}$. A third reaction lacking both 4-vinylphenol and 4-coumaric acid was used as a negative control, to account for the slow degradation of apigeninidin under these conditions.

**Large-Scale Synthesis of Apigeninidin Adducts.** To a solution of synthetic apigeninidin chloride (0.0323 g, 0.115 mmol) in 1 mM hydrogen chloride (30 mL, not degassed) was added a 10% solution of 4-vinylphenol in propylene glycol (0.430 mL, 3.25 equiv). After stirring in the dark for 24 h, the mixture was passed through a Phenomenex Strata C18-E column (MeOH elution) to remove excess water. This methanol/water mixture (1:1, 20 mL) was then purified via preparative HPLC on a Phenomenex Luna 5 $\mu$m C18(2) column as described above. Numerous new peaks with absorbances at 254 or 480 nm were detected. Those with strong absorbances at 480 nm were investigated further, and the structures of compounds **8** and **13** were determined via $^1$H NMR (Table 1).

**Offline ESI-MS/MS and Hydrogen/Deuterium Exchange Analysis of Novel Deoxyanthocyanidins.** Five $\mu$L of each purified compound was added into 1 mL of methanol/$H_2O$ (60:40, v/v) and directly injected into a Thermo LTQ-Orbitrap high-resolution mass spectrometer at a flow rate of 15 $\mu$L min$^{-1}$. The hydrogen/deuterium exchange (H/DX) reactions were initiated by diluting 5 $\mu$L of enriched solutions of each novel deoxyanthocyanidin into 1 mL of methanol-$d_4$/$D_2O$ (60:40, v/v). The MS experiments included full scan and MS/MS fragmentation in positive-ion mode to determine elemental compositions of ion formula and fragmentation pathways for the new 3-deoxyanthocyanidins and corresponding deuterated 3-deoxyanthocyanidins. Meanwhile, enhanced product ion (EPI) scan by AB Q-TRAP 4000 was also carried out to investigate the fragmentation pathways of

novel compounds via direct injection method, using a Harvard Apparatus syringe pump at a flow rate of 15 $\mu$L min$^{-1}$.

## RESULTS

**Conversion of 3-Deoxyanthocyanidins in Sorghum Sourdoughs.** Sorghum sourdoughs were fermented with a binary strain combination of ting isolates as previously described.[4] During fermentation of sorghum sourdoughs with *L. plantarum* and *L. casei*, the pH decreased from 6.1 to 3.7 and the cell count increased from $(5.8 \pm 0.6) \times 10^7$ to $(2.5 \pm 0.3) \times 10^8$ cfug$^{-1}$ after 48 h of fermentation. Cell counts of chemically acidified doughs remained below $10^5$ cfu g$^{-1}$ throughout fermentation. The separation of phenolic acids and flavonoids confirmed changes previously reported by Svensson et al.[4] by using the same strain combination but a different sorghum cultivar (data not shown). Separation of 3-deoxyanthocyanidins was achieved by LC-DAD-MS. Sourdough samples were additionally analyzed after concentration of 3-deoxyanthocyanidins by solid-phase microextraction and elution with 70% methanol. Retention times and mass spectra of 3-deoxyanthocyanidins detected in unfermented and fermented sorghum sourdoughs in positive-ion mode are listed in Table 1.

Compounds **1** and **2** were identified as luteolinidin and apigeninidin by comparison of retention times and mass spectra with external standards. Compounds **3**, **4**, and **5** were identified as methoxyluteolinidin and methoxyapigeninidins according to their molecular weights and fragmentation patterns.[21] Compounds **7**, **9**, **11**, **12**, **16**, **17**, **18**, **19**, **21**, and **22** were identified as various anthocyanidin dimers, according to their molecular weights.[22,23] The remaining compounds, **6**, **8**, **10**, **13**, **14**, **15**, and **20**, could not be identified with external standards or published mass spectra, although the molecular mass of compound **13** matched the mass of pyrano-3-apigeninidin 4-vinylphenol.[24] Deoxyanthocyanidin adducts were identified exclusively in sorghum sourdoughs. The relative quantitation of deoxyanthocyanidins in sorghum sourdoughs based on the peak height at 480 nm revealed that the pattern of deoxyanthocyanidins remained essentially unchanged in chemically acidified dough. During lactic fermentation, concentration of monomeric deoxyanthocyaninidins decreased and the relative abundance of adducts **6**, **8**, **10**, **13**, **14**, **15**, and **20** increased. To confirm that the formation of deoxyanthocyanidin adducts is dependent on microbial metabolism, sorghum sourdoughs were fermented with single strains of *L. plantarum* and *L. casei*. Adduct formation was detected in sorghum sourdoughs fermented with *L. plantarum* but not in sorghum sourdoughs fermented with *L. casei*. While both strains produce lactate as the main product of carbohydrate metabolism, only *L. plantarum* metabolizes phenolic acids. *L. plantarum* FUA3171 decarboxylates caffeic and coumaric acids to vinylphenols; ferulic acid is converted to dihydroferulic acid.[4] The formation of deoxyanthocyanidin derivatives thus corresponds to the formation of vinylcatechol and vinylphenol from caffeic and coumaric acids, respectively.

[a]Deuterated compound **6**.

**Structure Elucidation of Novel Deoxyanthocyanidins.** Compounds **6**, **8**, **10**, **13**, **14**, **15**, and **20** were purified from sorghum sourdoughs. The elemental compositions of the 3-deoxyanthocyanidin derivatives and the corresponding deuterated compounds were determined by offline LTQ-Orbitrap mass spectrometry (Table 2).[25] Compounds **8** and **13** were purified in sufficient quantities to allow structure elucidation by $^1$H NMR (Table 3), although they proved unstable at room temperature and were not of sufficient concentration for heteronuclear single quantum coherence (HSQC), heteronuclear multiple-bond correlation (HMBC), or $^{13}$C analysis in the limited time window. While compound **8** displayed most of the peaks found in apigeninidin, the doublets at 6.66 and 6.95 ppm were absent. Instead a singlet was found at 7.01 ppm, suggesting substitution at C6.[20] Para-substituted phenols are excellent electrophiles, and both flavonoids and anthocyanins are known to undergo electrophilic aromatic substitution, although substitution is more common at C8 than at C6.[26] Peak assignments and the proposed structure of this vinylphenol/apigeninidin adduct are shown in Table 3.

The $^1$H spectra of compound **13** matched that of a symmetric pyrano-3-deoxyanthocyanidin that has been previously reported in sorghum extracts, although its biosynthesis was not determined.[24] The structure and peak assignments of compound **13** are also shown in Table 3. Under IUPAC naming conventions, compound **8** is 6-(1-(4-hydroxyphenyl)ethyl)-apigeninidin chloride and compound **13** is 8-hydroxy-2(4′-hydroxyphenyl)-5(4″-hydroxyphenyl)pyrano[4,3,2-*de*]1-benzopyrylium chloride.

Compounds **8** and **13**, as well as the other new deoxyanthocyanidins, were found only in sorghum sourdough fermented caffeic acid decarboxylase positive lactobacilli.[4] To confirm the role of vinyl derivatives of hydroxycinnamic acids as reactants in the formation of apigeninidin adducts, synthetic apigeninidin[18] was treated with 4-vinylphenol or 4-coumaric acid according to the procedure of Fulcrand et al.[27] While no reaction was observed between 4-coumaric acid and apigeninidin under these conditions, HPLC analysis of the 4-vinylphenol reaction revealed numerous new peaks with absorbance at 480 nm. The previously reported pyranoapigeninidin 4-vinylphenol[24] was a main component in a number of these peaks, often coeluting with compounds that had exact masses of 373.1067 and 375.1224. At least two different compounds with the latter mass were found, and $^1$H NMR analysis determined one was compound **8**, previously isolated during analysis of the fermentation samples (vide supra).

**MS Fragmentation Pathways of Deoxyanthocyanidin Adducts.** With the structure of compound **13** known and the structure of compound 8 tentatively assigned, we were able to identify the remaining unknown compounds (**6**, **10**, **14**, **15**, and

[a]Due to an imperfection in the cold probe used to collect several spectra, a deformation in signal is observed around high-intensity solvent peaks. This proved impossible to fully correct, although a minor baseline correction has been applied. [b]–, quarternary C atom; n.a., not applicable.

**20**) by comparing mass spectrometry fragmentation and isotope exchange patterns. In deuterated methanol/water, compound **8** gave a *m*/*z* of 379.1476, which corresponds to a molecular formula of $C_{23}H_{15}D_4O_5^+$ and the replacement of four protons with deuterium. Peaks at *m*/*z* 378.1413, *m*/*z* 377.1350, and *m*/*z* 376.1287 were also observed, suggesting ready back-exchange of the deuterated protons with water clusters during the ionization process.[28] This facile exchange suggests the presence of four hydroxyl groups, one more than apigeninidin. Supporting this conclusion was the fragmentation of compound **8** in protic media to a *m*/*z* of 281.0805, which corresponds to a molecular formula of $C_{17}H_{13}O_4^+$ and loss of phenol. This mass is ∼26 Da greater than that for apigeninidin, suggesting expulsion of phenol results in an alkene on the apigeninidin core (Figure 2a). One potential fragmentation pathway is transfer of a proton from a neighboring phenol via a six-membered ring transition state;[29] the other fragmentation pathway involves transfer of the hydrogen atom in the methyl group to the phenol group via a four-membered ring transition state.[30]

Similar to compound **8**, in deuterated media compound **6** displayed an increase in mass corresponding to proton-to-deuterium exchange. However, compound **6** gave a *m*/*z* of 396.1487, corresponding to a molecular formula of $C_{23}H_{14}D_5O_6^+$ (Table 2, Figure 2b). Fragmentation of compound **6** gave the same ions as in compound **8**, suggesting that the two share an apigeninidin core and that the difference in mass/deuterium substitution is a result of a different phenolic adducts. Compound **8** is formed from condensation of apigeninidin and 4-vinylphenol, the product of decarboxylation of coumaric acid. Both coumaric and caffeic acids are abundant in sorghum and both are decarboxylated by *L. plantarum* FUA3171, suggesting that compound **6** is the product of condensation between apigenindin and vinylcatechol.[4] The tentative structure of compound **6** is shown in Figure 3, and the fragmentation pathways of deuterated compound **6** are shown in Figure 2b.

Fragments generated with Q-TRAP 4000 were used to explain the structures of the symmetric pyrano-3-deoxyanthocyanidins, typified by compound **13**.[31] The conjugate $\pi$ system ordinarily provides a challenge for the structure elucidation of pyrano-3-deoxyanthocyanidins by MS/MS experimentation,[32] but by using pyranoapigeninidin 4-vinylphenol (compound **13**) as a reference, the structures of the remaining pyrano-3-deoxyanthocyanidins can be deduced. As in compounds **6** and **8**, comparison between mass spectra in deuterated and protic media was used to determine the number of phenolic hydrogens in compounds **10**, **14**, **15**, and **20** (Figure 3 and Table 4).

thus odd-electron radical cations.[31] The fragments of such homolytic cleavage of flavonoids should have stable aromatic structures;[33] the presence of two D atoms in the corresponding deuterated ions indicates the presence of two phenolic hydroxyl groups. Other fragments were even-electron cations.

In the low-mass region, the product ions of compounds **10**, **14**, **15**, and **20** are almost the same as those observed by fragmentation of pyranoapigeninidin 4-vinylphenol, including peaks at *m/z* 226, 202, 165, and 121. This suggests that all five compounds share a common pyrano-3-deoxyanthocyanidin core, with variation confined to the attached aromatic rings.

dx.doi.org/10.1021/jf503330b | J. Agric. Food Chem. 2014, 62, 11536−11546

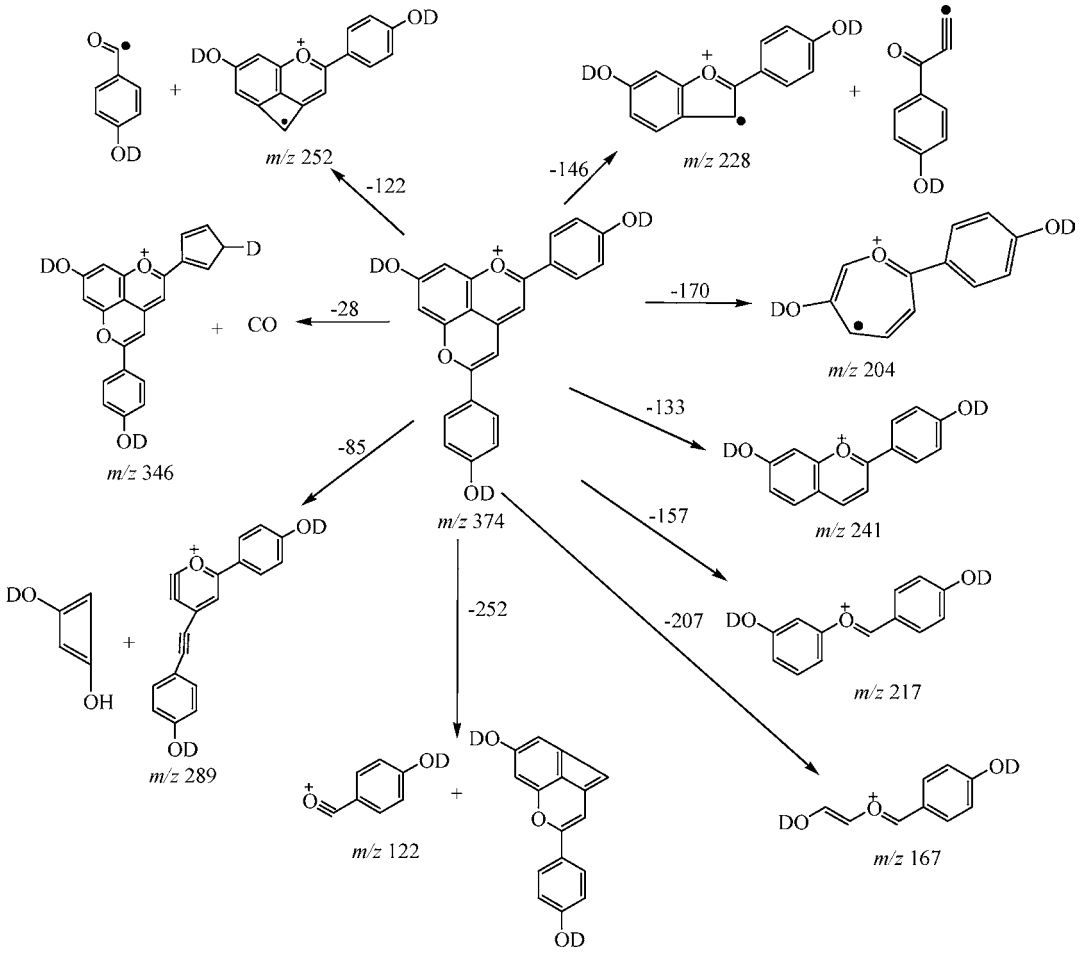

**Figure 4.** Proposed fragmentation pathways of deuterated compound **13**.

For compound **10**, the deuterated ion at *m*/*z* 343 was generated by the loss of $D_2O$ and CO, suggesting that compound **10** contains two adjacent phenolic hydroxyls (Figure 3b). Compounds **14**, **15**, and **20** all had peaks corresponding to the loss of $CH_3^{\bullet}$ and $COCH_3^{\bullet}$ radicals, which likely indicates the presence of OMe moieties.[34] Compounds **14** and **15** have the same molecular ion, suggesting that they are constitutional isomers. To determine the different connectivities, we ran multifragmentation experiments on an Orbitrap mass spectrometer. While both compounds gave precursor ions at *m*/*z* 358, significant differences in the $MS^4$ spectra were observed. Compound **14** largely yielded a single peak at *m*/*z* 329, corresponding to expulsion of COH•. In contrast, compound **15** appears to first lose H• to generate an ion at *m*/*z* 357 and then further degrade to a number of fragment ions.[33] The single peak in compound **14** indicates that loss of COH• is unusually facile, suggesting that there is a hydroxyl moiety adjacent to the OMe (Figure 5). As the core structure of the pyranoanthocyanidin was found in both compounds **14** and **15**, this suggests that one of the attached aromatic rings contains the pattern of interest. In contrast, compound **15** does not appear to be able to rapidly expel COH•, and thus the OMe group is not adjacent to a free hydroxyl. The two most likely structures for these compounds are shown in Figure 5. Compound **14** is formed analogous to pyranoapigeninidin 4-vinylphenol by condensation of apigeninidin and the decarboxylative product of caffeic acid, whereas compound **15** is likely a product of 7-methoxyapigeninidin and ferulic acid. Compound **20** can be identified analogously to compound **15** and is believed to be a product of 4-vinylphenol and 7-methoxyapigenidin (Figure 3e).

## DISCUSSION

Pyranoanthocyanidins are derivatives of anthocyanins that are generated during food processing. They have been previously identified in wine as well as juice from berries, blood orange, and black carrots.[14,35−37] This study tentatively identified four novel pyrano-3-deoxyanthocyanidins by MS/MS experimentation and comparison to a chemically synthesized reference compound, and it confirmed the presence of novel 3-deoxyanthocyanidin adducts with vinylphenol (Table 3 and Figure 3). Fragmentation pathways of pyranodeoxyanthocyanidins were elucidated by using the hydrogen/deuterium exchange technique in mass spectrometry.

A symmetric pyrano-3-deoxyanthocyanidin was previously identified in sorghum, but the pathways leading to its formation remained unknown.[24] Yeast metabolism contributes to the formation of pyranoanthocyanidins in wine maturation;[14,15] however, the formation of pyranoanthocyanidins in wine and unfermented juices was predominantly attributed to a reaction of hydroxycinnamic acids and anthocyanidins.[36−38] The use of defined decarboxylase-positive or -negative lactobacilli indicates that the formation of pyrano-3-deoxyanthocyanidins in fermented sorghum depends on bacterial decarboxylation of hydroxycinnamic acids. This hypothesis was confirmed by chemical synthesis of 3-deoxyanthocyanidin derivatives with

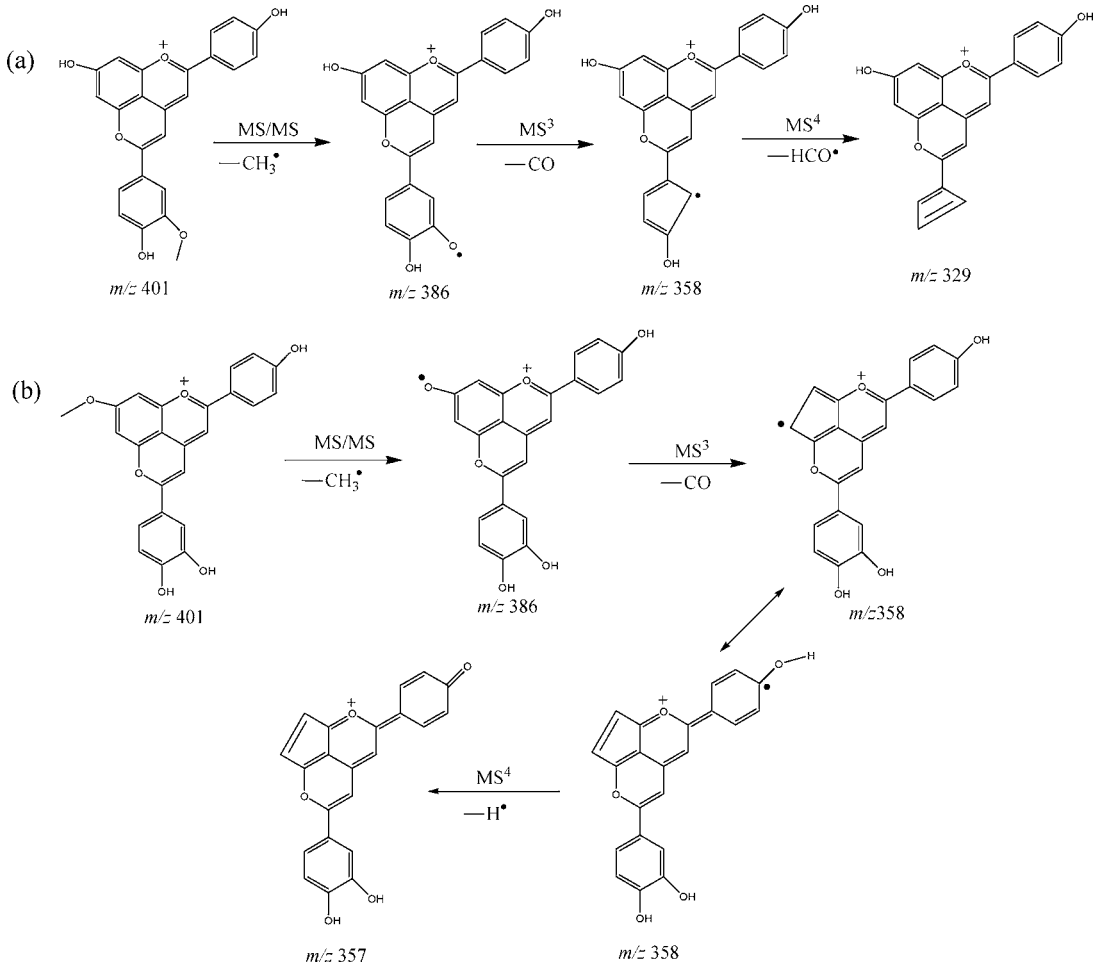

**Figure 5.** Fragmentation pathway of the isomer: (a) compound **14** and (b) compound **15**.

vinylphenol as a reactant; the use of 4-coumaric acid as reactant did not yield comparable adducts (Figure 6).

The novel pyrano-3-deoxyanthocyanidins found (Table 3 and Figure 3) are created via reaction of the most abundant 3-deoxyanthocyanidins in sorghum,[3,5] apigeninidin, and methoxyapigeninidin, with the decarboxylation products of the most abundant hydroxycinnamic acids, vinylphenol (coumaric acid), vinylcatechol (caffeic acid), and vinylguaiacol (ferulic acid) (Figure 6).[3,4,10] In contrast to previous reports,[24] pyrano-3-deoxyanthocyanidins were not identified in unfermented sorghum. We employed pure cultivar sorghum grains that were milled just prior to fermentation, thus minimizing the potential of chemical, microbial, or enzymatic conversions prior to extraction.

In addition to pyrano-3-deoxyanthocyanidins, we identified a second class of compounds, 3-deoxyanthocyanidin−vinylphenol adducts, which are also formed by reaction of 3-deoxyanthocyanidins with vinylphenols (Figure 6). Our study does not provide quantitative data on adduct formation; unfortunately, the compounds were isolated in minute quantity and were unstable in the liquid phase. Both derivatives are formed from the same reactants, 3-deoxyanthocyanidins and vinylphenols, suggesting that the formation of pyrano-3-deoxyanthocyanidins is favored at the conditions of sorghum sourdough fermentation. The identification of 3-deoxyanthocyanidin adducts linked at the C6 position may be attributable to a different reactivity of 3-deoxyanthocyanidins when compared to anthocyanidins or may simply relate to the higher concentration of reactants in sorghum sourdough when compared to wine or fruit juices. Of note, over several hours of storage in deuterated methanol we observed that the proton at C6 in apigeninidin was replaced with deuterium, via corresponding loss of signal at 6.66 ppm. The proton at C8 was unaffected under these conditions, suggesting that the C6 position is the more nucleophilic of the two.

The formation of pyranoanthocyanidins corresponds to color changes during aging of wine and may serve as an indicator of aging.[14,39] Pyranoanthocyanidins are also of interest as food colorants with increased stability, as well as because of their antioxidant properties.[39,40] The elucidation of microbial and chemical pathways leading to conversion of 3-deoxyanthocyanidins in sorghum fermentations is a major milestone toward an improved understanding of sorghum processing and fermentation on nutritional and sensory properties of the resulting cereal products. Results enable further studies to elucidate chemical and biological properties of novel pyrano-3-deoxyanthocyanidins and 3-deoxyanthocyanidin adducts and thus may aid to improve food quality, food security, and health benefits, particularly anticancer activities[7,21] of foods containing bioactive phenolic compounds.[8]

were extracted by shaking the leaf powder in a solution containing 50% (v/v) phenol, 0.45 M sucrose, 5 mM EDTA, 0.2% (v/v) 2-mercaptoethanol, and 50 mM Tris-HCl, pH 8.8 for 30 min at 4 °C. After centrifugation at 5000*g* at 4 °C for 10 min, the phenol phase was transferred to clean tube and proteins were precipitated by adding 5 volumes of ice-cold 0.1 M ammonium bicarbonate (ABC) in methanol followed by overnight incubation at −20 °C. After centrifugation at 5000*g* for 10 min at 4 °C, protein pellets were washed twice with ice-cold 0.1 M ammonium acetate in methanol, twice with ice-cold 80% acetone, and once in ice-cold 70% ethanol.

**Two-Dimensional (2D) Gel Electrophoresis and "In-Gel" Digestion.** Proteins were dissolved in rehydration sample buffer (8 M urea, 2 M thiourea, 2% (w/v) CHAPS, 2% (w/v) Triton X-100, 50 mM DTT, 0.5% ampholytes pH 3−10), and protein concentrations were determined according to Bradford.[23] Then, 50 μg of proteins were analyzed by 2-dimensional electrophoresis (2DE) using 7 cm immobilized pH gradient (IPG) strips with pH range 5−8, as described earlier.[24] Briefly, isoelectric focusing (IEF) was performed using a Protean IEF Cell (Bio-Rad) programmed for active rehydration for 12 h at 50 V followed by 150 V for 150 VH, 500 V for 500 VH, and 4000 V for 15000 VH. After IEF, the IPG strips were equilibrated in 6 M urea containing 30% (v/v) glycerol, 70 mM SDS, and 0.006% (w/v) bromphenol blue) for 15 min in equilibration solution with 1% (w/v) DTT, and then for an additional 15 min in equilibration solution containing 2.5% (w/v) iodoacetamide. Equilibrated IPG strips were placed on top of 10% SDS gels, and electrophoretic separation was performed at 10 mA per gel. Finally, triplicate gels were stained with colloidal Coomassie blue, the images digitalized (GS-800, Bio-Rad, Hercules, CA) at 300 dpi/16 bit grayscale and quantified using PDQuest 8.0 software (Figure 1 of the Supporting Information).

Protein spots present in at least two of the triplicate gels were excised, destained in wash solution [50% acetonitrile (ACN), 50 mM ABC], and dehydrated in 100% ACN. The dehydrated gel plugs were rehydrated in 50 mM ABC containing modified sequencing grade trypsin (Promega) and digested at 37 °C overnight. Tryptic peptides were extracted with 60% ACN containing 1% formic acid (FA). Solutions were reduced to dryness using a Concentrator plus (Eppendorf, Germany). The tryptic peptides were dissolved in 2% ACN containing 0.1% FA and stored at −80 °C until used.

**Protein Identification by Liquid Chromatography-Tandem Mass Spectrometry.** In total, 5 μL of tryptic peptides were separated using a nanoAcquity UPLC system (Waters). Samples were injected onto a Symmetry C18 trap column (20 mm length, 180 μm diameter, and 5 μm particle size). After 3 min of desalting/concentration with 3% ACN containing 0.1% FA at a flow rate 10 μL $min^{-1}$, peptides were separated on an analytical BEH130 C18 column (150 mm length, 75 μm diameter, and 1.7 μm particle size). For quick profiling, a 15 min gradient of 6−40% ACN containing 0.1% FA at a flow rate of 350 nl $min^{-1}$ was applied. The column outlet was connected to a precut noncoated PicoTip emitter (360 μm outer diameter, 20 μm inner diameter, 10 μm tip diameter; New Objective), mounted into the nanospray source of a Q-TOF Premier tandem mass spectrometer (Waters). The instrument was controlled by MassLynx software v. 4.1 (Waters). Basic settings were source temperature, 70 °C; nanospray voltage, 3.4 kV; nebulizer gas pressure, 0.4 bar; and collision gas flow, 0.48 mL $min^{-1}$. Data were acquired using the $MS^E$ method, which performed alternate scans at low and high collision energies. The quadrupole analyzer was operated in the radio frequency mode, allowing all ions to reach the TOF analyzer, so that in a single full-scan run, both precursor ions and accurate fragment masses were detected. In the MS channel, data were collected at a constant collision energy of 4 eV, while in tandem (MS/MS), channel fragments were recorded while the collision energy was ramped up from 20 to 35 eV. Spectra acquisition scan rate was 0.8 s, with a 0.05 s interscan delay; ions with 100−1900 m $z^{-1}$ were detected in both channels. The quadrupole mass profile settings allowed efficient deflection of masses of less than 400 in the low-energy mode, enabling filtering of contaminating ions.

**Analysis of the MS/MS Data.** Peak smoothing was performed, including background-subtraction, centroiding, and deisotoping. Noise filtering thresholds where set at intensity, 1200; low energy, 150; high energy, 20 counts. All data were lock-spray calibrated against Glu-Fibrinopeptide B, using data collected from the reference line during acquisition (500 fmol $\mu L^{-1}$ in 25% ACN with 0.1% FA, flow rate 350 nl $min^{-1}$, scans every 30 s). The lockmass-corrected data were deconvoluted to produce a single accurate monoisotopic mass for each peptide and associated fragment ions. Differently charged precursors were summed. The initial correlation of precursor and fragment ions was achieved by means of time alignment.

The MS/MS data were processed by the ProteinLynx Global Server (PLGS) v. 2.4 (Waters) against an in-house database consisting of sequences downloaded from UniProt during July 2013. In total, 742 Ginkgo species entries, 856836 Spermatophyta UniRef90 databank entries (taxonomy filter *Spermatophyta* and 90% sequence redundancy grouping), and 1573198 *Viridiplantae* entries were included. The databank was randomized to allow efficient correction for false-positive matches. The search parameters used were fixed modification, carbamidomethyl-Cys; variable modification, oxidized Met; one missed cleavage site; at least seven fragment ions per protein; and an automatic error tolerance value. Protein identifications were accepted after manual inspection of probabilistic PLGS assignment at the 95% confidence level. Additional parameters to accept protein identification required at least two peptides matched to the protein sequence, a minimum of three fragment ions per peptide, a 50 ppm tolerance of database-generated theoretical peptide ion masses, and a PLGS score greater than 50. The PLGS score is a statistical measure of accuracy of assignation and was calculated using a Monte Carlo algorithm. A higher score indicates a greater confidence in the assigned protein identity.

## RESULTS

Two-DE combined with MS/MS was used for analysis of the abundant gingko leaf proteins (Figure 1). Using this approach, we reliably quantified 190 abundant 2-DE spots (Table 1 of the Supporting Information), of which 157 were identified by MS/MS (Table 1). These data were used to establish the initial ginkgo leaf proteome reference map (Figure 2). As expected, the most abundant 2-DE spots were identified as ribulose-1,5-bisphosphate carboxylase/oxygenase (RuBisCO) subunits

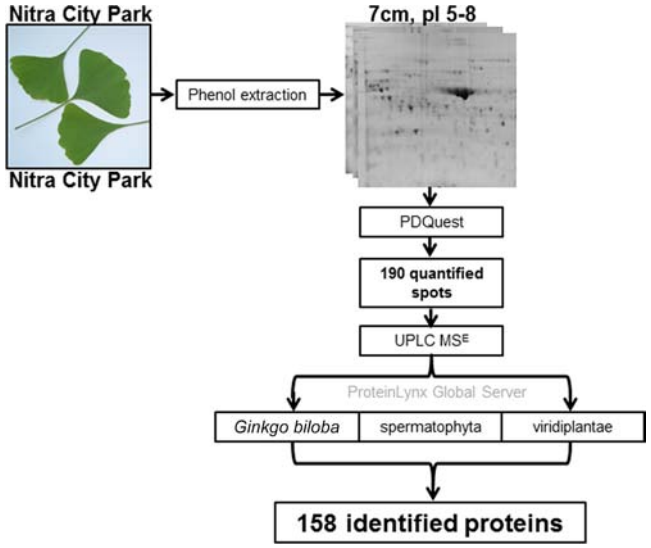

**Figure 1.** Experimental workflow. Proteins were isolated from ginkgo leaves using a phenol-based extraction method and separated by 2D electrophoresis. Protein spots were quantified using the PDQuest software. Excised spots were digested with trypsin, separated by nanoAcquity UPLC and analyzed by MS/MS in the $MS^E$ mode. Proteins were identified using ProteinLynx Global Server.

[a]The table includes 2-DE spot number, UniProt accession number; description/name, observed MW (kDa)/p*I*, deduced MW (kDa)/p*I*, PLGS (Protein Lynx Global Server) score, number of peptides matched to protein sequence, and relative volume of 2-DE spot ± SD (%V ± STDEV) of biological triplicate analyses (Table 1 of the Supporting Information).

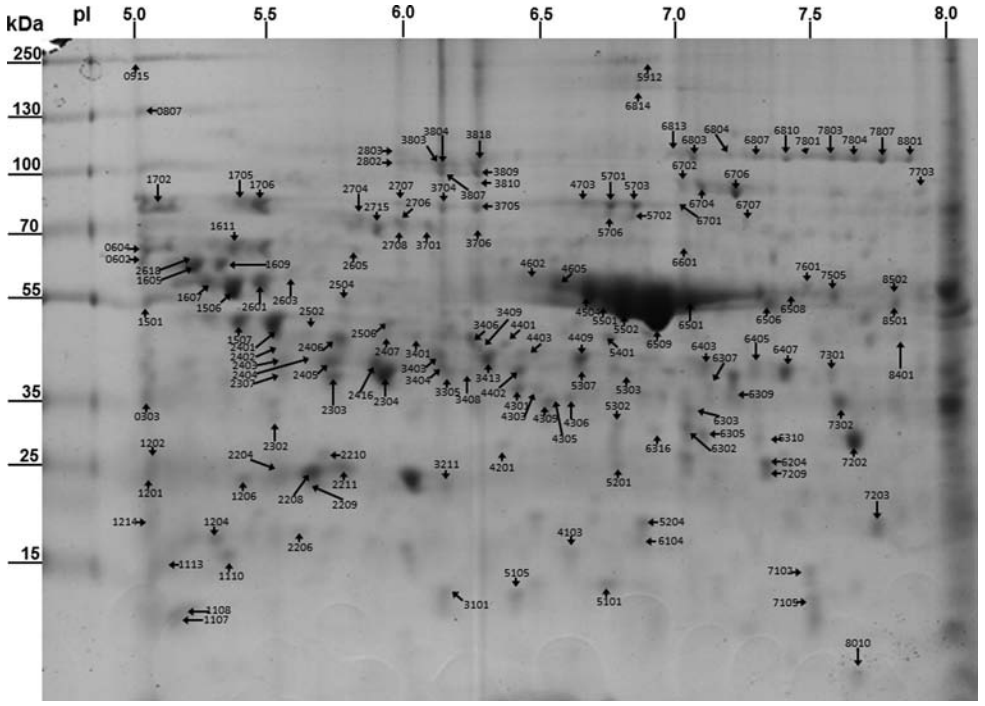

**Figure 2.** Map positions of 157 proteins extracted from *Ginkgo biloba* L. leaves. This quantitative reference map was established using 7 cm IPG strips (p*I* 5−8), PDQuest software (version 8.0), and Q-TOF Premier mass spectrometer.

(spots 5502, 6509, 4504, 6501, and 5501). The next most abundant proteins were ATP synthase (spot 1506), RuBisCO activase (spot 2304), and the class III homeodomain leucine-zipper protein C3HDZ3 (spot 2401) (Figure 2). The 2-DE spots with the lowest abundance values that contained an identifiable protein were spot 2708 (ginancin), followed by spot 8401 (alanine aminotransferase), spot 5105 (superoxide dismutase), and spot 6307 (protein similar to glycerate dehydrogenase/hyrdoxypyruvate reductase.

**Most of the Identified Ginkgo Leaf Proteins Were Assigned to the Energy Group.** Identified proteins presented on the reference map were assigned to one of 10 functional groups (Figure 3) according to Bevan et al.[25] Only one primary function was assigned per protein. Most of the identified proteins were associated with the energy group (61). Within this group, 24 2-DE spots were identified as subunits of RuBisCO. In total, 10 2-DE spots were identified as ATP synthase subunits (Table 1), 4 spots were identified as fructosebisphosphate aldolase, and another 4 as phosphoglycerate-kinase.

The second most populated category is proteins associated with destination/storage.[31] Within this group, 14 2-DE spots were identified as ginnacin, the 11S ginkgo seed storage protein.[26] Four 2-DE spots were identified as subunits of the ATP-dependent Clp protease (Table 1). A total of 16 proteins associated with disease/defense comprise the third largest functional group (Table 1). Five 2-DE spots contained proteins associated with abscisic acid stress and ripening (ASR).[27] The fourth largest functional group was proteins of unknown function (PUF).[15]

The relative volumes of all proteins within a particular functional class were summed in order to determine the most abundant functional group (Figure 2 of the Supporting Information. Proteins associated with energy contributed more than 70% to total protein abundance, followed by those associated with destination/storage, and disease/defense. The

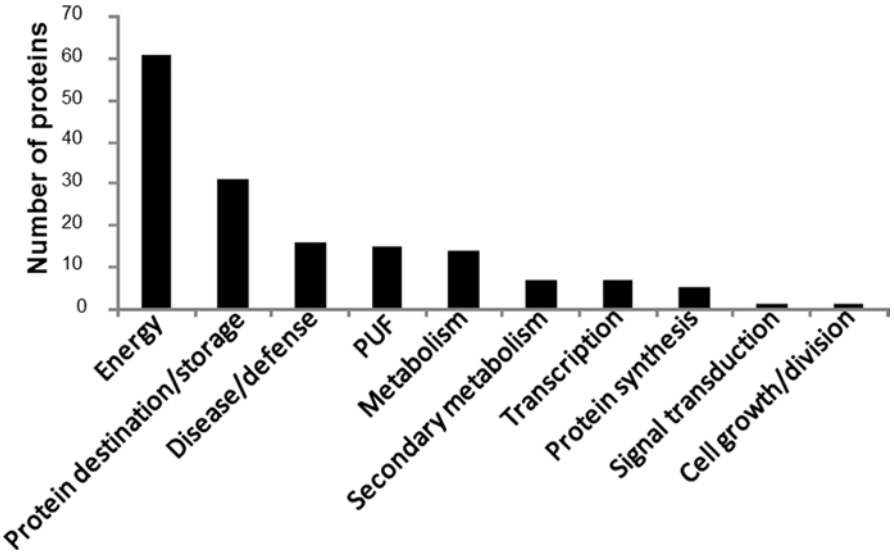

**Figure 3.** Functional classification of 157 proteins identified from *Ginkgo biloba* L. leaves, based upon the method of Bevan et al.[25]

fourth most abundant functional group was proteins associated with transcription, followed by PUF (Figure 2 of the Supporting Information).

**Abundant Protein of Unknown Function Is Similar to Nucleolar Protein 58 of the King Cobra.** We detected 14 proteins of unknown function (PUF). These proteins were subjected to BLASTP searches in order to reveal similarity with known proteins (Table 2 of the Supporting Information). The most abundant protein in this group was Os01g0217100 (spots 1201, 3403, and 7301) with UniProt accession number Q5QNF4 (Table 1). The NCBI Blast search revealed that the amino acid sequence of this unknown protein is 53% similar to the amino acid sequence of a purine permease from Foxtail millet (*Setaria italica*) (Table 2 of the Supporting Information). Unexpectedly, the second most abundant PUF was a putative uncharacterized protein (G7KFS4, spot 1501) that has the closest similarity (56%) to nucleolar protein 58 from the king cobra (*Ophiophagus hannah*) (Table 2 of the Supporting Information). Third most abundant PUF was the uncharacterized protein with UniProt accession M0TUE2 (Table 1). A BLAST search failed to reveal similarity to any known protein (Table 2 of the Supporting Information).

## DISCUSSION

The aim of this study was to use 2-DE based proteomics approach to establish a reference map of most abundant ginkgo leaf proteins. The application of a proteomics strategy for the characterization of medicinal plants is not new (e.g., studies of *Catharanthus roseus*,[28] *Pinellia ternata*,[29] *Podophyllum hexandrum*,[30] and Indian ginseng[31]). The previous analyses yielded meaningful results, such as in the case of *Gynura procumbens*, where the 92 characterized proteins from leaves included miraculin, a taste-masking agent with high commercial value.[32]

The majority of the proteins presented on the reference map (Figure 2) are involved with photosynthesis and energy metabolism. The abundance of many of these proteins in leaf proteomes has been noted previously (e.g., teak,[13] Indian ginseng,[31] *Gynura procumbens*,[32] barrel medic,[33] tomato,[34] holm oak,[18] and *Miscanthum sinensis*[35]). In the present study, we detected multiple spots containing subunits of RuBisCO (spots 5502, 6509, 4504, 6501, and 5501), the enzyme that catalyzes the first step of carbon fixation in the Calvin cycle, and the most abundant protein in the Ginkgo leaf proteome. Chloroplastidial ATP synthase, which generates ATP using a proton gradient, was represented by 10 2-DE spots on the reference map and was the second most abundant leaf protein (Figure 2). Half of the ATP synthase spots were identified as the $\alpha$-subunit and the other five as the $\beta$-subunit (Table 1).

Glycolytic enzymes are well-represented on the 2-DE reference map. Four spots were identified as fructose-bisphosphate aldolase (FBA), which catalyzes the aldol cleavage of fructose-1,6-bisphosphate to glyceraldehyde 3-phosphate and dihydroxyacetone-phosphate. Another three 2-DE spots (6407, 6403, and 7302) were identified as glyceraldehyde 3 phosphate dehydrogenase, which catalyzes the conversion of glyceraldehyde 3 phosphate to D-glycerate-1,3-bisphosphate. Two 2-DE spots (5302 and 6305) were identified as the Krebs cycle enzyme NAD-malate dehydrogenase.

Several stress-related proteins are present on the 2-DE map, including ascorbate peroxidase (APX, spots 5204 and 6104) and superoxide dismutase (SOD, spots 3101, 5105, and 7105). The APX reaction is part of the ascorbate-glutathione cycle for protection against oxidative stress. It uses two molecules of ascorbate to reduce $H_2O_2$ to water.[36] The SOD reaction is also involved with $H_2O_2$ detoxification.[37]

**Proteins Associated with Secondary Metabolism and Proteins of Unknown Function are Abundant in the Ginkgo Leaf Proteome.** Many of the spots on the reference map correspond to enzymes involved in secondary metabolism. Secondary metabolites are valuable targets for industrial applications.[38,39] It is known that Ginkgo leaves contain biologically active terpenes and a range of flavonoid glycosides.[40] More than 38 leaf flavonoids have been isolated so far.[41] Elaboration of the flavone core structure yields structurally related compounds with diverse functions.[42,43] In the present study, we detected 5 proteins associated with flavonoid metabolism: caffeoy-CoA O-methyltransferase (spot 1206), cinnamoyl-CoA reductase (spot 303), anthocyanidin reductase (spot 4306), an isoflavone reductase-like protein (spot 6204), and chalcone synthase (spot 6405). Chalcone synthase catalyzes the first committed step in flavonoid biosynthesis,[44] producing chalcone from which all other

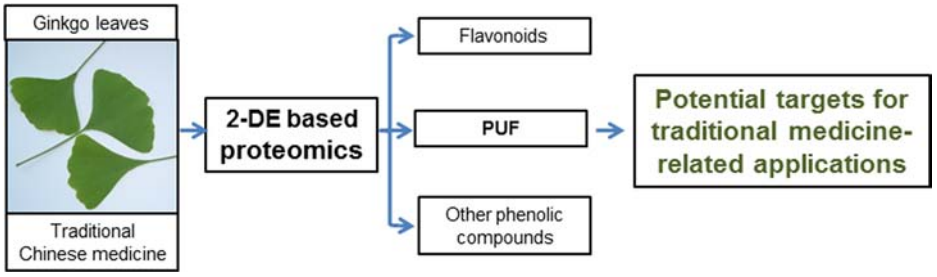

**Figure 4.** Quantitative analysis of proteins associated with synthesis of phenolic and flavonoids compounds with ethnobotanical applications. This approach was also applied to analysis of proteins of unknown function (PUF) that are potential targets for further analysis and with potential use in nontraditional medical applications.

flavonoids are derived. Anthocyanidin reductase (spot 4306) converts anthocyanidins to their corresponding 2,3-cis-flavan-3-ols and is responsible for formation of epicatechin and epigallocatechin in *Arabidopsis* and *Medicago*.[45] Flavonoids comprise a diverse group of polyphenolic compounds with neuroprotective properties in models of Alzheimer's disease, stroke, and Parkinson's disease.[46] Isoflavone reductase reduces achiral isoflavones to chiral isoflavanones in Ginkgo.[47] Cinnamoyl-CoA reductase (CCR) and caffeoyl-CoA O-methyltransferase (CCoAOMT) are enzymes active in phenylpropanoid biosynthesis. The CCR-catalyzed reaction is the first step of the lignin-specific branch of the phenylpropanoid pathway and is a key enzyme responsible for quality and quantity of lignin.[48−50]

Proteins with unknown function (PUF) are the fifth-most abundant functional group on an established map of ginkgo leaf proteome (Figure 2). Most abundant PUF was Os01g0217100 protein from rice (spot s1201, 3403, and 7301) with UniProt accession number Q5QNF4 (Table 1). Using the BLAST algorithm to search the NCBI databases revealed that the amino acid sequence of this protein is 77% similar to rice amino acid transporter-like protein (Table 2 of the Supporting Information). The nucleotide sequence for this protein was described during the sequencing of rice genome.[51]

The second-most abundant PUF was a putative uncharacterized protein (G7KFS4) that is for 56% similar to nucleolar protein 58 characterized from the blood of the king cobra (*Ophiophagus hannah*)[52] (Table 2 of the Supporting Information). Third-most abundant PUF protein was uncharacterized protein (spot 5101, M0TUE2). This protein showed similarity only to other unknown proteins (Table 2 of the Supporting Information). Additionally, this study quantified 10 other unknown proteins from ginkgo leaves (Table 1). It should be noted that unknown proteins constitute more than half of the proteins in plant genomes.[53] The characterization of unknown proteins is one of the greatest challenges of postgenomics biology and should lead to a broader understanding of metabolic processes. The ginkgo leaf PUF's constitute a pool of targets related to traditional medicine-related applications (Figure 4).

## CONCLUSIONS

A quantitative proteomics approach to analysis of the ginkgo leaf proteome led to detection of several proteins associated with secondary metabolism (Figure 4). Additionally, we also detected 14 proteins of unknown function that constitute pool of potential targets for ethnobotanical applications (Figure 4). Follow-up studies will be required to further characterize the ginkgo leaf PUF's and their potential contributions to the health benefits alluded to for centuries in traditional Chinese medicine.

addition, methods to improve the stability of SLN suspensions have been proposed, including (1) using a lipid source that prevents or retards the $\alpha$ to $\beta$ polymorphic transition, (2) adding sufficient emulsifier to completely cover the LNP surfaces in both the liquid and solid states, and (3) using an emulsifier that prevents particle aggregation by increasing the repulsion.

Despite the general use in foods, the permissible amount of emulsifier is often limited by regulations in many countries. Thus, it is not appropriate to use much emulsifier in the preparation of the LNP system for food applications. Meanwhile, sonication is commonly used to prepare emulsion systems, and the cavitation caused by sonication has various physical effects including dispersing molecules in liquids. In this paper, to prevent severe aggregation of LNPs, the effect of sonication during the cooling process was exploited rather than the addition of more emulsifier. For the LNP system, fully hydrogenated canola oil (FHCO) and liquid canola oil (LCO) were used as the solid and liquid lipids, respectively. We explored how the lipid oil (LCO) contents in the FHCO LNPs and the sonication time during the cooling process affected the stability of the dispersion system.

## MATERIALS AND METHODS

**Chemicals.** Lotte Samkang Co. Ltd. (Seoul, Korea) provided us with FHCO, which was composed of 79.5 wt % stearic acid, 8.8 wt % palmitic acid, 4.2 wt % oleic acid, 1.8 wt % lauric acid, 1.6 wt % arachidic acid, 1.4 wt % linoleic acid, 0.9 wt % myrisitc acid, and 1.8 wt % other ingredients. LCO was obtained from CJ Cheiljedang Co. (Seoul, Korea) and consisted of 58.3 wt % oleic acid, 20.0 wt % linoleic acid, 8.3 wt % linolenic acid, 4.4 wt % palmitic acid, 1.8 wt % stearic acid, 1.3 wt % erucic acid, 0.6 wt % arachidic acid, and 5.3 wt % other ingredients. Tween 20 (polyoxyethylene sorbitan monolaurate) was purchased from Sigma-Aldrich Co. (St. Louis, MO, USA). All other chemicals were of analytical reagent grade.

**Lipid Nanoparticle Preparation.** Oil-in-water emulsions were prepared by mixing 5 wt % lipid phase with 95 wt % aqueous phase (10 mM phosphate buffer, 1.67 wt % Tween 20, i.e., a third of the lipid phase weight, pH 7) at 85 °C. The lipid phase was prepared using blended bulk lipid consisting of FHCO and LCO. FHCO was liquefied by heating to 85 °C, and LCO was heated to 85 °C. A range of LCO-to-FHCO weight ratios was used to prepare the lipid phases (0, 10, 20, and 30 wt % of LCO). Coarse oil-in-water emulsions were prepared by homogenizing the oil and aqueous phases together using a high-speed blender (Ultra-Turrax T25D, Ika Werke GmbH & Co., Staufen, Germany) at 8000 rpm for 1 min and then at 11000 rpm for 1 min. The droplet size was further reduced by sonication (VCX 750, Sonics & Materials Inc., Newtown, CT, USA) for 4 min at an amplitude of 60% and a duty cycle of 1 s. To prevent lipid crystallization during emulsion preparation, all experiments were conducted at 95 °C, which was above the melting temperature of FHCO. After droplet size reduction, postsonication (4, 5, or 6 min) was applied to the emulsions as they cooled to 25 °C in a jacketed beaker, after which samples were maintained at room temperature (25 °C). The temperature changes in the emulsion samples during the process were monitored using a data logger (Agilent 34970A, Agilent Technologies Inc., Santa Clara, CA, USA).

**Microscopic Observation.** A drop of LNP sample was placed on a microscope slide and covered using a coverslip. The microstructure of the aggregated particles was observed using a conventional optical microscope (DCM130, Hangzhou HauXin IC Technology Inc., Hangzhou, China) equipped with a digital camera (DCM130E, BW Optics Co., Nanjing, China) and digital image processing software (ScopePhoto version 3.0, Hangzhou Scopetek Opto-Electric Co., Hangzhou, China).

The nanostructure of LNPs prepared using the postsonication process was observed using a transmission electron microscope (JEM1010, JEOL, Tokyo, Japan). First, LNP samples diluted with double-distilled water were placed on a film-coated copper grid and negatively stained with a 1% (w/v) aqueous solution of phosphotungstic acid for 30 s; ultimately, the overflow phosphotunstic acid on the sample was wiped off by filter paper before drying for 1 day at room temperature before observation.[27]

**Determination of Rheological Properties.** Storage modulus ($G'$) and phase angles ($\delta$) of the LNPs undergoing a sol-to-gel transition were measured using a Rheostress RS 100 (Haake Instruments, Karlsruhe, Germany) equipped with a cone and plate measurement system (diameter = 35 mm, cone angle = 1°) and a designated gap of 50 $\mu$m to avoid the effects of single particles. Initially, the shear stress that could cause the gelation of all fresh samples but not destoy the networks among gelled LNPs was determined by the rotational flow test. The stress level of 3 Pa was suitable to observe a time effect of shearing to gelation. Consequently, all time sweep tests were conducted under the controlled stress mode at a stress of 3 Pa and a frequency of 1 Hz.

**Differential Scanning Calorimetry (DSC) Measurement.** The polymorphism of the blended bulk lipids and lipid phases in the prepared suspensions was determined using a differential scanning calorimeter (Diamond DSC, PerkinElmer, Waltham, MA, USA). Each sample (20 ± 5 mg) was placed in a hermetic aluminum pan, which was sealed and equilibrated at room temperature overnight prior to the measurements. An empty pan was used as a reference. The DSC scan started at 25 °C, increased by 5 °C $min^{-1}$ to 95 °C, and then decreased by 5 °C $min^{-1}$ to 10 °C. The crystallinity index (CI) was calculated on the basis of heating thermograms to determine the degree of crystallinity of lipid nanoparticles using the equation[28]

$$\mathrm{CI}\ (\%) = \frac{\Delta H_{\mathrm{m\ LNP}}(\mathrm{J\ g^{-1}}) \times 100}{\Delta H_{\mathrm{m\ FHCO}}(\mathrm{J\ g^{-1}}) \times c_{\mathrm{L}}(\%)} \times 100$$

where $\Delta H_{\mathrm{m\ LNP}}$ is the melting enthalpy of LNPs, $\Delta H_{\mathrm{m\ FHCO}}$ is the melting enthalpy of bulk FHCO, and $c_{\mathrm{L}}$ is the concentration of the lipid phase (i.e., 5 wt %).

**Powder X-ray Diffraction (XRD) Analysis.** The XRD patterns for FHCO stored overnight at room temperature were collected using the X-ray diffractometer (Bruker model D8 advance, Karlsruhe, Germany) with Cu K$\alpha$ radiation at $\lambda$ = 1.54 Å (30 kV, 30 mA). Both results of small-angle X-ray scattering ($2\theta$ = 0−9.1°, 0.005°/s) and wide-angle X-ray scattering ($2\theta$ = 0−40°, 0.2°/s) were obtained with a general area detector diffraction system.

**Measurement of Lipid Nanoparticle Size.** The microstructural size of the LNP microstructure was measured using a laser diffraction analyzer (S3500, Microtrac Inc., Montgomeryville, PA, USA) to figure out the size distribution of aggregated LNPs in the fresh LNP system before (fresh sample) and after the gelation (gelled sample). Samples were stirred continuously throughout the measurements to ensure that they were homogeneous with the water flow option. The particle size was reported as the mean diameter in micrometers of the volume distribution, MV = $\sum V_i d_i / \sum V_i$ (where $V_i$ is the volume percent of particles of diameter $d_i$ in the population).

The gelled LNPs (4.5 mL) were diluted with 40.5 mL of double-distilled water (DDW) in a vial. For the separation of the layer containing the creamed (creaming layer) and noncreamed LNPs (aqueous layer), the vial containing diluted LNPs was tightly sealed with a screw cap and kept overnight at room temperature. The LNPs in the aqueous layer were collected by filtering with a glass microfiber filter with a 1 $\mu$m pore size (GF/B, Whatman Ltd., Fisons, Loughborough, UK) to figure out the size of noncreamed LNP, and their mean nanostructural diameter ($z$-average) was measured using a Zetasizer (Nano ZS, Malvern Instruments Ltd., Worcestershire, UK) using a helium−neon laser ($\lambda$ = 633 nm).

**Quantification of Stable Lipid Nanoparticles.** The diluted LNPs in the vials were passed through a glass microfiber filter with a 1 $\mu$m pore size (GF/B, Whatman Ltd.). The micrometer-sized and aggregated LNPs remaining on the filter were weighed after drying in an oven at 50 °C. The difference in filter weight before and after the

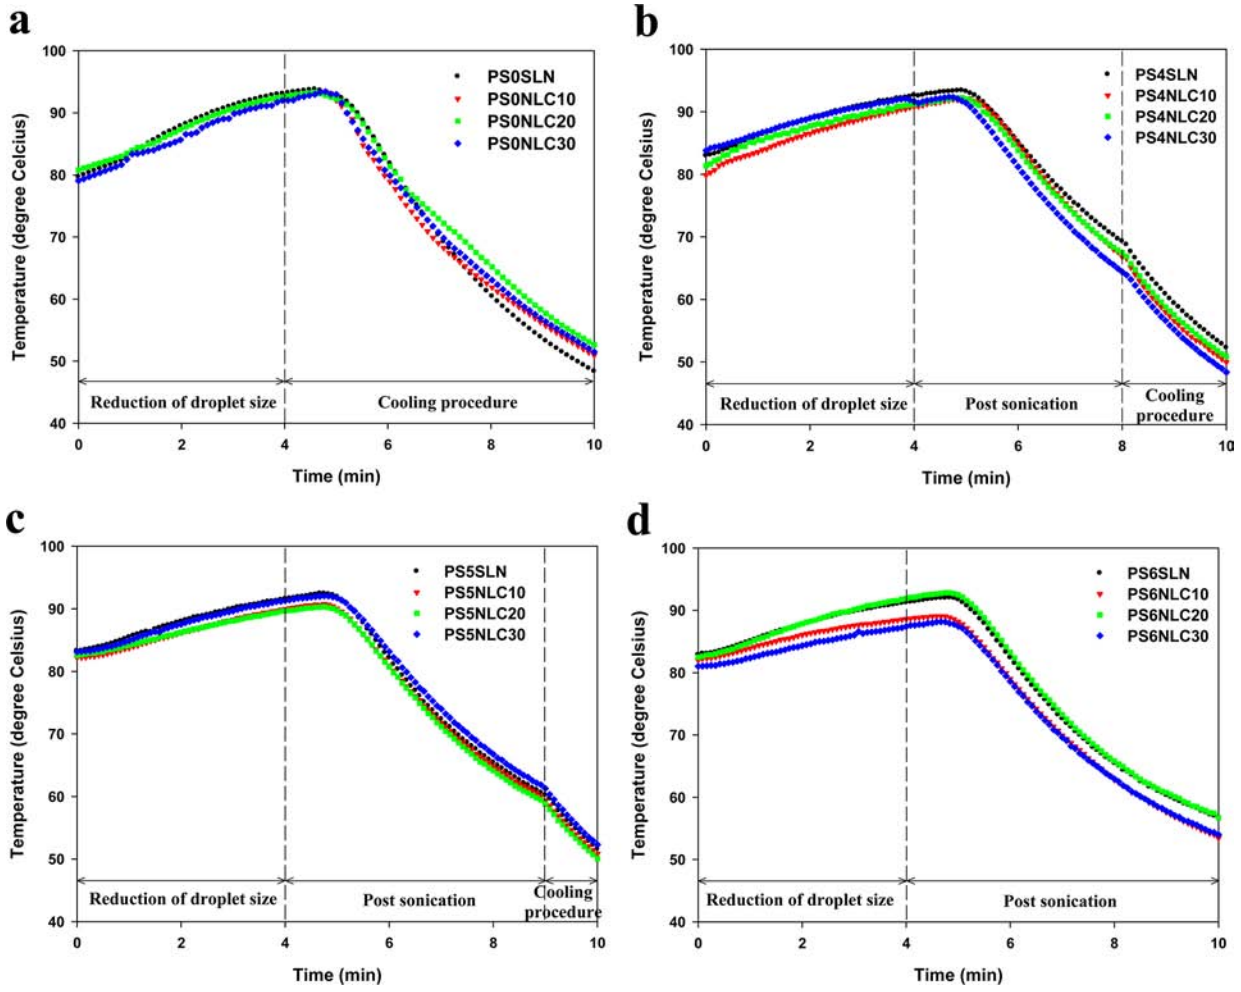

**Figure 1.** Temperature profiles during preparation of lipid nanoparticle suspensions by postsonication for (a) 0, (b) 4, (c) 5, and (d) 6 min, respectively. In the legend, the number following PS (0, 4, 5, and 6) represents the PS procedure time; SLN, NLC10, NLC20, and NLC30 indicate samples prepared using 0, 10, 20, and 30 wt %, respectively, liquid canola oil in the lipid phase.

procedure, which is the weight of the gelled or aggregated LNPs, was recorded.

**Determination of Tween 20 Surface Load.** From the TEM observations, the shape of LNPs was close to a sphere. Therefore, Tween 20 surface load ($\Gamma_s$) was calculated as $\Gamma_s = C_a D/6\Phi$, where $C_a$ is the concentration of the emulsifier adsorbed to the surface of lipid nanoparticles, $D$ is the mean diameter ($z$-average), and $\Phi$ is the lipid phase volume fraction (i.e., 0.05 lipid phase).[29] $C_a$ was determined by subtracting the concentration of Tween 20 suspended as single molecules or micelles from the initial concentration of total emulsifier in the water phase. A total of 2.5 mL of the previously diluted and filtered LNP dispersion was injected into the Sephadex G-25 column (GE Healthcare, Chalfont St Giles, UK) filled with DDW. Next, 1 mL of DDW was serially added, and then each fraction eluted from the column was collected in a microtube. Next, aliquots (1 mL) of the fractions in the fifth and sixth microtubes were selected as samples in which the Tween 20 molecules did not participate in emulsifying activity. Colorimetry for Tween 20 quantification has been reported previously.[30] Briefly, each sample (1 mL) was dried at 80 °C in an oven. The sample was then cooled, and 0.4 mL of ammonium cobaltothiocyanate (ACTC) solution and 0.8 mL of dichloromethane were added. The ACTC solution was fabricated using 3 g of cobalt nitrate hexahydrate and 18 g of ammonium thiocyanate in 100 mL of DDW. Samples were vortexed for 5 s and centrifuged at 10400 RCF for 10 min (Centrifuge Smart 15, Hanil Science Industrial Co., Ltd., Incheon, Korea). After centrifuging, the dichloromethane layer was transferred to a micro quartz cell, and the absorbance at 623.5 nm was determined using a spectrophotometer (Pharmaspec UV-1700, Shimadzu Corp., Kyoto, Japan). The amount of Tween 20 molecules in the LNP dispersion was calculated using standard curves ranging from 0.0167 to 0.0833 wt % for Tween 20 ($r^2$ = 0.9976).

**Statistical Analysis.** All results were analyzed using Tukey's significant difference test with IBM SPSS Statistics version 21.0 (IBM Co., Armonk, NY, USA). Data represent the averages of at least three independent experiments or measurements.

## RESULTS AND DISCUSSION

**Lipid Nanoparticle Preparation.** To differentiate our LNP preparation method from the general methods,[1,6,31] a new step, postsonication (PS), was added. After size reduction, sonication was performed for <6 min in a jacketed beaker maintained at 25 °C. Regardless of the PS time and the liquid oil content in the oil phase, all LNP solutions reached the melting temperature ($T_m$) and the crystallization temperature ($T_c$) of their lipids in approximately 4 and 6 min in the jacketed beaker at 25 °C, respectively (Figure 1). When the temperature of the LNP solution was lower than the $T_c$ of the blended oil, the sonication could partially coalesce the crystallized particles and the oil droplets as the source of turbulent flow rather than preventing the aggregation of LNPs.[21,22] Therefore, all PS should be performed at temperatures above the $T_c$ of the lipid phase, that is, 4−6 min.

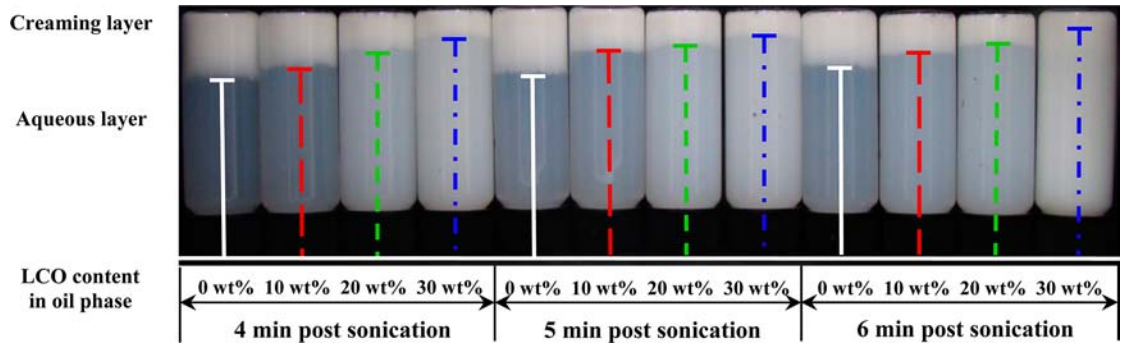

**Figure 2.** Creaming pattern of lipid nanoparticle dispersions diluted 10-fold.

All LNP samples prepared using the lipid containing the LCO concentration at 0−30 wt % would be solidified after the preparation. In other words, the LNP samples were not separately prepared as each of the solidified particles and the liquid droplets in a system, but fabricated as the solid state particles. However, in the LNP system prepared using the lipid containing 40 wt % LCO, both the solid state particles and the liquid state droplets were indirectly verified with DSC thermograms cooling from 95 to −65 °C and then heating from −65 to 95 °C (Figure S1 in Supporting Information). In both the cooling and heating graphs, LNP samples prepared using the lipid at 0−30 wt % LCO did not have the characteristic peaks, whereas distinguishing subzero peaks were observed in both LNP and an emulsion system prepared with 40 wt % LCO and 100 wt % LCO. Thus, the maximum LCO concentration for preparing the LNP system in the present study should be < 40 wt %.

**Visual Stability of Lipid Nanoparticles.** Collisions between some crystallized particles and some noncrystallized droplets could bring partial coalescence during cooling procedure for the LNP preparation,[21] which could force the solid particles together after the fabrication. Additionally, the hydrophobic patches exposed to aqueous solution interacted and aggregated to reduce the surface area exposed to aqueous solution.[32] As a result, the partially coalesced LNPs and the LNPs with surfactant-depleted patches on the surfaces naturally formed aggregates of a micrometer-level size. The creaming phenomenon of highly aggregated LNPs by the partial coalescence and the aggregation when the gelled LNP dispersion was diluted by a 10th part is observed in Figure 2. All samples were divided into two layers, that is, the creaming layer and the aqueous layer, and the length of the vertical line on the samples represents the thickness of the aqueous layer. These observations suggested that increases in the PS time and the LCO content of the oil phase enhance LNP stability.

Stokes' law for hindered settling could explain the creaming phenomenon of the dispersion system composed of LNPs.[33] Under the same composition, the effect of the particle size on the creaming rate predominates over the density difference. Therefore, the aggregated and gelled particles in micrometer size creamed readily, whereas the stable nanosize LNPs were well-dispersed in aqueous solution. Particle size measurement of the aqueous layer was conducted to verify this conjecture. All LNPs in the aqueous layer had mean particle size values (*z*-average) of 114.7−202.3 nm and a unimodal size distribution in the nanoscale range (Table S1 and Figure S1 in the Supporting Information). This supports our hypothesis that LNPs in the aqueous layer are nonaggregated particles.

**Morphological Characteristics of Lipid Nanoparticles and Gelation Phenomenon.** The freshly fabricated LNPs showed fluid properties. However, gelation of all LNP samples had occurred after the application of shear stress >3 Pa, and the fluid characteristics were lost (data not shown). This phenomenon is in agreement with a previous study.[19] Gelation of the LNPs can be accelerated by the interaction between hydrophobic patches on the LNPs, which were created by morphological changes, because the probability of particle collision is increased by shearing. Meanwhile, the partial coalescence among particles could not happen by shearing because the lipid matrix composing LNPs was solidified after the preparation.[21] Therefore, hydrophobic interactions could be an important factor for network formation with LNPs, resulting in their gelation.

Panels a−d of Figure 3 show microstructural morphologies of LNPs fabricated using LCO at diverse concentrations (0−30 wt %) using the PS step for 5 min after shearing and aggregating. LNP flocs at a micrometer-size were independently observed in all samples. The flocs consisted of LNPs, and comparatively small LNPs were suspended in the remaining space within the flocs. The LNPs comprising flocs might have hydrophobic patches or partially coalesced particles; that is, nonstable LNPs and the small LNPs suspended in the water phase might have been covered with Tween 20, that is, stable LNPs. Although it was assumed that LNPs composing flocs underwent morphological changes, shapes extremely deviated from a sphere were not observed among the LNPs in flocs.

After gelation by shearing, the aggregated LNP size changed significantly (Table 1). Before shearing, the LNPs generally showed a large decrease in mean particle diameter with increasing LCO content in the lipid phase. At the same LCO content in the lipid phase, intensive aggregation of the LNPs was observed as the PS time increased, with the exception of the 0 and 30 wt % LCO LNP. However, there was no trend in the change in LNP size following gelation. In addition, multiple peaks in the particle size distribution became unimodal after shearing, independent of the PS time and the LCO-to-FHCO weight ratio. For example, on aggregation in samples fabricated using PS for 5 min, whereas a single peak in a sample prepared using 0 wt % LCO contents simply shifted from 20.17 to 16.96 $\mu$m, multiple peaks in samples fabricated using 10, 20, and 30 wt % LCO contents (10% LCO, 1.50 and 14.27 $\mu$m; 20% LCO, 1.26 and 11.00 $\mu$m; 30% LCO, 1.16, 11.00, and 44.00 $\mu$m) formed unimodal peaks at 16.96, 16.96, 15.56, and 18.50 $\mu$m, respectively (Figure S2 in the Supporting Information). Surfactants on the surface of solidified LNPs could not re-emulsify the interface of LNP aggregates. Moreover, LNP

[a]Different letters a–i in a column are significantly different at $p < 0.05$.

aggregates could not be fully coalesced, which could be just rearranged in another size. Therefore, these results could indirectly support that the shearing in LNP systems could cause the aggregation and gelation of LNPs.

Panels e–h in Figure 3 show the nanostructural morphologies of LNPs prepared using various LCO contents (0–30 wt %) in the oil phase. The majority of each LNPs observed in the TEM images were nanoscaled, whereas micrometer-sized particles were rarely observed. In other words, either the LNPs making up the flocs or the LNPs suspended individually were composed of nanoscale LNPs. This observation suggested that although PS could not completely prevent floc formation, it facilitated maintenance of single particles at a nanoscale size. In addition, the shape of all LNPs in the microscopy was more similar to the sphere rather than the needle-shape referred to by several researchers.[16,19] This morphological shape similar to the sphere might come from the effects of the PS and the LCO content in the lipid matrix, which could cause the increase of surfactant coverage and improve the colloidal stability of the LNP system.

**Rheological Properties of Lipid Nanoparticles.** Changes in $G'$ and $\delta$ were monitored to determine the gelation time during the oscillatory dynamic measurement (Figure 4). Before a certain time, $G'$ remained close to zero and $\delta$ was maintained at a relatively high level (close to 90°), which indicated that the LNP suspension remained fluid. However, over time, the $G'$ of all LNP suspensions increased and their $\delta$

decreased, indicating that gelation occurred. With a higher LCO content in the oil phase and a longer PS time, gelation time was extended. Because the gelling phenomena of LNPs were derived from the building of networks with the LNPs and their flocs, a greater gelation time meant that the collision of LNPs and their flocs to create the gel network occurred less frequently at the same shear force. This may be indirect evidence that the LNPs prepared using a longer PS time and greater LCO contents in the oil phase contained more LNPs that did not play a role in gel network formation.

**Thermal Properties of Bulk Lipids and Lipid Nanoparticles.** The most abundant fatty acid in FHCO was stearic acid, which suggests that FHCO was composed of tristearin and other minor triacylglycerides. Therefore, the thermal

[a]Different letters w−z and a−k in a column within bulk lipid and lipid phase are significantly different at $p < 0.05$, respectively.

properties of FHCO were expected to be similar to those of tristearin.

In the present study, the DSC thermogram taken after overnight storage at 25 °C showed a single peak corresponding to the melting of $\beta$-polymorphic form crystals (Figure 5a). In other studies, multiple melting peaks of $\alpha$, $\beta'$, and $\beta$ forms were reported.[34] The reason for this discrepancy is transformation of $\alpha$-form into $\beta$-form crystals during overnight storage. The melting temperature ($T_m$) of the $\beta$-polymorphic forms of pure tristearin was 72.1 °C, and the $T_c$ of the $\alpha$-polymorphic form was 51 °C.[35] The $T_m$ (69.6 °C for $\beta$-polymorphic form) and $T_c$ (44.8 °C for $\alpha$-polymorphic form) of FHCO were similar to those of tristearin (Table 2). The specific XRD lines (0.46, 0.39, and 0.37 nm with WAXS and 4.49 nm with SAXS) for the $\beta$ form of FHCO in the current study were similar to the previous findings in the case of tristearin (Figure S4 in the Supporting Information).[35,36]

The thermogram patterns of FHCO blended with LCO in various weight ratios would be similar to the pattern of FHCO, which comprised a melting peak of the $\beta$ form and a crystallization peak of the $\alpha$ form (Figure 5b−d). However, the $T_m$ and $T_c$ of the $\beta$- and $\alpha$-polymorphic forms for each blended lipid differed from those for FHCO (Table 2).

During heating from 25 to 95 °C, the $\beta$-form $T_m$ (69.1 °C) of the lipid mixed with 90 wt % FHCO and 10 wt % LCO was similar to the $T_m$ (69.6 °C) of FHCO, whereas melting temperatures (both 67.3 °C) of the blended FHCOs with 20 and 30 wt % LCO were lower than the $T_m$ of the FHCO. Melting enthalpies ($\Delta H_m$) of bulk lipids decreased with increasing LCO contents, although enthalpies for the FHCO and the lipid mixed with 90 wt % FHCO and 10 wt % LCO were similar. In addition, all $\Delta H_m$ values for the lipids blended with LCO at each ratio (10−30 wt %) were greater than their own theoretical $\Delta H_m$ values. In other words, lipids mixed with FHCO and LCO formed more $\beta$-form crystals than all $\beta$ crystals of FHCO comprising the blended lipid matrix. This result suggested that triacylglycerol molecules in FHCO could be cocrystallized with molecules in LCO as the $\beta$-form crystals, which is in agreement with other research.[37,38]

With regard to melting of the lipid phase in the LNP system, in the lipid and LNP suspension prepared using the same LCO contents, the $T_m$ values of the lipid phase in the LNP suspension were generally ∼2.5 °C lower than those of the bulk lipid. However, the trend of the LNP, in which greater LCO contents decreased the $T_m$, was similar to those of bulk lipids. Moreover, $T_m$ values of the lipid phase were independent of PS times for preparation. The crystallinity indices (CI) decreased with increasing PS time and LCO contents. In other words, the additional sonication, PS, and the LCO in the lipid phase would inhibit lipid crystal formation.

The CI values of LNP suspensions were lower than those at the time for the crystallization of all FHCO molecules. For example, the lipid phase of the PS6NLC30 sample (Table 2) consisted of 70 wt % FHCO; nevertheless, the CI of the sample was 57.5%. This may be because LCO in the LNP interferes with formation of the perfect arrangement among FHCO $\beta$ crystals.[39] As a result, the decrease in crystal formation, which originated from increasing both the LCO content and PS time, improved the stability of the LNP system, which is discussed in the following section.

During cooling from 95 to 10 °C, the $\alpha$-form $T_c$ (44.8 °C) of the FHCO was lower than the $T_c$ (45.2 °C) of the lipid mixed with 90 wt % FHCO and 10 wt % LCO, and the $T_c$ values of the remainder, which were bulk lipids blended with 80 and 70 wt % FHCO and 20 and 30 wt % LCO, decreased with increasing LCO contents. The absolute values of the crystallization enthalpy ($\Delta H_c$) of bulk lipids from 0 to 20 wt % LCO contents decreased from 61.5 to 52.7 J g$^{-1}$, whereas the

absolute values of the $\Delta H_c$ of bulk lipids containing 20 and 30 wt % LCO were similar. In addition, on the basis of a comparison of experimental data and the theoretical values corresponding to the amount of FHCO, this result was in agreement with the melting enthalpies ($\Delta H_m$).

The $T_c$ of the $\alpha$-polymorphic form of emulsified tripalmitin at the nanoscale is lower than that of bulk tripalmitin.[25] This phenomenon was also observed in our study (Table 2). During the DSC scan, the LNPs melted during heating from 25 to 95 °C and then crystallized during cooling from 95 to 10 °C. The LNPs that did not participate in gelation formed individual liquid droplets at the nanoscale during heating, but either they partially coalesced during the LNP preparation or the highly gelled LNPs, which were attached to each other by hydrophobic interactions, underwent full coalescence and eventually formed large micrometer-scale liquid oil droplets. The DSC thermograms during cooling showed that LNP crystallization occurred at lower temperatures ($T_{c2}$) for the lipid droplets that were not coalesced compared to the coalesced ($T_{c1}$) LNPs. The $T_{c1}$ was similar to the $T_c$ of the bulk lipid (FHCO or blended FHCO/LCO), which is in agreement with previous studies.[15,25,40,41]

The ratios of the enthalpy values ($\Delta H_{c2}/\Delta H_{c1}$, $\Delta H_{c2}$, and $\Delta H_{c1}$ for $T_{c2}$ and $T_{c1}$, respectively) could be used to determine the quantity of LNPs that did not take part in the partial coalescence and the gelation. As $\Delta H_{c2}/\Delta H_{c1}$ increased, the quantity of particles not participating in the destabilization (the partial coalescence and the gelation) of LNPs increased. The increase in the LCO content in the oil phase increased $\Delta H_{c2}/\Delta H_{c1}$ (Table 2). Previous findings stated that a higher liquid oil content in the oil phase enhanced the stability of LNPs.[41,42] In this study, the increase in the LCO content of the oil phase improved the stability of the LNPs. In addition, the $\Delta H_{c2}/\Delta H_{c1}$ values increased with increasing PS time. This observation supported our hypothesis that additional sonication during the cooling step of LNP preparation improves the stability of LNPs.

**Proposed Mechanisms of the Increased Stability of Lipid Nanoparticles Due to Additional Sonication and Liquid Canola Oil in the Oil Phase.** Emulsifiers densely covering the surface of LNPs could prevent the FHCO from forming $\beta$-polymorphic crystals during cooling and storage.[15] As discussed above, the formation of $\beta$ crystals increases the likelihood of formation of hydrophobic patches on the surface of the particle. Thus, the increase in emulsifier density on the particle surface could prevent gelation and enhance the stability of LNPs. In the present study, the amount of Tween 20 per unit surface area of LNPs is shown in Table 3, which was based on the assumption that the shape of all LNPs was similar to a sphere. The Tween 20 surface load increased in proportion with increasing PS processing time or the LCO content in the oil phase. In particular, the surface load of the sample prepared using 6 min of PS and a 30 wt % LCO content was 10.29 mg $m^{-2}$. Despite the lower ratio (1/3) of the amount of Tween 20 to the lipid phase volume, this value was greater than that (8.1 mg $m^{-2}$) for SLN prepared using 10 wt % lipid and 10 wt % Tween 20 (1/1) reported by Nik et al.[34] Therefore, both the additional sonication process during cooling and the presence of liquid oil in the lipid matrix might result in effective emulsification of LNP by Tween 20 in contrast to that found by other researchers.

The nonaggregated stable LNPs were nanosized particles, but the aggregated nonstable particles were micrometer-sized. The stable particles could pass through the filter (pore size = 1 $\mu$m), whereas the aggregated particles remained on the filter. The contents of the nonaggregated LNPs are shown in Table 3. The amount of stable nanoparticles increased with increasing PS time and LCO content in the oil phase, which was similar to the tendency in the Tween 20 surface load. This result confirmed that a longer PS time and a greater LCO content in the oil phase are suitable conditions for preparing stable LNP systems.

**Table 3. Tween 20 Surface Load and the Quantity Values of Nonaggregated Lipid Nanoparticles[a]**

| sample | | | |
|---|---|---|---|
| postsonication (min) | LCO content (wt %) | Tween 20 surface load (mg $m^{-2}$) | content of nonaggregated particle (%) |

[a]Different letters a–i in a column are significantly different at $p < 0.05$.

In the conventional method for LNP preparation (Figure 6a), the formation of Tween 20 micelles at high temperature could reduce the amount of Tween 20 molecules available to stabilize the interface between the oil and water phases[23,24] and induce the formation of coalesced micrometer-sized oil droplets. During the cooling procedure, these coalesced micrometer droplets at $T_{c1}$ could be crystallized and transformed to destabilized particles with hydrophobic patches, which may be partially coalesced with noncrystallized liquid droplets.[21] What was worse, nanoparticles with low Tween 20 surface load levels could be crystallized at $T_{c2}$ and transformed into unstable particles having hydrophobic patches,[25,26] which could be aggregates of nonstable particles. Consequently, flocs of these nonstable particles, which are the partially coalesced particles or the particles aggregated by hydrophobic patches, could float and be creamed.

In the present study, the positive effects on LNP stability of PS and liquid oil content could be explained by two mechanisms. First, the PS during the cooling procedure induces Tween 20 molecules to form micelles, which move and stabilize the LNP surface (Figure 6b). That is, Tween 20 molecules at higher temperature would be more stable in the form of micelles and less likely to adsorb at the interface of the LNP.[23,24] The PS could break the micelles and enhance the coating of the LNP by Tween 20. Therefore, the nanosized oil droplets processed with the PS, which are not coalesced, could crystallize at the $T_{c2}$ and disperse throughout the system.

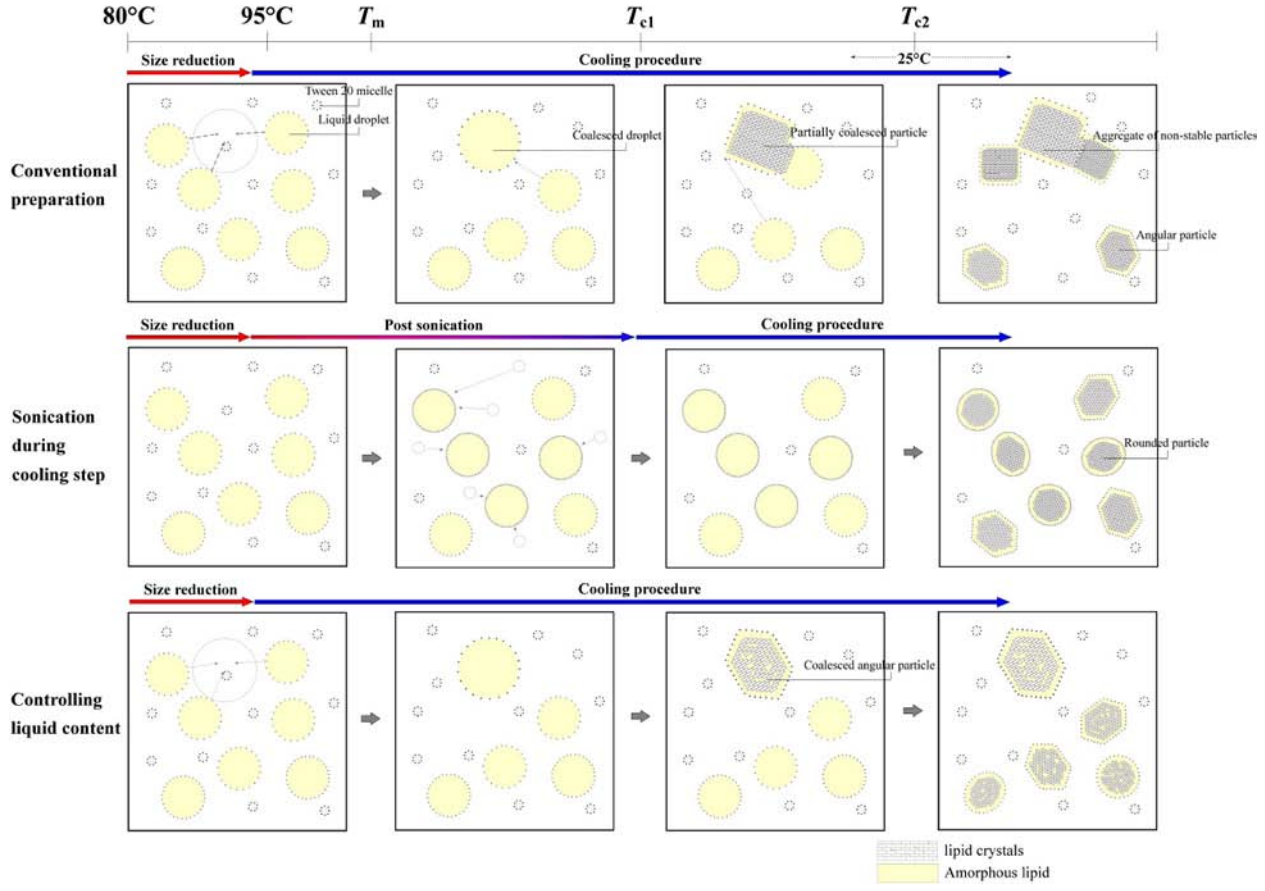

**Figure 6.** Schematic representation of the dispersion stability of lipid nanoparticles fabricated using the (a, top) conventional preparation, (b, middle) additional sonication (postsonication) during cooling, and (c, bottom) a solid lipid phase containing liquid canola oil.

Because the surfactant covering the lipid would compete with the lipid crystallization at the interface,[28,34] the PS process could decrease the CI of LNPs, as discussed in a previous section (Table 2). In other words, the better adsorption of surfactants at the interface, caused by the longer PS, could more effectively inhibit the crystallization of lipid matrices. Second, the liquid oil could interfere with crystallization of the oil phase and decrease the likelihood of morphological transition from a sphere to a rod shape (Figure 6c). Thus, the increase in liquid oil content in the oil phase could not only prevent the formation of hydrophobic patches but also reduce the surface area. This could contribute to the reduction of Tween 20 surface load (Table 3). Consequently, these synergetic effects that originated from the additional sonication during cooling and the presence of liquid oil in the oil phase increased the stability of the lipid nanoparticle system.

According to the characteristics of the blended lipid, FHCO and LCO are appropriate for use as carrier matrix lipids and for the application of LNPs in food systems. The PS step prevents the intensive aggregation and gelation of LNPs, which have been problems in LNP systems. These results confirmed our hypothesis that PS and the LCO content of a lipid matrix could improve LNP stability. Compared with the traditional methods for LNP preparation, the process introduced in this study could allow food companies to fabricate more stable LNPs. In conclusion, stable FHCO LNP systems as carrier systems of bioactive materials could be used for functional foods.

by the LC−chip/TOF MS system,[13,14,20] but the reliability of such an approach for OS quantification is yet to be proven. In addition, all of the reports concerning OS profiling and/or quantification adopted a rather complex sample pretreatment procedure for protein elimination, thus affording limited sample throughput. Because OS are receiving increasing commercial attention for their role in enhancing human health, alternative LC−MS methods and simpler sample preparation protocols for the quantification of major OS species are needed.

Here, we report on the development and validation of a LC−MS method for the quantitative analysis of major OS in bovine milk based on the use of hydrophilic interaction liquid chromatography (HILIC) coupled to a linear ion trap (LTQ) Orbitrap mass spectrometer. We show that this method is sensitive, accurate, and able to quantify 13 major OS within a single run of 50 min with minimum sample pretreatment.

## MATERIALS AND METHODS

**Cows, Diets, and Milk Samples.** For method development, a full cream fresh milk (Farmdale) from the local market was used as a reference sample. For method application, milk samples from 32 individual Holstein-Friesian cows subjected to three different feeding treatments were analyzed. At the beginning of the experiment, the cows had body weights of 614 ± 57.6 kg, were 147 ± 18.2 days in milk (DIM), and were producing 25.2 ± 2.0 L of milk/day. All animal experimentation was conducted in accordance with the Australian Code of Practice for the Care and Use of Animals for Scientific Purposes.[23] Animal use was approved by the Animal Ethics Committee of the Department of Environment and Primary Industries, Victoria, Australia. The cows were fed one of three dietary treatments: (1) a control diet (CON), in which cows were individually offered daily, 6.0 kg of dry matter (DM) of crushed corn grain, 2.0 kg of DM of cold pressed canola meal, 0.2 kg of DM of minerals, and 14.0 kg of DM of alfalfa cubes; (2) an almond hull diet (ALH), in which cows were individually offered a diet similar to the CON diet, except that 4.0 kg of DM of almond hulls was substituted for 4.0 kg of DM of alfalfa cubes; and (3) a citrus diet (CIT), which was similar to the CON diet, but 3.0 kg of DM of citrus pulp (orange skins) was substituted for 3.0 kg of DM of alfalfa cubes. These diets were fed to the cows for 28 days, and samples of milk were collected on the last day of the experiment and kept at −80 °C before analysis.

**Chemicals.** OS standards [3′-sialyllactose (3′-SL), 6′-sialyllactose (6′-SL), 6′-sialyllactosamine (6′-SLN), stachyose, and verbascose] were purchased from Sigma. Molecular weight cutoff filters (10 kDa, Amicon) were obtained from Merck Millipore. Solvents were of analytical grade (for acetonitrile, Merck) or chromatographic purity (for water containing 0.1% formic acid and acetonitrile containing 0.1% formic acid, Fluka).

**Method for Removing Fat and Protein from Milk.** Full cream milk was centrifuged for 15 min (5000*g*), and the upper layer (fat) was removed. For protein elimination, three different methods were compared. Method 1 (chloroform extraction, standard method): to the defatted milk sample, 4 volumes of chloroform/MeOH (2:1, v/v) and 2 volumes of Milli-Q water were added.[13] The mixture was then centrifuged for 20 min (13000*g*) for complete phase separation. The upper layer, which contains the OS fraction, was carefully transferred to a new tube and dried by a SpeedVac concentrator (SPD2010, Thermo Scientific). The dried OS were reconstituted in water before LC−MS analysis. Method 2 (acetonitrile precipitation): acetonitrile was added to the defatted milk at a 1:1 ratio, and the mixture was placed in a fridge (4 °C) for 60 min to allow for protein precipitation.[24] After centrifugation (13000*g* for 20 min), the supernatant was analyzed directly by LC−MS. Method 3 (ultrafiltration): defatted milk was diluted by adding an equal volume of Milli-Q water and then filtered through a 10 kDa molecular weight cutoff filter in a microfuge (13000*g* for 30 min). Filtrate is expected to contain all OS and other low-molecular-weight compounds and was analyzed directly by LC−MS.

**OS Analysis by LC−MS.** Chromatographic separation of OS was achieved using a Luna HILIC column (250 × 4.6 mm, 5 μm, Phenomenex) on an Agilent 1290 Infinity HPLC system (Agilent, Walbronn, Germany), including a degasser, binary pump, temperature-controlled autosampler (maintained at 4 °C), and column compartment (maintained at 30 °C). The mobile phase was composed of water containing 0.1% formic acid (A) and acetonitrile containing 0.1% formic acid (B). The flow rate was 0.5 mL/min with a gradient elution of 5−50% A over 42 min and then increased to 1 mL/min for post-acquisition column washing and equilibration. The injection volume was 5 μL for both standards and milk samples. Analyte detection was by mass spectrometry LTQ Orbitrap Velos (Thermo Scientific, Waltham, MA) with a heated electrospray ionization (HESI) source. The heated capillary was maintained at 270 °C with a source heater temperature of 350 °C, and the sheath, auxiliary, and sweep gases were at 40, 15, and 8 units, respectively. The source voltage was set to 3.2 kV for negative mode.

The mass spectrometer was operated with full scan (*m*/*z* 120−2000) in negative Fourier transform (FT) mode (at a resolution of 60 000) for all OS analyses. Deprotonated molecular ions ($[M - H]^-$) were extracted from the full-scan chromatograms, and peak areas were integrated using Xcalibur software (Thermo Scientific). For structural confirmation of major OS identified on the basis of accurate mass information, tandem mass spectrometry (MS/MS) data were acquired in collision-induced dissociation (CID) mode using a normalized collision energy of 25 arbitrary units.

**Method Validation.** *Limit of Detection (LOD), Limit of Quantitation (LOQ), and Linear Range Determination.* Because of the fact that standards are not available for most milk OS, the LOD, LOQ, and linear range of the method were assessed for three representative acidic OS (3′-SL, 6′-SL, and 6′-SLN) and two neutral OS analogues (stachyose and verbascose). A series of 13 dilutions (ranging from 0.000 01 to 0.1 mg/mL) of the five OS standards were prepared in water and analyzed 3 times, and the LOD, LOQ, and linear range for each compound were determined as described previously.[25]

*Method Precision and Accuracy Assessment.* Three concentrations (one close to LOQ, one intermediate, and one close to the upper limit of the linear range) of the 5 OS standards were prepared in water and analyzed 5 times. Method precision was assessed by the variation [as judged by the relative standard deviation (RSD)] of the peak area between repeated injections of each standard dilution. Method accuracy was estimated by the ratio of the actual measured concentration to the nominal concentration prepared for each OS.

*Method Recovery.* A mix of four OS standards (6′-SL, 6′-SLN, stachyose, and verbascose) was spiked to the defatted reference milk sample at two different levels (0.1 or 1 μg each in 400 μL of milk) before ultrafiltration. The recovery of the standards was calculated using the following formula: recovery (%) = [(total mass in the spiked sample − mass in the non-spiked sample)/mass spiked] × 100.

**Method Application.** Having confirmed the precision, accuracy, and OS recovery using standards and the reference milk sample, we applied the method to relative and absolute quantification of the major OS in 32 milk samples. The results were analyzed for overall abundance of different OS, variation of OS content between samples, correlation between different OS species, and effect of feed on the milk OS profile.

## RESULTS

**Major OS Detected in the Reference Milk Sample.** Because the building blocks of cow milk OS are known to include glucose, galactose, *N*-acetylglucosamine, fucose, *N*-acetylneuraminic acid (NeuAc), and *N*-glycolylneuraminic acid (NeuGc),[3] an accurate mass of OS of different compositions can be calculated. This allowed us to detect a total of 18 OS in the non-enriched reference milk sample based on mass accuracy of less than 5 ppm. A total of 13 of them are

Table 1. Major OS Identified in the Reference Milk Sample[a]

| name (abbreviation) | composition | $m/z$ (exp) | $m/z$ (calcd) | retention time (min) |
|---|---|---|---|---|
| trisaccharides (Trisa) | 3 Hex | 503.1625 | 503.1612 | 29.00 |
| 3′-sialyllactose (3′-SL) | 2 Hex, 1 NeuAc | 632.2048 | 632.2038 | 35.86 |
| 6′-sialyllactose (6′-SL) | 2 Hex, 1 NeuAc | 632.2048 | 632.2038 | 35.19 |
| 6′-sialyl-*N*-acetyllactosamine (6′-SLN) | 1 Hex, 1 HexNAc, 1 NeuAc | 673.2314 | 673.2304 | 34.17 |
| disialyllactose (DSL) | 2 Hex, 2 NeuAc | 923.3011 | 923.2992 | 37.37 |
| *N*-acetylgalactosaminyllactose (GNL) | 2 Hex, 1 HexNAc | 544.1893 | 544.1878 | 27.80 |
| OS-A | 3 Hex, 1 NeuAc | 794.2585 | 794.2566 | 38.00 |
| OS-B | 4 Hex, 1 HexNAc | 868.2964 | 868.2934 | 33.37 |
| OS-C | 3 Hex, 1 HexNAc | 706.2417 | 706.2406 | 31.13 |
| OS-D | 3 Hex, 2 HexNAc | 909.3214 | 909.3200 | 32.91 |
| OS-E | 2 Hex, 1 NeuGc | 648.2002 | 648.1987 | 36.67 |
| OS-F | 2 Hex, 1 HexNAc, 1 NeuAc | 835.2836 | 835.2832 | 37.51 |
| OS-G | 4 Hex, 1 HexNAc, 1 NeuAc | 1159.3911 | 1159.3888 | 40.31 |

[a]exp and calcd, experimental and calculated $m/z$ values for deprotonated molecular ions (detected in negative mode); Hex, glucose or galactose; HexNAc, *N*-acetylglucosamine or *N*-acetylgalactosamine; NeuAc, *N*-acetylneuraminic acid (sialic acid); and NeuGc, *N*-glycolylneuraminic acid.

quantifiable and are thus considered as major OS (Table 1 and Figure 1).

It is worth noting that all 13 major OS are of lower degree of polymerization (DP) type and the dominant species (Trisa, OS-A, 3′-SL, 6′-SL, DSL, and GNL) contain three or four monosaccharide units. The composition of the major OS identified using accurate mass data was further confirmed by the standards (in the case of 3′-SL, 6′-SL, and 6′-SLN) and/or MS/MS data (see Figure S-1 of the Supporting Information). It is interesting to note that, of the pure hexose-based OS category, species containing more than three sugar units were not found in the sample nor were any fucose-containing OS species. Lactose, lactose phosphate, and *N*-acetyllactosamine were not considered as OS in this work.

**Comparison of Sample Pretreatment Methods.** Stachyose was used as an internal standard in our preliminary analysis, and comparable results were obtained with and without the internal standard. Therefore, no internal standards were used in subsequent experiments. The concentrations (as judged by peak areas) of the 13 major OS in the reference milk sample following different protein elimination procedures were measured in parallel. The experiment was designed in such a way that a same dilution factor was applicable to all three methods. The peak areas of the 13 OS generated with method 2 (acetonitrile precipitation) were highly correlated with those of method 1 (standard method), but the overall response was about 20% lower ($y = 0.7992x$; $R^2 = 0.9996$). This suggests that using acetonitrile to precipitate milk protein could lead to a significant underestimation of OS.

In contrast, the peak areas of the major OS measured using protein elimination method 3 (ultrafiltration) were not only highly correlated with those obtained with method 1 but also showed slightly higher overall ion abundance ($y = 1.0733x$; $R^2 = 0.9998$), implying a higher OS recovery using this new sample pretreatment method.

The ultrafiltration method (method 3) also displayed better measurement reproducibility than the standard method (method 1), with a RSD of the peak area of replicate extractions below 4% for 12 of the 13 major OS (Table 2). Consequently, the ultrafiltration was chosen as the protein elimination technique for further method validation.

**LOD, LOQ, and Linear Range of Representative OS.** This LC−MS method is highly sensitive for the detection of both acidic and neutral OS with a LOD for all species below 0.1 ng and a LOQ of 0.25 ng (Table 3). The linearity ranges from 0.25 to ≥100 ng ($R^2 > 0.99$).

**Precision and Accuracy of the Method.** This method also shows excellent reproducibility in the peak area for all representative OS and all injection levels. The peak area variation between repeated analyses of the five representative OS standards is below 9% for the low injection level (0.5 ng) and below 3% for intermediate (5 ng) and high (100 ng) injection levels (Table 4). The overall measurement accuracy of the method ranges from 91 to 104% for the three concentrations of OS standards (Table 4).

**Recovery of Spiked Standards.** The overall recovery of the four representative OS (stachyose, verbascose, 6′-SL, and 6′-SLN) spiked at two different levels (0.1 and 1 μg in 0.4 mL of defatted milk) is between 91 and 105% (Table 5). This suggests that no significant loss of the OS occurred during the ultrafiltration step nor was there a significant matrix effect on the detection of these compounds.

**Method Application.** The OS concentrations in 32 samples of milk were determined using the validated method. The major OS detected in these samples were the same as those found in the reference sample. The relative abundances (averaged from the 32 samples) of the 13 OS are shown in Table 6. Again, six OS (Trisa, OS-A, 3′-SL, 6′-SL, DSL, and GNL) were found in a larger amount, with 3′-SL and 6′-SL being the most dominant species, followed by Trisa, whereas OS-B, OS-C, OS-D, OS-E, OS-F, OS-G, and 6′-SLN were the lower abundance OS species in these samples.

Large variation was also observed between samples in the concentration of all major OS. For example, the 3′-SL content varied from 116 to 199 μg/mL across the 32 samples; the 6′-SL content varied from 6 to 32 μg/mL across the 32 samples; and the 6′-SLN content varied from 0.27 to 1.2 μg/mL across the 32 samples (Figure 2). The magnitude of variation appeared to be similar for milks from three different diets.

It is also interesting to note that the contents (as measured by peak areas) of some of the major OS are correlated with each other, with the most significant correlation ($R^2 > 0.6$) being found between the pairs 6′-SL/6′-SLN, OS-C/GNL, and OS-D/OS-G (Figure 3).

When the whole data matrix (13 OS contents of 32 samples) was subjected to PCA analysis, no clear separation was observed between the three feed groups, indicating that the intake of almond hulls or citrus pulp had little effect on the OS

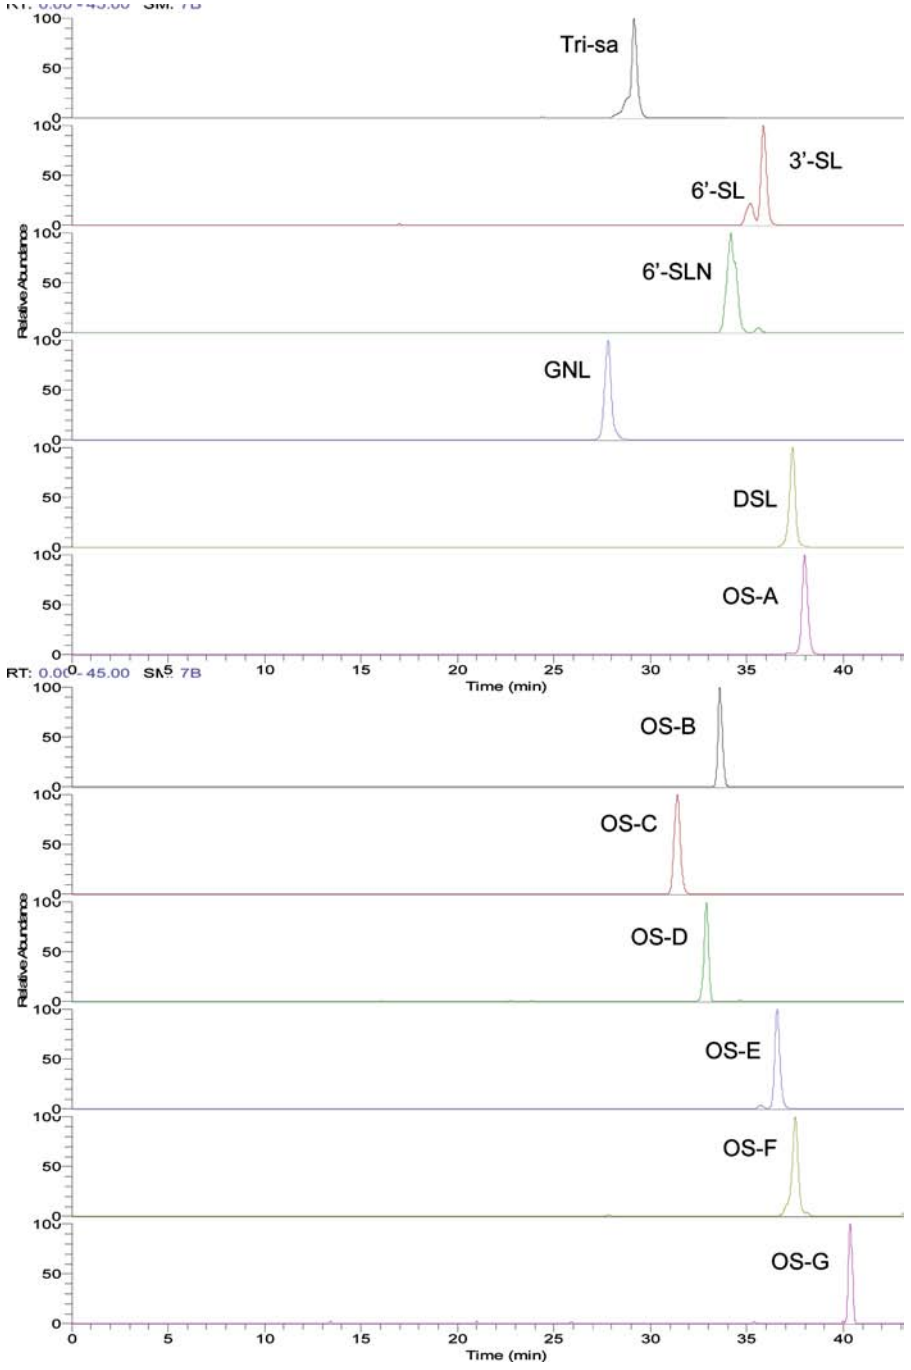

**Figure 1.** Extracted ion chromatogram of the 13 major OS detected in the reference milk sample. The deprotonated ion of each compound was extracted using a window of calculated accurate mass of $m/z$ ±0.005.

accumulation in milk (see Figure S-2 of the Supporting Information).

## DISCUSSION

The beneficial biological functions of OS are increasingly being recognized especially for neonates. It is generally accepted that the OS found in bovine milk are structurally similar to those in human milk.[5] Consequently, the use of bovine milk OS in infant formula and pharmaceutical and food industries is expected to intensify. Because OS in bovine milk are present as a mixture of a large number of linear and branched molecules with 3−10 monosaccharide units, measuring the total OS concentration in bovine milk is not as straightforward as determining the concentration of total fructo-oligosaccharide in plant tissue.[26] As a result, measuring the concentration of the major OS species is important to evaluate the potential beneficial value of OS in a milk sample.

Irrespective of analytical methods, absolute quantification of individual OS is currently possible only for a few major species, for which the standards are available.[16,18] Consequently, relative quantification (using ion intensity or peak area) is the only feasible way for estimating the content of most OS in milk. Indeed, ion intensity was used in a number of studies to estimate the relative content of OS in various milk samples,[13,14,20] but a robust and validated method for relative quantification of major OS is still lacking. Besides, all of the

| verbascose | $[M - H]^-$ | 0.05 | 0.25 | 0.25−250 | 0.9937 |

previous analyses adopted a standard and complex protocol for protein elimination in milk samples, which consists of chloroform/methanol extraction, residual protein precipitation by ethanol, and OS fraction drying/reconstitution. Such a multi-step sample pretreatment procedure constitutes a bottleneck for measurement throughput. To simplify the sample preparation step, we have evaluated the performance of two new methods that are simpler than the standard method.

Acetonitrile precipitation appeared to be effective for protein elimination from milk, but this solvent also caused partial loss of OS in the supernatant, leading to a significant reduction in the OS yield. This may simply result from co-precipitation of OS in the presence of acetonitrile as reported by Ku et al. in the case of fructo-oligosaccharides.[27] In contrast, ultrafiltration is not only simple to perform but also afforded a higher OS yield with better reproducibility compared to the standard method. Consequently, we believe ultrafiltration has clear advantages over the standard method for protein elimination in milk samples prior to OS analysis.

Nano-LC−chip/TOF MS has been a technique of choice for OS profiling in milk and also for glycan profiling in human serum.[19,28,29] We have shown that HILIC separation coupled to an Orbitrap MS is also highly suitable for OS profiling, owing to its superior sensitivity and high mass accuracy capability.

**Table 5. Recovery (%) of Spiked Standards ($n$ = 3)**

| OS | spike I (0.1 μg) | | | spike II (1 μg) | | |

Moreover, the Luna HILIC stationary phase that we used separated all major OS from lactose, thus avoiding the potential ion suppression effect of this most abundant sugar on the detection of other minor analogues. The minimal matrix effect observed in the recovery test may well have resulted from this. It is worth indicating that, except for 3′-SL and 6′-SL, no attempt was made to separate and quantify individual isomers of other major OS species. As a result, most major OS elute as a single peak, facilitating relative quantification.

Because of the limited availability of OS standards, we have used two galacto-oligosaccharides, stachyose (DP of 4) and verbascose (DP of 5), in the method validation to represent neutral OS. Given the similarity in molecular size and structure between these two compounds and the major neutral OS in milk, it is appropriate to assume that they have comparable ionization efficiency for MS detection. The fact that all of the tested OS standards had an on-column LOD of 0.05 ng suggests that, without any enrichment step, low-abundance OS (from 0.01 μg/mL) can be detected by this method. It should be pointed out that all OS species showed much higher response in negative ESI mode than in positive mode in our system and deprotonated molecular ions are dominant in all cases.

All OS detected in the reference sample have been identified previously in different studies.[9,14] Among the 13 major OS (of

**Table 4. Method Precision (% RSD; $n$ = 5) and Accuracy (% ± SD; $n$ = 5)**

| OS | 0.5 ng | | 5 ng | | 100 ng | |

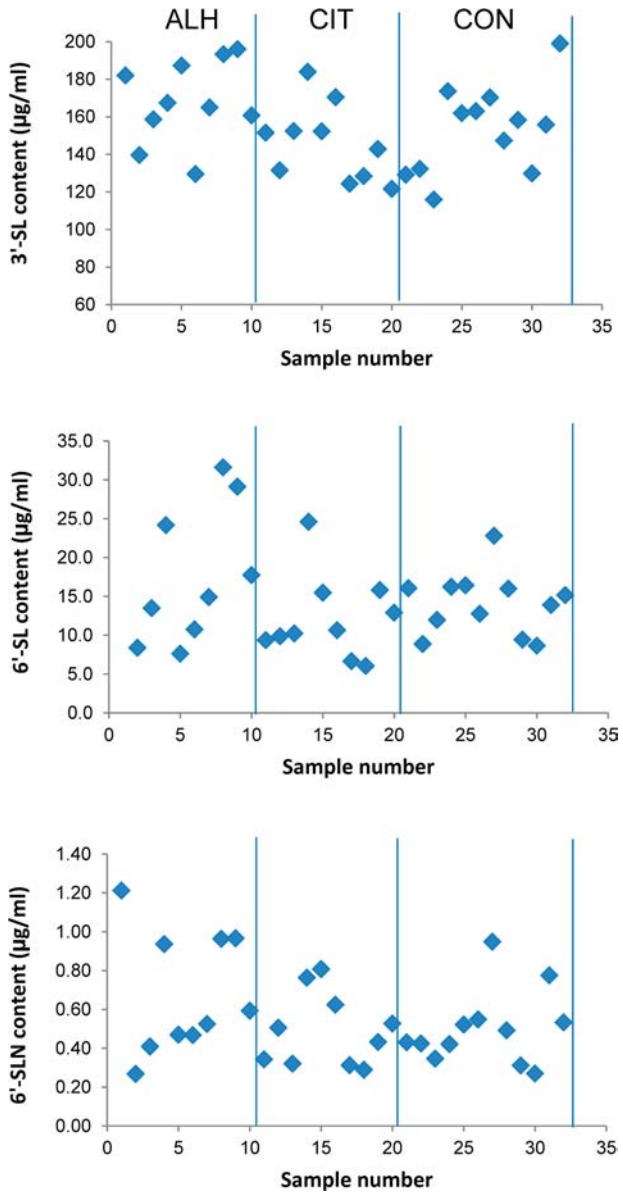

**Figure 2.** Variation in 3′-SL, 6′-SL, and 6′-SLN concentrations across the 32 samples (numbers 1−10, ALH; numbers 11−20, CIT; and numbers 21−32, CON.

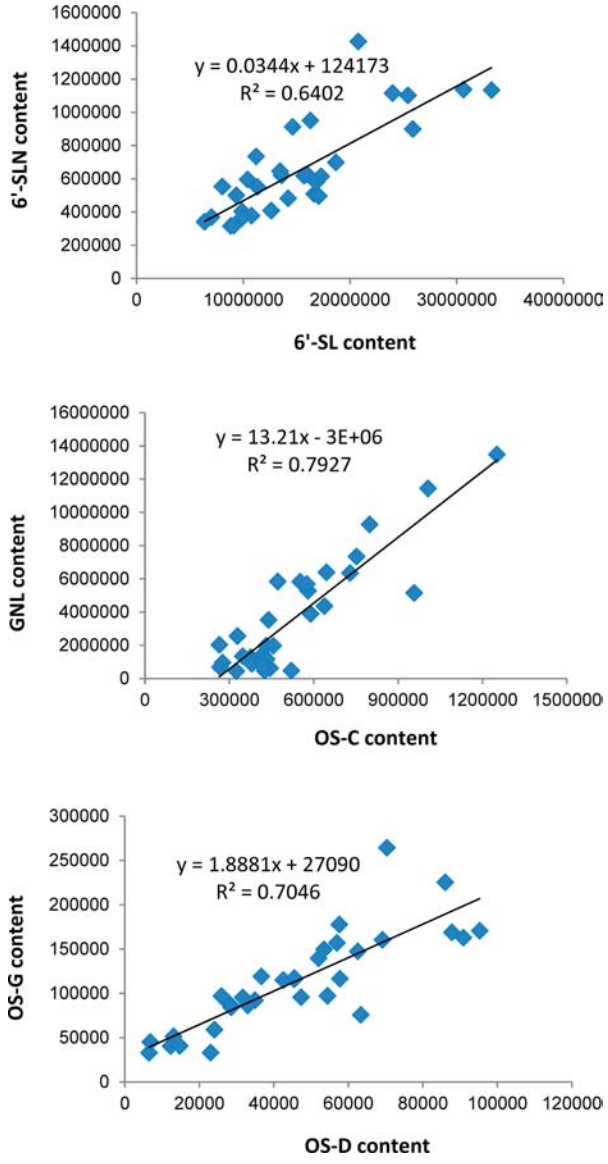

**Figure 3.** Significant correlations between the contents of some OS species ($n$ = 32).

which two are isomers) quantifiable, the structure of 12 have been reported previously.[9] Our observation of 3′-SL and 6′-SL being the most abundant OS across all samples has confirmed the results of other researchers.[12,16,18] The fact that 3′-SLN was not detected in any sample is also in agreement with the observation by Fong et al.[18] However, our finding of 6′-SLN being a low-abundance OS is significantly different to the results of Martin-Sosa et al.[15] and Tao et al.,[9] who found this same compound to be one of the most abundant OS. Such a discrepancy may be attributable to samples being derived from different cow breeds and/or lactation stages. An exhaustive search for more minor OS through sample enrichment was not the aim of this work.

Most of the previous work focused on the comprehensive identification of OS in human milk and animal milk and on the variation of the most abundant OS species, as influenced by various factors, e.g., lactation stages, mammal species, and bovine breeds. Our study has revealed the large variation of OS contents produced by individual cows of the same breed and under the same feeding regime. More samples over different seasons need to be tested to ascertain whether this is genetically based. Moreover, to increase the concentration of OS in cow milk requires a thorough understanding of OS metabolism in the mammary gland and in milk itself.[21] It has already been demonstrated that key genes for oligosaccharide synthesis undergo temporal changes in expression, and this expression differs between species.[30] In this regard, our finding regarding the correlation between some OS, which has not been reported previously to the best of our knowledge, is valuable for elucidating the biosynthesis pathways of OS. The correlation found between some OS species may be an indication of common biochemical steps used in their biosynthesis.

Our work also demonstrates the variability in the concentration of OS in milk from different cows in the same herd that is not associated with the feeding regime used in this study. This suggests that cows may be selected for their ability to produce larger quantities of certain OS that may be of value in human health products.

dx.doi.org/10.1021/jf5037849 | J. Agric. Food Chem. 2014, 62, 11568−11574

In conclusion, a novel LC−MS method has been developed, which, using a routine HILIC−LC and an Orbitrap mass analyzer, is able to provide relative quantification of 13 major OS in bovine milk with minimum sample preparation. The method is sensitive, accurate, and reproducible and can be used as an alternative to the widely used nano-LC−chip/TOF-based method. The applicability of this method to a large number of mature milk samples collected from cows after different feed treatments allowed us to confirm that almond hulls and citrus pulp when used as a feed supplement have no adverse effect on the accumulation of OS in milk.

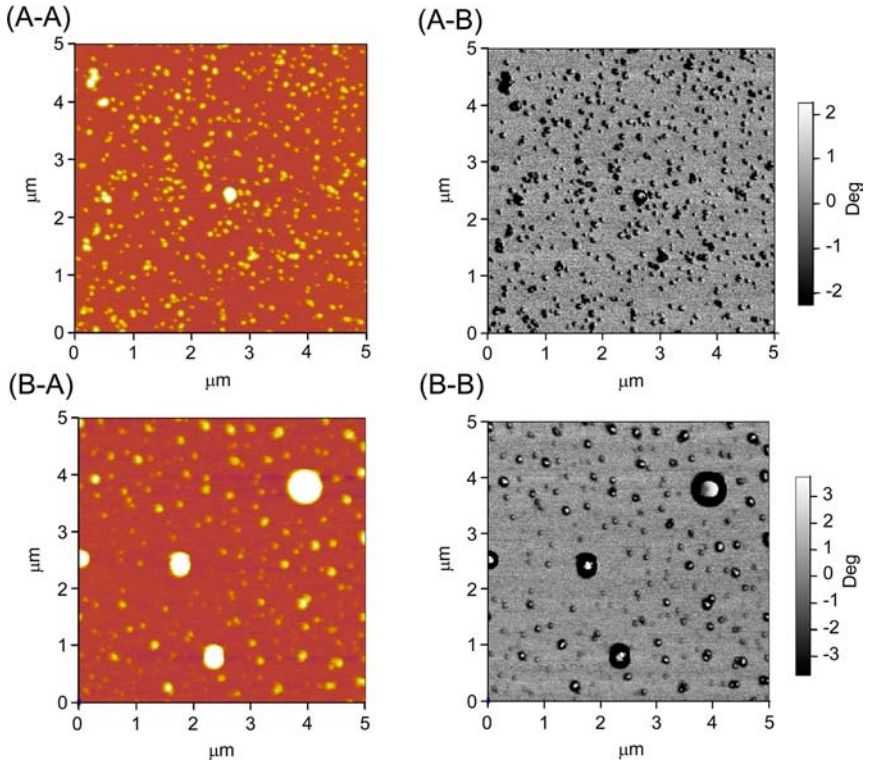

**Figure 1.** Atomic force microscopy images of fresh soybean O/W emulsions (10% w/w oil) prepared with 11.1 mg/mL Tween 20 + 20 mg/mL PPH using height retrace mode (A-A) and phase retrace mode (A-B) or with Tween 20 only using height retrace mode (B-A) and phase retrace mode (B-B) .

chased from Sigma-Aldrich Co. (St. Louis, MO, USA). All other chemicals were purchased from Sinopharm Chemical Reagent Co. (Shanghai, China), and they were of analytical grade unless otherwise specified. Deionized water was used for the preparation of all solutions.

**Preparation of Potato Protein Hydrolysate (PPH).** PPH was prepared through 1 h of hydrolysis of intact potato protein (40 mg/mL) in an aqueous solution at pH 8.0 and 50 °C using Alcalase.[3] The enzyme/protein substrate was at a weight ratio of 1:100. After hydrolysis, the broth was adjusted to pH 7.0 with 1 M NaOH and then heated at 80 °C for 15 min to inactivate the enzyme. The hydrolysate was freeze-dried, placed in sealed plastic bags, and stored at 4 °C. This PPH has been shown to be strongly antioxidative in an O/W emulsion due to its potent radical-scavenging capability.[3,14]

**Emulsion Preparation.** O/W emulsions were prepared from the mixture of 10% (w/w) soybean oil (Eastocean Oils and Grains Industries Co., Zhang Jiagang, Jiangsu, China) and 90% (w/w) 0.01 M phosphate buffer (pH 7.0) containing 11.1 mg/mL Tween 20 + 20 mg/mL PPH (treatment) or 11.1 mg/mL Tween 20 alone (control). In treatment emulsion, Tween 20 was used as coemulsifier because, unlike lecithin, Tween 80, or some other surfactants, it helps stabilize O/W emulsion droplets without affecting the oxidative stability.[13] Fine emulsions were produced by blending the mixture using a T18 Ultra-Turrax high-performance disperser (Ika-Werke Gmbh & Co., Staufen, Germany) at 21500 rpm for 2 min followed by passing through an ATS AH-basic high-pressure (32 MPa) valve homogenizer (ATS Engineering Inc., Brampton, Canada) twice.[13] The average particle size of the emulsions was determined by dynamic light scattering (DLS) (Mastersizer Nano-ZS, Malvern Instruments, Worcestershire, UK).

**Emulsion Microstructure.** Emulsion samples were diluted 10 times for the examination of the microstructure. For AFM, 2 μL of a diluted emulsion was dried on freshly cleaved mica. AFM images were obtained on Asylum MFP-3D-SA (Asylum Research, Santa Barbara, CA, USA) using the tapping mode and the phase mode. The surface of mica was scanned in air using OMCL-AC160TS cantilevers at a set point of 0.63 V, a 1 Hz scan rate, and a drive frequency of 336.3 kHz.

For CLSM, the procedure of Kerstens et al.[15] was followed. An aliquot of of 2 μL diluted emulsions was placed on a microscope slide, covered with a coverslip, and observed using a Carl Zeiss LSM 710 confocal system (Carl Zeiss MicroImaging GmbH, Göttingen, Germany) with an oil immersion 63× objective. Images were captured by a digital camera connected to the microscope. Photographs of the emulsions were analyzed using software ZEN 2008 Light Edition (Carl Zeiss MicroImaging GmbH) and recorded. The oil droplets in an emulsion were stained using Nile Red in such a way that 2.5 mL of emulsion was mixed with 25 μL of 0.1 mg/mL dye solution prepared with ethanol. On the other hand, peptides were stained with Nile Blue through mixing 2.5 mL of emulsion with 12.5 μL of the dye solution in a dye/protein ratio of 1:100. Nile Red and Nile Blue were excited at 488 and 639 nm, respectively. Emitted light was collected between 653 and 750 nm for Nile Red and between 503 and 613 nm for Nile Blue in two independent channels.

For cryo-TEM, 2 μL of a diluted emulsion was placed on a lacy carbon film supported by a copper grid and allowed to stabilize for 10 min. A filter paper was used to remove liquid for thin liquid films formation. The grid was then immersed in liquid nitrogen (−180 °C) for quenching. After 1 min, the specimen was mounted into the prechilled cryogenic sample holder (Gatan-626 Cryo-tansfer, Gatan, Inc., Tokyo, Japan), followed by being loaded to a JEOL JEM-2100 transmission electron microscope (JEOL Ltd., Tokyo, Japan) immediately. The acceleration voltage of 200 kV was used and the temperature of the holder was kept below the −170 °C during operation. The images of the specimen were captured using a digital camera connected to the microscope.

**Recovery of Interfacial Peptides.** PPH peptides present at the interfacial membrane were collected by means of centrifugation. Emulsion samples were placed in 50 mL tubes and centrifuged for 45 min at 50000*g* at 20 °C to separate into a cream layer and a serum layer. The cream layer was carefully removed using a syringe and dispersed in the same volume of 0.01 M phosphate buffer (pH 7.0). After centrifugation again under the same conditions as above to remove loosely bound peptides, the cream layer was collected and

extracted using chloroform/methanol mixture (2:1, v/v).[16] The methanol phase was dried, and the peptides were dissolved in water before analysis.

**Identification of Peptides at the Interface.** The peptide mixture obtained above was fractionated using Sephadex G15 gel filtration, and 50 fractions (2 min each) were collected. To obtain sufficient amounts of peptide samples, identical fractions from 10 separate gel filtration runs were combined and lyophilized. Each individual peptide fraction was tested for $ABTS^{\bullet+}$ scavenging activity at the protein concentration of 20 $\mu$g/mL; the fractions that exhibited strong radical scavenging aqctivity were subjected to solid phase extraction (SPE) to remove Tween 20 using a 3 mL Cleanert PCX SPE column (Agela Technologies Inc., Tianjin, China) preconditioned with 6 mL of methanol followed by 6 mL of deionized water. Peptide fractions loaded in the column were washed with 8 mL of deionized water and then 8 mL of a methanol/water solution (5:95, v/v) to remove Tween 20. Afterward, the samples were eluted with 3 mL of ammonia−water/methanol (5:95, v/v) and then dried by purging with nitrogen gas.

The purified peptide fractions were dissolved in 1 mL of water/acetonitrile (1:1, v/v). Ten microliters of the sample solutions was loaded and eluted in an Acquity UPLC BEH C18 column (2.1 × 120 mm) (Waters Corp., Milford, MA, USA). The mobile solvent (acetonitrile and formic acid for mobile phases A and B, respectively) flow rate was set at 0.3 mL/min, where a linear gradient (10−20% in 20 min for acetonitrile) was used. Eluted peptides were subjected to mass spectrometry sequencing using a Waters Synapt Mass Quadrupole TOF mass spectrometer (Waters Corp.) through an electrospray ionization source. Automated data acquisition using the information-dependent mode was performed using MassLynx software (Waters Corp.). The spectra were interpreted using the peptide sequencing module of the MassLynx software.

Properties of identified peptides were calculated using peptide property calculator from Innovagen (Innovagen AB, Lund, Sweden), which is also available at http://www.innovagen.se/peptide-design-tools.asp. The sequences identified were matched to the published sequences of potato proteins from the National Center for Biotechnology Information (NCBI) database.

**Evaluation of Radical Scavenging Activity.** The peptide fractions from the above gel filtration were diluted to 20 $\mu$g/mL and then subjected to the ABTS radical scavenging assay.[14] Briefly, samples (20 $\mu$L each) were reacted with 1980 $\mu$L of diluted $ABTS^{\bullet+}$, and the absorbance (734 nm) after 10 min was read. Radical scavenging activity was expressed as Trolox equivalent ($\mu$M) based on a standard curve generated with a series of concentrations of Trolox (0−3 mM).

**Statistical Analysis.** All experiments were repeated a minimum of three times ($n \geq 3$) in independent replication trials, each with duplicate or triplicate sample analyses. Data were subjected to one-way analysis of variance (ANOVA) using the Origin 7.5 statistics program (OriginLab Corp., Northampton, MA, USA). Differences ($P < 0.05$) between means were identified by Tukey's test.

## RESULTS AND DISCUSSION

**Emulsion Physical Stability.** The emulsions prepared either with Tween 20 alone or with Tween 20 + PPH had DLS-measured particle sizes of 215.3 and 218.1 nm, respectively. The value for the latter emulsion was larger than expected, which could have resulted from clustering of emulsion particles or peptide aggregates. Nevertheless, both the control and PPH treatment emulsions were very stable, showing no creaming even after 2 weeks of storage at 37 °C. During this period, the average particle size for both emulsions also did not show any significant change ($P > 0.05$).

**AFM.** The microscope images of emulsions prepared with Tween 20 with or without 20 mg/mL PPH are displayed in Figure 1. They represent height retrace and phase retrace obtained under the tapping mode. The emulsions prepared with combined Tween 20 and PPH (Figure 1A-A,A-B) consisted of numerous smaller and more uniformly distributed oil droplets when compared with those prepared with Tween 20 alone (Figure 1B-A,B-B). The particle numbers per measurement area (5 × 5 $\mu$m) for the two different emulsion systems were 365 and 137, respectively. This remarkable disparity was attributed to the surface activity of peptides present in PPH allowing more efficient dispersion of oil in the aqueous system.[13] In a typical O/W emulsion, the emulsifier concentration and type affect the particle size of emulsion droplets. Therefore, when PPH was combined with Tween 20, the peptides could impart additional emulsifying power by a sheer concentration effect. The imaging analysis result confirmed that the particle size measured by DLS in the PPH + Tween emulsion was likely an overestimate due to interactions between peptide-covered oil droplets and between peptides themselves. Because PPH alone was not capable of producing a stable emulsion (result not shown), there existed a cooperativity between Tween 20 and peptides.

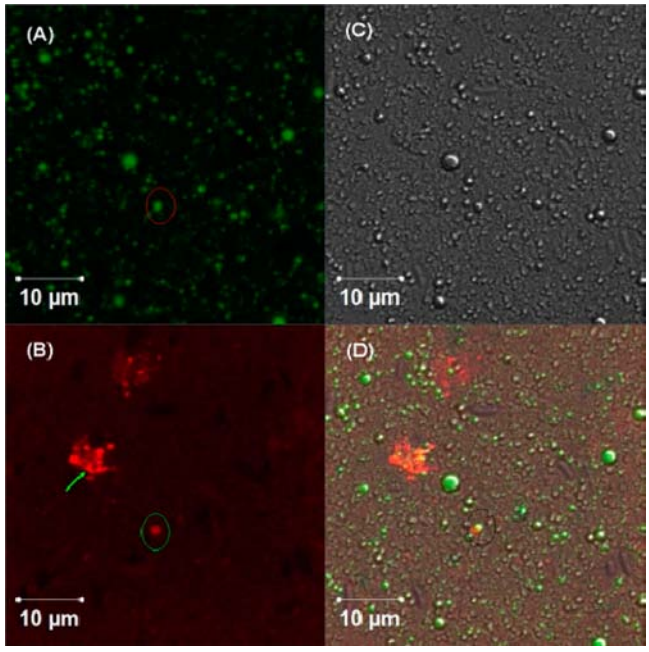

**Figure 2.** Confocal laser scanning micrographs of soybean O/W emulsions (10% w/w oil) prepared with 11.1 mg/mL Tween 20 + 20 mg/mL PPH: (A) image from Nile Red fluorescence (highlighting the oil phase); (B) image from Nile Blue/protein fluorescence; (C) phase contrast image without fluorescence; (D) overlay image combining fluorescence from both dyes. The arrow identifies a circular dark hole in the Nile Blue/protein image corresponding to a single large oil droplet. Scale bar represents 10 $\mu$m.

Phase angle shift, which is able to enhance the contrast of the AFM images, is a derivation of the tapping mode.[17,18] A phase image, taken by detecting the phase angle shift, is useful in distinguishing different chemical or physical features of the sample.[18−20] In phase images, dark and bright regions indicate different levels of hardness of the material.[20] It has been reported that interfacial characteristics and particle size affect not only the physical stability but also the chemical activity of emulsions.[21,22] An O/W emulsion could be regarded as a particle consisting of an oil core and a emulsifier shell. Because free oil inside an emulsion droplet is expected to have a higher fluidity than surface oil molecules with surfactants and the area-to-volume ratio is $3r^{-1}$ (where $r$ is radius), a large oil droplet would be softer than a small oil droplet. The poorly covered

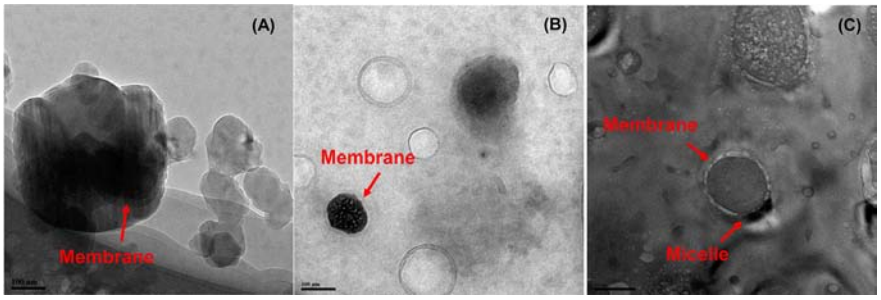

**Figure 3.** Cryo-TEM images of soybean O/W emulsions (10% w/w oil) prepared with (A) 11.1 mg/mL Tween 20, (B) 20 mg/mL PPH, and (C) 11.1 mg/mL Tween 20 + 20 mg/mL PPH. Bar = 100 nm.

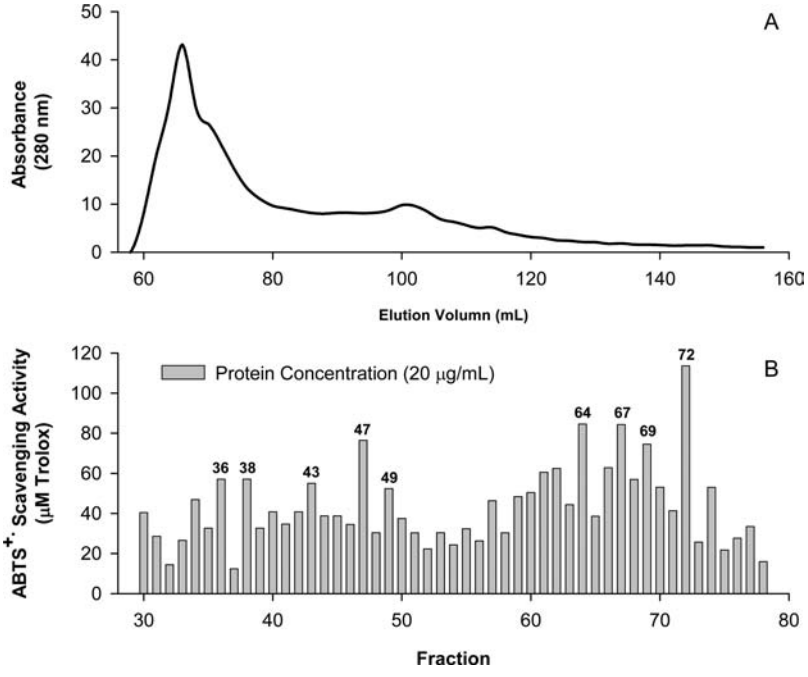

**Figure 4.** (A) Gel filtration spectra of PPH in the interface of soybean O/W emulsion prepared using 11.1 mg/mL Tween 20 + 20 mg/mL PPH; (B) $ABTS^{\bullet+}$ scavenging activity of gel filtration fractions from interfacial PPH. Every 2 mL of liquid was collected for one tube.

core region would be soft and appear bright, whereas the shell region would be hard and appear dark.

Indeed, in the Tween 20-stabilized oil emulsion, the emulsion droplets displayed a quite noticeable bright region in the surface center of the particles, indicating a soft matrix. In comparison, the emulsion prepared with combined PPH and Tween 20 exhibited a relatively dark region in the center of the oil droplets, indicating a harder or more intact membrane due to peptides. However, other parts of the surface of the emulsion droplets were not uniformly dark, suggesting that the distribution of PPH as a coemulsifier at the interface was not consistent. Moreover, the intensity of darkness appeared to be variable between oil droplets. If surface dilatational rheology measurements were carried out to determine the surface rheology, the results of AFM would be more convincing and mechanistic.

Inadequately covered (i.e., relatively exposed) surfaces of the emulsion droplets, notable for Tween 20 emulsions, would predispose the O/W emulsions to oxidative stress. When subjected to radicals and other oxidant species, the less well-protected oil particles would be prone to chemical degradation through oxidative chain reactions. Because peptides are emphateric ions, the less abundant presence of peptides at the interface would mean fewer charge repulsions against pro-oxidaitve metal and other oxidizing ionic species such as superoxide anion. Peptides located at the interface protect oil from oxidative stress through their radical scavenging activity and metal chelating actions. In addition, peptides dispersed in the aqueous phase are capable of enhancing the oxidative stability of emulsions by neutralizing radicals and sequestering pro-oxidaitve metal ions.[13,14,23]

**CLSM.** To substantiate that the physical location of peptides is an important factor for the inhibition of emulsion oxidation, CLSM images were presented to illustrate the distribution of peptides in different emulsion samples (Figure 2). Although CLSM was not able to display all particle sizes, we had found some typical particles to support out hypothesis. In these images, oil and peptides were labeled with fluorescent Nile Red and Nile Blue, respectively, enabling the delineation of peptide coating around the oil droplets. At the excitation wavelength of 639 nm, Nile Red-stained oil gave rise to a green color (Figure 2A), whereas at 488 nm, peptides stained with Nile Blue exhibited a red color (Figure 2B). The emulsion prepared with Tween 20 only showed numerous particles of varying sizes that emitted a green color. Because Tween 20 produces no fluorescence signals, these particles were oil droplets. On the

other hand, when PPH was also present during the emulsion sample preparation, the product showed several conspicuous and many faint red droplets, indicting the presence of peptides surrounding the interface. In particular, a salient oil droplet and a remarkable cluster of red-colored particles are displayed (pointed by arrows), and these were peptide-coated particles (Figure 2B). Therefore, in these emulsions, Tween 20 and PPH coexisted at the interface for improved emulsion stability. Interestingly, apparently fewer oil droplets were visible in Nile Blue-stained samples (Figure 2B) than in Nile Red-stained samples (Figure 2A). This could be due to the lesser sensitivity of Nile Blue reacting with proteins than Nile Red reacting with oil.

Similar phenomena have been observed by Gallier et al.,[24] who used CLSM to analyze the membrane of milk fat globules. When some components absorbed in the membrane were replaced by other components with no fluorescence, their position in the membrane might turn to dark pores. The most prominent particle present in Figure 2A,B (arrow) was the same particle. When these two images were superimposed (Figure 2C), the color of the particle turned yellow, which was the overlay of green and red.[15] This was clear evidence that peptides in PPH were adsorbed at the interface as coemulsifiers. It was also shown in Figure 2B that some emulsion particles were surrounded by the aqueous environment consisting of peptides. This is in agreement with the result we reported previously with common transmission electron microscopy.[13]

On the basis of the results of AFM and CLSM, peptides from PPH were present at the interface, and they were distributed either through direct adsorption on the surface of oil droplets or by reinforcing the interface covered by Tween 20. Both scenarios are in agreement with the findings of Girardet et al.[25] that $\beta$-casein(f114−169) may cover the interface with Tween 20 or adsorb around the Tween 20 covering in the interface. Thus, the peptides partitioning in the interface filled in the space between individual Tween 20 molecules and prevented the exposure of oil to oxidants by means of physical obstacles in addition to chemical mechanisms. Peptides absorbed around Tween 20 might improve the interfacial charges and modify the electric double layers of the interface. This would lead to a stronger steric hindrance and enhanced electrostatic repulsions between oil droplets and oxidizing compounds as mentioned above to prevent oxidative chain reactions.

**Cyro-TEM.** Whereas CLSM yielded strong evidence that peptides in PPH were adsorbed at the interface of the soybean O/W emulsions, the structural details of the interfacial membrane were still missing. Hence, cyro-TEM, which operates in a nondestructive mode allowing emulsion samples to be examined in their intact state, was used to analyze the morphological characteristics of the interfacial membrane. The cyro-TEM images of the emulsion prepared with Tween 20 only exhibited no clear membrane (Figure 3A), whereas the emulsion prepared with PPH only showed a relatively uniform interfacial membrane-like structure (Figure 3B). On the other hand, the interface of the emulsion prepared using combined Tween 20 and PPH displayed a structurally heterogeneous membrane made up of several fragments with different lengths (Figure 3C). It appeared that the interface membrane was not composed of a single component; both Tween 20 and peptides were present. These two emulsifiers appeared to adsorb on the surface of the oil droplets alternatively but in an irregular pattern.

The dark segment in Figure 3C might be micelles of Tween 20 surrounding the surface of the emulsifier layer. A similar interfacial structure identified as a casein micelle sheath was found by other researchers who applied cyro-TEM to analyze the ultrastructure of dairy products.[26] It is possible that Tween 20 micelles, together with peptides from PPH, acted as physical barriers to prevent the penetration of peroxides and metal pro-oxidants, thereby inhibiting the oxidation of the oil.[12] Although the interfacial membrane of the emulsions prepared with combined Tween 20 and PPH appeared to be less tight than

[a]From National Center for Biotechnology Information (NCBI).

the thin film in the emulsions prepared with Tween 20, the former clearly exhibited higher oxidation stability. This was not surprising because, in addition to the proposed physical effect, peptides can act as strong radical scavengers and reducing agents.[13,14] Emulsions stabilized by $\alpha$-lactalbumin and $\beta$-lactoglobulin, which exhibited similar thickness when absorbed in the emulsion interface, showed different oxidative stabilities for their different structures and properties in the interface.[27,28] It has been demonstrated that antioxidants partitioning at the O/W interface are more effective than antioxidants present in the aqueous phase in suppressing free radical.[29]

**Identification and Characterization of Interfacial Peptides.** As PPH distributed in the interface was still a mixture of peptides, it was fractionated using G15 gel filtration. Fractions 36, 38, 43, 47, 49, 64, 67, 69, and 72, which exhibited notably higher ($P < 0.05$) ABTS radical scavenging ability than most other fractions and represented a broad fraction distribution (Figure 4), were further analyzed. These selected fractions were subjected to UPLC-Q-TOF-MS for peptide separation and sequence identification. They were also characterized for physical properties to help explain their physical role in the mechanism of oxidation inhibition by PPH at the interfacial membrane. As displayed in Table 1, altogether 17 peptides were identified. The molecular weights ranged from 200 to 800 Da, corresponding to dipeptides to heptapeptides. The anchorage of peptides at the interface was thought to be independent of peptide length;[30] short peptides were able to participate at the interface and might fill the gap between monolayer Tween 20 molecules. Lysine, arginine, glutamic acid, aspartic acid, proline, and leucine were the most abundant amino acids in the peptides identified. The free amino group in lysine and arginine and free carboxyl group in glutamic acid and aspartic acid, which possess a pair of free electrons, were able to chelate pro-oxidative metal ions such as $Fe^{2+}$ and $Cu^{2+}$ through electrostatic coordination. The sequestration action would lead to less catalysis activity of metal ions and, hence, reduced lipid oxidation.

Proline and leucine, which were prone to oxidation, were contained in the peptides that exhibited high ABTS radical scavenging ability. It has been widely reported that many bioactive peptides are made up of two to nine amino acids. Proline, lysine, and arginine, along with most hydrophobic amino acids, were commonly present in antioxidative peptides.[31] This was not surprising because, during the course of neutralizing free radicals as antioxidants, these amino acid residues were sacrificed.[32] The hydrophobic amino acids that were identified in the peptides were leucine, methionine, phenylalanine, and tyrosine. These amino acids can effectively associate with hydrophobic group in lipids or Tween 20 through hydrophobic effect, shielding the oil droplets from oxidant attack.

Of the total amino acid constituents, the ratio of hydrophilic residues to total number of residues was 45% (Table 2). A similar ratio also applied to hydrophobic residues. The well-balanced hydrophilicity−hydrophobicity explained excellent partitioning of these identified peptides at the interface. Furthermore, the average hydrophilicity of the peptides displayed a small part of the peptides being negatively charged but a large part carrying positive charges. That could lead to different partitions of the peptides. In general, strongly hydrophobic peptides would effectively partition in the oil−water interface with Tween 20, whereasa strongly hydrophilic peptides would have the propensity to form a secondary layer surrounding the inner layer made up of hydrophobic peptides and Tween 20 by weak interactions. Most of the hydrophilic peptides exhibited a net positive charge. The ability of peptides to repel metal ions or other oxidizing ionic species from lipid in the microenvironment of the interface would improve the oxidative stability of emulsified lipid.[4,5]

The identified peptides extracted from the emulsion interface were matched with the known sequence of potato proteins available in the database (BLAST program in NCBI). A portion of several peptides matched the peptide sequences of potato protein either partially or totally (Table 3). Although most of the proteins are not the major proteins in potato, the peptide SFDIK matched the peptide sequence of patatin, which is the most abundant potato protein. However, the peptide SFDIK was not among the antioxidative peptides identified in our previous work.[14,23] This indicated that antioxidative peptides identified in our previous studies might be mostly located in the aqueous phase of the emulsions and act as an active blocking agent to prevent the passage of oxidants to the interface. It was clear that antioxidative peptides, including SFDIK, in the interfacial membrane functioned through both physical and chemical mechanisms.

In conclusion, the partition of peptides in the soybean O/W emulsion membrane was demonstrated using several biophysical methods. The results implied that peptides may be present in two different modes: (1) as an integral part of the interfacial membrane through partitioning and (2) forming a surrounding layer immediately adjacent to the inner interface layer through weak forces. The peptides comprising the interface were mostly small peptides made up of hydrophobic and hydrophilic amino acids, of which peptide SFDIK matched

the sequence of patatin. The antioxidant mechanism of peptides in the emulsion interface seemed to be both physical action including steric hindrance and possibly electrostatic effects and chemical action including radical scavenging capability. Further research should be carried out to measure the interfacial rheology in relation to the complex membrane structure so as to produce oxidation-resistant food emulsions.

degree of flavan-3-ol polymerization was found to have little effect on the kinetics of ACN loss and the color of pigments produced,[9,15] potentially indicating a minor role for tannin molecular mass in conferring a specific reactivity with ACN.

Yet, as highlighted above, skin tannin has a far higher mDP than seed tannin, and the relative reactivities of tannins of different sizes and compositions for ACN have not yet been studied. Whereas the detailed identification and quantification of low molecular mass ACN derivatives in model and commercial wines has been achieved using mass spectroscopy,[14,16,17] the pigmented tannin fraction is only partially resolved using LC-MS.[18] A review[11] has highlighted that research in this area is limited by a lack of information on the molecular mass distribution of grape flavanols and their reaction products in wine. In particular, there is limited information regarding grape tannins and their pigmented reaction products with ACN. A recent paper has indicated that the progression of red color incorporation to wine tannin is skewed in favor of smaller pigments in young wines, with a gradual conversion of larger, unpigmented tannin to smaller colored species during aging.[19] This highlights that the factors which drive partitioning of ACN to either complex with tannin or form low molecular mass pigments are currently unknown, leaving scope for aspects of earlier experiments[1,9,15] to be revisited.

It remains to be established how nonbleachable pigments, including polymeric pigments, form in the presence of tannins of very different structural characteristics. Using traditional techniques for colorimetric analysis of wines[20,21] in conjunction with newer methods to characterize wine pigmented polymers by solid-phase extraction (SPE),[22] phloroglucinolysis,[23] and gel permeation chromatography (GPC),[24] these knowledge gaps have been explored.

## MATERIALS AND METHODS

**Instrumentation.** An Agilent model 1100 HPLC (Agilent Technologies Australia Pty Ltd., Melbourne, Australia) was used with Chemstation software for chromatographic analyses.

**Grape Tannin Isolation.** Grapes were obtained from a 10-year-old commercial *V. vinifera* L. cv. Cabernet Sauvignon vineyard in the Langhorne Creek growing region of South Australia. Grapes were harvested corresponding with a commercial harvest point of ≅23 °Brix in the 2009 season. Skin and seed components were prepared from a 300-berry sample and were visually free of flesh material at the point of extraction. Tannin was extracted from frozen skins and seeds in 70% v/v acetone/water for 18 h and then purified from acetone extracts as described previously.[25] Extracts were concentrated under reduced pressure at 35 °C to remove acetone and then extracted with hexane to remove residual lipophilic material. The aqueous fraction was then recovered using a separatory funnel and made up to a final concentration of 60% v/v methanol containing 0.05% v/v trifluoroacetic acid (TFA) and applied (∼18.3 mL/min) to a 300 mm × 21 mm glass column (Michel-Miller, Vineland, NJ, USA) containing Sephadex LH20 chromatography resin (Amersham, Uppsala, Sweden) to a bed volume of 93 mL. Low molecular weight phenolics were eluted with 300 mL of 60% (v/v) HPLC grade methanol containing 0.05% v/v TFA. Tannin was then eluted with 250 mL of 70% v/v acetone containing 0.05% v/v TFA. The column was re-equilibrated with 60% v/v methanol containing 0.05% v/v TFA after each sample. The tannin fractions eluted were concentrated under reduced pressure at 35 °C to remove organic solvent and the aqueous fraction recovered (≅5 mL). The aqueous fraction was frozen at −80 °C and lyophilized to a dry powder. Dried tannin isolates were stored in the dark and under nitrogen at −20 °C prior to use.

**Grape Anthocyanin Isolation.** Shiraz grapes were sourced from the Coombe Vineyard, University of Adelaide, South Australia, at commercial ripeness (24 °Brix) in the 2011 season. Whole bunches were frozen at −20 °C until used. A 1 kg bunch sample was destemmed, allowed to thaw at room temperature, crushed, and partially homogenized using a blender. A 250 g sample of the coarse homogenate was extracted for 18 h with 2 L of 50% v/v MeOH, filtered, and concentrated under reduced pressure at 30 °C. The aqueous extract was loaded in 100 mL batches to a Toyopearl (660 mL bed volume) column equilibrated with 0.1% v/v aqueous TFA, and water-soluble nonadsorbent compounds were eluted in a further 2 L of 0.1% v/v TFA. The 3-*O*-monoglucoside ACN fraction was eluted with 1.5 L of 30% v/v MeOH containing 0.1% v/v aqueous TFA. The column was then washed with 2 L of 2:1 v/v acetone/water and re-equilibrated with 2 L of 0.1% v/v aqueous TFA. The eluate was concentrated under reduced pressure, frozen at −80 °C, and then lyophilized, yielding ≅200 mg of dry 3-*O*-monoglucoside ACNs, which were stored under nitrogen at −80 °C until used. Extract purity was verified by HPLC,[26] indicating the extract was free of acetylated or coumaroylated ACNs, other monomeric flavonoids, and polymeric material. It was found to have trace quantities of early eluting material at 280 nm, but this was below the detection limit for quantification. A calibration curve was established for the gravimetric concentration of the ACN isolate and the concentration estimated spectrophotometrically according to the method in ref 26 and is shown as Supporting Information (S1). This was to approximate the concentration of ACN addition (using the spectral method) to the concentration expected in grapes.

**Treatments.** Chemically defined medium (CDM) was based on the compositional specifications described by Schmidt et al.[27] All components used to prepare CDM were from Sigma-Aldrich, St. Louis, MO, USA. CDM was prepared in Milli-Q water as described by Contreras et al.[28] and contained (per L) glucose, 100 g; fructose, 100 g; citric acid, 0.2 g; malic acid, 3 g; potassium hydrogen tartrate, 2.5 g; $K_2HPO_4$, 1.1 g; $MgSO_4{\cdot}7H_2O$, 1.5 g; $CaCl_2{\cdot}2H_2O$, 0.4 g; $H_3BO_3$, 0.04 g; and proline, 0.84 g. To this solution were added stock solutions (described below) of nitrogen (20 mL), trace elements (1 mL), and vitamin (1 mL); the pH was adjusted to 3.5, and the mixture was sterile-filtered. The nitrogen stock solution contained the following (per L): 30% ammonium hydroxide solution, 27.7 g; alanine, 10.5 g; γ-amino butyrate, 7.2 g; arginine, 26.9 g; asparagine, 0.4 g; aspartate, 3.0 g; citrulline, 0.4 g; glutamate, 6.0 g; glutamine, 8.4 g; glycine, 0.4 g; histidine, 1.2 g; isoleucine, 1.2 g; leucine, 1.2 g; lysine, 0.4 g; methionine, 0.4 g; ornithine, 0.4 g; phenylalanine, 0.8 g; serine, 5.4 g; threonine, 6.0 g; tryptophan, 0.4 g; tyrosine, 0.4 g; valine, 2.1 g; and cysteine, 1.2 g. The trace elements stock solution contained (per L) $MnSO_4{\cdot}H_2O$, 3.5 g; $ZnCl_2$, 1.0 g; $FeSO_4{\cdot}7H_2O$, 6.0 g; $CuSO_4{\cdot}5H_2O$, 1.5 g; $KIO_3$, 0.01 g; $Co(NO_3)_2{\cdot}6H_2O$, 0.03 g; $Na_2MoO_4{\cdot}2H_2O$, 0.025 g; LiCl, 0.1 g; $NiSO_4{\cdot}6H_2O$, 0.05 g; and RbCl, 0.7 g. The vitamin stock solution contained (per L) thiamin HCl, 0.5 g; riboflavin, 0.2 g; pyridoxine HCl, 1.0 g; calcium D-pantothenate, 1.0 g; nicotinic acid, 1.0 g; *myo*-inositol, 10 g; biotin, 0.05 g; folic acid, 0.05 g; and 4-aminobenzoic acid, 0.05 g. Following sterile filtration, fatty acid and sterol (both 1 mL) stock solutions were added. The fatty acid stock solution contained (per L absolute ethanol) palmitic acids, 2.0 g; oleic acid, 1.0 g; linoleic acid, 3 g; and linolenic acid, 0.5 g. The sterol stock solution contained 1 g/L β-sitosterol in absolute ethanol.

Purified ACN, skin (Sk), and seed (Sd) tannin extracts were prepared as separate solutions either in sterile CDM or as a weakly acidified solution in 15% v/v ethanol containing 0.01% v/v TFA. Triplicate treatments were prepared with or without additions according to the experimental outline in Figure 1 to a final volume of 30 mL in 50 mL centrifuge tubes. Target final gravimetric ACN and tannin additions in 30 mL of CDM or 15% v/v acidified ethanol were to achieve concentrations of 1.15 and 1.5 g/L, respectively. For 15% v/v ethanol 0.01% v/v TFA treatments, additions were made at the same time, and tubes were sealed and mixed by shaking for 24 h prior to analysis. For ferments in CDM, ACN additions were made as a 5 mL aliquot in CDM prior to inoculation of yeast. Tannin addition was made as a 5 mL aliquot in CDM 24 h after inoculation to minimize the risk of yeast inhibition by excess tannin. The difference in the timing and type of additions was not found to affect fermentation kinetics.

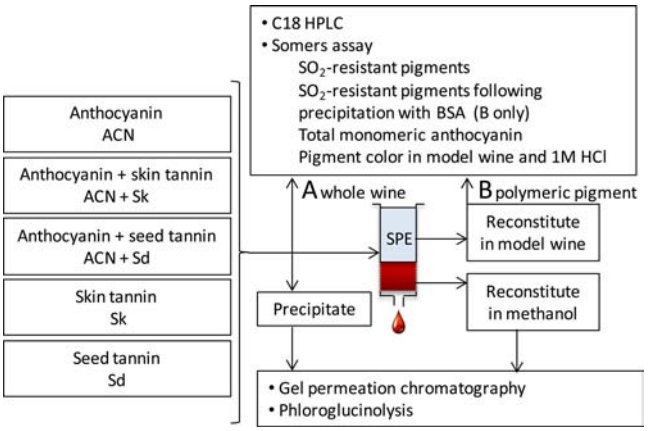

**Figure 1.** Diagrammatic representation of treatments, isolation of polymeric pigments, and general analysis performed.

For CDM ferments, the yeast added was *Saccharomyces cerevisiae* PDM (Maurivin, Sydney, Australia) at 200 ppm. After inoculation with yeast, tubes were sealed with a lid fitted with a gas release port. Ferments were carried out open to the atmosphere for 24 h at 22 °C in a temperature-controlled room and then sealed in plastic containers fitted with an airlock to continue fermentation. Glucose concentration was tracked during ferment using the Keto Diabur 5000 test strips (Roche Diagnostics, NSW, Australia), and following each sampling point, dry ice was added to the plastic ferment receptacles to minimize oxidation. When glucose fermented to dryness, a final aliquot was removed and tested for residual fructose and final ethanol concentrations by HPLC.[29] Fructose concentration was <0.5% w/v and ethanol was 10% v/v for all treatments, indicating complete fermentation. Although the target alcohol concentration of CDM ferments is lower than that of red wine, the approach was selected in favor of bottled wine or fresh grape juice to conduct the experiments under controlled conditions, in accordance with published experiments,[28] enabling comparison and replication in future studies. Model ferments did not undergo malolactic fermentation, were sealed under $CO_2$, and cold-settled at 4 °C. Completed ferments were centrifuged at 1730*g* for 5 min. Aliquots of wines and 15% v/v ethanol controls were sealed in glass vials with no ullage and placed in kegs that were fitted with a PreSens Pst6 oxygen sensor (Presens, Regensburg, Germany) and flushed with nitrogen. This system is described in detail in the Supporting Information (S2). A slight positive pressure of nitrogen was maintained and the oxygen concentration in the kegs maintained below 10 ppb. Samples were stored anaerobically for 6 months at 22 °C.

**Analysis of Tannin, Anthocyanin, and Pigments.** General analyses performed are summarized in Figure 1. Treatments at 0 and 6 months were centrifuged for 5 min at 16000*g*. Tannin concentration was analyzed in duplicate according to the published methyl cellulose precipitation assay.[26] ACN and pigment analysis was only done in treatments containing ACN, except for the Sk treatments. For Sk treatments with ACN addition, the Sk control was included as sample blank due to a minor contribution of color (but not monomeric ACN), which resulted from the tannin preparation step. Sample aliquots were analyzed by HPLC according to the method described by Mercurio et al.[26] ACNs, derived pigments, and polymeric pigments were quantified using their peak areas at 520 nm as malvidin-3-glucoside units based on a commercial standard (Polyphenols Laboratories, Norway). Vitisin A was identified according to its retention time and UV−visible spectrum (200−600 nm) in comparison with a synthesized standard[30] (Supporting Information S3). Vitisin B was not detected under the chromatographic conditions. The polymeric fraction, coeluting with tannin[26] as well as other nonpolymeric red pigments apparent by HPLC with absorbance maxima at 520−540 and 270 nm (Supporting Information S3), were quantified as malvidin-3-glucoside equivalents. After 6 months, polymeric pigments from triplicate experiments were purified from wine samples using SPE[22] with the modifications outlined in Kassara and Kennedy.[31] Duplicate extractions were done on 1 mL wine aliquots as preparation for different types of analysis. The first of the duplicate SPE extracts was reconstituted in 1 mL of model wine buffer containing 0.5% (w/v) tartaric acid and 12% (v/v) ethanol (pH 3.4). Color characteristics of unpurified treatments and SPE isolates were determined using a published protocol,[26] for which a brief description follows. All spectral analysis was performed in duplicate in a 370 μL 96-well UV plate, and 420 and 520 nm absorbances were measured using a SpectraMax M2Microplate Reader (Molecular Devices, Australia). Readings were corrected using an appropriate sample blank and a water constant correct function to approximate a 1 cm path length. For determination of total ACN, a 20 μL sample aliquot was added to 980 μL of 1 M HCl and mixed. Samples were left to stand in the dark for 1 h and a 300 μL aliquot analyzed. The 1 h period was modified from the original method stipulating 3 h, as we had demonstrated that maximal ionization of ACNs was achievable within this period (data not shown). A further 100 μL sample aliquot was added to 900 μL of model wine buffer and mixed, and a 300 μL aliquot was analyzed immediately. Buffer solution was also prepared containing 0.375% (w/v) sodium metabisulfite, and 900 μL was combined with a 100 μL sample aliquot, mixed, and left to stand in the dark for 1 h. Thereafter, a 300 μL aliquot was analyzed. Estimates of ACN were determined according to the calculations outlined in the published method.[26] The 520 nm analysis in the respective solutions were used to determine pigment color at pH 3.4 in 1 M HCl and in the presence of sodium metabisulfite ($SO_2$-resistant pigment). The 420 nm measure was not found to vary significantly during the limited aging period and was thereafter not included in the assessment of pigment color. Furthermore, the SPE isolate reconstituted in model wine was analyzed for protein precipitability of nonbleachable pigments using a published protocol.[32]

The second of the duplicate SPE extracts and a 1 mL aliquot of the treatments stored in 15% v/v ethanol were dried under a stream of nitrogen at 30 °C and reconstituted in 100 μL of methanol. Lyophilized powders of purified Sk and Sd tannins (pre-ferment) were reconsituted in methanol to a gravimetric concentration of 10 g/L and analyzed in duplicate, as described for the other samples. In wines, a small amount of precipitate was observed after 6 months of aging, which was not found for tannin solutions stored in 15% v/v acidified ethanol. The wine layer was carefully removed using a glass dropper to recover the precipitate. Wine precipitates were dried under a stream of nitrogen at 30 °C and reconstituted in methanol. Methanolic solutions of purified tannins, SPE isolates, dried (aged) ethanol solutions, and precipitates were analyzed by phloroglucinolysis and GPC using published protocols.[25,33] For phloroglucinolysis, (−)-epicatechin (Sigma-Aldrich, St. Louis, MO, USA) was the quantitative standard. To determine the proportion of wine tannin as precipitate, or retained in solution, the assumption was made that conversion yield differences would not differ significantly between the two fractions. Therefore, the proportion (%) of total wine tannin as precipitate was calculated directly from phloroglucinolysis product yields (on a mg/L wine volume basis). For GPC, separate calibration curves were established for skin and seed tannins using molecular mass standards reported previously.[33] This decision was based on our previous observation that seed and skin tannins differ in their hydrodynamic volume. In addition, oligomeric ACN-derived pigments and a standard of the chloride of malvidin-3-*O*-glucoside of molecular mass 528.9 g/mol (Polyphenols Laboratories, Norway) were analyzed by GPC, and nominal molecular mass values were assigned using the skin tannin calibration.

**Mass Spectrometric Analysis.** The SPE isolates of the 0- and 6-month-aged ACN wines and purified ACNs were mixed with the same portion of 0.25% v/v formic acid in 50% v/v methanol and then analyzed by direct infusion MS and MS/MS. The sample was infused to an electrospray (ESI) interface at a flow rate of 5 μL/min using a syringe pump (Harvard, Holliston, MA, USA). Mass spectrometric analysis was carried out using a 4000 QTrap mass spectrometer equipped with a Turbo ion source (AB Sciex, Mount Waverly, VIC, Australia). Data acquisition and processing were performed using

Table 1. General Compositional Analysis of Grape Skin and Seed Tannins and Their Combinations with Anthocyanin (ACN), Prepared in Acidified Aqueous Ethanol (15% EtOH) or Fermented and Stored Anaerobically for 6 Months[a]

[a]Data are the mean ± standard error. The control treatment was the respective purified seed or skin tannin powder at the point of addition to 15% v/v ethanol solution or model ferment. ACN, anthocyanin addition. Significant differences between ACN, seed tannin, or skin tannin additions in 15% v/v aqueous ethanol (15% EtOH) or wine after 6 months are compared with the respective skin and seed control preaddition using Dunnett's control test, where a significant difference is indicated by an asterisk. [b]Mass conversion is the recovery of tannin as its component subunits by phloroglucinolysis, as a proportion of the control, as the gravimetric mass. [c]Mean degree of polymerization. [d]Molar proportion of (−)-epicatechin-3-*O*-gallate expressed as the percentage galloylation. [e]Molar proportion of (−)-epigallocatechin expressed as the percentage prodelphinidin.

Analyst software 1.4.2 (AB Sciex). All ESI mass spectrometric data were obtained in positive ion mode. Nitrogen was used as curtain and nebulizer gases set at 10 and 12 (arbitrary units), respectively. The electrospray and declustering potentials were set at 5000 and 120 V, respectively. Mass spectra were obtained by linear ion trap mode. A full scan spectrum ranging from $m/z$ 300 to 2500 and a product ion spectrum from precursor ions of interest were consecutively accumulated until approximate ion intensity was obtained. For MS/MS, nitrogen was used as a collision gas setting at "high" and the collision energy was optimized in the range 30−60 eV as appropriate.

**Statistical Analysis.** Significant differences between treatments were determined by one-way analysis of variance (ANOVA). When ANOVA data were significant at $p < 0.05$ and follow-up statistics were required, differences between sample sets were analyzed by a post hoc Student's $t$ test. Dunnett's test was used for comparison of multiple treatments against a single pretreatment control. The JMP 5.0.1 statistical software package (SAS, Cary, NC, USA) was used for all statistical analysis.

## RESULTS AND DISCUSSION

**Tannin Concentration and Subunit Composition.** Tannin compositional information determined by phloroglucinolysis is shown in Table 1. According to the respective subunit yields by phloroglucinolysis, the Sd tannin extract prior to fermentation and aging had a higher conversion to component subunits on a w/w basis (% mass conversion) than the corresponding Sk tannin extract, at 76 and 65%, respectively (Table 1). It has been shown in various studies that seed and skin tannins differ in their conversion yields from phloroglucinolysis by ripeness stage and grape variety.[23,25,33,34] The composition of the Sd and Sk isolates pre-addition were clearly different, with Sd tannins having a far lower mDP as determined by phloroglucinolysis compared with Sk tannin. Sd tannins were distinguished by a high degree of galloylation (Table 1), which was low in Sk tannin at <2% (data not shown). Sk tannin contained a high molar proportion of trihydroxylated prodelphinidin as an extension unit (Table 1). It is important to note that the tannin preparation method using 70% v/v acetone extract tannins of a higher molecular mass than would be expected in wine. The tannins studied therefore provide a useful comparison of two extremes in tannin size distribution, molecular mass, and subunit composition, but cannot be said to be compositionally specific to wine. A marked decrease in tannin mass conversion was found following the 6 month aging of wines (Table 1). For the corresponding tannin combinations stored in acidified 15% v/v ethanol, mass conversion decreased ≅20% for Sk solutions after 6 months, but was unchanged in Sd solutions. The reduction in tannin mass conversion in aged ferment treatments was between 45 and 61%, and no trend was observed for Sd or Sk tannin preferentially or their respective combinations with ACN. Noting that the reduction in mass conversion could have been the result of tannin loss through precipitation, this was also quantified (Supporting Information S4). In wines, tannin precipitates were observed in all treatments, but were not found for stored acidified 15% v/v ethanol solutions. The absolute loss of wine tannin as precipitate was approximately 10% of the initial addition, with the exception of the Sd wine, for which tannin loss was only 4% (Supporting Information S4). Analysis of tannin before and after the 6 month aging period using the methyl cellulose precipitable tannin assay[26] confirmed these observations, showing that a reduction in tannin concentration did not occur during fermentation, but only during the aging of wine samples (data not shown).

Although the current results indicate that the reduction in wine tannin mass conversion with aging was the result of some tannin becoming insoluble, the decrease in percent conversion yield exceeded losses through precipitation. The decrease in mass conversion most likely reflects an altered tannin structure, with the incorporation of bonds resistant to acid-catalyzed depolymerization in the presence of phloroglucinol. This process is expected during wine aging[19,35,36] and has been suggested to be the result of multiple reactions, namely, acid-catalyzed depolymerization, condensation, rearrangement, and oxidation.[35] Specifically regarding the effect of oxidation reactions, a small reduction in the mass conversion of seed tannins (3.7%) has been reported following direct oxidation, with little change in tannin mDP.[37] The current study showed only small, nonsignificant changes in tannin mDP after 6 months (Table 1). However, the expected loss in tannin mass conversion resulting from oxidation (3.7−11.5%)[37] is far less than that observed during wine aging.[19,35,36] Although oxidation reactions cannot be definitively be excluded, it would be expected to contribute minimally to the observed changes and fails to account for the large difference in mass conversion between wines and 15% ethanol treatments.

An additional possibility that might reduce tannin mass conversion is depolymerization reactions under wine-like pH conditions.[38] At wine-like pH, decreased tannin mDP has been noted in model solutions of tannin and monomeric flavan-3-ols, consistent with the acid-catalyzed cleavage of interflavan bonds and subsequent incorporation of a flavan-3-ol. This process is supported by observed decreases in tannin mDP during the aging of real wine systems.[19,35,39] However, when monomeric

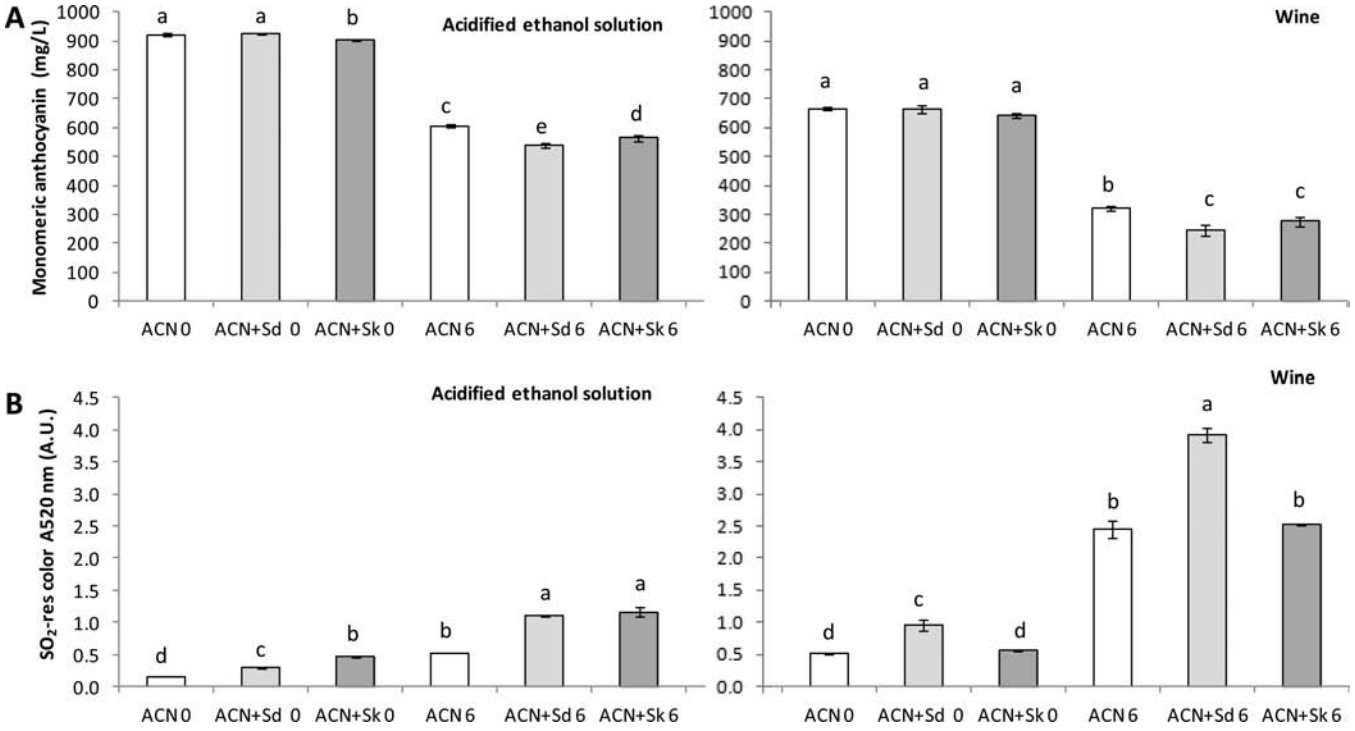

**Figure 2.** Changes in (A) monomeric anthocyanin and (B) nonbleachable pigments during the aging of anthocyanin (ACN, white bars) and its respective combinations with seed tannin (ACN+Sd, light gray bars) or skin tannin (ACN+Sk, dark gray bars) stored anaerobically for 6 months (initial analysis indicated as 0, after aging as 6) in 15% v/v acidified ethanol solution or as wine following fermentation. Significant differences between additions in their respective storage solutions are indicated by different letters, determined by one-way ANOVA, $P < 0.0001$, $n = 9$, followed by a post hoc Student's $t$ test.

flavan-3-ol is not present, such as in the current study, the loss of tannin subunits following acidic cleavage could lead to less significant changes in tannin mDP. This would appear to be supported by the current results. However, at wine-like pH[38] the condensation of ACN with tannin could occur in the absence of competing flavanols.[40] Evidence for this process exists up to the level of oligomers.[18,41,42] It would be expected that under mildly acidic conditions, that cleavage of the tannin polymer could yield smaller polymeric species with the addition of ACN, but would be expected to result in detectable changes in mDP subunit composition. On the contrary, in addition to the minimal effect on mDP, we also observed that the change in tannin subunit composition was minor, with Sd and Sk wines having only a marginally lower percent galloylation and percent prodelphinidin in comparison with the original tannin isolate (Table 1). Furthermore, no significant differences were observed in either tannin mass conversion or composition in the presence or absence of ACN. It is therefore likely that the aging reactions proceeded with tannin polymers in the nucleophilic form under the weakly acidic pH conditions.

On the basis of these observations, it appears that neither oxidation nor interflavan cleavage contributed significantly to the loss in mass conversion by phloroglucinolysis. Both of these mechanisms also fail to account for the marked differences in the responses of wine and 15% v/v ethanol preparations during aging. Although the CDM ferment approach has a lower target alcohol level than found in standard red wines, it enables the effect of a defined "wine matrix" in terms of yeast metabolites to be produced during fermentation. For the current results, we therefore propose that conditions produced during fermentation enhanced the formation of interflavan linkages leading to a reduction in tannin mass conversion, but there was limited evidence for cleavage of the tannin under the storage conditions.

**Anthocyanin, Pigment, and Color Properties.** ACN was found to decrease during the aging of both 15% v/v ethanol solutions and wines (Figure 2A). The estimate of ACN using the spectral method[26] approximates monomeric ACNs by subtracting the contribution of the $SO_2$-resistant fraction from total red color in ionized form[20] and is expected to correlate well with HPLC analysis.[26] In 15% v/v ethanol solutions ACN, measures of monomers using the spectral and HPLC methods were well-related, decreasing with age (Table 2). There were small increases in $SO_2$-resistant pigments in 15% v/v ethanol

solutions with aging (Figure 2B). However, apart from monomeric ACN, and a small increase in pigmentation within the tannin peak[26] during aging, no small (nonpolymeric) derived pigments were detected by HPLC (data not shown). Although potentially limited by the techniques used, this may indicate that the losses in monomeric ACN in aqueous ethanol were due to degradation or ACN−ACN condensation reactions[12] resulting in the colorless flavene ACN form. The reduction in monomeric ACN and the formation of $SO_2$-resistant pigments was higher in ethanol solutions containing tannin, confirming that some condensation of ACN and tannin may have occurred, maintaining the colored flavylium form of the ACN.[42] However, as alluded to in earlier studies,[8] it appears that this route of pigment formation is slow.

In contrast, the development of $SO_2$-resistant pigments in wine treatments was rapid, being similar to the aged 15% v/v ethanol treatments at the end of fermentation and then increasing markedly after 6 months of aging (Figure 2). The pattern of ACN loss and pigment formation in wine treatments differed markedly from that in 15% v/v ethanol solutions. In young wines, a reduction in monomeric ACN had already occurred during fermentation, with significant formation of $SO_2$-resistant pigments, including vitisin A and a number of derived pigments that were not identified, but quantified on the basis of their 520 nm absorbances (Table 3; Figure 2; Supporting Information S3). Hence, the initial concentration of monomeric ACN was lower in young wines than in ethanol solutions (Table 2). The correlation between measures of monomeric ACN using the spectral approach and HPLC were well-related in young wines, but were poorly related after aging (Table 3), likely indicating the high bleachability of a fraction of derived pigments by bisulfite.[20]

In wines, the reduction of monomeric ACN with aging was greatest in the treatment containing Sd tannin, followed by Sk tannin (Table 3). Consequently, the production of $SO_2$-resistant pigments was consistently greater in ACN+Sd wine, both at the end of fermentation and after 6 months of aging, whereas the ACN and ACN+Sk treatments were similar (Figure 2B). At the end of fermentation, only minor differences in the concentration of vitisin A and small derived pigments were observed between wine treatments (Table 3). After the aging period, vitisin A increased in ACN and ACN+Sk wines while remaining constant in the ACN+Sd treatment. Changes in total small derived pigments during aging differed between wine treatments, increasing in ACN wines, staying constant in the ACN+Sk wines, and decreasing in the ACN+Sd. This result suggests that in the case when tannin is present together with ACN in the wine matrix, the pool of derived pigments may undergo conversion to other forms during aging. Considering that the most remarkable aging-related increase in the color of the derived pigment fraction occurred within the polymeric pigment component (Table 3), this may reflect conversion of derived pigment intermediates to a polymeric form. The ACN +Sd wine had the highest concentration of polymeric pigment at 6 months, with ACN and ACN+Sk wines being equivalent. Changes within this fraction most closely reflected the changes observed in $SO_2$-resistant pigment formation.

From these results, it is evident that the Sd tannin favored the partitioning of ACN to form polymeric pigment by comparison with the Sk treatment. From the preliminary results, it would appear that the formation of polymeric pigments with Sk tannin was limited, such that the concentration of polymeric pigment did not differ from wines containing only ACN. Assessing the sum of total derived pigments (Table 3), the ACN+Sk wines produced the lowest total concentration, whereas the ACN+Sd and ACN treatments were similar. This may indicate that in the ACN+Sk treatment, a greater proportion of ACN was converted to a colorless form. The similarity in the total derived pigment concentrations formed in the ACN+Sd and ACN treatments is an important consideration. This potentially indicates that when conversion of ACN to the polymeric form was restricted due to the absence of tannin, the ongoing formation of small derived pigment forms was favored during aging.

Table 4. Spectrophotometric Analysis of Polymeric Pigments Isolated from 6-Month-Aged Wines Prepared from the Fermentation of Anthocyanin (ACN) Alone or in Combination with Grape-Derived Seed (Sd) and Skin (Sk) Tannin[a]

| | ACN | ACN+Sd | ACN+Sk |

| polymeric pigment color $A_{520\ nm}$ 1 M HCl[e] (AU) | 6.84b ± 0.25 | 8.25a ± 0.37 | 7.00a ± 0.05 |

[a]Data are the mean ± standard error. $SO_2$-res, bisulfite-resistant pigments. Significant differences between ACN, Sd, or Sk additions in wine after 6 months are indicated by different letters determined by one-way ANOVA, $P < 0.05$, followed by Student's $t$ test. [b]Total wine color and polymeric pigment color following isolation by solid-phase extraction at 520 nm in model wine buffer. [c]Bisulfite-resistant absorbance of whole wine or polymeric pigments at 520 nm. [d]Proportion of bisulfite-resistant polymeric pigments precipitable by bovine serum albumin. [e]Absorbance of polymeric pigments at 520 nm in 1 M HCl.

To summarize the preliminary experiments, the main observation made was that following fermentation, the "matrix" conditions in wine facilitated a far greater production of bisulfite-resistant products than under acidified hydroalcoholic conditions. No further experimentation was performed on aged ethanol solutions. In aged wines, analysis was conducted to determine differences between the color and size distribution of the polymeric pigments formed.

**Color Characteristics of Wine Polymeric Pigments.** In 6-month-aged wine treatments, an SPE fractionation method that specifically selects for the polymeric fraction was used.[22] This method quantitatively recovered the fraction coincident with polymeric pigments identified by HPLC[22,26] and completely removed monomeric ACN and small derived pigments. Phloroglucinol analysis of the ACN treatment confirmed that proanthocyanidin cleavage products were not detected.

The contribution of the polymeric fraction to total pigment color was compared under wine-like conditions (pH 3.4), with and without the presence of bisulfite (Table 4). The results generated present minimum absorbance values, which exclude possible copigmentation effects that may have existed in the native wine matrix, becausse all samples were diluted in the modified Somers assay. The analysis confirmed the preliminary observations with HPLC described previously: that the ACN +Sd wines had the highest total polymeric color at wine pH and retained higher color in the presence of bisulfite of the wine treatments (Table 4). Total ionized color (in 1 M HCl) was also highest in the ACN+Sd polymeric pigment isolate, indicating that a greater quantity of ACN in the flavylium form was associated with this fraction. With regard to the previous observations with HPLC that the quantities of polymeric pigments formed in ACN and ACN+Sk were similar, this was found in terms of $SO_2$-resistant pigments, but it was found that the color of ACN+Sk polymeric pigments at pH 3.4 and in 1 M HCl was higher than for the ACN treatment. However, these differences were very small.

An important observation was that whereas significant differences between the wine treatments in terms of wine or polymeric pigment bleachability by bisulfite were found, absolute differences in total wine and polymeric pigment color were small by comparison. This indicates that the polymeric pigments formed in the presence of Sd tannins were less bleachable that those formed in the other treatments and points to differences in their structure. To qualify these observations, protein precipitation of polymeric pigments was performed with bovine serum albumin[32] (Table 4), and it was found that $SO_2$-resistant polymeric pigments from ACN+Sk wines were less effectively bound by protein than those isolated from ACN+Sd wines (Table 4). $SO_2$-resistant polymeric pigments formed from ACN were not precipitable by protein. This suggests differences in the extent of ACN incorporation by Sk and Sd tannins had occurred, but it is noteworthy that both model ferment treatments had proportionally low levels of protein-precipitable bisulfite-resistant pigments compared to real wines.[32] This result indicates that the omission of tannin (ACN wine) or reduced incorporation of ACN to tannin (ACN +Sk) potentially increases the formation of smaller (oligomeric) polymeric pigments, which were not precipitable by protein.

These results present a significant step forward in our understanding of the importance of polymeric pigments in conferring the color properties of wine. Recent work on the role of ACN pigment families in wine color properties has shown that the addition of pyranoanthocyanidins and flavanol–ACN condensation products to monomeric ACNs imparts quantitative increases in optical color, even at low concentration.[43] On the basis of the methodology used to fractionate wine pigments in that study,[43] it does not appear that oligomeric pigments were assessed. To add to these observations, the current results indicate that the polymeric ACN fraction makes an important contribution to wine optical properties, in addition to smaller ACN-derived pigments. In addition, the formation of small ACN-derived pigments appears to be favored in the absence of tannin.

**Assessment of Polymeric Pigment Size Distribution.** It is well-known that yeast-derived metabolites drive the formation of a diverse array of flavonoid linkages between flavan-3-ols, ACNs, and ACN-derived pigments in wine and are significantly correlated with increases in polymeric pigment with wine aging.[44−46] However, the current results indicate that differences in tannin structure may underpin the type of polymeric pigments formed. Sd tannins, which have a lower degree of polymerization and a higher degree of galloylation than Sk tannins (Table 2), appear to favor greater incorporation of ACN, yielding a higher concentration of polymeric pigments, which are resistant to $SO_2$ bleaching. Although limited incorporation of ACN by Sk tannin may point to a restriction imposed by tannin molecular mass, this could also reflect differences in the reactivity of flavan-3-ol subunits in pigment formation between Sk and Sd tannins. Our data therefore do not conclusively show an effect of tannin mDP as conferring reactivity for ACN and will require follow-up research.

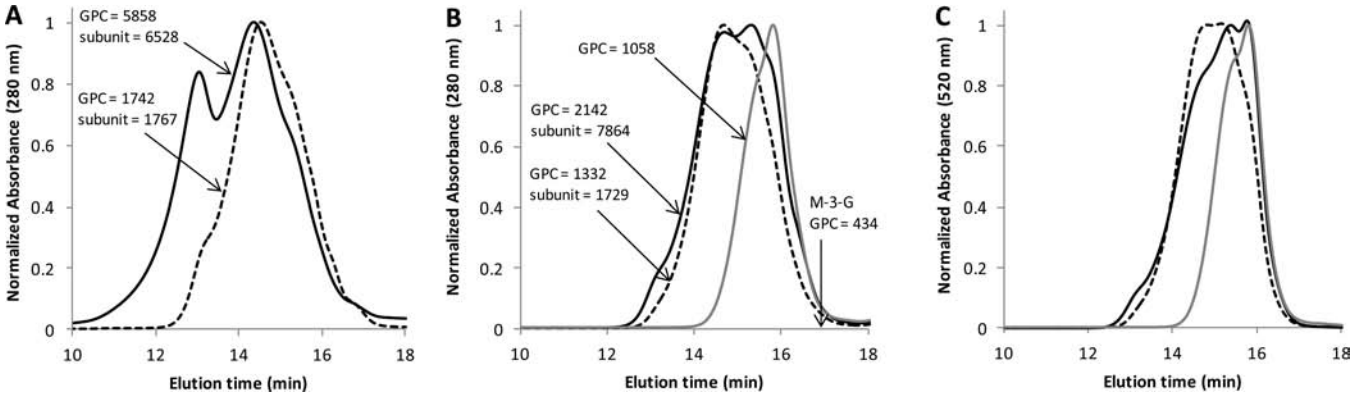

**Figure 3.** Elution profile of polymeric pigments in 6-month-aged wines containing skin (Sk, solid curve) and seed (Sd, broken curve) tannins, their respective combination with anthocyanin (ACN), or ACN only (gray curve) determined by gel permeation chromatography: (A) Sd and Sk wines produced without ACN, monitored at 280 nm; (B) Sd and Sk wines containing ACN in comparison with wine containing only ACN monitored at 280 nm; (C) Sd and Sk wines containing ACN in comparison with wine containing only ACN monitored at 520 nm. Annotations indicated as ↓ give the molecular mass average as g/mol by gel permeation chromatography (GPC), and when applicable a comparison with that determined by phloroglucinolysis (subunit) is given. The elution point of a malvidin-3-glucoside standard (M-3-G, 528.9 g/mol) is indicated as a reference.

To determine whether the differences in the type of polymeric pigments formed resulted in detectable changes in their molecular mass distribution (or hydrodynamic volume), GPC was performed on SPE isolates from 6-month-aged wines. The normalized chromatograms show size distribution differences on a comparable scale (Figure 3), but it was evident that the incorporation of ACN to polymeric pigments introduced large increases in 280 nm absorbance, which are included as Supporting Information (S5). Due to existing differences in conformational structure between seed and skin tannins, different molecular mass calibrations were used for the two tannin types. The presence of a significant proportion of early eluting, high molecular mass tannin in the Sk wine was evident (Figure 3A), which was absent in the Sd wine. The contribution of 520-nm-absorbing material from the Sk and Sd tannins themselves was negligible under the GPC conditions (data not shown). Molecular mass data obtained with GPC and phloroglucinolysis were similar in Sd and Sk wines without added ACN (Figure 3A). The molecular mass determined by GPC was also not significantly different between Sd and Sk wines and the corresponding tannin samples pre-ferment (data not shown).

When ACN was combined with Sd or Sk in wines, the apparent hydrodynamic volume of polymeric pigments determined by GPC was decreased significantly by comparison to Sd or Sk wines alone, and this was more significant for ACN +Sk (Figure 3B). An overlaid elution profile of the polymeric pigments isolated from wines containing only ACN showed that these eluted earlier than monomeric malvidin-3-*O*-glucoside (Figure 3B). Although the assigned molecular masses for ACNs are only nominal using the GPC (skin tannin) calibration, it was of interest to note that the predicted molecular mass for malvidin-3-*O*-glucoside of 434 g/mol (Figure 3B) was within the expected range for the compound and was higher than the lowest standard of calibration for monomeric epicatechin, 290.27 g/mol. The predicted molecular mass average of the ACN-derived wine pigments by GPC, assigned nominally as 1058 g/mol, therefore suggests an oligomeric form.

Material absorbing at 520 nm was evenly dispersed in ACN +Sd distribution (Figure 3C). In the case of ACN+Sk polymers, the 520 nm color was biased toward the lower molecular mass range. As a result, the overlaid elution profiles of ACN+Sk and ACN polymeric pigments were closely aligned within the lower molecular mass range. This possibly reflects a greater proportion of oligomeric pigments, not directly associated with tannin, in the ACN+Sk treatment. Because the 280 nm elution profile of ACN+Sk wine tannin showed a distinct loss of early eluting, high molecular mass material present in the Sk treatment (Figure 3A,B), which was not attributed to losses by precipitation (Supporting Information S4), this could indicate that the incorporation of ACN to high molecular mass Sk tannins rendered them more compact, thus eluting later by GPC.

In the absence of yeast-derived metabolites such as acetaldehyde and pyruvic acid, ACN and tannin can react directly with each other. Depending upon the intermediates of this reaction, the products may be rendered colorless. Oligomeric forms of ACNs can additionally polymerize with flavan-3-ols.[12,47] However, these processes all require acidic conditions, in particular, those processes that are facilitated by interflavan cleavage of the tannin polymer.[38] Under our experimental conditions, however, we hypothesized that hydrolysis was minimal due to limited changes in wine tannin composition (Table 1). Conversely, ethyl or vinyl linkages, formed in the presence of yeast metabolites, can facilitate reaction between ACN and tannin, as well as between tannin molecules.[48] Enhancement of ethyl linkages through manipulation of acetaldehyde concentration or wine aging has been related to increases in polymeric pigments.[44−46] Apart from this, intra- and intermolecular associations could occur within and between tannin molecules, respectively, leading to significant changes in tannin conformation (3-D structure).[37] Additional Π−Π stacking between aromatic rings of flavan-3-ols and bound ACN could also alter tannin conformation. It is noteworthy that tannin hydrodynamic volume determined by GPC was not affected when ACN was omitted from the ferment, which suggests ACN plays a significant role in conferring conformational changes to wine tannin during fermentation and aging (Table 1).

A reduction in hydrodynamic volume has also been observed for pigmented tannins with higher color incorporation, independent of wine tannin concentration and mDP.[19,49] Due to the use of dimethylformamide and lithium chloride in the

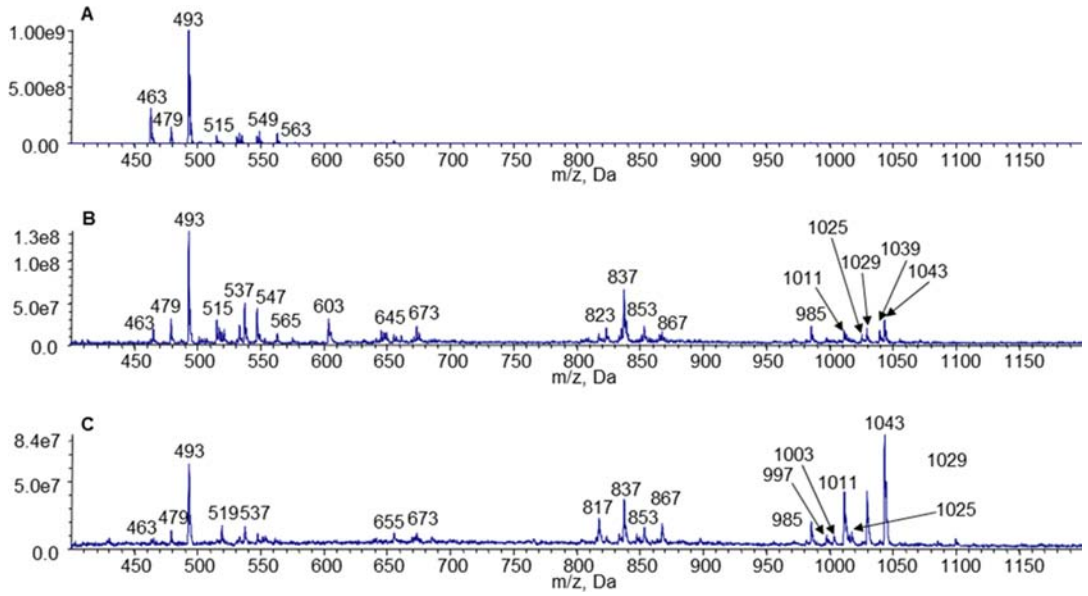

**Figure 4.** Mass spectra of (A) anthocyanin (ACN) solution, (B) 0-month-aged ACN wine, and (C) 6-month-aged ACN wine obtained by direct infusion MS.

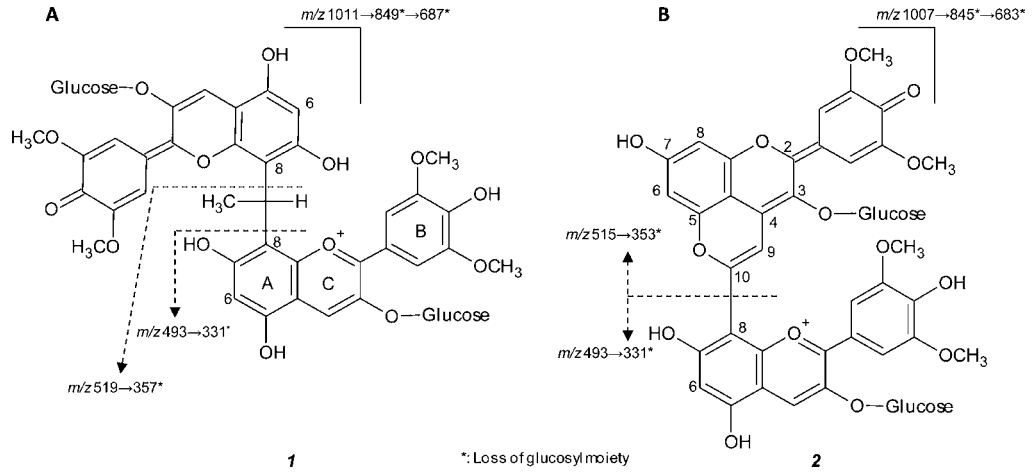

**Figure 5.** Possible structures of (A) ethyl-linked and (B) vinyl-linked malvidin-3-glucoside dimers.

GPC mobile phase, it is expected that interactions with the column itself are minimal. The reduction in the hydrodynamic volume of tannin/polymeric pigment isolates therefore reflects a possible dual effect of ACN on the mass distribution of wine polymeric pigments: first, a significant contribution of oligomeric pigments derived directly from ACNs; and second, a more compact tannin conformation following ACN incorporation, in particular for skin tannins.

From the current results, it is likely that a significant proportion of the pigment formed during the 6-month aging period was derived from reaction pathways other than direct condensation of ACN with tannin subunits, although this pathway is expected to contribute somewhat on the basis of the results of tannin and ACN combinations stored in acidified aqueous ethanol. What was unexpected was the formation of a significant quantity of polymeric pigments in wines containing only ACN, which contributed significantly to aging-related increases in total and bisulfite-resistant color. On the basis of the differences in the properties on polymeric pigments formed from Sk and Sd tannins, we can propose that tannin composition may limit the incorporation of ACN during fermentation and aging and could be due to differences in tannin molecular mass. Notably, the lack of ACN incorporation to tannin appears to facilitate the formation of small polymeric pigments, which are not precipitated by protein.

**Characterization of Anthocyanin-Derived Polymeric Pigments using Mass Spectrometry.** To confirm that the ACN wines formed pigments that were polymeric in nature, SPE isolates of the 0- and 6-month-aged ACN wines and ACN in aqueous ethanol solution were analyzed by direct infusion MS (Figure 4). Detailed fragment ion information on SPE isolates is provided as Supporting Information (S6). The ethanolic ACN solution gave a dominant ion at $m/z$ 493 corresponding to a mass of malvidin 3-glucoside (MvG), followed by $m/z$ 463 and 479 for the glucosides of peonidin (PnG) and petunidin (PtG), respectively (Figure 4A), which is an expected result. There were no obvious ion signals derived from ACN-related polymeric compounds.

On the other hand, the 0- and 6 month-aged ACN wines gave ions in a mass range greater than $m/z$ 1000 (Figure 4B,C), and the relative abundance ratio of these ions to the $m/z$ 493 (MvG) was markedly higher for 6-month-aged ACN wine than

dx.doi.org/10.1021/jf503922h | J. Agric. Food Chem. 2014, 62, 11582−11593

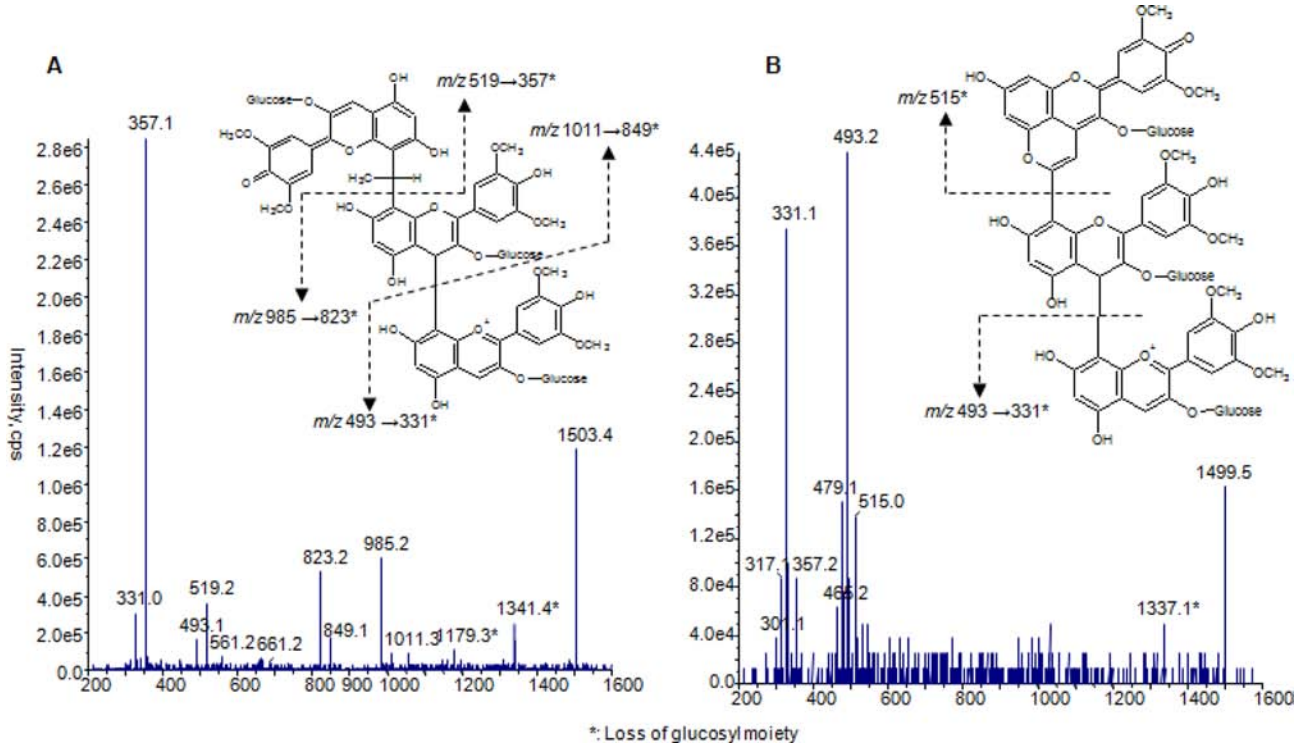

**Figure 6.** Product ion spectra and possible structures of (A) ethyl-linked and (B) vinyl-linked malvidin-3-glucoside trimers.

the young ACN wine. Direct infusion MS/MS analysis revealed that ions at *m/z* 1011, 1029, and 1043 were fragmented to common ions at *m/z* 849, 687, 519, 493, 357, and 331 (Supporting Information S7). In addition, both *m/z* 1029 and 1043 were fragmented to *m/z* 1011, indicating that these ions were likely hydrates (>18 Da) and methanol adducts (>32 Da). The ions at *m/z* 1011 and 1029 corresponded to masses of ethyl-linked MvG dimers containing one flavylium cation and either one quinoidal base (**1**) or hydrated form (Figure 5A). A doubly charged ion at *m/z* 506 was also detected by direct infusion MS analysis, demonstrating that the ethyl-linked MvG dimer with diflavylium cation was also present (data not shown). This result was consistent with the studies by Atanasova et al.[13] and Sun et al.,[50] who observed the formation of the same types of ethyl-linked MvG dimers in wine-like model solution containing MvG and acetaldehyde.

The fragment ions at *m/z* 519 (the loss of MvG in neutral quinoidal form), 357 (the losses of MvG and G), 493 (MvG), and 331 (Mv) (Supporting Information S8) were well-fitted with a possible fragmentation pattern of the proposed ethyl-linked MvG dimer. The ion at *m/z* 1043 (methanol adduct) was likely formed during the electrospray process due to the use of methanol as the solvent for LC-MS analysis. The ions at *m/z* 1025 and 1039 were fragmented into the same ion at *m/z* 1007, followed by giving the same fragment ions at *m/z* 845, 683, 515, 493, 353, and 331 as those derived from *m/z* 1007 (Supporting Information S8). Additional ions were observed at *m/z* 533 and 547 derived from *m/z* 1025 and 1039, respectively. The ion at *m/z* 1007 was assigned to be a vinyl-linked MvG dimer composed of pyranoMvG in quinoidal form and MvG in flavylium cation (**2**) (Figure 5B). The fragment ions appeared to be simply derived by the cleavage between the C10 position in the pyrano-MvG (*m/z* 515, probably vinyl carbocation) and C8 (or C6) position of MvG (*m/z* 493).

Pyranoanthocyanins have been reported to be highly stable and resistant to sulfur dioxide and water attack due to the substitution at the anthocyanin C4 position in ring C, resulting in no occurrence of hydration on these pigments.[51,52] Accordingly, the ion at *m/z* 1025 could be due to the adduction of a water molecule on the pyrano-MvG rather than the involvement of hydrated pyrano-MvG in dimerization. The adduction of a water or methanol molecule on the pyrano-MvG was also observed at fragment ions with *m/z* 533 or 547. In addition to the abundant ions derived from both dimers **1** and **2**, direct infusion MS analysis on the SPE isolates of the 0- and 6-month-aged ACN wines exhibited a large number of ions with low abundance in a mass range up to *m/z* 1600 (data not shown). The ions included *m/z* 997, 983, 981, and 967 and *m/z* 993, 979, 977, and 963 corresponding to masses of ethyl-linked and vinyl-linked dimers of MvG-PtG, MvG-DpG (delphinidin glucoside), MvG-PnG, and MvG-CyG (cyanidin glucoside), respectively.

Product ion spectra of these ions supported their identity by giving characteristic fragment ions derived from the cleavage of either the ethyl-linked or vinyl-linked ACN dimers (data not shown). Furthermore, a number of ions corresponding to masses of ethyl-linked and vinyl-linked ACN trimers were also observed (data not shown). For instance, the ions at *m/z* 1503 and 1499 were consistent with masses of ethyl-linked and vinyl-linked MvG trimers (Figure 6). Their product ions fitted well with their proposed structure.

The structural diversity of the ethyl- and vinyl-linked ACN oligomers can be extensive due to the variability in the composition and oxidation state of ACN units, linkage position and type, and molecular size. In addition, many structural isomers of the ACN oligomers can coexist, and the formation of adduct ions makes the structural elucidation of these pigments very difficult using the mass spectrometric techniques used here. In real wines, the possibility exists that ACN

condensation would occur with phenolics other than ACN itself, and these products have received greater attention in the literature to date. Due to the abundance of ACN in ferments and wines, the possibility exists that ACN-derived oligomers may be important intermediate products during wine aging and may in an ongoing manner form colored condensation products with polyphenols. Our work has demonstrated the existence of a broad range of ethyl- and vinyl-linked dimers and trimers in the 0- and 6-month-aged ACN wines, and to the best of our knowledge, the formation of vinyl-linked ACN oligomers is reported for the first time.

**General Implications of the Results.** This study has shown that the composition of grape tannin can significantly influence the formation of polymeric pigments in wine after reaction with ACN, notably their 520 nm absorbance properties and apparent hydrodynamic volume. A pertinent research direction will be to determine the long-term stability of polymeric pigments derived from tannins of different composition, in particular with respect to tannin size distribution and mDP. Whereas pigment reactions between ACN and Sd tannin were correlated with enhanced wine color stability, as inferred by lower pigment bleachability, the current study has shown that ACN alone can form significant quantities of polymeric pigments. Although these pigments are more bleachable by bisulfite than those formed with tannin, they contribute a strong 520 nm absorbance at wine pH. Using GPC and mass spectrometry, we have been able to demonstrate that pigments derived from ACN are oligomeric in nature. These may be important intermediates in the pathway for pigmented polymer formation in wine, which includes downstream condensation reactions with tannins and/or other polyphenols. The important contribution of these pigments to color at wine pH may have hitherto been overlooked due to their bleachability by bisulfite. The enhanced formation of non-bleachable pigments in wines as opposed to acidified ethanol solution suggests that reactions other than direct condensation or biphenyl linkages may drive their formation. Mass spectrometry confirmed that these are most likely to be ethyl or vinyl linkages.

[a]Standard error values were calculated from three measurements for each analyte by software itself.

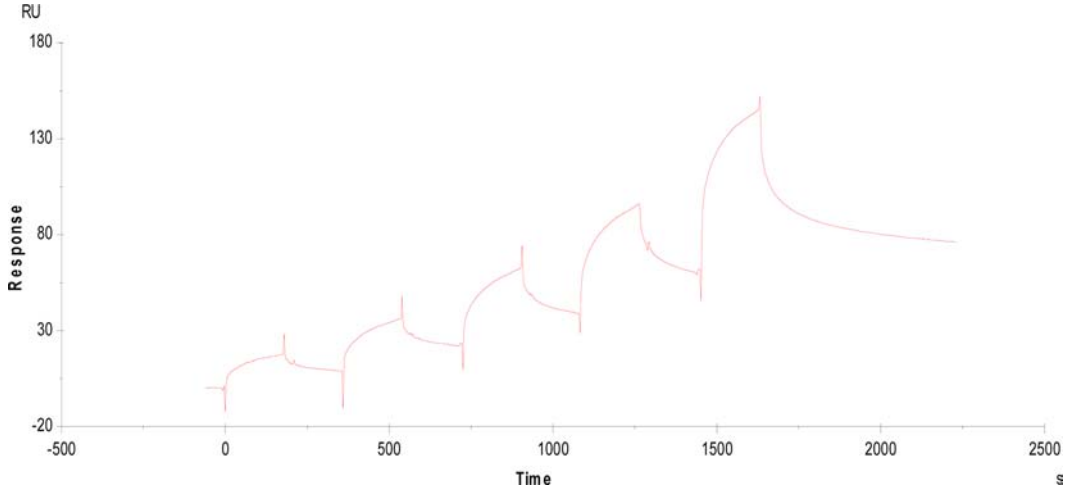

**Figure 2.** Binding sensogram for pyrogallol interaction with immobilized mushroom tyrosinase. Increasing concentrations of pyrogallol from 6.25, 12.5, 25, 50, to 100 $\mu$M were injected over the enzyme surface. Flow rate (30 $\mu$L/min) contact time and dissociation time were kept at 120 s. Regeneration was carried out with 10 mM glycine HCl, pH 2.5, for 30 s and at 30 $\mu$L/min. Data analysis was done with Biacore X100 evaluation software ver. 2.0.1, and data were fit to two states.

the surface of the flow cell was activated for 7 min using a 1:1 mixture of 100 mM EDC and 100 mM NHS (both dissolved in water), and subsequently tyrosinase was injected for 7 min; residual activated carboxymethyl groups on the surface were blocked by a 7 min injection of 1 M ethanolamine, pH 8.5. A total of 2353 RU of tyrosinase was immobilized. The activity of enzyme after immobilization was confirmed by plotting RI (RU) response against concentration of substrate (L-DOPA and L-tyrosine).

**Screening of Different Small Molecules.** For this study, one of the flow cells was blank immobilized (without protein) for use as a reference. Different analytes such as monohydroxy-, dihydroxy-, and trihydroxyphenols were screened against mushroom tyrosinase. Flow rate was maintained constant throughout the binding (10 $\mu$L/min) and kinetics experiment (30 $\mu$L/min); contact time and dissociation time were kept at 120 s. Regeneration was carried out with 10 mM glycine HCl, pH 2.5, for 30 s and at 30 $\mu$L/min. Kinetics was performed with various concentrations of compounds (12.5−200 $\mu$M) in a single-cycle kinetics[33,34] or multicycle kinetics mode. Data analysis was done with Biacore X100 evaluation software ver. 2.0.1, and data were fit to a 1:1 binding model or two-state fit.

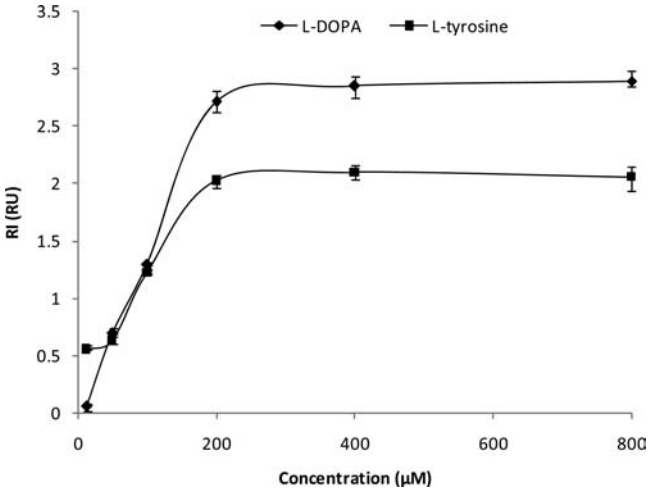

**Figure 3.** Activity of enzyme after immobilization was confirmed by plotting RI (RU) response against concentration of substrate for L-DOPA (◆) and L-tyrosine (■).

**Circular Dichroism (CD) Spectroscopy.** The CD spectra were recorded on a Jasco J-815 CD spectropolarimeter to give the content of regular secondary structure in mushroom tyrosinase. Protein solutions of 0.05 mg mL$^{-1}$ were prepared in the 0.1 mM PBS buffer at pH 6.8. Scans were performed at 20 °C using a 0.1 cm path length quartz cuvette with 8 s differential integration time at a scan rate of 50 nm min$^{-1}$. The protein solutions of 0.05 mg mL$^{-1}$ were incubated with and without pyrogallol, phloroglucinol, tannic acid, saffron, and catechol at a concentration of 200 $\mu$M for 15 min and were used to obtain the spectra. All spectra were collected in triplicate from 200 to 280 nm and a background corrected against buffer blank. The results were expressed as molar ellipticity (deg cm$^2$ dmol$^{-1}$) on the basis of a mean amino acid residue weight (MRW) of mushroom tyrosinase. The molar ellipticity was determined as $[\theta_{obs}] = (100 \times (MRW) \times \theta_{obs}/cl)$, where $\theta$ is the observed ellipticity in degrees at a given wavelength, $c$ is the protein concentration in mg/mL, and $l$ is the length of the light path in cm.[35]

## RESULT AND DISCUSSION

It has been recently discovered that various dermatological disorders such as age spots and freckles are caused by hyperpigmentation.[1] Hyperpigmentation in human skin and enzymatic browning in fruits are not desirable.[36] Thus, hyperpigmentation becomes a major problem in the food industry and one of the main causes of quality loss during postharvest handling and processing.[31] The regulation of melanin synthesis via the inhibition of tyrosinase is a current area of research in the context of preventing hyperpigmentation.[37] As a result, tyrosinase inhibitors have become increasingly important in the food, medical, and cosmetic industries.[38,39]

Various tyrosinase-based biosensors have been developed in the past few years.[22−26] Using these sensors, the detection of the large group of phenolic compounds as tyrosinase inhibitors was possible. However, low sensitivity is one of their major drawbacks.[40] In the present paper, the affinity and binding kinetics of various small molecules toward mushroom tyrosinase using SPR has been evaluated. In addition, this sensor has the ability to detect the number of different inhibitors of enzyme in a single run with high sensitivity and accuracy. Label-free interactions are more sensitive and less

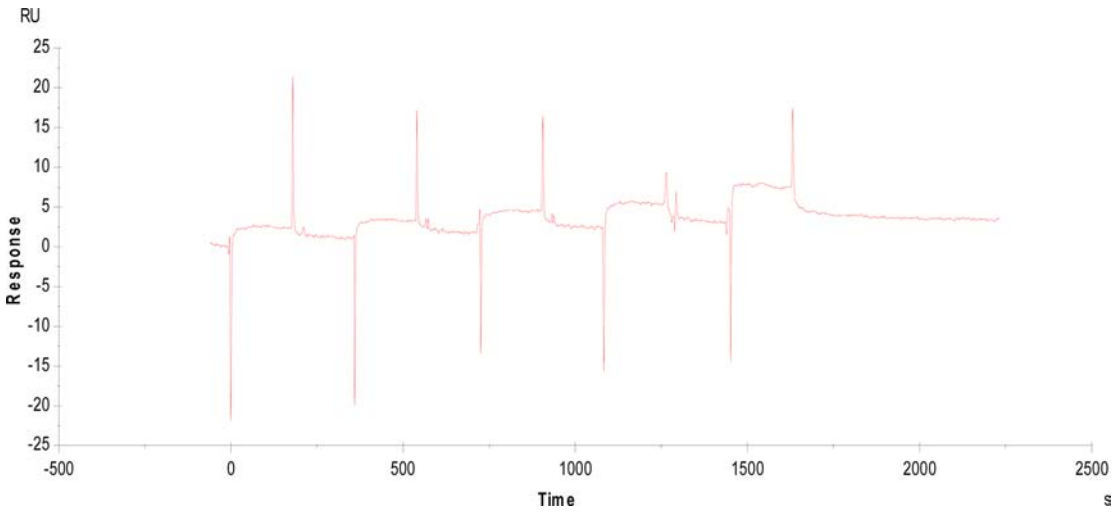

**Figure 4.** Binding sensogram for catechol interaction with immobilized mushroom tyrosinase. Increasing concentrations of catechol from 12.5, 25, 50, 100, to 200 $\mu$M were injected over the enzyme surface. Flow rate (30 $\mu$L/min) contact time and dissociation time were kept at 120 s. Regeneration was carried out with 10 mM glycine HCl, pH 2.5, for 30 s and at 30 $\mu$L/min. Data analysis was done with Biacore X100 evaluation software ver. 2.0.1, and data were fit to two states.

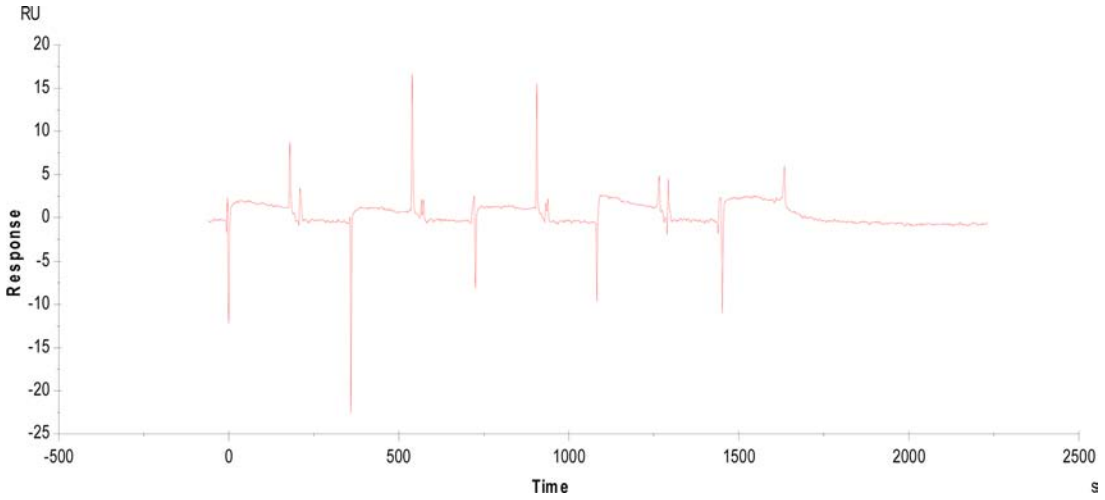

**Figure 5.** Binding sensogram for saffron interaction with immobilized mushroom tyrosinase. Increasing concentrations of saffron from 12.5, 25, 50, 100, to 200 $\mu$M were injected over the enzyme surface. Flow rate (30 $\mu$L/min) contact time and dissociation time were kept at 120 s. Regeneration was carried out with 10 mM glycine HCl, pH 2.5, for 30 s and at 30 $\mu$L/min. Data analysis was done with Biacore X100 evaluation software ver 2.0.1, and data were fit to two states. The resulting equilibrium dissociation constants are reported in Table 1.

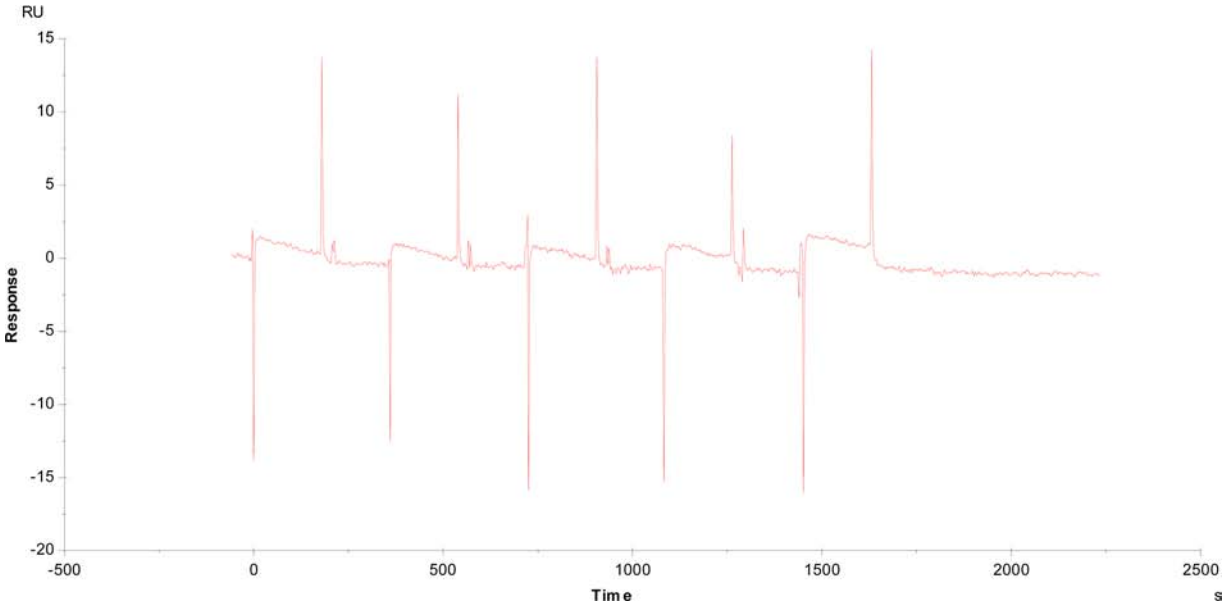

**Figure 6.** Binding sensogram for phloroglucinol interaction with immobilized mushroom tyrosinase. Increasing concentrations of phloroglucinol from 12.5, 25, 50, 100, to 200 $\mu$M were injected over the enzyme surface. Flow rate (30 $\mu$L/min) contact time and dissociation time were kept at 120 s. Regeneration was carried out with 10 mM glycine HCl, pH 2.5, for 30 s and at 30 $\mu$L/min. Data analysis was done with Biacore X100 evaluation software ver. 2.0.1, and data were fit to two states. The resulting equilibrium dissociation constants are reported in Table 1.

error prone compared with the conventional spectroscopic methods, which are based on color formation.

The screening results showed that the affinity toward mushroom tyrosinase varies from molecule to molecule, which is clearly observed from Figure 1. Many compounds showed high affinity for tyrosinase but possess low stability. Low-stability compounds were found to display a higher dissociation rate. On the basis of binding studies, various small molecules such as catechol, pyrogallol, saffron, tannic acid, and phloroglucinol were selected further for affinity and kinetic analysis against mushroom tyrosinase. This study shows that pyrogallol has a higher binding affinity for mushroom tyrosinase with a $K_D$ value of $7.981 \times 10^{-6}$ M. The data with different concentrations were fit to a two-state equation and are shown in Table 1. Pyrogallol has higher rates of association and dissociation and a higher equilibrium dissociation constant as evident from Figure 2. Pyrogallol is trihydroxyphenol: it perhaps binds more rapidly as compared to L-DOPA and L-tyrosine, which are dihydroxy- and monohydroxyphenols, respectively. Tyrosinase action on phenolic substrates follows the order trihydroxy > dihydroxy > monohydroxyphenol. The $K_D$ value for L-DOPA was reported by us before.[32] L-DOPA was also run between inhibitors during the kinetic runs to ascertain the activity of tyrosinase. The activity of enzyme after immobilization was proportional with increasing concentrations of L-DOPA and L-tyrosine (Figure 3), which confirmed the stability and reactivity of mushroom tyrosinase after immobilization. Pyrogallol was reported as a suicide inhibitor of tyrosinase and predicted to bind with high affinity.[41] The low affinity of catechol ($1.557 \times 10^{-5}$ M) (Figure 4) compared to

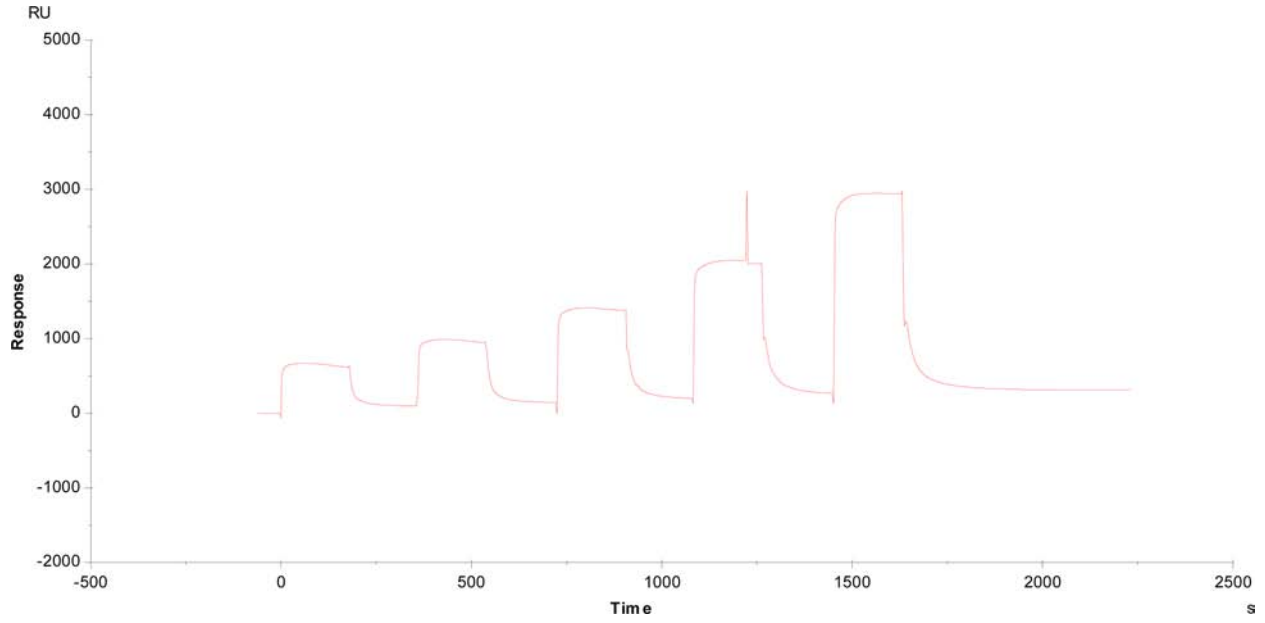

**Figure 7.** Binding sensogram for tannic acid interaction with immobilized mushroom tyrosinase. Increasing concentrations of tannic acid from 6.25, 12.5, 25, 50, to 100 $\mu$M were injected over the enzyme surface. Flow rate (30 $\mu$L/min) contact time and dissociation time were kept at 120 s. Regeneration was carried out with 10 mM glycine HCl, pH 2.5, for 30 s and at 30 $\mu$L/min. Data analysis was done with Biacore X100 evaluation software ver. 2.0.1, and data were fit to two states. The resulting equilibrium dissociation constants are reported in Table 1.

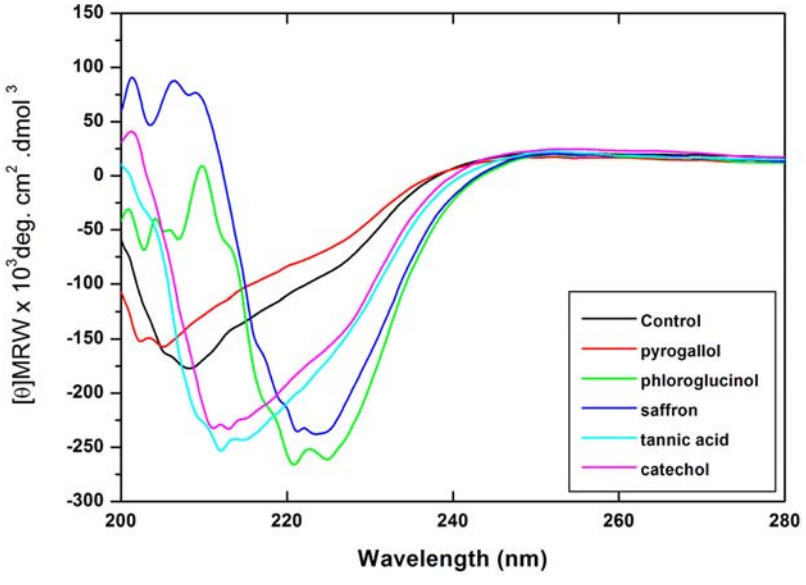

**Figure 8.** CD spectrum of mushroom tyrosinase without (black curve) and with pyrogallol (red curve), phloroglucinol (green curve), tannic acid (light blue curve), saffron (dark blue curve), and catechol (pink curve) at 200 $\mu$M concentration each.

pyrogallol may be because catechol follows "cresolase presentation", catechol being oxidized to form a product able to undergo deprotonation and reductive elimination, resulting in inactivation of the enzyme through the formation of copper at the active site. However, because the OH groups are equivalent, the probability of catalysis and inactivation increases in the cases of pyrogallol (trihydroxyphenol) and catechol (*o*-diphenol).[42] Catechol showed fast association and slow dissociation time as it is a substrate for tyrosinase (Table 1).

Saffron, phloroglucinol, and tannic acid have low binding affinities toward mushroom tyrosinase with $K_D$ values of $3.111 \times 10^{-5}$, $7.136 \times 10^{-5}$, and $1.213 \times 10^{-4}$ M, respectively (Table 1). Also, these three compounds showed slow association and fast dissociation in comparison with pyrogallol and catechol (Table 1). The binding kinetics for saffron (Figure 5), phloroglucinol (Figure 6), and tannic acid (Figure 7) with 1:1 fit clearly indicate almost similar association and dissociation rate constants, which perhaps suggests a similar mode of inhibition. The key component in saffron is crocin, reported as a potent inhibitor of tyrosinase.[32] Also, phloroglucinol ($IC_{50}$ > 300 $\mu$M) and tannic acid are reported as inhibitors of mushroom tyrosinase.[43,44] Inhibition of tannic acid is a reversible reaction.

The structural changes of the mushroom tyrosinase in the presence of inhibitors was studied by CD spectroscopy technique. As illustrated in Figure 8, there were significant

Table 2. Changes in Secondary Structure of MT in the Presence of Inhibitors

| | inhibitors | | | | | | | | | | | |
|---|---|---|---|---|---|---|---|---|---|---|---|---|
| | pyrogallol | | phloroglucinol | | tannic acid | | saffron | | catechol | |
| | 208 nm | 222 nm | 208 nm | 222 nm | 208 nm | 222 nm | 208 nm | 222 nm | 208 nm | 222 nm |
| % change | 21.97 ± 4.3 | 23.13 ± 4.16 | 78.03 ± 14.82 | 147 ± 29.4 | 60.41 ± 10.26 | 124.17 ± 24.83 | 9.63 ± 1.15 | 92.57 ± 16.6 | 73.87 ± 14.03 | 15.08 ± 2.41 |

differences in the secondary structure of the native enzyme and mushroom tyrosinase in the presence of inhibitors. CD studies also confirm the secondary structural changes analyzed using SPR. The percent changes in $\alpha$-helix in the presence of inhibitors are given in Table 2.

A number of tyrosinase inhibitors have earlier been reported to decrease hyperpigmentation resulting from the enzyme action. Most of these tyrosinase inhibitors were mono-, di-, and trihydroxylphenols, flavonoids, and peptides.[36,45] These reported activators and inhibitors are phenols and other common cosmetic ingredients well studied on mushroom tyrosinase.

The Biacore sensor has the ability to detect changes in protein conformation in addition to binding of inhibitors. Direct detection of low molecular weight analytes by SPR has been reported for binding of $Ca^{2+}$ ions to transglutaminase[46] and sulfonamide inhibitors to carbonic anhydrase.[47] The present study demonstrates for the first time direct detection of tyrosinase inhibitor binding using an SPR sensor. The study proves the ability of this sensor to screen the binding ability of different types of inhibitors toward mushroom tyrosinase at various concentrations and also to be used for the screening of new tyrosinase inhibitors. In addition, the sensor was relatively simple to make and did not require the use of antibodies to detect small-size inhibitors employed in the study. Once the enzyme is immobilized on the sensor surface, it will be useful for a long time through proper storage. Moreover, by immobilizing other enzymes or cell receptors of interest in the SPR sensor surface, their response on exposure to inhibitors and ligands can also be assessed, resulting in the development of novel and rapidly sensing biosensors. Other undesirable properties relate more to how the target and ligand interact. One such mechanism, recently described by McGovern et al.,[48,49] involves the formation of ligands into aggregates of 30−400 nm in diameter. These aggregates were proposed to inhibit either by absorption onto the surface of enzymes or by incorporating enzymes within them. Inhibitors acting in this manner were termed "promiscuous" inhibitors, as they appeared to inhibit a number of unrelated enzymes, although it is likely that there are other mechanisms by which compounds may inhibit numerous enzymes. McGovern et al.[48,49] identified and characterized a number of these promiscuous inhibitors by testing for properties that distinguished them from classical 1:1 reversible inhibitors.

In conclusion, pyrogallol, catechol, saffron, phloroglucinol, and tannic acid had anti-tyrosinase activity, but showed differences in their binding affinities for the tyrosinase. Therefore, this enzyme-based biosensor has the potential to be used in the detection and screening of new inhibitor drug candidates. Another advantage is that label-free interactions are more sensitive compared with the spectroscopic methods. Inhibitors may therefore have good potential as antibrowning agents to be applied in food industries as well as in cosmetics. The sensors can be used for high-throughput screening of potential pharmaceutical drug candidates.

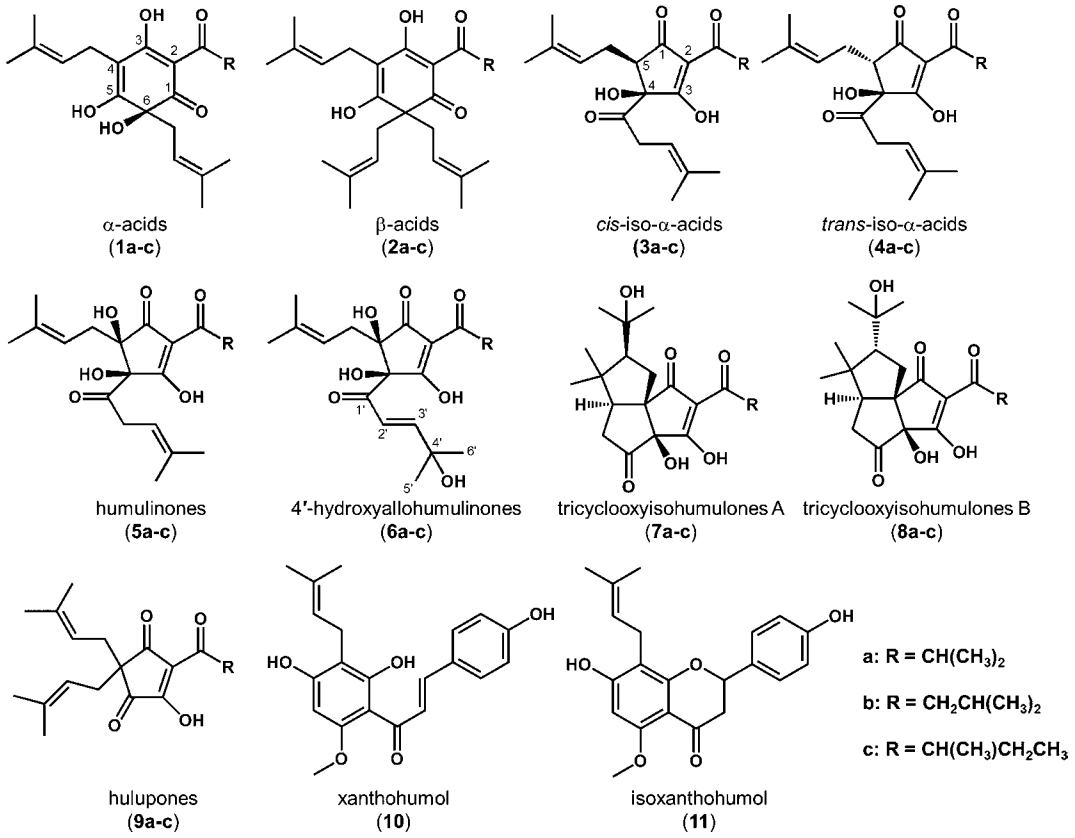

**Figure 1.** Structures of α-acids, cohumulone (**1a**), *n*-humulone (**1b**), and adhumulone (**1c**); β-acids, colupulone (**2a**), *n*-lupulone (**2b**), and adlupulone (**2c**); *cis*-iso-α-acids, *cis*-isocohumulone (**3a**), *cis*-iso-*n*-humulone (**3b**), and *cis*-isoadhumulone (**3c**); *trans*-iso-α-acids, *trans*-isocohumulone (**4a**), *trans*-iso-*n*-humulone (**4b**), and *trans*-isoadhumulone (**4c**); humulinones, cohumulinone (**5a**), *n*-humulinone (**5b**), and adhumulinone (**5c**); 4′-hydroxyallohumulinones, 4′-hydroxyallocohumulinone (**6a**), 4′-hydroxyallo-*n*-humulinone (**6b**), and 4′-hydroxyalloadhumulinone (**6c**); tricyclooxyisohumulones A, tricyclooxyisocohumulone A (**7a**), tricyclooxyiso-*n*-humulone A (**7b**), and tricyclooxyisoadhumulone A (**7c**); tricyclooxyisohumulones B, tricyclooxyisocohumulone B (**8a**), tricyclooxyiso-*n*-humulone B (**8b**), and tricyclooxyisoadhumulone B (**8c**); hulupones, cohulupone (**9a**), *n*-hulupone (**9b**), and adhulupone (**9c**); xanthohumol (**10**); and isoxanthohumol (**11**).

reported that the hard resin positively contributed to the foam stability of beer and produced a more pleasant bitter taste as opposed to the sharper bitterness of iso-α-acids. However, the hard-resin-enriched extracts used in the study were not subjected to rigorous chemical compositional analysis.[11] Thus, a suitable method to fully analyze the chemical composition of the hard resin was needed to properly examine its effect on the properties of beer. Furthermore, transformation of the hard-resin components during the wort boiling process, which is known to have a significant effect on beer taste, was not understood, except for the conversion of xanthohumol (**10**) into isoxanthohumol (**11**).[20] Knowledge of the transformation of hard-resin components during the wort boiling process is also essential to evaluate and optimize the effect of the hard resin on beer quality.

In our previous studies, we developed a high-performance liquid chromatography (HPLC) method suitable for investigation of the oxidation products in stored hops, which showed that α-acids are oxidized into humulinones (**5a**–**5c**), 4′-hydroxyallohumulinones (**6a**–**6c**), and tricyclooxyisohumulones A (**7a**–**7c**) and tricyclooxyisohumulones B (**8a**–**8c**) and that β-acids are oxidized into hulupones (**9a**–**9c**) (Figure 1).[21,22] These oxidation products are thought to be components in the soft or hard resins.

In this study, we analyzed the soft and hard resins derived from stored hops using our newly developed analytical method and clarified the existence of these oxidation compounds for the first time. We also investigated the transformation of the hard-resin components through wort boiling by using model boiling experiments and successively isolated and determined the structures of the transformation products. The concentration changes of these products and their precursors during the boiling process were also investigated.

## MATERIALS AND METHODS

**Chemicals and Materials.** The following chemicals were obtained commercially: ethylenediaminetetraacetic acid (EDTA), $H_3PO_4$, MeCN, EtOH, hexane, diethyl ether, and $CH_2Cl_2$ (Wako Pure Chemicals, Osaka, Japan) and xanthohumol and isoxanthohumol (Funakoshi, Tokyo, Japan). Deionized water for chromatography was purified by means of a Milli-Q Gradient A10 system (Millipore, Billerica, MA). Hop pellets, cultivar Hallertau Perle (HPE), were purchased from Hopsteiner (Mainburg, Germany).

**Preparation of Humulinones (5a–5c), Hulupones (9a–9c), Tricyclooxyiso-*n*-humulone A (7b), and Tricyclooxyiso-*n*-humulone B (8b).** Humulinones (**5a**–**5c**) and hulupones (**9a**–**9c**) were prepared according to a protocol reported previously.[21] Tricyclooxyiso-*n*-humulone A (**7b**) and tricyclooxyiso-*n*-humulone B (**8b**) were isolated from the autoxidation products of *n*-humulone.[22]

**Preparation of 4′-Hydroxyallohumulinones (6a–6c and 6c′) from Stored Hops.** Hop pellets (850 g) were stored at 60 °C for 120 h and extracted with $H_2O$ (8.5 L) at 50 °C for 1 h. The extract was filtered and then lyophilized to yield a brown powder (176 g). A portion of this powder (120 g) was dissolved in $H_2O$ (8.1 L) and

partitioned with $CH_2Cl_2$ (16.2 L) after adding 1 N HCl (810 mL) to the solution. The $CH_2Cl_2$ layer containing 4′-hydroxyallohumulinones was collected and dried over anhydrous $Na_2SO_4$ and concentrated to dryness *in vacuo* to give a yellowish brown oil (22 g). This oil was dissolved in EtOH and repeatedly subjected to preparative HPLC [column, 150 × 22 mm inner diameter, 5 μm, Alltima $C_{18}$ column (Systech, Tokyo, Japan); solvent, 100:1 (v/v) $H_2O/H_3PO_4$ (85%) (solvent A) and MeCN (solvent B), a linear gradient from 30 to 90% B in 0 → 40 min and 90% B for 40 → 45 min; flow rate, 18.8 mL/min; detector, 270 nm; and column temperature, room temperature] and divided into 11 fractions depending upon their elution times. Compounds **6a**, **6b**, and **6c**/**6c**′ were contained in fractions 3 ($t_R$, 8.6−9.5 min), 6 ($t_R$, 11.0−12.1 min), and 7 ($t_R$, 12.1−12.9 min), respectively. Compound **6a** in fraction 3 and compound **6b** in fraction 6 were further purified by repeatedly subjecting them to a second preparative HPLC step [column, 50 × 20 mm inner diameter, 5 μm, L-column 2 ODS (Chemicals Evaluation and Research Institute, Tokyo, Japan); solvent, 10 mM $NH_4HCO_3$ (solvent A) and MeCN (solvent B), isocratic elution at 20% B; flow rate, 9.5 mL/min; detector, 270 nm; and column temperature, 40 °C]. Compounds **6a** and **6b** were eluted at 3.8−4.7 and 5.5−7.5 min, respectively. Each eluate was immediately diluted 2 times with $H_2O$, adjusted to pH 2.0 with 1 N HCl, and partitioned with $CH_2Cl_2$ ($^1/_2$ volume of the diluted eluate, 2 times). The respective $CH_2Cl_2$ layer was dried over anhydrous $Na_2SO_4$ and concentrated to dryness to yield pure compounds **6a** (814 mg) and **6b** (1.2 g). Similarly, compounds **6c**/**6c**′ in fraction 7 were further purified by repeatedly subjecting them to a second preparative HPLC [column, 150 × 20 mm inner diameter, 5 μm, L-column 2 ODS (Chemicals Evaluation and Research Institute, Tokyo, Japan); solvent, 100 mM $NH_4HCO_3$ (solvent A) and MeCN (solvent B), isocratic elution at 20% B; flow rate, 18.8 mL/min; detector, 270 nm; and column temperature, room temperature]. Compounds **6c** and **6c**′ were eluted separately at 9.8−10.8 and 10.8−11.8 min, respectively. Pure compounds **6c** (40.3 mg) and **6c**′ (37.2 mg) were recovered from each eluate in the same way as that described for compounds **6a** and **6b**.

*4′-Hydroxyalloadhumulinone A (**6c**).* Pale yellow oil; $[\alpha]_D^{20}$, +4.01 (*c* 0.4, MeOH); $^1$H and $^{13}$C nuclear magnetic resonance (NMR) data, see Table 2; and high-resolution electrospray ionization mass spectrometry (HRESIMS) (negative), *m*/*z* 393.1916 $[M - H]^-$ (calcd for $C_{21}H_{29}O_7$, 393.1919).

*4′-Hydroxyalloadhumulinone B (**6c**′).* Pale yellow oil; $[\alpha]_D^{20}$, +12.1 (*c* 0.3, MeOH); $^1$H and $^{13}$C NMR data, see Table 2; and HRESIMS (negative), *m*/*z* 393.1914 $[M - H]^-$ (calcd for $C_{21}H_{29}O_7$, 393.1919).

**Preparation of Soft and Hard Resins.** Soft and hard resins from hops were prepared according to Analytica-EBC,[3] with some modification.

Hop pellets (100 g) were stored at 60 °C for 48 h, and a portion (10 g) was extracted with MeOH (100 mL) by stirring at room temperature for 1 h and then filtered. The filtrate was kept at 4 °C for 1 day, and a waxy precipitate that formed was removed by filtration. To a portion of the filtrate (20 mL), MeOH (10 mL), hexane (80 mL), and 1 N HCl (20 mL) were added, and the two-layer solution (hexane/acidic MeOH/$H_2O$) was partitioned in a separating funnel. The hexane layer, prepared by repeating the above partition 4 times (320 mL), was evaporated to dryness to give a yellowish brown oil (250 mg, soft resin).

The residual acidic MeOH/$H_2O$ layer was partitioned with diethyl ether (80 mL, 2 times). The diethyl ether layer (160 mL) was washed with saturated NaCl solution (160 mL), dried over anhydrous $Na_2SO_4$, and concentrated to dryness to give a brown solid (200 mg, hard resin).

**Boiling Test for the Hard Resin.** To 500 μL of 10 mM citrate buffer (pH 5.5) preheated to 100 °C was added a 25 μL solution of the hard resin in EtOH (5.0 mg/mL). The combined solution was kept at 100 °C and analyzed by HPLC at 30, 60, 90, and 120 min.

**Boiling Test of 4′-Hydroxyallohumulinones (6a−6c and 6c′).** To a 500 μL aliquot of 10 mM citrate buffer (pH 5.5) preheated to 100 °C was added a 25 μL solution of either 4′-hydroxyallocohumulinone (**6a**), 4′-hydroxyallo-*n*-humulinone (**6b**), 4′-hydroxyalloadhumulinone A (**6c**), or 4′-hydroxyalloadhumulinone B (**6c**′) (1.0 mg/mL in EtOH). Each combined solution was kept at 100 °C and analyzed by HPLC at 30, 60, 90, and 120 min.

**Isolation of the Transformation Products Produced by Boiling of 4′-Hydroxyallocohumulinone (6a) and 4′-Hydroxyallo-*n*-humulinone (6b).** 4′-Hydroxyallocohumulinone (**6a**) (200 mg) was dissolved in EtOH (50 mL), added to 10 mM citrate buffer (pH 5.5, 1 L) preheated to 100 °C, and maintained at this temperature for 90 min. After cooling to room temperature, the solution was acidified with 1 N HCl (100 mL) and partitioned with $CH_2Cl_2$ (250 mL, 3 times). The $CH_2Cl_2$ layer (750 mL) was washed with saturated NaCl solution (400 mL), dried over anhydrous $Na_2SO_4$, and concentrated to dryness to give a yellowish brown oil (150 mg).

The oil was dissolved in EtOH and repeatedly subjected to preparative HPLC [column, 150 × 10 mm inner diameter, 5 μm, Alltima $C_{18}$ column (Systech, Tokyo, Japan); solvent, 100:1 (v/v) $H_2O/H_3PO_4$ (85%) (solvent A) and MeCN (solvent B), a linear gradient from 30% B for 0 → 15 min, from 30 to 90% B in 15 → 18 min, and 90% B for 18 → 22 min; flow rate, 4.7 mL/min; detector, 270 nm; and column temperature, 40 °C]. In this preparative HPLC, 4′-hydroxyallo-*cis*-cohumulinone (**12a**) was eluted at 8.6−10.0 min and *cis*-oxycohumulinic acid (**13a**) was eluted at 10.0−10.6 min. Each eluate was diluted with $H_2O$ to lower the concentration of MeCN to less than 10% and extracted with $CH_2Cl_2$ ($^1/_4$ volume of the diluted eluate, 3 times). The $CH_2Cl_2$ layer was dried over anhydrous $Na_2SO_4$ and concentrated to dryness to yield compounds **12a** (33.4 mg) and **13a** (4.0 mg).

The transformation products (**12b** and **13b**) of 4′-hydroxyallo-*n*-humulinone (**6b**) were prepared and purified in almost the same way as described for compounds **12a** and **13a**. In summary, 4′-hydroxyallo-*n*-humulinone (**6b**) (200 mg) was boiled and partitioned between $CH_2Cl_2$ and acidic $H_2O$. The $CH_2Cl_2$ layer was concentrated to give an oil (167 mg). The oil was repeatedly subjected to preparative HPLC [column, flow rate, detector, and column temperature are identical to those used for the isolation of compounds **12a** and **13a**; solvent, 100:1, (v/v) $H_2O/H_3PO_4$ (85%) (solvent A) and MeCN (solvent B), a linear gradient from 30 to 48% B in 0 → 12 min, from 48 to 90% B in 12 → 18 min, and 90% B for 18 → 21 min]. In this preparative HPLC, 4′-hydroxyallo-*cis*-*n*-humulinone (**12b**) and *cis*-oxy-*n*-humulinic acid (**13b**) were eluted at 9.0−9.6 and 10.0−10.3 min, respectively. Pure compounds **12b** (41.3 mg) and **13b** (5.9 mg) were recovered from each eluate in the same way as described for compounds **12a** and **13a**.

*4′-Hydroxyallo-cis-cohumulinone (**12a**).* Pale yellow oil; $[\alpha]_D^{20}$, ±0 (*c* 0.7, MeOH); $^1$H and $^{13}$C NMR data, see Table 1; and HRESIMS (negative), *m*/*z* 379.1753 $[M - H]^-$ (calcd for $C_{20}H_{27}O_7$, 379.1762).

*4′-Hydroxyallo-cis-n-humulinone (**12b**).* Pale yellow oil; $[\alpha]_D^{20}$, ±0 (*c* 0.4, MeOH); $^1$H and $^{13}$C NMR data, see Table 1; and HRESIMS (negative), *m*/*z* 393.1911 $[M - H]^-$ (calcd for $C_{21}H_{29}O_7$, 393.1919).

*cis-Oxycohumulinic Acid (**13a**).* White, amorphous solid; $[\alpha]_D^{20}$, ±0 (*c* 0.1, MeOH); $^1$H and $^{13}$C NMR data, see Table 1; and HRESIMS (negative), *m*/*z* 267.1230 $[M - H]^-$ (calcd for $C_{14}H_{19}O_5$, 267.1238).

*cis-Oxy-n-humulinic Acid (**13b**).* Pale yellow oil; $[\alpha]_D^{20}$, ±0 (*c* 0.1, MeOH); $^1$H and $^{13}$C NMR data, see Table 1; and HRESIMS (negative), *m*/*z* 281.1390 $[M - H]^-$ (calcd for $C_{15}H_{21}O_5$, 281.1395).

**Preparation of *cis*-Oxy-*n*-humulinic Acid (13b) and *trans*-Oxy-*n*-humulinic Acid (14b) by Hydrolysis of *n*-Humulinone (5b).** Both *cis*- and *trans*-oxy-*n*-humulinic acids were prepared by alkaline hydrolysis of *n*-humulinone (**5b**) according to the previous report,[23] with some modification.

*n*-Humulinone was prepared according to a protocol reported previously.[21] To 2 M aqueous NaOH (300 mL) preheated at 100 °C, 30 mL of solution of *n*-humulinone in MeOH (10 mg/mL) was added and mixed well. The temperature was maintained at 100 °C for 10 min before cooling the solution to room temperature, acidifying with 6 N HCl (120 mL), and partitioning with $CH_2Cl_2$ (200 mL, 2 times). The $CH_2Cl_2$ layer was dried over anhydrous $Na_2SO_4$ and concentrated to dryness to give a yellow oil (270 mg). The oil was dissolved in EtOH and repeatedly subjected to preparative HPLC [column, 150 × 22 mm inner diameter, 5 μm, Alltima $C_{18}$ column (Systech, Tokyo, Japan);

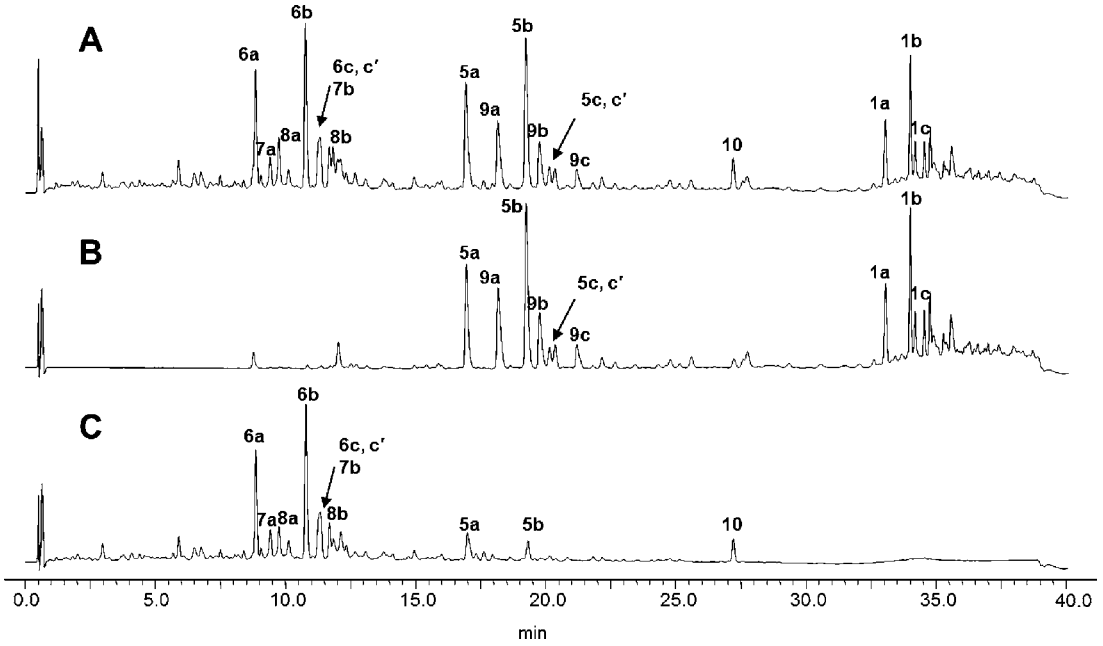

**Figure 2.** HPLC chromatograms of the (A) MeOH extract of hops stored at 60 °C for 48 h, (B) soft-resin fraction prepared from the MeOH extract, and (C) hard-resin fraction prepared from the MeOH extract. Structures of the compounds are given in Figures 1 and 6.

solvent, 100:1 (v/v) $H_2O/H_3PO_4$ (85%) (solvent A) and MeCN (solvent B), isocratic elution at 45% B; flow rate, 22.8 mL/min; detector, 270 nm; and column temperature, room temperature]. In this preparative HPLC, *cis*-oxy-*n*-humulinic acid (**13b**) and *trans*-oxy-*n*-humulinic acid (**14b**) were eluted at 5.1−5.5 and 6.7−7.2 min, respectively. Pure compounds **13b** (74.6 mg) and **14b** (94.6 mg) were recovered from each eluate in the same way as described for compounds **12a** and **13a**.

*trans-Oxy-n-humulinic Acid (**14b**).* White, amorphous solid; $[\alpha]_D^{20}$, ±0 (*c* 0.3, MeOH); $^1H$ and $^{13}C$ NMR data, see Table 1; and HRESIMS (negative), *m/z* 281.1389 $[M - H]^-$ (calcd for $C_{15}H_{21}O_5$, 281.1395).

**HPLC.** A Shimadzu Prominence UFLC system (Shimadzu, Kyoto, Japan) was used for all HPLC analyses. Data were processed with LCsolution software (Shimadzu, Kyoto, Japan).

HPLC analyses were performed to investigate the constituents in the soft and hard resins of hops and to analyze compositional changes in the hard-resin components in the boiling tests using the following conditions:[21,22] column, 100 × 2.1 mm inner diameter, 3 μm, Alltima $C_{18}$ column (Systech, Tokyo, Japan); solvent, 1000:0.2 (v/v) $H_2O/H_3PO_4$ (85%) containing EDTA (0.02%, w/v) (solvent A) and MeCN (solvent B), a linear gradient from 10 to 52% B in 0 → 26.7 min, 52% B for 26.7 → 30 min, from 52 to 75% B in 30 → 32.7 min, from 75 to 85% B in 32.7 → 36.7 min, and 85% B for 36.7 → 37.7 min; flow rate, 0.6 mL/min; detector, 270 nm; and column temperature, 40 °C. The injection volume was 3.0 μL. In the boiling tests, transformation products were quantified using isolated reference compounds. 4′-Hydroxyallo-*cis*-adhumulinone A (**12c**) and 4′-hydroxyallo-*cis*-adhumulinone B (**12c′**) were quantified using the calibration curve of 4′-hydroxyallo-*cis*-*n*-humulinone (**12b**), and *cis*-oxyadhumulinic acid A (**13c**) and *cis*-oxyadhumulinic acid B (**13c′**) were quantified using the calibration curve of *cis*-oxy-*n*-humulinic acid (**13b**).

To separate and check the purity of 4′-hydroxyalloadhumulinone A (**6c**) and 4′-hydroxyalloadhumulinone B (**6c′**) by HPLC (Figure 7), the following LC conditions were used: column, 100 × 2.1 mm inner diameter, 3 μm, L-column 2 ODS (Chemicals Evaluation and Research Institute, Tokyo, Japan); solvent, 5 mM $HCOONH_4$ (pH 8.5) (solvent A) and MeCN (solvent B), a linear gradient from 10 to 36% B in 0 → 39 min, from 36 to 80% B in 39 → 44 min, and 80% B for 44 → 52 min; flow rate, 0.25 mL/min; detector, 270 nm; and column temperature, 40 °C. The injection volume was 3.0 μL.

**HRESIMS.** HRESIMS of the purified compounds was measured using a Thermo Scientific LTQ Orbitrap mass spectrometer (Thermo Fisher Scientific, San Jose, CA). Before the samples were measured, accurate mass calibration was carried out using polytyrosine-1,3,6 as a mass standard (CS Bio Company, Menlo Park, CA).

**NMR.** $^1H$, $^{13}C$, and 2D NMR spectra were measured with a Bruker AVANCE400 spectrometer (Bruker BioSpin, Rheinstetten, Germany). Samples were dissolved in methanol-$d_4$. Chemical shifts were referenced to the solvent signals ($\delta_H/\delta_C$, 3.30/49.0). Data processing was performed using TopSpin-NMR software (version 3.0) (Bruker BioSpin). *J*-Resolved heteronuclear multiple-bond correlation (HMBC) experiments were conducted on a Varian INOVA-500 NMR spectrometer (Agilent, Santa Clara, CA) using the previously reported method.[24]

## RESULTS AND DISCUSSION

**Identification of the Components in the Soft and Hard Resins Derived from Stored Hops.** Recently, we reported the transformation of α-acids to humulinones (humulinones were further transformed to 4′-hydroxyallohumulinones) and to tricyclooxyisohumulones A and B because of oxidation.[21,22] During these studies, we also developed a HPLC method that is suitable for the analysis of α- and β-acid-derived oxidation compounds.[21,22] Using this HPLC method, we analyzed a MeOH extract of the stored hops and soft and hard resins prepared from the MeOH extract. The results are shown in Figure 2 (Figure 2A, MeOH extract of the stored hops; Figure 2B, soft resin; and Figure 2C, hard resin).

As shown in Figure 2B, the presence of humulinones (**5a**−**5c** and **5c′**) and hulupones (**9a**−**9c**) in addition to α-acids (**1a**−**1c**) in the soft resin can clearly be observed. This is the first study reporting the presence of humulinones (**5a**−**5c** and **5c′**) and hulupones (**9a**−**9c**) in soft resin.

The compounds contained in the soft resin were barely detectable in the hard resin (Figure 2C). Indeed, xanthohumol (**10**) and the hydrophilic α-acid-derived oxidation products, such as tricyclooxyisohumulones A (**7a** and **7b**) and tricyclooxyisohumulones B (**8a** and **8b**) and 4′-hydroxyallohumulinones (**6a**−**6c** and **6c′**), were found only in the hard-resin

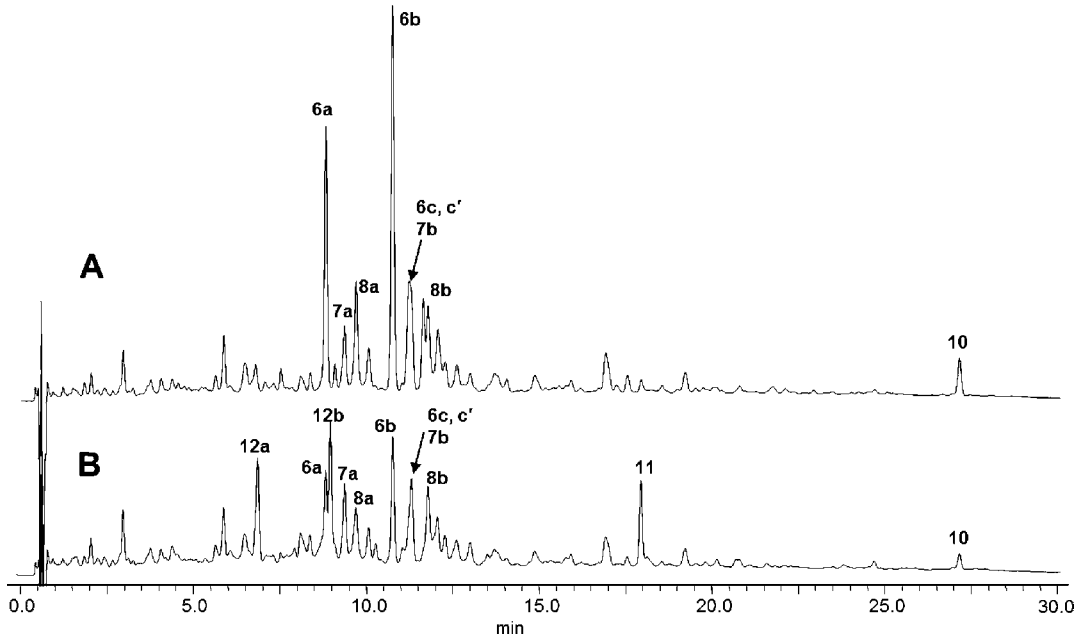

**Figure 3.** HPLC chromatograms of the hard resin (A) before and (B) after boiling in an aqueous buffer (pH 5.5) for 90 min. Structures of the compounds are given in Figures 1, 5, and 6.

extract. This is the first study to report the existence of these $\alpha$-acid-derived oxidation products in hard resin.

These findings also verify changes in the composition of the soft- and hard-resin constituents of hops caused by oxidation, because the concentration changes in $\alpha$- and $\beta$-acid-derived oxidation products in soft and hard resins detected in this study during oxidation of hops have been clarified in our previous studies.[21,22]

**Transformation of the Constituents of Hard Resin during the Wort Boiling Process.** There has been little reported data on the compositional changes in hard resin during the wort boiling process. Thus, we investigated the constituents in the hard resin after wort boiling. Changes in the chemical composition of hard-resin constituents were determined using a model boiling experiment conducted in an aqueous buffer (pH 5.5). HPLC analysis of the hard resin after 90 min of boiling (Figure 3B) clearly showed the transformation of xathohumol (**10**) into isoxanthohumol (**11**), which was reported previously.[20] In addition, the HPLC analysis also detected a decrease in the concentration of 4′-hydroxyallohumulinones [4′-hydroxyallocohumulinone (**6a**), 4′-hydroxyallo-*n*-humulinone (**6b**), and 4′-hydroxyalloadhumulinone (**6c**/**6c**′)] and the appearance of some new compounds (Figure 3B). These findings suggested, for the first time, further transformation of 4′-hydroxyallohumulinones in the hard resin during the wort boiling process.

**Isolation and Structural Elucidation of the Transformation Products of 4′-Hydroxyallocohumulinone (6a) and 4′-Hydroxyallo-*n*-humulinone (6b).** To verify the transformation of 4′-hydroxyallohumulinones into new compounds, isolated 4′-hydroxyallocohumulinone (**6a**) and 4′-hydroxyallo-*n*-humulinone (**6b**) were boiled in the same buffer. The HPLC analyses clearly showed the transformation of compound **6a** into compounds **12a** and **13a** (panels A1 and A2 of Figure 4) and compound **6b** into compounds **12b** and **13b** (panels B1 and B2 of Figure 4). We also boiled tricyclooxyiso-*n*-humulone A (**7b**) and tricyclooxyiso-*n*-humulone B (**8b**), but the compounds were stable (i.e., unchanged) under these conditions (data not shown).

To identify the transformation products of 4′-hydroxyallocohumulinone (**6a**) and 4′-hydroxyallo-*n*-humulinone (**6b**), each 200 mg sample of isolated compounds **6a** and **6b** was subjected to the boiling test. The compounds in the reaction products were purified using a two-phase solvent partition and preparative ODS HPLC, affording compounds **12a** (33.4 mg) and **13a** (4.0 mg) from compound **6a** and compounds **12b** (41.3 mg) and **13b** (5.9 mg) from compound **6b**.

Compound **12b** was obtained as a pale yellow oil. The HRESIMS data showed a $[M - H]^-$ ion at $m/z$ 393.1911 and, together with the $^{13}C$ NMR data, indicated a molecular formula of $C_{21}H_{30}O_7$, which is identical to that of compound **6b**. Analysis of the $^1H$ and $^{13}C$ NMR, $^1H-^1H$ correlation spectroscopy (COSY), heteronuclear multiple-quantum coherence (HMQC), and HMBC spectra of compound **12b** in methanol-$d_4$ established that compounds **12b** and **6b** possessed the same planar structure, whereas the $^{13}C$ NMR chemical shifts of C-5 and C-1″ were different between compounds **12b** [$\delta$ 85.1 (C-5) and 36.7 (C-1″)] and **6b** [$\delta$ 81.6 (C-5) and 31.3 (C-1″)][21] (Table 1). Furthermore, the nuclear Overhauser effect (NOE) observed between H-2′ and H-1″ in compound **6b**[21] was not observed in compound **12b**. From these results, compound **12b** was determined to be the C-5 epimer of compound **6b** and named 4′-hydroxyallo-*cis*-*n*-humulinone, which has not been previously reported (Figure 5).

Compound **13b** was obtained as a pale yellow oil. The HRESIMS data showed a $[M - H]^-$ ion at $m/z$ 281.1390 and, together with the $^{13}C$ NMR data, indicated a molecular formula of $C_{15}H_{22}O_5$ (**12b**$-C_6H_8O_2$). Analysis of the $^1H$ and $^{13}C$ NMR, $^1H-^1H$ COSY, HMQC, and HMBC spectra of compound **13b** in methanol-$d_4$ established that the *trans*-4-hydroxy-4-methyl-2-pentenosyl side chain attached at C-4 in compound **12b** was absent in compound **13b** (Table 1). Thus, the planar structure of compound **13b** was determined as oxy-*n*-humulinic acid (Figure 5). To determine relative configurations at C-4 and C-5 in compound **13b**, we prepared *cis*- and *trans*-oxy-*n*-humulinic

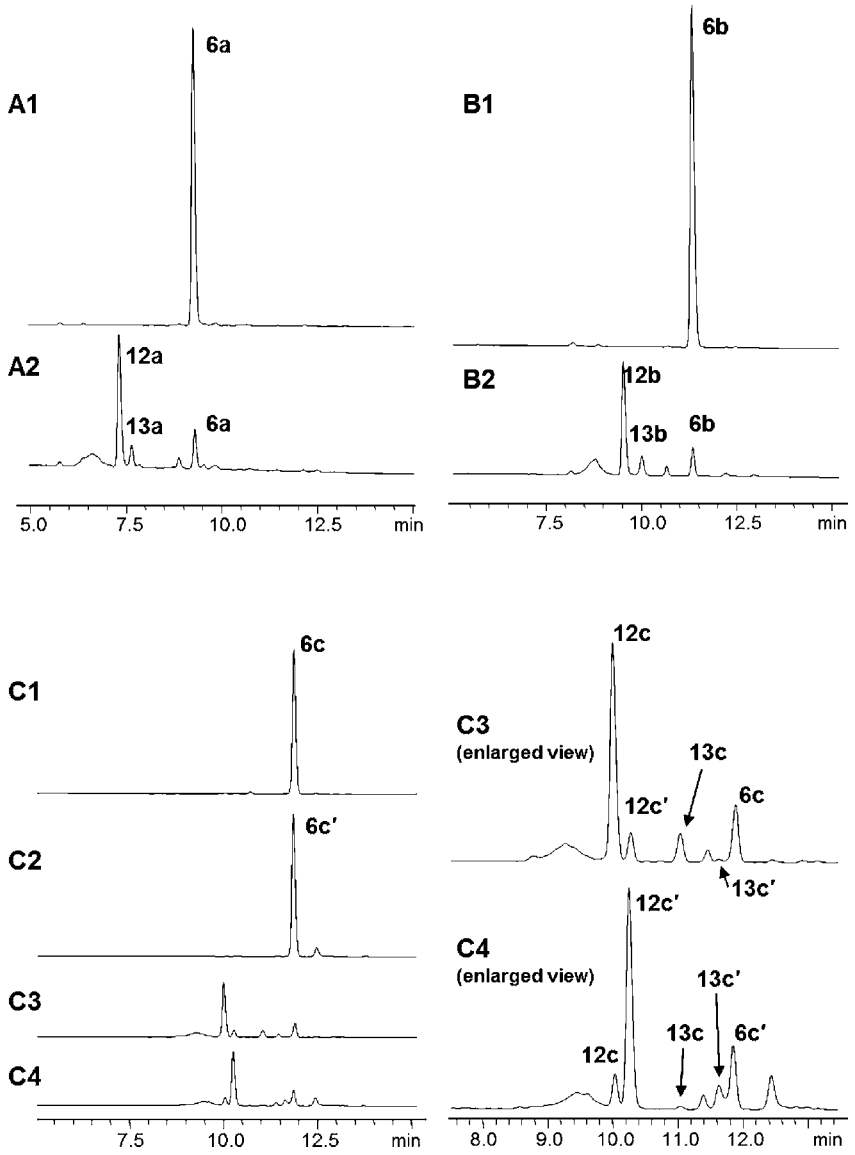

**Figure 4.** HPLC chromatograms of the isolated compounds before and after boiling in an aqueous buffer (pH 5.5) for 90 min. 4′-Hydroxyallocohumulinone (**6a**) (A1) before and (A2) after boiling, 4′-hydroxyallo-*n*-humulinone (**6b**) (B1) before and (B2) after boiling, and 4′-hydroxyalloadhumulinone A (**6c**) and 4′-hydroxyalloadhumulinone B (**6c′**) (C1 and C2, respectively) before and (C3 and C4, respectively) after boiling.

acids (epimers at C-5) by alkaline hydrolysis of *n*-humulinone (**5b**)[23] as a mixture and then isolated each isomer using preparative ODS HPLC. By $^{1}H$ and $^{13}C$ NMR analyses (Table 1), one of the two isomeric compounds was identified to be compound **13b**, and thus, the other (**14b**) was determined to be the C-5 epimer of compound **13b**. In the nuclear Overhauser effect spectroscopy (NOESY) experiments on compounds **13b** and **14b**, the NOE between H-4 and H-1″ (prenyl $CH_2$ attached at C-5) was clearly observed in compound **14b** but was barely detected in compound **13b** (see Figure S1 of the Supporting Information). Furthermore, *J*-resolved HMBC experiments[24] on compounds **13b** and **14b** showed that the absolute value of the two-bond $^{13}C-^{1}H$ coupling constant between H-4 and C-5 was greater in compound **13b** than in compound **14b** [$^{2}J$(C5, 4H) = 5.9 Hz in compound **13b**, and $^{2}J$(C5, 4H) $\leq$ 3.0 Hz in compound **14b**] (see Figure S2 of the Supporting Information), indicating a larger dihedral angle between H-4 and 5-OH in compound **14b** than compound **13b**.[25] These observations clearly indicated that H-4 and 5-OH were in the $\alpha$-orientation in compound **13b** and that H-4 and the prenyl group attached at C-5 were in the $\alpha$-orientation in compound **14b**. Thus, compound **13b** was determined as *cis*-oxy-*n*-humulinic acid, and compound **14b** was determined as *trans*-oxy-*n*-humulinic acid (Figure 5). Although the structures of compounds **13b** and **14b** were reported about 50 years ago,[23] we present their NMR data for the first time (Table 1).

Compound **12a** was obtained as a pale yellow oil. The HRESIMS data showed a $[M - H]^-$ ion at *m*/*z* 379.1753 and, together with the $^{13}C$ NMR data, indicated a molecular formula of $C_{20}H_{28}O_7$, which was the same as for compound **6a**. Analysis of the $^{1}H$ and $^{13}C$ NMR, $^{1}H-^{1}H$ COSY, HMQC, and HMBC spectra established that compound **12a** possessed an isobutyryl side chain at C-2 instead of an isovaleryl side chain in compound **12b** (Table 1). Thus, compound **12a** was identified

[a]Arbitrary numbering according to structures **12a**, **12b**, **13a**, **13b**, and **14b** shown in Figure 5.

dx.doi.org/10.1021/jf504394h | J. Agric. Food Chem. 2014, 62, 11602−11612

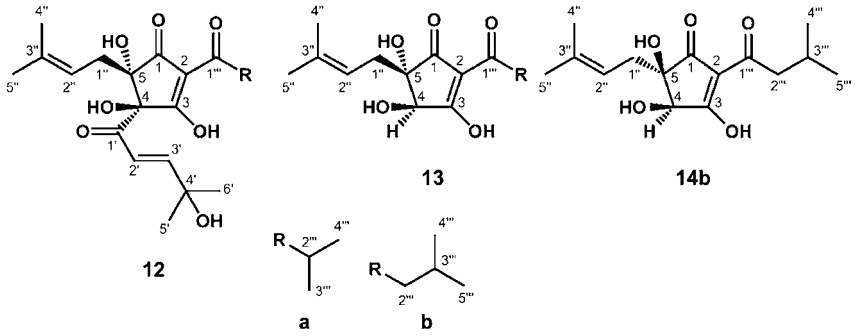

**Figure 5.** Chemical structures of 4′-hydroxyallo-*cis*-cohumulinone (**12a**), 4′-hydroxyallo-*cis*-*n*-humulinone (**12b**), *cis*-oxycohumulinic acid (**13a**), *cis*-oxy-*n*-humulinic acid (**13b**), and *trans*-oxy-*n*-humulinic acid (**14b**).

as 4′-hydroxyallo-*cis*-cohumulinone, which has not been previously reported (Figure 5).

Compound **13a** was obtained as a white, amorphous solid. The HRESIMS data showed a $[M - H]^-$ ion at *m*/*z* 267.1230 and, together with the $^{13}C$ NMR data, indicated a molecular formula of $C_{14}H_{20}O_5$ (**12a**−$C_6H_8O_2$). Analysis of the $^1H$ and $^{13}C$ NMR, $^1H$−$^1H$ COSY, HMQC, and HMBC spectra established that compound **13a** also possessed an isobutyryl side chain at C-2 instead of an isovaleryl side chain in compound **13b** (Table 1). Thus, compound **13a** was identified as *cis*-oxycohumulinic acid, which has not been previously reported (Figure 5).

Compounds **12a**, **12b**, **13a**, and **13b** were determined to be racemates because none of these compounds showed optical activity. Moreover, compounds **12a**, **12b**, **13a**, and **13b** were formed via a simple thermal reaction in aqueous solution from the precursors **6a** and **6b**, which do exist as racemates.[21]

**Analyses of the Transformation Products of 4′-Hydroxyalloadhumulinone (6c/6c′).** Adhumulinone, a precursor of 4′-hydroxyalloadhumulinone, is a mixture of two diastereomers (**5c** and **5c′**) (Figure 6).[21] Thus, 4′-hydroxyalloadhumulinone in hard resin is also a mixture of two diastereomers (**6c** and **6c′**) (Figure 6). Although ODS HPLC analysis using an acidic buffer could not separate the diastereomers (**6c** and **6c′**) (panels C1 and C2 of Figure 4), we successfully separated them through ODS HPLC analysis using a basic buffer (Figure 7). By employing a mobile phase containing the basic buffer, we isolated each diastereomer successively and named the former eluate in analytical HPLC ($t_R$, 16.6 min) as 4′-hydroxyalloadhumulinone A (**6c**) and the latter eluate ($t_R$, 17.5 min) as 4′-hydroxyalloadhumulinone B (**6c′**) (Figure 7). The $^1H$ and $^{13}C$ NMR data of compounds **6c** and **6c′** were almost identical (Table 2), and we could not analyze the respective stereochemistries of compounds **6c** and **6c′**.

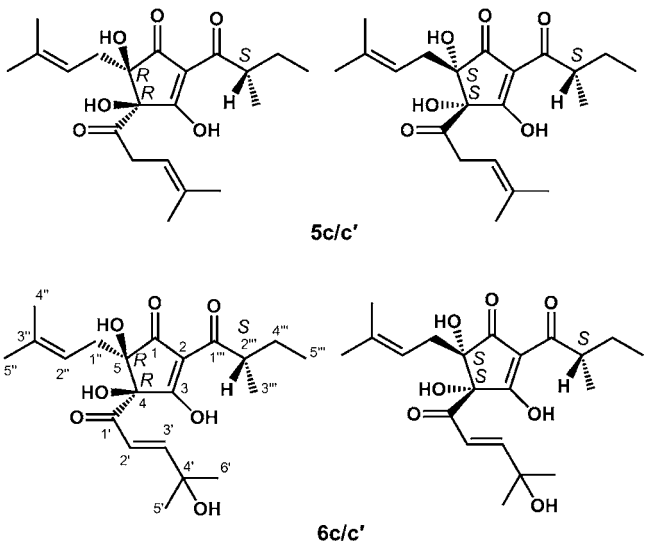

**Figure 6.** Chemical structures of adhumulinone diastereomers (**5c** and **5c′**) and 4′-hydroxyalloadhumulinones A and B (**6c** and **6c′**).

The yield of isolated compounds **6c** and **6c′** was too low to enable the separation of their transformation products in the boiling tests and perform structural determination by NMR analyses. Thus, we tentatively identified compound **12c** (main transformed product of compound **6c**) as 4′-hydroxyallo-*cis*-adhumulinone A and compound **13c** (minor transformed product of compound **6c**) as *cis*-oxyadhumulinic acid A, by comparison to the transformation products from 4′-hydroxyallocohumulinone (**6a**) and 4′-hydroxyallo-*n*-humulinone (**6b**) (Figure 4C3). Similarly, compounds **12c′** and **13c′** (transformed products of compound **6c′**) were tentatively identified as 4′-hydroxyallo-*cis*-adhumulinone B and *cis*-oxy-adhumulinic acid B, respectively (Figure 4C4).

The HPLC analysis of isolated compound **6c** demonstrated that it did not contain compound **6c′** (Figure 7B). Moreover, HPLC analysis of isolated compound **6c′** also showed that it did not contain compound **6c** (Figure 7C). However, the boiling test on compound **6c** afforded a small amount of compounds **12c′** and **13c′** in the HPLC analysis (Figure 4C3). A small quantity of compounds **12c** and **13c** was also obtained in the boiling test of compound **6c′** (Figure 4C4). These results suggested that the configuration at C-2‴ in compounds **6c**, **6c′**, **12c**, **12c′**, **13c**, and **13c′** may convert through proton exchange of H-2‴ during the boiling process. Figure 8 shows a plausible thermally induced epimerization of compound **12c** into the enantiomer of compound **12c′** and epimerization of compound **12c′** into the enantiomer of compound **12c**.

**Quantitative Analyses of 4′-Hydroxyallohumulinones and Their Transformation Products during the Boiling Process.** We aimed to quantitatively evaluate the changes in 4′-hydroxyallohumulinones and their transformation products during boiling. Thus, boiling solutions of compounds **6a**, **6b**, and **6c**/**6c′** were sampled at 30, 60, 90, and 120 min and analyzed by HPLC. Figure 9 shows the time-dependent decrease in 4′-hydroxyallohumulinones and compositional changes in the transformation products. The degree of conversion of 4′-hydroxyallo-*cis*-humulinones (**12a**, **12b**, and **12c**/**12c′**) increased until around 60 min and then slowly

[a]Arbitrary numbering according to structures **6c** and **6c′** shown in Figure 6.

decreased thereafter. In contrast, the amount of *cis*-oxyhumulinic acids (**13a**, **13b**, and **13c**/**13c′**) increased in inverse proportion to the decrease in the amount of 4′-hydroxyallo-*cis*-humulinones.

These results suggested that, during boiling, 4′-hydroxyallohumulinones (**6a**−**6c** and **6c′**) primarily isomerized into 4′-hydroxyallo-*cis*-humulinones (**12a**−**12c** and **12c′**), which then decomposed to *cis*-oxyhumulinic acids (**13a**−**13c** and **13c′**). The total amount of generated 4′-hydroxyallo-*cis*-humulinones and *cis*-oxyhumulinic acids accounted for 40−50% of the decomposed 4′-hydroxyallohumulinones. Our analysis indicates that, under these experimental conditions, about 10−15% of ad-congener substrates (**6c** and **6c′**) are epimerized through proton exchange at C-2‴ [calculated from the ratio of compounds **12c** and **12c′** generated from compound **6c** (Figure 9C) and compounds **12c′** and **12c** generated from

dx.doi.org/10.1021/jf504394h | J. Agric. Food Chem. 2014, 62, 11602−11612

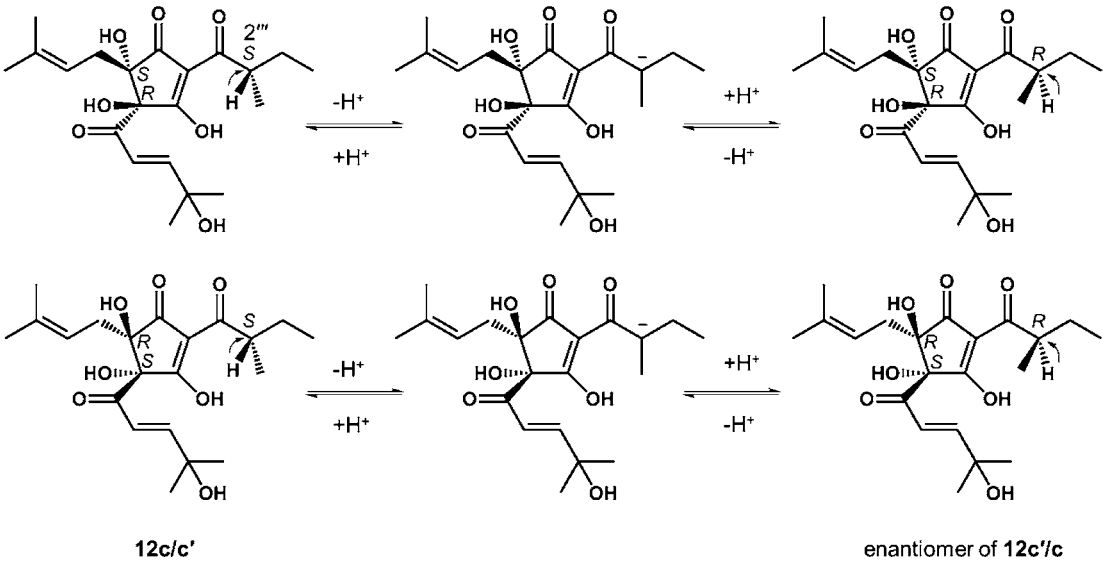

**Figure 8.** Proposed epimerization of 4′-hydroxyallo-*cis*-adhumulinones A and B (**12c** and **12c′**) through the proton exchange at C-2‴ as a result of boiling the sample.

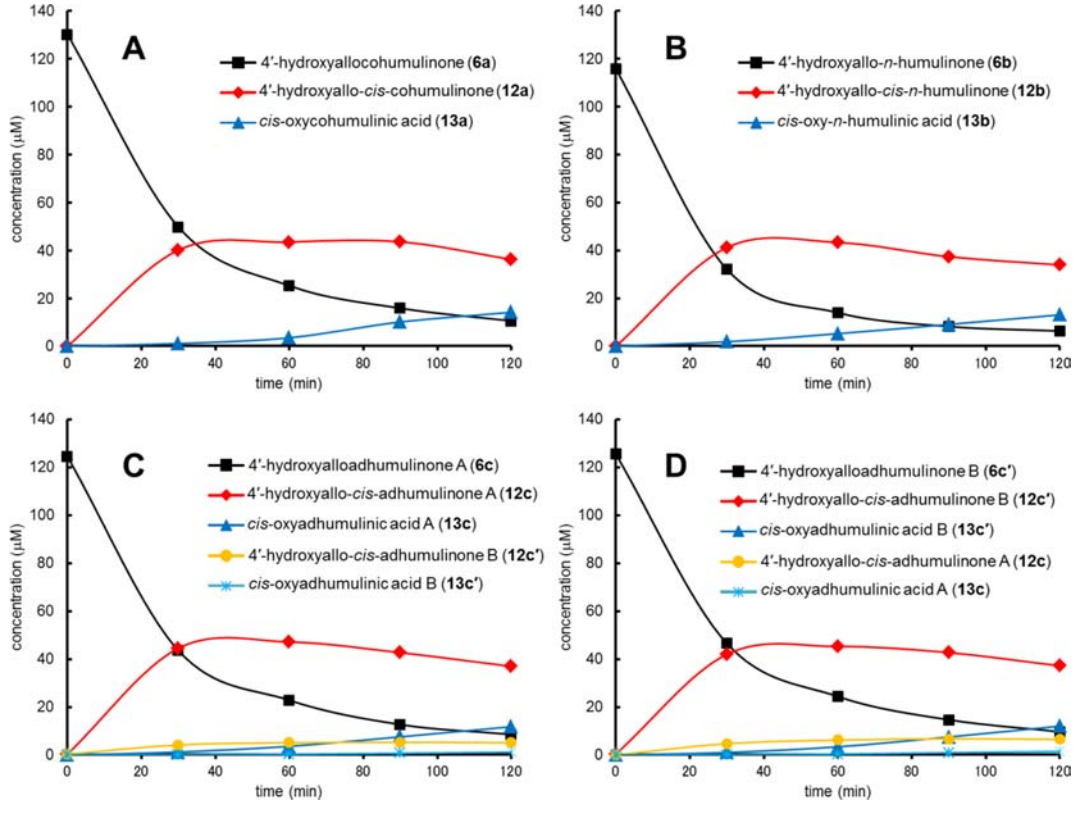

**Figure 9.** Concentration changes in (A) 4′-hydroxyallocohumulinone (**6a**), 4′-hydroxyallo-*cis*-cohumulinone (**12a**), and *cis*-oxycohumulinic acid (**13a**), in (B) 4′-hydroxyallo-*n*-humulinone (**6b**), 4′-hydroxyallo-*cis*-*n*-humulinone (**12b**), and *cis*-oxy-*n*-humulinic acid (**13b**), in (C) 4′-hydroxyalloadhumulinone A (**6c**), 4′-hydroxyallo-*cis*-adhumulinones A and B (**12c** and **12c′**), and *cis*-oxyadhumulinic acids A and B (**13c** and **13c′**), and in (D) 4′-hydroxyalloadhumulinone B (**6c′**), 4′-hydroxyallo-*cis*-adhumulinones A and B (**12c** and **12c′**), and *cis*-oxyadhumulinic acids A and B (**13c** and **13c′**) during boiling in an aqueous buffer (pH 5.5).

compound **6c′** (Figure 9D)]. This is the first study to report time-dependent changes of $\alpha$-acid-derived oxidation products in the hard resin during boiling. We believe these findings will be extremely valuable when evaluating effects of the hard resin generated through the oxidation of hops on beer properties.

In conclusion, we have clarified the main constituents, other than $\alpha$- and $\beta$-acids, of the soft and hard resins from stored hops. Furthermore, we investigated the compositional changes in the hard resin through wort boiling using model experiments and found that 4′-hydroxyallohumulinones (main constituents of the hard resin) were transformed to 4′-hydroxyallo-*cis*-humulinones and *cis*-oxyhumulinic acids. We believe our results will help to systematically evaluate the hard resin to optimize the effects of the hard resin on beer quality.

such natural materials as animals, plants, bacteria, and certain minerals".[3]

Biopesticides would be those things included in the definition of pesticide,[4] but with several modifications as noted above, in particular, "naturally occurring". Some people include synthetic pesticides derived from natural compounds as biopesticides. Third-generation pest control agents, reduced-risk pesticides, and biobased pesticides are other terms sometimes used interchangeably with biopesticides. Whatever the definition, the desirable qualities are

- Naturally occurring chemicals or their derivatives
- Reduced toxicity to nontarget organisms
- Reduced persistence in the environment
- Usable in organic agriculture
- Low mammalian toxicity
- Safe for farmworkers and nearby residents
- "Green" technology
- Nonrestricted use

Few products would fit all of these criteria. For example, no natural product-inspired or -derived synthetic compounds are approved for organic agriculture, nor would they be considered a biochemical biopesticide by the U.S. EPA.

## TRENDS

The market is growing, but still no biopesticides appear on the list of top 10 chemicals used in California. Some biopesticides are effective at low doses and would not be expected to appear on the list of pesticides used in largest quantities (Figure 1).[5] A

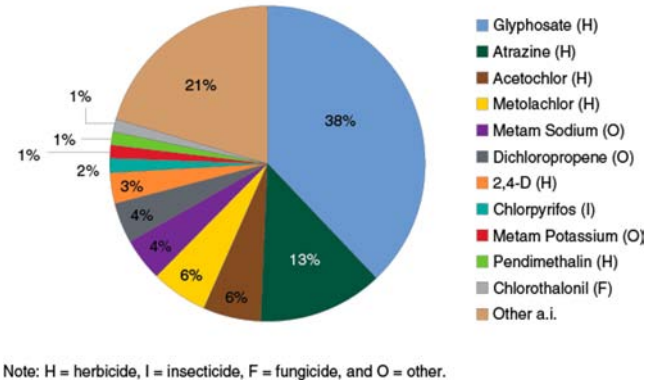

**Figure 1.** Most heavily used pesticides on 21 selected crops in the United States.[5]

reflection of the growing use of biopesticides may be found in trends in pesticide use, in California and worldwide, with compounds of nonconventional, bioderived structures such as spinosad and avermectins finding steadily increasing usage.

The trend both worldwide and in the United States is to reduce the amounts of pesticides since the peak in usage in the 1980s (Figure 2).[5] This trend reflects the phase-out of many high-dose chemicals such as toxaphene, DDT, and methyl bromide because of their environmental persistence and/or mammalian toxicity. More attention has been given to application methods that reduce drift and otherwise more precisely deliver the chemical to the target, thus reducing the amount of pesticide applied. The introduction of transgenic corn, soybeans, and cotton that are protected from insects by means of transgenes encoding *Bt* toxins (a PIP biopesticide) in the host plant has greatly decreased insecticide use in these crops. Integrated pest management tools, such as intercropping, cover crops, crop rotation, and use of hedgerows, have reduced pest populations without the use of external chemical application. The introduction of reduced risk pesticides such as spinosad that are effective at generally lower doses than conventional pesticides has furthered the reductions of amounts of pesticide applied.

Mechanical control, cover crops, solarization, and cultural methods can play a role in reducing the overall need for herbicides, as well as for other classes of pesticides. Agriculture is ripe for innovative approaches. Acquisitions and mergers may play into this as well as a society's desire for "green" technologies in helping with market development. In some cases the major retailers may favor organic or biopesticide approaches in products they market.

Smaller, specialty companies such as AgraQuest, Trécé, and Marrone Bio Innovations are leading the biopesticide technology as did Zoecon in the past, but larger companies such as Dow, DuPont, Monsanto, Syngenta, Merck, BASF, and Bayer are developing or marketing biopesticides along with the conventional chemicals that are their mainstays. The EPA has helped to catalyze the introduction of biopesticides by offering some regulatory relief for their registration. They include insect repellants and attractants, biochemical insecticides, fungicides, herbicides, nematicides, and others that were topics during this symposium. Figure 3 provides some examples of biochemical biopesticides approved by the EPA under their biopesticide program. The California Department of Pesticide Regulation (CDPR) does not offer a "fast track" for pesticide products involving biopesticides. However, if the biopesticide contains a new active ingredient, the applicant for registration can submit its application to CDPR concurrently with the application for federal registration with EPA. In addition, data requirements for biopesticides are reduced as compared to conventional chemicals, so the evaluation time period for a biopesticide may be shorter than for a conventional chemical.[6]

The trend toward reduced-risk pesticides, or toward little or no pesticide chemical at all, will likely continue and thus continue to lessen the load of xenobiotic chemicals in the environment. This said, it will be critical that practical levels of pest control be maintained, or even increased, so that agriculture can meet its challenge of providing more food within existing resources of land, water, and other resources to a world population expected to exceed 9 billion by 2050.

## NEEDS, OPPORTUNITIES, AND ALTERNATIVES

The case for new bioherbicides is particularly compelling in that the introduction of biochemical bioherbicides is lagging far behind those for pests other than weeds. Furthermore, there are strong needs for any new weed management technology because of the rapid evolution and spread of herbicide resistance.[7] Due to the widespread adoption of transgenic glyphosate-resistant (GR) crops, glyphosate has been over-used, resulting in evolution of extremely problematic GR weeds.[8,9] New herbicides with new modes of action are badly needed to combat GR weeds, as well as weeds with resistance to other herbicides, but no new herbicide mode of action has been introduced for well over 20 years.[10] Many natural phytotoxins that might be considered biochemical bioherbicides have novel modes of action that might fill this need.[11,12]

Weed management is the most costly pest management problem in organic agriculture.[13] In comparison to crop disease

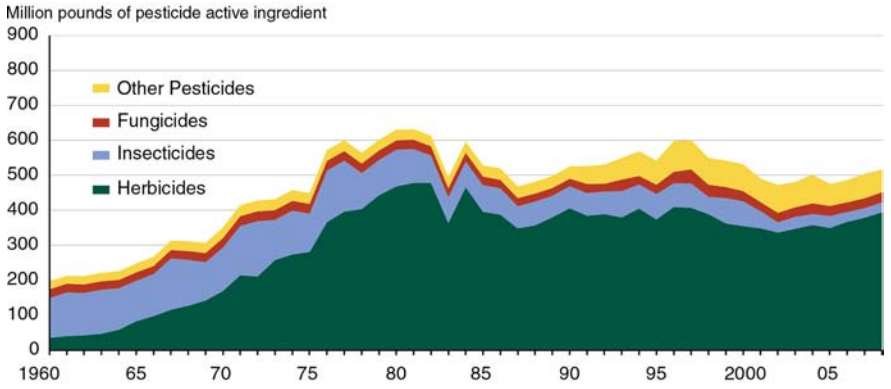

**Figure 2.** Pesticide use in U.S. agriculture, 21 selected crops, 1960–2008.[5]

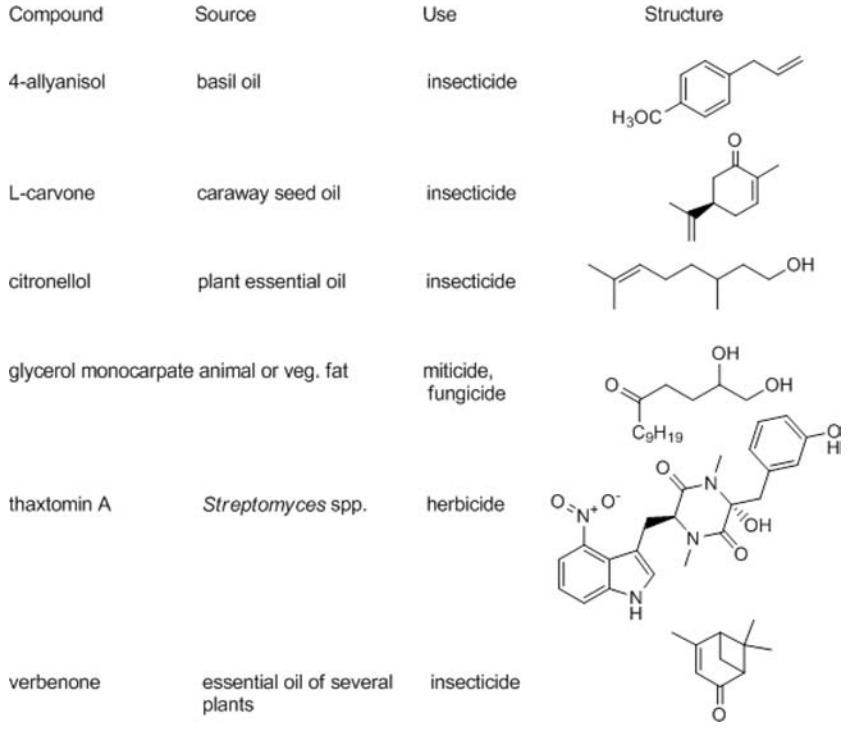

**Figure 3.** Examples of active ingredients for biochemical biopesticides registered by the U.S. EPA.

and insect management tools, organic farmers have relatively ineffective weed control products. Products such as corn gluten-based herbicides and vinegar require high dosage rates for control, and even then their performance is generally poor compared to that of synthetic herbicides. Furthermore, weed management with such tools is usually much more expensive than with conventional herbicides.[14] There are effective new bioherbicides in the pipeline (e.g., thaxtomin[15] from Marrone Bio Innovations), but some hurdles need to be surmounted before they are available for widespread use.

Similarly, new bionematicides for soil application and for use in stored products are critically needed. This is due to the mandated (Montreal Protocol) phase-out of methyl bromide and off-target movement and exposure issues with other fumigants such as methyl isothiocyanate (MITC) and chloropicrin.[16]

Semiochemicals, or sensing/communication chemicals, are another promising class of biopesticides that are far along in development including use in crop protection and related pest control needs. They include pheromones, allomones, kairomones, and other attractants and repellants for both monitoring and population control of pests. Some of the promising tools for orchard pest management come from the use of plant-biosynthesized pheromone mimics, such as the pheromone alternative found in pear leaves that can aid in control of the codling moth, a worldwide pest of apple, pear, walnut, almond, and other crops that is the reason for extensive pesticide-based control.[17] Controlling this damaging pest, and other boring insects that affect cotton seed and peanuts, is a critical element in controlling invasion of *Aspergillus* fungi, which can affect pome fruits, tree and ground nuts, and seeds, producing aflatoxins, a group of carcinogens, and other toxic mold metabolites. The use of semiochemicals to monitor insect pests in pistachio orchards was described by Beck et al.[18] in a presentation during the "Biopesticides: State of the Art and Future Opportunities" symposium.

Microbially produced biopesticides have been very successful in the past, with such products as bialaphos (bilanafos),

spinosyns, blasticidin, abamectins, validamycin, streptomycin, and milbemectin being sold as pesticides.[19] Semisynthetic modification of microbial products has also had some success in the generation of products such as emamectin from avermectin, lepimectin from milbemectin, and spinetoram from spinosyns. The impact of natural product-inspired pesticides (not biopesticides) has been tremendous, with such products as the strobilurin-based fungicides (e.g., azoxystrobin), and the synthetic version (glufosinate) of the natural herbicide phosphinothricin. Furthermore, there is an almost U.S. $1 billion market in live microbes as biocontrol agents, with or without natural product active ingredients. These include *Bacillus thuringiensis*, *Bacillus subtilis*, *Thichoderma* spp., and many others. New biopesticide products from microbes are being or may be introduced, such as the herbicides thaxatomin and mevalocidin. Microbial bioinsecticide products, such as formulations of *Chromobacterium subtsugae*, have been introduced into the marketplace. This product should be highly sustainable, in that it has a complex mode of action that causes repellency, oral toxicity, reduced egg hatch, and reduced fecundity.[20]

Pest management products from plants are also an important segment of the biopesticide market, including such products as pyrethrum and neem for insect control and many essential oil formulations for a range of pest management options. Isman[21] discussed botanical insecticides from a global perspective, noting that in 1980 <2% of all journal papers on insecticides dealt with botanicals, but the number exceeded 21% in 2011. There has been an explosive growth in reported studies of the insecticidal activity of plant essential oils, but this activity has not been reflected in increased commercialization of botanical insecticides, at least not in the major North American and European markets. Much of the interest in botanical insecticides has come from China and other Asian nations, Latin America, and Africa, perhaps a consequence of the potentially lower cost, local sourcing, and lower mammalian toxicity of many of these products relative to mainstream synthetics that have, regrettably, resulted in well-publicized human poisonings in earlier times.

Some of these plant products have inspired synthetic pesticides such as pyrethroids or could have inspired neonicotinoid and ryanodine receptor insecticides.[22−25] Although natural plant-derived triketones such as leptospermone show promise as bioherbicides, they provided the molecular scaffold for the synthetic triketone herbicides such as mesotrione.[26] Other phytochemicals are being used directly as biochemical biopesticides. These include an extract of the weed *Reynoutria* spp., which induces resistance to pathogens in crops,[27] and the compound sarmentine from *Piper longum*, which provides burndown-type weed management.[28]

Ashworth and coauthors[29] addressed MITC and other biofumigants using, for example, *Brassica* species incorporation in soil, which releases volatile isothiocyanate chemicals into the soil. They pointed out the disadvantages of the plant release scenario in soil, including relatively low release efficiency and rapid degradation and sorption within the soil, causing growers' reluctance to rely on biofumigants. On the other hand, bionematicides that do not operate by diffusion as vapors in the soil, such as ivermectins and ivermectin mixed with other chemicals, are showing promise in transitioning to a "fumigant-free" control strategy.[30]

RNAi is being rapidly developed for pest management.[31−37] RNAi may be ruled a biopesticide by the U.S. EPA because it leads to natural compounds that can be made to be highly selective with very little or no adverse environmental impact. Patents for different double-stranded RNA (dsRNA)-derived constructs to be used as insecticides, fungicides, nematicides, and herbicides have been filed by companies and public sector laboratories. Some of these products are at the trade name stage, and development is rapid.

## HIGHLIGHTS AND CHALLENGES

At the symposium it was stated that high levels of pest management (95% or better almost all of the time) that are expected with conventional pesticides may not be realistic for some biopesticides. Also, high levels of pest control with many biopesticides are more likely in integrated pest management systems that do not rely on a single technology for the control of a pest. In the long run, such an approach, although more complicated for the farmer, may be more sustainable because of the lower probability of evolved resistance to multiple technologies.

It is abundantly clear that research on semiochemicals for control of pests is advancing rapidly, especially the use of repellents and attractants. Attractants can be deployed several ways: (1) in traps for monitoring populations of pests (numbers and timing); (2) in attract-and-kill strategies that use baits laced with toxicants; or (3) in mating-disruption approaches, whereby an attractant pheromone is released in a large area to mask the gradients of pheromone emitted by female moths (for example), which would allow males to use the plume of pheromone to locate the female for mating, termed a "confusion" strategy. In addition, attractants can be utilized as part of a "push-pull" scenario, in which a repellent can push a pest species away from a specific habitat while an attractant pulls that species toward a different location, away from the host that needs protection from the pest.

One exciting highlight in the utilization of semiochemicals was the presentation of the novel delivery technology called specialized pheromone and lure application technology (SPLAT). Because nearly all attractants and repellents utilized in pest control are highly biodegradable (as well as chemically and physically degradable), their residence time in the environment is often less than optimal for the management of a pest. Progress on development of new slow-release technology has been gathering momentum recently, and the advances presented by Mafra-Neto et al.[38] are highly encouraging. The maximum value of highly specific pheromones, kairomones, or repellents will be realized only when a broadly applicable technology is developed for uses in multiple situations and becomes a somewhat standardized technology; the SPLAT slow-release methodology shows considerable promise toward that end.

Development of new classes of insecticides has often followed from identification of a natural pesticide's mechanism of toxic action. The current search for new target sites in insects, ticks, mites, and nematodes has focused on elucidation of receptors that are sensitive to natural ligands that may be encountered in a pest's habitat. Many secondary compounds in plants and microbes apparently have defensive functions, and we may be able to exploit that chemistry if we can determine the effects of those defensive compounds, for example, at specific receptors that are functionally important in the physiology of the pest species. Several classes are notable for being under-exploited in the management of pests: octopamine receptors, tyramine receptors, neuropeptide receptors, and

potassium channels are examples of target sites currently under investigation for expanded utility in pest management. Once mechanisms are understood, the natural ligands may be supplemented by the development of biorational derivatives and analogues and sometimes unrelated synthetic molecules. Among invertebrate groups of animals (insects, acarines, arachnids, nematodes, mollusks), their receptors vary in ways that can make a pesticide less broadly useful, but which may allow improved selectivity for controlling pests with minimal effects on nontarget species of many kinds. Creating selective toxicity differences for target/nontarget impacts is one of the inherent advantages to be gained from comprehension of how receptors function normally and how those processes can be disrupted biochemically or chemically. If a substantial series of closely related compounds are obtained (through bioprospecting or synthesis), quantitative structure−activity relationships can be developed, which often represent predictive information for us to find or design improved bioactive molecules.

The excitement offered in the 1970s with the publication of "third-generation pest control" by Carroll M. Williams[39] waned in the intervening years but is now on the upswing. Biopesticides are still only 3% of the global annual market for pesticides, but the market share is increasing, in part due to successful biopesticide products such as spinosad and avermectin. These products and others in the pipeline must offer efficacy against key pests, a useful spectrum of activity, robust performance, and a viable manufacturing and supply chain for continued success. The genes controlling the activity in some products, such as the Gram-positive Bt toxins, can be moved in such a way that control is delivered through the seed rather than through the air, water, or soil, an advantage for some biopesticides. However, Bt toxins are not efficacious against all pest species; for instance, hemipterans are less susceptible to Bt toxins.[40] Bonning and co-workers[41] discussed important advances in the modification of Bt toxins allowing them to be more effective pest control agents among less susceptible insects. This includes the addition of a short peptide sequence on a Bt cytolytic toxin (Cyt2A) showing efficacious effects against hemipteran pests (*Acyrthosiphon pisum* and *Myzus persicae*). This advance in biotechnology allows for a wider utilization of Bt toxins against a variety of pests.

It is evident that there is accelerated growth in biotechnology for pest control. The use of dsRNA has made rapid advances as a biotechnological tool for pest control. The RNAi pathway is a naturally evolved pathway, which creates a response against sequence-specific invading nucleic acids and is triggered by dsRNA. Successful use of RNAi machinery includes the identification of genes that have an essential physiological function, gene targets with high transcript levels and high protein turnover, and genes that have specific sequences that can be targeted. Siegfried[42] identified several areas of advancement of RNAi in pest management. Advancements include the use of baits for urban pest management,[43] nanoparticle stabilization for controlling the African malaria mosquito,[44] microbial formulation for spraying,[45] and plant expression for row crop agriculture.[46] This form of biopesticide offers new levels of target specificity for possible control of Varroa mites[47] or viruses[48] inside a bee hive without harm to the bees, a remarkable feat.

High-throughput discovery and microencapsulation (including in nanoparticle-based formulations) are technologies that can speed the development of biopesticides. Combinations of active chemicals are the rule in nature, perhaps because of synergies and/or reduced chances of evolved resistance. An organism may biosynthesize hundreds of related terpenes, for example, only some of which are active and then only in limited proportions. For example, there is good evidence of synergies in insect-active essential oil components, even involving compounds that are inactive when tested in isolation.[49] Whether mixtures will become more common in biopesticide products is an open question. Mixtures can increase the range of product properties, but they also raise regulatory questions for an approval process that values single, or just a few, active ingredients in a new pesticide product.

An example of the pitfalls to avoid with mixtures is provided by the second-generation insecticide toxaphene, for which a few of the more than 175 plus isomers and congeners of chlorinated camphene were responsible for most of the useful insecticidal activity. At least some of the compounds in this witch's brew were herbicidal, as toxaphene was also sold as a herbicide. The herbicidal components were never identified.[50] The bulk of the 175 related compounds contributed to widespread environmental contamination, and some possessed significant toxicity to nontarget organisms, including threatened or endangered wildlife.[51] It is important to understand the physical, chemical, and toxicological properties of each component of a mixture and its role in the utility of the mixture prepared for commercial use. This is often difficult for complex mixtures of naturally occurring or synthetic chemicals.

Goldblum, Warren, and Burlingame of Allylix discussed the future opportunities for novel pest control agents composed of terpenes, the most diverse class of biomolecules, or their derivatives.[52] Technology now exists for sustainable production of sesquiterpenes, a group of terpenes with many high-value applications including flavors and fragrances, cosmetic products, food ingredients, pharmaceuticals, and insecticides. Nootkatone, the flavor- and fragrance-defining chemical in grapefruit, is an effective acaricide and repellant. Terpene-based biopesticide products have the potential to compete with conventional pesticides on both efficacy and economic bases.

Because of the economic hurdles on the path from discovery to commercialization of new pesticides and new uses of existing pesticides, the IR-4 project was established in 1963 as a public sector program to facilitate registration of minor-use or specialty pesticides, including biopesticides. The biopesticide program of IR-4 was established in 1982 to assist in the registration of biochemical biopesticides such as plant extracts, pheromones, and minerals in addition to microbial and biotechnology projects.[53,54] Since its inception, IR-4 has provided over U.S, $6.7 million in grants for biopesticide R&D efforts.

Many of the symposium attendees echoed the need for additional sources of funds for research, development, education, and commercialization of biopesticides to advance this relatively new industry, much as public funds and incentives are being devoted to biofuels, bioenergy, and other aspects of the bioeconomy.

*High-Performance Liquid Chromatography (HPLC) Fraction Preparation.* Sample preparation was as optimized by Lytra et al.[7] A 500 mL wine sample was extracted with 80, 80, and 50 mL of dichloromethane, successively, for 10 min. The organic phases were collected, blended, dried over sodium sulfate, and concentrated using a Rotavapor (Laborota 4010 digital Rotary Evaporator, Heidolph, Germany) with a 20 °C bath temperature to obtain 1.25 mL of wine extract. Reversed-phase (RP) HPLC was performed on this raw extract using a Nova-Pak C18 column (300 × 3.9 mm i.d., 4 μm, 60 Å, Waters, Saint-Quentin, France) without a guard cartridge. The HPLC system consisted of an L-6200A pump (Merck-Hitachi, Germany). Chromatographic conditions were as optimized by Pineau et al.:[8] flow rate, 0.5 mL/min; injection volume, 250 μL wine extract; program gradient, phase A, water, phase B, ethanol; 0−2 min, 100% A, linearly programmed until 100% B at minute 50. The effluent was collected in 1 mL fractions. Twenty-five fractions with various aromas were obtained in dilute alcohol solution.

*HPLC Fraction Extraction.* Each fraction was diluted in distilled water to obtain 12% ethanol and then re-extracted by using the same method as for the wine, but with 4, 2, and 2 mL of dichloromethane (5 min stirring for each extraction). The organic phases were collected, dried over sodium sulfate, and concentrated under nitrogen flow to obtain 100 μL of extract.

**Gas Chromatography−Olfactometry (GC-O).** Olfactometry analyses were carried out by a panel of three judges during 40 min, using an HP-4890 gas chromatograph (Hewlett-Packard, Wilmington, DE, USA), equipped with a flame ionization detector (FID) and a sniffing port (ODO-I SGE, Ringwood, Australia), connected by a flow-splitter to the column exit. GC effluent was combined with humidified $N_2$ (Linde, France) at the bottom of the glass sniffing nose (SGE, Victoria, Australia) to avoid nasal dehydration. Two microliters of organic extract was injected in splitless mode (injector temperature, 250 °C). The column was a BP21 (SGE), 50 m × 0.32 mm i.d., film thickness = 0.25 μm. The oven was programmed at 40 °C for the first minute, and the temperature was increased at a rate of 4 °C/min to a final isotherm at 220 °C for 20 min. The carrier gas was hydrogen 5.0 (Linde) with a column head pressure of 15 psi.

**2-Bromo-4-methylphenol Identification.** Two microliter samples taken from the 100 μL of organic extract of fraction 19, corresponding to an initial volume of 3 L of wine, were injected in splitless−split mode (injector temperature, 250 °C; interface temperature, 280 °C; splitless time, 45 s; split flow, 50 mL/min) using an HP 7890 gas chromatograph (Hewlett-Packard) coupled to a mass spectrometer (HP 5975). The column was a BP21 (SGE), 50 m × 0.32 mm i.d., film thickness = 0.25 μm. The oven was programmed at 40 °C for the first minute and then heated at a rate of 4 °C/min to a final isotherm at 220 °C for 20 min. The carrier gas was helium N55 (Linde) with a column head pressure of 8 psi. The MSD was used in full-scan mode ($m/z$ 40−300, 3.09 scans/s). MS data were recorded and processed using Chemstation software equipped with NIST 2011 MS library (U.S. National Institute of Standards and Technology, Gaithersburg, MD, USA). The compound was then characterized by comparing its LRI and mass spectra with those of a standard.

**2-Bromo-4-methylphenol Quantitation.** *Solid Phase Microextraction (SPME).* Sample preparation was inspired by the protocol of OIV analysis of methods.[9] The fiber used was coated with polyacrylate stationary phases and an 85 μm film thickness. It was conditioned before use by insertion into the GC injector set at 280 °C during 1 h as recommended by the manufacturer. To a 20 mL headspace vial was added a 10 mL sample of either wine, spiked wine, or a blank solution of 12% (v/v) in water. To this were added 3 g of sodium chloride and 20 μL of a 5.6 mg/L solution of 2,4-dibromoanisole as internal standard, and then the vial was tightly sealed with a PTFE-lined cap. The solution was homogenized with a vortex shaker for 5 s and then loaded onto a Gerstel MPS2 autosampling device provided by R.I.C. (Saint Priest, France). The program consisted of whirling the vial at 500 rpm for 2 min at 60 °C, then inserting the fiber into the headspace for 50 min at 60 °C as the solution was swirled again, and then transferring the fiber to the injector for desorption at 250 °C for 5 min. Finally, the fiber was cleaned in a thermal desorption cleaner for 15 min at 200 °C.

*Gas Chromatography−Mass Spectrometry (GC-MS) Analysis.* The GC parameters were the same as those described in the identification method. The mass spectrometer was operated in electron ionization mode at 70 eV in selected-ion-monitoring (SIM) mode. The ions monitored were $m/z$ 107, 186, and 188 fragments from 20 to 37.2 min and $m/z$ 251, 264, 266 fragments from 37.2 min to the end of run with dwell time of 50 msec.

The limits of detection (LODs) (concentration for signal/noise = 3) and the limits of quantitation (LOQs) (concentration for signal/noise = 10) were calculated manually from the ratio of the peak heights to the average noise before and after each peak. These data are listed in Table 2.

For validation, repeatability assays were carried out on white, rosé, and red wines, which were not affected by the defect, spiked with **1** at 80, 60, and 100 ng/L, respectively. Recovery assays were carried out on white, rosé, and red wines, which were not affected by the defect, spiked with 50.5 ng/L.

**1** quantitation method parameters are shown in Table 2.

*Method Optimization.* Spiked white wine (Bordeaux, 2011) was use to optimize the method. Seven different fibers were tested to select

**Table 2. 2-Bromo-4-methylphenol Quantitation Method[a]**

| matrix | LOD (ng/L) | LOQ (ng/L) | linear range (ng/L) | $R^2$ | CV (%) | recovery (%) |
|---|---|---|---|---|---|---|
| white wine | 9 | 30 | 16–2736 | 0.9996 | 3.9 | 101.5 |
| rosé wine | 9 | 29 | 16–2736 | 0.9991 | 2.8 | 104.8 |
| red wine | 11 | 36 | 16–2736 | 0.9999 | 1.9 | 104.5 |

the best one for extracting 2-bromo-4-methylphenol. They were coated with various stationary phases and film thicknesses: 50/30 μm divinylbenzene/carboxen/polydimethylsiloxane (DVB/CAR/PDMS), 85 μm carboxen–polydimethylsiloxane (CAR-PDMS), 100 μm polydimethylsiloxane (PDMS-100), 65 μm polydimethylsiloxane–divinylbenzene (PDMS-DVB), 85 μm polyacrylate (PA), 70 μm carbowax–divinylbenzene (CW-DVB), and 60 μm polyethylene glycol (PEG) purchased from Supelco (Bellefonte, PA, USA). They were conditioned before use by insertion into the GC injector as recommended by the manufacturer. Adsorption time was set at 20 min at a temperature of 35 °C. Figure 1a shows that 85 μm polyacrylate (PA) fiber resulted in the highest signal-to-noise ratio for **1** and was thus selected as the best one for this analysis.

The effect of temperature was examined by sampling a spiked white wine at 30, 40, 50, 60, and 70 °C using the PA-85 fiber with a constant extraction time of 20 min. A temperature of 70 °C resulted in the highest absolute area for **1**, but 60 °C produced a better signal-to-noise ratio, as shown in Figure 1b. Consequently, 60 °C was selected as the adsorption temperature. A range of extraction times (20–70 min) were tested at 60 °C, using the PA-85 fiber to optimize the SPME sampling period. As shown in Figure 1c, adsorption onto the fiber increased with extraction time, reaching the best signal-to-noise ratio at 50 min.

To check the effect of ionic strength, the solution was supplemented with 0–4 g of sodium chloride and tested at 60 °C. The addition of 3 g resulted in the best signal-to-noise ratio for **1**, compared to 2 and 4 g (Figure 1d). All tests were duplicated.

**Sensory Studies.** *General Conditions.* Sensory analyses were performed according to the relevant ISO standards[10] and as described by Martin and de Revel.[11] Samples were evaluated in individual booths in a ventilated tasting room at controlled room temperature.

All samples were evaluated only orthonasally (all data were collected via olfaction alone).

*Materials.* Several matrices were used for sensory analyses: reverse osmosis water, a white wine (AOC Entre-deux-Mers, 2012), a rosé wine (AOC Buzet, 2012), and a red wine (Merlot Pays d'Oc). None of the wines contained **1** before it was added for sensory analysis (sensory and analytical controls).

Commercial **1** served as a base material. To make this compound soluble, a stock solution was prepared, containing an average of 1.1 g/L in ethanol.

*Panels.* Samples were selected (wine samples and HPLC fractions) for physicochemical analysis by a panel of three judges. Judges were selected on the basis of availability and interest. Participants (27–37) in the sensory panels were volunteers. All panelists were research laboratory staff at ISVV, Bordeaux University, with homogeneous sensory expertise. Detection threshold measurements in reverse osmosis water or in white wine as well as the qualitative effect of **1** addition in reverse osmosis water and in commercial wines naturally

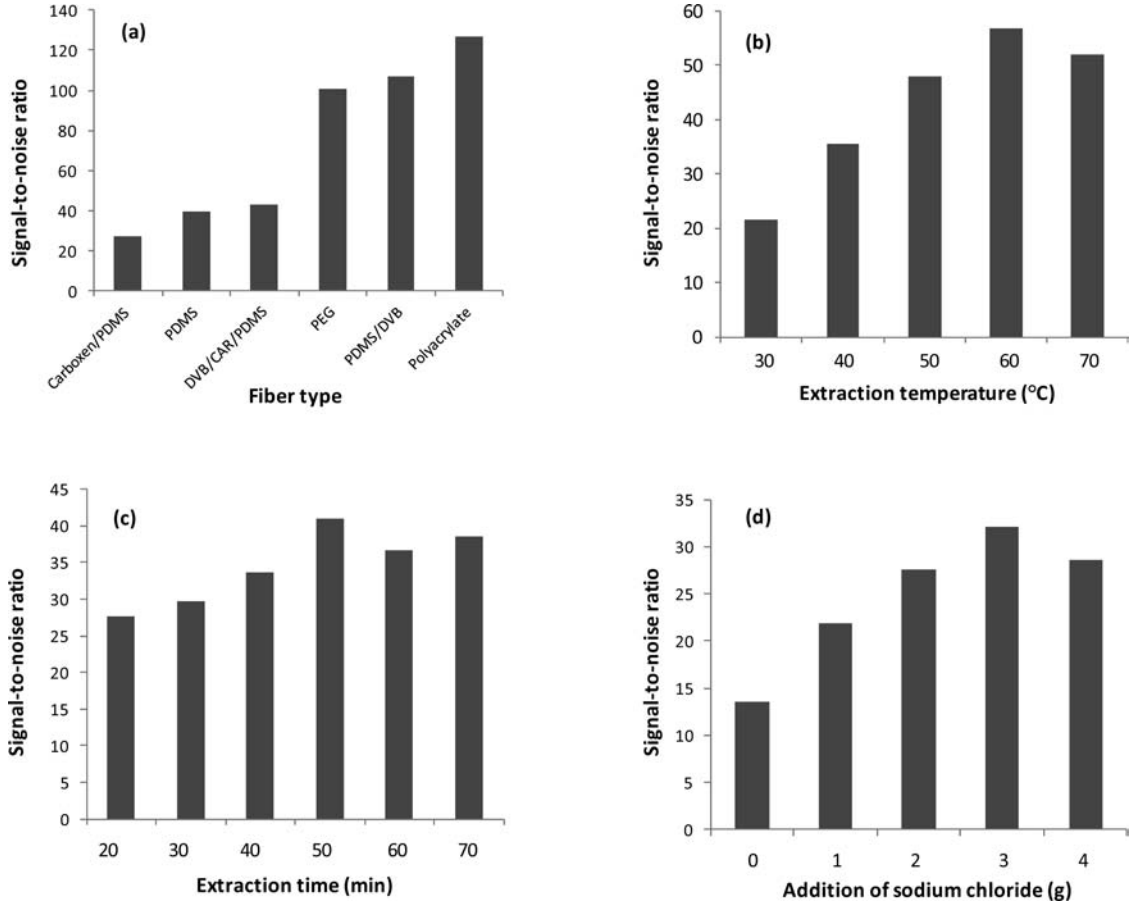

**Figure 1.** Signal-to-noise ratio in white wine depending on (a) fiber type, (b) extraction temperature, (c) extraction time, and (d) addition of sodium chloride.

affected by the defect were carried out by 37 assessors (panel 1), detection threshold in rosé wine by 27 assessors (panel 2), and detection threshold measurements in red wine by 35 assessors (panel 3). Ages ranged between 21 and 53 years, and the panels consisted of 54−68% females. The qualitative effect of **1** addition in red wine matrix was realized with a panel of 53 students (panel 4, 32 females and 21 males with an average age of 24) in enology in the first 6 months of their training.

**Quantitative Effect of 2-Bromo-4-methylphenol.** The detection thresholds were determined in water or in selected wines, with an ascending procedure (ten concentrations) and the three-alternative forced choice presentation method (AFC).[12]

For each concentration, the subject received a set of three covered ISO glasses coded with three-digit numbers.[13] Two of these glasses were blank samples (reverse osmosis water or selected wines) and one contained the **1** dilution (positive sample). For each concentration, the order of presentation was randomized.

For the whole series of dilution sets, each assessor was required to first sniff each glass in the prescribed order and then close the spiked sample in each set of three glasses.

The stimulating perithreshold concentration ranges to be used were determined on the basis of preliminary experiments (Table 3).

**Table 3. Concentration Ranges of 2-Bromo-4-methylphenol Used for Sensory Analysis**[a]

| matrix | concentration range used (ng/L) |
|---|---|
| reverse osmosis water | 0.2−109.4 |
| white wine | 0.5−273.6 |
| rosé wine | 2.1−1094.4 |
| red wine | 2.1−1094.4 |

[a]Concentration ranges were prepared in a geometric series (2-fold), and this table shows the extreme values of the ranges.

The individual detection threshold was estimated as the geometrical mean between the last concentration missed and the first concentration detected.[12]

**Qualitative Effect of 2-Bromo-4-methylphenol.** *Qualitative Effect of Adding 2-Bromo-4-methylphenol to Reverse Osmosis Water.* Each participant (panel 1) received a glass containing **1** solution at a supraliminal concentration (3283 ng/L), prepared in reverse osmosis water and presented in a covered ISO glass.[13] Participants were required to give the most precise olfactory description of the stimulus and answer the following question: "What terms would you use to characterize this sample?" No limit to the number of attributes was imposed on the subjects, and no specific instructions were given to participants concerning hedonic or subjective terms.

All of the descriptors for **1** evoked by the participant were recorded. The quotation frequency (QF) was calculated for each term, using the following formula: QF = NQ/$N$ (NQ = the number of participants who quoted the terms and $N$ = the number of terms quoted). Synonyms were included within an umbrella term or a higher level family.

*Qualitative Effect of Adding 2-Bromo-4-methylphenol to Red Wine.* This sensory task was conducted using red wine spiked with 22 ng/L **1**, antimode of the detection threshold distribution. Participants (panel 4) were required to give the most precise olfactory description of the wine presented. The QF was calculated for each term, using the following formula: QF = NQ/$N$ (NQ = the number of participants who quoted the terms and $N$ = the number of terms quoted).

*Qualitative Effect of 2-Bromo-4-methylphenol in Commercial Wines Naturally Affected by the Defect.* Six red and 7 rosé wines affected by the defect were presented to 37 assessors (panel 1), and they were asked if they perceived any off-odor. Participants who perceived an off-odor were then asked to describe the nuances in that sample by choosing a descriptor. For each sample, the subject rated the intensity of these descriptors on a 0−8 point structured scale, where 0 = no odor and 8 = high intensity.

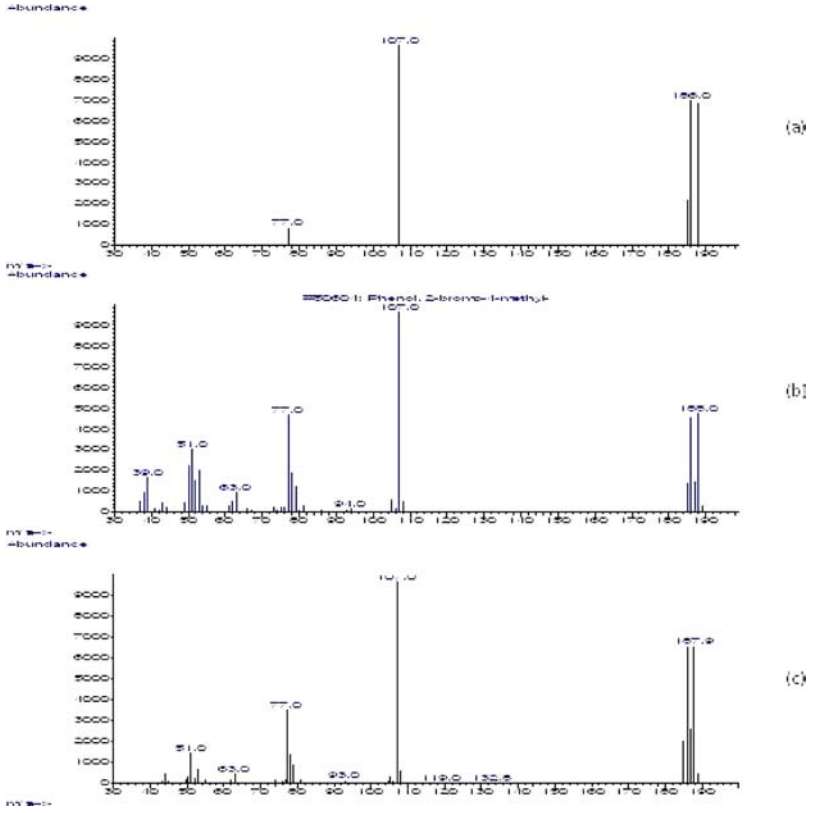

**Figure 2.** (a) Mass spectrum of a peak naturally present only in an affected wine. (b) Mass spectrum of 2-bromo-4-methylphenol from NIST 2011 Spectral Library (NIST Registry No. 50599; CAS Registry No. 006627-55-0). (c) Mass spectrum of 2-bromo-4-methylphenol reference compound.

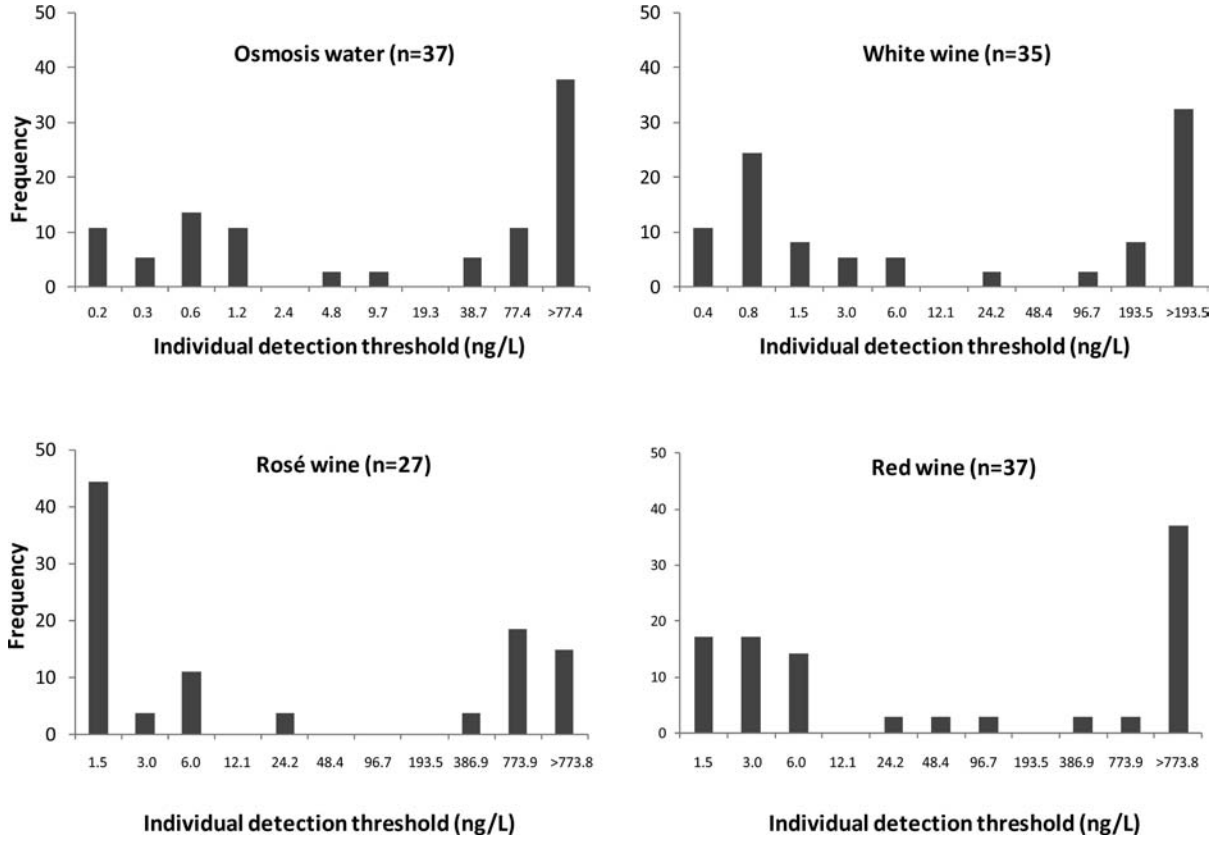

**Figure 3.** Individual detection threshold distribution for 2-bromo-4-methylphenol in different matrices. *n* = number of subjects tested.

## RESULTS AND DISCUSSION

**2-Bromo-4-methylphenol Identification.** Among 25 wine HPLC fractions, from 4 samples affected by this off-flavor, only fraction 19 was characterized by an iodine odor.

Its composition was analyzed using gas chromatography coupled to olfactometry (GC-O) and mass spectrometry (GC-MS). The olfactometry approach revealed that, in the wine fraction extract, only one iodine odor zone (OZ), with a linear retention index (LRI) of 2094, was perceived by the three members of the panel, who described it as "iodine" and "oysters".

GC-MS was used to identify the compound responsible for the iodine OZ. This OZ was first targeted by its LRI. GC-MS revealed that the spectrum of the OZ "iodine" compound, naturally present only in affected wines, exhibited the same peak, identical fragmentation, and comparable relative abundances to **1**, indexed in the NIST 2011 library. These results were confirmed by comparing the LRI and mass spectrum of the compound detected in wine with that of reference compound **1** (2095 on the BP21 column). The chromatograms and mass spectra obtained are presented in Figure 2. Finally, olfactometry (GC-O) confirmed that the odor quality of the pure compound matched that of the corresponding OZ eluted from the wine extract.

To our knowledge, this compound had never previously been identified in wine, so neither the concentrations present nor its aromatic impact had previously been described.

**2-Bromo-4-methylphenol Levels in Wines.** The **1** levels in the 8 white, 44 rosé, and 13 red wines assayed are shown in Table 1. The wines presented a wide range of levels, with maximum concentrations of 28900, 7556, and 48000 ng/L and minima of 260, 35, and 63 ng/L in white, rosé, and red wines, respectively. However, 4 white (Table 1A), 20 rosé (Table 1B), and 5 red wines (Table 1C) presented levels below the quantitation limit of this method. The average concentration was about 2754 ng/L in the wines studied where **1** was present at levels higher than the quantitation limit.

This study highlighted the occurrence of a new wine contaminant, 2-bromo-4-methylphenol, detected in wines acidified using ion-exchange resins. This compound was found at levels between 35 and 48000 ng/L, and this diversity suggests that levels may vary at different times during the resin treatment cycle. Regulations concerning cation-exchange resins are not necessarily in disagreement with our results. Indeed, only the maximum release of organic compounds is regulated (1 mg/kg when the first 40 volumes of liquid flow through the resin), and there is no specific limit value expressed for any individual compounds.[14] At this stage in our research, nevertheless, it is not possible to incriminate ion-exchange resins directly: the presence of **1** may also be linked to various processes accompanying the use of resins, such as regeneration conditions, washing, and flow rate, and further investigation is thus necessary.

**Quantitative Effect of 2-Bromo-4-methylphenol.** Figure 3 shows the distribution of individual detection thresholds for **1** in different matrices. In water, individual thresholds ranged from 0.15 to >77.4 ng/L, with a very wide distribution, suggesting the presence of two populations, sensitive and nonsensitive. Additional measurement revealed that some subjects were able to detect **1** in water at a concentration of 0.005 ng/L (2/37 subjects). Moreover, a few subjects (3/37 subjects) failed to detect **1** at a concentration of 2500 ng/L.

The range of dilution factors between the two extreme sensitivities revealed a panelist variability >5 × $10^5$.

Determination of anosmic frequencies for different compounds has been studied extensively,[15−17] but such a wide variation in sensitivity for a compound such as **1** had never been reported. These considerable variations in olfactory sensitivity to **1** affect the ability to detect this compound in wine. Individual thresholds ranged from 0.4 to >193.5 ng/L in white wine, from 0.5 to >774 ng/L in rosé wine, and from 0.5 to >774 ng/L in red wine. Moreover, the frequency distributions were apparently bimodal (continuous probability distribution with two different modes).[18] No gender or age effect was observed.

The pertinence of the olfactive detection threshold has been undermined by highlighting some remarkable perceptual interactions involving compounds at levels well below their individual detection thresholds in the experimental mixture.[19] In this study, the concept of an olfactive detection threshold may also be challenged, because **1** was perceived very differently depending on the subject and considering the detection threshold to be the "average" between those of sensitive and nonsensitive subjects would be meaningless.

**Qualitative Effect of Adding 2-Bromo-4-methylphenol to Reverse Osmosis Water.** After a session during which a glass containing a large subthreshold concentration of **1** was presented to the panel, 48 terms used by the subjects were counted: 25 different terms designating objects or families of objects were collected, and 2 hedonic descriptions (e.g., "unpleasant") were used. However, 8 of 37 subjects did not perceive any odor. In view of the wide range of sensitivities observed, only the results of the more sensitive group (16 subjects, representing 43% of the panel, whose individual detection thresholds in water were <19.3 ng/L) were considered (Figure 4). These more sensitive subjects used 19 different terms on varying levels. Therefore, synonyms were included within an umbrella term or a higher level family, as shown in Table 4.

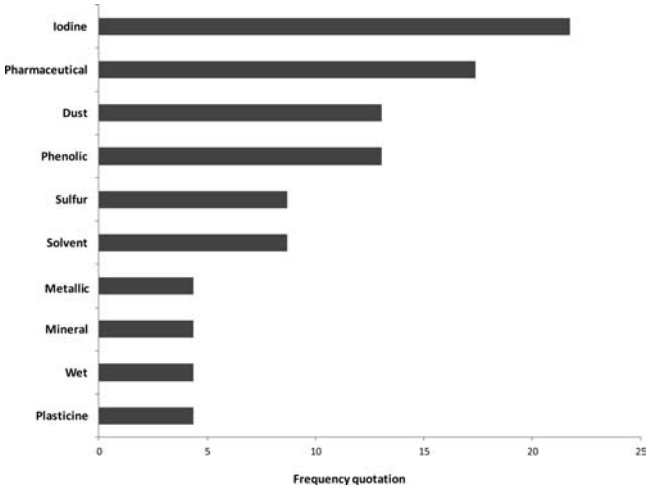

**Figure 4.** Quotation frequency, expressed in percentage, for each term cited by the 16 sensitive subjects (of 37) when 2-bromo-4-methylphenol was added to reverse osmosis water. Quotation frequency is the ratio of the number of participants who quoted the term to the number of terms collected.

**Table 4. Terms and Synonyms Cited by Sensitive Subjects Describing Reverse Osmosis Water Supplemented with 2-Bromo-4-methylphenol**

| terms | umbrella term |
|---|---|
| chlorine, bleach | chlorine |
| pharmaceutical, drug, laboratory, hospital | pharmaceutical |
| burnt rubber, tar, gouache, plastic | phenolic |
| fish, mud, iodine, oysters | iodine |
| solvent, glue | solvent |

The sum of the citations for umbrella terms and others was computed from the sensitive subjects' responses. The lexicon quoted by the participants is illustrated in Figure 4.

The characteristic odor descriptors for **1** had "iodine" or "pharmaceutical" connotations. This result is in agreement with those of Griffiths[4] and Strube et al.,[5] who indicated that halogenated compounds are generally characterized by musty, medicinal/chemical/iodine, or phenolic terms.

**Qualitative Effect of Adding 2-Bromo-4-methylphenol to Red Wine.** Fifteen of 53 subjects did not perceive any off-flavor in the wine spiked with **1** at 22 ng/L. Sixteen different terms were used by sensitive participants (38 subjects). **1** mainly imparted "iodine" notes to red wine, as described by sensitive panelists (Figure 5).

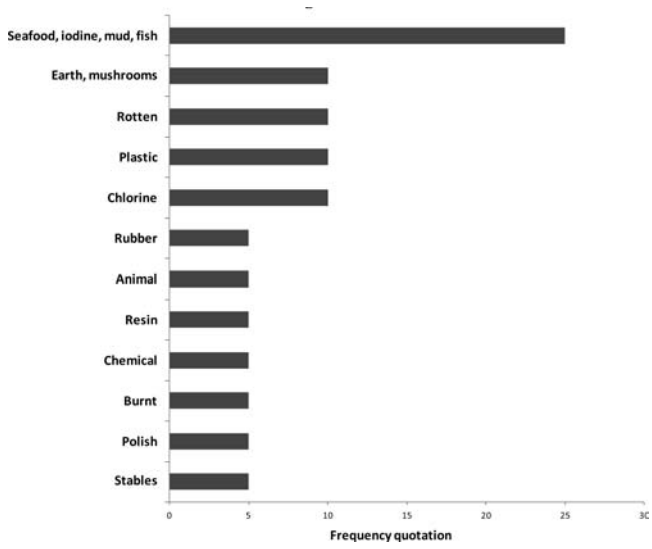

**Figure 5.** Quotation frequency, expressed in percentage, for each term cited by the 38 sensitive subjects (of 53) when 2-bromo-4-methylphenol was added to a red wine matrix. Quotation frequency is the ratio of the number of participants who quoted the term to the number of terms collected.

These results are in agreement with the individual detection thresholds: a 50/50 distribution of the population was found according to their sensitivity, thus explaining the wide variation in wine assessment. Olfactory perception of wine is dependent on mental construction;[20] however, when two sections of a population exhibit such wide variations in olfactory sensitivity, this is likely to have a significant impact on their evaluation of the product.

**Qualitative Impact of 2-Bromo-4-methylphenol on Commercial Wines Naturally Affected by the Defect.** The levels of **1** in commercial wines naturally affected by the defect were correlated with the sensory evaluation of each wine.

Panel 1 (37 subjects) strongly distinguished these wines according to their **1** levels. The average scores for defect intensity were significantly higher for wines containing the highest concentrations of **1**, thus confirming the sensory importance of this compound in wine quality perception (Figure 6). The terms used by sensitive subjects for rosé and red wines were retained: seafood, iodine, chemical, plastic, chlorine, moldy, mushroom, earth, rubber, burnt, pharmaceutical, mineral (chalk), and wet. As shown in Figure 7, the presence of **1** was not detected by a high proportion of subjects, irrespective of its concentration in the corresponding wine. This wide diversity of defect assessment was observed for both rosé and red wines (Figure 7). Figure 8 shows the distribution of perceived intensities of the defect attributed to the presence of **1** in rosé (concentration = 342.2 ng/L) and red (concentration = 787 ng/L) wines. These results demonstrate the wide diversity in perception among subjects: 46% of panelists perceived no defect when 19% gave a score of 7 (on the 8-point scale) to the commercial rosé wine naturally affected by the defect. Similarly, in the commercial red wine naturally affected by the defect, 30% of panelists perceived no defect when 16% gave a score of 7 (Figure 8).

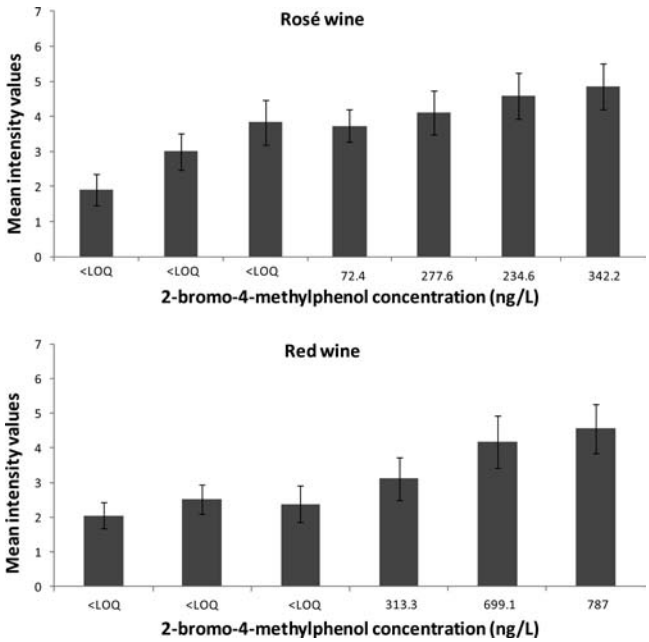

**Figure 6.** Mean aromatic defect intensities in wines with various concentrations of 2-bromo-4-methylphenol. Error bars indicate the 95% confidence interval on the mean intensity values.

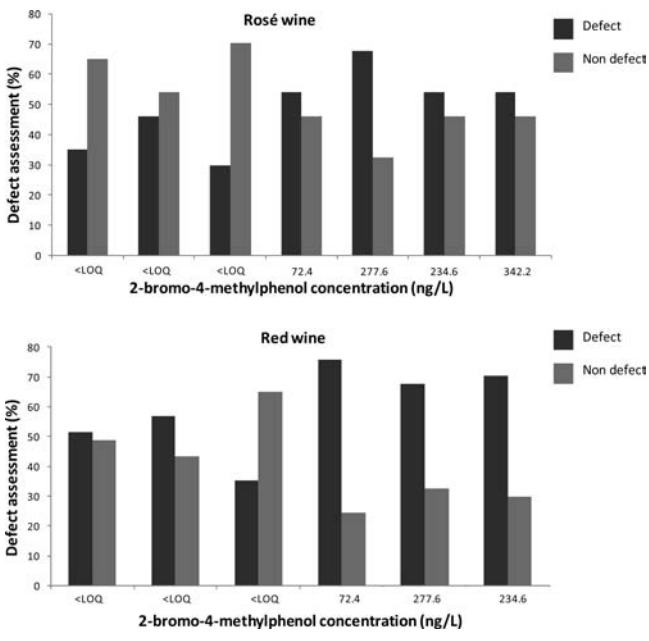

**Figure 7.** Percentage of subjects who detected a defect in commercial wines naturally containing 2-bromo-4-methylphenol.

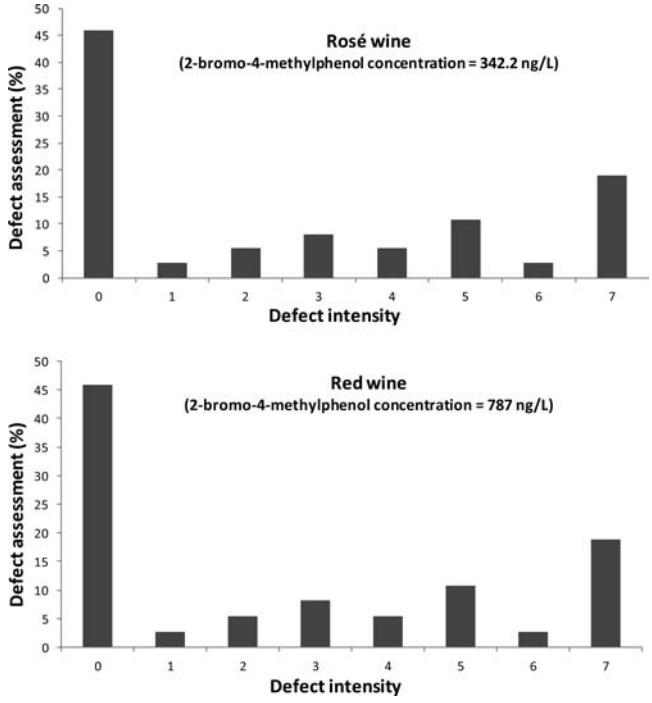

**Figure 8.** Distribution of perceived iodine defect intensity scores for rosé and red wines containing 342.2 and 787 ng/L 2-bromo-4-methylphenol, respectively.

Sensory studies concerning **1** gave very interesting results. This compound was perceptible at levels around 1 ng/L, which indicates its very powerful olfactive impact and highlights the major sensory consequences of its presence in the affected wines. **1** was identified as being responsible for a "chemical (phenolic)" taint in brine-salted Gouda cheese.[21] Several halogenated volatiles have been described as powerful odorants and identified as off-odors in mineral water, orange juice, salted Gouda cheese, cocoa powder, dried fruit, wine, fish sauce, and chicken.[5,22,23] For example, 2,4,6-trichloroanisole is responsible for "cork taint" in wine and the "Rio off-flavor" in coffee.[24] The odor detection threshold values for various halogenated volatiles in water generally range from milligrams per liter to the nanograms per liter.[5] Although these values depend on the matrix studied, some of these compounds had a major impact on odor. The odor detection threshold for the musty taint of 2,3,6-trichloroanisole was reported as $3 \times 10^{-10}$ mg/L in water.[5] In a recent study on the odor characteristics of ortho- and para-halogenated phenols and cresols, it was demonstrated that 2-halogenated-4-methylphenols had the lowest odor detection thresholds. Moreover, these compounds are almost fully characterized by medicinal, plaster-like descriptors.

The perception of **1** by the judges was very unusual, with a huge difference between the individual perception thresholds of sensitive and nonsensitive subjects, revealing a bimodal distribution. Similar phenomena were observed in all the test matrices. These results revealed the limitations of sensory analysis as a general tool for product quality control and assessment. For instance, according to individual sensitivity, an enologist may or may not be able to detect whether resin treatment has led to wine spoilage, with all of the consequences that may have. In the same way, a product's appreciation by consumers will be conditioned by their sensitivity, which will affect its economic value. Specific anosmia or hyperosmia for other organohalogenated compounds, such as 2,4,6-trichloroanisole, has also previously been reported.[25−27]

polarities. The present extraction method, as well as the column and mobile phase used for the retention and isolation of HAAs or sugars, may not suitable for their simultaneous analysis in a single run. Meanwhile, due to the absence of a chromophore, the amino acids, sugar and creati(ni)ne often need to be derivatized with different derivatization reagents, which complicates detection.[22−24] To solve the extraction and retention problems, a suitable extraction solvent and a special column that promotes superior polar compound retention should be used. LC−MS/MS—a very sensitive technique for HAA determination at trace levels[25,26]—could eliminate the need for derivatization. Recently, this technique has been used as a tool to determine both amino acids and sugars in some published studies.[27,28]

In the present study, a robust method for the simultaneous quantification of two HAAs (PhIP and 4′-OH-PhIP) and their precursors (phenylalanine, tyrosine, creatine, creatinine, and glucose) in pork samples was established using ultra high-performance liquid chromatography coupled with triple quadrupole mass spectrometry (UHPLC−TQD−MS/MS). The appropriate extraction solvents and chromatographic columns for the simultaneous extraction and isolation of compounds with different polarities were compared and selected. The method was validated with regard to linearity, detection limitations, matrix effects, and recoveries. Finally, the new kinetic tools were applied to a kinetic study of HAAs and their precursors in fresh pork model systems with different heating time treatments.

## MATERIALS AND METHODS

**Reagents and Standard Solutions.** Optima LC/MS methanol, acetonitrile and HPLC-grade formic acids (99.9%) were obtained from Thermo Fisher Scientific (Waltham, MA). Distilled water was purified using a Milli-Q filtration system from Millipore Corp. (Bedford, MA). All of the reagents were filtered through a 0.22 $\mu$m nylon or cellulose filter before injecting them into the UHPLC−MS/MS system.

The SPE used Supelclean LC-18 columns were ordered from Supelco Corp. (St. Louis, MO). The Oasis MCX cartridges (60 mg, 3 mL) were obtained from Waters Corp. (Milford, MA) and the STYRE-SCREEN $SSH_2P$ columns were acquired from Sepax Technologies (Newark, NJ). The screw cap Tuf-Bond Teflon-fitted glass reaction vials (50 mL of capacity) were purchased from Pierce Company (Rockford, IL). All of the other chemicals used in this study were of analytical grade and purchased from Sinopharm Chemical Reagent Beijing Co. Ltd. (Beijing, China).

Creatine, creatinine, and two HAAs standards, PhIP and 4′−OH-PhIP (Figure 1), were purchased from Santa Cruz Biotechnology, Inc.

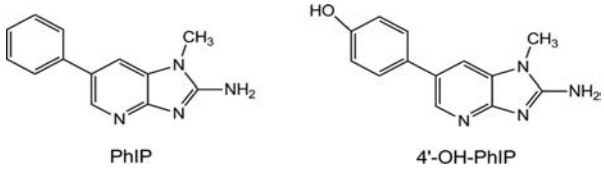

**Figure 1.** Structures of PhIP and 4′-OH-PhIP.

(Santa Cruz, CA). L-phenylalanine (Phe), L-tyrosine (Tyr) and D-glucose (Glc) were obtained from Sigma-Aldrich Company (St. Louis, MO). The standard stocking solutions of each compound (about 125 mg $L^{-1}$ for HAAs, about 1000 mg $L^{-1}$ for amino acids, creatine, creatinine, and glucose) were prepared and stored at −20 °C in the dark. The working standards of all of the above-mentioned chemicals were prepared by making the appropriate dilutions of stock solutions with a mixed solution of 0.1% formic acids and 50% methanol in water, and stored at 4 °C.

**Model System.** The dried fresh meat model system was established according to an earlier study, with some modification.[8] Pork was purchased at a local market and freeze-dried for 48 h. The lyophilized samples of raw pork (0.7 g) were mixed with diethylene glycol (3 mL) in the glass reaction vials and heated at 195 °C for 0−120 min using a thermostat-controlled oil-bath with electronically controlled temperature and temperature probe from RKC Instrument Inc. (Tokyo, Japan). The heating block was preheated for 2 h before sealing and inserting the vials. The temperature was checked every 30 s, and temperature fluctuations were within 2 °C. After heating, the vials were immediately cooled in an ice-bath to stop any further reaction. The model system experiments were performed in triplicate.

**Sample Preparation Procedures.** The content of the reaction vials was diluted and homogenized with 12 mL of 0.1 M hydrochloricacid (HCl) (four times for 15 s). Then the homogenate was extracted for 15 min using ultrasound. After the centrifugation of the mixture (11363 g for 20 min at 4 °C), the supernatant was collected. The extraction procedures were repeated twice, and then the extracting solutions were combined and the volume was fixed to 25 mL with the HCl solution. Ethanol was added to 10 mL of acidic solution with an end concentration of 80% to remove the protein.[29] The protein-free extract obtained was concentrated until it was dry in a rotary evaporator at 39 °C and then dissolved in 2 mL by solution of 0.1% formic acids and 50% methanol in water before being passed through a 0.22 $\mu$m filtration membrane. Alternatively, the SPE purification procedure with three cartridges (Supelclean LC-18, Oasis MCX, and STYRE-SCREEN $SSH_2P$) was implemented instead of the membrane filtration. For MCX cartridge, columns were first activated continuously with 6 mL of methanol, 6 mL of distilled water, and 6 mL of 0.1 M HCl solution, and were then rinsed sequentially with 6 mL of 0.1 M HCl solution and 6 mL of methanol after loading the sample. The retained analytes were finally eluted by a 6 mL mixture of methanol and ammonium hydroxide (25%) at a ratio of 95:5. For the LC-18 column, after conditioned with 6 mL of methanol and water, the columns were loaded the sample. First 1 mL of the sample solvents were discarded. And the subsequent sample solvents and the eluates from the 6 mL of the methanol were collected. With regard to the $SSH_2P$ cartridge, similar activate procedures as MCX were implemented. After loading the sample, the cartridges were then washed with water and 50% methanol in water. The target compounds were ultimately eluted with 6 mL of the methanol. All the elution obtained from the SPE procedure were then evaporated to dryness under a stream of nitrogen and then resuspended in 300 $\mu$L of the mixed solution (0.1% formic acids and 50% methanol in water). Finally, the filtrate or SPE elution was diluted to proper concentrations and transferred to an autosampler vial for UHPLC−MS/MS analysis.

**UHPLC−MS/MS Analysis.** The chromatographic analysis was performed on a Waters Acquity UPLC system equipped with a quaternary pump system, micro vacuum degasser, autosampler and column compartment setting the temperature at 35 °C. The separation was carried out on a Waters Atlantics $dC_{18}$ column (250 × 4.6 $mm^2$ i.d., 3.0 $\mu$m) (Milford, MA), which was selected from three other columns: Waters Acquity UPLC BEH $C_{18}$ (50 × 2.1 $mm^2$ i.d., 1.7 $\mu$m), Waters Acquity UPLC HSS $T_3$ (100 × 2.1 $mm^2$ i.d., 1.8 $\mu$m) and Waters XSELECT HSS $T_3$ (150 × 4.6 $mm^2$ i.d., 3.5 $\mu$m). The gradient elution was achieved with a binary mobile phase of methanol (A) and formic acid (0.1%, v/v) (B) at a flow rate of 0.5 mL $min^{-1}$. The gradient elution—0−10 min 5−100% A phase—was finally returned to its initial composition and equilibrated for 5 min before the next injection. Separation and stabilization were achieved in 15 min. The single injection volume was set at 1 $\mu$L.

The MS/MS detection was performed on a Waters Quattro Premier XE triple quadrupole mass spectrometer (TQD) (Milford, MA) using an electrospray ionization (ESI) source in positive mode. The data acquisition was carried out by MassLynxv 4.1 SCN 805 software from Waters. The capillary and extractor voltages were 3.5 kV and 3 V, respectively. Nitrogen (99.9% of purity) was used as the desolvation gas with the gas flow set to 800 L $h^{-1}$ at a temperature of 350 °C. The flow rate of the cone gas was set to 50 L $h^{-1}$ at a source temperature of 130 °C. Argon (99.9% of purity) was used as the collision gas at a flow

Table 1. Retention Time and MS/MS Parameters of the HAAs and Their Precursors

| compound | dwell time (secs) | cone voltage (V) | quantitation transition[a] | proposed assignation | conformation tranition[a] |
|---|---|---|---|---|---|
| PhIP | 0.037 | 54 | 225.03 > 210.01 (42) | $[M + H - \cdot CH_3]^+$ | |
| 4′-OH-PhIP | 0.037 | 54 | 241.03 > 225.76 (32) | $[M + H - \cdot CH_3]^+$ | |
| Phe | 0.037 | 22 | 165.98 > 119.68 (40) | $[M + H - COOH - H]^+$ | 165.98 > 102.80 (28) |
| Tyr | 0.037 | 24 | 181.98 > 122.73 (24) | $[M + H - COOH - NH_2 + 2H]^+$ | 181.98 > 90.81 (34) |
| creatine | 0.037 | 28 | 131.97 > 89.83 (16) | $[M + H - NH_2 - CN]^+$ | 131.97 > 43.77 (22) |
| creatinine | 0.037 | 34 | 114.03 > 44.02 (20) | $[M + H - NH_2 - CO - HCN]^+$ | 114.03 > 85.84 (16) |
| Glc | 0.037 | 14 | 382.90 > 202.73 (20) | $[2M + Na - M]^+$ | |

[a]Collision energy (V) is given in parentheses.

rate of 0.13 mL $min^{-1}$. The specific MS/MS parameters (compound transitions, collision energy, cone voltage, and dwell times) were optimized with 1 ng $\mu L^{-1}$ target compounds (Table 1).

**Validation.** The proposed method was validated in terms of linearity, recovery, limit of detection (LOD), limit of quantification (LOQ), and matrix effects. The calibration curve was established by plotting the peak area ratios of standards to the internal standard against seven analyte concentrations. The recoveries of the sample preparation were determined by analyzing blank samples spiked with two concentration mixed standards (low and high) and calculated as [(levels in spiked samples − levels in blank samples)/amount added] × 100.The precision of the overall method was studied by implementing intraday (repeatability) and interday (reproducibility) precision experiments. Intraday precision was investigated at a low spiked level in a recovery study with three replicates, whereas interday precision was evaluated at a high spiked level in a recovery study that was accomplished over three consecutive days. The matrix effects were evaluated using the slope comparison method.[30] The food sample extracts, which were spiked with diminishing concentrations of the standards, were used to establish standard addition calibration curves. Then, the slopes of these curves (A1, A2,···A*n*) were compared with the slopes obtained from the pure standards (B1, B2,···B*n*) at the same concentration levels, and the slope ratios $R_n$ were equal to A*n*/B*n*. The matrix effects could then be decided with $R_n$ as the ionization suppression effect (<1), ionization enhancement effect (>1) or without matrix effects (= 1).

## RESULTS AND DISCUSSION

**UHPLC−MS/MS Determination.** Given that the polarities of HAAs, sugars and creati(ni)ne are considerably different, the simultaneous detection of the HAAs and their precursors in a single run appears difficult. Therefore, the selection of a suitable chromatographic column is of great importance. Four columns, including Waters Acquity UPLC BEH $C_{18}$ column, Waters Acquity UPLC HSS $T_3$ column, Waters XSELECT HSS $T_3$ column, and Waters Atlantis $dC_{18}$ column were tested for obtaining well isolation and the suitable sensitivity of analytes (Figure 2). The BEH $C_{18}$ column, while widely used for the isolation of HAAs in previous studies,[26] was not suitable for the retention of Glc, creatine, creatinine, and Tyr, which are eluted before 1 min and could not have been isolated from their matrixes (Figure 2A). Both the UPLC HSS $T_3$ and Select HSS $T_3$ columns were developed by manufacturers to promote polar compound retention, and a charged surface hybrid (CSH) technique that controlled a small amount of charges on the surface of the fixed phase was applied to the latter column to further enhance the retention efficiency, according to the product description. The appropriate retentions of HAAs and amino acids were found when a UPLC HSS $T_3$ column was used, but for Glc, creatine, and creatinine, the retention remained poor (Figure 2B). Conversely, the Select HSS $T_3$ column provided proper retentions for all of the target compounds, but the poor symmetry for Glc and the bad separation between creatinine and Glc limit its application (Figure 2C). Using the same CSH technique, the Atlantics dC18 column is improved by the designer to pursue a simultaneous retaining and isolating of both the polar and nonpolar compounds with symmetrical peaks and proper retaining efficient. Compared with all of the above-mentioned columns, the use of the $dC_{18}$ column not only achieved favorable retention for all analytes, but also offered acceptable separation between creatinine and Glc. Therefore, this column was ultimately selected (Figure 2D). In order to improve the separation between Glc and create(ni)ne, different mobile phase and gradient conditions were tested. Due to the surface charge used in the packing to enhance the polar compound retention, no significant improvements were observed. However, without the baseline separation for all analytes, the quantifications are acceptable, since these compounds could be separated by their molecular ions in MRM mode, according to a statement from a previous study.[26] Therefore, a simple gradient condition was finally used to simultaneously detect the two HAAs and their precursors.

The ESI−MS/MS parameters were optimized by injecting 1 ng $\mu L^{-1}$ of the standard solution into the ESI source. Both the positive and negative ion modes were evaluated, and the results showed that all of the analytes were detectable in the positive mode. Amino acids could also be detected in the negative mode with relatively low sensitivity. Thus, the positive ion mode was ultimately preferred.

As for the ionization, saccharides were suggested to possess multiple ionization options. Previous studies have reported cesium positive ions $[M + Cs]^+$ or monosodiated cluster ions $[2M + Na]^+$ as the precursor ions of sugars.[27,31] Thus, the fragmentations of Glc were determined in this study. Supporting Information (SI) Figure S1 shows the fragmentation of Glc from monosodiated cluster ions $[2M + Na]^+$($m/z$ 383) to monosodiated adduct ions $[M + Na]^+$ ($m/z$ 203)—a transition that was ultimately chosen for the quantification of Glc in multiple reaction monitoring (MRM) mode. The ionization conditions for all seven targets are summarized in Table 1.

**Sample Extraction and Clean-Up.** To obtain the best extraction efficiency for PhIP, 4′-OH-PhIP, and their precursors, including Phe, Tyr, creatine, creatinine, and Glc, four solvents were tested with the same samples: water, 0.1% formic acids in water, 0.1 M HCl, and the solution of 0.1% formic acids and 50% methanol in water. The recoveries of all seven compounds after extraction are summarized in Table 2, which shows that all four solvents could successfully extract all of the target compounds with recoveries over 56.7%. Compared with the other three solvents, 0.1 M HCl could extract more PhIP and 4′-OH-PhIP, and was thus chosen.

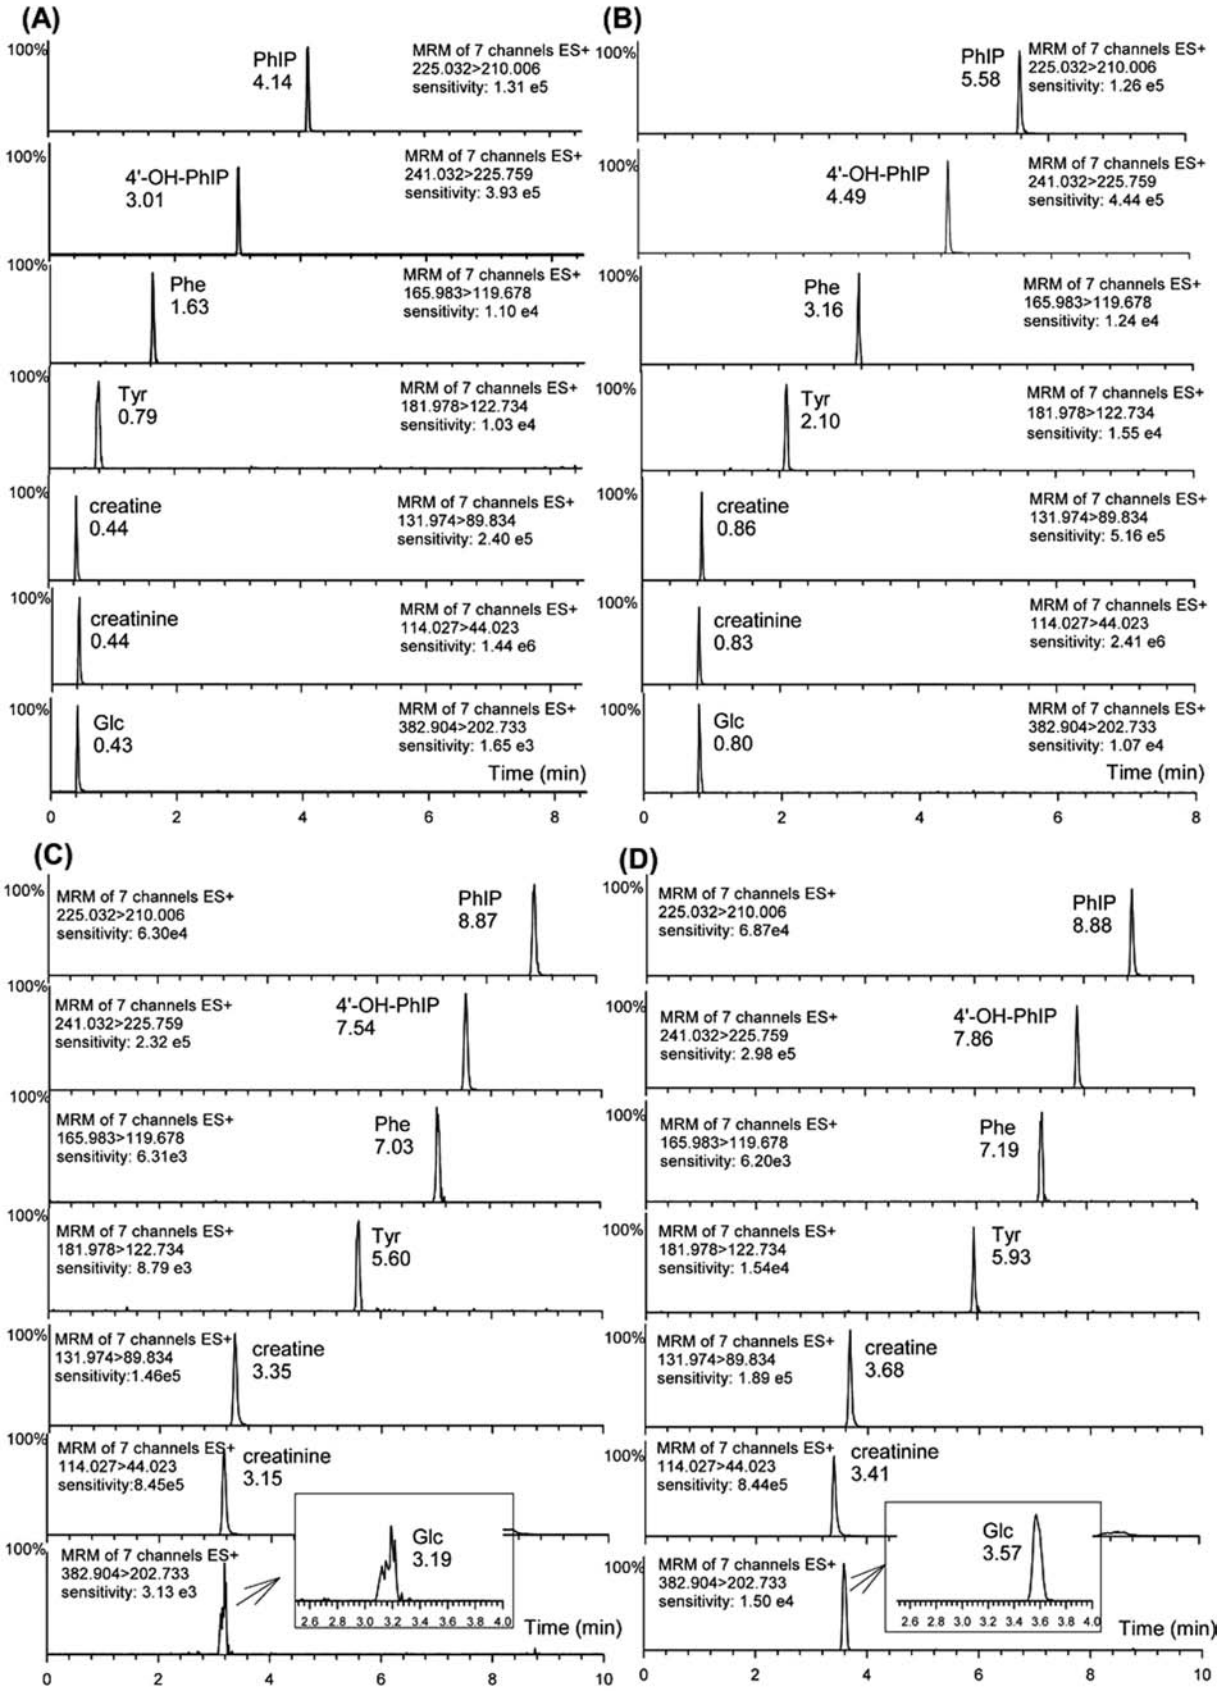

**Figure 2.** Comparison of separation effects for PhIP, 4′-OH-PhIP, and their precursors (Phe, Tyr, creatine, creatinine, and Glc) in same standard concentrations among four different candidate columns: (A) Waters Acquity UPLC BEH $C_{18}$ (50 × 2.1 $mm^2$ i.d., 1.7 $\mu$m), (B) Waters Acquity UPLC HSS $T_3$ (100 × 2.1 $mm^2$ i.d., 1.8 $\mu$m), (C) Waters XSELECT HSS $T_3$ (150 × 4.6 $mm^2$ i.d., 3.5 $\mu$m) and (D) Waters Atlantis $dC_{18}$ (150 × 4.6 $mm^2$ i.d., 3 $\mu$m). The $m/z$ of fragment and signal sensitivity values for each compounds channels were enclosed in these figures.

**Table 2. Recoveries (Mean ± SD) of HAAs and Their Precursors by Extraction with Different Solvents**

| compound | water | 0.1% formic acid in water | 0.1 M HCl | 0.1% formic acid and 50% methanol in water |
|---|---|---|---|---|
| PhIP | 79.8 ± 16.2 | 73.4 ± 15.3 | 100.7 ± 7.3 | 72.0 ± 12.2 |
| 4′-OH-PhIP | 56.7 ± 6.9 | 57.9 ± 6.1 | 70.9 ± 12.3 | 57.5 ± 9.4 |
| Phe | 72.0 ± 7.8 | 71.6 ± 9.5 | 72.6 ± 9.8 | 71.0 ± 6.1 |
| Tyr | 98.8 ± 10.3 | 96.8 ± 14.5 | 105.7 ± 10.0 | 97.8 ± 12.3 |
| creatine | 98.6 ± 14.7 | 99.2 ± 8.8 | 99.7 ± 12.4 | 97.3 ± 9.8 |
| creatinine | 82.4 ± 8.7 | 80.5 ± 7.7 | 82.7 ± 16.8 | 79.7 ± 7.6 |
| Glc | 65.8 ± 9.6 | 61.4 ± 6.2 | 64.1 ± 11.4 | 63.7 ± 11.7 |

The SPE procedure used for purification was tested using three different SPE cartridges. The spiked solution obtained from the 0.1 M HCl extraction was used to evaluate the performance of every cartridge. The results are expressed by recovery rates and are summarized in Figure 3. As the figure shows, the HAAs were retained strongly on the MCX column (recoveries higher than 95%), agreeing with the previous study of MCX cartridge selected to purify the meat sample in HAAs analysis.[32] However, this column was found to be unsuitable for retaining the Glc. Appropriate spiked recoveries (>70%) for Glc were observed using both LC-18 and $SSH_2P$ columns, similar to the previous study which obtained appropriate recoveries of acrylamide and sugars using these two columns,[28] whereas the poor retaining efficiency for creatine and creatinine limited the application of these two types of columns. Therefore, the necessity of the SPE procedure should be considered for optimization purposes.

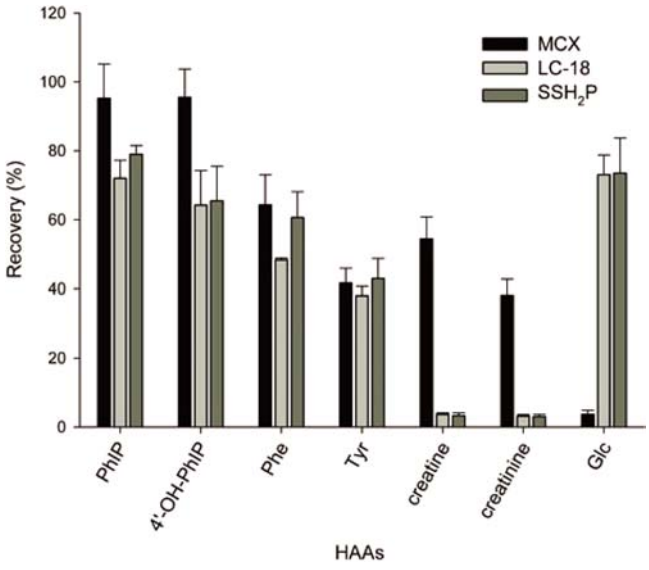

**Figure 3.** Recoveries of PhIP, 4′-OH-PhIP, and their precursors (Phe, Tyr, creatine, creatinine, and Glc) for SPE cleanup procedure using three different cartridges. The error bars were calculate from the three repeated tests ($n$ = 3).

The samples were then alternatively pretreated without SPE. After being spiked with the standards, the extraction solution was diluted and filtrated through a 0.22 $\mu$m membrane and then injected into the UHPLC−MS/MS. The chromatograms demonstrated that no impurities were found in any of the channels, except for Glc (Figure 4). Because the small interferential peak appearing in the Glc channel could be isolated to baseline from the Glc peak, this interference would not affect the quantification. Therefore, without the interference (including macro-interference, e.g., protein and fat), the pretreatment procedures could be simplified by omitting SPE cleanup. The simplified sample pretreatment used in the present study could contribute to the establishment of a rapid and robust quantification method for the simultaneous analysis of HAAs and their precursors, and thus may save analytical time in kinetic studies.

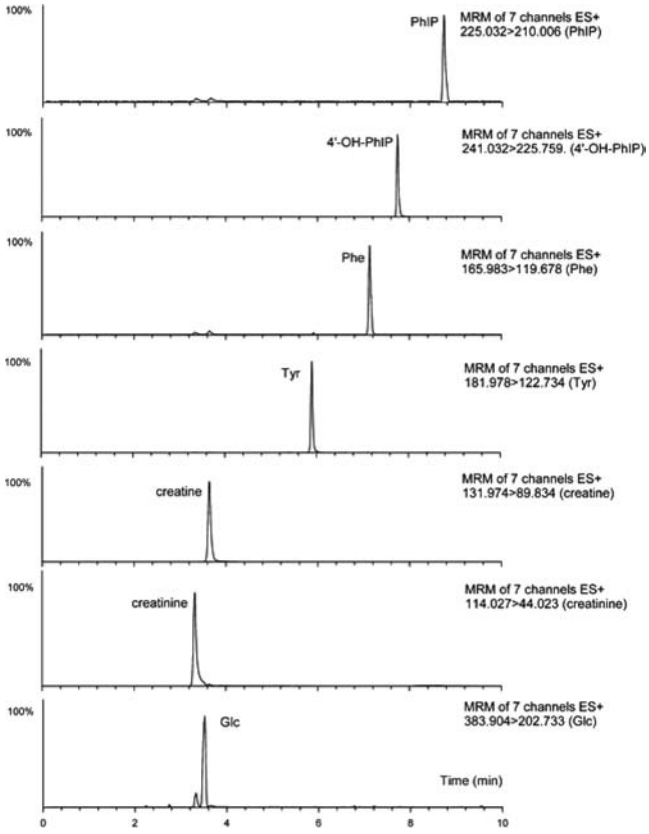

**Figure 4.** Representative UHPLC−MS/MS chromatograms of simultaneous determination of PhIP, 4′-OH-PhIP, and their precursors (Phe, Tyr, creatine, creatinine, and Glc) in a fresh pork model after heating and spiking with standards.

**Validation of the Proposed Method.** The characteristics of the proposed method were demonstrated by a validation procedure studying linearity, LOD, LOQ, recovery, precision, and matrix effects.

The linearity was evaluated by injecting different concentrations of standards and plotting the peak area versus the concentrations. As Table 3 shows, the detector response for individual compounds was linear over a broad concentration, with coefficients higher than 0.991. Glc was a fitted quadratic with a coefficient of 0.996 (SI Figure S2), which confirms an earlier study that reported the quadratic fitting of both Glc and sucrose.[27]

**Table 3. Validation Parameters of the Proposed Method**

| compound | linear range ($\mu$g L$^{-1}$) | coefficients ($r^2$) | LOD ($\mu$g L$^{-1}$) | LOQ ($\mu$g L$^{-1}$) | spiked level ($\mu$g g$^{-1}$) | mean recovery %[a] (RSD%) | matrix effects[b] (Rn ± SD) |

[a]Intraday and interday precisions are given in parentheses ($n$ = 3). [b]Matrix effects was expressed as the slope ratios ($R_n$) of standard spiked calibration curve to pure standard calibration curves at same analyte concentration. A value of >1.00 shows ionization enhancement, while <1.00 indicates ionization suppression ($n$ = 3). [c]Glc was fitted quadratic with calibration curves shown in SI Figure S2.

The LODs and LOQs, respectively defined as the amount of an analyte producing a signal-to-noise ratio of ≥3 and ≥10, were determined using standards (Table 3). The ranges were 0.14−325.00 $\mu$g L$^{-1}$ for LODs and 0.58−650.00 $\mu$g L$^{-1}$ for LOQs. Glc showed the highest detection limit of 325.00 $\mu$g L$^{-1}$, similar to a previous study,[33] which performed a new analytical setup to simultaneously analyze the precursors and products of the Maillard reaction using high-performance anion exchange chromatograph and obtained a LOQ of 1.00 $\mu$mol L$^{-1}$ for the Glc.

The standard spiking recoveries of the proposed method were evaluated using samples obtained from the fresh pork model system after heating. The results are also summarized in Table 3. The recoveries of compounds in the fresh pork model system ranged from 64.3% to106.4% at a low spiked level and 59.2% to122.2% at a high spiked level, demonstrating the accuracy of the proposed method compared with other published methods in terms of Glc or HAA recoveries.[28,32,34,35]

The precisions expressed as relative standard deviations (RSDs) were lower than 15.4% (19.9%) for intra(inter-)day studies, demonstrating the stability of the proposed method when large amounts of samples must be detected (Table 3).

The suppression or enhancement of ionization caused by coelute from the column was a common problem in LC−MS/MS when analyzing complex food samples, also known as matrix effects. In this study, the matrix effects for HAAs and their precursors were evaluated with the slope ratios ranging from 0.67 to 0.89, further verifying that the extracts obtained from the simple sample pretreatment used in the present work are relatively clean for UHPLC−MS/MS detection.

Summarizing all of the method validation results, the developed method proposed here can be regarded as a rapid and potent quantification method that could be successfully applied to the simultaneous analysis of PhIP, 4′-OH-PhIP, Phe, Tyr, creatine, creatinine, and Glc in a pork model system corresponding to the kinetic study, with simple and fast sample pretreatment procedures, appropriate recoveries and excellent method repeatability (Figure 5).
