Olive fruit is derived from a small evergreen tree in the family Oleaceae, genus *Olea*. California is the only U.S. state to commercially produce olives. About 50% of the production is destined for canning as in California-style black olives; another 46% is pressed into olive oil.[1] Raw olive fruit is very bitter due to the presence of high concentrations of phenolic compounds and in particular the *o*-diphenol oleuropein. Before olives can be consumed, they must be cured (processed) to remove the bitter components. There are numerous methods used worldwide to cure olives. One of the most popular is the California-style processing method created by Freda Ehmann in the 1890s.[2] To make California-style black ripe olives, the olives are picked green (unripe) and are cured by exposing them to a series of lye and oxygenated water baths over multiple days.[3] The main olive variety grown in California and used in the production of California-style black ripe olives is Manzanilla.[4−6] In 2012, canning olive production was 78,500 tons, of which 86% was Manzanilla olives.[6] Olives are harvested in California between September and November. Olives that cannot be processed directly after harvesting are stored in acidic brine solution (0.2−0.4% calcium chloride) to prevent the growth of spoilage organisms until they can be processed. During processing, the fresh or brine-stored olives are immersed in a 1−2% sodium hydroxide solution (lye) for 2−24 h over 3−7 consecutive days. During the intervals between lye treatments, the olives are suspended in water and air is bubbled through the tank to oxidize the olives and form the black color (air oxidation). These pigments, formed through oxidation and polymerization of *o*-diphenols (primarily hydroxytyrosol and caffeic acid), are not stable.[3] To prevent color deterioration, iron salts such as ferrous gluconate, ferrous sulfate, or ferrous lactate are added to fix the color. Olives are then neutralized with lactic acid or carbon dioxide, packed into cans in a sodium chloride solution, and sterilized. In the United States, olives are sterilized at 115.6 °C for 60 min or at 121.1 °C for 50 min.[2,3] A diagram of the steps involved in California-style black ripe olive processing is shown in Figure 1.

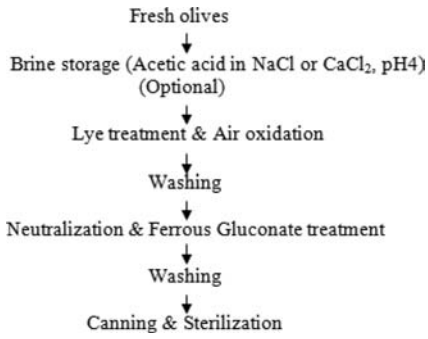

**Figure 1.** Processing diagram for the production of California-style black ripe olives.

Recently, the carcinogen acrylamide was found in California-style black ripe olives at relatively high concentrations (226−1925 $\mu$g kg$^{-1}$) as compared to other foods such as French fries (20−1325 $\mu$g kg$^{-1}$), baked goods (<364 $\mu$g kg$^{-1}$), and nut products (<457 $\mu$g kg$^{-1}$).[7] Acrylamide is classified as a probable human carcinogen (group 2A) by the International Agency for Research on Cancer on the basis of studies in laboratory animals.[8] In 2002, the Swedish National Food Administration and the University of Stockholm announced the finding of high

levels ($\mu$g kg$^{-1}$ to mg kg$^{-1}$) of acrylamide in foods cooked at elevated temperatures.[9] This finding led to worldwide concern and increased research activities investigating the formation and mitigation of acrylamide in foods.[9−14] Although the relevance to human health of dietary exposure to acrylamide is unclear, regulatory agencies such as the World Health Organization (WHO) continue to encourage food manufacturers to take measures to reduce acrylamide levels in processed foods.[15]

In general, acrylamide is formed through reactions between free amino acids and carbonyl compounds (e.g., reducing sugars) via the Maillard reaction at temperatures above 120 °C.[9−14] Stable isotope-labeling studies in potato-based foods and model systems indicate that the backbone of acrylamide arises from asparagine.[14] Alternative formation mechanisms have also been suggested to occur in lipid-rich foods.[16,17] For example, studies of model systems containing asparagine and unsaturated lipids demonstrate that the aldehydes and ketones, produced through the thermal degradation of lipids, can react with asparagine and lead to acrylamide formation.[16] Additionally, acrylamide was found to form through the reaction of acrolein and/or acrylic acid with ammonia.[16] Acrylic acid is generated from the oxidation of acrolein, a product of thermal degradation and/or oxidation of free fatty acids or glycerol.[18] In these cases, the backbone of acrylamide would arise from either acrylic acid or acrolein, and the amine group derived from the ammonia evolved from the thermal degradation of amino acids.[16]

The formation of acrylamide during California-style black ripe olive processing was studied by Casado and Montaño in 2008.[19] These studies demonstrated that there were undetectable amounts of acrylamide in the olives before sterilization, whereas the sterilized olives contained acrylamide ranging from 243.30 to 1349.00 $\mu$g kg$^{-1}$. This information suggests that acrylamide in California-style black ripe olives forms during sterilization. These studies also show very low concentrations (52.80−198.00 $\mu$g kg$^{-1}$) of asparagine in the nonsterilized olives and no correlation between the concentration of glucose and amino acids (both total and individual amino acids) and acrylamide formation.[19] More recently, using olive juice in a model system, Casado et al. proposed that peptides and proteins were responsible for acrylamide formation in sterilized olives and that the California-style black ripe olive processing method had no effect on acrylamide levels in the final products.[20]

To date, information on the mechanism of acrylamide formation in California-style black ripe olives is limited, and it remains unclear if acrylamide is formed through the California-style black ripe processing method or if it is an artifact of the sterilization process. Herein, we evaluate the effect of individual processing steps employed in the California-style black ripe olive processing method (i.e., brine storage, lye treatment, air oxidation, neutralization, and sterilization) on the formation of acrylamide to better understand the formation mechanism of acrylamide during processing and to provide information for mitigating acrylamide formation through processing.

## MATERIALS AND METHODS

**Reagents.** All reagents were of analytical grade unless otherwise stated. Acrylamide (99+%), $D_3$-Labeled acrylamide (2,3,3-$D_3$, 98.0%), and formic acid (∼98%) were purchased from Sigma-Aldrich (St. Louis, MO, USA). HPLC grade methanol and hexane were obtained from Fisher Scientific (Fair Lawn, NJ, USA).

**Olives.** To estimate acrylamide levels in various table olives, olives including Greek-style, Spanish-style, California-style black ripe, and California-style green ripe olives were studied. Three different commercial brands of each table olive style were purchased from local markets in at least triplicate over two years (2010 and 2014). A 15 kg sample of fresh and a 70 kg sample of brine-stored olives were kindly supplied by two independent commercial olive processors located in central California (processor A and processor B). These olives were graded as medium-sized Manzanilla harvested in 2009 and 2012. Olives represent pooled samples from numerous orchards. Directly after receipt of fresh olives, the processors prepared brine-stored olives and delivered both fresh and brine-stored olives to the University of California, Davis. Brine-stored olives were stored on site in brine for 6 months at room temperature before they were analyzed for acrylamide.

Graded medium-sized Manzanilla olives harvested in 2010 and 2011 were used to study the influence of the individual processing steps on acrylamide formation. A 30 kg sample of fresh and a 70 kg sample of brine-stored olives were also supplied by processors A and B and represent pooled samples from numerous orchards.

**Laboratory-Scale Models Mimicking California-Style Black Ripe Olive Processing.** A laboratory-scale model of the California-style black ripe olive processing method was developed for these studies. This model system enabled duplicate processing of small-scale samples (∼30 olives per sample). Briefly, olives were hand selected for no defect and placed into one of two sample chambers. The olives were exposed to a 1% sodium hydroxide solution for 5 h for lye processing. Next, the olives were rinsed and placed in fresh water for 19 h to remove residual sodium hydroxide. During this washing step, air was bubbled into the surrounding medium to oxidize olives. This lye−wash cycle was repeated for 4 days to allow sodium hydroxide to penetrate to the pit of the olive. A solution of 1% phenolphthalein in isopropanol was used to verify the penetration depth of the sodium hydroxide. After the final lye−wash, olives were treated with 0.15% ferrous gluconate solution for 4 h to fix the color. During the ferrous gluconate treatment, carbon dioxide gas was bubbled into the solution to neutralize olives and phenolphthalein solution was used to verify the pH of olives. When the pH was <8, the olives were rinsed and put into fresh water for 30 min to remove residual ferrous gluconate. Olives were then packed in a glass flask, which was filled with 2% sodium chloride. Finally, the olives were sterilized in an autoclave at a temperature of 127 °C for 30 min.

**Brine Storage.** To evaluate the influence of brining on acrylamide levels in the finished olive product, olives (harvested in 2010 and 2011) were stored in a standardized brine solution for 0−8 months at room temperature prior to processing as described above. Experiments were performed in duplicate. Preprocessing brine solutions reflected typical commercial brine solutions and were composed of calcium chloride (0.2−0.4%) and sodium benzoate (0.2−0.3%). The pH of the brine solutions was maintained at 3.7−4.0 with acetic acid. The influence of calcium chloride, sodium benzoate, or acetic acid was evaluated in olives harvested in 2011 from the two olive processors. This was achieved by omitting one of these individual components in three independent brine solutions and storing the olives in these solutions at room temperature for 3 months prior to processing as described above. The study was performed in duplicate.

**Effect of Lye, Air Oxidation, Ferrous Gluconate, Neutralization, and Sterilization.** Olives (harvested in 2010 from the two olive processors) were processed as described above. Individual processing parameters (i.e., air oxidation step, ferrous gluconate treatment, neutralization, and sterilization) were systematically omitted, and the levels of acrylamide were evaluated in the resulting products. The olives were stored in brine for 6 months prior to these studies. The studies were performed in duplicate.

**Analysis of Acrylamide.** *Preparation of Samples for Acrylamide Analysis.* Samples consisting of 30 g of olives were extracted with 60 mL of ultrapure water. A 1 mL aliquot of 4 ng mL$^{-1}$ of $D_3$-acrylamide was added to samples as an internal standard. The mixture was homogenized. Twenty-five grams of the mixture was collected, and 15 mL of hexane was added to remove oil and other nonpolar

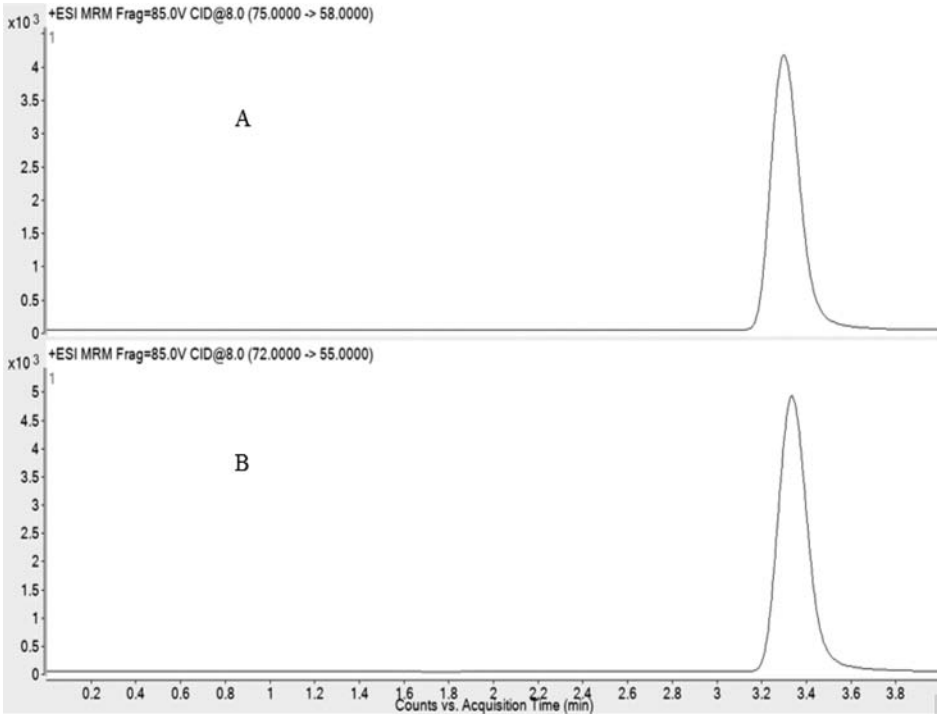

**Figure 2.** UHPLC-(ESI) MS/MS ion select chromatogram of $D_3$-labeled acrylamide (a) and acrylamide (b).

compounds. Then the mixture was centrifuged at 4000 rpm for 30 min. The aqueous layer was collected. Interfering compounds were removed, and sample was concentrated using solid phase extraction on a Strata-X-C cartridge (3 mL, 200 mg) preconditioned with two 1 mL aliquots of methanol, followed by two 1 mL aliquots of water at a flow rate of 2 mL $min^{-1}$. Acrylamide was eluted with 1 mL of 0.1% formic acid in water/methanol, 90:10, v/v. The eluted solution was collected and filtered through a 0.22 $\mu$m membrane prior to analysis by ultrahigh-pressure liquid chromatography electrospray ionization mass spectroscopy [UHPLC-(ESI)MS/MS].

*Acrylamide Analysis by UHPLC-(ESI)MS/MS.* Acrylamide was quantified in samples using a modified method of Zhang et al.[21] Samples were analyzed using an Agilent 1290 Infinity ultrahigh-pressure liquid chromatography (UHPLC) system coupled to an Agilent 6460 triple-quadrupole mass spectrometer interfaced with electrospray ionization (ESI) via jet stream technology (Agilent Technologies, Santa Clara, CA, USA). The UHPLC was equipped with a binary pump with integrated vacuum degasser (G4220A), an autosampler (G4226A), and a thermostated column compartment (G1316C). The olive extracts were separated on a Polaris C18-A column (2.0 × 150 mm, 3 $\mu$m, Agilent Technologies), and the column temperature was controlled at 30 °C. The mobile phase consisted of 0.1% formic acid in water (A) and methanol (B) as follows: 0% B, 0−1 min; 0−20% B, 1−2 min; 20% B, 2−4 min, at a flow rate of 0.2 mL/min. The column was re-equilibrated between injections for 4.5 min with 0.1% formic acid in water. The injection volume was 5 $\mu$L. To quantify acrylamide levels in olives, transition ions of $m/z$ 72 → 55 for acrylamide and $m/z$ 75 → 58 for $D_3$-labeled acrylamide were monitored. The UHPLC-(ESI)MS/MS was optimized using a fragmentor voltage of 85 V, a collision energy of 8 V, and a cell accelerator of 7 V in positive mode ESI. The drying gas temperature and flow rate were 300 °C and 5 L/min, respectively. The sheath gas temperature and flow rate were 400 °C and 11 L/min, respectively. The nebulizer gas pressure, nozzle voltage, and capillary voltage were 45 psi, 500, and 3000 V, respectively. The limit of detection (LOD) and the limit of quantification (LOQ) of this method were 0.71 and 1.42 $\mu$g $kg^{-1}$, respectively.

**Measurement of pH of Olives.** To measure the pH of olives, five olive fruits were homogenized and the pulp was filtered through cheesecloth. The pH was measured in the resulting olive juice using a SevenMulti pH meter (Mettler Toledo, Columbus, OH, USA).

**Statistical Analysis.** Means (duplicates or triplicates) of acrylamide concentrations in olives were statistically analyzed using one-way ANOVA followed by multiple-comparison test using Tukey (HSD). The difference among samples was at the 95% confidence level. ANOVA was performed using XLSTAT version 2013.

## ■ RESULTS AND DISCUSSION

The acrylamide concentrations of fresh, brine-stored, Greek-style, Spanish-style, California-style black ripe, and California-style green ripe olives were measured using UHPLC-(ESI)MS/MS monitoring transition ions of $m/z$ 72 → 55 for acrylamide and $m/z$ 75 → 58 for $D_3$-labeled acrylamide (Figure 2). The results are presented in Table 1. Acrylamide was undetected in fresh and brine-stored olives. Acrylamide levels in processed olives, over two harvest years, were not significantly different. Significant amounts of acrylamide were present in the California-style black ripe (409.67 ± 42.60−511.91 ± 34.08 $\mu$g $kg^{-1}$) and California-style green ripe olives (44.02 ± 3.55−105.79 ± 22.01 $\mu$g $kg^{-1}$) but not in the Greek-style or Spanish style olives. California-style green ripe olives are processed fresh (not brine stored) and are not subject to air oxidation or ferrous gluconate treatment. California-style black ripe and green ripe processing methods required the olives to be sterilized at temperatures >110 °C.[2,3] In contrast, Spanish- and Greek-style table olive processing methods preserve olives using additives and/or pasteurization at temperatures <65 °C.[2] These results are in agreement with those obtained from Casado and Montaño and indicate that sterilization plays an important role in the formation of acrylamide.[19] The difference in the levels of acrylamide found in the California-style black ripe and green ripe olives indicates that other processing steps (i.e., brine storage, air oxidation, and ferrous gluconate treatment) also influence the levels of acrylamide in the final

[a]Results are mean values of three measurements. Means with different letters are significantly different at the 95% confidence level. There were 10 different commercial brands (A–J) used in the survey of acrylamide levels in olives. Fresh and brine-stored olives were received in 2009 and 2012. Commercial table olives (Greek-style, Spanish-style, California-style green, and California-style black ripe olives were purchased in 2010 and 2014.

product. Therefore, each of these parameters was evaluated independently as discussed below.

The influence of brining olives was evaluated by monitoring acrylamide in olives stored in brine over 8 months and processed into California-style black ripe olives. Acrylamide levels were lowest in processed fresh olives (95.85 ± 8.52–402.57 ± 12.07 $\mu$g kg$^{-1}$) as compared to processed brine-stored olives (408.96 ± 2.84–1135.29 ± 48.99 $\mu$g kg$^{-1}$). During storage, the acrylamide levels increased during the first month and then declined with increasing storage time (Figure 3). Acrylamide levels were highest in olives stored in brine for 1 month (590.01 ± 23.43–1135.29 ± 48.99 $\mu$g kg$^{-1}$). These data indicate that precursors of acrylamide formation either degrade

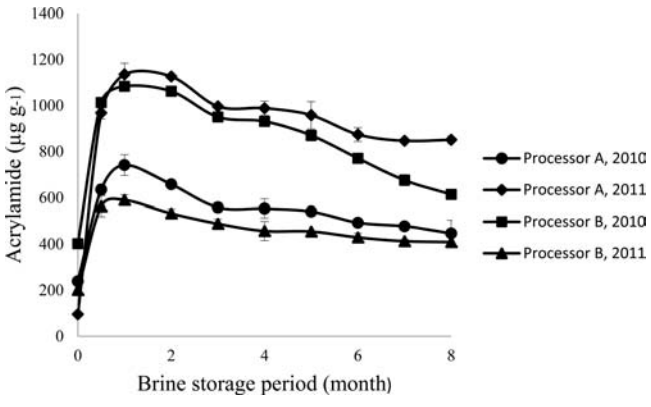

**Figure 3.** Effect of brine storage time (0–8 months) on acrylamide formation.

or diffuse into the surrounding medium during prolonged brine storage. This trend was observed in olives received from both olive processors and over the two harvest years (2010 and 2011). This result suggests that holding olives in brine may facilitate the reduction of acrylamide in final products.

The influence of the composition of preprocessing brine solutions was evaluated to identify relationships between individual brining components (i.e., calcium chloride, sodium benzoate, or acetic acid) and the formation of acrylamide (Table 2). The complete brine solution was composed of

**Table 2. Effect of Brine Composition on Acrylamide Formation in California-Style Black Ripe Olives[a]**

| brine composition | acrylamide ($\mu$g kg$^{-1}$) |
|---|---|
| sample a (complete brine) | 685.86 ± 26.98a |
| sample b (brine without sodium benzoate) | 642.55 ± 44.02a |
| sample c (brine without acetic acid) | 563.74 ± 36.21a |
| sample d (brine without calcium chloride) | 303.17 ± 43.31b |

[a]Means with different letters are significantly different at the 95% confidence level.

calcium chloride (0.2–0.4%) and sodium benzoate (0.2–0.3%) and acidified to a pH of 3.7–4.0 with acetic acid (sample a). The olives stored in brine solutions without added acidic acid (sample b) or sodium benzoate (sample c) did not differ significantly from the brine solution containing these compounds (sample a). However, the olives stored in the brine solution without added calcium chloride (sample d) had significantly lower levels of acrylamide in the finished products (303.17 ± 43.31 $\mu$g kg$^{-1}$). In general, calcium ions helps maintain structural firmness, stability of cell wall, and cell turgor of fruits by forming cross-linkages between pectin molecules, thereby strengthening and preventing the collapse of plant cells.[22,23] Our data suggest that calcium in the brine solutions helps retain precursors to acrylamide formation by improving cell wall integrity and that acrylamide levels in finished products may be reduced through the omission of calcium in brining solutions. The olives stored in the brine solution with no calcium chloride addition appeared to shrink to a greater degree than olives stored with calcium chloride during sterilization. Although it appears that acrylamide could be reduced through lowering the calcium content of the storage brine, consumer acceptance may be affected.

The influence of the individual processing steps involved in the production of California-style black ripe olives on acrylamide formation was evaluated and is given in Table 3. The levels of acrylamide in fully processed California-style black

ripe olives (i.e., the olives that were subjected to lye hydrolysis, air oxidation, ferrous gluconate treatment, and sterilization) were the highest (569.42 ± 38.34 $\mu$g kg$^{-1}$). In comparison, olives processed without the air oxidation step had significantly lower levels of acrylamide (310.27 ± 0.71 $\mu$g kg$^{-1}$). Ferrous gluconate had no effect on acrylamide levels. Olives processed with no air oxidation or ferrous gluconate treatment (344.35 ± 14.91 $\mu$g kg$^{-1}$) were not significantly different from olives processed with no air oxidation (Table 3). Air oxidation significantly increases the formation of acrylamide during processing. Comparisons of the sterilized olives with non-sterilized olives demonstrate low levels of acrylamide (51.83 ± 12.781 $\mu$g kg$^{-1}$) in nonsterilized olives as compared with sterilized olives and confirmed that acrylamide forms during sterilization.

Lye processing was found to significantly decrease the levels of acrylamide (and/or its precursors) in finished California-style black ripe olives. The levels of acrylamide in fresh (11288.29 ± 5.68 $\mu$g kg$^{-1}$) or brine-stored olives (7694.27 ± 37.63 $\mu$g kg$^{-1}$) that were directly sterilized were 10 times greater than levels found in olives that underwent lye processing for 4 days (569.42 ± 38.34 $\mu$g kg$^{-1}$) prior to sterilization. This finding is in contrast to the results reported by Casado et al.,[20] who suggested that lye treatment did not affect acrylamide formation in olives. However, this difference may be explained by the use of olive juice in the Casado et al. study and the use of olive fruit in the current study.

Neutralization with carbon dioxide after lye treatment had a significant influence on the formation of acrylamide in olives (Table 4). The initial pH of the lye-treated olives was 9.76; after neutralization with carbon dioxide, the pH was reduced to 7.11. The lowest level of acrylamide (338.67 ± 9.23 $\mu$g kg$^{-1}$) was found in sterilized olives that were not previously neutralized with carbon dioxide, whereas the highest level of acrylamide (681.60 ± 11.36 $\mu$g kg$^{-1}$) was found in sterilized olives that had been neutralized. These results indicated that the formation of acrylamide in olives is pH dependent. This is in agreement with the results reported by Casado et al.[24]

**Table 4. Effect of Neutralization with Carbon Dioxide (pH) on Acrylamide Formation in California-Style Black Ripe Olives**[a]

| neutralization time (h) | measured pH | acrylamide ($\mu$g kg$^{-1}$) |

| 4 | 7.11 | 681.60a ± 11.36 |

[a]Means with different letters are significantly different at the 95% confidence level.

The studies described herein demonstrate that the formation of acrylamide is dependent upon the processing methods used in the production of table olives and that sterilization temperatures are required for the formation of acrylamide. Additionally, our results indicate that fresh olives contain precursors of acrylamide which either degrade and/or diffuse into surrounding medium during brine storage. Calcium ions in brine storage solutions appear to prevent the short-term diffusion of acrylamide and/or its precursor from olives into brine storage solutions. Longer term (>1 month) brine storage results in lower acrylamide levels in finished products. The observation that the air oxidation step results in increased levels of acrylamide in olives suggests that acrylamide precursors form via oxidation reactions during lye treatment and that these are converted into acrylamide during sterilization. Neutralization prior to sterilization increases acrylamide formation during sterilization, indicating that this is a pH-dependent process. These results suggest that employing small modifications during traditional processing methods (e.g., holding olives for longer periods in brining solutions, decreasing oxygen exposure time, reducing sterilization temperatures, etc.) may be useful in lowering acrylamide levels in finished table olive products.

Ongoing studies in our laboratory are focused on identifying the precursors of acrylamide in olives and determining the mechanism by which they form in olives.

**ABSTRACT:** Cuticle composition and structure may be relevant factors affecting the storage potential of fruits, but very few studies have analyzed fruit cuticle composition from a postharvest perspective. In this work, the chemical composition of waxes and cutin (major cuticular components) was analyzed in cuticle samples isolated from "Celeste" and "Somerset" cherries (*Prunus avium* L.) after cold storage at 0 °C. Total cuticle amounts per surface unit ($\mu$g cm$^{-2}$) increased along with cold storage. The triterpene ursolic acid, the alkane nonacosane, linoleic acid, and $\beta$-sitosterol were the most abundant components of cuticular waxes, whereas cutin composition was dominated by $C_{18}$-type monomers. In spite of being comprised of similar chemical families, cultivar-related differences were found regarding the abundance and the evolution of some compound families during cold storage. To the best of our knowledge, this is the first report on changes in cuticle composition of sweet cherry during postharvest storage.

**KEYWORDS:** *cold storage, cuticle, cutin, Prunus avium L., postharvest, waxes*

## INTRODUCTION

The plant cuticle is a lipidic layer synthesized by the epidermis, which surrounds aerial, nonlignified organs, including fruits. Cuticles are composed mainly by cutin, a polyester polymer matrix rich in hydroxylated and epoxy-hydroxylated $C_{16}$ and $C_{18}$ fatty acids, embedded with amorphous waxes and a minor fraction of phenolics. The outer side of the cuticle is covered by epicuticular waxes, while in its inner side the cutin matrix mixes with polysaccharides from the epidermal cell walls.[1] Because the cuticle covers the epidermis of the fruit, it represents the first barrier against the abiotic and biotic conditions in which it develops. The composition and structure of this surface layer have a noticeable influence on the postharvest storage potential of fruits, inasmuch as it protects against transpirational water loss, mechanical injuries and microbial infections, and provides mechanical support.[2]

In spite of this relevance, there are few reports on cuticle modifications taking place along the life span of a fruit, which have often focused on physiological or morphological rather than on biochemical aspects. Some studies, though, have reported the evolution of the chemical composition of the cuticle during on-tree development of fruit,[3−9] and some genes putatively involved in the biosynthesis of cuticular wax and cutin components during fruit development have been identified.[10,11] Even more limited research attention has been apparently paid to the changes in fruit cuticle composition along its postharvest life. For apple, there seems to exist considerable cultivar-associated variability as to the progress of total wax amounts, properties, or chemical components during long-term cold storage[8,12] or in response to controlled atmosphere storage and subsequent shelf life.[13] The observations that 1-methylcyclopropene attenuated composition changes in cuticular waxes during storage of "Autumn Gold" and "Royal Gala" apples[14] and that exogenous ethylene induced structural and compositional changes in surface waxes of "Navelate" oranges[15] suggest that the biosynthesis of cuticular waxes in these fruit species might be under ethylene control.

Sweet cherry (*Prunus avium* L.) fruit is very perishable, owing to high respiration and water loss rates which favor rapid postharvest deterioration due to weight loss, detrimental effects on appearance, and increased susceptibility to infections and mechanical injuries, which notably restrict storage and shelf life potential. Postharvest quality of fruit produce is greatly impacted by cuticle composition, structure, and properties (reviewed in ref 2). Cuticles of sweet cherry fruit have been studied at commercial maturity[16] and during on-tree development regarding their chemical composition,[6] mechanical properties,[17] and frequency and distribution of microcracks.[18] However, no study has addressed the compositional changes in sweet cherry cuticles after harvest or during the refrigerated storage commonly used for its preservation. Therefore, the purpose of this work was to assess the evolution of the chemical constituents of the cuticle of two important cherry cultivars during cold storage.

## MATERIALS AND METHODS

**Plant Material, Assessment of Standard Quality, and Postharvest Handling.** Cherries (*Prunus avium* L. cv. "Celeste" and "Somerset") were hand-collected in 2011 (May 23rd and June 7th, respectively) from the same commercial orchard located in Corbins, in the area of Lleida (NE Spain), at marketable maturity according to the usual indices (size and color) in the producing area. Uniform, defect-free samples were selected and transported directly to the laboratory. Standard quality parameters were determined immediately thereafter in order to check adequate maturity of samples. Firmness was measured with a Durofel DFT 100 durometer (Agro-Technologie, Forges Les

Eaux, France) fitted with a 5.64 mm tip, on two opposite faces on the cheek region of 30 fruit, and results were expressed as Durofel units (1, no resistance, to 100, maximum resistance). For the assessment of juiciness, three replicate samples (10 fruit each) were stoned in each case and squeezed until no more juice was released. After filtration, the volume of juice recovered was measured and expressed as mL 100 $g^{-1}$ fresh weight. Soluble solids content (SSC) and titratable acidity (TA) were assessed in juice obtained as described above. SSC was determined with a hand-held refractometer (Atago, Tokyo, Japan), and results expressed as °Brix. For TA determination, 10 mL of juice were diluted in 10 mL of distilled water, and titrated with 0.1 M NaOH to pH 8.1; results were given as g malic acid $L^{-1}$. Skin color was determined at two opposite equatorial points of 30 fruit using a portable tristimulus colorimeter (Chroma Meter CR-200, Minolta Corp., Osaka, Japan), with CIE $D_{65}$ illuminant and 8 mm aperture diameter. Lightness ($L^*$) values were recorded, and hue angle was calculated from $a^*$ and $b^*$ parameters.

After quality assessments, fruits were stored at 0 °C and 92% relative humidity during 14 days followed by 3 days at 20 °C to simulate commercial shelf life. Skin samples were taken at harvest, upon removal from cold storage, and 3 days thereafter, and cuticles isolated and analyzed in triplicate as described below.

**Cuticle Isolation.** Exocarp segments were excised from the cheek region of 15 fruit using a cork borer (13 mm, i.d.). Four skin disks were so obtained from each individual fruit (5.31 $cm^2$ per fruit). Cuticular membranes (CM) were isolated enzymatically by incubation at 37 °C in 1.6 U $mL^{-1}$ cellulase and 100 U $mL^{-1}$ pectinase in 50 mM citrate buffer (pH 4.0) until no more material was released, in the presence of 1 mM $NaN_3$ to prevent microbial growth. After isolation, CM were washed in citrate buffer (50 mM, pH 4.0) at 37 °C until no material was left in suspension, thoroughly rinsed in distilled water in order to remove materials sorbed during isolation,[19] dried at 40 °C, and kept in hermetically capped vials until use. CM mass was determined gravimetrically and expressed per unit of fruit surface area ($\mu$g $cm^{-2}$) as well as on total fruit surface basis (mg $fruit^{-1}$). The reagents and standards used for the analysis of cuticular components were supplied by Sigma-Aldrich (Steinheim, Germany). All standards used were of analytical grade.

**Extraction and Analysis of Cuticular Wax Compounds.** Waxes were recovered from the 60 dry CM disks (a total of 79.64 $cm^2$ per cultivar and analysis date) obtained in each case. CM samples were dewaxed three times by shaking in $CHCl_3$ (1 mg sample $mL^{-1}$) 24 h at room temperature, followed by incubation (15 min) in an ultrasonic bath. After filtration, the chloroform extracts were pooled and concentrated using a rotary evaporator at 50 °C and the waxes transferred to a preweighed vial, dried under $N_2$ until complete dryness, and weighed in a microbalance for calculation of total wax yield ($\mu$g $cm^{-2}$). Free hydroxyl and carboxyl groups were converted respectively into their trimethylsilyl (TMSi) ethers and esters by derivatizing with *N*,*O*-bis(trimethylsilyl)trifluoroacetamide (BSTFA) in pyridine (2:1, v/v) for 15 min at 100 °C.

After derivatization, wax samples were added eicosane ($C_{20}$) and dotriacontane ($C_{32}$) as internal standards and injected (1 $\mu$L) in on-column mode into a gas chromatography−mass spectrometry (GC-MS) system for compound identification. A GC equipment (Agilent 7890A) coupled with a quadrupole mass selective detector (Agilent 5973N) was used for these analyses, equipped with a capillary column (BPX5, 30 m × 0.25 mm, 0.25 $\mu$m; SGE Europe Ltd., Milton Keynes, UK). Wax compounds were identified by comparing their retention indices with those of standards and by matching their electron ionization-mass spectra (EI-MS) (70 eV, $m/z$ 50−700) with those from the NIST 08 MS library. The oven was set at 50 °C (2 min), and the temperature was raised initially by 40 °C $min^{-1}$ to 200 °C, kept at 200 °C for 2 min, raised again by 3 °C $min^{-1}$ to 310 °C, and then kept constant at 310 °C for 30 min. Helium was used as the carrier gas (2 mL $min^{-1}$). Quantitative determination of wax compounds was carried out under the same chromatographic conditions using a GC system equipped with a flame ionization detector (FID). Data were expressed as relative %.

**Extraction and Analysis of Cutin Monomers.** Dewaxed cuticular membranes (DCM) were hydrolyzed in 3 mL of 1 M HCl in 100% MeOH and esterified in the same solvent for 2 h at 80 °C. After cooling, 2 mL of saturated NaCl was added to the methanolysate. The cutin monomers were extracted three times in 2 mL of hexane for 10 min, followed by thorough mixing and centrifugation at 20 °C. The monomer extracts were combined and evaporated to dryness in a $N_2$ steam. Cutin yields were determined gravimetrically as $\mu$g $cm^{-2}$. Dry cutin samples were derivatized with BSTFA for 15 min at 100 °C, then added heptadecanoate ($C_{17}$) and tricosanoate ($C_{23}$) as internal standards, and injected (1 $\mu$L) to GC-FID for quantitative determination.

Cutin compounds were identified by comparison with standards, and from their EI-MS spectra (70 eV, $m/z$ 50−700) after GC-MS analysis using the same GC-MS system as described in the previous section on wax analysis. The oven was set and held at 50 °C for 2 min, and then the temperature was raised to 250 °C by 10 °C $min^{-1}$, kept at 250 °C for 1 min, raised again by 3 °C $min^{-1}$ to 310 °C, and kept at that temperature for 20 min. The same chromatographic conditions were used for quantitative determination of cutin compounds by GC-FID. Results were expressed as relative %.

**Statistical Analysis.** A multifactorial design with storage and shelf life periods as factors was used to statistically analyze the results within each cultivar. All data were tested by analysis of variance (ANOVA) with the Minitab 16 program package, and means were separated by the Fisher's LSD test at $P \leq 0.05$.

## RESULTS AND DISCUSSION

The usual indicators of commercial quality show that samples were picked at marketable maturity according to the standards in the producing area (Table 1). Average weight and diameter at harvest were higher for "Somerset" than for "Celeste" fruit (Table 1). "Somerset" cherries were also firmer, juicier, and displayed higher SSC and TA values. Skin color of "Celeste" fruit was less red, but lighter, than that of "Somerset", as indicated by higher hue and lightness values.

**Table 1. Maturity and Quality Indicators of "Celeste" and "Somerset" Sweet Cherry Fruit at Commercial Harvest**

| parameter[a] | 'Celeste' | 'Somerset' |
|---|---|---|
| weight (g) | 9.02 b | 10.49 a |
| diameter (mm)[b] | 27.95 b | 30.73 a |
| firmness (Durofel units) | 77.67 a | 80.43 a |
| juiciness (mL 100 $g^{-1}$ FW) | 61.07 b | 65.37 a |
| SSC (°Brix) | 16.07 b | 19.43 a |
| TA (g $L^{-1}$) | 6.70 b | 7.32 a |
| hue (°) | 21.88 a | 16.97 b |
| lightness ($L^*$) | 33.51 a | 27.01 b |

[a]Values represent means of 30 or three (SSC, TA, juiciness) replicates. Mean values followed by a different lower-case letter within the same row are significantly different at $P \leq 0.05$ (LSD test). [b]Diameter is given as the average between the wider and the narrower sides of each fruit.

In addition to these differences in the usual quality indicators, both cultivars also differed in relation to cuticle amount recovered from fruit skin (Table 2). Cuticle yields ($\mu$g $cm^{-2}$) obtained from 60 skin disks were noticeably lower in "Celeste" than in "Somerset" fruit (100 vs 206 at harvest, respectively). Higher cuticle amounts per surface area might be indicative of thicker cuticles, but no measurements of cuticle thickness were undertaken in this study. Incidentally, weight loss and firmness changes after 3 days at 20 °C were more pronounced in "Celeste" than in "Somerset" samples (Table 3), showing a somewhat better conservation potential for "Somerset" fruit. However, published studies on the relevance of cuticle thickness for postharvest weight loss have reported contradictory results

[a]Values are the means of 30 replicates. Mean values followed by a different lower-case letter within the same row are significantly different at $P \leq 0.05$ (LSD test). [b]Diameter is given as the average between the wider and the narrower sides of each fruit. [c]Total surface and volume were estimated from the average diameter of each fruit assuming a spherical shape.

(reviewed in ref 2), and such a relationship has been actually shown in only a few instances.[20] The composition and/or structure of the fruit surface may be of more relevance for postharvest performance-related physiological traits.

**Cuticular Wax and Cutin Composition at Harvest.** Cutin and cuticular waxes were extracted from cuticles obtained enzymatically from fruit samples and analyzed chromatographically. In spite of being comprised of similar chemical families, both types of cuticular components showed cultivar-related differences in the specific composition and in the abundance of particular compounds. Noticeable differences in the total content of cuticular waxes and cutin were also observed between both cherry cultivars.

Total wax yields of fruit at harvest were around 33 ("Celeste") and 48 ("Somerset") $\mu$g cm$^{-2}$, corresponding to 33 and 23% of total cuticle material recovered, respectively. Triterpenes were the most abundant class of wax components in both cherry cultivars considered (Table 4), with ursolic acid as the dominating compound (49% and 47% of total waxes at harvest for "Celeste" and "Somerset", respectively). This is in accordance with an early report on "Bing" cherries.[16] The prevalence of ursolic acid agrees as well with a more recent investigation[6] in which cuticular wax composition was analyzed in four cherry cultivars ("Hedelfinger", "Kordia", "Sam", and "Van") during on-tree fruit development, although in that study the amount of triterpenes was found to account for up to 76% of total wax, which is higher than the levels observed in this work at harvest (55−57%). This difference was due to greater contents of ursolic acid (around 60%) because the relative amounts of oleanoic acid, the second triterpene in quantitative terms, were equivalent to those found in this study (7.5%).

Alkanes were the second most important class of wax components in quantitative terms, among which *n*-nonacosane ($C_{29}$) was the most abundant compound, followed by *n*-heptacosane ($C_{27}$) (Table 4), which is also consistent with previous observations.[6,16] However, "Somerset" cuticles were richer in alkanes than those obtained from "Celeste" fruit (roughly 15 vs 10% at harvest, correspondingly), particularly in those with longer chains ($C_{27}$ to $C_{31}$), and also contained higher percentages of phytosterols. In contrast, "Celeste" cuticles were richer in fatty acids than those of "Somerset" fruit, although in both cultivars linolenic acid predominated quantitatively among this type of wax components. Cuticular waxes of "Bing" cherries were also characterized to be rich in palmitic, stearic, oleic, and linoleic acids and to contain significant amounts of sitosterol.[16] None of these fatty acids, and only trace amounts of sitosterol, which are characteristic for membrane lipids, were found in a subsequent study,[6] leading to the suggestion that their presence in the previous report was due to the use of pressed, dehydrated fruit skins as the source of wax. Nevertheless, we wish to point out that we used enzymatically isolated cuticles herein as the source material for wax extraction. Therefore, presence of these compounds in the wax fraction is not likely to be artifactual but rather to be reflecting actual cultivar-related differences in cuticular wax composition.

Similarly to the observations for waxes, total cutin content was also higher in "Somerset" than in "Celeste" samples, expressed per unit surface area (85 vs 45 $\mu$g cm$^{-2}$, respectively) as well as on a whole fruit basis (2.5 vs 1.1 mg per fruit), even though it was a bit lower when expressed as a percentage over total cuticle yield (41 vs 45%) (Table 2). The analysis of cutin monomer composition revealed discrepancies with previous reports that the cutin fraction of mature "Kordia" fruit consisted mainly of $C_{16}$ (69.5%) and, to a much lesser extent, $C_{18}$ (19.4%) monomers.[6] In this work, in contrast, we found that the cutin fraction of "Celeste" and "Somerset" cherry fruit at harvest maturity was composed mainly of $C_{18}$ monomers (65.3%), comprising $\alpha$-monocarboxylic, $\alpha,\omega$-dicarboxylic, and $\omega$-hydroxylated acids (Table 5). The most abundant of these $C_{18}$ constituents were octadecane-1,18-dioic acid, 18-hydroxy-linoleic acid, 18-hydroxy-oleic acid, and oleic acid, whereas hexadecane-1,16-dioic

acid predominated among the $C_{16}$-type monomers. Only minor quantitative differences in cutin composition were found between both cultivars considered at harvest, the main constituent compounds being the same. Because the procedures for cuticle isolation and cutin depolymerization were similar, the discrepancies with that report[6] may illustrate cultivar-related differences which should be explored in relation with their potential relevance for distinctive agronomic, physiological, and quality traits of each particular genotype, such as keeping potential, water loss rates or predisposition to cracking. For example, the prevalence of monohydroxylated monomers (Table 5) instead of di- and trihydroxy acids[6] may have consequences for the cross-linking of the cutin network. Although currently available information on the specific composition of fruit cuticles is limited, significant differences have been found among different cultivars of apple,[5,8,12,13,21] grape,[22−24] pepper,[25,26] persimmon,[27] or tomato mutants.[28−30] At least for apple, pepper, persimmon, and tomato, these differences appeared to be connected to relevant physiological traits related to cuticle functionality such as water loss rates or mechanical properties.

**Changes in Cuticular Wax and Cutin Composition after Harvest.** After harvest, fruit remained 3 days at 20 °C, after which the amount of cuticle per unit surface area and per fruit increased in "Celeste" (Table 2). While this could have arisen from decreased surface area leading to apparently higher cuticle yields per surface unit, data show that fruit diameter, surface, and volume were similar to those at harvest (Table 3). These data thus suggest that some deposition of cuticle material took place during that period. The physiological significance of this postharvest cuticle formation is unclear. Although cuticle deposition in sweet cherry is known to cease early during fruit development,[10] postharvest modifications in the regulation of cuticle-related metabolic pathways cannot be ruled out, as no postharvest studies on sweet cherry cuticles have been published to date. In contrast, CM mass per surface area did not change significantly in "Somerset" samples, and it was actually found to decrease when expressed on a whole fruit basis (Table 2), which suggests the existence of cultivar-related differences in cuticle dynamics.

Significantly higher wax yields in absolute terms ($\mu g\ cm^{-2}$) were observed in both cases. However, due to augmented cuticle amounts during the shelf life period, the percentage of cuticular waxes decreased ("Celeste") or remained unchanged ("Somerset"). The main difference between cultivars, though, was found for cutin yields, which decreased in both absolute and relative terms in "Celeste" fruit, while the opposite was observed for "Somerset" cherries (Table 2).

Detailed analysis of cuticle composition revealed different evolution of particular compounds after harvest. For example, in the case of "Celeste", the percentage of triterpenes and alkanes was higher after 3 days at 20 °C, while that of free fatty acids and alcohols decreased after the same period (Table 4). The decreased content of fatty acids could be related to increases in alkanes, which are believed to arise from fatty acid decarboxylation or fatty aldehyde decarbonylation (reviewed in ref 31). On the contrary, no significant differences in the percentage of the main wax compound families were found for "Somerset" cuticles (Table 4). However, triterpenes must have been also actively synthesized in this cultivar after harvest in order to keep pace with increased cuticle yields, as shown by clearly augmented amounts in quantitative terms (Figure 1). Some increase was also observed for alkane content in spite of unchanged alkane percentages over total waxes (Table 4). Little information has been published to date on postharvest changes in cuticular waxes, but epicuticular waxes increased in ripe "Navelate" oranges (*Citrus sinensis* L. Osbeck) kept at 22 °C for 14 days, this increase being accentuated in ethylene-treated fruit.[15] Formation of new waxes was suggested to serve protective purposes, covering stomata, cracks or areas lacking wax, and improving physical barriers against pathogen penetration.[15,32] Significant increases in the amount per surface unit of different classes of wax compounds have also been reported for "Jesca" peach fruit, likewise cherry a *Prunus* species,[33] accounting for augmented cuticle yields after harvest and suggestive of up-regulation of the biosynthetic pathways involved in cuticle biosynthesis.

In contrast to waxes, the percentages of particular cutin monomer types in fruit cuticles showed limited changes after shelf life at 20 °C, the only significant variations observed being restricted to some decline in monocarboxylic acids, particularly in "Somerset" samples (Table 5). Yet, some differences in the evolution of these compound families were found between both cultivars. For "Celeste", the content of hydroxy acids declined also in absolute terms (Figure 2A). In contrast, the observation of increased contents of dicarboxylic and hydroxy acids in cuticles of "Somerset" fruit after harvest (Figure 2B) suggests net biosynthesis taking place thereafter and accounting, at least

[a]Values represent means of three replicates (nd, nondetectable). Mean values followed by a different lower-case letter within the same row are significantly different at $P \leq 0.05$ (LSD test).

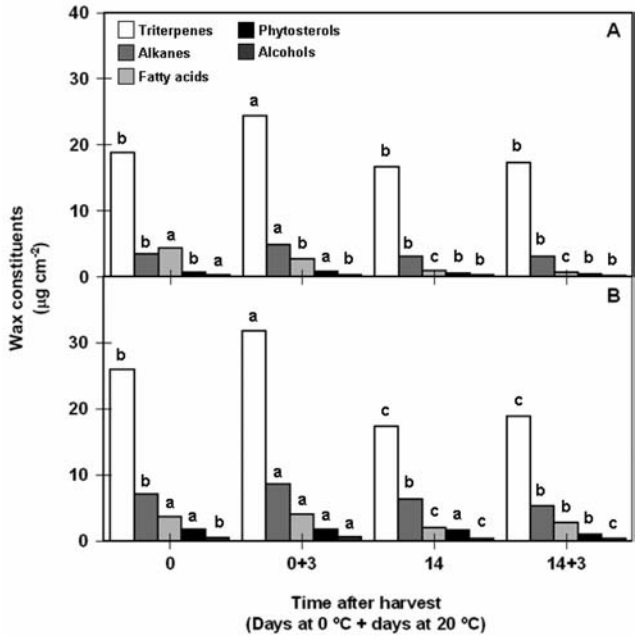

**Figure 1.** Amount ($\mu$g cm$^{-2}$) of the main classes of wax constituents identified in cuticles of "Celeste" (A) and "Somerset" (B) sweet cherries at harvest and after cold storage. For each class of wax constituents, values bearing different letters are significantly different at $P \leq 0.05$ (LSD test).

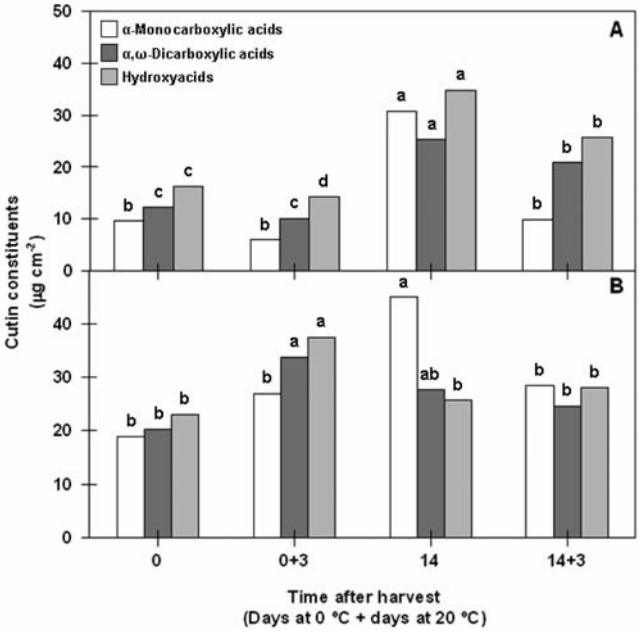

**Figure 2.** Amount ($\mu$g cm$^{-2}$) of the main types of cutin monomers identified in cuticles of "Celeste" (A) and "Somerset" (B) sweet cherries at harvest and after cold storage. For each type of cutin monomers, values bearing different letters are significantly different at $P \leq 0.05$ (LSD test).

partially, for the augment in cutin percentage over total cuticle material (Table 2). Differences in the postharvest evolution of particular types of cutin monomers also seem to exist between melting- and nonmelting-type peach genotypes.[33]

**Changes in Cuticular Wax and Cutin Composition after Cold Storage.** For both cultivars, the amount of cuticle per unit surface area and per total area increased after storage of fruit at 0 °C for 2 weeks, but decreased again during the subsequent 3 days of shelf life at 20 °C (Table 2), in parallel to lowered fruit surface and volume (Table 3). In the case of "Celeste", augmented cuticle yields after cold storage were detectable as soon as after only 7 days (data not shown). Total wax yield and wax percentage in both cultivars decreased significantly after keeping fruit at 0 °C for 14 days. In contrast, although cutin contents were higher in absolute terms than those at harvest (per surface unit as well as per fruit), the percentage over total cuticle amount remained the same owing to augmented cuticle yields per unit surface area (Table 2).

dx.doi.org/10.1021/jf502650t | J. Agric. Food Chem. 2014, 62, 8722−8729

Many metabolic processes in fruit are enhanced or redirected in response to low temperatures. Data shown herein put forward the possibility that cuticle formation is one of such processes. A few reports have described the changes in cuticular waxes after cold storage of apple[8,12−14] and shown considerable cultivar-associated variability for this fruit species. For instance, total wax contents after long-term cold storage were found to remain unchanged in "Sturmer" but to increase in "Granny Smith" and "Dougherty" apples,[12] while in contrast a sharp decline was observed for "Red Fuji" samples.[8] Changes in the composition of cuticular waxes during cold storage of apples were modulated in response to usual postharvest procedures such as controlled atmosphere storage[13] or 1-methylcyclopropene treatment.[8,14] However, we are not aware of any similar works for other fruit species. To the best of our knowledge, cutin changes after cold storage have not been previously reported for any fruit commodities either. We therefore analyzed the fate of wax and cutin components in cuticles isolated from "Celeste" and "Somerset" fruit kept at 0 °C. The modifications described below are indicative of intense alterations taking place in cuticle composition, and hence probably also in cuticle structure and properties, during cold storage.

The content of triterpenes ($\mu$g cm$^{-2}$) in cuticular waxes of "Celeste" fruit was unchanged after cold storage (Figure 1A). Still, owing to lower wax content in cuticles of cold-stored fruit as compared with values at harvest (roughly 25 vs 33 $\mu$g cm$^{-2}$, respectively), the percentage of triterpenes increased, ursolic and oleanoic acids representing approximately 58 and 10% of total waxes, in that order (Table 4). Although to a lower extent, some increase was also found in alkane percentage, particularly in that of *n*-nonacosane, the main alkane in quantitative terms, even though the absolute content was likewise unaffected (Figure 1A). Similar results were obtained for phytosterols, while in contrast the content of fatty acids decreased sharply, the main reduction being found for linoleic acid (Table 4). The total content of triterpenes after cold storage was also lower in cuticles of "Somerset" cherries, both in absolute (Figure 1B) and relative (Table 4) terms, while the percentage of alkanes and sterols increased. This is interesting in the light of previous suggestions that the waterproofing properties of fruit cuticles are defined primarily by the *n*-alkane components.[34] Reduced wax alkanes and enhanced triterpenoids would lead to increased content of amorphous waxes, thus impairing the transpiration barrier function of cuticles,[29] and in fact the ratio of alkanes to triterpenoids plus sterols has been found to correlate inversely with dehydration rates in pepper fruit.[26] Indeed, this ratio was 0.18 in "Celeste" and 0.33 in "Somerset", which would be consistent with the observation of higher weight loss rates for "Celeste" (15.8%) than for "Somerset" (7.2%) after cold storage (Table 3).

In relation to cutin monomers, some differences in the evolution of the content of particular compounds were also found between both cultivars considered. In "Celeste" samples, the percentage of monocarboxylic fatty acids was higher in fruit kept at 0 °C for 2 weeks, resulting from parallel increases in palmitic and linoleic acids (Table 5). However, the percentage of total fatty acids decreased again after 3 days of shelf life. In spite of a significant augment in the amount of $\alpha,\omega$-dicarboxylic and $\omega$-hydroxy acids per unit surface area (Figure 2), the percentage of these compounds (particularly those of the $C_{18}$-type) over total cutin mass decreased after cold storage. This is indicating that actual production of these cutin monomers must have taken place during the experimental period but that biosynthesis rates were not sufficient to keep pace with enhanced cuticle deposition (Table 2). This must have had consequences for cuticle structure and properties, as $\alpha,\omega$-diacid compounds are thought to be important for cross-linking of the cutin polymer.[35] In turn, the $\omega$-hydroxyl group in $\omega$-hydroxyacids is also necessary for the formation of the polymer.[36] Similar trends were observed in "Somerset" fruit for the evolution of the main types of cutin monomers, although some differences were found for particular compounds. For example, the content of oleic acid was higher after cold storage, in contrast with findings for "Celeste" fruit, and the increase in alkane content was also more perceptible (Table 5). Although the content of $\alpha,\omega$-dicarboxylic and $\omega$-hydroxy acids recovered after 3 days at 20 °C, the declining trend for the percentage of these families of cutin monomers along cold storage was accentuated in fruit kept at 0 °C for a longer period (data not shown), after which the contents of these compounds remained low. A little percentage of alkanes was noticed among the cutin constituents detected after cold storage, particularly for "Somerset" samples (data not shown). This may be an artifact representing wax constituents not completely released during the dewaxing procedure, which may have remained enclosed within the cutin matrix even though the chloroform extraction was repeated three times.

In summary, the most abundant components identified in cuticular waxes of "Celeste" and "Somerset" fruit agree with previous reports for other cherry cultivars,[6,16] but remarkable differences were found as to the main types of cutin monomers. These data suggest cultivar-related variability in the specific composition and in the abundance of particular compounds in cuticles of sweet cherry fruit. Such dissimilarities in the chemical composition of fruit cuticles and in their evolution during postharvest preservation of produce might account, at least partially, for some of the quality or storability characteristics of each cultivar, including weight loss, firmness, or susceptibility to infections or physiological disorders.[2] To the best of our knowledge, this is the first study reporting changes in cuticle composition of sweet cherry fruit during cold storage and one of the few works addressing postharvest modifications in the components of this outer layer of fruit surface. Further work on modifications in the relative amounts of the different cuticle components in response to internal and external factors will be required to shed light on the physiological consequences of these compositional changes, thus helping dissect the contribution of each particular compound family to the biological role of fruit cuticles.

# Effect of the Biopolymer Mixing Ratio on the Formation of Electrostatically Coupled Whey Protein−κ- and ι-Carrageenan Networks in the Presence and Absence of Oil Droplets

Ricky S. H. Lam and Michael T. Nickerson*

Department of Food and Bioproduct Sciences, University of Saskatchewan, 51 Campus Drive, Saskatoon, Saskatchewan, Canada S7N 5A8

**ABSTRACT:** The rheological properties of 1.0% (w/w) whey protein isolate (WPI)−κ-/ι-carrageenan (CG) mixtures were investigated during a slow acidification process by glucono-δ-lactone from pH 7.00 to ∼4.20 as a function of biopolymer mixing ratio and in the presence and absence of oil droplets. In all cases, electrostatic coupled biopolymer and emulsion gel networks were formed at pH values corresponding to where attractive interactions between WPI and CG began. Formed WPI−CG complexes were found to be surface active, capable of lowering interfacial tension and forming viscoelastic interfacial films within emulsion-based systems. Both biopolymer and emulsion-based gels increased in strength and elasticity as the CG content increased, regardless of the type of CG present. However, WPI−ι-CG coupled networks were stronger than WPI−κ-CG networks, presumably due to the higher number of sulfate groups attracting the WPI molecules.

**KEYWORDS:** *emulsion, electrostatic coupled gel, coacervation, whey proteins, carrageenan*

## INTRODUCTION

Whey protein and carrageenan (CG) are commonly used as food ingredients in many applications (e.g., baked goods, beverages, desserts, confectionary and meat products) due to their gelling, emulsifying,or thickening abilities.[1] Whey proteins represent a mixture of proteins that are dominated by α-lactalbumin and β-lactoglobulin. These proteins have been intensively studied over the years for their functional attributes such as gelation[2−4] and their capacity to stabilize emulsions.[5−7] In contrast, carrageenan polysaccharides are extracted from red seaweeds (*Rhodophyta* species)[8] and consist of disaccharide repeating units composed of D-galactose and 3,6-anhydro-D-galactose residues, with one, two, or three sulfate groups associated each repeat unit for κ-, ι-, and λ-type carrageenans, respectively.[9] Although other minor types of CG have been identified by Knutsen and co-workers,[10] the present research will focus only on the κ- and ι-types due to their abilities to form strong gels.[11−13]

Mixtures of proteins and polysaccharides are known to undergo associative liquid/liquid phase separation (also known as complex coacervation) under conditions where biopolymers are oppositely charged and/or experiencing a significant amount of electrostatic attraction.[14] Whey protein−carrageenan mixtures have been explored previously in this respect by de Kruif and co-workers,[14] Weinbreck and co-workers,[9] and Stone and Nickerson.[15] During coacervation, the pH is lowered until a negatively charged protein (i.e., pH > p*I*) becomes neutral (i.e., at p*I*) and then positively charged (i.e., pH < p*I*), when it then can interact with a negatively charged polysaccharide. In the case of whey protein and CG, the initial interaction typically occurs at pH > p*I*, when both biopolymers carry similar net charges due to the interaction between CG and positively charged "patches" on a protein surface.[9] This initial interaction is denoted $pH_c$ and is evident by a slight increase in the absorption or light scattering in the protein−polysaccharide solution.[14] As the pH continues to decline, a sharp rise in the absorbance or light scattering of the biopolymer solution (designated $pH_{\phi 1}$) follows as the solution becomes turbid.[14] This sustained increase in absorbance and light scattering continues until a maximum is reached (designated $pH_{opt}$).[14] Beyond this point, continual acidification causes the complex to dissociate and dissolve.[14] The area of complex coacervation has been well studied with a number of reviews in the area.[14,16,17]

Recently, researchers have sought to use complexes as a means to stabilize emulsions.[18−24] Emulsions are formed when two immiscible liquids are mechanically agitated until one is dispersed as tiny droplets within the other. Because emulsions are thermodynamically unstable, amphiphilic biopolymers (e.g., proteins) can be used to inhibit emulsions from phase separation by reducing the surface tension between the droplets and the continuous solvent. Depending on the level of interactions, the biopolymers involved, and the processing conditions, systems may become stable or unstable. For instance, in dilute systems, the addition of a polysaccharide to a protein-stabilized oil droplet could lead to the formation of a viscoelastic bilayer where the polysaccharide complexes to the interfacial film, leading to increased emulsion stability[25] or causing instability via flocculation by the depletion interaction or bridging flocculation of neighboring droplets.[26] In more concentrated systems, various mixed protein−polysaccharide systems may take on a gel-like structure.[27] The nature of the gel may be considered as an "emulsion-filled protein gel, whereby oil droplets are simply encased within a gelled protein or a protein-stabilized emulsion gel", whereby the gel structure

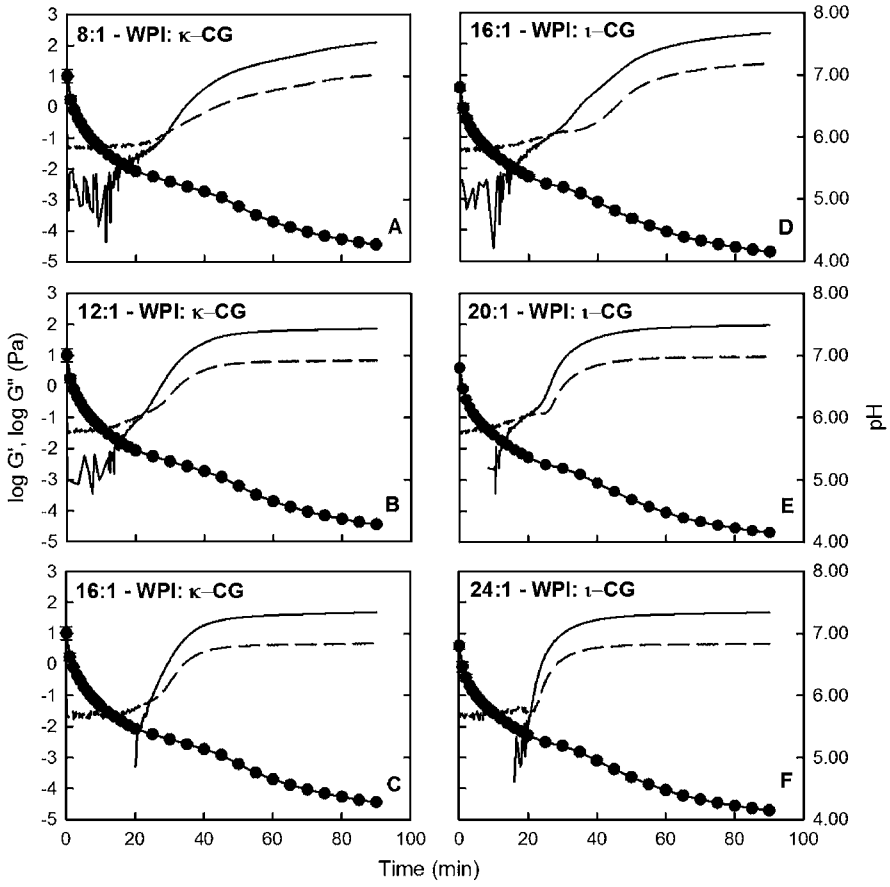

**Figure 1.** Dynamic viscoelastic storage ($G'$, solid line) and loss ($G''$, dashed line) moduli measured at 1 Hz with 1.0% constant strain for mixtures of WPI–$\kappa$-CG (A–C) and WPI–$\iota$-CG (D–F) at various mixing ratios as a function of pH (solid circles) and time (min). Each curve is the mean ± one standard deviation of three separate time sweep runs on separate samples. All solutions had a total biopolymer concentration of 1.0% (w/w) and were acidified using 0.5% (w/w) GDL.

consists of an interconnected flocculated network of oil droplets stabilized by an interfacial coacervate film.[27]

The inclusion of polysaccharides to protein-based emulsion systems has recently been researched as a means to reduce the oxidation of the emulsified oil for bioactive delivery[28] and for developing novel applications in controlled-release systems.[29] This body of work will continue to enhance our understanding of protein–polysaccharide interactions in emulsified systems.[30] The overall goal of the present study is to examine the underlying mechanisms driving the formation of electrostatically coupled biopolymer and emulsion gel networks, as a function of CG type ($\kappa$- and $\iota$-types) and mixing ratio between whey protein isolate (WPI) and the CG molecules. Stone and Nickerson investigated the formation of electrostatic complexes involving WPI and CG molecules as a function of CG type under dilute conditions (0.25% w/w) and reported the optimal mixing ratio to occur at a 12:1 ratio for WPI–$\kappa$-CG mixtures and at a 20:1 ratio for the WPI–$\iota$-CG system.[15] Information arising from this study will aid in controlling and optimizing their use in food or controlled delivery-type applications where gelation is important.

## MATERIALS AND METHODS

**Materials.** Whey protein isolate used in this study was generously donated by Davidson Foods International, Inc. (Le Sueur, MN, USA). The chemical composition of the commercial WPI powder was determined according to AOAC[31] methods; 925.10 (moisture), 923.03 (ash), 920.87 (crude protein), and 920.85 (lipid). Carbohydrate content was determined on the basis of present differential from 100%. The WPI powder was composed of 89.78% protein (%N × 6.38), 0.10% lipid, 4.92% moisture, 2.06% ash (including 0.08% $Ca^{2+}$, 0.01% $Mg^{2+}$, 0.02% $K^+$, and 0.66% $Na^+$), and 3.13% carbohydrate (wet basis). Carrageenan (CG) ($\kappa$- and $\iota$-) and glucono-$\delta$-lactone (GDL) were purchased from Sigma-Aldrich (Oakville, ON, Canada). For the two types of CG, the supplier information indicated that $\kappa$-CG was composed of 66.50% carbohydrate, 10.65% moisture, and 22.86% ash (including 2.4% $Ca^{2+}$, 0.16% $Mg^{2+}$, 5.4% $K^+$, 0.49% $Na^+$) and that $\iota$-CG contained 64.40% carbohydrate, 10.82% moisture, and 24.97% ash (including 3.4% $Ca^{2+}$, 0.18% $Mg^{2+}$, 3.2% $K^+$, 1.2% $Na^+$). Canola oil used in this study was purchased from a local supermarket. All other chemicals used in this study were of reagent grade and purchased through Sigma-Aldrich. The water used in this research was filtered using a Millipore Milli-Q water purification system (Millipore Corp., Milford, MA, USA). WPI and CG were used without further purification and were corrected for protein and polysaccharide content, respectively.

**Sample Preparation.** Biopolymer solutions (1.0% w/w biopolymer) were prepared by dispersing WPI and CG powders in water by mechanical stirring (500 rpm) at room temperature (21–23 °C) for 60 min. Afterward, 0.5% (w/w) of GDL was added to the biopolymer solution and stirred for 1 min prior to analysis to slowly acidify the solution. WPI and CG were mixed at ratios above and below the optimal ratio determined by Stone and Nickerson.[15] Mixing ratios of 8:1, 12:1, and 16:1 were tested for WPI–$\kappa$-CG, and ratios of 16:1, 20:1, and 24:1 were tested for WPI–$\iota$-CG. A total of 1.0% (w/w) biopolymer into the aqueous phase was used for all experiments. All WPI and CG powder weights used were corrected for both protein

dx.doi.org/10.1021/jf5023669 | J. Agric. Food Chem. 2014, 62, 8730–8739

and carbohydrate concentrations, respectively. Changes in pH upon GDL addition was monitored for each mixture using a Fisher Scientific Accumet pH meter equipped with an Ag/AgCl pH probe (Fisher Scientific, Ottawa, ON, Canada) over time.

*Emulsion Preparation.* Initially, biopolymer solutions were prepared as previously mentioned. Upon addition of the GDL, and equal ratio (1:1) of the aqueous biopolymer solution and canola oil was mixed to a total weight of 10 g. The mixture was subsequently homogenized at 7200 rpm for 5 min using an Omni Macro Homogenizer (Omni International Inc., Marietta, GA, USA) equipped with a 20 mm sawtooth generating probe.

**Interfacial Tension.** The interfacial tension for each WPI−CG mixture was measured using a Lauda TD 2 tensiometer (Lauda-Königshofen, Germany) equipped with a Du Nüoy ring (20 mm diameter). Within a 40 mm diameter glass sample cup, a 20 g biopolymer solution was added and then stirred for 1 min after the addition of 0.5% w/w GDL, followed by the immersion of the Du Nüoy ring and then the addition of the upper canola oil layer (20 g). The ring was then pulled upward to stretch the interface to measure the maximum force without breaking into the oil phase. Interfacial tension was measured over time (50 min) every 600 s, where the mean of three replicates ± one standard deviation was reported. Interfacial tension was calculated from the maximum force ($F_{max}$; units of mN; instrument measures mg × gravity) using equation 1)

$$\gamma = \frac{F_{max}}{4\pi R\beta} \quad (1)$$

where $\gamma$ is the interfacial tension (mN/m), $R$ is the radius of the ring (20 mm), and $\beta$ is a correction factor that depends on the dimensions of the ring and the density of the liquid involved.[32] All measurements are reported as the mean ± one standard deviation ($n$ = 3).

**Oscillatory Shear Deformation of the Bulk Solution.** Oscillatory shear deformation of the bulk biopolymer and emulsion solutions during a GDL acidification was monitored over time using an AR-G2 rheometer (TA Instruments, New Castle, DE, USA) equipped with a 40 mm diameter 2° acrylic cone. A time sweep was performed over a 90 min period to monitor changes in the dynamic storage ($G'$) and loss ($G''$) moduli. Measurements were made within the linear viscoelastic region at a frequency of 1 Hz every 10 s, where the maximum amplitude for strain was set at 1.0%. Following the time sweep, a frequency and strain sweep was performed on the same material to better characterize the formed gel network. During frequency sweeps, frequencies were increased continuously from 0.05 to 100 Hz with 15 points per logarithmic decade being captured, with maximum strain set at 1%. In contrast, strain sweeps were conducted by increasing the applied strain continuously from 0.01 to 500% with 15 data points per logarithmic decade captured at a frequency of 5 Hz. Each sample was prepared in triplicate.

**Oscillatory Shear Deformation at the Oil−Water Interface.** Interfacial oscillatory shear deformation was applied at the oil−water interface using the AR-G2 rheometer equipped with their interfacial bicone fixture. Interfacial oscillatory shear was performed in time sweep mode for 90 min at a frequency of 1 Hz and maximum strain set at 1.0%. Biopolymer solutions with GDL comprised the denser phase beneath the bicone, whereas canola oil comprised the less dense phase above the bicone. All measurements were made within the linear viscoelastic regimen. Each sample was prepared in triplicate.

## RESULTS AND DISCUSSION

**Formation of Electrostatic Coupled Biopolymer Networks.** The rheological properties of WPI−CG mixtures as a function of CG type and mixing ratio during a slow acidification from pH 7.00 to ∼4.20 using GDL are given in Figure 1. In all cases, gel-like properties ($G' > G''$) were evident once the solution pH was reduced to induce complexation between the WPI and CG molecules. In the absence of CG, WPI solutions did not exhibit gel-like properties (data not shown). In the case of the WPI−κ-CG mixture, the crossover point (denoted as the gel point[33]) of $G'$ with $G''$ was found to correspond to pH 5.37, 5.33, and 5.29 for the 16:1, 12:1, and 8:1 WPI−κ-CG mixing ratios, respectively (Figure 1a-c). The pI of WPI has been reported to be at pH 4.6,[34] suggesting that complexation is occurring where both biopolymers are carrying a negative net charge and most likely involve CG interactions with positively charged patches on the protein's surface.[9] At pH above the gel point, biopolymers were assumed to be cosoluble and noninteracting, leading to fluid-like flow behavior ($G' < G''$). Afterward, $G'$ increased substantially indicating a rise in network strength. In the case of the 8:1 mixing ratio, $G'$ approached a plateau regime whereas for the 12:1 and 16:1 ratio a plateau was reached (Figure 1A−C). The magnitude of $G'$ was found to increase as the CG concentration increased within the ratio, where $G'$ was found to be 45.4, 73.1, and 108.0 Pa for 16:1, 12:1, and 8:1 WPI−κ-CG mixing ratios, respectively (Table 1). It was hypothesized that the lower pH at the gel point for the 8:1 mixing ratio reflects a greater viscosity imparted by the higher CG content. Similarly, Perez and co-workers reported that an increase in polysaccharide content led to slower mobility of whey protein−polysaccharide complexes.[35] Therefore, it was hypothesized that the reduced mobility of WPI−CG complexes led to a slower gelation time due to the high viscosity imparted by the high CG content of the system. In the case of the WPI−ι-CG mixture, the gel point was found to correspond to pH 5.34, 5.34, and 5.20 for the 24:1, 20:1, and 16:1 mixing ratios, respectively (Figure 1D,E). A similar increase in the maximum $G'$ was seen with increasing CG content, where the magnitude was found at 52.9, 93.1, and 256.9 Pa for mixing ratios 24:1, 20:1, and 16:1, respectively (Table 1), suggesting it was following a similar mechanism of network formation.

**Table 1. Dynamic Storage ($G'$) and Loss ($G''$) Moduli for Electrostatic Coupled Networks Involving WPI−CG Mixtures As a Function of Mixing Ratio and in the Absence and Presence of Oil after a 90 min Time Sweep Measured at 1 Hz while a 1.0% Constant Strain Was Applied[a]**

| | biopolymer gel | | emulsion gel | |

| 24:1 | 52.9 ± 12.5 | 5.1 ± 1.0 | 70.8 ± 16.6 | 15.8 ± 1.2 |

[a]All solutions had a total biopolymer concentration of 1.0% (w/w) and were acidified using 0.5% (w/w) GDL to pH 4.28 and 4.15 for the WPI−κ-CG and WPI−ι-CG mixtures, respectively. Data represent the mean value ± one standard deviation.

An increase in the $G'$ or the stiffness of the network has been previously reported by Tavares and co-workers, where the stiffness of whey protein−galactomannan networks was found with an increase in the polysaccharide content.[36] In the absence of CG, acidified WPI solutions did not form a network (data not shown). Therefore, it is assumed that the formation of WPI−CG networks is attributed to the formation of WPI−CG electrostatic complexes due to GDL acidification, which act as junction zones within the gel. Complex formation has been previously reported by others[9,14,15] and is a well-known

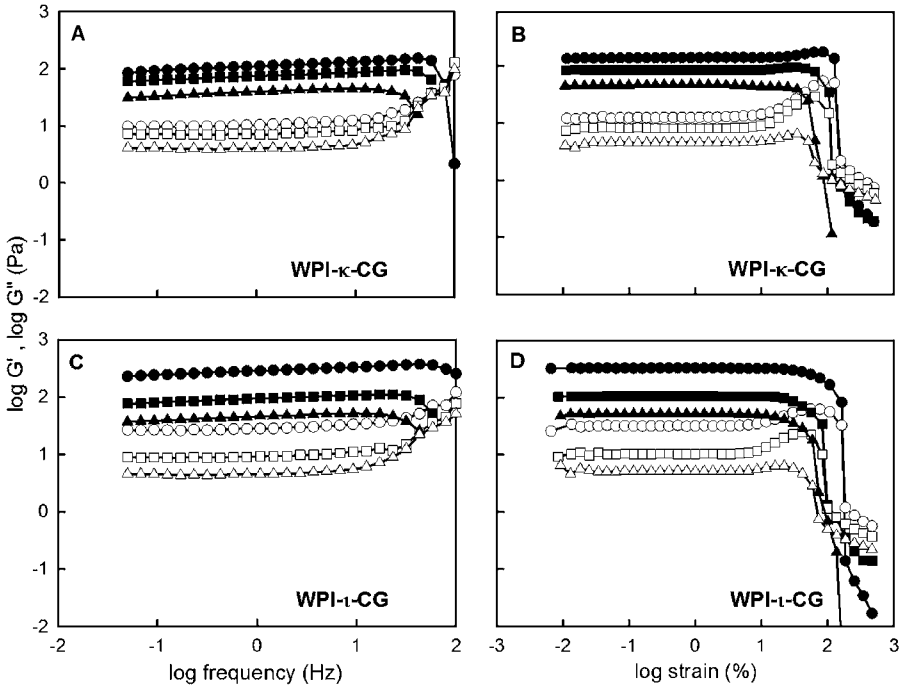

**Figure 2.** Dynamic viscoelastic storage ($G'$, solid symbols) and loss ($G''$, open symbols) moduli for mixtures of WPI−$\kappa$-CG (A, B) and WPI−$\iota$-CG (C, D) at various mixing ratios as a function of frequency (A, C) and strain (B, D). WPI−$\kappa$-CG (A, B) mixtures were mixed at ratios of 8:1 (circles), 12:1 (squares), and 16:1 (triangles), whereas WPI−$\iota$-CG (C, D) mixtures were mixed at 16:1 (circles), 20:1 (squares), and 24:1 (triangles). Each curve is representative of three separate sweep runs on separate samples. All solutions had a total biopolymer concentration of 1.0% (w/w) and were measured at a pH of 4.28 or 4.15 for WPI−$\kappa$-CG and WPI−$\iota$-CG mixtures, respectively.

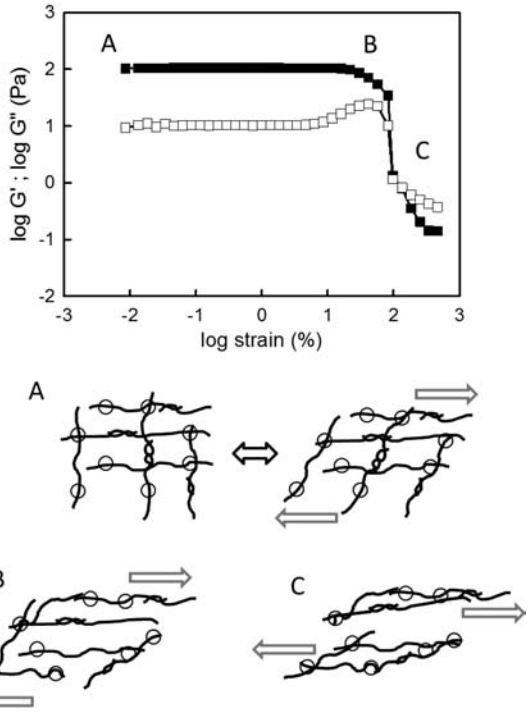

**Figure 3.** Schematic of a sample WPI−$\iota$-CG biopolymer gel at the ratio of 20:1 in response to strain ($G'$, solid symbols; $G''$, open symbols) where gelled networks composed of WPI (open circles) coupled with CG (lines) are elastic at low strains (A) and rearrange in their molecular bonding at higher strains (B), which leads to the breakdown of the network (C). The gray arrows indicate the direction of the applied shear.

phenomenon and therefore is beyond the scope of this paper. In part, coacervation requires the phase separation of the networks, where it is presumed that as proteins approach their p*I*, the precipitation of the proteins and their coacervation with polysaccharides enhance the strength of these networks. In a study of the effects of $\beta$-glucans complexed onto egg yolk stabilized oil-in-water emulsions, Santipanichwong and Suphantharika reported that insoluble $\beta$-glucans compared to soluble $\beta$-glucans exhibited a greater degree of structuring on their own.[37] To gain greater insights into the nature of these networks and to uncover their structural mechanism, they were physically characterized using frequency and strain sweeps.

Oscillatory frequency sweeps for both WPI−$\kappa$-CG and WPI−$\iota$-CG systems after the 90 min time sweep indicated that all materials exhibited gel-like features, regardless of the mixing ratio. Within this regimen, both moduli were slightly frequency dependent, and the magnitude of $G'$ was greater than that of $G''$ (Figure 2A,C). Without acidification, frequency sweeps of these WPI−CG biopolymer solutions were strongly frequency dependent, suggesting a noninteracting mixed biopolymer solution (data not shown). The slight dependence of these GDL acidified WPI−CG mixtures indicates a weak gel structure. Similarly, whey protein−galactomannan networks were also found to be slightly frequency dependent.[36]

Critical strains are helpful in characterizing the breakup of these gels under strain. In a previous study on pure CG gels, Azevedo and co-workers reported that in low ionic content CG mixtures, the critical strain was dependent on the CG content.[38] Similar to the present study, the critical strain decreases with increasing CG content.[38] CG content allowed for greater elasticity within these networks such that critical strains increased with CG content. Critical strain at break for WPI−$\kappa$-CG was found at ∼58.83, ∼73.41, and ∼116.4% for

dx.doi.org/10.1021/jf5023669 | J. Agric. Food Chem. 2014, 62, 8730−8739

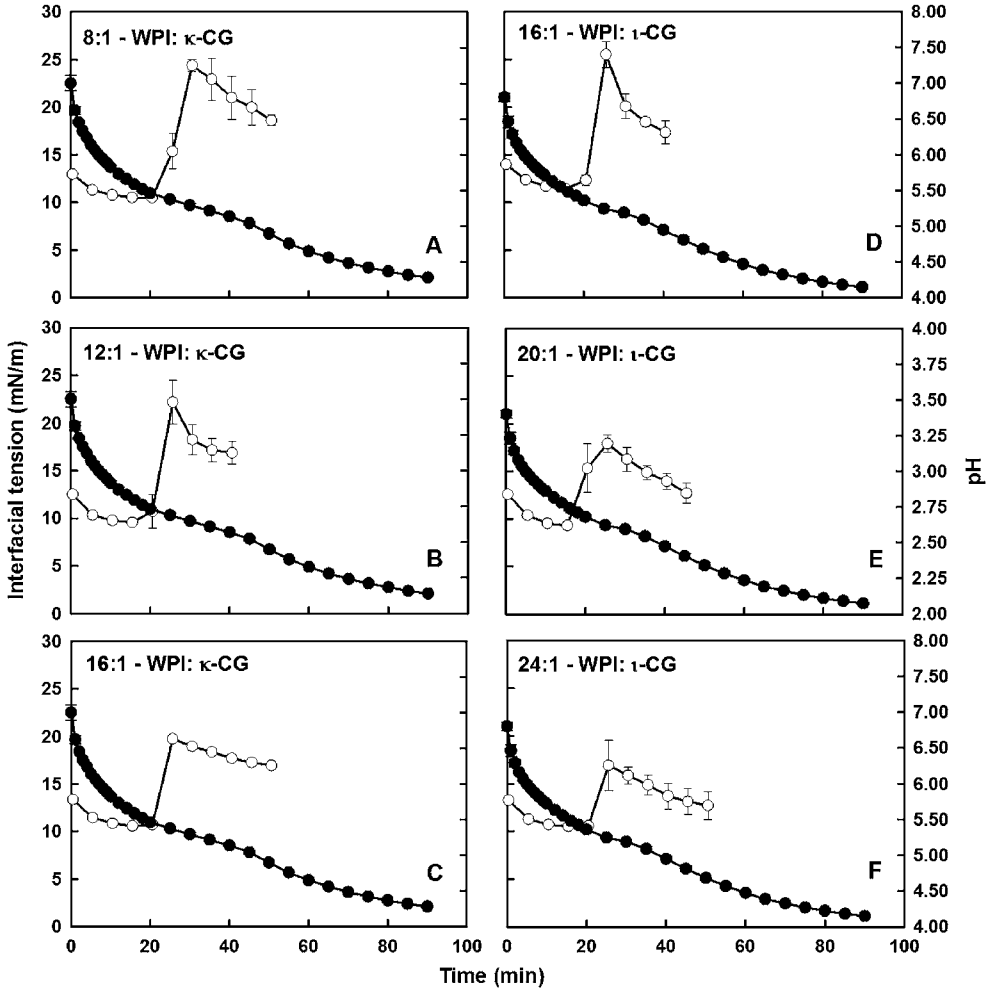

**Figure 4.** Interfacial properties of WPI/CG mixtures at the canola oil−water interface measured by interfacial tension (open circles) reported as the mean ± one standard deviation for mixtures of WPI−*κ*-CG (A−C) and WPI−*ι*-CG (D−F) at various mixing ratios as a function of pH (solid circles) and time (min). All solutions had a total biopolymer concentration of 1.0% (w/w) and were acidified using 0.5% (w/w) GDL.

mixing ratios of 16:1, 12:1, and 8:1, respectively, whereas for WPI−*ι*-CG, critical strain at the break occurred at ∼46.67, ∼74.52, and ∼98.25% for mixing ratios of 24:1, 20:1, and 16:1 respectively (Figure 2B,D). For both systems, the most elastic networks were formed at the highest CG content (i.e., lowest WPI/CG ratios). Networks were also more brittle (i.e., lower critical strain) when *κ*-CG was present relative to *ι*-CG, possibly due to its lower linear charge density, which reduces the number of potential bonds while allowing it to have greater conformational entropy (e.g., flexibility) and possibly more flexible cross-links between WPI molecules within the electrostatic coupled network. In contrast, *ι*-CG would have a higher number of sulfate groups present, leading to a stiffer polysaccharide molecule between the WPI molecules, which builds a stronger network.

The breakdown behavior in the strain sweep reveals the nature of these networks (Figure 2B,D) where the strain-independent behavior observed initially is a result of the elasticity exhibited by the network under low strains. At higher strains, the loss modulus increases slightly before decreasing along with the storage modulus. This strain behavior has been previously characterized as weak strain overshoot behavior by Hyun and co-workers.[39] In weak strain overshoot behavior, although frequency sweeps demonstrate gel-like behavior, their anionic polysaccharide (e.g., xanthan gum in a study by Hyun et al.[36] and CG in this study) was explained to possess large conformational entropy due to electrostatic repulsion within its structure.[39] This allows for alignment and association between biopolymers allowing for a network to form.[39] Hyun and co-workers later reported that weak strain overshoot behavior which results in a local $G''$ maximum is the result of junctions both breaking and forming new ones within the network under high strains.[40] Others have suggested that this localized $G''$ maximum is due to structural rearrangements due to the shear imposed onto the network.[41] Weak strain overshoot behavior was observed for all biopolymer networks formed with WPI−*ι*-CG mixtures and for WPI−*κ*-CG mixtures at a ratio of 16:1. In the case of WPI−*κ*-CG mixtures at ratios of 8:1 and 12:1, strong overshoot behavior was observed,[39] which is caused by the strong interactions formed by the interacting biopolymers. Under strong overshoot behavior, a local maximum for both $G'$ and $G''$ is observed before both rapidly decrease at higher strains. The decrease in both moduli is attributed to the breakdown of the network by shearing. This strain overshoot phenomenon is not unique to these WPI−CG systems but has also been previously reported in other associative biopolymer solutions.[42,43] WPI−CG networks within the present study are formed as a result of GDL acidification causing coacervation.

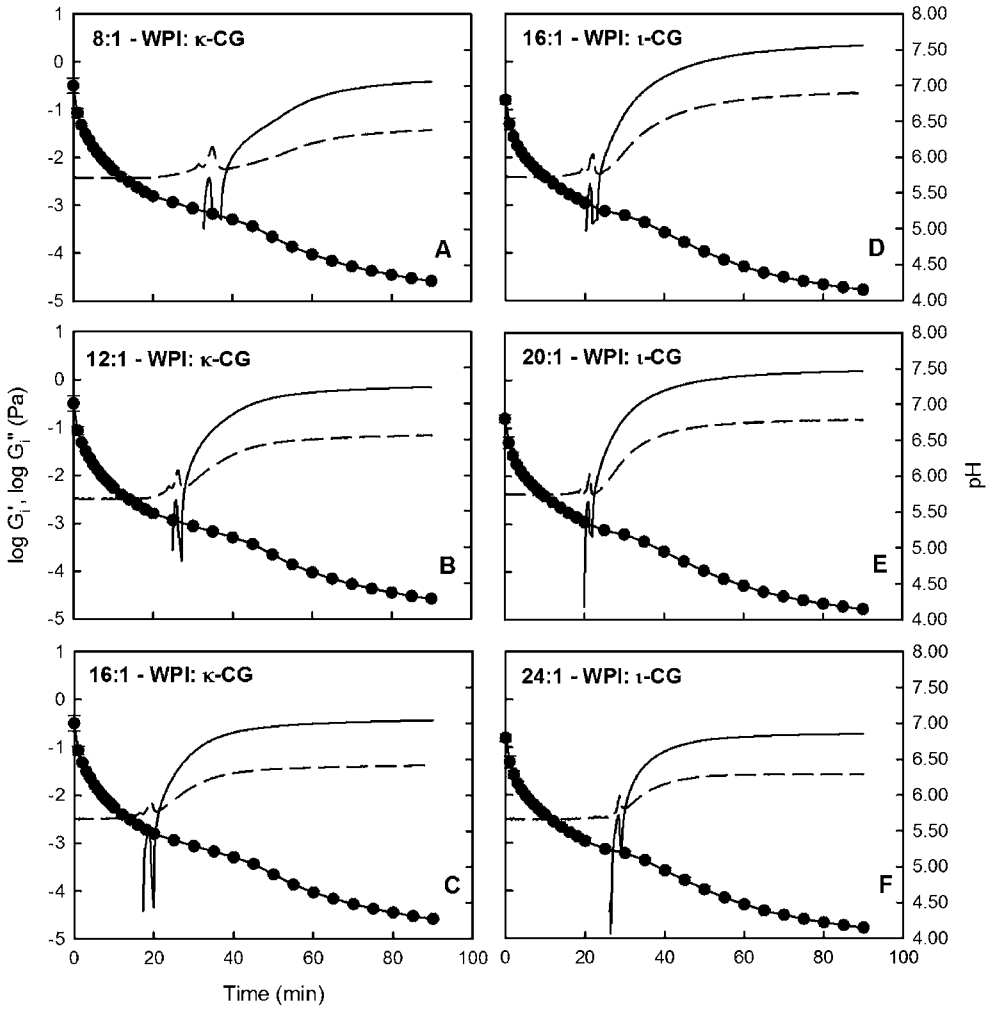

**Figure 5.** Interfacial rheological properties of WPI/CG mixtures at the canola oil−water interface measured by interfacial storage moduli (solid line) and interfacial loss moduli (dashed line) for mixtures of WPI−*κ*-CG (A−C) and WPI−*ι*-CG (D−F) at various mixing ratios as a function of pH (solid circles) and time (min). All solutions had a total biopolymer concentration of 1.0% (w/w) and were acidified using 0.5% (w/w) GDL.

The conformational entropy associated with CG allows for junction zones to be formed with either other CGs or WPIs present in solution (i.e., WPI−WPI, CG−CG, and WPI−CG interactions). These interactions, formed due to acidification over time, allow for a continuous network to be formed as captured by time sweeps under oscillatory stress measurements. Although a continuous network is formed, it is by no means uniform. Figure 3 provides a visual representation of the breakdown of networks under strain which are linked together via CG chains with other CG or WPI biopolymers. These networks are elastic under low-strain amplitudes (Figure 3A) but undergo stress overshoot behavior at higher strains (Figure 3B), which eventually leads to their breakdown (Figure 3C).

**Interfacial Properties of WPI−CG Complexes at the Water-and-Oil Interface.** Due to the amphiphilicity of WPI, the surface activity of WPI−CG mixtures during acidification was measured at the canola oil−water interface. In the absence of biopolymers, the interfacial tension between canola oil and water was found to be ∼28 mN/m, where the addition of WPI alone lowered the interfacial tension to ∼12 mN/m, where interfacial tension remains relatively constant between ∼10 and ∼12 mN/m for the duration for GDL acidification. Interfacial tension and interfacial rheology for WPI−CG mixtures as a function of mixing ratio during a slow acidification with GDL are given in Figures 4 and 5, respectively. Interfacial tension for all systems was found to decrease until reaching a pH where WPI and CG formed electrostatic complexes (Figures 4 and 5). This decline in tension is presumed to be caused by a highly surface active WPI molecule, which is presumed to be integrating alone into the interface rather than the CG molecule over this pH range (from 7.00 to 5.46 and 5.36 for WPI−*κ*-CG and WPI−*ι*-CG mixtures, respectively). At ∼20 min (pH 5.46 and 5.36 for WPI−*κ*-CG and WPI−*ι*-CG mixtures, respectively), a dramatic increase in tension was seen believed to be associated with the electrostatic interactions between WPI and CG. The rise in tension suggests that, possibly, WPI adhering to the interface is being pulled away by electrostatic attractive forces with CG molecules in solution, reducing its ability to lower the interfacial tension. Upon electrostatically interacting with CG molecules, WPI−CG complexes can readhere to the interface to form a stable film, to lower the interfacial tension once again. The decrease in interfacial tension can only be measured until ∼45 min/pH ∼5.00, after which the Du Nüoy ring punctures through the interface due to the formation of an electrostatic coupled gel network within the continuous phase, which would restrict the mobility of the interfacial film (Figure 4). However, it is presumed that free WPI and WPI−CG complexes not involved

dx.doi.org/10.1021/jf5023669 | J. Agric. Food Chem. 2014, 62, 8730−8739

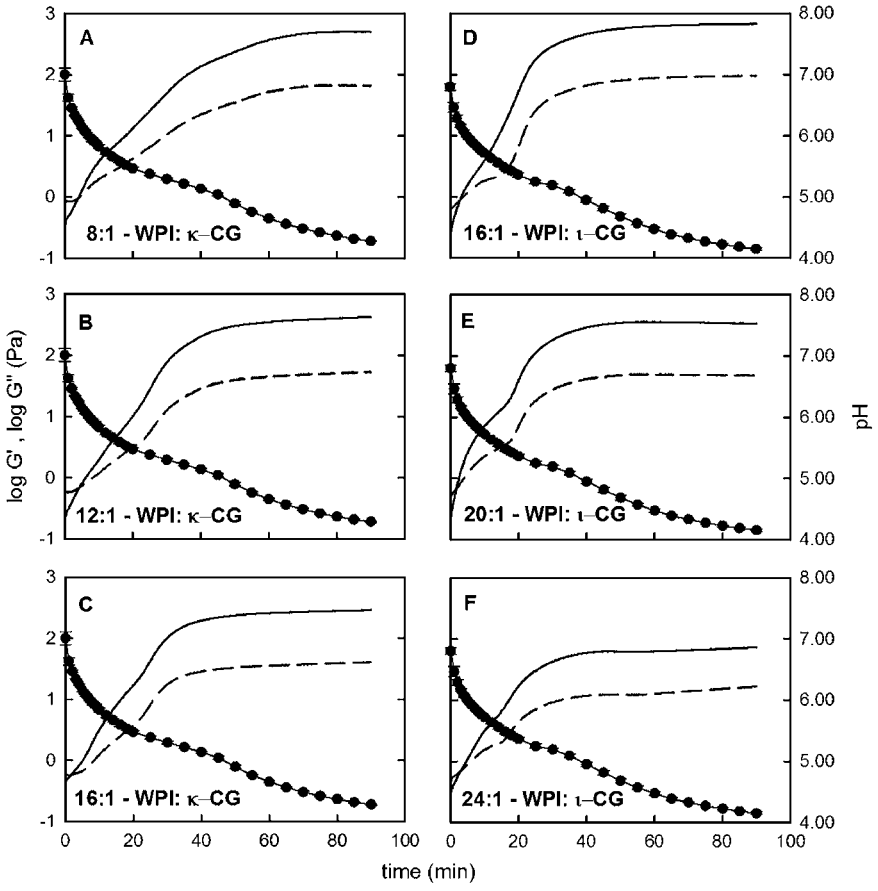

**Figure 6.** Dynamic viscoelastic storage ($G'$, solid line) and loss ($G''$, dashed line) moduli for 1:1 water/canola oil emulsions stabilized with WPI–$\kappa$-CG (A–C) and WPI–$\iota$-CG (D–F) at various mixing ratios measured at 1 Hz with 1.0% constant strain as a function of pH (solid circles) and time (min). Each curve is representative of three separate time sweep runs on separate samples. All solutions had a total biopolymer concentration of 1.0% (w/w) and were acidified using 0.5% (w/w) GDL.

within the network may still adhere to the interface to form a viscoelastic interfacial film.

The interfacial $G_i'$ and $G_i''$ values (Figure 5) within the pH range (7.00–5.41) where the two biopolymers were non-interacting (electrostatically) remained relatively constant. Because the interfacial tension decreased during this interval (Figure 4), it is possible that only WPI molecules were adhering to the oil–water interface. Near the time/pH corresponding to the rise in interfacial tension, small fluctuations or peaks in the $G_i'$ and $G_i''$ data were evident for all materials (Figure 5). These small peaks were found to be dependent upon the mixing ratio, suggesting they might be related to biopolymer interactions and complex formation. In the case of WPI–$\kappa$-CG mixtures, a small peak was observed in both $G_i'$ and $G_i''$ near pH ~5.22, ~5.33, and ~5.42 for the mixing ratios of 8:1, 12:1, and 16:1, respectively (Figure 5A–C). Similarly, for WPI–$\iota$-CG mixtures, a small peak was observed in both $G_i'$ and $G_i''$ within the pH range of ~5.37, ~5.33, and ~5.27 for the mixing ratios of 16:1, 20:1, and 24:1, respectively (Figure 5D,E). As the pH is reduced further, a rise in $G_i'$ values (i.e., so that they become greater than $G_i''$) occurs, until a plateau is reached corresponding to the formation of a viscoelastic interfacial film (Figure 3). For the WPI–$\kappa$-CG mixtures at pH ~4.2, the magnitude of $G_i'$ values was found to be 366.5, 729.6, and 424.2 mPa for the mixing ratios of 16:1, 12:1, and 8:1, respectively (Figure 5A–C), whereas for the WPI–$\iota$-CG mixtures at pH ~4.2, the magnitude of $G_i'$ values was found to be 173.6, 1358, and 2149 mPa for the mixing ratios of 24:1, 20:1, and 16:1, respectively (Figure 5D,E). Differences in the interfacial rheological properties of these two WPI–CG mixtures are attributed to the nature of their coacervation and their sensitivity toward changes in mixing ratio. Whereas WPI–$\kappa$-CG mixtures were reported by Stone and Nickerson to be sensitive toward changes in mixing ratio such that a peak optical density was reached when a 12:1 ratio was used, in contrast, WPI–$\iota$-CG mixtures were not found to be as sensitive to changes in mixing ratio, whereas at the ratio of 20:1 the optical density approached its plateau region.[15] This would account for the viscoelastic maxima at the interface observed for 12:1 WPI–$\kappa$-CG mixtures and the increasing moduli values observed as a function of CG content in WPI–$\iota$-CG mixtures.

**Formation of Electrostatically Coupled Biopolymer Emulsion Gels.** The rheological properties of WPI–CG mixtures as a function of CG type and mixing ratio during a slow acidification from pH 7.00 to ~4.20 using GDL, after being homogenized with canola oil to make an O/W emulsion, are given in Figure 6. For all materials, electrostatically coupled networks were formed as evident by a constant plateau region where $G'$ was greater than $G''$ (Figure 6). For both biopolymer mixtures, the magnitude of $G'$ at pH ~4.2 was found to increase as the mixing ratio decreased, corresponding to an increasing CG content indicating an increase in network strength (Figure 6). For instance, $G'$ was found to be 257.3, 435.3, and 522.9 Pa for the 16:1, 12:1, and 8:1 mixing ratios,

dx.doi.org/10.1021/jf5023669 | J. Agric. Food Chem. 2014, 62, 8730–8739

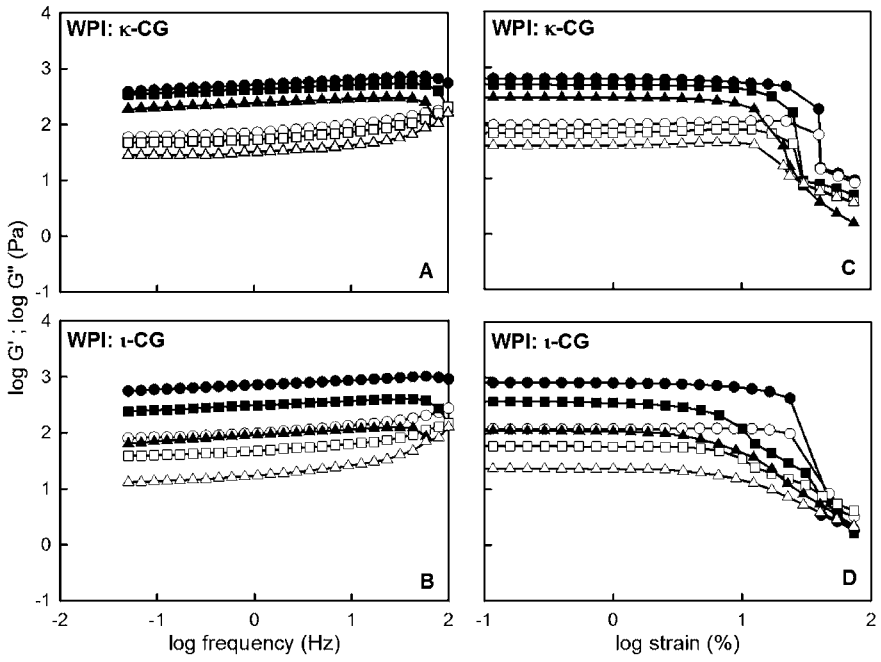

**Figure 7.** Dynamic viscoelastic storage ($G'$, solid symbols) and loss ($G''$, open symbols) moduli for 1:1 water/canola oil emulsions stabilized with WPI−κ-CG (A, C) and WPI−ι-CG (B, D) at various mixing ratios as a function of frequency (A, B) and strain (C, D). WPI−κ-CG (A, C) mixtures were mixed at ratios of 8:1 (circles), 12:1 (squares), and 16:1 (triangles), whereas WPI−ι-CG (B, D) were mixed at 16:1 (circles), 20:1 (squares), and 24:1 (triangles). Each curve is representative of three separate sweep runs on separate samples. All solutions had a total biopolymer concentration of 1.0% (w/w) and were measured at a pH of 4.28 or 4.15 for WPI−κ-CG and WPI−ι-CG mixtures, respectively.

respectively, for the WPI−κ-CG mixture (Table 1). Similarly, $G'$ was found to be 70.8, 320.4, and 658.5 Pa for the 24:1, 20:1, and 16:1 mixing ratios, respectively for the WPI−ι-CG mixture (Table 1). Similar to their biopolymer counterparts, CGs are known for their gelling ability and capacity to form coacervates with WPI. CGs are speculated to form bonds among themselves and with WPI. The conformational entropy associated with CGs allow for a greater number of bonds. It is presumed that three intermolecular interactions are present in this system: CG−CG, WPI−CG coacervate, and CG−CG. Therefore, an increase in CG content leads to better coverage of CG polymers throughout the solvent, leading to a greater number of junction zones and a stronger network. Therefore, the primary difference between mixtures containing κ-CG and ι-CG is that the latter contains a greater number of sulfated groups allowing for a greater number of bonds, leading to its comparatively stronger networks.

After the 90 min time sweep, the frequency and strain dependence of the viscoelastic moduli were measured to characterize these networks (Figure 7). For both the WPI−κ-CG and WPI−ι-CG mixtures, moduli were relatively frequency independent with $G' > G''$ (Figure 7A,B). The slight frequency dependence seen suggests that these networks may be considered as weak gels (Figure 7A,B). In the absence of acidification by GDL, these emulsions were found to be largely frequency dependent (data not shown). This suggests that the coacervation of WPI with CG led to the formation of a continuous gel-like network. Therefore, the strain response of these networks was captured to understand the nature of these networks to propose how these emulsion networks are structured.

Critical strain at the break was found to be ∼26.22, ∼17.77, and ∼8.83% for WPI−κ-CG with mixing ratios of 8:1, 12:1, and 16:1, respectively, and ∼27.35, ∼9.33, and ∼2.41% for WPI−ι-CG with mixing ratios of 16:1, 20:1, and 24:1, respectively (Figure 7C,D). Findings from this study indicate that as the CG content is higher (i.e., lower mixing ratios) within the sample, a more brittle network is formed. Compared to their biopolymer counterparts, these emulsion networks are much more brittle in nature. These emulsion networks were found to be elastic under low strain stresses and broke down when exposed to higher strains. These networks exhibited strain thinning behavior,[40] where structures within the network reorient in the direction of the applied strain. At higher strains, these networks begin to break in the direction of the applied strain and the viscous drag of the system decreases.[40] Beyond this point, increasing strains further break down the network.

Emulsion-based gels also were found to have higher network strength than the corresponding material in the biopolymer-only gels (Figures 1 and 6; Table 1). It is presumed that the greater stiffness of the network is attributed to the incompressibility of droplets and interdroplet interactions occurring within the continuous phase. The critical strains were found to increase with increasing CG content similar to the biopolymer-only networks; however, the strain needed for the emulsion-based gels to induce breakage was much less than the biopolymer gel counterparts, suggesting that they were more brittle in nature. These networks are more brittle in nature in part due to the presence of WPI−CG coacervates at the water−oil interface. Interfacial properties for WPI-CG coacervates reveal their ability to form a viscoelastic film at the water−oil interface. This does not fully explain why increasing CG content leads to stronger networks and does not explain why a similar trend was not observed in interfacial viscoelasticity. At interface, the rheological properties are sensitive to mixing ratio due to the limited space at the surface for bond formation, whereas in a continuous network, network strength is enhanced depending on the availability and

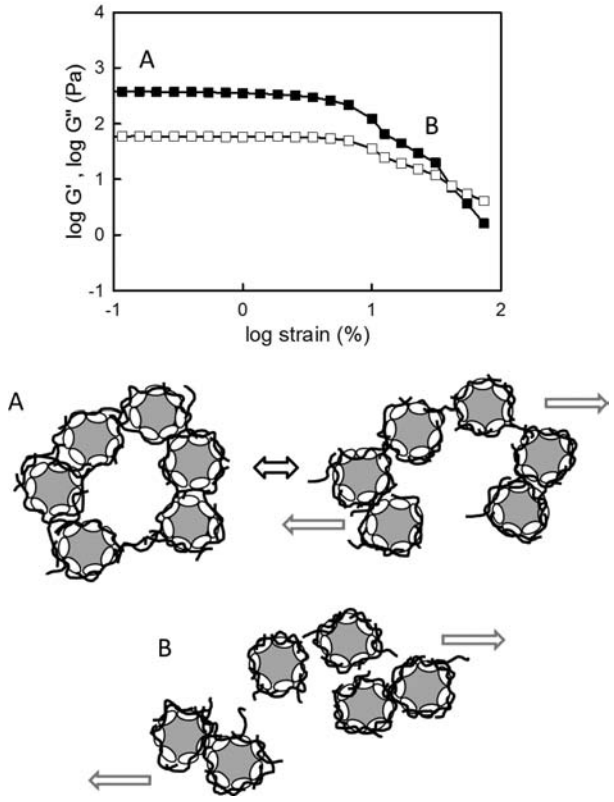

**Figure 8.** Schematic of a sample WPI–*ι*-CG emulsion gel at the biopolymer ratio of 20:1 and an aqueous/oil ratio of 1:1 in response to strain ($G'$, solid symbols; $G''$, open symbols) where the gelled network composed of WPI (open ovals) coupled with CG (lines) stabilizing oil droplets (gray circles) is elastic at low strains (A) and its breakdown at higher strains (B). The gray arrows indicate the direction of the applied shear.

opportunity to form bonds, which create junction zones that give the network strength.

In a study by Santipanichwong and Suphantharika, *β*-glucans were found to enhance the stability of egg yolk emulsions.[37] They were speculated to enhance emulsion stability by either increasing the viscosity of the continuous phase or creation of a three-dimensional network of flocculated droplets.[37] Similar to results reported here, frequency sweeps revealed that Santipanichwong and Suphantharika formed weak gels as well and that the addition of *β*-glucans to egg yolk emulsions had improved their creaming stability.[37] Furthermore, an addition of the polysaccharides to the emulsions had increased the storage modulus (i.e., stiffness) of the networks formed.[37] Kontogiorgos and co-workers, who also studied the influence of *β*-glucans on egg yolk stabilized emulsions, reported that the mechanism for stability depended on the molecular weight of the polysaccharide.[44] Polysaccharides containing lower molecular weights tended to form a network in the continuous phase, whereas higher molecular weight polysaccharides increased the viscosity of the continuous phase.[44] Therefore, enhanced emulsion stability in systems containing multiple biopolymers is reliant on the interactions between the biopolymers involved.

It is speculated that as WPI adheres to the water–oil interface, GDL acidification leads to a coacervate formed at the interface whereby the CG on the outside could bind and cause flocculation with other WPI or CG molecules bound to other droplets. This allows for a continuous network of droplets to form, which becomes the primary means for structuring these emulsion networks. Their brittleness may be attributed to the limited surface interactions between flocculated droplets. This reduces the number of available bonds between the biopolymers, which are needed to stabilize the network. A schematic of these emulsion systems is presented in Figure 8, which represents the breakdown of these emulsion networks under strain. It is speculated that any biopolymers not bound to the water–oil interface becomes available for interacting in the continuous phase, which provides additional strength to the network.

In conclusion, WPI–CG mixtures were found to form an electrostatically coupled continuous network during a slow acidification process using GDL. Networks formed with WPI–*ι*-CG complexes were found to be stronger than those with WPI–*κ*-CG. Although a similar mechanism is proposed for network formation, the difference is attributed to the number of sulfated bonds whereby *ι*-CG may form a greater number of bonds compared to *κ*-CG. Frequency sweeps determined that the networks formed were relatively frequency independent and gel-like. An increase in the CG content led to increased stiffness of these gels. Strain sweeps revealed that gels became increasingly elastic with rising CG levels within the mixing ratio. WPI–CG complexes were found to be surface active and capable of forming viscoelastic films at the water–oil interface. Furthermore, as WPI–CG formed electrostatic complexes, they had a profound impact on the interface, which was observed both by interfacial tension and by interfacial rheology. Due to the surface active properties of the WPI–CG complexes, they were used to stabilize the formed emulsions during gelation. Emulsion gels made with WPI–CG complexes were stiffer compared to their biopolymer counterparts but were comparatively much more brittle. The comparative difference in brittleness is attributed to the differences in the structure of these two networks. It is speculated that the large conformational entropy associated with CGs enabled their capacity to form a three-dimensionsal network as a biopolymer solution. Overall, the surface activity of WPI and their coacervation with CGs enabled a WPI-stabilized, flocculated emulsion interlinked by CGs.

# High Concentrations of Furan Fatty Acids in Organic Butter Samples from the German Market

Christine Wendlinger and Walter Vetter*

Institute of Food Chemistry (170b), University of Hohenheim, Garbenstraße 28, D-70599 Stuttgart, Germany

Supporting Information

**ABSTRACT:** Furan fatty acids (F-acids) are valuable antioxidants containing a furan moiety in the central part of the molecule. They occur in the lipids of different foodstuffs and plants, with grass being the main source for their presence in milk fat and butter. Because cows from organic farming receive higher portions of grass-based feed, it was tested whether organic butter samples ($n$ = 26) contain more F-acids than conventional ones ($n$ = 25) in Germany. For this purpose, samples were melted, and the lipid phase was separated and transesterified into methyl esters, which were enriched using silver ion chromatography and analyzed by GC-EI/MS in the selected ion monitoring (SIM) mode. Levels of F-acids in butter were higher in summer than in winter, and in both seasons, organic samples contained significantly higher levels of F-acids than conventional ones (one-way ANOVA: $p < 0.001$). Furthermore, the daily intake of F-acids via milk fat and other foodstuffs was calculated.

## INTRODUCTION

Recent lipid research has shown that not only major fatty acids but also different classes of bioactive minor fatty acids, such as furan fatty acids (F-acids), contribute to the nutritional benefits of fats or oils.[1−3] F-acids are fatty acids containing a furan moiety in the central part of the acyl chain. The $\alpha$-position of the furan ring carries a carboxyalkyl chain typically with 7, 9, 11, or 13 carbons, and the $\alpha'$-position is substituted with a propyl or pentyl chain.[1] In addition, the $\beta$- and $\beta'$-positions may be substituted with one (methyl-substituted F-acids) or two methyl groups (dimethyl-substituted F-acids). F-acids are known to serve as hydroxyl and peroxyl radical scavengers and thus are able to protect polyunsaturated fatty acids from lipid peroxidation.[4,5] Furthermore, the anti-inflammatory activity of F-acids had been confirmed in vivo.[6] These natural antioxidants occur widely in foods including fish,[7−10] olive oil,[11] soybean oil,[12−14] rapeseed oil,[12] and butter.[15] Plants are able to synthesize F-acids from acetate, methionine, and oxygen from air, whereas F-acids in fish originate from the intake of algae and those in milk fat from the intake of grass and other plants by cows.[1] Concentrations of F-acids in butter ranged from 4.5 to 47.6 mg/100 g.[15,16] High amounts of F-acids also occurred in grass,[17] and because F-acids in milk fat originate from the cow's feed, we aimed to investigate whether there is a difference in the concentrations of F-acids in butter samples from organic and conventional farming due to higher proportions of pasture and hay fed in organic farming. For this purpose, F-acid methyl esters of 51 butter samples were enriched using silver ion microcolumn chromatography and analyzed by gas chromatography with mass spectrometry (GC-MS) operated in the selected ion monitoring (SIM) mode according to the method of Vetter et al.[16] On the basis of our results for butter and published concentrations of F-acids in other foodstuffs, we estimated the dietary daily intake of F-acids, as well as the corresponding share of milk fat in Germany.

## MATERIALS AND METHODS

**Samples.** Butter samples (26 organic and 25 conventional ones) were purchased from different supermarkets located in Stuttgart, Germany, between January 2012 and January 2014. Most of the samples originated from southwestern, southeastern, and northeastern Germany. Samples from summer and winter were included in the study. Information about the type of butter (sweet or sour cream), the farming system (organic or conventional), and the minimum durability dates (MDD) were provided on the packaging. Samples were assigned to winter/summer season by backdating MDD for 2 months to take into account the period from milking to the date printed as MDD on the label. The "summer" period was set from May to October and "winter" from November to April. This division resulted in four groups: winter conventional ($n$ = 14), winter organic ($n$ = 13), summer conventional ($n$ = 11), and summer organic ($n$ = 13).

**Chemicals and Standards.** Methanol and $n$-hexane (both of HPLC grade, ≥95% purity) were from Th. Geyer (Renningen, Germany). Sulfuric acid was from BASF (Ludwigshafen, Germany). Diethyl ether (for synthesis, ≥99%) and NaCl (≥99.5%) were from Carl Roth (Karlsruhe, Germany). Silica gel 60, $AgNO_3$, and myristic acid were from Sigma-Aldrich (Steinheim, Germany). The abbreviated nomenclature and preparation of the internal standard (IS) 10,13-epoxy-11-methyloctadeca-10,12-dienoic acid ethyl ester (9M5-EE) were according to Vetter et al.[16] Myristic acid ethyl ester (14:0-EE) was prepared by heating myristic acid with 1% sulfuric acid in ethanol.

**Sample Preparation and Transesterification.** Butter samples (~4 g) were melted at ~70 °C, and the supernatant clear lipid phase was separated (~2 g). For the formation of fatty acid methyl esters (FAME) about ~20 mg per sample was treated with 1.5 mL of 1% sulfuric acid in methanol in a small sealed tube at 80 °C for 1 h, which was shaken from time to time. Then, 1 mL of saturated aqueous NaCl solution and 1 mL of demineralized water were added, and FAME were extracted once using 2 mL of $n$-hexane.

**Enrichment of F-Acids by Silver Ion Micro Column Chromatography.** Silver ion microcolumn chromatography was performed according to the method of Vetter et al. with slight amendments.[16] In brief, an aliquot of the organic layer (~180−250 μL) was supplemented with 0.87 μg of the internal standard 9M5-EE, and the solution was placed on a Pasteur pipet (the tip was plugged with glass wool) containing ~0.6 g of 1% deactivated silica gel with 20% $AgNO_3$. Fraction 1 containing saturated and the majority of the monounsaturated fatty acids was eluted with 15 mL of *n*-hexane/diethyl ether (99.5:0.5, v/v). Fraction 2 containing F-acids was eluted with 15 mL of *n*-hexane/diethyl ether (97:3, v/v). Both fractions were individually evaporated at 38 °C by means of a gentle stream of nitrogen, the residue was transferred with *n*-hexane into a GC vial, and the volume of the solution was adjusted to 1 mL. Afterward, the second internal standard, 14:0-EE, was added, and the solution was analyzed by GC-MS. During the sample preparation, oxidation of F-acids was minimized by using amber glass and performing each step under the lowest possible lighting level.

**Gas Chromatography Coupled to Electron Ionization Mass Spectrometry (GC-EI/MS).** All analyses were carried out with a 5890 series II/5971A GC/MS system in combination with a 7673A autosampler (Hewlett-Packard/Agilent, Waldbronn, Germany). The carrier gas, helium (purity 5.0), was transported at a flow rate of 1 mL/min through two serially coupled 30 m columns (Rtx-2330, internal diameter = 0.25 mm, coated with 0.1 μm of 10% cyanopropylphenyl, 90% biscyanopropyl polysiloxane, Restek, Bellefonte, PA, USA). The GC oven program started at 60 °C for 1 min. It followed ramps of (i) 13 °C/min to 180 °C, (ii) 3 °C/min to 225 °C, and (iii) 20 °C/min to 250 °C. The final temperature was held for 5 min, and the solvent delay was set to 8 min. GC-MS measurements in the full scan mode covered *m/z* 50−500. In the SIM mode four ions (*m/z* 137, 151, 165, and 179) were measured throughout the run. Additionally, three further ions, divided into four time windows, were recorded: (I) 8−13 min, *m/z* 74, 88, 101; (II) 13−19.5 min, *m/z* 74, 294, 308; (III) 19.5−23 min, *m/z* 322, 336, 350; (IV) 23−31 min, *m/z* 364, 378, 392. Peak identification was carried out in the full scan mode, whereas quantification was performed in the SIM mode using 14:0-EE and 9M5-EE as internal standards.[16]

**Quantification Mode, Data Reporting, and Statistical Analysis.** The IS 9M5-EE was calibrated against 12,15-epoxy-13-methyleicosa-12,14-dienoic acid ethyl ester (11M5-EE) and 12,15-epoxy-13,14-dimethyleicosa-10,12-dienoic acid ethyl ester (11D5-EE). Because the peak areas at the same concentration did not deviate by more than 5%, 9M5-EE was used for the quantification of all F-acids as methyl esters. The quantitative results were further verified by standard addition experiments using 11D5-ME. All preparation steps were performed in duplicate, and for each sample mean values were calculated (individual values of replicates did not vary by more than 10%); the results were expressed as milligrams per 100 g of fat. The limit of quantification (LOQ) and the limit of detection (LOD) were 0.4 and 0.12 mg/100 g fat, respectively. For the calculation of total concentrations of F-acids in the samples, individual values below LOD were taken into account by using half the LOD (i.e., 0.06 mg/100 g fat). The F-acid concentrations were evaluated by one-way ANOVA as integrated in EXCEL. Significance was based on a probability of 0.05.

## RESULTS AND DISCUSSION

**F-Acid Variety and Pattern in Butter Samples.** Between two and six F-acids were detected by GC-MS in the 51 butter samples (Figure 1; Supporting Information Table S1). Highest concentrations were generally determined for 10,13-epoxy-11,12-dimethyloctadeca-10,12-dienoic acid (9D5) and 11D5, which represented 60−100% of the total amount of F-acids in the samples. A clear dominance of dimethyl-substituted F-acids (11D5 and 9D5) over methyl-substituted F-acids was also reported in previous studies.[15,16] These two major F-acids were partly accompanied by 11M5, 8,11-epoxy-9,10-dimethylhexadeca-8,10-dienoic acid (7D5), 9M5, and 14,17-epoxy-15,16-dimethyleicosa-14,16-dienoic acid (13D3). Depending on the abundance of the individual F-acids, most commonly four (7D5, 9M5, 9D5, and 11D5; 18 samples) or five (additionally 11M5; 17 samples) F-acids were present in the samples (Figure 1; Table S1). In five butter samples only two F-acids and in nine samples only three F-acids were detectable, whereas six F-acids were present in two cases (Figure 1; Table S1). A similar F-acid pattern was also reported in grass (blade).[16,17] Thus, it seems obvious that the occurrence of (especially dimethyl-substituted) F-acids in grass lipids and pasture was linked with the presence of F-acids in milk and butter fat.

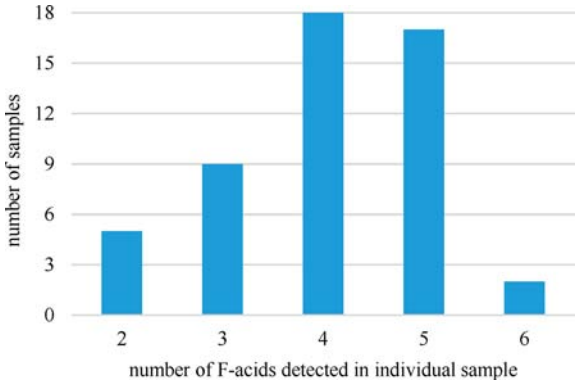

**Figure 1.** Frequency of the number of F-acids in butter samples from the German market.

**Concentrations of F-Acids in Organically or Conventionally Produced Butter Samples.** The total F-acid content in the samples ranged from 1.6 to 16.5 mg/100 g fat. Sweet cream and sour cream butter samples showed no difference in the F-acid pattern, yet the concentrations of F-acids were 3-fold lower than those reported by Guth and Grosch.[15] Concentrations of F-acids in organic butter samples (5.4−16.5 mg/100 g fat, $n = 26$) were significantly higher than in conventional samples (1.6−7.1 mg/100 g fat, $n = 25$) (one-way ANOVA: $p < 0.001$). The same result could be obtained by the sole evaluation of the summed concentration of 9D5 and 11D5 (one-way ANOVA: $p < 0.001$). However, 13 organic samples (all winter samples) with the lowest content of F-acids showed lower concentrations than the conventional sample with the highest F-acid content. This overlap did not allow unequivocally distinguishing organic from conventional butter samples.

Subsequently, the samples were further divided depending on the season into four groups (see Materials and Methods), that is, winter conventional ($n = 14$), winter organic ($n = 13$), summer conventional ($n = 11$), and summer organic ($n = 13$) (Table 1). Organic samples collected in summer (May−October) generally contained higher amounts of F-acids than samples from the winter months (November−April) (Table 1; one-way ANOVA: $p < 0.001$). Also, no overlap of the F-acid concentration range was observed for conventional samples collected in summer versus winter (Table 1; one-way ANOVA: $p < 0.001$). The widest ranges for F-acid concentrations were observed for conventional samples in winter and organic samples in summer, whereas ranges in organic butter samples collected in winter and conventional ones of the summer season were surprisingly small (Table 1). These wider ranges in the F-acid content could be due to a higher flexibility in the composition of the feed. Analysis of samples from the same producer in summer and winter showed the typical seasonal dependency of the F-acid concentrations. Accordingly, the

| mean (Σ) | 3.4 | 5.9 | 6.0 | 10.6 |
| median (Σ) | 3.4 | 6.0 | 6.0 | 9.5 |

[a]Values below LOQ were included to sum with 1/2 LOD (i.e., 0.06 mg/100 g fat).

processing technology of butter did not have a primary effect on the F-acid concentrations in butter. Moreover, the potential impact of the geographical origin of the milk samples was evaluated as follows. The four previously mentioned groups were further divided according to their geographical origins in southeastern, southwestern, and northeastern Germany. Irrespective of the sample group, the F-acid concentration ranges of the geographical groups were overlapping, and data analysis by one-way ANOVA did not show significant deviations ($p > 0.2$). Accordingly, organic or conventional farming systems could not be differentiated by their geographical position in Germany. However, by taking the season into account, it was possible to distinguish organic from conventional samples without exception (Figure 2).

Thus, the concentrations of F-acids may serve as a useful marker for the authentication of organic butter, especially in combination with other analytical markers such as the concentration of n-3 fatty acids,[18−21] the concentration and diastereomer ratio of phytanic acid,[22−25] the $\delta^{13}C$ values of milk fat,[26,27] or the fatty acid and triacylglycerol profiles.[28,29]

**Nutritional Intake of F-Acids in Germany.** Our data suggested that the intake of F-acids through milk and dairy products may vary up to the factor of 3, depending on the season and farming system (Table 1). From these findings we estimated the daily intake of F-acids by the consumption of milk and butter, as well as their percentage contribution of the nutritional intake.

The average daily milk fat intake in Germany was reported to be about 20−45 g per day.[30] On the basis of the mean values (Table 1), the daily intake of F-acids via milk fat amounted to 0.7−1.5 mg (full range, 0.3−2.3 mg; 1.1 mg mean of mean, which corresponds to 32.5 g milk fat) for conventional samples in winter, 1.2−2.7 mg (full range, 1.1−3.0 mg, mean of mean 1.9 mg) for organic samples in winter, 1.2−2.7 mg (full range, 1.0−3.2 mg, mean of mean 2.0 mg) for conventional samples in summer, and up to 2.1−4.8 mg (full range, 1.5−7.4 mg, mean of mean 3.4 mg) for organic ones in summer (Figure 3). Thus, the daily intake of F-acids via milk fat was highest for organic samples in summer.

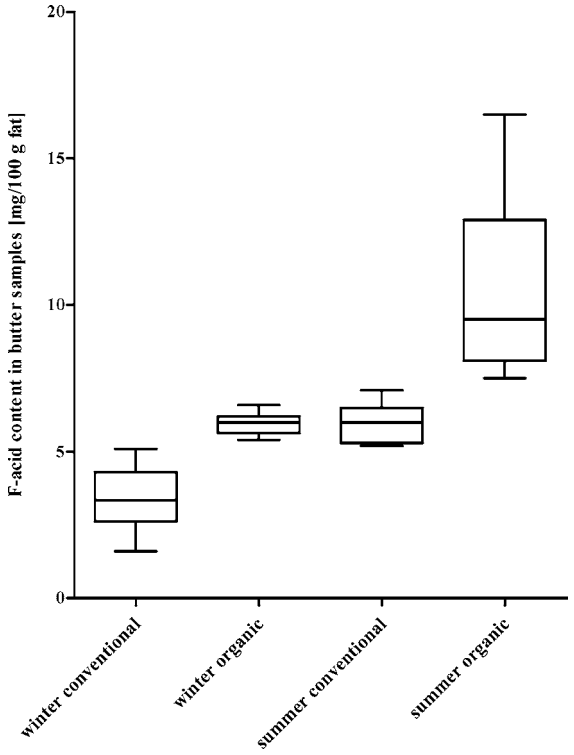

**Figure 2.** Concentration ranges of F-acids (mg/100 g fat) in organic and conventional butter samples collected in summer and winter in Germany.

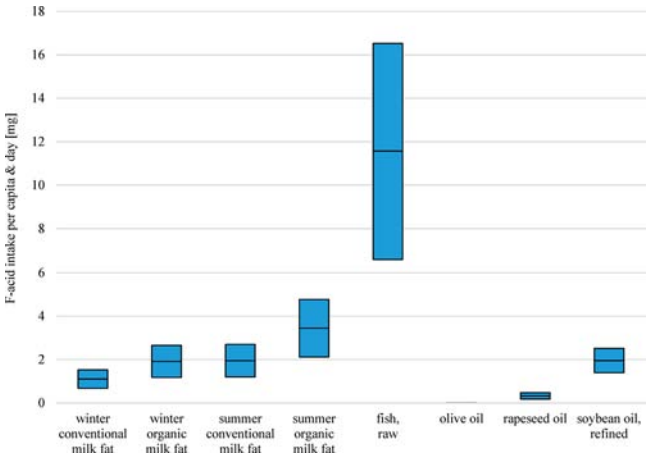

**Figure 3.** F-acid intake per capita and day (mg) from different food items in Germany with mean value (line in the middle) and minimum to maximum ranges.

According to national consumption data in Germany, the average per capita consumption of fish was about 40 g/day in 2012.[31] The intake of F-acids via fish was calculated on the basis of the six most popular fish species consumed in Germany: *Theragra chalcogramma*, Alaska pollock; *Clupea harengus*, herring; *Salmo salar*, salmon; *Thunnus*, tuna; *Pangasius hypophthalmus*, iridescent shark; and *Salmo trutta*, trout.[31] These six species contributed ∼80% to total fish consumption in Germany.[31] On the basis of these species, fish consumed in Germany contained an average of ∼8% lipids (weighted average). With an average F-acid content of 200 mg/100 g lipids (own determinations, data not shown) or 500 mg/100 g lipids (according to Pacetti et al.[10]), the daily intake of F-acids

by the consumption of fish accounted for ~6.6−16.5 mg (Figure 3). However, it should be noted that these values are calculated for raw fish and that cooking may result in lower F-acid contents due to their partial decomposition.

About 1.7 g of olive oil was consumed per capita and day in Germany in 2009.[32] According to Boselli et al. the average F-acid content in olive oil was about 2 mg/kg.[11] On the basis of these data, the daily F-acid intake through olive oil amounted to 0.003 mg. In Germany, the daily intake for rapeseed oil was 14 g and for soybean oil, 15 g, in 2009.[32] The average F-acid content was determined to be 1.3−3.4 mg/100 g in rapeseed oil, 26.3−42.4 mg/100 g in crude soybean oil, and 9.3−16.8 mg/100 g in refined soybean oil.[12] Thus, the F-acid intake via refined soybean oil, which is the primary source for human consumption, is much lower than the calculated values for crude soybean oil (Figure 3). Accordingly, the F-acid intake per capita and day would be 0.2−0.5 mg via rapeseed oil and 1.4−2.5 mg via refined soybean oil (Figure 3). Accordingly, the intake of F-acids by the consumption of vegetables and fruits is rather low.[1] However, plants are the origin of F-acids in both milk and fish.[1]

On the basis of these individual contributions of different foodstuffs to the overall nutritional daily intake of F-acids, it was apparent that intake based on raw fish represented the highest single source (Figure 3). Compared to fish, the F-acid intake via milk fat was relatively small for winter conventional samples (8 vs 77% from fish to the total F-acid intake), whereas organic samples milked during the summer had a larger share (20 vs 67% from fish to the total F-acid intake). By contrast, olive oil did not play any noticeable role in the dietary intake of F-acids in Germany. Even for Mediterranean diets with a per capita consumption for olive oil of about 38 g/day,[32] the F-acid intake would be only 0.08 mg/day, that is, <10% of the share of milk fat. The contribution of refined soybean oil to the daily intake of F-acids was between the intake via the consumption of conventionally produced milk fat in winter and organic milk fat in summer (Figure 3). Especially for persons who do not consume fish, milk fat represents a valuable source for the nutritional intake of F-acids.

Supporting Information

**ABSTRACT:** The detection of adulteration of high priced oils is a particular concern in food quality and safety. Therefore, it is necessary to develop authenticity detection method for protecting the health of customers. In this study, fatty acid profiles of five edible oils were established by gas chromatography coupled with mass spectrometry (GC/MS) in selected ion monitoring mode. Using mass spectral characteristics of selected ions and equivalent chain length (ECL), 28 fatty acids were identified and employed to classify five kinds of edible oils by using unsupervised (principal component analysis and hierarchical clustering analysis), supervised (random forests) multivariate statistical methods. The results indicated that fatty acid profiles of these edible oils could classify five kinds of edible vegetable oils into five groups and are therefore employed to authenticity assessment. Moreover, adulterated oils were simulated by Monte Carlo method to establish simultaneous adulteration detection model for five kinds of edible oils by random forests. As a result, this model could identify five kinds of edible oils and sensitively detect adulteration of edible oil with other vegetable oils about the level of 10%.

**KEYWORDS:** *fatty acid profiles, adulteration identification, edible oil, GC/MS, chemometrics*

## INTRODUCTION

Edible vegetable oils are a kind of important food in our daily life, which provide human being with energy and nutritional components including but not limited to essential fatty acids, phytosterols, tocopherols, phenolic compounds, vitamins, and volatile organic compounds (VOC).[1,2] All over the world, palm, soybean, rapeseed, sunflower, and peanut oils are major cooking oil. Among them, palm and soybean oils possess the largest market share in vegetable oil consumption.[3] However, owing to pleasant flavor and nontransgenic merit, the proportion of peanut, rapeseed and sunflower oils gradually increase though their prices are higher than soybean and palm oils. Moreover, sesame oil is a high price edible vegetable oil, which is often used as a flavor enhancer in Asian countries. Ensuring the authenticity of food has been a problem for millennia.[4] Edible vegetable oil is also not an exception. As the same as adulteration of olive oil in western countries, adulteration in other high-price oils is still the biggest source of agricultural fraud problems. Therefore, it is a great demand for a reliable method to detect such adulterations.

The main compound in vegetable oil is triglyceride (~95%), which is composed of fatty acids.[5,6] Fatty acid profiles can serve as a characteristic of edible vegetable oil. Traditionally, only high-abundance fatty acids were analyzed and employed to classify edible vegetable oils. Recently, however, some common fatty acids (especially oleic acid) become a target of oilseed breeding, and the distribution of common fatty acids in different vegetable oils become increasingly overlapped. On the contrary, the low-abundance fatty acids are more specific to edible vegetable oils, such as erucic acid in rapeseed oil. Though these low-abundance fatty acids were not so attractive to nutritionist, they possess high sensitivity to adulteration identification of edible oils. The entire family of fatty acids, which is referred to as "fatty acidomics",[7] was therefore taken as a key marker and quality parameter of different oilseeds and their products.[8]

Fatty acids are usually analyzed by gas chromatography mass spectrometry (GC-MS) with derivatization[9] and routinely identified by comparing retention index (equivalent chain length, ECL[10]) with those of the authentic FAME standards and/or doing similarity search in reference mass spectra library.[11−13]

As the same as metabolomics, the multivariate chemometric methods are important to the application of fatty acid profiles. One often resorts to multivariate chemometric methods for fatty acids in edible oils, mainly including principal component analysis (PCA), hierarchical clustering analysis (HCA), soft independent modeling of class analogy (SIMCA), partial least-squares discriminant analysis (PLS-DA) and support vector machine (SVM).[14−16] As described by Ai et al.,[5] machine learning techniques of an ensemble of classification models are of particular interest. Among them, Random Forests (RF) is powerful to deal with multivariate classification,[17,18] in which, a

visual exploration of the proximity matrix could be obtained using the multidimensional scaling (MDS) technique to intuitively measure similarity between different samples. Besides, it can also provide a measurement for variable importance.

In this study, we developed a simultaneous adulteration detection method based on fatty acid profiles for vegetable edible oils and selected soybean, rapeseed, sunflower, peanut and sesame oils as target oils to illustrate and validate this method. First, fatty acid profiles of five main edible oils were established by GC-MS in selected ion monitoring mode. Using mass spectral characteristics of selected ions and equivalent chain length (ECL), fatty acids were identified and employed to classify five kinds of edible oils by using unsupervised (principal component analysis and hierarchical clustering analysis) and supervised (random forests) multivariate statistical methods. Moreover, since triacylglycerols are relatively stable and no chemical reaction happens when physical blend of vegetable oils, adulterated oils were simulated by adulterating the one oil with at least 10% of other four oils or mixtures thereof and employed to establish simultaneous adulteration detection model for five types of edible oils by random forests.

## 2. EXPERIMENTAL SECTION

**2.1. Materials and Regents.** To ensure that the oil samples could represent the actual status of edible oils, we adhere to the following sampling rules: (a) with respect to oil seeds selected for laboratory pressing, the oilseed samples were collected from the main produce areas of China; (b) the oilseeds were collected from farmers and local markets without considering their varieties. Totally, the 17 soybean samples, 75 peanut samples, 57 sunflower seed samples, 76 rapeseed samples, and 73 sesame samples were collected from different product areas. The detailed information was shown in Supporting Information Table S1. The seed oils were prepared by oil mill machinery (TZC-0502, Brand of TEN GUARD, China). Supelco 37 component FAME mix (No. 47885-U) was purchased from Sigma (St. Louis, MO, USA). 11-Octadecenoic acid (C18:1n-7, >97.0 purity) and 7-hexadecenoic acid methyl ester were purchased from Sigma (St. Louis, MO, USA).

**2.2. Experimental Procedure of Derivatization.** As described in the previous study,[19] 0.06 g of vegetable oil sample was diluted with 2 mL of a solvent of diethyl ether and petroleum ether (v/v 1:1), and 1 mL of 0.4 M KOH−$CH_3OH$ was added. Then, it was vortex-mixed for 30 s and placed at room temperature for 2.5 h, and then, 2 mL of redistilled water was added. It was then vortex-mixed and centrifuged at 4500 rpm for 2 min. The organic phase (200 $\mu$L) was collected and diluted by 800 $\mu$L of petroleum ether, prior to analysis by GC-MS.

**2.3. GC-MS Analysis.** The analyses were performed by Agilent GC-7890 gas chromatograph interfaced to a Agilent 5973 mass spectrometer. In the gas chromatography system, a fused silica capillary column DB-23 (30 m × 0.25 mm i.d. 0.15 $\mu$m film) (Agilent Technologies) was used. Helium (99.999% purity) was used as carrier gas at a flow-rate of 1.2 mL $min^{-1}$. The column was first set at 100 °C and held for 0.2 min, temperature was subsequently increased to 215 °C at the rate of 10 °C/min and held for 0.1 min, finally to 224 °C at the rate of 2 °C/min, which was held for an additional 0.2 min (total program time, 16.5 min). This is the optimum temperature programming for the conditions of both separation effect and run time. Mass spectrometric conditions were as follows: ionization mode: EI; electron energy 70 eV; temperatures of injector, ion-source and detector at 220, 250, and 150 °C, respectively. Solvent cut time was 3 min. Splitting ratio was 20:1. Selected ion monitoring (SIM) mode: $m/z$ 55, 67, 74 and 79.

**2.4. Identification of Fatty Acid Methyl Esters (FAME).** Identification of fatty acids in SIM mode was proposed in our pervious study.[19] The procedures mainly include (1) an automatic mass spectral search was conducted to identify straight saturated FAMEs and (2) the retention times of straight saturated FAMEs were used to calculate the ECLs of unsaturated FAMEs according to eq 1. If the retention times of interest were out of straight saturated FAMEs, extrapolation will be employed using retention times of two nearest straight saturated FAMEs; and (3) ECL of FAMEs in the sample were compared with those in freely available databases to identify the unsaturated FAMEs.[12,13]

$$\mathrm{ECL}(x) = n + \frac{RT(x) - RT(n)}{RT(n+1) - RT(n)} \quad (1)$$

where $n$ and $n + 1$ represent the numbers of carbons in the straight saturated FAME eluted immediately before and after the compound of interest, respectively.

Fatty acid percentage composition (percentage of peak area) was employed as quantitative results for edible oils.

**2.5. Multivariate Analysis.** Data matrix includes the relative content of fatty acids in edible oils. Data simulation of adulterated oils was conducted in Matlab 2011a for windows (The Mathworks, Natick, MA). Since the chemical properties of fatty acids and triacylglycerols are relatively stable, the fatty acid composition of blended oil equals to the summary of fatty acid composition of individual oils. To establish more precise adulteration detection model for five kinds of edible oils, two types of spurious edible oils were simulated by Monte Carlo method, including blending and adulterated oils. In this study, we defined the blended oil to mixing oil with random proportions of vegetable oils, while the adulterated oil was termed as spurious edible oil adulterated with low proportions of one or more than one vegetable oils. At first, 300 blended oils were simulated by blending five oils with random mixing proportions. In more details, for a blended oil, (1) random mixing proportions for five types of edible oils are created and then the sum of these proportions is normalized to unity; (2) one real edible oil of each type of edible oils is picked out at random; (3) fatty acid composition of this blended oil is calculated by weighted sum of five selected real oils; (4) repeat 1−3 for 300 times. For adulterated oils, one proportion of each kind of edible is set to 0.9 and other four proportions are created and the sum of these proportions is normalized to 0.1. Other procedures are the same with blended oils. For example, we could obtain an adulterated sesame oil sample by adding 10% content of soybean, peanut, sunflower, and rapeseed with random mixing proportions to 90% of sesame oil.

The data matrix was preprocessed through generalized log transformation and Pareto scaling (mean-centered and divided by the square root of standard deviation of each variable). As exploratory data analysis, principal component analysis (PCA) and hierarchical clustering analysis were employed to screen cluster of sampling and variable distribution in five groups. Then, the classification model for five kinds of edible oils was built by Random Forests. At last, the classification model for five types of edible oils and their blended and adulterated oils was also established by Random Forests. The model validation was conducted by OOB (out-of-bag) error in 3-fold cross validation.

Programs of automatic search tool for straight saturated FAMEs, and calculation of theoretical and experimental ECL were coded in Matlab 2011a for windows (The Mathworks, Natick, MA). Data preprocessing (Pareto scaling), Clustering (PCA and hierarchical clustering analysis) and classification (RF) were conducted by metabolomic data analysis tool of MetaboAnalyst 2.0.[20,21]

## 3. RESULTS AND DISCUSSION

**3.1. Identification and Quantitation of Fatty Acids in Five Types of Edible Oils.** In this study, fatty acidomics developed by GC/MS in SIM mode for classification and adulteration identification of edible vegetable oils. To detect more fatty acids in edible oils than the existing studies, selected ion monitoring mode (SIM) was used. The identification of FAMEs in samples was conducted using selected ions and retention indices (ECL).[13,19,22] At first, saturated FAMEs were automatically identified from background subtracted GC-MS data if the base peak of mass spectrum was at $m/z$ 74. Totally,

[a]Shorthand annotation according to *A*:*B* n-*i* z, where *A* is the number of carbon atoms in the fatty acid chain, *B* is the number of double bonds, *n*-*i* is the location of the double bond on the *i*th carbon−carbon bond, counting from the terminal methyl carbon toward the carbonyl carbon and z is the geometrical configuration expressed as c for cis and t for trans.[12] [b]Normal: ECL values in database in ref 13. Bold: ECL values in Chrombox database. Possible structure is deduced by mass spectral characteristics. [c]Not detected.

11 saturated FAMEs, 12:0, 14:0, 15:0, 16:0, 17:0, 18:0, 20:0, 21:0, 22:0, 23:0, and 24:0 included, were identified. Their retention times and relative abundances (RA) at *m*/*z* 55, 67, and 79 were then employed to validate whether saturated FAMEs are straight chain. The retention times of 11 straight saturated FAMEs were used to calculate the ECL values for other FAMEs. Identification of unsaturated FAMEs in the edible oils was conducted by searching their ECL values in the customized database constructed in the previous studies[13,14] for the FAME with the nearest ECL value as the candidate.

The threshold of difference between the experimental ECL and reference ECL in the database is set to 0.1. Using this method, as shown in Table 1, 17 unsaturated FAMEs were identified. Among them, 12 unsaturated FAMEs were validated by comparing the retention time and mass spectra with the authentic standards, while 3 unsaturated FAMEs were exploratively identified by searching freely available Chrombox database.[12] The other 2 unsaturated FAMEs were inferred to the type using their mass spectral characteristics. Totally, 28 FAMEs were identified and quantified, which are significantly higher than full scan mode (23 FAMEs).[5] Fatty acid composition of vegetable oils is described by percentage content of total amount of all fatty acids and shown in Table 1.

**3.2. Exploratory Data Analysis.** After determination and quantification of fatty acids in five vegetable oils, the data matrix of relative contents was preprocessed through generalized log transformation and Pareto scaling. In exploratory data analysis, principal component analysis (PCA) and hierarchical clustering analysis (HCA) were employed to screen cluster of sampling and fatty acid distribution in five groups. From the score plot obtained from PCA in Figure 1a, five kinds of edible oils were clearly classified into five groups, among which rapeseed and peanut oils are far from sunflower, sesame and soybean oils, respectively.

To investigate variable distribution in five groups, heat map of fatty acid profiles of five vegetable oils was illustrated. In heat map, the Euclidean distance was used for measuring the similarities using Wards' linkage by clustering to minimize the sum of squares of any two clusters. As shown in Figure 1b, the similar cluster analysis results were obtained as PCA. More importantly, we can find the fatty acids distribution in five groups from this heat map as follows: (a) soybean oils, relatively high content of 16:3 n-3, 17:0, and 18:3 n-6c (γ linolenic acid); (b) peanut oils, relatively high content of 20:0, 22:0, and 24:0; (c) rapeseed oils, relatively high content of 12:0, 16:1 n-5, 16:1 n-7, 17:1 n-7, 16:2 n-5, 18:1 n-7, 20:1 n-9, and 22:1 n-9; and (d) sunflower oils, the highest content of 18:2 n-6 (linoleic acid).

**3.3. Classification of Five Types of Edible Oils by Random Forests.** After exploratory data analysis, we can find that five kinds of vegetable oils could be clearly classified into five groups. To build classification model for five types of edible oils, an effective supervised multivariate statistical method of random forests (RF) was used. Random forests are a

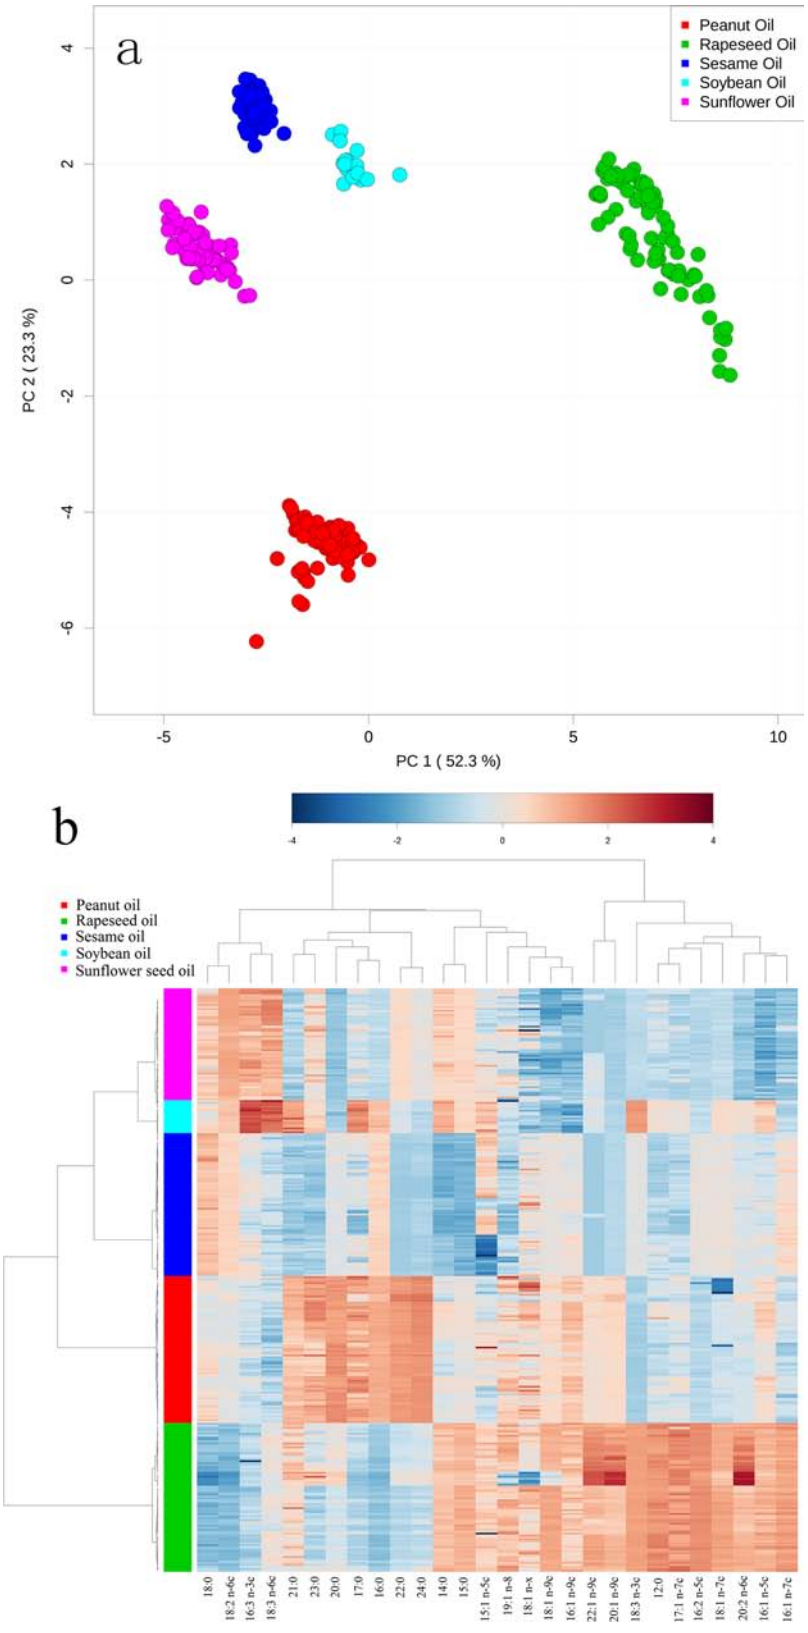

**Figure 1.** (a) Score plot between the first 2 PCs. (b) Heat map of five kinds of edible oils.

combination of tree predictors such that each tree depends on the values of a random vector sampled independently and with the same distribution for all trees in the forest.[23] The sample proximity matrix derived from these training trees is generated to collect the similarity information on the samples for classification of samples. Class prediction is based on the majority vote of the ensemble. Compared with other supervised multivariate statistical methods such as partial least-squares-discriminant analysis (PLS-DA) and support vector machine (SVM), random forests could be directly employed to

| sunflower oil | 0 | 0 | 0 | 0 | 0 | 0 | 57 | 0.00 |

multiclass classification. Furthermore, the RF classifier needs optimize only one parameter of the number of classification trees, which is relatively insensitive to predictive effect. In study, the number of classification trees is set to 500. During tree construction, about one-third of the samples are left out of the bootstrap sample. This out-of-bag (OOB) data is then used as test sample to obtain an unbiased estimate of the classification error (OOB error). From Figure 2a, it is found that the five errors decrease to zero after less than 20 trees. OOB error equals to 0 in the final classification model.

Random forests could provide the measure for variable importance. Figure 2b shows the contribution of each variable to the classification. According to the mean decrease, all important fatty acids except 18:2 n-6 (linoleic acid) and 16:0 (palmitic acid) are of low content. These results indicate that low abundant fatty acids might be more important to classification of five types of edible oils. Therefore, fatty acid profiles could reflect more information on fatty acids in edible oils, which benefit classification and adulteration identification.

**3.4. Adulteration Identification by Fatty Acid Profiles.** From the above analysis, it seems it is very easy to classify these five kinds of edible oils. Indeed, classification of commonly used edible oils is not hard thing by fatty acid analysis. However, classification of edible oils is not enough to ensure identity of edible oils. The most important thing is to identify adulteration of expensive oils with low price oils. Therefore, to test whether fatty acid profiles could serve adulteration detection, 300 blended oils were simulated by mixing five oils with random proportions, while, 60 adulterated oils were simulated by blending 10% content of other four oils with random proportions to 90% soybean, peanut, sunflower, rapeseed, and sesame oil, respectively. Then, the discriminative model for five pure oils and their blend and adulterated oils was built by RF after generalized log transformation and Pareto scaling. From Figure 3a, blend oils appear in the center of PCA score plot. It is found that fatty acid profiles could detect adulteration of peanut, sunflower and sesame oils with other vegetable oils about the level of 10%. For soybean and rapeseed oils, pure and adulterated oils are heavily overlapped.

Therefore, RF has been used to obtain high effective model. As shown in Figure 3b, except soybean oils, the OOB errors decrease to 0 or near 0 ($\leq$0.01) and the total OOB error is 0.00557. As illustrated in Table 2, peanut, sesame, and sunflower oils could completely separate from other oils and their blend and adulterated oils, respectively. Among them, peanut and sesame are key target of oil fraud in China market. Moreover, only one adulterated oil and one rapeseed oil were misidentified by RF model. The main reason is that fatty acids possess broad range, such as high and low erucic acid rapeseed. Thus, the rapeseed oil with 10% adulterated with other oils still stay at the space of rapeseed oils. However, only one rapeseed and one adulterated oils were misidentified. Finally, 3 out of 14 soybean oils were misidentified to be blend oils, suggesting more other parameter like phytosterol should be employed to assess the authenticity of soybean oils.[24] Fortunately, the soybean oil is the cheapest one in five types of edible oils, which has low risk to be adulterated.

From the above analysis, the established RF model could serve the authenticity assessment for four expensive oils. To validate the RF model, 16 real adulterated oils were physically blended. The blend proportions of these 16 adulterated oils were shown in Supporting Information Table S2. The results indicate that all of 16 blend oils could be identified as adulterated oil. Therefore, fatty acid profiles could be a good strategy to identify adulterated oils for edible oils. Compared with the pervious studies,[5,6,14] the adulteration detection method possess the following advantages: (1) it can simultaneously detect adulteration of more than one edible oils; (2) it can also detect the adulteration with more than one edible oils.

In conclusion, fatty acid profiles of five kinds of edible oils were established by GC-MS in SIM mode and employed to classify five types of edible oils with the help of multivariate statistical methods. The results indicate that fatty acid profiles of edible oils could completely classify the five kinds of edible oils into five groups and are therefore taken as markers of these four edible oils. Moreover, simulated data test indicate that fatty acid profiles could be used to detect adulterated by 10% or little more than 10% other oils for peanut, sunflower, rapeseed and sesame oil. The strategy of fatty acid profiles might be also useful to simultaneously identify the origin of various edible oils and detect suspected economically motivated the adulteration with more than one vegetable oils.

Supporting Information

**ABSTRACT:** To develop a more sensitive immunoassay for malachite green (MG) and leucomalachite green (LMG), we identified the immunocomplex binding phage-borne peptides for use in the noncompetitive phage anti-immunocomplex assay (PHAIA). An anti-LMG monoclonal antibody (mAb) was used to select immunocomplex binding peptides from a circular random eight-amino-acid phage-displayed library. After three rounds of panning-elution, five peptides that bound the LMG−mAb immunocomplex were obtained. One of the phage-borne peptide clones that resulted in an assay with the highest sensitivity was chosen for further research. The concentration of LMG producing 50% of the saturated signal and the limit of detection of the assay were 7.02 and 0.55 ng/mL, respectively, with a linear range of 1.35 to 21.56 ng/mL. The PHAIA based on the same antibody was 16 times more sensitive compared to the competitive immunoassay. PHAIA was used to analyze LMG, MG, and two mixtures of spiked fish samples, with validation by high-performance liquid chromatography (HPLC) with fluorescence detector. Results showed a good correlation ($R^2_{LMG}$ = 0.9841; $R^2_{MG}$ = 0.993; $R^2_{Mixture}$ = 0.9903) between the data of PHAIA and HPLC, thus the assay was an efficient method for monitoring food safety.

**KEYWORDS:** *malachite green, leucomalachite Green, phage anti-immunocomplex assay*

## INTRODUCTION

The antimicrobial and antiparasitic triphenylmethane dye malachite green (MG) is widely used in aquaculture because it is active against skin flukes and gill flukes as well as protozoas and fungi.[1,2] MG is readily absorbed by fish, then metabolized to the colorless, lipophilic leucomalachite green (LMG).[3] Because both MG and LMG are suspected carcinogens, mutagens, and teratogens in humans, residues are not permitted in food of animal from many countries, including the United States, China, Canada, and the European Union (minimum required performance limit of 2 μg/kg).[4−6] Nevertheless, it is still used worldwide because it is cheap and effective. Therefore, a sensitive analytical method is needed to monitor its use in aquatic production.

Immunoassays can have a low limit of detection (LOD), which permits quantification at trace levels. It is a simple tool for detection and quantification of analytes, allowing relatively fast, high-throughput analysis.[7] According to the format, immunoassays fall into two main categories, competitive and noncompetitive assays. In theory, noncompetitive immunoassays are potentially superior to their competitive counterparts in term of precision, working range, sensitivity, and kinetics.[8] However, the noncompetitive assay are fundamental limited by the fact that the target antigen must have at least two epitopes, a drawback that essentially eliminates measurement of low molecular weight compounds. To overcome this limitation, several novel noncompetitive immunoassay approaches for small molecules have been proposed in the past few years. These were based on anti-idiotype antibody,[9,10] split recombinant variable region fragments of antibody,[11−15] and anti-metatype antibody.[16−18] It is quite difficult and time-consuming to prepare these antibodies requiring immunization with antibody or analyte−antibody complexes, making these methods rarely successful except in special cases. However, to circumvent the problems, the phage anti-immune complex assay (PHAIA) technology was developed for noncompetitive assays of small analytes. In this technique, selection of a phage-borne peptide from the phage-displayed library utilizes the analyte−antibody immune complex for selection. The phage clones, which recognize the immune complex instead of the free antibody, are the second binding reagents using an antiphage antibody coupled to horseradish peroxidase (HRP) to generate the signal. The noncompetitive PHAIA technology has been used in the detection of clomazone,[19] molinate and atrazine,[20] phenoxybenzoic acid,[21] and brominated diphenyl ether 47.[22] Significantly enhanced sensitivity was obtained compared to the chemically synthesized competing hapten-based enzyme-linked immunosorbent assays (ELISA).

So far, all of the immunoassays reported previously for MG and LMG are based on conventional competitive immunoassays.[23−27] To expand the sensitive immunoassay for MG and

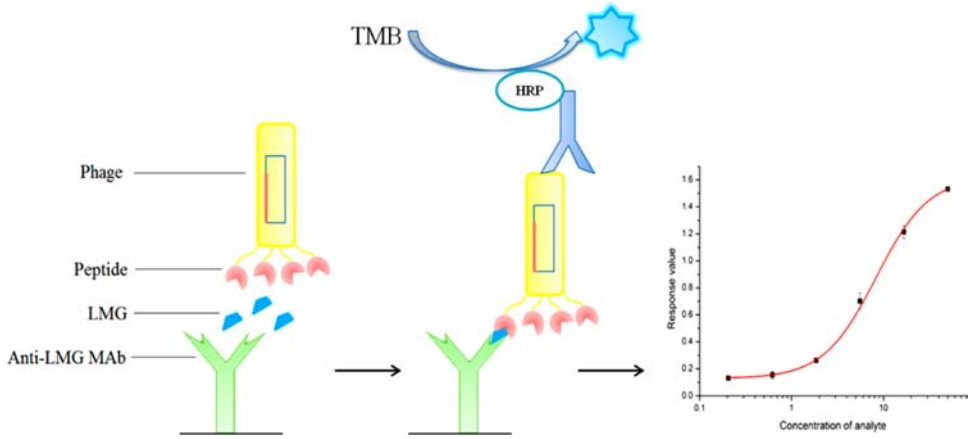

**Figure 1.** Schematic model of phage anti-immune complex assay (PHAIA). The peptide displayed on phage clones recognizes the immune complex to form the sandwich-model immunoassay. The detectable signal is amplified with antiphage antibody conjugated horseradish peroxidase(HRP), which catalyzes 3,3′,5,5′-tetramethylbenzidine(TMB) to produce a blue colored solution.

LMG, we developed the noncompetitive PHAIA with the anti-LMG monoclonal antibody (mAb), as shown in Figure 1. The phage-displayed peptides that were selective for the LMG-immunocomplex were chosen from the circular random eight-amino-acid library. One of the phage clones was used to establish noncompetitive immunoassays for quantitative estimation of MG and LMG in fish samples.

## MATERIALS AND METHODS

**Reagents.** All reagents were of analytical grade unless otherwise specified. MG, LMG, crystal violet (CV), leucocrystal violet (LCV), brilliant green (BG), parafuchsin (PA), methylene blue (MB), bovine serum albumin (BSA), ovalbumin (OVA), 3,3′,5,5′-tetramethylbenzidine (TMB), and protein A-based affinity columns to purify IgG were from Sigma Chemical Co. (St. Louis, MO, U.S.A.). Mouse anti-M13 mAb-HRP was obtained from GE Healthcare (Piscataway, NJ, U.S.A.). Polyethylene glycol 8000 (PEG 8000), Tween-20, tryptone, yeast extract, acetonitrile (ACN, HPLC grade), and dichloromethane (DCM) were obtained from Fisher Scientific Co. (Fair Lawn, NJ, U.S.A.). Bond Elut PRS columns were obtained from Agilent Technologies (Palo Alto, CA, U.S.A.). *Escherichia coli* (*E. coli*) ER2738 was obtained from Invitrogen Life Technologies (Carlsbad, CA, U.S.A.).

**Phage Displayed Peptide Library.** A random phage-displayed disulfide-constrained peptide library with an estimated diversity of $3.4 \times 10^{13}$ independent clones was constructed on the M13KE vector that expressed random peptide of eight amino acids.[28] These peptides are flanked by two cysteine residues and linked to the N terminus of the major pIII phage coat protein.

**Synthesis of Hapten and Production of Anti-LMG mAb.** 2-(3-(bis(4-(Dimethylamino)phenyl)methyl)phenoxy)-acetic acid (LMGH8) and LMGH8-BSA/OVA were synthesized and conjugated as described by Shen et al.[27] with 2-(3-formyl-phenoxy)acetic acid instead of 2-(4-formylphenoxy)acetic acid. The anti-LMG mAb was identified by competitive ELISA following immunization with LMGH8-BSA, cell fusion, hybridoma selection, ascites growth, and mAb purification processes, which were carried out as reported by Campbell.[29]

**Biopanning Procedure.** Two wells of a microtiter plate (Nunc-Immuno 96-MicroWell Plate) were coated with purified anti-LMG mAb (10 $\mu$g/mL) in 100 $\mu$L of 0.1 mol/L $NaHCO_3$ (pH 8.6) at 4 °C overnight. Two additional microtiter plates coated with 100 $\mu$L of 3% BSA and mAb, respectively, in 0.1 mol/L $NaHCO_3$ were used for preabsorption eliminating binding to BSA or mAb. Nonspecific binding was blocked by incubation with 300 $\mu$L of 0.1 mol/L $NaHCO_3$ containing 5 mg/mL BSA for 1 h at room temperature. Panning-elution was conducted by diluting the phage library ($1 \times 10^{10}$ pfu/mL) with phosphate-buffered saline (PBS). The diluted phage was then added to the BSA preabsorption plate. Following room temperature incubation for 1 h, the solution was transferred to a preabsorption plate containing mAb and incubated at room temperature for 1 h. Then, the unbound phage peptides were transferred into the other wells of the mAb coated plate that had been preincubated with 300 ng/mL LMG and washed seven times with PBS containing 0.1% (v/v) Tween-20 (PBST), followed by incubation at room temperature for 1 h. The wells were washed 10 times with PBST. The bound phage was eluted with 100 $\mu$L of 0.1 mol/L glycine-HCl (pH 2.2) per well and neutralized with 4.5 $\mu$L of 1 mol/L Tris (pH 9.0). After 10 min incubation, the elution solution was collected, and *E. coli* ER2738 was infected by adding the elution solution for amplification and titration. The amplified phage was used for a subsequent round of panning. The concentration of coating antibody was reduced to 5 and 1 $\mu$g/mL in the second and third rounds of panning. The ability to bind to the LMG−mAb immune complex was tested after three rounds of panning-elution selection. Individual plaques were picked from LB/IPTG/X-gal plates.

**Phage ELISA Screening.** A noncompetitive phage ELISA was set up to screen phage capable of binding the LMG immune complex. The microtiter plates were coated with the anti-LMG mAb or BSA and blocked as described before. Equal volumes of LMG solution (50 ng/mL) diluted with PBST were mixed with the culture of individual amplified phage clones. The mixture was then added to wells (100 $\mu$L/well) and incubated at room temperature for 1 h. After seven washes with PBST, 100 $\mu$L of a 1/5000 dilution of anti-M13 monoclonal labeled HRP was dispensed into each well. One hour later, the plates were washed another seven times, and 100 $\mu$L of peroxidase substrate, which contains 12.5 mL of 0.1 mol/L citrate acetate buffer with pH 5.5, 0.2 mL of TMB (6 mg/mL in dimethyl sulfoxide solution), and 0.1 mL of 1% $H_2O_2$, was added into each well. The enzymatic reaction was stopped with

dx.doi.org/10.1021/jf5019824 | J. Agric. Food Chem. 2014, 62, 8752−8758

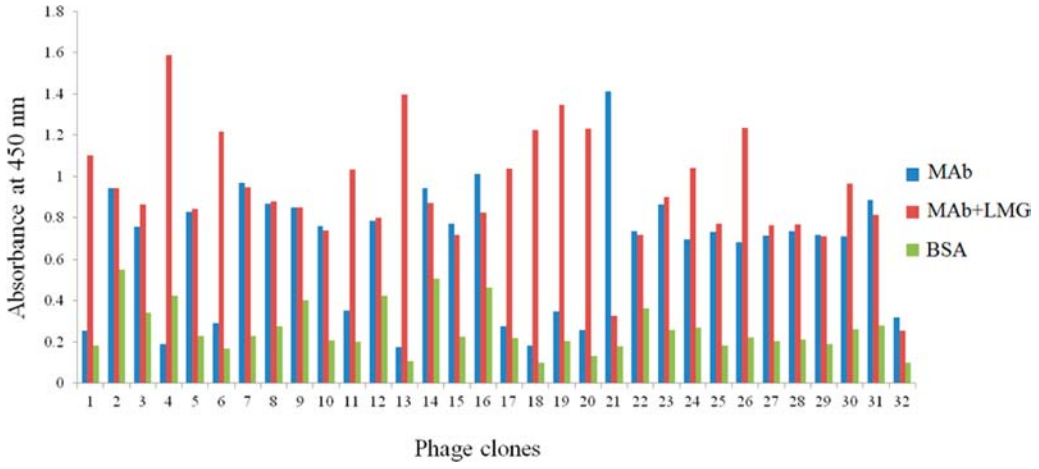

**Figure 2.** Screening of positive clones by noncompetitive phage ELISA. Clones 1, 4, 6, 11, 13, 17, 18, 19, 20 reacting specifically with the leucomalachite green-monoclonal antibody (LMG-mAb) immunocomplex showed little or negligible signal with the bovine serum albumin (BSA) or uncombined mAb.

50 $\mu$L of $H_2SO_4$ (4 mol/L) after 10 min, and the absorbance at 450 nm was recorded in a microtiter plate reader (Molecular Devices, Sunnyvale, CA, U.S.A.). The positive clones demonstrating high absorbance in wells coated with the immune complex and low absorbance in antibody or BSA-coated wells were selected and used for further analysis.

**DNA Sequencing and Analysis for the Positive Clones.** The positive clones as described above were further amplified and used for single-stranded DNA isolation as introduced in the Ph.D. peptide library kit instruction manual (New England Biolabs, Berverly, MA, U.S.A.). The product of phage DNA was submitted for DNA sequencing using the primer 96gIII (CCCTCATAGTTAGCGTAACG) (Division of Biological Sciences, Automated DNA Sequencing Facility, University of California, Davis, CA, U.S.A.). The program of DNAMAN 4.0 (Lynnon Biosoft, Quebec, Canada) was used to translate and align the amino acid residue sequences of the phage-display peptide from the inserted DNA sequences.

**Preparation of Purified Phage Suspensions.** Phage clones showing different amino acid residue sequences were selected and individually amplified as described above. After two steps of precipitation with PEG 8000-NaCl (20% (w/v) PEG-8000/2.5 mol/L NaCl), the phage particles were suspended with 0.5 mL of Tris-buffered saline (TBS, 50 mmol/L Tris-HCl, 150 mmol/L NaCl, pH 7.5) and stored at 4 °C.

**Noncompetitive Phage ELISA Protocol.** For checkerboard titration, 100 $\mu$L of various concentrations of the purified anti-LMG mAb (1 $\mu$g/mL, 0.5 $\mu$g/mL, 0.25 $\mu$g/mL, and 0.125 $\mu$g/mL) was used for coating as described before. The plates were blocked with 3% skim milk in PBS for 1 h at room temperature. After the plates were washed three times by PBST, the dilutions of purified phage suspensions were added to the mAb-coated wells in the presence or absence of LMG (50 ng/mL). Following the procedure of incubation, addition of anti-M13-HRP conjugate and color development as described in phage ELISA screening section, the concentration of coating antibody and phage particle combinations that resulted in an absorbance at about 1 were selected for the further assay.

After the confirmation of the coating antibody and phage particle dilutions, different concentrations of LMG (0−50 ng/mL in PBST solution) were mixed with equal volumes of phage to establish the noncompetitive standard curve for each clone.

**Cross-Reactivity Assay.** The specificity of the noncompetitive assay was evaluated by using some triphenylmethane analogues. We determined the average compound concentration corresponding to the midpoint of the curve (which corresponds to the concentration of analyte producing 50% saturation of the signal [$SC_{50}$]) and compared the values to the value from a standard curve for LMG run on the same plate. Cross-reactivity was calculated as follows: 100 × $SC_{50}$ (LMG)/$SC_{50}$ (cross-reactive compound).

**Matrix Effect and Assay Precision.** The PHAIA was used to detect MG and LMG in tilapia samples obtained from a local California market. Fish samples were minced and then homogenized. The homogenates (2.5 g) were spiked with MG, LMG, or the two-mixture standard solution (5, 10, or 20 ng/g). These samples stood for 5 min or more at room temperature prior to extraction. ACN (10 mL) was added and the sample was homogenized for 30 s at room temperature. Alumina (2.5 g) was added, and the samples were shaken for an additional 2 min. The samples were then centrifuged at 4000 rpm for 5 min and the supernatant was transferred to a clean tube. ACN (10 mL), 0.75 mL of hydroxylamine hydrochloride (20% mass ratio in deionized water), 1.25 mL of *p*-toluenesulfonic acid (0.05 mol/L), and 2.5 mL of ammonium acetate buffer (0.125 mol/L, pH 4.5) were used to re-extract the pellet. After shaking for 2 min, the samples were centrifuged again. Then, the supernatant was combined with the previous supernatant fraction. The extraction was repeated once more. Potassium borohydride (0.2 mol/L; 2.25 mL) was added to the supernatant fraction. After a 10 min incubation, DCM (5 mL) was added. These combined fractions were shaken vigorously for 15 s and centrifuged at 4000 rpm for 5 min. The lower organic layer was then transferred into a clean borosilicate glass tube and dried on a vacuum rotary evaporator at 45 °C. The dry residue was redissolved in 2.5 mL of ACN for solid-phase extraction.

The PRS solid phase extraction columns (Agilent Technologies, Palo Alto, CA, U.S.A.) were preconditioned with 5 mL of ACN. The sample extract was loaded onto the column followed by a 2 mL ACN wash. Two milliliters of the sample eluent solution (ACN/ammonium hydroxide, 90:10, v/v) was added to the column and the eluents were collected into a borosilicate glass tube. The extract was evaporated to dryness under a stream of nitrogen. Finally, the dry residue was

reconstituted and sonicated for 10 min in 2 mL of PBST for the noncompetitive PHAIA and HPLC analysis. The matrix effects determination was conducted according to the procedure described above using a pure extract to dilute the LMG.

**HPLC Analysis.** HPLC was carried out on an Agilent 1290 series HPLC system, equipped with an online-degasser, a binary pump, and an autosampler. A fluorescence detector (model G1321B, Agilent, U.S.A.) was adjusted at wavelengths of 265 and 360 nm for excitation and emission. The analysis procedure was run with an isocratic mobile phase consisting of ACN and 0.125 mol/L ammonium acetate (4:1, v/v) at a flow rate of 1.3 mL/min. A Phenomenex Luna 5 $\mu$m C18 column (250 mm × 4.6 mm; Torrance, CA, U.S.A.) was used. The injection volume was 20 $\mu$L.

## RESULTS AND DISCUSSION

**Purified Anti-LMG mAb Production and Identification.** A hybridoma 6D1 that stably secretes mAbs against LMG was obtained from ascites and purified by a protein A affinity column. The half inhibitory concentration ($IC_{50}$) of the purified mAb was determined to be 113.12 ng/mL by the indirect competitive ELISA.

**Screening of the Peptides by Phage ELISA.** In this study, we used the circular random eight-amino-acid library which was displayed on the pIII coat protein of filamentous phage. Compared with the other major coat protein, pVIII, pIII can tolerate the insertion of longer peptides because pIII is the longest coat protein and only 3−5 peptides copies are displayed.[30] We believed that the space between each peptide makes the immunocomplex more accessible for binding. The principle of noncompetitive immunoassay requires the phage-displayed peptides to recognize the antibody−analyte complex rather than any other part of antibody. After three rounds of panning, 32 clones were picked randomly and tested for binding to the anti-LMG mAb-coated wells in the presence or absence of LMG. Nine of 32 clones showed negligible binding to the uncombined antibody, although bounding specifically to the immunocomplex in the presence of 50 ng/mL LMG (Figure 2).

**Analysis of Positive Peptides Amino Acid Sequences.** After the isolation and sequencing of single stranded DNA from the positive phage clones, five different sequences were obtained (NCB1, NCB4, NCB6, NCB11, NCB13). The deduction of the amino acid sequences are shown in Table 1. The clones NCB 4, NCB 6, and NCB 13 shared the consensus motif of LPXHL, while HEXHXH was common to NCB1 and NCB11, where X represents any amino acid. The results indicated that the two motifs of LPXHL and HEXHXH contributed significantly to the LMG immune complex recognition.

**Table 1. Peptide Sequences Isolated with LMG Immunocomplex**

| phage clones | amino acid sequence |
|---|---|
| NCB-1 | C LNHEFHLHC (2) |
| NCB-4 | CT Y RLPLHLC (1) |
| NCB-6 | CTFTLPRHLC (1) |
| NCB-11 | CVPHEHHTHC (4) |
| NCB-13 | CLFTLPRHLC (1) |

**PHAIA for LMG.** The PHAIA sensitivity is associated with the concentration of coating mAb and the number of phage particles. To determine the optimal concentration of mAb and phage particles, a checkerboard procedure was performed for each clone. Serially diluted phage particles were added to the plates coated with purified antibody (1, 0.5, 0.25, and 0.125 $\mu$g/mL) in the absence or presence of LMG (50 ng/mL). The best results were obtained with antibody concentration of 0.5 $\mu$g/well and phage concentrations of $2.40 \times 10^{12}$ pfu/mL for clone NCB1, $1.20 \times 10^{12}$ pfu/mL for clone NCB4, and $1.27 \times 10^{12}$ pfu/mL for NCB13, whereas antibody concentrations of 0.25 $\mu$g/well and phage concentrations of $1.12 \times 10^{12}$ pfu/mL for clone NCB6, and $3.00 \times 10^{12}$ pfu/mL for clone NCB11, were identified (Figure S1−S5).

The assay with clone NCB1 demonstrated the highest sensitivity ($SC_{50}$ = 7.02 ng/mL), followed by clones NCB4, NCB13, NCB6, and NCB11 ($SC_{50}$ values of 8.39, 10.58, 13.00, and 16.15 ng/mL, respectively). For each of the five clones, standard curves were estimated using the optimized conditions. The noncompetitive standard curves are presented in Figure 3.

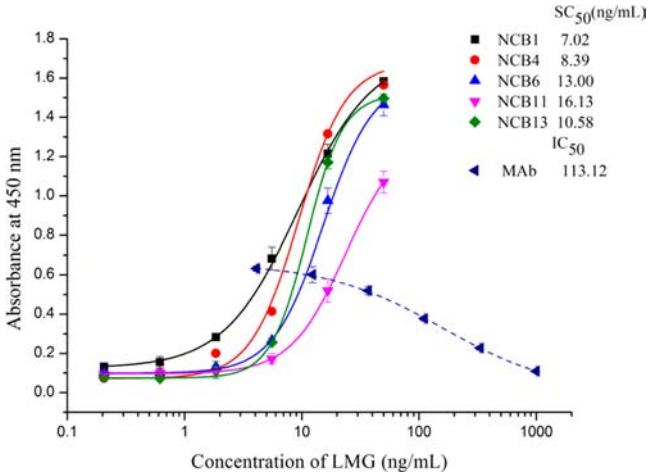

**Figure 3.** Noncompetitive ELISA for LMG performed with different phage-displayed peptide and competitive ELISA based on mAb for LMG. Results are the average of three replicates. The full lines are the standard curves of phage anti-immune complex assay. The dotted line is the inhibitory curve determined by competitive model. The 50% saturation of the signal ($SC_{50}$) and the half inhibitory concentration ($IC_{50}$) was calculated using a logistic plot equation with OriginPro 8.5 (OriginLab, Northampton, MA).

The linear range of NCB1 was 1.35 to 21.56 ng/mL. By altering the traditional competitive assay to the noncompetitive model, we improved the sensitivity of the assay by 16-fold using the same mAb. The sensitivity improvement is consistent with previously reported results.[19]

**Cross-Reactivity.** The cross reactivity of other structurally related compounds was determined to identify the specificity of the PHAIA, and the results are listed in Table 2. LCV and MG (6.89% and 2.93%, respectively) showed low cross-reactivity. The cross-reactivity was less than 0.01% for other compounds, similar to the competitive assay.

**Matrix Effect.** Due to the presence of the extraction agent, the sample component, and other ions, false positive or negative results from the matrix could be observed in the immunoassay. For the extraction of lipophilic LMG, it is necessary to minimize the matrix effect by using solid-phase extraction (SPE).[23] In our study, the maximum absorption with

**Table 2. Cross-Reactivity of LMG-PHAIA**[a]

| Analogues | Structure | Cross-reactivity(%) |
|---|---|---|
| LMG |  | 100 |
| MG |  | 2.93 |
| LCV |  | 6.89 |
| CV |  | <0.01 |
| BG |  | <0.01 |
| PA |  | <0.01 |
| MB |  | <0.01 |

[a]The specificity was presented by cross-reactivity using the malachite green (MG), leucocrystal violet (LCV), crystal violet (CV), brilliant green (BG), parafuchsin (PA), methylene blue (MB).

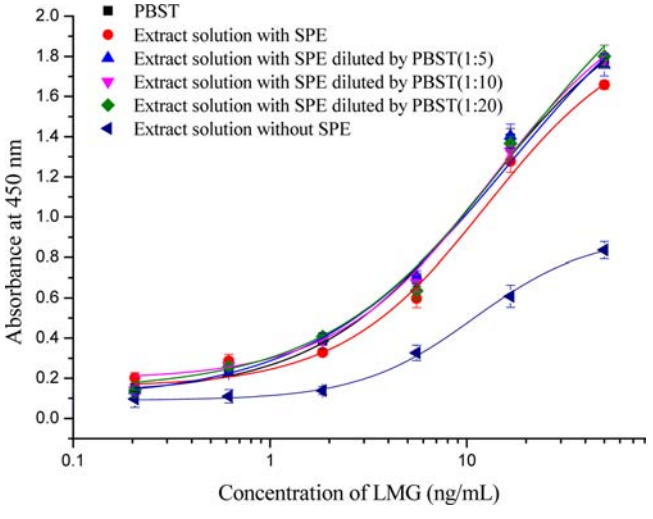

**Figure 4.** Standard curves of LMG in PBST and in sample extracts of different dilution with or without solid-phase extraction (SPE) ($n$ = 3). The matrix effect was studied by comparison of standard curves obtained in PBST, in sample extracts cleaned up with SPE of 1:1, 1:5, 1:10, 1:20 dilution, and in sample extracts without SPE.

**Table 3. Recovery of Spiked Fish Samples Determined by LMG-PHAIA ($n$ = 3)**

| analyte | spike level (ng/g) | mean ± SD (ng/g) | average recovery (%) | CV (%) |
|---|---|---|---|---|
| LMG | 0 | ND | | |
| | 5 | 3.77 ± 0.58 | 75.33 | 15.33 |
| | 10 | 8.20 ± 0.76 | 82.03 | 9.24 |
| | 20 | 17.60 ± 1.52 | 88.00 | 8.64 |
| MG | 0 | ND | | |
| | 5 | 4.14 ± 0.32 | 82.80 | 7.67 |

| | 20 | 16.89 ± 0.69 | 84.45 | 4.11 |
| LMG + MG(1:1) | 0 | ND | | |
| | 5 | 3.78 ± 0.56 | 75.60 | 14.82 |
| | 10 | 7.92 ± 0.74 | 79.20 | 9.29 |
| | 20 | 16.79 ± 1.01 | 83.93 | 5.99 |

ND means not detectable.

50 ng/mL LMG in 1:1, 1:5, 1:10, and 1:20 extract dilutions was 1.66 ± 0.02, 1.76 ± 0.06, 1.79 ± 0.03, and 1.80 ± 0.05 ($n$ = 3 per dilution), respectively, compared to 1.77 ± 0.02 in PBST (Figure 4). The $SC_{50}$ values were 8.09, 7.44, 7.64, and

dx.doi.org/10.1021/jf5019824 | J. Agric. Food Chem. 2014, 62, 8752−8758

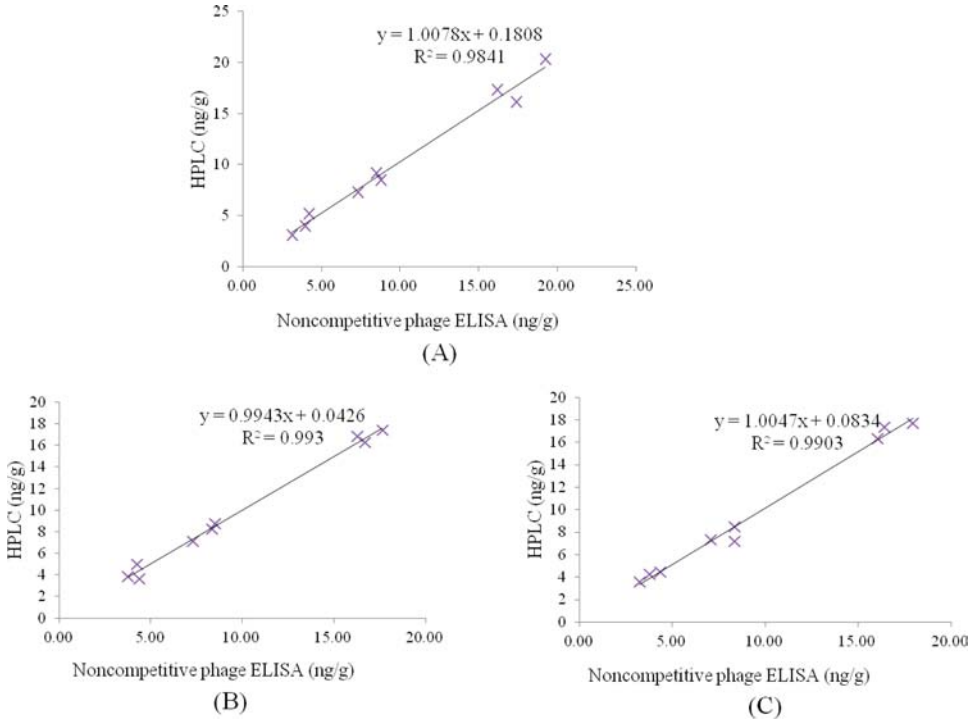

**Figure 5.** Correlation analysis between the PHAIA and HPLC ($n$ = 3). (A) Samples spiked with LMG. (B) Samples spiked with MG. (C) Sample spiked with a mixture LMG and MG (1:1). All the sample extracted by the same procedure were divided into two equal parts and tested by PHAIA and HPLC.

7.66 ng/mL compared with 7.37 ng/mL for PBST, indicating that the matrix effects of the three fish samples were completely eliminated after pretreatment by PRS solid phase extraction. Although the 1:10 dilution showed less matrix effect, the higher limit of quantitation makes it unattractive. Thus, LMG was extracted at a proportion of 1:5, and the extracts were diluted 5-fold with PBST to minimize matrix effects.

**Analysis of Spiked Samples by PHAIA and HPLC.** The accuracy and precision of the PHAIA format were evaluated by determination of MG and LMG in spiked fish samples as well as by spiking with the mixtures of the two analytes. The MG was reduced to LMG by potassium borohydride so that it could be detected by the specific anti-LMG mAb. As shown in Table 3, the mean recovery rate measured using the LMG-PHAIA standard curves were 75.33−88.00% for LMG, 80.67−84.45% for MG, and 75.60−83.93% for the LMG and MG mixture. The comparison of results with HPLC shown in Figure 5 indicated that good correlations were obtained at the 5, 10, and 20 ng/mL spiked levels.

The current work described a sensitive detection of MG and LMG using a noncompetitive PHAIA assay. The peptide-based sandwich can work as a simple method to convert competitive assays to more versatile noncompetitive formats for small molecules which will provide significantly improved sensitivity (~16-fold in this work) and more adaptable to other immunoassay detection systems. However, the biological *E. coli* infectivity of phage might be a concern in some laboratories and industry. Further research will focus on the novel phage-free peptide ELISA by using the chemical synthetic peptide or genetic fusion peptide.

# Cadmium and Lead in Chocolates Commercialized in Brazil

Javier E. L. Villa, Rafaella R. A. Peixoto, and Solange Cadore*

Institute of Chemistry, University of Campinas, Post Office Box 6154, 13083-970 Campinas, São Paulo, Brazil

**ABSTRACT:** Cadmium (Cd) and lead (Pb) concentrations and their relationship to the cocoa content of chocolates commercialized in Brazil were evaluated by graphite furnace atomic absorption spectrometry (GF AAS) after microwave-assisted acid digestion. Several chemical modifiers were tested during method development, and analytical parameters, including the limits of detection and quantification as well as the accuracy and precision of the overall procedure, were assessed. The study examined 30 chocolate samples, and the concentrations of Cd and Pb were in the range of <1.7−107.6 and <21−138.4 ng/g, respectively. The results indicated that dark chocolates have higher concentrations of Cd and Pb than milk and white chocolates. Furthermore, samples with five different cocoa contents (ranging from 34 to 85%) from the same brand were analyzed, and linear correlations between the cocoa content and the concentrations of Cd ($R^2$ = 0.907) and Pb ($R^2$ = 0.955) were observed. The results showed that chocolate might be a significant source of Cd and Pb ingestion, particularly for children.

**KEYWORDS:** *chocolate, cadmium, lead, cocoa, GF AAS*

## INTRODUCTION

Chocolates are a type of food widely consumed around the world. The large consumption of chocolate is attributable mainly to its pleasant flavor and the feeling of well-being promoted by its ingestion,[1] which make it a very popular food among people of all ages, although children are often the major consumers.

The primary base of chocolate products is cocoa, the seed of the *Theobroma cacao* tree.[1−3] To be considered as chocolate, a food product must contain at least 25% cocoa solids or 20% cocoa butter.[4] According to the International Cocoa Organization, American production of cocoa beans accounts for approximately 16% of the worldwide production, and Brazil and Ecuador are the largest American producers.[5] In addition to being a large producer, Brazil is also an important market for cocoa derivatives. Dark, milk, and white are the main types of chocolates available on the Brazilian market, and the compositions of these varieties differ in terms of their cocoa solids, milk fat, and cocoa butter contents.[6]

Numerous studies have demonstrated that the ingestion of cocoa and its derivatives can benefit health, mainly because of the high levels of flavonoids and antioxidants present in cocoa-based foods.[2,7,8] This type of food may prevent harmful effects caused by free radicals in the human body, contributing to the reduction of cardiovascular disease and cancer risk.[9,10] In addition, cocoa and its derivatives are also an important source of essential inorganic constituents in the diet, such as Ca, P, Fe, Mg, Cu, Zn, K, and Mn.[2,11,12] However, the presence of potentially toxic elements has also been reported,[13−17] particularly lead and cadmium.[18,19]

The presence of lead in cocoa and its derivatives has been discussed for many years.[20] Although lead is naturally found in the environment, this element has no recognized function in the human body and is harmful even at trace levels. Once in the human body, lead can affect the metabolism of calcium and other essential nutrients by competing for binding sites in biological systems.[21,22] In adults, the primary symptoms of lead poisoning are abdominal pain, arthralgia, hypertension, headache, increased intracranial pressure, central nervous system dysfunction, anemia, and renal dysfunction. In children, the effects are more severe and are associated with long-term effects, such as growth failure, behavioral changes, language delay, and anemia.[23] Some studies have also noted a relationship between childhood exposure to lead and delayed intellectual development.[24−28]

Cadmium, another element that is potentially toxic at trace levels, is found in certain food crops grown in soils containing high levels of this element and is the major cause of non-workplace-related exposure to this element.[29] The presence of cadmium in the human body results in damage to several organs and can, thus, cause hepatic damage or kidney failure.[30,31] In addition, it may cause pneumonitis, destruction of mucous membranes, glomerular and tubular damage, testicular necrosis, estrogen-like effects, disruption of steroid-hormone synthesis, and numerous other harmful effects.[32]

Thus, controlling the cadmium and lead contents in chocolate products is a public health concern, especially because children are more susceptible to lead and cadmium poisoning through the consumption of chocolate products. However, the assessment of cadmium and lead concentrations in chocolate products remains an analytical challenge because of the complexity of the matrix. A successful approach must combine adequate sample treatment with a sensitive analytical technique.[1]

In this study, the concentrations of cadmium and lead found in different brands and types of chocolate bars available in the Brazilian market are presented. The relationship between lead and cadmium and the cocoa content of chocolates commercialized in Brazil were also evaluated.

## MATERIALS AND METHODS

**Chemicals.** Deionized water (Milli-Q system, 18.2 MΩ cm, Millipore, Bedford, MA) and analytical-grade reagents were used to prepare all solutions and standards. Nitric acid (65%) and hidrogen peroxide (30%, v/v) were purchased from Merck (Darmstadt, Germany). Pure argon (99.999%) purchased from White Martins (São Paulo, SP, Brazil) was used as purge and protective gas.

The palladium working solution (10 g/L) was purchased from PerkinElmer (Norwalk, CT). Magnesium nitrate was purchased from Merck (Darmstadt, Germany), and the corresponding working solution (10 g/L) was prepared by diluting an appropriate amount of the salt in ultrapure water. Ammonium dihydrogen phosphate was obtained from Fluka (Buch, Switzerland), and its working solution (100 g/L) was prepared by diluting the appropriate amount of the salt in deionized water.

The analyte solutions were prepared from 1000 mg/L standard solutions (Merck Darmstadt, Germany) in 0.2% (v/v) $HNO_3$. Appropriate dilutions were made from the standard solutions and stored in polyethylene flasks under refrigeration. All glass and quartz materials were treated with a 10% (v/v) $HNO_3$ solution for 24 h and then rinsed with deionized water prior to use.

**Instrumentation.** All measurements were carried out using an AAnalyst 600 atomic absorption spectrometer (PerkinElmer, Norwalk, CT) with Zeeman background correction that was equipped with a transversely heated graphite tube atomizer and an AS-800 autosampler. Electrodeless discharge lamps for Cd and Pb were operated at 230 and 440 mA, respectively. The selected wavelengths were 228.8 nm for Cd and 283.3 nm for Pb. Aliquots of 20 μL of the samples and calibration solutions were injected with 5 μL of chemical modifier directly into the graphite tube. Pure argon (99.999%) was used as the purge and protective gas. The optimum operating parameters for GF AAS are shown in Table 1.

**Table 1. Heating Programs for Cd and Pb Determination by GF AAS in Chocolate Samples Using 5 μg of Pd + 3 μg of $Mg(NO_3)_2$ and 3 μg of $Mg(NO_3)_2$ + 50 μg of $NH_4H_2PO_4$ as Chemical Modifiers**

| 5 | 2450 | 1 | 3 | 250 |

[a]Cadmium. [b]Lead.

**Certified Materials and Sample Collection.** Three certified reference materials (CRMs) from the National Institute of Standards and Technology (Gaithersburg, MD), specifically, corn bran (NIST 8433), wheat flour (NIST 1567a), and whole milk powder (NIST 8435), were used to verify the accuracy of the proposed method.

A total of 30 chocolate samples of different types (labeled by the manufacturers as white, milk, or dark chocolate) and brands (designated as brands A–K) were analyzed in this study. They were purchased in the local market of Campinas, State of São Paulo, Brazil, in the period of January–March 2014.

**Sample Treatment.** Sample treatment was performed using a microwave digestion system (ETHOS1, Milestone, Sorisole, Italy) equipped with closed polytetrafluoroethylene vessels and sensors for temperature and pressure control. Sample masses of 500 mg were accurately weighed into the closed vessels, and 1.5 mL of 30% (v/v) hydrogen peroxide and 6.5 mL of nitric acid at a concentration of 12, 9, 6, or 3 mol/L were subsequently added. The closed vessels were then placed inside the microwave oven, and the heating program was performed over six steps: (1) heat from room temperature to 80 °C in 3 min, (2) hold for 3 min at 80 °C, (3) heat from 80 to 140 °C in 3 min, (4) hold for 4 min at 140 °C, (5) heat from 140 to 200 °C in 8 min, and (6) hold for 16 min at 200 °C. After digestion, the resulting solutions were left to cool, transferred to individual 25.0 mL volumetric flasks, and diluted to the mark with deionized water.

A total organic carbon analyzer (TOC-VCPN, Shimadzu, Kyoto, Japan) was used to determine the residual carbon content (RCC). Acid–base titration of the digests was performed to determine the final acidities of the samples. The titrations were performed with a standard solution of sodium hydroxide (0.0989 mol/L) and phenolphthalein [1.0% (m/v) in ethanol].

**Validation Studies.** The method was validated by determining various figures of merit, such as the linearity, precision, accuracy, characteristic mass, and detection limit, as recommended by Welz and Sperling.[33] The accuracy of the method was evaluated using the following CRMs: corn bran (NIST 8433), wheat flour (NIST 1567a), and whole milk powder (NIST 8435). Furthermore, analyte addition and recovery experiments were performed for three different chocolate types at two concentration levels (0.2 and 0.5 μ/L for Cd and 1 and 4 μ/L for Pb) and in triplicate for each spiked level. The limits of detection (LOD) and quantitation (LOQ) of each analyte were also calculated.

## RESULTS AND DISCUSSION

**Sample Digestion.** The study of sample digestion procedures is an important topic for the improvement of analytical methods for the routine determination of trace elements in food materials. The sample decomposition using the minimal amount of reagents can offer advantages as reducing costs and the amounts of residue generated.[34−36] For this, the digestion procedure was evaluated at four different $HNO_3$ concentrations (12, 9, 6, and 3 mol/L) by comparing the RCCs and the residual acidities of the digests. The digestion solutions were free from solid residues when the nitric acid concentration was greater than 3 mol/L. The RCC for each

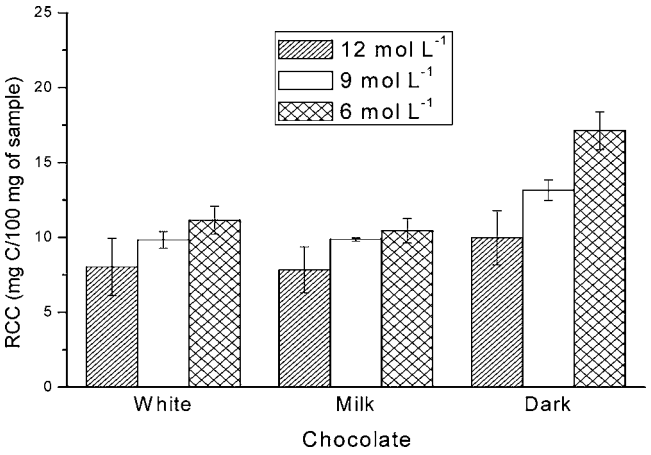

**Figure 1.** RCC in samples of each chocolate type digested using different nitric acid concentrations.

**Table 2. Pyrolysis Temperatures and Characteristic Masses ($m_o$) Obtained for Cd and Pb in a Sample of Dark Chocolate Using Different Chemical Modifiers**

| analyte | chemical modifier | $T_{pyrolysis}$ (°C) | $m_o$ (pg) |
|---|---|---|---|
| Cd | 10 μg of $NH_4H_2PO_4$ | 600 | 1.5 |
| | 3 μg of $Mg(NO_3)_2$ + 50 μg of $NH_4H_2PO_4$ | 700 | 1.5 |
| | 5 μg of Pd + 3 μg of $Mg(NO_3)_2$ | 600 | 1.4 |
| Pb | 10 μg of $NH_4H_2PO_4$ | 850 | 30.8 |
| | 3 μg of $Mg(NO_3)_2$ + 50 μg of $NH_4H_2PO_4$ | 850 | 31 |
| | 5 μg of Pd + 3 μg of $Mg(NO_3)_2$ | 1000 | 36.6 |

**Table 5. Figures of Merit for the Determination of Cd and Pb in Chocolate**

| element | linear range (μg/L) | LOD (ng/g) | LOQ (ng/g) | $RSD_{repeat}$ (%) |
|---|---|---|---|---|
| Cd | 0.034−2 | 0.5 | 1.7 | 1.6 |
| Pb | 0.45−10 | 6.3 | 21 | 2.1 |

type of chocolate is shown in Figure 1, and the residual acidities of the digests prepared using nitric acid at 6, 9, and 12 mol/L ranged from 1 to 2.7 mol/L.

A concentration of 6 mol/L $HNO_3$ was used in subsequent experiments to digest 500 mg of chocolate, even though this condition presented the highest RCC value, considering that the technique of GF AAS has a pyrolysis step, which main function is to eliminate the matrix organic matter prior to the atomization. As already demonstrated, when using this technique, it is possible to do the introduction of samples with high contents of organic matter, including slurry and solid samples.[14,33]

**Optimization of the GF AAS Conditions.** Pyrolysis and atomization curves were established using the sample with the highest RCC (dark chocolate) to guarantee that the heating program would be adequate for all of the samples. The pyrolysis temperature and characteristic masses of Cd and Pb using different chemical modifiers are shown in Table 2. With respect to the chemical modifiers, the best detectability, analytical signal, and background signal for Cd determination were observed using 3 μg of $Mg(NO_3)_2$ + 5 μg of Pd, whereas the highest detectability and repeatability for Pb determination were observed when 3 μg of $Mg(NO_3)_2$ + 50 μg of $NH_4H_2PO_4$ was used.

**Analytical Features.** No chocolate reference material with certified Cd and Pb concentrations is currently available. However, three CRMs (NIST 8433, NIST 1567a, and NIST 8435) were used. The observed Cd and Pb concentrations were in agreement with the certified values at the 95% confidence level (Student's $t$ test); the results are shown in Table 3. Considering the analyte addition and recovery experiments, values ranging from 92 to 102% were obtained, as shown in Table 4.

The LOD and LOQ were calculated as $3S_{blank}/b$ and $10S_{blank}/b$,[33] respectively, where $S_{blank}$ is the standard deviation of 10 measurements of the blank and $b$ is the slope of the calibration curve. A further multiplication by a factor of 50, considering the mass of the sample (0.5 g) and the final volume of the solution (25 mL), allowed us to obtain the LOD and LOQ in ng/g. The repeatability was obtained by analyzing a control sample of dark chocolate 6 times within a short period of time.

The figures of merit for the determination of Cd and Pb are provided in Table 5.

[a]ni = not informed.

**Analytical Determinations.** Cadmium and lead concentrations were determined in 30 chocolate samples of different types and brands using the proposed method. The results are shown in Table 6.

The concentrations of Cd and Pb found ranged between <1.7−107.6 and <21−138.4 ng/g, respectively, and the highest concentrations of Cd and Pb were found in dark chocolates. The results were in agreement with those found by Rehman et al.[13] (Cd and Pb ranged between 4.3 and 190 and between 29 and 1400 ng/g, respectively) and, in general, lower than those found by Dahiya et al.[18] (Cd and Pb ranged between 1 and 2730 and between 49 and 8040 ng/g, respectively).

The Cd and Pb concentrations of all of the samples analized in this work were below the maximum levels recommended by the Brazilian legislation,[37] the European Union,[38] and the Food and Agriculture Organization (FAO)/World Health Organization (WHO).[39] According to the U.S. Food and Drug Administration (FDA), the levels of Pb in candies must not exceed 100 ng/g. In this study, two samples of dark chocolates

dx.doi.org/10.1021/jf5026604 | J. Agric. Food Chem. 2014, 62, 8759−8763

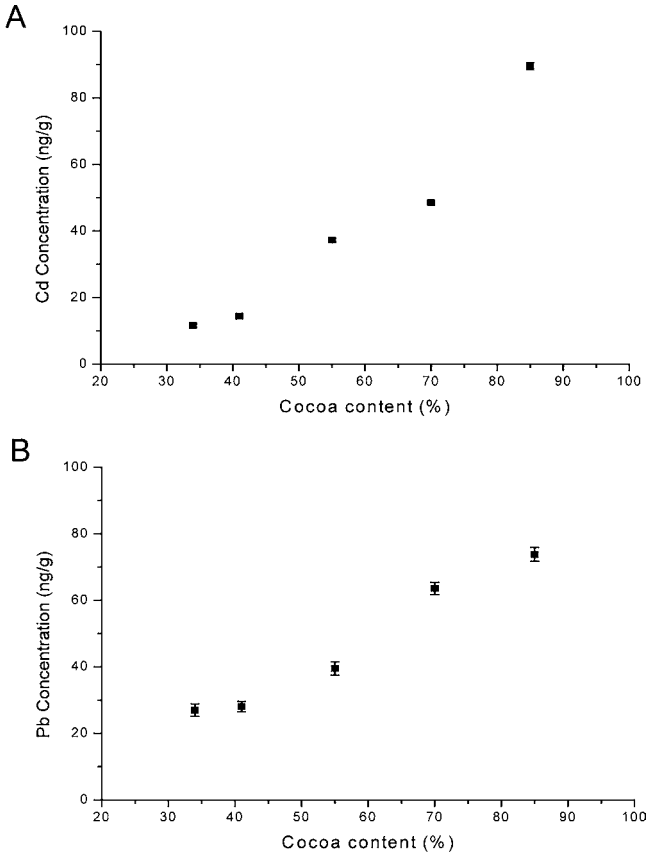

**Figure 2.** Correlation between the cocoa content (%) and the (A) cadmium and (B) lead concentrations.

have presented higher concentrations, what is already expected, considering that the cocoa liquor might be the principal source of lead.[40]

The provisional tolerable monthly intake (PTMI) for Cd recommended by the FAO/WHO is 25 $\mu$g/kg of body weight.[41] Considering an average weight of 15 kg for children and 70 kg for adults and a consumption of 10 g of chocolate per day, the maximum contribution for Cd was 8.6% of the PTMI for children and 1.8% for adults.

The European Union recommends a tolerable weakly intake (TWI) of 2.5 $\mu$g/kg of body weight for Cd,[42] and in this case, the maximum contribution was 20.1% of the TWI for children and 4.3% for adults. Thus, the dark chocolate consumption might be a significative source of Cd, especially for children.

Although the determination of the total concentrations allowed us to evaluate the maximum levels and tolerable intakes of Cd and Pb, it is important to point out that the evaluation of the risk assessment associated with the ingestion of metallic elements from a food matrix should estimate its bioaccessibility and bioavailability, considering that only a fraction of the ingested element is released from the food matrix into the gastrointestinal tract and is absorbed by humans to finally reach the bloodstream.[21,43,44]

With regard to the presence of Cd and Pb in chocolate samples, the possible sources of contamination include the raw materials used, the manufacturing processes, and the wrappers in which the chocolates are stored. As shown in Table 6, the concentrations of Cd and Pb in chocolates with the same cocoa content were slightly different depending upon the brand, which may be due to the different manufacturing processes used.

To evaluate the relationship between the cocoa content and the concentrations of Cd and Pb in chocolate, five samples with different cocoa contents (ranging from 34 to 85%) from the same brand were analyzed and the measured concentrations were plotted against the cocoa content. The results are shown in Figure 2.

According to the results, a linear correlation exists between the cocoa content and the concentrations of Cd ($R^2$ = 0.907) and Pb ($R^2$ = 0.955), which suggests that the main source of contamination of Cd and Pb in chocolates is the cocoa used in the manufacturing process.

# Metabolite Profiling of Red and White Pitayas (*Hylocereus polyrhizus* and *Hylocereus undatus*) for Comparing Betalain Biosynthesis and Antioxidant Activity

Dong Ho Suh,[†] Sunmin Lee,[†] Do Yeon Heo,[†] Young-Suk Kim,[‡] Somi Kim Cho,[§] Sarah Lee,*[,†] and Choong Hwan Lee*[,†]

[†]Department of Bioscience and Biotechnology, Konkuk University, Seoul 143-701, Republic of Korea

[‡]Department of Food Science and Engineering, Ewha Womans University, Seoul 120-750, Republic of Korea

[§]Faculty of Biotechnology College of Applied Life Sciences, SARI, Jeju National University, Jeju 690-756, Republic of Korea

**ABSTRACT:** Metabolite profiling of red and white pitayas (*Hylocereus polyrhizus* and *Hylocereus undatus*) was performed using gas chromatography−time-of-flight−mass spectrometry and ultraperformance liquid chromatography−quadrupole-time-of-flight−mass spectrometry with multivariate analysis. Different species and parts of pitayas (red peel, RP; white peel, WP; red flesh, RF; and white flesh, WF) were clearly separated by partial least-squares discriminate analysis. Furthermore, betalain-related metabolites, such as betacyanins and betaxanthins, or their precursors were described on the basis of their metabolites. The results of antioxidant activity tests [1,1-diphenyl-2-picrylhydrazyl (DPPH), 2,2′-azinobis(3-ethylbenzothiazoline-6-sulfonic acid) diammonium salt (ABTS), and ferric reducing ability of plasma (FRAP)], total phenolic contents (TPC), total flavonoid contents (TFC), and total betacyanin contents (TBC) showed the following: RP ≥ WP > RF > WF. TPC, TFC, TBC, and betalain-related metabolites were higher in the peel than in the flesh and suggested to be the main contributors to antioxidant activity in pitayas. Therefore, peels as well as pulp of pitaya could beneficially help in the food industry.

**KEYWORDS:** *Hylocereus polyrhizus, Hylocereus undatus, metabolite profiling, GC−TOF−MS, UPLC−Q-TOF−MS, antioxidant activity, betalain biosynthesis pathway*

## INTRODUCTION

Pitayas, commonly known as dragon fruit, belong to the genus *Hylocereus* of the order Caryophyllales. The *Hylocereus* species originate from Latin America and West Indies and are cultivated in the tropical and subtropical regions worldwide. There are several types of pitayas, such as *Hylocereus undatus*, *Hylocereus polyrhizus*, and *Hylocereus megalanthus*. Among them, *H. undatus* and *H. polyrhizus* are the most widely cultivated[1] and have the same red fruit skin color but different flesh colors, white and red, respectively.

Recently, the interest in the natural pigments of plants has increased, because a natural source of pigments is considered nutritionally important in the food processing and pharmaceutical industries, particularly when, in the food industry, red pigments have been commonly used as food additives. Anthocyanins and carotenoids are mainly used, while betalains are less commonly used in food processing.[2] Pitayas contain two betalain pigments, namely, the red−violet betacyanins and yellow−orange betaxanthins.[3] These pigments are biosynthesized from tyrosine by enzymatic and spontaneous chemical reactions.[4] They are water-soluble nitrogen-containing pigments that also contain betalamic acid as the chromophore. Furthermore, betalain pigments have been studied for their antioxidant,[5−7] chemopreventive,[8] and anti-inflammatory activities.[9]

Metabolomics is used to compare the relative differences between biological samples based on their metabolites and changes in their environment. Metabolite analysis commonly involves the use of multiple experimental platforms, including nuclear magnetic resonance (NMR) and mass spectrometry (MS) coupled with separation techniques, such as gas chromatography (GC), liquid chromatography (LC), and capillary electrophoresis (CE).[10] These techniques produce large amounts of data and require data processing analyses, combined with multivariate analysis.[11] Data processing and data analyses affect the quality of metabolite identification and quantification. Data analyses include multivariate analysis, such as the clustering of metabolite profiles or discovering of important differences between groups of samples, which has been used in several previous studies. Metabolite profiling, short-term responses of rice leaves,[11] different-sized *Aloe vera*,[12] and Korean traditional meju during fermentation[13] were assessed using MS-based analysis.

The objective of this study was to investigate the different metabolites in red and white pitayas and compare their antioxidant activities [1,1-diphenyl-2-picrylhydrazyl (DPPH), 2,2′-azinobis(3-ethylbenzothiazoline-6-sulfonic acid) diammonium salt (ABTS), and ferric reducing ability of plasma (FRAP)], total phenolic contents (TPC), total flavonoid contents (TFC), and total betacyanin contents (TBC). Furthermore, we investigated the level of metabolites in the betalain biosynthesis pathway and tried to find major metabolites contributing to antioxidant activity.

## MATERIALS AND METHODS

**Chemicals and Reagents.** Methanol, acetonitrile, hexane, and water were purchased from Fisher Scientific (Pittsburgh, PA). Methoxyamine hydrochloride, *N*-methyl-*N*-(trimethylsilyl)-trifluoroacetamide (MSTFA), formic acid, pyridine, potassium persulfate, ABTS, DPPH, 6-hydroxy-2,5,7,8-tetramethylchromane-2-carboxylic acid (Trolox), 2,4,6-Tris(2-pyridyl)-striazine (TPTZ), iron(III) chloride hexahydrate, sodium acetate, acetic acid, sodium carbonate, sodium hydroxide, naringin, gallic acid, Folin and Ciocalteu's phenol reagent, diethylene glycol, and standard compounds were obtained from Sigma Chemical Co. (St. Louis, MO).

**Plant Materials.** Red and white pitayas (*H. polyrhizus* and *H. undatus*) were collected from a farm near Hallim Park, Jeju Island, in October 2007. All fruits were washed with distilled water and wiped with paper. Fruit was cut into two portions and separated into peel and flesh. Many seeds were embedded in the flesh. Pitaya samples were freeze-dried over 3 days and stored at below −20 °C before experiment. Four biological replications of each red and white pitaya sample were used in this study.

**Sample Preparation.** Freeze-dried samples were powdered using a mortar and pestle. Each ground sample (0.2 g) was extracted with 80% methanol by sonication for 30 min and then using a twist shaker (BioFree, Seoul, Korea) for 6 h at room temperature. After extraction, the extract was centrifuged at 5000 rpm for 15 min at 4 °C (Hettich Zentrifugen Universal 320, Tuttlingen, Germany). The supernatant was filtered through a 0.2 μm polytetrafluoroethylene (PTFE) filter and dried up using a speed vacuum concentrator (Biotron, Seoul, Korea). The final concentration of samples was 10 mg/mL with 80% methanol for ultraperformance liquid chromatography−quadrupole-time-of-flight−mass spectrometry (UPLC−Q-TOF−MS) and liquid chromatography−electrospray ionization−ion trap−tandem mass spectrometry (LC−ESI−IT−MS/MS) analyses. For gas chromatography−time-of-flight−mass spectrometry (GC−TOF−MS) analysis, the dried extracts had to undergo oximation and silylation. The dried extracts were oximated with 50 μL of methoxyamine hydrochloride in pyridine (20 mg/mL) for 90 min at 30 °C using a thermomixer (Eppendorf, Hamburg, Germany). After oximation, silylation was performed with 50 μL of MSTFA for 30 min at 37 °C using a thermomixer. Three analytical replications of each sample were used.

**GC−TOF−MS Analysis.** An Agilent 7890A GC system equipped with an Agilent 7693 autosampler (Agilent, Atlanta, GA) was coupled with a Pegasus HT TOF-MS (LECO Corp., St Joseph, MI). A Rtx-5MS capillary column (30 m × 0.25 mm × 0.25 μm particle size, Restek Corp., Bellefonte, PA) was used with a constant flow of 1.5 mL/min of helium. The front inlet and transfer line temperatures were set at 250 and 240 °C, respectively. The oven temperature was held at 75 °C for 2 min, followed by 300 °C from 2 to 17 min, with a 15 °C/min hold, and a final holding for 3 min. The electron ionization was set at 70 eV, and the mass spectra were recorded over the range of $m/z$ 50−600. A total of 1 μL of derivatized samples was injected into GC−TOF−MS with a split ratio of 20:1.

**UPLC−Q-TOF−MS and LC−ESI−IT−MS/MS Analyses.** UPLC−Q-TOF−MS analysis was performed using a Waters Micromass Q-TOF Premier with an UPLC Acquity system (Waters, Milford, MA) equipped with a binary solvent delivery system, an autosampler, and an ultraviolet (UV) detector. The column selected was an Acquity UPLC BEH $C_{18}$ column (100 mm × 2.1 mm × 1.7 μm particle size, Waters Corp.). The injection volume was 5 μL; the flow rate was 0.3 mL/min; and the column temperature was set at 37 °C. Elution conditions consisted of 0.1% formic acid in water (solvent A) and 0.1% formic acid in acetonitrile (solvent B). The initial condition was 5% solvent B for 1 min, gradually increasing to 100% over 9 min, maintained at 100% B for 1 min, and then decreased to 5% over 3 min. The total run time was 13 min. The Waters Q-TOF Premier (Micromass MS Technologies, Manchester, U.K.) MS data were collected in the range of $m/z$ 100−1000 within negative- and positive-ion modes. The source temperature was 100 °C, and the desolvation gas (nitrogen) was set to 600 L/h at a temperature of 200 °C; the cone gas (nitrogen) was set to 50 L/h. The capillary voltage and cone voltage were set at 2.5 kV and 50 V, respectively. Data were collected with a scan accumulation time of 0.2 s in the centroid mode. Leucine enkephalin (10 ppm) was used as the reference lock mass [$m/z$ 554.2615 (−) and 556.2771 (+)] at a flow rate of 10 μL/min.

LC−ESI−IT−MS/MS analysis was performed using a Varian 500-MS ion-trap mass spectrometer (Palo Alto, CA) equipped with a 212-LC binary solvent delivery system, an autosampler (Prostar 410), and a photodiode array detector (Prostar 335). The column selected was a Varian PurSuit XRs $C_{18}$ column (100 mm × 2.0 mm × 3 μm particle size) with a MetaGuard 2.0 PurSuit XRs $C_{18}$ guard column (Varian, Lake Forest, CA). The injection volume was 10 μL; the flow rate was 0.2 mL/min; and the column temperature was set at 40 °C. Elution conditions consisted of 0.1% formic acid in water (solvent A) and 0.1% formic acid in acetonitrile (solvent B). The initial condition was 10% solvent B for 2 min, which was increased to 40% solvent B at 10 min, then 70% solvent B at 20 min, and 90% solvent B at 25 min, after which was isothermally held for 5 min, and then decreased to 10% B, and maintained for 10 min. The total run time was 40 min. Mass spectra were acquired using electrospray ionization (ESI) over the range of $m/z$ 100−1000 within both negative- and positive-ion modes.

**Data Processing and Multivariate Analysis.** The GC−TOF−MS data were converted into NetCDF format (*.cdf) using the LECO ChromaTOF software (version 4.44, LECO Corp.). The UPLC−Q-TOF−MS data were analyzed with MassLynx software (version 4.1, Waters Corp.), and raw data files were converted to the NetCDF format (*.cdf) using the MassLynx DataBridge (version 4.1, Waters Corp.). After that, the MS data were processed using the MetAlign software package (http://www.metalign.nl) to obtain data containing retention times, normalized peak intensities, and accurate masses. The resulting data were exported to an Excel file, and statistical analysis was performed using SIMCA-P+ software (version 12.0, Umetrics, Umea, Sweden). Partial least-squares discriminant analysis (PLS-DA) was used to compare different metabolites of red and white pitaya samples. Differences in antioxidant activities, TPC, TFC, and TBC were tested by Duncan's multiple-range test using PASW Statistics (version 18.0, SPSS, Inc., Chicago, IL).

**Antioxidant Activity Tests.** The DPPH assay was carried out using the method by Dietz et al.,[14] with some modifications. Each pitaya extract (5 mg/mL, 20 μL) was combined with 180 μL of 0.2 mM DPPH in 80% methanol solution, and the reaction took place for 30 min at room temperature in the dark. Then, the samples were measured at 515 nm using a microplate reader (Thermo Electron, Spectronic Genesys 6, Madison, WI). The ABTS assay procedure followed the method by Roberta et al.,[15] with some modifications. The 7 mM ABTS solution was prepared by mixing with 2.45 mM potassium persulfate solution. Then, the ABTS solution reaction took place for 12 h at room temperature in the dark until it reached a stable state. The ABTS solution was diluted in deionized water to an absorbance of 0.7 (±0.02) at 734 nm. Each pitaya extract (5 mg/mL, 20 μL) was combined with 180 μL of 7 mM ABTS solution for 6 min at room temperature in the dark. After that, the samples were analyzed at 734 nm using a microplate reader. The FRAP assay was carried out using the modified procedure by Benzie and Strain et al.,[16] with some modifications. The FRAP solution, including 10 mM TPTZ and 20 mM ferric chloride, was diluted in 300 mM sodium acetate buffer (pH 3.6) at a ratio of 1:1:10. Each pitaya extract (5 mg/mL, 10 μL) was combined with 300 μL of FRAP solution, and the reaction took place for 6 min at room temperature in the dark. Then, the samples were analyzed at 593 nm using a microplate reader. All assays were performed in triplicate. For each antioxidant activity test, a Trolox aliquot was used to develop a 0.0156−0.5 mM standard curve, and all data were expressed as Trolox equivalents (mM).

**Determination of TPC, TFC, and TBC.** TPC and TFC were determined as described by Singleton et al.,[17] with some modifications. To measure TPC, 20 μL of each sample was combined with 100 μL of 0.2 N Folin and Ciocalteu's reagent placed in 96-well plates for 6 min at room temperature in the dark. Then, 80 μL of 7.5% sodium carbonate solution was added to the 96-well plate. The mixture was allowed to stand for 1 h at room temperature and analyzed at 750 nm using a microplate reader. The results are presented as the gallic acid

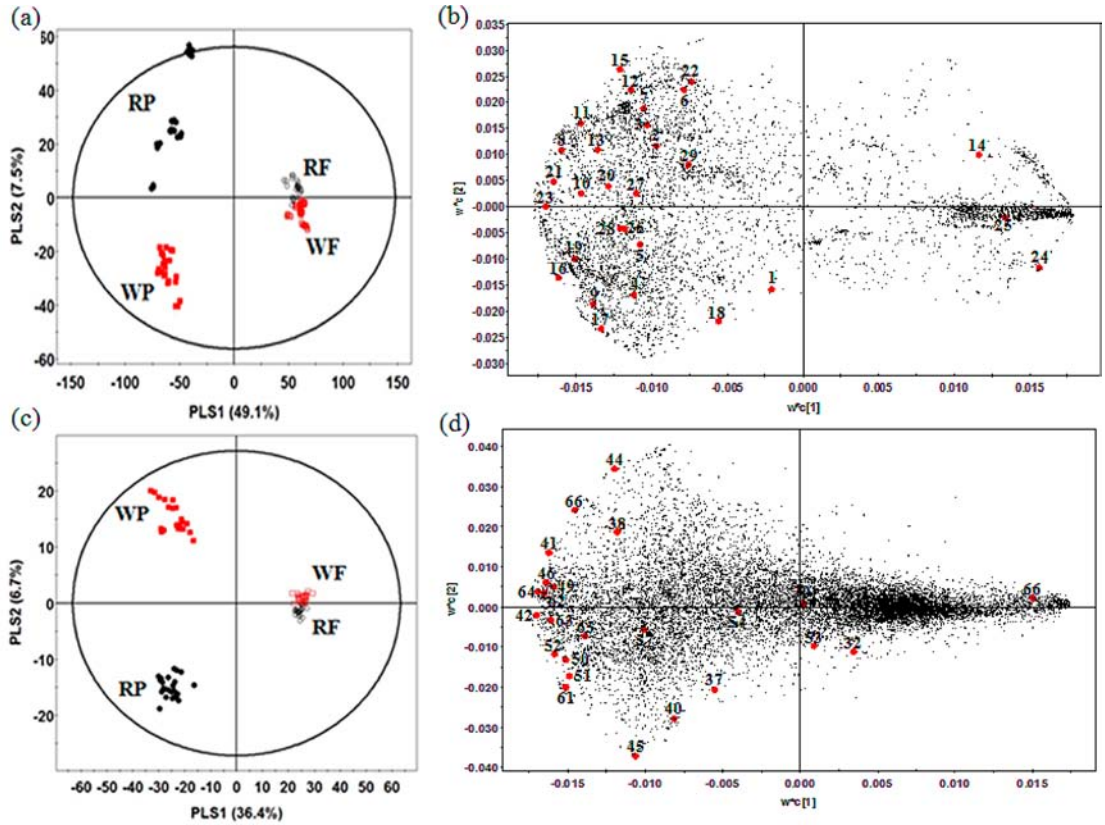

**Figure 1.** PLS-DA score plots and loading plots of red and white pitaya samples analyzed using (a and b) GC−TOF−MS and (c and d) UPLC−Q-TOF−MS. RF, red flesh; WF, white flesh; RP, red peel; and WP, white peel. Loading plot variable numbers are the same as the metabolite numbers shown in Tables 1 and 2.

equivalent concentration (31.25−500 ppm). TFC was measured as follows: 20 $\mu$L of 1 N NaOH, 180 $\mu$L of 90% diethylene glycol, and 20 $\mu$L of each sample were mixed and incubated for 60 min in the dark in 96-well plates. Then, the samples were analyzed at 450 nm using a microplate reader. The results are presented as the naringin equivalent concentration (15.625−200 ppm). TBC was measured using the method by Cai et al.,[18] with some modifications. The pitaya-dried extracts were calculated and expressed as betanin equivalents (mg/100 g of dried extract weight) using the following formula: concentration of betacyanins = $A_{538}(\mathrm{MW})V(\mathrm{DF}) \times 100/\varepsilon LW$, where $A_{538}$ is the absorbance at 538 nm ($\lambda_{max}$), MW = 550, $V$ is the dried extract solution volume (mL), DF is the dilution factor, $\varepsilon$ (molar extinction coefficient) = 65 000, $L$ (path length) = 1.0 cm, and $W$ is the dried extract weight (g). All assays were performed in triplicate.

## RESULTS AND DISCUSSION

**Metabolite Profiling of Red and White Pitaya Samples by GC−TOF−MS and UPLC−Q-TOF−MS.** Different species of pitaya samples were analyzed using GC−TOF−MS and UPLC−Q-TOF−MS with multivariate analyses. The characteristics of the data sets were represented using PLS-DA (Figure 1). The pitaya samples were separated using PLS-DA according to not only the different parts (peel and flesh) but also species (red and white). Metabolite profiling of the samples was used to investigate the different metabolites according to their species (red and white) and parts (peel and flesh). To discriminate significantly different metabolites between different parts and species, variable importance in projection (VIP) of >0.7 and $p$ value of <0.05 were used to select the variables in PLS-DA. The selected variables were identified and presented in loading plots (panels b and d of Figure 1).

According to GC−TOF−MS analysis, the PLS-DA score plot showed the separation of each sample with $R^2X$ = 0.693, $R^2Y$ = 0.98, and $Q^2$ = 0.971 (Figure 1a). The cross-validation results were $R^2Y$ intercept = 0.3687, $Q^2Y$ intercept = −0.464 18, and $p$ value < 0.05. The different parts of pitayas were separated using PLS 1 (49.1%), and the different species were separated using PLS 2 (7.5%). Different metabolites were identified on the basis of their retention times and mass fragmentation in comparison to standard compounds (Table 1). A total of 29 metabolites were present, including 15 amino acids and amines, 4 organic acids, 8 sugars and sugar alcohols, and 2 fatty acids. These metabolites were significantly distinguished between different parts, while ethanolamine (**3**), proline (**4**), serine (**6**), threonine (**7**), aspartic acid (**8**), $\gamma$-aminobutyric acid (GABA) (**9**), glutamic acid (**10**), phenylalanine (**11**), glutamine (**12**), tyrosine (**13**), L-DOPA (**14**), tryptophan (**15**), succinic acid (**16**), fumaric acid (**17**), malic acid (**18**), xylitol (**21**), rhamnose (**22**), and fucose (**23**) were separated on the basis of the species. Primary metabolites are directly involved in fruit growth, development, taste, and reproduction and are also important as the precursors of secondary metabolites.[4,19] In pitayas, several soluble sugars and organic acids affect fruit taste and, thereby, affect fruit quality. In particular, glucose, fructose, and citric acid mainly affected fruit taste.[20] Sugars, such as glucose and fructose, are associated with the sweet taste of fruits,[21] and citric acid is the major compound that contributes to fruit acidity.[22] Amino acids and amines are also responsible for fruit taste and, as betaxanthin precursors, are important for better understanding betalain biosynthesis.[4] Primary metabolites, such as amino acids, organic acids, and fatty acids, were

[a]tR = retention time. [b]Metabolites = metabolites were identified using STD (standard compound) and selected according to VIP > 0.7 and $p$ value < 0.05. [c]Derivatized = TMS, trimethylsilyl; MeOX, methyloxime. [d]Different metabolites separated between peel and flesh from PLS-DA score plot by VIP 1. [e]Different metabolites between red and white pitayas derived from PLS-DA score plot by VIP 2.

relatively higher in the peel than in the flesh (Figure 2). The levels of organic acids, such as succinic acid (**16**), fumaric acid (**17**), malic acid (**18**), and citric acid (**19**), were higher in the peel, while the levels of fructose (**24**) and glucose (**25**) were higher in the flesh. In a previous study, fructose and glucose were the main sugars, and their levels were significantly high in pitaya flesh.[1] The fatty acids stearic acid (**28**) and oleamide (**29**) were detected, and their levels were higher in the peel than in the flesh, in both red and white pitaya. According to a study, red and white pitaya seed oils have essential fatty acids and two oleic acid isomers.[23] Essential fatty acids are important in that they are necessary fatty acids in animal metabolism and cannot be synthesized *in vivo*.[24]

In the UPLC−Q-TOF−MS analysis, the PLS-DA score plot showed the distribution of each pitaya sample (RP, WP, RF, and WF) with $R^2X$ = 0.479, $R^2Y$ = 0.982, and $Q^2$ = 0.959 (Figure 1c). The cross-validation results were $R^2Y$ intercept = 0.3716, $Q^2Y$ intercept = −0.291 94, and $p$ value < 0.05. Different parts and species were separated using PLS 1 (36.4%) and PLS 2 (6.7%), respectively. A total of 37 metabolites were tentatively identified using measured mass, retention time, elemental composition, i-FIT, $MS^n$ fragments, and $\lambda_{max}$ data obtained using UPLC−Q-TOF−MS and LC−ESI−MS/MS by standard compounds and references (Table 2). A total of 17 metabolites, including betanin (**30**), phyllocactin (**32**), betanidin (**38**), lampranthin II (**40**), tricarboxylated hylocerenin (**41**), decarboxylated neohylocerenin (**42**), dehydrogenated, decarboxylated neohylocerenin (**44**), neohylocerenin (**45**), miraxanthin V (**49**), 3-methoxytyramine−betaxanthin (**50**), phenylalanine−betaxanthin (**51**), portulacaxanthin II (**52**), dopamine (**53**), dopamine quinone (**54**), phlorizin (**60**), and two unknown metabolites (**61** and **62**) were significantly different between the parts (peel and flesh), whereas six metabolites, including bidecarboxylated hylocerenin (**46**), L-tryptophan (**57**), and four unknown metabolites (**63**−**66**), were significantly different between the species (red and white). Betalain-related metabolites were divided into three types, such as betacyanins, betaxanthins, and their precursors. Betalains have been important criteria for the classification of members of the order Caryophyllales. These pigments replace the anthocyanins in the plants of most families of Caryophyllales.[4] The structure of betacyanin showed the dihydropyridine moiety with some variations in the acyl groups and sugar moieties, while betaxanthin exhibited the same dihydropyridine moiety but showed conjugation with several amines and amino acids (Figure 3).[25] The maximum

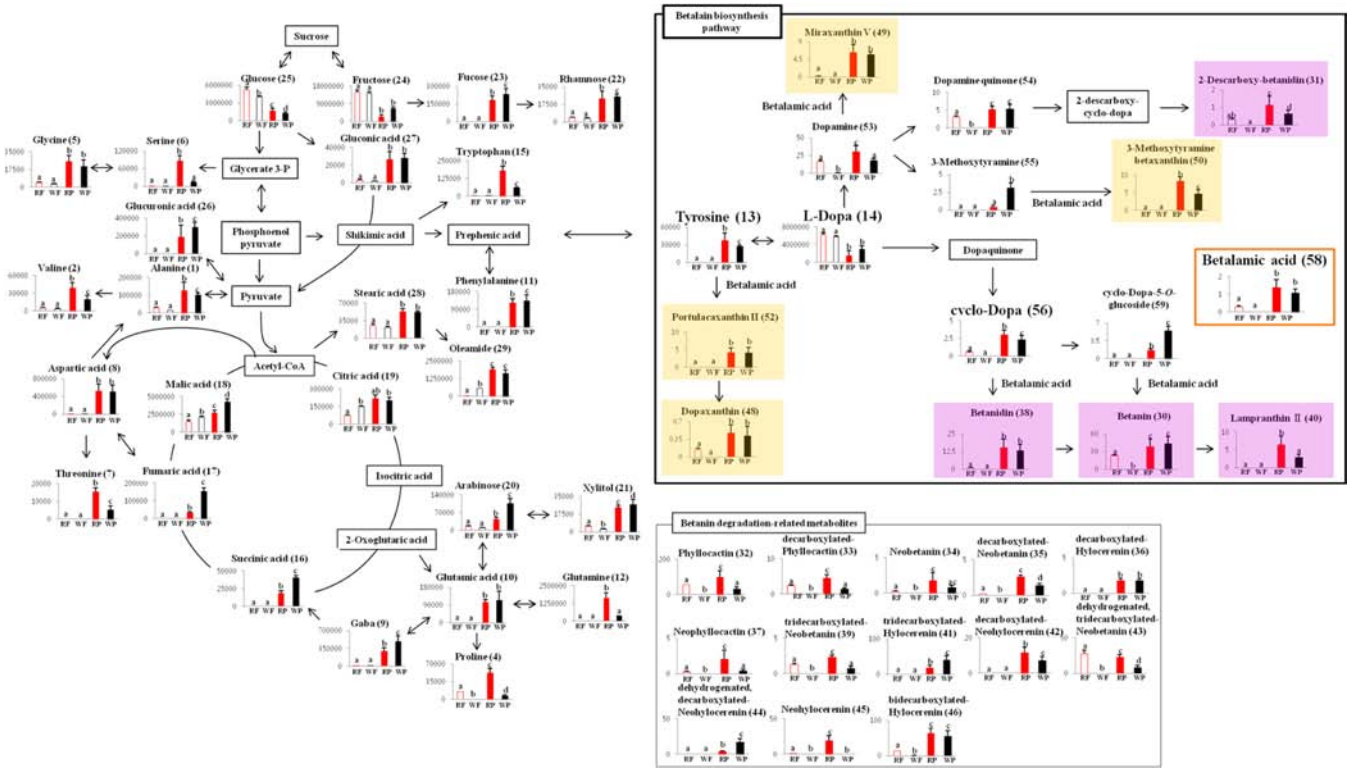

**Figure 2.** Betalain biosynthesis pathway and relative contents of metabolites in different pitaya samples. RF, red flesh; WF, white flesh; RP, red peel; and WP, white peel. The *y* axis of the histogram represents peak areas. Red−violet boxes are betacyanins, and yellow boxes are betaxanthins. Large characters represent the main betalain precursors. Different letters are significantly different by Duncan's multiple-range test. The pathway was modified from the KEGG database (http://www.genome.jp/kegg/).

absorption of betaxanthins varied between 460 and 480 nm, depending upon the structure of the amino acid compound. On the other hand, in comparison to betaxanthins, betacyanins showed a different maximum absorption shift of 50−70 nm because of the aromatic structure of cyclo-DOPA.[26]

**Comparison of Antioxidant Activity Tests (DPPH, ABTS, and DPPH), TPC, TFC, and TBC of Red and White Pitaya Samples.** Several assays, including the antioxidant activity tests (DPPH, ABTS, and FRAP), TPC, TFC, and TBC, were performed using both the red and white pitaya samples (Figure 4). The results of the antioxidant activity tests were as follows: RP ≥ WP > RF > WF. Similar results have been shown in other previous studies as well.[6,7,27] The TPC and TFC results were as follows: RP ≥ WP > RF > WF. The TPC and TFC of the peel of both red and white pitayas were approximately 2- and 3-fold higher than those of the flesh in red and white pitayas. The TBC result was as follows: RP > WP > RF > WF; this result reflects the sample pigment concentration. Pitayas have two betalain pigments, i.e., red−violet betacyanins and yellow−orange betaxanthins.[4] Betacyanins have antioxidant and radical-scavenging activities.[7,27] Furthermore, they contribute to certain oxidative, stress-related disorders.[7] Betaxanthins also have antioxidant activity and are used as food colorants and essential dietary amino acids by the simple technique of semi-synthesis.[28] Recently, several studies on the antioxidant activity of purified betalain-related compounds, such as betanin, decarboxylated betanin, neobetanin, betanidin, indicaxanthin, miraxanthin V, and 3-methoxytyramine−betaxanthin, were evaluated using the DPPH and ABTS assays in plants of the order Caryophyllales.[29−31] Furthermore, the antioxidant activity of betalain pigments has been shown to be higher than that of rutin, ascorbic acid, and catechin, which are known high antioxidant compounds.[32] Cai et al. discussed that betalain molecules were very good electron donors. The position of hydroxyl groups or glycosylation of betalain aglycones and numbers of hydroxyl (−OH) or imino (=NH) groups in the molecular structure led to higher antioxidant activity.[32] In this study, most of the betacyanins (**30**−**46**) were higher in the peel of both pitaya species than in their flesh (Figure 2). These data suggest that there are positive correlations between TPC, TFC, TBC, and betalain-related metabolites and antioxidant activity.

**Betalain Biosynthesis Pathway and Relative Contents of Metabolites in Different Pitaya Samples by GC−TOF−MS and UPLC−Q-TOF−MS Analyses.** To investigate the betalain biosynthesis pathway of different metabolites in red and white pitayas, betalain biosynthesis-related metabolites were obtained using GC−TOF−MS and UPLC−Q-TOF−MS analyses. Several metabolites were detected by target analysis for the supplemented betalain biosynthesis pathway. Each relative level of metabolites was represented by its peak area (Figure 2). According to Figure 2, betalain biosynthesis-related metabolites and their precursors were higher in the peel than in the flesh. To explain the betalain biosynthesis pathway in detail, we used tyrosine and L-DOPA because they are the two important precursors of betalain pigments.[4,33] L-DOPA is converted to betalamic acid, which is an important chromophore of both betacyanins and betaxanthins.[4] Cyclo-DOPA and its derivatives are essential to produce betacyanin. Betanidin, the aglycone of betanin, mediates condensation of cyclo-DOPA with betalamic acid.[4] According to the betanin (**30**) biosynthesized pathway in this study, in most of the

[a]tR = retention time. [b]ID = STD, standard compound; ref, reference. [c]Different metabolites separated between peel and flesh from PLS-DA score plot by VIP 1. [d]Targeted metabolites for the betalain biosynthesis pathway. [e]Different metabolites between red and white pitayas derived from PLS-DA score plot by VIP 2. [f]NI = not identified.

samples, the levels of betalain precursors and aglycone (**13**, **38**, **56**, and **58**), except that of L-DOPA (**14**), were as follows: RP ≥ WP > RF > WF. Several metabolites, such as betanin (**30**), decarboxylated betanin (**31**), phyllocactin (**32**), decarboxylated hylocerenin (**36**), neophyllocactin (**37**), tridecarboxylated neobetanin (**39**), dehydrogenated, decarboxylated neohylocerenin (**44**), bidecarboxylated hylocerenin (**46**), indicaxanthin (**47**), dopaxanthin (**48**), dopamine (**53**), dopamine quinone (**54**), and cyclo-5-*O*-glucoside (**59**), were not present in WF but were identified in other parts (RP, WP, and RF) because they were betalain-related metabolites or their precursors.

Betalamic acid was also condensed with amino acid or amine to give rise to a concentration of betaxanthins.[34] Amino acids, such as alanine, valine, proline, glycine, serine, glutamic acid, phenylalanine, glutamine, tyrosine, and tryptophan, are prerequisites for better understanding betaxanthin biosynthesis.[4] Betaxanthin was higher in the peel than in the flesh of both pitaya samples, because, together with betalamic acid, amino acids, such as alanine (**1**), valine (**2**), proline (**4**), glycine (**5**), serine (**6**), glutamic acid (**10**), phenylalanine (**11**), glutamine (**12**), tyrosine (**13**), and tryptophan (**15**), are condensed and may produce betaxanthins. Citric and ascorbic

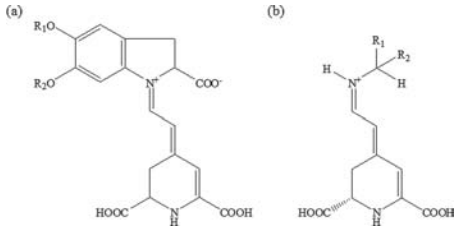

**Figure 3.** Two classes of betalains: (a) betacyanins and (b) betaxanthins. Both groups are condensation products from the precursor betalamic acid. R1 and R2 represent the functional groups (amino acids, amines, sugars, and decarboxyl sugars).

acids were higher in the peel than in the flesh of both pitaya samples. They are used as an additive for betalain stabilization in the food industry.[25,35] As a result, primary metabolites could help in understanding betalain biosynthesis-related metabolites as precursors and the stability of the betalain pigments and providing nutrient information on the different parts.

In conclusion, our study characterized different metabolites according to not only different species (red and white) but also different parts (peel and flesh) of pitayas by metabolite profiling (GC−TOF−MS and UPLC−Q-TOF−MS with multivariate analysis). Furthermore, through the MS-based metabolite profiling, we investigated the different metabolites and their relative contents in both red and white pitayas. The relative contents of primary and secondary metabolites within the betalain biosynthesis pathway were also explained. Thus, primary metabolite analysis could help in understanding betalain biosynthesis and the precursors and explaining the nutrient information on different parts of both pitaya species. Most of the betalain-related metabolites were significantly higher in the peel than in the flesh of pitayas. The results of the antioxidant activity tests (DPPH, ABTS, and DPPH), TPC, TFC, and TBC also showed higher metabolite contents in the peel than in the flesh of pitayas. As a result, betalain-related metabolites were suggested to be the main contributors to antioxidant activity in pitaya samples.

# Delta 5 Fatty Acid Desaturase Upregulates the Synthesis of Polyunsaturated Fatty Acids in the Marine Diatom *Phaeodactylum tricornutum*

**ABSTRACT:** Microalgae are important primary producers in the marine ecosystem and excellent sources of lipids and other bioactive compounds. The marine diatom *Phaeodactylum tricornutum* accumulates eicosapentaenoic acid (EPA, 20:5n-3) as its major component of fatty acids. To improve the EPA production, delta 5 desaturase, which plays a role in EPA biosynthetic pathway, was characterized in *P. tricornutum*. An annotated delta 5 desaturase *PtD5b* gene was cloned and overexpressed in *P. tricornutum*. The transgene was integrated into the genome demonstrated by Southern blot, and the overexpression of *PtD5b* was verified by qPCR and Western blot analysis. Fatty acid composition exhibited a significant increase in the unsaturated fatty acids. Monounsaturated fatty acids (MUFA) and polyunsaturated fatty acids (PUFA) showed an increase of 75% and 64%, respectively. In particular, EPA showed an increase of 58% in engineered microalgae. Meanwhile, neutral lipid content showed an increase up to 65% in engineered microalgae. More importantly, engineered cells showed a similar growth rate with the wild type, thus keeping high biomass productivity. This work provides an effective way to improve the production of microalgal value-added bioproducts by metabolic engineering.

**KEYWORDS:** *microalga, polyunsaturated fatty acid, desaturase, lipid*

## INTRODUCTION

To meet the increasing demand for PUFA (polyunsaturated fatty acid) consumption from human nutrition and animal feed, microalgae, as the main natural producer of PUFAs, have been attracting much attention. The marine diatom *Phaeodactylum tricornutum*, which accumulates eicosapentaenoic acid (EPA, 20:5n-3) as its major component of fatty acids, has been tested for large scale production of EPA.[1] The content of PUFA is a critical criterion in industrial production, and an effective way is to create ideal strains by genetic modification of the biosynthetic pathway.[2] The desaturase and elongase were demonstrated by radiolabeled precursors to be involved in long chain PUFA biosynthetic pathways in the marine microalga *Pavlova lutheri*.[3] Δ5 desaturase, as a rate-limiting enzyme in the synthesis of PUFA, has been studied in some bacteria, fungi, and humans. A human Δ5 desaturase was expressed in Chinese hamster ovary cells and enabled the cells to convert 20:3(n-6) to 20:4(n-6).[4] *Saccharomyces cerevisiae* expressing a Δ5 desaturase from *Paramecium tetraurelia* successfully produced EPA.[5] Though Δ5 desaturase has been studied a great deal; however, so far few studies have focused on its role in PUFA accumulation in microalgae. The current study attempted to effectively improve PUFA accumulation in the diatom by overexpressing endogenous Δ5 desaturase.

## MATERIALS AND METHODS

**Diatom Cultures.** *Phaeodactylum tricornutum* Bohlin (CCMP2561) was used in this study. The diatom was grown in f/2-Si medium which was prepared as f/2 medium by omitting Si and sterilized with 0.22-$\mu$m filters (Millipore, USA). Cultures were grown at (21 ± 0.5 °C) in 15h/9h (light/dark). To detect the growth of microalgae, cells were counted with a hemacytometer.

**Cloning of PtD5b and Generation of Transgenic Diatoms.** An amino acid sequence homologous with putative PtD5b was searched by BLAST at NCBI (http://blast.ncbi.nlm.nih.gov/Blast/) and aligned with Clustal Omega (http://www.ebi.ac.uk/Tools/msa/clustalo/). The phylogenetic tree of PtD5b was constructed by using software MEGA. Genomic DNA of *P. tricornutum* was extracted with a HP Plant DNA Kit (Omega, USA). The full-length cDNA of Δ5 desaturase gene in *P. tricornutum* (*PtD5b*) (GenBank accession: XM_002182822.1) was amplified by PCR using primers: Pt61inf (5′-TTACAATCCAGTGGTACCATGGACGTGTCGTTACGGA-3′) and Pt62inf (5′-TTTTGTTCCAGGTGTTCCAATTTGGTAA-TTGCGTCC-3′). The PtD5b was cloned into plasmid pHY18 by infusion ligation, and the resultant plasmid was introduced into *P. tricornutum* by electroporation using Bio-Rad GenePulserXcell apparatus (Bio-Rad, USA) according to Niu et al.[6]

**Neutral Lipid Content and Fatty Acid Composition Analysis.** Neutral lipid content in diatom cells was analyzed by Nile red staining according to Yang et al. with modifications.[1] Cell cultures in the stationary phase were first treated with 20% DMSO for 20 min at room temperature. Then 30 $\mu$L of Nile red (0.1 mg/mL in acetone) was added to a 3 mL aliquot of pretreated cell culture in triplicates, mixed by rapid inversion, and incubated in darkness for 20 min at room temperature. The stained cells were transferred to a 96-well plate for the detection of fluorescence intensity with a F4600 microplate reader (Hitachi, Japan). The wavelengths used were the following: excitation at 530 nm and emission at 580 nm. The relative fluorescence intensity values provided a quantitative comparison of neutral lipid contents between samples. Total lipids of microalgae were extracted and analyzed by gas chromatography−mass spectrometry (GC−MS) according to Yang et al.[1] To determine the content of EPA and DHA at dry cell weight (DCW), 150 $\mu$L of *N*-nonadecyl ester (1 mg/mL) was added as an internal standard to the samples for analysis of fatty acid composition by gas chromatography−mass spectrometry (GC−MS). Fatty acid concentration ($C_{FA}$,mg/g) was calculated by comparing the peak area of fatty acid in the sample with the peak area of internal standard (*N*-nonadecyl ester) according to the following equation: $C_{FA} = A_S/A_{IS} \times C_{IS}/W_S$, where *A* indicates peak area; *C*, concentration; *W*, weight; IS, internal standard; S, sample.[7] Three parallely grown cultures were used for the above assays, and the results were tested by one-way ANOVA analysis and *t*-test.

**Detection of PtD5b Expression in Transgenic Microalgae by Molecular Approaches.** PtD5b mRNA expression was verified by

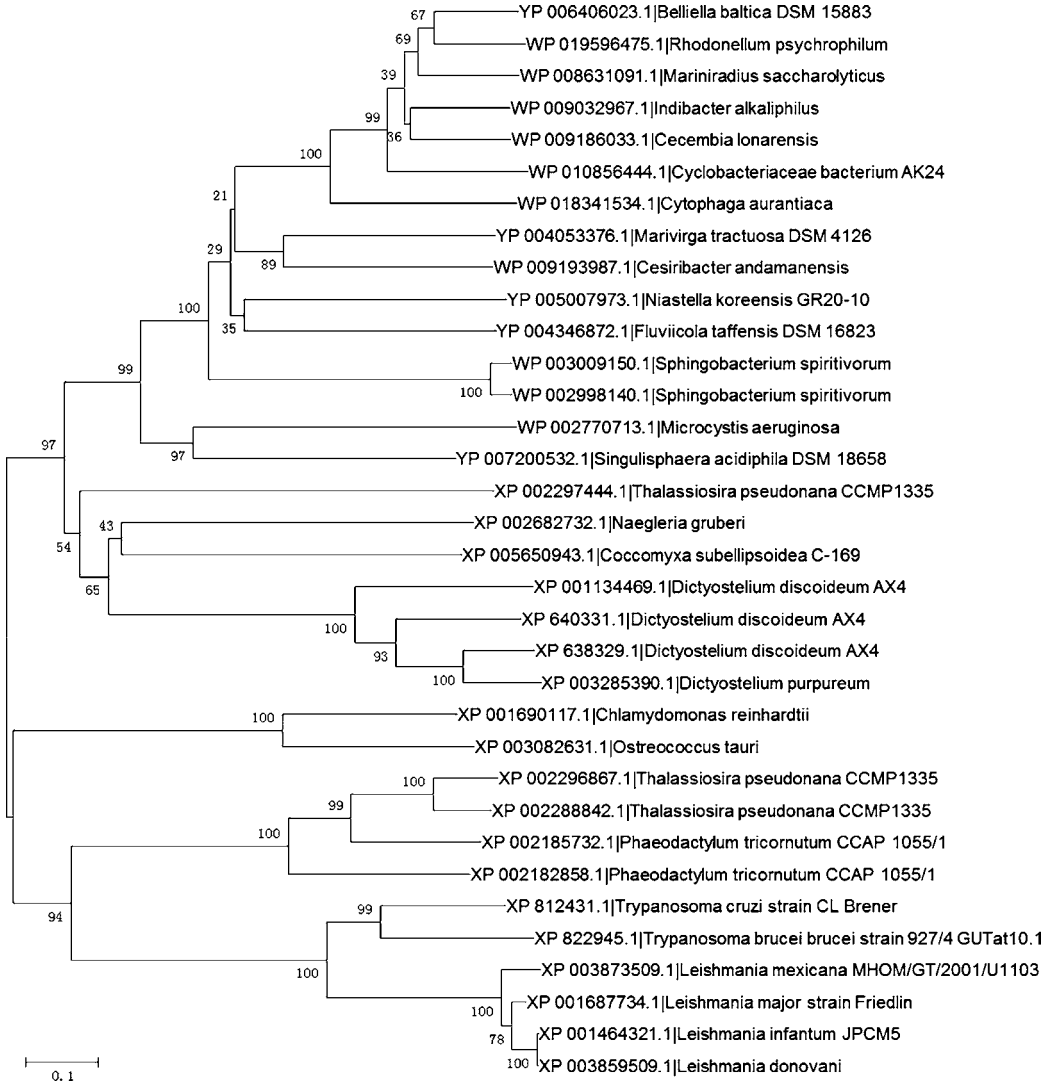

**Figure 1.** Phylogenetic relationships of PtD5b with related species. Amino acid sequences of fatty acid desaturases from various species retrieved from BLAST were analyzed with MEGA5.

quantitative real-time PCR (qPCR), and relative expression levels of PtD5b gene were calculated by normalization against the expression of *β*-actin. Primers used for qPCR were as follows: PtD5b (Forward primer: CATCACGGACCCAATCAATAC, Reverse primer: CGACGGACAATCTGGAAGAC); *β*-actin (Forward primer: AGGCAAAGCGTGGTGTTCTTA, Reverse primer: TCTGGGGAGCCTCAGTCAATA). To verify the foreign gene integration into the genome, Southern blot was performed with a fragment of CAT to prepare a DIG-labeled probe. PtD5b protein expression was detected by Western blot analysis using an anti-Myc antibody (Invitrogen). GAPDH was used as internal housekeeping control. Algal cell cultures in the stationary phase were used in the above assays.

## RESULTS AND DISCUSSION

**Prediction and Subcellular Localization of Δ5 Desaturase.** Phylogenetic tree of retrieved sequences homologous to the annotated *P. tricornutum* Δ5 desaturase (PtD5b) was initially constructed to verify its functional annotation. As shown in Figure 1, PtD5b had a close relationship with the other annotated Δ5 fatty acid desaturase (PtD5p) from *P. tricornutum* and that from the marine diatom *Thalassiosira pseudonana*,[8] and they were clustered into one group. PtD5b also exhibited a high homology with those Δ5 fatty acid desaturases from protozoa including *Trypanosoma* and *Leishmania* and microalgae species including *Chlamydomonas* and *Ostreococcus*.

Proteins are targeted to specific subcellular locations for their proper function.[9] According to software Target P ver1.1 (http://www.cbs.dtu.dk/services/TargetP/), a signal peptide was predicted in PtD5b (with a possibility of 0.318). According to software Cell-PLoc 2.0 (http://www.csbio.sjtu.edu.cn/bioinf/Cell-PLoc-2/), the subcellular localization of PtD5b was predicted to be the endoplasmic reticulum (ER). The most likely location was also predicted to be the ER (possibility of 77.8%) by software PSORT II, followed by the cytoplasm (11.1%) and the plasma membrane (11.1%). Taken together, PtD5b could be predicted to target to the ER.

**Growth and Neutral Lipid Analysis of Transgenic *Phaeodactylum tricornutum*.** The neutral lipid content was determined by Nile red fluorescence staining and indicated as the relative fluorescence intensity. As shown in Figure 2A, a significant increase of 24% in neutral lipid content was detected in transgenic line PtD5b-1 compared to the wild type ($P < 0.01$). A much more significant increase of 65% in neutral lipid content was detected in transgenic line PtD5b-2 ($P < 0.01$).

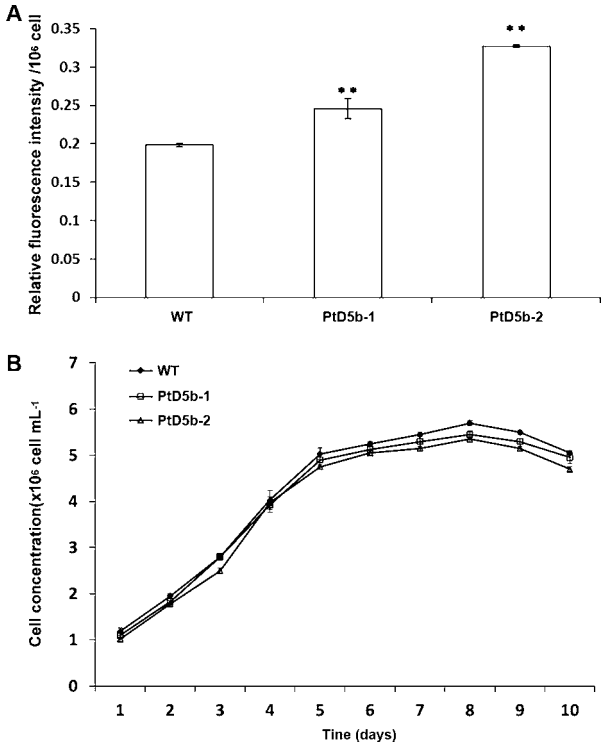

**Figure 2.** Neutral lipid content and growth of transgenic microalgae. a) Neutral lipid content. ** indicates extremely significant difference ($p < 0.01$). b) Growth curves.

The results demonstrated that overexpression of PtD5b could promote neutral lipid accumulation in *P. tricornutum*. This could be due to the overproduction of PUFA thus subsequently promoting the upstream biosynthetic pathways of fatty acids. The growth properties of transgenic cells were also examined. As shown in Figure 2B, transgenic and wild type microalgae showed quite similar growth curves. Cells started to reach the stationary phase at the sixth day after subculture. The results indicated that overexpression of PtD5b could induce the increase in neutral lipid content without compromising the growth properties.

**Fatty Acid Composition.** Marked changes in fatty acid composition were detected by GC-MS analysis in transgenic microalgae (Figure 3). Monounsaturated fatty acids (MUFAs) showed a significant increase of 75%, whereas polyunsaturated fatty acids (PUFAs) showed an increase of 64%. In particular, EPA (C20:5) showed an increase of 58% in transgenic microalgae, reaching up to 38.9 mg/g of dry cell weight. The results demonstrate that overexpression of PtD5b could successfully promote the synthesis of PUFAs. The proportions of saturated fatty acids (SFA) decreased by 16% in transgenic line PtD5b-1, suggesting that overexpressed PtD5b could redirect the flux of fatty acids toward the biosynthetic pathway of PUFA. Moreover, 0.44 mg/g DHA was detected in transgenic algae, while not detected in the wild type. Results implicated that *P. tricornutum* might lack suitable enzyme system or enough enzymatic activities of desaturase and/or elongase which are indispensable for the biosynthesis of DHA. Thus, further study is needed to investigate the key enzymes involved in DHA synthesis in *P. tricornutum*.

**Molecular Analysis of PtD5b Expression Transgenic Microalgae.** The transcript abundance of PtD5b in transgenic microalgae was determined by qPCR (Figure 4A). It showed a

significant increase in the transgenic lines compared to the wild type, with a similar increase of 3.2-fold in both transgenic lines PtD5b-1 and PtD5b-2. The protein expression of introduced PtD5b in transgenic lines were detected by Western blot analysis with an anti-Myc antibody (Figure 4B). A specific cross-reacting band was present in transgenic lines, while no similar band was present in the wild type. These results indicated that the introduced PtD5b significantly increased both mRNA and protein expression of PtD5b.

Gene integration in the transgenic microalgae was verified by genomic Southern blot analysis in the overall better transgenic line PtD5b-2. As shown in Figure 4C, two hybridized bands detected with the CAT probe were present in the transgenic microalgae, whereas no band was present in wild type, demonstrating the integration of two copies of the transgene in the genome of transgenic line PtD5b-2.

In the current study, overexpression of PtD5b in *P. tricornutum* resulted in a significant increase in the unsaturated fatty acids. Further studies such as cotransformation of other key genes and transcriptional regulation can be conducted to achieve even higher PUFA productivity. This study has paved a way to engineer microalgae for sustainable production of value-added bioactive compounds.

Supporting Information

**ABSTRACT:** Mung bean plants were grown under controlled conditions and supplemented with macro- and micronutrients. The objective of this study was to determine the response of manganese nanoparticles (MnNP) in nitrate uptake, assimilation, and metabolism compared with the commercially used manganese salt, manganese sulfate (MS). MnNP was modulated to affect the assimilatory process by enhancing the net flux of nitrogen assimilation through NR-NiR and GS-GOGAT pathways. This study was associated with toxicological investigation on in vitro and in vivo systems to promote MnNP as nanofertilizer and can be used as an alternative to MS. MnNP did not impart any toxicity to the mice brain mitochondria except in the partial inhibition of complex II−III activity in ETC. Therefore, mitochondrial dysfunction and neurotoxicity, which were noted by excess usage of elemental manganese, were prevented. This is the first attempt to highlight the nitrogen uptake, assimilation, and metabolism in a plant system using a nanoparticle to promote a biosafe nanomicronutrient-based crop management.

**KEYWORDS:** *manganese nanoparticles, nitrogen metabolism, manganism, mitochondrial dysfunction*

## INTRODUCTION

Nitrogen assimilation is a vital process controlling plant growth and development. Plants biosynthesize both the suite of nitrogenous compounds that are present in all living organisms and many chemical species unique to plants. The most important and rate-limiting step is the assimilation of inorganic nitrogen into organic metabolites catalyzed by a series of enzymes through a high-flux process subjected to extensive regulation in all plants.[1] Nitrogen moves along a complex branching and merging pathway, which interacts at numerous sites with the carbon flow, pH regulation, and ions, assimilating flow at the cell within whole plant level. Superimposed on these metabolic fluxes, nitrate and nitrogen metabolism influences plant development and architecture including changes in root physiology, the timing of senescence, and flowering.[2] The largest requirement of nitrogen is the synthesis of amino acids, which function as the building blocks of proteins as well as precursors to many other metabolites. It is also prerequisite to nucleic acid, which is a cofactor to many physiological processes and a major component of chlorophyll.[3] In addition, several plant hormones contain nitrogen and/or nitrogenous precursors.[4] Plants can take up nitrogen from soil by roots in the form of nitrate ion ($NO_3^-$) and utilize it in nitrogen metabolism. Assimilation of $NO_3^-$ requires subsequent uptake, reduction, and conversion of $NO_3^-$ to ammonium ion ($NH_4^+$) and incorporation to organic compounds.[5] However, the availability of nutrients including nitrogen within the plant system is the limiting factor for its productivity. Henceforth, greater attention is demanded for crop improvement within the realm of nitrogen metabolism in both nodulated and non-nodulated plants. Presently several nanoparticles have been designed to work in agricultural industry by changing their size, shape, and surface functionality. Most of the works demonstrated the improvement of the biocidal activity of a compound so that it can break the resistance of pests and fungi,[6−9] whereas others showed detrimental roles in plant physiology and growth.[10,11] Little attention has been paid in crop improvement to modulating the structural or functional properties of existing plant nutrients for the atonement of plant nutritional deficiency. It has already been established that plant cells have the capacity to execute active transport of $NH_4^+$ during nitrogen assimilation. Some literature has shown that low availability of $NO_3^-$ concentration results from the decrease in the rate of nitrogen assimilation in acidic soil.[12] Meanwhile, manganese salt (Mn), as a fertilizer for nitrogen metabolism, has been used in acidic soil for many years, which also influences the assimilatory process as a cofactor.[13]

In this context, we introduce manganese nanoparticles (MnNP) within the framework that is already known to modulate the photochemical pathways in photosynthesis even better than its elemental/bulk counterpart.[14] MnNP increase the

ACS Publications © 2014 American Chemical Society

activity of the electron transport chain by binding with the CP43 protein chain of photosystem II.[14] They also enhance the oxygen evolution process, being a part of the water splitting complex in light reaction of photosynthesis; as a consequence, photophosphorylation capacity is improved, too.[14] MnNP thus improve the photosynthetic ability of the plants, thereby producing more sugar, and can be useful in the agricultural sector for the improvement of plant productivity. As an afterthought, we have tried to investigate the route of nitrate uptake, assimilation, ammonium assimilation, and further downstream nitrogen metabolism in both source and sink tissues of legumes using MnNP to abate the problems of nitrogen metabolism. Thereafter, nitrogen reductase protein has been isolated from leaf tissue of treated plants followed by protein profiling and Western blot analysis to evaluate the mode of action of MnNP in accelerated nitrogen assimilation. Interestingly, MnNP are found to be more effective by both biochemical and molecular techniques in nitrogen assimilation and metabolism in contrast to their bulk counterpart, manganese sulfate (MS). To the best of our knowledge this is the first effort to use MnNP in the process of nitrogen metabolism for beneficial crop management study.

Mn is an essential trace element for human nutrition but also a toxicant at high concentration. Therefore, its biosafety impact has to be evaluated in light of in vivo experimentation for future research and development studies. As a consequence, MnNP have been injected intravenously to Swiss albino mice, and after 15 days of observation, the animals were sacrificed for biosafety studies following standard guidelines. Mn is also known to induce mitochondrial dysfunction and causes neurotoxicity, called manganism.[15] Manganism is characterized by neuropsychiatric symptoms and extrapyramidal dysfunction such as hypokinesia, rigidity, and tremor that often resembles Parkinson's disease.[16] Therefore, detailed toxicity profiling of MnNP is required related to mitochondrial dysfunction and neurotoxicity; as a result, the effect of MnNP in energy metabolism and ETC activity in isolated brain mitochondria has been assessed. Biosafety studies with newly synthesized engineered nanoparticles are important because they may be found to be hazardous for biological systems; if it is related to the agricultural sector, then it is necessarily obligatory to profile the entire biosafety experiments, which ensure the complete screening of the particles in mammalian systems. In a recent work MnNP have been found to decimate the level of dopamine, imparting mitochondrial dysfunctioning and generation of more ROS in vivo as a result of metal toxicity in PC-12 cells such as free $Mn2^{+}$ ions.[17] Besides, there are several studies on metal toxicity performed in cell lines[18−20] and mammalian systems[21−24] to access the biological importance and environmental hazard measurements. In our previous paper we have reported that our custom-made MnNP are biosafe on the basis of acute oral toxicity parameter, although detailed research is explicitly demanded for its future endeavor in agricultural sectors. Herein, histopathological analysis of MnNP-treated mice is performed after intravenous injection with emphasis on brain mitochondrial toxicity studies. A series of detailed in vitro and in vivo studies including studies on human lymphocytes, hemolysis, and murine model system with an emphasis on brain mitochondria has been carried out. Our studies reveal that severe toxicity symptoms are avoided in the treated sets with minor alterations noted in complex II−III activity in ETC. Excess oxidative stress, severe mitochondrial dysfunction, and neurotoxicity are avoided, thereby paving the way toward the development of a biosafe crop management study based on nitrogen assimilation and metabolism with the aid of MnNP.

## MATERIALS AND METHODS

**Characterization of MnNP.** Custom-made manganese nanoparticles were purchased from MK Implex, Canada. The surface morphology was determined by field emission scanning electron microscope (FESEM; FEI Quantum-200 MK-2), and particle size was observed through a transmission electron microscope (TEM) (JEOL 2010). Surface topology of MnNP was obtained using atomic force microscopy (AFM). Hydrodynamic size distribution was obtained by dynamic light scattering (DLS) spectroscopy.

**Experiments with Plant Model System.** Seeds of mung bean (*Vigna radiata*) were purchased from Berhampur Pulse and Oil Research Centre, West Bengal. These seeds were selected from Chaiti mung. Seeds were soaked in 5% sodium hypochloride solution for surface sterilization and imbibed with the treatment solutions (control; MnNP, 0.05, 0.1, 0.5, and 1 mg/L; MS, 0.05, 0.1, 0.5, and 1 mg/L) for a minimum of 4−6 h prior to germination for various analyses. After 24 h of germination, seeds were planted in pots filled with perlite supplemented with Hoagland's solution with or without manganese solution (control plants were treated without manganese solution) for 15 days in a growth cabinet (GC-300, Lab companion) with 14 h daytime temperature of 25 °C and night temperature of 20 °C at a relative humidity of 40−60% and a light intensity of 440 $\mu$mol/m$^2$/s. After 15 days of treatments, plants were uprooted and used to carry out further experiments.

**Preparation of Leaf and Root Enzyme Extract for the Assays of Nitrogen Metabolism.** Plant samples were ground with a ratio of 1:10 (w/v) in 50 mM phosphate buffer (pH 7.5) containing 2 mM EDTA, 1.5% (w/v) soluble casein, 2 mM DDT, and 1% (w/v) insoluble PVPP at cold. The homogenate was filtered and centrifuged at 3000*g* for 5 min. Supernatant was then centrifuged at 30000*g* for 20 min. The extract was then used for enzymatic assays.

*Determination of $NO_3^-$.* Enzyme extract was added to 10% salicyclic acid solution dissolved in 12 N sulfuric acid (w/v). $NO_3^-$ content was measured as described by Cataldo et al.[25] The results were expressed as micromoles per gram of fresh weight.

*Determination of Nitrate Reductase (NR) Activity.* The reaction mixture contained 100 mM phosphate buffer (pH 7.5), 100 mM $KNO_3$, 10 mM cysteine, 2 mM NADH, and enzyme extract. After 30 min of incubation at 30 °C, reaction was stopped by 1 M zinc acetate. The nitrite formed was determined at 540 nm after azocoupling with sulfanilamide and naphthylethylenediamine dihydrochloride. The NR activity was expressed as micromoles of $NO_2^-$ formed per gram fresh weight per hour.

*Determination of Nitrite Reduction (NiR) Activity.* The reaction mixture contained 50 mM phosphate buffer (pH 7.5), 20 mM $KNO_2$, 5 mM methyl viologen (MV), 300 mM $NaHCO_3$, and enzyme extract. After 30 min of incubation at 30 °C, NiR activity was determined by the disappearance of $NO_2^-$ from the reaction medium and expressed as micromoles of $NO_2^-$ per gram of fresh weight per hour.

*Determination of Glutamine Synthetase (GS) Activity.* Enzyme extract was mixed with the reaction mixture containing 100 mM phosphate buffer (pH 7.5), 4 mM EDTA, 1 M sodium glutamate, 450 mM $MgSO_4{\cdot}7H_2O$, 300 mM hydroxylamine, and 100 mM ATP. Two controls were prepared, one without glutamine and another without hydroxylamine, and all of the treatments were incubated for 30 min at 28 °C. The formation of glutamylhydroxamate was measured at 540 nm after complexing with acidified ferric chloride. GS activity was expressed as formed glutamylhydroxamate in grams of fresh weight per hour.

*Determination of NADH-Glutamate Synthase (GOGAT) Activity.* The reaction mixture contained 50 mM phosphate buffer (pH 7.5) with 0.1% (v/v) mercaptoethanol, 1 mM EDTA, 18.75 mM 2-oxoglutarate, 15 mM aminoxyacetate, 1.5 mM NADH, 75 mM L-glutamine, and enzyme extract. Two controls, without ketoglutarate and without glutamine, were used to correct for endogenous NADH oxidation. The decrease in absorbance was recorded for 5 min at 28 °C. The activity was expressed as micromoles of NAD per gram fresh weight per hour.

*SDS-PAGE and Western Blot of Isolated NR Protein.* NR protein was purified from mung bean leaves following a standard procedure.[26] NR protein was dissolved in a buffer containing 0.09% (w/v) *n*-decyl-β-D-maltopyranoside (β-DM), 20 mM NaCl, 70% (v/v) glycerol, and 20 mM HEPES (pH 7.5). After isolation of the protein, 12% SDS-PAGE was performed using a Bio-Rad protein gel apparatus, and subsequent Western blot analysis was also carried out by using NR antibody (Agrisera).

**Experiments with Mouse Model System.** Healthy young nulliparous, Swiss albino mice (average body weight = 20 g) of 8 weeks of age were kept in the animal house at 22 ± 2 °C), 60 ± 10% relative humidity, and 12 h light/dark cycle. The animals were kept in clean polypropylene cages and were provided with commercial rat pellet diet and deionized water. After 7 days of acclimatization, the mice were randomly assigned to control and treatment groups. There were five mice of each sex in each group. Water as control and MnNP as treatment were injected intravenously, and animals were weighed before and after the completion of the experiment. The animals were kept under close observation for 14 days. Skin and fur changes, eye secretion, and behavior patterns of the mice were observed. Special attention was paid to the clinical signs of toxicity including tremors, convulsions, salivation, nausea, vomiting, diarrhea, lethargy, etc. At the end of 14 days, they were sacrificed. Blood and serum from control and treated mice were analyzed for total count (TC), differential count (DC), platelet count (PLT), lactate dehydrogenase (LDH), creatinine, alkaline phosphatase (ALP), total protein (TP), cholesterol, triglyceride (TG), uric acid, blood urea nitrogen (BUN), serum glutamic oxaloacetic transaminase (SGOT), serum glutamic pyruvic transaminase (SGPT), and phosphorus. Brain, heart, lungs, liver, stomach, kidney, spleen, uterus, and testis were carefully removed and fixed in 10% formalin solution containing neutral phosphate-buffered saline (PBS). Thereafter, the organs were embedded in paraffin, stained with eosin−hematoxylin, and examined under a light microscope.

*Isolation of Mice Brain Mitochondria.* Mouse brain mitochondria (after 24 h of treatment) were isolated by a method based on differential centrifugation with digitonin treatment. The final mitochondrial pellet was suspended in isotonic buffer A (145 mM KCl, 50 mM sucrose, 1 mM EGTA, 1 mM magnesium chloride, 10 mM phosphate buffer, pH 7.4) and used immediately for the experiments related to measurement of membrane potential and phosphorylation capacity.[27] For the measurement of activity of respiratory complexes, the mitochondrial pellet was suspended in 50 mM phosphate buffer, pH 7.4, stored at 20 °C, and used within 3 days.

*Measurement of Transmembrane Potential of Mouse Brain Mitochondria.* Mitochondrial transmembrane potential was measured by using a mitochondrial membrane potential sensitive carbocyanine dye, 5,5′,6,6′-tetrachloro-1,10,3,30-tetraethylbenzamidazolocarbocyanine iodide (JC-1). When excited at 490 nm, the monomeric form of JC-1 had an emission maximum at 527 nm, but the aggregated form (J-aggregates) showed an emission maximum at 590 nm. Briefly, an aliquot of mitochondria (control or MnNP treated) was incubated at 37 °C for 30 min in isotonic buffer A containing 10 mM pyruvate, 10 mM succinate, and 1 mM ADP in the presence of 5 μM JC-1. At the end of the incubation, the dye-loaded mitochondria were collected by centrifugation and resuspended in the same buffer in appropriate dilution, followed by the measurement of fluorescence intensity ($\lambda_{ex}$ 490 nm, $\lambda_{em}$ 590 nm) in a spectrofluorometer.

*Measurement of Phosphate Utilization of Mitochondria.* In a total volume of 250 μL, an aliquot of 25 μL of mitochondrial suspension from control or MnNP-treated mitochondria was diluted into a medium containing 125 mM KCl, 75 mM sucrose, 0.1 mM EGTA, 1 mM $MgCl_2$, 10 mM HEPES, 2 mM phosphate, 0.3% bovine serum albumin, 0.5 mM ADP, 5 mM pyruvate, 10 mM succinate, and 10 mM glucose, followed by the immediate addition of 5 units of hexokinase, and the incubation was continued at 37 °C for 30 min. The incubation was terminated by the addition of 5% ice-cold trichloroacetic (TCA) acid, and the amount of inorganic phosphate was estimated spectrophotometrically. A 0 min sample was also assayed for inorganic phosphate content where hexokinase addition was immediately followed by treatment with 5% ice-cold TCA. Glucose and hexokinase in the reaction mixture acted as a trap for ATP to maintain the level of ADP in the system and also to prevent the release of free inorganic phosphate from ATP by the action of various phosphatases.

*Measurement of Respiratory Chain Activity of Isolated Brain Mitochondria after MnNP Treatment.* The activity of NADH−ferricyanide reductase (complex I) was assayed by using ferricyanide as the electron acceptor in a system containing 0.17 mM NADH, 0.6 mM ferricyanide, and Triton X-100 (0.1% v/v) in 50 mM phosphate buffer, pH 7.4, at 30 °C. The reaction was initiated by the addition of mitochondrial suspension (10−30 μg of protein) to the sample cuvette, and the rate of oxidation of NADH was measured by the decrease in absorbance at 340 nm.

The activity of succinate cytochrome *c* reductase (complex II−III) was assayed by following the succinate-supported reduction of ferricytochrome *c* to ferrocytochrome *c* at 550 nm in an assay mixture containing 100 mM phosphate buffer, 2 mM succinate, 1 mM KCN, 0.3 mM EDTA, and 1.2 mg/mL cytochrome *c* in a total volume of 1 mL. The reaction was initiated by adding mitochondrial suspension (10−30 μg) into the sample cuvette.

The activity of cytochrome *c* oxidase (complex IV) was assayed by measuring the rate of decrease in absorbance at 550 nm at room temperature following the oxidation of reduced cytochrome *c* (50 μM) in 10 mM phosphate buffer, pH 7.4. Ferricyanide (1 mM) was added to oxidize ferrocytochrome *c* in the blank cuvette and the reaction initiated in the sample cuvette by the addition of mitochondrial suspension (10−30 μg). The activity of the enzyme was calculated from the first-order rate constant.

*(a) Measurement of Mitochondrial Respiratory Control Ratio (RCR).* Polarographic study of oxygen consumption using freshly isolated mitochondria allows measurement of respiratory control ratios (RCR) calculated as the ratio of state III to state IV. The chamber of the oxygraph was filled with fresh respiratory buffer along with ADP, glutamate, pyruvate, maleate, succinate, and DNP. A low (state IV) oxygen consumption rate was achieved. After that, 100−200 nmol with or without treated mitochondria was added for inducing state III respiration. After 2 min, the data were recorded, and RCR was calculated accordingly.

*(b) Measurement of Reactive Oxygen Species (ROS).* ROS generation in treated and untreated brain was determined using the nitrotetrazolium blue (NBT) reduction assay.[28] The assay is based on the reduction of yellow water-soluble NBT powder to a blue insoluble substance upon reduction. The treated and control brains were incubated in NBT solution for 1 h. The reaction was stopped by the addition of acetic acid solution. After centrifugation (1 min, 12000*g*), intracellular reduced content was solubilized by adding 50% (v/v) acetic acid to the cell pellet followed by vortexing for 5 min. Cell debris was then pelleted, and the absorbance of the supernatant was determined at 595 nm using a UV−vis spectrophotometer.

*(c) Protein Estimation.* The protein was estimated after the membranes had been solubilized in 1% SDS according to Lowry's method.

**Experiments with Lymphocytes.** *Isolation of Lymphocyte from Blood.* Human peripheral blood was obtained by venipuncture from healthy volunteers into heparinized vacutainers. Lymphocytes were isolated from fresh blood according to the method of Boyum et al.[29] with some modifications using Histopaque.[30] The cells were washed with PBS and resuspended in RPMI-1640 medium at a concentration of $10^6$ cells $mol^{-1}$ for further use.

*Treatment of Lymphocytes.* Freshly isolated human lymphocytes were treated with different concentrations of MnNP and incubated for at least 3 h at 37 °C in RPMI-1640 medium. After incubation, cytotoxicity studies were carried out with treated lymphocytes.

*(a) Cell Proliferation Assay (WST).* The number of mononuclear cells remaining alive after reacting with the cellular mitochondrial dehydrogenase could be quantified by using a Biovision cell proliferation assay kit by measuring the absorbance of the dye solution at 440 nm. The formazan dye is produced by the breakdown of tetrazolium salt, and the amount of dye generated by the activity of dehydrogenase was directly proportional to the number of living cells.

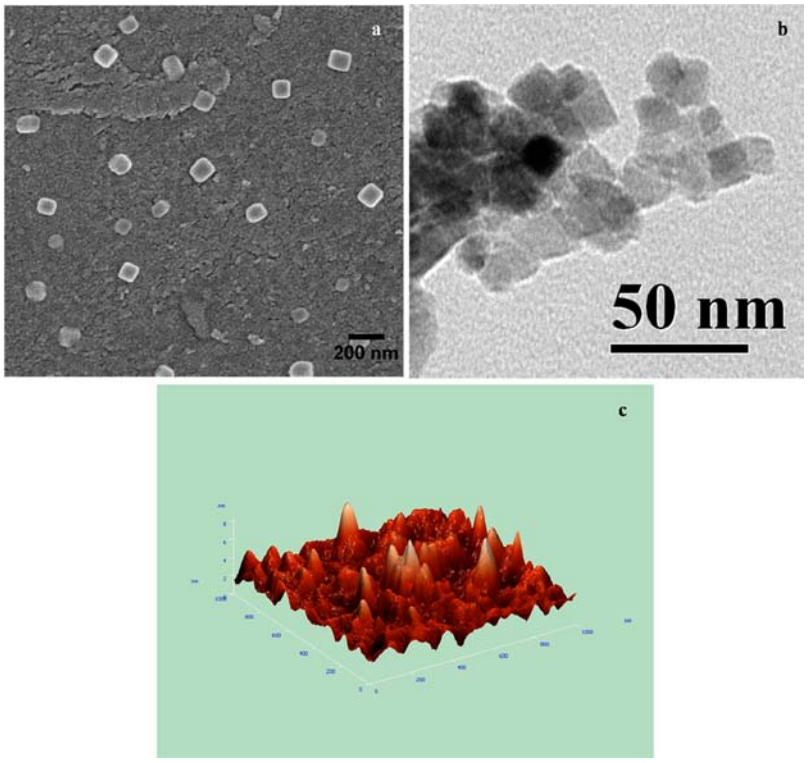

**Figure 1.** Characterization of MnNP: (a) FESEM image; (b) TEM image; (c) AFM micrograph of MnNP.

*(b) NO Content.* Measurement of NO involved a two-step process; in the first step, nitrate was converted to nitrite by nitrate reductase, and in the second step a deep purple azo compound was developed by Griess reagents, supplied externally to the system. The intensity of the azochromophore developed by this process could be measured spectroscopically to determine the amount of NO present in the samples.[31]

*(c) LDH Cytotoxicity Assay.* LDH cytotoxicity assay was performed using Cayman's LDH Cytotoxicity Assay Kit by reducing a tetrazolium salt to highly colored formazan, which absorbed strongly at 490−520 nm.

*(d) ROS/RNS Assay.* Total ROS/RNS generated within the treatments could be measured from fluorescence intensity. DCF could be used as standard, and the free radical content generated could be compared with the predetermined standard intensity using a Cell Biolab Assay Kit.

*Hemolysis.* To perform in vitro hemolysis experiments, human blood was centrifuged twice at 3000 rpm for 15 min to remove residual plasma from the erythrocyte-enriched fraction of blood. RBCs were washed three times with PBS, pH 7.4, and resuspended in the same buffer. Six hundred and ninety microliters of the above RBC stock was suspended with 10 $\mu$L of MnNP treatments (1, 10, and 25 mg/L) along with control, and then the volume was adjusted to 1.5 mL with PBS for each of the treatments. The cells were then centrifuged again at 3000 rpm for 15 min at 4 °C and washed three times with PBS before measurement at 540 nm in a UV−vis spectrophotometer.[32]

**Statistical Analysis.** We tested for the effect of MnNP and MS for different biochemical and biosafety features. For each of the biosafety experiments, we considered three levels of concentration of the nanoparticles, 1, 10, and 25 mg/L, and compared the effects of the various concentrations with respect to the control and also relative to each other. For each concentration in the design, we had three replicates and so, the total numbers of experiments conducted for a specific nanoparticle were $n = 12$ (3 replicates for the 4 levels: control and 1, 10, and 25 mg/L). Although the data size was small, from a biological point of view, normality of the replicate data for each experiment could be assumed. Because there were three replicates for each concentration, two errors were attached to each concentration with a total error degrees of freedom of 8. The degrees of freedom for the prediction space was (number of levels − 1) 3. Therefore, in an ANOVA table, we performed the $F_{3,8}$ distribution and calculated the $P$ value corresponding to this underlying distribution. In the case of biochemical assays of plants, four of each MnNP and MS concentrations were taken into account along with the control, so we had nine replicates altogether and for this case $n = 27$ (control, four concentrations of each MnNP and MS).

If the ANOVA $F$ test was found to be significant, then the next step would be to check which level significantly affected the response, thereby influencing the $F$ test to reject the null. This was achieved by using Tukey's post hoc called HSD (honestly significant difference) test. We used alphabetic labels to check if one level was significantly different from the previous one as concentrations of the nanoparticles were considered as ordered factors. We also observed the box plot response for various levels to get a better indicative picture.

## RESULTS

**Characterization of MnNP.** The morphology of MnNP was investigated by using FESEM and TEM images. Cubic-shaped MnNP of size around 20.88 ± 0.44 nm were more or less homogeneously distributed as revealed from FESEM (Figure 1a) and TEM (Figure 1b) images, respectively. It was previously mentioned that the surface of MnNP contained hydroxyl groups, which contributed to their hydrophilic character. Hydrophilic character was one of the key features of MnNP to study their interaction with plant systems.[14]Although due to the higher reactivity and oxophilicity of Mn,[33] synthesis of MnNP was quite difficult; however, these custom-made MnNP were stable for a long time. Hydrodynamic radius measurement revealed a hydrodynamic radius of around 101.5 ± 13.395 nm, which changed insignificantly over time (Supporting Information (SI) Figure S1). Surface topology of MnNP was obtained from an AFM micrograph (Figure 1c), which justified the average 10 point height of around 6 nm. Chemical purity of the nanoparticles was determined by EDX analysis (SI Figure S2), where Mn was the major component in the sample powder.

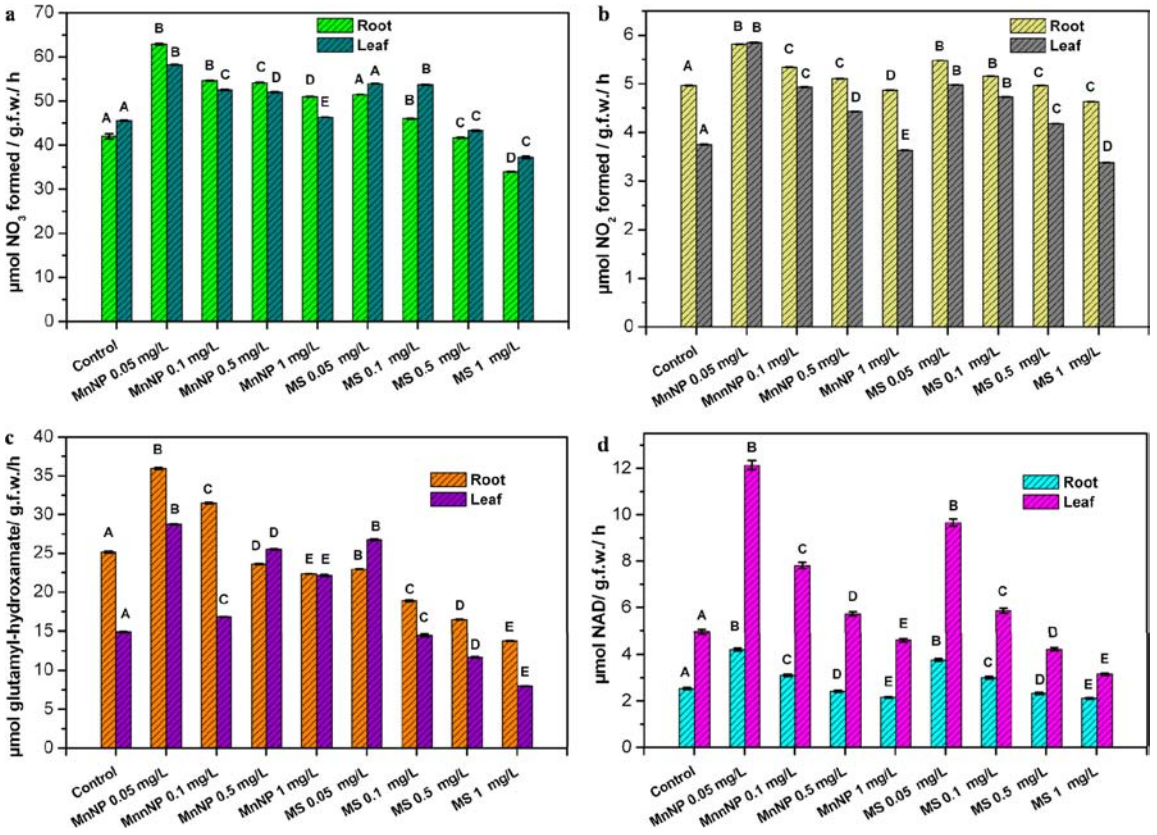

**Figure 2.** Effect of MnNP and MS on nitrogen metabolism of 15-day-treated mung bean plants. (a) NR activity. MnNP leaves: $F = 20.42$, $P < 0.0001$. MnNP roots: $F = 7.59$, $P < 0.01$. MS leaves: $F = 2.64$, $P < 0.1$. MS roots: $F = 8.18$, $P < 0.01$. (b) NiR activity. MnNP leaves: $F = 14.16$, $P < 0.01$. MnNP roots: $F = 8.83$, $P < 0.01$. MS leaves: $F = 19.95$, $P < 0.0001$. MS roots: $F = 8.09$. $P < 0.01$. (c) GS activity. MnNP leaves: $F = 39.21$, $P < 0.00001$. MnNP roots: $F = 23.66$, $P < 0.0001$. MS leaves: $F = 31.68$, $P < 0.0001$. MS roots: $F = 23.44$. $P < 0.0001$. (d) GOGAT activity. MnNP leaves: $F = 20.02$, $P < 0.0001$. MnNP roots: $F = 122.23$, $P < 0.0000001$. MS leaves: $F = 26.03$, $P < 0.0001$. MS roots: $F = 223.94$ $P < 0.000000001$. Within each type of treatment, mean data (±SE, $n = 3$) followed by the same upper case letter are not significantly different for a particular dose; within each dose, means followed by the same lower case letter are not significantly different (Tukey–Kramer HSD test).

Aqueous dispersion of MnNPs was fairly stable. No significant change in the hydrodynamic radius was noted up to 24 h under experimental condition. Even its XRD pattern was unchanged in aqueous dispersion after 24 h, which corroborated our previous report (SI Figure S3).[14] To produce some response in nitrogen assimilation and metabolism, MnNP should be bioavailable to the root system. In our previous study we have already demonstrated the bioavailability of MnNP in roots through confocal microscopy;[14] therefore, bioavailable MnNP on the root system could execute some response, which also triggered us to focus on a series of biochemical and molecular assays related to nitrogen assimilation and metabolism discussed below. Small-sized MnNP resulted in a better bioavailability with their nanosized effect, which was also consistent with the literature.

**Effect on Nitrogen Metabolism in Treated Plants.** The maximum $NO_3^-$ concentration was observed at the highest dose of MS in both root and leaf tissues, whereas a significant decrease in $NO_3^-$ concentration was noted in all of the MnNP-treated sets as shown in Figure S4 (SI). The amount of $NO_3^-$ present in the root was more than in the foliar tissue in all treatments. However, there were increases in both NR and NiR activities in root and leaf tissue of MnNP-treated plants in all treated sets, although the 0.05 mg/L MnNP dose was the most effective (Figure 2a,b). In non-nodulated plants activity of NR-NiR is the initial step for nitrogen metabolism, which is also a determining factor for the assimilation of inorganic nitrogen to organic metabolites in living tissues. Interestingly, $NO_3^-$ concentration in 0.05 mg/L MnNP treatment was lowest but NR and NiR activities were both maximum in the aforementioned dose. MnNP possibly influenced the process of enzymatic reduction during the course of assimilation; hence, NR and NiR activities were enhanced. The responses of GS and GOGAT, in the synthetic process of AA from the assimilated product of NR–NiR activities (Figure 2c,d), were similar. Maximum activity was found in 0.05 mg/L MnNP treatment in both root and leaf tissues, although functions of all of these enzymes were much greater in root tissue compared to foliar tissue. In all of the experiments, the highest doses of MS were found to be toxic to the plant tissues as expected.

Elevated NR activity was further confirmed by protein profiling and Western blot techniques shown in Figure S5 (SI). NR, a homodimer or homotetramer of 110 kDa protein, is present in shoot mesophyll cells and is tightly regulated to reduce nitrate to nitrite.[34] It plays a pivotal role in the nitrogen assimilatory pathway in plants. It was interesting to note that NR activity was increased biochemically; the result was further confirmed by SDS-PAGE and subsequent Western blot analysis of the protein. In both cases MnNP-treated plants showed enhanced activity with respect to control. This justified our hypothesis that MnNP modulated the activity of NR protein, the first assimilatory enzyme and also presumptive candidate responsible for nitrate inhibition step of nitrogen fixation. They bind to and inhibit nitrogenase and leghemoglobin,[35]

simultaneously increasing the activities of all interlinked proteins in the course of nitrogen metabolism.

**Toxicity Study of MnNP with Mouse Model System.** MnNP was injected intravenously at different doses, and the mice were sacrificed after 15 days of observation. No significant changes were noted in general appearance or weight gain between control and treated mice during the observational period (SI Table 1). Treated animals did not show histological abnormalities except in brain tissue at very high doses (SI Figure S6), and even pathological changes (SI Table 2) were negligible. Thus, MnNP were considered to be safe at the recommended dosage after 15 days of treatment, which justified its biocompatibility for future perspectives. Anomalies in brain tissues at higher MnNP concentration forced us to conduct detailed brain mitochondrial assays as it might trigger manganism to the mammalian system. In all toxicity studies we have only accounted for MnNP, as MS is a known toxicant to mammalian systems at experimental doses according to the literature.[15,16]

**Experiments with Mouse Brain Mitochondria.** As shown in Figure 3a, there was a dose-dependent loss of mitochondrial membrane potential after MnNP treatment, although significant inhibition was observed at the highest dose of 25 mg/L. A gradual increase in inorganic phosphate utilization was observed in dose-dependent manner with MnNP treatment shown in Figure 3b. Complex I activity of treated brain mitochondria (Figure 3c) was not significantly altered, but the activities of complex II−III and complex IV were significantly increased at the highest dose of MnNP treatment (Figure 3d,e). MnNP at much higher doses might impair the activity of complex II−III and/or complex IV, resulting in a reduction in energy conversion through electron transport chain (ETC). RCR was left unaltered even after MnNP treatment, showing no negative influence in the respiratory process as shown in Figure 3f. However, more ROS were found to be generated at 25 mg/L MnNP treatment (Figure 4), whereas the lowest dose (1 mg/L) showed no significant change in ROS level with respect to control.

**Experiments with Lymphocyte and Hemolysis.** Figure 5a represents the cytotoxicity of mononuclear cells by MnNP treatment; minor alteration was noted in treated sets with respect

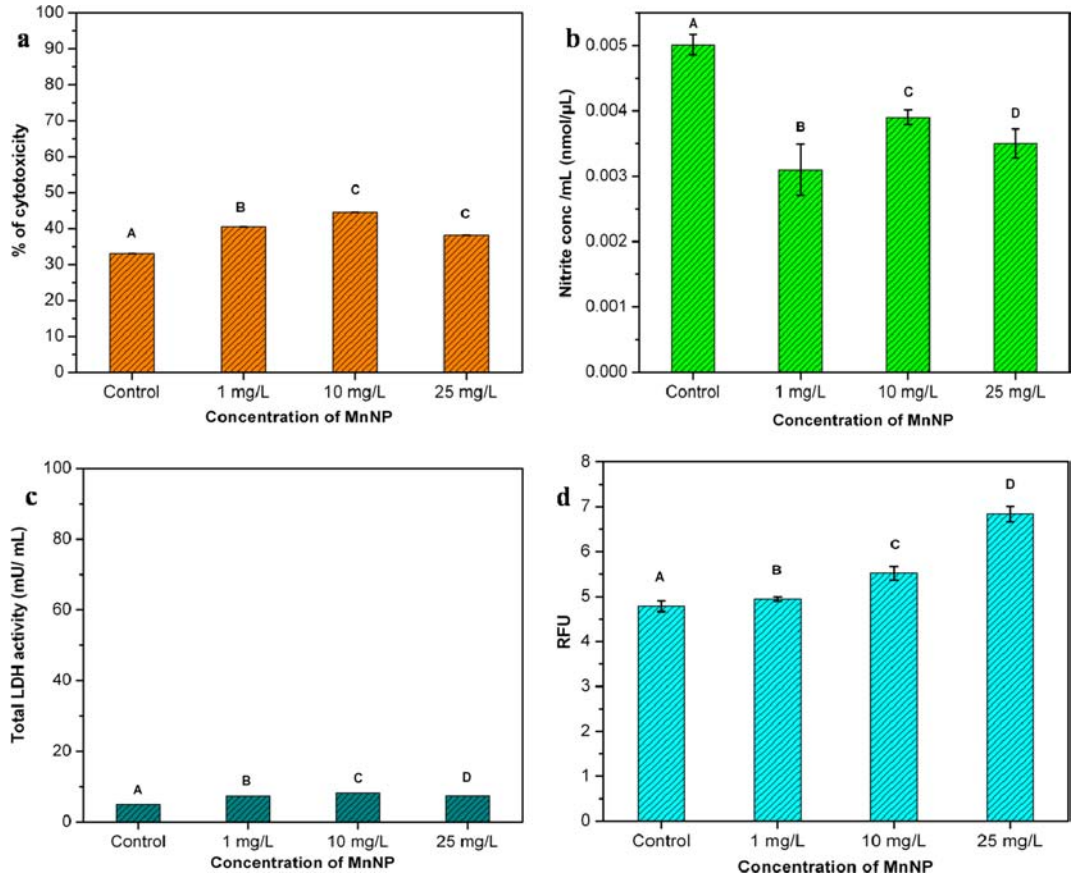

**Figure 5.** Effect of MnNP on human lymphocyte cells. (a) Cytotoxicity assay by WST method. $F = 10.57$, $P < 0.01$. (b) NO content. $F = 197.69$, $P < 0.000001$. (c) Cell viability assay by LDH method. $F = 10.57$, $P < 0.01$. (d) ROS generation. $F = 21.26$, $P < 0.001$. Within each type of treatment, mean data (±SE, $n = 3$) followed by the same upper case letter are not significantly different for a particular dose; within each dose means followed by the same lower case letter are not significantly different (Tukey–Kramer HSD test).

to control. Meanwhile, in the case of NO content (Figure 5b), LDH cell viability assay (Figure 5c), and ROS generation (Figure 5d), no significant alterations were noted between control and treated sets. Altogether MnNP did not impair dose-dependent cytotoxicity in any of the above-mentioned enzymatic assays expect in ROS content, although cytoxicity was seen at higher doses in treated lymphocytes. Similar results were noted in hemolysis experiments. No significant hemolysis was noted in any of the treated sets (SI Figure S7); the highest dose of MnNP treatment (25 mg/mL) exhibited 5.31% hemolysis, which was comparable with the control one (4.96%).

## DISCUSSION

This study revealed that MnNP might modulate the nitrogen metabolism process and thereby could be used as a suitable alternative for MS. MnNP, because of its size and properties, was absorbed readily by the root from soil and transported to the leaf, where it acted as a cofactor in the series of enzymatic reactions during the assimilation of nitrate salt into organic nitrogen compounds. That was probably the reason it did not participate in the process of $NO_3^-$ uptake and the level of $NO_3^-$ in the plant tissue was not influenced by uptake of MnNP. Nitrogen metabolism in plants is a linear pathway that involves the uptake and subsequent transport of nitrate within plant tissues, followed by nitrogen and ammonium assimilation and ultimately amino acid and protein synthesis. However, there had been complexities related to storage and remobilization of nitrate in different parts of the plants: de novo ammonium assimilation and its recycling in the course of photorespiration;[36] unpredictable interactions with carbon assimilatory pathways, which allowed malate to inhibit alkalization[37] and also 2-oxoglutarate to act as the primary acceptor of ammonium in GOGAT pathways.[38] These complexities made it difficult to develop new methodologies and innovations to enrich the status of nitrate assimilation within this complex biological network.

The first step in nitrogen metabolism was the reduction of $NO_3^-$ to $NO_2^-$ in the cytosol by NR. MnNP at all doses directly or indirectly increased NR activity in foliar tissue with respect to control, whereas no significant alterations were noted in root tissue even at the highest dose. Therefore, MnNP could influence the entry of $NO_3^-$ to the cells, resulting in the hyperpolarization of the plasma membrane. The influence of MnNP over NR activity was supported by biochemical and molecular techniques. Enhanced expression of NR protein after MnNP treatment with respect to the control validated our speculation that MnNP could enhance protein activity. This in turn improved nitrogen status in the mung bean crop. It might stimulate NR activity, which was further validated by the enhanced activity of NiR, an enzyme required for the conversion of $NO_2^-$ to $NH_4^+$ in the cytosol. Both NR and NiR were induced by the same factors, explaining their similar responses to the micronutrient treatments.

Plants assimilate inorganic nitrogen into nitrogen-transport amino acids (AAs), glutamate and glutamine, which are destined to transfer nitrogen from source to sink tissues and to build up reserves during periods of nitrogen availability for subsequent use in growth, defense, and reproductive processes. It also

decimated the level of ammonium toxicity. The immediate step thereafter was to convert $NH_4^+$ to amino acid with the help of glutamine synthetase (GS) and glutamate synthase (2-oxoglutarate aminotransferase, or GOGAT). These two very important enzymes are involved in the primary assimilation of inorganic nitrogen from soil along with reassimilation of free ammonium into the plants. GS catalyzed the ATP-dependent assimilation of $NH_4^+$ into glutamine using glutamate as a substrate. Mn is a known cofactor in this reaction, and thereby the presence of MnNP triggered more GS activity and also the activity of GOGAT. Because GOGAT was known to be stimulated by elevated plastid levels of glutamine during ammonium assimilation, GOGAT was required to produce 2-oxoglutamate, which ultimately produced dicarboxylic acids as carbon skeletons for glutamate, aspartate synthesis, and their corresponding amides. A couple of studies demonstrated the influence of high GS activity on vegetative growth and photosynthesis upliftment;[39] even earlier flower and seed development were also observed under accelerated GS activity.[40] MnNP triggered enhanced GS activity; thereby, it may function as an enzymatic cofactor in nitrogen assimilation in non-nodulated plants. It might work as a boon for agriculture as it was able to overcome the drawbacks of the commercially available MS salt at higher doses.

MnNP was already established as a micronutrient fertilizer over commercially available MS, but it was well recognized that excess use of Mn salt could induce manganism; therefore, the toxicity issues associated with MnNP could not be ruled out. As a consequence, we carried out a series of detailed toxicological evaluations on mononuclear cells and murine model system at relatively high dosages (1, 10, and 25 mg/mL) in contrast to the one used in nitrogen assimilation and metabolism. In murine model system MnNP was injected intravenously, and after 15 days of observation, mice were sacrificed for histopathological evaluation. From the results we confirmed that MnNP was biosafe for further implementation, although minor anomalies were noted in brain tissues. Therefore, we deliberately carried out a brain mitochondrial assay in the murine model system in light of manganism. The assays were carried out after 24 h of injection followed by isolation of brain tissues. In all of the experiments it was observed that 25 mg/L MnNP partially impaired the activity of complex II−III, but it had no effect in mitochondrial complex I, complex IV protein domains, and RCR activity. This justified that MnNP limited the efficiency of brain mitochondrial functions to some extent but did not hamper the entire physiological process. There was no loss of mitochondrial membrane potential at any of the dosages; increased phosphorylation capacity ensured no loss of phosphate utilization and hence ATP synthesis. The key function of the mitochondrial ETC was to supply reducing equivalents because the majority of electrons were provided by NADH. In our experiments, MnNP did not show any alteration in complex I activity of brain mitochondrial ETC like it did with its elemental counterpart. Therefore, MnNP could easily overcome the problem of inactivation of energy metabolism leading to mitochondrial dysfunction influenced by Mn salts. Partially inhibited complex II−III activity decreased electron transfer activity leading to ROS by leaking electrons from ETC complexes during respiration, particularly in complex III.

In addition, a detailed in vitro cytotoxicity experiment on human lymphocytes was carried out using MnNP of aforementioned dosages. No significant cytotoxic response was found in any of the treated sets with respect to control as noted from our detailed systematic evaluation. These results were consistent with the in vivo experiments mentioned earlier, which signified the biocompatibility of MnNP for biological perspectives. Interestingly, hemolysis experiments justified its biocompatibility as well, which also corroborated the results noted for mononuclear cells.

To the best of our knowledge, this is the first study in which MnNP has been used to enhance nitrogen metabolism in a plant model system. MnNP probably stimulated the activity of NR directly or indirectly as noted from biochemical and molecular techniques. They also enhanced the function of both GS and GOGAT enzyme activities, being an active cofactor in the biochemical reactions. They not only surpassed the difficulties raised due to low availability of inorganic ions during nitrogen assimilation but also alleviated enzymatic activities of the same physiological process. Hence, MnNP can be used as fertilizer for both carbon and nitrogen assimilatory processes. Biosafety experiments were carried out in both mouse and human mononuclear cells. Brain mitochondria of treated mice were isolated to check functional activities in respiration and energy production. Results demonstrated that MnNP were fairly biosafe, although minor toxic responses were noted at a very high dosage. We have good reason to believe that MnNP could be used as a fertilizer with great efficiency together with their biocompatibility relative to the commonly used salt counterpart, MS.

# Effect of Second Cooling on the Chemical Components of Essential Oils from Orange Peel (*Citrus sinensis*)

Yulong Chen, Jijun Wu, Yujuan Xu,* Manqing Fu, and Gengsheng Xiao

Sericultural and Agro-Food Processing Research Institute, Guangdong Academy of Agricultural Sciences, Guangzhou 510610, People's Republic of China

**ABSTRACT:** A second cooling was added to the oil collectors of an improved Clevenger-type apparatus (ICT) to investigate the thermal reaction of essential oils from orange peel compared to a traditional Clevenger-type apparatus (CT). The results demonstrated the yield rate of essential oil from ICT was significantly higher ($p < 0.05$) than that from CT. The major components of the essential oils consisted of monoterpenes, such as *d*-limonene, *β*-myrcene, *β*-pinene, *γ*-terpinene, *α*-pinene. Interestingly, ICT prevented the thermal reaction—the transformation of *β*-myrcene to *β*-thujene—and reduced the oxidation on *α*-pinene and *β*-pinene of the essential oil in comparison to CT. In addition, the yield rate of *γ*-terpinene can also be improved via ICT compared to CT. Thus, ICT is an effective improvement to traditional CT.

**KEYWORDS:** *Clevenger-type apparatus, extraction, essential oil, thermal reaction*

## INTRODUCTION

The essential oils from various species of citrus can be used as ingredients for food flavor in, for example, beverages or ice cream, as well as materials in the fragrance industry.[1] Although the common way to get the essential oils is by cold pressing citrus peels, hydrodistillation is still adopted in some countries as an economical way to obtain the oils.[2]

The advantage of hydrodistilled extraction is evident. As a hydrodistillation of two mixed immiscible liquids, each exerts a vapor pressure, as if each liquid were pure.[3] The total vapor pressure of a boiling mixture is therefore equal to the sum of the partial pressures given by each of the individual components of the mixture. When the total vapor pressure reaches atmospheric pressure, the mixture starts to boil. This means that the boiling point of the mixture is reached at a lower temperature than the boiling points of the individual components. Therefore, hydrodistillation is able to separate volatile from nonvolatile components at a reduced boiling point, thus avoiding the high temperatures of boiling points.[4,5] Moreover, the displacement of atmospheric oxygen by steam, which protects compounds from oxidation, is another plus point of this method.[6] Thus, a Clevenger-type apparatus (CT), a popular method of hydrodistillation for the extraction of essential oils,[7] was employed in our research (Figure 1).

However, the drawback of this process is also obvious. As known, hydrolyzable compounds such as esters, as well as thermally labile components, may be decomposed during the distillation process.[3] In addition, partial loss of more polar constituents of the oil, due to their affinity for water, may also occur.[4,8] For this reason, the improved Clevenger-type apparatus (ICT) was used to avoid partial heat loss due to the volatilization of oils because the ICT equipment is modified with a water-cooled oil collector as the second cooling to reduce the temperature of the collector during hydrodistillation (Figure 1). This improvement has also been used in the extraction of essential oil of *Pericarpium Citri Reticulatae* in our laboratory.[9] In addition, the ICT equipment was used to tentatively determine other differences from CT due to overheating of oils, such as the degradation of volatile and thermolabile compounds and the formation of artifacts.

The orange (*Citrus sinensis*) is widely grown in China, and the peel of the orange, as one of the byproducts of orange processing, can be used for the extraction of oil. Although some modified CTs were used in the literature,[10,11] few studies demonstrated the difference between CT and ICT. Thus, the focus of this study was on the variation of chemical compositions of the essential oils isolated from orange peels by CT and ICT. Through the research, evidence of the advantage of ICT was found in comparison with CT. Accordingly, the research can supply an improved classical extraction method of essential oils, which possesses not only the interest of solvent inertness and nontoxicity but also more effective fractionation at moderate temperatures.[12]

## MATERIALS AND METHODS

**Chemicals.** Homologous series of $C_6$−$C_{22}$ *n*-alkanes were purchased from Sigma Chemical Co. (St. Louis, MO, USA). Reference chemicals such as *d*-limonene and *γ*-terpinene were obtained from Aladdin Chemistry Co., Ltd. (Shanghai, China). Other reference chemicals, such as *β*-myrcene, *α*-caryophyllene, *α*-pinene, decanal, and *p*-menth-1-en-8-ol, were supplied by College of Food Science and Technology, Huazhong Agricultural University (Wuhan, China).

**Plant Materials.** Orange peel (*C. sinensis*) was purchased from Guangxi province, China. The specimens were dried in the sun to constant weight, ground to a fine powder, and stored in waterproof bags at 4 °C before use.

**Isolation of the Essential Oils.** One hundred grams of dried and ground powder (80 mesh) from orange peel was hydrodistilled with 400 g of water for 2 h, using a CT[7] and an ICT (Figure 1), respectively. When using a CT, the distilled essential oil mixed with vapor is condensed by the top condenser and dropped into the

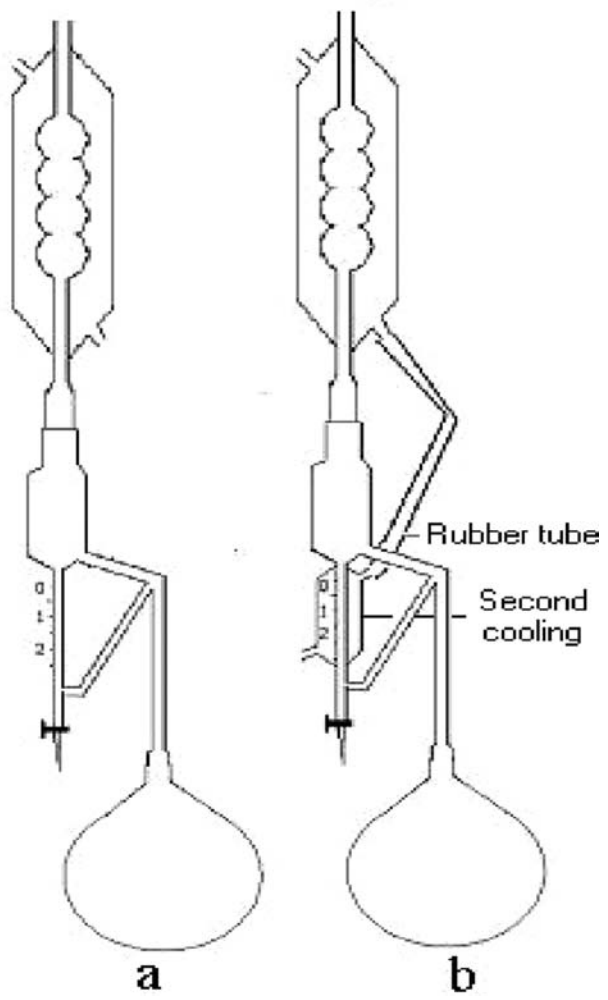

**Figure 1.** Improved (b) and conventional (a) Clevenger-type apparatus.

essential oil collector. Superficial essential oil is obtained after the water in the collector is drained. When a second condenser is added to the essential oil collector of a CT, the improved apparatus, namely, ICT, becomes different. The second condenser is linked with the top condenser with a rubber pipe. When cooling, running water first enters the second condenser and then goes out of the top condenser. Different from a CT, the distilled essential oil is first condensed by the top condenser and dropped into the essential oil collector and then cooled again by the second condenser. Anhydrous sodium sulfate was used to dry the distilled essential oils. After filtering, the oils were stored in sealed vials at 4 °C for further analyses. This experiment was performed in triplicate.

**Analysis of Gas Chromatography (GC).** A PerkinElmer (Norwalk, CT, USA) gas chromatograph model 8700 equipped with a flame ionization detector (FID) and an HP-Wax bonded polyethylene glycol capillary column (30 m × 0.25 mm, film thickness = 0.25 μm; Agilent Technologies, Little Falls, CA, USA) was employed to analyze the essential oils. Injector and detector temperatures were 220 and 250 °C, respectively. Column temperature was set from 50 to 230 °C at a rate of 5 °C/min and, lower and upper temperatures were maintained for 4 and 5 min, respectively. Helium was regarded as carrier gas at a flow rate of 1.0 mL $min^{-1}$. When a sample of 10 μL was injected, split mode (split ratio, 1:30) was adopted. All quantifications were finished using a built-in data-handling program provided by the manufacturer of the gas chromatograph. The quantification of compositions was reported using a relative percentage of the total peak area.

**Analysis of Gas Chromatography–Mass Spectrometry (GC-MS).** The essential oil was analyzed using an Agilent Technologies 6890N network gas chromatographic (GC) system, equipped with an Agilent Technologies 5975B inert XL mass selective detector and an Agilent Technologies 7683B series autoinjector to obtain the qualitative GC-MS results. Chromatographic conditions were set the same as described above. An electron ionization mode with an ionization energy of 70 eV was used for MS detection. Injector and MS transfer line temperatures were 220 and 250 °C, respectively.

**Compound Identification.** The identification of the essential oil constituents was performed by comparison of their retention indices relative to ($C_6$–$C_{22}$) *n*-alkanes, published data, and spectra of authentic compounds. Moreover, compounds were further identified and authenticated by comparing their MS data to the NIST mass spectral library and published mass spectra.[13]

**Statistical Analysis.** SAS 8.1 (SAS Institute Inc., Cary, NC, USA) was used to analyze the data. A variance analysis (ANOVA) was followed by an analysis of least significant difference ($p < 0.05$) among means by Duncan's multiple-range test.

## RESULTS AND DISCUSSION

**Yield Rates of the Essential Oils.** In Table 1, the yield rate of essential oils from ICT (ca. 1.98%) is significantly higher than that of CT (ca. 1.00%) ($p < 0.05$). As the second condenser was added to the collector of essential oil, the temperature of the essential oil in the collector of ICT was lower than that of CT. This result is in line with our previous report.[9] On the contrary, in the process of CT extraction, the collector of oil is connected to the bottom of the CT, which is being heated by steamed vapor; the temperature of the collector is nearly similar to that of the CT bottom. Thus, the temperature of the essential oil in the collector of the CT is higher than that of the ICT and, therefore, the volatilization of essential oils was accelerated. As a result, the yield rate of essential oil extracted from ICT was greatly increased in comparison with CT.

**Main Compositions.** The compositions of essential oils from CT and ICT methods were different (Figure 2; Table 1). The major ingredients of essential oils from the hydrodistilled method are *d*-limonene, γ-terpinene, β-thujene, *p*-cymene, β-myrcene, α-pinene, β-pinene, and (+)-4-carene. These components are similar to the result from *Pericarpium Citri Reticulatae* essential oil.[9] According to Yang et al.,[14] essential oil of citrus fruit waste contained limonene (80.51%), γ-terpinene (6.80%), *p*-cymene (4.02%), β-myrcene (1.59%), α-pinene (1.02%), and α-terpinolene (0.56%). Although the major components of the oils are not completely the same as found by Yang et al.,[14] *d*-limonene and γ-terpinene are predominant constituents in the orange essential oils. This result is in accord with the literature.[15,16] *d*-Limonene and γ-terpinene are monocyclic terpenes that are consumed by humans predominantly as an ingredient of traditional foods such as citrus fruits, carrots, coffee, orange, and nutmeg.

To our best knowledge, the monoterpenes and monoterpenoids, comprising the most important class of terpenic compounds, have been best investigated. This class is further subcategorized as these molecules reveal various structures and diversity of internal C,C linkage.[17,18] Subclasses are classified according to the similarity of molecular structures of compounds in this class. Accordingly, citral, nerol, and myrcene are regarded as the 3, 6-dimethyloctane subclass, whereas limonene, pulegone, and menthol are the *p*-menthane subclass.[19] Therefore, the major components of the essential oils extracted from orange peel consisted of monoterpenes,

including *d*-limonene, β-myrcene, α-pinene, γ-terpinene, and β-pinene.

**Comparison of Components of Essential Oils.** Both β-thujene and β-myrcene were found in the oil from ICT, whereas only β-thujene was detected in the oil from CT (Figure 2; Table 1). Interestingly, the relative content of β-thujene in the oil from CT was almost the sum of the relative contents of β-thujene and β-myrcene in the oil from ICT. Because β-thujene and β-myrcene are isomers, β-myrcene can be changed into β-thujene via electrocyclic reaction and rearrangement under long duration of high temperature in the oil collector of the CT (Figure 3). With regard to the CT, when the mixture of steam and oil was first condensed into the oil collector, the oil was still affected by the heating. Accordingly, it is postulated that CT may be involved in the thermal reaction that turned β-myrcene into β-thujene in the process of oil extraction. Various papers in the literature have reported thermal rearrangements of small molecules.[20,21] The dienes bearing internal C═C bonds are prone to thermal rearrangement.[22] Thus, thermal rearrangement of β-myrcene is prone to happen as the molecule has intramolecular C═C bonds. β-Myrcene is first rearranged into an intermediate, and then the intermediate is cyclized via intramolecular reaction under the condition of heating.[19,23] Ultimately, the cyclized molecule is thermally induced and rearranged, leading to β-thujene by isomerization[19] (Figure 3). On the contrary, the unsaturated monoterpene β-thujene can also undergo the reverse transformation: ring opening via 1, j-H shift reaction,[20,22] turning into an acyclic monoterpene.

As known, the relative contents of α-pinene and β-pinene in the oil from ICT were significantly lower ($p < 0.05$) than those from CT. The result indicates that CT extraction can obviously promote the formation of α-pinene and β-pinene in comparison with ICT. In the process of extraction of oils, the difference of CT and ICT is attributed to the different collectors. Because the CT oil was heated at the higher temperature of the collector over ICT, greater amounts of α-pinene and β-pinene in the oil of CT may be produced through thermal reaction, in which the transformation of other ingredients can be achieved. On the other hand, α-pinene and β-pinene, as bicyclic monoterpenes, can be also formed via electrocyclic reaction of monoterpenes. This conclusion has been reported. Mcgraw et al.[24] have found that part of α-pinene has been rearranged or oxidized in the presence of air at temperatures of 90−130 °C. The products included β-pinene, α-pinene oxide, etc. The thermal rearrangement of β-pinene produces limonene, myrcene, and ψ-limonene.[19] Obviously, the different colors of oils from CT and ICT can also be observed in our experiment. The phenomenon is in accord with the report that the color of orange oils obtained by hydrodistillation was observed to deepen, expressing the composition change of isolated orange oils.[25] This further confirmed the postulated fact that ICT could effectively reduce the thermal reaction of monoterpenes in the oil.

γ-Terpinene is one of the major constituents in the orange essential oils. The concentration of γ-terpinene from ICT is 10.28%, which is significantly higher ($p < 0.05$) than that (9.87%) from CT (Table 1). This indicates that ICT can also benefit the extraction of γ-terpinene to avoid its loss. The

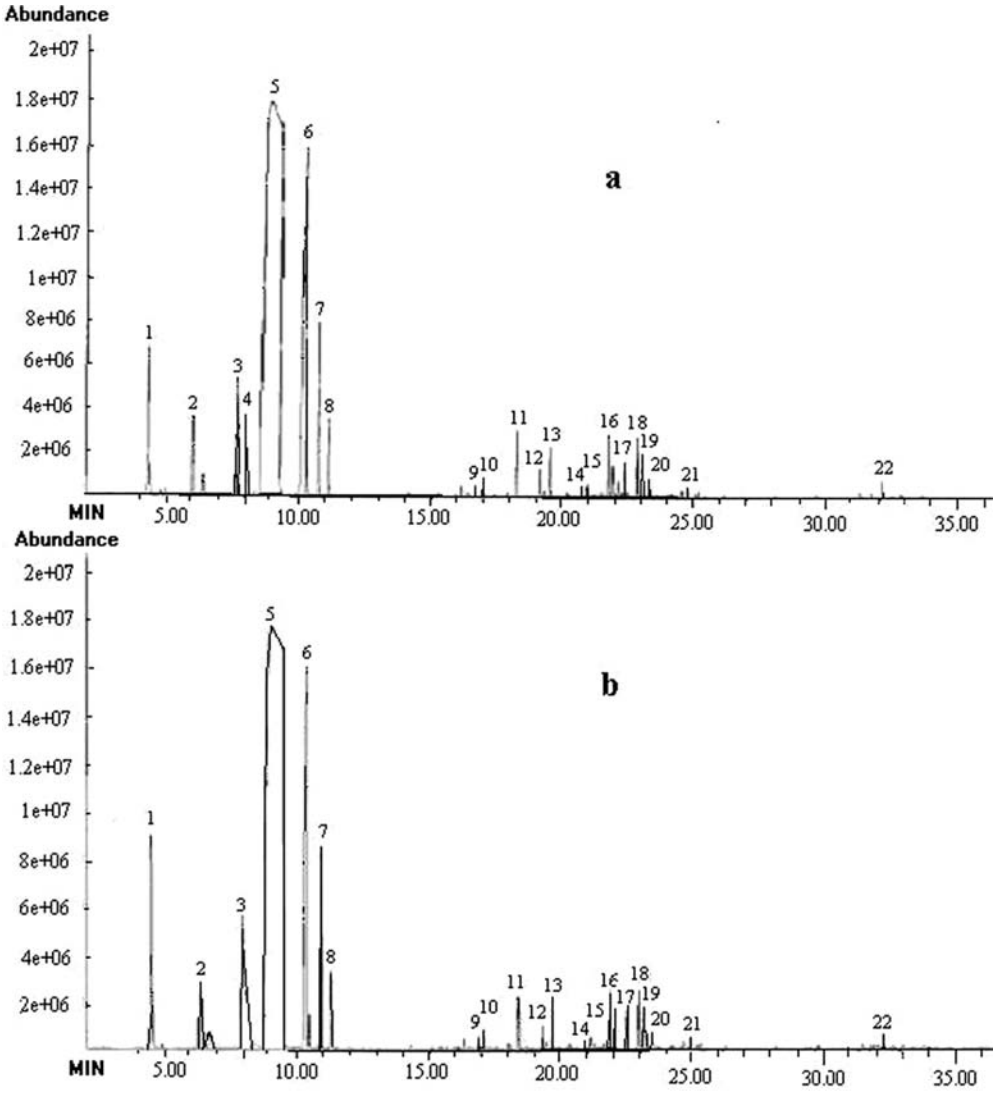

**Figure 2.** GC chromatograms of essential oils of orange peel from hydrodistilled methods: (a) ICT; (b) CT. Component numbers of chromatograms are from Table 1.

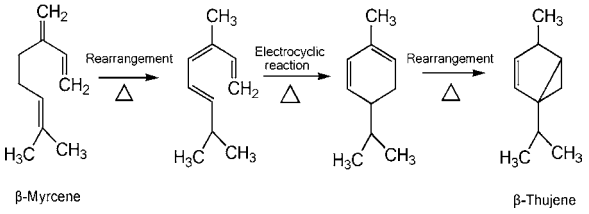

**Figure 3.** Possible pathway of $\beta$-thujene formation from $\beta$-myrcene.

cooling collector of essential oils in ICT can markedly reduce volatilization of $\gamma$-terpinene. Maybe ICT can also reduce the formation of other compounds from $\gamma$-terpinene[26] in comparison with CT.

In general, as a cooling collector was added the CT, the low temperature of the oil collector in ICT can significantly increase the yield rates of essential oils ($p < 0.05$) compared to CT. In addition, ICT avoided the transformation of $\beta$-myrcene to $\beta$-thujene, improved the yield rate of $\gamma$-terpinene, and reduced the thermal reaction on $\alpha$-pinene and $\beta$-pinene of oil in comparison to CT. Thus, ICT is an effective improvement to traditional CT.

Supporting Information

**ABSTRACT:** The ability to visualize the movement of glycosyl insecticides contributes to learning their translocation and distribution in plants. In our present work, a novel fluorescent glucose−fipronil conjugate *N*-[3-cyano-1-[2,6-dichloro-4-(trifluoromethyl)phenyl]-4-[(trifluoromethyl)sulfinyl]-1*H*-pyrazol-5-yl]-1-(2-[*N*-(7-nitrobenz-2-oxa-1,3-diazol-4-yl)amino]-2-deoxy-β-D-glucopyranosyl)-1*H*-1,2,3-triazole-4-methanamine (2-NBDGTF), was obtained via click chemistry. Disk uptake experiments showed that an active carrier-mediated system was involved in the 2-NBDGTF uptake process. Meanwhile, 2-NBDGTF exhibited comparable phloem mobility with GTF in castor bean seedlings. Visualization of 2-NBDGTF uptake and transport experiment showed that this fluorescent glucose−fipronil conjugate could be loaded into sieve tubes after transiting through epidermal cells and mesophyll cells and then translocate from cotyledon to hypocotyl via phloem in castor bean seedlings. The results above determined that it is a promising fluorescence tagging approach for revealing the activities of glycosyl insecticides and 2-NBDGTF is a reasonable and feasible fluorescent surrogate of GTF for tracing the distribution of glucose−fipronil conjugates.

**KEYWORDS:** *visualization, carrier-mediated, phloem mobility, fluorescence tagging, castor bean*

## INTRODUCTION

Insecticides with phloem mobility are desirable for controlling piercing and sucking insects as well as vascular insects in agriculture. Despite the positive implications of such insecticides, only a few phloem mobile or ambimobile insecticides are currently available. An optional strategy used in developing phloem-mobile pesticides is to chemically modify parent pesticides. Such modifications include sugar conjugation, acid functionalization, and formation of quaternary salts from the parent pesticides.[1] The addition of carboxyl groups to immobile or poorly mobile pesticides has proven to be an efficient method of imparting phloem mobility to parent pesticides.[2,3] The conjugation of parent pesticides to endogenous substances, such as amino acids and monosaccharides, is another approach that is used for developing propesticides with phloem mobility.[4,5]

In our previous work, we demonstrated that the glucose−fipronil conjugate *N*-[3-cyano-1-[2,6-dichloro-4-(trifluoromethyl)phenyl]-4-[(trifluoromethyl)sulfinyl]-1*H*-pyrazol-5-yl]-1-(β-D-glucopyranosyl)-1*H*-1,2,3-triazole-4-methanamine (GTF) exhibits moderate phloem mobility in the phloem of castor bean seedlings.[6] That the hydroxyl of the monosaccharide significantly affects the phloem mobility of the monosaccharide−fipronil conjugates was also demonstrated using castor bean seedlings.[7] Additionally, the uptake and transport of GTF within castor bean seedlings demonstrated the involvement of an active carrier-mediated mechanism.[8] Despite the progress made in this field, the uptake mechanisms of GTF analogues and the distribution within plants remain unknown. The ability to visualize GTF analogues within plants has great potential for addressing these questions.

Fluorescence tagging techniques are promising approaches to trace uptake pathways, transport routes, and distributions of xenobiotics within plants. Compared with radiolabeling techniques, which have been widely used to investigate the uptake and translocation of xenobiotics,[9,10] fluorescence tagging offers both high spatial and temporal resolution. Moreover, the use of fluorescence tagging could provide dynamic and real-time information on xenobiotics at the cellular level. In order to visualize transport of xenobiotics within plants, several studies were performed using various fluorescent dyes with similar physicochemical properties.[11,12] Recently, fluorescently labeled plant hormones were used to reveal the distribution and signaling receptor of hormones within plants.[13,14]

To visualize the uptake activity and translocation of GTF analogues in plants, a novel fluorescently labeled GTF derivative was synthesized with the modification of an NBD moiety at the C-2 position of the glucose−fipronil conjugate (Figure 1). The uptake mechanism and the phloem mobility of

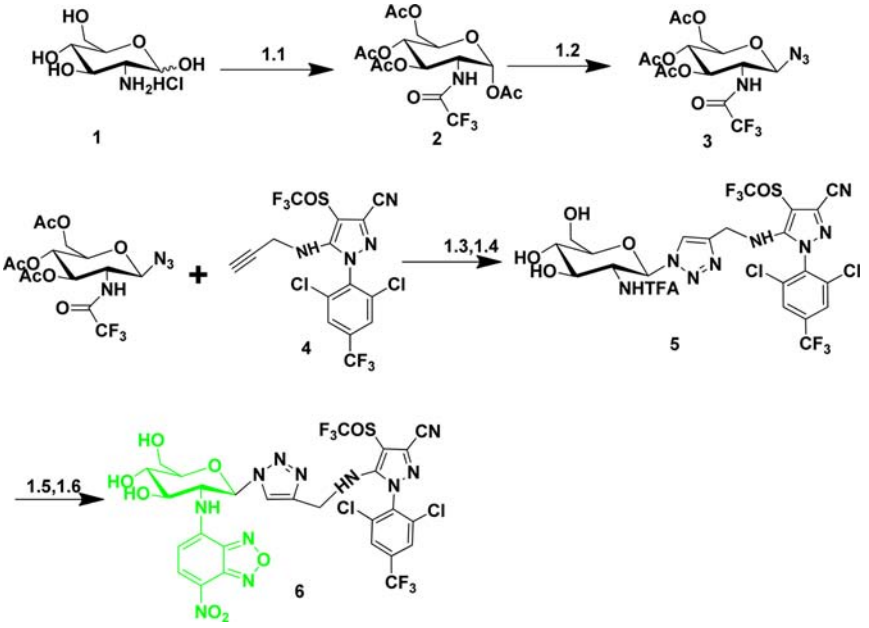
**Scheme 1. Synthesis of 2-NBDGTF; Reaction conditions: 1.1 $CF_3COOC_2H_5$, $Et_3N$, MeOH; 1.2 $SnCl_4$, $TMSN_3$, $CH_2Cl_2$; 1.3 $CuSO_4{\cdot}5H_2O$, sodium ascorbate; 1.4 MeOH, NaOMe; 1.5 1M NaOH; 1.6 NBD-Cl, $K_2CO_3$, MeOH**



2-NBDGTF were investigated to prove that the fluorescent glucose−fipronil derivative 2-NBDGTF is a reasonable fluorescent GTF surrogate. Then 2-NBDGTF was used to visualize the movement of GTF analogues within castor bean seedlings using confocal laser scanning microscopy.

## MATERIALS AND METHODS

**General Information.** Reagents and anhydrous solvents were used directly. Melting points were determined on an FP62 digital micro melting point apparatus; data were left uncorrected. NMR spectra were obtained from a Bruker AV-600 instrument. Deuterated solvents were obtained from Cambridge Isotope Laboratories (Andover, MA). $CD_3OD$ and $CDCl_3$ solvent peaks (3.31 and 7.26 ppm for 1H; 49.0 and 77.0 ppm for 13C, respectively) were used as internal chemical shift references. The mass spectra (MS) of new compounds were obtained by Bruker maXis with an electrospray ionization (ESI) spectrometer. Silica gel was used for column chromatography. GTF was prepared according to our previously described procedure.[6] The compounds to be added to the incubation medium were purchased from Sigma [carbonyl cyanidem-chlorophenylhy-drazone (CCCP)] and Aladdin (phloridzin, MES, and mannitol).

**Chemicals (Scheme 1).** *1,3,4,6-Tetra-O-acetyl-2-deoxy-2-trifluoroacetamido-α-D-glucopyranoside (2).* 2-Deoxy-2-trifluoroacetamido-D-glucopyranose (2 g, 7.24 mmol) was dissolved in pyridine (15 mL) and acetic anhydride (5 mL). The reaction mixture was kept at room temperature overnight and poured into ice water and stirred for 1 h. The mixture was extracted with dichloromethane, and the organic layer was washed with 1 M HCl and saturated aqueous $NaHCO_3$ and dried on $Na_2SO_4$. The solution was concentrated and purified by silica gel column chromatography to obtain a light yellow solid. Slightly yellow solid: yield 78%; mp 123.5 °C; $^1$H NMR (600 MHz, $CDCl_3$) $\delta$ 6.27 (d, $J$ = 3.9 Hz, 1H), 5.32 (br,1H), 5.22 (dd, $J$ = 10.0 Hz, 10.0 Hz, 1H), 4.44 (m, 1H), 4.28 (dd, $J$ = 12.0 Hz, 4.2 Hz, 1H), 4.07 (dd, $J$ = 12.0, 2.2 Hz, 1H), 4.04 (m, 1H), 2.19 (s, 3H), 2.09 (s, 3H), 2.06 (s, 3H), 2.05 (s, 3H); $^{13}$C NMR (150 MHz, $CDCl_3$) $\delta$ 171.8, 170.6, 169.0, 168.2, 157.7, 116.7, 89.4, 69.8, 69.8, 67.0,61.3, 52.2, 20.7, 20.6, 20.5, 20.4; ESI-MS, $m/z$ 442.2 $[M - H]^-$.

*3,4,6-Tetra-O-acetyl-2-trifluoroacetamido-2-deoxy-β-D-glucopyranosyl Azide (3).* Compound **2** (170 mg, 0.384 mmol) and azidotrimethylsilane (TMS-$N_3$, 56 μL, 0.423 mmol) were dissolved in anhydrous $CH_2Cl_2$ (5 mL), and $SnCl_4$ (45 μL, 0.384 mmol) was added dropwise. The resulting mixture was stirred at room temperature until TLC indicated the disappearance of starting material (about 2 h). The mixture was extracted with $CH_2Cl_2$ (3 × 20 mL) and then washed with $NaHCO_3$ (3 × 20 mL) and water (20 mL). The organic layer was dried ($Na_2SO_4$) and filtered, and the solvent was evaporated under reduced pressure. The residue was purified by flash chromatography (petroleum ether:ethyl acetate = 2:1) to give **3**. Needle solid: yield 75%; $^1$H NMR (600 MHz, $CDCl_3$) $\delta$ 7.17 (d, $J$ = 8.8 Hz, 1H), 5.39−5.27 (m, 1H), 5.10 (t-like, $J$ = 9.7 Hz, 1H), 4.81 (d, $J$ = 9.2 Hz, 1H), 4.28 (dd, $J$ = 12.5, 5.0 Hz, 1H), 4.20 (dd, $J$ = 12.5, 2.2 Hz, 1H), 4.03 (dd, $J$ = 19.7, 9.4 Hz, 1H), 3.88 (ddd, $J$ = 10.0, 4.9, 2.3 Hz, 1H), 2.10 (s, 3H), 2.04 (s, 3H), 2.03 (s, 3H); $^{13}$C NMR (150 MHz, $CDCl_3$) $\delta$ 171.41, 170.95, 169.49, 157.78, 115.61, 87.82, 74.14, 71.72, 68.30, 61.96, 54.35, 20.81, 20.67, 20.46.

*N-[3-Cyano-1-[2,6-dichloro-4-(trifluoromethyl)phenyl]-4-[(trifluoromethyl)sulfinyl]-1H-pyrazol-5-yl]-1-(2-trifluoroacetamido-2-deoxy-β-D-glucopyranosyl)-1H-1,2,3-triazole-4-methanamine (5).* Fipronil-alkyne **4** (474 mg, 1 mmol) was added to a vigorously stirred suspension of compound **2** (426 mg, 1 mmol) in 3 mL of *tert*-butyl alcohol. The reaction was initiated by the addition of a solution of $CuSO_4{\cdot}5H_2O$ (100 mg, 0.4 mmol) and sodium ascorbate (173 mg, 0.8 mmol) in distilled water (3 mL). The deep yellow suspension was stirred vigorously at 50 °C for 3 h. Distilled water (10 mL) was added, and the aqueous layer was extracted with chloroform (10 mL × 3). The combined organic extracts were washed with aqueous sodium hydrogen carbonate and brine, dried with sodium sulfate, filtered, and evaporated in vacuo. The crude compound was added to a solution of sodium methoxide in dry methanol (0.05 M, 15 mL). The resultant solution was stirred for 30 min at room temperature. The mixture was neutralized with Amberlite IR 120 ($H^+$) resin and filtered, and the filtrate was then evaporated. The residues were purified by column chromatography to obtain compound **5**. White solid: yield 78%; $^1$H NMR (600 MHz, MeOD) $\delta$ 8.12 (s, 1H), 8.09* (s, 1H), 8.06 (dd, $J$ = 7.6, 6.3 Hz, 2H), 5.88 (d, $J$ = 5.7 Hz, 1H), 5.86* (d, $J$ = 5.7 Hz, 1H), 4.64 (d, $J$ = 4.1 Hz, 1H), 4.62* (d, $J$ = 4.1 Hz, 1H), 4.45 (d, $J$ = 2.3 Hz, 1H), 4.43* (d, $J$ = 2.3 Hz, 1H), 4.30 (t, $J$ = 7.3 Hz, 1H), 4.27* (t, $J$ = 7.3 Hz, 1H), 3.92 (t-like, 1H), 3.90 (t-like, 1H), 3.84−3.73 (m, 2H), 3.63−3.55 (m, 2H); $^{13}$C NMR (150 MHz, MeOD) $\delta$ 157.93, 150.54, 144.27, 136.57, 136.45, 134.68, 126.63, 126.54, 126.44, 124.42, 123.12, 121.47, 116.66, 114.76, 110.79, 96.26, 85.99, 79.92, 79.90*, 73.76, 73.66*, 69.88, 69.88*, 60.77, 60.74*, 55.75, 55.65*, 39.66, 39.59* (*enantiomer); ESI-MS, $m/z$ 807.4 $[M - H]^-$.

*N-[3-Cyano-1-[2,6-dichloro-4-(trifluoromethyl)phenyl]-4-[(trifluoromethyl)sulfinyl]-1H-pyrazol-5-yl]-1-(2-[N-(7-nitrobenz-2-oxa-1,3-diazol-4-yl)amino]-2-deoxy-β-D-glucopyranosyl)-1H-1,2,3-triazole-4-methanamine (**6**).* Compound **5** (774 mg, 1 mmol) was dissolved in 1 M NaOH (5 mL) and was stirred for 5 h. The mixture was extracted with ethyl acetate, dried on $Na_2SO_4$, and filtered, and the filtrate was evaporated. The residue and $K_2CO_3$ (140 mg, 2.5 mmol) were suspended in methanol (3 mL), and the reaction mixture was cooled to 0 °C on an ice bath. To the suspension was added in small portions NBD-Cl (300 mg, 1.5 mmol), and the reaction mixture was kept at room temperature for another 12 h. Solvent was evaporated under reduced pressure, and the crude product was purified by TLC. Red brown solid: yield 68%; $^1$H NMR (600 MHz, MeOD) $\delta$ 8.40 (d, $J$ = 8.8 Hz, 1H), $\delta$ 8.40* (d, $J$ = 8.8 Hz, 1H), 8.20 (s, 1H), 8.17* (s, 1H), 7.96 (m, 2H), 6.46 (d, $J$ = 8.8 Hz, 1H), 6.43* (d, $J$ = 8.8 Hz, 1H), 6.01* (d, $J$ = 9.5 Hz, 1H), 5.99* (d, $J$ = 9.5 Hz, 1H), 4.60 (s-like, 1H), 4.51 (dd, $J$ = 16.5, 4.86 Hz, 1H), 4.30 (dd, $J$ = 16.5, 9 Hz, 1H), 3.95 (dd, $J$ = 12.1, 3.8 Hz, 1H), 3.96* (dd, $J$ = 12.1, 3.8 Hz, 1H), 3.91−3.85 (m, 1H), 3.81 (dd, $J$ = 12.1, 7.7 Hz, 1H), 3.81* (dd, $J$ = 12.1, 7.4 Hz, 1H), 3.70−3.65 (m, 2H); $^{13}$C NMR (150 MHz, MeOD) $\delta$ 151.7, 146.2, 145.72, 145.5, 145.2, 137.8, 137.7, 137.6*, 136.2, 136.0, 135.9, 127.9, 127.8, 127.8, 124.5, 123.5, 123.3, 122.6, 112.1, 112.0, 97.4, 81.4, 77.5, 77.2*, 71.1, 62.2, 56.0, 40.7, 40.5* (*enantiomer); ESI-MS, $m/z$ 842.0499 $[M + H]^+$, 840.0331 $[M - H]^-$.

**Plant Materials.** Castor bean seeds (No. 9) were obtained from the Agricultural Science Academy of Zibo Shandong China. The seeds were treated and grown as previously described.[8] Six day old seedlings were selected for the further experiments.

**Uptake by *Ricinus communis* Foliar Disks.** Disks were obtained and treated with incubation medium containing 20 mM MES (pH 5.6), 250 mM mannitol, 0.25 mM $MgCl_2$, and 0.5 mM $CaCl_2$ as described formerly.[8,15] Then the disks were transferred to the incubation medium supplemented with 2-NBDGTF to perform the time-course uptake experiment and to investigate the concentration dependence of 2-NBDGTF uptake. Disks were incubated with incubation medium, pH ranging from 4.0 to 8.0, to investigate the pH dependence, and treated at 4 or 28 °C to examine the temperature effect on the 2-NBDGTF uptake. For the inhibition experiments, the disks were preincubated with 50 μM CCCP, 1 mM phloridzin, 1 mM GTF, and 2 mM monosaccharide (glucose, xylose, arabinose, mannose, and galactose) in the incubation medium for 30 min, respectively. Then the disks were coincubated with 50 μM 2-NBDGTF and these substrates for 1 h. Incubation was run under mild agitation on a reciprocal shaker at 28 °C. After the total incubation period, the disks were rinsed using the incubation solution three times to remove the residuals. Then the disks were freeze-dried using liquid nitrogen and then ground with 10 mL of methanol and ultrasonically treated for 30 min. The extract solutions were centrifuged at 12000 rpm/min for 10 min and then filtered with 0.22 μm filter. Then the extract solution was analyzed by HPLC system (Shimadzu, Japan).

**Phloem Sap Collection.** As described previously,[6] the cotyledons, from which the endosperm had been removed, were incubated in the buffer solution containing test compound 2-NBDGTF at a 100 μM concentration. GTF synthesized in our previous work was set as the positive control in this experiment. The roots of seedlings were immersed in 0.5 mM $CaCl_2$ solution. After 1 h of incubation, the hypocotyl was severed in the hook region for phloem exudation. The interval of phloem sap collection was 1 h, and the duration was 5 h. The collected phloem sap was quantified by an HPLC system after dilution with pure water (phloem sap/pure water, 1/4, v/v).

**Visualization of Cotyledon Uptake and Translocation of 2-NBDGTF in *R. communis* Seedlings.** Visualization of uptake and translocation of 2-NBDGTF was investigated using 6 day old castor bean seedlings as described in our previous work.[16] After treatment with 100 μM 2-NBDGTF incubation solution, cotyledons and stems were excised at 1 h, 2 h, and 3 h and washed thoroughly with incubation solution to remove the residual conjugate. Freehand cross sections of midveins and petioles were taken from the treated cotyledons, and sections of hypocotyl were immediately taken above the hook. Then sections were observed with confocal laser scanning microscopy (Zeiss LSM780, Germany) directly. Photos of at least five sections from each treatment were taken with a 10× or 20× Plan-Apochromat (0.8 M27) objective using an argon laser with 488 nm excitation and 500−535 nm emission filter.

**Determination of 2-NBDGTF.** Disk extracts and phloem sap were analyzed using an HPLC system (Shimadzu, Japan) equipped with a LC-20A fluorescence detector. The fluorescence detection conditions of 2-NBDGTF were excitation at 470 nm and emission at 530 nm. The determination of GTF was performed with a HP 1100 (Agilent) HPLC system. Separations were made with a C8 reversed-phase column. The solvent system consisted of acetonitrile and water (60:40, v/v). The injection volume was 10 μL, and the flow rate was 1 mL/min. The calibration curve of 2-NBDGTF (ranging from 1 μM to 100 μM, $r$ = 0.999) and GTF (ranging from 2.5 μM to 100 μM, $r$ = 0.998) was linear.

The presence of 2-NBDGTF in disk extracts and phloem sap was further identified by HPLC−HRMS (high resolution mass spectrometry) (Bruker maXis, Germany) using electrospray ionization. The mass spectrometer was operated in the positive electrospray ionization mode ($ESI^+$). The HPLC system was an Agilent 1290 Infinity LC system which was equipped with a diode array detector. The operating conditions of the HPLC were the same as described above.

**Physicochemical Properties.** Physicochemical properties [molecular mass (MW), ionization constant in aqueous solution ($pK_a$), octanol/water partitioning coefficient (log $K_{ow}$)] of GTF and 2-NBDGTF were predicted using ACD LogD suite version 14.0 software. The chemical structures of conjugates 2-NBDGTF and GTF are shown in Figure 1, and the physicochemical properties of 2-NBDGTF are summarized in Table 1. The excitation and emission fluorescence spectra are shown in Figure 2.

**Table 1. Properties of the Tested Conjugates[a]**

| properties | GTF | 2-NBDGTF |
|---|---|---|
| mol wt | 680.4 | 842.5 |
| LogP | 2.06 | 3.31 |
| $pK_a$ | 12.8 ± 0.7 (acid) | 12.8 ± 0.7 (acid) |

[a]The value of log $K_{ow}$ and $pK_a$ of GTF and 2-NBDGTF were predicted by ACD Laboratories Percepta program, version 14.0. Log $K_{ow}$ and $pK_a$ value was classic value.

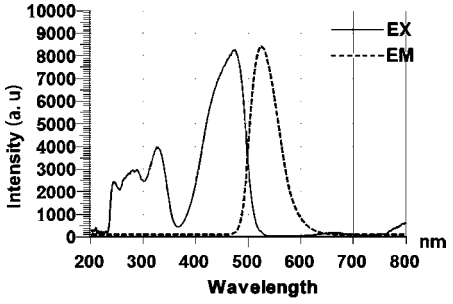

**Figure 2.** Excitation and emission fluorescence spectra of fluorescent conjugate 2-NBDGTF. The maximum fluorescence excitation wavelength was at 470 nm, and the maximum emission wavelength was at 530 nm.

## RESULTS AND DISCUSSION

**Synthesis of 2-NBDGTF.** As outlined in Scheme 1, glucosamine hydrochloride was chosen as starting material, and the amino group was protected by the trifluoroacetyl group to obtain compound **2**. Reaction of compound **2** and TMS-$N_3$ in the presence of $SnCl_4$ afforded compound **3**.[17] Compound **5** was synthesized via click chemistry by introducing an azide group or an alkyne moiety to the corresponding compounds **3**

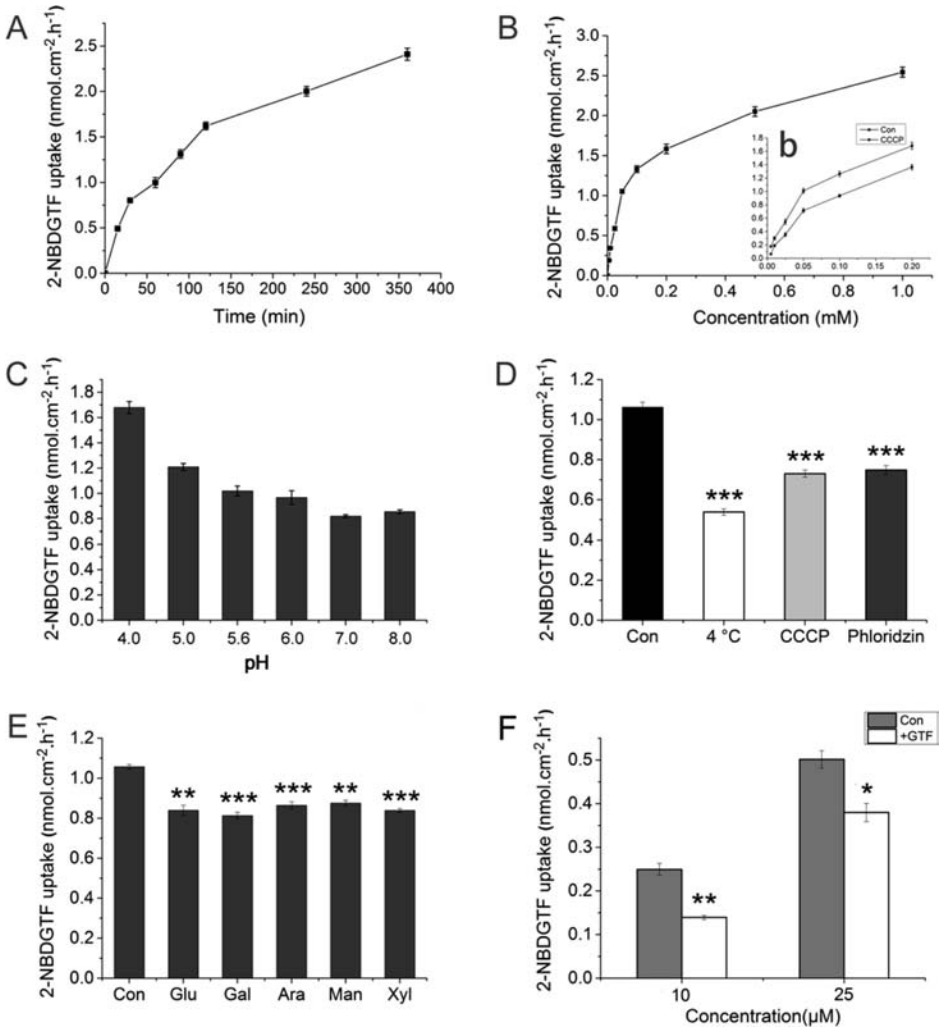

**Figure 3.** Uptake of 2-NBDGTF by cotyledon disks obtained from castor bean seedlings. (A) Time course of 2-NBDGTF uptake by disks. Disks were incubated in a buffered solution containing 50 $\mu$M 2-NBDGTF at pH 5.6. Shown are the averages of 12 disks ± SE ($n$ = 4). (B) Concentration dependence of 2-NBDGTF uptake. Disks were incubated in a buffered solution at pH 5.6 containing 2-NBDGTF concentration ranged from 0.005 mM to 1 mM. Disks coincubated with 50 $\mu$M CCCP were set as the complementary set (b). Each point was the mean of 12 disks ± SE ($n$ = 6). (C) pH dependence of 2-NBDGTF uptake by disks. Each bar represents the mean of 12 disks ± SE ($n$ = 4). (D) Effect of low temperature (4 °C) and inhibitor (50 $\mu$M CCCP and 1 mM phloridzin) on the 2-NBDGTF uptake. Each bar represents the mean of 12 disks ± SE ($n$ = 5). (E) Effect of 2 mM monosaccharides on the uptake of 50 $\mu$M 2-NBDGTF at pH 5.6. Data are mean of 12 disks ± SE ($n$ = 4). (F) Effect of 1 mM GTF on the uptake of 2-NBDGTF. Shown are the averages of 12 disks ± SE ($n$ = 4). Statistical analysis was performed using the ANOVA test, and Dunnett's test was used to analyze differences in the mean of each group with control group. *, $p < 0.05$; **, $p < 0.01$; ***, $p < 0.001$.

and **4**. NaOMe/MeOH was used to remove the acetyl and trifluoroacetyl groups. However, the trifluoroacetyl group remained intact after reaction to get compound **5**. The trifluoroacetyl group was finally deprotected with 1 M NaOH solution and then reacted with NBD-Cl to obtain target product 2-NBDGTF.

All products were identified by $^{1}$H and $^{13}$C NMR spectroscopy and mass spectrometry. The $^{1}$H NMR spectra of these compounds are complicated because fipronil has a symmetrical sulfoxide and forms two enantiomers.[18,19] Their configurations were confirmed on the basis of a chemical shift, coupling constants, and band shape of H-1. For example, the NMR signals of product 2-NBDGTF were immediately measured after the dissolution of the glucosyl conjugates in denatured methanol.

The doublet, observed at 6.01 and $J_{1,2}$ = 9.5 Hz, was assigned to H-1 of the $\beta$-D-pyranose anomer. The synthesized compound $C_{27}H_{19}Cl_2F_6N_{11}O_8S$ (2-NBDGTF) was further identified by HRMS-ESI analysis (calculated for 2-NBDGTF $[M + H]^+$, 842.0420; found, 842.0499;). From these results, the synthesized product was identified as 2-NBDGTF.

**The Foliar Disk Uptake of 2-NBDGTF Is Carrier-Mediated.** When castor bean foliar disks were incubated with buffer solution supplemented with 50 $\mu$M 2-NBDGTF at pH 5.6 for up to 360 min, the rate of 2-NBDGTF uptake increased rapidly and almost linearly during the 120 min incubation period and then decreased until 360 min (Figure 3A). The results suggested that the uptake of 2-NBDGTF will reach equilibrium rapidly with increasing incubation times.

To investigate the concentration dependence of 2-NBDGTF uptake, castor bean foliar disks were incubated with buffer solution supplemented with 2-NBDGTF at concentrations ranging from 0.005 to 1 mM for 1 h. Concentration dependence data clearly show that there were two components involved in 2-NBDGTF uptake. The first component is a saturable component that occurs between 0.005 and 0.2 mM,

dx.doi.org/10.1021/jf502838m | J. Agric. Food Chem. 2014, 62, 8791−8798

suggesting that part of 2-NBDGTF uptake is carrier-mediated at low concentrations. The second component is a roughly linear component at higher concentrations, indicating the existence of passive diffusion (Figure 3B). Upon cotreatment with 50 $\mu$M CCCP, which is widely utilized in studies of transmembrane transport to dissipate the proton motive force,[8,15,20] the saturable component of 2-NBDGTF uptake appeared to be apparently inhibited (Figure 3b). To study the pH effect of incubation medium on 2-NBDGTF uptake, the disks were incubated with different pH buffer solution (pH ranging from 4.0 to 8.0). The results showed that uptake of 2-NBDGTF was sensitive to pH changes in the incubation medium. The uptake of 2-NBDGTF apparently increased with decreasing incubation pH, and the reduction of pH from 8.0 to 4.0 increased the uptake of 2-NBDGTF approximately 2-fold (Figure 3C). The results above confirmed that 2-NBDGTF uptake in lower concentrations is proton motive force dependent.

To further understand the uptake mechanism, the effect of temperature on 2-NBDGTF uptake was investigated. The uptake of 2-NBDGTF maintained at low temperature (4 °C) was reduced about 47% compared with normal incubation conditions (28 °C), suggesting that the 2-NBDGTF uptake machinery is energy dependent (Figure 3D). Phloridzin is an inhibitor of the sodium-linked glucose transporters,[21] and it is also used as an inhibitor of plant hexose transporter.[22,23] When treated with 1 mM phloridzin or 50 $\mu$M CCCP alone, the 2-NBDGTF uptake was remarkably decreased about 29% and 31%, respectively (Figure 3D). The results suggested that the 2-NBDGTF uptake machinery is also sensitive to phloridzin.

To clarify the competitive inhibition of substrates, the effect of monosaccharides on the uptake of 2-NBDGTF was investigated. At 2 mM concentration, both monosaccharides significantly inhibited 2-NBDGTF uptake by 10−15% (Figure 3E). In the case of the CCCP-sensitive component of the conjugate, the influx was only about 31% of the total uptake when the disks were incubated with 50 $\mu$M 2-NBDGTF. At 2 mM concentrations, these monosaccharides led to a 0.05 mM 2-NBDGTF uptake of the CCCP sensitive component, totaling 30−50%. In addition, the effect of GTF on 2-NBDGTF uptake was also evaluated. When treated with 1 mM GTF, the uptake of 2-NBDGTF was dramatically reduced about 42% at 10 $\mu$M and 24% at 25 $\mu$M, respectively (Figure 3F). The results above suggested that both monosaccharides and GTF exhibited strong competition with the uptake of 2-NBDGTF.

The characteristics of carrier-mediated transport mainly include that it is concentration dependent (saturable), subject to inhibition, more structure specific compared to passive transport, and cell type specific, which requires expression of the transporter.[24] In the present research, the disk results showed that the uptake of 2-NBDGTF was concentration dependent, energy dependent, and subject to CCCP and phloridzin inhibition and involved competitive inhibition of monosaccharides. Besides, GTF exhibited strong competition with the uptake of 2-NBDGTF. Altogether, these disk uptake results demonstrated the involvement of a carrier-mediated system in the 2-NBDGTF uptake process.

**Phloem Sap Determination of 2-NBDGTF.** Castor bean seedling is an ideal system to identify endogenous molecules moving in sieve tubes[25,26] and to evaluate phloem systemicity of xenobiotics.[27] Thanks to the cotyledon epidermis being thin and highly permeable and making contact with the external space directly, the system could respond to incubation with solutes readily. Therefore, the castor bean seedling system is employed to evaluate phloem mobility of 2-NBDGTF in the present work.

When the cotyledons were incubated in buffer solution containing 100 $\mu$M 2-NBDGTF, the conjugate was clearly detected in the phloem sap. Time-course experimental results indicated that the concentrations of 2-NBDGTF in the phloem sap increased almost linearly during the experimental period, which is consistent with GTF (Figure 4). The measured 2-

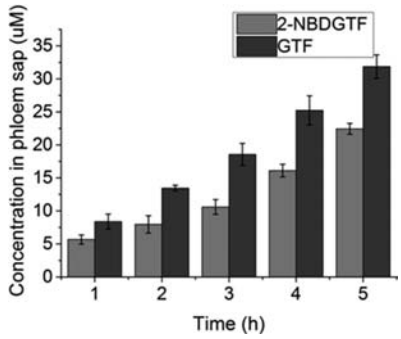

**Figure 4.** Time course of the concentration of conjugates 2-NBDGTF and GTF in *R. communis* phloem sap. The cotyledons were incubated in a buffered solution containing 100 $\mu$M 2-NBDGTF or GTF at pH 5.0. The hook of the hypocotyl was severed after 1 h incubation, and then the sap was collected per hour during 5 h. Each bar represents the mean of 12 plants ± SE, $n$ = 4.

NBDGTF concentrations in the phloem sap were 5.68 ± 0.69 $\mu$M, 10.61 ± 1.11 $\mu$M, and 22.45 ± 0.83 $\mu$M (mean ± SE) at 1 h, 3 h, and 5 h, respectively. These values represent GTF concentrations in the phloem sap of 0.68-fold, 0.64-fold, and 0.70-fold, respectively. The results showed that 2-NBDGTF exhibited comparable phloem mobility with GTF in castor bean seedlings.

Moreover, the fluorescent glucose−fipronil conjugate present in the foliar disk extracts and phloem sap at 5 h was further identified by HPLC−HRMS (high resolution mass spectrometry) analysis. Calculated for 2-NBDGTF ($C_{27}H_{19}Cl_2F_6N_{11}O_8S$) was $[M + H]^+$ 842.0420; and the found mass $[M + H]^+$ of 2-NBDGTF in disk extracts was 842.0482 (Supporting Information, Figure 1B) and in phloem sap was 842.0480 (Supporting Information, Figure 1D), respectively. These results established that it was the intact molecule that was detected in the disk extracts and phloem sap, indicating that the fluorescent molecule 2-NBDGTF was relatively stable during the experimental period.

The "Kleier model" was widely employed to predict the mobility of xenobiotics based on the physicochemical properties (log $P$ and p$K_a$).[3,28] Taking the given physicochemical properties into consideration, 2-NBDGTF is a compound ranging into the non-phloem-mobile area which is similar to GTF (Figure 5). However, 2-NBDGTF presented comparable phloem mobility with GTF in castor bean seedlings. Most xenobiotics fitted well into this model except for some xenobiotics whose transport was carrier-mediated. This inconsistency between the predicting results and phloem mobility test confirmed that 2-NBDGTF was an exception to the "Kleier model" and the involvement of a carrier-mediated system in the uptake process.

Introduction of fluorophores will inevitably bring some changes to physicochemical properties of the parent com-

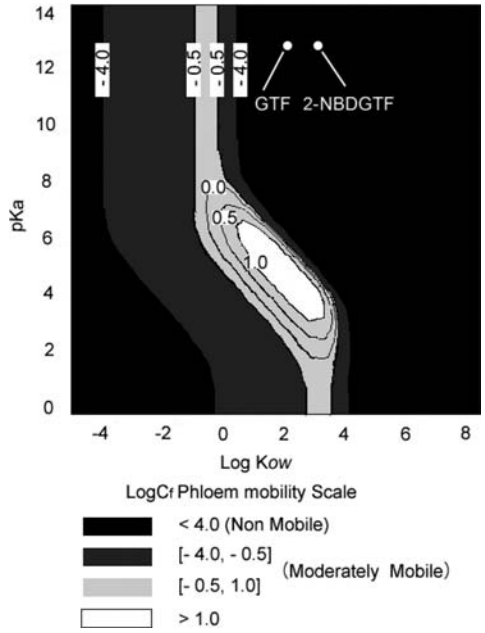

**Figure 5.** Prediction of phloem mobility of GTF and 2-NBDGTF using Kleier map;[1,32] log $K_{ow}$ and p$K_a$ values were calculated by ACD Laboratories Percepta program version 14.0.

pounds, including enlarging the molecular weight, increasing the octanol/water partitioning coefficient value, etc., which is consequently to have some effects on the parent compound characteristics. Compared with fluorescein (Fl) and Alexa Fluor 647 (AF), which have been employed successfully to label the gibberellins and castasterone,[13,14] NBD is a fluorophore with lower molecular weight and good cell permeability and thus has been widely utilized to label the glucose. The fluorescent conjugate of glucose 2-NBDG, fluorescently modified with a small fluorescent moiety NBD of glucose at the C-2 position, has been employed as a fluorescent glucose replacement and widely used to monitor the cellular glucose uptake activity.[29,30] It seems that the effect of the fluorescent tag NBD on the parent conjugate is tolerable. In comparison with GTF, 2-NBDGTF is indeed a compound with larger MW, and higher log *P* and HBA value (Table 1). Our results showed that the fluorescent conjugate 2-NBDGTF retained the carrier-mediated uptake mechanism and moderate phloem mobile property of GTF. Hence, 2-NBDGTF is regarded as a reasonable fluorescent surrogate of GTF and is believed to be capable of revealing the movement of glucose−fipronil analogues within plants.

**Visualization of Uptake and Transport of 2-NBDGTF in Castor Bean Seedlings.** The visualization of uptake and transport of 2-NBDGTF within castor bean seedlings was performed using confocal laser scanning microscopy (CLSM). The CLSM observation results showed the presence of remarkable fluorescence in epidermal cells and mesophyll cells (Figure 6B) of the midveins of the cotyledons treated with 2-NBDGTF for 1 h. Moreover, enormous fluorescence was observed present in the phloem. *Ricinus* is a symplastic−apoplastic loader, meaning that endogenous molecules from the seedling endosperm or incubation solution found in the phloem sap via the symplastic pathway may originate from the transfer cells of the lower epidermis. These molecules may have also been taken up directly from the phloem apoplast.[26,27] The observed results of the presence of remarkable

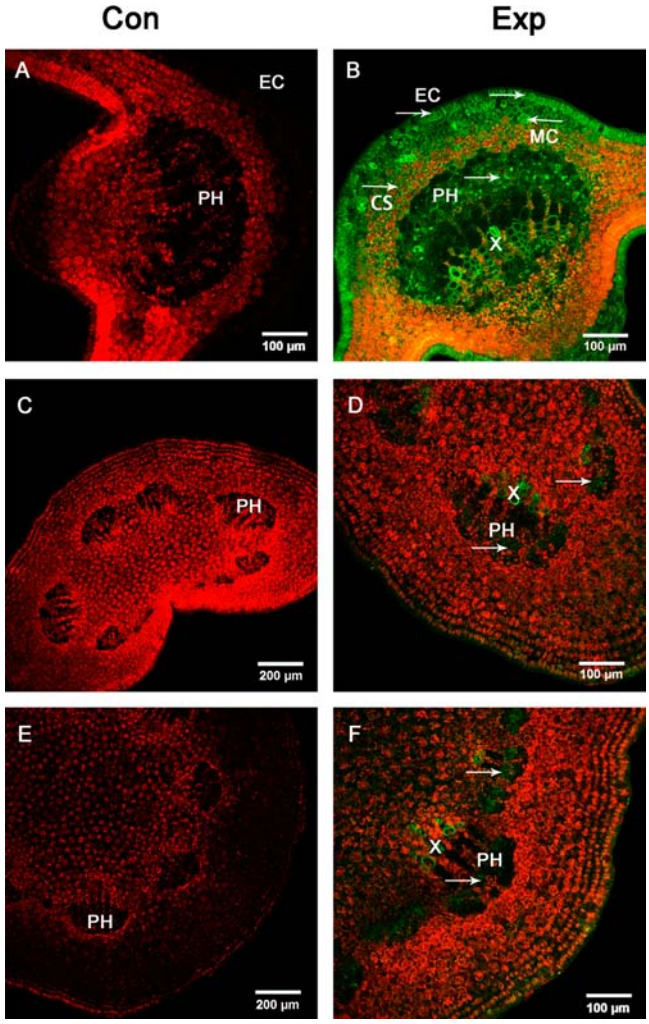

**Figure 6.** Representative fluorescence photographs of six day old caster bean seedlings: The cotyledons were incubated in a buffered solution containing 100 $\mu$M 2-NBDGTF. (A, B) Cross sections of midveins of cotyledons, (C, D) cross sections of petioles of cotyledons, and (E, F) cross sections of hypocotyl of caster bean seedlings. All photos were observed by confocal laser scanning microscope (Zeiss780, Germany). No significant fluorescence was observed in the mesophyll cells or phloem of control set (A, C, E). The presence of fluorescent xenobiotics was indicated by arrowheads. EC: epidermal cells. CS: cell wall space. MC: mesophyll cells. PH: phloem. X: xylem.

fluorescence in epidermal cells and mesophyll cells obtained using 2-NBDGTF suggest that cotyledons could take up 2-NBDGTF from the medium readily via lower epidermal cells. The cotyledons could then load the 2-NBDGTF into sieve tubes from the apoplast after transission through mesophyll cells in an indirect apoplasmic loading process or via plasmodesmata after uptake by mesophyll cells in a symplasmic loading process. The obvious fluorescence observed in the cell wall and intercellular space (Figure 6B) suggests that cotyledons may load 2-NBDGTF into sieve tubes directly via an apoplasmic loading pathway. The observed results show that the loading pathway of 2-NBDGTF is consistent with the phloem loading pathway of sucrose in *Ricinus* cotyledons.[26]

After a 2 h incubation, intense fluorescence was also detected in the phloem of cotyledon petiole (Figure 6D), signifying that the 2-NBDGTF efflux can rapidly export via the phloem of the

cotyledon petiole. Intense fluorescence was also observed in the phloem of the hypocotyls after receiving 3 h of treatment (Figure 6F). These results indicate that 2-NBDGTF is phloem mobile and can translocate at a distance (from cotyledon to hypocotyl) via phloem.

The cells of 6 day old *Ricinus* seedling cotyledons appear as meristematic cells with well-developed organelles lacking large central vacuoles.[31] Fluorescence present in epidermal and mesophyll cells was homogeneously distributed in the cytoplasm, but was not caused by the compartmentation trapping by the vacuole. Alternatively, the intense fluorescence present in the xylem of the treated cotyledons was likely caused by the direct loading into the vessels. The fluorescence observed in the xylem of petioles and hypocotyls may be the result of lateral diffusion during phloem translocation and the adsorption of the lipophilic xenobiotic on lignins.

Since 2-NBDGTF was stable in the phloem during the experimental period, the fluorescence observed in the epidermal cells, mesophyll cells, and phloem could reflect the distribution of 2-NBDGTF, which would in turn reveal the distribution of GTF within plants. Accumulation spots of 2-NBDGTF likely represent the tissue sites of GTF, meaning that GTF was also loaded into the sieve tubes after transiting through epidermal cells and mesophyll cells along a symplastic−apoplastic loading route and was able to translocate at a distance (from cotyledon to hypocotyl) via phloem within seedlings.

In conclusion, a fluorescent glucose−fipronil conjugate was obtained via click chemistry. The uptake of disks of 2-NBDGTF was demonstrated to involve a carrier-mediated uptake process, and the phloem mobility in castor bean seedlings was comparable with GTF. Visualization of 2-NBDGTF movement showed that this fluorescent glucose−fipronil conjugate could be loaded into sieve tubes after transiting through epidermal cells and mesophyll cells and translocate at a distance via phloem within seedlings. From this information, 2-NBDGTF was determined to be a reasonably fluorescent surrogate of GTF and capable of revealing the movement of GTF analogues. The wide utilization of 2-NBDG provides us a substantial belief that 2-NBDGTF is a promising fluorescent conjugate. Moreover, this fluorescently labeled approach presents a great potential for revealing the activities of other glucose insecticides in plants.

**ABSTRACT:** On the basis of the structure of natural product (−)-incrustoporin (**1**), a series of lactone compounds **4a**−**i** and **5a**−**i** were designed and synthesized from nitroolefin. The antiviral and antifungal activities of these compounds were evaluated in vitro and in vivo. The small changes between **4** and **5** at the 3,4-position result in large differences in bioactivities. Compounds **4** exhibited significantly higher antiviral activity against tobacco mosaic virus (TMV) than dehydro compounds **5**. However, the antifungal activity of **4** is relatively lower than that of **5**. Compounds **4a**, **4c**, and **4i** with excellent in vivo anti-TMV activity emerged as new antiviral lead compounds. Compounds **5d**−**g** showed superiority over the commercial fungicides chlorothalonil and carbendazim against *Cercospora arachidicola* Hor at 50 mg $kg^{-1}$. The present study provides fundamental support for the development and optimization of (−)-incrustoporin derivatives as potential inhibitors of plant virus and pathogenic fungi.

**KEYWORDS:** *2,5-dihydrofuran-2-ones, (−)-incrustoporin derivatives, anti-TMV, antifungal activity*

## INTRODUCTION

Plant diseases are caused primarily by fungal and bacterial pathogens, leading to severe losses for agriculture and horticulture crop production worldwide, and constitute a great threat to global food security.[1] The yield of major food and cash crops was reduced nearly 20% by pathogenic fungi.[2] Plant viral diseases, known as "plant cancer", are serious threats after fungal diseases. They cause a variety of detrimental effects, and usually the infected plants are more susceptible to damage by pests and pathogens. Tobacco mosaic virus (TMV), one of the most well-studied plant viruses, is known to infect more than 400 plant species belonging to 36 families, such as tobacco, tomato, potato, and cucumber. It is found that in certain fields 90−100% of the plants show mosaic or leaf necrosis by harvesting time.[3]

Many of the currently available antifungal and antiviral agents have several drawbacks, such as pesticide related toxicity, severe pesticide resistance, and serious pesticide interactions.[4−7] Therefore, there is a growing need to develop new antifungal agents to effectively control these agricultural diseases.

Using natural products as lead compounds to develop new pesticides with novel structures and mechanisms is one of the most effective pesticide design methods.[8,9] (−)-Incrustoporin (**1**, Figure 1), isolated from *Incrustoporia carneola* (Bres.) Ryv. (Basidiomycetes) by Zapf in 1995,[10] is found to possess antifungal activity against a wide array of pathogenic fungi (*Candida albicans* strains, *Candida krusei*, *Candida glabrata*, and so on).[11−17] Biological screening has revealed that the endocyclic double bond is necessary for the antifungal effect, and the substitution of the C(3)-aryl ring with halogens could boost their antifungal activity. The preparation of (−)-incrustoporin and its derivatives has been reported by Mori,[18] Rossi,[19] Wu,[20] Fontes,[21] Oh,[22] and Fernandes[23] successively. Until now, most of the studies about (−)-incrustoporin and its derivatives were focused on antifungal activity against a panel of human pathogenic fungi; there have been no reports about the antiviral activity against TMV and only a few reports about antifungal activity against plant pathogenic fungi.[10]

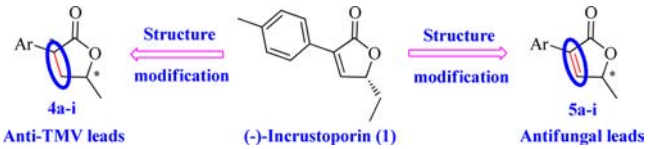

**Figure 1.** Design of (−)-incrustoporin derivatives **4a**−**i** and **5a**−**i**.

In the process of developing new potent plant virus inhibitors, phenanthroindolizidine alkaloids,[24] phenanthroquinolizidine alkaloids,[25] and β-carboline alkaloids[26] have been found to have good anti-TMV activity. As a continued work, 3-aryl-5-methyl-γ-butyrolactones **4** and 3-aryl 5-methyl-2,5-dihydrofuran-2-ones **5** were designed, synthesized from nitroolefin on the basis of the structure of the natural product (−)-incrustoporin (**1**). Their antiviral activity against TMV and

antifungal activity against plant pathogenic fungi were systematically investigated for the first time.

## MATERIALS AND METHODS

**Instruments.** The melting points of the products were determined on an X-4 binocular microscope (Gongyi Yuhua Instrument Co., China) and were not corrected. NMR spectra were acquired with a Bruker 400 MHz (100 MHz for $^{13}C$) instrument at room temperature. Chemical shifts were measured relative to residual solvent peaks of $CDCl_3$ as internal standards ($^1H$, $\delta$ = 7.26 ppm; $^{13}C$, $\delta$ = 77.0 ppm). The following abbreviations were used to designate chemical shift multiplicities: s, singlet; d, doublet; t, triplet; m, multiplet; and bs, broad singlet. All first-order splitting patterns were assigned on the basis of multiplet appearance. Splitting patterns that could not be easily interpreted were designated multiplet (m) or broad (br). Enantiomeric excesses were determined with an HP1-100 instrument (chiral column; mobile phase of hexane/2-propanol). HRMS data were recorded with a Varian QFT-ESI instrument. Analytical TLC was performed on silica gel GF 254. Column chromatographic purification was performed using silica gel. All reagents were of analytical reagent grade or chemically pure and purified prior to use when necessary. The $\beta$-nitrostyrene **2a**−**i** were prepared according to the literature.[27] (*S*)-**3d** were prepared according to our previously reported procedure.[28]

**General Experimental Procedures.** *General Procedures for the Preparation of Intermediate **3a**−**i**.*[29] To a mixture of $CHCl_3$ (10 mL), $Et_3N$ (20−30 mol %), and acetone (40.0 mmol, 3 mL) was added the corresponding nitroolefin (4.0 mmol) followed by (±)-proline (20−30 mol %), and the resulting mixture was stirred at room temperature until TLC indicated the reaction was complete. The reaction mixture was evaporated under vacuum, and the residue was dissolved in $CH_2Cl_2$ (30 mL). The mixture was treated with 1 M HCl (20 mL) solution, the layers were separated, and the aqueous layer was extracted several times with $CH_2Cl_2$, dried with anhydrous $MgSO_4$, and evaporated. The pure products **3a**−**g** were obtained by recrystallization from methanol. **3h** and **3i** were purified by column chromatography on silica gel (100−200 mesh, petroleum ether/ethyl acetate = 5:1).

*General Synthetic Procedures for Intermediate **4a**−**i** (Diastereomers of **4a**−**g** Shown as A and B, Respectively).*[32] $NaBH_4$ (0.19 g, 5 mmol) was added to a solution of **3a**−**i** (5 mmol) in MeOH/$CH_2Cl_2$ (v/v = 1:1, 10 mL) at 0 °C. The mixture was stirred for 15 min at the same temperature, and $H_2O$ (10 mL) was added. After evaporation of the methanol under reduced pressure, HCl (aq) 1 M (10 mL) was added, and the aqueous phase was extracted with $CH_2Cl_2$ (3 × 15 mL). The combined organic layers were dried over $MgSO_4$ and evaporated to afford the expected nitroalcohol, which was redissolved in DMSO (8.5 mL). Sodium nitrite (0.80 g, 12.75 mmol) and acetic acid (1.7 mL, 42.5 mmol) were then added, and the solution was stirred at room temperature overnight and at 40 °C for 6 h. The mixture was allowed to cool, and HCl (aq) 1 M (50 mL) was added. The aqueous phase was extracted with $CH_2Cl_2$ (3 × 50 mL). The organic layers were combined, dried over $MgSO_4$, and evaporated under vacuum to afford the γ-butyrolactones **4a**−**i**, which were then purified by flash column chromatography on silica gel (100−200 mesh, petroleum ether/ethyl acetate = 12:1).

*General Procedures for the Preparation of Furanones **5a**−**5i**.*[13] Butyllithium (11.0 mmol) was added to a solution of diisopropylamine (10.6 mmol) in dry THF (30 mL) at 0 °C under $N_2$. After 30 min, the LDA solution was cooled to −60 °C, and a solution of a saturated lactone (**4a**−**i**) (10.0 mmol) in THF (5 mL) was added. The reaction temperature was maintained at −60 °C for 30 min, and a solution of phenylselenenyl chloride (15.0 mmol) in THF (10 mL) was added. The resultant mixture was slowly warmed to room temperature, diluted with ethyl acetate (50 mL), washed with saturated aqueous $NH_4Cl$, dried over $Na_2SO_4$, and concentrated. The crude phenylselanyl derivative was rapidly purified by column chromatography and dissolved in $CHCl_3$ (20 mL), and then *m*-CPBA (15.0 mmol) was added to the solution in several portions at 0 °C. The reaction mixture was then stirred for 2 h at room temperature or until TLC indicated the reaction was complete. A further portion of $CHCl_3$ (10 mL) was added along with 5% aqueous $Na_2CO_3$ (20 mL). The layers were separated, and the organic phase was washed with 5% aqueous $Na_2CO_3$ (20 mL), dried over $Na_2SO_4$, and evaporated. Products **5a**−**i** were purified by column chromatography on silica gel (100−200 mesh, petroleum ether/ethyl acetate = 15:1) and were obtained with overall yields in the range 31−51% over two steps.

*3-Phenyl-5-methyl-2,5-dihydrofuran-2-one (**5a**):* white solid; yield 40%; mp 49−51 °C (lit.[13] 45−46 °C); $^1$H NMR $\delta$ 1.52 (d, $J$ = 6.8 Hz, 3 H), 5.15 (qd, $J$ = 6.4 and 13.2 Hz, 1 H), 7.40−7.43 (m, 3 H), 7.55 (s, 1 H), 7.85 (d, $J$ = 6.4 Hz, 2 H); $^{13}$C NMR $\delta$ 171.8, 149.2, 131.3, 129.5, 129.3, 128.7, 127.1, 76.8, 19.2; HRMS (ESI) calcd for $C_{11}H_{10}O_2$ $(M + H)^+$ 175.0754, found 175.0756.

*3-(4-Methylphenyl)-5-methyl-2,5-dihydrofuran-2-one (**5b**):* white solid; yield 39%; mp 53−54 °C (lit.[13] 55−57 °C); $^1$H NMR $\delta$ 1.50 (d, $J$ = 6.8 Hz, 3 H), 2.37 (s, 3 H), 5.14 (qd, $J$ = 6.8 and 13.6 Hz, 1 H), 7.22 (d, $J$ = 8.0 Hz, 2 H), 7.49 (s, $J$ = 2.0 Hz, 1 H), 7.75 (d, $J$ = 8.0 Hz, 1 H); $^{13}$C NMR $\delta$ 171.9, 148.1, 139.4, 131.2, 129.4, 126.9, 126.7, 76.7, 21.4, 19.2; HRMS (ESI) calcd for $C_{12}H_{12}O_2$ $(M + H)^+$ 189.0910, found 189.0912.

*3-(4-Fluorophenyl)-5-methyl-2,5-dihydrofuran-2-one (**5c**):* white solid; yield 32%; mp 71−73 °C (lit.[13] 81−83 °C); $^1$H NMR $\delta$ 1.52 (d, 3 H, $J$ = 6.8 Hz), 5.16 (m, 1 H), 7.08−7.13 (m, 2 H), 7.51 (d, 1 H, $J$ = 2.0 Hz), 7.85−7.88 (m, 2 H); $^{13}$C NMR $\delta$ 171.6, 164.5, and 162.1 ($J_{C-F}$ = 248.1 Hz), 148.5, 130.4, 129.1, and 129.0 ($J_{C-F}$ = 8.3 Hz), 125.69 and 125.66 ($J_{C-F}$ = 2.9 Hz), 115.8 and 115.6 ($J_{C-F}$ = 21.6 Hz), 76.7, 19.1; HRMS (ESI) calcd for $C_{11}H_9FO_2$ $(M + H)^+$ 193.0659, found 193.0661.

*3-(4-Chlorophenyl)-5-methyl-2,5-dihydrofuran-2-one (**5d**):* white solid; yield 31%; mp 101−102 °C (lit.[13] 99−101 °C); $^1$H NMR $\delta$ 1.51 (d, $J$ = 6.8 Hz, 3 H), 5.15 (qd, $J$ = 6.4 and 13.2 Hz, 1 H), 7.36 (d, $J$ = 8.0 Hz, 2 H), 7.56 (s, 1 H), 7.80 (d, $J$ = 8.4 Hz, 1 H); $^{13}$C NMR $\delta$ 171.5, 149.5, 135.26, 130.1, 128.9, 128.4, 128.0, 76.9, 19.1; HRMS (ESI) calcd for $C_{11}H_9ClO_2$ $(M + H)^+$ 209.0364, found 209.0362.

*(R)-3-(4-Chlorophenyl)-5-methyl-2,5-dihydrofuran-2-one (**5d**):* white solid; yield 51%; $[\alpha]_D^{20}$ = −15.5° (*c* 1.0, $CHCl_3$); mp 38−40 °C; $^1$H NMR $\delta$ 1.51 (d, $J$ = 6.4 Hz, 3 H), 5.15 (qd, $J$ = 6.4 and 12.8 Hz, 1 H), 7.38 (d, $J$ = 7.6 Hz, 2 H), 7.55 (s, 1 H), 7.81 (d, $J$ = 7.6 Hz, 1 H); $^{13}$C NMR $\delta$ 171.4, 149.2, 135.4, 130.3, 128.9, 128.4, 127.9, 76.8, 19.1; HRMS (ESI) calcd for $C_{11}H_9ClO_2$ $(M + H)^+$ 209.0364, found 209.0367; HPLC analysis (Chiralpak OJ-H column, hexane/2-propanol = 98:2, flow rate = 1.0 mL/min, wavelength = 254 nm) $t_R$ = 57.23 (minor) and 68.66 min (major), 56% ee.

*3-(2,4-Dichlorophenyl)-5-methyl-2,5-dihydrofuran-2-one (**5e**):* yellow oil; yield 42%; 47−49 °C; $^1$H NMR $\delta$ 1.55 (d, $J$ = 7.2 Hz, 3 H), 5.23 (qd, $J$ = 6.8 and 13.6 Hz, 1 H), 7.32 (dd, $J$ = 6.4 and 8.4 Hz, 1 H), 7.47 (d, $J$ = 2.0 Hz, 1 H), 7.66 (d, $J$ = 8.4 Hz, 1 H), 7.78 (d, $J$ = 1.2 Hz, 1 H); $^{13}$C NMR $\delta$ 171.4, 154.9, 135.3, 133.9, 131.6, 130.0, 128.3, 127.3, 126.9, 77.4, 19.0; HRMS (ESI) calcd for $C_{11}H_8Cl_2O_2$ $(M + H)^+$ 242.9974, found 242.9975.

*3-(4-Bromophenyl)-5-methyl-2,5-dihydrofuran-2-one (**5f**):* white solid; yield 44%; mp 103−104 °C (lit.[13] 105−106 °C); $^1$H NMR $\delta$ 1.52 (d, $J$ = 6.8 Hz, 3 H), 5.15 (qd, $J$ = 6.8 and 13.6 Hz, 1 H), 7.54−7.56 (m, 3 H), 7.75 (d, $J$ = 8.4 Hz, 2 H); $^{13}$C NMR $\delta$ 171.4, 149.4, 131.9, 130.4, 128.6, 128.4, 123.7, 76.9, 19.1; HRMS (ESI) calcd for $C_{11}H_9BrO_2$ $(M + H)^+$ 252.9859, found 252.9854.

*3-(4-Trifluoromethylphenyl)-5-methyl-2,5-dihydrofuran-2-one (**5g**):* white solid; yield 43%; mp 88−90 °C (lit.[13] 91−93 °C); $^1$H NMR $\delta$ 1.55 (d, $J$ = 6.8 Hz, 3 H), 5.20 (qd, $J$ = 6.8 and 13.6 Hz, 1 H), 7.66 (s, 1 H), 7.67 (d, $J$ = 8.8 Hz, 2 H), 8.00 (d, $J$ = 8.1 Hz, 2 H); $^{13}$C

NMR $\delta$ 171.14, 150.96, 132.91, 131.3, and 130.9 (d, $J_{C-F}$ = 32.4 Hz), 130.3, 127.4, 125.6 (q, $J_{C-F}$ = 3.2 and $J_{C-F}$ = 7.1 Hz), 125.3, 77.0, 19.0; HRMS (ESI) calcd for $C_{12}H_9F_3O_2$ $(M + H)^+$ 243.0627, found 243.0624.

*3-(Furan-2-yl)-5-methyl-2,5-dihydrofuran-2-one (**5h**):* colorless oil; yield 36%; $^1$H NMR $\delta$ 1.49 (d, $J$ = 6.4 Hz, 3 H), 5.18 (qd, $J$ = 6.4 and 12.8 Hz, 1 H), 6.47 (s, 1 H), 7.13 (s, 1 H), 7.41(s, 1 H), 7.47 (s, 1 H); $^{13}$C NMR $\delta$ 170.1, 145.3, 144.2, 143.6, 123.0, 111.8, 111.1, 77.1, 19.2; HRMS (ESI) calcd for $C_9H_8O_3$ $(M + H)^+$ 165.0546, found 165.0542.

*3-(Thiophen-2-yl)-5-methyl-2,5-dihydrofuran-2-one (**5i**):* colorless oil; yield 38%; $^1$H NMR $\delta$ 1.51 (d, $J$ = 6.8 Hz, 3 H), 5.17 (qd, $J$ = 6.8 and 13.6 Hz, 1 H), 7.09 (t, $J$ = 3.6 Hz, 1 H), 7.38 (d, $J$ = 5.2 Hz, 1 H), 7.75 (d, $J$ = 3.2 Hz, 1 H); $^{13}$C NMR $\delta$ 170.9, 145.2, 131.5, 127.8, 127.5, 127.2, 126.3, 77.4, 19.2; HRMS (ESI) calcd for $C_9H_8SO_2$ $(M + H)^+$ 181.0318, found 181.0316.

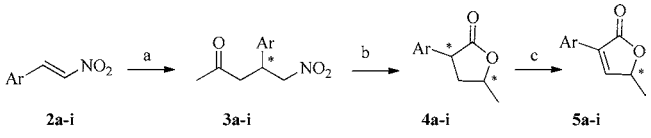
**Biological Assay.** All bioassays were performed on representative test organisms reared in the laboratory. Percentage mortalities were evaluated according to a percentage scale of 0−100, in which 0 indicates no activity and 100 indicates total kill.

*Antiviral Biological Assay.* The procedure of purifying TMV and the method to test the anti-TMV activity of the synthesized compounds were the same with those reported previously in the literature.[24,25]

*Antifungal Biological Assay.* The detailed assay method to test the antifungal activity of the synthesized compounds was described in the literature.[33]

## RESULTS AND DISCUSSION

**Chemistry.** *Synthesis of Compounds **5a−i**.* Compounds **5a−i** were synthesized according to procedures in Figure 2.



a: acetone, (± )-proline, $Et_3N$, $CH_2Cl_2$, rt;
b: 1)$NaBH_4$, $CH_3OH$, $CH_2Cl_2$, rt; 2)$NaNO_2$, AcOH, DMSO, 40 °C;
c: 1)LDA, THF, PhSeCl; 2) m-CPBA, $CHCl_3$

**a**: Ar = Ph; **b**: 4-$MeC_6H_4$; **c**: 4-$FC_6H_4$; **d**: 4-$ClC_6H_4$; **e**: 2,4-$Cl_2C_6H_3$; **f**: 4-$BrC_6H_4$; **g**: 4-$CF_3C_6H_4$; **h**: 2-furyl; **i**: thienyl

**Figure 2.** Synthesis of (−)-incrustoporin derivatives **4a−i** and **5a−i**.

Under the catalysis of proline, acetone reacted with different nitroolefins to give corresponding adducts **3a−i** in high yield (83−97%). Via reactions of reduction, oxidation, and intramolecular esterification successively, **3a−i** were converted to corresponding 3-aryl-5-methyl-$\gamma$-butyrolactone **4a−i**.[32] Finally, the double bond was introduced by enolization of the lactones **4a−i** followed by treatment with phenylselenenyl chloride, oxidation, and spontaneous selenoxide elimination to yield the target compounds **5a−i**.[13]

*Synthesis of the Compound (R)-**5d**.* To explore the effect of chirality at C(5) on biological activity, (*R*)-**5d** was prepared from (*S*)-**3d** by using the method shown in Figure 2. (3*S*,5*RS*)-**4**, obtained via reactions of reduction, oxidation, and intramolecular esterification of (*S*)-**3d**, were separated by column chromatography to give (3*S*,5*R*)-**4d** and (3*S*,5*S*)-**4d** with excellent diastereoselective (*trans*/*cis* = 23:1 and 1:15, respectively) determined by $^1$H NMR analysis. Their absolute configurations were confirmed by spectroscopic data ($^1$H NMR, $^{13}$C NMR) and single-crystal X-ray diffraction analysis (Figure 3). Unfortunately, (*R*)-**5d** was obtained with moderate enantioselectivities (56% ee) under the above reaction conditions from (3*S*,5*R*)-**4d**, and (*R*)-**5d** was obtained with enantioselectivities (16% ee) from (3*S*,5*S*)-**4d**.

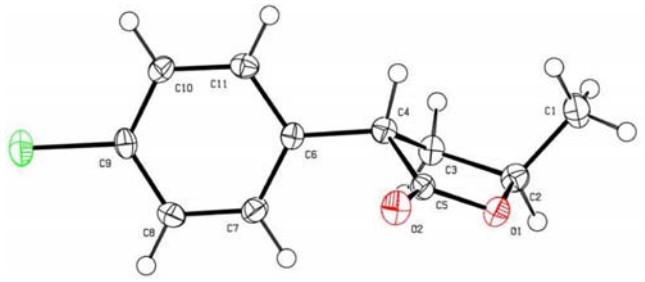


**Figure 3.** ORTEP drawing of compound (3*S*,5*R*)-**4d** (CCDC 1009910).

**Phytotoxic Activity.** Compounds **4a−i** and **5a−i** were first tested for their phytotoxic activity against the test plant. The results indicated that compounds **4a−i** showed no phytotoxic activity at 500 $\mu$g mL$^{-1}$. However, dehydro compounds **5a−g** displayed phytotoxic activity to tobacco (*Nicotiana tabacum* var. Xanthi nc), so the antiviral activity of **5a−g** was not tested at 500 $\mu$g mL$^{-1}$.

**Antiviral Activity.** The anti-TMV activity of compounds **4a−i** and **5a−i** was tested. The commercial plant virucide ribavirin was used as the control.

*In Vitro Anti-TMV Activity.* The in vitro antiviral assay results of all of the synthesized compounds are listed in Table 1. As the control, ribavirin exhibited a 41% inhibitory effect at 500 $\mu$g mL$^{-1}$, whereas most of the synthesized compounds **4a−i** exhibited higher antiviral activity than ribavirin; especially compound **4i** with 61% inhibitory effect emerged as a new lead compound for anti-TMV research. When the concentration was lowered to 100 $\mu$g mL$^{-1}$, compounds **4c**, (3*S*,5*R*)-**4d**, **4i**, and **5i** displayed nearly equal or higher inhibitory effect than that of ribavirin. To investigate the influence of chirality at C(5) and C(3) on the anti-TMV activity, compounds (3*S*,5*R*)-**4d**, (3*S*,5*S*)-**4d**, and (3*RS*, 5*RS*)-**4d** (or **4d** for short) were tested, which exhibited 48, 43, and 40% inhibitory effect at 500 $\mu$g mL$^{-1}$, respectively. The bioassay results also showed that the (3*S*, 5*R*) configuration is the preferred antiviral configuration for 3-aryl-5-methyl-$\gamma$-butyrolactone [(3*S*,5*R*)-**4d** > (3*S*,5*S*)-**4d** > **4d**].

As shown in Table 1, most of the compounds **4a−i** displayed good in vitro activity against TMV; however, almost all of the compounds **5a−i** displayed phytotoxic activity against the test plant at 500 $\mu$g mL$^{-1}$. Therefore, compounds **4a−i** were bioassayed further to investigate their antiviral activity in vivo.

*In Vivo Anti-TMV Activity.* As shown in Table 2, most of the compounds also displayed higher in vivo activity than that of the ribavirin. **4i** showed the best in vivo anti-TMV activity (inactivation activity = 52% at 500 $\mu$g mL$^{-1}$ and 20% at 100 $\mu$g mL$^{-1}$; curative activity = 57% at 500 $\mu$g mL$^{-1}$ and 30% at 100 $\mu$g mL$^{-1}$; and protection activity = 56% at 500 $\mu$g mL$^{-1}$ and 28% at 100 $\mu$g mL$^{-1}$), which is significantly higher than that of ribavirin (inactivation activity = 40% at 500 $\mu$g mL$^{-1}$ and 12% at 100 $\mu$g mL$^{-1}$; curative activity = 37% at 500 $\mu$g mL$^{-1}$ and 14% at 100 $\mu$g mL$^{-1}$; and protection activity = 40% at 500 $\mu$g mL$^{-1}$ and 17% at 100 $\mu$g mL$^{-1}$).

Unlike in vitro antiviral assay results, **4d** displayed higher in vivo activity than that of (3*S*,5*R*)-**4d** and (3*S*,5*S*)-**4d** (in vivo activity: **4d** > (3*S*,5*R*)-**4d** > (3*S*,5*S*)-**4d**), except for the protection effect of (3*S*,5*R*)-**4d**.

[a]Average of three replicates. All results are expressed as mean ± SD.

Introduction of a methyl or trifluoromethyl group at the 4-position of the phenyl ring dramatically decreased inhibition effect (in vivo activity: **4a** > **4g** > **4b**). Compounds **4d−f** containing halogen atoms such as chlorine and bromine on the phenyl ring also exhibited lower inhibitory effect than that of **4a**. However, 4-fluorophenyl-substituted compound **4c** gave relatively higher activity (48, 57, and 60% at 500 $\mu$g mL$^{-1}$).

Compound **4h** containing a furan ring at C(3) exhibited a lower activity than the others, whereas **4i** containing a thiofuran ring was the optimal compound for anti-TMV research.

**Fungicidal Activity.** The fungicidal activities of compounds **4a−i** and **5a−i** were investigated. The commercial fungicides chlorothalonil, carbendazim, and azoxystrobin were used as the controls.

*In Vitro Fungicidal Activity.* The target compounds **5** and **4** were evaluated for their in vitro antifungal activity on 14 kinds of plant fungi at 50 mg kg$^{-1}$ (Table 3). Unlike the antiviral activity, saturated lactones **4** displayed moderate fungicidal activity, whereas most of the unsaturated lactones **5** exhibited excellent fungicidal activity against the tested fungi, which indicated that the small changes between **4** and **5** at the 3,4-position result in large differences in bioactivities. Compound **5g**, containing a trifluoromethyl group at the 4-position of phenyl ring, exhibited broad-spectrum and good fungicidal activity against 13 kinds of fungi. Compounds **5d−g** exhibited higher fungicidal activity than chlorothalonil and carbendazim against *C.H* (*Cercospora arachidicola* Hori) at 50 mg kg$^{-1}$. Some of these compounds selectively exhibited fungicidal activity to certain fungi. For example, the inhibitory effect of compound **5b** (against *Rhizoctonia solani*), compound **5c−d** (against *Sclerotinia sclerotiorum*), and **5d−g** (against *Cercospora arachidicola* Hori, *Rhizoctonia cerealis*, *Rhizoctonia solani*, *Botrytis cinerea*) were >90%, which is much higher than that for other fungi.

The fungicidal activities of compound **5b** (against *Rhizoctonia solani*) and compounds **5d−g** (against *Cercospora arach-idicola* Hori, *Rhizoctonia cerealis*, *Rhizoctonia solani*, *Botrytis cinerea*) were also excellent at 25 mg kg$^{-1}$ (>70%, except for **5g** against *Rhizoctonia cerealis*). Compounds (*R*)-**5d** and **5g** exhibited >50% inhibition rate against *Rhizoctonia solani* at 6.25 mg kg$^{-1}$ (Table 4).

[a]Average of three replicates. All results are expressed as mean ± SD. NT, not tested. [b]The commercial agricultural fungicides were used for comparison of antifungal activity.

*In Vivo Fungicidal Activity.* Compounds **4a−i** and **5a−i** were evaluated in a series of in vivo fungicidal tests. The pathogens tested in this screen were *Puccinia sorghi* on corn, *Puccinia triticina* on wheat, *Blum eria graminis* f. sp.*tritici* on wheat, *Sclerotinia sclerotiorum* on rape, *Rhizoctonia solani* on rice, *Botrytis cinerea on* cucumber, and *Corynespora cassiicola* on cucumber with protection. The resulting data (Table 5) revealed that compounds **5a−i** displayed a degree of in vivo fungicidal activity. Compounds **5b−d** with ≥60% inhibitory effect against *Puccinia sorghi* on corn emerged as new antifungal lead compounds.

In summary, a series of lactone compounds **4a−i** and **5a−i** were designed and synthesized on the basis of the structure of natural product (−)-incrustoporin (**1**) and characterized by $^1$H NMR and mass spectroscopy. Their antiviral activity against TMV and antifungal activity against 14 fungi were systematically evaluated. The bioassay results showed that the small changes between **4** and **5** at the 3,4-position result in large differences in bioactivities. 3-Aryl-5-methyl-$\gamma$-butyrolactone **4** exhibited good to excellent anti-TMV activity, and some of the compounds displayed higher antiviral activity than commercial ribavirin. Especially, the inactivation, curative, and protection activities of compound **4i** (52, 57, and 56%, respectively, at 500 $\mu$g mL$^{-1}$) were much higher than those of ribavirin (40, 37, and 40% at 500 $\mu$g mL$^{-1}$). Compounds **5** exhibited good fungicidal activity; especially (*R*)-**5d** displayed excellent fungicidal activity both in vitro and in vivo. To our knowledge, this is the first report on 3-aryl-5-methyl-$\gamma$-butyrolactone and 3-aryl-5-methyl-2,5-dihydrofuran-2-one as potential disease control agents against tobacco mosaic virus and plant pathogenic fungi.

# Stabilization of the Potent Odorant 2-Acetyl-1-pyrroline and Structural Analogues by Complexation with Zinc Halides

Ming-Chih Fang[†] and Keith R. Cadwallader*[,‡]

[†]Taiwan Food and Drug Administration, 161-2 Kunyang Street, Nangang District, Taipei City, Taiwan 115

[‡]Department of Food Science and Human Nutrition, University of Illinois, 1302 West Pennsylvania Avenue, Urbana, Illinois 61801, United States

**ABSTRACT:** 2-Acetyl-1-pyrroline (2AP) and the structurally similar compounds 6-acetyl-2,3,4,5-tetrahydropyridine (ATHP, along with its tautomer 6-acetyl-1,2,3,4-tetrahydropyridine), 2-propionyl-1-pyrroline (2PP), and 2-acetyl-2-thiazoline (2A2T) are well-known potent odorants in various food products. However, due to the highly unstable nature of these compounds, especially 2AP and ATHP, they are scarcely used commercially in flavor formulations. A novel and attractive method for the stabilization of these potent odorants in dry powder form is presented. Coordination of 2AP, ATHP, 2PP, and 2A2T to zinc ions ($ZnI_2$, $ZnBr_2$, or $ZnCl_2$) resulted in the formation in high yields of stable crystalline complexes, which upon hydration release the free odorant. Infrared spectroscopy was used to study the coordination complexes. 2AP contains donor atoms, which coordinate (with covalent character) through both the heterocyclic nitrogen and carbonyl oxygen atoms to the zinc ion. This is also the case for ATHP and 2PP, but not for 2A2T, because the sulfur group in 2A2T provides a third possible donor site. Stability studies showed that the 2AP-$ZnI_2$ complex (with 14% loading) maintained >94% retention of 2AP after 3 months of storage at ambient temperature in a dry environment. Meanwhile, the ATHP−$ZnI_2$ complex was similarly stable and retained 89% of the ATHP after 3 months of storage. This stabilization technology may enable the commercial use of this powerful aroma compound as a flavoring agent.

## INTRODUCTION

2-Acetyl-1-pyrroline (2AP) was first identified in cooked rice[1] and was regarded as the most powerful odorant among all rice volatiles identified.[2] 2AP, with an odor threshold of 0.1 $\mu g\ L^{-1}$ in water,[1] dominates the structurally related analogues 6-acetyl-2,3,4,5-tetrahydropyridine (ATHP, including the tautomer 6-acetyl-1,2,3,4-tetrahydropyridine), 2-propionyl-1-pyrroline (2PP), and 2-acetyl-2-thiazoline (2A2T), all of which possess roasted, cracker-like, and popcorn-like aroma notes and are also important odorants in numerous food products.[3]

The specialty fragrant or aromatic rice varieties contain high levels of 2AP. In an effort to boost the production of 2AP, the gene linked to the accumulation of 2AP in fragrant rice has been identified[4] and later transferred into nonaromatic rice varieties, which enabled them to accumulate greater levels of 2AP.[5] 2AP is of potential commercial interest to the flavor industry because of its pleasant and characteristic flavor. However, the highly unstable nature of the compound has hindered its widespread commercial use. In popcorn 2AP decreased by about 80% during room temperature storage for 1 week in polyethylene bags.[6] In raw aromatic rice, the concentration of 2AP was shown to diminish by about half its original content after 3 months.[7] Pure 2AP turns red and degrades in 10 min while standing at ambient temperature. The instability of 2AP has been postulated to occur via a polymerization reaction.[1] The cyclic imine of 1-pyrroline was shown to form trimers during workup, which then undergo condensation with neighboring molecules to form polymeric products.[8]

Some efforts have been made to increase the stability of 2AP. Duby et al.[9] patented a process for encapsulation of 2AP with $\beta$-cyclodextrin ($\beta$-CD); however, 2AP (10% loading) was decomposed by 91% after 13 days of storage at 20 °C. At a loading of 1%, 2AP decomposed by 99% after 110 days of storage. Additional efforts to stabilize 2AP were made by Srinivas et al.[10] through encapsulation, where gum acacia and/or starch were applied to form a stabilized dry powder; however, no proven stability was demonstrated. In another study, a crude extract from pandan leaves served as a natural source of 2AP, which was mixed with $\beta$-CD to form a powder. However, no storage stability data were reported to demonstrate the effectiveness of this approach.[11] In a different study 2AP was maintained at a level of 70% after 72 days of storage at ambient temperature when encapsulated at very low loading (0.003%) in a gum acacia/maltodextrin matrix.[12] 2AP can be stabilized by chemical means, such as the addition of an acetal protection group. The synthesis of 6-acetyl-1-isopropyl-1,2,3,4-tetrahydropyridine and 6-(1,1-diethoxyethyl)-2,3,4,5-tetrahydropyridine after purification by preparative gas chromatography provided the more stable acetal and enol ether derivatives of ATHP.[13]

Previous attempts to stabilize 2AP suffer to some extent from at least one of the following three deficiencies: (1) stability of 2AP was either not mentioned or was insufficiently studied; (2)

low loadings of 2AP were used; and (3) 2AP was only stable during storage at low temperature (4 and −20 °C). In this study, a novel and attractive stabilization method is described. The compound 2AP is coordinated as a ligand onto a zinc halide, thus forming a powdered stable complex. Complexes of 2AP, as well as some other acylheterocyclic compounds, such as 2PP, ATHP, 2A2T, 2-acetylpyrazine (APra), 2-acetylpyridine (APri), and 2-acetylthiazole (ATz), can be prepared with $ZnI_2$, $ZnBr_2$, and $ZnCl_2$ in a similar manner. The chemical characteristics of these complexes and the stability of the 2AP−$ZnI_2$ complex during storage are described.

## MATERIALS AND METHODS

**Chemicals.** 2-Acetyl-2-thiazoline (2A2T), 2-acetylthiazole (ATz), 2-acetylpyridine (APri), 2-acetylpyrazine (APra), piperidine, pyrrolidine, 2,4,6-trimethylpyridine, nonane, zinc chloride (1.0 M solution in diethyl ether), zinc bromide, iodomethane, bromoethane, magnesium (turnings), zinc (dust, <10 μm), iodine, boric acid, zincon monosodium salt, silver nitrate, potassium cyanide, *tert*-butanol, triethylamine, and sodium methoxide (25 wt % in methanol) were purchased from Sigma-Aldrich (St. Louis, MO, USA). 2A2T was purified by precipitating out impurities in anhydrous diethyl ether and by subsequent distillation in vacuo. Zinc iodide was prepared by stirring zinc and iodine in anhydrous diethyl ether for 3 days. Anhydrous diethyl ether and methylene chloride were obtained from Fisher Scientific (Fair Lawn, NJ, USA). 2AP (yield = 10% from pyrrolidine; purity = 91% after vacuum distillation, by GC-FID) and ATHP (yield = 5% from piperidine; purity = 83% after vacuum distillation, by GC-FID, with two tautomers, 6-acetyl-2,3,4,5-tetrahydropyridine and 6-acetyl-1,2,3,4-tetrahydropyridine, at a ratio of 7:3) were synthesized using published methods.[14−16] 2PP was prepared by reacting 2-cyano-1-pyrroline with ethylmagnesium bromide in diethyl ether, by following closely the published procedure for the synthesis of 2-acetyl-1-pyrroline (yield = 4% from pyrrolidine; purity = 72% after vacuum distillation, by GC-FID).[15] 2-Ethyl-1-pyrroline was synthesized as described by Fuganti et al.[17]

**General Procedure for the Preparation of 2AP−Zinc Halide Complexes and Other Acylheterocyclic Complexes.** An anhydrous etheric solution of 2AP or other acylheterocyclic compound listed in Table 1 (1 mmol in 10 mL ether) was added to $ZnI_2$, $ZnBr_2$, or $ZnCl_2$ in anhydrous diethyl ether (0.1M) in a 50 mL centrifuge tube cooled in an ice−water bath with good stirring and nitrogen purging for 1 min. During addition, a significant amount of precipitate was observed. The reaction mixture was stored at −20 °C for 5 min and then centrifuged (3000*g*, 3 min) to isolate the precipitate. The precipitate was washed with fresh anhydrous diethyl ether (10 mL × 3) and then collected. Solvent was removed by gentle purging with nitrogen to obtain a fine powdered 2AP zinc halide complex, which was stored at −20 °C in a vial equipped with a PTFE-lined silicon cap.

**Content of an Acylheterocyclic Compound in the Complex.** 2AP or other acylheterocyclic zinc complex (5−10 mg) was placed in a 1.5 mL vial, then 0.5 mL of aqueous phosphate buffer (50 mM, pH 7) was added (this solution turned cloudy/white because of the insoluble metal content). Subsequent extraction was conducted via addition of methylene chloride (0.5 mL) containing an internal standard (2,4,6-trimethylpyridine, 1.00 mg $mL^{-1}$) to form a mixture. This mixture was vigorously shaken by hand for 1 min and then centrifuged (3000*g*, 5 min). The solvent layer was recovered and dried over sodium sulfate prior to GC analysis. Pure 2AP (91%) or other acylheterocyclic compound was prepared in phosphate buffer and extracted with methylene chloride following the above procedure to generate a response factor for each acylheterocyclic compound against the internal standard. The content of each acylheterocyclic compound in its respective complex was calculated using the following equation:

$$\text{loading (\%)} = \text{peak area of 2AP/peak area of 2,4,6-timethylpyridine} \times \text{concentration of 2,4,6-trimethylpyridine (mg mL}^{-1}\text{)} \times 0.5\ \text{mL} \times \text{response factor/sample weight (mg)} \times 100\%$$

**Stability of 2AP with Zinc Iodide in Solution.** 2AP (2.00 mg $mL^{-1}$) in pentane (1 mL) and $ZnI_2$ in diethyl ether solution (0.2M, 0.2 mL) were combined with 8 mL of methylene chloride (containing nonane as internal standard at 1.00 mg $mL^{-1}$) in a 10 mL volumetric flask and the volume immediately made up to the mark with methylene chloride to form a solution. The solution was incubated at room temperature for a period of 20 h, during which time the 2AP content was periodically monitored by transferring a 0.5 mL aliquot of the solution into a 1.5 mL vial followed by the addition of 0.5 mL of a quenching solution (phosphate buffer, 50 mM, pH 7) to form a mixture. The mixture was shaken and centrifuged (3000*g*, 5 min), and the solvent layer was immediately analyzed by GC. To check the stability of the quenched 2AP extract, the initial sample (time zero, quenched immediately after $ZnI_2$ addition) was held at room temperature and analyzed periodically by GC for up to 20 h. To serve as a control, a separate 2AP solution that did not contain $ZnI_2$ was also stored at room temperature and monitored periodically during this same time period.

**Gas Chromatography (GC).** GC was performed using either a (1) 6890N GC/5973N mass selective detector (MSD; Agilent Technologies Inc., Palo Alto, CA, USA) equipped with a fused-silica capillary column (Stabilwax, 30 m × 0.25 mm × 0.25 μm film thickness; or Rtx-5, 15 m × 0.32 mm × 0.5 μm film thickness; Restek, Bellefonte, PA, USA) or (2) 5890 series II GC equipped with a split/splitless injector, flame ionization detector (FID), and HP-1 column (30m × 0.32 mm × 0.25 μm film thickness, Agilent). Helium was the carrier at a constant flow of 1 mL/min. The injector was held at 250 °C in the split mode. GC oven temperature was programmed from 50 to 225 °C at 10 °C/min with initial and final hold times of 5 and 20 min, respectively. Other conditions for the MSD were as follows: MSD interface temperature, 260 °C; ionization energy, 70 eV; mass range, 35−350 amu; EM voltage, Autotune +165 V; scan rate, 4.45 scans/s.

**Determination of the Zinc Content.** Zinc content was measured spectrophometrically using a published procedure.[18] A sample of 2AP−zinc halide or other complex (5−10 mg) was diluted in water (pH 2, adjusted using HCl) in a 25 mL volumetric flask. A 70 μL aliquot of this solution and 100 μL of Zincon dye (1.6 mM; 37 mg Zincon in 1 mL of NaOH (1M) followed by dilution into 50 mL of water) and 3 mL of borate buffer (53 mM, pH 9.0) were then combined in a test tube. After incubation of this solution for 5 min, absorbance was measured at 620 nm using a Lambda 1050 UV/vis/NIR spectrophotometer (PerkinElmer Inc., Shelton, CT, USA). A six-point calibration plot was constructed from a dilution series of a zinc stock solution (100 mg of zinc dust in 1 mL of HCl for 4 h prior to dilution to 1 L).

**Infrared Spectra.** Infrared spectra of 2AP and the other acylheterocyclic compounds as well their zinc halide complexes were recorded using a Spectrum 100 FT-IR (PerkinElmer Inc., Waltham, MA, USA) with attenuated total reflectance (ATR) accessory (resolution = 4 $cm^{-1}$, 4 scans/spectra, range = 500−4000 $cm^{-1}$). Liquid samples were analyzed in neat form. Solid complexes were applied directly to the diamond ATR top plate.

**Stabilities of 2AP and ATHP Zinc Iodide Complexes in Dry Powder Form.** 2AP−$ZnI_2$ complex (5−10 mg) was stored in sealed (PTFE-lined silicon cap) 1.5 mL glass vials at 25, 10, or −20 °C. ATHP−$ZnI_2$ complex was stored at 25 °C. The residual 2AP or ATHP in each complex was monitored during a 3 month storage period as previously described.

## RESULTS AND DISCUSSION

**Complexation of 2AP and Other Heterocyclic Compounds to Zinc Halides.** The addition of anhydrous $ZnI_2$ to an anhydrous solution of 2AP in diethyl ether caused a

[a]Yield = $W/(\mathrm{mM} \times \mathrm{MW} \div n) \times 100\%$ [$W$ = amount (mg) of obtained complex; mM = amount (mM) of starting acylheterocyclic compound; MW = molecular weight of complex (base on the formula in this table)]. [b]Proposed stoichiometry. [c]6-Acetyl-2,3,4,5-tetrahydropyridine plus its tautomer 6-acetyl-1,2,3,4-tetrahydropyridine.

yellowish precipitate to form immediately. This reaction mixture was incubated in the freezer for 5 min and then triturated with fresh anhydrous diethyl ether to remove excess $ZnI_2$ and other impurities from the 2AP−$ZnI_2$ complex. A fine powder, pale yellow in color, was obtained after collecting the precipitate and purging with nitrogen gas. The free 2AP ligand could be freed from the powdered 2AP−$ZnI_2$ complex via hydration with water, in which case a white cloudy metallic substance also appeared at neutral pH and the yellow color faded immediately, indicating the loss of the complex structure. GC-MS analysis of a methylene chloride extract of this aqueous mixture yielded a main peak (recovery = 54−111%, by GC-FID) with a mass spectrum and retention index in agreement with those of authentic 2AP.

One possible explanation for the stabilization effect observed could be through the coordination of the ring nitrogen and carbonyl oxygen atoms of the compound to the zinc ion. Coordination of 2AP with other zinc salts such as $ZnBr_2$ and $ZnCl_2$ acts in a similar fashion.

**Stoichiometry of Complex Formation.** Table 1 shows the yields, color, proposed stoichiometry, and component analysis of 2AP-$ZnI_2$, 2AP-$ZnBr_2$, 2AP-$ZnCl_2$, and 17 other acylheterocyclic−zinc halide complexes. Contents of acylheterocyclic compounds and zinc halide in the various complexes were determined by GC and spectrophotometric analyses, respectively. The theoretical loadings of 2AP were 26, 33, and 45% in the $ZnI_2$, $ZnBr_2$, and $ZnCl_2$ complexes, respectively. We found the content of 2AP was 29, 35, and 50% in the $ZnI_2$, 2AP−$ZnBr_2$, and 2AP-$ZnCl_2$ complexes, respectively, indicating a one-to-one stoichiometry of 2AP to zinc halide in the complexes. Similar results were observed for the complexes of 2PP and ATz for which the same molar ratios were found between the metal and heterocyclic ligands. For APri, ATz, and APra more complex stoichiometries were observed with 2, 2/3, and 2/3 of the acylheterocyclic molecules, respectively, binding to the zinc halides. For ATHP, lower loadings were observed for its complexes compared to the theoretical values. For example, only 16% ATHP was recovered from ATHP−$ZnI_2$. However, the theoretical recovery was 28%. This could be due to the great instability of ATHP, which may have degraded during the complexation step. Higher recoveries might be obtained by optimizing the method of preparation. Due to poor recovery of ATHP, only the zine contents were used to determine the proposed stoichiometry of the ATHP-zinc halide complexes.

Zinc halide was postulated to have two binding sites in its complex;[19] however, due to its flexible coordination, four or even six chelate rings have also been reported.[20] Because 2AP, 2PP, and ATHP contained two donor atoms (a nitrogen and a carbonyl oxygen), they were postulated to form one-to-one metal−ligand complexes. However, although APri contained two donors as well, it was found to form bivalent metal complexes[21] and, accordingly, the APri−zinc complexes were found to have four binding sites. 2A2T and APra were believed to form $(ZnX_2)_3L_2$ complexes (where X = I, Br, or Cl; L = 2A2T or APra ligands) because both had three possible donor sites (nitrogen, carbonyl, and sulfur atoms for 2A2T; two nitrogens and one carbonyl for APra). However, the same rule did not apply to ATz, for which a one-to-one stoichiometry was observed for the complexes even though ATz contains three donor atoms. The same ligands or structurally similar ligands that link to the zinc halide may have various coordinations. For example, pyrazine−$ZnBr_2$ could yield two reversible coordination polymers, (pyrazine)$_2$−$ZnBr_2$, which forms 2D regular square-grid coordinations, and pyrazine−$ZnBr_2$, which forms a zigzag chain polymer with a network having an octahedral center.[22] Further work such as elemental analysis or X-ray diffraction may be useful in elucidating the complex multi-

dimensional structures of the acylheterocyclic−zinc ion complexes or even to correct the proposed stoichiometry. However, this was beyond the scope of the present study.

**Infrared Spectra and Nature of Coordination.** The infrared spectra of the Zn(II)−acylheterocyclic complexes were recorded in the range 4000−400 $cm^{-1}$, but only the 2000−600 $cm^{-1}$ region was considered. The carbonyl (C═O) band assignments for the complexes are given in Table 2. It was observed that the carbonyl vibration shifted to lower wavenumbers for the complexes as compared to their free ligands, indicating the existence of a coordination complex. This was observed for all complexes except for those of 2A2T. For example, 2AP produced a very strong absorption around 1695 $cm^{-1}$, which was attributed to C═O stretching. The corresponding bends shifted to the lower wavenumbers at 1627, 1630, and 1633 $cm^{-1}$ for its $ZnI_2$, 2AP−$ZnBr_2$, and 2AP−$ZnCl_2$ complexes, respectively. This provides evidence for coordination through the carbonyl oxygen. In addition, the broadened bandwidth at around 1695 $cm^{-1}$ in the complexes may be considered as further evidence for metal chelation.[23] The heterocyclic ring nitrogen was suggested to undergo bond formation with the metal, thus increasing the dipolar contribution of $C{=}N^+$.[21] Bands at 1632 or 1619 $cm^{-1}$ may be assigned as ring nitrogen vibration. However, the C—C vibration occurred at around 1600−1650 $cm^{-1}$ with broad and split or multipeak shapes, which always overlapped the nitrogen (C—N═C) region, which made it more difficult to determine the coordination between the metal and ring nitrogen. We believed nitrogen was involved in coordination because many heterocyclic−metal complexes containing only nitrogen and carbon have been previously observed, including (1-pyrroline)$_2$−$ZnI_2$,[19] (pyridine)$_2$−$ZnCl_2$, (pyridine)$_6$−$CdCl_2$,[24] pyrazine−$ZnBr_2$,[22] and (2-ethyl-1-pyrroline)$_2$−$ZnI_2$, which was observed in our laboratory.

For ATHP, the carbonyl vibration located at 1695 and 1666 $cm^{-1}$ for the free ligand shifted upon O-complexation to lower wavenumbers of 1632, 1635, and 1637 $cm^{-1}$ in its $ZnI_2$, 2AP−$ZnBr_2$, and 2AP−$ZnCl_2$ complexes, respectively. The two bands for ATHP indicated the carbonyl groups of two tautomers. However, there was only one band observed in their complexes, which suggested a single stable ATHP−zinc halide complex was constructed. However, for 2A2T complexes, the differences between coordinated and noncoordinated carbonyl groups was evidenced by only the broadening and splitting of this band, which was located at around 1700 $cm^{-1}$. A strong C═N stretching band at 1592 $cm^{-1}$[25] shifted to lower wavenumbers at 1574, 1576, and 1576 $cm^{-1}$ for its $ZnI_2$, $ZnBr_2$, and $ZnCl_2$ complexes, respectively, apparently indicating N coordination.

**Unstable Nature of 2AP.** It was observed that 2AP−$ZI_2$ complex solutions prepared in polar solvents, such as methanol, acetone, dimethyl sulfoxide (DMSO), propylene glycol, or glycerin, turned red immediately, which is indicative of 2AP polymerization; however, solutions of the free 2AP ligand in these solvents remained colorless or pale yellow. We suggest that zinc ion may catalyze the polymerization of 2AP, because 2AP alone in these solvents was relatively stable but was unstable in the presence of zinc ion. The 2AP−$ZnI_2$ complex in tetrahydrofuran (THF), chloroform, and methylene chloride

dx.doi.org/10.1021/jf5020186 | J. Agric. Food Chem. 2014, 62, 8808−8813

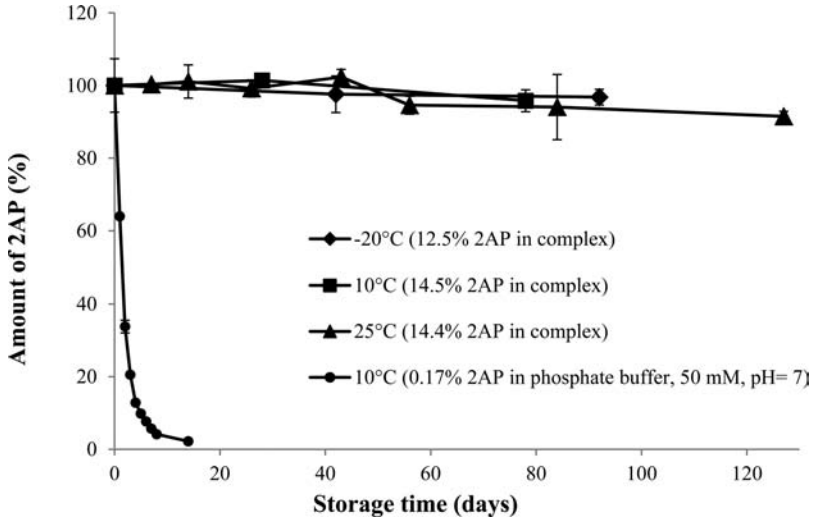

**Figure 2.** Stability of 2-acetyl-1-pyrroline (2AP) and its zinc iodide complex during storage at various temperatures (mean ± SD, $n$ = 2).

(polarity = 3−4) was yellow in color and turned red gradually. A sticky dark red material that adhered to the wall of the beaker was observed due to the poor solubility of the 2AP polymer in solvents of intermediate polarity. 2AP−$ZnI_2$ complex did not go into solution in nonpolar solvents, such as pentane, benzene, and diethyl ether, and the complex remained as a stable, solid powder that did not undergo zinc-mediated polymerization.

To study the zinc-mediated deterioration, 2AP in methylene chloride was added to $ZnI_2$ (4 mM), which caused the solution to turn red. A quenching solution (phosphate buffer, 50 mM, pH 7, 0.5 mL) was added to the methylene chloride solution prior to GC analysis, which not only inhibited zinc-mediated polymerization but also minimized the chromatographic interference caused by zinc. The results showed 2AP decayed by 70% in 4 h (Figure 1) in the presence of zinc ion. However, when a 2AP/zinc ion solution was treated with the above-mentioned quenching solution within 1 min 2AP was retained at 97% and remained stable throughout a 20 h period. The quenching solution acted to remove the zinc ion from methylene chloride, and thus 2AP was relatively stable in the zinc free solvent. The results indicated the zinc ion catalyzed the deterioration of 2AP in methylene chloride in the absence of the quenching solution.

**Stability of 2AP Zinc Iodide Complex.** The tendency of metal−ligand coordination complexes to form can be applied for the protection of unstable compounds, such as the stabilization of 1-pyrroline as a stable crystalline complex with zinc ion.[19,26] In the present study, the stability of 2AP−$ZnI_2$ complex was studied over a period of 3 months. A 0.17% aqueous solution of 2AP (pH 7) showed an 80% reduction after 3 days and a 90% reduction after 5 days. However, the 2AP complex stored at three different temperatures showed significantly increased stability (Figure 2). As expected, lower temperature storage was found to favor stability. During storage at −20 °C the 2AP content was retained by 97% in the complex (2AP content = 12.5%) after 92 days of storage. About 96% retention was observed after 78 days of storage when the 2AP complex (14.5% 2AP) was stored at 10 °C. Meanwhile, in a moisture-free environment 2AP (14.4% complex) declined by only 6% after 3 months of storage at 25 °C. The ATHP−$ZnI_2$ complex was similarly stable, and only 11% of the ATHP was lost after 3 months of storage at 25 °C under anhydrous conditions (Figure 3).

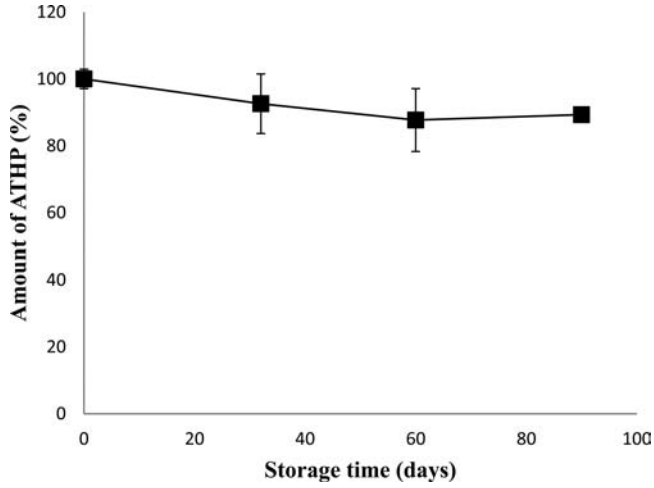

**Figure 3.** Stability of ATHP (sum of tautomers)-zine iodide complex stored at 25 °C (mean ± SD, $n$ = 2).

The results of the present study demonstrate that complexation of 2AP with $ZnI_2$ forms a stable, solid complex in powder form. This complex is stable at ambient temperature (only 6% reduction during 3 months of storage at 25 °C), which may enable its use as a flavoring agent. When this complex is applied to foods, the temperature, moisture, and other possible food matrix components may influence its stability. Therefore, an appropriate package or encapsulation technology, such as dispersion in an edible oil or lipid, or wax encapsulation is suggested to protect the complex from moisture and from interactions with other food components. It may be preferable to prepare complexes with $ZnCl_2$ because it has GRAS status. It is hoped that this novel stabilization process can enable the practical use of the labile, yet powerful, flavor compound 2-acetyl-1-pyrroline and its analogues as flavoring agents.

Fernandez-Gonzales et al. evaluated molecularly imprinted sol−gel materials for the detection of nafcillin.[13] For the β-lactam antibiotic cephalexin, MIPs were synthesized and evaluated by Guo and He.[14] Skudar et al. produced MIPs for penicillin V and oxacillin. However, the developed MIPs also possessed an affinity for other antibiotics of the β-lactam group.[15] Cederfur et al. synthesized MIPs for benzylpenicillin using a molecularly imprinted polymer library.[10] Caro et al. developed two MIPs using tetracycline and oxytetracycline as template molecules.[16] Zhang et al. investigated the use of MIPs for the determination of benzylpenicillin in milk, but their detection limit was only 1 mg/kg.[17] Kempe et al. tested the influence of salt ions on the binding properties of MIPs and applied this to benzylpenicillin in milk.[18] The recoveries obtained amounted to 87%, but the control polymer showed also a high recovery of 73%, indicating a high level of nonspecific binding. Finally, Guardia et al. developed molecularly imprinted sol−gel materials for the determination of nafcillin in milk-based products, and a detection limit of 13.2 mg/kg was obtained.[19] Several MIPs for the detection of other antibiotics in different fields have been developed: for example, trace analysis of quinolones in eggs,[20] determination of nitroimidazoles and fluoroquinolones in egg-based products,[21,22] extraction of sulfonamides from honey,[23] and determination of sulfonamides in pork and chicken.[24] Even MIPs for extraction of several antibiotics from complex matrices are already commercially available.

In this study, MIPs were developed through suspension polymerization for application in an SPE procedure for the detection of benzylpenicillin in milk, which has a maximal residue level (MRL) of 4 μg/kg.

Binding properties (cross-reactivity, recoveries, number of binding sites, etc.) were evaluated via binding experiments. The MIPs were validated in acetonitrile and then in a milk matrix, where the limit of detection (LOD) and limit of quantitation (LOQ) were determined. Finally, the molecularly imprinted solid-phase extraction (MISPE) procedure was compared (Pearson correlation) with a traditional sample preparation method performed in an accredited laboratory.

## MATERIALS AND METHODS

**Solvents and Solid Reagents.** All products [benzylpenicillin, nafcillin, piperacillin, ampicillin, amoxicillin, oxacillin, cloxacillin, dicloxacillin, cephalexin, cephapirin, sulfadiazin, oxytetracycline, methacrylic acid, trimethylolpropane methacrylate, ethylene glycol dimethacrylate, and azobis(isobutyronitrile)] were purchased from Sigma-Aldrich (St. Louis, MO), except for acetonitrile (AcN), formic acid, and methanol (MeOH), which were purchased from Biosolve (Valkenswaard, The Netherlands). Water ($H_2O$) was purified by a Millipore (Billerica, MA) Milli-Q gradient system to high-performance liquid chromatography (HPLC) grade.

**Standard Solutions of the Antibiotics.** Analytical standards were dissolved at a concentration of 1 mg/mL (stock solutions) in a 1/1 (v/v) AcN/$H_2O$ mixture. The working standard solutions were made by dilution with AcN. The stock solutions were kept at −20 °C, and the working solutions were freshly prepared before use.

**Apparatus.** A shaker (Bühler, Hechingen, Germany), a centrifuge (model 4K15, Sigma, Osterode am Harz, Germany), a vortex mixer (Scientific Industries, Bohemia, NY), and a vacuum manifold (Varian, Palo Alto, CA) were used during the experiments and sample preparation. A high-performance liquid chromatograph combined with a mass spectrometer was used for the detection and quantification of benzylpenicillin. The high-performance liquid chromatographic−tandem mass spectrometry (LC−MS/MS) system consisted of a LC system (Alliance, Waters, Milford, MA) with a model 2695 separation module coupled to a quattro LCZ tandem quadrupole mass spectrometer (Micromass, Altrincham, U.K.) equipped with a z-spray electrospray ion interface or an Acquity Ultra Performance liquid chromatograph (Waters) coupled to a Xevo TQ mass spectrometer (Waters) also equipped with a z-spray system. The mass spectrometers were fully controlled by MASSLYNX version 4.0 or 4.1 (Waters). The separations on the LC system were conducted on an Xterra MS $C_{18}$ column [Waters, 5 μm, 150 mm × 2.1 mm (inside diameter)] protected with an Alltima $C_{18}$ guard column [Alltech, Deerfield, IL, 5 μm, 7.5 mm × 2.1 mm inside diameter)]. The ultra performance liquid chromatography (UPLC) separations were performed on a Waters UPLC BEH $C_{18}$ column [Waters, 1.7 μm, 100 mm × 2.1 mm (inside diameter)].

**Synthesis of the MIP for Benzylpenicillin.** Benzylpenicillin (2 mmol or 0.7 g), methacrylic acid (16 mmol or 1.4 g), trimethylolpropane methacrylate (7 mmol or 2.4 g) or ethylene glycol dimethacrylate (7 mmol or 1.4 g), and azobis(isobutyronitrile) (0.4 mmol or 0.07 g) were dissolved in 6 mL of AcN (bulk polymerization) or in 70 mL of AcN (suspension polymerization). These solutions were polymerized for 20 h in a water bath at 75 °C under nitrogen saturation. After the MIP had been dried in an oven at 60 °C for 48 h, the template molecule was washed out with a MeOH/$H_2O$ mixture [95/5 (v/v)] according to the Soxhlet principle.

**Equilibrium Binding Experiments in Acetonitrile or Milk Extracts.** Ten milligrams of MIP or NIP was incubated on a shaker for 4 h in 1 mL of AcN or milk extract containing different amounts of benzylpenicillin. For the binding experiments in AcN, the following protocol was used. First, the solution was centrifuged for 15 min at 4302*g*, after which 500 μL of the supernatant was dried at 60 °C under a flow of nitrogen. Then, the residue was redissolved in 1 mL of a 1/1 (v/v) AcN/$H_2O$ mixture and 1 mL of internal standard (containing 1 μg/mL nafcillin or piperacillin solution in AcN). This solution was filtered through a syringe-driven filter unit with a pore size of 0.22 μm (Millipore, Bedford, MA) and analyzed via LC−MS/MS. The protocol for the binding experiments in milk extracts was similar. These binding experiments were used for the evaluation of the binding capacities, the determination of the cross reactivity, and the Scatchard analysis of the developed MIP.

**Extraction of Bound Benzylpenicillin from a Previously Used MIP or NIP.** The suspension of 10 mg of MIP or NIP in 1 mL of AcN containing 5 μg of benzylpenicillin used for the equilibrium binding experiments was passed through a syringe-driven filter unit with a pore size of 0.22 μm (Millipore). A light vacuum (maximum of 0.17 bar) was produced, and the solvent that came through the filter was analyzed using LC−MS/MS as fraction 1 using the same preparative steps described above (see Equilibrium Binding Experiments in Acetonitrile or Milk Extracts). The vial used during the equilibrium binding experiment was rinsed with AcN to pass the total amount of MIP or NIP used during the binding experiment through the filter unit. Again a light vacuum was developed, and the collected solvent was analyzed as fraction 2. The total amount of MIP or NIP on the filter was then washed with MeOH to recover the bound benzylpenicillin. This was repeated in fractions of 1 mL. These fractions (3−6) were also analyzed using LC−MS/MS. These tests were performed to prove the reversibility of the binding of benzylpenicillin to the MIP or NIP.

**Extraction of the Milk Samples.** The blank milk samples were skimmed (centrifugation at 3399*g* for 10 min). An equal amount of AcN was added to the skimmed milk sample together with NaCl (0.2 g/mL). After the solution had been mixed with a vortex mixer and centrifuged for 10 min at 3399*g*, a portion of the supernatant was evaporated and spiked with different concentrations of benzylpenicillin, dissolved in AcN, before application to the MIP or NIP.

**MISPE and Non-molecularly Imprinted Solid-Phase Extraction (NISPE) for the Analysis of AcN Solutions or Milk Samples.** An empty SPE cartridge was packed with 50 mg of the (non)imprinted polymer. The polymers were packed between two glass wool frits and washed with 50 mL of MeOH and 15 mL of a MeOH/$H_2O$ mixture [95/5 (v/v)] to remove the remaining benzylpenicillin after Soxhlet treatment. The last 5 mL was collected and analyzed by HPLC−MS/MS to rule out template bleeding.

Before the sample was loaded, the polymers were conditioned with 5 mL of a MeOH/AcN mixture [50/50 (v/v)] to remove the remaining impurities. Next, the AcN solution or the extract of the milk sample was loaded onto the MIP dissolved in 5 mL of AcN. The loading was followed by a washing step with 2 mL of AcN, and finally, the MIP was treated with 6 mL of a MeOH/$H_2O$ mixture [50/50 (v/v)] to elute the benzylpenicillin. This eluent was collected, dried at 60 °C under a flow of nitrogen, and redissolved in 1 mL of a 1/1 (v/v) water/acetonitrile mixture and 1 mL of internal standard (containing 1 μg/mL piperacillin solution in acetonitrile). This solution was filtered through a syringe-driven filter unit with a pore size of 0.22 μm (Millipore) and analyzed using LC−MS/MS.

**Validation Study in Acetonitrile and Milk.** The validation of the performance of the MIP is based on the criteria mentioned in EU Commission Decision 2002/657/EG. Solutions of AcN and spiked milk sample extracts were percolated through the MIP and NIP. The experiments were performed in triplicate, and the recovery was calculated. The recovery is expressed in percent, i.e., the amount of benzylpenicillin obtained after the cleanup step (over MIP or NIP) in relation to the amount of benzylpenicillin added to the AcN solution or milk extract. The goal of the study is to validate the MIP cleanup procedure and not the extraction protocol. That is why we chose to spike the milk samples after extraction to prevent variations originating from the extraction step. Validation of the developed method (including extraction and cleanup step) was conducted during the analysis of contaminated milk samples (see below). The precision was evaluated by calculating the standard deviation for the three experiments executed on different days. The LOD and LOQ were calculated using a calibration curve and the equations

$$\mathrm{LOD} = 3 \times \frac{\mathrm{SEB}}{M}$$

$$\mathrm{LOQ} = 6 \times \frac{\mathrm{SEB}}{M}$$

where SEB is the standard error value on the intercept of the calibration curve and $M$ the slope of the calibration curve.

**Analysis of Contaminated Milk Samples.** To evaluate the implementation of the developed MIP as an SPE sorbent, the concentration of benzylpenicillin present in contaminated milk samples was determined. The results were compared with those obtained after the execution of the traditional protocol (extraction with AcN) for the determination of benzylpenicillin in milk samples in a Beltest-accredited laboratory.

**Liquid Chromatography.** The HP liquid chromatographic separation of benzylpenicillin was performed at room temperature on a $C_{18}$ column. Mobile phase A consisted of $H_2O$ and phase B AcN. In both phases, 0.1% formic acid was added to increase the ionization efficiency. To increase the separation capacity and to decrease the retention times, gradient elution was applied. The gradient program was as follows: 100% A (from 0 to 0.5 min), 100 to 55% A and 45% B (from 0.5 to 0.6 min), 55% A and 45% B to 35% A and 65% B (from 0.6 to 8.5 min), 35% A and 65 to 100% B (from 8.5 to 8.6 min), 100% B (from 8.6 to 18.6 min), 100% B to 100% A (from 18.6 to 20.0 min), and 100% A (from 20.0 to 30.0 min) to re-equilibrate. Before the start of the analyses, the column was conditioned with 100% A until the pressure was stable for at least 15 min. The flow rate was 0.25 mL/min, and a volume of 40 μL of sample extract was injected into the LC−MS/MS apparatus.

The UPLC separation was conducted on a Waters HPLC BEH $C_{18}$ column held at 30 °C. The injection volume was set at 10 μL and the eluent flow at 0.40 mL/min. Mobile phase A consisted of a $H_2O$/AcN mixture [95/5 (v/v)] with 0.3% acetic acid and phase B an AcN/$H_2O$ mixture [95/5 (v/v)] with 0.3% acetic acid. Gradient elution was applied here, as well. The gradient program was as follows: 100% A (from 0 to 2 min), 100 to 70% A and 30% B (from 2 to 8 min), 70% A and 30 to 100% B (from 8 to 12 min), 100% B (from 12 to 13 min), 100% B to 100% A (from 13 to 13.01 min), and 100% A (from 13.01 to 14.6 min) to re-equilibrate. Before the start of the analysis, the column was conditioned with 100% A until the pressure was stable for at least 15 min.

**Mass Spectrometry.** The method and optimized $ESI^+$ mass spectrometric conditions described by Daeseleire et al.[25] for detecting penicillins in milk were used. The data obtained were analyzed using MassLynx version 4.0 or 4.1 (Waters).

**Statistical Analysis.** To test the influence of the applied cross-linker on the polymerization yield, one-way analysis of variance (ANOVA) was conducted. A Sheffé post hoc test was performed. In addition, one-way ANOVA was used to determine the effect of the application of NIP and MIP on the binding capacity toward benzylpenicillin.

SAS version 9.4 (SAS Institute Inc., Cary, NC) was used for all analyses. Significant differences were assumed when $p < 0.05$.

## RESULTS AND DISCUSSION

This study builds upon the literature.[14,15] Our experiments for the production of MIPs used benzylpenicillin as the template molecule, methacrylic acid (MAA) as the monomer, trimethylolpropane methacrylate (TRIM) or ethylene glycol dimethacrylate (EDMA) as the cross-linker, and AcN as the solvent. The MIP was produced through polymerization using azobis(isobutyronitrile) (AIBN) as the heat-induced initiator.

The first step was to select the most suitable polymerization technique for the production of MIPs for benzylpenicillin (bulk polymerization vs suspension polymerization). The initial screening tests we performed indicated that the latter technique generated the best results in terms of higher production yields (data not shown) and the more refined way of working that could be applied, i.e., no grinding and sieving required. Second, using the selected suspension polymerization technique, the possible effect of the selected cross-linker on the polymerization yield was evaluated. EDMA and TRIM were selected as bi- and trifunctional cross-linkers, respectively (Table 1).

**Table 1. Effects of Cross-Linker Type on Polymerization Yield (expressed in percent)**

| applied cross-linker | batch 1 | batch 2 | batch 3 | mean | standard deviation |
|---|---|---|---|---|---|
| TRIM | 81.0 | 90.1 | 89.0 | 86.7 | 5.0 |
| TRIM blank | 94.0 | 89.3 | 90.1 | 91.1 | 2.5 |
| EDMA | 78.0 | 81.3 | 80.9 | 80.1 | 1.8 |
| EDMA blank | 80.8 | 78.8 | 79.3 | 79.6 | 1.0 |

The yields of the MIPs produced using TRIM as a cross-linker were higher, although not significantly so ($p > 0.05$) (Table 1). The higher yields can most likely be explained by the differences in the number of reactive functional groups between EDMA (bifunctional) and TRIM (trifunctional). On the basis of these data, we decided to continue all further experimental work using TRIM as the cross-linker.

After optimization of the template/functional monomer/cross-linker molar ratio, the composition applied for the development of a benzylpenicillin selective MIP was as follows: benzylpenicillin (2 mmol), MAA (16 mmol), TRIM (7 mmol), and AIBN (0.4 mmol) dissolved in 70 mL of AcN. Using this formulation, the MIP produced was visualized by scanning electron microscopy (SEM). Uniformly sized microspheres were obtained by applying the suspension polymerization method (Figure 1). The microspheres had an average size of 1.2 μm.

To determine the binding specificity of the developed MIP for benzylpenicillin in AcN, we first performed an equilibrium

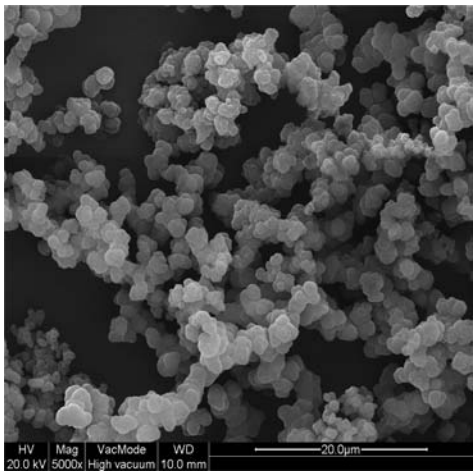

**Figure 1.** Size of benzylpenicillin selective MIP as visualized by SEM.

experiment by comparing the produced MIP and NIP. The obtained results of three independently performed equilibrium binding studies show a statistically significant ($p < 0.01$) difference in binding capacity between the MIP or NIP and benzylpenicillin (68.3 ± 3.1 or 13.2 ± 8.2%, respectively). This represented the first convincing proof that the developed MIP possessed a high affinity for benzylpenicillin.

The reversibility of the binding of benzylpenicillin to the MIP or NIP was proven by washing out the MIP or NIP used during an equilibrium binding experiment. The amounts of benzylpenicillin detected in the different fractions are expressed in relation to that of an internal standard (nafcillin). The experiments were executed in duplicate, and the results (Table 2) clearly show that the total amount of benzylpenicillin (5 μg) used to execute the binding experiment is recovered. This indicates the total reversibility of the binding of benzylpenicillin to the MIP or NIP. The observation that more than half of the benzylpenicillin (fractions 1 and 2) is not retained by the MIP sorbent is in contradiction with the observations in all other experiments and can be explained by the excess of benzylpenicillin present in the solution used during this experiment (5 ppm), resulting in a large amount of benzylpenicillin that was not specifically bound to the MIP.

**Table 2. Results of the Recovery of Benzylpenicillin out of MIP or NIP of an Equilibrium Binding Experiment**

| benzylpenicillin/nafcillin ratio | MIP (first experiment) | MIP (second experiment) | NIP (first experiment) | NIP (second experiment) |
|---|---|---|---|---|
| fraction 1[a] | 0.530 | 0.541 | 1.177 | 1.168 |
| fraction 2[a] | 0.506 | 0.514 | 0.735 | 0.735 |
| fraction 3[b] | 0.758 | 0.774 | 0.044 | 0.067 |
| fraction 4[b] | 0.004 | 0.003 | 0.003 | 0.007 |
| fraction 5[b] | 0.000 | 0.000 | 0.001 | 0.001 |

[a]Collected fractions when rinsing the used MIP or NIP. [b]Collected fractions when washing out the used MIP or NIP to recover the bound benzylpenicillin.

The next step in evaluating the binding characteristics of the MIP was to test the cross-reactivity of the developed MIP or NIP with respect to structural analogues of benzylpenicillin. This was done by performing the equilibrium binding experiments in AcN with solutions containing seven molecules belonging to the group of the β-lactam antibiotics (benzylpenicillin is one of them). The selected molecules included ampicillin, amoxicillin, oxacillin, cloxacillin, dicloxacillin, cephalexin, and cephapirin. In addition, one molecule of the group of sulfonamides (sulfadiazin) and one of the group of the tetracyclines (oxytetracycline) were also included. All equilibrium binding tests were repeated three times (Table 3).

**Table 3. Results of the Cross-Reactivity Tests for the Developed NIP**

| % binding components | first test | second test | third test | mean | standard deviation |
|---|---|---|---|---|---|
| benzylpenicillin | 3.8 | 16.9 | 18.8 | 13.17 | 8.17 |
| ampicillin | 92.0 | 91.0 | 94.0 | 92.33 | 1.53 |

| oxytetracycline | 87.8 | 94.2 | 91.5 | 91.17 | 3.21 |

[a]Results not included because of problems with the internal standard.

The results of the tests for both the NIP and the MIP clearly show that the compounds included in this study can be classified into three separate groups. A first group showed binding efficiencies of >90% for the MIP and >70% for the NIP (ampicillin, amoxicillin, cephalexin, cephaphirin, and oxytetracycline). A second group showed binding percentages between 42 and 68% for the MIP and between 10 and 22% for the NIP (oxacillin, cloxacillin, and dicloxacillin). The last group showed binding degrees of <20% for the MIP and <10% for the NIP (sulfadiazin).

These results can be explained by comparing the chemical structures of the substances included in the cross-reactivity test (see Figure 2). For the substances of group I, very high binding efficiencies were observed for the MIP and the NIP. This can most likely be attributed to the oppositely charged MIP and template molecule. The template contains an amino group that is protonated under the experimental conditions (pH 6.34), while the methacrylic acid from the MIP or NIP has a negative charge at this pH value. This most likely results in a strong electrostatic attraction between both compounds. The substances of group II possess a structure analogous to that of benzylpenicillin. The only difference among the molecules oxacillin, cloxacillin, and dicloxacillin is the number of chlorine substituents. As we anticipated, the binding efficiency decreased as the number of chlorine atoms increased, because of the

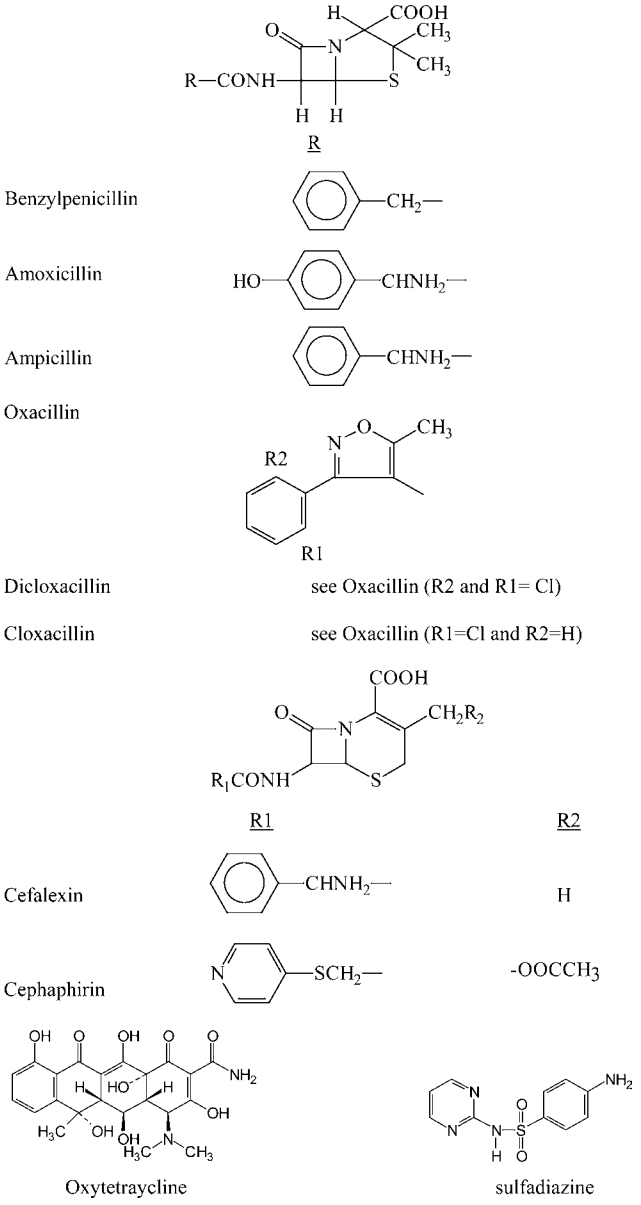

**Figure 2.** Structures of the substances tested in the cross-reactivity test.

increasing sterical effects with an increasing number of chlorine atoms. Members of group III possessed a low binding efficiency because of the absence of chemical structural similarities between sulfadiazin and benzylpenicillin. These observed cross-reactivities will not interfere with the results of our proposed analysis protocol, because the purification step with the developed MIP (MISPE) is followed by a LC−MS/MS analysis, which makes it possible to focus on specific substances. This makes it impossible for the "cross-reactivity" compounds to interfere. This approach can even be an advantage because these cross-reactivity compounds can be detected using the same cleanup step.

Three independent binding equilibrium experiments were also performed to assess the binding affinity of benzylpenicillin for the imprinted particles. The binding isotherm was determined in a concentration range of 0.0015−0.0299 μmol/mL (0.5−10 mg/kg) benzylpenicillin (Figure 3).

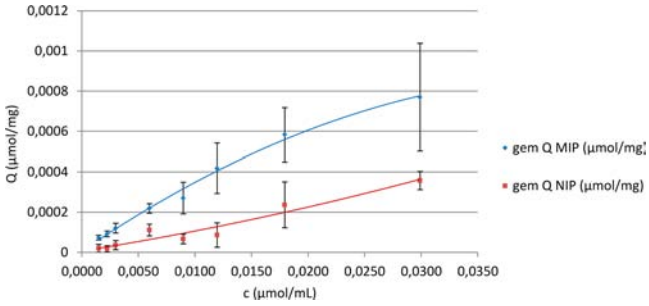

**Figure 3.** Binding isotherms of benzylpenicillin on the MIP and the NIP.

We observed that the amount of benzylpenicillin bound to the MIP and the NIP at equilibrium increased along with the initial concentration of benzylpenicillin and that the amount of benzylpenicillin bound to the MIP was larger than the amount bound to the NIP (the degree of difference depends on the initial concentration), which indicates high-affinity binding by the imprinted binding sites.

The binding affinity can be calculated from the Scatchard equation:

$$\frac{Q}{[\mathrm{PenG}]} = \frac{Q_{\max} - Q}{K_D}$$

where $Q$ is the amount of benzylpenicillin bound to 1 mg of MIP or NIP at equilibrium, [PenG] is the free analyte concentration at equilibrium, $Q_{max}$ is the maximal number of binding sites, and $K_D$ is the equilibrium dissociation constant of the binding sites. The units of $Q$ and $K_D$ are micromoles per milligram and micromoles per milliliter, respectively.

The Scatchard plot (Figure 4) shows that the binding sites in the MIP are heterogeneous, while those of the NIP are

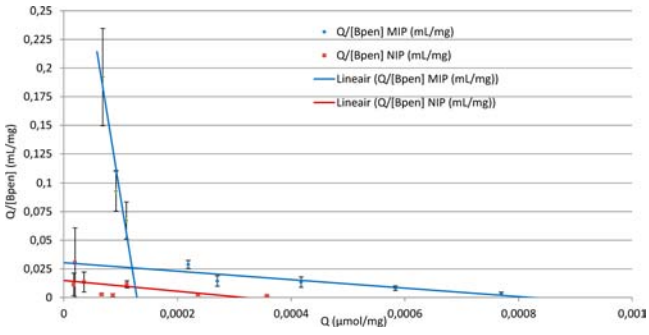

**Figure 4.** Scatchard plot for benzylpenicillin on the MIP and the NIP.

homogeneous. Analysis of the plot gives the linear regression equations of the high- and low-affinity binding sites in the MIP: $Q/[\mathrm{PenG}] = -3061Q + 0.394$, and $Q/[\mathrm{PenG}] = -36.96Q + 0.0303$.

With these equations, $K_D$ and $Q_{max}$ can be calculated. For the high-affinity binding sites, $K_D$ and $Q_{max}$ amounted to 0.33 μmol/L and 0.13 μmol/g, respectively, while for the low-affinity binding sites, the values were found to be 27.1 μmol/L and 0.82 μmol/g, respectively. The homogeneous binding sites of the NIP had $K_D$ and $Q_{max}$ values of 21.3 μmol/L and 0.32 μmol/g, respectively.

The explanation of these findings lies in the synthesis of the imprinted polymers according to the noncovalent method, thus exhibiting heterogeneous binding sites because of the

dx.doi.org/10.1021/jf502331h | J. Agric. Food Chem. 2014, 62, 8814−8821

incomplete association between the benzylpenicillin and methacrylic acid molecules. Specific binding sites are the result of this association, but because of its incompleteness, the polymer also shows nonspecific binding sites. Therefore, only a small number of the binding sites in the MIP are tailor-made in shape and size for the template benzylpenicillin.

The last part of the evaluation of the binding characteristics was the development and validation of a protocol for the application of the MIP in a molecularly imprinted solid-phase extraction (MISPE). The AcN solutions analyzed were fortified with 1, 2, 3, 4, 6, 8, and 10 μg of benzylpenicillin/kg. These concentrations were chosen around the MRL value in milk of 4 μg/kg. The results of the MISPE experiments are listed in Table 4. The experiments were repeated three times.

**Table 4. Recovery of Benzylpenicillin after Cleanup of Acetonitrile Solutions using the MIP (MISPE) and the NIP (NISPE)**

| | recovery [% ($n$ = 3)] | |
|---|---|---|
| spiking level (μg/kg) | MISPE | NISPE |
| 1 | 94.9 ± 3.5 | 14.6 ± 12.9 |
| 2 | 94.9 ± 1.0 | 12.0 ± 10.7 |
| 3 | 83.8 ± 11.1 | 4.5 ± 2.3 |
| 4 | 89.6 ± 3.2 | 4.5 ± 4.0 |
| 6 | 91.8 ± 5.0 | 6.6 ± 2.9 |
| 8 | 92.8 ± 4.1 | 4.8 ± 1.1 |
| 10 | 92.3 ± 5.2 | 5.0 ± 1.4 |

In addition to a satisfying level of precision, a significant difference in binding between MIP and NIP (up to 88%) was observed. We can also conclude that the recovery percentages are independent of the spiking level, because no significant differences were observed between the results obtained with the MIP and the NIP.

To validate these results, a validation study was conducted in AcN at three spiking levels (2, 4, and 6 μg/kg). The study was repeated on three separate days. At each spiking level, five samples were spiked and analyzed. Standard deviations were calculated to evaluate the precision (Table 5).

**Table 5. Recovery of Benzylpenicillin during the Validation Study in Acetonitrile Solutions Spiked at Three Levels Using MISPE and NISPE**

| | recovery [μg/kg ($n$ = 5)] | |
|---|---|---|
| spiking level (μg/kg) | MISPE | NISPE |
| 2 | 1.91 ± 0.13 | 0.04 ± 0.31 |
| | 2.06 ± 0.22 | 0.00 ± 0.19 |
| | 2.19 ± 0.29 | 0.43 ± 0.11 |
| 4 | 4.18 ± 0.64 | 0.14 ± 0.31 |
| | 4.24 ± 0.34 | 0.41 ± 0.38 |
| | 4.30 ± 0.12 | 0.19 ± 0.57 |
| 6 | 6.64 ± 1.20 | 0.00 ± 0.36 |
| | 6.32 ± 0.64 | 0.31 ± 0.43 |
| | 6.07 ± 0.90 | 0.44 ± 1.17 |
| | average recovery [% ($n$ = 15)] | |
| spiking level (μg/kg) | MISPE | NISPE |
| 2 | 102.7 ± 12.0 | 7.5 ± 14.5 |
| 4 | 105.9 ± 10.0 | 6.2 ± 10.7 |
| 6 | 105.7 ± 15.3 | 0.0 ± 16.4 |

The results confirm the conclusions from the recovery experiments in AcN, i.e., a good precision and a significant difference in binding between the MIP and the NIP. Individual differences of up to 100% can be perceived between the MIP and the NIP. Additionally, we can conclude that 100% of the benzylpenicillin in the AcN solutions can be recovered using MISPE.

After the validation of the MISPE protocol, the MIP was applied in a milk matrix. First, the MIP in MISPE for milk samples was validated. Subsequently, naturally contaminated samples were analyzed, and the results were compared with the results obtained by a traditional sample preparation.

Analogous with the validation study in AcN, the validation study in a milk matrix was conducted, at three spiking levels (2, 4, and 6 μg/kg). The study was repeated on three days, and at each spiking level, five samples were spiked and analyzed. Standard deviations were calculated to evaluate the precision (Table 6).

**Table 6. Recovery of Benzylpenicillin during the Validation Study in Milk Extracts Spiked at Three Levels Using MISPE and NISPE**

| | recovery [μg/kg ($n$ = 5)] | |
|---|---|---|
| spiking level (μg/kg) | MISPE | NISPE |
| 2 | 1.67 ± 0.40 | 0.37 ± 0.16 |
| | 1.71 ± 0.26 | 0.00 ± 0.07 |
| | 1.62 ± 0.09 | 0.39 ± 0.10 |
| 4 | 3.47 ± 0.51 | 0.00 ± 0.30 |
| | 3.85 ± 0.16 | 0.00 ± 0.16 |
| | 3.28 ± 0.42 | 0.00 ± 0.11 |
| 6 | 4.57 ± 0.25 | 0.00 ± 0.27 |
| | 5.39 ± 0.28 | 0.00 ± 0.48 |
| | 5.77 ± 0.36 | 0.30 ± 0.43 |
| | average recovery [% ($n$ = 15)] | |
| spiking level (μg/kg) | MISPE | NISPE |
| 2 | 83.2 ± 13.5 | 11.4 ± 12.3 |
| 4 | 88.3 ± 11.1 | 0.0 ± 4.9 |
| 6 | 87.3 ± 9.8 | 0.0 ± 9.1 |

The results show high recoveries (up to 88%) using MISPE for the cleanup of spiked milk extracts, while the use of NISPE resulted in low recoveries between 0 and 11%. We can thus conclude that significant differences in cleanup performances between MIP and NIP can be obtained when used in SPE analysis. The MIP developed by Kempe et al.[18] to detect benzylpenicillin in milk also showed recoveries of up to 87%, but the control polymer also showed very high recovery percentages (73%), indicating a large contribution of nonspecific binding between the template molecule and the sorbent.

Intriguingly, the recoveries obtained after MISPE were in accordance with the criteria set by the EC (Commission Decision 2002/657/EC): for benzylpenicillin levels between 1 and 10 μg/kg, recoveries between 70 and 110% should be achieved. This demonstrates the potential for implementation of the imprinted polymer in the cleanup of benzylpenicillin-contaminated milk samples.

Comparison of Tables 5 and 6 reveals that the milk matrix interfered with the performance of the MIP (in AcN average recoveries are obtained up to 100%, while in milk extract up to 88%). Despite the preparatory steps of the milk samples, the

dx.doi.org/10.1021/jf502331h | J. Agric. Food Chem. 2014, 62, 8814−8821

somewhat lower recoveries can most likely be explained by the interference of matrix factors such as lactose, which were not eliminated during the pretreatment of the samples. We would expect even larger differences if the fat molecules and proteins had not been removed, because the cavities in the used MIP would be less accessible and there would be a greater risk of obstruction of the MIP. For this reason, a defatting and deproteinating step is common in the analysis of antibiotics or other components in milk samples.[26,27]

The LOD and LOQ obtained for the MISPE analysis of milk extracts spiked with benzylpenicillin are 0.51 and 1.02 μg/kg, respectively. These values are very low compared with the LOD of the MIP developed by Guardia et al.[19] to determine naficillin in milk-based products (13.2 mg/kg).

These results indicate that the MIP developed in our study is an appropriate sorbent for the detection and quantification of low concentrations of benzylpenicillin in milk samples.

The same conclusion could also be drawn from the results of the analysis of positive samples. The contamination level of the samples ranged between 3 and 20 μg/kg. The samples were analyzed using MISPE and the classic sample preparation applied in a Beltest-accredited laboratory at the Institute for Agricultural and Fisheries Research (ILVO) (Table 7). The Pearson correlation between the MISPE results and the results of the accredited classic analyses was calculated. An excellent correlation of 0.989 was obtained.

**Table 7. Results of the Analysis of Positive Milk Samples Using MISPE and a Classical Sample Preparation Step**

| | [benzylpenicillin] (μg/kg) | |
|---|---|---|
| sample number | MIP | classic cleanup |
| 13/4102 | 17.36 | 15.29 |
| 13/5312 | 9.77 | 9.96 |
| 13/1022 | 4.04 | 3.32 |
| 13/0206 | 9.58 | 8.37 |
| Pearson correlation, 0.989 | | |

These results confirm that the implementation of molecularly imprinted polymers during the cleanup step is a good alternative for the determination of benzylpenicillin in milk matrices and makes it possible to detect concentrations of benzylpenicillin in milk samples at a level 8 times lower than the MRL. However, direct application of the milk sample on the MISPE cartridge would offer a real advantage to the accredited classic analysis, which is therefore the subject of further research. Because of the risk of obstruction of the used MIP sorbent during the cleanup step, it may be necessary to remove certain matrix components or to add clarifying agents during a short preparation step to make the milk filterable. Possible strategies include a decreaming step to remove the fat molecules, the use of Carrez clarification solutions I and II (Boehringer Mannheim Biochemica[28]), or the use of clarifying agents such as L-NRS (Reybroeck et al.[29]), Somex A (Meyer et al.[30]), or Enliten (Technical Bulletin Enliten ATP assay system bioluminescence detection kit for ATP measurement, Promega).

$Fe_3O_4$ microspheres (MFMs) sorbents for SPE has not been reported.

Rhei Radix et Rhizoma, the root or rhizome of perennial herbaceous plant *Rheum palmatum* L., *Rheum tanguticum* Maxim. ex Balf., or *Rheum officinale* Baill., is not only consumed as a health food supplement in China or other countries, but it also represents one of the most popular medicinal herbs used in clinical practice for the treatment of blood stagnation syndrome as well as a purgative agent. Recent publications have demonstrated that anthraquinone derivatives were thought to be the major active components responsible for the pharmacological activities and therapeutic efficacy.[24] In this study, the use of IL-coated MFMs sorbents combined with ultraperformance liquid chromatography (UPLC) was developed to preconcentrate and determine the anthraquinones in dietary supplements, namely, aloe emodin, rhein, emodin, chrysophanol, and physcion. Furthermore, various parameters, including IL type, concentration of ILs and MFMs, diluent pH, and concentration of acetic acid in eluent were optimized in detail. The experimental results indicated that the established method was reliable and feasible for the analysis of real rhubarb samples.

## MATERIALS AND METHODS

**Reagents and Standards.** 1-Dodecyl-3-methylimidazolium bromide ($[C_{12}mim]Br$), 1-dodecyl-3-methylimidazolium chloride ($[C_{12}mim]Cl$), 1-butyl-3-methylimidazolium tetrafluoroborate ($bminBF_4$), and 1-butyl-3-methylimidazolium polystyrenesulfonate (bminPSSA) were purchased from Shanghai Cheng Jie Chemical Co., Ltd. (Shanghai, China). Methanol (HPLC grade) was supplied by Sigma-Aldrich Shanghai Trading Co., Ltd. (Shanghai, China). Purified water was obtained from Hangzhou Wahaha Group Co., Ltd. (Hangzhou, China). All other chemicals and reagents were of analytical grade and were used without further purification.

The investigated standards, including emodin, rhein, aloe emodin, and physcion, were purchased from Shanghai Winherb Medical Technology Co., Ltd. (Shanghai, China). Chrysophanol was obtained from the National Institute for the Control of Pharmaceutical and Biological Products (Beijing, China). The purity of each standard was higher than 98%, and their structures are shown in Figure 1. The herb and granules of Rhei Radix et Rhizoma were collected from the local drugstore (Hangzhou, China).

**UPLC Analysis.** The separation and quantitation of anthraquinones was accomplished using UPLC with ultraviolet (UV) detection (Waters Co., Milford, MA, U.S.A.) with solvent A (0.1% formic acid, v/v) and B (methanol) at a flow rate of 0.5 mL $min^{-1}$ as eluents. The gradient eluent program was as follows: 0−1 min, 25%−30% B; 1−3 min, 30%−45% B; 3−5 min, 45%−60% B; 5−7 min, 60%−80% B; 7−8 min, 80%−100% B; 8−8.5 min, 100%−100% B. An Acquity UPLC BEH $C_{18}$ analytical column (1.7 $\mu$m, 2.1 mm × 50 mm) was supplied by Waters Co. During the separation, the injection volume was 1 $\mu$L for standards and sample solutions. UV detection was performed at a wavelength of 254 nm.

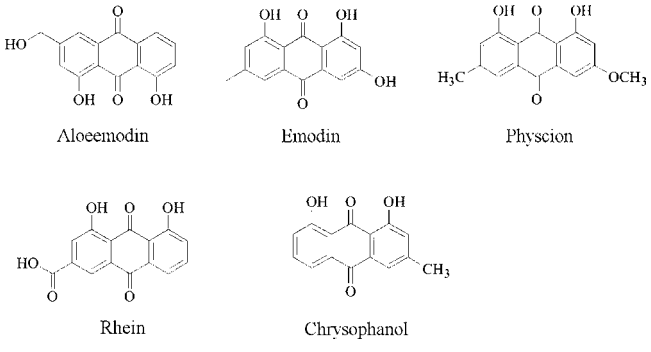

**Figure 1.** Chemical structures of the five compounds investigated.

**Preparations of Standard Solution and Sample Solutions.** Standard solutions of emodin (500 $\mu$g $mL^{-1}$), rhein (250 $\mu$g $mL^{-1}$), aloe emodin (500 $\mu$g $mL^{-1}$), physcion (250 $\mu$g $mL^{-1}$), and chrysophanol (500 $\mu$g $mL^{-1}$) were prepared in methanol and then diluted to the appropriate concentration using pure water prior to MSPE.

Rhei Radix et Rhizoma sample was prepared according to the approach described in the Chinese Pharmacopoeia 2010 without any modifications. First, a 0.15 g sample of powdered rhubarb herb was extracted with methanol (25 mL) by refluxing for 60 min. Next, the solution was cooled to room temperature, and the weight lost was compensated with methanol in the extraction process. After shaking and filtering, 5 mL of filtrate was transferred to a small flask and evaporated to dryness. The residue was redissolved in 10 mL of 8% HCl and then sonicated at 100 W (40 kHz) for 2 min. Next, 10 mL of chloroform was added in acidified solution. The solution was refluxed for 60 min and allowed to cool. The mixture was then transferred to a separating funnel and extracted three times with 10 mL of chloroform, and the combined solutions were dried to a residue under reduced pressure. The residue was dissolved with methanol and transferred to a 10 mL volumetric flask, and methanol was added to the mark. The rhubarb granules were prepared using the same method.

**Preparation of MFMs.** Monodispersed $Fe_3O_4$ microspheres of average size were synthesized according to previous reports.[25,26] For a typical synthesis of $Fe_3O_4$ microspheres, $FeCl_3$ (0.406 g) and NaAc (1.026 g) were dissolved in 49.02 mL of ethylene glycol and 0.98 mL of water. After vigorous stirring of the mixture for 8 h, the homogeneous solution was transferred to a Teflon-lined stainless-steel autoclave (100 mL in volume), sealed, and heated to 200 °C. After a 12 h reaction period, the autoclave was cooled to room temperature. The obtained $Fe_3O_4$ microspheres were washed with ethanol and water and then dried in a vacuum for 12 h. Finally, the resulting $Fe_3O_4$ MMNPs were stored at 25 °C before being used for the following MSPE process.

**Material Characterization.** Transmission electron microscope (TEM) (Zeiss Supra 55, Oberkochen, Germany) was used to obtain the micrographs of MFMs (100 kV), which were used to characterize their particle size and morphology.

**MSPE Procedure.** The extraction procedure, elaborately depicted in Figure 2, was as follows. First, 20 $\mu$L of the standard/sample solutions was homogeneously mixed with 6.6 mg $mL^{-1}$ MFMs and 0.32 mg $mL^{-1}$ $[C_{12}mim]Cl$ dispersions in a 1.5 mL Eppendorf tube. Subsequently, 1000 $\mu$L of purified water was slowly added to the tube, and the mixture was vortexed for 10 s at fast speed before being allowed to stand for 5 min. A magnet was deposited outside the bottom of the centrifuge tube for 1 s to separate the $Fe_3O_4$-retrieval anthraquinone sorbents from the sample solution. Next, the supernatant was decanted, and each of the target analytes was eluted from the sorbents using 200 $\mu$L of methanol (containing 1% acetic acid). The collected eluents (eluted thrice, yielding

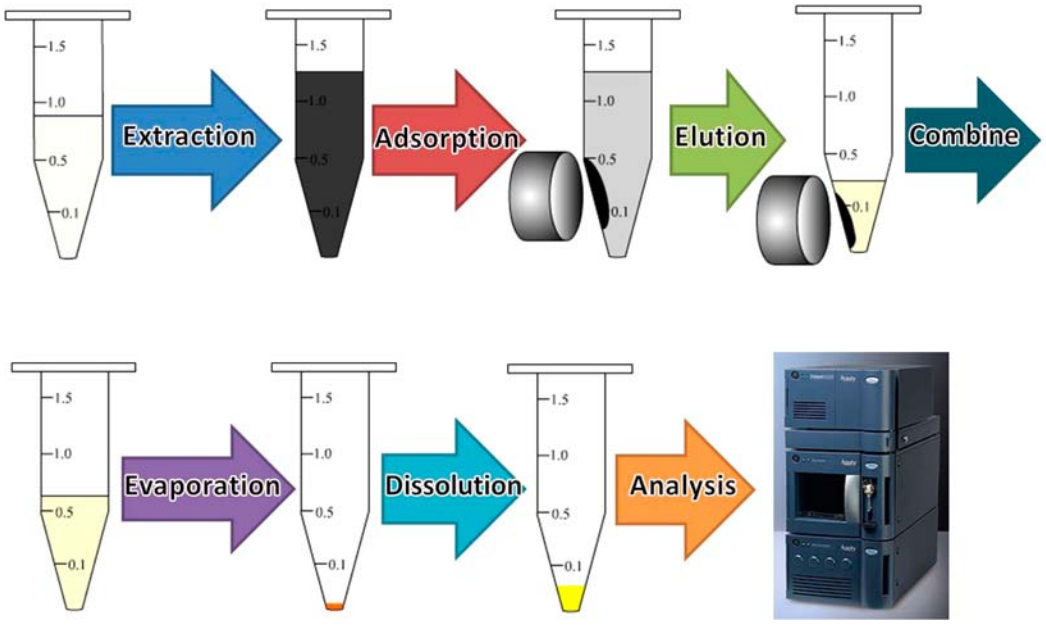

**Figure 2.** Schematic of the magnetic SPE process using IL-functionalized MFMs.

600 μL) were transferred to a new Eppendorf tube and then evaporated to dryness in an 80 °C water bath. The residues were redissolved with 50 μL of methanol, sonicated at 100 W (40 kHz) for 2 min, and then centrifuged at 13 000 rpm for 5 min. Finally, 1 μL of the standard or sample solution of interest was injected into UPLC for identification and quantification of the anthraquinones.

## RESULTS AND DISCUSSION

**Characterization of MFMs.** The morphology and size of MFMs were characterized by TEM with 200 nm (A), 100 nm (B), and 50 nm (C) in scale bars. As indicated from the TEM image (Figure 3), the sample consisted of a large quantity of tiny primary $Fe_3O_4$ nanocrystals with an average size of 100 nm. In addition, the uniform shape and hierarchical structure of mesoporous $Fe_3O_4$ were observed from Figure 3. When the nanocrystals were used as building blocks, they were assembled into a mesoporous structure. It was obvious that the TEM image confirmed the loosely packed character with lots of void space between microspheres.

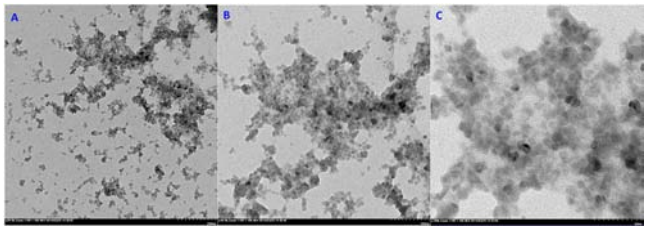

**Figure 3.** TEM image of MFMs with 200 nm (A), 100 nm (B), and 50 nm (C) in scale bars.

To achieve the best extraction efficiency of MSPE for the target analytes, several variables, including IL type, concentration of ILs and MFMs, diluent pH, and concentration of acetic acid in the eluent, were investigated in depth in the optimization process following a univariate method.

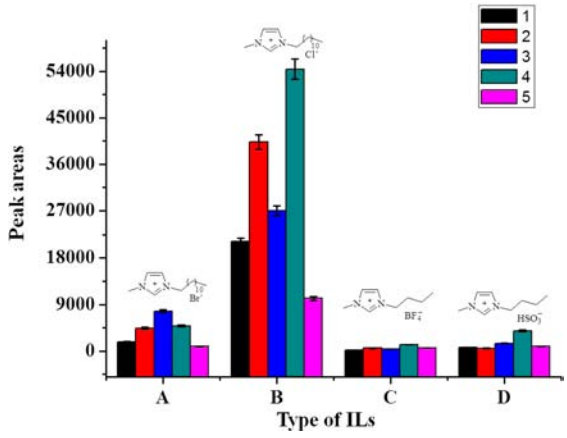

**Figure 4.** IL selection. Extraction conditions: sample volume, 1230 μL; spiked working solution, 20 μL; IL concentration, 0.32 mg $mL^{-1}$; MFMs concentration, 6.6 mg $mL^{-1}$; pH, 11. Desorption conditions: 200 μL of methanol (containing 1.0% acetic acid), thrice. Types of ILs: (A) $[C_{12}mim]Br$, (B) $[C_{12}mim]Cl$, (C) $bminBF_4$, (D) bminPSSA. Peak identification: 1, aloe emodin; 2, rhein; 3, emodin; 4, chrysophanol; 5, physcion.

**Selection of ILs.** The principal aims of this study were to investigate the unique characteristics of an adsorbent comprising MFMs and ILs in dispersion and to select a suitable type of IL for the preparation of dispersants. To this end, four types of ILs ($[C_{12}mim]Br$, $[C_{12}mim]Cl$, $bminBF_4$, and bminPSSA) containing different inorganic anions were selected in this work. For all IL species investigated, a good dispersion was achieved by adding MFMs to the IL solutions. The dispersions, which were optically inhomogeneous at the microcosmic level, exhibited more intense UV absorption with increasing IL alkyl chain length. As shown in Figure 4, a significantly higher extraction efficiency was obtained by mixing with long-chain ILs ($[C_{12}mim]Br$, $[C_{12}mim]Cl$) in the magnetic functionalization process than when using short-aliphatic-chain ILs ($bminBF_4$ and bminPSSA). This may due to the following. (a) The long-alkyl-chain ILs possessed surface-

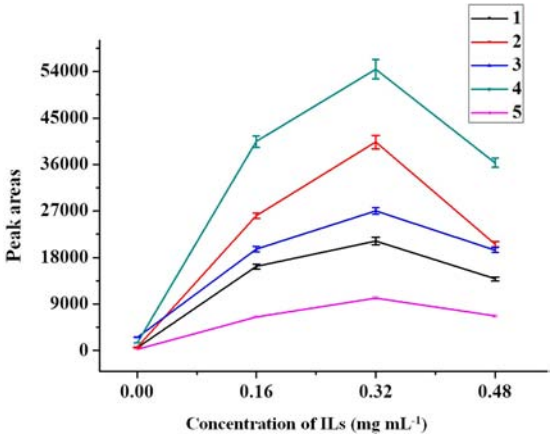

**Figure 5.** Effect of IL concentration on the extraction of five compounds. Extraction conditions: sample volume, 1230 $\mu$L; spiked working solution, 20 $\mu$L; MFMs concentration, 6.6 mg mL$^{-1}$; pH, 11; [$C_{12}$mim]Cl concentration, 0–0.48 mg mL$^{-1}$. Peak identification: 1, aloe emodin; 2, rhein; 3, emodin; 4, chrysophanol; 5, physcion. The other conditions were the same as in Figure 4.

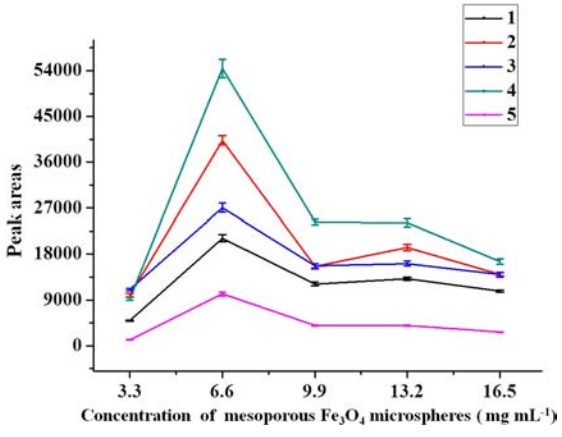

**Figure 6.** Influence of MFMs concentration on the extraction of five compounds. Extraction conditions: sample volume, 1230 $\mu$L; spiked working solution, 20 $\mu$L; [$C_{12}$mim]Cl concentration, 0.32 mg mL$^{-1}$; pH, 11; MFMs concentration, 3.3–16.5 mg mL$^{-1}$. Peak identification: 1, aloe emodin; 2, rhein; 3, emodin; 4, chrysophanol; 5, physcion. The other conditions were the same as in Figure 4.

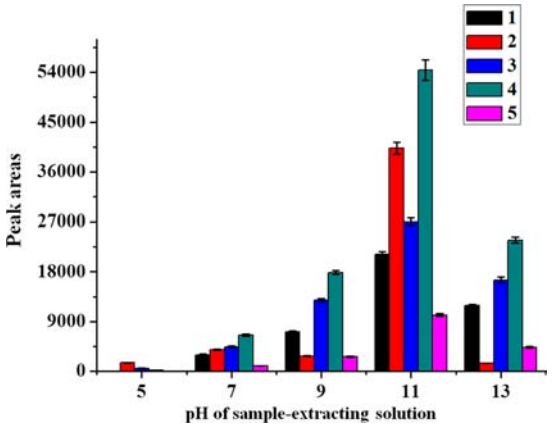

**Figure 7.** Influence of pH on the extraction of five compounds. Extraction conditions: sample volume, 1230 $\mu$L; spiked working solution, 20 $\mu$L; [$C_{12}$mim]Cl concentration, 0.32 mg mL$^{-1}$; MFMs concentration, 6.6 mg mL$^{-1}$; pH, 5–13. Peak identification: 1, aloe emodin; 2, rhein; 3, emodin; 4, chrysophanol; 5, physcion. The other conditions were the same as in Figure 4.

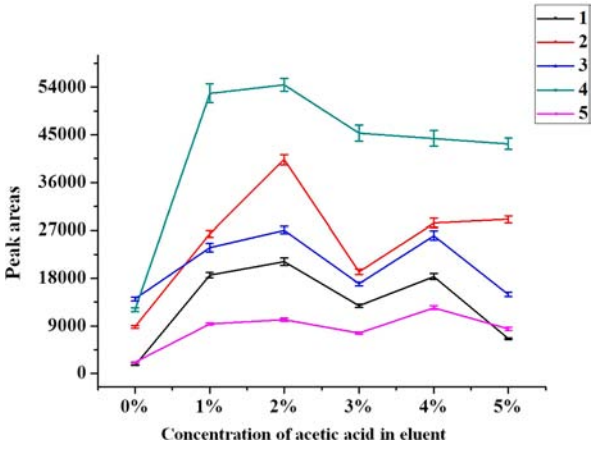

**Figure 8.** Effect of acetic acid concentration on the extraction of five compounds. Extraction conditions: sample volume, 1230 $\mu$L; spiked working solution, 20 $\mu$L; [$C_{12}$mim]Cl concentration, 0.32 mg mL$^{-1}$; MFMs concentration, 6.6 mg mL$^{-1}$; pH, 11. Desorption conditions: 200 $\mu$L of methanol (containing 0%–5% acetic acid), thrice. Peak identification: 1, aloe emodin; 2, rhein; 3, emodin; 4, chrysophanol; 5, physcion.

active characteristics similar to conventional cationic surfactants and may be amphiphilic when dissolved in water.[27] Moreover, the IL with longer alkyl chains at the cation featured a higher distribution ratio in the functionalization process. (b) Imidazolium-based ILs with longer alkyl side chains strengthened the directionality of hydrogen bonds and other weak forces (e.g., van der Waals),[28] which provided a greater interaction with MFMs and target analytes. In addition, the application of [$C_{12}$mim]Cl-functionalized magnetic dispersion achieved the optimum UV absorption due to the stronger conjugated and inductive effect induced by the chloride anions. It also can be clearly seen that the addition of four ILs in MSPE ultimately yielded yellow liquids. Among these ILs, the deepest color was observed using [$C_{12}$mim]Cl dispersion. The results indicated that [$C_{12}$mim]Cl employed in functional magnetic materials indeed had a significant effect on the extraction of analytes in the types of ILs investigated. Therefore, [$C_{12}$mim]Cl was selected as the optimal IL and used in further study.

**Effect of IL Concentration.** The IL concentration generally has a strong effect on the extraction efficiency and the site of action of target compounds. During the optimization of the method, the effect of IL concentration was evaluated at concentrations ranging from 0 to 0.48 mg mL$^{-1}$. The results indicated that when the concentration of [$C_{12}$mim]Cl in the dispersions increased from 0 to 0.32 mg mL$^{-1}$, the detected anthraquinone peak areas greatly improved by factors of 20 to 60 (Figure 5). It was also apparent that the maximum adsorption of target analytes was obtained with 0.32 mg mL$^{-1}$ of [$C_{12}$mim]Cl in the dispersion. However, further increasing the concentration of ILs to 0.48 mg mL$^{-1}$ resulted in serious deterioration of the extraction efficiency, although the dispersion of the sample was good for high IL concentrations, indicating that the partition of the analytes between the sorbents and aqueous phase was reduced. Additionally, the yellow color of the solutions was observed in the final step of the extraction process, especially when 0.32 mg mL$^{-1}$

| physcion | 4.32 | 0.21 | 2.8 | 9.4 | 96.48 |

[$C_{12}$mim]Cl was added into the MFMs dispersion. The overall results indicated that the extraction efficiency was significantly improved by various interactions between the ions themselves,[1,29,30] such as van der Waals forces, electrostatic interactions, and hydrogen bonding. As a result, 0.32 mg mL$^{-1}$ [$C_{12}$mim]Cl was chosen in this experiment.

**Influence of MFMs Concentration.** The concentration of MFMs is also a vital parameter for magnetic SPE, as it is directly related to the extraction efficiency of the tested analytes. In this study, to investigate the adsorption capacity of MFMs and to choose the optimal content, 0.32 mg mL$^{-1}$ ILs and 20 $\mu$L of rhubarb-herb-extracting solution were added into diluents containing MFMs ranging in concentration from 3.3 to 16.5 mg mL$^{-1}$. As illustrated in Figure 6, the adsorption capacity sharply increased with the MFMs concentration up to 6.6 mg mL$^{-1}$ but then decreased significantly when 9.9 mg mL$^{-1}$ MFMs was used in the dispersion, decreasing the efficiency of the magnetic SPE. Furthermore, the UV absorption of the five compounds remained substantially unchanged as the MFMs concentration increased from 9.9 to 16.5 mg mL$^{-1}$. These observations demonstrated that the capacity of MFMs adsorbing compounds was saturated, and it was difficult to elute more analytes from the sorbent in the presence of high concentrations of MFMs in dispersions. According to the above results, 6.6 mg mL$^{-1}$ was selected as the optimal MMNP concentration and employed in the following studies.

**Effect of pH.** The pH of the sample-extracting solution played an important role in the extraction process, as it determined the type of compounds present and the state of the ILs. Additionally, it was a critical parameter for the MSPE method optimization. In the experiment, the pH of the sample solution was adjusted using 1 M phosphoric acid or 1 M sodium hydroxide to values ranging from 5 to 13. The effect of pH on the extraction efficiency of the analytes is shown in Figure 7. It was apparent that with the increment of pH values from 5 to 11, the magnitude of the extracted peak areas of the target compounds was progressively increased, especially in the

case of the absorption of rhein (peak 2) and chrysophanol (peak 4). This result is ascribed to the presence of the hydroxyl groups (OHs) in the molecular structures of anthraquinones. The lone-pair electrons exposed in OHs could interact with the $\pi$ electrons in the imidazole structure of IL-coated MFMs, which increased the extraction efficiency of the target analytes. However, the peak areas of the analytes greatly decreased when the pH value increased to 13, indicating that stronger alkalinity of the solution resulted in more difficult desorption of target analytes from functionalized magnetic materials. This finding may imply that the enrichment effect was strongly pH dependent. As a result, a pH of 11 was found to be optimal.

**Concentration of Acetic Acid in the Eluent.** After the IL-coated MFMs and extracted compounds were separated from the aqueous phase, an elution procedure with an organic solvent was required to remove the target compounds from the sorbents. On the basis of our experience and the nature of the desorption solvent, methanol was chosen as an eluent. In addition, the eluent efficiency of methanol was investigated by adding from 0% to 5% acetic acid to adjust the eluent pH. Initially, poor extraction efficiencies were obtained, and the aloe emodin and physcion signals (peaks 1 and 5) were extremely weak (Figure 8) in pure methanol. The extraction efficiency then improved as the acetic acid concentration increased from 1% to 2%. However, when larger volumes of acetic acid (from 3% to 5%) were applied, the peak areas of the five compounds decreased sharply. This may be due to the decreased hydrogen bonding, ionic interactions, and solubilities between the analytes and eluent.[31,34] Thus, based on the above observations, 2% acetic acid in methanol was chosen as the optimal eluent.

**Validation of the Proposed Method.** Once optimized, the proposed process was analytically characterized in terms of linearity, precision, repeatability, limits of detection (LODs), limits of quantification (LOQs), and recovery. The calibration curves were established using five target compounds at concentrations ranging from 0.0084 to 2.4537 $\mu$g mL$^{-1}$. The results summarized in Tables 1 and 2 indicate good linearity over the concentration range investigated, and the correlation coefficients of determination ($r^2$) were all greater than 0.9994. To confirm the repeatability, five different working solutions prepared from rhubarb samples using MSPE were analyzed, and the RSDs of peak areas and retention times were found to be lower than 4.32% and 0.46%, respectively. The intra- and interday precision of the proposed method were also calculated as the RSD among concentrations in the middle of the linear range. As listed in Table 1, the RSDs of the peak areas and retention times based on six replicated injections for interday precision were in the range of 0.95%−1.19% and 0.18%−0.30%, respectively. For the intraday precision test, the peak areas and retention times were less than 0.25% and 0.66%, respectively. The LOD values calculated based on a signal-to-noise ratio (S/N) of 3 ranged from 0.0004 to 0.0028 $\mu$g mL$^{-1}$. Using an S/N ratio of 10, the LOQ values of these analytes were 0.0014−0.0094 $\mu$g mL$^{-1}$. Good recoveries were obtained by IL-coated MFMs SPE, ranging from 89.25% to 96.48%. The results indicated that the proposed method could provide good qualitative results for the analysis of the target analytes.

**Sample Analysis.** The optimized IL-based MFMs SPE coupled with UPLC method was applied to the extraction of anthraquinones in dietary supplements collected from a local drugstore. Figure 9 presents representative chromatograms of the standards (Figure 9A) and extracted samples (Figure 9B−E) under the determined optimal conditions. Without the sample pretreatment step (Figure 9B,D), five anthraquinones were not obviously detected by UPLC (below the LOQ of the method) in rhubarb herb and rhubarb granules. On the other hand, target compounds were notably determined using magnetic SPE (Figure 9C,E) without any interference. It was observed that the obtained extraction efficiency of the samples using magnetic SPE was remarkably greater, and the enrichment factors for all analytes were in the range from 23 (for physcion) to 60 (for emodin). The rhubarb herb and rhubarb granules contained 0.0146 mg g$^{-1}$ and 0.0071 mg g$^{-1}$ aloe emodin, 0.0089 mg g$^{-1}$ and 0.0047 mg g$^{-1}$ rhein, 0.0056 mg g$^{-1}$ and 0.0024 mg g$^{-1}$ emodin, 0.1411 mg g$^{-1}$ and 0.0692 mg g$^{-1}$ chrysophanol, and 0.0334 mg g$^{-1}$ and 0.0227 mg g$^{-1}$ physcion, respectively. It was obvious that the contents of anthraquinones in the rhubarb granules were much lower than those in the rhubarb herb, which may due to the complexity of the production process. The experimental results clearly indicated that the proposed method was a useful tool for the analysis of multiple ingredients in real plant samples.

**Comparison with Other Methods.** Table 3 presents a comparison of the proposed method with other counterparts based on the use of SPE. The comparison is performed on the basis of some operational (sample volume, sorbent) and analytical (LODs, recovery, and analysis time) properties. In the majority of the cases, the extraction method is performed using the principles of magnetic SPE. Our proposal provides low LODs (0.4−2.8 ng/mL) for target analytes by using the lowest amount of sample volume, which is comparable with the HPLC-FLD method. Moreover, the recoveries are comparable with the other counterparts, requiring a shorter analysis time. In summary, IL-MFMFMs can be considered as a promising alternative for the extraction of phytochemical compounds.

In conclusion, a novel IL-coated MFMs SPE method coupled with UPLC was developed for the preconcentration of five anthraquinones in dietary supplements. The contents of target

components were successfully determined with satisfactory precision, recovery, and repeatability. Compared with traditional extraction modes, this proposed method has the advantages of simplicity, rapidity, ease of operation, and environmental-friendliness. Therefore, IL-functionalized MFMs SPE could have high analytical potential for the extraction of other analytes from complex plant samples.

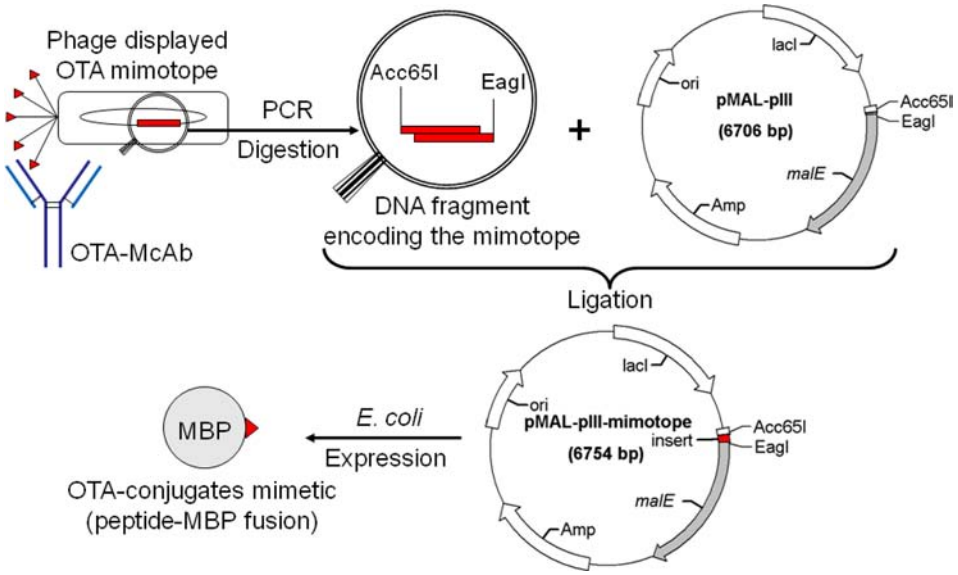

**Figure 1.** Schematic presentation of the construction of expression plasmid for mimetic OTA conjugate.

mL.[26] Nevertheless, current research concerning the mimotope is usually based on the phage serving as a competitive antigen, and there are few reports of mimotopes used as a coating antigen in quantitative immunoassay.

In addition to using mimotopes in the form of phage-displayed peptides, the chemosynthetic peptide has also been employed as a substitute for mycotoxin conjugate in immunoassays.[27−29] The chemosynthetic peptide allows precise control of peptide concentration and conformation, with a simple molecular weight and structure, and thus is conducive to analyzing the peptide structure−function relationship. However, the problem of environmental pollution and high cost during the chemosynthesis of peptide conjugate chemosynthesis is still inevitable.

We have previously reported ochratoxin A (OTA) mimotopes selected from a second-generation peptide library.[30] Here, using OTA as a model analyte, substitutes for OTA conjugates were produced by genetically fusing OTA mimotopes to a maltose binding protein (MBP) and expressed in *Escherichia coli* cells. The resulting peptide−MBP fusion proteins (mimetic OTA conjugate), which are "cloneable" homogeneous and OTA-free products, worked successfully in quantitative and qualitative immunoassays for measuring OTA in cereals and would facilitate standardization of immunoassays for mycotoxin OTA.

## MATERIALS AND METHODS

**Chemicals and Reagents.** Mycotoxin ochratoxin A, aflatoxin $B_1$ ($AFB_1$), zearalenone (ZEN), citrinin (CIT), and horseradish peroxidase (HRP)-conjugated goat anti-mouse antibody were obtained from Sigma (St. Louis, MO, USA). Phage particles displaying OTA mimotopes (named L12-204, L12-206, L12-214, L12-311, L12-314, L12-317, and L12-330), anti-OTA monoclonal antibody (OTA-McAb), and OTA conjugated with ovalbumin (OTA−OVA) were previously prepared in our laboratory.[30,31] Anti-MBP Tag mouse monoclonal antibody was purchased from CWBIO (Beijing, China). 3,3′-Diaminobenzidine (DAB) substrate was purchased from Bio Basic Inc. (Toronto, ON, Canada). SuperSignal ELISA Pico chemiluminescent substrate was obtained from Thermo Scientific (Waltham, MA, USA). Polyvinylidene fluoride (PVDF) membrane was purchased from Millipore Co. (Bedford, MA, USA). The *p*MAL-pIII vector, restriction enzymes *Acc*65I and *Eag*I, and amylose resin were purchased from New England Biolabs, Inc. (Beverly, MA, USA). Taq polymerase, minibest DNA fragment purification kit, and T4 DNA ligase were purchased from TaKaRa (Dalian, China). Commercial ELISA kit for OTA was purchased from Defeng (Taiyuan, China). All inorganic chemicals and organic solvents were of reagent grade.

**Construction of Expression Plasmid for Mimetic OTA Conjugate.** An expression plasmid was constructed aiming to reproducibly prepare mimetic OTA conjugate (peptide−MBP fusion protein). The schematic diagram of constructing expression plasmid is presented in Figure 1. First, phage particles displaying OTA mimotopes were used for single-stranded phage DNA isolation and purification as described by He et al.[25] Then phage DNA fragment encoding the selected OTA mimotope was amplified by polymerase chain reaction (PCR) using the forward primer (5′-CAT GCC CGG GTA CCT TTC TAT TCT C-3′) and reverse primer (5′-CCC TCA TAG TTA GCG TAA CG-3′). The PCR was performed in a total volume of 100 μL (containing 200 μM each dNTP, 100 nM each forward and reverse primer, 1 U TaKaRa Taq, and 1 μL of single-stranded phage DNA; 95 °C for 30 s, 55 °C for 30 s, and 72 °C for 30 s, cycled 30 times). PCR product was purified using a DNA fragment purification kit (Tiangen, Beijing, China) and then digested with *Acc*65I and *Eag*I restriction enzymes (37 °C for 5 h). After the digested DNA fragment was purified by 8% polyacrylamide gel electrophoresis (PAGE), it was ligated into an *Acc*65I and *Eag*I-digested vector pMAL-pIII and transformed into *E. coli* TB1. The constructed expression plasmid was extracted from the transformants and sequenced as described previously.[32]

**Preparation and Characterization of Mimetic OTA Conjugate.** After the construction of expression plasmid, the mimetic OTA conjugate (peptide−MBP fusion protein) was prepared through the technique of protein engineering. Initially, expression plasmid was transformed to *E. coli* TB1 cells and cultured in LB medium (containing 0.2% glucose and 100 μg/mL ampicillin) at 37 °C by shaking (250 rpm) to $OD_{600}$ ∼0.5. The culture was then induced with 0.4 mM isopropyl-*β*-D-thiogalactopyranoside (IPTG) and shaken at 25 °C for 16 h. After that, the periplasmic fusion proteins were extracted by osmotic shock as described previously.[33] Following the preparation of the cold osmotic shock fluid, the OTA conjugates mimetics were purified by amylose affinity chromatography.[33] Afterward, a Western blot analysis was carried out to validate the mimetic OTA conjugates according to the protocol described previously.[32]

**Chemiluminescent Immunoassay Established with Mimetic OTA Conjugate.** A quantitative chemiluminescent enzyme-linked immunoassay (CLEIA) for OTA was developed with mimetic OTA conjugate. Briefly, purified mimetics (diluted in PBS, pH 7.4) was

dx.doi.org/10.1021/jf5028922 | J. Agric. Food Chem. 2014, 62, 8830−8836

coated in microplate wells for 2 h at 37 °C and blocked for 1 h at 37 °C with 3% skim milk in PBS. The plate was washed three times with PBST. Afterward, 50 μL of anti-OTA monoclonal antibody (OTA-McAb) (diluted in PBS, pH 7.4) was added in the coated wells in the presence of 50 μL of sample extracted solution or OTA standard solution at 37 °C for 30 min. The plate was then washed three times, and 100 μL of a 1:2000 dilution of HRP-conjugated goat anti-mouse antibody was added to the wells for 30 min at 37 °C. The peroxidase activity was finally developed with 100 μL of chemiluminescent substrate, and chemiluminescent intensity was measured by a luminescence reader (Thermo Scientific). To measure the optimized dilution of the immunoassay reagents, a checkerboard assay was conducted by using different dilutions of mimetics and anti-OTA-McAb in advance. To compare the performance as coating antigen in immunoassay, chemosynthetic OTA−OVA conjugates and phage particles (OTA mimotope displays on phage) were also coated in microplate wells, respectively, and tested as above-described in CLEIA procedures.

**Qualitative Immunoassay Based on Mimetic OTA Conjugate.** A qualitative dot immunoassay was also developed using mimetic OTA conjugate. The procedure was performed as follows: A 0.45 μm PVDF membrane marked with 7 mm × 7 mm squares was soaked with methanol at room temperature for 10 s and placed on a drenched filter paper as previously described.[31] Then 3 μL of serial dilutions of mimetic OTA conjugate in PBS was spotted onto the squares and incubated at 37 °C for 2 h. After washing with PBST, the membrane was blocked by soaking in 3% skimmed milk in PBS for 30 min. After rinsing in PBST, 7 mm squares were cut, dried, and stored at 4 °C until used.

After the preparation of mimetics-spotted membrane, the assay was performed as follows: Membrane strips were soaked in 10% (v/v) methanol−PBS spiked with sample extracts or various concentrations of OTA and containing the appropriate dilution of OTA-McAb, incubated for 15 min at room temperature. After washing with PBST, the strips were incubated for 15 min in a dilution solution of HRP-conjugated goat anti-mouse antibody, washed, and incubated with TMB substrate. The membrane was rinsed with tap water, and the color intensity of the OTA-positive control and sample test zones was visually compared to that of the OTA-negative control (which has the most intense color).

**Validation of Mimetic OTA Conjugate-Based Immunoassay.** Validation of the mimetic OTA conjugate-based immunoassay was performed by analyzing the reproducibility and by determining the OTA concentrations in spiked cereal samples and incurred samples.

For the determination of reproducibility, CLEIAs were performed using the mimetic OTA conjugate produced within one batch (intra-assay) and three batches (interassay), respectively. Then the coefficients of variation (CVs) of the $IC_{50}$ of the calibration curves for intra- and interassays were calculated.

To measure the recovery of OTA, OTA-negative samples (corn, rice, and wheat samples) confirmed by HPLC (<0.6 μg/kg) were spiked with OTA at various concentrations, respectively. Both OTA-negative samples and spiked samples were extracted as described below: 5 g of finely ground samples mixed with 10 mL of methanol/water (50:50, v/v) was ultrasonically extracted for 20 min; after centrifuging, the supernatant was diluted 5-fold with PBS for the dot immunoassay analysis or diluted 5-fold with PBS and subsequently diluted 4-fold with PBS containing 10% methanol for the CLEIA analysis. As to the analysis of incurred samples, cereals and feedstuffs were prepared as above.

## RESULTS AND DISCUSSION

**Production and Characterization of Mimetic OTA Conjugate.** Phage single-stranded DNA fragment isolated from seven selected OTA mimotopes (L12-204, L12-206, L12-214, L12-311, L12-314, L12-317, and L12-330) were PCR amplified, respectively (Figure 2A), and digested by *Eag*I and *Acc*65I (Figure 2B). As to the vector of *p*MAL-pIII, it was digested with the same enzymes and isolated by 8% agarose gel

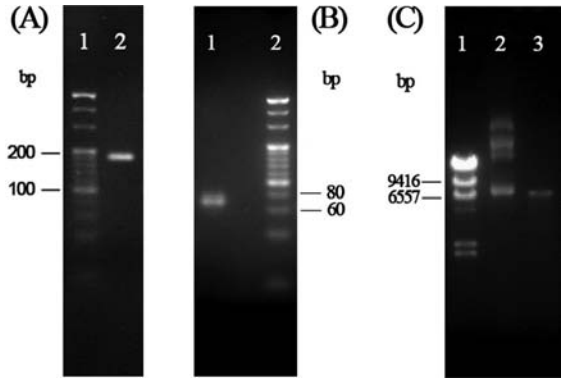

**Figure 2.** Agarose gel electrophoresis of the results for PCR and digestion: (A) PCR product of DNA fragment (182 bp) that encodes the OTA mimotope (L12-206, others not shown;. (B) DNA fragment (68 bp) digested with restriction enzymes *Acc*65I and *Eag*I; (C) vector pMAL-pIII (6.7 kb) before (lane 2) and after (lane 3) digestion with the same restriction enzymes.

electrophoresis (6.7 kb) (Figure 2C). Seven expression plasmids of mimetic OTA conjugate were constructed and confirmed by sequencing, respectively (data of DNA sequencing is available in the Supporting Information Figure S1).

The constructed expression plasmids were transformed into *E. coli* TB1 cells, and peptide−MBP fusion proteins (mimetic OTA conjugate) were expressed by IPTG inducing. An orthogonal experiment was implemented to analyze the effect of IPTG concentration, induction temperature, and time, which showed that the optimal fusion protein expression was induced with 0.4 mM IPTG at 25 °C for 16 h. As shown in the results of SDS-PAGE and Western blot, the purified mimetic OTA conjugates (named L12-204−MBP, L12-206−MBP, L12-214−MBP, L12-311−MBP, L12-314−MBP, L12-317−MBP, and L12-330−MBP, respectively) all ran as a single band at the predicted molecular mass (calculated as 44 kDa for the 1:1 fusion of peptide and MBP) and specifically bind to the anti-MBP antibody (Figure 3).

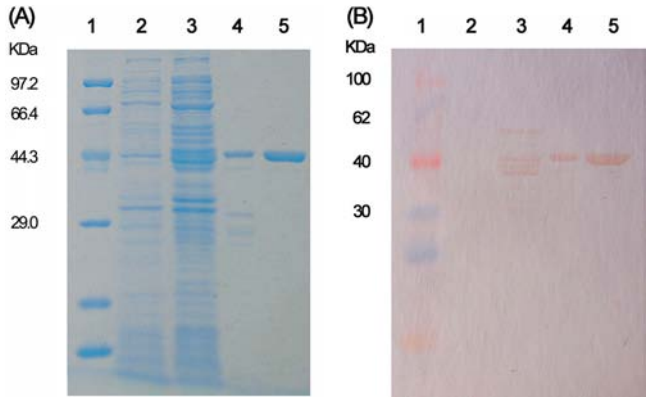

**Figure 3.** (A) SDS-PAGE and (B) Western blot of expression of mimetic OTA conjugate (L12-206−MBP, others not shown). Blots were stained with Coomassie brilliant blue or probed with anti-MBP mouse monoclonal antibody. Lanes: 2, whole-cell extract harvested immediately prior to IPTG induction or, 3, 16 h after IPTG induction; 4, osmotic shock supernatant; 5, purified L12-206−MBP by amylose affinity chromatography.

dx.doi.org/10.1021/jf5028922 | J. Agric. Food Chem. 2014, 62, 8830−8836

**Chemiluminescent Immunoassay for OTA Using Mimetic OTA Conjugate.** Competitive inhibition curves of chemiluminescent immunoassay based on mimetic OTA conjugate (L12-204−MBP, L12-206−MBP, L12-214−MBP, L12-311−MBP, L12-314−MBP, L12-317−MBP,and L12-330−MBP) were established, respectively, and the sensitivity of immunoassay was determined. Among the seven mimetic-based inhibition curves, the $IC_{50}$ values were 1.23 ± 0.11, 0.88 ± 0.05, 1.62 ± 0.12, 1.92 ± 0.17, 1.30 ± 0.06, 1.54 ± 0.12, and 1.30 ± 0.10 ng/mL, respectively (Figure 4A, the value is the average of five replicates ± standard deviation). According to the cross-reactivity test, no reaction with mycotoxin $AFB_1$, ZEN, or CIT was found in mimetic-based chemiluminescent immunoassay (Figure 4B). Among the seven curves, inhibition curves established with L12-206−MBP revealed the highest sensitivity; the $IC_{50}$ was 0.82 ng/mL, and linearity ranged (20−80% inhibition of the maximal chemiluminescent intensity) from 0.31 to 2.17 ng/mL (Figure 4C, the value is the average of three replicates). For comparison, the value of $IC_{50}$ and working range for conventional OTA−OVA cojugate -based immunoassay were 0.90 and 0.21−3.88 ng/mL; the competitive inhibition curves between the OTA−OVA conjugate and mimetic OTA conjugate had no significant difference. However, the phage-displayed OTA mimotope-based immunoassay did not exhibit a typical sigmoid curve; with the addition of OTA standard, the chemiluminescent intensity did not decrease for the phage-displayed peptide-coated microwells (Figure 4C), which indicated that phage-displayed mimotopes of OTA are not adaptable for polystyrene microwells directly serving as coating antigens in quantitative immunoassays.

The influences of buffer ionic strength and pH were investigated to evaluate the effect on mimetic-based immunoassay for OTA. The appropriate buffer ionic strength was tested with 5, 10, 25, and 50 mM methanol−PBS (Figure 5A). According to the result, ionic strength between 10 and 50 mM has little significant influence on the assay. Taking both $IC_{50}$ and $RLU_{max}/IC_{50}$ into consideration, optimized performance was achieved at 10 mM. At the optimal ionic strength, the pH effect was investigated between 6.0 and 9.0 (Figure 5B). The result suggests the best performance at pH 7.4 when the $RLU_{max}/IC_{50}$ was the highest. In addition, methanol that affects antigen−antibody interaction is generally utilized as OTA solvent and extraction agent; the proper content of methanol was estimated using OTA prepared in various concentrations of (5, 10, 20, and 40%, v/v). The relative luminescent intensity declined and $IC_{50}$ increased significantly when methanol concentration was >10%. The highest $RLU_{max}/IC_{50}$ and the lowest $IC_{50}$ were observed at 10% methanol−PBS (Figure 5C).

**Qualitative Immunoassay Based on the Mimetic OTA Conjugate.** After being employed in the quantitative immunoassay, the mimetic OTA conjugate (L12-206−MBP) was also utilized to develop a qualitative dot immunoassay to visually detect OTA without instrumentation. A checkerboard assay was performed by using different dilutions of immunoreagents (mimetic OTA conjugate and OTA-McAb). The selected mimetic OTA conjugate diluted to 10, 25, 50, and 100 μg/mL and OTA-McAb diluted to 1:500, 1:1000, 1:2000, and 1:4000 were tested, respectively. The assay incubated with 100 μg/mL mimetic OTA conjugate and 1:2000 dilution of OTA-McAb for 15 min was chosen to be the minimum concentration of immunoreagents for a clear and sufficient intensity of spot (Figure 6A). Increasing the incubation time beyond 15 min did not increase the spot color intensity (data not shown).

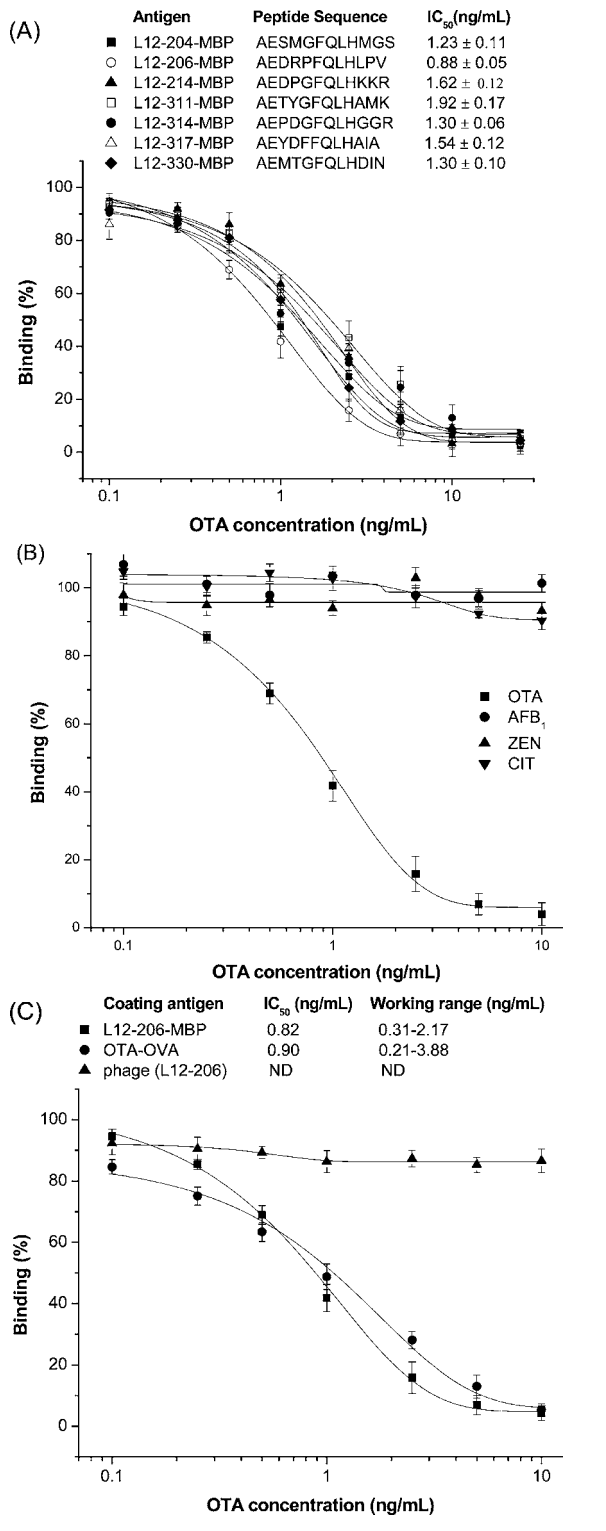

**Figure 4.** (A) Dose−response curves of the CLEIAs for OTA established with seven mimetic OTA conjugates (L12-204−MBP, L12-206−MBP, L12-214−MBP, L21-311−MBP, L12-314−MBP, L12-317−MBP, and L12-330−MBP. The value is the average of five replicates ± standard deviation. (B) Cross-reactivity of the mimetic OTA conjugate (L12-206−MBP)-based CLEIA toward mycotoxin OTA, $AFB_1$, ZEN, and CIT. (C) Dose−response curves of the CLEIAs using the mimetic OTA conjugate (L12-206−MBP, 5 μg/mL), OTA−OVA conjugate (2 μg/mL) and phage (L12-206, 2.5 × $10^8$ pfu/mL) as coating antigens, respectively. The vertical bars indicate the standard deviation ($n$ = 3).

dx.doi.org/10.1021/jf5028922 | J. Agric. Food Chem. 2014, 62, 8830−8836

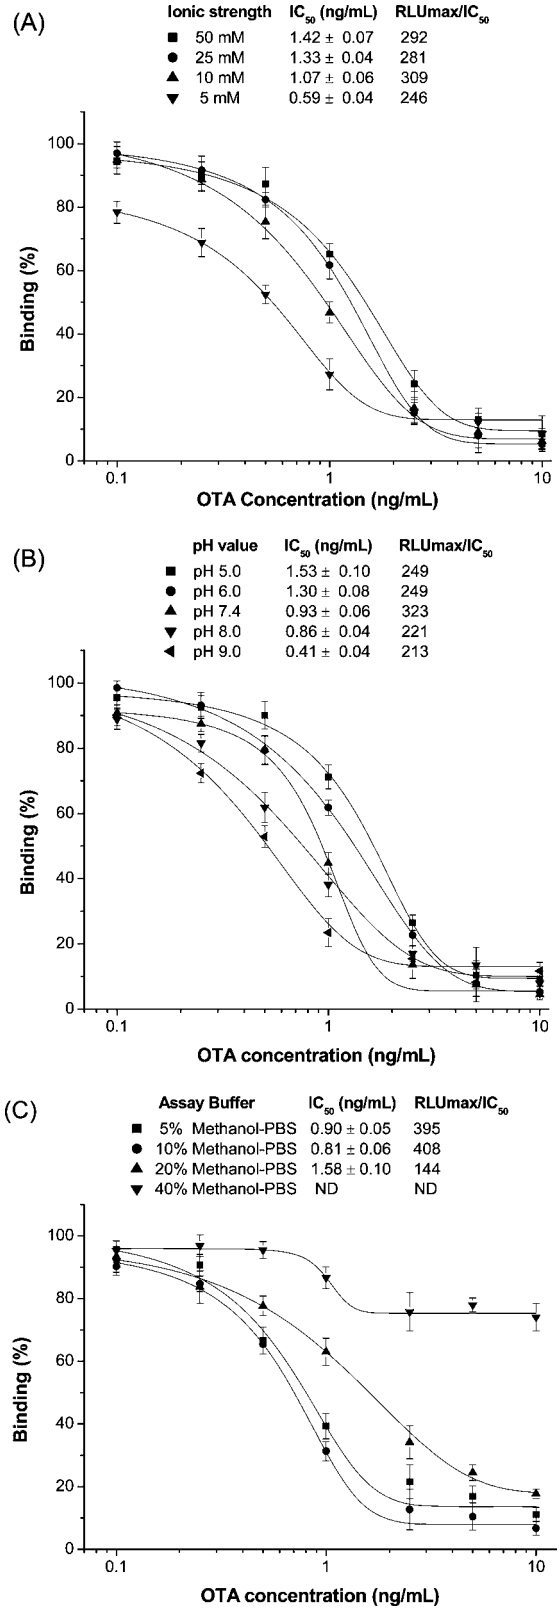

**Figure 5.** (A) Ionic strength, (B) pH, and (C) methanol effects on the performance of the mimetic OTA conjugate-based chemiluminescent ELISA. Each experiment was implemented in triplicate, and the means of the triplicates are plotted (error bars represent the standard deviation).

To visually evaluate the cutoff levels (the lowest concentration of OTA able to achieve 100% inhibition and therefore

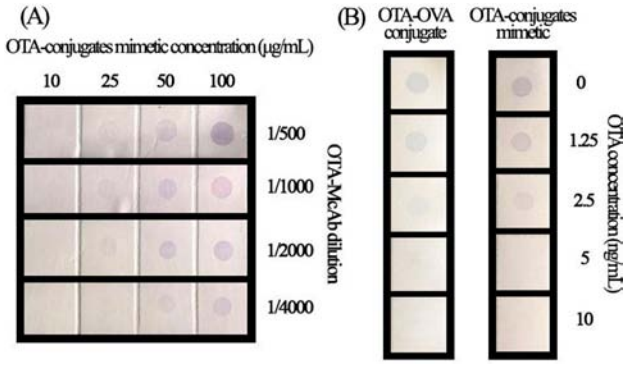

**Figure 6.** OTA−OVA conjugates and mimetic OTAconjugate-based dot immunoassays: (A) mimetic OTA conjugate (ranging from 10 to 100 μg/mL) spotted onto PVDF membranes incubated with different dilutions of OTA−McAb (ranging from 1/500 to 1/4000); (B) evaluation of the cutoff level (smallest amount of OTA able to achieve 100% inhibition and therefore no spot color development) of the dot immunoassay assessed visually. Mimetic OTA conjugate and conventional OTA−OVA conjugates were applied to the assay as coating antigen, and OTA levels (0, 1.25, 2.5, 5.0,10 ng/mL) were analyzed, respectively.

no color development) of the mimetic OTA conjugate-based dot immunoassay, OTA was analyzed at different concentrations (0, 1.25, 2.5, 5.0, 10 ng/mL). As presented in Figure 6B, the intensity of the spot decreased with increasing OTA concentration, and no spot color development on the membrane was obtained when the OTA standard concentration rose beyond 5.0 ng/mL. The cutoff level of the mimetic OTA conjugate-based dot immunoassay was 5.0 ng/mL, which was equal to that of the OTA−OVA conjugate-based dot immunoassay (thecutoff level was 5.0 ng/mL, Figure 6B).

**Validation Studies.** The validation of the CLEIA based on the mimetic OTA conjugate (L12-206−MBP) was carried out by measuring the OTA recovery and reproducibility. Table 1 shows the recoveries of OTA added to corn, rice, and wheat samples analyzed by three methods. In the first two assays (CLEIAs set up with both the mimetic OTA conjugate and OTA−OVA), the spiked and detected OTA contents were in accord with each other. The recovery of cereals spiked with 10−100 μg/kg OTA ranged from 82.6 to 134.0% determined by the mimetic OTA conjugate-based CLEIA and from 90.2 to 132.0% by conventional OTA−OVA-based assay. In the case of the dot immunoassay, a clear dot was observed for adding cereals OTA <50 μg/kg, but no dot appeared for OTA ≥50 μg/kg.

As for the reproducibility, it is evaluated by determining the CVs of the $IC_{50}$ of the calibration curves. The CV was 5.3% for intra-assay and 10.4% for interassay, respectively. Furthermore, the mimetic OTA conjugate kept at −20 °C until use for 1 year remained effective, indicating the stable performance of the mimetic OTA conjugate-based immunoassay (data not shown).

Twenty samples of cereal and feedstuffs purchased from the Chinese market were analyzed using mimetic OTA conjugate-based CLEIA, dot immunoassay, and commercial ELISA kit for OTA, respectively. Among the 20 samples, 5 were positively detected by CLEIA and commercial ELISA kit (their limits of detection were both 5.0 μg/kg). The results obtained from CLEIA and commercial ELISA kits were in agreement with each other. However, no positive sample was detected by dot immunoassay because of its cutoff level (50 μg/kg), higher than

the OTA concentration in contaminated samples (data are available in the Supporting Information, Table S1).

In conclusion, we described a new approach for developing coating antigen mimetics in immunoassay. The conventional antigen, OTA conjugates, was replaced with mimetic OTA conjugate (peptide−MBP fusion protein). This fusion protein mimics the reaction between the OTA and antibody and serves as a substitute for the OTA conjugates in immunoassays. These peptide−MBP fusion proteins (mimetic OTA conjugate) are cloneable and homogeneous products expressed from constructed express plasmids, which can be prepared reproducibly in large scale and with low cost. The peptide−MBP fusion protein provides practical sensitivity, specificity, and reliability in the standard qualitative and quantitative immunoassays.

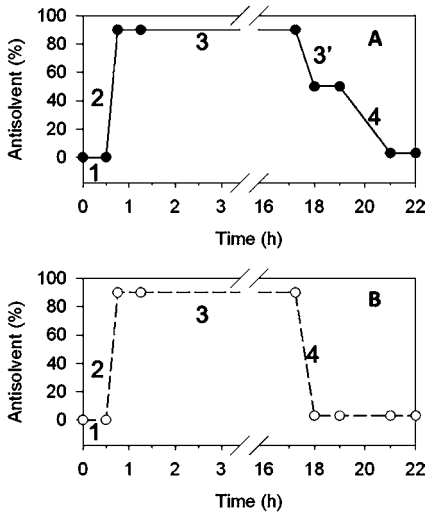

**Figure 1.** Change in antisolvent content during the preparation of protein nanoparticles. Steps 1, 2, 3, and 4 represent dispersion, desolvation, cross-linking, and evaporation, respectively. Compared to the conventional method (B), a new step (3′) was added between steps 3 and 4 in the new method (A) to lower the antisolvent content to 40−60% before evaporation.

Meanwhile, lower levels of glutaraldehyde were applied for preparing BLG nanoparticles with higher curcumin/BLG ratios. This was inspired by a series of recent studies on epigallocatechin gallate (EGCG)-loaded protein nanoparticles.[27,28] As suggested by these studies, protein aggregated into nanoparticles in the presence of polyphenols such as EGCG, and these particles remained stable without additional cross-linkers. The strong interaction between protein and polyphenols, including hydrogen bonding and $\pi-\pi$ interaction,[29] made EGCG a possible cross-linker surrogate. Likewise, if the target compound (e.g., resveratrol or curcumin) shows certain similarity in the structure and protein affinity with EGCG, the dose of glutaraldehyde could be lowered accordingly. An excessive dose of glutaraldehyde may not only cause higher toxicity but also lead to lower LE, considering that excessive cross-linking by both glutaraldehyde and the phenol might cause extensive formation of insoluble complexes.

It should be pointed out that great efforts have been made to seek alternative cross-linkers (e.g., genipin and transglutaminase) for the preparation of protein network structures, such as protein oligomers or hydrogels.[30−32] However, with regard to protein nanoparticles, glutaraldehyde remains the major cross-linking agent. This is probably because nanoparticles are compact assemblies of proteins that are very close to each other. Glutaraldehyde is a relatively small molecule, which can easily approach the functional groups (primary amino groups which is likely to be exposed at the surface of proteins) on protein nanoparticles. Other cross-linkers, such as transglutaminase, are relatively bulky molecules that are difficult to react with the required functional groups due to the steric hindrance. By replacing glutaraldehyde partially with phenolic compounds such as CUR, one may achieve a satisfactory cross-linking effect while reducing the toxicity of the final product.

In this study, BLG was chosen as a model protein to implement these strategies. BLG is the major component of whey protein and a natural carrier for various lipophilic nutrients.[33,34] Curcumin as an antioxidant[35] and chemopreventive[36] compound was selected as a model nutraceutical to be incorporated. According to previous literature (excluding those studies that might have counted coprecipitated curcumin molecules as encapsulated ones), the LE of curcumin-loaded protein nanoparticles varied from 2 to 5%.[3,9,12,37,38] The binding between curcumin and BLG nanoparticles in different water−acetone binary systems was first assessed by investigating the distribution of curcumin in different phases. The optimal acetone content before evaporation was then determined on the basis of the result. The effect of glutaraldehyde level and curcumin loading on the LE was also investigated. The formed nanoparticles were characterized for their size, surface charge, and morphology. Finally, because BLG is known for its remarkable resistance against pepsin and moderate digestibility by trypsin,[39] the nanoparticles were anticipated to show controlled-release property, that is, minimal and maximal release in the stomach and small intestine, respectively. Therefore, the nanoparticles were studied for their integrity as well as releasing profile in PBS and simulated gastric/intestinal fluids.

## MATERIALS AND METHODS

**Materials.** Bovine BLG (90% purity), pepsin (3200−4500 units/mg), trypsin (10000 BAEE units/mg), and curcumin (98% purity) were purchased from Sigma-Aldrich (St. Louis, MO, USA). Simulated gastric and intestinal fluids (abbreviated SGF and SIF, respectively) were obtained from Ricca Chemical (Arlington, TX, USA). All other chemicals (acetone, glutaraldehyde, buffers, etc.) were of analytical grade.

**Preparation of Curcumin-Loaded BLG Nanoparticles.** BLG nanoparticles were prepared by desolvation method[5] with several modifications. The whole process was undertaken in the dark under constant stirring (800 rpm). BLG was dissolved in deionized water at 10 mg/mL, and curcumin was dispersed in acetone at 4 mg/mL. Both dispersions were equilibrated for 1 h. To 2 mL of BLG dispersion was added dropwise 3 mL of pure acetone, after which an appropriate amount of curcumin solution was introduced to achieve predetermined curcumin/protein ratios (5, 10, and 15%, w/w, same hereinafter). Additional pure acetone was then added to a total volume of 20 mL. After 30 min of equilibration, glutaraldehyde (5 mg/mL aqueous solution) was introduced as a cross-linker. Theoretically, each milligram of BLG needs 40 $\mu$g of glutaraldehyde for stoichiometric cross-linking.[33] This ratio is defined as 100% glutaraldehyde equivalent, and three levels of glutaraldehyde (25, 50, and 100% equivalent) were applied in this study. After 16 h of cross-linking, aliquots of 2 mL were withdrawn and mixed with 4 mL of aqueous acetone. The composition of the aqueous acetone was designed so that the final acetone content ranged from 30 to 90% (v/v, same hereinafter) after mixing. After 1 h of equilibration, the acetone was evaporated mildly at room temperature under reduced pressure using a VWR Symphony vacuum oven (VWR International, Radnor, PA, USA). The pressure was first kept to $5 \times 10^4$ Pa for 20 min to remove dissolved air and then maintained at $4 \times 10^3$ Pa until all acetone was removed. This procedure typically lasted for 2−3 h, and additional water was then supplemented to achieve a final volume of 6 mL. The dispersion (defined as the "final dispersion") was stored at 4 °C for subsequent assays. The initial and final pH values of the dispersions ranged from 7.2 to 7.6.

**Quantitative Analysis of Free and Bound Curcumin.** Following the procedures described above, BLG−curcumin nanoparticles were prepared in 90% acetone, cross-linked using 100% equivalent of glutaraldehyde, and mixed with aqueous acetone to achieve various acetone contents. After equilibration for 1 h, the dispersion was centrifuged (9000*g*, 15 min, room temperature). The insoluble curcumin was recovered in the precipitate and dissolved in pure acetone, whereas the supernatant was subjected to dialysis centrifugation (5000*g*, 30 min, room temperature) using a Macrosep centrifuge tube (MW cutoff 10 kDa; Pall Corp., Ann Arbor, MI, USA).

A preliminary study was conducted with 90% aqueous acetone containing 1 mg/mL curcumin. More than 90% of the dissolved curcumin was able to pass the dialysis membrane and recovered in the filtrate. The filtrate containing freely dissolved (nonbound) curcumin was recovered and diluted with acetone. Both dispersions mentioned above were further diluted with acetone, so that the final water content in the mixture was <1%. The resultant mixtures were then measured for their absorbance at 426 nm by a DU-730 UV−vis spectrophotometer (Beckman Coulter Inc., Fullerton, CA, USA). The percentages of insoluble and dissolved curcumin were calculated using an established standard curve ($R^2$ = 0.9991), and the ratio of BLG nanoparticle-bound curcumin was derived by subtracting these two proportions from 100%.

**Characterization of Curcumin-Loaded BLG Nanoparticles.** Freshly prepared "final dispersions" of curcumin-loaded BLG nanoparticles were subjected to the following measurements.[33] The particle size and count rate were determined by dynamic laser scattering (DLS) using a BI-200 SM Goniometer version 2 (Brookhaven Instrument Corp., Holtsville, NY, USA) equipped with a 35 mW He−Ne laser beam. No dilution was undertaken prior to the assays. Two separate measurements were carried out on each sample to obtain accurate results. For count rate determination, the aperture pinhole size was fixed at 400 $\mu$m. To measure the particle size, appropriate aperture sizes were chosen to achieve a count rate between 100 and 300 kcps (kilo counts per second, same hereinafter). The obtained data were analyzed using the Cumulant algorithm, and the quadratic mean particle size ($z$-average size) was reported.

The electrophoretic mobility of nanoparticle dispersions was determined by laser Doppler velocimetry using a Nano ZS90 Zetasizer (Malvern, UK). Each sample was measured three times, and at least 12 runs were performed per measurement. The data were then converted to zeta potentials using the Smoluchowski model.

The structure of curcumin-loaded BLG nanoparticles was investigated by Fourier-transform infrared (FT-IR) analysis. Samples (3−5 mg) were freeze-dried and mounted onto a Jasco FT/IR 4100 spectrometer (Jasco Inc., Easton, MD, USA). The infrared transmittance was recorded at wavenumbers between 1000 and 4000 $cm^{-1}$ with a resolution of 4 $cm^{-1}$. At least 100 scans were undertaken for each sample. The spectra were averaged, smoothed, and corrected for their baselines using the Spectra Manager software (Jasco Inc.).

The morphology of nanoparticles was observed under scanning electron microscopy (SEM). Approximately 40 $\mu$L of the dispersion (after evaporation and water supplementation) was cast dried on an aluminum pan, mounted on a conductive carbon tape, coated with gold/platinum using a sputter coater (Hummer XP, Anatech, Union City, CA, USA), and observed under SEM (Hitachi SU-70, Pleasanton, CA, USA). Representative images were reported.

**Determination of Encapsulation Efficiency (EE) and Loading Efficiency (LE).** The EE of curcumin-loaded nanoparticles was determined as follows.[9] After evaporation and water supplementation as described under Preparation of Curcumin-Loaded BLG Nanoparticles, the final dispersions were allowed to stand at room temperature for 1 h and then centrifuged at 9000$g$ for 30 min. The insoluble curcumin was recovered from the precipitate and dissolved in pure acetone. The supernatant was subjected to dialysis centrifugation as was discussed under Quantitative Analysis of Free and Bound Curcumin, and the free curcumin was collected in the filtrate. The two parts of curcumin were diluted with acetone and measured for their absorbance at 426 nm, which was converted to the curcumin content using the same standard curve as described before. The EE was calculated as follows:

$$\mathrm{EE} = 100 - \frac{\text{amount of precipitated curcumin}}{\text{total amount of curcumin}} \times 100 \quad (1)$$

In addition, after the dialysis centrifugation mentioned above, the retentate containing the curcumin-encapsulated nanoparticles was collected and lyophilized. The dry nanoparticles were weighed, and the LE was calculated as follows:

$$\mathrm{LE} = \frac{\text{weight of encapsulated curcumin}}{\text{total weight of nanoparticles}} \times 100 \quad (2)$$

**In Vitro Release of Curcumin in Different Buffering Systems.** *Release in PBS.* Samples prepared with the following parameters were chosen for in vitro release study: curcumin loading of 5, 10, and 15% (w/w), initial acetone content of 90%, pre-evaporation acetone content of 50%, and glutaraldehyde levels that resulted in optimal EE for each curcumin loading ratio. Samples were taken after evaporation but prior to supplementation of water. All buffers used in this section contained 5 mg/mL Tween 20. Unless specified, the PBS used in this section was at pH 7.2 and 0.1 mol/L.

Two milliliters of the above-mentioned samples was mixed with 2 mL of PBS (pH 7.2, 0.2 mol/L). After incubation at 37 °C for 30 min, the mixture was injected into a sealed dialysis tube (MW cutoff 10 kDa), which was then placed in a flask containing 60 mL of PBS (preheated at 37 °C). The flask was then incubated in a reciprocal shaking bath (Thermo Scientific, Odessa, TX, USA) at 37 °C under constant shaking at 120 rpm. At predetermined time intervals, aliquots of 2 mL were withdrawn from the flask and diluted with an appropriate amount of PBS. The resultant dispersion was measured for its absorbance at 426 nm, which was converted to the mass of released curcumin using a linear standard curve ($R^2$ = 0.9993). After each measurement, 2 mL of fresh PBS was added to the flask to maintain sink condition. The kinetic release profile of curcumin was plotted as a function of time and curve fitted to the first-order kinetic model

$$C = C_0 + k \ln t \quad (3)$$

where $C$ indicates the cumulative percentage of released curcumin, $C_0$ represents the initial percentage of curcumin present in the buffer, and $t$ stands for time.

*Release in SGF and SIF.* The nanoparticle dispersion with a curcumin loading of 10% was chosen for this study. Two milliliters of the sample was incubated at 37 °C and then diluted with 8 mL of two preheated buffers: SGF-2 (commercial SGF, adjusted to pH 2.0, added with pepsin at a BLG/pepsin ratio of 100:1, w/w) or SGF-5 (same as SGF-2 except that the pH was adjusted to 5.0). These buffers mimicked the gastric environment at fasting and fed states, respectively.[40] After mixing, 0.5 mL of the dispersion was withdrawn immediately, diluted with 2.0 mL of PBS, and then subjected to dialysis centrifugation (5000$g$, 30 min) using a Macrosep centrifuge tube (MW cutoff 100 kDa; Pall Corp.). The filtrate containing released curcumin was diluted appropriately with PBS before spectrophotometric measurement at 426 nm. The absorbance was converted to the amount of released curcumin as described before. Meanwhile, the above-mentioned mixture was incubated at 37 °C in the reciprocal shaking bath (120 rpm), and aliquots of 0.5 mL were withdrawn and measured as mentioned above at predetermined time intervals. Fresh SGF was supplemented after each measurement to maintain sink condition.

On the other hand, another batch of the nanoparticle dispersions were mixed with SGF and digested for 60 min at 37 °C in the reciprocal shaking bath. The digesta was diluted with PBS and centrifuged as mentioned above, and the retentate containing intact nanoparticles was supplemented with PBS to 2 mL. The dispersion was incubated at 37 °C for 15 min and then mixed with 8 mL of preheated SIF (commercial SIF with added trypsin at a BLG/trypsin ratio of 100:1, w/w). Immediately after mixing, 0.5 mL of the dispersion was withdrawn and subjected to dialysis centrifugation (5000$g$, 45 min, 4 °C), after which the filtrate was diluted with PBS and measured as discussed before. Similar procedures were followed to determine the percentage of released curcumin at desired time intervals, and fresh SIF was supplemented to maintain sink condition. The combined kinetic release profile of curcumin in SGF and SIF was plotted against time.

**In Vitro Disintegration of BLG Nanoparticles.** The nanoparticle dispersion with a curcumin loading of 10% was chosen for this study. Digestion in SGF was carried out following the same procedure as described in the previous section. Digestion in SIF was initiated by diluting the nanoparticle dispersion directly with SIF, without prior

treatment with SGF. This was because the nanoparticles were either largely degraded (at pH 2.0) or intact (at pH 5.0), as indicated by the particle sizes, count rates, and size distribution profiles observed at these two pH values. At desired time intervals, samples were withdrawn, diluted with PBS and then measured for their particle sizes and count rates.

**Statistics.** All measurements were performed in triplicates. The results were expressed as means ± standard error. The data were subjected to analysis of variance followed by Tukey's test with an experimental confidence level of $\alpha = 0.10$ using SAS 9 software (SAS Institute Inc., Cary, NC, USA).

## RESULT AND DISCUSSION

**Binding of Curcumin to BLG Nanoparticles as a Function of Acetone Content.** In a water/acetone binary system containing BLG nanoparticles, curcumin molecules may exist in three forms: insoluble curcumin that was found in the precipitate, dissolved curcumin that was collected in the filtrate, and BLG-bound curcumin molecules obtained in the retentate. Figure 2 shows the distribution of curcumin in the nanoparticle dispersion as a function of acetone content. The data were obtained after rapidly diluting the cross-linked dispersion with appropriate water/acetone mixtures. As can be seen, the percentage of free curcumin increased significantly at acetone content >30% (v/v, same hereinafter). Similar results were obtained from a relevant study on BLG monomers,[41] which reported that the secondary structure and the capability of binding retinol were decreased in 30% or higher concentration of ethanol. The results from previous and current studies suggested weak interaction between curcumin and BLG nanoparticles.

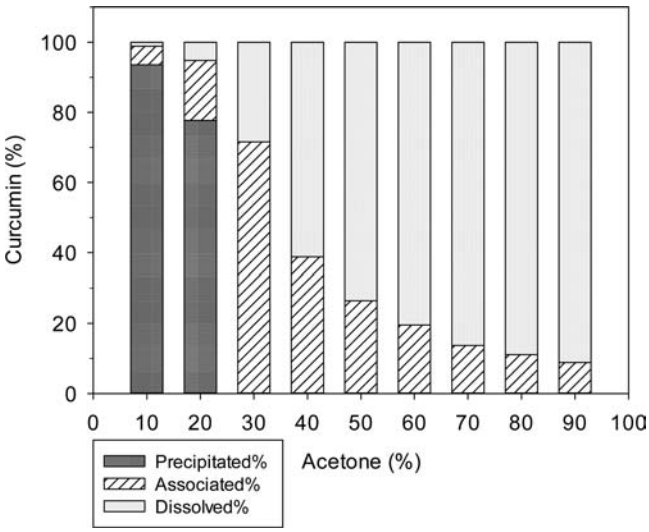

**Figure 2.** Effect of acetone content on the distribution of curcumin in BLG nanoparticle dispersion. The nanoparticles were cross-linked with 100% equivalent of glutaraldehyde.

On the other hand, >80% of curcumin molecules were detected in the precipitate in the presence of 10−20% acetone. This was probably because (1) curcumin as a hydrophobic compound exhibits low solubility in 10−20% acetone and (2) most protein molecules were partly or fully folded, so that there were insufficient hydrophobic sites that associated with curcumin.[9] It was noteworthy that previous studies on BLG monomers[41,42] showed considerable binding to ligands (such as retinol) at low organic solvent concentrations (such as 10−20% ethanol). However, the native binding sites on BLG were limited, and the ligand/BLG ratio in our study was much higher than that of the previous study (equimolar, which was translated to a weight ratio of 1.4%). In addition, most of these ligand-binding sites lost their activity at high level of organic solvents during the preparation of nanoparticles.[43] Therefore, the curcumin−BLG association involved in our study might have taken place mostly on the hydrophobic sites exposed by desolvation,[9] rather than the native binding sites. As acetone content decreased rapidly from 90 to 20%, these sites were possibly buried inside the protein molecules. In addition, the solubility of curcumin was greatly reduced as the acetone content decreased to 20%. As a result, the originally dissolved curcumin molecules might not be able to establish strong association with BLG before extensive precipitation occurred.

In 30% acetone, a considerable percentage (71.5%) of curcumin molecules was found to associate with BLG. This phenomenon was possibly ascribed to two factors. First, the high polarity of 30% acetone compared to 90% acetone drove more curcumin molecules to associate with other hydrophobic molecules, to minimize their contact with water. Second, a greater number of hydrophobic sites in BLG molecules were exposed in 30% acetone than in 20% acetone,[9] which enabled the association and stabilization of more curcumin molecules. Such association might have been relatively strong, so that the majority of originally dissolved curcumin molecules were converted into the bound form without significant precipitation.

On the basis of the dependence of curcumin distribution on acetone content, it can be inferred that the evaporation process during which the acetone content decreases continuously may be critical for the encapsulation of curcumin. We hypothesized that the LE of BLG nanoparticles might be improved by lowering the acetone content from 90 to 30−50% after cross-linking and equilibrating the dispersion for a period of time to allow sufficient curcumin−BLG binding. Thereafter, the dispersion should be evaporated mildly, so that the acetone content could be maintained slightly above 30% for maximal time before declining gradually to lower levels. This hypothesis will be tested in the next section.

**Effect of Acetone Content and Glutaraldehyde Level on EE.** Figure 3 depicts the EE of curcumin-loaded BLG nanoparticles as a function of acetone content (before evaporation, same in this section) and glutaraldehyde level. In general, lower EE was observed as the curcumin content increased. In addition, regardless of the curcumin/BLG weight ratio and the glutaraldehyde concentration, a V-shaped dependence of EE on acetone content was observed, with the highest EE achieved in the presence of 40−50% acetone. At 90% acetone, the LE was only 3.6 and 2.3% for the nanoparticles mixed with 10 and 15% curcumin, respectively. These values increased to 5.3 and 3.4% in the presence of 30% acetone, and they increased more significantly to 9.1 and 10.9% when the acetone content was adjusted to 50%. The low LE at 90% acetone could be ascribed to two factors. First, as discussed in the previous section, the majority of curcumin molecules existed in the freely dissolved form in 90% acetone. Due to the high acetone concentration in the bulk dispersion, the evaporation might have proceeded rapidly, leading to a sudden decrease in the local acetone concentration on the surface of the dispersion. Such a phenomenon resulted in a marked increase in local solvent polarity, which drove free curcumin molecules to precipitate rapidly without establishing a

strong association with BLG nanoparticles. Second, a higher acetone percentage suggested a lower content of water and consequently a lower volume in the final dispersion. For instance, the final volume of a 6 mL water/acetone mixture was 3 or 0.6 mL if its initial acetone content was 50 or 90%, respectively. As a result, dispersion with 90% acetone content underwent more significant increase in the concentration of curcumin and BLG. This might have led to more extensive aggregation and precipitation as a result of intermolecular attraction.

For the samples containing 30% acetone, the curcumin−BLG interaction was maximal as shown in the previous section. However, after evaporation began, the acetone content was lowered immediately to critical values (≤20%) that favored the precipitation of curcumin, and such a condition was maintained virtually during the whole process of evaporation. As a result, the EE values obtained from these samples were also not satisfactory, although they were generally higher than those achieved by samples with 80−90% acetone.

When the acetone content of the nanoparticle dispersion was adjusted to 50%, a relatively large number of curcumin molecules were bound to BLG nanoparticles, as is shown in Figure 2. During the slow evaporation process, the acetone content of the dispersion was maintained for a considerable period of time in an optimal range (30−50%) where maximal curcumin−BLG association was observed. In addition, the mild evaporation led to a gradual increase in solvent polarity, which served as a driving force for dissolved curcumin to associate

with BLG nanoparticles.[7,9] These factors resulted in minimal precipitation and maximum protein binding of curcumin, both of which contributed to higher EE.

Besides acetone content, the glutaraldehyde level also played a critical role in the EE of BLG nanoparticles (Figure 3). At 5% curcumin loading, the EE increased gradually as the glutaraldehyde level increased from 25 to 100% equivalent. Glutaraldehyde acts as a cross-linker that hardens the structure of nanoparticles via intermolecular amide bonds.[44] Higher glutaraldehyde concentration was beneficial for maintaining the compact structure of curcumin-loaded BLG nanoparticles, thus preventing the release and precipitation of curcumin molecules.[9] As the content of curcumin increased to 10 and 15%, however, the highest EE was observed when 50% equivalent of glutaraldehyde was applied. In fact, flocculation occurred probably as a result of excessive cross-linking at a glutaraldehyde level of 100% and a curcumin/BLG ratio of ≥15%, resulting in low EE under these conditions (data not shown).

On the basis of these results, adjustment of acetone content was critical for achieving optimal LE and EE. In addition, a lower glutaraldehyde dose could be applied to BLG nanoparticles with higher curcumin loading. This result further suggested that toxic cross-linkers such as glutaraldehyde could be partly replaced by natural phenolic compounds. Further studies need to be carried out to test this hypothesis.

**Evidence for the Cross-Linking Effect of Curcumin.** To confirm the role of curcumin as a partial cross-linking agent, we measured the particle sizes and count rates of a series of samples containing different amounts of curcumin as well as glutaraldehyde. The rationale of this experiment was that well-cross-linked nanoparticles are able to maintain their shape and size. Therefore, the average size and count rate of their dispersion after the evaporation of acetone should be similar to those before evaporation.[3,9] As shown in Table 1, the dispersions with higher glutaraldehyde levels (e.g., 100%) showed less significant change in the particle sizes after evaporation. In addition, the ratio of count rate after evaporation to that before evaporation was significantly higher for the samples with higher glutaraldehyde contents. These phenomena provided indirect evidence of the cross-linking effect of glutaraldehyde. On the other hand, at any given glutaraldehyde level, the dispersions with higher curcumin-to-BLG weight ratios exhibited less significant change in the particle size and count rate after evaporation. This was especially remarkable at the 25% glutaraldehyde level, when the sample with 15% curcumin exhibited a much higher retention in count rate (65%) compared to that containing no curcumin (21%). These results shed some light on the possible cross-linking effect of phenolic compounds such as curcumin.

The interaction between phenols and proteins has been extensively studied in the past decades. Although the exact mechanism has not been fully established, it is generally recognized that hydrogen bonding, hydrophobic interaction, and $\pi-\pi$ stacking[29,45] were involved in the complexation between these two types of compounds. In this study, FT-IR was applied to investigate the possible mechanisms involved in the cross-linking role of curcumin. Figure 4 shows the FT-IR spectra of BLG nanoparticles containing different contents of curcumin and glutaraldehyde. The amide I (1627 $cm^{-1}$, C═O stretching) and amide II bands (1526 $cm^{-1}$, N—H bending and C—N stretching) in empty BLG nanoparticles shifted

significantly in the presence of 5 or 15% curcumin, suggesting the possible involvement of the backbone carbonyl and/or amino groups in the BLG−curcumin interaction.[9] Furthermore, the wide band occurring at 3276 $cm^{-1}$ (O−H stretching) exhibited a marked increase in its intensity in the presence of curcumin. This phenomenon suggested the extensive involvement of hydrogen bonding in the curcumin-loaded nanoparticles.[14] Interestingly, at 15% curcumin/BLG ratio, the sample with 25% glutaraldehyde exhibited a significantly higher absorbance at 3276 $cm^{-1}$ than that with 75% glutaraldehyde. This was confirmed by analyzing the relative percentage of areas of these two peaks (data not shown). This difference implied that more hydrogen bonds were formed between BLG and curcumin to stabilize the complex nanoparticles at low glutaraldehyde levels. Further studies need to be conducted to test this hypothesis.

**Characterization of Curcumin-Loaded BLG Nanoparticles.** Table 2 summarizes the properties of curcumin-loaded BLG nanoparticles. For each curcumin loading ratio, the formula (shown in Table 2) yielding the highest EE was chosen for subsequent evaluation. The nanoparticles exhibited an average size of 164−184 nm, with highly negative zeta potential. These properties were favorable for the dispersion stability of the formed particles. The polydispersity of the samples fell in the range of 0.100−0.250, indicating a relatively narrow size distribution. The difference in the zeta potentials for BLG nanoparticles with 5 and 10% curcumin loading was statistically significant, and it was probably due to the consumption of the cationic amine groups in BLG molecules by different amounts of glutaraldehyde.[9] The EE decreased with increasing curcumin/BLG ratio, but the LE kept increasing and reached 10.9% at the curcumin/BLG ratio of 15%. This value was considerably higher than those for a number of protein-based nanoparticles and comparable to some synthetic polymeric encapsulation systems, which were summarized in the Introduction.

Figure 5 shows the morphology of curcumin-loaded BLG nanoparticles observed under SEM. Because no significant difference was observed among the BLG nanoparticles with different curcumin/BLG weight ratios, only the images corresponding to 10% curcumin loading are presented. The particle appeared approximately spherical and exhibited a smooth surface. Two major groups of particles were identified from the image: larger particles with an average size of around 200 nm (Figure 5A) and smaller ones showing diameters of 40−50 nm (Figure 5B). Figure 5C demonstrates that the former type of particles was possibly assembled from the latter ones. Such aggregates might have existed in the nanoparticle dispersion before drying, because their size was comparable to the average size in dispersions obtained by DLS.

**In Vitro Release of Curcumin from BLG Nanoparticles.** Figure 6A shows the release of curcumin from BLG nanoparticles in a PBS/Tween 20 system. The three formulas (one for each curcumin loading ratio) shown in the previous section were chosen for this study. It is noteworthy that curcumin degrades rapidly in PBS, but its stability could be greatly improved in the presence of nonionic surfactants such as Tween 20.[46] Regardless of the curcumin loading ratio, the releasing profile showed satisfactory fit with the first-order kinetic model (Table 3). This result suggested that the release of curcumin was controlled by its dissociation from the porous polymer matrix.[47] Possible reasons why the release rate for nanoparticles with low curcumin loading was higher than that with high curcumin loading were as follows: (1) the particles with higher curcumin loading exhibited greater sizes, and their specific surface area was hence lower; (2) the solubility of curcumin in the PBS/Tween 20 system is a constant in a given environment, and the dissolution of curcumin was slowed as its concentration approached the equilibrium value; and (3) higher

| 15 | 2.62 | 11.76 | 0.965 |

[a]CUR, curcumin/BLG weight ratio.

loading indicated higher concentration of curcumin accumulated in the outer buffer, which slowed the diffusion of curcumin through the dialysis membrane. Further study needs to be conducted to validate these hypotheses.

The release of curcumin in SGF and SIF is shown in Figure 6B. Our preliminary results indicated overlapping releasing patterns for nanoparticles with 5, 10, and 15% curcumin loadings (data not shown). Hence, only the releasing profile for nanoparticles with 10% curcumin loading is presented. The release in SGF was investigated at two different pH values: pH 2, which represents the gastric condition in the fasting state; and pH 5, which corresponds to the fed state.[40] After 1 h of digestion, the mixture was transferred to SIF to determine the release profile under simulated intestinal conditions. It was noteworthy that >70% of encapsulated curcumin was released in SGF at pH 2 (Figure 6B). This result is unexpected because BLG is known for its remarkable resistance against peptic digestion,[39] and it was anticipated to prevent curcumin from being released in the stomach. We hypothesized from this result that the BLG nanoparticles were actually decomposed in SGF at pH 2, although the individual BLG monomers remained intact. This hypothesis will be tested and discussed in the next section.

When dispersed in SGF at pH 5 (Figure 6B), the BLG nanoparticles exhibited a significantly lower rate of release than at pH 2, with only 24% of encapsulated curcumin being released in 1 h. This phenomenon could be explained by two reasons. First, pepsin tends to be much less active at pH 5 than at pH 2. Second, BLG exhibits an isoelectric point at around pH 5; therefore, the nanoparticles formed with BLG tended to form large agglomerates that were more resistant to peptic digestion. As a result, the curcumin molecules were more compactly encapsulated at pH 5 than at pH 2, leading to a lower release rate.

After being transferred to SIF (Figure 6B), the remaining curcumin molecules continued to be released from the nanoparticles. This was probably due the degradation of residual BLG nanoparticles as well as the monomers, because of the known capability of trypsin to digest BLG.[39] The significant difference in the releasing pattern of dispersions previously treated at pH 2 and 5 was probably due to the different residual concentrations of curcumin after the first digestion step. At the end of the two-step digestion, 70−80% of curcumin was recovered from the two buffers (SGF and SIF). On the basis of these results, BLG nanoparticles might not be suitable for the controlled release of curcumin in the fasting state, but they could release curcumin in a controlled and sustained manner if administered during the fed state.

**Disintegration of BLG Nanoparticles in Different Buffers.** We further investigated the disintegration of BLG nanoparticles in different buffers. The formula with 10% curcumin loading was chosen for this section. When incubated in SGF at pH 2 (Figure 7A), BLG nanoparticles exhibited a two-stage pattern of degradation. In the first 30 min, they showed a constant average size while the count rate decreased continuously. These data suggested that, despite the decrease in number, there still existed a considerable number of BLG nanoparticles that maintained their size and probably morphology.[9] Thereafter, a rapid increase in the average size was observed, together with a slow decrease in the count rate. A possible explanation for this trend was that the majority of smaller particles (around 160 nm) were decomposed by pepsin after 30 min, but some larger aggregates remained intact. As a result, the average size shifted markedly to higher values, whereas the count rate declined only mildly because larger particles contributed much more significantly to the count rate than did smaller ones.[5,9] This was supported by the fact that the polydispersity index increased gradually from 0.177 (uniform distribution, Figure 8A) to 0.855 (broad distribution, Figure 8B), because of the increase in the relative content of larger particles. The data on size distribution obtained by DLS (Figure 8) also supported the disintegration of BLG nanoparticles.

Intriguingly, BLG nanoparticles were susceptible to peptic digestion, considering that BLG itself is resistant against pepsin. Previous literature on BLG−EGCG nanoparticles[28] showed that BLG molecules remained intact after 120 min of peptic digestion (as evidenced by SDS-PAGE). The same results were obtained in our preliminary study. However, that study did not indicate whether BLG maintained the morphology as spherical aggregates. On the basis of the findings from previous and current studies, we deduced that the intermolecular amide bonds produced by glutaraldehyde, instead of the original

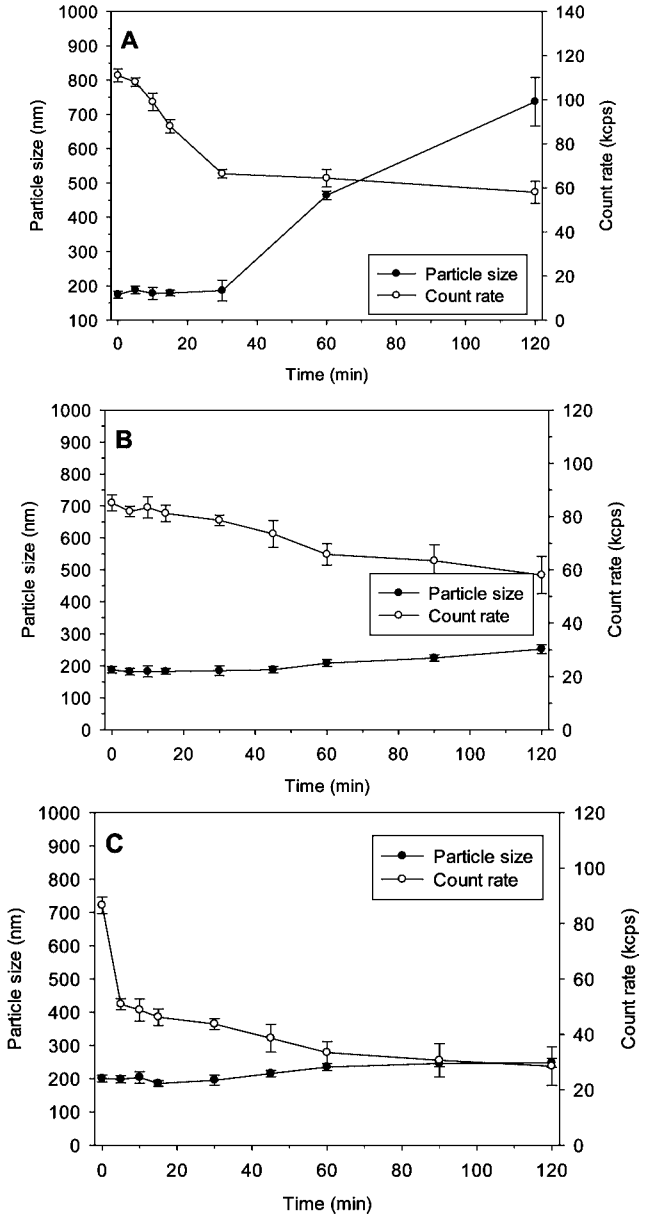

**Figure 7.** Time-dependent disintegration of curcumin-loaded BLG nanoparticles in (A) SGF at pH 2, (B) SGF at pH 5, and (C) SIF.

peptide bonds within BLG molecules, might be more prone to peptic digestion, and the breakage of these bonds might be responsible for particle disintegration. Our follow-up study (unpublished data) showed that nanoparticles prepared with cationized BLG (CBLG) exhibited remarkable resistance to pepsin, although this protein showed virtually the same resistance against pepsin as native BLG. Because CBLG contains abundant modified amine groups that could also be cross-linked by glutaraldehyde,[33,48] it is likely that the different conformations of glutaraldehyde-induced amide bonds in native and cationized BLG dictated the particle digestibility. Another relevant study using turbidity also pointed out cross-linked BLG nanoparticles could be digested by pepsin, but the time needed for complete degradation was as long as 7 h.[49] The discrepancy between that and our study may be ascribed to the use of different enzyme activities and different measuring techniques (turbidity versus DLS measurement). However, that

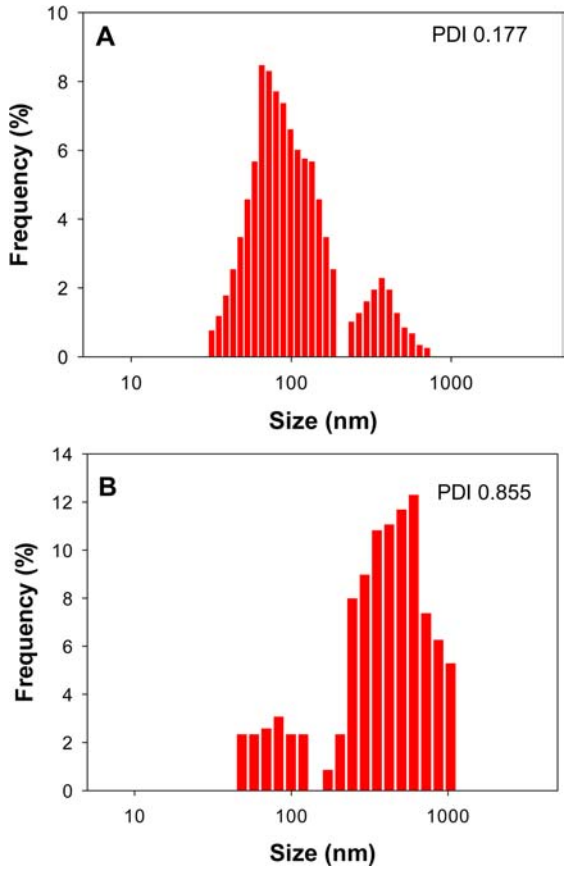

**Figure 8.** Intensity-based size distribution of CUR–BLG nanoparticle dispersions before (A) and after (B) digestion in SGF (pH 2, containing pepsin).

study was consistent with the present one in that proteins with poor digestibility can assemble into digestible nanoparticles.

On the contrary, the degradation of BLG nanoparticles proceeded at a much lower rate in SGF at pH 5 than at pH 2 (Figure 7B). During the experiment that lasted for 2 h, the average particle size did not show any significant change, whereas the count rate decreased by only 24%. The polydispersity remained stable at 0.127–0.159 during the digestion (Suppporting Information Table S1), which also suggested the stability of the nanoparticles. These results were consistent with the slow release of curcumin as indicated in the previous section. Lower activity of pepsin and the agglomeration of BLG at this pH were possible reasons for this difference, as discussed before.

When the particles were incubated with SIF, the particles were more rapidly digested, as was indicated by the sharp decrease in the count rate (Figure 7C). As discussed before, trypsin shows a higher capacity to digest BLG,[39] which was probably the main reason for the rapid digestion of BLG nanoparticles. Interestingly, the average size was kept steady at around 200 nm, a trend that was different from the situation in SGF at pH 2.0. The polydispersity index varied from 0.135 to 0.164 without any significant difference (Supporting Information Table S1). This result suggested that trypsin could not only break down smaller nanoparticles but also disintegrate larger aggregates. In the follow-up study that lasted for 4 h, a very low count rate (<10 kcp) was detected (data not shown) in SIF, suggesting that BLG nanoparticles were nearly completely decomposed.

dx.doi.org/10.1021/jf503199g | J. Agric. Food Chem. 2014, 62, 8837–8847

In summary, the encapsulation and releasing processes of curcumin-loaded BLG nanoparticles were systematically investigated. The association between BLG nanoparticles and curcumin was affected significantly by the content of antisolvents such as acetone. Therefore, adjustment of acetone to moderate values (40−50%) followed by mild evaporation led to a remarkable improvement in EE and LE. In addition, the optimal dose of glutaraldehyde decreased at higher curcumin loadings, which suggested that curcumin could replace part of the toxic cross-linkers and aid the maintenance of particle structure. The nanoparticles formed through the optimized procedure showed average sizes between 164 and 214 nm, high zeta potential of −42 mV, and loading efficiency of at most 11%. Moreover, this study suggested that proteins that are resistant to peptic digestion could form nanoparticles that were digestible by pepsin at pH 2, probably because of the breakage of amide bonds formed with glutaraldehyde. As a result, no controlled release of curcumin was observed under simulated fasting condition. However, satisfactory controlled release was achieved under simulated fed condition, that is, digestion in SGF at pH 5 and then in SIF. The conclusions from this study may apply not only to the curcumin−BLG system but also to a wide array of encapsulation systems consisting of a water-soluble protein encapsulant and a hydrophobic target compound. Therefore, this study provides insight into the assembly and disassembly of protein nanoparticles, and it may shed some light on the development of encapsulating systems with satisfying LE and reduced toxicity.

[a]RRI, relative retention indices calculated against *n*-alkanes; % calculated from FID data. [b]Identification method: $t_R$, identification based on the retention times ($t_R$) of genuine standard compounds on the HP Innowax column; MS, identification was performed on the basis of computer matching of the mass spectra with those of the Wiley and MassFinder libraries and comparison with literature data. [c]tr, <0.01.

received greater attention as natural sources of potentially useful biopesticides targeting a diversity of pests including plant pathogens, *Varroa* mites, cockroaches, mosquitoes, stored-product insects, and house flies.[4,6−16]

*Angelica dahurica* (Fisch. Ex Hoffm.) Benth. & Hook. and *Angelica pubescentis* Maxim. are well-known in TCM, and their roots are recorded as Baizhi and Duhuo, respectively, in the Chinese pharmacopoeia.[17] Both *Angelica* roots have a long history of use in Asian countries. *A. dahurica* roots have been used for the treatment of headache, rhinitis, nose problems, skin problems,[18−23] and toothache.[17,24,25] *A. pubescentis* roots have been used for the treatment of rheumatoid arthritis, headache, paralysis,[17,24] and insomnia.[17,26] The pharmacological activities associated with *A. dahurica* include antibacterial, antifebrile, analgesic, and antispasmodic,[17,27] and those for *A. pubescentis* include antibacterial, analgesic, antirheumatic, antispasmodic, antifungal, and antitumor.[17,28−30]

As part of our research program aimed at the identification of new natural-based insecticides and fungicides, we previously investigated two *Angelica* essential oils for their antifungal activity.[4] In our previous study, *A. sinensis* root oil showed good antifungal activity against three *Colletotrichum* species; however, *A. archangelica* root oil did not show any antifungal activity.[4] The bioassay-guided isolation was followed, and the active compound (*Z*)-ligustilide was isolated. This compound also demonstrated potent biting deterrent activity against *Aedes aegypti* and *Anopheles stephensi*.[4] In a continuing effort to investigate new alternative biopesticides from other *Angelica* species, *A. dahurica* and *A. pubescentis* root essential oils from China were explored in the current study for their pest management properties. Both *Angelica* essential oils were analyzed by gas chromatography (GC) with a flame ionization detector (FID) and gas chromatography−mass spectrometry (GC-MS) using an Agilent GC-mass selective detector (MSD) system. In addition, a nuclear molecular marker to distinguish between these two *Angelica* species was also investigated.

dx.doi.org/10.1021/jf5024752 | J. Agric. Food Chem. 2014, 62, 8848−8857

## MATERIALS AND METHODS

**Chemicals.** Myrcene (CAS Registry No. 123-35-3), 1-tridecanol (CAS Registry No. 112-70-9), 1-dodecanol (CAS Registry No. 112-53-8), thymol methyl ether (CAS Registry No. 1076-56-8), carvacrol methyl ether (CAS Registry No. 6379-73-3), *p*-cymene (CAS Registry No. 99-87-6), (−)-terpinen-4-ol (CAS Registry No. 20126-76-5), and (+)-terpinen-4-ol (CAS Registry No. 2438-10-0) were purchased from Sigma-Aldrich (St. Louis, MO, USA). Sabinene (CAS Registry No. 3387-41-5) was purchased from ChromaDex (Irvine, CA, USA). Fungicide standards benomyl, cyprodinil, azoxystrobin, and captan were purchased from Chem Service, Inc. (West Chester, PA, USA).

**Plant Material.** *A. dahurica* and *A. pubescentis* roots were purchased from Beijing Heng Yu Hua Kang Pharmaceutical Co., Ltd. Species were identified by Professor Dr. Yu-Ning Yan, School of Chinese Materia Medica, Beijing University of Chinese Medicine, Beijing, China. Voucher specimens of these samples (No. 20 and 21) were deposited at the Herbarium of the Faculty of Pharmacy, Anadolu University, Eskisehir, Turkey. For the molecular analysis, additional samples of *Angelica* species were chosen: *A. acutiloba* 2935; *A. gigas* 2944, and *A. sinensis* 14427. Vouchers 2935 and 2944 were from the repository at the National Center for Natural Products (NCNPR), The University of Mississippi, University, MS, USA. Voucher 14427 was deposited at the Herbarium of the Faculty of Pharmacy, Anadolu University.

**Isolation of the Essential Oils.** Air-dried roots of *A. dahurica* and *A. pubescentis* were water distilled for 3 h using a Clevenger-type apparatus to produce essential oils at yields of 0.45 and 0.65%, respectively.

**Gas Chromatography (GC) and Gas Chromatography−Mass Spectrometry (GC-MS) Conditions.** The *A. dahurica* and *A. pubescentis* root oils were analyzed by GC-FID and GC-MS using an Agilent GC-mass selective detector (MSD) system. The GC-MS analyses were carried out with an Agilent 5975 GC-MSD system. An Innowax fused silica capillary column (60 m × 0.25 mm, 0.25 μm film thickness) was used with helium as the carrier gas (0.8 mL/min). The oven temperature was kept at 60 °C for 10 min, then programmed to 220 °C at a rate of 4 °C/min, then maintained constant at 220 °C for 10 min, and finally programmed to 240 °C at a rate of 1 °C/min. The injector temperature was set at 250 °C. The split flow was adjusted at 50:1. Mass spectra were recorded at 70 eV over the mass range $m/z$ 35−450.

The GC analyses were performed using an Agilent 6890N GC system. The FID detector temperature was set to 300 °C, and the same operational conditions were used with a duplicate of the same column employed in GC-MS analyses. Simultaneous autoinjection was done to obtain equivalent retention times. Relative percentages of the separated compounds were calculated from integration of the peak areas in the GC-FID chromatograms (Table 1).

Identification of essential oil components was accomplished by comparison of retention times with authentic samples or by comparison of their relative retention index (RRI) to a series of *n*-alkanes.[31,32] Computer matching for identification was accomplished with commercial mass spectral libraries (Wiley GC/MS Library, MassFinder 3 Library) and with an in-house "Baser Library of Essential Oil Constituents", which includes over 3200 genuine compounds with MS and retention data from pure standard compounds and components of known oils as well as MS literature data.[33,34]

**DNA Extraction and ITS Amplification from Plant Tissue.** DNA from *Angelica* species (dried root/rhizome) was extracted with a DNeasy Plant Mini Kit (Qiagen Inc., Valencia, CA, USA). The ITS region (internal transcribed spacer region, consisting of 18S rRNA gene, partial sequence; internal transcribed spacer 1, 5.8S rRNA gene; internal transcribed spacer 2, complete sequence; and 28S rRNA gene, partial sequence) was amplified from genomic DNA using the forward primer ITS1 (5′-TCCGTAGGTGAACCTGCGG-3′) and ITS4 (5′-TCCTCCGCTTATTGATATGC-3′).[35] PCR amplifications were carried out in a 50 μL reaction mixture containing 1× PCR reaction buffer, 0.2 mM dNTP mixture, 0.2 μM of each forward and reverse primer, 1.5 mM $MgCl_2$, and 2 U of Platinum Taq DNA Polymerase (Invitrogen, Carlsbad, CA, USA). The PCR program consisted of one initial denaturation step at 96 °C for 3 min followed by 35 cycles at 96 °C for 30 s, 50 °C for 30 s, and 72 °C for 2 min, with a final extension at 72 °C for 7 min. PCR products were cut with one of the restriction endonucleases, *Cac*8I, *Hae*III, *Rsa*I, or *Sau*96I (New England Biolabs, Ipswich, MA, USA), without prior purification or precipitation.[36] In brief, 2 μL of the appropriate restriction buffer and 5−10 units of restriction enzyme *Cac*8I, *Hae*III, *Rsa*I, or *Sau*96I (New England Biolabs) were added to 20 μL of PCR product and incubated at 37 °C for 15 h, followed by 60 °C for 10 min to inactivate the enzyme. PCR and restriction reactions were run in an M&J Research Gradient Cycler PTC-225. After amplification and restriction, an aliquot was analyzed by electrophoresis on a 1−2% TAE agarose gel and visualized under UV light. The PCR products were compared to the molecular size standard 1 kb plus DNA ladder (Invitrogen).

**Antifungal Bioassay against Plant Pathogens.** The antifungal assay was carried out by using the direct bioautography bioassays against *Colletotrichum acutatum*, *Colletotrichum fragariae*, and *Colletotrichum gloeosporioides*, and the detailed assay procedures were described previously.[4,8−10,14,15] Fungal growth inhibition was evaluated 4−5 days after treatment by measuring zone diameters. Conidia were harvested from 7−10-day-old cultures by flooding plates with 5 mL of sterile distilled water, and conidia concentrations were determined photometrically from a standard curve based on the percent transmittance (%T) at 625 nm. Suspensions were then adjusted with sterile distilled water to a concentration of $1.0 \times 10^5$ conidia/mL.[4−8,14,15] The essential oils of *A. dahurica* and *A. pubescentis* were applied at 80 and 160 μg/spot in *n*-hexane onto a silica plate. To detect biological activity directly on the TLC plate, silica gel plates were sprayed with one of the three spore suspensions adjusted to a final concentration of $3.0 \times 10^5$ conidia/mL with liquid potato dextrose broth (PDB, Difco) and 0.1% Tween-80. Using a 50 mL chromatographic sprayer, each TLC plate with a fluorescent indicator (250 μm, silica gel GF Uniplate, Analtech, Inc., Newark, DE, USA) was sprayed lightly (to a damp appearance) three times with the conidial suspension. Inoculated plates were then placed in a 30 × 13 × 7.5 cm moisture chamber (398 °C, 100% relative humidity, Pioneer Plastics, Inc., Dixon, KY, USA) and incubated in a growth chamber at 24 °C and a 12 h photoperiod under 60 ± 5 μmols $m^{-2}$ $s^{-1}$ light. Inhibition of fungal growth was measured 4 days after treatment. The sensitivity of each fungal species to each test compound was determined by comparing sizes of inhibitory zones. Clear zones of fungal growth inhibition on the TLC plate indicated the presence of antifungal constituents in each extract. Antifungal metabolites were readily located on the plates by visually observing clear zones where the active compounds inhibited fungal growth. Fungicide standards of benomyl, cyprodinil, azoxystrobin, and captan were used as positive controls at 1.16, 0.9, 1.61, and 1.2 μg, respectively, in 95% EtOH.

**Insects.** *Ae. aegypti* L. used in these studies were from a laboratory colony maintained at the Mosquito and Fly Research Unit at the Center for Medical, Agricultural and Veterinary Entomology, USDA-ARS, Gainesville, FL, USA.[37] For biting deterrence bioassays, pupae were maintained in the laboratory at 27 ± 2 °C and 60 ± 10% relative humidity (RH), and 7−15 d-old adult females were used. For repellent activity, pupae were maintained in the laboratory at 28 ± 1 °C and 30−60% RH, and the resulting adult females aged 5−9 days were selected from the stock cages by a hand-draw box.[38] For larval bioassays, the eggs were hatched and the larvae were maintained at a temperature of 27 ± 2 °C and 60 ± 10% RH in a photoperiod regimen of 12/12 h (L/D). Adults of azalea lace bug, *Stephanitis pyrioides* (Scott), were collected by using electric aspirators (Hausherr's Machine Works, Tom's River, NJ, USA) from bouquets of azalea terminals (*Rhododendron* species). These plants were constantly maintained in plant growth chambers (Percival Scientific, Perry, IA, USA) at a temperature of 27 °C and 65% RH with a photoperiod of 14/10 L/D.

**Mosquito Biting Bioassay.** Experiments were conducted by using a six-celled in vitro Klun and Debboun (K&D) module bioassay system, developed by Klun et al.,[39] for quantitative evaluation of biting deterrent properties of candidate compounds. Briefly, the assay system

consists of a 6-well reservoir with each of the 3 × 4 cm wells containing 6 mL of blood. As described by Ali et al.,[8] a feeding solution consisting of CPDA-1 and ATP was used instead of blood. Green fluorescent tracer dye (www.blacklightworld.com) was used to determine the feeding by the females. *A. dahurica* and *A. pubescentis* root essential oils and some of their pure compounds were tested in this study. Treatments of essential oils were applied at 10 $\mu g/cm^2$, and DEET (97%, *N*, *N*-diethyl-*m*-toluamide) (Sigma-Aldrich, St. Louis, MO, USA) at 4.8 $\mu g/cm^2$ was used as positive control. All of the treatments were freshly prepared in molecular biology grade 100% ethanol (Fisher Scientific Chemical Co., Fair Lawn, NJ, USA) at the time of bioassay. The temperature of the solution in the reservoirs was maintained at 37.5 °C by continuously passing warm water through the reservoir using a circulatory bath. The reservoirs were covered with a layer of collagen membrane (Devro, Sandy Run, SC, USA). The test compounds were randomly applied to six 4 × 5 cm areas of organdy cloth and positioned over the membrane-covered CPDA-1 + ATP solution with a Teflon separator placed between the treated cloth and the 6-cell module to prevent contamination of the module. A 6-cell module containing five female mosquitoes per cell was positioned over cloth treatments covering the six CPDA-1 + ATP solution membrane wells, and trap doors were opened to expose the treatments to these females. The number of mosquitoes biting through cloth treatments in each cell was recorded after a 3 min exposure, and mosquitoes were prodded back into the cells to check the actual feeding. Mosquitoes were squashed, and the presence or absence of green fluorescent tracer dye in the gut was used as an indicator of feeding. A replicate consisted of six treatments: four test oils/compounds, DEET (a standard biting deterrent), and ethanol-treated organdy as solvent control. Two sets of five replications each with five females per treatment were conducted on two different days using a newly treated organdy and a new batch of females in each replication. Treatments were replicated 10 times.

**Mosquito Repellent Bioassay.** Repellency was determined as the minimum effective dosage (MED), which is the minimum threshold surface concentration necessary to prevent mosquitoes from biting through the treated surface.[40] Approximately 500 (±10%) mosquitoes were collected and loaded into a test cage (size of 45 cm × 37.5 cm × 35 cm) and held in the cage for 25 (±2.5) min before initiating repellency assays. Serial dilutions were then made such that the concentrations on the cloth for the remaining 1 mL of solution were 1.5, 0.75, 0.375, 0.094, 0.047, 0.023, and 0.011 $mg/cm^2$. Each concentration was tested to determine the point at which the repellent failed for each of the volunteers in the study; this concentration was averaged and reported. Each test was conducted by having a volunteer affix the treated cloth onto a plastic sleeve to cover a 32 $cm^2$ window previously cut into the sleeve. Each of the volunteers wore this sleeve/cloth assembly above a nylon stocking covering their arm, with their hands protected by a glove.[41] The arm with the sleeve/cloth assembly was inserted into a cage, where approximately 500 female *Ae. aegypti* mosquitoes (aged 6−10 days) had been preselected as host-seeking using a draw box.[38] Failure of the repellent treatment was 1% bite through; that is, the volunteer received five bites through the cloth over the sleeve window in the 1 min assay. There were three human volunteers in this study, and all three provided written informed consent to participate in this study as part of a protocol (636-2005) approved by the University of Florida Human Use Institutional Review Board (IRB-01).

**Larval Bioassay.** Bioassays were conducted to test *A. dahurica* and *A. pubescentis* root essential oils and some of their pure compounds for larvicidal activity against 1-day-old *Ae. aegypti* larvae by using the bioassay system described by Pridgeon et al.[42] Five 1-day-old *Ae. aegypti* larvae were added in a droplet of water to each well of 24-well plates (BD Labware, Franklin Lakes, NJ, USA) by use of a disposable 22.5 cm Pasteur pipet. Fifty microliters of larval diet [2% slurry of 3:2 beef liver powder (Now Foods, Bloomingdale, IL, USA) and brewer's yeast (Lewis Laboratories Ltd., Westport, CT, USA)] was added to each well by using a Finnpipette stepper (Thermo Fisher, Vantaa, Finland). All chemicals tested were diluted in dimethyl sulfoxide (DMSO). Eleven microliters of the test chemical was added to the labeled wells, whereas 11 $\mu L$ of DMSO was added to control treatments. After the treatment application, the plates were swirled in clockwise and counterclockwise motions, front to back, and side to side five times to ensure even mixing of the chemicals. Larval mortality was recorded 24 and 48 h post treatment. Larvae that showed no movement in the well after manual disturbance of water were recorded as dead. Permethrin (46.1% cis −53.2% trans, Chemical Service, West Chester, PA, USA) was used as positive control. Five concentrations ranging between 300 and 6.25 ppm were used in each treatment to obtain a range of mortality between 0 and 100. Treatments were replicated 10 times for each oil or pure compound.

**Data Analyses.** The parameter of proportion not biting (PNB) mosquitoes was calculated as described earlier by Ali et al.[43] The K&D module bioassay system can handle only four treatments along with negative and positive controls at the one setup experiment. To make direct comparisons among more than four test compounds and to compensate for variation in overall response among replicates, the biting deterrent activity was quantified as the biting deterrence index (BDI). BDIs were calculated using the formula

$$[\mathrm{BDI}_{i,j,k}] = \left[\frac{\mathrm{PNB}_{i,j,k} - \mathrm{PNB}_{c,j,k}}{\mathrm{PNB}_{d,j,k} - \mathrm{PNB}_{c,j,k}}\right]$$

where $\mathrm{PNB}_{i,j,k}$ denotes the proportion of females not biting when exposed to test compound $i$ for replication $j$ and day $k$ ($i$ = 1−4, $j$ = 1−5, $k$ = 1−2), $\mathrm{PNB}_{c,j,k}$ denotes the proportion of females not biting the solvent control $c$ for replication $j$ and day $k$ ($j$ = 1−5, $k$ = 1−2), and $\mathrm{PNB}_{d,j,k}$ denotes the proportion of females not biting in response to DEET $d$ (positive control) for replication $j$ and day $k$ ($j$ = 1−5, $k$ = 1−2). This formula makes an adjustment for interday variation in response and incorporates information from the solvent control as well as the positive control. A BDI value of 0 indicates an effect similar to that of ethanol, whereas a value significantly greater than 0 indicates biting deterrent effect relative to ethanol. BDI values not significantly different from 1 are statistically similar to DEET. BDI values were analyzed using SAS Proc ANOVA [single factor: test compound (fixed)],[44] and means were separated using the Ryan−Einot−Gabriel−Welsch multiple-range test. To determine whether confidence intervals include the values of 0 or 1 for treatments, Scheffe's multiple-comparison procedure with the option of CLM was used in SAS. $LC_{50}$ values for larvicidal data were calculated by using SAS, Proc Probit. Control mortality was corrected by using Abbott's formula.[45] Toxicity was compared among treatments based on nonoverlapping 95% CI.[46]

**Adulticidal Activity against Azalea Lace Bug.** Bioassay and statistical methods follow those of Sampson et al.,[12,13] with some modifications. For these bioassays, *A. dahurica* and *A. pubescentis* essential oils as well as five chemical constituents [*p*-cymene, carvacrol methyl ether (CME), (+)-terpinen-4-ol, (−)-terpinen-4-ol, thymol methyl ether (TME)] were tested against adult azalea lace bug at a single dose of 10000 ppm (1% oil). In addition, *Angelica sinensis* and *Angelica archangelica* essential oils from our previous study[6] were also included to identify chemical diversity and activity relationship. Mortality data for lace bugs exposed to the two isomers of terpinen-4-ol were combined before analysis (total $n$ = 16). Selection of 10000 ppm as our trial dose was based on standard evaluation methods used for essential oil-based insecticides such as Ecotrol and previous bioassay results with other essential oils.[12−15] Oil emulsions were freshly prepared using DMSO as a solvent and a 10% aqueous solution of DMSO as the solvent's control. Positive controls used for evaluating *Angelica* spp. included 1% emulsions of two essential oils that are currently commercialized as insecticides and acaricides (*Chenopodium ambrosioides* (Requiem EC, AgraQuest, Inc., Davis CA, USA) and azadirachtin (ChemService, Inc.). Twenty microliters of each treatment and control emulsions was pipetted into individual plastic wells of a standard 96-well microtiter plate in a randomized complete block design. To prevent bugs from drowning in residual fluid, an absorbent disk of Whatman no. 2 filter paper was placed at the bottom of each well. Three adult azalea lace bugs were transferred from their holding vials to treatments and control wells. Mortality data were recorded by observing lace bugs under a dissecting microscope at 1 h intervals for 5 h at 21 °C. Lace bugs that remained motionless in the well after

manual disturbance with a probe were recorded as dead. Between observations, bugs were kept at 23 °C in a separate growth chamber.

## RESULTS AND DISCUSSION

Water-distilled essential oils from roots of *A. dahurica* and *A. pubescentis* were analyzed by GC-FID and GC-MS systems. The components identified are given in Table 1 with their relative percentages. Forty-three compounds were characterized in the oil of *A. dahurica*, making up 92.1% of the oil. Forty-six compounds were identified in the oil of *A. pubescentis*, representing 86.2% of the oil. The oil of *A. dahurica* was characterized with $\alpha$-pinene (46.3%), sabinene (9.3%), myrcene (5.5%), and 1-dodecanol (5.2%) as major constituents. $\alpha$-Pinene (37.6%), *p*-cymene (11.6%), limonene (8.7%), cryptone (6.7%), and $\beta$-phellandrene (3.8%) were characterized as main compounds in the oil of *A. pubescentis*. Both *Angelica* species were mainly rich in monoterpene hydrocarbons in our study. Tetradecanol (19.4%), limonene (15.3%), $\delta$-3-carene (11.0%), 1-dodecanol (5.8%), and $\alpha$-pinene (3.9%) were reported as major compounds of *A. dahurica* root oil.[47] $\delta$-3-Carene (9.0%), $\beta$-phellandrene (8.4%), $\alpha$-bisabolol (6.0%), and *m*-cymene (5.0%) were found as the main components in *A. pubescentis* radix oil.[48] The observed differences in the constituents of these two *Angelica* essential oils even collected inside the same country may be due to different environmental and harvesting season of the plants.

The coding ribosomal 18S, 5.8S, and 28S RNA genes are highly conserved, but the regions that separate them (internal spacer) are variable in length and nucleotide sequence. The diversity of the spacer region can be used as an identification basis.[49,50] In addition to the chemical profiling, a PCR–restriction fragment length polymorphism (PCR-RFLP) method was applied on the internal transcribed spacer region (ITS) using *Cac*8I, *Hae*III, *Rsa*I, or *Sau*96I restriction endonucleases to help distinguish between *A. dahurica* and *A. pubescentis*, *A. acutiloba*, *A. gigas*, and *A. sinensis*. Using the ITS primers, a single fragment of >600 bp was produced from all of the analyzed samples. PCR products were digested with restriction endonucleases *Cac*8I, *Hae*III, *Rsa*I, and *Sau*96I. A RFLP was observed from almost all of the samples analyzed (Figure 1). The digestion showed that *Cac*8I, *Rsa*I, or *Sau*96I produced polymorphic patterns that distinguished the *A. dahurica* from the *A. pubescentis* sample and from the other analyzed *Angelica* samples (*A. acutiloba*, *A. gigas*, and *A. sinensis*). A powerful tool for plant material identification, the PCR-RFLP approach was also successfully employed for the identification of plant materials such as *Bursaphelenchus* species[49] and for the discrimination of *Mitragyna* species[50] and the parasitic nematode *Anisakis* species.[51]

To discover natural product fungicides, essential oils of *A. dahurica* and *A. pubescentis* were evaluated for antifungal activity using direct bioautography assays leading to the discovery of promising antifungal compounds against three *Colletotrichum* species, which cause anthracnose diseases of strawberry.[4,8−10,14,15] The *A. pubescentis* essential oil demonstrated clear zones (2.83 ± 0.29 mm) against plant pathogens *C. acutatum*, *C. fragariae*, and *C. gloeosporioides* at 160 $\mu$g/spot, whereas the *A. dahurica* essential oil did not show antifungal activity at the same concentration (Figure 2). Antifungal activity was evident by the presence of clear zones with a dark background where fungal mycelia or reproductive stroma were not present on the TLC plates. *A. pubescentis* essential oil demonstrated weaker antifungal activity compared to the positive control captan. The commercial fungicide captan, which is a well-known multisite inhibitor fungicide standard, showed clear inhibitory zones of 18.67 ± 1.53 mm at 1.2 $\mu$g concentration. The TLC profile of *A. pubescentis* in *n*-hexane/diethyl ether (8:2, v/v) was subsequently tested against three *Colletotrichum* species to identify the active inhibitory zones. The minor polar compounds appeared to be responsible for antifungal activity (Figure 3).

BDI values representing the biting deterrent activity of *A. dahurica* and *A. pubescentis* root essential oils against *Ae. aegypti* are given in Figure 4. Both *Angelica* oils were tested at 10 $\mu$g/cm$^2$, and *A. dahurica* oil demonstrated slightly higher biting deterrent activity than *A. pubescentis*, but both were less active than DEET. Therefore, we selected possible active compounds that were present in *A. dahurica* oil but not present in the *A.*

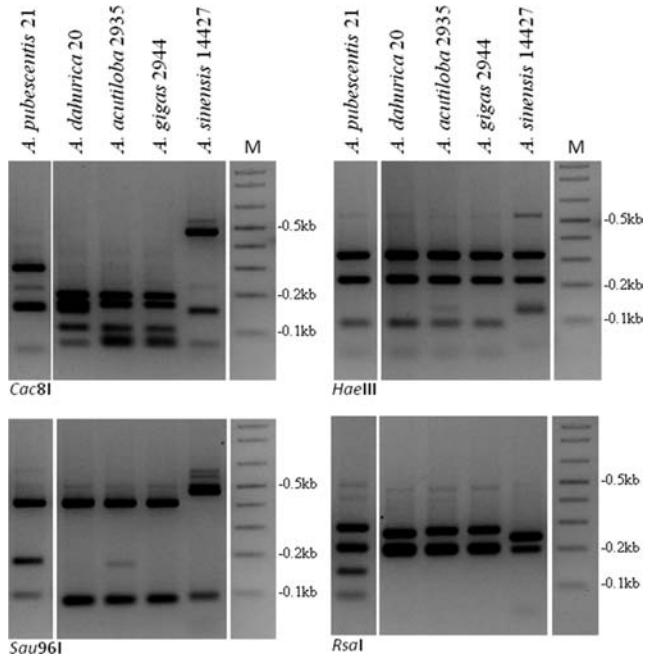

**Figure 1.** Agarose gel image of digested ITS PCR products with various restriction endonucleases (PCR-RFLP analysis). A different RFLP was observed from almost all of the samples analyzed. *A. dahurica* can be distinguished from *A. pubescentis* or any of the tested *Angelica* samples by cutting the amplified ITS region with *Cac*8I, *Rsa*I, or *Sau*96I. M = molecular size standard; fragment sizes are given in kilo base pairs (kb).

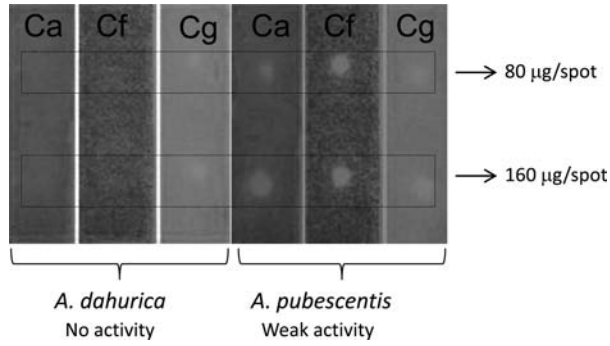

**Figure 2.** Bioautography of *A. dahurica* and *A. pubescentis* essential oils at 80 and 160 mg/spot against *C. acutatum* (Ca), *C. fragariae* (Cf), and *C. gloeosporioides* (Cg). Clear inhibitory zones indicate the antifungal activity.

dx.doi.org/10.1021/jf5024752 | J. Agric. Food Chem. 2014, 62, 8848−8857

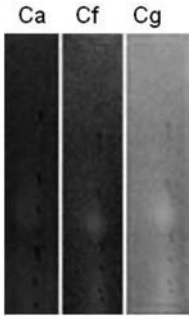

**Figure 3.** 1D-bioautography of *A. pubescentis* essential oil against *C. acutatum* (Ca), *C. fragariae* (Cf), and *C. gloeosporioides* (Cg) in *n*-hexane/diethyl ether (8:2, v/v) at 160 μg/spot concentration. The *A. pubescentis* essential oil showed weak antifungal activity with the diffuse zones against all three *Colletotrichum* species.

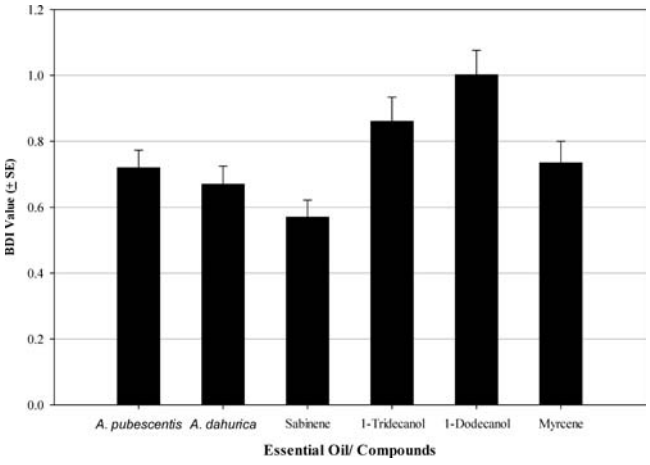

**Figure 4.** Mean biting deterrent index (BDI) value of *Angelica* species and active pure compounds. Essential oils were evaluated at 10 μg/cm$^2$ and the pure compounds were tested at 25 nmol/cm$^2$. DEET at 25 nmol/cm$^2$ was used as a positive control.

*pubescentis* oil. The major compound, α-pinene, and its β isomer, β-pinene, showed in our previous paper low biting deterrent activity at 25 nmol/cm$^2$.[52] The other monoterpene hydrocarbons sabinene and myrcene were present in higher concentration in *A. dahurica* oil than in *A. pubescentis* oil. Myrcene showed higher biting deterrence activity than sabinene, and the activity was similar to that of *A. dahurica* oil (Figure 4). We previously tested (+)- and (−)-terpinen-4-ol for biting deterrent activity, and both enantiomers showed biting deterrent activity greater than that of the solvent control.[53] Two aliphatic alcohols, 1-dodecanol and 1-tridecanol, that were present only in *A. dahurica* oil were individually tested for their biting deterrent activity. On the basis of 95% CI values, 1-dodecanol (C12:0) and 1-tridecanol (C13:0) at 25 nmol/cm$^2$ showed biting deterrent activity similar to that of DEET, whereas all the other compounds, such as sabinene and myrcene, were lower than 1-dodecanol and 1-tridecanol. In our research group it was previously reported that carboxylic acid forms of these alcohols, dodecanoic acid (C12:0) and tridecanoic acid (C13:0) showed higher BDI than other short- and long-chain fatty acids.[43] It appears that the number of carbons in the aliphatic compounds influences the biting deterrent activity. These two aliphatic alcohols (1-dodecanol and 1-tridecanol) may not be active at the concentrations present in the *A. dahurica* oil, and, although they are not also present in *A. pubescentis* essential oil, the activity of these oils may be due to the combined effect of all the compounds present in the complex oil. Active biting deterrent compounds 1-dodecanol and 1-tridecanol were also tested in cloth patch assays. 1-Tridecanol showed positive repellency in the cloth patch bioassay, with a minimum effective dosage (MED) of 0.086 ± 0.089 mg/cm$^2$ as compared to that of DEET, 0.007 ± 0.003 mg/cm$^2$, whereas 1-dodecanol did not show repellency at the maximum dose of 0.375 mg/cm$^2$.

Essential oils of *A. dahurica* and *A. pubescentis* did not show any larvicidal activity against 1-day-old *Ae. aegypti* larvae at the highest screening dose of 125 ppm. The pure compounds 1-dodecanol and 1-tridecanol demonstrated good larvicidal activity, with $LC_{50}$ values of 2.1 (1.8−2.3) and 5.2 (4.7−5.7) ppm, respectively. Myrcene showed weak toxicity with a $LC_{50}$ value of 120.3 (103.6−141.9) ppm, whereas sabinene killed only 40% of the larvae at the highest screening dose of 100 ppm (Table 2). Therefore, dose response bioassays were not necessary for sabinene. The $LC_{50}$ value of permethrin, which was used as positive control, was 0.0034 ppm against *Ae. aegypti*. In a previous study, 1-dodecanol was reported to have larvicidal activity against *Ae. aegypti* and *Ae. scutellaris* at low doses,[54] and both dodecanol and tridecanol exhibited good toxicity against first instar *Culex tartalis* larvae.[55] Sinniah has suggested that aliphatic alcohols can act as irritants, so they can break down the cellular structure to cause the death of larvae.[54]

The azalea lace bug *S. pyrioides* is a major leaf pest of azalea plants in commercial nurseries and residential landscapes. Foliar injury inflicted by this insect is mostly cosmetic and appears as black ovipositional scabs, leaf stippling, and leaf chlorosis. However, if there is no early control for lace bug feeding, leaf chlorosis induced by unrestricted herbivory can lead to necrosis, leaf abscission, and, in severe cases, plant death. Azalea lace bugs are difficult to control. Adult females protect their offspring by laying eggs underneath leaves and

[a]Insect toxicity rankings based on *t* comparisons and Tukey's HSD test ($P < 0.05$; 1, active; 5, least active). [b]Malathion, azadirachtin, and *C. ambrosioides* extract were used as positive controls for testing the relative biological activity of the other materials. Malathion served as the baseline control.

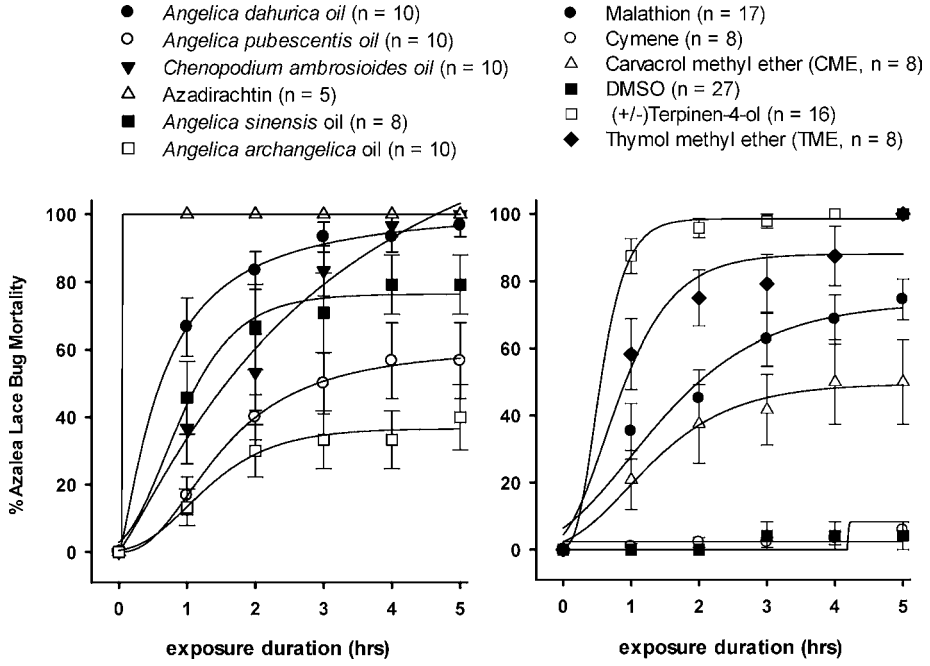

**Figure 5.** Azalea lace bug *S. pyrioides* mortality during 5 h of exposure to 1% emulsions of root essential oils from *Angelica dahurica*, *A. pubescentis*, *A. sinensis*, and *A. archangelica*, four constituent compounds of *A. dahurica* and *A. pubescentis* (*p*-cymene, carvarol methyl ether, thymol methyl ether, and terpinen-4-ol), and three insecticide standards (azadirachtin, *C. ambrosioides* oil, and malathion).

covering them with a hard fecal dome. Such egg-laying behaviors minimize an immature bug's exposure to natural enemies and water-soluble insecticides.[15] Natural oil-based insecticides, such as those based on extracts of the terpenoid-rich *Angelica* species and *Chenopodium ambrosioides*, show promise for development into commercial products for the control of highly gregarious insect herbivores such as *S. pyrioides*. Four *Angelica* essential oils (*A. dahurica*, *A. pubescentis*, *A. sinensis*, and *A. archangelica*) were then tested in insecticidal bioassays against *S. pyrioides* with *A. sinensis* and *A. archangelica* oils originating from the mosquito study[4] to compare their insecticidal activity. *A. sinensis* oil was composed of 81% phthalides, whereas *A. archangelica* included 72% monoterpene hydrocarbons.[4] There was good chemical diversity between these two species, which helped reveal their insecticidal activity results. Azalea lace bugs were most susceptible to emulsions of azadirachtin, in particular to the *Angelica* component terpinen-4-ol. Adult lace bugs exposed to these two compounds suffered 100% mortality within the first 4 h of exposure (Table 3; Figure 5). In fact, *A. dahurica* and *A. sinensis* essential oils compared favorably with the active ingredients of the two broad-spectrum commercial biopesticides azadirachtin and *Chenopodium* oil. *A. dahurica* oil was as bioactive as azadirachtin in killing nearly 100% of azalea lace bugs within 5 h (Table 3; Figure 5). Oils from *A. dahurica*, *A. sinensis*, and *C. ambrosioides* were more lethal to bugs than malathion. The other two TCM plant species tested (*A. pubescentis* and *A. archangelica*), which were high in monoterpene hydrocarbons (65 and 72%, respectively),

dx.doi.org/10.1021/jf5024752 | J. Agric. Food Chem. 2014, 62, 8848−8857

were less toxic than malathion and other essential oil extracts assessed, and they were only weakly active against lace bugs. *p*-Cymene was relatively nontoxic to lace bugs and can be associated with mortality rates no greater than those induced by the DMSO control. Although we did not test the bioactivity of *Angelica*'s major promising component, $\alpha$-pinene, both species had roughly the same proportion of this molecule. Therefore, *A. dahurica*'s greater toxicity to lace bugs may originate from the presence of terpinen-4-ol, which at a concentration of 1% can kill >85% adult *S. pyrioides* within the first hour of exposure and all bugs within 4 h of exposure. Conversely, the weaker activity of *A. pubescentis* oil may stem from its higher concentration of the relatively nontoxic monoterpene hydrocarbons. It was also interesting to see that two phenolic compounds, thymol methyl ether and carvacrol methyl ether, showed different levels of toxicity against azalea lace bugs. The position of functional group plays an important role in this insecticidal activity. Myrcene and sabinene were present in higher concentration here than in *A. pubescentis* oil. Higher proportions of 1-dodecanol and 1-tridecanol in *A. dahurica* oil may also contribute to its potency; however, these compounds remain to be bioassayed against *S. pyrioides*.

As a conclusion, in this study, *A. dahurica* and *A. pubescentis* essential oils were evaluated for the first time for detailed antifungal and insecticidal activity. The diverse chemical characteristics between these two species play important roles for their biological activity. The 1D-TLC bioautography of *A. dahurica* and *A. pubescentis* oils proved that monoterpene hydrocarbons are not antifungal. Therefore, the antifungal activity of *A. pubescentis* observed in this study might be related to the presence of polar compounds such as cryptone and cumin alcohol or due to possible synergistic effects of the oil's minor compounds. Terpenoid substances, however, are naturally involved in antibiosis, many being potent antifeedents or insecticides. Monoterpene hydrocarbons are significantly less active in the insecticidal activity against *Ae. aegypti* or *S. pyrioides*. Multiple modes of action enhance pesticidal efficacy. With *A. dahurica* rich in alcohols and *A. sinensis* rich in phthalides, the chemical diversity within this genus offers promise as novel sources of broad-spectrum insecticides capable of quick knockdown of small arthropod pests. They compare favorably with the bioactivity of the active ingredients of commercially available botanical pesticide (*C. ambrosioides*). Terpinen-4-ol appears to be the leading active compound in *A. dahurica* root oil. Aliphatic alcohols play an important role in mosquito control, with the chain length and the degree of unsaturation important factors for bioactivity. Plants contain fatty alcohols with carbon numbers ranging from C6 to C16, which are important features for future tests for biting deterrent, repellent, and larvicidal activity against *Ae. aegypti*. Using the PCR-RFLP method, we were able to distinguish between *A. dahurica* and *A. pubescentis* samples, which can be a feasible method for the identification and authentication of *Angelica* samples.

confined to its bionomics, nutritional and functional components, and cultivation.[20] To our knowledge, there are as yet no reports about the hepatoprotective effect of polysaccharides from *R. vinosa* against $CCl_4$-induced hepatotoxicity in rats. Hence, in this study, we used in vitro biochemical tests and an in vivo mouse model of $CCl_4$ intoxication to investigate the activities of *R. vinosa* water-soluble and alkali-soluble polysaccharides. Our data demonstrate that they elicited pronounced antioxidant and hepatoprotective effects, suggesting that the mushroom can be used as a functional food additive for hepatoprotection.

## MATERIALS AND METHODS

**Mushroom and Chemicals.** Dried fruiting bodies of the mushroom *R. vinosa* Lindblad were collected from Fujian province in China. The diagnostic kits for assaying activities of aspartate aminotransferase (AST), alanine aminotransferase (ALT), malondialdehyde (MDA), superoxide dismutase (SOD), and glutathione peroxidase (GSH-Px) were purchased from Nanjing Jiancheng Bioengineering Institute (Nanjing, China). Ascorbic acid, linoleic acid, 1,1-diphenyl-2-picrylhydrazyl (DPPH), and monosodium salt of (2-pyridyl)-5,6-diphenyl-1,2,4-triazine-4′4″-disulfonic acid (ferrozine) were purchased from Sigma-Aldrich (Steinheim, Germany). All other chemicals were of analytical grade and purchased from Beijing Chemical Co. (Beijing, China).

**Extraction and Isolation of Polysaccharides.** The polysaccharides of *R. vinosa* were isolated by employing a previously described procedure.[21,22] Briefly, dried fruiting bodies of the mushroom (100 g) were crushed into powder by using a disintegrator. The powder was extracted twice with 95% ethanol (2 L) for 2 h to remove lipid, and the residue was extracted with 10 volumes of water (w/v) at 90 °C for 6 h. The supernatant was obtained after centrifugation (9000*g*, 4 °C, 10 min), and then the residue was extracted with 0.5 M NaOH solution at room temperature for 5 h. The extract was concentrated 10-fold and precipitated with ethanol (1:4, v/v) at 4 °C overnight. The precipitate was collected by centrifugation and deproteinated by employing the Sevage method.[23] Finally, the deproteinated supernatant was extensively dialyzed against distilled water and lyophilized to give crude *R. vinosa* polysaccharides (cRVLWP/cRVLAP). cRVLWP/cRVLAP was dissolved in distilled water, then applied to a 5 cm × 20 cm column of DEAE-cellulose (Sigma, USA), and eluted at a flow rate of 3.0 mL/min with distilled water. The eluent was concentrated, lyophilized, and then subjected to gel filtration on a Superdex 75 HR 10/30 column (GE Healthcare) in 0.15 M $NH_4HCO_3$ buffer (pH 8.5). The eluent was collected automatically, and carbohydrates were determined by the authrone−sulfuric acid colorimetric method.[24] The main fraction was pooled and lyophilized to yield RVLWP/RVLAP, which were used for further study.

**Preliminary Characterization of RVLWP/RVLAP.** Total carbohydrate content of the polysaccharide was determined by using the authrone−sulfuric acid colorimetric method, with glucose as the standard.[24] The protein content in polysaccharide was measured by using Bradford's method.[25] UV absorption was determined with a UV−visible spectrophotometer (Thermo Scientific, USA) in the range of 200−400 $cm^{-1}$.[23,26]

Gel filtration on an FPLC-Superdex 75 column, which had been calibrated with a molecular mass marker, was conducted to determine the molecular masses of RVLWP and RVLAP.

The monosaccharide compositions of RVLWP/RVLAP were analyzed by ion exchange chromatography on a Dionex ICS-5000 HPIC system (Thermo Scientific, USA). RVLWP/RVLAP was hydrolyzed with 2 M trifluoroacetic acid (TFA) (2 mL) at 110 °C for 4 h. After removal of TFA with methanol, the hydrolyzed product was dissolved in distilled water. The supernatant was filtered through a 0.22 μm nylon membrane (MSI, Westborough, MA, USA), and 10 μL of the filtrate was injected into the Dionex CarboPac PA-200 anion exchange column (3 mm × 250 mm), eluted with 1 mM NaOH solution. The flow rate was 0.45 mL/min, and the column temperature was 30 °C. Sugar identification was done by comparison with reference sugars (D-glucose, D-galactose, L-arabinose, and L-fucose).

**Analysis of Antioxidant Activities in in Vitro Systems.** *DPPH Radical Scavenging Activity.* The activity was measured by using the method reported by Cheng et al.[27] with slight modifications. Briefly, 200 μL of different concentrations (0−5 mg/mL) of the sample were added to 600 μL of DPPH solution (0.004% in methanol solution). The mixture was shaken thoroughly and allowed to stand at room temperature in the dark for 30 min. The absorbance was measured at 517 nm. The scavenging percentage was calculated by using the equation

$$\text{scavenging of DPPH radical (\%)} = (A_{\text{control}} - A_{\text{sample}})/A_{\text{control}} \times 100$$

where $A_{\text{control}}$ is the absorbance of control (water used instead of sample) and $A_{\text{sample}}$ is the absorbance in the presence of the sample.

*Inhibitory Effect on Lipid Peroxidation.* The inhibitory effect on lipid peroxidation was determined in accordance with the conjugated diene method but with some modifications.[28] Samples at different concentrations (0−5 mg/mL) were prepared and incubated with 500 μL of linoleic acid emulsion (10 mM) in 0.2 M sodium phosphate buffer (pH 6.5) for 15 h at 37 °C. Then 1.5 mL of 60% methanol in deionized water was added, and the absorbance of the mixture was measured at 234 nm. The inhibitory effect on lipid peroxidation was calculated according to the formula

$$\text{inhibition of lipid peroxidation (\%)} = (A_{\text{control}} - A_{\text{sample}})/A_{\text{control}} \times 100$$

where $A_{\text{control}}$ is the absorbance of the control sample (water used instead of sample) and $A_{\text{control}}$ is the absorbance in the presence of the tested sample. Ascorbic acid was used for comparison.

*Hydrogen Peroxide Scavenging Activity.* The ability to scavenge hydrogen peroxide ($H_2O_2$) was determined according to the reported method,[1] with minor modifications. The reaction mixture was composed of 200 μL of phosphate buffer (0.1 M, pH 7.4), 40 μL of $H_2O_2$ solution (0.3%), and 100 μL of RVLWP/RVLAP solution (0−5 mg/mL). Absorbance of the reaction mixture at 234 nm was determined after 10 min. Ascorbic acid was used as a reference compound. The scavenging of $H_2O_2$ was expressed as

$$\text{scavenging of } H_2O_2\ (\%) = (A_{\text{control}} - A_{\text{sample}})/A_{\text{control}} \times 100$$

where $A_{\text{control}}$ and $A_{\text{sample}}$ are the absorbance readings of the control group (water used instead of sample) and sample group at 234 nm, respectively.

*Reducing Power.* The reducing power was determined according to the method reported[29] with some modifications. Different concentrations of 1 mL of sample (0−5 mg/mL) were mixed with 1 mL of phosphate buffer (0.2 M, pH 6.6) and 1 mL of potassium ferricyanide (0.1%). The mixtures were incubated at 50 °C for 20 min. Trichloroacetic acid solution (1 mL, 10%) was added to the mixture, which was then centrifuged at 3000 rpm for 10 min. The upper layer of the solution (1 mL) was mixed with 1 mL of distilled water and 0.2 mL of ferric chloride (0.3%), and the absorbance was measured at 700 nm. All assays were carried out in triplicate. Ascorbic acid was used as a positive control at the same concentration.

*Ferrous Ion Chelating Activity.* For each sample, the chelating effect on $Fe^{2+}$ ions was measured according to the reference method[30] with some modifications. Briefly, the reaction mixture, containing 200 μL of sample (0−5 mg/mL), 10 μL of ferrous chloride ($FeCl_2$), 40 μL of ferrozine solution (5 mM), and 550 μL of distilled water, was shaken well and incubated for 10 min at room temperature. The absorbance of the mixture was determined at 562 nm. A lower absorbance indicated stronger chelating activity. Ethylenediaminetetraacetic acid disodium salt (EDTA·2Na) was used as a positive control in the present study. The $Fe^{2+}$ chelating activity was calculated according to the formula

dx.doi.org/10.1021/jf502632c | J. Agric. Food Chem. 2014, 62, 8858−8866

$$Fe^{2+}\text{chelating activity } (\%) = (A_{control} - A_{sample})/A_{control} \times 100$$

where $A_{control}$ is the absorbance of the control sample (water used instead of sample) and $A_{sample}$ is the absorbance in the presence of tested sample.

**Animal Experiments.** *Animals.* Male Kunming mice (weighing 18−22 g) were provided by Xinglong Experimental Animal Breeding Factory in Haidian District, Beijing, China. The animals were allowed to acclimatize for 7 days to conditions in the animal room and were maintained on standard pellet diet and water ad libitum at a temperature of 20−25 °C under a 12 h light/dark cycle throughout the experiment. All experiments were performed in accordance with the Regulations of Experimental Animal Administration issued by the State Committee of Science and Technology of the People's Republic of China.

*In Vivo Hepatoprotective Activity.* The mice were randomly allocated into seven groups (I−VII) of eight animals each: I, control; II, $CCl_4$; III, bifendate (200 mg/kg + $CCl_4$); IV, RVLWP (100 mg/kg + $CCl_4$); V, RVLWP (200 mg/kg + $CCl_4$); VI, RVLAP (100 mg/kg + $CCl_4$); and VII, RVLAP (200 mg/kg + $CCl_4$). In the normal control group and $CCl_4$-intoxicated group, animals were given a single dose of distilled water (0.2 mL, ig) once daily. The positive control group was treated with bifendate (200 mg/kg in 0.5% sodium carboxymethyl cellulose, ig) once daily for 10 days. In the four experimental groups, the mice were pretreated with RVLWP and RVLAP (100 and 200 mg/kg, ig) once daily for 10 consecutive days. On the 11th day, all mice except those in the normal control group were given a $CCl_4$/peanut oil mixture (1%, 5 mL/kg, ig) 2 h after the last administration, whereas the normal control group received peanut oil alone.[31−33] All animals were sacrificed by anesthesia 16 h after $CCl_4$ administration. The livers perfused with saline were dissected and processed immediately for further analysis.

*Biochemical Assays.* After blood collection, serum was obtained by centrifugation at 5000 rpm for 10 min. The activities of the enzymes ALT and AST were measured with commercially available diagnostic kits, and the results were expressed as units per liter (IU/L).

The liver was excised, weighed, and homogenized (10% w/v) in ice-cold physiological saline. The homogenate was centrifuged (8000*g*, 4 °C, 10 min), and the supernatant obtained was stored at −20 °C. The activities of hepatic superoxide dismutase (SOD), glutathione peroxidase (GSH-Px), and malondialdehyde (MDA) and hepatic protein concentrations were assayed using commercially available diagnostic kits. The activities of SOD, GSH-Px, and MDA were normalized with reference to protein, and the results were expressed in units per milligram of protein, units per milligram of protein, and nanomoles per milliggram of protein, respectively. The hepatosomatic index (HI) was calculated according to the following formula: HI = liver weight/body weight × 1000%.

*Histopathological Study on the Liver.* Tissue samples were taken immediately from the liver and fixed in 10% buffered formalin, dehydrated in alcohol, and embedded in paraffin. Sections of 4−5 $\mu$m thickness were cut and stained with hematoxylin-eosin. For evaluation of morphological changes, the slides were examined under the microscope. Finally, the images were examined (× 400 magnification) and evaluated for pathological changes.

*Acute Toxicity Study.* Male Kunming mice were randomly divided into five groups of eight animals each. In the control group, mice were given distilled water by gavage. In the experimental group, mice were given RVLWP and RVLAP (500 and 1000 mg/kg, respectively). The animals were observed continuously in the first 24 h for any gross behavioral changes and toxic symptoms in the first 48 h for mortality.

**Statistical Analysis.** All data are presented as the mean ± standard deviation (SD) from three independent experiments. Significant differences among the groups were determined by one-way ANOVA using the IBM SPSS Statistical software (version 20) package program. $p < 0.05$ was considered to be statistically significant.

## RESULTS

**Isolation and Characterization of Polysaccharides.** RVLWP and RVLAP were isolated from *R. vinosa* through hot water extraction followed by 0.5 M NaOH extraction, ethanol precipitation, deproteinization, and lyophilization. As a result, the yields of RVLWP and RVLAP attained approximately 2.67 and 3.19% of dried *R. vinosa* fruiting bodies by weight, respectively. The extracts were further fractionated on a DEAE-cellulose column and then on a Superdex 75 HR 10/30 column. The main eluted fraction named RVLWP/RVLAP was collected for further structural characterization and bioactivity assay.

The chemical compositions of the purified polysaccharides were determined as shown in Table 1. The total carbohydrate contents of RVLWP and RVLAP were 96.7 and 97.3%, respectively. The negative results in Bradford's test and the lack of absorption at either 280 or 260 nm in the UV−visible spectrum indicated that RVLWP/RVLAP contained no protein or nucleic acid.[22] As can be seen from Table 1, RVLWP was mainly composed of glucose and galactose in a molar ratio of 41.69:2.51. RVLAP consisted of glucose, galactose, and fructose with a molar ratio of 63.93:1.3:0.18. The average molecular weights of RVLWP and RVLAP were $8.71 \times 10^4$ and $10.72 \times 10^4$ Da, respectively.

**Table 1. Compositions and Molecular Weights of RVLWP and RVLAP**

| sample | RVLWP | RVLAP |
|---|---|---|
| carbohydrate (wt %) | 96.7 | 97.3 |
| protein (wt %) | 0 | 0 |
| galactose (mol %) | 2.51 | 1.3 |
| arabinose (mol %) | 0 | 0.18 |
| glucose (mol %) | 41.69 | 63.93 |
| molecular weight (Da) | $8.71 \times 10^4$ | $10.72 \times 10^4$ |

**In Vitro Antioxidant Activity.** To analyze the antioxidant activities of RVLWP/RVLAP in vitro, five parameters were monitored, and the results are as follows.

*DPPH Radical Scavenging Activity.* The DPPH radical scavenging activities of RVLWP, RVLAP, and ascorbic acid are presented in Figure 1A. It was observed that the DPPH radical scavenging effects of the samples increased dose-dependently. At the higher concentration (5 mg/mL) of RVLWP and RVLAP, respectively, 85.89 and 52.53% of DPPH radicals were scavenged. The antioxidant activity of the water-extracted polysaccharide, RVLWP ($IC_{50}$ = 1.55 ± 0.04 mg/mL), was higher than that of RVLAP ($IC_{50}$ = 3.37 ± 0.21 mg/mL) at the tested concentration as determined by the DPPH radical scavenging assay.

*Inhibitory Effect on Lipid Peroxidation.* The abilities of RVLWP, RVLAP, and ascorbic acid to inhibit lipid peroxidation are presented in Figure 1B. Using the conjugated diene method, RVLWP, RVLAP, and ascorbic acid ($IC_{50}$ = 0.12 ± 0.048 mg/mL), all when tested at 1 mg/mL, elicited respectively 64.39, 54.72, and 87.24% inhibition of lipid peroxidation. The results demonstrated that RVLWP ($IC_{50}$ = 0.52 ± 0.095 mg/mL) and RVLAP ($IC_{50}$ = 0.86 ± 0.043 mg/mL) manifested potent activity in inhibiting linoleic acid peroxidation.

*Hydrogen Peroxide Scavenging Activity.* The abilities of RVLWP and RVLAP to scavenge hydrogen peroxide are shown

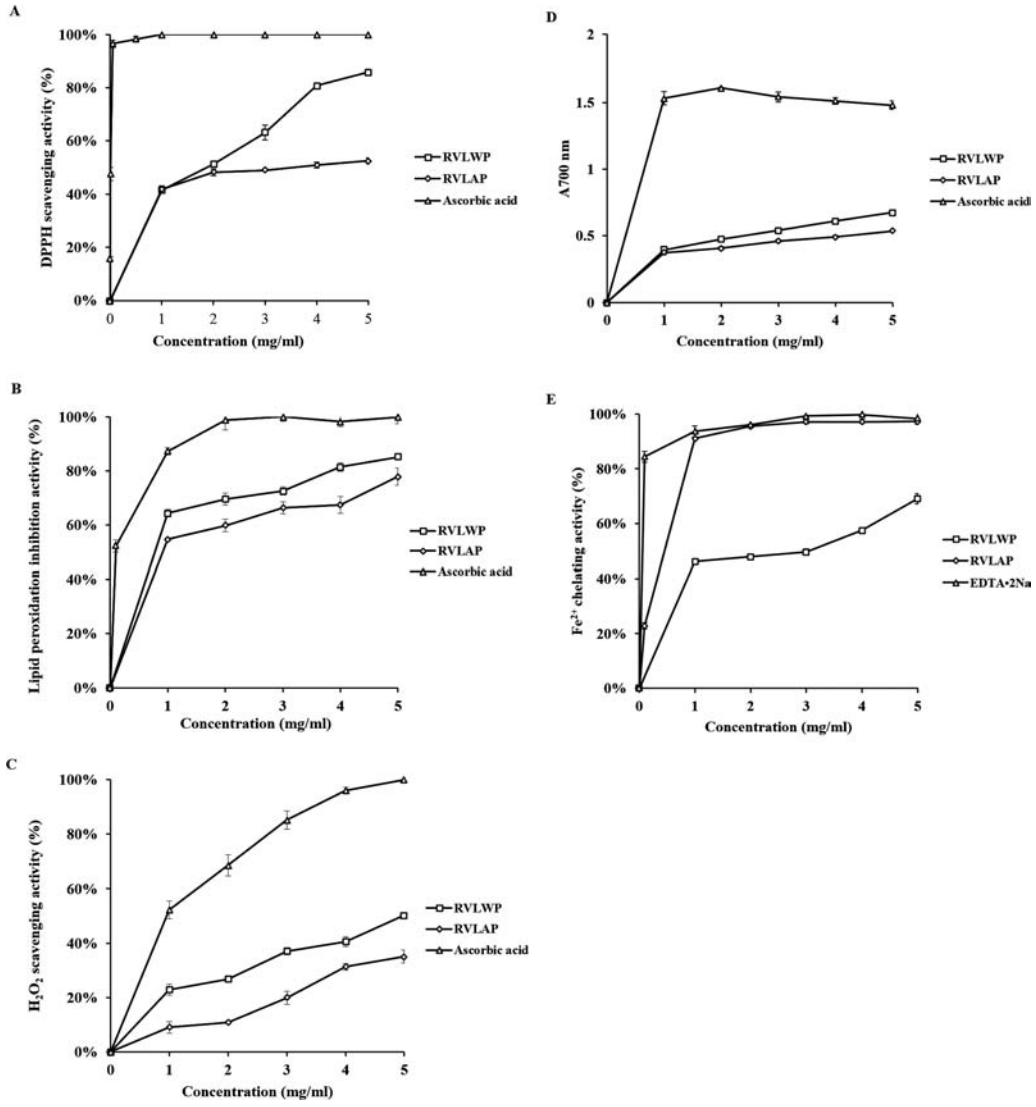

**Figure 1.** Antioxidant activities of RVLWP and RVLAP: (A) scavenging of DPPH radicals; (B) inhibitory effect on lipid peroxidation; (C) hydrogen peroxide scavenging activity; (D) reducing power; (E) $Fe^{2+}$ ion chelating activity. The values are representative of three separate experiments.

**Table 2. Effects of RVLWP and RVLAP on Body Weight, Liver Weight, and Hepatosomatic Index (HI) in $CCl_4$-Treated Mice[a]**

| treatment | dose (RVLWP/RVLAP) (mg/kg) | body wt (g) | liver wt (g) | HI (%) |
|---|---|---|---|---|
| normal control | | 29.13 ± 3.22 | 1.23 ± 0.20 | 42.24 ± 2.87 |
| $CCl_4$ only | | 29.07 ± 1.50 | 1.54 ± 0.09## | 53.25 ± 3.48### |
| $CCl_4$ + bifendate | 200 | 29.86 ± 1.10 | 1.39 ± 0.12** | 46.66 ± 4.12*** |
| $CCl_4$ + RVLWP | 100 | 27.37 ± 1.44 | 1.36 ± 0.09** | 49.55 ± 2.27* |
| $CCl_4$ + RVLWP | 200 | 27.97 ± 2.32 | 1.35 ± 0.11** | 48.23 ± 1.83** |
| $CCl_4$ + RVLAP | 100 | 28.17 ± 2.71 | 1.41 ± 0.24* | 49.71 ± 4.68* |
| $CCl_4$ + RVLAP | 200 | 27.52 ± 1.67 | 1.35 ± 0.18** | 49.04 ± 4.38* |

[a]Mice were randomized into seven groups as follows: control group (normal control), $CCl_4$ intoxication ($CCl_4$ only group), pretreatment with bifendate at 200 mg/kg plus $CCl_4$ intoxication ($CCl_4$ + bifendate group), pretreatment with RVLWP at 100 mg/kg plus $CCl_4$ intoxication ($CCl_4$ + RVLWP group), pretreatment with RVLWP at 200 mg/kg plus $CCl_4$ intoxication ($CCl_4$ + RVLWP group), pretreatment with RVLAP at 100 mg/kg plus $CCl_4$ intoxication ($CCl_4$ + RVLAP group), pretreatment with RVLAP at 200 mg/kg plus $CCl_4$ intoxication ($CCl_4$ + RVLAP group). $CCl_4$-induced hepatotoxic mice were given a $CCl_4$/peanut oil mixture (1%, 5 mL/kg, ig), whereas the normal control group received peanut oil alone. The values are reported as the mean ± SD of eight mice per group: ###, $p < 0.001$ compared with normal control; ***, $p < 0.001$, **, $p < 0.01$, and *, $p < 0.05$ compared with the $CCl_4$ group.

in Figure 1C and compared with that of ascorbic acid. All samples demonstrated a dose-dependent $H_2O_2$ scavenging activity. When the concentration of the samples tested was raised from 1 to 5 mg/mL, the percentages of $H_2O_2$ scavenged increased from 22.91 to 50.23% for RVLWP and from 8.97 to 35.03% for RVLAP. Ascorbic acid scavenged 52.28% $H_2O_2$ at 1 mg/mL. Compared with ascorbic acid ($IC_{50}$ = 1.28 ± 0.04 mg/mL), RVLWP ($IC_{50}$ = 6.07 ± 0.24 mg/mL) and RVLAP ($IC_{50}$

dx.doi.org/10.1021/jf502632c | J. Agric. Food Chem. 2014, 62, 8858−8866

= 9.23 ± 0.54 mg/mL) exhibited moderate $H_2O_2$ scavenging activity.

*Reducing Power.* As shown in Figure 1D, RVLWP and RVLAP brought about reduction of the $Fe^{3+}/K_3Fe(CN)_6$ complex to $Fe^{2+}$ ions and, consequently, the $Fe^{2+}$ ions could be monitored by measurement of the enhanced formation of Perl's Prussian blue at 700 nm.[31] In the concentration range of 1−5 mg/mL, a concentration-dependent effect was discernible. At 5 mg/mL, RVLWP and RVLAP exhibited reducing powers of 0.67 and 0.54, respectively. The data presented here indicate that both RVLWP and RVLAP have potential to be exploited as strong antioxidants, albeit somewhat inferior to the reference ascorbic acid in antioxidant capacity.

*Ferrous Ion Chelating Activity.* Figure 1E shows the $Fe^{2+}$ ion chelating activity of RVLWP and RVLAP when compared to the standard, EDTA·2Na ($IC_{50}$ < 0.1 mg/mL). The $Fe^{2+}$ ion chelating activity of RVLWP and RVLAP increased with concentration. The percentage of $Fe^{2+}$ ions chelated by RVLWP, RVLAP, and EDTA·2Na was respectively 69.08, 97.28, and 98.38% at a concentration of 5 mg/mL. The present results demonstrated that RVLWP ($IC_{50}$ = 1.86 ± 0.0036 mg/mL) and RVLAP ($IC_{50}$ = 0.22 ± 0.0057 mg/mL) elicited strong activity in chelating $Fe^{2+}$ ions.

**Animal Experiments.** *Effects of Polysaccharides on Body Weight, Liver Weight, and HI in Mice.* Table 2 shows the changes in body weight, liver weight, and HI of different groups of experimental mice. The liver weight and HI of the mice increased significantly after $CCl_4$ treatment when compared to the normal control (#, $p$ < 0.01; #, $p$ < 0.001). However, the $CCl_4$-induced increases in the liver weight and HI could be mitigated by pretreatment with RVLWP and RVLAP at two different doses (100 and 200 mg/kg), similar to results of pretreatment with the positive control bifendate at a dose of 200 mg/kg (*, $p$ < 0.01; *, $p$ < 0.001, respectively). These results are in agreement with a previous study.[31] The body weights of the experimental groups did not show statistically significant differences compared with the normal control group.

*Effects of Polysaccharides on AST, ALT, MDA, GSH-Px, and SOD Activities.* Several enzymes in serum such as AST and ALT were used as biochemical markers for early acute hepatic damage. As displayed in Figure 2, $CCl_4$ treatment significantly increased the activities of AST and ALT in serum. When compared with the normal control group, mice treated with $CCl_4$ alone showed acute liver damage as evidenced by a significant rise in the serum activities of AST and ALT (both with #, $p$ < 0.001), which are indicators of hepatocyte damage and loss of functional integrity. Interestingly, pretreatment with RVLWP and RVLAP significantly suppressed elevations in the serum levels of AST (∗, $p$ < 0.05) and ALT (∗, $p$ < 0.05), especially at the dose of 200 mg/kg (∗, $p$ < 0.01). The results signified that supplementation with RVLWP and RVLAP could depress the serum activities of AST and ALT in $CCl_4$-intoxicated mice and appeared to be protective in undermining the deleterious effect of $CCl_4$. Bifendate (positive control) at a dose of 200 mg/kg demonstrated the most significant hepatoprotective effect (∗, $p$ < 0.001).

In this study, the product of membrane lipid peroxidation (MDA) was also examined. As illustrated in Figure 3A, $CCl_4$ treatment significantly raised the hepatic level of MDA (#, $p$ < 0.001). RVLWP and RVLAP at 100 and 200 mg/kg significantly suppressed the level of MDA in a dose-dependent manner. Bifendate-treated mice also manifested a significant

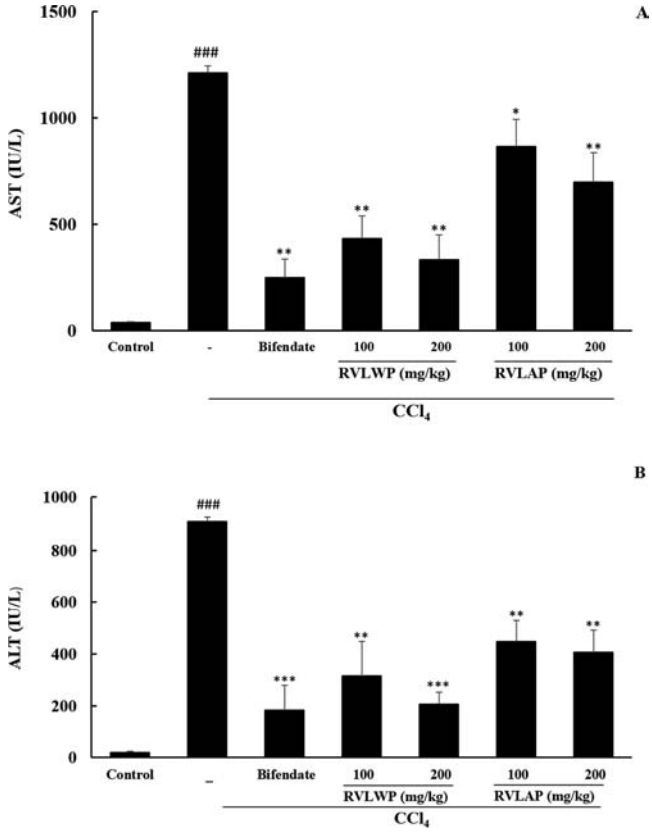

**Figure 2.** Effects of RVLWP and RVLAP on the activities of serum AST (A) and ALT (B) in $CCl_4$-treated mice. The values are reported as the mean ± SD of eight mice per group: (###)$p$ < 0.001 compared with normal control; (∗∗∗) $p$ < 0.001, (∗∗) $p$ < 0.01, and (∗)$p$ < 0.05 compared with the $CCl_4$-treated group.

decline in hepatic MDA compared to $CCl_4$-treated mice (∗, $p$ < 0.001).

The hepatic activities of GSH-Px and SOD in experimental animals are shown in Figure 3B, C. When compared to the normal control group, the acute administration of $CCl_4$ to mice induced characteristic hepatotoxicity that affected the antioxidant parameters of liver tissue, as indicated by a significant decrease in SOD and GSH-Px levels (#, $p$ < 0.001). The $CCl_4$-induced decrement was dose-dependently attenuated by pretreatment with RVLWP and RVLAP at 100 mg/kg (∗, $p$ < 0.05) and 200 mg/kg (∗, $p$ < 0.01). When tested at a dose of 200 mg/kg, bifendate as a positive control also effectively protected against the fall in hepatic activities of GSH-Px and SOD (∗, $p$ < 0.001).

*Liver Histopathological Study.* In the current study, histopathological observation of the liver was performed to corroborate the evidence from biochemical analyses. In comparison with the cellular architecture of hepatic tissue from the normal control group (Figure 4A), acute administration of $CCl_4$ to mice induced extensive liver damage characterized by moderate to severe cellular degeneration, hepatocyte necrosis, and lipid droplet accumulation (Figure 4B). However, bifendate pretreatment effectively protected against $CCl_4$-induced liver damage (Figure 4C). Likewise, RVLWP and RVLAP pretreatment ameliorated liver damage, as evidenced by a diminution of necrotic zones and attenuation of lipid droplet accumulation (Figure 4D−G). This finding was

dx.doi.org/10.1021/jf502632c | J. Agric. Food Chem. 2014, 62, 8858−8866

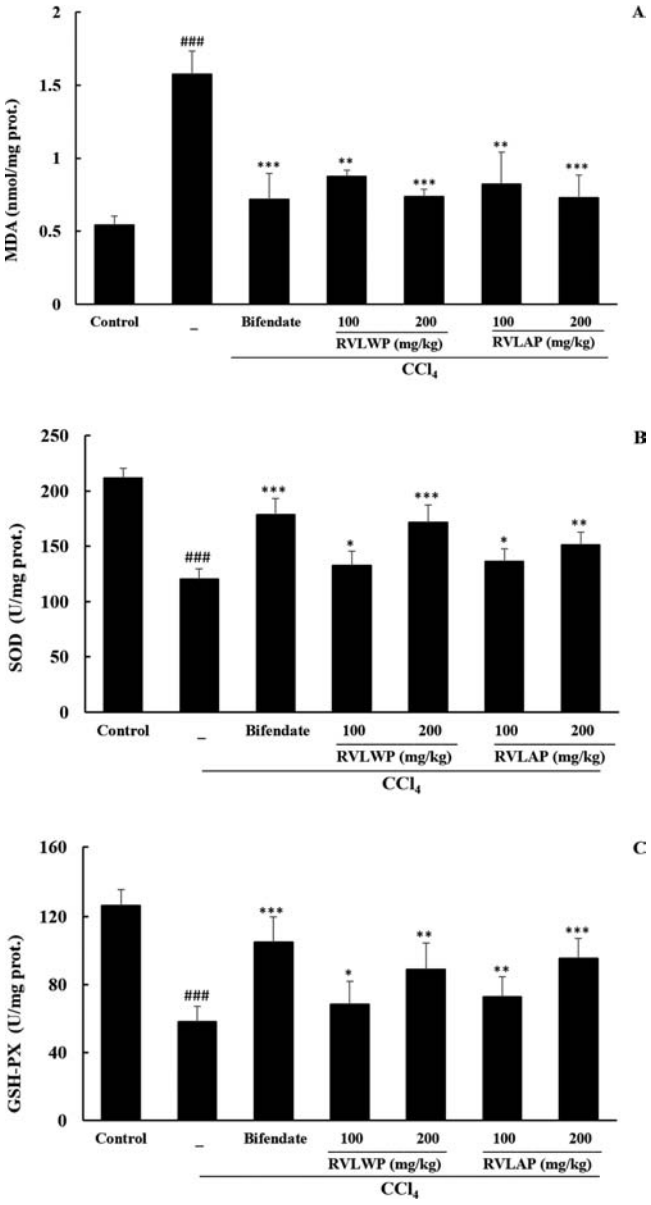

**Figure 3.** Effects of RVLWP and RVLAP on (A) hepatic MDA content, (B) hepatic GSH-Px activity, and (C) hepatic SOD activity in $CCl_4$-treated mice. The values are reported as the mean ± SD of eight mice per group: (###) $p < 0.001$ compared with normal control; (***) $p < 0.001$, (**) $p < 0.01$, and (*) $p < 0.05$ compared with the $CCl_4$-treated group.

consistent with the levels of serum and hepatic enzyme markers.

*Acute Toxicity Study.* In the acute toxicity studies, RVLWP and RVLAP exhibited no toxicity in experimental mice. No mortality occurred within 48 h either in the control or in the treated group. No gross behavioral abnormalities were detected in the treated mice during the first 24 h.

## ■ DISCUSSION

Metabolism of chemicals takes place largely in the liver, which accounts for the organ's susceptibility to metabolism-dependent injury.[31,34,35] Many compounds, including clinically useful therapeutic drugs, can cause cellular damage in the liver through metabolic activation of chemicals to highly reactive compounds such as free radicals, ensuing in oxidative stress.[3]

Hence, it is possible to limit oxidative tissue injury and hence prevent disease progression by employing antioxidant defense supplements. Some of the natural polysaccharide-containing extracts from plants and fungi possess free radical scavenging activities.[9,19,36] In our study, the antioxidant effects of water-soluble and alkali-soluble polysaccharides from *R. vinosa* Lindblad were determined using enzymatic and nonenzymatic methods under in vivo and in vitro conditions.

The DPPH-based assay system is a rapid and efficient method for measuring the free radical scavenging activities of antioxidants. In this assay, the absorbance decreases due to a color change from deep violet to colorless as the radical is scavenged by RVLWP/RVLAP. DPPH radical is characterized as a stable free radical and can accept an electron or a hydrogen radical to become a stable diamagnetic molecule. To our knowledge, cysteine, glutathione, ascorbic acid, and aromatic amines could reduce and decolorize DPPH by virtue of their hydrogen-donating ability.[37] Similarly, in this investigation, RVLWP and RVLAP exhibited significant dose-dependent DPPH radical scavenging activities. Thus, the results implied that RVLWP/RVLAP might also, like the antioxidants cysteine, glutathione, and ascorbic acid and aromatic amines, act as an electron or a hydrogen donor to scavenge DPPH radicals.

Lipid peroxidation is a complicated process involving the interaction of oxygen-derived free radicals with polyunsaturated fatty acids, resulting in a variety of highly reactive electrophilic aldehydes.[38] In this study, a well-known polyunsaturated fatty acid, linoleic acid, was oxidized in a water emulsion. Peroxyl ($LOO^{\bullet}$) and alkoxyl ($LOS^{\bullet}$) radicals, the products of linoleic acid oxidation, form pre-existing lipid peroxide (LOOH) to initiate lipid peroxidation.[39,40] Antioxidants could inhibit lipid peroxidation by scavenging lipid-derived radicals ($LOO^{\bullet}$ or $LOS^{\bullet}$).[41,42] As observed in this investigation, RVLWP and RVLAP displayed significant activity in combatting the peroxidation of linoleic acid, indicating that these polysaccharides can serve as good antioxidants.

The measurement of $H_2O_2$ scavenging activity is one of the useful methods for determining the ability of antioxidants to lower the level of pro-oxidants such as $H_2O_2$.[43] Hydrogen peroxide causes toxicity to cells because it depletes antioxidants and produces strand breaks in DNA and oxidative degradation of most biological macromolecules such as lipids, proteins, carbohydrates, and nucleic acids.[44] At the concentration of 5 mg/mL, the percentage inhibition of RVLWP and RVLAP on $H_2O_2$ observed was 50.23 and 35.03%, respectively. The present results disclosed that RVLWP and RVLAP evinced moderate dose-dependent $H_2O_2$ scavenging activity.

The reducing power of a compound may serve as an indicator of its potential antioxidant activity.[45] It has also been reported that the reducing properties were generally associated with the presence of reductones.[46] Our results suggest that RVLWP and RVLAP have moderate but concentration-dependent reducing power. They might play a role as hydrogen donors and could react with free radicals to stabilize and terminate radical chain reactions.

$Fe^{2+}$ chelation might ensue in important antioxidative effects by retarding metal-catalyzed oxidation.[47] Some transition metals could trigger free radical reactions to magnify the cellular damage. Among the transition metals, Fe is known as the most important pro-oxidant due to its high reactivity. The ferrous state of iron can stimulate lipid oxidation by generating reactive free radicals via the Fenton reaction.[48,49] RVLAP showed stronger activity than RVLWP in chelating ferrous ions

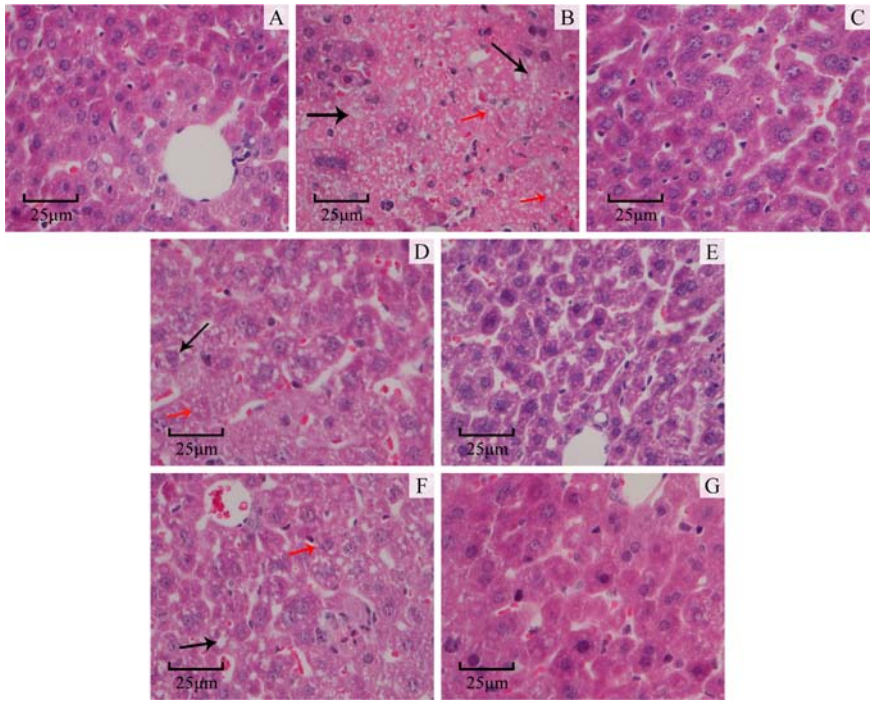

**Figure 4.** Effects of RVLWP and RVLAP on liver as disclosed by morphological analysis (×400 H&E staining): (A) normal control group; (B) $CCl_4$-intoxicated group; (C) bifendate positive control group (200 mg/kg) + $CCl_4$; (D) RVLWP (100 mg/kg) + $CCl_4$; (E) RVLWP (200 mg/kg) + $CCl_4$; (F) RVLAP (100 mg/kg) + $CCl_4$; (G) RVLAP (200 mg/kg) + $CCl_4$. Black arrows indicate necrotic zones; red arrows indicate lipid droplet accumulation.

and at 1 mg/mL concentration had a closer $Fe^{2+}$ chelating activity to that of EDTA·2Na. The chelating effect of RVLWP and RVLAP might be partly due to the presence of $Fe^{2+}$ chelating groups in their structure.

Tsiapali et al. proposed a model for the antioxidant ability of carbohydrate polymers.[42,50] They demonstrated that the antioxidant effect of glucans and nonglucan polymers, which are significantly better free radical scavengers than monosaccharides, does not correlate with the type of intrachain linkages, molecular weight, or degree of polymer branching, but rather with the monosaccharide composition of the polymer. The weak activity of monosaccharides is attributed to abstraction of the anomeric hydrogen and the enhanced activity of the polymers to the greater ease of abstraction of anomeric hydrogen from one of the internal monosaccharide units rather than from the reducing end. RVLWP and RVLAP were mainly composed of glucose and galactose. The higher antioxidant ability of RVLWP than of RVLAP is likely due to more facile anomeric hydrogen abstraction than RVLAP.

Many studies have shown that the hepatoprotective effects may be associated with an antioxidant capacity to scavenge ROS.[51] The present study was undertaken to evaluate the hepatoprotective effects of RVLWP/RVLAP on $CCl_4$-induced oxidative stress in the liver of Kunming mice. Bifendate (biphenyldicarboxylate) is a synthetic hepatoprotective agent derived from Schisandrin C. It is active against a variety of hepatotoxins and has been used as a curative agent for the treatment of hepatitis with minimal observable side effects at the prescribed dosage. Many authors considered bifendate as a hepatoprotective agent against drug-induced liver injuries in animals.[52] In this study, bifendate was utilized as a positive control medicine for exploring the hepatoprotective effect of water-soluble and alkali-soluble polysaccharides from *R. vinosa* (RVLWP and RVLAP).

The serum levels of AST and ALT have been used as biochemical markers for acute liver damage.[53] When liver cells are damaged, these enzymes leak into the bloodstream from the liver tissue and produce markedly heightened serum levels.[54] Our results demonstrate that $CCl_4$ administration causes severe acute liver damage as evidenced by a dramatic rise of the serum levels of AST and ALT. It has been reported that the leakage of large quantities of enzymes into the bloodstream was associated with massive centrilobular necrosis, ballooning degeneration, and cellular infiltration of the liver.[51,55] Our results demonstrate that $CCl_4$ administration causes severe acute liver damage as evidenced by a dramatic rise of the serum levels of AST and ALT. The suppression of AST and ALT activities brought about by RVLWP/RVLAP indicates stabilization of plasma membrane as well as repair of hepatic tissue damage caused by $CCl_4$. This hepatoprotective effect was also confirmed by the histopathological observations of diminished necrotic zones and lipid droplet accumulation.

$CCl_4$-mediated hepatotoxicity arises from the cytochrome P450-catalyzed biotransformation of $CCl_4$ to the trichloromethyl free radicals ($^{\bullet}CCl_3$), which is further converted to the highly reactive trichloromethylperoxy radicals ($CCl_3OO^{\bullet}$) capable of bombarding biomolecules, thus engendering lipid peroxidation and depletion of the antioxidant enzymes and eventually liver damage.[31] MDA is widely used as a marker of lipid peroxidation and oxidative stress.[56] Enhanced hepatic MDA levels reflect a causal role of lipid peroxidation in $CCl_4$-induced liver damage. Our results revealed that pretreatment with RVLWP and RVLAP significantly reversed these deleterious changes. This effect might, at least in part, be derived from the capability of RVLWP/RVLAP to scavenge ROS. Free radical scavenging enzymes such as SOD and GSH-Px are in the first line of defense against oxidative injury. The status of these antioxidant enzymes is an appropriate indirect

way to assess the pro-oxidant−antioxidant status in tissues.[47] SOD and GSH-Px catalyze, respectively, reduction of the superoxide radical ($O^{2-}$) into $H_2O_2$ and $O_2$, and reduction of $H_2O_2$ to $H_2O$ and $O_2$, thereby preventing the formation of hydroxyl radicals.[27,47,53] The results of the present study showed that the activities of SOD and GSH-Px in the livers of $CCl_4$-treated mice were suppressed compared with normal control mice, indicating escalated oxidative damage to the liver. However, pretreatment with RVLWP and RVLAP could notably restore the levels of SOD and GSH-Px in the livers of $CCl_4$-treated mice, implying that RVLWP/RVLAP exerted a substantial protective effect against $CCl_4$-induced acute hepatotoxicity in mice.

A review of the recent literature revealed that the hepatoprotective activities of a diversity of extracts and compounds were related to antioxidant and free radical scavenging activities.[53−56] Likewise, the hepatoprotective effect of water-soluble and alkali-soluble polysaccharides from *R. vinosa* might be a consequence of their free radical scavenging effect, antioxidant activity and inhibitory action on lipid peroxidation. The anticoagulant activities of different sea cucumber polysaccharides are probably related to monosaccharide composition and sulfate content.[57] Hence, it is likely that the physicochemical differences between RVLWP and RVLAP may account for the observation that the former appeared to have higher activity. In conclusion, the wild edible mushroom *R. vinosa* has shown to be an excellent source of antioxidant and hepatoprotective polysaccharides, which could be developed as a natural functional food ingredient or a novel nutraceutical to enhance health.

phenylacetophenone (BDK), methanol, sodium hydroxide, and sodium chloride were from Beijing Chemical Works (Beijing, China). All agents were of analytical grade.

**Preparation of MB−PAA and PAA Superabsorbent Composite.** A certain amount of AA was neutralized in an ice bath with 20 wt % NaOH solution in a 500 mL glass beaker with constant stirring until 85% neutralization degrees of AA solution was obatined. Certain amounts of MB, MBA (0.02 g $mL^{-1}$), APS, and BDK (0.05 g $mL^{-1}$) (the mass ratio of AA, MB, MBA, APS, and BDK was 100:40:0.12:0.40:0.25) were added to 2.0 mL of prepared AA solutions in 50 mL glass beakers, and the mixtures were treated ultrasonically for 1 min. Then, the homogeneous mixtures were exposed under a UV lamp (1000 W) for 5 min. (The self-regulated UV irradiation system consisted of an iron box containing a UV lamp with a wavelength of 365 nm.) The distance between the light source and the reaction mixtures was 37 cm. After complete polymerization, the resulting products were immersed in methanol to remove water-soluble oligomer, un-cross-linked polymer, and unreacted monomer. Finally, the gels were dried in an oven to a constant weight (at 70 °C) and pulverized through 80, 60, and 20 mesh steel screens. The particles obtained were used to determine the effect of grain diameter on water absorbency, and 80 mesh particles were used in the rest of the experiments. PAA was prepared using the above method, except without MB.

**Water Absorbency Measurement.** The swelling characteristics of the prepared hydrogel were measured via gravimetric analysis. Approximately 0.10 g of hydrogel was immersed in 500 mL of distilled water at room temperature (25 °C) at different intervals ($t$; 5, 10, 15, 20, 25, 30, 40, 50, 60, 120, 150, 200, 240, 300 min). The swollen sample was filtered through a 100 mesh nylon bag to separate unabsorbed water and then weighed. The water absorbency of hydrogel ($Q_t$; g $g^{-1}$) was calculated by using the equation

$$Q_t = \frac{m_t - m_0}{m_0} \quad (1)$$

where $m_0$ (g) and $m_t$ (g) are the weights of the samples in the dry state and the swollen state at a certain time, respectively. Water absorbency in salt solutions was tested in the same way, and $Q_e$ is defined as the water absorbency at the equilibrium swelling state. All of the experiments were performed in triplicate, and the results were averaged.

**Water Retention Measurement.** The percentage of water retention (WR) was determined under high temperature and high pressure. A certain quantity of water-swollen gel ($M_0$) was centrifuged at 6000 rpm (centrifugal radius is 8.6 cm) or heated at 60 °C in an air oven for different intervals ($t$; min), respectively. Then the quantity of remaining gel was weighed and denoted by $M_t$. The WR of the sample was calculated according to eq 2:

$$\mathrm{WR}\ (\%) = \frac{M_t}{M_0} \times 100 \quad (2)$$

**Characterization.** A scanning electron microscope (SEM) (Shimadzu SSX-550, Japan) was used to analyze the morphology of the samples. Before the test, all samples were sprayed with gold by using an ETD-2000 autosputter coater (Beijing, China) for 2 min (with a current of 4 mA). A Fourier transform infrared spectrometer (Shimadzu, 1.50SU1, Japan) was used to record the vibration in functional groups of the samples (spectral range from 4000 to 400 $cm^{-1}$ and data averaged over 20 scans). Thermal gravimetric analysis (TGA) was carried out by using a PerkinElmer Pyris 1 TGA (Boston, MA, USA) from 25 to 850 °C at a heating rate of 10 °C $min^{-1}$ under a flowing nitrogen atmosphere. A Techcomp CT14D centrifuge (Shanghai, China) was used to calculate WR.

## RESULTS AND DISCUSSION

**Hydrogel Preparation.** The proposed mechanism for chemically cross-linking reactions of MB−PAA is outlined in Figure1. First, initiators decomposed into sulfate and benzoyl

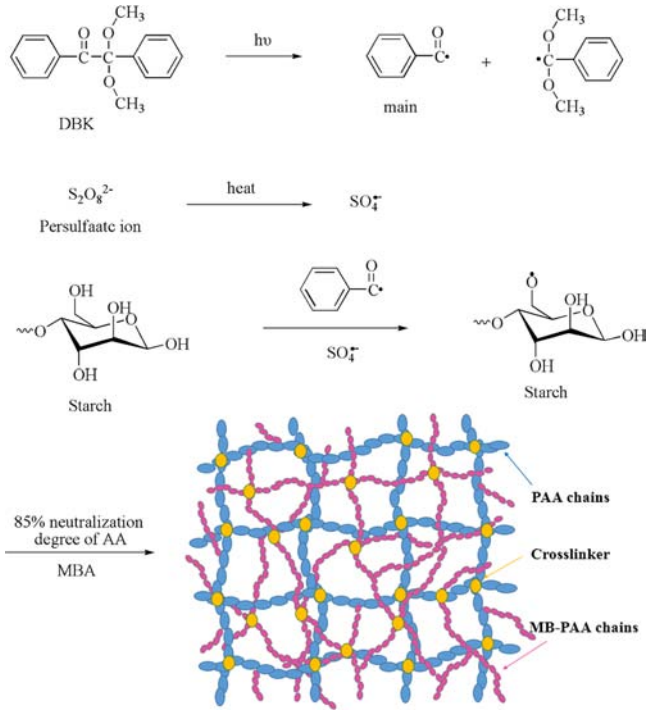

**Figure 1.** Proposed reaction mechanism for the synthesis of MB−PAA.

radicals under UV irradiation. Second, the radicals extracted hydrogen from the hydroxyl group of the active ingredients in MB to form alkoxy radicals on the substrate. Then the monomer molecules became acceptor of the radicals, resulting in chain initiation and thereafter themselves became free radical donors to neighboring molecules, which led to the growth of polymer chains. Finally, the end vinyl groups of the cross-linker (MBA) reacted with the polymer chains during chain propagation. In this way a cross-linked structure combined with network structure was formed gradually.[27]

**Characterization of Materials.** *Elemental Analysis.* Elemental analysis of MB, PAA, and MB−PAA is shown in Table 1. Compared with PAA, C content in MB−PAA

**Table 1. Elemental Analysis of MB, PAA, and MB−PAA**

| sample | C (%) | N (%) | H (%) |
|---|---|---|---|
| MB | 45.91 | 1.98 | 7.084 |
| PAA | 34.16 | 0.13 | 4.859 |
| MB−PAA | 35.32 | 0.33 | 5.126 |

increased from 34.16 to 35.32%, N content increased from 0.13 to 0.33%, and H content increased from 4.859 to 5.126%. This was because that C content in MB (45.91%) was approximately 10% higher than in PAA, and the polysaccharide molecules with relatively high carbon contents in MB reacted with the monomer molecules and changed the polymer chains. Meanwhile, part of the nitrogen-containing compound such as protein in MB was added to polymer chains; thus, for the above reasons, the contents of C, N, and H are increased.

*Morphology.* The SEM images revealed the morphology of the employed MB, PAA, and MB−PAA (Figure 2a−c). As can be seen, MB showed a lamellar and loose morphology. PAA displayed a tight, smooth, and porous surface. However, MB−PAA exhibited a comparatively coarse, loose, and porous

dx.doi.org/10.1021/jf5021279 | J. Agric. Food Chem. 2014, 62, 8867−8874

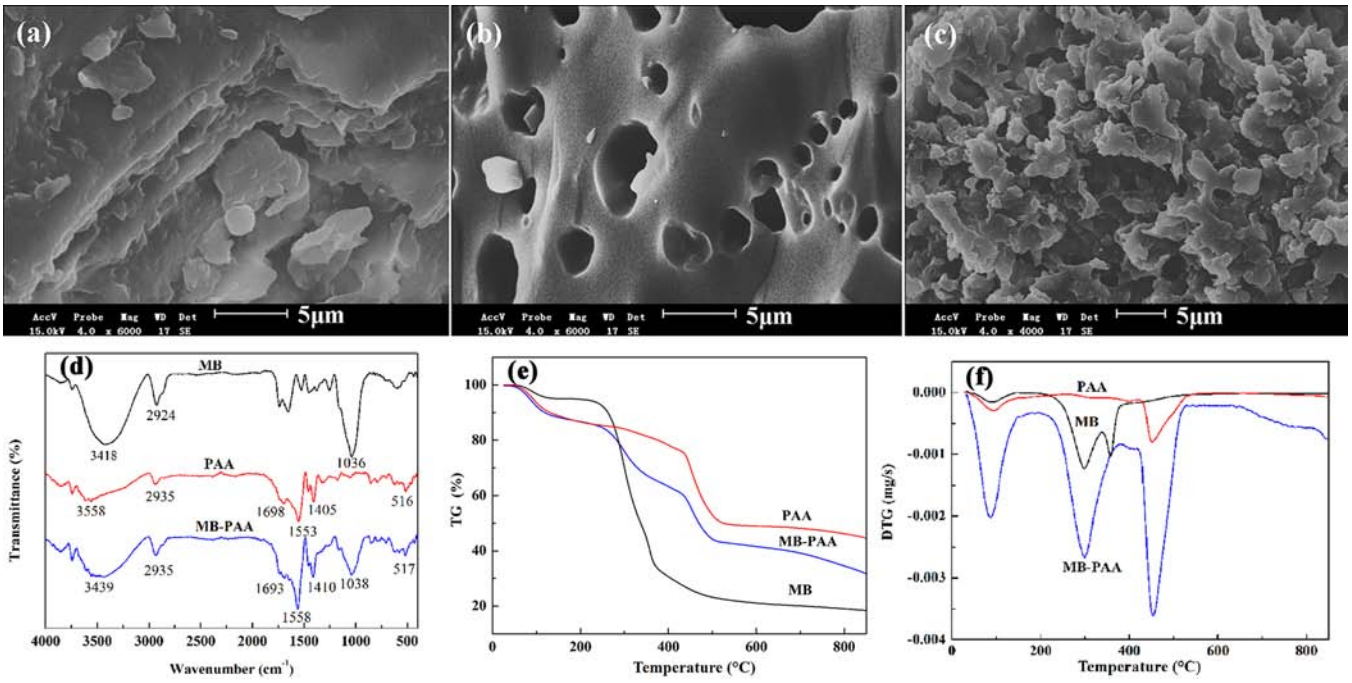

**Figure 2.** SEM micrographs of (a) MB, (b) PAA, and (c) MB−PAA; (d) FTIR spectra of MB, PAA, and MB−PAA; (e) TG curves of MB, PAA, and MB−PAA; (f) DTG curves of MB, PAA, and MB−PAA.

surface, which combined the characteristics of both MB and PAA. The morphology of MB−PAA illustrates that the starch particles were added to polymer chains and many irregular aggregates were formed during the copolymerization reaction. The larger specific surface area of MB−PAA led to a larger contact area with the solution than that of PAA, which facilitated the permeation of water into the polymeric network.[28]

*FITR Spectroscopy.* The FTIR spectra of the MB, PAA, and MB−PAA are shown in Figure 2d. In the spectrum of MB, the absorption bands at 3418 and 2924 $cm^{-1}$ were due to the stretching vibrations of the hydroxyl group (OH) and C−H, respectively. The band at 1036 $cm^{-1}$ was related to −CH−O−CH stretching vibration.[29] The three bands were all characteristic absorptions of starch structures. In the spectrum of PAA, the bands at 3558, 2935, 1698, and 1405 $cm^{-1}$ were assigned to the stretching vibrations of O−H and N−H, C−H, CO−NH, and symmetric stretching of $-COO^-$, respectively. The band at 1553 $cm^{-1}$ was due to the C═O asymmetric stretching of $-COO^-$ and amide II stretching.[30] Compared with the spectrum of PAA, the absorption peaks of MB−PAA revealed some changes. The absorption band at 3439 $cm^{-1}$, which corresponded to stretching vibrations of O−H and N−H groups, showed a major shift, and the peaks at 1693 $cm^{-1}$ (CO—NH), 1558 $cm^{-1}$ (C═O asymmetric stretching of $-COO^-$ and amide II stretching), and 1410 $cm^{-1}$ (symmetric stretching of $-COO^-$) showed a slight shift. They were due to the chemical interaction of MB with the copolymer. Furthermore, an additional absorption peak at 1038 $cm^{-1}$ (−CH−O−CH stretching vibration) was observed,[31] providing evidence of functional groups of MB grafting to PAA during the polymerization.

*Thermal Properties.* The TG/DTG curves of MB, PAA, and MB−PAA are presented in Figure 2e,f. The TG curve of MB exhibited four steps, 25−138, 138−333, 333−530, and 530−850 °C, with weight losses of 4.83, 43.60, 29.20, and 3.92%, respectively. Meanwhile, three peaks in the DTG curve at about 90, 298, and 358 °C corresponded to the first three stages, which represented the maximum decomposition speeds. The PAA had a four-step thermogram, 25−150, 150−415, 415−558, and 558−850 °C, with weight losses of 11.11, 11.84, 27.82, and 4.69%, respectively. Compared with PAA, the TG curves of MB−PAA also had four stages, but the various stages of weightlessness showed large differences. Similar to PAA, the first stage occurring before 159 °C (11.97% weight loss) was due to the loss of absorbed moisture.[28] The major weight loss, 23.12%, occurred in the second stage from 159 to 379 °C; this was assigned to splitting of the starch structure, chain scission eliminating CO and $CO_2$, and the formation of carbonaceous residues.[31] At this stage, the decomposition rate was much faster than that of PAA, which was due to the rapid degradation of MB. The 21.97% weight loss occurring between 379 and 530 °C was the contribution of the elimination of the water molecule from the two neighboring carboxylic groups of the polymer chains with the formation of anhydride, main-chain decomposition of the polymer, and destruction of cross-linked network structure.[32] The last weight loss (11.27%) region occurring from 530 to 850 °C was associated with the further decomposition or degradation of residual organic matter at high temperatures. Ultimately, the weight of the residual sample was 31.67% [less than that of PAA (44.57%) but more than that of MB (18.45%)]; this was attributed to part of the decomposition products and inorganic salts. The TG/DTG results confirmed that chemical reaction between MB and AA occurred, and the incorporation of MB reduced the thermal stability of MB−PAA.

**Water Retention.** The water retention capacity was determined under the condition of centrifugal separation (6000 rpm) and high-temperature drying (60 °C). The results are shown in Figure 3a, which indicates that the WR maintained 39 and 0.5% after centrifugation for 60 min and drying for 70 h, respectively. van der Waal's forces and the hydrogen-bonding interaction between the superabsorbent and

dx.doi.org/10.1021/jf5021279 | J. Agric. Food Chem. 2014, 62, 8867−8874

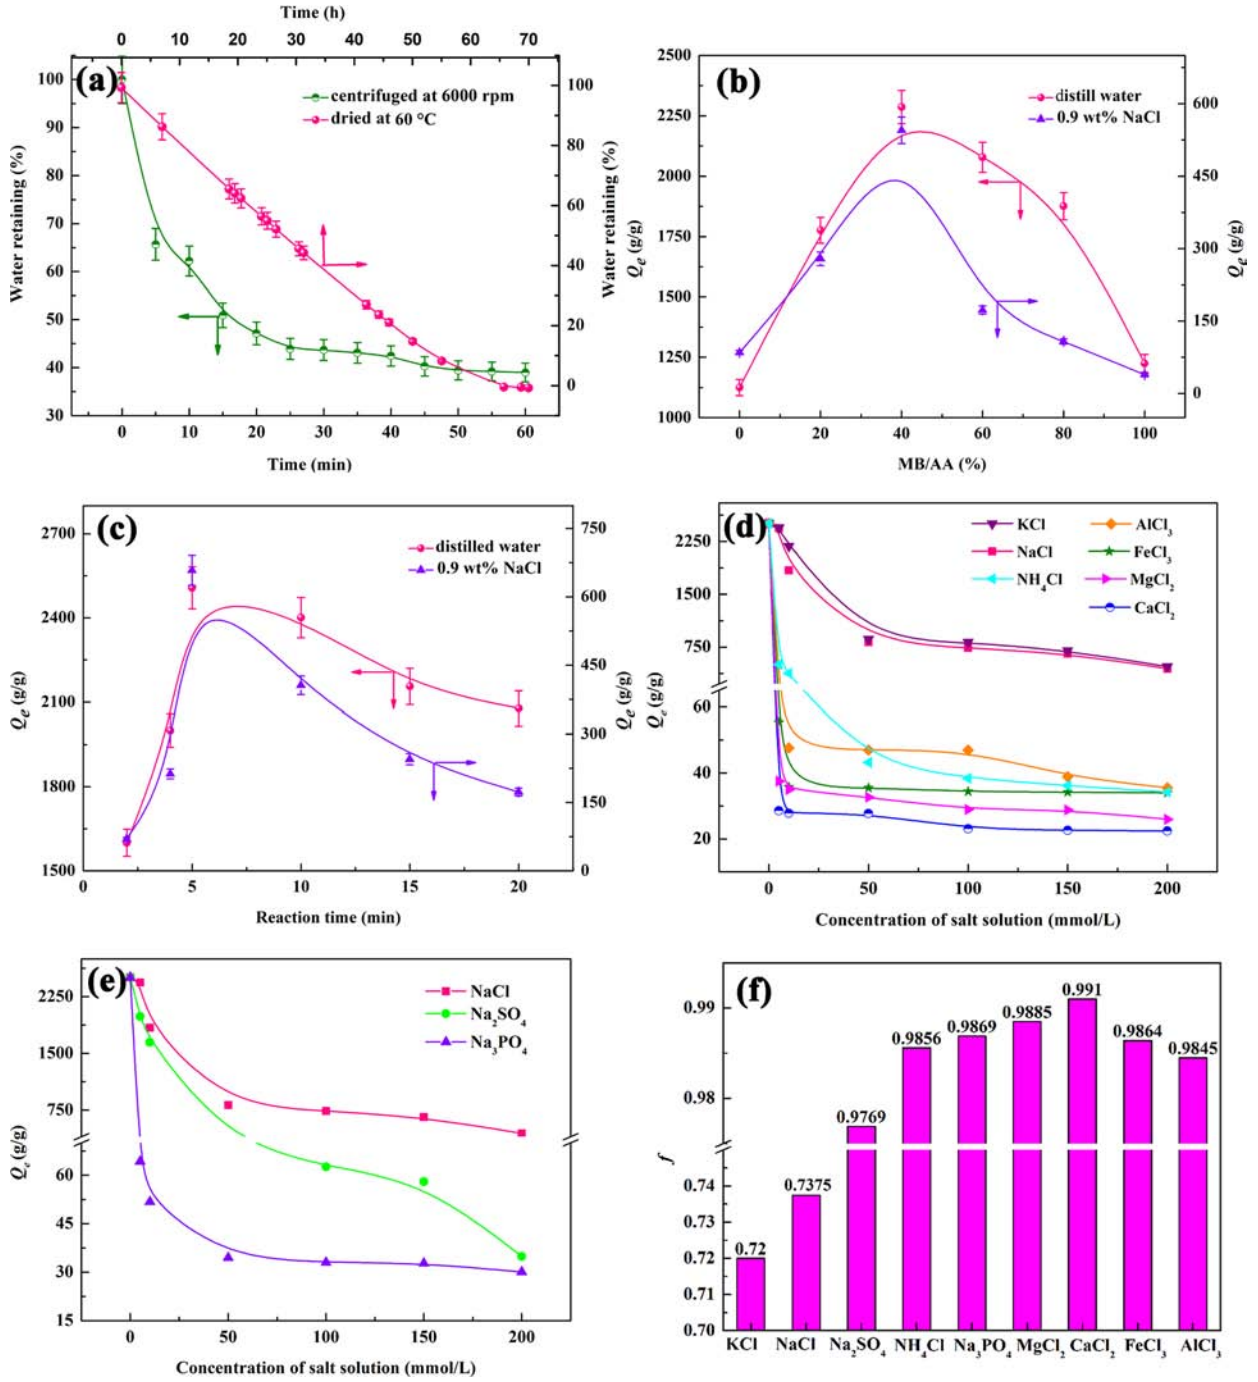

**Figure 3.** (a) Water-retaining capacity of MB−PAA centrifuged at 6000 rpm and dried at 60 °C; effect of (b) maize bran content on AA and (c) reaction time on water absorbency; water absorbency of superabsorbent hydrogel in (d) KCl, NaCl, $NH_4Cl$, $CaCl_2$, $MgCl_2$, $FeCl_3$ and $AlCl_3$ and (e) NaCl, $Na_2SO_4$, and $Na_3PO_4$ aqueous solutions; (f) salt sensitivity factor of various salts at a concentration of 150 mmol $L^{-1}$.

water molecules directly affected the water retention performance of the absorbent resin.[33] The substantial carboxylate groups contained in MB−PAA made the chemical interaction stronger, which could improve the WR. From the centrifugation curve, it can be seen that in the first 20 min, the curve showed a sharp decline, whereas 20 min later, the water retention went down slowly. The reasons for this phenomenon were that, initially, more weak absorption water contained in the gel was more easily broken free, and with the passage of the centrifugation time, the relative proportion of strong absorption water increased, leading to a relatively slow dehydration. The drying curve showed similar properties, but the changes in the rate of water loss were not so obvious. This indicates that the water-absorbing resin was more sensitive to pressure than to temperature. The obtained good water absorbency and retention properties would allow for a further development of the material, such as in agricultural, forestry, and horticulture applications as a water-retaining agent in arid soils.

**Swelling Behavior.** *Effect of Maize Bran Content.* The effect of the weight ratio of MB to AA on the water absorbency was studied. It is observed from Figure 3b that with an increase in content of MB, water absorbency increased to 2286 g $g^{-1}$ in

dx.doi.org/10.1021/jf5021279 | J. Agric. Food Chem. 2014, 62, 8867−8874

distilled water and to 545 g $g^{-1}$ in 0.9 wt % NaCl solution and then decreased (reaction conditions, AA/MBA/APS/BDK = 100:0.2:0.3:0.75; reaction time, 20 min; neutralization degree of AA, 85%). A number of hydrophilic functional groups (−OH, $-NH_2$, and −COOH) are contained in MB, which could react with the monomer and enhance the water absorbency. The ratio of MB was from 0 to 40%, because of the introduction of these hydrophilic groups, and the polymeric network was enhanced and the water absorption increased. When the amount of MB exceeded the best quantity, the water absorbency was reduced. This phenomenon may be due to the conformation of more cross-linking points in the polymeric network; this would lead to an excessive increase in the cross-linking density of the superabsorbent hydrogel. Moreover, too much MB may have resulted in a relative ratio reduction in hydrophilic groups, such as −OH, −COOH, $-NH_2$, and $-COO^-$, in the superabsorbent composite. The above two causes decreased the water absorbency.[34]

*Effect of Reaction Time.* As shown in Figure 3c, the water absorbency in distilled water increased from 2 to 5 min and then decreased from 5 to 20 min (reaction conditions, AA/MBA/APS/BDK/MB = 100:0.2:0.3:0.75:40; neutralization degree of AA, 85%). The water absorbency in 0.9 wt % NaCl solution exhibited a similar trend. The maximum absorbency (2507 g $g^{-1}$ in distilled water and 658 g $g^{-1}$ in 0.9 wt % NaCl solution) was observed at 5 min. On the one hand, a short reaction time resulted in incomplete polymerization and a short polymer chain, which were not conducive to water absorption; on the other hand, too long an irradiation time caused an increase in polymer cross-linking degree, and many branched chains were formed in the network structure, which tangled with each other and produced small holes in three-dimensional networks, which obstructed the expansion of the polymer.[35] Therefore, both of these resulted in a low water absorbency.

*Effect of Various Cations.* The characteristics of external solution such as salt concentration and ionic valence greatly influence the swelling behavior of the superabsorbent polymers. To achieve a comparative measure of sensitivity of the hydrogels to the kind of aqueous fluid, a dimensionless salt sensitivity factor ($f$) for 150 mmol $L^{-1}$ salt solution was calculated by using the equation[29]

$$f = 1 - \frac{Q_s}{Q_d} \tag{3}$$

where $Q_s$ and $Q_d$ are the swelling in salt solution and in deionized water, respectively.

The effect of the ionic strength on the water absorbency can be expressed by Flory's equation[32]

$$Q^{5/3} \approx \frac{(i/2V_uI^{1/2})^2 + (1/2 - x_1)/V_1}{v_e/V_0} \tag{4}$$

where $Q$ is water absorbency, $i/V_u$ is the charge density of polymer, $I$ is the ionic strength of solution, $(1/2 - x_1)/V_1$ is the polymer−solvent affinity, and $v_e/V_0$ is the cross-linking density.

The effect of various ions on water absorbency can be concluded from Figure 3d and Table 2. Three conclusions were obtained from Figure 3d; first, the water absorbency was appreciably decreased as the salt concentration of the solutions increased from 0 to 50 mmol $L^{-1}$ and gently decreased in the concentration >50 mmol $L^{-1}$. This was because, for ionic hydrogels, the additional cations causing an anion−anion electrostatic repulsion, leading to a reduced osmotic pressure difference between the external solution and the polymer network, resulted in decrreased swelling.[36] Second, the order of water absorbency of the hydrogel in the chloride salt solutions was KCl > NaCl > $NH_4Cl$ > $AlCl_3$ > $FeCl_3$ > $MgCl_2$ > $CaCl_2$ when the solution concentrations were <50 mmol $L^{-1}$. We found that hydrogels were hard and very rubbery after swelling in $MgCl_2$ and $CaCl_2$ solution. In contrast, they exhibited lower strength in other solutions. This may be due to the ionic cross-linking of the polymer particles; different ions affected the cross-linking density differently, which influenced the gel strength to different degrees. The effects of seven cationic on the swelling were in the order $K^+ > Na^+ > NH_4^+ > Al^{3+} > Fe^{3+} > Mg^{2+} > Ca^{2+}$, but $Al^{3+} > NH_4^+$ when the concentration was >50 mmol $L^{-1}$. The curves of water absorbency for monovalent metal cationic salt solution were gentler than those for divalent and trivalent cationic salt solutions. This was because the polyvalent metal ion would form complexes with the carboxylate group and the solutions had higher ionic strength. As shown in Table 2, the ionic strength of 150 mmol $L^{-1}$ salt solution was trivalent cationic > divalent cationic > monovalent cationic. According to eq 4, when the ionic strength of saline solution increased, the water absorbency decreased. Interestingly, the water absorbencies in $AlCl_3$ and $FeCl_3$ solution were better than in $MgCl_2$ and $CaCl_2$ solutions, whereas their ionic strength was higher (Table 2). This may be due to divalent and trivalent cations affecting the charge density of polymer in different degrees, being greater for trivalent cations, leading to stronger water absorbency. Third, we found that the larger the radius of monovalent metal cations, the greater was the water absorption capacity ($K^+ > Na^+$), and the less the radius of the same polyvalent monatomic cation, the larger the water absorbency ($Mg^{2+} > Ca^{2+}$ and $Al^{3+} > Fe^{3+}$). Moreover, the water absorbency decreased more in polyatomic monovalent cationic ($NH_4^+$) solution than in single atom monovalent cationic ($K^+$ and $Na^+$) solutions. The sensitivity of the gel to various cations was $K^+ < Na^+ < NH_4^+ < Al^{3+} < Fe^{3+} < Mg^{2+} < Ca^{2+}$ at a concentration of 150 mmol $L^{-1}$ (Figure 3f).

**Table 2. Effect of Salt Solutions on Water Absorption**

| solution (150 mmol $L^{-1}$) | ionic strength[a] (mol-ion $dm^{-3}$) | $Q_e$ (g $g^{-1}$) |
|---|---|---|
| KCl | 0.15 | 702.0 |
| NaCl | 0.15 | 658.0 |
| $NH_4Cl$ | 0.15 | 36.2 |
| $CaCl_2$ | 0.45 | 22.6 |
| $MgCl_2$ | 0.45 | 28.8 |
| $FeCl_3$ | 0.90 | 34.2 |
| $AlCl_3$ | 0.90 | 38.9 |
| $Na_2SO_4$ | 0.45 | 58.0 |
| $Na_3PO_4$ | 0.90 | 32.8 |

[a] $I = 0.5\sum(C_iZ_i^2)$, where $I$, $C_i$, and $Z_i$ are the ionic strength, the ionic concentration, and the charge on each individual ion, respectively.

*Effect of Various Anions.* Figure 3e shows the effects of monovalent ($Cl^-$), divalent ($SO_4^{2-}$), and trivalent anions ($PO_4^{3-}$) with $Na^+$ on water absorbency of the superabsorbent composite. The water absorbency showed the tendency $Cl^- > SO_4^{2-} > PO_4^{3-}$. This may be due to the ionic strength $Na_3PO_4$ > $Na_2SO_4$ > NaCl. These results indicate that trivalent anion and divalent anion salt solutions showed a larger influence on water absorbency. The sensitivity factors of $Na_3PO_4$, $Na_2SO_4$, and NaCl were 0.9869, 0.9769, and 0.7375, respectively (Figure 3f). The sensitivity of the gel to multivalent anions was much

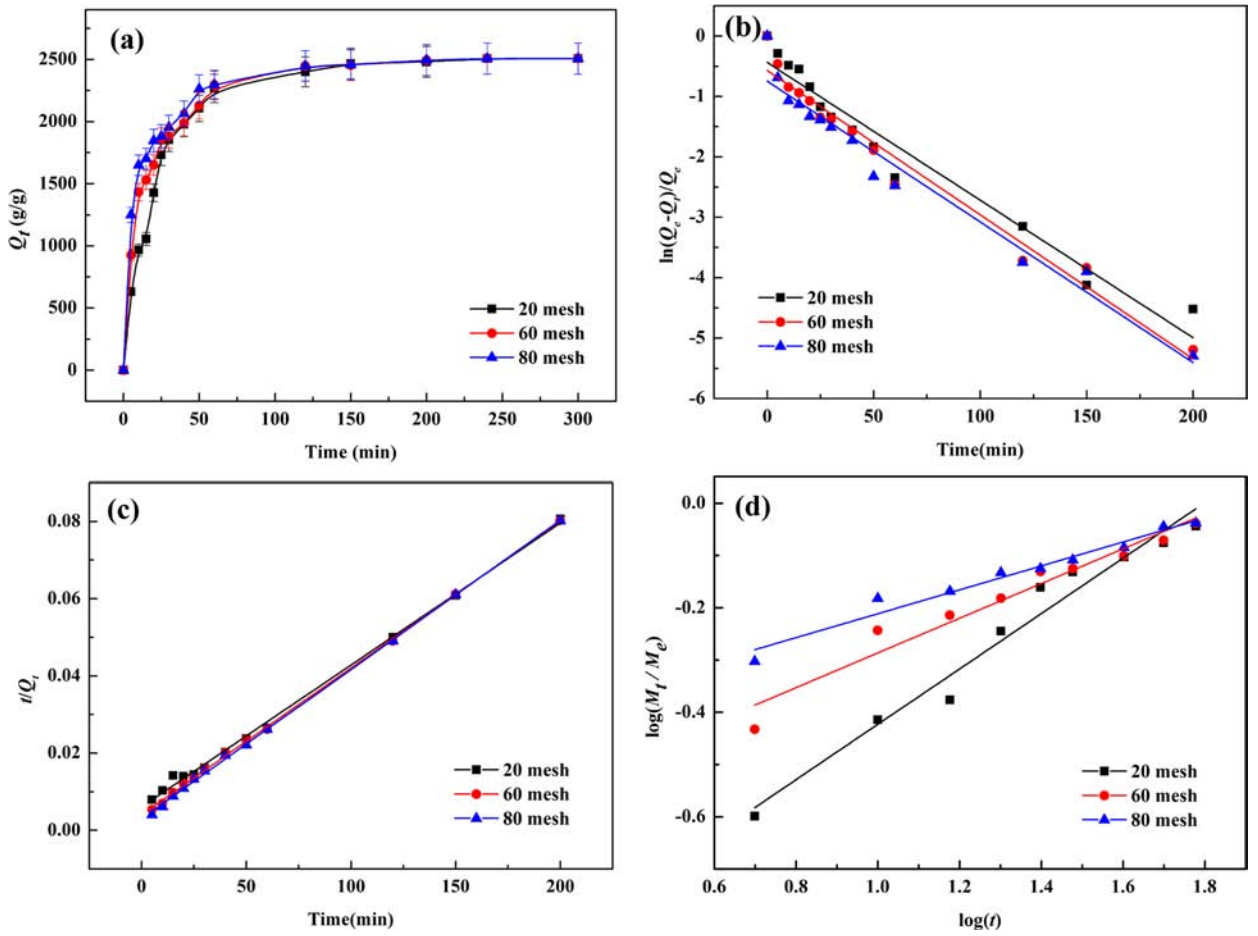

**Figure 4.** (a) Swelling behavior of different hydrogel particle sizes in distilled water absorbency; (b) pseudo-first-order kinetic model; (c) pseudo-second-order kinetic model; (d) water diffusion behavior for different hydrogel particle sizes.

**Table 3. Kinetic Parameters for the Water Absorbency of MB−PAA in Distilled Water**

| | | pseudo-first-order swelling kinetic | | | pseudo-second-order swelling kinetic | | |
|---|---|---|---|---|---|---|---|
| sample (mesh) | $Q_{e,exp}$ (g g$^{-1}$) | $R^2$ | $K_1$ (min$^{-1}$) | $Q_{e,cal}$ (g g$^{-1}$) | $R^2$ | $K_2$ ($10^{-5}$ g g$^{-1}$ min$^{-1}$) | $Q_{e,cal}$ (g g$^{-1}$) |
| 20 | 2507 | 0.9516 | 0.0228 | 1618 | 0.9974 | 2.63 | 2720 |
| 60 | 2507 | 0.9659 | 0.0239 | 1416 | 0.9994 | 3.96 | 2629 |
| 80 | 2507 | 0.9554 | 0.0233 | 1188 | 0.9994 | 5.29 | 2588 |

larger than that to monovalent anions at the same concentration.

*Effect of Hydrogel Particle Size.* To study the effect of particle size of the hydrogel on water absorbency, composite hydrogel particles with different granularities were examined. Figure 4a shows the influence of the hydrogel particle size on water absorbency at different times. It is clear that the hydrogel particle size had a significant influence on water absorbency before equilibrium and had almost no impact on the equilibrium water absorbency. Smaller particles had a larger water absorption rate before equilibrium, particularly at the first 20 min. This was because the smaller particles had a greater surface area, leading to a larger contact area and a higher water absorbency.[8] The process of water absorption (80 mesh) consisted of three steps: (1) 0−10 min, a rapid increase phase, in which the water absorption rate was fastest and up to 39% of equilibrium absorption capacity; (2) 10−120 min, a slower increase phase, for which the contribution to equilibrium absorption was approximately 59%; (3) 120−300 min, an equilibrium phase, when absorption remained almost constant. The other two (60 mesh and 20 mesh) had similar swelling processes.

**Kinetic Analysis.** *Swelling Kinetics in Distilled Water.* To investigate the kinetic mechanism, the pseudo-first-order and pseudo-second-order models were adopted to fit the experimental data. The pseudo-first-order swelling kinetic model is based on the approximation that the absorption rate relates to the quantity of unoccupied sites. The model[9,37] can be expressed in eq 5:

$$\ln(Q_e - Q_t) = \ln Q_e - K_1 t \quad (5)$$

The pseudo-second-order swelling kinetic model is deduced on the basis of the concept that the absorption relates to the squared product of the difference between the number of available equilibrium absorptive sites and that of occupied sites. The model[38,39] is expressed in eq 6

$$\frac{t}{Q_t} = \frac{1}{K_2 Q_e^{\,2}} + \frac{t}{Q_e} \quad (6)$$

dx.doi.org/10.1021/jf5021279 | J. Agric. Food Chem. 2014, 62, 8867−8874

where $Q_e$ (g g$^{-1}$) is the equilibrium water absorbency, $Q_t$ (g g$^{-1}$) is water absorbency at contact time $t$ (min), and $K_1$ (min$^{-1}$) and $K_2$ (g g$^{-1}$ min$^{-1}$) are the rate constants.

Panels b and c of Figure 4 are the pseudo-first-order and pseudo-second-order plots. The values of $K_1$, $K_2$, and $Q_{e,cal}$ along with those of the correlation coefficient ($R^2$) are summarized in Table 3. On the basis of the values of the correlation coefficient ($R^2$), the experimental data fit better with the pseudo-second-order swelling kinetic than with the pseudo-first-order swelling kinetic. In addition, the $Q_{e,cal}$ values as obtained from the pseudo-first-order swelling kinetic model appeared to be largely different from the experimental data, and the values from the pseudo-second-order swelling kinetic model were very close to the experimentally observed values. Therefore, the swelling process in distilled water followed the pseudo-second-order swelling kinetic model better.

*Diffusion Kinetics in Distilled Water.* The diffusion behavior of water into polymers networks was analyzed using the empirical equation[10]

$$\log(M_t/M_e) = \log(k) + n\log(t) \quad (7)$$

where $M_t$ and $M_e$ are the mass of water absorbency at time $t$ (min) and at equilibrium, respectively. $k$ is a characteristic constant of the polymer, and $n$ is a diffusional exponent. From the slope and intercept of the plot of $\log(M_t/M_e)$ versus $\log(t)$, the kinetic parameters $n$ and $k$ were calculated. The results are presented in Figure 4d and Table 4. According to the classification of the diffusion mechanism, at a value of $n < 0.5$, the rate of water moving into the polymer is dominated by a Fickian diffusion mechanism. At $n > 0.5$, it conforms to the non-Fickian diffusion mechanism, in which the relaxation rate was greater than or equal to the water diffusion rate. Therefore, it complied with a non-Fickian diffusion mechanism at the particle size of 20 mesh and corresponded to a Fickian diffusion mechanism at 60 and 80 mesh. We believed that the smaller particles had a relatively larger contact area with the liquid, making easier the macromolecular chain relaxation, the relaxation rate being greater than the water diffusion rate.[10]

selected, and associations between the chemical composition, structure, and processing behavior were studied.

## MATERIALS AND METHODS

**Barley Material.** The barley material consisted of 14 lots representing seven spring barley cultivars: three 6-row feed type varieties (Pilvi, Vilde, Voitto), three 2-row malting type varieties (Saana, Scarlett, SW Makof), and one 2-row waxy barley variety (Magdalena). Each variety was grown in the same field in Hauho (southern Finland, 60°48′ N, 23°30′ E) in 2006 and 2007. The preceding crop was the same for all lots. Fertilizer (N, K) was placed in the seed bed at sowing. Samples of 6-row and 2-row barley were from the separate trials in which 50 and 80 kg N/ha were applied, respectively. Weeds and plant diseases were controlled with herbicides and fungicides.

**Composition Analysis.** Moisture, protein, lipids, and ash contents were analyzed using methods described in Nordlund et al.[15] Starch quantification was carried out in triplicate using an enzymatic–spectrophotometric method.[16] β-Glucan contents were determined in triplicate with a fluorometric method based on Calcofluor binding, according to the protocol recommended by the European Brewing Convention (Analytica-EBC: 3.10.2).[17]

**Milling.** Whole-grain barley samples were milled with a fine impact mill (100 UPZ-lb, Hosokawa Alpine, Augsburg, Germany) with stainless steel pin disk grinders using maximum speed (17700 rpm; tip speed 180 m/s) for the pin disk. Particle size distributions of pin-milled and two commercial barley flours were determined in triplicate using a set of 11 sieves with apertures from 1250 to 75 μm.

**Water Uptake during Malting and Friability of Malts.** Sixty gram lots of barley were malted in duplicate using a Joe White micromalting unit (Joe White Maltings Pty. Ltd., Adelaide, Australia). Malting consisted of steeping for a total of 48 h (8 h wet, 16 h dry, 8 h wet, 16 h dry) at 14 °C, germination for 5 days at 15 °C, and kilning for 19 h to a final temperature of 80 °C. Water uptake during malting was measured by weighing the duplicate grain lots after 24, 48, and 72 h of malting. Distribution of water in endosperm was determined according to the method described in detail in Holopainen et al.[14] For this purpose, grain samples were taken after steeping or 48 h of malting. Grains were classified into four groups based on the proportion of hydrated endosperm.

The friability of the malt samples was determined using the EBC method (Analytica-EBC: 4.15)[17] optimized for smaller sample size according to Holopainen et al.[14] using a malt with friability of 84.9 as a standard. The analysis was performed in triplicate for each sample. Due to down-scaling of the standard procedure, the numerical values for friability are not directly comparable to the standard EBC method, but results describe the relative friability of the samples assayed.

**Localization of Grain Components by an Abrasive Method.** To study the localization of β-glucan, total protein, and hordeins, grain batches of 100 g were pearled using a custom-made barley dehuller-pearler (VTT Technical Research Centre of Finland). The grain material was pearled for 60 s four times consecutively. This resulted in grain samples with 13–17, 21–24, 29–33, and 35–40% of the outer layers removed. Protein and β-glucan contents of the pearled grains were determined in triplicate as described above.

For localization of salt-soluble proteins and hordeins, the amounts of these protein fractions were analyzed from both intact and pearled barley kernels. Protein fractions were extracted from 150 mg of ground grain in triplicate using a modified Osborne fractionation method described in Holopainen et al.[11] with the following modifications: a protease inhibitor tablet (Complete Mini, Roche) was added into 0.5 M sodium chloride solution, and the extractions with 0.5 M sodium chloride, water, and 50% (v/v) 1-propanol were carried out with constant shaking at room temperature.

Protein contents of these extracts were determined with a 2D Quant protein kit (Amersham Biosciences). NaCl extracts containing albumins and globulins were analyzed as such. Two hundred microliters of the 1-propanol- and the 1-propanol+dithiothreitol (DTT)-soluble hordein fractions were precipitated in 4 volumes of acetone at −20 °C and resuspended in 100 μL of rehydration solution containing 7 M urea, 2 M thiourea, and 0.5% (v/v) Triton-X-100 (BDH, Dorset, UK) prior to protein assay. The total hordein content per dry matter of barley was defined as the sum of the two hordein extracts.

For SDS-PAGE, a 25 μL aliquot of each triplicate 1-propanol- or 1-propanol+DTT-soluble hordein fraction was precipitated as described above and resuspended in 40 μL of sample buffer (62.5 mM Tris-HCl buffer (pH 6.8), 20% (v/v) glycerol, 2.0% (v/v) SDS, 0.05% (w/v) bromophenol blue, and 5% (v/v) mercaptoethanol) for 16 h at 4 °C. Samples were then boiled for 3 min, centrifuged (20800*g*, 10 min, 4 °C) and separated in 12% Tris-borate gels (pH 8.9) using 0.125 M Tris-borate with 0.1% (v/v) SDS (pH 8.9) as a running buffer.[18] Gels were rinsed, stained with Coomassie Brilliant Blue G 250 (Fluka, Buchs, Switzerland), and fixed according to the method of Neuhoff et al.[19] using ethanol instead of methanol in both staining and washing solutions. After fixation, gels were scanned with GS-710 calibrated

Table 2. Correlations between Barley Grain Components and Grain Processing Parameters Calculated as Spearman Correlation Coefficients ($n$ = 14)

imaging densitometer (Bio-Rad Laboratories, Hercules, CA, USA). B, C, and D hordeins separated in the gels were quantified using QuantityOne software (Bio-Rad) based on the band intensity and protein content of the hordein extracts. The average content of each hordein fraction and their relative proportions were calculated on the basis of the results of three replicate extracts.

**Statistical Analysis.** The results were calculated as averages of the replicates. The results of the composition analysis, excluding $\beta$-glucan contents, were presented with the standard uncertainty corresponding to one standard deviation calculated from the extended uncertainty of measurement of each validated method. For the $\beta$-glucan results, respective standard uncertainty was calculated from the 95% confidence interval. For the water uptake results, pooled standard deviations were calculated on the basis of two replicate micromaltings. When applicable, the results were examined statistically using correlation analysis and analysis of variance (ANOVA) with Tukey's honestly significant difference posthoc test (IBM SPSS Statistics software for Windows v20.0; IBM Corp., Somers, NY, USA).

## RESULTS AND DISCUSSION

**Composition of Different Barley Lots.** For comparison with processing properties, the chemical composition of the barley samples was analyzed (Table 1). The starch contents varied from 61.2 to 71.8%, and the feed varieties had somewhat higher contents (65.0−71.8%) compared to other samples. The starch contents of the feed varieties were higher than reported earlier, which may be explained by their lower nitrogen fertilizer application rate in this study.[20−22] The lower starch content of the waxy barley variety in comparison to the other varieties is in accordance with earlier literature.[21,22]

Protein contents of the samples ranged from 9.7 to 12.5% (Table 1). The variation in protein content was a little lower compared to the data of Holtekjølen et al.,[22] which included 29 hulled barley samples with protein contents from 8.4 to 14.5%. In the current study, lower nitrogen application to feed varieties resulted in lower protein contents compared to the malting type varieties. Higher protein contents of the malting barley varieties were most likely due to unrealized yield potential resulting in excessive nitrogen availability.

The variation in $\beta$-glucan content (2.9−5.7%; Table 1) was consistent with results published earlier.[23,24] Both genotype and growing conditions are known to influence $\beta$-glucan content.[23,25,26] The 6-row ear type and waxy barley varieties have been associated with low and high contents of $\beta$-glucan, respectively,[23,27] and similar results were obtained in the current study. In addition to genotypic association, each cultivar showed also crop year dependency, the $\beta$-glucan contents of each variety being substantially higher in 2006 than in 2007. The ranges of raw fat and ash contents were similar to those reported earlier.[20,28]

The correlation coefficients calculated between the main grain components showed significant negative correlations between starch and protein contents as well as starch and $\beta$-glucan contents (Table 2; $p < 0.01$ and $p < 0.05$, $n$ = 14). Both of these correlations are in line with earlier studies (e.g., Holtekjølen et al.[22]). Protein and $\beta$-glucan contents did not show a positive correlation as in previous studies.[22] Raw fat and ash contents showed no significant correlations with other components. Overall, the compositional variation in the sample set used was considered to be adequate and suitable for further investigation of the relationship between composition and processing behavior of grains.

**Association of Milling Behavior with Grain Composition.** The dissociation of endosperm into flour particles was studied by analyzing particle size distribution of flours produced by pin milling. All of the studied barley samples yielded flour

[a]Different letters indicate statistically significant difference ($p < 0.05$) between samples based on Tukey's HSD test.

with similar, bimodal particle size distribution with peaks at 75−95 and 250−355 μm (data not shown). However, certain differences between samples were observed in the cumulative particle size distributions (Table 3). The results were comparable to particle size distribution of commercial barley flours available in Finland. Compared to other samples, the milling of the grains of waxy variety Magdalena resulted in coarser flour containing significantly fewer particles smaller than 132 μm ($p < 0.05$, $n = 3$). Excluding samples of Voitto, each variety produced finer flour from the 2007 crop than from the 2006 crop. This difference was observed at least in one of the cumulative proportions of particles smaller than 132 μm ($p < 0.05$, $n = 3$). Nair et al.[31] have shown that the flours produced from harder grains contain more particles >106 μm than the flours from grains with softer structure. Therefore, the grains from crop 2006 may have been harder compared to those grown in 2007.

For examination of the effect of composition on milling properties, particle size distributions of flours were compared with the results of composition analysis. The composition analysis had revealed that starch content correlated negatively with protein and β-glucan contents, which, however, were not positively correlated with each other (Table 2). It was therefore considered reasonable to examine associations of starch with β-glucan content and protein content separately. Higher starch and lower protein and β-glucan contents were significantly linked to a higher fragility of the grain as indicated by the increased formation of flour particles of size from 132 to 180 μm upon milling (Table 2). Also, the proportion of the finer flour particles (from 95 to 132 μm) correlated positively with starch content and negatively with β-glucan content. Negative correlations were observed between the proportion of coarser flour particles (from 355 to 633 μm) and starch and β-glucan contents. Moreover, negative correlations were found between the proportion of the finest flour and β-glucan content as well as between the proportion of the coarsest flour and starch content. These results suggest that starch, protein, and β-glucan contents each affect the dissociation of the endosperm into flour particles.

The current results are consistent with the previous findings that starch content correlates negatively and β-glucan content positively with milling energy and kernel hardness.[4,8,29,30] Additionally, finer flours are produced from softer grains.[31] The more fragile structure of the grains with higher starch content could be a consequence of their lower β-glucan content (Table 2). The lower β-glucan content might indicate thinner cell walls and/or larger cell size causing a more easily breakable endosperm. Accordingly, thicker cell walls have been associated with hard-structured, steely barley grains.[10] However, varieties representing both low and high β-glucan levels showed crop year-related differences in flour coarseness, indicating that also factors besides β-glucan content affected grain milling properties and the hardness of grains. This is in line with the fact that a relationship between β-glucan content and grain hardness has not been found in all studies.[30,32]

In the sample set studied, also a lower protein content (associated with higher starch content) was linked to higher grain fragility in milling. Accordingly, protein content correlates positively with grain hardness.[3,29] Protein influences grain hardness via two mechanisms, both related to the dissociation of starch granules from the protein matrix during milling. First, a discontinuous or less compact protein matrix surrounding the starch granules is associated with softer grain structure.[3,10] Second, limited adhesion of protein to starch granules has been linked to a more fragile endosperm structure.[9,10] A correlation between protein content and milling energy or grain hardness has, however, not been observed in all studies, probably because grain hardness is associated also with β-glucan content, as described above.[4,30,32] It can be concluded therefore that barley grain composition greatly defines its milling properties, although the structure of endosperm must also be considered.

**Association of Water Uptake and Endosperm Modification with Grain Composition.** Water uptake was monitored during malting by measuring the increase in the

water content of the grains (Table 4). Water uptake was faster in the samples grown in 2007 than in the samples of 2006. This

[a]Results on water uptake are expressed as means of two replicate malting lots and friability values as averages of triplicate analyses. [b]Relative value of friability. [c]Different letters indicate statistically significant difference ($p < 0.05$; $n = 3$) between samples based on Tukey's HSD test. [d]Pooled standard deviation.

difference in water uptake was observed in all varieties after 24 and 48 h of malting, except for samples of Scarlett, in which there was no difference between the crop years at the 48 h time point. After the first day of germination (72 h from the beginning of malting), all of the samples had reached at least a water content of 45%, which is considered optimal for germination. Distribution of water in the grains was analyzed after 48 h of malting (Figure 1). By that time point, hydration had proceeded further in the samples of Vilde, Voitto, Scarlett, and Magdalena grains from the 2007 crop compared to those from 2006. This difference was observed in the proportion of grains having 50−75 and/or 75−100% of endosperm hydrated. In addition, the water content of grains after 24 and 48 h of malting correlated positively with the proportion of grains having 50−75% of endosperm hydrated after 48 h of malting ($p < 0.05$, $n = 14$, data not shown).

Similarly to the results of Gamlath et al.,[4] hydration of the grains at the time points of 24 and 48 h correlated negatively with $\beta$-glucan content (Table 2; $p < 0.05$, $n = 14$). Due to higher $\beta$-glucan content, grains grown in 2006 may have had a harder structure, which is known to be negatively correlated with water uptake.[3] However, $\beta$-glucan did not explain all of the variation observed in the extent of hydration, and no significant correlations between the distribution of water and grain composition were observed (Table 2). Therefore, water uptake was probably regulated also by packing or distribution of components in the endosperm rather than by the chemical composition only, as shown by, for example, Brennan et al.[33]

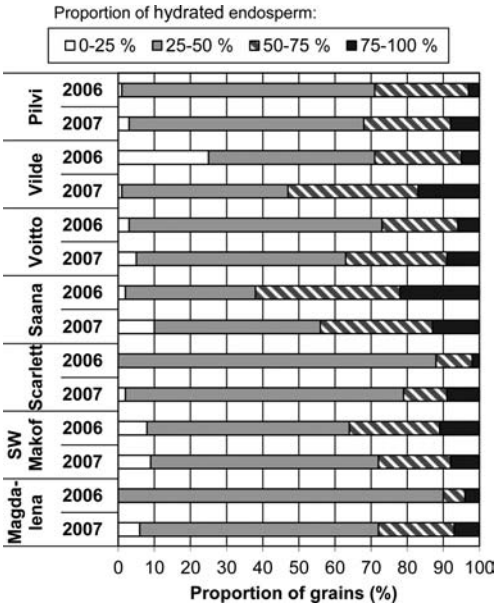

**Figure 1.** Distribution of water in barley grains after 48 h of malting. Results are based on 100 grains/sample.

and Chandra et al.[3] Although the steeping phase in the malting process represents a discontinuous hydration method, the effect of $\beta$-glucan content on water uptake observed in this study is likely to be applicable to other procedures requiring entry of water into grain.

The extent of endosperm modification during malting was determined by analyzing friability, the tendency of the endosperm to break into flour in a specified milling process. The higher the friability value, the more extensively the endosperm has been modified during malting, mostly with respect to degradation of cell walls and protein matrix.[34,35] Quite large variation in the friability values was observed among the barley samples in this study (Table 4). Malts of the samples of malting type variety SW Makof and feed variety Voitto were the most friable. SW Makof is known to have high activities of hydrolyzing enzymes, leading to release of high concentrations of fermentable sugars for distilling processes. The lower friability values of the other malting barley varieties were explained by high protein contents, which are known to cause insufficient modification.[36] The good modification of the Voitto samples was likely a consequence of low protein content.

The samples of waxy barley variety Magdalena had the lowest friability values (Table 4; $p < 0.05$, $n = 3$). This variety also showed high water uptake as mentioned above. The rapid hydration of waxy barley grains has been linked to starch composition, as low-amylose starch is known to differ from regular barley starch with respect to its physicochemical properties.[37,38] Although water uptake is a fundamental requirement for endosperm modification by enabling the synthesis and activity of hydrolyzing enzymes, fast hydration does not necessarily ensure good friability. Modification is also greatly dependent on hydrolytic enzyme activities not analyzed in this study.[33] Enzyme activities, the rate of enzyme activation, and the accessibility of the substrate to the enzyme may vary due to genetic background.[24,33]

Starch content correlated positively with friability (Table 2; $p < 0.05$, $n = 14$). Due to the inverse relationship of starch and protein contents of the grains, higher starch content could be associated with higher modification because of a more easily

dx.doi.org/10.1021/jf500857e | J. Agric. Food Chem. 2014, 62, 8875−8882

hydrolyzed, less dense protein matrix surrounding starch granules.[3] No significant correlation between protein content and friability was found. A negative association between protein content and friability is usually observed in studies of malting barley varieties and feed-type varieties.[11,33,36,39] The lack of correlation may be due to different nitrogen application given to 2-row and 6-row barley varieties.

The association between crop year and friability was not consistent; friability was higher in 2007 samples except for those of Pilvi, Saana, and SW Makof. This was probably due to varietal differences related, for example, to enzymatic hydrolysis of the endosperm during germination. Furthermore, no direct correlation was found between barley $\beta$-glucan content and friability in this study, although $\beta$-glucan content has been linked to grain hardness, which is known to correlate negatively with endosperm modification and friability.[29,30] In the case of $\beta$-glucan, the role of enzyme action during germination is significant, and the amount of $\beta$-glucan left in barley malt has been shown to correlate more strongly with friability than the $\beta$-glucan content of unmalted barley.[40]

**Association of Grain Processing Behavior with Localization of $\beta$-Glucan, Total Protein, and Hordeins.** The distribution of different components within the grain was examined by progressively pearling grains of the varieties Scarlett and Vilde from crop years 2006 and 2007 and analyzing the composition of the pearled kernels. In all samples, protein content decreased gradually toward the center of the grain at pearling rates >15% (Figure 2a). $\beta$-Glucan, in turn, was enriched in the remaining kernel up to a pearling rate of 30%. Similar changes in the protein and $\beta$-glucan contents of the pearled kernels have been linked to removal of the protein-rich aleurone layer and enrichment of subaleurone and starchy endosperm cell walls rich in $\beta$-glucan.[38,41] Grains of Scarlett samples had consistently higher contents of protein and $\beta$-glucan in the endosperm at all pearling rates compared to samples of Vilde, indicating a less fragile endosperm structure, which may explain the coarser flour produced from sample lots of Scarlett. Higher protein contents in the endosperm of grains of Scarlett samples were probably a consequence of the higher nitrogen fertilizer application given for this cultivar. The distribution of total protein or $\beta$-glucan showed no clear association with water uptake or friability.

The decrease in concentrations of water- and salt-soluble proteins (globulins and albumins) was more pronounced toward the center of the grain relative to the total protein content (Figure 2b). Hordein was rather evenly distributed in the grains of Scarlett samples, but in the grains of Vilde samples it decreased at the pearling rates of 20−30% (Figure 2c). Distribution of these protein fractions is in line with the known location of hordeins in the subaleurone and starchy endosperm cells and globulins and albumins in the aleurone layer.[42] Clear correlations between the distribution of these protein fractions and processing behavior including milling, water uptake, and friability were not observed.

Hordeins were extracted from whole and pearled grains sequentially in 50% (v/v) 1-propanol first without and thereafter with DTT for the reduction of interchain disulfide bonds of B and D hordein aggregates (Table 5). Irrespective of the pearling rate, most of the hordeins were monomeric B and C hordeins. Some C hordein was extracted after reduction, showing its entrapment among the aggregated B and D hordeins. The inner endosperm (pearling rate approximately 30%) of Vilde and Scarlett grown in 2007 contained

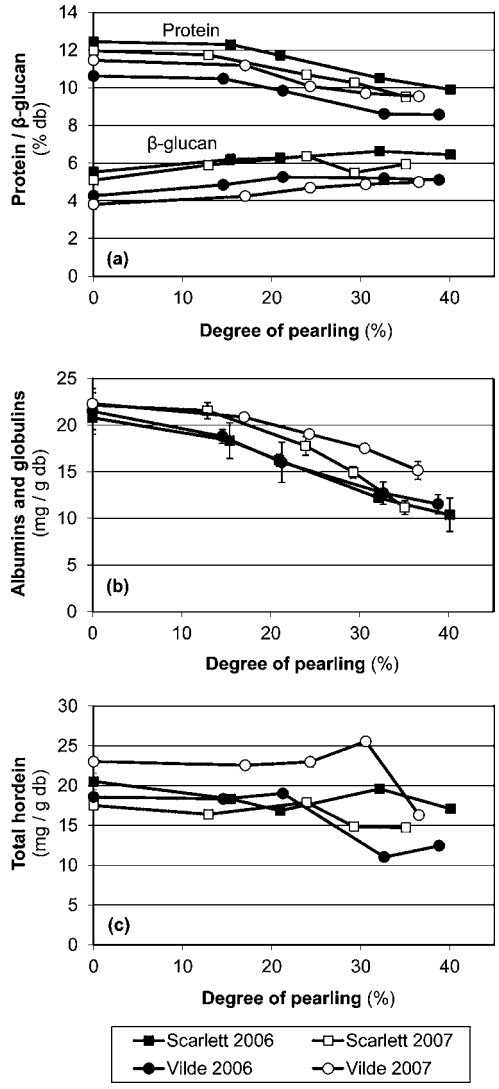

**Figure 2.** Effect of pearling on content of (a) protein and $\beta$-glucan, (b) water- and salt-soluble proteins or albumins and globulins, and (c) total hordeins in barley grains. Analyses and extractions were performed in triplicate. Error bars indicate the 95% confidence intervals ($n$ = 3).

proportionally less 1-propanol-soluble C hordein and more 1-propanol+DTT-soluble B, C, and D hordeins in the endosperm compared to the samples harvested in 2006 (Table 5; $p < 0.05$, $n$ = 3). Moreover, 1-propanol+DTT-soluble B hordein was more concentrated in the peripheral endosperm in the grains of both varieties grown in 2006.

Both the hordein localization and $\beta$-glucan content in the grains of Scarlett and Vilde were associated with the crop year, suggesting that their formation during grain filling could be affected by similar environmental conditions. Furthermore, distribution of hordein fractions and $\beta$-glucan was associated with processability in the samples of these two cultivars. In both cases there was a lower $\beta$-glucan content, localization of aggregated hordeins (with entrapped C hordein) within the more central endosperm, and nonentrapped C hordein located less deeply. These characteristics correlated positively with the proportion of fine flour after milling, water uptake after 24 h of malting, and proportion of hydrated endosperm after 48 h of malting and friability.

[a]Values are expressed as means of triplicate hordein extractions. [b]Proportions of the same variety followed by different letters differ significantly from each other ($p < 0.05$) based on Tukey's HSD test.

Although the effect of hordein localization and $\beta$-glucan content on processing behavior cannot be fully separated on the basis of the current results, several earlier studies suggest that hordeins influence grain properties. For example, the concentration of aggregated B hordein in the peripheral endosperm has been associated with impaired malting quality,[43] and the deeper localization of C hordein entrapped by aggregated B and D hordeins improved water uptake during steeping.[14] Moreover, this minor proportion of C hordein might assist hydration and modification, restricting the aggregation of B hordein or changing the number and orientation of disulfide bonds between aggregated hordeins.[12,44] The nonentrapped C hordein, representing the majority of the C hordein, could in turn limit water uptake and endosperm modification on the basis of its hydrophobic structure, effect on endosperm hardness, and slow hydrolysis during malting.[44−46] Hordeins could also influence milling properties, because steely grains, which generally produce coarser flour upon milling, are rich in C hordein.[31,45] Therefore, a lower proportion of nonentrapped C hordein within the central starchy endosperm could be expected to facilitate dissociation of the protein matrix and starch granules into finer flour particles. However, the more specific mechanisms by which the degree of hordein aggregation affects properties of barley endosperm such as dissociation of flour particles, hydration, or modification during germination are not known.

This study has shown that the processing properties (milling behavior, water uptake, and modification) of barley grains are associated not only with their main constituents (starch and protein) but also with $\beta$-glucan content. The distribution of hordein within the grain could also contribute to grain structure and processing performance. These results further indicate that understanding the role and biochemical action of macromolecules located inside cells, as well as macromolecules that make up cell walls, is necessary to accurately predict the functional performance of individual lots of barley grains.

furosine levels (0.91 mg/kg) in a dry dog food, providing evidence that at least FL can be found in pet foods.[13] As pet animals usually consume processed foods throughout their lives, chronic ingestion of advanced MRPs could induce long-term effects on pet health.

The aim of this study was to quantitate key MRPs in commercial pet foods to calculate the daily intake of MRPs in pet animals. The MRP data were subjected to multivariate analysis to identify diet formulation factors such as processing type, animal species, life stage, and nutrient composition that could affect the variation in MRP concentrations in these foods.

## MATERIALS AND METHODS

**Materials.** L-Lysine monohydrochloride (Fluka, Buchs, Switzerland), furosine dihydrochloride, ε-*N*-carboxymethyl-L-lysine, lysinoalanine (PolyPeptide Group, Strasbourg, France), and 5-hydroxymethyl-2-furaldehyde (Sigma-Aldrich, Steinheim, Germany) were used as external chemical standards. External standards of all other amino acids were purchased from Serva Electrophoresis (Heidelberg, Germany). Other chemicals of analytical grade were nonafluoropentanoic acid (NFPA) (Fluka), barium hydroxide octahydrate and trichloroacetic acid (TCA) (Merck, Darmstadt, Germany), hydrochloric acid 37% (HCl) and *O*-methylisourea hemi sulfate (OMIU) (Sigma-Aldrich), water, acetonitrile (ACN), and methanol (UPLC-MS, Biosolve BV, Valkenswaard, The Netherlands), and buffers for amino acid analyses (Frank Gutjar Chromatographie, Balingen, Germany).

**Diets and Sample Preparation.** A sample set was created containing 153 extruded, canned, and pelleted pet foods commercially available on the Dutch market. Pet food types were categorized according to species (dog or cat) and life stage (junior and adult). From each category in the sample set, five pet foods (single batch) were randomly selected, resulting in a selection of 50 foods. In addition, 11 extruded dry foods for growing dogs and 6 extruded dry foods for growing cats were obtained from Australia, Brazil, China, Germany, Mexico, Thailand, the United Kingdom, and the United States. This results in a total of 67 foods that were included in the study. The moist canned foods were freeze-dried, and all of the foods were ground to pass through a 1 mm sieve in a centrifugal mill (Retsch ZM100, Retsch BV, Ochten, The Netherlands). All samples were stored in airtight plastic containers at 4 °C prior to analyses.

**Proximate Analyses.** Dry matter (DM) and crude ash contents were determined by drying to a constant weight at 103 °C (ISO 6496, 1999) and combustion at 550 °C (ISO 5984, 2002), respectively. Crude protein (CP; N × 6.25) was determined using the Dumas method (AOAC 990.03), and crude fat (CFat) was gravimetrically determined after hydrolysis with HCl and extraction with light petroleum ether (boiling point 40−60 °C; ISO 6492, 1999). Crude fiber (CFiber) was gravimetrically determined as the remaining insoluble organic fraction after acid and alkaline digestion (ISO 6865, 2000). All analyses were performed in duplicate. The content of nitrogen-free extract (NFE, g/kg DM) of foods was calculated as described by eq 1, and metabolizable energy (ME, in kJ "as is") content was calculated using predictive equations for ME (eq 2, 3, 4, and 5).[14]

$$\text{NFE (g/kg DM)} = 1000 - \text{CFat} - \text{CP} - \text{crude ash} - \text{CFiber} \quad (1)$$

$$\text{Dogs: ME (kJ "as is")} = \text{digestible energy (DE, kJ)} - (4.35 \times g\ \text{CP})$$

$$\text{Cats: ME (kJ "as is")} = (\text{DE, kJ}) - (3.22 \times g\ \text{CP}) \quad (2)$$

$$\text{DE (kJ)} = \text{gross energy (GE, kJ)} \times \text{energy digestibility (\%)}/100 \quad (3)$$

$$\text{Dogs: energy digestibilty (\%)} = 91.2 - (1.43 \times \%\ \text{CFiber in DM})$$

$$\text{Cats: energy digestibilty (\%)} = 87.9 - (0.88 \times \%\ \text{CFiber in DM}) \quad (4)$$

$$\text{GE (kJ)} = (23.85 \times \text{g CP}) + (39.33 \times g\ \text{CFat}) + (17.15 \times (\text{g NFE} + g\ \text{CFiber})) \quad (5)$$

**Amino Acid Analyses.** Samples were defatted by extraction with light petroleum ether without acid hydrolysis (ISO 6492, 1999) and ground using a mixer mill (Retsch MM2000, Retsch BV). Total lysine (TL) was analyzed using traditional amino acid analysis and represents both reactive as well as unreactive lysine that reverts back to reactive lysine during acid hydrolysis. Amino acids including TL were determined according to the method of Hendriks et al.[15] Samples (5 mg) were hydrolyzed using 1 mL of 6 M HCl during 23 h at 110 °C in glass tubes that were sealed under vacuum. The tubes were opened, norleucine was added as an internal standard, and the tubes were dried under vacuum (Savant SpeedVac Plus, SC210A). The dried pellet was redissolved in 2 mL of loading buffer (0.1 M sodium acetate; pH 2.2). Amino acids were separated by ion exchange chromatography using a Biochrom 20 AA analyzer (Biochrom, Cambridge, UK) and analyzed by postcolumn derivatization with ninhydrin, using photometric detection at 570 nm. Reactive lysine (RL) was measured using the OMIU procedure that transforms RL into homoarginine through a guanidination reaction. OMIU-RL was determined according to the method of Moughan and Rutherfurd.[16] Samples (5 mg) were incubated during 7 days with 1 mL of OMIU to convert all lysine with a free ε-amino group into homoarginine. Homoarginine was measured in the dried sample according to the amino acid analysis procedure described previously. The amount of OMIU-RL was calculated from the molar amount of homoarginine and the molecular weight of lysine. All analyses were performed in duplicate. The ratio between TL and OMIU-RL was calculated using eq 6.

$$\text{RL/TL ratio} = \text{OMIU} - \text{reactive lysine/total lysine} \quad (6)$$

**RP-UPLC-MS.** The MRPs furosine (as an indirect measurement for FL, see below), CML, HMF, and the cross-linked amino acid LAL were analyzed. Defatted samples (10 mg) were hydrolyzed according to the amino acid analysis procedure described previously. The samples were redissolved in 2 mL of 5 mM NFPA and filtered (0.2 μm) into vials for RP-UPLC-MS analysis. Because HMF is not stable during acid hydrolysis, the sample preparation was performed according to the method of Ameur et al.[17] For this, 10 mg of defatted sample was dissolved in 1 mL of Milli-Q and 250 μL of 40% TCA. The sample was stirred for 5 min and centrifuged for 5 min at 9000*g*. Then, 800 μL of the supernatant was separated, dried under vacuum (Savant SpeedVac Plus, SC210A), redissolved in 1 mL of 5 mM NFPA, and filtered (0.2 μm) into vials for RP-UPLC-MS analysis.

Samples were analyzed using an Acella RP-UHPLC system (Thermo Scientific, San Jose, CA, USA). Samples (5 μL) were injected on an Acquity UPLC BEH C18 column (2.1 × 150 mm, 1.7 μm particle size; Waters, Milford, MA, USA) with an Acquity UPLC BEH C18 Vanguard precolumn (2.1 × 5 mm, 1.7 μm particle size; Waters) housed in a column oven at 40 °C. The mobile phases were eluent A, 5 mM NFPA in Milli-Q water, and eluent B, 100% ACN. The flow rate was 300 μL/min. The following elution profile was used: 0−11 min, eluent B linear gradient from 20 to 24%; 11−12 min, eluent B linear gradient from 24 to 100%; 12−17 min, eluent B isocratic on 100%; 17−18 min, eluent B linear gradient from 100 to 20%; 18−25 min, eluent B isocratic on 20%.

Mass spectrometric (MS) data were obtained by analyzing the eluate on a Thermo Scientific LTQ-Velos Pro equipped with an HESI-MS probe coupled to the RP-UHPLC; 300 μL/min of the flow from the RP-UHPLC was directed to the MS. Nitrogen was used as sheath gas and as auxiliary gas. Data were collected in positive ionization mode with selected reaction monitoring (SRM); for details, see Table

1. Data-dependent $MS^n$ analyses were performed with a normalized collision energy of 35%. Settings were optimized using "LTQ tune plus" (Velos Pro 2.7, Thermo Scientific) via automatic tuning using standard stock solutions. The capillary temperature was 300 °C, the source heater 230 °C, and the source voltage 3.0 kV. Compounds were quantified by reference to an external standard calibration curve by plotting MS area ratio in base peak SRM against amount ratio using external standard concentrations of 0.1, 0.05, 0.01, 0.005, 0.001, 0.005, and 0.0001 mg/mL. Data acquisition and reprocessing was done with Xcalibur 2.1 software (Thermo Scientific).

**Table 1. Selected Reaction Monitoring Conditions**

| compound | parent mass (Da) | fragment mass (Da) | range ($m/z$) |
|---|---|---|---|
| furosine | 255 | 130 | 127.50−132.50 |
| carboxymethyllysine | 205 | 130 | 127.50−132.50 |
| hydroxymethylfurfural | 127 | 108 | 106.50−111.50 |
| lysinoalanine | 234 | 198 | 195.50−200.50 |

Furosine is an indirect measurement of FL; during acid hydrolysis in 6 M HCl, peptide-bound FL is transformed into approximately 32% furosine, 56% regenerated (unreactive) lysine, and 16% pyridosine.[18] RL can be calculated using this furosine procedure. FL, regenerated lysine, and FUR-RL were calculated using eqs 7, 8, and 9, respectively.[18,19]

$$\text{FL (g/kg DM)} = \text{furosine (g/kg DM)}/(32/100) \quad (7)$$

$$\text{regenerated (unreactive) lysine (g/kg DM)} = \text{FL (g/kg DM)} \times (56/100) \quad (8)$$

$$\text{FUR-RL (g/kg DM)} = \text{total lysine (g/kg DM)} - \text{regenerated lysine (g/kg DM)} \quad (9)$$

**Statistical Analyses.** Statistical analyses were performed using SAS 9.2 for Windows (SAS Institute, Cary, NC, USA). Data analysis to identify factors associated with variation in dietary MRPs was performed by ANOVA using the GLMSELECT procedure. CML and HMF were square root transformed, and FL was logarithmically transformed (Ln) to attain normal distribution of the residuals evaluated with the Sharpiro−Wilk test. Using stepwise regression and the Schwarz Bayesian information criteria, the best model explaining the variance of the dependent variables FL, CML, HMF, and LAL was selected. The following independent variables were used: animal species (dog, cat), processing type (extruded, canned, pelleted), life stage (adult, junior), DM (in g/kg), CP, CFat, CFiber, crude ash, NFE (g/kg DM). Correlations were assessed by use of the Pearson correlation method. Regressions were assumed significant when $P < 0.05$.

## RESULTS AND DISCUSSION

**Proximate Composition of Commercially Available Pet Foods.** The selected commercial pet foods differed considerably in proximate composition and ME content (Table 2). With regard to animal species, cat foods contain, on average, higher CP and CFat but lower DM and lower CFiber and NFE contents on a DM basis compared to corresponding dog foods. This result could be expected as cats require more protein and fat for growth and maintenance compared to dogs.[14] Crude ash content was comparable among foods in the category animal species. For processing type, canned foods contain on average more crude ash, CP, and CFat on a DM basis compared to extruded and pelleted foods. The lower CFiber and NFE contents of the canned foods are due to little or no inclusion of starch sources in the latter foods. In the category life stage, foods formulated for animals at different life stages did not differ in proximate composition. However, nutrient composition can vary within this category; CP contents, for example, varied considerably in extruded adult dog foods (range 211−445 g/kg DM), canned junior dog foods (range 364−710 g/kg DM), canned adult dog foods (range 294−591 g/kg DM), and canned adult cat foods (range 489−712 g/kg DM). The mean NFE content was higher in pelleted dog foods than in extruded dog and cat foods, with the latter foods showing larger ranges in NFE contents.

**Reactive Lysine Content of Commercially Available Pet Foods.** The mean values for TL and RL of the commercial pet foods are shown in Table 3. RL contents met the minimal lysine requirements for dogs and cats; however, levels could be at risk of not meeting lysine requirements in weaning diets for growing dogs as described in Van Rooijen et al.[12] To estimate the extent to which the MR affected the RL content of pet foods, two procedures (OMIU or FUR method) were applied to analyze the RL contents. The two methods showed a strong correlation ($r = 0.98$; $P < 0.0001$). The mean RL content of the pet foods was lower compared to the mean TL content regardless of the procedure that was used to measure RL, with some samples having equal OMIU-RL and TL values. Except for the canned dog diets, mean OMIU-RL values were lower than FUR-RL values. A difference between OMIU-RL and FUR-RL was also reported using corn distillers' dried grains with solubles.[19] The regenerated (unreactive) lysine calculated from the furosine procedure originates specifically from the Amadori compound,[18] and the FUR-RL calculation assumes that the remaining lysine is reactive. The conversion factors used in the furosine calculation are uncertain as these depend on the origin of the Amadori compound and the hydrolysis conditions.[18,20] The OMIU-RL calculated using the OMIU procedure measures the actual amount of free $\varepsilon$-amino groups when complete conversion occurs of lysine to homoarginine. Why the difference between OMIU-RL and FUR-RL is reversed when canned pet foods are analyzed is unknown. The analyzed concentration of RL can be affected by the measuring procedure, and it is important to take into account using either of the two procedures to measure RL.

The RL/TL ratio is often used as an indication of lysine damage during processing. Pelleted dog foods had the lowest mean RL/TL ratio (0.85), compared to extruded (0.89) and canned (0.97) dog foods and extruded (0.93) and canned (0.90) cat foods, respectively (Table 3).[12] Using OMIU-RL, the lowest RL/TL ratio was 0.67 and was found in an extruded junior cat food. The reported mean and minimal RL/TL ratios of the foods were higher compared to previous studies. Rutherfurd et al.[10] reported mean RL/TL ratios of 0.51 (minimum 0.38, maximum 0.61) for canned cat foods and of 0.59 (minimum 0.51, maximum 0.80) for dry cat foods. Williams et al.[9] reported mean RL/TL ratios of 0.85 (minimum 0.44, maximum 1.06) for adult dog foods and of 0.75 (minimum 0.47, maximum 0.98) for foods for growing dogs. It is, however, known that depending on the extent of the MR, some lysine may be converted to compounds that do not revert back to lysine during acid hydrolysis, thus reducing the total lysine content of the food. The RL/TL ratio, therefore, is valid when the RL/TL ratio of the unprocessed ingredient mixture is known, but is not suitable as an indicator of advanced MRPs that could have formed in processed pet foods.

**Presence of Common Markers of the Maillard Reaction.** The current study is the first to quantitate levels

dx.doi.org/10.1021/jf502064h | J. Agric. Food Chem. 2014, 62, 8883−8891

of various MRPs in commercial pet foods. High variation in MRP content was seen between as well as within processing type. Canned pet foods contained on average the most FL, CML, and HMF followed by pelleted and extruded foods (FL, 4534, 844, 706; CML, 37, 20, 12; HMF, 1417, 1161, 715 mg/kg DM, respectively; Table 3). However, when expressed on an "as is" basis, canned pet foods contain the lowest CML and HMF contents. In dry dog foods, the mean contents of FL, CML, and HMF were higher in pellets than in extrudates (FL, 844 vs 646 mg/kg DM; CML, 20 vs 13 mg/kg DM; HMF, 1161 vs 880 mg/kg DM, respectively). The HMF content in pelleted dog foods is much higher than previously reported in a pelleted piglet starter diet (16.66 mg/kg).[21] For LAL, the means are comparable between processing types. The only study to date focusing on MRP content in pet foods reported a FL content of 2840 mg/kg "as is" in one dry dog food.[13] This level is twice as high as the highest level for the dry extruded dog foods in the present study (1440 mg/kg DM), but not as high as the highest level for pelleted junior dog foods (4050 mg/kg DM). No data are available for comparison of the CML, HMF, and LAL in pet foods. However, several studies are available that evaluated these advanced MRPs in human food items. CML concentrations in human foods were found to range between 0.1 and 68.7 mg/kg in meat and fish products, between 1.0 and 423.9 mg/kg in meat dishes, between 7.6 and 54.2 mg/kg in cereals, and between 0.5 and 39.4 mg/L in infant formulas.[22−27] The manner of processing has an influence on the level of CML; raw minced beef contained less CML (0.7 mg/kg) than boiled and fried minced beef (5.0 and 11.2 mg/kg CML, respectively).[28] Increasing CML levels with increasing severity of processing was also found in roasted beef joint (1.5, 2.5, and 4.2 mg/kg for rare, medium-rare, and well-done, respectively)[22] and chicken breast (3.8, 4.6, 5.1, and 23.9 mg/kg, for boiled, roasted, fried, and casseroled breast, respectively). HMF levels in human foods were found in the ranges of 91.3−3060 mg/kg in instant coffee (values for ground roasted coffee beans were found within this range),[29−31] 6.6−241 mg/kg in breakfast cereals,[32] 0.2−69 mg/kg in white bread,[31,33] 0.5−74.6 mg/kg in cookies,[17] and 0.2−34.7 mg/L in infant formulas.[34−37] LAL levels of 10−70 mg/kg for baby food, 200−300 mg/kg for cereal products, 150−920 mg/kg for dry infant formulas, and 140−540 mg/kg for meat products were reported in human foods.[3] However, Raymond[38] reported lower levels for LAL, 0−70 mg/kg for ready-to-eat cereals, 0 mg/kg for pasta, 0−50 mg/kg for infant formula, 0 mg/kg for prepared meat, and 0−120 mg/kg for canned fish. The CML, HMF, and LAL levels of the analyzed pet foods are within the range reported for human foods (Table 3).

**Daily Intake of Common Markers of the Maillard Reaction.** On the basis of the MRPs and the calculated ME contents of the pet foods, daily MRP intake can be estimated. A 20 kg adult dog having a daily energy requirement of 5.15 MJ ME[14] would ingest 0.50 mg CML and 34.58 mg HMF/kg body weight (BW)$^{0.75}$/day when eating an extruded diet with an average content of 3.83 and 266.00 mg CML and HMF/4.18 MJ ME (Figure 1). An adult cat (4 kg) with a daily energy requirement of 1.06 MJ ME[14] would ingest 0.28 mg CML and 10.90 mg HMF/kg BW$^{0.75}$/day when consuming an extruded diet with an average of 3.12 and 121.80 mg CML and HMF/4.18 MJ ME. For canned and pelleted diets, these values were even higher (Figure 1). Limited estimates are available for humans, and these may be influenced by country, region, social class, and age. For Spanish adolescents, a mean daily intake of

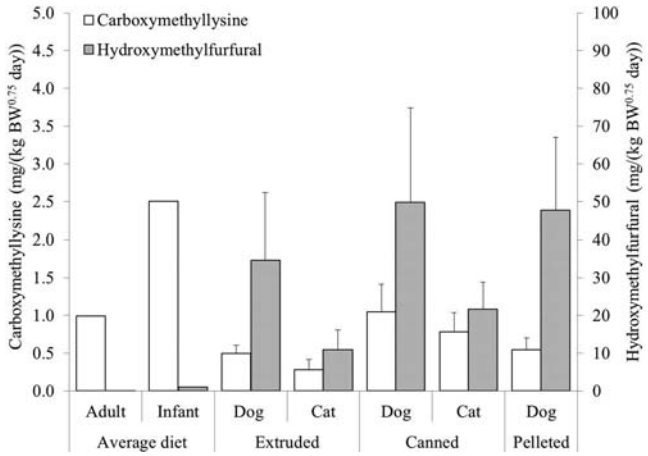

**Figure 1.** Estimated daily intake (mg/kg body weight (BW)$^{0.75}$) of carboxymethyllysine and hydroxymethylfurfural of a 70 kg adult human consuming a standard Western diet,[22,31,32,39] a 6 kg human infant consuming 1 L of an average infant formula,[23−27,34−37] and a 20 kg adult dog and a 4 kg adult cat fed either an extruded, canned, or pelleted diet for adult dogs and cats at maintenance (using a standard daily energy requirement[14]) containing an average ± standard deviation content of carboxymethyllysine and hydroxymethylfurfural as reported in the current study.

0.99 mg CML/kg BW$^{0.75}$ (70 kg BW) was estimated.[39] The CML content in infant formulas was quantified in five studies. Assuming a daily intake of 1 L for a 6 kg infant, daily CML intake ranges from 0.49 to 39.38 mg corresponding to mean values of 1.23, 3.69, 4.60, 4.75, and 33.77 mg.[23−27] For HMF, the mean intake for adult humans in three different studies was 5.08, 5.56, and 10 mg per day,[31,32,39] resulting in an average daily intake of 0.28 mg HMF/kg BW$^{0.75}$. HMF levels in infant formulas range from 0.158 to 34.7 mg/L,[34−37] resulting in average daily values of 0.16, 0.32, 0.38, and 13.9 mg/L. This results in an average daily intake of 0.96 mg HMF/kg BW$^{0.75}$. Compared to the calculated average for human adults, dogs may ingest up to 122 times more HMF when consuming an average extruded dog food (Figure 1). In addition, dogs may ingest up to 36 times more HMF compared to human infants fed infant formula. Cats consuming an average extruded cat food may ingest up to 38 times more HMF compared to adult humans and 11 times more HMF compared to human infants. Dogs and cats fed canned and pelleted diets are more likely to ingest higher amounts of HMF and CML compared to animals that are fed an extruded diet. No data are available regarding the average daily intake of LAL in humans. Both CML and HMF from consumed foods can cross the intestinal wall and enter the circulation. In rats, dietary HMF has been shown to be rapidly absorbed, metabolized into 5-hydroxymethyl-2-furoic acid and *N*-(5-hydroxymethyl-2-furoyl)glycine as main metabolites, and 70−82% of the ingested HMF is excreted via the urine within 48 h.[40] No evidence for prolonged accumulation in body tissues was observed. No adverse effects regarding acute and subacute toxicity in rats and mice ingesting HMF concentrations of 80−100 mg/kg body weight was reported.[41] In humans, intake of dietary CML resulted in an increase in circulatory CML concentration.[42] In rats, approximately 26−29% of the ingested CML was excreted in the urine, whereas in humans 14% of ingested dietary CML was excreted in urine.[8,43] Around 50% of the ingested CML was not recovered, and it is unknown if it is deposited in organs, degraded by colonic

microbiota, or metabolized. Whether the MRPs in pet foods are absorbed and excreted when consumed, and subsequently add to the endogenous AGE load in dogs and cats, remains to be investigated.

**Dietary Factors Associated with the Occurrence of the Maillard Reaction.** Dietary factors associated with variation in advanced MRP content of pet foods are shown in Table 4. The levels of MRPs in pet foods were not related to animal species or life stage; however, type of pet food shows a correlation for FL, CML, and HMF (Table 4). The processing conditions between pelleting, extrusion, and canning differ considerably. Extruded kibbles are processed at temperatures of 80−200 °C for 10−270 s under high pressure.[44] Canned foods are heated until the center of the can reaches temperatures of 121 °C for >10 min to sterilize the product.[45] Pelleted foods are relatively mildly heat treated using temperatures of 60−90 °C for 30−45 s.[46] In addition, pet food ingredients can be extensively processed (i.e., rendered, cooked, dried, and/or ground) before inclusion. Depending on the severity of the processing, the MR progresses through several stages of the reaction. Overall, pelleted foods contain more CML and HMF compared to extruded foods (and canned foods when expressed on an "as is" basis). This result is unexpected considering the rather mild heat treatment used during pelleting compared to extrusion conditions. Because of this mild heat treatment, ingredients used during pelleting are often preprocessed. Carbohydrate sources, for example, are often pretreated as pelleting processing temperatures and residence times are not sufficiently high to fully gelatinize the starch in the raw ingredients during processing.[47] It could, therefore, be that the MRP contents in pellets mainly originate from the preprocessed ingredients rather than de novo formation due to the processing itself. Analyses of ingredients and food mixtures prior to processing are required to confirm this hypothesis. LAL content in pet foods is comparable between processing types and is not associated with type of processing. With regard to the chemical composition, CML was associated with CFat content. Besides the MR, lipid peroxidation during processing results in the intermediate glyoxal, which can react with lysine to form CML.[48] Next to the association with CFat, CML content showed a strong correlation with FL content ($r$ = 0.78; $P$ < 0.0001), which reflects the formation of CML from FL via an oxidation pathway.[49] HMF was associated with a decreased CP content and increased CFiber content. CML is moderately correlated to HMF ($r$ = 0.45; $P$ = 0.0001). The MR pathways that result in the formation of CML and HMF are different but apparently occur in a certain ratio during the processing of pet foods. No factor was associated with the content of LAL in the analyzed pet foods.

In conclusion, this study demonstrates that pet foods do contain Maillard reaction products. Type of processing seems to be a key factor for the concentration of FL, CML, and HMF, with on average higher amounts in wet canned pet foods than in dry extruded or pelleted pet foods (DM basis). LAL contents were similar for wet canned and dry pet foods. Further research is required to determine the contribution of pet food processing and the use of processed ingredients in the observed concentrations of Maillard reaction products in pet foods. Average daily intake of MRPs in pet animals can be higher compared to limited adult human and infant data. As commercial pet foods are most often the only source of food for dogs and cats, future research focus should be on the bioavailability and long-term health implications of MRP consumption by dogs and cats.

All authors contributed fundamentally to the present manuscript. C.v.R. contributed to all facets including data collection, calculations, and writing the initial manuscript. Other authors contributed to study design, data interpretation, and manuscript preparation.

### Funding

The project for which this work was conducted is jointly financed by the European Union, European Regional Development Fund, and The Ministry of Economic Affairs, Agriculture and Innovation, Peaks in the Delta, the Municipality of Groningen, the Province of Groningen, and MARS Petcare as well as the Dutch Carbohydrate Competence Center (CCC WP 5). MARS Petcare was involved in study design, data interpretation, and manuscript preparation. All other funders had no role in the design, analysis, or writing of this paper.

### Notes

The authors declare the following competing financial interest(s): Lucille Alexander is an employee of Mars Petcare.

## ACKNOWLEDGMENTS

We thank Michel Breuer and Edwin Bakx for their assistance during the analyses.

## ABBREVIATIONS USED

ACN, acetonitrile; AGEs, advanced glycation end-products; BW, body weight; CML, *ε-N*-carboxymethyllysine; CFat, crude fat; CFiber, crude fiber; CP, crude protein; DM, dry matter; FL, fructoselysine; HCl, hydrochloric acid; HMF, (5-hydroxymethyl)-2-furfural; LAL, lysinoalanine; ME, metabolizable energy; MR, Maillard reaction; MRPs, Maillard reaction products; MS, mass spectrometric; NFE, nitrogen-free extract; NFPA, nonafluoropentanoic acid; OMIU, *O*-methylisourea; RL, reactive lysine; SEM, standard error of the mean; SRM, selected reaction monitoring; TCA, trichloroacetic acid; TL, total lysine

oxygen through the barrel depends on the permeability of the wood used, its thickness, and the oxygen concentration difference between both sides. Thus, the rate of gas diffusion $dV/dt$ can be calculated by Fick's law, where $V$ is the volume of oxygen diffused, $t$ is time, $\mu$ is permeability, $d$ is the thickness of the stave, $\Delta P$ is the difference in the partial pressure of the gas, and $A$ is area. Thus, oxygen transfer rates (OTRs) of up to 2.2 mL/L per month (37 mg/L per year) are theoretically justified.[5]

$$\frac{dV}{dt} = \mu A \times \frac{\Delta P}{d}$$

In this work, results are shown from studying the OTRs of barrels by measuring the temporal variations in oxygen in the barrel. A system was used to measure dissolved oxygen in liquids without altering the environment. To date, different authors who have studied oxygen supply to wine in oak barrels have measured the processes at one point during aging (6 months) and have extrapolated this value to obtain annual data without considering possible changes in the rate of oxygen supply with time. This work demonstrates a more realistic approach to what (until now) has been called the OTR, which studies the dynamics of oxygen supply to wine in barrels with aging time. This study focused on the importance of the type of wood of the barrel (American oak, *Quercus alba*; and French oak, *Quercus petraea*), as well as the aging time of the wine, during 1 year of study.

Overall, the oxygen permeability of the barrels was modified by aging time. Thus, 50% of the total oxygen was received by the wine within the first 4 months of the 1 year aging period.

## MATERIALS AND METHODS

**Oak Barrels.** The characteristics of the 12 Bordeaux barrels (225 L) that were used in this study are presented in Table 1. This experiment was conducted in three parts. First, the dissolved oxygen gradient in the liquid within the barrel was studied (B0, Table 1). Next, OTRs were assessed for new American oak (B1–B8, Table 1) and French oak (B9–B12, Table 1) barrels. Finally, four of the new barrels from the same American oak cooperage (B5–B8, Table 1) that were previously analyzed in part 2 were systematically analyzed for 12 months. This trial made it possible to determine the kinetic variations of oxygen infiltration into the barrel with time and to establish the annual OTR.

**Table 1. Characteristics of Tested American and French Oak Barrels with Medium Toast**

[a]Origin according to cooperage information.

**Dissolved Oxygen (DO) Distribution Measurements of a Model Wine in the Barrel.** To determine the oxygen distribution within the liquid in the barrel, it was important to guarantee that no wine compounds were consuming oxygen. Thus, a model wine (pure water and ethanol at 15% v/v, pH 3.5) was chosen without oxygen scavengers to monitor the formation and evolution of DO gradients. In addition, an oxygen mass balance was conducted to determine the OTR.

The temperature of the fluid inside the barrel was measured on different days at the eight different depths of the DO probes to verify that no temperature gradient occurred (Figure 1). Thus, oxygen gradient tests were conducted in the synthetic wine. During the tests with the model wine in a climatically controlled cellar, the room temperature was maintained at 15 ± 1 °C and the humidity was maintained at 65–75% to mimic the common hydrothermal properties of the air in actual cellars. During the first part of the study, eight independent channels were used to measure the DO evolution simultaneously during the test. The DO concentrations were measured with eight optical probes that were immersed at different depths (Table 2) inside the oak barrel (Figure 1). These probes were equipped with a luminescent sensor on their extremity. The luminescent systems selected for this work were of the Oxy-trace (PreSens GmbH, Germany) series and worked with the PSt6 (detection limit = 1 ppb, 0–4.2% oxygen) trace oxygen sensor coating type as described in previous studies.[6] Eight submergible oxygen probes were monitored with two OXY-4 trace transmitters (PreSens GmbH) that were connected to a PC.

During the second and third parts of this study, two optical fibers with submergible probes were placed in each of the barrels through the silicone bung to obtain simultaneous continuous measurements from the four barrels. The study of the equations representing DO evolution enables selection of two probes, of the eight placed to measure it, of which average measurements are representative of the whole barrel DO average.

The oxygen systems were calibrated in a tonometer[7] by using the conventional two-point calibration method in the synthetic wine that was saturated with nitrogen (cal 0). A calibration gas mixture of 2.001% (±0.5% rel) pure oxygen gas in nitrogen (9.55% air saturation) was used as the second calibration standard (Carburos Metálicos, Spain). Both gases were sparged into the tonometer for 10 min at 15 ± 0.01 °C until stable conditions were achieved by a Julabo FP40-ME thermostatic bath (Seelbach, Germany). For more details regarding the calibration procedure, please see ref 6.

**Measurement Conditions.** Prior to use, the barrels were washed to remove toasting powder before filling with the model wine. Four sintered stainless steel diffusers were placed inside each barrel. Each diffuser had a pore size of 1 $\mu$m and was connected to a nitrogen line to displace DO from the model wine until it reached DO concentrations between 0.01 and 0.1 hPa. This process was performed before each test for 12 h to prevent overflow of the barrels. Because the solubility of oxygen is almost half the solubility of nitrogen in synthetic wine, nitrogen was selected in this study (Henry's constant for oxygen in ethanol–water mixtures at a mole fraction of 0.15 = $k_H$atm ($O_2$, 20 °C) = 23900; $k_H$atm ($N_2$, 20 °C) = 42600).[8]

Once readings from the submergible probes showed stable values in the absence of dissolved oxygen, the barrels were completely filled with the deoxygenated solution and a modified expandable silicone bung, similar to those used in cooperage to test the barrels, was inserted. This bung was modified to weld on it a multiple optical fiber feed for the eight optical fibers in test 1 (B1, Table 1) or for the two optical fibers (the rest of the tests) for the submergible oxygen probes that were introduced to each barrel. Each test lasted for 18–24 days. The lengths of the tests were dependent on the rate of oxygen entry into the barrels because the upper limit of the experiment was determined by the measurement range of the probes that were equipped with the PSt6 sensors (DO partial pressure of 0–41.4 hPa). When the DO variations in the model wine were measured within the barrel, the DO concentrations increased because DO was not consumed. This procedure would prevent the necessity of maintaining normal operating conditions in which the oxygen concentration gradient or

[a]Distance from the bung (in mm) is given in parentheses.

$pO_2$ in and out of the barrel remains constant due to oxygen consumption by the wine. Normally, the barrel's volume is so large that the $pO_2$ of the permeated gas remains negligibly small ($pO_2$ inside ≤5% $pO_2$ in the atmosphere) even upon reaching steady-state permeation. The $pO_2$ was measured with time in a previously oxygen-evacuated barrel that contained the model wine to maintain an initial $pO_2$ between 0.01 and 0.1 kPa.[9] The slope of the resulting oxygen evolution represents the flux of oxygen that permeates the liquid in the barrel from the atmosphere, or the $pO_2$ as a function of time. All $pO_2$ measurements were corrected to compensate for any interference by ethanol according to the model developed in previous studies.[10] Henry's law was applied to evaluate the oxygen concentration in milligrams per liter. In addition, the solubility of oxygen in hydroalcoholic mixtures was used[11] to avoid underestimation of the readings when the solubility of oxygen in water is used.[12]

After completion of each test, the barrels were not emptied and the model wine was degassed according to the previously described procedure. The microbiological analysis of the liquid confirmed the absence of microorganisms, probably due to the characteristic toasting process of oak wood barrels in cooperage. Thus, this liquid does not consume oxygen, which makes it suitable for the next test. By not emptying the barrel, the kinetics of the model wine absorption through the wood are not altered, and the humidity of the barrel oak staves is maintained. To test each barrel further, the same initial preparation procedure was applied. After all of the oxygen was displaced, DO measurements began again with the system of submergible probes.

**Oxygen Transfer Rate.** The OTR of barrels is usually expressed in milligrams per liter per year.[3,13] However, given the importance of time in studying the kinetics of oxygen entry, oxygen transfer is expressed as micrograms per liter per day.

The daily increase of oxygen within each barrel was determined by considering the mean values that were obtained from the two probes that were installed in each barrel. Daily values were added to determine the cumulative concentrations of DP that reached the model wine in each barrel for each day of the test. At this point, it is important to use a liquid that does not consume oxygen, has the same pH and ethanol content as wine, and allows for oxygen mass balance calculations. By using the model wine in the measurements, the OTR could be calculated because there were no compounds to consume the oxygen. The potential roles that the compounds in the wood would have in oxygen consumption[14,15] are considered in these trials, which allowed the determination of the true OTR of wine barrels.

**Statistical Analysis.** Regression analysis was conducted in the Statgraphics Centurion XVI statistics software (version XVI; StatPoint Inc., USA). Multiple regression analysis was used to compare the differences between the regression lines that were obtained from measuring the DO concentrations at different points in the oak barrel.

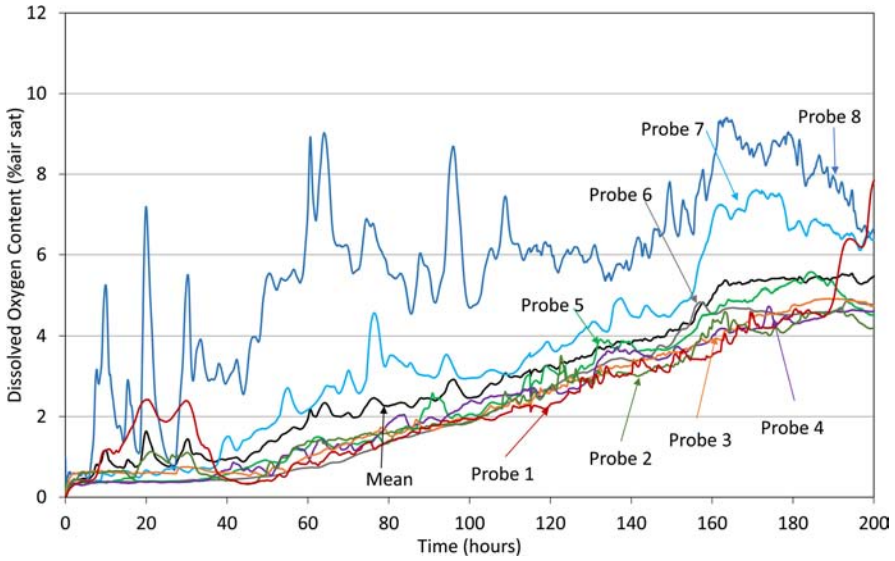

**Figure 2.** Measured dissolved oxygen (% air saturation) at each of the eight probes placed inside the barrel when no vacuum was generated inside the barrel.

The regression lines for the DO measurements with aging were conducted in Excel 2013 (Microsoft Office Professional Plus 2013) and are shown in Tables 2 and 3.

## RESULTS AND DISCUSSION

**Oxygen Distribution in the Barrel.** Figure 1 shows the arrangement of the eight probes within the barrel. Simultaneous measurements of DO within the barrels were used to determine the oxygen distribution inside the barrels. Measurements were conducted for 200 h, and the accumulated DO content is expressed in percent air saturation. The amount of DO read by the probes decreased as the distance from the bung increased (Figure 2). The highest DO concentrations were found at the top of the barrel (measured with probes 5, 6, 7, and 8), and the DO concentrations decreased with increasing distance from the bung. Lower DO concentrations were observed at the bottom of the barrel (measured with probes 4, 3, 2, and 1). Therefore, a high to low concentration gradient formed from the top to the bottom of the barrel.

Due to liquid losses, gaseous headspace rapidly forms near the bung. This space contains air with 21% oxygen, which diffuses into the wine through its surface and produces a decreasing gradient of DO with barrel depth.[16] These results agree with the results of Vivas and Glories,[17,18] who emphasized that the DO concentrations in wine oak barrels differed with distance from the bung. Thus, oxygen levels were much greater at 10 cm from the bung than at the center or bottom of the barrel. This result was observed in barrels after 1, 3, and 4 years of use.

The results indicated that the position of the dissolved oxygen probe is critical when evaluating DO throughout the entire barrel. Therefore, measurements must be made at representative points throughout the barrel. To reduce the number of probes required for an OTR assessment, the number of measurement points in each barrel was reduced from eight to two while accounting for the geometry of the barrel. By using the average of two representative DO measurements to represent the DO concentrations of an entire barrel, four barrels were monitored simultaneously in the second and third parts of the study.

To select two of the eight positions, a comparative study using equations that represented the evolution of DO at each submergible probe within the barrel was conducted. The equations that describe the DO variations with time in the bottom of the barrel (probes 1, 2, 3, and 4) and the mean of the four probes ($DO_{1-4}$) are provided in Table 2. In addition, Table 2 contains the $p$ values that were obtained by comparing the equations for each probe with the equation that was determined for the average of the four probes, which were representative of the DO evolution in the lower half of the barrel. The DO concentrations measured by probe 3 were not significantly different from the average DO ($p = 0.5248$, Table 2) concentrations. Thus, the position of probe 3 was selected as a representative measuring point for the lower half of the barrel.

dx.doi.org/10.1021/jf502333d | J. Agric. Food Chem. 2014, 62, 8892−8899

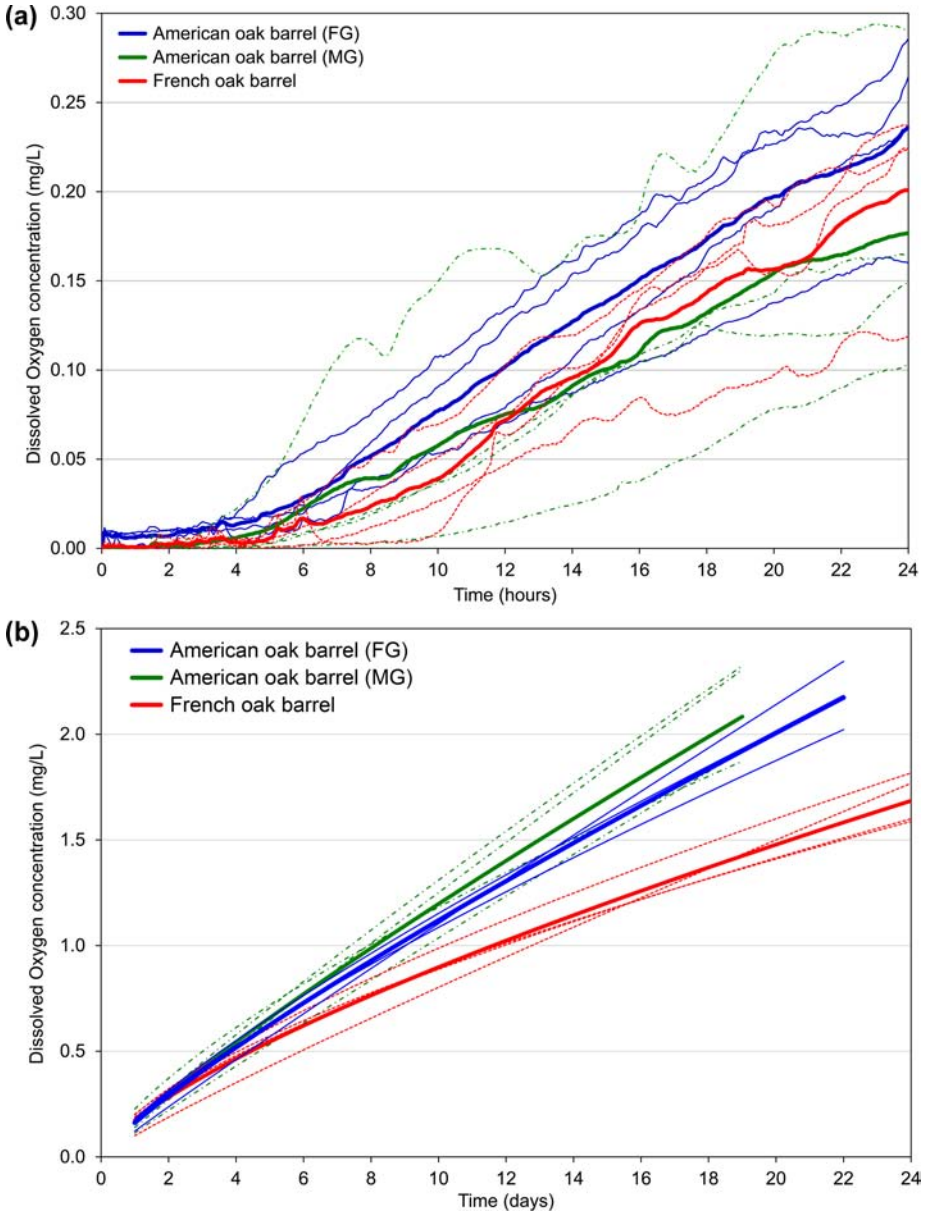

**Figure 3.** (a) Dissolved oxygen concentrations ($\mu$g/L) during the first 24 h; (b) fitted curves of the dissolved oxygen concentrations ($\mu$g/L) in the first few weeks. Measurements were taken in 12 American medium grain (MG) and fine grain (FG) and French oak barrels.

A similar analysis of the equations that describe DO variations with time at the top of the barrel (probes 5, 6, 7, and 8) was conducted. This analysis indicated that the equation describing the average DO evolution at probe 7 yielded results that were statistically equivalent to those obtained from the equation that described the mean values for probes 5, 6, 7, and 8 ($DO_{5-8}$) ($p$ = 0.5089). A comparative analysis between the equations that represented the average DO evolution at all eight probes ($DO_{1-8}$) and the average DO evolution at probes 3 and 7 ($DO_{3-7}$) was conducted. This comparison indicated that no statistically significant differences occurred between these equations ($p$ = 0.8285). Thus, the positions of probes 3 and 7 were used to represent the evolution of DO within each barrel.

**Kinetics of Oxygen Entry into the Barrels.** Figure 3a shows oxygen entry into the 12 American (B1−B8) and French (B9−B12) oak barrels during the first day expressed as accumulated DO concentration in milligrams per liter. The oxygen entry profiles in the American and French oak were not significantly different. However, the American oak barrels provided higher oxygen concentrations during the first 10 h than the French oak ones.

The initial oxygen contribution differs depending on the characteristics of the barrel and represents an extra oxygen input in addition to that produced during wine transport and barrel filling. The initial oxygen contributions were 230 and 281 $\mu$g/L for the fine- and medium-grain American oak barrels and 238 $\mu$g/L for the French oak barrels, respectively. Subsequently, oxygen entry was monitored in each of the studied barrels for 3 weeks. Figure 3b shows the accumulated oxygen trends between 18 and 23 days for the 12 studied American and French oak barrels. The oxygen provided from the initial degassing of the wood, the joints between the staves (gaps), and the permeability to oxygen of the wood was greater in the medium- and fine-grain American oak barrels than in the French oak barrels.

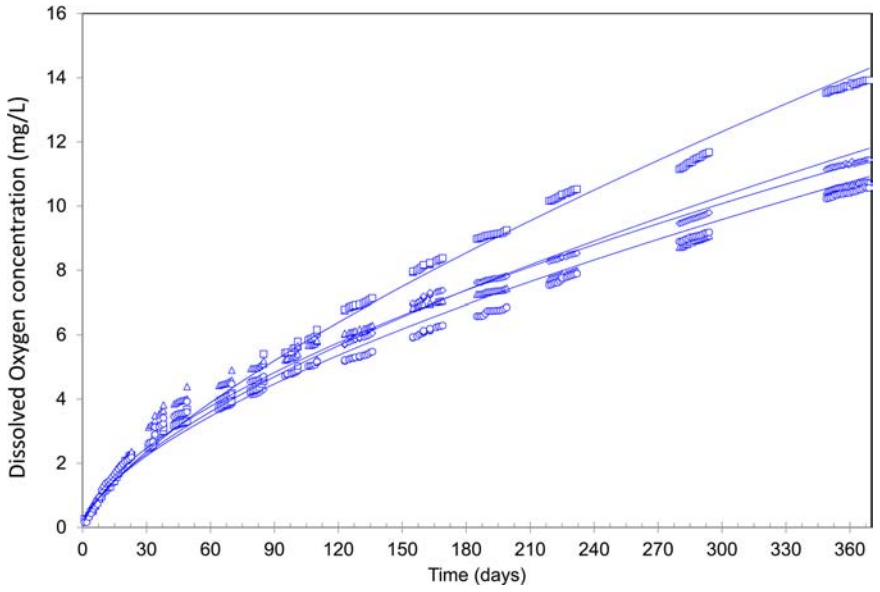

**Figure 4.** Fitted curves of the total dosed dissolved oxygen ($\mu$g/L) concentrations for 1 year in the four fine-grain American oak barrels.

Relative to the French oak barrels, these results indicated that the wine in the medium- and fine-grain American oak barrels would receive 30 and 10% more oxygen, respectively, during aging. This difference was maintained throughout the study. These differences were mainly explained by the initial contributions that resulted from wood degassing during the first few days. In addition, this result is easily explained by the different types of treatment that each type of oak receives in cooperage. American oak has a high rate of tyloses, which allows sawing the logs to obtain the staves without any leakage problems.[14,19] In contrast, French oak has a low rate of tyloses, which requires splitting the logs open into a series of sections (quarters), which are worked into staves by following the rays of the wood. The medullary rays in French oak are mainly parallel to the face of the stave in contact with the wine, which slows the wood degassing process. In contrast, sawing American oak does not guarantee parallel arrangement, which favors the release of air from the wood because the wine can access deeper layers of the staves. Tylosis itself facilitates this process because it is permeable to oxygen but not liquids.[19]

The oxygen entry trends were very similar for the analyzed barrels during the first few weeks of the experiment (Table 3). The kinetics of oxygen entry into the barrels with time followed the potential line $y = ax^b$. Here, $a$ is a constant that varies from 113 to 226 for medium-grain American barrels, from 122 to 180 for fine-grain American barrels, and from 98 to 201 for French barrels. In addition, $b$ represents the mathematical power of the aging time (ranging from 0.72 to 0.96 for medium-grain American barrels, from 0.79 to 0.96 for fine-grain American barrels, and from 0.65 to 0.91 for French barrels).

The regression equations that described oxygen entry in the 12 barrels followed a $t^{0.5}$ trend that was inverse to the equation defining wood impregnation[19] ($y = 0.63t^{-0.5}$). According to this author, liquid impregnation resembles a linear function of the square root of time during the first kinetics phase and is characteristic of liquid impregnation in wood. Subsequently, deceleration occurs because the wood is heterogeneous regarding stave thickness and consists of layers (early wood and late wood) of different thicknesses and characteristics.

The importance of wood moisture content for allowing oxygen permeation has already been evaluated by Vivas et al.[13] These authors showed that dry wood is 20−100 times more permeable to oxygen than wet wood. Other authors have emphasized the importance of wood moisture contents in the radial transport of oxygen in oak[21] and have highlighted how wood can be modeled as a porous solid in which the porosity is occupied by air when the wood is dry or below its fiber saturation point (FSP). However, these pore spaces are occupied by free water when the moisture content is greater than the FSP, which would decrease the oxygen permeability of the wood. These results are based on the diffusion coefficients of oxygen in air ($1.95 \times 10^{-5}$ m$^2$/s) and water ($2.0 \times 10^{-9}$ m$^2$/s) at 20 °C and 101.3 kPa.[20] Thus, $O_2$ diffusion is approximately $10^4$ times slower in water than in air. The movement of $O_2$ in water is extremely retarded by the interactions of $O_2$ with $H_2O$ molecules (hydrogen bonding).[22] The diffusion coefficient for oxygen in ethanol has been reported as $DO_2 = 2.64 \times 10^{-9}$ m$^2$/s at 303 K. At 293 K, the diffusion coefficient for oxygen in ethanol was estimated as $2.1 \times 10^{-9}$ m$^2$/s (by assuming that the diffusion coefficient for ethanol follows the same temperature dependence as the diffusion coefficient for water). This hypothesis was formulated because the temperature dependencies of the water and ethanol viscosities are nearly the same.[23]

Even though coopers assign importance to the type of grain, no significant differences were observed between the fine-grain and medium-grain American oak barrels. However, the fine-grain barrels provided more oxygen to the model wine during the first few hours as the wood degassed and began to moisten. This result agrees with the results described by Vivas et al.,[13] who found that fine-grain French oak (*Q. petraea*) was more permeable to oxygen than medium-grain French oak when analyzing small pieces of dry wood with varying thicknesses (2, 4, 8, and 12 mm). Here, the permeation of oxygen through the wood and the gaps was evaluated (i.e., the full barrel was analyzed). Consequently, the results were not maintained throughout this study, as previously described.[13] This observation potentially resulted from wetting the wood, which changed the oxygen permeability. In addition, the

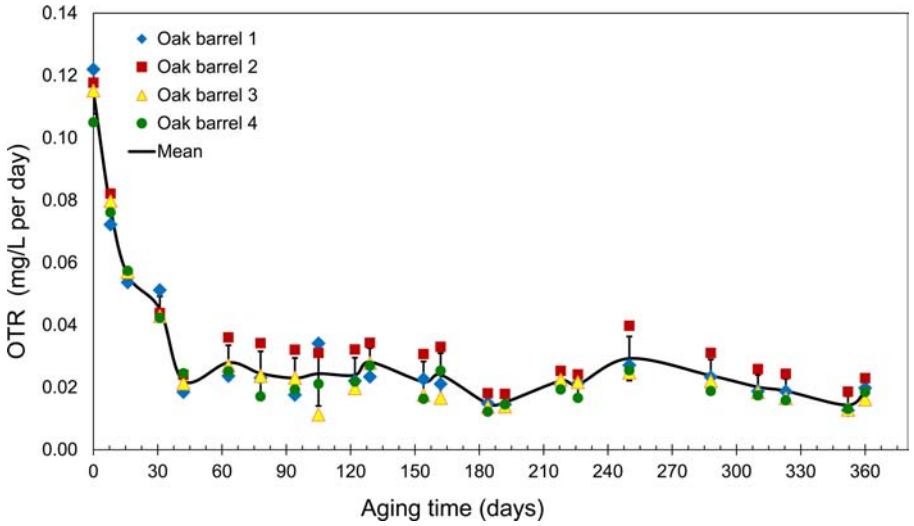

**Figure 5.** Oxygen transfer rate (mg/L per day) in the tested fine-grain American oak barrels.

entry of oxygen through the gaps is not the same in all barrels. Three weeks after filling the barrels, the medium-grain American oak barrels resulted in slightly higher average oxygen doses in the model wine relative to the oxygen doses observed in the fine-grain American oak barrels (Figure 3b).

**Annual Rate of Oxygen Entry into the Barrels.** The tests that were performed for the 12 barrels indicated that the oxygen supply decreases as the barrel is moistened. This phenomenon was mentioned previously and described by Sorz and Hietz.[21] These authors indicated that increases in wood moisture were responsible for the decreasing permeability of wood to oxygen because atmospheric oxygen diffuses better through dry wood.

To evaluate the overall rate of oxygen entry into moist oak barrels, the initial analysis was extended from 3 weeks (conducted for eight barrels) to 12 months in the remaining four barrels. In this experiment, aging was monitored for 1 year in the four fine-grain American oak barrels (B5, B6, B7, and B8) under the previously described conditions.

Figure 4 shows the evolution of the cumulative daily intake throughout the year, which was calculated by adding the oxygen contributions that were evaluated in successive tests for 12 months as described under Materials and Methods. Analysis of the cumulative daily intake for 12 months indicated that the observed trend during the first few weeks continued throughout the entire year of aging. In addition, the DO content decreased following the first 3−4 weeks.

Figure 4 shows the evolution of the accumulated oxygen that was dosed by each of the studied barrels throughout the year. The previously described equations correspond to the first few weeks and were modified by defining a constant $a$ that varied from 206 to 309 and a potential gaining time of $b$ that varied from 0.61 to 0.71. These results indicated that the actual rate of oxygenation per year is much lower than the rate that was estimated during the first weeks of testing. Therefore, it is important to test the evolution of oxygen entry kinetics for 1 year. Specifically, the daily average dose throughout the year was 32 $\mu$g/L (B5 = 31.1 $\mu$g/L, B6 = 38 $\mu$g/L, B7 = 30 $\mu$g/L, and B8 = 28.7 $\mu$g/L). Therefore, after the first month of aging, the fine-grain American oak barrels continued to provide the wine with between 28.7 and 38 $\mu$g/L oxygen daily for the remainder of the year. These levels can vary for different types of aged wine because precipitation, condensation, and the polymerization of phenols, salts, and other compounds in wine can block the wood and the gaps and decrease the rate of oxygen entry.[18] Prolonged barrel use progressively blocks the wall of the wood and diminishes the DO content.

According to these results, the total dose of oxygen that wine would receive in a fine-grain American oak barrel was calculated as 11.62 mg/L per year.

These results were significantly lower than the results that were published by other authors who measured oxygen entry into new barrels. For example, Riberau-Gayon[1] observed an oxygen entry rate of 15−20 mL/L per year, and Vivas and Glories[2] observed an oxygen entry rate of 20 mg/L per year in two new Limousin barrels from central France. In these studies, the sulfate formed from $SO_2$ in solution inside the barrel was evaluated at 6 months. Thus, these results did not assess the entire year of oxygen entry into the barrels. Instead, these results were obtained from theoretical approaches or were extrapolated from 6 months of aging data at different times of the year. The methodologies of these studies may explain the high rates of oxygen entry postulated by these authors when considering OTR as a constant rate with time and without considering the influences of the progressively increasing wood moisture contents with decreasing OTR.

The results obtained are also lower than those estimated by Kelly and Wolan.[5] These authors treated the wood as a semipermeable membrane that allowed for oxygen diffusion according to Fick's law. On the basis of their calculations, the maximum amount of oxygen that could enter a barrel is 26 mL/L per year. However, this approach is erroneous because wood is a porous membrane that does not always function the same. Specifically, the moisture content of wood can modify its properties and oxygen permeability.

On the basis of the annual dose results of oxygen in the four barrels in the third part of this study, the percentage of daily oxygen intake for each barrel was calculated relative to the oxygen that was supplied throughout the year (which is considered to be 100%). On average, the fine-grain American oak barrels supply wine with 7% of the total yearly oxygen within the first week. After a month, 23% of the total oxygen (B5 = 22.63%, B6 = 17.90%, B7 = 28.72%, and B8 = 25.06%) was supplied. Finally, 4 months (120 days) was required to

dose the wine with 50% of the total oxygen received in a year. These results suggest that adding wine to new barrels before the filling or development of young oak wine (which corresponds with maintaining these wines in new barrels for 2−4 months) reduces the potential for barrel oxygenation. For example, if barrels are used for 2−4 months for one batch of wine and are used for 9 months for a second batch of wine, the latter receives only 50% of the potential oxygen that these barrels would provide in a year.

Figure 5 shows the annual evolution of the daily measured oxygen permeability rates for the four fine-grain American oak barrels. The results show that the daily rate fell significantly in the first few months before stabilizing for the remainder of the year. In addition, a simple visual analysis indicates that a kinetics study is necessary to establish the annual rate of oxygen supply to wine in oak barrels.

These results can be used to extrapolate the behaviors and annual rate calculations for the other eight studied barrels between 19 and 24 days during the second phase of the study. After approximately 3 weeks, the oxygen received by the wine in a barrel represents 17−20% of the total oxygen that will be received in a year (observed in fine-grain American oak barrels and valid for medium-grain American and French oak barrels). Thus, these results could be extracted and the annual oxygen entry rates could be calculated for the barrels that were analyzed in phase 2. For the medium-grain American oak barrels, it took 19 days to dose B1 = 1.81 mg/L, B2 = 1.84 mg/L, B3 = 2.07 mg/L, and B4 = 2.10 mg/L with 17.3% of the total yearly oxygen dose. Therefore, these barrels would provide an average of 11.3 mg/L per year (B1 = 10.46 mg/L, B2 = 10.64 mg/L, B3 = 11.96 mg/L, and B4 = 12.14 mg/L) of oxygen to aged wine French oak barrels measured after 24 days (B9 = 1.61 mg/L, B10 = 1.63 mg/L, B11 = 1.59 mg/L, and B12 = 1.82 mg/L). Thus, the annual rate of supply for these barrels was 8.18 mg/L per year (B9 = 7.93 mg/L, B10 = 8.01 mg/L, B11 = 7.81 mg/L, and B12 = 8.97 mg/L per year).

In summary, this paper was the first to analyze the kinetics of oak barrel oxygen permeability for 1 year to establish the kinetics of the annual OTR of a barrel. The results of this study indicated that the American oak barrels resulted in greater oxygen doses than the French oak barrels. In addition, different wood grains (fine and medium) did not significantly affect the oxygenation rates of the barrels.

## MATERIALS AND METHODS

**Materials.** BC (≥97.0%, UV), β-lactoglobulin, dextran (MW 69800), FITC−dextran (MW 4000), pepsin, and trypsin were purchased from Sigma-Aldrich (St. Louis, MO, USA). Transwell permeable supports (polycarbonate membrane, pore size = 0.4 μm, area = 4.2 $cm^2$) were obtained from Millipore Corp. (Billerica, MA, USA). Dulbecco's modified Eagle's medium (DMEM) (containing 4.5 g/L D-glucose and GlutaMAX), penicillin and streptomycin (100×), fetal bovine serum (FBS), TrypLE Select, Hanks' balanced salt solution (HBSS), and phosphate buffer solution (PBS) (10×) were purchased from GIBCO (Grand Island, NY, USA). The human colon carcinoma cell lines (Caco-2 cells, ATCC, Manassas, VA, USA) were grown in DMEM. Cells after 100−120 passages were used for this study. All other chemicals and reagents used were of HPLC grade and obtained from Sigma-Aldrich. Ultrapure water (18 mΩ) was supplied by a Milli-Q apparatus (Millipore Corp.).

**Methods.** *Preparation of Glycation Conjugates.* BLG−dextran conjugates were prepared according to the method published by Liu et al. with minor changes.[13] Solutions containing 1% BLG and 1% dextran were hydrated overnight in ultrapure water. The solutions were adjusted to pH 7 and lyophilized. The powders were incubated for 24, 48, and 72 h, respectively, at 60 °C and 79% relative humidity in an incubator to produce the glycated dextran. The samples were then collected and stored at −20 °C for further use.

*Characterization of Maillard-Based Conjugates. (a) Sodium Dodecyl Sulfate−Polyacrylamide Gel Electrophoresis (SDS-PAGE).* A 4−20% gradient polyacrylamide gel was prepared in-house for SDS-PAGE. Five microliters of sample (protein content = 5 mg/mL) was mixed with 5 μL of ultrapure water and 10 μL of 2× SDS sample buffer (100 mM Tris-HCl, pH 6.8, 4% SDS, 0.2% bromophenol blue, 20% glycerol, and 200 mM 2-mercaptoethanol) and then heated for 5 min at 95 °C. Fifteen microliters of each sample was loaded to a designated well for electrophoresis at 120 V with a Tris−HEPES−SDS running buffer (100 mM Tris, 100 mM HEPES, 3 mM SDS, pH 8.0). The gel was stained using the Colloidal Coomassie G-250 Staining protocol.[14] The stained gel was scanned with an ImageQuant LAS 4000digital imaging system (GE Healthcare, Piscataway, NJ, USA). EZ-Run Rec protein ladder (10−200 kDa) was obtained from Fisher BioReagents.

*(b) Circular Dichroism (CD).* A J-815 CD spectrometer (Jasco, Tokyo, Japan) was used to analyze the conformational changes of the protein after glycation in the wavelength range of 195−260 nm using a cell with a 2.0 mm path length. Samples were prepared with 10 mM PB (pH 7.0) at a protein concentration of 0.2 mg/mL. Scanning was performed at 50 nm/min at 20 °C. CD spectra were collected 10 times for each sample and displayed as mean residue ellipicity (degrees·$cm^2$/dmol) using 113 for the average number of amino acid residues per molecule of BLG.

*(c) Degree of Glycation (DG).* The DG was determined from the analysis of the free amino groups in BLG and conjugates. The level of free amino groups in the BLG−dextran conjugates was determined according to the trinitrobenzenesulfonic acid (TNBS) method.[8] In brief, BLG and conjugates dispersions (protein content = 1.0%, w/w) were prepared in 50 mM phosphate buffer (pH 8.5) containing 50 mM NaCl. One milliliter of a 0.1% (w/v) TNBS solution was thoroughly mixed with 1 mL of protein dispersion, and the resultant mixtures were incubated in a 50 °C water bath for 2 h in the dark and then cooled to room temperature. One milliliter of 10% SDS and 0.5 mL of 1.0 M HCl were added to the protein mixtures. The absorbance was measured at 335 nm. The degree of glycation was determined as

$$\mathrm{DG}\ (\%) = ((A_0 - A_s)/A_0) \times 100\%$$

where $A_0$ is the absorbance of the sample without glycation and $A_s$ is the absorbance of the sample after glycation.

*BC-Loaded Nanoparticle Preparation.* Native BLG or the 72 h glycated BLG−dextran was dispersed (1.0%, w/w) in ultrapure water at pH 7.0 containing 0.02 wt % sodium azide as antimicrobial agent. The dispersions were stirred for 2 h at room temperature, and then 0.1% BC (w/w) solutions were prepared in ethyl acetate. BC-loaded nanoparticles were prepared according to the method described by Tan and Nakajima[15] with minor changes. Water (100 mL) was saturated with 8.3 g of ethyl acetate[16] prior to formulating the protein solution to prevent precipitation of BC during homogenization. The BC in ethyl acetate solution was combined with the ethyl acetate saturated protein solution at a ratio of 1:9. The mixtures were homogenized for 10 min at 8000 rpm using an Ultra-Turrax homogenizer (T25, Ika-Werke, Staufen, Germany) to form a coarse emulsion before additional homogenization using a two-stage valve homogenizer (APV-1000 high-pressure homogenizer, Wilmington, MA, USA) for one cycle at 70 MPa. After the homogenization, ethyl acetate was removed from the emulsions on a rotary evaporator at 40 °C. The residual ethyl acetate was determined by headspace gas chromatography and found to be <0.001% (data not shown).

*Nanoparticle Characterization.* The characteristics of BC-loaded nanoparticle solutions were determined by measuring the mean particle diameter, diameter distribution, and ζ-potential of nanoparticles by dynamic light scattering technique using a Malvern Zetasizer (Nano-ZS; Malvern Instruments, Worcestershire, UK). Refractive indices of 1.47 for BC and 1.33 for ultrapure water were used. To reduce multiple scattering effects, the nanoparticle dispersions were diluted 100 times with ultrapure water and the pH was adjusted to 7.0 prior to acquiring triplicate measurements.

The BC contents of the nanoparticles were determined by HPLC. The content of free BC suspended in aqueous phase was extracted with *n*-hexane. The total BC in aqueous phase was obtained by demulsification−extraction with ethanol and *n*-hexane. The BC content in nanoparticles was obtained by subtracting free BC from total BC. The encapsulation efficiency (EE) and the loading capacity (LC) were calculated using the following equations:

$$\mathrm{EE} = \text{BC quantity encapsulated in nanoparticles} / \text{BC quantity in total nanoparticles solution} \times 100\%$$

$$\mathrm{LC} = \text{BC quantity encapsulated in nanoparticles} / \text{quantity of total nanoparticles} \times 100\%$$

*Transmission Electron Microscopy (TEM).* TEM was used to observe the shape of the formed nanoparticles and to confirm diameter by dynamic light scattering. Samples were prepared by the conventional negative-staining method. Nanoparticles were placed on copper grids and negatively stained with 2% (w/v) phosphotungstic acid for several minutes at room temperature. Grids bearing nanoparticles were analyzed with a Hitachi H-700 transmission electron microscope (Hitachi, Tokyo, Japan).

*Stability in Different pH Condition.* The influence of pH on the mean particle diameter of nanoparticles was evaluated. The pH of nanoparticle solutions was adjusted with HCl or NaOH from pH 2.0 to 7.0, and the prepared samples were kept for 4 h at room temperature before particle characterization analysis. The mean particle diameter, diameter distribution, and ζ-potential of nanoparticles by dynamic light scattering technique using a Malvern Zetasizer were determined as described previously.

*Release of BC-Loaded Nanoparticles in Vitro.* Two proteases were used to study the release of BC-loaded nanoparticles in vitro to simulate gastric and intestinal digestive environments. The gastric stage digestion was simulated by suspending 2 mg/mL of BC nanoparticle powder in 0.1 M HCl, adjusting to pH 2, and treating with pepsin solution (pH 2.0, 1 mg/mL) while stirring at 250 rpm at 37 °C. An aliquot of reactant was removed, and the hydrolysis was terminated by adjusting the pH at several time intervals during 120 min of digestion time. The released BC was extracted with *n*-hexane. The BC content was determined by the HPLC method described below. The intestinal protein hydrolysis was simulated by trypsin digestion in 0.1 M PBS (pH 7.0, 1 mg/mL) at 37 °C.

*MTT Cytotoxicity Assay.* Cell viability after treatment with BLG or BLG−dextran nanoparticles was determined by the MTT (3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide) assay. The MTT assay measures the activity of cellular enzymes by the reduction

of MTT to its insoluble purple formazan form.[1] Caco-2 cells were incubated in DMEM containing 10% FBS, 1× nonessential amino acid (NAA), and 1× penicillin and streptomycin. Caco-2 cells in DMEM were seeded at a density of $1.2 \times 10^5$ cells/well onto tissue-treated 96-well plates and incubated (Sanyo, Osaka, Japan) at 37 °C in an atmosphere of 95% humidified air−5% $CO_2$. After 2 days of incubation, the medium was discharged, and 100 μL of BC-loaded nanoparticles diluted with DMEM at different protein concentrations (0.1−10.0 mg $mL^{-1}$) was added to the wells. After 24 h of incubation at 37 °C, the nanoparticles containing medium were replaced with 100 μL of DMEM containing MTT (10 μL, 5 mg $mL^{-1}$ in 1× PBS, pH 7.2) and incubated for 2 h at 37 °C. Finally, the supernatant was removed and 100 μL of dimethyl sulfoxide (DMSO) added. The absorbance of each well was measured with a Multilabel microplate counter (Victor$^3$, PerkinElmer, Waltham, MA, USA) at 570 nm. Cell viability was calculated by the percentage of absorbance relative to control (treated with DMEM only).

*Caco-2 Cell Monolayer Incubation.* Caco-2 cells were incubated (Sanyo) in DMEM containing 10% FBS, 1× nonessential amino acid (NAA), and 1× penicillin and streptomycin at 37 °C in an atmosphere of 95% humidified air and 5% $CO_2$ onto transwell permeable supports (Millipore), with membrane area of 4.2 $cm^2$, in 6-well plates. Caco-2 cells were seeded at a density of $1.2 \times 10^5$ cells $well^{-1}$. The medium was changed every second day. Transport experiments were performed at 21−28 days. Before BC transport experiment, both the trans-epithelial electrical resistance (TER) value and the apparent permeation rate of the paracellular permeation marker ($P_{app}$, FITC−dextran) were measured to ensure the integrity of Caco-2 cell monolayers. In this study, after 3 weeks of incubation, the TER was measured with an Evohm2 epithelial voltmeter (World Precision Instruments, Sarasota, FL, USA) and was >350 Ω $cm^2$; the $P_{app}$ of 1 mg/mL FITC−dextran detected with a Multilabel microplate counter (Victor$^3$, PerkinElmer) at an excitation wavelength of 487 nm and an emission of 518 nm was $(4.3 \pm 1.1) \times 10^{-8}$ cm $s^{-1}$. Both the TER, which was higher than reported values (260 ± 65 Ω $cm^2$),[17] and $P_{app}$, which was lower than reported values, indicated that the Caco-2 cell monolayers were confluent and suitable for permeation study.

*BC Transport with Caco-2 Monolayers.* The Caco-2 monolayers were washed with DMEM three times. Both BLG and BLG−dextran conjugate-encapsulated BC nanoparticles were diluted in DMEM to a final BC concentration of 20 μg $mL^{-1}$. Free BC in THF/DMSO (1:1, v/v) after dilution in DMEM (20 μg $mL^{-1}$) was used as control. One and a half milliliters of the BC-encapsulated nanoparticle and control solution was added to separate inserts. The medium in the basal side was sampled at several time intervals, extracted with solvent, and analyzed for BC content by HPLC (procedure given below).

The TER was also measured at several time intervals (0, 0.5, 1, 2, 3, and 4 h) to measure the integrity of Caco-2 monolayers.

The apparent permeability coefficient ($P_{app}$, cm $s^{-1}$) was calculated using the equation

$$P_{app} = (dQ/dt)(1/(AC_0))$$

where $dQ/dt$ is the permeability rate (μg $s^{-1}$), $A$ is the surface area of the filter ($cm^2$), and $C_0$ is the initial concentration in the donor chamber (μg $mL^{-1}$).

*Extraction and Quantification of BC.* BC was extracted from the nanoparticles with 3 mL of ethanol/*n*-hexane (1:2, v/v) three times. The hexane extracts were combined and brought up to 10 mL for HPLC analysis. Five microliters of 5 μg/mL *trans*-β-apo-8′-carotenal (internal standard) in ethanol was added to 1.0 mL samples. The transport samples (1.0 mL) were extracted three times with 3 mL of ethanol/*n*-hexane (1:2, v/v). Organic fractions were removed and combined with transfer pipets, and the extract was dried under a stream of nitrogen gas at 40 °C. The BC extract was dissolved in 0.1 mL of methanol/dichloromethane (1:1, v/v) containing 0.1% BHT for HPLC analysis. The recovery of *trans*-β-apo-8′-carotenal was >94%.

HPLC quantification of BC was performed using an Agilent 1100 HPLC system with a DAD UV−vis absorption detector (Agilent, Santa Clara, CA, USA), according to the published method.[2] BC quantitation range (0.1−100 ug $mL^{-1}$) was established for HPLC analysis of BC in nanoparticles and in Caco-2 cell transport. A polymeric $C_{30}$ reverse-phase analytical column (250 × 4.6 mm i.d., 5 μm, YMC, Inc., Wilmington, NC, USA) was used to separate BC with a flow rate of 1 mL $min^{-1}$ at room temperature. The guard column was a reverse-phase $C_{18}$ column (50 × 3.0 mm i.d., 5 μm, YMC, Inc.). The injection volume was 20 μL, and the detection wavelength was 450 nm. The chromatography conditions were as follows: solvent A, methanol/acetonitrile/$H_2O$ (84:14:2, v/v/v); solvent B, dichloromethane. The solvent gradient program was 80% A/20% B at 0 min and was changed linearly to 45% A/55% B in 15 min, maintained for 5 min, and followed by a linear return to 80% A/20% B at 25 min.

*Statistics.* All experiments were performed at least three times and were reported as the mean ± standard deviation. The data were analyzed by analysis of variance (ANOVA) using the SPSS 17.0 package (IBM, Armonk, NY, USA). Duncan's multiple-range test was used to determine significant differences of the mean values ($P < 0.05$).

## RESULTS AND DISCUSSION

**BLG Glycation.** *SDS-PAGE.* The characterization of BLG glycation products was determined by SDS-PAGE. The bands corresponding to native BLG, BLG glycation with dextran for 24, 48, and 72 h, and BLG heated for 72 h under reducing conditions are shown in Figure 1. One obvious band

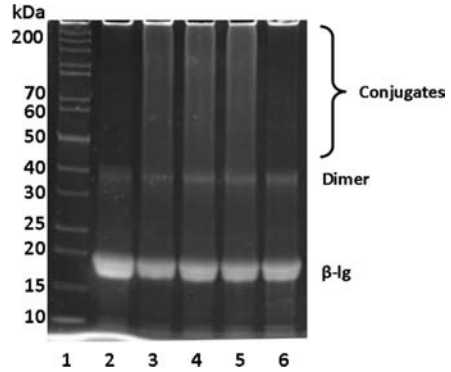

**Figure 1.** SDS-PAGE analysis under reducing conditions of BLG and BLG−dextran conjugates. Lanes: 1, protein markers; 2, native BLG; 3, 4, and 5, BLG−dextran conjugates treated by glycation for 24, 48, and 72 h, respectively; 6, BLG treated for 72 h (control).

corresponding to BLG was found at about 18 kDa.[18] Small amounts of BLG dimers are observed at about 40 kDa. There appears to be a slight decrease in intensity of the BLG band after heating for 72 h (control), but no absorption in the 40−200 kDa range. After glycation with dextran for 24, 48, and 72 h, smeared zones were formed between 50 and 200 kDa. Dextran-glycated ovalbumin[19] show similar smeared zones. Carbohydrate staining but not protein staining confirmed glycation by SDS-PAGE of gelatin.[20] In this study the smeared zone densities appear to become more intense with increasing treatment time (from 24 to 72 h), suggesting that more conjugates were formed. The TNBS assay shows that the extent of glycation increased from 6.7 to 14.5% with increasing treatment time (from 24 to 72 h) (Table 1). The SDS-PAGE and TNBS results confirm that BLG−dextran conjugates were formed by dry-heating.

*CD.* Changes in the secondary structure of BLG after glycation by the much larger dextran molecule were determined by far-UV CD spectroscopy (Figure 2). The negative peak at 216 nm indicates that BLG is rich in β-sheet secondary

**Table 1. Degree of Glycation of BLG and the Conjugates**

| sample | degree of glycation (%) |
|---|---|
| BLG native | 0 |
| BLG−dextran conjugates (24 h) | 6.7 ± 1.5 |
| BLG−dextran conjugates (48 h) | 9.4 ± 2.0 |
| BLG−dextran conjugates (72 h) | 14.5 ± 1.7 |
| BLG control | 0 |

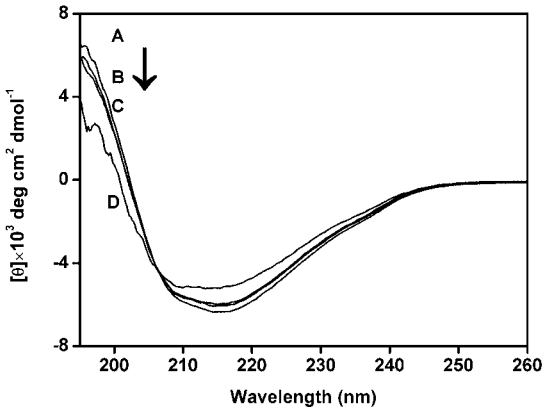

**Figure 2.** Far-UV CD spectra (195−260 nm) of BLG native (A) and BLG−dextran conjugates treated by glycation for 24 h (B), 48 h (C), and 72 h (D).

structure.[21] The mean residue ellipticity was decreased slightly by 72 h of Maillard-based reaction (Figure 2). The secondary structure composition of native BLG and BLG−dextran conjugates was calculated according to DichroWeb online (Table 2). The composition of native BLG in this study was α-helix, 9.3%; β-sheet, 39.5%; turn, 22.5%; and unordered, 27%; whereas BLG was reported to have 15% α-helix, 50% β-sheet, and 15−20% reverse turn.[22] The differences may be due to the different sources of BLG and different curve fitting analysis programs.[23] SELCON3 was used in this study. After glycation, the α-helix and β-sheet structure increased, whereas the turn and unordered structure slightly decreased. The highly ordered structure content (α-helix + β-sheet) was increased slightly by 4.5, 4.1, and 2.9%, corresponding to 24, 48, and 72 h of incubation time, compared to native BLG. Levels of 40−75% glycosylation of kidney bean vicilin with glucose by large molar excess of glucose resulted in marked shifts in wavelength and ellipticity in the CD spectra.[24] However, no significant change of secondary structure compositions was reported by Enomoto et al. after glycation with maltopentaose and phosphorylation with pyrophosphate.[21] In this study the small changes may be due to the low degree of glycosylation.[24]

**Table 2. Secondary Structure Composition of Native BLG and BLG−Dextran Conjugates[a]**

| sample | incubation time (h) | α-helix (%) | β-sheet (%) | turns (%) | unordered (%) |
|---|---|---|---|---|---|
| native BLG | | 9.3 | 39.5 | 22.5 | 27 |
| BLG−dextran | 24 | 11 | 40 | 21.7 | 26 |
| BLG−dextran | 48 | 10.6 | 40.2 | 21.4 | 25.8 |
| BLG−dextran | 72 | 10.1 | 40.1 | 21.1 | 26.2 |

[a]The secondary structure composition was calculated from far-UV CD spectra data using DichroWeb online (http://dichroweb.cryst.bbk.ac.uk/html/home.shtml).

*Characterization of BC Nanoparticles.* BC-loaded nanoparticles were encapsulated with native BLG and BLG−dextran conjugates (72 h) (the conjugates used below were all conjugates after 72 h of incubation) by the homogenization−evaporation method.[1] The characteristics of both nanoparticles are shown in Table 3. There were no significant differences in particle diameter. The unimodal particle diameter distributions of BLG and BLG−dextran-conjugated nanoparticles are shown in Figure 3. Both polydispersity index (PDI) values were below 0.200, indicating a narrow particle size distribution. The BC nanoparticles were spherically shaped, approximately 50 nm in diameter, confirming light scattering results, and uniformly dispersed (Figure 3). Although similar in diameter, the BC nanoparticles' ζ-potential values were different. Glycation with dextran significantly decreased the apparent ζ-potential from −32.9 ± 0.8 mV for native BLG to −14.0 ± 0.7 mV for BLG−dextran ($P < 0.05$). Although only a fraction (∼15%) of the BLG was glycated, Lesmes and McClements have suggested that steric barriers may screen the positively charged surface from the continuous phase.[12] The encapsulation efficiency of BC was 98.6 and 98.4% for native BLG and BLG−dextran conjugates, respectively, and the loading capacity was 1.07 and

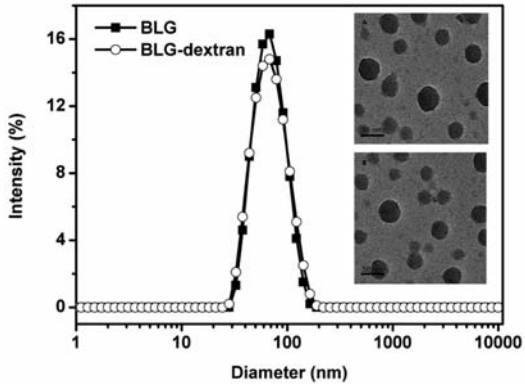

**Figure 3.** Particle diameter distributions of BLG and BLG−dextran conjugate (72 h)-encapsulated BC loaded nanoparticles (1.0% protein content, w/w) and (inset) transmission electron micrographs of BC-loaded nanoparticles prepared with BLG (A) and BLG−dextran conjugates (B), respectively, at a final protein concentration of 1% (w/w). Scale bar indicates 50 nm.

**Table 3. Mean Particle Diameter (Z-Average), Polydispersity Index (PDI), ζ-Potential, Loading Efficiency, and Loading Capacity of BC-Encapsulated BLG and BLG−Dextran (72 h) Nanoparticles[a]**

| nanoparticle | Z-average (nm) | PDI | ζ-potential | encapsulation efficiency (%) | loading capacity (%) |
|---|---|---|---|---|---|
| BLG | 66.6 ± 1.2 | 0.178 ± 0.035 | −32.9 ± 0.8 | 98.6 ± 1.0 | 1.07 ± 0.02 |
| BLG−dextran | 68.2 ± 2.9 | 0.171 ± 0.034 | −14.0 ± 0.7 | 98.4 ± 1.2 | 1.06 ± 0.03 |

[a]Data are expressed as the mean ± STD.

1.06% for native BLG and BLG−dextran conjugate, respectively.

*pH Stability against Aggregation.* Protein-based nanoparticles may flocculate or aggregate around their isoelectric point,[12,25−27] leading to increased particle size[28] and restricting their application in food systems, especially in mildly acidic beverages, such as juice, yogurt, and functional beverages. The glycation of lysine groups by the Maillard reaction to reduce the number of basic groups and increase steric hindrance by the use of large carbohydrates was used to overcome this problem. In this study, both native BLG and BLG−dextran conjugate-based BC nanoparticles were exposed to pH 2−7 (Figure 4). The

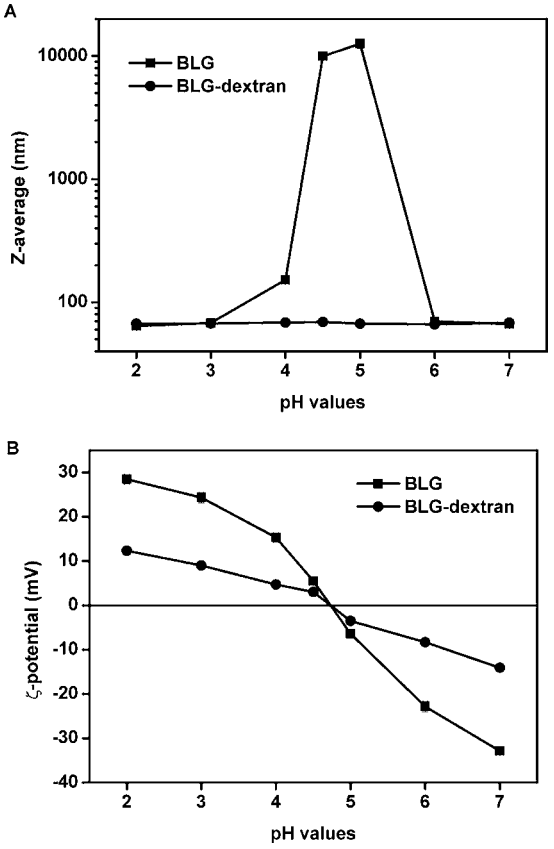

**Figure 4.** Effects of pH (2.0−7.0) on mean particle diameter (A) and ζ-potential (B) of BC-loaded nanoparticles stabilized by native BLG or BLG−dextran conjugates.

diameters of native BLG nanoparticles were stable at pH 2.0−3.0 and 6.0−7.0, but the particle diameters increased significantly to 152, 9964, and 12619 nm for pH 4.0−5.0 (Figure 4A). The large particle size about the isoelectric point suggests that the nanoparticles were strongly flocculated. Nanoparticles encapsulated by BLG−dextran conjugates did not show changes in particle diameter under the same pH conditions. The lack of aggregation and ζ-potential data support the role of steric hindrance by dextran at the interface to prevent nanoparticle flocculation or aggregation and separation of the protein surface from the continuous media.[12,19,27]

*BC Release during in Vitro Digestion.* As shown in Figure 5A, after 120 min of digestion by pepsin at pH 2.0, 6.2 and 5.4% of BC were released from BLG and BLG−dextran nanoparticles, respectively. Native BLG is resistant to proteolysis by pepsin at pH 2.0[6,29] because the peptic cleavage

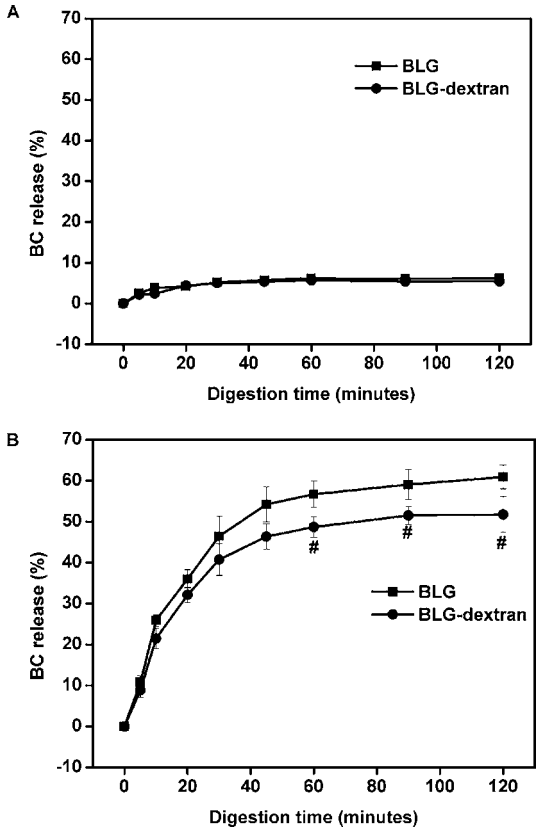

**Figure 5.** In vitro release of BC in nanoparticles encapsulated with native BLG or BLG−dextran conjugates treated with pepsin (1.0 mg/mL) and trypsin (1.0 mg/mL) at simulated gastrointestinal juice (A, pepsin at pH 2.0; B, trypsin at pH 7.0). (#) Significant ($P < 0.05$) difference.

sites are in the interior of the protein and inaccessible for hydrolysis.

BC-loaded nanoparticles were digested with trypsin (Figure 5B). Note that chymotrypsin was not used in intestinal digestion. It is possible that the combined use of trypsin−chymotrypsin could change the release rate of BC encapsulated either in BLG or BLG−dextran nanoparticles. The release of BC from native BLG nanoparticles was relatively rapid during the first 30 min, and 46.4% BC was released, whereas only 40.7% was released for BLG−dexran conjugates, suggesting BC release was prevented by glycation. After 120 min of trypsin digestion, 60.9 and 51.8% BC were released from native BLG nanoparticles and BLG−dextran nanoparticles ($P < 0.05$), respectively (Figure 5B). There are at least two possible explanations. First, the proteolysis of glycated Lys and Arg residues of BLG was largely reduced.[9,29,30] Alternatively, glycation by the large dextran used in this study sterically hindered access of the enzyme to the BLG at the surface of the nanoparticles.[12,31]

*Cell Toxicity of BC-Loaded Nanoparticles.* The viability of Caco-2 cells treated with BC-loaded nanoparticles was evaluated after the MTT assay as previously described (Figure 6).[1] The cell viability after treatment with native BLG-based nanoparticles, at protein contents of 5 and 10 mg/mL, was greater than 98 and 91 ± 2%, respectively, indicating that native BLG-based nanoparticles were nontoxic and biocompatible.

There are concerns about the health risks and benefits of the intake of Maillard reaction or glycation products.[32,33] The

dx.doi.org/10.1021/jf502639k | J. Agric. Food Chem. 2014, 62, 8900−8907

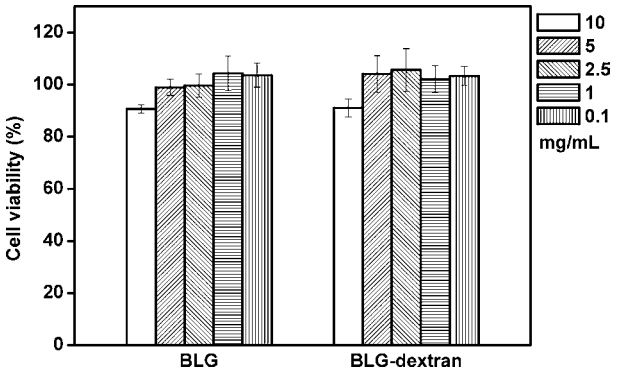

**Figure 6.** In vitro cytotoxicity of BC-loaded nanoparticles encapsulated with native BLG or BLG−dextran conjugates at different protein concentrations on Caco-2 cells measured by MTT assay. Cell viability is expressed as the mean ± STD ($n$ = 3).

results of the MTT cell viability assay of Maillard-based conjugate nanoparticles were similar to that of native BLG-based nanoparticles even at 10 mg/mL (91 ± 3%), indicating that glycation did not induce toxicity. The results above clearly showed both native BLG and BLG−dextran conjugate-based nanoparticles are safe and may be useful for BC carriers.

*Transport in Caco-2 Cells.* The uptake of lipophilic carotenoids was studied in Caco-2 cell monolayers, a model for intestinal absorption.[34−36] Caco-2 monolayers were grown to confluence, and there were no differences in TER in cells treated with free BC or BC-loaded nanoparticles (data not shown). The transport of BC into the cells was proportional to the incubation time (Figure 7A). The cumulative transport, $P_{app}$, of free BC (control, suspended in THF/DMSO) was (2.3 ± 0.5) × $10^{-7}$, whereas $P_{app}$ values for native BLG and BLG−dextran conjugate nanoparticles were (3.5 ± 0.3) × $10^{-6}$ and (3.4 ± 0.3) × $10^{-6}$, respectively ($P$ < 0.05) (Figure 7B). Compared to free BC (control), the $P_{app}$ was significantly increased by 15.4- and 14.5-fold for native BLG and BLG−dextran conjugates, respectively. The results showed that the bioavailability of carotenoids can be significantly improved by nanoencapsulation with proteins. The cellular uptake of nanoparticles is believed to occur by endocytosis. There were three main endocytic pathways: clathrin-mediated endocytosis, lipid raft/caveolae-mediated endocytosis, and macropinocytosis.[37,38] Conner et al. suggested that nanoparticles with mean diameters between 60 and 70 nm were mainly transported through lipid raft/caveolae-mediated endocytosis.[37] After internalization, the BC nanoparticles are then intracellularly transported from endosome to lysosomes. Nanoparticles were excreted from lysosomes to basolateral compartments by exocytosis.[39,40] According to a recently published paper, Golgi was involved in the nanoparticle exocytosis.[38] There were no differences in the permeability rate between native BLG and BLG−dextran conjugates ($P$ > 0.05), which indicated that polysaccharide molecules on the surface of nanoparticles had no adverse effects on bioavailability.

In conclusion, we prepared BLG glycated to very large dextran molecules. Although only about 15% of the BLG was glycated, agglomeration and ζ-potential were consistent with steric hindrance. BLG−dextran conjugated nanoparticles improved the stability in simulated gastrointestinal environment around the isoelectric point (pH 4.0−5.0) to control the release of encapsulated BC. Neither native BLG nor BLG−dextran-conjugated nanoparticles affected Caco-2 cell viability.

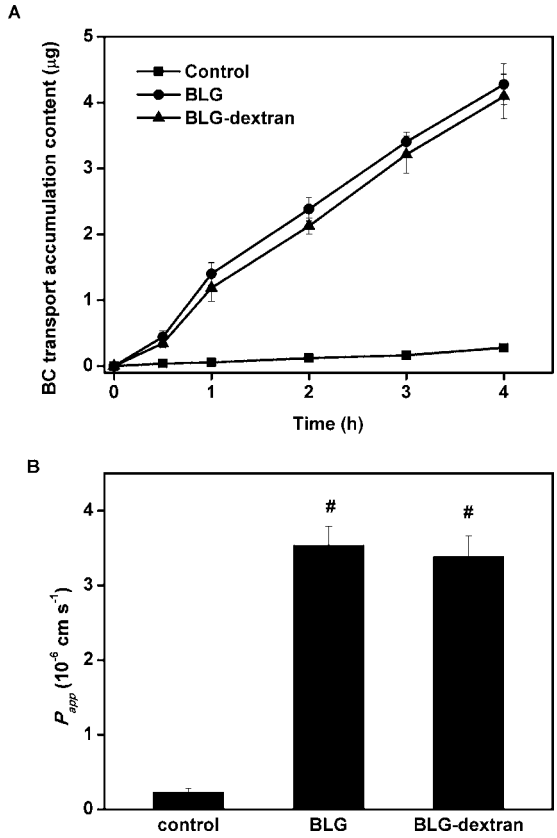

**Figure 7.** Accumulation transport (A) and apparent permeability coefficient ($P_{app}$) (B) of BC by Caco-2 cell monolayers incubated with BC THF/DMSO suspension, native BLG-stabilized BC-loaded nanoparticles, and BLG−dextran conjugate-stabilized BC-loaded nanoparticles at a BC concentration of 20 μg/mL. Values are expressed as the mean ± STD ($n$ = 3). (#) Significant ($P$ < 0.05) difference.

Transport of BC by BLG and BLG−dextran-conjugated nanoparticles increased about 15 times compared to that of free BC. The results found in this study can be used in better designing carotenoid delivery systems.

body weight (bw) per day. The toxin was also evaluated by the Scientific Committee on Food, which proposed that exposure should be below 5 ng/kg (bw) per day.[21] The Joint FAO/WHO Expert Committee for Food Additives (JECFA) reconfirmed the provisional tolerable weekly intake (PTWI) of OTA as 100 ng $kg^{-1}$ $week^{-1}$.[22] At present, the International Office of Vine and Wine (OIV) is considering the application of a limit of 2 μg/kg OTA for wine;[23] however, there is no regulation or limit standards with respect to OTA in wine from China currently. In 2013, Zhang et al.[24] analyzed a total of 119 wines, which were obtained from four major regions around China from 1999 to 2009; the OTA levels ranged from <0.1 to 5.65 μg/L, with an average concentration of 2.18 μg/L. However, other results showed the OTA content of Chinese wine at levels of 0−0.94 μg/kg ($n$ = 100) and 0.02−1.18 μg/L ($n$ = 105),[11,25] far below the research of Zhang. Among the reasons for the difference, sample mode, sample types, and determination method were the main factors. Therefore, the OTA level of Chinese wine should be further generally surveyed and analyzed with a reasonable sampling scheme and accurate determination method.

As an important factor, very sensitive analytical methods for OTA detection are needed. The most common analytical method for OTA determination in foodstuff is HPLC coupled to fluorescence detection.[26,27] Other methods, such as photodiode array detection (LC-DAD)[28] or mass spectrometry (LC-MS) and tandem MS (LC-MS/MS),[29] have also been established. Alternative applied techniques are thin layer chromatography (TLC),[30] gas chromatography coupled with MS (GC-MS),[31] and fluorescence polarization immunoassay.[32] Also, capillary electrophoresis (CE) with UV−vis detection has also been proposed for the determination of OTA in wine.[33] As for the sample preparation, more extraction and cleanup methods for the determination of OTA have been reported. Most of them are based on immunoaffinity columns (IACs) to higher cleanup and sample purification. However, this methodology is high-cost and tedious. Solid-phase extraction (SPE),[26] liquid−liquid extraction (LLE),[34] and SPE with molecular imprinted polymers (MISPE) in different matrices,[35] have been also used for the determination of OTA. The stability of OTA during its extraction using microwave-assisted extraction (MAE), PLE, ultrasound-assisted and magnetic stirring-assisted extraction,[36] and dispersive liquid−liquid microextraction (DLLME)[37] has also been evaluated in the determination of OTA in wine.

In the present study, OTA contents were analyzed from a large number of Chinese wine samples, which were from the main producing areas and different production years and varieties, using the SPE method in combination with HPLC-FLD (better resolution, lower detection limits, and lower solvent consumption). Then, OTA exposure assessment of Chinese wine consumers was analyzed with a point evaluation model based on a wine consumption survey in China, which was also in great accordance with the literature,[11,20] and by the daily intake (DI) of OTA from the wine consumption data provided by the invited participants to the comparison of the DI of OTA from analysis of the wine consumption data. Although maximum limits of OTA content have been applied to some foods, no limit or regulation currently exists for OTA in Chinese wines so far. The results of this study will provide essential data for establishing the maximum limit of OTA in Chinese wine.

## MATERIALS AND METHODS

**Samples.** A total of 223 samples were obtained from wine manufacturers of the major wine-producing areas of China: Shandong, Hebei, Tianjin, Beijing, Xinjiang, Gansu, and Yunnan (all of Chinese wine in circulation was manufactured in these areas). The samples include 183 red wines and 40 white wines. All samples have different origins, years, cultivars, and types, which can represent the real status of Chinese wine sufficiently.

**Chemicals.** Acetonitrile, methanol, methanoic acid, and other chemical reagents were all of HPLC grade and were supplied by Merck (Darmstadt, Germany). The standard of OTA (≥98% (HPLC) was also purchased from Sigma. Analytically pure phosphoric acid and potassium hydroxide were also used, and double-distilled water was used in all experiments. Stock standard solutions of 100 mg/mL OTA were prepared in methanol. Working standard solutions were prepared daily by diluting the stock solution with methanol/water (98:2, v/v). All working standard solutions were stored at 4 °C in the dark. Anion-exchange SPE columns (150 mg/mL Agela Technologies, China) were used for cleanup.

Extract solutions were prepared from 0.1 M KOH/ethanol/water (2:60:38, v/v/v). The concentrations of potassium hydroxide solution used were 10 and 0.1 M, respectively.

**Apparatus.** Purification and determination of the preconcentration of OTA prior to quantitative analyses were performed using the Waters 2695 HPLC (Waters, Milford, MA, USA) and the Waters 2475 FLD. Chromatography software (Empower; Waters) was used to collect and process the chromatographic data. Separation was performed on a C18 analytical column (5 μm, 250 × 4.6 mm, Waters, Atlantis T3).

**Sample Pretreatment.** The anion-exchange SPE column was used for cleanup following this procedure: First, 6 mL of extract solution was added into 10 mL of sample, which was shaken in a vortex device and then adjusted to pH 8−9 with 10 mol/L potassium hydroxide solution. After activation and conditioning of the cartridges by rinsing with 5 mL of methanol and 3 mL of extract solution, the prepared sample was then added to the SPE column at a flow of 1−2 drops per second. Third, 3 mL of a mixture of acetonitrile/water/0.1 M KOH (50:47:3, v/v/v) was used to wash the SPE column using the same flow rate. Fourth, 1.2 mL of double-distilled water was added to remove neutral and basic interferences. Finally, the OTA of the wine was eluted using 5 mL of a mixture of methanol/acetonitrile/methanoic acid/water (40:50:5:5, v/v/v/v) at the rate of 1 drop per second, and the eluate was collected in a glass test tube. The eluate was evaporated to dryness at 45 °C with nitrogen and dissolved again immediately in 0.5 mL of the HPLC mobile phase (A/B = 1:1, v/v) and kept at 4 °C until the HPLC analysis.

**HPLC Analysis.** The fluorescence detector (Waters 2475) was set at excitation and emission wavelengths of 333 and 443 nm, respectively. A C18 column (5 mm, 250 m × 4.6 mm) at 30 °C and mobile phase A and B solutions composed of phosphate solution adjusted to pH 2.5 by the addition of 5% phosphate and acetonitrile, at a flow rate of 1 mL $min^{-1}$, were used to separate the OTA. The gradient elution program started with a linear gradient from 12 to 20% acetonitrile in 10 min, followed by a 2 min linear gradient from 20 to 30% acetonitrile, a 7 min linear gradient from 30 to 50% acetonitrile, was maintained at 50% acetonitrile isocratic until 30 min, followed by a 1 min linear gradient from 50 to 100% acetonitrile then maintained at 100% acetonitrile isocratic until 39 min, and then finally returned to the initial conditions; the column was re-equilibrated with the initial mobile phase composition for 15 min. The injection volume was set to 10 μL.

**Method Validation.** A five-point calibration curve of OTA was created for quantification of the following concentrations: 0.5, 1.0, 2.0, 5.0, and 10.0 μg/L. Every level was injected three replicates to acquire the mean value of the area. The calibration curve was derived by plotting concentrations as a function of peak area of OTA, which resulted in a good linear regression. Reproducibility of the results was investigated by injecting three replicates of the same sample on seven different days and on the same day seven times.

**Wine Consumption Data.** A questionnaire method was further used to collect quantitative survey data related to wine consumption. A total of 1268 completed questionnaire surveys about the amount and frequency of consumption of wine were obtained. Wine consumers between 18 and 60 years old were invited to fill in the wine consumption questionnaire survey; people who never drink wine were excluded. The survey was carried out in the major wine-producing areas, main cities, and bars of China, including ordinary citizens, winery staff, company executives, etc. It may represent the consumption of wine by residents of China comprehensively. The weekly wine consumption equals the average amount of wine drunk per time multiplied by the frequency of wine consumption per week.

**Risk Assessment.** Previous exposure assessments had been based on a deterministic approach (point estimate) or on the estimation of the empirical probability for consumers to exceed the toxicological reference value.[53,54] In both cases, various levels of consumption were combined with the mean concentrations of OTA in wine. Two mathematical approaches of the point evaluation and the Monte Carlo assessment model were combined to perform the risk assessment of OTA in the present study according to eq 1

$$y = xc/w \quad (1)$$

where $y$ is the DI value of OTA (ng/kg bw), $x$ is the food consumption (g day$^{-1}$), $c$ is the concentration level of OTA in wine (ng g$^{-1}$), and $w$ is body weight (kg).

## RESULTS AND DISCUSSION

**Quality Control.** A high correlation coefficient ($R^2$ = 0.9999) was obtained for the tested interval, and the linear regression equation was $Y = 2883.2x - 293.64$. The standard deviation of the slope and intercept were 9.91and 3.59 ($n$ = 3), respectively, which meet requirements of methodology absolutely. The relative standard deviations (RSDs) of both the intraday and interday precision were 5.8 and 12.6%, respectively.

As shown in Table 1, average recoveries of OTA were 94.47% and the RSD was 4.03%. These results demonstrate

**Table 1. OTA Recovery and Relative Standard Deviations (RSDs) ($n$ = 3)**

| sample | wine OTA content (μg/L) | lead spiked (μg/L) | determined result (μg/L) | recovery (%) | mean recovery (%) | RSD (%) |
|---|---|---|---|---|---|---|
| white wine | 0.13 | 0.05 | 0.177 | 94.00 | | |
| | | 0.10 | 0.225 | 95.00 | | |
| | | 0.20 | 0.326 | 98.00 | | |
| | | 0.40 | 0.541 | 102.75 | | |
| | | | | | 97.47 | 4.03 |
| red wine | 0.36 | 0.05 | 0.406 | 92.00 | | |
| | | 0.15 | 0.504 | 96.00 | | |
| | | 0.40 | 0.758 | 99.50 | | |
| | | 0.80 | 1.180 | 102.50 | | |

that this method is suitable and efficient for analyzing OTA content. The recovery range fell within the guidelines for acceptable recovery limits of the Association of Analytical Chemists (AOAC) and the Codex Alimentarius: 70−125% at the 10 ng/mL level (AOAC) and 70−110% at the 10−100 ng/mL level and 60−120% at the 1−10 ng/mL level (Codex Alimentarius).[38]

As shown in Figure 1, the peak of OTA in standard and sample was symmetrical with good separation at 32 min, but there weas no peak for free-OTA sample. The retention time of OTA in another HPLC method was less than this method, and the minimum was approximately 5 min;[39,46,48] however, every method has a different mobile phase and pretreatment method. Moreover, the pretreatment method was immunoadsorption or the sample also needed to derive in another method. All of them would increase the cost. For anion-exchange/reversed-phase cleanup, Reinsch et al. determined OTA in wine by LC-MS, and the retention time was about 9.5 min.[40]

The limit of detection (LOD) was obtained using free-OTA wine samples spiked with OTA at low concentration levels at a signal-to-noise (S/N) ratio of 3. The LOD and the limit of quantification (LOQ) (normally based on S/N = 10) were 0.01 and 0.03 μg/L, respectively. As can be seen, the sensitivity of the method allowed the quantification of OTA at concentrations much lower than the maximum level established for wine samples.[41]

**General Investigation.** The LOQ of the established HPLC-FLD method was 0.03 μg/L for the determination of OTA in Chinese wine, and the concentration of OTA in the analyte-free wine was recorded as 0.015 μg/L (half of the LOQ), which was used for the risk assessment. The maximum concentration of OTA in wine was 0.98 μg/L. The mean concentration of OTA in all samples was 0.146 μg/L; the $P_{50}$ and $P_{95}$ values were 0.510 and 0.767 μg/L, respectively. The OTA level was lower than that found (from <0.1 to 5.65 μg/L) by Zhang[24] in 2013, but similar to the research (0.02−1.18 μg/L) of Wu[25] and Han (0−0.94 μg/L).[11] The mean of OTA concentration in white wine was 0.05 μg/L, lower than in red wine (0.17 μg/L) (Table 2), which was similar to other research in Chinese wine.[11,25,42] In Europe, the OTA content in wine production generally varies between 0.01 and 15.60 μg/kg, with a mean of 0.357 μg/kg. In addition, the means were 0.159 and 0.453 μg/kg in white wine and red wine, respectively.[19] Red wine generally contains higher OTA than white wine. This fact evidences a clear relationship between the maceration of the must with grape skins and OTA solubilization in the must. That is because dark grape skins are easily infected by mycete, and grape skins are sometimes discarded in the brewing process of white wine.[43] The survey results showed that OTA contamination in Chinese wine was lower than in European wine reported by European studies.[44−47] Furthermore, the incidence (45.2%) studied in this paper was higher than reported by Han et al. (35%) of Shanghai and Wu et al. (17.6%, 2011; 11.8%, 2012) of China,[11,25,42] but similar to the results reported by Solfrizzo.[48]

As listed in Figure2, the highest mean OTA concentration was observed in wine from Henan province (0.24 μg/L), whereas the lowest mean value was observed in Jilin (0.07 μg/L). The considerable climatic differences, related to geographic regions, have also an influence on OTA occurrence in wine. The means of southern and northern Europe were 0.181 and 0.636 μg/kg, respectively.[4,49,50] The distribution trend was just like results of Chinese wine.[24,25] Italian and Spanish surveys confirm that OTA levels were high in wines produced in areas with warm climatic conditions, suggesting that OTA production could be due to fungi belonging to the genus *Aspergillus*.[6,51,52]

**Consumption Survey.** There were 1268 questionnaires finished during June−August 2011, and 948 questionnaires had been confirmed as valid by logic questions in 1268 questionnaires (effective rate of 74.76%). After collection of the questionnaires, there were 607 males and 341 females. The average weights of the males and females were calculated as 64 and 56 kg, respectively. The ages of the participants registered were in the range of 18−60 years old, and the ages between 30

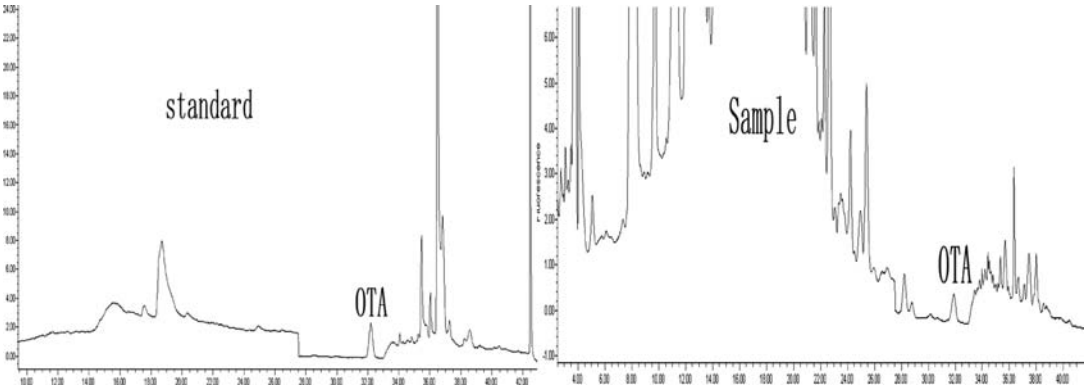

**Figure 1.** HPLC chromatograms: left, OTA standards; right, wine sample.

**Table 2. OTA Levels of Wine Samples and Consumption Analysis**

| | OTA levels of wine | | | |
|---|---|---|---|---|
| | all wines ($\mu$g/L) | red wine ($\mu$g/L) | white wine ($\mu$g/L) | wine consumption (mL/week/person) |
| *n* | 223 | 183 | 40 | 948 |
| mean | 0.15 | 0.17 | 0.05 | 342.3 |
| median | 0.08 | 0.09 | 0.01 | 116.7 |
| minimum | 0.00 | 0.00 | 0.00 | 0.0 |
| maximum | 0.98 | 0.20 | 0.36 | 7000.0 |
| $P_{95}$ | 0.51 | 0.59 | 0.22 | 1400.0 |
| $P_{97.5}$ | 0.75 | 0.79 | 0.36 | 1750.0 |

and 40 were the maximum proportion with 38%. As Table 3 shows, the weekly wine consumption of the Chinese population was statistically analyzed on the basis of these questionnaires. The median, mean, and $P_{95}$ values were 116.7, 342.3, and 1400 mL/week, respectively. The statistical result was higher than the values surveyed by Su[20] in China from 1989 to 2006 and quantitative assessment of risk associated with OTA (mean = 2.8 ± 5.8 g/day, $P_{90}$ 38.8 g/day) on the adult inhabitants in Shanghai of China by Han.[11]

**Exposure Assessment.** Statistical results show that the weight of 71% of consumers surveyed was between 45 and 75 kg, and the average weights of the maled and femaled were calculated as 64 and 56 kg, respectively. The weight distribution of the surveyed population was in close proximity with 60 kg, which was used to carry out the assessment in international organizations. Therefore, consumers with 60 kg weight were used as reference.

According to these data, the intake of OTA for the average adult consumer varies between 0.86 and 1.08 ng/kg bw/week. These data indicate that the intake of OTA for consumers of higher consumption ranges from 4.38 to 5.54 ng/kg bw/week (Table 3). As shown in Figure 3, there were different exposures of OTA in wine of different provinces. The exposure levels of Henan, Hebei, and Gansu were higher than those in Yannan, Xinjiang, and Ningxia. The dietary intake of OTA except for consumers reporting higher consumption was low, which had been higher than 5% PTWI (100 ng/kg/week) by the JECFA.

In conclusion, an exposure assessment of OTA in wine was conducted to evaluate the potential health risks of the estimated dietary exposure in comparison with the PTWI of OTA recommended by the JECFA. The results suggested that dietary intake of OTA had very low health risks in wine except for high percentile (97.5) consumers. Nonetheless, on the basis of the exposure assessment, the suggested safe limit value of OTA for Chinese wine was suggested to be 2.0 $\mu$g/kg. Not only was this

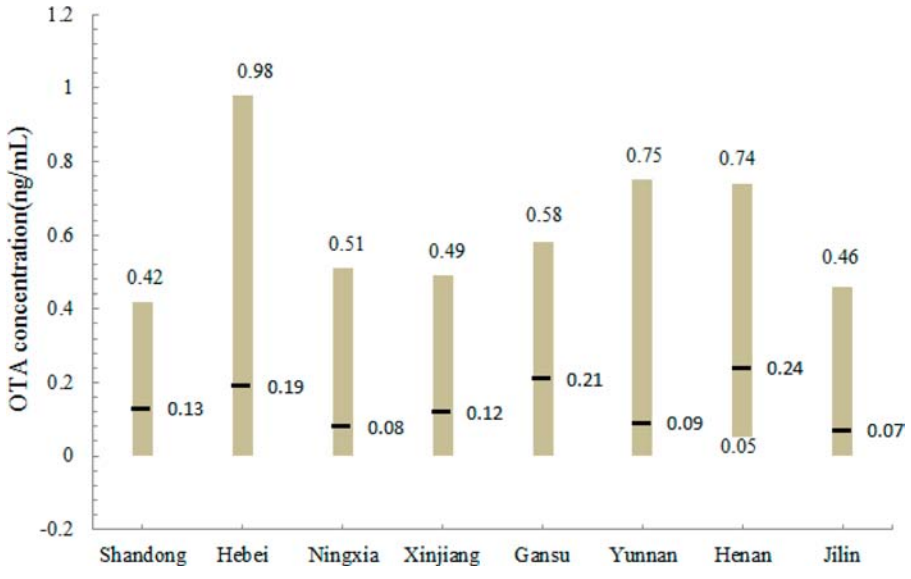

**Figure 2.** OTA levels of wine from different wine-producing areas.

[a]Within each column and for each essential oil, means having the same letters are not significantly different ($p > 0.05$) from each other.

plasticizing agent, and CAR, CIN, and EUG, which are antimicrobial agents, were purchased from Fisher Scientific, Inc. (Pittsburgh, PA). All other chemicals and solvents were of analytical grade.

**Preparation of Essential Oils and β-CD Complex.** The complex of β-CD and essential oils (β-CD/EO) was prepared using a co-precipitation method described by Ayala-Zavala et al.,[14] with minor modification. Briefly, 5 g (± 0.01) of β-CD was dissolved in 100 mL of an ethanol/distilled water (1:2, v/v) mixture and maintained at 60 ± 2 °C on a hot plate. After cooling the β-CD solution to 40 ± 2 °C, a portion of 0.5 g of EO dissolved in ethanol (1:1, v/v) was then slowly added to the solution with continuous agitation. The resultant mixture was treated by ultrasonic cleaners at 90 W for 4 h. The final solution was maintained overnight at 4 °C. The cold precipitated β-CD/EO complex was recovered by vacuum filtration. The precipitate was washed twice with 30% ethanol solution to clear EO, which was absorbed on the surface of β-CD and dried in a vacuum oven at 40 °C for 4 h until the weight was kept constant. The final dry complex powders were stored in an airtight glass desiccator at room temperature for further analysis.

**Film Preparation.** The edible films were prepared by dissolving 1% (w/v) of CS in a 1% acetic acid solution and stirred, at room temperature, until CS was completely dissolved. Glycerol at 30% (w/w of CS) was added as a plasticizer. Films without β-CD/EO were designated as the control sample. To make the antimicrobial films, a constant amount (150 mL) of the film solutions with varying concentrations of β-CD/EO (0.25, 0.5, 0.75, and 1%) were spread in a glass plate (200 × 200 $mm^2$) and dried at 35 ± 2 °C in an incubator (New Brunswick Scientific Excella E24, Fisher Scientific, Inc., Pittsburgh, PA). The films were removed from the glass plate with a thin spatula and conditioned at 23 ± 2 °C and 50 ± 2% relative humidity (RH) before running further tests.[15]

**Bacterial Strains and Cultures.** Four types of bacterial strains, *E. coli* ATCC 25922 and *S. typhimurium* ATCC 19585 were used representing Gram-negative bacteria. *Staphylococcus aureus* NCTC 8325 and *L. monocytogenes* ATCC 23074 were used representing Gram-positive bacteria. They were incubated in nutrient broth media at 37 °C for 24 h.

**Antimicrobial Activity.** Antimicrobial properties of the crafted films were determined by the log reduction method, with a slight modification.[16] Briefly, culture medium broth was inoculated with 1% suspension of bacteria. The bacterial concentration in the seeding culture was approximately 6 × $10^8$ colony forming units (CFU)/mL. Serial dilutions of the suspension were performed, and the optical density values were tested to achieve a standard curve. Square film pieces (20 × 20 $mm^2$) were sterilized and introduced into a test tube containing 5 mL of fresh suspension of bacteria and incubated at 37 °C for 24 h. The optical density of culture media was measured at 620 nm using a PerkinElmer HTS 7000 Bio Assay reader, and cell concentrations were determined. All samples/standards were run in triplicate.

**Film Thickness (FT).**[17] FT was measured with a 0−25 mm dial thickness gauge with an accuracy of ± 0.01 mm in five random locations for each film. The average was calculated for mechanical properties, water vapor permeability (WVP), and oxygen permeability.

**Mechanical Properties.** Tensile strength (TS) and elongation at break (EB) tests were performed at room temperature (23 ± 2 °C) using a universal testing machine [PARAM XLW (B) Auto Tensile Tester, Jinan, China] according to the standard testing method ASTM D882-01. Sample films, previously equilibrated at 23 ± 2 °C and 50 ± 2% RH, were cut into strips 15 mm wide and 130 mm long. Five specimens from each film were tested. The initial grip separation and mechanical crosshead speed were set at 80 mm and 50 mm/min, respectively.[18]

TS[19] was calculated using the following equation:

$$TS = F_{max}/A$$

where $F_{max}$ is the maximum load (N) needed to pull the sample apart and $A$ is the cross-sectional area ($m^2$) of the samples.

EB (%) was calculated using the following equation:

$$EB = (L/80) \times 100$$

where $L$ is the film elongation (mm) at the moment of rupture and 80 is the initial grip length (mm) of samples.

**WVP.** The WVP of the films was determined by a WVP tester (PERME TSY-TIL, Labthink Instruments Co., Ltd., Jinan, China) according to the standard testing method ASTM E-96-95. Test cups were $^2/_3$ filled with distilled water. The circular sample was tightly covering the cup. The different water vapor pressures between the inside and outside of the cup causes the water vapor diffusion through the sample. Water vapor transmission rates were determined at 23 ± 2 °C and 50 ± 2% RH using saturated salt solutions of $MgCl_2$. The weight of the cups was measured at 1 h intervals for 24 h to determine the water vapor transmission rate and transmission coefficient. For each sample, at least five replicates were tested.

**Statistical Analysis.** Analysis of variance (ANOVA) was carried out by SPSS software (version 17). A significance level was set at 0.05.

## RESULTS AND DISCUSSION

**Antimicrobial Activity.** The antimicrobial activity of β-CD/EO in CS films against *E. coli*, *S. typhimurium*, *S. aureus*, and *L. monocytogenes* was tested, and the results are shown in Table 1. The CS films incorporated with different concentrations of β-CD/EO significantly improved the antimicrobial activities of the CS film against all of the tested bacteria ($p <$

dx.doi.org/10.1021/jf5027873 | J. Agric. Food Chem. 2014, 62, 8914−8918

0.05). The log reduction increases with the increase of the β-CD/EO concentration, which illustrates the antimicrobial activity of β-CD/EO.

The results show that the log reductions for β-CD/CIN CS and β-CD/CAR CS films were higher than β-CD/EUG CS films. The β-CD/CIN CS films at 1% CIN could reduce the number of *E. coli* and *S. aureus* up to 2.11 and 2.52 logs, respectively. The β-CD/CAR CS films showed the best inhibition to *S. aureus*, and the log reduction of it was about 3. β-CD/CAR CS films were able to inhibit *E. coli* and *S. aureus* growth significantly.

Essential oils capable of preventing the growth of foodborne bacteria have been well-documented.[7] Studies have shown that essential oils are able to disrupt and penetrate the lipid structure of the cell membrane and the mitochondrial membrane, leading to the disruption of the cell membrane, cytoplasmatic leakage, cell lysis, and eventually, cell death.[20] It has been suggested that the antimicrobial activity of essential oils may be related to their involvement with enzymatic reactions, which regulate wall synthesis.[21] The lipophilic properties of essential oil components might have also aided its ability to penetrate the plasma membrane.[22] The observations made with light microscopy are in accordance with previous studies, in which essential oils of aromatic plants caused morphological alterations on the fungal hyphae.[21]

The antibacterial activities of CIN, EUG, and CAR against *E. coli* were compared in a previous study, and the minimum inhibitory concentrations (MIC) of CIN and CAR were 400 mg/L; however, MIC of EUG was 1600 mg/L, indicating that EUG has weaker antimicrobial activity against *E. coli*.[23] It is possible that this resulted from the lower aqueous solubility of EUG that would prevent maximum contact with the pathogens in solution.[24] CIN may act upon the pathogens without being fully released from the inclusion complex.[25] The inhibition zones of CAR and EUG against *S. typhimurium* were larger than *L. monocytogenes* indicating that *L. monocytogenes* was more resistant to CAR and EUG than *S. typhimurium*.[24] *E. coli*, *L. monocytogenes*, and *S. typhymurium* were destroyed completely by four essential oils at concentrations of ≤ 0.8% (v/v), whereas *S. aureus* was destroyed completely by 26 essential oils at concentrations of ≤ 0.4% (v/v), demonstrating that *S. aureus* was the most sensitive bacteria to essential oils.[26] Our results shown in Table 1 are in agreement with those results.

The β-CD/EO complexes were shown to be able to inhibit *Salmonella enterica* and *Listeria innocua* at low active compound concentrations, and the MIC values for free essential oils, such as EUG and CIN, were significantly higher than β-CD/EO complexes ($p < 0.05$), which is probably due to the increased water solubility of β-CD/EO complexes that led to increased contact between pathogens and essential oils, thus improving the antimicrobial activity of EO at lower concentrations of active compound.[11] The cinnamon bark and clove bud extract β-CD complexes were the most powerful antimicrobials, despite showing the lowest entrapment efficiencies among the oils.[11] Results suggest that the application of these antimicrobial complexes in food systems may be effective at inhibiting pathogens.

Furthermore, the films showed a higher effectiveness against *S. aureus* compared to *E. coli* and *S. typhimurium*, which may be due to the characteristic difference of the outer membrane between Gram-positive bacteria and Gram-negative bacteria.[27] It was reported that Gram-negative bacteria were more resistant to the essential oils.[6] However, *L. monocytogenes* (Gram-positive bacteria) was more resistant than other bacteria tested, which is in agreement with the previous work.[24]

**Mechanical Properties.** The results of TS and EB are shown in Figures 1 and 2. The effect on these properties of the type and concentration of β-CD/EO in CS films were evaluated.

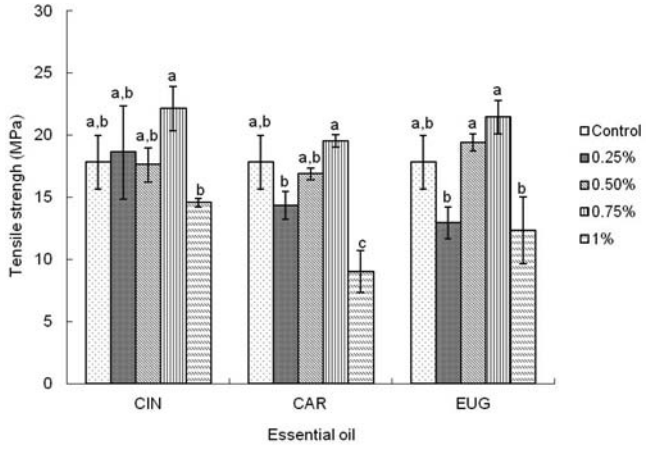

**Figure 1.** TS of β-CD/EO in CS films at four different concentrations (0.25, 0.5, 0.75, or 1%) of β-CD/EO (CIN, CAR, or EUG) were incorporated into 1% chitosan solution, and the one without β-CD/EO was taken as the control.

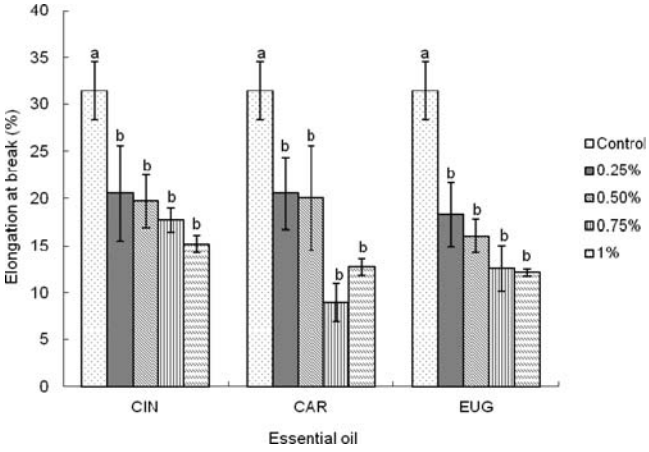

**Figure 2.** EB of β-CD/EO in CS films at four different concentrations (0.25, 0.5, 0.75, or 1%) of β-CD/EO (CIN, CAR, or EUG) were incorporated into 1% chitosan solution, and the one without β-CD/EO was taken as the control.

The CS control film had TS and EB values of 17.82 ± 3.75 MPa and 31.46 ± 5.31%, respectively (Figures 1 and 2). These values are comparable to the previous reports with TS and EB in the range of 12−20 MPa and 17−42%, respectively.[28] The addition of β-CD/EO to the CS films produced changes in their mechanical properties. The films exhibited the highest TS when the concentration of β-CD/EO was 0.75% (Figure 1). However, the EB was significantly ($p < 0.05$) reduced by the incorporation of β-CD/EO at all four concentrations. The EB values of the films decreased significantly ($p < 0.05$) with increasing β-CD/EO concentrations (Figure 2).

The TS and EB of CS films are affected by the type of CS used, the presence of glycerol, and the temperature during film drying.[29] Interestingly, the incorporation of 0.75% β-CD/EO

dx.doi.org/10.1021/jf5027873 | J. Agric. Food Chem. 2014, 62, 8914−8918

into CS films significantly increased the TS of the films with 1% β-CD/EO ($p < 0.05$). The addition of a relatively lower dose of β-CD/EO (0.75%) exhibited the highest TS among the films, which could be attributed to the formation of intermolecular hydrogen bonding between $NH_3^+$ of the CS backbone and $OH^-$ of β-CD/EO.[30] The intermolecular hydrogen bonding between CS and β-CD/EO could enhance the cross-linkage, which decreases the molecular mobility and the free volume of CS.[31] This phenomenon was reported by other researchers in similar systems. For example, the cross-linking of microcrystalline wheat-bran cellulose and soy protein isolate films resulted in an increased TS because of the enhancement of the structural bonds in the polymer network.[32] However, when the added concentration of β-CD/EO is higher than 0.75%, the TS of the resulting films decreased with increasing the β-CD/EO concentration. It is possible that the excessive β-CD/EO could aggregate and destroy the inner structure of β-CD/EO and the CS matrix.

The decrease of EB values in β-CD/EO in CS films indicated that β-CD/EO acted as fillers for the CS matrix, decreasing the strain of the films. The incorporation of β-CD/EO into the CS film resulted in a strong reaction between fillers and matrix, which decreased EB by the motion restriction of the matrix.[10] It has been reported that the filler cellulose whiskers produce a significant decrease in the EB of CS films, indicating that the strong interactions between matrix and filler restricted the motion of the matrix.[33]

**WVP.** The effect of different concentrations of EO on the resistance to permeability of water vapor was evaluated for the films, and the results are presented in Figure 3.

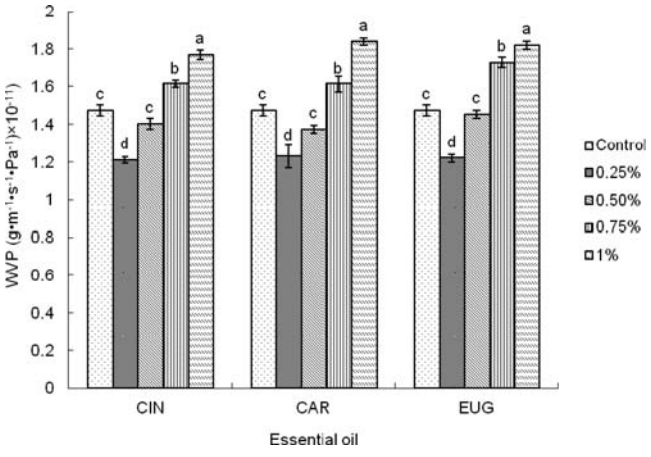

**Figure 3.** WVP of β-CD/EO in CS films at four different concentrations (0.25, 0.5, 0.75, or 1%) of β-CD/EO (CIN, CAR, or EUG) were incorporated into 1% chitosan solution, and the one without β-CD/EO was taken as the control.

The presence of a lower concentration of β-CD/EO in the CS matrix resulted in an improvement in the water vapor barrier property. The WVP value was $1.22 \times 10^{-11}$ and $1.40 \times 10^{-11}$ g m$^{-1}$ s$^{-1}$ Pa$^{-1}$ when the concentration of β-CD/EO was 0.25 and 0.5%, respectively. The WVP values of the films decreased significantly ($p < 0.05$) with increasing β-CD/EO concentrations when added β-CD/EO was below 0.5%, which could be because the presence of β-CD/EO appeared to produce an antiplasticizing effect on the film, as reported after the incorporation of fillers in polymers.[10] β-CD/EO interactions and the structural rigidity of β-CD/EO could create steric hindrance and decrease segmental mobility, restricting water vapor diffusion between the CS matrix and β-CD/EO. The fillers provide an excellent water vapor barrier property because they contain a large number of hydrogen bonds between the matrix, which has a strong holding property to keep water trapped and prevent water diffusion through the films,[32] thus reducing WVP values.

However, when the concentration of β-CD/EO was higher than 0.5%, the WVP of the film increased ($p < 0.05$), which may be related to the excessive β-CD/EO scattered in the film, which subsequently decreased the intermolecular forces between polymer chains and increased the free volume and segmental motions.[34]

In conclusion, it was shown that incorporation of low amounts of β-CD/EO in the CS film significantly improves its antimicrobial properties. The mechanical properties of films incorporated with β-CD/EO in CS were confirmed to be at least as effective for active food packaging as films without the additional incorporation of β-CD/EO in CS. The interaction between CS and β-CD/EO could improve tensile strength of the CS films. The CS films with a lower concentration of β-CD/EO improved the barrier properties by reducing WVP. Because of the antimicrobial, mechanical, and physical properties, the films developed could be used as functional food packaging.

still possible that lower short-term levels can occur in air downwind of treatment sites from multiple field sources over a fumigation season.

This paper reports on a rugged and sensitive field sampling and analysis procedure for assessing MIC air concentrations in residential air. We also report for the first time on observed MIC air concentrations that were concurrently monitored with MITC during a period of metam soil fumigations near a residential area in southern Franklin county, Washington state, USA. Understanding the combined contributions of MITC with MIC will be important especially to residential communities existing in close proximity to where agricultural soil fumigations occur.

## MATERIALS AND METHODS

**MIC Air Sampling.** A batch (~30 g) of XAD-7 medium-polarity polymeric adsorbent (XAD7HP; Sigma-Aldrich) was washed and drained several times by swirling with excess pesticide grade acetonitrile (Fisher). The final rinse was vacuum filtered until the adsorbent was dry and flowable. Three milliliter portions of the dry adsorbent (ca. 1.12 g by weight) were each packed into separate 5 $cm^3$ plastic Bond Elut reservoirs containing a porous frit at the tip end (Agilent) and capped with a plug of glass wool. Using a syringe, 80 $\mu$L of 1-(2-pyridyl)piperazine (1-2PP, 98%; Sigma-Aldrich) was dissolved in 20 mL of pesticide grade methylene chloride (Fisher), yielding a concentration of ~4.3 mg/mL. The 1-2PP solution was transferred to the reservoir of the cartridge-coating apparatus (Figure 1). The free end of the flexible tubing extending from the bottom of the reservoir was attached to the tip end of a cartridge containing XAD-7, and the cartridge was lowered to allow the 1-2PP solution to flood the cartridge up to the glass wool plug. The cartridge was then raised to drain the solution. This was repeated three times. The coated cartridge was then transferred to a vacuum source for air-drying (~1 h for each cartridge). Each dry, coated cartridge was wrapped in aluminum foil and stored under refrigeration (1–7 °C) in an amber screw-cap jar. The cartridges were prepared no more than 5 days prior to use in the field.

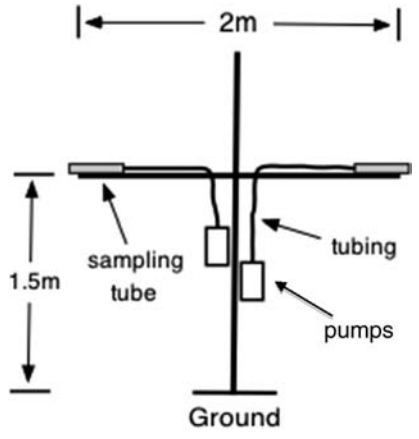

**Figure 3.** MIC air sampling mast.

**MIC Residential Air Monitoring.** MIC receptor stations were set up at three separate sampling sites, two in yards of single-family homes and one at an outdoor commercial building location (site 1). All were bordered by agricultural land (Figure 2, sites 1, 3, and 5). These sampling locations have been routinely used for past MITC area-wide assessments in this residential area.[20,21] The site 3 location consisted of

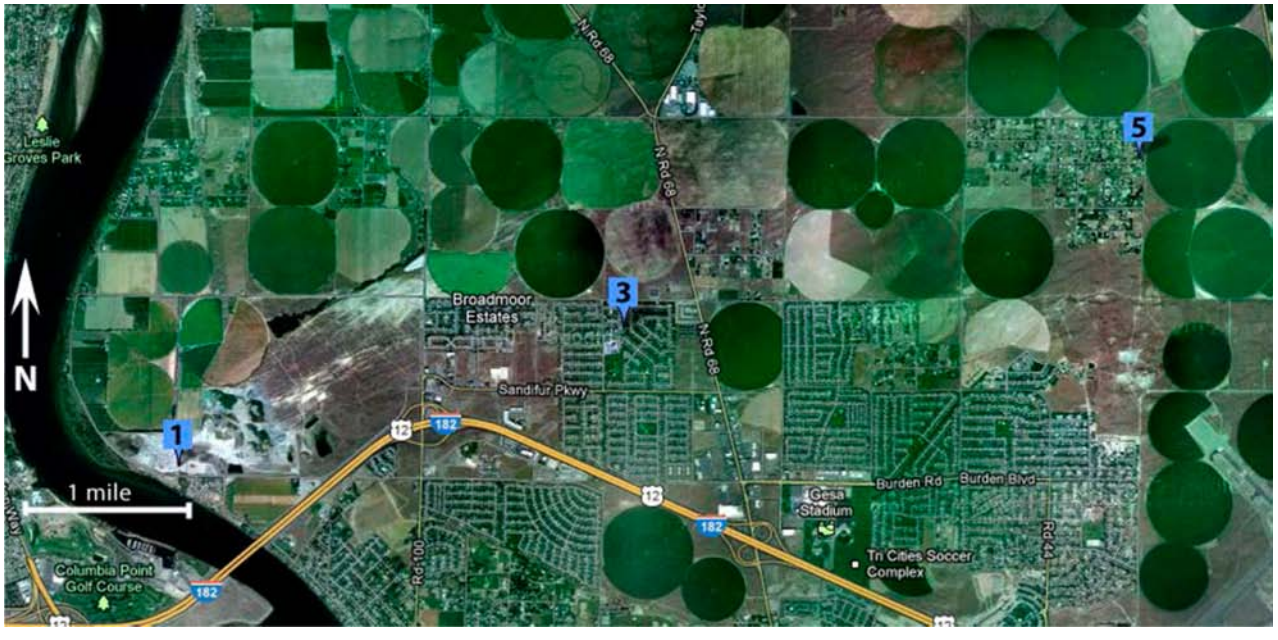

**Figure 2.** 2012 MIC residential sampling site map (southern Franklin county, Washington state, USA).

a collocated duplicate cartridge sampling system that served to corroborate capture efficiency among the collocated cartridges. Each station consisted of a 2 m horizontal metal rod attached to a vertical rod at 1.5 m above the ground to sample air at a child's approximate breathing zone level (Figure 3). Sampling cartridges were attached horizontally to the end(s) of the horizontal bar and the cartridges were connected to tubing attached to portable pumps (model 224 PCXR8; SKC) preset to a flow rate of ca. 450 mL/min. Rotameter flow meters were used to measure actual start and stop flows. The cartridges were operated for 4 h and then wrapped in foil and transported on ice packs to the laboratory where they were stored under refrigeration (1−7 °C) to await analysis.

Field fortification (FF) samples were included on each day of air sampling. For field fortifications, the intakes of coated XAD-7 cartridges were spiked with a known amount of MIC and placed on a sampling mast located at a site remote from the metam applications. Air was sampled through the FF cartridges, and corresponding field control cartridges to sample background air, at ca. 500 mL/min for 4 h (0.12 $m^3$ total volume). Additionally, to verify sample integrity during transport and storage, spiked trip blank (STB) and trip blank (TB) samples accompanied each day of sampling. STB cartridges were fortified with MIC and stored in an ice-packed cooler throughout all six 4 h sampling intervals (24 h). The TB and STB samples were momentarily deployed on a pump without flow and immediately removed to simulate sampling procedures for the other cartridges. The TB and STB samples were analyzed with the field samples.

Fortification solutions of MIC (99%; ChemService) in methylene chloride (at 1, 10, and 500 $\mu$g/mL) were used for the laboratory and field cartridge fortifications. The concentrations of these solutions were verified against standards of the MIC-1-2PP-substituted urea derivative by spiking cartridges with the fortification solutions and then recovering the MIC-1-2PP derivative.

The MIC-1-2PP derivative was prepared for use as an analytical standard according to the guidelines of OSHA method 54, section 3.3.1.[22] One-tenth of a gram of MIC was dissolved in 25 mL of methylene chloride. This solution was slowly added to a dilute solution of 1-2PP in methylene chloride with stirring. The mixture was stirred for an hour and then evaporated to <10 mL. The remaining methylene chloride solution was added dropwise to hexane, resulting in the precipitation of the MIC-1-2PP derivative. The precipitate was dried and weighed for a stock solution of MIC-1-2PP in acetonitrile (0.5 mg/mL). From this stock, standards of the MIC-1-2PP derivative were prepared to bracket the range of concentrations expected in the air samples (1, 2, 5, 10, 20, and 40 ng/mL). All standard and fortification solutions were stored in a freezer at ca. −15 °C.

**Sample Analysis.** The amounts of MIC-1-2PP derivative in the samples were determined using an Agilent 1200 HPLC coupled to an Agilent 6460 triple-quadrupole mass spectrometer (LC-MS/MS) equipped with a positive atmospheric pressure chemical ionization (APCI) interface. The contents of each air-sampling cartridge were emptied into separate 25 mL screw-cap tubes, and each was extracted with 10 mL of acetonitrile by vortexing periodically for an hour. A 1−2 mL aliquot from each tube was filtered through 0.2 $\mu$m Teflon filters, 5 $\mu$L portions of filtrate were then injected onto an Eclipse XDB-C18 column (4.6 mm × 50 mm; Agilent), and the analyte was eluted with a 15:85 water/methanol mobile phase at 0.3 mL/min. The $m/z$ 221 → 163.5 transition was used for quantitation. Prior to the analysis of any samples, the working method was validated by fortifying and recovering MIC from treated XAD-7 cartridges. The method was validated in triplicate at three concentration levels,10 ng, 50 ng, and 6 $\mu$g of MIC, on-cartridge. Figure 4 shows example chromatograms of the MIC-1-2PP derivative and a 1-2PP-coated XAD-7 cartridge blank. Analyte retention time was ca. 2.4 min. The low-end fortification (10 ng of MIC on-cartridge) was designated as the method's limit of quantification (mLOQ). The method's limit of detection (mLOD) was empirically estimated to be roughly half of the mLOQ, or 5 ng MIC on-cartridge, due to a low-level but consistent background interference in the control samples.

Each laboratory analytical set (ca. 8 field cartridges) included a blank cartridge and an MIC laboratory-fortified cartridge (at various concentrations) with the field samples. The recovery fortification sample was prepared by injecting a known volume of MIC fortification solution into a 1-2PP-coated XAD-7 cartridge. For each analytical set, percent recovery for the fortified sample was calculated after the average peak area of the corresponding control sample had been subtracted. At least four external standards were used to generate the linear regression curve. All field samples were analyzed within 5 days of collection.

## RESULTS AND DISCUSSION

**MIC Cartridge Performance and Quality Control.** The successful sampling of gaseous MIC in air was made possible by the rapid reaction of MIC with 1-2PP. As an electrophile, MIC reacts with the nucleophilic cyclic amine of 1-2PP to form the urea derivative according to the following equation:

[a]Recoveries are corrected for controls.

Our sampling method was a modification of OSHA Method 54.[22] The OSHA method minimum quantitation level was reported to be about 4.8 $\mu$g/m$^3$ for a sample collection volume of no more than 15 L at 50 mL/min through tubes of 120 mg of XAD-7 coated with 1-2PP. For this study, our goal was to capture MIC on-cartridge during 4 h of air sampling at a flow rate of about 500 mL/min (~0.12 m$^3$ total volume) with minimal breakthrough. Therefore, we increased the amounts of the XAD-7 adsorbent (~1.1 g) and 1-2PP (4−5 mg/XAD-7 cartridge), allowing for ~10 times higher sampling flow rates. Compared to OSHA Method 54, the modified higher sampling volume cartridge, coupled with the use of positive APCI LC-MS/MS, resulted in an appreciable 60-fold increase in sensitivity for the MIC-1-2PP derivative.

The modified cartridge design and sampling method were validated in triplicate at 10 ng, 50 ng, and 6 $\mu$g of MIC spiked to the 3 mL 1-2PP-coated XAD-7 cartridges (Table 1). These levels were equivalent to air concentrations of 0.08 , 0.42, and 50 $\mu$g/m$^3$, respectively, based on air sampling rates of 500 mL/min for 4 h. From this, a mLOQ was established at 0.08 $\mu$g/m$^3$ with a mLOD of 0.05 $\mu$g/m$^3$. Subsequent to the cartridge validation, a breakthrough test was conducted to examine retention of MIC-1-2PP on the sampling media. Three prepared cartridges were spiked with 50 ng of MIC and attached to air sampling pumps for 5 h at ca. 500 mL/min air flow (0.15 m$^3$ total sampling volume) at ambient room temperature. The breakthrough sample recoveries ranged from 106 to 118% with an average recovery of 112 ± 6% ($n$ = 3).

Table 1 provides field fortification recoveries and also reports recoveries for spiked trip MIC-1-2PP cartridges that accompanied the three sampling day shipments. Laboratory recoveries of the MIC-1-2PP derivative prepared with each analytical set are also reported in Table 1. We also examined if MITC in the ambient residential air could in itself result in an increase of the MIC-1-2PP derivative. Here, a separate validation was performed with replicate 1-2PP XAD-7 control cartridges and control cartridges separately fortified at various concentrations with MITC. A slight 2.5% signal enhancement corresponding to MIC-1-2PP was estimated for the replicated spiked MITC cartridges compared to the blank control cartridges. This estimated level of response was within method and instrument errors. All residential air monitoring data are reported without recovery correction.

Table 2 provides 4 h TWA MIC air concentrations along with 4 h TWA MITC air concentration data that were concurrently determined at the three-receptor locations during this 2012 study. Although the focus of this investigation was MIC, MITC air concentrations were concurrently gathered with the MIC data to examine the combined presence of these metam products in residential air (Table 2 and Figure 5). The

[a]Air sampling device failure.

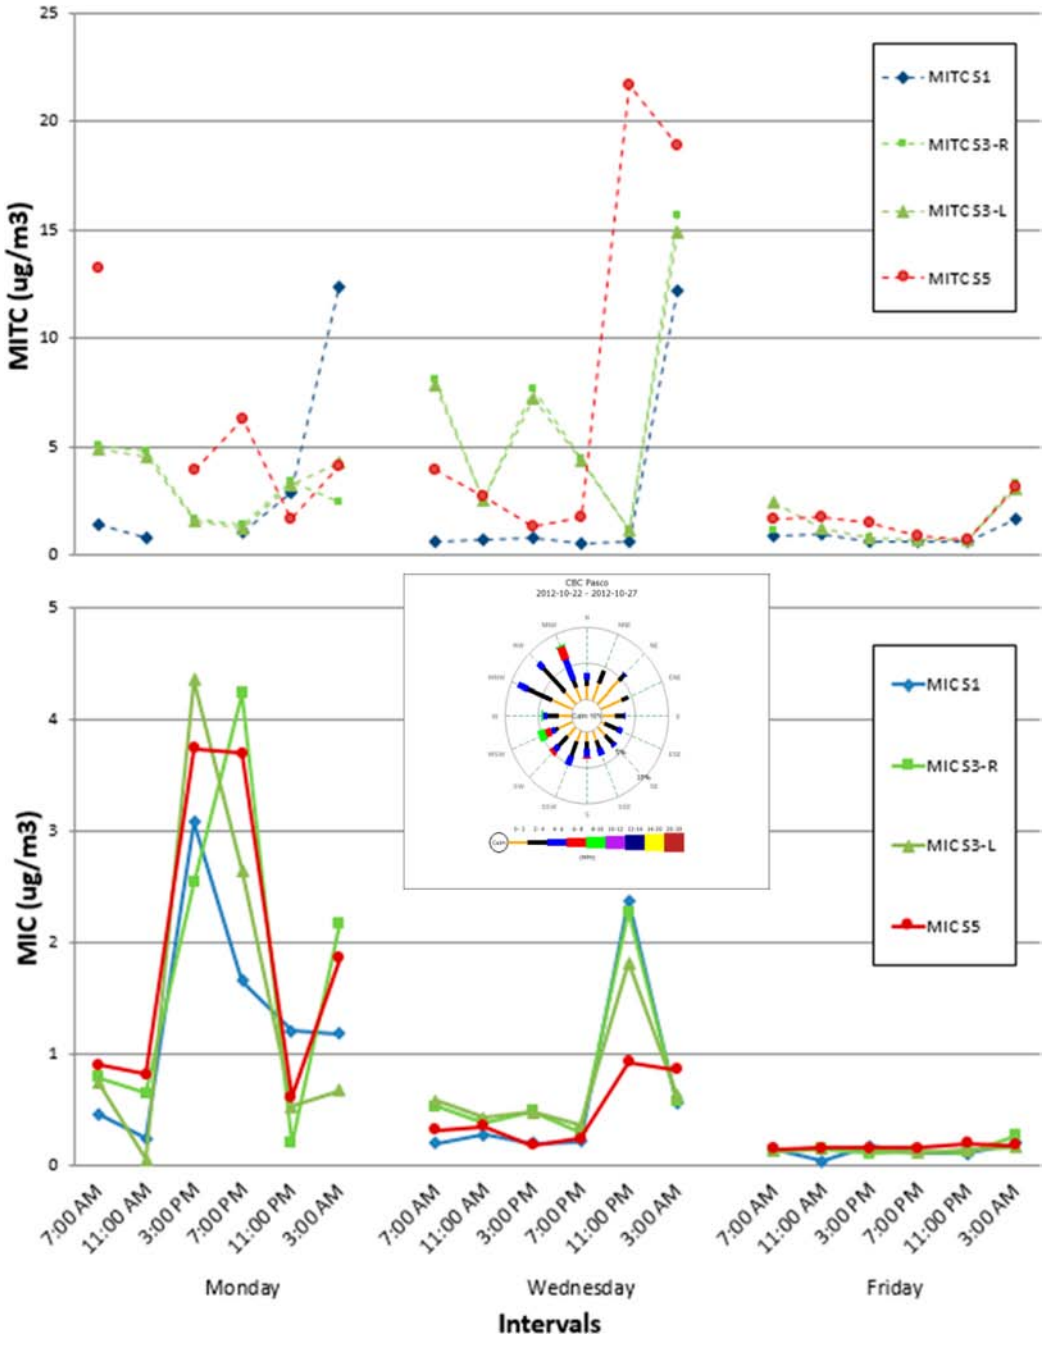

**Figure 5.** Four-hour time-weighted average MIC and MITC air concentrations (week of October 22−27, 2012). Columbia Basin College meteorological windrose was provided by WSU-AgWeather Net, Prosser, WA, USA.

analytical method for quantifying MITC was previously developed and validated in our facility for a 2005 residential air monitoring study.[20] This method was adapted from a California Department of Pesticide Regulation method and relied on solvent extracting MITC from activated charcoal using an 80:20 proportion, respectively, of ethyl acetate to carbon disulfide followed by sonication and microfiltration.[23] MITC air concentrations were determined by gas chromatography with nitrogen phosphorus detection (GC-NPD). Details of this companion 2012 MITC air monitoring assessment can be found in Hastings and Hebert.[24]

The MIC-1-2PP derivative was observed in 68 of the 72 air samples giving equivalent MIC concentrations that were greater than the mLOQ (0.08 $\mu g/m^3$), from 0.11 $\mu g/m^3$ to a maximum of 4.4 $\mu g/m^3$. The maximum was observed in the afternoon on Monday, October 22, 2012 (Table 2 and Figure 5). MIC residues at the other two receptor locations, although lower, were also elevated during that time interval, and all concentrations gradually decreased through the evening hours (Figure 5). Wednesday, October 24, was the last day water was supplied to this irrigation district for conducting center pivot metam fumigations. MIC and MITC concentrations were evident on this day but were appreciably lower soon after irrigation cutoff as can be seen for Friday, October 26 (Figure 5). This pattern of increasing fumigant air concentrations just before irrigation cutoff has been consistently observed for MITC in residential air in this basin.[20,21,24]

MITC was usually higher in the early morning hours (Figure 5). Some of the higher MIC residues were observed in outdoor residential air during the mid-to-late afternoon sampling period. These higher concentrations may be attributed to the reported short 12−16 h atmospheric half-life for the conversion of MITC to MIC.[14,15] MIC, although of higher volatility, is appreciably less reactive toward hydroxyl radical oxidation, with a reported gas-phase half-life of 66 h.[15] Given that MITC can transform to less reactive MIC in the presence of atmospheric oxidants and sunlight, the measured residential air concentrations reasonably confirm that MIC, along with MITC, will be present in air during soil fumigation. In 1995, a near-field shank fumigation air study by the California Air Resources Board also observed MIC from 0.21 to 5.8 $\mu g/m^3$ (12 h TWA samples), with concurrent measurements of MITC from 0.24 to 250 $\mu g/m^3$.[19] These earlier MITC to MIC near-field fumigation conversion observations taken over a 3 day application period are in agreement with our 2012 residential air study observations.

We observed measurable MIC concentrations in >90% of residential air samples. Of the 68 confirmed measurements, 15 (22%) were above CalEPA's chronic inhalation reference level of 1 $\mu g/m^3$, with some several times greater than this level, but were about $^1/_{10}$ of the REL/PEL of 50 $\mu g/m^3$ for an 8 h work shift. The CalEPA reference level is not a direct indicator of risk but rather a reference point to gauge potential effects. For short-term exposures greater than the reference exposure level, the potential for adverse health effects increases.

South Franklin county, Washington, USA, continues to undergo rapid residential and commercial expansion onto large production rotational potato, corn, wheat, and alfalfa crop circle systems (each circle ca. 48−64 ha). This study was initiated to address public health agency concerns that earlier reported 2005−2008 MITC residential air concentrations could also result in significant MIC air contributions during periods of active soil fumigation.[20,21] These earlier air monitoring studies indicated that MITC air concentrations were uniformly distributed throughout this basin and intermittently exceeded EPA regulatory acute [67 $\mu g/m^3$ (1−8 h)] and short-term (15 $\mu g/m^3$ over a 24 h period) inhalation exposure levels of concern (LOC). In 2008, stagnant air/inversion conditions just before the irrigation district's water cutoff date contributed to MITC residential air levels exceeding the EPA acute LOC on 3 days, with a 4 h TWA observed maximum air concentration of 650 $\mu g/m^3$. The EPA short-term MITC LOC threshold was exceeded on 20% of the days monitored.[21] On the basis of the reported daytime high rate of oxidative conversion of MITC to MIC,[14,15] 2008 MITC levels could have potentially led to MIC air concentrations greater than the REL/PEL of 50 $\mu g/m^3$, suggesting that monitoring of MIC is warranted.

In 2012, windy conditions from early October through irrigation cutoff resulted in fewer soil fumigations occurring than in previous monitoring years (personal communications with Washington State Department of Agriculture). Although many soil fumigations were delayed by growers to spring 2013, the 2012 MITC emission profile does show consistency in seasonal trends with previous 2005, 2007, and 2008 monitoring seasons, with higher MITC concentrations during the peak period of fall soil fumigation 1 week before irrigation water cutoff (Figure 5).

Traditionally, metam applications in Franklin county, WA, USA, have been performed mid-September to late October by center-pivot surface chemigation, which typically led to MITC levels much greater than those resulting from soil-incorporated shank injection.[9] As of winter 2012, the EPA Office of Pesticide Programs adopted mitigation measures to increase protections for agricultural workers and bystanders.[10] It is anticipated that this adoption of fumigation field edge set back distances (buffers) based on field size, application method, and rate will shift practices away from traditional surface-applied center-pivot chemigation to soil-incorporated shank injection. This transition will be especially significant in reducing MITC emissions in potato-growing regions in close proximity to residential communities, commercial development, and difficult-to-evacuate zones.

Metam product labels now specify that fumigant shank injection can be conducted at a minimum 8 cm depth from the soil surface. The high porosity and low organic content of soils typically found in field crop production agriculture in the inner Pacific Northwest will remain favorable to high MITC emission rates,[25] especially at very shallow shank depths. Because prescribed buffer zone specifications allow large potato field shank fumigations to occur in close proximity to homes and residential communities (ca. 8−20 m), there continues to be concern among public health officials that shallow depth metam soil incorporation can result in appreciable MITC off-target movement and bystander/residential exposure. Evaluating first-hand the impact of changing fumigation practices driven by recent metam 2012 label changes will remain important for confirming that there is a substantial reduction in MITC with associated MIC emissions at the rural−urban interface over the entire soil fumigation season.

**Figure 2.** Synthesis of the title compounds $A_1$–$A_{30}$.

Our research showed that 4(3*H*)-quinazolinone derivatives possess excellent anti-TMV activities. The third position of 4(3*H*)-quinazolinones is particularly an active site. Futhermore, 1,4-pentadien-3-one belongs to natural product derivatives, which exhibits outstanding antiviral bioactivity. However, no study has investigated 4(3*H*)-quinazolinone derivatives containing 1,4-pentadien-3-one moieties to date. In this study, we incorporated a 1,4-pentadien-3-one unit to the backbone of 4(3*H*)-quinazolinone, which may result in 4(3*H*)-quinazolinone derivatives with good antiviral activity. The 4(3*H*)-quinazolinone analogues $A_1$ to $A_{30}$ were designed and synthesized, and their antiviral activities against TMV were evaluated (Figure 1). The biological assay revealed that some of the title compounds displayed moderate to good antiviral activity. For example, the title compounds $A_5$, $A_{12}$, $A_{25}$, and $A_{27}$ showed superior curative activities against TMV in vivo relative to the commercial agricultural antiviral agent ningnanmycin. To the best of our knowledge, this study is the first to report the synthesis and antiviral activity of 3-((2-((1*E*,4*E*)-3-oxo-5-arylpenta-1,4-dien-1-yl)phenoxy)methyl)-4(3*H*)-quinazolinone derivatives.

## MATERIALS AND METHODS

**Equipment.** The melting points of the products were determined under an XT-4 binocular microscope (Beijing Tech Instrument Co., China) and were left untouched. IR spectra were recorded on a Bruker VECTOR 22 spectrometer in a KBr disk. $^1$H and $^{13}$C nuclear magnetic resonance (NMR) (solvent $CDCl_3$ or DMSO-$d_6$) spectra were obtained on a JEOL-ECX500 NMR spectrometer at room temperature using tetramethylsilane as an internal standard. Elemental analysis was performed through an Elementar Vario-III CHN analyzer. Analytical thin-layer chromatography (TLC) was conducted on silica gel GF254 (400 mesh). TLC purification was conducted using silica gel. All reagents and reactants were purchased from commercial suppliers and were analytical reagent grade or chemically pure. All solvents were dried, deoxygenated, and redistilled prior to use.

**General Procedure for Preparation of the Key Intermediates.** 3-Chloromethyl-4(3*H*)-quinazolinone and 3-chloromethyl-8-methyl-4(3*H*)-quinazolinone were prepared according to the literature.[32] (*E*)-4-(2-Hydroxyphenyl)-3-butylene-2-one and (*E*)-4-(4-hydroxyphenyl)-3-butylene-2-one were prepared according to a previous report.[33] Intermediate **5** was prepared following reported methods.[34]

**General Procedure for Preparation of the Title Compounds $A_1$ to $A_{30}$.** Figure 2 shows the synthesis of the target compounds $A_1$ to $A_{30}$. A 50 mL round-bottomed flask equipped with a magnetic stirrer was charged with intermediates **3** (2.62 mmol) and **5** (1.31 mmol), acetone (50 mL), and $K_2CO_3$ (5.24 mmol). The flask was stirred at room temperature for 10 min, after which KI (1.31 mmol) was added. The resulting mixture was refluxed and stirred at 56 °C for 5 to 10 h. TLC was used to monitor the progress of the reaction. After the reaction was completed (as indicated by TLC), the solvent was removed under depressurization, and the residue was dissolved with $CH_2Cl_2$. The crude product was then separated through TLC purification using silica gel. The solid was recrystallized from dichloromethane/petroleum ether (2:1, v/v) to obtain the title compounds $A_1$ to $A_{30}$ at 25% to 55% yields. The experimental protocols show the physical characteristics, IR, $^1$H NMR, $^{13}$C NMR, and elemental analysis data for all the synthesized compounds. The data for compound $A_5$ are shown below, and the data for compounds $A_1$ to $A_{30}$ are shown in the Supporting Information.

**Antiviral Biology against TMV.** *Purification of TMV.* Using the Gooding method,[35] the virus was multiplied in *N. tabacum* cv. K326 and purified. The absorbance values were estimated at 260 nm using an ultraviolet spectrophotometer.

$$\text{virus concn} = (A_{260} \times \text{dilution ratio})/E_{1\text{cm}}^{0.1\%,260\text{nm}}$$

*Half-Leaf Method Protective Effects of Title Compounds against TMV in Vivo.* The compound solution was smeared on the left side of growing *N. tabacum* L. leaves of the same age. The solvent was smeared on the right side of the leaves to serve as the control. The leaves, which were previously scattered with silicon carbide, were inoculated with the virus after 12 h using a brush dipped in $6 \times 10^{-3}$ mg/mL TMV and subsequently washed with water and rubbed softly along the nervature once or twice. The local lesions that appeared 3 to 4 d after the inoculation were counted.[36,37] Three replications were reproduced for each compound.

*Inactivation Effects of Title Compounds on TMV in Vivo.* The virus was inhibited after it was mixed with a compound solution of the same volume for 30 min. The right side of the *N. tabacum* L. leaves was then inoculated with the solvent and virus mixture for control. All of the leaves were previously scattered with silicon carbide. The number of local lesions was recorded 3 to 4 d after the inoculation.[37] Three replications were reproduced for each compound.

*Curative Effects of Title Compounds against TMV in Vivo.* Growing *N. tabacum* L. leaves of the same age were selected. The leaves were inoculated with TMV (concentration of $6 \times 10^{-3}$ mg/mL) by dipping and brushing the whole leaves, which were previously scattered with silicon carbide. The leaves were then washed with water after inoculation for 0.5 h. The compound solution was smeared on the left side of the leaves, and the solvent was smeared on the right side for control. The number of local lesions was counted and recorded 3 to 4 d after the inoculation.[37] Three replications were reproduced for each compound. The inhibitory rate of the compound was calculated according to the following formula ("av" means average):

## RESULTS AND DISCUSSION

**Chemistry.** Figure 2 shows the summary of the synthetic route designed for the 4(3*H*)-quinazolinone analogues. The starting materials were substituted with 2-aminobenzoic acid, formamide, salicylaldehyde, hydroxybenzaldehyde, and acetone. The substituted *o*-aminobenzoic acid was allowed to react with formamide for 4.5 h at 140 to 145 °C to obtain the intermediate 4(3*H*)-quinazolinone **1**, and then with 37% formaldehyde for 5 h at 80 °C to obtain the intermediate substituted 3-hydroxymethyl-4(3*H*)-quinazolinone **2**. The substituted 3-chloromethyl-4(3*H*)-quinazolinone **3** was prepared by chlorination reaction with $SOCl_2$ in 1,4-dioxane. Intermediates **5a** to **5m** were obtained through the condensation of the (*E*)-4-(2-hydroxyphenyl)-3-butene-2-ones and (*E*)-4-(4-hydroxyphenyl)-3-butene-2-ones with the substituted aldehydes in ethanol for 12 h at room temperature. The title compounds 4(3*H*)-quinazolinone derivatives ($A_1$−$A_{30}$) were synthesized by the etherification reaction of intermediates **5** and **3** with $K_2CO_3$/KI in acetone refluxed at 56 °C for 5 to 10 h. The final step of the reaction yielded some by-products. The purification compound obtained by the TLC and recrystallization methods involved the loss of some products. Thus, the yield of the title compounds is low. All compounds were confirmed by spectroscopic data and elemental analysis.

Table 1 shows the structures of all the compounds confirmed through IR, $^1$H NMR, and $^{13}$C NMR spectral and elemental analyses. The IR spectra of the title products $A_1$ to $A_{30}$ exhibited characteristic absorption bands at 3421 to 3460 $cm^{-1}$, which indicate the presence of amidic N−CH−N. The stretching frequency at 1690 to 1650 $cm^{-1}$ was assigned to C═O vibrations. The characteristic absorptions at 1491 to 1620

dx.doi.org/10.1021/jf502162y | J. Agric. Food Chem. 2014, 62, 8928−8934

$cm^{-1}$ and 1219 to 1316 $cm^{-1}$ were attributed to the presence of C═C and C−O−C groups, respectively. $^1H$ NMR indicated that all of the phenyl protons had multiplets at 7.50 to 6.71 ppm. The main characteristic of the $^1H$ NMR spectra for the compound was the presence of a high-frequency downfield singlet $\delta_H$ 8.18−8.62 for N−C−H protons. N−$CH_3$ absorption peaks showed a singlet at 2.56 ppm to 3.87 ppm. The chemical shifts at nearly 188.00 ppm, 71.81 to 73.75 ppm, and 17.35 to 17.42 ppm in $^{13}C$ NMR also confirmed the presence of C═O, $-CH_2-$, and $-CH_3$, respectively.

**Antiviral Activity Screening of Title Compounds against TMV in Vivo.** The antiviral tests of $\mathbf{A_1}$ to $\mathbf{A_{30}}$ against TMV were conducted, and the results are summarized in Table 2. Most of the title compounds generally exhibited good antiviral activity against TMV in vivo, and some of them even showed higher antiviral activity than the control ningnanmycin. Our results indicated that compounds $\mathbf{A_5}$, $\mathbf{A_{12}}$, $\mathbf{A_{25}}$, and $\mathbf{A_{27}}$ exhibited higher curative activity than ningnanmycin, with values of 64.3%, 63.5%, 69.0%, and 64.7% at 500 $\mu$g/mL, respectively. The other compounds showed moderate curative activities at 500 mg/L. Among these compounds, $\mathbf{A_8}$, $\mathbf{A_{10}}$, $\mathbf{A_{14}}$, $\mathbf{A_{16}}$, $\mathbf{A_{17}}$, $\mathbf{A_{25}}$, and $\mathbf{A_{29}}$ exhibited significant protective effects against TMV and produced relatively high inhibitory activities with values of 68.7%, 66.9%, 63.1%, 71.7%, 64.6%, 66.5%, and 71.6% at 500 $\mu$g/mL, respectively. These values are similar to those of ningnanmycin (68.4%) against TMV at 500 $\mu$g/mL. Compounds $\mathbf{A_2}$, $\mathbf{A_3}$, $\mathbf{A_5}$, $\mathbf{A_6}$, $\mathbf{A_{10}}$, $\mathbf{A_{12}}$, $\mathbf{A_{14}}$, $\mathbf{A_{16}}$, $\mathbf{A_{24}}$, $\mathbf{A_{28}}$, and $\mathbf{A_{29}}$ inactivated efficacy at 88.4%, 90.2%, 87.5%, 91.9%, 89.2%, 85.1%, 89.3%, 86.1%, 87.8%, 90.0%, and 91.2%, respectively. These compounds exhibited slightly lower inactivation activities than ningnanmycin (95.8%) at 500 $\mu$g/mL.

Based on previous bioassays, all the test compounds showed moderate to excellent activity against plant viruses (TMV). Table 3 lists the $EC_{50}$ values of some of the synthesized compounds. In short, the $EC_{50}$ values of about 18 compounds with inhibition rate higher than 40% were obtained. Compounds $\mathbf{A_5}$, $\mathbf{A_{12}}$, $\mathbf{A_{25}}$, and $\mathbf{A_{27}}$ exhibited remarkable curative effects against TMV, with $EC_{50}$ values of 132.25, 138.01, 156.10, and 135.89 $\mu$g/mL, respectively. These values indicate stronger curative activity against the tested virus of the compounds than those of the commercial agent ningnanmycin ($EC_{50}$ = 281.22 $\mu$g/mL). However, the $EC_{50}$ values of the others are higher than that of ningnanmycin. The results show that their anti-TMV activities are very good. These findings suggest that these compounds can be used as lead structures in discovering new antiviral agents.

**Antiviral Activity and Structure Activity Relationship against TMV.** Some of the compounds showed potential potency against TMV. Various 1,4-pentadien-3-one substituent groups were introduced into the 4(3*H*)-quinazolinone ring system to establish a structure−activity relationship based on the experimental data. Ningnanmycin, a commercially available plant virucide in China, was used as control. Most of the final compounds showed low to high antiviral activities against TMV at 500 $\mu$g/mL. Several title compounds showed comparably good activities relative to ningnanmycin. When $R_1$ was H and $R_2$ was substituted with 2-methoxyphenyl, 2-furyl, 4-methylthiazol-5-yl, or 3,4,5-trimethoxyphenyl groups, the corresponding target compounds exhibited excellent activity against TMV. The relationships of the antiviral activities to different $R_1$ and $R_2$ were deduced, as shown by the activity values in Table 2. The strongest curative activity against TMV was observed when $R_1$ was H and $R_2$ was changed to 2-methoxyphenyl, thiophen-2-yl, 3,4-dimethoxyphenyl, or 4-methoxyphenyl groups. Some of the title compounds were as potent as ningnanmycin. When $R_1$ was H and $R_2$ was substituted with 2-fluorophenyl, 4-methylthiazol-5-yl or 3,4,5-trimethoxyphenyl groups, the target compounds exhibited remarkable protective activities against TMV that surpassed those of ningnanmycin. Compounds $\mathbf{A_3}$, $\mathbf{A_{10}}$, $\mathbf{A_{28}}$, and $\mathbf{A_{29}}$ displayed good inactivation activities. The inactivation activities of these compounds were further investigated at various concentrations, using ningnanmycin as commercial control. The presence of 2-fluorophenyl, 2-furyl, 2-methoxyphenyl, or 3,4,5-trimethoxyphenyl groups in a compound effectively improved the antiviral activity of the compound more than that of other groups.

**Table 3. $EC_{50}$ Values of Some Compounds against TMV in Vivo**

| Compd. |  | | | $EC_{50}$ ($\mu$g/mL)[a] |

| $A_{30}$ | H | 3, 4, 5-tri-$OCH_3$-Ph | 2-O | 300.18±3.1 |
| Ningnanmycin[b] | | | | 281.22±2.0 |

[a]Average of three replicates. [b]The commercial, agricultural, and antiviral product ningnanmycin was used for comparison of activity.

In summary, 4(3*H*)-quinazolinone analogues containing a 1,4-pentadien-3-one moiety were prepared in moderate yield and evaluated for their antiviral activities against TMV. Some of the synthesized compounds exhibited moderate to excellent antiviral activity in vivo. The preliminary structure−activity relationships established the importance of the presence of a 1,4-pentadien-3-one moiety in the 4(3*H*)-quinazolinone component in obtaining title compounds with the desired antiviral activity. Compounds $\mathbf{A_5}$, $\mathbf{A_{12}}$, $\mathbf{A_{25}}$, and $\mathbf{A_{27}}$ possessed appreciable curative bioactivities against TMV in vivo, and such bioactivities were superior to those of ningnanmycin. Therefore, based on the antiviral studies on the biological efficacies, crop safety, and toxicities of these compounds, they can be considered for further development as a new class of tobacco protection agents.

matrices and minimize or correct matrix suppression from coeluted matrix components in the electrospray ionization (ESI) source.[22−24] However, optimization of extraction conditions is time-consuming and may be matrix and mycotoxin dependent. As a result a single extraction method may not be applicable to all food/feed matrices.[25] In addition, ESI-based LC−MS/MS analysis of mycotoxins is prone to matrix suppression. Despite extensive cleanup using immunoaffinity cartridges, matrix-matched calibration was still required for quantitation.[26] Although dilution could alleviate matrix suppression, dilution factors still have to be determined on a case by case basis.[27] Standard addition is feasible for

dx.doi.org/10.1021/jf503943r | J. Agric. Food Chem. 2014, 62, 8935−8943

samples containing a single mycotoxin, but preparation of fortified samples is very complex for samples with multiple mycotoxins with significantly different concentrations.

Isotope dilution mass spectrometry has been used for the quantitative analysis of elements and chemicals in biological, environmental, and food samples.[28−30] This mass spectrometry approach is based on the fortification of samples with isotope labeled internal standards (IS) (e.g., [$^{13}$C]-IS) prior to sample preparation or instrumental analysis. The target analytes and fortified IS have the same or similar physicochemical properties, which results in identical recoveries and MS responses. By measuring the relative response ratio between a target analyte and its corresponding labeled IS, signal variations caused by sample loss or ionization suppression are corrected as the relative response ratio would remain constant.

Stable isotope dilution would be a viable approach for multimycotoxin analysis in challenging matrices such as animal feed, cereal/grain-based baby formula, dry botanicals, and spices. To eliminate matrix interferences and achieve satisfactory recoveries of target mycotoxins, one often has to perform laborious matrix/mycotoxin-dependent cleanup or prepare matrix-matched calibration standards for quantitation. In theory, the application of stable isotope dilution should be instrument-, matrix-, and mycotoxin-independent, as long as the target mycotoxin and the corresponding labeled internal standard could be detected. This way, sample preparation and quantitation would be significantly simplified and developed stable isotope dilution methods could be expanded to other matrices of interest. Furthermore, a developed stable isotope dilution method could be easily shared by laboratories using different LC−MS instruments. Although using [$^{13}$C]-mycotoxins as IS would simplify the analysis of multimycotoxins in food/feed, researchers have only tested the applicability and benefits of this approach in a few food and feed matrices.[31−33] The application of stable isotope dilution has not been a well-establish practice among mycotoxin laboratories due to the lack of commercially available isotope labeled internal standards. Recently, certified isotope labeled mycotoxins can be obtained from various commercial sources. The increasing sensitivity of LC−MS makes it more cost-effective to use these labeled internal standards because only a small amount of the labeled standards is required to be used. To take advantage of the available isotope labeled mycotoxins and the sensitivity of today's LC−MS, we used stable isotope dilution and LC−MS for multimycotoxin analysis in milk, milk-based infant formula, and food grade gums.[34,35] The aim of this work was to further assess the applicability of the stable isotope dilution mass spectrometry approach using important but more challenging matrices, animal feeds and cereal-based baby foods, for the determination of aflatoxin $B_1$, $B_2$, $G_1$, and $G_2$, deoxynivalenol, fumonisin $B_1$, $B_2$, and $B_3$, ochratoxin A, T-2 toxin, and zearalenone. Although the FDA has only established action or advisory levels for aflatoxins, deoxynivalenol, and fumonisins, we also included ochratoxin A, T-2 toxin, and zearalenone for exploratory purposes. Our method consisted of simple extraction and filtration steps. Quantitation for all target mycotoxins was achieved without using matrix-matched calibration.

## MATERIALS AND METHODS

**Chemicals and Materials.** Aflatoxins $B_1$, $B_2$, $G_1$, and $G_2$; deoxynivalenol; fumonisins $B_1$, $B_2$, and $B_3$; ochratoxin A; T-2 toxin; and zearalenone standards were purchased in neat form from Romer Laboratories, Inc. (Union, MO). Stable isotope labeled internal standards, [$^{13}C_{17}$]-aflatoxin $B_1$ (500 ng/mL), [$^{13}C_{17}$]-aflatoxin $B_2$ (500 ng/mL), [$^{13}C_{17}$]-aflatoxin $G_1$ (500 ng/mL), [$^{13}C_{17}$]-aflatoxin $G_2$ (500 ng/mL), [$^{13}C_{15}$]-deoxynivalenol (25,000 ng/mL), [$^{13}C_{34}$]-fumonisin $B_1$ (25,000 ng/mL), [$^{13}C_{34}$]-fumonisin $B_2$ (10,000 ng/mL), [$^{13}C_{34}$]-fumonisin $B_3$ (10,000 ng/mL), [$^{13}C_{20}$]-ochratoxin A (10,000 ng/mL), [$^{13}C_{24}$]-T-2 toxin (25,000 ng/mL), and [$^{13}C_{18}$]-zearalenone (25,000 ng/mL) were purchased from Romer Laboratories, Inc. (Union, MO). The names, molecular formulas, weights, structures, and LC−MS parameters of mycotoxins are included in Table 1.

Two European reference materials, ERM-BE375 (low level aflatoxins in compound feeding stuff) and ERM-BE376 (high level aflatoxins in compound feeding stuff), were purchased from Analytical Reference Materials International (Golden, CO). Dry cat (2)/dog food (2) and animal feed samples (10) and grain/rice/oatmeal-based baby formulas (17) were purchased from local stores in the Washington, DC, metropolitan area or other commercially available sources. Animal feeds are cotton seed meal, DDGs, hog, fish, and sheep feed. The dry cat/dog foods are mix of chicken meal, dried veggies/fruits, oat, rice, and grain. Fat, protein, fiber, vitamins, and minerals are listed as major ingredients on the labels. Baby food samples are rice, grain, or oatmeal-based cereal. Milk is not listed as one of the ingredients for these baby foods.

LC grade acetonitrile, methanol, water, and MS grade formic acid and ammonium formate were purchased from Fisher Scientific (Pittsburgh, PA). Amicon Ultra-4 centrifugal filters with Ultracel-3 membrane (3 kDa) were purchased from EMD Millipore (Billerica, MA).

**Stock and Calibration Solutions.** Stock standard solutions of aflatoxins $B_1$, $B_2$, $G_1$, and $G_2$; deoxynivalenol; fumonisins $B_1$, $B_2$, and $B_3$; ochratoxin A; T-2 toxin; and zearalenone were prepared by dissolving each mycotoxin (5.0 ± 0.1 mg) in 25.00 mL of acetonitrile in volumetric flasks. Three working solutions containing these mycotoxins (A, B, C), were prepared by diluting and pipetting an appropriate amount of each individual stock standard solution to a 10 mL volumetric flask and bringing it up to volume with acetonitrile/water (1:1, v/v). Stock solutions and working standard solutions used in this study were stored in the dark at −20 °C. In working solution A, concentrations of the mycotoxins were prepared as follows: 1,000 ng/mL for aflatoxins $B_1$, $B_2$, $G_1$, and $G_2$; 20,000 ng/mL for deoxynivalenol and fumonisins $B_1$, $B_2$, and $B_3$; 10,000 ng/mL for ochratoxin A; and 20,000 ng/mL for T-2 toxin and zearalenone. Working solution B consisted of 200 ng/mL of aflatoxins $B_1$, $B_2$, $G_1$, and $G_2$; 4,000 ng/mL of deoxynivalenol and fumonisins $B_1$, $B_2$, and $B_3$; 2,000 ng/mL of ochratoxin A; and 4,000 ng/mL of T-2 toxin and zearalenone. Working solution C consisted of 40 ng/mL of aflatoxins $B_1$, $B_2$, $G_1$, and $G_2$; 1,000 ng/mL of deoxynivalenol and fumonisins $B_1$, $B_2$, and $B_3$; 400 ng/mL of ochratoxin A; and 800 ng/mL of T-2 toxin and zearalenone. Calibration solutions were prepared from the working standard solutions by a series of dilutions on the day of experiment.

A mixed [$^{13}$C]-IS solution was prepared by mixing an appropriate amount of each [$^{13}$C]-IS in a 5 mL volumetric flask and bringing it up to volume with acetonitrile/water (1/1, v/v). The final concentrations were 100 ng/mL for [$^{13}C_{17}$]- aflatoxin $B_1$, [$^{13}C_{17}$]- aflatoxin $B_2$, [$^{13}C_{17}$]- aflatoxin G1, and [$^{13}C_{17}$]- aflatoxin $G_2$; 2,000 ng/mL for [$^{13}C_{15}$]-deoxynivalenol, [$^{13}C_{34}$]- fumonisin $B_1$, [$^{13}C_{34}$]- fumonisin $B_2$, and [$^{13}C_{34}$]- fumonisin $B_3$; 500 ng/mL for [$^{13}C_{20}$]-ochratoxin A; and 1,000 ng/mL for [$^{13}C_{24}$]-T-2 toxin and [$^{13}C_{18}$]-zearalenone.

**Sample Preparation and Recovery Studies.** Samples were homogenized with dry ice in a Robot Coupe blender (Ridgeland, MS) to a powdery consistency and then put into polypropylene freezer bags and stored at −20 °C. The bags were not immediately sealed to allow residual carbon dioxide to sublime. Ground samples (0.5 ± 0.01 g) were weighed into 15 mL disposable glass vials with solid green melamine cap and PTFE liner (Sigma, St. Louis) and then fortified with 50 μL of [$^{13}$C]-IS solution, prior to extraction This way the fortified standard would go through the sample preparation and instrumental analysis as the target mycotoxin and the signal variation of target mycotoxin caused by sample preparation or matrix suppression could be offset by monitoring the relative response

between the mycotoxin and the corresponding [$^{13}$C]-IS. The glass vials were capped, placed on a shaker with pulsation (Glas-Col, Terre Haute, IN, USA), and shaken for 10 min at a speed set to 50 and pulsation frequency set at 30−35 pulsations/min. After the addition of 5.0 mL of acetonitrile/water (50:50, v/v), the vials were shaken again for 15 min at a speed set to 50 and pulsation frequency set at 30−35 pulsations/min. A 2.0 mL aliquot of the sample was transferred to an Amicon Ultra-4 centrifugal filter with Ultracel-3 membrane (molecular weight cutoff value of 3 kDa) and centrifuged for 30 min at 4500 rpm (4200*g*). The aliquots of the resulting filtrates were transferred into autosampler vials with polypropylene cap and PTFE/silicone septa for LC−MS/MS analysis. Recovery studies were carried out using dry cat/dog food, animal feed, and grain/oatmeal/rice-based infant formula at three fortification levels (Tables 3, 4). The prepared working solution A, B, or C (25 $\mu$L for baby foods and 50 $\mu$L for dry cat/dog food and animal feed) and IS solution (50 $\mu$L) were added to samples and then prepared following the extraction, centrifugation, and filtration procedures described above. At each fortification concentration, samples were prepared in quadruplicate. No mycotoxins were detected in blank samples used for recovery studies.

Quantitation was performed using solvent only calibration standards. The concentration of each target mycotoxin was determined using the peak area ratio of response of the mycotoxin to that of the corresponding [$^{13}$C]-IS, and calculating the concentration by preparing a calibration curve using the peak area ratios of solvent-only calibration standards to that of the same [$^{13}$C]-IS. Each calibration curve consisted of multiple calibration standards and was constructed using least-squares regression. Recoveries were calculated using the formula "detected concentration/fortified concentration × 100%".

**Matrix-Dependent Limit of Detection and Quantitation.** The matrix-dependent limits of detection and quantitation (LOD and LOQ) for each analyte were obtained by following the U.S. Environmental Protection Agency's (EPA) protocol.[36] The matrix-dependent LOD was determined by analyzing ten replicates of matrix-matched calibration standards prepared by fortifying 5.0 mL of blank matrix with 25 and 50 $\mu$L of working solution C. The mean and standard deviations (SD) of each target mycotoxin were obtained from the ten replicates. The method-dependent LOD was calculated using the formula LOD = 2.821 × SD (critical $t_{0.01}$ = 2.821 for degree of freedom (df) of 9). The corresponding method dependent LOQ was calculated as 3 × LOD. At the determined LODs the confirmation transitions were detectable.

**Matrix Effects.** Calibration standards at multiple concentrations were prepared in the extraction solvent, and the blank baby food, dry cat/dog food, and animal feed extracts were prepared following sample preparation procedures. [$^{13}$C]-IS (5.0 $\mu$L) was fortified into each calibration standard (0.5 mL) prior to LC−MS/MS analysis. Matrix-matched and solvent calibration curves for all mycotoxins were established with coefficients of correlation ($r^2$) >0.99, including aflatoxins $B_1$, $B_2$, $G_1$, and $G_2$ (0.05−25 ng/mL); deoxynivalenol and fumonisins $B_1$, $B_2$, and $B_3$ (5.0−500 ng/mL); ochratoxin A (1.0−250 ng/mL); and T-2 toxin and zearalenone (2.5−250 ng/mL). A slope ratio of a pair of matrix-matched and solvent calibration curves was used to suggest ionization suppression. It is worth noting that only in-depth statistical analysis could determine whether two slopes are different.

**LC−MS/MS Conditions.** All sample analyses were performed on a Shimadzu Prominence/20 series (Columbia, MD) liquid chromatograph coupled with an Applied Biosystems (Forest City, CA) 6500 quadrupole linear ion trap (QTrap) mass spectrometer equipped with an electrospray ionization (ESI) interface source. LC separation was achieved using a Phenomenex Kinetex XB-C18 LC column (100 mm × 2.1 mm i.d., 2.6 $\mu$m) and a 10 × 2.1 mm guard cartridge (Torrance, CA). The LC mobile phases consist of 10 mM ammonium formate/0.1% formic acid/water (A) and 10 mM ammonium formate/0.1% formic acid/methanol (B). Gradient elution at 0.3 mL/min flow rate started at 5% B, was ramped to 40% B in 2 min via linear gradient mode and then to 100% B by 9 min via exponential gradient mode (pump B curves 3 to 6), was held for 2.5 min, and was changed to 5% B at 12 min. Total run time was 15 min including 3 min of column conditioning time. Injection volume was 10 $\mu$L, and the column temperature was 40 °C. Ionization source dependent parameters were set as follows: curtain gas (CUR), 30 psi; ion spray voltage, 4,500 V for the positive mode and −4,500 V for the negative mode; nitrogen collision gas (CAD), medium; source temperature (TEM), 500 °C; ion source gases 1 and 2 (GS1 and GS2), each at 60 psi. Resolutions at Q1 and Q3 were set to unit.

Two MRM transitions of each [$^{13}$C]-labeled or native mycotoxin were determined in a previous study[34,35] or generated using direct infusion. All native mycotoxins and [$^{13}$C]-IS were monitored in polarity switching ionization mode. Switching time was 20 ms, scan time was 0.2 s, and the scheduled MRM window was set to 30 s. Zearalenone and [$^{13}$C]-zearalenone were analyzed in the negative mode, and the other mycotoxins and [$^{13}$C]-IS were analyzed in the positive mode. Nitrogen gas (99% purity) was used in the ESI source and the collision cell. The identification of target mycotoxins was based on two specific MRM transitions. Retention time, values of DP, CE, and CXP, and the two selected MRM transitions are listed in Table 1.

## RESULTS AND DISCUSSION

**MS/MS Optimization.** One of the limitations associated with MS/MS analysis is that it is difficult to predict whether a selected MRM transition will be free from coextracted/eluted matrix interferences from food or feed samples. The molecular ions ($[M + H]^+$ or $[M - H]^-$) for all target myxotoxins and [$^{13}$C]-mycotoxins in full-scan MS experiments were determined using positive or negative ionization mode. For each analyte, the two most intense fragments (MRM transitions) were generated and selected using MRM compound optimization tuning. Because these transitions were determined using solvent-only standards, it is possible that MRM transitions may be suppressed due to matrix interferences compromising the sensitivity and specificity needed to identify and quantitate

mycotoxins. This is especially true in complex matrices prepared without using extensive sample cleanup. In the course of developing the method, some MRM transitions such as 319.2 $m/z$ → 128.0 $m/z$ of zearalenone and 328.8 $m/z$ → 115.1 $m/z$ of aflatoxin $G_1$ became difficult to monitor in some animal feed samples, though they worked well in solvent or baby food matrices. Because of this, the method was modified to use different MRM transitions (328.8 $m/z$ → 200.0 $m/z$) for aflatoxin $G_1$ and using negative ionization mode to monitor zearalenone. This modification allowed the two mycotoxins to be unambiguously identified in animal feed samples. Figure 1 shows that the new transition (328.8 $m/z$ → 200.0 $m/z$) of aflatoxin $G_1$ can be clearly detected in the same animal feed samples. Under positive ionization mode, the absolute signal intensity of zearalenone is higher than that under negative ionization mode, but the sensitivity (single-to-noise ratio) was offset by the corresponding high background noise caused by coeluted matrix components. The second transition was barely detected. Switching to negative ionization mode produced a much cleaner background, and even though the absolute signal intensity of zearalenone decreased, the resulting signal-to-noise became sufficient for identification and quantitation (Figure 2).

**Matrix Effects.** For this study slope ratios between matrix-matched calibration curves and solvent calibration curves were used to graphically suggest matrix effects in the test samples. If the suppression or enhancement is marginal, the ratio (matrix-matched/solvent-only standard) would equal or be very close to 1.00; if there is severe suppression/enhancement, the ratio would deviate from one. Specifically, using [$^{13}$C]-IS, the ratios of the 11 mycotoxins in the six tested matrices center toward 1.00, ranging from 0.86 (aflatoxin $G_2$ in animal feed extract) to 1.09 (ochratoxin A in grain-based baby food extract) as illustrated in Figure 3. As previously discussed, [$^{13}$C]-IS and the unlabeled mycotoxins undergo the same ionization conditions, and therefore the coeluted matrix components have the same impact on a target mycotoxin and its [$^{13}$C]-IS during ionization.

dx.doi.org/10.1021/jf503943r | J. Agric. Food Chem. 2014, 62, 8935−8943

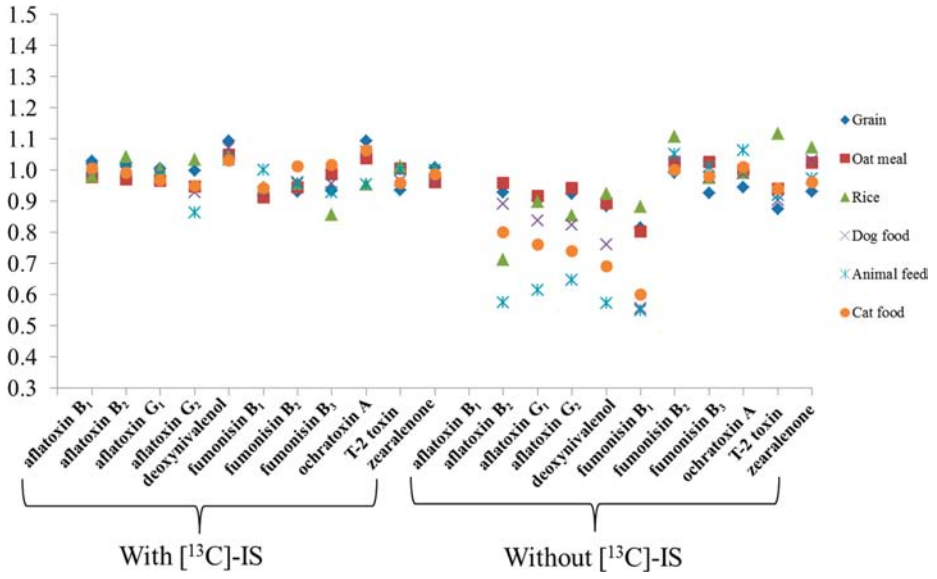

**Figure 3.** Slope ratios of matrix-matched and solvent calibration curves used to suggest matrix effects in baby food and animal feed matrices.

Therefore, if a calibration curve is established using relative responses of the mycotoxin and [$^{13}$C]-IS, the matrix suppression would be corrected. True matrix suppression or enhancement on the calibration curves can only be demonstrated by statistically evaluating the difference between the slopes and using the standard error of the slopes. However, here we have calculated a slope ratio to graphically suggest matrix effects in the different test samples (Figure 3). For example, without using [$^{13}$C]-aflatoxin $B_1$, the average slope ratio of aflatoxin $B_1$ in the six matrices is 0.81 with a RSD of 18%; while using [$^{13}$C]-aflatoxin $B_1$, the average ratio is 1.01 with a RSD of 2%. The same pattern is clearly observed for the other mycotoxins. These results emphasize the unpredictable and complex nature of matrix suppressions that would affect quantitation in the course of LC−MS/MS analysis, although it is well-known that matrix suppressions are determined by various factors such as physicochemical properties of target matrices and mycotoxin, sample preparation procedures, LC separation conditions, and MS ionization. There are no universal sample cleanup procedures, LC separation programs, or ionization sources that can eliminate/separate coeluted matrix interferences for these target mycotoxins. A common practice is to use matrix-matched calibration standards. It would be a heavy burden for researchers to find blank matrices and prepare matrix-matched calibration standards when analyzing multiple mycotoxins in a wide range of matrices, which has been the bottleneck for routine mycotoxin analysis that compromises sample throughput and increases labor cost per sample. Obviously, the use of [$^{13}$C]-IS eliminated the need for matrix-matched calibration standards for quantitation in this study, achieving satisfactory accuracy and precision in an efficient manner. If such a practice could be adopted for routine mycotoxin analysis, the corresponding sample throughput would be improved with ensured data quality.

**Matrix-Dependent LOQs and Recovery Studies.** It is important to determine the LODs/LOQs in an objective manner by factoring in the impact of matrix interferences and background noise. Whether the stable isotope dilution approach can be successfully applied for mycotoxin analysis is determined by the detectability of the native mycotoxins and their [$^{13}$C]-IS. Therefore, we chose to use the matrix-matched calibration standards at realistic low concentrations to estimate the instrument LODs/LOQs. This way we would be able to find out the instrument performance in terms of the sensitivity in the presence of matrix components without overestimating or underestimating the sensitivity of the 11 target mycotoxins. Generally, LODs and LOQs are estimated using signal-to-noise (S/N) ratio (e.g., LOD = 3 × S/N and LOQ = 10 × S/N), but in extracted ion chromatograms, there is little or no background noise, making it difficult to accurately assess the sensitivity of target mycotoxins. Based on a well-established EPA protocol,[36] the LOQs of the 11 mycotoxins were determined by measuring the standard deviations of repeat injections of matrix-matched calibration standards at low concentrations. The LOQs were statistically estimated using a predefined confidence interval (e.g., 99%). Estimated LOQs ranged from 0.02 ng/g (aflatoxin $B_1$ in rice-based baby food) to 8.3 ng/g (deoxynivalenol in animal feed) (Table 2).

The major interferences in cereal-based baby food and animal feed matrices could be fat, proteins, and fibers. Complete separation of target mycotoxins with low concentrations from these matrix components would require extraction, solvent exchange, defatting, and extensive cleanup procedures. The diversity of physicochemical properties of the 11 target mycotoxins further complicates the selection of extraction and cleanup procedures.[13,14,37] Because quantitation was achieved based on the relative response between fortified [$^{13}$C]-IS and mycotoxins, only a simple dilution and filtration was used to prepare our samples. As long as a fortified [$^{13}$C]-IS and its native counterpart reached equilibration in extraction solvent and sample, the accuracy and precision would be maintained.[28] Recoveries at three fortification concentrations in the six selected matrices are listed in Tables 3 and 4. The majority of the recoveries are in the range of 70−120% with RSDs less than 20%. Obviously, using [$^{13}$C]-IS enabled us to achieve the confidence in quantitative analysis via a simple sample preparation. It is worth noting that at the lowest fortification concentration, 4 ng/g, aflatoxin $G_2$'s recoveries in all pet food and feed matrices are just around 70%, which is much lower than those of the other three aflatoxins. It is speculated that the ion suppression caused the signal intensity of aflatoxin $G_2$ to approach the detection limit, leading to the

low recoveries. Further studies need to be conducted to better understand the observation.

**Sample Analysis.** Two reference materials (animal feed) were analyzed to demonstrate the accuracy of the stable isotope dilution and LC−MS/MS method. In sample ERM-BE375, aflatoxins $B_1$ and $B_2$ were detected at 2.4 ± 0.2 ng/g (reference value: 2.6 ± 0.4 ng/g) and <LOQ (reference value: 0.2 ± 0.04 ng/g). Aflatoxins $G_1$ and $G_2$ (reference values: 0.4 ± 0.1 and <0.2 ng/g) were not detected. The current FDA action concentration for aflatoxins is 20 ng/g, and so we did not further modify our method to be able to detect aflatoxin $G_1$ or $G_2$ at these sub ng/g concentrations. The performance of the method was ensured with the detection of [$^{13}$C]-aflatoxins $B_1$, $B_2$, $G_1$, and $G_2$ around 0.5 ng/g in the same sample. For sample ERM-BE376, the detected concentrations of aflatoxins $B_1$, $B_2$, and $G_1$ were 11.8 ± 1.0 ng/g (reference value: 12.9 ± 1.8 ng/g), 0.69 ± 0.1 (0.68 ± 0.1 ng/g), and 4.9 ± 0.3 ng/g (reference value: 5.2 ± 0.8 ng/g). Aflatoxin $G_2$ was not detected, and no reference value was provided.

Previous studies have reported the presence of various mycotoxins in baby foods.[15,38] In order to determine applicability, the method was used to analyze market samples of baby food and animal feed (Table 5) as described in the Materials and Methods. In the 10 domestic grain/oatmeal/rice-based baby food samples, no mycotoxins were detected. Deoxynivalenol was detected in 4 out of the 7 rice/corn-based baby food samples collected from foreign countries, ranging from 46 ± 10 to 877 ± 57 ng/g (mean ± SD, $n$ = 3). Trace amounts of aflatoxin $B_1$, ochratoxin A, and zearalenone were detected in the foreign baby food samples as well, but the corresponding concentrations are lower than the method LOQs. Co-occurrence of multiple mycotoxins (including aflatoxins, fumonisins, and zearalenone) was observed in 2 of the 7 foreign baby food samples. No reported concentrations were above the FDA action or advisory concentrations. Mold contamination in rice and corn has been a persistent health issue, so it is not surprising to detect deoxynivalenol, fumonisins, or the other mycotoxins in related food products.

Multiple mycotoxins were detected in every animal feed or feed ingredient sample analyzed in this study. Except for aflatoxins $G_1$ and $G_2$, the other 9 mycotoxins were detected ranging from <LOQ to 5 ng/g for aflatoxin $B_1$, 0.3−1 ng/g for aflatoxin $B_2$, 62−2732 ng/g for deoxynivalenol, <LOQ to 2280 ng/g for fumonisin $B_1$, <LOQ to 5 ng/g for ochratoxin A, 6−67 ng/g for T−2 toxin, and 14−109 ng/g for zearalenone. The formulations of animal feed are complex and diverse,[18,39] and some of the major ingredients used for animal feed, such as distiller's dry grains (DDGs) or cotton seed meal, are prone to mold contamination.[20,40] Although the individual concentration of each detected mycotoxin is lower than FDA action or advisory levels, the health effects, if any, associated with cocontamination, additive toxicity, or other synergic effects of these mycotoxins in feeds are poorly understood.

In summary, a stable isotope dilution and LC−ESI-MS/MS method was developed that allowed for the simultaneous quantification of 11 mycotoxins of regulatory significance for the purpose of screening for these toxic compounds in cereal-based baby foods, dry cat/dog food, and animal feeds. Validation parameters were established in accordance with FDA method validation guidelines for sensitivity, accuracy, precision, and recovery. The method was applied to certified animal feed reference materials as well as baby food and feed samples collected from markets, showing that the method achieved identification and quantitation in a quick, easy, and reliable manner without using extensive sample cleanup or matrix-matched calibration. The method could be modified for application to other food matrices. Further applications of this stable isotope dilution mass spectrometry method for the analysis of multiple mycotoxins in other food matrices such as spices and dry botanicals are currently under way.

(GC), coupling with a flame ionization detector (FID) or mass spectrometer (MS).[14−16] $^{31}P$ NMR spectroscopy was reported to be convenient for the routine analysis of phospholipids from biological sources.[17] Along with the rapid development of soft ionization techniques, such as electrospray ionization (ESI) or matrix-assisted laser desorption and ionization time-of-flight (MALDI-TOF), mass spectrometry also became applicable to lipid analysis.[18,19] Han et al. developed a multidimensional mass spectrometry (MDMS)-based shotgun lipidomics method for comprehensively profiling lipids in biological samples.[20] Verardo et al. used HILIC and MS for the determination of phospholipids in virgin olive oil.[21] Jackson et al. successfully employed MALDI-TOF/MS and MALDI ion mobility (IM)-TOF/MS for direct analysis of phospholipids in rat brain tissue.[22]

In this study, we aimed to establish an efficient method for selective extraction of phospholipids from a complex shrimp waste sample (cephalothorax). Titania-coated silica ($TiO_2/SiO_2$) core−shell composites were synthesized and used as the sorbent for homemade solid-phase extraction (SPE) cartridge. The eluates were analyzed by a hydrophilic interaction chromatography (HILIC) coupled with quadrupole time-of-flight tandem mass spectrometry (QTOF/MS/MS).

## MATERIALS AND METHODS

**Chemicals and Regents.** Phospholipid standards, including phosphatidylcholine (PC, 14:0/14:0), phosphatidylethanolamine (PE, 15:0/15:0), phosphatidylinositol (PI, 16:0/16:0), and phosphotidylserine (PS, 14:0/14:0), were obtained from Avanti Polar Lipids, Inc. (Alabaster, AL) and prepared in solvents to a final concentration of 1 $\mu g\ mL^{-1}$. Titanium butoxide, chloroform, ethanol, and methanol were purchased from Fisher Scientific (Waltham, MA). Titanium dioxide and silica were purchased from Aladdin (Shanghai, China). Water with a resistivity of 18 MΩ cm was purified by a Milli-Q system from Millipore (Billerica, MA). Other chemicals and solvents were in the highest quality without additional purification unless specified otherwise.

**$TiO_2/SiO_2$ Synthesis.** $TiO_2/SiO_2$ composite was synthesized through a water-vapor-induced internal hydrolysis method with modification. Briefly, 3.5 g of titanium butoxide was dissolved in 14 mL of ethanol. The mixture was sealed, vortexed, and heated to 60 °C. A mass of 8 g of silica was added to the mixture under stirring until dryness. The obtained solid material was stored at 100 °C for 6 h. Afterward, 1 g of titania-precursor-loaded silica was placed in an open glass vial and kept inside an autoclave containing 20 mL of water at 60 °C for 5 h. Subsequently, the power was dried completely at room temperature and calcined under air at 500 °C for 5 h. Finally, 10 wt % $TiO_2/SiO_2$ composites were obtained.

**Sample Preparation.** Fresh shrimp was collected from a local market and well-stored at −20 °C in the Laboratory of Natural Products, City University of Hong Kong. The cephalothorax of shrimp was separated from muscles, rinsed with cold distilled water, and homogenized. A mass of 0.1 g of shrimp waste sample was accurately weighted, placed in a 5 mL polytetrafluoroethylene tube, mixed with 2 mL of $CHCl_3$/MeOH (2:1, v/v) solution, and extracted by an ultrasonic cleaning device for 15 min. Then, a potion of 2 mL of water was added, and the sample tube was centrifuged at 8000*g* for 10 min. The lower organic phase was recovered, and the aqueous phase was re-extracted with 2 mL of $CHCl_3$ for another 2 times, as described before. The collected organic phase were combined and evaporated under nitrogen flow. To minimize the risk of oxidation of the polyunsaturated fatty acids or lipid hydrolysis during the process of isolation, it is always recommended that the extractions process of lipids should be completed at a low temperature (4 °C) as soon as possible after collecting the cephalothorax of shrimp from a living shrimp body.

**SPE Procedure.** A mass of 150 mg of $TiO_2/SiO_2$ composite was packed into a 1 mL syringe. Polypropylene materials were set as frits at both sides to hold the sorbent (a bed of 0.6 cm height of $TiO_2/SiO_2$ was obtained). Before use, the homemade SPE cartridge was preconditioned and activated by washing with 3.0 mL of methanol and water (pH 5), respectively. The crude extract was loaded on and passed through the cartridge at a flow rate of 0.2 mL $min^{-1}$. Then, the cartridge was washed with 10% aqueous methanol to remove the matrix. After that, the analytes retained on the SPE sorbent were eluted with 1 mL of mixture of chloroform and methanol (1:2). The

dx.doi.org/10.1021/jf503040p | J. Agric. Food Chem. 2014, 62, 8944−8951

eluent was dried and redissolved in aqueous methanol for HILIC–QTOF/MS.

**HILIC–QTOF/MS Analysis.** Liquid chromatographic experiments were on an Agilent 1100 LC system, equipped with a quaternary pump and degasser, thermostatic autosampler (4 °C), and column compartment (50 °C). A YMC Triart diol HILIC column (4.6 × 250 mm, 3 μm) was employed for the chromatographic separation. The column was operated under gradient conditions with mobile phase A, 53 mM formic acid in ACN (pH ca. 4.0–4.5), and mobile phase B, 60 mM ammonium formate and 53 mM formic acid in water (pH ca. 3.6). The binary gradient program consisted of 0–15 min, 2% A (and 98% B); 15–60 min, from 2 to 40% A; 60–70 min, 40% A; and 70–80 min, from 40 to 2% A. The flow rate was set at 200 μL $min^{-1}$.

QTOF/MS was performed using a QSTAR mass spectrometer (AB Sciex, Foster City, CA) equipped with a TurboIonSpray source. Mass calibration and optimization of instrumental parameters were performed using a mixture of phospholipid standards dissolved in methanol at a flow rate of 10 μL $min^{-1}$. The TurboIonSpray source worked in negative-ion and full-spectrum mode. Mass spectra were acquired over the $m/z$ 400–2000 range at a scan rate of 1 s per spectrum. The optimized parameters were as follows: declustering potential (DP), 50 V; focusing potential (FP), 200 V; turbo ionspray voltage, 4500 V; declustering potential 2 (DP2), 10 V; gas source 1 (GS1), 50 psi; gas source 2 (GS2), 45 psi; curtain gas (CUR), 40 psi; and temperature (TEM), 400 °C. A collision energy (CE) of 20 V was applied to obtain MS/MS spectrum for the product ion scan (PIS). All of the acquisition and data analyses were performed using Analyst QS version 2.0 (AB Sciex, Foster City, CA).

## RESULTS AND DISCUSSION

**Characterization of $TiO_2/SiO_2$ Composites.** The scanning electron microscopy (SEM) characteristic of the silica gel and $TiO_2/SiO_2$ composites are shown in Figure 1. Before titania coating, the surface of silica gel was smooth and solid, as shown in panels A and B of Figure 1. After synthesis, a porous surface could be clearly observed (Figure 1C), and the shell was constructed by numerous $TiO_2$ microspheres (Figure 1D). All of these characteristics indicated that the $TiO_2/SiO_2$ composites were potential sorbents for selective enrichment and separation of phospholipids from the shrimp waste sample.

**SPE Parameter Optimization.** The efficiency of sample preparation and the cleanness of phospholipid extracts depend upon the factors of the SPE procedure, including sample loading, matrix washing, and analyte recovering. Therefore, the $TiO_2/SiO_2$-based SPE optimization was carried out by sequential selection of the pH conditions of the loading solvent, the polarity of the washing solvent, and the type and amount of eluting solvents, to achieve extracts with the highest recovery and the lowest amount of the matrix effect. The optimization experiments were performed using homemade SPE tubes packing with $TiO_2/SiO_2$ core–shell composites and a standard solution containing PC (14:0/14:0), PE (15:0/15:0), PI (16:0/16:0), and PS (14:0/14:0) at a concentration of 1000 ng $mL^{-1}$ each in methanol.

The retention behavior of phospholipids on $TiO_2/SiO_2$ composites is governed by their chemical properties and ionization state. Therefore, the pH value of loading solvents is important for the quantitative recoveries of phospholipids during the SPE procedure by influence of the interaction between the phospholipids and $TiO_2/SiO_2$ composites. There are studies reporting that phosphonate and phosphate moieties confer high affinity to $TiO_2$ under acidic pH, and the most favorable bonding mode is bidentate, involving two oxygen atoms in each bond.[23] Consequently, the adsorption capability of $TiO_2/SiO_2$ composites was tested by varying the pH from 2 to 9. The results were depicted in Figure 2A, and it can be found that the acidic condition is obviously better than the alkaline condition. The recoveries of the four standards decreased dramatically when the pH was increased to 8. Meanwhile, an extreme acidic condition is also not applicable because the signals of phospholipids are unstable and suppressed in the negative-ion mode. Finally, pH 5 was used, and maximal peak areas are acquired.

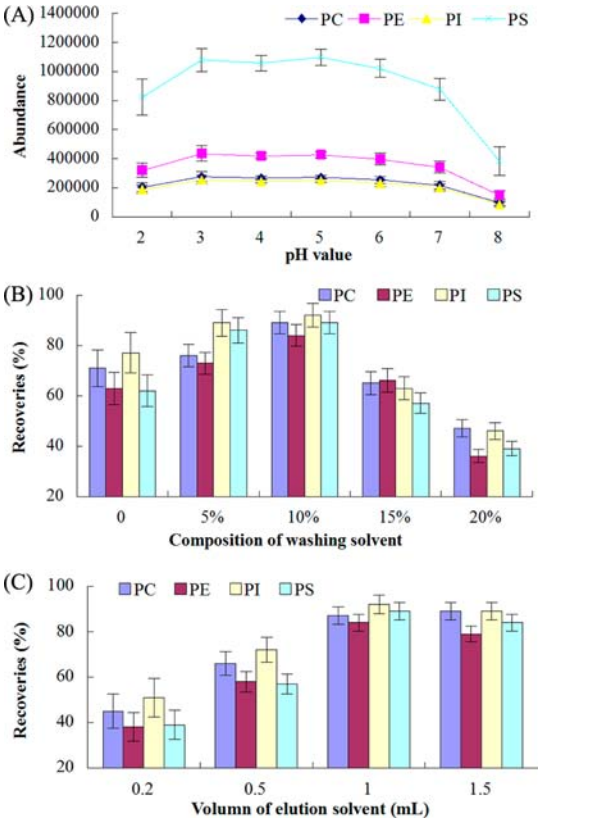

**Figure 2.** (A) Signal abundance of phospholipid standards PC (14:0/14:0), PE (15:0/15:0), PI (16:0/16:0), and PS (14:0/14:0) under different pH of loading solvents. Recoveries of phospholipid standards when the (B) polarity of the washing solvent and (C) type and amount of eluting solvents were varied. The standard solution, containing PC (14:0/14:0), PE (15:0/15:0), PI (16:0/16:0), and PS (14:0/14:0) at a concentration of 1000 ng $mL^{-1}$ each, was freshly prepared in methanol.

Given that the constitutes in the cephalothorax of shrimp are quite complex and they may easily influence the ionization efficiency of phospholipids in the ESI source, the polarity of the washing solvent was studied by varying the organic modifier from 0 to 20% methanol. It can be seem from Figure 2B that the recoveries of the four phospholipid standards increased gradually when the concentration of the organic modifier was raised from 0 to 10%. It indicated that some interfering matrix could be efficiently removed by the washing solvent. However, if the proportion of methanol was further increased to 15% or even 20%, the recoveries of phospholipids were decreased significantly. Finally, 10% aqueous methanol was chosen as the washing solvent.

After washing the $TiO_2/SiO_2$ SPE cartridge, the target analytes need to be eluted out using elution solvent with an appropriate amount. The elution solvents are characterized by their polarity and elution strength for a specific sorbent, and the

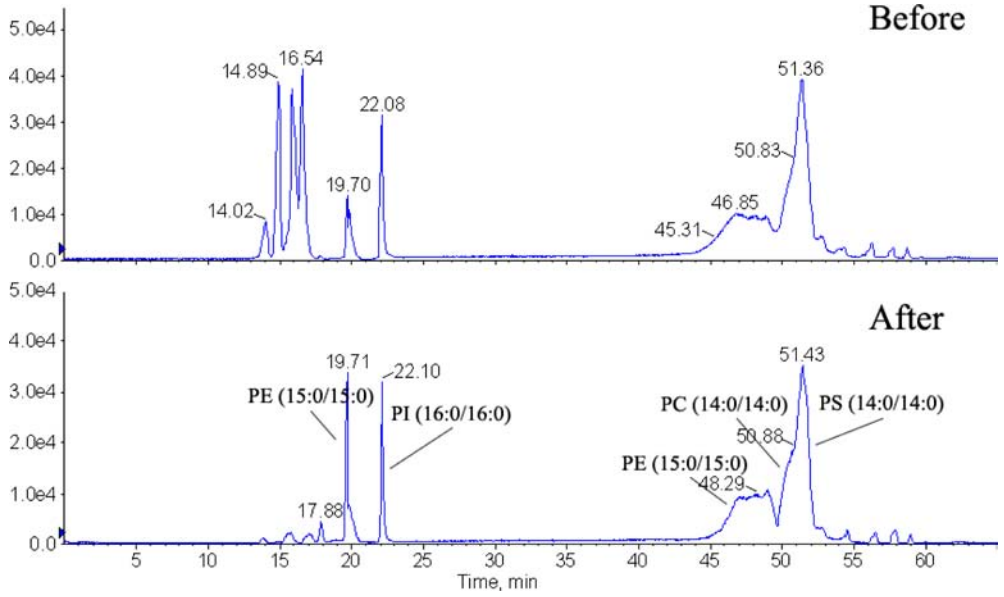

**Figure 3.** HILIC−QTOF/MS chromatograms relevant to the extract of shrimp waste using the (A) Bligh & Dyer method and (B) $TiO_2/SiO_2$ microsphere-based SPE method.

most suitable solvent was selected by testing a variety of solvents, including methanol, acetonitrile, and mixtures of chloroform and methanol (2:1, 1:1, and 1:2, v/v). During the study, it was found that a mixture of chloroform and methanol (1:2, v/v) can recover almost all of the phospholipids from the SPE sorbent, while the other solvent systems did not perform so well. After that, the optimum volume was tested by varying it from 0.2 to 1.5 mL. The results were demonstrated in Figure 2C, and it showed that the recoveries of phospholipid standards climbed up gradually and reached the highest value when 1.0 mL of elution solvent was used. Finally, 1.0 mL of chloroform/methanol (1:2, v/v) was used as the elution solvent.

**HILIC−QTOF/MS Development.** Prior to the application of the $TiO_2/SiO_2$ core−shell composite-based SPE for the determination of each phospholipid species in the cephalothorax of shrimp by HILIC−QTOF/MS, the following performance studies were implemented, including linearity, limit of detection (LOD) and limit of quantification (LOQ), accuracy and precision, and recovery. The method linearity (peak area versus concentration) was evaluated to overcome ion suppression/enhancement, matrix effects and variations caused by instrument parameters, sample preparations, and injections. A linear matrix-matched calibration model was used on the basis of the analysis of the data with six levels of concentration by linear regression with intercepts and $1/x$ weighting factor. All of the compounds displayed good linearity in selected concentration ranges (Table 1). The correlation coefficients ($R^2$) of the calibration curves were in the range between 0.9964 and 0.9978 ($n = 6$), which indicated good linearity between the peak area ($y$) and investigated compound concentration ($x$, ng $mL^{-1}$). LOD and LOQ were calculated on the basis of the signal-to-noise ratio (S/N = 3 for LOD and S/N = 10 for LOQ) on the mass spectrograms of the tested waste samples. The results (Table 1) showed that the LOD and LOQ were less than 0.25 and 0.78 $\mu g\ mL^{-1}$, which indicated enough sensitivity for conducting the determination process. Accuracy and precision were expressed in terms of repeatability by running seven extracts of shrimp waste samples on a single day (intraday), and reproducibility was quantified using five replicate samples spiked at the same levels on five different days (interday). Three replicates were performed at each spiking level to determine the relative standard deviation (RSD). The RSD of intra- and interday accuracy for the four phospholipid standards in shrimp waste extracts were in the ranges of 4.3−6.3 and 5.8−8.1%, respectively. These data indicated that the repeatability, intermediate precision, and bias values of the assay are regarded as quite satisfactory. The performance of recovery was determined on the basis of the ratio of the measured concentration/fortified level × 100% at low, middle, and high different levels. The results of recoveries ranging from 74.2 to 102.4% (Table 1). It suggested that all of the phospholipid standards could be recovered well at low and medium concentration levels. However, when a high concentration of analytes was injected, the recoveries were easily influenced because of the MS/in-source fragmentation, leading to the cross-effect of phospholipids during ionization.

[a]Fatty acid chain constituents (sn-1/sn-2) were confirmed by $MS^2$ analysis and referred to other results already published. [b]The concentration data of phospholipids are shown as the mean and standard deviation (SD) ($n$ = 6). [c]In the notation *a*16:0/18:3, *a* means alkyl linkage (1-*O*-alkyl or plasmanyl). [d]ud stands for undetected.

**Analysis of Phospholipids in Shrimp Waste.** The well-optimized strategy, $TiO_2/SiO_2$ composite-based SPE and liquid chromatography−tandem mass spectrometry (LC−MS/MS), was then applied to shrimp waste samples (*L. vannamei*). The chromatograms of lipid extracts before and after SPE purification were recorded in Figure 3. As shown, many peaks could be observed in the chromatogram of crude lipid extract (Figure 3A). After the mass spectra were checked, many of them, especially the four significant peaks in the retention time window from 14 to 18 min, could be regarded as interferences, because no unique fragments can be observed in their MS/MS spectrum, for example, $+m/z$ 184 (PC), $-m/z$ 196 (PE), $-m/z$ 241 (PI), etc. The results were further confirmed by $MS^2$ analysis. The complexity of the crude lipid extract could be attributed to the composition of the cephalothorax of shrimp, which comprised almost all of the organs, such as the brain, stomach, heart, and glands. Meanwhile, the extraction solvent, a mixture of chloroform and methanol, can dissolve a wide range of compounds, such as lipids, carbohydrates, organometallic compounds, and even some environmental contaminants. After SPE purification, the chromatogram (Figure 3B) became much cleaner and the non-phospholipid peaks were well-reduced. In addition, the intensity of the peak at 19.7 min was enhanced, and the resolution between two adjacent peaks in the retention time window from 45 to 53 min was improved as well. The results indicated that the $TiO_2/SiO_2$ core−shell composite-based SPE cartridge is efficient in selectively extracting phospholipids from the crude lipid mixture. Meanwhile, the well-purified phospholipid sample could be separated on a diol column and detected by a mass spectrometer with enhanced signal intensity and resolution.

The identity of each peak in the chromatogram (Figure 3B) was characterized by comparing their retention time to that of phospholipid standards and analyzing the mass spectra based on our experience. The fraction of PC class is eluated at ca. 50.5 min in the mass range from $m/z$ 800 to 900, and it was half-overlapped with the fraction of PS class, which is eluated at ca. 51.5 min in the mass range from $m/z$ 750 to 850. Fortunately, the overlap will not interfere with the calculation of the content of each phospholipid species, because they can be well-determined using an extracted-ion chromatogram (XIC). For PE class, two peaks could be observed in the chromatogram (at ca. 19.7 and 48.3 min, in the mass range from $m/z$ 680 to 820),

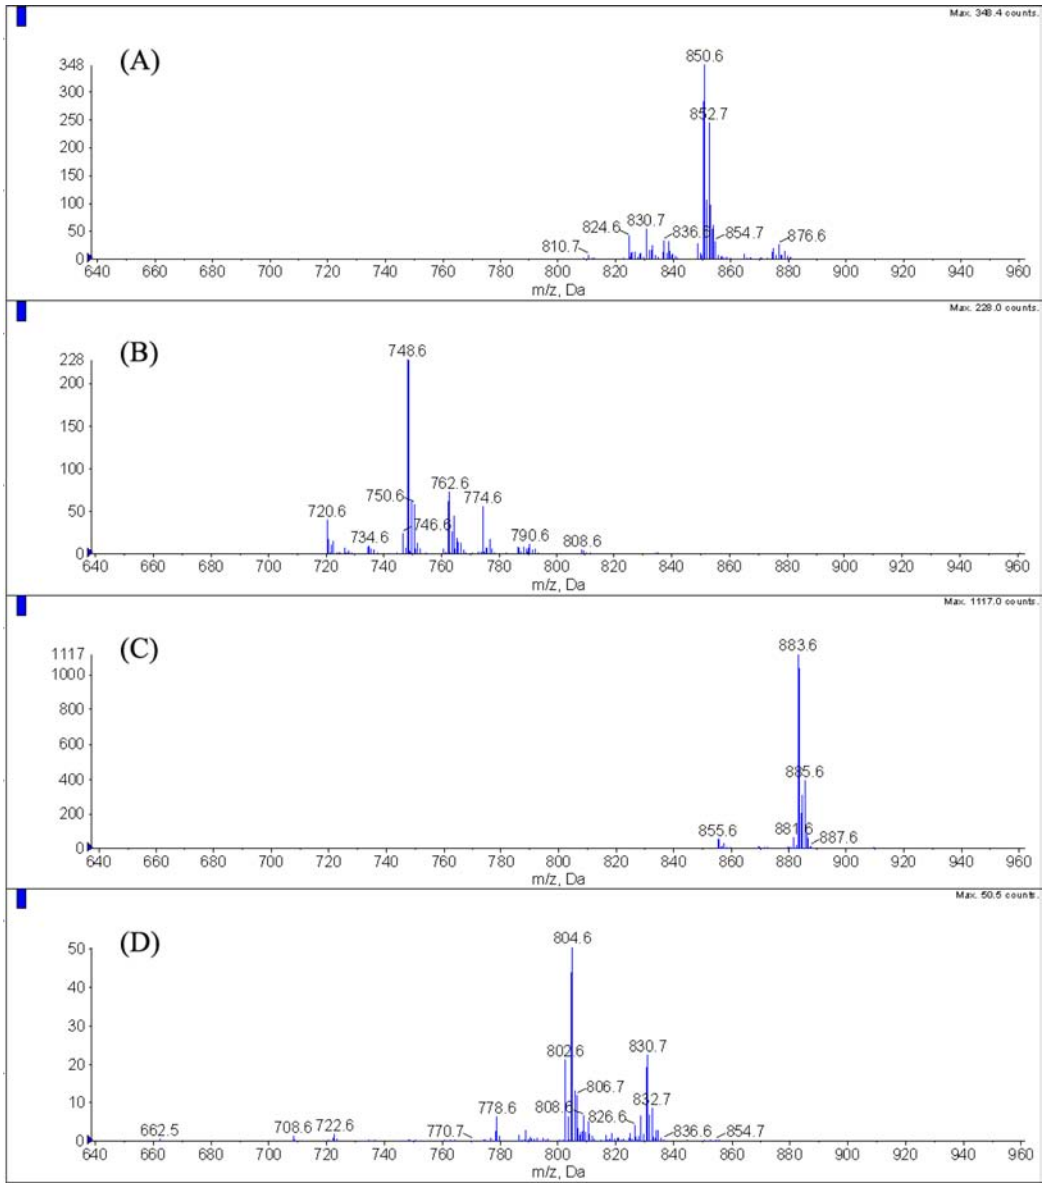

**Figure 4.** MS spectra of phospholipid classes: (A) PC, (B) PE, (C) PI, and (D) PS.

and the mass spectrum of these two peaks was identical. It was speculated that there were two states of PE molecules when they were dissolved in the acidic mobile phase, and the retention behavior of these two states of PE molecules was different. After evaporation and charging in the ESI source, the PE molecules became uniform, that is, $[PE - H]^-$. In fact, this phenomenon also could be found in another publication.[24] The PI class was eluated at a retention time of 22.1 min in the mass range from $m/z$ 850 to 900, with a sharp and symmetrical peak.

Identification of individual molecular species of each phospholipid class was based on the expected retention time and mass spectrum. The information on fatty acyl chain constituents (sn-1/sn-2) was obtained using $MS^2$ data, aided with the lipid map database and other results already published.[25] The characteristics of all of the detected phospholipids were summarized in Table 2. It is worth mentioning that, in the negative-ion mode, the species of PE, PI, and PS were all detected as $[M - H]^-$ ions, while the PC class was detected as formate adducts $[M + HCOO]^-$ because of the choline group at the polar head. Meanwhile, some minor peaks of $[M - 15]^-$ could also be observed in the mass spectrum of PC, resulting from the loss of the methyl group of choline. In this study, a total of 69 phospholipid species were detected and analyzed, including 20 PC species, 20 PE species, 8 PI species, and 21 PS species. Figure 4 demonstrated the mass spectra of the four phospholipid classes. The mass spectrum of PC species is shown in Figure 4A. All of the peaks were formate adducts in the mass range from $m/z$ 800 to 900. The most abundant peaks were $m/z$ 850.6 and 852.7, which were elucidated as [PC 16:0/22:6 + HCOO]$^-$ and [PC 18:0/20:5 + HCOO]$^-$, respectively. The others were also identified, and their sn-2 acyl chain proved to be unsaturated or polyunsaturated, such as 18:1, 18:2, 20:5, and 22:6. Besides, another sample injection was conducted under the same conditions but in positive-ion mode. All of the above-described PC species could be well-observed as protonated ions $[M + H]^+$ (data not shown), which well-confirmed the characteristics of PC species. PE species were quite diverse and mainly located in the mass range from $m/z$ 700 to 820, as shown in Figure 4B. A total of 20 PE species were successfully detected. The

dx.doi.org/10.1021/jf503040p | J. Agric. Food Chem. 2014, 62, 8944−8951

dominant ion at $m/z$ 748.6 was identified as [PE $a$18:1/20:5 − H]$^-$, where the symbol $a$ stands for alkyl linkage (1-$O$-alkyl or plasmanyl). Ions of $m/z$ 720.6, 750.6, 762.6, and 774.7 were also significant, and they were corresponding to [PE $a$16:1/20:5 − H]$^-$, [PE $a$18:0/20:5 − H]$^-$, [PE 18:1/20:5 − H]$^-$, and [PE $a$18:1/22:6 − H]$^-$, respectively. The mass spectrum of the PI class is shown in Figure 4C. Actually, not many PI species could be found, and only 6 species were detected, with a mass-to-charge ratio ranging from $m/z$ 850 to 900. The peak at $m/z$ 883.6 ([PI 16:0/22:5 − H]$^-$ and [PI 18:0/20:5 − H]$^-$) was the dominant ion, accompanied with some minor peaks, such as 855.6 ([PI 16:0/22:4 − H]$^-$). PS is also an important phospholipid class in the cephalothorax of shrimp (Figure 4D), and a total of 21 PS species were detected and elucidated, as summarized in Table 2. The most significant peaks were at $m/z$ 802.6, 804.6, and 830.6, and their structures were speculated to be PS 18:3/20:5, PS 16:1/22:6, and PS 18:2/22:6, respectively. In general, the phospholipids extracted from the cephalothorax of shrimp are diverse and concentrated in polyunsaturated fatty acyl chains at the sn-2 position, such as 18:3 [$\alpha$-linolenic acid (ALA)], 20:5 (EPA), and 22:6 (DHA), which are important for normal metabolism but cannot be synthesized by the human body. The phospholipid species in the cephalothorax of shrimp are very similar to that of other aquatic products, such as shark liver and Pacific oyster.[26,27]

Determination of phospholipids in the cephalothorax of shrimp was conducted on the basis of an external calibration model. The total contents of PC, PE, PI, and PS classes were calculated to be 1264.1, 904.4, 68.6, and 134.5 $\mu$g g$^{-1}$, respectively. As expected, PC was the most abundant class in the cephalothorax of shrimp, amounting to almost 53.3% of the total. PE is a close second, whose proportion is as much as 38.1%. The percentages of PI and PE are relatively lower, accounting for 2.9 and 5.7%, respectively. The content of each phospholipid species was determined using the normalization method. The principle is that the ionization efficiency of different covalently linked compounds in the ESI source depends upon the dipole potentials of each analyte. For phospholipids, the headgroup component contributes to the dominant dipole of the molecules, while other dipole components are neglectable. Therefore, the ionization efficiency of different naturally occurring phospholipid species is essentially identical within experimental error after correction for $^{13}$C isotope effects.[20] On the basis of that, all of the molecular species were quantitatively analyzed and listed in Table 2. The major phospholipid species of each class were PC 16:0/22:6 (480.7 $\mu$g g$^{-1}$), $a$PE 18:1/20:5 (378.0 $\mu$g g$^{-1}$), PI 18:0/20:5 (45.2 $\mu$g g$^{-1}$), and PS 16:1/22:5 (47.6 $\mu$g g$^{-1}$), and the proportions in their corresponding classes are 38.0, 41.8, 66.0, and 35.4%, respectively. The contents of phospholipid-containing saturated acyl chains (SAC), monounsaturated acyl chains (MUAC), and polyunsaturated acyl chains (PUAC) were depicted in Figure 5. It is obvious that the proportion of PUAC phospholipids takes as much as half of the total phospholipids. MUAC phospholipids were abundant in PE (33.8%) and PS (22.7%) classes. SAC phospholipids could be frequently found in PC (45.1%) and PI (49.8%) classes. It is well-known that polyunsaturated fatty acids (PUFAs) and monounsaturated fatty acids (MUFAs) are beneficial to human health. For example, PUFAs lower heart attacks and cardiovascular disease, while MUFAs reduce low-density lipoprotein (LDL) cholesterol but increase high-density lipoprotein (HDL) cholesterol. The high content of PUAC

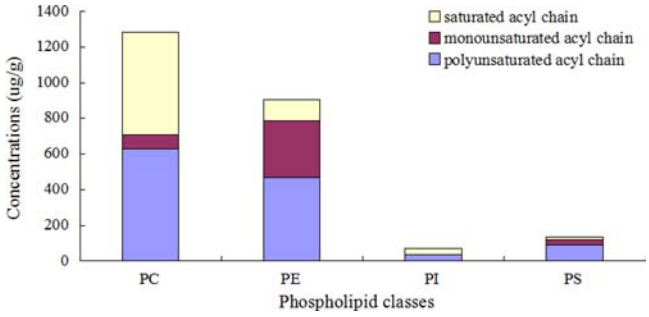

**Figure 5.** Content of SAC phospholipids, MUAC phospholipids, and PUAC phospholipids of each phospholipid class in the extract of shrimp waste.

phospholipids and MUAC phospholipids makes the shrimp waste an excellent recourse for industrial use.

**Method Comparison.** Most lipid extraction methods are designed for extracting the crude lipid mixture, while the method for selective extraction of phospholipids is still quite limited. It is reported that hybrid SPE−precipitation (hybrid SPE−PPT) and the $TiO_2$-based $\mu$SPE method can well remove the interferences and retain the phospholipids.[13,28] Unfortunately, the recovery information on these two techniques was not mentioned in the literature. As we known, the consumable materials of hybrid SPE−PPT are very expensive. On the other hand, $TiO_2$ is easily dispersed in the solvent; thus, it is unsuitable to be used directly as a sorbent of SPE. Montanari et al. introduced a supercritical carbon dioxide (SC-$CO_2$) method for selective extraction of phospholipids from soybeans.[29] However, its recovery of total phospholipids was only 74.8%, which is lower than that of the $TiO_2/SiO_2$-based SPE method (~90%). In summary, $TiO_2/SiO_2$-based SPE is a cost-effective and efficient method for selective extraction of phospholipids.

In conclusion, a $TiO_2/SiO_2$-based SPE method was successfully employed for selective extraction of phospholipids from shrimp waste (cephalothorax) samples. Under the optimized conditions, the interfering matrix is removed and the phospholipids are well-recovered. After that, a HILIC−QTOF/MS method was developed and fully validated to achieve baseline separation of phospholipid classes and characterization the distinctive phospholipid profile. As a result, a total of 69 phospholipid species were successfully identified and determined in shrimp waste. It is found that there is a great amount of phospholipids in shrimp waste, most of which contain PUAC, such as 18:3 (ALA), 20:5 (EPA), and 22:6 (DHA). Further effort will put in investigating the recycle of $TiO_2/SiO_2$ composite-based SPE cartridge. Preparative and process chromatography $TiO_2/SiO_2$ composites will also be studied for expanding the production and industrial application.

of type 1 diabetes. Moreover, insulin is also the only drug that triggers insulin signaling pathway via binding to IR.

*Momordica charantia* Linn. (MC) is a common vegetable that displays antidiabetic potential.[8−12] In a previous study, we have demonstrated that an aqueous extract of MC stimulates the insulin signaling pathway and displays a hypoglycemic effect in mice. By proteomic and docking analyses, we have found that trypsin inhibitor might interact with IR.[13] Trypsin inhibitor, also named as bitter gourd trypsin inhibitor or MC trypsin inhibitor, has been isolated from MC, and its amino acid sequences have been identified.[14] Trypsin inhibitor consists of 68 amino acid residues and inhibits not only trypsin but also subtilisin Carlsberg. In this study, we renamed this protein as MC IR-binding protein (mcIRBP) because of its novel function on glucose homeostasis. The physical and functional interactions between mcIRBP and IR were clearly elucidated here. Recombinant mcIRBP was purified from *Escherichia coli* (*E. coli*) overexpression system. The physical and functional interactions between mcIRBP and IR were analyzed by photo-cross-linking coupled with mass spectrometry (MS), IR-binding assay, and IR kinase activity assay. Furthermore, the hypoglycemic effect and mechanism of mcIRBP were evaluated in normal and type 1 diabetic mice. Our data showed that mcIRBP bound to the sites different from the insulin-binding sites on IR and consequently enhanced the uptake of glucose in cells and the clearance of glucose in mice.

## MATERIALS AND METHODS

**Chemicals.** Chemicals, unless indicated, were purchased from Sigma (St. Louis, MO). SuperScript III, RPMI-1640, and Dulbecco's modified Eagle's medium (DMEM) were purchased from Invitrogen (Carlsbad, CA). Fetal bovine serum (FBS) and calf serum were purchased from Hyclone (Logan, UT). [$^{125}$I]Insulin, [$\gamma$-$^{32}$P]ATP, and 2-[1,2-$^{3}$H(N)]-deoxy-D-glucose were purchased from PerkinElmer (Boston, MA). Rabbit monoclonal antibodies against IR, phospho-IR, phosphoinositide-dependent kinase 1 (PDK1), phospho-PDK1, Akt, phospho-Akt (Ser473), and phospho-Akt (Thr308) were purchased from Cell Signaling (Beverly, MA). Mouse monoclonal antibody against $\beta$-actin was purchased from Santa Cruz (Dallas, TX).

**Cloning of mcIRBP Gene.** To clone the mcIRBP cDNA, total RNA was extracted from MC, reverse transcribed by SuperScript III, and amplified with P1 (5′-GATCAAGCTTATGTGTCAGGGGA-AGTCGTCGTGGCCGCAG-3′) and M1 (5′-GATCGAGCTCT-CAACCGATGGTGGGGGGGCGGGCGACGAT-3′) primers. The resulting 216-bp mcIRBP cDNA fragment was inserted into *Hin*dIII and *Sac*I sites of pBluescript II KS(−) vector to create pBKS-mcIRBP. pBKS-mcIRBP was further amplified with P2 (5′-GATCACATGTG-TCAGGGGAAGTCGTCGTGG-3′) and T7 (5′-AATACGACTCA-CTATAG-3′) primers. The 242-bp mcIRBP cDNA fragment was then inserted into *Nco*I and *Sac*I sites of pET-28a(+) vector to create pET-mcIRBP (Figure 1A). The plasmid DNA, which was created in this study, was confirmed as an in-frame construction by sequencing. The template sequences for primer design are originated from GenBank (accession number: 2111250B). The protein sequences of mcIRBP have been deposited in GenBank (accession number: AGU04661.1).

**Expression and Purification of Recombinant mcIRBP.** Recombinant mcIRBP was expressed in *E. coli* BL21(DE3) pLysS strain, which was transformed with pET-mcIRBP. Expression and purification of recombinant mcIRBP were performed as described previously.[15] Molecular mass of mcIRBP was analyzed by sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS−PAGE), and the concentration of mcIRBP was quantified by a Bradford method (Bio-Rad, Hercules, CA).

**Photo-Cross-Linking Coupled with MS.** Photoinduced cross-linking was performed as described previously.[16] Briefly, mcIRBP was mixed with IR in a molar ratio of 10:1 in 10 mM sodium phosphate buffer (pH 7.4). To a total volume of 18 $\mu$L of protein solution were

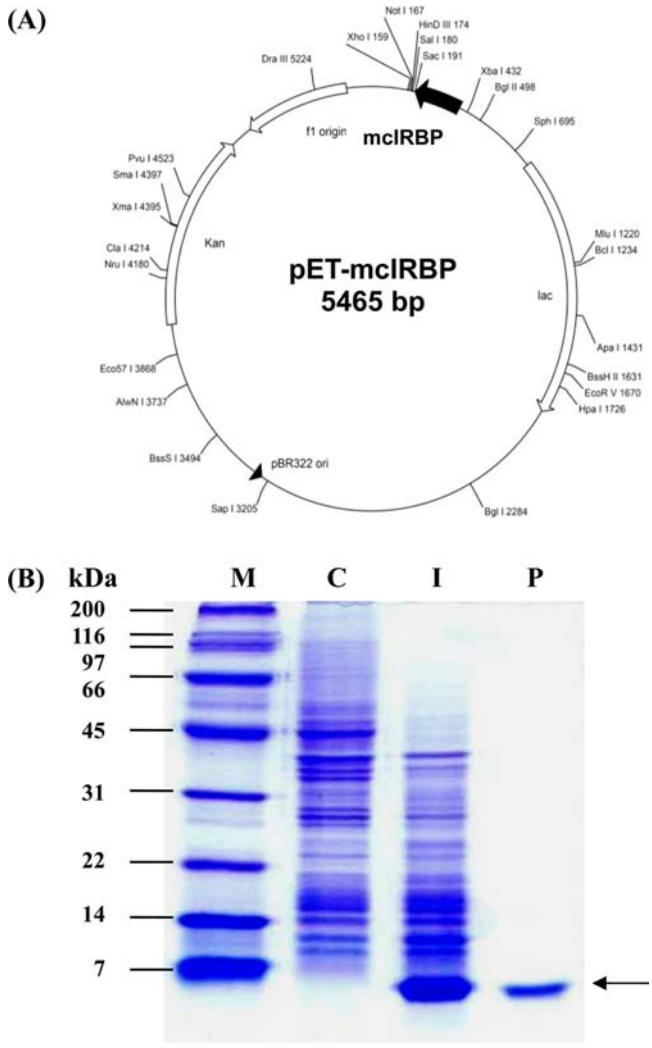

**Figure 1.** Cloning, expression, and purification of recombinant mcIRBP. (A) Map of pET-mcIRBP. The diagram represents the location of mcIRBP gene in the pET-28a(+) vector. Closed arrow represents mcIRBP gene. (B) SDS−PAGE analysis. The preparations of uninduced *E. coli* containing pET-mcIRBP (lane C), isopropyl-$\beta$-D-thiogalactoside-induced *E. coli* containing pET-mcIRBP (lane I), and purified mcIRBP (lane P) were analyzed by 15% SDS−PAGE and stained by Coomassie Brilliant Blue. The molecular masses of protein standards (lane M) are shown at the left. Recombinant mcIRBP is indicated by the arrow.

then added 1 $\mu$L of tris(bipyridyl)Ru(II) (RuBpy) solution (1 mM RuBpy in 10 mM sodium phosphate buffer, pH 7.4) and 1 $\mu$L of ammonium persulfate (APS) solution (20 mM APS in 10 mM sodium phosphate buffer, pH 7.4). The reaction mixture was exposed to ultraviolet light for 30 s and quenched by adding 1 $\mu$L of 1 M dithiothreitol. Protein solution was further identified using an Ultimate capillary liquid chromatography system (LC Packings, Amsterdam, The Netherlands) coupled to a QSTARXL quadrupole-time-of-flight MS (Applied Biosystem/MDS Sciex, Foster City, CA).

**Docking Calculations.** The PatchDock was used for the prediction of ligand-binding sites.[17] The PDB files of IR (PDB code 3LOH), mcIRBP (PDB code 1VBW), and insulin (PDB code 1JCO) were obtained from Protein Data Bank (http://www.rcsb.org/pdb/). The PDBQ files of these proteins were derived from PDB2PQR version 1.8 (http://nbcr-222.ucsd.edu/pdb2pqr_1.8/).[18]

**Cell Culture.** IM-9 myeloma cells, HepG2 hepatocytes, and 3T3-L1 preadipocytes were purchased from Bioresource Collection Research Center (Hsinchu, Taiwan). IM-9 cells were maintained in

dx.doi.org/10.1021/jf5002099 | J. Agric. Food Chem. 2014, 62, 8952−8961

RPMI-1640 supplemented with 10% FBS. HepG2 cells were maintained in DMEM supplemented with 10% FBS. 3T3-L1 preadipocytes were maintained in DMEM supplemented with 10% heat-inactivated calf serum. All cell lines were incubated at 37 °C in a humidified atmosphere containing 5% $CO_2$.

**IR-Binding Assays.** The binding of mcIRBP to IR was measured by IR-binding assay, IR kinase activity assay, and enzyme-linked immunosorbent assay (ELISA). IR-binding assay was performed as described previously.[19] Briefly, IM-9 cells ($1.2 \times 10^6$ cells/mL) were incubated with different amounts of mcIRBP for 15 min at 25 °C. $^{125}$I-labeled insulin (60,000 cpm/mL of cells) was then added and incubated for 90 min at 16 °C. Cells were centrifuged at 3000*g* for 10 min, and the supernatant containing unbound ligands was removed. The radioactivity of cell pellet containing bound $^{125}$I-labeled insulin was measured by scintillation counter (Beckman Coulter, Fullerton, CA).

IR kinase activity assay was performed as described previously.[13] Briefly, mixtures containing IR and various amounts of mcIRBP in kinase buffer (25 mM HEPES, pH 7.6, 25 mM $MgCl_2$, 100 $\mu$M ATP, 100 $\mu$M sodium orthovanadate, 2.5 mg/mL poly(Glu,Tyr), 25 $\mu$Ci/mL [$\gamma$-$^{32}$P]ATP) were incubated at 30 °C for 10 min and spotted on chromatography papers. Poly(Glu,Tyr) was precipitated on papers by soaking papers in 10% trichloroacetic acid solution, and the radioactivity incorporated into the precipitated poly(Glu,Tyr) was counted by scintillation counter.

For ELISA, HepG2 cells were treated with various amounts of mcIRBP, incubated at 37 °C for 10 min, and solubilized in lysis buffer (1% NP-40, 20 mM Tris-HCl, pH 8.0, 137 mM NaCl, 10% glycerol, 2 mM EDTA, 1 mM sodium orthovanadate, 10 $\mu$g/mL aprotinin, 10 $\mu$g/mL leupeptin) on ice for 15 min. After the centrifugation at 2000*g* for 5 min, the supernatant was collected, and the protein concentration was quantified. ELISA was performed with the DuoSet IC Human Phospho-IR set (R&D Systems, Minneapolis, MN). Briefly, microtiter plates (MaxiSorp, Nunc, Denmark) were coated with antibody against phospho-IR at 4 °C overnight, incubated with cellular proteins (250 $\mu$g) at room temperature for 2 h, and then incubated with horseradish peroxidase-conjugated antibody against phospho-tyrosine at room temperature for 2 h. Following four washes, chromogenic substrate tetramethylbenzidine was added, incubated at room temperature for 20 min, and stopped with 2 N $H_2SO_4$. The absorbance at 450 nm was measured in an ELISA plate reader.

**Western Blot Analysis.** HepG2 cells were cultured in 25 cm$^2$ flasks, treated with various amounts of mcIRBP for 30 min, collected using cell scrapers, and lysed with sample buffer (62.5 mM Tris-HCl, pH 6.8, 2% SDS, 10% glycerol, 50 mM dithiothreitol). HepG2 cells were also treated with LY294002 (50 $\mu$M) to block the PI3K activity. Proteins (10 $\mu$g) were separated by 10% SDS−PAGE and transferred electrophoretically to nitrocellulose membranes. Membranes were then probed with anti-IR, anti-phospho-IR, anti-PDK1, anti-phospho-PDK1, anti-Akt, anti-phospho-Akt (Ser473), anti-phospho-Akt (Thr308), and anti-$\beta$-actin antibodies. The bound antibody was detected with horseradish peroxidase-conjugated anti-rabbit antibody followed by chemiluminescence and X-ray film exposure.

**Adipocyte Differentiation and Glucose Uptake Assay.** The differentiation of 3T3-L1 preadipocytes was induced by the addition of 0.5 mM 3-isobutyl-1-methylxanthine, 0.5 $\mu$M dexamethasone, 10 $\mu$g/mL insulin, and 10% FBS in DMEM for 3 days. The aforementioned medium was then replaced with 10% FBS/DMEM containing 10 $\mu$g/mL insulin. After another 3 days, the medium was subsequently replaced with fresh culture medium (10% FBS/DMEM), which was changed every 2 days until the cells were fully differentiated, judged by oil red O staining. Fully differentiated 3T3-L1 adipocytes were used for glucose uptake assay. Glucose uptake assay was performed as previously described.[20] Briefly, 3T3-L1 adipocytes were cultured in 24-well plates. After a 4.5 h starvation, adipocytes were incubated in Krebs−Ringer bicarbonate buffer (118 mM NaCl, 4.7 mM KCl, 1.3 mM $CaCl_2$, 1.2 mM $MgSO_4$, 1.2 mM $Na_2HPO_4$, 2% bovine serum albumin, 0.5 mM glucose, 25 mM $NaHCO_3$, pH 7.4) without or with various amounts of mcIRBP for 30 min at 37 °C. [$^3$H]-2-Deoxy-D-glucose (0.1 $\mu$Ci) was then added to adipocytes and incubated for another 10 min. Finally, cells were solubilized in 0.1% SDS and the radioactivity uptaken by cells was measured by scintillation counter.

**Animals.** BALB/c mice were obtained from National Laboratory Animal Center (Taipei, Taiwan). Mouse experiments were conducted under ethics approval from China Medical University Animal Care and Use Committee (Permit Number: 101-188-N). Type I diabetic mice were induced by streptozotocin.[21] Briefly, male BALB/c mice (6 weeks old) were injected intraperitoneally with streptozotocin (200 mg/kg in 200 $\mu$L of normal saline). Two weeks later, mice were bled via tail veins after 4 h starvation, and the blood glucose was measured by glucose oxidase method using a glucometer (ACCU-CHEK Advantage, Roche Diagnostics, Basel, Switzerland).

**Glucose Tolerance Assay.** Normal and type I diabetic mice were fasted for 18 and 4 h, respectively. mcIRBP (2.5 nmol/kg) was then given intraperitoneally 15 min before intraperitoneal administration of glucose solution (4 g/kg for normal mice and 1 g/kg for diabetic mice).[22] Blood samples were collected from tails at 15 min before and at 15, 30, 60, 90, 120, 150, 180, 240, and 270 min after glucose challenge. Blood glucose was measured by glucose oxidase method using a glucometer. Data were also expressed as area under the curve (AUC). Mice were sacrificed 5 h after glucose challenge, and muscles were collected for microarray analysis.

**Microarray Analysis.** Five hours after glucose challenge, mice were sacrificed and muscle tissues were collected for microarray analysis. Total RNAs were extracted from muscle tissues using RNeasy Mini kit (Qiagen, Valencia, CA). Total RNA from three mice was pooled, and three microarray replicates for each pooled RNA were performed. Microarray analysis was performed as described previously.[23−25] Briefly, fluorescence-labeled RNA targets were hybridized to Mouse Whole Genome OneArray (Phalanx Biotech Group, Hsinchu, Taiwan). The Cy5 fluorescent intensity of each spot was analyzed by Genepix 4.1 software (Molecular Devices, Sunnyvale, CA). The signal intensity of each spot was corrected and further normalized by R program in the limma package.[26] Fold changes of genes were calculated by dividing the normalized signal intensities of genes in mcIRBP-treated tissues by those in untreated tissues. We used the geneSetTest function to test which biological pathways were affected by mcIRBP. This function computes a *p*-value to test the hypothesis that the selected genes in a pathway tend to be differentially expressed. Kyoto Encyclopedia of Genes and Genomes pathways (http://www.genome.jp/kegg/pathway.html) was extracted and used for this analysis. Microarray data are MIAME compliant, and raw data have been deposited in the Gene Expression Omnibus (accession number: GSE39689).

**Statistical Analysis.** Data were presented as mean ± standard error. Student's *t* test was used for comparisons between two experiments. A value of $p < 0.05$ was considered statistically significant.

## RESULTS

**Expression and Purification of mcIRBP.** In our previous study, we identified a trypsin inhibitor, named as mcIRBP here, that might interact with IR. The mcIRBP gene was therefore amplified by PCR and cloned for expression. mcIRBP was expressed and purified from *E. coli* BL21 (DE3) pLysS strain, which was transformed with pET-mcIRBP. After the induction with isopropyl-$\beta$-D-thiogalactoside, mcIRBP with molecular mass of approximately 7 kDa was observed by SDS−PAGE analysis (Figure 1B). The amount of purified mcIRBP recovered was approximately 2 mg per 100 mL of bacterial culture.

**Analysis of the Physical Interaction between IR and mcIRBP.** Photo-cross-linking coupled with MS was performed to analyze the physical interaction between IR and mcIRBP. mcIRBP was cross-linked with IR by ultraviolet light oxidized $Ru^{2+}$, and the cross-linked proteins were further identified by LC-MS/MS. We mixed mcIRBP and IR in the molar ratio of 1:1 and 10:1 and found that the cross-linking efficiency at 10:1

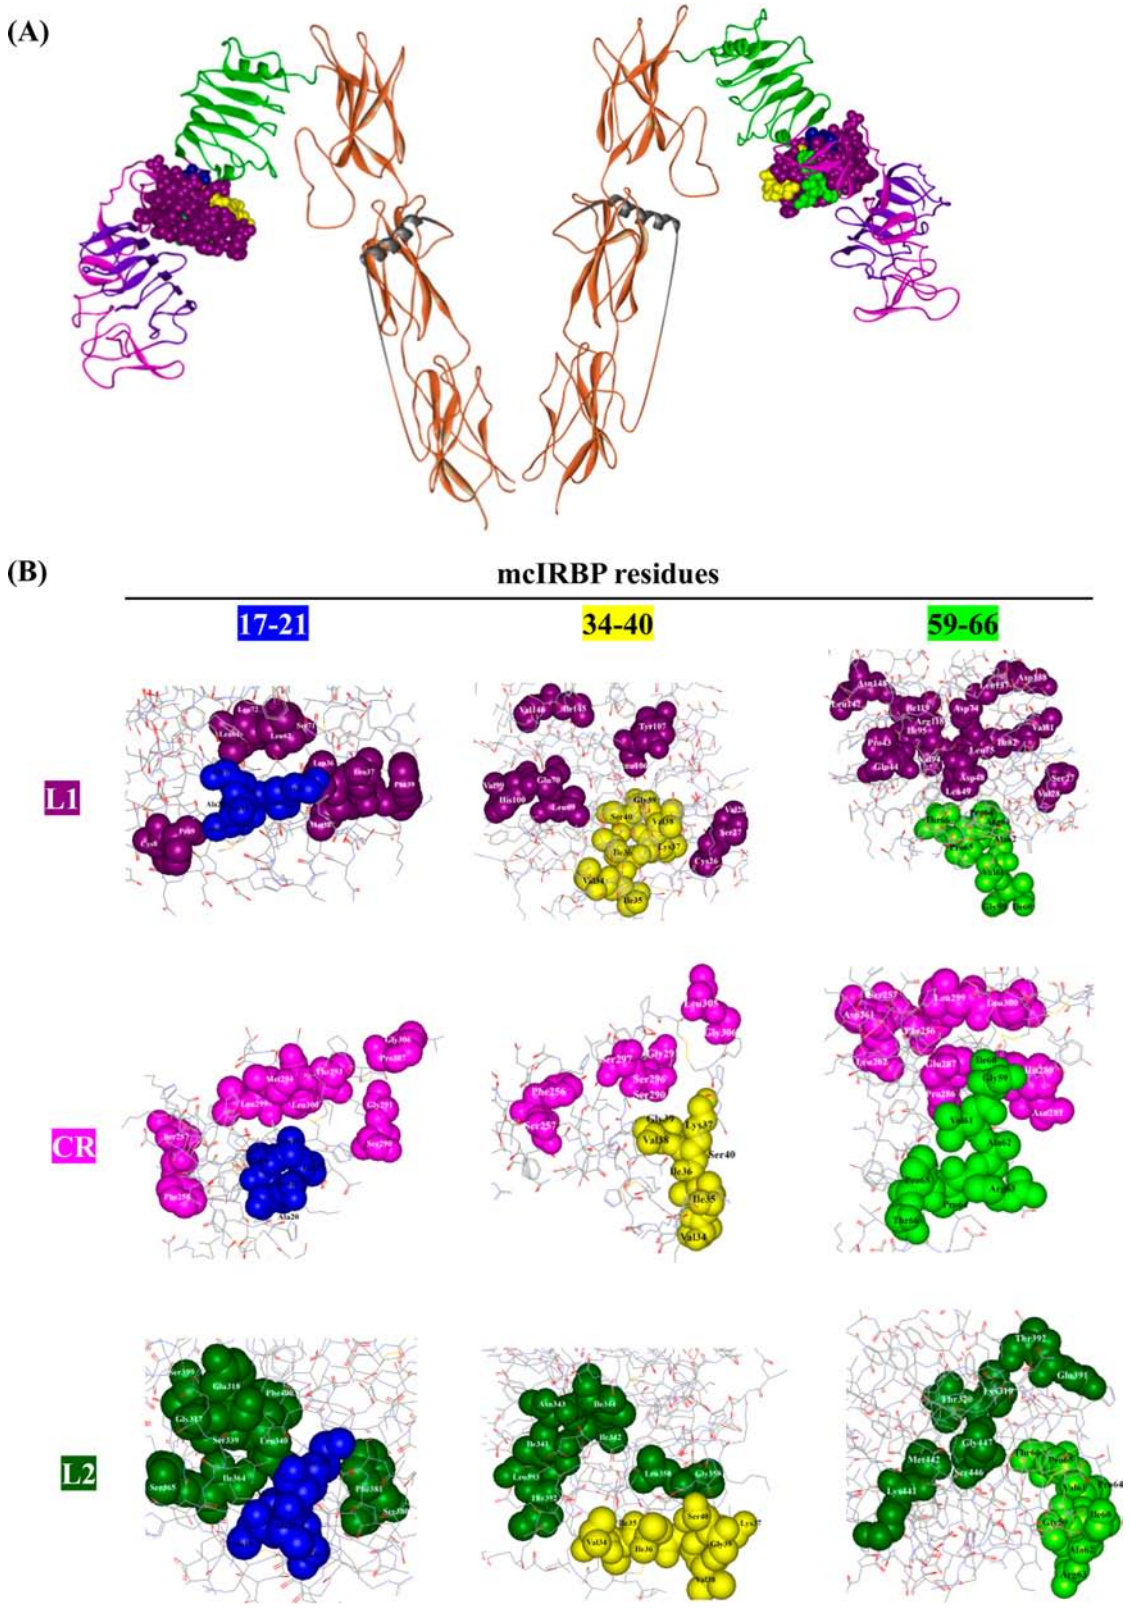

**Figure 2.** Physical interaction between mcIRBP and IR. (A) Docking structure of IR and mcIRBP. The IR ectodomain monomer is shown in a schematic presentation. L1, CR, L2, fibronectin domains, and $\alpha$-CT segment are colored purple, pink, green, orange, and gray, respectively. mcIRBP is shown in an atomic sphere representation. The 17−21, 34−40, and 59−66 amino acid residues of mcIRBP are colored blue, yellow, and light green, respectively. The remaining regions of mcIRBP are colored violet. (B) Close-up view of mcIRBP complexes with IR. The 17−21, 34−40, and 59−66 amino acid residues of mcIRBP and the amino acid residues located on L1, CR, and L2 regions of IR are shown in atomic sphere representations. The remaining regions of mcIRBP and IR are represented by stick styles.

dx.doi.org/10.1021/jf5002099 | J. Agric. Food Chem. 2014, 62, 8952−8961

was better (data not shown). A total of 2,731 peptide fragments was identified by MS/MS, and 1,518 fragments were chosen after excluding the repeated fragments. We further picked up the fragments that had ≥3 consecutive amino acid sequences of mcIRBP on the central region and ≥2 consecutive amino acid sequences of IR on either terminus. A total of 146 fragments fulfilling aforementioned criteria were selected. We found that three regions located on 17−21, 34−40, and 59−66 residues of mcIRBP physically interacted with the amino acid residues located on leucine-rich repeat domains and cysteine-rich (CR) region of IR.

We further built the docking structures of IR and mcIRBP based on photo-cross-linking data. As shown in Figure 2A, the crystal structure of IR ectodomain monomer formed an inverted "V" layout of which one side consists of leucine-rich repeat domains (L1 and L2) and CR region, and another side is composed of fibronectin domains and $\alpha$-CT segment. mcIRBP interacted with L1/CR/L2 segments on IR, and the docking score between mcIRBP and IR was 14,636. In comparison with mcIRBP, insulin, as expected, interacted with the $\alpha$-CT segment on IR, with a docking score of 14,134 (Supporting Information, Figure S1).[27] Close-up view of mcIRBP and IR showed that three regions located on 17−21, 34−40, and 59−66 residues of mcIRBP were close to the amino acid residues located on the L1, CR, and L2 regions of IR (Figure 2B). These data suggested that mcIRBP was a novel IRBP that bound to the sites different from the insulin-binding sites on IR.

We analyzed the binding behavior of mcIRBP on IR by incubating cells with various amounts of mcIRBP, radioisotope-labeled insulin (hot insulin), and/or non-radioisotope-labeled insulin (cold insulin). As shown in Figure 3A, when more hot insulin was added to a fixed amount of IR, an increasing fraction of IR was occupied by hot insulin. However, when more cold insulin was added to a fixed amount of IR and hot insulin, a decreasing fraction of IR was occupied by hot insulin (Figure 3B). These results indicated that cold insulin competed with hot insulin and blocked the insulin-binding sites on IR. Then, we measured the IR-binding behavior of mcIRBP by incubating IM-9 cells with various amounts of mcIRBP and 6 pM of hot insulin. As shown in Figure 3C, an increasing fraction of IR was occupied by hot insulin when an increasing amount of mcIRBP was added to a fixed amount of IR and hot insulin. These data suggested that mcIRBP bound to a site other than the insulin-binding sites on IR and enhanced the binding of hot insulin to IR. However, the amount of bound hot insulin in the presence of 10 nM mcIRBP was dramatically decreased by the addition of an excessive amount (1 $\mu$M) of cold insulin, suggesting that the mcIRBP-dependent enhancement of insulin binding on IR was specifically blocked and abolished by cold insulin. These results indicated that mcIRBP might bind to the allosteric site of IR and further enhance the effectivity of IR on the insulin binding.

**mcIRBP Enhanced the Kinase Activity and Autophosphorylation of IR.** IR is a transmembrane protein that exhibits tyrosine kinase activity. Insulin binding to IR stimulates the intrinsic tyrosine kinase activity, leading to the autophosphorylation of IR.[6] Therefore, we analyzed the kinase activity of IR by kinase activity assay and evaluated the level of autophosphorylated IR by ELISA. Figure 4A shows that the addition of insulin stimulated the kinase activity of IR by (7.35 ± 0.89)-fold. mcIRBP also enhanced the kinase activity of IR in a dose-dependent manner. Moreover, the maximal enhancement [(5.87 ± 0.45)-fold] of kinase activity was achieved in the

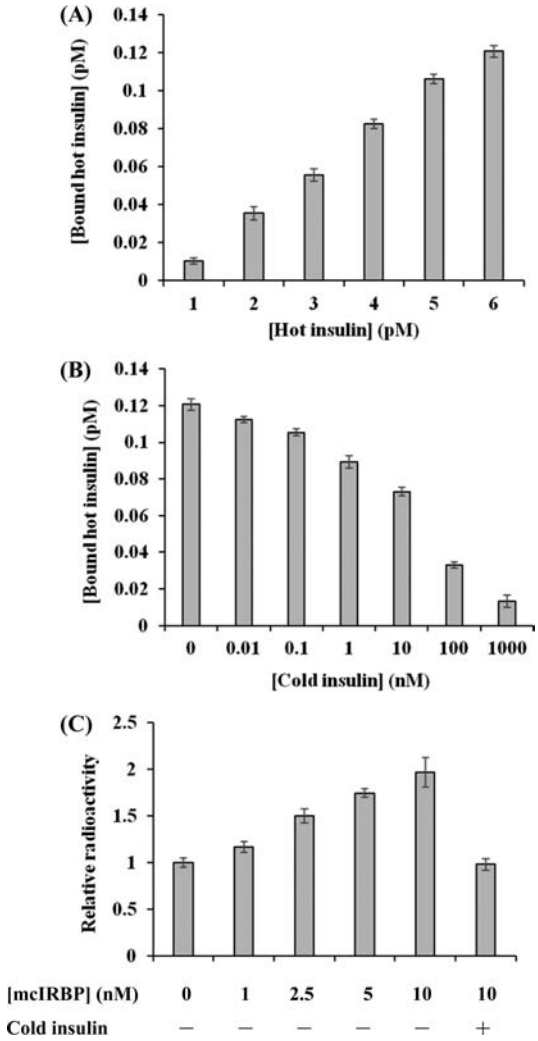

**Figure 3.** IR-binding assay of mcIRBP. IM-9 cells were treated with various amounts of $^{125}$I-labeled insulin (A), 6 pM $^{125}$I-labeled insulin and various amounts of insulin (B), or various amounts of mcIRBP, 6 pM $^{125}$I-labeled insulin, and/or 1 $\mu$M insulin (C). The reaction was incubated for 90 min at 16 °C, and the radioactivity of bound $^{125}$I-labeled insulin was counted by scintillation counter. Values are mean ± standard error ($n$ = 3).

presence of 5 $\mu$M mcIRBP. Figure 4B shows that insulin increased the level of phosphorylated IR in HepG2 cells, as compared with mock. mcIRBP significantly stimulated the autophosphorylation of IR in a dose-dependent manner. Moreover, the maximal increase [(1.31 ± 0.03)-fold] of phosphorylated IR was achieved by 5 $\mu$M mcIRBP. These findings indicated that mcIRBP bound to IR, activated the kinase activity of IR, and sequentially stimulated the autophosphorylation of IR.

**mcIRBP Affected IR/PI3K/Akt Signaling Pathway.** We further performed Western blot to analyze the IR-downstream signaling pathway affected by mcIRBP. As shown in Figure 5A, insulin and mcIRBP stimulated the phosphorylation of IR, which was consistent with aforementioned data (Figure 4). Insulin enhanced the phosphorylations of PDK1 and Akt at Ser473 and Thr308, as compared with mock. mcIRBP also increased the amounts of phosphorylated PDK1 and Akt in a dose-dependent manner. However, LY294002, a PI3K inhibitor, inhibited the mcIRBP-induced phosphorylation of

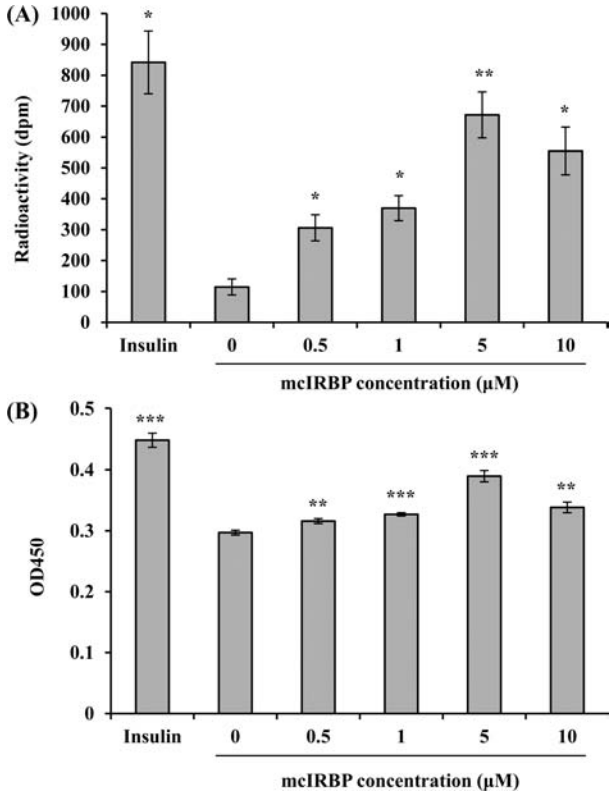

**Figure 4.** Effect of mcIRBP on the kinase activity and autophosphorylation of IR. (A) Kinase activity assay. IR was mixed with 0.5 $\mu$M insulin or various amounts of mcIRBP in the presence of [$\gamma$-$^{32}$P]ATP and poly(Glu,Tyr). The radioactivity (dpm) incorporated into the precipitated poly(Glu,Tyr) was counted by scintillation counter. (B) ELISA. HepG2 cells were treated with 0.5 $\mu$M insulin or various amounts of mcIRBP. Ten minutes later, cellular proteins were collected and the phosphorylated IR was quantitated by ELISA. Values are mean ± standard error ($n$ = 3). *$p$ < 0.05, **$p$ < 0.01, ***$p$ < 0.001, compared with no treatment.

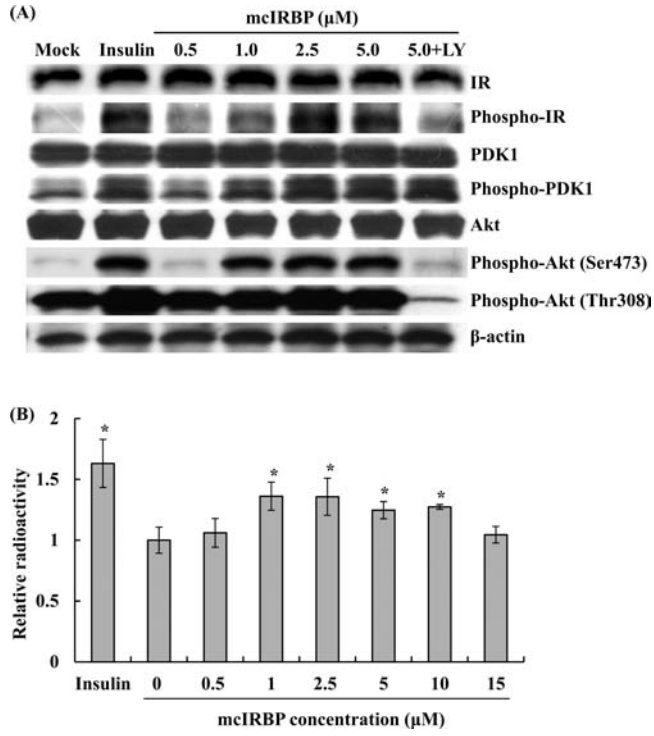

**Figure 5.** Effect of mcIRBP on the insulin signaling pathway in HepG2 cells and the glucose uptake of 3T3-L1 adipocytes. (A) Western blot. HepG2 cells were treated with 1 $\mu$M insulin or various amounts of mcIRBP for 30 min. LY294002 (50 $\mu$M) was used to inhibit PI3K activity. IR, phosphorylated IR, PDK1, phosphorylated PDK1, Akt, phosphorylated Akt (Ser473), and phosphorylated Akt (Thr308) were then detected by Western blot and visualized by chemiluminescence. Similar results are obtained in three independent experiments. Photos are representative images. (B) Glucose uptake assay. Fully differentiated 3T3-L1 adipocytes were treated with 1 nM insulin or various amounts of mcIRBP. Thirty minutes later, [$^3$H]-2-deoxy-D-glucose was added and the radioactivity uptaken by cells was counted. Data are expressed as relative radioactivity, which is presented as the comparison with the radioactivity relative to mock. Values are mean ± standard error ($n$ = 3). *$p$ < 0.05, compared with mock.

Akt. These findings suggested that mcIRBP bound to IR, stimulated the kinase activity of IR, and sequentially activated the PI3K/PDK1/Akt pathway.

**mcIRBP Stimulated the Uptake of Glucose in 3T3-L1 Adipocytes.** PI3K has a pivotal role in the metabolic action of insulin. Activation of PI3K stimulates the activation of Akt and subsequently stimulates the translocation of GLUT4 to the cell surface, a crucial event for glucose uptake by skeletal muscle and fat.[28] Therefore, we further evaluated the effect of mcIRBP on glucose uptake in 3T3-L1 adipocytes. As shown in Figure 5B, insulin and mcIRBP significantly enhanced the uptake of glucose in 3T3-L1 by (1.63 ± 0.20)-fold and (1.36 ± 0.12)-fold, respectively. The enhancement displayed a dose-dependent manner, and the maximal enhancement was achieved by 1 $\mu$M mcIRBP. These data suggested that mcIRBP bound to IR, stimulated PI3K/PDK1/Akt pathway, and, in turn, increased the uptake of glucose in adipocytes.

**mcIRBP Displayed the Hypoglycemic Effect in Normal and Diabetic Mice.** To analyze whether mcIRBP was capable of lowering the blood glucose levels in sera, we evaluated the hypoglycemic effect of mcIRBP by glucose tolerance assay in normal and diabetic mice. As shown in Figure 6, fasting blood glucose levels of normal and diabetic mice were approximately 40 mg/dL and 450 mg/dL, respectively. After glucose challenge, the blood glucose concentrations were dramatically increased at 30 min. The mock group displayed a poor glucose clearance, while intraperitoneal administration of mcIRBP resulted in a more rapid clearance of glucose in both normal and diabetic mice. The AUC was significantly decreased by 20.9 ± 3.2% and 10.8 ± 3.6% in mcIRBP-treated normal and diabetic mice, respectively. The AUC was significantly decreased by 34.7 ± 2.1% in insulin-treated diabetic mice. These data indicated that mcIRBP exhibited hypoglycemic effects in mice.

**Signal Transduction Pathways of mcIRBP on Glucose Metabolism in Normal and Diabetic Mice.** Microarray analysis was performed to investigate whether insulin signaling pathway and glucose metabolism were affected by mcIRBP in mice. Although muscle and adipose tissues are dominant tissues for glucose uptake, we chose muscle tissues only to analyze the gene expression profiles affected by mcIRBP because of the similar pathway pattern between muscle and adipose tissues in our previous study.[13] In a total of 29,922 genes, 636 and 1,523 genes with fold changes ≥2 or ≤−2 in normal and diabetic mice, respectively, were selected and tested for the biological pathways by geneSetTest function. Top 20 upregulated and downregulated genes are listed in Table S1 and Table S2 (Supporting Information). A total of 108 pathways and 95

dx.doi.org/10.1021/jf5002099 | J. Agric. Food Chem. 2014, 62, 8952−8961

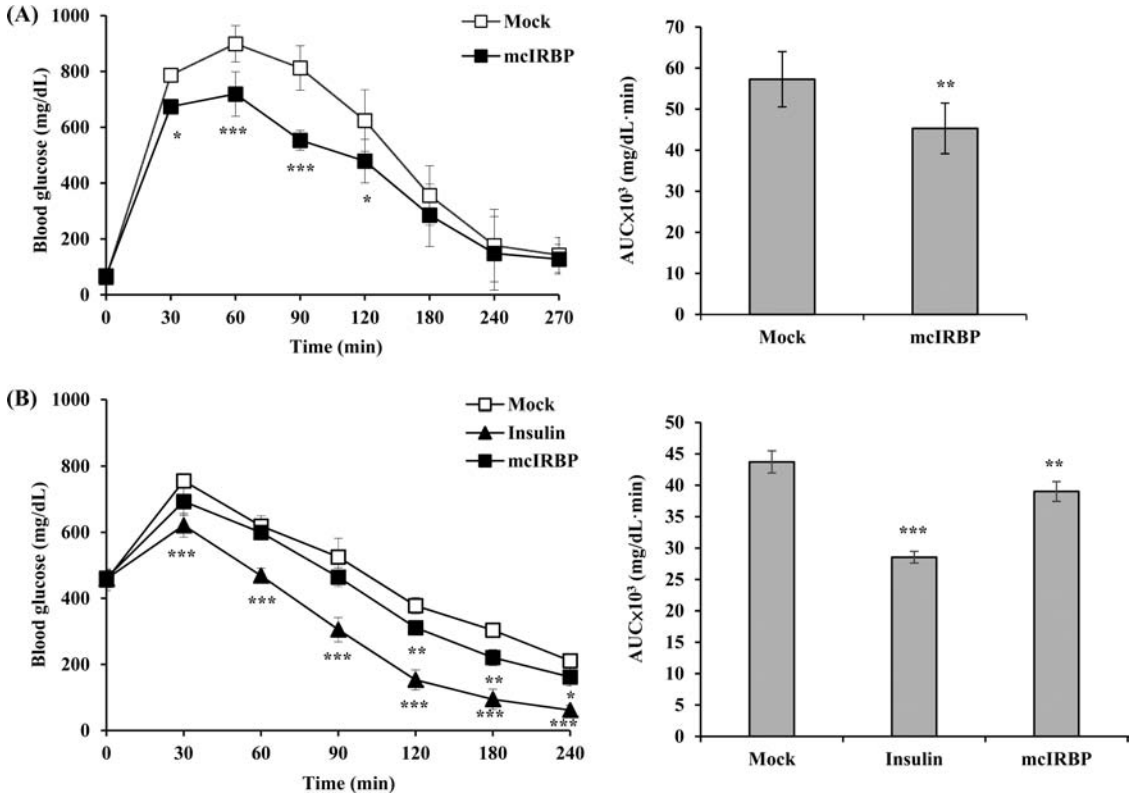

**Figure 6.** Hypoglycemic effects of mcIRBP in normal and type 1 diabetic mice by glucose tolerance assay. Normal (A) and type 1 diabetic mice (B) were administrated mcIRBP (2.5 nmol/kg) or insulin (2.5 nmol/kg) intraperitoneally. Fifteen minutes later, glucose was administrated intraperitoneally, blood samples were collected at intervals, and blood glucose levels were measured by the glucometer. AUC of glucose tolerance assay is shown at the right. Values are mean ± standard error ($n$ = 6). *$p$ < 0.05, **$p$ < 0.01, ***$p$ < 0.001, compared with mock.

pathways was significantly affected by mcIRBP in normal and diabetic mice, respectively (Supporting Information, Table S3 and Table S4). The information on genes for each of the significant pathways listed in Table S3 and Table S4 (Supporting Information) is shown in Table S5 and Table S6 (Supporting Information), respectively. As shown in Table 1, insulin signaling pathway and glucose metabolism, such as glycolysis/gluconeogenesis, citrate cycle, pentose phosphate pathway, and pyruvate metabolism, were significantly regulated by mcIRBP in both normal and diabetic mice. Moreover, PPAR signaling pathway, adipocytokine signaling pathway, leptin signaling pathway, and fatty acid metabolism were also significantly regulated by mcIRBP. These findings suggested that administration of mcIRBP triggered the insulin signaling pathway and subsequently affected the glucose and lipid metabolism in mice.

## DISCUSSION

In this study, we identified that a novel protein, mcIRBP, from MC directly bound to IR and triggered the insulin signaling transduction pathway in vitro and in vivo. Recently, the interaction of insulin with its primary binding site on IR was reported.[27] IR is a disulfide-linked homodimer, and each IR monomer contains two different insulin binding sites. Insulin binds asymmetrically to two different sites in IR dimer via bivalent growth hormone-receptor-binding mechanism.[29] The primary binding site with high affinity is located on both the $\alpha$-CT segment of one IR monomer and the central $\beta$-sheet of L1 of another IR monomer. The second site is located on both fibronectin domains and L2 segment of each IR monomer.

**Table 1. Pathways Significantly Affected by mcIRBP in Normal and Diabetic Mice**

| | $p$ value[b] (obsd/total[c]) for mcIRBP-treated mice | | obsd/total[c] for insulin-treated tissue | |
|---|---|---|---|---|
| pathway[a] | normal | diabetic | human skeletal muscle[d] | L6 skeletal muscle cells[e] |
| insulin signaling pathway | $4.06 \times 10^{-7}$ (16/132) | $2.48 \times 10^{-6}$ (24/132) | 4/132 | 29/132 |
| PPAR signaling pathway | $1.02 \times 10^{-10}$ (23/72) | $6.92 \times 10^{-7}$ (26/72) | 2/72 | 2/72 |
| adipocytokine signaling pathway | 0.000898 (11/69) | 0.000173 (14/69) | 1/69 | 11/69 |
| leptin signaling pathway | 0.000206 (6/25) | 0.000448 (11/25) | 1/25 | 0/25 |
| glycolysis/ gluconeogenesis | $2.27 \times 10^{-6}$ (15/54) | $3.53 \times 10^{-5}$ (19/54) | 5/54 | 3/54 |
| citrate cycle | $6.86 \times 10^{-6}$ (5/26) | $1.80 \times 10^{-9}$ (17/26) | 0/26 | 0/26 |
| pentose phosphate pathway | 0.000209 (11/25) | 0.000516 (6/25) | 3/25 | 3/25 |
| pyruvate metabolism | 0.001912 (10/39) | $2.06 \times 10^{-7}$ (19/39) | 2/39 | 0/39 |
| fatty acid metabolism | $4.57 \times 10^{-7}$ (11/42) | $5.61 \times 10^{-8}$ (23/42) | 2/42 | 0/42 |

[a]Pathways associated with glucose and lipid metabolism are shown. [b]$p$ values were calculated by the geneSetTest function implemented in the limma package. [c]Obsd/total means the number of selected genes/ the number of total genes in this pathway. [d]Microarray data were cited from Rome et al.[39] [e]Microarray data were cited from Di Camillo et al.[40]

Docking structure of IR and insulin in this study displayed that insulin interacted with two different sites with different docking scores on IR, as described previously.[27] Analysis of the physical interaction between IR and mcIRBP by docking and photo-cross-linking showed that mcIRBP interacted with L1/CR/L2 region on IR, on opposite site of the primary binding site of insulin on IR. Moreover, IR-binding assay showed that the binding behavior of mcIRBP and insulin on IR was cooperative. These data suggested that mcIRBP was a novel IR-binding protein that bound to the sites different from the insulin-binding sites on IR. Additionally, IR is a tyrosine kinase and, in the basal state, the kinase domain of IR is wrapped up by the juxtamembrane regions proximal to the catalytic domain. Upon binding to insulin, rearrangement within the ectodomain of IR results in the removal of the juxtamembrane region, the release of tyrosine kinase domain, and the *trans*-phosphorylation of IR.[30] Binding of mcIRBP to IR might induce the conformational change and release the kinase domain. This might explain why the incubation of mcIRBP and IR in tubes resulted in the activation of tyrosine kinase activity of IR.

IR significantly plays an important role in glucose homeostasis. Upon binding to insulin, tyrosine kinase activity of IR is activated, leading to the activation of PI3K/Akt and the subsequent translocation of GLUT4. Defects in the IR-mediated signaling pathways in tissues from diabetic patients or animal models also emphasize the importance of the IR pathway in the regulation of glucose metabolism.[6,29] In this study, we found that mcIRBP bound to IR, affected IR/PI3K/Akt pathway and, in turn, stimulated glucose uptake in 3T3-L1 cells. The hypoglycemic mechanism of mcIRBP was similar to that of insulin but was different from those of other glucose-lowering agents. For example, thiazolidinediones, such as troglitazone, rosiglitazone, and pioglitazone, bind to PPAR-$\gamma$, resulting in the enhancement of fatty acid storage, the increase of adiponectin levels, and the subsequent reduction of insulin resistance. Biguanides, such as metformin, improve insulin sensitivity and lower blood glucose levels mainly through the activation of AMP-activated protein kinase pathway.[7] In addition, some compounds exhibit hypoglycemic effects by affecting the PI3K/Akt pathway. For example, herbal compounds, such as ginsenoside Rb1, 6-gingerol, tea catechins, honokiol, and embelin, stimulate the phosphorylations of PI3K and Akt, leading to the translocation of GLUT4.[31−34] Cellular proteins, such as nexillin (a cardiomyopathy-associated F-actin binding protein), apelin (a cytokine mainly secreted by adipocytes), and obestatin (ghrelin gene-derived peptide), affect glucose homeostasis by activating the PI3K/Akt pathway.[35−38] However, none of these compounds or proteins targets to IR even though they activated the PI3K/Akt pathway. These data suggested the unique mechanism of mcIRBP on the regulation of glucose homeostasis. Furthermore, mcIRBP stimulated the phosphorylation of Akt proteins at both Ser473 and Thr308. Because mammalian target of rapamycin complex 2 (mTORC2) induces the phosphorylation of Akt at Ser473 and PDK1 activates Akt activity by phosphorylating Akt at Thr308,[28] we suggested that mcIRBP might also activate mTORC2 activity downstream from IR. In addition, in Figure 5A, we found that PI3K inhibitor LY294002 inhibited mcIRBP-induced phosphorylation of IR. Previous study indicates that PTP1B is a protein tyrosine phosphatase that negatively regulates insulin sensitivity by dephosphorylating the IR. However, phosphorylation of PTP1B by Akt negatively modulates its phosphatase activity and impairs it ability to dephosphorylate IR.[39] Because LY294002 inhibits PI3K and PI3K-downstream Akt activities, we proposed that the decreased amount of phosphorylated IR in the presence of insulin resulted from the increased amount of unphosphorylated PTP1B.

The hypoglycemic effect of mcIRBP was analyzed by glucose tolerance assays in normal and diabetic mice. The AUC was significantly decreased by 20.9% in mcIRBP-treated normal mice, while the AUC was significantly decreased by 10.8% and 34.7% in diabetic mice treated with mcIRBP and insulin, respectively. Although the hypoglycemic effects of mcIRBP and insulin displayed a significant manner, mcIRBP was less effective than insulin in blood glucose-lowering ability. Photo-cross-linking assay suggested that mcIRBP interacted with L1/CR/L2 region on IR, on opposite site of the primary binding site of insulin on IR. IR-binding assay further showed that mcIRBP cooperated with insulin for binding to IR. Therefore, we proposed that the mcIRBP-binding site on IR was minor, in comparison with primary insulin-binding site on IR, in stimulating the IR signaling pathway and subsequently the clearance of glucose. That might explain why the blood glucose-lowering ability of mcIRBP was less effective than that of insulin.

We performed microarray analysis to study gene expression profiles of mcIRBP in normal and diabetic mice. Microarray profiles of insulin in human skeletal muscle and rat L6 skeletal muscle myoblasts have been reported.[40,41] Their data show that insulin regulates several genes involved in intermediary and energy metabolism, transcriptional and translational regulation, cell cycle, cytoskeleton, vesicle traffic, and immune response. By pathway analysis, we found the consistency of gene expression profiling between mcIRBP and insulin. Among mcIRBP-regulated pathways, the majority of pathway was associated with glucose, lipid, and energy metabolism. There were 20 and 45 differentially expressed genes in insulin-treated human skeletal muscle and insulin-stimulated rat skeletal muscle myoblasts, respectively, involved in glucose and lipid metabolism pathways (Table 1). The dominant affected pathway in insulin-treated human skeletal muscle, insulin-stimulated rat skeletal muscle myoblasts, and mcIRBP-treated mouse muscle was insulin signaling pathway. Moreover, pathways involved in transcriptional and translational regulation, such as ribosome, proteasome, RNA polymerase, SNARE, and protein transport, were affected by mcIRBP. Cell cycle- and cytoskeleton-associated pathways, such as tight junction, focal adhesion, cell cycle, regulation of actin cytoskeleton, gap junction, apoptosis, and cell adhesion molecules, were also regulated by mcIRBP. Additionally, mcIRBP significantly affected four immune response-associated pathways, namely, complement and coagulation cascades, leukocyte transendothelial migration, antigen processing and presentation, and Toll-like receptor signaling pathway, and five signaling pathways, namely, PPAR, insulin, adipocytokine, mitogen-activated protein kinase, and gonadotropin-releasing hormone signaling pathways (Supporting Information, Table S3 and Table S4). These findings suggested that although mcIRBP bound to the sites different from the insulin-binding sites on IR, mcIRBP stimulated the similar biological pathways as insulin in mice.

In conclusion, our findings suggested that mcIRBP was a novel IR-binding polypeptide that bound to the sites different from the insulin-binding sites on IR. After binding to IR, mcIRBP activated IR-downstream signaling transduction path-

way, regulated genes involved in glucose and lipid metabolism, and, in turn, enhanced the glucose uptake in cells and the clearance of glucose in normal and diabetic mice.

models.[3,23,24] However, most studies on soybean and skin inflammation were performed using an atopic dermatitis (AD) model for human AD, the NC/Tnd mouse model.[25,26] Research on the effect of soybean on UVB-induced skin inflammation and skin photoaging has been focused on the topical application of isoflavone extract and anthocyanins prior to UVB irradiation of hairless mice.[27,28] Despite being considered a good dietary supplement, there is no report on anti-inflammatory effects of soybean long-term supplementation in UVB-treated animal models.

Fermentation is widely used in food processing. Fermentation is defined as the conversion of carbohydrates to alcohols and carbon dioxide or organic acids using yeasts, bacteria, or a combination of both. Through the process of fermentation, daidzin and genistin in soybean are converted into daidzein, and genistein, which have been shown to protect against UV-induced photodamage in human skin fibroblast cells.[4] Based on these previous reports, we investigated the anti-inflammatory effects of long-term dietary supplementation with fermented soybean in UVB-induced skin photodamage in hairless mice. Additionally, we compared the effectiveness of soybean (S) and fermented soybean (FS) long-term dietary supplementation in relieving skin inflammation pain caused by UVB irradiation in hairless mice.

## MATERIALS AND METHODS

**Chemicals.** Dulbecco's modified Eagle's medium (DMEM), fetal bovine serum (FBS), and penicillin streptomycin were purchased from Gibco BRL (Grand Island, NY, USA). 3-(4,5-Dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT), dimethyl sulfoxide (DMSO), and a Masson's trichrome stain kit were purchased from Sigma-Aldrich (St. Louis, MO, USA). ELISA assay kits to measure levels of IL-16 were purchased from R&D Systems (R&D Systems, Inc., Minneapolis, MN, USA).

**Standard and Sample Preparation.** Daidzin, daidzein, genistin, and genistein were purchased from Sigma-Aldrich (St. Louis, MO). The standard stock solutions were prepared by dissolving 1 mg of each compound in 1 mL of methanol and stored at −20 °C. Soybean was supplied by Aqua Green Technology Co., Ltd. (Jeju, South Korea) in February 2012. A voucher specimen was deposited in the herbarium at the R&D Center of SEMPIO Food Company (Seoul, South Korea). Soybean was stored at −4 °C during the preparation. Soybean was roasted at 100 °C and ground prior to lyophilization. *Aureobasidium pullulans* (KCCM 12017) was purchased from the Korean Culture Center of Microorganisms (Seoul, South Korea) and *Pichia jadinii* (KFCC 11487P) was obtained from SEMPIO Food Company.

**Fermentation Conditions.** Fermented soybean was prepared according to a previously described method by Cho et al.[29] Briefly, synthetic medium containing soybean (40 g/L), 1.0 g/L ammonium nitrate, 0.5 g/L dipotassium phosphate, 0.1 g/L magnesium sulfate, and 1.0 g/L sodium chloride was autoclaved at 121 °C for 15 min. The two yeast cultures (*A. pullulans* and *P. jadinii*) were inoculated into a synthetic medium containing soybean in a 5-L bioreactor. The synthetic medium was incubated at 30 °C with shaking at 20*g* for 48 h. The samples were then sterilized at 121 °C for 10 min to prevent contamination, after which they were freeze-dried and stored at −18 °C. The yield of the fermented sample was 90%.

**HPLC Analysis.** The HPLC analysis was carried out on a Waters system (Waters Corp., Milford, MA), consisting of a separation module (e2695) with an integrated column heater, an autosampler, and a photodiode array detector (2998). UV absorbance was monitored at 200−400 nm. Quantification was carried out by integration of the peak areas at 254 nm. The injection volume was 10 μL. A column (J'shpere ODS-H80, 250 mm × 4.6 mm; particle size, 4 μm; YMC Co. Ltd., Japan) was installed in a column oven and maintained at 40 °C.[28] The mobile phase was composed of water containing 1% acetic acid (solvent A) and acetonitrile (solvent B). The flow rate was 1.0 mL/min. The gradient was 0.0 min, 8% B; 3.5 min, 15% B; 12.0 min, 17% B; 23.0 min, 24% B; 28.0 min, 50% B; 33.0 min, 100% B; 38.0 min, 100% B; and 40.0 min, 8% B. The re-equilibration time between runs was 20 min.

**Cell Culture.** Normal human dermal fibroblasts (NHDFs) were purchased from ScienCell Research Laboratories (CA, USA). Human keratinocytes (HaCaT) were supplied by professor Tae-Yoon Kim. These cells were grown in DMEM supplemented with 10% FBS, 100 U/mL of penicillin, and 100 U/mL of streptomycin at 37 °C, in a 5% $CO_2$ humidified atmosphere.

**Co-cultivation of NHDF and HaCaT Cells and Treatment of UVB.** NHDF and HaCaT cells were cocultivated according to a previously described method with some modifications.[30] Fibroblast NHDF cells were seeded at $6 \times 10^4$ cells/mL in 40 mm cell culture dishes. And it was incubated in a DMEM culture medium. After 24 h, keratinocyte HaCaT cells ($6 \times 10^4$ cells/mL) were added to the NHDF cultures in the DMEM culture medium. After 24 h, the cell mixture was washed with PBS and was treated with 100 mJ/cm$^2$ of UVB irradiation under a BLX-312 UV irradiation system (Vilber Lourmat, Marne-La-Vallée, France). The cell mixture was washed with PBS and changed into fresh serum-free medium. The cell mixture was then treated 10 μM of diadzin, daidzein, genistin, and genistin and incubated at 37 °C in a humidified air atmosphere in the presence of 5% $CO_2$ for 72 h. Finally, conditioned medium and cells were harvested for the ELISA assay and Western blot analysis, respectively.

**Animals.** Seven-week-old albino and hairless male mice (SKH:HR-1) (20−27 g; $n$ = 40) were obtained from Japan SLC, Inc. (Hamamatsu, Japan). The experimental protocol for this study was approved by the Institutional Animal Care and Use Committee of Kyunghee University (KHUASP (SU)-12-09). Mice were housed in a temperature- and humidity-controlled room (22 ± 1 °C, 60 ± 5% humidity) with 12 h light/dark cycles. After a week of quarantine, mice were randomly divided into 4 groups with 10 mice/cage and acclimated. During the experimental period, access to food and water was provided *ad libitum*.

**UVB Exposure to Hairless Mice.** The UV source was supplied by a closely spaced array of five Sankyo Denki sunlamps, which have an irradiance peak at 310 nm (Kanagawa, Japan). Bulbs were positioned 15 cm above the mice. Irradiance (0.1 mW/cm$^2$) was measured with an IL1700 Research Radiometer (International Light, Inc., Newburyport, MA) equipped with a UVB sensor. Mice were exposed to 100 mJ/cm$^2$ UVB radiation (minimal erythemal dose) every day for the first week, and at 200 mJ/cm$^2$ three times per week thereafter for 11 weeks. UVB irradiation was applied to the dorsal skin of mice.

**Diet.** Forty hairless male mice were randomly assigned to four groups of ten mice per cage: (a) normal (N) (control diet only), (b) control (C) (UVB irradiation + control diet), (c) soybean (S) 2.5% (UVB irradiation + diet containing 2.5% soybean), and (d) fermented soybean (FS) 2.5% (UVB irradiation + diet containing 2.5% fermented soybean). All the mice were fed solid formula feed. Animals in each group received the experimental diets for 8 weeks concurrently with the UVB irradiation regimen. Dietary sources were provided (500 g/cage) every week. To calculate the feed intake, we measured the weight of the remaining feed each week. The animals were allowed free access to food and water. The body weight of mice was measured once a week.

**Histological Skin Analysis.** The animals were euthanized after the final UVB exposure, and biopsies were obtained from the dorsal skin. Biopsies were fixed in 4% paraformaldehyde for 24 h and embedded in paraffin. Four-micrometer-thick sections were stained with hematoxylin for 10 min, washed, and then stained with eosin for 2 min. After washing with water, the slides were gradually dehydrated in 50%, 70%, 90%, and 100% ethanol. For immunohistochemistry, the sections were incubated in 0.1% protease in PBS for antigen retrieval. Then the sections were incubated in 3% $H_2O_2$ in PBS for 10−15 min to block endogenous peroxidase activity. The sections were then incubated with 2% normal horse serum in PBS for 20 min to block nonspecific binding of secondary immunoglobulin. After blocking, the sections were incubated with primary antibody CD11b and iNOS (Cell Signaling Technology, Danvers, MA). After washing in PBS, the

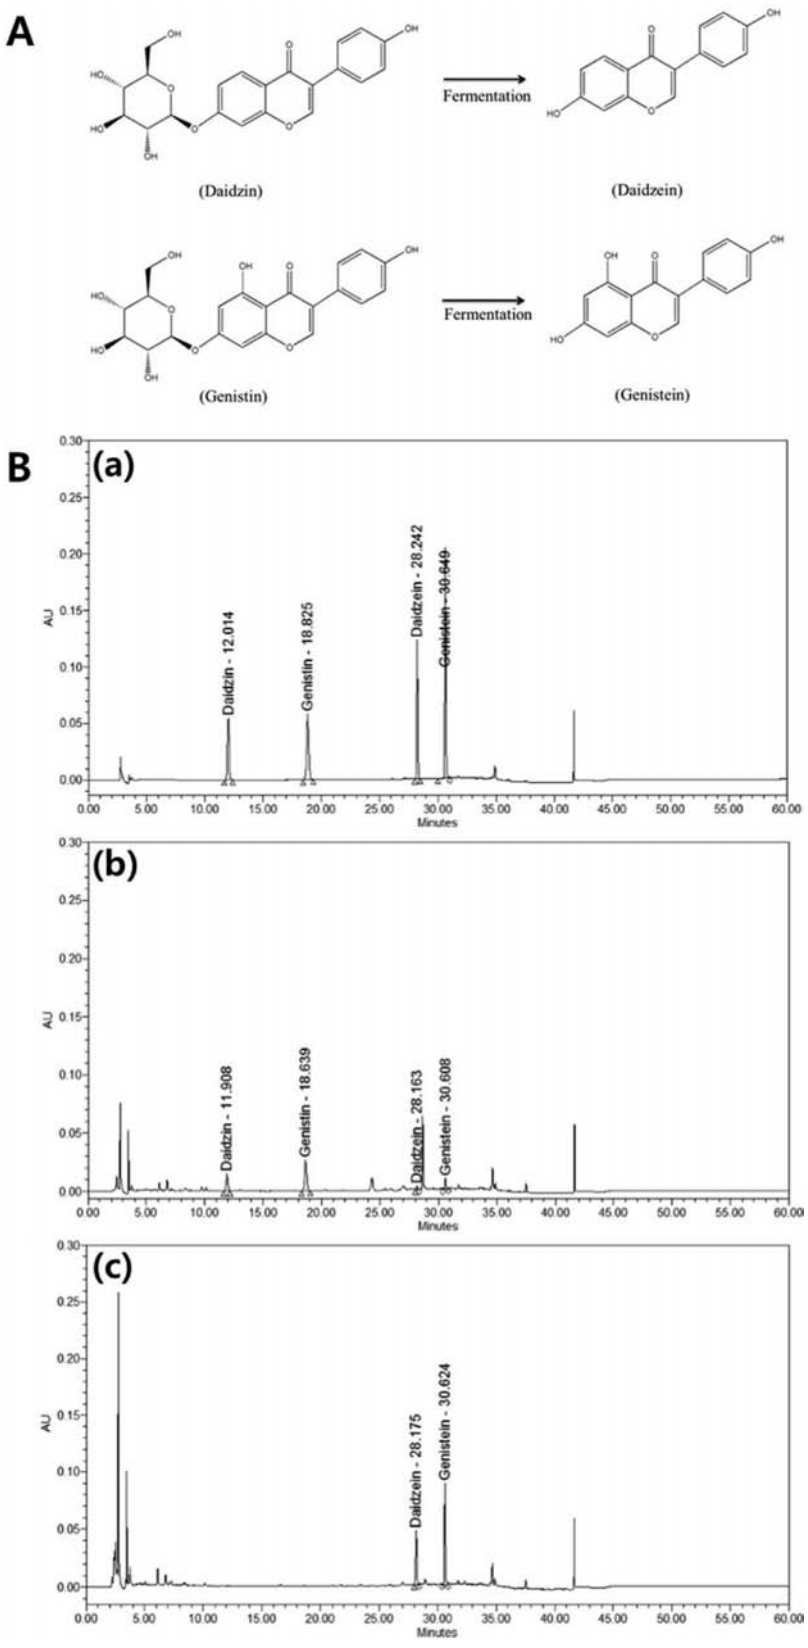

**Figure 1.** (A) Bioconversion of soy isoflavones by fermentation process. (B) Representative HPLC chromatogram of soybean: standard (a); soybean (b); fermented soybean (c).

slides were incubated in Vectastain ABC reagent (Vector Laboratory, Piscataway, NJ) for 1 h. The color was developed with 3,3′-diaminobenzidine (DAB). Images were recorded using a Zeiss inverted microscope connected to a digital CCD camera (Axiocam, Zeiss, Oberko, Germany). For immunohistofluorescence analysis, the method is the same as above up to the blocking step. Then slides were

dx.doi.org/10.1021/jf5018252 | J. Agric. Food Chem. 2014, 62, 8962−8972

incubated in COX-2 antibodies (Cell Signaling Technology, Danvers, MA) at 4 °C for overnight. After a wash with PBS, the sections were incubated with FTIC-conjugated secondary antibodies (Santa Cruz Biotechnology Inc., CA). Nuclei were counterstained with 4′,6-diamidino-2-phenylindole (DAPI). The sections were then observed under a Zeiss LSM 700 confocal microscope (Carl Zeiss, Oberkochen, Germany).

**Western Blot Analysis.** Western blotting was performed using cells and skin tissue lysates. Following treatment, cells and tissues were harvested and washed in PBS. Tissue samples were homogenized with lysis buffer containing 50 mM Tris-Cl, pH 8.0, 0.1% SDS, 150 mM NaCl, 1% NP-40, 0.02% sodium azide, 0.5% sodium deoxycholate, 100 Pg/mL PMSF, 1 pg/mL aprotinin, and a phosphatase inhibitor. The lysates were then subjected to centrifugation at 12,000*g* for 20 min. Cells and tissue lysates were analyzed in triplicate. Protein concentrations were measured using the Bradford reagent (Bio-Rad, Hercules, CA) with bovine serum albumin as the standard. Cells and skin tissue lysates containing equal amounts of total protein were separated on 10% or 12% SDS-PAGE gels and then transferred to a nitrocellulose membrane (Amersham Pharmacia Biotech, UK). Next, the membranes were blocked with a solution containing 5% nonfat milk in TBST for 1 h at room temperature and then incubated overnight with a primary antibody at 4 °C. The membranes were then washed three times with TBST and incubated with secondary antibodies (Santa Cruz Biotechnology Inc., CA) for 1 h at room temperature. Finally, the immune complexes were detected with a chemidoc XRS+ imaging system (Bio-Rad, CA). Densitometry analysis of the bands was performed using imagequant TL version 8.1 (GE Healthcare, Madison, WI).

**Statistical Analysis.** All experiments were carried out in triplicate. The data are expressed as means ± standard deviation (SD). Statistical comparisons between different treatment groups were performed using one-way analysis of variance (ANOVA) with Tukey' multiple comparisons test. The level of statistical significance was set at $*P < 0.05$, $**P < 0.01$, and $***P < 0.001$.

## RESULTS

**Soybean and Fermented Soybean Isoflavonoid Content.** Daidzin and genistin were converted into daidzein and genistein by a fermentation process in soybean (Figure 1A).[31] Daidzin, daizein, genistin, and genistein contents in soybean and fermented soybean were measured by HPLC. The retention time of each compound is presented in Figure 1. The linearity of each compound was calculated using three concentrations of each specific compound. The daidzin, daidzein, genistin, and genistein contents in soybean were 0.1197, 0.0053, 0.2220, and 0.0170 μg/mg, respectively. The daidzein and genistein contents in fermented soybean were 0.1870 and 0.2083 μg/mg, respectively (Table 1). Daidzin and genistin peaks were not detected in fermented soybean (Figure 1B). Our HPLC results confirmed the significant bioconversion of the isoflavonoidal glycosides into their corresponding aglycone types in fermented soybean.

**Table 1. Isoflavone Content (μg/mg) in Soybean and Fermented Soybean**

| | $r^2$ | soybean | fermented soybean |
|---|---|---|---|
| Daidzin | 0.9997 | 0.1197 ± 0.0008 | - |
| Daidzein | 0.9997 | 0.0053 ± 0.0003 | 0.1870 ± 0.0020 |
| Genistin | 0.9997 | 0.2220 ± 0.0002 | |
| Genistein | 0.9998 | 0.0170 ± 0.0001 | 0.2083 ± 0.0021 |

**Daidzein and Genistein Inhibited IL-6 and Phosphorylation of MAPK Signaling in HaCaT Keratinocytes and NHDF Fibroblasts Coculture Systems.** We confirmed that diadzein and genistein are major isoflavones of fermented soybean (Figure 1). To investigate the anti-inflammatory activities of these two compounds, we used coculture systems with keratinocytes and fibroblasts. These different cells were grown in a single dish. When the cell mixtures were treated with 100 mJ/cm$^2$ of UVB irradiation, they were mildly damaged. The cell viability of UVB treated control cells was decreased by 76.6% ± 1.3% compared with UVB nontreated normal cells (Figure 2B). When the cell mixtures were treated with 10 μM of daidzin, daidzein, genistin, and genistein, there was no effect on cell viability in UVB treated cells (Figure 2A, B).

UVB irradiation stimulated the cell mixture. As a result, secretion of pro-inflamatory cytokines increased. We measured two major pro-inflamatory cytokines: interleukin-6 (IL-6) and tumor necrosis factor-α (TNF-α). The concentration of IL-6 was higher in the conditioned medium of the UVB control group compared with the normal group. Although the difference was not statistically significant, we confirmed the inhibitory effect of daidzein and genistein on IL-6 production (Figure 2C). TNF-α was not detected in conditioned medium (data not shown).

We investigated the MAPK signaling cascade, which is known to regulate inflammation. All compounds (daidzin, daidzein, genistin, and genistein) inhibited UVB-induced phosphorylation of ERK (Figure 2E). In particular, genistein inhibited phosphorylation of p38, ERK, and JNK (Figure 2D–F). Moreover, the inhibitory activity of genistein was significantly different for genistin and genistein (Figure 2D, E)

**Measurement of Food Efficiency Ratio.** There was no significant difference in the average body weight among the four groups of mice after 12 weeks. The groups did not differ significantly in their food efficiency ratios (Figure 3C).

**FS Dietary Supplementation Improved UVB-Induced Skin Erythema and Inflammation.** Mouse dorsal skin physiological changes were recorded after dietary supplementation with S or FS, and after 12 weeks of UVB irradiation. Prolonged skin exposure to UVB leads to skin inflammation erythema and epidermal thickness. In our study, the group FS presented a decrease in UVB-induced erythema (Figure 4A). In addition, the thickness of the epidermis in the UVB treated control group was significantly larger than the normal group. However, this increase in epidermal thickness was lower in the S (79.4 ± 0.8%) and the FS (83.4 ± 0.8%) group (Figure 4B, C).

Our histological analysis indicated that UVB radiation induced typical skin inflammation in hairless mice. Prolonged exposure to UVB increased the macrophage population in the upper dermis and epidermis (Figure 4D). Scoring of the four groups was done by Dr. Young Lyun Oh, who is a pathologist at SMC, Korea, based on our H&E staining analysis. The inflammation score was classified as either 0, +, ++, or +++. The score "0" indicates no inflammation, and the number of + symbols indicates the degree of inflammation. Therefore, "+++" represents severe skin inflammation. Group N had a score of "0" and group C was "+++", group S was "+," and group FS was "0−+." Inflammatory symptoms such as intrahorn and subepithelial vacuolization were observed in group C. However, these symptoms were not observed in other groups. Based on immunohistochemical analysis, the population of CD11b$^+$ macrophages was significantly reduced in the group FS compared with the control group (Figure 4D). Particularly,

dx.doi.org/10.1021/jf5018252 | J. Agric. Food Chem. 2014, 62, 8962−8972

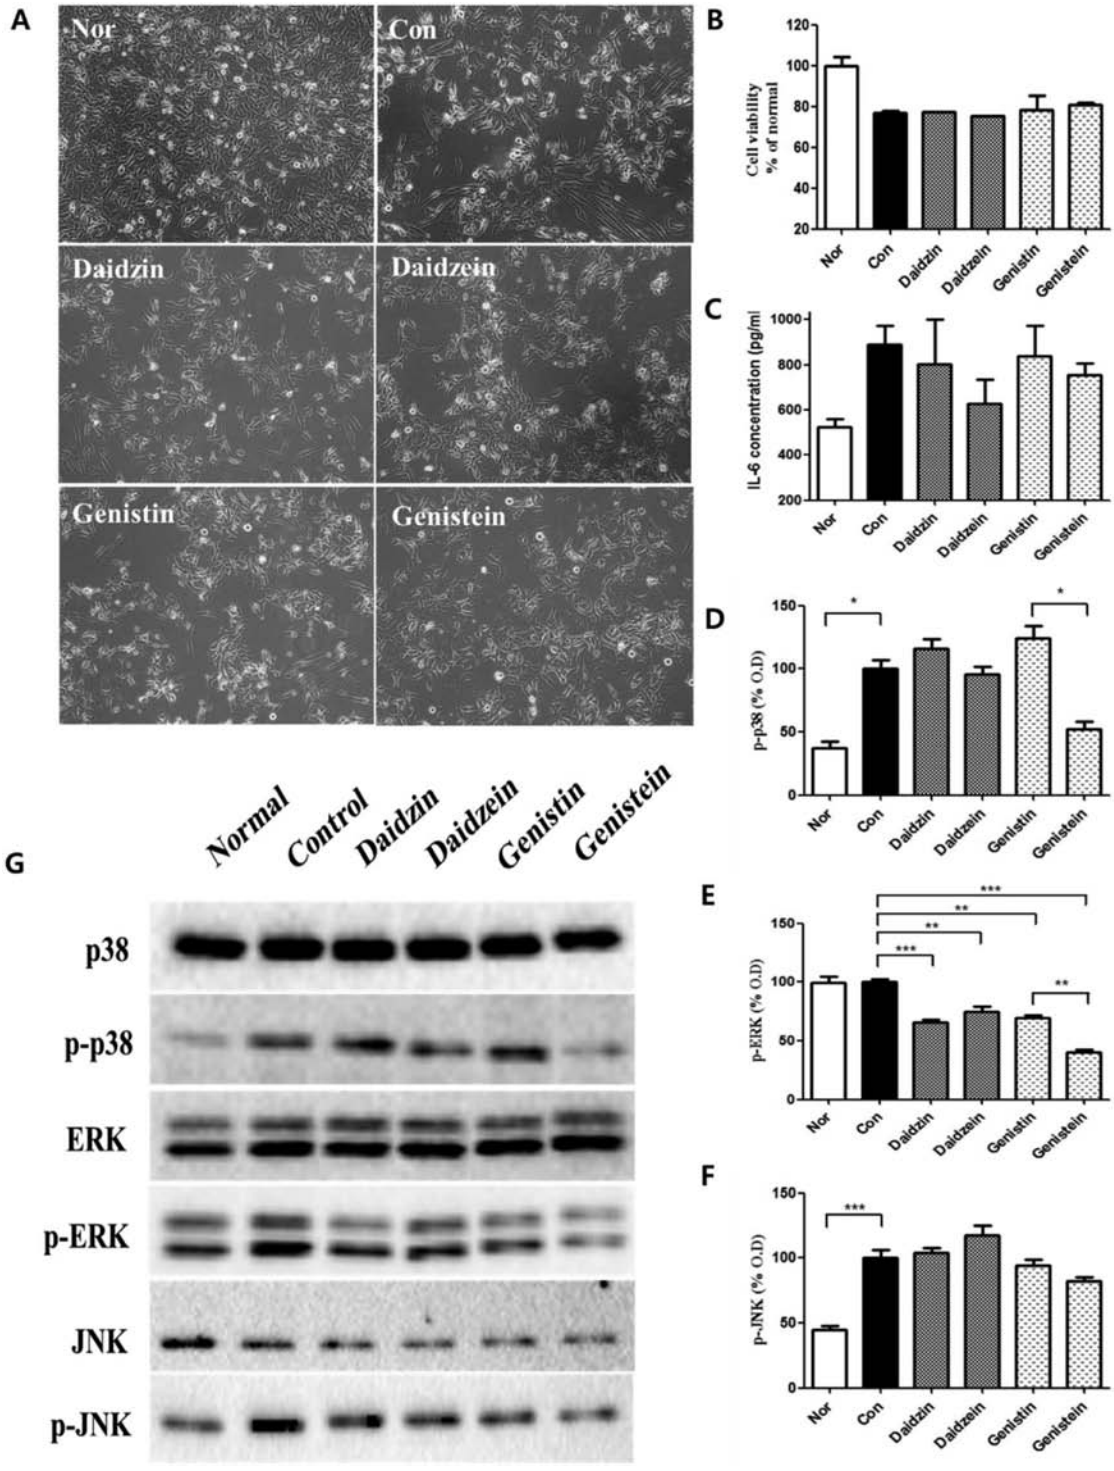

**Figure 2.** Effect of Daidzin, Daidzein, Genistin, and Genistein on the production of IL-6 and MAPK signaling in a UV-irradiated HaCaT and NHDF coculture. NHDF cells and HaCaT cells were grown in the same dish (1:1 cellular mixture). After treatment with 10 $\mu$M of each of the four compounds for 72 h, cells were observed using an Olympus CKX-41 microscope (×100 in bright field) (A) and cell viability was measured by an MTT assay (B). Conditioned medium was cultivated and the IL-6 concentration was measured (C). For Western blot analysis, the mixtures were treated with 100 mJ/cm$^2$ of UVB irradiation and 10 $\mu$M of each of the four compounds, treated at the same time. After 1 h, the mixture cells were harvested and the protein levels were measured (D−G). *$P$ < 0.05, **$P$ < 0.01, and ***$P$ < 0.001 indicate statistically significant differences.

the anti-inflammatory effect was more intense in group FS than in group S.

**FS Inhibits iNOS and COX-2 Expression.** In the immunohistological analysis, group C showed a marked increase in iNOS expression, especially in the epidermis (Figure 5A). We also confirmed the increase in iNOS expression in group C by Western blot analysis (Figure 5B). Interestingly, dietary supplementation with S and FS inhibited the protein expression of iNOS at 70.3% ± 7.0% and 7.7% ± 0.4%, respectively ($p$ < 0.05) (Figure 5C). The increase of COX-2 expression in group C (Figure 6A) was inhibited by

**FS Regulates MAPK Signaling in the Skin Dermis of UVB-Irradiated Hairless Mice.** The UVB-induced inflammatory responses were remarkably reduced by FS long-term treatment. To evaluate the FS anti-inflammatory mechanism on UVB-induced skin inflammation, we investigated the MAPK signaling pathways in the skin dermis by Western blot analysis. UVB radiation increased the phosphorylation of p38, ERK, JNK, and c-Jun in the skin.[1,10] As shown in Figure 7, phosphorylation of p38, ERK, JNK, and c-Jun was increased in UVB-irradiated skin dermis. In contrast, long-term FS treatment significantly inhibited the phosphorylation of MAPK (p-p38, 61.3 ± 0.5%; p-ERK, 78.9 ± 3.3%; p-JNK, 14.4 ± 0.5%; and p-c-Jun, 37.6 ± 0.6%) (Figure 7B–E).

## DISCUSSION

Dietary supplements such as vitamins, minerals, or essential fatty acids have been reported to restore damaged skin.[21,32] Particularly, dietary supplements can help control skin aging as well as inflammation and hyperpigmentation due to overexposure to UVR. However, there is only a paucity of evidence in the literature; therefore, in depth studies are required. Natural and functional food sources will allow the development of nutraceutical and cosmeceutical treatments for skin photodamage. Evidence suggests that soybeans containing isoflavones may be useful for the regulation of skin problems.[33−35] However, no report is available on the anti-inflammatory effect of long-term soybean dietary supplementation on skin inflammation in UVB-irradiated animals. First, we chose the safest and potential soybean as a natural source of functional food for the regulation of photoinduced skin inflammation. Raw soybeans are rich in soyasaponins and isoflavonol glycosides. Namely, soybeans generally contain more isoflavonol glycosides, such as daidzin, genistin, and glycitin, than aglycone type, such as daidzein, genistein, and glycitein.[36] Because long-term use of soybean may be associated with allergic reactions involving rash, itching, food protein-induced enterocolitis, constipation, bloating, and nausea,[20,21] long-term dietary supplementation is difficult to achieve. Although natural products have many great benefits as dietary supplements, there are some limits in terms of efficacy and side effects. In an attempt to increase the efficacy of soybean supplementation, we established an optimal fermentation process design. The strategy included fermentation optimization using a mixed native yeast culture composed of *Pichia jadinii* and *Aureobasidium pullulans*. The optimization standards were based on isoflavonoid glycoside contents and efficacy as well as flavor and taste. Our goal was to increase the efficiency and activity as well as the flavor and taste compared to raw soybeans. In fact, several studies have already reported that biological activities of natural products might be improved by fermentation. Kim et al. reported that fermented red ginseng showed higher antiobesity effect on obesity-mediated metabolic disorders than nonfermented red ginseng.[37] Our recent study proved the enhanced antiphotoaging activity of *Opuntia ficus-indica* by fermentation using two species of yeast, *Pichia jadinii* and *Aureobasidium pullulans*.[29] For this reason, we designed a powerful strategy, such as soybean fermentation with *Pichia jadinii* and *Aureobasidium pullulans*. Based on our HPLC analysis, we found that FS contained only aglycone type. Isoflavone glycosides were not detected in FS. Soy isoflavone aglycones were increased through the fermentation process, which converts glucosides into aglycone by deconjugation of the glycosyl group of a glycoside (Figure 1).[31] According to several studies, daidzein and genistein show higher bioavailability and bioactivity than daidzin and genistin. Iovine et al. reported that daidzein and genistein present synergic effects on UVB-mediated DNA damage.[4] In fact, aglycones may be absorbed faster and better than glucosides in the human body.[38] In conclusion, this fermented soybean may be biochemically and technically superior to its raw material.

Dermatitis is a representative problem that is related to skin inflammation. Chronic and overexposure to UVR can induce photosensitivity and photoallergy, which can subsequently lead to phototoxic dermatitis. Particularly, UVB is a potent factor, which induces skin inflammation. Our histological data indicate that the UVB-irradiated group typically showed severe inflammation of the intrahorn. Other groups previously reported that UVB radiation triggered skin inflammation by inflammatory cellular infiltration into the upper dermis and epidermis.[39] We also confirmed inflammatory cellular infiltration in the skin dermis of the UVB-induced group (Figure 4).

Macrophages, important inflammatory cells, are involved in the initiation of inflammation by the production of various proinflammatory mediators such as nitric oxide (NO) and prostaglandins (PGs). The production of NO and PGs are

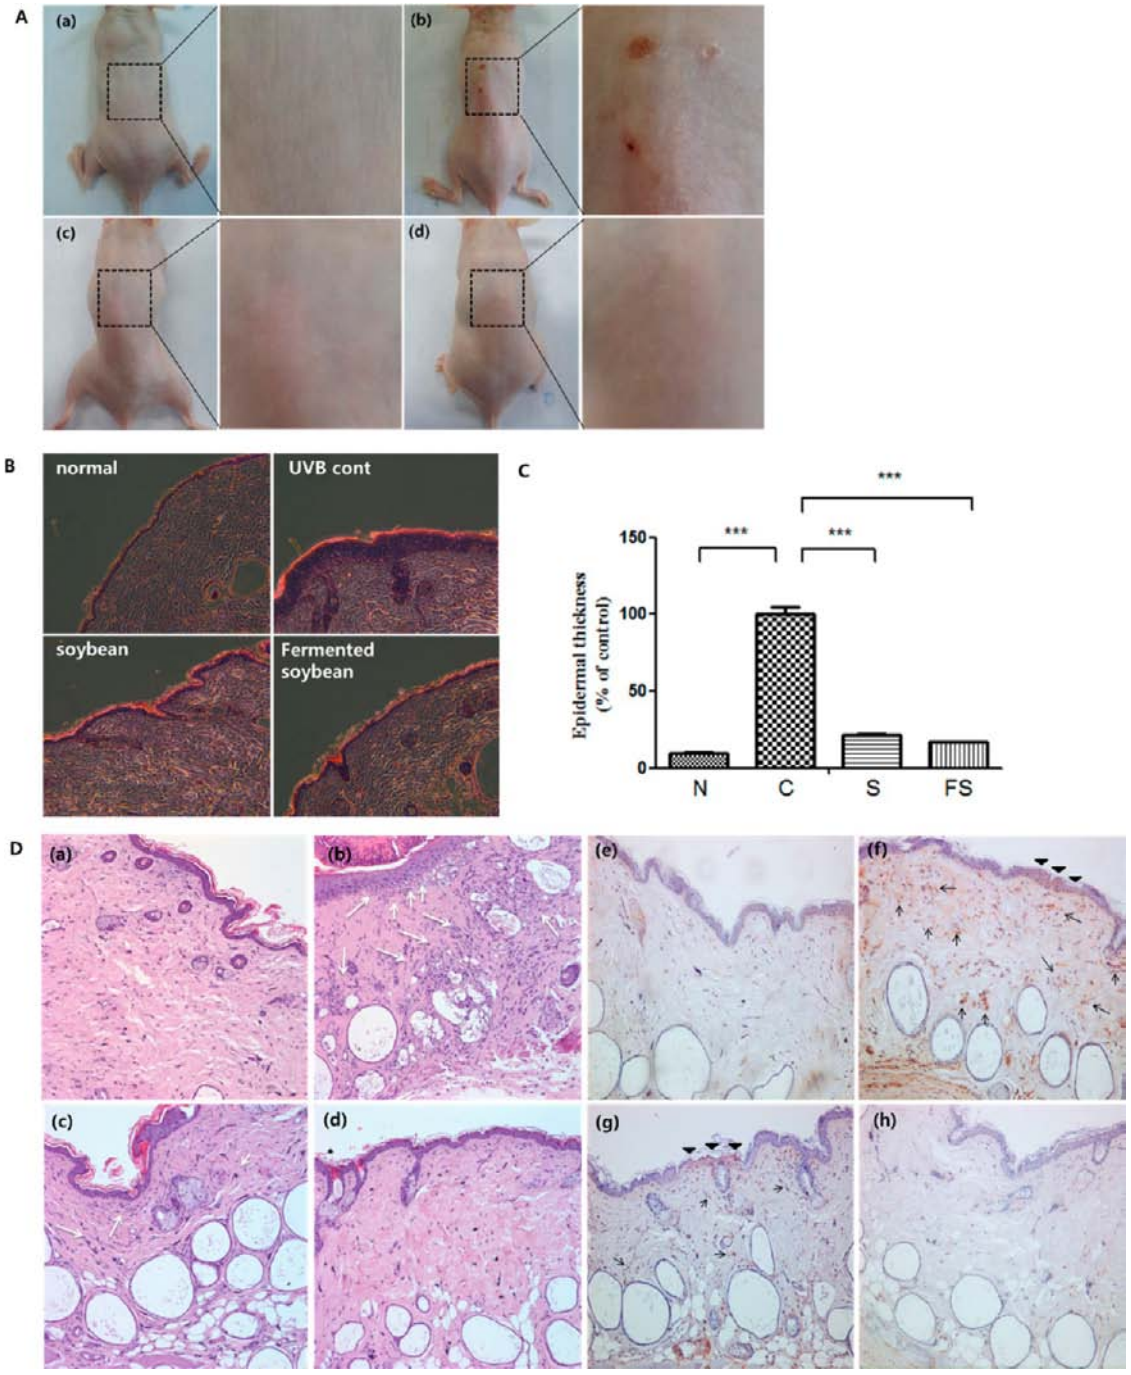

**Figure 4.** (A) Effects of S and FS on the histology of UVB irradiated hairless mouse skin. regulated by iNOS and COX-2 enzymes, respectively.[40,41] Thus, overexpression of COX-2 in the skin may result in edema and epidermal hyperplasia.[28,42] Our immunohistological study indicated that UVB overexposure increased iNOS and COX-2 expression in the dermal cells of the dorsal skin (Figures 5 and 6). Interestingly, a dietary supplement of FS significantly decreased iNOS and COX-2 expression in the skin. Recent studies report a link between iNOS, COX-2, and photoinflammation in mouse skin. In particular, the up-regulation of COX-2 is often accompanied by overexpression of iNOS.[43] In conclusion, FS inhibited both iNOS and COX-2 expression in dermal skin. FS ameliorated skin inflammation by UVB irradiation, which regulates MAPK signaling. Furthermore, activation of MAPK can cause the induction of iNOS and COX-2 expression and, consequently, may induce skin cancer.[44]

UVB-induced skin inflammation is usually conducted under acute UV exposure conditions in *in vivo* models.[10,45,46] After 24 h of UVB exposure, inflammatory signaling was significantly changed. Kim et al. reported that phosphorylation of p38 MAPK was increased by UVB exposure in a time dependent manner at 24 h. Thus, their studies support that p38 MAPK plays an important role in UVB-induced inflammatory responses in the skin of SKH-1 hairless mice.[47] Generally, recovery from skin inflammation is easy and spontaneous in acute UVB exposure models. Therefore, identifying the anti-inflammatory effects of a product in acute conditions can be challenging. In this study, we focused on chronic skin inflammation, which is induced after long-term UVB exposure (12 weeks). From our results, we showed that chronic skin inflammation by UVB exposure significantly changed the MAPK signaling pathway. Soybean inhibited the UVB-induced activation of p38, JNK, and c-JUN. Furthermore, FS was more effective in inhibiting p-JNK activation than S. Raw soybean had no effect on the regulation of ERK, but FS treatment strongly affected ERK phosphorylation in the dorsal skin. Thus, the anti-inflammatory effect of FS on UVB-induced skin inflammation could mainly be attributed to the regulation of MAPK signaling. However, additional studies on fermented and raw soybean are warranted to confirm these results. Based on our HPLC data, the chemical patterns of FS were different from that of raw soybean in the polar region, distinguishing the isoflavonoid region. Further studies are required to definitively identify the most biologically active component in FS. Our

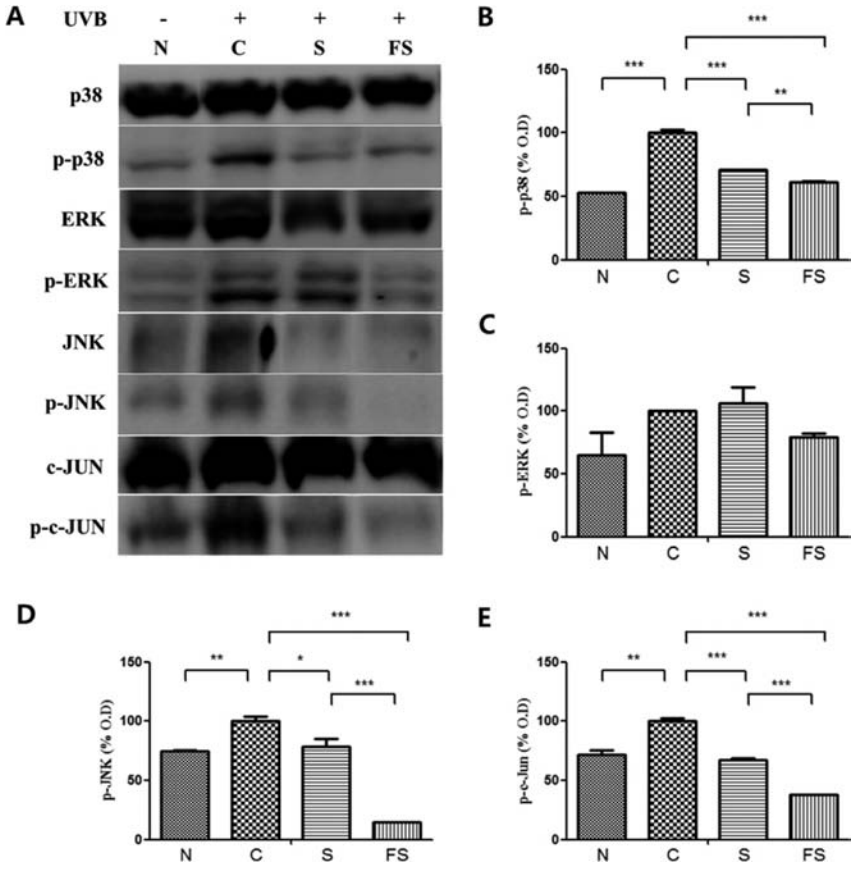

**Figure 7.** Effects of S and FS on UVB-induced MAPK signaling in skin lysates by Western blot and densitometric analysis. Forty micrograms of total protein from the tissue lysates were used for Western blot analysis. Significance was determined using a one-way ANOVA followed by a Tukey's multiple comparison test. $^{*}P < 0.05$, $^{**}P < 0.01$, and $^{***}P < 0.001$ indicate statistically significant differences.

study only investigated the efficacy of fermented soybean in resolving chronic skin inflammation. However, our findings indicate that future research on the use of natural resources such as soybean in the treatment of chronic skin inflammation may be promising.

In conclusion, this study provides meaningful evidence that long-term dietary supplementation with isoflavone-rich, fermented soybean improves skin inflammation induced by chronic exposure to UVB. We suggest that natural fermented soybean will be a safe, potential functional food for skin inflammation due to photodamage.

| L+C | - | 215 °C / 2 min | - |
| C | - | 200 °C / 2 min | - |
| H | - | 215 °C / 2 min | - |

**Figure 1.** Scheme of the fractionation treatments of whole olive stones (stone and seed), olive stones (seed husks fragments), and olive cake (residual seed husks, seed, pulp, and peel) after steam explosion pretreatment. [a]Previous impregnation with dilute solution of strong mineral acid.

and antioxidant properties. In a previous study, low-molecular-weight phenols solubilized by the steam pretreatment were characterized.[5] The present study is focused on the residual insoluble material, polyphenolic polymerized and strongly bound to cell wall components that were extractable with an alkaline solution post-treatment. This aromatic (phenolic) polymer was dissolved in an alkali solution, probably as occurs in alkali-extracted lignin with a stable colloid structure by the negative charge (electrostatic interactions) due to the phenolic hydroxyl and carboxyl groups in the alkaline medium, which precipitated when the solution was changed to an acidic pH.[12] In addition, the lignin, an amorphous polyphenol of high molecular weight, can vary in structure according to their method of extraction and their plant source. Therefore, the properties and health benefits of the lignin will depend on the used lignocellulosic material, in this case olive stones and olive cake. The uses of fiber from new origins will probably widen the field of application for dietary fiber.

The aim of this work was the fractionation of olive stones (whole and fragmented, without seeds) and olive cake by a two-stage process based on a previous work,[3] involving a steam explosion pretreatment and alkaline solution post-treatment. Each fraction enriched in cellulose, hemicelluloses, and lignin was characterized and investigated for the potential use of these polymers. We highlight their physicochemical and functional properties, with special focus on bile acid binding and the glucose retardation index, using in vitro studies.

## MATERIALS AND METHODS

**Raw Material.** Whole olive stones were obtained from pitted table olives and, following incubation in an air stove at 30 °C, rubbed vigorously on filter paper to remove any loosely adhering pulp tissue.

The fragments of olive stones (seed husks) with an average length of 2−6 mm were supplied by an oil extraction plant (Oleícola el Tejar, Córdoba, Spain). The husks (9% moisture) were obtained from olive pomace after separating peel, pulp, and seeds.

Olive cake was also supplied as pellets by Oleícola el Tejar. The olive cake, which included the residual olive stone, was subjected to vibratory ball milling before determination of its chemical composition.

**Steam Explosion and Fractionation.** Steam explosion was carried out using a 2 L pilot-scale reactor, with a maximum operating pressure of 4.12 MPa, equipped with a ball valve opening. All experiments were carried out with samples of 100 g (dry weight). The samples were steamed at various temperatures for 2 min, prior to rapid decompression (explosion). Lignin was isolated from whole olive stone with a treatment at 230 °C/2 min (with acid), the lignin fraction from olive cake was obtained at 200 °C/2 min, the fractions of lignin + cellulose and hemicellulose were obtained at 215 °C/2 min from olive stone, and cellulose was isolated from olive stone at 200 °C/2 min.

One treatment (whole olive stones) was carried out with previous impregnation with an acid solution (0.1% $H_2SO_4$ w/v) for a period of 1 h under vacuum (to remove the air from the material and facilitate the penetration of acid through the structural matrix). The material was drained in a sieve and rinsed thoroughly with distilled water to remove all traces of acid, prior to loading into the steam reactor.

After steam explosion (Figure 1), the sample was vacuum filtered through Albet filter paper (weight, 73 g/cm$^2$; Albet, Barcelona, Spain) in a Buchner funnel. The residue was washed three times with 500 mL of distilled water for 30 min at 60 °C and filtered to remove the water-soluble fraction. The filtrate was concentrated to 250−300 mL by rotary evaporation at 40 °C. The aqueous concentrate was continuously extracted for 5−6 h with ethyl acetate (refluxed at 77 °C). The aqueous and organic phases were rotary evaporated under vacuum at 40 °C for several hours to remove all traces of ethyl acetate. The aqueous phase was freeze-dried (fraction H). The water-insoluble material (fraction L+C) was extracted with 0.5 M NaOH (250 mL) for 15 min at room temperature to remove the lignin from the cellulose residue. The residual solid was thoroughly washed with warm water until all traces of alkali were removed or brought to a neutral pH (fraction C). The dissolved lignin was acidified with 5 M $H_2SO_4$ to pH

dx.doi.org/10.1021/jf502062b | J. Agric. Food Chem. 2014, 62, 8973−8981

2−3. The precipitate was centrifuged, washed to neutral pH, and freeze-dried (fraction L).

**Ultraviolet Spectroscopy.** The ultraviolet spectra of samples were recorded at a concentration of 0.0027% in methanol on a UV−vis Hewlett-Packard (Waldbronn, Germany), model 8452 A.

To study the difference in spectra, $\Delta\varepsilon_i$, 10 mg of lignin was dissolved in 25 mL of dioxane/water (9:1). The neutral solution was prepared by diluting 3 mL of this solution in 25 mL of dioxane. The alkaline solution was prepared by the addition of 100 mg of NaOH. The alkaline-neutral difference spectra were determined by running the alkali solution against the neutral solution.

**Infrared Spectroscopy.** Infrared spectra were recorded on a Bio-Rad FTS 7PC using KBr disks. Lignin (1 mg) was mixed and thoroughly ground with 300 mg of KBr to reduce particle size and to obtain a uniform dispersion of the sample in the disks. The conditions of analysis were as follows: resolution, 8 $cm^{-1}$; co-adding 250 scans; frequency range, 400−4000 $cm^{-1}$.

**Analytical Method.** Moisture, fat, and ash contents were determined according to the AOAC method.[13] The uronic acids were estimated according to the *m*-hydroxydiphenyl method described by Blumenkrantz and Asboe-Hansen.[14] Total phenolic content was determined by the Folin−Ciocalteu spectrophotometric method and expressed as grams of gallic acid equivalents.[15]

The content of water-soluble low-molecular-weight sugars was determined by analysis with trifluoroacetic acid (TFA) hydrolysis (2 N TFA at 121 °C for 1 h) prior to reduction, acetylation, and analysis by gas chromatography.[16] Inositol was used as an internal standard. The chromatographic conditions applied were described by Lama-Muñoz et al.[17]

Klason lignin was determined gravimetrically.[18] The $\alpha$-cellulose determination of the insoluble fraction was carried out from bleached cellulose, which was extracted with 17.5% NaOH, and the residue was measured gravimetrically.[3] The hemicelluloses were determined as the difference between bleached cellulose and $\alpha$-cellulose. Bleached cellulose was prepared by sodium chlorite delignification.[19]

**Functional Properties.** *Water/Oil-Holding Capacity (WHC/OHC).* These properties were determined by centrifugation using the method described by Fuentes-Alventosa et al.[20] The OHC was determined under the same conditions as the WHC using soybean oil (0.92 g/mL density) and was expressed as grams of oil retained per gram of sample.

*Emulsification Activity (EA) and Emulsion Stability (ES).* EA and ES were evaluated in duplicate using the method of Betancur-Ancona et al.[21] EA was expressed as the volume of the emulsified layer as a percentage of the volume of the entire layer in the centrifuge tube. ES was determined using the prepared emulsions heated at 80 °C for 30 min. The emulsion was cooled to room temperature and centrifuged at 1200*g* for 5 min in a Sorvall RT 6000D (DuPont, Mechelen, Belgium). ES was expressed as the percentage of the remaining emulsified layer volume of the original emulsion volume.

*Binding of Bile Acid (BA).* The capacity of the fractions for binding BA in vitro was evaluated following the method described by Camire and Dougherty[8] with some modifications. Binding for each fraction was estimated from the change in BA concentration on exposure of the solution to the soluble fiber during an in vitro digestion process, which included an acidic digestion of the sample at pH 2, followed by pancreatic digestion. The individual BAs cholic acid (CA), deoxycholic acid (DCA), and chenodeoxycholic acid (CDCA) (Sigma, St. Louis, MO, USA) were selected for analysis. The results obtained for each sample of isolated pectin were compared with the results obtained for cholestyramine resin (Sigma C 4650), cellulose (Macherey Nagel, GmbH & Co. KG), and commercial pectin from citrus peel (Sigma P 9135).

*(a) In Vitro Digestion Procedure.* Each BA was dissolved in 0.1 M $NaHCO_3$ to make a 31.25 mM BA solution, which, in the final mixture, will be in a range of BA concentration close to the human body concentration in the final mixture (1.5−7 mM). One hundred milligrams of sample, pectin, cholestyramine, and cellulose were added to each tube (50 mL plastic centrifuge tubes) in triplicate. The individual sample without BA was used as a blank, and a tube for reagents including BA but without sample was considered as 100% of BA concentration. Samples were digested in 1 mL of 0.01 M HCl for 1 h at 37 °C in a shaking water bath (P-Selecta Unitronic 320 OC). After this acidic incubation, which simulated gastric digestion, the sample was neutralized with 0.1 M NaOH to pH 7.0. To each test sample was added 4 mL of BA solution. For the sample blank, 4 mL of $NaHCO_3$ was added without bile acid. After the addition of 5 mL of porcine pancreatin (activity equivalent 8 × USP) with a concentration of 10 mg/mL in 0.01 M buffer phosphate, pH 7.0, the tubes were incubated for 1 h at 37 °C in a shaking water bath. The mixtures were centrifuged for 10 min at 1120*g* in a Sorvall RT 6000D (DuPont). The supernatants were transferred to new tubes. An additional 5 mL of phosphate buffer was used to rinse out the incubation tube, which was vortexed and centrifuged as before, and the supernatants were combined.

*(b) Bile Acid Analysis.* BA was analyzed by a colorimetric method (a modified Pettenkofer reaction) that was described by Boyd et al.[22] One hundred microliters of supernatant (samples, blank, and standards of individual BAs) was collected and heated for 1 h at 137 °C, after the addition of 5 mL of sulfuric acid (70%). Five minutes later 1 mL of a freshly prepared solution of furfural (0.25%) was also added. The solutions were thoroughly mixed after each addition. A pink color appears, which takes 60 min to reach maximum intensity. The readings were made at the absorption maximum of 490 nm in an iMark microplate absorbance reader (Bio-Rad, Hercules, CA, USA), and the values were determined from the obtained standard curve. The ranges for the different standards were 0−30 $\mu$g for CA, 0−750 $\mu$g for DCA, and 0−750 $\mu$g for CDCA. Binding capacity was expressed as millimolar bile acid per 100 mg of fraction and was calculated from the decrease in BA concentration (mM) in the test solution after exposure to 100 mg of added fraction.

*Glucose Dialysis Retardation Index (GDRI).* GDRI was determined as described by Fuentes-Alventosa et al.[20] Samples of 400 mg were thoroughly hydrated with 15 mL of distilled water containing 30 mg of glucose and stirring during 1 h. Then samples were transferred to a dialysis bag (12000 MWCO, Sigma Chemical Co.). Each bag, blank of sample (with sample, without glucose), and a control bag (with glucose, but without sample) were put into a reservoir containing 400 mL of distilled water and held in a thermostatic water bath at 37 °C for 1 h with constant shaking. At 10 min intervals, 0.5 mL of dialysate was collected, and the glucose concentration was determined spectrophotometrically by using the anthrone method.[23]

$$\mathrm{GDRI} = 100 - \left(\frac{\text{total glucose diffused sample}}{\text{total glucose diffused control}} \times 100\right)$$

**Statistical Analysis.** Results were expressed as mean values ± standard deviations. To assess differences in the composition and functional characteristics among the different isolated fractions, a sample comparison was performed using Statgraphics Plus program version 2.1. A multivariate analysis of variance (ANOVA), followed by Duncan's comparison test, was performed. The level of significance used was $p < 0.05$.

## RESULTS AND DISCUSSION

**Chemical Characterization of the Main Fraction Obtained after Steam Explosion Pretreatment.** Table 1 shows the operation conditions of steam explosion carried out for each of the samples used in the present work. These samples were chosen by the best yield and/or the more representative chemical composition of hemicelluloses, cellulose, and lignin from pretreated whole olive stones (stone and seed), fragmented olive stones (seed husks), or olive cake (byproduct derived from olive oil extraction by a continuous triphasic extraction system, with seed husks, seed, pulp, and peel) as was described in previous works.[3−5] The lignocellulosic olive byproduct materials were treated in a steam explosion reactor, with or without a previous impregnation with a dilute

**Table 1. Composition and Recovery Yield of the Water-Insoluble and Soluble Fraction (Sample L+C; Sample H[a]) and Composition of Water-and-Alkali-Insoluble Fraction (Sample C) of Steam-Exploded Olive Stones at 215 and 200 °C during 2 min, Respectively**

[a]aAfter steam explosion of olive stone at 215 °C/2 min, and after ethyl acetate extraction. [b]Hemicellulose was determined by difference between bleached cellulose and $\alpha$-cellulose. [c]Sugar determined by 2 N trifluoroacetic acid (TFA) hydrolysis at 120 °C for 2 h prior to gas chromatography derivatization to alditol acetates. [d]Quantified by difference (100% − known compounds).

solution of strong mineral acid, followed by fractionation (Figure 1). The major part of hemicelluloses (sample H) and a small part of lignin become soluble in the aqueous phase and can be separated from the remaning lignin and cellulose insoluble material (sample L+C). Lignin was recovered from the insoluble material by an alkaline extraction followed by acid precipitation (sample L), resulting in a cellulose fraction (sample C) and the remaining lignin and hemicellulose.

The maximum yield of lignin from whole olive stones was achieved at 230 °C/2 min with acid impregnation (sample L). A fraction of lignin was also obtained from olive cake steam-treated at 200 °C/2 min (sample Lp). These milder conditions (lower temperature and no acid impregnation) were chosen to avoid the autohydrolysis of the residual fragment of olive stones present in the olive cake, obtaining the lignin from the pulp only. The lignin recovered by alkali extraction followed by acid precipitation from steam-exploded olive stones was a de-etherified lignin with an extensive cleavage of $\beta$-aryl ether linkages, similar to exploded hardwood lignin.[3] However, the "lignin" obtained by alkaline delignification from steam-exploded olive cake did not resemble a true lignin. The parenchymal cells of olive fruit pulp are scarcely lignified,[24] and the "lignin" is composed mostly of condensed and polymerized polyphenols and other polymers, with variable levels of polymerization during the processing of the olive cake. Studies on ultraviolet and infrared spectroscopy of both extracted and autohydrolyzed lignin were followed to match the difference in functional groups. The two lignin fractions (L and Lp) exhibited the basic UV spectra typical of lignin (Figure 2a), with an absorption maximum around 240 nm and a second maximum at 280 nm, associated with a nonconjugated phenolic group (aromatic ring), and a slight shoulder at 340−350 nm. The difference spectra, obtained by subtracting the spectra of the alkaline lignin from the neutral lignin (ionization difference, $\Delta\varepsilon_i$) are shown in Figure 2b. The two lignins (lignin from whole olive stones, L, and lignin from olive cake, Lp) were found to have three characteristic maximums at 254−256, 298−300, and 360−370 nm in their ultraviolet ionization spectrum, which indicate that both contain phenolic hydroxyls conjugated to the $\alpha$ carbonyl group, carbon−carbon double bonds, or biphenyl group.[25] A list of previously reported absorption coefficients $E(\%_{cm})$ from steam-exploded olive stones at various wavelengths in the 260−350 nm region[3] showed similar absorption coefficients to guaicyl-syringyl lignin of hardwoods, in contrast to the results for exploded olive cake lignin with

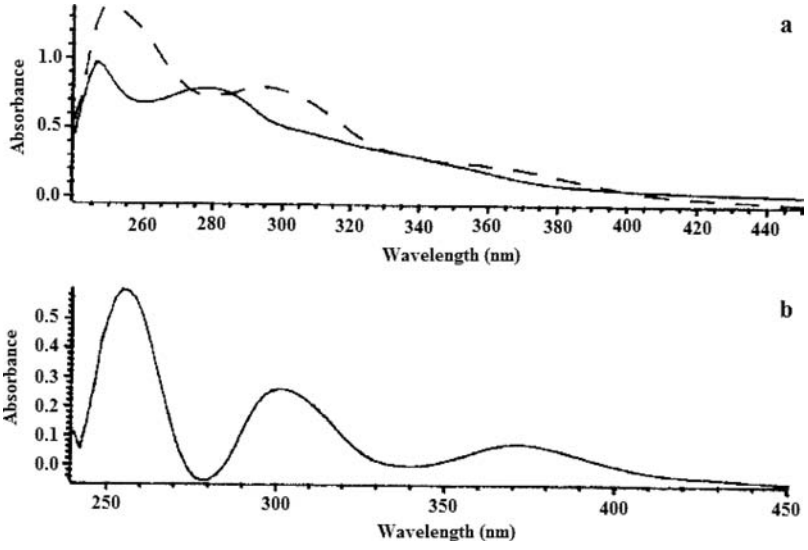

**Figure 2.** (a) Ultraviolet spectrum for alkaline (dash line) and neutral solution (solid line) of alkali-extracted lignin from steam-exploded olive cake (sample Lp); (b) alkaline-neutral difference spectra, ultraviolet ionization, $\Delta\varepsilon_i$.

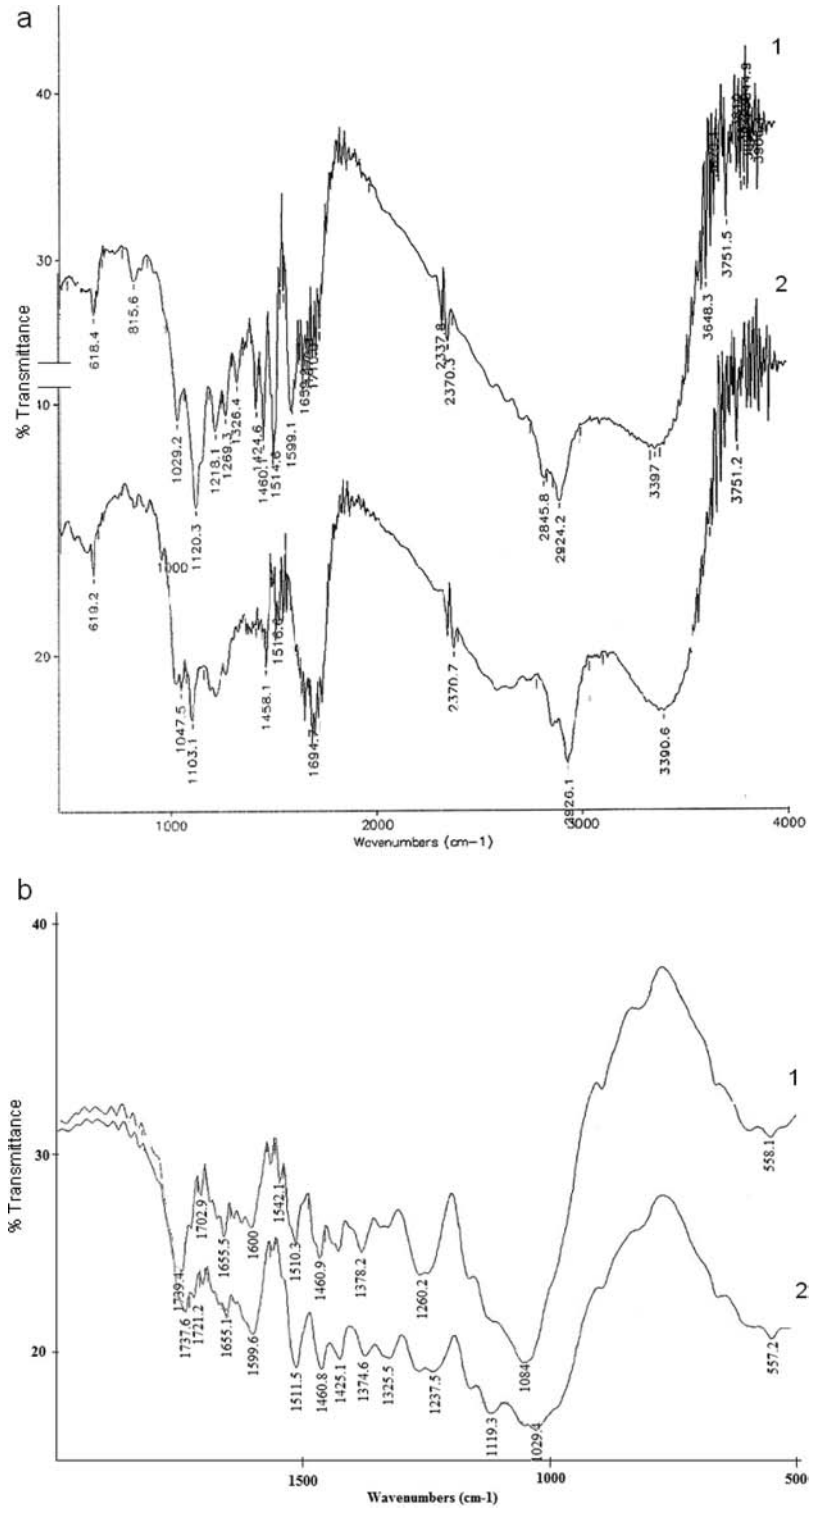

**Figure 3.** (a) Infrared spectra of alkali-extracted lignin (1) from steam-exploded whole olive stones (sample L) and (2) from steam-exploded olive cake (sample Lp); (b) infrared spectra of (1) milled and steam-untreated olive stones and (2) insoluble fraction isolated from steam-exploded olive stones (sample L+C).

very low absorption coefficients. The lignin isolated from steam-exploded olive stones showed a typical infrared lignin spectrum of guaicyl-syringyl lignin (Figure 3a1), with a characteristic lignin band in the region 1327−815 $cm^{-1}$ due to aromatic ether ring breathing and aromatic C−H deformation of the syringyl and guaicyl units.[26] In both lignin samples, a wide absorption band focused at 3396 $cm^{-1}$, originated from the OH− stretching vibration in the aromatic and aliphatic OH group, and a band at 2926 $cm^{-1}$, from the C−H stretching, were present. In addition, the occurrence of obvious aromatic skeleton vibration bands at 1600, 1515, and 1460 $cm^{-1}$ confirmed the presence of "lignin bands" in both alkaline-extractable lignins, although in the case of lignin from olive cake, a lower intensity relative to other bands indicates a

smaller content of aromatic ring. However, the lignin fraction isolated from olive cake showed some significant differences (Figure 3a2), with a strong multiple and broad absorption band between 1736 and 1675 $cm^{-1}$ attributed to conjugated/unconjugated carbonyl groups, carboxylic acid, and ester, indicating the presence of hemicelluloses, and a conjugated aryl carbonyl group, absent in the lignin of olive stone. These results confirm that the lignin fraction isolated from olive stones had a typical exploded hardwood lignin structure, distinguishable from steamed olive cake lignin, although with the presence of certain similar functional groups.

The water-insoluble fraction (sample L+C) was recovered from olive stone steam-treated at 215 °C/2 min (with previous acid impregnation) prior to alkali extraction, and the overall yield represents a recovery of total solid matter, including $\alpha$-cellulose and lignin (Table 1). However, the efficiency of the process is more associated with the extent of transformation in the substrate. Because the steam explosion results in the hydrolysis of the major part of the hemicelluloses and a small part of the lignin remains soluble in the aqueous fraction, a residue of $\alpha$-cellulose and lignin remains. In these conditions the material defibrates efficiently and then favors the release of lignin in the alkaline solution to achieve a maximum yield of lignin fraction, which then falls gradually with the severity of treatment.[3] The infrared spectra of the insoluble fraction isolated from steam-exploded olive stones was compared to the initial olive stone, which was milled and steam-untreated (Figure 3b1,b2). The relative intensities of the bands for aromatic skeleton vibration assigned at 1600, 1510, and 1425 $cm^{-1}$ were rather similar in milled and steam-pretreated samples, indicating a similar core structure of the lignins.[27,28] However, it appears that olive stone exhibited considerable changes following steam explosion, with the disappearance or decrease in characteristic absorption peaks of hemicelluloses. A wide absorption band focused on the ester group at 1740 $cm^{-1}$ with another at 1240 $cm^{-1}$, and it is also possible to relate the enhancement of the cellulose peaks at 1120 and 1030 $cm^{-1}$ to the disappearance of the characteristic vibration at 1080 and 1047 $cm^{-1}$ of the C−O stretching bands of hemicelluloses.

Cellulose was the major component in the insoluble water fraction of olive stones after the steam explosion (200 °C/2 min) and alkali extraction of lignin (sample C), in which the remaining lignin (36%) and hemicellulose (8%) were present (Table 1).

The water-soluble fraction obtained after extraction by ethyl acetate for a selected sample of olive stones steam-extracted at 215 °C/2 min was rich in hemicelluloses (sample H). The main components were carbohydrates (61%) from polysaccharides extracted from the cell wall with quite different structures (xylans, arabinoxylan, xyloglucan; Table 1), although a substantial portion of the water-soluble material produced during the pretreatment (30%) was not identified.[4] This may be explained by the high percentage of chemical transformation and by the condensation reaction between carbohydrates, their degradation products, and the phenol derived from lignin degradation.[29]

**Functional Properties: WHC, OHC, EA, and ES.** The functional properties of the fractions obtained by steam explosion and alkali delignification of olive byproducts were compared to those of commercial citrus pectin (Table 2). Citrus pectin showed significantly the highest WHC (10.3 g water/g sample), which is an important property of dietary fiber (related to soluble fiber) to absorb and retain water. WHC is an important quality from both a physiological and a technological point of view, increasing the bulk volume of food and modifying the viscosity and texture of formulated products in addition to reducing calories.[30] Sample L+C had significantly the highest WHC, compared to samples C and L, with a value similar to that of sample Lp. Becausee WHC is related to soluble dietary fiber content, the low WHC of sample H could be attributed to the degradation or changes in the structure of some fiber components by heating, leading to a loss of ability to retain water in the fiber.

Ingredients with a high OHC allowed for the stabilization of high-fat food products and emulsions, facilitating the solubilization or dispersion of two immiscible liquids.[31] The mechanism of oil adsorption is not well characterized, but a high OHC could be related to a high pectin content. The OHC of the fiber fraction studied varied between 2.0 and 3.4 g oil/g dry matter for samples H and L, respectively. Although the values obtained for commercial citrus pectin were low, higher levels were found in the literature for dietary fiber from asparagus byproducts (around 7.5−8 g/g dry matter), with high contents in insoluble fiber, 51−67 and 8.3−11% of soluble fiber.[20]

To evaluate the functionality of these samples as emulsifier agents, the EA and ES were studied. Citrus pectin had the highest EA value, 64.6%, despite the fact that the OHC of commercial pectin was lower, followed by sample L with a value around 45%. The other samples could not be considered as good emulsifiers as their EAs were <50%.[32] However, almost all of the samples showed good emulsification stability (75−100%) after the emulsion had been heated at 80 °C for 30 min. Despite the low emulsifying capacity and stability indices, the use of the material obtained may stabilize foods with a high percentage of fat and emulsion as noted by Borchani et al.[33] for date fiber concentrates with an EA below 13%.

**In Vitro BA Binding.** The in vitro digestion procedure used in this study was designed to mimic aspects of the human digestion system, including acid digestion of a sample at pH 2 followed by a pancreatine digestion at pH 7.[8] Three of the major BAs present in human bile were individually used for the

binding assays. Cholic acid (CA) and chenodeoxycholic acid (CDCA) are the two primary BAs secreted by the liver. Deoxycholic acid (DCA) is one of the secondary BAs formed through the transformation of primary acid by intestinal bacteria. Secondary acids are thought to be involved in the etiology and development of colorectal cancer.[34]

The samples prepared from olive stones and olive cake byproducts on dry matter were compared to the BA binding of citrus pectin, cholestyramine, a well-known BA binding anionic resin, and the negative control, commercial cellulose (Figure 4a–c). The results obtained for cholestyramine (which bound 6.7, 12.7, and 6.4 mM CA, DCA, and CDCA per 100 mg of sample, equal to 81.8, 96.6, and 91.8% of the total added BA) and cellulose (which bound only 0.08, 1.12, and 0.59 mM CA, DCA, and CDCA in 100 mg of sample, or 1.0, 9.6, and 7.6% of the total added BAs) are similar to previously published results.[7] The BA binding values of the material fractionated from different steam explosion treatments of olive byproducts were in the range of 0.6–7.7 mM/100 mg of sample depending on the type of BA. The sample rich in lignin from olive stones, sample L, bound similar amounts of the secondary bile acid, DCA, as citrus pectin (8.5 mM DCA per 100 mg), a dietary fiber component that is known to interact with bile acids.[35] However, it is noteworthy that the BA binding values of sample L, as well as sample Lp, were significantly higher for the two primary bile acids, CA and CDCA, than those of citrus pectin. These results are in agreement with the fact that lignin is another of the dietary fiber components that interacts with BA.[36] The CA and CDCA binding of samples H, C, and L+C were not statistically different and had slightly lower values than those determined for citrus pectin. Although the mechanism of interaction with BA is currently not fully understood, the structural parameter of the different polymers extracted from olive byproducts may influence this interaction. It is remarkable that the fraction of the olive stone rich in lignin (sample L) behaves similarly to cholestyramine, commonly used in the treatment of hypercholesterolemia. However, the lignin within the matrix of cellulose (sample L+C) showed a very small capacity for adsorption, not being statistically different from the fraction rich in cellulose (sample C) in the case of CA and CDCA, and in the case of DCA even lower than sample C, with values similar to the cellulose negative control. The fiber fractions studied, except samples L+C and Lp, showed higher percentages of bile acid binding with DCA (secondary BA) than with CDCA and CA (primary BAs). This was similar to results obtained by other authors who showed that BA adsorption decreases with the hydroxyl groups' increment in steroid nuclei.[37] In the case of the fraction of lignin from olive cake, sample Lp, with a composition somewhat different from that of a true lignin, a more substantial difference in BA binding between primary and secondary BAs was seen that may be related to the polymer's structure or composition.

A comparison of these results with those from previous studies on lignin[8] and other dietary fibers[7,9] shows a high bile acid binding capacity of primary and secondary acids, especially for sample L with CA, which points to their possible health-promoting activity. The captation of bile acid in the organism cause its excretion in the feces. The continued depletion of bile acid in this way appears to be related with the levels of reduced serum cholesterol, thereby reducing the risk of cardiovascular disease.[38] This binding to bile salts (carcinogenic agents) also causes a reduction of the excessive level of bile in the colon, thus reducing the risk of developing cancer in the intestine.[9]

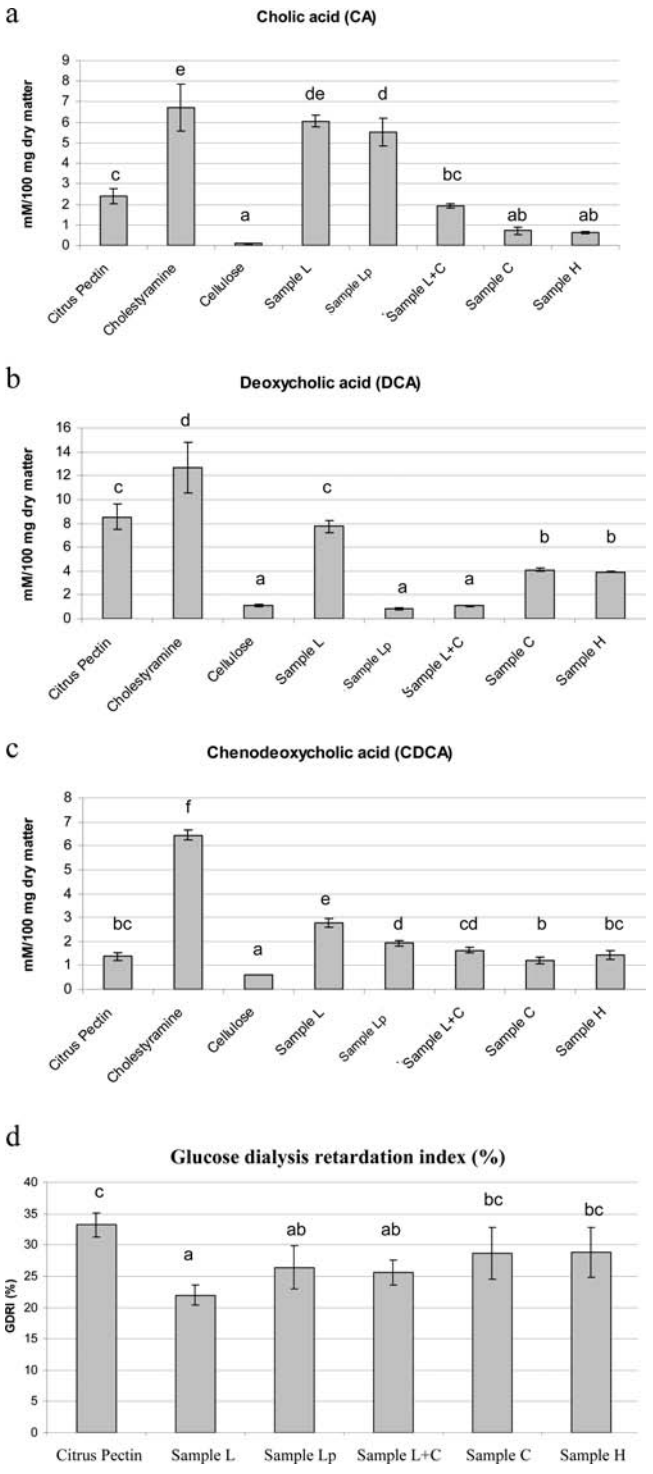

**Figure 4.** In vitro bile acid binding ability of olive stones and olive cake byproducts fractionated by steam explosion pretreatment combined with alkali delignification, compared to cholestyramine, cellulose, citrus, and pectin (a–c); (d) glucose dialysis retardation index (%) of the samples prepared from olive stones and olive cake byproducts steam-exploded on in vitro glucose diffusion, compared to citrus pectin. Data are presented as the means of three replicates ± SDs. Different letters indicate significantly different results ($p < 0.05$).

**Glucose Dialysis Retardation Index (GDRI).** The GDRI is a useful in vitro index to predict the effect that fiber has on the delay of glucose absorption in the gastrointestinal tract.[10] The GDRI phenomenon seems to be related to the soluble

dx.doi.org/10.1021/jf502062b | J. Agric. Food Chem. 2014, 62, 8973–8981

dietary fiber and uronic acid contents of insoluble fiber, although other authors have pointed to the relationship between the internal structure and surface properties of fiber and glucose diffusion.[39]

In Figure 4d the graphs for GDRI are presented. The results showed that both factors, composition and internal structure, could probably modulate this functional property, because values ranged from 22 to 29% for very different composition and nature of samples. The citrus pectin tested presented the highest value of GDRI (34%), although without significant differences between the sample of soluble fiber (sample H) or insoluble fiber (sample C).

The results obtained for the different components of olive stones and olive cake fractionated by steam explosion pretreatment combined with alkali delignification were similar to those reported in the literature for mango peel (21%),[9] artichoke fiber (27%),[39] and carambola pomace (25%),[40] lower than for fiber from asparagus byproduct (48%)[19] yet higher than those reported for wheat bran (5.3%).[41]

**General Comments.** The processing of olive byproducts obtained from olive oil extraction (fragmented olive stones and olive cake) and pitted table olives (whole olive stones) by steam explosion pretreatment/alkali delignification allowed for the fractionation of the three main polymers present in the lignocellulosic matrix with a reasonable yield and purity. This study showed that the pretreatment converted the hemicelluloses into a water-soluble fraction (sample H) rich in carbohydrates. The resulting insoluble material (sample L+C) was characterized by the spectroscopy method and compared with the material without steam explosion (ball-milled material). As such, we showed that the hemicelluloses were autohydrolyzed and the material had undergone important structural modifications during the steam explosion treatment. The cellulose was associated with a high proportion of lignin, which was partially recovered by alkaline extraction followed by acid precipitation (sample L), although some remains in the cellulose-rich fraction (sample C).

The functional properties were analyzed, and the fractions were found to have a WHC similar to those described for other agricultural byproducts, with an average OHC. The in vitro studies showed an important activity of bile acid binding for the lignin fraction from olive stones (sample L). This lignin fraction bound significantly more bile acid than any other fraction, with values similar to those for cholestyramine, especially when CA was tested. For the alkaline-extractable fraction from olive cake and subsequent precipitate by acid solution (sample Lp), substantially different UV and IR spectra were obtained from those of guaicyl-syringyl lignin of olive stones; the binding values were also significantly higher than those of the rest of the fractions, except for DCA. Therefore, both lignin fractions (L and Lp) could contribute to the reduction of serum cholesterol levels and a decreased risk of bowel cancer. Furthermore, the GDRI is a useful predictor of the in vitro health-promoting properties of the fractions and showed that the water-soluble fraction (sample H) and the fraction rich in cellulose (sample C) had high activities similar to those of pectin and other agricultural byproducts. These results would suggest the suitability of these fractions, extracted from olive byproducts, for incorporation as low-calorie bulk ingredients in high-fiber foods to lower postprandial serum glucose levels.

[a]Values are means ± SD of three determinations. Cooking methods that were not significantly different are assigned the same letter ($p > 0.05$).

## MATERIALS AND METHODS

**Plant Materials.** Fresh sweet potato leaves (cv. Pushu 53, a popular leaf-vegetable sweet potato cultivar in mainland China) were obtained from the Academy of Agricultural and Forestry Sciences in Hebei Province, China. All sweet potatoes were planted with standard production practices at the experimental farm of the Academy of Agricultural and Forestry Sciences in Shijiazhuang city, Hebei province, at the beginning of June 2013. The average temperatures during the growth period of 2013 were as follows: June, 26 °C; July, 26 °C; August, 31 °C; September, 23 °C; and October, 12 °C. The leaves were collected in the middle of August.

**Cooking Methods.** The sweet potato leaves were thoroughly cleaned with tap water and wiped with tissue paper. Eighteen hundred grams was taken and divided into six portions (300 g for each application). One portion was retained raw; the others were cooked in five different methods (reported by Perla et al.,[4] Palermo et al.,[11] and Tudela et al.[12] with slight modification) in triplicate, as given below.

For boiling, sweet potato leaves (100 g) were cooked in a stainless steel pan for 2 min after distilled water (500 mL) had come to a boil. For steaming, sweet potato leaves (100 g) were placed on tray in a steam cooker (Supor Co., Ltd., Hangzhou, Zhejiang, China) covered with a lid and steamed over boiling water for 2 min under atmospheric pressure. For microwave cooking, sweet potato leaves (100 g) were placed in a glass dish and cooked in a commercial 1000 W microwave oven for 2 min. For baking, sweet potato leaves (100 g) were baked at 204 °C for 2 min in a commercial oven after the oven had come to the prescribed temperature. For frying, sweet potato leaves (100 g) were cooked in a stainless steel pan for 2 min after corn oil (50 mL) had come to 180 °C. The treated and raw samples were freeze-dried and ground in a commercial grinder and stored at −20 °C in sealed aluminum bags until analyzed.

**Proximate Composition.** Ash, crude fat, and crude protein contents were determined according to AOAC methods.[13] Ash content was determined by weighing leaf samples before and after heat treatment (550 °C for 12 h). Crude fat content was determined according to AOAC method 960.39. Crude protein was assessed by the micro-Kjeldahl method, with a nitrogen to protein conversion factor of 6.25 (AOAC method 976.05).

Crude fiber was determined according to ISO method 5498:1981.[14] First, a sample of leaf powder was boiled in 0.255 M sulfuric acid for 30 min. The resulting insoluble residue was filtered, washed, and boiled in 0.313 M sodium hydroxide. After the sample had been filtered and washed, it was dried at 130 ± 2 °C for 2 h. Weight loss was determined at 350 ± 25 °C. Crude fiber content was expressed relative to the dry weight (DW) of leaf powder.

**Total Polyphenol Content (TPC).** TPC was measured by using the Folin−Ciocalteu method.[15] Briefly, 1 g of leaf powder was extracted with 20 mL of 70% (v/v) ethanol for 30 min at 50 °C and subjected to ultrasonic wave treatment. Following centrifugation at 5000*g* for 10 min at 4 °C, the residue was re-extracted twice with 70% ethanol as described above. The supernatants were pooled, concentrated in a rotary evaporator, and freeze-dried, thereby obtaining a crude extract. The crude extract was dissolved in 100 mL of distilled water; an aliquot (0.5 mL) was mixed with 1.0 mL of Folin−Ciocalteu reagent (Sigma-Aldrich, Inc., St. Louis, MO, USA), previously diluted 10 times, and allowed to react at 30 °C for 30 min. Subsequently, 2.0 mL of saturated $Na_2CO_3$ (10%, w/v) was added to the mixture. Following 30 min, absorbance was measured at 736 nm in a UV1101 spectrophotometer (Hitachi, Japan). A calibration curve consisting of chlorogenic acid (CHA) standards (Sigma-Aldrich, Inc.), ranging from 0.02 to 0.10 mg/mL, was prepared. The linear regression equation was $y = 8.7671x + 0.0068$ and $R^2 = 0.9994$. TPC of sweet potato leaves was calculated according to the following equation and expressed as milligrams per gram on a DW basis (mg/g DW).

$$\mathrm{TPC} = (A - 0.0068)/8.7671 \times V/M$$

$A$ is the absorbance, $V$ is the volume of the crude extract diluent (mL), and $M$ is the mass of the tested sweet potato leaf powder on a DW basis (g).

**Antioxidant Activity.** Antioxidant activity of sweet potato leaf powder samples was determined by using the ORAC assay, as reported by Blasa et al.[16] Briefly, 1 g of leaf powder sample was extracted with 20 mL of 70% (v/v) ethanol for 30 min at 50 °C and subjected to ultrasonic wave treatment. Following centrifugation at 5000*g* for 10 min at 4 °C, the residue was re-extracted twice with 70% ethanol as described above. The supernatants were pooled, concentrated in a rotary evaporator, and freeze-dried, thereby obtaining a crude extract. The assay was carried out using a microplate reader (Chameleon, Hidex, Turku, Finland) equipped with a temperature-controlled incubation chamber and an automatic injection pump. Incubator temperature was set at 37 °C. The reaction mixture for hydrophilic assay was the following: 200 μL of 0.096 μM fluorescein sodium salt in 0.075 M sodium phosphate buffer (pH 7.0) and 20 μL of sample or Trolox. A calibration curve was made each time with the standard Trolox (100, 50, 25 μM). The blank was 0.075 M sodium phosphate buffer (pH 7.0). The reaction was initiated with 40 μL of 0.33 M AAPH. Fluorescence was read at 485 nm excitation and 520 nm emission until complete extinction. ORAC values were expressed as micrograms of Trolox equivalents (TE) per milligram DW of sweet potato leaves and were the means ± standard deviation (SD) of three analyses.

**Quantification of Phenolic Compounds by RP-HPLC.** Phenolic compounds in sweet potato leaf extract were evaluated by reversed-phase high-performance liquid chromatography (RP-HPLC, Agilent Technologies, Palo Alto, CA, USA). Detection and quantification were carried out with a four-channel gradient pump, a diode array detector, a column heater, a degasser, and an autosampler (Agilent Technologies). Separations were conducted at 30 °C on an Agilent ZORBAX Eclips Plus C-18 reversed-phase column (150 mm × 4.6 mm length, 5 μm particle size). The mobile phases were (A) 0.1% (w/v) phosphoric acid solution and (B) acetonitrile. Flow rate was 1.0 mL/min. For analysis, 2 mg of dry sweet potato leaf extract was dissolved in 10 mL of 80% (v/v) methanol, and the injection volume of the sample solution was 20 μL. The gradient program was as follows: from 20 to 65% B from 0 to 15 min, from 65 to 80% B from 15 to 15.1 min, and 80% B maintained from 15.1 to 20 min. Spectral data from 200 to 800 nm were recorded, and the polyphenol chromatograms were monitored at 326 nm. Rutin, quercetin, caffeic acid, 3-*O*-caffeoylquinic acid, 4-*O*-caffeoylquinic acid, 5-*O*-caffeoylquinic acid, 3,4-di-*O*-caffeoylquinic acid, 3,5-di-*O*-caffeoylquinic acid, 4,5-di-*O*-caffeoylquinic acid, and 3,4,5-tri-*O*-caffeoylquinic acid (Sigma-Aldrich, Inc.) were used as standards. Identification and quantitative analysis were done by comparison with standards. The amount of each phenolic compound was expressed as milligrams per gram of sweet potato leaves (DW).

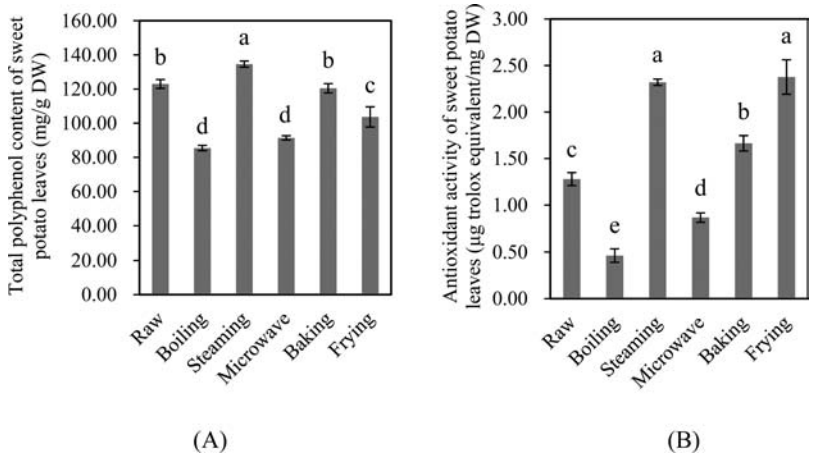

**Figure 1.** Effect of different domestic cooking methods on total polyphenol content (A) and antioxidant activity (B) of sweet potato leaves. Values are means ± SD of three determinations. Cooking methods that were not significantly different are assigned the same letter ($p > 0.05$).

**Table 2. Retention Time, Maximum Absorbance, and Linear Calibration Curves of Phenolic Compounds Found in Sweet Potato Leaves**

| peak | retention time (min) | HPLC-DAD $\lambda_{max}$ (nm) | identity | linear calibration curve | $R^2$ |
|---|---|---|---|---|---|
| 1 | 1.47 | 326 | 5-*O*-caffeoylquinic acid | $y = 11.372x - 0.428$ | 0.996 |
| 2 | 1.91 | 326 | 3-*O*-caffeoylquinic acid | $y = 9.909x + 0.286$ | 0.999 |
| 3 | 2.10 | 326 | 4-*O*-caffeoylquinic acid | $y = 25.894x - 17.128$ | 0.998 |
| 4 | 2.92 | 326 | caffeic acid | $y = 28.183x - 1.211$ | 0.999 |
| 5 | 4.16 | 326 | 4,5-di-*O*-caffeoylquinic acid | $y = 9.208x - 7.244$ | 0.998 |
| 6 | 4.54 | 326 | 3,5-di-*O*-caffeoylquinic acid | $y = 18.056x - 18.405$ | 0.998 |
| 7 | 4.88 | 326 | 3,4-di-*O*-caffeoylquinic acid | $y = 15.353x - 12.021$ | 0.998 |
| 8 | 6.87 | 326 | 3,4,5-tri-*O*-caffeoylquinic acid | $y = 6.218x - 5.158$ | 0.995 |

**Statistical Analyses.** The results were expressed as means ± SD of three replicates. Statistical analyses were performed using SAS version 8.1 software (SAS Institute Inc., Cary, NC, USA). Statistical significance was set at $p < 0.05$.

## RESULTS AND DISCUSSION

**Proximate Composition.** The effect of cooking methods on proximate composition of sweet potato leaves is shown in Table 1. Compared with the crude protein content in raw sweet potato leaves, boiling, steaming, microwaving, and baking increased crude protein content significantly, whereas frying decreased crude protein content significantly ($p < 0.05$). The possible reason was that, in the processes of boiling, steaming, and baking, other constituents, for example, fat and fiber, were partially lost or destroyed, resulting in the relative increase of protein content in sweet potato leaves; in contrast, the absorption of fat through frying caused an increase of dry matter, resulting in the relative decrease of protein content in sweet potato leaves.

Compared with the crude fat content in raw sweet potato leaves, the crude fat contents of sweet potato leaves cooked by boiling, steaming, microwaving, and baking were decreased significantly, whereas frying increased crude fat content significantly ($p < 0.05$). During boiling, steaming, and microwaving treatments, volatile and water-soluble fatty acids would be partialy lost or destroyed, which induced the decrease of fat content in sweet potato leaves. Fried samples had a higher level of fat than raw or other cooked samples, mainly due to the absorption of fat by the sweet potato leaves. Similar findings were already reported by Donya et al., who investigated the effects of cooking methods on the proximate composition of bitter melon vegetable and found that the fat content of fried sample increased from 3.6 to 67%, because frying resulted in the expulsion of water and the absorption of fat.[17] Fillion and Henry have already reported that the initial composition of the food (water and fat content) has a great effect on fat uptake during frying, and plant foods, which initially have high water and low fat contents, will absorb a large amount of frying fat.[18]

There was no significant difference between the crude fiber content of raw sweet potato leaves and that of baked sweet potato leaves. Compared with raw sweet potato leaves, boiling, steaming, and microwaving decreased the crude fiber content of sweet potato leaves significantly, whereas frying increased the crude fiber content significantly ($p < 0.05$). It was suggested that boiling caused a great loss of water-soluble dietary fiber. Although sweet potato leaves were not exposed to water, a large amount of cytochylema would flow out during steaming and microwaving treatments, causing the loss of water-soluble dietary fiber. In contrast, fried samples had a higher level of fiber than raw or other cooked samples. Murniece et al. investigated the nutritional composition and energy content of several varieties of potatoes prepared by traditional cooking methods and got the similar result we did, that the fiber content of deep-fat-fried samples was higher than that of uncooked samples.[19] The possible reason was that frying could lead to structural damage of vegetable cells to maximum extent, inducing great loss of other liposoluble constituents in sweet potato leaves; as a result, the fiber content was relatively increased.

The ash content of sweet potato leaves cooked by boiling, steaming, and microwaving did not show significant difference when compared with that of raw sweet potato leaves. Baking

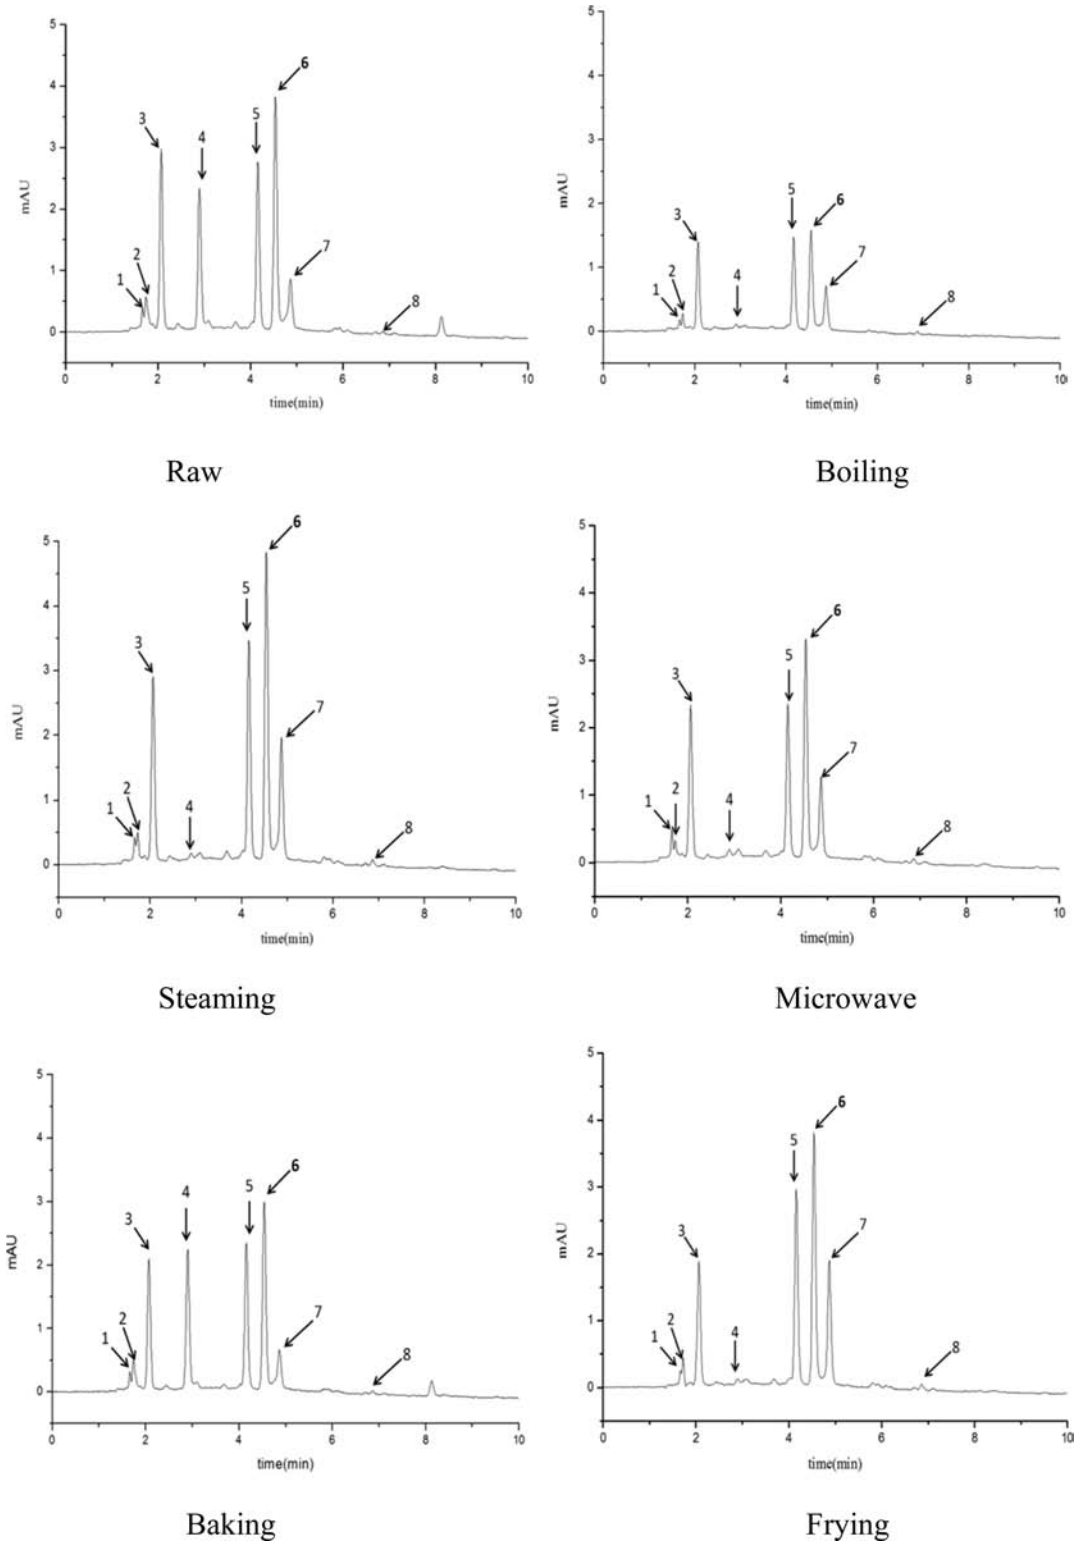

**Figure 2.** Chromatograms of phenolic standards and sweet potato leaf extracts at 326 nm in HPLC. The identities of the compounds identied by numbered peaks are given in Table 2.

increased the ash content of sweet potato leaves significantly, whereas frying decreased the ash content significantly ($p < 0.05$). Our results were very different from those reported by Gidamis et al., who investigated the effect of traditional cooking methods on nutrient contents in young *Moringa* leaves and immature pods and found a significant reduction of ash content as the result of cooking.[20] Baking caused the least loss of ash, compared to other cooking treatments. Besides, baking induced greater loss of other constituents, for example, fat, from raw sweet potato leaves, resulting in the relative increase of ash content. On the contrary, inorganic solids partly flowed out from sweet potato leaf cells during frying treatment, causing the decrease of ash content.

| sum of phenolic compounds | 100.92 ± 6.62a | 75.95 ± 0.30b | 104.58 ± 7.52a | 90.82 ± 4.01ab | 106.21 ± 9.04a | 102.07 ± 0.82a |

[a]Values are means ± SD of three determinations. Cooking methods that were not significantly different are assigned the same letter ($p > 0.05$).

**Total Polyphenols.** Figure 1A shows the effect of cooking methods on TPC of sweet potato leaves. Compared with raw sweet potato leaves, the TPC of sweet potato leaves cooked by boiling, microwaving, and frying decreased significantly, whereas steaming increased the TPC of sweet potato leaves significantly ($p < 0.05$). There was no significant difference between the TPC of raw and baked sweet potato leaves. An increase of 9.44% in TPC was observed after steaming, whereas decreases of 30.51, 25.70, and 15.73% was noted after boiling, microwaving, and frying, respectively. The changes in TPC agreed with the findings of Wachtel-Galor et al., who investigated the effect of cooking on TPC in cauliflower and found that steaming showed the highest TPC (an increase of 45%), followed by boiling (a loss of 4%), and microwaving (a loss of 39%) showed the lowest value.[21] On the other hand, Pellegrini et al. found that oven steaming was the most disadvantageous method for cooking fresh Brussels sprouts.[6] The effect of cooking depends on several factors, such as the cooking procedure, degree of heating, leaching into the cooking medium, solvent used for extraction, pH, and surface area exposed to water and oxygen.[21] For example, Roy et al. investigated the effect of water temperature (50−100 °C) and cooking time (10, 30, 75 min) on TPC in cabbage and found a decrease of TPC as temperature and cooking duration increased.[22] Besides, different plants contain various compounds, some of which are thermally labile and some are not and, therefore, the same cooking method may have different effects on different types of plants.[23] In this study, the depletion of TPC in sweet potato leaves after boiling, microwaving, and frying could be due to phenolic breakdown during cooking.[24] For steaming and baking, the basis of the increased or unchanged TPC in sweet potato leaves could not be categorically stated; however, it could be attributed to the possible breakdown of complex structures liberating individual phenolics and/or phenolic degradation products, which could also react with the Folin−Ciocalteu reagent.[25]

**Antioxidant Activity.** The effect of cooking method on antioxidant activity of sweet potato leaves is shown in Figure 1B. The antioxidant activity of raw sweet potato leaves was 1.28 ± 0.07 μg Trolox equiv/mg, DW. Compared with raw sweet potato leaves, the antioxidant activity of sweet potato leaves cooked by boiling and microwaving was decreased significantly, whereas that of sweet potato leaves cooked by steaming, baking, and frying was increased significantly ($p < 0.05$). Decreases of 63.82 and 32.35% in antioxidant activity were noted after boiling and microwaving, respectively, which was in agreement with the loss of TPC in sweet potato leaves. Price et al. found that only 18% of TPC was retained in broccoli after boiling, the rest being largely leached into cooking water,[26] which supported the data in this study and suggested that boiling caused a decrease of antioxidant activity of sweet potato leaves. The lower antioxidant activity of microwaved samples was perhaps due to a greater thermal effect, rather than the microwaving per se.[21] In contrast, increases of 81.40, 30.09, and 85.82% in antioxidant activity were observed after steaming, baking, and frying, respectively, which was not in accordance with the changes of TPC in sweet potato leaves. This was perhaps due to the production of other redox-active secondary plant metabolites or breakdown products, but was highly likely to be related to the more efficient release of other antioxidants from intracellular proteins, changes in plant cell wall structure, and matrix modifications.[27]

**Quantification of Phenolic Compounds by RP-HPLC.** It is obvious that the TPC measured by the Folin−Ciocalteu method does not give a full picture of the qualification or quantification of the phenolic compounds in the sweet potato leaf extracts. Therefore, the phenolic compounds in the sweet potato leaf extracts cooked by different methods were determined by the HPLC method, and the HPLC results are presented in Table 2 and Figure 2. Eight phenolic compounds, 5-*O*-caffeoylquinic acid, 3-*O*-caffeoylquinic acid, 4-*O*-caffeoylquinic acid, caffeic acid, 4,5-di-*O*-caffeoylquinic acid, 3,5-di-*O*-caffeoylquinic acid, 3,4-di-*O*-caffeoylquinic acid, and 3,4,5-tri-*O*-caffeoylquinic acid, were identified by comparison with the retention times and UV spectra of authentic standards analyzed under identical conditions, whereas the quantitative data were calculated from their respective regression equations.

On the basis of the plots of the peak area ($y$) versus concentration ($x$, mg/g, DW), the regression equations of the eight phenolic compounds detected in sweet potato leaves and their correlation coefficients ($R^2$) were obtained and are shown in Table 2. The contents of individual phenolic compounds in sweet potato leaves treated by different cooking methods are shown in Table 3. In a comparison of the amounts of the eight phenolic compounds present in raw sweet potato leaves, 4,5-di-*O*-caffeoylquinic acid > 3,5-di-*O*-caffeoylquinic acid > 3,4-di-*O*-caffeoylquinic acid > 4-*O*-caffeoylquinic acid > 3,4,5-tri-*O*-caffeoylquinic acid > caffeic acid > 3-*O*-caffeoylquinic acid > 5-*O*-caffeoylquinic acid.

For 5-*O*-caffeoylquinic acid, boiling, steaming, baking, and frying decreased its content significantly, whereas microwaving did not cause a significant change. For 3-*O*-caffeoylquinic acid, boiling, steaming, microwaving, and frying induced significant losses, whereas baking did not change its content significantly.

dx.doi.org/10.1021/jf502328d | J. Agric. Food Chem. 2014, 62, 8982−8989

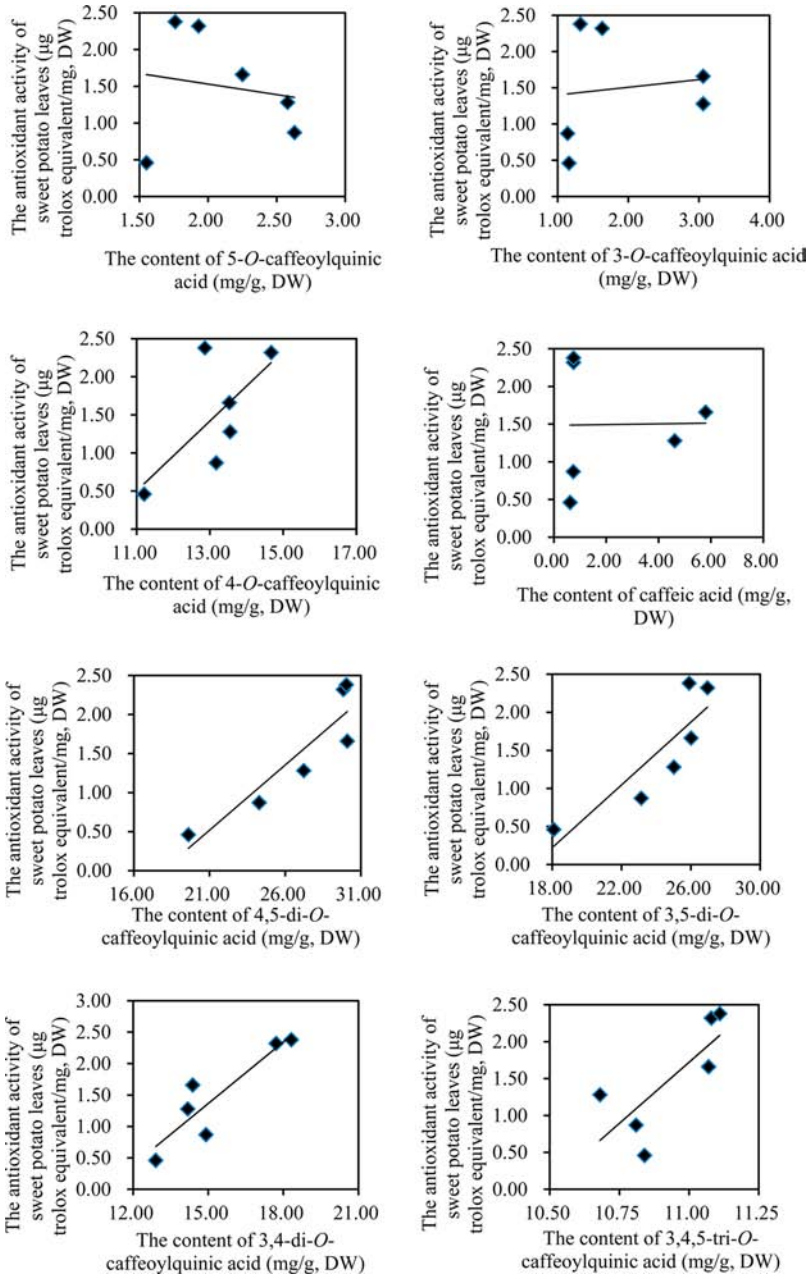

**Figure 3.** Correlation between the content of (a) 5-*O*-caffeoylquinic acid content and antioxidant activity ($R = -0.16433$; $p = 0.7557$); (b) 3-*O*-caffeoylquinic acid content and antioxidant activity ($R = 0.12552$; $p = 0.8127$); (c) 4-*O*-caffeoylquinic acid content and antioxidant activity ($R = 0.67485$; $p = 0.1414$); (d) caffeic acid content and antioxidant activity ($R = 0.01559$; $p = 0.9766$); (e) 4,5-di-*O*-caffeoylquinic acid content and antioxidant activity ($R = 0.90926$; $p = 0.0120$); (f) 3,5-di-*O*-caffeoylquinic acid content and antioxidant activity ($R = 0.86450$; $p = 0.0263$); (g) 3,4-di-*O*-caffeoylquinic acid content and antioxidant activity ($R = 0.90267$; $p = 0.0137$); and (h) 3,4,5-tri-*O*-caffeoylquinic acid content and antioxidant activity ($R = 0.76352$; $p = 0.0773$) of sweet potato leaves treated by different domestic cooking methods.

4-*O*-Caffeoylquinic acid was the most abundant monocaffeoylquinic acid in sweet potato leaves, and among the used cooking methods, only boiling decreased its content significantly. For caffeic acid, baking increased its content significantly, whereas the rest of the cooking methods caused significant losses of caffeic acid. Wang and Ho reported that during thermal treatment, the hydrolysis of chlorogenic acid could produce caffeic acid,[28] but our result was not in accordance with it, suggesting that boiling, steaming, microwaving, and frying induced the leaching out or degradation of caffeic acid. Guillot et al. reported that under mild pyrolysis caffeic acid could be degraded into tetraoxygenated 1,3-*cis*- and 1,3-*trans*-phenylindane isomers, which showed comparable antioxidant activity and were 8-fold more active than butylated hydroxytoluene (BHT),[29] and this might make some contribution to the relatively high antioxidant activity of steamed and fried sweet potato leaves. 4,5-Di-*O*-caffeoylquinic acid was the most abundant dicaffeoylquinic acid in sweet potato leaves, and only boiling induced significant loss of 4,5-di-*O*-caffeoylquinic acid. For 3,5-di-*O*-caffeoylquinic acid, only boiling decreased its content significantly. For 3,4-di-*O*-caffeoylquinic acid, steaming and frying increased its content significantly, whereas boiling decreased its content significantly. For 3,4,5-tri-*O*-caffeoylquinic acid, steaming, baking, and frying induced significant increases,

dx.doi.org/10.1021/jf502328d | J. Agric. Food Chem. 2014, 62, 8982−8989

whereas there were no significant differences between raw and other treated sweet potato leaves. The above-mentioned results indicated that most of the individual phenolic compounds measured by HPLC in sweet potato leaves showed the same general trend in their content, that is, decreases after boiling and better retention after other cooking methods. Especially, there is a common point for steamed and fried sweet potato leaves that the contents of both 3,4-di-*O*-caffeoylquinic acid and 3,4,5-tri-*O*-caffeoylquinic acid increased significantly compared with raw samples, which is in accordance with the trend of antioxidant activity, indicating that 3,4-di-*O*-caffeoylquinic acid and 3,4,5-tri-*O*-caffeoylquinic acid might be the main contributor to the antioxidant activity of sweet potato leaves. A sum of individual phenolic compounds detected by HPLC of 100.92 mg/g DW was obtained for raw sweet potato leaves. In steamed sweet potato leaves, the sum of individual phenolic compounds was 104.58 mg/g DW, 3.63% more than for raw samples. This value is far from the increase in antioxidant activity of 81.4% of steamed samples. The same trend could be seen for baked sweet potato leaves and fried ones. This result demonstrated a production of antioxidant compounds other than polyphenols. The interesting fact that has to be more pointed out is that these substances do not react in the Folin−Ciocalteu system, because in Figure 1A, only a slight increase of TPC has been detected in steamed sweet potato leaves in comparison with raw sweet potato leaves. It is very hard to identify which individual phenolic compound was the biggest contributor to the antioxidant activity of sweet potato leaves. Palermo et al. found that different cooking treatments caused an increase in total antioxidant activity of artichokes and ascribed this increase to the increase of 5-*O*-caffeoylquinic and 1,5-di-*O*-caffeoylquinic acid.[11] However, our result was very different from theirs. To tell the relationship between individual phenolic compounds and antioxidant activity of sweet potato leaves clearly, we analyzed the correlation between the content of individual phenolic compounds and antioxidant activity of sweet potato leaves by Pearson test using SAS version 8.1 software (Figure 3). 4,5-Di-*O*-caffeoylquinic acid showed the biggest correlation coefficient, followed by 3,4-di-*O*-caffeoylquinic acid, 3,5-di-*O*-caffeoylquinic acid, 3,4,5-tri-*O*-caffeoylquinic acid, 4-*O*-caffeoylquinic acid, 3-*O*-caffeoylquinic acid, caffeic acid, and 5-*O*-caffeoylquinic acid. Therefore, the antioxidant activity of sweet potato leaves could be mainly attributed to the increases in the contents of 4,5-di-*O*-caffeoylquinic acid, 3,4-di-*O*-caffeoylquinic acid, 3,5-di-*O*-caffeoylquinic acid, and 3,4,5-tri-*O*-caffeoylquinic acid. The antioxidant activity of phenolics compounds is mainly due to redox properties, which allow them to act as reducing agents, hydrogen donors, singlet oxygen quenchers, heavy metal chelators, and hydroxyl radical quenchers.[30] The di- and tricaffeoylquinic acids have more hydroxyl groups in their molecular structure,[31] making them more active than monocaffeoylquinic acids.

The TPC calculated from the data obtained by HPLC analysis was lower than that estimated by using the Folin−Ciocalteu method. One of the possible reasons is that the Folin−Ciocalteu method suffers from a number of interfering substances [particularly sugars, aromatic amines, sulfur dioxide, ascorbic acid and other enediols and reductones, organic acids, and Fe(II)].[32] Another possible reason is the limitation of individual phenolic compounds used as standard.[33]

In conclusion, sweet potato leaves are good sources of protein, fiber, and minerals, and the polyphenols therein are important antioxidants. Understanding the antioxidant activity of sweet potato leaves can help human beings enhance antioxidant intake, and this work must consider the effects of cooking on antioxidant activity. The results presented here clearly demonstrated that cooking could make the antioxidant activity of cooked sweet potato leaves quite different from that of the uncooked leaves. This was perhaps due to a variety of effects, including damage, flowing out, and transformation of the constituents in sweet potato leaves. In this study, steaming was found to retain or enhance TPC and antioxidant activity of sweet potato leaves best, followed by frying, baking, microwaving, and then boiling. Cooking in water seemed to cause a leakage of polyphenols into the cooking water. The correlation between the content of individual phenolic compounds and antioxidant activity suggested that the antioxidant activity of sweet potato leaves could be mainly attributed to 4,5-di-*O*-caffeoylquinic acid, 3,4-di-*O*-caffeoylquinic acid, 3,5-di-*O*-caffeoylquinic acid, and 3,4,5-tri-*O*-caffeoylquinic acid.

cancer,[10] breast cancer,[11] leukemia,[12] and lung cancer.[13] In our previous studies, PGG suppresses the functions of ER$\alpha$ by lysosome-dependent depletion and modulating the ErbB/PI3K/Akt pathway in hormone-dependent breast cancer cells.[14] Moreover, PGG exerts an anti-invasive effect in androgen-independent prostate cancer by controlling MMP-9 expression through the suppression of the EGFR/JNK pathway and suppresses bone metastasis in nude mice treated with intratibial injection of prostate cancer (PC-3) cells.[15]

We still need to establish a comprehensive method to study how PGG affects EGF-induced prostate cancer bone metastasis. Therefore, we utilized 2D-PAGE and MALDI-TOF to analyze the effect of PGG treatment on EGF-induced prostate cancer bone metastasis. Our results showed that PGG suppressed EGF-induced eIF3i expression through inhibition of the PI3K/AKT/mTOR pathway. Therefore, EGF-induced eIF3i expression played an important role in prostate cancer bone metastasis.

## MATERIALS AND METHODS

**Materials and Antibodies.** PGG was isolated from the leaves of *Macaranga tanarins* (L.) as described previously.[16] The purity was determined by HPLC to be approximately 99%. For treatment of cells, PGG was dissolved in dimethyl sulfoxide (DMSO) as a stock solution. The final DMSO added to cell culture medium was below 0.1%. EGF, LY294002, PD98059, SB203580, and SP600125 were obtained from Sigma (St. Louis, MO, USA). Antiphospho-ERK1/2 (Thr 202/Tyr 204) and ERK1/2 were from Upstate Biotechnology, Inc. (Lake Placid, NY, USA). Antibodies against p-Akt (Ser473), Akt, p-p38, p38, JNK, and p-JNK were from Cell Signaling (Beverly, MA, USA). Antibodies for $\beta$-actin, eIF3i, p-PI3K, PI3K, p-mTOR, mTOR, p-4EBP1, and 4EBP1 were purchased from Santa Cruz Biotechnology, Inc. (Santa Cruz, CA, USA). Anti-mouse and anti-rabbit antibodies conjugated to horseradish peroxidase were also obtained from Santa Cruz Biotechnology, Inc.

**Cell Cultures.** PC-3 cells were obtained from the American Type Culture Collection (Rockville, MD, USA). PC-3 cells were cultured in RPMI 1640 supplemented with 10% fetal bovine serum (FBS) and 1% penicillin–streptomycin in a 5% $CO_2$ atmosphere at 37 °C.

**Two-Dimensional Gel Electrophoresis (2-DE).** In the first dimension, isoelectric focusing (IEF) was done with commercially available preformed immobilized pH gradients (IPGs) (linear pH gradient 3–10, 13 cm). The gels were rehydrated overnight by placing the strips gel-side-down in sample-containing rehydration solution in an IPGphor strip holder and covering them with mineral oil. IEF was conducted using an IPGphore IEF System (Amersham Pharmacia Biotech, Piscataway, NJ, USA) with a three-phase program. The first phase was set at 500 V for 1 h, the second phase was set at 1000 V for 1 h, and the final phase was a linear gradient spanning from 8000 to 16000 V for 2 h. Before second-dimensional electrophoresis, the IPG gel strips were incubated at room temperature for 15 min in equilibration solution (50 mM Tris-HCl, pH 8.8, 6 M urea, 2% SDS, 30% glycerol) containing 1% DTT and then in equilibration solution containing 2.5% iodoacetamide for 5 min. The gels were then submitted to a second dimension run on a Hoefere SE 600 (Amersham Pharmacia Biotech), at 4 °C, on running 12.5% SDS-PAGE gels (16 × 15 cm), without stacking gels. The IPG gel strips were embedded on top of the gels with 1% agarose. Electrophoresis was conducted at 30 mA/gel for 5 h. The 2-D polyacrylamide gels were stained with CBB. Protein p*I* and $M_w$, respectively, were assigned by calibration of 2-D PAGE gels with carbamylyte p*I* calibration markers and molecular weight markers (Amersham Pharmacia Biotech). On 2-DE, only those significantly and consistently altered protein spots in at least two independent experiments (over 2-fold up- or down-regulation) were selected for analysis by MALDI-TOF. Protein spots were quantified using ImageMaster 2D Elite software (Amersham Pharmacia Biotech).

**In-Gel Digestion.** Protein spots excised from the CBB-stained gel were destained in microtubes with 0.2 mL of acetonitrile (ACN) for 15 min and dried completely in a centrifugal evaporator. The dried gels were rehydrated on ice for 45 min with a digestion buffer composed of 0.04 mg/mL of modified trypsin (Promega, Madison, WI, USA) in 0.005% zwittergent 3-16 and 50 mM $NH_4HCO_3$. After removal of excess solution, proteins were further digested at 37 °C for 15 h. The resultant peptides were extracted with 5% ACN in 5% formic acid, desalted, and concentrated using in-tip reversed phase resin (Zip tip C18; Millipore, Bedford, MA, USA).

**Western Blotting.** Western Blot was done as described previously.[17] After treatment, cells were harvested, washed twice with cold PBS, and then lysed in gold lysis buffer. A total of 50 $\mu$g of protein was separated by SDS-PAGE and transferred to the PVDF membrane. The filters were probed with appropriate primary antibodies. Reactive bands were visualized using an enhanced chemiluminescence system (Amersham Biosciences, Arlington Heights, IL, USA).

**Tranfection.** One day before transfection, $2 \times 10^5$ cells without serum and antibiotics were plated in six-well plates. Starved PC-3 cells were grown to 90% confluence and transfected on the following day by Lipofectamine 2000 (Invitrogen, Carlsbad, CA, USA) and premixed plasmid DNA with OPTI-MEM (GIBCO) for 5 min and then added to each well. After 24 h of incubation, the transfection was completed.

**Reverse Transcription Real-Time Quantitative PCR.** Total RNA was extracted from cancer cells using a TRIzol kit (MDBio, Taipei, Taiwan). The reverse transcription was carried out using 2 $\mu$g of total RNA that was reversely transcribed into complementary DNA using oligo (dT) primer by Superscript RT (Invitrogen, Burlington, ON, Canada). qPCR assays were performed with a StepOne-Plus sequence detection system in triplicate. The cycling conditions were 10 min of polymerase activation at 95 °C followed by 40 cycles at 95 °C for 15 s and 60 °C for 60 s. Data were analyzed by relative quantification normalized with GAPDH gene.

**Cell Invasion Assay.** A Boyden chamber (8 $\mu$m pore size) was used for in vitro invasion assay. Cells ($1 \times 10^5$) in medium containing 0.5% serum were seeded in the upper chamber, and 15% FBS was added to the medium in the lower chamber as a chemoattractant. For invasion assays, the upper side of the filter was covered with Matrigel (Collaborative Research, Inc., Boston, MA, USA). After 24 h for invasion assays, cells on the upper side of the filter were removed, and cells that remained adherent to the underside of membrane were fixed in 4% formaldehyde and stained with Hoechst 33342 dye. Ten contiguous fields of each sample were examined using a microscope

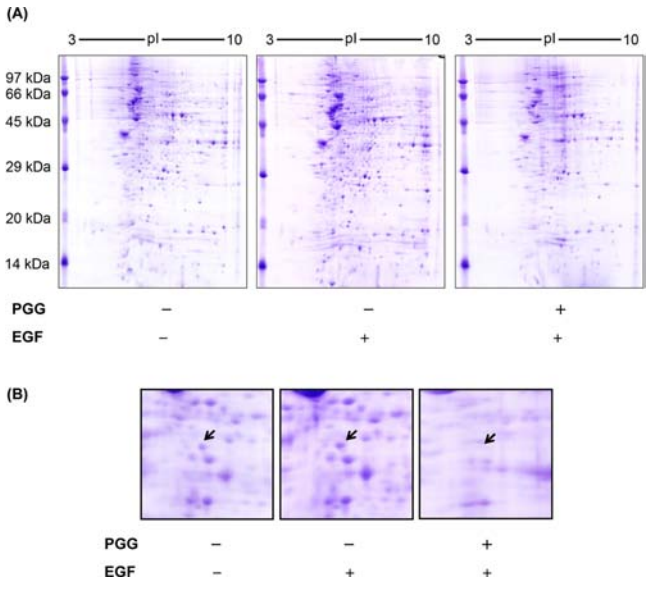

**Figure 1.** Proteomics analysis: (A) representative 2-DE gel images from PC-3 cells pretreated with/without 10 $\mu$M PGG for 1 h and then added to 25 ng/mL EGF for 24 h; (B) magnified regions of identified differently expressed protein spots. Spots within the arrow were identified as differently expressed eIF3i proteins.

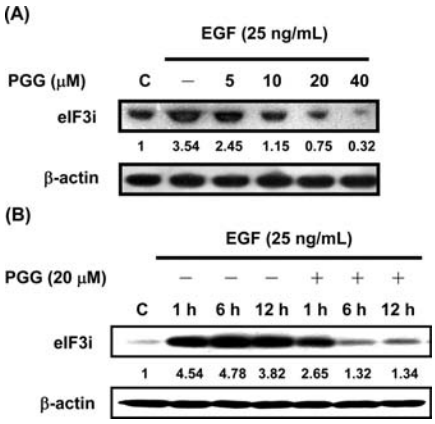

**Figure 2.** PGG blocked EGF-induced eIF3i expression in PC-3 cells. (A) PC-3 cells were pretreated with DMSO (control) or increasing PGG concentrations (5−40 $\mu$M) for 1 h prior to EGF stimulation (25 ng/mL) for 24 h. (B) PC-3 cells were incubated with DMSO (control) or 20 $\mu$M PGG for 1, 6, or 12 h prior to EGF stimulation (25 ng/mL) for 24 h. The cells were then harvested and lysed for the detection of eIF3i and $\beta$-actin. Western blot data presented are representative of those obtained in at least three separate experiments. Immunoblots were quantified, and relative expression to control is indicated.

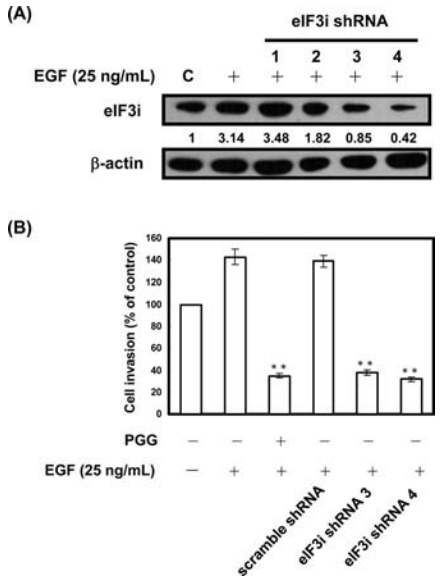

**Figure 3.** shRNA knockdown of eIF3i revealed a critical role for EGF-induced prostate cancer cells invasion. (A) PC-3 cells were transfected with eIF3i shRNA and then stimulated with EGF (25 ng/mL) for 24 h. The cells were then harvested and lysed for the detection of eIF3i and $\beta$-actin. Western blot data presented are representative of those obtained in at least three separate experiments. Immunoblots were quantified, and relative expression to control is indicated. (B) Invasion ability of P-C3 cells transfected with scramble shRNA or eIF3i shRNA and then stimulated with EGF (25 ng/mL) for 24 h. Data represent means ± SEM ($n$ = 3). Asterisks indicate $P < 0.01$ compared with PC-3 cells stimulated with EGF. Two independent clones are shown, as indicated.

and a 40× objective to obtain a representation of the number of cells that had invaded across the membrane.

## RESULTS

**Proteomic Profile of EGF-Induced Prostate Cancer Cells Treated with or without PGG.** Our previous studies showed that PGG could suppress prostate cancer cell (PC-3) bone metastasis by transcriptionally repressing EGF-inducing MMP-9 expression.[15] However, the protein expression profile of EGF-induced prostate cancer cells treated with PGG was not investigated. We utilized 2D-PAGE and MALDI-TOF to analyze the differences of protein expression profile between EGF-induced prostate cancer cells treated with or without PGG. In 2D-PAGE, the protein spots were clearly visualized, with around 1400 protein spots on each gel (Figure 1A). The protein expression profile of PC-3 cells treated with neither EGF nor PGG was used as a control. PC-3 cells were pretreated without and with 10 $\mu$M PGG for 1 h and then added to 25 ng/mL EGF for 24 h. Six proteins were identified during EGF-stimulated expression and reduced by PGG treatment (Table 1). The eukaryotic translation initiation factor 3 subunit 2 (eIF3i) was one of these six proteins (Figure 1B).

**PGG Suppressed EGF-Induced eIF3i Expression in PC-3 Cells.** To further confirm whether PGG could suppress EGF-induced eIF3i expression, Western blotting was performed. PC-3 cells were pretreated with indicated concentrations of PGG for 1 h prior to stimulation with EGF. Figure 2A showed that PGG inhibited EGF-induced eIF3i expression in a dose-dependent manner. To address this time-dependent pretreatment effect, we pretreated PC-3 cells with 20 $\mu$M PGG for various periods of time from 1 to 12 h prior to EGF addition. As shown in Figure 2B, 20 $\mu$M PGG exerted its inhibitory effect on EGF-induced eIF3i expression in a time-dependent manner. Our data suggested that PGG inhibited EGF-induced eIF3i expression in PC-3 cells.

**EGF-Induced eIF3i Expression Involved in Prostate Cancer Cell Bone Metastasis.** PGG suppressed EGF-induced prostate cancer cell bone metastasis and also decreased EGF-induced expression of eIF3i. To understand the biological functions of eIF3i involved in EGF-induced prostate cancer cells invasion, we employed the loss-of-function approach, that is, by knocking down the expression level of eIF3. We transiently transfected PC-3 cells with four shRNA clones specifically targeting eIF3i (Figure 3A). Clones 3 and 4 were good enough for reducing EGF-induced eIF3i expression in PC-3 cells. Subsequently, we examined the effect of EGF-induced eIF3i expression involved in PC-3 cell invasion. The results showed

dx.doi.org/10.1021/jf502447e | J. Agric. Food Chem. 2014, 62, 8990−8996

that PGG suppressed EGF-induced invasion in PC-3 cells. Moreover, down-regulation of EGF-induced eIF3i expression resulted in significant reduction of PC-3 cells' invasive ability (Figure 3B). The studies indicated that PGG suppressed EGF-induced prostate cancer cell bone metastasis through the down-regulation of eIF3i.

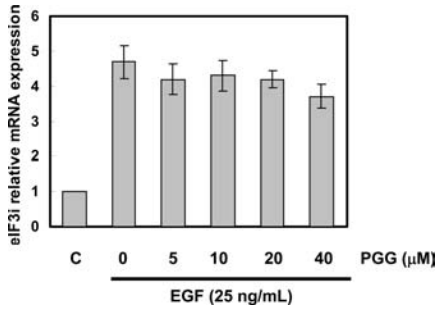

**Figure 4.** PGG does not inhibit EGF-induced eIF3i mRNA expression. PC-3 cells were pretreated with DMSO (control) or increasing PGG concentrations (5−40 $\mu$M) for 1 h prior to EGF stimulation (25 ng/mL) for 24 h. Real-time PCR analysis was employed on total mRNA. Data represent means ± SEM ($n$ = 3).

**PGG Did Not Suppress EGF-Induced eIF3i mRNA Expression in PC-3 Cells.** To investigate whether the suppression of EGF-induced eIF3i expression by PGG was due to reduced eIF3i mRNA expression, real-time PCR analysis was employed. As shown in Figure 4, the results showed that EGF-induced eIF3i mRNA expression. However, PGG did not repress EGF-induced eIF3i mRNA expression in a dose-dependent manner (Figure 4). The data suggested that PGG did not modulate EGF-induced eIF3i expression at the transcriptional level.

**PGG Suppressed EGF-Induced eIF3i Expression through the Inhibition of PI3K Signaling Pathway.** EGF signaling activates multiple important pathways such as RAS/mitogen-activated protein kinase (MAPK) and phosphatidylinositol 3-kinase (PI3K)-Akt.[3] To confirm which pathways participated in EGF-induced eIF3i expression, we examined the phosphorylation state of p38, JNK, PI3K, and ERK by Western blotting. As shown in Figure 5A, 25 ng/mL EGF activated the phosphorylation of p38, JNK, PI3K, and ERK, and PGG inhibited EGF-induced PI3K/JNK/p38 phosphorylation. We also use ERK inhibitor (PD98059), PI3K inhibitor (LY294002), JNK (SP600125), and p38 inhibitor (SB203580) to further

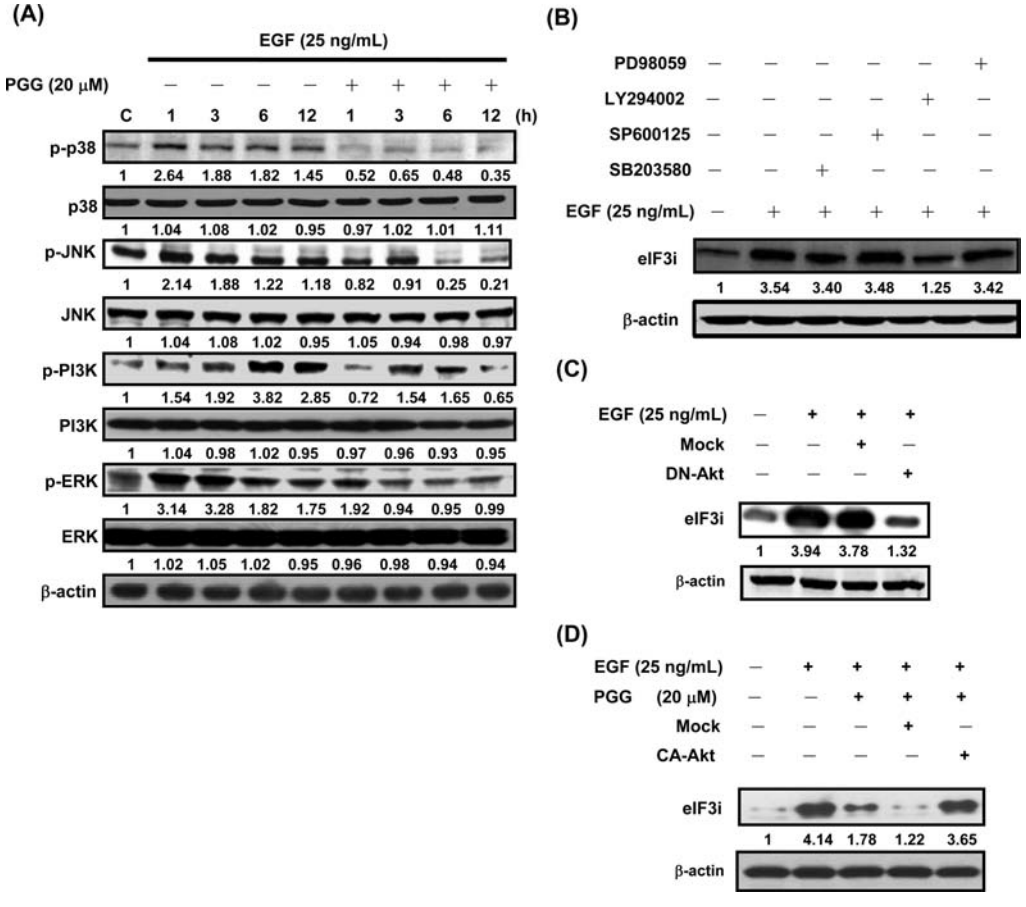

**Figure 5.** PGG inhibited EGF-induced eIF3i expression through inhibition of the PI3K signaling pathway. (A) PC-3 cells were preincubated in the presence or absence of 20 $\mu$M PGG for 1 h prior to EGF stimulation (25 ng/mL) for various times. The cells were then harvested and lysed for the detection of p-p38, p38, p-JNK, JNK, p-PI3K, PI3K, p-ERK, ERK, and $\beta$-actin. (B) PC-3 cells were pretreated with 20 $\mu$M PGG, PI3K inhibitor (40 $\mu$M LY294002), JNK inhibitor (20 $\mu$M SP600125), or p38 inhibitor (30 $\mu$M SB203580) for 1 h and then treated with EGF (25 ng/mL) for 24 h. (C) PC-3 cells were transfected with 50 nmol/L DN-Akt or mock. Twenty-four hours after transfection, cells were incubated with EGF (25 ng/mL) for 24 h. The cells were then harvested and lysed for the detection of eIF3i and $\beta$-actin. (D) PC-3 cells were transfected with 50 nmol/L CA-Akt or mock. Twenty-four hours after transfection, they were preincubated in the presence or absence of 20 $\mu$M PGG for 1 h prior to EGF stimulation (25 ng/mL) for 24 h. The cells were then harvested and lysed for the detection of eIF3i and $\beta$-actin. Western blot data presented are representative of those obtained in at least three separate experiments. Immunoblots were quantified, and relative expression to control is indicated.

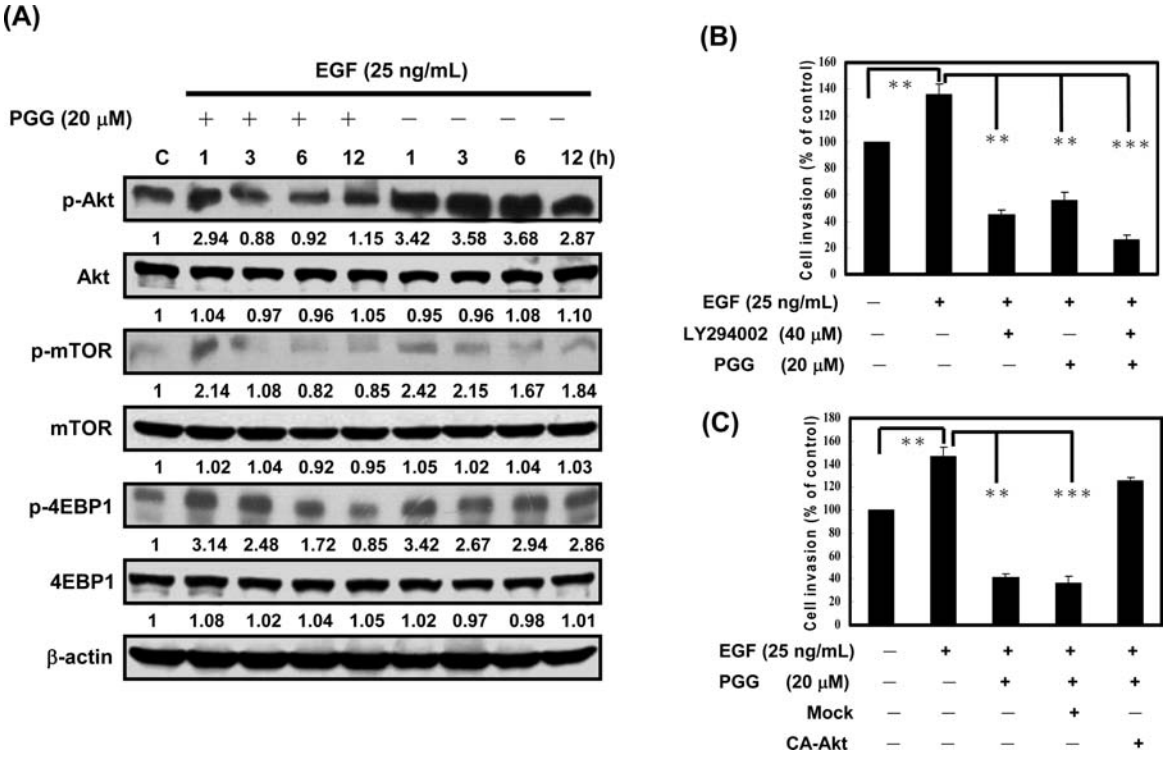

**Figure 6.** PGG reduced EGF-induced eIF3i expression through the PI3K/AKT/mTOR pathway. (A) PC-3 cells were preincubated in the presence or absence of 20 $\mu$M PGG for 1 h prior to EGF stimulation (25 ng/mL) for various times. The cells were then harvested and lysed for the detection of p-AKT, AKT, p-mTOR, mTOR, p-4EBP1, 4EBP1, eIF3i, and $\beta$-actin. Western blot data presented are representative of those obtained in at least three separate experiments. Immunoblots were quantified, and relative expression to control is indicated. (B) PC-3 cells were pretreated with 20 $\mu$M PGG or 40 $\mu$M LY294002 or a combination of 40 $\mu$M LY294002 and 20 $\mu$M PGG for 1 h and then treated with EGF for 24 h, and then cell invasion was determined. Data represent means ± SEM ($n$ = 3). An asterisk indicates that the values are significantly different (**, $P < 0.01$; ***, $P < 0.001$). (C) PC-3 cells were transfected with 50 nmol/L CA-Akt or mock. Twenty-four hours after transfection, cells were preincubated in the presence or absence of 20 $\mu$M PGG for 1 h prior to EGF stimulation (25 ng/mL) for 24 h, and then cell invasion was determined. Data represent means ± SEM ($n$ = 3). An asterisk indicates that the values are significantly different (**, $P < 0.01$; ***, $P < 0.001$).

investigate which signaling pathways are involved in EGF-induced eIF3i expression. Interestingly, only pretreatment with PI3K inhibitor (LY294002) could abolish EGF-induced eIF3i expression in PC-3 cells (Figure 5B). To further investigate which signaling pathways are involved in EGF-induced eIF3i expression, we performed an Akt inhibition experiment using dominant negative Akt (DN-Akt). The result showed that DN-Akt abolished EGF-induced eIF3i expression in PC-3 cells (Figure 5C). To test whether PI3K was involved in PGG-inhibited EGF-induced eIF3i expression, we performed an Akt-overexpression experiment using constitutively active Akt (CA-Akt). The result showed that CA-Akt abolished the ability of PGG-inhibited EGF-induced eIF3i expression (Figure 5D). The results suggested that the inhibition of PI3K signaling pathway was involved in PGG-suppressed EGF-induced eIF3i expression.

**PGG Suppressed EGF-Induced eIF3i Expression through Inhibition of the PI3K/AKT/mTOR Pathway.** The PI3K/AKT/mammalian target of rapamycin (mTOR) signaling pathway is a master regulator of protein translation and plays important roles in other biological processes, such as cancer cell invasion.[18] Our data showed that EGF-induced eIF3i expression was completely suppressed by PI3K inhibitor (Figure 5B) and PGG could decrease PI3K phosphorylation (Figure 5A). We further confirmed whether PGG inhibited EGF-induced eIF3i expression through inhibition of the PI3K/AKT/mTOR pathway. Our results demonstrated that PGG inhibited the EGF-induced phosphorylation of AKT, mTOR, and its downstream 4EBP1 (Figure 6A). To understand whether PGG inhibited EGF-induced prostate cancer cell invasion via the PI3K/Akt/mTOR pathway, a cell invasion assay was employed. Figure 6B shows that EGF-induced cell migration was significantly inhibited by pretreatment with 40 $\mu$M LY294002. In the cotreatment of LY294002 (40 $\mu$M) and PGG (20 $\mu$M), EGF-induced cell invasion was more potent than pretreatment with LY294002 or PGG alone. Moreover, our result showed that CA-Akt abolished the ability of PGG-inhibited EGF-induced cell invasion (Figure 6C). The data suggested that PGG suppressed EGF-induced eIF3i expression through the inhibition of protein translation.

## ■ DISCUSSION

EGF signaling stimulates prostate cancer cell bone metastasis directly by increasing cancer cell proliferation and indirectly by engaging bone stromal cell in metastasis-promoting activities. In this study we verified the differences of protein expression profile between EGF-induced prostate cancer cell bone metastasis treated with or without PGG using a 2-DE-based proteomic approach. Six proteins differentially expressed by EGF stimulation but reduced by PGG treatment were successfully identified. Among them, prenylcysteine oxidase was involved in the cellular metabolism of prenylcysteines,[19] heterogeneous nuclear ribonucleoprotein L[20] and exosome component 2[21] were RNA-binding proteins, and eIF3i was involved in the translation process.[6] Interestingly, we found that EGF-induced

dx.doi.org/10.1021/jf502447e | J. Agric. Food Chem. 2014, 62, 8990−8996

eIF3i expression and was reduced by PGG treatment in androgen-independent prostate cancer cell lines (PC-3).

Recent studies suggest that aberrant mRNA and protein levels of several eIF3 subunits have been detected in several different cancers. Most eIF3 subunits (a, b, c, h, and i) are oncogenic. Deregulation of these oncogenic eIF3 subunits will cause abnormal gene expression, leading to altered cell growth and possibly cancer. For example, eIF3a was overexpressed in human cancers of the lung,[22] stomach,[23] breast,[24] and cervix.[25] eIF3b expression was related to human prostate and bladder cancer prognosis and was required for tumor growth.[26] The down-regulation of eIF3c decreased the global protein synthesis and mediated G0/G1 or G2/M arrest in a tissue-dependent manner, which led to a reduction in cell proliferation and eventually to cancer cell death.[27] In colorectal cancer, an elevated level of the *eIF3h* gene was found.[28]

eIF3i was overexpressed in human colon cancer, head and neck cancer, breast cancer, hepatocellular carcinoma, neuroblastoma, and melanoma, suggesting that eIF3i overexpression might be an oncogenic factor.[6,8,29] Clearly, deregulation of eIF3i can contribute to tumorigenesis, but its oncogenic mechanisms remain unknown. To our best knowledge, our studies are the first to report that eIF3i participates in EGF-induced prostate cancer cell bone metastasis. To support this conclusion, we transiently transfected PC-3 cells with eIF3i shRNA, and our results showed that down-regulation of EGF-induced eIF3i expression resulted in a significant reduction of PC-3 cells' invasive ability (Figure 3B). Further studies using in vivo animal models are needed to demonstrate the participation of eIF3i in EGF-induced prostate cancer bone metastasis.

PGG has been shown to exhibit antiprostate cancer effects. Our previous study showed that PGG suppressed in vivo invasion and xenograft growth in nude mice with intratibially injected PC-3 human prostate cancer cells.[15] Recently, Hu et al. have shown that PGG could serve as a multitargeting agent for the chemoprevention and therapy of prostate cancer.[30] Lee et al. reported the inhibitory effect of PGG on the androgen receptor (AR) signaling pathway in human prostate cancer LNCaP cells.[31] Moreover, treatment with subapoptotic doses of PGG induced S phase arrest, whereas apoptotic doses of PGG induced not only S phase arrest but also G1 phase arrest in prostate cancer cells.[32] Overall, these data supported the potential role of PGG as a novel therapeutic or chemopreventive agent for prostate cancer. However, these effects need to be validated in vivo.

In the present study, we first evaluated the effects of PGG on EGF-induced eIF3i expression in PC-3 cells. Our study showed that EGF-induced eIF3i expression could be effectively blocked by PGG. Pretreatment with PGG blocked EGF-induced eIF3i expression. How PGG affects these changes remains to be determined. To further delineate the molecular mechanism of PGG in inhibiting EGF-induced eIF3i expression, related pathways were investigated. In the study, both MAPK and PI3K/AKT signaling pathways were investigated in PGG-treated PC-3 cells. Our experiments showed that PGG significantly decreased the PI3K/AKT pathway in PC-3 cells. Park et al. revealed that PGG inhibits hypoxia-induced transcriptional activation, mRNA expression, and protein accumulation of HIF-1$\alpha$ and its downstream signaling to VEGF and PI3K/AKT/mTOR pathway in LNCaP prostate cancer cells.[33] On the basis of these findings, PGG may be an ideal inhibitor for the PI3K/AKT signaling pathway.

extract, 20 g of sucrose, 1 g of peptone, and 20 g of agar in 1 L of distilled water). The plates were incubated aerobically in a chamber for 72 h at 28 ± 0.5 °C, and colonies were transferred and purified on new MEA mediums to obtain pure cultures.

The fungal strain was differentiated by the morphological characteristics according to the manual description by Cappuccino and Sherman. Genomic DNA was extracted, and the internal transcribed spacer (ITS) region sequence was amplified using the universal primers ITS1 and ITS4. Then, the sequence was submitted to GenBank (accession number KJ490634) and analyzed by BLAST search with reference sequences. Phylogenetic analysis was performed by neighbor joining in MEGA 5.0 with 1000 bootstrap replicates. The strain was deposited at China Center for Type Culture Collection (CCTCC) as M2013257.

**Fermentation.** The strain was cultured on MEA medium at 28 ± 0.5 °C for 3 days until the colony emerged. Then, pieces of fresh mycelium were inoculated into 250 mL Erlenmeyer flasks each containing 100 mL of malt-extract (ME) liquid medium, after 2 days of incubation at 28 ± 0.5 °C on rotary shakers at 150 rpm. A 20 mL suspension of the strain was transferred as seed into 1 L Erlenmeyer flasks each containing 500 mL of ME liquid medium. The flask cultures were incubated at 28 ± 0.5 °C for 7 days.

**Phytogrowth Inhibitory Bioassay of Ethyl Acetate Extracts.** The phytotoxic effects of the ethyl acetate extracts of ZS07 were evaluated on radicle growth of *A. retroflexus* L., and selected crops (*Brassica campestris* L., *Glycine max*, *Lycopersicon esculentum* Mill., and *Capsicum annuum*) were easily affected by *A. retroflexus* L. on the base of a Petri dish bioassay.[14] Briefly, seeds were first pretreated with sodium hypochlorite (1%) and washed with sterile distilled water before germination. Then, 25 pregerminated seeds were placed in 9 cm diameter Petri dishes on filter paper disks imbibed with 5.0 mL sample solution (100 μg/mL). To avoid the toxic effect of solvents, filter papers were placed in a cabinet to evaporate the solvent. Subsequently, 5.0 mL of distilled water was added to each Petri dish. 2,4-Dichlorophenoxyacetic acid (2,4-D) was used as the positive control, and three replicates were prepared for each sample. Dishes were then kept in a growth chamber at 25 °C under continuous light. After 2 days, the root length were measured and compared to the proper untreated control. The inhibition percent[15] was calculated using the formula below

$$\text{inhibition}\ (\%) = (L_{\text{control}} - L_{\text{treatment}})/L_{\text{control}} \times 100$$

where $L_{\text{control}}$ is the radicle length of seedlings in the control and $L_{\text{treatment}}$ is the radicle length of seedlings treated.

**Isolation and Characterization of Secondary Metabolites.** A total of 40 L of fermentation broth was filtered and extracted 3 times with an equal volume of EtOAc at room temperature. The solvent was then removed *in vacuo* to give a crude extract (3.0 g). The extract was subjected to a silica gel column eluting with a stepwise gradient of $CH_2Cl_2$/MeOH (100:0−100:4, v/v) to afford four fractions (Fr-1−Fr-4). Fr-1 was further chromatographed over silica gel ($CH_2Cl_2$/MeOH, 100:0−100:2) to give five subfractions (R1−R5). Compound **2** (30 mg) was crystallized from the MeOH solution of subfraction R2. The remaining fractions of R4 and R5 were combined and purified by Sephadex LH-20 using a $CH_2Cl_2$/MeOH mixture (1:1) as the eluent to give compound **6** (3 mg). Fr-2 ($CH_2Cl_2$/MeOH, 100:1) was repeatedly purified on Sephadex LH-20 (MeOH) and detected by thin-layer chromatography (TLC) to yield compound **4** (6 mg). Fr-3 ($CH_2Cl_2$/MeOH, 100:2) was also loaded onto a Sephadex LH-20 column (MeOH) to give compounds **3** (35 mg), **5** (5 mg), and **1** (50 mg).

Structural identifications of the secondary metabolites were made by the spectroscopic analysis. $^1$H nuclear magnetic resonance (NMR), $^{13}$C NMR, and distortionless enhancement by polarization transfer (DEPT) spectra were measured with a Bruker AVANCE-400 (Bruker, Switzerland) spectrometer at 400 MHz, and chemical shifts were reported as parts per million ($\delta$) by referring to the solvent signals and tetramethylsilane (TMS) as internal standards. $^1$H and $^{13}$C NMR assignments were supported by the $^1$H−$^1$H correlation spectroscopy (COSY), heteronuclear multiple-quantum coherence (HMQC), and heteronuclear multiple-bond correlation (HMBC) experiments. The electrospray ionization mass spectrometry (ESI−MS) spectra were acquired on a Mariner Mass 5304 instrument.

**Phytogrowth Inhibitory Bioassay of Metabolites.** The phytotoxic effects of compounds **1**−**4** were evaluated on radicle growth of *A. retroflexus* L., as described above. Concentrations of compounds **1**−**4** at 1, 10, and 100 μg/mL were prepared with acetone. Then, 5.0 mL of varying concentration solution was applied to each Petri dish. After the solvent was evaporated, 5.0 mL of distilled water was added to the Petri dish before the sowing of pregerminated 25 seeds of *A. retroflexus* L. Root length were measured, and 2,4-D was used as the positive control.

**Detection of Antibacterial Activity.** The disc diffusion method was employed for the determination of antibacterial activity of the bioactive metabolites. Bacterial strains *Escherichia coli* (ATCC 8739), *Bacillus subtilis* (ATCC 6633), *Staphylococcus aureus* (ATCC 6538), and *Salmonella typhimurium* [CMCC(B) 50115] were cultured overnight at 37 °C in Mueller Hinton broth (MHB), and then a 0.2 mL suspension of the tested microorganisms ($1.0 \times 10^8$ cfu/mL) were spread on the solid media plates. Filter paper disks containing 5 μL of each metabolite solution (6 mg/mL) were applied to the surface of agar plates. The plates were incubated at 37 °C for 18 h. The diameters of the inhibition zones were measured, and average diameter values were calculated for each compound. All tests were performed in triplicate. The minimum inhibitory concentrations (MICs) of purified compounds against bacteria were determined using the microbroth dilution method[16] in disposable 96-well microtiter dishes. A stock solution of each sample was prepared at a concentration of 200 μg/mL in MHB [supplemented with 1% dimethyl sulfoxide (DMSO) and 4% Tween 80, v/v], which was further 2-fold diluted and micropipetted separately into individual microplate wells (100 μL/well) with a series of concentrations ranging from 100 to 0.78 μg/mL. Then, a standard amount of the tested microbes ($1.0 \times 10^6$ cfu/mL) were added per well and incubated 24 h at 37 °C for *E. coli*, *S. aureus*, *B. subtilis*, and *S. typhimurium*. The antibacterial activity was evaluated by comparing to a control well containing culture broth and microorganisms without the compound. The MIC was defined as the minimum concentration of compounds at which the bacterial growth was inhibited, as indicated by the absence of turbidity. Each test was performed in duplicate, and gentamicin served as the reference compound.

## RESULTS AND DISCUSSION

**Identification of the Fungus.** Morphological characteristics of the fungus were observed in potato dextrose agar (PDA) medium. The colonies were slow growing at first, becoming floccose with age and purple in color. Reddish purple appeared in the reverse of the colony when aerial mycelium reached the edge of the medium. Sporulation started early in aerial mycelium. Microconidia were produced in false head and variable in shape. Conidiophores originated erect from the substrate, sympodially branched and bearing nearly cylindrical monophialides. The isolated fungus would be located in the Liseola section and showed high similarity in morphology with *Fusarium*. Phylogenetic taxonomy with sequence alignment of ITS rDNA of the fungus was performed with MEGA 5.0 software. The phylogenetic tree (Figure 1) indicated that the title fungus was closely related to *Fusarium proliferatum* (FJ648201), with the ITS sequence similarity of 99.5%. In combination with the morphological characteristics, the fungus was identified as *F. proliferatum*.

**Phytotoxic Activity of the Ethyl Acetate Extracts.** A Petri dish bioassay was used to evaluate the phytotoxic activities of ethyl acetate extract from *F. proliferatum* against the radicle growth of *A. retroflexus* L. and selected crops. The results (Figure 2) indicated that the crude extract showed selectivity greater than 2 times for weed over the tested crop. Under the concentration of 100 μg/mL, the crude extract produced

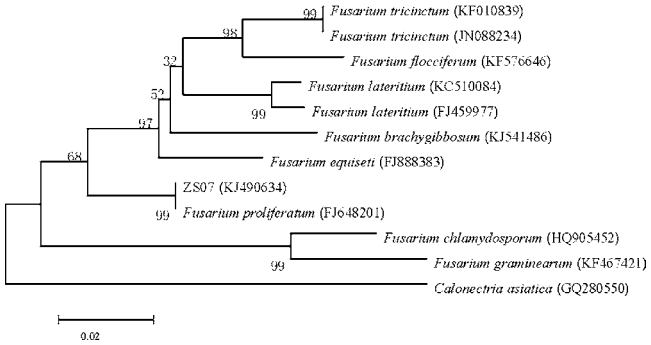

**Figure 1.** Phylogenetic tree of the fungus ZS07 based on the 5.8S rDNA sequences.

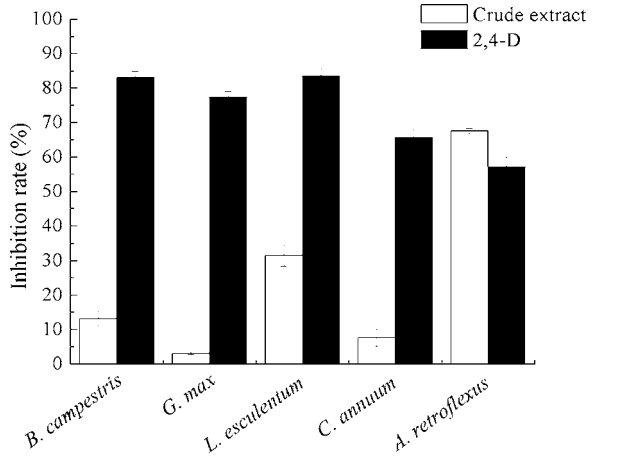

**Figure 2.** Phytotoxic effects of the crude extract of ZS07 on the radicle growth of *A. retroflexus* L. and tested crops (100 $\mu$g/mL).

significant inhibition against the radicle growth of *A. retroflexus* L. with the inhibition rate of 67.6%, while it produced weak inhibition against the radicle growth of *B. campestris* L., *G. max*, *L. esculentum* Mill., and *C. annuum* with the inhibition rate of less than 35%. Our research provided evidence that the extract of *F. proliferatum* showed good selective phytotoxic activities for *A. retroflexus* L.

**Identification of Active Compounds.** Bioassay-guided fractionation of the constituents in the ethyl acetate extract of *F. proliferatum* ZS07 yielded a novel derivate **2** and five known active metabolites (Figure 3).

Compound **2** was obtained as an orange powder, and its molecular formula $C_{19}H_{16}O_7$ was deduced from high-resolution

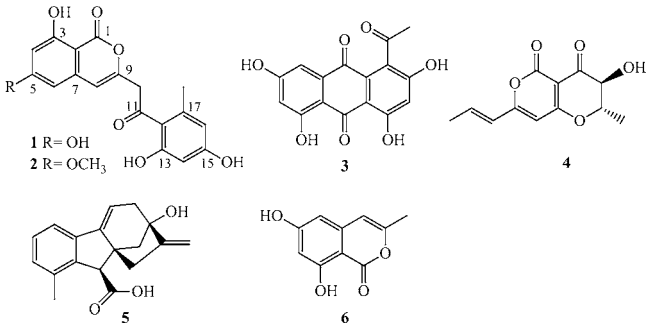

**Figure 3.** Chemical structures of secondary metabolites **1**–**6** of *F. proliferatum* ZS07.

(HR)-ESI–MS ($m/z$ 379.0789 $[M + Na]^+$, calcd for $C_{19}H_{16}O_7Na$, 379.0794), which was consistent with the $^1H$ and $^{13}C$ NMR data. The $^1H$ NMR (Table 1) of compound **2**

**Table 1. $^1H$ and $^{13}C$ NMR Data of Compound 2 in DMSO-$d_6$**

| position | $\delta_H$, mult. ($J$ in Hz) | $\delta_C$ |
|---|---|---|
| 1 | | 165.7 |
| 2 | | 99.6 |
| 3 | | 163.0 |
| 4 | 6.55, d (2.3) | 101.1 |
| 5 | | 167.0 |
| 6 | 6.63, s | 101.9 |
| 7 | | 139.7 |
| 8 | 6.62, d (2.3) | 107.2 |
| 9 | | 152.9 |
| 10 | 4.14, s | 48.4 |
| 11 | | 199.7 |
| 12 | | 119.2 |
| 13 | | 158.5 |
| 14 | 6.23, d (2.3) | 100.7 |
| 15 | | 160.5 |
| 16 | 6.13, d (2.3) | 110.0 |
| 17 | | 139.7 |
| 18 | 2.14, s | 20.8 |
| 3-OH | 10.96, s | |

| 13-OH | 10.26, s | |
| 15-OH | 9.79, s | |

indicated the presence of the 1,3-disubstituted benzene ring ($\delta_H$ 6.13, $J$ = 2.3 Hz; $\delta_H$ 6.23, $J$ = 2.3 Hz), one methoxyl ($\delta_H$ 3.87), one methyl ($\delta_H$ 2.14), and one methylene ($\delta_H$ 4.14). Three proton signals at $\delta_H$ 10.96, 10.26, and 9.79 were assigned to hydroxy groups because no HMQC correlation was observed. The $^1H$ and $^{13}C$ NMR data were similar to those of SMA93 (**1**),[17] except the substituent at position 5 in compound **2** appeared to be $OCH_3$, which was corresponding to the increase in molecular weight of compound **2** by 14 amu compared to compound **1**. This was further confirmed by the HMBC correlation of MeO-5 to C-5 ($\delta_C$ 167.0). Further confirmation was achieved by the HMBC correlation of H-4 to C-2 ($\delta_C$ 99.6), C-3 ($\delta_C$ 163.0), C-5, and C-6 ($\delta_C$ 101.9); H-6 to C-2, C-5, C-7 ($\delta_C$ 139.7), and C-8 ($\delta_C$ 107.2); H-10 to C-8, C-9 ($\delta_C$ 152.9), and C-11 ($\delta_C$ 199.7); H-14 to C-12 ($\delta_C$ 119.2), C-13 ($\delta_C$ 158.5), C-15 ($\delta_C$ 160.5), and C-16 ($\delta_C$ 110.0); H-16 to C-12, C-14 ($\delta_C$ 100.7), and C-17 ($\delta_C$ 139.7); and H-18 to C-16 and C-17. Thus, the structure of compound **2** was determined as an O-methylated derivative of compound **1**.

The other secondary metabolites were identified as rhodolamprometrin (**3**),[18,19] radicinin (**4**),[3] dehydroallogibberic acid (**5**),[20,21] and 3-methyl-6,8-dihydroxyisocoumarin (**6**),[22] by spectroscopic data analyses and comparison of their or derivative data in the literature.

The genus of *Fusarium* species was well-known to produce a variety of secondary metabolites. Previous investigations led to the isolation of several compounds, such as toxic fumonisins,[23,24] mycotoxins,[25] antibiotic and insecticidal beauvericin,[26] histone deacetylase (HDAC) inhibitor apicidin,[27] and other compounds related to the precursors.[19] However, to the best of our knowledge, it was the first report that the new polyketide **2** and the following metabolites **1** and **3**–**5** were isolated from the

title strain *F. proliferatum* ZS07, a fungus residing in the gut of long-horned grasshoppers.

**Phytotoxic Activity of the Bioactive Metabolites.** Compounds **1**−**4** were assayed for their ability to inhibit radicle growth of *A. retroflexus* L. using a Petri dish bioassay. The result (Figure 4) showed that compound **2** was very active

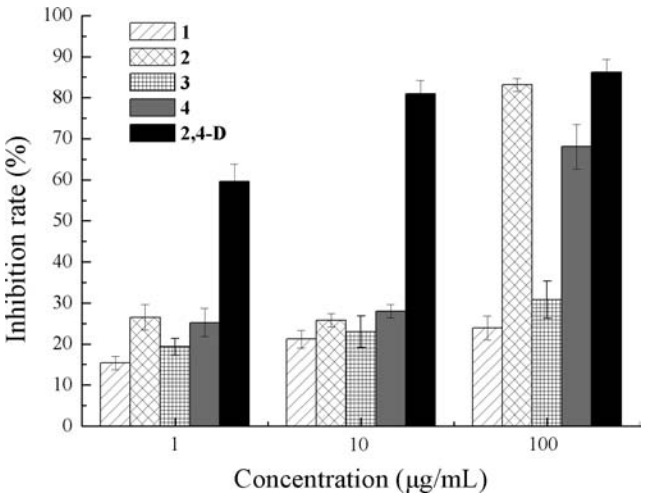

**Figure 4.** Phytotoxic effects of compounds **1**−**4** on radicle growth of *A. retroflexus* L.

to reduce radicle growth of *A. retroflexus* L. under the concentration of 100 μg/mL. With a little morphological alterations of the radicle, the relative inhibition rate of compound **2** was 83.0%, which was comparable to that of positive 2,4-D with the inhibition rate of 86.4%. Compound **4** showed moderate phytotoxic activity with the inhibition rate of 65.2% at the concentration of 100 μg/mL. However, compounds **2** and **4** showed weak inhibitory effect in a low concentration. No obvious inhibitory effects were displayed by the compounds **1** and **3** in this bioassay.

**Antibacterial Activity of the Bioactive Metabolites.** The disc diameters of zone of inhibition (ZOI) and MIC values of compounds **1**−**5** against different bacteria were presented in Table 2. The results showed that compound **3** had the greatest antibacterial effect against *B. subtilis* with ZOI of 24.8 mm and MIC value of 3.13 μg/mL, which were comparable to those of referenced gentamicin with the ZOI and MIC value of 25.6 mm and 3.13 μg/mL, respectively. Similar to the inhibition zone result of 19.5 mm, compound **1** possessed moderate antibacterial effect against *B. subtilis* with MIC value of 6.20 μg/mL, followed by the new derivate **2** with MIC value of 12.50 μg/mL. The replacement of the phenolic hydroxyl group by one methoxy group in the phenolic nucleus of compound **1** resulted in the weaker antibacterial activity for *B. subtilis*, which was in agreement with the earlier postulate.[28] Compounds **4** and **5** inhibited the growth of *B. subtilis* in disc diffusion tests, but the MIC values of them were not detected in the concentrations of 100 μg/mL. Similarly, compounds **1**−**3** possessed weak antibacterial activities against *S. aureus* in disc diffusion tests, but no inhibition was found in the MIC test. The remaining microorganisms *E. coli* and *S. typhimurium* were not susceptible to all compounds.

**Table 2. ZOI (mm) and MIC (μg/mL) of Compounds 1−5 against the Tested Bacteria**

| | *B. subtilis* | | *S. aureus* | |
|---|---|---|---|---|
| compound | ZOI[a] | MIC | ZOI | MIC |
| **1** | 19.5 ± 0 | 6.20 | 11.7 ± 0.5 | >100 |
| **2** | 13.8 ± 0.6 | 12.50 | 8.4 ± 0.4 | >100 |
| **3** | 24.8 ± 0.6 | 3.13 | 8.0 ± 0 | >100 |
| **4** | 6.6 ± 0 | >100 | NI[b] | >100 |
| **5** | 9.2 ± 0.6 | >100 | NI | >100 |
| GEN[c] | 25.6 ± 0.5 | 3.13 | 30.0 ± 0 | 3.13 |

[a]ZOI = zone of inhibition; results were presented as the mean ± standard deviation for triplicate experiments. [b]NI = not inhibited. [c]GEN = gentamicin, 30 μg/disc.

In summary, we identified one new polyketide together with five known compounds from a fungus *F. proliferatum* ZS07. The new polyketone **2** and the known compound **4** attenuated the radicle growth of *A. retroflexus* L., and for the first time, we found that compounds **1** and **3** possessed potent or moderate antibacterial activity against *B. subtilis in vitro*. These results suggested that the compounds **1**−**4** have some potential as agents for weeds and pathogenic bacteria control. Further studies will be carried out to better understand the mechanism of action associated with phytotoxic and antibacterial effects. In addition, the discovery of our study provided additional evidence that uninvestigated habitats, just like the title strain, may inspire the discovery of chemical agents with interesting biological activity.

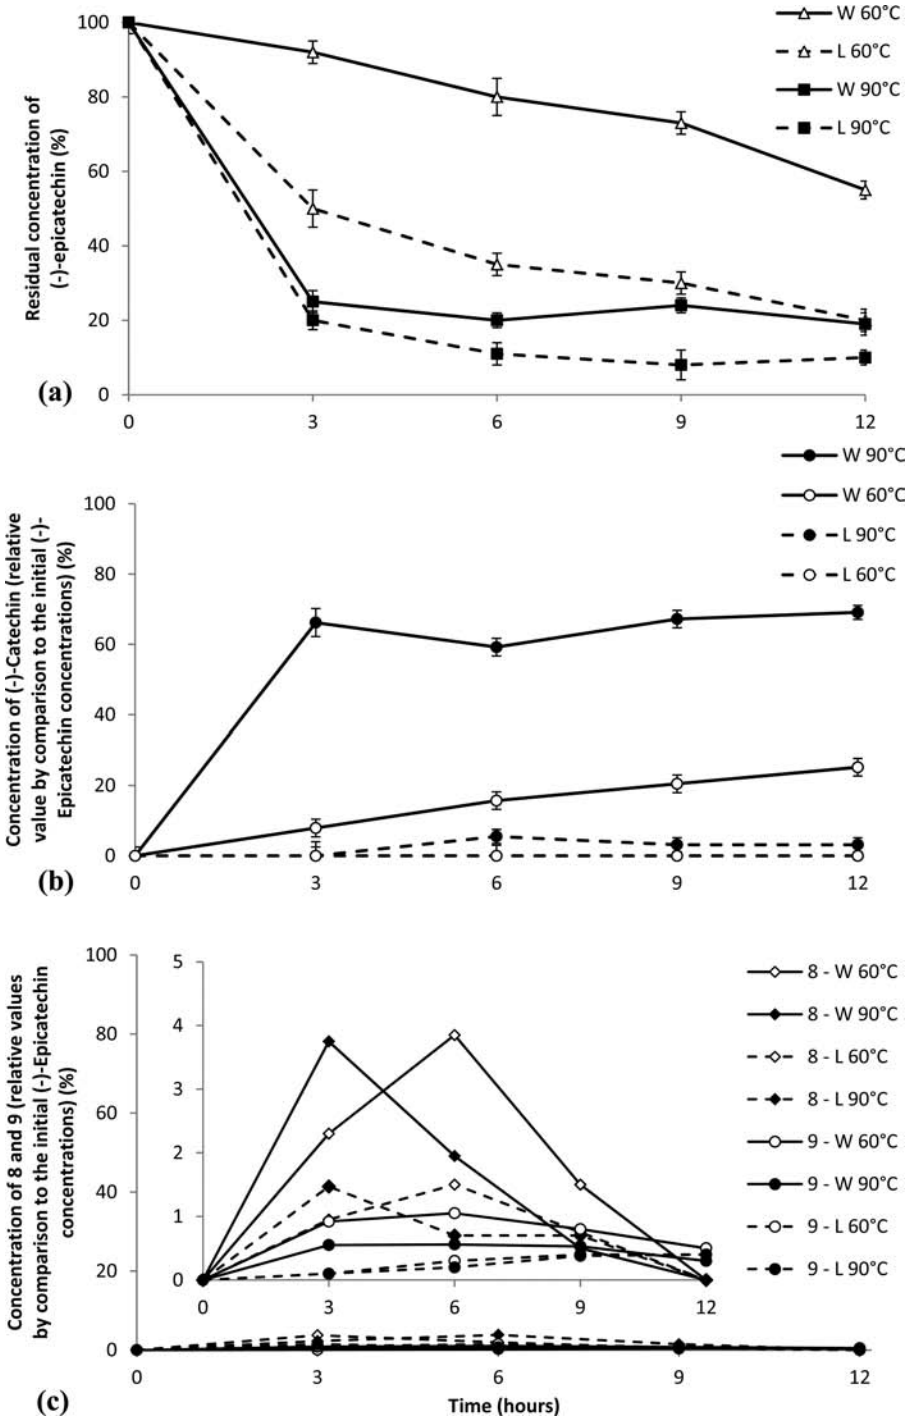

**Figure 2.** Evolution of the (−)-epicatechin model medium at 60 and 90 °C: (a) degradation of (−)-epicatechin; (b) synthesis of (−)-catechin; (c) synthesis of compounds **8** and **9**. Quantitation is in epicatechin equivalents by ESI(−)-MS/MS. Standard deviation was <5%.

supplied by VWR (Leuven, Belgium). Formic acid (99%) was obtained from Acros Organic (Geel, Belgium). (−)-Epicatechin (98%), (+)-catechin (98%), caffeine, and theobromine (>99%) were supplied by Sigma-Aldrich (Bornem, Belgium). (−)-Epicatechin-4$\beta$-8-(−)-epicatechin (B2, 90%), (−)-epicatechin-2*O*-7,4$\beta$-8-(−)-epicatechin (A2, 99%), and kaempferol (>90%) were obtained from Extrasynthese (Genay, France). (−)-Epicatechin-4$\beta$-8-(−)-epicatechin-4$\beta$-8-(−)-epicatechin (C1, 99%) and (−)-epicatechin-4$\beta$-8-(+)-catechin (B1, 99%) were supplied by PhytoLab GmbH & Co. KG (Vestenbergsgreuth, Germany). Aqueous solutions were made with Milli-Q (Millipore, Bedford, MA, USA) water (resistance = 18 m$\Omega$). Cocoa butter, sugar, and lecithin were obtained from Belcolade (Puratos Group, Erembodegem, Belgium).

**Cocoa and Chocolate Samples.** Ecuadorian National cocoa beans (before and after roasting for 30 min at 150 °C) and derived chocolate (72% cacao, conching step of 12 h at 75 °C) were provided by the chocolate factory Pierre Marcolini (Brussels, Belgium).

**Preparation of Model Media.** Aqueous model media were obtained by diluting (−)-epicatechin or B2 at a concentration of 1000 mg/L in ultrapure water (stock solution of 10000 mg/L prepared in methanol). Lipidic model media contained sugar (59.7% w/w), cocoa butter (39.8% w/w), and lecithin (0.5% w/w, addition after 6 h) and (−)-epicatechin or B2 (1000 mg/L). All media were treated in duplicates at 60 or 90 °C, and samples were taken at 0, 3, 6, 9, and 12 h.

**Extraction of Flavan-3-ols from Lipidic Model Systems.** This method has been adapted from the one developed in our laboratory for

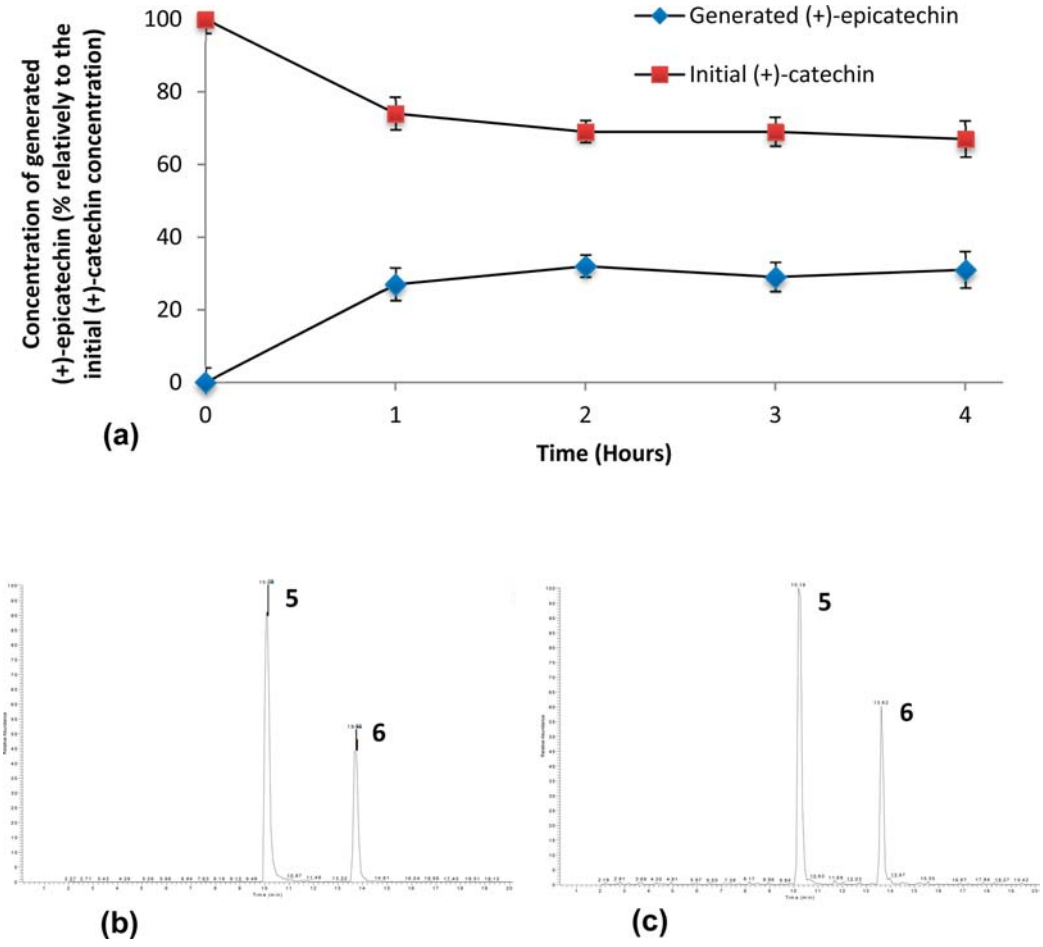

**Figure 3.** (a) Evolution of the (+)-catechin model medium at 90 °C. (b, c) RP-HPLC-MS chromatograms obtained after 12 h at 90 °C, from the (+)-catechin or (−)-epicatechin aqueous model media, respectively.

the analysis of flavan-3-ols in chocolate.[14] All extraction steps have been done in duplicate.

*Lipid Removal.* Lipidic model systems (500 mg) were introduced into a centrifugal vial. By successive 10 min extractions, lipids were removed with 3 × 1.5 mL diethyl ether at room temperature under gentle stirring. At the end of each step, the sample was centrifuged for 10 min at 2500*g*, and the supernatant was eliminated. After the last step, the powder was dried under vacuum to get rid of residual solvent.

*Flavan-3-ol Extraction.* Defatted samples were extracted three times with 3 mL of acetone/water/acetic acid (70:28:2, v/v/v), each time for 1 h under shaking at room temperature. After each extraction, the suspension was centrifuged for 10 min at 2500*g*, and the supernatant was collected. The combined supernatants were concentrated by rotary evaporation to obtain ∼3 mL of extract, and residual particles were removed by filtration.

*Solid-Phase Extraction Purification Step.* To purify the flavan-3-ol extract, a 360 mg C18 Sep-Pak cartridge (Waters, Millipore) was preconditioned with 10 mL of methanol and 20 mL of water. The extract was loaded on the cartridge, and sugars were removed with 5 mL of water. Flavan-3-ols were finally eluted with 5 mL of acetone/water/acetic acid (70:28:2, v/v/v). The eluates were concentrated by rotary evaporation (<40 °C) and freeze-dried. The extract was dissolved in methanol and stored under nitrogen at −80 °C in the dark until used.

**Extraction of Flavan-3-ols from Cocoa and Chocolate.** The method was close to the one used here above for model systems. Seven grams of cocoa beans or chocolate was defatted by diethyl ether (3 × 50 mL) at room temperature under gentle stirring. After centrifugation, samples were dried under vacuum. Defatted samples spiked with 500 μL of kaempferol at 10000 mg/L in methanol (used as internal standard; 714 mg/kg if calculated in beans) were extracted with 3 × 50 mL of acetone/water/acetic acid (70:28:2, v/v/v) and purified on a 10 g C18 Sep-Pak cartridge (Waters, Millipore) preconditioned with 200 mL of methanol and 300 mL of water. The samples were finally eluted with 50 mL of acetone/water/acetic acid (70:28:2, v/v/v), concentrated by rotary evaporation/ and freeze-dried.

**RP-HPLC-DAD-ESI(−)-MS/MS Quantitation of Flavan-3-ols.** Quantitations were performed on a C18 Kinetex column (150 × 2.1 mm, 2.6 μm) (Phenomenex, Torrance, CA, USA) using a linear gradient from A (water containing 1% acetonitrile and 2% formic acid) to B (acetonitrile containing 2% formic acid). Gradient elution was as follows: from 97% A to 91% in 5 min, from 91 to 85% in 25 min, from 85 to 64% in 35 min, from 64 to 10% in 10 min, and isocratic for 20 min at a flow rate of 200 μL/min. Five microliters of the sample was injected in duplicates onto the column kept at 20 °C. A SpectraSystem equipped with an AS3000 autosampler and a P4000 quaternary pump was used. The system was controlled with Xcalibur software version 1.2 (Thermo Fisher Scientific, Austin, TX, USA). Flavan-3-ols were monitored from 200 to 800 nm with a UV6000LP diode array detector. Mass spectra were acquired using an LCQ ion trap mass spectrometer equipped with an ESI source (ThermoFisher). Collision-induced dissociation spectra were recorded at a relative collision energy of 30, 35, and 40%, respectively, for singly charged $[M - H]^{-1}$ ions of monomers ($m/z$ 289), dimers ($m/z$ 577, 575, and 573), and trimers ($m/z$ 865). The ESI inlet conditions were as follows: source voltage, 4.9 kV; capillary voltage, −4 V; capillary temperature, 200 °C; and sheath gas, 39 psi. For ESI(−)-MS/MS semiquantitation in cocoa beans and chocolate (kaempferol used as internal standard), a relative recovery factor = 1 was applied for all compounds. Flavan-3-ol monomers were quantitated according to the calibration curve of (−)-epicatechin (0, 10, 25, 50, 100 mg/L, $R^2$ = 0.99648), procyanidins B2 and B5 with the one of B2

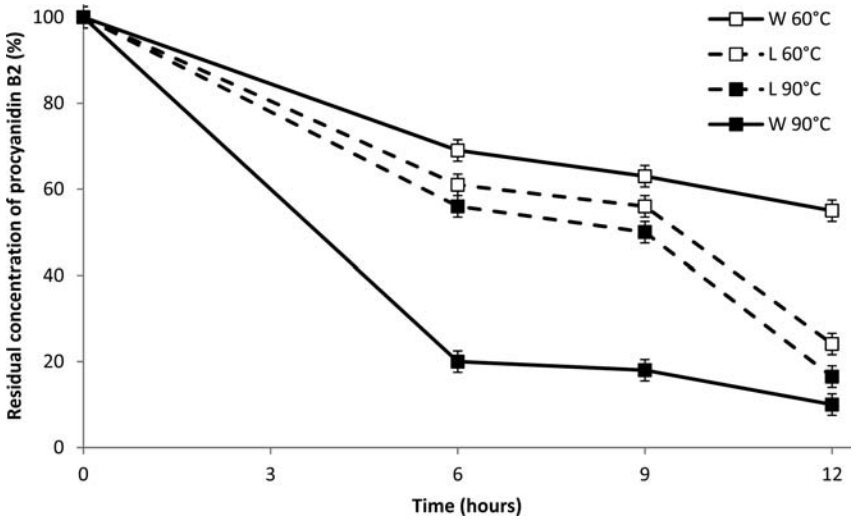

**Figure 5.** Evolution at 60 and 90 °C of the procyanidin B2 model medium. Quantitation was in B2 equivalents by ESI(−)-MS/MS. Standard deviation was <5%.

(0, 10, 25, 50, 100 mg/L, $R^2$ = 0.99831), and C1 with itself (0, 10, 25, 50, 100 mg/L, $R^2$ = 0.99873). No extraction was applied on aqueous model systems. For the lipidic model systems, a theoretical recovery factor of 100% was also used (relative values by comparison to the initial concentrations).

**HRMS/MS Identification.** High-resolution MS/MS spectra were obtained by connecting the same colomn with the same elution program to an Exactive system composed of Accela LC coupled to the Orbitrap mass spectrometer and controlled with Xcalibur software version 2.0.7 (Thermo Fisher Scientific). The ESI inlet conditions were as follows: sheet gas flow rate, 70; auxiliary gas flow rate, 5; sweep gas flow rate, 0; spray voltage, 3.50 kV; capillary temperature, 320 °C; S-lens level, 80%; heater temperature, 50 °C.

## RESULTS AND DISCUSSION

The stability of (−)-epicatechin and procyanidin B2 was monitored by investigating model media after 0, 3, 6, 9, and 12 h at 60 and 90 °C. After a first series of experiments conducted in water (W; extraction steps here not required before HPLC separation), lipidic media (L) were also investigated. As for typical Belgian consumer chocolates,[47] the lipidic medium was composed of 59.7% (w/w) saccharose and 39.8% (w/w) cocoa butter spiked at midtime with lecithin (0.5%). Lecithin is often added in the last part of the conching process chocolate (heat treatment of 6−18 h at 60−90 °C) to improve rheological properties (0.1% of lecithin provides a similar effect as 1% cocoa butter).

**Monitoring (−)-Epicatechin Degradation in Aqueous Medium.** As depicted in Figure 1a, eight new peaks were detected in the aqueous (−)-epicatechin medium heated for 12 h at 60 °C (six at 280 nm and two at 410 nm). Most of them were already apparent after 3 h, especially when the temperature was increased to 90 °C (73% loss of (−)-epicatechin after 3 h at 90 °C versus only 11% loss at 60 °C; solid lines in Figure 2a).

The epimerization of (−)-epicatechin (peak 6) to (−)-catechin (peak 5, Figure 1a,b) accounted for 25% of the degradation of the monomer at 60 °C and even reached 70% at 90 °C (Figure 2b). Of course, catechin can also epimerize to epicatechin, but as depicted in Figure 3, because of lesser steric hindrance, catechin epimerization is less favored ((+)-catechin used in this experiment). Thus, whatever the initial epimer used, an equilibrium between epicatechin and catechin is reached before 3 h at 90 °C, with the same final ratio close to 70:30 in favor of catechin (Figure 3). At 60 °C, on the other hand, (−)-epicatechin remained the major monomer in epicatechin-spiked medium after 12 h (Figure 1a).

Although not found in the 280 nm UV chromatogram (peaks 8 and 9 in Figure 1a), two yellow-orange compounds clearly appeared at 410 nm during (−)-epicatechin degradation, explaining the observed color of the medium (Figure 2c). Dehydrodi(epi)catechins A, previously described in a model medium[21] and in 5-day-stored beer[5] as arising through (+)-catechin degradation, eluted at the corresponding retention times (structures detailed in Table 1).

Three "chemically derived" dimers similar to the dehydrodi-(epi)catechin B4 described by Guyot et al.[21] and Sun and Miller[38] in model apple media were evidenced at 280 nm (peaks 2, 3, and 4, Figure 1a). They are here referred to as "chemical dimers" because contrary to native flavan-3-ols, the interflavan linkage is always created between aromatic rings. The formulas of these chemical dimers were confirmed by high-resolution mass spectrometry ($C_{30}H_{26}O_{12}$ experimental $m/z$ = 577.13687; theoretical $m/z$ 577.13460; $\delta$ 3.93). In all three ESI(−)-HRMS/MS spectra (Figure 1c), the characteristic $m/z$ peak = 393.09914 ($C_{21}H_{12}O_{16}$, not found for the natural procyanidin B2, Figure 4b) was evidenced, allowing further differentiation between "natural" (C4−C8 or C4−C6 linkages) and "chemical" (C2′−C8 or C6′−C8) dimers in complex media. Due to different possible structures that cannot be distinguished by HRMS/MS, the bold lines drawn in Table 1 and Figure 1 do not specify the precise position of the chemical bonds. Also worth stressing is the presence of compound **7**, which elutes much later than compounds **2**, **3**, and **4**, but with exactly the same mass spectrum (Figure 1c). We suspect it could be another chemical dimer, dehydrodi(epi)catechin B (Table 1), previously described by Guyot et al.[21] and Poupard[42] (same theoretical $m/z$ 577.13460). All four compounds together account for <6%.

A trimer (peak 1; $C_{45}H_{38}O_{18}$, experimental $m/z$ 865.20094; theoretical $m/z$ 865.19854; $\delta$ 2.77) was also detected at 280 nm and suspected to have arisen through addition of a "chemical dimer" to an oxidized monomer (Figure 1d). The commercial C1 trimer eluted 13.3 min after compound **1** by RP-HPLC (RT = 23.3 and 10 min, respectively). Only trimers containing (+)- or (−)-catechin units could elute before catechin.[49] Therefore, we

[a]Trimer only observed in the medium containing both (−)-epicatechin and procyanidin B2 * Comparison with purified commercial standards (retention time and ESI(−)-HRMS/MS spectra). ** From refs 38 and 42 and ESI(−)-HRMS/MS. *** From refs 21 and 42 and ESI(−)-HRMS/MS. **** Similitudes with the ESI(−)-HRMS/MS of a commercial epimer.

suspect that peak 1 could be a chemical trimer containing one to three units of (−)-catechin.

**Monitoring Procyanidin B2 Degradation in Aqueous Medium.** Figures 4 and 5 show that procyanidin B2 (peak 12) was also degraded in aqueous medium, especially at 90 °C, and yielded a large number of derived compounds (Table 2). Again, epimerization was found to occur, leading to three peaks (10, 11, and 13) in addition to B2 (12), all with an ESI(−)-HRMS/MS spectrum identical to that of the native dimer (epimers commercially unavailable) (Figure 4b). Those epimers are (−)-epicatechin-4$\beta$-8-(−)-catechin, (−)-catechin-4$\beta$-8-(−)-epicatechin, and (−)-catechin-4$\beta$-8-(−)-catechin. In B2 equivalents, none of them exceeded 5% of the initial procyanidin B2 concentration. Compound **10** could be suspected to coelute with commercially available procyanidin B1 [(−)-epicatechin-4$\beta$-8-(+)-catechin]. Our gradient elution applied on the C18 column was able to differentiate the natural procyanidin B1 from the suspected (−)-epicatechin-4$\beta$-8-(−)-catechin epimer, called here "B1-like" (elution of compound **10** 0.6 min after B1; data not shown). It was nonetheless impossible in our model medium to create B1 that includes a (+)-catechin moiety in its structure.

dx.doi.org/10.1021/jf502016z | J. Agric. Food Chem. 2014, 62, 9002−9016

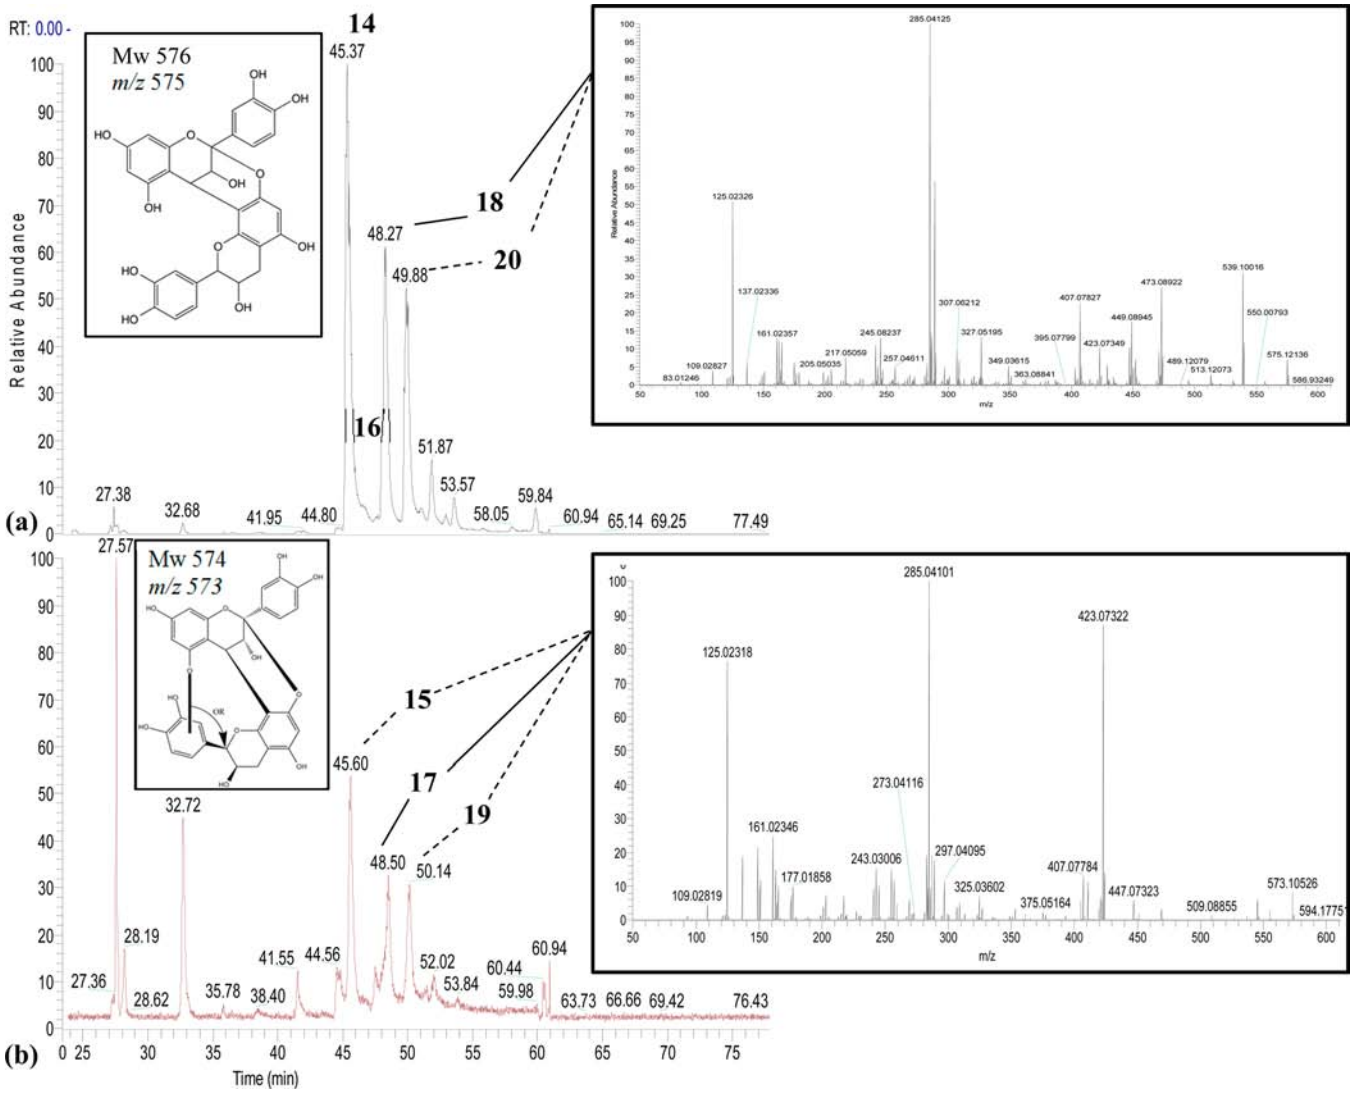

**Figure 6.** RP-HPLC-ESI(−)-HRMS/MS chromatogram of B2 heated at 90 °C for 12 h in aqueous media: (a) $m/z$ 575 ± 0.1; (b) $m/z$ 573 ± 0.1. The bold lines in the molecule indicate that the precise position of the chemical bonds is not known. The dotted lines indicate that these compounds gave an HRMS/MS spectrum very similar to that here displayed.

Depolymerization and further epimerization also generated some peaks [all discussed here above in relation to Figure 1): (−)-epicatechin (peak 6), (−)-catechin (peak 5), and dehydrodiepicatechins A (peaks 8 and 9, resolved only at 410 nm). The aqueous B2-containing media were, as expected, slightly yellow after degradation at 60 °C and red-brown at 90 °C. Only 50 mg/L (−)-epicatechin and (−)-catechin were observed after 12 h at 90 °C, accounting for <5% of the initial procyanidin B2 (1000 mg/L).

No trimer (**1**) was detectable on the UV chromatogram (Figure 4a). Yet traces were found by selecting $m/z$ 865 at the mass detector (fragmentation similar to that of compound **1** in the epicatechin model system). These results are in line with those previously published by Vidal et al.[7]

Procyanidin A2 (compound **14**, Figure 4a,c) was also produced from B2 (detectable only at 90 °C). Poupard et al.[42] also evidenced A2 in apple juice media. Three analogues (**16**, **18**, and **20**) with the same mass spectrum (Figure 6a) were found in lower amounts. They are suspected to be three A2 epimers ($C_{30}H_{24}O_{12}$: experimental $m/z$ for **18** 575.12136; theoretical $m/z$ 575.11950; $\delta$ 3.23). These compounds can undergo further oxidation leading to compounds **15**, **17**, and **19** ($C_{30}H_{22}O_{12}$: experimental $m/z$ for **17** 573.10526; theoretical $m/z$ 573.10385; $\delta$ 2.46 ppm; Figure 6b). The position of the third interunit linkage must still be determined.

**Comparison between Aqueous and Lipidic Media.** (−)-Epicatechin degradation at 60 °C proved much faster in lipidic medium (dotted lines in Figure 2a, 11% loss after 3 h in water versus 50% in cocoa butter). This contrasted with the epimerization pathway, an important degradation pathway in aqueous medium, which proved to be much slower in lipidic medium (<5% after 12 h at 90 °C, Figure 2b). Epimerization of epicatechin involves the breaking of the C-ring, leading to a radicalar intermediate. The higher efficiency of epimerization in the aqueous medium is most probably explained by the higher relative stability of this intermediate in an aqueous environment.

In contrast to (−)-catechin, dehydrodi(epi)catechins A were formed more quickly in lipidic medium and obviously much more quickly at higher temperature (Figure 2c). Yet none of the studied modalities allowed generating more than the equivalent of 4% of the epicatechin initially present. The "chemical" dimers (**2**, **3**, and **4**), intermediate compounds involved in the reaction

dx.doi.org/10.1021/jf502016z | J. Agric. Food Chem. 2014, 62, 9002−9016

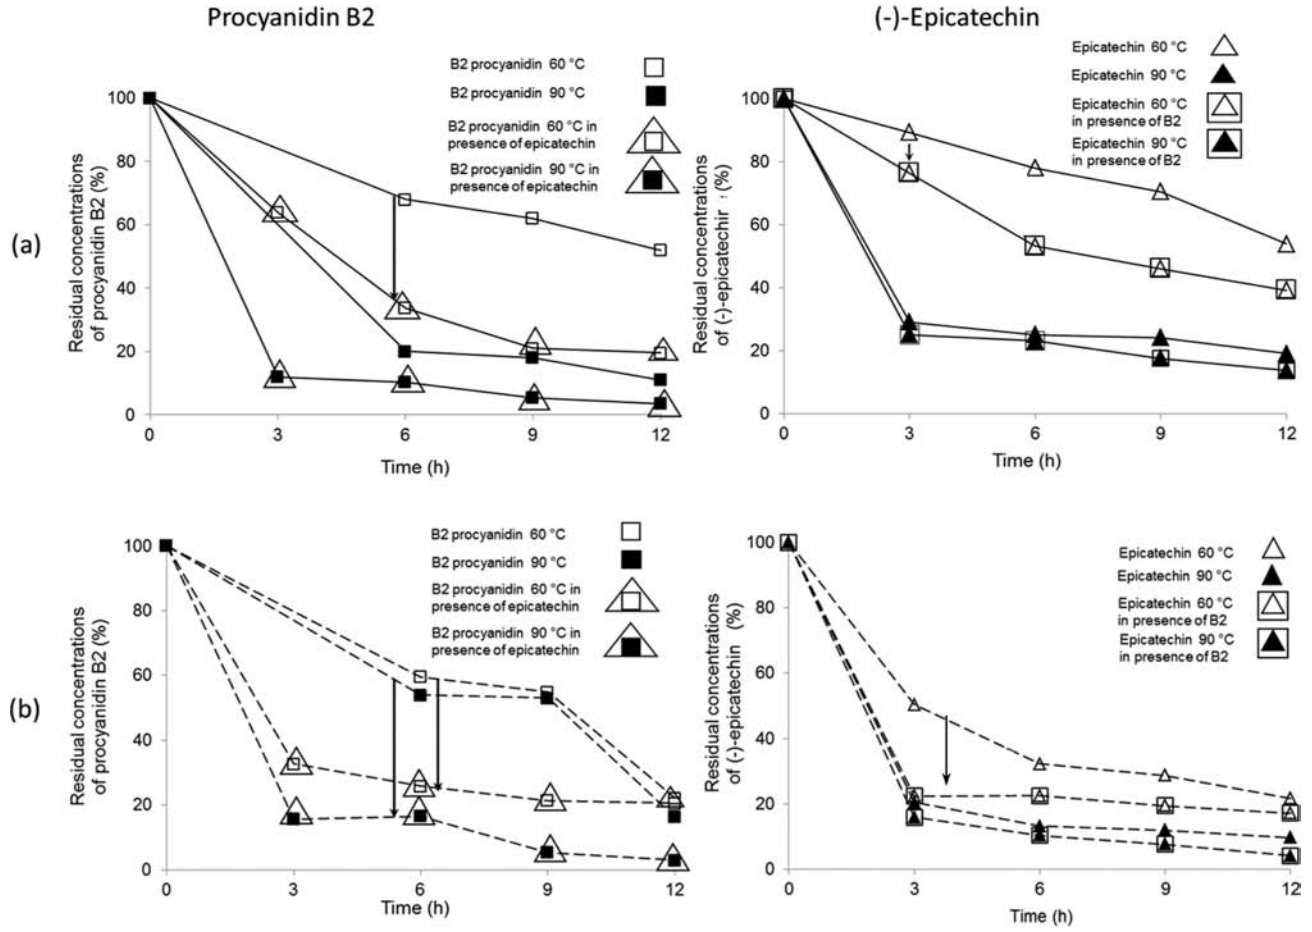

**Figure 7.** Comparison of the evolution at 60 and 90 °C of (−)-epicatechin and procyanidin B2 in (a) aqueous and (b) lipidic media, pure or mixed together. Quantitation was by ESI(−)-MS/MS. Standard deviation was <5%.

forming the dehydrodi(epi)catechins A, were found in both media, but in lower amounts in the lipidic environment.

Dimer B2 also behaved differently in the fatty environment. At 90 °C, B2 was degraded more slowly in the lipidic medium, although the two systems showed similar residual concentrations after 12 h (Figure 5). At 60 °C on the other hand, as previously seen for the monomer, the procyanidin B2 concentration decreased more rapidly in lipidic medium than in water (78% degradation versus 42%, after 12 h at 60 °C) (Figure 5).

**Synergy between Monomers and Dimers.** To determine whether a monomer might influence the degradation of the dimer or vice versa, aqueous and lipidic model media containing (−)-epicatechin and procyanidin B2 together (1000 mg/L each) were analyzed.

As depicted in Figure 7, the presence of the monomer was found to strongly accelerate degradation of the dimer, in both aqueous (Figure 7a) and lipidic (Figure 7b) media (e.g., 34% residual procyanidin B2 for the aqueous medium after 6 h at 60 °C in the presence of monomer versus 68% in its absence).

Likewise, the degradation rate of (−)-epicatechin was influenced, at least at 60 °C, by the presence of procyanidin B2. After 3 h, the residual concentrations of (−)-epicatechin were significantly lower in the presence of the dimer (76% in water and 22% in lipidic medium) than in its absence (89% in water and 50% in lipidic medium, coefficient of variation below 5% for our data). Epimerization, in contrast, was 10% less efficient than in the media containing only the monomer. At 90 °C, the (−)-epicatechin degradation rate was not significantly influenced by the presence of procyanidin B2.

As depicted in Figure 8a,b, in addition to the previously described "chemical" trimer **1**, a new trimer (**21**) emerged in this mixed medium, with a retention time of 28.1 min (HRMS/MS confirmation of $C_{45}H_{38}O_{18}$: experimental $m/z$ 865.20094; theoretical $m/z$ 865.19854; $\delta$ 2.77). Most probably, this was due to polymerization of an oxidized monomer with the natural dimer (both at 60 and at 90 °C). Not present for the natural C1 trimer (Figure 8c), the $m/z$ 319 fragment was found for both chemical trimers. Further investigations are required to reveal their accurate structure.

**Occurrence of Native Flavan-3-ol Degradation Products in Roasted Cocoa and Chocolate.** As depicted in Figure 9, unroasted Ecuadorian cocoa beans (Figure 9a) contained (−)-epicatechin (1523 mg/kg, **6**) and very little catechin (77 mg/kg, **5**), procyanidins B2 (561 mg/kg, **12**), B5 (397 mg/kg), and C1 (309 mg/kg). As expected, high temperature during roasting (30 min at 150 °C) significantly decreased the amount of natural monomer (−51% epicatechin), dimers (−50% B2 and −57% B5), and trimer (−81% C1). On the other hand, degradation through conching (12 h at 75 °C) was moderate except for the monomer (−53% epicatechin, −12% dimer B2, −8% dimer B5, and −9% trimer C1, taking into account the 72% cocoa content in the resulting chocolate). Of course, due to the presence of various higher oligomers in cocoa (not detectable in our RP-HPLC chromatograms), part of the "natural" monomers and

dx.doi.org/10.1021/jf502016z | J. Agric. Food Chem. 2014, 62, 9002−9016

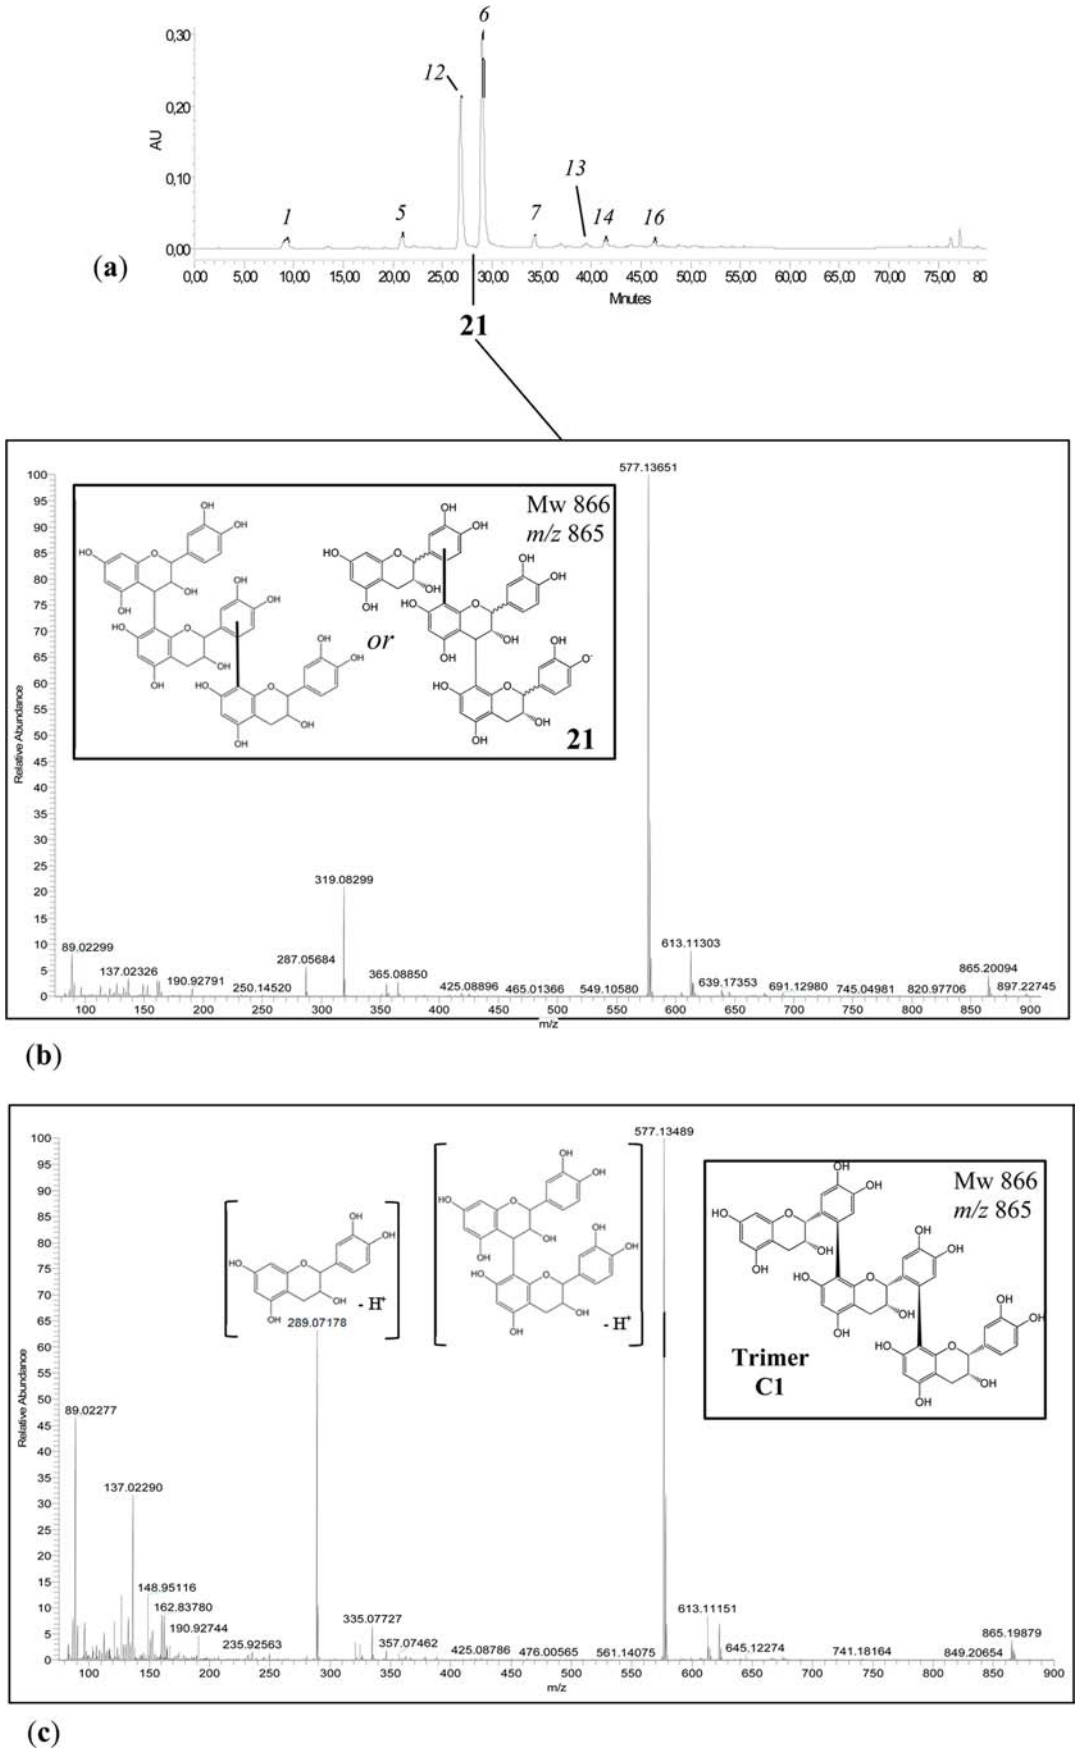

**Figure 8.** (a) RP-HPLC-UV chromatogram (280 nm) of B2 heated at 60 °C for 12 h in aqueous media in the presence of (−)-epicatechin and ESI(−)HRMS/MS spectra of (b) compound **21** and (c) the natural procyanidin C1.

dx.doi.org/10.1021/jf502016z | *J. Agric. Food Chem.* 2014, 62, 9002−9016

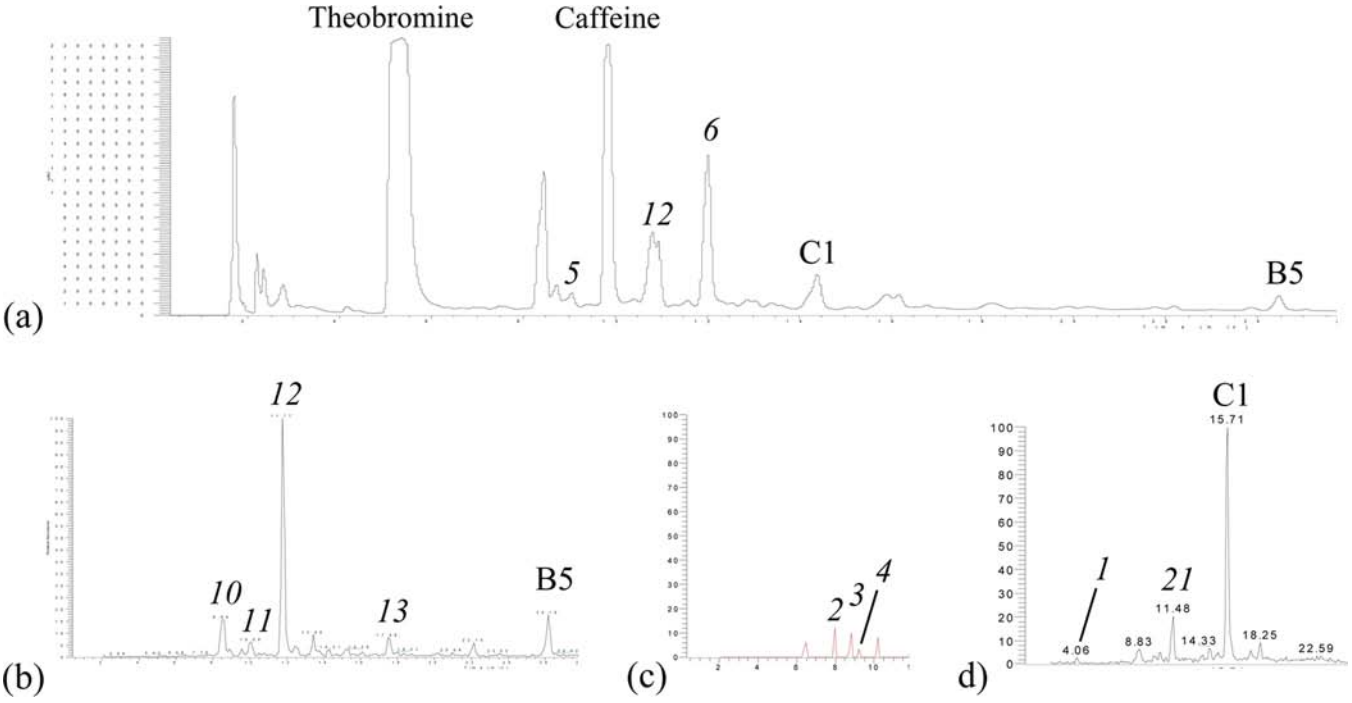

**Figure 9.** (a) RP-HPLC-UV(280 nmm) chromatogram of the polyphenolic extract issued from unroasted cocoa beans. (b–d) RP-HPLC-MS/MS chromatograms of the extract issued from the corresponding roasted cocoa beans at (b) $m/z$ 577, (c) $m/z$ 577 → 393, and (d) $m/z$ 865.

dimers found in roasted cocoa beans could also be issued from depolymerization.

Most of the degradation products evidenced in our model media have been found in the roasted cocoa beans (Figure 9b,c) as well as in chocolate. Epimerization of (−)-epicatechin significantly occurred through roasting, as shown by the epicatechin/catechin ratios of 19.8 and 5.2 before and after roasting, respectively. B2 epimers (peaks 10, 11, and 13) were also formed (observed only by MS/MS on $m/z$ 577, Figure 9b). Epimerization was revealed to be less efficient during chocolate conching (the epicatechin/catechin ratio remained close to 5 in the derived chocolate).

Compounds **2**, **3**, and **4**, all three suspected to be "chemical" newly formed dimers, were absent in unroasted beans but were evidenced after heat treatment (Figure 9c; selection of the specific fragment 393 issued from $m/z$ 577). In the same way, **1** and **21** suspected to be "chemical" trimers were detectable after roasting (Figure 9d). To our best knowledge, this is the first work that states the presence of chemical oligomers in processed cocoa.

The "chemical" dimers and oligomers produced during cocoa processing still require deeper investigations (detailed structure, antioxidant capacity, bioavailability, etc.). The further step of this research will be to optimize the roasting and conching temperature programs to maximize the content of bioavailable antioxidant polyphenols.

antioxidant capacity of methanolic-water okara extracts was examined.[16] It is clear that many food items have insoluble components that cannot be solubilized without altering their molecular nature by chemical or enzymatic treatments.[25,26] However, the insoluble components are not necessarily chemically inert. The contribution of insoluble matter to total antioxidant capacity is especially high for cereal-based and dietary-fiber-rich foods.[27] So far, the total antioxidant capacity of both soluble and insoluble components of okara has not been reported.

The mineral content in okara is relatively well researched. Okara contains macro- and microelements that increase its nutritional value.[1,3,28,29] Mateos-Aparicio et al.[28] emphasize that within the group of macroelements potassium is the main mineral, whereas iron is the predominant microelement. In the literature there are no data on the contents of Cd, Co, Cr, and Pb in okara, although the amounts of these microelements in foods are strictly limited.[30]

Lipoxygenase (Lox) is an important bioactive protein in soybean. This enzyme catalyzes the addition of molecular oxygen to polyunsaturated molecules containing a *cis*,*cis*-1,4-pentadiene structure to pentadienyl and further results in a pentadienyl radical intermediate, which could interact with other lipids to form many other derivatives such as aldehydes and ketones.[11] Because of this activity of Lox, sensory characteristics of soy foods are significantly affected. Lox produces off-flavors in soybeans by hydroperoxidation of fatty acids and by interaction with protein in flours, concentrates, and isolates.[31] The undesirable flavors, characterized as beany, green, grassy, painty, astringent, and bitter, reduce acceptance of soy foods by many consumers who may prefer a bland flavor in soy products. Nowadays, efforts are made to produce soy foods with more efficient Lox inactivation because in this way the off-flavor in soy foods could be eliminated.[32]

Traditionally prepared soy milk has beany and painty flavors owing to lipid oxidation catalyzed by Lox during soaking and grinding. In Western societies, this flavor is unacceptable for most consumers. A steam infusion cooking process, known as hydrothermal cooking (HTC), was developed to produce soy milk continuously from ground full-fat soybeans. During HTC processing the temperature is higher and the processing time shorter than for conventional methods. HTC-processed soy milk had less beany flavor because of the much shorter time for Lox activity and because steam flashing stripped volatiles. The process also increased recoveries of dry matter and protein in the soy milk from 60 and 70% for traditional soy milk to 87 and 90%, respectively.[33] Characteristics with advantages over conventionally processed soy milk have been demonstrated by physical and chemical analyses of hydrothermally cooked soy milk.[33] Hydrothermal cooking results in an acceptable decrease in activities of trypsin inhibitors[7] as well as in levels of lysinoalanine and browning products. However, previous papers have not documented the nutritional performance in mineral element content of hydrothermally processed okara. Also, total antioxidant capacity arising from both soluble and insoluble matters of okara has not been studied.

Therefore, the aim of this study was to assess the influence of a pilot plant method that uses high-pressure hydrothermal conditions on mineral composition and antioxidative capacity as well as lipoxygenase activity in okara produced from different soybean genotypes. The results obtained in this study would complement our previous work on bioactive proteins and nutritional properties of okara produced by this proccess.[2,7]

## MATERIALS AND METHODS

**Materials.** For okara preparation six commercial soybean genotypes grown in field conditions were used: ZPS-015 (0 maturity group), Krajina (00 maturity group), Novosađanka and Balkan (I maturity group), and Nena and Lana (II maturity group). Three genotypes (Lana, Nena, and ZPS-015) were selected by the Maize Research Institute Zemun Polje (Belgrade, Serbia) and the others (Novosadjanka, Krajina, and Balkan) by the Institute of Field and Vegetable Crops (Novi Sad, Serbia). All of the genotypes were of food grade and were characterized by high protein content in grain.

**Okara Processing.** Okara was made on the pilot plant scale using the production method that includes HTC[34] for soy milk preparation, as modified by Stanojevic et al.[35] Briefly, soybeans were soaked for 14 h in water at 5−7 °C. Soaked beans were ground and cooked by steam injection system at 1.8 bar/110 °C/8 min (SoyaCow VS 30/40, model SM-30, Russia). Thereafter, the slurry was filtered to separate soy milk from okara.

**Sodium Dodecyl Sulfate−Polyacrylamide Gel Electrophoresis (SDS-PAGE).** The soybean powder and defatted raw okara were prepared for SDS-PAGE analyses according to the method of Stanojevic et al.[7] Briefly, the soybean powder and raw okara were defatted using hexane. Thereafter, proteins were extracted for 120 min at room temperature with 0.03 M Tris-HCl buffer, pH 8.00, which contained 0.01 M $\beta$-mercaptoethanol. For defatted soy flour, the sample to buffer ratio was 1:20; for okara, the sample to buffer ratio was 1:10. The mixture was centrifuged at 7558*g* for 15 min at room temperature. The protein extracts were diluted with sample buffer (pH 6.80) to a concentration of 2 mg/mL, then heated at 90 °C for 5 min, and cooled to room temperature.

Dissociating electrophoresis for all samples was performed according to the Fling and Gregerson[36] procedure, as modified by Stanojevic et al.,[2,7] using 5% (w/v) (pH 6.80) stacking and 12.5% (w/v) separating gels (pH 8.85). Briefly, 25 $\mu$L of sample containing 0.05 mg of protein was loaded onto each well, and then the gels were run at 80 mA per gel for 6 h in a buffer solution (pH 8.30). The gels were fixed for 50 min, stained with 0.23% (w/v) Coomassie brilliant blue R-250, and destained with 8% (v/v) acetic acid and 18% (v/v) ethanol. Molecular weight markers that were used were phosphorylase B (94 kDa), bovine albumin (67 kDa), ovoalbumin (43 kDa), carbonic anhydrase (30 kDa), trypsin inhibitor (20.1 kDa), and $\alpha$-lactalbumin (14.4 kDa) (Pharmacia, Uppsala, Sweden).

**Densitometric Analysis.** All gels were destained, then scanned, and subsequently analyzed by SigmaGel software version 1.1 (Jandel Scientific, San Rafael, CA, USA). Quantitative analysis of each identified polypeptide was calculated as the percentage of the respective area with respect to total area of the densitogram.

**Lipoxygenase Activity.** The Lox (EC 1.13.11.12) was extracted from fresh okara with 5 volumes (w/v) of 0.2 M sodium phosphate buffer (pH 6.5) at 4 °C for 120 min. Supernatant obtained by centrifugation at 10000*g* for 10 min was used to measure the activity of Lox I. The reaction was carried out at 25 °C in a quartz cuvette with a 1.0 cm light path. The assay mixture contained 0.060 mL of 10 mM linoleate substrate and 0.1 mL of the extract in 2.440 mL of 0.2 M borate buffer, pH 9.0. The initial rate of the absorbance changes at 234 nm ($\varepsilon = 2.5 \times 10^4$ $M^{-1}$ $cm^{-1}$) was recorded, and the activity of Lox I was expressed in micromoles of conjugated diene formed per minute and per gram of dry matter.[37]

**Total Antioxidant Capacity.** The antioxidant capacity was measured by QUENCHER method described by Serpen et al.[27] using 7 mM aqueous solution of 2,2-azinobis(3-ethyl-benothiazoline-6-sulfonic acid) (ABTS). Radical cation was generated by reacting ABTS stock solution with 2.45 mM potassium persulfate (final concentration), and the mixture was kept in the dark at room temperature for 12−16 h before use. The working solution of $ABTS^{\bullet+}$ was obtained by diluting the stock solution with water/ethanol (50:50, v/v). Finely ground sample (10 mg) was mixed with 20 mL of $ABTS^{\bullet+}$ working solution, and the mixture was vigorously shaken for 25 min. After centrifugation at 10000*g* for 5 min, the absorbance was recorded at 734 nm. The total antioxidant capacity was expressed as Trolox

equivalent antioxidant capacity (TEAC) in millimoles of Trolox per kilogram of dry matter.

**Mineral Content.** The mineral content in fresh okara was analyzed by atomic absorption spectroscopy (AAS) (Varian Spectra AA 220). The microelement Fe, Mn, Cu, Zn, Cr, Pb, Co, and Cd contents in okara were analyzed after the destruction in concentrated $HNO_3$ and $HClO_4$ with the addition of 33% $H_2O_2$ by wet ashing.[38] Contents of Ca and Mg in okara were detected after the destruction with concentrated acids $HNO_3$ and HCl by dry ashing.[39] Contents of P, K, and Na in okara were determined after the destruction with concentrated acids $H_2SO_4$ and $HClO_4$ by dry ashing. Phosphorus was determined by the colorimetric method, whereas K and Na were determined by the flame-photometry method.[39]

**Other Analyses.** Total nitrogen content in okara was determined by using the micro-Kjeldahl method,[40] and protein content was calculated (N × 6.25). Ash content was calculated from the weight of okara after burning at 550 °C for 2 h in a muffle furnace.[41] Okara moisture and volatiles were determined according to standard AACC procedures.[42] The pH of a 1:10 okara water suspension (w/v) was measured using a Consort-C931 pH meter (Belgium) with automatic temperature compensation.

**Statistical Analysis.** Data were assessed by analysis of variance (ANOVA) using the Statistical software version 7.0 (StatSoft Co., Tulsa, OK, USA). The Tukey multiple-range test was used to separate means, and significance was accepted at $p < 0.05$. Regression analyses were also carried out. The different parameters were correlated with each other by Pearson two-tailed significance correlation at the $p < 0.05$ level. The experiments were performed in triplicate.

## RESULTS AND DISCUSSION

**Lipoxygenase Content and Activity.** The sensory quality of soy foods is limited by the soybean's content of Lox. By SDS-PAGE analysis of investigated soybean genotypes and okara extractable protein composition, we registered the presence of Lox (Figures 1 and 2); the first significant single broad band

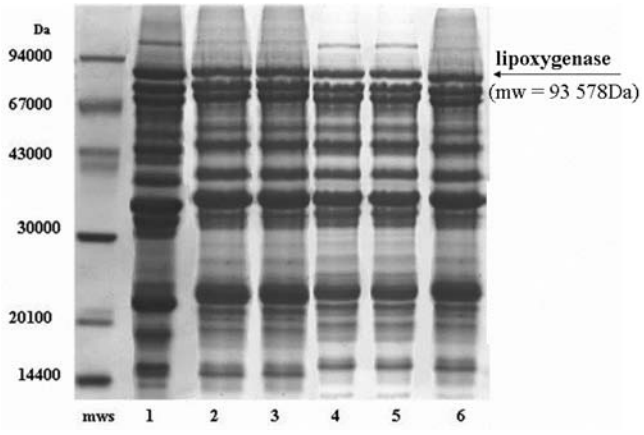

**Figure 1.** SDS-PAGE analysis of protein composition in soybeans from investigated genotypes. Lanes: mws, molecular weight standards; 1, Lana; 2, Krajina; 3, Novosadjanka; 4, Balkan; 5, Nena; 6, ZPS-015.

corresponds to lipoxygenase. Soybeans have three Lox isoforms (Lox-I, Lox-II, and Lox-III), which have homologous sequences and MW of about 96 kDa.[43,44] According to the results of densitometric analysis (Table 1) all genotypes had very similar contents of Lox, which ranged from 4.32 to 5.62% of total extractable proteins. Nowadays, lipoxygenase-free soy genotypes have been developed. Soy milk made from lipoxygenase-free soybeans has a less beany aroma, a less beany flavor, and less astringency and was rated darker and more yellow than that made from soybeans synthesizing lipoxygenase.[12] In addition to

the development of lipoxygenase-free soy genotypes, there is permanent striving to reduce the content or activity of this enzyme by technological process.[32] Our results showed that thermal/pressure treatment applied to soybeans was sufficient to get such a result in okara. When compared to soybeans, the applied treatment significantly reduced Lox content in okara (0.03−0.54%; Table 1). This result was expected because the denaturation temperature of Lox is at 69−74 °C,[45] and the applied temperature in the production of okara was 110 °C. We did not register a significant correlation between the content of Lox in soybean and in okara ($r = 0.21$; Table 2). This indicates that the content of this enzyme in okara significantly depended on the technological process but not on soybean genotype.

On the basis of this very low Lox content in okara, a very low activity of this enzyme was expected. Our results confirmed that applied thermal/pressure treatment was sufficient to inactivate Lox activity in okara. Because the most stable isomer is Lox-I, we registered only its activity. Because of its stability, most kinetic, structural, and spectroscopic studies have involved this isoform.[43] Okara Lox-I activity was registered in traces (0.004−0.007 $\mu$mol $g^{-1}$ $min^{-1}$; Table 3). The okara's pH value might contribute to such low Lox-I activity. Okara pH was from 6.88 to 7.04 (Table 4), whereas the value for the optimum activity of Lox-I is about 9.0.[44] These results suggested that the applied thermal/pressure treatment produced okara with very low Lox content and activity. Therefore, when used for the preparation of food, this okara would not give undesirable sensory effects.

| okara ash content/okara Pb content | 0.14 |

[a]Lox, lipoxygenase; [b]Significant at $p < 0.05$.

Literature data show that the correlation between Lox content in soybeans and respective enzymatic activity was positive but not significant ($r = 0.57$, $p < 0.05$).[11] On the contrary, our results showed very strong correlation ($r = 0.99$; Table 2) between okara Lox content and activity. This indicates that the most stable isoform of this enzyme survived the heat/pressure treatment that resulted in the proportional relationship between Lox content and activity.

**Total Antioxidant Capacity.** To examine the influence of the applied heat/pressure treatment on okara total antioxidant capacity arising from both soluble and solid okara particles, we implemented the direct procedure developed by Serpen et al.[27] to include the activity arising from insoluble matter. According to our results (Table 3), very high values of okara antioxidant capacity were registered. The lowest antioxidant capacity was found for genotype Lana (19.06 mmol Trolox $kg^{-1}$ dm) and the highest for genotype Novosadjanka (29.36 mmol Trolox $kg^{-1}$ dm). Other genotypes had very similar antioxidant capacities ranging from 23.31 to 29.31 mmol Trolox $kg^{-1}$ dm. When compared to raw soybeans. the antioxidant capacity of okara was decreased by around 34−58%. When compared with the published results for different foods, our values are higher than for oat flour or breakfast cereals.[27] Our results are similar to the antioxidant capacity of pumpkin or beet and much higher than those of broccoli, tomato, onion, or carrot.[46] Registered okara antioxidant capacity is more than twice higher than the antioxidant capacity of green beans, a plant belonging to the same family of legumes as soybeans.[46] Registered antioxidant activity certainly contributed to the functional value of fresh okara.

**Content of Mineral Elements.** The okara ash content of only 3.50−4.25% suggested that during production minerals of the soybeans mainly found their way into the soymilk, Table 5. Osthoff et al.[47] have come to the same conclusion. This result is in agreement with literature data.[1,28,29,47] Total ash content in okara was not significantly correlated with the content of certain mineral elements Table 2. Smith and Circle[48] pointed out direct dependence of ash and phosphorus contents in soybeans, but this was not the case with the investigated okara ($r = -0.25$; $p = 0.05$; Table 2). We have registered a slightly higher correlation coefficient between the okara ash content and calcium, iron, and chrome contents, but they were not in significant dependence (Table 2). This result of correlation analysis showed that the content of total minerals could not indicate a trend change in the content of certain mineral elements. Smith and Circle[48] noted that the mineral compositions of soybeans vary depending on the origin of the crop or the specific cultivar. Our results have shown that there were differences in the content of certain mineral components of the okara from different genotypes. However, these differences were not for all mineral elements statistically significant (e.g., P, Na). These results of statistical analysis suggest that the technological process of okara production has a much greater influence on mineral composition of okara than soybean genotype.

With the exception of nitrogen, within the group of macroelements, potassium was the main mineral in the okara (1.04−1.21 g/100 g dm), approximately 2 times higher than the amount of phosphorus (0.45−0.50 g/100 g dm; Table 5). Calcium also appeared in significant amounts (0.26−0.39 g/100 g dm). Okara contains significant amount of dietary fiber (54.3%).[28] Van der Rietet et al.[29] indicated a possible association of calcium, potassium, phosphorus, and sodium with the fiber. Because of this, it is possible that these elements are bound for fiber and remain in okara, thus comprising its nutritional value. In addition, nondigestible polysaccharides can positively affect the absorption of calcium.[50] Jiménez-Escrig et al.[20] evaluated the metabolism of calcium, magnesium, and zinc in rats fed a diet supplemented with okara, and a significant enhancement on the absorption of calcium was found. In addition, literature data indicate that okara contains very small amounts of phytic acid (0.5−1.2%).[29] Van der Riet et al.[29] note that phytic acid largely remains in tofu. Phytic acid is nutritionally significant because of its potential to chelate essential dietary minerals such as calcium and zinc.[49] Due to the low phytic acid content, and hence the lower chelating capacity, calcium remained in available form.

Iron is the predominant microelement ranging from 5.45 to 10.95 mg/100 g dm, whereas the manganese content is very similar in all samples (1.43−1.85 mg/100 g dm; Table 5).

Legumes are generally rich in iron; nevertheless, the bioavailability of this microelement is low, and therefore its value as a source of iron is diminished. The content of zinc significantly depended on the soybean genotype (1.50−7.97 mg/100 g dm). Zinc bioavailability is relatively good in legumes, approximately 25% from the zinc intake;[50] however, there is no evidence of an increase of zinc absorption in rats fed diets supplemented with okara during 4 weeks.[20] Copper is in low amount in all of the samples (0.70−1.70 mg/100 g dm; Table 5). Okara micro- and macroelements present similar values in this study as those given by Van der Riet et al.[29]

Because the plant material may contain harmful substances, we examined the contents of Cd, Co, Cr, and Pb in okara produced from the investigated genotypes using hydrothermal processes. The content of these microelements in raw okara is presented in Table 5. Our results have shown that chromium (0.43−2.04 mg/kg dm) and lead (2.78−3.47 mg/kg dm) were both registered in okara (Table 5). In the literature there are no data on the content of these microelements in okara, but our results indicated their presence in very low amounts, and therefore their content should be controlled in food and feed products. According to the FAO/WHO Expert Committee on food additives,[30] acceptable daily intakes (ADI) of these elements are for Cr, 200 μg/daily, and for Pb, 214 μg/daily. Okara is considered to be a functional food, a rich natural source of nutritional ingredients. Okara is mainly incorporated into baked goods to enhance their dietary fiber and protein contents. New bakery products such as cakes and cookies fortified with high amounts of okara have been developed. The best scores for sensory characteristics were given to cookies prepared with the addition of 60%[9] and 70%[8] okara. If we calculate the daily intake of both of these harmful elements for the consumption of 100 g of cakes, our results suggest that the lead content can be problematic in biscuits containing 70% okara, because the result was on the border or slightly increased than the allowable value for Pb (Table 6). These results suggest that the content of potentially harmful microelements should be controlled when okara is incorporated in foods and feeds.

**Table 6. Daily Intake (Micrograms per Day) of Microelements in the Consumption of 100 g of Biscuits with Okara Different Content**

| | with 60% okara | | with 70% okara | |
|---|---|---|---|---|
| genotype | Cr | Pb | Cr | Pb |
| Nena | 25.50 | 212.80 | 29.70 | 259.53 |
| Krajina | 76.55 | 166.95 | 79.10 | 194.78 |
| Novosadjanka | 122.25 | 191.55 | 142.63 | 223.47 |
| Balkan | 54.75 | 208.05 | 63.87 | 242.72 |
| ZPS-015 | 37.05 | 184.05 | 43.23 | 214.72 |
| Lana | 27.30 | 182.55 | 31.85 | 212.97 |

The investigated samples of okara bear no health risk regarding the contents of Cd and Co as these elements were below the limit of detection. Accumulation and translocation of Cd and Co as well as other toxic metals by plants depends not only of their content in soil but also on soil characteristics such as pH and its granulometric composition as well as organic

dx.doi.org/10.1021/jf501800s | J. Agric. Food Chem. 2014, 62, 9017−9023

matter content, etc., which all influence the availability of these metals to plants.[51] The fact that Cd and Co were not detected points out favorable conditions that were present in the soil where soybeans were grown.

In summary, the investigated soybean genotypes all produced okara containing very similar concentrations of Lox with Lox-I activity only in traces. Therefore, this okara would not produce undesirable effects on the sensory characteristics of foods. No significant correlation between the content of Lox in soybean and in okara was registered, thus indicating that the content of this enzyme in okara depended more on the technological process than on soybean genotypes. There was very strong correlation between okara Lox content and activity. Registered total antioxidant activity (soluble and insoluble components) certainly contributed to the nutritional value of raw okara. The minerals of the soybeans mainly found their way into the soy milk. The value of total mineral content could not indicate a trend change in the content of particular mineral elements. Potassium was the main macroelement in okara, approximately 2 times higher than phosphorus. Calcium also appeared in significant amounts. Iron was the predominant microelement, whereas the manganese contents were very similar in all samples. The content of zinc significantly depended on the soybean genotype. As the presence of some potentially harmful microelements was registered, their contents should be controlled in products intended for consumption. Finally, we can summarize that HTC treatment opens the way to a more effective use of okara as a plant source of nutritionally valuable minerals and antioxidants that could be used as feed or in food fortification.

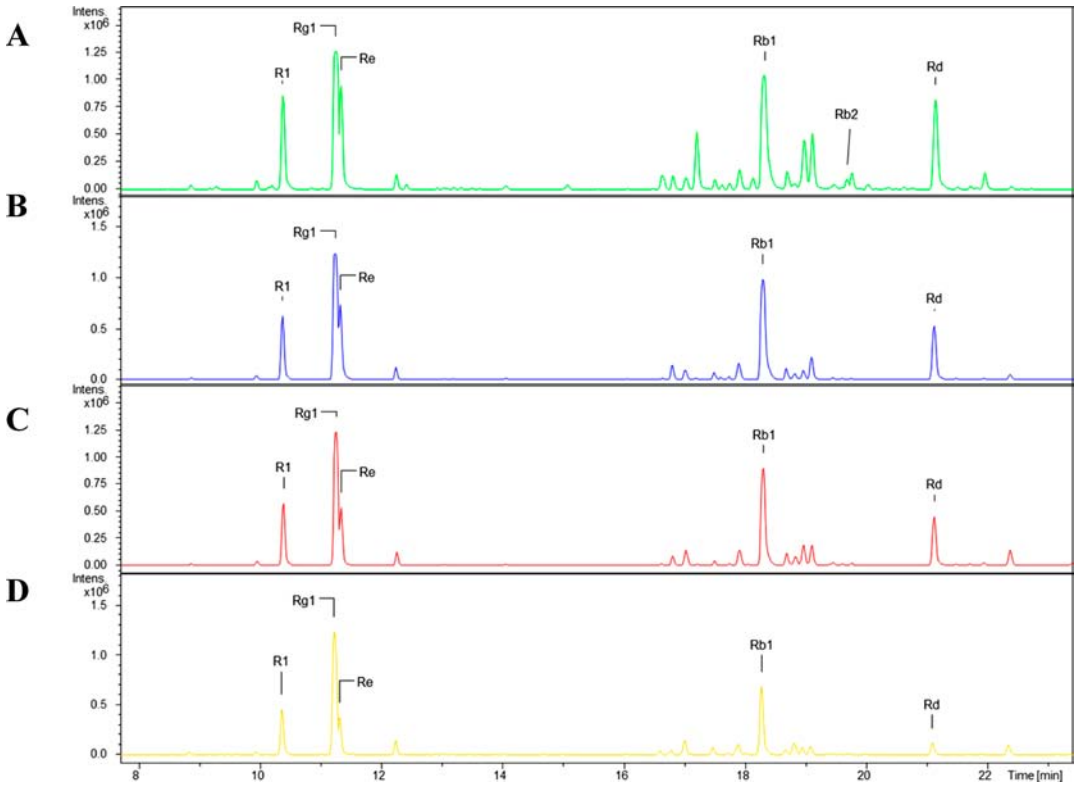

**Figure 1.** Total ion chromatogram (TIC) of rhizome (A), main root, (B) branch root (C), and fibrous root (D) of *Panax notoginseng*.

number of quantified saponins is still quite limited. (2) Metabolite profiling by using UPLC-ESI-MS has been applied for evaluating the chemical characteristics of different parts of *P. notoginseng*, that is, flower, leaf, seed, rhizome, and main root,[19,39,40] or raw notoginseng and steamed notoginseng.[40] However, this approach is still not well applied for the examination of different underground parts of *P. notoginseng*. Especially, comparison among the four parts of notoginseng by using a metabolomics approach is absent. (3) Comparison was often made among the different parts sampled from roots of diverse origin (e.g, roots collected from different regions or collected at different seasons). However, the different origin itself might introduce significant variation in the content of chemical constituents. As such, the "real" variation resulting from biosynthesis in different portions of the root might be compromised by the origin-derived variation.

Therefore, we herein conducted a quantitative comparison on the different parts derived from the whole root of *P. notoginseng* collected from the major production region of notoginseng, Wenshan city, Yunnan province. Eight dammarane-type saponins were quantitatively compared by using the validated UPLC-Q-TOF MS method. Commercial samples of individual parts of notoginseng were also analyzed to verify the chemical difference. A nontargeted metabolomics approach was subsequently applied for discrimination of different parts of the root. This combinative comparison approach facilitated an overall evaluation of chemical difference among these closely related samples.

## MATERIALS AND METHODS

**Plant Materials.** Twelve batches of the whole root of *P. notoginseng* (3 years) were collected from the wholesale markets of Wenshan, Yunnan province, China, in December 2008. For each batch of the root, three to five of the whole roots were divided into rhizome, main root, branch root, and fibrous root. The obtained individual parts were then mixed to yield the representative portion of each batch. The yield of each part from the whole root was measured to be 15% (rhizome), 66% (main root), 18% branch root, and 2% (fibrous root) on average. Commercial samples of individual parts of notoginseng were also collected from the markets of Wenshan during 2006−2008, including

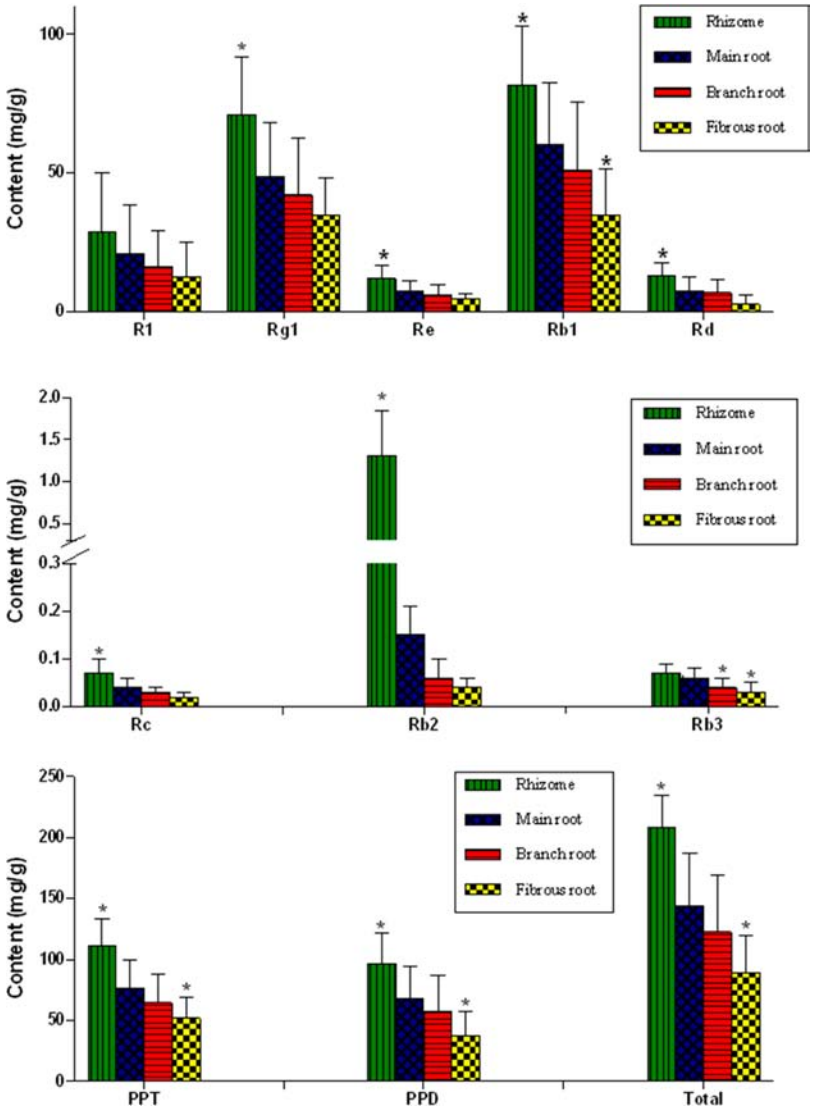

**Figure 2.** Contents of eight dammarane-type saponins and total saponins in rhizome, main root, branch root, and fibrous root of *P. notoginseng*. Each bar represents the mean ± SD ($n$ = 12). (∗) $p < 0.05$, one-way ANOVA (compared with main root).

four batches of rhizome; main roots with growing years of 3 years (four batches), 4 years (two batches), and 5 years (two batches); four batches of main root without growing year information; four batches of branch root; and six batches of fibrous root.

**Chemicals.** Notoginsenoside $R_1$ and ginsenoside $Rg_1$ (purity > 98%) were purchased from Kunming Zhongzheng Biotech Co., Ltd. (Kunming, China); ginsenosides Re, $Rb_1$, $Rb_2$, $Rb_3$, Rc, and Rd (each purity > 98%) were purchased from Chengdu Scholar Biotech Co., Ltd. (Chengdu, China). HPLC grade methanol and acetonitrile were purchased from Anaqua Chemicals Supply Inc., Ltd. (Houston, TA, USA), and distilled water was purified by a Milli-Q system (Millipore).

**Preparation of Standard and Sample Solution.** Stock solutions of notoginsenoside $R_1$ and ginsenosides $Rg_1$, Re, $Rb_1$, $Rb_2$ and Rd in 70% methanol were diluted to a series of working solutions (0.125, 0.625, 1.25, 2.5, 5, and 10 μg/mL), whereas those of ginsenosides $Rb_3$ and Rc were diluted to yield working solutions of 0.05, 0.25, 0.5, 1, 2, and 4 μg/mL.

Sample solutions were prepared following the procedures developed in our previous studies.[41,42] Briefly, 200 mg of powdered samples of each representative part was accurately weighed into a PTFE-stopped tube and sonicated with 10 mL of 70% methanol for 1 h. The mixture was centrifuged, and the supernatant was collected and then diluted by 200- and 4-fold for the quantitation of major ginsenosides ($R_1$, $Rg_1$, Re, $Rb_1$, Rd, and $Rb_2$) and minor ginsenosides ($Rb_3$ and Rc), respectively. All samples were filtered through a 0.2 μm filter before analysis.

**LC-MS Analysis.** LC-MS was performed using a Waters Acquity UPLC system (Waters, Milford, MA, USA) coupled to a Bruker MicroTOF mass spectrometer with an ESI source (Bruker, Bremen, Germany). All of the operation, acquisition, and data analysis were operated by Hystar software (Bruker). MS/MS experiments were carried out on an Agilent 1290 infinity UHPLC system (Santa, Clara, CA, USA) coupled with an Agilent 6550 QTOF.

Chromatographic separation was performed on an Acquity UPLC BEH $C_{18}$ column (2.1 mm × 100 mm, 1.7 μm). The mobile phase consisted of 0.1% formic acid in water (A) and 0.1% formic acid in acetonitrile (B), with a flow rate of 0.35 mL/min. The following gradient was used: 0−23 min, 10−40% B; 23−27 min, 40−85% B; 27−29 min, 85−100% B; 29−32 min, 100% B; 32−36 min, 10% B. The column was maintained at 40 °C, and the injection volume of each sample was 1 μL.

The mass spectrometer was operated in the negative mode with a scanning range of $m/z$ 100−3000. The optimized mass conditions were as follows: drying gas ($N_2$) flow rate, 8 L/min; drying gas temperature, 180 °C; capillary voltage, 4500 V; nebulizing gas ($N_2$) pressure, 2.5 bar; end plate offset, −500 V. The following ions were extracted for the quantitative analysis of different compounds: $m/z$ 977.5 ($[M + HCOO]^-$, notoginsenoside $R_1$), $m/z$ 845.5 ($[M + HCOO]^-$, ginsenoside $Rg_1$), $m/z$ 991.5 ($[M + HCOO]^-$, ginsenosides

dx.doi.org/10.1021/jf502214x | J. Agric. Food Chem. 2014, 62, 9024−9034

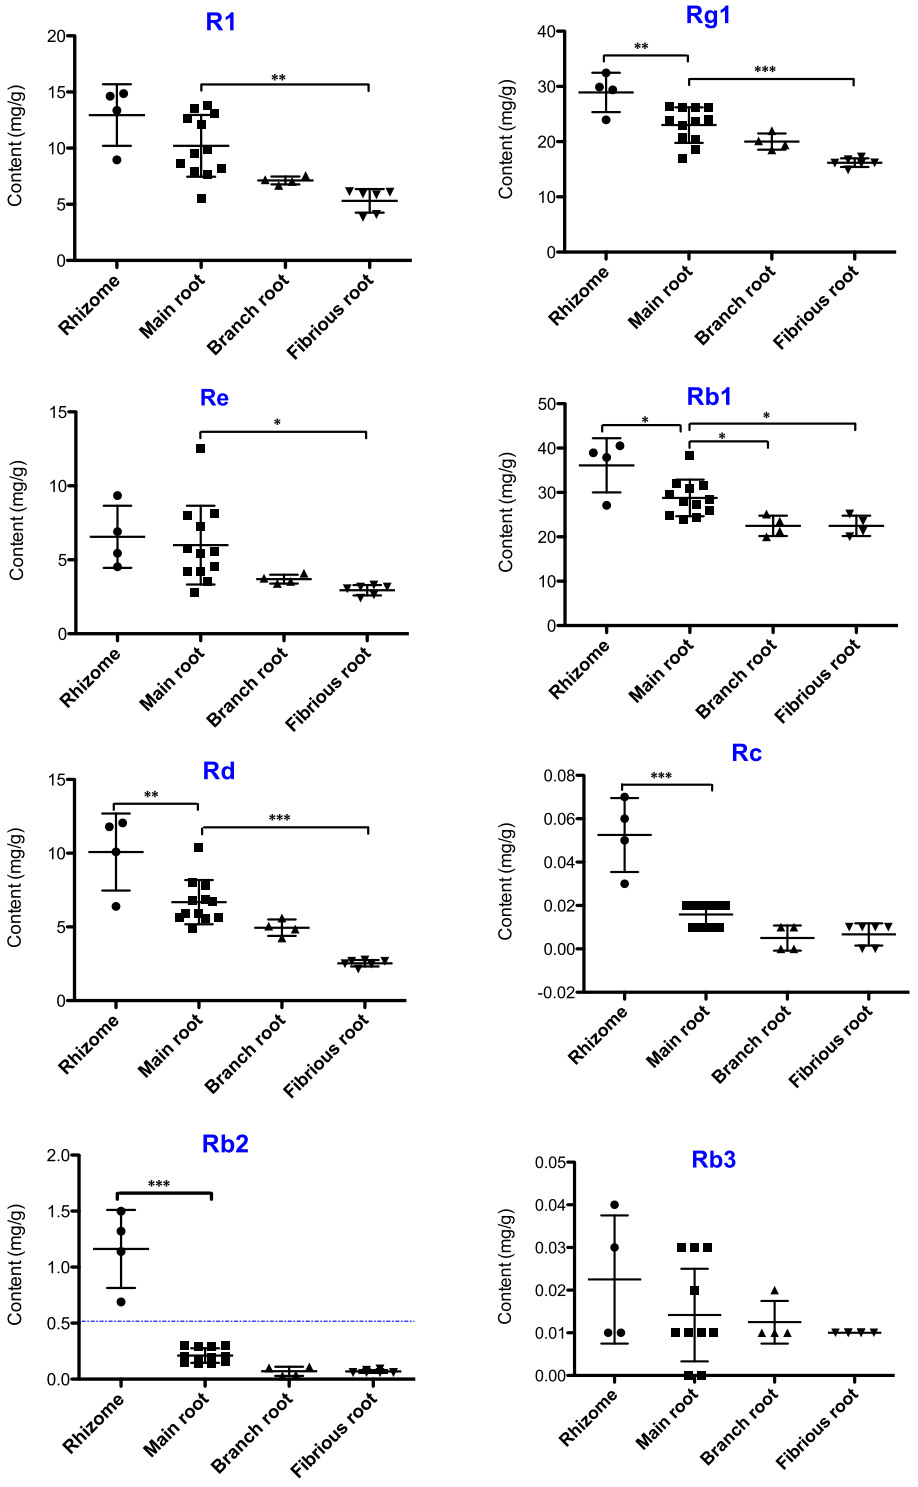

**Figure 3.** Contents of eight dammarane-type saponins in the commercial sample of rhizome ($n$ = 4), main root ($n$ = 12), branch root ($n$ = 4), and fibrous root ($n$ = 6) of *P. notoginseng*. (*) $p < 0.05$, (**) $p < 0.01$, (***) $p < 0.001$, one-way ANOVA (compared with main root).

Re and Rd), $m/z$ 1153.5 ($[M + HCOO]^-$, ginsenoside $Rb_1$), $m/z$ 1123.5 ($[M + HCOO]^-$, ginsenosides $Rb_2$, $Rb_3$, and Rc).

**Method Validation for Quantitation.** The calibration curve ($y = a + bx$) for each ginsenoside was constructed by plotting the peak area against concentration, and the linearity was verified by correlation coefficients ($r^2$). The lower limit of detection (LOD) and lower limit of quantification (LOQ) were determined on the basis of response at signal-to-noise ratios (S/N) of 3 and 10, respectively. The precision was determined by intra- and interday variations. The intraday precision was performed by six replicate analyses of a mixed standard solution within a day, and the interday precision was carried out by analyzing the same mixed standard solution on five consecutive days. The repeatability was evaluated by carrying out six replicate analyses of the same sample. The recovery test was performed by spiking a sample with the mixed standards, and the recovery rate was calculated by using the following formula: recovery rate (%) = (observed amount − original amount)/spiked amount × 100%. Variations were expressed as relative standard deviations (RSD%).

**Multivariate Analysis.** The UPLC-Q-TOF MS data of different parts of notoginseng were first exported as cdf format. The peak

dx.doi.org/10.1021/jf502214x | J. Agric. Food Chem. 2014, 62, 9024−9034

finding, alignment, and filtering of raw data were preprocessed by MassLynx V4.1 (Waters, Milford, MA, USA). The parameters were set as the following conditions: retention time of 2−27 min, mass range of 100−1500 Da, mass tolerance of 0.05 Da. The resulting three-dimensional matrix using retention time, mass to charge ratio, and intensities of all detected peaks were tabulated and exported for subsequent analysis. Principal component analysis (PCA), partial least squares discriminate analysis (PLS-DA), and orthogonal partial least squares discriminate analysis (OPLS-DA) were performed by using SIMCA 13.0 software (Umetrics, Umea, Sweden). Components that played important roles in differentiation were picked out according to the variable importance in the projection (VIP) value.

## RESULTS AND DISCUSSION

**Method Validation for Quantitation.** All calibration curves showed good linearity ($r^2$ > 0.999). The LOD ranged from 0.0038 to 0.0146 μg/mL, and the LOQ ranged from 0.0171 to 0.0541 μg/mL. The calibration curves, correlation coefficients, LOD, and LOQ of each compound are given in Table 1. The UPLC-Q-TOF MS method showed good precision for the quantitation of the eight saponins with intra- and interday variations of 1.28−3.00 and 1.22−3.44% and repeatability variations of 1.08−3.84%. The overall recoveries ranged from 97.70 to 103.03%, with variations of 1.60−3.46% (Table 1). These results demonstrated that the established UPLC-Q-TOF MS method was sensitive, accurate (with recovery accuracy within the criteria of 95−105%), and precise (with precision of <5%) and thereby appropriate for the quantitative analyses of notoginsenoside $R_1$ and ginsenosides $Rg_1$, Re, $Rb_1$, $Rb_2$, $Rb_3$, Rc, and Rd in different parts of notoginseng.

**Quantitative Comparison of Different Parts of Notoginseng.** The contents of chemical constituents are always influenced by various factors such as the place of origin, the growing year, and the harvesting season. To evaluate the variation of ginsenosides inherently associated with the different parts of the root, we specially collected the whole root for the comparative study. The qualitative results revealed quite similar content distribution of eight dammarane-type saponins in different parts of the root (Figure 1). As can be seen in Table 1, in all parts of the root, ginsenosides $Rb_1$ and $Rg_1$ were shown to be the most abundant ginsenosides, both accounting for >20% of the total saponins (Table 2). Notoginsenoside $R_1$ was less abundant than $Rg_1$ and $Rb_1$, but with great variation among individual samples in both absolute content and relative composition of the total amount of saponins. Content of ginsenosides Re and Rd also varied greatly among individual samples, but their percentage in the total amount of saponins remained at about 1−10% in most portion samples of the root, whereas ginsenosides $Rb_2$, Rc, and $Rb_3$ were minor constituents in all parts of the root (Supporting Information, Table S1). In commercial samples, similar patterns were observed for all individual parts of notoginseng (Figure 3).

Among different parts of the root, the content of each saponin was always the highest in rhizome, followed by main root and branch root, and then fibrous root. This observation was consistent with previous studies.[24,39,43] Individually, except for notoginsenoside $R_1$, contents of all ginsenosides in rhizome were significantly higher than those in main root (Figure 2), among which $Rb_2$ was the most important ginsenoside as featured by up to 8-fold content in rhizome of that in main root (Figure 2). The higher content of each saponin in rhizome accumulatively led to the significantly higher content of subtotal PPD-type and PPT-type ginsenosides, as well as the content of total saponins than that in main root (Figure 2). On average,

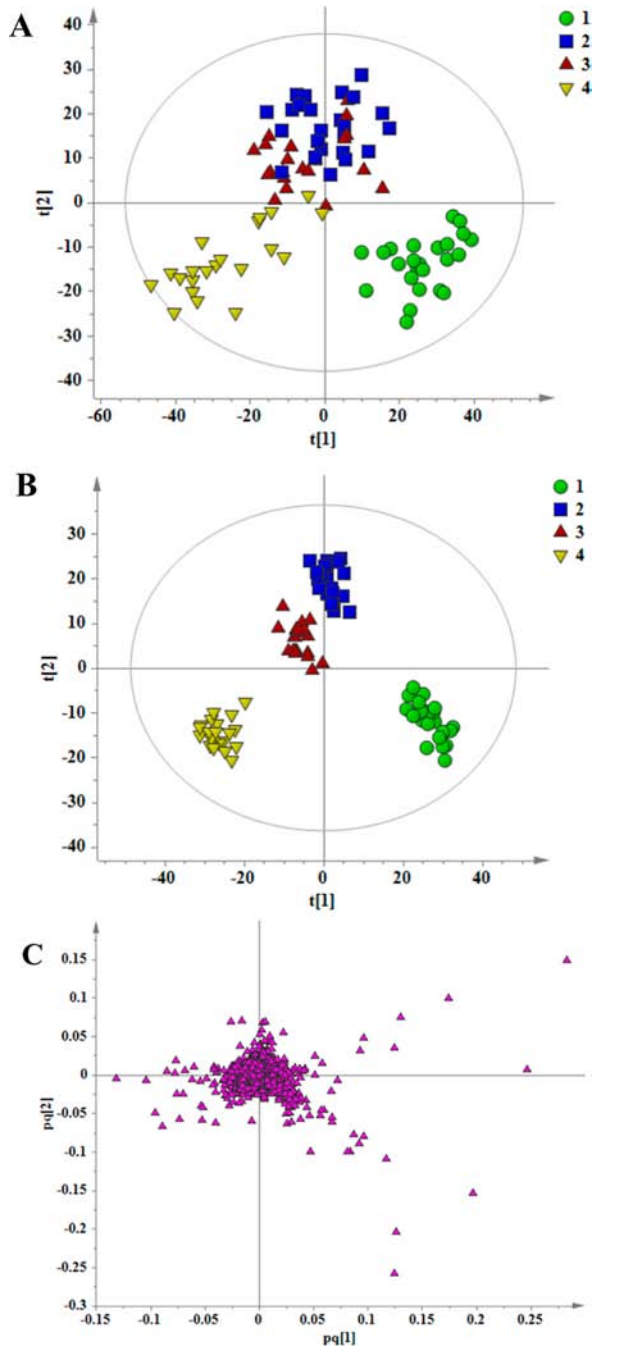

**Figure 4.** PLS-DA scores plot (A), OPLS-DA scores plot (B), and loading plot (C) of UPLC-Q-TOF MS data of rhizome (1), main root (2), branch root (3), and fibrous root (4) of *P. notoginseng*.

the content of total ginsenosides in rhizome is about 20−60% higher than that in main root and about 50−90% higher than that in branch root. The higher saponin content, together with the considerable biomass of the rhizome (about 15% of the whole root), supported the utilization of rhizome as the raw material for manufacturing ginsenoside-based products.

The contents of all eight ginsenosides in branch root appear to be lower than that in main root, but statistical significance for such difference was not observed ($p$ value > 0.05). Moreover, in PLS-DA scores plot (Figure 4A), branch root is almost superimposed with main root but separated from rhizome and fibrous root. In OPLS-DA scores plot, branch root is separated

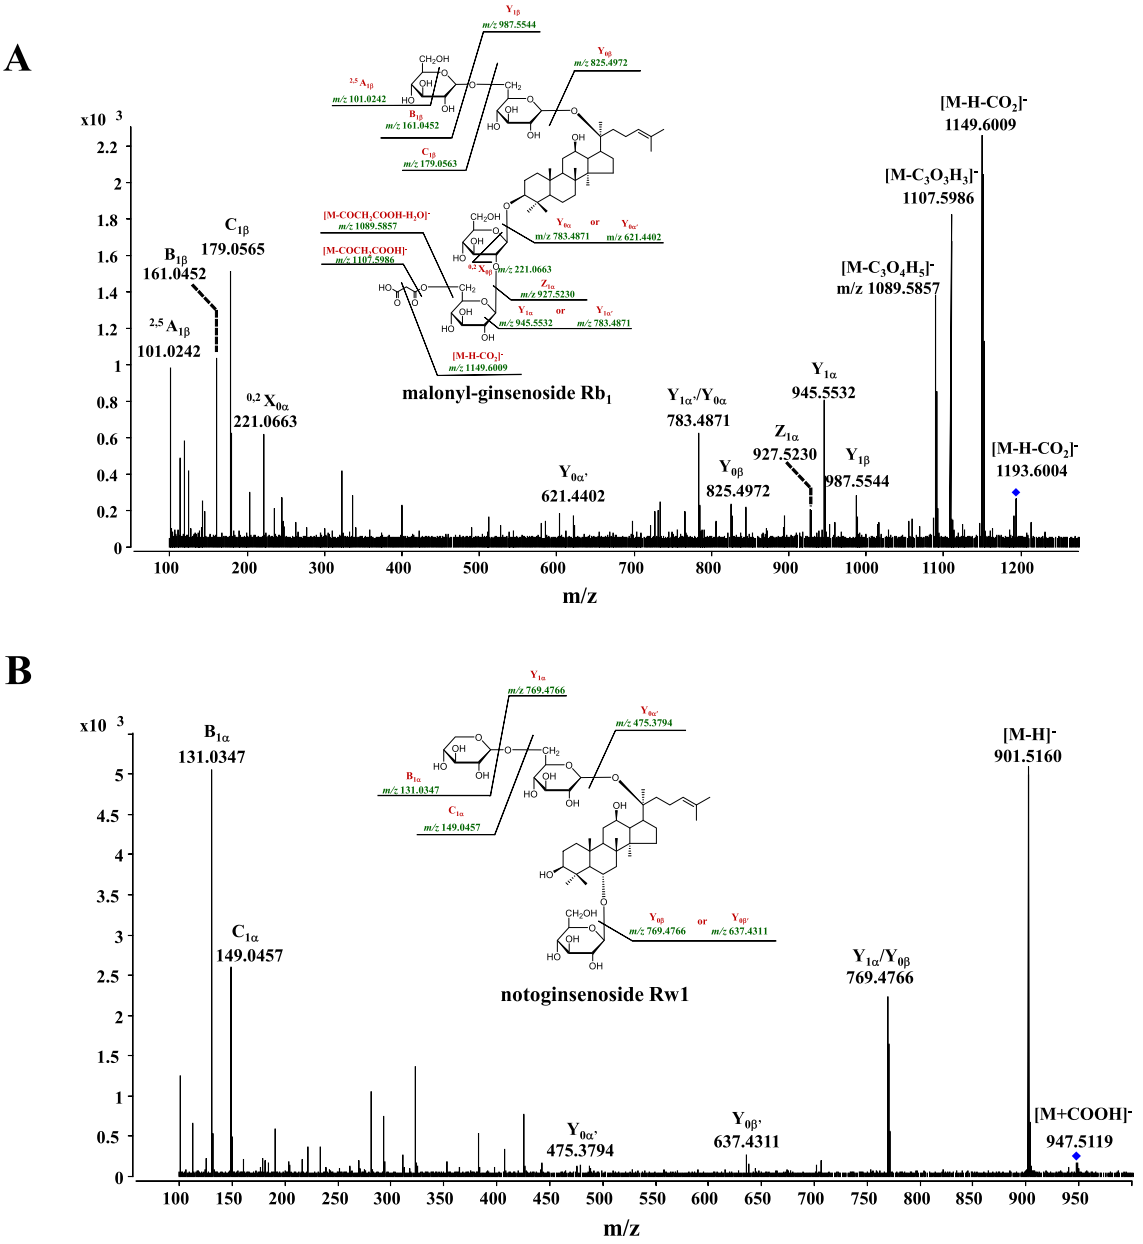

**Figure 5.** Targeted MS/MS of representative markers (A, malonyl ginsenoside $Rb_1$; B, notginsenoside $Rw_1$) contributing to the differentiation of different parts of notoginseng. Nomenclature of the fragments was assigned according to a systematic nomenclature for carbohydrate fragmentations.[46]

from main root but still very close to the main root in the space. These results indicated an overall similar chemical profile of branch root with main root, therefore supporting the equivalent usage of branch root and main root as indicated in "Chinese Pharmacopeia".

In commercial unassorted samples, the content of individual saponins in the rank order of rhizome > main root ≥ branch root > fibrous root was also observed, demonstrating this is an overall pattern of saponin distribution in different parts of notoginseng. Consistent with that revealed in whole root-derived samples, significant differences in the content of ginsenosides $Rg_1$, $Rb_1$, Rd, Rc, and $Rb_2$ between rhizome and main root were observed, despite the great intragroup variation (Figure 3). In addition, significant difference in the contents of $R_1$, $Rg_1$, Re, and $Rb_1$ between main root and fibrous root were observed. Most notable is the significantly different contents of $Rb_2$ in rhizome and other parts (Figure 3). It has been found that the content of $Rb_2$ in rhizome was >0.5 mg/g in all samples, whereas the contents in other parts were all <0.3 mg/g and mostly <0.2 mg/g. This evidence facilitated 0.5 mg/g of $Rb_2$ as a threshold value for the discrimination of rhizome and other parts of notoginseng.

**Multivariate Analysis of Different Parts of Notoginseng.** Untargeted metabolomics has the ability to profile diverse classes of metabolites and thereby has been widely used for comparing the overall metabolic composition between samples.[44] Among the techniques used for untargeted metabolomics, UPLC-Q-TOF MS has been especially widely utilized for profiling metabolites due to its superiority in high-resolution mass, precision, and sensitivity. In the current study, >15000 ions were achieved in the UPLC-Q-TOF MS data of notoginseng. Analysis results of these ions were exported for subsequent multivariate analysis by using SIMCA 13.0. As

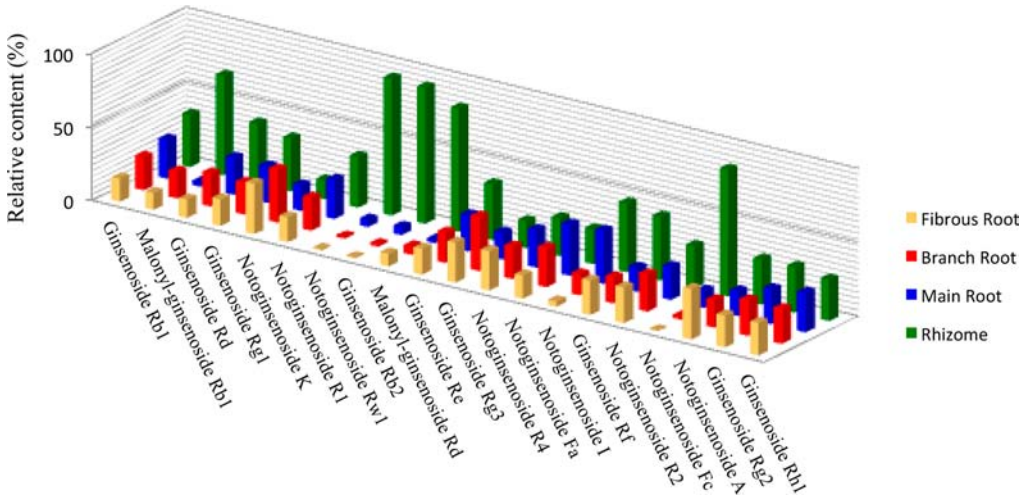

**Figure 6.** Relative contents of 20 marker compounds in different parts of notoginseng. To compare the level of individual markers between different parts, the content of each marker compound was normalized as a relative content, which was calculated by using the following equation: relative content = content in individual part/sum of the contents in four parts × 100%.

shown in Figure 4A, separation of rhizome, fibrous root, and main/branch root can be observed in the PLS-DA plots. $Q^2$, the parameter that estimates how well the model predicts $Y$, was calculated to be 63.8% (five significant components, $R^2Y$ = 91.2%) for this PLS-DA model, suggesting the good predictive capacity of the model. To minimize any effects of nonrelevant metabolite variability, OPLS-DA analyses were also carried out to identify the differences between groups (Figure 4B). Consistent with the results obtained from quantitative analysis, branch root and main root were very close in the OPLS-DA plot, indicating high similarity of the two parts. In a loading plot, the ions farthest away from the main cluster of ions possess the higher VIP value and play more important roles in the differentiation. As shown in Figure 4C, a number of ions were distant from the main cluster and were identified as the marker ions. These marker ions were identified according to the accurate mass, retention time, and targeted MS/MS data. Figure 5 represents examples for the identification of potential markers by MS/MS data. A list of the identified marker ions is shown in Table 2, which included both major and minor constituents in notoginseng. This result suggested ginsenosides Rf, $Rg_1$, Re, $Rg_2$, $Rh_1$, $Rb_1$, $Rb_2$, Rd, and $Rg_3$ and notoginsenosides A, Fa, Fc, I, K, $R_1$, $R_2$, $R_4$, and $Rw_1$, as well as malonyl-ginsenosides $Rb_1$ and Rd were the major potential marker compounds responsible for differentiation of rhizome, main root, branch root, and fibrous root of *P. notoginseng*.

The relative contents of the first 20 potential marker compounds in each part of notoginseng were then compared on the basis of their peak areas. As shown in Figure 6, notoginsenosides Fc and $Rw_1$, malonyl-ginsenoside Rd, and ginsenoside $Rb_2$ were found to present in rhizome at significantly higher content than in other parts. It is worth pointing out that both quantitative and multivariate analyses showed that the content of ginsenoside $Rb_2$ was much higher in rhizome than in other parts of notoginseng. This implied the potential marker compounds identified from the multivariate analysis were instructive.

In the current study, quantitative comparison by using a validated UPLC-Q-TOF MS method and metabolite profiling approach was combinatively employed for evaluating the similarities and differences among rhizome, main root, branch root, and fibrous root of *P. notoginseng*. Both quantitative analysis and metabolite profiling study suggested that rhizome was significantly different from the other parts. It contained the highest contents of individual saponin and total saponins, clearly suggesting the suitability of this part as the raw material for the manufacture of ginsenoside-based products. The chemical compositions of the main root and branch root are quite similar and thereby can be utilized equivalently. The fibrous root also showed a clear separation from the other parts and contained the lowest content of saponins. The multivariate study suggested that notoginsenosides Fc and $Rw_1$, malonyl-ginsenoside Rd, and ginsenoside $Rb_2$ could be potential chemical markers for discrimination of different parts of notoginseng. Because processing (e.g., steaming) and transformation in the gastrointestinal tract would further introduce chemical diversity of saponins,[32,45] chemical differences among individual parts of notoginseng might be amplified or become more complicated after processing or oral consumption. Overall, our work represents the first comprehensive study dealing with four parts of notoginseng by using an approach integrating quantitative and qualitative comparison. The result is of importance for the appraisal of the chemical characteristics of different parts of notoginseng and provides chemical evidence for the rational application of each part of notoginseng.

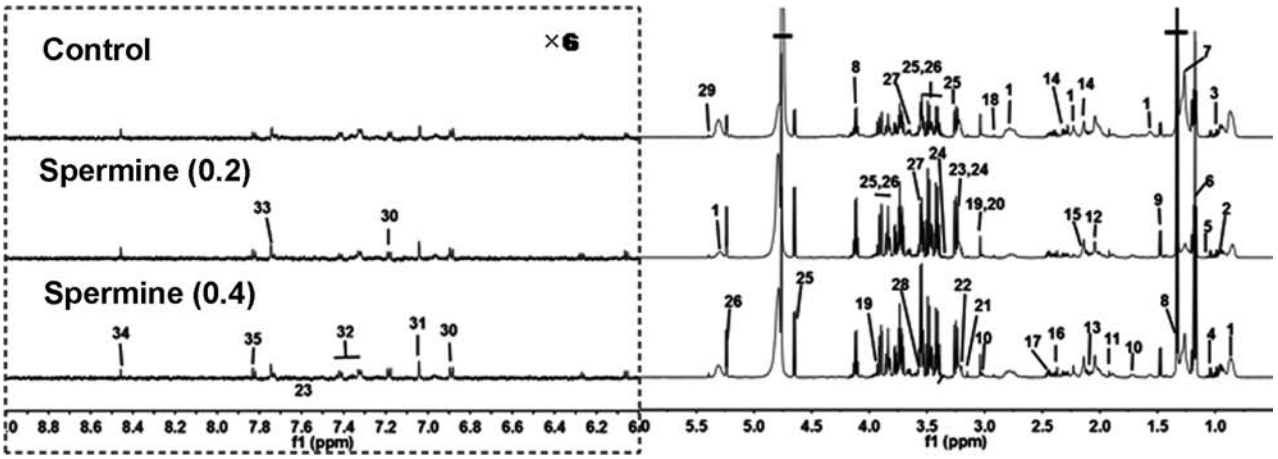

**Figure 1.** Typical one-dimensional $^1$H NMR spectra of plasma metabolites taken from the control and spermine (0.2 and 0.4 $\mu$mol/g BW) groups. The region of $\delta$ 6.0−9.0 was magnified 6 times compared with the corresponding region of $\delta$ 0.5−6.0 for clarity. A total of 34 metabolites were unambiguously assigned. The chemical shifts and peak multiplicities of these metabolites are given in Table 1.

response of animal or human biological systems to spermine supplementation.

To explore the molecular mechanisms of the role of spermine in ameliorating weaning stress, variations in the plasma metabolome were examined by using a metabolomic strategy. Plasma is a complex mixture of many constituents, and the $^1$H NMR spectra of plasma from animals under similar physiological conditions are reproducible. Each peak in the $^1$H NMR spectra of plasma is accurately correlated with the hydrogen atom of different metabolic chemicals. The relative signal intensity of each peak represents the contents of each component detected in the samples compared with the control. The metabolic profiles of spermine supplementation in rats can improve the current understanding of the association between metabolites and spermine supplementation, provide clues on the correlation between the metabolite and nutritional biochemical mechanisms of spermine, and create baseline data for future metabolomic experiments on spermine metabolism. This approach is also potentially valuable to the study of spermine metabolism and the search for other relationships between spermine administration and health or disease risk. This study would help define the effects of metabolic modifiers and the refinement of nutritional requirements. This should allow for the better formulation of nutritional support for growth and health. This experiment aims to examine the effect of spermine administration on the plasma compositions of rats by employing an explorative metabolomic approach via $^1$H NMR spectroscopy and chemometrics.

## MATERIALS AND METHODS

**Animal Experiment and Sample Collection.** The protocol used in this study was approved by the Animal Care and Use Committee of the Animal Nutrition Institute of Sichuan Agricultural University and was conducted according to the *Guide for the Care and Use of Laboratory Animals* of the National Research Council. A total of 18 19-day-old male Sprague−Dawley rats weighing 38−54 g were habituated in individual metabolic cages and were allowed to acclimatize for 1 day. The rats received intragastric administration of either 0.2 or 0.4 $\mu$mol/g body weight (BW) of spermine (Sigma Chemical Co., St. Louis, MO, USA) or saline (control) once a day for 3 days. Six rats were allocated for each group. Blood samples were collected (9:00 a.m.) from the eye after anesthesia with ether and were placed into Eppendorf tubes that contain sodium heparin 48 h after the last spermine administration. Centrifugation at 3500*g* for 10 min at 4 °C was performed on whole blood samples to obtain plasma. All plasma samples were stored at −80 °C pending NMR spectroscopic analysis. The dosage selected for this study was based on a prior experiment.[10,16] The rats were allowed ad libitum access to food and drinking water. Temperatures between 22 and 25 °C, a cycle of 12 h light/12 h dark, and humidity from 50 to 70% were maintained throughout the study. Clinical observations were made during the experimental period.

**Sample Preparation and NMR Spectroscopy.** Plasma samples were thawed from −80 °C. Six hundred and thirty microliters of plasma samples was mixed with 70 $\mu$L of Anachro certified DSS standard solution containing 99.9% v/v $D_2O$ (for field frequency lock purposes), 0.2% w/v $NaN_3$ (for inhibiting bacterial growth), and 4.08 mM DSS as a reference at 0 ppm (Anachro Technology Co., Ltd. Wuhan, China). After vortexing and centrifugation at 12000 rpm for 10 min (4 °C), 550 $\mu$L of the samples was placed into 5 mm NMR tubes for NMR analysis.

The proton NMR spectra of the plasma samples were achieved at 300 K on a Bruker Avance II 600 MHz spectrometer (Bruker Biospin, Rheinstetten, Germany) operating at a $^1$H frequency of 600.13 MHz with broadband-observe probe. A water-presaturated Carr−Purcell−Meiboom−Gill pulse sequence (recycle delay−90°−$(\tau-180°-\tau)_n$−acquisition) was used to attenuate the NMR signals from macromolecules. A spin−spin relaxation delay ($2n\tau$) of 76.8 ms and a spin−echo delay $\tau$ of 400 $\mu$s were employed. A 90° pulse was set to 13.7 $\mu$s with a recycle delay of 2 s and acquisition time of 2.56 s. A total of 32 transients were collected into 49178 data points for each spectrum with a spectral width of 15 ppm. For assignment purposes, $^1$H−$^1$H correlation spectroscopy and $^1$H−$^1$H total correlation spectroscopy were acquired for selected samples.

**NMR Spectroscopic Processes and Analysis.** Before Fourier transformation, the free induction decays were multiplied by an exponential window function with a 1 Hz line-broadening factor. All NMR spectra were then manually phase- and baseline-corrected. The plasma spectral region $\delta$ 0.5−9.0 was integrated into regions with equal widths of 0.002 ppm by using Mestrenova 8.1.2 software (Mestrelab Research S.L., Spain). Plasma chemical shifts were referenced to the peak of the methyl proton of L-lactate at $\delta$ 1.33. The ethanol signals from the process of blood collection were carefully excluded together with the regions containing urea and $H_2O$ signals to obtain only the endogenous metabolite changes induced by spermine exposure. This treatment helps avoid any contributions of ethanol, urea, and $H_2O$ to intergroup differentiations. In the plasma spectra, the discarded regions contain $\delta$ 4.19−5.23 and $\delta$ 5.40−6.80 for $H_2O$ and urea, and $\delta$ 1.16−1.19 and $\delta$ 3.60−3.62 for ethanol. Subsequently, each integral region was normalized to the total sum of all integral regions for each spectrum prior to pattern recognition analysis.

**Table 1. $^1$H NMR Data for Metabolites in Rat Plasma**

| key | metabolite | moieties | $\delta$ $^1$H (ppm) and multiplicity |
|---|---|---|---|
| 1 | lipid | $CH_3(CH_2)_n$, $CH_3CH_2CH_2C{=}$, $(CH_2)_n$, $CH_2CH_2CO$, $CH_2C{=}C$, $CH_2CO$, $C{=}CCH_2C{=}C$, $-CH{=}CH-$ | 0.84(t), 0.89(t), 1.28(m), 1.58(m), 2.01(m), 2.24(m), 2.76(m), 5.30(m) |

Multivariate data analysis was performed on normalized NMR data sets with the software package SIMCA-P+ (version 11.0, Umetrics, Sweden). Principal component analysis (PCA) was performed on the data set to examine group clustering and to find possible outliers. The results were viewed in the form of score plots, where each point represented an individual sample, and loading plots, where each coordinate represented one NMR spectral region. Projection to latent structure−discriminant analysis (PLS-DA) and orthogonal projection to latent structure−discriminant analysis (OPLS-DA) were performed by using the NMR data (scaled to unit variance) as the *X*-matrix and the class information as the *Y*-matrix.[17] The quality of the model was evaluated by the parameters $R^2X$, representing the total explained variation, and $Q^2$, standing for the model predictability. The models were validated by using a 7-fold cross-validation method and a permutation test.[18,19] A model was considered significant if the $Q^2$ value was significant ($P < 0.05$) through permutation. The OPLS-DA models were interpreted by coefficient-coded loading plots. The loadings were backtransformed in Excel (Microsoft, USA) and plotted with the color-coded absolute coefficient values ($|r|$) of the variables in MATLAB (The Mathworks Inc., Natwick, MA, USA; version 7.1).[18] In these loading plots, the warm-colored (e.g., red) variables contributed more to intergroup differentiation than cool-colored (e.g., blue) variables. In the current study, appropriate correlation coefficients were used as the cutoff values (depending upon the number of animals used for each group) for the statistical significance based on the discrimination significance ($P < 0.05$). These coefficients were determined by using Pearson's product-moment correlation coefficient.[18]

## RESULTS AND DISCUSSION

**$^1$H NMR Spectra of Plasma Samples.** Figure 1 demonstrates the representative $^1$H NMR spectra of rat plasma from the control and spermine-treated groups. NMR signals were assigned to specific metabolites for $^1$H NMR resonances (Table 1). The spectra of the plasma samples mainly contained resonances from glucose, lactate, lipids, choline metabolites, and a series of amino acids.

**Multivariate Data Analysis of NMR Data.** PCA was initially performed on plasma spectral data. Two principal components were calculated for the treatment groups, with 55.8 and 12.9% of the variables explained by PC1 and PC2, respectively. PCA results (Figure 2A) showed that separation were absent in the metabolic plasma profiles of rats from the treatment and control groups. Moreover, PLS-DA was conducted on the plasma spectra of the spermine-treated and control groups. The score plots clearly highlighted three clusters corresponding to the three groups (Figure 2B). Furthermore, the plasma metabolic changes in the rats from the spermine-treated and control groups were analyzed by using OPLS-DA. The corresponding coefficient analysis demonstrated that spermine (0.2 μmol/g BW) significantly increased the plasma levels of 1-methylhistidine, 3-hydroxybutyrate, alanine, glutamine, glycerolphosphocholine (GPC), phosphorylcholine, *myo*-inositol, phenylalanine, tyrosine, valine, trimethylanine, and α-glucose compared with the control group ($P < 0.05$; Table 2 and Figure 3B). Spermine (0.4 μmol/g BW) significantly increased the plasma levels of 1-methylhistidine, alanine, formate, glutamate, glutamine, GPC, phosphorylcholine, lysine, lipid, phenylalanine, tyrosine, trimethylanine, α-glucose, and β-glucose compared with the control groups ($P < 0.05$; Table 2 and Figure 3A). Furthermore, spermine (0.4 μmol/g BW) significantly decreased the plasma levels of 3-hydroxybutyrate, acetate, choline, lactate, and *myo*-inositol and increased the plasma levels of glutamine compared with the spermine-treated (0.2 μmol/g BW) groups ($P < 0.05$; Table 2 and Figure 3C).

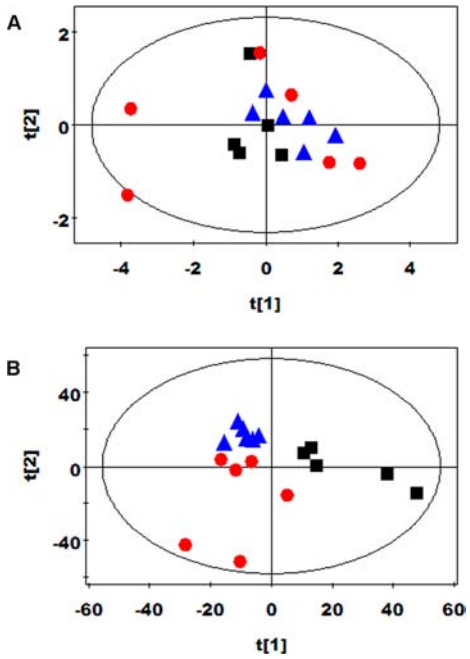

**Figure 2.** PCA score plots ($R^2X = 0.865$, $Q^2 = 0.638$; A) and PLS-DA score plots ($R^2X = 0.639$, $R^2Y = 0.987$, $Q^2 = 0.537$; B) based on the $^1$H NMR spectra of 48 h plasma metabolites taken from the spermine-treated groups (0.2 (red circles) and 0.4 μmol/g BW (blue triangles)) and the control group (black squares). One sample from the control group was excluded because of hemolysis.

**Spermine Supplementation Induces Alterations to Cell Membrane Metabolism and Lipid Metabolism.** Spermine supplementation can alter cell membrane metabolism. Phosphorylcholine and GPC are essential elements for the structural integrity of cell membranes and play critical roles in cell metabolism and signaling processes.[20,21] In this study, plasma phosphorylcholine and GPC levels were increased by spermine ingestion. Spermine supplementation can enhance intestinal maturation (data not shown). Therefore, the structural integrity of the cell membrane is ameliorated. Moreover, spermine supplementation can alter lipid metabolism. GPC synthesis in mammalian and bacterial cells occurs with choline.[22] GPC acts as an inhibitor of lysophospholipase, which catalyzes the hydrolysis of physiologically important lysophospholipid substrates (containing lysophosphatidic acid and sphingosine 1-phosphate). These lipids play a critical role in cellular signaling and nutrient metabolism regulation.[23] The plasma concentrations of *myo*-inositol were increased in response to spermine supplementation. This carbocyclic polyol provides the structural basis for many secondary messengers (e.g., inositol phosphates, phosphatidylinositol, and phosphatidylinositol phosphate) in eukaryotic cells.[24] Therefore, inositol is linked to the regulation of intracellular calcium (Ca) concentrations, insulin signal transduction, gene expression, and fatty acid oxidation.[24,25] This result is in agreement with a previous study that shows that spermine enhances electrogenic $Ca^{2+}$ uptake and increases mitochondrial $Ca^{2+}$ retention.[26] Phosphorylcholine is an essential component for the assembly and secretion of very-low-density lipoproteins in the liver, and an increased level of phosphorylcholine can cause high lipid transfer into the blood. This result is in agreement with that of

**Table 2. OPLS-DA Coefficients, *P* Values, and Main Functions Derived from the NMR Data of 48 h Plasma Metabolites Obtained from the (A) Control Group and Spermine-Treated Groups ((A) 0.2 and (B) 0.4 μmol/g BW)**

[a]Correlation coefficients: positive and negative signs indicate positive and negative correlation in the concentrations, respectively. The correlation coefficient of $|r| > 0.755$ (for B vs A and C vs A) or 0.707 (for C vs B) was used as the cutoff value. "'−'" means the correlation coefficient $|r|$ is <0.755 (for B vs A and C vs A) or <0.707 (for C vs B). [b]Normalized integral of metabolites in the spectrum (normalized to 100). Integrals of the altered metabolites were analyzed statistically using one-way analysis of variance (ANOVA) of SPSS 17.0 software (SPSS Inc., Chicago, IL, USA). Date sets were further analyzed using post hoc tests (least significant difference, LSD) for multiple comparisons to determine the statistical differences between groups. *P* values are significant at the <0.05 or <0.01 level, and *P* values are not significant at >0.05.

the present study. GPC and phosphorylcholine also have critical roles in lipid cholesterol transport and metabolism.[21] Furthermore, ketone body production (e.g., acetone, 3-hydroxybutyrate, and acetoacetate) provides fuel for vital organs (e.g., heart, brain), thus increasing the chance of survival from metabolic problems. Acetoacetate and 3-hydroxybutyrate are products of fatty acid oxidation in the liver, and their ratios are useful indicators of the mitochondrial redox state. Spermine supplementation increased 3-hydroxybutyrate concentrations but did not change acetoacetate concentrations in plasma, thus decreasing the acetoacetate to 3-hydroxybutyrate ratio. This result suggests the decreased oxidized state of cells, which can be given by the decreased oxidation of fatty acids. Collectively, spermine supplementation can alter cell membrane and lipid metabolism.

**Spermine Intakes Cause Changes in Glucose−Alanine Cycle Metabolism.** The spermine-treated group exhibited a significant increase of plasma glucose and alanine levels compared with the control group. Glucose is a major energy substrate that plays a role in animal growth and development. Alanine is an important participant and regulator in glucose metabolism. Alanine levels are correlated with blood sugar levels in both diabetes and hypoglycemia, and alanine alleviates both severe hypoglycemia and ketosis in diabetes. Alanine is an important amino acid for lymphocyte reproduction and immunity.[27] These findings suggest that spermine supplementation can affect the glucose−alanine cycle metabolism.

**Spermine Supplementation Alters Amino Acid Metabolism.** Spermine exposure can alter amino acid metabolism. In this study, spermine decreased urinary *N*-acetylglutamate levels (data not shown). Urea plays an important role in the metabolism of nitrogen-containing compounds. *N*-Acetylglutamate is necessary for the normal functioning of the urea cycle, and variations in its concentration affect the urea production rate and other urea synthesis substrates.[28] The increase of blood urea nitrogen is related to the decrease of *N*-

dx.doi.org/10.1021/jf500882t | J. Agric. Food Chem. 2014, 62, 9035−9042

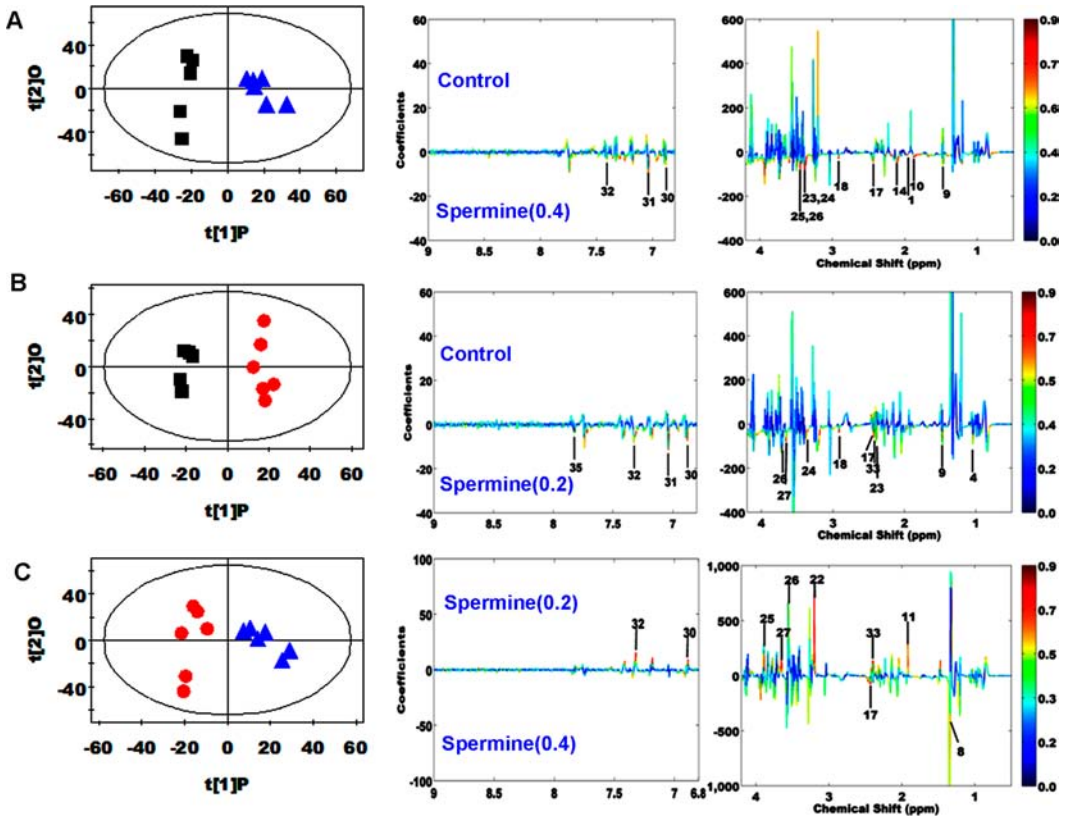

**Figure 3.** OPLS-DA score plots (left panel) and the corresponding coefficient loading plots (right panel) derived from the $^{1}$H NMR spectra of 48 h plasma metabolites obtained from the spermine-treated group (0.2 (red circles) and 0.4 $\mu$mol/g BW (blue triangles)) and the control (black squares) groups (A, $R^2X = 0.397$, $Q^2 = 0.327$; B, $R^2X = 0.294$, $Q^2 = 0.457$; C, $R^2X = 0.364$, $Q^2 = -0.0257$). One sample from the control group was excluded because of hemolysis. The color scale in the coefficient plot shows the significance of metabolite variation between the spermine (0.2 and 0.4 $\mu$mol/g BW) and control groups.

acetylglutamate, thus indicating that urea production is modulated by *N*-acetylglutamate. Amino acids in the intestine increased during protein synthesis to promote intestinal maturation, thus leading to increased levels of amino acids present in plasma. The other possible reason is that spermine-induced energy expenditure may also lead to elevated consumptions of amino acids as an energy source. Our results demonstrated that the levels of branched-chain amino acids (BCAAs) were increased by spermine supplementation. BCAAs are known as key metabolites involved in protein synthesis and cell growth. BCAAs are some of the most efficient energy-generating amino acids in mammals. The increase of BCAA may further indicate increased energy expenditure during intestinal maturation. In the present study, we observed an increase in the levels of plasma tyrosine by spermine supplementation. This result is in accordance with the increase of phenylalanine levels in plasma because phenylalanine is the precursor for the amino acid tyrosine. This result also agrees with that of previous study; that is, spermine supplementation can ameliorate protein synthesis.[29] Moreover, we observed an increase in the levels of plasma lysine, glutamate, and glutamine; this result agrees with the role of spermine in increasing protein synthesis in rats.[29] Glutamine can activate signaling pathways to enhance protein synthesis, thus influencing animal growth and development. Glutamine is the principal carrier of nitrogen in the body and is an important energy source for many cells. A significant body of evidence links glutamine-enriched diets with intestinal effects. Glutamine aids in the maintenance of gut barrier function and intestinal cell proliferation and differentiation, as well as the reduction of septic morbidity and irritable bowel syndrome symptoms.[6,30] The possible explanation for the increase in glutamine is that the structural integrity of the cell membrane is ameliorated. Taken together, spermine ingestion can change amino acid metabolism.

**Spermine Supplementation Results in Changes in Gut Microbiota Functions.** A novel and unexpected finding from this work is that plasma formate and nitrogenous compounds (trimethylamine) were increased. Plasma formate and trimethylamine are microbial metabolites of carbohydrates and amino acids, which are probably produced in the lumen of the small and large intestines.[31,32] Intestinal microbes convert dietary nondigestible fibers into short-chain fatty acids and other nutrients that can be used by the mammalian host as energy sources or as precursors for fatty acid synthesis.[33] The introduction of spermine supplementation into the mammalian system may disrupt baseline mammalian-to-microbe behavior, thereby leading to a disruption in microbial populations and metabolism. Changes in these metabolites may be caused by the reduced number and/or altered activity of intestinal microorganisms. An in vitro experiment has showed that spermine supplementation can inhibit some microbes, thus leading to a decrease in microbe number and/or metabolic activity.[34] A decrease in the number of intestinal bacteria is believed to be consistent with decreased fat accretion,[35] although the underlying mechanisms are still unknown.

In conclusion, our results provide the metabolic processes associated with spermine supplementation in modulating

weaning stress, including cell membrane metabolism, lipid metabolism, glucose−alanine cycle metabolism, amino acid metabolism, and gut microbiota metabolism, which have important implications in nutritional research in infants. This study also highlights the potential for the development of a metabolomic strategy in probing the effects of nutritional intervention in a mammalian system. To the best of our knowledge, this is the first study to identify systematically the expressed metabolites in plasma from spermine supplementation. Future studies may be directed toward a mechanistic understanding of the effects of spermine on animal tissue intermediary metabolism.

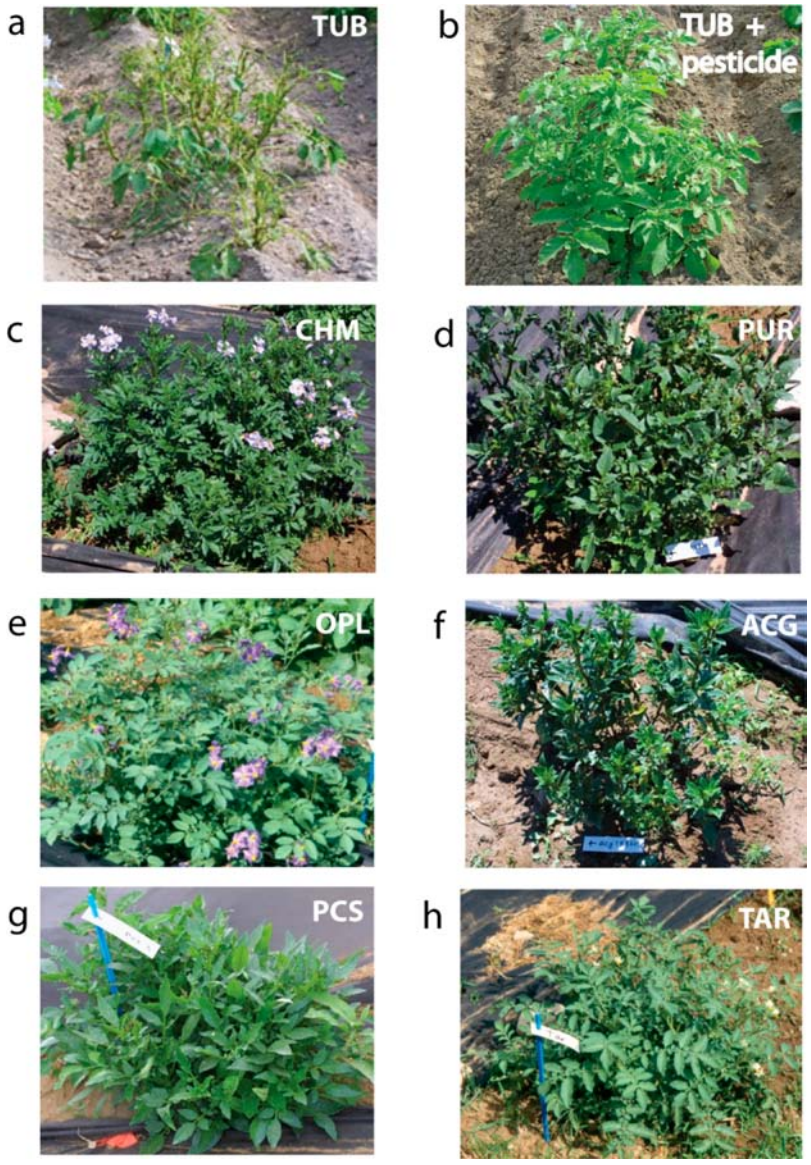

**Figure 1.** *Solanum* plants grown in the field: (a) *S. tuberosum* cv. Shepody (TUB); (b) *S. tuberosum* cv. Shepody treated with imidacloprid (TUB + pesticide); (c) *S. chomatophilum* (CHM); (d) *S. oplocense* (OPL); (e) *S. paucissectum* (PCS); (f) *S. piurae* (PUR); (g) *S. acroglossum* (ACG); (h) *S. tarijense* (TAR). Plants were grown in the absence of imidacloprid pesticide treatment except as indicated.

in the greenhouse in pots with potting mix and weekly fertilizer application of 20−20−20. Sampling of foliage was done on fully grown plants at 12 weeks after planting. The apical leaflets from five leaves for each plant were pooled in 15 mL conical tubes and flash frozen in liquid nitrogen. Samples were stored at −80 °C prior to extraction. A minimum of three replicate plants were sampled for all species.

**Growth of Plants in the Field.** Four plants from each wild *Solanum* species and *S. tuberosum* were grown in pots in the greenhouse in May 2008 and transplanted to a field at the Potato Research Centre 4 weeks after planting. The field was not treated with pesticide to allow for CPB infestation. For comparison, *S. tuberosum* was also planted in a field with imidacloprid (Admire) pesticide treatment in the soil prior to planting and two foliar treatments in July. The presence/absence of CPB and defoliation was noted during July and August, and photographs were taken.

**Extraction.** The frozen foliar samples were ground into a fine powder using a mortar and pestle while immersed in liquid nitrogen. One hundred milligrams of frozen ground tissue was placed in a 1.5 mL polyethylene screw-cap tube and kept frozen in a liquid nitrogen holding station (SPEX Sampleprep, Metuchen, NJ, USA) until all samples were ground. The ground powder was extracted with 400 μL of extraction solution (92% methanol, 0.1% formic acid LC-MS grade v/v) (Sigma-Aldrich, Oakville, ON, Canada). The samples were briefly vortexed and placed on ice until all samples were prepared. Samples were then sonicated in a Branson sonicator bath for 15 min and filtered through a 0.2 μm syringe filter into an LC-MS autosampler vial. Sample dilutions were optimized to ensure peak intensities were in the linear range and to avoid detector saturation. Wild *Solanum* and *S. tuberosum* samples were diluted 4-fold with extraction buffer. The samples were allowed to equilibrate at 23 °C in the dark for 1 h prior to analysis and were maintained under these conditions for the duration of the LC-MS analysis.

**UPLC-qTOF-MS.** Metabolite analysis was carried out using Acuity ultraperformance liquid chromatography− Xevo quadrupole time-of-flight mass spectrometry (UPLC-qTOF-MS) (Waters, Milford, MA, USA). Using a 5 μL loop, 0.75 μL injections were made for all samples in the study. The same volume of test mixture (rutin hydrate, caffeic acid, benzoic acid, *p*-coumaric acid, quercetin, L-phenylalanine, resveratrol, ferulic acid, L-tryptophan, sinapic acid, naringenin, *trans*-cinnamic acid, and isorhamnetin) (Sigma-Aldrich) was injected. All components of the test mixture were present at approximately 35 μg/mL in 60:40 acetonitrile/water v/v. All chromatographic separations

dx.doi.org/10.1021/jf502508y | J. Agric. Food Chem. 2014, 62, 9043−9055

were carried out on a 1 mm × 100 mm BEH C18 reverse phase column. The mobile phase was composed of LC-MS grade water with 0.1% formic acid (phase A) and LC-MS grade acetonitrile with 0.1% formic acid (phase B). The linear gradient consisted of six segments as follows: initial segment, 95% A, 5% B; 13:33 min, 25% A, 75% B; 13:53 min, 5% A, 95% B; 18:00 min, 5% A, 95% B; 18:01 min, 95% A, 5% B; and 20:00 min, 95% A, 5% B. The flow rate was 45.0 μL/min for all segments. The autosampler bed was maintained at 23 °C and the column at 35 °C. Samples were injected in a randomized fashion. Each sample was injected in triplicate with the exception of the test mixture which was injected after every six samples to evaluate the stability of retention time and mass accuracy over the duration of the experiment. Mass spectrometry data were collected over the duration of the LC ramp from 0 to 800 s. Mass-to-charge ratios ($m/z$) between 100 and 1500 were detected by electrospray ionization in positive ionization mode. A lockmass solution of dilute leucine enkephalin (LE) in acetonitrile/water (50:50 v/v) was introduced via the lockspray probe at 25 μL/min as directed by the MS manufacturer.

**Data Processing.** Mass spectrometry data were processed using Waters Markerlynx XS software. The UPLC-MS data were detected and noise-reduced in both the UPLC and MS domains such that only true analytical peaks were further processed by the software. Each peak was a feature that was identified using the chromatographic retention time from the chromatogram and $m/z$ of the positive molecular ion. The molecular ion adduct most commonly observed was $[M + H]^+$. No retention time correction was used as retention time stability was sufficient for UPLC. Quantification of peak intensity was done by integrating peaks with a mean retention time in the window of 100−800 s. The retention time window was selected on the basis of visual evaluation of chromatograms to exclude column void and washout. Features were tentatively assigned compound identities through matching $m/z$ against theoretical masses of compounds in the MetLin (http://metlin.scripps.edu/metabo_search_alt2.php) and KNApSAcK v1.200.3 (http://kanaya.naist.jp/KNApSAcK/) databases. Metabolites present in plant species with molecular masses within 6 ppm of the features were listed.

**Statistical Analysis.** The Multi-Experiment Viewer (MeV 4.7.4) software (http://www.tm4.org/mev/) was used for statistical analysis of the data. Samples for the biological replicates for each species were each injected three times for each species. The data was $\log_{10}$ transformed after adding $1 \times 10^{-12}$ to all data to remove zeros. The $\log_{10}$-transformed peak intensity data for all of the features were averaged for each of the species, and hierarchical clustering of the *Solanum* species was done using Euclidean distance. Additionally, one-way analysis of variance (ANOVA) was used to find features with variation between species at $p \leq 0.01$. Bonferroni correction was applied. The null hypothesis tested was that there were no differences between the mean peak intensities between species; the alternative hypothesis was that there were differences between species. The features with significant species variation were further analyzed. The untransformed peak intensity data for these features were averaged and further filtered as follows: (a) features with average peak intensity 100-fold increased in each of the wild species over *S. tuberosum* and with a minimum untransformed peak intensity of 10 in at least two wild species; (b) features with peak intensity data 100-fold increase in *S. tuberosum* over all of the wild species and with a minimal untransformed peak intensity of 10 in *S. tuberosum*.

## RESULTS AND DISCUSSION

**Comparative Analysis of Wild Species and *S. tuberosum*.** Studies have shown that the wild species *S. acroglossum*, *S. tarijense*, *S. chomatophilum*, *S. oplocense*, *S. paucisectum*, and *S. piurae* have CPB resistance.[17,18,23,24] These wild species along with *S. tuberosum* were grown in the field in the absence of the pesticide imidacloprid. CPB defoliation was observed on *S. tuberosum* in the absence (Figure 1a), but not in the presence, of imidacloprid (Figure 1b). The wild species showed low levels of defoliation in the field without imidacloprid (Figure 1c−h), which concurs with previous observations.[17,18,23,24] An objective of the study was to find metabolites that can be used as markers for screening CPB resistance in potato germplasm grown in greenhouses. Therefore, comparative analysis of foliar metabolites in *S. tuberosum* and the wild species was done with greenhouse-grown plants. The total ion chromatograph of extracted metabolites in positive ionization mode (Figure 2) and processed peak intensity data (Supporting Information Table S1) demonstrated metabolite variation between species.

The *Solanum* species were grouped using hierarchical clustering of all feature peak intensities from Table S1 (Figure

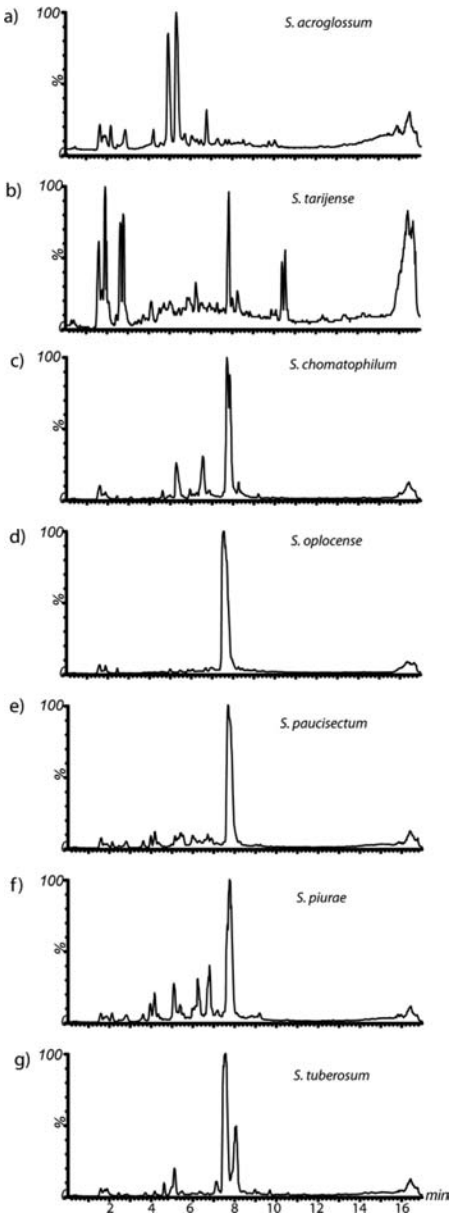

**Figure 2.** Total ion chromatograms for (a) *S. acroglossum* (4.87\307.1725), (b) *S. tarijense* (1.89\121.0636), (c) *S. chomatophilum* (7.56\1046.5571), (d) *S. oplocense* (7.56\1046.5571), (e) *S. paucisectum* (7.56\1046.5571), (f) *S. piurae* (7.77\578.4045), and (g) *S. tuberosum* (7.60\868.5004). The base peak features are given in parentheses. One hundred percent peak intensity for each was set at the intensity of the base peak. Each chromatogram is for a single representative sample for each species.

3). *S. tuberosum* was found to be the most distant from the other species. *S. chomatophilum* and *S. oplocense* were found to

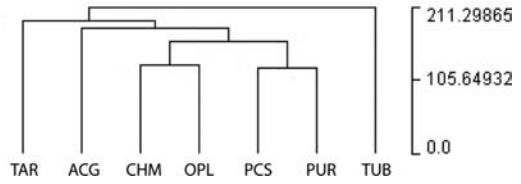

**Figure 3.** Hierarchical clustering of species based on metabolite profiles. TUB, *S. tuberosum* cv. Shepody; CHM *S. chomatophilum*; OPL, *S. oplocense*; PCS, *S. paucissectum*; PUR, *S. piurae*; ACG, *S. acroglossum*; TAR, *S. tarijense*. The scale is the Euclidean distance.

be closely related as were *S. paucisectum* and *S. piurae*. *S. acroglossum* and *S. tarijense* were more distant from these wild species. The results from hierarchical clustering were compared to published taxonomic groupings for species. All of the species studied were members of *Solanum* section Petota Dumortier, including *S. tuberosum*. Using morphological and genetic markers *S. piurae*, *S. acroglossum*, *S. paucisectum*, and, more recently *S. chomatophilum* were all placed in series Piurana.[25] Interestingly, our results showed that *S. acroglossum* did not cluster with the other three species on the basis of foliar metabolite profiles. *S. tarijense* has been recently found to be synonymous with *S. berthaultii*.[26] *S. tarijense* and *S. berthaultii* were designated as belonging to series Tuberosa III and Yungasensa by Hawkes. *S. oplocense* is part of the series Tuberosa, and more recently this species has been classified as belonging to the *S. brevicaule* complex, which encompasses some 20 species.[27] The clustering of metabolites places *S. oplocense* close to the Piurana species *S. chomatophilum* and, to a lesser extent, *S. paucisectum* and *S. piurae*. The results show that metabolite diversity occurs within a taxonomic grouping, and similarities occur between species described as more distantly related. Chemotaxonomic analysis of sapogenins from wild *Solanum* species also demonstrated clustering of species not found to be grouped together taxonomically.[28] Variability between accessions of the same species was also noted.

**Glycoalkaloid Variation between Species.** Features with $m/z$ corresponding to known glycoalkaloids found in *S. tuberosum* and other *Solanum* species[7−10] were identified from Table S1 and are listed in Table 1. The glycoalkaloid peaks in the chromatographic spectra were found at retention times between 7.00 and 8.50 min. The major peaks for *S. tuberosum*, *S. chomatophilum*, *S. oplocense*, *S. paucisectum*, and *S. piurae* were glycoalkaloids (Figure 2 and Table 1). *S. tarijense* and *S. acroglossum* had major peaks outside the range for glycoalkaloids (Figure 2) and lower levels of known glycoalkaloids (Table 1). *S. acroglossum*, in particular, did not have high peak intensity in the range between 7.00 and 8.50 min. The total peak intensity for all features across all species was similar (Table S1). The differences were in the distribution of peaks in the spectra (Figure 2).

The feature 8.05\852.514 had a $m/z$ that was a match with chaconine. 8.05\852.514 was barely detectable in the wild species but had high levels of production in *S. tuberosum*. Solanine, the other glycoalkaloid found in *S. tuberosum*, was a match with 7.60\868.5004 and had high peak intensity *S. tuberosum* but not the wild species (Table 1). These results were similar to those reported by others.[7,9] The assignment of chaconine and solanine was also verified using standards (data not shown). 7.60\868.5004 could also be assigned to $\beta$-solamarine, solamargine and leptinine I; however, these glycoalkloids were not found to be at high levels in *S. tuberosum* by others.[7,9] These glycoalkaloids could also be assigned to features 8.32\868.5086 and 7.96\868.5099, which were not found at high levels in *S. tuberosum*, consistent with published studies.[7,9] Feature 7.46\884.5049 had an $m/z$ that matched glycoalkaloids leptinine II, solasonine, and solamarine. Table 1 shows that 7.46\884.5049 was found at high levels in *S. tuberosum*, which was not consistent with published information showing that these glycoalkaloids were not found in *S. tuberosum*.[8] An alternative explanation is that 7.46\884.5049 is the $[M + CH_3OH + H]^+$ molecular ion adduct of chaconine (theoretical mass of 884.5366), which can form in positive ionization mode in ESI. Assignment of the feature to the $[M + CH_3OH + H]^+$ adduct would concur with the high levels in *S. tuberosum* observed for 7.46\884.5049. *S. oplocense* had the next highest intensity for 7.46\884.5049 followed by four other wild species at lower levels (Table 1).

The remaining glycoalkloids in Table 1 were all not detectable in *S. tuberosum* but were produced in wild species. Feature 7.56\1046.5571 was found in the largest number of wild species (four) and was assigned to the glycoalkaloid dehydrocommersonine, which had been previously characterized from *S. oplocense*.[29−31] The peak intensity for dehydrocommersonine was highest in *S. oplocense* and was the highest peak intensity of all the features in any species. High levels were also found in *S. paucisectum*, *S. chomatophilum*, and *S. piurae*. Feature 7.94\1034.5581 was assigned to tomatine, which is a tomato glycoalkaloid associated with CPB resistance.[11] It was detectable in *S. piurae* at lower levels than dehydrocommersonine and was at very low levels in *S. chomatophilum*. Removal of the xylose sugar converts tomatine to $\beta$-tomatine. The feature 7.80\902.5148 had a $m/z$ matching $\beta$-tomatine and, like tomatine, was also found in *S. piurae* and *S. chomatophilum*. The feature 7.73\1064.568 was assigned to the glycoalkloid neotomatine, which had highest levels in *S. piurae* followed by *S. chomatophilum* and very low detection in *S. paucisectum*. 7.72\1016.5479 was assigned to dehydrodemissine, which was previously described in *Solanum commeronii* Dun ex. Poir.[32] Dehydrodemissine was found in *S. piurae* at levels over 300-fold lower than dehydrocommersonine. 8.01\1018.5629 and 6.92\1032.5429 were assigned to glycoalkaloids demissine and dehydrotomatine, respectively. These glycoalkloids had very low peak intensities.

The chemical structures of chaconine and solanine were compared with glycoalkaloids from the wild species. Figure 4 shows that the glycoalkaloids found in *S. tuberosum* had triose sugar side chains compared to wild species, where there were tetrose side chains. The results suggest that the larger tetrose side chain glycoalkaloids were associated with resistance to CPB. These findings correlate with studies showing that CPB has a preference for potato over tomato, which produces the tetrose glycoalkaloid tomatine.[33] Other studies have shown that decreasing the sugar side chain on glycoalkaloids reduces their toxicity[34] and capacity to disrupt membranes.[35]

**Non-glycoalkaloid Metabolites Associated with CPB Resistance.** Previous studies on *S. berthaultii* have demonstrated that resistance was associated with glandular trichomes.[16] However, it was also observed that CPB feeding remains low in *S. tarijense* after the mechanical removal of trichomes, indicating that there are other components of the leaf involved in resistance.[36] Our observations indicate that *S.*

[a]Metabolites with $m/z$ matching with known glycoalkaloids are shown. The feature ID is the retention time\$m/z$ combination. Compounds in the MetLin database that matched the $m/z$ are listed along with their molecular formulas and theoretical mass of the $[M + H]^+$ molecular ion. Differences between $m/z$ of the feature and theoretical masses of matching compounds are indicated as Δ ppm. TUB, *S. tuberosum* cv. Shepody; CHM, *S. chomatophilum*; OPL, *S. oplocense*; PCS, *S. paucissectum*; PUR,*S. piurae*; ACG, *S. acroglossum*; TAR, *S. tarijense*. The average Markerlynx processed peak intensity across the replicates for each species is presented. [b]Theoretical mass is for the $[M + H]^+$ molecular ion unless otherwise indicated. [c]Theoretical mass is for the $[M + CH_3OH + H]^+$ molecular ion.

dx.doi.org/10.1021/jf502508y | J. Agric. Food Chem. 2014, 62, 9043−9055

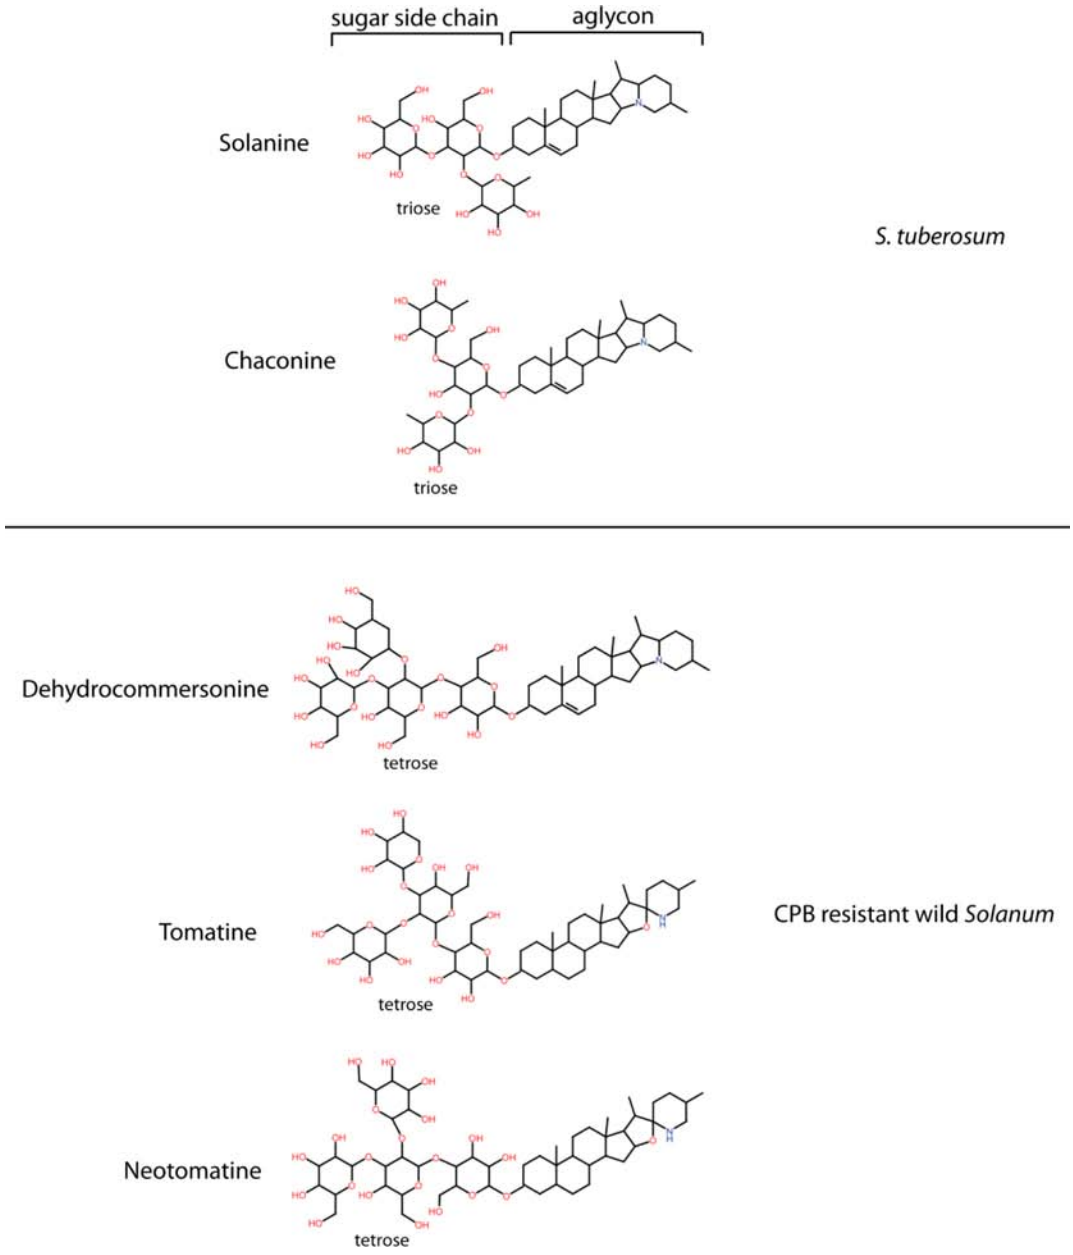

**Figure 4.** Chemical structures of glycoalkaloids. Chaconine and solanine were produced in *S. tuberosum*; dehydrocommersonine, tomatine, and neotomatine were produced in the CPB-resistant wild *Solanum* species. Triose and tetrose sugar side chains are indicated.

*acroglossum* did not have trichomes, which agrees with previous descriptions of the species as glabrous.[37] Hence, resistance in *S. acroglossum* is not associated with high levels of either glycoalkaloids or trichomes. An analysis of foliar metabolites shared between the wild species in the study but not *S. tuberosum* was done to identify non-glycoalkaloid and non-trichome metabolites associated with resistance to CPB. An ANOVA analysis was done to find features with significant variation between the species. Eight hundred and sixty-seven features had significant variation in peak intensity between the species (see Supporting Information Table S2). The 867 features were screened to identify features with peak intensities 100 times increased over *S. tuberosum* for all of the wild species (Table 2). Additionally, features had to have untransformed peak intensities of at least 10 in two of the wild species. The criteria were used to select for features highly associated with CPB resistance and to eliminate features that were produced at very low levels or only in a single wild species. Features 3.60\163.0387 and 4.02\163.0393 had an $m/z$ that was matched to hydroxycoumarin. This feature was present in all of the wild species. There are six isomers of hydroxycoumarin, each with the hydroxyl group in a different position. 7-Hydroxycoumarin or umbelliferone is a precursor to other coumarins, including bergamottin, which is ovicidal to CPB.[38] 4-Hydroxycoumarin itself can act as a blood anticoagulant in humans but is often used as a precursor for synthesis of more powerful anticoagulants such as warfarin.[39] Derivatives of 4-hydroxycoumarin also have larvicidal activity against *Aedes aegyti*.[40] Hydroxycoumarin produced in the wild species may directly affect CPB or may be a common precursor to other metabolites that are antifeedants.

5.80\319.0417 was assigned to 3-deoxy-D-*manno*-octulosonate 8-phosphate (KDOP). Plants synthesize KDOP for polysaccharide cross-links of pectin.[41] KDOP is a precursor

[a]The feature ID is the retention time\$m/z$ combination. Compounds in the MetLin database that matched the $m/z$ are listed along with their molecular formulas and theoretical mass of the $[M + H]^+$ molecular ion. Differences between $m/z$ of the feature and theoretical masses of matching compounds are indicated as Δ ppm. TUB, *S. tuberosum* cv. Shepody; CHM, *S. chomatophilum*; OPL, *S. oplocense*; PCS, *S. paucissectum*; PUR, *S. piurae*; ACG, *S. acroglossum*; TAR, *S. tarijense*. The average MarkerLynx processed peak intensity across the replicates for each species is presented.

for KDO, which is component of rhamnogalactouronan II, a borate-binding cross-linked component of pectin in cell walls.[42] *S. acroglossum* and *S. oplocense* produce the highest levels of KDOP among the species. The results suggest that these two species may have altered cell wall structures.

7.81\400.3566 was assigned to demissidine, a glycoalkaloid aglycon; additionally, the feature could also be assigned to veramiline, an alkaloid with the same chemical formula. The levels were highest in *S. chomatophilum* and *S. piurae*. Demissidine could be a fragment ion of the glycocoalkaloid demissine, which was detected in *S. chomatophilum* and *S. paucisectum* at low levels (Table 1). Demissine is the major glycoalkloid of *Solanum demissum* Lindl., another species with resistance to CPB, and is an antifeedant for CPB.[43] However, the feature identified as demissine, 8.01\1018.5629, had a retention time slower than 7.81\400.3566, which is inconsistent with a parent molecular ion for a demissidine aglycon fragment ion. It is possible that demissidine serves as an aglycon to an unknown glycoalkaloid.

Tomatidine and soladucidine were aglycons that were both assigned to 7.78\416.3512. Tomatine, a glycoalkaloid with a tomatidine aglycon, was identified as feature 7.94\1034.5581 (Table 1). However, 7.94\1034.5581 had a slower retention time than 7.78\416.3512, indicating that 7.78\416.3512 was unlikely a fragment ion. Alternatively, 7.78\416.3512 may be the aglycon of an unknown glycoalkaloid. It is also possible that 7.78\416.3512 is an unknown non-glycoalkaloid metabolite with a mass similar to that of tomatidine and soladucidine.

7.83\459.2213 was assigned to marioside, a norcarotane sesquiterpene glucoside found in ferns.[44] This metabolite had high peak intensity in *S. tarijense*. There is very little information on the biological functions of marioside. 7.84\145.0502 and 4.84\177.0546 were assigned to multiple metabolites that were not previously associated with plant insect interactions.

5.99\933.2699 had highest peak intensity in *S. piurae* followed by *S. acroglossum*. 5.99\933.2699 had a large number of $m/z$ matches in the chemical databases. Chief among these metabolites were anthocyanins and other flavonoid glycosides in the phenylpropanoid biosynthetic pathway. 3.61\251.1384 was assigned to the polyamine-conjugated phenylpropanoid, caffeyolputrescine, in addition to other metabolites. Phenylpropanoids have been noted for their role in plant defense against pathogens, herbivores, and environmental stress. The loss of flavonoids in tomatoes was associated with increased herbivory by coleopterans.[45] Increased expression of phenylpropanoid biosynthetic enzyme genes were also noted with CPB herbivory.[46] The results of the current study demonstrate that phenylpropanoids were increased in CPB-resistant wild species. Flavonoids also have health benefits for humans,[47] as opposed to glycoalkaloids that are toxic.[5]

Several of the features in Table 2 were unknowns with no metabolites in the MetLin and KNApSAcK databases with matching masses.

**Metabolites Increased in *S. tuberosum*.** The metabolites with increased levels in *S. tuberosum* relative to the wild species would not be associated with CPB resistance. Metabolites highly enriched in *S. tuberosum* over each of the wild species were screened by selecting features with 100-fold increased peak intensity in *S. tuberosum* over each of the wild species (Table 3). Features with $m/z$ matching chaconine and solanine, the two major glycoalkaloids for *S. tuberosum*,[8] were found, which concurs with the analysis of glycoalkloids (Table 1).

**Table 3. Metabolites Increased in *S. tuberosum* over All Wild Species[a]**

dx.doi.org/10.1021/jf502508y | J. Agric. Food Chem. 2014, 62, 9043−9055

Metabolites from other organisms that had the same $m/z$ as solanine, chaconine, and solanidine that were found in the MetLin database are also shown in Table 3. These metabolites are less likely to occur in *S. tuberosum*.

Feature 11.34\411.0882 had a $m/z$ that matched to newbouldiaquinone A, a metabolite from the medicinal plant *Newbouldia laevis* that is a naphthoquinone−anthroquinone coupled pigment.[48] 11.34\587.2077 was matched with blestrianol C, a biphenanthrene isolated from the tubers of the orchid *Bletillla striata*.[49] Alternatively, the latter two features may be derived from the same unknown metabolite as they share the same retention time, indicating that 11.34\411.0882 could be a fragment ion of 11.34\587.2077. 9.14\867.479 and 10.54\885.4881 were assigned to several metabolites with structures corresponding to steroidal glycoside saponins.[50] 11.34\411.0882, 11.34\587.2077, 9.14\867.479, and 10.54\885.4881 were found at lower levels in *S. tuberosum* compared with glycoalkaloids.

In summary, the comparative analysis of wild species with CPB resistance against CPB-susceptible *S. tuberosum* done in this study has resulted in the identification of several metabolites correlated with resistance. Glycoalkaloids solanine and chaconine were found to be unique to *S. tuberosum*, whereas glycoalkaloids with tetrose side chains dehydrocommersonine, tomatine, and neotomatine were associated with CPB-resistant species *S. oplocense*, *S. paucisectum*, *S. chomatophilum*, and *S. piurae*. This study has added to the evidence that tetrose side chain glycoalklaoids are associated with CPB resistance. The results can also be applied to the development of selection methods for CPB-resistant breeding material derived from intercrosses of *S. tuberosum* with species enriched in tetrose glycoalkaloids. For example, a high ratio of tetrose glycoalkaloids to solanine and/or chaconine can be used to select for CPB resistance. Non-glycoalkaloids hydroxycoumarin and phenylpropanoid metabolites were also found increased in all wild species and have also application as markers for CPB resistance.

automated, dynamic in-syringe liquid-phase microextraction, which was more efficient for extracting pesticides from water samples.[28] Several studies have employed low-density solvents as substitutes for toxic halogenated solvents. These developments widened the selection of solvents available for DLLME and extended its application.[17,29−34]

Ultrasound-assisted emulsification microextraction (USAEME) for DLLME has also been developed to improve the generation of droplets with or without using dispersive solvent.[34−38] Another alternative to ultrasound assistance is the use of surfactants. As some surfactants are just soluble in an organic solvent and some are just water-soluble, their presence improves the generation of fine droplets in DLLME.[39−41] However, high concentrations of surfactants are generally required to disperse the extraction solvents. Water with a low concentration of surfactant in dispersed solvent-assisted emulsion dispersive liquid−liquid microextraction (WLSSAE-DLLME) was developed recently,[42,43] which used in combination with an improved solvent collection system (ISCS) avoids the problems associated with DLLME to analyze water samples.[33]

In the present study, WLSSAE coupled with gas chromatography−mass spectrometry (GC-MS) was developed to analyze six fungicides in wine samples. The accuracy, precision, linearity, enrichment factor (EF), and LOD of WLSSAE in the analysis of wine samples were evaluated and tested.

## MATERIALS AND METHODS

**Reagents and Samples.** All solvents and chemicals used in the study were of analytical grade. Cyprodinil (CYP), procymidone (PRC), fludioxonil (FLD), flusilazole (FLU), benalaxyl (BEN), tebuconazole (TEB), anthracene-$d_{10}$ (ANT-$d_{10}$; internal standard), 1-heptanol, 1-octanol, 1-nonanol, Triton X-114, Triton X-100, Tween 80, and Tween 60 were purchased from Sigma-Aldrich (St. Louis, MO, USA). Methanol (liquid chromatography (LC)-MS grade) was obtained from J. T. Baker (Phillipsburg, NJ, USA). Acetone (LC grade) and sodium chloride were purchased from Merck (Darmstadt, Germany). Deionized water (DI water) was obtained by using a Milli-Q reagent water system (Millipore, Milford, MA, USA).

Stock solutions of each fungicide and of ANT-$d_{10}$ were prepared by dissolving each in methanol to obtain a 1000 mg $L^{-1}$ solution, which was then stored at 4 °C. Standard working solutions and ANT-$d_{10}$ solution were prepared by diluting each stock solution with methanol to 10 mg $L^{-1}$. Each sample solution was prepared by spiking pure water with 10 and 5 $\mu$g $L^{-1}$ fungicide and ANT-$d_{10}$. Two kinds of white wine and one kind of red wine made in California (USA) were purchased from a local supermarket (Hsinchu, Taiwan). All wine samples contained 12% alcohol. The samples were filtered through 0.45 $\mu$m membrane filters from Millipore (Bedford, MA, USA) and then stored at 4 °C overnight before analysis.

**Instrumentation.** To separate the aqueous and organic phases, microtubes that were designed in-house (15 × 3 mm; inner diameter, 1.8 mm; total volume, 38 $\mu$L; Qing-Fa Co., Hsinchu, Taiwan) were used in the ISCS system. A CN-2200 centrifuge (Hsiantai Machinery Industry, Taipei, Taiwan) and a miVac DUC-12060-C00 centrifuge (Stockholm, Sweden) were used in the study.

Analyses were carried out by using a 6850 Agilent Technologies gas chromatograph (Wilmington, DE, USA) with a split/splitless injector operated at 300 °C and a single quadrupole (Agilent Technologies mass detector 5975B). The splitless time was 1 min. The flow rate of helium was 1.0 mL $min^{-1}$. A 30 m DB-5MS UI-fused silica capillary column (0.25 mm i.d., 0.25 $\mu$m film thickness; J&W Scientific, Folsom, CA, USA) was employed in the determination of fungicides. The temperature of the column was initially held at 100 °C, raised to 250 °C at 35 °C $min^{-1}$, held at 250 °C for 3 min, raised to 300 °C at 10 °C $min^{-1}$, and then held at 300 °C for 1 min. The carrier gas was helium (purity = 99.9995%), which was further purified by passage through a helium gas purifier (Agilent Technologies model RMSH-2). The temperature of the GC-MS transfer line was 280 °C, 230 °C for ion source, and 150 °C for quadrupoles. A mass detector in the electron impact mode (70 eV) was used. Spectra were scanned over the $m/z$ range of 50−400 to confirm the retention times of the analytes. Selected ion monitoring mode (SIM) was applied for the determination of fungicides. In the determination of fungicides, two or three ions were selected in Table 1.

**Table 1. Retention Time and $m/z$ Values Selected for SIM Mass Detection**

| compd | retention time (min) | selected ions ($m/z$) |
|---|---|---|
| ANT-$d_{10}$ | 4.96 | 187, 188, and 189 |
| CYP | 5.87 | 210, 214, and 225 |
| PRC | 6.07 | 96, 283, and 285 |
| FLD | 6.61 | 182 and 248 |
| FLU | 6.76 | 206, 233, and 234 |
| BEN | 7.78 | 91, 148, and 206 |
| TEB | 8.22 | 120, 250, and 252 |

**Extraction Procedure.** A diagram of the WLSSAE procedure is shown in our previously published work.[42] A 5 mL portion of the blank white wine and DI water (1:1, v/v) spiked with analytes at 5 $\mu$g $L^{-1}$ were transferred to a 10 mL conical-bottom glass centrifuge tube. A mixture of 12 $\mu$L of extraction solvent (1-octanol) and 240 $\mu$L of water containing 10 mg $L^{-1}$ Triton X-100 (dispersed solvent) was transferred to an Eppendorf tube. A 500 $\mu$L syringe (Reno, NV, USA) was used to pump the mixture back and forth four times within 10 s, and then a cloudy emulsion was formed. This emulsion was then injected into the sample solution. After centrifugation for 5 min at 5000 rpm, an organic droplet formed on the surface of the solution. The phase separation after DLLME of white and red wines is also shown in ref [44]. The floating phase, which had a volume of approximately 3.0 ± 0.5 $\mu$L, was hard to withdraw into a microsyringe. Therefore, the mixture of the floating phase and aqueous solution was first transferred to a in-house-designed microtube (15 × 3 mm). After centrifugation for 1 min, the organic phase was collected from the upper portion of the microtube by using a 10 $\mu$L microsyringe and then injected into the GC-MS system. The ambient temperature was 25 °C.

## RESULTS AND DISCUSSION

**Impact of Solvent on Extraction Efficiency.** The selection of extraction solvent is important in maximizing the extraction efficiency. The solvents should be immiscible with

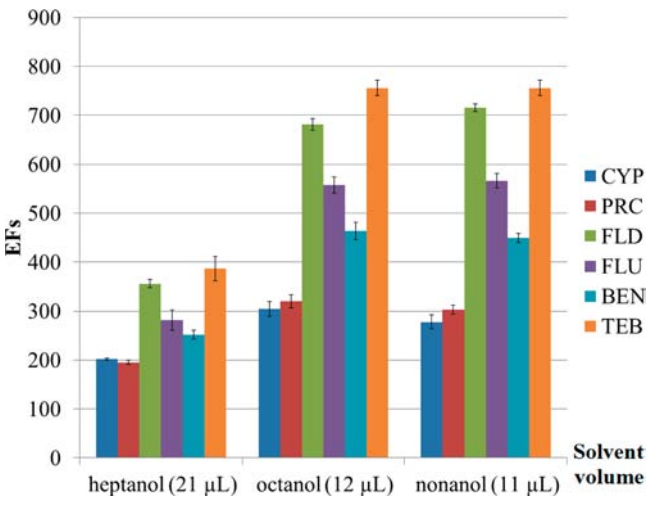

**Figure 1.** Effect of the type of extraction solvent ($n$ = 3). Samples were spiked with 5 $\mu$g $L^{-1}$ of each analyte. Extraction conditions: dispersed solvent volume, 240 $\mu$L; surfactant, 1 mg $L^{-1}$ Triton X-100.

dx.doi.org/10.1021/jf5036096 | J. Agric. Food Chem. 2014, 62, 9059−9065

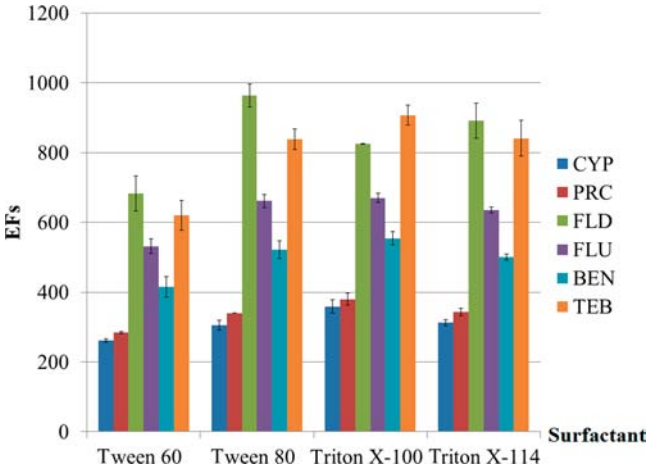

**Figure 2.** Effect of the type of surfactant for the first extraction solvent ($n$ = 3). Samples were spiked with 5 $\mu$g $L^{-1}$ of each analyte. Extraction conditions: extraction solvent, 1-octanol; volume, 12 $\mu$L; dispersed solvent volume, 240 $\mu$L; concentration of the surfactant, 1 mg $L^{-1}$.

water and have low toxicity, and analytes should be highly soluble in such solvents. To apply the above conditions, alcohols 1-heptanol, 1-octanol, and 1-nonanol were tested. To consistently collect 3.0 $\mu$L of the floating organic phase, various amounts of extraction solvent (21 $\mu$L of 1-heptanol, 12 $\mu$L of 1-octanol, and 11 $\mu$L of 1-nonanol) had to be combined with 240 $\mu$L of Triton X-100 (1 mg $L^{-1}$) in a microsyringe.[43] The mixture was subsequently injected into the sample solution. The results are shown in Figure 1. The experiment revealed that 1-octanol had better EFs than those of the other solvents; it was thus chosen as the extraction solvent for use in subsequent experiments.

**Type of Surfactant.** The selection of surfactant is crucial to the success of the proposed method. As surfactants are soluble in the extraction solvent and in water, they are commonly used to improve the dispersion of extraction solvents. A surfactant with high hydrophilic−lipophilic balance (HLB) has higher hydrophilicity. When the HLB value of a surfactant is between 12 and 16, the surfactant is considered as an oil-in-water emulsifier. Two kinds of well-known polyoxyethylene-type nonionic surfactants, Tween and Triton (Figure 2), were studied. The HLBs of Tween 60, Tween 80, Triton X-100, and Triton X-114 are 14.9, 15.0, 13.4, and 12.3, respectively. Compared with other surfactants, using Triton-X-100 resulted in higher EFs for five of six compounds, especially for BEN and TEB, which had lower extraction efficiency. On the basis of the experimental results, Triton X-100, which had better extraction efficiency and precision for most fungicides, was selected as the dispersed solvent.

**Volume of Extraction Solvent.** Different volumes of the extraction solvent (12, 14, 16, and 18 $\mu$L) were tested. When the solvent volume was <12 $\mu$L, the amount of organic phase was insufficient for analysis. As the volume of the extraction solvent increased, the volume of the floating phase increased accordingly. This resulted in dilution of the extractants. The EFs were maximal when the solvent volume was 12 $\mu$L. Hence, 12 $\mu$L was selected as the volume of extraction solvent.

**Concentration of Surfactant.** The concentration of surfactant in aqueous solution plays an important role in effective extraction. The influence of the Triton X-100 concentration was investigated by studying the results obtained with concentrations of 1, 5, 10, and 50 mg $L^{-1}$. At >50 mg $L^{-1}$ surfactant, the solution was still an emulsion after centrifugation. The floating phase could not be collected. Therefore, the maximum concentration of surfactant used was 50 mg $L^{-1}$. When the concentration of

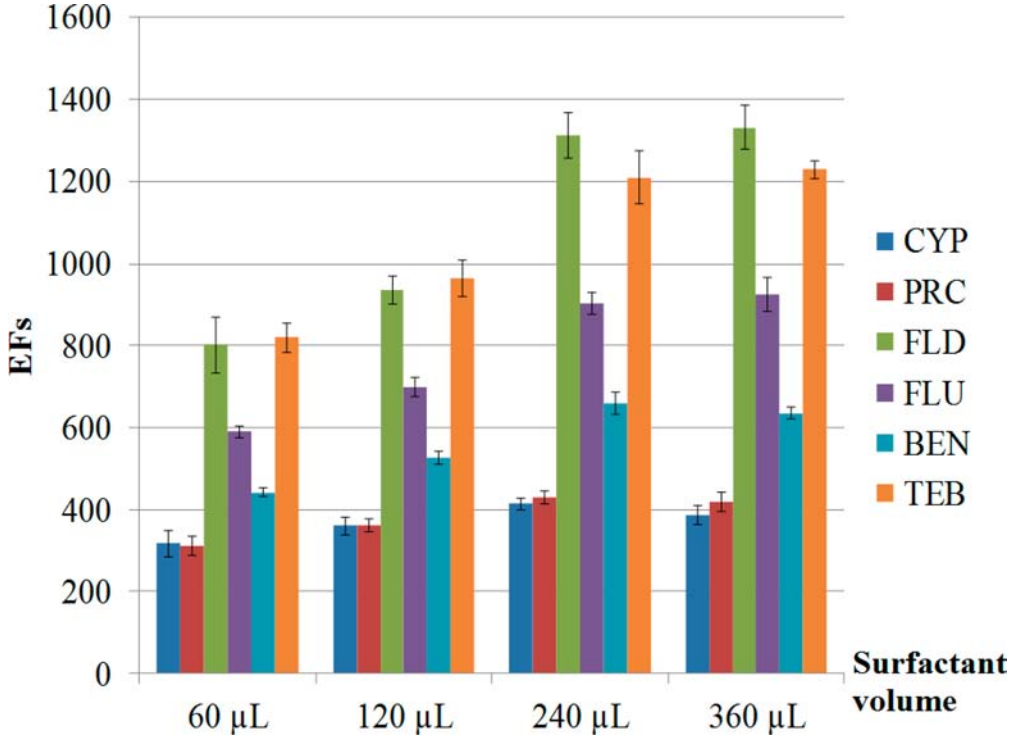

**Figure 3.** Effect of the volume of the surfactant ($n$ = 3). Samples were spiked with 5 $\mu$g $L^{-1}$ of each analyte. Extraction conditions: extraction solvent, 1-octanol; volume, 12 $\mu$L; dispersed solvent, Triton X-100; concentration, 10 mg $L^{-1}$.

[a]Blank white and red wine samples spiked with 0.05, 0.1, 0.5, 1, 5, 10, 50, and 100 $\mu$g L$^{-1}$. [b]Blank white and red wine samples spiked with 5 $\mu$g L$^{-1}$, $n$ = 3. [c]LODs were determined as 3 times the standard deviation obtained from seven replicate runs of blank white wine samples spiked with 0.1 $\mu$g L$^{-1}$ of each fungicide. [d]LOQs were determined as 10 times the standard deviation obtained from seven replicate runs of blank white and red wine samples spiked with 0.1 $\mu$g L$^{-1}$ of each fungicide. [e]Blank wine samples were spiked with 0.5 $\mu$g L$^{-1}$.

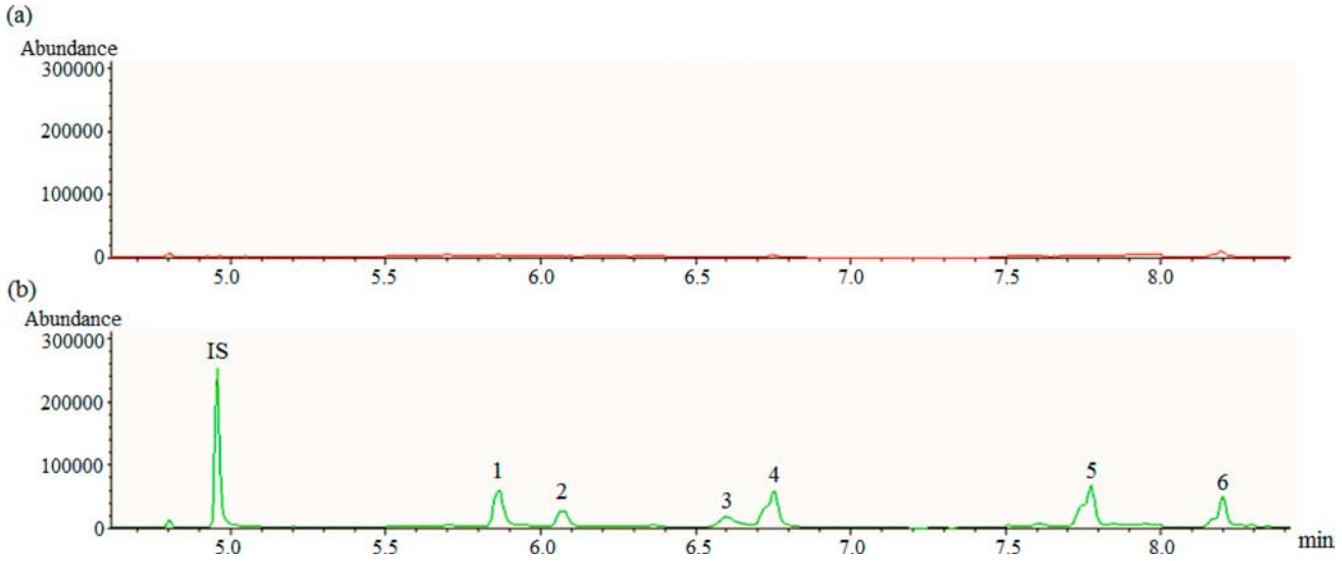

**Figure 4.** GC-MS selected ion chromatograms for the analysis of (a) white wine sample and (b) sample spiked with 5 $\mu$g L$^{-1}$ fungicides: IS, ANT-$d_{10}$; 1, CYP; 2, PRC; 3, FLD; 4, FLU; 5, BEN; 6, TEB.

surfactant in the aqueous solution was increased from 0 to 10 mg L$^{-1}$, the extraction EF was significantly improved. However, EFs declined slightly upon spiking with >10 mg L$^{-1}$ Triton X-100. Evidently, higher concentrations of Triton X-100 increased the solubility of analytes in the aqueous solutions, resulting in lower EFs. The optimal surfactant concentration in the aqueous solution was therefore 10 mg L$^{-1}$.

**Volume of the Surfactant Solution.** To investigate the impact of the volume of the aqueous solution, different volumes of aqueous solution (60, 120, 240, and 360 $\mu$L) containing 10 mg L$^{-1}$ Triton X-100 were evaluated (Figure 3). When the volume of aqueous solution was changed from 60 to 240 $\mu$L, the EFs were increased. On the other hand, the EFs decreased when the volume of aqueous solution was increased from 240 to 360 $\mu$L. Therefore, the volume of aqueous solution was fixed at 240 $\mu$L. The surfactant concentration was approximately equivalent to 0.48 mg L$^{-1}$ in the total volume (5 mL) of the sample solution.

**Quantitative Aspects.** The linearity obtained by using 12 $\mu$L of 1-octanol was evaluated under optimum conditions. Calibration curves were constructed by analyzing solutions of white and red wines with DI water (1:1, v/v) at concentrations of 0.05, 0.1, 0.5, 1, 5, 10, 50, and 100 $\mu$g L$^{-1}$. Curves for all fungicides have coefficients of determination ($R^2$) >0.9977. Data on the linear range (LR), $R^2$, LOD, limit of quantification (LOQ), precision (as relative standard deviation, RSD), and EF are summarized in Table 2. $R^2$ values of the calibration curves are in the range of 0.9977−0.9999, indicating high linearity within the concentration range used for each analyte. The LODs were calculated as 3 times the standard deviation of seven replicate runs of blank white and red wines spiked with low concentrations of the analytes. LODs for determination of fungicides in the blank wine samples differed substantially and ranged from 0.013 to 0.155 $\mu$g L$^{-1}$. Intra- and interday RSDs for determination of the analytes ranged from 0.9 to 12.7% and from 3.4 to 14.1%, respectively.

**Application in the Analysis of Wine Samples.** To demonstrate the capability of WLSSAE, the procedure was applied to the analysis of fungicides in white wine and red wine samples. The results show that the analyzed samples were free of fungicides (Figure 4). FLU, BEN, and TEB have a broad shoulder (Figure 4b), which might result from the surfactant partially extracted into the 1-octanol phase or from matrix effect of the samples. The wine samples were spiked with the analytes at 0.5, 5, and 50 $\mu$g L$^{-1}$ levels. The absolute recovery (AR) was defined as the percentage of the total analyte ($n_0$) that was extracted into the floating organic phase ($n_{org}$).

$$AR = n_{org}/n_0 \times 100$$

[a]Solid phase extraction/liquid chromatography quadrupole time-of-flight tandem mass spectrometry. [b]Bar adsorptive microextraction combined with liquid desorption/gas chromatography−mass spectrometry. [c]Dispersive liquid−liquid microextraction based on solidification of floating organic drop/gas chromatography−mass spectrometry. [d]Ultrasound-assisted surfactant-enhanced emulsification microextraction/high-performance liquid chromatography with diode array detection. [e]Water with low concentration of surfactant in dispersed solvent-assisted emulsion dispersive liquid−liquid microextraction.

ARs were between 30 and 83% for white wine and between 30 and 92% for red wine. The relative recovery (RR) is defined by the following equation:

$$RR = [(C_{found} - C_{real})/C_{added}] \times 100$$

$C_{found}$, $C_{real}$, and $C_{added}$ are defined as the concentration of analyte after addition of a known amount of standard in the real sample, the concentration of analyte in the real sample, and the concentration of known amount of standard that was spiked to the real sample, respectively. RRs were between 81 and 108% for white wine and between 81 and 110% for red wine. RSDs for the determination of the analytes ranged from 1.0 to 8.9% for white wine and from 1.0 to 7.2% for red wine (Table 3). This shows that after the wine samples were diluted with DI water there was no significant matrix effect using WLSSAE.

In Table 4, the performance of WLSSAE is compared with that of other extraction techniques for the determination of fungicides in wine. The results indicate that the proposed method is sensitive and applicable to the analysis of fungicides at trace levels. The method requires a very short extraction time (a few seconds) and 12 $\mu$L of extraction solvent only, in contrast to other methods.

To extract fungicides from wine samples through the ISCS technique, 0.48 mg L$^{-1}$ of surfactants was required in using water with low concentration of surfactant as dispersed solvent. The results suggest that high EFs were achieved in a few seconds. The approach afforded high repeatability and high recovery within a short extraction time. WLSSAE employed a few microliters of low-toxicity, halogen-free organic solvents to extract fungicides in wine samples. The analysis had a wide linear range and low LODs, as well as high precision, EFs, and RRs. The LODs were much lower than the tolerance of procymidone in wine prescribed by the FDA.[16] The method is a desirable application for the separation and preconcentration of fungicides at trace levels in wine samples.

enantiomeric proportion of various enantiomeric compositions thus far. Moreover, microorganisms in soils are considered as the main cause of enantioselective processes,[25−28] and enantiomeric degradation constantly changes due to soils with different microbial communities. Our study systematically investigated the selective degradations of two enantiomers in indoxacarb concentrate (2.33S/1R) and in its racemate (1S/1R) in five soils to determine the differences between the racemate and concentrate with respect to enantiomer degradation (In this article, mixtures of the two enantiomers enriched with the S-enantiomer (S/R = 2.33:1) are called concentrate). We also investigated the degradation of pure *R*-indoxacarb and pure *S*-indoxacarb applied to five soils. The steric configuration of *S*-(+)-indoxacarb and *R*-(−)-indoxacarb was first confirmed here by X-ray diffraction. The results provide new aspects of the enantioselective behavior of indoxacarb, which should be considered to achieve better understanding of the profiles and fate of chiral pesticides in the environment.

## MATERIALS AND METHODS

**Chemicals and Reagents.** The analytical standard of racemic indoxacarb was purchased from Dr. Ehrenstorfer GmbH. Indoxacarb powder enriched with the *S*-enantiomer (2.33S/1R, 97.3% purity) was provided by Yancheng Limin Agrochemical Co., Ltd. (Jiangsu, China). The two indoxacarb enantiomers were prepared by semipreparative high-performance liquid chromatography (HPLC) in our laboratory.[29] HPLC-grade *n*-hexane and isopropanol (IPA) were purchased from Jiangsu Hanbang Science and Technology Co., Ltd. (Jiangsu, China). All other chemicals and solvents used were of analytical grade and purchased from commercial sources.

**Single-Crystal X-ray Investigation of Enantiopure *S*-Indoxacarb and Enantiopure *R*-Indoxacarb.** The stereochemical configuration was determined using X-ray diffraction. Diffraction patterns were obtained at 293 K with a Bruker SMART II diffractometer using Mo-K$\alpha$ radiation ($\lambda$ = 0.71073 Å) under $\varphi-\omega$ scan. Empirical absorption correction (SADABS) was applied to raw intensities. The structures were determined by direct methods (SHELXS-97) and refined by full matrix least-squares procedures on $F^2$ in the anisotropic approximation for all of the atoms except hydrogen. The absolute configurations were determined by anomalous dispersion effects and corresponding calculations of Flack's absolute structure parameters.[30]

**Soil Samples.** Five soil samples representing different physicochemical properties and climatic environments were collected at 0 to 10 cm plow layer from geographically distinct regions of China (Haozhou city, Anhui Province, Northern China; Guiyang City, Guizhou Province, Southwest China; Jilin city, Jilin Province, Northern China; Hangzhou city, Zhejiang Province, Southeastern China; and Haikou City, Hainan Province, Southern China). No indoxacarb was found at detectable levels in soils. After collection, the soil samples were air-dried at room temperature, homogenized, passed through a 2 mm sieve, and then stored in the dark until use within a few days. Details about soil sites and specific physicochemical characteristics (particle size, texture, pH, and organic carbon) are presented in Table1.

**Incubation of Indoxacarb Concentrate (2.33S/1R) and Racemate (1S/1R) in Soils.** Separate incubation experiments with indoxacarb concentrate and with racemate compounds in five soils were conducted in 50 mL of polypropylene centrifuge tubes covered with aluminum foil. Before pesticide treatment, the soils were preincubated in the dark at 25 ± 2 °C for 7 days to activate the soil microorganisms. The soil sample (5.0 g, dry weight equivalent) was treated with 50 $\mu$g of indoxacarb (50 $\mu$L 1000 $\mu$g/mL stock solution in acetone) and then air-dried for 30 min before homogenization. The soil samples were then rehydrated by adding 1.2 mL of purified water [approximately 60% of the field holding capacity (w/w)] and incubated at 25 °C in the dark. The samples were weighed regularly, and purified water was added to the samples to compensate for water loss during the entire experiment. Triplicate samples were removed from each treatment at different time intervals (0, 1, 3, 5, 7, 10, 14, 21, 33, and 51 d) and immediately transferred into a freezer (−20 °C).

**Incubation of Enantiopure *R*-(−)- and *S*-(+)-Indoxacarb.** Separation of the two pure indoxacarb enantiomers is necessary to understand the differences in their dissipation behaviors and detect potential enantiomerization of indoxacarb. Separate incubations were conducted with the enantiopure *R*-(−)- and *S*-(+)-indoxacarb in five soils. The tested soils were fortified with the pure enantiomers at the 10 $\mu$g/g level and incubated in the same way as the other soil experiments.

**Incubation of Indoxacarb Racemate (1S/1R) or Concentrate (2.33S/1R) in Soils under Sterilized Conditions.** To determine whether the enantioselective degradation was a result of microbially mediated transformations, portions of the 5.0 g soil set in 50 mL polypropylene centrifuge tubes were sterilized with the use of an autoclave (twice) at 121 °C for 40 min with 24 h intervals to eliminate microbial activity. In a biologically clean workbench, the sterilized samples were treated with 50 $\mu$g of indoxacarb racemate or concentrate (50 $\mu$L of a 1000 $\mu$g/mL stock solution in acetone). After eliminating the acetone by air-drying for 20 min, 1.2 mL of sterile water was added to the samples. The samples were then sealed with a stopper and membrane to maintain sterile conditions. The samples were incubated at 25 °C in the dark. Three or two replicate samples were removed from each treatment at different time intervals (0, 5, 10, 20, 40, 60, and 93 d) and immediately transferred to a freezer (−20 °C).

**Extraction of Soil Samples.** Three replicate samples were removed from each treatment at different time intervals after pesticide addition and immediately transferred into a freezer (−20 °C) to stop dissipation. For extraction, 25 mL of methanol/water (6:4, v/v) was added into a 50 mL polypropylene centrifuge tube containing 5 g (dry weight basis) of incubated soil sample. The sample was ultrasonically extracted for 20 min and centrifuged at 6000 rpm for 5 min. The extract was transferred to a 150 mL separatory funnel. The extraction was repeated by adding 15 mL of methanol/water (6:4, v/v) to the 50 mL polypropylene centrifuge tube. The tube was then stirred for 30 s on a vortex mixer and centrifuged at 6000 rpm for 5 min. The extracts were combined in the 150 mL separatory funnel and extracted two times using 40 mL of dichloromethane. Afterward, the organic phase (dichloromethane) was collected, concentrated to dryness, and reconstituted with 1.0 mL of methanol. Each sample was filtered

dx.doi.org/10.1021/jf5018803 | J. Agric. Food Chem. 2014, 62, 9066−9072

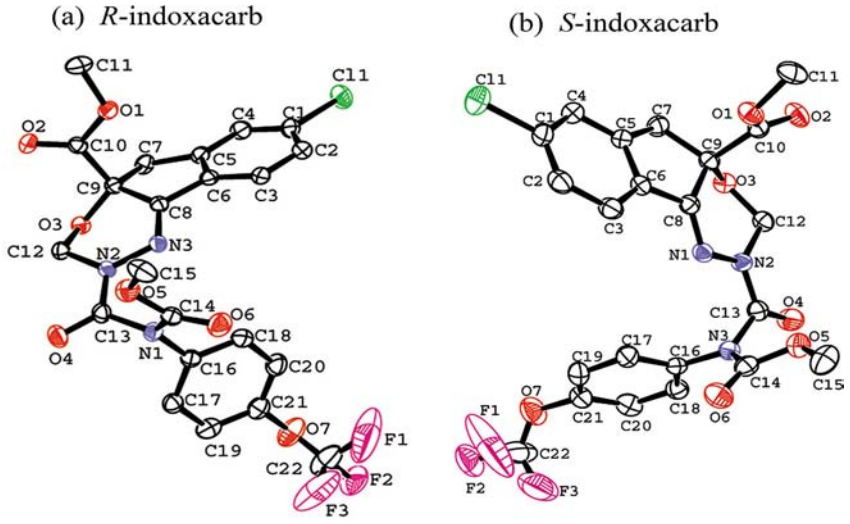

**Figure 2.** Stereoview of the indoxacarb enantiomers ($C_{22}H_{17}ClF_3N_3O_7$, M.W. = 527.83) (a) *R*-indoxacarb and (b) *S*-indoxacarb.

through a 0.45 $\mu$m nylon membrane filter and analyzed by HPLC (20 $\mu$L final extract).

**Instrumental Conditions (Enantioselective HPLC Analysis of Indoxacarb).** HPLC analysis of racemic indoxacarb was performed using an Agilent 1200 series apparatus composed of a quaternary pump, an autosampler, a diode array detector, a vacuum degasser, a column oven, and Agilent Chemstation software. The chiral analytical column amylose tris(3,5-dimethylphenyl carbamate) immobilized on silica-gel (Chiralpak IA) was purchased from Daicel (Tokyo, Japan). The dimensions of the column were 250 mm × 4.6 mm i.d., and it was packed with 5 $\mu$m particles.

The samples were analyzed using a mixture of *n*-hexane/isopropanol (70:30 v/v) at 1.0 mL/min flow rate on a Chiralpak IA column. The UV detection wavelength was 310 nm, and the temperature for separation was 30 °C. Under the selected conditions, the R-(−)-enantiomer eluted before the S-(+)-enantiomer.

**Method Validation.** A series of rac-indoxacarb standard solutions (0.25, 2.5, 5, 50, and 100 $\mu$g/mL) was prepared for HPLC analysis to determine the linearity of the method and quantify the analyte. The obtained regression equations and respective correlation coefficients were $A = 44.3880C - 1.8603$ ($R^2 = 0.9999$) for the R-(−)-enantiomer and $A = 43.325x + 2.9917$ ($R^2 = 0.9999$) for the S-(+)-enantiomer. A series of blank samples fortified with rac-indoxacarb at 0.1, 1.0, and 10 mg/kg was prepared for method validation and analyzed by the described procedure. The recovery and precision data for the samples in five soils are summarized in Table S2 (Supporting Information). For indoxacarb enantiomers, the recovery ranges in low, intermediate, and high spiked levels were 86.1−98.3, 86.3−99.2, and 95.5−103%, respectively, and each recovery value was acceptable for enantiomer determination. The limit of quantitation (LOQ) for each indoxacarb enantiomer was 0.05 $\mu$g/g in soil samples based on the acceptable RSDs of 5.14% to 10.2% for the two enantiomers. The limit of detection (LOD), defined as the concentration that produces a signal-to-noise (S/N) ratio of 3, was estimated to be 0.01 $\mu$g/g for each enantiomer by analyses of spiked samples at low concentration levels.

**Kinetic Analysis and Calculation.** The kinetic study of indoxacarb in soil was performed by plotting the residue concentration against time, and the corresponding rate constants $k$ for the *S*-(+)-enantiomer and *R*-(−)enantiomer were calculated using the first-order kinetic eq 1 by regression analysis; the half-life ($t_{1/2}$) was determined using eq 2.

$$C_t = C_0 e^{-kt} \quad (1)$$

$$t_{1/2} = \ln 2/k \quad (2)$$

where $C_0$ is the initial concentration ($\mu$g/g) of the enantiomer, $C_t$ is its concentration ($\mu$g/g) at time $t$ (d), and $k$ is the degradation rate constant.

The enantiomer fraction (EF) was used to express enantioselectivity as defined by the equation EF = peak area of the (+)-enantiomer/[(+)-enantiomer + (−)-enantiomer]. EF values ranged from 0 to 1, with an EF value of 0.50 indicating a racemic mixture and EF value of 0.70 indicating indoxacarb enriched with the S-enantiomer (2.33S:1R).

Enantioselectivity (ES), which reflects the overall trend in enantioselective dissipation, was defined as ES = $(k_S - k_R)/(k_S + k_R)$ in a previous study,[31] where $k_S$ is the degradation rate constant of *S*-indoxacarb, and $k_R$ is the degradation rate constant of *R*-indoxacarb. Positive values ($0 < ES \leq 1$) indicate a more rapid degradation of the S-enantiomer, whereas negative values ($-1 \leq ES < 0$) indicate a more rapid dissipation of the R-enantiomer. Dissipation is not enantioselective at an ES value of 0, whereas degradation is fully enantioselective at an ES value of 1.

## RESULTS AND DISCUSSION

**Absolute Configuration Assignment.** Individual enantiomers with enantio purity >99.0% were obtained by enantioselective separation of the indoxacarb racemate using semipreparative HPLC.[29] Single crystals of enantiopure *S*-indoxacarb and enantiopure *R*-indoxacarb were obtained by recrystallization from dimethyl sulfoxide and ethanol mixture at room temperature.

The molecular structures of *R*-indoxacarb and *S*-indoxacarb are illustrated in Figure 2, and the crystallographic data are summarized in Table S1, Supporting Information. Both compounds crystallize in the monoclinic crystal system in space group *C*2, and absolute structure parameters are −0.09 (13) and 0.10 (15), respectively. On the basis of these results, the first eluted enantiomer on the Chiralpak IA column was confirmed as the R-enantiomer followed by *S*-indoxacarb. The complete set of experimental and computational data was deposited in the Cambridge Crystallographic Data Center (CCDC# 911685 for *S*-indoxacarb and CCDC# 921088 for *R*-indoxacarb).

Melting points were measured on a Tech X-4 melting point apparatus, and optical rotations were measured on a WZZ-ZS automatic polarimeter, and they were not corrected. The isolated enantiomers were characterized as follows: *R*-indoxacarb, $[\alpha]_D^{20} = -68.4$ (menthol) and mp 86 to 89 °C;

and *S*-indoxacarb, $[\alpha]_D^{20}$ = +69.4 (menthol) and mp 88 to 90 °C.

**Degradation of Indoxacarb Concentrate (2.33S/1R) in Soil.** The degradation of the two enantiomers in the indoxacarb concentrate (2.33S/1R) followed first-order kinetics (Table 2 and Figure S1, Supporting Information), with $R^2$ values of 0.9691 to 0.9931, which indicated acceptable linearity. Half-lives ($t_{1/2}$) in the two alkaline soils (alk-1 and alk-2) were about 10.1 and 9.96 days for *R*-(−)-indoxacarb and 8.36 and 6.04 days for *S*-(+)-indoxacarb. This finding suggests that the two enantiomers degraded selectively in weakly alkaline soil and that the (*S*)-(+)-indoxacarb was preferentially degraded. The corresponding ES values were 0.095 and 0.245. The half-lives ($t_{1/2}$) of the two enantiomers were 11.2 and 24.0 d in neutral soil (neut-3). In soil neut-3, the degradation rates varied by a factor of 2, and the ES value of −0.365 indicates that (*R*)-(−)-indoxacarb was preferentially degraded. Furthermore, the two enantiomers display different degradation trends in the two acid soils (ac-4 and ac-5). In soil ac-4, the half-lives ($t_{1/2}$) of the two enantiomers were almost equal at 7.47 and 7.49 d. The ES value was −0.001; thus, the degradations of the two enantiomers was not selective. In soil ac-5, the half-lives ($t_{1/2}$) of the two enantiomers were 18.3 and 34.5 d, with an ES value of −0.306. This result indicates that (*R*)-(−)-indoxacarb was preferentially degraded.

**Degradation of Indoxacarb Racemate (1S/1R) in Soil.** The degradation of the two enantiomers in the indoxacarb racemate (1S/1R) followed first-order kinetics (Table 3 and Figure S2, Supporting Information), with $R^2$ values of 0.8796 to 0.9958. In addition to a half-life of 35.4 d of *S*-(+)-indoxacarb in soil ac-5, the other half-lives were similar to the results studied by Li et al.[16] and Sun et al.,[20] which were less than 23 d. Table 3 presents the statistically significant differences in the degradation half-life of the two enantiomers in the two weakly alkaline soils (alk-1 and alk-2) at 2.37 and 3.48 d, respectively. The corresponding ES values were 0.121 and 0.207, thus suggesting that the two enantiomers degraded selectively in weakly alkaline soil and that the (*S*)-(+)-indoxacarb was preferentially degraded. It is also consistent with the findings with the concentrate. In the neutral soil (neut-3), the half-lives ($t_{1/2}$) of the two enantiomers were 13.2 and 22.0 d. In soil neut-3, the ES value was −0.251, and (*R*)-(−)-indoxacarb was preferentially degraded. The degradation trends of the two enantiomers differed in acid soils ac-4 and ac-5. In soil ac-4, the half-lives ($t_{1/2}$) of two enantiomers were almost equal at 7.93 and 7.85 d, and the ES value was −0.005. Thus, the degradations of the two enantiomers were not selective. In soil ac-5, the half-lives ($t_{1/2}$) of two enantiomers were 22.5 and 35.4 d. The corresponding ES value was −0.222, thereby indicating that the (*R*)-(−)-indoxacarb was preferentially degraded. Only one alkaline soil and one acid soil were selected for enantioselective degradation of indoxacarb racemate by Sun et al.[20] Our result was consistent with the result reported by Sun et al. that *S*-(+)-indoxacarb degraded faster than *R*-(−)-indoxacarb in alkaline soil. In one of the acid soils (ac-5), our result was consistent with the result reported by Sun et al. that *R*-(−)-indoxacarb degraded faster than *S*-(+)-indoxacarb in acid soil. In the other acid soil (ac-4) in our study, the two enantiomers were nonselective.

**Comparison of Racemate (1S/1R) and Concentrate (2.33S/1R) in Terms of Selective Degradation.** With the indoxacarb racemate, *S*-(+)-indoxacarb was preferentially degraded in the two alkaline soils (alk-1 and alk-2). Thus, the amount of *S*-(+)-indoxacarb residue was lower than that of *R*-(−)-indoxacarb residue in the soil. As a result, the soil was enriched in *R*-(−)-indoxacarb. With the indoxacarb concen-

**Table 4. Kinetic Data for Dissipation of Pure *S*-Indoxacarb and Pure *R*-Indoxacarb in Soils**

| soil no. | soil origins | enantiomer | regressive function | $R^2$ | $t_{1/2}$ (d) |
|---|---|---|---|---|---|
| alk-1 | Haozhou | pure R-(−) | $C = 8.6953\ e^{-0.0742t}$ | 0.9870 | 9.34 |
| | | pure S-(+) | $C = 8.5341\ e^{-0.0846t}$ | 0.9930 | 8.19 |
| alk-2 | Guiyang | pure R-(−) | $C = 7.6505\ e^{-0.0806t}$ | 0.9916 | 8.60 |
| | | pure S-(+) | $C = 7.819e^{-0.1668t}$ | 0.9859 | 4.16 |
| neut-3 | Jilin | pure R-(−) | $C = 8.7672\ e^{-0.0853t}$ | 0.9380 | 8.13 |
| | | pure S-(+) | $C = 9.000e^{-0.0287t}$ | 0.9480 | 24.2 |
| ac-4 | Hangzhou | pure R-(−) | $C = 9.4875e^{-0.0929t}$ | 0.9732 | 7.46 |
| | | pure S-(+) | $C = 9.5389e^{-0.0815t}$ | 0.9664 | 8.50 |
| ac-5 | Haikou | pure R-(−) | $C = 9.8631e^{-0.0386t}$ | 0.9970 | 18.0 |
| | | pure S-(+) | $C = 10.4155e^{-0.0171t}$ | 0.9836 | 40.5 |

trate, the *S*-(+)-indoxacarb was also preferentially degraded in the two alkaline soils. Therefore, the difference between the R-(−)- and S-(+)-residues in soil was reduced. As depicted in Figure 3a, the amount of *S*-(+)-indoxacarb was 2.33 times that of the *R*-(−)-indoxacarb at 0 d when the indoxacarb concentrate was added into soil alk-2. At 21 d, however, the amount of *S*-(+)-indoxacarb was only 0.90 times that of the *R*-(−)-indoxacarb. In soils neut-3 and ac-5, the directions of selective degradation in indoxacarb racemate and concentrate were the same. In these soils, the *R*-(−) indoxacarb was preferentially degraded in both racemate and concentrate enantiomers. Consequently, the soil was enriched in *S*-(+)-indoxacarb and S-(+)-residue was significantly more abundant than R-(−) residue, as shown in Figure 3b. In soil ac-4, the degradations of the two enantiomers in both racemate and concentrate were not selective, and the degradation rates of S-(+) and R-(−) were similar, as presented in Figure 3c. The ES values of the racemate and the concentrate varied greatly; these values indicated the degree of selective difference. In soil alk-1, the ES value was 0.095 in the concentrate, and it was 0.121 in the racemate, indicating the selective degradations of enantiomers differ more in the racemate than in the concentrate. In three of the soils (alk-2, neut-3, and ac-5), the ES values were 0.245, −0.365, and −0.306 in the concentrate, respectively, and were 0.207, −0.251, and −0.222 in the racemate, respectively, which showed the selective degradations of enantiomers varied more in the concentrate than in the racemate. Overall, the results indicate that the directions of selective degradation of the enantiomers in the concentrate are analogous to directions in the racemate for all five soil types.

**Degradation of Enantiopure Indoxacarb in Soil.** The determination of samples of separate incubations with enantiopure *R*-(−)- and *S*-(+)-indoxacarb is necessary to understand the differences in their dissipation behaviors and detect potential enantiomerization of the compound. We therefore conducted separate incubations with enantiopure *R*-(−)- and *S*-(+)-indoxacarb in all soils. As exhibited in Table 4, the half-lives ($t_{1/2}$) of pure *R*-(−)-indoxacarb and pure *S*-(+)-indoxacarb were 9.34 and 8.19 d in soil alk-1, and 8.60 and 4.16 d in soil alk-2, which was similar to the directions of enantioselective degradation in the concentrate and the racemate, namely, *S*-(+)-indoxacarb degraded faster than *R*-(−)-indoxacarb. The half-lives ($t_{1/2}$) of pure *R*-(−)-indoxacarb and pure *S*-(+)-indoxacarb were 8.13 and 24.2 d in soil neut-3, and 18.0 and 40.5 d in soil ac-5, respectively. The degradation rate of the pure *R*-(−)-indoxacarb was higher than that of pure *S*-(+)-indoxacarb, as with the directions of enantioselective degradation in the concentrate and the racemate in soils neut-3 and ac-5.

[a]Values represent the mean ± SD ($n$ = 3 or 2).

These results differed from the degradation study of enantiopure indoxacarb by Sun et al. that showed conversion between *R*-(−)-indoxacarb and *S*-(+)-indoxacarb in soils.[20] However, no enantiomerization was observed in our study. The current experiment results show that neither (*S*)-(+)-indoxacarb nor (*R*)-(−)-indoxacarb convert directly; both enantiomers are configurationally stable in the selected soils.

**Degradation of Indoxacarb Racemate (or Concentrate) in Soils under Sterile Conditions.** No significant difference in enantioselectivity was found for indoxacarb racemate (or concentrate) degradation in five soils under sterile conditions, the degradation rates of *S*-(+)- and *R*-(−)-indoxacarb were the same. The concentrations of the two enantiomers of indoxacarb in sterile soils were determined. The EF values of indoxacarb in sterile soils were approximately 0.50 (for the racemate) and 0.70 (for the concentrate) before, during, and after incubation (Table 5). In sterilized soils, indoxacarb enantiomers showed slow dissipation rates. The spiked concentrations dissipated 73%, 84%, 18%, 13%, and 24% in soils alk-1, alk-2, neut-3, ac-4, and ac-5, respectively, after 93 d of incubation. The results indicated that the biological process by microorganisms played important roles in the enantioselective degradation of indoxacrb, consistent with the other studies about many chiral chemicals in soils.[20,25−28] The correlation between enantioselectivity and microbial biomass carbon was considered. However, we observed no clear linear relationship between the selective degradation of indoxacarb and soil microbial biomass. Incubation conditions in different types of soils from various locations may have affected the makeup of microorganisms and hence influenced the rate and direction of the observed enantioselectivity.

**Relationship between the Selective Degradation of Indoxacarb and Soil Properties.** The selective degradation of indoxacarb concentrate (or racemate) varies across the five selected soils. In the two alkaline soils, with positive ES values, the degradation rate of the (*S*)-(+)-indoxacarb was faster than that of the (*R*)-(−)-indoxacarb. In two other soils, one acid and one neutral, with negative ES values, the degradation rate of the (*R*)-(−)-indoxacarb was faster than that of the (*S*)-(+)-indoxacarb. In the other acid soil, the degradation rates of enantiomers were similar and are not selective. Hence, its ES value was 0. The activity and types of soil microorganisms were affected by pH level, organic substances in soil, and soil texture. Therefore, the correlation between ES value and pH was considered, along with that between organic substances and the content of sand and clay and silt in soil. However, we observed no clear linear relationship between the selective degradation of indoxacarb and soil properties. Combined with the results of previous research of indoxacarb in soils,[16,20] we believed the selectivity may vary with different soils, which contained different microorganisms affected by the collective soil environment.

In conclusion, we investigated the enantioselective degradation of the indoxacarb concentrate (2.33S/1R) and racemate (1S/1R) in five types of soil using a chiral Chiralpak IA column under normal-phase conditions. We initially determined the absolute configuration of indoxacarb enantiomers based on single-crystal X-ray diffraction. We found that the directions of selective degradation of the enantiomers in the concentrate are analogous to directions in the racemate for all five soil types. Even in the five soils, the degradation of enantiopure *R*-(−)- and *S*-(+)-indoxacarb was similar to the directions of enantioselective degradation in the concentrate and racemate. As our study shows, enantioselective degradation and soil properties such as pH level, organic substances, and soil texture were not linearly correlated.

identify different cultivation locations of eight wolfberry samples.[8] Although HPLC−UV fingerprints were obtained, no compositional information was related to the clustering tree. The mass spectrometric technique offers mass-to-charge ratio measurements that generally furnished greater specificity for differentiation and component characterization than the UV fingerprints. Bondia-Pons et al. applied ultraperformance liquid chromatography coupled with mass spectrometry (UPLC−MS) with partial least-squares-discriminant analysis (PLS-DA) to differentiate the geographic origin of wolfberries.[20] However, samples from only three origins (Tibet, Northern China, and Mongolia) were analyzed. It is interesting to test whether the UPLC−MS and FIMS may be applied to differentiate Chinese wolfberries produced in Ningxia and other locations, or the different wolfberry cultivars from a selected growing region.

In this study, the PLS-DA of UPLC−MS and FIMS fingerprints was tested for possible differentiation of Chinese wolfberries produced in Ningxia from those grown in other locations. The PLS-DA was also utilized to possibly distinguish the four wolfberry cultivars grown in Ningxia. The prediction accuracies for both approaches were calculated. In addition, the phytochemical compositions of the wolfberries were examined. The results from this study may serve as a scientific foundation for the authentication of Chinese wolfberries.

## MATERIALS AND METHODS

**Materials and Reagents.** Twenty-nine wolfberry samples harvested in 2012 were obtained from Professor Jinming Gao at Shaanxi Engineering Center of Bioresource Chemistry & Sustainable Utilization, College of Science, Northwest A&F University. The sample set included 19 Ningxia (NX) wolfberry samples and 10 samples from five other provinces of China, including three Inner Mongolia (IM), three Qinghai (QH), two Gansu (GS), one Hebei (HB), and one Xinjiang (XJ) samples, respectively. All samples were *L. barbarum* fruits, except that one was *Lycium ruthenicum* Murr. fruits from QH. Out of all 19 NX samples, the cultivars of 16 NX *L. barbarum* fruit were recorded, including five NX wolfberry No. 1 (NX1), five NX wolfberry No. 4 (NX4), two NX wolfberry No. 5 (NX5), and four NX wolfberry No. 7 (NX7) samples. Three other samples had no cultivar information and were removed in the statistical analysis related to wolfberry cultivars. The fruits were air-dried immediately after harvest and stored in zip-lock plastic bags at −20 °C. Deionized water was obtained using a Milli-Q purification system (Millipore Laboratory, Bedford, MA, USA). The HPLC grade methanol and acetonitrile were purchased from Merck (Darmstadt, Germany). The high-performance liquid chromatographic grade formic acid was purchased from Sigma-Aldrich (St. Louis, MO, USA). The analytical grade ethanol was purchased from Yangyuan Chemical (Changshu, Jiangsu, China). Other chemicals or solvents were of the highest commercial grade and used without further purification.

**Instrumentation.** A Precellys 24 Dual homogenizer (Bertin Technologies, Bretonneux, France) was used for sample homogenization. A KH7200 sonicator was used for sonication during sample extraction (Kunshan Hechuang Ultrasonic Corporation, Kunshan, Jiangsu, China). UPLC−MS analysis was performed by an Acquity UPLC coupled with a Xevo G2 quadrupole time-of-flight (QTOF) mass spectrometer (Waters, Milford, MA, USA).

**Sample Preparation.** The dried fruits (dry weight: 0.512 ± 0.010 g) were placed in a 7 mL homogenizing tube with 1 mL of deionized water. The homogenization was performed twice at a speed of 5500 rpm. Each cycle lasted for 20 s with a 5 s hold time between cycles. Then 4 mL of analytical grade ethanol was added. The extraction was performed at ambient temperature for 30 min using 80% (v/v) ethanol under sonication. After the mixture was centrifuged at 3901*g* for 5 min, 1 mL of supernatant was transferred to a clean tube, and the solvent was removed with nitrogen flow. The extract was redissolved in 1 mL of 50% acetonitrile (v/v) with sonication at ambient temperature for 5 min, and then centrifuged at 13400*g* for 10 min to remove the nondissolvable impurities. The supernatant was subjected to UPLC−MS and FIMS analysis.

**Ultraperformance Liquid Chromatography−Mass Spectrometry (UPLC−MS).** An Acquity UPLC BEH C18 column (2.1 mm i.d. × 100 mm, 1.7 $\mu$m) attached with a VanGuard precolumn (2.1 mm i.d. × 5 mm, 1.7 $\mu$m) (Waters, Milford, MA, USA) was used. A binary solvent system of 0.1% (v/v) formic acid in deionized water (solvent A) and 0.1% (v/v) formic acid in acetonitrile (solvent B) was used. It has been studied that the addition of formic acid as a mobile phase modifier would reduce peak tailing and improve the performance of separation for flavonoids and phenolic acids, the major functional components of wolfberries.[21] The gradient elution program was 0−8 min, 10−100% B with a concave (curve parameter was 8); 8−13 min, 100% B; 13−15 min, 100−10% B with a linear gradient; and 15−16.5 min, 10% B. The column temperature was 40 °C, and the flow rate was 0.4 mL/min.

Based on the previous liquid chromatography−mass spectrometry (LC−MS) studies of Chinese wolfberries, the negative ion mode was better at characterizing the major functional components such as flavonoids and phenolic acids in wolfberries than the positive ion mode.[20,21] The electrospray ionization (ESI) source was operated under the negative ion mode without applying collision energy. The capillary voltage was 2.5 kV, and the cone voltage was 40 V. The ionization temperature was 120 °C, and desolvation temperature was 250 °C. The sodium formate (0.34 g/L in 90% isopropanol, v/v) was used for QTOF-MS startup calibration under the same ESI conditions for sample measurement, and leucine enkephalin (2 mg/L in 50% acetonitrile, v/v) was used for QTOF-MS lockspray calibration. The sodium formate was introduced prior to the ESI interface during the startup calibration. The mass spectra from 0.5 to 8.5 min were recorded. Two channels of MS measurements were recorded. The first channel was for the data collection of MS signals ranging from 100 to 1500 Da without collision energy. The second channel offered additional fragmentation information for the compound identification, which collected mass fragments of 100 to 1000 Da with a 35 eV collision energy. The scanning speed was 0.3 s/scan. Each sample was injected in triplicate by a sequence of random block design. Three blocks were injected sequentially, and each block contained a replicate of 29 samples in a randomized order. The methanol blank solution was injected at the beginning and the end of each block to reduce sample cross-contaminations. The entire UPLC−MS sequence ran for two consecutive days.

**Flow Injection Mass Spectrometry (FIMS).** The same MS instrumentation and method were applied in FIMS fingerprinting as that described in the UPLC−MS analysis section, without the UPLC column. The solvent was 0.1% (v/v) formic acid in 50% acetonitrile:-water (v/v). The solvent pH was 3.0 with a flow rate of 0.5 mL/min. The MS signals from 100 to 1000 Da were collected from 0 to 0.5 min after injection.

**Data Analysis.** The peak areas and PLS-DA plots were calculated using the Waters MarkerLynx software (version 4.1). For UPLC−MS data, the component peaks were extracted with a chromatogram mass window of 0.01 Da, and a retention time window of 0.2 min. Twenty characteristic peaks appearing in all NX samples were selected manually, in addition with five characteristic peaks in QH sample to validate peak selection. For each FIMS spectrum, peaks were extracted by a mass window of 1 Da. The peak areas and FIMS spectra were preprocessed by dividing the mass of each sample weighed before homogenization, followed by the autoscaling transformation, i.e., each feature was subtracted by its mean value, and divided by their standard deviation. The number of classes was 2 for wolfberries produced in NX and other locations. When differentiating NX cultivars, the number of classes was 4.

The bootstrapped Latin partition[22] of 10 bootstraps and 5-fold Latin partition was applied for validation to evaluate the model prediction power. The bootstrapping applied resampling, and achieved multiple evaluations with a statistical power similar to permutation. Also, Latin partition is an improved method derived from cross-

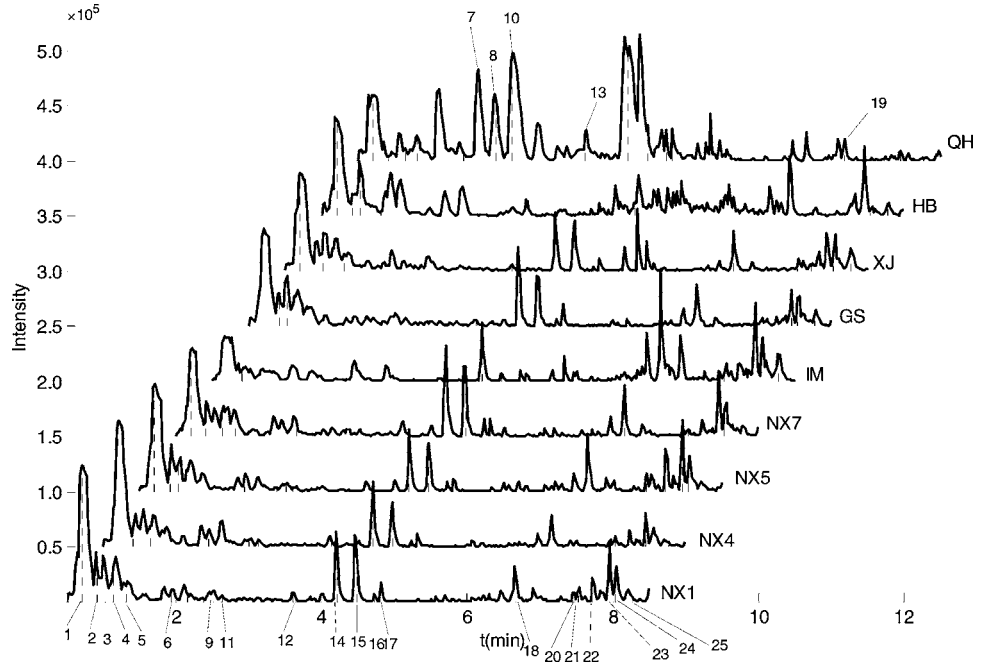

**Figure 1.** UPLC−MS base peak chromatograms of Chinese wolfberries. QH, HB, XJ, GS, and IM represent samples from Qinghai, Hebei, Xinjiang, Gansu, and Inner Mongolia, respectively. NX1, NX4, NX5, and NX7 represent Ningxia (NX) wolfberry No. 1, No. 4, No. 5, and No. 7 cultivars, respectively.

validation, in which the ratio between different classes is maintained. The validation result was reported as the percentage of correct predictions to reflect the prediction accuracy. Afterward, a two-way analysis of variance (ANOVA) was applied to determine whether the prediction models were statistically different from each other. In addition, the average regression coefficients of PLS-DA could be plotted with confidence intervals. Positive and negative coefficients represent the relationships of the peaks to different classes. The importance of each peak could be quantified by the absolute magnitude of each regression coefficient. The peak would be insignificant for classification, if the confidence interval crossed zero. The PLS-DA model validation and ANOVA were performed by an in-house program using MATLAB R2013b (The MathWorks, Natick, MA, USA). The number of latent variables to build the PLS-DA model is an important parameter that affects its prediction ability. If the number of latent variables is too large, overfitting may occur, and underfitting may occur otherwise. The optimized number of latent variables was determined by achieving the best mean prediction accuracy when applying the same bootstrapped Latin partition procedure (10 bootstraps and 5-fold Latin partition) on each training partition in the validation process. The algorithm of PLS was the nonlinear iterative partial least-squares (NIPALS), and the binary encoding was applied to handle the multiclass problem.

## RESULTS AND DISCUSSION

**UPLC−MS Chromatograms.** Figure 1 reports the representative UPLC−MS base peak chromatograms of the nine Chinese wolfberry extracts. The base peak chromatogram plots the intensity of the most abundant ion, the base peak intensity, in each MS scan. More components can be observed in the base peak chromatograms than in the total ion chromatogram, because the base peak intensity is less influenced by noise than the total intensity. The peak profiles of a sample from QH significantly differed from samples grown in other locations. This probably was because this QH sample was a wild grown *Lycium* species (*L. ruthenicum*), which has a unique composition according to a previous study.[23] Besides location and genotype, significant differences in the chemical composition could occur due to planting season, or the interactions between factors such as season and location, or season and genotype. Peaks 7, 8, 10, 13, and 19 were the typical components in this QH sample. Peaks 13 and 19 were tentatively identified as quercetin-di(rhamno)-hexoside and cirsimaritin. The overall profiles of HB were also different from the NX samples. This result was consistent with a previous UPLC−UV fingerprinting study in which HB samples furnished the largest dissimilarity compared to other samples from eight locations.[8] However, it was difficult to predict the growing location of a commercial wolfberry sample based only on direct observation of its base peak chromatogram. For all NX wolfberries, most of the peaks were identical except for variations in their relative concentrations. This observation was consistent with the previous genetic diversity studies on NX wolfberry cultivars that demonstrated high genetic similarities of NX wolfberries,[24] indicating a challenging objective to distinguish the cultivars by manually inspecting the chromatogram.

**Differentiating Samples from Ningxia and Other Locations by UPLC−MS Peak Areas.** Figure 2A depicts the PLS-DA scores plot of the UPLC−MS for the 29 wolfberry samples using the peak areas of 20 and 5 peaks selected from NX and the wild grown QH sample, respectively. Most samples from NX were separated from the samples grown in other locations regardless of cultivar differences.

Figure 1 demonstrated that the wolfberry samples from locations outside NX may contain many characteristic components to help differentiation. However, it is not possible to perform an exhaustive compositional analysis on all species of *Lycium*. Consequently, it should be verified that 20 primary peaks selected from NX samples alone was adequate for differentiation. Comparing the PLS-DA scores plots which included (Figure 2A) or excluded (Figure 2B) peaks 7, 8, 10, 13, and 19 that were only detected in wild grown QH samples, a similar clustering trend was observed. In both plots, the wild

dx.doi.org/10.1021/jf502156n | J. Agric. Food Chem. 2014, 62, 9073−9080

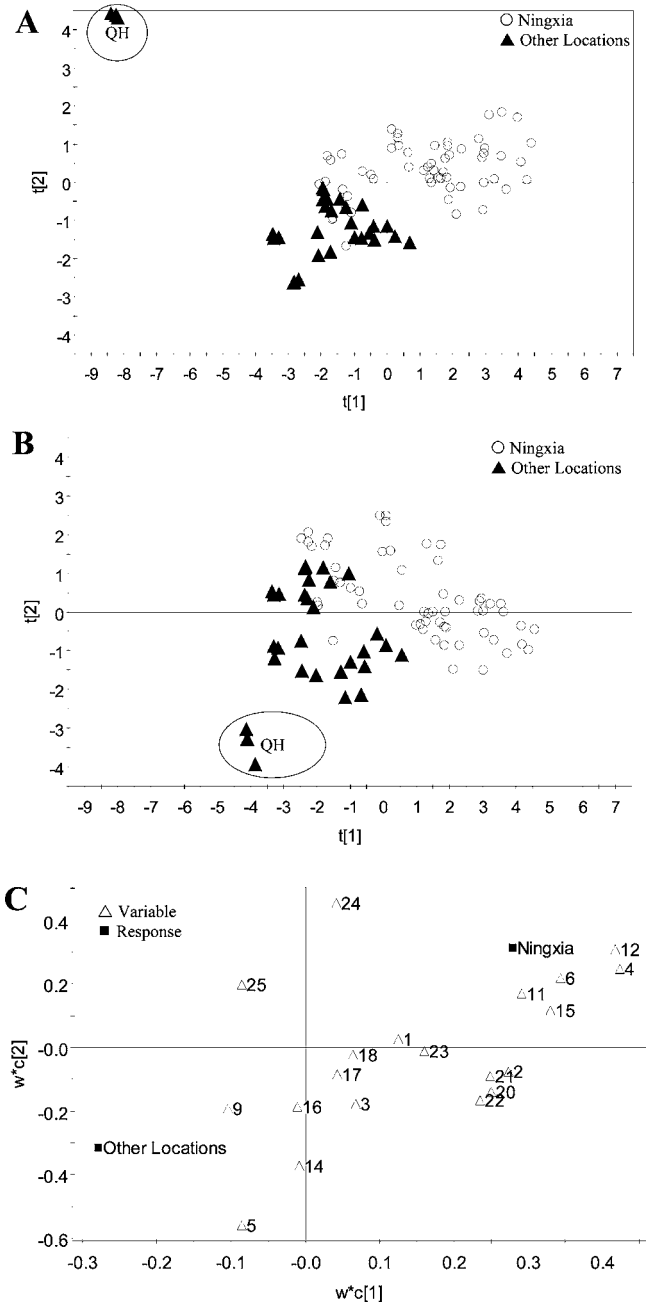

**Figure 2.** PLS-DA scores and loading plots differentiating wolfberries produced in NX and other locations using UPLC−MS peak areas: (A) the scores plot by 20 and 5 peaks respectively selected from NX and wild grown Qinghai (QH) sample; (B) the scores plot by 20 peaks only selected from NX samples; and (C) the corresponding loading plot of B. In both A and B, the wild grown QH sample is circled.

grown QH samples were away from all other samples and respectively positioned at the top-left and bottom-left corners. As a result, any peaks observed only in non-NX samples were excluded for further analysis.

The loading plot (Figure 2C) reflects the importance of each compound for each data cluster. The closer a peak was to the respective sample response, the more characteristic it was in that class of sample. It can be observed that peaks 4, 6, 11, 12, and 15 were mainly related to NX samples. According to the tentative identification by QTOF-MS, peaks 4 and 6 were glycosides of coumaric acid; peak 11 was scopoletin; and peak 12 was 1,3-dihydro-2-benzofuran. In addition, 18 components were tentatively identified according to the high-resolution measurements with QTOF-MS (Table 1). The phenolic acids including quercetin-rhamno-dihexoside, quercetin-di(rhamno)-hexoside, quercetin-3-*O*-rutinoside, kaempferol-3-*O*-rutinoside, and isorhamnetin-3-*O*-rutinoside were consistent with the findings of a previous study using a liquid chromatography with ultraviolet detection.[21] Citric acid, citric acid glycoside, coumaric acid glycoside, ferulic acid glycoside, scopoletin glycoside, isocoumaran, trihydroxy octadecenoic acid, dihydroxy octadecadienoic acid, hydroperoxy octadecatrienoic acid, dihydroxy octadecadienoic acid, and hydroxy linoleic acid were not reported in wolfberry previously.

**Differentiating Cultivars from a Selected Location by UPLC−MS Peak Areas.** With the application of PLS-DA on the subset of 16 NX samples, different cultivars were also separated into distinctive clusters (Figure 3A). Data points representing NX1 were located in the center of the plot, indicating that less characteristic components were extracted compared to the other three cultivars. Because NX1 was the earliest commercial breed of NX wolfberry cultivar, all other cultivars from NX were developed from NX1. The cultivation process led to the occurrences of characteristic components and variations in concentrations. The locations of peaks differed in Figure 2C, suggesting a different component profile of NX cultivars as compared to the fruits outside NX province. Specifically, peak 21 (tentatively identified as hydroperoxy octadecatrienoic acid) and peaks 12, 16, and 18 (tentatively identified as 1,3-dihydro-2-benzofuran, kaempferol-3-*O*-rutinoside, and trihydroxy octadecenoic acid, respectively) were respectively related to NX5 and NX7. The loading plots (Figures 2C and 3B) clearly demonstrated UPLC−MS advantages in discovering the relationships between phytochemical compounds and different sample classes, with the trade-off of analysis time. The PCA was also performed. Similar clustering trends could be observed by comparing Figures 2B and 3A with the principal component scores plots (Figures S1 and S2 in the Supporting Information). As a supervised method, the PLS-DA achieved better separations between different sample classes than PCA.

**FIMS Fingerprints.** FIMS fingerprinting is a novel technique without chromatographic separation. It is suitable for a high-throughput assay of food materials. In the present study, FIMS fingerprinting was compared to the conventional UPLC−MS base peak fingerprints under the same instrumentation configurations. Nine representative FIMS fingerprints were plotted in Figure 4. Distinctively unique patterns of wild grown QH and HB samples were observed in Figure 4, in good agreement with the chromatograms obtained by UPLC−MS (Figure 1). The peaks at $m/z$ 191.0192 and 191.0555 were tentatively identified as citric acid and scopoletin, respectively. The peaks at $m/z$ 111.0082 and 133.0136 were tentatively identified as the fragments of citric acid, which were consistent with the UPLC−MS measurements of peak 1 (Table 1).

**Differentiating Samples from Ningxia and Other Locations by FIMS Fingerprints.** Figure 5 is the PLS-DA plot to differentiate samples from Ningxia and other locations by their FIMS fingerprints. The scores plots (Figure 5A) indicated a similar clustering trend as the UPLC−MS plots (Figure 2B). The wild grown QH samples presented in Figure 5A were located at the bottom of the plot away from the other samples, consistent with the FIMS fingerprints in Figure 4 and the scores plot of Figure 2B. There were many variables in the

[a] $t_R$, retention time; exp $[M-H]^-$ and theor $[M-H]^-$ were experimental and theoretical $m/z$ of molecular ions, respectively; nd, not detected; the formulas were determined by achieving the smallest mass error between theoretical and experimental $m/z$, taking the fragment ions into consideration; [b] The fragment ions observed in the second mass spectral channel.

loading plots (Figure 5B), but few $m/z$ peaks could be related to differentiation by the FIMS fingerprints. For the FIMS method, the PCA was not able to effectively differentiate the production location (Figures S3 in the Supporting Information).

**Differentiating Cultivars from a Selected Location by FIMS Fingerprints.** Figure 6A is the PLS-DA scores plot to differentiate cultivars of a selected location. Different cultivars were separated, except NX1 and NX4 were overlapped. This was probably due to the greatest similarity between NX1 and NX4, compared with other cultivars. This close relationship was also observed in the loading plot in Figure 6B. Similar to Figure 5B, the extraction of characteristic components was relatively difficult due to the large amount of variables in the FIMS fingerprints. Compared with the conventional chromatographic methods, the FIMS fingerprinting reduced the analysis time significantly while retaining enough information for differentiation. On the other hand, the UPLC−MS method has advantages in providing detailed component information. The PCA results indicated less degree of separation between the cultivars (Figure S4 in the Supporting Information), compared to the PLS-DA scores plot (Figure 6A).

**Partial Least-Squares-Discriminant Analysis (PLS-DA) Validation.** A quantitative evaluation of the accuracies for differentiation is necessary since there were no definite boundaries between different classes of samples in the scores plots for both UPLC−MS and FIMS fingerprints (Figures 2, 3, 5, and 6). The PLS-DA with bootstrapped Latin partition was applied as a classifier to achieve the automatic prediction. Table 2 is the validation result. The FIMS fingerprinting yielded 71% averaged prediction accuracy when differentiating the NX cultivars, since the autoscaling data transformation elevated noise in the FIMS spectra, especially when handling the multiclass problem. For UPLC−MS, because the peak-selection step ensured the removal of most noises, the averaged prediction accuracy did not decrease with the application of autoscaling. The scaling step was removed and the model was re-evaluated afterward for differentiating the NX cultivars using FIMS fingerprints. To achieve an unbiased spectrometric comparison to the predictions, the total ion spectra (TIS) obtained from UPLC−MS by averaging all MS spectra from 100 to 1000 Da across retention times were also evaluated. The autoscaling was also applied to TIS because the spectrometric noise was reduced by signal averaging. All prediction accuracies were above 90%. The TIS and UPLC−MS achieved higher prediction accuracies than the FIMS fingerprinting method. The two-way ANOVA was performed on the prediction accuracies. The result indicated that the prediction accuracies using UPLC−MS, TIS, or FIMS methods were statistically different at a 95% confidence level. The results proved the

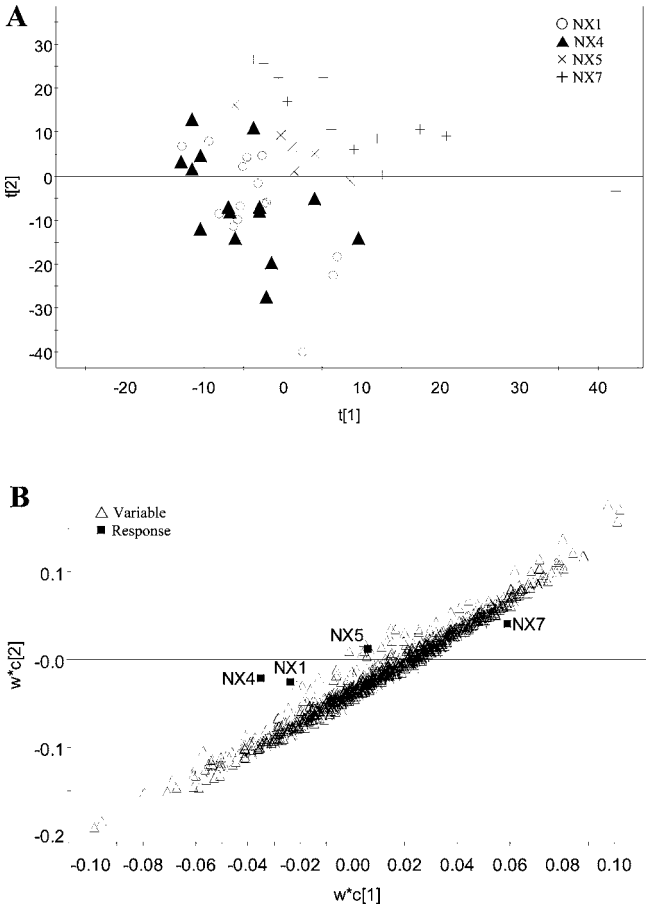

**Figure 6.** PLS-DA scores (A) and loading (B) plots differentiating NX cultivars using FIMS fingerprints. NX1, NX4, NX5, and NX7 respectively represent NX wolfberry No. 1, No. 4, No. 5, and No. 7 samples, respectively.

**Table 2. Statistical Validation Results of PLS-DA Classification Model by Bootstrapped Latin Partition[a]**

| | | UPLC−MS | TIS | FIMS |
|---|---|---|---|---|
| cultivation location | APA (%) | 94 ± 3 | 97 ± 2 | 93 ± 4 |
| | nLVs | 17 ± 1 | 51 ± 10 | 47 ± 12 |
| NX cultivar | APA (%) | 93 ± 6 | 95 ± 4 | 91 ± 4[b] |
| | nLVs | 16 ± 2 | 28 ± 3 | 25 ± 8 |

[a]The deviations were reported as 95% confidence interval; APA, averaged prediction accuracy; nLVs, number of latent variables. [b]Calculated by the mean-centering preprocessing method.

effectiveness of the PLS-DA projection plots as a convenient visualization technique for the differentiation. In addition, the average regression coefficients with confidence limits from all the latent variables in the PLS-DA model were calculated and plotted (Figure S5−S8 in the Supporting Information). Each extracted chromatographic peak or $m/z$ measurement can be estimated for its statistical significance in the PLS-DA model for each class of sample. For example, in Figure S8 in the Supporting Information, peaks of $m/z$ 792 and 794 were positively related to cultivars NQ1 and NQ7, and negatively related to cultivars NQ4 and NQ5.

In summary, the UPLC−MS chromatogram and the FIMS fingerprints combined with PLS-DA projection plots were quantitatively validated for their potential utilization in differentiating wolfberries from Ningxia and other locations, as well as the different cultivars grown at a selected location. Compared with each other, FIMS fingerprinting has advantages in reducing the analysis time significantly, and UPLC−MS offers more information when relating the differentiation model to chemical compositions. Both methods could be developed for the quality assurance, quality control, and authentication of wolfberry and wolfberry-containing foods.

samples has been detected using HPLC,[18,19] GLC,[20] GC headspace,[21] GC-MS,[22] and spectrophotometric methods[23,24] or FTIR.[25]

Another approach, mostly used in industry, is basic titration, again based on the methanol release from ester induced by the basic environment.[26,27]

Methods combining both acetic acid and methanol determination are limited. There have been attempts measuring both using HPLC[18,19] or GC-MS[22] for the detection after saponification. No methods were found allowing the simultaneous detection of methylation, acetylation, and feruloylation degree of pectin. Ferulic acid in pectin was generally determined by spectroscopic methods[28] or HPLC-UV methods.[29]

NMR was extensively used to study pectin and, more in general, food carbohydrates at a structural level,[30] whereas the application of this technique as a quantitative analytical tool in carbohydrate determination is still limited, despite its huge possibilities.[31]

With regard to the determination of the degree of esterification in pectin by NMR, few studies can be found in the literature,[32−34] and only two papers report the simultaneous measurement of the methylation and acetylation degrees of pectin by NMR.[35,36] In most of these studies, the NMR analysis is performed on intact pectin and the degree of methylation is based on the integration of the signals of the protons adjacent to the carboxylate in free or esterified form. However, the determination of the methylation degree of intact pectin is affected by difficulties related to the low spectral resolution due to the gelling properties of pectin. In fact, in an attempt to reduce the poor resolution, all of the NMR experiments reported in the literature are registered at high temperatures (60−90 °C). The low spectral resolution leads to an enlargement and a deviation from the Lorentzian form of the NMR signals, which become more difficult to integrate, thus affecting the error of the measurement. Bedouet et al.[36] explored the possibility to determine acetylation and methylation degrees of pectin by $^1$H NMR measurement after saponification of pectic material directly in the NMR tube. However, also in this case experiments were performed at 80 °C, due to the known jellying properties of pectin also after saponification. Neumuller et al.[37] proposed a quantitative NMR-based method to determine phenoyl and acetyl esters of different polysaccharides as corn fiber and potato starch after saponification. The method was in good agreement with a conventional HPLC analyses, with the advantage of significantly reduced analysis time.

Here, we suggest a simpler method for the simultaneous detection of methylation, acetylation, and feruloylation degrees of pectin, which consists of an easy preparation of the sample for $^1$H NMR analysis by performing an alkaline saponification (Figure 1) on the pectin isolated from the food sources. This step allows very resolved NMR spectra to be obtained at room temperature, where the peaks of methanol, acetic acid, and ferulic acid can easily be integrated and quantified with respect to the amount of pectin.

## MATERIALS AND METHODS

**Materials and Chemicals.** Standard of pectin from citrus peel, deuterium oxide, 3-(trimethylsilyl)propionate-$d_4$ (TSP), methanol, acetic acid, ferulic acid, galacturonic acid, sulfamic acid, potassium hydroxide, sodium tetraborate, *m*-hydroxydiphenyl, sodium hydroxide, *trans*-1,2-diaminocyclohexane-*N*,*N*,*N*′,*N*′-tetraacetic acid (CDTA), phenol, 4-(2-hydroxyethyl)piperazine-1-ethanesulfonic acid (HEPES), dimethyl sulfoxide, porcine pancreatic α-amylase, and sulfuric acid, of analytical grade were purchased from Sigma-Aldrich (Taufkirchen, Germany).

Three samples of pectin with different methylation degrees determined by titration were provided by Silvaextracts (Cuneo, Italy) as freeze-dried powders. Sugar beet flakes, pea hulls, olive pomace, grape pomace, and apple cake were provided by IGV (Nuthetal, Germany) as part of the NOSHAN EU project.

**Methods of Analysis.** *Extraction of Soluble Pectic Polysaccharides by a Chelating Agent Solution.* The isolation of cell wall was performed following the instructions of Melton and Smith[38] for samples containing starch. To inactivate enzymes, the samples were homogenized (Ultraturrax T-50 basic, IKA-Werke, Staufen im Breisgau, Germany; 2−3 min, 4000 rpm) with 80% phenol−0.5 M HEPES buffer (w/v). Soluble cell matrix contents were solubilized by 50 mM HEPES buffer (pH 6.7) and separated by centrifuge (Eppendorf AG, Hamburg, Germany; 20 min, 3220*g*, RT, HDPE centrifuge bottles). The pellet was treated (incubation for 6 and 24 h) with DMSO 90% (v/v) and further incubated for 1 h at 40 °C with 200 U of porcine pancreatic α-amylase stabilized by 20 mM HEPES buffer with 20 mM $CaCl_2$ (pH 6.9), to remove starch. Cell walls were treated twice (6 and 12 h) with 50 mM CDTA in 50 mM potassium acetate buffer (pH 6.5). The supernatants were separated by centrifuge, combined, and dialyzed with 0.1 M ammonium acetate buffer (pH 6.5, 1 day, three changes, 4 °C) followed by $H_2O$ (3 days, three changes at 4 °C). All samples were freeze-dried and stored at −18 °C.

*Galacturonic Acid Determination.* The galacturonic acid content was determined with *m*-hydroxydiphenyl as described by Melton and Smith[39] using galacturonic acid as standard. Pectin samples were hydrolyzed using 1 mL × 2 concentrated sulfuric acid, mixed, and cooled in an ice bath. Bidistilled water, 0.5 and 5 mL, was added, respectively, centrifuged (Eppendorf 5810R, Eppendorf, Augsburg, Germany), and the supernatant was used for spectrophotometric measurements (UV−vis Lambda BIO 20 spectrophotometer, PerkinElmer, Waltham, MA, USA). To 400 μL of supernatant or standard were added 40 μL of 4 M sulfamic acid/potassium sulfamate solution (pH 1.6) and 2.4 mL of 75 mM sodium tetraborate/sulfuric acid solution. The mixture was heated (100 °C) for 20 min and then cooled. To the sample control was added 80 μL of 0.5% NaOH to determine the sugar coloring. To the sample and standard was added 80 μL of 8.8 mM *m*-hydroxydiphenyl in 0.5% NaOH. The absorbance was measured after 10 min of incubation time at 525 nm against a water blank.

*Methylation, Acetylation, and Feruloylation Degree.* Pectic polysaccharides were incubated (2 h, room temperature) with 1 mL of 0.4 M NaOH in $D_2O$ and 0.1 mL of internal standard (TSP, 0.2 mg/mL in $D_2O$). The supernatant was centrifuged (Centrifuge Eppendorf 5810R, Eppendorf, Augsburg, Germany), clarified (nylon syringe filter system, 0.4 μm), and transferred in NMR tubes. $^1$H NMR spectra were acquired on a Varian-Inova 600 MHz spectrometer, equipped with a triple-resonance inverse probe (HCN), operating at 599.736 MHz for proton. Spectra were collected at 298 K, with 32K complex points, using a 90° pulse length. Sixty-four scans were acquired with a spectral width of 7196.8 Hz, an acquisition time of 2.53, and a relaxation delay (d1) of 5 s. The experiments were carried out with water suppression by low-power selective water signal presaturation during 5 s of the relaxation delay. The accuracy of the quantitative data was assured by the relaxation delay, determined by the longitudinal relaxation time (T1) measurements, which is set in order to allow the complete relaxation of the nuclei. The T1 time was determined by the T1 inversion recovery pulse sequence consisting of a 180° pulse followed by a variable delay ($\tau$), a 90° pulse, and an acquisition.

The NMR spectra were processed by MestreC software. The spectra were Fourier transformed with FT size of 64K and 0.2 Hz line-broadening factor, phased and baseline corrected, and referenced to the TSP peak (0 ppm). The quantitative determination of acetic acid, methanol, and ferulic acid was obtained by manual integration of the

corresponding signals (1.920 ppm for acetic acid, 3.358 ppm for methanol, and 6.233 ppm for ferulic acid) and comparison with the TSP area. Integrals were converted in mass value (mg) according to the following formula, as previously reported.[40]

$$A\ x \times \frac{\mathrm{EW}\ x}{\mathrm{mg}\ x} = A\ \mathrm{TSP} \times \frac{\mathrm{EW\ TSP}}{\mathrm{mg\ TSP}}$$

$A\ x$ is the spectral area of the analyte, $A$ TSP is the spectral area of the internal standard, EW $x$ is the equivalent weight of the analyte, EW TSP is the equivalent weight of the internal standard, and EW = (molecular weight/number of hydrogens in the signal).

Through the content of methanol and the content of galacturonic acid, the degree of methylation (or acetylation/feruloylation) was calculated, using the following equation:

$$\text{degree of methylation} = \frac{\text{mol of methanol}}{\text{mol of galacturonic acid}} \times 100\%$$

*Linearity, Limit of Detection, and Limit of Quantification.* The linearity of the method was checked at a range between 0.1 mM (detection limit) and 100 mM for each analyte. Three replicates were performed for each concentration. Each solution was subjected to the entire experimental protocol. The limit of detection (LOD) and the limit of quantification (LOQ) were calculated utilizing the S/N ratio methods, based on the determination of the peak to peak noise.[41] LOD and LOQ were therefore calculated as the minimum concentrations producing a recognizable peak with a signal-to-noise ratio of, respectively, 3.3 or 10.

*Accuracy, Precision, Recovery, and Robustness of the Method.* The accuracy of the analyte's recovery was determined by assaying samples with known concentrations of methanol, acetic acid, and ferulic acid, both as pure compounds and as spiked matrix. Accuracy was determined by the following equation: accuracy = $(p^2 + b^2)^{1/2}$, where $p$ is precision and $b$ is the bias (difference between NMR value and the true or "accepted" value). Precision was evaluated both intraday and interday (intermediate precision), and the data were compared after three consecutive analyses (intraday) and from data obtained over a 15 day period (interday). The precision was expressed as coefficient of variation (CV%). Recovery of analytes was determined by spiking a sample of sugar beet pectin with pure compounds. The evaluation of robustness was performed by varying two parameters of the analytical procedure as hydrolyzing volume and time of hydrolysis.

## RESULTS AND DISCUSSION

**Development and Optimization of the Sample Preparation.** The proposed method involves pectin saponification (Figure 1) followed by separation of the polysaccharidic component by filtration and direct $^1$H NMR analysis at room temperature. The filtration step is necessary to eliminate from the solution the de-esterified polysaccharidic polymers. In fact, preliminary tests aiming to evaluate the possibility of analyzing directly the solution after saponification showed that pectin gave very poorly resolved spectra, also when de-esterified. For this reason, in the method we proposed, the polysaccharidic components were separated by filtration prior to NMR analysis. In a previous paper,[36] the authors determined the acetylation and methylation degree of pectin by $^1$H NMR measurement of the product of in-tube saponification of pectic material, and in an attempt to reduce the poor resolution of pectin solutions, NMR experiments were registered at high temperatures (80 °C). However, from a technical point of view, 80 °C is the maximum permitted temperature for many common NMR probes, thus limiting the applicability of the methods. Moreover, this approach is not optimal when the goal is the accurate determination of methanol, because at high temperatures a repartition of methanol in the headspace of the NMR tube may occur, and this might represent a delicate point that affects the robustness of the procedure.

The method proposed was initially tested on a standard of pectin sample, namely, citrus peel pectin with a declared methylation degree of 63−66%. To obtain satisfactory efficiency, the effect of the main variables involved in the hydrolysis of pectin, time of hydrolysis and volume of NaOH in $D_2O$, were varied to determine the optimal conditions allowing the complete reaction. Variable volumes of NaOH in $D_2O$ (1, 2, and 3 mL) and different incubation times (30, 60, 120, and 180 min) were tested. The results were evaluated by applying two-way ANOVA at a $p$ level of 0.05, considering also the interactions of the two factors. ANOVA results showed that the incubation time had a significant effect in enhancing the hydrolysis degree ($p$ = 0.007), whereas the NaOH in $D_2O$ volume and the interactions among the parameters were not found to be significant ($p$ = 0.079 and $p$ = 0.629, respectively). The incubation times of 30 and 60 min gave results significantly different from those obtained with incubation times of 120 and 180 min (as determined by post hoc Tukey-HSD tests). Thus, the use of 1 mL of NaOH in $D_2O$, to avoid deuterated solvent consumption, and 120 min of incubation, to minimize analysis time, was chosen in the final method.

**Method Validation.** The optimized method was subjected to validation in terms of precision, accuracy, linearity, detection and quantitation limits, repeatability, reproducibility, recovery, and robustness following recommendations of the International Conference on Harmonization (ICH (2005)): validation of analytical procedures, text and methodology; harmonized tripartite guideline, Q2(R1)). The validation tests were performed on a pure solution of methanol, acetic acid, and ferulic acid.

To determine the accuracy and precision of the methanol, acetic acid, and ferulic acid analysis by $^1$H NMR, a solution containing all of the analytes was obtained by weighing the compounds and dissolving them in the hydrolyzing solution (1 mL of 0.4 M NaOH in $D_2O$ and 0.1 mL of 0.2 mg/mL TSP in $D_2O$ as internal standard) and analyzed by $^1$H NMR in the experimental conditions previously reported. The same solution was used to spike a real matrix of sugar beet pectin. Measured results of the standard solution were in agreement with the amounts weighed in the range of concentrations of 0.1−100 mM, a range that corresponds with the final in-tube concentration of the analytes in real samples of pectin. Linearity was demonstrated in the same range. The instrumental quantification limit (LOQ, signal-to-noise ratio >10) in the experimental conditions reported was about 0.1 mM for methanol and acetic acid and 0.2 mM for ferulic acid, whereas the LOD was obtained at 0.03 mM for methanol and acetic acid and at 0.05 mM for ferulic acid (S/N ratio 3.3).

Standard solutions were also subjected to the entire experimental protocol to verify eventual loss of methanol and acetic acid during the various steps of sample preparation. Results are reported in Table 1 as precision, bias, and accuracy. A spiked matrix (sugar beet) was also analyzed, and the corresponding recoveries are reported in Table 1.

**Reproducibility and Robustness of the Method.** To determine the interday reproducibility, a pectin standard, after the first measurement, was kept refrigerated and reanalyzed by $^1$H NMR spectrometer after 3, 7, and 14 days. On each day three repetitions of the experiment were performed. The data were treated with one-way ANOVA for each analyte, and the results showed that no significant differences had arisen in the

**Table 1. Precision (Percent; Standard Deviation), Accuracy, Bias, and Recovery of the NMR Measurement of Methanol, Acetic Acid, and Ferulic Acid**

| | methanol | acetic acid | ferulic acid |
|---|---|---|---|
| precision (CV%)[a] | 2.22 | 1.94 | 2.01 |
| bias[a] | 0.024 | 0.093 | 0.002 |
| accuracy[a] | 2.22 | 1.94 | 2.00 |
| recovery %[b] | 93 ± 2 | 96 ± 2 | 90 ± 2 |

[a]Calculated on a standard solution subjected to the entire experimental protocol. [b]Calculated on sugar beet pectin spiked with standard solution and subjected to the entire experimental protocol.

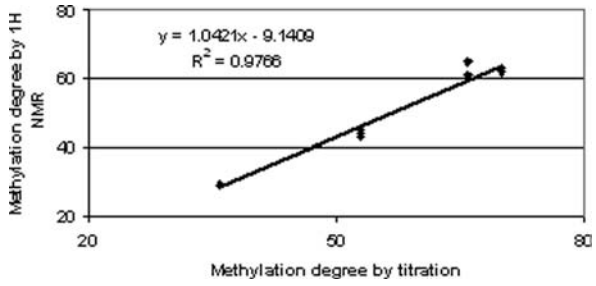

**Figure 2.** Correlation observed between the results obtained from the titration method and the $^1$H NMR-based method for citrus peel pectin methylation degree.

time interval under study. The coefficients of variation (CV) calculated on all 12 data (3 repetitions for 4 days) were 2.4% for acetic acid and 2.5% for methanol.

The data obtained from method optimization trials were analyzed to test the robustness of the method: the non-significant effect of the hydrolyzing agent volume and of hydrolysis time in the range of 120−180 min, as reported above, demonstrated that the method is robust to the variation of these factors. In this case the CV% calculated for methanol was 3.9%.

**Comparison of $^1$H NMR-Based Method and Titration Method.** The method was applied to three commercial pectin samples from citrus peel with different values of methylation, certified by the producer (Silvaextracts) and determined by titration. The titration method[26] is based on the determination of the ratio between the volume of NaOH used for the titration of the carboxylic groups "covered" by methyl groups ($V_2$) on the sum of $V_2$ + the volume of NaOH used for the titration of free carboxylic groups ($V_1$).

$$\text{degree of methylation} = \frac{V_2}{V_1 + V_2} \times 100\%$$

Results obtained by the proposed $^1$H NMR method (determined in triplicate) compared to the values provided are shown in Table 2.

The values determined are in line with the data provided by Silvaextracts. The correlations between couples of data were obtained by applying the regression analysis and are shown in Figure 2 for methylation degree. A good correlation ($R^2$ = 0.9766) was obtained. It can be observed that in general data from NMR were lower than those obtained by titration. The differences between the two methods can be ascribed to interfering substances present in pectin able to react with the sodium hydroxide, thus "inflating" the methylation degree. Also, similar differences between the method of titration and saponification combined with HPLC were reported previously.[18,19] The method here presented, based on the actual visualization of methanol and acetic acid, is expected to be more accurate.

As compared to the HPLC methods reported in the literature, the $^1$H NMR-based method here proposed presents the advantages of reduced time of analysis and the possibility to obtain in a single analysis data on methylation, acetylation, and feruloylation, which generally require separate chromatographic analyses. Another important advantage is that NMR allows absolute quantitative data to be obtained, avoiding the need of reference compounds and calibration curves.

**Analysis of Real Samples.** The validated method was applied to samples of soluble pectin extracted by chelating agent solutions from different food waste sources: sugar beet flakes, apple cake, pea hulls, olive pomace, and grape pomace. Figures 3 and 4 show the $^1$H NMR spectra for sugar beet flakes and olive pomace. $^1$H NMR spectra show the optimal resolution of methanol, acetic acid, and ferulic acid, which can be easily detected and quantified in samples of various origins. It is worth noting that besides signals of methanol and acetic acid, it is possible to detect in the spectra some other minor signals (evidenced in the spectra enlargements) that correspond to other chemical molecules linked to the pectin backbone. In the case of pectin originating from sugar beet, the main minor signals are in the aromatic zone and can be attributed to ferulic acid analogues.

The degree of methylation, acetylation, and feruloylation determined in the samples of industrial byproducts having variable levels of esterification degrees are reported in Table 3. Feruloylation degree is expressed with respect to galacturonic acid to make the data compatible with methylation and acetylation, even if ferulic acid in pectin can be linked also to arabinose side chains.

Results showed that, as expected, methanol is the main compound linked via ester bond to the pectin backbone. Sugar beet flakes and pea hulls contain also a significant amount of acetic esters, whereas ferulic acid esters were detected only in sugar beet.

**Table 2. Methylation and Acetylation Degree (Mole Percent of Galacturonic Acid) of Standard Citrus Peel Pectin Determined by Titration or $^1$H NMR**

| | standard[a] | | low methylation degree[b] | | medium methylation degree[b] | | high methylation degree[b] | |

**Table 3. Galacturonic Acid Content (Percent) and Methylation, Acetylation, and Feruloylation Degrees (Mole Percent of Galacturonic Acid) of Some Industrial Byproducts Determined by NMR[a]**

| | galacturonic acid content | methylation degree | acetylation degree | feruloylation degree |
|---|---|---|---|---|
| sugar beet flakes | 67.1 ± 0.9 | 29.1 ± 0.8 | 18.0 ± 0.5 | 0.268 ± 0.001 |
| pea hulls | 44.6 ± 0.8 | 29.83 ± 0.03 | 10.5 ± 0.9 | nd |
| apple cake | 40.8 ± 0.5 | 40 ± 1 | 5.6 ± 0.1 | nd |
| olive pomace | 72 ± 1 | 10.5 ± 0.5 | 7.5 ± 0.1 | nd |
| grape pomace | 89 ± 2 | 5.0 ± 0.2 | 1.0 ± 0.1 | nd |

[a]Galacturonic acid content was determined spectrophotometrically.

The values determined for pea hull sample using our method are in line with the values obtained by similarly extracted pectic polysaccharides of this byproduct reported previously[42] (methylation degree of 24%).

For sugar beet samples, lower values for methylation degree were observed with respect to the data published by Renard and Thibault[43] (29.1% for our sample vs 52%). This can be attributed to the different sample origins: the current sample was dried sugar beet flakes, whereas the sample analyzed by Renard and Thibault[43] was fresh sugar beet pulp. This indicates that the process of drying sugar beet pulp to obtain flakes can actually lower the degree of methylation. The same behavior is also observed by comparing the feruloylation degree obtained (0.2%) that is lower with respect to previously published data.[28]

The method is currently being applied to a wide number of different food and byproduct samples, showing that it is suitable for all food matrices.

The overall data demonstrate that the quantitative [1]H NMR methodology proposed can be considered a high-throughput analysis that combines the determination of methylation, acetylation, and also feruloylation degree of pectin using a small sample amount and short preparation time. Furthermore, the method can be applied to pectic polysaccharides originating from a wide range of sources and having very different physical properties. It can detect small amounts of methanol, acetic acid, and ferulic acid.

The method is expected to be more accurate with respect to titration in determining the methylation degree without confusing it with other esterified forms present in pectin and also offers the advantage to obtain structural information on other compounds possibly linked via ester bond to pectin.

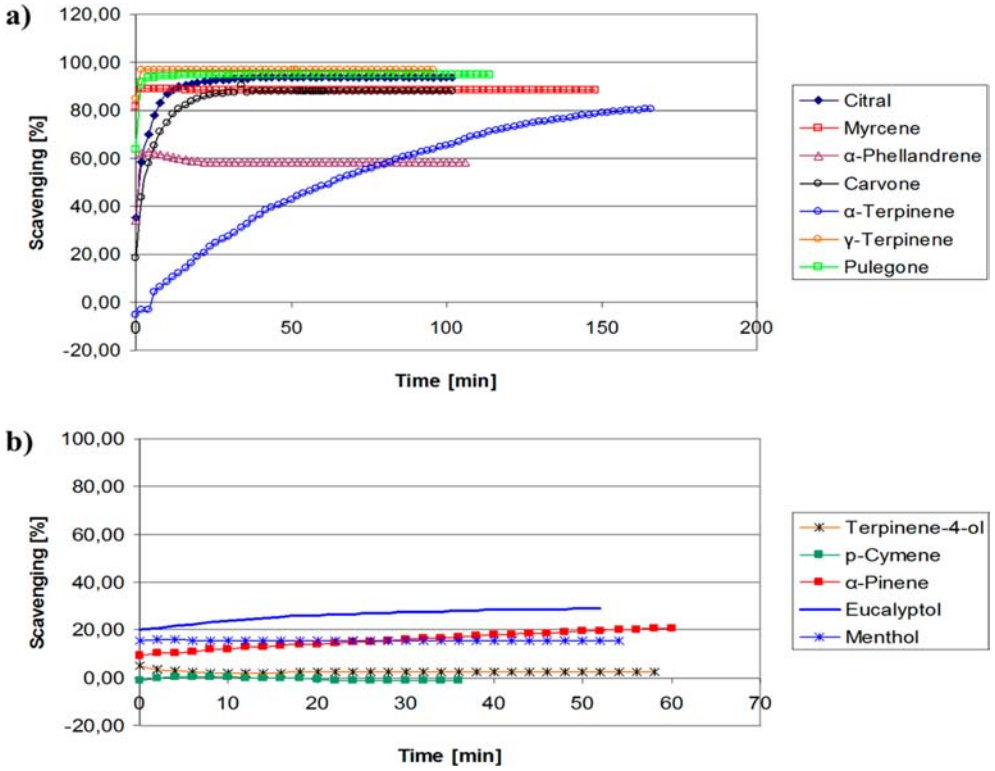

**Figure 1.** Free radical scavenging activity toward DPPH•, in methanol, for (a) monoterpenes with conjugated $\pi$ bonds and (b) monoterpenes lacking conjugated double bonds.

obtained from Polish Reagents (Gliwice, Poland). All solvents were of analytical purity grade.

**DPPH• Radical Scavenging Assay.** The radical scavenging activity of the analyzed compounds was determined spectrophotometrically by using the DPPH• assay.[12−15] Absorbance was measured by a Genesys 20 UV−vis spectrophotometer (Thermo Fisher Scientific, Waltham, MA, USA) in a 1 cm quartz cell. DPPH• solution was prepared by mixing 0.004 g ($10^{-5}$ mol) of DPPH• with 100 mL of each of the five solvents used in the study: methanol, 2-butanone, ethyl acetate, chloroform, and *n*-heptane. The concentration of the resulting solution was 0.1 mM. Fresh reagent was always prepared prior to analysis. A reference sample was prepared by mixing 2.5 mL of DPPH• (0.1 mM) with 0.7 mL of appropriate solvent. Afterward, each of the examined compounds was mixed with DPPH• solution. For each sample, the same amount (0.003 mol) of the compound was added to 2.5 mL of 0.1 mM DPPH• solution (the exact volumes of all liquid compounds and the weighed amounts of thymol and menthol are given in all tables in the Supporting Information). To obtain the exact volume for each of the measurements, the samples were made up to 3.2 mL volume, with the use of proper solvent. The samples were prepared with the same molar ratio of DPPH• to terpene. The loss of DPPH• absorbance was measured in the excess of examined compounds. Each measurement was repeated three times at 517 nm at room temperature. The final result is the average of three replicates. Free radical scavenging activity was calculated as a percentage of DPPH• decoloration according to the formula

$$\text{scavenging}\,\% = 100 \times (A_{\text{blank}} - A_{\text{sample}}/A_{\text{blank}}) \quad (1)$$

where $A_{\text{blank}}$ is the absorbance of the sample except tested substances and $A_{\text{sample}}$ is the absorbance of the sample with a tested compound.

**DPPH• Radical Scavenging Assay in the Presence of Silver Nitrate.** To check the influence of double bonds on the DPPH• scavenging activity of terpenes, a test with $AgNO_3$ was performed. Silver ions are known to form stable complexes with dienes. A reference sample was prepared by mixing 2.5 mL of DPPH• (0.1 mM) in methanol with 0.003 mol of $AgNO_3$ dissolved in a 1.2 mL of mixture of 0.4 mL of distilled water and 0.8 mL of methanol. Tested samples were prepared by mixing the proper volume of monoterpene containing 0.003 mol of the compound, with $AgNO_3$ (0.003 mol) solution in 0.5 mL of 70% aqueous methanol. After 2 min, 2.5 mL of DPPH• in methanol (0.1 mM) was added to the mixture, and the volume was always made up to 3.7 mL with methanol. The activity of tested samples was compared to the activity of samples that contained a proper amount of methanol instead of $AgNO_3$ solution. For each sample, the absorbance was measured at 517 nm directly after mixing. The measurements were repeated three times. Free radical scavenging activity was calculated according to eq 1.

**Statistical Analysis.** All of the experiments were performed in triplicate, and the data are presented as mean values (±standard deviation values are given in the Supporting Information).

## RESULTS AND DISCUSSION

In the attempt to develop a pharmacophore model of monoterpene chain-breaking antioxidant, the experiments aimed at identification of structural elements responsible for free radical scavenging activity. The literature broadly covers the problem of polyphenols' structure−activity relationships; however, in the case of monoterpenes such data are scarce, and no evidence has been delivered at to which part of the molecule is responsible for direct antioxidant activity or for its enhancement. Twenty compounds (17 monoterpnes, 1 sesquiterpene, 1 monoterpenic phenol, and 1 phenyl propanoid) commonly present in essential oils were used in the study.

The loss of DPPH• absorbance was read in the presence of an excess of the analyzed compounds. The DPPH•/analyte molar ratio was kept constant for all of the analyzed compounds. Keeping this ratio constant was crucial to give the possibility to properly compare the activity of individual analytes (the amount of moles of all the studied terpenoids, which reacted with DPPH•, was equal). In the literature equal

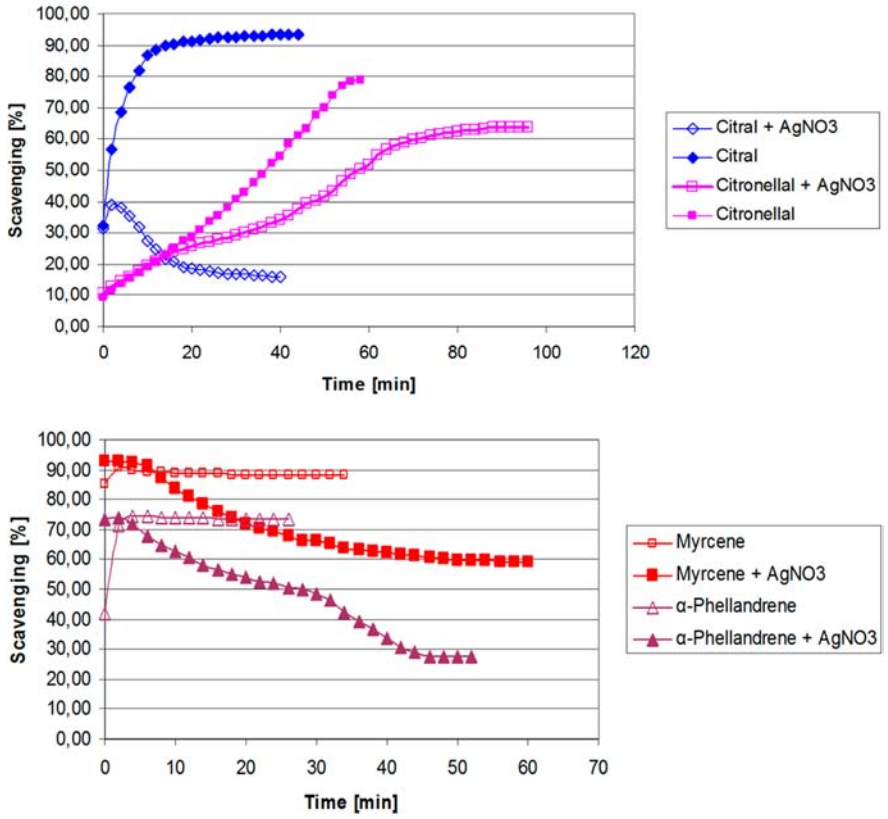

**Figure 2.** Influence of silver nitrate addition on free radical scavenging activity of selected monoterpenes. For experimental details, please refer to Materials and Methods.

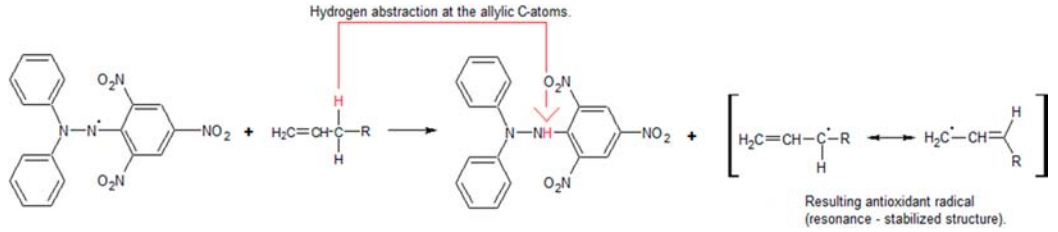

**Figure 3.** Proposed reaction mechanism between DPPH• and monoterpenes possessing conjugated double bonds.

volumes of liquid terpenes are usually added to DPPH• without taking into account that these volumes refer to different amounts of moles.

The radical scavenging activity of terpenoids was expressed as the percentage quenching of DPPH• radical.[8] The absorbance was read every 2 min from the beginning of the reaction until a plateau was reached. In the literature the activity of individual compounds is compared, for example, after 5 or 30 min.[8,12−15] However, the reaction of each free radical scavenger with DPPH• may be different, even among the compounds characterized with potent free radical scavenging activity, as can be seen for several terpenoids in Figure 1. The following terpenes have been found inactive or of weak activity in methanol (insoluble hydrocarbons are not taken into consideration): α-pinene, *p*-cymene, eucalyptol, menthol, and terpinene-4-ol (see Figure 1b). Another group of compounds has been found to scavenge DPPH• radical very quickly, reaching plateau values after several minutes: citral, carvone, myrcene, γ-terpinene, and pulegone. α-Terpinene and α-phellandrene, although found active in methanol, exerted lower scavenging activity when compared to the aforementioned five very active monoterpenes (see Figure 1a).

All of the analyzed compounds that were found to scavenge DPPH• free radical possessed a double bond in their molecule. Terpenes with conjugated double bonds quickly scavenged DPPH• radical, reaching plateau values within minutes, as seen in Figure 1a. To check the influence of blocking π bonds on monoterpenes' free radical scavenging activity, another test was performed. The π bonds were blocked with the use of silver ions as the Ag(I)−diene complexes are easily formed.[31] As can be seen in Figure 2, addition of silver nitrate leads to the decrease of chain-breaking antioxidant activity of terpenes. The decrease is more significant for terpenoids possessing conjugated double bonds (citral, myrcene, α-phellandrene) than for those without conjugation of double bonds, for example, citronellal. It can be concluded that π bonds are responsible for the chain-breaking antioxidant activity of terpenes. It has been proved, for the first time, that blocking conjugated double bonds leads to inhibition of the chain-breaking antioxidant activity of terpenes, which proves

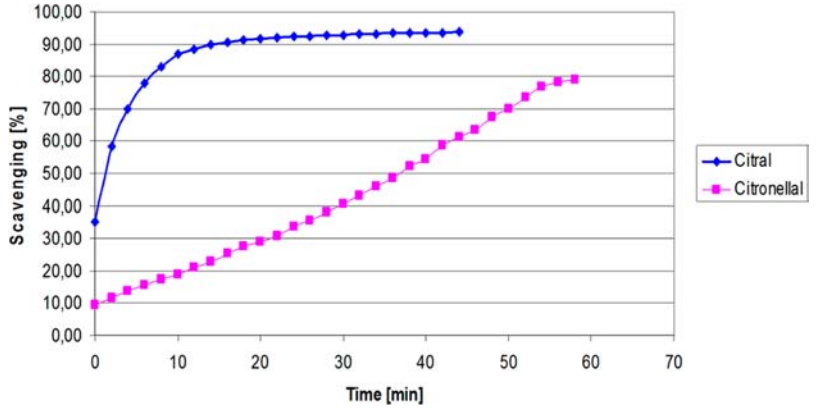

**Figure 4.** Comparison of free radical scavenging activity of two monoterpenes with very similar structures (citral, with conjugated double bonds; and citronellal, without conjugated double bonds) toward DPPH• in methanol.

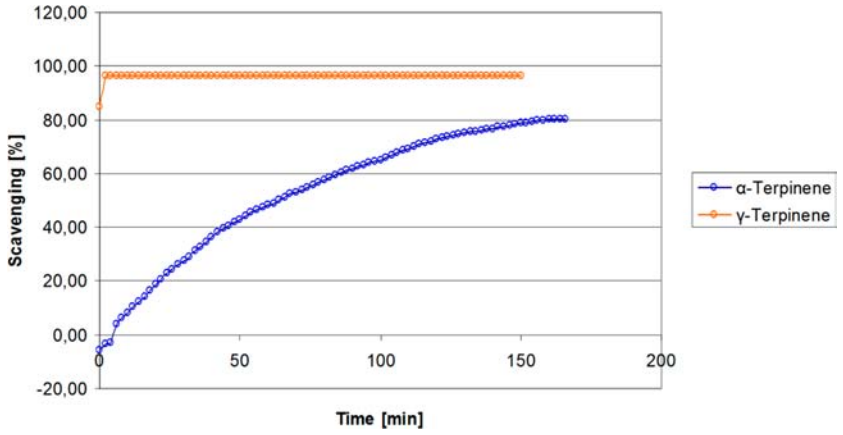

**Figure 5.** Comparison of free radical scavenging activity of $\alpha$- and $\gamma$-terpinene toward DPPH• in methanol.

conjugated $\pi$ bonds are essential for the free radical scavenging activity of monoterpenes.

To explain the influence of conjugated double bonds on terpenes' chain-breaking antioxidant activity, the possible reaction mechanism with DPPH• is proposed, as seen in Figure 3. Terpenes may lose allylic hydrogen atoms (C−H allylic bond dissociation energy = 364 kJ/mol, compared to those of alkylic C−H bonds = 410 kJ/mol and vinylic C−H bonds = 452 kJ/mol) and neutralize a radical, as also postulated by Öztürk.[28] In the presence of free radical scavenger DPPH• is reduced to hydrazine, and resulting antioxidant radical is formed. The resulting antioxidant radical may either propagate or terminate radical chain reaction. To be an effective direct antioxidant, a new radical, formed in the reaction with DPPH•, should not propagate the chain reaction. The resulting antioxidant radical should be unreactive to terminate radical chain reaction quickly. The reaction of DPPH• with conjugated double-bond terpenes results in the formation of resonance-stabilized structure. The stabilization is associated with the charge delocalization over the whole molecule, possibly due to the presence of conjugation of $\pi$ bonds (Figure 3).

The following terpenes have been characterized with potent chain-breaking antioxidant activity, as they quickly terminated radical chain reaction in methanol (Figure 1a): citral, pulegone, $\gamma$-terpinene, carvone, and myrcene. The influence of conjugated double bonds on terpene's activity can be easily noted when two monoterpenes, with very similar structures, are compared, for example, citral and citronellal (Figure 4). The only difference between these two structures is the presence of a conjugated double bond (additional $\pi$ bond) in citral. However, this small difference leads to a substantial change of citral chain-breaking antioxidant activity in comparison to the activity of citronellal.

Quite surprising were the results obtained for terpinenes: $\alpha$-terpinene, possessing conjugated $\pi$ bonds in its structure, was a less potent free radical scavenger than $\gamma$-terpinene (Figure 5). In the literature $\gamma$-terpinene has been defined as a very effective antioxidant with the possibility to easily lose allylic hydrogen atoms in the 3- and 6-positions (1,4-cyclohexadiene derivative).[28] In the case of $\alpha$-terpinene (1,3-cyclohexadiene derivative) allylic H atoms are at the 5- and 6-positions. Therefore, it may be postulated that in case of cyclic monoterpenes, containing double bonds, the 1,4-cyclohexadiene moiety enhances their free radical scavenging activity. The spare electron of the resulting antioxidant is better delocalized over the whole molecule when double bonds are between the C1−C2 and C4−C5 atoms. This effect can be compared to a similar good resonance stabilization of radicals formed in the reaction between DPPH• and hydroquinone (benzene-1,4-diol) derivatives.[6] Further studies with the use of terpenes containing 1,4-cyclohexadiene moiety (of natural and synthetic origin) can be performed to provide additional proof. Generally, terpenes, which quickly lead to stable (plateau) radical scavenging activity values, can be considered as good free radical scavengers, as they terminate radical chain reaction. Those that form non-resonance-stabilized radicals, in the

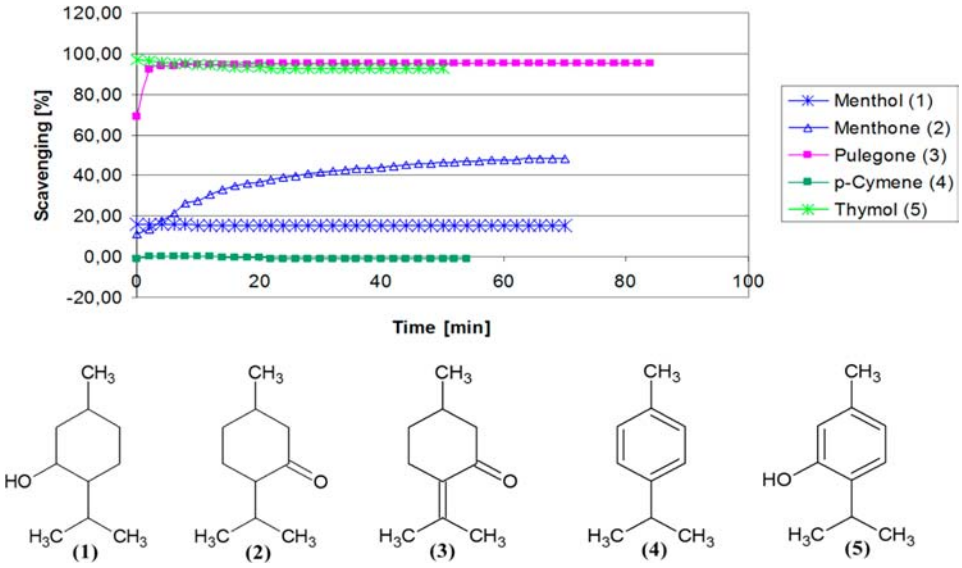

**Figure 6.** Comparison of free radical scavenging activity of selected monoterpenes and thymol, as influenced by their structures.

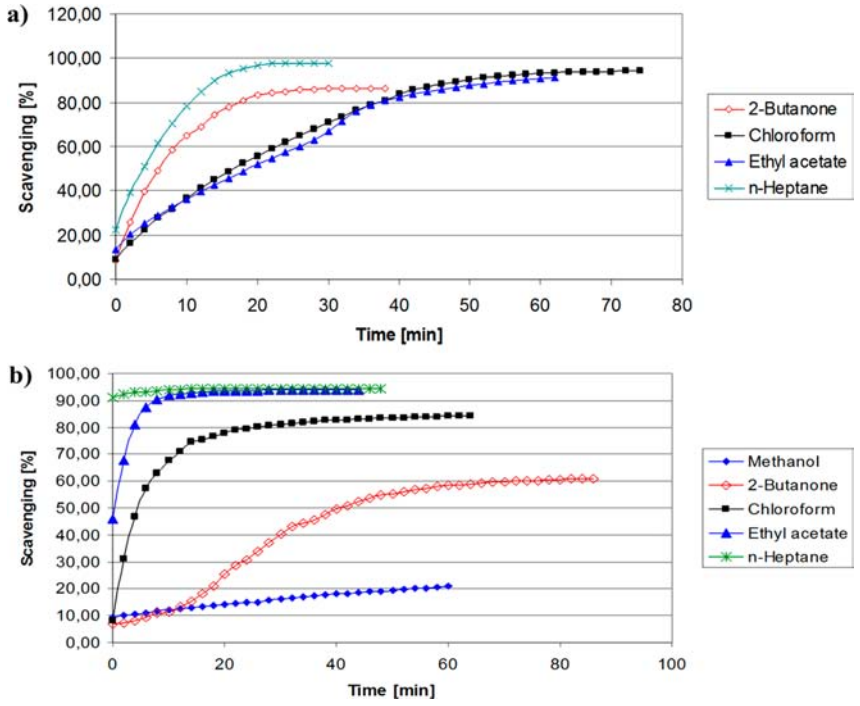

**Figure 7.** Influence of solvent type, used in the DPPH• assay, on free radical scavenging activity of two exemplary monoterpenes: (a) ocimene and (b) $\alpha$-pinene.

reaction with DPPH•, for example, citronellal (a molecule without $\pi$ bond conjugation), may propagate radical reactions and may not be regarded as efficient free radical scavengers.

To grasp the idea of how the molecular structure influences direct antioxidant activity of common terpenes, the activities of selected terpenes and thymol have been compared (Figure 6). Monoterpenes without a $\pi$ bond, for example, menthol, do not exert free radical scavenging activity in the DPPH• assay. When one double bond appears in the molecule, DPPH• scavenging ability increases, as, for example, for menthone. Compounds with two double bonds, as already explained, quickly terminate radical chain reaction and can be considered as potent free radical scavengers, for example, pulegone. Direct antioxidant activity disappears when a diene molecule is replaced by an aromatic ring, as was observed for *p*-cymene. A molecule regains its activity when a hydroxyl group appears, as, for example, in thymol.

In the last part of the experiment, the activity of the analyzed compounds was investigated in a set of five solvents, representing a continuous scale of polarity: *n*-heptane, chloroform, ethyl acetate, 2-butanone, and methanol (Figure 7). The first stimulus to measure the activity of compounds in the above-mentioned solvents was due to terpenes' solubility problems in DPPH• methanolic solution. The other one was related to the fact that the reaction environment, for example, the polarity of solvent, was found to influence the antioxidant activity of fragrance phenols.[13] Less polar terpenes, for example, myrcene, $\alpha$-pinene, farnesene, and ocimene, were characterized

dx.doi.org/10.1021/jf502857s | J. Agric. Food Chem. 2014, 62, 9088−9094

with better antioxidant activity in nonpolar solvents than in polar ones, which is the opposite of the results obtained for monoterpenic phenols. Hydrogen bond accepting solvents (HBA) (ketones, esters, ethers) formed hydrogen bonds with phenols' hydroxyl groups, making them less accessible to DPPH$^{\bullet}$. For terpenes, another mechanism may be suspected, as hydrogen abstraction from phenols is due to the presence of hydroxyl groups, which may form hydrogen bonds with HBA solvents. As the free radical scavenging activity of terpenes is due to $\pi$ bonds, therefore HBA solvents will not decrease the activity of terpenes as substantially as in the case of phenols. The results presented in Figure 7 clearly show that the free radical scavenging activity of terpenes depends on the solvent type used in the study. It is well seen with the example of $\alpha$-pinene, which quickly reaches scavenging activity plateau values in *n*-heptane, although $\alpha$-pinene possesses only one $\pi$ bond. This compound is a representative of bicyclic monoterpenes. Further studies are required to study the aforementioned phenomenon. It may be concluded that compounds exerting potent free radical scavenging activity in nonpolar solvents may act as efficient antioxidants in lipophilic end-use products, whereas those active in a polar environment may be efficient in scavenging free radicals in polar end-use products' media.

The presented results should stimulate additional research in the field of terpenoid antioxidants. Further studies may consider the influence of different substituents on the exerted activity, for example, for chemically modified structures. As interesting results have been obtained for $\alpha$-pinene, in nonpolar solvents, the analysis of a broader group of bicyclic monoterpenes may provide interesting data. In nature, individual terpenes are found in complex mixtures; therefore, synergistic and antagonistic interactions should be considered. Structure−activity relationships for terpenes may also be checked with other antioxidant tests, for example, ABTS$^{\bullet+}$, $\beta$-carotene assays, and other methods measuring antioxidant activity.

42 min), **2** (27 mg, 46 min), and **3** (11 mg, 36 min) were isolated from fraction D-8.

Fraction F was subjected to flash chromatography elution with $H_2O$−MeOH (from 100:0 to 0:100) in gradient to yield 10 fractions (fractions F-1−10). Fraction F-3 was obtained with the mobile phase of MeOH−$H_2O$ (10:90), and was further purified using reversed-phase preparative HPLC with MeOH−$H_2O$ (27:73) as the mobile phase at a flow rate of 5 mL/min to give **4** (33 mg, 31 min) and **10** (20 mg, 47 min). Fraction F-5 was obtained with the mobile phase of MeOH−$H_2O$ (20:80), and was subjected to chromatography over Sephadex LH-20 with $H_2O$ as the mobile phase to give **9** (15 mg) and **13** (27 mg). Fractions F-6 and F-7 were obtained with the mobile phase of MeOH−$H_2O$ (30:70). Fraction F-6 was chromatographed over Sephadex LH-20 with $H_2O$ elution to give **15** (31 mg). Fraction F-7 was purified using reversed-phase preparative HPLC with MeOH−$H_2O$ (30:70) as the mobile phase at a flow rate of 5 mL/min to give **14** (19 mg, 55 min) and **16** (21 mg, 51 min).

Fraction H was subjected to flash chromatography elution with $H_2O$−MeOH in gradient to yield 12 fractions (fractions H-1−12). Fraction H-5 was obtained with the mobile phase of MeOH−$H_2O$ (20:80), and was further purified by reversed-phase preparative HPLC with MeOH−$H_2O$ (30:70) as the mobile phase at a flow rate of 5 mL/min to give **5** (18 mg, 33 min) and **11** (10 mg, 39 min). Fraction H-6 was obtained with the mobile phase of MeOH−$H_2O$ (30:70), and was purified using reversed-phase preparative HPLC with MeOH−$H_2O$ (30:70) as the mobile phase at a flow rate of 5 mL/min to give **6** (13 mg, 35 min) and **12** (14 mg, 37 min). Fraction K was chromatographed over Sephadex LH-20 with $H_2O$ elution to give **18** (106 mg). The structures of compounds **1**−**18** are shown in Figure 1.

*Spectral Data. (7S,8R,7′S)-Dihydrodehydrodiconiferyl Alcohol-7′-hydroxy-4-O-β-D-glucopyranoside (**1**).* White amorphous powder; soluble in water or methanol; $[\alpha]^{20}_D$ −32.8° (*c* 0.07, MeOH); CD (MeOH) $\lambda_{max}$ ($\Delta\varepsilon$) 292 (+0.53), 245 (+0.81), 226 (−1.59) nm; IR $\nu_{max}$ 3384, 2933, 1601, 1518, 1464, 1335, 1268, 1136, 1076, 859, 803 cm$^{-1}$; $^1$H NMR (DMSO-$d_6$, 500 MHz) data, see Table 1; $^{13}$C NMR (DMSO-$d_6$, 125 MHz) data, see Table 2; (+)-HRESIMS *m*/*z* 561.1954 (calcd for $C_{26}H_{34}O_{12}Na$, 561.1942).

*(7S,8R,7′S,8′S)-4,9,4′,7′-Tetrahydroy-3,3′-dimethoxy-7,9′-epoxylignan-4-O-β-D-glucopyranoside (12).* White amorphous powder; soluble in water or methanol; $[\alpha]^{20}_{D}$ +55.2° ($c$ 0.06, MeOH); CD (MeOH) $\lambda_{max}$ ($\Delta\varepsilon$) 281 (+0.61), 231 (+1.92) nm; IR $\nu_{max}$ 3372, 2933, 1601, 1514, 1463, 1426, 1269, 1157, 1076, 859, 820 cm$^{-1}$; $^1$H NMR (DMSO-$d_6$, 500 MHz) data, see Table 3; $^{13}$C NMR (DMSO-$d_6$, 125 MHz) data, see Table 2; (+)-HRESIMS $m/z$ 561.1952 (calcd for $C_{26}H_{34}O_{12}Na$, 561.1942).

*Enzymatic Hydrolysis of 1−12.* Compound **1** (6.0 mg) was dissolved in 0.1 M acetate buffer (3.0 mL). The reaction mixture was added to cellulase (9.0 mg, Sigma-Aldrich, St. Louis, MO) and left at 38 °C for 2 h. The solution was then transferred to a liquid−liquid extractor and extracted with $CHCl_3$. The aqueous fraction was subjected to silica gel thin layer chromatography (TLC) [$CHCl_3$−MeOH−$H_2O$ (7:3:1)] to show the presence of D-glucose ($R_f$ = 0.16). The organic layer was evaporated in vacuo and purified using reversed-phase preparative HPLC with MeOH−$H_2O$ (45:55) as the mobile phase to give **1a** (3 mg), which was identified using NMR. Hydrolysis of **2**−**12** and sugar identification were performed according to the procedure described for **1**.

*Hepatoprotective Effects on Cytotoxicity Induced by D-Galactosamine in HL-7702 Cells.* Compounds **1**−**18** were tested for hepatoprotective effects using an MTT assay in HL-7702 cells. Each cell suspension containing 1 × 10$^{-5}$ cells in 1 mL of Dulbecco's modified Eagle's medium containing fetal calf serum (10%), penicillin (100 units/mL), and streptomycin (100 μg/mL) was placed in a 96-well microplate and precultured for 24 h at 37 °C under a 5% $CO_2$ atmosphere. Fresh medium containing bicyclol and the test samples was added, and the cells were cultured for 1 h. The cultured cells were exposed to 25 mM D-galactosamine for 24 h. The medium was then replaced with fresh medium containing 0.5 mg/mL MTT. After incubation of 4 h, the medium was removed, and DMSO was added to dissolve formazan crystals. The optical density (OD) of the formazan solution was measured using a microplate reader at 492 nm.

Inhibition (%) was calculated using the following formula:

$$\text{inhibition (\%)} = [(OD_{sample} - OD_{control})/(OD_{normal} - OD_{control})] \times 100$$

## RESULTS AND DISCUSSION

A previous study has shown strong inhibitory effects of two tetrahydrofuranoid lignans, taxiresinol and (7′*R*)-7′-hydroxytaxiresinol, on the elevation of serum levels of tumor necrosis factor-alpha (TNF-$\alpha$) by D-galactosamine/LPS toxication.[10] Furthermore, these two lignans protected hepatocytes from cytotoxicity induced by D-galactosamine/TNF-$\alpha$ in primary cultured mouse hepatocytes. Therefore, in the present study, all isolated compounds were tested for hepatoprotective effects on D-galactosamine-induced cytotoxicity in HL-7702 hepatic cells. Compounds **1**, **2**, **7**−**12**, and **17** showed significantly stronger hepatoprotective activity than the positive control bicyclol at a concentration of $1 \times 10^{-5}$ M. Analysis of structure−activity relationships revealed that the tetrahydrofuran ring in lignan glucosides might contribute to the hepatoprotective activity.

**Structure Elucidation.** Compound **1** was obtained as a white powder, and its molecular formula was determined to be $C_{26}H_{34}O_{12}$ on the basis of HRESIMS findings at *m*/*z* 561.1954 $[M + Na]^+$. The $^1$H NMR spectrum of **1** (see Table 1) revealed an ABX system aromatic ring [$\delta$ 7.06 (1H, d, $J$ = 8.5 Hz), 6.96 (1H, d, $J$ = 2.0 Hz), 6.84 (1H, dd, $J$ = 8.5, 2.0 Hz)] and a 1,3,4,5-tetra-substituted aromatic ring [$\delta$ 6.83 (1H, d, $J$ = 2.0 Hz), 6.81 (1H, d, $J$ = 2.0 Hz)] in the downfield region. $^1$H NMR spectrum analysis revealed two methoxy groups at $\delta$ 3.78 (3H, s) and 3.75 (3H, s) and a glucopyranosyl anomeric proton at $\delta$ 4.88 (1H, d, $J$ = 7.5 Hz). Additionally, the $^1$H NMR spectrum revealed a methylene group at $\delta$ 1.75 (1H, m) and 1.68 (1H, m); two oxymethylene protons at $\delta$ 3.73 (1H, m), 3.63 (1H, m), 3.48 (1H, m), and 3.44 (1H, m); two oxymethine protons at $\delta$ 5.49 (1H, d, $J$ = 6.5 Hz) and 4.57 (1H, m); and a methine proton at $\delta$ 3.42 (1H, m).

The $^{13}$C NMR spectrum of **1** (see Table 2) showed 26 carbon signals, of which eight could be assigned to a glucose unit ($\delta$ 100.1, 77.0, 76.9, 73.2, 69.8, 60.7) and two methoxy groups ($\delta$ 55.8, 55.7), and the remaining 18 carbons could be assigned to a lignan skeleton.[11] In the heteronuclear multiple-bond correlation (HMBC) spectroscopy spectrum (see Figure 2), the correlation peaks of H-7 resonated at $\delta$ 5.49 with C-1, C-2, C-6, C-8, C-9, C-4′, and C-5′, and H-7′ resonated at $\delta$ 4.57 with C-1′, C-2′, C-6′, C-8′, and C-9′, which confirmed the benzofuran-type lignan of **1**. A detailed HMBC spectrum analysis revealed the positions of two methoxy groups located at C-3 and C-3′, respectively. Furthermore, the glucose unit was connected at C-4, according to the correlation from anomeric proton H-1″ resonated at $\delta$ 4.88 to C-4; **1** was hydrolyzed with cellulase to yield **1a** and D-glucose, which was identified by TLC analysis. The $\beta$ form of glucose was determined by the presence of an anomeric proton at $\delta$ 4.88 (1H, d, $J$ = 7.5 Hz, H-1″). On the basis of the above analysis, the planar structure of **1** was defined as dihydrodehydrodiconiferyl alcohol-7′-hydroxy-4-*O*-$\beta$-D-glucopyranoside.

The relative configuration of H-7 and H-8 in **1** was defined as *trans* from the characteristic correlation peak of H-7 with H-9 in the ROESY spectrum (see Figure 3). The positive Cotton effects at 245 and 292 nm in the CD spectrum revealed the 7*S*,8*R* configuration for **1**.[11] A positive Cotton effect at 346 nm in the $Rh_2(OCOCF_3)_4$-induced CD spectrum indicated the 7′*S* configuration for **1a**.[12] Thus, compound **1** was defined as (7*S*,8*R*,7′*S*)-dihydrodehydrodiconiferyl alcohol-7′-hydroxy-4-*O*-$\beta$-D-glucopyranoside.

Compound **2** had the same molecular formula as **1**, which was determined from HRESIMS at *m*/*z* 561.1951 $[M + Na]^+$. Its NMR data (Tables 1 and 3) were almost identical to those of compound **1**, which indicated that compound **2** had the same planar structure as **1**. The absolute configurations for C-7, C-8, and C-7′ of **2** were identified by the same method as that used for **1**. In the ROESY experiment, the correlation peak of H-7 with H-9 determined the *trans* configuration of H-7 and H-8 in **2**. The 7*R*,8*S* configuration for **2** was confirmed by the negative Cotton effects at 243 and 282 nm in the CD spectrum.

dx.doi.org/10.1021/jf501859x | J. Agric. Food Chem. 2014, 62, 9095−9102

Hydrolysis of **2** with cellulase yielded **2a** and D-glucose, which was identified by comparison with the D-glucose standard in TLC analysis. The absolute configuration for C-7′ in **2a** was defined as *S* based on a positive Cotton effect at 350 nm in the $Rh_2(OCOCF_3)_4$-induced CD spectrum. Therefore, compound **2** was defined as (7*R*,8*S*,7′*S*)-dihydrodehydrodiconiferyl alcohol-7′-hydroxy-4-*O*-*β*-D-glucopyranoside.

Compound **3** exhibited the molecular formula $C_{26}H_{34}O_{13}$, as determined using HRESIMS at *m*/*z* 577.1900 $[M + Na]^+$. The $^1H$ NMR spectrum (see Table 1) of **3** showed six aromatic proton signals at *δ* 7.75 (1H, dd, *J* = 8.5, 2.0 Hz), 7.57 (1H, d, *J* = 2.0 Hz), 7.18 (1H, d, *J* = 8.5 Hz), 6.92 (1H, brs), 6.68 (1H, overlap), and 6.68 (1H, overlap), revealing the presence of two ABX system aromatic rings. In addition, the $^1H$ NMR spectrum revealed two methoxy groups at *δ* 3.81 (3H, s) and 3.74 (3H, s) and a glucopyranosyl anomeric proton at *δ* 5.08 (1H, d, *J* = 7.5 Hz). In the $^{13}C$ NMR spectrum (see Table 2), apart from two methoxy carbons and a glucose unit, the remaining 18 skeleton carbon signals suggested that the aglycone of **3** was also a lignan. In the HMBC spectrum (see Figure 2), the characteristic correlation of H-8 at *δ* 5.58 with C-4′ at *δ* 145.6 indicated that **3** was an 8-*O*-4′ neolignan. The correlation peaks of two methoxy groups at *δ* 3.81 and 3.74 with C-3 and C-3′ confirmed that the linkage position of these methoxy groups was at C-3 and C-3′, respectively. The correlation of H-1″ (*δ* 5.08) with C-4 (*δ* 151.1) indicated that the linkage point of the glucose unit was at C-4. On the basis of the above data, **3** was defined as 4,9,7′,9′-tetrahydroxy-3,3′-dimethoxyl-7-oxo-8−4′-oxyneolignan-4-*O*-*β*-D-glucopyranoside.

To designate the absolute configuration of C-8 and C-7′ in compound **3**, CD exciton chirality and the $Rh_2(OCOCF_3)_4$-induced CD spectrum were assayed. Cellulase hydrolysis of **3** resulted in **3a** and D-glucose. A negative exciton-split Cotton effect at 332 nm (Δ*ε* −0.05) and 261 nm (Δ*ε* +0.07) in **3a** exhibited in the CD spectrum indicated that the two transition dipole moments of the chromophores (benzoyl moiety and benzene moiety) were oriented in an anticlockwise manner (see Supporting Information Figure S26). Thus, the absolute configuration of C-8 was assigned as 8*R*. Moreover, the positive Cotton effects at 328 and 374 nm in the $Rh_2(OCOCF_3)_4$-induced CD spectrum indicated the 7′*S* configuration for **3a**. From the above analysis, **3** was defined as (8*R*,7′*S*)-4,9,7′,9′-tetrahydroxy-3,3′-dimethoxyl-7-oxo-8−4′-oxyneolignan-4-*O*-*β*-D-glucopyranoside (**3**).

Compound **4**, a white powder, had the same molecular formula ($C_{26}H_{34}O_{13}Na$, *m*/*z* 577.1905) as **3**. The UV, IR, and NMR spectroscopy data of **4** indicated that it was an 8-*O*-4′ system neolignan and an optical isomer of **3**. Cellulase hydrolysis of **4** resulted in **4a** and D-glucose. In the CD spectrum, a positive exciton-split Cotton effect at 332 nm (Δ*ε* +0.04) and 265 nm (Δ*ε* −0.06) caused by the exciton coupling of the benzoyl and benzene chromophores indicated the 8*S* configuration of **4a** (see Supporting Information Figure S35). In the $Rh_2(OCOCF_3)_4$-induced CD experiment, a positive Cotton effect at 367 nm indicated the 7′*S* configuration for **4a**. Thus, compound **4** was defined as (8*S*,7′*S*)-4,9,7′,9′-tetrahydroxy-3,3′-dimethoxyl-7-oxo-8−4′-oxyneolignan-4-*O*-*β*-D-glucopyranoside (**4**).

Compound **5** had the molecular formula $C_{26}H_{32}O_{12}$ (*m*/*z* 559.1787 for $C_{26}H_{32}O_{12}Na$ in HRESIMS), and exhibited hydroxyl (3386 $cm^{-1}$), carbonyl (1757 $cm^{-1}$), and phenyl (1601 and 1514 $cm^{-1}$) groups in the IR spectrum. The $^1H$ NMR spectrum (see Table 1) showed two sets of ABX system aromatic rings [*δ* 6.96 (1H, d, *J* = 8.5 Hz), 6.78 (1H, d, *J* = 2.0 Hz), 6.72 (1H, d, *J* = 8.5 Hz), 6.66 (1H, dd, *J* = 8.5, 2.0 Hz), 6.65 (1H, d, *J* = 2.0 Hz), and 6.57 (1H, dd, *J* = 8.5, 2.0 Hz)]. In addition, two methylene protons [*δ* 2.70 (1H, dd, *J* = 13.5, 6.5), 2.49 (1H, overlap), 4.13 (1H, t, *J* = 8.5), 4.01 (1H, t, *J* = 8.5)], three methane protons [*δ* 4.34 (1H, t, *J* = 5.0), 2.84 (1H, dt, *J* = 8.5, 6.0), 2.46 (1H, m)], two methoxy groups [*δ* 3.73(3H, s), 3.71 (3H, s)], and a glucopyranosyl anomeric proton [*δ* 4.83 (1H, d, *J* = 7.5 Hz)] were observed in the upfield region. The $^{13}C$ NMR spectrum of **5** revealed 26 carbon resonances (Table 2) corresponding to the glucose unit, two methoxy groups, and two C6−C3 units. These data indicated that **5** was a dibenzylbutyrolactone lignan with substitution of two methoxy groups and a glucose unit.

In the HMBC spectrum (see Figure 2), correlation peaks from H-8 to C-1, C-7, C-9, C-7′, C-8′, and C-9′, from H-8′ to C-1′, C-7′, C-9′, C-7, C-8, and C-9, from $OCH_3$-3/3′ to C-3/3′, and from H-1″ to C-4 confirmed the dibenzylbutyrolactone skeleton of **5**, as well as the location of two methoxy groups and a glucose unit. The ROESY correlation (see Figure 3) from H-8 to H-7′ determined the *trans* configuration of H-8/8′. The 8*R*,8′*R* configuration was verified by the negative Cotton effect at 229 nm in the CD spectrum.[13] **5** was hydrolyzed with cellulase to yield **5a**, which was treated with $Rh_2(OCOCF_3)_4$ at room temperature. A negative Cotton effect at 340 nm in the $Rh_2(OCOCF_3)_4$-induced CD spectrum indicated the 7′*R* configuration for **5a**. Thus, compound **5** was defined as (7′*R*)-hydroxy matairesinol-4-*O*-*β*-D-glucopyranoside.

Compound **6**, an optical isomer of **5**, displayed spectroscopic data features that were almost identical to those of **5**. In the ROESY spectrum, the correlation peak of H-8/H-7′ was uncertain because of the overlap between H-8 and H-7a; therefore, the DMSO-$d_6$ was replaced with $CD_3OD$. 1D NMR data assignments were completed by comprehensive analysis of the 2D NMR data in $CD_3OD$. The chemical shift of H-8 was separated with H-7a in the $^1H$ NMR spectrum. The relative configuration of H-8/8′ was determined to be *trans* by the unambiguous correlation peak of H-8 with H-7′ in the ROESY spectrum. In combination with the negative Cotton effect at 225 nm in the CD spectrum, the absolute configuration of C-8 and C-8′ was established as 8*R*,8′*R*. Using the same method as that used for **5**, the 7′*S* configuration was determined. Thus, **6** was defined as (7′*S*)-hydroxy matairesinol-4-*O*-*β*-D-glucopyranoside.

Compound **7** was obtained as a white powder with a molecular formula of $C_{26}H_{34}O_{12}$, on the basis of HRESIMS at *m*/*z* 561.1945 $[M + Na]^+$ (calculated for $C_{26}H_{34}O_{12}Na$, *m*/*z* 561.1942). In the $^1H$ NMR spectrum (see Table 3), two sets of ABX system aromatic rings [*δ* 7.03 (1H, d, *J* = 8.0 Hz), 6.96 (1H, d, *J* = 2.0 Hz), 6.87 (1H, brs), 6.84 (1H, dd, *J* = 8.0, 2.0 Hz), 6.72 (1H, overlap), and 6.72 (1H, overlap)], together with two methine protons at *δ* 2.45 (1H, m), 2.14 (1H, m), two oxymethine protons at *δ* 4.46 (1H, d, *J* = 8.0 Hz), 4.41 (1H, dd, *J* = 8.5, 2.5 Hz), two oxymethylene protons at *δ* 3.60 (1H, m), 3.49 (1H, m), 3.48 (2H, m), two methoxy groups at *δ* 3.77 (3H, s), 3.76 (3H, s), and a glucopyranosyl anomeric proton at *δ* 4.87 (1H, d, *J* = 7.5 Hz), were observed. The $^{13}C$ NMR spectrum (see Table 2) showed 26 carbon signals, consisting of two methoxy carbon signals, six carbon signals of a glucose unit, and 18 skeleton carbon signals of two C6−C3 units. These spectroscopic data were very similar to those of lanicepsides A, which was isolated from *Saussurea laniceps*.[14] In the HMBC spectrum (see Figure 2), the correlation peaks of H-7 at *δ* 4.46

dx.doi.org/10.1021/jf501859x | J. Agric. Food Chem. 2014, 62, 9095−9102

with C-1, C-2, C-6, C-8, C-9, C-8′, and C-9′, and of H-7′ at $\delta$ 4.41 with C-1′, C-2′, C-6′, C-8′, C-9′, and C-8 helped verify that **7** was a tetrahydrofuranoid lignan. The location of the glucose unit was determined to be at C-4′ from the correlation of H-1″ with C-4′ in the HMBC spectrum. All of the above data indicated the same planar structure for **7** as for lanicepsides A.

The spectroscopic data of compounds **8** and **9** were in agreement with those of **7**, which indicated that these two compounds were optical isomers of **7**. The absolute configurations of these three compounds were determined by the ROESY spectrum, CD spectrum, and $Rh_2(OCOCF_3)_4$-induced CD assay. In the ROESY spectrum (see Figure 3), the correlation peaks of H-7/H-9, H-8/H-7′, and H-8′/H-9 helped confirm the *trans* configurations of H-7/H-8 and H-8/H-8′ in **7**, **8**, and **9**. In the CD spectrum, a negative Cotton effect at 230 nm indicated the 8*S* configuration for **7**.[15] Moreover, positive Cotton effects at 235 and 234 nm indicated the 8*R* configuration for **8** and **9**.[16] From the above analysis, the absolute configurations of C-7, C-8, and C-8′ for these compounds were determined as 7*R*,8*S*,8′*R* (**7**), 7*S*,8*R*,8′*S* (**8**), and 7*S*,8*R*,8′*S* (**9**).

To determine the absolute configuration at C-7′, the $Rh_2(OCOCF_3)_4$-induced CD assay was performed; **7** was hydrolyzed with cellulase to yield **7a**, which was treated with $Rh_2(OCOCF_3)_4$ at room temperature. A positive Cotton effect at 371 nm in the $Rh_2(OCOCF_3)_4$-induced CD spectrum indicated the 7′*S* configuration of **7a**. The absolute configurations of C-7′ in **8** and **9** were confirmed using the same method as that used for **7**. A negative Cotton effect at 350 nm for **8a** and a positive Cotton effect at 350 nm for **9a** indicated the 7′*R* and 7′*S* configurations, respectively. From the above analysis, compounds **7**−**9** were defined as (7*R*,8*S*,7′*S*,8′*R*)-4,9,4′,7′-tetrahydroy-3,3′-dimethoxy-7,9′-epoxylignan-4′-*O*-$\beta$-D-glucopyranoside (**7**), (7*S*,8*R*,7′*R*,8′*S*)-4,9,4′,7′-tetrahydroy-3,3′-dimethoxy-7,9′-epoxylignan-4′-*O*-$\beta$-D-glucopyranoside (**8**), and (7*S*,8*R*,7′*S*,8′*S*)-4,9,4′,7′-tetrahydroy-3,3′-dimethoxy-7,9′-epoxylignan-4′-*O*-$\beta$-D-glucopyranoside (**9**).

The molecular formulas of compounds **10**, **11**, and **12** were determined to be $C_{26}H_{34}O_{12}$ from HRESIMS ion *m*/*z* of 561.1948 $[M + Na]^+$, 561.1954 $[M + Na]^+$, and 561.1952 $[M + Na]^+$, respectively. The UV, IR, and NMR spectroscopic data of **10**−**12** were almost identical to those of compounds **7**−**9**. In comprehensive analysis of the ROESY and HMBC spectra of **10**−**12**, the correlation peak of H-1″ with H-5 in the ROESY spectrum, and with C-4 in the HMBC spectrum, indicated that the glucose unit was located at C-4. The absolute configurations of these three compounds were established using the same methods as those used for **7**−**9**. Compounds **10**−**12** were identified as (7*R*,8*S*,7′*S*,8′*R*)-4,9,4′,7′-tetrahydroy-3,3′-diethoxy-7,9′-epoxylignan-4-*O*-$\beta$-D-glucopyranoside (**10**), (7*S*,8*R*,7′*R*,8′*S*)-4,9,4′,7′-tetrahydroy-3,3′-dimethoxy-7,9′-epoxylignan-4-*O*-$\beta$-D-glucopyranoside (**11**), and (7*S*,8*R*,7′*S*,8′*S*)-4,9,4′,7′-tetrahydroy-3,3′-dimethoxy-7,9′-epoxylignan-4-*O*-$\beta$-D-glucopyranoside (**12**).

On the basis of MS data, NMR data, and comparison with literature, known compounds (see Figure 1) were identified as (7*R*,8*S*)-7,9,9′-trihydroxy-3,3′-dimethoxy-8-*O*-4′-neolignan-4-*O*-$\beta$-D-glucopyranoside (**13**),[17] (7*S*,8*R*)-7,9,9′-trihydroxy-3,3′-dimethoxy-8-*O*-4′-neolignan-4-*O*-$\beta$-D-glucopyranoside (**14**),[17] (7*R*,8*R*)-7,9,9′-trihydroxy-3,3′-dimethoxy-8-*O*-4′-neolignan-4-*O*-$\beta$-D-glucopyranoside (**15**),[17] (7*S*,8*S*)-7,9,9′-trihydroxy-3,3′-dimethoxy-8-*O*-4′-neolignan-4-*O*-$\beta$-D-glucopyranoside (**16**),[17] (7*R*,7′*R*,8*S*,8′*S*)-(+)-neo-olivil-4-*O*-$\beta$-D-glucopyranoside (**17**),[18] and arctiin (**18**).[19]

**Cytotoxic Activity.** In previous studies, arctigenin, the main component of Arctii Fructus, inhibited proliferation of and promoted apoptosis in SMMC-7721 human hepatocellular carcinoma cells.[9] To clarify whether lignan glucosides in Arctii Fructus have cytotoxic activity, all of the isolated compounds were tested for cytotoxic activity using an MTT assay in HCT-8, Bel-7402, BGC-823, A549, and A2780 cells. All of the tested compounds exhibited no significant cytotoxicity in cell model systems. Analysis of structures indicated that the glucose moiety in lignans may have reduced cytotoxic activity.

**Hepatoprotective Activity.** Compounds **1**−**18** were tested for hepatoprotective activities against D-galactosamine-induced toxicity in HL-7702 cells. Compounds **1**, **2**, **7**−**12**, and **17** showed stronger hepatoprotective activities than that shown by the positive control bicyclol at a concentration of $1 \times 10^{-5}$ M. Among them, compounds **1** and **2** reduced D-galactosamine-induced damage in HL-7702 cells (cell survival rate of 51%) with 79% and 71% inhibition, respectively, while the positive control bicyclol gave a 61.0% inhibition. Meanwhile, compounds **7**−**12** and **17** had 61−70% inhibition. From the above experimental data, only benzofuran-type neolignans and tetrahydrofuranoid lignans showed hepatoprotective activity. Tetrahydrofuran rings in lignans might contribute to the hepatoprotective activity observed. Furthermore, compounds **1** and **2**, which owned benzofuran rings, revealed stronger hepatoprotective activities than those of compounds **7**−**12** and **17**, which owned tetrahydrofuran rings.

In conclusion, we conducted a phytochemical investigation of Arctii Fructus, from which a series of 12 novel 7′-hydroxy lignan glucosides were isolated, along with six known lignan glucosides. To determine the absolute configurations for chiral carbons, the ROESY assay was combined with the CD exciton chirality method and $Rh_2(OCOCF_3)_4$-induced CD spectrum analysis. Further investigation of the in vitro bioactivities of **1**−**18** revealed that some compounds showed significantly stronger hepatoprotective activities than that shown by the positive control bicyclol. The structure−activity relationships revealed that the tetrahydrofuran ring in lignan glucosides might contribute to the hepatoprotective activity observed. These results provide additional phytochemical and bioactive information on Arctii Fructus, which is widely used in traditional Chinese medicine.

| Butyl (C4-) |  C4-IB Y; 85.8%, P;98.2% |  C4-2MB Y; 69.6%, P; 99.0% |  C4-IV Y; quant., P; 99.9% |  C4-IP Y; 96.8%, P; 96.2% | - | - |
| Pentyl (C5-) |  C5-IB Y; 99.0%, P; 99.0% |  C5-2MB Y; 95.9%, P; 99.0% |  C5-IV Y; 95.6%, P; 99.9% |  C5-IP Y; 99.7%, P; 96.3% | - | - |

[a,c,d]These compounds were synthesized following synthetic method A with isobutyl chloride, isovaleryl chloride, and 3,3-dimethylacryloyl chloride, respectively. [b,e,f]These compounds were synthesized following synthetic method B with the corresponding acids (see first footnote). [g]These compounds were purchased from Tokyo Chemical Industry. Y: yield (by isolation), P: purity (determined by GC).

(purity: 98%) and 3-methylbutyl angelate (i.e., = isoamyl angelate; purity, 99%) were purchased from Tokyo Chemical Industry (Tokyo, Japan).

**Instrumental Analysis.** Gas chromatography (GC) analysis was performed using an Agilent 6890N equipped a DB-1MS column (30 m × 0.25 mm i.d., 0.25 $\mu$m film thickness; J&W Scientific, Folsom, CA). GC-mass spectrometry (GC-MS) analysis was performed on an Agilent 7980A coupled with a 5975C mass selective detector (MSD). A DB-5MS (30 m × 0.25 mm i.d., 0.25 $\mu$m film thickness; J&W Scientific, Folsom, CA) was used for the separation of the analytes. The oven temperature was programmed as 40 °C for 1 min, then raised to 250 °C at 6 °C/min, and the temperature held for 4 min. Purities of synthesized compounds were checked by GC. NMR spectra were taken on a Varian UI500 spectrometer ($^1$H; 500 MHz, $^{13}$C; 125 MHz) using TMS in $CDCl_3$ as an internal standard at the Korea Basic Science Institute (Seoul, Korea). Infrared (IR) spectra were recorded on a Nicolet FT-IR spectrometer (Thermo Fisher Scientific Inc.). The structure was confirmed by comparison of its mass spectrum with data from the NIST mass spectrum library, IR data, and the NMR spectrum.

**Synthesis of Esters.** The esters listed in Table 1 were synthesized using two different procedures (i.e., methods A and B). In method A, the desired esters were synthesized with their corresponding alcohols and acyl chlorides. Briefly, a solution of alcohol (1.0 equiv) and acyl chloride (1.5 equiv) in $CH_2Cl_2$, pyridine (1.5 equiv), and a catalytic amount of DMAP were added at 0 °C. After 30 min of stirring at 0 °C, the solution was stirred for 2 h at room temperature. The solution was diluted with ether, and the organic phase was washed with 2 N HCl, water, and brine and then dried. After the solvent was removed, the residue was distilled and subjected to silica gel chromatography to give the desired ester (5% ether in hexane fraction). In method B, the esters were synthesized with their corresponding alcohols and acids, DMAP and DCC, following the method by Neises and Steglich.[19] Alcohol (2.0 equiv), acid (1.0 equiv), and DMAP (1.6 equiv) were dissolved in $CH_2Cl_2$ at 0 °C. DCC (2.2 equiv) was added to the solution over a 4 min period. The solution was stirred for 30 min at 0 °C and then for 3 h at room temperature. The precipitate was removed by filtration; the filtrate was diluted with ether and then worked up. The purification procedure was the same as that in method A.

Isobutyl isobutanoate (IB-IB): GC-MS, $m/z$ (%); 129 (0.1, $M^+-CH_3$), 101 (7.2), 89 (27.4), 71 (100.0), 56 (39.8).

2-Methylbutyl isobutanoate (2MB-IB): GC-MS, $m/z$ (%); 129 (0.5, $M^+-CH_2CH_3$), 101 (5.8), 89 (8.9), 71 (100.0), 70 (63.7), 55 (17.8).

3-Methylbutyl 3-methyl-2-butenoate (3MB-IP): GC-MS, *m/z* (%) 170 (3.0, $M^+$), 155 (0.3), 113 (0.4), 101 (23.9), 100 (42.2), 83 (100.0), 82 (10.3), 71 (19.6), 70 (23.2), 67 (2.2), 55 (40.7).

3-Methyl-2-butenyl 3-methyl-2-butenoate (IP-IP): GC-MS, *m/z* (%) 168 (0.7, $M^+$), 153 (0.7), 109 (6.9), 100 (42.2), 95 (0.8), 83 (43.3), 77 (1.4), 69 (24.6), 68 (69.6), 67 (100.0), 55 (10.4), 53 (60.9).

Butyl 3-methyl-2-butenoate (C4-IP): GC-MS, *m/z* (%) 156 (7.5, $M^+$), 141 (0.9), 113 (0.6), 101 (19.3), 100 (57.2), 85 (11.1), 83 (100.0), 82 (19.6), 55 (25.6).

Pentyl 3-methyl-2-butenoate (C5-IP): GC-MS, *m/z* (%) 170 (5.4, $M^+$), 155 (0.4), 101 (32.1), 100 (68.9), 83 (100.0), 82 (17.3), 71 (3.2), 70 (5.6), 55 (33.8).

2-Methylbutyl angelate (2MB-A): GC-MS, *m/z* (%) 170 (1.6, $M^+$), 100 (100.0), 83 (90.0), 71 (23.4), 70 (21.9), 55 (85.4). IR (neat, $cm^{-1}$), 3005 (w), 2980 (s), 1710 (s), 1670 (m), 1220 (s), 1160 (s), 850 (s).

3-Methylbutyl tiglate (3MB-T): $^1$H NMR (ppm), $\delta$ 0.936 (6H, d, $J$ = 6.5), 1.567 (2H, dt, $J$ = 7, 6.5), 1.722 (1H, nonet, $J$ = 6.5), 1.785 (3H, dq, $J$ = 7, 1.5), 1.829 (3H, quin., $J$ = 1.5), 4.159 (2H, t, $J$ = 7), 6.840 (1H, qq, $J$ = 7, 1.5); $^{13}$C NMR (ppm), $\delta$ 12.03 ($CH_3$), 14.13 ($CH_3$), 22.52 ($CH_3$ × 2), 25.22 (CH), 37.47 ($CH_2$), 63.07 ($CH_2$), 128.83 (=C), 136.79 (=CH), 168.22 (O=C). IR (neat, $cm^{-1}$), 2980 (s), 2105 (m), 1710 (s), 1670 (m), 1280 (s), 1110 (s), 730 (s).

**Nematicidal Activity.** To test the nematicidal activity of ester compounds, test compounds were suspended in ethanol (100 mg/mL). Test solutions (1 $\mu$L) were placed in the wells of a 96-well plate (Falcon, USA) containing 50−150 nematodes (mixture of juvenile and adult nematodes, male−female−juvenile ≈1:1:2) in 99 $\mu$L of water. Thus, the total volume of the solution in each well was 100 $\mu$L, and the concentration of the test ester compounds was 1 mg/mL. As a control, four wells were treated with ethanol (1 $\mu$L) in the same volume as the test samples. In four adjacent wells (i.e., in a column) on the plate, nematodes were treated with the ester compounds, and a set of treatment samples was placed in the wells of every second column. The entire completely experiment was repeated four times. The order of the ester compounds was randomly determined. The tested plates were stored under a 14:10 h (light−dark) regime at 25 ± 1 °C and 60% relative humidity. Nematode mortality was recorded after 48 h of treatment as follows: 10 $\mu$L of the test suspension was transferred to 100 $\mu$L of fresh water with a micropipette. Ten minutes after transfer, nematode mortality was observed under a microscope. Nematodes were classified as dead if their bodies were motionless and straightened. The mortality of termites was transformed to the arcsine square root values for analysis of variance (ANOVA). Mean values for treatment data were compared and separated by Scheffé's test.[20] Five chemicals (i.e., isobutyl 2-methylbutanoate, 3-methylbutyl 2-methylbutanoate, 3-methyl-2-butenyl 2-methylbutanoate, 3-methylbutyl tiglate, and pentyl 2-methylbutanoate) that showed strong nematicidal activity at a concentration of 1 mg/mL against the pine wood nematode were chosen for testing at a lower concentration. These chemicals were serially diluted with ethanol to obtain four different concentrations; the final concentrations were 0.250, 0.125, 0.0625, and 0.03125 mg/mL for pentyl 2-methylbutanoate; 0.125, 0.0625, 0.03125, and 0.015625 mg/mL for isobutyl 2-methylbutanoate, 3-methylbutyl 2-methylbutanoate, and 3-methyl-2-butenyl 2-methylbutanoate; and 0.0625, 0.03125, 0.015625, and 0.0078125 mg/mL for 3-methylbutyl tiglate. The $LC_{50}$ was estimated by probit analysis.[20]

## RESULTS AND DISCUSSION

The nematicidal activity of the ester compounds is shown in Table 2. Among the ester compounds tested, isobutyl 2-methylbutanoate, 3-methylbutyl 2-methylbutanoate, and 3-methylbutyl tiglate showed 100% nematicidal activity against the pine wood nematode at a concentration of 1 mg/mL. The nematicidal activities of 3-methyl-2-butenyl 2-methylbutanoate and pentyl 2-methylbutanoate were 98.73% and 97.63% against the pine wood nematode at a concentration of 1 mg/mL, respectively. The nematicidal activities of the other ester compounds were <11%. The nematicidal activities of isobutyl 2-methylbutanoate, 3-methylbutyl 2-methylbutanoate, 3-methylbutyl tiglate, 3-methyl-2-butenyl 2-methylbutanoate, and pentyl 2-methylbutanoate, which showed strong nematicidal activities at a 1 mg/mL concentration, were also tested at a lower concentration (Table 3). The $LC_{50}$ values of 3-methylbutyl tiglate, isobutyl 2-methylbutanoate, 3-methylbutyl 2-methylbutanoate, 3-methyl-2-butenyl 2-methylbutanoate, and pentyl 2-methylbutanoate were 0.0218, 0.0284, 0.0326, 0.0402, and 0.0480 mg/mL, respectively. Nematicidal activities of many phytochemicals from essential oils have been reported.[9−17] Choi et al.[9] reported that $LC_{50}$ values of thymol, carvacrol, citral, citronellol, and citronellal were 0.119, 0.125, 0.187, 0.245, and 0.321 mg/mL, respectively. Some natural ester compounds tested in this study have been reported as the main compounds of certain plant essential oils.[21,22] Isobutyl angelate was the most abundant compound identified in *Chamaemelum nobile* plant essential oil, followed by 2-methylbutyl angelate, isobutyl isobutyrate, methyl 2-methylbuyrate, prenyl acetate, 2-methylbutyl 2-methylbutyrate, and 2-methylbutyl acetate.[21] Mierendorff et al.[22] reported that the main compounds of *Eriocephalus punctulatus* were 2-methylbutyl isobutanoate (21.2%), 2-methylbutyl 2-methylbutanoate (5.6%), isobutyl isobutanoate (5.3%), and linalyl acetate (4.4%). Bail et al.[21] reported the antimicrobial activities of some ester compounds identified in *Chamaemelum nobile* plant essential oils. Seo et al.[23] reported the fumigant toxicities of some ester compounds derived from *E. punctulatus* and *C. mobile* plant essential oils against Japanese termites (*Reticulitermes speratus*); however, there have been no reports on the nematicidal activities of the natural ester

compounds utilized in the current study against the pine wood nematode.

Among the ester compounds tested in the current study, there was a significant difference in nematicidal activity against the pine wood nematode. The nematicidal activities of the ester compounds with 2-methylbutyric acid moiety, such as isobutyl 2-methylbutanoate, 3-methylbutyl 2-methylbutanoate, 3-methyl-2-butenyl 2-methylbutanoate, and pentyl 2-methylbutanoate, were stronger than those of the other ester compounds, except 3-methylbutyl tiglate. This result indicates that the 2-methylbutyric acid moiety may play an important role in nematicidal activity against the pine wood nematode. Specific functional groups in the chemical structure are closely related to the nematicidal activity against the pine wood nematode.[9,16] Choi et al.[9] investigated the nematicidal activities of monoterpenoids typically found in plant essential oils and found that chemicals belonging to the phenols, alcohols, and aldehydes were generally more toxic than the other monoterpenoid groups such as the ketones and hydrocarbons. Park et al.[16] compared the nematicidal activities of eugenol, methyl eugenol, isoeugenol, methyl isoeugenol, and acetyl eugenol and insisted that a functional group at the C1 position of the benzene ring was very important for nematicidal activity.

There was a significant difference in nematicidal activities among the ester compounds with a 2-methylbutyric acid moiety. Nematicidal activities of isobutyl 2-methylbutanoate, 3-methylbutyl 2-methylbutanoate, 3-methyl-2-butenyl 2-methylbutanoate, and pentyl 2-methylbutanoate were strong; however, 2-methylbutyl 2-methylbutanoate and butyl 2-methylbutanoate did not show nematicidal activity against the pine wood nematode. Grodnitzky and Coats[24] investigated the QSAR of monoterpenoids against the house fly, *Musca domestica*. They insisted that the optimum shape and size of monoterpenoids was necessary to fit into a site of toxic action. Seo et al.[25] studied the structure−activity relationship of aliphatic compounds for nematicidal activity against the pine wood nematode. There was a significant difference in nematicidal activity according to chain length. Among the aliphatic compounds belonging to the alkanols and 2*E*-alkenols, compounds with a $C_9$−$C_{11}$ chain length showed strong nematicidal activity when compared to the other compounds with different chain lengths. In the case of the 2*E*-alkenals and alkanoic acids groups, compounds with $C_8$−$C_9$ and $C_9$−$C_{10}$ chain lengths, respectively, showed strong nematicidal activity; however, compounds with $C_{12}$−$C_{14}$ chain lengths showed weak nematicidal activity against the pine wood nematode. The current study is in accordance with a previous study, indicating that an optimum shape and size of chemicals are necessary for the nematicidal activity against the pine wood nematode.

*α,β*-Unsaturated carbonyl compounds such as citral, 2-decenal, *trans*-cinnamate, and 2*E*-alkenal were reported to be responsible for nematicidal activities against the pine wood nematode.[9,13,14,25] Ester compounds with 3-methyl-2-butenoic acid, angelic acid, and tiglic acid moiety provide *α,β*-unsaturated carbonyl structure, but only 3-methylbutyl tiglate showed strong nematicidal activity. The relationship between nematicidal activity and *α,β*-unsaturated carbonyl structure was not clarified in the current study.

The structure−activity relationships of the *cis*- and *trans*-isomers of various compounds have been well-studied. Park et al.[26] reported that the insecticidal activity of *cis*-asarone was stronger than that of *trans*-asarone against *Sitophilus oryzae*, *Callosobruchus chinensis*, and *Lasioderma serricorene*. Lee et al.[27] also reported that the insecticidal activity of *cis*- and *trans*-asarone were different against *Nilaparvata lugens* (Homoptera: Delphacidae) and *Plutella xylostella* (Lepidoptera: Yponomeutoidae). Park et al.[16] reported that the nematicidal activity of geranial was ∼4.3 times stronger than that of neral, a

dx.doi.org/10.1021/jf503631e | J. Agric. Food Chem. 2014, 62, 9103−9108

geometrical isomer of geranial. In the current study, there was a difference in the nematicidal activity of two geometrical isomers—3-methylbutyl angelate and 3-methylbutyl tiglate. The nematicidal activity of 3-methylbutyl tiglate was much stronger than that of 3-methylbutyl angelate. The current study and previous studies indicate that the position of the substituent in the geometrical isomer is very important for nematicidal or insecticidal activities.

Clarifying the mode of action for active compounds is of practical importance for nematode control because it provides valuable information for developing the most appropriate methods for delivery. Lei et al.[28] reported that the nematicidal activity of thymol and carvacrol against two nematodes, *Caenorhabditis elegans* and *Ascaris suum*, might be mediated through a tyramine receptor (TyrR). Recently, Kang et al.[29] investigated the inhibition activities of phytochemicals from plant essential oils against acetylcholinesterases of the pine wood nematode. They reported that (+)-α-pinene, (−)-α-pinene, 3-carene, *o*-anisaldehyde, coniferyl alcohol, and *cis*-nerolidol showed inhibition activities against acetylcholinesterases of the pine wood nematode. Kang et al.[30] also reported the inhibition of acetylcholinesterase and glutathione *S*-transferase of the pine wood nematode by aliphatic compounds. They found that the nematicidal activity of the 2*E*-alkenal compounds is related to the inhibition of BxACE (*B. xylophilus* acetylcholinesterase); however, ester compounds tested in the current study did not show inhibition activity against BxACE (data not shown here). Moreover, the exact mode-of-action for ester compounds used in current study remains unclear.

In conclusion, natural ester compounds such as isobutyl 2-methylbutanoate, 3-methylbutyl 2-methylbutanoate, 3-methylbutyl tiglate, 3-methyl-2-butenyl 2-methylbutanoate, 3-methyl-2-butenyl 2-methylbutanoate, and pentyl 2-methylbutanoate showed very strong nematicidal activity against the pine wood nematode. We also investigated the structure−activity relationship of natural ester compounds and their analogues. For the practical use of these ester compounds as novel nematicides, further studies investigating systemic action, phytotoxicity, mode-of-action, and formulation for improving nematicidal potency and stability are necessary.

(OXPHOS) machinery. Reprogramming energy metabolism has been demonstrated to be a cancer hallmark.[14] Most cancer cells exhibit high glycolysis capacity and low mitochondrial respiration even in the presence of oxygen, which is recognized as the "Warburg effect". Compelling evidence suggests that the Warburg effect might result from mitochondrial dysfunction, activation oncogenes (e.g., Ras and Myc), oncogenic alterations (e.g., c-myc and p53), or environmental stresses (e.g., hypoxia and inflammation).[15] Recent studies demonstrate that glycolysis not only generates ATP but also provides carbon-containing intermediates (such as pyruvate and glucose-6-phosphate) for cancer progression. These intermediates can be diverted to amino acid and ribose for nucleotide to supply the nutrients that the fast-growing cancer cells need. In addition, the over-expression of glycolysis in cancer cells will produce a lot of lactate, which can acidify the tumor microenvironment.[16] The acidity of the microenvironment has been reported to promote cancer metastasis, which is probably mediated by pH-dependent activation of proteases, such as MMPs and cathepsins, that degrade the tumor extracellular matrix.[17] Thus, targeting both mitochondrial OXPHOS and glycolysis to selective inhibition of energy metabolism of cancer cells may be an attractive strategy for the treatment of metastatic cancer.

Butein (3,4,2′,4′-tetrahydroxychalcone) is a chalcone derivative extracted from the heartwood of *Dalbergia odoriferau*. Butein can also be identified in the barks of *Rhus verniciflua* and *Semecarpus anacardiu*.[18] The extract of natural chalcone butein has been found with reported benefits including antioxidant, anti-inflammatory, and antirestenosis activities.[19−21] Emerging studies have shown that butein exhibits an antiangiogenesis property and antiproliferation and apoptotic effects against numerous lines of cancer cells.[22−25] However, the effects of butein on cancer metastasis and the energy metabolism of cancer cells are not fully understood. The purpose of this study was to determine the antimetastatic effect and mechanism of butein in vitro and in vivo.

## MATERIALS AND METHODS

**Materials.** Butein was purchased from Extrasynthese Corp. (Genay, France). Crystal violet and other chemicals were obtained from Sigma-Aldrich (St. Louis, MO, USA). Rabbit monoclonal antibodies specific for p-ERK1/2, ERK1/2, and p-p70S6K, as well as mouse monoclonal antibody specific for p-IκBα, were obtained from Cell Signaling Technologies (Boston, MA, USA). Rabbit monoclonal antibodies specific for p-Akt, Akt, p-mTOR, p-NF-κB/p65, MMP-9, and GAPDH were obtained from Epitomics (Burlingame, CA, USA). Anti-mouse and anti-rabbit IgG-conjugated horseradish peroxidase and rabbit polyclonal antibody specific for uPA were obtained from Santa Cruz Biotechnology (Santa Cruz, CA, USA). Dulbecco's modified Eagle's medium (DMEM), fetal bovine serum (FBS), and other cell culture reagents were purchased from Gibco (Grand Island, NY, USA).

**Cell Culture.** The human hepatocellular carcinoma (HCC) cell line SK-Hep-1 was purchased from American Type Culture Collection (ATCC, Manassas, VA, USA). SK-Hep-1 cells were maintained in humidified air containing 5% $CO_2$ at 37 °C with DMEM containing 10% FBS, penicillin (100 units/mL), streptomycin (100 μg/mL), and L-glutamine (2 mM).

**In Vitro Metastasis Analysis.** Cell invasion and migration assays were performed using Transwell inserts (Corning, Corning, NY, USA) to assess in vitro metastasis of cancer cells. For invasion assay, filters were precoated with 30 μL of Matrigel (BD Biosciences, Bedford, MA, USA) for 30 min. Approximately $5 \times 10^4$ cells in 100 μL of serum-free medium were placed in the upper chamber, and 500 μL of the same medium containing 10% FBS in the absence or presence of butein was placed in the lower chamber in both invasion and migration assays. After 12 h of treatment, cells on the upper side of the filters were mechanically removed by cotton-tipped swabs, then cells on the lower side were fixed in methanol for 15 min and stained with 0.05% crystal violet for 15 min. The invaded or migrated cells were photographed and quantified by counting the number of stained cells under a microscope.

**In Vivo Metastasis Analysis.** The chorioallantoic membrane (CAM) intravasation model was performed to evaluate tumor cell metastasis as described previously.[26] After treatment with butein for 12 h, surviving cells ($10^6$ cells) were collected and resuspended in 50 μL of serum-free DMEM and inoculated onto the CAM of a 9-day-old chick embryo, in which an artificial air sac was created (designated "upper CAM"). After 48 h of incubation, the lower half of the CAM (designated "lower CAM") was removed and stored frozen at −80 °C. Genomic DNA of the frozen tissue was purified from lower CAM by the DNA Isolation Kit. To determine human cells in the chick tissues, the primers specific for human *alu* sequence (5′-ACGCCTGTAATCCCAGCACTT-3′/5′-TCGCCCAGGCTGGAGTGCA-3′) were used to amplify the human *alu* repeats present in genomic DNA that was isolated from chick tissues. A quantitative measure of amplifiable chick DNA was examined by amplification of chick GAPDH genomic DNA sequence with chGAPDH primers (5′-GAGGAAAGGTCGCCTGGTGGATCG-3′/5′-GGTGAGGACAAGCAGTGAGGAACG-3′). The cycling conditions were 10 min of polymerase activation at 95 °C followed by 30 cycles at 95 °C for 30 s, 58 °C for 45 s, and 72 °C for 45 s and a final incubation at 72 °C for 10 min. Finally, PCR products were conducted on the agarose gel and visualized using ethidium bromide.

**Cell Viability Analysis.** Cells ($10^4$ cells/well) were incubated in 96-well plates. After 24 h of incubation, the culture medium was removed and treated with butein for 12 or 24 h. Then, cell survival was determined using the MTT colorimetric assay. The absorbance at 550 nm was measured using a FlexStation 3 microplate reader (Molecular Devices, Sunnyvale, CA, USA).

**MMP-9 and uPA Activity Assay.** After treatment, the medium was collected and stored at −80 °C. Then, MMP-9 and uPA activities in the medium were determined and quantified using MMP-9 and uPA ELISA kits (R&D Systems, Minneapolis, MN, USA).

**Western Blot Analysis.** The cellular lysates were prepared according our previous instruction.[27] Proteins were resolved by 8−12% sodium dodecyl sulfate−polyacrylamide gel electrophoresis and immunoblotted with specific primary antibodies. Then, the blots were subsequently incubated with the secondary antibody, and the signals were determined using the chemiluminescent assay kit (Amersham, Buckinghamshire, UK).

**RT-PCR Analysis.** Total RNA was extracted from cells by using a TRIzol kit (MDBio Inc., Taipei, Taiwan). First-strand cDNA was synthesized with random primer and moloney murine leukemia virus reverse transcriptase (M-MLV RT). The primer sequences used for amplification were listed as follows: MMP-9, 5′-TGGGCTACGTGACCTATGAC-3′/5′- CAAAGGTGAGAAGAGAGGGC-3′; uPA, 5′-AGAATTCTACCGACTATCTC-3′/5′- ATTCTCTTCCTTGGTGTGAC-3′; PAI, 5′-TGGTTCTGCCCAAGTTCTCC-3′/5′-GACAGCTGTGGATGAGGAGG-3′; uPAR, 5′- CCGAGGTTGTGTGTGGGTTA-3′/5′-ATGCATTCGAGGTAACGGCT-3′; TIMP-1, 5′-TTGGCTTCTGCACTGATGGT-3′/5′-TAAATGTCCACGCTAGGGGC-3′; GAPDH, 5′-TGATGACATCAAGAAGGTGGTGAAG-3′/5′-TCCTTGGAGGCCATGTGGGCCAT-3′. The cycling conditions were 5 min of polymerase activation at 94 °C followed by 30 cycles at 94 °C for 1 min, 60 °C for 1 min, and 72 °C for 1 min and a final incubation at 72 °C for 10 min. The PCR products were separated on the agarose gel and visualized using ethidium bromide.

**Bioenergetic Function Analysis.** The XF24 Analyzer (Seahorse Bioscience, North Billerica, MA, USA) was used to determine the bioenergetic metabolism of cancer cells. Cells ($2 \times 10^4$ cells/well) were seeded in an XF24 24-well plate and were allowed to grow for 1 day. Culture medium was next replaced 1 h prior to measurement by the assay medium that contained unbuffered DMEM with or without butein and incubated in a 37 °C incubator for 30 min to stabilize the pH and temperature. Then, the plate was transferred into the incubation chamber of the XF24 Analyzer for real-time determination of the oxygen consumption rate (OCR) and extracellular acidification rate (ECAR).

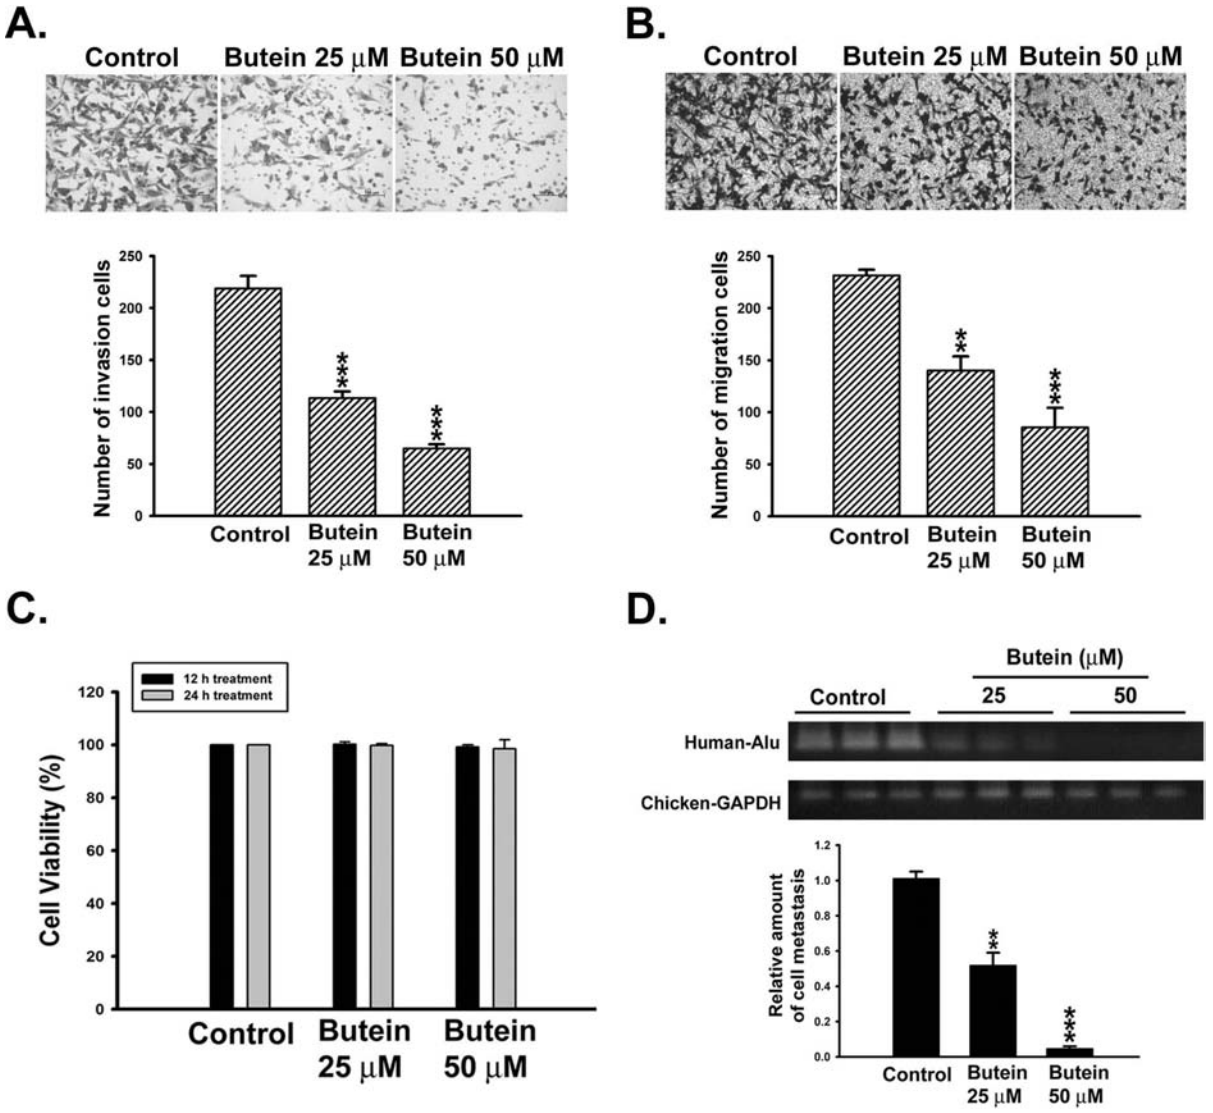

**Figure 1.** Effect of butein on cancer metastasis in vitro and iv vivo. SK-Hep-1 cells were seeded onto the upper chamber consisting of 8 mm pore size filters and then treated with the indicated concentration of butein for 12 h in medium containing 10% FBS as a chemoattractant in the lower chamber for the analysis of cell invasion (A) and migration (B). (C) SK-Hep-1 cells were treated with the indicated concentrations of butein for 12 and 24 h in medium containing 10% FBS, and the cell viability was determined using the MTT assay. (D) SK-Hep-1 cells were treated with the indicated concentrations of butein for 12 h and then subjected to CAM-intravasation assay coupled with the Alu PCR-based assay. The cancer cells in the chick embryo lower CAM were determined using PCR of the human genome-specific Alu sequence with chick GAPDH specific primers as the control. The quantitative detection for the relative amount of cell metastasis was represented and normalized against chick GAPDH. Data are expressed as the mean ± SEM of four independent experiments. (**) $p < 0.01$ and (***) $p < 0.001$ compared with the control group.

The program Seahorse of the XF24 Analyzer was set according to the manufacturer's protocol, and the data were represented in picomoles per minute per $10^4$ cells for OCR and in milli-pH units per minute per $10^4$ cells for ECAR to allow comparison between independent experiments.

**ATP Content Assay.** The intracellular ATP level was measured by Luminescent ATP Detection Assay (Abcam, Cambridge, UK). After treatment, 50 $\mu$L of detergent was added to 100 $\mu$L of medium in each well to release the intracellular ATP. Half of the mixture was then transferred into a black 96-well plate containing 50 $\mu$L of substrate solution, and the luminescence intensity was measured using FlexStation 3 (Molecular Devices).

**Reporter Gene Assay.** Transfection was performed using Lipofectmine 2000 (Invitrogen, Carlsbad, CA, USA) according to the manufacturer's protocol. Cells were cotransfected with NF-$\kappa$B promoter plasmid (pNF-$\kappa$B-Luc) and *Renilla* luciferase reporter vector (phRG-TK). After 24 h of transfection, cells were treated with butein for 12 h. Cell extracts were then prepared, and the activities of firely and *Renilla* luciferases were measured by DLR assay system (Promega, Madison, WI, USA) using FlexStation 3 (Molecular Devices).

**Statistics.** Data are presented as the mean ± standard error of mean (SEM). Statistical analyses of data were done with one-way ANOVA followed by Student's *t* test. The difference is significant if the *p* value is <0.05.

## RESULTS

**Butein Inhibits Cancer Metastasis without Cytotoxicity.** We first applied a Transwell chamber assay to explore the antimetastatic effect of butein in vitro. As shown in Figure 1A,B, butein significantly inhibited both invasion and migration of hepatocellular carcinoma SK-Hep-1 cells in a concentration-dependent manner after 12 h of treatment. We next examined the cytotoxicity of butein by the MTT assay. Butein did not inhibit cell viability at 12 h. The cytotoxicity of butein was limited even

dx.doi.org/10.1021/jf502370c | J. Agric. Food Chem. 2014, 62, 9109−9117

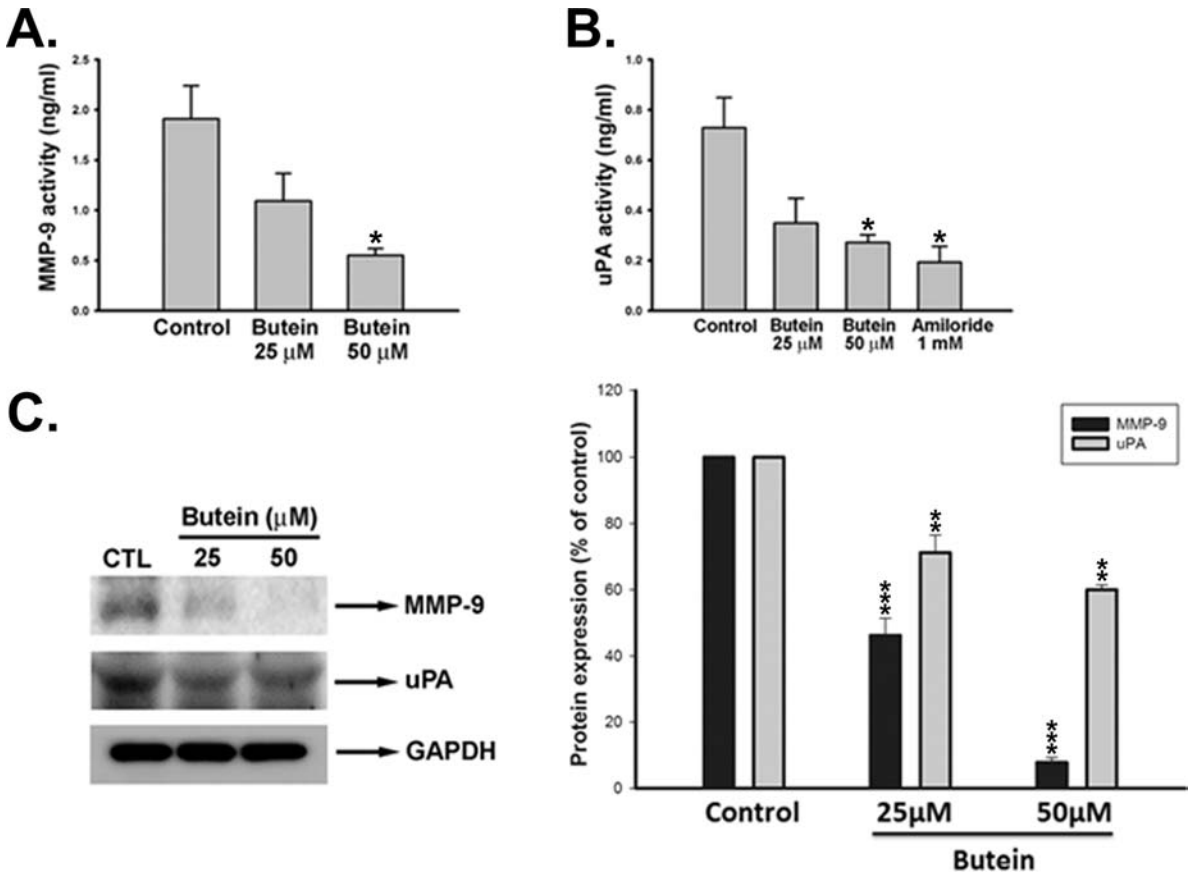

**Figure 2.** Effect of butein on the enzyme activity and protein expression of MMP-9 and uPA. SK-Hep-1 cells were treated with the indicated concentration of butein for 12 h in medium containing 10% FBS. Then each conditioned medium was collected and subjected to ELISA for analysis of proteolytic activities of MMP-9 (A) and uPA (B). Total cell lysates were corrected for the detection of MMP-9 and uPA protein expression by Western blot analysis (C). The quantitative densitometry of the relative level of protein was performed with Image-Pro Plus. Data are expressed as the mean ± SEM of three independent experiments. (∗) $p < 0.05$, (∗∗) $p < 0.01$, and (∗∗∗)$p < 0.001$ compared with the control group.

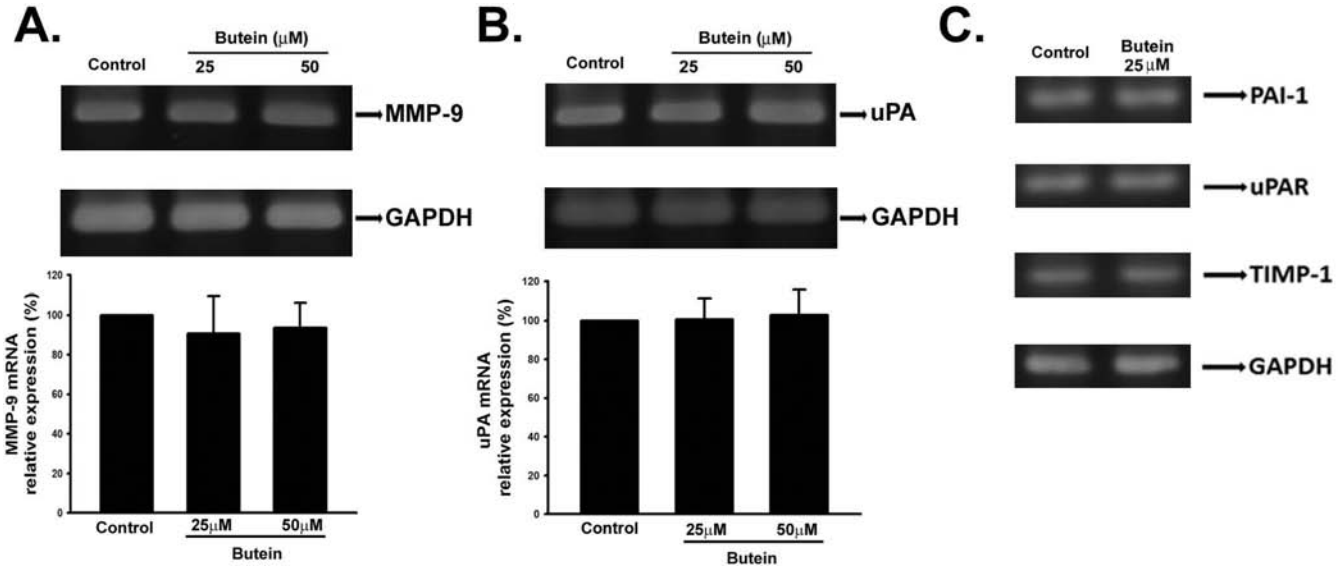

**Figure 3.** Effect of butein on the mRNA expression of MMP-9 and uPA. SK-Hep-1 cells were treated with the indicated concentration of butein for 6 h. The mRNA level of MMP-9 (A), uPA (B), and PAI-1, uPAR, and TIMP-1 (C) was determined using reverse RT-PCR. The quantitative densitometry of the relative level of mRNA was performed with Image-Pro Plus. Data are expressed as the mean ± SEM of four independent experiments.

under the long-term (24 h) treatment (Figure 1C). Our results demonstrate that the inhibitory effect of butein on cell invasion and migration is not due to its cytotoxicity. To investigate whether butein affects cancer metastasis in vivo, we performed a metastatic animal model by CAM-intravasation assay. SK-Hep-1 cells were treated with butein for 12 h before being seeded on the

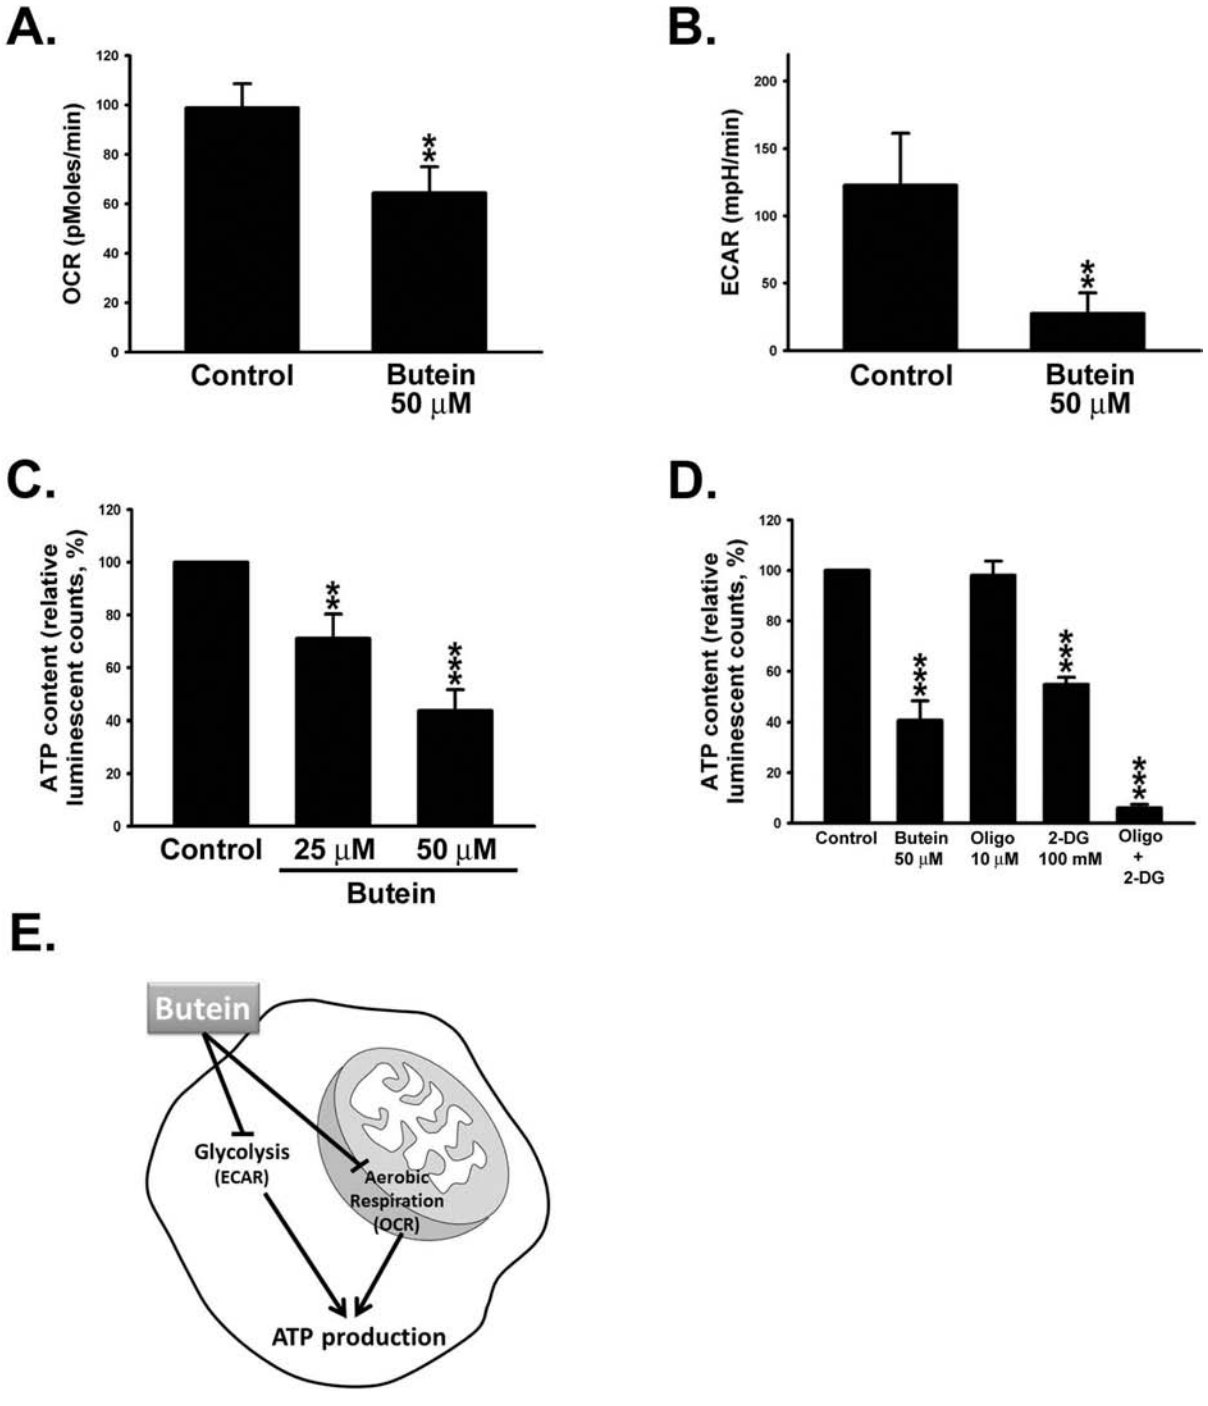

**Figure 4.** Effect of butein on the changes of bioenergetics. SK-Hep-1 cells were treated without or with butein (50 $\mu$M) for 2 h, and the OCR (A) and ECAR (B) were determined using Seahorse XF24 analyzer. Cells were treated with the indicated concentration of butein for 6 h, and the ATP production was examined by ATP content assay (C). In addition, cells were exposed to oligomycin (Oligo), 2-deoxyglucose (2-DG), or oligomycin combined with 2-DG to validate the effect of butein on ATP production in SK-Hep-1 cells (D). Data are expressed as the mean ± SEM of four independent experiments. (**) $p < 0.01$ and (***)$p < 0.001$ compared with the control group. (E) Schematic presentation of butein-mediated bioenergetics modulation. Butein inhibits ATP production through suppression of mitochondrial respiration and glycolysis on cancer cells.

upper CAM. Following 48 h of incubation, cells invading the lower CAM were determined by PCR for human *Alu* gene (h-Alu) and then normalized to chick GAPDH. We found that butein repressed the metastasis of SK-Hep-1 cells, which was in accordance with the results from the Trasnwell chamber assay (Figure 1D). Collectively, our findings indicate that noncytotoxic concentrations of butein significantly inhibit cancer metastasis in vitro and in vivo.

**Butein Inhibits MMP-9 and uPA Expression and Activity without Repressing Their mRNA Expression.** MMP-9 and uPA are the key enzymes participating in cell migration and invasion as well as metastasis.[2] We next investigated the molecular targets of butein-mediated inhibition of the invasive phenotype of SK-Hep-1 cells by determining the involvement of MMP-9 and uPA. ELISA was used to examine the effects of butein on MMP-9 and uPA enzyme activities. The data

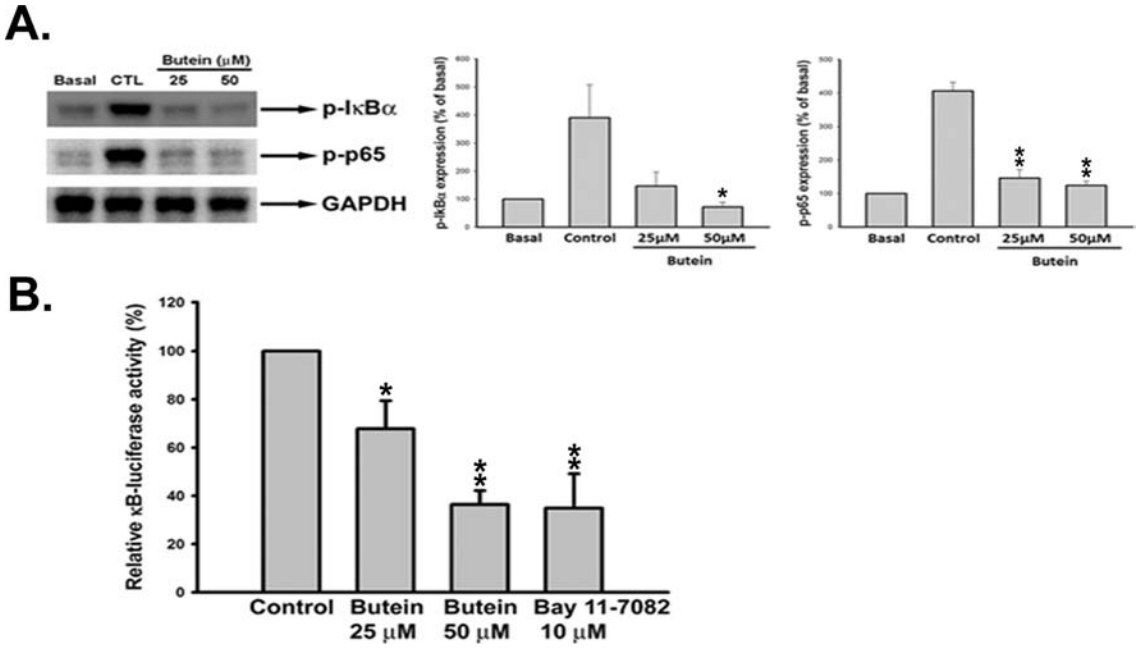

**Figure 5.** Effect of butein on NF-$\kappa$B activation. (A) Serum-starved cells were treated with vehicle (basal) or 10% FBS in the absence (control) or presence the indicated concentration of butein for 15 min. Cells were harvested and lysed for the detection of p-I$\kappa$B$\alpha$ and p-p65 by Western blot analysis. The quantitative densitometry of the relative level of protein was performed with Image-Pro Plus. (B) Cells cotransfected with pNF-$\kappa$B-Luc and phRG-TK vector were treated with butein (25, 50 $\mu$M) or BAY 11-7082 (10 $\mu$M) in medium containing 10% FBS. After 12 h of treatment, the promoter luciferase activities were detected using a luminometer. Data are expressed as the mean ± SEM of three independent experiments. (*) $p < 0.05$ and (**) $p < 0.01$ compared with the control group.

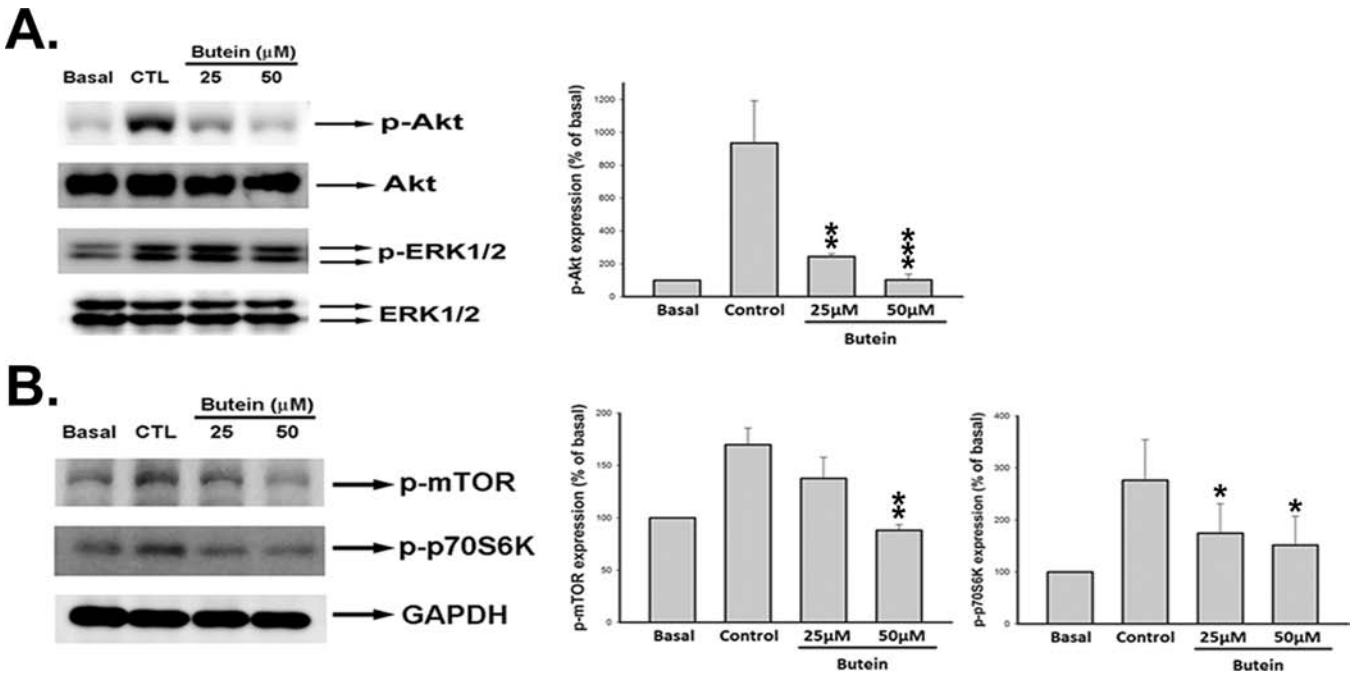

**Figure 6.** Effect of butein on Akt/mTOR/p70S6K translational signaling pathway. Serum-starved cells were treated with vehicle (basal) or 10% FBS in the absence (control) or presence of the indicated concentration of butein for 15 min. Cells were harvested and lysed for the detection of p-Akt and p-ERK1/2 (A) or p-mTOR and p-p70S6K (B) by Western blot analysis. The quantitative densitometry of the relative level of protein was performed with Image-Pro Plus. Data are expressed as the mean ± SEM of four independent experiments. (*) $p < 0.05$, (**) $p < 0.01$, and (***) $p < 0.001$ compared with the control group.

showed that butein dramatically repressed both MMP-9 and uPA activities (Figure 2A,B). Amiloride was used as a positive control for suppressing uPA activity. We further found that treatment with butein for 12 h caused the concentration-dependent inhibition of MMP-9 and uPA protein expression (Figure 2C). However, butein did not affect the mRNA expression of MMP-9 and uPA at the earlier time point (6 h) (Figure 3A,B). We then investigated whether butein inhibits TIMP-1 and PAI-1, which are MMP-9 and uPA endogenous inhibitors, respectively. It turned out that butein did not repress the mRNA expression of

dx.doi.org/10.1021/jf502370c | J. Agric. Food Chem. 2014, 62, 9109−9117

TIMP-1 and PAI-1. We also found that butein did not repress the mRNA expression of uPAR, which is a uPA receptor (Figure 3C). These results suggest that TIMP-1, PAI-1, and uPAR are not molecular targets of butein-mediated antimetastatic effect. Butein may suppress cancer metastasis through inhibition of MMP-9 and uPA proteolytic activities at the translational level.

**Butein Inhibits ATP Synthesis through Suppression of OXPHOS and Glycolysis.** Deregulated energetics is a property of most cancer cells. Aerobic glycolysis and mitochondrial oxidative biogenesis can produce the intracellular ATP that cells need.[13] Here, we further evaluated the impact of butein on energy metabolism of cancer cells. We evaluated the oxidative metabolism by measuring the oxygen consumption rate (OCR) and aerobic glycolysis by measuring the extracellular acidification rate (ECAR) after treatment of butein for 2 h using the Seahorse Bioscience XF24 cellular bioenergetics analyzer platform. As shown in Figure 4A, SK-Hep-1 cells treated with butein exhibited significantly reduced OCR compared with the respective control. Additionally, butein also markedly suppressed ECAR in SK-Hep-1 cells (Figure 4B). To understand if the inhibition of OCR and ECAR is correlated with energy levels, the intracellular ATP content was measured in butein-treated cells. We found that butein decreased the ATP production in a concentration-dependent manner (Figure 4C). To validate butein-mediated ATP reduction, mitochondrial OXPHOS inhibitor oligomycin and glycolysis inhibitor 2-deoxyglucose (2-DG) were used as positive controls in ATP content analysis. The results showed that oligomycin did not affect the intracellular ATP content, but 2-DG significantly inhibited the ATP production (Figure 4D). Moreover, the combination of oligomycin and 2-DG induced a dramatic reduction of ATP content. These results suggest that butein may repress ATP production and block cancer metastasis by suppressing both oxidative and glycolytic metabolism.

**Butein Inhibits NF-κB and Akt/mTOR/p70S6K Signaling Pathways.** We then investigated the signaling pathway underlying the butein-mediated antimetastasis property. It has been reported that butein inhibits the NF-κB activation pathway to exhibit antitumor and anti-inflammatory activities.[18] As shown in Figure 5A, treatment of 10% FBS for 15 min potently increased the phosphorylation of IκBα and p65, and butein significantly suppressed FBS-induced IκBα and p65 phosphorylation. Additionally, a NF-κB binding site-driven luciferase activity assay was carried out to confirm this result. We found that FBS-induced κB-luciferase activity was attenuated by butein (Figure 5B). A selective NF-κB inhibitor (BAY 11-7082) was used as the positive control. Because butein does not inhibit the transcription of MMP-9 and uPA, we next investigated whether the translational machinery was involved in butein-regulated protein inhibition of MMP-9 and uPA. Our data indicated that butein significantly decreased the phosphorylation of Akt, but did not decrease the phosphorylation of ERK1/2 in SK-Hep-1 cells (Figure 6A). The important downstream effector of PI3K/Akt pathway termed mTOR is recognized to modulate the translational machinery by inducing p70S6K phosphorylation.[28] Herein we investigated whether butein regulated these signaling pathways in SK-Hep-1 cells. As shown in Figure 6B, 10% FBS dramatically increased the phosphorylation of mTOR and p70S6K. Butein inhibited the phosphorylation of mTOR and its downstream effector p70S6K in a concentration-dependent manner. On the basis of these finding, we suggest butein may repress MMP-9 and uPA proteolytic activities and subsequently inhibit cancer metastasis via the Akt/mTOR/p70S6K translational signaling pathway.

## DISCUSSION

Metastasis is one of the most deadly steps in cancer progression, and the acquisition of the ability to invade surrounding tissue is one of the most important prerequisites for cancer cells to undergo metastasis.[1,2] The development of promising therapeutic agents against cancer invasion and metastasis is urgently needed. This study showed that butein, a naturally occurring chalcone derivative, significantly inhibited invasion and migration of cancer cells without acting in a cytotoxic fashion (Figure 1A−C). It has been reported that butein decreased cell growth, migration, and invasion of SK-Hep-1 cells.[25] Those results showed that butein inhibited migration and invasion at concentrations of 50 and 75 μM with 24 and 48 h of treatment; under this condition butein also dramatically induced cell death in SH-Hep-1 cells. These data indicate that the finding of butein-mediated inhibitory effects on cancer migration and invasion is due to its cytotoxicity. As compared with the Ma et al. study, our experiments provided promising evidence for the anti-invasive function of butein. Here, we demonstrated that butein exhibited an anti-invasive property at low concentration (25 and 50 μM) under short-term treatment (12 h) without inducing significant cell death of SK-Hep-1 cells. Notably, we found that butein significantly attenuated the metastasis of SK-Hep-1 cells using an in vivo CAM-intravasation model. The chicken CAM assay is one of the models for evaluating angiogenesis. Several innovative studies have established the chicken embryo as a useful model to investigate cancer metastasis.[26,29] Our results showed that butein induced a concentration-dependent inhibition of the intravasation of cancer cells in chick embryo CAM (Figure 1D). Taken together, we demonstrate that noncytotoxic concentrations of butein exert the antimetastatic effect in vitro and in vivo, suggesting butein may be a potential therapeutic agent worthy of further development for cancer treatment.

MMP-9 and uPA are two crucial matrix-degrading proteases in the progression of cancer invasion. They enable cancer cells to decompose and escape from the ECM of the primary tumor site and undergo the invasion−metastasis cascade.[4,11] Here, we found that butein markedly inhibited both MMP-9 and uPA enzyme activities (Figure 2). Moreover, butein repressed the protein expressions of MMP-9 and uPA without altering the mRNA level of MMP-9 and uPA (Figure 3). Several studies have shown that targeting and blocking the expression of MMP-9 or uPA profoundly suppressed the invasion of cancer cells.[30,31] Furthermore, in vivo evidence from the chicken CAM assay showed that u-PA and MMPs are interdependent and play the important role in the intravasation of cancer cells.[26] Thus, we suggest that butein may reduce cancer metastasis through suppression of MMP-9 and uPA. Because butein caused the inhibition of MMP-9 and uPA proteolytic activities at the translation level, we examined the translational signaling pathway in butein-treated cells. The translation of protein from mRNA is modulated by many signaling pathways. Among these pathways, Akt/mTOR translational machinery is the most intensively studied pathway.[32] Emerging evidence indicates that mTOR controls cap-dependent mRNA translation by activation of its downstream p70S6K and 4E-BP1. Importantly, the mTOR signaling pathway is commonly up-regulated in various tumor cells and is a potential target for cancer therapy.[28,33] Herein we demonstrated that butein dramatically blocked the phosphorylation of Akt, mTOR, and p70S6K, which could repress the recruitment of signals needed for protein translation of MMP-9 and uPA (Figure 6). Previous papers showed that activation of

the mTOR pathway can promote the synthesis of MMP-9 and uPA.[34−36] Our previous study also indicated that butein inhibited angiogenesis through the Akt/mTOR translational pathway in human endothelial progenitor cells.[22] Collectively, these results demonstrate the antimetastatic effect of butein may be through down-regulation of MMP-9 and uPA regulated by Akt/mTOR/p70S6K translational machinery.

Glycolysis and mitochondrial oxidative phosphorylation are the major sources of cellular energy. Deregulated cellular energetics is now recognized as an emerging hallmark of cancer.[15] The Warburg effect or aerobic glycolysis is characterized by increased glucose uptake, lactate export, and extracellular acidification of cancer cells to acquire energy, even in the presence of oxygen. Aerobic glycolysis is predominately up-regulated in cancer cells and contributes to tumor growth and aggressiveness through acidification of the extracellular environment.[14] However, the modulation of butein on energy metabolism of cancer cells has not been well explored. The present study demonstrated that suppression of glycolytic and oxidative metabolism by butein resulted in the reduction of ATP contents in SK-Hep-1 cells, although cell viability was not affected (Figure 4). In addition, we found that glycolysis inhibitor 2-DG but not OXPHOS inhibitor oligomycin reduced ATP production in SK-Hep-1 cells. Wu et al. have shown that the cellular ATP content was nearly unchanged by oligomycin in H460 and A549 cells, suggesting that glycolytic ATP generation was sufficient to maintain the energy balance.[37] On the other hand, 2-DG markedly decreased ATP production in both cell lines, indicating these cancer cells were intimately dependent on the glycolysis pathway to generate ATP. Here, we showed that SK-Hep-1 cells exhibited a dependency on glycolysis for bioenergetics. This extremely high glycolysis activity of SK-Hep-1 cells may be associated with its highly invasive characteristic. Several findings demonstrated that the inhibition of glycolysis can indeed repress the invasion and metastasis of cancer cells.[38] Extracellular acidity is the important constituent of the invasive microenvironment that promotes cancer progression. Thus, we suggest that butein may partly suppress cancer metastasis by down-regulating ATP synthesis via glycolytic and oxidative metabolism. It has been reported that mTOR is a direct sensor of intracellular ATP concentration. The phosphorylation of mTOR can also be affected by intracellular ATP levels. An enzyme kinetics study shows that the Michaelis constant ($K_m$) of mTOR for ATP is about 1 mM, whereas most protein kinases have $K_m$ values for ATP of 10−20 $\mu$M, indicating that there is a tighter positive correlation between the phosphorylation level of mTOR and the concentration of ATP than for other kinases.[39] Therefore, butein-mediated ATP reduction may repress mTOR signaling and its downstream cascades in cancer cells.

Earlier studies have shown that the activity of transcription factor NF-$\kappa$B is responsible for the transcription of MMP-9 and uPA.[40] Butein can suppress the transcription activity of NF-$\kappa$B to block cancer progression.[18] Our data also demonstrated that NF-$\kappa$B activation was attenuated by butein (Figure 5). However, butein did not affect the mRNA levels of MMP-9 and uPA, indicating butein may inhibit cancer metastasis through suppression of MMP-9 and uPA via a NF-$\kappa$B-independent pathway. In conclusion, this study provides evidence that butein may inhibit Akt/mTOR/p70S6K translational machinery, leading to down-regulation of MMP-9 and uPA, and subsequently exhibit the antimetastatic effect. We demonstrate for the first time that butein may alter oxidative and glycolytic metabolism to suppress ATP-dependent cancer metastasis. The detailed mechanism between butein-mediated bioenergetics modulation and the antimetastasis property needs to be investigated in the future.

would exhibit a better affinity with lipophilic membrane constituents of drug target cells.[8] This property would make from ascorbyl derivatives good candidates to be used in pharmaceutical and cosmetic lipophilic formulations.[9] The interest in new compounds with antimicrobial properties has been revived because of current problems associated with the use of antibiotics.[10] Aissa et al.[11] have synthesized a large series of tyrosyl esters with increasing lipophilicity using lipase of *Candida antarctica*. The authors showed that the parent tyrosol does not have any effect on various pathogenic bacteria. However, tyrosyl esters and especially medium chain tyrosyl derivatives exhibited an antimicrobial activity against staphylococcus strains.

In the wake of resistance to pentavalent antimonial drugs, new therapeutic alternatives are desirable.[12] Hence, it is of interest to analyze the performance of the amphiphilic ascorbyl derivatives and study the relationship between their structure and their antileishmanial activity.

Based on the above-mentioned information, a large series of ascorbyl fatty acid esters with increasing lipophilicity was synthesized by the direct esterification of ascorbic acid with various fatty acids using *Staphylococcus xylosus* immobilized onto silica aerogel produced in our laboratory as catalyst and evaluated for their antioxidant, emulsifying, and antimicrobial activity against several pathogenic strains and their antileishmanial effects on both cutaneous (*Leishmania major*) and visceral parasites (*Leishmania infantum*). Finally, the interaction of the ester derivatives with a mimetic phospholipid film mixture was evaluated using a monomolecular film technique.

## 2. MATERIALS AND METHODS

**2.1. Materials.** Ascorbic acid was purchased from Bio Basic Inc. (Switzerland); chloroform and methanol were purchased from Scharlau (Spain); acetonitrile and acetic acid from Pharmacia (Uppsala, Sweden); caprylic, capric, lauric, palmitic, stearic, and oleic acids and 2-methyl-2-propanol from Fluka (Germany); 4,5-dimethylthiazol-2-yl-2,5-diphenyltetrazolium bromide (MTT) and 2,2-diphenyl-1-picrylhydrazyl (DPPH) were purchased from Fluka (Switzerland); BHT (purity ≥99%), α-tocopherol (purity ≥96%) and arabic gum (purity 99%) from Sigma; soya lecithin (verolec F-62) was purchased from LASENOR. EggPC, cholesterol, phosphatidylethanolamine (PE), phosphatidylglycerol (PG), and sphingolipid (SL) were purchased from Avanti. The egg-yolk lecithin was extracted from fresh egg yolks using a modified method described by Palacios and Wang.[13] The purity of egg-yolk lecithin was checked by TLC. *Staphylococcus xylosus* lipase was produced as described by Mosbah et al.[14] Enzyme immobilization was made onto silica aerogel as previously described by Kharrat et al.[15]

**2.2. Methods.** *2.2.1. Esterification Reactions.* Ascorbyl lipophilic esters (Asc-$C_2$ to Asc-$C_{18:1}$) were prepared by direct esterification between ascorbic acid (Asc) and various fatty acids in screw-capped flasks. Asc (8 mg/mL) was dissolved in 2-methyl-2-propanol to an acetonitrile volume ratio of 0.2 (3 mL of total volume). The fatty acid concentration was adjusted to obtain an ascorbic acid/fatty acid molar ratio of eight. The mixture was stirred at 45 °C in an orbital shaker at 220 rpm and in the presence of *Staphylococcus xylosus* lipase immobilized onto silica aerogel (600 IU). Control reactions in the absence of lipase were also carried out parallelly. Aliquots from the mixture reaction were withdrawn after 72 h of incubation and filtered to be used for HPLC analysis. The conversion yield of ascorbyl derivatives was calculated as the ratio of the number of moles of ascorbic acid converted per the total number of moles of ascorbic acid. All experiments were performed in triplicate. Study has been selected from five microorganism lipases produced in our laboratory. This enzyme presented the higher yield conversion (data not shown).

*2.2.2. Purification and Identification of Ascorbyl Esters.* The reaction mixture resulting from the esterification of ascorbic acid with different fatty acids contains a mixture of ascorbic acid ester and residual substrates. After enzyme removal by centrifugation at 8000 rpm for 15 min, the solvent (2-methyl-2-propanol) was evaporated at 45 °C under vacuum and the synthesized ester was purified as follows: 100 mg of target product was taken up in 2 mL of chloroform. The purification of esters was achieved by chromatography on a silica gel 60 column (Merck) (25 cm × 2 cm) according to Aissa et al.[16] The column was previously equilibrated in chloroform. Elution was carried out using chloroform/methanol/acetic acid mixtures (78:18:4). The collected solvent fractions were analyzed by TLC. The spots were identified under evaporated iodine. Purified fractions were pooled and solvents evaporated at 45 °C under vacuum. Final purity of the products obtained was checked using LC/MS analysis.

*2.2.3. HPLC Analysis.* The identification and conversion yields of ascorbyl derivatives were carried out by HPLC analysis (Ultimate 3000, Dionex, Germany). The HPLC system was equipped with a pump (LPG-3400SD), column oven, and diode-array UV−vis detector (DAD-3000RS). The output signal of the detector was recorded using Dionex Chromeleon chromatography Data System. Separation was executed on an Inertsil ODS-4 C-18 column (5 μm, 4.6 mm × 250 mm; Shimpack) maintained at 30 °C. The flow rate used was 1.5 mL/min, and the detection UV wavelength was set at 254 nm. The used mobile phase was 0.05% acetic acid in water (A) versus 0.1% acetic acid in acetonitrile (B) for a total running time of 12 min, and the following proportions of solvent (B) were used for elution: 0−3 min, 10−30%; 3−5 min, 30−90%; 5−10 min, 90%; and 10−12 min, 90−10%.

*2.2.4. LC−-MS/MS Analysis.* An analytical LC−UV−MS/MS analysis was performed on a Phenomenex Luna C18 (2) column (150 × 4.6 mm i.d., 5 μm particle size), using a 1 mL/min linear mobile phase gradient of 20−50% aqueous MeOH (containing 1% HOAc) in 30 min, and mass spectra were recorded by a Thermo Scientific "LCQ Classic" ion trap mass spectrometer fitted with an ESI source. Accurate mass measurements were performed on Finnigan MAT900 XLT or Thermo Scientific LTQ Orbitrap XL mass spectrometers in negative and positive ESI mode.

*2.2.5. NMR and FT-IR Experiments.* $^1$H and $^{13}$C NMR spectra were recorded in deuterated chloroform ($CDCl_3$) on a Bruker TOPSPIN spectrometer operating at 400 MHz. IR spectra were recorded on FT/IR-410 (JASCO).

Asc-C10: $^1$H NMR (400 MHz, $CDCl_3$): 4.25 (2H ($H_{1'}$), d); 3.85 (1H ($H_{2'}$), dd); 4.35 (1H ($H_{3'}$), d); 4.27 (1H ($H_{7'}$), s); 4.9 (1H ($H_{8'}$), s); 5.19 (1H ($H_{9'}$), s); 2.3 (2H ($H_2$), t, $-CH_2CO$); 1.6 (2H ($H_3$), m); 1.3 (nH ($H_4$−$H_9$), m, $(CH_2)_6$); 0.9 (3H ($H_{10}$), t, $CH_3$).

$^{13}$C NMR (400 MHz, $CDCl_3$): 14.08 ($C_{10}$), 22.68 ($C_3$), 24.74−33.81 ($C_4$−$C_9$), 34.11 ($C_2$), 64.16 ($C_{1'}$), 67.47 ($C_{2'}$), 130.16 ($C_{4'}$), 130.88 ($C_{5'}$), 153.05 ($C_{3'}$), 172.48 ($C_{6'}$, C═O); 178.35 ($C_1$, C═O).

IR (liquid) cm$^{-1}$: 3108−3023 (HO-Ø), 2905 (C−H), 1700 (C═O), 1200− 1350 ($CH_2$) stretching, 1100 (C−O).

*2.2.6. Antioxidant Activity.* The free radical scavenging activity of Asc and its derivatives was determined using the method of Brand-Williams et al. with a little modification.[17] An aliquot of ethanol absolute solution (0.1 mL) containing different concentrations (1:2 serial dilutions from the initial sample) of Asc and its esters was added to 3.9 mL of DPPH solution (0.06 mM in ethanol). The mixture was vortexed vigorously and incubated at room temperature (25 °C) in darkness for 60 min, and then the absorbance was read at 517 nm against ethanol blank using a spectrophotometer (Uvi Light XT5).

The $IC_{50}$ values denote the concentration of tested compounds, which is required to scavenge 50% of DPPH free radicals. The corresponding inhibition percentages were calculated according to the following equation:

$$\text{radical scavenging activity (\%)} = \frac{(A_{\text{blank}} - A_{\text{sample}})}{A_{\text{sample}}} \times 100$$

where $A_{\text{blank}}$ is the absorbance of the control (prepared in the same manner without test compound), and $A_{\text{sample}}$ is the absorbance of the

test compound. Ascorbic acid, butylated hydroxytoluene (BHT), and α-tocopherol were used as standard control. The values are presented as the means of triplicate analyses.

*2.2.7. Lipophilicity Evaluation.* The partition coefficients (miLogP) values and the molecular weight of ascorbyl esters were calculated using Molinspiration software (available online at www.molinspiration.com). The lipophilic character of ascorbyl esters was evaluated as described by Viskupicova et al.[18]

*2.2.8. Measurement of Conjugated Diene (CD) and Triene (CT).* The effect of ascorbyl esters on the oxidative state of oil was evaluated by the measuring of conjugated diene (CD) and conjugated triene (CT) as previously described by Della et al.[19] Oxidation was induced during 20 days by storing soya oil at 70 °C. Every 2 days, the absorbance was measured at 232 nm (for CD) and 270 nm (for CT), using hexane as a blank. All measurements were performed in triplicate. BHT and α-tocopherol were used as standard control.

*2.2.9. Emulsifying Activity.* The ability of the purified ascorbyl esters to form oil-in-water (o/w) emulsions against soya oil was determined using the method described by Gutierrez et al.[20] Activities were compared under neutral (0.1 M phosphate-buffered saline, pH 7), acidic (0.1 M sodium acetate buffer, pH 4), and basic (0.1 M Tris-HCl buffer, pH 8.5) conditions. 5 mL of buffer was vortexed for 2 min at 2200 rpm with 0.8 mL of soya oil containing 0.02% (w/v) of each emulsifier. The turbidity of the lower aqueous layer was measured using a spectrophotometer at 540 nm. All measurements were carried out in triplicate, and the mean values of the triplicates were reported with standard error. Egg-yolk lecithin, soya lecithin, and Arabic gum were used as commercial emulsifiers.

*2.2.10. Determination of the Minimum Inhibitory Concentration (MIC) and the Minimum Bactericidal Concentration (MBC).* The antibacterial activities of Asc, Asc + FAs (separated substrates taken together at the same concentration), and ascorbyl derivatives were tested against several bacteria strains using Luria broth (LB) medium. The minimum inhibitory concentration (MIC) values, which correspond to the lowest compound concentration that completely inhibits the growth of microorganisms, were determined by a microwell dilution method as previously described by Eloff[21] using 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT). The inoculum of each bacterium was prepared, and the suspensions were adjusted to $10^7$ CFU/mL. All the compounds were dissolved in 100% ethanol, and then dilution series were prepared in a 96-well plate, ranging from 3.125 μg/mL to 4 mg/mL. Each well of the microplate contained 175 μL of the growth medium, 5 μL of inoculum, and 20 μL of the diluted sample extract. Ethanol was used as a negative control. The plates were incubated at 37 °C for 24 h, and then 40 μL of MTT, at a final concentration of 0.5 mg/mL freshly prepared in sterile water, was added to each well and incubated for 30 min. The change to purple color indicated that the bacteria were biologically active. The MIC was taken where no change of MTT color was observed in the well.

To determine the minimum bactericidal concentration (MBC), a liquid portion from each well that showed no change in color will be placed on solid LB and incubated at 37 °C for 24 h. The lowest concentration that yielded no growth after this subculturing will be taken as the MBC.[22] All experiments were made in duplicate. Several bacterial strains were used: i.e., *Bacillus cereus* (*BC*), *Bacillus subtilis* (*BS*), *Staphylococcus aureus* (*Sa*), *Staphylococcus epidermidis* (*SEp*), *Enterococcus faecalis* (*EF*), *Enterococcus faecium* (*EFa*), *Enterobacter cloacae* (*EC*), *Micrococcus luteus* (*ML*), *Brevibacterium flavum* (*BF*), *Pseudomonas aeruginosa* (*Ps*), *Salmonella typhimurium* (*STyphi*), *Klebsielle pneumonia* (*KP*), *Echerichia coli* (*Ecoli*), and *Staphylococcus xylosus* (*Sx*).

*2.2.11. Leishmanicidal Activity.* (These experiments have been performed in the Pasteur Institute of Tunis (Tunisia)). *L. major* (MHOM/TN/95/GLC94)[23] and *L. infantum* (MHOM/TN/94/LV50)[24] strains isolated from Tunisian patients were used within this study. Promastigotes were cultured in solid medium at 26 °C during 6 days. They must be in their infective metacyclic forms as mentioned by Aissa et al.[11] The effects of ascorbyl derivatives on *Leishmania* promastigotes were evaluated by the MTT assay as described by Dutta et al.[25] Parasites ($10^7$ parasites/well in the complete medium) were incubated for 24 h in the presence of serially diluted concentrations of ascorbyl derivatives (ranging from 25 to 400 μg/mL).[11] After this treatment, microtiter plates were centrifuged at 1700*g* for 10 min and supernatants were removed and replaced with the same volume of 1 mg/mL of MTT freshly dissolved in PBS. Plates were then incubated overnight at room temperature. After centrifugation at 2500*g*, formazan salt formed inside the parasite mitochondria was solubilized by discarding supernatants and adding SDS 10% for 2 h at 37 °C in the dark. Absorbance was measured at 540 nm using an ELISA plate reader. Negative controls were conducted without addition of ascorbyl derivative solutions. Each assay was performed in duplicate.

*2.2.12. Monolayer Study of the Ascorbyl Derivatives.* Experiments were carried out on KSV 2200 Baro-stat equipment as described by Aissa et al.[11] A Teflon trough was equipped with two hydrophilic Delrin barriers (symmetric compression) and a Wilhelmy plate as a surface-pressure sensor. Software KSV 2200 was used to control the experiments. Before each utilization, the Teflon trough was cleaned and brushed in the presence of distilled ethanol, subsequently washed again with tap water, and finally rinsed with double-distilled water. The aqueous subphase (buffer A) was composed of 10 mM Tris−HCl, pH 8, 100 mM NaCl, 21 mM $CaCl_2$, and 1 mM EDTA. Buffer was prepared with double-distilled water and filtered through a 0.45 μM Millipore filter. Residual surface active impurities were removed before each assay by sweeping and suction of the surface.[26]

*2.2.13. Measurement of the Ascorbyl Derivatives Penetration into Mixture Film Monolayer.* The surface pressure increase, due to the penetration of the ascorbyl derivatives into a mixture film monolayer, was measured in a cylindrical trough drilled into a Teflon block (surface area 17.42 $cm^2$, total volume 15 mL). The aqueous

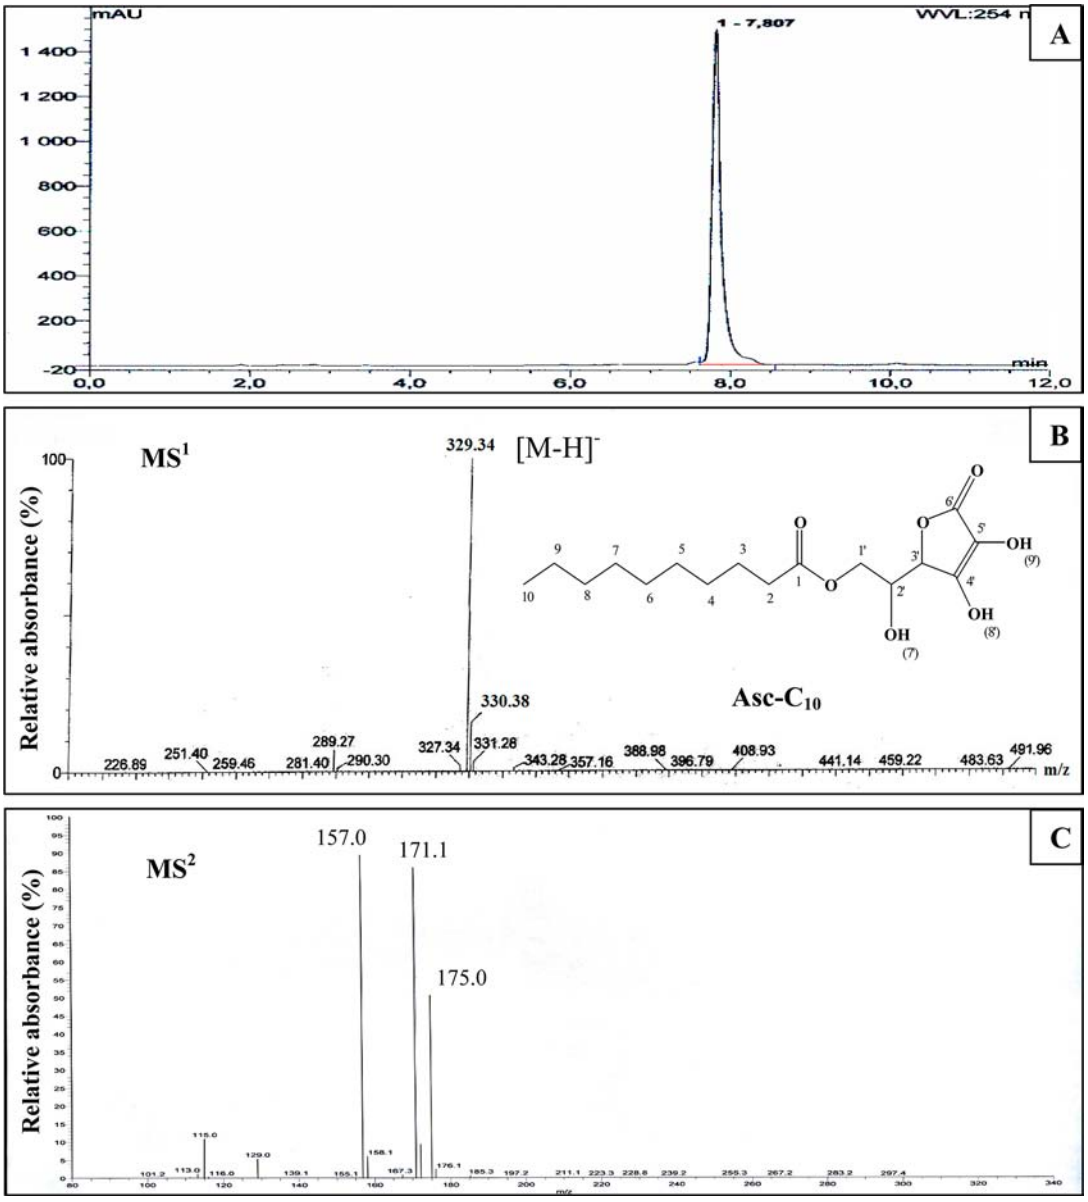

**Figure 1.** (A) HPLC profile of ascorbyl caprate (Asc-$C_{10}$) after biosynthesis and purification. The biosynthesis reaction of ascorbic acid with capric acid (ascorbic acid/fatty acid molar ratio of eight) was catalyzed by *Staphylococcus xylosus* lipase immobilized onto silica aerogel at 45 °C and 220 rpm in 2-methyl-2-propanol to acetonitrile volume ratio of 0.2 (72 h). HPLC analysis was carried out on a C-18 column by gradient elution using acidified water and acetonitrile at a flow rate of 1.5 mL/min. (B) $MS^1$ spectra of purified ascorbyl caprate (Asc-$C_{10}$). (C) $MS^2$ spectra of purified ascorbyl caprate (Asc-$C_{10}$).

subphase (buffer A) was stirred continuously at 250 rpm with a magnetic rod. The critical surface pressures were determined as described previously.[27] A sample of Asc or synthesized ester solution (0.5 $\mu$M) was injected with a Hamilton microsyringe, under a monomolecular film of mixture film spreads at an initial surface pressure ($\pi_i$) ranging from 4 to 37 mN/m. To mimic the lipidic components of leishmania membrane, a mixture of phospholipids was used, containing 40% EggPC, 30% cholesterol, 10% phosphatidylethanolamin (PE), 10% phosphatidylglycerol (PG) and 10% sphingolipid (SL).[28]

*2.2.14. Statistical Analysis.* All analyses were carried out in triplicate. Results were expressed as mean values ± standard deviation (SD) ($n$ = 3). The differences were calculated using one-way analysis of variance (ANOVA), and statistically significant differences were reported at $P < 0.05$. Data analysis was carried out using the SPSS 10.0 software.

## 3. RESULTS AND DISCUSSION

**3.1. Enzymatic Synthesis and Characterization of Ascorbyl Fatty Acid Esters.** A chemoselective enzymatic esterification was used to synthesize lipophilic ascorbyl ester derivatives (Asc-$C_2$ to Asc-$C_{18:1}$). Several solvents such as hexane, chloroform, acetone, and toluene were used as reaction media. However, among all these organic solvents tested, only cosolvent 2-methyl-2-propanol/acetonitrile was suitable for this esterification reaction.

The conversion yields calculated after 72 h of incubation using lipase from *Staphylococcus xylosus* immobilized onto silica aerogel as a catalyst are presented in Table 1. As it can be seen, the highest ester synthesis yield was obtained when using short acyl chain ester Asc-$C_2$. For medium and long chain esters (Asc-$C_8$ to Asc-$C_{18:1}$), the conversion yield decreased

dx.doi.org/10.1021/jf5029398 | J. Agric. Food Chem. 2014, 62, 9118−9127

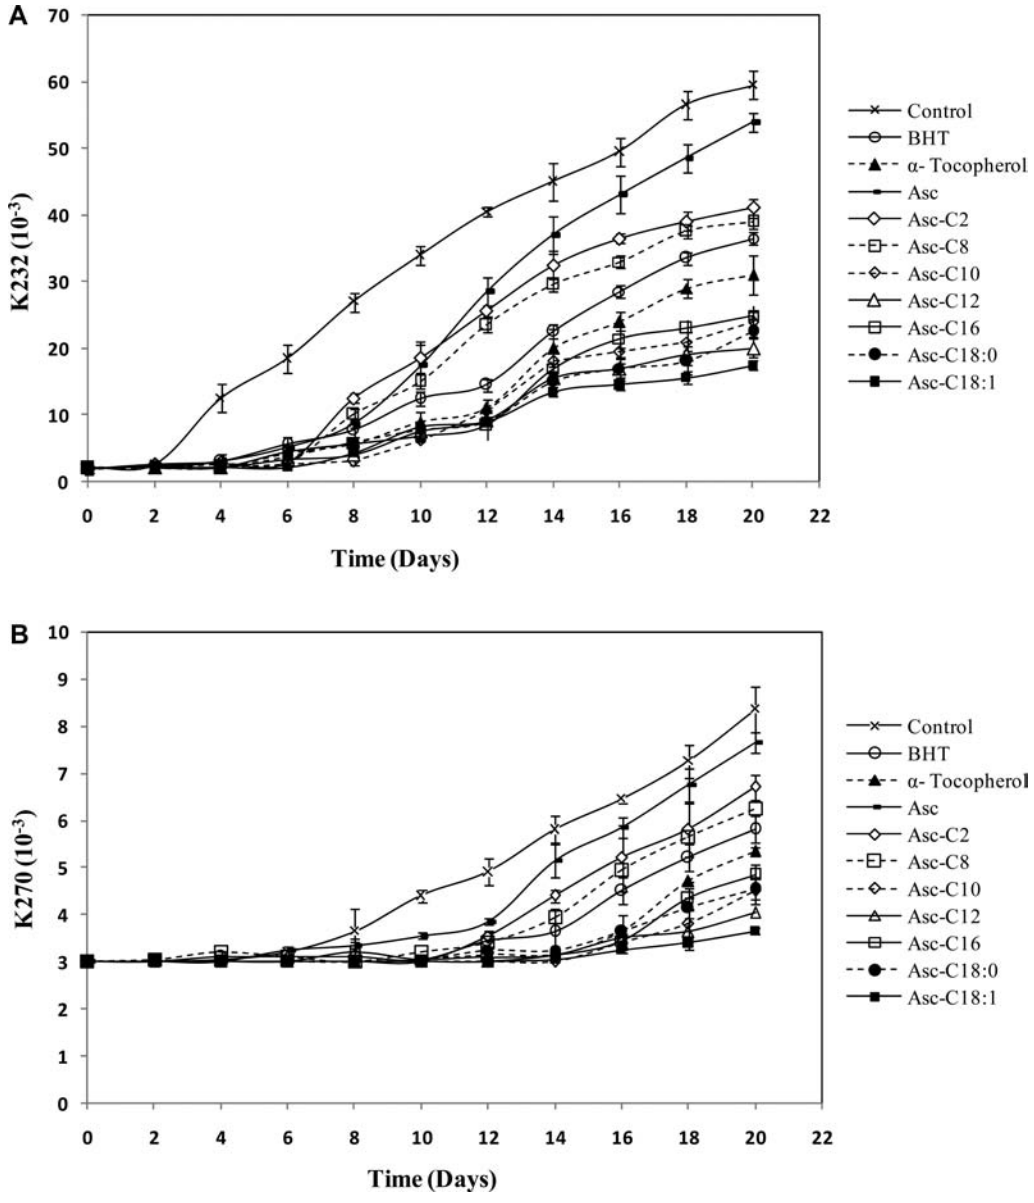

**Figure 2.** Antioxidant activities of ascorbyl ester derivatives (Asc-$C_2$ to Asc-$C_{18:1}$) tested by the measurement of conjugated diene (A) and conjugated triene (B) of refined soy oil during storage at 70 °C. For each test, negative and positive controls using BHT and $\alpha$-tocopherol were run in parallel. Values are mean ± SD ($n$ = 3) of three determinations.

progressively with the increase of the acyl chain length (Table 1) although *Staphylococcus xylosus* lipase hydrolyzes triacylglycerols without significant chain length preference.[14]

These results are in line with those observed previously by Aissa et al.[16] The fatty acid unsaturation seems to affect the synthesis yield. In fact, the ester conversion yield reached 52.86% with ascorbyl palmitate and decreased to 40.96% of ascorbyl oleate when using oleic acid as acyl donor. Our observations are in agreement with those described by Selmi et al.[29] They concluded that the increase of the unsaturation number is responsible for the lower rate of triacylglycerol synthesis using immobilized *Rhizomucor miehei* lipase. These results are however in contradiction with those described by Song et al.,[30] which showed that $C_{18}$ unsaturated FAs gave better conversion yield as compared to $C_{18}$ saturated FAs using Novozym 435 as catalyst. These contradictions between these findings could be attributed to the nature of the lipase used and the composition of the reaction medium (solvent, water content, substrate chemistry) or the operating conditions.[31,32]

**3.2. Purification and Identification of Ascorbyl Fatty Acid Esters.** The purification of each ascorbyl ester was achieved by chromatography on a silica gel 60 column according to Aissa et al.[16] as described above in Materials and Methods. The purity of these products was then checked via HPLC analysis (Figure 1A); their retention time is mentioned in Table 1. RMN, $MS^1$, and IR analysis were used to identify the purified products.

As shown in Figure 1B, $MS^1$ analysis in the negative mode of pure Asc-$C_{10}$, taken as a typical compound, exhibited a molecular ion at $m/z$ = 329.34 $[M - H]^-$ attributed to the molecular weight of calculated ester using Molinspiration software (330.37 g/mol) shown in Table 1.

The $MS^2$ experiments focusing on the fragment generated from the peak in $m/z$ = 329.34 $[M - H]^-$ revealed a fragment corresponding to the pseudo molecular ion at $m/z$ = 171.1

dx.doi.org/10.1021/jf5029398 | J. Agric. Food Chem. 2014, 62, 9118−9127

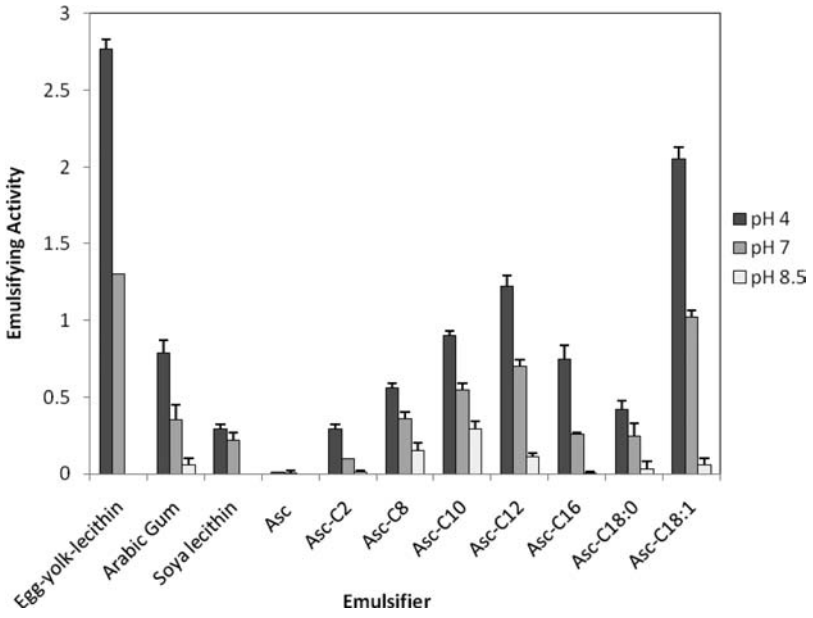

**Figure 3.** Emulsifying activity at pH 4, pH 7, and pH 8.5 of ascorbic acid and its derivatives (Asc-$C_2$ to Asc-$C_{18:1}$). The activity reflects the capacity of the emulsifier to form soya oil-in-water emulsions. Egg-yolk lecithin, arabic gum, and soya lecithin were used as control emulsifiers. Values are mean ± SD ($n$ = 3) of three determinations.

attributed to capric acid and $m/z$ = 175.0 attributed to ascorbic acid ion. The ion at $m/z$ = 157 was formed by the cleavage of the capric acid and neutral losses of $H_2O$ linked to the ascorbic acid (Figure 1C).

**3.3. Antioxidant Activity.** Ascorbic acid exhibits low solubility and stability in the lipophilic media, which can limit its efficient use in these conditions. Hence, the lipophilic derivatives of Asc and, in particular, long acyl chain esters, would exhibit a better affinity with lipophilic matrices. Being a lipophilic compound may improve its solubility as well as maintain or enhance its radical scavenging capacity.[16,32] This property would make ascorbyl derivatives strong candidates for pharmaceutical and cosmetic lipophilic formulation.

The antioxidant efficiency of ascorbic acid was checked after lipophilization using DPPH in an ethanolic medium, a rapid and sensitive scavenging test. As indicated in Table 1, ascorbic acid and its synthesized esters were shown to be strong DPPH radical scavengers. Esterification of Asc-$C_2$ to Asc-$C_{18:0}$ seems to slightly affect the radical-scavenging potential. All ascorbyl derivatives exhibited a high antioxidant activity with an $IC_{50}$ varying between 3 and 3.5 $\mu$g/mL, which are near the $IC_{50}$ value of ascorbic acid (2.01 $\mu$g/mL). Moreover, the antioxidant effect of ascorbic acid and its derivatives was twice as efficient as the known synthetic antioxidants such as BHT and $\alpha$-tocopherol. These results are, however, in contradiction with those described by Burham et al.,[33] who showed that ascorbic acid exhibited a higher antioxidant activity than ascorbyl palmitate and pure palm-based ascorbyl esters. The radical-scavenging capacity of ascorbic acid and its derivatives can be explained by the number and position of hydrogen-donating groups (OH) in hydroxyl headgroup.[32]

**3.4. Ascorbyl Ester Derivatives Effect on Oil Oxidative Stability.** The effect of lipophilic ascorbyl derivatives on the oxidative stability of oils was determined by the measurement of conjugated diene (CD) and triene (CT). Ascorbic acid and its acyl esters (Asc-$C_2$ to Asc-$C_{18:1}$) were added to refined soy oil. CD and CT of the different preparations were measured upon 20 days storage at 70 °C in the open air (Figures 2A and 2B). The CD and CT determine the primary products of oil oxidation.[34] A remarkable increase in the CD and CT of refined soya oil was observed. As shown in Figures 2A and 2B, the addition of ascorbyl derivatives, as antioxidants, prevented oil oxidation as well as BHT and $\alpha$-tocopherol. Interestingly, the protective effect against oxidation by ascorbyl derivatives was higher than that of Asc and increased with the fatty acid chain length. However, Asc, Asc-$C_2$, and Asc-$C_8$ derivatives displayed the lowest protective effect of soya oil against oxidation. Based on the increasing trend of miLogP values (Table 1), it seems that ascorbyl esters having a high lipophilicity (miLogP higher than 3.2) display the best antioxidant capacities. Ascorbyl derivatives, the amphiphilic natural antioxidants, could be used for increasing protection of target lipids from oxidation such as skin creams, facial treatments (acne or wrinkle removers), bath oils, sunscreens, preshave, and makeup.

**3.5. Emulsifying Activity.** Today, more than ever, a large amount of surfactant is required for a microemulsion system used for pharmaceutical/cosmetic purposes.[35] However, a surfactant may exhibit undesirable effects like skin irritation, allergy, etc. when used excessively. Therefore, one must choose materials that are biocompatible, nontoxic, and clinically acceptable and use emulsifiers in an appropriate concentration range that will result in mild and nonaggressive micro-emulsions.[35] The excipients generally regarded as safe (GRAS) are being increasingly preferred. For these reasons, the ability of purified ascorbic acid derivatives to emulsify soya oil in water was tested. The emulsifying capacity of the different ascorbyl derivatives was determined under acidic, neutral, and basic conditions. Arabic gum, soya lecithin, and egg-yolk-lecithin were taken as control emulsifiers since they are the most important hydrocolloid ingredients in the formulation of many food products. Based on average results provided in acidic, neutral, and basic pH conditions presented in Figure 3, the ascorbyl derivatives produced emulsifying activities that were significantly different from those of control. In fact, apart from Asc and Asc-$C_2$, all ascorbyl derivatives (Asc-$C_8$ to Asc-$C_{18:1}$) produced a significantly higher emulsifing activity than

dx.doi.org/10.1021/jf5029398 | J. Agric. Food Chem. 2014, 62, 9118−9127

**Table 3. $IC_{50}$ Activities of Ascorbic Acid and Its Acyl Chain Derivatives against *L. major* and *L. infantum* Parasite Species Evaluated by the MTT Assay**

| | $IC_{50}$ (μg/mL) | | | | | | | |
|---|---|---|---|---|---|---|---|---|
| | Asc | Asc-$C_2$ | Asc-$C_8$ | Asc-$C_{10}$ | Asc-$C_{12}$ | Asc-$C_{16}$ | Asc-$C_{18:0}$ | Asc-$C_{18:1}$ |
| *L. major* | *a* | *a* | *a* | 217.74 ± 13.33 | 196.26 ± 10.53 | *a* | *a* | 154.23 ± 12.41 |
| *L. infantum* | *a* | *a* | *a* | 347.12 ± 12.32 | 284.80 ± 20.33 | *a* | *a* | 205.81 ± 14.35 |

[a]Without effect up to 400 μg/mL.

arabic gum and soya lecithin, but lower than egg-yolk lecithin. Comparable results were obtained by Kuwabara et al.,[36] who demonstrated that caproyl and lauroyl L-ascorbates are useful emulsifiers for emulsions. In addition, under acidic conditions, the emulsifying activities of all ascorbyl esters were significantly higher compared to those measured under basic or neutral conditions (Figure 3). Among all the tested derivatives, Asc-$C_{18:1}$ was found to be the most potent as emulsifier.

**3.6. Determination of the Minimum Inhibitory Concentration (MIC) and the Minimum Bactericidal Concentration (MBC).** The antibacterial activity of Asc, FAs, Asc + FAs, and the synthesized esters (Asc-$C_2$ to Asc-$C_{18:1}$) was checked against Gram-positive (*Bacillus cereus* (*BC*), *Bacillus subtilis* (*BS*), *Brevibacterium flavum* (*BF*), *Micrococcus luteus* (*ML*), *Staphylococcus xylosus* (*Sx*), *Staphylococcus aureus* (*Sa*), *Staphylococcus epidermidis* (*SEp*), *Enterococcus faecalis* (*EF*), and *Enterococcus faecium* (*EFa*)) and Gram-negative (*Enterobacter cloacae* (*EC*), *Pseudomonas aeruginosa* (*Ps*), *Salmonella typhimurium* (*STyphi*), *Klebsielle pneumonia* (*KP*), and *Echerichia coli* (*Ecoli*)) bacteria by the determination of MIC and MBC values. As can be seen from Table 2, sections A and B, ascorbic acid does not show any inhibitory or bactericidal effect up to a concentration of 4 mg/mL. Compared to Asc and mixed solution of Asc + FAs, synthesized ester exhibits the most effect against the bacteria tested, in particular Gram (+) ones. In fact, with Gram (+) bacteria, MIC values ranged from 0.0625 to 2 mg/mL and the MBC values are between 0.500 and 4 mg/mL, while Gram (−) bacteria appear to be less sensitive to the tested compounds. Previous studies reported that Gram (−) bacteria presented lower sensitivity than Gram (+) bacteria to various polyphenols.[37] This higher resistance may be related to minor differences present in the outer membrane in the cell wall composition.[37] As it can be seen from Table 2, panel A, MIC and MBC values showed that ascorbyl derivatives exhibit a similar or a slightly higher inhibitory activity and more bactericidal effect against Gram (+) bacteria than the separated substrates (Asc + FAs). These results indicate that we have significantly enhanced the antimicrobial activity of the ascorbic acid after esterification. These findings are in agreement with those of Aissa et al.,[11] who showed that only medium chain tyrosyl esters had an antibacterial activity especially against *Staphylococcus* strains.

These results could be explained by their hydrophobicity, which may allow them to partition the lipids of the bacterial cell membrane, making them more permeable and leading to ion leakage and other cell constituents.[38] The authors suggested that these compounds could be able to infiltrate the cell and interact with some metabolic mechanisms, which allowed us to show their bacteriostatic effect.

**3.7. Antileishmanial Activity.** Ascorbic acid and its lipophilic derivatives were screened for their leishmanicidal activity. Screening was carried out using two *Leishmania* species: *L. major* GLC94[23] and *L. infantum* LV50.[24] As shown in Table 3, only Asc-$C_{10}$, Asc-$C_{12}$, and Asc-$C_{18:1}$ ascorbyl

dx.doi.org/10.1021/jf5029398 | J. Agric. Food Chem. 2014, 62, 9118−9127

derivatives were effective against both *Leishmania* species, while either ascorbic acid or Asc-$C_2$, Asc-$C_8$, Asc-$C_{16}$, and Asc-$C_{18:0}$ derivatives had no leishmanicidal activity up to 400 $\mu$g/mL. Interestingly, the three effective derivatives showed a higher activity against *L. major* promastigotes compared to that obtained against *L. infantum* promastigote. Indeed, $IC_{50}$ values were approximately two times higher against the former than the latter. This indicates that *L. major* parasites are more sensitive to these compounds than *L. infantum* ones. Asc-$C_{18:1}$, the most effective derivative, showed an $IC_{50}$ of 154.23 $\mu$g/mL and 205.81 $\mu$g/mL against *L. major* and *L. infantum*, respectively. Also, Asc-$C_{12}$ showed a moderate activity of 196.262 $\mu$g/mL and 284.8 $\mu$g/mL against *L. major* and *L. infantum*, respectively. Finally, Asc-$C_{10}$ was the less active compound of the three derivatives, which showed an $IC_{50}$ of 217.74 $\mu$g/mL and 347.12 $\mu$g/mL against the dermotropic and the viscerotropic strain, respectively. These results are in line with those observed previously by Aissa et al.,[11] who showed that the medium chain tyrosyl esters had an antileishmanial effect. However, for our case, the most effective derivative was ascorbyl oleate (Asc-$C_{18:1}$). These results could be attributed to the nature of the hydroxyl headgroup of ascorbic acid and besides their amphiphilicity degree.

**3.8. Interactions of Ascorbyl Derivatives with Mixture Film Monolayer.** In order to study the influence of the length and the nature of the ascorbyl derivatives acyl chain on the esters adsorption properties, their critical surface pressures ($\pi_c$) were compared using a mixture film monolayer, containing the principal components of leishmania membranes: 40% EggPC, 30% cholesterol, 10% phosphatidylethanolamine (PE), 10% phosphatidylglycerol (PG), and 10% sphingolipid (SL).[28]

The maximum surface pressure increase was determined at different initial pressures ($\pi_i$) of mixture film ranging from 5 to 40 mN/m (Figure 4). The critical surface pressure ($\pi_c$) for each ester was estimated by the linear extrapolation of the experimental curves at zero surface pressure increase. A critical pressure for penetration ($\pi_c$) may thus be defined; it corresponds to the extrapolated value of initial beyond which there is no increase in surface pressure. The value of the maximum surface pressure increase ($\Delta\pi_{max}$) reached at equilibrium (around 40 min after the injection of the ascorbyl derivative in the aqueous subphase) was determined and plotted as a function of $\pi_i$ (Figure 4). For all ascorbyl derivatives, a general trend was observed: the higher the $\pi_i$, the lower the interaction of the ascorbyl derivatives with the monolayer because of the higher packing of phospholipids. Asc, Asc-$C_2$, and Asc-$C_8$ cannot interact with the mixture film (data not shown). It can be seen from Table 4 that all ascorbyl esters

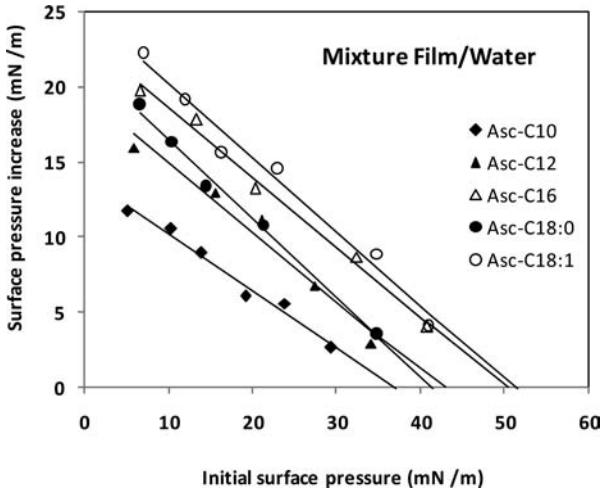

**Figure 4.** Maximal increase in surface pressure after ascorbyl derivative injection with respect to the initial surface pressure of mixture films (40% PC, 30% cholesterol, 10% SL, 10% PG, 10% PE) spread in a cylindrical Teflon trough (volume, 15 mL; surface, 17.42 $cm^2$). Final ascorbyl derivative concentration, 0.5 $\mu$M. Buffer, 10 mM Tris−HCl, pH 8.0, 100 mM NaCl, 21 mM $CaCl_2$, and 1 mM EDTA.

**Table 4. Critical Surface Pressure ($\pi_c$) of the Ascorbic Acid and Ascorbyl Acyl Esters**

| compounds | $\pi_c$ (mixture film) (mN/m) |
|---|---|
| Asc | 0 |
| Asc-$C_2$ | 0 |
| Asc-$C_8$ | 0 |
| Asc-$C_{10}$ | 36.96 |
| Asc-$C_{12}$ | 42.07 |
| Asc-$C_{16}$ | 50.06 |
| Asc-$C_{18:0}$ | 41.30 |
| Asc-$C_{18:1}$ | 50.74 |

(Asc-$C_{10}$ to Asc-$C_{18:1}$) could interact with the mimetic membrane of leishmania. The critical surface pressures ($\pi_c$) of these esters on mixture film monolayer range from 36.96 mN/m to 50.74 mN/m (Table 4). Mottola et al.[39] showed that the Asc-$C_{16}$ is an anionic amphiphilic molecule, which allowed them to penetrate phospholipid monolayers. These results are in line with those observed previously by Aissa et al.,[16] who showed that the medium and long chain tyrosyl esters could interact with biological membrane. We can also notice that unsaturation in the acyl chain (Asc-$C_{18:1}$) seems to strengthen its interaction with the mixture film. In fact, the critical surface pressures of Asc-$C_{18:1}$ and Asc-$C_{18:0}$ are 50.74 mN/m and 41.30 mN/m, respectively (Table 4). Makyla and Paluch[40] demonstrated that the presence of the unsaturated fatty acid in cholesterol/DPPC mixed monolayer makes the membrane more fluid. Asc-$C_{16:0}$ and Asc-$C_{18:0}$ showed an interaction with the mimetic membrane model but not an antileishmanial activity. This result could be explained by the self-aggregation and the reduced mobility of long saturated ascorbyl derivatives in the aqueous phase of the parasite culture medium as it was hypothesized by Laguerre et al.[41] In light of these results, if one takes the $\pi_c$ as a threshold value to appreciate the capacity of the ascorbyl esters to penetrate mixture film monolayers, we can tentatively conclude that the medium and long chain ascorbyl esters (Asc-$C_{10}$ to Asc-$C_{18:1}$) could interact efficiently with a biological membrane, characterized by a surface pressure between 25 and 35 mN/m.[42]

In conclusion, from all the tested derivatives, only medium and unsaturated ascorbyl derivatives (Asc-$C_{10}$, Asc-$C_{12}$, and Asc-$C_{18:1}$) exhibited potent antimicrobial and antileishmanial activities. These amphiphilic antioxidants could be used as membrane-perturbing surfactants in clinical applications such as for dermatological and pharmacological uses.
