previous studies, the grafting substitution by chemical reagents is also limited. The reported maximum grafting ratio of GA onto CS was 128.3 mg GA equivalents (GAE)/g via free radicals generated by ascorbic acid and the hydrogen peroxide-mediated method.[19] For 1-ethyl-3-(3′-dimethylaminopropyl) carbodiimide/*N*-hydroxysuccinimide (EDC/NHS)-mediated activated ester method, the maximum grafting ratio of GA onto CS was only about 65 mg GAE/g CS.[31] Furthermore, the rheological potential of GA-grafted-CS (GA-*g*-CS) compared to free GA has seldom been studied. Therefore, the objectives of this work are to establish an efficient method to graft large amounts of GA onto CS and to study the influence of grafted GA on CS, especially the antioxidant activities and rheological properties. In the present study, a new synthetic method to implant GA to CS with significantly improved graft ratio was developed, in which CS was dissolved, assisted with hydroxybenzotriazole (HOBt), and the synthesized GA-*g*-CS was characterized by UV−vis spectroscopy and proton nuclear magnetic resonance ($^1$H NMR) spectroscopy. Then, GA-*g*-CS with different degrees of substitution were prepared and investigated systematically with various in vitro antioxidant assays, including assays of scavenging activities on 2,2-diphenyl-1-picrylhydrazyl (DPPH), superoxide, and 2,2′-azino-bis(3-ethylbenzothiazoline-6-sulfonic acid) (ABTS) free radicals, reducing power, chelating power, inhibition of lipid peroxidation, ferric reducing antioxidant potential, and $\beta$-carotene-linoleic acid assay. Finally, the viscosities of GA-*g*-CS with different grafting ratios were investigated.

## MATERIALS AND METHODS

**Materials and Reagents.** CS (viscosity-average molecular weight ~$1.5 \times 10^5$, degree of deacetylation ≥90.0%), EDC hydrochloride (EDC-HCl), Folin-Ciocalteau reagent were purchased from Kayon Biological Technology Co., Ltd. (Shanghai, China). GA, nitrotetrazolium blue (NBT) chloride, and HOBt were obtained from Sinopharm Chemical Reagent Co., Ltd. (Shanghai, China). DPPH, $\beta$-carotene, linoleic acid, ABTS, phenazine methosulfate (PMS), 2,4,6-tris(2-pyridyl)-*s*-triazine (TPTZ) were purchased from Sigma Chemical Co. (St. Louis, MO). Ferrozine (3-(2-pyridyl)-5,6-diphenyl-1,2,4-triazine-*p*,*p*′-disulfonic acid monosodium salt) was purchased from Aladdin Industrial Inc. (Shanghai, China). Reduced nicotinamide adenine dinucleotide disodium salt (NADH) was purchased from Roche Ltd. (Basel, Switzerland). Deuterium oxide ($D_2O$) and acetic acid-$d_4$ ($CD_3COOD$) for NMR were purchased from J&K Scientific Ltd. (Beijing, China). All of other reagents were of analytical grade.

**Synthesis of GA-*g*-CS.** The synthesis of GA-*g*-CS was performed based on the reported one-pot method[32] with some modifications. CS (0.303 g, 1.85 mmol) was stirred in deionized water (30.0 mL) with HOBt (0.282 g, 1.85 mmol) overnight until a clear solution was obtained. GA (0.311 g, 1.85 mmol) was introduced into the CS solution followed by the dropwise addition of an alcoholic solution of EDC-HCl (0.355 g, 1.85 mmol, 2.0 mL). The reaction was carried out for 24 h in ambient temperature and atmosphere. The resultant liquid was poured into dialysis tubes (MWCO 3500 Da) and dialyzed against deionized water for 48 h with eight changes of deionized water. The resulting solution was lyophilized to afford solid copolymer of GA-*g*-CS. Thin layer chromatography (TLC) was performed to verify whether free GA was removed from the product of GA-*g*-CS. Briefly, silica plates with applied CS, GA, and GA-*g*-CS were developed with acetic acid−water−*n*-butanol (v/v/v, 1:4:5) as the mobile phase at laboratory temperature. After development and air-drying, the spots on the silica plate were detected by using iodine vapor. Blank CS, acting as a control, was prepared in the same conditions but in the absence of GA. GA-*g*-CS with different substitutions of GA, named as GA-*g*-CS I, II, and III, were prepared by changing the ratio of GA and EDC.

**Characterization of GA-*g*-CS.** Structural characterization of GA-*g*-CS was performed by UV−vis and NMR analysis. The UV−vis spectra were determined by a UV-2600 spectrophotometer (Shimadzu, Kyoto, Japan) by scanning from 200 to 600 nm. $^1$H NMR spectra were recorded at 25 °C with samples dissolved in $CD_3COOD/D_2O$ (v/v, 1%) by using AVANCE III 500 MHz NMR Spectrometer (Bruker, Switzerland).

**Determination of Phenolic Content.** Phenolic content was determined according to the previous reported method.[33] Briefly, 0.5 mL of GA-*g*-CS solution was mixed with 1.0 mL of Folin-Ciocalteau reagent for 5 min in the dark, followed by the addition of 2.0 mL 20% sodium carbonate ($Na_2CO_3$) solution. The mixture was shaken and kept at 30 °C for 1 h, absorbance (Abs) of which was measured at 747 nm by using a 722S Visible Spectrophotometer (Shnghai Jinghua Science & Technology Instruments Co., Ltd., China). GA was used as a standard. The grafting ratios of GA-*g*-CS were expressed as milligram GAE per gram of copolymer (mg GAE/g).

**Assay of Antioxidant Activity of GA-*g*-CS in Vitro.** *Assay of Scavenging Activity on DPPH Free Radicals.* DPPH free radicals scavenging activity was determined according to the reported procedure[34] with slight modifications. Briefly, GA, CS, and GA-*g*-CS (I, II, and III) were homogeneously dispersed in deionized water for preparation of a series of concentrations (0.125, 0.25, 0.5, 1.0, 1.5, and 2.0 mg/mL). The solutions were pipetted into a 96-well plate (50 $\mu$L/well), and to each well, 200 $\mu$L of methanolic DPPH solution (0.4 mM) was added and mixed. After a 30 min reaction at room temperature in the dark, the Abs at 517 nm was measured by a microplate reader (BioTek Instruments Inc., Winooski, VT).

$$\text{DPPH free radicals scavenging activity (\%)} = \left(1 - \frac{\text{Abs}_1 - \text{Abs}_2}{\text{Abs}_0}\right) \times 100$$

where $Abs_0$ is the Abs of the control (water instead of sample), $Abs_1$ is the Abs of the sample, and $Abs_2$ is the Abs of the sample under identical conditions as $Abs_1$ with methanol instead of DPPH solution.

*Evaluation of Reducing Power.* Reducing powers of the samples were determined by the previously described method[35] with some modifications. The reactions were carried out in 96-well microplates, each well of which contained a mixture of 50 $\mu$L of sample solution, sodium phosphate buffer (PBS, 0.2 M, pH 6.6), and $K_3Fe(CN)_6$ solution (1%, w/v), and were incubated at 50 °C for 20 min. After the addition of 50 $\mu$L of trichloroacetic acid (10%, w/v) and 30 $\mu$L of $FeCl_3$ (0.1%, w/v), the Abs was measured at 700 nm.

$$\text{reducing power} = \text{Abs}_1 - \text{Abs}_2$$

where $Abs_1$ is the Abs of sample and $Abs_2$ is the Abs of the sample under identical conditions as $Abs_1$ with water instead of $FeCl_3$ solution only.

*Assay of Scavenging Activity on Superoxide Radicals.* Superoxide radicals scavenging activities of the samples were evaluated according to the literature[35] with some modifications. NADH, NBT, and PMS were diluted in PBS (0.1 M, pH 7.4). The mixture of 50 $\mu$L of sample, NADH (468 mM), NBT (156 mM), and PMS (60 mM) was added in the well of the microplate and incubated at 25 °C for 5 min, and then the Abs was measured at 560 nm.

$$\text{superoxide radicals scavenging activity (\%)} = \left(1 - \frac{\text{Abs}_1 - \text{Abs}_2}{\text{Abs}_0}\right) \times 100$$

where $Abs_0$ is the Abs of the control (water instead of sample solution), $Abs_1$ is the Abs of the sample, and $Abs_2$ is the Abs of the sample under identical conditions as $Abs_1$ with 0.1 M phosphate buffer instead of NBT solution.

*Assay of Metal Chelating Ability.* The metal chelating ability for $Fe^{2+}$ was tested according to the reported method[34] with some

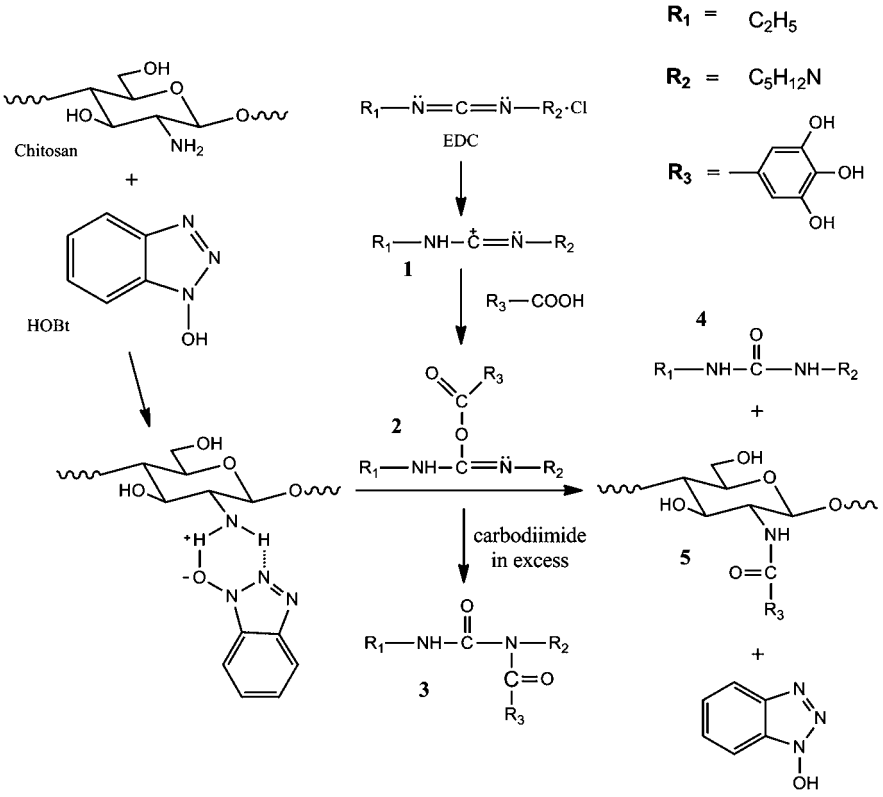

**Figure 1.** Proposed mechanism for grafting gallic acid onto chitosan.

modifications. Briefly, 50 $\mu$L of sample, 30 $\mu$L of $FeCl_2$ (0.3 mM), and 120 $\mu$L of ferrozine (0.3 mM) solutions were mixed and incubated at 25 °C for 10 min, and then Abs at 562 nm was determined.

$$\text{chelating activity (\%)} = \left(1 - \frac{\text{Abs}_1 - \text{Abs}_2}{\text{Abs}_0}\right) \times 100$$

where $Abs_0$ is the Abs of the control (water instead of sample), $Abs_1$ is the Abs of the sample, and $Abs_2$ is the Abs of the sample under identical conditions as $Abs_1$ with deionized water instead of $FeCl_2$ solution.

*Assay of Lipid Peroxidation Inhibition.* The lipid peroxidation inhibitory effect was determined by thiobarbituric acid reactive substances (TBARS) assay.[34] First, 1.0 g of mouse liver was homogenated in 100.0 mL purified water to afford lipid-rich media. Then, 0.2 mL of sample was mixed with 1.0 mL of liver homogenate, and 50 $\mu$L $FeCl_2$ solution (0.1 mM) and $H_2O_2$ (0.1 mM) were added. After incubation at 37 °C for 1 h, the peroxidizing reaction was quenched by the addition of 0.3 mL of trichloroacetic acid (20%, w/v) and thiobarbituric acid (0.8%, w/v). The resulting mixture was incubated at 100 °C for 15 min and then centrifuged (4000 rpm, 10 min), and 200 $\mu$L of the supernatant was added to the well of the 96-well microplate. Abs was measured at 532 nm.

$$\text{lipid peroxidation inhibitory effect (\%)} = \left(1 - \frac{\text{Abs}_1 - \text{Abs}_2}{\text{Abs}_0}\right) \times 100$$

Where $Abs_0$ is the Abs of the control (water instead of sample), $Abs_1$ is the Abs of the sample, and $Abs_2$ is the Abs of the sample only (water instead of liver homogenate).

*Assay of Total Antioxidant Capacity.* The ferric reducing antioxidant potential (FRAP) was used to determine the total antioxidant capacity according to the previous procedure[34] with some modifications. The FRAP working solution was obtained by mixing 100.0 mL of sodium acetic buffer (0.3 M, pH 3.6), 10.0 mL of TPTZ (10 mM, dissolved in 40 mM HCl), and 10.0 mL of $FeCl_3$ solution (20 mM) together. The mixture containing 40 $\mu$L of sample and 200 $\mu$L of FRAP solution was incubated at 25 °C for 10 min, and the Abs was detected at 593 nm.

*Assay of Scavenging Activity on ABTS Free Radicals.* The preformed radicals of ABTS were generated by oxidation of ABTS (7.0 mM) with potassium persulfate ($K_2S_2O_8$, 4.95 mM) for 12 h in the dark at room temperature.[33] After generation, ABTS was diluted with PBS (0.2 M, pH 7.4) to an appropriate concentration, affording the working solution. The Abs of a mixture of a 20 $\mu$L sample and a 200 $\mu$L working solution was measured at 734 nm.

$$\text{ABTS free radicals scavenging activity (\%)} = \left(1 - \frac{\text{Abs}_1 - \text{Abs}_2}{\text{Abs}_0}\right) \times 100$$

where $Abs_0$ is the Abs of the control (water instead of sample), $Abs_1$ is the Abs of the sample, and $Abs_2$ is the Abs of the sample only (PBS instead of ABTS).

*β-Carotene-Linoleic Acid Assay.* GA-*g*-CS inhibiting peroxidation in a linoleic acid model was determined by a β-carotene bleaching test[15] with some modifications. Briefly, 2.0 mL of β-carotene solution (1.0 mg/mL in chloroform) was added to 40 mg of linoleic acid and 400 mg of Tween 20. The mixture was evaporated by a rotary evaporator at 40 °C to remove chloroform. After that, the mixture was immediately diluted with 200.0 mL of distilled water and followed by ultrasonication to form an emulsion. The emulsion (1.25 mL) was transferred to the microcentrifuge tube containing 50 $\mu$L of sample. The tubes were then shaken gently and incubated at 45 °C for 1 h. The Abs of resulting liquid was measured at 470 nm by using the microplate reader.

$$\text{antioxidant activity (\%)} = \left(1 - \frac{\text{Abs}_0 - \text{Abs}_{60}}{\text{Abs}_0^0 - \text{Abs}_{60}^0}\right) \times 100$$

where $Abs_0$ and $Abs_0^0$ are the Abs measured at the initial incubation time for samples and control, respectively, whereas $Abs_{60}$ and $Abs_{60}^0$ are

dx.doi.org/10.1021/jf503207s | J. Agric. Food Chem. 2014, 62, 9128−9136

the Abs of the samples and control, respectively, after incubation for 60 min.

**Analysis of Rheological Property.** Rheological behavior of sample was measured on a MCR 301 Rheometer (Anton Paar GmbH, Austria) at a temperature of 20 °C. The samples, CS and GA-*g*-CS (I, II, and III), were dissolved in acetic acid solution (v/v, 1%) to a concentration of 1% (m/v). The viscosity was measured as a function of increasing shear rate, varying from 2 to 256 $s^{-1}$. The viscosity at every point was recorded five times, and each sample was tested in triplicate.

**Statistical Analysis.** Data were expressed as the mean ± standard deviation (SD) of triplicates. The least significant difference (LSD), Duncan's multiple range test, and one-way analysis of variance (ANOVA) were used for multiple comparisons by SPSS 16.0. The difference was considered to be statistically significant if $p < 0.05$.

## RESULTS AND DISCUSSION

**Synthesis of GA-*g*-CS.** CS was chosen as the polymeric backbone to synthesize the biomaterial containing the antioxidant groups of GA since it is natural, edible, and biocompatible and processes the amino groups of which can be grafted onto easily. For the grafting reaction, CS is generally dissolved in acetic acid solution. In the present study, however, CS was dissolved with the assistance of HOBt. As we know, HOBt is an organic compound used as a racemization suppressor and also for improving the yield in peptide synthesis. There are relatively intense hydrogen bonds or even ionic bonds between the amino groups of CS and the hydroxyl groups of HOBt.[36] The transparence in the mixture of CS and HOBt means it is possible to modify CS in an aqueous system without the organic solvent, avoiding the side reactions resulting from the presence of acetic acid. As a result, CS was efficiently conjugated with GA in the present study via a water-soluble carbodiimide conjugating agent.[37] The detailed reaction mechanism is depicted in Figure 1. EDC was protonated by HCl coexisting in the carbodiimide conjugating reagent, forming carbocation **1** that further reacted with the carboxyl group of GA to form *O*-acylisourea **2**. In order to avoid the hydrolyzation of EDC to urea **4**, EDC was dissolved in ethanol and added slowly into the solution of CS-HOBt and GA. When EDC was in excess, *N*-acylurea **3** could be by-produced. Herein, the presence of HOBt in combination with EDC is designed to reduce **3** and also to improve the reaction rate.[32] The conjugation might occur at C-2 of CS to afford amide or at C-3 and C-6 of CS to afford ester linkages. Although the hydroxyl group is reactive, the reaction at C-3 can be omitted due to the steric hindrance.[32] HOBt and byproduct urea **4** were removed from the resulting solution by dialysis against water. It has been reported that the binding constant ($K$) of HOBt with CS is 112.32 L/mol,[38] which means HOBt may be present a little in the resulting product. The absence of HOBt in the target copolymer **5** was confirmed by $^1$H NMR.

**Characterization of GA-*g*-CS.** The UV−vis spectra of GA, CS, and GA-*g*-CS (I, II and III) are displayed in Figure 2. During 240 to 500 nm, CS showed no absorption peak, and GA exhibited two characteristic absorption bands at 212 and 262 nm, respectively, assigned to the $\pi$-system of the benzene ring. In the spectra of GA-*g*-CS (I, II, and III), it was found that the UV−vis absorption peak at 262 nm shifted toward a longer wavelength (272 nm). It is consistent with the reported result for GA-*g*-carboxymethyl CS.[14] The results indicated that GA was successfully grafted onto CS.[2] The red shift might be attributed to the smaller amount of energy required for the

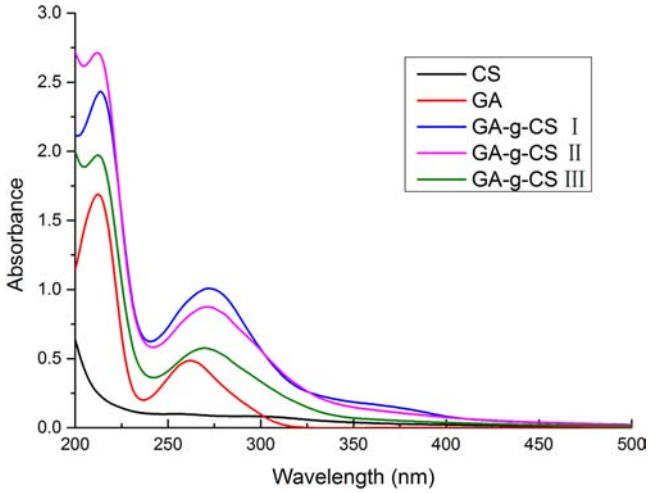

**Figure 2.** UV−vis spectra of chitosan (CS), gallic acid (GA), and GA grafted CS (GA-*g*-CS I, II, and III).

$\pi-\pi^*$ transition due to the longer conjugated system brought by the covalent linkage of GA with CS.

Further characterization of GA-*g*-CS was performed by $^1$H NMR. As shown in Figure 3, GA showed only one peak at 7.1 ppm (H-a of benzene ring). CS exhibited a single peak at 3.1 ppm (H-2), multiple peaks at 3.6−3.9 ppm (H-3 to H-6), a small peak at 4.6 ppm (H-1), and a single peak at 2.0 ppm, representing the three protons of the *N*-acetyl group. The spectrum of GA-*g*-CS contained all the peaks of CS, and a new peak at around 7.1 ppm originated from GA, confirming again the successful grafting of GA onto CS. In addition, the peaks at 7.4−8.0 ppm, the signals of HOBt, did not appear in the spectrum, assuring that there was no HOBt remaining in the copolymer.

The substitution of GA on CS could be evaluated by determining the phenolic groups of GA-*g*-CS. In the Folin-Ciocalteu reaction, phenolic compounds undergo a complex redox reaction with phosphotungstic and phosphomolybdic acids.[39] The transfer of electrons at basic pH reduces the phosphomolybdic/phosphotungstic acid complexes to form chromogens, and then the color is developed. For GA-*g*-CS I, II, and III, these values were 209.9 ± 2.0, 117.8 ± 1.3, and 99.6 ± 0.7 mg GAE/g of dry copolymers, respectively. Interestingly, the 209.9 mg GAE/g copolymer is the highest substitution ratio of GA grafted onto CS among those that have been reported so far. As the reason, it might be due to the use of HOBt that resulted in more efficient grafting than traditional ways. In addition, it is meaningful to express the antioxidant potential in terms of phenolic content, since the activity of GA-*g*-CS conjugate is mainly originated from the phenolic groups in the polymeric backbone.

**Antioxidant Activity of GA-*g*-CS.** CS has been exploited as a natural macromolecular antioxidant recently. However, three main obstacles including the poor solubility, chemical inertness based on the strong inter- and intramolecular hydrogen bonds network, and poor H atom-donating ability have to be overcome. Introduction of GA onto CS gives a solution to such problems, and GA-*g*-CS has been synthesized as a novel potential polysaccharide antioxidant.[40] The antioxidant activities of compounds are attributed to various mechanisms, such as breaking radical chain, prevention of introduction of initiating radicals, hindering metal-catalyzed initiation reactions, decomposition of lipid hydroperoxides,

dx.doi.org/10.1021/jf503207s | J. Agric. Food Chem. 2014, 62, 9128−9136

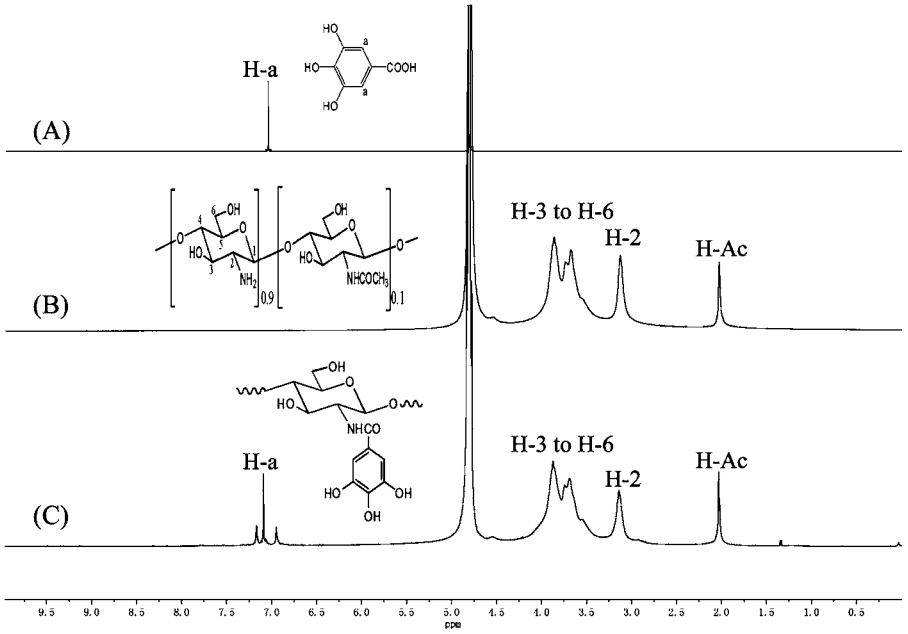

**Figure 3.** $^{1}$H NMR spectra of (A) gallic acid, (B) chitosan, and (C) GA grafted CS (GA-*g*-CS).

singlet oxygen quenching, oxygen scavenging, and blocking the prooxidant effects by binding certain proteins containing catalytic metal sites.[41] Therefore, various in vitro chemical-based assays, such as assays of oxygen radical absorbance capacity (ORAC), scavenging activity on DPPH free radicals, and ferric reducing capacity, have been developed to determine antioxidant activity. Furthermore, a single in vitro chemical method is not enough to evaluate and compare their antioxidant properties by considering the complexity involved in their in vivo mechanisms of action.

The results of antioxidant assays are displayed in Figure 4. The results showed that the antioxidant ability decreased in the order of GA-*g*-CS I, GA-*g*-CS II, GA-*g*-CS III, and CS. Obviously, GA-*g*-CS showed great antioxidant potential. In addition, the antioxidant capacities of all samples were well-correlated with the increase of concentrations and the amount of GA grafted onto the backbone.

The DPPH and ABTS free radicals have been widely used for testing the preliminary radical scavenging capacity of plant extracts or antioxidant compounds. The DPPH and ABTS free radical scavenging activities of GA-*g*-CS are shown in Figure 4 (panels A and B), respectively. The results of the two assays were presented in a similar manner that the scavenging activities of samples decreased in order of GA, GA-*g*-CS I, GA-*g*-CS II, GA-*g*-CS III, and CS at a low concentration corresponding to the quantities of GA contained, and there was no significant difference between the scavenging activities of GA-*g*-CS and GA at high concentrations.

Superoxide radical, arising from the addition of one electron to dioxygen either through metabolic processes or following oxygen activation by physical irradiation, is considered as the primary reactive oxygen species (ROS). It can interact with other molecules to generate secondary ROS either directly or prevalently through enzyme- or metal-catalyzed processes, including hydroxyl radical, $H_2O_2$, and singlet oxygen.[42] The superoxide radical scavenging activities of CS, GA-*g*-CS, and GA are shown in Figure 4C. All the samples exhibited scavenging activities on superoxide radicals. The scavenging abilities of all the three GA-*g*-CS were above 80%, and GA-*g*-CS I was equal to GA ($p > 0.05$) at a concentration of 2.0 mg/mL.

The reducing power of a compound is a significant index of its potential antioxidant activity. As shown in Figure 4D, the reducing power of all samples increased with concentrations. The reducing power of GA-*g*-CS I was stronger than GA-*g*-CS II and GA-*g*-CS III ($p < 0.05$) and equal to GA at high concentrations (>1.0 mg/mL).

Metal ion chelating activity plays a vital role in antioxidant mechanism since transition metals are known to catalyze the formation of ROS and aggravate oxidative stress.[43] The $Fe^{2+}$ chelating ability was determined by measuring the iron-ferrozine complex, and the results are summarized in Figure 4E. GA-*g*-CS showed much higher metal chelating activity than GA and CS. Especially, GA-*g*-CS I and GA-*g*-CS II showed stronger chelating capacity than GA-*g*-CS III ($p < 0.05$), except at a low concentration (0.125 mg/mL). Phenolics grafted onto CS lead to an exponential increase in iron-chelating ability and open a novel strategy for the development of a new generation of CS-based chelating therapeutic polymers for iron overload.[44]

Lipids, especially polyunsaturated fatty acids in the cell membrane, are vulnerable to both enzymes and nonenzymatic oxidants and are readily oxidized by free radicals, leading to membrane damage and eventually to various disorders and diseases.[45] Antioxidant may directly react with initiator radicals or lipid peroxides involved in lipid peroxidation processes, and it may also inhibit the formation of active radicals. As shown in Figure 4F, the lipid peroxidation inhibition effect of GA-*g*-CS was about 50% at a high concentration, much higher than CS ($p < 0.05$) but lower than GA ($p < 0.05$). And the inhibition increased with the elevation of concentration.

The $\beta$-Carotene–linoleic acid system is a rapid method for evaluation of antioxidants developed by Marco.[46] In this method, the linoleic acid free radical formed attacks the highly unsaturated $\beta$-carotene molecules and rapidly bleached the orange color of $\beta$-carotene in the absence of an antioxidant.[47] The lowest $\beta$-carotene discoloration rate exhibited the highest antioxidant activity. The inhibition effect of GA-*g*-CS was

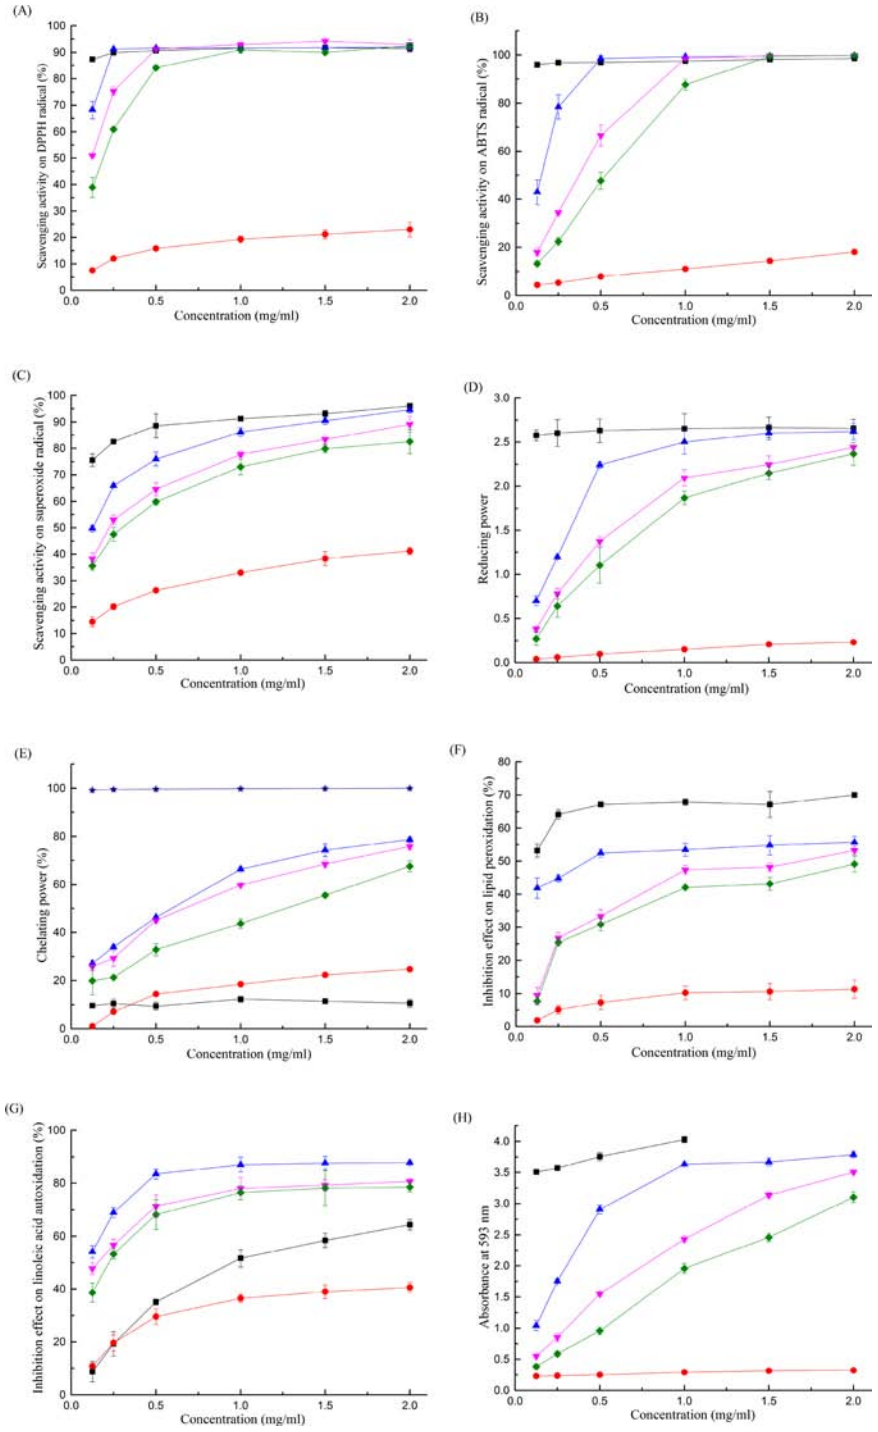

**Figure 4.** Scavenging activities on (A) 2,2-diphenyl-1-picrylhydrazyl (DPPH) radical, (B) 2,2′-azino-bis(3-ethylbenzothiazoline-6-sulfonic acid) (ABTS) radical, and (C) superoxide radical. (D) reducing power, (E) chelating power, (F) lipid peroxidation, (G) linoleic acid autoxidation inhibition effect, and (H) total antioxidant capacity of gallic acid (GA, ■), chitosan (CS, red ●), GA-*g*-CS I (blue ▲), GA-*g*-CS II (pink ▼), GA-*g*-CS III (green ◆), ethylene diamine tetraacetic acid (EDTA, blue ★). Data are presented as means ± SD of triplicates.

around 80% at 1.0 mg/mL (Figure 4G), higher than that of CS ($p < 0.05$) and notably even much better than GA ($p < 0.05$).

The FRAP assay is based on the ability of antioxidant compounds to reduce complex (Fe (III)-TPTZ) to (Fe (II)-TPTZ) that gives a blue color. The results of the FRAP assay are presented in Figure 4H. The activities increased in order of CS, GA-*g*-CS III, GA-*g*-CS II, GA-*g*-CS I, and GA ($p < 0.05$), related to the reductant (GA) content of the sample.

The assays used in the present study can roughly be classified into two types, depending upon the reactions involved: assays based on hydrogen atom transfer (HAT) reactions and the ones based on electron transfer (ET) reactions.[48] The ET-based assays included the total phenol assay by Folin-Ciocalteu reagent, DPPH and ABTS radicals scavenging assays, reducing power, and total antioxidant potential assays with FRAP. The antioxidant activities measured by these assays are correlated with the reducing agent present in samples, the GA grafted

dx.doi.org/10.1021/jf503207s | J. Agric. Food Chem. 2014, 62, 9128−9136

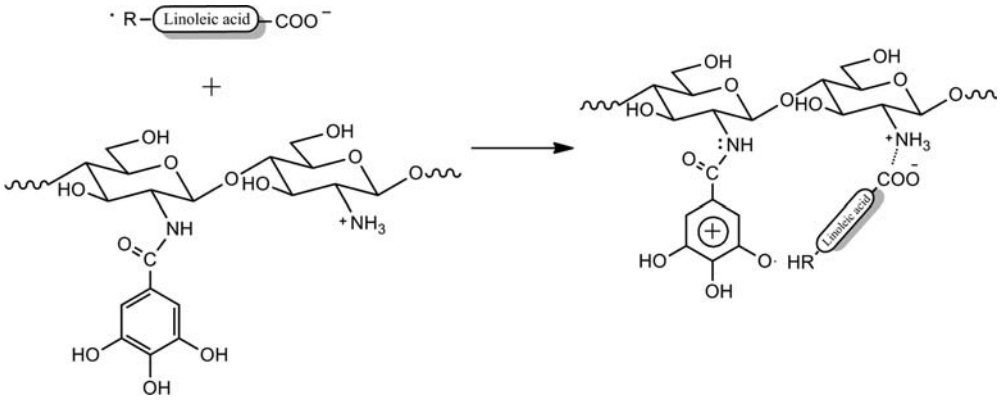

**Figure 5.** Proposed interaction between gallic acid–chitosan and free linoleic acid radicals.

onto CS in our case. It could easily be understood that the antioxidant potential obtained from these assays decreased in the order of GA, GA-*g*-CS I, GA-*g*-CS II, GA-*g*-CS III and CS, which was associated with concentration of sample.

CS showed little antioxidant potential in our assays. However, previous studies reported that CS dissolved with acetic acid, HOBt, thiamine pyrophosphate (CS-TPP), and the ethylenediaminetetraacetic acid (CS-EDTA) solution possessed superoxide and hydroxyl radicals scavenging abilities.[49] It was supposed that the antioxidant capacity of CS dissolved in pure water was suppressed due to its limited solubility.

Notably, GA-*g*-CS showed stronger antioxidant activity than GA in the *β*-carotene-linoleic acid assay. *β*-Carotene-linoleic assay, different from DPPH assay, is a HAT-based antioxidant assay. It was observed that the extract of mushroom with great antioxidant potential in the DPPH assay did not perform well in *β*-carotene-linoleic acid assay, as variation of phenolic contents did not directly influence the antioxidant activity in the *β*-carotene-linoleic acid assay.[50] During the oxidation in this model, an atom of hydrogen is abstracted from the active bis-allylic methylene group of linoleic acid located at C-11 between two double bonds and then the formed pentadienyl free-radical attacks highly unsaturated *β*-carotene molecules in an effort to reacquire a hydrogen atom. As the *β*-carotene molecules lose their conjugation, the carotenoids lose their characteristic orange color in the absence of an antioxidant.[51] It has been reported that CS could absorb fatty acids by electrostatic interaction,[52] and the antioxidant activity of phenolic compounds depends on various structural features such as the O–H bond dissociation energy, resonance delocalization of the phenoxyl radical, and the steric hindrance due to bulky groups substituting hydrogen in the aromatic ring.[53] Considering that, we hypothesize that the interaction between GA-*g*-CS and linoleic acid radicals could occur as illustrated in Figure 5, GA-*g*-CS attracting linoleic acid radicals by electrostatic affinity and quenching them with the GA groups rapidly. Furthermore, grafting GA onto CS developed amide linkages that enlarged the conjugated system of GA and contributed to an increase in electron donating groups, making GA-*g*-CS more stable than free GA. We suppose that GA-*g*-CS with swelling macromolecular structure could capture the linoleic acid free radicals, while small molecule GA could not. Linoleic acid radicals had larger size and had more potential for interacting with CS than superoxide radicals so that they were more easily captured. Those might be the reasons why GA-*g*-CS exhibited higher free radical scavenging ability than GA in the *β*-carotene-linoleic acid assay.

**Rheological Property of GA-*g*-CS.** The flow curves of CS and GA-*g*-CS are shown in Figure 6. It was observed that GA-*g*-

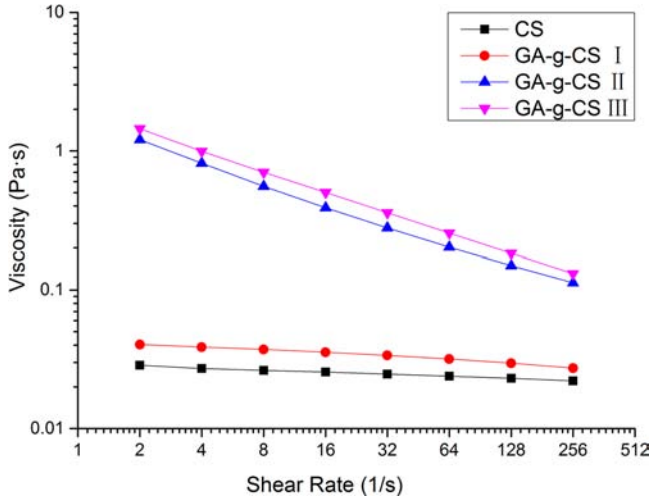

**Figure 6.** Viscosity of chitosan (CS) and gallic acid (GA) grafted CS (GA-*g*-CS I, II, and III).

CS (I, II, and III) was more viscous than plain CS significantly ($p < 0.05$). The viscosity of GA-*g*-CS decreased in order of GA-*g*-CS III, GA-*g*-CS II, GA-*g*-CS I, and CS, and the viscosity of GA-*g*-CS III was 50 times higher than that of CS at 2 $s^{-1}$ and 5 times higher at 256 $s^{-1}$. Similar phenomenon had also been found in natural macromolecules. The polysaccharide-containing ferulic acid extracted from the seeds of *Plantago asiatica* L. exhibited much higher apparent viscosity compared to that of the polysaccharide depleted ferulic acid.[54] Additionally, arabinoxylan samples with different ferulic acid contents had been employed to obtain gels by enzymatic covalent cross-linking of the phenolic acid.[55] For GA-*g*-CS, the grafting of GA onto CS provides the possibility that links the different GA-*g*-CS macromolecular chains by the formation of phenolic dimers or trimers and even the covalent junction between GA and amino group from glucosamine residue. The new bonds may lead to larger molecular weight, longer chain length, and a more viscous solution. Therefore, it was hypothesized that the high viscosity of GA-*g*-CS was attributed to the covalent cross-linking junctions produced by the oxidation of GA groups.

For GA-*g*-CS (I, II and III), the viscosity of the sample decreased with the increase of the substituting degree. The GA-*g*-CS III with a substituting degree of 99.6 mg GAE/g of dry

dx.doi.org/10.1021/jf503207s | J. Agric. Food Chem. 2014, 62, 9128–9136

copolymers appeared more viscous than both the plain CS and copolymer with a higher degree of substitution (I or II). A similar tendency was also observed in GA-gelatin. The gel strength and modulus of viscosity ($G''$) increased with increasing GA concentration up to 20 mg/g dry gelatin and then decreased at further elevated GA concentrations.[56] The results indicated that the viscosity of GA-*g*-CS was related to the grafting amount of GA.

The introduction of GA onto CS takes many properties to GA-*g*-CS copolymer. On one hand, GA may reduce the intra- and intermolecular hydrogen bond networks and eliminate crystal structure, but on the other, the grafting provides the sites to form covalent bonds and further affects the solubility and rheological property of CS. A balance may be achieved by regulating the grafted amount of GA. As the previous study suggested, GA-*g*-CS of a certain substitution was more soluble than plain CS, and higher substitution led to higher solubility in some range.[13] In addition, reacting conditions, especially the oxygen content and pH, could be the main factors contributing to the oxidative polymerization of the copolymer. GA-*g*-CS with a different viscoelastic property and gelling capacity could be obtained by controlling oxidative conditions.[55] The results suggest that GA-*g*-CS possesses the potential to be employed as thickener or gel-forming material in food industries.

In conclusion, GA-*g*-CS with GA grafted up to 209.9 mg/g of the copolymer, strong antioxidant activity, and an adjustable rheological property was synthesized and characterized in the present study. The results suggested that high content of GA could be easily grafted onto CS by the developed one-pot method with EDC and HOBt. GA-*g*-CS, possessing the advantages of both GA and CS, showed greater antioxidant potential and stronger antioxidant power than GA in the $\beta$-carotene-linoleic acid assay. It was the first time to observe that polyphenol-polysaccharide conjugate exhibited stronger antioxidant power than its corresponding polyphenol. In addition, GA grafted onto CS altered the rheological property of the biopolymer, making GA-*g*-CS with a higher viscosity than plain CS, which could be adjustable through modifying the amount of grafted GA. Our present study developed a novel approach to synthesize GA-*g*-CS that could be explored as promising biomaterials in food industries.

reaction. Concretely, Demuth et al.[12] and Côté et al.[14,17] showed isomaltulose to be a moderate acceptor for glucansucrases, and only the corresponding trisaccharide acceptor product could be structurally characterized as isomaltotriulose following transglucosylation reaction catalyzed by an alternansucrase from *L. mesenteroides* NRRL B-21297.[17] However, the rest of the acceptor products were neither structurally characterized nor quantified. Finally, isomaltotriulose was also detected in trace amounts in broths of dextran-producing cultures of *Streptococcus bovis* containing sucrose as substrate.[20]

In this work the efficient enzymatic synthesis of a homologous series of isomaltulose-derived oligosaccharides catalyzed by a dextransucrase from *L. mesenteroides* B-512F, as well as their comprehensive NMR structural characterization, is reported.

## MATERIALS AND METHODS

**Chemicals, Reagents, Standards, and Enzymes.** Fructose, glucose, sucrose, maltotriose, maltotetraose, maltopentaose, and maltohexaose were purchased from Sigma-Aldrich (Steinheim, Germany), whereas isomaltulose was bought from Carbosynth (Compton, UK). Acetonitrile (HPLC grade) was obtained from Lab-scan (Gliwice, Poland) and deuterium oxide from Merck Millipore (Darmstadt, Germany). Ultrapure water quality (18.2 MΩ cm) with 1−5 ppb of total organic carbon (TOC) and <0.001 EU $mL^{-1}$ pyrogen levels was produced in-house using a laboratory water purification Milli-Q Synthesis A10 system from Millipore (Billerica, MA, USA). Purified dextransucrase (EC 2.4.1.5) from *L. mesenteroides* B-512F was purchased from CRITT Bio-Industries (Toulouse, France). Specific activity was 0.4 U $mg^{-1}$, where 1 unit is the amount of enzyme required to transfer 1 μmol of glucose per minute, with 100 g sucrose $L^{-1}$ as the substrate in 20 mM sodium acetate buffer (pH 5.2) with 10 mg $L^{-1}$ $CaCl_2$ at a working temperature of 30 °C. All other chemicals were of analytical grade and commercially available.

**Enzymatic Synthesis of Isomaltulose-Derived Oligosaccharides.** Oligosaccharide synthesis was carried out by transglucosylation reaction catalyzed by dextransucrase from *L. mesenteroides* B-512F (0.8 U $mL^{-1}$) at 30 °C in 20 mM sodium acetate buffer with 0.34 mM $CaCl_2$ (pH 5.2) in the presence of 250 g $L^{-1}$ sucrose (donor) and 250 g $L^{-1}$ isomaltulose (acceptor). The reaction was allowed to proceed up to 48 h, and aliquots were repeatedly taken from the reaction mixture at suitable time intervals (1, 3, 5, 8, 24, and 48 h). The enzyme was inactivated by heating at 100 °C for 5 min, and inactivated samples were then 40-fold diluted with acetonitrile/water (50:50, v/v), filtered using a 0.45 μm syringe filter (Symta, Madrid, Spain), and analyzed by liquid chromatography with a refractive index detector (LC-RID). All enzymatic syntheses were carried out in triplicate.

**Chromatographic Determination of Carbohydrates by Liquid Chromatography with Refractive Index Detector.** The progress of the synthesis process of isomaltulose-derived oligosaccharides was monitored by LC-RID on an Agilent Technologies 1220 Infinity LC System 1260 RID (Boeblingen, Germany). The separation of carbohydrates was carried out with an analytical Zorbax $NH_2$ column (150 × 4.6 mm, 5 μm particle size) and an analytical Zorbax $NH_2$ guard column (12.5 × 4.6 mm, 5 μm particle size) (Agilent Technologies) using isocratic elution with acetonitrile/water at 75:25 or 70:30 (v/v) as the mobile phase to quantify mono- and disaccharides or oligosaccharides, respectively, and at a flow rate of 1.0 mL $min^{-1}$ for 60 min. Injection volume was 50 μL (750 μg of total carbohydrates). Data acquisition and processing were performed using Agilent ChemStation software (Agilent Technologies).

Carbohydrates in the reaction mixtures were identified by comparing their retention times with those of standard sugars. Quantitative analysis was performed by the external standard method, using calibration curves in the range of 0.1−5 mg $mL^{-1}$ for fructose, glucose, sucrose, isomaltulose, maltotriose, maltotetraose, maltopentaose, and maltohexaose. Individual maltodextrins were used to quantify the isomaltulose-derived oligosaccharides with the same degree of polymerization (DP). Maltohexaose was also used for the quantification of oligosaccharides with DP above 6. All analyses were carried out in triplicate. Determination coefficients obtained from these calibration curves, which were linear over the range studied, were high ($R^2 > 0.999$). Reproducibility of the method was estimated on the basis of the intraday and interday precision, calculated as the relative standard deviation (RSD) of concentrations of oligosaccharide standards obtained in $n \geq 6$ independent measurements, obtaining RSD values below 10% in all cases.

**Purification and Structural Characterization of the Isomaltulose-Derived Oligosaccharides by Nuclear Magnetic Resonance (NMR).** Isomaltulose-derived oligosaccharides from DP3 to DP7 were isolated and purified by LC-RID from sucrose/isomaltulose mixtures after 24 h of transglucosylation reaction and using a semipreparative column Kromasil (100-$NH_2$) column (250 × 10 mm, 5 μm particle size) (Akzo Nobel, Brewster, NY, USA). Thus, 500 μL of reaction mixtures (7.5 mg of total carbohydrates) was repeatedly eluted with acetonitrile/water (70:30, v/v) as the mobile phase at a flow rate of 5 mL $min^{-1}$, and fractions corresponding to the main synthesized oligosaccharide were manually collected, pooled, evaporated in a rotatory evaporator R-200 (Büchi, Flawil, Switzerland) below 25 °C/ and freeze-dried for their subsequent characterization.

Structure elucidation of the purified oligosaccharides was accomplished by NMR. NMR spectra were recorded at 298 K, using $D_2O$ as solvent, on a Varian System 500 NMR spectrometer ($^1H$ 500 MHz, $^{13}C$ 125 MHz) equipped with a 5 mm HCN cold probe. Chemical shifts of $^1H$ ($\delta_H$) and $^{13}C$ ($\delta_C$) in parts per million were determined relative to an external standards of sodium [2,2,3,3-$^2H_4$]-3-(trimethylsilyl)propanoate in $D_2O$ ($\delta_H$ 0.00) and 1, 4-dioxane ($\delta_C$ 67.40) in $D_2O$, respectively. One-dimensional (1D) NMR experiments ($^1H$ and $^{13}C$) were performed using standard Varian pulse sequences. Two-dimensional (2D) ($^1H$, $^1H$) NMR experiments [gradient correlation spectroscopy (gCOSY) and total correlation spectroscopy (TOCSY)] were carried out with the following parameters: delay time of 1 s, spectral width of 1675.6 Hz in both dimensions, 4096 complex points in t2, 4 transients for each of 128 time increments, and linear prediction to 256. The data were zero-filled to 4096 × 4096 real points. 2D ($^1H-^{13}C$) NMR experiments [gradient heteronuclear single-quantum coherence (gHSQC) and gradient heteronuclear multiple-bond correlation (gHMBC)] used the same $^1H$ spectral window, a $^{13}C$ spectral window of 30165 Hz, 1 s of relaxation delay, 1024 data points, and 128 time increments, with a linear prediction to 256. The data were zero-filled to 4096 × 4096 real points. Typical numbers of transients per increment were 4 and 16, respectively.

## RESULTS

The optimal conditions, that is, pH, temperature, enzyme charge, and concentration ratio of donor/acceptor, for the transglucosylation activity of dextransucrase in acceptor reactions using disaccharides as lactose or lactulose were previously established by Díez-Municio et al.[21,22] On the basis of these reaction conditions, the enzymatic synthesis was monitored by LC-RID as a function of time. Figure 1, which depicts a typical chromatogram obtained after 48 h of transglucosylation reaction of isomaltulose, shows a series of oligosaccharide acceptor products with DP values ranging from 3 to 9 resolved in 60 min using an isocratic elution with acetonitrile/water 70:30 (v/v). Sucrose and isomaltulose could not be well resolved under these chromatographic conditions, and a mobile phase composition with a weaker elution strength (i.e., acetonitrile/water 75:25, v/v) was used to quantify mono- and disaccharides (chromatograms not shown).

As indicated in Table 1, sucrose was readily hydrolyzed throughout the enzymatic reaction and only 3.5% remained after 48 h, whereas fructose was progressively released as the sucrose hydrolysis advanced. Concomitantly, only traces of

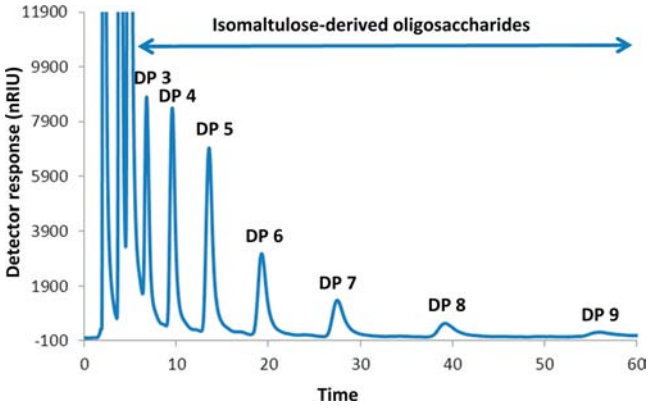

**Figure 1.** LC-RID profile of transglucosylation reaction with 250 g isomaltulose $L^{-1}$ and 250 g sucrose $L^{-1}$ as initial substrates and catalyzed by dextransucrase from *Leuconostoc mesenteroides* B-512F (0.8 U $mL^{-1}$) at 30 °C, in 20 mM sodium acetate buffer at pH 5.2, for 48 h. DP, degree of polymerization.

glucose could be detected, whereas isomaltulose content substantially decreased, which was indicative of the efficient transfer of glucose moieties as well as of the capacity of isomaltulose to act as acceptor. With regard to oligosaccharide acceptor products, the isomaltulose-derived trisaccharide was the predominant acceptor product during the first 8 h of reaction, whereas at 24 and 48 h of reaction the most abundant oligosaccharides were the tetrasaccharide and the pentasaccharide acceptor products, respectively (Table 1). Overall, the maximum formation of isomaltulose-derived oligosaccharides was obtained after 24−48 h of reaction by producing 101.6−104 g $L^{-1}$, which is equivalent to a yield of 41−42% (in weight with respect to the initial amount of isomaltulose).

Figure 2 shows the evolution of each individual oligosaccharide acceptor product expressed as percent of the total carbohydrate composition (including fructose, sucrose, and isomaltulose). The maximum relative percentage of the trisaccharide reached a plateau from the fifth hour of reaction, and this was kept until the end of the reaction, whereas the tetrasaccharide reached a plateau at 24 h and the pentasaccharide exhibited a moderate increase between 24 and 48 h of reaction. In contrast, hexa-, hepta-, octa-, and nonasaccharides were initially detected at 3, 5, 8, and 24 h of reaction, respectively, and did not reach a maximum formation at 48 h of reaction. This behavior clearly indicated that oligosaccharide acceptor products of low molecular weight could in turn act as an acceptor for further transglucosylation, thus yielding a homologous series of oligosaccharide products with an elongated chain.

To comprehensively characterize the synthesized oligosaccharides as well as to confirm the enzyme mechanism in the synthesis of oligosaccharides, the resulting carbohydrate mixture obtained after 24 h of reaction was repeatedly analyzed using a semipreparative LC column to purify the oligosaccharides with DP ranging from 3 to 7. These isolated oligosaccharides (structures DP3, DP4, DP5, DP6, and DP7, respectively; Figure 3) were then fully characterized by 1D ($^1$H and $^{13}$C) and 2D ($^1$H, $^1$H and $^1$H, $^{13}$C) NMR experiments (gCOSY, TOCSY, multiplicity-edited gHSQC, and gHMBC). $^1$H and $^{13}$C NMR chemical shifts observed are summarized in Table 2.

These compounds showed duplicate NMR signals in 1D $^1$H and $^{13}$C NMR spectra, indicating the presence of two quite

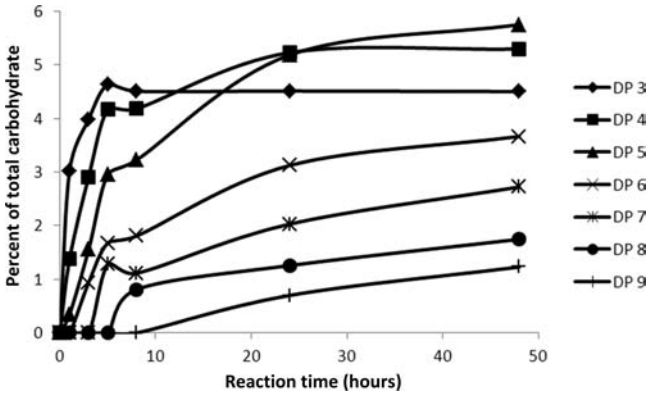

**Figure 2.** Isomaltulose-derived oligosaccharide synthesis during the time course of the transglucosylation reaction performed at 30 °C at an initial concentration of 250 g isomaltulose $L^{-1}$ with 250 g sucrose $L^{-1}$ and 0.8 U $mL^{-1}$ enzyme in 20 mM sodium acetate buffer at pH 5.2. DP, degree of polymerization.

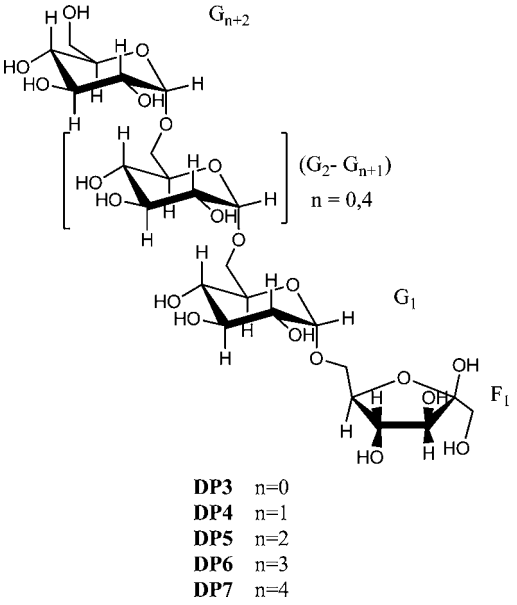

**Figure 3.** Structures of the isomaltulose-derived oligosaccharides from DP3 to DP7.

different populated isomers at room temperature, probably due to an anomeric mixture of $\beta$- and $\alpha$-fructose anomers. Structural determinations were performed on the major isomer for all structures.

The 1D $^{13}C$ spectrum of DP3 showed a major set of signals corresponding to 18 carbons including 3 anomeric carbons ($\delta$ 102.31, 98.95, and 98.40), indicative of the presence of a trisaccharide with 3 hexose sugars in its structure. A multiplicity-edited gHSQC spectrum was used to link the carbon signals to the corresponding proton resonances, so the anomeric carbon at $\delta$ 98.95 correlated with an $\alpha$-anomeric proton at $\delta$ 4.98 ($J$(H1,H2) = 3.8 Hz) and the anomeric carbon at $\delta$ 98.40 correlated with an $\alpha$-anomeric proton at $\delta$ 4.95 ($J$(H1,H2) = 3.8 Hz). The anomeric carbon at $\delta$ 102.31 was a quaternary carbon. In addition, four methylene carbons at $\delta$ 68.61, 66.12, 63.22, and 61.05 were identified. Careful analysis of the 2D gCOSY and TOCSY spectra revealed the $^1H$ signals of two units of glucopyranose and a unit of fructofuranose (Figure 3). To assign the configuration of each anomeric center, the values of the vicinal coupling constants for the glucopyranose anomeric protons and the $^{13}C$ chemical shift values of the fructofuranose anomeric carbons were used.[23] These results were consistent with the structure of a trisaccharide with the presence of two $\alpha$-D-glucopyranose residues ($G_1$ and $G_2$) and as the reducing terminal unit $F_1$ a fructose residue in the form of a furanosyl ring with $\beta$ and $\alpha$ forms in a 3:1 ratio. The position of glycosidic linkages was analyzed as follows: gHMBC experiment showed correlations between the anomeric proton of $G_1$ (4.98 ppm) and C-6 of the terminal fructose $F_1$ (68.61 ppm), between the anomeric carbon of $G_1$ (98.95 ppm) and the methylene H6 protons of the terminal fructose $F_1$ (3.88, 3.70 ppm), between the anomeric proton of $G_2$ (4.95 ppm) and C-6 of $G_1$ (66.12 ppm), and between the anomeric carbon of $G_2$ (98.40 ppm) and the methylene H6 protons of $G_1$ (3.97, 3.76 ppm). Finally, the major isomer of compound DP3 was identified as $\alpha$-D-glucopyranosyl-(1→6)-$\alpha$-D-glucopyranosyl-(1→6)-$\beta$-D-fructofuranoside, commonly called isomaltotriulose.

The 1D $^1H$ NMR spectrum of DP4 showed three resonances in the anomeric region, and besides the 1D $^{13}C$ NMR spectrum showed a major set of signals corresponding to 24 carbons including 4 anomeric carbons ($\delta$ 102.31, 98.94, 98.35, and 98.32), indicative of the presence of a tetrasaccharide. Careful analysis of the 2D gCOSY and TOCSY spectra revealed the $^1H$ signals of three units of glucopyranose and a unit of fructofuranose. To assign the configuration of each glucopyranose, the values of $^3J$(H1,H2) coupling constants (3.8, 3.8, and 3.8 Hz) were used. Following the same procedure used for the trisaccharide, using multidimensional solution NMR and $^{13}C$ chemical shift comparison (Figure 4), the major isomer of compound DP4 was identified as $\alpha$-D-glucopyranosyl-(1→6)-$\alpha$-D-glucopyranosyl-(1→6)-$\alpha$-D-glucopyranosyl-(1→6)-$\beta$-D-fructofuranoside.

1D $^1H$ NMR spectra of DP5, DP6, and DP7 showed one, two, and three additional doublets in the anomeric region, respectively. Likewise, the corresponding 1D $^{13}C$ NMR spectra showed five ($\delta$ 102.32, 98.95, 98.35, 98.34, and 98.24), six ($\delta$ 102.31, 98.94, 98.35, 98.34, 98.29, and 98.27), and seven anomeric carbons ($\delta$ 102.31, 98.94, 98.35, 98.34, 98.29, 98.28, and 98.27), consistent with the presence of a penta-, hexa-, and heptasaccharide, respectively. Following the same procedure as for DP3, compound DP5 was identified as $\alpha$-D-glucopyranosyl-(1→6)-$\alpha$-D-glucopyranosyl-(1→6)-$\alpha$-D-glucopyranosyl-(1→6)-$\alpha$-D-glucopyranosyl-(1→6)-$\beta$-D-fructofuranoside, compound DP6 as $\alpha$-D-glucopyranosyl-(1→6)-$\alpha$-D-glucopyranosyl-(1→6)-$\alpha$-D-glucopyranosyl-(1→6)-$\alpha$-D-glucopyranosyl-(1→6)-$\alpha$-D-glucopyranosyl-(1→6)-$\beta$-D-fructofuranoside, and compound DP7 as $\alpha$-D-glucopyranosyl-(1→6)-$\alpha$-D-glucopyranosyl-(1→6)-$\alpha$-D-glucopyranosyl-(1→6)-$\alpha$-D-glucopyranosyl-(1→6)-$\alpha$-D-glucopyranosyl-(1→6)-$\alpha$-D-glucopyranosyl-(1→6)-$\beta$-D-fructofuranoside.

## DISCUSSION

This work describes the efficient synthesis of a homologous series of 6-*O*-$\alpha$-glucosylated isomaltuloses with DP ranging from 3 to 9 by transferring the glucosyl moiety from sucrose to the C-6 of the nonreducing end of isomaltulose. To the best of our knowledge, this paper contains the first structural NMR data of isomaltulose-derived oligosaccharides from DP4 to DP7. Côté et al.[17] previously published the NMR shifts for the isomaltulose trisaccharide product derived from a transglucosylation reaction catalyzed by an alternansucrase from *L.*

[a]Chemical shifts ($\delta$) and coupling constants ($J$ in hertz, in parentheses).

*mesenteroides* NRRL B-21297. Also, Seo et al.[24] identified isomaltulose and the corresponding 6-O-α-glucosylated isomaltuloses of DP3, DP4, and DP5, which were produced in minor amounts when dextransucrase was used to hydrolyze concentrated sucrose solutions, although in that case, the authors used a combination of enzymatic approaches and MALDI-TOF MS analysis.

The formation of α-(1→6) glucosidic bonds is in good agreement with the reaction mechanism described for the dextransucrase from *L. mesenteroides* NRRL B-512F, which catalyzes the formation of the polysaccharide dextran with 95% of α-(1→6)-linked glucan and 5% of α−(1→3) branch linkages. In addition, the bond formed during the acceptor reaction is normally an α-(1→6) glucosidic linkage.[10,25,26] As an example, this was the case for maltose, which gave rise to a series of seven homologous acceptor products having isomaltodextrin residues attached to the C-6 of the nonreducing glucosyl residue of maltose.[16] However, some exceptions have been described for this enzyme as was the case of the main production of 2-α-glucosyl-cellobiose, 2-α-glucosyl-lactose, or lactulosucrose through the formation of an α-(1→2) glucosidic linkage to the reducing end of cellobiose, lactose, or lactulose, respectively.[21,22,27]

Elegant works led by Robyt and coauthors determined that at high sucrose concentrations (≥200 mM) in the presence of equimolar amounts of suitable acceptors, dextransucrase tends to catalyze the synthesis of negligible amounts of dextran but does catalyze large amounts of acceptor products.[28−30] Our data confirmed this observation and revealed the suitability of isomaltulose as acceptor to yield around 42% of oligosacchar-

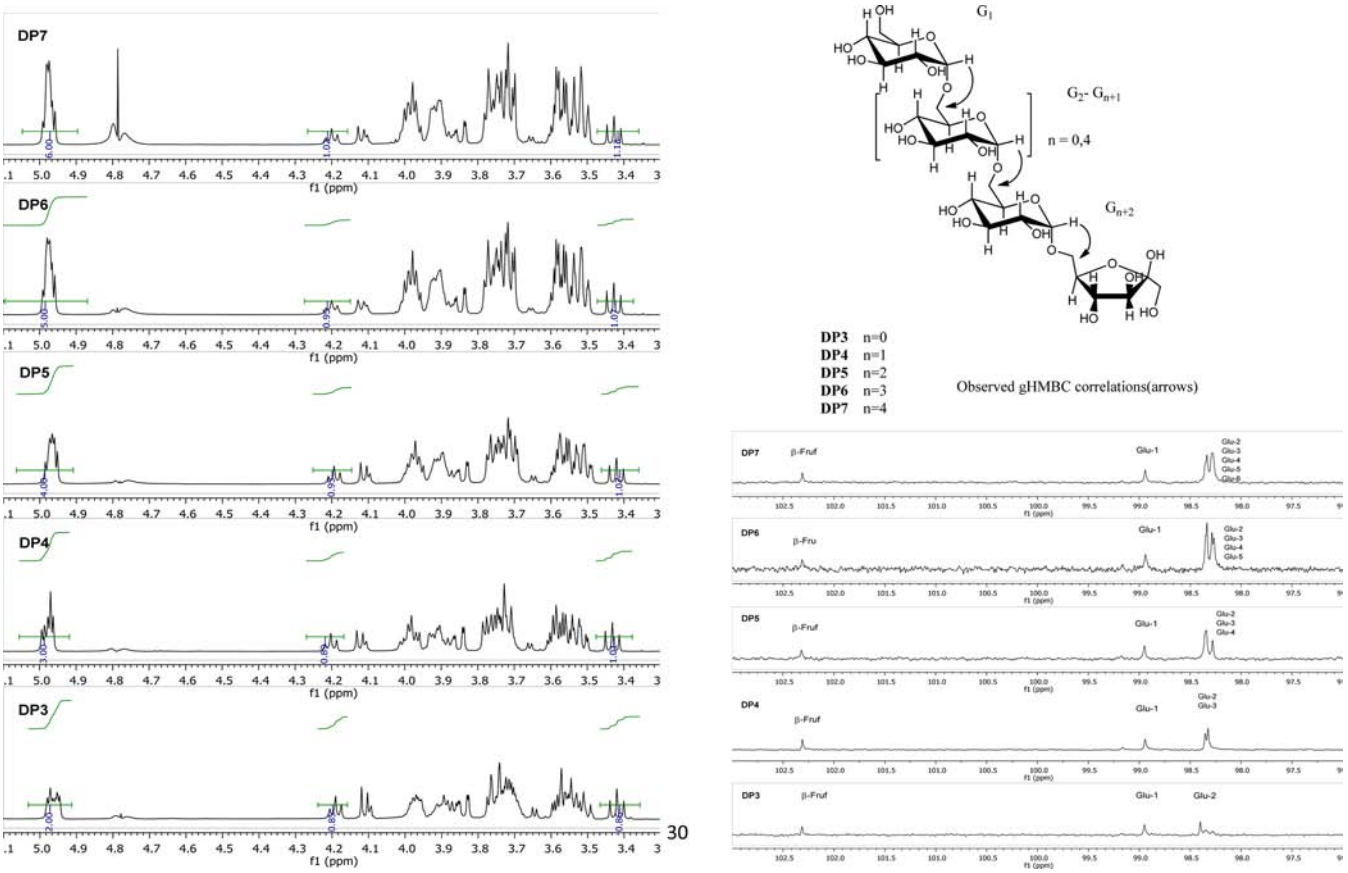

**Figure 4.** One-dimensional NMR spectra of isomaltulose-derived oligosaccharides from DP3 to DP7 at 500 MHz in $D_2O$. Data represent $^{1}H$ (left) and $^{13}C$ (right) anomeric region spectra.

ides after 24 h of reaction using equimolar amounts of sucrose and isomaltulose (Table 1). Likewise, the progress of the content of the acceptor products throughout the enzymatic reaction (Figure 2) as well as their characterized structures indicated the ability of the acceptor products to also serve as acceptors to give oligosaccharides of higher DP, thus yielding a homologous series of isomaltulose-derived oligosaccharides of decreasing amounts as DP increase (Table 1).

The produced isomaltulose-derived oligosaccharides can be considered as IMOs in the strict sense because they are linked by only α-(1→6) bonds. In addition, bearing in mind that isomaltulose is the core structure, these oligosaccharides could possess a series of bioactive properties based on isomaltulose functionality. In this sense, Seo et al.[24] synthesized a series of oligosaccharides from high concentrations of sucrose (2.5−4 M) using a dextransucrase prepared from a mutant *L. mesenteroides* strain. Among these oligosaccharides, low levels (between 2.7 and 3.7%) of 6-O-α-glucosylated isomaltuloses of DP3, DP4, and DP5 were present. These authors reported that the mixture of oligosaccharides effectively inhibited the formation of insoluble glucan by *Streptococcus sobrinus*, which plays an important role in the etiology of dental caries, suggesting their potential use as anticariogenic sucrose substitute. Interestingly, Kashimura et al.[31] demonstrated that isomaltulose and its hydrogenated disaccharide products, which were also linked through an α-(1→6) glucosyl bond, that is, α-*O*-D-glucopyranosyl-1,6-D-sorbitol and α-*O*-D-glucopyranosyl-1,6-D-mannitol, competitively inhibited rat small intestinal α-glucosidases (sucrase, maltase, and glucoamylase) and reduced the rate of hydrolysis of sucrose and other α-glucosylsaccharides such as maltose, dextrin, or soluble starch. Considering that maltitol, a disaccharide alcohol with an α-(1→4) glucosyl linkage, did not exert inhibitory effects, these authors suggested that the inhibitory action of isomaltulose and its derivatives could be related to the α-(1→6) glucosyl linkage. Given that the rates of hydrolysis of isomaltulose[3] and its hydrogenated derivatives are low in the small intestine,[32] they could contribute to reduce glycemic and insulinemic responses following their ingestion. In fact, there is solid scientific evidence that points out isomaltulose as an efficient low-glycemic sweetener with the capacity to reduce the speed of digestion and absorption, resulting in lower postprandial blood glucose.[33−40] In this context, and given that the isomaltulose-derived oligosaccharides described in the current work possess an α-1,6 glucosyl linkage as a unique structural bond, it will be of interest to investigate their role in glycemic control.

Considering their inhibitory action on small intestinal α-glucosidases and reduced absorption, IMO-like structures might have the ability to reach the large intestine, at least partially, intact.[8] Nevertheless, IMOs do not conform strictly to the nondigestibility criterion as they could be hydrolyzed by the membrane-bound isomaltase and maltase−glucoamylase enzymatic complexes in the small intestine, despite not all IMO species being digested at the same rate.[41] In this context, composition and dosage in the diet should be key parameters for the prebiotic potential of IMOs[8] and, consequently, additional studies on the effect of isomaltulose-derived oligosaccharides on the modulation of both the composition and activity of the gut microbiota should be warranted. In this sense, some in vivo studies carried out in humans have

provided evidence on the prebiotic effect after IMO administration in adults and elderly individuals.[42,43] Furthermore, Yen et al.[44] also observed an improvement in bowel movement in chronically constipated elderly subjects, as well as a beneficial effect on blood cholesterol levels after long-term supplementation (8 weeks) of IMOs.

To conclude, this paper reports the efficient enzymatic synthesis of a homologous series (DP3−DP9) of 6-O-α-glucosylated oligosaccharides derived from the transglucosylation reaction of isomaltulose catalyzed by a *L. mesenteroides* B-512F dextransucrase (EC 2.4.1.5). According to the oligosaccharide structures elucidated using a comprehensive NMR approach, these isomaltulose-derived oligosaccharides are consecutively elongated by the addition of glucose moieties linked by α-(1→6) glycosidic bonds at the nonreducing glucose residue while they keep the fructose unit at the reducing end. By having isomaltulose as the core structure and the α-(1→6) linkage as a unique structural feature, these IMO-like structures could possess appealing bioactive properties, which might warrant their potential use as functional ingredients. The reported enzymatic synthesis offers a good yield of isomaltulose-derived oligosaccharides, as well as provides a relatively noncomplex carbohydrate mixture that should make easier their purification for further investigation of their functional properties.

Keratin, the major protein in poultry feathers, hairs, and horns of animals, was water-stable and biocompatible and could be a promising biomaterial for medical applications. Keratin has molecular structures similar to collagen, the prominent protein in native extracellular matrices (ECMs). Furthermore, tripeptides "Arg-Gly-Asp" (RGD) and "Leu-Asp-Val" (LDV) existing in keratin molecules could bind with cell surface ligands and promote cell adhesion on keratin-based materials.[21] In addition, because of the highly cross-linked molecular structures attributed to the 7% cysteine in the amino acid components,[21] keratin might not suffer from poor water stability, the prominent problem that restricted biomedical applications of many proteins.

Because of its intrinsic water stability, keratin is advantageous over other proteins as nanoparticles. As a satisfactory biomaterial,[22] keratin was used to coat silver nanoparticles to improve their water stability.[23] Keratin has been fabricated into microparticles[24] and nanoparticles with polyethylene glycol grafting or using toxic solvent.[25] A better method should be developed, and the biodistribution should be investigated for drug delivery purposes.

## MATERIALS AND METHODS

**Materials.** Chicken feather barbs were provided by Featherfiber Corporation, Nixa, MO. Sodium bisulfite (98.0%), sodium hydroxide, hydrochloric acid, and ethylene glycol were purchased from AMRESCO LLC, Solon, OH. Purity of chemicals was considered in all of the calculations of concentrations.

**Preparation of Nanoparticles.** Chicken feathers were washed with reflux of ethanol in a Soxhlet extractor for 12 h to remove lipid and other impurities, followed by rinsing in distilled water 3 times to remove water-soluble impurities. After drying under 50 °C, the cleaned chicken feathers were hydrolyzed using 0.1 M sodium hydroxide at a ratio of 15:1 with sodium bisulfite (30% on weight of feathers) for 2 h at 80 °C. Hydrochloric acid was added to precipitate hydrolyzed feather keratin. The dispersion was centrifuged at 8000 rcf for 20 min, and subsequently, the obtained precipitated keratin was washed using distilled water 3 times. The feather keratin was dried under 50 °C and pulverized into powder.

To prepare nanoparticles, the obtained keratin powder was dissolved in ethylene glycol at designated concentrations (1, 2, 3, 4, 5, 10, and 20%, w/w) under room temperature. To precipitate keratin microparticles, ethylene glycol solution of keratin was added to distilled water with a weight ratio of keratin/water at 1:500. To further break the keratin microparticles into nanoparticles, 30 min of ultrasonication was applied using an ultrasonic processor (VCX 500:500 W, Sonics & Materials, Newton, CT) with an amplitude of vibration at 40%. At last, the dispersion of keratin nanoparticles were dialyzed (molecular weight cutoff of 7000) against distilled water for 4 days to remove ethylene glycol. The concentration of the keratin nanoparticles was adjusted via evaporation under reduced pressure.

**Size Measurement via Dynamic Light Scattering.** The sizes and $\zeta$ potential of keratin nanoparticles were measured on a Delsa Nano C particle analyzer (Beckman Coulter, Inc., Brea, CA) at least 1 h after particle formation. Sodium hydroxide and hydrochloric acid were used to adjust pH values of the dispersion to study the effects of pH on the size and surface charge of keratin nanoparticles. At least three measurements from separate samples were performed for each condition, and the average and standard deviation of the data are reported.

**Transmission Electron Microscopy (TEM).** Nanoparticle dispersion was placed on the copper mesh, dried, and then observed under a transmission electron microscope (Hitachi H7500 transmission electron microscope, Hitachi, Inc., Parlin, NJ).

**Crystallinity Analysis.** An X-ray diffraction (XRD) study was carried out on raw chicken feathers and freeze-dried keratin nanoparticles. The data were obtained using a Rigaku SmartLab X-ray diffractometer with Bragg–Brentano parafocusing geometry, a diffracted beam monochromator, and a conventional copper target X-ray tube set ($\lambda$ = 1.54 Å) to 40 kV and 44 mA at 26 °C. Diffraction intensities were recorded with $2\theta$ ranging from 3° to 40° at a scan speed of 0.02°/s.

**Stability of the Nanoparticles.** To evaluate the dimensional stability, physiological conditions of pH 7 and 37 °C and pH 6 and 37 °C and storage conditions of pH 2 and 4 °C were used to store the keratin nanoparticle dispersion with a concentration of 1 wt %. At designated time points, sizes of keratin nanoparticles were measured in the particle size analyzer. Three samples were measured for each condition to obtain average and standard deviation.

***In Vitro* Study.** To evaluate the biocompatibility, dispersion of keratin nanoparticles (10% on weight of the medium) was added to Dulbecco's modified low-glucose Eagle's medium (DMEM, Sigma-Aldrich, St. Louis, MO). NIH 3T3 mouse fibroblast cells (ATCC CRL-1658, Manassas, VA) with a seeding density of $1 \times 10^5$ cells/mL were cultured in humidified 5% $CO_2$ at 37 °C for 5 days. After every 24 h, the metabolic activity of the cells were analyzed using the MTS assay (Promega, Madison, WI) according to standard procedures with a multi-well plate Multiskan reader (Thermo Scientific, Waltham, MA). To prepare control samples, aliquots of distilled water with the same volume of keratin nanoparticle dispersion were added to the cell culture medium. For each data point, 6–9 replication experiments were conducted. Cells cultured in DMEM without keratin nanoparticles were used as a control.

***In Vivo* Study.** Biodistribution of keratin nanoparticles in mice was studied. The nanoparticles were first labeled with fluorescein isothiocyanate (FITC, Sigma-Aldrich, St. Louis, MO) in dimethyl sulfoxide (DMSO) with the addition of pH 9.5 carbonate–bicarbonate buffer in the dark. Free FITC was removed after dialyzed against distilled water for 4 days. The concentration of the FITC–keratin dispersion was readjusted to 100 mg/mL via evaporation under reduced pressure.

Mice were injected intravenously with 0.17 mL of dispersion of keratin nanoparticles (1%, w/w) every 24 h for up to 5 days. The mice were sequentially sacrificed 24 h after injection for up to 5 days. Mice sacrificed after the first 24 h had one injection of the nanoparticles; mice sacrificed after 48 h had two injections; etc. At the required time, mice were euthanized using $CO_2$ to collect the major organs, including liver, kidney, spleen, heart, and lungs. Organs stored in RPMI solution at 4 °C were analyzed in 5 h after collection. All experiments were carried out according to the Institutional Animal Care and Use Committee (IACUC)-approved protocol, and two mice were sacrificed for each time point.

The organ tissues were minced using a 70 $\mu$m cell strainer (Falcon, Tewksbury, MA) to obtain single-cell suspension in RPMI solution. For each organ, an aliquot of 500 $\mu$L of cell suspension was measured on the flow cytometer (BD Accuri, Franklin Lakes, NJ). The population of single cells was defined in a plot of 90° side scattering (SSC) versus forward scattering (FSC), and the percentage of nanoparticle-loaded cells was counted by measuring the fluorescence signal in the green fluorescence channel (FL1).

**Statistical Analysis.** All of the data obtained were analyzed by the one-way analysis of variance with the Scheffé test with a confidence interval of 95%. For characterizations of keratin nanoparticles, at least four specimens were measured or analyzed for each sample under one treatment. A statistically significant difference was indicated with a $p$ value smaller than 0.05. The data in the figures labeled with different numbers or characters indicated significant differences among different conditions.

## RESULTS AND DISCUSSION

**Characterizations of Keratin Nanoparticles.** Morphologies of the nanoparticles were shown in the TEM image in Figure 1. The dark shade indicated that the particles had solid structures. The particle sizes varied from around 50 to 130 nm. The sizes of keratin nanoparticles made them not easily being immediately filtered via kidney, because it has been reported

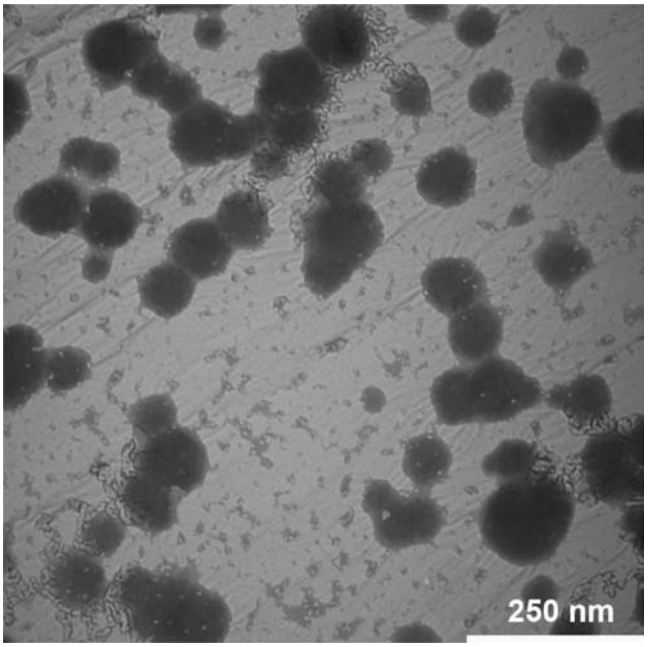

**Figure 1.** Morphologies of keratin nanoparticles in a TEM image showing the diameters from 50 to 130 nm and solid structures.

that nanoparticles with diameters smaller than 5.5 nm could be completely removed from the blood and then body.[26]

Figure 2 shows that the particle sizes obtained from particle analyzer measurement did not change significantly as the keratin concentration increased from 1 to 5% and then increased significantly from less than 100 nm to larger than 350 nm. The average diameter of 70 nm measured using the particle size analyzer was consistent with the results of TEM observation, as shown in Figure 1. A lower concentration of keratin resulted in less polypeptides that could wrap on keratin nanoparticles to increase the particle size. However, agglomeration tended to occur while the keratin concentration increased.

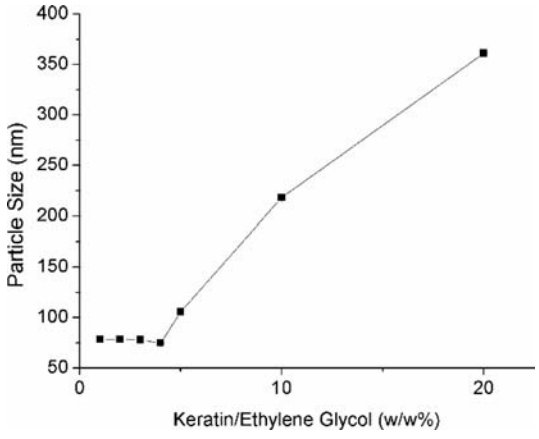

**Figure 2.** Effect of keratin/ethylene glycol ratio on the particle sizes of keratin nanoparticles. Keratin was dissolved in ethylene glycol at concentrations of 1, 2, 3, 4, 5, 10, and 20% based on the weight of ethylene glycol.

Figure 3 demonstrates that the hydrolyzed keratin had an isoelectric point (PI) of around 4.4 and a strong net surface charge at high or low pH values. $\zeta$ potential of keratin nanoparticles could increase to higher than 50 mV at pH below 3. A negative charge was shown on the keratin particles at pH values above 6.0, and the $\zeta$ potential decreased to −60 mV when pH was around 10. The range of surface charge variation reached 120 mV (from 60 to −60 mV) as pH varied from 2.0 to 12.0. The net charge on keratin nanoparticles was much higher than nanoparticles from other proteins, indicating higher potential for keratin to attract adsorbates with opposite charges.[27] Therefore, keratin nanoparticles may serve as good adsorbents to both positively or negatively charged substances.

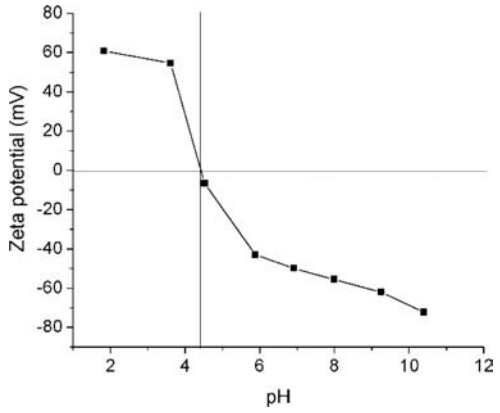

**Figure 3.** $\zeta$ potential of keratin nanoparticles. Sodium hydroxide solution and hydrochloric acid solution were used to adjust pH values of the keratin dispersion before ultrasonication. The nanoparticles were stabilized for 1 h before measurement.

Figure 4 shows the wide-angle XRD profiles of raw chicken feathers and dry keratin nanoparticles. For both samples, a prominent $2\theta$ peak at 20° and a minor peak at 9° indicated a typical diffraction pattern of $\alpha$-keratin with crystalline spacings of 4.4 and 9.8 Å, respectively. The proportion of the $2\theta$ peak at 20° increased and that of $2\theta$ peaks at 9° decreased after dissolution and precipitation of keratin, inferring that raw feathers had a larger amount of more tightly packed crystals than regenerated keratin nanoparticles. A certain degree of damage might occur to the original molecular structures during preparation of nanoparticles.

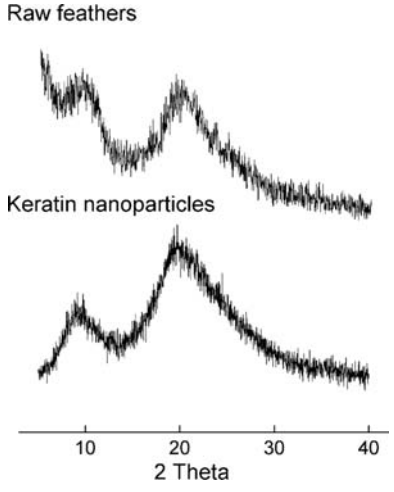

**Figure 4.** XRD spectrogram of keratin nanoparticles and raw feathers.

**Stability of Keratin Nanoparticles.** Figure 5 shows that the sizes of keratin nanoparticles increased from 75 to 130 nm as pH increased from 2 to 5 and then decreased from 130 nm

dx.doi.org/10.1021/jf502242h | J. Agric. Food Chem. 2014, 62, 9145−9150

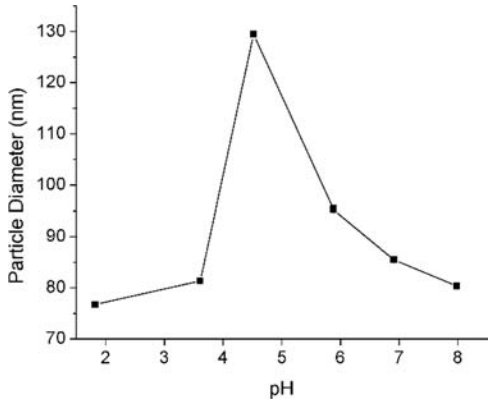

**Figure 5.** Effect of pH on the particle sizes of keratin nanoparticles. Sodium hydroxide solution and hydrochloric acid solution were added to the dispersion before ultrasonication to adjust pH values of the keratin dispersion. The nanoparticles were stabilized for 1 h before measurement.

to less than 85 nm as pH decreased from 5 to 8. The keratin nanoparticles had large diameters at pH similar to pI, because lower surface charge reduced electrical repulsion among nanoparticles and, thus, induced aggregation of small nanoparticles into larger nanoparticles. However, under physiological pH of 7.4 and storage pH of 2, keratin nanoparticles did not show hydrodynamic diameters larger than 100 nm.

Figure 6 indicated that keratin nanoparticles increased in the first 8 h and stabilized for up to 50 h when stored in phosphate-

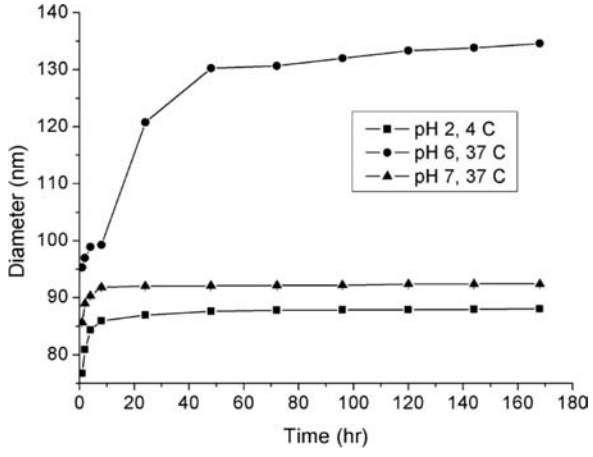

**Figure 6.** Influence of pH and temperature on the sizes of the keratin nanoparticles between 0 and 170 h. The diameters of keratin nanoparticles increased rapidly during the first 10 h and became stable at pH 2 under 4 °C and pH 7 under 37 °C.

buffered saline (PBS) medium. Keratin nanoparticles were highly stable at pH 2 under 4 °C, moderately stable at pH 7 under 37 °C, but unstable at pH 6 under 37 °C. Instability of the nanoparticles at a higher temperature should be due to the higher mobility, and therefore, chances of collision between particles could lead to agglomeration. Under the same temperature, pH 6 was closer to pH 4.5 compared to pH 7, suggesting weaker electrostatic repulsion among the keratin nanoparticles, as indicated in Figure 2, and therefore, better stability was seen at pH 7. However, even under high temperatures at pH 6, the diameters of keratin nanoparticles were still below 150 nm, indicating that the nanoparticles had remarkable water stability. The intrinsically high cross-linking degree of keratin might contribute to the water stability of the keratin nanoparticles.[27]

***In Vitro* Study for Biocompatibility.** The effects of keratin nanoparticles on cell growth and proliferation *in vitro* are shown in Figure 7. Cells in the culture medium containing keratin

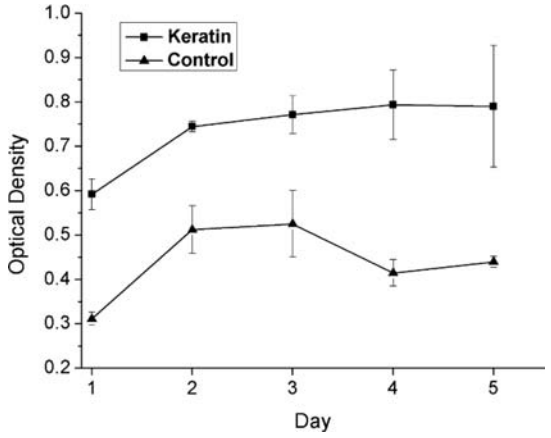

**Figure 7.** Comparison of the optical densities of mouse fibroblast cells with and without nanoparticles based on the MTS assay. The cells were cultured at 37 °C for 5 days.

nanoparticles showed continued proliferation of cells from day 1 to day 5, while the cells in culture medium without any additional additives showed maximum population on days 2 and 3, followed with a decrease on days 4 and 5. Keratin nanoparticles could hydrolyze into peptides and amino acids in the culture medium that could act as a nutrient to support cell growth, leading to higher proliferation.

***In Vivo* Study for Biodistribution.** As shown in Figure 8, keratin nanoparticles were predominantly found in the kidneys,

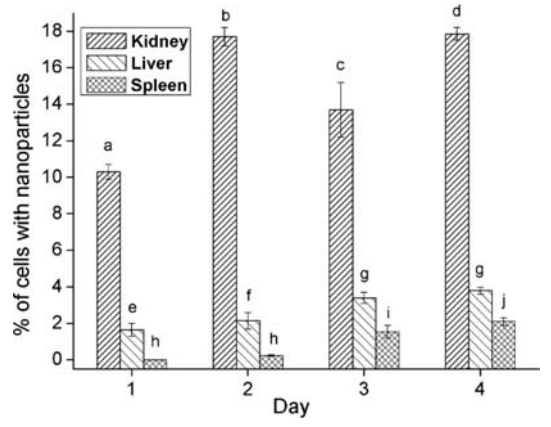

**Figure 8.** Comparison of the percentage of cells containing nanoparticles detected in kidneys, liver, and spleen in mice using flow cytometer after 1, 2, 3, and 4 days of injection. The uptake of nanoparticles did not increase continuously in kidneys but increased gradually in liver and spleen.

followed by liver and spleen in mice. The amount of nanoparticles in kidneys was not affected by dosage, while the amount of the nanoparticles in liver and spleen gradually increased as the dosage increased. Nanoparticles with diameters up to about 5.5 nm could be completely filtered by kidneys.[28] Keratin nanoparticles had significantly larger average diameter

dx.doi.org/10.1021/jf502242h | J. Agric. Food Chem. 2014, 62, 9145−9150

and were probably trapped in the kidneys before they were degraded into diameters smaller than 5.5 nm. The undegraded particles are removed via hepatic clearance through liver, which clears nanoparticles in the range of 10−20 nm.[29] Therefore, considerable amounts of nanoparticles were also found in the liver. Fewer nanoparticles could reach the spleen after being accumulated or filtered in the kidneys and liver. Successive injections were made every 24 h to ensure that sufficient nanoparticles were available to reach the targeted organs. After multiple injections, the amount of nanoparticles did not change significantly in kidneys. However, the quantity of nanoparticles slightly increased in liver and spleen in 2 days but also leveled off at the third and fourth days. The phenomenon suggested that the keratin nanoparticles could effectively degrade in the body. Keratin nanoparticles could be effective drug delivery vehicles to target kidney and liver for sustained release.

Cross-linking degrees of proteins might markedly affect the biodistribution of nanoparticles in different organs. Nanoparticles from highly cross-linked keratin with 7% cysteine[30] showed a similarly high content of accumulation in kidneys compared to those from other highly cross-linked protein, such as wheat glutenin.[31] However, nanoparticles from zein with a trace content of cysteine among its amino acids[32] were mainly found in liver.[33] In nature, keratin is a protein that takes a considerably long time to degrade because of the cross-linked structure. Even with partially destroyed physical structures, as indicated by the XRD results in Figure 4, the remaining cross-linkage still might render the keratin nanoparticles stable at physiological pH, as shown in Figure 6. It could be inferred that the cross-linking degree of proteins might have major effects on the water stability and enzymatic degradation rate of nanoparticles in physiological environments and, thus, might influence the biodistribution of protein nanoparticles.

In this research, the highly cross-linked keratin was developed into nanoparticles at around 70 nm via a phase separation and ultrasonication method. The influence of conditions, such as ratios of keratin/ethylene glycol and pH of dispersion on the particle sizes, was investigated. The isoelectric point of keratin was around pH 4.4. The keratin nanoparticles were highly stable after stored in physiological pH of 7 and storage condition of pH 2. The *in vitro* study indicated that keratin nanoparticles supported the attachment and proliferation of fibroblast cells. After injection into mice, it was found that up to 18% of the cells in kidneys and 4% of the cells in liver of mice were penetrated by the keratin nanoparticles. In summary, keratin nanoparticles could be potential vehicles for efficient drug delivery in treatments of livestock diseases.

Materials Inc., Newtown, CT, USA; 750 W power output with frequency of 20 kHz ± 50 Hz) using a sonication probe of 13 mm tip diameter for 5 min with on/off pulse of 5 s. The cell lysate was then clarified by centrifugation at 11627*g* for 20 min. The processing temperature was maintained at 4 °C throughout. Subsequently, the crude extract was concentrated by acetone precipitation (1:1, v/v) and purified by Q-Sepharose anion-exchange chromatography (column dimensions, 8 cm × 1.5 cm; flow rate, 3 mL/min) using 10 mM Tris-HCl buffer (pH 9.0). Protein was eluted with a 0.1−3 M NaCl gradient. Five milliliter fractions were collected, and their protein content (at 280 nm) and GGT activity (at 410 nm) were determined.

**GGT Assay.** GGT assay was performed according to the method described by Ikeda.[16] One milliliter of reaction volume contained 1 mM γ-glutamyl-*p*-nitroanilide hydrochloride (γ-GpNA), 10 mM glycylglycine (excluded in hydrolytic reactions), and appropriately diluted enzyme. Unless otherwise indicated, GGT assay was performed in 50 mM Tris-HCl buffer (pH 9.0) at 60 °C for 5 min. Reaction was stopped by adding 100 μL of 3 M acetic acid, and the activity was monitored by measuring hydrolyzed γ-GpNA at 410 nm. One enzyme unit was defined as the amount of enzyme required to release 1 μmol of *p*-nitroaniline per minute under standard assay conditions.

End product inhibition was studied by adding L-theanine (10−40 mM) to the reaction while the GGT assay was performed and monitoring the change in transpeptidase activity.

**Electrophoresis, Western Blotting, and Activity Staining.** SDS-PAGE of purified rBLGGT along with the crude enzyme was carried out according to the procedure of Laemmli[17] to determine the molecular mass and subunit composition of the enzyme. A 12% (v/v) resolving gel stacked with a 5% (v/v) stacking gel was run at 20 mA for approximately 1 h using a Bio-Rad power pac. Gels were then stained with 0.25% (w/v) Coomassie Brilliant blue R-250 at mild shaking and destained thereafter.

Western blot analysis was done by transferring the protein to a PVDF membrane (Bio-Rad). The membrane was then blocked for 1 h in 3% (w/v) BSA prepared in 1× PBS and thereafter incubated with 1:5000 streptactin antibody conjugated with horseradish peroxidase (HRP) for 1 h on mild shaking at room temperature. Subsequently, the membrane was washed with 0.05% (v/v) Tween-20 in 1× PBS. The protein band was then visualized using diaminobenzidine (DAB, 0.1% w/v) solution prepared in hydrogen peroxide.

Native PAGE (10% v/v) was prepared, and purified rBLGGT was loaded in two wells of the gel along with native molecular markers and was run at 20 mA for 1 h. Thereafter, one of the lanes containing rBLGGT sample was sliced using a scalpel and subjected to activity staining, whereas the remaining gel was stained with 0.25% (w/v) Coomassie Brilliant blue R-250 to analyze the molecular mass of the native protein.

For acitivity staining, the gel piece was first equilibrated at 50 mM Tris-HCl buffer (pH 9.0) for 10 min and then placed over an agar plate containing the substrates (γ-GpNA and glycylglycine). Gel was incubated at 45 °C until the yellow color of *p*-nitroaniline appeared. To intensify the stain, gel was further treated with *N*-(1-naphthyl)-ethylenediamine employing the method described previously.[18]

**Biochemical Characterization of rBLGGT.** *Effect of pH and Temperature.* GGT assay was performed at various pH values (5.0−12.0), using universal pH buffer (Britton−Robinson buffer) to determine the effect of pH on transpeptidase activity. pH stability was studied by preincubating the enzyme at pH 5.0−12.0 (10 mM) for 1 h and then performing the assay under standard conditions. The effect of temperature on enzyme activity and stability was determined by incubating the reaction at various temperatures ranging from 40 to 80 °C. All of the experiments were performed in triplicate. Relative and residual enzyme activities were plotted, and the activity obtained under standard assay conditions was regarded as 100%.

Steady-state kinetics of purified rBLGGT was performed with various concentrations of γ-GpNA ranging from 0.016 to 0.2 mM at its optimal pH and temperature. The $K_m$ and $V_{max}$ values were calculated using a Lineweaver−Burk plot (graph was plotted using Systat Software, Inc., SigmaPlot for Windows).

*Substrate Specificity for γ-Glutamyl Acceptors.* Substrate specificity of rBLGGT toward various amino acids as γ-glutamyl acceptors, namely, alanine, threonine, leucine, methionine, phenylalanine, glycine, asparagine, isoleucine, tryptophan, glutamine, glutamic acid, aspartic acid, serine, histidine, valine, arginine, and lysine, was studied considering activity with glycylglycine, as an acceptor, as 100%.

*Effect of Metal Ions and Inhibitors.* The effect of various metal ions on enzyme activity was studied by pre-incubating the enzyme in the respective metal ion solution (pH 9.0) for 5 min and then performing the assay as mentioned. Enzyme was investigated for nine different metal ions, namely, $Co^{2+}$, $Cu^{2+}$, $Ca^{2+}$, $Cd^{2+}$, $Mn^{2+}$, $Mg^{2+}$, $Ni^{2+}$, $Zn^{2+}$, and $Pb^{2+}$, at a final concentration of 5 mM in the reaction. The influence of various inhibitors, for example, phenylmethanesulfonyl fluoride (PMSF), *N*-bromosuccinamide (NBS), bromoacetic acid, ethylenediaminetetraacetic acid (EDTA), β-mercaptoethanol, idoacetamide, sodium azide, iodoacetic acid, dithiothreitol, and 1,10-phenanthroline, on GGT activity was also investigated along with some specific inhibitors of GGT such as 6-diazo-5-oxo-L-norleucine (DON) and azaserine.

**Theanine Biosynthesis: Optimization of Reaction Parameters.** Initially, theanine synthesis was determined in a 5 mL reaction containing 20 mM L-glutamine (donor) and 200 mM ethylamine (acceptor) at pH 9.0 and 37 °C using 0.4 U/mL rBLGGT for a period of 6 h to select an appropriate time for further optimization. Reactions were stopped by an equal volume of 0.5% (v/v) trifluoroacetic acid (TFA) and were then filtered through a 0.2 μm filter. The products were analyzed with a Shimadzu high-performance liquid chromatograph (HPLC) equipped with a $C_{18}$ reverse phase column (Luna 5 μm C18 (2); dimensions, 250 × 4.6 mm). L-Theanine was detected according to the method of Zhang[19] with a few modifications in the mobile phase: 0.05% (v/v) TFA in water; flow rate, 0.5 mL/min; oven temperature, 40 °C. UV−vis absorbance detection was done at 203 nm without any derivatization, and the L-theanine peak was identified by running commercial standards. However, a measurable amount of L-theanine was obtained within 1 h of the reaction; thus, further parameters, such as the concentrations of donor, acceptor, and enzyme, were optimized using a one variable at a time approach for a 1 h reaction at pH 9.0 and 37 °C.

**One Variable at a Time Approach.** Ethylamine concentration was varied from 40 to 400 mM in a reaction containing 20 mM L-glutamine and 0.4 U/mL rBLGGT in the above specified conditions. Similarly, L-glutamine (10−100 mM) was varied at a constant concentration of ethylamine (200 mM) and rBLGGT (0.4 U/mL). The effect of enzyme concentration was also studied in reactions containing 40 mM L-glutamine and 200 mM ethylamine at pH 9.0 and 37 °C by varying its concentration from 0.1 to 1.0 U/mL. All of the reactions were done in triplicate, and theanine yield was determined after 1 h of incubation according to the method described above.

**Statistical Approach: Response Surface Methodology (RSM).** The interaction pattern of three main components of L-theanine synthesis reaction, namely, L-glutamine ($X_1$), ethylamine ($X_2$), and rBLGGT ($X_3$), was studied by employing RSM strategy. The experiment was designed using the Box−Behnken model following Design Expert software (version 6.0.10). Each of the independent variables was studied at three different coded levels of −1, 0, and +1, resulting in 17 sets of experiments (5 replications of the central run). The actual and coded forms with respect to the full experimental plan of all three variables are listed in Table 1. L-Theanine yield ($Y_1$) and percent conversion ($Y_2$) of L-glutamine to L-theanine were taken as the two responses for this study. All of the reactions were performed in 50 mM Tris-HCl buffer (pH 9.0) and were incubated at 37 °C for 4 h. A second-

**Table 1. Experimental Ranges and Levels of the Three Independent Variables Used in RSM in Terms of Actual and Coded Factors**

| variable | actual | coded | actual | coded | actual | coded |
|---|---|---|---|---|---|---|
| L-glutamine (mM) | 20 | −1 | 80 | 0 | 140 | +1 |
| ethylamine (mM) | 200 | −1 | 400 | 0 | 600 | +1 |
| rBLGGT (U/mL) | 0.5 | −1 | 1.0 | 0 | 1.5 | +1 |

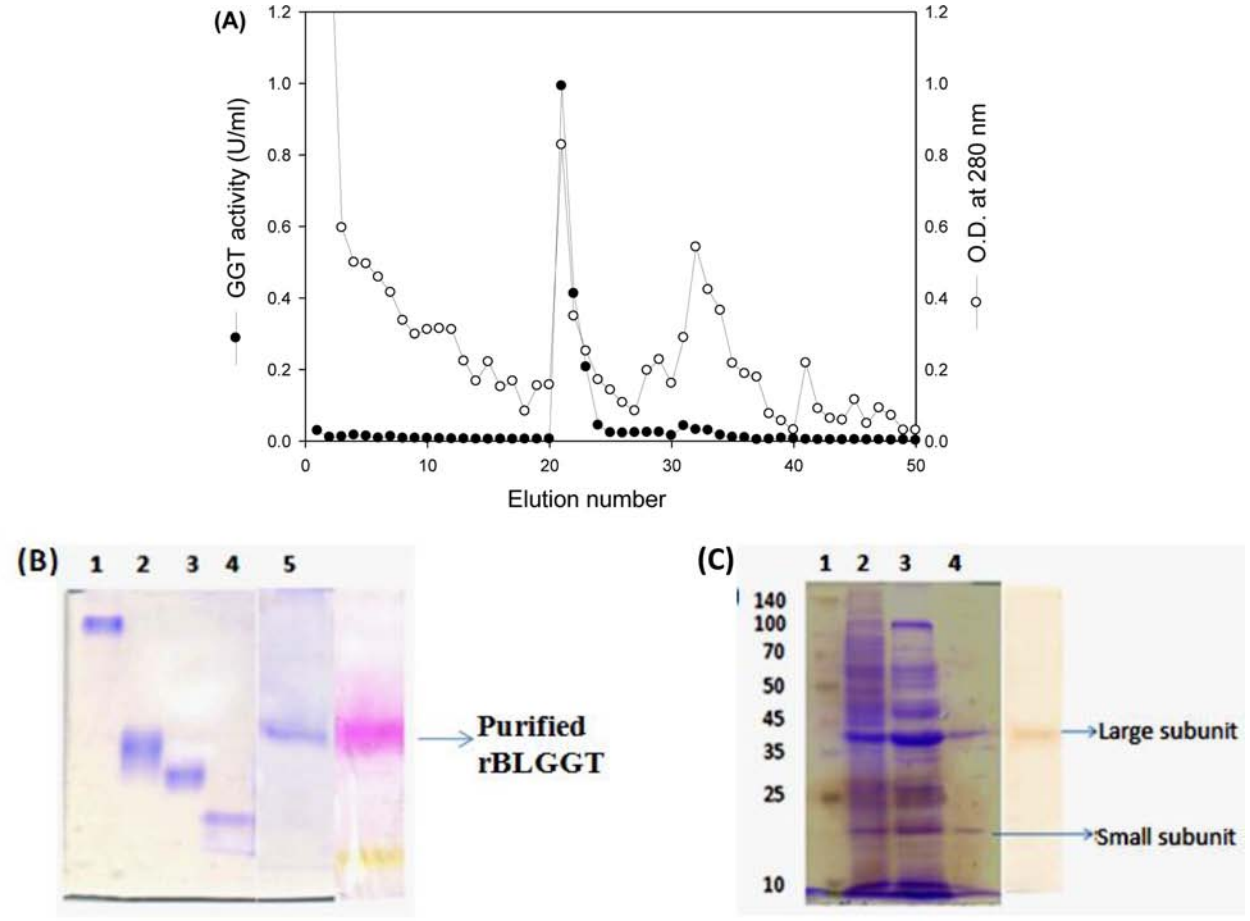

**Figure 1.** (A) Elution profile of rBLGGT from Q-Sepharose fast flow column pre-equilibrated with 10 mM, pH 9.0, Tris-Cl buffer (fractions 21, 22, and 23 were pooled together for biochemical characterization). (B) Native-PAGE (lane 5) and zymogram of purified rBLGGT (native protein markers used; lanes: 1, catalase, 240 kDa; 2, bovine albumin, 67 kDa; 3, egg albumin, 43 kDa; 4, trypsin soybean inhibitor, 20.1 kDa). (C) SDS-PAGE and Strep-tag Western blot of rBLGGT (lanes: 1, SDS protein marker; 2, crude cell lysate; 3, acetone precipitated fraction; 4, purified rBLGGT).

degree polynomial equation was generated using a modified quadratic model

$$Y_{1or2} = \beta_0 + \beta_1 X_1 + \beta_2 X_2 + \beta_3 X_3 + \beta_{11} X_1^2 + \beta_{22} X_2^2 + \beta_{33} X_3^2 + \beta_{12} X_1 X_2$$

where $\beta_0$ is the constant coefficient, $\beta_1$, $\beta_2$, and $\beta_3$ are linear, $\beta_{11}$, $\beta_{22}$, and $\beta_{33}$ are quadratic, and $\beta_{12}$ is the interaction coefficient.

**Statistical Analyses.** RSM results were analyzed by performing an analysis of variance (ANOVA) test. *F* value and Prob > *F* generated by ANOVA were used to determine the statistical significance of the regression coefficients. Also, the model applicability was assessed by observing the values of $R^2$, adjusted $R^2$, and the coefficient of variance. Subsequently, the model was validated by setting up 10 random experiments (9 within the design space and 1 beyond), and the results thus obtained were checked against their predicted values.

**Enzyme Immobilization.** rBLGGT was immobilized by entrapping the enzyme in calcium alginate beads. Acetone-precipitated enzyme (9.0 U/mL) was added to an equal volume of 6% (w/v) sodium alginate and mixed thoroughly, resulting in a 3% (w/v) sodium alginate enzyme mixture. Beads were prepared by adding the above mixture dropwise to a 0.2 M $CaCl_2$ solution at 4 °C. Beads were left in the $CaCl_2$ solution for 3 h at 4 °C for hardening, subsequently washed with ultrapure water, and air-dried. GGT activity retained in the beads as compared to the free enzyme was estimated by hydrolytic assay using oxidized glutathione (GSSG) as substrate.

A 10 mM stock solution of GSSG was prepared in 50 mM Tris-HCl buffer (pH 9.0). GGT assay of free as well as immobilized enzyme was done using GSSG as substrate for hydrolytic reaction. Enzyme units were calculated by monitoring the decrease in substrate concentration with time, and thus units were defined as micromoles of GSSG utilized per minute under standard assay conditions. GSSG peak was analyzed on HPLC using the same protocol as employed for theanine detection.

Assuming equal distribution of the enzyme in the beads, theanine synthesis reaction was carried out by adding calcium alginate beads equivalent to 1.0 U/mL in 50 mL of reaction volume and was kept at 37 °C and 100 rpm for 4 h. Reaction was repeated five times by harvesting the beads from the previous reaction. Subsequently, the reaction was scaled up to 1 L.

**Purification of L-Theanine.** A 50 mL reaction under optimized conditions was set up and terminated by lowering its pH to 3.0 by adding 3% (v/v) HCl solution. Batch purification was done by adding 10 g of Dowex 50W X 8 hydrogen form resin to the reaction vessel and kept at mild shaking (50 rpm) for 10 min at room temperature. The vessel was then allowed to stand for 10 min so that the resin settled at the bottom and was separated by decantation. L-Theanine was then eluted with 5 volumes of ammonia−water (pH 11.6; pH was adjusted by diluting 30% (v/v) ammonium hydroxide solution with ultrapure water), five times. Each fraction was analyzed on HPLC. Resin was regenerated using 2% (v/v) sulfuric acid and ultrapure water.

The fraction containing purified theanine was then lyophilized and compared with the commercial standards on HPLC. $^1$H NMR analysis was done by dissolving 10 mg of the sample in 500 $\mu$L of $D_2O$ followed by analysis on a Bruker Avance 400 MHz spectrophotometer at the University Science Instrumentation Centre (USIC), University of Delhi, with TMS as internal standard. $^1$H NMR was done as single pulse (1D) at 23.7 °C, and acquisition duration and relaxation delay were 1.37 and 4 s per scan, respectively, with a pulse angle of 45°.

## RESULTS AND DISCUSSION

**Purification and Characterization of rBLGGT.** rBLGGT was purified by Q-Sepharose ion-exchange chromatography, and the active fraction was eluted in 0.3 M NaCl (Figure 1A) with a yield of 28.8% and a specific activity of 4.58 U/mg (Table 2). The purity of the enzyme was checked with native-PAGE gel, which showed a single band of around 64 kDa. Activity staining was done to check the enzyme activity of the corresponding band (Figure 1B).

**Table 2. Purification Summary of rBLGGT**

| step | total protein (mg) | total activity (U) | specific activity (U/mg) | yield (%) | purification fold |
|---|---|---|---|---|---|
| cell lysate | 125 | 55.75 | 0.446 | 100 | 1.0 |
| acetone precipitated | 7.8 | 29.64 | 3.80 | 53.1 | 8.5 |
| Q-Sepharose ion-exchange purified (0.3 M fraction)[a] | 3.5 | 16.06 | 4.588 | 28.8 | 10.2 |

[a]Acetone-precipitated fraction was purified in two lots from Q-Sepharose fast flow column.

rBLGGT is a heterodimeric protein, which was confirmed by SDS-PAGE gel (Figure 1C). The apparent molecular masses of large and small subunits were approximately 42 and 22 kDa, respectively. The molecular masses of GGTs from other microbial sources range from 50 to 63 kDa, with variable sizes of large subunits, whereas the molecular masses of small subunits were almost constant.[20,21]

*Biochemical Characterization.* rBLGGT exhibited maximum activity at pH 9.0 and a temperature of 60 °C, similar to wild enzyme (Figure 2A,B). However, wild GGT showed a steep fall in activity when the pH was increased to 10.0, whereas rBLGGT retained around 60% of its activity until pH 11.0. GGTs from *Bacillus* sp. have been reported to work at alkaline pH ranging from 8.0 to 10.0, but there is a wide range (37−62 °C) with respect to temperature optima.[21] rBLGGT was stable in a broad pH range of 6.0−12.0, following almost the same pattern as wild type (Figure 2C). During temperature stability experiments it was observed that the enzyme was stable at 40 °C up to 3 h, whereas at 50 °C enzyme activity decreased gradually with a $t_{1/2}$ of 56 min. On the contrary, wild GGT was found to be more stable with a $t_{1/2}$ of 192 min at 50 °C (Figure 2D and Figure S2 in the Supporting Information). rBLGGT was found to be stable for 3 months at 4 °C and for 1 week at 37 °C.

Steady state kinetics of rBLGGT revealed a $K_m$ value of 45 $\mu$M against $\gamma$-GpNA, whereas that of wild GGT was 84 $\mu$M (Supporting Information Figure S3). This difference in $K_m$ values could be attributed to some conformational changes incurred by the recombinant protein while attaining its tertiary

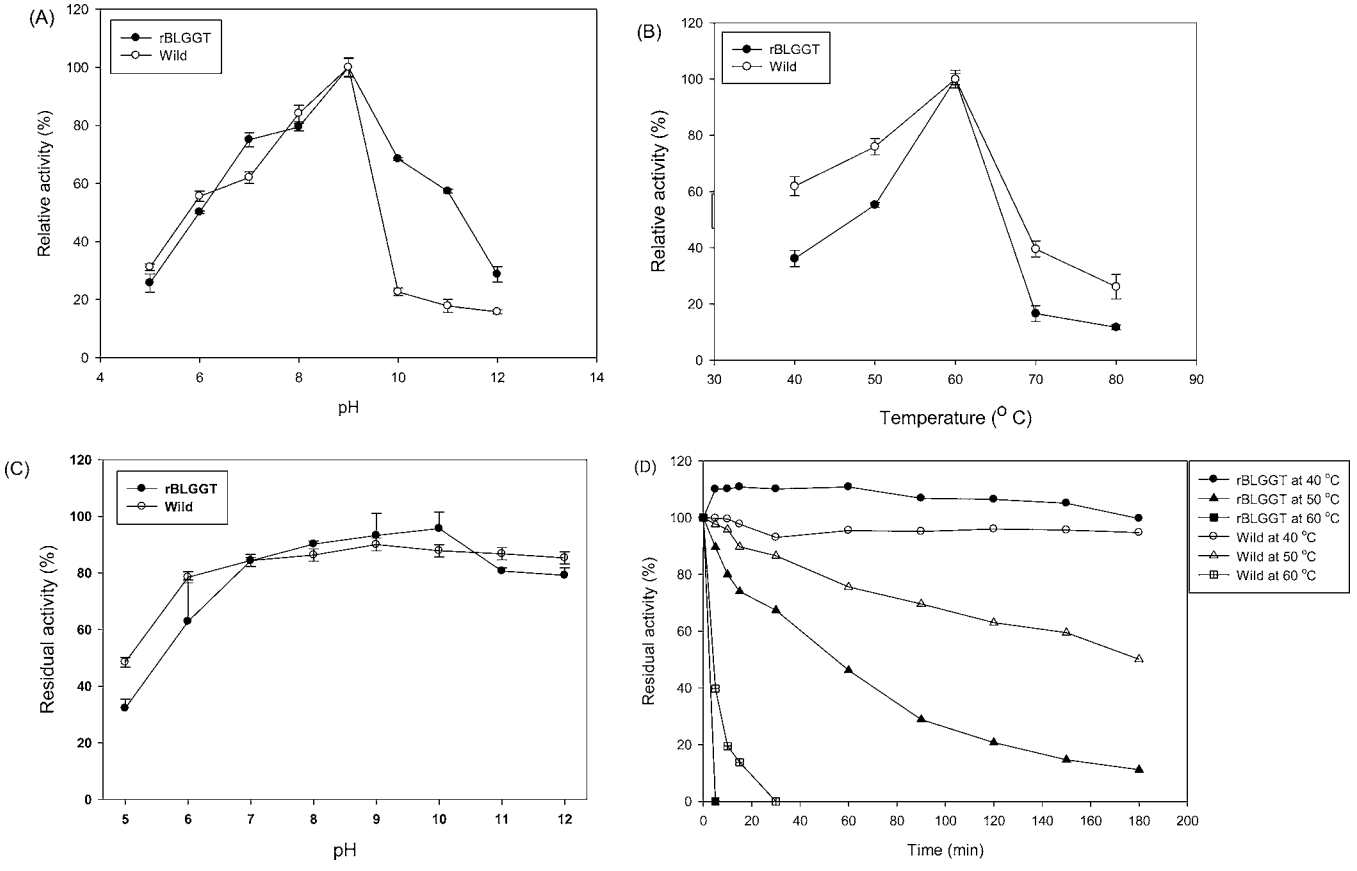

**Figure 2.** (A) Effect of pH on rBLGGT activity. For pH optimization GGT assay was performed in different pH buffers (5.0−12.0) at 60 °C. rBLGGT activity of 0.53 U/mL at 60 °C was taken as 100%. All reactions were done in triplicate. (B) Effect of temperature on BLGGT activity. GGT assay was performed by incubating the reaction at specific temperatures (40−80 °C) for 5 min. (C) rBLGGT stability in different pH buffers. Enzyme was preincubated in different pH buffers (5−12; 10 mM) for 1 h, and then GGT assay was performed at pH 9.0 and 60 °C. (D) Determination of temperature stability of rBLGGT. Enzyme was preincubated at different temperatures, and then GGT assay was performed under standard conditions after every 30 min interval. At 60 °C enzyme stability was checked for 5 min intervals. rBLGGT was also compared with wild GGT form *B. licheniformis* ER-15 for pH and temperature optima and stability (0.37 U/mL of wild GGT under standard conditions was taken as 100%).

dx.doi.org/10.1021/jf5022913 | J. Agric. Food Chem. 2014, 62, 9151−9159

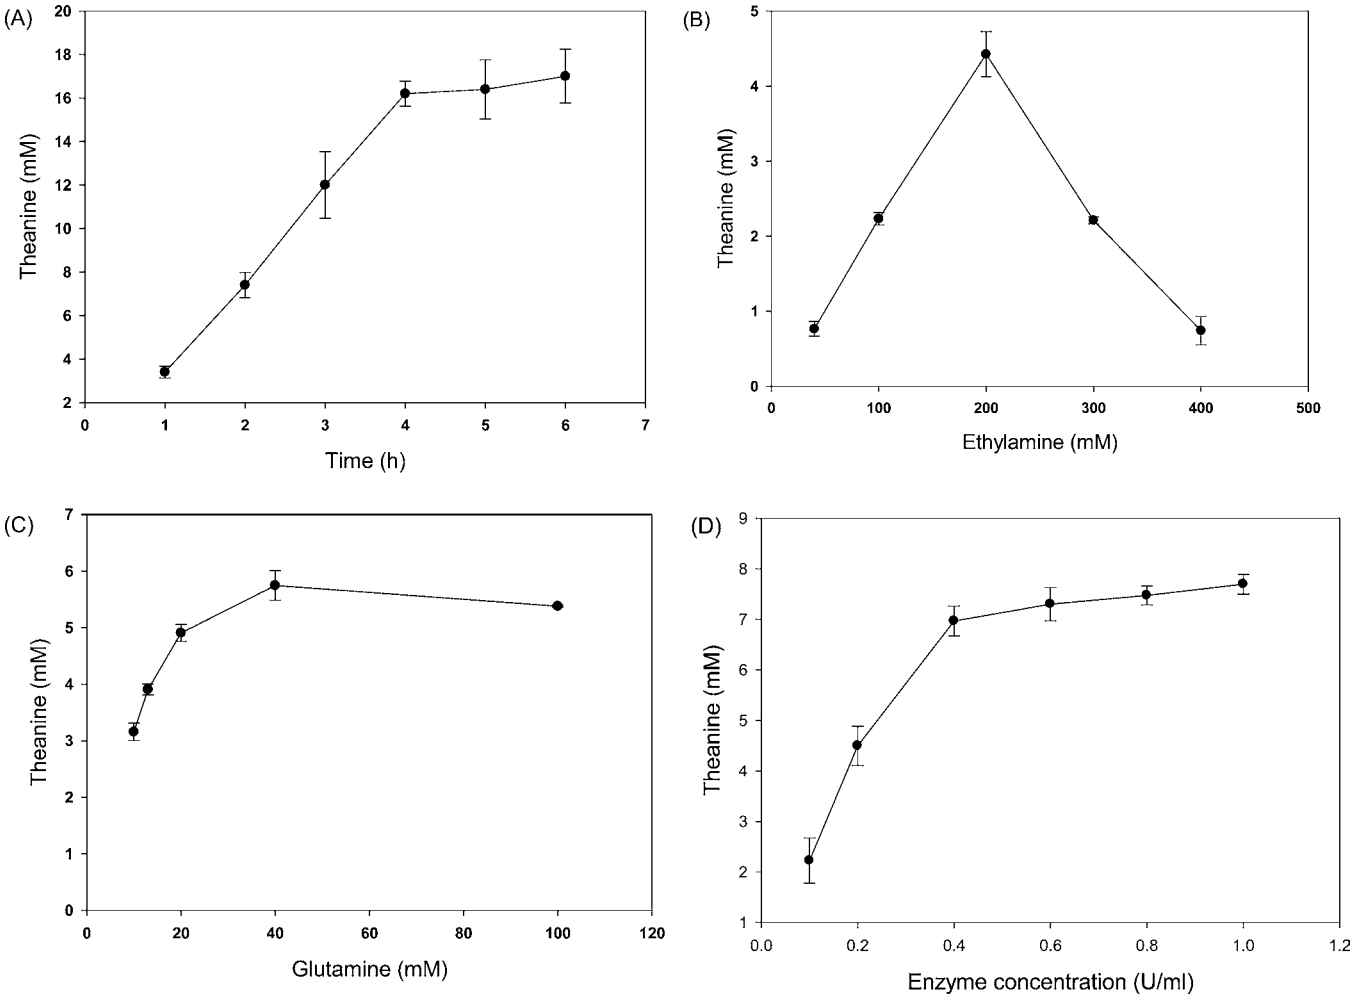

**Figure 3.** (A) Time profile for L-theanine synthesis (reaction containing 20 mM L-glutamine, 200 mM ethylamine, and 0.4 U/mL BLGGT in Tris-Cl, pH 9.0, buffer (50 mM), kept at 37 °C). (B) Optimization of acceptor concentration by a one variable at time approach (L-glutamine was kept constant at 20 mM. (C) Effect of L-glutamine concentration (ethylamine concentration was kept constant at 200 mM). (D) Optimization curve of enzyme concentration for theanine synthesis (5 mL reaction containing 40 mM L-glutamine and 200 mM ethylamine). All of the above reactions were done in triplicate and were carried out at 37 °C and pH 9.0 for 1 h.

structure. The affinity of rBLGGT for γ-GpNA as substrate is around 2 times that of *B. licheniformis* ATCC 27811 GGT,[20] whereas the $K_m$ of *B. subtilis* SK11.004 GGT has been reported to be 7500 μM.[21]

Inhibition studies of rBLGGT and the wild type revealed that the two amino acids, namely, serine and tryptophan, are of utmost importance with respect to its activity as the enzyme is strongly inhibited by PMSF and NBS, which correlates with the previously reported results of Inoue et al.,[22] wherein it has been shown that N-terminal threonine residue is crucial for both autocatalysis and activity of the enzyme. Although inhibition with NBS supports the hypothesis of Shuai et al.,[21] complete inhibition of both the enzymes by GGT specific inhibitors such as DON and azaserine confirmed the nature of the enzymes as γ-glutamyl transferases (Supporting Information Figure S4). Metal ion inhibition studies demonstrated some contrasting features between the recombinant and wild enzymes. rBLGGT inhibition was observed with $Zn^{2+}$, $Mn^{2+}$, $Ni^{2+}$, and $Pb^{2+}$ metal ions, whereas there was apparently no change in GGT activity in the presence of $Mg^{2+}$, $Ca^{2+}$ $Cu^{2+}$, and $Cd^{2+}$ ions. On the other hand, wild-type GGT showed more sensitivity toward all of the metal ions used. Moreover, complete inhibition of the wild type was observed in the presence of $Co^{2+}$, whereas rBLGGT retained around 80% of the activity (Supporting Information Figure S5). rBLGGT was also inhibited by ethylene glycol tetraacetic acid (EGTA) with 37% residual activity, which was completely regained in the presence of $Ca^{2+}$ or $Mg^{2+}$ but not with $Cd^{2+}$ metal ions; similar observations were also reported previously in the case of GGT from *B. licheniformis*.[20] Inhibition with EGTA was not observed in case of wild- type.

Substrate specificity of rBLGGT with various amino acids as γ-glutamyl acceptors was analyzed, and it showed >50% transpeptidase activity with most of the amino acid acceptors, whereas serine, alanine, and aspartic acid were weak acceptors. With respect to substrate specificity, rBLGGT showed a behavior highly similar to that of its wild counterpart Supporting Information Figure S6). High substrate specificity of rBLGGT makes the enzyme a good choice for synthesizing γ-glutamyl compounds. There are a very few reports of GGTs from *Bacillus* sp. having >50% transpeptidase activity with respect to monomers.[23,24]

**Theanine Synthesis.** Various parameters affecting the conversion of L-theanine from L-glutamine were investigated. L-Theanine was quantified using HPLC, where theanine eluted in a linear fashion in the range from 0.25 to 2 mM between 10.8 and 11.4 min using 0.05% (v/v) TFA as a mobile phase. This is the

[a]Actual values are the average of the values obtained from three independent experiments.

modification of the method reported by Zhang et al.[19] where the pH of the mobile phase was adjusted to 3.0 using formic acid instead of TFA. Generally, theanine is detected by reverse phase HPLC equipped with fluorescence detectors using pre- or post-column derivatization,[25−27] but simple methods are also available that are free from reagent interference and cumbersome processing of the samples.

L-Theanine biosynthesis was carried out at pH 9.0 and 37 °C throughout the study. Although the temperature optimum of rBLGGT is 60 °C, by keeping in mind the lower boiling point of ethylamine (bp = 20 °C), synthesis was done at 37 °C.

During time profiling 16 mM theanine was obtained using 20 mM L-glutamine and detectable amounts of L-theanine can be obtained within 1 h (Figure 3A). Therefore, further parameters were studied for 1 h of reaction using a one variable at a time approach.

The substrate ratio was taken into consideration because it has been reported that the donor to acceptor ratio plays a significant role in transpeptidation reactions carried out by GGTs.[28] It is known that GGTs catalyze three different reactions, depending on the substrates availability, namely, transpeptidation, hydrolysis, and autotranspeptidation. Therefore, initially, ethylamine (acceptor) concentration was standardized in the ratios of 1:2, 1:5, 1:10, 1:15, and 1:20 in the presence of 20 mM L-glutamine. Maximum yield of 4.5 mM was achieved when the donor to acceptor ratio was 1:10 within 1 h (Figure 3B). Subsequently, the donor concentration was optimized keeping ethylamine constant at 200 mM, and the optimal ratio obtained was 1:5, that is, 40 mM L-glutamine and 200 mM ethylamine with 5.7 mM theanine yield (Figure 3C). This is in agreement with a previous study[14] in which a lower ratio of 1:2.5 was reported for *Bacillus subtilis* GGT but a higher ratio was needed for GGTs from *E. coli*.[11−15] This shows that GGTs from *Bacillus* sp. are better transpeptidases with respect to ethylamine as an acceptor.

Enzyme concentration was optimized to be 0.5 U/mL as no significant increase in theanine yield was observed when the enzyme concentration was increased from 0.4 to 0.6 U/mL (Figure 3D). With further increase in the enzyme concentration (1.2 U/mL), byproduct formation was observed, which shows that at higher concentrations, enzyme also catalyzes side reactions such as hydrolysis and autotranspeptidation (Supporting Information Figure S7). Subsequently, the time kinetics revealed that 33 mM theanine yield could be obtained within 4 h, which was 2 times the initial yield (Figure 5). Around 80% conversion of L-glutamine to L-theanine could be achieved in a reaction consisting of 40 mM L-glutamine, 200 mM ethylamine, and 0.5 U/mL rBLGGT at pH 9.0 and 37 °C within 4 h, in contrast to previous studies in which a similar conversion has been reported in >6 h[29] except for GGT from *B. subtilis*[14] where 94% conversion has been reported in 4 h.

Statistical optimization was employed using Box−Behnken design. The actual and predicted values for both of the responses, L-theanine yield (mM) and percent conversion of L-glutamine to L-theanine, are listed in Table 3A. ANOVA studies revealed the model to be significant with $F$ values of 45.38 ($P > F < 0.0001$) and 18.48 ($P > F = 0.0001$) for the former and the latter,

dx.doi.org/10.1021/jf5022913 | J. Agric. Food Chem. 2014, 62, 9151−9159

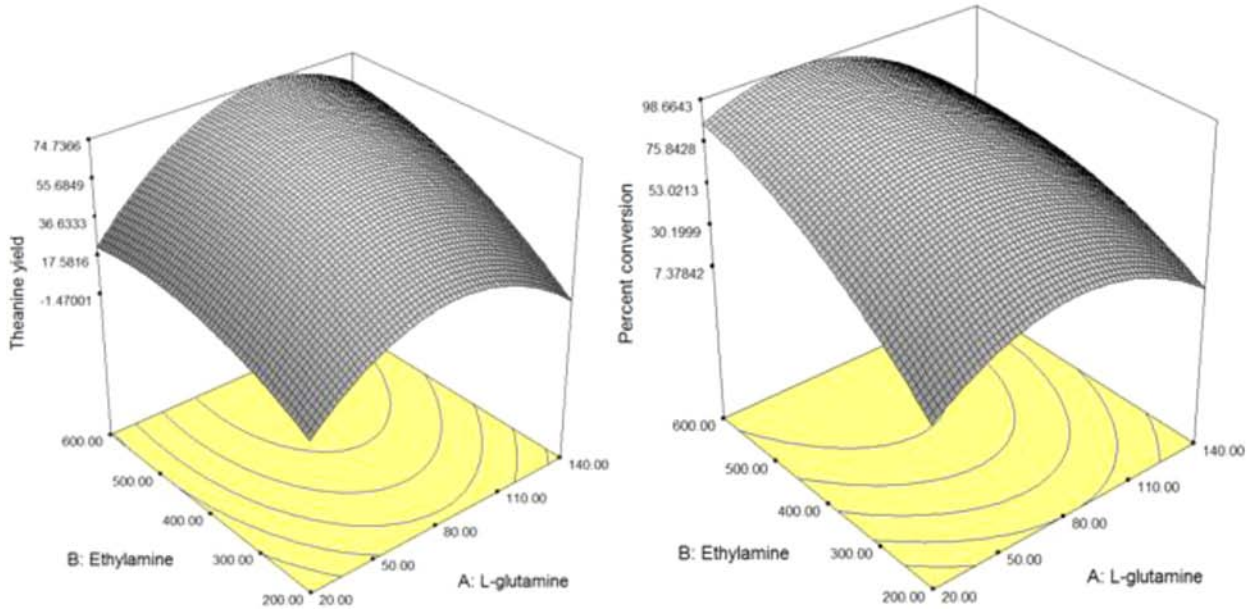

**Figure 4.** 3D plot for L-theanine yield (mM) and percent conversion of L-glutamine to L-theanine: effect of L-glutamine and ethylamine concentrations at a constant concentration of rBLGGT (1 U/mL).

respectively. Also, the adjusted $R^2$ values were in good agreement with the predicted $R^2$ for both responses (Table 3B). Thus, it can be concluded that the empirical model fits the experimental values very well. On the basis of the regression analyses the following equations were generated for $Y_1$ and $Y_2$:

$$\text{theanine yield } (Y_1) = 63.42 + 11.14X_1 + 19.44X_2 + 3.12X_3 - 30.99X_1^2 - 10.97X_2^2 - 14.13X_3^2 + 7.66X_1X_2$$

$$\%\ \text{conversion } (Y_2) = 79.27 - 10.77X_1 + 28.37X_2 + 9.33X_3 - 30.66X_1^2 - 12.78X_2^2 - 18.60X_3^2 - 10.85X_1X_2$$

$X_1$, $X_2$, and $X_3$ are three independent variables included in the study. The interacting parameters, $X_{13}$ and $X_{23}$, were found to be insignificant and thus excluded from the model.

From analysis of the interaction plots (Figure 4), it can be observed that on increasing the ethylamine concentration, yield as well as the percent conversion for L-theanine also increases at a constant concentration of L-glutamine and rBLGGT, whereas on increasing L-glutamine at a constant concentration of ethylamine, a decrease in percent conversion was observed. This could be attributed to either overcrowding of the active sites of rBLGGT or end product inhibition. However, with increasing enzyme, no benefit regarding percent conversion was encountered. Therefore, end product inhibition studies were carried out and a gradual decrease in enzyme activity was observed when the theanine concentration was increased from 10 to 40 mM during the GGT assay (Supporting Information Figure S8). The model was validated by conducting a set of 10 random experiments (9 within and 1 outside the design space), and the results were found to be in good agreement with the predicted values (Supporting Information Table S1).

Thus, following RSM a maximum of 85−87% conversion of L-glutamine to L-theanine was obtained with the total theanine yield of 68−70 mM in a reaction containing 80 mM L-glutamine, 600 mM ethylamine, and 1 U/mL rBLGGT at pH 9.0 and 37 °C within 4 h, which is nearly 4.25-fold the initial yield. rBLGGT enzyme concentration used in the current study is higher than in earlier studies[14] because the enzyme has a temperature optimum of 60 °C and retains only 30% of its activity at 37 °C (Figure 2B).

Furthermore, to make the reaction cost-effective, rBLGGT was immobilized by entrapment method using calcium alginate beads. Enzyme activity was retained at a level of 40−50% after entrapment as assessed by GGT assay using GSSG as substrate (retention time = 25 min). Immobilization had no effect on pH and temperature optima of the enzyme, whereas the thermal stability of the enzyme was enhanced with >80% activity at 60 °C until 15 min, in contrast to free rBLGGT that lost its activity at 60 °C within 5 min (Supporting Information Figure S9).

Under optimized conditions 84% conversion was achieved using immobilized enzyme in 50 mL of reaction volume within 4 h, which was scaled up to 1 L with similar yields (Figure 5). Beads were reused for five times with >90% efficiency retained up to the third cycle.

More than 90% of pure L-theanine was recovered by using the method of Zhu et al.[30] with a few modifications. The purification was done in batch, and theanine was eluted using ammonia−water at pH 11.6 instead of pH 11.3. The purified fractions were then subjected to lyophilization, and finally a white theanine powder was obtained.

The purity of the final product was assessed by HPLC (see Supporting Information Figure S10), and it was >95% pure. L-Theanine was further identified by $^1$H NMR analysis (see Supporting Information Figure S10).

Finally, through this process 35.2 g of theanine was obtained in three cycles of 1 L each. A brief comparison with the previously optimized methods for the synthesis of L-theanine using γ-glutamyl transpeptidase from various sources is listed in Table 4. This is the first report of the synthesis of L-theanine from *B. licheniformis* GGT. To date only *E. coli* and *B. subtilis* GGTs have been explored with 80−95% conversion efficiency. *B. subtilis* GGT has been reported to convert 94% L-glutamine to L-theanine within 4 h[14] in contrast to rBLGGT (84%), but the

dx.doi.org/10.1021/jf5022913 | J. Agric. Food Chem. 2014, 62, 9151−9159

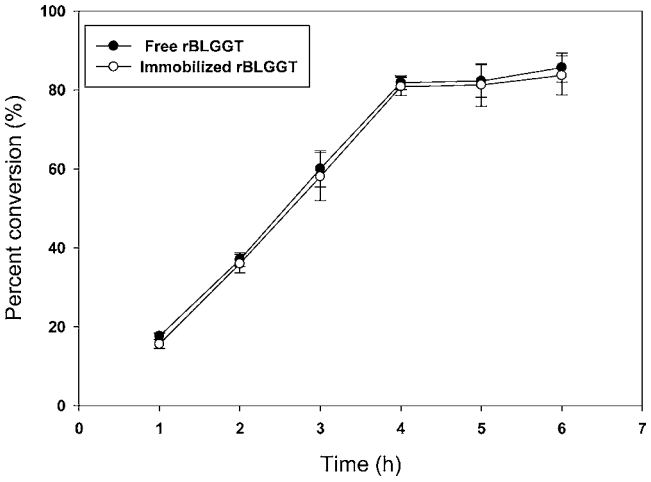

**Figure 5.** Time profiling of theanine synthesis using free and immobilized enzyme. After all of the reaction conditions had been optimized, time was again standardized for 50 mL of reaction using free and immobilized enzyme.

overall yield was less, as only 20 mM L-glutamine was used in that study. However, higher L-glutamine (or other γ-glutamyl donors) concentration (100−300 mM) in the case of *E. coli* GGTs resulted in higher yields, but accordingly high donor to acceptor ratios (1:7.5 or 1:10) and longer reaction times (8−24 h) were required to achieve >80% conversion. Thus, rBLGGT can be employed for the enzymatic synthesis of L-theanine with appreciable catalytic efficiency.

Stereoselective synthesis of L-theanine with appreciable yields can thus be obtained from enzymatic reactions, as documented in Table 4. Also, *Bacillus* GGTs have been demonstrated to provide higher conversion rates as well as least reaction times. Thus, scaling up of the process, for L-theanine synthesis, at the industrial level could be achieved using *B. licheniformis* GGT. In contrast to natural extraction and chemical synthesis processes for L-theanine production, enzymatic synthesis has many advantages such as lower reaction time, high specificity, and higher yields. However, for such large-scale productions enzyme could be a limiting factor; therefore, now more emphasis should be given to increasing the enzyme production and immobilization. Reusability of the enzyme is one the most important parameters that should be focused on to make the process more cost-effective.

reflux in an acid−water solution including two water addition products. This study only incorporated 5-CQA, and the brewing time was not in line with common consumer practice. No comprehensive mechanistic study has been previously reported that investigated the intra- versus intermolecular acyl migration under different conditions incorporating all major commercially available regioisomers of mono- and dicaffeoyl chlorogenic acids. Most importantly, data on acyl migration under roasting conditions are absent from the literature.

The complexity in the data interpretation for the structural analyses of the CGAs present in the roasted coffee melanoidins arises from the regio- and stereoisomeric compounds in the natural sources. For this reason, model roasting experiments on the commercially available mono- and dicaffeoylquinic acids were attempted in the present work to study the trans-

dx.doi.org/10.1021/jf5017384 | J. Agric. Food Chem. 2014, 62, 9160−9170

formations taking place in CGAs during the early roasting stages. Also, isomerization (acyl migration) was induced by both basic hydrolysis and simple hydrolysis (brewing) in these reference standards to observe the isomeric transformations on the basis of relative quantitation. Recently, tandem mass spectrometry has allowed accurate structural assignment and identification of the CGA regioisomers. The advantage of multidimensional specificity of LC-MS$^n$ enabled isomeric resolution and relative quantitation of the early roasting transformations in the CGAs.[13]

## MATERIALS AND METHODS

**Chemicals and Materials.** All of the chemicals (analytical grade) were purchased from Sigma-Aldrich (Bremen, Germany). Commercially available mono- and dicaffeoylquinic acids such as 5-*O*-caffeoylquinic acid (**3**), 3-*O*-caffeoylquinic acid (neo-chlorogenic acid) (**2**), 4-*O*-caffeoylquinic acid (crypto-chlorogenic acid) (**4**), 1,3-di-*O*-caffeoylquinic acid (cynarin) (**5**), 3,4-di-*O*-caffeoylquinic acid (**8**), 3,5-di-*O*-caffeoylquinic acid (**9**), and 4,5-di-*O*-caffeoylquinic acid (**10**) were purchased from PhytoLab GmbH & Co. KG (Vestenbergsgreuth, Germany).

**Hydrolysis by Tetramethylammonium Hydroxide (TMAH).** All seven CGA reference standards were treated with aqueous TMAH (25 g/L). Each sample was diluted by 5 mL of aqueous TMAH and stirred at room temperature. The pH of the mixture was observed to be around 12. One milliliter of solution from each sample was taken out at 2, 5, 10, 30, and 60 min time intervals. Each sample was saturated with brine and extracted twice with ethyl acetate. Combined organic layers were concentrated in vacuo, and each sample was prepared in 1 mL of methanol for analysis by LC-MS*n* for intramolecular acyl migration.

To study the intermolecular acyl migration (crossover experiment), 5-CQA (25 mg, 0.07062 mmol) was added to a round-bottom flask containing ferulic acid (13.7 mg, 0.07062 mmol). Five milliliters of 10 times diluted (25 g/L) TMAH was added to the flask, and the mixture was stirred at room temperature. One milliliter samples were taken from the flask at 2, 5, 10, 15, and 30 min time intervals. Each sample was saturated with brine and extracted twice with ethyl acetate. The combined organic layers were concentrated in vacuo, and each sample was prepared in methanol to be analyzed by LC-MS*n*. The same procedure was repeated with *p*-coumaric acid (11.57 mg, 0.07062 mmol) and 5-CQA (25 mg, 0.07062 mmol).

**Model Roasting.** All seven CGA reference standards were heated at 180 °C for 12 min separately to study the intramolecular acyl migration. Equimolar quantities of 5-CQA with *p*-coumaric acid and 5-CQA with ferulic acid were heated together at 180 °C for 12 min to study the intermolecular acyl migration (crossover experiment). All of the samples were heated in a Buechi Glass Oven B-585 and prepared in 1 mL of methanol for LC-MS*n* analysis.

**Brewing of CGAs (2−5 and 8−10).** Commercially available chlorogenic acid standards (each sample 500 μg) were infused in 3 mL of hot water each and stirred for 5 h under reflux. The pH of each sample was determined to be 5 with a pH meter. The solvent was removed under low pressure, and the samples were dissolved in 1 mL of MeOH and used for LC-MS$^n$.

**LC-MS$^n$.** The 1100 series LC equipment (Agilent, Bremen, Germany) comprised a binary pump, an autosampler with a 100 μL loop, and a DAD detector with a light-pipe flow cell (recording at 254 and 320 nm and scanning from 200 to 600 nm). This was interfaced with an ion-trap mass spectrometer fitted with an HCT Ultra ESI source (Bruker Daltonics, Bremen, Germany) operating in full scan, auto MS$^n$ mode to obtain fragment ion $m/z$. Tandem mass spectra were acquired in auto MS$^n$ mode (smart fragmentation) using a ramping of the collision energy. Maximum fragmentation amplitude was set to 1 V, starting at 30% and ending at 200%. The MS operating conditions (negative mode) had been optimized using 5-caffeoylquinic acid with a capillary temperature of 365 °C, a dry gas flow rate of 10 L/min, and a nebulizer pressure of 10 psi.

**HPLC.** Separation was achieved on a 150 × 3 mm i.d., 5 μm diphenyl column, with a 5 mm × 3 mm i.d. guard column (Varian, Darmstadt, Germany). Alternatively, separation was also achieved on a 250 mm × 3 mm i.d., 5 μm, C18-amide column, with a 5 mm × 3 mm i.d. guard column of the same material (Varian) for the cases of hydrolysis (brewing) of reference standard experiments. Solvent A was water/formic acid (1000:0.05, v/v), and solvent B was methanol. Solvents were delivered at a total flow rate of 500 μL/min. The gradient profile was from 10 to 70% B linearly in 60 min followed by 10 min isocratic and a return to 10% B at 90 and 10 min isocratic to re-equilibrate.

**Preliminary Assessment of Data.** All of the data for the chlorogenic acids use the recommended IUPAC numbering system;[14] the same numbering system was adopted for chlorogenic acids, their *cis*-isomers, their acyl migration isomers, and water addition products (Figure 1). The relative concentrations of the transformed products are expressed here in terms of the peak areas obtained in their UV chromatograms assuming the relative response factor in UV close to 1, based on identical absorptivity of all mono CGAs.[13,15] In the tables and figures, the peak area values are stated accordingly.

## RESULTS AND DISCUSSION

**Intramolecular Acyl Migration: Hydrolysis by TMAH of 2−5 and 8−10.** The most common CGAs in the green coffee bean, **2**−**5** and **8**−**10**, were selected and subjected to aqueous TMAH, with samples taken at intervals from 2 to 60 min. Samples were directly analyzed by LC-MS with compound identification and assignment achieved through comparison of retention times and fragment spectra.[2,18−23] Relative or absolute quantitation was carried out using HPLC-UV traces monitoring cinnamoyl absorption at 320 nm. The concentration of the samples was chosen to be sufficiently low (1−1.5 mg/mL) to prevent intermolecular acyl migration or transesterification, yet corresponding to typical coffee brew CGA levels (around 200 mg/cup = 1 mg/mL), therefore allowing observation of intramolecular acyl migration exclusively. In the hydrolysis of 3-CQA (**2**), 5-CQA (**3**), and 4-CQA (**4**), all of the other monoacyl derivatives were identified during the hydrolysis except for 1-CQA (**1**). Also, we did not observe the formation of any diacyl derivatives in the hydrolysis of the monoacyl quinic acids. This observation confirms that the acyl migration we observed in this study was in fact an intramolecular process. Figure 2 represents the UV chromatograms of the 5-CQA in basic solution at different time intervals. It should be noted that the UV response in mono- and diacylquinic acids has been used in the past as a reliable relative response factor.[1] Hanson et al.[16] used radiolabeled quinic acid to investigate the acyl migration pathway in cinnamoylqunic acids; in accordance with these findings, we assumed that the mechanism of the acyl migration follows the 1,2-*ortho*-ester intermediate formation. This assumption is also supported by the study of Xie et al.[17] The transformations of 5-CQA (**3**), 4-CQA (**4**), and 3-CQA (**2**) with time are presented in Figure 3. From the results, we can conclude that 5-CQA is much more stable than 4-CQA and 3-CQA, and the order of the stability is **5** > **4** > **3** in terms of the hydrolysis of the caffeoyl ester. This stability was observed to provide resistance to decomposition, thus allowing 5-CQA to form the acyl migrated products over longer hydrolysis durations. On the other hand, with 3-CQA being the least stable of the three monoacylquinic acids, it decomposes to form caffeic acid and quinic acid even before acyl migration takes place.

Considering the mechanism of the acyl migration proceeding through an 1,2-*ortho*-ester intermediate formation as 5-CQA ⇋ 4-CQA ⇋ 3-CQA, the reverse equilibrium, through which the

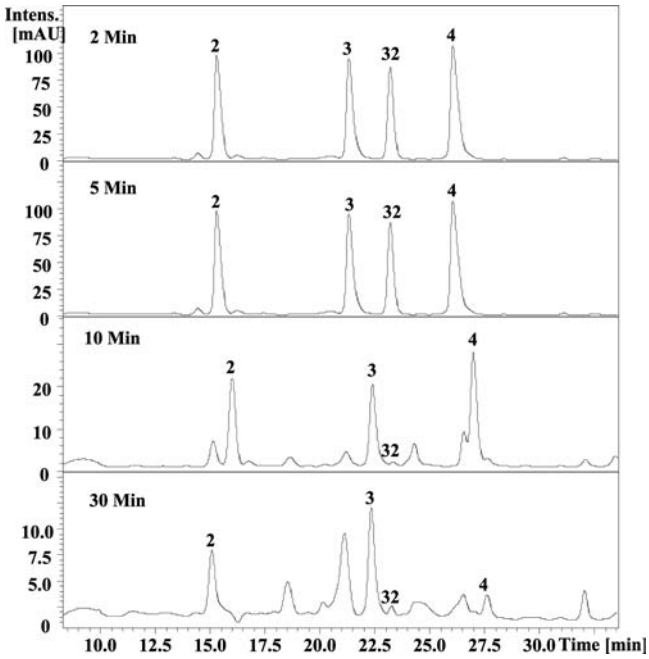

**Figure 2.** UV chromatograms (318−322 nm) at 2, 5, 10, and 30 min of basic hydrolysis of 5-CQA.

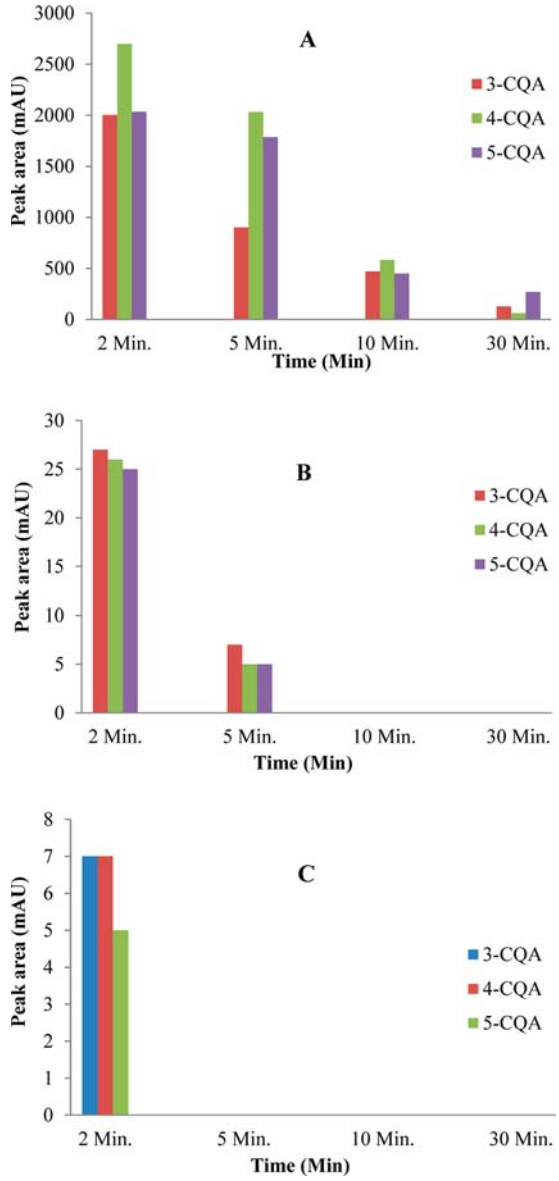

**Figure 3.** Amount of transformation products after basic hydrolysis for different time intervals of (A) 5-CQA, (B) 4-CQA, and (C) 3-CQA.

migrated acyl group reverts to its original position, appears to be slower. It is difficult to comment on the thermodynamic equilibrium of the acyl migration because of the ongoing simultaneous ester hydrolysis competing with the acyl migration process.

The equilibrium between 3-CQA (**2**) and 4-CQA (**4**) is readily achieved because the *ortho*-ester intermediate is more stable due to the *cis* geometry (Figure 4). Compound **2** shows a tendency to hydrolyze to generate caffeic acid and quinic acid rather than to undergo acyl migration, presumably due to the 1,3-*syn*-diaxial arrangement between the $C_1$ hydroxyl group and the $C_3$ ester. The hydrogen bonding between $C_1$−OH and the carbonyl oxygen on the ester on $C_3$ results in steric hindrance, preventing nucleophilic attack on the carbonyl carbon by the $C_4$ hydroxyl group, and facilitates the hydrolysis of the ester bond, thus dissociating the caffeoyl moiety in basic conditions. At the same time this hydrogen bonding presumably activates the ester at $C_3$ for hydrolytic cleavage.

Similar to monocaffeoyl derivatives, dicaffeoylquinic acids were subjected to aqueous TMAH treatment and analyzed in the same manner. Previous studies have shown that 1,5-diCQA (**7**) was converted into 1,3-diCQA (**5**) and 5-CQA (**3**) rapidly and extensively by TMAH treatment within 1 min of hydrolysis.[18,19] In the present study, however, basic hydrolysis of 1,3-diCQA (**5**) did not show any presence of 1,5-diCQA (**7**) or 1,4-diCQA (**6**). 1,3-DiCQA (**5**) decomposed largely into 1-CQA (**1**) rather than 3-CQA (**2**) in the ratio 2.2:1 after 2 min of base treatment. 1,3-DiCQA (**5**) did not transform preferably into 3,5-diCQA (**9**), whereas 3,4-diCQA (**8**) and 4,5-diCQA (**10**) were formed in very small quantities from (**5**) (Figure 5). 1-CQA (**1**) was found to be present entirely as a decomposition product of 1,5-diCQA (**7**) or 1,4-diCQA (**6**) or 1,3-diCQA (**5**) rather than a product of acyl migration as it was not observed as an acyl migration product of any other mono- or diacylated substrates; this fact also supports the *ortho*-ester propagation of acyl migration process. Moreover, this observation confirms the hydrolytic lability of the esters in the 3-acylated position.

In the case of hydrolysis of 4,5-diCQA (**10**), we observed that 4,5-diCQA transformed mainly into 3,4-diCQA (**8**) after 2 min of base treatment. Additionally, CQAs, in particular 5-CQA (**3**), 4-CQA (**4**), and 3-CQA (**2**), were observed after 2 min of reaction time. This trend continued for 5 min during the base treatment, after which all of the CGA derivatives were completely decomposed. 3,4-DiCQA (**8**) was observed to be the least stable isomer during the base treatment study. At 2 min, **8** was found to be in equilibrium with 3,5-diCQA (**9**); however, after 5 min of treatment, 3,5-diCQA (**9**) was observed to display a slightly larger peak area than 3,4-diCQA (**8**). 3-CQA (**2**) was not observed in any sample throughout the duration of the base treatment of 3,4-diCQA due to its tendency to decompose rapidly by hydrolysis.

Observations based on the results from the base treatment on 3,5-diCQA (**9**) were quite distinctive. After 5 min, 3,5-diCQA (**9**) was observed to possess surprising stability to the

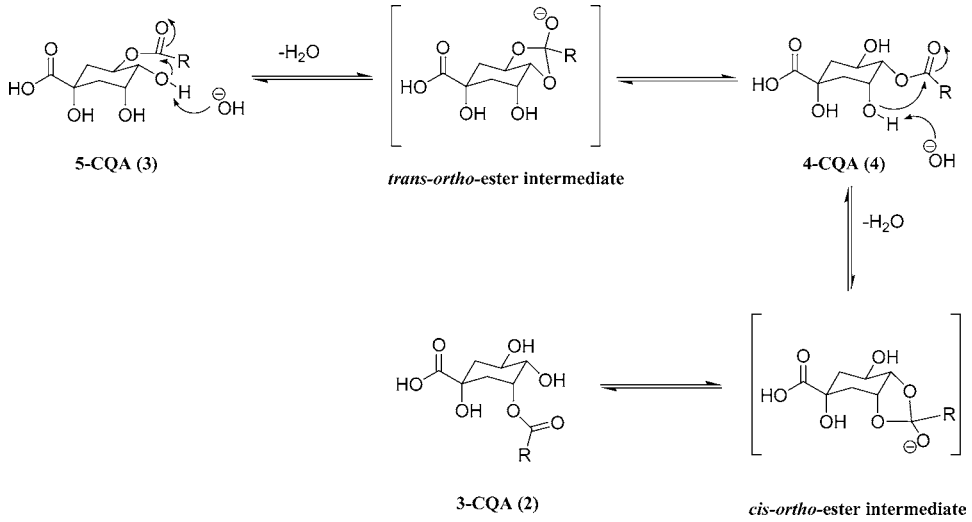

**Figure 4.** Mechanism of the acyl migration through an *ortho*-ester intermediate formation.

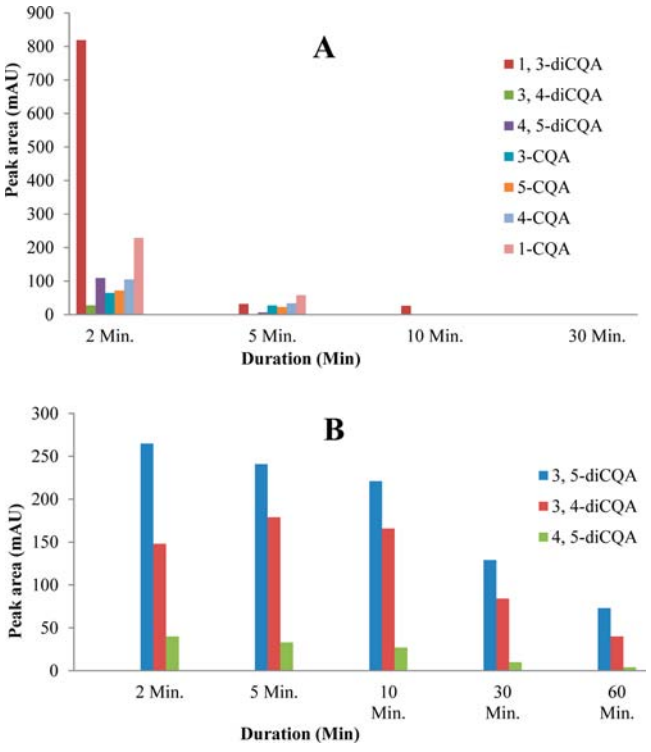

**Figure 5.** Amount of the transformation products after basic hydrolysis for different time intervals of (A) 1,3-diCQA and (B) 3,5-diCQA.

hydrolysis of the ester as we did not detect any of the mono-CQA derivatives even after 60 min of base treatment (Figure 5). 3,5-DiCQA (**9**) transformed mainly into 3,4-diCQA (**8**) followed by 4,5-diCQA (**10**). The ratio of **9**:**8**:**10** remained approximately constant throughout the 60 min of base treatment.

**Intermolecular Acyl Migration (Transesterification): Hydrolysis by TMAH (Crossover Experiment).** In these experiments, we investigated intermolecular acyl migration by carrying out crossover experiments, in which 5-CQA was reacted with the free acids such as ferulic and *p*-coumaric acids at 1:1 stoichiometry in the presence of a base. The change of substituents hereby allows easy identification of products by LC-MS based on the *m*/*z* value of the pseudomolecular ions of the products. The intermolecular acyl migration was found to be simultaneously competing with intramolecular acyl migration as well as hydrolysis of the CQA. The products identified in the reaction of 5-CQA with ferulic acid and *p*-coumaric acid at 2, 5, 10, 15, and 30 min of crossover experiment are summarized in Table 1. Along with the transesterification products of 5-CQA and respective free acid, formation of the *cis*-cinnamoyl isomers was also observed in ferulic, caffeic, and *p*-coumaric acids. All products were identified according to the fragmentation schemes reported previously.[18−21]

In the case of the base treatment of an equimolar mixture of *p*-coumaric acid and 5-CQA (**3**), the intramolecular acyl migration within 5-CQA seemed to be dominating the hydrolysis and the intermolecular acyl migration. According to the peak areas observed, the formation of the intermolecular acyl migrated species (transesters) was found to be least favored (Figure 6). For example, 3-CQA (**2**), 5-CQA (**3**), and 4-CQA (**4**) formed predominantly over caffeic acid (**32**) during 2 min of TMAH treatment of 5-CQA. *p*-Coumaric acid (**33**) did not esterify with the quinic acid generated from the hydrolysis of the 5-CQA (**3**) after 2 min; hence, no *p*-coumaroylquinic acids were observed. However, after 5 min of base treatment, the first transesterification product appeared in the form of 4-*p*CoQA (**14**), and after 10 min, both 5-*p*CoQA (**13**) and 4-*p*CoQA (**14**) were observed. Unfortunately, due to very low concentration, we could not compare the peak areas of compounds **13** and **14** in the UV chromatogram and hence cannot comment on the kinetics of the acyl migration. Although it was clear that 4-*p*CoQA (**14**) was formed earlier than 5-*p*CoQA (**13**), it was not obvious whether **13** was an acyl migration product of **14**. Formation of intramolecular acyl migration products takes place according to the conclusions established earlier in this study. After 2 min, the rate of hydrolysis of 5-CQA was very low and the amounts of 3-CQA (**2**), 5-CQA (**3**), and 4-CQA (**4**) were the highest. Between 5 and 10 min of basic hydrolysis, equilibrium was reached where 5-CQA was found to be the predominant isomer. Formation of the *cis*-cinnamoyl derivatives supposedly follows a water addition−elimination pathway to the double bond in the cinnamoyl moiety during the basic hydrolysis as described earlier.[25]

When an equimolar mixture of ferulic acid (**31**) and 5-CQA (**3**) was treated with base, we observed three regioisomers of

feruloylquinic acid resulting from intermolecular transesterification: 3-FQA (**22**), 5-FQA (**23**), and 4-FQA (**24**).[22] The peak area of compounds **22**−**24** is very low compared to the intramolecular acyl migration products formed in this experiment; hence, they do not appear in the plot shown in Figure 6. The same was not observed in the case of the *p*-coumaric acid experiment. After 2 min, 3-FQA (peak area = 3215) was formed predominantly over 5-FQA and 4-FQA. 5-FQA (**23**) and 4-FQA (**24**) showed negligible peak areas. Only 5-FQA remained stable enough to be detected after 10 and 15 min of basic hydrolysis. After 30 min, all of the transesters and the substrate 5-CQA were found to be decomposed completely as we could identify caffeic acid only. Formation of 3-FQA was found to be kinetically favored. This was found to be consistent with the fact that during the first few minutes of the base treatment of 5-CQA to study intramolecular acyl migration, 3-CQA dominates the acyl migration product spectrum. We also identified *cis*-1-*O*-caffeoylquinic acid (**47**) in the extracted ion chromatogram (EIC) of *m/z* 353 and the UV chromatogram on the basis of its early elution and fragmentation (Figure 7).[23] Similar to 1- *cis*-CQA (**47**), 4-*cis*-CQA (**48**) was also identified as another isomerized caffeoylquinic acid derivative, both of which are assumed to be formed by an addition elimination of the water molecule across the double bond in caffeic acid. 4-*cis*-CQA (**48**) was observed to be in equilibrium with 4-*trans*-CQA (**4**) after 2 min, but with an increase in the reaction time only

dx.doi.org/10.1021/jf5017384 | J. Agric. Food Chem. 2014, 62, 9160−9170

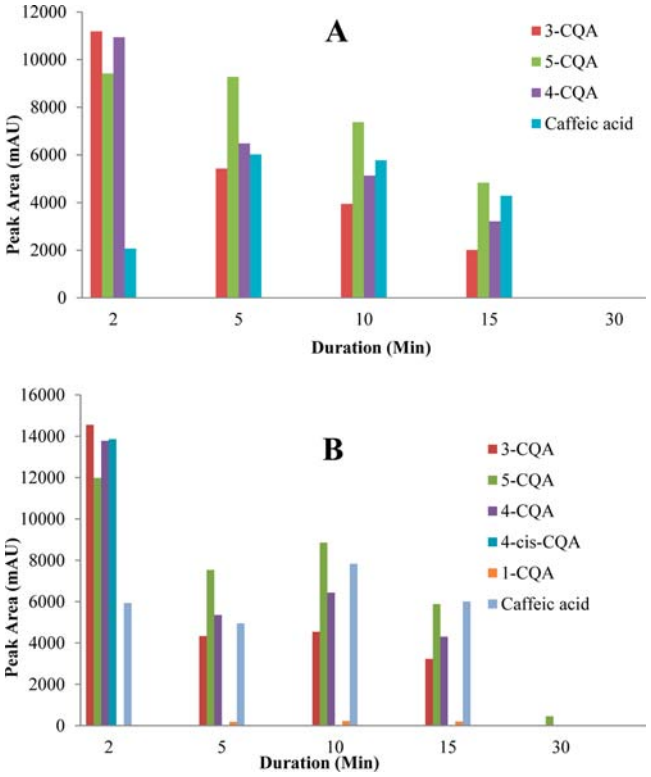

**Figure 6.** Comparison between the peak areas of compounds formed during TMAH treatment of (A) 5-CQA (**3**) with *p*-coumaric acid (*p*CoA) and (B) 5-CQA with ferulic acid (FA).

4-CQA was observed to survive the base treatment. Unexpectedly, we identified two chlorogenic acid lactones as minor by products, namely, 3-CQL (**37**) and 4-CQL (**38**) in this sample. Under basic conditions the dehydrated product of caffeoylquinic acid must be in continuous equilibrium with caffeoylquinic acid. A single heterodiacyl chlorogenic acid was observed in the chromatogram in the form of caffeoyl-feruloylquinic acid (**49**) after 5−15 min of basic hydrolysis (Figure 6). Figure 7 shows the fragmentation pathway for compound (**49**), in which it loses the ferulic acid moiety and undergoes simultaneous dehydration to give *m*/*z* 335 as a base peak in $MS^2$. Furthermore, in $MS^3$ the dehydrated caffeoylquinic acid entity undergoes decarboxylation to give a base peak at *m*/*z* 291 and also shows the presence of ferulic acid as a secondary peak at *m*/*z* 193. This fragmentation pathway for a caffeoyl-feruloylquinic acid was found to be inconsistent with the fragmentation pathways of 1-caffeoyl-3-feruloylquinic acid, 3-feruloyl-5-caffeoylquinic acid, *cis*-4-feruloyl-5-caffeoylquinic acid, 4-feruloyl-5-caffeoylquinic acid, 4-caffeoyl-5-feruloylquinic acid, and *cis*-3-feruloyl-5-caffeoyl-quinic acid previously reported by Jaiswal et al.[21] Hence, the regiochemistry of the acyl groups in caffeoyl-feruloylquinic acid (**49**) remains unknown.

**Intramolecular Acyl Migration: Model Roasting of 2−5 and 8−10.** Compounds 3-CQA (**2**), 5-CQA (**3**), 4-CQA (**4**), 1,3-diCQA (**5**), 3,4-diCQA (**8**), 3,5-diCQA (**9**), and 4,5-diCQA (**10**) were heated at 180 °C for 12 min separately to study the intramolecular acyl migration in the absence of solvents in conditions closely mimicking coffee roasting. From the data summarized in Table 2, we clearly see that only 4-CQA (**4**), 3,4-diCQA (**8**), and 3,5-diCQA (**9**) undergo transformations to generate various dehydrated products mainly in

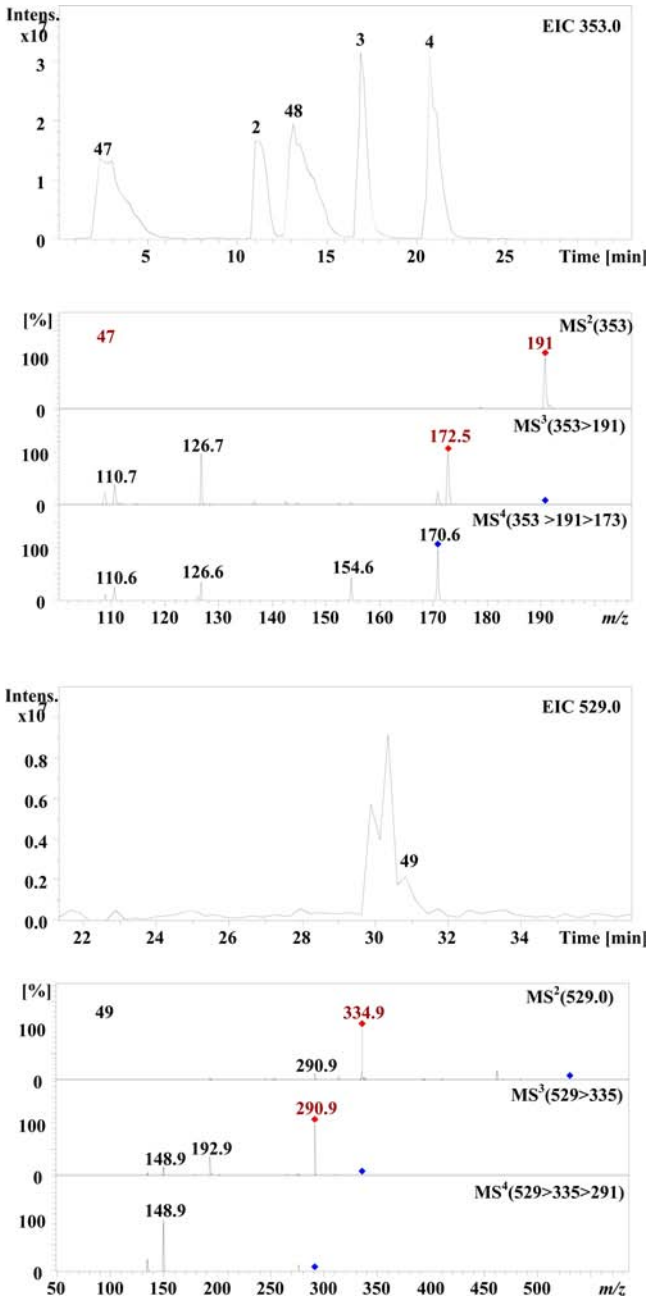

**Figure 7.** EIC and fragmentation patterns for 1-*cis*-caffeoylquinic acid (**47**) at *m*/*z* 353 and caffeoyl-feruloylquinic acid (**49**) at *m*/*z* 529 in transesterification induced by TMAH.

the form of caffeoylquinic acid lactones. In the case of monoacylated chlorogenic acid reference standards, only 4-CQA undergoes acyl migration with simultaneous dehydration. 3-CQL (**37**) was found to be the predominant transformation product in the heat treatment of 4-CQA. 5-Caffeoyshikimic acid was also identified but was found to be the least favored dehydration product after 4-CQL. In this experiment, we observed that 3-CQL (**37**) was forming predominantly over 4-CQL (**38**) irrespective of the substrate, possibly because of the additional stability gained by the equatorial position that 3-CQL assumes in the inverted chair conformation required for stereoelectronic reasons for lactonization. Therefore, we suggest that the dehydration processes such as lactone and shikimic acid formation at the quinic acid moiety follow acyl

| **10** | 4,5-diCQA | **10** | 46.3 | 26560 |

migration; that is, in the simulated roasting environment, acyl migration takes place before dehydration at the quinic acid moiety. Additionally, lactonization dominates over the alternative shikimate formation in the model roasting of all substrates (Table 2). 1,3-DiCQA (**5**) did not undergo noticeable transformation by the heat treatment, whereas 3,4-diCQA (**8**) generated most of the transformation products among all four di-CQAs. It is likely that the observed products 3-CQL (**37**) and 4-CQL (**38**) resulting from 3,4-diCQA (**8**) were formed by lactonization and loss of one of the two acyl moieties following the order of the processes as dissociation first and dehydration at the quinic acid moiety later, attributed to the fact that both of the caffeoyl lactones possess similar peak areas. 3,4-Di-*O*-caffeoyl-1,5-quinide (**46**) was preferably formed in the heat treatment of 3,4-diCQA. The presence of the two different peaks eluting at 51.2 and 52.4 min having the same fragmentation pattern as 3,4-diCQL (**46**) suggested the presence of a *cis* isomer of compound **46** (Figure 8). Both isomers of 3,4-diCQL (**46**) generate a base peak at $m/z$ 335 with virtually nonexistent secondary peaks confirming the regiochemistry of 3,4-diCQL.

Among the unchanged substrates throughout the heat treatment at 180 °C for 12 min, such as 5-CQA, 3-CQA, 1,3-diCQA, and 4,5-diCQA, the stability of 5-CQA (**3**) and 1,3-diCQA (**5**) to high temperatures was confirmed by heating them at 200 °C for 10 min.

**Transesterification (Intermolecular Acyl Migration): Model Roasting (Crossover Experiment).** In these sets of experiments, we explored the possibilities of transesterification or intermolecular acyl migration by carrying out crossover experiments in which 5-CQA was subjected to heat treatment in the presence of free acids such as ferulic acid and *p*-coumaric acid at 1:1 stoichiometry. In the first case an equimolar mixture of *p*CoA and 5-CQA (**3**) was heated. It was observed that 5-CQA (**3**) mostly remained unchanged by the heat treatment

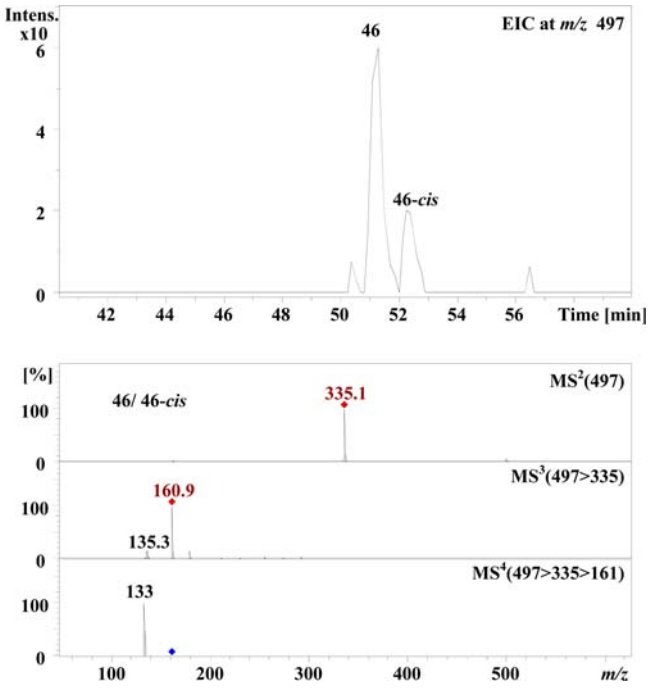

**Figure 8.** EIC and fragmentation patterns for the ion at $m/z$ 497 observed during model roasting.

with the peak area corresponding to 5-CQA accounting for 5 times the peak area of all the transformation products combined (Table 3). Again, caffeoylquinic acid lactones

| | | | **52** | 39.9 | 138 |
| | | | **52** | 41.9 | 500 |

dominated as the main transformation products. Because it was established earlier by Clifford et al.[3] that acyl migration takes place before dehydration in chlorogenic acid when there is still some water present in the sample, it can be assumed that the 5-acyl group migrates to positions $C_3$ and $C_4$ first and then both products undergo dehydration to yield the corresponding lactones in the form of 3-CQL and 4-CQL. 4-CQL (**38**) was formed in larger quantities if compared to 3-CQL (**37**). Only a single transesterification product was identified in the form of 4-*p*CoQA (**14**), which formed during model roasting (Table 3 and Figure 8). It is speculated that the formation of the 1,5-quinide takes place earlier, making $C_5$ on quinic acid unavailable for the possible condensation with *p*-coumaric acid; hence, we do not observe 5-*p*CoQA (**13**) but 4-*p*CoQA (**14**).

dx.doi.org/10.1021/jf5017384 | J. Agric. Food Chem. 2014, 62, 9160−9170

Model roasting experiment between 5-CQA (**3**) and ferulic acid (**31**) generated a larger number of transformation products compared to the number of transformation products detected from the same experiment with *p*CoA (**33**) and 5-CQA (**3**). A similar trend in terms of the number of transformed products was observed in the crossover experiment by TMAH treatment. The list of the transformation products in this experiment looks very similar to the list in Table 3. An additional two products are found to be the acyl migration products of 5-CQA. The acyl group in 5-CQA (**3**) was found to presumably migrate intramolecularly to produce 3-CQA (**2**) and 4-CQA (**4**), but the corresponding caffeoyllactones 3-CQL (**37**) and 4-CQL (**38**) were formed in greater quantity. The ratio of 3-CQL (**37**) to 3-CQA (**2**) was 11:1, whereas the ratio of 4-CQL (**38**) to 4-CQA (**4**) was found to be 1:1.3 because 4-CQL formed in higher quantity if compared to 3-CQL judged by comparison of the corresponding peak areas (Table 3). In this experiment it was observed that 5-CQA (**3**) remained unchanged by the heat treatment to an even greater extent than in previous experiments because the peak area under 5-CQA alone is >16 times the sum of peak areas of all the transformation products combined (Table 3). 5-FQA (**23**) was formed in considerable quantity, confirming intermolecular acyl migration between ferulic acid and 5-CQA (**3**) (Figure 9).

**Intramolecular Acyl Migration: Brewing of CGAs.** In these experiments we investigated acyl migration products of mono- and diacyl CGAs (**2**−**5** and **8**−**10**) formed during the brewing process (Table 4). Typically, the pH of a coffee brew is between 4.7 and 5.1. In our case the pH of the model brew was measured at 5.0. We observed that hot water also serves as a reactive reagent rather than just as a simple solvent in coffee brewing, similar to previous work on tea fermentation, where water was shown to be the key reagent in thearubigin formation.[24] Apart from the acyl migration products and *trans*−*cis* isomerization (*cis*-caffeoylquinic acids) products, the resulting chromatograms showed transformation products referred to here as hydroxy-dihydrocaffeoylquinic acids arising

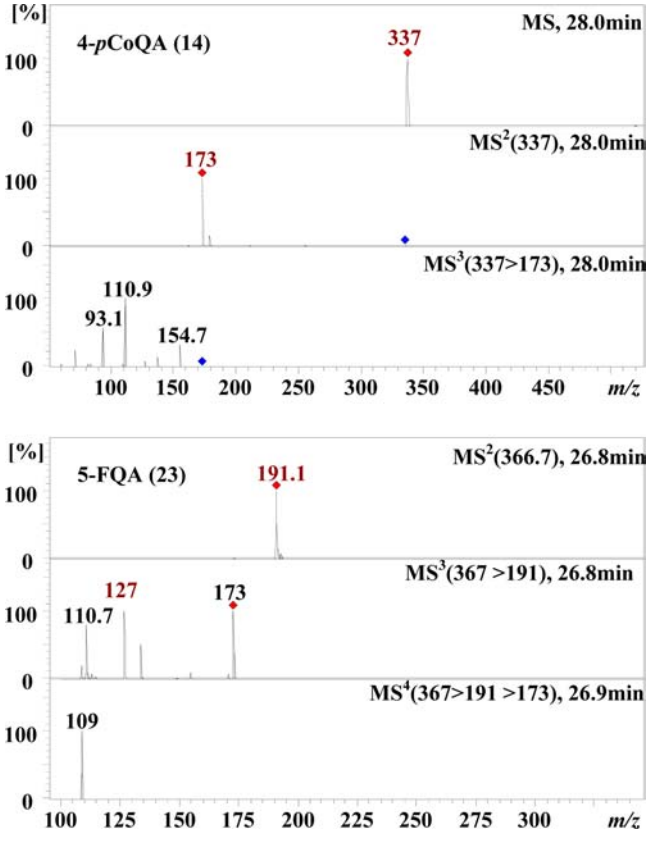

**Figure 9.** $MS^3$ and $MS^4$ of 4-*p*CoQA (**14**) and 5-FQA (**23**), respectively, observed during crossover experiment by model roasting.

through conjugate addition of a water molecule to the olefinic cinnamoyl moiety.[25]

Similar to the model roasting experiment, 5-CQA (**3**) did not show any acyl migrated products in hydrolysis (brewing). The acyl moiety in 4-CQA (**4**) and 3-CQA (**2**) did not migrate to $C_5$ of the quinic acid, but acyl moiety interchange between $C_3$ and $C_4$ was observed due to the stability of the *ortho*-ester intermediate arising from the *cis* geometry (Figure 4). Acyl migration to $C_5$ from $C_3$ and $C_4$ was found to be highly pH dependent as we only observed it in the case of basic hydrolysis.

Cynarin (1,3-diCQA) did not show any transformation products under acidic brewing conditions after 5 h of reflux. Among the remaining diacylated reference standards, 3,4-diacylated esters were preferably formed irrespective of the substrate. This observation can possibly be attributed to the fact that the parallel aromatic rings allow for $\pi-\pi$ stacking interactions providing added stability to the 3,4-diCQA in the minimum energy chair conformation of qunic acid moiety. By comparing the peak areas in the UV chromatogram it was observed that the decomposition of the di-CQAs to produce mono-CQAs was taking place in minute quantity as compared to the basic hydrolysis experiment to study intermolecular acyl migration. In the case of monoacylated chlorogenic acids, up to 1.5−2.0% of the chlorogenic acids were transformed into their hydroxylated derivatives and the diacylated chlorogenic acids up to 4−4.5% if the relative peak areas in EIC are considered.[25] However, their peak areas in UV chromatograms were found to be negligible. The structures for the water addition compounds can be found in our previous publication[25] and are not further commented on here.

In this work we investigated acyl migration under three conditions relevant to the processing of coffee, aqueous basic and acidic and dry roasting conditions. Under all three conditions acyl migration was observed, however, dominating only as a pathway under aqueous basic conditions. Under aqueous acidic and dry roasting conditions acyl migration products were in contrast observed as minor products. Acyl migration in aqueous solution is under typical chlorogenic acid concentrations in a coffee brew predominantly a reversible intramolecular process, showing a strong pH dependency. We could furthermore show that the acyl migration phenomena occurs in dry roasting before dehydration takes place in the quinic acid moiety. Acyl migration is facilitated in the presence of the liquid media, as the esters present on the $C_3$ position of the quinic acid are prone to hydrolysis of the ester bond, rather than undergoing acyl migration in any experimental condition. In crossover experiments (TMAH and model roasting), 5-CQA (**3**) ferulic acid compared to *p*-coumaric acid showed increased reactivity generating a large number of transesterification products. A significant proportion of 3-CQA and 4-CQA quantities and their derivatives in a cup of coffee must be assumed to be a result of acyl migration occurring in roasting and brewing processes originating from 5-CQA.

cytokines) in macrophages stimulated with LPS have not yet been investigated. The aim of this study was to determine the effects on these mediators and cytokines and possible regulation mechanisms of 6-DG in LPS-treated macrophages.

## MATERIALS AND METHODS

**Reagents.** LPS (*Escherichia coli* O26:B6), negative control esiRNA (EHURLUC), and STAT1 esiRNA (EMU071921) were all purchased from Sigma Chemical (St. Louis, MO, USA). All other chemical buffers and reagents were purchased at the highest commercial purity and quality possible.

**DG Purification Procedures.** The rhizomes (25.6 kg) of *Z. officinale* were chipped and air-dried and extracted repeatedly with $CHCl_3$ (50 L × 4) at room temperature. The combined $CHCl_3$ extracts (896.5 g) were then evaporated and further separated into 20 fractions by column chromatography on silica gel (3.8 kg, 70−230 mesh) with *n*-hexane/chloroform/methanol. Fraction 8 (81.2 g), eluted with chloroform/methanol (60:1), was next subjected to silica gel CC (chloroform/methanol (100:1)) and yielded 6-DG (163 mg). The other fractions were further processed for other components unrelated to this study. The identity and purity of 6-DG were confirmed by NMR and HPLC.[20,22,23]

**Cytotoxicity.** The cytotoxic properties were evaluated in an Alamar Blue assay. Briefly, 200 μL of 10% Alamar Blue reagent (Serotec, BUF012B) was added into medium, $2 \times 10^4$ cells/200 μL/well, the cells of which were pretreated with indicated concentrations of 6-DG 30 min before stimulation with LPS (100 ng/mL) for 24 h. Cells were incubated with Alamar Blue reagent (37 °C, 5% $CO_2$) for 4 h, and the colorimetric readings were evaluated with the ELISA plate reader at 570 and 600 nm.

**Cell Culture.** RAW 264.7 cells, derived from murine macrophages, were obtained from the Bioresource Collection and Research Center (BCRC 60001). RAW 264.7 cells were cultured in DMEM (with 10% heat-inactivated fetal bovine serum, 100 U/mL penicillin, 100 μg/mL streptomycin, 25 g/mL amphotericin B, and 2 mM L-glutamine, all purchased from Biological Industries (Kibbutz Beit Haemek, Israel)). Various concentrations of 6-DG were dissolved in DMSO.

**Nitrite Quantification.** The nitrite concentration in the supernatant was measured as an indicator of NO production, determined by Griess Reagent System (G2930, Promega Biotech Co., Ltd., Madison, WI, USA) according to the manufacturer protocols. The cells ($4 \times 10^5$ cells/mL) were pretreated with indicated concentrations of 6-DG for 30 min before stimulation with LPS (100 ng/mL) for 24 h.

**Extraction of Cytosol, Nuclear, and Total Proteins of RAW 264.7 Cells.** RAW 264.7 cells were plated at a density of $5 \times 10^6$ cells in each 6 cm dish. Cells were pretreated with 25 μM 6-DG and harvested protein of cytosol and Nuclear at 15, 30, 60, 120 min after stimulation with LPS. Buffer A (10 mM HEPES (pH 7.9), 10 mM KCl, 1.5 mM $MgCl_2$, 10 mM DTT, 4% 25× protease inhibitors (PI), 0.375% NP-40 in $ddH_2O$) and buffer C (20 mM HEPES, 400 mM NaCl, 1 mM EDTA, 1 mM EGTA, 10 mM DTT, 4% 25× PI in $ddH_2O$) were prepared immediately before use. The supernatant was removed and followed by two washings of 1× PBS. Then 300 μL of buffer A was added into each dish and ensuring that buffer A covered cells completely. Ten minutes later, the edges of the dish were knocked to allow cells to shed from the bottom of dish, and then a scraper was used to collect cells. After 10 s of vortex mixing, the cytosol extract was prepared by 1 min centrifugation at 10000*g*. The resulting pellet contained the nuclear extract. The pellet was washed twice with 1× PBS, then 100 μL of buffer C was added into each sample, and the nuclear envelope was broken by using a stir bar for 20 min. Nuclear extracts were prepared by 10 min centrifugation at 10000*g*. All above procedures should be performed on ice. In addition, total proteins were extracted from RAW 264.7 cells with RIPA buffer,[23] and the protein concentration was measured using the bicinchoninic acid assay (BCA) (Thermo Fisher Scientific, Rockford, IL, USA).

**Reverse Transcription (RT) PCR.** Total RNA was isolated from RAW 264.7 cells using an RNAspin Mini RNA isolation kit according to the manufacturer's instructions (GE Healthcare, 25-0500-71). The level of iNOS, COX-2, or GAPDH mRNA expression was assessed by RT-PCR. Briefly, total RNA (2 mg) was reverse-transcribed into cDNA using random primers (Promega, C1181) and oligo-dT (Promega, C1101) DNA amplification in 20 cycles of iNOS, 94 °C for 30 s, 60.5 °C for 40 s, and 72 °C for 30 s, followed by a 2 min extension at 72 °C. The thermal cycle conditions of COX-2 were 20 cycles of amplification (94 °C for 30 s, 52 °C for 40 s, 72 °C for 30 s, and 72 °C for 2 min). DNA amplification of GAPDH thermal cycle condition was 94 °C for 30 s, 56 °C for 40 s, and 72 °C for 30 s, followed by a 2 min extension at 72 °C. The PCR products were separated by electrophoresis on a 1.5% agarose gels and visualized by SYBR Safe DNA Gel Stain (Invitrogen, S33102).

The amplification of GAPDH acted as an internal control for sample loading. PCR was performed using the following primers:

iNOS forward primer, 5′-CCCTTCCGAAGTTTCTGGCAG-CAGC-3′′ reverse primer, 5′-GGCTGTCAGAGAGCCTCGTGG-CTTTGG-3′.

COX-2 forward primer, 5′-CATTGATGGTGGCTGTTTTG-3′; reverse primer, 5′-GTTGCTGGGGGAAGAAATGT-3′.

GAPDH forward primer, 5′-TCCACCACCCTGTTGCTGTA-3′; reverse primer, 5′-ACCACAGTCCATGCCATCAC-3′.

**Western Blotting.** Western blotting was performed as mentioned previously.[23] Briefly, equal amounts of total proteins were resolved by 10% SDS−polyacrylamide gel and transferred onto polyvinylidene difluoride membranes. The membrane was blocked for 30 min at room temperature with blocking buffer (20 mM Tris-HCl, pH 7.4, 125 mM NaCl, 0.2% Tween 20, 2% BSA, and 0.1% sodium azide). Antibodies were all purchased from Cell Signaling Technology, except iNOS (610432, BD PharMingen, San Diego, CA, USA), tubulin (sc-5286, Santa Cruz), GAPDH (MAB374, Millipore), and Lamin B (sc-6216, Santa Cruz). The membrane was then incubated with the primary antibody of COX-2, iNOS p-Erk1/2 (9100), Erk (4695), p-p38 (9215S), p-38 (9212), p-JNK (9250), JNK (9258S), p-c-Jun (9164), c-Fos (2250), p-IκB (9246), p-p65 (3033S), STAT1 (9172), p-STAT1 (9171), STAT3 (4904), p-STAT3 (9134), p-JAK2 (3776), tubulin, GAPDH, or Lamin B overnight. The membrane was incubated with blocking buffer and primary antibody overnight at 4 °C. The membranes were subsequently probed with anti-mouse (sc-2005, Santa Cruz) or anti-rabbit (7074, Cell Signaling) or anti-goat IgG (81-1620, Zymed) antibody conjugated to horseradish peroxidase and visualized using enhanced chemiluminescence (ECL, Amersham). The densities of the bands were quantitated with the GelPro 32 analysis program.

**Transient Cell Transfection and Luciferase Assay.** Transfection of RAW 264.7 cells was performed with TurboFect Transfection Reagent (Thermo Scientific) according to the manufacturer's instructions. Briefly, cells were plated onto 60 mm dish at a density of $2 \times 10^6$ cells/dish for 18−24 h and then transfected with 5 mg of pNF-kB-luc or p-AP-1-luc plasmid, cells were cultured for 24 h and then reseed cell onto 24-well plate at a density of $2 \times 10^5$ cells/plate overnight, then pretreated with 6-DG for 30 min before 100 ng/mL LPS treatment. Cells were harvested after 6 h, and luciferase activity was assessed using the Luciferase reporter assay system (Promega) according to manufacturer's instructions.

**Enzyme-Linked Immunosorbent Assay (ELISA).** RAW 264.7 cells were plated at a density of $4 \times 10^5$ cells per well in 12-well plates. Cells were pretreated with different concentrations of 6-DG, and the supernatants were collected 24 h later after stimulation with LPS. The amounts of various proteins were measured by ELISA kits for IL-10 (eBioscience; 88-104-88), IL-6 (eBioscience; 88-7064-88), IL-6 (eBioscience; 88-7064-88), IL-1β (eBioscience; 88-7013-88), TNF-α (eBioscience; 88-7324-88), and PGE2 (R&D Systems; KGE004), respectively. Each assay was performed in duplicate.

**Electroporation.** Negative control esiRNA and STAT1 esiRNA were transfected into RAW 264.7 cells by using Amaxa Nucleofector (Lonza), following the manufacturer's protocol (Nucleofector solution V, Nucleofector program D-032), respectively, with 1.5 ng of esiRNA/$2 \times 10^6$ cells. Cells were incubated at 37 °C for 24 h. Cells were then

pretreated with 25 $\mu$M 6-DG 30 min before stimulation with 100 ng/mL LPS, and the supernatant was harvested after 24 h.

**Statistical Analysis.** All assays were performed in triplicate, and the mean values were calculated. The data were subjected to analysis of variance (ANOVA), and Student's $t$ tests were used to assess differences between means. Significant differences were concluded at a level of $p < 0.05$.

## RESULTS

**6-DG Has an Unapparent Toxicity and Suppresses iNOS in RAW 264.7 Stimulated with LPS.** To investigate the cell toxicity of 6-DG (Figure 1), four indicated concentrations (5, 10, 25, and 50 $\mu$M) were selected to treat macrophages stimulated with LPS, as shown in Figure 2A. The cell toxicity of 6-DG was determined by Alamar Blue assay and showed there was no significant difference between these four concentrations compared to the vehicle. Results revealed that pretreatment with 25 and 50 $\mu$M 6-DG was more efficient in the attenuation of LPS-induced iNOS protein expression than post-treated 6-DG. However, no suppression effect was found in the group with 6-DG post-treatment after LPS given (Figure 2B,C). 6-DG treatment for 48 h alone has no effect on the cell viability of RAW 264.7 cells at different concentrations, as shown in Figure 2D.

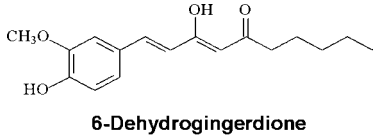

**Figure 1.** Chemical structure of 6-DG.

**6-DG Down-regulates the IKK-NF-$\kappa$B Pathway To Inhibit the Expression of p-p38.** When LPS stimulates macrophages, MAPK pathways are reported to regulate the transcription factor NF-$\kappa$B and AP-1 (c-Jun/c-Fos).[9] Western blotting data demonstrated that pretreatment with 6-DG (25 $\mu$M) down-regulates the phosphorylation of both p38 and I$\kappa$B induced by LPS for 30 min and inhibits the expression of p-p65 induced by LPS for 15 min, but will up-regulate the phosphorylation of JNK induced by LPS for 10 min. There was no effect on p-Erk, p-c-Jun, or c-Fos expression induced by LPS (Figure 3). 6-DG significantly suppressed the NF-$\kappa$B signaling pathway (Figure 3C) but had little effect on the AP-1 signaling pathway (Figure 3D). According to a past study, p38 MAPK regulates the LPS-induced NF-$\kappa$B activation pathway through two different mechanisms that contribute to the phosphorylation of I$\kappa$B-$\alpha$ or p65 NF-$\kappa$B.[24] It may be concluded that 6-DG might down-regulate both I$\kappa$B and p65 phosphorylation by attenuating the phosphorylation of p38 (Figure 3A,B).

**6-DG Inhibits LPS-Induced Nitrite and PGE2 Production via the Suppression of iNOS and COX-2 Expression.** COX-2 and iNOS play the key roles in the production of PGE2 and NO during inflammation, and COX-2 and iNOS inhibitors block their synthesis.[6,13] Our PCR data revealed that

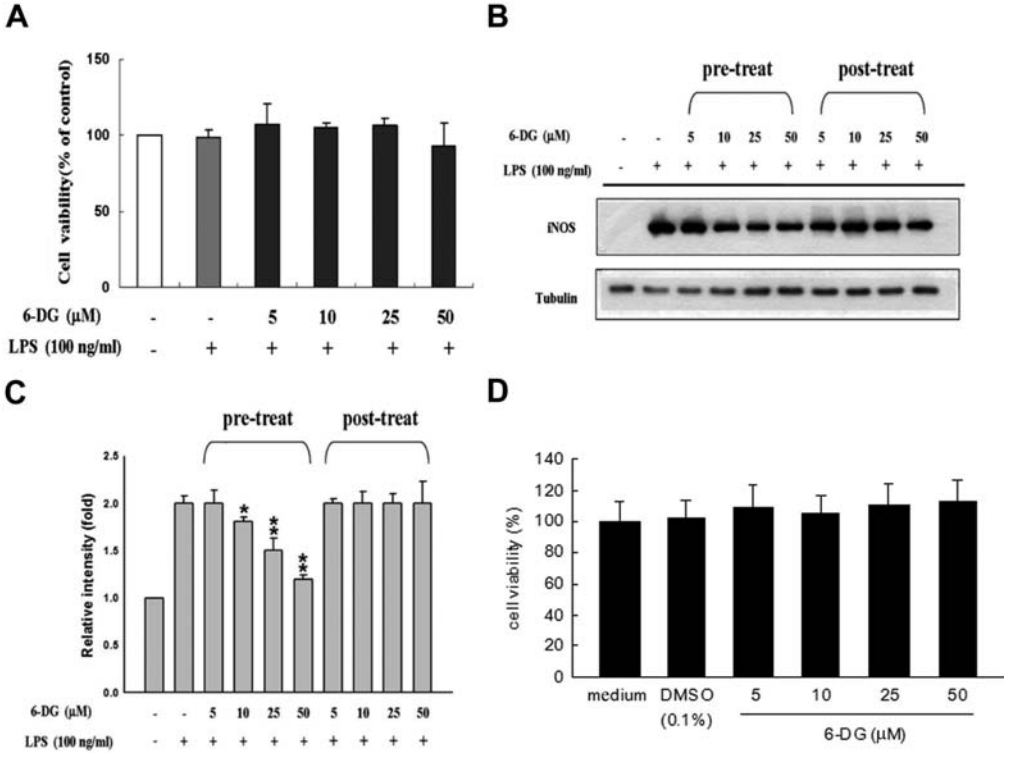

**Figure 2.** Effect of 6-DG treatment in RAW 264.7 stimulated with LPS. (A) Effects of 6-DG in cell viability. Cells were pretreated with 6-DG for 30 min in various concentrations (5, 10, 25, and 50 $\mu$M) before being stimulated with LPS (100 ng/mL) for 24 h and then measured by Alamar Blue assay. Data are expressed as the mean ± SD of three independent experiments. (B) Different treatment conditions: pretreatment where 6-DG was administered 30 min before LPS and post-treatment where 6-DG was administered 30 min after LPS treatment. (C) Corresponding quantification data of iNOS protein levels. (D) 6-DG treatment for 48 h alone to examine the cell viability in RAW 264.7. Results show the mean ± SD of three experiments. (*) $p < 0.05$ and (**) $p < 0.001$ versus LPS treatment, by Student's $t$ test, $n = 3-5$. The relative intensity was normalized to tubulin and relative to the control.

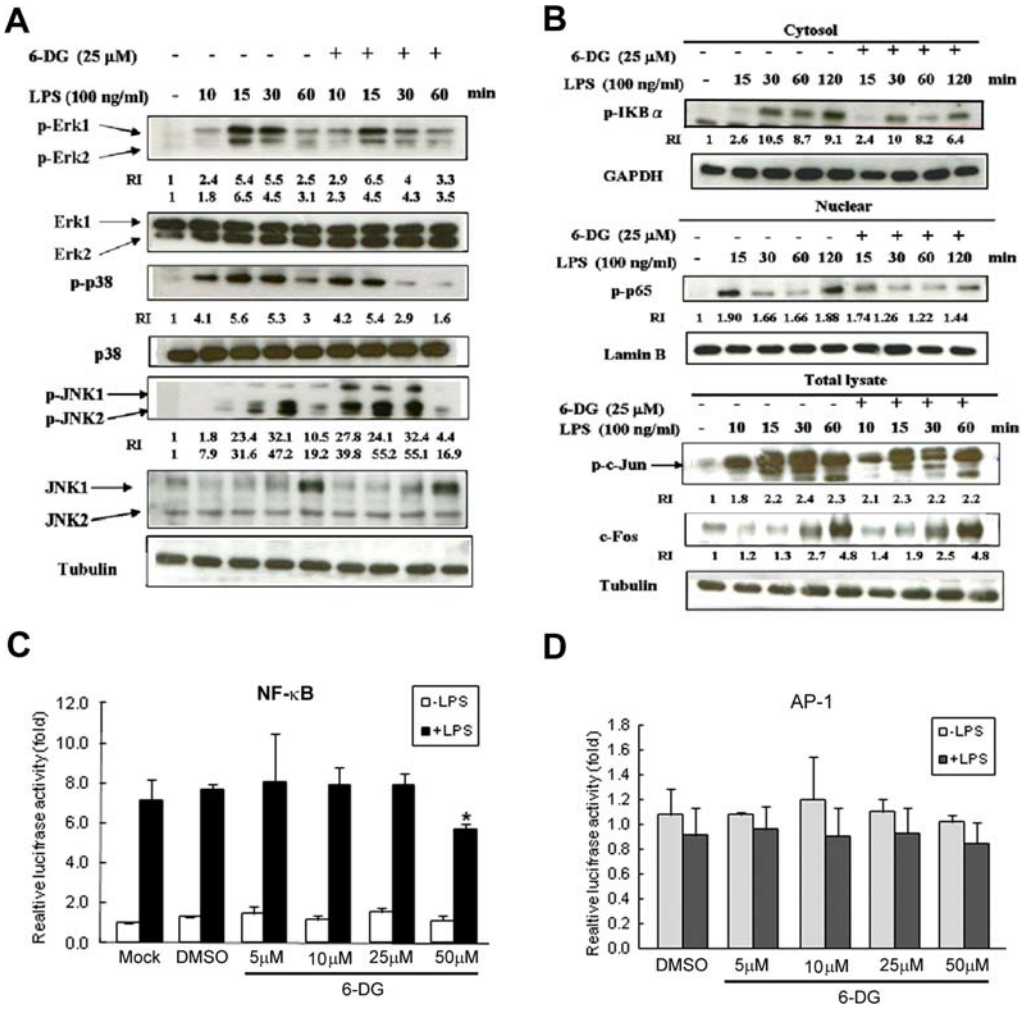

**Figure 3.** Effects of 6-DG on LPS-induced phosphorylation and the MAPK and Ikk-NFκB pathway. (A) Western blot analysis of the phosphorylation of Erk, p38, and JNK expression induced by LPS. Cells were pretreated with 25 μM 6-DG for 30 min, and the total protein was harvested at four different time points (10, 15, 30, and 60 min) after stimulation with LPS (100 ng/mL). (B) Western blot analysis of the phosphorylation of p65 NF-κB, and IκBα induced by LPS. Cells were pretreated with 25 μM 6-DG for 30 min, and cytosol and nuclear extract were harvested at four different time points (15, 30, 60, and 120 min) after stimulation with LPS (100 ng/mL). Expression levels of p-c-Jun and c-Fos were determined by Western blot analysis. Cells were pretreated with 25 μM 6-DG for 30 min, and total protein was harvested at four different time points (10, 15, 30, and 60 min) after stimulation with LPS (100 ng/mL). RAW 264.7 macrophages were transfected with the luciferase reporter pAP-1-luc (C) and pNF-κB-luc (D). Twenty-four hours after transfection, cells were pretreated with 6-DG for 30 min and then exposed to LPS (100 ng/mL) at the indicated concentrations. After 6 h, the luciferase activity was determined. (*) $p < 0.05$ versus LPS treatment group. Bars represent the mean ± SD of three independent experiments. All intensity of results was normalized to internal control and relative to the control. These experiments were repeated three times with similar results.

pretreatment with 5, 10, 25, and 50 μM 6-DG could inhibit the RNA expression of both COX-2 and iNOS induced by LPS (Figure 4A). Western blotting results indicated that pretreatment with 10, 25, and 50 μM 6-DG can inhibit the protein production of both COX-2 and iNOS induced by LPS (Figure 4B). Furthermore, pretreatment with 5, 10, 25, and 50 μM 6-DG significantly down-regulated the production of both NO and PGE2 induced by LPS (Figure 4C,D).

**6-DG Suppresses LPS-Induced TNFα, IL-6, IL-1β, and IL-10 Production.** In patients with sepsis, plasma concentrations of TNF-α, IL-1β, IL-6, and IL-10 were significantly higher in nonsurvivors than in survivors.[3] According to our ELISAs, pretreatment with 25 and 50 μM 6-DG was found to significantly inhibit the production of TNF-α, IL-6, and IL-10 in RAW 264.7 macrophages through LPS simulation (Figure 5A,C,D), and pretreatment with 5, 10, 25, and 50 μM 6-DG could inhibit the secretion of IL-1β induced by LPS (Figure 5B).

**6-DG Inhibited STAT3-Mediated Genes through Elevating the p-STAT1/p-STAT3 Ratio.** A past study indicated that LPS-stimulated macrophages could activate JAK2, STAT1, and STAT3.[25] Many studies revealed that the JAK−STAT pathway is one of the main pathways that regulated cytokine gene expression. Western blotting data showed that pretreatment with 25 μM 6-DG can decrease the phosphorylation of both JAK2 and STAT3 (ser) after stimulation with 100 ng/mL LPS as shown in (Figure 6A). Reversely, pretreatment with 25 μM 6-DG enhanced the expression of p-STAT1 (Figure 6A). There were no changes of these three total protein levels.

STAT1 and STAT3 mutually inhibited one another, and another study indicated that STAT1 levels and activity increased in the absence of STAT3.[26−28] Our results revealed

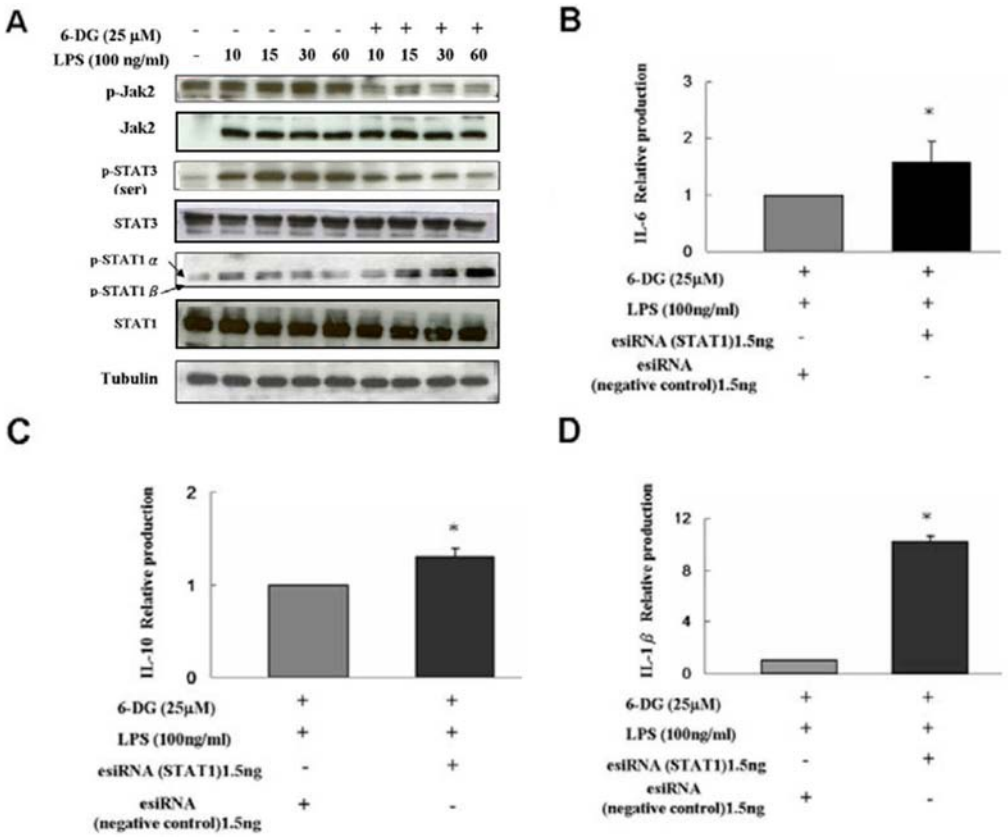

**Figure 6.** Effects of 6-DG on LPS-induced p-JAK2, p-STAT1, and p-STAT3 expression and effects of STAT1 knockdown on 6-DG inhibition of IL-1$\beta$, IL-6, and IL-10 productions induced by LPS. (A) Western blot analysis of phosphorylated and total amount of key proteins in the JAK/STAT pathway induced by LPS. Intensities of the bands for p-JAK2, p-STAT3, p-STAT1 were normalized to tubulin and relative to the control. There were no changes of these three total protein levels. (B–D) Cells were transfected with negative control or STAT1 esiRNA for 24 hand then pretreated with 6-DG for 30 min in various concentrations (5, 10, 25, and 50 $\mu$M) before stimulation with LPS (100 ng/mL) for 24 h. The concentrations of IL-1$\beta$, IL-6, and IL-10 were meausred by using ELISA. Results show the mean ± SD of three experiments. (*) $p < 0.05$ versus LPS treatment, by Student's $t$ test, $n = 3–5$.

down experiments confirmed this assumption, whereas the knockdown of STAT1 significantly reversed the 6-DG inhibition of LPS-induced cytokines (IL-6, IL-1$\beta$, and IL-10) (Figure 6B–D).

## DISCUSSION

Our study demonstrated 6-DG, one novel component of ginger, restrained several key inflammatory responses in RAW 264.7 macrophages induced by LPS and further investigated their potential molecular regulation mechanisms. 6-DG has the potent ability to inhibit the production of several major LPS-induced inflammatory mediators and cytokines, including NO, PGE2, IL-1$\beta$, IL-6, IL-10, and TNF-$\alpha$ induced by LPS via the regulation of several inflammation-related signal transduction pathways, including IKK-NF-$\kappa$B, p38, and JAK2/STAT1/STAT3.

The inflammation response is a complex reaction of the immune system regulated by many inflammatory mediators, such as NO, prostaglandins, and cytokines. An overproduction of iNOS-derived NO and COX-2-derived PGE2 can have cytotoxic effects in pathological processes, especially in inflammatory and autoimmune disorders.[29] These mediators play a regulatory role in a variety of physiological and pathological processes following an immune response and inflammation.[30] In addition, macrophages play a central role to mediate several immunopathological conditions and inducing overexpression of the pro-inflammatory mediators of the inflammatory process.[31] In the present study, we showed that the pretreatment of LPS-stimulated RAW 264.7 macrophages with 6-DG (5–50 $\mu$M) inhibited COX-2 and iNOS expression, thereby suppressing COX-2-derived PGE2 and iNOS-derived NO production (Figure 4). PGE2 has been proved able to up-regulate the levels of both IL-10 and IL-6 produced by activated murine macrophages.[32] Moreover, 6-DG suppressed LPS-induced TNF-$\alpha$ and IL-1$\beta$ production in RAW 264.7 macrophages. These results suggest that 6-DG exerts its anti-inflammatory effects via the suppression of inflammatory enzymes and mediators such as iNOS, COX-2, NO, PGE2, TNF-$\alpha$, and IL-1$\beta$ (Figures 4 and 5).

Recent studies showed that emphasis on attenuating inflammatory response may exacerbate the progressive development of immunosuppression.[3,33,34] MAPKs regulate inflammatory and immune responses,[35] and the MAPK signaling pathways are known to be involved in expressing iNOS and COX-2, as well as producing pro-inflammatory cytokines in LPS-induced macrophages.[36] The inhibition of p38 MAPK pathways is sufficient to block the induction of pro-inflammatory mediators by LPS.[37] One of the past studies suggested that p38 MAPK mediates the LPS-induced NF-$\kappa$B activation pathway through two different mechanisms that contributed to the phosphorylation of p65 NF-$\kappa$B.[24] NF-$\kappa$B activation regulates many gene encoding inflammatory

dx.doi.org/10.1021/jf501665v | J. Agric. Food Chem. 2014, 62, 9171–9179

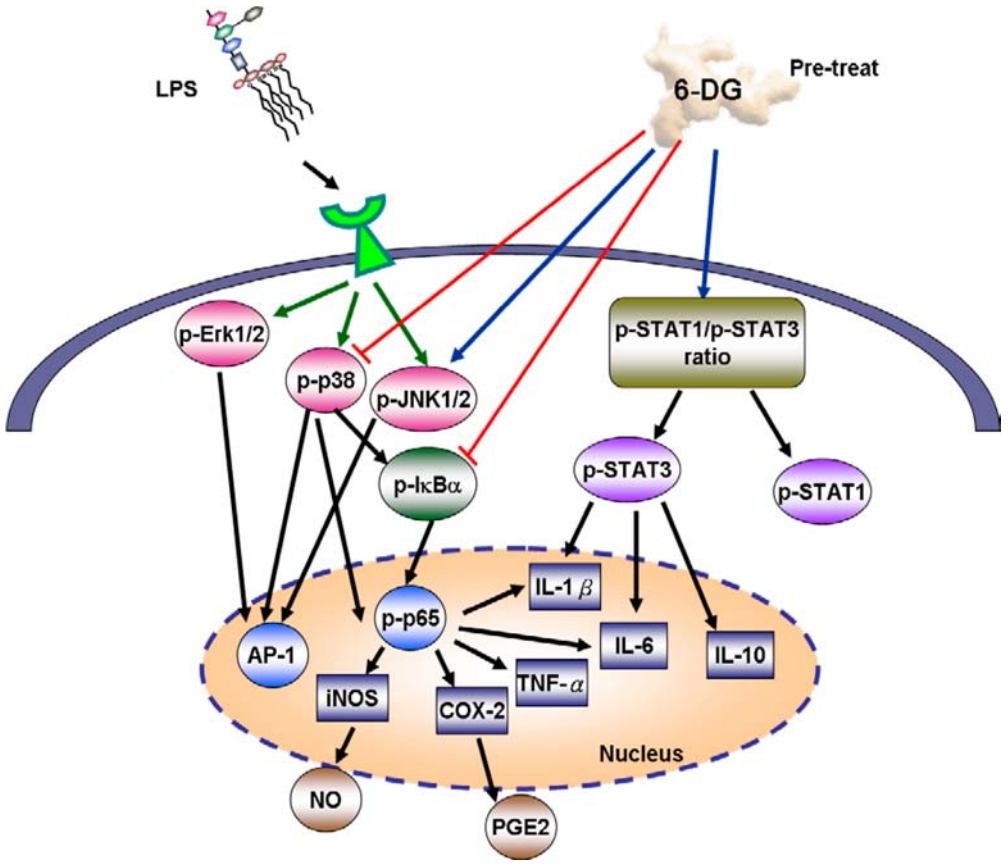

**Figure 7.** Schematic representation of suppression of LPS-induced production of NO, PGE2, IL-1$\beta$, IL-6, and TNF-$\alpha$ on 6-DG may be through the inhibition of p38 and I$\kappa$B$\alpha$ phosphorylation to prevent p-p65 NF$\kappa$B from entering the nucleus. Besides, 6-DG decreased LPS-induced IL-1$\beta$, IL-6, and IL-10 may be through elevating the p-STAT1/p-STAT3 ratio and down-regulating those genes (IL-1$\beta$, IL-6, and IL-10) mediated by STAT3.

mediators, and our results suggested that 6-DG may down-regulate both I$\kappa$B and p65 phosphorylation by attenuating the phosphorylation of p38 (Figure 3) expression and further decreases the expression of iNOS, COX-2, IL-1$\beta$, IL-6, TNF-$\alpha$ (Figures 4 and 5).

Another important pathway in inflammatory mediator production is Janus-kinase/signal transducers and the activators of transcription (Jak/STAT) pathway.[38] Prompt activation of JAK2, STAT1, and STAT3 was demonstrated after LPS stimulation. STAT1-mediated production will regulate pro-inflammatory mediators, such as COX-2[39] and iNOS.[40] Another previous study indicated that STAT3 activation is also critical for IL-1$\beta$,[41] IL-6,[42] and IL-10[43] production. A recent study indicated the regulatory mechanism of iNOS gene expression via cooperation of ISGF3 (a complex containing STAT1, STAT2, and IRF9 subunits) and NF-$\kappa$B.[44] The DNA binding for STAT3 in the promoter of acute-phase proteins was found to compete with NF-$\kappa$B.[45] Our data showed that 6-DG could inhibit the expression of p-p65 NF-$\kappa$B, but increase the expression of STAT1, and we presume that 6-DG decreases the expression of iNOS through the disruption of ISGF3 and NF-$\kappa$B cooperation (Figure 6A). Past research revealed that the overexpression of STAT1 suppresses the COX-2 promoter activity in insulin-secreting RINm5F cells.[46] Our data indicated 6-DG increased p-STAT1 (Figure 6A), but suppressed COX-2 (Figure 4), which might link to this regulation mechanism. STAT1 and STAT3 have similar structures and were found to not only act as functional antagonists but also work to mutually inhibit one another.[26] A previous study revealed STAT1 levels and activity elevated in the absence of STAT3.[28] The balance of pSTAT1 and pSTAT3, which was investigated in cancer immunity, played a pivotal role in regulation of cancer immune responses.[47,48] The higher pSTAT1/pSTAT3 ratio in tumor cells or in immune cells is related to the longer survival time of cancer patients.[47,49−51] However, this balance has not been studied in the regulation of IL-1$\beta$, IL-10, or IL-6 induced by LPS. On the basis of our Western blotting results, the expression of p-STAT increased and p-STAT3 was reduced (Figure 6A). We postulated that 6-DG may decrease LPS-induced IL-1$\beta$, IL-6, and IL-10 through elevating the p-STAT1/p-STAT3 ratio and down-regulating the genes (IL-1$\beta$, IL-6, and IL-10) mediated by STAT3. Furthermore, we have verified this assumption by using STAT1 esiRNA (Figure 6).

JNKs have been implicated in apoptotic response of cells exposed to pro-inflammatory cytokines.[52,53] We have previously shown that blocking the 6-DG-induced activation of JNK by chemical inhibitor could prevent Bax up-regulation and caspase-9 activity.[20] In this paper, our data suggested that 6-DG-induced JNK activation may contribute to 6-DG-induced mitochondrial apoptotic pathways.

In summary, we demonstrated that 6-DG decreased LPS-induced production of iNOS, COX-2, IL-1$\beta$, IL-6, and TNF-$\alpha$, which may be through the inhibition of p38 and I$\kappa$B$\alpha$ phosphorylation to prevent p-p65 NF$\kappa$B from translocating into the nucleus. Furthermore, 6-DG decreased LPS-induced IL-1$\beta$, IL-6, and IL-10 perhaps also through elevating the p-STAT1/p-STAT3 ratio and down-regulating the IL-1$\beta$, IL-6, and IL-10, mediated by STAT3 (Figure 7). The inhibition of

dx.doi.org/10.1021/jf501665v | J. Agric. Food Chem. 2014, 62, 9171−9179

p38 MAPK has been proposed as a mechanism by which the 5-hydroxytryptamine receptor type 3 (5-HT3) antagonist tropisetron could manifest its anti-inflammatory effects.[53] 6-DG is a potent antioxidant with 5-HT3 inhibitor.[20] Our experimental results indicate that 6-DG showed potential for the development of novel therapeutic targets for patients with sepsis in the future.

nism assumed in our previous work[18] contradicts the studies of Faria et al.[15] and Brazinha et al..[16] To clearly identify the limiting step of the oxygen transport through the cork stopper, a further study is required. This work presents the effect of oxygen pressure on diffusion coefficient to determine the underlying transport mechanism, Fick or Knudsen.

To answer this question, measurements of oxygen transfer through the cork stopper have been performed for different pressure gradients. Data are analyzed to determine permeabilities, and effective diffusion coefficients, interpreted by means of activation theory.

## THEORY

**Gas Transport.** Let us consider the diffusion of a gas through a semi-infinite wafer of solid when a pressure gradient of gas between the two sides of the wafer is imposed.

The permeability $P$ is defined by the general relationship

$$P = \frac{-J}{\nabla p} \approx \frac{-Je}{\Delta p} \tag{1}$$

where $J$ is the mass flow of gas diffusing through the membrane of thickness $e$, $\nabla_p$ the pressure gradient, $\Delta_p$ the difference in pressure between the two sides of the membrane, and $p$ the pressure. If one side of the wafer is maintained under vacuum while the other side is in contact with a gas under pressure $p$, $\Delta p = -p$.

In steady state, the mass flow $J$ can be calculated by doing a mass balance on the gas phase from the decrease in pressure as a function of time, using the equation

$$J = -\frac{VM}{RTS}\frac{\mathrm{d}p}{\mathrm{d}t} \tag{2}$$

where $V$ is the gas volume on one side on the cork wafer, $M$ the molecular weight of gas, $R$ the gas constant, $T$ the temperature, $S$ the cork surface in contact with the gas, and $\mathrm{d}p/\mathrm{d}t$ the derivative of pressure with time $t$.[18]

This expression is the same whatever the transfer mechanism of gas through cork, Darcy's, Knudsen's, or Fickian regime (or even a mix of them).

Therefore, combining eqs 1 and 2 leads to the permeability expression as

$$P = -\left(e\frac{VM}{RST}\right)\left(\frac{\mathrm{d}\ln p}{\mathrm{d}t}\right) \tag{3}$$

Integration of eq 3 leads to the relationship

$$\ln\left(\frac{p_0}{p}\right) = kt \tag{4}$$

with $p_0$ the initial pressure and $k$ the rate constant, which can be easily determined from measurements of the pressure with time by plotting $\ln(p_0/p) = f(t)$. The permeability can then be calculated from $k$ with the equation

$$P = \left(e\frac{VM}{RST}\right)k \tag{5}$$

In the Knudsen regime, the permeability is independent of the pressure as shown by the following expression of permeability, referred to as $P_K$:

$$P_K = \frac{d}{3}\sqrt{\frac{8M}{\pi RT}} \tag{6}$$

$d$ is the pore diameter in which the gas diffuses.

However, if the diffusion process follows a Fickian regime, the permeability, referred to in that case as $P_F$, can be dependent on the pressure according to the pressure range investigated and the shape of the adsorption isotherm of the diffusive species:

$$P_F = \frac{D\Psi M}{RT} \tag{7}$$

with the concentration factor

$$\Psi = \frac{C_a}{C_g} = \frac{C_a RT}{p} \tag{8}$$

$C_a$ is the concentration of gas adsorbed by the solid, and $C_g$ is the gas concentration at equilibrium (oxygen in the present case). Both $C_a$ and $C_g$ are given by the sorption isotherm of gas on the solid. $D$ is the diffusion coefficient, which can be calculated from $k$ using eqs 5 and 7.

**Transition State Theory.** In transition state theory, diffusion is considered as an activated process.[21] Thus, the dependence of the diffusion coefficient on the temperature is defined by an Arrhenius-type equation

$$D = D_0\, \mathrm{e}^{-\Delta G^*/k_B T} \tag{9}$$

where $D_0$ is a pre-exponential factor and $\Delta G^*$ the activation free enthalpy.

The activation free enthalpy $\Delta G^*$ corresponds to the energy barrier that the diffusing molecule has to get over for moving from one site to another one. As the free enthalpy is related to the pressure by the relationship

$$\mathrm{d}G = V\,\mathrm{d}p - S\,\mathrm{d}T \tag{10}$$

at constant temperature the entropic term vanishes and the dependence of the activation free enthalpy on the pressure is

$$\left(\frac{\partial G^*}{\partial p}\right)_T = \Delta V^* \tag{11}$$

where $\Delta V^*$ is the activation molecular volume.

By combining eqs 9 and 11 we obtain the relationship between the diffusion coefficient and the pressure

$$D = D_0\, \mathrm{e}^{-\Delta V^* p/k_B T} \tag{12}$$

or in the linear form

$$\ln D = \ln D_0 - \frac{\Delta V^*}{k_B T}p \tag{13}$$

Activation volume can be either positive (which means a decrease of $D$ with increasing $p$) or negative (an increase of $D$ with increasing $p$).[22] $\Delta V^*$ is the molecular volume difference between the activated complex and the nonactivated state. It represents the free space needed by a molecule to move from one adsorption site to another. Molecular transport is due to a redistribution of free volume and not due to a thermal activation, according to the free volume theory. Molecules can move from one site to another only when the local free volume exceeds a certain critical volume.[23]

## MATERIALS AND METHODS

**Cork Stopper.** Raw natural cork stoppers, from *Quercus suber* L. oak trees in the Mora (Portugal) production area, were supplied by the

dx.doi.org/10.1021/jf501918n | J. Agric. Food Chem. 2014, 62, 9180−9185

company Bouchons Trescases S.A. (Boulou, France). Cork was of high quality (class 0). Stoppers were neither washed nor surface treated (with paraffin or silicone) prior to use. Two cork wafers were cut with a cutting machine, Mecatome T201, with resinoid cutoff wheels of 180 mm diameter and 0.5 mm thickness (Presi S.A., France). They were cut following the section perpendicular to the axial axis of the stopper, which corresponds to the surface in contact with wine in a bottle. Cork wafers display a diameter of 24 mm and a thickness of 3 mm. Wafers were then inserted in a metal ring seal and stuck at the periphery of each axial section with Araldite 2012 glue to avoid gas transfer at the cork/ring interface. In this experiment, the cork wafer is not compressed and offers an effective surface area for oxygen transfer of $4.52 \times 10^{-4}$ m$^2$.

**Sorption of Oxygen.** Sorption of oxygen by cork was studied by means of a manometric device constructed in-house. The sorption isotherm of oxygen was measured on cubic pieces (around 3 mm edge) of cork at 298 K for pressure ranging from 0.1 to 1000 hPa. The mass of the sample was 1.028 g. Prior to sorption, cork was dehydrated at room temperature under vacuum (0.1 hPa) for 2 days.

**Oxygen Transfer.** Transfer of oxygen through cork wafer is measured using a homemade manometric apparatus. The equipment and the procedure used to determine the permeability and then the diffusion coefficient have been described in detail in a previous work.[18] For the present experiments, the initial pressure of oxygen is fixed between 50 and 800 hPa, at one side of the cork wafer, whereas the other side is maintained under dynamic vacuum (0.1 hPa). In the case of a bottle of wine, the partial pressure of oxygen is 210 hPa outside, whereas it can be considered to be 0 inside (under the hypothesis that the oxygen immediately reacts with the liquid phase).

Temperature is kept constant at 298 (±1) K, and the pressure sensor accuracy is 0.1 hPa. Moreover, the errors in thickness ($e$), surface ($S$), and volume ($V$) are negligible compared to instrumental error, <0.5%. The maximum instrumental error is 1%, and model fit lower than 0.5%, which allow an error below 2% on permeability and diffusion coefficient measurements.

In a previous work[18] focusing on a large number of samples to extract a statistical distribution for oxygen transfer through cork, we found that effective oxygen diffusion coefficients through 3 mm cork wafers were spread over four decades in the range from $10^{-10}$ to $10^{-6}$ m$^2$ s$^{-1}$ with a maximum between $10^{-9}$ and $10^{-8}$ m$^2$ s$^{-1}$ (values were determined at $T$ = 298 K and for an initial oxygen pressure of $p_i$ = 220 hPa). This is however largely reduced when considering the extrapolation to a full cork stopper of 48 mm, with effective diffusion coefficient values ranging from $2 \times 10^{-10}$ to $10^{-8}$ m$^2$ s$^{-1}$, which corresponds to permeabilities between $5 \times 10^{-16}$ and $2 \times 10^{-14}$ kg m$^{-1}$ s$^{-1}$ Pa$^{-1}$. In the present work, two cork wafers from two different cork stoppers were chosen according to this distribution, as two representative samples around the mean value. They are referred to as cork wafer 1 and 2. Their diffusion coefficients were $1.34 \times 10^{-8}$ and $4.68 \times 10^{-9}$ m$^2$ s$^{-1}$, respectively (for initial pressure, $p_i$ = 220 hPa and $T$ = 298 K).

## RESULTS AND DISCUSSION

**Sorption Isotherm of Oxygen.** The sorption isotherm of oxygen on cork at 298 K is shown in Figure 1. It exhibits a type III shape of the IUPAC classification,[24] characteristic of the sorption on a nonporous or macroporous material with a weak adsorption affinity. These data are in very good agreement with those of Lequin et al.[18] obtained on cork powder from another harvest. The sorption isotherm is well fitted with the FHH model defined by the relationship

$$\frac{C^a}{C^a_m} = \left[K_{FHH} \ln\left(\frac{C^g_s}{C^g}\right)\right]^{-1/s} \quad (14)$$

where $C^a_m$ is the concentration of adsorbate in the "equivalent" monolayer, $C^g_s$ is the concentration of gas in equilibrium with its liquid phase at the sorption temperature, $K_{FHH}$ is an adjustable parameter taking into account the energy of sorption, and $s$ is related to the nature of gas−solid interaction. Usually, $s$ = 3. A deviation of $s$ from this value is attributed to energy or geometric heterogeneity effects. Values of the FHH parameters are given in Table 1. The low values of $K_{FHH}$ and $s$ compared to those found for water on polymers (0.7 and 2, respectively, for a poly(styrenesulfonic acid), sodium salt, for example, by Toribio et al.,[25]) show that the sorption process of oxygen on cork is highly heterogeneous and involves very weak gas−solid interactions.

**Fick or Knudsen Regime?** Figure 2 displays the permeability of oxygen through cork wafer as a function of the initial pressure of oxygen at constant temperature, 298 K.

For both cork samples, permeability is increasing with initial pressure following a linear trend. For sample 1, permeability values range between $1.5 \times 10^{-14}$ and $2.3 \times 10^{-14}$ kg m$^{-1}$ s$^{-1}$ Pa$^{-1}$. For sample 2, values vary between $6.3 \times 10^{-15}$ and $1.0 \times 10^{-14}$ kg m$^{-1}$ s$^{-1}$ Pa$^{-1}$ and are less dispersed.

As in the Knudsen regime the permeability is independent of the pressure (see eq 5), the fact that we observe an increase in the permeability with the initial oxygen pressure means that the limiting step of oxygen transport in cork is not the transfer of gas through lenticels or palsmodesmata as claimed by other authors.[15,16] Moreover, the permeability values are much too low to account for a gas transport in spaces as large as plasmodesmata (around 100 nm diameter). According to the Knudsen law, permeability can be calculated following the equation

$$P_K = \frac{d}{3}\sqrt{\frac{8M}{\pi RT}} \quad (6)$$

where $d$ is the pore diameter, $M$ the molar mass of $O_2$, $R$ the gas constant, and $T$ the temperature.

From the permeability range experimentally investigated, this would mean a pore diameter lying between $1.04 \times 10^{-4}$ and

dx.doi.org/10.1021/jf501918n | J. Agric. Food Chem. 2014, 62, 9180−9185

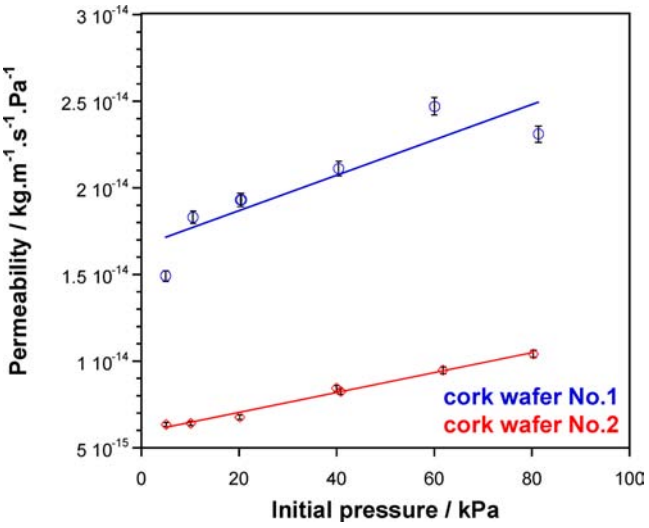

**Figure 2.** Dependence of the permeability of oxygen through 3 mm cork wafers on the initial oxygen pressure at 298 K (○, cork wafer 1; ◇, cork wafer 2; —, linear regression).

$3.80 \times 10^{-4}$ nm. These values are unrealistic. Cork is composed of empty cells (of characteristic dimension around 50 $\mu$m[26]), separated from each other by cell walls of 1 $\mu$m thickness, and of large pores called lenticels (which are macroscopic defects between 200 $\mu$m and 1 mm). Even plasmodesmata, if not obstructed, are pores of 100 nm diameter. It is also worthy of note that the mean free path, which is a function of pressure and temperature,[27] ranges between 130 and 2085 nm for oxygen pressures between 800 and 50 hPa, respectively, at 298 K. Therefore, considering the characteristic dimensions of voids in cork, the limiting step of the transfer cannot be governed by Darcy or Knudsen's mechanisms.

In addition, the probability that a molecule passes from one side to the opposite side of a cork wafer having a thickness of 3 mm by diffusing only in large channels such as lenticels or plasmodesmata is extremely low. When crossing the wafer, the oxygen molecule will inevitably encounter cork walls. Knudsen diffusion can occur in cork, but in any case it cannot be the limiting step. On the contrary, the dependence of the permeability on the pressure is well taken into account by the Fick law (eqs 7 and 8). These results reinforced what we still advanced in our previous paper.[18] The limiting step of oxygen transfer in cork is the diffusion between the polymeric chains of suberin, lignin, cellulose, and hemicellulose, which constitute the cork walls.

All stoppers have basically the same chemical composition and the same cell size. However, the heterogeneity lies in the distribution in size and number of lenticels. For 3 mm thickness samples this heterogeneity is thus probed through the determination of an effective diffusion coefficient. This largely reduces when increasing the length of the sample (from $10^{-10}$ to $10^{-6}$ m$^2$ s$^{-1}$ for a 3 mm sample down to $2 \times 10^{-10}$ to $10^{-8}$ m$^2$ s$^{-1}$ when extrapolated to a 48 mm stopper).[18] Nevertheless, for values of effective diffusion coefficients in the higher range of the distribution for 3 mm thickness sample, it tends to be out of the range for diffusion in solids, and obviously that could mean that another transport mechanism (Knudsen, Darcy) can occur. Very locally, at the millimeter scale, a faster transport mechanism (Knudsen, Darcy) may significantly contribute, but for a bigger system size, a full cork stopper of >12 times this size, these faster steps become completely hidden by the slower Fickian diffusion regime. This is the dominating mechanism at the scale of a full-length stopper.

**Activation Volume.** The effect of initial pressure on the diffusion coefficient is displayed in Figure 3, $D$ being

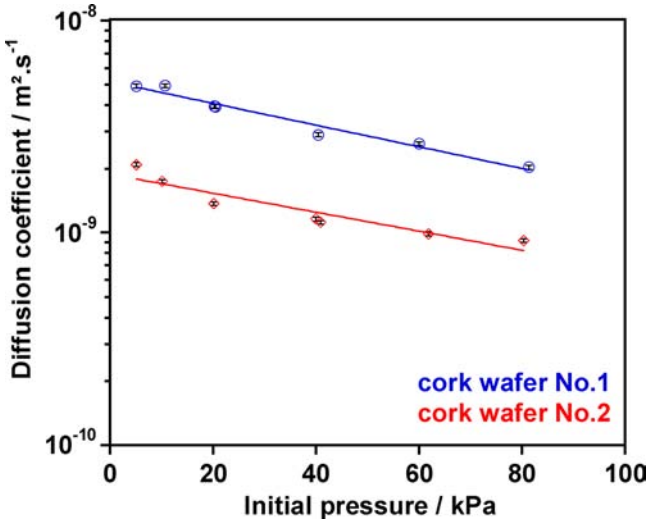

**Figure 3.** Effect of the initial oxygen pressure on the diffusion coefficient (○, cork wafer 1; ◇, cork wafer 2; —, exponential regression).

determined from eq 4. For both samples, the diffusion coefficient is not constant, but varies with pressure. Diffusion coefficients decrease from $4.93 \times 10^{-9}$ to $2.04 \times 10^{-9}$ m$^2$ s$^{-1}$ and from $2.09 \times 10^{-9}$ to $0.92 \times 10^{-9}$ m$^2$ s$^{-1}$ for the first and second cork wafers, respectively, for pressure increasing from 50 to 800 hPa. According to the semilog representation, this decrease is linear and the slopes are almost of the same order ($-1.18 \times 10^{-5}$ and $-1.00 \times 10^{-5}$ m$^2$ s$^{-1}$ Pa$^{-1}$ with coefficients of correlation of 0.98 and 0.94, respectively). By applying the transition state theory, the activation volume can be determined from the slope of the curves $\ln D = f(p)$ according to eq 13.

Surprisingly, the activation volumes are very high, 48 and 41 nm$^3$ per oxygen molecule. These activation volumes are of the same order as that found for an ideal gas at 298 K under 1 bar of pressure (41 nm$^3$).

There are many scientific papers related to the effect of pressure on the diffusion coefficient and activation volume in metals and crystals (Table 2) but not so much in natural polymer. As far as we know, there is no study reporting the dependence of diffusion coefficient on pressure in cork or other natural or synthetic polymeric materials having an alveolar structure.

Activation volumes in metals are very small, around $10^{-3}$ nm$^3$, which is around 45000 times smaller than in cork. Metals are dense and rigid, whereas cork has good elastic properties. Moreover, it is an alveolar solid containing >80% of empty space.[28] Such a high activation volume is closely related to this specific structure and the mechanism of diffusion of gas in this material. Therefore, it is worth noting that in the case of a heterogeneous material such as cork, $\Delta V^*$ must be considered as an apparent activation volume, $\Delta V^*_{app}$, because the diffusion coefficients are not the same inside the alveolus and the cell walls. Figure 4 represents a schematic view of the oxygen transfer through an alveolar structure such as cork. Such a system is composed of two environments (cork walls and

|---|---|---|---|---|---|
| cork | oxygen | 572 | $5 \times 10^3 < p < 80 \times 10^3$ | $45 \pm 4$ | this work |
| germanium | arsenic | 848 | $0.1 \times 10^9 < p < 4 \times 10^9$ | $-2.82 \times 10^{-3} \pm 2.32 \times 10^{-3}$ | 22 |
| amorphous $Co_{18}Zr_{19}$ | $^{57}$Co | 563 | $3 \times 10^9 < p < 8 \times 10^9$ | $(1 \pm 1.3) \times 10^{-4}$ | 29 |
| $(Fe_xMg_{1-x})SiO_4$ olivine | Ni | 1673 | $6 \times 10^9 < p < 12 \times 10^9$ | $9.0 \times 10^{-3} < \Delta V^* < 11.6 \times 10^{-3}$ | 30 |
| $(Fe_xMg_{1-x})SiO_4$ olivine | Mn | 1673 | $6 \times 10^9 < p < 12 \times 10^9$ | $(7.6 \pm 2.8) \times 10^{-3}$ | 30 |
| silicon | boron | 1083 | $10^9 < p < 5 \times 10^9$ | | 31 |

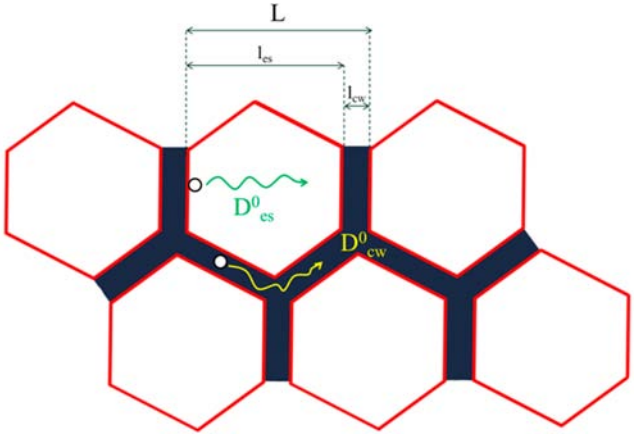

**Figure 4.** Schematic representation of oxygen diffusion through cork ($l_{es}$, cell length; $l_{cw}$, thickness of cell walls; $D^0_{es}$ and $D^0_{cw}$, diffusion coefficients of oxygen in empty cell and cell walls, respectively).

alveolus) in which the resistances of mass transfer are different. Lenticels and plasmodesmatas are not taken into account in this very simple model, but they can be considered as empty spaces.

Therefore, following ref 18, we can consider in this system two mass resistivities in series. As the mass resistivity is proportional to the length of the diffusing environment and to the inverse of the diffusion coefficient and using eq 12, the mean diffusion coefficient, $\bar{D}$, can be written as a harmonic average of local diffusion coefficients

$$\frac{L}{\bar{D}} = \frac{l_{cw}}{D_{cw}} + \frac{l_{es}}{D_{es}} = \frac{l_{cw}}{D^0_{cw}\, e^{-\Delta V^*_{cw} p/k_B T}} + \frac{l_{es}}{D^0_{ew}\, e^{-\Delta V^*_{ew} p/k_B T}} \quad (15)$$

where $l_{cw}$ and $l_{es}$ are respectively the thickness of the cell walls and the length of empty spaces, $L = l_{cw} + l_{es}$, $\bar{D}$ is the mean coefficient diffusion through cork, $D_{cw}$ and $\Delta V^*_{cw}$ are the diffusion coefficient and the activation volume in cell walls, and $D_{es}$ and $\Delta V^*_{es}$ are the same for empty spaces.

Therefore, the apparent activation volume is composed of two terms: one related to the activation in the empty space and one to the polymeric phase. However, it is not possible to experimentally determine $\Delta V^*_{cw}$ or $\Delta V^*_{es}$ as well as the respective diffusion coefficients.

As a whole, this work clearly shows that the limiting step of oxygen transport through cork is the diffusion in cell walls according to a Fickian mechanism. Even if Knudsen diffusion can occur, it will not govern the oxygen transport through cork. The apparent activation volume for oxygen diffusion in cork is $45 \pm 4$ nm$^3$. This value is very close to the molecular volume of the ideal gas (41 nm$^3$). This means that oxygen molecules do not reside only within the cell walls moving through the polymeric chains. In such a case, activation volume would be much lower. The large value of activation volume suggests that oxygen molecules also diffuse through a gas phase in large spaces such as lenticels, plasmodesmatas (if not obstructed), or, more probably, inside the empty cells (which have a volume around $5 \times 10^4$ $\mu$m$^3$) when moving from one site to another one. The limiting step of the transfer obviously remains the diffusion through the cell walls to cross cork. This better understanding of the diffusion mechanism of oxygen through cork is therefore interesting for applying the right model for prediction purposes and for saving time when doing permeation measurement on cork closures.

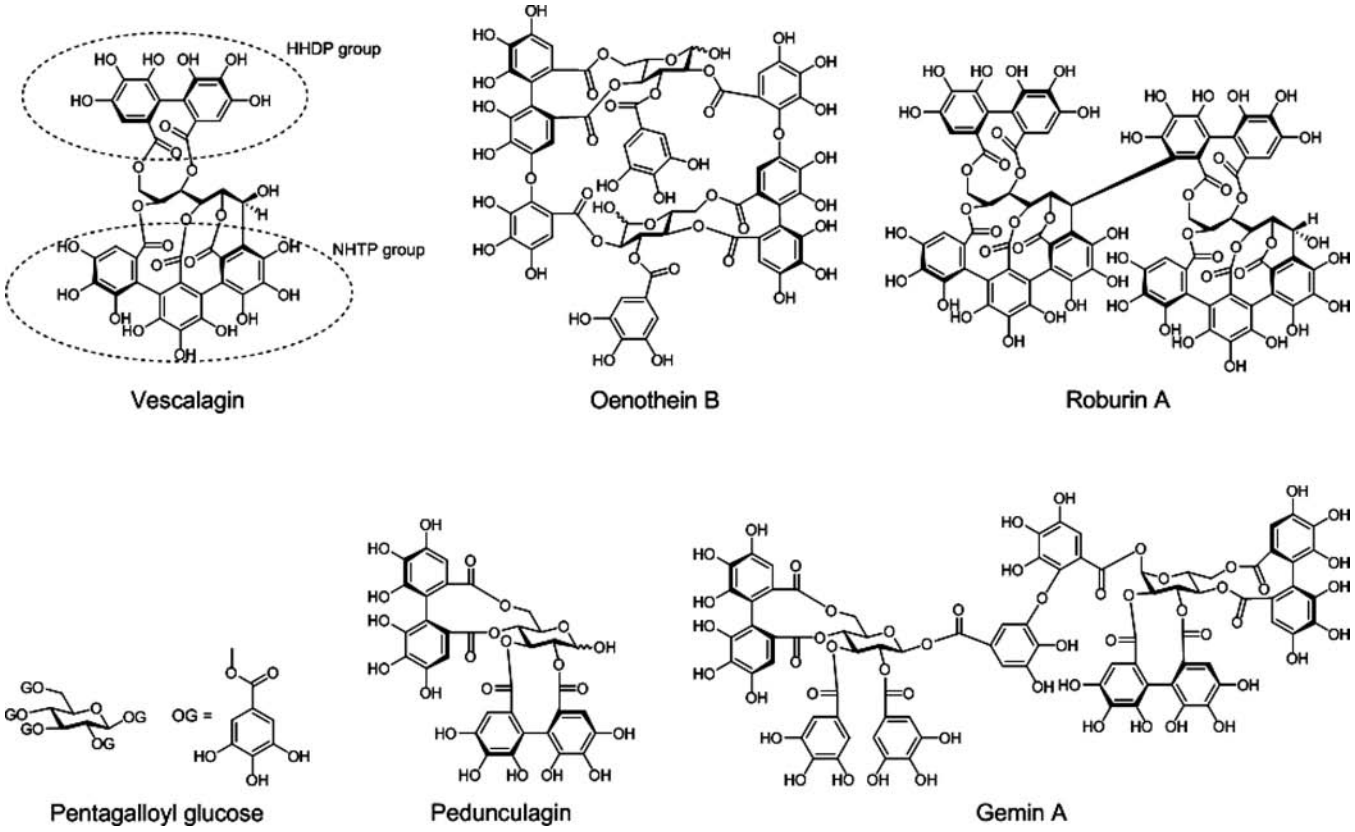

**Figure 1.** Structures of ellagitannins and pentagalloyl glucose.

$10^5$ $M^{-1}$, and for ETs interacting with the highly flexible gelatin these were ca. $10^6$ $M^{-1}$.[19]

ETs are unique among tannins as (i) they can be isolated as pure compounds (unlike most condensed tannins, which tend to be obtained as closely related mixtures), (ii) they possess a wide range of molecular flexibilities (in contrast to gallotannins or condensed tannins), and (iii) their water solubilities are inversely correlated to their protein precipitation capacities.[9] ETs, therefore, offer an opportunity for investigating the relative importance of molecular flexibility and size within a series of matched tannin compounds.

We chose two monomeric and three dimeric ETs that differ in molecular flexibility (i.e., their bond rotational flexibility) and water solubility. Vescalagin and its dimer, roburin A, represent ETs with NHTP groups that are linked to an acyclic glucose. They are consumed in wine that has been stored in oak barrels. Walnuts are a rich source of pedunculagin, which represents ETs with HHDP groups and a cyclic glucose. The dimers, oenothein B and gemin A, can be found in several European and Japanese herbal medicines[1,26] and differ in their molecular flexibilities. The water solubilities of these ETs decrease in the following order: vescalagin > pedunculagin ≈ roburin A > oenothein B > gemin A.[9]

The present study investigated the effects of flexibility and size on the thermodynamics of the ET−protein interaction using isothermal titration calorimetry and fluorescence spectroscopy to probe their interaction mechanisms and binding sites. We chose bovine serum albumin (BSA) as the protein-binding partner for two reasons. First, BSA is a widely used model for globular proteins such as Rubisco, which is a major dietary protein.[27,28] Recent studies have shown that the binding affinity in tannin−protein complexes was negatively correlated with digestibility.[29−31] Second, albumins are involved in transporting dietary polyphenols[32,33] and drugs to their molecular targets[34,35] and exhibit a large sequence homology, for example, 76% in the case of BSA and human serum albumin.[36] It is, therefore, important to understand how ellagitannins interact with globular proteins, as this may also affect protein−drug interactions in the digestive tract and in blood plasma.[35]

## MATERIALS AND METHODS

**Ellagitannins.** Two monomeric ellagitannins (pedunculagin and vescalagin) and three dimeric ellagitannins (oenothein B, roburin A, and gemin A) were extracted from plants and purified as described previously.[37]

**Isothermal Titration Calorimetry.** Titrations of BSA (purity ≥ 99%, essentially globulin free, 66 kDa; Sigma, Poole, Dorset, UK) with ellagitannins were performed using a NanoITC instrument (TA Instruments Ltd., Crawley, West Sussex, UK) as described previously[19,28] with few adaptations. All solutions were prepared in 50 mM citrate buffer at pH 6 and were degassed under vacuum prior to use. In a typical experiment, buffered BSA solution (20 $\mu$M) was placed in the 950 $\mu$L sample cell of the calorimeter, and buffered ellagitannin solution (3 mg $mL^{-1}$) was loaded into the injection syringe. Ellagitannin was titrated into the sample cell at 298 K as a sequence of 24 injections of 10 $\mu$L aliquots for monomeric ellagitannins (pedunculagin and vescalagin) and 48 injections of 10 $\mu$L aliquots for dimeric ellagitannins (oenothein B, roburin A, and gemin A). The time delay (to allow equilibration) between successive injections was 360 s. The contents of the sample cell were stirred throughout the experiment to ensure thorough mixing.

Raw data were obtained as plots of heat ($\mu$J) against injection number and featured a series of peaks for each injection. These raw data peaks were transformed using the instrument software to obtain a

dx.doi.org/10.1021/jf502174r | J. Agric. Food Chem. 2014, 62, 9186−9194

plot of observed enthalpy change per mole of injectant ($\Delta H_{obs}$, kJ mol$^{-1}$) against molar ratio (see ITC Data Analysis).

Control experiments included the titration of buffered ellagitannin solutions into buffer, buffer into BSA, and buffer into buffer; controls were repeated for each BSA concentration. Control experiments of buffer titrated into buffer or protein solutions both resulted in small and equal enthalpy changes for each successive injection of buffer and, therefore, were not further considered in the data analysis.[38] Experimental data were analyzed after subtraction of the tannin into buffer control data from the sample data. Ellagitannin molecules tend to self-associate into aggregates due to hydrophobic groups; therefore, when injected from the syringe into buffer the ellagitannin molecules undergo an endothermic process of deaggregation, analogous to surfactant demicellization.[39] The extent of deaggregation depends inversely on the concentration of ellagitannin already present in the sample cell; therefore, successive injections of ellagitannin into buffer lead to the observation of progressively lower endothermic enthalpy changes as has been illustrated in earlier work.[39] The data are shown after subtraction of the effects of ellagitannin deaggregation, which means that the assumption is made that ellagitannins dissociate prior to binding.

**Isothermal Titration Calorimetry Data Analysis.** Estimated binding parameters were obtained from ITC data using the Bindworks (version 3.1.13, Applied Thermodynamics, Hunt Valley, MD, USA) data analysis program. Data fits were obtained using a model for two independent sets of multiple binding sites. For this model, the analytical solution for the total heat measured ($Q$) is determined by the formula

$$Q = V[\mathrm{M}]\left\{\frac{n_1\Delta H_1 K_1[\mathrm{L}]}{1 + K_1[\mathrm{L}]} + \frac{n_2\Delta H_2 K_2[\mathrm{L}]}{1 + K_2[\mathrm{L}]}\right\} \quad (1)$$

where $n_1$ and $n_2$ are the molar ratios of interacting species, $\Delta H_1$ and $\Delta H_2$ are the enthalpies, and $K_1$ and $K_2$ are the equilibrium binding constants (syn. affinity constants) for each of the two sets of multiple binding sites.[40] The quality of fit was determined by calculation of $\chi^2$; the data fits were acceptable in each case because the $\chi^2$ values were less than the critical values for the appropriate degree of freedom.

**Tryptophan Fluorescence Quenching.** Fluorescence intensity was recorded using an FP-6200 spectrofluorometer (JASCO UK Ltd., Great Dunmow, Essex, UK) with selective excitation of tryptophan residues in BSA at 295 nm. The excitation and emission slits were 5 nm, and the emission spectrum was recorded between 300 and 500 nm. The measured fluorescence intensities are reported without correction for inner filter effects.[41]

Titration of BSA (5 $\mu$M, 2 mL) with ellagitannin (3 mg mL$^{-1}$, 500 $\mu$L) was carried out as a sequence of aliquots (10 $\mu$L up to volume of 100 $\mu$L, 20 $\mu$L up to a volume of 460 $\mu$L). For the calculation of quenching constants, the data were plotted as a Stern−Volmer plot of $F_0/F$ against [Q] and the quenching constant, $K_{SV}$, calculated by linear regression.[42] According to the Stern−Volmer equation

$$\frac{F_0}{F} = 1 + k_q\tau_0[\mathrm{Q}] = 1 + K_{SV}[\mathrm{Q}] \quad (2)$$

where $F_0$ and $F$ are the fluorescence intensities before and after the addition of the quencher, respectively, $k_q$ is the bimolecular quenching constant, $\tau_0$ is the lifetime of the fluorophore in the absence of quencher, [Q] is the concentration of the quencher (in this case tannin), and $K_{SV}$ is the Stern−Volmer quenching constant.

However, in the case of combined dynamic and static quenching, where the Stern−Volmer plot exhibits an upward curvature (concave toward the $y$-axis), an alternative equation[42]

$$\frac{F}{F_0} = 1 + K_{app}[\mathrm{Q}] \quad (3)$$

can be used for fitting, where

$$K_{app} = \left[\frac{F}{F_0} - 1\right]\frac{1}{[\mathrm{Q}]} = (K_D + K_S) + K_D K_S[\mathrm{Q}] \quad (4)$$

The actual plot of $K_{app}$ or $((F/F_. - 1)/Q)$ versus [Q] yields a straight line with an intercept of $K_D + K_S$ and a slope of $K_D K_S$.

**Molecular Modeling.** Molecular modeling was performed with MOE2011.10 (Chemical Computing Ltd., Montreal, Canada). Atomistic models of the respective tannins were built from chemical structures on an atom by atom basis using the Builder Module of MOE. All models were energy minimized to convergence (rms gradient of 0.05 kcal/mol) using the MMX94x force field by smart minimization (steepest descents, followed by conjugate gradient, and truncated Newton−Raphson methods). Physical parameters were calculated from these models using the QuasAR module in MOE. Parameters calculated were accessible surface area (ASA) and hydrophobic accessible surface area (ASA_H). Molecular flexibility was calculated by performing a conformational energy search about the torsion angles of each model using Lowmode Molecular Dynamics in the Conformational Analysis module of MOE. Results from conformational analysis were stored in databases of conformations for each tannin indexed by final energy.

## RESULTS AND DISCUSSION

This study investigated the interaction between BSA and five ellagitannin compounds using ITC and fluorescence spectroscopy. The molecular flexibility and surface areas of five ellagitannins and pentagalloyl glucose were modeled to improve our understanding of these interactions.

**Molecular Flexibility of Ellagitannins.** Molecular simulation was used to assess molecular flexibility in terms of numbers of low-energy conformations located and energy of these conformers (Table 1). Modeling experiments[43] demonstrated previously that the nonahydroxytriphenoyl (NHTP) group is much less flexible than the hexahydroxydiphenoyl (HHDP) group (Figure 1) and the low-energy conformers of the monomers clearly reflect the extent of these structural constraints: pentagalloyl glucose conformers ($n$ = 21) ranged from 110 to 116 kcal mol$^{-1}$ (no NHTP or HHDP groups), pedunculagin conformers ($n$ = 4) from 158 to 164 kcal mol$^{-1}$ (2 HHDP groups), and vescalagin conformers ($n$ = 18) from 229 to 236 kcal mol$^{-1}$ (1 NHTP, 1 HHDP group). The low-energy conformers of the dimers followed a similar trend: oenothein B conformers ($n$ = 2) had 278−280 kcal mol$^{-1}$ (2 HHDP groups), gemin A ($n$ = 1) had 323 kcal mol$^{-1}$ (3 HHDP groups), and roburin A conformers ($n$ = 4) had 406−412 kcal mol$^{-1}$ (2 NHTP, 2 HHDP groups).

**Table 1. Modeling of Minimized Energies and Associated Numbers of Conformers, Accessible Hydrophobic Surface Area (ASA_H), and Accessible Surface Area (ASA)**

| compound | mol wt (Da) | energy of conformers (kcal/mol) | no. of conformers | ASA_H (nm$^2$) | ASA (nm$^2$) |
|---|---|---|---|---|---|
| vescalagin | 935 | 229−236 | 18 | 253 | 914 |
| roburin A | 1843 | 406−412 | 4 | 407 | 1587 |
| pedunculagin | 769 | 158−164 | 4 | 293 | 867 |
| oenothein B | 1569 | 278−280 | 2 | 524 | 1485 |
| pentagalloyl glucose | 927 | 110−116 | 21 | 373 | 1041 |
| gemin A | 1841 | 323 | 1 | 574 | 1748 |

**Isothermal Titration Calorimetry of Ellagitannin−Bovine Serum Albumin Interactions and Data Fitting.** ITC experiments for ellagitannin titration into BSA were carried out for five ellagitannins (depicted in Figure 1). Figure 2 shows the ITC binding isotherms for the interaction with BSA of vescalagin and its dimer, roburin A, consisting of the

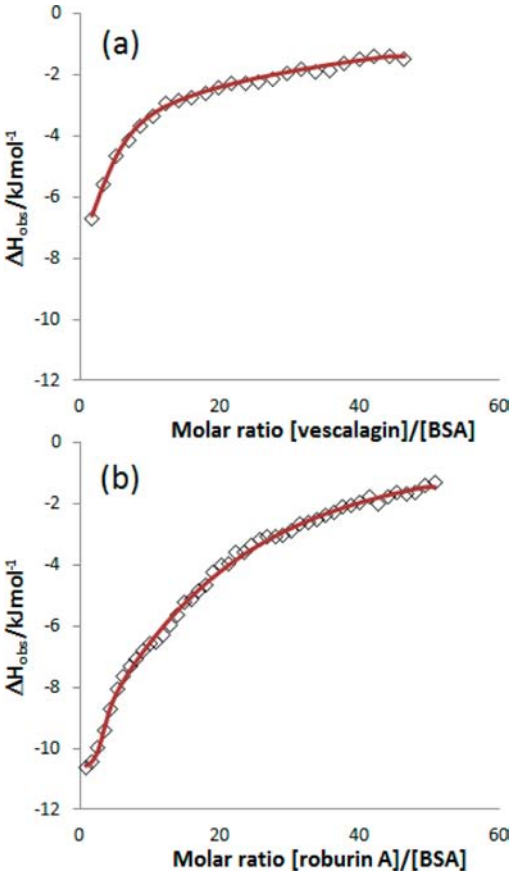

**Figure 2.** ITC binding isotherms for the interaction of bovine serum albumin with the monomer−dimer pair of (a) vescalagin and (b) roburin A. Data were fitted assuming a model for two independent binding sites, and values obtained from these fits are given in Table 2.

experimental data (as points) and the binding model that best fitted to each data set (as lines). For both ellagitannins, the binding interaction led to an exothermic response, which decreased in magnitude with successive titration injections and signifies a saturation of binding sites on BSA.

As found in previous studies,[24,39] small but significant exothermic peaks were observed at higher tannin/protein molar ratios at and beyond the point of apparent binding site saturation. This means that titration experiments did not reach zero enthalpy change, even after removal of effects from control experiments (e.g., tannin titration into buffer). Therefore, we have assumed that the interaction between ellagitannin and BSA has not reached completion at the higher ellagitannin/protein ratios measured. As a consequence, upon fitting the data to a binding model, this long tail of exothermic peaks prevents the use of a model based on a single set of multiple binding sites (one-site model), and, therefore, all data were fitted to a two independent binding site model. A previous study of the interaction between pentagalloyl glucose with BSA or Rubisco described the selection of the two independent binding site model in more detail.[28]

Figure 3 shows the ITC binding isotherms for pedunculagin and the related dimers oenothein B and gemin A. As observed for the vescalagin and roburin A isotherms, the binding isotherm for the dimers shows a clear two-phase shape to the isotherm that signifies two or more binding sites are involved in the interaction. For the oenothein B and gemin A ellagitannins, the titration experiments were extended by increasing the number of titration injections to observe the interaction at higher molar ratios (see Materials and Methods for more details). The thermodynamic binding parameters for the ellagitannin−BSA interaction were obtained from a two-site model and are shown in Table 2, which also includes data from our previous study on pentagalloyl glucose binding to BSA for comparison.[28]

**Thermodynamic Parameters of Ellagitannin−BSA Interactions in Relation to Molecular Flexibility.** In these studies, the excellent fits of the ITC data have enabled us to probe the effects of different structural characteristics of the ellagitannins on their interaction with BSA. The results will be discussed in terms of monomer−dimer pairs and molecular flexibilities. The weakness of the second binding site allows, however, for some uncertainties in exact values for these fits, but does confirm our previous observations, which included related ellagitannins and suggested that these were able to bind (adsorb) nonselectively.[24,28,39]

The ellagitannin monomers, pedunculagin and vescalagin, show equivalent strengths of interaction ($K_1$ = 4.2 and 5.2 × $10^4$ $M^{-1}$), and so do the roburin A and oenothein B dimers ($K_1$ = 2.3 and 6.5 × $10^5$ $M^{-1}$) (Table 2). In contrast, the $K_1$ affinity constants of pentagalloyl glucose and gemin A were 1 order of magnitude larger than for the other monomers and dimers ($K_1$ = 1.8 × $10^5$ and 1.8 × $10^6$ $M^{-1}$, respectively). This coincides with the fact, as pointed out above, that both have low conformational energies and are flexible molecules. Taken together, gemin A has several features, that is, single bonds and "free" galloyl groups, which may allow selective binding to specific amino acids on the protein surface. These findings are in line with two other studies that reported weaker binding by vescalagin[44] and by its isomer, castalagin,[29] to BSA compared to pentagalloyl glucose. It appears that pentagalloyl glucose and gemin A have optimal structures for BSA binding within the group of tannins studied here.

For both binding sites the interaction in terms of the affinity constants, $K_1$ and $K_2$, is approximately 1 order of magnitude different between monomers and dimers (Table 2). For each of the comparable ellagitannin monomer−dimer pairs, the dimer was shown to bind more strongly than the monomer. It can also be seen that $K_2$ is 1 order of magnitude weaker than $K_1$. This weaker second binding site is likely to correspond to nonspecific adsorption of tannins that may lead to coating of the protein surface[28,45] and eventual precipitation of the tannin−protein complex in some systems. The binding isotherms in Figures 2 and 3 for the dimers show a greater exothermic response than for the corresponding monomers, for example, roburin A versus vescalagin ($\Delta H_1$ = −15.3 vs −7.5 kJ $mol^{-1}$), oenothein B versus pedunculagin ($\Delta H_1$ = −21.6 vs −10.9 kJ $mol^{-1}$), and gemin A versus pentagalloyl glucose ($\Delta H_1$ = −47.4 vs −29 kJ $mol^{-1}$) (Table 2).

A closer look at the monomer series and the dimer series (each having tannins with similar molecular weights) suggests that the strength of binding is inversely related to the minimized energies and increases with a greater potential for rotational flexibility as follows (Table 1). The low-energy conformers and binding constants, $K_1$, of the monomers are 229−236 kcal/mol and 5.2 × $10^4$ $M^{-1}$ for vescalagin, 158−164 and 4.2 × $10^4$ for pedunculagin, and 110−116 and 1.8 × $10^5$ for pentagalloyl glucose, respectively. For the dimer series the corresponding values are 406−412 kcal/mol and 2.3 × $10^5$ $M^{-1}$ for roburin A, 278−280 and 6.5 × $10^5$ for oenothein B, 323 and 1.8 × $10^6$ for gemin A.

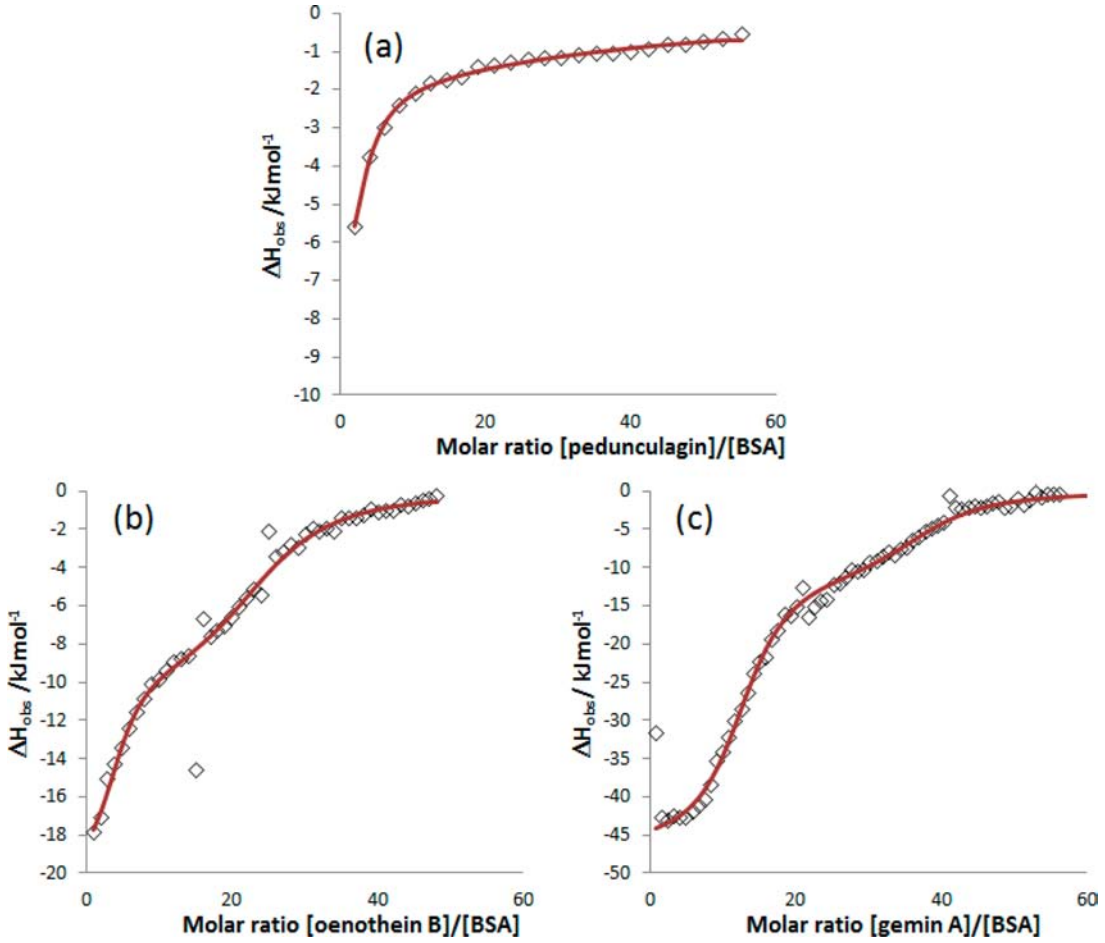

**Figure 3.** ITC binding isotherms for the interaction of bovine serum albumin with the monomer−dimer pairs of (a) pedunculagin, (b) oenothein B, and (c) gemin A. Data were fitted assuming a model for two independent binding sites, and values obtained from these fits are given in Table 2.

**Table 2. Estimated Thermodynamic Binding Parameters for the Interaction between Five Ellagitannins and Pentagalloyl Glucose[b] with Bovine Serum Albumin at pH 6[a]**

| | vescalagin | roburin A | pedunculagin | oenothein B | pentagalloyl glucose[b] | gemin A |
|---|---|---|---|---|---|---|
| $n_1$ | 2.5 ± 0.5[c] | 1.9 | 2.1 | 4.1 | 26 | 13 |
| $K_1$ ($M^{-1}$) | 5.2 (±2.3) × $10^4$ | 2.3 × $10^5$ | 4.2 × $10^4$ | 6.5 × $10^5$ | 1.8 × $10^5$ | 1.8 × $10^6$ |
| $\Delta H_1$ (kJ $mol^{-1}$) | −7.5 ± 1.0 | −15.3 | −10.9 | −20.6 | −29 | −47.4 |
| $\Delta S_1$ (J $mol^{-1}$ $K^{-1}$) | 65.1 | 33.2 | 51.9 | 42.2 | 3.3 | −39.3 |
| $n_2$ | 30 ± 4 | 16 | 30 | 20 | 26 | 25 |
| $K_2$ ($M^{-1}$) | 1.1 (±0.07) × $10^3$ | 1.8 × $10^4$ | 1.1 × $10^3$ | 3.3 × $10^4$ | 8 × $10^2$ | 6.3 × $10^4$ |
| $\Delta H_2$ (kJ $mol^{-1}$) | −6.7 ± 1.3 | −8.17 | −5.1 | −10.3 | −29 | −11.4 |
| $\Delta S_2$ (J $mol^{-1}$ $K^{-1}$) | 35.7 | 54.0 | 41.1 | 51.9 | −41.7 | 53.6 |
| $\chi^2$ | 0.65 ± 0.16 | 0.87 | 1.99 | 8.07 | | 3.29 |

[a] $\Delta H_1$ and $\Delta H_2$ are the enthalpies, and $K_1$ and $K_2$ are the equilibrium binding constants for two binding sites. [b] Data are included for comparison (Dobreva et al.[28]). [c] ± standard deviation, $n$ = 3.

The number of strong (type 1) binding sites increases for ellagitannins with more flexibility and "free" galloyl groups from $n_1$ = 1.9 for roburin A to $n_1$ = 4.1 for oenothein B and $n_1$ = 13 for gemin A. The binding parameters for two of the monomer−dimer pairs, that is, the vescalagin−roburin A and pedunculagin−oenothein B pairs, show similarities in the stoichiometry of the interaction. For the vescalagin−roburin A pair the stronger binding site $n_1$ is 2.5 for the monomer and 1.9 for the dimer, and for the second weaker binding site $n_2$ is 30 for the monomer and 16 for the dimer. For the pedunculagin−oenothein B pair $n_1$ is 2.1 for the monomer and 4.1 for the dimer, and $n_2$ is 30 for the monomer and 20 for the dimer. However, for the most flexible monomer−dimer pair, which will be able to better support H-bonding, the stoichiometric values were much higher for the stronger binding site: $n_1$ was 26 for pentagalloyl glucose and 13 for gemin A. The difference reflects the fact that gemin A is twice the molecular size of pentagalloyl glucose. We reported previously that the sum of $n_1$ and $n_2$ indicated that 52 pentagalloyl glucose molecules are bound to BSA, and this suggested surface coating as the BSA surface can theoretically accommodate 40−120 pentagalloyl glucose molecules.[28] Similarly, the sum of $n_1$ and $n_2$ for gemin A indicated that 38 gemin A dimers were bound (which equates to 76 "monomers") and matches with the calculated surface

dx.doi.org/10.1021/jf502174r | J. Agric. Food Chem. 2014, 62, 9186−9194

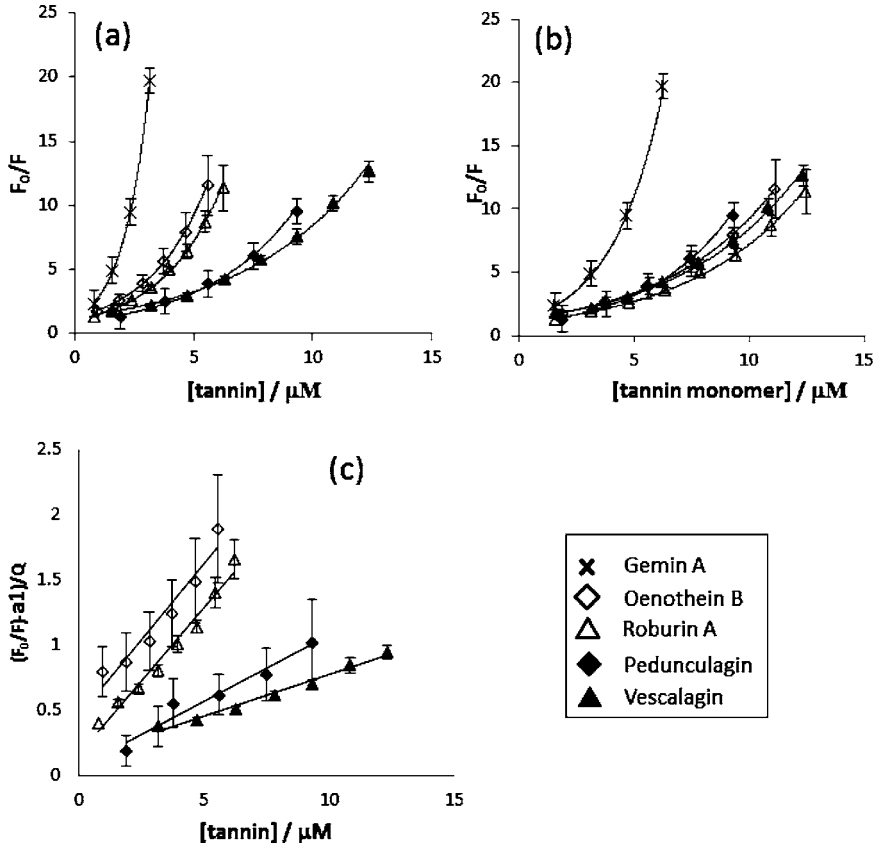

**Figure 4.** Fluorescence quenching of tryptophans in BSA by vescalagin, roburin A, pedunculagin, oenothein B, and gemin A plotted as (a) the ratio of initial fluorescence intensity to total fluorescence intensity versus ellagitannin concentration, (b) the ratio of initial fluorescence intensity to total fluorescence intensity versus ellagitannin monomer concentration, and (c) a modified Stern–Volmer plot to reflect contributions from both static and dynamic quenching (data are shown for vescalagin, roburin A, pedunculagin, and oenothein B only).

area. It also suggests that gemin A due to its flexibility is capable of coating the whole BSA protein just like pentagalloyl glucose.[28] Comparable stoichiometries were found for commercial preparations of the flexible taratannins when a molecular weight of 1500 was assumed: that is, 48:1 for the taratannin/BSA ratio.[39]

It is, however, of note that this molecular size effect was not observed to the same extent for the other pairs as monomers and dimers had similar $n_1$ values (2–4) and similar sums of $n_1 + n_2$ (i.e., 33 for vescalagin/18 for roburin A and 32 for pedunculagin/24 for oenothein B). This indicates that the less flexible structures and especially roburin A were less able to stretch out on the BSA surface.

Many more binding constants are available for flavonoids and condensed tannins than for ellagitannins. Nevertheless, pure flavonoid compounds tend to have affinities comparable to those of the ellagitannins investigated here. $K_a$ constants with BSA of $10^2$–$10^5$ $M^{-1}$ were reported for monomeric and polymeric flavanols[19,31] and of $10^4$–$10^5$ $M^{-1}$ for flavones and flavonols.[46−49] Examples of polyphenol complexes with human serum albumin include epigallocatechin gallate and diosmetin interactions that exhibited comparable Stern–Volmer affinity constants of ~$10^5$ $M^{-1}$ from fluorescence data.[50,51]

The findings also match results from previous studies, in which less pure tannins had been used, and confirm that the tannin components of those fractions did indeed dominate the interaction observed.[19,24,39] The present study used a two-site binding model and found $K_1$ of $10^4$–$10^5$ and $K_2$ of $10^3$–$10^4$ $M^{-1}$ for the monomers in BSA complexes. In comparison, data obtained with a single-site model gave $K$ values of ~$10^3$ $M^{-1}$ for chestnut– and myrabolan–BSA complexes.[24]

Quideau et al.[5] reported that most polyphenols, including ellagitannins, when bound at protein surfaces, exhibited affinity constants that were rarely above the micromolar range, that is, $K_a$ of ≤$10^6$ $M^{-1}$. However, Xiao et al.[52] also reported much larger constants of up to $10^8$ $M^{-1}$ for some flavanoid and flavonoid–human serum albumin complexes. Not surprisingly, some receptor and enzyme targets had particularly high selectivities with affinity constants at the subnanomolar scale and varied between ellagitannins even if these were of similar molecular weights.[5,53]

The data in Table 2 showed positive entropies at both types of binding sites for all but one ellagitannin, that is, gemin A. Positive $\Delta S_1$ values ranged from 33 to 65 and $\Delta S_2$ values from 36 to 54 J $mol^{-1}$ $K^{-1}$ and are indicative of a dominance of hydrophobic interactions.[19,50,54] Gemin A was the only ellagitannin giving a negative entropy, −39 J $mol^{-1}$ $K^{-1}$. For comparison purposes, we have included here also the entropies for pentagalloyl glucose, which show that the highly flexible pentagalloyl glucose and gemin A had noticeably lower entropies at the stronger binding site than the other ellagitannins and were, therefore, apparently better able to form hydrogen bonds.[54] The positive entropies for all ellagitannins at the second binding site are consistent with hydrophobic stacking on the BSA surface, although some uncertainty exists with these values as the affinities were very low for some tannins ($K_2$ = $10^3$ $M^{-1}$). The literature contains examples of both hydrogen bonding and hydrophobic

Table 3. Estimated Quenching Parameters for the Interaction of Ellagitannins with Bovine Serum Albumin ($n$ = 3)

| fluorescence parameter | vescalagin | roburin A | pedunculagin | oenothein B | gemin A |
|---|---|---|---|---|---|
| $K_{SV}$ ($M^{-1}$) | 0.42 (±0.07) × $10^5$ | 1.03 (±0.07) × $10^5$ | 0.53 (±0.1) × $10^5$ | 1.44 (±0.28) × $10^5$ | 3.13 (±0.06) × $10^5$ |
| bathochromic (red) shift of $\lambda_{max}$ (nm) | 8.7 ± 0.4 | 8.7 ± 0.4 | 4.7 ± 0.9 | 4.0 ± 1.0 | 10.3 ± 0.4 |

interactions in tannin−protein complexes.[16,19,22,50,55] Taken together, the present study also suggests that both types of bonding interactions occur in these ellagitannin−BSA complexes, and slight structural differences appear to dictate which of these will dominate.

**Quenching of the BSA Tryptophan Fluorescence by Ellagitannins.** To complement the ITC measurements, ellagitannin binding to BSA was also investigated by fluorescence spectroscopy. These experiments measure the quenching of the intrinsic tryptophan fluorescence of BSA[32] after binding with each of the tannins. Two tryptophan residues are found near the BSA surface, one is within its hydrophobic binding pocket (Trp 212) and the other within the surface region of the protein (Trp 134).[49] Figure 4a shows Stern−Volmer plots that describe tryptophan quenching as a function of tannin concentration. In these plots $F_0/F$ increases as fluorescence intensity decreases in the presence of quencher ($F$) relative to the native fluorescence in the absence of quencher ($F_0$). The data suggest that the rate of decrease in fluorescence with respect to quencher concentration depends on the molecular size and flexibility of the tannin. The data in Figure 4a revealed that four of the tannins fall into either monomer or dimer groups: the monomers, vescalagin and pedunculagin, exhibit similar quenching behaviors, and the dimers, roburin A and oenothein B, also behave similarly to one another. The dimers were more efficient quenchers than the monomers, requiring approximately half the molar tannin concentration to produce equivalent levels of quenching. Indeed, if the quenching data are normalized, as in Figure 4b where Stern−Volmer plots are given as a function of "tannin monomer" concentration, thus removing the effects of molecular weight, it can be seen that related monomer−dimer pairs overlay, which demonstrates similar quenching efficiency per monomer unit. In contrast to these four tannins, the most flexible dimer, gemin A, is a much more efficient quencher at much lower concentrations. Pentagalloyl glucose is also a more efficient quencher, $K_{SV} \sim 2 \times 10^6$ $M^{-1}$,[28] than vescalagin and pedunculagin, but pentagalloyl glucose and gemin A are not a true monomer−dimer pair and thus do not overlay exactly.

The purpose of the Stern−Volmer plot of fluorescence quenching data is to generate a linearized data set that allows assessment of the ability of tannins to quench the BSA tryptophan residues. The slope of the straight line of best fit is termed the Stern−Volmer quenching constant ($K_{SV}$). From the data shown in Figure 4a, $K_{SV}$ values of $10^4$−$10^5$ $M^{-1}$ have been calculated from a straight-line plot through the linear region at low tannin concentrations (Table 3) and are comparable with $K_{SV}$ values of $10^4$ $M^{-1}$ for tea, coffee, and cocoa extracts[31] and with 6.85 × $10^4$ $M^{-1}$ for quenching of human serum albumin by epigallocatechin gallate (EGCg).[50] These fluorescence data complement the ITC data by providing additional support for the findings outlined above. The trend in terms of the quenching constants, $K_{SV}$, matches that seen from ITC measurements of the affinity constants, $K_1$, with a linear correlation ($R^2$ = 0.988) between $K_{SV}$ and the binding affinity constant, $K_1$ (Tables 2 and 3).

However, it should be noted that each of the Stern−Volmer plots is nonlinear and curves toward the $y$-axis with higher tannin concentration. This is not unusual in Stern−Volmer plots and provides information on the type of quenching. An upward slope suggests a combination of both static and dynamic quenching in these ellagitannin−BSA systems.[42] Static quenching is associated with a strong coupling (e.g., formation of a ground-state complex) between interacting molecules, whereas dynamic quenching is associated with weak coupling (e.g., through-space interactions or collisions).[42] To further confirm that the curvature was indeed due to combined static and dynamic quenching, a modified form of the Stern−Volmer equation was used (see Materials and Methods) that is second order with respect to [Q], and this gave as predicted a linear plot (Figure 4c).

**Polarity of the Tryptophan Environment.** Fluorescence spectra can also yield information on another parameter, that is, the position of the emission peak maximum ($\lambda_{em}$), which can reflect the polarity of the tryptophan environment.[50] The presence of ellagitannins led to a bathochromic or red shift in $\lambda_{em}$ (Table 3), suggesting that the tryptophan environment became more polar upon interaction with ellagitannins. The observed red shift may suggest a change to the protein's tertiary structure and thus account for the associated increase in the polarity of the tryptophan environment.[28] However, it is difficult to conclude this solely on the basis of the data reported here. A shift to a more polar environment could suggest unfolding of the protein and thus greater solvent exposure or more H-bonding between BSA and the tannins. However, Li et al.[30] reported a slight blue shift upon binding of tannic acid (i.e., a mixture of gallotannins containing either a central glucose or quinic acid) to ferritin, whereas Dobreva et al.[28] measured a red shift of 5 nm when pure pentagalloyl glucose bound with BSA. The magnitude of the red shift appears to be linked to tannin structure as related monomer−dimer pairs showed some similarities: vescalagin and roburin A generated a 8−9 nm shift and pedunculagin and oenothein B a 4−5 nm shift, but gemin A caused the greatest shift in $\lambda_{em}$ of 10.3 nm. A similarly large red shift of 12 nm was observed for Trp during EGCg binding to human serum albumin.[50] Other experiments will be needed to establish the precise reasons for the observed differences in red shifts.

In conclusion, our ITC data suggest that there are two types of binding sites for ellagitannin binding to BSA. A stronger binding site may well be more selective and dependent on tannin flexibility and the presence of free galloyl groups. Indeed, our previous study suggested a link between the number of aromatic residues on the surface of a globular protein, Rubisco, and pentagalloyl glucose binding.[28] This could explain the relationship between $K_1$ and the hydrophobic accessible surface area, ASA_H (Figure 5), that is, $K_1 = 0.2125e^{0.0114ASA_H}$ ($R^2$ = 0.965), and points to the fact that hydrophobic interactions are an important driver for affinity during BSA−ellagitannin complex formation as supported by positive entropies for five of the six ellagitannins studied here.

A second weaker binding site was required to fit our data to allow for the binding interactions observed at high tannin/

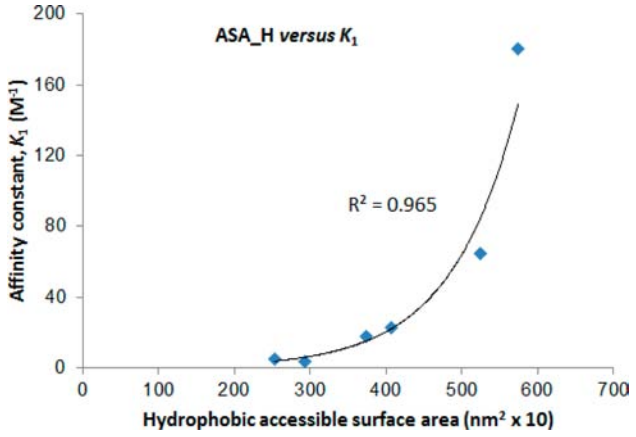

**Figure 5.** Relationship between the affinity constant, $K_1$, and the modeled accessible hydrophobic surface area (ASA_H).

protein molar ratios. This second binding site was associated with high values of $n_2$ for all tannins and suggests nonselective adsorption of tannin to the protein surface. Such findings suggest tannin binding to BSA is concentration dependent, where specific binding might dominate at low concentrations and nonselective adsorption at higher concentrations of tannin.[16] These studies have shown that ellagitannin binding to BSA increases in strength and affinity for the larger tannins (dimers) compared to their monomer forms. Bond rotational flexibility of the tannin also plays a role by increasing the strength of interaction and number of stronger (possibly hydrogen bonding) binding sites on the protein surface.

the goals of this work were the validation of appropriate methodologies for monitoring of total chromium and Cr(VI) in different lager beers to understand the variability between lager beer styles packaged in glass or cans and estimation of the contribution of beer to daily dietary intake of total Cr and Cr(VI).

## MATERIALS AND METHODS

**Reagents and Materials.** Hydrogen peroxide, nitric acid, hydrochloric acid, sodium hydroxide, ammonium nitrate, alizarin, sodium acetate, and acetic acid were of Suprapure grade and purchased from Merck (Rahway, NJ). Total Cr standards were prepared daily from a 1000 $\mu$g mL$^{-1}$ solution of Cr(III) nitrate (Spectrosol, BDH) in $HNO_3$ [0.2% (v/v)]. An aqueous stock solution of Cr(VI) at 1000 $\mu$g mL$^{-1}$ was prepared by dissolving 0.2829 g of potassium dichromate (Riedel-de-Haen) in 100 mL of doubly deionized water. Diluted standard solutions were prepared daily from these stock solutions. The chemical modifiers were a 1 g L$^{-1}$ $Mg(NO_3)_2$ solution and a mixture of 2 g L$^{-1}$ $Mg(NO_3)_2$ and a 3 g L$^{-1}$ $Pd(NO_3)_2$ solution, Suprapure grade from Merck, prepared in 15% (v/v) $HNO_3$. Chromabond $NH_2$, 3 mL, 500 mg columns (Macherey-Nagel, Düre, Germany) were used to selectively separate Cr(VI) both in standards and in beer samples before tis quantification.

A rigorous decontamination to eliminate possible contamination due to detergents was performed for all materials (Teflon vessels, test tubes, pipets, micropipet tips, and micro vessels). For this purpose, all materials were immersed for 24 h in freshly prepared 15% (v/v) $HNO_3$. Subsequently, they were rinsed thoroughly with doubly deionized water and dried in a dust-free environment before being used. The gloves used were of powder-free material.

**Instrumentation.** Chromium quantifications were conducted in a PerkinElmer HGA-850 furnace installed in a model Analyst 300 spectrometer with Zeeman background correction, equipped with an AS-800 autosampler. Then, measurements were performed using PerkinElmer HGA tubes with an integrated platform. Water purification systems were a Seralpur PRO 90 CN system and a Seradest LFM 20 system. All analytical weights were determined with a Mettler Toledo (Greifensee, Switzerland) AB265-S balance. The samples were homogenized in a GFL 3006 oscillating agitator and centrifuged in a 5810R Eppendorf. The pH-meter was a WTW pH 330/SET-2, Best NR 100 788 instrument.

**Samples.** Seventy beer samples from 38 brands were analyzed, including 56 bottled beers and 14 canned beers. Sampling included Portuguese and imported beers, one or two samples of each brand packed at different dates that were randomly acquired in local supermarkets in Porto, Portugal. All the samples had at least 3−6 months prior to their expiration dated and were lager type beers of different styles: pale lager (B1−B17; $n$ = 24), low-alcohol (B18−B26; $n$ = 13), fruit beer (B27 and B28; $n$ = 3), Dunkel (B29−B31; $n$ = 5), Schwarzbier (B32; $n$ = 2), premium lager (B33; $n$ = 2), amber (B34 and B35; $n$ = 3), and Heller Bock (B36−B38; $n$ = 4). Canned beers were all pale lager and were from the same brands as bottled beers; these samples were named C1−C8 ($n$ = 14). The major ingredients of the beer samples were sorghum, wheat, malt, barley, roasted barley, hops, and water. The percentage of alcohol by volume in the samples ranged from 0.3 to 6.4%; the mean pH value was 4.12, ranging between 3.90 and 4.24. The samples were stored at 4 °C until they were analyzed. All beer samples were degassed by centrifugation at 5000$g$ and 4 °C for 15 min and were analyzed twice for total Cr and Cr(VI), and some of them were also used to validate the analytical procedure.

**Pretreatment Procedure for Total Chromium Quantification.** Sample digestion and mineralization were conducted according to the procedure described by Soares et at.[13] Five milliliters of each beer sample was accurately measured and transferred to Teflon containers and supplemented with 0.4 mL of $H_2O_2$ and 2.0 mL of $HNO_3$ at room temperature for 3 h, and the Teflon containers covered with their caps overnight were heated in a thermostatically controlled stove at 105 °C. After the samples had cooled to room temperature, 1 mL of HCl was added, and the closed Teflon containers were heated again for 17 h at 105 °C to completely dissolve the samples. The cooled containers were opened, and the digests were transferred to decontaminated tubes and diluted to 5 mL with doubly deionized water. Blank reagent samples were processed in parallel with via digestion of the beer sample and subjected to the same procedure.

**Pretreatment Procedure for Chromium(VI) Quantification.** For selective extraction of Cr(VI), a procedure previously adopted by our group to other matrices[12,13] was adapted and validated for beer analyses. Briefly, 10 mL of beer was mixed with 1.5 mL of 3% sodium acetate and 750 $\mu$L of 0.001% alizarin until a final pH of 5.5 was achieved, which was selected according to the instructions of the Chromabond $NH_2$, 500 mg column. Each sample was agitated for 2 min for complete homogenization and transferred into previously conditioned columns. The conditioning was conducted with 2 mL of 1 N $HNO_3$ followed by 2 mL of doubly deionized water. Selective retention of Cr(VI) in the column was quantitatively achieved by passing the supernatant through the column. Afterward, it was dried under vacuum, and the Cr(VI) was eluted with 2 mL of 2 N $HNO_3$. Finally, Cr(VI) was measured in the eluate using the same instrumental conditions applied for total chromium. Cr(VI) standard solutions and blank reagents were submitted daily to pretreatment procedures similar to that applied for the beer samples.

**Analytical Conditions.** Both total Cr and Cr(VI) were quantified by graphite-furnace atomic absorption spectroscopy (GFAAS). The spectrometer settings and furnace programs used with pyrolytic graphite-coated tubes were as follows: drying temperature, 100−130 °C (10 s for ramp time and 20 s for hold time); ashing temperature, 1200 °C (20 s for ramp time and 20 s for hold time); atomization temperature, 2400 °C (30 s for ramp time and 30 s for hold time); chemical modifier, 3 g L$^{-1}$ $Pd(NO_3)_2$ and 2 g L$^{-1}$ $Mg(NO_3)_2$; Zeeman background correction; HGA tubes with an integrated platform; gas stop flow, atomization step. All data were taken at 353.7 nm. The slit width was 0.7 nm, and argon was used as the purge gas, with an internal flow rate of 300 mL min$^{-1}$. Readings on the spectrometer were taken by using the peak area mode (integrated absorbance) both for total chromium and for hexavalent chromium. The autosampler was programmed to pipet sequentially the modifier (10 $\mu$L) followed by the standard solution/acid digest/acid eluate mixture (20 $\mu$L) and to dispense them together onto the platform.

**Validation of Methods.** The analytical methods were evaluated according to linearity, precision, limit of detection (LOD), limit of quantification (LOQ), accuracy, and matrix effects. Standard solutions of both total Cr and Cr(VI) were prepared daily at the working concentrations for the determination of linearity. The calibration curve of total Cr and Cr(VI), plotted as concentration versus absorbance, was statistically evaluated using the straight line by the least-squares method of linear regression. For the evaluation of instrumental precision, 20 measurements of absorbance signals were taken using the same standard solution, while for evaluation of the analytical method, precision absorbance signals were determined 20 times in the same beer sample. Precision is presented as the ratio of the standard deviation to the mean [coefficient of variation (CV%)]. The limit of detection was calculated by the equation LOD = $3sm^{-1}$; the limit of quantification was calculated by the equation LOQ = $10sm^{-1}$ (where $s$ is the standard deviation of the measurements of the blank and $m$ is the slope in the calibration curve). Because Certified Reference Materials for Cr and Cr(VI) in a beer matrix are not available on the market, the method of addition of standards was applied for the evaluation of accuracy. Four different concentrations (1.0, 2.5, 5.0, and 10.0 $\mu$g L$^{-1}$) of standard solutions of Cr(VI) were added to different aliquots of the same beer sample (six replicates for each concentration) and subjected to the extraction procedure. After determination of the initial concentration of Cr(VI) in the unspiked beer samples and the final concentrations in the spiked beer samples, the respective Cr(VI) recoveries and coefficient of variation were calculated.

**Statistical Analysis.** Nonparametric comparison tests (Kruskal−Wallis test and Mann−Whitney U-test) with a statistical significance

Table 1. Analytical Features of the Quantification of Total Cr and Cr(VI) in Beer Samples

| | linearity ($\mu$g L$^{-1}$) | precision (CV%) | | limit of detection ($\mu$g L$^{-1}$) | limit of quantification ($\mu$g L$^{-1}$) |
|---|---|---|---|---|---|
| | | instrumental procedure | analytical procedure | | |
| total Cr | 0.26−20.0 | 1.5 | 10.7 | 0.26 | 0.87 |
| Cr(VI) | 0.68−15.0 | 2.5 | 5.9 | 0.68 | 1.61 |

set at $p < 0.05$ were conducted with SPSS version 17 (SPSS Inc., Chicago, IL).

## RESULTS AND DISCUSSION

**Validation of Methods.** Linearity ranged between 0.26 and 20.0 and between 0.68 and 15.0 $\mu$g L$^{-1}$ for total Cr and Cr(VI), respectively, as presented in Table 1. The precision, evaluated for instrumental and analytical procedures, was ≤10.7% for total chromium and Cr(VI). The LODs were 0.26 and 0.68 $\mu$g L$^{-1}$ for total Cr and Cr(VI), respectively. The LOQs were 0.87 and 1.61 $\mu$g L$^{-1}$ for total Cr and Cr(VI), respectively. These figures highlight that the method is precise and sensitive, allowing the quantification of low levels of total Cr and Cr(VI).

Recovery experiments were performed to evaluate the accuracy and specificity of the digestion and extraction methods. The total Cr and Cr(VI) concentrations obtained by the standard method of additions presented very small deviations from the expected values, between 1.6 and 3.3%, corresponding to mean recoveries of ≥93.3% (Table 2). These results highlight the absence of matrix interference and suggest that the wet acid digestion procedure in a closed vessel, including digestion with $H_2O_2$ and $HNO_3$ and subsequent mineralization with HCl and $HNO_3$, was effective for the simplification of the beer sample matrix to obtain the necessary dissolution of total chromium for GFAAS determination. In addition, the Chromabond $NH_2$, 500 mg column adopted for the extraction of Cr(VI) allowed the selective separation of this species from the beer matrix as verified by the results obtained during the validation procedure. Thus, the techniques applied for Cr total and Cr(VI) in beer samples were accurate and precise.

**Application of the Validated Methods to the Determination of Total Cr and Cr(VI) in Lager Beers.** The validated methods were applied to the analyses of chromium in 70 beer samples. Table 3 presents the concentrations of total chromium and Cr(VI) in bottled and canned beers. The concentrations of total chromium in the different samples of bottled beers ranged from lower than the LOQ (<0.87 $\mu$g L$^{-1}$) to 16.4 $\mu$g L$^{-1}$. The content of total Cr in canned beers ranged from lower than the LOQ (<0.87 $\mu$g L$^{-1}$) to 2.79 $\mu$g L$^{-1}$. Comparison between the chromium content of pale lager canned beers and the same brands of bottled beers showed that canned beers presented significantly lower total Cr contents ($p = 0.045$; $n = 38$). According to Farri et al.[6] who studied the occurrence of chromium in raw materials and its fate in the brewing process, the raw materials such as malt and rice are the major contributors of chromium to beer; however, a significant increase in the level of chromium was observed after the bottling process because of a transfer of chromium from the glass, caps, or steed used in the bottling machine. Kovács et al.[18] compared the composition of eight brands of beer from Hungary, Slovakia, and Czech Republic stored in cans and glass and observed similar total Cr contents ranging between 0.6 and 13.6 $\mu$g L$^{-1}$; however, they did not find significant differences in the Cr content of canned and glass bottled beers. Other previous studies analyzed the total Cr content of beer in 74 brands of Belgian and imported beers. The content ranged between 0.2 and 46 $\mu$g L$^{-1}$;[19] beers consumed in Spain contained 3.94−30.1 $\mu$g L$^{-1}$.[20] Higher contents of total Cr are described in beers from Venezuela and Nigeria, ranging between 10 and 104 $\mu$g L$^{-1}$ and between 100 and 400 $\mu$g L$^{-1}$, respectively,[16,21] and in beers from Brazil with a mean of total chromium content of 66 $\mu$g L$^{-1}$.[15]

[a] $C_1$ is the initial concentration of total chromium and Cr(VI) in a beer sample matrix. [b] $C_2$ is the concentration of standard total chromium and Cr(VI) solution added to beer sample matrix prior to the application of the overall procedure. [c] $C_3$ is the final concentration of total chromium and Cr(VI) found in the spiked beer sample matrix. [d] Maximal and minimal values measured in spiked beer samples are in parentheses.

The Cr(VI) content of pale lager beers ranged from below the LOQ (<1.61 $\mu$g L$^{-1}$) to 9.9 $\mu$g L$^{-1}$, whereas in low-alcohol beers, Cr(VI) varied from below the LOQ (<1.61 $\mu$g L$^{-1}$) to 13 $\mu$g L$^{-1}$. The Cr(VI) content in fruit beer, Dunkel, Schwarzbier, premium lager, amber lager, Heller Bock, and canned beers was below the LOQ (<1.61 $\mu$g L$^{-1}$) in all analyzed samples.

Mean contents expressed as micrograms per liter of total and hexavalent chromium, maximal and minimal values, and the Cr(VI)/total chromium ratio in bottled and canned beer samples grouped according to beer style are summarized in

| B34 and B35 | amber lager | 3 | 1.66 ± 1.40 | <LOQ−3.06 | 1.67 | <LOQ | <LOQ | − |
| B36−B38 | Heller Bock | 4 | 2.38 ± 0.76 | 1.82−3.49 | 2.10 | <LOQ | <LOQ | − |
| C1−C8 | canned pale lager | 14 | 1.13 ± 1.10 | <LOQ−2.92 | 1.46 | <LOQ | <LOQ | − |

[a]For calculations, when the total chromium and Cr(VI) values were lower than the LOQ, the value of the detection limit was taken.

Table 4. For mean calculations, when the total Cr or Cr(VI) values were lower than the LOQ (<0.87 and <1.61 $\mu$g L$^{-1}$, respectively), it was assumed as the LOD value (0.26 and 0.68 $\mu$g L$^{-1}$, respectively). In the different beer styles, the mean content of total Cr ranged between 1.13 $\mu$g L$^{-1}$ in canned pale lager and 4.32 $\mu$g L$^{-1}$ in low-alcohol beer, whereas the mean content of Cr(VI) was <2.51 $\mu$g L$^{-1}$. In these samples, the ratio of Cr(VI) to total Cr was 0.29 in lager beer and 0.58 in low-alcohol beer. Other beer styles presented Cr(VI) contents lower than LOQ values; thus, the ratio could not be evaluated. Comparable ratios were observed in previously studied foods, namely, milk (0.21−0.44),[12] bread (0.12),[14] or tea (0.12−0.24).[7] Although Cr(VI) is a genotoxic species well absorbed through the gastrointestinal tract, risks from these levels in beer are not foreseen, although efforts should be made to keep Cr content in beer as low as possible, because the two samples that presented higher levels of total Cr (~16.4 $\mu$g L$^{-1}$) also presented higher levels of Cr(VI), namely, 13.0 and 9.9 $\mu$g L$^{-1}$.

**Estimated Daily Intake of Total Cr and Cr(VI) Based on the Consumption of Beer.** To determine the daily estimated intake of total Cr and Cr(VI) from beer, a daily intake of 500 mL was considered. This was selected because most people do not consume beer on a daily basis, but when they consume beer, the intake is ~500 mL. Thus, the estimated intake of total Cr in beer ranged between 0.57 and 2.16 $\mu$g/day taking into consideration the mean total Cr contents found in canned and bottled beers, respectively. Estimation of Cr(VI) intake could be performed for only pale lager (0.47 $\mu$g/day) and low-alcohol beers (1.26 $\mu$g/day).

The Food and Nutrition Board of the U.S. National Academy of Sciences recommends that the chromium dietary intake for adults be set at 25 and 35 $\mu$g/day for women and men, respectively.[22] Considering these guidelines, it can be assumed from our study that beer ingestion can contribute approximately with 2.28−8.64% of the recommended daily intake of chromium for women and 1.62−6.17% for men.

In the past decades, due to the significant effect on the prevention and treatment of livestock diseases, antimicrobial agents have been widely used in clinical veterinary. Unfortunately, the accumulation of drug residues and metabolites in eggs, meat, and milk has led to potential hazards for humans.[18−20] Thus, the investigation of the metabolism of antimicrobial agents in food animals becomes very necessary. Valnemulin is one of the antimicrobial agents in animal husbandry. However, the literature on the metabolic research of valnemulin in animals is limited. Therefore, the aim of the present study is to investigate in detail the in vivo and in intro metabolism of valnemulin in different species and to provide the metabolic differences among different species. Valnemulin was separately incubated with rat, chicken, swine, goat, and cow liver microsomes, and the incubation mixtures were then analyzed using a sensitive UPLC-Q/TOF-MS method. In addition, the metabolites of valnemulin in in vivo rats, chickens, and swines were also investigated. As a result, many metabolites were identified, and the proposed metabolic pathways of valnemulin are presented in this paper. This work will contribute to comprehensively clarifying the differences among in vitro systems of different species and will give useful data for the explanation of the residues of valnemulin among different species and, moreover, will further facilitate food safety evaluation of valnemulin.

## MATERIALS AND METHODS

**Chemicals.** The valnemulin standards were obtained from the Council of Europe's European Pharmacopoeia. S-oxidized valnemulin (metabolite V6) was synthesized at the College of Science, China Agricultural University (Beijing, China). Acetonitrile and formic acid (HPLC grade) were purchased from Fisher Chemical Co. (USA). Water was purified using a Milli-Q system (Millipore, USA). $\beta$-Nicotinamide adenine dinucleotide phosphates (NADPH) was purchased from Roche Chemical Co. (Beijing, China). All other chemicals and reagents were of the highest analytical grade available.

**Animals.** Twelve Wistar rats (weight 200−250 g, six males and six females) were purchased from Vital River Laboratory Animal Technology Co. Ltd. (Beijing, China). Twelve Avian chickens (weight 1.0−1.2 kg, six males and six females) were purchased from Beijing Huadu Co. Ltd. (Beijing, China). Twelve Changbai swines (weight 20−25 kg, six males and six females), eight goats (weight 20−25 kg, four males and four females), and four cows (weight 150−250 kg, two males and two females) were purchased from Zhoukou Village Nursery (Beijing, China). All animals, after acclimatizing for 1 week in an animal room with standardized temperature (25−28 °C), humidity (50−60%), and 12 h light/dark cycle conditions before the experiment, were fed different commercial standard diets and given water ad libitum. All care and handling of animals was performed with approval of the Institutional Authority for Laboratory Animal Care.

**Preparation of Liver Microsomes.** Following a 12 h fast, animals (three male and three female rats, chickens, and swines; two male and two female goats; and one male and one female cow) were exsanguinated. Hepatic microsomes were prepared as a procedure reported in previous studies.[21] The livers were rapidly removed and washed several times with ice-cold 0.1 mol/L PBS (pH 7.4) and 0.05 mol/L Tris-HCl buffer (pH 7.4) to wash away residual blood, gently blotted, and weighed. The pooled livers were minced and immediately homogenized with 3 volumes of ice-cold 0.05 mol/L Tris-HCl buffer (pH 7.4) containing 1 mmol/L EDTA and 0.25 M sucrose using a glass homogenizer. The liver S9 fraction was obtained by centrifuging the homogenate at 10000*g* for 20 min at 4 °C, and then the supernatant was collected and centrifuged at 100000*g* for 60 min at 4 °C. The microsomal pellets were suspended in 0.05 mol/L Tris-HCl buffer, and the protein content of the microsomes was estimated according to the method of Lowry et al. using crystalline bovine serum albumin as standard.[22] To evaluate the activities of CYP enzymes in liver microsomes prepared in this work, the carbon monoxide (CO) difference spectrum and the metabolism of probe drug coumarin were applied. The liver microsomes of rat, chicken, swine, goat, and cow were incubated with coumarin, and then the metabolites of coumarin were analyzed by UPLC-Q/TOF-MS. The results showed that the maximum absorption wavelength of microsomes was 450 nm, but not 420 nm, which was consistent with the results of Pearce et al.[23] The CO difference spectrum of CYP in rat, chicken, pig, goat, and cow liver microsomes is shown in the Supporting Information (Figure 9). In addition, coumarin could be metabolized to 7-hydroxycoumarin in liver microsomes, indicating the systems had the activities of drug metabolism enzymes.

**Incubation of Valnemulin with Liver Microsomes.** Valnemulin was separately incubated with liver microsomes of rats, chickens, swines, goats, and cows under the same conditions. The incubation mixture, in 0.05 M Tris-HCl buffer (pH 7.4), consisted of 2 mg protein/mL liver microsomes, 100 mM valnemulin, and 1 mM NADPH with the total volume of 500 mL. After 2 h of incubation at 37 °C in a metabolic shaker, the reaction was terminated by adding 500 $\mu$L of ice-cold acetonitrile. After volution and centrifugation at 12000 rpm at 4 °C for 15 min, the supernatant was filtered through a 0.22 $\mu$m microbore cellulose membrane into an autosampler vial and analyzed by UPLC-Q/TOF-MS for identification of metabolites. Parallel controls include the absence of NADPH and incubation without valnemulin, respectively. All experiments were conducted in triplicate.

**Preparation of in Vivo Samples.** After a 12 h fast and free access to water, animals (three male and three female rats, chickens, and

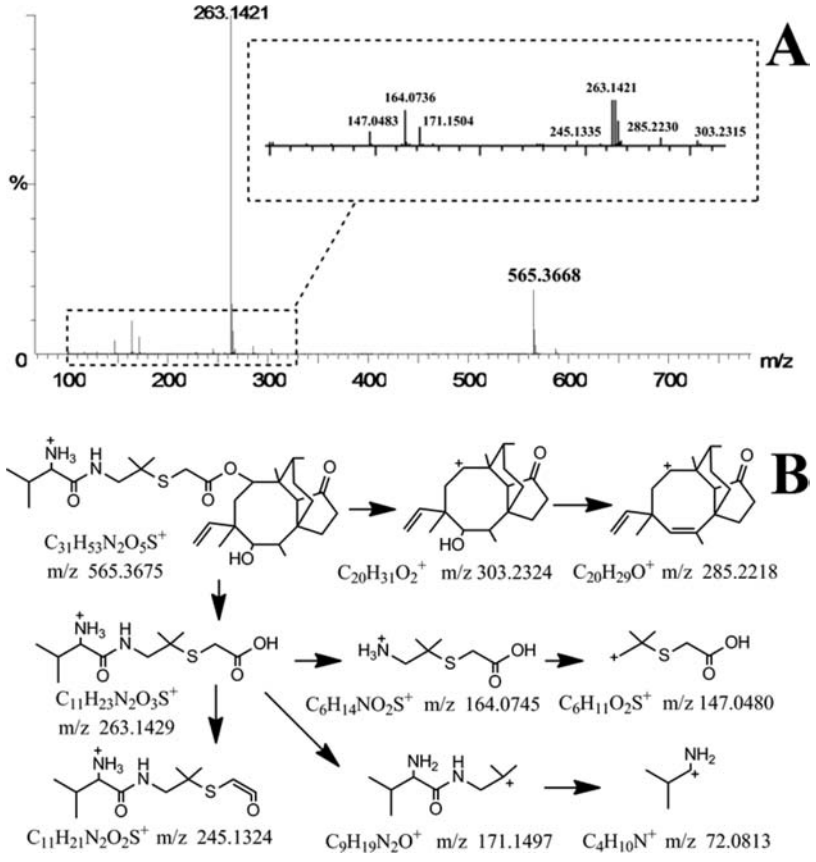

**Figure 2.** Accurate MS/MS spectra (A) and proposed fragmentation pathways (B) of valnemulin.

swines) were administered a single dose of valnemulin (100 mg/kg, dissolved in water) by oral gavage. The urine and feces samples were individually collected prior to the experiment and during 0−24, 24−48, and 48−72 h postdose. All of the samples were frozen at −20 °C until analysis. Each fecal sample was well homogenized before weighing. Ten milliliters of ethyl acetate was added to 2 g of feces, and then the mixture was vortexed for 5 min and centrifuged at 9000*g* at 4 °C for 10 min. The organic layer was transferred into a new polypropylene tube, and the extraction of the feces was repeated following the same procedure. The resulting supernatants were pooled and evaporated to dryness with a gentle nitrogen flow at 45 °C. The residue was redissolved in 1.0 mL of acetonitrile/water (15:85, v/v), and then the resulting solution was loaded onto a preconditioned activated Oasis HLB cartridge (3 mL, 60 mg); the cartridge should be activated with 3 mL of methanol and then preconditioned with 3 mL of water. Furthermore, the cartridge was washed with 6 mL of water, and then the metabolites were eluted with 3 mL of methanol. The eluate was evaporated to dryness under nitrogen at 45 °C, and the residues were eventually reconstituted in 1.0 mL of acetonitrile/water (15:85, v/v). The redissolved solution was centrifuged at 12000*g* at 4 °C for 15 min. Finally, the supernatant was filtered through a 0.22 $\mu$m microbore cellulose membrane into an autosampler vial and analyzed by UPLC-Q/TOF-MS for the identification of metabolites. As to the urine samples, 10 mL of urine from rats and pigs was loaded onto a preconditioned activated Oasis HLB cartridge (3 mL, 60 mg). Afterward, the rest of the steps were performed as described for feces samples.

**Instrumental Conditions.** Identification of valnemulin metabolites was conducted using an ACQUITY UPLC system (Waters Co., USA) coupled with a hybrid Q/TOF-MS SYNAPT HDMS (Waters, UK). Chromatographic separation of valnemulin metabolites was performed on the ACQUITY ultraperformance liquid chromatography system with ambient temperature, using an Acquity BEH RP18 column (50 mm × 2.1 mm i.d., 1.7 $\mu$m particle size) (Waters, USA). The mobile phase of 0.1% formic acid in water (solvent A) and 0.1% formic acid in acetonitrile (solvent B) was pumped at a flow rate of 0.3 mL/min. The gradient elution program was as follows: 0−3.0 min, 5−15% solvent B; 3.0−16.0 min, 15−40% solvent B; 16.0−18.0 min, 40−

70% solvent B; 18.0−19.0 min, 70−100% solvent B; 19.0−20 min, 100% solvent B; 20.0−21.0 min, 100− 5% solvent B; 21.0−22.0 min, 5% solvent B. The injection volume was 10 μL.

Mass spectrometric analysis was operated using a hybrid Q/TOF-MS SYNAPT HDMS (Waters, UK). Typical source conditions for maximum intensity of precursor ions were as follows: capillary voltage, 3.0 kV; source temperature, 120 °C; desolvation temperature, 300 °C; cone gas ($N_2$) flow rate, 10 L/h; desolvation gas ($N_2$) flow rate, 600 L/h. The argon pressure in the collision cell was $3.5 \times 10^{-3}$ mbar. For parent drug and metabolites, ESI source was operated in the positive ionization mode. Data were acquired from 100 to 700 Da and centroid during acquisition using an internal reference comprising a 1 ng/μL solution of leucine enkephalin infused at 50 μL/min, generating a reference ion at $m/z$ 556.2771 in ESI positive ionization mode. Low-energy data were acquired at a collision energy of 5 eV and high-energy data using a ramped collision energy of 10−45 eV.

**Data Processing.** Data processing was carried out using Metabolynx$^{XS}$ software (version 4.1), which could automatically identify metabolites by comparing the samples with the controls. A threshold of 5 mDa was set as a limit to filter the processed data for calculation of possible elemental composition. The mass window was 0.05 Da for both expected and unexpected mass chromatograms, and the absolute area was 50. The intensity threshold of spectrum condition was 10%. The availability of accurate masses and elemental composition data on precursor and all fragment ions in each MS/MS spectrum greatly enhanced confidence in the ion structure assignments.

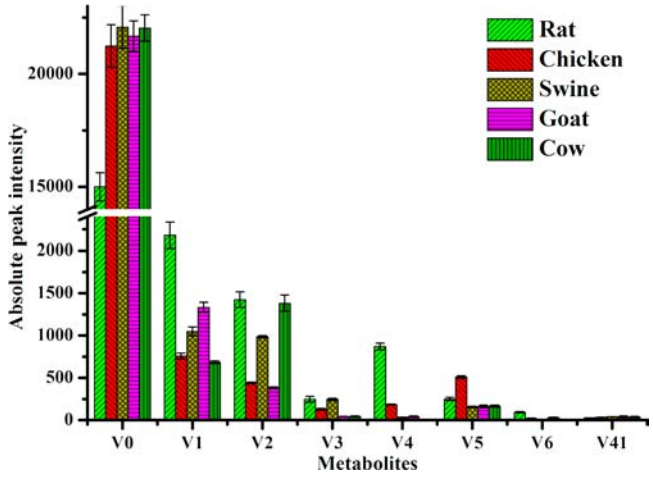

**Figure 5.** Peak areas of extraction ion chromatograms on valnemulin metabolites detected in rat, chicken, swine, goat, and cow liver microsomes.

## RESULTS AND DICUSSION

**Structural Assignment of Product Ions of Valnemulin.** Because it is critical to figure out the fragmentation pathways of valnemulin, UPLC-Q/TOF-MS was applied initially to analyze the protonated valnemulin. The product ion mass spectrum of valnemulin is shown in Figure 2A, which was used not only as a

dx.doi.org/10.1021/jf5012402 | J. Agric. Food Chem. 2014, 62, 9201−9210

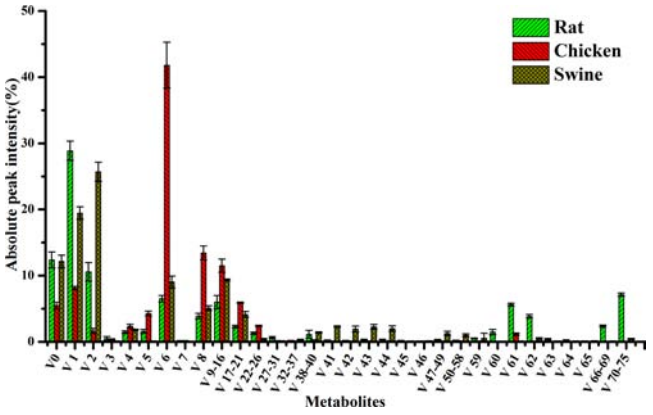

**Figure 7.** Peak areas of extraction ion chromatograms on valnemulin metabolites detected in in vivo rats, chickens, and swines.

reference to aid in the interpretation of product ions of the metabolites but also to examine the high resolution and mass accuracy of the instrument. With the help of formula predictor software, the formulas, the observed and calculated masses, and the mass errors of protonated valnemulin and its fragment ions are listed in Table 1. Relatively good accuracy was obtained with values between the measured and calculated masses ranging from −0.9 to 1.1 mDa (from −6.9 to 4.6 ppm), which powerfully enhanced the reliability for the structures of product ions.

As shown in Figure 2A, the main fragment ion at $m/z$ 263.1421 corresponded to cleavage of the ester bond from the protonated valnemulin. Meanwhile, $m/z$ 303.2315 can also be generated with cleavage of the ester bond. Subsequently, $m/z$ 285.2230 was generated with the loss of $H_2O$ from $m/z$ 303.2315. In addition, $m/z$ 263.1421 generates $m/z$ 164.0736 by losing $C_5H_9O$, which accorded with cleavage of the acidamide bond. Afterward, $m/z$ 147.0483 was generated by the loss of $NH_3$ from the $m/z$ 164.0736. In addition, $m/z$ 171.1504 can be generated by cleaving the bond of S−C in the absence of $C_2H_4O_2S$. According to the results above, the fragmentation pathways of valnemulin are proposed in Figure 2B.

**Identification of Valnemulin Metabolites in Swine Liver Microsomes.** To rapidly characterize the metabolism of valnemulin, incubation of swine liver microsomes with valnemulin and NADPH was initially carried out. The samples and the controls were first analyzed by UPLC-Q/TOF-MS. Subsequently, Metabolynx$^{XS}$ data-processing software utilizing MDF (mass defect filtering) technique was used to identify metabolite ions. As a result, seven potential metabolites were listed by the software. In addition, the accurate extracted ion chromatograms (EIC) (the window was 0.05 Da) of the potential metabolites V1−V6 ($m/z$ 581.3624) and V41 ($m/z$ 466.2991) are shown in the Supporting Information (Figure 10). To elucidate the molecular structure of the potential metabolites, the MS/MS experiments were conducted. Furthermore, the accurate MS/MS spectra of these metabolites are indicated in Figure 3. With the assistance of chromatographic behaviors, accurate mass measurements, and basic rules of drug metabolism, the chemical structures of metabolites were elucidated or clarified.

**Metabolites V1−V5.** Metabolites V1−V5 showed the same $[M + H]^+$ ions at $m/z$ 581.3620 ($[C_{31}H_{53}N_2O_6S]^+$), which was 16 Da higher than the protonated valnemulin at $m/z$ 565.3675, suggesting that they were isomers of mono-oxidized metabolites of valnemulin. Their difference was the position of hydroxylation. Fragment ions from MS/MS spectra of V1−V5 were $m/z$ 263, 171, 164, and 147, which were identical to valnemulin, implying that the side chains of these metabolites were not oxidized. Moreover, the fragment ions at $m/z$ 319 and 301 of V1−V5 were 16 Da higher than the ions at $m/z$ 303 and 285 of valnemulin, respectively, further suggesting that the

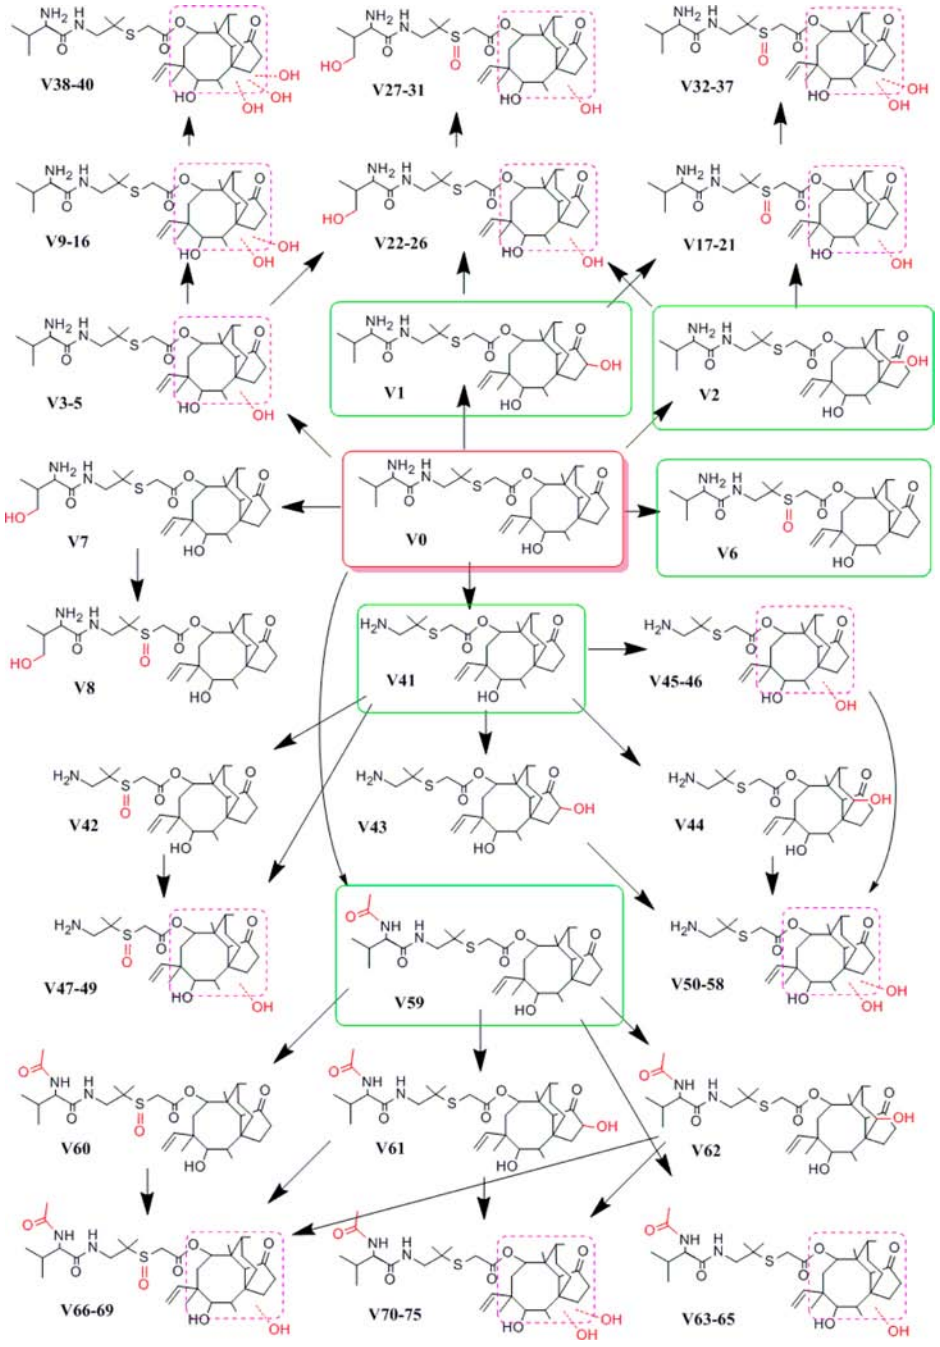

**Figure 8.** Metabolic pathways of valnemulin in in vivo rats, chickens, and swines.

hydroxylation takes place in the mutilin part (the ring system) of valnemulin. Owing to the complex structure of valnemulin with many similar moieties, it would be extremely difficult to unambiguously identify the exact position of hydroxylation in the mutilin part solely using mass spectrometry. NMR analysis would be ideal for such compounds, but it may be difficult to generate sufficient amounts of metabolites. However, earlier studies have shown that the derivates of pleuromutilin were often metabolized by hydroxylation on the 1$\beta$-, 2$\beta$-, and 8$\alpha$-positions. Therefore, it is probable that valnemulin and tiamulin can also be hydroxylated on these positions, which was confirmed by later research conducted by Lykkeberg et al.[17] After incubation of tiamulin with the liver microsomes of pigs, two hydroxylated metabolites were detected as 8$\alpha$-hydroxytiamulin and 2$\beta$-hydroxytiamulin by using LC-MS, $^{1}$H NMR, and $^{13}$C NMR.[17] In the present research, more than five metabolites hydroxylated in the mutilin part (V1−V5) were found, and two (V1 and V2) had larger amount output. On the basis of the analysis, metabolites V1 and V2 were probably 2$\beta$-hydroxyvalnemulin and 8$\alpha$-hydroxyvalnemulin, respectively. As to the trace metabolites V3−V5, it was hardly possible to identify the exact position of hydroxylation in the mutilin part.

**Metabolite V6.** The $[M + H]^+$ ion of metabolite V6 ($m/z$ 581.3627, $C_{31}H_{53}N_2O_6S^+$) was 16 Da higher than the protonated valnemulin. The main product ion at $m/z$ 279 was also 16 Da higher than the ion at $m/z$ 263 of valnemulin, implying that the side chain of V6 was alternatively hydroxylated or oxidized at the sulfur. The key fragment ion at $m/z$ 171 (loss of $C_2H_4O_3S$ from $m/z$ 279) of V6 further suggests that the side chain was oxidized at the sulfur to form *S*-

dx.doi.org/10.1021/jf5012402 | J. Agric. Food Chem. 2014, 62, 9201−9210

oxides. In addition, V6 showed the same retention time and fragment ions on the MS/MS spectrum as the synthesized S-oxidized valnemulin. Consequently, metabolite V6 was identified as S-oxidized valnemulin.

**Metabolite V41.** Metabolite V41 was eluted at 8.85 min with the $[M + H]^+$ ion at $m/z$ 466.2995 ($C_{26}H_{44}NO_5S^+$), which was 99 Da less than the protonated valnemulin at $m/z$ 565.3675, implying that the amido bond of the side chain was hydrolyzed. In addition, the major fragment ion at $m/z$ 164 from metabolite V41, corresponding to cleavage of the ester bond, was also 99 Da less than the main fragment ion at $m/z$ 263 of valnemulin, further suggesting that the amido bond was hydrolyzed.

**Metabolism of Valnemulin in Rat, Chicken, Swine, Goat, and Cow Liver Microsomes.** Considering that metabolic enzymes and metabolic rates were different among various species, the quantitative and qualitative evaluation of metabolites of valnemulin may present some distinctions. Therefore, it was essential and urgent to investigate the metabolism of valnemulin in rats, chickens, swines, goats, and cows, which will be very helpful for its application in pharmacology and clinical use in veterinary practice. Figure 9 (Supporting Information) shows the accurate EICs of valnemulin metabolites formed in liver microsomes of rats, chickens, goats, and cows. The results reveal the same number of valnemulin metabolites for incubation with liver microsomes of different species. Except that metabolite V4 was not detected in cow liver microsomes, seven metabolites (V1−V6 and V41) in swine liver microsmoes were also observed in the other four species. On the basis of these results, the possible metabolic pathways of valnemulin in liver microsomes were hydroxylation, S-oxidation, and hydrolysis, which are proposed in Figure 4.

However, as to the amount of metabolites, there were some differences in the five species. To better analyze the species differences in the metabolism of valnemulin, a semiquantitative analysis was conducted in in vitro systems using the peak areas of extracted ion chromatograms (the window was 0.05 Da) about metabolites; the results are summarized in Figure 5. The results indicated that the ability to metabolize valnemulin in rat liver microsomes was higher than that of the other four species, because the residual level of the unchanged valnemulin in rats was the lowest and there were many metabolites with larger production detected in rats. As to the other four animals, their abilities to metabolize valnemulin were roughly equivalent. The present results also suggest that hydroxylation in the mutilin part was the main metabolic pathway because abundant 2$\beta$-hydroxyvalnemulin (V1) and 8$\alpha$-hydroxyvalnemulin (V2) were produced during the incubation. Moreover, quantitative species differences in the metabolism of valnemulin among the five species were observed. For metabolite V1, the rank order of metabolism ability was rat > goat > pig > chicken > cow and that for metabolite V2, rat > cow > pig > chicken > goat. In addition, the amount of metabolite V1 produced in the liver microsomes of rats, chickens, swines, and goats was greater than that of V2, whereas in cow the amount of metabolite V1 was less than that of V2. Additionally, rat and chicken liver microsomes produced considerable yields of metabolites V4 and V5. The marked quantitative differences in the formation of valnemulin metabolites among the various animal species were perhaps in relation to the levels of the involved enzymes in the liver. As to the S-oxidized (V6) and hydrolyzed metabolites (V41), they were minor products in liver microsomes of the five species. In the absence of the NADPH, only two metabolites (V1 and V2) were detected with minor production in liver microsomes. The amount of metabolites V1 and V2 in the presence of the NADPH was 50-fold higher than that in the absence of the NADPH. These results indicate that NADPH-cytochrome P450 oxidase may be involved in hydroxylation in the mutilin part because NADPH was absolutely essential for this reaction.

**Metabolite Profiles of Valnemulin in in Vivo Rat, Chicken, and Swine.** Seven metabolites were detected and characterized in liver microsomes of different species. To investigate the correlation of in vitro findings with in vivo metabolism, animals (rats, chickens, and pigs) were orally dosed with valnemulin, and urine and feces were collected at different times (0−24 and 24−48 h). Then, these biological samples and the control samples after pretreatment were injected into the UPLC-Q/TOF-MS for analysis. In addition to the unchanged valnemulin, totald of 75, 61, and 74 metabolites of rats, chickens, and pigs were identified, respectively. Among the identified metabolites, 7 known metabolites have been confirmed in the in vitro research, and 68 new metabolites were found in vivo. In addition, the accurate extracted ion chromatograms (EIC) of valnemulin metabolites detected in vivo are shown in the Supporting Information (Figure 11). We assume that they were valnemulin metabolites because comparison of the samples with the control samples as well as the agreement between the accurate mass measurement in MS spectra and predicted formula calculation within 10 ppm. The predicted elemental compositions, exact masses, and mass errors of the metabolites are indicated in the Supporting Information (Table 2). The exact and measured masses agree to within <5 ppm, providing support for the proposed elemental compositions of the metabolites.

**Identification of Valnemulin Metabolites in Rats, Chickens, and Pigs after Oral Administration.** The metabolites were proposed by the Metabolynx$^{XS}$ software, and then the structures were confirmed using the MS/MS mode. As shown in Table 2 (Supporting Information), there were totally 75 metabolites of valnemulin discovered in rats, chickens, and swines, and the majority are being reported for the first time. In addition, the MS/MS spectra of the detected metabolites are shown in Figure 6. Using Q-TOF, the accurate masses for the protonated molecular ions of the metabolites and their product ions in MS and MSMS were obtained, respectively. The measured accurate masses, mass errors, fragment ions, and retention times for these proposed metabolites are presented in Table 2. In all cases, the structures of metabolites and their fragment ions were rapidly and reliably characterized on the basis of the determined elemental composition and accurate MS/MS spectra. Previously, seven metabolites (V1−V6 and V41) have been confirmed in liver microsomes, whereas the other metabolites detected in vivo need further identification.

**Metabolite V7.** The $[M + H]^+$ ion of metabolite V7 ($m/z$ 581.3627, $C_{31}H_{53}N_2O_6S^+$) was 16 Da higher than that of the protonated valnemulin. The main product ion at $m/z$ 279 was also 16 Da higher than the ion at $m/z$ 263 of valnemulin, implying that the side chain of V7 was hydroxylated. Furthermore, the ions at $m/z$ 164 and 147 of metabolite V7 were identical to those of valnemulin, suggesting that the position of hydroxylation should be located at the terminus of the side chain.

**Metabolites V8−V26.** The protonated molecule ions of metabolites V8−V26 were at *m/z* 597.3569 ($C_{31}H_{53}N_2O_7S^+$), which were 16 Da higher than the metabolites V1−V7 at *m/z* 581.3620, implying that they were further hydroxylated or oxidized products of metabolites V1−V7. The fragment ion at *m/z* 295 from metabolite V8 was 16 Da higher than the ion at *m/z* 279 of metabolites V6 and V7, implying that the side chain of V8 was not only hydroxylated but also oxidized at the sulfur in the side chain. Furthermore, the ion at *m/z* 187, generated by cleaving the S−C bond, was 16 Da higher than the ion at *m/z* 171 of metabolite V6, further proving the above point. Similar characteristic product ions were shown in the eight metabolites V9−V16 with different retention times, suggesting that they were the isomers. Fragment ions at *m/z* 263, 171, 164, and 147 from metabolites V9−V16 were identical to those of valnemulin, implying that their side chains were not hydroxylated. In addition, the fragment ions at *m/z* 335 and 317 of metabolites V9−V16 were 16 Da higher than the ions at *m/z* 319 and 301 of metabolites V1−V5, respectively, further implying that there was a couple of hydroxylated sites in the mutilin part of metabolites V9−V16.

Compared with metabolite V6, similar ions at *m/z* 279 and 171 were also detected in metabolites V17−V21, suggesting that oxidization at the sulfur occurs in the side chain. As to the fragment ions at *m/z* 279, 261, and 243 of metabolite V7, they were also available in metabolites V22−V26, implying that their side chains were hydroxylated. In addition, the ions at *m/z* 319 and 301 of metabolites V17−V21 and V22−V26 were identical to those of metabolites V1−V5. This indicated that the hydroxylation also occurs in the mutilin part of these metabolites.

**Metabolites V27−V40.** Mass spectra of metabolites V27−V40 showed the same $[M + H]^+$ ions at *m/z* 613.3530 ($C_{31}H_{53}N_2O_8S^+$), and their product ions were similar to those of V8−V26 except for a 16 Da (an oxygen atom) mass value shift, suggesting that they were further hydroxylated or oxidized on the basis of metabolites V8−V26. The fragment ion at *m/z* 295 from metabolites V27−V31, which is identical to metabolite that of V8, hints that they were further hydroxylated on the mutilin part on the basis of metabolite V8. As to the fragment ion at *m/z* 279 of metabolites V32−V37, it was identical to metabolites that of V17−V26, indicating that their side chains were hydroxylated or oxidized and they were also hydroxylated in the mutilin part on the basis of metabolites V17−V26. In addition, compared with metabolites V9−V16, the similar ions at *m/z* 263, 171, 164, and 147 were also detected in metabolites V38−V40, suggesting that the hydroxylation was in the mutilin part on the basis of metabolites V9−V16.

**Metabolites V42−V46.** Metabolites V42−V46 (*m/z* 482.2940, $C_{26}H_{44}NO_6S^+$) were 16 Da higher than the metabolite V41, suggesting that they were hydroxylated or oxidized at the sulfur to form *S*-oxides on the basis of metabolite V41. Fragment ion at *m/z* 180 of metabolite V42 was 16 Da higher than ion *m/z* 164 of metabolite V41, implying that the side chain of metabolite V42 was oxidized at the sulfur. Compared with metabolite V41, the major fragment ions at *m/z* 164, 147, 129, and 101 were also detected in metabolites V43−V46. Furthermore, the fragment ions at *m/z* 319, 301, and 283 of metabolites V43−V46, which were 16 Da higher than the ions at *m/z* 303, 285, and 267 of metabolite V41, further suggest that the mutilin part of metabolites V43−V46 was hydroxylated.

**Metabolites V47−V58.** Metabolites V47−V58 (*m/z* 498.2875 $C_{26}H_{44}NO_7S^+$) were detected during 3.11−6.03 min, and their product ions were similar to those of V42−V46 except for a 16 Da (an oxygen atom) mass value shift, suggesting that they were further hydroxylated. The fragment ions at *m/z* 180 and 162 from metabolites V47−V49, which were identical to metabolite V42, hinted that they were hydroxylated on the mutilin part on the basis of metabolite V42. Compared with metabolites V43−V46, the major fragment ions at *m/z* 164, 147, 129, and 101 were also detected in metabolites V50−V58, whereas other fragment ions at *m/z* 335, 317, and 299 of metabolites V50−V58 were 16 Da higher than the ions at *m/z* 319, 301, and 283 of metabolites V43−V46. On the basis of the analysis, it was concluded that metabolites V50−V58 were further hydroxylated on the mutilin part of metabolites V43−V46.

**Metabolite V59.** Metabolite V59 showed the $[M + H]^+$ ion at *m/z* 607.3775 ($C_{33}H_{55}N_2O_6S^+$), which was 42 Da higher than that of the protonated valnemulin, implying that it was acetylated. The main fragment ion at *m/z* 305 of metabolite V59, which corresponded to cleavage of the ester bond, was 42 Da higher than the fragment ion *m/z* 263 from valnemulin. Furthermore, the fragment at *m/z* 164, generated by cleavage of the amido bond from the ion at *m/z* 305, further suggests that the acetylization occurs on the amido side chain.

**Metabolites V60−V65.** Metabolites V60−V65 (*m/z* 623.3721, $C_{33}H_{55}N_2O_7S^+$) were 16 Da higher than metabolite V59. In addition, the fragment ion at *m/z* 321 from metabolite V60 was also 16 Da higher than the ion *m/z* 305 of metabolite V59, indicating that it was not only acetylated on the side chain but also oxidized at the sulfur. Fragment ions at *m/z* 305, 164, and 147 from metabolites V61−V65 were identical to the those of metabolite V59, implying that the side chain was not hydroxylated. Therefore, the mutilin part of metabolites V61−V65 should be hydroxylated. For metabolites V1−V4, it was hardly possible to know their exact position of hydroxylation in the mutilin part.

**Metabolites V66−V75.** Metabolites V66−V75 were detected during 7.56−10.98 min with the same $[M + H]^+$ ion at *m/z* 639.3684, which was 16 Da higher than those of metabolites V60−V65. Compared with metabolite V60, the major fragment ions at *m/z* 321 and 213 were also detected in metabolites V66−V69, implying that the mutilin part was hydroxylated on the basis of metabolite V60. Likewise, fragment ions at *m/z* 305, 164, and 147 of metabolites V70−V75 were identical to those of metabolites V61−V65, implying that the mutilin part was further hydroxylated on the basis of metabolites V61−V65.

**Comparison of Metabolism of Valnemulin in Rats, Chickens, and Swines.** Table 2 lists the metabolites of valnemulin detected in rats, chickens, and swines. There were 72 and 62 metabolites detected in the urine of rats and swines, respectively, whereas in the feces 71 and 72 metabolies were detected, suggesting that valnemulin undergoes extensive metabolism. Because the urine and feces are excreted together in chickens, it was difficult to naturally separate them. Thus, the excreta (mixture of feces and urine) of chicken were analyzed together, and totally 61 metabolites were detected. To find the major metabolites of valnemulin in the animals, the area of the every peak corresponding to the metabolites of valnemulin was surveyed. Owing to the different ionizations based on ESI resource in mass spectrometry, the peak areas can only be used to roughly quantify the metabolites. The majority of

metabolites of valnemulin were eliminated in 0−24 h, but there were a few metabolites detected in 24−48 h in three animals. Therefore, the excreta of three animals in the 0−24 h were used to roughly quantify the metabolites. The result is summarized in Figure 7, which shows that there were no major qualitative matabolites in the biotransformation of valnemulin between rats and pigs. Both main metabolites were 2$\beta$-hydroxyvalnemulin (V1) and 8$\alpha$-hydroxyvalnemulin (V2), which was consistent with the in vitro results. However, the metabolite V6, *S*-oxides, was the major metabolite in chickens and accounts for approximately 42.1% of total metabolites' peak area, which was very different from the in vitro results. This was because there were larger numbers of metabolic enzymes involved in valnemulin metabolism in vivo than in the liver microsomes. In addition, gastrointestinal microflora also participated in the metabolism of valnemulin, whereas, in vitro, the number of enzymes involved in drug metabolism was very limited in the liver microsomes. The above facts resulted in metabolic differences of valnemulin between in vivo and in vitro chickens. As to the metabolic differences of valnemulin among different species, it may be that metabolic enzymes in chickens were different from rats and pigs.[24,25] In addition, Figure 7 also reveals that the hydrolysis capabilities in three species were swines > rats > chickens, whereas they were chickens ≫ swines > rats for oxidation on the sulfur and rats > swines > chickens for acetylization.

**Metabolic Pathways of Valnemulin in Rats, Chickens, and Swines.** According to the summary report from EMEA, valnemulin was extensively metabolized to more than 22 different metabolites when rats were orally dosed with $^{3}$H-labeled valnemulin.[9,10] After pigs were given oral doses of 25 mg/kg bw valnemulin, twice a day, for 7.5 days, 11 metabolites were detected in bile, and 6 of these were also found in the liver.[9] Those studies indicate that valnemulin was extensively metabolized in various animals. Although $^{3}$H-labeled valnemulin was used, unfortunately, it did not succeed in the identification of exact molecular structures of the detected metabolites. In addition, the main metabolites of valnemulin were not indicated yet. The EMEA report shows that all of these metabolites retain the intact valnemulin skeleton and were oxidized either in the side chain or in the pleuromutilin ring. In this study, metabolism of valnemulin in rats, chickens, and swines was investigated using UPLC-Q/TOF-MS technology, and more than 75 metabolites were detected. The results showed that the main metabolic pathways of valnemulin were hydroxylation in the mutilin part and the side chain, oxidization on the sulfur of the side chain to form *S*-oxides, hydrolysis of the amido bond, and acetylization in the amido of the side chain. Numerous hydroxylated metabolites of valnemulin were detected. In addition, many metabolites (V9−40) having the mutilin part double or triple oxidized were first detected in the present research. This suggests that the pleuromutilin ring tends to be further oxidized on the basis of metabolites V1−V5. Metabolite V6, in which the sulfur of the side chain was oxidized to form *S*-oxides, was also found in three species, which have been reported by EMEA.[9] In addition, the metabolites of hydrolysis (V41−V58), acetylization (V59−V75), and hydroxylation (V7) in the side chain were also found first in this study. On the basis of the metabolites identified, the proposed metabolic pathways of valnemulin in rats, chickens, and pigs are shown in Figure 8.

In summary, UPLC-Q/TOF-MS was used to investigate the metabolic fate of valnemulin in in vitro rats, chickens, pigs, goats, and cows and in in vivo rats, chickens, and pigs. As a result, 7 and 75 metabolites of valnemulin were detected in vitro and in vivo, respectively, and most of them are reported for the first time. The results showed that the metabolic pathways of valnemulin were hydroxylation in the mutilin part (the ring system) and the side chain, and the former was the major metabolic route. In addition, the results also revealed that the metabolic pathways and the main metabolites of valnemulin in three species are different. All in all, the proposed metabolic pathways of valnemulin in rats, chickens, pigs, goats, and cows will give useful data for the explanation of the residue of valnemulin among different species and, moreover, will further facilitate food safety evaluation of valnemulin.

natural antioxidants for protection against ROS-induced health disorders.

In the ocean, the extreme environment, such as low light intensities and high oxygen concentrations, leads to the formation of free radicals and other ROS in cells. Therefore, for self-protection against serious oxidative damages, marine algae could produce potent antioxidants.[17] In fact, marine algae have been considered as a rich source of natural antioxidants due to the presence of various secondary metabolites with antioxidant effect.[18] Especially, the antioxidant activities of some protein hydrolysates or peptides from marine algae have been investigated. The protease extracts from brown seaweeds *Scytosiphon lomentaria* and *Ishige okamurae* displayed high scavenging activities.[19,20] A pepsin-hydrolyzed peptide (VECYGPNRPQF) from *Chlorella vulgaris* protein waste was reported to have potent antioxidant activity against various free radicals; especially, it exhibited gastrointestinal enzyme resistance, but no cytotoxicity was observed in human lung fibroblasts cell lines (WI-38).[21] Enzymatic hydrolysates from a benthic diatom *Navicula incerta* exhibited free radical scavenging effects on 2,2-diphenyl-1-picrylhydrazyl (DPPH), hydroxyl, and superoxide radicals.[22] In another study,[23] they purified two antioxidative peptides from the papain hydrolysate of *Navicula incerta*: NIPP-1 (PGWNQWFL) and NIPP-2 (VEVLPPAEL). Interestingly, NIPP-1 and NIPP-2 also displayed inhibition of ethanol-induced cytotoxicity in HepG2/CYP2E1 cells. Using different proteases (pepsin, papain, trypsin, and $\alpha$-chymotrypsin), protein hydrolysates were produced from the marine *Chlorella ellipsoidea*, and an antioxidant peptide LNGDVW (702.2 Da) was identified, which showed potent free radical (peroxyl, DPPH, and hydroxyl radicals) scavenging activities.[24]

However, these antioxidant activities of marine algae-derived peptides (Table 1) are based on in vitro assay; it is unknown if the in vitro antioxidant activities are consistent with their in vivo activities. On the one hand, many in vitro assays frequently use chemically generated radicals that do not occur in vivo, although in vitro assay is valuable. Therefore, it may be more reasonable to use biologically relevant radicals that occur in vivo.[25] For example, oxygen radical absorbance capacity (ORAC) is such an assay.[26] In this assay, a nonfluorescent product is formed by interaction between a fluorescent probe and the peroxyl radicals from the decomposition of 2,20-azobis-2-methyl-propanimidamide dihydrochloride (AAPH), and the antioxidant capacity is determined by changes in the fluorescent product formed over time. The ORAC assay has been applied to analyze the antioxidant capacity of nearly 300 fruits and vegetables by the U.S. Department of Agriculture.[27] Thus, in vivo antioxidant activities can be evaluated by plasma ORAC, malondialdehyde (MDA; a marker of lipid peroxidation), and antioxidant enzymes (glutathione peroxidase (GPX), superoxide dismutase (SOD), and catalase (CAT)), as well as thiobarbituric acid reactive substances (TBARS) in organs (heart, liver, and kidney).[28,29] On the other hand, the in vivo environment is much more complicated than the in vitro environment. Upon in vivo ingestion of a protein hydrolysate or a peptide, its availability is influenced by various factors such as the rate of gastric transit, intestinal motility, luminal hydrolysis, and mucosal absorption. At least, peptides must pass through the gastrointestinal tract to reach their target site intact. In addition, in human blood, there are a large number of serum peptidases, which can further hydrolyze bioactive peptides and reduce their activity. Therefore, it is very

necessary to conduct simultaneous evaluation of the in vitro and in vivo antioxidant capacity. Unfortunately, to date, no studies have evaluated the antioxidant efficacy of marine algae-derived peptides using animal models, except for a few papers related to extracts or compounds or whole algae, such as the in vivo antioxidant activity of carotenoids from *Dunaliella salina*, a green microalga;[30] the antioxidant effect of alcoholic extract from the marine alga *Chlorella vulgaris* against naphthalene-induced oxidative stress in the albino rats;[31] and the antioxidant activity of whole *Spirulina* in rats.[32]

**Anticancer Biopeptides.** Cancer is a continually increasing threat for human health. Radiotherapy and chemotherapy are the main approaches to fighting cancers, despite the presence of side effects and development of resistance. Marine algae-derived peptides have been shown to possess cytotoxic effects on human cancer cells (Table 2).[33] For example, from *Chlorella vulgaris* protein waste Sheih et al.[34] isolated a undecapeptide with the sequence VECYGPNRPQF, which exhibited strong dose-dependent antiproliferation ($IC_{50}$ value = 70.7 ± 1.2 μg/mL) and induced a post-G1 cell cycle arrest in gastric cancer AGS cells and no cytotoxicity in normal lung fibroblast WI-38 cells in vitro. Using low-temperature high-pressure extraction, enzymatic hydrolysis, ion exchange, and gel filtration chromatography, Wang and Zhang[35] isolated a polypeptide CPAP from *Chlorella pyrenoidosa*, which had inhibitory activity on human liver cancer HepG2 cells with an $IC_{50}$ value of 426 μg/mL. Phase contrast microscopy showed that HepG2 cells exhibited the characteristics of apoptosis, including cell membrane shrinkage, fragmentation of nuclear chromatin, and formation of black apoptotic bodies, in a high-dose group (0.3−0.5 mg/mL), suggesting the presence of CPAP-induced apoptosis and necrotic death in HepG2 cells. In addition, the micro- and nanoencapsulation of CPAP demonstrated the resistance of CPAP to gastrointestinal enzymatic degradation. Similarly, an antitumor polypeptide Y2 was obtained from the trypsin digest of *Spirulina platensis* proteins.[36] The polypeptide Y2 exhibited cytotoxicity toward MCF-7 and HepG2 cells with an $IC_{50}$ value of ∼61 μg/mL, suggesting that the activity of Y2 is 7-fold stronger than that of CPAP.

These results reveal that the use of peptides from marine algae has potential for the prevention and treatment of cancer, but their mechanisms of action (Figure 2) need to be extensively elucidated. Generally, marine anticancer peptides kill cancer cells by different mechanisms, including apoptosis induction, tubulin−microtubule imbalance, and angiogenesis inhibition.[37] Apoptosis, as a form of programmed cell death, occurs primarily through two well-characterized pathways initiated by caspase activation in cells: one is the extrinsic death receptor pathway, and another is the intrinsic mitochondrial pathway.[38] Many peptides originated from marine animals were reported to adopt a strategy of triggering apoptotic processes,[39] which should be useful for demonstrating the detailed mechanism of action of marine algae-derived peptides.

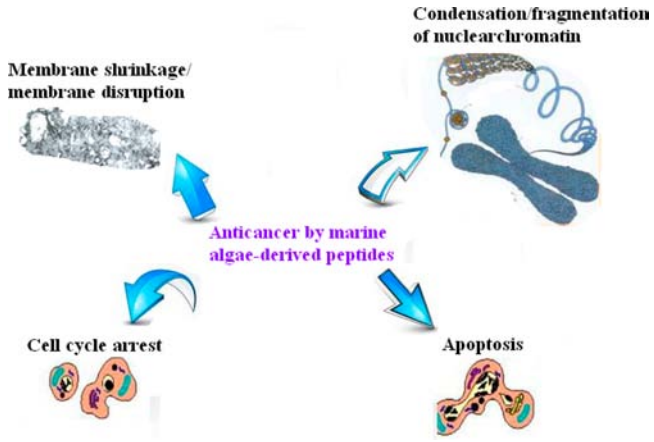

**Figure 2.** Anticancer mechanisms of marine algae-derived bioactive peptides. Apoptosis and cell cycle arrest could be involved.

**Antihypertensive Biopeptides.** Hypertension is recognized as a key target for controlling cardiovascular disease-related mortality.[40] There has been continuing interest in the search for bioactive peptides with antihypertensive bioactive peptides from marine algae (Table 3).[12] From *Undaria pinnatifida*, Suetsuna et al.[41] characterized 10 kinds of dipeptides; among them, four peptides (YH, KY, FY, and IY) significantly decreased the blood pressure in spontaneously hypertensive rats. Cha et al.[42] reported that five different enzymatic digests from a brown seaweed *Ecklonia cava* exhibited potent angiotensin-converting enzyme (ACE) inhibitory effects with $IC_{50}$ values of 2.33−3.56 μg/mL. Sheih et al.[43] observed that a purified undecapeptide (VECYGPNRPQF) from *Chlorella vulgaris* possessed ACE inhibitory activity ($IC_{50}$ = 29.6 μM). Similarly, a potent ACE inhibitory peptide (VEGY) from *Chlorella ellipsoidea* was discovered to have ACE inhibitory activity ($IC_{50}$ value = 128.4 μM).[44] In addition, the oral administration of purified peptide can significantly decrease systolic blood pressure in spontaneously hypertensive rats. Recently, from cultured marine microalga *Nannochloropsis oculata*, Samarakoon et al.[45] purified two novel peptides, GMNNLTP and LEQ; their $IC_{50}$ values of ACE inhibitory activity were 123 and 173 μM, respectively. However, in contrast, up to now, few rennin inhibitory peptides from marine algae have been reported. The first example is IRLIIVLMPILMA isolated from the macroalga *Palmaria palmata*, which inhibited renin activities by 58.97% at a concentration of 1 mg/mL.[46]

The renin−angiotensin system (RAS) and kinin−arginine−nitric oxide system pathways are the key targets for controlling blood pressure.[47] The enzyme rennin, after its release from the kidney, cleaves the inactive peptide angiotensinogen secreted from the liver and converts it into angiotensin-I. Subsequently,

ACE converts angiotensin-I into angiotensin-II and inactivates the vasodilator bradykinin, leading to a rise in blood pressure. Thus, there are two ways to control blood pressure by modulating RAS; one is direct inhibition of angiotensin-I generation from angiotensinogen by rennin, and another is blockage of conversion from angiotensin-I to angiotensin-II by ACE. Therefore, rennin and ACE inhibitory factors are considered as the way to treat hypertension. On the other hand, the kinin−nitric oxide system works in concert with the RAS systems to regulate blood pressure. Bradykinin activates $Ca^{2+}$/calmodulin-dependent endothelial nitric oxide synthase (eNOS), which catalyzes the conversion of arginine to nitric oxide (NO) and citrulline, leading to a drop in blood pressure. Studies confirmed that eNOS knockout and NO deficiency can lead to clinical hypertension.[48,49] Therefore, the arginine-rich peptides can also be considered as a strategy for hypertension therapy.[50] As mentioned above, the acting mechanisms of marine algae-derived peptides are related to ACE and rennin inhibitions, and the eNOS/NO pathway is temporarily not involved (Figure 3).

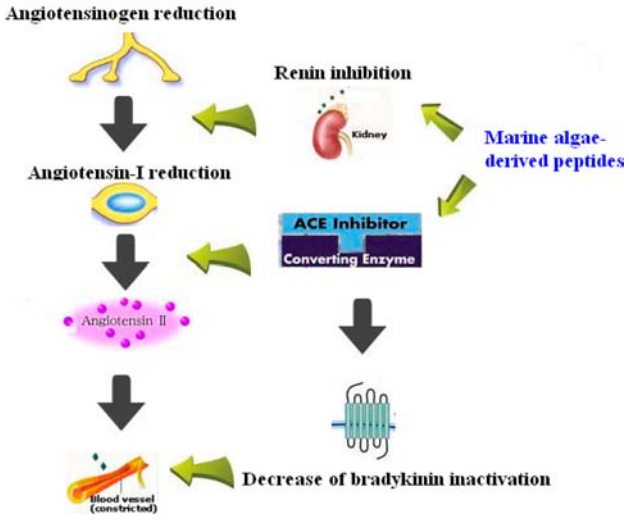

**Figure 3.** Antihypertension mechanisms of marine algae-derived bioactive peptides. ACE and rennin inhibitions are involved.

**Antiatherosclerotic Biopeptides.** Atherogenesis is a process by which plaques are gradually formed by fatty materials, which can lead to high blood pressure and cardiovascular disease as a result of compromised arteries. A recent study[51] showed that a *Chlorella* undecapeptide, with the amino sequence VECYGPNRPQF, significantly suppressed the levels of E-selectin, intercellular cell adhesion molecule-1 (ICAM-1), vascular cell adhesion molecule-1 (VCAM-1), monocyte chemoattractant protein (MCP-1), and endothelin-1 (ET-1) gene expression. On the other hand, the vascular inflammatory role of platelet activating factor acetylhydrolase (PAF-AH) is considered a promising therapeutic target for the prevention of atherosclerosis. Several oligopeptides were isolated and characterized from the red macroalga *Palmaria palmata*.[52] Among them, NIGK showed PAF-AH inhibition with an $IC_{50}$ value of 2.32 mM, suggesting a valid drug template for PAF-AH inhibitors. Furthermore, Vo and Kim[53] purified two bioactive peptides P1 (LDAVNR) and P2 (MMLD) from the gastric enzymatic hydrolysate of *Spirulina maxima*. P1 and P2 inhibited the production of adhesion molecules including P-selectin and E-selectin by down-regulating early growth response factor 1 (Egr-1) expression via histamine receptor and PKCδ-dependent MAPKs activation pathway. Additionally, P1 and P2 were shown to have anti-inflammatory activity by reducing ROS production and inhibiting histamine release and IL-8 expression.[54]

In the early stage of atherogenesis, the activation of endothelial cells leads to the production of IL-6 and MCP-1. IL-6 is a pro-atherogenic cytokine, and MCP-1 is implicated in the development of atherosclerosis by recruiting monocytes into the subendothelial cell layer.[55,56] ICAM-1, VCAM-1, MCP-1, and ET-1 are believed to have important roles in the etiology of atherosclerotic vascular disease.[57,58] Reduction of these molecules' expression has been demonstrated to be an effective approach to blocking the development of atherosclerosis.[59]On the other hand, inflammatory processes in endothelial cells are crucial events to initiate and promote early stage atherosclerotic lesions.[60] ROS is a common product of inflammatory processes; H1 receptor and platelet activating factor acetylhydrolase play a central role in the induction and maintenance of inflammatory reaction.[61] Moreover, Egr-1 is the target of some inflammatory genes including cytokines, chemokines, adhesion molecules, etc.[62] Thus, ROS, H1 receptor, and Egr-1 are also considered as key targets for atherosclerosis treatment. The above data suggest that the antiatherosclerosis effects of marine algae-derived peptides (Table 4) could be associated with adhesion molecule reduction, platelet activating factor acetylhydrolase inhibition, and anti-inflammation (Figure 4).

**Immunomodulatory Biopeptides.** In undernourished Balb/c mice, Morris et al.[63] reported that oral administration of protein hydrolysate from *Chlorella vulgaris* activates both innate and specific immune responses, including markedly increasing the lymphocyte pool, production of T cell-dependent antibody responses, and reconstitution of delayed-type

hypersensitivity (DTH) responses. In another study,[64] *Ecklonia cava* hydrolysate was shown to have the immune-stimulating effect on murine splenocytes in vitro. Additionally, in ICR mice treated with *E. cava* hydrolysate, the proliferation of splenocytes was dramatically enhanced; the numbers of CD4+ T cells, CD8+ T cells, and CD45R/B220+ B cells were markedly increased; TNF-α and IFN-γ were down-regulated, and IL-4 and IL-10 were up-regulated. Cian et al.[65] found that enzymatic hydrolysates from a phycobiliprotein byproduct of *Porphyra columbina* exhibited immunosuppressive effects on rat splenocytes by enhancing IL-10 production and inhibiting the production of TNF-α and IFN-γ.

As an anti-inflammatory cytokine, IL-10 is expressed by spleen macrophages and regulatory T lymphocytes (Tregs). It is capable of inhibiting synthesis of pro-inflammatory cytokines such as IFN-γ, IL-2, IL-3, and TNF-α. IL-10 also can block NF-κB activity and enhances B cell survival, proliferation, and antibody production. IL-4 is a cytokine that induces differentiation of naive helper T cells (Th0 cells) to Th2 cells. It can stimulate B-cell and T-cell proliferation and decreases the production of IFN-γ, IL-12, Th1 cells, macrophages, and dendritic cells. CD4+T cells are an essential part of the human immune system, which primarily function in sending signals to other types of immune cells, including CD8 killer cells. The above observations suggest that the immunomodulatory mechanism of marine algae-derived proteins or peptides (Table 5) is primarily involved in cytokine regulation and T cell and B cell proliferation pathways (Figure 5).

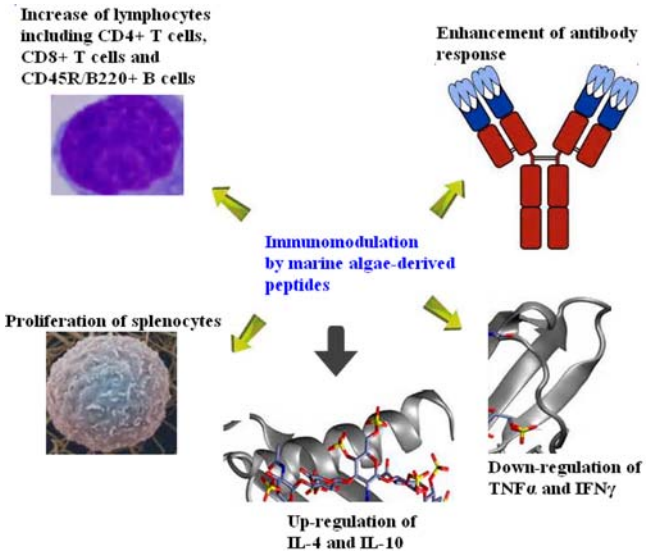

**Figure 5.** Immunomodulation mechanisms of marine algae-derived bioactive peptides, which are primarily involved in cytokine regulation and T cell and B cell proliferation pathways.

**Other Biopeptides.** Solar ultraviolet (UV) irradiation damages human skin and induces premature aging. UV irradiation leads to activation of transcription factor activator protein-1 (AP-1), increases matrix metalloproteinases (MMPs) expression, and causes collagen degradation.[66] Cysteine-rich 61 (CYR61) is an extracellular matrix-associated signaling

**Table 5. Marine Algae-Derived Immunomodulatory Peptides**

| peptide name or sequence | source | enzyme | $IC_{50}$ | in vitro/ in vivo | mechanism of action | ref |
|---|---|---|---|---|---|---|
| protein hydrolysates | *Chlorella vulgaris* | pancreatin | | in vivo (mice) | stimulation of both humoral and cell-mediated immune functions (T-dependent antibody response and the reconstitution of delayed-type hypersensitivity response) | 63 |
| protein hydrolysates | *Ecklonia cava* | Kojizyme | | in vivo (mice) | increases in lymphocytes, monocytes, and granulocytes; down-regulation of TNF-α and IFN-γ, up-regulation of IL-4 and IL-10 | 64 |
| protein hydrolysates | *Porphyra columbina* | trypsin, alcalase | 2.1−5.6 g/L | in vivo (rats) | cytokine modulations (inhibition of TNF-α and IFN-γ, increase of IL-10) | 65 |

**Table 6. Marine Algae-Derived Anti-UV Radiation and Antiosteoporosis Peptides**

| peptide name or sequence | source | enzyme | $IC_{50}$ | in vitro/in vivo | mechanism of action | ref |
|---|---|---|---|---|---|---|
| Chlorella derived peptide | *Chlorella* sp. | no enzyme used | | in vitro (skin fibroblast 966SK) | inhibition of MMP-1, AP-1, CYR61, and MCP-1 | 68, 69 |
| MPDW | *Nannochloropsis oculata* | Alcalase, Neutrase, Flavourzyme, trypsin, and Protamex | | in vitro (human osteosarcoma (MG-63) and murine mesenchymal stem cell (D1)) | increases in ALP, osteocalcin, collagen type I, BMP-2, BMP2/4; phosphorylation of MAPK/Smad pathways | 76 |

molecule; it not only inhibits procollagen synthesis by decreasing transforming growth factor (TGF)-b receptor II (TbRII) but also up-regulates MMP-1 by activating AP-1.[67] Studies indicated that *Chlorella*-derived peptide (CDP) reduced UV-induced MMP-1 and CYR61 mRNA expression and MCP-1 production, restored UV-suppressed procollagen, and inhibited UV-induced c-fos and c-jun expressions.[68,69] These results (Table 6) suggest that the protective effect of CDP on UV radiation-induced damage in the skin is associated with the ameliorative effects of CDP on the expressions of AP-1, CYR61, and MCP-1 (Figure 6).

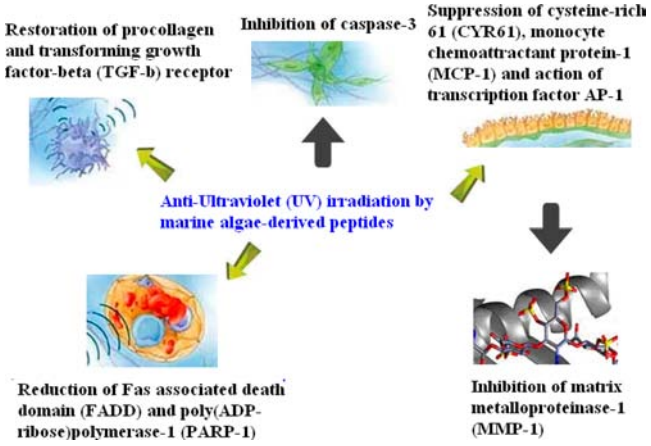

**Figure 6.** Anti-ultraviolet irradiation mechanisms of marine algae-derived bioactive peptides, which is related to the reduction in the expressions of AP-1, CYR61, and MCP-1.

Osteoporosis is a systemic skeletal disease and has become an important public health problem.[70] There are various signaling pathways involved in osteoblast differentiation, including mitogen-activated protein kinases (MAPKs), Smad, and nuclear factor kappa-light-chain-enhancer of activated B cells (NF-κB).[71−73] During osteoblast differentiation, many osteomarkers (alkaline phosphatase (ALP), collagen type I, and osteocalcin) are highly expressed, and the MAPK signaling cascades (ERK (p-ERK), p-p38, and p-JNK) are activated.[74] Smad 1, Smad5, and Smad8 become phosphorylated by interacting with activated bone morphogenetic proteins (BMPs) receptors and form a complex with Smad 4 to regulate the transcription of various target genes.[75] Nguyena et al.[76] purified an osteoblast-differentiatory peptide MPDW from biodiesel byproducts of microalgae *Nannochloropsis oculata*. The purified peptide was found to facilitate osteoblast differentiation by increasing the expression of several osteoblast phenotype markers, including osteocalcin, collagen type I, alkaline phosphatase (ALP), BMP-2, BMP2/4, and bone mineralization in both human osteoblastic cells (MG-63) and murine mesenchymal stem cells (D1). Moreover, the peptide increased phosphorylation of MAP kinases (p-ERK, p-JNK, p-p38) and Smads (p-Smad1/5/8) expression. This suggests potential application of algae-derived peptide (Table 6) in bone health, and its mechanism of action is shown in Figure 7.

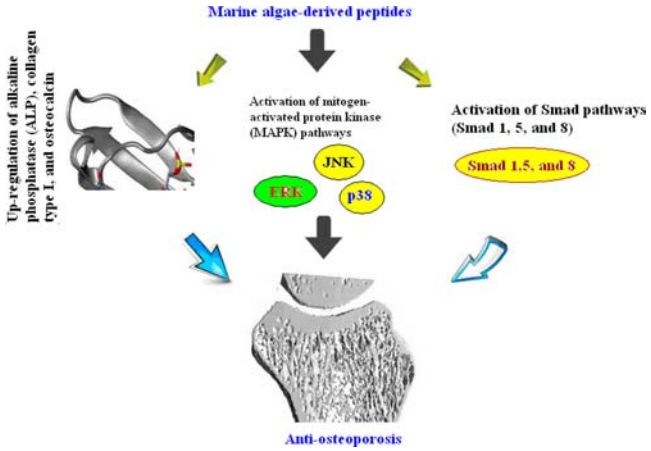

**Figure 7.** Antiosteoporosis mechanisms of marine algae-derived bioactive peptides, which are associated with the up-regulation of osteocalcin, collagen type I, alkaline phosphatase (ALP), and bone morphogenetic proteins (BMP)-2 and BMP2/4 and the increased phosphorylation of MAP kinases (p-ERK, p-JNK, p-p38) and Smads (p-Smad1/5/8).

## FUTURE CHALLENGES

**In Silico Proteolysis and Quantitative Structure−Activity Relationship Studies.** The traditional hydrolysis−purification−characterization protocol for bioactive peptide discovery is labor-intensive and costly. In addition, this strategy might exclude minor but potent peptides in the hydrolysate.[77] An emerging approach in the production of bioactive peptide is the use of an in silico approach, which generally involves the selection of appropriate protein/enzyme combinations by database search, generation of peptides of interests following in silico hydrolysis, quantitative structure−activity relationship (QSAR) model prediction, and synthesis and bioassay of satisfactory peptides. Among them, the in silico hydrolysis is able to select a suitable enzyme for the hydrolysis of a given protein, using some programs such as BIOPEP, POPS, NeuroPred, and PeptideCutter.[78] QSAR modeling provides a method to find mathematical expressions for describing the relationship between peptide structure and bioactivity, which may be useful for estimating the activity of any related peptides and for predicting structures with high activity. To date, information about the structural characteristics associated with specific bioactivity is limited, although some information is available, such as all of the most potent ACE-inhibitory peptides contain at least one proline residue,[79] and the very

dx.doi.org/10.1021/jf502420h | J. Agric. Food Chem. 2014, 62, 9211−9222

potent antimicrobial peptides have been known to be cationic with hydrophobic amino acid residues.[80]

On the basis of the QSAR modeling of antioxidative peptides for scavenging radicals in three databases, namely, Trolox equivalent antioxidant capacity (TEAC), oxygen radical absorption capacity (ORAC), and superoxide radical (SOR), a relationship between the physicochemical properties of the C-/N-terminal region and antioxidant potency was established.[81] Specifically, the C-terminal is more important than the N-terminal; the contribution of amino acids to antioxidant activity is ordered as C2 > C1 for TEAC, C3 > C4 > C1 for ORAC, and C4 > C1 > N1 for SOR. Bulky hydrophobic amino acids at the C-terminal are related to the antioxidant activity of peptides in the three free radical systems. Several publications explore the potential of in silico methods for the screening of bioactive peptides. For example, by in silico digestion of egg white protein and QSAR analysis of more than 20000 peptides generated from 75 in silico hydrolysates, Majumder and Wu[82] found that thermolysin−pepsin digestion of ovotransferrin was the best condition, and three novel antihypertensive peptides were identified. Sargadia et al.[83] identified six novel peptides with ACE-inhibitory activity ($IC_{50}$ values = 4−32 $\mu$M) from 231 peptides of milk proteins, using matrix-assisted laser desorption/ionization tandem time-of-flight (MALDI-TOF-TOF) mass spectrometry and QSAR modeling on ACE-inhibitory peptides with an amino acid length larger >5.

**In Vivo Fate of Bioactive Peptides.** Due to the susceptibility of peptides to protease degradation, the fate of bioactive peptides during gastrointestinal transit is a major problem. In fact, the antihypertensive peptide $\beta$-LG f(142−148) obtained from $\beta$-lactoglobulin could not be detected in the sera of human volunteers following its oral ingestion; that is, the peptide is not sufficiently stable to gastrointestinal and serum proteases.[84] To enhance the stability of peptides, one solution is chemical modification of peptides and the incorporation of unnatural amino acids (including D-amino acids). For example, at the carboxyl terminal end of a peptide, the presence of a proline residue has been shown to increase the peptide's resistance to degradation by digestive enzymes.[85] Shen et al.[86] developed a new chemical method of peptide synthesis to generate cyclic peptides by incorporating unnatural amino acids into a peptide chain, hence increasing stability. Another solution is encapsulation of peptides with polymers or particles such as dendrimers, liposomes, and polyectrolyte microspheres. For example, Wang and Zhang[35] investigated the micro- and nanoencapsulation of a *Chlorella pyrenoidosa* antitumor polypeptide (CPAP) by complex coacervation and ionotropic gelation. The in vitro release tests showed that CPAP was well preserved against gastric enzymatic degradation after micro/nanoencapsulation, and the slowly controlled release in the intestine could be potentially achieved. On the other hand, due to the existence of intestinal bacterial communities, it is necessary to consider whether or not potential toxic metabolites could be generated by fermentation of gut microbiota on bioactive peptides.[87] For example, the increased protein fermentation and decreased carbohydrate fermentation by gut microbiota was shown to cause a significant decrease in fecal cancer protective metabolites (e.g., butyrate) and the greatest formation of hazardous metabolites such as *N*-nitroso compounds, which is probably detrimental to colonic health.[88]

## NOVEL TECHNOLOGIES IN BIOACTIVE PEPTIDES STUDIES AND PRODUCTION

**Enzyme-Assisted Extraction Technology.** To obtain bioactive peptides from marine algae, the first step is to effectively extract proteins. Marine algae cell walls are made of sulfated and branched polysaccharides.[89] It is essential to break down cell walls for extracting marine algal proteins. Enzyme-assisted extraction (EAE) has received more attention than its counterparts; it is a highly sophisticated technique and can also be applied for large-scale operations.[3,90] EAE is an ecofriendly, nontoxic, high-bioactivity, and relatively low-cost technology. The commonly used food grade enzymes include cellulase, $\alpha$-amylase, and pepsin.[91] Compared to extracts obtained using conventional extraction methods, enzyme-assisted extracts have higher antioxidant activity.[92] Similarly, enzyme proteolysis was found to enhance extraction of ACE inhibitory and antioxidant peptides from *Porphyra columbina* residual cake.[93]

**Subcritical Water Extraction (SWE) Technology.** Besides EAE, another novel technology for algae protein extraction is SWE. It is reported that subcritical water hydrolysis is a feasible technique for high-yield protein and amino acid production from animal and vegetable materials.[94] Using subcritical water conditions (100−220 °C) for 30 min, high yields of peptides and amino acids (about 219 and 8.0 mg/g of dry bran, respectively) were produced from deoiled rice bran; importantly, the product obtained at 200 °C after 30 min of hydrolysis exhibited high antioxidant activity.[95] On the basis of SWE of microalga *Haematococcus pluvialis* at different temperatures (50−200 °C), antioxidant and antimicrobial compounds were obtained.[96] Employing flash hydrolysis (a few seconds of residence time and subcritical water conditions),[97] >60% of the total nitrogen content (dry basis) in microalgae *Scenedesmus* sp. was extracted within 10 s of residence time above 240 °C. The NMR spectra indicated that the extracted protein is present mainly as water-soluble peptides and free amino acids.

**Other Technologies.** In peptide preparation, a major challenge is how to conduct large-scale production of bioactive peptides. It is known that chemical synthesis is relatively expensive and not suitable for large-scale production.[80] In this respect, biotechnological methods may provide opportunities for manufacturing large amounts of bioactive peptides. Enzymatic hydrolysis under the condition of immobilized enzymes can avoid the generation of secondary metabolites by enzymatic autolysis and can be recycled. Enzymatic hydrolysis in continuous enzyme membrane reactor system allows faster reactions, higher yields, cleaner products, and lower operating costs, which are advantageous in industrial-scale production.[1,79,98] These methods have been applied to the production of some plant-derived bioactive peptides.[99−101] In addition, bioactive peptides can be produced by in situ microbial fermentation of parent proteins. Usually, lactic acid bacteria and bifidobacteria are widely used for the production of bioactive peptides,[102] for example, production of antibacterial peptide nisin by *Lactococcus lactis* and *Saccharomyces cerevisiae*[103] and antioxidant peptide production from bovine casein using *Bifidobacterium longum*.[104] Of course, other bacteria are also possible, such as the productions of antimicrobial peptides and ACE inhibitory peptide by *Streptococcus thermophilus*[105]

The second major challenge is how to realize the isolation of individual peptides with higher bioactivity from the hydrolysate,[106] because protein hydrolysates consist of complex

peptide mixtures with similar molecular weights. The most frequently used technologies include chromatography and pressure-driven filtration processes.[107,108] However, some drawbacks, such as the high cost of chromatographic technology and membrane fouling formation for pressure-driven processes, limit their wide application.[2] Recently, a patented electrodialysis with ultrafiltration membranes (EDUF) was developed to replace traditional separation methods for peptide recovery.[109] The driving force of EDUF is the electric field; hence, there is no significant fouling formation at the membrane interface due to the absence of pressure.[110] EDUF technology has been applied to the isolation of peptides from various hydrolysates.[111−114]

The third challenge is to understand the mechanisms of action of bioactive peptides. Fluorescence lifetime imaging (FLIM) technique is able to distinguish interacting and noninteracting fractions and to resolve changes in the binding, conformation, and composition of biologically relevant compounds in live cells.[115] Therefore, FLIM has become an inevitable technique for spatially resolving cellular processes and physical interactions of cellular components in real time.[116] Thus, it offers the opportunity to understand the mechanism of action for increasingly generated bioactive peptides, such as the interaction mechanisms of antimicrobial peptide (melittin) with live bacterial cells.[117] However, FLIM is unable to determine the detailed molecular changes in such an interaction process. In this respect, omics technologies (transcriptomics, proteomics, and metabolomics) could make contributions. For instance, proteomics is a promising technology in understanding mechanism of action for bioactive peptides. By two-dimensional electrophoresis (2DE) coupled to mass spectrometry, Huang and Chen[118] profiled proteome changes in antibacterial peptide epinecidin-1-treated zebrafish. A possible protein−protein interacting network regulated by epinecidin-1 was constructed, suggesting a potential role of epinecindin-1 in cytoskeletal assembly and organization to promote resistance to bacterial infection.

Currently, these novel methods are rarely applied to the production and study of marine algae peptides, but should be promising. Specifically, EAE and SWE technologies are first employed to extract proteins from marine algal biomass. On the one hand, the extracted proteins are subject to fermentation by probiotics such as lactic acid bacteria and bifidobacteria for peptide production. On the other hand, the extracted proteins are enzymatically hydrolyzed under the condition of immobilized enzymes or in a continuous enzyme membrane reactor system. Then, EDUF technology is employed to simultaneously isolate bioactive peptides from the complex peptides mixture. Finally, the mechanisms of action of bioactive peptides are investigated by FLIM and omics such as proteomics techniques (Figure 8).

In conclusion, bioactive peptides generated by enzymatic hydrolysis of algae protein or algae processing waste exhibit diverse biofunctionalities, which are promising in applications of functional foods, pharmaceuticals, and cosmeceuticals. However, there are still many challenges before bioactive peptides can be translated into practical use for human nutrition and health. In silico proteolysis and QSAR modeling can accelerate the discovery of bioactive peptides. Innovative technologies need to be developed for transferring laboratory-scale preparations to industrial-scale production. Extensive research is highly required to explore metabolic products of bioactive peptides during gastrointestinal digestion and to elucidate the detailed mechanisms of action in vivo. It is envisaged that the bioactive peptides market will become a self-standing industry in the next few decades. Hence, some regulations and standards that govern the production, utilization, and marketing of bioactive peptides should be set.

Table 1. Preventive Effect of Salts in the Control of Potato Soft Rot Caused by *P. atrosepticum* and *P. carotovorum* subsp. *carotovorum*

| | disease inhibition (%)[a] | |
|---|---|---|
| salt | *P. atrosepticum* | *P. carotovorum* subsp. *carotovorum* |
| aluminum dihydroxy acetate | 10.3 ef[b] | 9.6 g |
| aluminum chloride | 70.1 a | 66.0 b |
| aluminum lactate | 49.8 bc | 33.7 de |
| ammonium acetate | 18.8 de | 29.0 e |
| ammonium chloride | 11.0 ef | 11.6 fg |
| ammonium hydrogen phosphate | 11.3 ef | 0.0 i |
| calcium chloride | 18.8 de | 25.7 e |
| potassium chloride | 3.8 f | 1.4 i |
| potassium sorbate | 27.4 cd | 39.0 cd |
| sodium acetate | 14.5 de | 5.7 hi |
| sodium benzoate | 33.8 c | 41.3 c |
| sodium bicarbonate | 10.9 ef | 7.9 h |
| sodium carbonate | 10.3 ef | 6.5 h |
| sodium chloride | 1.0 f | 0.0 i |
| sodium formate | 6.7 ef | 0.0 i |
| sodium lactate | 10.3 ef | 0.0 i |
| sodium metabisulfite | 57.3 b | 71.9 a |
| sodium hydrogen phosphate | 11.0 ef | 0.0 i |
| sodium propionate | 27.4 cd | 28.4 e |
| sodium tartrate dibasic | 11.0 ef | 3.8 i |
| trisodium phosphate | 15.2 de | 14.9 f |

[a]Disease inhibition was calculated as follows: {[disease severity (control tubers) − disease severity (salt-treated tubers)]/disease severity (control tubers)} × 100. [b]Values of the same column followed by the same letter are not significantly different ($p < 0.05$) according to Fisher's protected LSD.

acids are highly saturated in bacteria,[27] lipid peroxidation by these salts in *Pectobacterium* sp. is unlikely to occur.

Previous work[28] showed an inverse sigmoidal relationship between the inhibitory effect of salts on the *in vitro* growth of *Pectobacterium* sp. and the water-ionizing capacity or p*K*′ (apparent acidity or basicity constant) of salt anions or cations primarily and lipophilicity of the salts, suggesting that these two parameters in combination may contribute to the antimicrobial action of the salts in the salt−microbe interactions. However, it is not known whether the observed *in vitro* antimicrobial action of the salts would persist *in vivo* in potato tubers. If it did, it raises the question whether those physicochemical characteristics of the salts could also provide a basis in the ternary salt−potato tissue−microbe interactions for the control of soft rot in potato tubers.

Thus, the objective of this work was to evaluate the inhibitory activity of several organic and inorganic salts against soft rot in potato tuber and to examine the general physicochemical basis of the inhibitory activity of salts on soft rot development when applied as preventive or curative treatments.

## MATERIALS AND METHODS

Strains of *P. carotovorum* subsp. *carotovorum* (ECC 1367) and *P. atrosepticum* (ECA 709) were provided by the Laboratoire de Diagnostic en Phytoprotection (MAPAQ, Quebec City, Quebec, Canada). The bacteria were maintained on nutrient agar (NA, Difco Laboratories, Detroit, MI) slants under mineral oil at 4 °C and served as stock cultures.

A total of 21 salts were used in these experiments (Table 1). All salts were purchased from Sigma Chemical Co. (St. Louis, MO), except for ammonium acetate, sodium chloride, and sodium bicarbonate (BDH, Inc., Toronto, Ontario, Canada) and aluminum lactate (Aldrich Chemical, Milwaukee, WI).

**Effect of Salts on Soft Rot Development.** Potato tubers (cv. Norland) were purchased from Propur, Inc. (St. Ambroise, Quebec, Canada) and stored at 4 °C until use. Selected tubers were washed with tap water, surface-sterilized by dipping in 0.525% sodium hypochlorite solution (10 min), rinsed by dipping twice in sterile distilled water for at least 10 min, and dried in ambient air. Four wounds (depth, 1 cm; diameter, 0.5 cm) were performed on each tuber from the apical to the basal ends,[29] using a pipet tip.

**Preventive Application of Salts.** Wounded tubers were immersed for 10 min in the different salt solutions (0.2 M) and dried in ambient air. Control tubers were immersed in sterile distilled water. Each wound was then inoculated with 20 μL of a suspension [$1 \times 10^7$ colony-forming units (CFU)/mL] of either *P. atrosepticum* or *P. carotovorum* subsp. *carotovorum*. Suspensions were prepared from 24 h old cultures grown in 20% tryptic soy broth (Difco). Tubers were subsequently incubated (24 °C) individually in a plastic chamber containing a wet sterile paper towel for 3 days. The disease severity was then assessed by measuring the largest diameter of each rotting lesion,[30] and the results were expressed in percentage of disease reduction compared to the control treatment (sterile distilled water; 1.3−2.2 cm lesion diameter). For each tuber, lesion diameter was a mean of the four inoculation sites. A completely randomized experimental design with three replicates was used, and the experiment was repeated twice.

**Curative Application of Salts.** Each wound was inoculated with 20 μL of one of the bacterial suspensions ($1 \times 10^7$ CFU/mL). After a 12 h incubation period at 24 °C, infected tubers were immersed (10 min) in the different salt solutions (0.2 M) or in distilled water (control). Tubers were then incubated (24 °C) individually in a plastic chamber containing a wet sterile paper towel for 3 days, and the disease severity was evaluated as previously described. A completely randomized experimental design with three replicates was used, and the experiment was repeated twice.

**Effect of Salt Treatments on Tissue pH.** The diffusion of salts in the tuber tissue was evaluated by monitoring the consequent modification of tissue pH for two acidic salts (aluminum chloride and sodium metabisulfite), two alkaline salts (trisodium phosphate and

Table 2. Curative Effect of Salts in the Control of Potato Soft Rot Caused by *P. atrosepticum* and *P. carotovorum* subsp. *carotovorum*

| | disease inhibition (%)[a] | |
|---|---|---|
| salt | *P. atrosepticum* | *P. carotovorum* subsp. *carotovorum* |
| aluminum dihydroxy acetate | 28.0 bc[b] | 7.6 cd |
| aluminum chloride | 41.3 a | 57.6 a |
| aluminum lactate | 30.7 bc | 29.6 b |

| sodium tartrate dibasic | 17.0 de | 0.0 e |
| trisodium phosphate | 15.0 de | 4.2 de |

[a]Disease inhibition was calculated as follows: {[disease severity (control tubers) − disease severity (salt-treated tubers)]/disease severity (control tubers)} × 100. [b]Values of the same column followed by the same letter are not significantly different ($p < 0.05$) according to Fisher's protected LSD.

sodium carbonate), and one lipophilic salt (sodium benzoate). Duplicate tuber slabs (1 cm wide × 3 cm long × 2 cm high) were dipped in 0.2 M of the salt solution and incubated at room temperature for up to 3 h. The slabs were removed from the salt solution at intervals and rinsed thoroughly using deionized water. Three consecutive 1 mm thick slivers (1 mm × 2 cm × 3 cm) were sliced from one end of the potato slab with a sharp knife. The slices were crushed using a garlic press (Atlantic Promotions, Inc., Longueuil, QC, Canada) and suspended in 30 mL of deionized water, and the pH of the slurry was measured. The experiment was repeated 3 times.

**Minimum Inhibitory Concentration (MIC) of Salts *in Vitro*.** The effect of the concentration of selected salts on the bacterial growth was evaluated. *P. carotovorum* subsp. *carotovorum* bacteria was grown in 250 mL flasks containing 50 mL of 20% tryptic soy broth (TSB, Difco) amended with 0−10 mM aluminum chloride, aluminum lactate, sodium metabisulfite, trisodium phosphate, or sodium carbonate or with 0−100 mM sodium benzoate, potassium sorbate, or sodium propionate by incubating at 24 °C with agitation (150 rpm, Lab-Line Instruments, Inc., Melrose Park, IL) for 24 h. The pH of the medium was not adjusted, and it varied with the type of salt. The flasks were inoculated with 100 μL of bacterial suspension ($1 \times 10^7$ CFU/mL). The bacterial growth was determined by turbidimetry at 600 nm on an ultraviolet/visible (UV/vis) spectrophotometer (Ultrospec 2000, Pharmacia Biotech, Ltd., Cambridge, U.K.), using appropriate blanks (non-inoculated media amended with salt). Results were expressed as the percentage of growth inhibition compared to the control (growth medium not amended with salt). A completely randomized experimental design with three replicates was used, with the experimental unit being a flask. The MIC of the salts was determined from the inhibition salt concentration plots.

**Statistical Analyses.** Analyses of variance were carried out with the GLM procedure of SAS (SAS Institute, Cary, NC). Treatment means were compared using Fisher's protected least significant difference (LSD) when the analysis of variation (ANOVA) indicated significant differences ($p < 0.005$).

## RESULTS AND DISCUSSION

The preventive inhibitory effect of the 21 salts against soft rot development in potato tuber is presented in Table 1. Disease lesion in the control tubers was 1.3−2.2 cm in diameter. Significant reduction of disease caused by *P. atrosepticum* and *P. carotovorum* subsp. *carotovorum* was obtained by the application of aluminum chloride (70.1 and 66.0%, respectively) and sodium metabisulfite (57.3 and 71.9%, respectively) and to a lesser extent by the application of sodium benzoate (33.8 and 41.3%, respectively), aluminum lactate (49.8 and 33.7%, respectively), and potassium sorbate (27.4 and 39.0%, respectively). Calcium chloride, ammonium acetate, and sodium propionate showed only a modest disease reduction. The other salts exhibited either negligible or no effect on disease development. When salts were applied as curative treatment, the highest inhibition of the disease caused by *P. atrosepticum* and *P. carotovorum* subsp. *carotovorum* was obtained with aluminum chloride (41.3 and 57.6%, respectively), sodium metabisulfite (42.0 and 52.8%, respectively), and sodium benzoate (33.3 and 33.5%, respectively) (Table 2). The other salts allowed for a disease reduction ranging from 10.0 to 30.7% on *P. atrosepticum* and from 0 to 29.0% on *P. carotovorum* subsp. *carotovorum*.

The dipping treatment of aluminum chloride, sodium metabisulfite, aluminum lactate, and sodium benzoate markedly decreased soft rot severity in infected tubers for both preventive and curative applications, whereas the *in vitro* test showed that a number of salts (aluminum dihydroxy acetate, aluminum chloride, aluminum lactate, ammonium acetate, potassium sorbate, sodium bicarbonate, sodium carbonate, sodium benzoate, sodium propionate, sodium metabisulfite, and trisodium phosphate) were effective against the causal agents of this disease.[28] We observed earlier that the inhibitory effect

of salts *in vitro* related primarily to the water ionization capacity of their ions, which is indicated by the acidity constant ($pK_a$) or basicity constant ($pK_b$) of the ions (the lower the $pK_a$ or $pK_b$ value of the ion, the greater its capacity to ionize water and alter the surrounding pH).[28] A greater ionization capacity of water was associated with a higher inhibitory effect *in vitro*. For higher salt concentrations (>0.1 M), apparent acidity or basicity constants ($pK'_a$ or $pK'_b$) of the ions are more appropriate, and hence, the $pK_a$ or $pK_b$ values were corrected for ionic strength of the salt solutions.[28]

Figure 1 shows that disease inhibition by the preventive application of salts relates inversely to the $pK_a'$ value of the cations (with common chloride anion) and that of the acidic bisulfite anion and the $pK_b'$ values of anions (with common sodium or potassium cation). It is seen clearly that some of the ions, bisulfite, aluminum, benzoate, sorbate, propionate, and calcium, are effective and exhibit a disease inhibition of more than 20%, whereas the other ions (acetate, bicarbonate, carbonate, chloride, formate, lactate, phosphate, potassium, sodium, and tartrate) show little effect. Although the inhibitory activities were attenuated overall for all of the salts tested in the presence of plant tissue compared to the *in vitro* activities, the decrease in the activity was drastic for salts, such as sodium phosphate, sodium carbonate, and sodium bicarbonate. In addition, both the effective and non-effective ions showed an apparent inverse linear relationship to the $pK'$ values of the ions in the presence of tissue, in contrast to the general inverse sigmoidal inhibitory pattern observed in *in vitro* inhibition,[28] suggesting that water ionization capacity of the ions should still play a role in their inhibitory activity in the tissue (Figure 1).

Disease inhibition by the curative application of salts in relation to the $pK'$ values of the ions is shown in Figure 2. While most ions exhibited no effect, three of the ions, $Al^{3+}$,

$HSO_3^-$, and benzoate, showed some inhibitory effect, suggesting that these ions may possess certain unique characteristics. The relationship between disease inhibition and the ion p$K'$ combined with the 1-octanol/water partition coefficient (p$K'$ − log $P_{o/w}$) generally followed the same pattern, with a slight improvement in the correlation coefficient for the effective salt group (Figures 3 and 4). Despite the

attenuated inhibitory effect of salts in the preventive and more so in the curative treatments, the water ionization capacity of the ions appears to play a role in the disease inhibition of the salts.

Figure 5 shows the time course of the migration of selected salts in the tuber tissue as implied by the changes in tissue pH, where the pH of the tissue dipped in water was 6.4. The pH of tissue dipped in the salt solutions reached a steady state in 2 h at 1 mm depth (Figure 5A) but not at the depths of 2 mm (Figure 5B) or 3 mm (Figure 5C). At the depth of 1 mm, the tissue pH was 11.2, 8.6, 6.2, 5.0, and 4.6 for trisodium

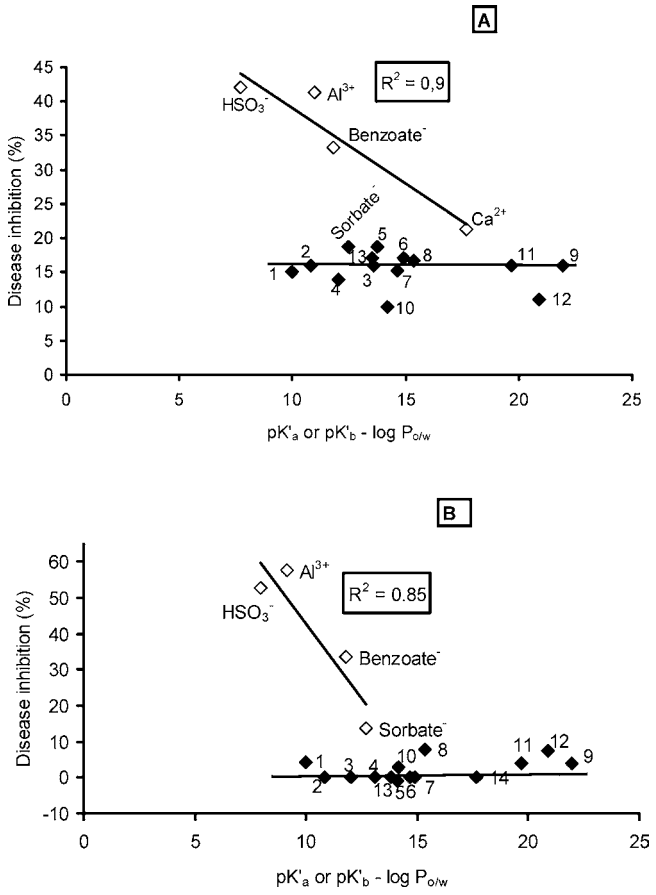

**Figure 4.** Relationship between inhibition of soft rot caused by (A) *P. atrosepticum* and (B) *P. carotovorum* subsp. *carotovorum* by curative application of salts and the addition parameter p$K'_a$ or p$K'_b$ − log $P_{o/w}$, which combines apparent acidity (p$K'_a$) or basicity (p$K'_b$) constants of the salt ions and their octanol/water partition coefficient ($P_{o/w}$): (1) $PO_4^{3-}$, (2) $CO_3^{2-}$, (3) $HPO_4^{2-}$, (4) $HCO_3^-$, (5) acetate$^-$, (6) tartrate$^2$, (7) formate$^-$, (8) lactate$^-$, (9) $Cl^-$, (10) $NH_4^+$, (11) $Na^+$, (12) $K^+$, (13) propionate$^-$, and (14) $Ca^{2+}$. Cations: common anion, chloride. Anions: common cation, sodium, except for sorbate, potassium.

phosphate, sodium carbonate, sodium benzoate, sodium metabisulfite, and aluminum chloride, respectively, after 2 h of dipping. There was little modification of tissue pH with sodium benzoate (pH 6.3). Whereas both trisodium phosphate and sodium carbonate increased the alkalinity of the tissue, both sodium metabisulfite and aluminum chloride acidified the tissue. At 2 mm depth, there was little change in tissue pH with sodium benzoate and aluminum chloride after 2 h of dipping, but changes in tissue pH were observed for trisodium phosphate (7.7), sodium metabisulfite (5.7), and to a small extent, sodium carbonate (6.7) (Figure 5B). At the depth of 3 mm, small changes in tissue pH were registered after 2 h of dipping only for trisodium phosphate (6.8) and sodium metabisulfite (6.2) (Figure 5C). The penetration of aluminum, a polyvalent cation, appeared to be restricted to the depth of 1 mm, presumably because of its binding to fixed negative charges in the cell wall.[31]

Among the salts, the *in vitro* MIC value of aluminum salts, metabisulfite, trisodium phosphate, sodium carbonate, and sodium propionate was ≤10 mM, whereas it was 100 mM for sodium benzoate and potassium sorbate. In effect, the inhibitory effect of salts *in vitro* did not bear a clear relationship

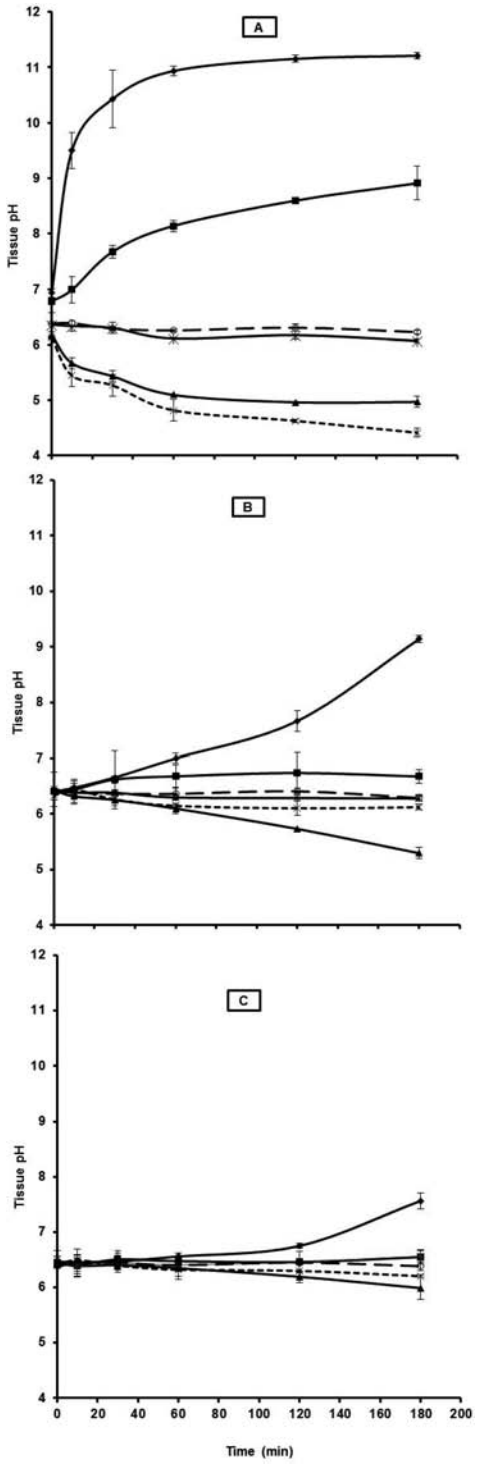

**Figure 5.** Kinetics of the migration of selected salts in the tuber tissue as indicated by changes in tissue pH. (A) pH change in the millimeter thick tissue, 1 mm from one end of the potato slab; (B) pH change in the millimeter thick tissue, 2 mm from the same end of the potato slab; and (C) pH change in the millimeter thick tissue, 3 mm from the same end of the potato slab, dipped in salt solutions for up to 3 h: (◆) trisodium phosphate, (■) sodium carbonate, (○) control, (∗) sodium benzoate, (▲) sodium metabisulfite, and (×) aluminum chloride. Vertical bars represent standard deviation.

to their activities in the presence of plant tissue. While trisodium phosphate and sodium carbonate (*in vitro* MIC, ≤10 mM) exhibited little activity *in vivo*, sodium benzoate and potassium sorbate (*in vitro* MIC, 100 mM) still maintained moderate activities *in vivo*. Overall, the acidic salts, such as aluminum chloride and sodium metabisulfite, and preservative salts, such as sodium benzoate, potassium sorbate, and propionate, still exhibited some significant effect, while alkaline salts, such as trisodium phosphate, sodium carbonate, and bicarbonate, showed little activity in the presence of the tissue compared to their *in vitro* activity. In addition, the inhibitory activity of all of the salts was attenuated to different degrees when applied as preventive treatment and, more so, when applied as curative treatment in potato tuber compared to their *in vitro* activity.

Several factors intrinsic to potato tubers, such as buffering capacity, or intrinsic to salts, such as water ionization, pH, and ion migration capacity, and salt−plant tissue interactions may be involved in the salt−plant−bacteria interactions, leading to the reduced activity of salts overall, and the near total loss of the activity of alkaline salts. As a result of salt−plant tissue interactions, the ions may undergo speciation, where the resulting ions may be less active against the bacteria. It is also possible that some of the salts that retain moderate activity even in the curative application may possess some unique properties that may have to do with the interaction with the plant tissue or their mobility in the tissue.

The buffering capacity of the tuber tissue could dissipate extreme pH conditions, and in the case of multiprotic salts (e.g., phosphates and carbonates), this could lead to their equilibrium favoring the formation of less effective ionic species, thereby dampening their inhibitory capacity in the plant tissue. In fact, the pH of the tuber tissue treated (10 min dipping, 1 mm from the wound surface) with trisodium phosphate (0.2 M solution at pH 12.5) was 10.1, where the predominant species, $HPO_4^{2-}$, is less inhibitory on the *Pectobacterium* bacteria than $PO_4^{3-}$ present in the salt solution.[28] Likewise, the pH of the tissue treated with sodium carbonate (solution pH of 11.1, predominant inhibitory species $CO_3^{2-}$) was 8.4, where $HCO_3^-$ predominates, which was shown *in vitro* to be slower than $CO_3^{2-}$ in killing those bacteria.[28] Although the buffering role of the tissue was evident when treated with aluminum chloride, sodium metabisulfite, or the organic acid salts, they still showed inhibitory activity in the tuber. For example, the pH of the treated tissue (10 min dipping, 1 mm from the wound surface) with sodium metabisulfite was 5.6 compared to the solution pH of 4.5, and that of aluminum chloride was 4.9 compared to the solution pH of 2.5.

A plausible argument can be made that salt−plant tissue interactions play a central role, leading to the attenuated inhibitory activity of salts in potato tuber by reducing the availability of the inhibitory ions for salt−bacteria interactions. The salt−plant interactions may involve alkalinization of plant cell walls and speciation of ions into less or more effective species by Donnan equilibrium[32] (ionic equilibrium of charged solutes in the presence of charged membranes or macromolecules such as the cell wall pectin) and electroneutrality, complexation of ions and their reduced migration into the tissue, and the partitioning of diffusible species, generated as a result of the salt−plant interactions, between the plant cells and the bacterial cells, leading to their reduced availability at the infection site.

The cell walls behave like a polyanion, owing to the presence of polygalacturonic acids, that sets up Donnan potential (electrostatic potential), resulting in the attraction of cations, including protons, and the repulsion of anions.[33−35] This cell

dx.doi.org/10.1021/jf5017863 | J. Agric. Food Chem. 2014, 62, 9223−9231

wall potential generates a proton gradient across the cell walls, which results in a difference of pH between the inside and outside of the walls[34] accompanied by hydrolysis of water. Entry of cations into the cell walls is driven by both chemical potential (higher concentration outside) and electrochemical potential (charges) across the cell walls. Thus, when a salt is present outside the cell walls, its cations would preferentially enter the cell walls, with its anions being excluded by the negative charges of the cell wall (Donnan exclusion), while the protons outflow would re-establish electroneutrality, thus rendering the cell walls more alkaline. However, in the presence of highly acidic salts, such as aluminum chloride (solution pH of 2.5), protons would also enter the cell walls with the cations ($Na^+$ and $Al^{3+}$) and the cell walls would become more acidic. In addition, water ionization by aluminum ions can generate protons and cause more acidification of the cell walls; otherwise, the cell walls would largely remain alkaline, arising from the Donnan effect, with $Na^+$ and $K^+$ cations, which possess low water ionization capacity.

The acidification of cell walls can also affect the activity of the bacterial macerating enzymes, such as the pectate lyases (optimum pH of 8.3−8.5), the cellulases and proteases (optimum pH of 7.0), and the polygalacturonase lyase (optimum pH of 8.5−9.5), which are secreted by the *Pectobacterium* bacteria.[36,37] When a neutral salt (NaCl, KCl, etc.) is present outside, the cell walls would be mainly loaded with the cation ($K^+$ or $Na^+$), to which the cell walls are also more permeable than $Cl^-$. Because the latter anion has low antimicrobial effect against the *Pectobacterium* bacteria, its presence outside the cell walls may have little effect on the pathogens.

The presence of aluminum and calcium salts would result in the cell walls being loaded by these multivalent cations, which can also complex with polygalacturonide residues, reinforcing the cell walls against pathogen attack. Thus, the tissue acidification and additional strengthening of the cell walls by complexation of multivalent aluminum species [$Al^{3+}$ and $Al(OH)^{2+}$] by pectins could contribute to the control of soft rot by the aluminum salts, such as $AlCl_3$. However, aluminum dihydroxy acetate exhibited disease inhibition to a lesser extent, probably because this salt solution contains mainly the monovalent $Al(OH)_2^+$ species, which has low cell wall complexing ability. The migration of aluminum ions into the plant tissue and the consequent water ionization (pH change) therein may have been limited to the depth of 1 mm (Figure 5A), in part, because of the complexation of aluminum ions to the pectic materials.[38] Nevertheless, the complexation of aluminum ions would also reduce their availability against the bacteria to a certain degree. Cell wall complexation of $Ca^{2+}$ ($CaCl_2$) and its strengthening could also explain the partial inhibitory effect of $CaCl_2$ on soft rot compared to either NaCl or KCl.

Although sodium metabisulfite is an acidic salt like aluminum chloride, it yields bisulfite anions which would be excluded by the negative charges of the cell wall (Donnan exclusion). However, proton efflux from the plant cell walls because of the Donnan effect may lead to the protonation of $HSO_3^-$ and $SO_3^{2-}$ species and the generation of molecular $SO_2$, which can diffuse freely through the plant cell walls and tissue. Thus, the presence of sulfite species can be expected deeper into the tissue, as seen by the tissue pH change profile (panels A and B of Figure 5). With respect to the organic acid salts (sodium benzoate, potassium sorbate, or sodium propionate) outside the cell walls, proton efflux could be expected to increase the concentrations of the non-dissociated and more effective antibacterial species, such as benzoic, sorbic, and propionic acids (by protonation) outside the cell, resulting in the inhibition of bacterial growth and the consequent tissue degradation to some extent.

In the presence of highly alkaline salts, such as trisodium phosphate (solution pH of 12.5) and sodium carbonate (solution pH of 11.1), which were effective in the *in vitro* inhibition of *P. atrosepticum* and *P. carotovorum* subsp. *carotovorum*, the electronegative status of the cell walls would limit the migration (Donnan exclusion) of the alkaline species ($HPO_4^{2-}$ or $PO_4^{3-}$ and $HCO_3^-$ or $CO_3^{2-}$) in the cell walls, which will be rather loaded with the sodium cation. In addition, protons would flow out from the cell walls to re-establish electroneutrality and pH gradient. Thus, not only would there be a lack of cell walls strengthening, but also the effective antibacterial alkaline species (e.g., $PO_4^{3-}$) will lose their inhibitory capacity because of gradual protonation into less inhibitory species, such as $HPO_4^{2-}$ and $H_2PO_4^-$. In addition, the efflux of protons from the cell walls would render them alkaline. Generation of less inhibitory species could therefore explain why these salts were ineffective in controlling soft rot in infected tubers, while they were highly effective inhibitors of bacterial growth *in vitro*. In contrast to alkaline anions, Donnan exclusion of bisulfite anions results in a different outcome as mentioned above, leading to the observed persistent inhibitory activity of sodium metabisulfite in the presence of plant tissue.

Disease inhibition upon preventive salt application was greater than in the curative treatment, indicating that a higher concentration of the salt ions is present at the wound site for salt−pathogen interactions. Presumably, the tissue had a head start in the tissue−pathogen interactions during the preventive treatment through its interactions with the salts as well as the tissue responses to wound stress. In contrast, the pathogen has the head start and advantage in invading the plant tissue in the curative application of salts. In curative salt application, $Al^{3+}$, $HSO_3^-$, and benzoate$^-$ maintained some activity in relation to their p$K'$ values, but the relationship to p$K'$ failed for those salts that exhibited less than 20% disease inhibition in the preventive treatment (Figure 2). Once the pathogen is well-established in the tissue, it becomes too late to ward off the infection for most of the ions that do not possess any special properties than simple modification of the surrounding pH (acid−base equilibria). The exceptions were the three ions, $Al^{3+}$, $HSO_3^-$, and benzoate$^-$, attributable to their inward diffusion into the tissue as ions or their speciated forms. Effectively, the generation of aqueous molecular $SO_2$ species from sodium metabisulfite, which can diffuse through the cell walls and membranes, may clarify the curative activity of this salt. Aluminum ions do not appear to penetrate far into the tissue (panels B and C of Figure 5), presumably because of complexation by pectins of the cell walls and their presence as complex hydrated ions in an aqueous medium. However, the migration of this ion into the cell walls of the exterior layers of the tissue is still appreciable (Figure 5A), attributable to its high electrochemical potential (electrostatic charge of +3). Because of the efflux of protons from the cell walls, benzoate, sorbate, and propionate ions can all be protonated into their corresponding non-dissociated acid forms, which are cell-wall-permeable and more potent bacterial growth inhibitors than their conjugated bases. In addition, benzoate and sorbate possess a conjugated double bond system that confers to them

a higher degree of hydrophobicity[28] and, consequently, a faster migration potential across the cell walls and a higher disease inhibition than propionate. The migration capacity across the cell walls of aliphatic sorbic acid (or propionic acid) can also be expected to be lesser than the aromatic benzoic acid and, hence, appears to be far less effective than benzoic acid in disease inhibition in the situation, where the pathogen has had a head start.

Finally, stimulation of defense mechanisms against diseases by certain salts has been shown in several plants. Jeandet et al.[20] observed that aluminum chloride stimulated the accumulation of phytoalexins (resveratrol) in grapevine leaves. The elicitation of callose synthesis by both aluminum and calcium has also been reported in several plants.[37] However, it is not known whether defense mechanisms are triggered in potato tuber in response to salts, such as aluminum chloride or sodium metabisulfite. It is conceivable that defense reaction may also be triggered in potato tubers, because the inhibitory effect of these salts is stronger in preventive application than in curative treatment, and this aspect deserves further investigation.

In conclusion, the results of this study support that aluminum chloride, sodium metabisulfite, and sodium benzoate have potential in controlling effectively soft rot development in potato tubers. This study also provides a general basis for the understanding of specific salt−tissue interactions and for salt selection to control plant diseases. The capacity of salt constituent ions to ionize water molecules appears to relate, in part, to their disease inhibition capacity for some ions, such as aluminum, bisulfite, and organic acid ions. The lack of activity of alkaline salts, such as trisodium phosphate and sodium carbonate, *in vivo* appears to be due to cell wall alkalinization by the Donnan effect and the speciation of their anions into less effective ions. The persistent, albeit reduced, *in vivo* activity of aluminum bisulfite, and organic acid salts may be attributed to their specific properties, in addition to the Donnan effect. The acidification of cell walls and complexation of ions by cell wall polymers (aluminum ions), the generation of highly diffusible molecular $SO_2$ (sodium metabisulfite), and generation of a more active and permeable acid form (sodium benzoate) may play a role in the persistent inhibitory activity of these salts in potato tuber, notwithstanding the induction of any biochemical defense mechanisms in the tissue in response to those salts, if any. The possible reduced aluminum ion penetration into the tissue by complexation and partitioning of the diffusible species, molecular $SO_2$ and acid form of benzoate, between the plant cells and the bacterial cells, leading to their reduced availability at the infection site, and the attenuated activity of these salts in the tissue. Further work would be required with respect to the formulation of salts exhibiting synergy and enhancement of disease inhibition in the tubers and the evaluation of potential health and environmental risks associated with salt applications before envisioning industrial application of these salts.

and different Sr sources. Furthermore, the compilation of $^{87}Sr/^{86}Sr$ data in soil and water covering all of South Korea offers a baseline for provenance studies by constraining $^{87}Sr/^{86}Sr$ in Sr sources on a national scale.

## MATERIALS AND METHODS

**Sampling Strategy and Study Area.** Soil, water (streamwater and groundwater), and plant (hot pepper and rice) samples were collected from September to October 2010 from every region in South Korea to obtain a representative nationwide sampling. Geologically, South Korea represents a remnant of the denudation of deformed Precambrian metamorphic basement rocks and sedimentary successions, as well as granitic intrusions and volcanics, concealing a long history of basin formation and crustal deformation.[13] The climate of Korea is temperate, with four distinct seasons and average monthly temperatures ranging from −1.1 °C in January to +24.9 °C in August (1971−2000). On the basis of the same 30 year period, the average annual precipitation is approximately 1302 mm, about 65% of which occurs from June to September.[14]

*Soil.* A total of 137 soil samples were collected at a depth of 5−10 cm, using high-density polyethylene (HDPE) measuring scoops to avoid any effects of fertilizers and plant litter, and stored in individual storage bags. All samples were air-dried, passed through a 2 mm mesh sieve, and then crushed in a shatter box equipped with a tungsten carbide grinding container. The exchangeable, carbonate, and silicate fractions were isolated using a sequential leaching and digestion procedure as follows.[12] Approximately 1.0 g of sample was reacted to isolate the exchangeable fraction with 10 mL of 1 M ammonium acetate ($NH_4OAc$) diluted using concentrated ultrapure $NH_4OAc$ (Fisher Scientific, Loughborough, UK) for 6 h. The mixture was centrifuged, and the supernatant was passed through a 0.45 $\mu$m polypropylene syringe filter, dried, and redissolved in 5% $HNO_3$ diluted using concentrated, ultrapure $HNO_3$ (reagent grade). The residue was reacted with 10 mL of 4 M acetic acid (HOAc) diluted using concentrated ultrapure HOAc (Fisher Scientific) for 6 h to isolate the carbonate fraction. The mixture was centrifuged, and the supernatant was passed through a 0.45 $\mu$m polypropylene syringe filter, dried, and dissolved in 5% $HNO_3$. The residue was dried, and a 0.1 g subsample was completely digested in a 5:3 mixture of HF (reagent grade) and $HNO_3$. The sample was dried, refluxed several times in 6.0 M HCl (reagent grade) to remove fluorides, and redissolved in 5% $HNO_3$.

*Water.* A total of 191 water (134 streamwater and 57 groundwater) samples were collected from the nearest location used for soil and plant sampling to avoid anthropogenic contamination. Water samples were passed through 0.45 $\mu$m filters, collected in I-CHEM low-density polyethylene (LDPE) bottles, and acidified to pH <2 using concentrated ultrapure $HNO_3$.

*Plants.* A total of 77 plant (31 hot pepper and 46 rice) samples were collected in plastic storage bags, cleaned several times by Milli-Q water to remove fine particles, dried at 75 °C for 24 h, and stored in a vacuum oven until analysis. Samples were crushed in a shatter box equipped with a tungsten carbide grinding container and homogenized. About 0.7 g of sample was sequentially reacted with ultrapure concentrated $HNO_3$ and a 4:1 (v/v) mixture of ultrapure concentrated $HNO_3$ and $HClO_4$ (reagent grade) for complete digestion. The sample was dried and redissolved in 5% $HNO_3$.

*Elemental and Isotope Analyses.* Strontium concentrations were measured using an X7 ICP-MS (Thermo Scientific, Bremen, Germany) at the Korea Basic Science Institute (KBSI). The following standard reference materials were also prepared and measured to verify the sample preparation and analytical quality of the instruments: SRMs 1570a and 1573a for hot pepper and rice; SRMs BCR-2 and MAG-1 for soil; and CRM NRC SLRS-5 for water. The average uncertainty associated with the whole procedure of all standard reference materials was ±6% ($n$ = 17).

For strontium isotope analysis, samples were first dried in Teflon vessels and redissolved in 8 M $HNO_3$. Strontium was then separated from matrix elements using Eichrom Sr resin (Eichrom Industries, Darien, IL, USA).[15] Strontium isotope ratios ($^{87}Sr/^{86}Sr$) were measured using a Neptune MC-ICP-MS (Thermo Scientific) at KBSI. $^{87}Sr/^{86}Sr$ ratios were normalized to $^{86}Sr/^{88}Sr$ = 0.1194,[9] and replicate analyses of NBS987 (U.S. National Bureau of Standards) gave $^{87}Sr/^{86}Sr$ = 0.710247 ± 0.000008 (2$\sigma$, $n$ = 24) with a background value of <0.1 ng.

**Statistical Analysis.** Nonparametric statistics were used to describe the $^{87}Sr/^{86}Sr$ distribution and to compare $^{87}Sr/^{86}Sr$ between samples. The structure of the data was visualized using kernel density estimation, which is a nonparametric method of estimating the probability density function of a random variable.[16] Differences in $^{87}Sr/^{86}Sr$ between samples were examined by applying a two-tailed Mann−Whitney $U$ test using freeware PAST software instead of the $t$ test due to important differences in sample sizes and some heterogeneity in variances.[17] A probability level of 5% was established to reject the null hypothesis of no difference between the ranks of two samples. The probability was given by the exact $p$ value when $n_1 + n_2 \leq 30$, based on all possible ground assignments.

The spatial $^{87}Sr/^{86}Sr$ patterns of samples were generated using ArcGIS 9.3 software (ESRI, Redlands, CA, USA). Spatial interpolation was performed using inverse distance weight (IDW), which assigns values to unknown points on the basis of a weighted average of the values at the known points.

## RESULTS AND DISCUSSION

**Soil.** Sr concentrations were variable within each fraction, ranging from 0.78 to 566 mg/kg (Table 1). Exchangeable and carbonate fractions had similar Sr concentrations, with averages of 8.22 ± 4.4 and 5.12 ± 5.01 mg/kg, respectively, accounting for 4 and 3% of the total Sr in soil, respectively. The silicate fraction had a much higher Sr concentration (171 ± 101 mg/kg), accounting for 93% of the total Sr in soil. These results

**Table 1. Sr Concentrations and $^{87}Sr/^{86}Sr$ Ratios of the Samples**

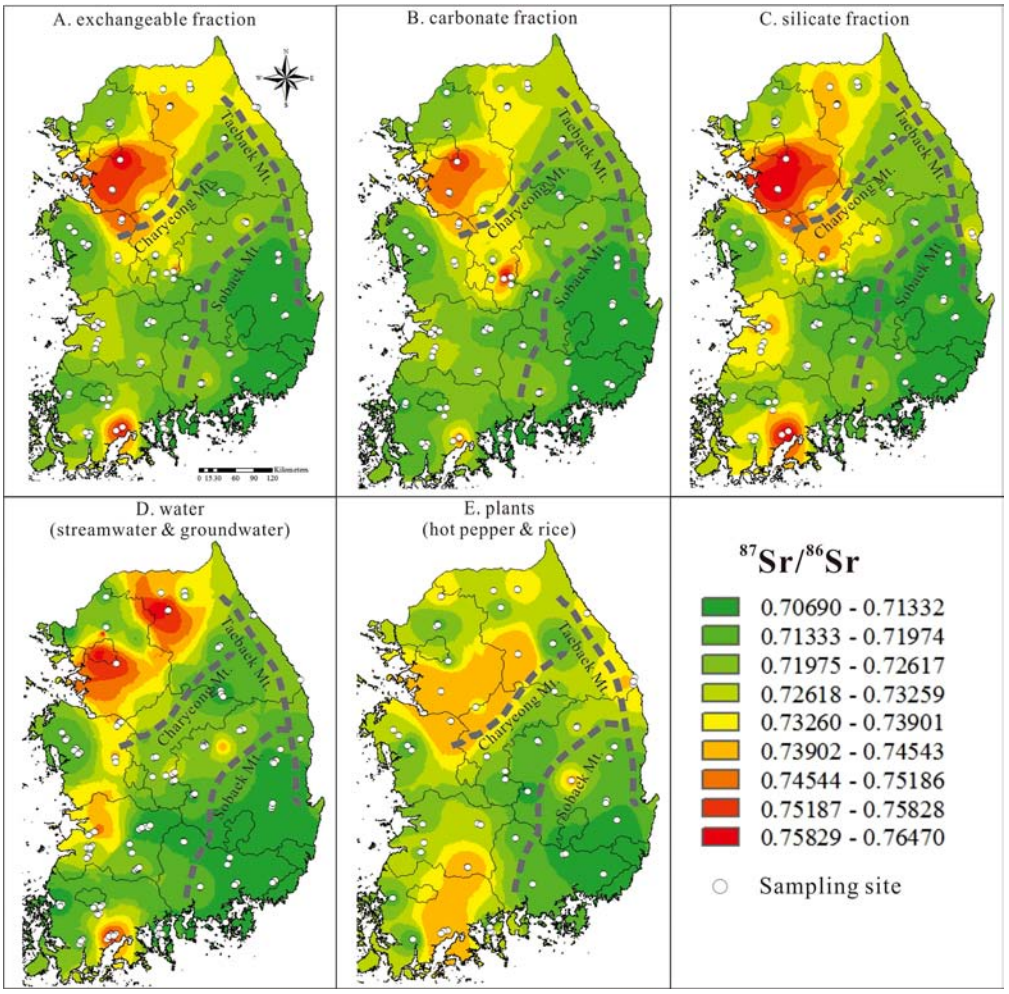

**Figure 1.** Maps showing the spatial $^{87}Sr/^{86}Sr$ distribution of (A–C) each soil fraction, (D) water, and (E) plants. Open circles display the sampling site.

indicate either that soil Sr is mostly incorporated into soil minerals protected from subsequent leaching or that the major part of Sr within a soil exists as structural Sr as a component of primary minerals. Although the exchangeable and carbonate Sr pools account for only 7% of the total Sr in soil, they are easily released into the soil solution, allowing the plant to take up Sr from the soil solution. On the other hand, the silicate Sr pool is available to the plant slowly over time because it is resistant to the weathering process. Therefore, it might be more feasible that plants will reflect Sr from bioavailable (exchangeable and/or carbonate) fractions rather than the silicate fraction.

The mean $^{87}Sr/^{86}Sr$ ratio spanned a wide range, from 0.71697 ± 0.00749 in the carbonate fraction to 0.72315 ± 0.01156 in the silicate fraction, indicating that the $^{87}Sr/^{86}Sr$ ratios are highly variable and on the whole broadly overlapping (Table 1). However, when observed in greater detail, the exchangeable fractions have slightly higher $^{87}Sr/^{86}Sr$ ratios than those measured in the carbonate fractions in all regions except one (Chungbuk), consistent with the fact that carbonates have low $^{87}Sr/^{86}Sr$ due to their low Rb content.[18] The silicate fractions have the highest radiogenic $^{87}Sr/^{86}Sr$ ratios (Table 1). These results indicate that Sr in the exchangeable and carbonate fractions is potentially different from that of the silicate fraction due to atmospheric deposition, cycling of Sr by plants, and weathering effects.[6] However, the effect of atmospheric deposition could be negligible because $^{87}Sr/^{86}Sr$ ratios of both fractions are different from those of either sea salt aerosol ($^{87}Sr/^{86}Sr$ = 0.70917)[19] or Asian dust ($^{87}Sr/^{86}Sr$ = 0.721).[19] On the basis of the Sr concentrations and $^{87}Sr/^{86}Sr$ ratios of each soil fraction, mass balance calculations showed that soils have similar $^{87}Sr/^{86}Sr$ ratios to the silicate fractions, suggesting that Sr in the bulk soil itself cannot elucidate the first-order relationship between soil and plant. With the fact that there is unlikely to be significant isotopic fractionation during plant uptake due to the small mass difference between Sr isotopes, it is reasonable to assume that plants have $^{87}Sr/^{86}Sr$ ratios different from those of the bulk soils because the exchangeable and carbonate fractions are vulnerable to weathering, whereas the silicate fraction is highly resistant to weathering.

Because little information about $^{87}Sr/^{86}Sr$ ratios of bedrocks in South Korea is available and is limited to typical areas, we were unable to obtain such data for the entire country.[20−41] Nevertheless, we compiled all reported data and compared those data with soil $^{87}Sr/^{86}Sr$ ratios to examine the relationship between them. The bedrock $^{87}Sr/^{86}Sr$ ratios are also variable, ranging from 0.70485 to 0.76090. In general, regions with Precambrian metamorphic and Mesozoic granitic rocks show much higher radiogenic $^{87}Sr/^{86}Sr$, whereas regions with carbonate and volcanic rocks yield the lowest $^{87}Sr/^{86}Sr$ values.[20−41] Differences in $^{87}Sr/^{86}Sr$ ratios were found between rock and soil, indicating either that Sr in soil is potentially

dx.doi.org/10.1021/jf503498r | J. Agric. Food Chem. 2014, 62, 9232−9238

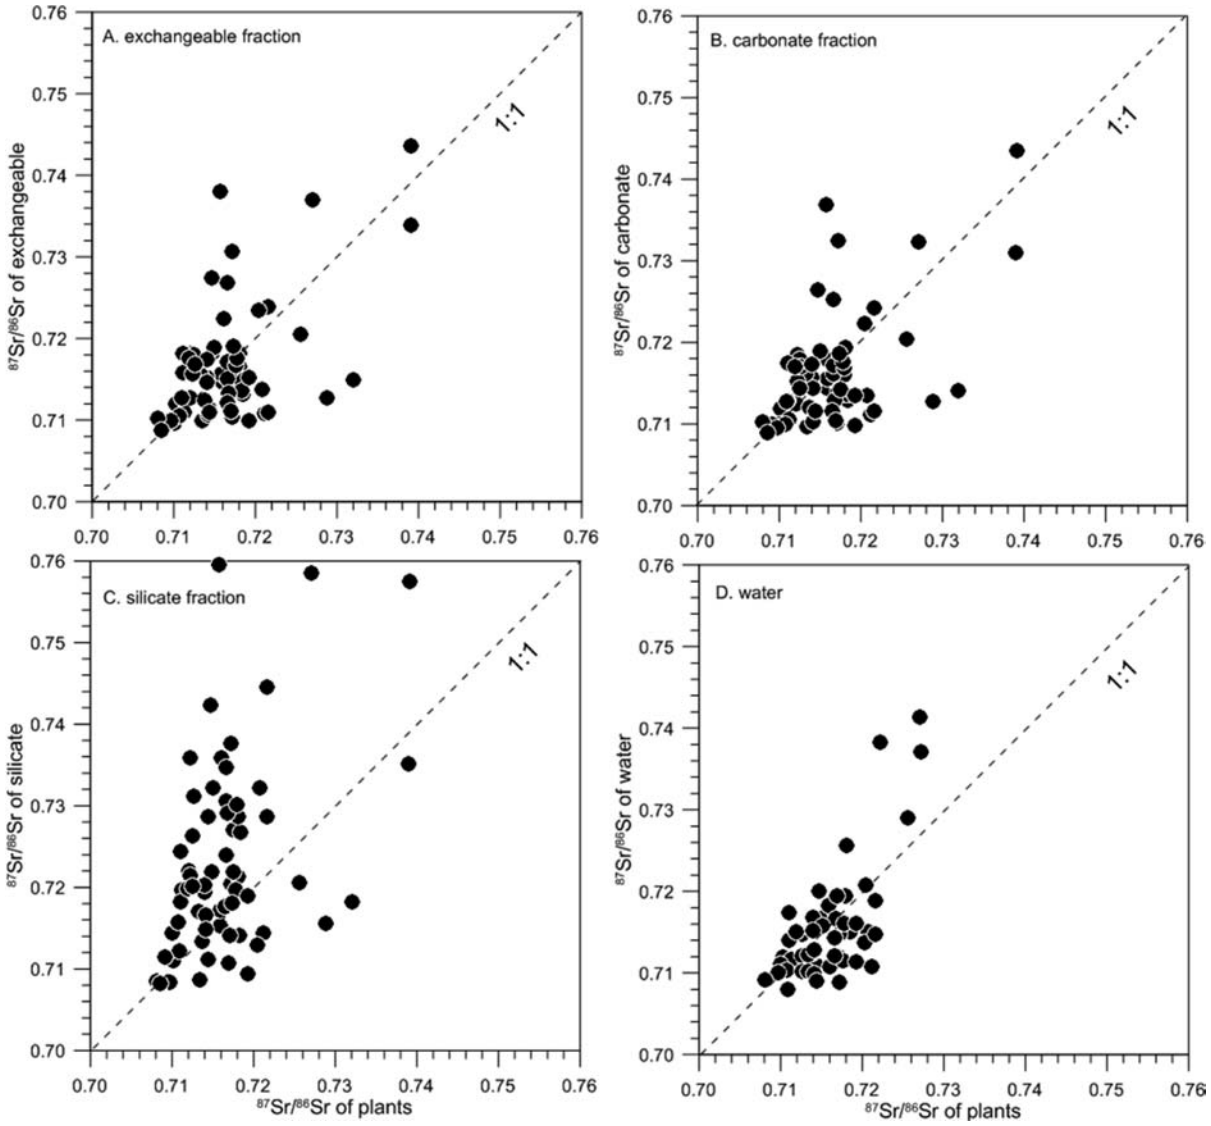

**Figure 2.** Plots of $^{87}Sr/^{86}Sr$ ratios of (A–C) each soil fraction and (D) water versus plants.

different from that of bedrock due to atmospheric deposition, cycling of Sr by plants, and weathering effects[6] or that reported bedrock $^{87}Sr/^{86}Sr$ ratios were insufficient to cover the whole country. Nevertheless, $^{87}Sr/^{86}Sr$ ratios between rock and soil collected at similar regions are consistent, indicating that soil inherits Sr and its isotopic composition from minerals in the bedrock even if there is a disturbance, such as cycling of Sr by plants.

**Water.** Sr concentrations and $^{87}Sr/^{86}Sr$ ratios in water come mainly from mineral dissolution with a minor contribution from atmospheric deposition and anthropogenic input.[42−44] However, a previous study[45] reported that the influences of atmospheric deposition and anthropogenic input on Sr concentrations and $^{87}Sr/^{86}Sr$ ratios in water are negligible in South Korea, and therefore rock/mineral dissolution can be considered the dominant Sr source in water. Sr concentrations in water were highly variable, ranging from 1.3 to 648 $\mu$g/L with an average of 33.6 ± 50.6 $\mu$g/L, and $^{87}Sr/^{86}Sr$ ratios ranged from 0.70698 to 0.75753, with an average of 0.71881 ± 0.00987. Although the range of $^{87}Sr/^{86}Sr$ ratios of water is similar to those of other samples, the mean value is consistent with those of the exchangeable and carbonate fractions rather than the silicate fraction, indicating that Sr in the exchangeable and carbonate fractions vulnerable to weathering is easily released into water, whereas Sr in the silicate fraction highly resistant to weathering is retained. Furthermore, there is a clear correspondence between soil fractions and water, whereas the correlation between water and bedrock is not exhibited clearly because reported $^{87}Sr/^{86}Sr$ data are limited to typical regions that do not represent the entire country (Figure 1). Nonetheless, it might be inferred that Sr released from minerals in the bedrock percolates through soil pore water and into the water, such as streamwater and groundwater, and thus water should reflect the $^{87}Sr/^{86}Sr$ ratio of soil fractions and/or bedrock.

**Plants.** The elemental and isotopic compositions of agricultural products are known to reflect the local geochemistry of the soil and water, but can also be influenced by agricultural practices.[5,6,46] In this context, Sr isotopic compositions are important because $^{87}Sr/^{86}Sr$ ratios are fractionated neither by low temperature nor by biogenic processes,[9,10] and therefore $^{87}Sr/^{86}Sr$ ratios of agricultural products reflect the sources of Sr available during their formation.[7] Sr concentrations ranged from 0.08 to 7.99 mg/

dx.doi.org/10.1021/jf503498r | J. Agric. Food Chem. 2014, 62, 9232−9238

kg, with an average of 0.99 ± 1.34 mg/kg, and $^{87}Sr/^{86}Sr$ ratios varied from 0.70803 to 0.73909, with an average of 0.71712 ± 0.00618, which are within the range of rock, each soil fraction, and water. These values indicate that agricultural products, in particular those relating to hot pepper and rice, reflect the combined local geochemistry of the environment in which they grow, as shown in the spatial interpolation in Figure 1. Although it is difficult to determine quantitatively which Sr source exerts dominant control over $^{87}Sr/^{86}Sr$ in agricultural products, the $^{87}Sr/^{86}Sr$ ratios appeared at first glance to be controlled much more by the exchangeable and carbonate fractions of soil and water than by bedrock and the silicate fraction of soil (Figure 2). Furthermore, it is interesting to note that agricultural products do not display radiogenic $^{87}Sr/^{86}Sr$ ratios comparable with other samples in the same region (Figure 1). As discussed above, because the influences of atmospheric deposition and anthropogenic input can be negligible, this is possibly due to cycling of Sr by plants because preferential assimilation of the light isotope ($^{86}Sr$) by plants can produce lower $^{87}Sr/^{86}Sr$ ratios. However, more detailed investigations are required to confirm this hypothesis.

**Relationships among the Isotopic Compositions of Soil, Bedrock, Water, and Plants.** Kernel density plots of $^{87}Sr/^{86}Sr$ ratios in rock, each soil fraction, water, and plants reveal the distribution mode for each sample, demonstrating that all samples possess one major mode lying between 0.70 and 0.73 and a few minor modes with higher $^{87}Sr/^{86}Sr$ values (Figure 3A). It is interesting to note that all soil fractions have higher $^{87}Sr/^{86}Sr$ ratios than bedrock, indicating that radiogenic, mafic, and bedrock-forming minerals, such as biotite and hornblende, are more easily weathered than felsic minerals, thus releasing their Sr easily into the soil, resulting in higher radiogenic $^{87}Sr/^{86}Sr$ values in soil than in bedrock. Although more bedrock $^{87}Sr/^{86}Sr$ data in South Korea are needed to support this result, our finding suggests that the assumption that the $^{87}Sr/^{86}Sr$ ratios of bedrock and soil should be the same should be considered carefully in investigations of the provenance and geographical origin. Hence, $^{87}Sr/^{86}Sr$ ratios can be used as tracers only if they are well understood and interpreted in the light of local geological, hydrological, and pedological assessment. Likewise, each soil fraction showed a different distribution mode; there was little difference between exchangeable and carbonate fractions but clear differences between these two fractions and the silicate fraction. This indicates that more radiogenic Sr exists in the silicate fraction, which is resistant to weathering. The distribution mode of plants was indistinguishable from the exchangeable and carbonate fractions, indicating that plants preferentially take up Sr from these fractions rather than from the silicate fraction. Water also showed distributions similar to that of plants, indicating that water also affects the $^{87}Sr/^{86}Sr$ ratio of plants. Our results indicate that among different Sr sources, the exchangeable and carbonate fractions in soil and water together influence the plant $^{87}Sr/^{86}Sr$ ratio, in agreement with previous studies.[17,47]

Statistical probability can specify which Sr source more reliably predicts the $^{87}Sr/^{86}Sr$ ratio of agricultural products. The two-tailed Mann−Whitney *U* test showed that water and the exchangeable fraction of soil had the highest probabilities, 90 and 89%, respectively, followed by the carbonate fraction (53%), but the silicate fraction and bedrock had zero probability (Figure 3B). Therefore, it can be inferred that bioavailable Sr mainly reflects water and the exchangeable fraction of soil. To the best of our knowledge, this is the first study showing that agricultural products best correspond to both water and the exchangeable fraction of soil in terms of their various potential Sr sources. Further investigations with other agricultural products are necessary to confirm our results.

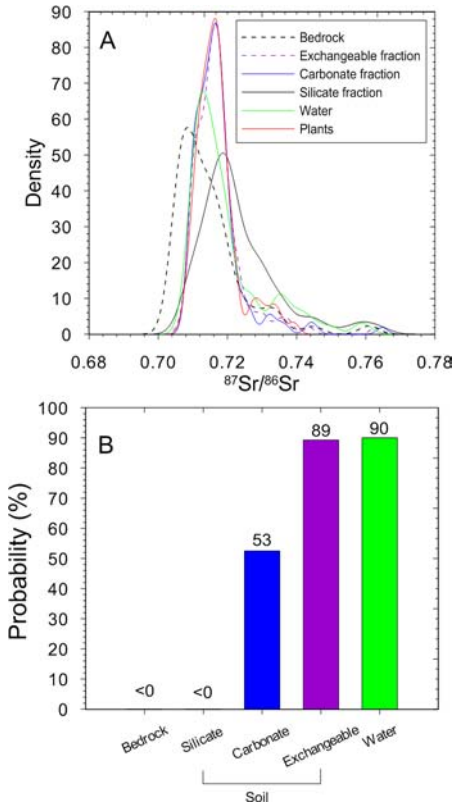

**Figure 3.** (A) Kernel density plots of $^{87}Sr/^{86}Sr$ ratios for all samples and (B) probability histogram of matching $^{87}Sr/^{86}Sr$ in plants and the $^{87}Sr/^{86}Sr$ of other samples.

Turkish raki. Long known as a carminative and expectorant, the essential oil of aniseed exhibits antibacterial and antioxidant properties.[34,35] The odor of aniseed is long-known to be elicited by *trans*-anethole, **1** (Figure 1), the major component of its

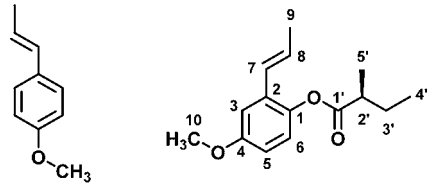

**Figure 1.** Chemical structures of *trans*-anethole (**1**) and *trans*-pseudoisoeugenyl 2-methylbutyrate (**2**).

essential oil.[36,37] By means of aroma extract dilution analysis and identification and quantitation of most intense odorants, followed by calculation of odor activity values, *trans*-anethole was confirmed to be the character impact compound responsible for the unique aniseed scent.[38] However, systematic study on the oro-sensory activities of aniseed components have not been performed.

Originally invented for the generation of compound libraries for high-throughput screening programs,[39−41] we here report for the first time the application of preparative HPLC-SPE-HPLC combined with a modified TDA for taste compound discovery using a sweet and licorice-like bitter-tasting aniseed extract as an example.

## MATERIALS AND METHODS

**Chemicals.** The following compounds were obtained commercially: formic acid, trifluoroacetic acid (Merck, Darmstadt, Germany), anethole, estragole (Sigma-Aldrich, Steinheim, Germany). Deuterated solvents were obtained from Euriso-Top (Gif-Sur-Yvette, France). Solvents were of HPLC grade (J. T. Baker, Deventer, The Netherlands) except for *n*-hexane and ethyl acetate (p.A.) (Merck), which were distilled prior to use. Water for HPLC analysis and extractions was obtained from a Milli-Q Advantage A10 high-purity water system (Millipore, Molsheim, France). For sensory analysis, 3 or 5% ethanol (>99.9%) (Merck) was added to Evian bottled water (Danone Waters Deutschland, Frankfurt, Germany). Aniseed was purchased from a local market (Bio Lebensmittel Zander, Mühlheim, Germany).

**Sequential Solvent Extraction.** After freezing with liquid nitrogen, aniseed was comminuted to a fine powder in an A11 basic batch mill (IKA Werke, Staufen, Germany). An aliquot (240 g) of the ground material was suspended in *n*-hexane (2.5 L) and ultrasonicated for 4 h at room temperature with vigorous stirring. After filtration through a 18.5 cm Schleicher & Schuell filter, the organic solvent was separated from the filtrate under vacuum (40 °C) to afford the solvent extractables. The residue was sequentially extracted with ethyl acetate (2.5 L), followed by methanol (2.5 L) and methanol/water (30:70, v/v; 2.5 L) using the same protocol to afford the *n*-hexane extractables (fraction I, yield = 14%), the ethyl acetate extractables (fraction II, yield = 5%), the methanol extractables (fraction III, yield = 17%), and the methanol/water extractables (fraction IV, yield = 21%); the latter two fractions were separated from solvent under vacuum and, then, freeze-dried twice.

For further separation of fraction I, an aliquot (25 g) was mixed with methanol/water (94:6, v/v; 500 mL) and, after 2 h, the bottom layer separated and again extracted with methanol/water (94:6, v/v; 500 mL). The supernatants were combined and kept at −20 °C until further use. After centrifugation (7000 rpm, 20 min, 0 °C), the liquid layer was separated from solvent under vacuum at 40 °C to afford the sensory active subfraction I-I.

**Dry-Injection and 2D-HPLC Separation of Subfraction I-I.** An aliquot (1.5 g) of fraction I-I was dissolved in methanol (50 mL), membrane filtered, mixed with Polygoprep 300-50 C4 silica (7 g) (Macherey-Nagel, Düren, Germany) and, after sonication for 20 min, the mixture was separated from solvent under vacuum, thus yielding a free-flowing powder. The stainless steel injection column (20 × 60 mm) was assembled, leaving one side open, and 1 g of blank C4 silica material (1.0 g) was added. After leveling the surface of the stationary phase, the adsorbed fraction I-I was funneled onto the top of the stationary phase, the surface was leveled, the remaining volume of the injection column was filled with blank C4 silica material, the column end fitting was attached, and, then, the injection column was connected to the Sepbox 2D-2000 2D-HPLC system (Sepiatec, Berlin, Germany). Using 0.1% formic acid and 0.02% trifluoroacetic acid in water as solvent A and 0.1% formic acid in acetonitrile as solvent B, the effluent of the injection column was continuously pumped onto a 150 × 32 mm i.d., 12 μm, VP150/32 Nucleoprep 100-12 C4-end-capped column (Macherey-Nagel) at a flow rate of 40 mL/min. Chromatography was performed with the following gradient: 0 min, 20% B; 6 min, 60% B; 16 min, 100% B; 20 min, 100% B; 21 min, 20% B; 27 min, 20% B. Concomitant with the separation, a flow gradient was run with water, which was mixed with the C4 column effluent using the following flow rates: 0 min, 0 mL/min; 1 min, 50 mL/min; 12 min, 25 mL/min; 16 min, 20 mL/min; 21 min, 20 mL/min; 24 min, 1 mL/min. The effluent was collected in 16 subfractions, namely I-I/1−I-I/16, which were trapped onto VP30/32 Nucleoprep 100-12 C4-end-capped SPE columns preconditioned with water (3 min, 40 mL/min) prior to the separation.

Each subfraction was further separated on a 250 × 21.2 mm, 5 μm, Luna Phenyl-Hexyl column (Phenomenex, Aschaffenburg, Germany) using the following gradient of water (solvent A), methanol (solvent B), and acetonitrile (solvent C) at a flow rate of 20 mL/min: fraction I-I/1, 0 min, A/B/C (83:17:0), 29 min, A/B/C (57:43:0), 30 min, A/B/C (0:100:0), 34 min, A/B/C (0:100:0); fraction I-I/2, 0 min, 38% B, 29 min, 58% B, 30 min, 100% B, 34 min, 100% B; fraction I-I/3, 0 min, A/B/C (56:44:0), 29 min, A/B/C (37:63:0), 30 min, A/B/C (0:100:0), 34 min, A/B/C (0:100:0); fraction I-I/4, 0 min, A/B/C (48:52:0), 29 min, A/B/C (23:67:0), 30 min, A/B/C (0:100:0), 34 min, A/B/C (0:100:0); fraction I-I/5, 0 min, A/B/C (32:68:0), 29 min, A/B/C (28:72:0), 30 min, A/B/C (0:100:0), 34 min, A/B/C (0:100:0); fraction I-I/6, 0 min, A/B/C (31:69:0), 29 min, A/B/C (20:80:0), 30 min, A/B/C (0:100:0), 34 min, A/B/C (0:100:0); fraction I-I/7, 0 min, A/B/C (22:78:0), 29 min, A/B/C (13:87:0), 30 min, A/B/C (0:100:0), 34 min, A/B/C (0:100:0); fraction I-I/8, 0 min, A/B/C (22:78:0), 29 min, A/B/C (9:91:0), 30 min, A/B/C (0:100:0), 34 min, A/B/C (0:100:0); fraction I-I/9, 0 min, A/B/C (21:79:0), 29 min, A/B/C (9:91:0), 30 min, A/B/C (0:100:0), 34 min, A/B/C (0:100:0); fraction I-I/10, 0 min, A/B/C (22:88:0), 29 min, A/B/C (7:93:0), 30 min, A/B/C (0:100:0), 34 min, A/B/C (0:100:0); fraction I-I/11, 0 min, A/B/C (7:93:0), 29 min, A/B/C (5:95:0), 30 min, A/B/C (0:100:0), 34 min, A/B/C (0:100:0); fraction I-I/12, 0 min, A/B/C (3:97:0), 16 min, A/B/C (3:97:0), 17 min, A/B/C (0:100:0), 29 min, A/B/C (0:93:7), 30 min, A/B/C (0:50:50), 34 min, A/B/C (0:50:50); fraction I-I/13, 0 min, A/B/C (3:97:0), 16 min, A/B/C (3:97:0), 17 min, A/B/C (0:100:0), 29 min, A/B/C (0:93:7), 30 min, A/B/C (50:50:0), 34 min, A/B/C (0:50:50); fraction I-I/14, 0 min, A/B/C (0:98:2), 29 min, A/B/C (0:89:11), 30 min, A/B/C (0:50:50), 34 min, A/B/C (0:50:50); fraction I-I/15, 0 min, A/B/C (0:98:2), 29 min, A/B/C (0:80:20), 30 min, A/B/C (0:50:50), 34 min, A/B/C (0:50:50); fraction I-I/16, 0 min, A/B/C (0:100:0), 29 min, A/B/C (0:34:66), 30 min, A/B/C (0:10:90), 34 min, A/B/C (0:10:90). Column equilibration for each separation was 11 min at the initial gradient conditions. Each subfraction, I-I/1−I-I/16, was separated into 16 additional subfractions; for example, fraction I-I/1 was cut into subfractions I-I/1-1−I-I/1-16.

**Identification of Key Taste-Active Compounds in 2D-HPLC Subfractions.** Aliquots of the first-dimension fractions I-I/1−I-I/16 were reconstituted by combining portions (10 mL) from each of the 16 subfractions collected in the second dimension. The reconstituted

fractions I-I/1−I-I/16 were diluted 1:1 with water and extracted with *n*-hexane (200 mL), and the organic layer was separated from solvent under vacuum at 40 °C and, then, used for sensory analysis. As reconstituted fractions I-I/8 and I-I/9 were judged with the highest sensory impact for sweetness and bitterness, aliquots of each individual of their second-dimension subfractions, namely, I-I/8-1−I-I/8-16 and I-I/9-1−I-I/9-16, were diluted 1:1 with water, extracted with *n*-hexane (50 mL), and, after solvent removal under vacuum (40 °C), the organic residues were kept at −20 °C until further used for sensory analysis. Fraction I-I/8-4, judged with the highest sensory impact, was identified as *trans*-anethole, **1**, by comparing chromatographic (retention time) and spectroscopic data (UV−vis, 1D/2D-NMR) with those of a commercially available reference material. Dried fraction I-I/9-5, judged with high sensory impact, was identified as *trans*-pseudoisoeugenyl 2-methylbutyrate, **2**, by means of LC-TOF-MS and 1D/2D-NMR experiments.

*trans-Anethole,* ***1***, Figure 1: UV−vis (water/methanol), $\lambda_{max}$= 260, 212 nm. NMR data were identical to those of the commercial reference.

*trans-Pseudoisoeugenol-2-methylbutyrate,* **2**, Figure 1: UV−vis (water/acetonitrile), $\lambda_{max}$ = 220, 248, 300 nm; UPLC-TOF-MS, *m/z* 249.1488 (measured), *m/z* 249.1491 (calculated for $[C_{15}H_{20}O_3 + H]^+$); $^1$H NMR (400 MHz, $CDCl_3$, COSY), $\delta$ 6.99 (d, *J* = 3.0 Hz, 1H, [H−C(3)]), 6.88 (d, *J* = 8.8 Hz, 1H, [H−C(6)]), 6.75 (dd, *J* = 8.8, 3.0 Hz, 1H, [H−C(5)]), 6.36 (dd, *J* = 15.8, 1.6 Hz, 1H, [H−C(7)]), 6.20 (dq, *J* = 15.8, 6.5 Hz, 1H, [H−C(8)]), 3.80 (s, 3H, [H−C(10)]), 2.65 (q, *J* = 7.0 Hz, 1H, [H−C(2′)]), 1.92−1.78 (m, 4H, [H−C(3′) and H−C(9)]), 1.63 (ddd, *J* = 13.7, 7.4, 6.4 Hz, 1H, [H−C(3′)]), 1.32 (d, *J* = 7.0 Hz, 3H, [H−C(5′)]), 1.03 (t, *J* = 7.4 Hz, 3H, [H−C(4′)]); $^{13}$C NMR (400 MHz, $CDCl_3$, HSQC, HMBC), $\delta$ 175.39 (C, [C(1′)]), 157.27 (C, [C(4)]), 141.35 (C, [C(1)]), 131.30 (C, [C(2)]), 128.42 (CH, [C(7)]), 124.49 (CH, [C(8)]), 123.14 (CH, [C(6)]), 113.25 (CH, [C(5)]), 110.98 (CH, [C(3)]), 55.56 (CH3, [C(10)]), 41.23 (CH, [C(2′)]), 29.51, (CH2, [C(3′)]), 18.79 (CH3, [C(9)]), 16.78 (CH3, [C(5′)]), 11.68. (CH3, [C(4′)]).

**Sensory Analyses.** *Training of the Sensory Panel.* Seven female and six male panelists (25−36 years in age), who had given informed consent to participate in the sensory tests of the present investigation and had no history of known taste disorders, participated in this study. Each panelist took place in a weekly training session for at least two years to get familiarized with the taste language and methodologies used. Aqueous solutions (2.0 mL; pH 5.9) of the following reference compounds were used for sensory training: sucrose (50 mmol/L) for sweet taste, L-lactic acid (20 mmol/L) for sour taste, NaCl (20 mmol/L) for salty taste, caffeine (1 mmol/L) for bitter taste, monosodium L-glutamate (3 mmol/L) for umami taste, and (+)-catechin (1 mmol/L) for astringency. Sensory analyses were performed by means of the sip-and-spit method in an air-conditioned room at 22−25 °C in three independent sessions. Aimed at preventing cross-model interactions with odorants, nose clips were used by the assessors.

*Taste Profile Analysis.* Aliquots of fractions I−IV were dissolved in ethanol and made up in water to a maximum content of 5% ethanol. The trained sensory panelists were then asked to judge the intensity of the sweet, sour, umami, salty, bitter, and astringent orosensation on a linear scale from 0 (not detectable) up to 5 (very intense).

*Taste Dilution Analysis (TDA).* Aliquots of the HPLC fractions were dissolved in "natural" ratios in 10.0 mL of bottled water containing 3% ethanol and sequentially diluted 1:1 with bottled water containing 3% ethanol. The serial dilutions of each of these fractions were then presented in order of increasing concentration to the trained sensory panel, which was asked to evaluate each dilution step by means of a two-alternative forced-choice test. As previously reported, the dilution at which a taste difference between the diluted extract and the blank (control) could just be detected was defined as the taste dilution (TD) factor.[2] The TD factors for each HPLC fraction evaluated by 10 different assessors in three different sessions were averaged. The TD factors between individuals and separate sessions did not differ by more than plus/minus one dilution step.

**Two-Dimensional High-Performance Liquid Chromatography System.** Preparative 2D-HPLC fractionation of fraction I-I was performed on a Sepbox 2D-2000 HPLC apparatus consisting of a Smartline UV Detector 2500 with a 4061 flow cell (Knaur, Berlin, Germany), a Sedex LT-ELSD detector model 80 (Sedere, Alfortville, France), and two 1800 pumps, one of which was equipped with an A4099-1 ternary low-pressure gradient unit (Knaur), a semipreparative two-channel degasser (Knaur), and a MIKA 3000 mixing chamber (Portman Instruments, Biel-Benken, Switzerland) and was connected to act on the first- and second-dimension flowpath (Figure 2). A self-made mixing chamber consisting of a 20 × 60 mm stainless steel column filled with glass beads (2 mm i.d.) was connected to the first-dimension flowpath (Figure 2). Valve manifolds and fraction collector were custom-made (Sepiatec GmbH, Berlin Germany). Chromatography of the first dimension was conducted using a preparative C4, 150 × 32 mm i.d., 12 μm, Nucleodur column (Macherey-Nagel), equipped with a 2 μm semipreparative frit (IDEX Health and Science, Oak Harbor, WA, USA) and operated at a flow rate of 40.0 mL/min. SPE trapping was facilitated by 16 C4 Nucleoprep VP 30/32 columns (Macherey-Nagel). Chromatography of the second dimension was conducted using a 250 × 21.2 mm i.d., 5 μm, Luna Phenyl-Hexyl column (Phenomenex) with a guard column of the same type at 20 mL/min. For both dimensions, the eluent split ratio was 1:20 (ELSD/UV). Data were acquired using Sepbox Control V2.0.0 software (Sepiatec GmbH, Berlin, Germany), and data analysis was conducted using Sepbox Reporter V2.0.0.3 software.

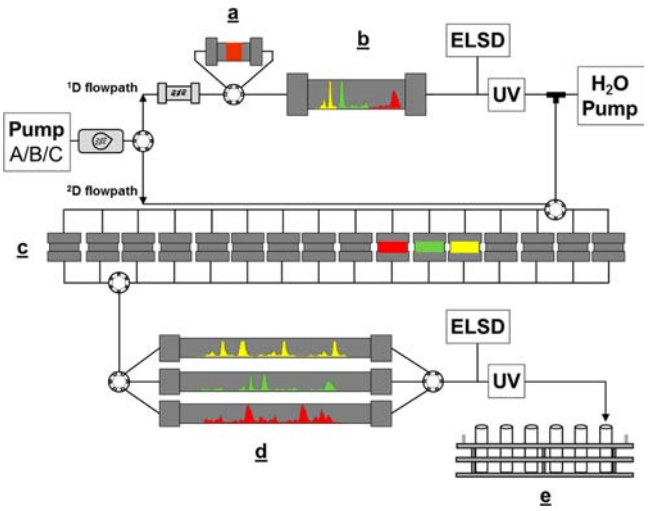

**Figure 2.** Scheme depicting the principle of operation of the preparative 2D-HPLC system. The sample is introduced using the injection column (a) and subsequently separated on the $^1$D column (b); fractions are then collected on SPE columns (c), and trapped fractions are further separated on the $^2$D column (d).

Analytical chromatography of fractions I-I/8-4 and I-I/9-5 was performed on a HPLC apparatus (Jasco, Groß-Umstadt, Germany) consisting of a DG-2080-53 degasser, an LG-2080-02S ternary gradient unit, a PU-2080 Plus pump, an AS-2055 Plus autosampler, an MD-2010 Plus detector with a 6824-H101A cell, and a Sedex LT-ELSD detector model 90 (Sedere). Chromatography was done using an analytical 250 × 4.6 mm i.d., 5 μm, HyperClone ODS 120 column (Phenomenex) operated with a flow rate of 1.0 mL/min. Data acquisition was done by means of Chrompass 1.9.302 (Jasco).

**UPLC/Time-of-Flight Mass Spectrometry (UPLC/TOF-MS).** High-resolution mass spectra were recorded on a SYNAPT G2S HDMS mass spectrometer (Waters UK Ltd., Manchester, UK) operated in the positive electrospray ionization and high-resolution modus. Sample aliquots (1 μL) in methanol were introduced into the instrument via an Acquity UPLC core system (Waters). The UPLC-TOF-MS system was equipped with a BEH Phenyl, 150 × 2.1 mm i.d., 1.7 μm, column (Waters) equipped with a guard column of the same type and operating at a flow rate of 0.3 mL/min and a temperature of 45 °C. The following gradient was used for chromatography: starting

with a mixture (40:60, v/v) of acetonitrile and aqueous formic acid (0.1% HCOOH), the acetonitrile content was increased to 100% within 3 min and kept at this level for 1 min. All data were lock mass corrected on the pentapeptide leucine enkephalin (Tyr-Gly-Gly-Phe-Leu, $m/z$ 556.2771, $[M + H]^+$) in a solution (2 ng/ $\mu$L) of acetonitrile/0.1% formic acid (1:1, v/v). Data acquisition and interpretation were performed by using MassLynx software version 4.1 (Waters) and the tools "isotope model" and "elemental composition".

**Nuclear Magnetic Resonance Spectroscopy (NMR).** 1D-NMR ($^1$H, $^{13}$C) and 2D-NMR experiments (COSY, HSQC, and HMBC) were acquired on a 400 MHz DRX spectrometer (Bruker, Rheinstetten, Germany). Experiments were carried out using the pulse sequences taken from the Bruker software library. Chemical shifts were referenced to TMS. Data processing and interpretation were performed using Topspin version 2.1 (Bruker) and MestRe-Nova version 7.0.2-10008 software (Mestrelab Research, La Coruna, Spain). Samples were analyzed in $CDCl_3$.

## RESULTS AND DISCUSSION

To introduce a fully automated, preparative HPLC-SPE-HPLC combined with a modified TDA for taste compound discovery in foods, a sweet and licorice-like tasting aniseed extract was used as an example. Prior to chromatographic separation, first, aniseed fruits were sequentially extracted with solvents of descending hydrophobicity to achieve a crude separation of sensory active components according to their polarity.

**Sequential Solvent Extraction and Taste Profile Analysis.** Ground aniseed fruits were sequentially extracted with *n*-hexane, ethyl acetate, methanol, and methanol/water (30:70, v/v) to afford fractions I–IV after removal of the solvent under vacuum. Aliquots of fractions I–IV were taken up in water containing 3% aqueous ethanol and were, then, sensorially evaluated by means of taste profile analysis using a linear five-point scale. Sweetness and bitterness were rated with the highest scores of 1.5 and 1.0 in fraction I, whereas fraction III showed the highest impact for astringency judged with a score of 1.2 (Table 1). To preseparate taste-active molecules from triglycerides in the *n*-hexane fraction, an aliquot of fraction I was further separated by extraction with methanol/water (94:6, v/v). The polar extract was separated from solvent under vacuum to afford subfraction I-I showing an increased intensity of sweetness (2.2) and bitterness (1.8) when compared to crude fraction I (Table 1). Therefore, subfraction I-I was used for automated HPLC-SPE-HPLC separation.

**Table 1. Taste Profiles of Fractions Isolated from Dried Aniseed Fruits**

| | fraction[a] | | | | |
|---|---|---|---|---|---|
| taste quality | I | II | III | IV | I-I |
| sweet | 1.5 | 0.8 | 0.4 | 0.3 | 2.2 |
| bitter | 1.0 | 0.8 | 0.5 | 0.5 | 1.8 |
| astringent | 1.1 | 1.2 | 1.2 | 1.1 | 1.4 |

[a]Fractions isolated from aniseed were sensorially evaluated in 5% aqueous ethanolic solution on a five-point scale from 0 (not detectable) to 5 (intensely perceived) (SD ±0.2).

**Setup of the HPLC-SPE-HPLC System.** To perform fully automated and comprehensive, offline two-dimensional separations,[42] a Sepbox 2D-2000 was used combining a first-dimension separation with SPE and a series of second-dimension separations (HPLC-SPE-HPLC). The 2D-HPLC instrument comprises two high-pressure pumps, a ternary pump delivering the solvent gradient (A/B/C pump) (Figure 2), and a second pump diluting the effluent of the first dimension with water ($H_2O$ pump) (Figure 2). Flowpath switching was accomplished via electrically actuated Rheodyne valves.

Because extract solubility is not a limiting factor and higher sample loads can be achieved, subfraction I-I was applied onto the column by means of dry-injection. To achieve this, RP4 carrier material was loaded with fraction I-I adsorbed and then placed on top of a layer of blank RP4 material into the injection column (a) (Figure 2) with one endfitting attached. Thereafter, another layer of blank RP4 material was added on top of the sample powder to support the distribution of the mobile phase stream entering the injection column during chromatography.

For chromatography, the mobile phase was delivered by the A/B/C gradient pump and the flow directed through the injection column to elute analytes from the injection column according to their polarity and to subsequently introduce them onto the first-dimension separation column filled with RP4 material (b) (Figure 2). The effluent of the main column was then split (1/20, v/v) between an evaporative light scattering detector (ELSD) and a UV–vis detector for comprehensive recording of eluting analytes. After running through the UV–vis detector, the effluent was diluted with water delivered from the water pump using a T-connector to decrease the acetonitrile content and the solubility of the analytes in the solvent (Figure 2). The effluent, cut into 16 subfractions (I-I/1–I-I/16), was pumped through RP4-end-capped SPE columns to subsequently trap the analytes according to their polarity (c) (Figure 2), whereas the mobile phase was sent to waste. The first dimension concludes with a flushing step of the main separation column, at which time no trap columns were placed in the flow path. To perform chromatography in the second dimension, the individual SPE columns loaded with the analytes of the fractions I-I/1–I-I/16 served as injection columns. One SPE column after the other was placed in the gradient flow path, and analytes are eluted from the trap column onto a second-dimension separation column filled with Phenyl-Hexyl stationary phase (d) (Figure 2). Using a ternary gradient of water, methanol, and acetonitrile, a total of 256 fractions was collected (e), corresponding to 16 fractions collected in the first dimension, each further separated into 16 subfractions, respectively.

**Identification and Sensory Analysis of Key Taste Compounds.** To effectively trace the compounds imparting the sweet and bitter taste in the 256 subfractions collected by means of 2D-HPLC, aliquots of the second-dimension subfractions corresponding to the same first dimension fractions were recombined to obtain the reconstituted first-dimension fractions I-I/1–I-I/16, and, after dilution with water, the hydrophobic taste compounds were extracted with hexane, the solvent was separated under vacuum, and the residues were taken up in 3% aqueous ethanol and used for taste dilution analysis.[2] To achieve this, the dissolved fractions were stepwise diluted 1:1 with 3% aqueous ethanol and then presented to the trained panelists, who were asked to determine their taste dilution (TD) factors by means of a two-alternative forced-choice procedure. Sweetness and bitterness of reconstituted fractions I-I/8 and I-I/9 were judged with the highest TD factors of 32 and 4, respectively (Figure 3). To trace the key taste molecules, a taste dilution analysis was applied onto aliquots of the corresponding second-dimension subfractions I-I/8-1–I-I/8-9 and I-I/9-1–I-I/9-9, thus showing subfraction I-

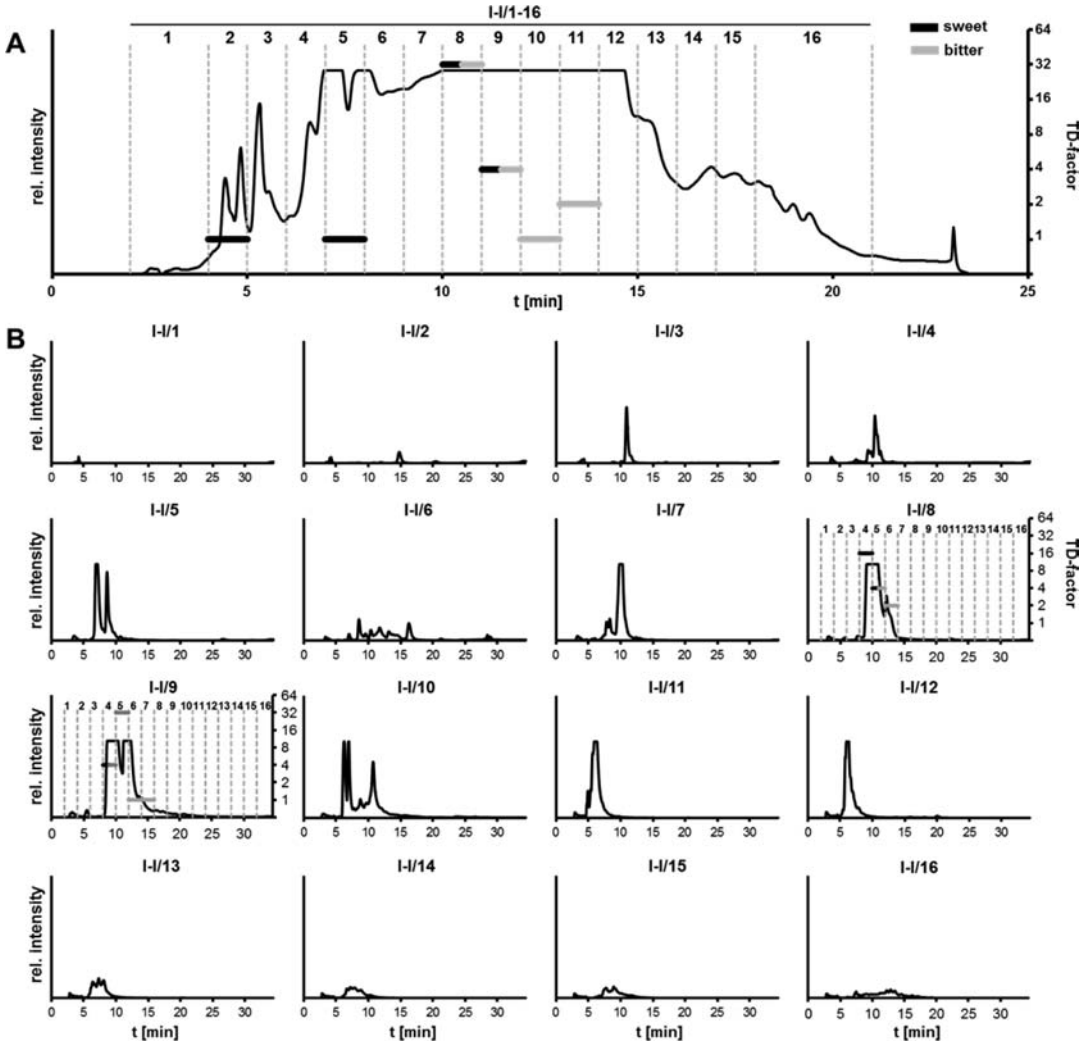

**Figure 3.** (A) First-dimension separation and taste dilution analysis of fraction I-I isolated from dried aniseed fruits and the corresponding second-dimension separations (B) with taste dilution analyses of the high-impact subfractions I-I/8 and I-I/9.

I/8-4 with the highest TD factor of 16 for licorice-like sweetness and I-I/9-5 with the highest TD factor of 32 for bitter taste, respectively.

Comparison of UV−vis, LC-MS, and 1D/2D-NMR data of the licorice-like sweet-tasting key compound in fraction I-I/8-4 with those found for a commercial reference compound led to the identification of *trans*-anethole (**1**), known to contribute to the typical flavor and sweetish taste of aniseed.[36,37,43,44]

UPLC-TOF-MS(ESI$^+$) analysis of the bitter-tasting key fraction I-I/9-5 revealed $m/z$ 249.1492 as the pseudomolecular ion ($[M + H]^+$), thus suggesting an elemental composition of $C_{15}H_{20}O_3$ for compound **2**. The $^1$H NMR spectrum of compound **2** showed the aromatic protons H−C(3), H−C(5), and H−C(6) in the chemical shift range between 6.75 and 6.99 ppm with the typical coupling pattern of a 3-fold substituted benzene ring, as well as two *trans*-configured olefinic protons (H−C(7), H−C(8)), resonating at 6.20 and 6.37 ppm with a coupling constant of 15.8 Hz. The remaining 15 aliphatic protons were assigned to the methoxy moiety H−C(10), resonating at 3.8 ppm, the methyl group of the propenyl substituent H−C(9), the terminal methyl protons of the 2-methyl butyrate side chain H−C(4′), the methylene group H−C(3′), the methine proton H−C(2′), and the methylene group H−C(5′) of the methyl branch of the 2-methyl butyrate side chain. Unequivocal assignment of all protons and carbon atoms could be successfully achieved by means of 2D-NMR spectroscopy. For example, the position of the substitutents in the aromatic ring could be assigned by means of an HMBC experiment, which showed a $^3J$ coupling of the methoxy protons H−C(10) to the quarternary carbon C(4) as well as $^2J$ and $^3J$ couplings between the carbon C(2) and H−C(7) at 6.37 ppm and H−C(8) at 6.20 ppm of the *trans*-propenyl substituent. The aliphatic side chain could be assigned by the $^{2,3}J$ C,H correlations of the carbonyl carbon resonating at 175.4 ppm with the protons H−C(2′), H−C(3′) and H−C(5′), respectively (Figure 4). With all spectroscopic data taken into consideration, the structure of bitter compound **2** was determined to be *trans*-pseudoisoeugenol 2-methyl butyrate. Figure 1 shows the (*S*)-enantiomer, which Karl et al.[49] described as the naturally occurring enantiomer. Although this compound has been reported earlier,[45−49] to the best of our knowledge, its bitter activity has not been previously reported in the literature.

To determine the recognition threshold concentration for the sweet taste of *trans*-anethole (**1**) and the bitter taste of pseudoisoeugenol 2-methyl butyrate (**2**), aqueous solutions containing 3% ethanol were evaluated by means of the two-alternative forced-choice test in linear ascending concentra-

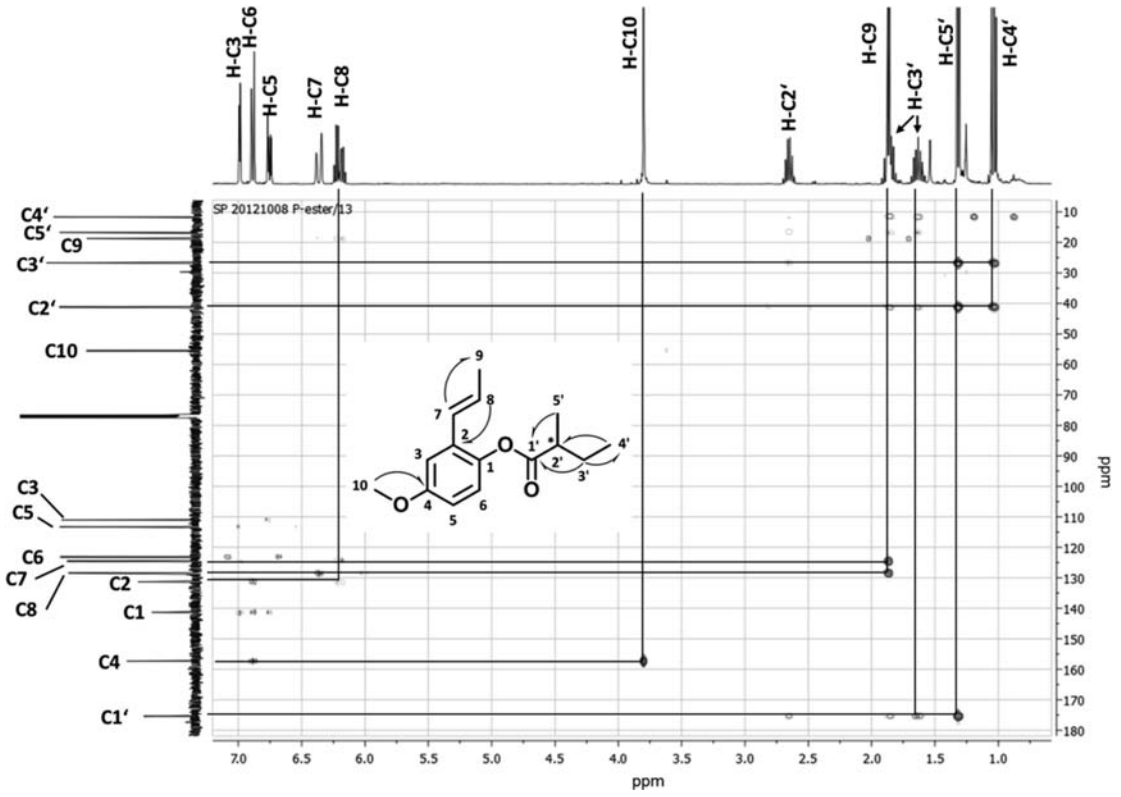

**Figure 4.** Excerpt of the HMBC spectrum (400 MHz, $CDCl_3$) of *trans*-pseudoisoeugenyl 2-methyl butyrate (**2**).

tions. Anethole was found to have a sweet taste recognition threshold of 70 μmol/L, whereas pseudoisoeugenol 2-methyl butyrate (**2**) showed a bitter recognition threshold of 68 μmol/L.

This is the first report on preparative, two-dimensional HPLC combined with sensory analysis in taste compound analysis. Compared to the traditional iterative fractionation of food extracts by sequential application of separation techniques and sensory analysis (e.g., MPLC → solvent separation → sensory evaluation → HPLC → solvent removal → sensory evaluation, etc.), the fully automated 2D-HPLC offers the possibility to comprehensively separate complex extracts into hundreds of subfractions and to reduce the fractionation time from about 1 week to <1day. Using a smart sensory strategy to locate high-impact fractions, e.g., by evaluating first-dimension fractions by reconstituting them from second-dimension subfractions, followed by straightforward application of the taste dilution analysis on the individual second-dimension subfractions seems to be a promising strategy to speed the discovery of the key players imparting the attractive taste of foods. Application of this technique to more complex food extracts and biofermentations, respectively, is currently in progress to fully evaluate the potential of this 2D-HPLC-Sensomics approach also when combined to cell-based taste receptor assays.

sample is affected by the penetration depth of the IR waves. Therefore, NIR spectroscopy is very useful in exploring bulk materials with little or no sample preparation. The difference in the penetration depths between the NIR and MIR regions influences the precision of developed multivariate analytical models as the NIR region can penetrate several millimeters into the sample, whereas the penetration power of the MIR region is measured in micrometers.[9−11]

Various studies have investigated the potential of NIR and MIR spectroscopies to determine melamine adulteration in infant formula powder,[12] in dairy milk,[13] and in soybean meal.[14] The effectiveness of FT-IR spectroscopy and hyperspectral imaging has already been evaluated for the detection of adulteration in black pepper powder.[15] In addition, FT-IR spectroscopy in combination with a partial least-squares (PLS) model has also proved competent to detect melamine adulteration in dairy milk.[16] The use of FT-Raman and FT-IR spectroscopies was investigated in the characterization of irradiated starch, meaning a starch irradiated at 3, 5, or 10 kGy using a Gammacell 220 $Co^{60}$ gamma irradiator.[17] This research group developed a regression model with the spectroscopic data and observed that NIR performed better than MIR in terms of predicting chemical parameters (e.g., reducing sugars, ethanol, total phenolics, and flavonoids) involved in the fermentation process.

Our study sought to quantitatively detect starch in onion powder using FT-NIR and FT-IR spectroscopic techniques. Spectral analysis of 18 concentrations of starch in onion powder samples, ranging from 0 to 35%, was conducted. On the basis of the results, different adulterant concentrations were identified and categorized by developing a multivariate analytical method. The ultimate objective of this study was to predict and classify the added starch concentration in onion powder using FT-NIR and FT-IR spectroscopic techniques.

## MATERIALS AND METHODS

**Sample and Adulterant.** Onion powder and cornstarch (purities of 100 and 95%, respectively) were obtained from a local market in Korea. Cornstarch was used as the adulterant in the onion powder because of its cheap price, lack of significant effects on human health, and similar physical property. The samples were stored at room temperature until use.

**Sample Preparation.** The moisture content of the samples was equilibrated by drying in an oven at 74 °C for 2 h prior to mixing because spectroscopic measurement is highly sensitive to moisture content. The given temperature was chosen to dry the sample effectively without interfering with the chemical integrity of the samples.[15] Both the dried sample and adulterant material weights were measured with an electronic balance (model AR2130, Ohaus Corp., Parasippany, NJ, USA). Then, the cornstarch was mixed with the onion powder to final concentrations (w/w) of 1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 12, 15, 18, 20, 25, 30, and 35%. Each combination was manually mixed and then transferred to a snap-cap vial. Further mixing was accomplished by placing the filled vials onto a high-speed shaker (Vortex-Genie 2, Scientific Industries, Inc., model G560, Bohemia, NY, USA) to reduce the variation in particle size. Ten samples of each of the pure and adulterated powders were used, and sample quantities were approximately 50 mg for the FT-NIR and 30 mg for the FT-IR studies.

**FT-NIR Spectra Collection.** NIR reflectance spectra of the pure and adulterated onion powder samples were obtained using an FT-NIR spectrometer (Antaris II FT-NIR analyzer, Thermo Scientific Co., Waltham, MA, USA) equipped with an InGaAs detector. The sample holder was furnished with an accessory that contained a central hole (20 mm thick × 20 mm diameter) to maintain a uniform shape and thickness for the sample over the irradiated surface during spectra collection. A reference scan was conducted with a golden slit before scanning each sample. The instrument measured the diffuse reflectance, and a total of 32 successive scans from each sample were collected over the wavelength range between 4000 and 10000 $cm^{-1}$ (1000−2500 nm) at 4 $cm^{-1}$ intervals. Averaged spectra were used for analysis.

**FT-IR Spectra Collection.** FT-IR measurements were performed in the mid-infrared region (4000−650 $cm^{-1}$) using a Nicolet 6700 (Thermo Scientific Co.) FT-IR spectrophotometer, configured with an attenuated total reflectance (ATR) sampling technique, deuterated triglycine sulfate (DTGS) detector, and KBr beam splitter controlled by OMNIC software. Samples to be analyzed were placed on a diamond crystal sampling plate and clamped with a pointed tip. A background scan was obtained before every sample scan with an empty sample plate. In addition, the ATR crystals and pointed tip were cleaned to remove any interference from the preceding sample. A total of 32 successive scans from each sample were collected at 4 $cm^{-1}$ intervals, and averaged spectra of each sample were used for analysis.

**Spectral Data Analysis.** The spectroscopic (NIR and mid-IR) detectors receive light from the sample in the form of diffuse reflectance after absorption, specular reflectance, and scattered light. Only the diffuse reflectance contains chemical information, whereas the latter two carry no useful information as there is no large variation in particle size between starch and onion powder (based on the result from Cilas 1090 particle size analyzer). The collected spectra might be affected by systemic noise due to light scattering, variation in particle size, and instrumental drift. Thus, to determine an accurate chemical composition from spectroscopic measurements, the raw spectra must be corrected at different levels by applying preprocessing methods.[18] In this study, both FT-NIR and FT-IR spectral data were treated with five preprocessing methods: three data normalization methods (minimum, maximum, and range), standard normal variate transformation (SNV), and multiple-scatter correlation (MSC). The original FT-NIR spectra of all the samples and the original spectra preprocessed by the SNV method are depicted in Figure 1, panels a and b, respectively. The raw FT-IR spectra for each sample and SNV-preprocessed spectra are shown in Figure 2, panels a and b, respectively.

For the data analysis, principal component analysis (PCA) was carried out on the SNV- and MSC-processed spectra from both FT-NIR and FT-IR. PCA can readily be applied to spectroscopic data to perceive the nature and scattering level of the data. The first principal component (PC1) describes the maximum of variation or spread in the samples. A second principal component (PC2), orthogonal to the first (i.e., completely uncorrelated), describes the maximum of the variation not described by the first eigenvector, and so on. With this procedure, the most important features of the data set can be seen in a low-dimensionality plot.[19] A multivariate calibration model of a partial least-squares regression (PLSR) was then developed using all of the preprocessed spectral data to predict the extent of adulteration in the pure onion and adulterated onion powder samples. PLSR is particularly suited when the matrix of predictors has more variables than observations, such as from spectral data. PLSR has been used in food authentication studies based in spectroscopic data.[11] Multivariate analysis was performed using MATLAB software version 7.0.4 (The Mathworks, Natick, MA, USA).

The whole data set (180 samples) was split into two sets: a calibration set consisting of 126 samples (7 samples from each group) and a prediction set consisting of 54 samples (3 samples from each group). The PLSR models were built with the calibration set using a full cross-validation method (leave-one-out), removing one observation at one time from the sample sets until all samples have been removed once. This is the method generally used in developing the PLSR model for detecting a specific material with a spectral data set.[20]

## RESULT AND DISCUSSION

**Interpretation of Spectral Analyses.** The FT-NIR original spectra of the pure and adulterated onion powder and the SNV-preprocessed spectra (Figure 1) reveal differences

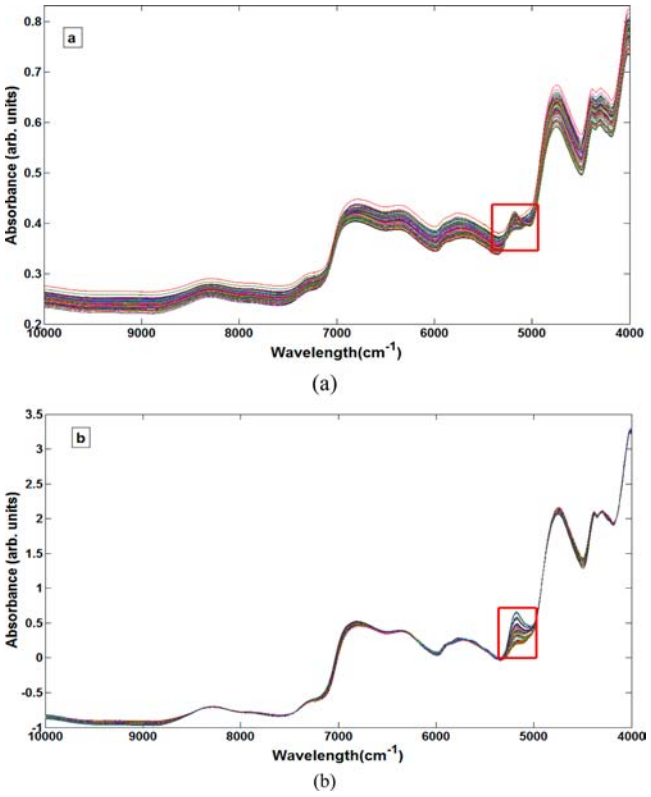

**Figure 1.** (a) Original FT-NIR spectra of pure onion and starch onion mixtures at different concentrations and (b) SNV-preprocessed original spectra.

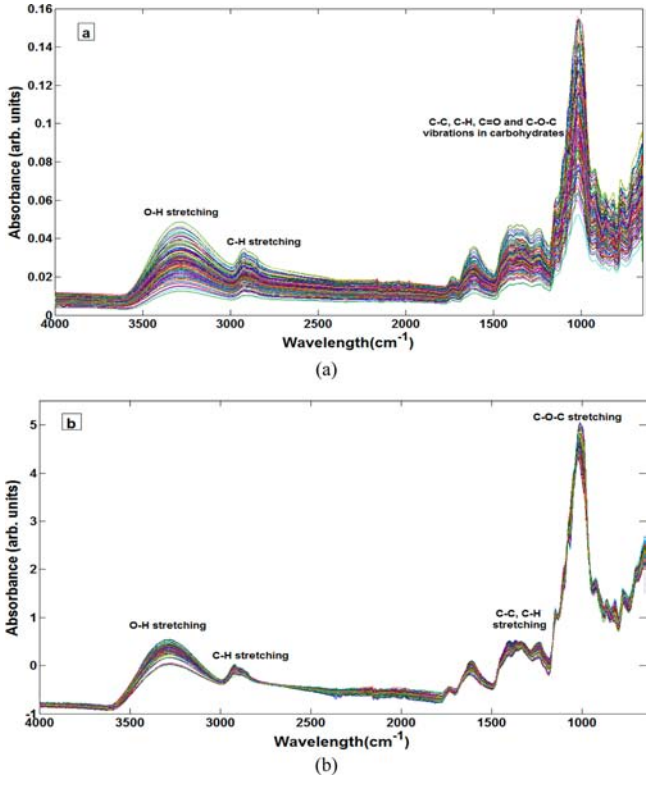

**Figure 2.** (a) Original FT-IR spectra of pure onion and starch onion mixtures at different concentrations and (b) the same spectra after SNV-preprocessing.

in the absorption intensities between 1920 and 1980 nm (marked) and can easily be identified. The absorption bands in this region correspond to the O−H stretch and O−H band combination and the H−O−H deformation combination, which represent the starch content.[21] Starch is a semicrystalline polymer composed of two polysaccharides, amylose and amylopectin. Amylose is a mostly linear chain consisting of up to 3000 glucose molecules interconnected primarily by $\alpha$-1,4-glycoside linkages.[13] The spectral fluctuations from 1400 to 1600 nm correspond to the first overtone of the hydroxyl group. The precise position of these bands is very sensitive to hydrogen bonding in the starch molecule.[22]

The regression coefficient plot (Figure 3) of the PLS model for the FT-NIR data indicates some meaningful bands that are

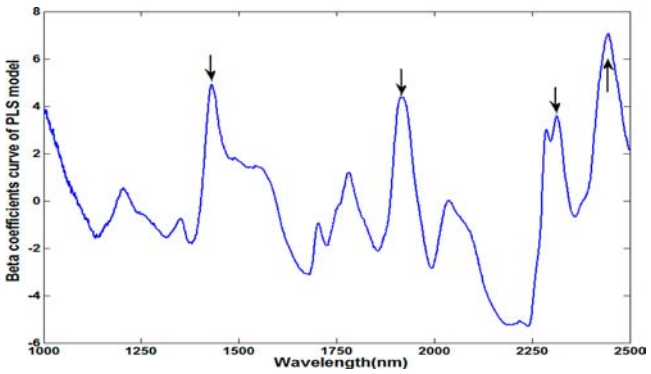

**Figure 3.** $\beta$ coefficient derived from the PLSR for the FT-NIR spectral data. Arrows indicate the characteristic wavelengths of starch.

attributable to the starch. The absorption band around 1420 nm corresponded to a combination of O−H first overtone. Another absorption band at 1920 nm related to CONH, which referred to an amide linkage. The absorption bands at 2312 and 2455 nm corresponded to C−H stretching and deformation vibrations, which represent starch content. Figure 4 shows the results of the PCA for the SNV-pretreated FT-NIR spectral data.

A data grouping was observed from the scatter plot of the PC scores (Figure 4a), but the data for samples adulterated at low concentration appear to overlap more. This confirmed our assumption that the different spectral attributes among the samples were associated with the concentration of the starch in the onion powder. Furthermore, we assessed the potential of PCA to distinguish among the low starch concentration samples (1−10%), but the data were overly scattered and overlapping (data not shown). The first three PC loadings account for nearly 99% of the total variance in the samples. PC loadings are correlation coefficients between the PC scores and the original variables, which measure the importance of each variable in accounting for the variability in the PC. It is possible to interpret the first few PCs in terms of overall effect of a contrast between groups of variables based on the structures of PC loadings. The PC loading plot (Figure 4b) shows the highest loading for PC1 and PC3 at ∼1960 nm, related to the starch. PC1 and PC2 show other important bands between 1435 and 1450 nm, corresponding to the first O−H stretching overtone, also assigned to the starch.

Typically, the MIR region can be divided into two distinct groups: The region of the spectrum below 1500 $cm^{-1}$ is called the fingerprint region.[23] Peaks in this region are very difficult to assign to specific molecular vibrations because each different

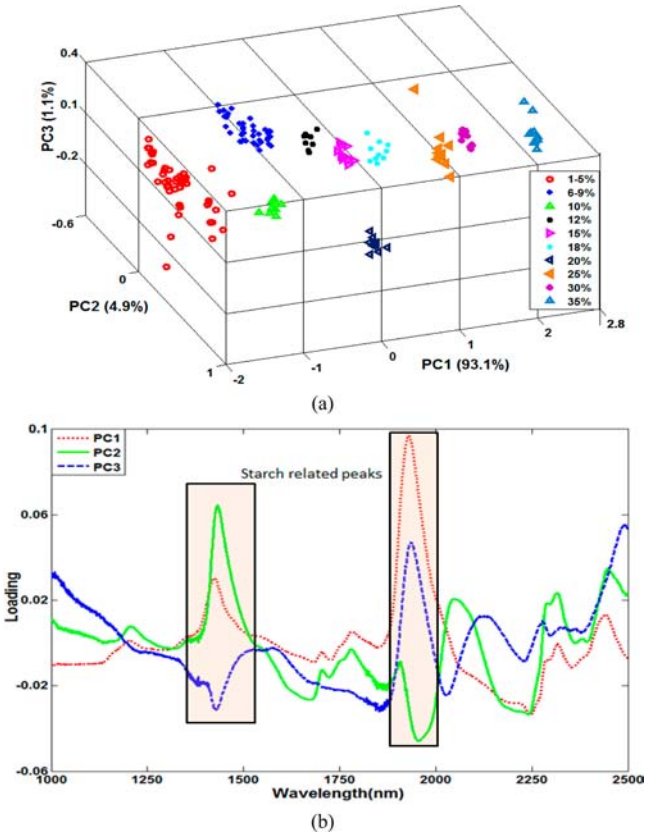

**Figure 4.** (a) Principal component score plot for the first three PCs for discrimination among different adulteration concentrations in onion powder and (b) the first three principal component loadings.

compound produces a different and unique absorption pattern in this part of the spectrum.[16] The MIR region from 4000−1500 $cm^{-1}$ is known as the functional group region. Most of the relevant information that is used to interpret the MIR spectrum usually obtains from the functional group region.[24] The most notable differences in the FT-IR spectra in this study can be categorized into three main regions, which interpret the significance of key bands (Figure 2). The first region was the fingerprint region (650−1500 $cm^{-1}$), which provided more complex spectra and fairly indistinguishable individual bands than the region at higher wavenumbers. The peaks in the region 1045−1087 $cm^{-1}$ are due to C—C bond vibrations related to the carbohydrate; those at 1170−1250 $cm^{-1}$ correspond to absorption bands for C—H, C═O, and C—C vibrations;[25] and the triplet bands for the C—O—C stretching absorption are found at 1147 and 1010 $cm^{-1}$.[26] The vibrations originate from the C—O—C bonds related to the $\alpha$-1,4-glycoside linkages, as these bonds are common in carbohydrates. The C−H stretching region, found between 2850 and 3000 $cm^{-1}$, includes a distinct band at 2920 $cm^{-1}$.[26] Finally, the higher wavenumber region (3000−3500 $cm^{-1}$) indicates the O—H stretching vibration bands. These peaks could be a result of moisture uptake in the samples during spectral analysis. The $\beta$ coefficient (Figure 5), which indicates the spectral differences among the samples, shows some important bands representative of the carbohydrates (starch) that contribute to the quantitative classification of the onion powder and adulterated samples.

PCA was executed on both the MSC- and SNV-preprocessed FT-IR spectral data to extract relevant information. However,

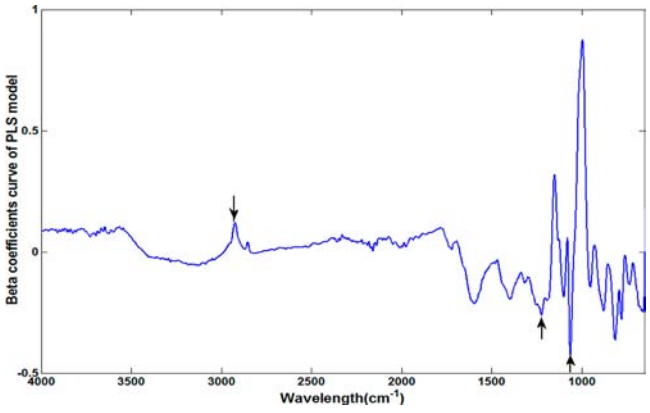

**Figure 5.** $\beta$ coefficient derived from the PLSR for the FT-IR spectral data. Arrows indicate the characteristic wavelengths of starch.

the data might be classified according to moisture content or particle size, rather than their chemical composition characteristics, because the IR data patterns are determined by not only absorption characteristics but also scattering characteristics. These spectral variations were removed by oven drying all of the samples and pretreating the spectra with MSC- and SNV-preprocessing methods. Neither the MSC- nor the SNV-preprocessed FT-IR data were able to quantify the level of adulteration by means of data clustering using PCA. The data were scattered over a vast range, and no distinct separations among the data groups were found from the PCA score plot (data not shown). PCA is a popular primary technique for data clustering. It is not, however, optimized for class separability. The loading plots of the first three PCs are depicted in Figure 6.

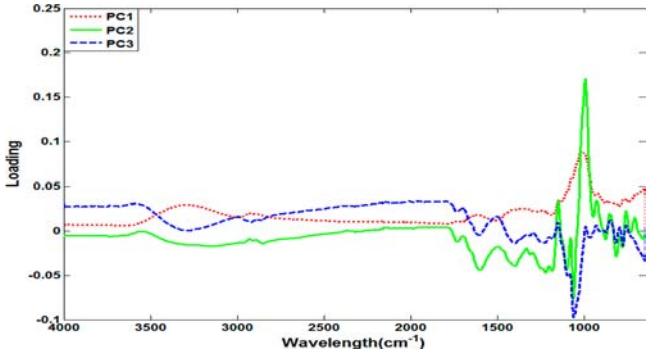

**Figure 6.** First three principal component loadings for starch-adulterated onion powder discrimination.

The PC1 loading accounts for 96.1% of the total sample variance, producing a pattern similar to the raw FT-IR spectra (Figure 2a). The loadings of PC1 and PC2 show the highest intensity at ∼980 $cm^{-1}$. Sankaran et al. also found a similar peak for starch in the spectral range of 950−1000 $cm^{-1}$.[27] In addition, Danwille observed a sharp peak at 975 $cm^{-1}$ arising from an $-OCH_3$ bond vibration related to cellulose.[15]

**Partial Least-Squares Regression Analysis.** A PLSR model was used to predict the added starch concentration in onion powder. The samples were categorized on the basis of the adulterant concentration, and a PLSR model was developed using the preprocessed spectra of samples from both FT-NIR and FT-IR spectroscopy. The highest correlation coefficient value, $R_p^2$, of 0.98 with a standard error of prediction (SEP) of 1.18% was observed by using the SNV-preprocessed FT-NIR

dx.doi.org/10.1021/jf500574m | J. Agric. Food Chem. 2014, 62, 9246−9251

spectra. The optimal number of factors used in the PLS models was automatically selected on the basis of the lowest value of predicted root-mean-square error (RMSE) in the cross-validation process. The PLSR results are listed in Table 1 for the FT-IR spectral data.

**Table 1. Ability of PLS To Predict Concentration of Added Starch in Onion Powder for SNV-Preprocessed FT-IR Spectra**

| | calibration | | validation | | prediction | | |
|---|---|---|---|---|---|---|---|
| spectral region ($cm^{-1}$) | $R_c^{2a}$ | SEC[b] (%) | $R_v^{2c}$ | SEV[d] (%) | $R_p^{2e}$ | SEP[f] (%) | factors |
| 650−4000 | 0.93 | 2.52 | 0.92 | 2.65 | 0.90 | 3.12 | 3 |
| 650−1500 | 0.93 | 2.58 | 0.92 | 2.70 | 0.89 | 3.24 | 3 |
| 1500−4000 | 0.92 | 2.65 | 0.90 | 3.04 | 0.84 | 4.04 | 4 |

[a]Calibration $R^2$. [b]SEC, standard error of calibration. [c]Validation $R^2$. [d]SEV, standard error of validation. [e]Prediction $R^2$. [f]SEP, standard error of prediction, respectively.

The PLSR result obtained for the FT-NIR data shows a strong relatioship ($R_p^2$ = 0.98) between the actual and predicted concentration values. The result suggests that four principal components were enough to extract 99% of the relevant information used to detect starch adulteration in onion powder.

On the basis of the pattern of the FT-IR spectra, the prediction efficiency of the PLSR model was evaluated using the SNV-preprocessed spectra of the full spectral region, as well as two different selected regions (i.e., the fingerprint region (650−1500 $cm^{-1}$) and the functional group region (1500−4000 $cm^{-1}$)). The highest correlation coefficients of prediction ($R_p^2$), 0.90 and 0.89, were obtained for the full spectral and fingerprint regions, respectively. In addition, these two spectral regions showed nearly the same $R_c^2$ and $R_v^2$ values, with a small difference in SEC and SEV (Table 1). The prediction by PLSR of the functional group region was acceptable ($R_p^2$ = 0.84) but lower than those of the first two groups.

Jawaid et al. and Sherman have suggested that the functional group region is better for classification and prediction than the fingerprint region, because most of the information used to interpret the MIR spectrum is usually obtained from the former, whereas the fingerprint region is normally complex with many frequently overlapped bands.[16,28] In our study, the fingerprint region gave better results than the functional group region with respect to the quantative prediction of starch adulteration in the onion powder samples. Moreover, Filippov also discribed the use of the fingerprint region of MIR for the identification of carbohydrates.[29] For more information readers should refer to ref 29 and references cited therein.

From the PLSR and PCA results, the FT-NIR spectral data were better able to quantitatively predict the extent of starch adulteration in onion powder samples than the FT-IR spectral data. It should be noted that limited amounts of sample are irradiated by MIR radiation during the FT-IR analysis. Additionally, the penetration of MIR radiation is usually less than that of the NIR. These reasons could be responsible for the low classification rate for the quantitative discrimination of adulteration using FT-IR spectroscopy. It is known that onions contain calcium, proteins, water-soluble carbohydrates (e.g., glucose, fructose, and sucrose), and other chemical components.[30] The concentration of added starch in the onion powder proportionally influences the concentration of these chemical compounds on a percentage basis. These chemical compounds have different absorption intensities at specific wavelengths in both the NIR and MIR regions. In our study, in addition to the starch concentration, these intrinsic chemical compounds might be responsible for distinct classifications.

In summary, two different vibrational spectroscopic techniques were investigated to quantitatively detect cornstarch contamination in onion powder. The potential of these techniques was evaluated by adding starch at various concentrations (1−35 wt %) into onion powder and by properly mixing the samples. Both FT-NIR and FT-IR spectroscopic methods demonstrated good potential; however, FT-NIR spectroscopy in combination with PLSR afforded a higher prediction accuracy ($R_p^2$ = 0.98) than FT-IR spectroscopy ($R_p^2$ = 0.90). SNV preprocessing, which has been useful in other quantitative applications, improved the accuracies overall. These techniques would seem to be promising for the effective, chemical-free, and rapid detection of product adulteration, as they require no sophisticated laboratory or well-trained personnel to perform the analysis. In addition, for quality control measurements, both FT-NIR and FT-IR spectroscopic techniques are fast and offer a solution for authenticity analysis of agricultural and food products. Further studies could be performed to establish qualitative methods for the detection of adulteration in spices.

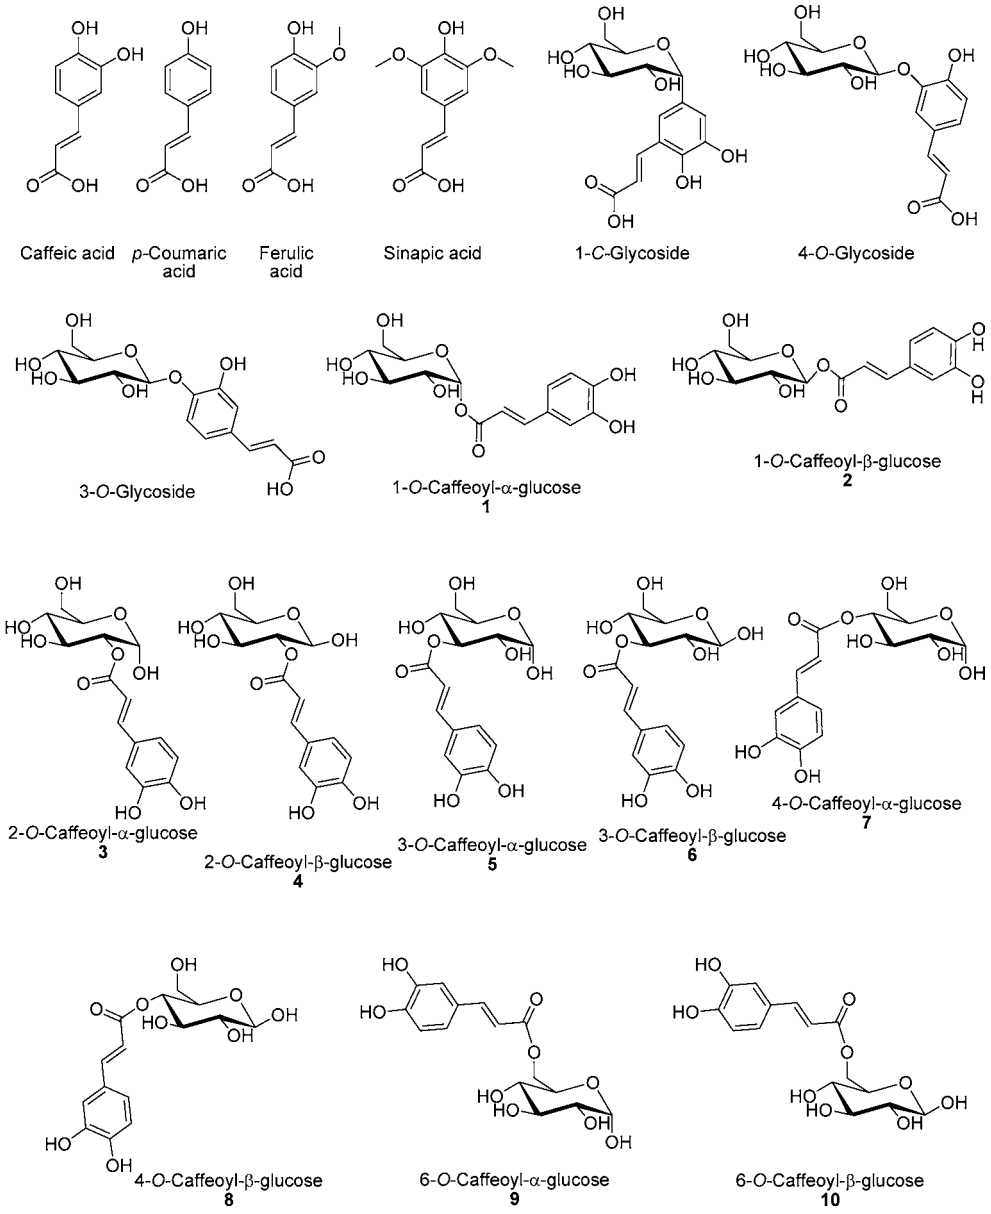

**Figure 1.** Selected structures of typical hydroxycinnamic acids present in the human diet and hydroxycinnamic acid carbohydrate conjugates.

showed that ferulic acid moieties bound to the 5-position of arabinose in arabinoglycans readily dimerized through a photochemical mechanism leading to cyclobutane dimers,[27,28] and, more importantly, they dimerized through radical coupling mechanisms[29] with dehydrodiferulates as reaction products, displaying a surprisingly rich structural chemistry. Caffeoylglucoses were also proposed as biosynthetic intermediates in the syntheses of other caffeoyl derivatives, including chlorogenic acids.

In our own experience, we have observed multiple isomers of caffeoylglucose over the past decade in at least one-half of all of the plant extracts analyzed. Following from many reports on caffeoylglucoses and other hydroxycinnamate conjugates to sugars, addressing and solving the structural assignment problem in this class of compounds constitutes an urgent problem. Only if an unambiguous analytical tool for structure elucidation becomes available with authentic reference materials available will we be able to fully assess the occurrence, dietary burden, and biological effects of this widespread but unexplored class of secondary plant metabolites.

Unambiguous structure elucidation of regioisomeric chlorogenic acids has become possible through the application of tandem $MS^n$ methods. This method has the advantage that chlorogenic acids do not need to be isolated but can be identified and their structure elucidated directly from analytical LC-tandem-MS runs, even if present as minor components or as chromatographically close eluting compounds. For example, we observed that all four regioisomeric mono caffeoylquinic acids and later all six regioisomeric dicaffeoylquinic acids showed dramatically different tandem mass spectra in the negative ion mode, using an ion trap mass spectrometer.[30,31] Because of the diagnostic differences in the tandem MS fragment spectra, a consistent and predictive structure diagnostic hierarchical key for chlorogenic acids structure elucidation has been established, which allows reliable determination of chlorogenic acids regiochemistry even for minor component chlorogenic acids from tandem MS data exclusively. The basis of these differences in fragment MS spectra was rationalized in terms of different hydrogen-bonding arrays found in gas-phase ions of regioisomeric

chlorogenic acids. In this study, we investigated methods for the chromatographic resolution and mass spectrometric characterization of all 10 isomers of caffeoylglucose present in yerba maté leaves (*Ilex paraguariensis*).

## MATERIALS AND METHODS

All of the chemicals were purchased from Sigma-Aldrich, Carl-Roth, and Iris Biotech (Bremen, Germany). Green dried maté leaves (of Argentinian origin) and kiwi fruit (of Italian origin) were purchased from a supermarket in Bremen, Germany.

**Methanolic Extract of Yerba Maté.** Yerba maté leaves (5 g) were ground to a fine powder and extracted with 70% aqueous methanol (100 mL) using ultrasonication for 30 min. This extract was filtered through a Whatman no. 1 filter paper. The methanol and the water were removed in vacuo, and the residue was stored at −20 °C until required, thawed at room temperature, dissolved in methanol (50 mg/10 mL), filtered through a membrane filter, and then used for LC−MS.

**LC−MS$^n$.** The LC equipment (1100 Series, Agilent, Karlsruhe, Germany) comprised a binary pump, an auto sampler with a 100 μL loop, and a DAD detector with a light-pipe flow cell, recording at 320 nm and scanning from 200 to 600 nm. This was interfaced with an ion-trap mass spectrometer fitted with an ESI source (HCT-Ultra, Bruker Daltonics, Bremen, Germany) operating in full scan, auto MS$^n$ mode to obtain fragment ion $m/z$ values. As necessary, MS$^2$, MS$^3$, and MS$^4$ fragment-targeted experiments were performed to focus only on compounds producing a pseudomolecular ion at $m/z$ 341. Tandem mass spectra were acquired in the auto-MS$^n$ mode (smart fragmentation) using a ramping of the collision energy. Maximum fragmentation amplitude was set to 1 V, starting at 30% and ending at 200%. The MS operating conditions (negative ion mode) had been optimized using 3-caffeoylglucoses (**5** and **6**) and 6-caffeoylglucoses (**9** and **10**) with a capillary temperature of 365 °C, a drying gas flow rate of 10 L/min, and a nebulizer pressure of 10 psi. High-resolution LC−MS was carried out using the same HPLC equipped with a high-resolution mass spectrometer (MicrOTOF Focus, Bruker Daltonics, Bremen, Germany) fitted with an ESI source, and internal calibration was achieved with 10 mL of a 0.1 M sodium formate solution injected through a six-port valve prior to each chromatographic run. Calibration was carried out using the enhanced quadratic mode, and the mass error was below 5 ppm.

**HPLC.** Separation was achieved on a 250 × 3 mm i.d. column containing 5 μm C18 amide, with a 5 mm × 3 mm inner-diameter guard column (Varian, Darmstadt, Germany). Solvent A was water/formic acid (1000:0.005 v/v), and solvent B was methanol. Solvents were delivered at a total flow rate of 500 μL/min. In the first HPLC method, the gradient profile was from 10% B to 70% B linearly in 60 min followed by 10 min isocratic and a return to 10% B at 90 min and finally 10 min isocratic to re-equilibrate. In the second HPLC method, 10% B was used isocratically for 80 min.

**NMR.** $^1$H and $^{13}$C NMR spectra were recorded on a JEOL-ECX 400 spectrometer operating at 400 MHz for $^1$H NMR and 100 MHz for $^{13}$C NMR at room temperature in $CDCl_3$, acetone-$d_6$, or methanol-$d_4$ using a 5 mm probe. The chemical shifts ($\delta$) are reported in ppm and were referenced to the residual solvent peak. The coupling constants ($J$) are quoted in hertz.

**Synthesis.** All synthetic procedures and spectroscopic data for intermediates, reference compounds, equilibration of anomers, and synthesis of mixtures of isomers are given below, employing strategies similar to those published before.[32,33]

**Synthesis of 3-*O*-Caffeoylglucoses (5 and 6).** To a solution of 1,2:5,6-di-*O*-isopropylidene-α-D-glucofuranose (1.00 g, 3.84 mmol) and 4-dimethylaminopyridine (200 mg, 1.63 mmol) in $CH_2Cl_2$ (50 mL) were added triethylamine (10 mL, 71.70 mmol) and 3,4-di-*O*-allylcaffeoyl chloride (1.58 g, 5.70 mmol)[32] at room temperature. The reaction mixture was refluxed for 24 h, cooled to room temperature, and acidified (pH ≈ 3) with 2 M HCl. The layers were separated, and the aqueous phase was extracted with $CH_2Cl_2$ (3 × 50 mL). The combined organic layers were dried over sodium sulfate, filtered, and the solvent was removed in vacuo. The crude product was purified by column chromatography on silica gel (ethyl acetate−petroleum ether, 30−50%) to give 3-*O*-(3,4-di-*O*-allyl)caffeoyl-1,2:5,6-di-*O*-isopropylidene-α-D-glucofuranose (75%) (Figure 2).

$\delta_H$ ($CDCl_3$): 7.61 (1H, d, *J* 16.0, $C_{Ar}$−C*H*), 7.11 (1H, dd, *J* 8.2, 1.9, $C_{Ar}H$), 7.09 (1H, d, *J* 1.7, $C_{Ar}H$), 6.87 (1H, d, *J* 8.2, $C_{Ar}H$), 6.24 (1H, d, *J* 15.5, $C_{Ar}$−CH=C*H*), 6.06 (2H, m, $CH_2$=C*H*), 5.90 (1H, d, *J* 3.6, *H*-3), 5.39 (2H, d, *J* 16.9, C*H*H=CH), 5.37 (1H, d, *J* 2.3, *H*-1), 5.31 (2H, d, *J* 9.6, CH*H*=CH), 4.64 (4H, m, $C_{Ar}$−OC$H_2$), 4.56 (1H, d, *J* 3.7, *H*-2), 4.28 (2H, m, *H*-6a, *H*-6b), 4.07 (2H, m, *H*-4, *H*-5), 1.53 (3H, s, OC$H_3$), 1.41 (3H, s, OC$H_3$), 1.30 (6H, s, OC$H_3$). $\delta_C$ ($CDCl_3$): 165.8 (−COOC), 151.1 ($C_{Ar}$−$OCH_2$), 148.6 ($C_{Ar}$−$OCH_2$), 146.0 ($C_{Ar}$−CH), 133.0 ($CH_2$=CH), 132.8 ($CH_2$=CH), 127.2 ($C_{Ar}$−CH), 123.1 ($C_{Ar}$), 118.1 ($CH_2$=CH), 114.7 (CH−COO), 113.4 ($C_{Ar}$), 112.7 ($C_{Ar}$), 112.3 ($H_3C$−O−*C*−O−$CH_3$), 109.4 ($H_3C$−O−C−O−$CH_3$), 105.1 (*C*-3), 83.5 (*C*-1), 79.8 (*C*-6), 75.9 (*C*-2), 72.7 (*C*-4), 70.0 ($C_{Ar}$−$OCH_2$), 69.7 ($C_{Ar}$−$OCH_2$), 67.2 (*C*-5), 26.9 ($OCH_3$), 26.8 ($OCH_3$), 26.2 ($OCH_3$), 25.3 ($OCH_3$).

To a solution of 3-*O*-(3,4-di-*O*-allyl)caffeoyl-1,2:5,6-di-*O*-isopropylidene-α-D-glucofuranose (1.00 g, 2.05 mmol) and *p*-toluenesulfonic acid (50 mg) in methanol−water (9:1, 50 mL) was added 10% Pd/C (300 mg) at room temperature. The reaction mixture was refluxed for 48 h, cooled to room temperature, filtered, and methanol was removed in vacuo. The aqueous reaction mixture was extracted with ethyl acetate (3 × 50 mL). The combined organic layers were dried over sodium sulfate, filtered, and the solvent was removed in vacuo. The crude product was purified by column chromatography on silica gel (ethyl acetate-petroleum ether, 50−95%) to give a mixture of 3-*O*-caffeoyl-1,2:5,6-di-*O*-isopropylidene-α-D-glucofuranose, 3-*O*-caffeoyl-1,2-*O*-isopropylidene-α-D-glucofuranose, and 3-*O*-caffeoyl-5,6-*O*-isopropylidene-α-D-glucofuranose (Figure 2).

The resulting mixture of the esters (500 mg) was dissolved in a mixture of 20 mL of trifluoroacetic acid and water (8:2) at room temperature and stirred for 1 h. The solvents were removed in vacuo to obtain the resulting esters 3-*O*-caffeoylglucoses (**5** and **6**) in quantitative yield (Figure 2).

$\delta_H$ (methanol-$d_3$): 7.51 (1H, d, *J* 16.0, $C_{Ar}$−C*H*), 7.03 (1H, s, $C_{Ar}$−*H*), 6.92 (1H, d, *J* 8.2, $C_{Ar}$−*H*), 6.77 (1H, d, *J* 8.2, $C_{Ar}$−*H*), 6.32 (1H, *J* 16.0, $C_{Ar}$−CH=*CH*), 5.31 (1H, t, *J* 9.6, α-gluc *H*-3), 5.15 (1H, *J* 3.2, α-gluc *H*-3), 5.02 (1H, t, *J* 9.6, β-gluc *H*-3), 4.59 (1H, t, *J* 7.8, β-gluc *H*-1), 3.60−3.90 (2H, m, gluc *H*-6a, gluc *H*-6b), 3.24−3.57 (3H, m, gluc *H*-2, gluc *H*-4, gluc *H*-5). $\delta_C$ (methanol-$d_3$): 168.1 (COOR), 148.1 ($C_{Ar}$), 145.6 ($C_{Ar}$-CH), 145.5 ($C_{Ar}$), 126.5 ($C_{Ar}$), 121.5 ($C_{Ar}$), 115.0 ($CH_2$=CH), 114.1 (CH−COO), 114.0 ($CH_2$=*C*H), 96.8 (β-gluc *C*-1), 92.6 (α-gluc *C*-1), 77.7 (β-gluc *C*-3), 76.5 (α-gluc *C*-3), 75.7 (β-gluc *C*-2), 75.5 (β-gluc *C*-5), 73.4 (α-gluc *C*-2), 71.5 (α-gluc *C*-5), 70.9 (α-gluc *C*-4), 68.6 (β-gluc *C*-4), 61.4 (β-gluc *C*-6), 61.1 (α-gluc *C*-6).

**Synthesis of 6-*O*-Caffeoylglucoses (9 and 10).** To a solution of 1,2-*O*-isopropylidene-α-D-glucofuranose (1.00 g, 4.54 mmol) and 4-dimethylaminopyridine (200 mg, 1.63 mmol) in $CH_2Cl_2$ (50 mL) were added pyridine (5 mL, 62 mmol) and 3,4-di-*O*-allylcaffeoyl chloride (1.58 g, 5.70 mmol)[32] at room temperature. The reaction mixture was stirred for 24 h at room temperature and acidified (pH ≈ 3) with 2 M HCl. The layers were separated, and the aqueous phase was extracted with $CH_2Cl_2$ (3 × 50 mL). The combined organic layers were dried over sodium sulfate, filtered, and the solvent was removed in vacuo. The crude product was purified by column chromatography on silica gel (ethyl acetate−petroleum ether, 30−50%) to give 6-*O*-(3,4-di-*O*-allyl)caffeoyl-1,2-*O*-isopropylidene-α-D-glucofuranose (80%) (Figure 2).

$\delta_H$ (acetone-$d_6$): 7.62 (1H, d, *J* 15.6, $C_{Ar}$−C*H*), 7.32 (1H, dd, *J* 1.8, $C_{Ar}H$), 7.17 (1H, dd, *J* 8.7, 2.3 $C_{Ar}H$), 6.99 (1H, d, *J* 8.2, $C_{Ar}H$), 6.41 (1H, d, *J* 16.0, $C_{Ar}$−CH=C*H*), 6.08 (2H, m, $CH_2$=C*H*), 5.85 (1H, d, *J* 3.6, *H*-3), 5.43 (2H, m, C*H*HCH), 5.23 (2H, m, CH*H*=CH), 4.65 (4H, m, $C_{Ar}$−OC$H_2$), 4.49 (1H, d, *J* 3.7, *H*-2), 4.31 (2H, m, *H*-6a, *H*-6b), 4.12 (2H, m, *H*-4, *H*-5), 1.39 (3H, s, OC$H_3$), 1.24 (3H, s, OC$H_3$). $\delta_C$ (acetone-$d_6$): 166.6 (−COOC), 150.9 ($C_{Ar}$−$OCH_2$), 148.9 ($C_{Ar}$−$OCH_2$), 144.5 ($C_{Ar}$−CH), 133.9 ($CH_2$=CH), 133.5 ($CH_2$=CH), 127.7 ($C_{Ar}$−CH), 122.9 ($C_{Ar}$), 116.9 ($CH_2$=CH), 116.5

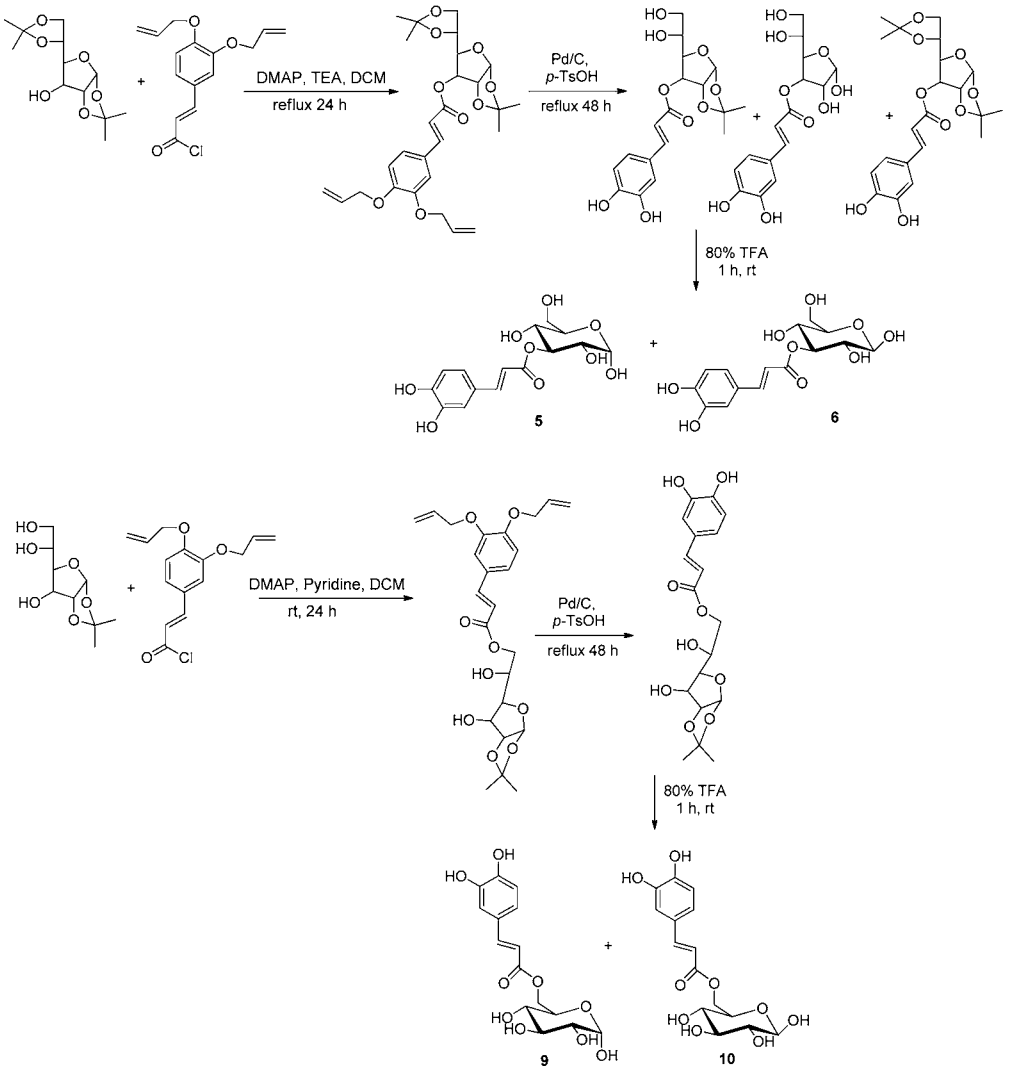

**Figure 2.** Synthesis pathway of 3-caffeoylglucoses (**5** and **6**) and 6-caffeoylglucoses (**9** and **10**).

(CH−COO), 115.7 ($C_{Ar}$), 113.7 ($C_{Ar}$), 112.6 ($H_3C-O-C-O-CH_3$), 111.2 ($H_3C-O-C-O-CH_3$), 105.0 (*C*-3), 85.3 (*C*-6), 80.4 (*C*-1), 74.4 (*C*-2), 69.4 (*C*-4), 69.2 ($C_{Ar}-OCH_2$), 67.1 ($C_{Ar}-OCH_2$), 66.8 (*C*-5), 26.4 ($OCH_3$), 25.6 ($OCH_3$).

To a solution of 6-*O*-(3,4-di-*O*-allyl)caffeoyl-1,2-*O*-isopropylidene-*α*-D-glucofuranose (1.00 g, 2.23 mmol) and *p*-TsOH (50 mg) in methanol−water (9:1, 50 mL) was added 10% Pd/C (350 mg) at room temperature. The reaction mixture was heated at 70 °C for 48 h, cooled to room temperature, filtered, and methanol was removed in vacuo. The aqueous reaction mixture was extracted with ethyl acetate (3 × 50 mL). The combined organic layers were dried over sodium sulfate, filtered, and the solvent was removed in vacuo. The crude product was purified by column chromatography on silica gel (ethyl acetate−petroleum ether, 50−95%) to give 6-*O*-caffeoyl-1,2-*O*-isopropylidene-*α*-D-glucofuranose (62%). The resulting ester 6-*O*-caffeoyl-1,2-*O*-isopropylidene-*α*-D-glucofuranose (400 mg, 1.10 mmol) was dissolved in a mixture of 20 mL of trifluoroacetic acid and water (8:2) at room temperature and stirred for 1 h. The solvents were removed in vacuo to obtain the resulting esters 6-*O*-caffeoylglucoses (**9** and **10**) in quantitative yield (Figure 2).

$\delta_H$ (methanol-$d_3$): 7.54 (1H, d, *J* 16.0, $C_{Ar}-CH$), 7.02 (1H, d, *J* 2.2, $C_{Ar}-H$), 6.92 (1H, dd, *J* 8.2, 1.4, $C_{Ar}-H$), 6.75 (1H, d, *J* 8.2, $C_{Ar}-H$), 6.25 (1H, *J* 16.5, $C_{Ar}-CH=CH$), 5.10 (1H, d, *J* 3.7, gluc *H*-1), 4.45 (1H, m, gluc *H*-6a), 4.30 (1H, m, gluc *H*-6b), 4.05 (1H, m, gluc *H*-4), 3.28−3.37 (2H, m, gluc *H*-2, gluc *H*-5). $\delta_C$ (methanol-$d_3$): 167.9 (COOC), 148.3 ($C_{Ar}$), 145.8 ($C_{Ar}-CH$), 145.5 ($C_{Ar}$), 126.4 ($C_{Ar}$), 123.6 ($C_{Ar}$), 121.6 ($C_{Ar}$), 115.2 ($CH_2=CH$), 113.7 (CH−COO), 113.6 ($CH_2=CH$), 96.8 (*β*-gluc *C*-1), 92.6 (*α*-gluc *C*-1), 76.7 (*β*-gluc *C*-3), 74.9 (*β*-gluc *C*-2), 74.1 (*β*-gluc *C*-5), 73.5 (*α*-gluc *C*-3), 72.2 (*α*-gluc *C*-2), 71.6 (*α*-gluc *C*-5), 70.4 (*α*-gluc *C*-4), 69.6 (*β*-gluc *C*-4), 63.6 (*β*-gluc *C*-6), 63.5 (*α*-gluc *C*-6).

**Synthesis of Stereo- and Regioisomeric Mixture of Caffeoylglucoses (1−6).** To a solution of 4,6-*O*-benzylidene-D-glucopyranose (268 mg, 1.00 mmol) and 4-dimethylaminopyridine (50 mg, 0.04 mmol) in $CH_2Cl_2$ (20 mL) were added pyridine (3 mL) and 3,4-di-*O*-acetylcaffeoyl chloride (387 mg, 1.38 mmol) at room temperature. The reaction mixture was stirred for 10 h and acidified with 1 M HCl (pH ≈ 3). The layers were separated, and the aqueous phase was re-extracted with ethyl acetate (2 × 20 mL). The combined organic layers were dried over $Na_2SO_4$ and filtered, and the solvents were dried in vacuo. The resulting esters were dissolved in a mixture of 20 mL of trifluoroacetic acid and water (7:3) at room temperature and stirred for 30 min. The solvents were removed in vacuo, and the resulting yellowish product was analyzed by HPLC−MS and shown to contain a mixture of caffeoylglucoses **1**−**6** (Figure 3).

**Synthesis of Stereo- and Regioisomeric Mixture of Caffeoylglucoses (1−10).** To a solution of D-glucose (180 mg, 1.00 mmol) and 4-dimethylaminopyridine (50 mg, 0.04 mmol) in $CH_2Cl_2$ (20 mL) were added pyridine (3 mL) and 3,4-di-*O*-acetylcaffeoyl chloride (387 mg, 1.38 mmol) at room temperature. The reaction mixture was stirred for 10 h and acidified with 1 M HCl (pH ≈ 3). The layers were separated, and the aqueous phase was re-extracted with ethyl acetate (2 × 20 mL). The combined organic layers were dried over $Na_2SO_4$ and filtered, and the solvents were dried in vacuo. The resulting

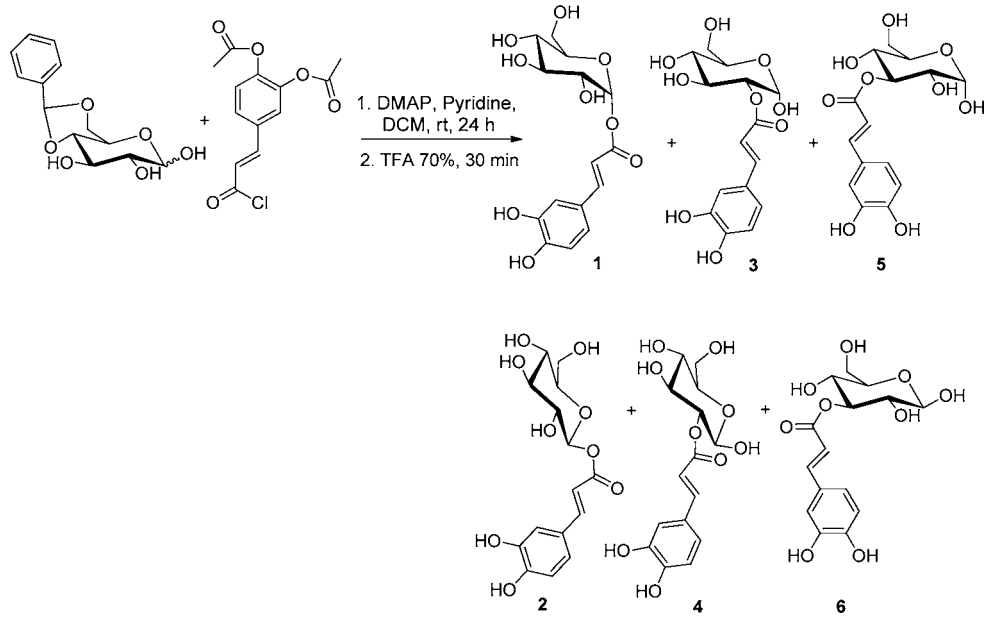

**Figure 3.** Synthesis pathway of 1-caffeoylglucoses, 2-caffeoylglucoses, and 3-caffeoylglucoses (**1**−**6**).

esters were dissolved in a mixture of 20 mL of trifluoroacetic acid and water (7:3) at room temperature and stirred for 30 min. The solvents were removed in vacuo, and the resulting yellowish product was analyzed by HPLC−MS and shown to contain a mixture of caffeoylglucoses **1**−**10** (Figure 4).

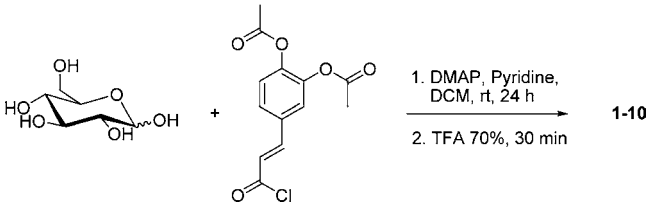

**Figure 4.** Synthesis pathway of regio- and stereoisomers of caffeoylglucose (**1**−**10**).

**Synthesis of 3-*O*-(3,4-Dimethoxy)cinnamoylglucoses (13 and 14).** To a solution of 1,2:5,6-di-*O*-isopropylidene-*α*-D-glucofuranose (1.00 g, 3.84 mmol) and 4-dimethylaminopyridine (200 mg, 1.63 mmol) in $CH_2Cl_2$ (50 mL) were added triethylamine (10 mL, 71.70 mmol) and 3,4-dimethoxycinnamoyl chloride (1.29 g, 5.70 mmol) at room temperature. The reaction mixture was refluxed for 24 h, cooled to room temperature, and acidified (pH ≈ 3) with 2 M HCl. The layers were separated, and the aqueous phase was extracted with $CH_2Cl_2$ (3 × 50 mL). The combined organic layers were dried over sodium sulfate, filtered, and the solvent was removed in vacuo. The crude product was purified by column chromatography on silica gel (ethyl acetate−petroleum ether, 30−40%) to give 3-*O*-(3,4-dimethoxy)cinnamoyl-1,2:5,6-di-*O*-isopropylidene-*α*-D-glucofuranose (80%).

$\delta_H$ ($CDCl_3$): 7.63 (1H, d, *J* 16.0, $C_{Ar}$−C*H*), 7.09 (1H, dd, *J* 9.0, 1.8 $C_{Ar}H$), 7.02 (1H, d, *J* 1.8, $C_{Ar}H$), 6.85 (1H, d, *J* 8.2, $C_{Ar}H$), 6.28 (1H, d, *J* 16.0, $C_{Ar}$−CHC*H*), 5.90 (1H, d, *J* 3.6, *H*-3), 5.37 (1H, d, *J* 2.7, *H*-1), 4.55 (1H, d, *J* 3.7, *H*-2), 4.28 (2H, m, *H*-6a, *H*-6b), 4.07 (2H, m, *H*-4, *H*-5), 3.90 (6H, s, $C_{Ar}$-O$CH_3$), 1.52 (3H, s, O$CH_3$), 1.40 (3H, s, O$CH_3$), 1.29 (6H, s, O$CH_3$). $\delta_C$ ($CDCl_3$): 165.8 (−COOC), 151.5 ($C_{Ar}$−$OCH_2$), 149.3 ($C_{Ar}$−$OCH_2$), 146.0 ($C_{Ar}$−CH), 127.1 ($C_{Ar}$−CH), 123.1 ($C_{Ar}$), 114.7 (CH−COO), 112.4 ($C_{Ar}$), 111.1 ($C_{Ar}$), 109.6 ($H_3C$−O−*C*−O−$CH_3$), 109.3 ($H_3C$−O−*C*−O−$CH_3$), 105.1 (*C*-3), 83.5 (*C*-1), 79.8 (*C*-6), 76.0 (*C*-2), 72.6 (*C*-4), 67.1 (*C*-5), 56.1 ($C_{Ar}$−O$CH_3$), 56.0 ($C_{Ar}$−O$CH_3$), 26.9 (O$CH_3$), 26.8 (O$CH_3$), 26.4 (O$CH_3$), 25.6 (O$CH_3$).

The resulting mixture of the esters (500 mg) was dissolved in a mixture of 20 mL of trifluoroacetic acid and water (8:2) at room temperature and stirred for 1 h. The solvents were removed in vacuo to obtain the resulting esters 3-*O*-(3,4-dimethoxy)cinnamoylglucoses (**13** and **14**) in quantitative yield.

$\delta_H$ (methanol-$d_3$): 7.65 (1H, d, *J* 16.0, $C_{Ar}$−C*H*), 7.19 (1H, s, $C_{Ar}$−*H*), 7.15 (1H, d, *J* 8.2, $C_{Ar}$−*H*), 6.95 (1H, d, *J* 8.2, $C_{Ar}$−*H*), 6.45 (1H, *J* 16.0, $C_{Ar}$−C*H*═*CH*), 5.32 (1H, t, *J* 9.6, *α*-gluc *H*-3), 5.15 (1H, *J* 3.2, *α*-gluc *H*-1), 5.02 (1H, t, *J* 9.6, *β*-gluc *H*-3), 4.59 (1H, d, *J* 7.8, *β*-gluc *H*-1), 3.65−3.90 (2H, m, gluc *H*-6a, gluc *H*-6b), 3.24−3.57 (3H, m, gluc *H*-2, gluc *H*-4, gluc *H*-5).

$\delta_C$ (methanol-$d_3$): 167.8, 167.6 (COOR); 151.4, 151.3 ($C_{Ar}$); 145.0 ($C_{Ar}$−CH); 148.1, 144.9 ($C_{Ar}$); 127.6, 127.5 ($C_{Ar}$); 122.6, 122.5 ($C_{Ar}$); 115.6 ($CH_2$═CH); 115.5 (CH−COO); 114.0 ($CH_2$═CH); 111.29, 110.16 ($C_{Ar}$−$OCH_3$); 96.9 (*β*-gluc *C*-1); 92.6 (*α*-gluc *C*-1); 77.8 (*β*-gluc *C*-3); 76.5 (*α*-gluc *C*-3); 75.8 (*β*-gluc *C*-2); 75.5 (*β*-gluc *C*-5); 73.4 (*α*-gluc *C*-2); 71.6 (*α*-gluc *C*-5); 70.9 (*α*-gluc *C*-4); 68.6 (*β*-gluc *C*-4); 61.3 (*β*-gluc *C*-6); 61.1 (*α*-gluc *C*-6).

**Synthesis of 6-*O*-(3,4-Dimethoxy)cinnamoylglucoses (15 and 16).** To a solution of 1,2-*O*-isopropylidene-*α*-D-glucofuranose (1.00 g, 4.54 mmol) and 4-dimethylaminopyridine (200 mg, 1.63 mmol) in $CH_2Cl_2$ (50 mL) were added pyridine (5 mL, 62 mmol) and 3,4-dimethoxycinnamoyl chloride (1.29 g, 5.7 mmol) at room temperature. The reaction mixture was stirred for 24 h at room temperature and acidified (pH ≈ 3) with 2 M HCl. The layers were separated, and the aqueous phase was extracted with $CH_2Cl_2$ (3 × 50 mL). The combined organic layers were dried over sodium sulfate, filtered, and the solvent was removed in vacuo. The crude product was purified by column chromatography on silica gel (ethyl acetate−petroleum ether, 30−40%) to give 6-*O*-(3,4-di-*O*-allyl)caffeoyl-1,2-*O*-isopropylidene-*α*-D-glucofuranose (75%).

$\delta_H$ (acetone-$d_6$): 7.68 (1H, d, *J* 16.0, $C_{Ar}$−C*H*), 7.32 (1H, dd, *J* 8.2, 1.8, $C_{Ar}H$), 7.17 (1H, d, *J* 1.8, $C_{Ar}H$), 6.86 (1H, d, *J* 8.2, $C_{Ar}H$), 6.33 (1H, d, *J* 16.0, $C_{Ar}$−CHC*H*), 5.97 (1H, d, *J* 3.6, *H*-3), 4.54 (1H, d, *J* 3.6, *H*-2), 4.31−4.40 (2H, m, *H*-6a, *H*-6b), 4.12 (2H, m, *H*-4, *H*-5), 3.90 (6H, s, $C_{Ar}$−O$CH_3$), 1.48 (3H, s, O$CH_3$), 1.31 (3H, s, O$CH_3$). $\delta_C$ (acetone-$d_6$): 168.2 (−COOC), 151.6 ($C_{Ar}$−$OCH_2$), 149.2 ($C_{Ar}$−$OCH_2$), 146.3 ($C_{Ar}$−CH), 127.2 ($C_{Ar}$−CH), 122.9 ($C_{Ar}$), 114.9 ($CH_2$═CH), 114.8 (CH−COO), 111.9 ($C_{Ar}$), 111.2 ($C_{Ar}$), 111.1 ($H_3C$−O−*C*−O−$CH_3$), 109.6 ($H_3C$−O−*C*−O−$CH_3$), 105.2 (*C*-3), 85.2 (*C*-6), 79.6 (*C*-1), 75.6 (*C*-2), 69.8 (*C*-4), 66.5 (*C*-5), 55.8 ($C_{Ar}$−$OCH_3$), 55.9 ($C_{Ar}$−$OCH_3$), 26.9 (O$CH_3$), 26.2 (O$CH_3$).

The resulting ester 6-*O*-(3,4-dimethoxy)cinnamoyl-1,2-*O*-isopropylidene-*α*-D-glucofuranose (400 mg) was dissolved in a mixture of 20 mL of

trifluoroacetic acid and water (8:2) at room temperature and stirred for 1 h. The solvents were removed in vacuo to obtain the resulting esters 6-*O*-(3,4-dimethoxy)cinnamoylglucoses (**15** and **16**) in quantitative yield.

$\delta_H$ (methanol-$d_3$): 7.55, 7.54 (1H, d, *J* 16.0, $C_{Ar}$–C*H*); 7.33 (1H, s, $C_{Ar}$–*H*); 7.20 (1H, d, *J* 8.2, $C_{Ar}$–*H*); 6.94 (1H, d, *J* 8.2, $C_{Ar}$–*H*); 6.55, 6.54 (1H, *J* 16.5, $C_{Ar}$–C*H*═C*H*); 4.88, 4.28 (1H, d, *J* 3.7, gluc *H*-1$\alpha$, 7.6, gluc *H*-1$\beta$); 4.37, 4.38 (1H, m, gluc *H*-6a); 4.10, 4.15 (1H, m, gluc *H*-6b); 3.77 (3H, s, $OCH_3$); 3.75 (3H, s, $OCH_3$); 3.41, 3.35 (1H, m, gluc *H*-4); 3.1 (2H, m, gluc *H*-2, *H*-3), 2.9 (1H, t, *J* 8.2, gluc *H*-5).

$\delta_C$ (methanol-$d_3$): 167.9 (COOC), 151.5 ($C_{Ar}$), 149.5 ($C_{Ar}$–CH), 145.5 ($C_{Ar}$), 127.4 ($C_{Ar}$), 123.6 ($C_{Ar}$), 115.9 ($CH_2$═CH), 112.0 (CH–COO), 110.8 ($CH_2$═CH), 97.4 ($\beta$-gluc *C*-1), 92.9 ($\alpha$-gluc *C*-1), 76.9 ($\beta$-gluc *C*-3), 75.2 ($\beta$-gluc *C*-2), 74.1 ($\beta$-gluc *C*-5), 73.4 ($\alpha$-gluc *C*-3), 72.7 ($\alpha$-gluc *C*-2), 71.1 ($\alpha$-gluc *C*-5), 70.6 ($\alpha$-gluc *C*-4), 69.7 ($\beta$-gluc *C*-4), 64.5 ($\beta$-gluc *C*-6), 64.4 ($\alpha$-gluc *C*-6), 56.2 ($OCH_3$), 56.1 ($OCH_3$).

**Synthesis of 2-*O*-(3,4-Dimethoxy)cinnamoylglucoses (17 and 18).** To a solution of 4,6-*O*-benzylidene-D-glucopyranose (268 mg, 1.00 mmol) and 4-dimethylaminopyridine (50 mg, 0.04 mmol) in $CH_2Cl_2$ (20 mL) were added pyridine (3 mL) and 3,4-dimethoxycinnamoyl chloride (312 mg, 1.38 mmol) at room temperature. The reaction mixture was stirred for 24 h and acidified with 1 M HCl (pH ≈ 3). The layers were separated, and the aqueous phase was re-extracted with ethyl acetate (2 × 20 mL). The combined organic layers were dried over $Na_2SO_4$ and filtered, and the solvents were dried in vacuo. The crude product was purified by column chromatography on silica gel (ethyl acetate–petroleum ether, 30–40%) to give 2-*O*-(3,4-dimethoxy)cinnamoyl-4,6-*O*-benzylidene-D-glucopyranose (25%). 2-*O*-(3,4-Dimethoxy)cinnamoyl-4,6-*O*-benzylidene-D-glucopyranose (100 mg) was dissolved in a mixture of 20 mL of trifluoroacetic acid and water (7:3) at room temperature and stirred for 30 min. The solvents were removed in vacuo, and the resulting yellowish product was analyzed by HPLC–MS and shown to contain a mixture of 2-*O*-(3,4-dimethoxy)cinnamoylglucoses **17** and **18**.

$\delta_H$ (methanol-$d_3$): 7.68, 7.64 (1H, d, *J* 16.0, $C_{Ar}$–C*H*); 7.19 (1H, s, $C_{Ar}$–*H*); 7.15 (1H, m, *J* 8.2, $C_{Ar}$–*H*); 6.95 (1H, d, *J* 8.2, $C_{Ar}$–*H*); 6.45, 6.42 (1H, *J* 16.0, $C_{Ar}$–C*H*═C*H*); 5.30 (1H, t, *J* 9.6, gluc *H*-2); 4.73 (1H, *J* 3.2, $\alpha$-gluc *H*-1); 4.65 (1H, m, *H*-3); 3.84 (6H, $C_{Ar}$–OCH3); 3.70–3.80 (2H, m, gluc *H*-6a, gluc *H*-6b); 3.56 (1H, m, gluc *H*-4); 3.30–3.40 (1H, m, gluc *H*-5).

$\delta_C$ (methanol-$d_3$): 167.2, 166.8 (COOR); 151.6, 151.5 ($C_{Ar}$); 145.0 ($C_{Ar}$–CH); 145.3 ($C_{Ar}$), 145.1 ($C_{Ar}$); 127.6, 127.4 ($C_{Ar}$); 122.7, 122.6 ($C_{Ar}$); 115.3 ($CH_2$═CH); 115.3 (CH–COO); 114.9 ($CH_2$═CH); 111.4, 110.2 ($C_{Ar}$-$OCH_3$); 95.4 ($\beta$-gluc *C*-1); 90.2 ($\alpha$-gluc *C*-1); 77.1 ($\beta$-gluc *C*-3); 75.4 ($\alpha$-gluc *C*-3); 75.0 ($\beta$-gluc *C*-2); 74.1 ($\beta$-gluc *C*-5); 71.7 ($\alpha$-gluc *C*-2); 70.9 ($\alpha$-gluc *C*-5); 70.7 ($\alpha$-gluc *C*-4); 70.4 ($\beta$-gluc *C*-4); 61.4 ($\beta$-gluc *C*-6); 61.3 ($\alpha$-gluc *C*-6).

**Synthesis of Stereo- and Regioisomeric Mixture of 3,4-Dimethoxycinnamoylglucoses (13–20).** To a solution of 4,6-*O*-benzylidene-D-glucopyranose (268 mg, 1.00 mmol) and 4-dimethylaminopyridine (50 mg, 0.04 mmol) in $CH_2Cl_2$ (20 mL) were added pyridine (3 mL) and 3,4-dimethoxycinnamoyl chloride (312 mg, 1.38 mmol) at room temperature. The reaction mixture was stirred for 24 h and acidified with 1 M HCl (pH ≈ 3). The layers were separated, and the aqueous phase was re-extracted with ethyl acetate (2 × 20 mL). The combined organic layers were dried over $Na_2SO_4$ and filtered, and the solvents were dried in vacuo. The resulting esters were dissolved in a mixture of 20 mL of trifluoroacetic acid and water (7:3) at room temperature and stirred for 30 min. The solvents were removed in vacuo, and the resulting yellowish product was analyzed by HPLC–MS and shown to contain a mixture of 3,4-dimethoxycinnamoylglucoses **13–20**.

## RESULTS AND DISCUSSION

The aqueous infusion of yerba maté was reported to be particularly rich in caffeoylglucoses[6,14] and therefore served as a model system for our investigations. In a typical extracted ion chromatogram (EIC) of an aqueous methanolic yerba maté extract, using a reversed phase LC–MS method, we observed 10 peaks with a *m*/*z* value of 341.0867 ± 0.005 (M–H, $C_{15}H_{17}O_9$) and $MS^2$ consistent with a caffeoyl ester of glucose. To assign the regio- and stereochemistry of the caffeoylglucoses, we first required authentic reference substances, both of individual compounds and of a mixture of possibly all 10 isomeric compounds, **1–10**, and an LC-method capable of resolving all 10 isomers.

A mixture comprising of all 10 isomeric caffeoylglucoses was obtained by reacting acetyl protected caffeoyl chloride with D-glucose, followed by trifluoroacetic acid mediated deprotection of the acetyl groups (Figure 4). For the analysis of the mixture, we optimized two complementary chromatographic methods. In the first method, baseline separation of seven isomers could be achieved. The remaining three isomers coeluted. In the second method, we achieved resolution of all 10 isomers, however, for four chromatographic peaks not to a baseline separation level. Therefore, the first method is suitable for the quantitation of 7 of the 10 isomeric compounds, whereas the second method is suitable for compound identification and structure assignment. Typical extracted ion chromatograms are shown in Figure 5.

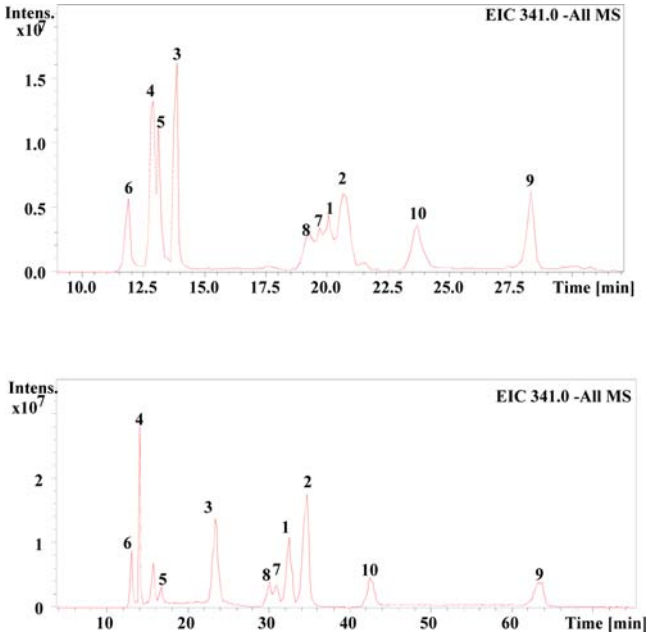

**Figure 5.** Extracted ion chromatograms (EICs) of regio- and stereoisomers of caffeoylglucose (**1–10**) at *m*/*z* 341 obtained by two different chromatographic methods.

Following the synthesis of a mixture of all 10 isomeric caffeoylglucoses, we embarked on a series of selective syntheses of caffeoylglucose regioisomers and dimethoxycinnamoylglucose isomers. In the first case, we employed diallylcaffeoyl chloride as the caffeic acid building block, while in the latter case we employed dimethoxycinnamoyl chloride. Using a selection of appropriately protected glucose derivatives, we could obtain 6-caffeoylglucoses (**9** and **10**),[32,33] 6-dimethoxycinnamoylglucoses (**15** and **16**), 3-caffeoylglucoses (**5** and **6**), 3- dimethoxycinnamoylglucoses (**13** and **14**), and 2-dimethoxycinnamoylglucoses (**17** and **18**), each as mixtures of $\alpha/\beta$ anomers (Figures 2 and 3). All of the compounds were characterized by NMR spectroscopy with 2-D NMR experiments clearly confirming the position of the caffeoyl and dimethoxycinnamoyl ester. A $\beta$-stereochemistry was assigned on the basis of the characteristic $^3J_{HCCH}$ coupling constant between the anomeric hydrogen at the hydrogen at C-2 of glucose, with $\alpha$-caffeoylglucoses showing values between

dx.doi.org/10.1021/jf501210s | J. Agric. Food Chem. 2014, 62, 9252–9265

3 and 4 Hz and β-caffeoylglucoses values between 7 and 8 Hz.[33] On standing in methanol-$d_3$, the mixtures of both 3-caffeoylglucoses and 6-caffeoylglucoses equilibrated, to yield after 1 day exclusively the β-anomers. We explain this observation by dipole moment considerations. The β-anomer of glucose is reported to have a larger dipole moment if compared to the α-isomer and is thus favored in polar solvents, overriding the anomeric effect. Despite all attempts, we failed to obtain 1-caffeoylglucoses and 4-caffeoylglucoses in purified form.

Access to the pure β-anomers of 3-caffeoylglucose and 6-caffeoylglucose allowed us to demonstrate that the α-anomer with smaller dipole moment eluted later from a reversed phase packing than the β-anomer with larger dipole moment. It seems reasonable to expect this effect to apply also to the other regioisomers unless there is a tendency for the β-anomer to form an internal hydrogen bond.

It was similarly possible to synthesize a mixture of all 10 dimethoxycinnamoylglucose esters. Fortunately, it was possible to synthesize specifically 2-dimethoxycinnamoylglucose, 3-dimethoxycinnamoylglucose, 4-dimethoxycinnamoylglucose, and 6-dimethoxycinnamoylglucose (as pairs of anomers), and this allowed the two 1-dimethoxycinnamoylglucose anomers to be identified by default. The order of elution of 3-caffeoylglucose and 6-caffeoylglucose corresponded to the order of elution of 3-dimethoxycinnamoylglucose and 6-dimethoxycinnamoylglucose, and we have tentatively concluded that the elution order of the dimethoxycinnamoylglucose regioisomers can be used to predict the elution order of the caffeoylglucose regioisomers.

To assign the 1-caffeoylglucoses (**1** and **2**), 1-dimethoxycinnamoylglucoses (**19** and **20**), 4-caffeoylglucoses (**7** and **8**), and 4-dimethoxycinnamoylglucoses (**21** and **22**), we obtained two further synthetic mixtures from 4,6-benzylidene protected glucose. On reaction with diallylcaffeoyl chloride followed by Pd-mediated deallylation, a mixture of six isomers was obtained. We assumed that the mixture exclusively contained the anomeric pairs of 1-caffeoylglucose/1-dimethoxycinnamoylglucose, 2-caffeoylglucose/2-dimethoxycinnamoylglucose, and 3-caffeoylglucose/3-dimethoxycinnamoylglucose. Both 2-dimethoxycinnamoylglucoses and 3-dimethoxycinnamoylglucoses were previously obtained by selective synthesis and could thus be readily identified on the basis of their retention times and unique tandem MS data. The remaining pair of isomers obtained in this unselective synthesis must therefore be the two anomers of 1-dimethoxycinnamoylglucose. In the initial chromatogram showing all 10 isomeric compounds, eight have now been identified, from which follows automatically that the regiochemistry of the two remaining isomers must be assigned as the two anomers of 4-caffeoylglucose with the β-anomer eluting earlier than the α-anomer (Figure 5).

**Tandem Mass Spectrometry and Compound Assignment.** In chlorogenic acids chemistry, all four regioisomers of monocaffeoylquinic acids can be readily identified on the basis of their unique tandem mass spectra.[31] The differences in observed fragment ions were rationalized by taking into account different hydrogen-bonding motifs in the gas-phase ions, activating groups for fragmentation depending on their relative stereochemistry.

To rationalize the fragmentation behavior of caffeoylglucoses, we propose to transfer the same approach successfully employed in chlorogenic acids chemistry, assuming different hydrogen-bonding motifs of gas-phase anions, depending on compound stereo- and regiochemistry. In the following discussion, we report on the fragmentation patterns of all 10 compounds **1**−**10** grouped according to their similarity in fragmentation behavior (Figure 6 and Table 1). Fragment ion elemental composition was determined using high resolution $MS^2$ experiments shown in Table 2. The discussion on fragmentation mechanisms always assumes that in the gas phase, anions of caffeoylglucoses exist in their cyclic pyranose form. This is not self-evident because under basic conditions, such as those employed in anion chromatography, hexoses with a $pK_a$ value between 12 and 13 are deprotonated in basic media at the anomeric hydroxyl group followed by rapid ring opening to shift the chemical equilibrium toward the open-chain aldehyde. The latter, however, would result in destruction of the anomeric stereogenic center and consequently in identical fragment spectra for both α/β anomers, which was not consistently observed here with $MS^2$ spectra of both anomers sometimes showing significant and always showing subtle differences, nor in any other tandem MS studies on carbohydrate derivatives carried out, and justifies the assumption made above.

**Fragmentation of 6-Caffeoylglucoses (9 and 10).** The two anomers (**9** and **10**) of 6-caffeoylglucose showed very similar fragment spectra in $MS^2$. The base peak in $MS^2$ could be observed at $m/z$ 281 ($C_{13}H_{13}O_7$, **D**) corresponding to a neutral loss of $C_2H_4O_2$ through a ring fission fragmentation (Figures 6, 7 and Tables 1, 2). Further fragment ions at $m/z$ 251 ($M - H^+ -$ caffeic acid, $C_{12}H_{11}O_6$, **B**), $m/z$ 221 ($C_{11}H_9O_5$, **C**), both obtained through ring fission fragmentation, $m/z$ 179 ($C_9H_7O_4$, caffeic acid anion **A**) and $m/z$ 323 ($M - H^+ - H_2O$, $C_{15}H_{15}O_8$, **E**) were observed with suggested structures of fragment ions shown in Figure 8 (Tables 1 and 2).

**Fragmentation of 2-Caffeoylglucoses (3 and 4).** The two anomers (**3** and **4**) of 2-caffeoylglucose showed very similar fragment spectra in $MS^2$. Anomers were assigned on the basis of their elution order with the more polar β-2-caffeoylglucose **4** eluting earlier. The $MS^2$ base peak at $m/z$ 203 was assigned as fragment ion **G** $[C_{11}H_7O_4]^-$ with a quinone methide ketene acetal structure (Figure 8 and Tables 1, 2).

The formation of **G** could be rationalized by assuming an inversion of the 2-caffeoylglucose derivative to its inverted chair conformation. In this inverted chair conformation, the caffeoyl moiety and the OH group at C-3 are in an *anti*-1,2 diaxial orientation, whereas the 3-OH and 6-OH are in a *syn*-1,3 diaxial position (Figure 8). Hence, the 6-OH is able to activate the 3-OH via hydrogen bonding as a leaving group with the 2-caffeoyl substituent acting as an intramolecular nucleophile in a 1,2 acyl-migration step, reminiscent of the Königs−Knorr reaction. This sequence of events results in bicyclic quinone acetal intermediate **F** seen as a weak $MS^2$ fragment at $m/z$ 323 $[M - H^+ - H_2O]^-$ or $[C_{15}H_{15}O_8]^-$ (Figure 8). Intermediate **F** undergoes subsequently a ring fission fragmentation to yield fragment ion **G** at $m/z$ 203. All intermediates and the proposed electron flow are shown in Figure 8.

**Fragmentation of 3-Caffeoylglucoses (5 and 6).** The two anomers (**5** and **6**) of 3-caffeoylglucose showed essentially identical fragment spectra in $MS^2$. The base peak of both anomers was $m/z$ 323 $[M - H^+ - H_2O]^-$ **E**/**F** accompanied by fragment ion signals at $m/z$ 203 $[M - H^+ - C_4H_8O_4]^-$ $[C_{11}H_7O_4]^-$ **G** and further minor fragments at $m/z$ 233 **H** and 179 **A** (Figures 6, 9 and Tables 1, 2). We assigned the $MS^2$ base peak as a quinone methide ketene acetal structure **F**.

There were significant differences between the anomers at $MS^3$, with the fragment ion at $m/z$ 219 exceeding 50% intensity in α-3-caffeoylglucose **5** but less than 10% in β-3-caffeoylglucose **6**, indicating that its precursor ion at $m/z$

323 must have retained the anomeric structure in the gas phase and therefore fragmentation occurs from a cyclic structure, most likely the pyranose form.

**Fragmentation of 4-Caffeoylglucoses (7 and 8).** The two anomers (7 and 8) of 4-caffeoylglucose showed very similar fragment spectra in $MS^2$; however, the difference was sufficiently large to allow discrimination through the intensity of the fragment ion at $m/z$ 233, being over 75% for $\alpha$-4-caffeoylglucose **7** and below 75% for $\beta$-4-caffeoylglucose **8** (Figure 6 and Table 1). The base peak for both anomers could be observed at $m/z$

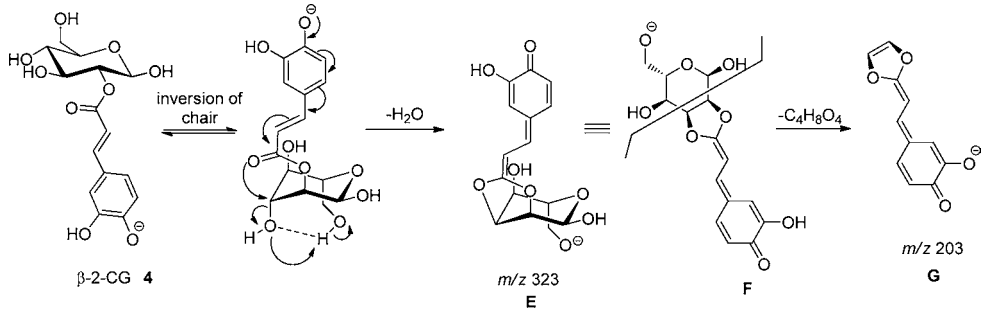

**Figure 8.** Fragmentation mechanism and pathway of 2-caffeoylglucoses (**3** and **4**).

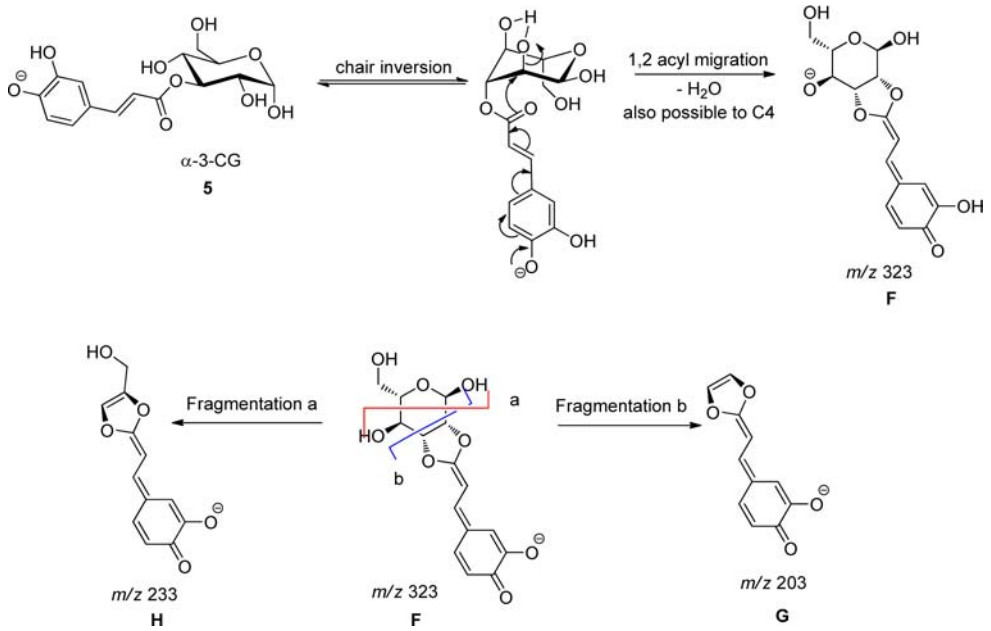

**Figure 9.** Fragmentation mechanism and pathway of 3-caffeoylglucoses (**5** and **6**).

203 and was assigned again to the quinone methide ketene acetal structure **G**, but in contrast to the fragment spectra of 2-caffeoylglucoses (**3** and **4**) and 3-caffeoylglucoses (**5** and **6**), a much larger number of fragments could be observed, at *m*/*z* 233 **H**, 135 **I**, 179 **A**, 251 **B**, 281 **D**, and 323 **E**/**F** (Figure 10 and Tables 1, 2).

We assigned the fragments at *m*/*z* 233 **H**, 179 **A**, and 323 **E**/**F** as previously. The fragments at *m*/*z* 251 **B** and 281 **D** were assigned as fragments resulting from a ring fission. It is interesting to note that 4-caffeoylglucoses showed these types of fragments, which could not be observed for 2-caffeoylglucoses (**3** and **4**) and 3-caffeoylglucoses (**5** and **6**). It appears that the loss of water by a 1,2 acyl participation mechanism is less favored for the 4-caffeoylglucoses (**7** and **8**), allowing ring fission fragmentation to compete with initial dehydration, in comparison to the 3-caffeoylglucoses (**5** and **6**) and 2-caffeoylglucoses (**3** and **4**).

Multiple reaction monitoring $MS^3$ experiments demonstrated that for 2-caffeoylglucose, 3-caffeoylglucose, and 4-caffeoylglucose, the $MS^2$ ion of *m*/*z* 323 fragmented identically, and this quinone methide ketene acetal **F** cannot be the precursor of the minor fragments that discriminate between the 3-caffeoylglucose and 4-caffeoylglucose anomers.

dx.doi.org/10.1021/jf501210s | J. Agric. Food Chem. 2014, 62, 9252−9265

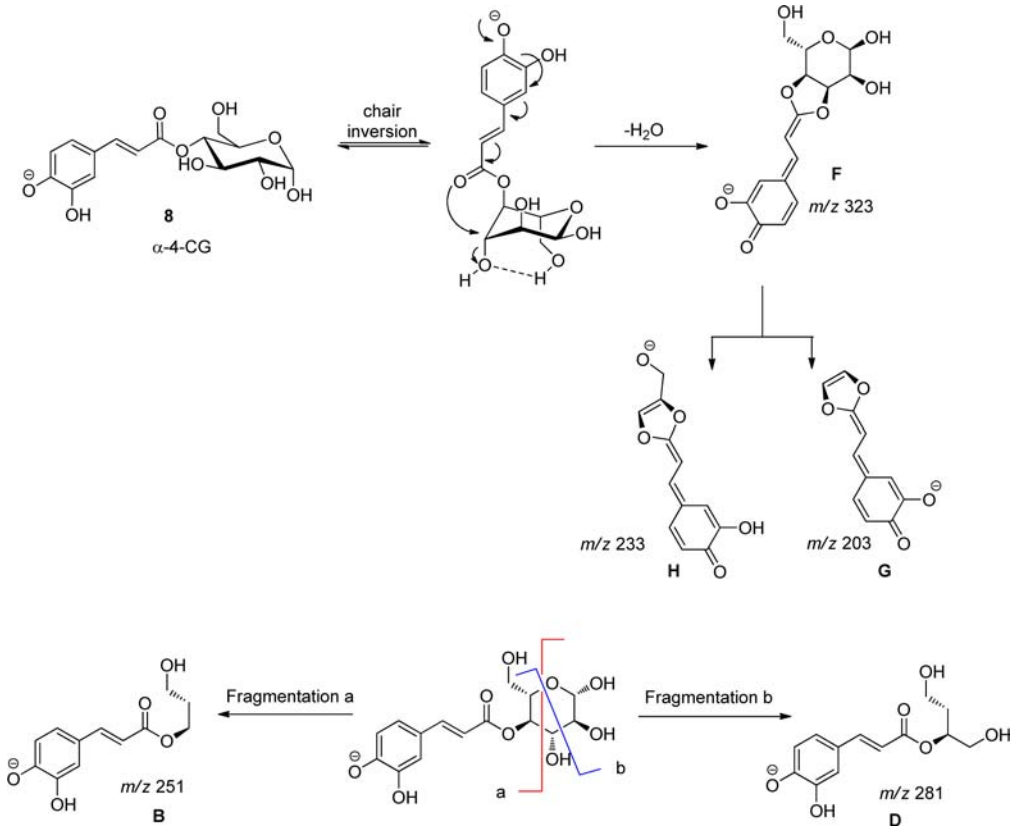

**Figure 10.** Fragmentation mechanism and pathway of 4-caffeoylglucoses (**7** and **8**).

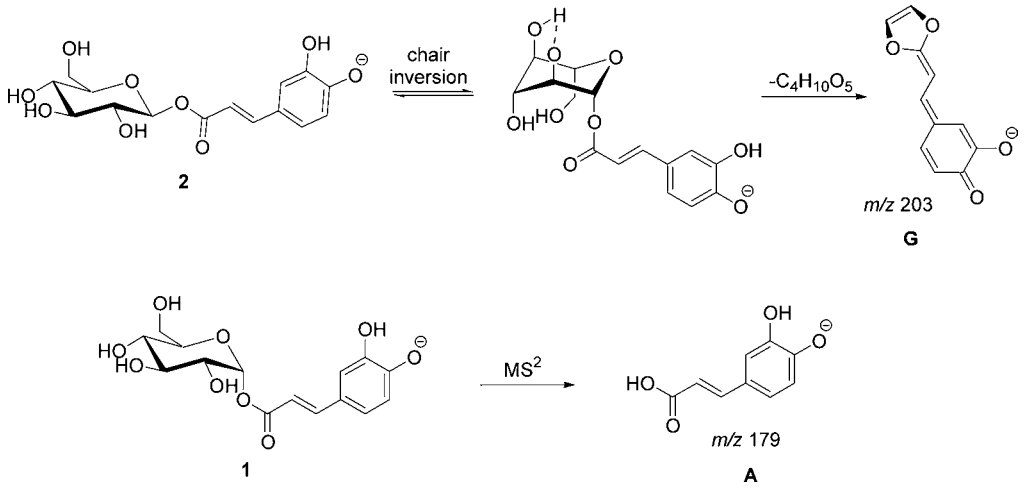

**Figure 11.** Fragmentation mechanism and pathway of 1-caffeoylglucoses (**1** and **2**).

**Fragmentation of 1-Caffeoylglucoses (1 and 2).** The two anomers (**1** and **2**) of 1-caffeoylglucose showed significantly different fragment spectra in $MS^2$ that could be rationalized mechanistically as set out in Figure 11. Our data showed that the earlier-eluting anomer gave a base peak at $m/z$ 179 corresponding to a neutral loss of glucose and a fragment **A** corresponding to caffeic acid anion. The later-eluting anomer gave an $MS^2$ base peak at $m/z$ 203 corresponding to the ketene acetal **J** (Figure 11). Following our previous arguments, the formation of ketene acetal fragment ion **J** is only possible for the $\beta$-1-caffeoylglucose **2** stereochemistry. The loss of the caffeic acid moiety should be facile in the $\alpha$-1-caffeoylglucose **1**, due to the anomeric effect.

The assignment of $\alpha$- and $\beta$-anomers was relatively straightforward for all four cases (except for 1-caffeoylglucoses **1** and **2**) where pure compounds were obtained by synthesis; isomerization furnished the more stable $\beta$-anomers in aqueous solvent, which could also be identified on the basis of their retention times. However, none of these arguments hold for 1-caffeoylglucose. $\beta$-1-Caffeoylglucose **2** was isolated by the group of Winterhalter,[13] and its structure was established by $^1$H NMR spectroscopy; however, no tandem MS data on this compound were reported by this group. Other groups have reported tandem MS data on 1-caffeoylglucoses (**1** and **2**), but assignment appeared to be random, and the two isomers obtained in the current study have been assigned previously

dx.doi.org/10.1021/jf501210s | J. Agric. Food Chem. 2014, 62, 9252−9265

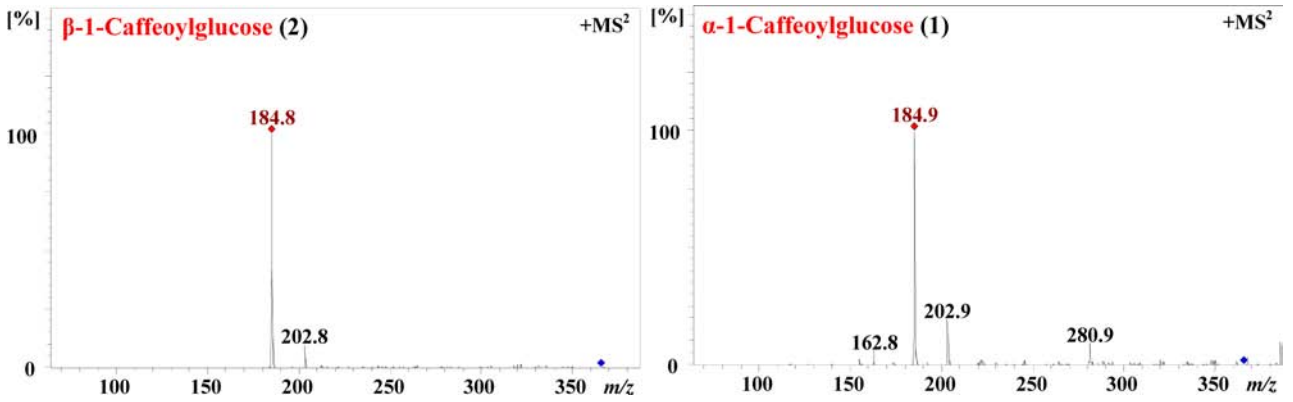

**Figure 12.** $MS^2$ spectra of 1-caffeoylglucoses (**1** and **2**) at $m/z$ 365 in positive ion mode.

in a nonconsistent way. The unambigious assignment of the two anomers of 1-caffeoylglucose must therefore be left open at this point.

**Positive Ion Mode Tandem Mass Spectra.** In the positive ion mode, all caffeoylglucoses can be observed as their sodiated ion at $m/z$ 347 $[M + Na^+]$ ($C_{15}H_{17}O_9Na$). All $MS^2$ spectra display fragment ions at $m/z$ 203 ($C_6H_{12}O_6 + Na^+$) and 185 ($C_9H_6O_3 + Na^+$) corresponding to sodiated glucose and the sodiated caffeoyl ions, respectively. As representative examples, the $MS^2$ spectra for 1-caffeoylglucoses (**1** and **2**) are shown in Figure 12. All positive mode $MS^2$ spectra of all further caffeoylglucose isomers are shown in the Supporting Information. As for the negative ion mode spectra, all five different regiochemistries can be distinguished on the basis of the different $MS^2$ spectra. However, it appears that in the positive ion mode the fragmentation is more difficult for all caffeoylglucoses with the exception of 1-caffeoylglucoses (**1** and **2**), which yield in the fragment spectra a rather large number of fragment ions with low intensities. For this reason, we refrain from a rigorous interpretation of the spectra at the current state.

**Tandem Mass Spectra of *O*-Caffeoyl Glycosides (Caffeic Acid-3-*O*-*β*-glucose 11 and Caffeic Acid-4-*O*-*β*-glucose 12).** To compare the data of the caffeoylglucose esters with those of isomeric *O*-caffeoyl-glycosides **11** and **12**, we recorded tandem MS spectra from an aqueous methanolic extract of kiwi fruit, which was reported to contain those exclusively (Figure 13).[8] The $MS^2$ spectra in negative ion mode showed in contrast to the esters a base peak at $m/z$ 179 [caffeic acid $- H^+$] and only one secondary peak at $m/z$ 135 [caffeic acid $- CO_2 - H^+$]. *O*-Caffeoyl glycosides do not show secondary peaks at $m/z$ 323, 281, 251, 221, 203, and 161 if compared to the esters. Compounds **11** and **12** produced identical MS spectra, and it was not possible to distinguish between them. However, in this particular case, we assigned the first eluting isomer as caffeic acid-3-*O*-*β*-glucose **11**, and the later eluting isomer as caffeic acid-4-*O*-*β*-glucose **12**. It is interesting to note that caffeic acid glycosides lose the glycone part in $MS^2$ spectra (negative ion mode), which is similar to other known phenolic glycosides, flavonoid glycosides, and chlorogenic acid glycosides.

**Hierarchical Key for Caffeoylglucose Isomers Assignment.** From the data shown, we present a hierarchical key or work flow for the analysis and assignment of all isomers of caffeoylglucoses.

All compounds that show in an LC–MS analysis a parent ion in the negative ion mode at $m/z$ 341.0867 $[M - H^+]$ and 365.0840 in the positive ion mode $[M + Na^+]$ with an additional absorption at 320 nm in the UV spectrum should be considered as caffeoylglucose derivatives. For assignment of the regiochemistry in the negative mode, the following key applies:

| | | |
|---|---|---|
| (1) | parent ion at $m/z$ 341 and base peak at $m/z$ 281 in $MS^2$ | 6-caffeoylglucoses (**9** and **10**) |
| (2) | parent ion at $m/z$ 341 and base peak at $m/z$ 323 in $MS^2$ | 3-caffeoylglucoses (**5** and **6**) |
| (2a) | $MS^2$ fragment at $m/z$ 232 >75% and $MS^3$ fragment at $m/z$ 219 <10% | *β*-3-caffeoylglucose (**6**) |
| (2b) | $MS^2$ fragment at $m/z$ 233 <75% and $MS^3$ fragment at $m/z$ 219 >50% | *α*-3-caffeoylglucose (**5**) |
| (3) | parent ion at $m/z$ 341 and base peak at $m/z$ 179 in $MS^2$ | *α*-1-caffeoylglucose (**1**) |
| (4) | parent ion at $m/z$ 341 and base peak at $m/z$ 203 in $MS^2$ accompanied by fragment ion at $m/z$ 161 (1-caffeoylglucose pending final sterochemical assignment) | *β*-1-caffeoylglucose (**2**) |
| (5) | parent ion at $m/z$ 341 and base peak at $m/z$ 203 in $MS^2$ with little further fragments | 2-caffeoylglucoses (**3** and **4**) |
| (6) | parent ion at $m/z$ 341 and base peak at $m/z$ 202.5 in $MS^2$ accompanied by fragment ion at $m/z$ 232.6 | 4-caffeoylglucoses (**7** and **8**) |
| (7) | assignment of *α* and *β* stereo chemistry is based on relative retention time with *β*-anomers eluting earlier on reversed phase if compared to *α*-anomers (exception 1-caffeoylglucoses) | |

**Assignment of Caffeoylglucoses from Yerba Maté.** A total of 10 peaks were detected in the extracted ion chromatograms, which produced a pseudomolecular ion at $m/z$ 341.0867 ± 0.005. These isomeric compounds were assigned as the 10 regio- and stereoisomeric caffeoylglucoses (**1**–**10**) after comparing their retention times, high resolution, and tandem MS data with the authentic caffeoylglucoses standards as outlined above. The two anomers of 6-caffeoylglucose dominate the extract. Similar to chlorogenic acid chemistry, this dietary plant produces a mixture of all possible stereoisomers of a given class of natural products.

## MATERIALS AND METHODS

**Materials and Reagents.** Xanthine (X0625-5G), xanthine oxidase (XO, X4875-10U), nitroblue tetrazolium chloride (NBT, N6876-5G), and allopurinol (A8003-5G) were purchased from Sigma-Aldrich (St. Louis, MO, USA). Potassium phosphate monobasic ($KH_2PO_4$), potassium phosphate dibasic ($K_2HPO_4{\cdot}3H_2O$), ethylenediaminetetraacetic acid disodium salt (EDTA), sodium hydroxide (NaOH), dimethyl sulfoxide (DMSO), acetone, acetonitrile, ethanol, isopropanol, tetrahydrofuran, and hydrochloric acid (HCl) were purchased from Sinopharm Chemical Reagent Co., Ltd. (Shanghai, China). Ultrapure water was prepared by an Advantage A10 water purifier (Milli-Q Academic, Molsheim, France). All other chemicals were of analytical grade and used without further purification.

Rosmarinic acid, resveratrol, and rutin (purity > 98%) were obtained from Shanghai R&D Center for Standardization of Chinese Medicines (Shanghai, China). The individual food extracts of rosemary (whole plant, 2012030), ginger (rhizoma, 2012021), and green tea (leaves, 2012020) were purchased from Sichuan Tongtai Plant Chemical Industry Co., Ltd. (Shifang, Sichuan Province, China). The lotus extract (leaves, 20120620) was purchased from Shanghai Moochun Biological Technology Co., Ltd. (Shanghai, China).

A 0.2 M stock phosphate buffer solution (PBS, pH 8.0) was prepared by mixing equal volumes of 0.2 M $KH_2PO_4$ and 0.2 M $K_2HPO_4{\cdot}3H_2O$ solutions. A 1.0 mM EDTA stock solution was prepared in ultrapure water.

Stock solutions of the pure antioxidants were prepared in DMSO at concentrations of 6.0 mM, and the stock solutions of the food extracts were prepared in a mixture of DMSO/ultrapure water (1:1, v/v). A series of working solutions were made by appropriate stepwise dilutions of the above stock solutions with 0.2 M PBS buffer (pH 8.0). A fresh substrate solution containing 4 mM xanthine and 4 mM NBT was prepared in 0.05 M PBS (pH 8.0) just before use. A 0.04 U/mL XO solution (250 mL) was prepared by dilution of the 10 U XO stock solution with a mixture solution of 1 mM EDTA (125 mL) and 0.1 M PBS (pH 8.0, 125 mL). The enzyme activity of XO was determined by a reference method[31] before preparation.

**Conventional Colorimetric Assay.** The conventional colorimetric $O_2^{\bullet-}$ scavenging capacity assay was carried out according to a previously described laboratory protocol.[32] Briefly, an aliquot of 100 $\mu$L of different concentrations of tested antioxidants was added to a 1 mL substrate solution containing 0.4 mM xanthine and 0.24 mM NBT. After the addition of 1 mL of XO solution (50 mU/mL), the reaction mixture was incubated in a water bath at 37 °C for 20 min. The reaction was then terminated by the addition of 1 mL of 0.6 M HCl, and the absorbance ($A$) of each reaction mixture at 560 nm was measured against a blank without XO using a microplate spectrophotometer (Power Wave, Bio-Tek, Winooski, VT, USA). The $O_2^{\bullet-}$ scavenging capacity for each reaction was calculated as

$$O_2^{\bullet-}\text{scavening capacity \%} = [1 - (A_s - A_{s\text{-}b})/(A_c - A_{c\text{-}b})] \times 100\% \quad (1)$$

where $A_s$, $A_{s\text{-}b}$, $A_c$, and $A_{c\text{-}b}$ represent the absorbances of samples, sample control (without addition of XO), control (without addition of tested antioxidants), and vehicle control (without addition of tested antioxidants and XO), respectively, at 560 nm after 20 min of reaction. The $EC_{50}$ value is the concentration of an antioxidant capable of quenching 50% of the radicals in the reaction mixture under the assay condition. Triplicate reactions were carried out for each level of every individual sample.

**High-Throughput $O_2^{\bullet-}$ Scavenging Assay.** The high-throughput $O_2^{\bullet-}$ scavenging assay was carried out using a 96-well microplate spectrophotometer (Power Wave, Bio-Tek). The 96-well plate was covered with a lid to prevent solvent evaporation during reaction. Six or eight different concentrations were used for each antioxidant extract and antioxidant compound in the study. The antioxidant sample solution (6.67 $\mu$L) and 193.33 $\mu$L of substrate solution (including 6.43 $\mu$L of 4 mM xanthine, 12.86 $\mu$L of 4 mM NBT, and 174.04 $\mu$L of 0.05 M PBS) were added to each well. Then 20 $\mu$L of 0.04 U/mL XO solution was added to start the reaction. After gentle shaking for 10 s, the reaction mixture was incubated in a water bath at 37 °C for 20 min. Finally, 20 $\mu$L of 0.6 M HCl was added to terminate the reaction, followed by shaking for another 10 s. The absorbance at 560 nm was measured. The total volume for each reaction mixture in each well was 240 $\mu$L. A blank test without XO and a control test without antioxidants were also conducted. Allopurinol was used as a positive control for the assay. The level of $O_2^{\bullet-}$ scavenging capacity for each reaction was also calculated as formula 1. The $EC_{50}$ values were calculated under the assay condition. Triplicate reactions were carried out for each level of every individual sample.

## RESULTS AND DISCUSSION

**Selection of the Detection Wavelength for the X/XO Reaction.** The X/XO enzymatic system is based on XO oxidation of xanthine giving $O_2^{\bullet-}$, which subsequently reacts with NBT to yield a purple formazan. The formation of formazan is generally detected by absorbance at 560 nm. However, several wavelengths such as 560 nm,[32] 510 nm,[33] and 595 nm[34] have also been reported for the detection of formazan production. This divergence prompted us to investigate a suitable wavelength for this reaction system. Theoretically, the individual components involved in the reaction mixture including xanthine, NBT, and XO might interfere with the formazan absorbance. As shown in Supporting Information Figure SI1A, all of the components except formazan (the reaction product) in the reaction system showed no absorption maximum between 500 and 800 nm. The absorbance of formazan from 550 to 650 nm reached a platform, among which 560 nm turned out to be stable. Therefore, 560 nm was chosen as the detection wavelength, consistent with that used in most of the X/XO literature.

NBT is a classical biochemical reagent for the detection of $O_2^{\bullet-}$. During the reaction process, ditetrazolium ($NBT^{2+}$) is attacked by $O_2^{\bullet-}$, along with one electron being transferred to turn $NBT^{2+}$ into tetrazolinyl radical ($NBT^{\bullet+}$). In the following step, one more electron transfer turns $NBT^{\bullet+}$ into monoformazan (MF).[35] It should be noted, therefore, that the excess of NBT or $O_2^{\bullet-}$ might theoretically lead to the production of only MF or diformazan (DF). The difference in molecular structures of MF and DF may result in the different maximum absorption wavelengths of these two substances. Thus, the different molar ratios of xanthine to NBT (1:1, 1:2, and 1:3) in the X/XO reaction mixture were scanned over 450−800 nm (Supporting Information Figure SI1B). The results showed that the effect of different molar ratios of xanthine to NBT was small and of marginal importance to the maximum wavelength of formazan. As the absorption behaviors of the molar ratios (1:2 and 1:3) of xanthine to NBT acted similarly, a 1:2 ratio of xanthine to NBT was chosen.

**Effect of Temperatures on the X/XO Reaction.** Several reaction temperatures such as 25 °C[20] and 37 °C[32] have been used for this X/XO enzymatic reaction system. To better understand the effect of temperature on the $O_2^{\bullet-}$ formation, different reaction temperatures including 25, 31, 37, 43, and 49 °C on this X/XO enzymatic system were tested. As a result, the absorbance values increased when the temperature was increased from 25 to 37 °C (Supporting Information Figure SI2A), and slight decreases were observed with a temperature of >37 °C. The results indicated that the extent of the reaction reached the maximum at 37 °C. Therefore, 37 °C was selected as the reaction temperature in further experiments, which is consistent with that of $O_2^{\bullet-}$ physiologically generated.

dx.doi.org/10.1021/jf502160d | J. Agric. Food Chem. 2014, 62, 9266−9272

**Effect of pH on the X/XO Reaction.** The effect of the PBS buffer with different pH values (6.0, 6.5, 7.0, 7.5, 8.0, 8.5, and 9.0) on the X/XO enzymatic system was studied. As shown in Supporting Information Figure SI2B, the absorbance values increased with the increase of the pH values from 6.0 to 8.0, whereas absorbance values decreased from pH 8.0 to 9.0. A possible explanation is that the conformation of XO might be affected by the pH of the buffers.[22] Therefore, a pH of 8.0 was selected in this study.

**Effects of Enzyme and Substrate Concentrations on the X/XO Reaction.** The rate of an enzyme-catalyzed reaction depends on concentrations of enzymes and substrates.[22] The effect of XO concentrations on the formazan formation was studied. At eight concentrations of XO over a 8-fold range (10−80 mU/mL), the enzyme was incubated with 4 mM substrate solution and DMSO (without antioxidants) at 37 °C for 20 min. The absorbance values gradually increased with increasing XO concentrations from 10 to 40 mU/mL, whereas there was no significant change of the absorbance values in XO concentrations up to 40 mU/mL (Supporting Information Figure SI2C). These data suggested that the optimal XO concentration in this reaction was 40 mU/mL.

Similarly, several substrate concentrations (2.0, 2.5, 3.0, 3.5, 4.0, 4.5, 5.0, and 5.5 mM) with a constant molar ratio to NBT (1:2) were studied. Supporting Information Figure SI2D shows the effect of substrate concentrations on the rate of the reaction. For a given enzyme concentration (40 mU/mL), the absorbance values showed a rapid and marked increase with substrate concentrations from 2.0 to 4.0 mM and a subsequent slow increase up to 5.5 mM, which is consistent with the Michaelis−Menten kinetics theory.[36] Therefore, the optimal substrate concentration in this reaction system was 4.0 mM.

**Effect of Reaction Time on the X/XO Reaction.** Several reaction times such as 5 min,[37] 20 min,[32] and 30 min[38] have been applied for this enzymatic reaction system. For the consideration of stability, the reaction time required to reach the steady state for this enzymatic system was studied. The change in absorbance was measured for 44 min at 2 min interval, without the addition of terminators. As shown in Supporting Information Figure SI3, the absorbance values increased rapidly within 20 min, and reached a plateau from 20 to 44 min. The result indicated that the reaction mixture can be considered to reach the "steady state" at 20 min or anytime after that. Thus, a reaction time of 20 min was used.

**Effect of Different Sample Dissolving Solvents on the X/XO Reaction.** Enzymatic reactions can be conducted not only in water but also in organic solvents.[39] This suggests the feasible use of organic cosolvents for the hydrophilic and lipophilic antioxidant samples tested in the enzymatic assay. Therefore, several organic solvents including DMSO, acetone, acetonitrile, isopropanol, and tetrahydrofuran, as well as water, were selected to investigate the solvent effect on the reaction system. With a fixed ratio of solvent volume to the reaction mixture (1:30), none of these organic solvents had shown a significant effect on absorbance values compared with water (Figure 1), indicating the potential use of these solvents as sample dissolving solvents. This is especially important and useful for samples with lower solubility in water.

In addition, three other different ratios of solvent volume to the reaction mixture (1:10, 1:20, and 1:40, v/v) were investigated and compared with the ratio of 1:30. As shown in Figure 1, no significant absorbance changes were observed among the 1:20, 1:30, and 1:40 ratios of solvent volume to

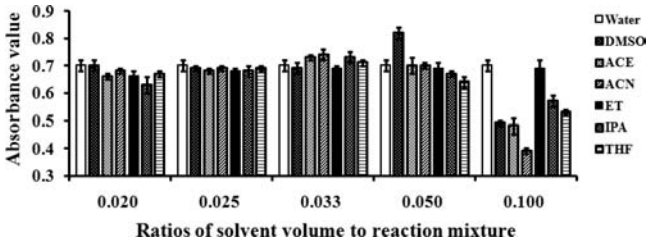

**Figure 1.** Effects of dissolving solvents and ratios of solvent volume to the reaction mixture on the xanthine/xanthine oxidase reaction. The reaction mixture contained 6.67 μL of different solvents, 193.33 μL of substrate solution (6.43 μL of 4 mM xanthine, 12.86 μL of 4 mM NBT, and 174.04 μL of 0.05 M PBS), and 20 μL of 40 mU/mL xanthine oxidase. The absorbance at 560 nm was determined for each reaction mixture after 20 min of reaction terminated by the addition of 20 μL of 0.6 M HCl. Four different volume ratios (1:10, 1:20, 1:30, and 1:40, v/v) were tested. ACE, ACN, ET, IPA, and THF represented acetone, acetonitrile, ethanol, isopropanol, and tetrahydrofuran, respectively. Data are means of triplicate measurements. Vertical bars represent the standard deviations.

reaction mixture, regardless of the nature of dissolving solvents. However, in a 1:10 ratio, all of the solvents except water and ethanol resulted in obvious decreases of the absorbance values (Figure 1). Therefore, the organic solvent effect should not be ignored in a relatively high ratio (1:10) of solvent volume to the reaction mixture (except water and ethanol). In consideration of its extensive use as a dissolving solvent in screening tests, DMSO with a 1:30 ratio of volume to the reaction mixture was used in this study.

**Effect of Different Terminators on the X/XO Reaction.** Significant pH changes can affect enzyme activity, which might be an effective way to terminate an enzymatic reaction. HCl, a commonly used acid terminator in the X/XO reaction,[40] was compared with NaOH, an alkaline terminator of other enzymes.[41] As shown in Figure 2A, the absorbance values increased with increasing concentrations of NaOH solutions (0.1−0.9 M), together with the production of green substances instead of the expected purple formazan. Thus, NaOH is not suitable to terminate the reaction due to the formation of side products with absorption at 560 nm.

In contrast to NaOH, a gradual decrease of the absorbance values was observed with the increase of HCl concentrations from 0.1 to 0.5 M (Figure 2B). Further increase of the HCl concentration to 1.0 M did not result in a further decrease in the absorbance values. Importantly, unlike with 0.1−0.4 M HCl solutions, the generation of the expected purple formazan cannot be observed with 0.5−1.0 M HCl, suggesting that the reaction could be totally terminated by 0.5−1.0 M HCl solutions. To further confirm the efficiency of the HCl terminator, the absorbances of the reaction mixtures at 10, 20, 40, and 60 min were determined after 10 min of reaction being terminated by 0.5−1.0 M HCl solutions. As shown in Figure 2C, no obvious increase of absorbance values was observed after the addition of 0.5−1.0 M HCl solutions at each time point, whereas that of the negative control (without addition of HCl solutions) increased rapidly from 10 to 20 min, indicating the great termination efficiency of HCl. Hence, a 0.6 M HCl solution beyond the inflection point was chosen as the optimal terminator.

Surface-active agents (SAAs) are also reported to terminate the enzymatic reactions, because SAAs could neutralize the surface charges of enzyme molecules, resulting in the

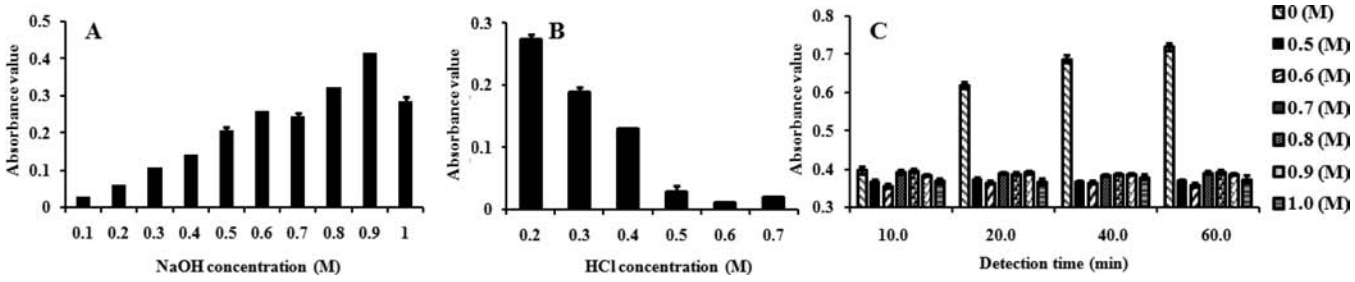

**Figure 2.** Effects of different terminators and HCl concentrations on the xanthine/xanthine oxidase reaction (A, NaOH; B, HCl; C, 0.5−1.0 M HCl). The reaction mixture contained 6.67 μL OF DMSO, 193.33 μL of substrate solution (6.43 μL of 4 mM xanthine, 12.86 μL of 4 mM NBT, and 174.04 μL of 0.05 M PBS), and 20 μL of 40 mU/mL xanthine oxidase. The absorbance at 560 nm was determined for each reaction mixture ternminated by 20 μL of 0.1−1.0 M NaOH (A) or 20 μL of 0.2−0.7 M HCl (B) after 20 min of reaction. For the termination efficiency of HCl, 20 μL of 0 M and 0.5−1.0 M HCl solutions was added to the xanthine/xanthine oxidase reactions, followed by determination of the absorbance at 10, 20, 40, and 60 min (C). Data are means of triplicate measurements. Vertical bars represent the standard deviations.

**Table 1. Linear Relationship between Antioxidant Concentrations and Percent $O_2^{\bullet-}$ Inhibition Obtained by the High-Throughput $O_2^{\bullet-}$ Scavenging Assay[a]**

| sample | slope | intercept | $r^2$ | linearity range | $n$[b] |
|---|---|---|---|---|---|
| allopurinol | 2954.4 | 41.619 | 0.9766 | 2.93−14.66 μM | 7 |
| rosmarinic acid | 932.94 | 23.971 | 0.9808 | 2.93−14.66 μM | 8 |
| resveratrol | 482.91 | −10.518 | 0.9911 | 58.65−131.97 μM | 8 |
| rutin | 275.58 | 13.265 | 0.9895 | 73.31−146.63 μM | 8 |
| rosemary | 399.36 | 7.1703 | 0.9844 | 18.33−146.63 μg/mL | 6 |
| ginger | 138.36 | −4.9684 | 0.9957 | 36.66−586.51 μg/mL | 6 |
| lotus | 126.24 | −5.9565 | 0.9789 | 73.31−586.51 μg/mL | 6 |
| green tea | 55.051 | 6.5041 | 0.9513 | 293.26−1173.02 μg/mL | 6 |

[a]The xanthine/xanthine oxidase reaction system included 193.33 μL of substrate solution (6.43 μL of 4 mM xanthine, 12.86 μL of 4 mM NBT, and 174.04 μL of 0.05 M PBS), 6.67 μL of antioxidant sample solution, and 20 μL of 40 mU/mL xanthine oxidase solution. The absorbance of each well was determined at 560 nm after 20 min of reaction terminated by the addition of 20 μL of 0.6 M HCl. [b]Number of concentrations tested for each antioxidant.

sedimentation of enzyme molecules.[42] As sodium dodecyl sulfonate (SDS) was previously used as a terminator for enzymatic sysytems,[32] its ability as a terminator was also studied. After the X/XO reaction for 20 min, 20 μL of 69 mM SDS was added to the reaction mixture without the addition of the other terminators. As a result, the sedimentation of enzyme molecules was indeed observed. However, the purple formazan was unexpectedly adsorbed by the sediments (data not shown), which in turn interfered with the analysis. Therefore, SDS was not a suitable termination agent for this reaction.

**Validation of the Proposed Assay.** The linear relationship between $O_2^{\bullet-}$ scavenging capacity and antioxidant concentrations was established using pure antioxidants and food extracts at different concentrations. Table 1 lists the linear calibration curves with their correlation coefficients $r^2$ and linear ranges of four pure antioxidants including allopurinol, rosmarinic acid, resveratrol, and rutin, along with four selected functional food extracts including rosemary, ginger, lotus, and green tea. As a result, all calibration curves showed good linear regression ($r^2 > 0.9513$) within test ranges.

The intraday and interday precisions of the assay were determined by analyzing three runs of allopurinol (0.07, 0.10, and 0.30 mM) in hexaplicate in one day and on three consecutive days, respectively. As shown in Table 2, the RSD values of the absorbance values were 4.05 and 5.05% (0.07 mM), 1.87 and 5.62% (0.10 mM), and 1.13 and 2.13% (0.30 mM), respectively, in the intraday and interday precision tests.

The accuracy of the proposed assay was assessed by quality control studies. Quality control samples were prepared in DMSO by adding known amounts of pure rosmarinic acid, resveratrol, and rutin to the reaction mixture. The accuracy was determined by analyzing three runs of the three individual standards at three different concentrations (rosmarinic acid, 0.0176, 0.0264, and 0.0411 μM; resveratrol, 0.0953, 0.11, and 0.1393 μM; and rutin, 0.0953, 0.1246, and 0.1393 μM) in triplicate. The accuracy data (expressed as percent of recovery)

[a]The xanthine/xanthine oxidase reaction mixture contained 193.33 $\mu$L substrate solution (6.43 $\mu$L of 4 mM xanthine, 12.86 $\mu$L of 4 mM NBT, and 174.04 $\mu$L of 0.05 M PBS), 20 $\mu$L of 40 mU/mL xanthine oxidase, and 6.67 $\mu$L antioxidants. Three pure antioxidants (rosmarinic acid, resveratrol, and rutin) at three different concentration levels were used for this accuracy study. The absorbance of each well was determined at 560 nm after 20 min of reaction terminated by addition of 20 $\mu$L of 0.6 M HCl. Values were expressed as means of triplicate measurements. RSD, relative standard deviation. Quality control (QC) samples including rosmarinic acid, resveratrol, and rutin at three different concentration levels (QC1, QC2, and QC3) were used for this accuracy test.

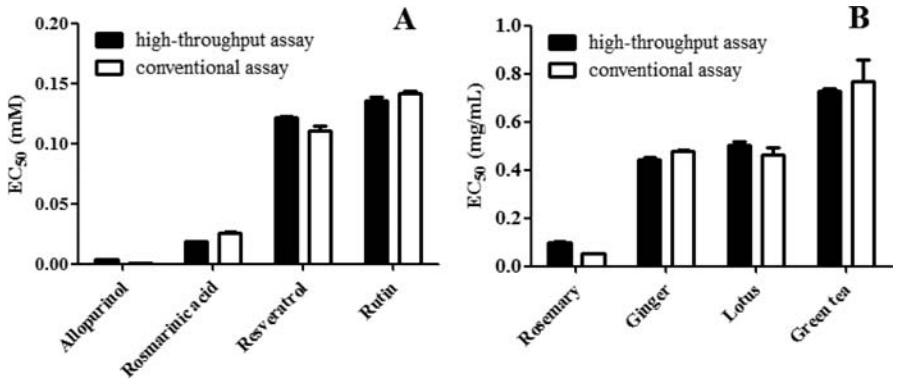

**Figure 3.** $EC_{50}$ values of four selected pure antioxidant compounds (A) and four food extracts (B) determined by the high-throughput and the conventional colorimetric methods. The xanthine/xanthine oxidase (X/XO) reaction system of the conventional colorimetric method contained 1 mL of a mixture of 0.4 mM xanthine and 0.24 mM NBT, 1 mL of 50 mU/mL xanthine oxidase solution, and 0.1 mL of tested samples. The X/XO reaction mixture of the high-throughput method contained 193.33 $\mu$L of substrate solution (6.43 $\mu$L of 4 mM xanthine, 12.86 $\mu$L of 4 mM NBT, and 174.04 $\mu$L of 0.05 M PBS), and 20 $\mu$L of 40 mU/mL xanthine oxidase. The absorbance at 560 nm was measured after 20 min of reaction terminated by 1 mL of 0.6 M HCl for the conventional colorimetric method and by 20 $\mu$L of 0.6 M HCl for the high-throughput assay. Data are means of triplicate measurements. Vertical bars represent the standard deviations.

from the calibration standard are listed in Table 3. The recovery values ranged from 86.62 to 104.17% for rosmarinic acid, from 90.87 to 105.64% for resveratrol, and from 87.83 to 106.90% for rutin, suggesting the acceptable accuracy of the assay.

The stability of the proposed assay was determined with blank (DMSO) and three different concentrations of allopurinol (0.07, 0.10, and 0.30 mM), respectively (Supporting Information Table SI1). After termination, the absorbances at 560 nm at different time periods (0, 10, and 30 min; 1, 2, 6, 12, and 24 h) were monitored. The RSD values of the absorbance values were all <6.19% (blank, 4.70%; allopurinol, 2.62, 3.93, and 6.19% for 0.07, 0.10, and 0.30 mM, respectively), indicating the acceptable stability of the assay.

**Determination of $O_2^{\bullet-}$ Scavenging Capacities for Pure Antioxidants and Food Extracts Using the High-Throughput Method.** Several known antioxidants including allopurinol, rosmarinic acid, resveratrol, and rutin were selected to evaluate their $O_2^{\bullet-}$ scavenging capacity by this high-throughput assay. The $EC_{50}$ value is the concentration of a selected antioxidant necessary to quench 50% $O_2^{\bullet-}$ radicals in the X/XO enzymatic system. A stronger antioxidant has a smaller $EC_{50}$ value. The $EC_{50}$ values of the four pure antioxidants are shown in Figure 3A. Their $O_2^{\bullet-}$ scavenging capacities were in the order allopurinol > rosmarinic acid > resveratrol > rutin determined at 20 min after the reaction was initiated. Our results were in accordance with the literature.[43] Similarly, four well-known antioxidant foods including rosemary, ginger, lotus, and green tea were also estimated for their $O_2^{\bullet-}$ scavenging capacities. The antioxidant activities of the four food extracts can be ranked in descending order of $EC_{50}$ values as follows: rosemary, ginger, lotus, and green tea (Figure 3B). The strongest antioxidant activity of rosemary might be ascribed to the presence of high levels of phenolic compounds (approximately 0.22% fresh weight, among which rosmarinic acid was 32.8 mg/100 g fresh weight).[44]

To validate the efficiency of the newly developed high-throughput 96-well microplate spectrophotometric assay, a comparison between the present method and the conventional colorimetric assay was conducted using a group of pure antioxidants and food extracts mentioned above, in terms of their $EC_{50}$ values. As shown in Figure 3A, the results obtained by the two methods were optimistically correlated to each other ($r$ = 0.991) for the pure antioxidants. As for the case of food extracts, the antioxidant activities were ranked in decreasing order rosemary > lotus > ginger > green tea, consistent with that of the conventional method (Figure 3B). The correlation coefficient was 0.994 between these two methods, indicating the feasibility of the present method.

It is worth noting that the consumption of the enzyme (0.8 mU) was much lower than that of the conventional colorimetric method (50 mU), which makes the current procedure less expensive.

In summary, a high-throughput $O_2^{\bullet-}$ scavenging capacity assay based on the X/XO enzymatic system was developed and validated. The method is easy to perform and time-saving, with a small amount of reagents and antioxidants consumed, and has acceptable precision, accuracy, and stability. The antioxidant data of the newly developed method are highly correlated with those of the conventional method. The high-throughput 96-well plate method can be used as an alternative method for screening and investigating potential antioxidant substances.

paraffin film as internal standard (30 ng/mL). All stock solutions were stored in darkness at −20 °C.

**Experimental Animals and Drug Administration.** *Experimental Animals.* Male Sprague−Dawley rats (230 ± 20 g) were purchased from the National Yang-Ming University Animal Center, Taipei, Taiwan. Rats were housed with a 12 h light/dark cycle. Laboratory rodent diet 5001 (PMI Feeds, Richmond, IN, USA) and water were provided freely at all times. The animal experimental protocol was approved by the Institutional Animal Care and Use Committee of National Yang-Ming University (IACUC no. 1011216) and was consistent with the guidelines of the National Research Council, USA.[12]

*Intravenous Administration of Ractopamine.* Rats were anesthetized with a mixture of urethane (1 g/kg) and $\alpha$-chloralose (0.1 g/kg) by intraperitoneal injection. Fur at the surgical site was shaved, and the skin was disinfected with 70% ethanol. The right jugular vein and the left femoral vein were catheterized with polyethylene tubing for blood sampling and drug administration, respectively.

After surgery, ractopamine was administered in normal saline at 1 or 10 mg/kg, intravenously (iv) ($n$ = 6 for each group). A 300 $\mu$L blood sample was collected from the jugular vein at 0, 15, 30, 45, 60, 90, 120, 180, 240, and 360 min after drug administration. Blood samples were placed in heparin-rinsed eppendorf vials and centrifuged at 6000$g$ for 10 min at 4 °C to obtain plasma. Plasma was stored at −20 °C until analysis.

If the concentration of ractopamine was above 50 ng/mL, the plasma sample was diluted with blank plasma, 5-fold (1 mg/kg, iv) or 50-fold (10 mg/kg, iv).

*Oral Administration of Ractopamine.* Pentobarbital sodium (50 mg/kg) was used to anesthetize the rats via intraperitoneal administration. Surgical sites were shaved and cleaned with 70% ethanol. The right jugular vein was catheterized with polyethylene tubing for blood sampling. The catheter was guided under the skin to the dorsal neck region and fixed.[13] After surgery, the rats were allowed to recover in a clean cage for at least 24 h before drug administration.

After the stabilization period, ractopamine in water (10 mg/kg, per os (po)) was administered to the rats ($n$ = 6). A 300 $\mu$L blood sample was collected from the jugular vein at 0, 5, 15, 30, 45, 60, 90, 120, 180, 240, and 360 min after drug administration. Blood samples were centrifuged at 6000$g$ for 10 min at 4 °C to obtain plasma. Plasma was stored at −20 °C until analysis.

*Organ Distribution.* Forty-five minutes after ractopamine administration (1 mg/kg, iv), blood samples were collected via cardiac puncture, and the rat was sacrificed by decapitation. The brain, liver, heart, spleen, lung, kidney, and gracilis muscle were collected and weighed. These organ samples were stored at −20 °C until analysis.

**Sample Preparation.** *Blood Samples.* Plasma samples (100 $\mu$L) were mixed with 10 $\mu$L of internal standard (nylidrin hydrochloride 30 ng/mL in acetonitrile) and 200 $\mu$L acetonitrile for protein precipitation. The mixture was centrifuged at 16000$g$ for 10 min at 4 °C. The supernatant was evaporated to dryness at 40 °C in a centrifuge evaporator. The dried residue was reconstituted in 100 $\mu$L of 0.1% formic acid/methanol (60:40, v/v) and filtered through a 0.22 $\mu$m filter. An aliquot (5 $\mu$L) of the filtrate was analyzed using HPLC-MS/MS.

*Organ Samples.* Organ samples were homogenized in 50% aqueous acetonitrile (1:5, w/v), and the homogenate was centrifuged at 16000$g$ for 15 min at 4 °C. The supernatant was collected and stored at −20 °C until analysis.

Organ sample preparation was as described under Blood Samples. In brief, the organ sample (100 $\mu$L) was mixed with 10 $\mu$L of internal standard, followed by 200 $\mu$L of acetonitrile for protein precipitation. Samples were then subjected to centrifugation, evaporation, reconstitution, and filtration. Finally, 5 $\mu$L of filtrate was introduced into the HPLC-MS/MS system for analysis.

If the concentration of ractopamine exceeded the upper limit of the linearity range (50 ng/mL), these organ homogenate samples were diluted with blank organ homogenate.

**HPLC-MS/MS.** The HPLC-MS/MS system consisted of an LCMS-8030 triple-quadrupole mass spectrometer (Shimadzu, Kyoto, Japan) equipped with an electrospray ionization interface, coupled to a Shimadzu LC-20AD HPLC system (Shimadzu). The HPLC system was equipped with two pumps, a system controller, an autosampler, a column oven, and an online degasser.

Chromatographic separation was carried out at 35 °C on an Acquity BEH $C_{18}$ column (100 × 2.1 mm, 1.7 $\mu$m) with an in-line filter (Phenomenex AF0-8497, 0.5 $\mu$m depth × 0.004 i.d.). Isocratic elution was used for separation. The mobile phase was 0.1% formic acid/methanol (60:40, v/v). The flow rate was 0.2 mL/min, and the injection volume was 5 $\mu$L. The temperature of the autosampler was 8 °C.

Before analysis, a standard solution of ractopamine (100 ng/mL) was injected into the tandem mass spectrometer. The precursor ion of ractopamine was found in full-scan positive-ion mode. The mass-to-charge ratio ($m/z$) of the precursor ion was 302. The product ion $m/z$ 164 was selected for quantification (Figure 1).

The mass transition of nylidrin was determined using the same procedure. The transition $m/z$ 300 → 150 was chosen for nylidrin (Figure 1).

The optimized parameters for the mass spectrometer were as follows: nebulizing gas (nitrogen) flow, 3.0 L/min; drying gas (nitrogen) flow, 15 L/min; collision gas (argon) pressure, 230 kPa;

dx.doi.org/10.1021/jf5026168 | J. Agric. Food Chem. 2014, 62, 9273−9278

dissolution line temperature, 250 °C; and heat block temperature, 400 °C.

**Method Validation.** *Linearity, Accuracy, and Precision.* The method validation confirms that the method used for the quantification of analyte in a biological sample is reliable and reproducible.[14] Calibration standards were prepared from stock solution of ractopamine and then added to blank plasma or homogenate to spike samples with concentrations of 0.5, 1, 5, 10, and 50 ng/mL. These spiked samples were processed as described under Sample Preparation. The calibration curve was constructed from the ratio of the peak areas of ractopamine and the internal standard (nylidrin) to the nominal concentration of ractopamine. The correlation coefficient ($r^2$) of all calibration curves was at least 0.995.

Six replications of the calibration curve were performed on the same day (intraday) and over six consecutive days (interday) to evaluate precision and accuracy. Accuracy describes the proximity of mean results (observed concentration, $C_{obs}$) of this method to the true concentration (nominal concentration, $C_{nom}$). Accuracy can be calculated as bias (%) = $[(C_{obs} - C_{nom})/C_{nom}] \times 100$. Precision means the closeness of each individual result to the others. Precision, quantified as relative standard deviation (RSD), was calculated as follows: RSD (%) = [standard deviation (SD)/$C_{obs}$] × 100.

The bias and coefficient of variation were kept within ±15%, except for the lower limit of quantification (LLOQ), which was not permitted to exceed ±20%.

*Matrix Effect and Recovery Evaluation.* The matrix effects and recovery were calculated using three sets of samples. Ractopamine was evaluated at 0.5, 5, and 50 ng/mL, and nylidrin was evaluated at 3 ng/mL. The three sets were as follows.

Set 1: For standard solutions of ractopamine, the ractopamine stock solution was diluted to 0.5, 5, or 50 ng/mL with 0.1% formic acid/methanol (60:40, v/v).

Set 2: Blank plasma or organ homogenate (100 μL) was processed as described under Sample Preparation and reconstituted to obtain blank matrix. Blank matrix (90 μL) was added to 10 μL of standard solution, giving postextraction spiked ractopamine samples at three different concentrations.

Set 3: Standard solution (10 μL) and blank plasma or organ homogenate (90 μL) were mixed and subjected to sample preparation and reconstitution. Then a pre-extraction spiked ractopamine sample was acquired and injected into the HPLC-MS/MS system.

The matrix effect is given as the ratio of mean peak area for the postextraction spiked samples (set 2) to that of the standard solution samples (set 1). Recovery was quantified as the ratio of mean peak area of the pre-extraction spiked samples (set 3) to that of the postextraction spiked samples (set 2).

*Stability.* The stability of ractopamine was evaluated by the following methods, as recommended by the FDA: 1, freeze and thaw; 2, short term; 3, long term; 4, postpreparative; and 5, stock solution.[14] Samples for freeze and thaw stability were stored at −20 °C for 24 h and thawed at room temperature. This freeze and thaw cycle was repeated a total of three times. The samples were analyzed after the third cycle. Short-term stability was measured by maintaining the samples at room temperature for 4 h and then analyzing them. Long-term stability was assessed by storing the samples at −20 °C for 30 days. The samples for postpreparative stability testing were processed as described under Sample Preparation. These samples were then maintained in an autosampler at 8 °C for 8 h. The stock solution stability was evaluated by keeping the stock solution at room temperature for 6 h.

Concentrations of 0.5, 5, and 50 ng/mL were used to measure the stability of ractopamine in plasma or organ homogenate. The stock solution for stability evaluation was prepared in the mobile phase before analysis. Stability was calculated using the relative error between the freshly prepared and stored samples. Sample stability was limited to within ±15%.

**Pharmacokinetic Analysis.** Pharmacokinetic parameters were calculated using WinNonlin Standard Edition 1.0 (Pharsight Corp., Mountain View, CA, USA) with compartmental and noncompartmental models for the intravenous and oral groups, respectively. Akaike's information criterion (AIC) was used to choose the pharmacokinetic models (one- or two-compartment).[15] The lowest AIC value indicated the best way to describe the pharmacokinetic data. The results are expressed as the mean ± standard deviation. The criterion of statistical significance was Student's $t$ test, with $p < 0.05$.

## RESULTS

**HPLC-MS/MS.** In positive-ion mode, the multiple reaction monitoring (MRM) transitions were $m/z$ 302 → 164 for ractopamine and $m/z$ 300 → 150 for nylidrin (internal standard). The fragmentation pathway of $m/z$ 302 → 164 was consistent with previous results for ractopamine.[16]

The second step was optimizing chromatographic separation. Peak shape, run time, and sensitivity were influenced by the composition of the mobile phase. To reduce tailing, 0.1% formic acid was selected as the aqueous phase. Different mobile phase ratios were examined: 0.1% formic acid/methanol (10:90, 60:40, and 90:10, v/v).

The experimental results revealed that 0.1% formic acid/methanol (60:40, v/v) gave the sharpest peak and the best run time. Thus, 0.1% formic acid/methanol (60:40, v/v) was chosen for the remaining experiments. Under these conditions, the retention time of ractopamine was 2.0 min and that of nylidrin was 5.5 min.

The similar structures of ractopamine and nylidrin justified the use of this internal standard. The similar fragmentation patterns and the structural similarity between ractopamine and nylidrin may ensure the specificity of this analytical method.[17] Thus, nylidrin was an ideal choice as internal standard.

Typical chromatograms are shown in Figures S1−S4 in the Supporting Information for blank plasma, liver, heart, spleen, lung, kidney, brain, and muscle homogenates; blank plasma or organ homogenates spiked with ractopamine; and finally samples collected from experimental animals after ractopamine administration (1 mg/kg, iv). There was no significant endogenous interference under optimized HPLC-MS/MS conditions (panels a and d of Figures S1−S4). These results show acceptable selectivity for the determination of ractopamine in the biological samples. Furthermore, carry-over effects were not observed in any experiment.

**Sample Preparation.** A pilot experiment was undertaken to determine the most appropriate sample preparation method. Liquid−liquid extraction and protein precipitation by methanol or acetonitrile were examined. Liquid−liquid extraction gave the lowest recovery of ractopamine in rat plasma, approximately 30%. The extraction recoveries via methanol and acetonitrile protein precipitation were 75 and 85%, respectively. The low recovery by liquid−liquid extraction may be due to the high polarity of ractopamine; thus, this method is not suitable.[18] Protein precipitation by acetonitrile was selected as the sample preparation method in this experiment. In the full study, the extraction recovery of ractopamine in rat plasma via acetonitrile protein precipitation was 86.7 ± 2.8% (Supporting Information Table S2, $n = 3$).

Unfortunately, the chromatographic peak obtained using acetonitrile protein precipitation was split, which made integration difficult. This problem was resolved by evaporating the supernatant after protein precipitation. After supernatant evaporation, the chromatographic peak was narrow and sharp.

**Method Validation.** *Linearity, Accuracy, And Precision.* To evaluate linearity, a calibration curve was derived from the peak area ratios of ractopamine and the internal standard, nylidrin. The linear range for ractopamine in rat plasma and

dx.doi.org/10.1021/jf5026168 | J. Agric. Food Chem. 2014, 62, 9273−9278

organ homogenates was 0.5−50 ng/mL; all correlation coefficients ($r^2$) were >0.999.

The limit of detection (LOD) for ractopamine was 0.01 ng/mL, with a signal-to-noise ratio of 3. The lower limit of quantification (LLOQ) in plasma and organ homogenate was 0.5 ng/mL.

Intraday and interday assays were used to evaluate accuracy (as % bias) and precision (as % RSD) for ractopamine (Supporting Information Table S1, $n$ = 6). All bias and RSD values were below 15%, except for the LLOQ (0.5 ng/mL). At this concentration, 20% is the maximum acceptable value.[14] These method validation results indicate that this analytical method is reproducible.

*Matrix Effect and Recovery.* The mean matrix effects for ractopamine in plasma, liver, heart, spleen, lung, kidney, brain, and muscle homogenates were 81.2 ± 4.2, 97.5 ± 2.3, 123.3 ± 2.6, 120.8 ± 3.7, 112.6 ± 2.9, 59.5 ± 2.6, 135.0 ± 4.5, and 113.1 ± 1.5%, respectively (Supporting Information Table S2, $n$ = 3). Compared with the standard solution (set 1) and postextraction spiked solution (set 2), it was very easy to determine ion suppression or enhancement in the plasma and organ samples. Thus, the matrix effect of ractopamine should not be ignored in these experiments.

Extraction recovery is defined as the difference between preextraction (set 3) and postextraction spiked (set 2) samples. The mean extraction recoveries for ractopamine varied from 86.7 ± 2.8 to 98.0 ± 0.6% (Supporting Information Table S2, $n$ = 3).

Significant matrix effects were observed in rat plasma and organ homogenates. However, within a given matrix, the matrix effects and recoveries were independent of concentration within the linear range. To examine the matrix effect and recovery in the whole experiment, samples collected from animals were diluted to within the linear range using blank plasma or organ homogenate. In addition, all experimental samples were diluted to the same linear range (0.5−50 ng/mL). The matrix effect and recovery, correlated with concentration, were not significantly different.

The average matrix effects and recoveries of nylidrin in rat plasma and organ homogenates ranged from 98.6 ± 1.3 to 106.9 ± 0.8 and from 80.8 ± 0.3 to 97.1 ± 0.2, respectively (Supporting Information Table S2, $n$ = 3). On the basis of these results, nylidrin had a small matrix effect and extraction loss after sample preparation. Thus, nylidrin is a suitable internal standard for this study.

*Stability.* Following FDA guidelines, five stability evaluation experiments (freeze−thaw cycle, long-term, short-term, postpreparative, and stock solution) were designed to simulate different conditions: sample collection, storage, preparation, or other handling conditions. Stability was quantified as the relative error in concentration between freshly prepared and stored samples. Stability in the freeze−thaw, short-term, long-term, postpreparative, and stock solution analyses were all within ±15% (Supporting Information Table S3, $n$ = 3). These results indicate that ractopamine was stable during all of these experimental processes.

**Pharmacokinetics of Ractopamine.** To investigate the pharmacokinetics and oral bioavailability of ractopamine, it was administered orally (10 mg/kg, po) and intravenously (1 and 10 mg/kg, iv) (Figure 2, $n$ = 6 for each group). Plasma samples were collected and analyzed by the validated method. To describe the pharmacokinetic profile precisely, it is important to select a proper compartmental model (one- or two-compartment models). Akaike's information criterion (AIC) provides a suitable criterion for the selection of compartmental models.[15] A smaller AIC value means the model has a better fit to the concentration−time curve calculated using WinNonlin. In this experiment, the average AIC values for the one-compartment model (ractopamine 1 and 10 mg/kg, iv) were −86.82 and −23.36, respectively. The mean AIC values of the two-compartment model were −98.27 and −41.16, respectively. The two-compartment model thus describes the pharmacokinetics of ractopamine better (Table 1).

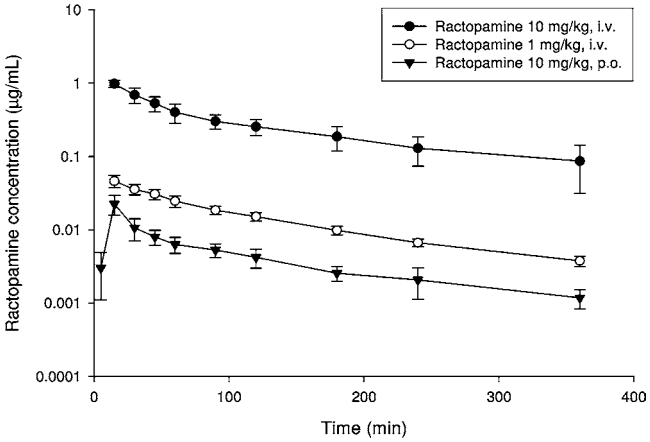

**Figure 2.** Concentration versus time profile of ractopamine in rat plasma (10 and 1 mg/kg, iv, and 10 mg/kg, po) Data are expressed as the mean ± SD ($n$ = 6).

**Table 1. Pharmacokinetic Data for Plasma Ractopamine in Rats**[a]

| pharmacokinetic parameter | ractopamine 1 mg/kg, iv | ractopamine 10 mg/kg, iv | ractopamine 10 mg/kg, po |
|---|---|---|---|
| AIC of one compartment | −86.82 ± 4.40 | −23.36 ± 2.93 | |
| AIC of two compartments | −98.27 ± 6.53 | −41.16 ± 6.92 | |
| AUC (min mg/mL) | 5.85 ± 0.70 | 123.92 ± 40.23[b] | 1.75 ± 0.24 |
| AUC/dose | 5.85 ± 0.70 | 12.39 ± 4.02[b] | |
| $t_{1/2,\alpha}$ (min) | 21 ± 7.4 | 18 ± 8.0 | |
| $t_{1/2,\beta}$ (min) | 118 ± 25 | 165 ± 49 | 113 ± 23 |
| $T_{max}$ (min) | | | 15 |
| $C_0$ (μg/mL) | 0.062 ± 0.015 | 1.65 ± 0.33[b] | |
| Cl (mL/min/kg) | 173 ± 22 | 87.4 ± 25.2[b] | 5800 ± 735 |
| MRT (min) | 146 ± 25 | 185 ± 65 | 148 ± 30 |
| $V_{ss}$ (L/kg) | 25.4 ± 5.7 | 14.9 ± 2.0[b] | 945 ± 196 |
| $F$ (%) | | | 2.99 ± 0.40 |

[a]Abbreviations: AIC, Akaike's information criterion; AUC, area under the concentration−time curve; $t_{1/2,\alpha}$, distribution half-life; $t_{1/2,\beta}$, elimination half-life; $T_{max}$, time of peak plasma level; $C_0$, initial drug concentration; Cl, clearance; MRT, mean residence time; $V_{ss}$, apparent volume of distribution at steady state; $F$, bioavailability. Data are expressed as the mean ± SD ($n$ = 6). [b]$p < 0.05$ compared with 1 mg/kg, iv.

The equation for the two-compartment model is $C_p = A\ e^{-\alpha t} + B\ e^{-\beta t}$. This reflects the sum of two different processes in the body: distribution and elimination, presented as $A\ e^{-\alpha t}$ and $B\ e^{-\beta t}$, respectively. The parameters $\alpha$ and $\beta$ are the distribution and elimination constants, respectively. The $A$ and $B$ values are the intercepts of the distribution and elimination phases.

dx.doi.org/10.1021/jf5026168 | J. Agric. Food Chem. 2014, 62, 9273−9278

Additional pharmacokinetic parameters are as follows. Distribution and elimination half-lives are referred to as $t_{1/2,\alpha}$ and $t_{1/2,\beta}$, respectively. AUC, the area under the concentration−time curve, is related to the extent of drug absorption. $C_0$, the initial drug concentration, is calculated by extrapolation using the pharmacokinetic equation. Cl, clearance, is an indicator of drug elimination. MRT, mean residence time, could be considered the average period of residence of individual molecules of the drug in the body. $V_{ss}$ is the apparent volume of distribution at steady state, derived from concentration and total amount. According to the pharmacokinetic parameters calculated using WinNonlin, intravenous ractopamine administration at 1 and 10 mg/kg gave the two-compartment models $C_p = 0.033\ e^{-0.037t} + 0.029\ e^{-0.006t}$ and $C_p = 1.258\ e^{-0.047t} + 0.392\ e^{-0.005t}$, respectively. The average elimination half-lives ($t_{1/2,\beta}$) for the two doses of ractopamine were 118 and 165 min, respectively (Table 1, $n = 6$ for each group).

The noncompartmental model was selected to describe the pharmacokinetic profile after oral administration of ractopamine (10 mg/kg, po) (Table 1, $n = 6$). The pharmacokinetic parameter $T_{max}$ indicates the time of peak plasma level. Bioavailability ($F$) was used to describe systemic availability: $F\ (\%) = 100 \times (AUC_{oral}/dose_{oral})/(AUC_{iv}/dose_{iv})$. $T_{max}$ was 15 min, indicating that ractopamine is rapidly absorbed in rats. Bioavailability was derived from the AUC after intravenous (1 mg/kg) and oral administration (10 mg/kg). The oral bioavailability of ractopamine ($F = 100 \times (1.75/10)/5.85$) was around 2.99%.

**Organ Distribution of Ractopamine.** To investigate the tissue distribution of ractopamine, tissues and organs were collected 45 min after administration (1 mg/kg, iv). The ractopamine levels in liver, heart, spleen, lung, kidney, brain, and muscle tissue were 307.85 ± 54.82, 391.11 ± 22.81, 675.77 ± 49.54, 1058.41 ± 78.44, 1211.17 ± 89.25, 24.35 ± 1.85, and 294.81 ± 28.00 ng/g, respectively (Figure 3, $n = 6$). Plasma samples for the organ distribution experiment were collected by cardiac puncture. Plasma ractopamine was 25.09 ± 3.51 ng/mL.

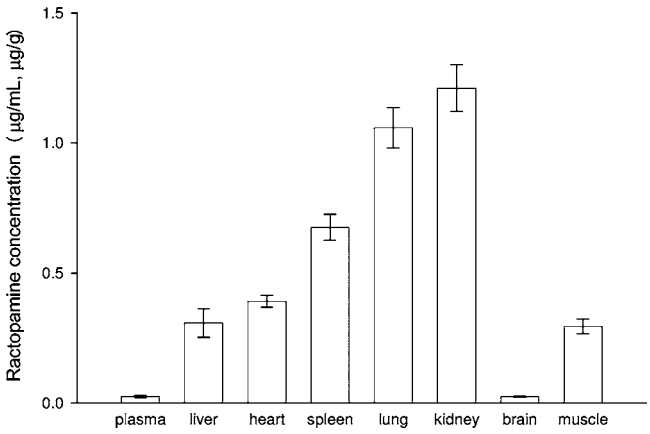

**Figure 3.** Plasma, liver, heart, spleen, lung, kidney, brain, and muscle levels of ractopamine after administration (1 mg/kg, iv). Data are expressed as the mean ± SD ($n = 6$). Concentrations in plasma and organs are micrograms per milliliter and micrograms per gram, respectively.

## DISCUSSION

**Nonlinear Pharmacokinetics of Ractopamine.** Significant differences were found ($p$ value < 0.05) in the pharmacokinetic parameters of the two intravenous doses: AUC/dose (5.85 ± 0.70 vs 12.39 ± 4.02), clearance (173.20 ± 21.75 vs 87.39 ± 25.21), and $V_{ss}$ (25402 ± 5734 vs 14879 ± 1971). That these pharmacokinetic parameters varied with dose may imply nonlinear pharmacokinetics after intravenous ractopamine administration at between 1 and 10 mg/kg.[19] From these results, we hypothesize that excess ractopamine may accumulate due to organ saturation and retarded elimination in the kidney.

**Oral Bioavailability of Ractopamine.** The oral bioavailability of ractopamine was derived from the AUC for intravenous and oral administration. Due to nonlinear pharmacokinetics at high doses, the AUC data for intravenous ractopamine (10 mg/kg) were not utilized. In this experiment, the oral bioavailability of ractopamine was 2.99%.

Oral bioavailability can be evaluated by comparing the amount of parent drug in the collected urine with the total amount administered. Smith and Paulson found, via urine collection, that the oral bioavailability of ractopamine in rats was 2%.[9] Although in our experiment the bioavailability of ractopamine was determined via plasma collection, the result is consistent with the previous study. However, due to the different methods of evaluation, the experimental results may differ. In addition, oral bioavailability has been studied in turkeys and swine, and the results were 8 and 4−16%, respectively.[8,20] Thus, bioavailability may vary between species.

**Ractopamine Accumulation in Rat Organs.** On the basis of the above pharmacokinetic results, a time point of 45 min was selected because that was close to the intersection of the first and second compartments.

The organ distribution results suggest that ractopamine is extensively distributed into tissues 45 min after intravenous administration. The lowest concentration was found in the brain, suggesting that the distribution of ractopamine, with its high polarity, may be restricted by the blood−brain barrier. The highest level was observed in the kidney, which may indicate that the kidney is the primary organ of elimination for this drug in rats. This is consistent with the hypothesis given under Nonlinear Pharmacokinetics of Ractopamine. The nonlinear pharmacokinetics of ractopamine in high doses may be due to nonlinear elimination in the kidney.

In a previous study, Smith and Paulson reported that after oral administration of ractopamine (9.9 mg/kg), approximately 59% of the drug was eliminated in bile. Thus, they suggested that bile excretion is the most important elimination pathway for ractopamine in rats.[9] Our findings differ. This inconsistency may be explained by the first-pass effect. If the rats were given ractopamine orally, most of the drug would be eliminated via bile and would not enter the circulation. Intravenous administration of ractopamine, however, avoids the first-pass effect. Thus, most of the drug may be eliminated by the kidney. This may also explain the low oral bioavailability of ractopamine in rats: most of it may be excreted in bile.

were obtained from Fluka (Buchs, Switzerland), whereas harmane, indoleacrylic acid (IAA), CHCA, 1,5-DAN, and harmine were obtained from Wako and DHB was purchased from TCI MARK (Tokyo, Japan). Strictinin was purchased from Nagara Science Co., Ltd. (Gifu, Japan). An indium tin oxide (ITO)-coated slide glass was obtained from Sigma-Aldrich.

**Animals.** Male 7-week-old BALB/C mice were purchased from Kyudo Co., Ltd. (Saga, Japan), housed in a temperature- and humidity-controlled room, and fed a commercial diet and water ad libitum. This experiment was carried out according to the guidelines for animal experiments at the Faculty of Agriculture, Kyushu University. The study protocol was approved (no. A26-090-0) by the Animal Care and Use Committee of Kyushu University, Fukuoka, Japan.

**Detection of Strictinin on a Stainless Steel MALDI Sample Plate.** Strictinin was dissolved in distilled water at 5 mM stock concentration and stored at −20 °C until use. The stock solution was diluted with 100% methanol, acetone, or acetonitrile to 100 μM to prepare the analyte solutions. Nine matrix candidate chemicals were initially examined as matrices for the detection of strictinin with MALDI-TOF-MS (AXIMA Performance; Shimadzu, Kyoto, Japan). Ten microliters of 100 μM strictinin was added to an equal volume of each matrix solution (10 mg/mL in 100% methanol, acetone, or acetonitrile). Aliquots (1 μL) of strictinin−matrix mixtures were spotted onto a 384-well stainless steel MALDI sample plate (50 pmol strictinin/well, on-plate, $n = 5$) and analyzed in both the negative and positive ionization modes. The experiment was performed under conditions in which the detection voltage of the base peaks was between 700 and 800 mV. This instrument was equipped with a 337 nm $N_2$ laser. Each sample spot was analyzed for 242 shots, and all spectrometric data were processed and analyzed using Shimadzu Biotech Lachlan software. Among the nine chemicals tested, we selected three matrix candidates (1,5-DAN, harmane, and ferulic acid) that could ionize strictinin. Next, the best condition for ionizing strictinin using 1,5-DAN (10 mg/mL in 80% acetone), harmane, and ferulic acid (10 mg/mL in 80% acetonitrile) was evaluated on the same MALDI sample plate.

**MALDI-MSI of Strictinin Spotted on Mouse Kidney Sections.** Sections (8 μm thick) of normal mouse kidney were prepared with a cryostat and then thaw mounted onto an ITO-coated glass slide. Strictinin (5 mM) was diluted with 80% acetone or 80% acetonitrile to prepare a series of solutions (5, 25, 50, 100, 250, and 500 μM). Diluted strictinin solution and a blank (0.2 μL) was spotted onto the mouse kidney sections. The final amounts of strictinin at each spot were 0, 1, 5, 10, 20, 50, or 100 pmol. Samples were allowed to dry for 5 min at room temperature before the matrix spray coating step. The matrix solution was prepared by dissolving 1,5-DAN in 80% acetone (10 mg/mL), harmane, or ferulic acid in 80% acetonitrile (10 mg/mL), respectively, and was sprayed in a draft hood using an airbrush (Testor, Rockford, IL, USA) at room temperature (22 °C, 50% humidity). In the MSI experiment, MALDI-TOF-MS (AXIMA Performance) was used. Data were acquired in the negative ionization mode with 50 μm spatial resolution (10 laser shots/data point), and signals between $m/z$ 100 and 1000 were collected. Acquired MSI data were normalized with the total ion count using SIMedit software (Shimadzu), and obtained data were further processed with the freely available BioMap software (Novartis, Basel, Switzerland). The signal intensity of each imaging datum is represented as the normalized intensity.

**Strictinin Treatment of Mouse and Tissue Sample Collection.** After 12 h of fasting, mice were given a single dose of strictinin (1000 mg/kg body weight, intragastric (ig)) as an aqueous solution with sterile saline containing 1% dimethyl sulfoxide (DMSO) and then sacrificed 1 h after administration. Mouse kidneys were collected and washed with an ice-cold 0.9% NaCl solution. Kidney samples were embedded in Tissue-Tek O.C.T. compounds (Sakura Finetechnical Co., Ltd., Tokyo, Japan) and stored at −80 °C until analysis by MALDI-MSI and LC-MS.

**LC-MS/MS Analysis of Strictinin in Mouse Kidney Samples.** Kidney samples were prepared and analyzed by Lambert's methods with modification.[19] Kidneys were homogenized in 4 volumes of ice-cold PBS (containing 2% ascorbic acid) using a mechanical TOMY MS mash homogenizer (TOMY, Tokyo, Japan) and extracted with ethyl acetate. The ethyl acetate fractions were pooled and dried under $N_2$ gas. Samples were reconstituted in 10% aqueous acetonitrile. All tissue extracts were subjected to electrospray ionization (ESI)-LC-MS analysis using an LCMS-IT-TOF instrument (Shimadzu). The column used was a 250 mm × 4.6 mm i.d., 5 μm, Luna C18 (2) 100 Å column (Phenomenex, Torrance, CA, USA). The oven temperature was 40 °C. The mobile phase was a binary gradient of solvent A ($H_2O$ containing 0.1% formic acid) and solvent B (methanol). Solvent B was increased from 5 to 60% over 2 min and then increased from 60 to 100% at 14 min. The mobile phase flow rate was 0.1 mL/min. Tissue homogenate extracts were resolved with sample buffer, 10% acetonitrile with 10 μM 4-hydroxybenzophenone, as an internal standard. Samples were filtered through a 0.2 μm polytetrafluoroethylene filter, and 20 μL was injected. The MS instrument was operated using an ESI source in the negative ionization mode with survey scans acquired from $m/z$ 100 to 800.

**MALDI-MSI of Strictinin in Kidney Sections from Mice Orally Administered Strictinin.** Strictinin-dosed mouse kidneys were sectioned (8 μm thick) with a cryostat and then thaw mounted onto an ITO-coated glass slide. As a positive control, 250 μM strictinin (0.2 μL) was directly spotted onto the tissue sections. Then, 1,5-DAN matrix solution (10 mg/mL in 80% acetone) was sprayed onto the kidney sections. Imaging data were acquired in the negative ionization mode with 50 μm spatial resolution (10 laser shots/data point) by MALDI-TOF-MS (AXIMA Performance), and signals between $m/z$ 100 and 1000 were collected. The signal intensity of each imaging datum in the figure is represented as the normalized intensity.

MSI analysis of orally dosed strictinin within kidney sections was also performed using an iMScope atmospheric pressure-MALDI-quadrupole ion trap (QIT)-TOF-MS (Shimadzu) equipped with a 355 nm Nd:YAG laser.[20,21] MSI analysis was performed in the negative ionization mode within a mass range of $m/z$ 600−900 for strictinin,

with a spatial resolution of 50 $\mu$m. The laser was irradiated at 50 shots/spectrum at a frequency of 1000 Hz, and the power was set to 80% using the Mass Microscope operation software.

## RESULTS AND DISCUSSION

**Determination of the Optimum Conditions for Ionization of Strictinin on a MALDI Sample Plate.** In MALDI-MS, matrix preparation including selection of the matrix and solvent is a critical step to effectively ionize the analyte because the detection of analyte is completely dependent on these conditions.[22] Because little is known about what matrices can ionize strictinin (Figure 1A), we first attempted to find the optimum conditions for detecting strictinin by selecting several determinants such as matrices, solvents, and ionization modes on the basis of peak detection conditions that achieve the maximum signal-to-noise (S/N) (Figure 1B).

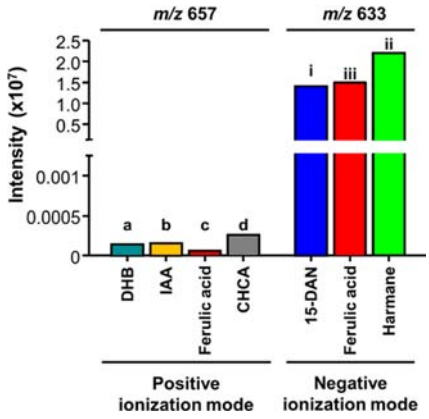

**Figure 4.** Comparison of ionization mode for detection of strictinin. Bar graphs represent the signal intensity at $m/z$ 657 $[M + Na]^+$ (positive ionization mode from Figure 3) or $m/z$ 633 $[M - H]^-$ (negative ionization mode from Figure 2B). Data are the mean of three independent experiments ($n$ = 5 in each experiment).

In this study, nine chemical compounds (Figure 1C) were investigated; some of these are generally used in the analysis of low-molecular-weight biomolecules (i.e., DHB,[23] CHCA,[24] and 9-AA[25−27]), and others are used in the identification and characterization of polyphenols (THAP,[28−30] IAA,[31,32] and ferulic acid[33]). Additionally, 1,5-DAN[34,35] and $\beta$-carbolines[36,37] (i.e., harmane and harmine) are known to be excellent matrices for high-mass proteins or lipids.

First, to detect the peak of strictinin, a matrix solution in 100% methanol was mixed with an equal volume of a strictinin solution in 100% methanol. The mixture of strictinin and matrix was spotted onto a stainless steel MALDI sample plate and analyzed by MALDI-TOF-MS in the negative ionization mode. The deprotonated ion peak at $m/z$ 633, corresponding to strictinin $[M - H]^-$, was detected using 1,5-DAN as a matrix without any background peaks (Figure 2A). Matrix−analyte interactions are important in the ionization/desorption process during MALDI-MS analysis, and they can potentially be modulated by solvent-mediated alternations in matrix−analyte pairing.[38] Next, we analyzed the best matrix and solvent to ionize strictinin among nine different chemical compounds dissolved in 100% methanol, acetone, or acetonitrile, respectively. As shown in Figure 2B, under conditions using the negative ionization mode and 100% methanol solvent, three matrices (1,5-DAN, ferulic acid, and harmane) showed higher sensitivity

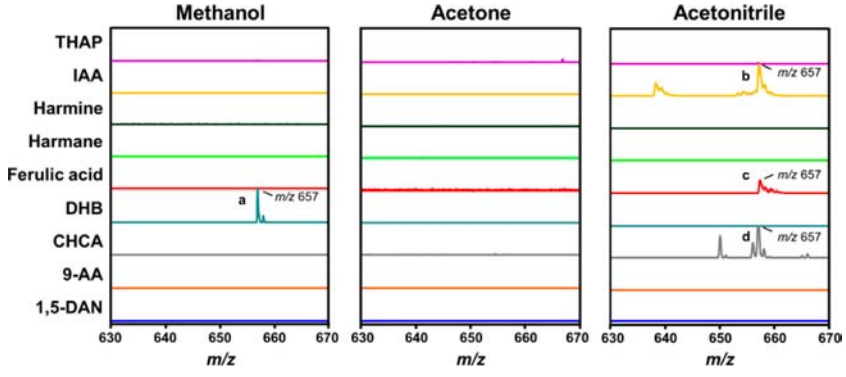

**Figure 3.** Mass spectra of each matrix or solvent on a stainless steel MALDI sample plate by MALDI-MS in the positive ionization mode. MS spectra of strictinin according to three different solvents (100% methanol, 100% acetone, and 100% acetonitrile) at $m/z$ 657 $[M + Na]^+$ in the positive ionization mode. Data represent the relative signal intensity when the intensity of the strongest intensity peak was 100%.

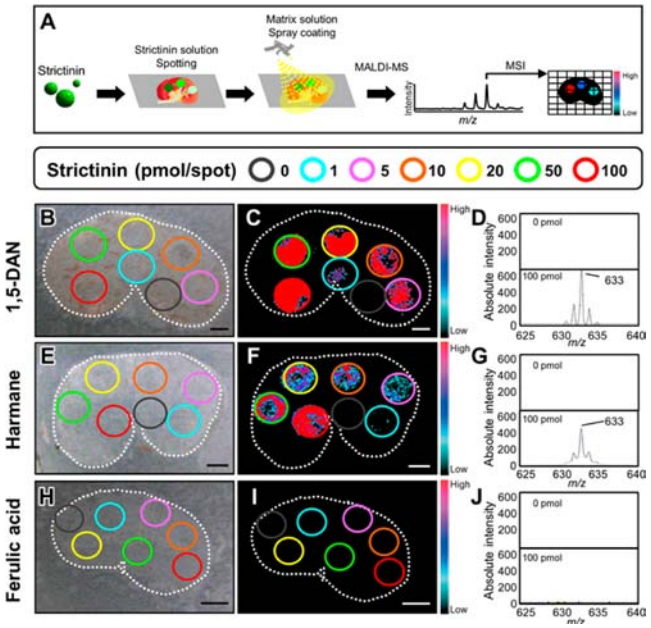

**Figure 5.** MALDI-MS imaging of strictinin spotted on mouse kidney sections: (A) schematic representation of matrix screening by MALDI-MSI; (B–J) MALDI-MSI of strictinin spotted on mouse kidney sections performed using three candidate matrices: (B, E, H) pptical microscopy images; (C, F, I) MALDI-MS images at $m/z$ 633 (scale bar = 1.0 mm); (D, G, J) mass observations of $m/z$ 633 obtained in the 0 and 100 pmol/spot in panels C, F, and I.

at $m/z$ 633 compared with DHB, CHCA, and 9-AA, which are the most effective major matrices for ionizing small molecules.[39,40] Although the peak intensities of CHCA, 9-AA, IAA, and THAP were not altered by different types of solvents, drastic changes in the detection ability were observed for DHB, 1,5-DAN, ferulic acid, harmane, and harmine (Figure 2B). However, when using the positive ionization mode, the protonated ion peak of strictinin $[M + H]^+$ at $m/z$ 635 was not detected with any combinations of matrices and solvents (Figure 3). Although the sodium adduct ion peak of strictinin $[M + Na]^+$ at $m/z$ 657 was observed in DHB, IAA, ferulic acid, or CHCA (Figure 3), they showed very poor intensity compared with peaks detected by the highly performing matrices (1,5-DAN, ferulic acid, and harmane) in the negative ionization mode (Figure 4). Thus, the negative ionization mode was preferable for ionizing strictinin as compared with the positive ionization mode.

Taken together, we found that an ellagitannin, strictinin, could be detected using 1,5-DAN, harmane, or ferulic acid as a preferable matrix in the negative ionization mode by MALDI-MS. Subsequent experiments were performed using these three matrices in the negative ionization mode.

**Determination of the Optimum Matrix for Visualizing Strictinin by MALDI-MSI.** Because ion suppressive effects are predominantly caused by competing endogenous species in tissues,[40] we determined which matrix candidates when dissolved in their corresponding optimum solvent (harmane or ferulic acid in acetonitrile or 1,5-DAN in acetone) could effectively ionize and visualize strictinin directly spotted onto sections of the representative tissue, kidney. Because strictinin solution dissolved in 100% solvent was diffused on kidney sections, the matrix and strictinin solution was prepared in 80% solvent, which could detect the strictinin spotted onto the MALDI sample plate (Supporting Information Figure S1). After strictinin solution had been spotted onto mouse kidney

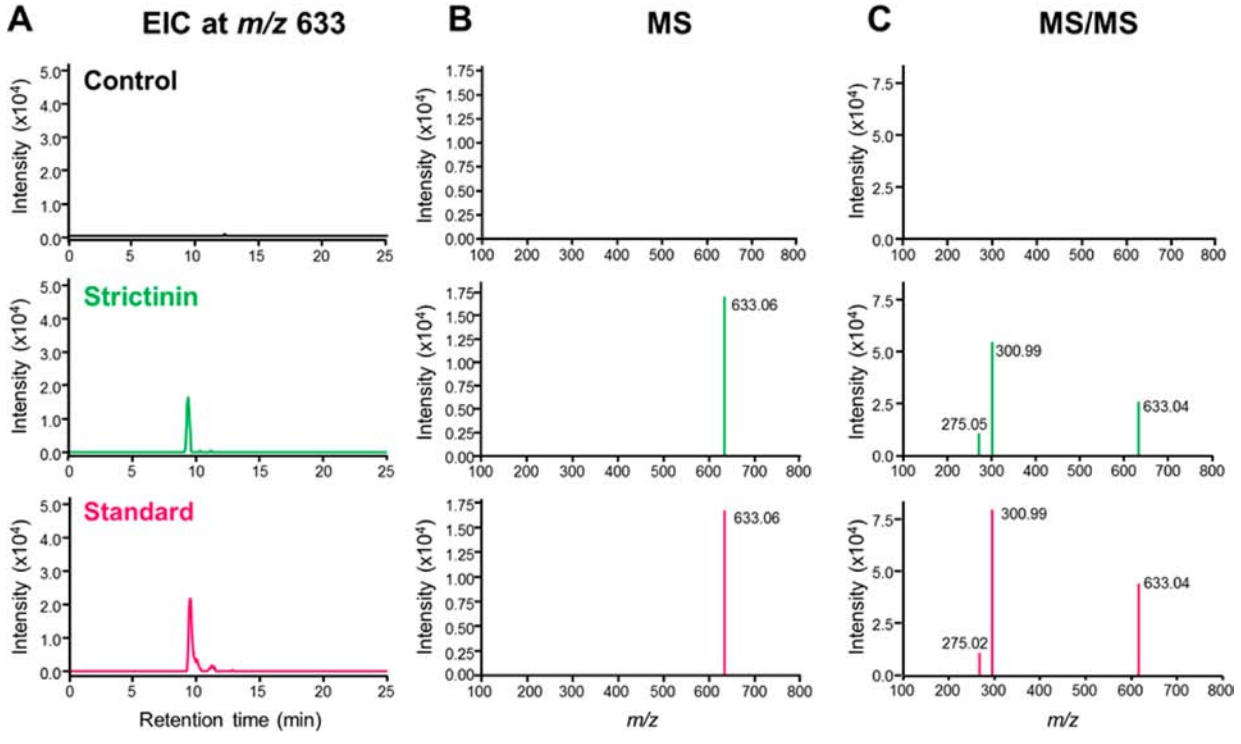

**Figure 6.** LC-MS-based identification of strictinin in mouse kidney after oral administration: (A) extracted ion chromatogram (EIC) at $m/z$ 633 of the strictinin standard (positive control) and kidney extracts in control and strictinin groups in the negative ionization mode; (B, C) mass spectra and tandem MS/MS spectra of strictinin at $m/z$ 633. Strictinin extracted from mouse kidney was determined by LC-MS analysis. MS data from kidney are shown.

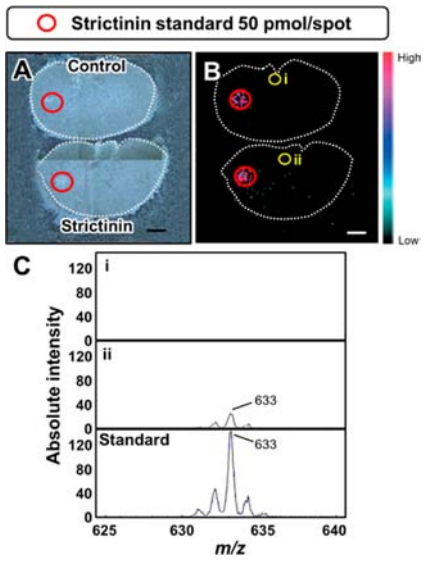

**Figure 7.** MALDI-MSI of orally administered strictinin in mouse kidney sections: (A) optical microscopy image; (B) MALDI-MS image at $m/z$ 633 (scale bar = 1.0 mm); (C) MS observation of $m/z$ 633 obtained in the region of interest (i and ii indicated in panel B).

cryosections, solutions of the three matrix candidates were applied by a spray coating method (Figure 5A). The ion image and peak of $m/z$ 633 $[M - H]^-$ were obtained using 1,5-DAN (Figure 5B–D) or harmane (Figure 5E–G). The best detection sensitivity was observed for 1,5-DAN at the level of 1 pmol/spot (Figure 5C). Although signal intensities were a little weaker than those with 1,5-DAN, harmane also could visualize the strictinin spot from 5 pmol/spot (Figure 5F). When ferulic acid was used as a matrix, no signal was observed (Figure 5H–J). Among the three matrix candidates, ferulic acid was most susceptible to the ion suppression on the kidney sections. These results suggest that 1,5-DAN is the best matrix for visualizing strictinin directly spotted onto intact tissue with high sensitivity in the negative ionization mode.

**In Vivo Administered Strictinin Can Be Visualized by 1,5-DAN-Based MALDI-MSI within Mouse Kidney Sections.** We next applied this label-free imaging technique, 1,5-DAN-based MALDI-MSI, to visualize orally administered strictinin within mouse kidney, a representative tissue capable of accumulating polyphenolic compounds[41,42] as well as being frequently used for MSI analysis.[43] Before the MALDI-MSI experiment, we evaluated whether strictinin can be observed by LC-MS analysis in the kidney 1 h after oral administration (Figure 6). An ion peak at $m/z$ 633.06, corresponding to the deprotonated ion of strictinin $[M - H]^-$, was observed in the strictinin-administered mouse kidney extract but not in the control (Figure 6A,B). Moreover, product ion peaks at $m/z$ 275.02 and 300.99 were detected by MS/MS of $m/z$ 633.06 (Figure 6C), which were identical to the standard peaks. These data suggested that strictinin was absorbed and localized in the kidney 1 h after oral dosing. Therefore, we next performed MALDI-MSI using kidney sections.

After strictinin (50 pmol) had been spotted onto kidney section as a positive control, 1,5-DAN was applied by the spray coating method and then subjected to MALDI-MS (Figure 7). The strictinin standard spot (red circle) was visualized, but the clear ion image of $m/z$ 633 was not obtained in strictinin-administered kidney sections (Figure 7A,B), although the ion peak of $m/z$ 633 was detected (Figure 7C). To obtain clear images of strictinin, we next used another type of MALDI-MS instrument, iMScope,[20,21,44] which is a MALDI-QIT-TOF-MS instrument with a higher performance level compared with the conventional MALDI-TOF-MS instrument (AXIMA Performance) used herein. MSI analysis was performed using the same matrix and the same series of sections tested in Figure 7. An ion image and peak of $m/z$ 633.067 was obtained only in the strictinin-dosed kidney sections (Figure 8). Tandem MS/MS analysis also showed that this peak was certainly strictinin (Supporting Information Figure S2). Interestingly, this label-free imaging technique revealed that the localization patterns of strictinin were different in kidney compartments (pelvis, medulla, and cortex) (Figure 8D). In particular, the highest abundance of strictinin was observed in the pelvis, in the funnel-like dilated proximal part of the ureter in the kidney. This result implies that absorbed strictinin may be immediately excreted from the body 1 h after oral administration.

Previously, MALDI-MS using the major matrix DHB was performed for determining the composition of ellagitannins in plant extract,[45] but this matrix did not allow us to sensitively detect one of ellagitannins, strictinin, at a concentration of <50 pmol (Figure 2B). In contrast, 1,5-DAN selected from matrix screening was able to visualize the in situ distribution of the strictinin in kidney sections after oral dosing, although the bioavailability of ellagitannins is very low.[46,47]

It is known that ellagitannins are quite stable in the stomach and undergo a massive metabolic transformation in the gut to ellagic acid and urolithins, and these gut metabolites play an

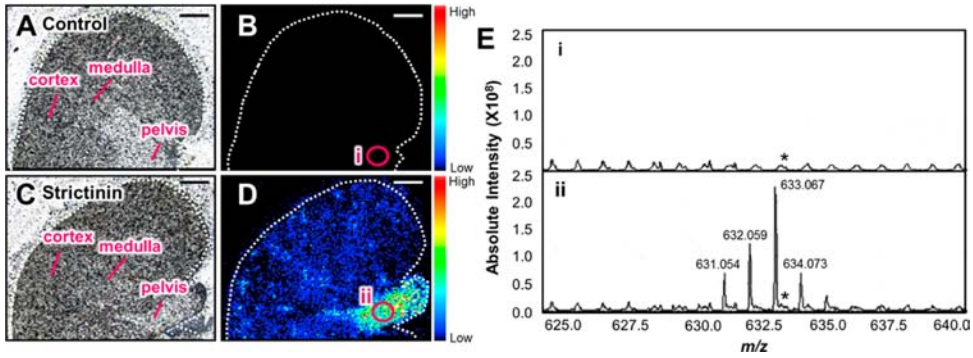

**Figure 8.** In situ visualization of orally administered strictinin using a MALDI-QIT-TOF-MS instrument, iMScope: (A, C) optical microscopy images; (B, D) MALDI-MS images at $m/z$ 633 (scale bar = 1.0 mm); (E) MS observation of $m/z$ 633 obtained in the region of interest (i and ii indicated in panels B and D; asterisk shows background peaks).

important role in the biological activities of ellagitannins.[48,49] In vivo bioactivity of an orally dosed strictinin has been reported,[5] but there was no information on the amount of the intact strictinin within tissues and plasma. In contrast, the present study showed, for the first time, the existence of the intact strictinin within kidney 1 h after oral dosing. Visualization of the intact form in tissue other than the gastrointestinal tract may contribute to elucidation of the in vivo mechanism for action of strictinin. In this study, a gut metabolite, ellagic acid, was observed in kidney extracts, but not visualized by 1,5-DAN-MALDI-MS imaging (Supporting Information Figure 3S). Further improvement of detection sensitivity, including matrix selection and development, is required for comprehensive understanding of the in vivo action of strictinin.

In the future, our proposed in situ label-free imaging technique may contribute to localization analysis and understanding of the mechanism of action of ellagitannins.

antioxidant activity of PC, we determined ROS and AA levels in SMP30/GNL KO mouse tissues after long-term oral ingestion of PC.

## MATERIALS AND METHODS

**Chemicals.** Ethylenediaminetetraacetic acid (EDTA) was purchased from Dojindo Laboratories (Kumamoto, Japan). Tris(2-carboxyethyl)-phosphine hydrochloride was purchased from Tokyo Chemical Industry Co., Ltd. (Tokyo, Japan). 5-(and 6)-carboxy-2′,7′-dichlorodihydrofluorescein diacetate (carboxy-$H_2$DCFDA) was purchased from Life Technologies Corp. (Carlsbad, CA, USA). Protease inhibitor cocktail (cOmplete, EDTA-free) was purchased from Roche Diagnostics GmbH (Mannheim, Germany). BCA protein assay reagent was purchased from Thermo Fisher Scientific Inc. (Waltham, MA, USA). L-Ascorbic acid used in the HPLC analysis and other reagents and chemicals were purchased from Wako Pure Chemical Industries, Ltd. (Osaka, Japan).

**Preparation of PC and PC Diet.** White potato (*S. tuberosum* cv. Toyoshiro) tubers of similar size and appearance were obtained for an experimental field in Hokkaido, Japan, in September 2010 and stored for several days. The unpeeled potatoes were washed with tap water and air-dried on filter paper. PC were prepared as the commercial product "Olivee" and were manufactured by CALBEE, Inc. (Tokyo, Japan). Briefly, peeled potatoes were sliced and immersed in tap water and then fried in olive oil for several minutes. After frying, the PC were finely ground and passed through a 1.5 mm sieve. To avoid AA degradation, the crushed PC were stored at −80 °C in a nitrogen gas-filled pouch with an aluminum vapor-deposited film. The stored-crushed PC were thawed before use and mixed with the AA-free powder CL-2 (CLEA Japan, Inc., Tokyo, Japan) to produce a final 20% (w/w) and 10% PC content. Diet compositions (moisture, crude protein, crude fat, crude fiber, crude ash, and nitrogen-free extract) of 20% PC CL-2, 10% PC CL-2, and CL-2 were analyzed at the Laboratories for Food and Environmental Science (Tokyo, Japan) and are shown in Table 1.

**Table 1. Nutritional Composition of PC Diets (in 100 Grams)**

| nutritional component | 20% PC CL-2 | 10% PC CL-2 | CL-2 |
|---|---|---|---|
| moisture (g) | 6.6 | 7.1 | 7.6 |
| crude protein (g) | 20.7 | 22.6 | 24.4 |
| crude fat (g) | 9.0 | 7.5 | 6.0 |
| crude fiber (g) | 3.3 | 3.4 | 3.6 |
| crude ash (g) | 7.9 | 8.4 | 8.9 |
| nitrogen-free extract (g) | 52.5 | 51.0 | 49.5 |
| calorie (kcal) | 387 | 376 | 364 |
| ascorbic acid (mg) | 13.6 | 6.0 | nd[a] |
| dehydroascorbic acid (mg) | 0.5 | 0.6 | nd |

[a]nd, not detectable.

**Assays of Oxygen Radical Absorbance Capacity (ORAC).** ORAC for hydrophilic and lipophilic antioxidants was measured using a previously described method.[16]

**Animals.** SMP30/GNL KO mice were established and maintained as described previously.[8] SMP30/GNL KO and C57BL/6N (wild type, WT) male mice were fed a commercial autoclaved chow diet (CRF-1, Oriental Yeast Co., Ltd., Tokyo, Japan) and had free access to water containing 1.5 g/L AA (DSM Nutrition Japan, Tokyo, Japan) and 10 μM EDTA until weaning. After weaning at the age of 4 weeks, all mice were used for the following two experiments. (1) All mice were fed CL-2 and divided into four groups: SMP30/GNL KO and WT mice given water with or without AA, that is, AA(−) KO, AA(+) KO, AA(−) WT, and AA(+) WT, whereas AA(+) mice had free access to water containing 1.5 g/L AA and 10 μM EDTA. AA(−) mice had free access to AA-free water containing 10 μM EDTA. (2) SMP30/GNL KO mice were divided into four groups that were given either 20% PC powder in CL-2 and AA-free water containing 10 μM EDTA, 10% PC powder in CL-2 and AA-free water containing 10 μM EDTA, powder CL-2 and AA-free water containing 10 μM EDTA, and powder CL-2 and water containing 1.5 g/L AA and 10 μM EDTA, that is, 20% PC, 10% PC, AA(−), and AA(+). Five mice were used in each group for these experiments. Mice were maintained on a 12 h light/dark cycle in a controlled environment. All experimental procedures using laboratory animals were approved by the Animal Care and Use Committee of the Tokyo Metropolitan Institute of Gerontology (permit no. 12016).

**Collection of Blood and Tissue Samples.** Mice were sacrificed, and each blood sample was drawn into an EDTA-containing syringe from the inferior vena cava. Plasma was obtained by centrifugation at 1700*g* for 15 min at 4 °C. Mice were then systemically perfused with ice-cold phosphate-buffered saline through the left ventricle to wash out any remaining blood cells. The tissues of interest were then collected. All samples were stored at −80 °C until use.

**Determination of AA and DHA.** Amounts of AA and dehydroascorbic acid (DHA), an oxidized form of AA, were determined by high-performance liquid chromatography using an Atlantis dC18 5 μm column (4.6 × 150 mm; Nihon Waters K.K., Tokyo, Japan) as described previously.[17] For determination of plasma AA, plasma was mixed with equal amounts of 10% metaphosphoric acid (MPA) and 1 mM EDTA and centrifuged at 21000*g* for 15 min at 4 °C. For analysis of AA content in PC, 20% PC powder diet, and 10% PC powder diet, 0.4 g samples were homogenized with 14 volumes of cold 5.4% MPA and 1 mM EDTA using a high-speed homogenizer (POLYTRON, Kinematica AG, Switzerland) and subsequently centrifuged at 21000*g* for 15 min at 4 °C. For AA determination in the brain, eyeball, heart, lung, testis, stomach, small intestine, large intestine, pancreas, kidney, liver, skin, and epididymal fat, tissues were homogenized with 14 volumes of cold 5.4% MPA and 1 mM EDTA using a Teflon homogenizer (model TH-M, Takashima, Tokyo, Japan). The soleus and plantaris muscles were homogenized with 14 volumes of cold 5.4% MPA and 1 mM EDTA using a Handy homogenizer (Moji-mojikun, Nippon Genetics Co., Ltd., Tokyo, Japan). Homogenates were then centrifuged at 21000*g* for 10 min at 4 °C. To reduce DHA to AA for determination of AA plus DHA, 90 μL of supernatant was incubated with 10 μL of 350 mM tris(2-carboxyethyl)phosphine hydrochloride for 2 h at 4 °C. The mobile phase was 50 mM phosphate buffer (pH 2.8), 0.2 g/L EDTA, and 2% methanol at a flow rate of 1.3 mL/min, and electrical signals were recorded using an electrochemical detector equipped with a glassy carbon electrode at +0.6 V. The value of DHA was determined by subtracting AA from AA plus DHA.

**Determination of ROS.** ROS were measured using carboxy-$H_2$DCFDA as described previously.[18,19] Carboxy-$H_2$DCFDA was de-esterified from diacetate by intracellular esterases and then oxidized to fluorescent 5-(and-6)-carboxy-2′,7′-dichlorofluorescein by various ROS such as hydroxyl radical, peroxynitrite anion, carbonate, nitrogen dioxide, peroxyl radical, and hydrogen peroxide according to the manufacturer's handbook and Wardman et al.[20] Briefly, tissues were homogenized with 14 volumes of cold homogenization buffer consisting of 50 mM sodium phosphate buffer (pH 7.4), 0.5 mM phenylmethanesulfonyl fluoride, 1 mM EDTA, and protease inhibitor cocktail using a Teflon homogenizer, and the homogenate was centrifuged at 900*g* for 15 min at 4 °C. One hundred microliters of 50 μM carboxy-$H_2$DCFDA, 25 μL of supernatants containing 15 μg total protein, and 75 μL of homogenization buffer were mixed to yield a 200 μL total reaction volume. Changes in fluorescence intensity were measured every 5 min for 60 min at 37 °C using a SPECTRAmax Gemini (Life Technologies Corp.) with excitation and emission wavelengths set at 485 and 530 nm, respectively. ROS in tissue homogenates were calculated using the values from 30 to 60 min and expressed as "counts/min/mg protein". The protein concentration was determined by BCA protein assay using bovine serum albumin as a standard.

**Statistical Analysis.** The values are expressed as means ± standard error of the mean (SEM). Statistical analysis was performed using Turkey's honestly significant difference test for multiple comparisons in body weight, AA plus DHA, and ROS among all groups, and in ORAC among all diets. All statistical analyses were performed using KaleidaGraph software (Synergy Software Inc., Reading, PA, USA). Statistically significant differences were defined as $p < 0.05$.

## RESULTS

**Body Weight of SMP30/GNL KO Mice during AA Depletion.** Compared to AA(+) KO mice, the body weights of AA(−) KO mice were reduced by 12 and 48% at 7 and 14 weeks, respectively, after weaning ($p < 0.05$ and $p < 0.001$, respectively) (Table S1 in the Supporting Information). Meanwhile, there were no significant differences in body weight among AA(+) KO, AA(−) WT, and AA(+) WT mice at 7 and 14 weeks. AA(−) KO mice at 7 weeks showed marginal initial manifestations of AA deficiency (e.g., bleeding from the knee junctions), and they had developed appreciable symptoms of scurvy (rachitic rosary and an abnormal gait) by 14 weeks.

**Depletion of AA and DHA Levels in SMP30/GNL KO Mice Fed an AA-free Diet and Water.** We first determined the AA and DHA levels in tissues and plasma from AA(−) KO mice during AA depletion. Seven weeks after weaning that occurred at 4 weeks, AA plus DHA concentrations in the brain, heart, lung, testis, soleus muscle, plantaris muscle, stomach, small intestine, large intestine, pancreas, kidney, liver, and plasma of AA(−) KO mice were 2.6, 3.4, 4.1, 8.5, 2.0, 3.6, 4.1, 3.1, 3.9, 3.5, 1.0, 2.0, and 0% that of AA(+) KO mice, respectively (Figure 1). There were no significant differences in AA plus DHA concentrations in tissues and plasma from AA(+) KO and AA(−) WT mice. The AA plus DHA concentrations in the lung, stomach, and liver were significantly (17, 20, and 29%, respectively) higher in AA(+) WT mice than those of AA(−) WT mice (Figure 1C,G,L). DHA per AA plus DHA levels in the brain, heart, lung, testis, soleus muscle, plantaris muscle, stomach, small intestine, large intestine, pancreas, kidney, liver, and plasma of AA(+) KO, AA(−) WT, and AA(+) WT mice were 1.6−4.9, 19.1−24.3, 6.4−20.2, 0−0.5, 25.2−29.6, 11.7−12.0, 4.3−7.8, 4.6−5.0, 1.0−2.2, 4.8−5.2, 5.6−9.0, 0−0.5, and 15.0−18.4%, respectively.

As shown in Figure S1 (Supporting Information), the AA plus DHA levels were lower in AA(−) KO mice at 14 weeks compared to 7 weeks. AA plus DHA concentrations in the brain, heart, lung, testis, soleus muscle, plantaris muscle, stomach, small intestine, large intestine, pancreas, kidney, liver, and plasma of AA(−) KO mice were 1.5, 2.2, 3.0, 5.6, 3.9, 2.0, 1.9, 1.9, 2.5, 2.1, 1.4, 0.9, and 0% that of AA(+) KO mice, respectively. AA plus DHA concentrations in these tissues and plasma did not differ significantly between AA(+) KO and AA(−) WT mice. The values in the testis and stomach of AA(+) WT mice were significantly (9 and 25%, respectively) higher than those of AA(−) WT mice. The DHA per AA plus DHA in the brain, heart, lung, testis, soleus muscle, plantaris muscle, stomach, small intestine, large intestine, pancreas, kidney, liver, and plasma of AA(+) KO, AA(−) WT, and AA(+) WT mice were 1.0−1.8, 19.6−27.5, 17.8−22.3, 0−0.1, 23.4−30.9, 20.7−22.0, 4.9−6.7, 3.4−8.0, 0−2.3, 4.5−7.2, 2.8−16.4, 0−0.7, and 15.6−38.9%, respectively.

**Increased ROS Levels in SMP30/GNL KO Mice Fed an AA-free Diet and Water.** To establish an evaluation method of the antioxidant activity of various foods using SMP30/GNL KO mice, we next investigated ROS levels in tissues from AA(−) KO mice using a simple method for ROS detection.[18] ROS levels in the brain, heart, lung, testis, soleus muscle, plantaris muscle, stomach, small intestine, and large intestine of AA(−) KO mice at 7 weeks were significantly (27, 39, 29, 32, 81, 28, 43, 42, and 64%, respectively) higher than those of AA(+) KO mice (Figure 2A−I). In the pancreas and kidney, ROS levels in AA(−) KO mice were 17 and 31% higher, respectively, than those of AA(+) KO mice, although the difference did not reach significant levels ($p = 0.09$ and 0.08, respectively) (Figure 2J,K). There were no significant differences in ROS levels in these tissues among AA(+) KO, AA(−) WT, and AA(+) WT mice. Interestingly, ROS levels in the liver of AA(+) KO mice were significantly (19%) higher than that of AA(−) WT mice. The ROS levels for AA(−) KO mice were 13% higher in the liver compared to AA(+) KO mice, although there were no significant differences ($p = 0.07$) (Figure 2L).

Likewise, at 14 weeks AA(−) KO mice showed increased ROS levels in tissues. ROS levels in the brain, heart, lung, testis, soleus muscle, plantaris muscle, stomach, small intestine, large intestine, pancreas, and kidney of AA(−) KO mice were significantly (74, 108, 117, 72, 95, 48, 29, 45, 35, 31, and 26%, respectively) higher compared with those of AA(+) KO mice (Figure S2A−K in the Supporting Information). No significant differences were observed in tissue ROS levels among AA(+) KO, AA(−) WT, and AA(+) WT mice. In livers, the ROS levels of AA(−) KO and AA(+) KO mice were 22 and 19%, respectively, higher than that of AA(−) WT mice, although the difference did not reach significant levels ($p = 0.14$ and 0.24, respectively) (Figure S2L in the Supporting Information).

**Nutritional Composition and ORAC of PC Diets.** For feeding PC to SMP30/GNL KO mice, we prepared PC diets by mixing the AA-free powder diet CL-2 and crushed PC to yield a final PC content of 10 or 20%. The AA content of the PC used in this study was 78.0 ± 1.6 mg/100 g, whereas DHA was under the detection limit. The nutritional composition of the PC diets was determined as listed in Table 1. Whereas moisture, crude protein, crude fiber, and crude ash were lower in the 20 and 10% PC diets compared with CL-2, crude fat, nitrogen-free extract, AA, and DHA, and calorie amounts of the 20 and 10% PC diets were higher than those of CL-2. Furthermore, we determined the radical scavenging ability of the PC diet and PC using the well-established ORAC method. The ORAC values of the 20 and 10% PC diets were significantly higher compared with PC, whereas the values were significantly (25 and 17%, respectively) lower than that of CL-2 (Figure S3 in the Supporting Information).

**Body Weight Change, Food Intake, and Water Intake of SMP30/GNL KO Mice Fed PC Diets.** To investigate the effect of the PC diet on growth, we compared SMP30/GNL KO mice fed a 20% PC diet and AA-free water, a 10% PC diet and AA-free water, an AA-free diet and water, or an AA-free diet and 1.5 g/L AA water after weaning at 4 weeks of age. Each group gained equal amounts of weight compared to the initial body weights (Figure 3A). Food and water intakes throughout the experimental period were 3.5 ± 0.1 g/day/mouse and 3.7 ± 0.1 mL/day/mouse in the 20% PC group, although there were no significant differences among all four groups (Figure 3B,C).

**Increase in AA and DHA Levels in SMP30/GNL KO Mice Fed PC Diets.** Because whether AA and DHA in PC diets were absorbed in intestines and transported into tissues was unclear, we determined the AA and DHA levels in tissues and plasma from SMP30/GNL KO mice fed PC diets (Figure 4). The AA plus DHA levels of the brain, heart, lung, testis, soleus muscle, plantaris muscle, stomach, small intestine, large intestine, eyeball, epididymal fat, skin, pancreas, kidney, liver, and plasma of the 10% PC group were 28, 34, 35, 36, 36, 32, 29, 24, 29, 51, 31, 25, 27, 18, 19, and 14%, respectively, those of the AA(+) group, which were significantly higher than those of the AA(−) group, although the differences in epididymal fat, liver, and plasma did not reach significant levels ($p = 0.830$, 0.222, and 0.179, respectively). The DHA per AA plus DHA levels in the brain, heart, lung, testis, soleus muscle, plantaris muscle, stomach, small

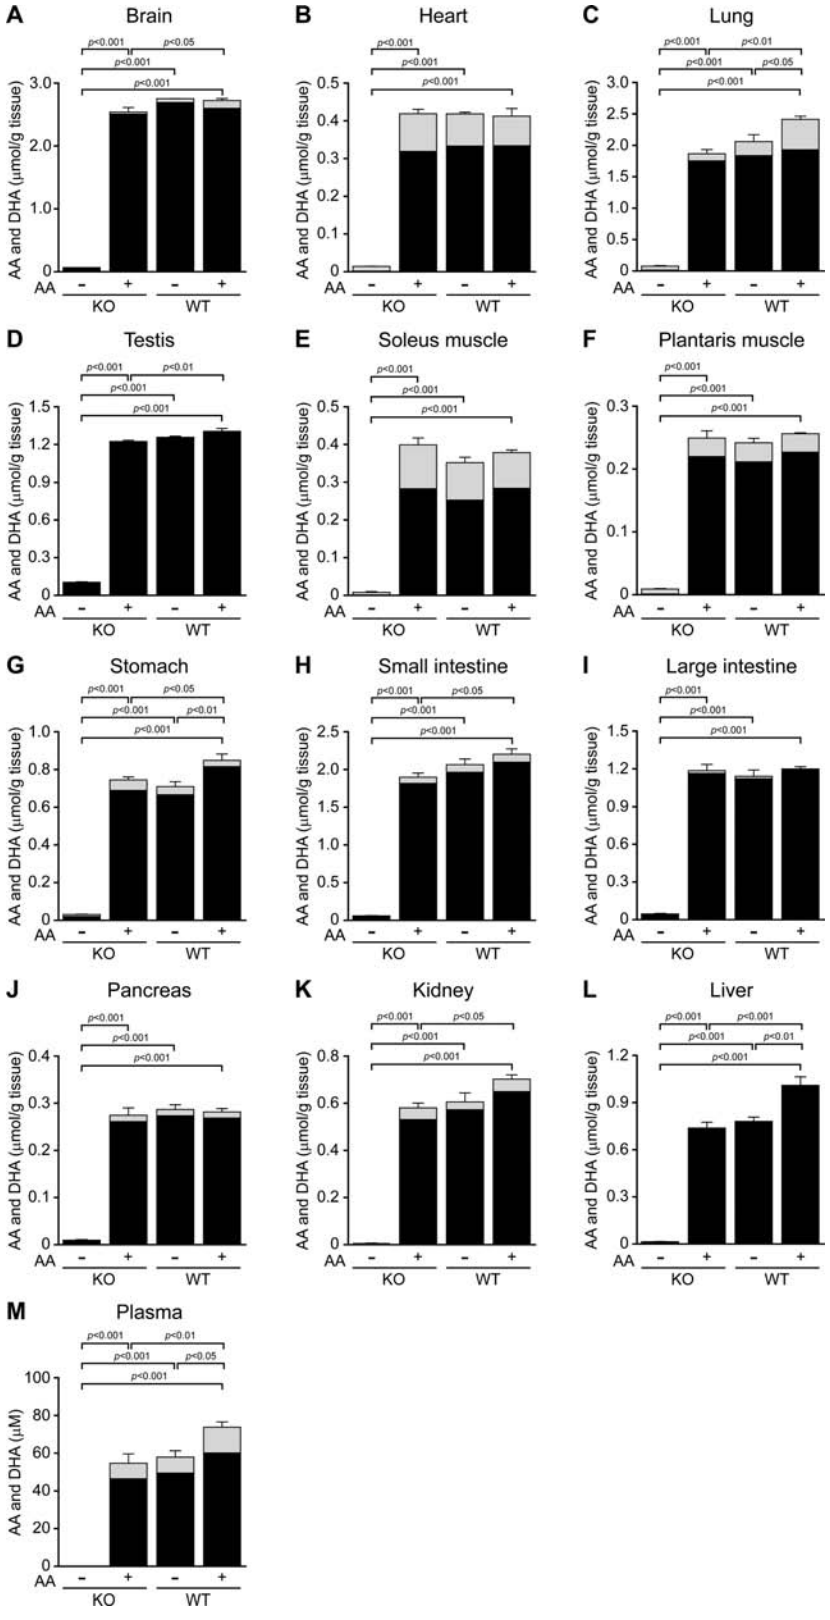

**Figure 1.** Ascorbic acid (AA) and dehydroascorbic acid (DHA) levels in SMP30/GNL KO mice fed an AA-free diet and water for 7 weeks: AA (black bars) and DHA (gray bars) concentrations in (A) brain, (B) heart, (C) lung, (D) testis, (E) soleus muscle, (F) plantaris muscle, (G) stomach, (H) small intestine, (I) large intestine, (J) pancreas, (K) kidney, (L) liver, and (M) plasma of AA(−) KO, AA(+) KO, AA(−) WT, and AA(+) WT mice. SMP30/GNL KO and WT mice were given water with or without AA for 7 weeks after weaning at 4 weeks of age. Values are given as means ± SEM (AA plus DHA) of five animals.

intestine, large intestine, eyeball, epididymal fat, skin, pancreas, kidney, liver, and plasma of the 10% PC group were 0, 25.6, 25.4, 3.1, 38.0, 15.6, 4.4, 0.2, 0, 17.6, 18.2, 16.9, 5.5, 17.7, 0.3, and 26.2%, respectively. The AA plus DHA levels in the brain, heart,

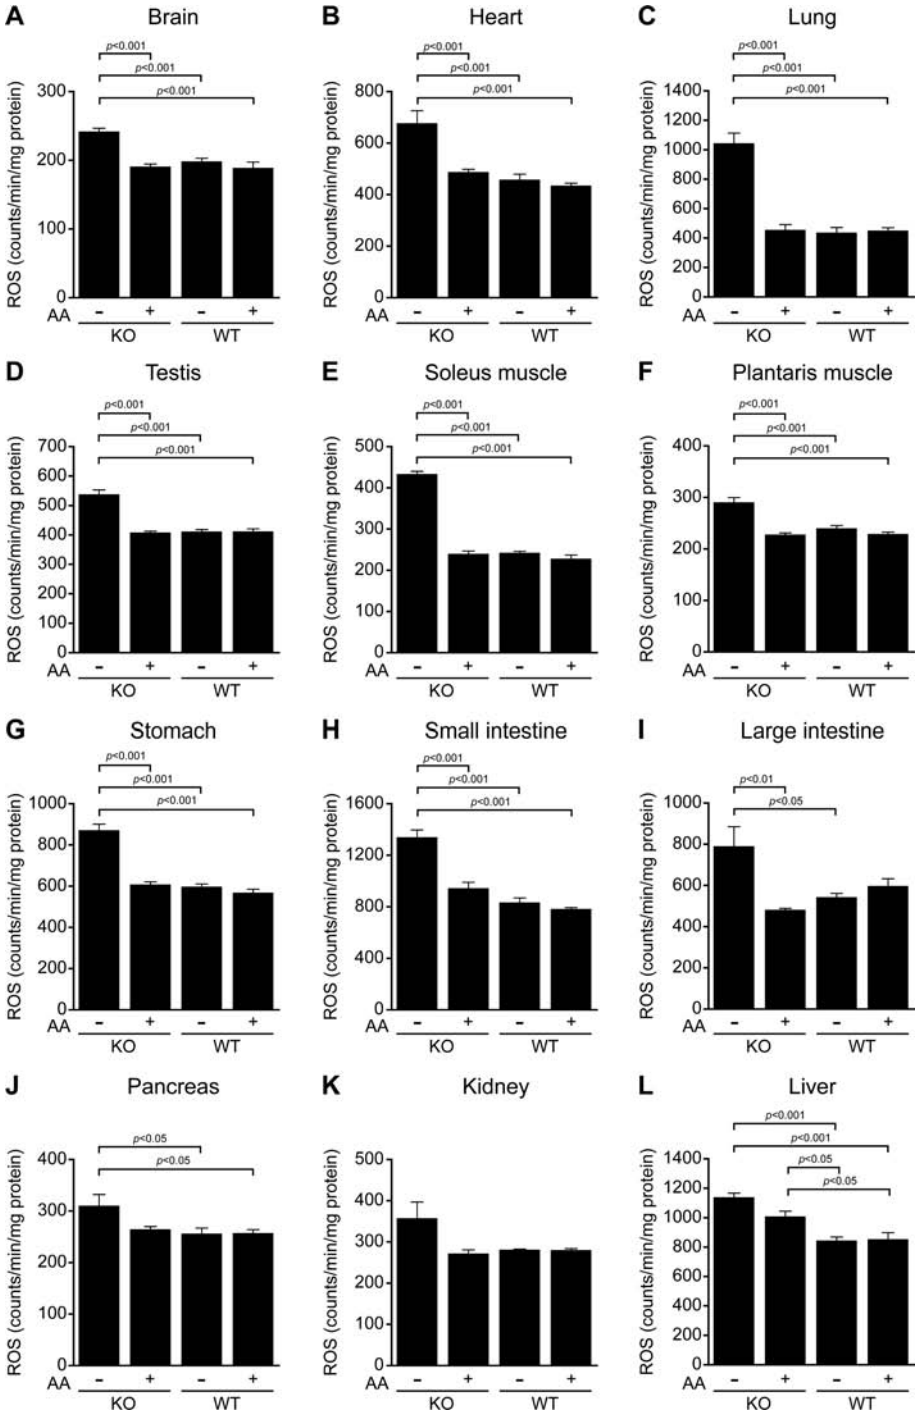

**Figure 2.** Reactive oxygen species (ROS) levels in SMP30/GNL KO mice fed an ascorbic acid (AA)-free diet and water for 7 weeks in (A) brain, (B) heart, (C) lung, (D) testis, (E) soleus muscle, (F) plantaris muscle, (G) stomach, (H) small intestine, (I) large intestine, (J) pancreas, (K) kidney, and (L) liver of AA(−) KO, AA(+) KO, AA(−) WT, and AA(+) WT mice. SMP30/GNL KO and WT mice were given water with or without AA for 7 weeks after weaning at 4 weeks of age. Values are given as means ± SEM of five animals.

lung, testis, soleus muscle, plantaris muscle, stomach, small intestine, large intestine, eyeball, epididymal fat, skin, pancreas, kidney, liver, and plasma of the 20% PC group were 97, 99, 83, 81, 99, 99, 86, 86, 87, 105, 100, 85, 91, 80, 89, and 89% of those of the AA(+) group, which were significantly higher than those of the AA(−) group. There were no significant differences in the AA plus DHA levels between the 20% PC and AA(+) groups except in the testis, small intestine, and kidney. The DHA per AA plus DHA in the brain, heart, lung, testis, soleus muscle, plantaris muscle, stomach, small intestine, large intestine, eyeball, epididymal fat, skin, pancreas, kidney, liver, and plasma of the 20% PC group were 0, 14.9, 7.2, 2.2, 20.2, 12.1, 1.9, 2.2, 0.1, 12.9, 3.9, 12.0, 4.8, 8.0, 1.7, and 25.2%, respectively.

**Decrease in ROS Levels of SMP30/GNL KO Mice Fed PC Diets.** To evaluate the antioxidant activity of PC in mice, we next determined ROS levels of tissues in SMP30/GNL KO mice fed a PC diet (Figure 5). Compared with the AA(−) group, ROS levels in the brain, heart, testis, soleus muscle, plantaris muscle,

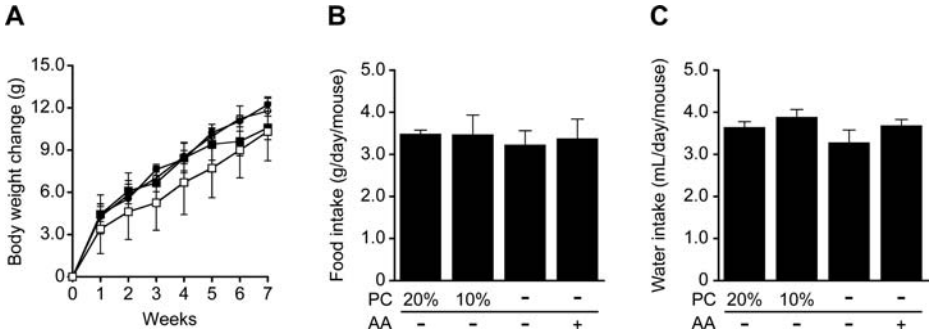

**Figure 3.** Body weight change, food intake, and water intake of SMP30/GNL KO mice fed a potato chip (PC) diet for 7 weeks: (A) body weight change of 20% PC (solid circles), 10% PC (open circles), AA(−) (solid squares), and AA(+) (open squares) groups from SMP30/GNL KO mice, that is, mice fed a 20% PC diet and AA-free water, a 10% PC diet and AA-free water, an AA-free diet and water, and an AA-free diet and 1.5 g/L AA water, respectively, for 7 weeks after weaning at 4 weeks of age (values are given as means ± SEM of five animals); (B) food intake and (C) water intake of each group (values are given as means ± SEM through the experimental period).

small intestine, and large intestine were significantly (40, 34, 18, 41, 29, 17, and 23%, respectively) lower in the 10% PC group, but the difference in tissues from the large intestine did not reach a significant level ($p = 0.08$). In the lung, stomach, eyeball, and epididymal fat, no significant differences were observed in ROS levels between the 10% PC and AA(−) groups. For the 20% PC group, ROS levels in the brain, heart, lung, testis, soleus muscle, plantaris muscle, stomach, small intestine, large intestine, eyeball, and epididymal fat were significantly (63, 46, 40, 27, 53, 54, 20, 33, 27, 33, and 42%, respectively) lower than those of the AA(−) group, and there were no significant differences between the 20% PC and AA(+) groups. Skin tissue showed a similar pattern, although it did not show significant differences. There were no differences among all four groups in tissue from the pancreas, kidney, and liver.

## DISCUSSION

In this study, we showed that AA depletion increases ROS levels in various tissues of SMP30/GNL-KO mice. Furthermore, we demonstrated that the dietary intake of PC increases total AA (AA plus DHA) levels and reduces ROS levels in tissues from SMP30/GNL KO mice. Our data suggest that SMP30/GNL KO mice are a promising model for evaluating the antioxidant activity of foods.

Here the ratio of DHA to total AA differed among tissues from AA(−) WT mice and was comparatively lower in the brain, testis, large intestine, and liver but higher in tissues from the heart, lung, soleus muscle, and plantaris muscle as well as in plasma (Figure 1 and Figure S1 in the Supporting Information). These results are consistent with our previous study.[17] DHA is transported into cells or generated from AA by a two-electron oxidation, but is rapidly and continuously reduced by dehydroascorbate reductase (DHAR) via a glutathione-dependent mechanism catalyzed by glutaredoxin, protein disulfide isomerase, and omega class glutathione transferase or by nicotinamide adenine dinucleotide phosphate (NADPH)-dependent mechanisms including reduction catalyzed by 3-$\alpha$-hydroxysteroid dehydrogenase.[3] DHAR activity was previously reported to be relatively higher in liver, adrenals, jejunum, ileum, colon, and testis, but lower in kidney, lung, thyroid, heart, and skeletal muscle.[21] Thus, our results suggest that the ratio of DHA to total AA might depend on DHAR activity in addition to ROS oxidation in tissues.

The superoxide anion radical is generated by the mitochondrial electron transport chain and in the enzymatic reaction that is catalyzed by NADPH oxidase. The reactivity and toxicity of the superoxide anion radical are reduced by the activity of superoxide dismutase (SOD), which catalyzes superoxide anion radical dismutation to hydrogen peroxide.[22] Hydrogen peroxide is relatively stable and thus can act as a signal molecule. Although glutathione peroxidase (GPX) and catalase convert hydrogen peroxide to water and oxygen, the Fenton reaction with excess hydrogen peroxide and $Fe^{2+}$ promote the production of the hydroxyl radical, which is extremely reactive and toxic. Peroxynitrite is generated from the reaction of the superoxide anion radical and nitric oxide produced by nitric oxide synthase and then converts into the hydroxyl radical and nitrogen dioxide radical. Accurate measurement of ROS in living tissues and animals is difficult because ROS are highly reactive and therefore have an extremely short life span. In our previous study, we used a real-time imaging system with lucigenin as a chemiluminescent probe to detect the superoxide anion radical,[9] although this approach is applicable only in the brain. Thus, for simple detection of ROS in a variety of tissues, we used tissue homogenates and fluorescein carboxy-$H_2$DCFDA to react with various ROS. Although the type of ROS generated during incubation of tissue homogenates was unclear, it is likely that superoxide anion radicals are generated first, and subsequently a series of ROS is produced. Therefore, this assay would be suitable for evaluating the antioxidant activity of foods that contain a wide variety of antioxidants.

AA can scavenge a broad spectrum of free radicals such as superoxide anion radical, hydroxyl radical, nitrogen dioxide radical, and carbonate.[22] A noteworthy finding of the present study is that compared to AA(+) KO mice, AA(−) KO mice exhibited much higher ROS levels in the brain, heart, lung, testis, soleus muscle, plantaris muscle, stomach, small intestine, large intestine, pancreas, and kidney (although not in the liver) with various levels for each tissue (Figure 2 and Figure S2 in the Supporting Information). Many previous studies have evaluated animal models that lack the capacity to synthesize AA. Harrison et al. reported that $F_4$-neuroprostanes, a brain-specific marker of lipid peroxidation, and malondialdehyde were elevated in the cortex and cerebellum of mice lacking Gulo that received low levels of AA.[23,24] AA-deficient Osteogenic Disorder Shionogi (ODS) rats were reported to exhibit increased lipid hydroperoxide levels in the brain, elevated thiobarbituric acid reactive substances (TBARS), and GPX activity in the heart and decreased amounts of glutathione in the plasma and liver.[25] TBARS levels were also increased in the plasma and liver of ODS rats, and lipid peroxide concentrations in plasma LDL and liver

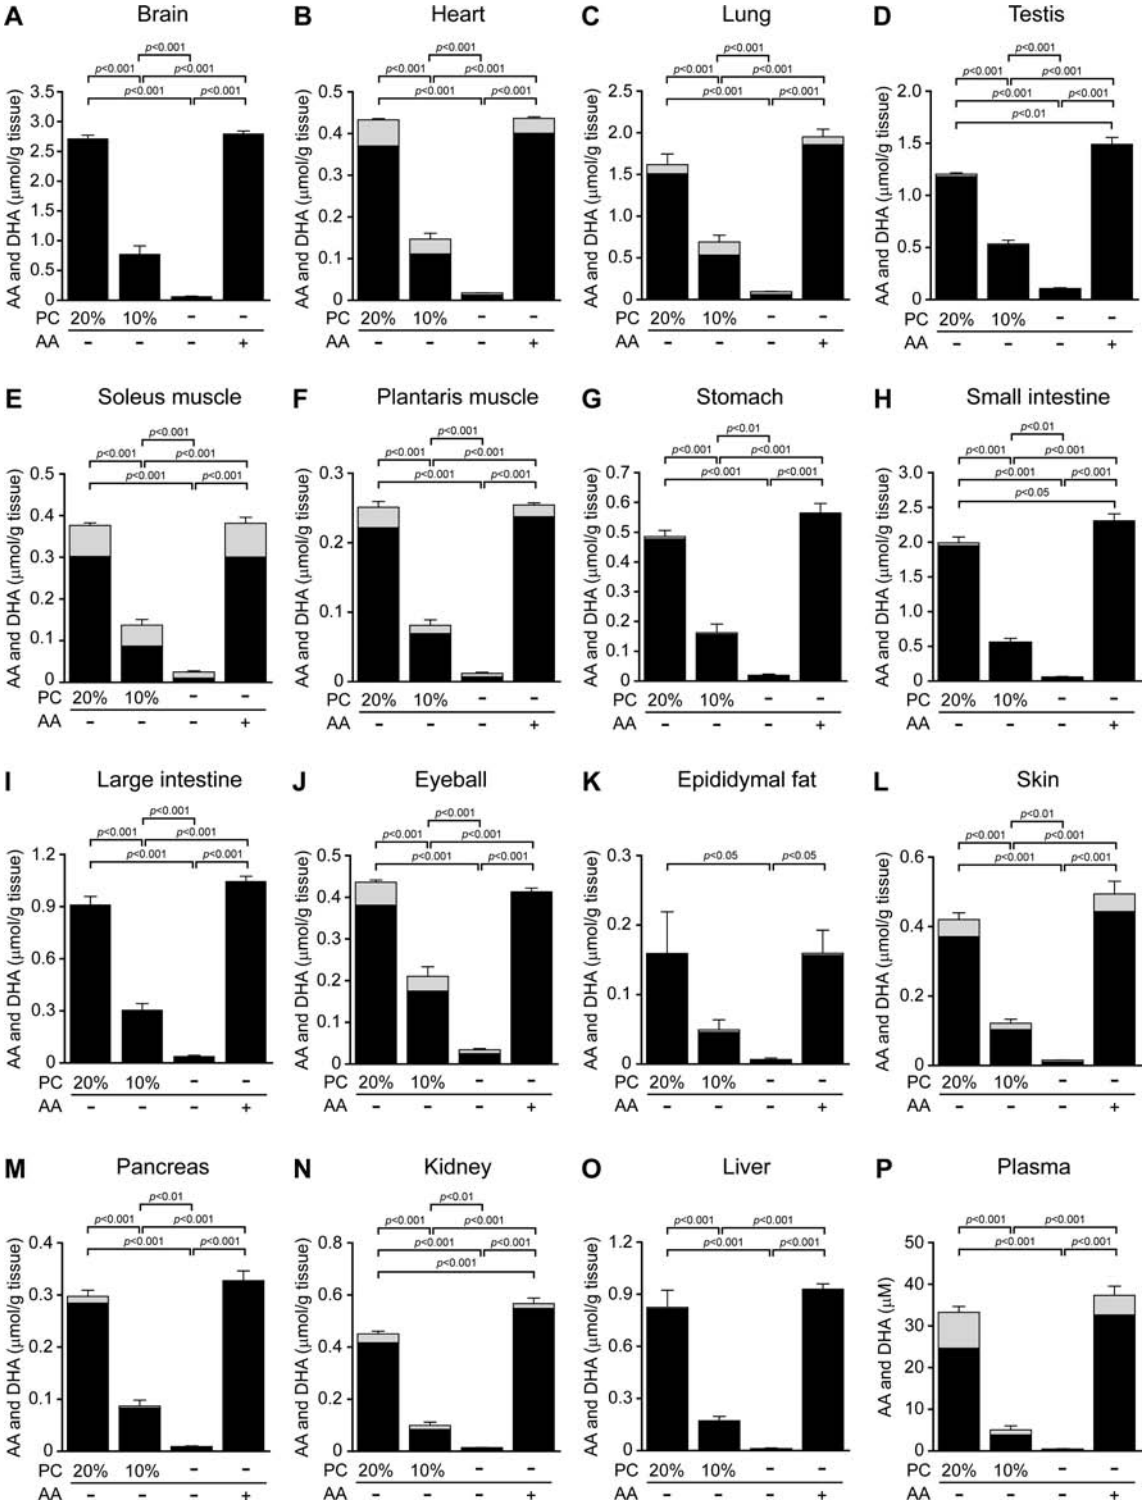

**Figure 4.** Ascorbic acid (AA) and dehydroascorbic acid (DHA) levels in SMP30/GNL KO mice fed potato chip (PC) diets for 7 weeks: AA (black bars) and DHA (gray bars) concentrations in (A) brain, (B) heart, (C) lung, (D) testis, (E) soleus muscle, (F) plantaris muscle, (G) stomach, (H) small intestine, (I) large intestine, (J) eyeball, (K) epididymal fat, (L) skin, (M) pancreas, (N) kidney, (O) liver, and (P) plasma of 20% PC, 10% PC, AA(−), and AA(+) groups from SMP30/GNL KO mice, that is, mice fed a 20% PC diet and AA-free water, a 10% PC diet and AA-free water, an AA-free diet and water, and an AA-free diet and 1.5 g/L AA water, respectively, for 7 weeks after weaning at 4 weeks of age. Values are given as means ± SEM (AA plus DHA) of five animals.

were elevated in animals fed an AA-free diet.[26] Lykkesfeldt et al. reported that guinea pigs 3 weeks after weaning showed decreases in tocopherols and glutathione as well as decreased SOD activity and an increase in protein oxidation in the liver. They also observed an increase in lipid and DNA oxidation but a decrease in protein oxidation in the brain.[27] On the other hand, the sodium-dependent vitamin C transporter (SVCT) 2 transgenic mouse showed that despite having increased AA levels

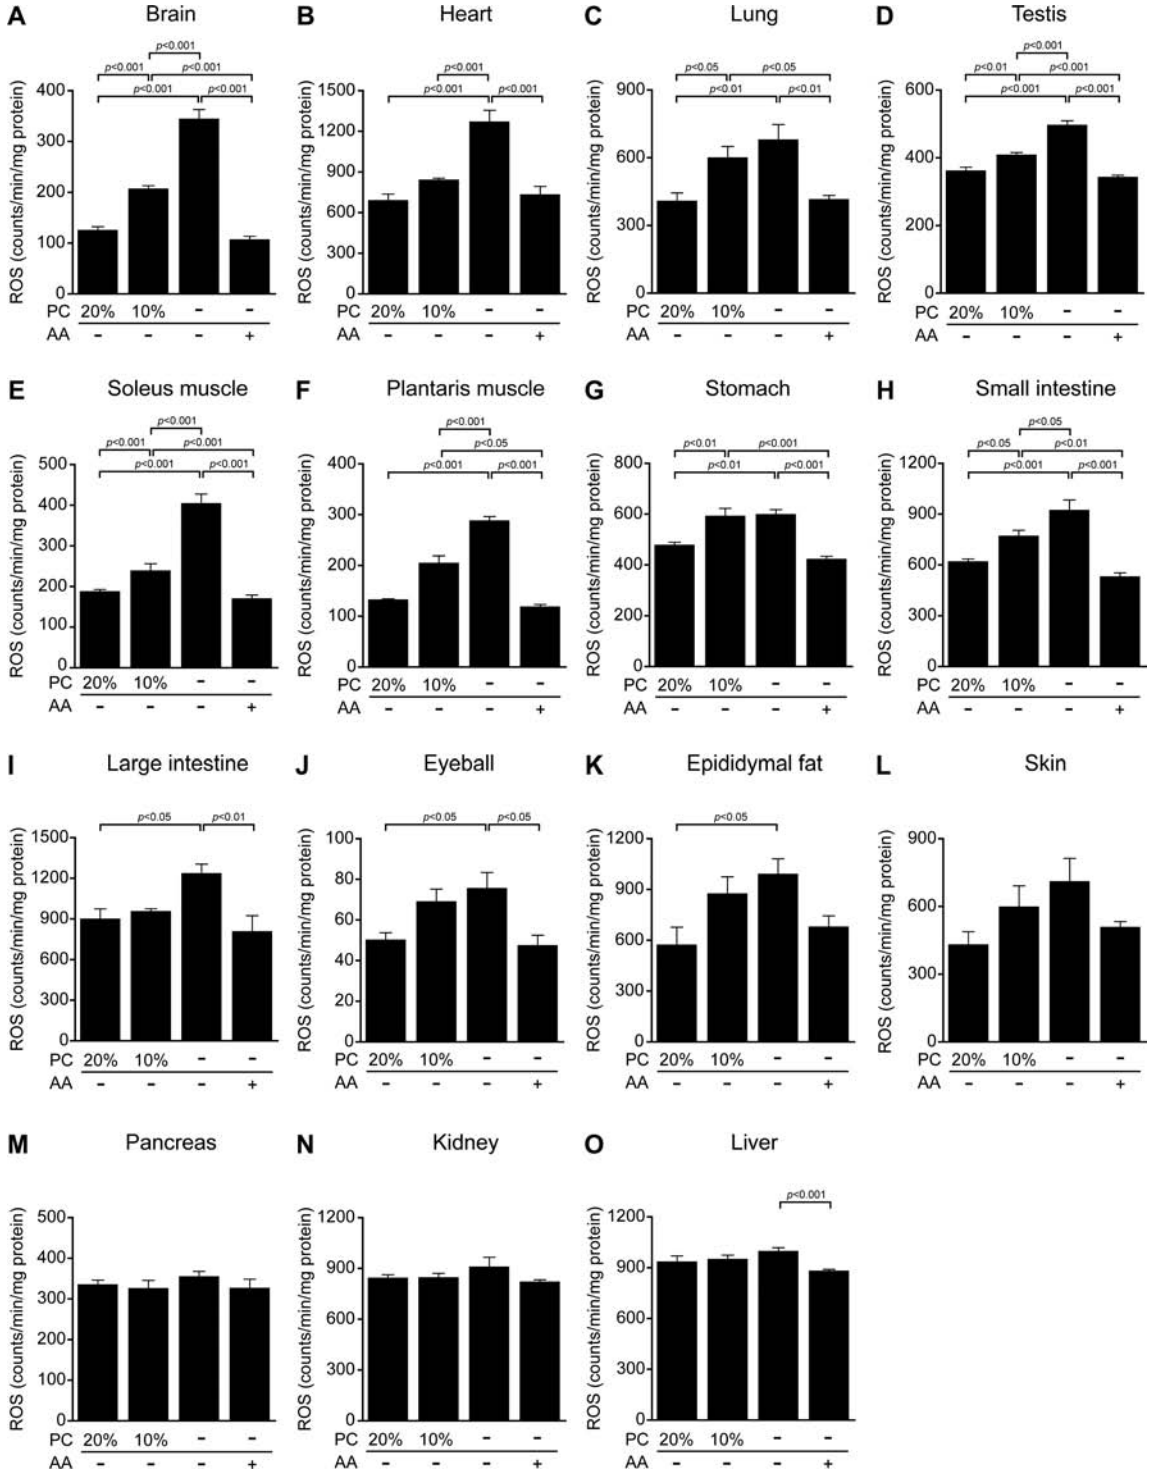

**Figure 5.** Reactive oxygen species (ROS) levels in SMP30/GNL KO mice fed potato chip (PC) diets for 7 weeks: ROS in (A) brain, (B) heart, (C) lung, (D) testis, (E) soleus muscle, (F) plantaris muscle, (G) stomach, (H) small intestine, (I) large intestine, (J) eyeball, (K) epididymal fat, (L) skin, (M) pancreas, (N) kidney, and (O) liver of 20% PC, 10% PC, AA(−), and AA(+) groups from SMP30/GNL KO mice, tht is, mice fed a 20% PC diet and AA-free water, a 10% PC diet and an AA-free water, an AA-free diet and water, and an AA-free diet and 1.5 g/L AA water, respectively, for 7 weeks after weaning at 4 weeks of age. Values are given as means ± SEM of five animals. AA, ascorbic acid.

in the cortex, spleen, kidney, heart, and lung, TBARS levels were not altered.[28] We previously reported that AA-depleted SMP30/GNL KO mice showed an increase in superoxide anion radical levels, although SOD activity was not altered in the brain.[9] In lung tissue of AA-depleted SMP30/GNL KO mice there were increased ROS and TBARS levels, but no alteration of GPX activity was observed.[10] Taken together, an AA deficiency is likely to have a different influence on ROS metabolism and oxidative stress in tissues. Because we do not presently have an explanation for the observed increase in ROS in AA-depleted SMP30/GNL KO mice, further work will be required to elucidate the molecular mechanisms involved in regulating oxidative stress markers such

dx.doi.org/10.1021/jf502587j | J. Agric. Food Chem. 2014, 62, 9286−9295

as lipid peroxidation, protein oxidation, and DNA oxidation, as well as the activity of antioxidants and antioxidative enzyme levels that could be responsible for this increase in ROS.

To our knowledge, no paper describes the bioavailability of AA from PC in animal tissues. Our data showed that the total AA levels in tissues such as the brain, heart, lung, soleus muscle, plantaris muscle, stomach large intestine, eyeball, epididymal fat, skin, pancreas, liver, and plasma of the 20% PC diet group were similar to those of the AA(+) KO group, whereas levels differed in the testis, small intestine, and kidney (Figure 4). The AA contents of 20 and 10% PC diets used in this experiment were 13.6 and 6.0 mg/100 g, respectively. The average AA intake in the 20 and 10% PC groups of SMP30/GNL KO mice was calculated using the food intake values for each 3.5 g/day/mouse to be 0.47 and 0.21 mg/day/mouse, respectively. Because AA(+) KO mice consumed 3.7 mL/day/mouse of 1.5 g/L AA water and thus AA intake was calculated to be 5.5 mg/day/mouse, the AA intakes of the 20 and 10% PC groups were only 8.6 and 3.7%, respectively, of AA(+) KO. SVCTs have high affinity and specificity and are capable of generating a steep AA concentration gradient. Despite small amounts of oral AA intake, the total tissue AA can therefore be maintained at a subsaturating concentration in the 20% PC groups. In contrast, the total tissue AA concentration showed tissue specificity in the 10% PC groups. SVCT1 having a low affinity for AA is known to be abundantly expressed in the liver and kidney,[29] which might be the reason why the ratio of total AA levels in the 10% PC group compared to AA(+) KO mice was lower in the kidney and liver (<20%).

An additional notable finding is that animals fed the 20% PC diet had completely reduced ROS levels that were similar to the AA(+) group in the brain, heart, lung, testis, soleus muscle, plantaris muscle, stomach, small intestine, large intestine, eyeball, and epididymal fat tissues (Figure 5). However, testing the ROS-suppressing effect of PC in the pancreas, kidney, and liver could not be performed, because there were no marked differences in ROS levels in these tissues between the AA(−) KO and AA(+) KO groups at 7 weeks. In the 10% PC group, ROS levels were decreased in the brain, heart, testis, soleus muscle, plantaris muscle, and small intestine, and large intestine tissues, but were unchanged in the lung, stomach, eyeball, and epididymal fat tissues. This tissue specificity may be attributed to the balance between ROS generation and antioxidant system that includes AA and other antioxidants. Many studies have shown that, other than AA, potato tubers contain antioxidants such as carotenoids and a wide variety of polyphenols such as chlorogenic acid, caffeic acid, gallic acid, protocatechuic acid, and quercetin and, therefore, exhibit significant antioxidant activity as measured by in vitro radical scavenging assays such as the ORAC.[30−32] Kaspar et al. also reported that consumption of pigmented potatoes containing high concentrations of antioxidants decreased plasma DNA oxidative damage and inflammation associated with IL-6 production in healthy adult human males.[33] Although there are no reports concerning the antioxidant activity of PC in animal tissues, these insights suggest that antioxidant nutrients included in PC also exhibit antioxidant activity in mouse tissues.

In contrast to the results of the present animal experiment, the ORAC values were significantly lower in the 20 and 10% PC diet compared to CL-2 (Figure S3 in the Supporting Information), suggesting that the ORAC value does not necessarily represent the antioxidant activity in the animal. Thus, an antioxidant activity assay using SMP30/GNL KO mice could be superior in that it reflects the bioavailability of dietary antioxidants in its targeted tissue.

Further studies will be required to define the exact molecular mechanism of the increase in ROS in AA-depleted SMP30/GNL KO mice and the antioxidant activity of PC in an animal model. However, our results suggest that PC intake increases total AA and enhances ROS scavenging activity in tissues of SMP30/GNL KO mice and that SMP30/GNL KO mice are a promising model for evaluating the antioxidant activity of various foods.

tumor growth and antiatherosclerotic and antimicrobial activities.[15] *Ganoderma atrum* is a member of the most representative medical mushrooms of *Ganodermataceae*. The polysaccharide is the major bioactive substance in *G. atrum*.[16] For our unremitting pursuit of novel agents with antitumor activities, we reorganized and qualified the structure of PSG-1, which is a polysaccharide of *G. atrum*. The purity of PSG-1 is more than 99.8%. The polysaccharide is composed of glucose, mannose, galactose, and galacturonic acid with molar ratio of 4.91:1:1.28:0.71.[17] Furthermore, PSG-1 comprises a backbone of 1,3-linked and 1,6-linked $\beta$-Glcp residues substituted at O-3 and O-6 positions as the branch points.[18,19] Our previous studies suggested that PSG-1 had potent antioxidant activity, even stronger than that of *Ganoderma lucidium*.[17,20] PSG-1 was also shown to induce apoptosis in S180 xenografts in vivo.[21] Recently, we verified that PSG-1 possessed potent antitumor activity by inducing apoptosis via mitochondrial pathways and enhanced the antitumor effect via improving immune system functions through the TLR4-mediated NF-$\kappa$B and MAPK signaling pathway.[22,23]

Although PSG-1 has been crowned as one of the most active antineoplastic agents in the past decades, the exact molecular mechanisms that integrate these events have remained largely unclear. Therefore, research and development of PSG-1 as a novel agent with antitumor activity are of great importance. This study was designed to evaluate and characterize the antitumor activity and potential molecular mechanism of PSG-1 in CT26-bearing mice. The data have verified the excellent antitumor effect of PSG-1 in the CT26-bearing mice model, in which enhanced tumor growth inhibition accompanied by increased apoptosis as compared with control group was verified. We further demonstrated that such action may be associated with induction of apoptosis via the cAMP/PKA signaling pathway and downregulation of the PKC pathway, as well as improving the host immune system. These findings would pave the way for novel therapeutic approaches to treat CRC patients and open up new possibilities for the cancer control.

## MATERALS AND METHODS

**Materials.** PSG-1 was extracted and purified following our previously published method.[18] RPMI 1640 and fetal bovine serum (FBS) were purchased from Hyclone (Logan, UT). Penicillin and streptomycin were purchased from Life Technologies, Inc. (Gaithersburg, MD). Antibodies for PKA and PKC were purchased from Abcam (Cambridge, MA). Anti-$\beta$-actin, goat anti-rabbit IgG-conjugated horseradish peroxidase (HRP) and goat anti-mouse IgG-conjugated HRP were purchased from ZSGB-Bio (Beijing, China). 5-Fluorouracil was purchased from Sigma-Aldrich (St. Louis, MO). PKA, PKC, cAMP, and cGMP assay kits were obtained from IBL (Hamburg, Germany). IL-1$\beta$ and TNF-$\alpha$ ELISA kits were purchased from SenXiong Biotechnology (Shanghai, China). Cell culture products were obtained from Life Technologies (Paisley, Scotland).

**Cell Line and Animals.** CT26 WT mouse colon cell line was purchased from Type Culture Collection of Chinese Academy of Sciences, Shanghai, China. BALB/c mice (female, 4−6-weeks old, weighted 20.0 ± 2.0 g) were purchased from Beijing HFK Biotechnology Co. [Beijing, China; quality certificate number SCXK (jing) 2009-0004]. The animals were maintained in accordance with the Guide for the Care and Use of Laboratory Animals (NRC 2011), and all procedures were approved by Nanchang University Animal Ethnics Committee.

**Cell Viability Assay.** The effect of PSG-1 on the viability of CT26 cells was determined by MTT assay. CT26 cells were seeded in a flat-bottomed 96-well plate ($2.0 \times 10^4$ cells/mL) and treated with PSG-1 (20−320 $\mu$g/mL). Controls were exposed to culture medium without PSG-1. After incubation for 48 h, 20 $\mu$L of MTT solution (5 mg/mL) was added to each well, and the cells were incubated at 37 °C for 4 h. Crystalline formazan was dissolved in 150 $\mu$L of dimethyl suroxide (DMSO), and the absorbance at 490 nm was measured immediately on a microplate reader (Thermo, Shanghai, China).

**Animal Experiments.** The mice were injected hypodermically with $1 \times 10^7$ cells/mL of CT26 in 0.2 mL at the right hind groin. The xenograft tumor-bearing mice were divided randomly into five groups (eight mice in each group). The mice were treated with PSG-1 via gastric tube at doses of 50, 100, and 200 mg/kg body weight (BW) for 2 weeks. The negative control group was treated with 0.9% saline, and the positive control received 5-Fu (20 mg/kg BW). At the end of the experiments, mice were weighed and sacrificed by cervical dislocation, and then the solid tumors, thymus, and spleen were harvested. Thymus and spleen indexes were expressed as the thymus and spleen weight relative to body weight. The rate of inhibition (IR) was calculated according to the following formula:

$$\begin{aligned} \mathrm{IR} = {} & (\text{the average tumor weight of the treated group}) \\ & - (\text{the average tumor weight of the control group}) \\ & / (\text{the average tumor weight of the control group}) \times 100\% \end{aligned}$$

Blood samples obtained from retrobulbar venous plexus of each group of mice were centrifuged (12 000 rpm) for 10 min at 4 °C to separate serum and blood cells. The serum was stored at −80 °C for determination of cytokines (IL-2, IFN-$\gamma$, and TNF-$\alpha$). The serum cytokine levels were determined using ELISA kits (R&D Systems, Minneapolis, MN).

**Preparation of Murine CT26 Cells in the Tumor of CT26-Bearing Mice.** The tumor was isolated using sterile tissue dissection techniques from tumor-bearing mice and transferred to PBS. The tumor tissues were subsequently minced. The cell suspensions were filtered through a Steriflip unit. Then the cells were washed twice in PBS and further purified using gradient centrifugation. After centrifugation, the cells were resuspended in RPMI 1640 medium with 10% FBS ($2 \times 10^6$/mL).

**Analysis of Cell Apoptosis.** To define the apoptosis of tumor cells, CT26 cells were strained with Annexin V-FITC/PI detection kit (KeyGen, Nanjing, China) according to the manufacturer's instructions. Briefly, the CT26 cells from tumor-bearing mice were harvested and resuspended in 500 $\mu$L of binding buffer containing the Annexin V-FITC and PI fluorescence dyes at 37 °C for 15 min in the dark. The strained cells were washed twice with PBS and resuspended. The fluorescence was detected by FACSCalibur (Becton Dickinson) in the FL1-H and FL2-H channels.

**Determination of cAMP and cGMP Concentrations.** The intracellular cAMP and cGMP levels were determined by using the cAMP and cGMP ELISA kits (Enzo Life Sciences). First, the CT26 cells ($2 \times 10^5$ cells/mL) were prepared as described above and then resuspended in lysis reagent provided in the kit, followed by centrifugation at 12 000$g$ for 30 min at 4 °C. The supernatant was immediately collected and quantified by the cAMP or cGMP kit. Each sample and standard value was derived from triplicate measurements.

**Measurement of DAG and Adenylyl Cyclase (AC) Contents.** The DAG and AC contents were determined by using the DAG and AC ELISA kits (Antibodies-Online, Atlanta, GA). A total of $10^6$ CT26 cells from tumor-bearing mice were washed with PBS and harvested by centrifugation. The cells were lysed by the lysis reagent provided in the kit. The supernatant was collected and used for the determination of intracellular DAG and AC contents.

**PKA and PKC Activity Assays.** The CT26 cells from mice model were harvested as described above. The activities of intracellular PKC and PKA were determined by PKC and PKA kits (Enzo Life Sciences International), respectively. In brief, CT26 cells were scraped into $Ca^{2+}$-free PBS supplemented with 2.5 mM of EDTA or EGTA and then pelleted by a brief centrifugation. Cells were lysed in an ice-cold homogenization buffer and then centrifuged at 15 000$g$ for 30 min at 4 °C. The cell samples were added to the appropriate wells. The reaction was then stopped with acid-stop solution, and the absorbance was measured at 450 nm in a microplate reader (Thermo, Shanghai, China).

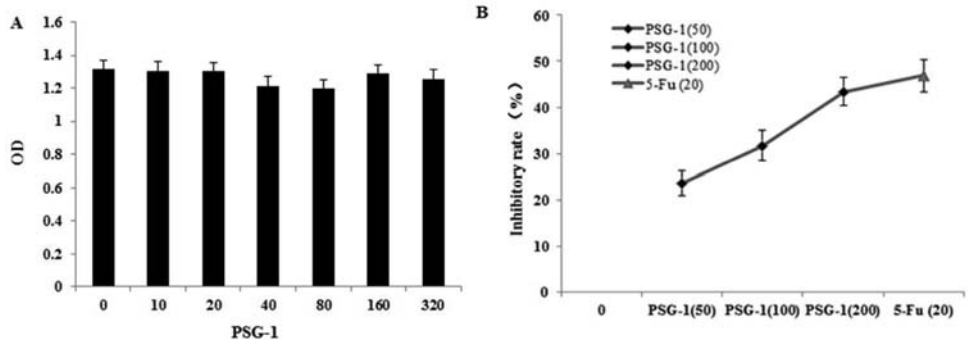

**Figure 1.** (A) Effect of PSG-1 on the proliferation of CT26 cells. CT26 cells were seeded into 96-well culture plates and treated with the indicated concentrations of PSG-1 for 48 h. Proliferation of CT26 was evaluated using the MTT method. (B) Antitumor effect of PSG-1 on the proliferation of tumor cells in CT26-bearing mice.

**Western Blot Analysis.** Total protein (15 $\mu$g) from CT26 cells was separated by SDS−PAGE and was transferred to nitrocellulose membranes. The membranes were blocked with Tris-buffered saline containing 5% fat-free dried milk for 2 h at room temperature and further incubated 16 h at 4 °C with anti-PKA or anti-PKC antibodies (Cell Signaling Technology, Danvers, MA). After washing three times with TBS-0.05% Tween 20, reactive bands were incubated with horseradish peroxidase-conjugated secondary antibody for 1 h at room temperature. The membranes were washed again, and the immunoreactive protein was visualized using enhanced chemiluminescent reagent (Beytin, Nanjing, China). The experiments were performed in triplicate, and representative results are shown.

**Neutral Red Phagocytosis Assay of Peritoneal Macrophages.** Macrophages were obtained from tumor-bearing mice peritoneal exudate cells (PECs). PECs were washed with PBS and resuspended in RPMI-1640 medium. Then PECs were seeded in a 96-well plate ($2 \times 10^5$ cells per well) and incubated at 37 °C, 5% $CO_2$ for 4 h in a humidified atmosphere to allow peritoneal macrophages to adhere. The supernatants were discarded, 100 $\mu$L 0.075% neutral red was added, and the mixture incubated for another 1 h. Cells were washed with PBS three times and incubated with cell lysis buffer (1 M acetic acid: ethanol = 1:1) overnight. The result was recorded with a microplate reader, using a test wavelength of 540 nm.

**Determination of Proliferation of Lymphocyte of CT26-Bearing Mice.** CT26-bearing mice were killed, and the spleens collected under aseptic condition were chopped into small pieces and filtered over a fine steel mesh. Lymphocytes were resuspended in lysis buffer to remove erythrocytes and then resuspended in 10% FBS RPMI-1640 ($2 \times 10^6$ cells per well) medium. The cells were planted into 96-well plates with or without ConA 1 mg/L or LPS 5 mg/L and incubated for 48 h. Cell proliferation was measured on the basis of the MTT method.

**Statistical Analysis.** All data were expressed as means ± SEM of at least three experiments. ANOVA was used to assess the statistical significance of the differences. Differences with $P$ values <0.05 were considered statistically significant.

## RESULTS

**PSG-1 Could Not Inhibit the Proliferation of CT26 Cells.** In order to examine whether PSG-1 possessed an antiproliferation effect on CT26 cells, we evaluated the proliferation of CT26 cells exposed to PSG-1. CT26 cells growing in 96-well plate were maintained in medium containing increasing concentrations of PSG-1 for 48 h. As seen in Figure 1A, PSG-1 at concentration 10−320 $\mu$g/mL showed little impact on the growth of CT26 cells and did not present any sign of toxicity in CT26 cells.

**Antitumor Effect of PSG-1 in CT26-Bearing Mice.** As shown in Figure 1B, the mice treated with PSG-1 had a marked reduction in the tumor volume when compared to the control group. The tumor inhibition of mice in the PSG-1 group was quite effective, and the inhibition rate was 44.68% at 200 mg/kg. It was also found that there was no significant difference between high dose PSG-1 (200 mg/kg) and 5-Fu treated group.

**Apoptosis in CT26-Bearing Mice.** Flow cytometry assays showed marked changes in cell profiles after treatment with 50, 100, and 200 mg/kg PSG-1. The apoptotic rates ranged from 1.68% to 41.04%; the 200 mg/kg PSG-1 group was the highest among them, indicating that administration of PSG-1 induced apoptosis (Figure 2A−E).

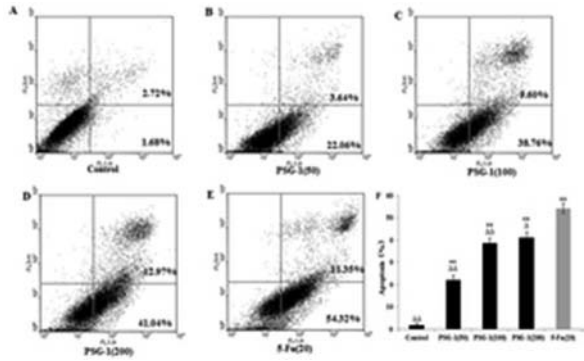

**Figure 2.** (A−E) Annexin V-FITC/PI double-staining assay of CT26 cells from the tumor-bearing mice. (F) Bar graph representing the percentage of CT26 cell apoptosis. Each value represents the mean of three experiments. $^{**}P < 0.01$ vs control group, $^{\Delta}P < 0.05$, $^{\Delta\Delta}P < 0.01$ vs 5-Fu group.

**Distinct Changes of Intracellular cAMP and cGMP Concentrations in Tumor.** Previous studies have indicated that the cAMP signaling pathway and cGMP mediator are known to be of paramount importance in PSG-1-induced apoptosis of S180 cells. To investigate the correlation between intracellular cAMP and cGMP levels and the percentage of apoptosis, we measured, for the first time, the intracellular cAMP and cGMP contents in CT26 cells from tumor-bearing mice treated with different doses of PSG-1. Significant improvement in the intracellular cAMP concentration was observed. In contrast, the intracellular cGMP level was decreased in the CT26 cells.

**Effect of PSG-1 Treatment on AC and DAG Contents.** Since the intracellular cAMP level is mainly regulated by the AC isoform, the activity of the AC system might be related to the alteration of cAMP levels triggered by PSG-1. DAG is a physiological activator of PKC. The production of DAG in the

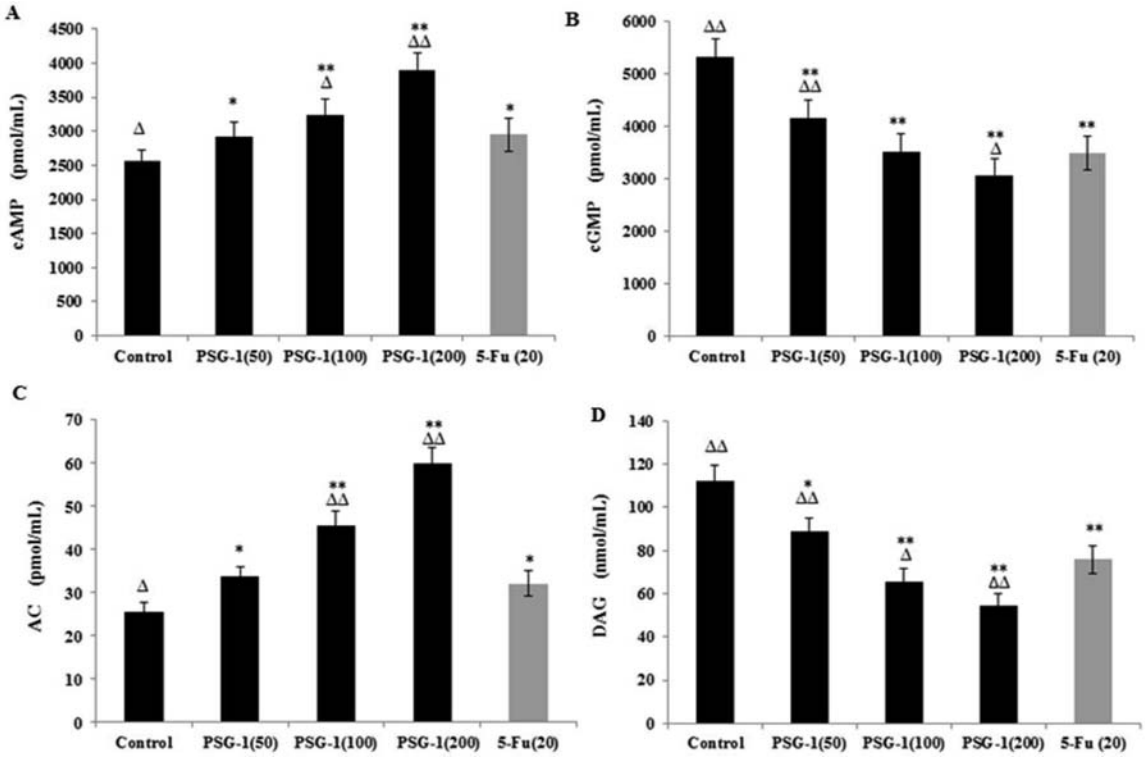

**Figure 3.** Effect of PSG-1 on intracellular (A) cAMP, (B) cGMP, (C) AC, and (D) DAG production in the tumor. The production was measured according to ELISA kit instructions. Bar graphs show mean ± SEM of three independent experiments performed. *$P$ < 0.05, **$P$ < 0.01 vs control group; $^{\Delta}P$ < 0.05, $^{\Delta\Delta}P$ < 0.01 vs 5-Fu group.

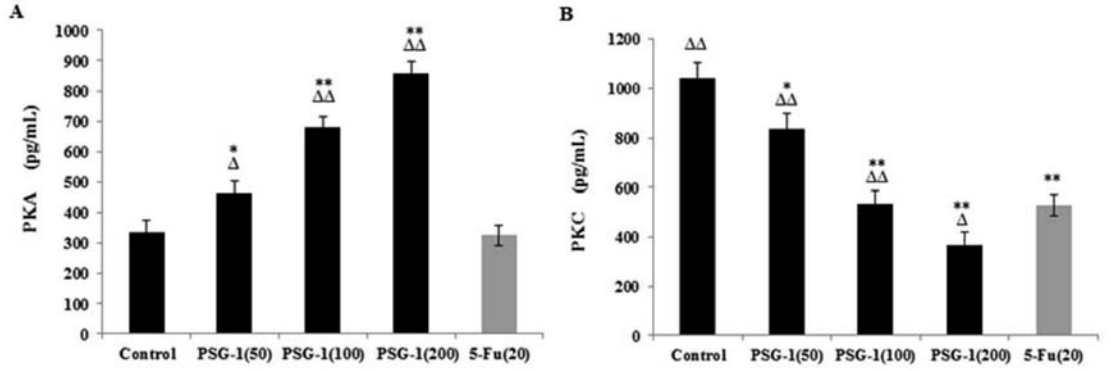

**Figure 4.** Effect of PSG-1 on the levels of (A) PKA and (B) PKC in tumor cells from tumor-bearing mice. *$P$ < 0.05, **$P$ < 0.01 vs control group; $^{\Delta}P$ < 0.05, $^{\Delta\Delta}P$ < 0.01 vs 5-Fu group.

membrane facilitates translocation of PKC from the cytosol to the plasma membrane. We thus determined the levels of intracellular AC and DAG. As shown in Figure 3C,D, a great change in the activity of AC was observed. The AC activity was enhanced along with the increase of the dose. However, the level of DAG was dramatically downregulated in the PSG-1 groups.

**Effect of PSG-1 on PKA and PKC in Tumor during PSG-1-Induced Apoptosis.** PKA, the cAMP-dependent kinase, is a central component of the signal transduction pathway. The activation of PKA is one of the primary elements in the cAMP signal transduction downstream cascade. As the crucial step toward understanding the mechanism of PSG-1-induced apoptosis, we thus measured intracellular PKA activity in the CT26 cells from tumor-bearing mice. It was found that in parallel to the significant increase of cAMP level, the activity of PKA was increased by PSG-1 treatment (Figure 4A), implying the importance of the cAMP-PKA pathway in PSG-1-induced apoptosis of CT26 cells.

PKC is transiently activated by DAG. It has been reported that PKA and PKC are critical signaling mediators in regulation of cell apoptosis. In the present study, we found that the intracellular PKC activity of the PSG-1-treated group was decreased significantly (Figure 4B).

To further confirm this potential role of PKA and PKC, we conducted Western blot experiments to examine the expression of PKA and PKC proteins. As shown in Figure 5, PSG-1 caused a marked increase in the expression of PKA protein. In contrast, the PKC level was decreased in the PSG-1-treated groups as compared to the control group.

**Immune Function of PSG-1 in CT26-Bearing Mice.** As shown in Table 1, compared with the control group, the thymus

dx.doi.org/10.1021/jf503250d | J. Agric. Food Chem. 2014, 62, 9296−9304

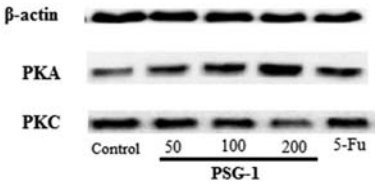

**Figure 5.** Expressions of PKA and PKC in tumor-bearing mice by Western blot. Total cellular proteins were separated by SDS−PAGE and analyzed by Western blot with specific antibodies.

and spleen indexes of tumor-bearing mice treated with 5-Fu at the dose of 20 mg/kg BW decreased significantly. Treatment with PSG-1 at different doses produced a marked and dose-dependent increase in both spleen and thymus indexes ($P < 0.05$), especially in the groups with high and middle doses. This finding suggested that PSG-1 enhanced the immunization of tumor-bearing mice.

**Effect of PSG-1 on Serum Cytokine Levels in CT26-Bearing Mice.** To further detect the immunomodulating effect of PSG-1, the levels of cytokines in serum from tumor-bearing mice were investigated. The treatment of PSG-1 markedly upregulated the levels of IL-2, TNF-$\alpha$, and IFN-$\gamma$ in serum when compared with control group ($P < 0.05$, Table 2). However, the levels of IL-2, TNF-$\alpha$, and IFN-$\gamma$ were slightly decreased by 5-Fu treatment during the experimental period, suggesting its immunosuppression effect in tumor-bearing animals. Therefore, PSG-1 is beneficial to the immune system in tumor-bearing mice.

**Effect of PSG-1 on Spleen Lymphocyte Proliferation in CT26-Bearing Mice.** To elucidate the mechanism of immunoregulatory activity of PSG-1, the effect on spleen lymphocyte proliferation was examined. Compared with the control group, proliferation of spleen lymphocyte induced by Con A and LPS was increased significantly in PSG-1-treated CT26-bearing mice. In contrast, 5-Fu administration decreased proliferation of spleen lymphocytes markedly in CT26-bearing mice (Table 3).

**Effect of PSG-1 on Peritoneal Macrophages Phagocytosis in CT26-Bearing Mice.** To verify the effect of PSG-1 on the activation of immune cells, we estimated the phagocytosis of macrophages from each group. As shown in Table 3, PSG-1 (50, 100, and 200 mg/kg) augmented the percentage of phagocytosis of NR by peritoneal macrophages in CT26-bearing mice, compared with the control group. We speculated PSG-1 restored impaired peritoneal macrophages phagocytosis.

## DISCUSSION

The health benefits of mushroom nutraceuticals have been widely reported.[24] Many studies support that *Cordyceps sinensis*, shiitake mushroom, and ganoderma have various biological

dx.doi.org/10.1021/jf503250d | J. Agric. Food Chem. 2014, 62, 9296−9304

activities and pharmacological function.[25,26] Polysaccharides are major contributors to most of the biological activities. Lentinan shows effective antitumor and immunopotentiating activity.[27] Polysaccharides from *Cordyceps gunnii* showed significant antitumor activities against HeLa and HepG2 in vitro.[28] The efficacy of ganoderma as an anticancer and tonic agent has been recognized for thousands of years. The proposed anticancer activity of ganoderma has prompted its use by cancer patients. Wang et al. have reported the effects of the polysaccharide from *G. lucidum* on cancer.[29] Sharing the same genus, *G. atrum* also has similar potent antitumor effects. Our previous studies have found that PSG-1 possessed potent antitumor activity by inducing apoptosis of tumor cells related to activation of host immune response in S180-bearing mice.[22] Many researchers have suggested that PSG-1 might inhibit other types of cancer and be mainly mediated by the specific apoptotic pathway and the host immunological mechanism. So we focused on investigating the molecular mechanism of CT26 tumor growth repression by PSG-1.

In the present study, we first investigated the antitumor activity of PSG-1 in vitro. Unexpectedly, PSG-1-treated CT26 cells did not show any differences in cell viability compared to untreated cells. The above results suggest that PSG-1 did not exert any direct cytotoxic effect on the CT26 cells. However, oral administration of PSG-1 (50, 100, and 200 mg/kg) markedly inhibited the tumor growth in the CT26-bearing mice, indicating that PSG-1 has potent antitumor activity in vivo. Therefore, we can assume that administration of PSG-1 might activate some signaling pathways and the host immune response, preventing tumor growth.

Tumor development and growth are considered a result of the high proliferative capacity of tumor cells. It was reported that apoptosis and its related signaling pathways contributed to the high rate of cell loss in malignant tumors and, moreover, could be a defense against tumor progression.[30] Apoptosis is the process of cell death occurring in various multicellular organisms, and it is well-known to induce characteristic changes of cell morphology, such as membrance blebbing, cell shrinkage, chromatin condensation, and chromosomal DNA fragmentation.[31] It is now well-established that anticancer agents induce apoptosis and that disruption of apoptotic programs can promote tumor initiation, progression, and treatment resistance.[32] Thus, to understand the association between PSG-1 and apoptosis, we assessed its apoptosis-inducing effect on tumor cells in CT26-bearing mice. The results indicated that PSG-1 induced tumor apoptosis in a concentration-dependent manner.

The cAMP/PKA signal transduction is regarded as one of the best-understood biochemical pathways. The rate of cAMP production and degradation is sensitive to a wide range of extracellular and intracellular signals, such that cAMP can directly regulate a variety of cell functions, from metabolism to ion channel activation, cell growth and differentiation, gene expression, and apoptosis.[33] The cAMP/PKA pathway in cancer is started with AC activation, which leads to the formation of cAMP. PKA is activated by the newly minted cAMP and causes reversible phosphorylation of protein substrates that regulate a number of cellular processes.[34] Excessive PKA activity in yeast could trigger mitochondria-dependent apoptosis via a distinct signaling mechanism.[35] Chen et al. reported that upregulation of the cAMP/PKA pathway decreased proliferation, induced differentiation, and led to apoptosis in malignant gliomas.[36] This is consistent with the report of Hanson that the growth of neuroblastoma cells is inhibited by an increase in cAMP.[37] Similar results were obtained in this study. We found that cAMP level was dramatically increased by PSG-1 in a dose-dependent manner. Furthermore, the concentrations of subsequent PKA and upstream AC were found to be upregulated. To provide further evidence, we used a Western blot to analyze the PKA protein expression and found that the expression of PKA protein was markedly increased in a dose-dependent pattern in PSG-1-treated groups. Meanwhile, the important meditator of apoptosis cGMP content was also inhibited. Therefore, we speculated that PSG-1-induced apoptosis may be associated with the cGMP level. These results suggest that upregulation of the cAMP/PKA pathway and cGMP may be involved in the CT26 tumor cell apoptosis and the elicit antitumor effect.

PKC is a family of serine/threonine kinases that is involved in the transduction of signals for cell proliferation and differentiation.[38] The important role of PKC in processes relevant to neoplastic transformation, carcinogenesis, and tumor cell invasion renders it a potentially suitable target for anticancer therapy.[39] Early studies suggested a role for PKC isozymes in tumor promotion. A direct correlation between the ability of individual phorbol esters to promote tumors and activation of PKC has been demonstrated.[40] Increased levels of PKC have been associated with malignant transformation in a number of cell lines, including breast, lung, and gastric carcinomas.[41−43] In colon cancer, PKC $\beta$ II appears to be overexpressed early in the colon carcinogenic process.[44] A decrease in the content of PKC $\alpha$ by antisense or phorbol ester led to apoptosis in many different cell types, such as glioma cells, endothelial cells, and promyelocytic U937 cells.[45−47] Dean et al. have reported that the antisense PKC $\alpha$ oligonucleotides inhibited tumor growth in nude mice bearing implanted human glioblastomas and human bladder, lung, and colon carcinomas.[48] In addition, PKC $\delta$ has been implicated in apoptotic response and cytochrome *c* release.[49,50] Hence, inhibition of PKC may have an impact on the invasive and metastatic potential of malignant cells, resulting in tumor cell apoptosis. In the present study, the results showed that the PKC level was decreased in PSG-1-treated mice. Likewise, an apparent decline in PKC protein expression was also presented by Western blot. It is well-known that when cells are stimulated, PKC is transiently activated by DAG, which is produced in the membrane during the signal-induced turnover of inositol phospholipids.[40] On the basis of the preceding results, we examined the effects of PSG-1 administration on DAG concentration. Our study showed that DAG was consistently downregulated. These results suggest that suppression of the PKC pathway may be implicated in PSG-1-induced apoptosis and the elicit antitumor effect.

The host immune function is another key factor for cancer treatment and recovery. Clinical verification is being obtained that the maximal potential of anticancer treatments is based on exploiting the host's own antitumor defense mechanism.[51] Immunostimulation is a crucial strategy to improve the body's defense mechanism. The antitumor immune response can be divided into specific and nonspecific immunity. The thymus and spleen are two important immune organs. The thymus and spleen indexes were important indexes for nonspecific immunity. The present result showed that the thymus and spleen indexes were markedly increased in CT26-bearing mice treated with PSG-1 compared with the control group. Phagocytes, including neutrophils, monocytes, and macrophages, play essential and important roles in nonspecific immune responses.[52] The phagocytic function of macrophages represents the final and most indispensable step of the immunological defense system.

Activated macrophages are considered to be one of the important components of the host defense against tumor growth, and phagocytosis plays an essential role in building and consolidating immunological defense systems of humans and animals against malignancies.[53] On the other hand, the specific immune response includes humoral immunity and cellular immunity. The humoral defense via antibody response is regulated by B cells and other immune cells involved in antibody production and immunization. Cell-mediated immune defense was mediated specifically by T cells, including nature killer cells. These cells are able to kill autologous cells infected with tumor cells and pathogens. In this study, we found that PSG-1 increased macrophage phagocytosis and spleen lymphocyte proliferation in the CT26-bearing mice, while the positive control 5-Fu with high tumor inhibitory rate had an immunosuppressive effect. These results suggested that PSG-1 could enhance specific and nonspecific immunity in CT26-bearing mice. That is to say, PSG-1 has potent tumor therapeutic activity by improving the immune system.

Cytokines are low molecular weight biologically active proteins and peptides that are involved in the generation and control of immunological responses. Many polysaccharides could modulate and stimulate cytokines production.[54] They can bind to specific cell surface receptors directly and affect cell proliferation, differentiation, and function. Released to the blood, they act on like hormones and affect different tissues and organs, often distant from the original tumor. Cytokines have an effect on immune processes, including antitumor defense and acute phase reaction. They regulate both cellular and humoral responses.[55] IL-2 is synthesized when antigen and mitogen are stimulated by T-cells. It is the most crucial cytokine in adjusting the activation, proliferation, and differentiation of lymphocytes. IL-2 could augment cytotoxicites of T cells and NK cells and in vivo generation of lymphokine-activated killer cells, which exhibit high cytolytic activities against autologous tumor cells. So IL-2 plays an important role in the antitumor immune adjustment. Tumor necrosis factor (TNF-$\alpha$) is a cytokine possessing antitumor and immunomodulatory properties. TNF-$\alpha$ was reported to increase the immunogenicity of tumor cells due to the enhanced expression of MHC antigens and thus to intensify the antitumor immune response.[56] Hence, TNF-$\alpha$ has been recognized as an important host defense cytokine that affects tumor cells. In addition, IFN-$\gamma$ has a variety of function, e.g., inhibition of viral replication, antiproliferation effect in tumor cells, and activation of immune cells.[57] It plays important roles in depressing tumor cell growth and inducing apoptosis of tumor cells.[58] In this study, the serum concentrations of TNF-$\alpha$, IFN-$\gamma$, and IL-2 apparently increased in PSG-1-treated groups. They are potential endogenous products in mediating the effect of PSG-1 on the immune system in vivo. The increase may also explain the antitumor properties of PSG-1. Hence, the host antitumor immune responses are associated with the antitumor mechanism of PSG-1.

In summary, our study has demonstrated that PSG-1 inhibited the tumor growth and ameliorated the immune response in tumor-bearing mice. Further studies showed that its mechanism of action might be implicated in initiating apoptosis. Our results showed that PSG-1 induced the apoptosis of CT26 tumor cells; stimulated AC, PKA, and cAMP production; and reduced the PKC and DAG levels in CT26 cells from tumor-bearing mice. Additionally, the administration of PSG-1 notably elevated the spleen and thymus indexes and increased macrophage phagocytosis and spleen lymphocyte proliferation. The serum concentrations of TNF-$\alpha$, IFN-$\gamma$, and IL-2 were also markedly increased. Hence, we speculate that the antitumor mechanism of PSG-1 may be related to the induction of CT26 cell apoptosis throughthe cAMP-PKA signaling pathway and downregulation of the PKC signal pathway, as well as the activation of the immune response of the host. Therefore, PSG-1 may be considered as an efficacious adjacent immunopotentiating therapy in the treatment of tumors. Further clinical trials are required to confirm the effectiveness of this novel polysaccharide. It may provide new threads of hope for cancer treatment.

## MATERIALS AND METHODS

**Standards and Reagents.** Recombinant Acc-royalisin (RAcc-royalisn) as standard peptide was expressed in *Eschericha coli* strain BL21 (DE3) containing RAcc-royalisin expression vector, pGEM-4T-2-Acc-royalisin, purified, and freeze-dried according to the method previously described.[12] Bovine serum albumin (BSA), goat antirabbit IgG-linked horseradish peroxidase (IgG/HRP), and diaminobenzidine (DAB) were purchased from Boster Biological Technology, Ltd. (Wuhan, China). Bradford kit was purchased from Najing Jiancheng Bioengineering Institute (Nangjing, China).

**Insects and Bacteria.** The Asian honeybee, *A. cerana cerana*, and the Western honeybee, *A. mellifera*, *Musca domestica*, *Tenebrio molitor*, *Barley pest*, were maintained at the Zhejiang University campus. Fresh royal jelly reserved under −80 °C was provided by Hnagzhou Biyutain Heath Food Corp., Ltd. (Hangzhou, China). Bacterium, *E. coli* CGMCC1.1139, preserved by our laboratory was incubated in sterile Luria−Bertani medium (10 g of polypepton, 5 g of yeast extract, 10 g of NaCl, and deionized water to 1000 mL, pH 7.0) at 37 °C for 12−15 h.

**Infection of Bacteria.** About 100 Western honeybee workers and 100 Asian honeybee workers at age of 3−5 days in summer were collected from their hives and maintained in a cage, respectively. Each worker was inoculated 2 μL of *E. coli* with a concentration of 50 cfu/g at intersegmental membrane with light $CO_2$ before workers were set into the cage. Workers fed with 10% honeybee solution were collected at 24 and 48 h post infection. The uninfected workers were used as a control (0 h).

**Preparation of the Hemolymphe.** The hemolymphe (insect blood) from 5 workers, which were cut head, was collected into 1.5 mL eppendorfs with a capillary. A small amount of phenylthiocarbamide was added in the hemolymphe to prevent oxidation. The hemolymphe was centrifuged under 10 000 rpm for 10 min, and the supernatant was reserved at −20 °C for detection. Three replications for each test were used. The hemolymphe of other insects was extracted with a protocol similar to that described above. The protein content in hemolymphe from different insect species was measured with a Bradford assay.[13]

Polyclonal antibody against recombinant Acc-royalisin (anti-RAcc-royalisin antibody) was previously obtained by immunization of male New Zealand white rabbits with a recombinant Acc-royalisin expressed in *E. coli* in our laboratory according to the method previously described[14] and stored at −80 °C. RAcc-royalisin antibody was purified with antigen affinity column filled in CNBr-activated Sepharose 4B conjucated to RAcc-royalisin. The column was washed with 10 volume PBS. The rabbit serum was filled with 0.45 through a Millex-GV 0.45 u filter, loaded to the column, and then washed with PBS. The purified antibody eluted with antibody elution buffer [7.5% (w/v) of glycine, pH 2.7] was collected, then dialyzed with deionized water ($ddH_2O$).

**Binding Activity of RAcc-Royalisin.** The binding activity (titer) of RAcc-royalisin antibody to react with RAcc-royalisin was tested by an indirect ELISA as described[15] with a Microplate spectrophotometer system, Multiskan MK3 (Thermo Scientific, U.S.). The diluted rabbit antiserum (1:5000−1:40 000), in a volume of 100 mL, was added to wells of microtitration plates coated with RAcc-royalisin for ELISA as later described. BSA was used as the control antigen. The lowest dilution of RAcc-royalisin antibody possessing significant difference of OD value with control is considered its binding activity. The specificity of the antibody was measured by comparison on binding activity of RAcc-royalisin antibody to react with different insect extracts with the same protein content by an indirect ELISA.

**Determination of Royalisin Content in Hemolymphe by ELISA.** Microtitration plates were coated overnight at 4 °C with 100 μL/well carbonate buffer solution (CBS: $Na_2CO_3$ 1.59 g, $NaHCO_3$ 2.93 g, pH 9.6) from 0 to 10 μg/mL (0, 2.3, 5.6, 11.3, 22.5, 55.0,110.0, 220.0, 330.0, 440.0, 550,0, 660.0, 770.0, 880.0, 990.0, 110.0, 1210, and 1320 ng/mL) of RAcc-royalisin, and then blocked with 1% dried milk in phosphate buffer saline (PBS; 137 mM NaCl, 2.7 mM KCl, 100 mM $Na_2HPO_4$, 2 mM $KH_2PO_4$, pH 7.4). Subsequently, 100 μL of anti-RAcc-royalisin antibody diluted with 0.1% dried milk in PBS was added and incubated in the coated wells for 1.5 h at 37 °C. The binding of anti-RAcc-royalisin antibody with antigen was visualized by using 100 mL of an antirabbit IgG conjugated to peroxidase for 1 h at 37 °C. The color reaction was initiated by adding 100 mL/well of TMB. The reaction was stopped after 15 min by adding 2 M $H_2SO_4$ to the wells. Optical density (OD) was measured at 450 nm with an ELISA plate reader. A calibration curve of RAcc-royalisin was generated on the basis of measurement of quantification limits.

The OD value of royalisin in hemolymphe of honeybee worker samples was determined by ELISA using anti-RAcc-royalisin antibody. The royalisin content of every well was performed through a calibration curve with its OD value. The royalisin content of hemolymphe (RCH) was used to quantify the antibacterial activity, respectively. Each assay was repeated with at least three independent replicates.

**Data Processing and Statistics.** For the ELISA, fitting curves were performed with Microsoft Office Exile 2007. The statistics analysis was carried out with the statistical software SPSS 16.0 (SPSS, Inc., Chicago, IL). One-way ANOVA with Duncan's post hoc tests was adopted to determine if there were any significant differences among treatment groups. The mean and standard deviation (SD) values are reported, and $p$-value <0.05 is considered statistically significant.

## RESULTS

**Binding Activity Assay of Anti-RAcc-royalisin Antibody in Antiserum to RAcc-Royalisin.** Table 1 presents the results for the binding activities of anti-RAcc-royalisin antibody in the antisera obtained from the immunized rabbits with antigen RAcc-royalisin. The OD valves of anti-RAcc-royalisin antibody at 40 000 dilution (0.2444) were higher than that of BSA (0.1811) ($p$ < 0.01). Therefore, 40 000 was considered as the binding activity of anti-RAcc-royalisin antibody.

Moreover, it was shown from Table 2 that the OD values of hemolymphe extracts from honeybee workers in both the Asian honeybee and the Western honeybee reacting to anti-RAcc-royalisin antibody were significantly higher than those of other insect extracts from *M. domestica*, *T. molitor*, *B. pest*, and royal jelly ($p$ < 0.00001), which suggests that the antibody possesses high binding activity and specificity to hemolymphe of honeybees.

**Standardization of ELISA.** First, a calibration curve of RAcc-royalisin in a broad concentration range from 2.3 to 1320 ng/mL was prepared in a 96-well plate in PBS, corresponding to the RAcc-royalisin content of diluted PBS. For exclusion of unspecific reactions, a control analysis was performed, without antigen (RAcc-royalisin). For routine determination of RAcc-royalisin in RJ antibody, the primary calibration curve (Figure 1A) in a concentration range from 2.3 to 1320 ng/mL of RAcc-royalisin in PBS was generated, and showed the quantification limits ranging from 55.0 to 1100.0 ng/mL. The formal calibration curve, $y = 0.001x + 0.108$, then was generated in a concentration range from 0 to 880 ng/mL of RAcc-royalisin in PBS, and showed a good correlation index of $R^2 = 0.995$ (Figure 1B).

Table 2. Specificity Test of RAcc-Royalisin Antibody Reacting to Different Insect Extracts with ELISA ($n$ = 3)

| | samples (500 μg/mL) | | | | | | |

| | *A. cerana* | *A. mellifera* | royal jelly | *M. domestica* | *T. molitor* | *B. pest* | CK |
| OD (450 nm)[a] | 0.2633 ± 0.0116 a | 0.2387 ± 0.0031 a | 0.1903 ± 0.0426 b | 0.1753 ± 0.0086 bc | 0.1740 ± 0.0079 bc | 0.1513 ± 0.0075 bc | 0.1093 ± 0.0032 c |

[a]The $p$-value <0.00001 on Duncan's multiple range test. Means denoted with the same letter (a−c) do not significantly differ from each other.

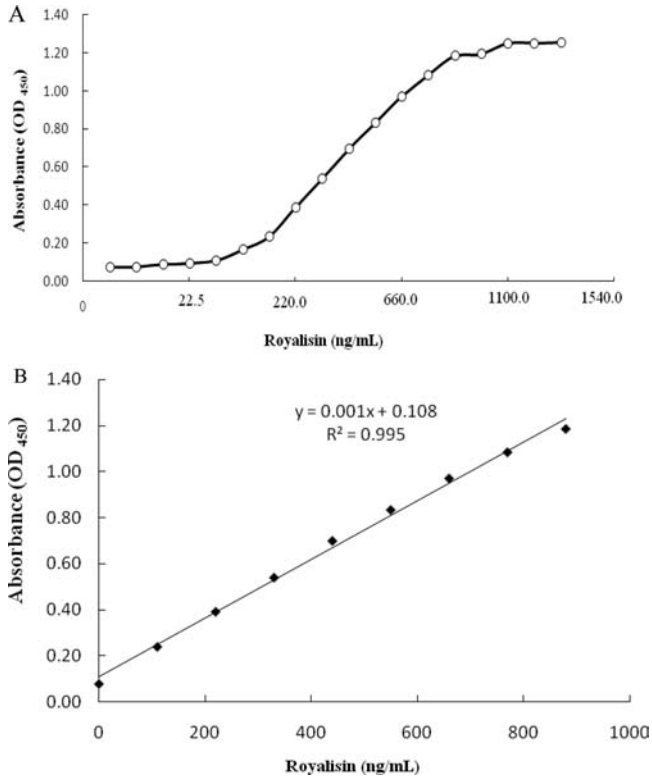

**Figure 1.** Calibration curve of royalisin in PBS. (A) The primary calibration curve from 2.3 to 1320 ng/mL of RAcc-royalisin in PBS solution. (B) The calibration curve from 0 to 880 ng/mL of royalisin in PBS solution was used for royalisin determination in 1.0% dilution of honeybee hemocytes samples. Curves were prepared using triplicates for each standard concentration.

**Quantification of Royalisin in the Hemolymphe of Honeybee Workers by Fast ELISA.** Ten microliters of hemolymphe of the Western honeybee and the Asian honeybee was diluted in 990 μL of PBS. 100 μL/well of the solution was distributed into 96-well microtitration plate. The obtained OD values detected by ELISA with anti-RAcc-royalisin antibody and the royalisin amount of every well were performed through a calibration curve with its OD values. It was shown from Figure 2 that the RCH of Asian honeybees collected before infection

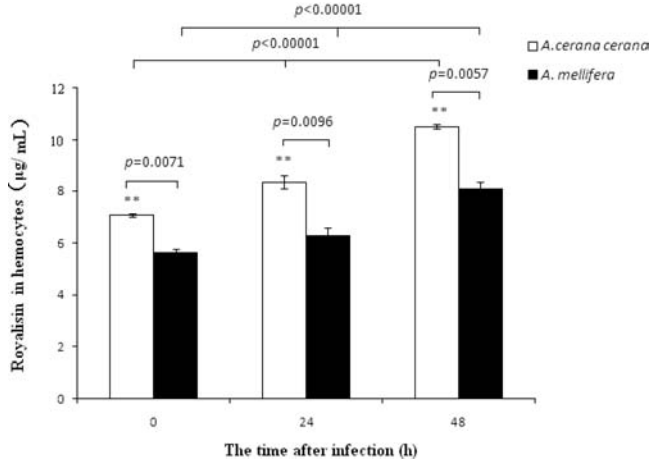

**Figure 2.** Comparison of RCH between *A. cerana cerana* and *A. mellifera* before and post infection.

dx.doi.org/10.1021/jf501637g | J. Agric. Food Chem. 2014, 62, 9305−9309

(7.06 ± 0.07 μg/mL) was significantly higher than that of the Western honeybee (5.64 ± 0.16 μg/mL, $p < 0.01$), which revealed that the innate immunity in the former is higher than that in the latter.

Moreover, it was shown that the RCH values of both the Asian honeybees and the Western honeybee were increased greatly post infection (Figure 2, $p < 0.01$). Relative to the sample before infection, the RCH of the Asian honeybees at 24 h (8.36 ± 0.25 μg/mL) and 48 h (10.49 ± 0.08 μg/mL) post infection increased 18.39 ± 4.60% and 48.55 ± 2.64%, respectively (Figure 3).

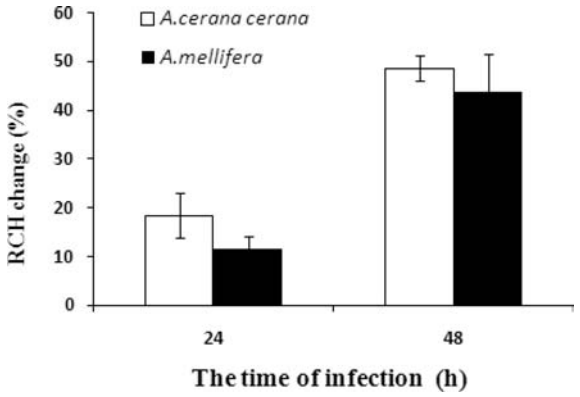

**Figure 3.** RCH change of *A. cerana cerana* and *A. mellifera* post infection (24 and 48 h) relative to non infection (0 h).

Relative to the sample before infection, the RCH of the Western honeybees at 24 h (6.29 ± 0.31 μg/mL) and 48 h (8.09 ± 0.23 μg/mL) post infection increased 11.56 ± 2.66% and 43.66 ± 7.84%, respectively (Figure 3). Meanwhile, the RCH post infection at 24 and 48 h in Asian honeybee were higher than those in the Western honeybee by 32.90% and 29.66%, respectively, which suggested that the Asian honeybees have a higher immune response against bacteria as compared to the Western honeybee.

## DISCUSSION

In the present work, the simple method for fast detection of immunity against pathogen bacteria in the Asian honeybee and the Western honeybee was developed on the basis of ELISA determination with anti-RAcc-royalisin antibody. The binding activity of anti-RAcc-royalisin antibody reached 40 000 dilution. The standard curve with the purified recombinant Acc-royalisin expressed in *E. coli* as standard was prepared. ELISA results on RCH of the Asian honeybee and the Western honeybee under infection and non infection of *E. coli* demonstrated that the former possesses higher innate immunity and immune response against pathogens than the latter.

Honeybees face a number of pathogens from bacteria, viruses, fungi, and parasites. When honeybees are infected by pathogens, four antimicrobial peptide families are synthesized, representing a broad spectrum of antimicrobial activity in the hemolymphe. All of these are cationic peptides identified as apidaecins, abaecin, hymenoptaecin, and defensin (defensin 1 or royalisin, and defensin 2).[6,16] It has been found that royalisin possesses bactericidal and fungicidal activity against bacterial pathogens and fungi such as *Botrytis cinerea*[3] and *Alternaria brassicae*,[17] food-borne bacteria;[11,12] hence, this peptide is a potential target for application of beekeeping and human therapeutics.[17] Evidence demonstrated that more cDNA sequences of royalisin in the hemocytes were found in the Asian honeybee than in the Western honeybee.[6] Honeybee brood food, RJ, containing royalisin is able to inhibit in vitro growth of the pathogen causing AFB. The royalisin mRNA levels of RJ in nurse worker header were used to evaluate the potential defense function of different colonies.[5] The immunoblot procedure employing antibodies generated against the recombinant peptide was developed.[5] Obtained data demonstrated that royalisin is constitutively expressed into RJ in colonies, and indicated that its levels in RJ are determined by genetic factors regulating transcription and/or translation/posttranslation processes in nurses.[5] Therefore, breeding novel honeybee lines expressing higher amounts of royalisin into RJ was suggested.[5]

Mite *V. destructor* is currently the most serious threat to beekeeping of the Western honeybee around the world.[18] This mite not only weakens honeybees by feeding hemolymphe but also serves as a vector and inducer of viral infections, causing severe damage to bee populations worldwide.[19] Furthermore, the mite has been attributed, in part, to the recent widespread Colony Collapse Disorder (CCD) as a disease vector.[20,21] However, colonies of the Asian honeybee (the original host of mite *Varroa*) suffer less damage from this parasite than the Western honeybee despite the presence of the mite in the hives.[7] Antibacterial peptides were observed in a humoral immune response of bees parasitized by mite *Varroa*, such as abaecin and defensin including royalisin, known to be immune-responsive.[2] Honeybees appear also to mount a cellular immune response at wound sites caused by mite *Varroa*.[23] Therefore, the detection of the difference of royalisin level between honeybee species and different colonies of the same honeybee species will be applied to evaluate the resistant characters against mite *Varroa*.

Hemolymphe is well-suited for studying insect immunity as it contains antimicrobial factors produced largely by the fat body and, to a lesser extent, hemocytes.[24] Several methods to detect the immune response of honeybee hemolymph have been employed. The levels of the immune factors prophenoloxidase, lysozyme, and the antimicrobial peptide hymenoptaecin were found to be increased from the analysis of mass spectrometry-based proteomics techniques on the hemolymph proteins of the Western honeybee against *P. larvae*.[24] Genes of the Western honeybees related to the infection of mite *Varroa* or to differences in bee tolerance were identified by microarrays.[25] Gene expression on honeybee immunity in responses to microbial pathogens was investigated by a quantitative-PCR array.[26] The expression of seven immune-related genes in the honeybee head after infection with *E. coli* was determined by qRT-PCR.[27] The consistency of gene expression changes for a subset of differentially expressed genes from the honeybee larvae samples at both 48 and 72 h post infection of *P. larvae* was measured by using qRT-PCR. It was found that for antimicrobial peptides, apidaecin was responsive at both time-points studied, whereas hymenoptaecin had the greatest increase in expression by RNA-seq analysis.[28] However, ELISA to determine the immune response of the hemolymph with antibody against antimicrobial peptides, including royalisin, remains to be developed.

ELISA as a fast and lower-cost diagnostic tool in medicine, toxicology, as well as a quality-control check in various industries has been widely applied around the world.[15] It is anticipated that, in the near future, such an ELISA method using recombinant royalisin as antigen and anti-RAcc-royalisin antibody for measuring RCH will be developed as a useful tool for both determining immunity against pathogens or disease resistance of

honeybee colonies in beekeeping, and as an anticorrosion property of RJ in commerce.

The release and synthesis of hydrolytic enzymes initiate starch, protein, and cell wall polysaccharide degradation. When germination has proceeded to an optimal state, it is stopped by kilning to avoid excess sugar and amino acid consumption. The kilning uses two levels of temperature, mild settings (~50−60 °C) to dry the seed and higher curing temperatures (~80−85 °C) to develop the color and aroma of the malt. After the completion of the malting process, the enzyme potential of the malt is established.

Dan'er is one of the most widely grown malt barley cultivars in China, especially along the Yangtze River. Its primary agronomic advantage is salt resistance for growing in Jiangsu province of China. However, the Dan'er malt quality traits are still not considered to be as good as those from the high-quality imported barley cultivars Metacalfe (Canada) or Gairdner (Australia). Besides the genetic deficiencies in the potential malt quality of Dan'er, the process used to produce malt may also limit its potential malting quality.[11] Chinese maltsters typically use two malting processes for Dan'er cultivar that produce malts with distinctly different malt qualities. Therefore, in this investigation we have applied comparative proteomics with 2D-DIGE (two-dimensional fluorescence difference in gel electrophoresis) to highlight the differences between malts made from the Dan'er barley cultivar grown under identical environmental conditions and to study the effect of malting process schedule on malt quality. These insights were considered to provide clues for optimizing the malting process for Dan'er.

## MATERIALS AND METHODS

**Commercial Malt Samples.** The malt samples were collected from two commercial malt companies in China. The barley cultivar of Dan'er was grown in Jiangsu province in China in 2011. The harvested barleys were then malted at industrial scale (150/300 t) under two different processes, process I and process II (Table 1), which were frequently used by commercial malt companies during the same year. Malt samples (malt I from malting process I and malt II under malting condition II) were stored in sterilized sample sacks at −20 °C in our laboratory after receipt.

**Determination of Malt Quality Traits and Macromolecule Contents.** The malt quality traits and macromolecule contents were determined as previously described.[8] In particular, the filtration volume of initial turbid wort for 30 min was defined as separation rate. The European Brewery Convention (EBC) Congress mash was carried out for malt quality parameters determination by EBC official analytical methods.[14] The contents of arabinoxylan (AX), β-glucan, starch, and polyphenol were determined according to the Douglas method,[15] Congo-red method,[16] iodine value,[17] and Folin−Ciocalteu colorimetry,[18] respectively. High-molecular-weight protein (HWP) representing the difference value between protein contents in the congress wort and that in the filtrate was precipitated with tannin[19] and then measured.

**Proteomic Analysis with 2D-DIGE.** Low-salt-soluble proteins of triplicates for each malt sample were extracted as described,[10] with 5 mM Tris-HCl (pH 7.5) buffer containing 1 mM $CaCl_2$. Protein concentrations were determined using the 2D-Quant kit (GE Healthcare, Pittsburgh, PA, USA).

The extracted protein samples were labeled with *N*-hydroxysuccinimidyl-ester dyes Cy2, Cy3, and Cy5 (GE Healthcare)[20] and separated by 2DE as described previously.[11] The differentially labeled coresolved proteome maps within each gel were imaged separately with dye-specific excitation and emission wavelengths using a Typhoon TRIO scanner (GE Healthcare). The gel images were analyzed using the software Decyder 7.0 (GE Healthcare). Spot positions in gels were defined with the Differential In-Gel Analysis (DIA) module, and their fluorescent intensity values were standardized by forming the ratio of Cy3 or Cy5 over the Cy2 signal of the internal standard. The DIA data sets for all gels of one sample were then collectively analyzed using the Biological Variation Analysis (BVA) module, which allowed for the matching of protein spot patterns across gels and statistical analysis of matched spots. Statistical significance was assigned using Student's *t* test based on log abundances of the standardized proteins (log standard abundance). Principal component analysis (PCA) was performed using the Extended Data Analysis (EDA) DeCyder module (GE Healthcare).

Preparative gels were run in parallel with 2D-DIGE gels and stained with Collidal Coomassie Blue G250 and scanned by Image Master LabScan (GE Healthcare).[10] Eight hundred micrograms of proteins extracted from each malt sample was loaded. Spots of interest assigned by DIGE analysis were located on the preparative 2D gels, then excised and subjected to in-gel trypsin digestion and an Ultraflex MALDI-TOF/TOF mass spectrometer (Bruker-Daltonics, Billerica, MA, USA) analysis as described previously.[11] An in-house Mascot server (http://www.matrixscience.com) was used for database search, and scores calculated by the Mowse scoring algorithm in MASCOT ($p < 0.05$) were considered as positive identifications.

**Activity of Amylase and Limit Dextrinase in Crude Extracts.** Crude enzyme was extracted from each malt for amylase and limit dextrinase activity assay. In detail, 2 g of malt was milled and then mixed with 20 mL of distilled water. Samples were vortexed for 3 min every 15 min during the 1 h crude enzyme extraction procedure, after which the extraction mixture was filtered.

Amylase activity was determined as described previously.[21] The reaction mixture comprised 1 mL of diluted crude enzyme and 1 mL of 1% (w/v) soluble starch solution in 0.05 M citrate buffer (pH 5.0). Reaction was carried out at 40 °C for 10 min and then quenched by adding 2 mL of DNS in the reaction tube. The control tube was added with dinitrosalicylic acid (DNS) prior to incubation at 40 °C. The reducing sugars liberated were estimated by DNS method[22] at 540 nm. One unit of amylase activity was defined as the release of 1 mg of reducing sugar as maltose per minute under the defined assay conditions. For α-amylase activity detection, the crude enzyme was incubated at 70 °C to inactivate β-amylase before mixing with the substrate. The activity of β-amylase was calculated by subtracting the activity of α-amylase from total amylase activity. Limit dextrinase

dx.doi.org/10.1021/jf5030483 | J. Agric. Food Chem. 2014, 62, 9310−9316

activity was determined with the same method as for amylase except that 0.5% (w/v) pullulan was used as substrate instead of 1% soluble starch. One unit of limit dextrinase activity was defined as the release of 1 mg of glucose reducing sugar equivalents per minute.

## RESULTS AND DISCUSSION

**Malt Quality Differences between Malts Produced by Different Malting Processes.** During malting, a series of biochemical changes of the grain occur, with perhaps the most important being the synthesis of hydrolytic enzymes. The enzymes synthesized hydrolyze grain storage materials such as starch and proteins so that the malt produced is in a suitable state for efficient brewing. There are three primary hydrolytic processes, namely, starch degradation, cell wall breakdown, and protein hydrolysis. It is therefore essentially differences in the malt quality traits linked to these hydrolytic processes that are directly determined by the different steps of the malting procedure.

Malt quality was measured by using the congress mash procedure and the wort produced by it for analysis by standard EBC analytical methods.[14] The results are shown in Table 2.

**Table 2. Comparison of Malt Quality Parameters and Macromolecule Contents in Congress Wort**

| malt parameter | malt I | malt II |
|---|---|---|
| moisture content (%) | 4.53 ± 0.06 | 4.60 ± 0.01 |
| total protein (g/100, dry) | 13.1 ± 0.2 | 13.0 ± 0.2 |

[a]Parameters with more significant differences between the two malts ($p < 0.05$).

The quality data showed that malt II exhibited superior malt quality compared to malt I, especially for DP and filterability. In addition, malt II required a shorter saccharification time, whereas the DP of malt II was higher. Comparison of the wort filtration volume of malt I was three-fourths that of malt II after the first 30 min after recirculation. Other studies have also shown that measuring the amount of wort filtered after mashing was indicative of potential malt lautering performance.[23,24] The wort turbidity and viscosity of malt I were slightly higher than those of malt II.

Comparison of wort macromolecule contents found that more β-glucan but less AX was present in the congress wort of malt I compared to malt II (Table 2). AX and β-glucan are well-known to reduce the mash separation rate.[25] Besides lipids and fatty acids, turbid worts contain more HWP or protein−polyphenol complexes, which cause an intensified precipitation of colloids and a lower bitter substance yield during wort boiling.[26] There was little difference in the wort HWP and polyphenol contents between malts I and II.

**Proteome Comparison between the Two Malts from Different Malting Processes.** Low-salt-soluble protein fractions containing most of the metabolic proteins were prepared from malts I and II simultaneously and resulted in high-quality 2D separation (Figure 1a,b). On average, for three replicate gels, approximately 430 protein spots were detected in each gel. In selecting candidates for further analysis, very faint spots and poorly resolved spots were eliminated, leaving 370 well-focused spots for quantitative analysis. Validated spots were matched and normalized against the internal standard. By quantitative analysis, 30 spots presented >1.5-fold change in protein abundance with Student's $t$ test $p$ values of <0.05 (as indicated in Figure 1c) between the two malts. Among the differentially abundant proteins, 19 were in higher expression levels in malt II, with the remainder being more abundant in malt I.

Thirty spots were efficiently excised from the preparative gels and submitted for MALDI-TOF/TOF identification (Table 3). For most of the proteins identified, there was generally good agreement between the experimental and theoretical molecular masses and p$I$, except for some discrepancies due to post-translational modifications that presumably occur during the malting process.

**Comparison of Cell Wall Polysaccharides Hydrolyzed in Malts Produced by the Two Malting Processes.** Efficient hydrolysis of cell wall polysaccharides is essential for good quality traits of the final malt, because it is one of the first steps in gaining access to endosperm cell components realized during the malting process. Insufficient degradation will result in filterability and viscosity problems, leading to increasing production time and cost. Therefore, understanding of the key elements in cell wall degradation is important for a malting process optimization. Compared with malt I, the β-D-glucan exohydrolase ExoI and arabinoxylan arabinofuranohydrolase isoenzyme AXAH-I were more abundant in malt II. β-Glucan and arabinoxylan are the two major components of the barley cell wall.[27] During cell wall breakdown, β-glucan can be degraded to glucose directly by β-D-glucan exohydrolase or in two steps with the enzymes β-gluconanase, β-glucosidase, and β-D-glucan exohydrolase.[28] Arabinoxylan in the barley cell wall consists of a D-xylanopyranosyl unit backbone and L-arabinofuranose branches.[1] AXAH-I has been proved to act as a bifunctional α-arabinofuranose/β-D-xylosidase enzyme, thus playing an important role in arabionxylan hydrolysis.[29]

**Comparison of Starch Hydrolase Differences between Malts Produced by the Two Malting Processes.** The conversion of starch to sugars during malting is catalyzed by the enzymes α-amylase, β-amylase, limit dextrinase, and α-glucosidase,[30] which are collectively known as the DP enzymes of malt. The hydrolysis of starch is achieved by the coordinated cleavage of the α-1,4 linkages that are hydrolyzed by α-amylase, the α-1,6 linkages that are hydroylzed by limit dextrinase, and the maltose from the end of dextrins by β-amylase, to contribute yeast fermentable sugars to the wort used for beer production.[31] Limit dextrinase was thought to be a limiting factor in the conversion of starch to sugars during malting,[32] and it has been proved that with β-amylase, α-amylase will hydrolyze starch much more rapidly.[33] β-Amylase was regarded as the major contributor to DP generation.[34] More recent studies have demonstrated that the amount and balance of all three DP enzymes are related to the extent of starch hydrolysis

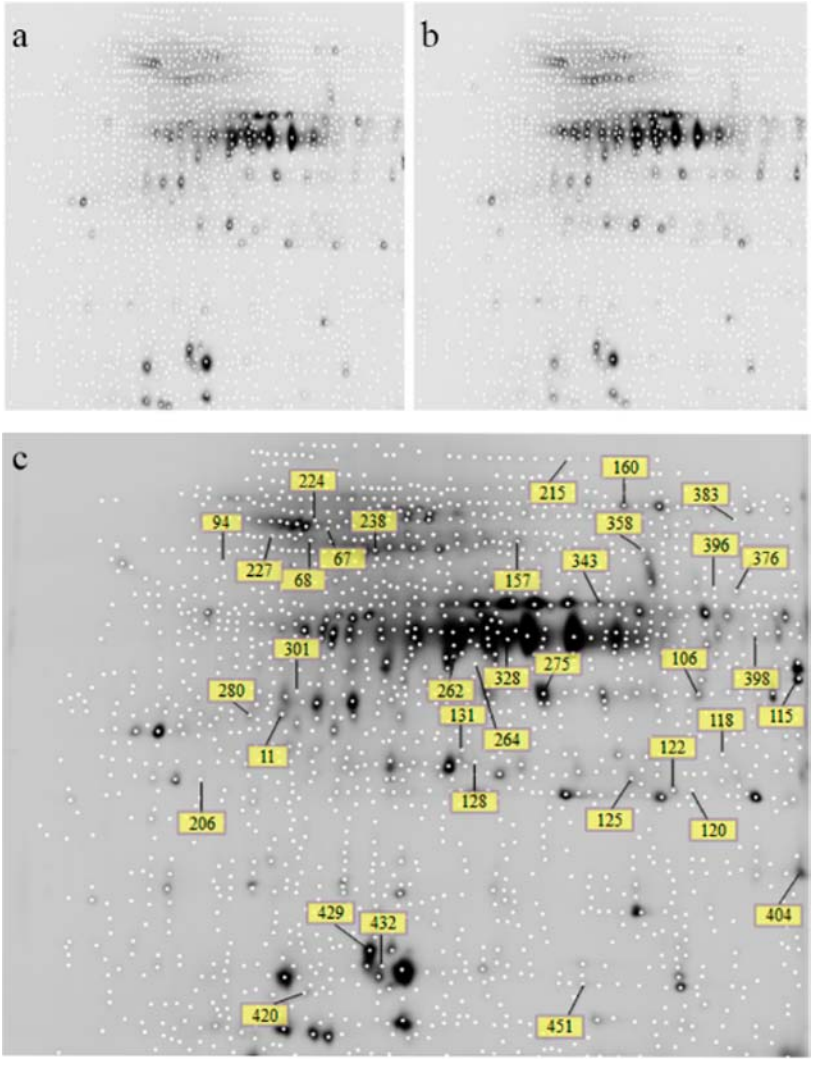

**Figure 1.** Representative 2DE gels of Dan'er malt I (a) and malt II (b) producing by different malting processes. Spots with significant difference between them are indicated by arrows and numbered in the preparative gel (c).

during mashing.[35] Compared between gels of the two malts, no differential spots were identified for limit dextrinase. However, malt extracts did show different limit dextrinase activities between the malts (Table 4). Both $\alpha$-amylase I and $\beta$-amylase exhibited more abundance in malt II than in malt I. However, amylase activity assay showed that the malt II extract exhibited higher total amylase and $\beta$-amylase activity but lower $\alpha$-amylase (as shown in Table 4). It was therefore concluded that the lower DP of malt I was the result of lower $\beta$-amylase despite the higher activity of limit dextrinase and $\alpha$-amylase.

**Comparison of Pathogenesis-Related Proteins (PRs) between Malts Produced by the Two Malting Processes.** Several PRs were found to be differentially expressed between the two malts. PRs are involved in protecting germinating cereal seeds against pathogenic microorganisms and pests. In addition, they have considerable quality importance for the brewing of beer, such as protein and starch degradation during malting and mashing, yeast fermentation during brewing, foam formation, and beer colloidal stability.[36]

PRs of barley and malt can affect the hydrolysis of the barley seed storage proteins, during the malting and mashing process, into peptides and amino acids that can be utilized by brewer's yeasts.[37] Malt contains four classes of endoproteinases.[37] The cysteine proteinases and metalloproteinase were found to hydrolyze barley storage proteins (hordeins) in vitro.[38,39] The serine proteinases were suggested to be present in malt to hydrolyze specific peptide bonds of a few specific proteins. The aspartic endoproteinase digests some of the components of a trypsin/amylase inhibitor protein mixture.[37] Besides endoproteinases, barley also contains a range of low-molecular-weight proteins that inhibit the activities of many of these endoproteinases.[6,37] High levels of inhibitors have been suggested to compromise the production of optimal levels of soluble proteins and amino acids, thereby potentially affecting yeast fermentation performance.[6] Between gels of the two malts, no differential spot was identified as endoproteinase. However, the ns-LTP1 and the storage protein B3-hordein in malt I exhibited greater abundance. The ns-LTP1 has been found to act as a cysteine protease inhibitor, potentially leading to reduced hordein hydrolysis in malt I compared with that in malt II. In addition, the B-hordein combined with D-hordein can form gel protein that slows the mash separation rate.[40] Except for ns-LTPs, members of the trypsin/amylase inhibitor protein family are able to inhibit serine proteinases.[41] The greater abundance of the trypsin/amylase inhibitor PUP38 in

[a]$p < 0.05$.

malt I indicated that it could be an important factor that negatively affects malt I quality traits.

In malt I, serpin Z7 that has been recognized as probable haze-active protein and pro-oxidant[42,43] was in greater abundance than in malt II and thus may reduce the colloidal and flavor stability of beer made from malt II. Serpin Z7 has also been suggested to be involved in foam stability.[36,44] Moreover, a higher content of peroxidase BP1, a negative effector of filterability,[11] in malt I was found. Peroxidases are heat stable and highly active enzymes involved in the oxidative polymerization of phenolic substrates that can result in increased wort color and turbidity.

**Comparison of Other Proteins between Malts Produced by the Two Malting Processes.** There are some other proteins with differential expression levels between the two malts, such as proteins involved metabolism, oxidation, and reduction. Enzymes responsible for aminopeptide and glucose metabolism were all more abundant in malt II, whereas enolase and triacylglycerol lipase for lipid metabolism showed higher contents in malt I. The more predicted aminopeptidase in malt II may improve its protein hydrolysis. At the same time, some enzymes involved in glucose metabolism, such as glucose and ribitol dehydrogenase, predicted aconitate hydratase and malate dehydrogenase, were with more abundance in malt II, which was proposed to be induced by the more complete hydrolysis of starch. Most of barley endosperm and embryo proteins undergo reduction during germination. Thereafter, the proteins became increasingly oxidized, concordant with their continued degradation. The proteins involved in oxidation and reduction were also more abundant in malt II, indicating the better hydrolysis of proteins. The more complete the hydrolysis

of proteins and starch, the better the filterability and stronger DP of the malt.

In conclusion, the present work has analyzed the effects of malting process, beyond the genetic background of barley cultivar, on malting quality traits. The proteomes of malt produced from the same cultivar by the two different malting processes I and II were also compared. The results showed that with malting condition II, the malt quality was superior to that of malt I in most aspects, such as macromolecular contents, turbidity, viscosity, DP, saccharification time, and especially mash filterability. This was attributed to the differentially expressed proteins involved in cell wall polysaccharide hydrolysis, and starch hydrolysis, PRs, and proteins involved in metabolism, oxidation, and reduction processes. The results are expected to indicate opportunities to modify the malting process to improve Dan'er malt quality for beer brewing.

UV−vis absorption spectra is discussed in the present paper. This method requires only a mathematical treatment of the measured oil absorption spectrum avoiding any chemical manipulation of the sample. Within this approach, the spectra of EVOOs are analyzed in terms of the molar absorption spectra of four main pigments dissolved in purified triolein, namely, lutein (a xanthophyll), $\beta$-carotene (a carotenoid), pheophytin-a and pheophytin-b (two chlorophylls derivatives). The choice of this set of "main pigments", suggested by experimental analytical data, is discussed, as well as the use of triolein as the best solvent. Several examples of the application of this method to real experimental cases are reported, underlining its possible uses for the assessment of quality, freshness, and aging effects in EVOOs.

## MATERIALS AND METHODS

**Oil Samples.** The oil samples from Spain (Coprovir, Poniente de Granada, Fuentes de Dios, Loja) were a gift from San Isidro Deifontes S.C.A. (Granada), and they are of the same vintage year. The Italian oils (mixed cultivar of different origin) were provided by Salov S.p.A. (Massarosa, Lucca), and they were from the 2012 and 2013 harvests. Tuscan oils of Frantoio cultivar were provided from Carapelli Firenze S.p.A, and the harvest year is indicated case by case. The rest of oils used in the present study were purchased directly in the supermarket, and they are of the same vintage year (2012). For each measurement reported in this work, a minimum of three replicates were performed. All oil samples were maintained in dark conditions, in 25 mL dark glass bottles, at a temperature between 1 and 5 °C.

**Solvents and Purification Methods.** Methanol, *n*-hexane, and acetone were Carlo Erba HPLC solvents (Milan, Italy).

$\beta$-Carotene (>97% purity) and triolein were purchased by Fluka (Milan, Italy). $\beta$-Carotene was used as such, while triolein was purified by washing cycles with pure MeOH and freezing/partial crystallization of the mixture at $T < -20$ °C, followed by a phase separation, until the measured absorbance of triolein was equal to that of the previous washing cycle (minimum four cycles).[24]

Lutein and zeaxanthin were obtained through HPLC semipreparative isolation/purification of methanol extracts of maize flour. The mobile phase was methanol. The column was a Waters Spherisorb S5-ODS2 10 × 250 mm RP-C18, the flux was 2.4 mL/min at $T$ = 25 °C, and the spectrophotometric detector was at 450 nm. Retention times (Rt) were 15 and 16 min, respectively, for lutein and zeaxanthin.

Pheophytin-a and pheophytin-b were obtained through HPLC semipreparative isolation, by Waters Spherisorb S5-ODS2 10 × 250 mm RP-C18 column, detector at 415 nm, of acetone extracts of leaves of *Acer Negundo L. (Aceraceae)* acidified with 1 N HCl, after complete pheophytinization of chorophylls present in these extracts. Pheophytinization was controlled through UV spectrophotometry by observing the sharp diminution of absorbance at 434 nm, where the maximum of chlorophyll-a is located, and the corresponding increase at 410 nm near the absorbance maximum of pheophytin-a (65% of spectral change in 12 min). Retention times were Rt (pheo-b) = 25.9 min; Rt (pheo-a) = 32.5 min; flux 4.5 mL/min; $T$ = 45 °C; mobile phase: methanol.

**Instruments.** Absorbance spectra were measured with a Jasco V-550 spectrophotometer using quartz cells with 0.1−1 cm optical path length in order to measure absorbances smaller than 2 absorbance units.

A HPLC Jasco 880-Pu pump equipped with a Shimadzu SP-10A spectrophotometric detector was used isocratically for analytic and semipreparative experiments.

**Spectrophotometric Measurements.** Before absorbance measurements, the oil samples were centrifuged for 30 min at 5000 rpm in order to minimize the light absorption due to suspended materials. The absorbances used in the present analyses of EVOOs spectra are referred to 1 cm optical path. Clearly, in the actual absorbance measurements, cells whose optical path was compatible with the requirement of precise measurements, in particular to avoid any sensible stray light effect, were used. Spectroscopic parameters included spectral bandwidth = 1 nm and measurement step $\delta\lambda$ = 1 nm.

**Extinction Coefficients of the Pigments.** Because of the lack of relevant literature, the molar extinction spectra of lutein, pheophytin-a, and pheophytin-b in triolein (see Figure 1) were obtained through the

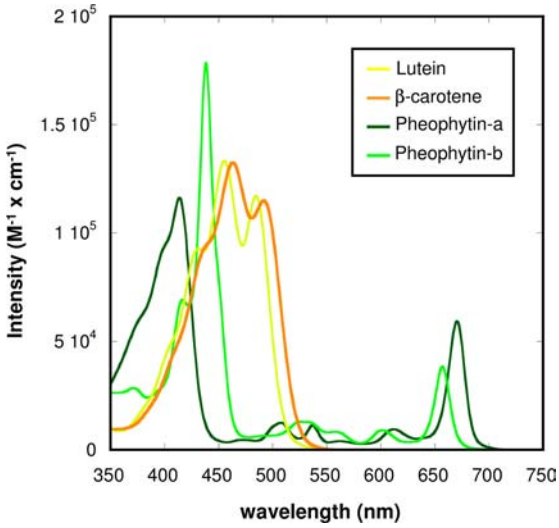

**Figure 1.** UV−vis molar extinction spectra of lutein, $\beta$-carotene, pheophytin-a, and pheophytin-b dissolved in purified triolein.

experimental procedure hereafter described. The methanol solutions of purified pigments from semipreparative HPLC were about $2 \times 10^{-5}$ M of pure pigments in volumes of 5−10 mL, i.e., sub-milligram masses of pigments. Their absorbance in methanol was measured, and the concentration of the pure analytes was calculated by using the values of their extinction coefficients found in the literature.[25−27] The volatile solvent in a precise volume (1 mL) of methanol solution was finally evaporated and a measured volume (1 mL) of purified triolein was added to the dry pigment.

For $\beta$-carotene a weighted mass (4.26 mg) was dissolved in a measured volume (25 mL) of *n*-hexane to obtain a relatively concentrated solution. A measured aliquot (40 $\mu$L) was conveniently diluted in 2 mL of solvent and its absorbance was measured. The molar extinction of $\beta$-carotene in hexane found in the literature was used to calculate its concentration. The volatile solvent was evaporated, and a measured volume of pure triolein was added. In this case, it was also possible to verify that the procedure was correct. In fact, the initial mass of $\beta$-carotene and the used volumes of solutions and solvents were measured, and the difference between the concentrations found by the two procedures is less than 2%.

The spectra were measured in pure triolein, since this *quasi*-transparent solvent is the most appropriate to represent the interactions of the olive oil matrix with the pigments. The spectra obtained was neatly different from the spectra in the more usual solvents (methanol, ethanol, acetone, diethyl ether, or hexane) reported in the literature.[28,29]

A sample of HPLC-pure zeaxanthin, a xanthophyll isomer of lutein, very common in nature, was also prepared. In two parallel experiments, known amounts of lutein and zeaxanthin were added to samples of a Tuscan EVOO. The measured increase of absorbance of the oil due to the added lutein, or zeaxanthin, was identical to the absorbance of an equal quantity of lutein, or zeaxanthin, dissolved in a volume of triolein equal to that of the EVOO used in the experiment. The two major peaks in the absorption spectrum of zeaxanthin in triolein were 4 and 7 nm red-shifted with respect to the corresponding lutein spectrum. The zeaxanthin spectrum peaks, in addition, seem to be less resolved than those of lutein. The above findings demonstrate the good choice of triolein as a solvent: no particular interactions of xanthophylls with the components of EVOOs different from triolein, should be present. Differences in the shapes and shifts of the order of

5−10 nm are expected for the absorption spectra of the other carotenoids present in EVOOs in concentration usually much smaller than lutein and β-carotene.

With a procedure similar to that used for lutein, triolein has been proven to well represent the *medium* in which pheophytin-a and pheophytin-b are present in olive oils.

**Mathematical Treatment of UV−vis Absorption Spectra.** In this section, the mathematical treatment of the EVOO absorption spectrum adopted in order to extract the concentration of the aforementioned four main pigments is reported.

As shown in Figure 1 and summarized in Table 1, while the two pheophytins spectra show sensible differences in their shapes and

**Table 1. Maxima in the UV-vis Absorption Spectra of Oil Pigments in Triolein**

| solvent: triolein | lutein | β-carotene | pheophytin-a | pheophytin-b |
|---|---|---|---|---|
| $\lambda_{max}$ (nm) | 486, 455, 432 | 490, 462 | 670, 414 | 657, 437 |
| $\varepsilon$ ($\lambda_{max}$) $M^{-1}$ $cm^{-1}$ | 11800, 133500, 95600 | 115200, 132500 | 59500, 116200 | 38500, 178500 |

absorption intensities, lutein and β-carotene show spectra similar in shape and intensity. In fact, the spectrum β-carotene is red-shifted and has a lower resolution of the peaks with respect to the xanthophyll one. However, there is no doubt about the linear independence of the four spectra, i.e., not one of them can be expressed as a linear combination of the other three spectra.

The UV−vis absorption spectrum of any EVOO can be conveniently described by four orthogonal functions (eigenvectors) by using a treatment similar to that adopted by Hennessey and Johnson[30] to calculate the contributions of various proteins basic structures (α-helix, β-sheet., etc.) to the measured circular dichroism (CD) spectra of proteins in solution.

First, the symmetric 4 × 4 overlap matrix, **S**, of the four molar extinction spectra $\varepsilon_i(\lambda)$ of the four pigments in triolein, is obtained. The elements $S_{i,j}$ are defined as

$$S_{i,j} = \int \varepsilon_i(\lambda)\varepsilon_j(\lambda)\, d\lambda \quad (1)$$

the integration being performed from 390 to 720 nm, the spectral range where light absorbance in EVOOs can be ascribed to the chosen pigments.

Then, four eigenvectors and the correspondent four eigenvalues are obtained by diagonalization of the **S** matrix.

The eigenvectors, $\Phi_j(\lambda)$, with $j$ = 1, 2, 3, and 4, are linear combinations of the four molar extinction coefficient of pigments, $\varepsilon_r(\lambda)$ according to eq 2, and they are reported in Figure 2.

$$\Phi_j(\lambda) = \Sigma_r P_r^j \varepsilon_r(\lambda) \quad (2)$$

where $P_r^j$, a fixed parameter, is the contribution to the eigenvector $\Phi_j(\lambda)$ of the molar extinction spectrum of pigment $r$. It must be observed that the diagonalization of the **S** matrix is possible only when the four spectra are linearly independent, as it is in this case.

The eigenvalues, $\alpha_i$ ($\times 10^{-12}$), are 0.022298, 0.202191, 0.403061, and 2.337122 $M^{-2}$ $cm^{-2}$ in correspondence to the eigenvectors $\Phi_j(\lambda)$. Only the eigenvector corresponding to the highest eigenvalue is positive in all the spectral range, while the other curves also have negative values in a number of spectral intervals separated by crossing points with the λ-axis. These progressively increase from 0 up to 7 (0, 2, 6, 7 with decreasing eigenvalues).

If the absorbance of an EVOO in the 390−720 nm range is due to the four pigments only, it can be expressed *exactly* as a linear combination of the above four functions $\Phi_j(\lambda)$. In any case, it is simple to calculate (eq 3) the four coefficients $\gamma_j$ of the linear combination that best represents the oil spectrum in terms of the spectra of the reference pigments:

$$\gamma_j = \int \Phi_i(\lambda)\mathrm{ABS}(\lambda)\, d\lambda/\alpha_j \quad (3)$$

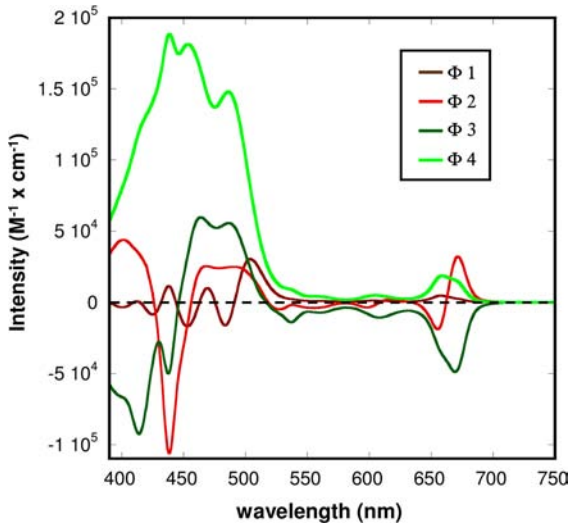

**Figure 2.** Eigenvector $\Phi_j(\lambda)$ calculated by the procedure described in the text.

where ABS $(\lambda)$ is the measured absorbance of the oil and $\alpha_j$ is the eigenvalue corresponding to $\Phi_j(\lambda)$.

Finally, the molar concentration of the pigment $r$, $C_r$, in the oil is determined through eq 4:

$$C_r = \sum_j \gamma_j P_r^j \quad j = 1, \ldots, 4 \quad (4)$$

With the values of the molar concentrations $C_{r=1,4}$ of the pigments, it is possible to calculate (eq 5) the absorption spectrum $\mathrm{ABS}_{calc}$ $(\lambda)$ of the EVOO, to be compared with the experimental one, ABS$(\lambda)$.

$$\mathrm{ABS}_{calc}(\lambda) = \sum_r C_r \varepsilon_r(\lambda) \quad (5)$$

From the discrepancies between these spectra, it is possible to evaluate the quality of the concentration values $C_{r=1,4}$ extracted from the experimental absorption spectrum, as well as the goodness of the procedure.

**Spectral and Data Analysis.** The measured spectra were mathematically treated by using properly adapted Excel sheets. The diagonalization of the matrix **S** was performed by using a package of MatLab 6. The evaluation of relevant statistic parameters was also performed by using Excel software.

**Validation of the Method.** In order to validate the method, the error due to both the experimental procedure and the mathematical treatment was evaluated. For the experimental contribution to the error, all UV−vis spectra were acquired by using rectangular quartz cuvettes with different path lengths of 0.1, 0.2, 0.5, and 1 cm and two cuvettes with the same path length of 0.1 cm, but with different geometry and shape were used: five spectra were acquired for each oil. After normalization for the path length, the five experimental spectra were scaled in order to have the absorbance values at $\lambda$ > 720 nm equal to zero. These five scaled spectra were used to calculate the average spectrum and the standard deviation, for each oil sample. From the statistical point of view, the method has been applied to more than 80 oils from Tuscany and Apulia,[31] and the average value of the standard deviation, $\sigma^{exp}$, calculated for each pigment, is reported in Table 2. It should be noticed, that the experimental error also contains a systematic error, which is not easy to evaluate, related to the intrinsic differences among the different cuvettes. In fact, by decreasing the path length, the effect of the stray light decreases, and it is not constant within the observed spectral window. However, the values reported in Table 2 can be taken as representative for the general case.

The analysis of the UV−vis spectra by using the mathematical approach presented above introduces an error, too. This error can be evaluated through the residues (see the Supporting Information for details). Moreover, the goodness of the mathematical treatment was

Table 2. Values of Standard Deviation of Concentration (M) for Investigated Pigments Due to Experimental ($\sigma^{exp}$) and Deconvolution ($\sigma^{calc}$) Contributions[a]

| | triolein [M] | β-carotene [M] | pheophytin-b [M] | pheophytin-a [M] | lutein [M] |
|---|---|---|---|---|---|
| $\sigma^{exp}$ | 0.3 | $3 \times 10^{-7}$ | $5 \times 10^{-8}$ | $1 \times 10^{-7}$ | $2 \times 10^{-8}$ |
| $\sigma^{calc}$ | 0.3 | $5 \times 10^{-7}$ | $1 \times 10^{-7}$ | $3 \times 10^{-7}$ | $2 \times 10^{-7}$ |
| LOD | | $1 \times 10^{-06} \pm 6 \times 10^{-7}$ | $7 \times 10^{-08} \pm 3 \times 10^{-8}$ | $1 \times 10^{-07} \pm 6 \times 10^{-8}$ | $8 \times 10^{-07} \pm 2 \times 10^{-8}$ |
| LOQ | | $1 \times 10^{-06} \pm 6 \times 10^{-7}$ | $7 \times 10^{-08} \pm 3 \times 10^{-8}$ | $1 \times 10^{-07} \pm 6 \times 10^{-8}$ | $1 \times 10^{-13} \pm 6 \times 10^{-8}$ |

[a]LOD and LOQ values calculated as reported in the text.

verified by the "R-square" test, which estimates the correlation between the experimental values and the values predicted by the deconvolution procedure:

$$R\text{-square} = 1 - \frac{\sum_{i=1}^{n}(y_i - f_i)^2}{\sum_{i=1}^{n}(y_i - \bar{y})^2} \quad (6)$$

where $f_i$ is the value predicted by the fitting, $\bar{y}$ is the mean of the observed data, and $y_i$ is the observed data value. In particular, two tests were done by choosing two EVOOs representative of two opposite situations: a good and a bad fit, due, for example, to the turbidity of the oil, as reported in the Supporting Information.

The values of $R$ are 0.85 for the bad case and 0.96 for the good one. The range 0.85 ÷ 0.96 can be taken as representative for all other intermediate cases.

The standard deviation due to the deconvolution procedure, $\sigma^{calc}$, reported in Table 2, can be determined according to the following equation:

$$\sigma^{calc} = \sqrt{\frac{\sum_{i=1}^{n}(x_i - \bar{x})^2}{n-1}} \quad (7)$$

where $x_i$ is the pigment concentration obtained after fitting process for each path lengths cuvette, $\bar{x}$ is the mean value of the pigment concentration, and $n$ is the number of the values considered. In this case, it is equal to five (number of cuvettes used). It can be noted that triolein concentration is visibly higher than the other values, because it represents the matrix of the oil without any pigment.

A sample of refined olive oil was used for the measurement of the limit of detection (LOD) and limit of quantitation (LOQ). According to IUPAC definition, LOD and LOQ are mathematically defined equal to 3 and 10 times, respectively, the standard deviation of the results for a series of replicates (five in our case) used to determine a reliable limit of detection. The respective values of LOD and LOQ are reported in Table 2.

## RESULTS AND DISCUSSION

**Discussion about the Mathematic Treatment.** In this work on the extraction of pigment information, four pigments were chosen. In principle, other pigments could be added to these four ones, provided that their molar spectra are linearly independent from each other and from the previous ones. The maximum number of basis spectra is actually defined by the dimensionality of the functional space of the absorption spectra of all extra virgin olive oils. Physical restrictions have to be taken into account. For example, the precision of the absorbance measurements both of the oil samples and of the reference spectra, ca. 1%, has to be considered. Two spectra differing only within the experimental error cannot be considered linearly independent, and pigment concentrations identical, within the experimental error, have to result using the above treatment of their absorption spectra, i.e., by using eqs 3−5, in the previous section.

Two independent spectra cannot be proportional to each other and they must be different in their shape. As shown in Figure 1, even if the differences in the shape of the molar extinction of lutein and β-carotene are much smaller than that of any other couple of reference pigments, they are sufficient to represent EVOOs carotenoids. From a quantitative point of view, the difference in shape between spectra can be evaluated by the values of the overlaps of normalized extinction spectra (see the Supporting Information).

In this work, the minimum number of pigments, normally present in EVOOs, whose absorption spectra are significantly different from each other, was chosen in order to obtain calculated absorption spectra nearest to the measured ones. The possible presence of other pigments not included among the above reference components has to be addressed as well. If the outsider pigment has a spectrum equal to any of the reference components, its contribution to the absorbance of the oil is simply added up to the absorbance of this component, through eq 3, thereby increasing its calculated concentration, through eq 4. This situation actually occurs for some isomers of lutein, for lutein esters,[17,18] and for some pheophytins.[32] It must be noticed that, while there are large differences in the CD spectra of pheophytin stereoisomers, differences in their absorption spectra are undetectable.[30] When the spectrum of the outsider component pertains to the functional space of two of the basic four pigments, its contribution to the whole spectrum is included in the calculated amounts of these two pigments. This case is here briefly described.

A known amount of zeaxanthin, i.e., a carotenoid isomer of lutein that, as far we know, has never been detected in EVOOs, was added to a multicultivar Italian EVOO. The absorption spectra of the EVOO before (curve a) and after the addition (curve b) are reported in Figure 3A. The spectrum (curve c) is the difference between spectra (b) and (a) and represents the measured increase of the absorbance of the EVOO due to the added zeaxanthin. The spectra (a), (b), and (c) were analyzed by means of the mathematical method described above, and the calculated spectra are shown in dashed lines. The spectrum calculated from experimental (c) overlaps perfectly with the difference between the two absorption spectra (a) and (b), even if zeaxanthin is a carotenoid not likely to be found in EVOOs. Moreover, Figure 3B shows the contributions to absorbance proceeding from the two reference pigments lutein and β-carotene. It is evident the prevalent contribution of β-carotene to the absorbance of this "oil", as expected from the spectral characteristics of zeaxanthin. An increase of the calculated concentrations of lutein and of β-carotene corresponds to the increased absorbance of the oil caused by the added zeaxanthin. These concentration increments are a mathematical consequence of the linear dependence of the zeaxanthin spectrum on the spectra of lutein and β-carotene.

From these findings several considerations can be drawn:

(1) The presence of a carotenoid (here zeaxanthin) different from lutein and β-carotene leads to concentrations different from their analytical (e.g., determined by HPLC) values.

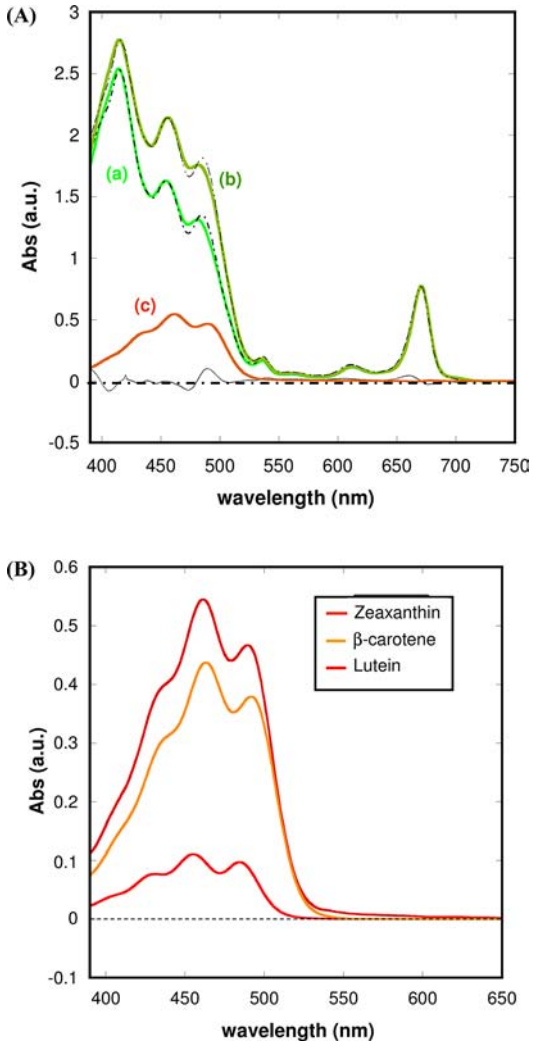

**Figure 3.** (A) UV−vis absorption spectra of an EVOO (a) and of the same one with the addition of a certain amount of zeaxanthin (b) with the respective calculated spectra (dashed lines) and residues (black line). The spectrum of the added zeaxanthin (c) is also reported. (B) Contributions of lutein and $\beta$-carotene to the same EVOO sample due the addition of zeaxantin.

(2) The introduction of zeaxanthin as a third carotenoid in the set of reference spectra would result in the impossibility to diagonalize the overlap matrix **S** (eq 1), given the evident linear dependence of its spectrum on those of lutein and $\beta$-carotene in the 390−720 nm spectral region.

Hence, this example demonstrates that it is impossible to extract specific and quantitative information about all carotenoids from the oil absorption spectrum, even when they are present in non-negligible concentrations.

Even if at least 15 carotenoids were found in extracts of different oils,[13,15,17,18,22,33] a much smaller number of carotenoids, two or three, is sufficient to describe their functional space. This is supported by two general observations: (1) the spectral range of their absorption spectra is limited to the 390−550 nm range; (2) most of them are typically shaped in a very similar way in this spectral range. For this reason, lutein and $\beta$-carotene have been chosen, since they are probably the most significant from both the analytical and the nutraceutical point of view.

**Addition of a Nonpigment Substance Spectrum to the Reference Spectra.** In our approach, a fifth spectrum vector has been added in order to reproduce the absorption in the 390−720 nm spectral region of an EVOO deprived of any pigment. In fact, other substances are present in oils, partially due to the degradation processes of the original components, including the same pigments. This absorption curve is well reproduced by the shape of the absorption spectrum of aged triolein or of refined olive oil. This absorption has an absorbance close to zero in the visible and gradually increases moving toward the near-UV spectral region. The absorption of an aged sample of triolein, reported in Figure 4 together with

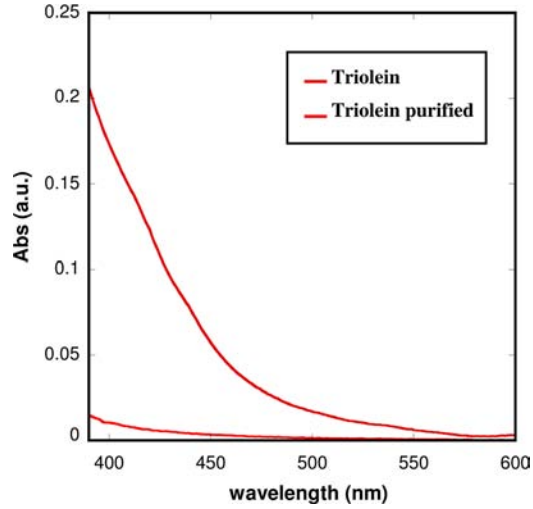

**Figure 4.** UV−vis absorption spectrum of purified (red) and "raw" commercial triolein (brown) curves.

the spectrum of purified triolein, is clearly due to impurities, whose concentration increases with the triolein aging: this absorption is used as that equivalent to an unspecified one-molar substance. It is interesting to observe that its shape is similar to the residual absorbance of EVOOs after complete photodestruction of the pigments.[19] Since the shape of this function is quite different from the absorbance of the pigments, it cannot be represented by the eigenvectors of the true pigment-space. Moreover, the presence of this function is especially interesting for studies of EVOO aging, as described in the following paragraph.

**Several Applications of the Method to EVOO Samples.** In Figure 5, the measured absorption spectra of four one-year-old EVOOs from Granada (Spain) are reported. Notable differences of their absorbance both in shape and in intensity can be observed. The calculated spectra (eq 5) and the difference between the calculated and the measured absorbances are reported as well. The experimental absorbance has been reproduced with remarkable precision by the absorptions of the four +1 light absorbers described: differences of ca. 1% are found only at the 485 nm maximum. The experimental spectra in Figure 5 present well resolved peaks. In correspondence to the differences of absorbance spectra, the four EVOOs have significant differences in pigment composition, as reported in Table 3.

However, not all the EVOOs are reproduced with the above quasi-absolute precision. In Figures 6A,B the spectra of two Italian EVOOs are represented. They show, respectively, medium and intense differences between experimental and

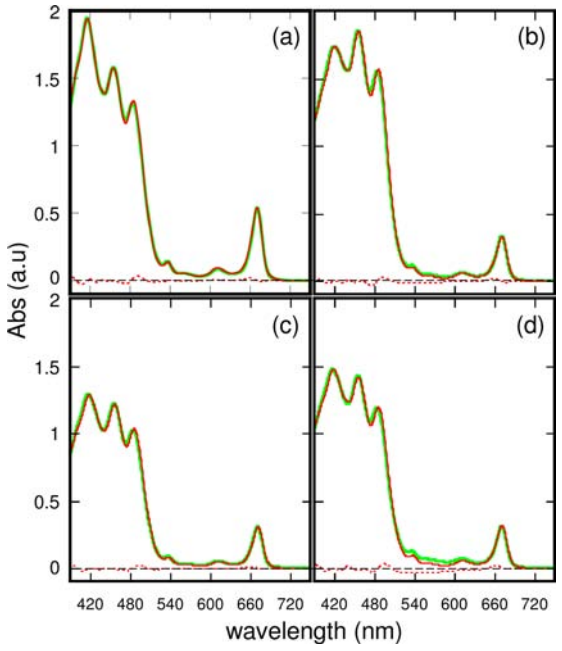

**Figure 5.** UV−vis absorption spectra of four Andalusian EVOOs (a, Coprovir; b, Poniente de Granada; c, Fuentes de Dios; d, Loja). Experimental spectrum (green), calculated one (red), and the residue curve (dashed red curve) are shown in each case.

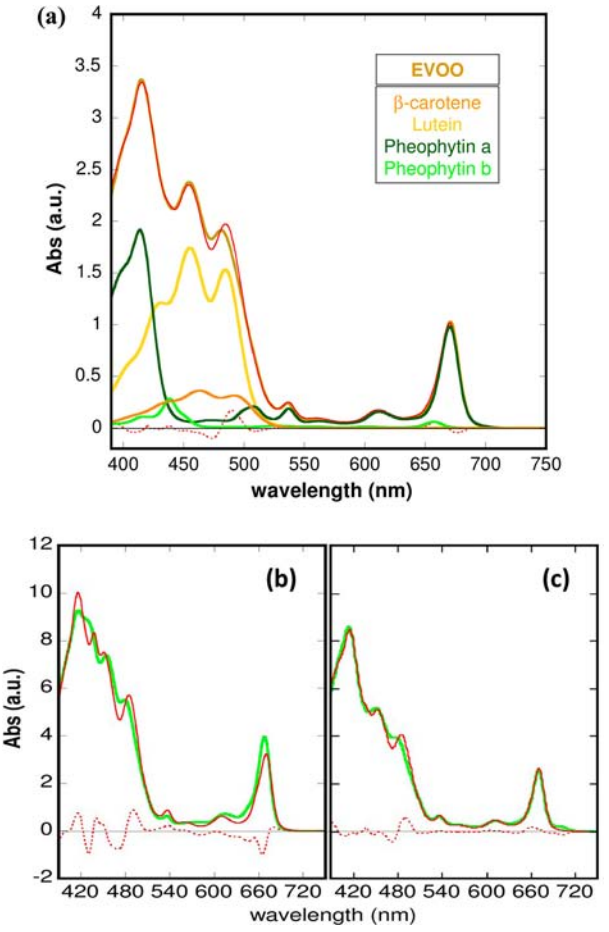

**Figure 6.** (a) Typical UV−vis absorption spectrum of a Tuscan EVOO produced from "Frantoio" olive cultivar. The concentration of the four pigments obtained from spectrum analysis is also reported (see Table 3). (b) UV−vis absorption of a young Tuscan EVOO (experimental and fitted spectra, with relative residues), (c) the same EVOO after three years at ∼3 °C in the darkness. See data about calculated concentration of pigments in Table 3.

calculated absorbance. In Table 3 the correspondent concentration of the pigments, calculated by means of eqs 3 and 4, is reported.

The spectrum in Figure 6A is typical of many Italian EVOOs. In the example (a one-year old monovarietal oil from fruits of "Frantoio" cultivar), the disagreement between calculated and experimental spectra is appreciable in a single spectral zone, i.e., in the 465−495 nm range (on the average 5.3%), where the calculated absorption is much more resolved than the experimental one. This disagreement regards part of the carotenoid spectral region, for which only lutein and $\beta$-carotene spectra define the spectroscopic functional space, as previously discussed. In Figure 6A, the contribution of these two pigments to the spectrum of "Frantoio" EVOO is also reported: the maxima of both pigments, at 484 and 491 nm, respectively, in the disagreement zone, are red-shifted with respect to the actual maximum (481 nm) of the oil. Thus, there is no possibility to obtain a maximum at 481 nm by combining the extinctions of lutein and $\beta$-carotene with positive coefficients. On the other hand, they are the only pigments, among the four mathematically present, appreciably absorbing light in the 480 nm region.

In a recent work on Italian EVOOs from different cultivars,[26] it has been shown that, on the average, lutein is present in these oils as 39% by weight of the sum of the weights of the other 12 xanthophylls HPLC-determined. In "Frantoio" oils lutein represents the 61%, i.e., the maximum content in the oils there investigated. Thus, minor carotenoids, such as neoxanthin, violaxanthin, luteoxanthin, antheraxanthin, mutatoxanthin etc., are present in concentrations well over the values reported for many Spanish EVOOs[17,34] in which the above minor xanthophylls are present in neatly lower percentage, and lutein is present from 61 up to 93.1% of total xanthophylls. The above data suggest that the contribute of minor xanthophylls to oil absorbance in the Italian EVOOs of Figures 3 and 6(a) is higher than in the Spanish EVOOs of Figure 5. As a consequence, the functional space of lutein and carotene spectra cannot represent the spectral contributions of some of these "minor" pigments. This is reflected by some inaccuracy in

**Table 3. Molar Concentration (mol/L) of the Four Pigments of the Four Andalusian EVOOs (Figure 5), of a Typical Tuscan "Frantoio" EVOO (Figure 6a), a Young Tuscan EVOO (2008 Harvest; Spectra Recorded in 2009) (Figure 6b) and the Aged Corresponding Tuscan EVOO (the Same Sample, but Spectra Recorded in 2013) (Figure 6c)**

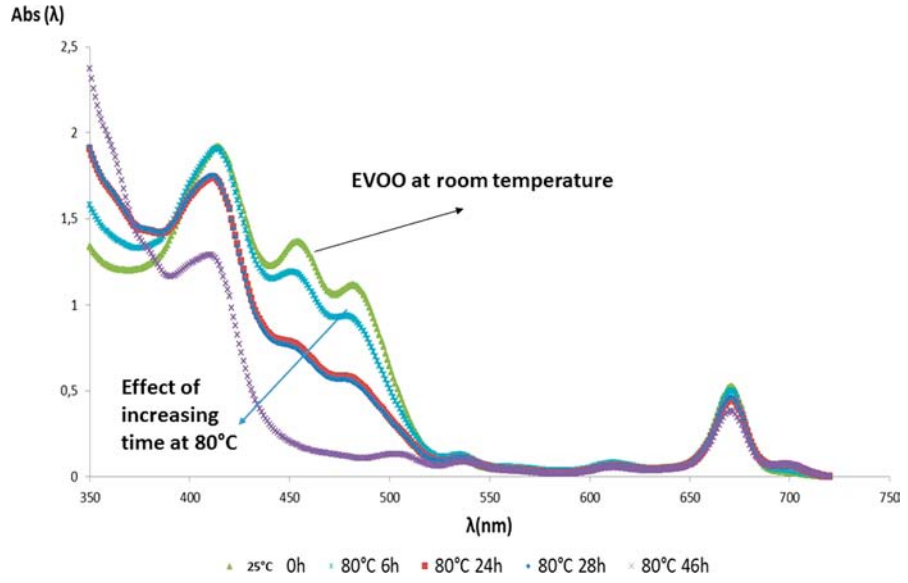

**Figure 7.** Series of UV−vis spectra of an EVOO sample at room temperature (green curve) and after several hours at 80 °C (see labels).

the calculated vs measured absorption spectra just in the 480 nm band.

Another interesting example is reported in Figure 6(a): in this case, the method fails in reproducing the intense experimental absorption spectrum of a young (less than two months) EVOO from southern Tuscany. In fact, there are two spectral intervals, centered at 430 and 665 nm, where the calculated absorption is about 1 absorbance unit lower than the measured one, in exact correspondence with the absorption peaks of chlorophyll-a in extra-virgin oils, as determined by addition of chlorophyll-a to triolein and to an EVOO. The same oil of Figure 6(b), after aging almost three years at ca. 4 °C in dark conditions and complete spontaneous pheophytinization, showed a changed absorption spectrum as shown in Figure 6(c), where the usual trend of calculated vs measured spectrum is observed. In Table 3, the calculated pigment concentrations are reported. In order to fit the spectrum of this particular oil before pheophytinization, it would be necessary to add in our treatment other pigments, i.e., chlorophylls. Since chlorophylls are present usually only in freshly extracted oils,[21,26] the number of pigments was limited to the four previously described. It is clear that the functional spectral space of chlorophylls pigments is complete only for oils in which pheophytinization processes are finished and pyropheophytinization processes are marginal.

In addition to the successful reproduction of the absorption spectra of nonfreshly extracted EVOOs, the method has been tested by measuring the spectra of some EVOO samples obtained by mixing, in defined proportions, two EVOOs with different spectra and pigments composition. The resulting composition in pigments reproduced the proportion of the constituent oils and their pigment compositions with an average error of 1.1 ± 0.6%.

**Use of the Method to Check Eventual Thermal Treatments.** An experiment was done in order to reproduce a case of bad storage. A sample of olive oil was forced to a controlled thermal degradation, to induce pigments degradation. Chlorophyll content generally reduces up to 80% during the oil extraction process, using only mechanical and physical processes for extraction. These processes result in a considerably reduced chlorophyll level in the oil compared to the olive fruit itself. Pyropheophytins are also produced by subsequent degradations of chlorophyll pigments, and the presence of pyropheophytins is an indication of probable heating or aging effects. In fact, chlorophyll converts to pheophytin and ultimately to pyropheophytins. The proportion of pyropheophytin-a to the total pheophytins is useful in discriminating fresh oil from oil which has been in long-term storage or which has been heated in the refining process.[35−37] Freshly extracted virgin olive oils do not contain pyropheophytins. However, they are generated during storage in different amounts depending on the conditions of exposition of oil. This reaction is boosted by heat treatments during refining processes, especially during deodorizing. This leads to the possibility of using these degradation products of chlorophyll as a marker for quality and traceability of virgin olive oils. For instance, in this way, it can be determined if an olive oil, labeled as virgin, was properly stored or, in contrast, if the virgin olive oil was cut with refined oils. For all investigations, it is essential to consider the exact harvesting date. Generally, the typical analysis according to ISO 29841:2009 is a chromatographic analysis. In this paragraph, we would like just to put the attention on the large spectral changes affecting the UV−vis spectra of EVOOs, when the temperature of storage increases. In Figure 7, a case of thermal degradation at 80 °C, after a different heating time, is shown. The curves obtained after heating at $T$ = 80 °C and after 6, 24, 28, and 46 h show a gradual change. It is possible to see that after few hours from the warming the oil spectrum changes in its shape and relative intensity. After more than 24 h, the changes are drastic. This method could indeed reveal the presence of oil undergone to a refined treatment or simply subjected to a bad storage condition for example during its transport, and further extentions of our method to include other pigments or to study different cases of thermal or illumination effects are expected to provide a useful, fast, and simple tool to check the quality of olive oils.

In this work, a mathematical treatment of UV−vis absorption spectra of olive oil is developed to extract quantitative information about four among the most important pigments in extra-virgin olive oils, namely, $\beta$-carotene, lutein, pheophytin-a, and pheophytin-b. To explain the reliability and applicability

dx.doi.org/10.1021/jf503818k | J. Agric. Food Chem. 2014, 62, 9317−9325

of this fast and not destructive method, several examples, underlining positive aspects and limits, have been reported.

The original aim of this research was to extract from the absorption spectrum (390−720 nm) of extra virgin olive oils the most complete information about the concentration of the *pigments* of interest. Our experiments show that reliable data on the concentration of the *chromophores* corresponding to these pigments can be extracted. For this reason, a direct comparison with data found by other techniques, such as HPLC, is not appropriate, as shown through an example in the Supporting Information. For instance, because of the typical presence in many EVOOs of fat acids-esterified lutein,[21] the concentration of lutein found by this spectral analysis is slightly higher than that determined by HPLC, since the absorption spectra of this xanthophyll and that of its known esterified-forms coincide within experimental errors. In parallel, the obtained UV-concentration of pheophytin-a represents the sum of the concentrations of pheophytin-a and its epimers, since the molar extinction spectra of these coincide almost exactly with the pheophytin-a one. This is also shown in the Supporting Information. The intrinsic differences between the HPLC method and that proposed in this work confirm that a direct comparison between them is not appropriate. However, as shown by the examples reported in this work, the data obtained from the analysis of UV−vis spectra, analytically oriented to the chromophores, preserve analytical interest for systems where the four pigments, chosen as mathematical spectral references, are dominant, as seems to be the case for most of the EVOOs analyzed so far.

Moreover, among the possible applications of this fast method, its successful applicability to put in evidence eventual thermal degradation or not-appropriate storage conditions of EVOOs is discussed. Despite its not strictly quantitative use, this method appears very useful for a fast screening of EVOOs.

## ■ ASSOCIATED CONTENT

### Supporting Information

Values of overlapped matrix for the four pigments used to perform the mathematical treatment. A detailed description of the validation of the method. A detailed comment about the comparison between data calculated from the method proposed and from HPLC analysis, with an example of HPLC determination of pigments quantity for an EVOO sample. This material is available free of charge via the Internet at http://pubs.acs.org.

accumulation make it difficult to study rheology in fermenting dough, our approach here focused on the direct addition of ethanol to the dough recipe to assess its potential impact on dough behavior. To study the ethanol-induced changes in dough mixing behavior and rheology, Mixograph, Farinograph, dough spread test, Kieffer rig, and Alveograph dough extensibility tests were used. Ethanol solvent retention capacity and gluten agglomeration experiments with chromatographic analyses of the gluten fractions were performed to gain further insight in the molecular mechanism at the basis of the observed changes in dough properties. They allowed assessment of the impact of ethanol on gluten properties as main determinant of dough rheology. Together, the results of these tests indicate that the ethanol is indeed a yeast metabolite that strongly influences the rheology of fermenting dough.

## MATERIALS AND METHODS

**Materials.** A low protein content flour (flour A, commercial biscuit flour) from Ceres Soufflet (Brussels, Belgium) and a medium protein content flour (Kolibri, flour B, bread making flour) from Meneba (Rotterdam, The Netherlands), both free of additives, were used for dough making. For flour A, two batches were used due to exhaustion of the first batch. Commercial wheat gluten [moisture content, 5.62%; crude protein content (N × 5.7), 83.2% on dry matter basis (dm)] was from Tereos Syral (Aalst, Belgium). All chemicals, solvents, and reagents used in the experiments were of analytical grade and from Sigma-Aldrich unless specified otherwise. Water used in the experiments was deionized unless specified otherwise.

**Flour Characterization.** Flour moisture and protein content were measured in triplicate according to AACC International Approved Methods 44-19.01[18] and a Dumas combustion method,[19] adapted for an automated Dumas protein analysis system (EAS, VarioMax N/CN, Elt, Gouda, The Netherlands), respectively. The moisture contents of flour A (batch 1), A (batch 2), and B were 13.1, 13.9, and 14.3% respectively. The protein contents (N × 5.7) of flour A (batch 1), A (batch 2), and B were 10.5, 8.9, and 11.5% on dm basis, respectively. Flour A (batch 1) was used for all experiments except for gluten agglomeration and sequential extraction analyses, where flour A (batch 2) was used. Optimal mixing time and water absorption were determined with a Mixograph (National Manufacturing, Lincoln, NE, USA) and a Farinograph (Brabender, Duisburg, Germany) based on AACC International Approved Methods 54-40.02 and 54-21.01, respectively.[18]

**Farinograph Analyses.** Farinograph analysis was performed on a Farinograph E with a 10 g mixing bowl (Brabender, Duisburg, Germany) at a constant temperature of 30 °C. The farinogram, representing the evolution of dough consistency as a function of mixing time, was obtained according to AACC International Approved Methods 54-21.01.[18] Flour (10.0 g, 14.0% moisture basis) was mixed for 20 min with the amount of deionized water (% v/w) that leads to a maximal average consistency of 500 Brabender units (BU), i.e., the Farinograph water absorption. It was 5.3 and 5.6 mL for flours A and B, respectively. To study the effect of ethanol on dough formation in the Farinograph, the water in the procedure was substituted with aqueous ethanol solutions of the correct molarity to reach ethanol concentrations of 0, 20, 40, 60, and 80 mmol per 100 g of flour in the dough.

**Mixograph Analyses.** Mixograph (National Manufacturing, Lincoln, NE, USA) analyses were performed on a 10 g scale according to the procedure of Finney and Shogren.[20] Flour (10.0 g, 14.0% moisture basis) was mixed with the optimum amount of water for 8 min at 25 °C in a Mixograph bowl. To study the effect of ethanol on dough formation in the Mixograph, the water in the procedure was substituted with aqueous ethanol solutions of the correct molarity to reach ethanol concentrations of 0, 20, 40, 60, and 80 mmol per 100 g of flour in the dough recipe. The resulting mixograms were analyzed to obtain three parameters. Dough development time (DDT, min) is the time at which the developing dough reaches its maximum consistency. Dough strength (DS, cm) is defined as the maximum height of the curve center, i.e., at the dough development time. The mixing tolerance index (MTI, %) is defined as the ratio of the difference between peak dough resistance and dough resistance at 3 min after the peak to peak dough resistance. The experiments were performed in duplicate.

**Dough Spread Test.** Dough spread behavior was studied by adapting the method described by Hoseney et al.[2] Dough was prepared with a 10 g scale pin bowl mixer (National Manufacturing). Flour (10.0 g, 14.0% moisture basis) was mixed with the optimum amount of water for 210 and 230 s for flours A and B, respectively. To test the effect of ethanol on dough properties, the water in the procedure was substituted with aqueous ethanol solutions of the correct molarity to reach ethanol concentrations of 0, 20, 40, 60, and 80 mmol per 100 g of flour. Mixed dough was transferred to a lightly greased bowl and was rested for 0, 60, 120, or 180 min in the fermentation cabinet with 90% relative humidity at 30 °C. Then the spread measurement was performed. Height ($H$) and orthogonal widths ($W_1$ and $W_2$) were measured immediately after rounding and after a time span of 60 min in which flow could take place. The $W/H$ and $\Delta(W/H)$ (measure for dough spread during proofing) were calculated according to the following formula, described previously by Decamps et al.:[21]

$$\Delta(W/H) = \text{average}(W/H)_{X+60\text{min}} - \text{average}(W/H)_{X\text{min}},$$

with $X$ representing the resting time before rounding the dough. All spread tests were performed in duplicate.

**Kieffer Rig Uniaxial Dough Extensibility Test.** For uniaxial dough extensibility measurements, dough was prepared in a 10 g scale pin bowl mixer and extension tests were performed using the Kieffer rig dough extensibility fixture (Stable Micro Systems Ltd., Surrey, U.K.) mounted on an Instron 3342 single column testing system (Norwood, MA, USA) with a 50 N load cell as described previously by Jayaram et al.[21] To study the effect of ethanol on dough properties, a part of the water was replaced with an aqueous ethanol solution of correct molarity resulting in dough containing 0, 20, 40, 60, and 80 mmol of ethanol per 100 g of flour. For each concentration of ethanol, three different doughs were made. From each dough, 6 to 8 dough strands were used for analysis. For the results, the average of the values obtained for the three separate doughs was considered and the respective standard deviation calculated. The parameters derived from the resulting load−displacement curve are maximum extensibility (mm), maximum force for extension (N), and the total force needed for breakage (mJ), i.e., the area under the load−displacement curve.[22,23]

**Alveograph Biaxial Dough Extensibility Analysis.** Alveograph parameters were determined according to AACC International Approved Methods 54-30.02[18] using a Chopin Alveograph (Chopin, Villeneuve-La-Garenne, France). Both flour samples used were mixed with the optimum amount of water for 6 min in the built-in mixer of the Alveograph. To study the effect of ethanol on dough properties, the water in the procedure was substituted with aqueous ethanol solutions of the correct molarity to reach ethanol concentrations of 0, 20, 40, 60, and 80 mmol per 100 g of flour in the dough recipe. Each Alveograph curve was analyzed for four factors: $P$, the maximum pressure needed to blow the dough bubble, represents dough elasticity ($mmH_2O$); $L$, the average abscissa at the bubble rupture, is a measure of dough extensibility (mm); $W$, the energy needed to make the bubble up to the point of rupture, expresses deformation energy ($10^{-4}$ J), and $P/L$ is the Alveograph ratio. The test was performed in duplicate, and five dough pieces were formed and measured for each replicate.

**Solvent Retention Capacity Test.** Flours A and B, commercially available gluten, gliadin enriched fractions, and glutenin enriched fractions were used to study the swelling behavior of protein in ethanol−water mixtures. A gliadin and a glutenin enriched fraction were prepared from this commercial wheat gluten. Gluten (20.0 g) was first extracted with 250 mL of 70% ethanol. Hereto, the gluten−ethanol suspension was homogenized and subsequently shaken for 1 h at 150 rpm. After centrifugation (10 min; 10000$g$), the supernatant

was separated from the residue. The ethanol was removed by evaporation at 30 °C under reduced pressure. After removal of the ethanol the samples were freeze-dried to remove the water. This fraction will be referred to as the gliadin enriched fraction. The residue remaining after the first extraction was extracted another two times with 60% ethanol to remove all remaining gliadins, and the supernatants were discarded. The insoluble residue after the third extraction was extensively washed with deionized water to remove starch. Hereto, the insoluble residue was kneaded under a flow of deionized water at room temperature. The sample was freeze-dried after washing. This fraction will be referred to as the glutenin enriched fraction. After freeze-drying, both fractions were ground with a laboratory mill (IKA, Staufen, Germany) and sieved (250 $\mu$m). The moisture content of these samples was determined before performing the SRC test.

The solvent retention capacity (SRC) tests of flour with aqueous solutions with different ethanol concentration (0, 5, and 10%), based on the concentration of ethanol in fermenting dough, was conducted according to AACC International Approved Methods 56-11.02[18] with some minor modifications. Flour samples (5.000 g) were weighed in 50 mL centrifuge tubes (height, 115 mm; internal diameter, 27 mm) with a conical bottom. Commercial gluten and gliadin and glutenin enriched fractions (1.000 g) were weighed in 10 mL centrifuge tubes. Then, 25.0 mL of water or respective water/ethanol solution for flour samples or 5.0 mL of water/ethanol solution for gluten and gliadin and glutenin enriched fractions was added, and the mixtures were shaken vigorously for 5 s to suspend the material. Thereafter, the samples were horizontally shaken for 20 min at room temperature at 150 strokes per minute (spm) to allow the samples to solvate and swell. Samples were centrifuged (15 min, 1000*g*, room temperature). Supernatant was decanted from the tubes, and the pellet was drained for 15 min and weighed. The SRC values were calculated as follows:[24]

$$\mathrm{SRC}\ (\%) = \left[\frac{\text{wet pellets (g)}}{\text{flour (g)}} - 1\right] \times \left[\frac{86}{100 - \text{flour moisture (\%)}}\right] \times 100$$

All SRC analyses were performed in triplicate.

**Gluten Agglomeration Analysis.** Gluten agglomeration was analyzed using a dough batter gluten starch separation procedure as described by Frederix et al.[25] Wheat flour (250.0 g, 14% moisture basis) was mixed with water (based on Farinograph water absorption) in a KitchenAid mixer (K5SS/KPM5, St. Joseph, MI, USA) equipped with a dough hook for 4 min. For ethanol containing dough, water was replaced with aqueous ethanol solution in the dough recipe resulting in dough containing 0 (control), 9, 17, 44, and 87 mmol of ethanol per 100 g of flour. The dough was then allowed to rest for 8 min. Additional tap water (250 mL) was added to the dough, and the resulting suspension was stirred using a flat beater for 25 min. After extra tap water (1000 mL) was added, the suspension was stirred for an additional 35 min. The suspension was poured over a set of vibrating sieves with decreasing pore size (400, 250, and 125 $\mu$m). The gluten retained on the different sieves was washed by pouring water (1000 mL) over the vibrating sieves. Gluten fractions were recovered from the three sieves, lyophilized, and ground to pass a 250 $\mu$m sieve. Protein content of the lyophilized gluten fractions was determined with the Dumas combustion method (AOAC, 1995, VarioMax N/CN).

The parameters derived from these experiments are gluten yield ($GY_x$), i.e., total mass (g dm) retained on the sieve with a pore diameter of $x$ $\mu$m per 100 g dm flour, total gluten yield ($GY_{tot}$), i.e., total mass (g) dm retained on the three consecutive sieves per 100 g dm flour, gluten protein recovery ($GPR_x$), i.e., the total amount of protein agglomerated on the sieve with a pore diameter of $x$ $\mu$m (g dm) per 100 g dm flour proteins, total gluten protein recovery ($GPR_{tot}$), i.e., the total amount dm protein agglomerated on the three consecutive sieves per 100 g of dm flour proteins, and gluten protein agglomeration index (GPAI), i.e., the percentage of proteins recovered on the 400 $\mu$m sieve compared to the protein recovery on the three consecutive sieves. These experiments were performed in triplicate.

**Protein Fractionation and Compositional Analysis.** Albumin−globulin and gliadin and glutenin fractions were obtained by an Osborne type sequential protein fractionation.[26] Samples containing 100.0 mg dm protein were extracted (10 min, 150 spm, room temperature) twice with 6 mL of 0.05 M disodium hydrogen phosphate−sodium dihydrogen phosphate (pH 7.6) containing 0.4 M sodium chloride (for the albumin and globulin fraction) and three times (10 min, 150 spm, room temperature) with 3.0 mL of 60.0% (v/v) ethanol (for the gliadin fraction). After each extraction, suspensions were centrifuged (10 min, 10000*g*, 20 °C) (J2-21, Beckman Coulter, Pasadena, CA, USA). The residual nonextracted protein fraction was considered to be the glutenin fraction. The protein levels of the three fractions were determined and expressed on a flour protein basis. Each sample was analyzed at least in duplicate. After filtration (Millex-HP 0.45 $\mu$m, poly(ether sulfone), Millipore, Carrigtwohill, Ireland), the gliadin and glutenin extracts were loaded (80 $\mu$L) on a Nucleosil 300-5 C8 column (Macherey-Nagel, Düren, Germany) and separated by reverse phase high-performance liquid chromatography (RP-HPLC) with a LC-2010HT system (Shimadzu, Kyoto, Japan). Elution was carried out with water containing 0.1% (v/v) trifluoroacetic acid (A) and acetonitrile containing 0.1% trifluoroacetic acid (v/v) (B) with a flow rate of 1 mL/min. Proteins were eluted with a linear gradient from 24% B to 56% B in 50 min and detected at 214 nm. $\alpha$-Gliadin, $\gamma$-gliadin, and $\omega$-gliadin were distinguished based on absorbance minima between specific peaks as outlined by Wieser.[27]

**Size Exclusion Chromatography.** Flour A samples containing 1.0 mg of protein were extracted using 1 mL of disodium hydrogen phosphate−sodium dihydrogen phosphate buffer (0.05 M; pH 6.8) containing 2% sodium dodecyl sulfate (SDS) for 1 h at room temperature. Samples were then centrifuged (10 min, 10000*g*, 20 °C) and filtered (Millex-HP 0.45 $\mu$m) before they were analyzed by size exclusion high-performance liquid chromatography (SE-HPLC) on a LC-2010 system (Shimadzu, Kyoto, Japan) with automatic injection. The column used was a Biosep-SEC S4000 (Phenomenex, Torrance, CA, USA). The used eluent was acetonitrile/water (1:1, v/v) containing 0.05% (v/v) trifluoroacetic acid. The flow rate was 1.0 mL/min at a temperature of 30 °C. The eluted proteins were detected at 214 nm.

**Sequential Ethanol Extraction of Flour.** 100.0 mg protein equivalent of flour A sample was sequentially extracted (10 min, 150 spm, room temperature) with 3.0 mL each of an aqueous 2%, 5%, 10%, 30%, and 60% (v/v) ethanol solution three times individually. After each extraction, suspensions were centrifuged (10 min, 10000*g*, 20 °C) (J2-21, Beckman Coulter, Pasadena, CA, USA). The residual nonextracted protein fraction was considered to be the glutenin fraction. Each sample was analyzed at least in duplicate. After filtration (Millex-HP 0.45 $\mu$m), the gliadin was loaded (80 $\mu$L) on a Nucleosil 300-5 C8 column and separated by RP-HPLC as explained above (Protein Fractionation and Compositional Analysis).

**Statistical Analysis.** Statistical analysis of the results was performed using SAS software 9.2 (SAS Institute, Inc., Cary, NC). For Mixograph, uniaxial and biaxial dough extensibility tests, and gluten agglomeration test, a one-way analysis of variation (ANOVA) was performed separately for each flour to study the effect of ethanol concentration. For dough spread test, a two-way ANOVA was performed to study the effect of resting time and ethanol concentration on each flour separately. A Tukey multiple comparison procedure was used with a 5% family significance level.

## RESULTS

**Effect of Ethanol on Dough Mixing Properties.** For the Farinograph and Mixograph dough mixing analyses, ethanol concentrations in the recipe (0, 20, 40, 60, and 80 mmol of ethanol per 100 g of flour) were chosen to be in the same range as the ethanol concentrations that accumulated during a 3 h dough fermentation, i.e., up to 60 mmol of ethanol per 100 g of flour.[11] Flour A is a biscuit grade flour, which means the flour

has a low protein content. Flour B is a bread making grade flour, which coincides with a higher protein level and better gluten quality. Mixogram data of flours A and B (Table 1) in the absence of ethanol showed slightly higher dough development time for flour B than flour A and similar dough stabilities, while a lower mixing tolerance index for flour B than flour A was observed. These results show that flour B was indeed a stronger flour than flour A, in accordance with the supplier's specifications.[28] With the addition of ethanol, there was no change in dough development time and dough strength for both flours A and B (Table 1). However, mixing tolerance index for flour A increased by 2.6-fold, and there were no significant changes in mixing tolerance index for flour B. The Farinograph water absorption, Farinograph dough development time, arrival time, and departure time were largely unaffected (results not shown).

**Table 1. Mixograph Parameters for Flours A and B with Ethanol in Concentrations of 0, 20, 40, 60, and 80 mmol per 100 g of Flour**[a]

| ethanol (mmol/100 g of flour) | DDT (min) | DS (cm) | MTI (%) |
|---|---|---|---|
| | Flour A | | |
| 0 | 2.8 ± 0.4 a | 4.4 ± 0.1 a | 9.1 ± 0.1 c |
| 20 | 2.7 ± 0.1 a | 4.4 ± 0.1 a | 8.0 ± 1.5 c |
| 40 | 2.9 ± 0.1 a | 4.3 ± 0.1 a | 17.6 ± 1.4 b |

[a]DDT, dough development time; DS, dough strength; MTI, mixing tolerance index. Mean values ± standard deviation; for each flour type, values followed by the same letter in the same column are not significantly different ($p < 0.05$).

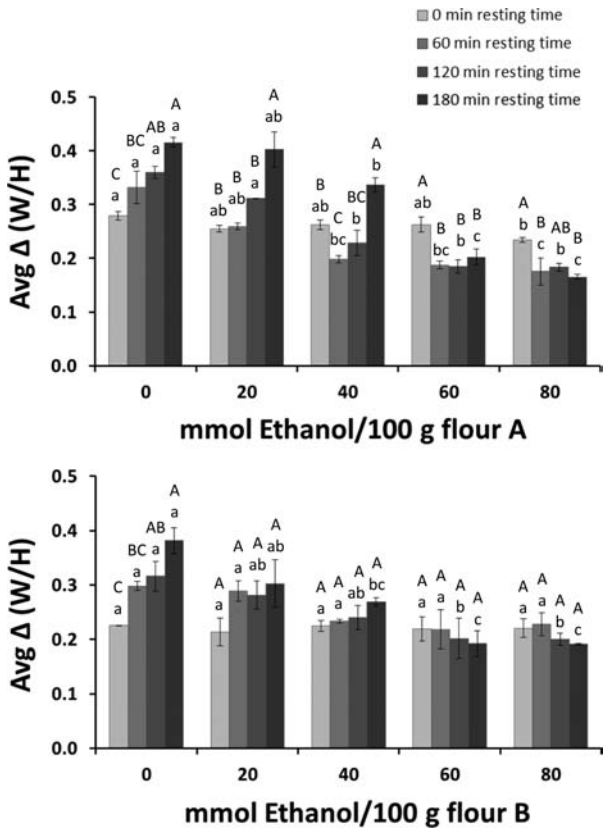

**Figure 1.** Effect of ethanol in concentrations of 0, 20, 40, 60, and 80 mmol per 100 g of flour on the dough spread behavior of flours A and B using the dough spread test. Average Δ [width ($W$)/height ($H$)] values (average $W/H_{X+60\text{min}}$ − average $W/H_{X\text{min}}$ with $X$ representing the resting time before rounding the dough) of spread of dough as a function of ethanol concentration for different resting times. The experiments were performed in duplicate. For each flour, bars with the same capital letter across the same ethanol concentration and bars with the same small letter across the same resting time are not significantly different from each other ($p < 0.05$).

**Effect of Ethanol on Dough Spread.** Dough spread tests allow easy and uncomplicated assessment of the flow behavior of dough. The procedure used in this study was adapted from that of Hoseney et al.[2] to simulate dough fermentation times. Figure 1 shows that the $\Delta(W/H)$ values of control dough gradually increased with resting time, going from 0.28 (0 min resting) to 0.42 (180 min resting) for flour A and from 0.22 (0 min) to 0.38 (180 min) for flour B. These results indicate that longer resting times prior to the actual spread measurement lead to a significant ($p < 0.05$) increase in dough spread. While at low ethanol concentrations a similar effect was observed, at higher ethanol concentrations the $\Delta(W/H)$ values decreased with resting time. For 80 mmol of ethanol per 100 g of flour, the $\Delta(W/H)$ value drops from 0.23 (0 min) to 0.16 (180 min) for flour A ($p < 0.05$) and from 0.22 to 0.18 for flour B. Dough hence shows less spread as a function of resting time with higher ethanol levels.

**Effect of Ethanol on Dough Extensibility.** To investigate the effect of ethanol on dough extension, both uniaxial Kieffer rig (Figure 2) and biaxial Alveograph dough extensibility tests (Figure 3) were performed. Ethanol was used in dough recipe by replacing the same volume of water. Flour A control dough showed more extensibility than flour B control dough in both the tests. In the uniaxial dough extensibility test, the maximum force needed for dough breakage was higher for flour B, which clearly indicates that flour A is weaker than flour B. Upon incorporation of increasing levels of ethanol, the maximum extensibility (Figure 2C) and the total force for dough breakage (Figure 2E) decreased significantly for both flours A and B. Flour A maximum extensibility, for example, decreased from 57.6 ± 1.9 mm (0 mmol of ethanol/100 g of flour) to 33.7 ± 0.7 mm (80 mmol of ethanol/100 g of flour), while the total work required for breakage decreased from 7.2 ± 0.4 mJ (0 mmol of ethanol/100 g of flour) to 4.1 ± 0.8 mJ (80 mmol of ethanol/100 g of flour). For both flour types (Figures 2A and 2B), the more extensible dough changed into a stiffer dough upon adding ethanol (Figure 2D).

For both flours, we observed up to about 40% reduction in maximum dough extensibility and 24% increase in maximum force required for extension with 80 mmol of ethanol per 100 g of flour. Addition of 80 mmol of ethanol per 100 g of flour on top of the water, instead of partially replacing water, resulted in similar results with a maximum dough extension decrease down to 41 ± 1.0 mm. The force needed to break the dough strand was then 3.8 ± 0.6 mJ, and the maximum force required for dough extension was 0.14 ± 0.01 N.

dx.doi.org/10.1021/jf502547a | J. Agric. Food Chem. 2014, 62, 9326−9335

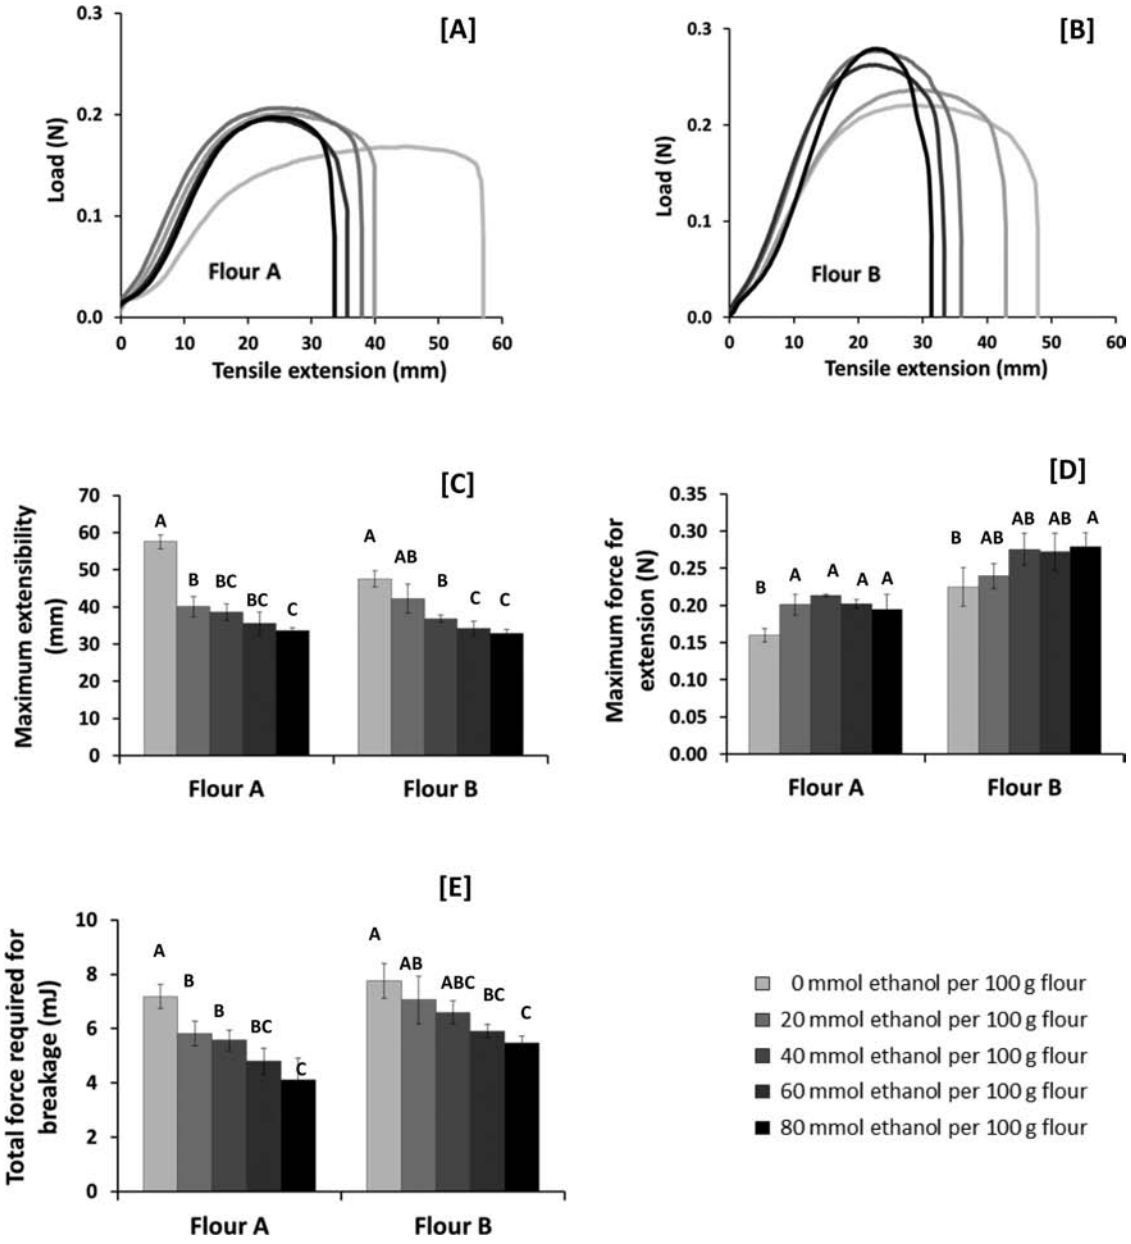

**Figure 2.** Effect of ethanol in concentrations of 0, 20, 40, 60, and 80 mmol per 100 g of flour on uniaxial dough extensibility of flours A and B using the Kieffer dough extensibility rig. Representative load−displacement curves are given for flour A (A) and flour B (B). The following analysis parameters are shown: maximum extensibility (C), maximum force for dough extension (D), and total force required for dough breakage (E). For each flour, bars with the same letter across the same ethanol concentration are not significantly different from each other ($p < 0.05$).

Biaxial dough extensibility results for ethanol (Figure 3) were in line with uniaxial dough extensibility results. For both flours, there was a significant increase in $P$ value, the parameter representing dough strength (Figure 3D), and a mostly linear decrease in the $L$ value, the parameter representing dough extensibility (Figure 3C). Ethanol (80 mmol/100 g of flour) in flours A and B gave up to a 31 and 20% increase in $P$ value, respectively, compared to the control dough. Biaxial measurement gave more insights on the dough tenacity as noticed in $P$ value. It shows that the maximum pressure needed for bubble rupture increased with the increase in ethanol inclusion. Conversely, the $L$ value decreased significantly with up to 64 and 63% for 80 mmol of ethanol per 100 g of flour for flours A and B, respectively. This is similar to the uniaxial test, showing the decreased dough extensibility. The Alveograph $P/L$ ratio, indicating the balance between dough strength and extensibility (Figure 3F), increased 3.8- and 3.1-fold with 80 mmol of ethanol per 100 g of flour for flours A and B, respectively. For flour A, the deformation energy ($W$) (Figure 3E) decreased from $(157 \pm 4) \times 10^{-4}$ J (0 mmol of ethanol/100 g of flour) to $(112 \pm 13) \times 10^{-4}$ J (80 mmol of ethanol/100 g of flour), whereas, for flour B, the decrease was from $(193 \pm 6) \times 10^{-4}$ J (0 mmol of ethanol/100 g of flour) to $(97 \pm 16) \times 10^{-4}$ J (80 mmol of ethanol/100 g of flour). Together, these Alveograph parameters provided insight into the effect of ethanol on dough properties. These experiments support the effect of ethanol on dough rheology, besides the possible effect of a loss of plasticizer caused by the use of less water in the dough recipe.

**Effect of Ethanol on Gluten Swelling.** To assess the molecular origin of the changes in dough rheology in the

dx.doi.org/10.1021/jf502547a | J. Agric. Food Chem. 2014, 62, 9326−9335

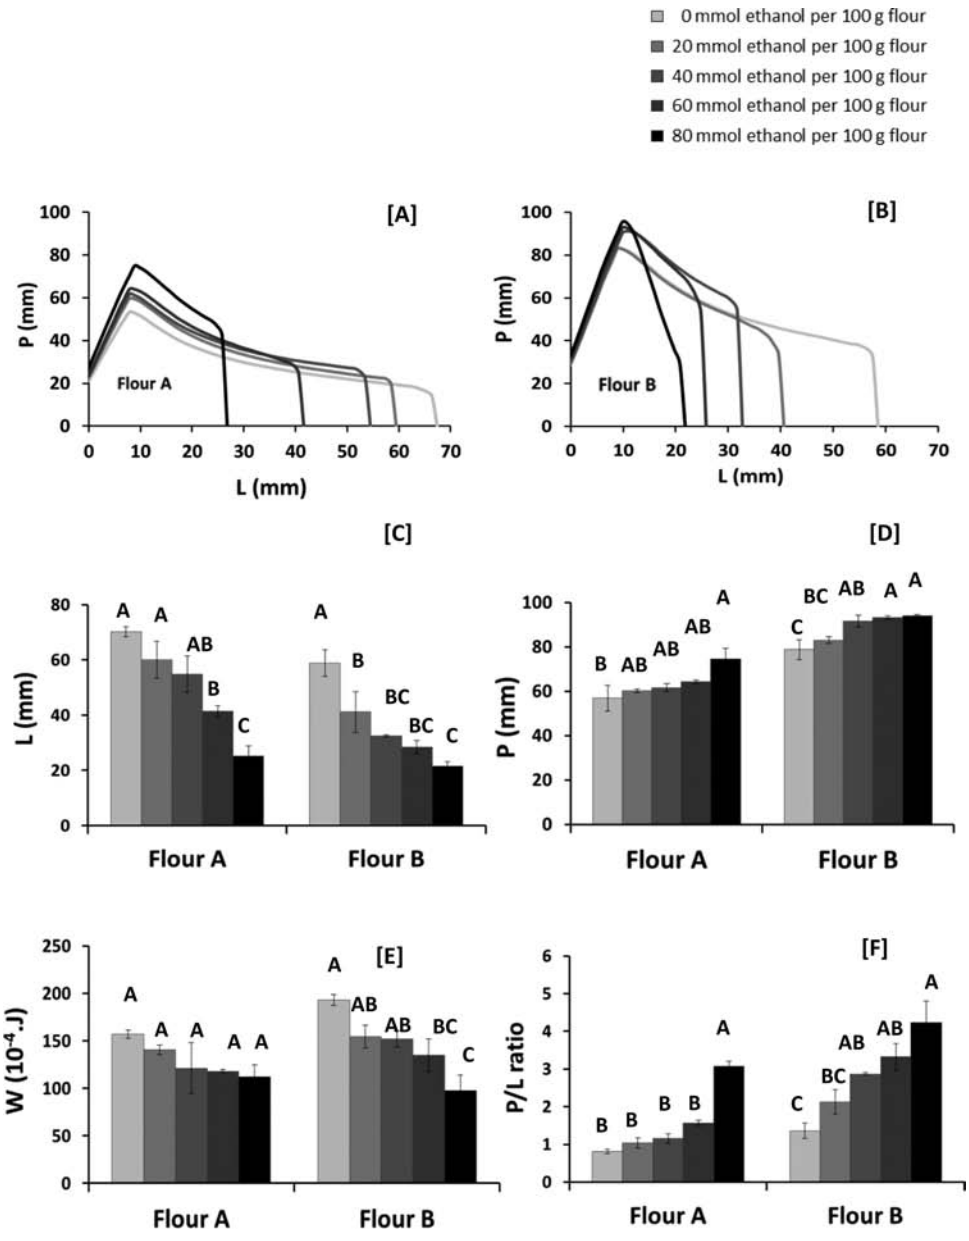

**Figure 3.** Effect of ethanol in concentrations of 0, 20, 40, 60, and 80 mmol per 100 g of flour on biaxial dough extensibility of flours A and B using the Alveograph. Representative Alveograph curves are given for flour A (A) and flour B (B). The following analysis parameters are shown: extensibility ($L$, mm) (C), maximum pressure ($P$, mm) (D), deformation energy ($W$, $10^{-4}$ J) (E), and the Alveograph $P/L$ ratio (F). For each flour, bars with the same letter across the same ethanol concentration are not significantly different from each other ($p < 0.05$).

presence of ethanol, flour and gluten swelling behavior was studied in aqueous ethanol solvents (0, 5, and 10%, v/v) using the SRC test. In the SRC methodology, the swelling behavior of flour polymer networks in a solvent and, hence, their ability to retain that solvent are quantified.[29] The results (data not shown) indicate that the polymer networks in flour showed no significant swelling with the ethanol concentrations used here. In order to test directly on gluten, commercial gluten material and the extracted gliadin- and glutenin-enriched fractions were used. No noticeable change in SRC was observed (data not shown).

**Effect of Ethanol on Gluten Agglomeration.** Gluten–starch separation experiments were performed using a dough batter method (Figure 4). Different ethanol concentrations were used in the dough recipe, but for the subsequent batter stages, only tap water was used. Nevertheless, gluten yields (GY) (Figure 4A) and protein recoveries (GPR) (Figure 4B) increased with increasing ethanol concentrations in the dough recipe of flour A. The pronounced impact of ethanol on flour A made its GY and GPR emulate those of strong flour (flour B results not shown). The largest increase in GPR upon inclusion of ethanol during the dough preparation was observed on the 125 $\mu$m sieve. The gluten protein agglomeration index (GPAI) (Figure 4C) dropped from 56.7 ± 2.0 to 46.9 ± 0.2% for 87 mmol of ethanol per 100 g of flour.

Because the effects of ethanol were mainly observed when using flour A, the protein composition of the fractions obtained on the different sieves was further determined for the latter flour (Figure 5). Although the albumin/globulin content on different sieve fractions remained almost same (results not shown), differences were observed in the gliadin fractions. Figure 5A–C shows the composition of gliadin proteins on the

dx.doi.org/10.1021/jf502547a | J. Agric. Food Chem. 2014, 62, 9326–9335

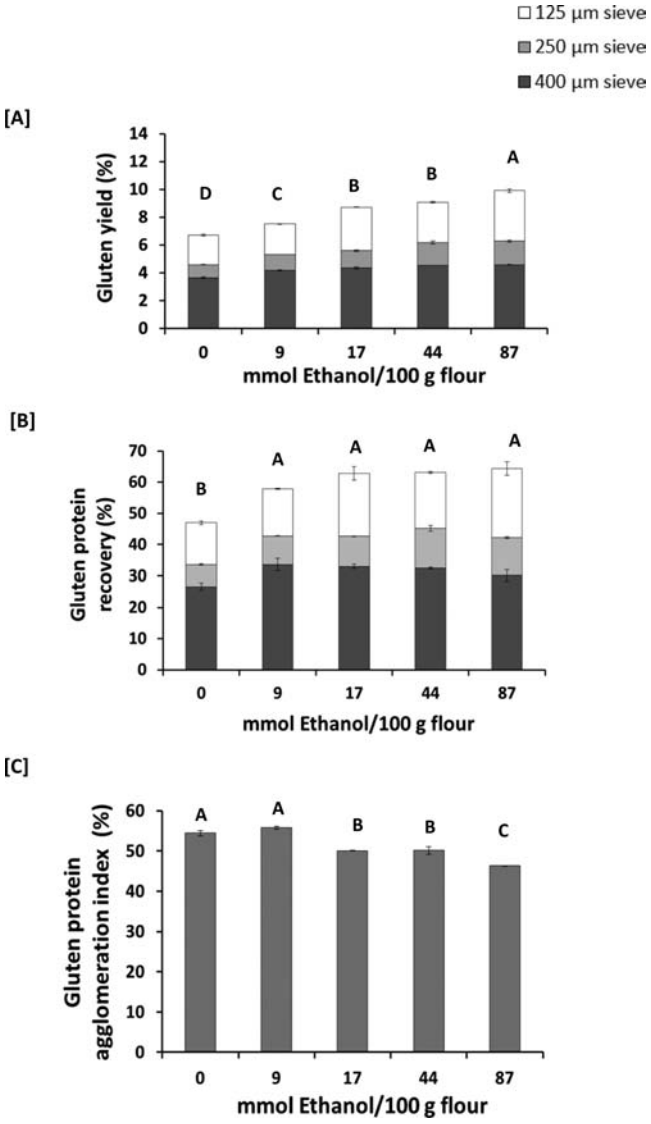

**Figure 4.** Effect of ethanol in concentrations of 0, 9, 17, 44, and 87 mmol per 100 g of flour on gluten agglomeration of flour A using a dough batter method. Gluten yield (A), gluten protein recovery on the different sieves (B), and gluten protein agglomeration index (C) for flour A are shown. For each sample, total bars with the same letter are not significantly different from each other ($p < 0.05$).

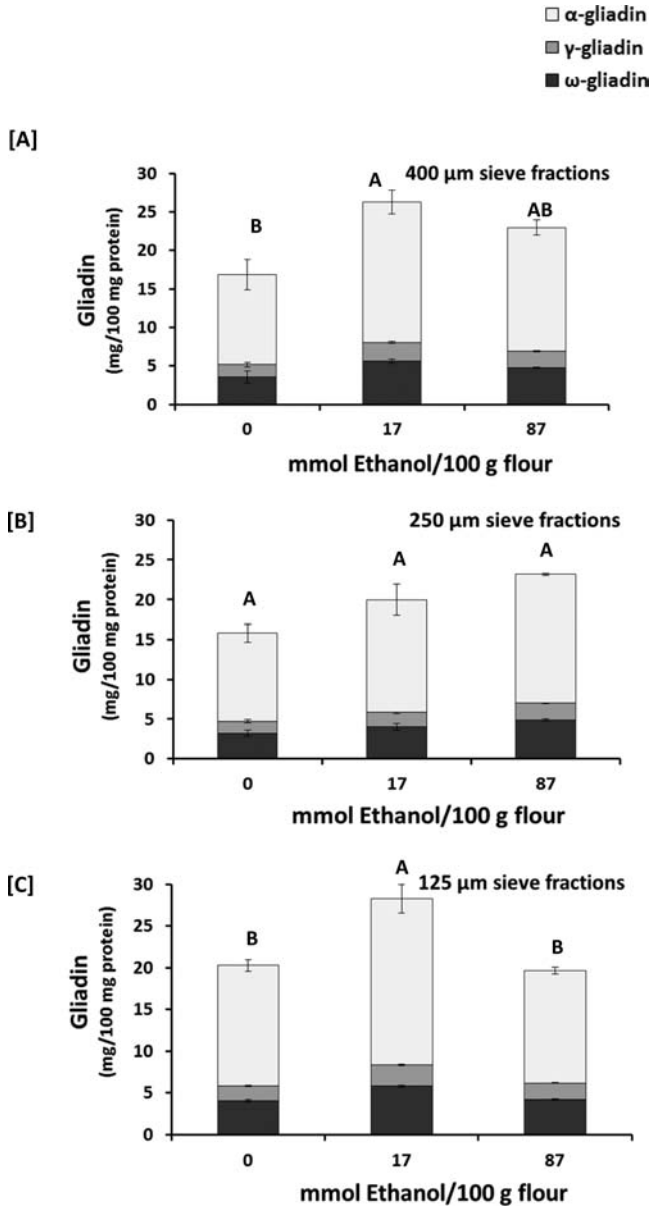

**Figure 5.** Composition of gliadins in gluten fractions obtained from gluten agglomeration experiment for flour A in concentrations of 0, 17, and 87 mmol of ethanol per 100 g of flour and determined using reversed-phase high-performance liquid chromatography (RP-HPLC). The composition of gliadin in the gluten fractions retained on the 400 $\mu$m (A), 250 $\mu$m (B), and 125 $\mu$m (C) sieves. For each sample, total bars with the same letter are not significantly different from each other ($p < 0.05$).

different sieves analyzed in more detail using RP-HPLC. Low ethanol concentrations added to dough from flour A led to significantly higher levels of gliadin retained on the three sieves. There was a noticeable increase in retention of all three gliadin types, but specially, $\alpha$-gliadin concentration increased from 11.6 $\pm$ 1.9 to 18.2 $\pm$ 1.5 mg/100 mg of protein on a 400 $\mu$m sieve, 11.0 $\pm$ 1.1 to 14.1 $\pm$ 1.9 mg/100 mg of protein on a 250 $\mu$m sieve and 14.4 $\pm$ 0.1 to 19.9 $\pm$ 1.7 mg/100 mg of protein on a 125 $\mu$m sieve.

**Sequential Extraction of Flour with Increasing Ethanol Concentration.** To further investigate the effect of ethanol on dough and gluten behavior, flour A was sequentially extracted with 2, 5, 10, 30, and 60% ethanol in water solutions. Prior to the ethanol extraction, the flour sample was pre-extracted with sodium phosphate buffer (0.05 M, pH 7.6) to remove albumins and globulins. Figure 6 shows the RP-HPLC profiles of the gliadin fractions. Addition of ethanol to water improved the solvent quality for gliadin, since increasing ethanol concentrations were able to increasingly dissolve the protein fractions defined as gliadins (Figure 6). The impact of low ethanol concentrations as used in this study became apparent by a selective dissolution of the more hydrophilic $\omega$-gliadins (Figure 6).

## DISCUSSION

During dough fermentation, a yeasted dough undergoes significant rheological changes. These changes could be mediated by one or more metabolites produced by yeast during the fermentation process. Surprisingly, research in this field has mainly been limited to studying effects of dough acidification by the progressive buildup of $CO_2$, acetic acid, or

dx.doi.org/10.1021/jf502547a | J. Agric. Food Chem. 2014, 62, 9326−9335

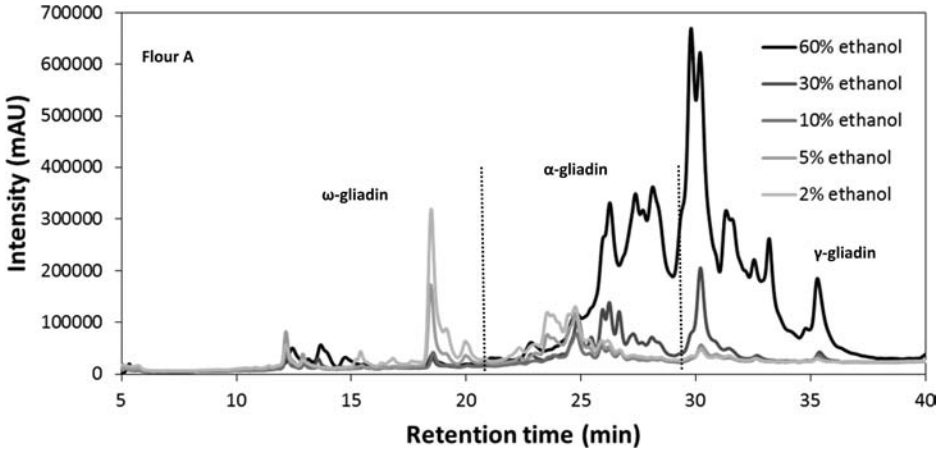

**Figure 6.** Reversed-phase high-performance liquid chromatography (RP-HPLC) profiles of flour A sample sequentially extracted with 2%, 5%, 10%, 30%, and 60% ethanol.

lactic acid[4] and of $H_2O_2$.[10] Recently, Jayaram et al.[8] showed that addition of succinic acid to the dough in the levels produced by the yeast during dough fermentation significantly decreases dough extensibility. With regard to $H_2O_2$, a recent study by Rezaei et al.[11] showed that yeast does not excrete $H_2O_2$ to the dough during fermentation, in contrast to an earlier report stating that $H_2O_2$ produced by yeast during dough fermentation is responsible for the oxidative-like effect of yeast on dough rheology.[10]

The impact of accumulating ethanol, produced in yeast's fermentative metabolism, has not been studied. The research here hence focused on the potential role that ethanol in a concentration range from 0 to 80 mmol per 100 g of flour has on mixing properties, dough spread behavior, and dough extensibility. Its effect on the gluten proteins was studied in more detail. Because the dynamic process of ethanol buildup during fermentation is very hard to implement in sound experiments, our approach comprehended the introduction of ethanol in the dough recipe at the levels at which it is produced in fermenting dough.[11]

As observed in Table 1, the dough development time and dough strength were unaffected with the inclusion of ethanol in both flours A and B. This indicates that the dough retained its stability throughout the mixing process. However, there was a slight increase in mixing tolerance index in flour A suggesting that the dough may turn softer. This was not the case in flour B as the mixing tolerance index remained the same here. Mixograph results indicate that ethanol has a positive effect on dough mixing characteristics as further supported by dough spread test and dough extensibility test results. In dough spread tests (Figure 1), the flow behavior of the dough changed in the presence of ethanol. Instead of having more spread with increasing resting time prior to the spread measurement, as seen for the control, the higher levels of ethanol led to reduced dough spread. The observed increase in $\Delta(W/H)$ values of control dough could possibly be explained in part by the presence of endogenous or kernel associated enzymes such as peptidases present in flour. When considering a constant resting time in the spread test, an increase in ethanol concentration resulted in a decrease in $\Delta(W/H)$. This reduction in spreadability of the dough was more pronounced in flour A, a weak flour, than flour B, a strong flour. While an increase in resting time of the control dough resulted in a higher dough spreadability, increasing levels of ethanol caused increasingly less pronounced changes in the $\Delta(W/H)$ with resting time. This observation could be explained by the ethanol counteracting the action of flour peptidases. This indicates that ethanol turns the dough stiffer. This observation is in line with the more elaborate analysis of dough behavior using the uniaxial Kieffer rig and biaxial Alveograph dough extensibility tests. In both procedures reduced extensibility and an increased maximum force needed to extend the dough were demonstrated as a function of ethanol concentration. This coincided with a decrease in the energy required for deformation until rupture.

To assess the contribution of gluten to these effects, several additional experiments were performed. On the one hand, the SRC of both flours A and B was similar in water and two ethanol−water solvents. Gluten agglomeration analysis for flour A, on the other hand, showed strongly increased gluten yield and gluten protein recovery with increasing ethanol concentration in the dough recipe using a lab scale gluten−starch separation procedure. These increases were mostly due to increases in the yield of smaller aggregates. Using ethanol as a washing liquid has previously been described to improve gluten yield.[30] However, small quantities of ethanol were used here, only in the dough formation and not in the batter formation.

Different hypotheses can be put forward to explain the effect of low levels of ethanol on dough properties. One of the explanations could be the evaporation of ethanol during resting, fermentation, or handling of dough. The dough is left with less solvent, and a stiffer dough results. The Kieffer rig results obtained with dough to which ethanol was added on top of the regular amount of water, instead of a replacement for part of the water, seems to disprove this hypothesis, as results were very similar in both instances.

As a second hypothesis, a change in gluten properties due to the presence of ethanol seems to better explain the observed results. It can be postulated that ethanol, possibly even in low levels in an aqueous environment, creates a different environment for proteins to interact and develop a network in. Aqueous ethanol can be assumed to be a better solvent for gluten proteins than water, in line with the use of ethanol containing solvents for extraction of gliadins and reduced glutenin subunits. In a good solvent, the protein network can be expected to swell and become more expanded,[31] but also have reduced cohesiveness due to a decrease in number or strength of intermolecular secondary structures. This could lead to an

dx.doi.org/10.1021/jf502547a | J. Agric. Food Chem. 2014, 62, 9326−9335

increased gluten yield but, at the same time, a less well-aggregated gluten network. This hypothesis seems to be supported by most results obtained in this study. Spread test, Kieffer rig, and Alveograph results show increased resistance to deformation and reduced extensibility of dough in the presence of ethanol. Gluten agglomeration analysis showed an increase in gluten yield, mostly due to an increase in gluten material on the smaller sieves (250 and 125 $\mu$m) for flour A. Sequential extraction with increasing levels of ethanol showed extraction and hence solubilization of specific gliadin fractions already at low ethanol concentrations, illustrating the better solvent quality of aqueous ethanol versus water alone. Next to the early work of Osborne,[26] the more recent studies of Robertson and co-workers also seem to corroborate this hypothesis. Using ethanol as a washing liquid in gluten starch separation, they observed an improved gluten yield.[30] Also rapid swelling of gluten and a concomitant volume increase was seen upon the use of aqueous ethanol with ethanol concentration up to 50% (v/v).[31,32] In our experiments, this swelling of the gluten matrix was not observed.

With regard to the gliadins, it is not clear what the consequences could be of their improved solvation or partial solubilization, such as observed for $\omega$- and $\alpha$-gliadins in the conditions tested. Their partial solubilization may reduce the plastic and/or viscous properties they confer on gluten. The outcome of this could be a more elastic but stiffer network, which coincides with the results of the flow and extensibility measurements. How the phenomenon of improved solvation or partial solubilization of gliadins has to be unified with the observation of somewhat increased relative levels of gliadins in the small gluten aggregates obtained in the gluten agglomeration test is not clear. Ethanol can be expected to have an effect not only on the chemical interactions but also on the physical interactions through network swelling and expansion.

Based on the results obtained in this manuscript, it is tempting to speculate that the rheological properties of weak flour can be partly brought to the level of good flour by partially changing the solvent and, hence, changing solvent protein interactions. Here, this change seemed to lead to better interactions but resulted in stiffer dough showing resistance to extension upon analysis. For bread making, dough strengthening is often desirable, but dough that is too strong or stiff will also not rise sufficiently.

In conclusion, it was demonstrated in this study that ethanol, at the levels at which it is formed during dough fermentation, has a significant impact on dough properties. Similar to organic acids produced by the yeast during dough fermentation, low levels of ethanol decrease dough extensibility and make dough more stiff and tenacious, albeit through a different mechanism of action than acid metabolites.[8] The results indicate that ethanol might have a more pronounced effect on weak flours than on strong flours. Aqueous ethanol enhances gluten agglomerate yield by acting as a better solvent than pure water, allowing small gluten aggregates to swell more extensively. Taking into account that ethanol, together with $CO_2$, is by far the most produced component by yeast in fermenting dough, it can be suggested that ethanol accumulation is one of the elements responsible for the changes observed in dough rheology upon fermentation. However, in view of the approach used in these experiments, i.e., using yeastless dough to which ethanol is added at the start of mixing, more research in fermenting dough itself is needed to corroborate these findings. Indeed, the difference in impact of providing a bolus amount of ethanol at the start of mixing versus gradual accumulation in dough during fermentation needs to be investigated.

**Table 1. Description of Calibration Set and Validation Set of Tea Samples**

| fermentation degrees | categories | calibration set | | | | | validation set | geographical origins |
|---|---|---|---|---|---|---|---|---|
| | | classes | | | | total | | |
| unfermented | green tea | steamed green tea | roasted green tea | baked green tea | sun-dried green tea | 164 | 10 | Zhejiang, Jiangsu and Fujian, China; |
| | | 30 | 69 | 50 | 15 | | | |
| partially fermented | white tea | Baihaoyinzhen | Baimudan | Gongmei | Shoumei | 50 | 10 | Fujian, China |
| | | 10 | 20 | 10 | 10 | | | |
| semifermented | oolong tea | faint-scent oolong | familiar scent oolong | | baking type oolong | 198 | 10 | Fujian and Guangdong, China; Taiwan |
| | | 60 | 75 | | 63 | | | |
| fully fermented | black tea | Lapsang Souchong | Gongfu black tea | | broken black tea | 51 | 10 | Fujian, Guangdong, Yunnan and Anhui, China |
| | | 15 | 21 | | 15 | | | |
| total | 522 | | | | | 463 | 40 | 19 (Japan, Sri Lanka) |

developed. Therefore, it is necessary to develop accurate and stable methods to distinguish different levels of fermented teas.

Flavor, frequently described as taste and aroma, is the most significant element for tea evaluation. Scientists are highly concerned about the relationship of flavor and biochemical nature. Tea is abundant in chemical components that differ in both content and their component ratio, which not only causes the multiple dimensions of tea quality but also brings some difficulties to the qualitative analysis of tea, especially when tea chemical information far exceeds the taster's subjective analysis. Thus, it is crucial to take advantage of quantitative indicators to identify the tea. More recently, the tea field has made its greatest progress in characterizing the nature of tea at the level of chemistry. Unremitting efforts have been made to research the key components of various teas on the basis of biochemistry and physical characteristics by instrumental techniques. So far, to analyze the characteristic constituents and identify the categories or geographical origins of teas, researchers have been using spectrophotometry,[6] high-performance liquid chromatography (HPLC),[7,8] gas chromatography−mass spectrometry (GC-MS),[9,10] inductively coupled plasma mass spectrometry (ICP-MS),[11] surface desorption chemical ionization mass spectrometry (DAPCI-MS),[12] total luminescence spectroscopy (TLS),[13] near-infrared spectroscopy (FT-NIRS),[14] electronic nose and electronic tongue,[15,16] and machine vision technique.[17,18] Among the various analytical tools, HPLC is widely used by the main exporting and importing countries for the purpose of identifying chemical compositions, providing high accuracy and sensitivity. As widely mentioned, the biochemical characteristics of tea should be attributable to the patterns composed of taste; however, such a method has not been applied systematically for the classification of tea categories. Therefore, we paid close attention to key components such as polyphenols and caffeine, which may be the first consideration for setting a discrimination standard.[19]

"Fermentation" in tea science is typically defined as the oxidation of polyphenols. Increased attention in potential health functions of flavonoid-rich tea has prompted the use of HPLC analysis and pattern recognition to optimize the method of qualitative and quantitative flavonoid analysis. There is certain progress in terms of Wuyi Rock tea distinction, accumulation, and identification of nonvolatile compounds of the tea by the application of HPLC.[20−23] As an effective chemometrics method, stepwise linear discriminant analysis (S-LDA) is incomparable to others in terms of discrimination for its good statistical learning theory and highly efficient discriminant functions,[24] which exclusively selected fewer useful variables by neglecting influences of other variables. Hence, this study applied HPLC analysis in combination with S-LDA to categorize the different fermented teas.

Conducting stable and accurate classification of different kinds of tea in the current tea market is an important issue as well as the essential component of the international standard system. For the above reasons, the proposal of tea chemical classification has passed at the 24th International Conference of International Organization for Standardization (ISO), along with the setup of working groups. Therefore, we aimed to develop an accurate and efficient method based on HPLC to discriminate teas by potential nonvolatile compounds. The study was based on the fact that the biochemical composition varies significantly among different degrees of fermented teas. In our study, numerous representational samples covering four main tea categories in accordance with different fermentation degrees were collected. Polyphenols and caffeine were taken as the distinct variables to establish internationally recognized models of teas, providing reference for the establishment of chemical classification, which would help international tea trade and consumers.

## MATERIALS AND METHODS

**Tea Samples.** A total of 522 tea samples were collected according to fermentation degree, as described in Table 1. Among these samples, 482 tea samples, as the calibration set, were produced in 2010 and 2011, which were collected and purchased from reliable sources in China (463 samples, Table S1 in the Supporting Information) and other countries (19 samples, Table S2 in the Supporting Information).

dx.doi.org/10.1021/jf5025483 | J. Agric. Food Chem. 2014, 62, 9336−9344

Another 40 samples, as the validation set, were produced in 2012 (Table S3 in the Supporting Information). Teas with different degrees of fermentation were sorted from different grades and producing regions and analyzed by HPLC and spectrophotometry for categories discriminate investigation. All samples were kept in ziplock bags and stored in a refrigerator at 4 °C until determined.

**HPLC and Spectrophotometry Analysis.** All of the determinations were assayed in triplicate according to International Standards, which have been applied to provide robust validated analytical tools in cases of international transactions and disputes. The determination of total polyphenols and catechins was performed according to the procedure described by previously reported ISO 14502.[23,25]

*Chemicals.* The following chemicals and solvents were used: Methanol (≥99.5%), Folin−Ciocalteu phenol reagent, sodium carbonate (≥99.8%), gallic acid (≥98.5%), ethylenediaminetetraacetic acid disodium salt, dehydrate (EDTA, ≥99.0%), and L-ascorbic acid (≥99.7%) were purchased from Sinopharm (Beijing, China). (+)-Catechin (C, ≥99%), (−)-epicatechin (EC, ≥98%), (−)-epigallocatechin (EGC, ≥95%), (−)-epigallocatechin gallate (EGCG, ≥95%), and (−)-epicatechin gallate (ECG, ≥98%) were obtained from Sigma-Aldrich (St. Louis, MO, USA.). Caffeine (Aladdin, Shanghai, China), acetonitrile (HPLC grade, ≥99.9%, Lichrosolv, Germany), and acetic acid (HPLC grade, ≥99.7%) were obtained from Fisher Scientific.

*Determination of Dry Matter Content.* The dry matter content was assayed according to the protocol described by ISO 1572 and ISO 1573. Processed tea leaves were milled into a dried fine powder by using a grinding mill and then passed through a sieve of aperture size 500 μm. A sample of 5 ± 0.001 g of tea was weighed to place in a preweighed aluminum dish and dried in a drying oven (DHG-9140A, Lantian, Hangzhou, China) at 103 ± 2 °C for 6 h and weighed until two successive weighings did not exceed 0.005 g. The dry matter content of the samples was calculated from the weight differences.

*Preparation of Extracts.* Samples weighing 0.2 ± 0.001 g were placed in extraction tubes (10 mL). Five milliliters of preheated 70% water/methanol extraction mixture was filled into each tube individually and incubated in the water bath for 10 min at 70 °C (DK-S22 Electric Water Bath, Jing Hong, Shanghai, China) and vortexed for 5 and 10 min, respectively. The extraction tubes were removed from the water bath, allowed to cool to room temperature, and centrifuged for 10 min at 3500 rpm using a centrifuge (Lu Xiang Yi, Shanghai, China). The supernatant was carefully decanted into graduated tubes. The extraction steps were repeated as described above. The extracts were combined and made up to 10 mL with cold methanol/water extraction mixture.

*Analysis of Total Polyphenols (TPs).* The total polyphenol content was determined spectrophotometrically according to International Standard ISO 14502-1:2005, using Folin−Ciocalteu's reagent. Using a pipet, 1 mL of sample extract was pipetted into a 100 mL volumetric flask and filled to the mark with distilled water. One milliliter of the diluted sample was transferred into each tube, mixed with 5 mL of diluted Folin−Ciocalteu phenol reagent, allowed to stand for 3−8 min, and then mixed with 4 mL of 7.5% sodium carbonate solution for 1 h before spectrometric analysis. Distilled water was used as blank, whereas the gallic acid standards were used for quantification. A best-fit linear calibration graph was constructed from the mass of anhydrous gallic acid. The total polyphenols content of tea was detected by using a Shimadzu UV-260 spectrophotometer with a maximum absorption of 765 nm.

*Analysis of Catechins and Caffeine Content.* Catechins and caffeine analyses were conducted according to ISO 14502-2:2005 protocol. One milliliter of the sample extract was made up to 5 mL with stabilizing solution (10% v/v acetonitrile, 500 μg/mL EDTA, and ascorbic acid). The mixture was filtered through a 0.45 μm Millipore filter and put into vials, and it can maintain stability for 24 h when stored at 4 °C. Catechins and caffeine analysis were assayed by using a Dionex UltiMate 3000 HPLC on a phenyl bonded column, using gradient elution with a thermostatically controlled column compartment and an ultraviolet detector set at 278 nm. Elution was performed according to the following system: flow rate, 1 mL/min; temperature, 35 ± 0.5 °C; injection volume, 10 μL; A = 9% acetonitrile (volume fraction), 2% acetic acid (volume fraction) with 20 μg/mL EDTA, B = 80% acetonitrile (volume fraction), 2% acetic acid (volume fraction) with 20 μg/mL EDTA. Binary gradient conditions were as follows: The 100% mobile phase A lasted for 10 min, followed by a linear gradient to 68% mobile phase A and to 32% mobile phase B for 15 min, and was retained at this composition for 10 min. The system was reset to 100% mobile phase A and allowed to remain stable before the next injection.

The five most abundant catechins from the extract, catechin (C), epicatechin (EC), epigallocatechin (EGC), epigallocatechin gallate (EGCG), and epicatechingallate (ECG), were assayed. Catechin and caffeine quantifications were performed using a caffeine calibration curve. For the quantification of the individual catechins, external catechin standards of defined purity and moisture content were used as a standard in conjunction with relative response factors (RRFs), calculated on a dry matter basis. The qualitative analysis of catechin monomer was performed by comparison of their peak areas and retention time on the basis of authentic compounds that were obtained from Sigma. Caffeine content was quantified as follows in accordance with ISO 14502-2:2005.

$$\%\ \text{caffeine} = \frac{(A_{\text{sample}} - A_{\text{intercept}}) \times F_{\text{std}} \times V_{\text{sample}} \times d \times 100}{S_{\text{caffeine}} \times m_{\text{sample}} \times 10000 \times w_{\text{DM,sample}}}$$

where $A_{\text{sample}}$ = peak area of the individual component in the test sample, $A_{\text{intercept}}$ = peak area at the point the caffeine calibration line intercepts the $y$-axis, $S_{\text{caffeine}}$ = caffeine calibration line slope, $V$ = sample extraction volume, $d$ = dilution factor, $m_{\text{sample}}$ = mass in grams of test sample, and $w_{\text{DM,sample}}$ = dry matter content of test sample.

As a percentage by mass on a sample dry matter basis, the total catechin content of tea was calculated by the summation of individual catechins. Nongalloylated catechins and galloylated catechins were calculated as follows:

$$\%\ \text{total catechins} = (\%\ \text{EGC}) + (\%\ \text{C}) + (\%\ \text{EC}) + (\%\ \text{EGCG}) + (\%\ \text{ECG})$$

$$\%\ \text{nongalloylated catechins} = (\%\ \text{EGC}) + (\%\ \text{C}) + (\%\ \text{EC})$$

$$\%\ \text{galloylated catechins} = (\%\ \text{EGCG}) + (\%\ \text{ECG})$$

**Data Analysis.** The instrumental data were constructed by several pattern recognition methods, such as principal component analysis (PCA) and stepwise linear discriminant analysis (S-LDA). PCA was performed by SIMCA (version 13.0.2), which was processed for the sake of having a better visualization of differences among the various objects by projecting them into the space of the first significant components. One-way ANOVA and S-LDA were processed by the SPSS statistical package (version 17.0 for Windows). The ANOVA analysis was used for calibration set (463 samples) covering four kinds of tea samples to identify statistical separation among the means. Experimental results were performed as means ± standard deviation (SD) by SigmaPlot (version 10.0). S-LDA was carried out to extract best discriminant variable separating tea categories, which enters or removes variables by analyzing their effects on the discrimination of the groups based on the Wilks' lambda criterion. In our study, EGC, C, EC, nongalloylated catechins (N-GC), EGCG, ECG, galloylated catechins (G-C), total catechins (TC), caffeine (CAF), and total polyphenols (TP) were assayed; considering the differences in processing, we also calculated the ratios of TC and TP, N-GC and G-C, N-GC and TC, G-C and TC, EGCG and TC, and EGC and TC.[26] For the discriminant four-class problem, we constructed three discriminant functions (DFs) by a linear combination of the extracted features. The $F$ values to enter and to remove were set at 3.84 and 2.71, respectively. The approach yielded four equations that matched each tea category. For the discrimination of oolong and other teas, the values were set at 2.6 and 1.6, respectively. All 16 variables were used in the above analysis. For the classification of different fermentation degrees of oolong tea, the values were set at 1.0 and 0.5, respectively, and the first 10 variables without the ratios were utilized. The

**Table 2. Polyphenols and Caffeine Content and ANOVA Analysis of Tea Categories[a]**

| | | content (%) of calibration set | | | | |
|---|---|---|---|---|---|---|
| no. | compound | GT ($n$ = 164) | WT ($n$ = 50) | OT ($n$ = 198) | BT ($n$ = 51) | $F$ value, significance * |

| 10 | TP | 14.94 ± 2.04 a | 16.03 ± 2.92 ab | 16.76 ± 3.11 bc | 11.73 ± 3.76 d | 45.67 * |

[a]Values are shown as means ± standard deviation, analyzed by one-way ANOVA, utilizing the Dunnett T3 test. Values that do not share a common letter within the same row are significantly different ($P$ < 0.05) from each other.

classification criterion of the equations was as follows: each equation is evaluated by substituting the biochemical data, for which the highest outcome can be regarded as the tea category. In our study, original classification, cross-validation (with the characteristic of "leaving-one-out"), and external validation were used to test the performance of models based on the feature variables.

## RESULTS AND DISCUSSION

**Theoretical Basis of Tea Classification.** As listed in Table 2 and shown in Figure 1, it is remarkable that several compounds were found to have statistically significant differences in tea categories. Almost all of the measured compounds had significant differences ($P$ < 0.05) of relative abundance with respect to categories. The highest compounds of green tea compared to other teas were EGCG, galloylated catechins, and total catechins as the steaming process preserves the greatest degree of polyphenols, resulting in the bitter and astringent taste, although caffeine was the lowest of all teas. With regard to white tea, ECG and caffeine showed the highest contents because the processes include neither pan-frying nor rolling. Because drying temperature and cell damage rates of white tea are lower than those of other teas, the sublimation of caffeine of white tea is much less than that of other teas. On the contrary, white tea showed the lowest content of C and EC; in addition, it also had lower EGCG, non-galloylated catechins, and TC compared to oolong and green teas.[27] For oolong tea, total content and constituents of nongalloylated catechins and total polyphenols were the maximum compared to other teas, but total content and constituents of galloylated catechins were significantly lower than in green tea. It is possible that galloylated catechins are the dominant autoxidation compounds in the oxidation process of oolong tea. The results showed that green tea contained higher ECG and EGCG, but lower EGC, than oolong tea,[1] but when compared to white tea it had lower ECG and higher EGC and EGCG. Except C, EC, and caffeine, other compounds of black tea were at the lowest level compared with other teas. Most polyphenols of black tea are dramatically decreased during enzymatic oxidation, involving polyphenol oxidase. Prevailing biochemistry of teas was mainly consistent with previous results.[26] Therefore, the significant

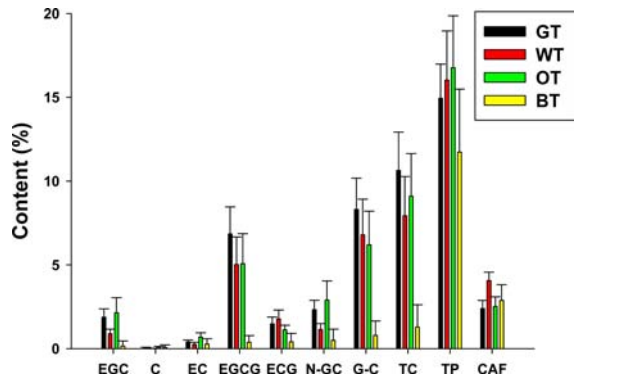

**Figure 1.** Differences of polyphenols and caffeine contents.

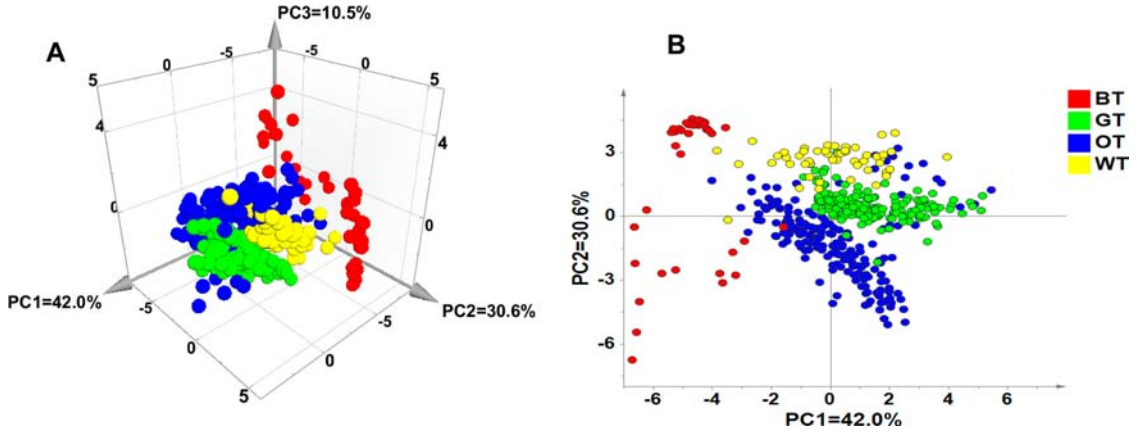

**Figure 2.** Scatter plots of (A) the three first principal components and (B) the two first principal components.

dx.doi.org/10.1021/jf5025483 | J. Agric. Food Chem. 2014, 62, 9336−9344

differences of chemical compounds of tea might provide the fundamental condition of tea classification and were preferred for further analysis using PCA and S-LDA.

**Tea Classification with PCA.** The 463 samples were divided into four groups ranked according to their fermentation degrees. PCA calculations using a reduced number of variables were performed to have a better recognition of the sample information. It is useful for data visualization because a multiplex data set can be effectively observed when it is reduced to a lesser dimensionality. Three significant components were obtained when PCA was performed using the calibration set, jointly accumulating 83.1% of the total variance. Figure 2A shows the PCA 3D score plot with the first, second, and third components explaining 42.0, 30.6, and 10.5% of the total variance, respectively. All 463 samples are projected as small balls of different colors depending on their categories in the plot.

Although there was no clear separation between the objects, some trends can be observed. As is shown in Figure 2A, clear separations of green tea (green balls) and black tea (red balls) samples can be detected, indicating that the degrees of fermentation were quite different from each other. The different producing methods may contribute to the distinctive chemical profile of green tea and black tea, besides their appearance differences. Normally, green tea is characterized by its nonfermentation by steaming process, whereas black tea is fully fermented by the fermentation process, which may explain their distinctive chemical profiles. Separation of white tea (yellow balls) and oolong tea (blue balls) samples was indistinct, indicating that their chemical profiles are much more similar in contrast to those of green tea and black tea. Although all 16 variables gave meaningful information to the classified differences in some degree, some might virtually detract from the simultaneous discrimination of the four tea categories. The results of separating fermented tea from nonfermented tea on the basis of the two first components were negative when some variables were concentrated by the procedure (Figure 2B). Therefore, a more effective feature selection and extraction procedure is desired.

**Tea Classification with S-LDA.** To extract the most discriminating features for the simultaneous discrimination of the four tea categories, S-LDA was performed with the whole variables. Twelve variables apart from EGCG, EGC, N-GC, and the ratio of G-C and TC were selected by Wilks' lambda criterion, whereas the three discrimination functions were constructed, describing 67.5% (DF1), 21.6% (DF2), and 10.9% (DF3) of the total variance, respectively, as shown in Table3. Furthermore, the absolute correlation and contribution of each variable were associated with discriminant function for reflecting its discriminant capacity. The feature variables contributing the most between green tea and oolong tea basically had significant differences, apart from the caffeine that was not of remarkable content, whereas EC was not significant between white tea and black tea (Table 2).

Figure 3 shows the biplot and 3D score plot of canonical discriminant functions, with corresponding tea categories that have been satisfactorily separated. All samples are projected as different shapes and colors depending on their categories in the plot. Green tea and oolong tea have a very distinct separation in the biplot of DF2 and DF3 (Figure 3A), whereas white tea and black tea have a very distinct separation in the biplot of DF1 and DF2 (Figure 3B). Figure 3C shows that green tea and white tea can be effectively classified by DF1 and DF3.

**Table 3. Prediction Results of S-LDA of Tea Categories Using the Original Cases and Cross-Validation and Corresponding Discriminant Functions and Chemical Compounds**

| | prediction of calibration set | | |
|---|---|---|---|
| tea category | original cases (%) | cross-validated (%) | discriminant functions and chemical compounds |
| green | 98.2 (161/164) | 97.6 (160/164) | DF2 and DF3: EC, EGC/TC, ECG, N-GC/TC, C, N-GC/G-C, CAF, TP |
| oolong | 96.5 (191/198) | 94.9 (188/198) | |
| white | 100.0 (50/50) | 98.0 (49/50) | DF1 and DF2: TC/TP, TC, G-C, EGCG/TC, EC, EGC/TC, ECG, N-GC/TC, C, N-GC/G-C |
| black | 100.0 (51/51) | 94.1 (48/51) | |
| total | 97.8 | 96.1 | |

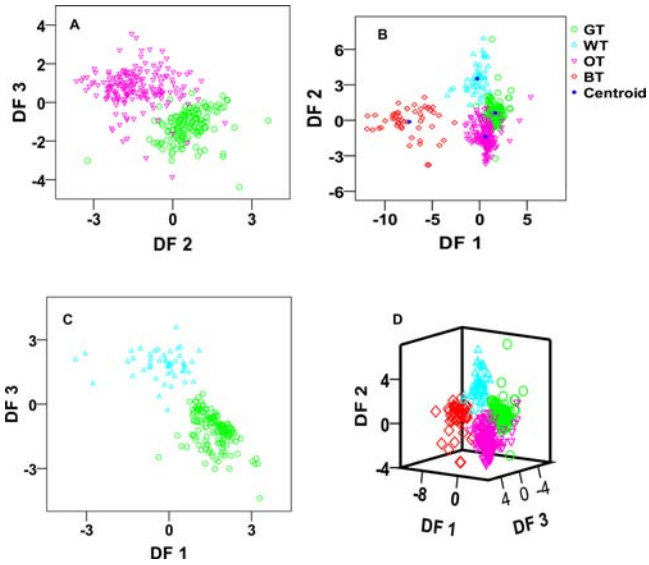

**Figure 3.** Scatter plots of (A) DF2 and DF3, (B) DF1 and DF2, (C) DF1 and DF3, and (D) 3D score of DF1, DF2, and DF3.

Meanwhile, Figure 3D shows the S-LDA 3D score plot with the first, second, and third functions explaining 100% of the total system variance, showing the three significant functions can maximally separate all samples. In summary, four categories can be well separated by using the three DFs extracted.

**Oolong and Other Tea Classification with S-LDA.** For the sake of establishing the International Standard of oolong tea, we also conducted the discrimination of oolong and other teas. Oolong tea usually has a higher unit price than green and black teas in the international tea market for its complex processing steps and limited supply.[1] Hence, it is important to distinguish oolong from other teas. There were 198 samples of oolong tea and 265 samples of other teas (total 463 samples), which were performed by S-LDA, yielding one DF derived from the canonical discriminant fuction (Table S4 in the Supporting Information) and two equations derived from classification function coefficients (Table S5 in the Supporting Information) with the best capacity of their discrimination. Most samples could be successfully differentiated according to their chemical markers. When DF1 yields a positive value, the tea is classified as oolong tea (group centroids, 1.574) and when negative, other teas (group centroids, −1.176).

dx.doi.org/10.1021/jf5025483 | J. Agric. Food Chem. 2014, 62, 9336−9344

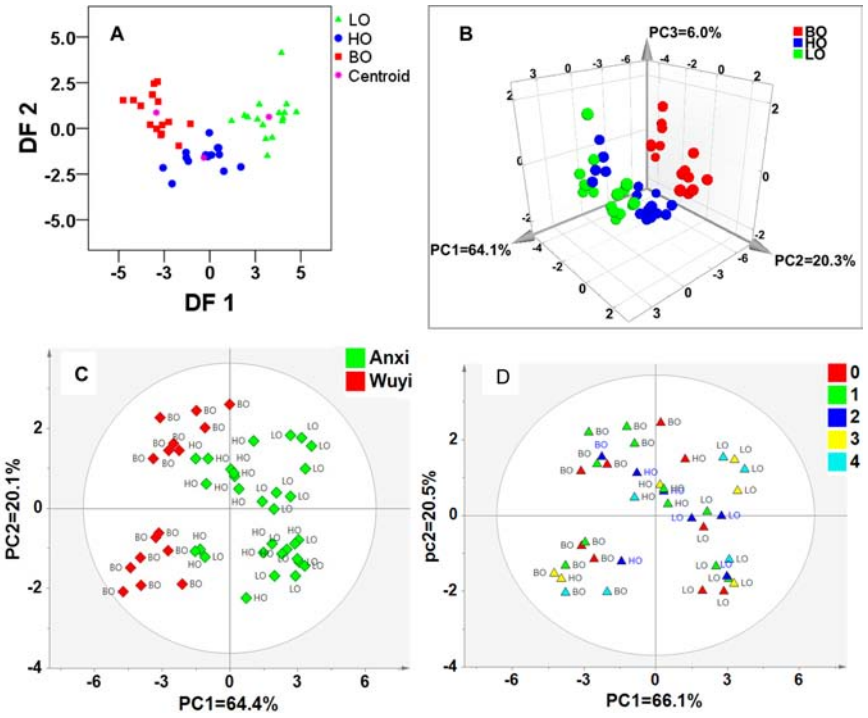

**Figure 4.** Scatter plots of (A) 48 samples elaborated by DF1 and DF2, (B) 48 samples of the three first principal components, (C) 47 samples from different producing regions (Anxi and Wuyi Mountain) of the two first principal components, and (D) 39 samples collected from high to low grades (special grade, levels 1, 2, 3, and 4) of the two first principal components.

$$\begin{aligned}\text{DF1} = {} & 5.406 \times \text{EC} - 1.616 \times \text{ECG} - 0.553 \times \text{N-GC} \\ & - 0.124 \times \text{TC} + 0.255 \times \text{TP} \\ & - 0.014 \times (\text{N-GC/G-C}) + 0.028 \times (\text{N-GC/TC}) \\ & + 0.035 \times \text{EGCG/TC} + 0.082 \times \text{EGC/TC} \\ & - 5.926\end{aligned}$$

An unknown sample also can be predicted by the following equations. After the feature compounds are detected, we bring the data into the two equations, the result of which is higher and could be regarded as the tea category. This method is more convenient and visualized than DF1.

$$\begin{aligned}\text{Equ (oolong)} = {} & 12.246 \times \text{EC} + 19.699 \times \text{ECG} \\ & + 16.712 \times \text{N-GC} - 10.745 \times \text{TC} \\ & + 3.716 \times \text{TP} + 0.114 \times (\text{N-GC/G-C}) \\ & + 1.127 \times (\text{N-GC/TC}) \\ & + 2.549 \times \text{EGCG/TC} \\ & - 0.315 \times \text{EGC/TC} - 110.037\end{aligned}$$

$$\begin{aligned}\text{Equ (others)} = {} & -2.621 \times \text{EC} + 24.144 \times \text{ECG} \\ & + 18.232 \times \text{N-GC} - 10.404 \times \text{TC} \\ & + 3.015 \times \text{TP} + 0.152 \times (\text{N-GC/G-C}) \\ & + 1.050 \times (\text{N-GC/TC}) \\ & + 2.452 \times \text{EGCG/TC} \\ & - 0.542 \times \text{EGC/TC} - 93.193\end{aligned}$$

**Fermentation Degree Classification of Oolong Tea with S-LDA.** For the purpose of further testing the applicability of chemical compounds coupled with S-LDA in different fermentation degrees of tea, this study conducted S-LDA of different fermentation degrees of oolong tea. It is important for us to know whether polyphenols and caffeine are suitable for the same tea category with different fermentation degrees. According to the processing procedure, oolong tea can mainly be divided into three typical kinds with the lightest, intermediate, and highest degree of fermentation, respectively. In this study, 48 observations (Table S6 in the Supporting Information) of 3 classes were selected from 198 samples of oolong tea: faint-scent Tieguanyin (LO, lightest fermentation degree) and familiar-scent Tieguanyin (HO, intermediate fermentation degree) derived from Anxi and baking type oolong (BO, highest fermentation degree) derived from Wuyi Mountain in Fujian province. These samples were collected at distinct grades so as to confirm the applied effect of chemistry on tea classification. Figure 4A shows different fermentation degrees of oolong tea have been well-separated by the biplot of canonical discriminant functions. As expected, a clear separation of the three kinds of oolong tea was achieved with the DF1 (84.4%) and DF2 (15.6%) representing 100% of the total variance, with a 100% correct rate. PCA of the three kinds of oolong tea were also separated dramatically (Figure 4B).

Although separations of the different fermentation degrees of oolong tea obtained by S-LDA and PCA are very encouraging results, we also want to ascertain how other features, such as producing region and quality, may affect the fermentation separations. In our study, PCA was put forward on 47 observations (Table S7 in the Supporting Information) of the above kinds of oolong tea derived from the two producing regions (Anxi and Wuyi Mountain, Fujian province). A clear separation according to fermentation degree was achieved, although producing areas were also considered (Figure 4C). To evaluate the effect of quality on fermentation discrimination, a

dx.doi.org/10.1021/jf5025483 | J. Agric. Food Chem. 2014, 62, 9336−9344

second PCA was put forward on 39 observations (Table S8 in the Supporting Information) of different kinds of oolong teas collected at distinct grades (special grade and levels 1, 2, 3, and 4). As expected, fermentation degrees still played a crucial role in sample clustering compared to quality grades, as shown in Figure 4D. Taking all of the results of PCA into consideration, it is possible to confirm that the processing technology clearly dominates over the other features (such as producing areas and quality) contained in the nonvolatile compounds of tea. On the basis of the results obtained in our work, fermentation discrimination by potential composition demonstrated that it is also applicative for different fermentation degrees of oolong tea.

It was previously reported that taste reconstruction experiments were conducted to identify the key nonvolatile compounds in ready-to-drink green teas using HPLC, and regression models were developed to assess the intensities of bitterness and astringency.[22] Our study confirmed that the HPLC method was also feasible for fermentation discrimination of various teas, even though the different fermentation degrees of the same tea category were of similar appearance and producing area. Moreover, our study provides an objective method based on chemical compounds for detecting fermentation degrees of teas.

**External Authentication of the Models of Teas.** To test the merits of the model, we also conducted two strategies of validation. Foremost, the discriminant ability of the model carried out by S-LDA was tested using the original cases and cross-validation procedure, as shown in Table 3. The external validation was carried out as the secondary validation strategy, as shown in Table S3 in the Supporting Information. It is a useful method that takes the accurate classification of the validation set as the outstanding criterion to evaluate the established tea models.

By the original cases program, the majority of samples (the correctly classified rate was 97.8%) of the four categories were correctly predicted. The results showed that there were few samples overlapping between green and oolong teas. There were three samples of green tea wrongly identified as oolong tea, whereas seven samples of oolong tea were misclassified as green tea (shown in Figure 3A). The major misclassified samples of oolong were of low grade. On the other hand, by the cross-validation procedure, the discriminant results were similar to the original cased program (the correctly classified rate was 96.1%). Furthermore, by the results of absolute correlation of each variable related to any discriminant function, which was not shown (in the SPSS processed results of S-LDA), it is possible to be the marker for each category. For instance, green tea and oolong tea were separated effectively by DF2 and DF3 (Figure 3A), indicating chemical compounds with the largest absolute correlation, with these two discriminant functions, contributing most to the distinction of the two kinds of teas.

In the classification of oolong and other teas, 93.4% samples of oolong tea and 95.5% samples of other teas were classified correctly using DF1. The results showed that four samples of green tea, seven samples of black tea, and one sample of white tea were wrongly discriminated as oolong tea. Thirteen samples of oolong tea were misclassified as other teas. The results indicated that it became more difficult to classify oolong tea from other teas when two-class discrimination was conducted. It is supposed that the feature information on each tea category was lost by their combination to be a class.

In our study, 10 samples of each category produced in 2012 were collected from the dominant market to perform the external validation. Both the discrimination of the four kinds of tea categories and the discrimination of separating oolong tea from other teas were ideal. In external validation of the four different teas, two samples of oolong tea were discriminated wrongly; one wrongly identified sample was oolong crude tea, and the other one was oolong dust tea. The two kinds of tea are of poor quality, resulting in their having lower levels of biochemical compounds than other oolong teas. Besides, there were each samples of green tea and white tea wrongly classified. In external validation of oolong and other teas, one sample of oolong and two samples of other teas were identified incorrectly.

**Comparison of S-LDA and PCA.** By S-LDA compared to PCA, sufficient information for the simultaneous discrimination of the four tea categories was provided, without nearly indistinctive separation, and a simple and effective discriminant model can be constructed on the basis of the reduced variable. In other words, it is possible that the chemicals or biochemicals can be extracted from the complex data when S-LDA was processed, which is most effective in sorting tea categories by different degrees of fermentation. Even so, PCA is still a useful tool for preliminary data analysis and effective visualization of the sample structure.[24]

**Comparison of Green and Black Tea from Other Countries.** To study whether this method can apply to international teas, we collected 10 samples of green tea from Japan and 9 samples of black tea from Sri Lanka and then conducted the two-class discrimination. Utilizing the same 16 variables, we carried out the S-LDA procedure; as expected, all 19 samples were classified correctly with the introduction of three variables. The variables were EGCG, TP, and the ratio of EGCG and TC. In addition, when these samples were added into the external validation to test the models of the four kinds of teas constructed by 463 samples, all 19 samples were discriminated correctly. This is a milestone for future research in chemical classification.

In conclusion, a novel approach to accurately identify analytical markers for discriminating fermentatin degrees of tea was provided, based on potential chemical compounds analyzed by HPLC and spectrophotometry. Moreover, this study discovered that significant differences in chemical compounds may remarkably discriminate tea categories and their fermentation degrees, even if the teas are similar in appearance and taste, which can only be correctly distinguished by experienced tea tasters. The feature of chemical compounds caused by processing also seems dominate over other features (such as producing region and quality). Feature extraction and selection achieved by S-LDA could successfully construct robust models for tea discrimination and fermentation degree. In the future, greater international samples should be collected to improve the applicability of the models. Other standardized methods for catechin oxidation polymers, such as theaflavins or thearubigins, might become available and useful to discriminate the tea categories.[19] Additional data will also contribute to establish more robust classification models of teas.

such that it becomes difficult to assess the role of conformational changes induced by enzymatic cross-linking.

An alternative to mTG-catalyzed protein cross-linking is oxidative cross-linking of endogenous or exogenous phenolic compounds, such as tyrosine residues, caffeic acid, or ferulic acid, that can be used to cross-link to either protein or polysaccharides (e.g., arabinoxylan) using various oxidative enzymes.[28−30] While tyrosine is the most reactive residue for enzymatic oxidation, oxidative enzymes are capable of reacting with phenylalanine, tryptophan, and cysteine and, thus, results in a range of different types of chemical bonds (tyrosine−tyrosine, lysine−tyrosine, cysteine−tyrosine).[31−33] In addition to phenylalanine, tryptophan, and cysteine, laccase has also been found to oxidize histidine, arginine, and methionine.[34] The functional and technological impacts of oxidative enzymes as an alternative mTG are still under investigation. Whereas promising results of enhanced functionality have already been reported for various oxidative enzymes,[35−38] little is known about conformational changes of globular proteins induced by oxidative enzymatic cross-linking so far.

Previously, we have investigated the development of protein nanostructures during enzymatic cross-linking of apo-$\alpha$-lactalbumin by horseradish peroxidase (HRP).[39,40] The apo-form or calcium-free form of $\alpha$-lactalbumin has a "molten globule" structure, making the protein quite accessible to enzymatic cross-linking, and thus allows for studying the enzymatic cross-linking of $\alpha$-lactalbumin without using heat treatment or denaturants.[41] Heijnis et al.[42] have shown that horseradish peroxidase induces the initial step of cross-linking between Tyr18 and Tyr50 in the apo-form. We have found that nanostructures evolve in a two-stage process: (1) In an initial phase, with rapid conversion of tyrosines, monomers are cross-linked to form oligomers. (2) Upon prolonged cross-linking, protein nanoparticles are formed via cross-linking of the oligomers. In this last phase, the conversion rate of the remaining tyrosines is much slower than that in the first phase. The final protein nanoparticles have a very open structure, are very heterogeneous in size and architecture, and exhibit a size-mass scaling of $R_H = M^a$, with an exponent $a \approx 0.4$, where $R_H$ is the hydrodynamic radius and $M$ is the molar mass. The internal protein density of the protein nanoparticles is approximately a few percent (w/v) for particles with a molar mass $M$ of $10^6$ Da and a hydrodynamic radius $R_H$ of 30 nm.[39,40]

In order to link the impact of cross-linking on food functionality across all length scales, we here investigate conformational changes in apo-$\alpha$-LA upon HRP-catalyzed cross-linking. We consider both conformational changes in the initial phase of cross-linking and the changes that occur upon prolonged cross-linking, and we find significant differences between these two cases. As we will show, these differences correlate with changes in the surface hydrophobicity that we also quantify, thus linking structure to the techno-functionality of cross-linked apo-$\alpha$-LA also at molecular length scales.

## MATERIALS AND METHODS

**Materials.** A commercial preparation of calcium-free $\alpha$-lactalbumin (here simply referred to as apo-$\alpha$-LA) was supplied by Davisco Foods International Inc. (Le Sueur, MN). The protein preparation is reported to consist of 85% apo-form ($Ca^{2+}$-depleted) and 15% holo-form ($Ca^{2+}$-saturated). For all experiments in this study, the same protein source and batch were used. Horseradish peroxidase (HRP) type VI-A (P6782) and 2,2′-azino-bis(3-ethylbenzothiazoline-6-sulfonic acid) (ABTS) were also supplied by Sigma-Aldrich. All other chemicals used were of analytical grade.

**Enzyme Activity.** In order to determine HRP activity, an ABTS assay was performed according to the published procedure.[40] The activity of the enzyme preparation as given by the manufacturer is ∼1000 units/mg). This is in agreement with our own determinations, for which we find a variation of enzyme activity from batch to batch of less than about 15%.

**Sample Preparation.** Stock solutions of apo-$\alpha$-LA (12 mg/mL) and HRP (15 mg/mL) were separately prepared by dissolving protein and enzyme powder in 0.1 M ammonium acetate buffer ($NH_4Ac$) at 25 °C, respectively. After centrifugation (3 h, 45 000*g*, 25 °C) of the protein solution, the pH was adjusted to 6.8 using 0.1 mM HCl. Finally, the protein concentration was determined using UV spectroscopy assuming an absorbance $A_{280}$ = 20.1 for a 1% (w/v) solution of $\alpha$-lactalbumin.[43] The concentration of HRP solutions was also determined using UV spectroscopy, assuming a molar extinction coefficient of $\varepsilon_{403}$ = 102 $mM^{-1}$ $cm^{-1}$.[44] To prepare hydrogen peroxide ($H_2O_2$) stock solutions, an aqueous solution of 30% (w/w) of $H_2O_2$ was diluted into deionized water to a concentration of 0.05 M. Before use, the precise concentration of the $H_2O_2$ stock solution was determined using UV spectroscopy, assuming a molar extinction coefficient of $\varepsilon_{240}$ = 43.6 $M^{-1}$ $cm^{-1}$.[45]

**Reactions.** *Reaction 1.* Conditions for the reaction leading to "partially" cross-linked apo-$\alpha$-LA, were similar to those published before.[39,40] The concentration of apo-$\alpha$-LA in the reaction mixture was 10 mg/mL (or 0.7 mM). The apo-$\alpha$-LA solution was incubated in a 50 mL water-jacketed glass vessel under continuously stirring at 37 °C in 0.1 M $NH_4Ac$ at pH 6.8 for 1 h. Next, HRP stock solution was added into protein solution (i.e., a final concentration of the enzyme of 0.5 mg/mL in the reaction mixture). Finally, small amounts (2 $\mu$L per mL of reaction mixture) of 50 mM $H_2O_2$ were added periodically into the reaction mixture, every 10 min. $H_2O_2$ addition was done using a computer-controlled Schott Geräte TA01 titration system. Every addition corresponded to a change in the $H_2O_2$ concentration of $\Delta[H_2O_2]$ = 0.1 mM. The total reaction consisted of 15 additions of $H_2O_2$ into the reaction mixture. The final reaction product was cooled down at room temperature and stored at 4 °C. Analysis on the mixture was performed the following day, without any further purification and filtration.

*Reaction 2.* Conditions for the reaction leading to "fully" cross-linked apo-$\alpha$-LA were identical to the conditions for reaction 1, except that 80 additions of $H_2O_2$ were used, in a 250 mL water-jacketed glass vessel.

**Freeze-Drying and Dialysis.** For long-term preservation of reaction mixture 2, after the enzymatic reaction, which was performed at 37 °C, it was first cooled down to 25 °C. Then, the reaction mixture was mixed with 1 M sucrose in a volume ratio of 1:1. Finally, the reaction mixture was freeze-dried at −80 °C. The resulting powder was stored at −80 °C. We have shown before that this procedure does not affect the particle properties when the freeze-dried powder is redissolved.[39] For sample preparation, the powder was redissolved and dialyzed in 10 mM sodium phosphate buffer using a 300 kDa cellulose ester membrane (Spectra/Por CE dialysis) to remove the sucrose and low molecular weight reaction products. The concentration of dialyzed protein nanoparticles was determined using UV spectroscopy, assuming an absorbance $A_{280}$ = 20.1 for a 1% (w/v) solution of fully cross-linked apo-$\alpha$-LA nanoparticles. Dialyzed samples (fully cross-linked apo-$\alpha$-LA nanoparticles, $M_w \geq 10^6$ Da) from the same batch were used for all experiments.

**Instrumental Analysis.** *Size Exclusion Chromatography (SEC) and Fractionation.* Reaction products were analyzed and fractionated by size exclusion chromatography (SEC) using a Superose 6 column (separation range reported for globular proteins between $5 \times 10^3$ and $5 \times 10^6$ Da; exclusion limit $4 \times 10^7$ Da) connected to an AKTA purifier system (GE Healthcare). A volume of 100 $\mu$L of reaction product was injected into the column and eluted with 10 mM sodium phosphate buffer (pH 7.0) at a flow rate of 0.5 mL/min. The UV absorbance of the eluate was monitored at wavelengths of 280 and 318 nm. For fractionation of reaction mixture 1, SEC fractions were

collected into 10 mL tubes at 1 mL intervals, with a collection volume of 0.5 mL for each fractionation step. Protein particles (F), oligomers (from P1 to P7), and un-cross-linked native apo-$\alpha$-LA were collected on the basis of retention volume: F, 7.5 mL ($M_w$ > 2000 kDa); P7, 9 mL, and P6, 10 mL (2000 kDa > $M_w$ > 660 kDa); P5, 11 mL (660 kDa > $M_w$ > 440 kDa); P4, 12 mL, P3, 13 mL, and P2 14 mL (440 kDa > $M_w$ > 66.5 kDa); P1, 15 mL (66.5 kDa > $M_w$ > 18.4 kDa); and $\alpha$-LA, 16.6 mL ($M_w$ = 14 kDa). For further analysis, SEC fractions were concentrated by a factor of 10 in volume using centrifugal filter devices (3 kDa cutoff). Concentrations of concentrated fractions were determined using UV spectroscopy, assuming an absorbance $A_{280}$ = 20.1 for a 1% (w/v) solution of $\alpha$-LA.[40] Finally, concentrations were adjusted to the required values by dilution with buffer.

**Structural Analysis.** *Secondary Structure Analysis.* Far-UV CD spectra (190−260 nm) were acquired using a JASCO J-715 spectropolarimeter (Tokyo, Japan) equipped with a PTC-348WI Peltier temperature-control system. Quartz cuvettes (Starna, Hainault, UK) with 1 mm cell length were used as a sample container. The concentration of all samples was 0.12 mg/mL. CD spectra of samples and blanks were recorded by averaging 20 scans. CD spectra of samples were corrected by subtracting spectra of blanks (10 mM sodium phosphate buffer). From the far-UV spectra, contents of secondary structure ($\alpha$-helix, $\beta$-strands, $\beta$-turns, and random coil) were estimated using the ridge regression algorithm CONTINLL as implemented by the Dichroweb server.[46−48]

*Tertiary Structure Analysis.* Near-UV CD spectra (250−350 nm) of nanoparticle solutions (1 mg/mL) were recorded in 3 mL quartz cuvettes (path length 1 cm) (Starna, Hainault, UK) at 25 °C for reaction 2. CD spectra of samples and blanks were determined by averaging 20 scans. CD spectra of samples were corrected by subtracting spectra of the blanks (10 mM sodium phosphate buffer).

*Secondary Structure of Extensively Heat-Denatured $\alpha$-LA.* Extensively heat-denatured apo-$\alpha$-LA was used for structural comparison with enzymatically cross-linked protein. In order to prepare the denatured protein,[49] apo-$\alpha$-LA (1 mg/mL or 0.07 mM) was dissolved into 10 mM sodium phosphate buffer at pH 7.0 at 25 °C containing 2-mercaptoethanol (2-ME) (1 mM) (Sigma, M6250). In order to allow for complete protein denaturation, the protein solution was heated for 24 h at 90 °C. Next, the sample was quickly cooled down using running tap water and diluted to final concentrations of 0.12 mg/mL for far-UV CD spectroscopy (performed as described above).

*Determination of Hydrodynamic Radius ($R_H$) and Zeta ($\zeta$) Potential.* Dynamic light scattering (DLS) and electrophoretic light scattering (ELS) experiments were done on dialyzed reaction products using a Malvern Nanosizer ZS (Malvern) equipped with an argon ion laser emitting vertically polarized light with a wavelength of 633 nm. For DLS measurements, the scattering angle was 173°. For ELS measurements, the scattering angle was 12.8°. Average hydrodynamic radii $R_H$ and $\zeta$-potential reported are the major peak from the peak analysis as performed by the Malvern DTS software (version 6.20). For DLS, protein samples were measured in a low-volume quartz batch cuvette (ZEN2112). For $\zeta$-potential measurements, a disposable capillary cell (DTS1070) was used. For both measurements, the concentration of sample is 1 mg/mL.

*Fluorescence Spectroscopy.* Fluorescence spectra of apo-$\alpha$-LA and partially and fully cross-linked apo-$\alpha$-LA nanoparticles were obtained using a PerkinElmer LS 50 B spectrofluorimeter at 25 °C. In all experiments, a quartz cuvette with a 1 cm excitation path length was used. For partially and fully cross-linked apo-$\alpha$-LA, samples were diluted to final concentrations of 0.12 mg/mL in 10 mM sodium phosphate buffer at pH 7.0 at 25 °C. In order to monitor fluorescence from cross-linked tyrosines, in particular dityrosines, an excitation wavelength of 315 nm was used. Emission was monitored for wavelengths between 330 and 550 nm. Excitation and emission slits were set at 5 nm.

In order to compare with the spectrum of free dityrosine, we synthesized dityrosine using HRP-catalyzed cross-linking of L-tyrosine. First, 0.72 mg of L-tyrosine was dissolved in 20 mL of 10 mM sodium phosphate buffer at pH 8.0 and transferred into 2 mL Eppendorf tubes. In order to ensure complete dissolution, L-tyrosine solutions were heated at 95 °C for 15 min in a thermal incubator (Thermomixer comfort, Eppendorf, Harmburg, Germany). A HRP stock solution was prepared by dissolving 1.77 mg of horseradish peroxidase (HRP) in 0.2 mL of 10 mM sodium phosphate buffer at pH 8.0. Next, protein and enzyme solutions were mixed at a molar ratio of protein to enzyme of 1000. The enzymatic reaction was performed by the periodic addition of $H_2O_2$ (2 $\mu$L of 0.03% into 2 mL) every 210 s at 37 °C for 2 h. For fluorescence measurements, the reaction mixture (containing L-tyrosine and dityrosine) was diluted to a final concentration of 0.12 mg/mL (based on the initial concentration of L-tyrosine) with 10 mM sodium phosphate buffer, pH 7.0.

*Surface Hydrophobicity.* The anionic fluorescent probe ANSA was used to measure the exposed surface hydrophobicity of proteins and protein particles.[50] First, an ANSA stock solution (2.4 mM) was prepared in 10 mM sodium phosphate buffer at pH 7.0 at 25 °C. The ANSA solution was stored at 4 °C overnight to ensure complete dissolution. Protein samples were diluted to a final concentration of 0.12 mg/mL using 10 mM sodium phosphate buffer at pH 7.0. Aliquots of ANSA stock solution (10 $\mu$L) were titrated into protein solutions (0.12 mg/mL, 1 mL). Between each addition, fluorescence emission spectra were recorded at wavelengths between 400 and 650 nm. The excitation wavelength was 385 nm and the scan rate 120 nm/min. Excitation and emission slits were set at 5 nm. The system was thermostated at 20 °C. The relative exposed hydrophobicity of each sample was expressed as the difference between the minimum and maximum area of an integrated titration curve between 400 and 600 nm after blank subtraction.

## RESULTS AND DISCUSSION

**Partially and Fully Cross-Linked $\alpha$-Lactalbumin.** We refer to the apo-$\alpha$-LA oligomers that are formed in the initial phase of the cross-linking process as "partially cross-linked" proteins (reaction 1: 150 min of reaction time or 15 additions of $H_2O_2$ in 10 min intervals). The larger hierarchical apo-$\alpha$-LA particles that formed at later stages of the cross-linking reaction are referred to as "fully cross-linked" protein (reaction 2: 800 min of reaction time or 80 additions of $H_2O_2$ in 10 min intervals). Conformational changes as compared to apo-$\alpha$-LA are studied separately for the two cases, such that we can also elucidate possible structural transitions in going from oligomers to larger protein particles. In addition, in the early stages, the reaction mixture contains a mix of monomers and a range of oligomers[40] that possibly differ strongly in the extent of conformational change. Therefore, for partially cross-linked proteins (P), we focus on a fixed, short reaction time of 2.5 h, separate the reaction mixture using size exclusion chromatography (fractions P1−P7 from reaction 1), and study conformational changes as compared to apo-$\alpha$-LA for all of the fractions. Figure 1A shows the size exclusion chromatogram (SEC) and indicates the retention volumes corresponding to the different SEC fractions (apo-$\alpha$-LA + P1−P7). Cross-linked tyrosines (i.e., dityrosines) exhibit a strong absorption at 318 nm; hence, Figure 1A also shows the ratio $A_{318}/A_{280}$ which is a qualitative measure for the conversion of tyrosines into cross-linked reaction products, mainly dityrosines. As can be seen in Figure 1A, the conversion of tyrosines increases with oligomer size for the different fractions, whereas apo-$\alpha$-LA fraction shows no signal at 318 nm, as expected. For fully cross-linked protein (F; from reaction 2), we dialyze the reaction product (using a 300 kDa cutoff membrane) to remove oligomers and any remaining monomers from the final reaction mixture. The fully cross-linked protein elutes in the void of the column (see Figure 1B).

**Changes in Secondary and Tertiary Structure upon Enzymatic Cross-Linking.** Changes in secondary structure

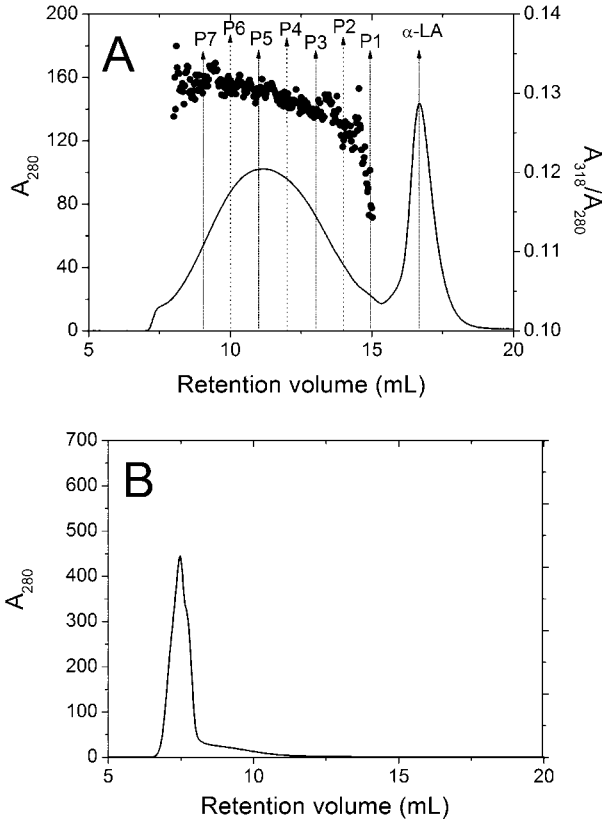

**Figure 1.** (A) SEC chromatograms of HRP-cross-linked apo-$\alpha$-LA. Solid line: UV absorption at 280 nm ($A_{280}$) versus retention volume for partially cross-linked apo-$\alpha$-LA. Retention volumes of SEC fractions from P1 to P7 used in further studies and monomeric protein (apo-$\alpha$-LA) are indicated by arrows (dotted lines). Spheres indicate the ratio $A_{318}/A_{280}$ (a measure for tyrosine conversion) versus retention volume. (B) UV absorption at 280 nm ($A_{280}$) versus retention volume for dialyzed fully cross-linked apo-$\alpha$-LA nanoparticles using 300 kDa cutoff membrane (F). The fully cross-linked nanoparticles elute in the void of the column.

upon enzymatic cross-linking for partially (P1−P7) and fully cross-linked protein (F) were quantified using CD spectroscopy. Far-UV CD spectra are shown in Figure 2 and compared with that of apo-$\alpha$-LA. The latter exhibits a typical spectrum of $\alpha$-helix-rich proteins, with two dips at 208 and 222 nm. For partially cross-linked $\alpha$-LA fraction P1, the ellipticity changes significantly as compared to the native apo-$\alpha$-LA. For the fractions P2−P7 with a higher molar mass and a larger extent of cross-linking (as determined by their $A_{318}/A_{280}$ ratio), there are no further major changes in the ellipticity with fraction number (Figure 2, inset). The spectrum of fully cross-linked $\alpha$-LA (F) is again distinctly different from that of the fractions P1−P7, with a pronounced dip at 208 nm (Figure 2). Hence, it appears that it is the earliest cross-linking event that leads to the formation of the smallest oligomers P1 and P2, which induce the biggest changes in protein conformation. Also it appears that there are significant changes in conformation when going from partially to fully cross-linked protein.

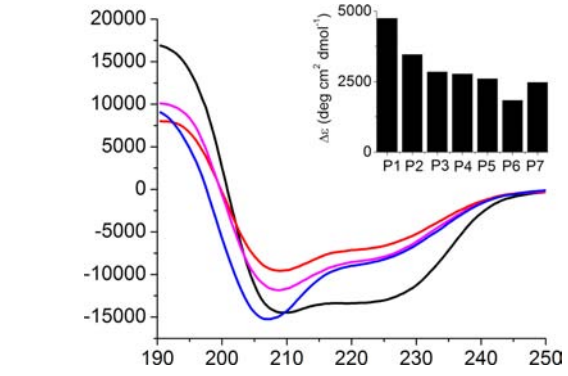

**Figure 2.** Far-UV CD spectra of apo-$\alpha$-LA and cross-linked apo-$\alpha$-LA: black, native apo-$\alpha$-LA; blue, fully cross-linked protein nanoparticles (F). The inset shows the evolution of ellipticity at 208 nm [$\Delta\varepsilon = \varepsilon_1$ (ellipticity of SEC fractions) − $\varepsilon_2$ (ellipticity of native $\alpha$-LA)] for SEC fractions of partially cross-linked protein oligomers, from P1 (red) to P7 (magenta). The solvent is 10 mM sodium phosphate buffer, pH 7.0 at 25 °C. The protein concentration of all samples is 0.12 mg/mL.

From the spectra, we have deduced approximate contents of secondary structure elements ($\alpha$-helix, $\beta$-strands, $\beta$-turns, and random coil) using the ridge regression algorithm CONTINLL as implemented by the Dichroweb server.[46−48] The estimated percentages of secondary structure elements obtained from this analysis are reported in Table 1. A plot of the percentage of $\alpha$-helix versus the fraction number is shown in Figure 3.

**Table 1. Percentages of Secondary Structure Elements for Native Apo-$\alpha$-LA (N, native form) and Partially Cross-Linked (fractions P1−P7) and Fully Cross-Linked Apo-$\alpha$-LA (F) As Deduced from the CD Spectra of Figure 2**

| sample | $\alpha$-helix | $\beta$-sheet | $\beta$-turns | random coil |
|---|---|---|---|---|
| N | 38.5 | 18.1 | 19.3 | 24.1 |
| P1 | 23.8 | 24.8 | 21.3 | 30.1 |
| P2 | 23.9 | 23.9 | 21.3 | 30.8 |
| P3 | 26.4 | 23 | 20.8 | 29.6 |
| P4 | 26.8 | 22.8 | 20.8 | 29.5 |
| P5 | 26.9 | 21.4 | 21.1 | 30.6 |
| P6 | 29.3 | 19.1 | 21.7 | 29.9 |
| P7 | 27.5 | 21.8 | 20.7 | 29.9 |
| F | 31.2 | 17.2 | 21.8 | 29.8 |

Somewhat surprisingly, the analysis of the far-UV CD spectra shows that the highest loss of $\alpha$-helical content as compared to native apo-$\alpha$-LA is observed for the partially cross-linked fractions P1 and P2, which have the lowest extent of tyrosine conversion, whereas the fully cross-linked $\alpha$-LA (F) exhibits the

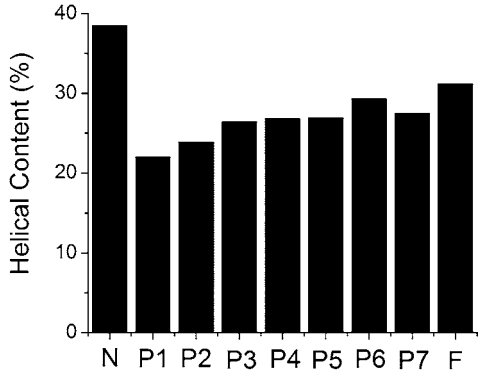

**Figure 3.** Total percentage of $\alpha$-helix as deduced from CD spectroscopy for native apo-$\alpha$-LA (N), SEC fractions of partially cross-linked apo-$\alpha$-LA (P1−P7), and fully cross-linked apo-$\alpha$-LA nanoparticles (F).

dx.doi.org/10.1021/jf502664q | J. Agric. Food Chem. 2014, 62, 9345−9352

lowest loss of $\alpha$-helical content as compared to native apo-$\alpha$-LA (Figure 3). This confirms that the first few tyrosines that are converted lead to the largest loss of $\alpha$-helicity, with further conversion leading to a partial recovery of $\alpha$-helicity.

We have also compared the impact of HRP-induced cross-linking on protein conformation (as deduced from CD spectroscopy) with that of extensively heat-denatured apo-$\alpha$-LA (i.e., heated for 24 h at 90 °C in 10 mM sodium phosphate buffer at pH 7 in the presence of 1 mM 2-ME). The far-UV CD spectrum of extensively heat-denatured apo-$\alpha$-LA (D) is shown in Figure 4 and compared with those of native apo-$\alpha$-LA and fully cross-linked apo-$\alpha$-LA (F).

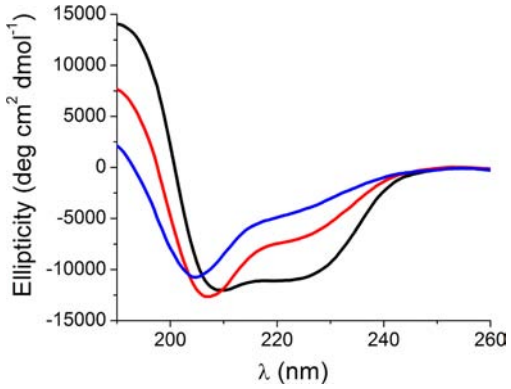

**Figure 4.** Far-UV CD spectra of native apo-$\alpha$-LA (black), fully cross-linked apo-$\alpha$-LA (red), and extensively heat-denatured apo-$\alpha$-LA (blue, 90 °C for 24 h in the presence of 1 mM 2-ME). Solution conditions for CD measurements were 10 mM sodium phosphate buffer at pH 7.0 at 25 °C.

As expected, conformational changes as compared to native apo-$\alpha$-LA are largest for heat-denatured $\alpha$-LA. From the far-UV CD spectra in Figure 4, it appears that the secondary structure of fully cross-linked apo-$\alpha$-LA is intermediate between that of native and extensively heat-denatured apo-$\alpha$-LA. This analysis is confirmed by a more quantitative interpretation of the CD spectra in terms of approximate contents of secondary structure elements. Results for native (N), heat-denatured (D), and fully cross-linked (F) $\alpha$-LA are given in Table.2. Our findings indicate that fully cross-linked apo-$\alpha$-LA has significantly higher secondary structure than fully denatured apo-$\alpha$-LA.

**Table 2. Percentages of $\alpha$-Helix, $\beta$-Strands, $\beta$-Turns, and Random Coil for Native Apo-$\alpha$-LA (N), Fully Cross-Linked Apo-$\alpha$-LA (F), and Extensively Heat-Denatured Apo-$\alpha$-LA (D), Estimated from the CD Spectra of Figure 4**

| sample | $\alpha$-helix | $\beta$-strands | $\beta$-turns | random coil |
|---|---|---|---|---|
| N | 38.5 | 18.1 | 19.3 | 24.1 |
| F | 31.2 | 17.2 | 21.8 | 29.8 |
| D | 20.5 | 23.3 | 24.2 | 32 |

With regards to the tertiary structure, earlier investigations have shown that in the "molten globule" structure of calcium-free apo-$\alpha$-LA, much of the tertiary structure is already lost, as compared to holo-$\alpha$-LA.[51] As is shown in Figure 5, apo-$\alpha$-LA nevertheless retains the characteristic features of the near-UV CD spectrum of holo-$\alpha$-LA, but with lower intensity. Note that complete removal of all $Ca^{2+}$ from the apo-$\alpha$-LA preparation that we have used does not change the near-UV CD spectrum,

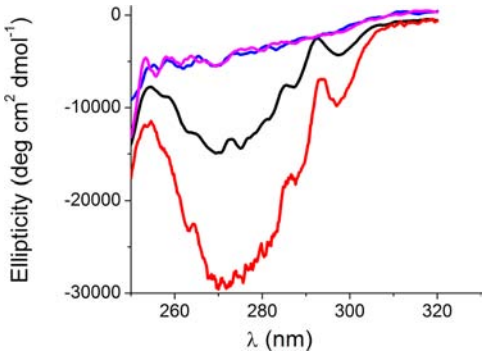

**Figure 5.** Near-UV spectra of apo-$\alpha$-LA (0.07 mM) (black), apo-$\alpha$-LA (0.07 mM) in the presence of $Ca^{2+}$ (1 mM) (red), fully cross-linked apo-$\alpha$-LA (0.05 mM) (blue), and fully cross-linked apo-$\alpha$-LA (0.05 mM) in the presence of $Ca^{2+}$ (1 mM) (magenta).

such that the remaining near-UV CD signature that we observe for our apo-$\alpha$-LA preparation is not due to the small fraction of holo-$\alpha$-LA that is also present (Supporting Information, Figure S1). In contrast, we find that the near-UV CD spectrum of partially and fully cross-linked $\alpha$-LA has lost all characteristic features and is nearly flat (Supporting Information, Figure S2B). It is worth mentioning that even an excess amount of $H_2O_2$ does not influence the secondary and tertiary structure of apo-$\alpha$-LA by itself, indicating that conformational changes that we observe are indeed due to enzymatic cross-linking (Supporting Information, Figure S3). Finally, whereas for native $\alpha$-LA the change from apo to holo (by the addition or removal of $Ca^{2+}$) is reversible, we find that the near-UV CD spectra of fully cross-linked apo-$\alpha$-LA are not affected by the addition of $Ca^{2+}$ (Figure 5), indicating irreversible loss of tertiary structure upon HRP-catalyzed cross-linking.

**Dityrosine Fluorescence upon Enzymatic Cross-Linking.** In order to study the changes around the local environment of dityrosine, we recorded fluorescence emission spectra, using an excitation wavelength of 315 nm. At this wavelength, it may be expected that mainly dityrosines are excited[52] and that excitation of tryptophan is negligible. First, in order to obtain a reference spectrum, we synthesized dityrosine by HRP-catalyzed cross-linking of tyrosine (see Materials and Methods). A comparison of fluorescence spectra [dityrosine reference, native apo-$\alpha$-LA, partially cross-linked fractions P1−P7 and fully cross-linked apo-$\alpha$-LA (F)] is shown in Figure 6. As expected, native apo-$\alpha$-LA does not exhibit any dityrosine fluorescence emission. Fluorescence intensity first increases and then saturates with increasing fraction number of the partially cross-linked $\alpha$-LA (P1−P7). The fluorescence intensity of fully cross-linked protein (F) is much lower. Also, in going from partially cross-linked (P1−P7) to fully cross-linked protein (F), the peak position shifts to the red spectrum by about 11 nm, ending up very close to the peak position of free dityrosine (Figure 6).

Most likely the increase and saturation of the fluorescence with increasing fraction number (from P1−P7) reflects the increase and then saturation of the number of dityrosines per molecule (and possibly trityrosines etc.) (Figure 6, the inset). This is consistent with a modest increase in dityrosine density (corresponding to $A_{318}/A_{280}$) from P2 to P7 (Figure 1A). On the other hand, the strong decrease of the fluorescence intensity for the fully cross-linked $\alpha$-LA (F) most likely is due to quenching, which must be caused by a local structural

dx.doi.org/10.1021/jf502664q | J. Agric. Food Chem. 2014, 62, 9345−9352

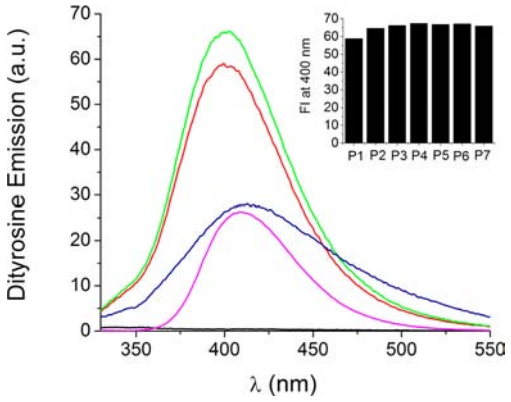

**Figure 6.** Dityrosine fluorescence emission spectra of native apo-$\alpha$-LA, partially and fully cross-linked apo-$\alpha$-LA, and dityrosine reference, at an excitation wavelength of 315 nm: black, native apo-$\alpha$-LA (N); blue, dialyzed fully cross-linked apo-$\alpha$-LA; magenta, dityrosine reference. The inset shows the dityrosine fluorescence intensity at 400 nm for SEC fractions of partially cross-linked apo-$\alpha$-LA from P1 (red) to P7 (green).

rearrangement around the dityrosines. This process might arise from the change in inter- and intramolecular interaction of dityrosine with solvent and neighboring amino acid residues. Finally, the shift of the peak position toward the direction of free dityrosines suggests that the dityrosines are becoming more exposed to the solvent when going from partially to fully cross-linked protein.

**Correlation of Changes in Conformation with Changes in Surface Hydrophobicity.** Changes in protein structure often correlate with changes in food functionality. Here we consider surface hydrophobicity as an underlying parameter that impacts properties such as emulsifying and foaming capacity and protein aggregation. In order to get a qualitative measure of the exposed surface hydrophobicity of apo-$\alpha$-LA and cross-linked protein, we use the ANSA fluorescent probe, which shows a strong enhancement of fluorescence when binding to hydrophobic surfaces.[50] The evolution of surface hydrophobicity of $\alpha$-LA upon enzymatic cross-linking is shown in Figure 7. Partial cross-linking rapidly induces a significant increase in hydrophobicity, which then saturates with increasing fraction number (P1−P7). Remarkably, full cross-linking leads to a decrease in surface hydrophobicity as compared with partially cross-linked protein

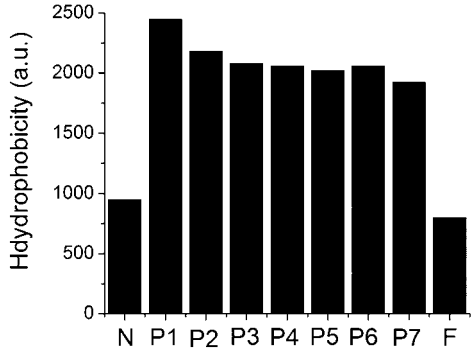

**Figure 7.** Surface hydrophobicity (arbitrary units) of native (N), partially cross-linked (P1−P7), and fully cross-linked apo-$\alpha$-LA (F) as determined using the fluorescent probe ANSA. Solution conditions: 10 mM sodium phosphate buffer at pH 7.0 at 25 °C.

(P1−P7), with final values that are (within the margin of error) similar to that of native apo-$\alpha$-LA.

The remarkable changes in local structure upon going from native apo-$\alpha$-LA to the smallest cross-linked oligomers (P1) with the lowest number of dityrosines (lowest ratio $A_{318}/A_{280}$) most probably relate to the initial steps of the cross-linking reaction. Heijnis et al. have shown that the initial step of cross-linking most likely involves a reaction between Tyr18 and Tyr50.[42] Our results show that apparently this first reaction already leads to a relatively large conformational change. The difference in dityrosine fluorescence and surface hydrophobicity for partially and fully cross-linked $\alpha$-LA might be a consequence of conformational changes induced by the additional cross-linking reactions involving the other tyrosine residues (Tyr36 and Tyr103) that occur at a later stage.

The objective of this study was to determine the conformational transition in apo-$\alpha$-LA in going from native apo-$\alpha$-LA, to oligomers, and then to larger protein particles upon HRP-catalyzed cross-linking. Our results show that, surprisingly, the surface hydrophobicity of apo-$\alpha$-LA first increases upon partially cross-linking and then decreases upon fully cross-linking. Differences between partially and fully cross-linked proteins that are consistent with this result are also found for the local environment of the dityrosines (as probed using fluorescence) and for the secondary structure (as probed using CD).

The impact of nonenzymatic oxidation of tyrosine on the conformations and surface hydrophobicity of globular proteins has also been investigated.[53−57] For example, Kanwar and Balasubramanian[55] reported that cross-linking of a range of globular proteins (calmodulin, bovine pancreatic ribonuclease A, and bovine eye lens $\gamma$-B-crystallin) had no major effect on the secondary and tertiary structure of the proteins. It has also been reported[56] that dimers of $\gamma$-B-crystallin, formed by chemical dityrosine cross-linking, have a significantly lower solubility than monomers. In contrast, we have found that fully cross-linked apo-$\alpha$-LA is highly soluble at neutral pH. In another study, Dalsgaard et al.[57] found that photo-oxidation of globular whey proteins resulted in a different level of structural changes. In general, secondary structure content (i.e., $\alpha$-helix for $\alpha$-lactalbumin and $\beta$-sheet for $\beta$-lactoglobulin, as measured by CD spectroscopy) of globular whey proteins decreased over time upon photo-oxidation, while random coil structure increased. Tryptophan fluorescence emission also indicated 10% and 3% unfolding in tertiary structures of $\alpha$-lactalbumin and $\beta$-lactoglobulin, respectively, after photo-oxidation. In contrast, we find that the loss in tertiary structure is already complete after a small number of additions of $H_2O_2$ (Supporting Information, Figure S2B).

With respect to the mTG-induced cross-linking of the globular whey proteins $\alpha$-LA and $\beta$-lactoglobulin (BLG), it has been found that $\alpha$-LA, and in particular apo-$\alpha$-LA, is a much better substrate for mTG than BLG,[24,25] such that in WPI, in fact, it may be expected that most of the cross-linking occurs for the $\alpha$-lac fraction in WPI. For whey protein isolate (WPI), only minor changes in tertiary structure have been reported upon cross-linking with mTG, and then only for very long reaction times. Also, it has been found that incubation with mTG does not lead to dramatic changes in secondary structure for WPI.[24,25] However, the changes in the apparent hydrophobicity have been reported for mTG-catalyzed cross-linking of whey proteins. Surface hydrophobicity of WPI gradually decreased upon increasing cross-linking degree. A decrease of the

dx.doi.org/10.1021/jf502664q | J. Agric. Food Chem. 2014, 62, 9345−9352

apparent hydrophobicity of WPI after TG-catalyzed cross-linking (as detected using the fluorescent dye ANSA) was attributed to occlusion of hydrophobic cavities in protein.[25] At the same time, however, it was reported that the reduction of net positive charge due to cross-linking of lysyl residues led to aggregation of TG-cross-linked WPI particles at acidic pH. In contrast, we find that the surface hydrophobicity of $\alpha$-LA particles first increases with the first cross-linking, but after full cross-linking, the surface hydrophobicity has decreased again to a value that is nearly the same of that of native $\alpha$-LA. In contrast to TG-catalyzed cross-linking, where the cross-linking led to changes in the surface charge that impacted colloidal stability, we have found that the $\zeta$-potential of $\alpha$-LA increases from −12.4 mV to −29.6 mV upon full cross-linking at neutral pH in 10 mM sodium phosphate buffer (please see the Supporting Information, Figure S4).

Taken together, we find that HRP-catalyzed cross-linking leads to physical properties of cross-linked protein that can be beneficial in beverages and for food structuring, in particular, the highly hydrophilic nature and high $\zeta$-potential of the particles, as well as the fact that a significant fraction of secondary structure is retained. As we have observed in the rheology of dispersions of these hydrophilic particles, the cross-linked apo-$\alpha$-LA particles are interesting novel protein-based thickeners, with a completely reversible yield-stress and shear thinning behavior that is highly unusual for globular protein systems (data not shown). Moreover, the tunability of the hydrophilicity/hydrophobicity may also have an impact on the interaction of the cross-linked $\alpha$-LA with other molecules and, thus, on their functionality as carrier molecules in delivery applications. For example, it is known that $\alpha$-LA specifically interacts with oleic acid, which has been exploited for applications in medicine.[58]

In combination with our earlier work on the structure of cross-linked $\alpha$-LA at larger length scales,[39,40] by zooming in on the structural impact of enzymatic cross-linking at nanometer length scales, we now have a complete overview of the impact of HRP-catalyzed cross-linking of apo-$\alpha$-LA across a range of length scales. Indeed, only by linking changes at nanometer length scales to the architecture and physical properties of cross-linked protein at larger length scales will we be able to rationally use enzymatic cross-linking to modulate food structure.

maize,[24,25] and rice.[9,26] Although some progress has been made in defining PL synthesis and metabolism in plants,[27] our understanding of the PL synthesis pathway is limited to knowledge of several genes in *Arabidopsis*,[28] with single nucleotide polymorphisms identified in seed-expressed phospholipase D, an important enzyme in PL biosynthesis.[29,30] There are few reports of the extent of genotypic diversity in specific PLs in rice grain due to the limited capacity of existing extraction and quantification assays.[3,26]

Rice grain lipids are influenced by both genetic and environmental factors.[31] During rice grain ripening, linoleic and linolenic acid content appear to decrease with increasing growing temperature, whereas the myristic, palmitic, and oleic acid content rise, although there is negligible seasonal and cultivar variation of these LPL precursors.[32] Sowing date and field location also appear to play a greater role in accounting for variation in rice LPL levels than genetic factors.[33] Although these studies suggest genotype and environment have a significant influence on rice PL components and accumulation, data that reveal the extent of genotype × environment (G × E) interaction on rice LPLs are still lacking.

The objective of this study was to quantify the variation in LPLs among 20 diverse rice accessions originating from a wide geographical distribution over two growing seasons. The results will contribute to our understanding of the factors that may contribute to selecting and managing rice grain LPL composition, either through breeding or agronomic manipulation.

## MATERIALS AND METHODS

**Plant Materials.** The 20 rice accessions (Table1) from the OryzaSNP project (http://www.oryzasnp.org/) were used in this study and represent a wide range of geographical origin and genetic diversity.[34] All were nonwaxy cultivars with apparent amylose content ranging from 11 to 26%.[35] These cultivars were grown in the field over two consecutive seasons (2010−2011 and 2011−2012) in a randomized block design with two replications in the same field in Lingshui, Hainan province, China (18.48°N).[35,36] Sowing was in early December and harvest in April. Associated metrological data (mean temperature, sunshine duration, and precipitation) were reported previously.[35] Grain was stored at 4 °C prior to milling to white rice using a Satake rice machine (Satake Corp., Japan) and grinding to flour in a Cyclone sample mill (UDY, Fort Collins, CO, USA) in the laboratory. When some accessions were of insufficient sample weights for analysis, mixed samples from two replications in the same year were used in this study.

**Chemicals.** All solvents and reagents were of HPLC grade. Four LPL standard samples, 1-palmitoyl-2-hydroxy-*sn*-glycero-3-phosphocholine (LPC16:0), 1-oleoyl-2-hydroxy-*sn*-glycero-3-phosphocholine (LPC18:1), 1-palmitoyl-2-hydroxy-*sn*-glycero-3-phosphoethanolamine (LPE16:0), and 1-oleoyl-2-hydroxy-*sn*-glycero-3-phosphoethanolamine (LPE18:1), were purchased from Avanti Polar Lipids Inc. (Alabaster, AL, USA).

**Starch Phospholipid Extraction.** A rapid single-step LPL extraction method[26] was used. Briefly, LPLs were extracted directly from triplicate milled rice flour samples with 75% *n*-propanol (v/v, 8 mL/0.16 g sample) at 100 °C in Pyrex culture tubes (capped) for 2 h. The weight of the capped culture tube before and after extraction was measured to ensure an accurate extraction solvent/sample ratio (m/m) was used for subsequent calculations of LPL content. A 1 mL aliquot of the extract was used for quantitative HPLC-MS analysis of LPLs.

**Determination of LPLs by HPLC-MS.** Quantitative analysis of LPLs was carried out with three technical replications according to the method of Liu et al.[26] using an Agilent HPLC-MS series 1290 (Agilent Technologies, Palo Alto, CA, USA) equipped with a vacuum degasser, binary pump, autoinjector, and an Agilent quadrupole mass detector (MSD, 6120). An Agilent Eclipse Plus C18 RRHD column with 1.8 μm, 50 × 2.1 mm internal diameter, was used to separate PLs.

The linear gradient elution program consisted of a mobile phase of acetonitrile with 0.005% TFA and water with 0.005% TFA. The solvent gradient was programmed from 10 to 99% acetonitrile in 10 min at a flow rate of 0.3 mL/min and held at 99% acetonitrile for 1.5 min. An electrospray ionization (ESI) source was used for MSD; the MS parameters were as follows: drying nitrogen gas flow, 12.0 L/min; nebulizer pressure, 35 psig; SIM mode same as our previous study;[26] fragmentor, 150; capillary voltage, 3000 V (positive); drying gas temperature, 350 °C; vaporizer temperature, 350 °C. Control of the HPLC-MS system was by Agilent ChemStation software. An external standard was applied, and each sample was measured in triplicate.

**Statistical Analysis.** Data analyses were conducted using SAS program version 9 (SAS Institute Inc., Cary, NC, USA). Analysis of variance (ANOVA) was used with the general linear model procedure (Proc glm). PROC means was performed for means of genotypes and environments, followed by Duncan's multiple-comparison tests ($P < 0.05$). Correlation between phenotypes was calculated with PROC CORR, and principal component analysis was conducted with PRINCOMP. Hierarchical cluster analysis was computed using Ward's method in SPSS version 19.0.

## RESULTS

Of the 20 rice genotypes studied, eight represented the *japonica* subspecies, eight the *indica* subspecies, and four belonged to the *aus* group. A total of 10 individual LPLs were identified in the classes of lysophosphatidylcholine (LPC14:0, LPC16:0, LPC18:1, LPC18:2, LPC18:3) and lysophosphatidylethanolamine (LPE14:0, LPE16:0, LPE18:1, LPE18:2, LPE18:3).

**Rice Lysophosphatidylcholine.** The effects of genotype by season (year) interaction for rice LPC components LPC14:0, LPC16:0, LPC18:1, LPC18:2, LPC18:3, and total LPC (TLPC) (where TLPC = LPC14:0 + LPC16:0 + LPC18:1 + LPC18:2 + LPC18:3) were significant ($P < 0.001$) (Table 2). In particular, genotypic variance of LPC14:0, LPC16:0, LPC18:1, LPC18:2, LPC18:3, and TLPC accounted for 79.9, 59.5, 93.2, 61.6, 83.2, and 59.5% of the total variance, respectively, whereas year accounted for 18.1, 33.9, 3.7, 36.6, 14.0, and 38.9% of the total variance, respectively. Genotype × season interaction also affected rice LPCs ($P < 0.001$), although they accounted for only 1.8−6.6% of the total variance (Table 2).

Extensive variation in LPC composition was observed among the 20 rice accessions (Table 1). The main LPC components were LPC16:0 and LPC18:2, which accounted for 54.7−64.7 and 19.5−31.0% of total LPCs, respectively. Minor components included LPC18:1, LPC14:0, and LPC18:3, which represented 5.6−14.8, 4.6−11.1, and 0.3−1.1% of total LPCs, respectively (Table 1; Figure 1).

Mean individual LPC content was similar across the two seasons, ranging from 406.2 to 436.0 μg/g for LPC14:0, from 3752.0 to 3918.6 μg/g for LPC16:0, from 562.8 to 576.2 μg/g for LPC18:1, from 1464.2 to 1581.5 μg/g for LPC18:2, and from 37.0 to 39.9 μg/g for LPC18:3 (Table 1; Figure 1). Significant difference between the two years ($P < 0.001$) was observed only for mean TLPC of the 20 accessions (Table 1). Among the three groups of rice accessions, the mean LPC18:1 content across two years in the *japonica* rice group was higher than those in *indica* and *aus* rice groups (Table 3).

**Rice Lysophosphatidylethanolamine.** Although genotype, season, and genotype × season interactions were significant (ANOVA; $P < 0.001$) for LPE14:0, LPE16:0, LPE18:1, LPE18:2, LPE18:3, and total LPE (TLPE) (where TLPE = LPE14:0 + LPE16:0 + LPE18:1 + LPE18:2 + LPE18:3) ($P < 0.001$; Table 2),

**Table 1. Mean of Rice Lysophospholipids of Different Genotypes at Different Years[a]**

| genotype | variety | group | LPC14:0 | LPC16:0 | LPC18:1 | LPC18:2 | LPC18:3 | TLPC | LPE14:0 | LPE16:0 | LPE18:1 | LPE18:2 | LPE18:3 | TLPE | TLPL |

[a] All mean square values were significant at the $P < 0.001$ level.

they were mainly affected by genotype, accounting for 75.4−95.5%, and season, accounting for 0.7−21.9% of the total variance. Genotype × season interactions accounted for only 2.1−4.8% of the total variance (Table 2).

The main LPE components were LPE16:0 and LPE18:2, accounting for 58.2−70.9 and 19.3−33.3% of total LPEs, respectively (Table 1 and Figure 1). LPE16:0 content ranged from 625.7 μg/g in genotype G08 to 1139.8 μg/g in G02. LPE18:2 varied from 170.6 μg/g in G08 to 481.6 μg/g in G14 (range = 311.0 μg/g). The mean LPE16:0 and LPE18:2 values were relatively stable over the two years, being 921.8 and 372.1 μg/g in 2011 versus 896.2 and 361.4 μg/g in 2012, suggesting environment had little effect on LPE16:0 and LPE18:2 contents (Table 2). TLPE varied from 882.8 μg/g in G08 to 1809.5 μg/g in G02 among the 20 different accessions (Table 1). There was little variation in mean TLPE between years, suggesting environmental influence on TLPE was minor (Table 2). The *japonica* rice group had higher mean LPE18:1 content than those in the *indica* and *aus* rice groups (Table 3).

**Rice Total Lysophospholipids (TLPL).** TLPL (where TLPL = TLPC + TLPE) content varied extensively among the 20 genotypes (ANOVA; $P < 0.001$) such that genotype accounted for 60.6% of the total variation (Table 2). Environment and genotype × environment interaction accounted for 35.8 and 3.6% of the total variance of TLPL, respectively, representing a small but significant effect ($P < 0.001$).

The lowest TLPL content was found in *indica* cultivar Minghui63 (G08, 5609.8 μg/g), whereas the highest was found in *japonica* cultivar Dom Sufid (G02, 9401.1 μg/g) (Table 1; Figure 2). Mean TLPL levels were similar between years, 7985.6 μg/g in 2011 and 7615.5 μg/g in 2012, reflecting the relatively stable response to environmental effects (Table 2).

**Correlation Analysis of Lysophospholipids.** LPL composition between years was significantly correlated ($P < 0.01$), suggesting rice LPLs were little affected by environment (Table 4). The lowest correlation coefficient between years was 0.810 for LPC16:0 ($P < 0.01$), whereas the highest was 0.967 for LPC14:0 ($P < 0.01$).

Correlations between LPL composition were all positive ($P < 0.01$). TLPL was correlated with its major components, that is, LPC16:0, LPC18:2, LPE16:0, LPE18:2 ($r > 0.723$, $P < 0.01$) (Table 4; Figure 1B,D,G,I). Additionally, the correlation between LPC and LPE components with the same fatty acid composition, for example, LPC14:0 and LPE14:0, LPC16:0 and LPE16:0, and so on, were higher than those between different fatty acid compositions.

**Cluster Analysis of Lysophospholipids.** Hierarchical cluster analysis of the 20 rice genotypes was based on individual LPLs. Two groups separated at a relative distance of 13 were identified, whereas there were three groups at a distance of approximately 11 (Figure 3). Genotypes G07, G08, G09, G12, G15, and G16 formed the first group, G01, G02, and G19 formed the second group, and the remaining genotypes formed the third group. Principal component analysis suggested that the first three components accounted for 51.8, 19.8, and 14.8% of the total variance, respectively. The three groups of 20 accessions were also clearly defined by the first two principal components (Figure 4). The mean LPL components were lowest in group 1, except for LPC18:1 and LPE18:1, and highest in group 2, whereas those of group 3 were intermediate to groups 1 and 2 (Table 5).

## DISCUSSION

Rice grain PLs are of significance for storage, consumption, processing, and eating quality[3] and, as with starch properties, may be

affected by both genotype and environment.[37] In the past decade, several reports of quantitative PL analysis by HPLC coupled with ESI-MS, silica column, or thin layer chromatography have been published.[25,38−40] Although these methods have demonstrated LPLs differ between rice accessions, the influence of environment was not investigated.[41,42] In the present study, the

dx.doi.org/10.1021/jf503213p | J. Agric. Food Chem. 2014, 62, 9353−9361

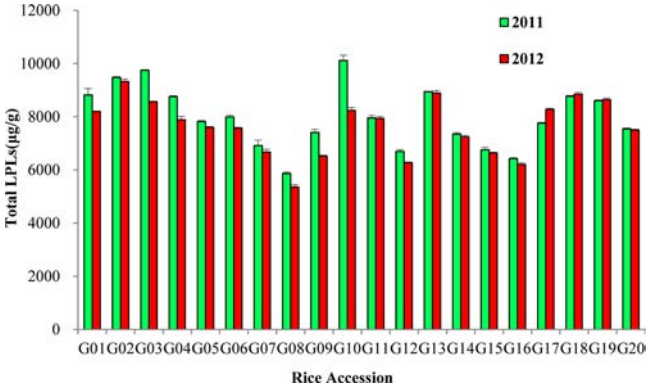

**Figure 2.** Total LPL content of 20 rice accession in two years. See Table 1 for rice accession information.

TLPL content varied from 5609.8 to 9401.1 μg/g in the 20 nonwaxy rice genotypes, which is similar to results from rice planted in the Philippines and Portugal, where TLPL concentration ranged from 5520 to 8310 μg/g in 12 nonwaxy rice cultivars.[41] LPC accounted for 80.0−84.3% of TLPLs, whereas LPE accounted for only 15.7−20.0%. We identified the main components of LPLs as including LPC16:0 43.7−54.0% (Figure 1B), LPC18:2 12.4−24% (Figure 1D), LPE16:0 10.2−13.0% (Figure 1G), and LPE18:2 4.6−12.4% (Figure 1C) in agreement with Majumder et al.[42] and Liu et al.[26] These four LPLs accounted for the TLPL content of Dom Sufid (G02) representing the highest among the genotypes in both years, and was consistently 1.68 times higher than Minghui63 (G08), the lowest in both years. This suggests a difference primarily attributable to genetic factors. Further investigation of the genetic control of LPLs may contribute to breeding superior rice varieties for human consumption or industrial use.

Although genetic factors accounted for the primary component of LPL variation, environmental factors may also affect grain lipid accumulation and concentration.[9,34,43] For example, cold can stimulate synthesis of unsaturated lipids during rice grain filling,[5,42] and the concentration of PL18:2 in rice planted in cold environments was higher than that in mild and tropical environments (37.2−40.0% compared to 30.3−33.1%). In contrast, the PL18:1 was lower in cold conditions than in warm conditions.[11] LPL content in nonwaxy rice cultivars accounted for 48−67% of starch lipids depending on growing location (Asia or Europe), highlighting the role of environment in controlling LPL content in rice.[41] In the present study, genotype, environment, and genotype × environment interaction effects on rice LPLs were significant at $P < 0.001$ (ANOVA) (Table 2). For individual LPC and LPE, genotype accounted for 57.3−95.5%, environment (season) for 0.7−38.9%, and genotype × environment interaction for 1.8−6.6% of the total variation. Thus, genotype appears to be the major factor determining the difference in rice individual LPL concentration in this study. Year of cultivation was a minor but significant factor influencing LPC18:2, LPC16:0, TLPC, and TLPL composition and variation. The extent and timing of how environmental factors such as temperature during grain filling, soil type, and water availability affect LPL content in rice need to be further investigated.

A previous study of brown rice found negative correlations between myristic (C14:0) and linoleic (C18:2), between C14:0 and linolenic (C18:3), between palmitic (C16:0) and oleic (C18:1), between C16:0 and C18:2, between C18:1 and C18:2, and between C18:1 and C18:3 acids, whereas positive correlations existed between C14:0 and C16:0 and between C18:2

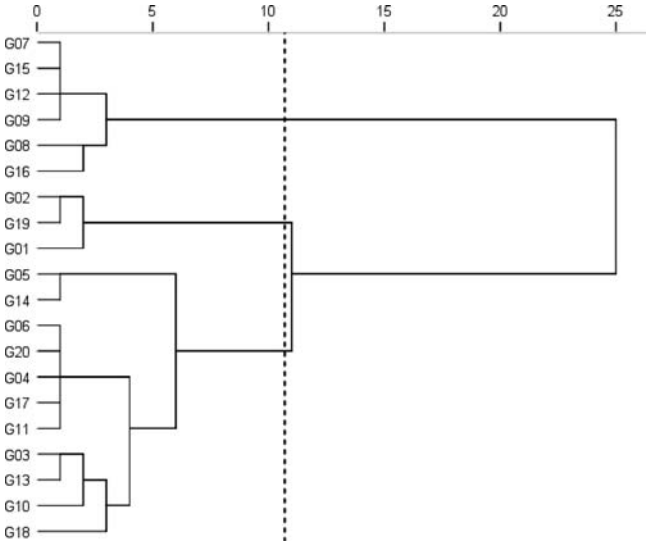

**Figure 3.** Hierarchical cluster analysis dendrogram (Ward's method) based on individual LPL content of 20 accessions. The vertical dashed line indicated all 20 accessions could be divided into 3 groups at a relative distance of 11. See Table 1 for rice accession information.

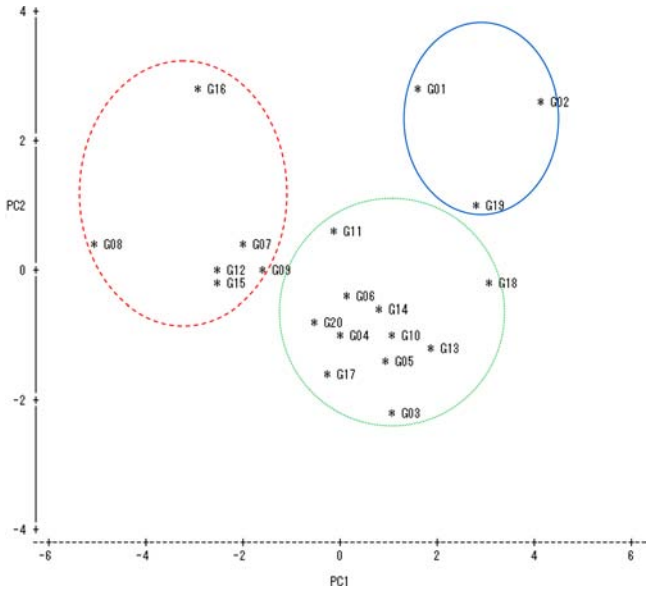

**Figure 4.** Principal component analysis for the genotypes based on their individual LPL content. PC1 and PC2 accounted for 73.9% of total variation, and a plot of PC1 and PC2 separates all 20 genotypes into 3 groups. See Table 1 for rice accession information.

and C18:3.[34] Several different relationships were discovered in this study. LPC16:0 was correlated with LPC18:2, TLPC, TLPE, and TLPL ($P < 0.01$), which may be caused by the abundance of LPC16:0 and its dominant role in synthesis and metabolism. The high correlations between LPC18:1 and LPE18:1 and between LPC18:2 and LPE18:2 as well as between LPC18:3 and LPE18:3 ($P < 0.01$) support the results of an earlier study,[9] suggesting there might be a relationship between unsaturated LPLs in rice. Positive correlations between LPC14:0 and LPE14:0, between LPC16:0 and LPE16:0, and between TLPC and TLPE are also observed in this study.

The results from the correlation analysis may provide insight into the putative biosynthesis pathways of LPLs in rice grain. PLs may be synthesized via three pathways in plants, the cytidinediphosphate-diacylglycerol pathway, the 1,2-diacylglycerol pathway, and the headgroup through exchange reactions with other PLs pathway.[44] As the main starch lipids, LPLs are probably the hydrolysis products of diacylphospholipid transferred from amyloplast membrane[3,45] or catalyzed by phospholipase $A_2$ from PLs.[46] The fatty acid composition (C14:0, C16:0, C18:1, C18:2, and C18:3) accounted for a similar percentage in LPC and LPE among different rice accessions (Table 1). If the LPLs were synthesized from PL, fatty acid distributions (C14:0, C16:0, C18:1, C18:2, and C18:3) in PLs were possibly in certain percentage, too. Previous study indicated that the fatty acids distributions were very similar to each other between PC and PE in rice endosperm[26] and bran.[7,40] These results may imply that each fatty acid composition reacted with choline or ethanolamine at an equal percentage to produce PC and PE, respectively. This possible relationship may provide a useful interpretation of detailed LPL biosynthesis and regulation in metabolism, although the biosynthetic pathway of LPL synthesis in grain endosperm is unclear, particularly the integration of headgroup and fatty acids.

Cluster analysis and principal component analysis demonstrated the 20 rice genotypes could be divided into 3 groups according to LPL composition (Figures 3 and 4; Table 5). Variation in LPL composition among the three groups may reflect their genetic relatedness because rice LPL concentration is primarily dependent on genotype.[3,5,9,41] Further genetic analyses such as quantitative trait locus (QTL) mapping and genome wide associations studies (GWAS) are warranted to identify the genes responsible for controlling LPLs in rice grain.

In summary, broad ranges of LPL composition and content were identified among the 20 rice genotypes over two years, and these differences arose primarily due to genotype differences with environment (season) and genotype × environment interaction effects playing a minor role. Correlation analysis between LPL components provided insight into the possible LPL biosynthesis pathway in plants. Further genetic studies are needed to characterize the genes or QTLs underlying LPLs in milled rice.

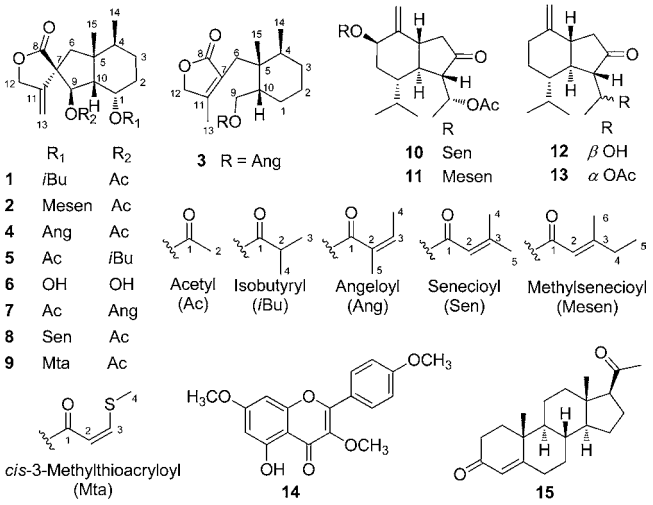

**Figure 1.** Structures of compounds **1**−**15** from *P. tatewakianus*.

used for column chromatography (200−300 mesh, Qingdao Marine Chemical Group Co. Ltd., China). Chemical reagents for isolation were of analytical grade and purchased from Tianjin Chemical Reagent Company, China. Biological reagents were from Sigma Company. The murine microglial BV-2 cell line was from Shanghai Institutes for Biological Sciences, Chinese Academy of Sciences (China).

**Plant Material.** The leaves of *P. tatewakianus* were collected in July 2013 from Changbai Mountain area, Jilin province, China. A voucher specimen (No. 20130716) was identified by Dr. Yuanqiang Guo (College of Pharmacy, Nankai University, China) and deposited at the laboratory of the Research Department of Natural Medicine, College of Pharmacy, Nankai University, China.

**Extraction and Isolation.** The air-dried leaves of *P. tatewakianus* (7.9 kg) were powdered and extracted with MeOH (3 × 48 L) under reflux. The organic solvent was evaporated to obtain a crude extract (910 g). The crude extract was suspended in $H_2O$ (0.9 L) and partitioned with EtOAc (3 × 0.9 L). The EtOAc soluble part (277 g) was subjected to a silica gel column chromatography (⌀ 9 × 70 cm), using a gradient of acetone in petroleum ether (1%−30%), to give seven fractions ($F_1$−$F_7$) based on TLC analyses. $F_1$ was fractionated by middle pressure liquid chromatography (MPLC) over octadecylsilyl (ODS) eluting with a step gradient from 75% to 95% MeOH in $H_2O$ to give three subfractions ($F_{1-1}$−$F_{1-3}$). $F_{1-3}$ was further purified by preparative HPLC (YMC-pack ODS-AM, 250 × 20 mm, 84% MeOH in $H_2O$) to produce compounds **1** ($t_R$ = 19 min, 11.3 mg), **2** ($t_R$ = 26 min, 12.4 mg), **5** ($t_R$ = 17 min, 15.6 mg), **10** ($t_R$ = 31 min, 11.6 mg), **11** ($t_R$ = 36 min, 12.1 mg), **12** ($t_R$ = 24 min, 13.2 mg), and **13** ($t_R$ = 29 min, 43.7 mg). By the above HPLC system, the purification of $F_{1-1}$ (75% MeOH in $H_2O$) afforded compounds **4** ($t_R$ = 34 min, 25.5 mg) and **7** ($t_R$ = 31 min, 24.4 mg). Fraction $F_3$ was subjected to the same MPLC (65−90% MeOH in $H_2O$)

to obtain four subfractions $F_{3-1}$–$F_{3-4}$, and the following purification of $F_{3-2}$ by the same HPLC system (94% MeOH in $H_2O$) yielded compound **3** ($t_R$ = 29 min, 4.5 mg), **8** ($t_R$ = 17 min, 14.7 mg), **9** ($t_R$ = 19 min, 17.1 mg), and **15** ($t_R$ = 26 min, 5.4 mg). Compounds **6** ($t_R$ = 26 min, 14.7 mg) and **14** ($t_R$ = 22 min, 15.4 mg) were isolated from $F_{5-3}$ (87% MeOH in $H_2O$), which was obtained from $F_5$ by the above MPLC.

**Tatewakipene A (1).** Colorless oil; $[\alpha]_D^{27}$: −75.7 (*c* 0.3, $CH_2Cl_2$); CD ($CH_3CN$): 201 ($\Delta\varepsilon$ −29.30) nm; IR (KBr) $\nu_{max}$ 2964, 2933, 1780, 1733, 1635, 1265, 1154, and 1045 $cm^{-1}$; $^{13}C$ NMR (100 MHz, $CDCl_3$) and $^1H$ NMR (400 MHz, $CDCl_3$) data, see Table 1; ESIMS *m*/*z* 401 $[M + Na]^+$; HR-ESIMS *m*/*z* 401.1935 $[M + Na]^+$, calcd. for $C_{21}H_{30}NaO_6$, 401.1940.

**Tatewakipene C (3).** Colorless oil; $[\alpha]_D^{27}$: +10.9 (*c* 0.1, $CH_2Cl_2$); CD ($CH_3CN$): 205 ($\Delta\varepsilon$ −0.73), 227 ($\Delta\varepsilon$ +2.84) nm; IR (KBr) $\nu_{max}$ 2925, 2857, 1750, 1637, and 1276 $cm^{-1}$; $^{13}C$ NMR (100 MHz, $CDCl_3$) and $^1H$ NMR (400 MHz, $CDCl_3$) data, see Table 1; ESIMS *m*/*z* 357 $[M + Na]^+$; HR-ESIMS *m*/*z* 357.2032 $[M + Na]^+$, calcd. for $C_{20}H_{30}NaO_4$, 357.2042.

**Computation.** For those compounds needed to determine the absolute configurations, their calculated ECD spectra were performed using TDDFT method as follows. A preliminary conformational search was carried out in Conflex 6.7 using MMFF94 force field.[8] Conformers within 6 kcal/mol were saved and further optimized on B3LYP/6-31+G(d,p) level in the Gaussian 09 package.[9] The stable conformers with populations greater than 1% were submitted to ECD calculation by the TDDFT [B3LYP/6-31+G(d,p)] method with CPCM model in acetonitrile, and the calculated ECD spectra of different conformers were simulated with a half bandwidth of 0.3 eV. The final ECD curve were generated according to the Boltzmann distribution of each conformer.

**Bioassay for NO Production.** Murine microglial BV-2 cells were cultured at 37 °C in DMEM supplemented with 10% (v/v) inactivated fetal bovine serum and 100 U/mL penicillin/streptomycin under a water-saturated atmosphere of 95% air and 5% $CO_2$. The cells were seeded in 96-well culture plates ($5 \times 10^4$ cells/well) and allowed to adhere for 24 h at 37 °C. The cells were incubated for 20 h with or without 0.15 $\mu$g/mL of LPS (Sigma Chemical Co., St. Louis, MO) in the absence or presence of the test compounds. 2-Methyl-2-thiopseudourea, sulfate (SMT) was used as a positive control. As a parameter of NO synthesis, the nitrite concentration was measured by the Griess reaction using the supernatant of the BV-2 cells. Briefly, 50 $\mu$L of the cell culture supernatant was reacted with 50 $\mu$L of Griess reagent [1:1 mixture of 0.1% *N*-(1-naphtyl)ethylenediamine in $H_2O$ and 1% sulfanilamide in 5% phosphoric acid] in a 96-well plate, and the absorbance was read with a microplate reader (Thermo Fisher Scientific Inc. America) at 550 nm. The experiment was performed three times, and the $IC_{50}$ values for the inhibition of NO production were determined on the basis of linear or nonlinear regression analysis of the concentration–response data curves.

## RESULTS AND DISCUSSION

Compound **1** was obtained as a colorless oil. Its HR-ESIMS provided the molecular formula, $C_{21}H_{30}O_6$, through the presence of a peak at *m*/*z* 401.1935 $[M + Na]^+$ (calcd. for $C_{21}H_{30}NaO_6$, 401.1940). The molecular formula indicated seven unsaturation degrees for **1**. The $^1H$ NMR spectrum of **1** exhibited five methyl signals [$\delta_H$ 0.90 (3H, d, *J* = 6.7 Hz, $H_3$-14), 1.10 (3H, s, $H_3$-15), 2.06 (3H, s, $COCH_3$-9), and 1.11 and 1.09 (each 3H, d, *J* = 7.1 Hz, $COCH(CH_3)_2$-1)] (Table 1), two olefinic protons of a terminal double bond [$\delta_H$ 5.22 and 5.18 (each 1H, s, $H_2$-13)], a set of oxygenated methylene protons [$\delta_H$ 4.61 and 4.71 (each 1H, d, *J* = 13.0 Hz, $H_2$-12)], and two oxygenated methine protons [$\delta_H$ 5.06 (1H, dt, *J* = 11.8, 4.8 Hz, H-1) and 5.80 (1H, d, *J* = 11.2 Hz, H-9)]. The $^{13}C$ NMR spectrum of **1** showed 21 carbon resonances. From the $^1H$ and $^{13}C$ NMR spectra, one acetyl group and one isobutyryl group were evident from the above methyl signals and corresponding carbon resonances ($\delta_C$ 169.8 and 21.2 and 176.3, 34.0, 18.7, and 19.1). Apart from the above six signals for two acyl groups, there are additional 15 resonances exhibited for the parent skeleton in the $^{13}C$ NMR spectrum, which comprised two methyls [$\delta_C$ 15.5 (C-14) and 19.6 (C-15)], five methylenes [$\delta_C$ 26.4 (C-2), 29.5 (C-3), 45.8 (C-6), 70.6 (C-12), and 108.4 (C-13)], four methines [$\delta_C$ 70.4 (C-1), 35.3 (C-4), 80.8 (C-9), and 51.9 (C-10)], and four quaternary carbons [$\delta_C$ 43.3 (C-5), 54.8 (C-7), 177.8 (C-8), and 147.6 (C-11)] based on the DEPT and HMQC spectra. The above spectroscopic features and the 15 skeletal carbons displayed in the $^{13}C$ NMR spectrum suggested that compound **1** should be a sesquiterpene with two acyloxy groups (one acetoxy and one isobutyryloxy group).[10−16] On comparing the chemical shifts from C-1 to C-15 of compound **1** with those of bakkenolide sesquiterpenes reported in the literature,[14−16] the presence of the same parent skeleton of bakkenolide-type was obvious. The following experiments and interpretation of HMQC and HMBC spectra corroborated the above deductions, which verified that compound **1** was a bakkenolide-type sesquiterpene with two acyloxy groups. The positions of the acyloxy groups were determined via interpretation of the HMBC data. The HMBC correlation of the proton signal at $\delta_H$ 5.06 (H-1) with the carbonyl signal at $\delta_C$ 176.3 (CO of the isobutyryloxy group), indicated the presence of the isobutyryloxy group at C-1. Similarly, the long-range coupling of the proton signal at $\delta_H$ 5.80 (H-9) with the carbonyl carbon signal at $\delta_C$ 169.8 demonstrated that the acetoxy group was located at C-9. By further analyzing the HMQC, HMBC, and $^1H$–$^1H$ COSY spectra (Figure 2), all the proton and carbon signals were assigned unambiguously, which resulted in the establishment of the planar structure for **1**.

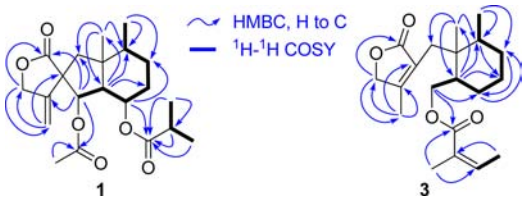

**Figure 2.** Selected HMBC and $^1H$–$^1H$ COSY correlations of compounds **1** and **3**.

The relative configuration of compound **1** was established based on the NOESY spectrum and Chem3D modeling (Figure 3). NOESY correlations observed for H-10/$H_3$-15, $H_3$-15/$H_3$-

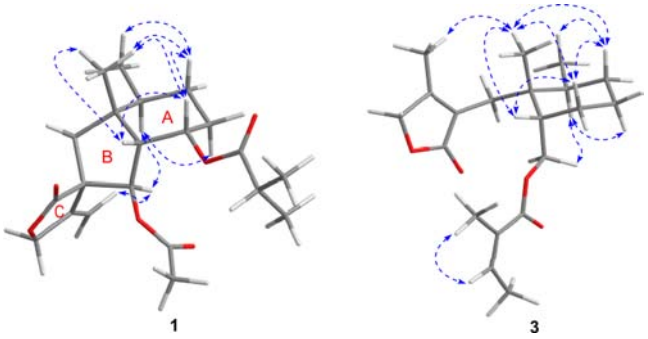

**Figure 3.** Key NOESY correlations of compounds **1** and **3**.

dx.doi.org/10.1021/jf5034224 | J. Agric. Food Chem. 2014, 62, 9362−9367

14, H-1/H-10, H-9/H-4, H-4/H-2$\alpha$, and H-9/H-13a, but not for H-9/$H_3$-15, H-9/H-1, and H-4/$H_3$-15, and the Chem3D modeling suggested a conformation for compound **1** as depicted in Figure 3, where the six-membered ring A and the five-membered ring B were *cis*-fused and existed in a chair and envelope conformation, and the lactone ring C was perpendicular to the five-membered ring B. The conformations of the three rings and the NOESY correlations required that the C-15 methyl group was $\beta$-axially oriented, the C-14 methyl group and the proton H-10 were $\beta$-equatorially oriented, the C-1 isobutyryloxy group was $\alpha$-equatorially oriented, and the C-9 acetoxy group was in a $\beta$-position. Thus, the relative configuration of **1** was assigned as shown in Figure 3. The absolute configuration of **1** was tentatively established by comparison of its experimental CD spectrum with those calculated by the TDDFT method. The optimized geometries were obtained by systematic conformational search with the MMFF94 force field and further optimized on B3LYP/6-31+G(d,p) level by Gaussian 09 package.[8,9] Then the ECD spectra were calculated at the CAM-B3LYP/SVP level with CPCM model in acetonitrile. The calculated ECD spectrum of **1**a (Figure 4) matches the experimental result very well. Thus,

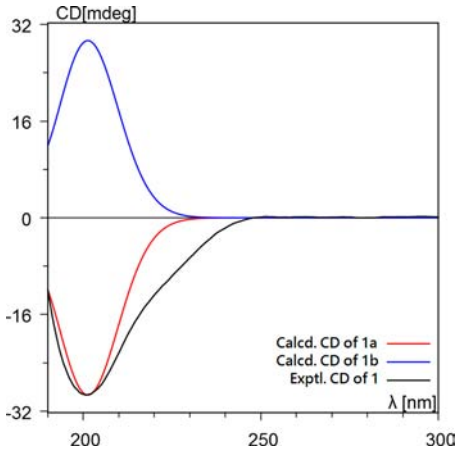

**Figure 4.** Calculated ECD spectra of **1**a (1*S*, 4*S*, 5*R*, 7*R*, 9*R*, 10*R*)- and **1**b (1*R*, 4*R*, 5*S*, 7*S*, 9*S*, 10*S*)-isomers and the experimental ECD spectrum of **1** in acetonitrile.

the absolute configuration of **1** was determined as 1*S*, 4*S*, 5*R*, 7*R*, 9*R*, 10*R*. The structure of **1** was therefore characterized and named tatewakipene A.

Compound **2**, a colorless oil, possessed a molecular formula of $C_{23}H_{32}O_6$ as determined from the HR-ESIMS (427.2095 [M + Na]$^+$, calcd. for $C_{23}H_{32}NaO_6$, 427.2097). From the $^1$H NMR spectrum of **2**, four methyl groups, six olefinic protons, and two oxygenated methine protons were displayed (Table 1). The $^{13}$C NMR spectrum of **2** showed 23 carbon resonances. From the $^1$H and $^{13}$C NMR spectra, one acetoxy was apparent from the methyl singlet and the corresponding carbon signals. In addition, one methylsenecioyloxy group was also deduced and defined from the observation of the following carbon signals ($\delta_C$ 165.7, 114.1, 162.1, 33.6, 11.7, and 18.8) and the corresponding proton signals (Table 1) based on the reported sesquiteprnes with acyloxy groups from the genus *Patesites* in the literature.[14−17] Apart from the above 7 resonances for the substituent groups, the remaining 15 carbon resonances displayed in the $^{13}$C NMR spectrum constitute a bakkenolide-type sesquiterpene skeleton, which was the same as that of compound **1**.[17] In order to confirm the above deductions and achieve the assignments of the proton and carbon signals, the following HMQC and HMBC experiments were performed. By interpretation of the 2D NMR spectra, the same bakkenolide-type sesquiterpene skeleton as that in **1** was defined, and the acyloxy groups, especially the methylsenecioyloxy group, were validated. The HMBC correlations of the proton signals at $\delta_H$ 5.10 (H-1) and 5.77 (H-9) with the carbonyl carbons at $\delta_C$ 165.7 and 169.9, respectively, demonstrated that the methylsenecioyloxy group was attached at C-1, and the acetoxy group was at C-9. Further analyses of the HMQC, HMBC, and $^1$H−$^1$H COSY spectroscopic data led to the assignments of all the proton and carbon signals. Thus, the planar structure with a bakkenolide-type sesquiterpene skeleton for **2** was disclosed. The same relative configuration was inferred for compounds **2** and **1** on the basis of comparison of their NOESY spectra. Compounds **2** and **1** had the same parent skeleton and there were no additional chiral carbons in compound **2**, so, from the biosynthetic point of view, the absolute configuration of compound **2** was also defined as 1*S*, 4*S*, 5*R*, 7*R*, 9*R*, 10*R*, which was also supported by the identical laeotropic optical rotation of two compounds. Therefore, the structure of compound **2** was characterized and named tatewakipene B.

Compound **3** possessed a molecular formula $C_{20}H_{30}O_4$ as determined by the HR-ESIMS ($m/z$ 357.2032 [M + Na]$^+$ calcd. for $C_{20}H_{30}NaO_4$, 357.2042), which implied six unsaturation degrees. The $^1$H NMR spectrum of compound **3** exhibited five methyl signals [$\delta_H$ 2.04 (3H, s, $H_3$-13), 0.90 (3H, d, $J$ = 7.2 Hz, $H_3$-14), 0.94 (3H, s, $H_3$-15), 2.00 (3H, dq, $J$ = 7.2, 1.5 Hz, COCH($CH_3$)=CH($CH_3$)-9), and 1.90 (3H, quint, $J$ = 1.5 Hz, COCH($CH_3$)=CH($CH_3$)-9], one olefinic proton [$\delta_H$ 6.06 (1H, qq, $J$ = 7.2, 1.5 Hz, COCH($CH_3$)=C*H*($CH_3$)-9)], and two sets of oxygenated methylene protons [$\delta_H$ 4.44 (1H, dd, $J$ = 10.8, 3.7 Hz, H-9a) and 4.03 (1H, dd, $J$ = 10.8, 8.9 Hz, H-9b), and 4.62 and 4.67 (each 1H, d, $J$ = 17.2, $H_2$-12)] (Table 1). The $^{13}$C NMR spectrum of **3** showed 20 carbon resonances. From the $^1$H and $^{13}$C NMR spectra, one angeloyl group in compound **3** was deduced from the above characteristic protons and the corresponding carbons ($\delta_C$ 168.3, 128.0, 137.8, 15.8, and 20.7). Apart from the five carbon signals for the angeloyl group, there were 15 residual resonances displayed in the $^{13}$C NMR spectrum, which were classified into three methyls [$\delta_C$ 13.8 (C-13), 14.9 (C-14), and 24.6 (C-15)], six methylenes [$\delta_C$ 25.6 (C-1), 20.1 (C-2), 29.0 (C-3), 27.2 (C-6), 65.5 (C-9), and 72.5 (C-12)], two methines [$\delta_C$ 35.0 (C-4) and 41.0 (C-10)], and four quaternary carbons [$\delta_C$ 40.0 (C-5), 125.7 (C-7), 175.6 (C-8), and 159.0 (C-11)] based on the DEPT and HMQC spectra. According to the unsaturation degrees, the aforementioned spectroscopic features, and the sesquiterpenes isolated from the genus *Petaistes*,[11−17] compound **3** might be a bicyclic sesquiterpene with an angeloyloxy group. In order to confirm the above assumption and elucidate the structure, the following HMBC and $^1$H−$^1$H COSY experiments were performed. By interpretation of the HMBC spectrum, one ring, the $\alpha,\beta$-saturated $\gamma$-lactone ring, was validated based on the long-range correlations of $H_2$-12 to C-7, C-8, C-11, and C-13, and $H_3$-13 to C-7, C-11, and C-12. The other ring was also deduced and defined from the HMBC correlations of H-10 to C-1, C-2, C-4, and C-5, $H_3$-14 to C-3, C-4, and C-5, and $H_3$-15 to C-4, C-5, and C-10. The above two rings, one $\alpha,\beta$-saturated $\gamma$-lactone ring and one six-membered ring, were connected through the methylene unit of C-6, which was demonstrated by the long-range couplings of the methylene protons at $\delta_H$ 2.75 and 2.09 (each 1H, d, $J$ = 13.6 Hz, $H_2$-6) to the carbons of two rings at $\delta_C$ 35.0 (C-4), 40.0 (C-5), 41.0 (C-10), 125.7 (C-7), 175.6 (C-8), and 159.0 (C-11). Accordingly, the

dx.doi.org/10.1021/jf5034224 | *J. Agric. Food Chem.* 2014, 62, 9362−9367

three methyl carbons at $\delta_C$ 13.8, 14.9, and 24.6 and the remaining oxygenated methylene carbon at $\delta_C$ 65.5 were assigned to C-13, C-14, C-15, and C-9, respectively, based on the HMBC correlations of the methyl and methylene protons to the corresponding carbons of the two rings. The skeleton of bicyclic sesquiterpene for **3** was therefore elucidated, which possessed an unusual skeleton of 7,9-seco-bakkenolide. After defining the 7,9-seco-bakkenolide skeleton, the HMBC correlations of the methylene protons $H_2$-9 to the carbonyl carbon at $\delta_C$ 168.3 indicated that the angeloyloxy group was attached at C-9. By further analyzing the HMQC, HMBC, and $^1H-^1H$ COSY spectra (Figure 2), all the proton and carbon signals were assigned unambiguously. Thus, the planar structure of 7,9-seco-bakkenolide sesquiterpene for compound **3** was established.

The relative configuration of compound **3** was established based on the NOESY spectrum. NOESY correlations observed for H-10/$H_3$-15, $H_3$-15/$H_3$-14, H-1$\beta$/H-10, H-9a/H-4, H-4/H-2$\alpha$, H-3$\beta$/$H_3$-15, H-3$\beta$/$H_3$-14, and H-1$\beta$/H-3$\beta$ (Figure 3), but not for H-9a(b)/$H_3$-15, and the Chem3D modeling revealed that the six-membered ring had the same conformation as those in compounds **1** and **2**, where the H-10 proton was $\beta$-equatorially oriented, the C-14 methyl group was in a $\beta$-position with an equatorial orientation, and the C-15 methyl group was in a $\beta$-position with an axial orientation. Thus, the relative configuration of **3** was assigned as depicted in Figure 3. After the relative configuration was determined, the absolute configuration of **3**, a new sesquiterpene with an unusual carbon skeleton, was also considered to elucidate. As in the case of compound **1**, the calculated CD spectra were performed using time-dependent density functional theory (TDDFT) method, and the experimental CD spectrum was recorded (Figure 5). By comparison of its experimental and calculated CD spectra, the absolute configuration of **3** was established as 4*S*, 5*R*, 10*S*. Thus, compound **3** was characterized as a new sesquiterpnene with an unusual carbon skeleton and named tatewakipene C.

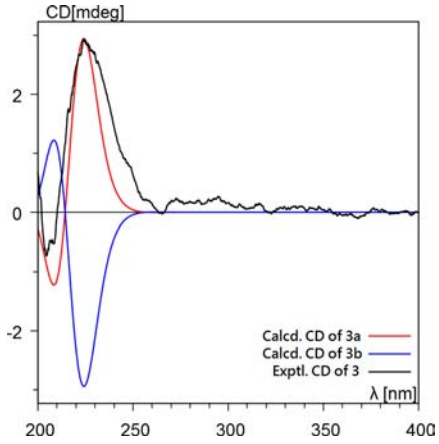

**Figure 5.** Calculated ECD spectra of **3**a (4*S*, 5*R*, 10*S*)- and **3**b (4*R*, 5*S*, 10*R*)-isomers and the experimental ECD spectrum of **3** in acetonitrile.

Based on the spectroscopic analyses and the comparison with the literature, the known compounds were identified as bakkenolide B (**4**),[18] japonipene A (**5**),[17] bakkenolide III (**6**),[14] valerilactone A (**7**),[18] petatewalide A (**8**),[3] bakkenolide D (**9**),[19] 14-acetoxy-7$\beta$-senecioyloxy-notonipetranone (**10**),[20] tussilagone (**11**),[21] [1*S*-[1$\alpha$(*R**), 3a$\beta$, 7$\alpha$, 7a$\alpha$] ]-octahydro-1-(1-hydroxyethyl)-4-methylene-7-(1-methylethyl)-2*H*-inden-2-one (**12**),[22] petasipaline B (**13**),[23] 5-hydroxy-3,7,4′-trimethoxy-flavone (**14**),[24] and pregn-4-ene-3,20-dione (**15**).[25]

Studies on the role of NO in the process of inflammation have demonstrated that reagents with NO inhibitory activities may be useful for the development of anti-inflammatory agents.[7] In order to search and obtain the bioactive substances inhibiting NO production as candidates of anti-inflammatory agents, these compounds isolated from *P. tatewakianus* were evaluated for their inhibitory effects on LPS-induced NO production in murine microglial BV-2 cells by the Griess reaction.[26] 2-Methyl-2-thiopseudourea sulfate (SMT) was used as a positive control ($IC_{50}$ 3.6 $\mu$M). All the evaluated isolates exhibited inhibitory effects on LPS-induced NO production and the inhibitory effects are shown in Table 2. Compounds **10**, **12**, and **14** inhibited LPS-induced NO production dose-dependently with $IC_{50}$ values of 38.7, 47.0, and 45.8 $\mu$M, respectively. Compounds **4**, **8**, **9**, **11**, **13**, and **15** showed moderate inhibitory effects and compounds **1**, **2**, and **5**−**7** showed weak activities ($IC_{50}$ values >100 $\mu$M). Compound **3** was not investigated for the NO inhibitory effects because of inadequate amount. Among these bioactive compounds, eight compounds (**1**, **2**, and **4**−**9**) had the same parent skeleton, and the analysis of the preliminary structure activity relationship (SAR) inhibiting NO production revealed that the presence of the C-1 *cis*-methylthioacryloyloxy group seems to increase NO inhibitory effects markedly. MTT assay indicated that all the assayed compounds had no significant cytotoxicity to the BV-2 cells at their effective concentrations for the inhibition of NO production (data not shown).

**Table 2. IC50 Values of Compounds 1, 2, and 4−15 Inhibiting NO Production in BV-2 Cells**

| compound | $IC_{50}$ ($\mu$M) | compound | $IC_{50}$ ($\mu$M) |
|---|---|---|---|
| **1** | >100 | **10** | 38.7 ± 3.1 |
| **2** | >100 | **11** | 64.4 ± 3.1 |
| **4** | 65.8 ± 2.5 | **12** | 47.0 ± 2.0 |
| **5** | >100 | **13** | 62.4 ± 3.2 |
| **6** | >100 | **14** | 45.8 ± 3.6 |
| **7** | >100 | **15** | 52.0 ± 1.5 |
| **8** | 84.1 ± 2.5 | SMT[a] | 3.6 ± 0.2 |
| **9** | 55.1 ± 4.1 | | |

[a]SMT (2-methyl-2-thiopseudourea, sulfate) was used as a positive control. Data are presented based on three experiments. Compound **3** was not assayed for the inhibitory effects because of inadequate amount.

In summary, 3 new sesquiterpenes (**1**−**3**), including one with an unusual carbon skeleton (**3**), and 12 known compounds (**4**−**15**) were successfully isolated from the leaves of *P. tatewakianus*. Their structures were elucidated on the basis of the spectroscopic data analyses and the TDDFT CD calculations. Biological studies disclosed that all of the evaluated isolates exhibited inhibitory effects on LPS-induced NO production and compound **10** exerted the most inhibition against LPS-induced NO production in BV-2 cells. The results of our chemical investigation, including two new bakkenolide sesquiterpenes (**1** and **2**), one new sesquiterpene with an unusual carbon skeleton (**3**), and the first report of compounds **5**−**7** and **10**−**15** from this species, further revealed the chemical composition of *P. tatewakianus* as an edible plant, and the biological studies implied that *P. tatewakianus*, containing bioactive substances with the inhibitory activities of NO production, may be potentially beneficial to human health.

Studies in animal subjects have demonstrated that phenolics are bioavailable and exert a protective role against oxidative stress and free radical damages. Oxidative damage triggered by free radicals can cause structural and functional alterations of cell macromolecules, leading to molecular mechanisms instrumental in human chronic diseases. Epidemiological studies have suggested that phenolic compounds such as flavonoids, phenolic acids, anthocyanins, and carotenoid compounds including quercetin, kaempferol, myricetin, *p*-coumaric acid, gallic acid, and ellagic acid can act as antioxidants and/or cancer-inhibiting compounds and thus may be involved in the prevention of degenerative diseases such as epithelial (but not hormone-related) cancers and cardiovascular diseases, type II diabetes, thrombotic stroke, obesity, and neurodegenerative diseases associated with aging and infections.[7] Although phenolic compounds have long been studied for their antioxidant properties, which are now well-characterized in vitro, recent studies have stressed that the mechanisms of biological actions of phenolics extend beyond their antioxidant properties. It is now believed that phenolics may exert their beneficial action through modulation of gene expression and the activity of a wide range of enzymes and cell receptors; however, the health effects of dietary phenolics depend on the amounts consumed, their chemical structure, and bioavailability.[8] Although polyphenols are ubiquitous in Rosaceous plants, their content, distribution, bioavailability, and identity vary depending on genetics, fruit location, plant structure, preharvest and postharvest factors, and climatic conditions. In this review, we will discuss the common phenolic compounds (and briefly summarize the newly emergent exploration into *nonextractable* phenolics) identified in representative Rosaceae crops in five subgroups, their health benefits, and pre- and postharvest factors as well as climatic conditions that affect their amounts and concentrations. Finally, we will discuss their bioavailabilty and profer suggestions on possible methods for biofortification to increase consumer appeal and enhance fruit consumption.

## ■ ECONOMIC AND HEALTH BENEFITS OF ROSACEOUS FRUIT AND NUT CROPS

Rosaceae is the 19th largest plant family, comprising >90 genera with >3000 distinct species and having a cosmopolitan distribution, being found just about everywhere except Antarctica. Four subfamilies are distinguished on the basis of fruit type including the Maloideae (apples, loquat, quince, and pear), the Prunoideae (*Prunus* being the largest genus of Rosaceae with cherries, plums, peaches, apricots, and almonds among the representative fruit), the Rosoideae (roses, strawberries, blackberries, and raspberries), and the Spiraeoideae. Rosaceous crops (some examples previously mentioned) contribute to human health and well-being and provide an economic foundation for many rural communities in North America.[1,2]

Included in the Rosaceae family is a huge variety of edible fruit and nut crops as well as highly valued ornamental trees and shrubs. Consumers prefer a wide range of choice in their purchases of produce or processed foods, and the Rosaceae provides it with colorful and flavorful health-promoting fruits and nuts. A huge variety of textures and flavors can be found in fruits from this family, which can be purchased fresh or processed.[1] In addition to the gustatory variety provided by these crops, Rosaceous fruits provide a major source of dietary phytochemicals (flavonoids and other phenolic compounds) purported to promote health by mitigating oxidative stress and inflammation, which can ultimately lead to chronic disease. Some well-known antioxidants and/or cancer-inhibiting compounds that have been identified in the Rosaceae are ascorbic acid, quercetin, kaempferol, myricetin, *p*-coumaric acid, gallic acid, and ellagic acid.

Ellagic acid present in Rosaceae members such as strawberry, red raspberry, cloudberry, apple, pears, and other Rosaceous fruits has been shown to affect cell proliferation and apoptosis in human pancreatic adenocarcinoma cell lines, suggesting a potential anticancer role.[9] Following the examination of 728 men aged 65−84 years in the Zutphen Elderly Study,[10] dietary Rosaceous catechins were shown to have a significant effect in the reduction of epithelial cancer. The same study showed that tea, which contributed 87% of the total catechin intake, has a lesser effect in decreasing epithelial lung cancer when compared to apple, which contributed only about 8% of the catechin consumption. Furthermore, the intake of Rosaceous fruits also reduces the risk of cardiovascular disease. For example, the role of anthocyanins in cardiovascular disease includes protecting lipids from oxidant damage, thereby aiding in the prevention of cardiovascular vessel plaque formation, providing anti-inflammatory action, induction of nitric oxide formation leading to vascular dilation, etc. Prior et al.[11] reported that the consumption of 280 g of cherries (the equivalent of ∼28 'Bing' sweet cherry fruits) caused a statistically significant increase in plasma lipophilic antioxidant capacity that was approximately 7 times greater compared to the control.

Tabak et al.[12] have demonstrated a beneficial relationship between consumption of catechin from solid fruit (apple/pear) and general pulmonary health. The study, consisting of >13000 adults in The Netherlands, observed a positive correlation between the consumption of solid fruit (especially apple and pear) and an increase in pulmonary function/decrease in symptoms of COPD. A separate study of approximately 2500 middle-aged men (age 45−59 years) suggested a strong positive correlation between apple consumption and lung function as measured by forced expiratory volume in 1 s ($FEV_1$).[13] Following adjustment for confounding influences such as smoking, body mass index, social class, and exercise, the consumption of fresh apple remained positively correlated with lung function, whereas the consumption of citrus fruit and/or fruit juices did not. Greater $FEV_1$ of 138 mL was recorded for those who consumed five or more apples per week when compared to those who did not consume apple.

Conceição de Oliveira et al.[14] reported that a high intake of quercetin, a major component of Rosaceous fruits, was associated with a decreased risk of type II diabetes. In addition, intake of myricetin, common in Rosaceous fruits such as strawberry, may also decrease the risk of type II diabetes. Although evidence is limited on the protective role of cherry in diabetes, a few researchers have reported the role of cherry anthocyanins in reducing insulin resistance and glucose intolerance.[15] Sweet cherry has a relatively low glycemic index of 22 compared to other fruits such as grapes, which scored 46. This lower glycemic index makes sweet cherry a potentially better fruit-based snack food for people with diabetes.

Cyanidins and malvidin, which are very abundant in sweet cherry and other Rosaceous fruits, have been shown to inhibit the cyclooxygenase (COX) enzymes responsible for inflammatory response. Thomson and Kubota[16] suggested that flavonoids and proanthocyanidin compounds, which are

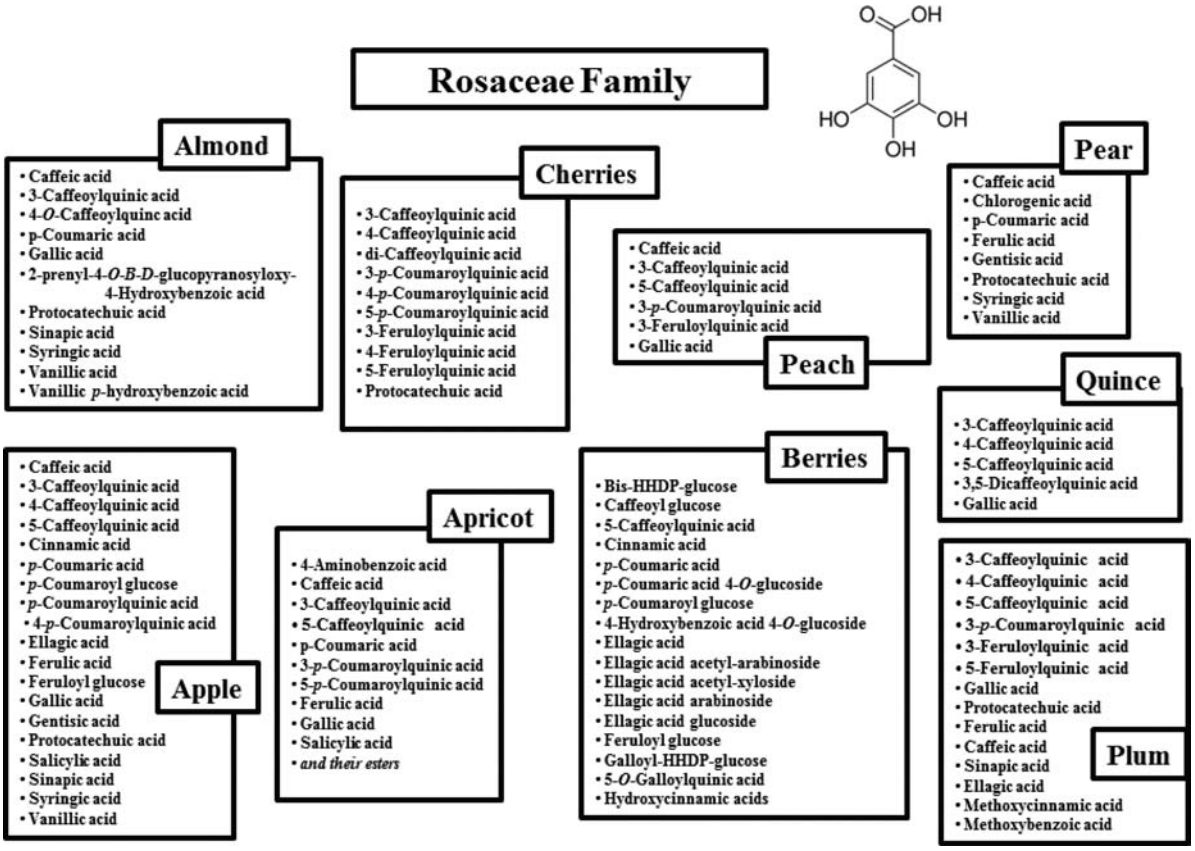

**Figure 1.** Phenolic acids.

common in Rosaceous plants, in particular, cherries, might reduce oxidative stress and amyloid production, thereby reducing the risk of Alzheimer's disease. Rosaceous fruits contain a large number of antioxidants (free radical neutralizers) that purportedly help prevent arthritis and brain dysfunctions. The accumulation of uric acid (the primary cause of gouty arthritis) and other toxic substances in the body is one of the ill effects of un-neutralized free radicals. Consumption of Rosaceous produce, extremely abundant in antioxidants, can effectively help alleviate such health hazards. Memory decline and loss of limb control are common in older individuals due to aging of the brain and the nervous system, facilitated, at least in part, by the action of free radicals present in the system. Dietary phenolics provide an additional mechanism of neutralizing the effect of these oxidants, thereby serving to protect the system.

A recent study[17] with mice implanted with aggressive breast cancer cells, MDA-MB-435, demonstrated an inhibition of a marker gene in the lungs after a few weeks of being fed peach extracts containing a mixture of phenolic compounds. This mixture of phenolic compounds was believed to be responsible for the tumor growth inhibition and metastasis in mice. The authors suggested that the dose necessary to see these effects in mice will be equivalent to the consumption of two to three peaches per day by humans.

## ■ PHENOLIC COMPOUNDS IN ROSACEAE FRUITS AND NUTS

The five major phenolic compounds including pheolic acids, flavanols, flavanols, anthocyanins, and dihydrochalcones will be discussed within each Rosaceous crop as follows.

**Apple (*Malus* × *domestica* Borkh.).** Apple is a good source of phytochemicals including phenolic acids, anthocyanins, flavan-3-ols, and flavonols.[6] No wonder the saying "an apple a day keeps the doctor away"! Major apple phenolic acids include 3-, 4-, and 5-caffeoylquinic acid (CQA) (neochlorogenic, cryptochlorogenic, and chlorogenic acids, respectively) and 3-coumarylquinic acid with chlorogenic acid as the main phenolic acid in apple juice. Minor phenolic acids identified and characterized are presented in Figure 1.[5,6,18−20] The concentration of phenolic acids varies depending on cultivar, with cider varieties in general having a higher phenolic acid concentration than dessert apples.[18]

The major flavonols are quercetin glycosides (arabinose, galactose, glucose, rhamnose, and rutinose) and kaempferol and are found mainly in the peel (Figure 2).[18,21,22] As with phenolic acids, apple cider varieties have a higher concentration of flavonols than dessert apples.[18] For example, the average quercetin glycoside content in the peel and pulp of a dessert apple is 0.5 mg/100 g, while cider apple peel and pulp contain 5.7 mg/100 g of quercetin glycoside (see http/phenol-explorer.eu/reports/39).

Flavan-3-ol compounds, also called flavanols, exist in both the monomer form (catechins) and the polymer form (proanthocyanidins) in apple. Many such compounds exist in apple (see Figure 2),[23,24] and apple is a rich source of (−)-epicatechin, (+)-catechin, and procyanidin (a proanthocyanidin) dimer B2.[24] The concentration of flavanols varies from one variety to the other, with cider apples having a comparatively high content of procyanidins, which are particularly responsible for their astringency and bitterness. Procyanidins are found in the whole apple fruit, and their levels

dx.doi.org/10.1021/jf501574q | J. Agric. Food Chem. 2014, 62, 9369−9386

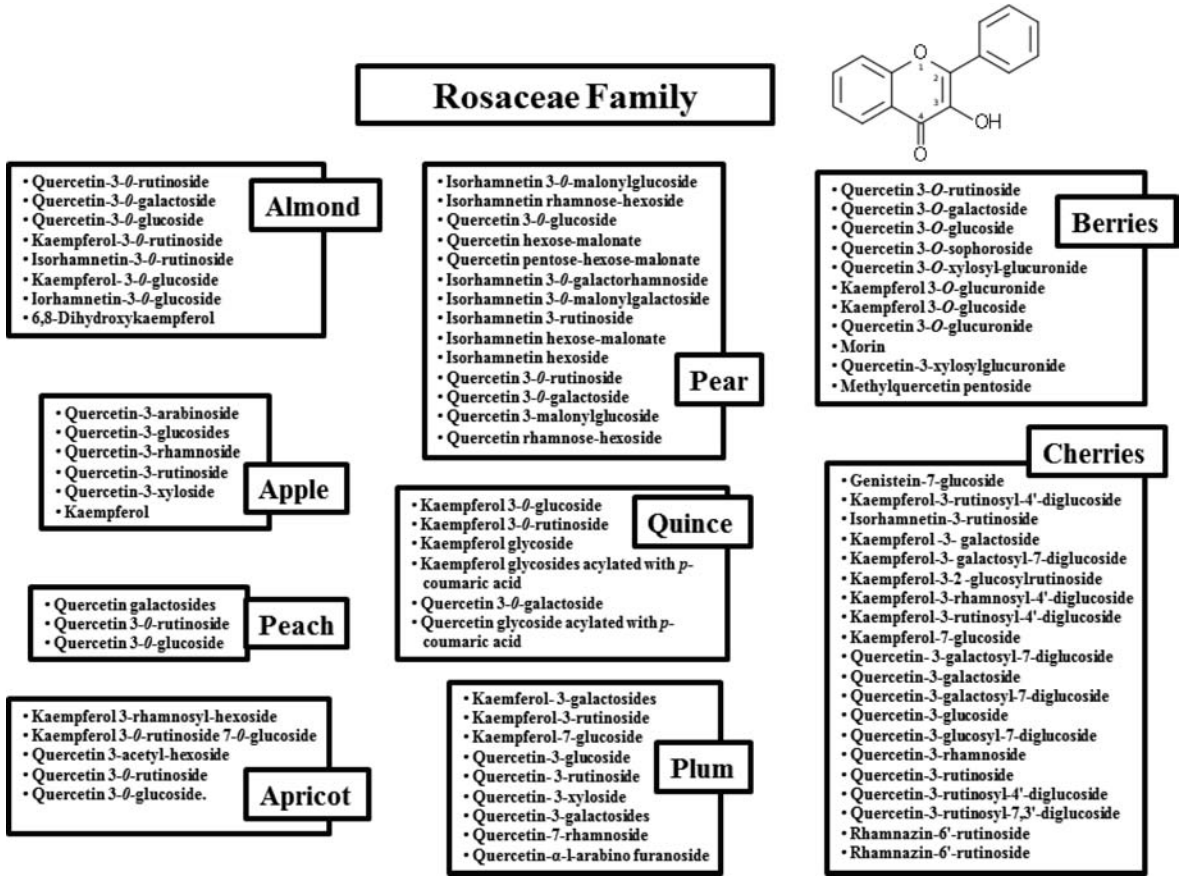

**Figure 2.** Flavanols.

gradually increase from 1232 mg/kg in the seeds to 4964 mg/kg in the epidermal tissue of the fruit.[25,26] The concentration of flavan-3-ols in apple is often affected by preparation methods. For example, only about 3% of the catechins are recovered in the juice, whereas a majority is retained in the pomace.[27] Pure juice of dessert apple contains ∼7.8 mg/100 mL (−)-epicatechin, whereas pure juice of cider apple contains ∼9.0 mg/100 mL (−)-epicatechin.

Some apple cultivars do not produce high anthocyanins in their skin except under high sunlight. Examples include 'Granny Smith' and 'Golden Delicious'. The main anthocyanins are cyanin derivatives such as cyanidin 3-galactoside (cy3-gal), cyanidin 3-glucoside (cy3-glu), cyanidin 3-arabinoside (cy3-ara), and cyanidin 3-xyloside (cy3-xyl) (Figure 4). Cyanidin 3-galactoside (cy3-gal) is the major pigment accounting for 80% of the total anthocyanins in apple.[28−30]

Studies including those of Spanos et al.[31,32] and Tomás-Barberán et al.[33] have shown that dihydrochalcone derivatives such as phloridzin (phloretin 2-*O*-D-glucoside) and phloretin 2-*O*-(6-D-xylosyl)-D-glucoside are major constituents of apple. However, phloretin xylogalactoside and phloretin xyloglucoside are much lower in concentration. Vrhovsek et al.[34] reported 2−6% of dihydrochalcones, whereas Lee et al.[35] found 5.59 mg/100 g phloretin glycosides in apple fruit. Phloridzin is highly concentrated in the seeds, representing 98% of seed flavonoids.[36] Awad et al.[37] reported 10 times more phloridzin in seeds than in skin and 100 times more than in the flesh. Gosch et al.[38] observed >90% phloridzin in the soluble phenolic compounds extracted from apple leaves. The high concentration of dihyrochalcones in apple makes apple unique among the Rosaceae as very low amounts (or none, as in pear) are found in other Rosaceous fruit.

**Sweet Cherry (*Prunus avium* L.) and Tart Cherry (*Prunus cerasus* L.).** Although sweet cherry and sour cherry have small fruit in comparison to other *Prunus* species including peach, nectarine, apricot, plum, etc., they contain a relatively high amount of phytochemicals. Phenolic acids in cherries have been characterized by different authors and summarized by Macheix and Fleuriet[39] and are listed in Figure 1. Sweet cherry contains about 70−80% hydroxycinnamic acid esters[40] with neochlorogenic acid (3-CQA) and 3′-*p*-coumaroylquinic acid being predominant. The ratio of neochlorogenic acid to 3′-*p*-coumaroylquinic acid differs among cherry cultivars as well. For example, 'Bing', a midseason variety, contains 60% neochlorogenic acid and 40% 3′-*p*-coumaroylquinic acid, whereas 'Burlat' (a founder variety for many modern early cultivars) contains 16.5% neochlorogenic acid and 75% 3′-*p*-coumaroylquinic acid.[41]

Flavonols, particularly quercetins and kaempferols, are found in high concentrations in cherry (Figure 2). Both sweet cherry and sour cherry contain a high number and concentration of flavonols when compared to other Rosaceous fruits, with the majority consisting of glycosylated quercetins and kaempferols (see Figure 2).[42,43] Both sour and sweet cherry share many of the same flavonols with differences mainly attributable to the sugar moiety of the derivative, for example, kaempferol-3-rhamnosyl-4′-diglucoside as opposed to kaempferol-3-rutinosyl-4′-diglucoside and quercetin-3-galactosyl-7-diglucoside as opposed to quercetin-3-rutinosyl-7,3′-diglucoside, etc. (see Figure 2).[40,44]

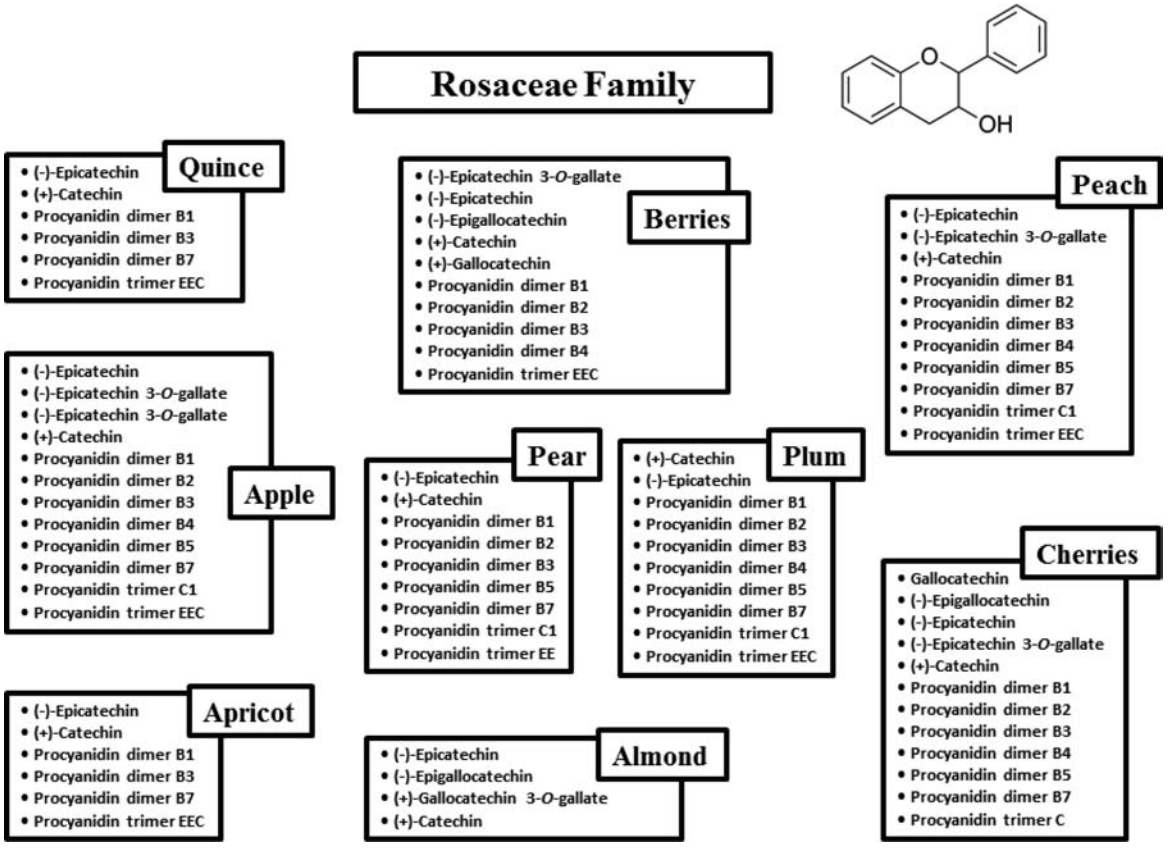

**Figure 3.** Flavan-3-ols.

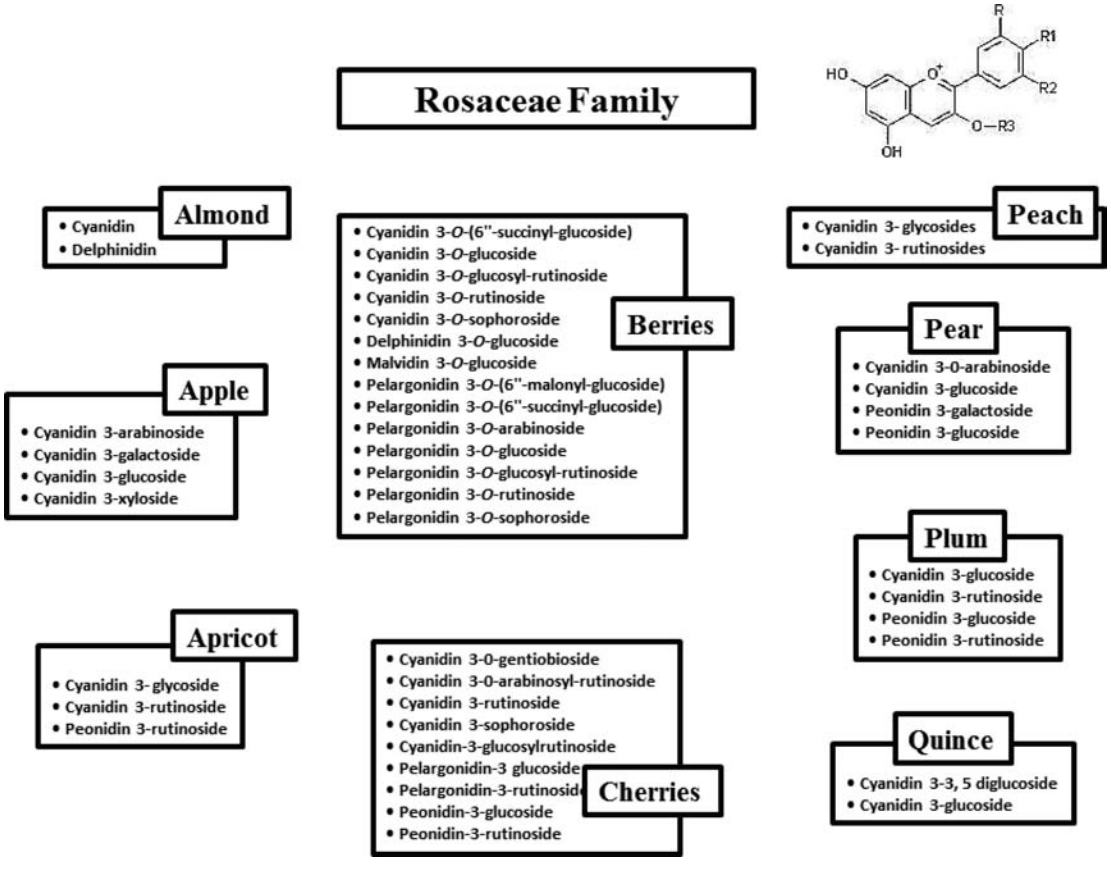

**Figure 4.** Anthocyanins.

dx.doi.org/10.1021/jf501574q | J. Agric. Food Chem. 2014, 62, 9369−9386

Sweet cherry and sour cherry contain flavanols including catechins, epicatechins, gallocatechin, and epigallocatechin (Figure 3).[39] The 2013 USDA Database for the flavonoid content of selected food reports that catechin and epicatechin values of raw sweet cherries are 4.4 and 5.0 mg/100 g, respectively, which is higher than in pear, quince, raspberry, or strawberry.[45,46] These results are corroborated in an independent study by Henning and Herrmann,[47] who reported an epicatechin content of 4.8 mg/100 g in sour cherry.

Different authors have identified and characterized major anthocyanin pigments in sweet and sour cherries. The eight anthocyanins identified are listed in Figure 4 and consist mainly of the glucosides and rutinosides of cyanidin, pelargonidin, and peonidin.[40] Cyanidin-3-rutinoside is the main anthocyanin in sweet cherry, representing 84% of the total anthocyanins, with cyanidin-3-glucoside making up most of the remainder. However, a different anthocyanin profile exists in sour cherry. Sour cherry contains all of the anthocyanidins found in sweet cherry except pelargonidin-3-rutinoside, in addition to the following cyanidins unique to sour cherry: cyanidin 3-*O*-glucosyl-rutinoside, cyanidin 3-*O*-sophoroside, cyanidin 3-*O*-arabinosyl-rutinoside, and cyanidin 3-*O*-gentiobioside.[48,49] Cyanidin-3-arabinosylrutinoside has been detected only in 'Balaton' sour cherry.[50] The predominant anthocyanin in sour cherry is cyanidin-3-*O*-glucosyl-rutinoside, which represents 80% of the total anthocyanins[40] Generally, the skin contains higher anthocyanins than the pit and flesh. Gao and Mazza[42] reported that 'Bing' was the only sweet cherry containing anthocyanins in the skin, flesh, and pit, with the pit having higher concentrations. However, skin pigmentation may not in most cases qualify as a determinant of anthocyanin concentration. For example, 'Bing' has pigmentation in the flesh, whereas other cherries such as 'Royal Ann' (sweet cherry) and 'Montmorency' (sour cherry) do not.[40] Cyanidin-3-rutinoside is the major anthocyanin in the skin and flesh (about 79 and 56%, respectively), whereas 'Bing's pit contains mainly cyanidin-3-glucoside (about 51%). Anthocyanins are absent in the flesh of 'Montmorency', 'Royal Ann', and 'Rainier' cherries. The distribution of cyanidin-3-sophoroside (unique to sour cherries) differs from that of other anthocyanins in that it is present in a higher proportion in 'Montmorency' pit than in the skin.

**Plum (*Prunnnus domestica* L.).** Both dried and fresh plums are rich sources of nutritive and bioactive compounds among which is phenolic acid. However, dried plum (prune) from prune-making varieties has higher amounts of phenolic acids than fresh plum due to concentration during the drying process despite partial degradation. Generally, plum varieties contain high quantities of hydroxycinnamic acids, especially neochlorogenic acid, with hydroxycinnamates (caffeoylquinic acids) constituting 86% of the total phenolic acids in plum.[50] Identified and characterized phenolic acids in plum and prune are listed in Figure 1.

Sultana and Anwar[51] detected 564.8 mg/kg total flavonols in plum, whereas Justesen et al.[52] reported 1.5 mg/100 g quercetin, 564.1 mg/kg myricetin, and 0.7 mg/kg kaempferol. The flavonol glycosides found in plum include 3-glucosides, 3-galactosides, 3-rutinosides, and 3-arabinoside-7-rhamnosides of quercetin and kaempferol.[39] Quercetin-3-rutinoside appears to be the major quercetin, constituting about 2% of all phenolics in plum.[47] The major and minor contributors to flavonol content in plum can be found in Figure 2.

The main flavan-3-ols in plum are catechins, procyanidin B1, procyanidin B2, procyanidin B3, epicatechin, and procyanidin B4 (Figure 3).[53] The same authors also reported the availability of A-type dimers and trimers in smaller concentrations. According to Donovan et al.,[54] plum is rich in proanthocyanidins, contributing about 70% of the total polyphenols in plum. Fresh plum contains flavan-3-ols in the range of 20−40 mg/kg.[55] The edible portion of plum has an average of 3.35 mg/100 g catechin and 2.84 mg/100 g epicatechin.[56] The peeled plum contains flavan-3-ols in the range of 662−1837 mg/kg (as catechin equivalent).[56] The concentration of catechins increases with fruit development and decreases when the fruit reaches maturity.[57]

Anthocyanins include cyanidin 3-*O*-rutinoside, cyanidin 3-*O*-glucoside, and peonidin 3-*O*-rutinoside (Figure 4). Anthocyanins have not been detected in prune and prune juice.[54] The total anthocyanin content ranges from 18 to 125 mg/100 g in fresh weight.[54,58,59] Cyanidin-3-rutinoside is predominant in plum (14.1−33.0 mg/100 g), whereas cyanidin-3-glucoside and peonidin-3-rutinoside are minor, ranging between 1.9 and 13.5 mg/100 g and between 1.1−1.2 mg/100 g, respectively.[59]

**Apricot (*Prunus armeniaca* L.).** Apricot contains a significant amount of phenolic acids that contribute to its nutritive value. The major phenolic acids are 3-CQA and 5-CQA, with 5-CQA being more dominant.[60] Sochor et al.[61] also confirmed that 5-CQA is the principal phenolic acid. See Figure 1 for identified phenolic acids in apricot. Processed and unprocessed apricots share similar qualitative phenolic acid profiles, although lower quantities are found in the processed products.

The flavonols occur mostly as glucosides and rutinosides of quercetin and kaemferol, with quercetin 3-rutinoside being the most identified in various cultivars (Figure 2).[39] The total flavonol level in apricot was estimated at 784.8 ± 32.6 mg/kg dry weight, whereas the concentrations of myricetin, quercetin, and kaempferol were 406.9 ± 16.3, 322.1 ± 6.4, and 5.8 ± 0.2 mg/kg dry matter, respectively.[51]

Flavan-3-ol is one of the major phenolic compounds in apricot, with (+)-catechin and (−)-epicatechin being the most important flavan-3-ols.[56] The concentrations of (−)-epicatechin in the fruit and jam are 4.6 and 0.5 mg/100 g, respectively, whereas (+)-catechin concentrations are 3.9 mg/100 g in the fruit and 0.4 mg/100 g in the jam.[36] The fruit also contains procyanidin B1, procyanidin B2, and procyanidin B3 (Figure 3).[61,62] Processed and unprocessed apricots share similar qualitative profiles, although lower quantities are found in the processed products.

The study of anthocyanins in apricot seems relatively rare, because the orange color of the unblushed side of the fruit is conferred by carotenoids. However, a study by Bureau et al.[63] looked at anthocyanin concentrations during ripening in two red apricot accessions. In addition to the presence of cyanidin-3-*O*-rutinoside (representing 75% of the total anthocyanins detected), these authors also found cyanidin-3-*O*-glucoside and peonidin-3-*O*-rutinoside at concentrations of approximately 12% each. Their study was the first to identify peonidin-3-*O*-rutinoside in apricot fruit. Figure 4 lists anthocyanins found in some apricot varieties.

**Peach and Nectarine (*Prunus persica* L.).** Peach and nectarine are similar in appearance and color, although they differ by a single gene for skin texture. They possess similar qualitative and quantitative phenolic acid profiles. Phenolic acids include chlorogenic acid, neochlorogenic acid, gallic acid,

and caffeic acid (Figure 1). The major phenolic acid is 5-CQA, which is about 15.6 mg/100 g in peach peel and cortex, 5.3 mg/100 g in peach cortex, 6.1 mg/100 g in nectarine peel and cortex, and 8.2 mg/100 g in nectarine cortex.[36] Peach and nectarine also contain a good amount of 3-CQA (8.8 mg/100 g in peach peel and cortex, 4.1 mg/100 g in peach cortex, 4.0 mg/100 g in nectarine peel and cortex, and 5.1 mg/100 g in nectarine cortex).[36] Lee et al.[64] reported that the concentrations of 5-CQA, 3-CQA, and caffeic acid decreased significantly in various peach cultivars sampled during the ripening process in New York state in 1987 and 1988, from a high at green immature stage (mid-July) to a level approximately 25% that value at harvest (mid-September).

Major flavonols include quercetin glucosides and galactosides (Figure 2). Chang et al.[65] observed malvidin 3,5-*O*-diglucoside (malvin), quercetin 3-*O*-rutinoside (rutin), and quercetin 3-*O*-glucoside (isoquercetin). These authors also reported that rutin and isoquercetin were the primary flavonols found in peach, particularly in the peels rather than in the flesh.

Peach and nectarine share similar flavan-3-ol profiles including catechins, epicatechin, procyanidin B1, and procyanidin B2 (Figure 3).[53]

The main anthocyanins in peach are cyanidin-3-glucoside and cyanidin-3-rutinoside, with the former being the most predominant (Figure 4).[66] Peach cultivars with dark red colored flesh have higher anthocyanin contents than those with white or yellow flesh.[67] The anthocyanin content ranges from 6.0 to 37 mg/100 g.

**Pear: European Pear (*Pyrus communis* L.) and Asian Pear (*P. pyrifolia* Nakai.).** Pear has a phenolic acid profile similar to that of apple, the major difference being (in pear) the presence of arbutin (a hydroquinone glucoside) and the lack of phloretin derivatives.[32] In fact, the presence of arbutin can be exploited as a chemical marker for pear in cases when suppliers might be tempted to cut apple juice with less expensive cider pear juice.[68] Identified and characterized pear phenolics are summarized in Figure 1.[69] Amiot et al.[46] reported that chlorogenic acid was the major hydroxycinnamic ester, whereas Spanos and Wrolstad[32] found chlorogenic acid to predominate with caffeic acid making a respectable second-place appearance.

Pear contains several quercetins and isorhamnetins including their glycosides.[69] See Figure 2 for a summary of the major and minor flavonol constituents of pear.

Studies have shown that pear contains 96% flavan-3-ol. Galvis Sánchez et al.[69] reported flavanols, particularly procyanidins, in the peel and not in the flesh.[46] Catechin, epicatechin, epigallocatechin, gallate, and proanthocyanidins have also been reported in pear (Figure 3).[70,71] Amiot et al.[46] reported concentrations of 0.6−8.7 and 0−0.5 mg/100 g for epicatechin and catechin, respectively, whereas Risch et al.[72] reported concentrations of 5−60 mg/kg for epicatechin and 0−10 mg/kg for catechin.

The major procyanidins in 'Bartlett' are B1 and B2.[32] Red pear skin contains cyanidins and peonidins (Figure 4).[71,73,74] Cyanidin-3-galactoside is the main anthocyanin in red pear with a relative percentage of 63% ,whereas the second main anthocyanin is peonidin 3-galactoside.[73] Galvis Sánchez et al.[69] reported that the peels of 'Red D'Anjou' and 'Forelle' contain 12.0 and 1.2 mg/100 g anthocyanins, respectively. The study also confirmed cyanidin 3-*O*-galactoside as the main pigment.

**Quince (*Cydonia oblonga* Miller).** Studies have shown that quince is a natural source of phenolic acids (Figure 1).[71,74,75] Quince fruit is very firm, acidic, and astringent and not well suited to raw consumption in the human diet. In Portugal a major use of the fruit is in the production of jams and jellies.[76] Six phenolic compounds can be found in quince pulps including 3-*O*-, 4-*O*-, and 5-*O*-CQAs, 3,5-*O*-diCQA, and two glycosylated quercetins. Quince peel contains the same six phenolic compounds as the pulp (but at a much higher concentration) plus seven flavonol derivatives, which, if detected in a jam product, can be used as an indicator of adulteration with unpeeled fruit.[77]

The concentration of phenolic acids in quince foodstuffs varies depending on the final product. According to the observations of Silva et al.,[77] 3-CQA can be found in quince pulp at a concentration of about 3.7 mg/100 g, but approximately 62% of this is lost in jam-making with an additional loss of 27% in jelly-making. Cryptochlorogenic acid (4-CQA; concentration in pulp is ∼0.5 mg/100 g) fares a little better, with no significant loss from fruit to jam and a 60% loss from fruit to jelly. The fate of 5-CQA (∼8.6 mg/100 g in pulp) is similar to that of 3-CQA. With respect to 3,5-diCQA (0.6 mg/100 g in pulp), only about 34% is lost from fruit to jam.[36,77]

According to Silva et al.[76,77] and Andrade et al.,[71] quince contains glycosides of quercetin and kaempferol and quercetin and kaempferol glycosides acylated with *p*-coumaric acid (Figure 2). Quince peel contains five phenolic compounds in common with the pulp, and, in addition, kaempferol 3-glucoside, kaempferol 3-rutinoside, and several partially identified compounds including kaempferol glycosides, quercetin glycosides acylated with *p*-coumaric acid, and kaempferol glycosides also acylated with *p*-coumaric acid. Higher concentrations of quercetin-3-*O*-rutinoside are found in the peel than in the pulp.[77]

Nine flavan-3-ols, mainly (−)-epicatechin, procyanidin B2, three procyanidin dimers and trimers, and one tetramer, have been identified and characterized (Figure 3).[78] Flavan-3-ols constitute between about 78 and 94% of the total polyphenolic compounds in quince.[79]

Unlike apple, cherry, and pear, quince is low in anthocyanins. However, Markh[79] reported two anthocyanins in red quince, including cyanidin-3-glucoside and cyanidin-3,5-diglucosides (Figure 4).

**Almond (*Prunus dulcis* Mill. syn. *Prunus amygdalus*).** The phenolic acid content of almond has been associated with astringent taste, discoloration, and inhibition of enzyme activity and antioxidant activities.[81] Various investigators have isolated and characterized phenolic acids in almond.[80−82] Most of these studies noted that the phenolic acid content occurs in the form of soluble esters and free phenolic acids.[81] It was observed that the total amount of free phenolic acid is ∼16.3 μg/g in the skin, whereas the total amounts of esterified phenolic acid in the skin, shell, and whole seed extract were ∼279.6, 167.1, and 40 μg/g, respectively. These phenolic acids are summarized in Figure 1[80,81] and are mainly benzoic acid or cinnamic acid derivatives. Glycosides of protocatechuic acid and vanillic *p*-hydroxybenzoic acid are common in the skins.[82] The seed contains mainly rutinose- and glucose-glycosides of kaempferol and isorhamnetin, whereas the skin and kernel largely contain quercetin-3-*O*-galactoside, kaempferol glycosides (as in seed), and isorhamnetin glycosylated with galactose instead of glucose.[82,83] The hulls also contain chlorogenic acid and its isomers such as cryptochlorogenic acid (4-CQA) and neochlorogenic acid (5-CQA).[84]

Glycosides of quercetin, kaempferol, and isorhamnetin have been identified in almond by several researchers, and their consolidated findings can be viewed in Figure 2.[85,86] According to Milbury et al.,[85] the predominant flavonoid across eight varieties tested in their examination of California almonds is isorhamnetin (as the 3-*O*-rutinoside or 3-*O*-glucoside), representing about 70% of the total, followed by catechin, kaempferol-3-*O*-rutinoside, epicatechin, quercetin-3-*O*-galactoside, and isorhamnetin-3-*O*-galactoside. The seed contains the majority of kaempferol- and isorhamnetin-3-*O*-rutinosides and glucosides, whereas the skin and kernel contain quercetin- and isorhamnetin- 3-*O*-galactoside in addition to the conjugates found in the seed.[86]

Information on anthocyanin content of almond is limited, but at least one report has suggested the presence of cyanidin and delphinidin (Figure 4).[86]

**Raspberry and Strawberry (*Rubus* spp. and *Fragaria* Species).** Raspberries and strawberries contain significant amounts of phenolic acids (Figure 1). Ellagic acid and its conjugates such as ellagic acid arabinoside, ellagic acid acetyl-xyloside, and ellagic acid acetyl-arabinoside are the most predominant phenolic acids in red raspberry.[87−89] However, this is quite different in strawberry, where the major phenolic acids are *p*-hydroxybenzoic acid and *p*-coumaric acid.[90] Berries also contain ellagitannins with the highest content in red raspberry and strawberry.[91,92] The ellagitanins found in raspberry include sanguiin H6, lambertianin C, and sanguiin H10.[36] Recent studies[93] reported two other compounds, bis-hexahydroxydiphenoyl-glucose (bis-HHDP-glucose) and galloyl-HHDP-glucose, in four cultivars including 'Jewel', 'Mira', 'Kent', and 'St. Pierre'. The author observed higher concentrations of bis-HHDP-glucose in 'Mira' than in other cultivars, whereas no significant differences were observed in galloyl-HHDP-glucose among cultivars.

Flavonols such as quercetin and kaempferol, including their glycosides, have been reported.[87,90] Mullen et al.,[87] in particular, reported the presence of various quercetins and kaempferols in raspberry (Figure 2). These studies also indicated that quercetin-3-glucuronide was the major flavonol in red raspberry juice. The flavonol profile of strawberry is similar to the exception of the predominance of kaempferol and the presence of myricetin in strawberry. Mahmood et al.[90] also reported that kaempferol was the dominant flavonol in strawberry followed by myricetin and quercetin.

There is limited information on raspberry and strawberry flavanols. However, Määttä-Riihinen et al.[92] and Gu et al.[94] reported that strawberry and raspberry proanthocyanidins occur in the form of procyanidins and propelargonidins. Flavanols isolated and characterized in both strawberry and raspberry include catechins, epicatechin, procyanidin B1, and procyanidin B2 (Figure 3). Lesser amounts of proanthocyanidins are found in strawberry compared to raspberry and other berries. De Pascual-Teresa et al.[95] and Pallauf et al.[96] have reported that the values of raspberry and strawberry flavanols ranged from 2 to 48 mg/100 g FW and from 10 to 29 mg/100 g FW, respectively.

The berries of Rosaceae, in particular strawberry and raspberry, are among the lowest in anthocyanin content compared to berries such as chokecherries, gooseberries, and blueberries. The anthocyanins in strawberry and raspberry are principally the glycosides of cyanidin and pelargonidin (Figure 4).[97,98] The anthocyanins in raspberry are glycosylated with glucose, galactose, arabinose, or rutinose and, to a lesser extent, sophorose. Cyanidin derivatives (sophorosides) are the major anthocyanins in red raspberry. The main anthocyanin in black raspberry is cyanidin 3-(6′-*p*-coumaroyl)-glucoside.[99] Pelargonidins in the form of pelargonidin 3-*O*-glucoside and pelargonidin 3-*O*-(6′-succinyl-glucoside) are also found in strawberry. Borges et al.[98] identified variously glycosylated cyanidins and pelargonidins, along with delphinidin and malvidin, in raspberry (see Figure 4). Cyanidin-3-*O*-sophoroside was characterized as the major anthocyanin in raspberry, at 42% of the total.

The anthocyanin profile in strawberry is quite different from that in raspberry, as the majority of strawberry anthocyanins are pelargonidins, with pelargonidin-3-glucoside representing 71% of the total.[97]

Although dihydrochalcone is more common in apple, Hilt et al.[100] reported the presence of phloridzin in strawberry.

## NONEXTRACTABLE POLYPHENOLS (NEPP) IN THE ROSACEAE

Arranz et al.[101−103] showed that apple and other Rosaceae crops including peach, nectarine, pear, and quince contain many NEPP. NEPP are a group of phenolic compounds that cannot be extracted using organic solvents or conventional analytical procedures but require acid hydrolysis of the corresponding residues to release the compounds from the food matrix. NEPP are mostly hydrolyzable tannins, high molecular weight proanthocyanidins, and phenolic acids closely associated with dietary fiber and protein occurring in the food matrix.[101,104,105]

Nonextractable phenolic acids are insoluble or associated with cell wall polysaccharides and can include (depending on the food type) caffeic acid, *p*-coumaric acid, ferulic acid, *o*-, *m*-, and *p*-hydroxybenzoic acid, sinapic acid, salicylic acid, syringic acid, and vanillic acid.[105] Although NEPP are not detectable using conventional procedures, studies have reported their existence in fruits and plant-based foods including the Rosaceae.[102,104] NEPP as dietary polyphenols are not released for digestion in the intestines by mastication, stomach pH,and enzymatic activity;rather, they pass intact into the colon for possible fermentation by colonic microflora.[104] Arranz et al.[102] reported a huge gap in the content of NEPP and extractable polyphenols (EPP) in the Rosaceae (Table 1). The study showed EPP content of ∼18.8−28 mg/100 g in methanol/acetone/water extracts of fresh apple, peach,and nectarine in comparison to NEPP of ∼112−126 mg/100 g of acidic hydrolysates of the extraction residue from the fruit, indicating that >80% of total phenolic compounds are left behind with conventional extraction techniques. As a specific example, apple gallic acid content was determined at ∼2.9 mg/100 g NEPP and ∼0.53 mg/100 g EPP, such that almost 85% of the total of this particular phenolic acid required acid hydrolysis for chemical conversion to the analyte detected as gallic acid. The NEPP determined in the study were mainly hydroxybenzoic and hydroxycinnamic acids. Although NEPP are often disregarded in nutritional studies, they do contribute to the antioxidant activity of polyphenols through a surface reaction in the small intestine. As observed in different animal models, NEPP have been shown to increase antioxidant and antiproliferative capacities, reduce intestinal tumorigenesis,and modify gene expression.[104,105]

**Table 1. Extractable Phenols (EPP) and Nonextractable Polyphenols (NEPP) in Representative Rosaceae Crops**

| crop | compound | NEPP content (mg/100 g fw) | EPP content (mg/100 g fw) | ref |

[a]Data not available.

## INFLUENCE OF STORAGE AND PROCESSING ON PHENOLICS

**Apple (*Malus* × *domestica* Mill.).** Van der Sluis et al.[21] reported that the content of some flavonols such as quercetin glycosides, phloridzin,and anthocyanins in 'Jonagold', 'Golden Delicious', 'Red Delicious', 'Elstar', and 'Cox's Orange Pippin' were not affected by 52 weeks of storage in controlled atmospheric conditions. The study also found that the concentration of chlorogenic acid and total catechins decreased slightly in 'Jonagold', whereas the total catechin concentration decreased slightly in 'Golden Delicious' but the chlorogenic acid concentrations remained stable. Furthermore, after 25 weeks of cold storage, there was no decrease in chlorogenic acid in any of the varieties, whereas catechins decreased slightly in 'Golden Delicious', 'Elstar', and 'Cox's Orange Pippin'. The effects of storage on apple peel phenolics by Golding et al.[106] confirmed that storage at 0 °C in air for up to 9 months has little effect on peel phenolic content. In further corroboration of the stability of apple peel phenolic content, Lattanzio et al.[107] studied the collective action of phenolic compounds for fungicidal properties in cold-stored (2 °C) 'Golden Delicious' apples and found no significant decrease in phenolic concentration after 200 days.[108]

Tokusoglu[108] reported variations in dihydrochalcone content among different apple varieties after processing into juice. In a review of studies conducted on polyphenolic content of whole apple compared to freshly prepared and commercially prepared juices, he reported a higher content and concentration of hydroxycinnamic acids, procyanidins, and anthocyanins in whole apple followed by (in decreasing range of concentrations) fresh juice (cider apples), fresh juice (dessert apples), "clear" commercial juice, and "cloudy" commercial juice. Anthocyanins were found in red apple peel but were not detected in the fresh or commercial juices tested. Chlorogenic acid, *p*-coumaroylquinic acid, procyanidins B2, procyanidins C1, (−) epicatechin, and (+) epicatechin were found in whole apple but not in apple juice. In a review of apple components and their relationship to human health, Hyson[109] cites work reporting a wide range of total polyphenolic contents in whole apple, fresh juice, and commercial juice. Depending on the variety and growing conditions, total polyphenolic content ranged from 5230 to 27240 mg/kg in freeze-dried whole apple representing 67 cultivars, from 154 to 970 mg/L in fresh juice (with greater values typically representing juice prepared from cider apples), and from 110 to 459 mg/L in commercial juices (with higher values found in "cloudy" versus "clear" juice preparations).[109]

**Sweet Cherry and Tart Cherry (*P. avium* L. and *P. cerasus* L.).** Processed and stored cherries are available year-round as frozen, whole canned, juice concentrate, etc. During their investigation into the changes in anthocyanins and polyphenolics during canning and canned storage of cherries, Chaovanalikit and Wrolstad[40] determined that approximately half of the anthocyanins and phenolic acids leach from the fruit into the syrup with minimal total loss. The proportions of cyanidin and pelargonidin rutinosides slightly decreased, whereas cyanidin and pelargonidin glucosides increased, perhaps due to partial hydrolysis of rutinose to glucose. The same investigator also determined that hydroxycinnamates and epicatechins were affected by storage and temperature, decreasing significantly after 5 months of storage at both 2 and 22 °C. The degradation of epicatechins was found to increase significantly at 22 °C. Flavonol glycosides were more stable, with a slight increase at 22 °C. Additionally, the anthocyanin and phenolic compositions of fresh frozen 'Bing' fruit stored at −23 and −70 °C for 3 and 6 months, respectively, were compared. A 67% loss of total anthocyanins was observed after 3 months of storage at −23 °C and an 88% loss after 6 months. At the much lower temperature of −70 °C, only 11 and 12% losses were observed after 3 and 6 months, respectively.[40] In corroboration, Polesello and Bonzini[110] observed 34−74% anthocyanin loss in sweet cherry after 4 months of storage at −20 °C.

dx.doi.org/10.1021/jf501574q | J. Agric. Food Chem. 2014, 62, 9369−9386

**Apricot (*P. armeniaca* L.).** The influence of drying parameters on the phenolic compounds in two apricot cultivars, Pelese and Cafona, using air temperatures of 55 and 75 °C was investigated by Madrau et al.[111] Relative to fresh fruit, total phenolic concentration experienced an across-the-board decrease. However, the study reported significantly greater decrease in chlorogenic acid, neochlorogenic acid, and catechin at 55 °C than at 75 °C, which was attributed to attenuation of polyphenol oxidase enzymatic activity at the higher temperature. Epicatechin and quercetin 3-*O*-glucoside incurred greater losses at the higher temperature than at the lower temperature. Processed and unprocessed apricots share similar qualitative profiles, but lower quantities of phenolic compounds were found in the processed products.

**Plum (*P. domestica* L.).** Bioactive compounds in plum are degraded during drying, and this affects anthocyanins in particular. The polyphenolic contents are degraded by half in commercial prune compared to fresh plum.[54] Hydroxycinnamic acids, (+)-catechin, and quercetin-3-*O*-rutinoside were slowly degraded as a function of drying time.[112] Piga et al.[113] reported the disappearance of anthocyanins in prune during the first month of storage. These authors also observed, in both fresh and dried fruits, that changes in catechins, hydroxycinnamic acids, anthocyanins, and flavonols were affected by both processing parameters and cultivar. Drying destroyed the anthocyanin compounds, and there was a significant decrease in the flavonols generally.

**Quince (*C. oblonga* Miller).** There are limited studies on the effect of storage and cultural practices on bioactive compounds in quince. However, homemade jellies showed lower concentrations of different phenolic compounds than commercial jams, with the exception of procyanidins.[114] Arbutin was identified in commercial but not in the homemade quince jam, suggesting adulteration of commercial jam with pear.

**Strawberry (*Fragaria* spp.).** In a study conducted by Amaro et al.,[115] the effects of cultivar choice and storage conditions were investigated as they relate to the fate of anthocyanins in strawberry jams. Homemade jam from two cultivars, stored at room temperature with and without exposure to light, was analyzed for total anthocyanin content and antioxidant activity. Anthocyanin content and stability are critical for an attractive red color as well as antioxidant capacity. Although the two cultivars chosen for this study had radically different anthocyanin profiles, the total anthocyanin contents of each jam were similar immediately after preparation. However, after 15 days of storage 'Camarosa' jam maintained its anthocyanin content at approximately the 90% level, whereas that of 'American 13' dropped by about 67%. After 60 days, approximately 50% of 'Camarosa' anthocyanins were quantified, whereas only about 14% of the 'American 13' anthocyanins were still detected. For both cultivars, jam stored in the dark fared just slightly better than jam stored with exposure to light.

**Raspberry (*Rubus* spp.).** Zafrilla et al.[116] conducted a study on the effect of processing and storage on the ellagic acid/derivatives and flavonoid content of raspberry jam. Ellagic acid glycosides and flavonol glycosides were found to be little affected by thermal processing; however, the content of free ellagic acid increased 2.5-fold after processing. Although a decrease in total flavonoids was observed, evaluation of individual phenolics in the processed jam during 6 months of dark storage at 20 °C showed that ellagic acid continued to increase during the first month of storage up to 45 mg/kg and then decreased slightly during the remaining storage period to a steady concentration of 20−25 mg/kg. The authors note this increase in free ellagic acid could be due to its chemical release from ellagitannins or through increased extractability afforded during processing. Quercetin glucoside content decreased significantly during the first 3 months from ∼66 to ∼40 mg/kg of fresh weight, then became stable during the rest of the storage period.[116] Häkkinen et al.[117] investigated the influence of processing and storage on flavonol content of various berries and found that quercetin was well preserved in frozen red raspberries during 9 months of storage at −20 °C, whereas myricetin and kaempferol were more susceptible to losses during storage.

**Peach (*P. persica* L.).** Asami et al.[118] investigated the impact of cold storage on total phenolics (TP). Peach stored at 4 °C for a period of 14 days was measured for TP levels in peeled and unpeeled fruits on days 0, 7, and 14. The study showed that cold storage for 14 days resulted in no loss of TP activity in either the peeled or unpeeled fruit compared to fresh peach. However, a small increase ($p < 0.05$) in TP levels was observed on day 14 in peeled fruit and on days 7 and 14 in unpeeled fruit. Peach stored in a climate-controlled temperature at 30 °C for a period of 48 h with total phenolics measured at 0, 12, 24 and 48 h showed that storage for 24 h at 30 °C resulted in a 69% increase in TP in peeled fruit and a 36% increase in unpeeled fruit. The study showed that the levels of TP began to decline after 24 h, with total phenolics being 50% higher than initial levels in peeled fruit and 28% higher in unpeeled fruit at 48 h. This apparent counterintuitive discrepancy is probably a result of activation of phenylalanine ammonia-lyase (PAL) in response to the stress of peeling; enzymes would be more active above room temperature such that PAL-catalyzed phenolic synthesis would cause levels in peeled fruit to be higher than in unpeeled fruit. The comparison of procyanidin oligomer profile in frozen peach and in processed peach at 104.4 °C for 10 min showed a profound reduction in procyanidins in canned peach relative to frozen peach. The flavonoid profile in canned freestone cultivars differed from that in clingstone types, as freestone cultivars contained higher levels of leucoanthocyanins than clingstone cultivars.[118]

**Almond (*P. dulcis* L. syn. *P. amygdalus*).** The polyphenolic content of almond is affected by roasting, pasteurization, and storage.[119] Pasteurization did not significantly change the flavonoids and phenolic acids, whereas roasted almonds had 26% less total phenolics and 34% less flavonoids than raw almonds. Storing almond at 4 and 23 °C for 15 months resulted in gradual increases in phenolic acid by up to 2%. At 4 °C during 15 months of storage, polyphenols increased up to 18-fold for *p*-hydroxybenzoic acid, whereas other phenolic acids increased up to 45-fold.[120] The total contents of phenolic compounds were higher in the roasted samples than in blanched almonds (freeze-dried). Roasting is the most suitable type of industrial processing of almond to obtain almond skin extracts with the greatest antioxidant capacity.[120]

## EFFECT OF FRUIT DEVELOPMENT STAGE AND ENVIRONMENTAL CONDITIONS ON PHENOLICS

Developmental stage and environmental factors such as nutrient availability, temperature, and (most particularly) light influence the synthesis of polyphenols.[121] Treutter[122] reported that sunlight induces many enzymes involved in flavonoid

synthesis. The effect of environmental factors on quercetin glycosides, phloridzin, catechins, and chlorogenic acid concentrations in 'Jonagold' and 'Elstar' apples has been shown to be the highest early in the season, decreasing to a steady level during maturation and ripening.[123] The same investigators reported anthocyanins decreasing midseason but rising rapidly just prior to maturation and quercetin glycosides being greater in fruit grown in the outer canopy. Awad et al.[37] also found that sun-exposed fruits (in 'Jonagold' and 'Elstar') had greater levels of anthocyanins and quercetin glycosides compared to shaded fruits, suggesting that exposure to sunlight affects production of these compounds. Although sunlight has no effect on phloridzin, catechin, and chlorogenic acid, Treutter[122] reported that many apple cultivars produced anthocyanins as red pigments when exposed to sun light. 'Fuji' apple grown in orchards where the ground was covered with light-reflecting films showed an increase in red pigmentation from 11 to 38%, which corresponds to an increase in anthocyanin concentrations in the peel from 0.18 to 0.37 mg/g fresh weight.[123] The same study also observed that the accumulation of anthocyanins and the concentration of flavonols in apple skin depended on the position of fruit on the tree.

Plant nutrition also contributes to the content and distribution of phenolic compounds in apple varieties. Awad amd de Jager[124] found that nitrogen fertilization was associated with a decrease in anthocyanins, catechins, and total flavonoids in apple. The same author associated an increase in anthocyanins and total flavonoids of 'Elstar' apple to calcium fertilization. According to Wang and Lin,[125] strawberry accumulates the highest phenolic amounts when grown under compost substrate and full-strength fertilizer (NPK, 20/20/20). These authors observed that the distribution and content of phenolic compounds such as anthocyanins, flavonols, hydroxycinamic acids, and ellagic acid significantly changed following fertilizer application.

Chemicals that enhance ripening can affect phytochemical biosynthesis. An example is the use of ethephon to increase anthocyanin production without increase in other flavonoid compounds and chlorogenic acid in 'Jonagold' apple.[126] Gibberellins, in particular, $GA_3$, and (*S*)-*trans*-2-amino-4-(2-aminoethoxy)-3-butenoic acid hydrochloride (ABG-3168) significantly decreased anthocyanin contents. However, application of other chemicals such as alar, cycocel (CCC), Prohexadione-Ca, $Ga_{4+7,}$ seniphos, shikimic acid, plantacur-E, and galactose was observed to have no effect on these phytochemicals.

Yearly weather changes can also affect thepolyphenol content of apple. Significantly higher concentrations of phenolic compounds in apple cultivars planted in 2006 and 2007 were observed by Mainla et al.[127] The study showed that 2007 plantings had higher contents of phenolic compounds due to longer sunlight hours, less precipitation, and a higher temperature in August 2007 compared to August 2006. The authors suggested that better light conditions in 2007 before harvest might have caused the higher polyphenol concentration in the apple peel.

Another factor that affects phytochemicals in apple as well as in other Rosaceous fruits is rootstock. According to a study in Estonia by Mainla et al.,[127] apples grown on vegetative rootstocks had significantly higher concentrations of polyphenols than those grown as seedlings. This is probably because rootstocks significantly influence the uptake of mineral elements from the soil. Other studies have also shown that the content of macronutrients in the leaves varies depending on rootstock.[128] Less vigorous rootstocks have a weaker root system and are therefore usually more susceptible to weather conditions.

Various studies have elucidated the effect of maturity and developmental stage on accumulation of phenolic compounds. Mahmood et al.[90] and Pineli et al.[129] reported that the total phenolic content (TPC) as well as the total flavonoid content (TFC) of strawberry and mulberry cultivars increases as fruit ripens. These studies observed that as fruit maturity progressed, TPC and TFC of strawberry fruit increased from ∼8.5 to ∼53.3%. The amount of individual phenolic acids and flavonoids in relation to different maturity stages varies. Major phenolic acids found in strawberry at maturity were *p*-hydroxybenzoic acid and *p*-coumaric acid. From unripened to fully ripened stage, concentrations in strawberry cultivars ranged from 21.4 to 65.4 mg/100 g DW *p*-hydroxybenzoic acid, followed by *p*-coumaric acid (17.3−47.5 mg/100 g DW), gallic acid (6.8−24.6 mg/100 g DW), ferulic acid (7.6−24.1 mg/100 g DW), chlorogenic acid (11.5−18.2 mg/100 g DW), and vanillic acid (2.8−16.1 mg/100 g DW).[90] In Wang et al.'s[130] look at the influence of maturity on fruit quality and phenolic content in red raspberry, anthocyanins were found to prevail in ripe fruit, whereas ellagic acid and quercetin-3-glucuronide were the most abundant in green fruit. Anthocyanins increased during fruit ripening, whereas other polyphenols decreased significantly during fruit ripening.

The effect of low night temperatures on anthocyanin accumulation in grape berries has been studied by Mori et al.[131] The authors found that berries grown under low night temperature conditions accumulated up to 5.5 mg anthocyanins/g fresh weight, whereas, those grown during warm nights accumulated 4 mg/g fresh weight. Treutter[132] reported a higher accumulation of phenolic compounds in strawberry with higher day/night temperatures up to 30/22 °C than lower temperatures. The least accumulation of phenolic compounds was obtained at temperatures of 18/22 °C. Of the five phenolic compounds studied, pelargonidin glycosides consistently showed the highest concentration with increasing temperatures up to 30/22 °C, whereas kaempferol glycosides had the lowest concentration.

The effect of light intensity on color enhancement and higher anthocyanin content has been reported in raspberry.[130,133] Wang et al.[130] showed that red raspberry harvested before full maturity continued to synthesize pigments during storage under favorable conditions, with no significant differences in color or total anthocyanins after 4 days. Light intensity does not affect the total phenolics in 50 and 80% mature fruit, but can affect immature berries (5 and 20% maturities).

Temperature, light intensity, and fruit maturity affect the content and stability of phytochemicals in sweet cherry. Different growing temperatures (i.e., day/night) affect total phenolic and anthocyanin contents.[134] High-temperature growing conditions (25/30 °C) significantly enhance anthocyanin and total phenolic content.[135] Total phenolic compounds decreased during the early stages of development, but later skin color development started with the accumulation of anthocyanins.[136] Also, rootstock affects the content and distribution of phytochemicals.[137] For example, 'Lapins' on 'PiKu 1' and 'Weiroot 13' produced significantly higher phenolic acid and flavonols. This could be attributed to the adjustment of the metabolism genetically between rootstock and scion varieties, which causes higher amounts of metabolic

Table 2. Pharmacokinetic Data from Bioavailability Studies[a]

stress. Furthermore, trees of different vigors may produce sweet cherry fruits with different phenolic acid and flavonol contents.[138]

Murray et al.[139] have linked plum color development to an increase in anthocyanin accumulation. Shading of plum fruit may reduce light intensity and will likely result in poor color development. Tomás-Barberán and Espin[140] reported that ultraviolet radiation is an indicator of anthocyanin accumulation because PAL, chalcone synthase, and dihydroflavinol reductase enzymes involved in phenylpropanoid metabolism are induced by UV radiation. Temperature differences between day and night affect anthocyanin accumulation in plums, and plums grown on soil covered with natural meadow (organic fertilizer) have higher total phenolics than conventional plums (without organic fertilizer)[141,142] Although Bourn and Prescott[143] suggested further studies to fully understand the influence of inorganic and organic fertilizers on the nutritional value of crops, Winter and Davis[144] disagreed that organically grown products are not nutritionally superior to those obtained by conventional agricultural techniques. Further studies are needed to confirm either of these arguments.

The studies of Kan and Bostan[145] on the phenolic content of organically and conventionally grown apricot have shown that apricot cultivars grown organically have higher (+)-catechin levels than those grown conventionally. A >30% decrease in epicatechin levels has been recorded in conventionally grown apricot, whereas higher ferrulic acid levels have been observed in organically grown apricot. Furthermore, the quality of soil and fertilizer level have pronounced effects on phenolic content. Hegedüs et al.[146] reported that the content of total phenolics varied during fruit ripening in two apricot genotypes, 'Gonci magyarkajszi' and 'Preventa'. The study showed that there is an increase in color during ripening from green to yellow and orange due to significant phenolic accumulation in unripe to fully ripe fruit.

## BIOAVAILABILITY AND METABOLISM OF PHENOLICS

Bioavailable substances are those delivered from the digestive system to the circulatory system for further distribution into designated tissues and are therefore biologically available for biochemical functions. Phenolics, like other micronutrients, are ingested, digested, and then transported across the gastrointestinal epithelium into circulatory vessels. Bioavailability also refers to the *extent* to which a drug or other substance enters a specific tissue or organ or to the *dose proportion* reaching systemic circulation intact (systemic availability) by alternate routes of administration to the intravenous system. Researchers have tried to establish that some phytochemicals can be linked to chronic diseases.[11,147] An important question worth asking is if these phytochemicals are in a bioavailable form as processed or fresh fruit. Studies have shown that anthocyanins are less bioavailable than flavonoids.[148] Poor anthocyanin absorption and efficiency in the system have been reported by Manach et al.[148] $C_{max}$ is reached between 75 min and 4 h after ingestion of an anthocyanin-containing meal in the plasma and at 2.5 h in urine excretion (Table 2). Most studies indicate a relatively low rate of urinary excretion of anthocyanins at 0.004−0.1% of the quantity ingested (Table 2), although Felgines et al.[149] reported 5% excretion after red wine or strawberry consumption.

Flavonoids occur as either glycosides or aglycones, with glycosides being the most common form in plants and foods.[150] Flavonoids are absorbed and metabolized in the small intestine to form methylated, glucuronidated, or sulfated metabolites in urine.[148] Flavanols (such as proanthocyanidins and tea catechins) and anthocyanins are poorly absorbed and therefore have low bioavailability, whereas isoflavones (a category to which phytoestrogens belong) are the most bioavailable.[151] Many different phytochemicals are found in members of the Rosaceae; thus, their concentrations and bioavailability are important in evaluating the effect on human health. The degree to which phenolic compounds are bioavailable depends on factors such as cell wall digestibility of the food source, chemical structure of the compound, how the food source was processed, and the individual efficiency of the human gastrointestinal system.

Determination of phenolic bioavailability is done via in vitro and in vivo approaches. DuPont et al.[152] conducted a human study on apple phytochemical bioavailability from alcoholic apple cider. The study found that quercetin is not efficiently absorbed in humans because it was not identified in the volunteers' plasma after administration. Rather, low levels of 3′-methylquercetin and 4′-methylquercetin were seen within 60 min after drinking 1.1 L of apple cider. In their investigation into the bioavailability of quercetin from various foods, Hollman et al.[153] reported that glucosides of quercetin are more efficiently and more rapidly absorbed than quercetin or quercetin rutinoside, and the specific sugar moiety has a predominant effect on absorption profile and plasma levels of quercetin. Catechin, epicatechin, and phloridzin were not identified in the plasma. Bioavailability of quercetin from apple, as well as from pure quercetin rutinoside, was 30% of that from onion, with plasma levels peaking after 0.7 h for onion, 2.5 h for apple, and 9 h for the pure rutinoside. It should be noted that

onions contain only quercetin glucosides, apples contain variously glycosylated quercetins, and tea contains mostly quercetin rutinoside. A separate study by Boyer and Liu[154] used Caco-2 colon cancer cells to ascertain the bioavailability of quercetin and quercetin-3-glycoside from apple peel extracts and onion extracts. No free quercetin was found in apple peel extracts, and no free quercetin accumulation was seen in the Caco-2 cells following incubation. However, low amounts of quercetin-3-glucoside were absorbed by the cells (4%). The absorption of quercetin into the cells from onion extract was much greater, most likely due to the fact that onions contain free quercetin (already available for assimilation into cells), and more quercetin glucosides, which are easily converted to the free form. Apples contain quercetin conjugates that are not easily hydrolyzed by lactase phloridzin hydrolase incubation and, so, most likely are not readily absorbed into the small intestine.

The studies of Fazzari et al.[155] on polyphenol bioaccessibility of cherry at different degrees of maturity indicated that immature cherry had high *percentages* of bioavailable phenolic compounds but lower overall *concentrations*. Higher concentrations of the readily absorbed forms of phenolic compounds in mature and overmature fruit made the actual bioavailable amounts of these compounds higher than in immature fruit. In a study to assess the bioavailability of phenolic compounds from five cultivars of frozen sweet cherry, fruit was digested to simulate either gastric or small intestine digestion and then dialyzed to determine serum-available and colon-available fractions. After pepsin digestion (stomach), the percentage recovery of the total phenolics increased, whereas the percentage anthocyanins did not change. With pancreatic digestion, the total phenolic available in the serum was about 26−30 and about 77−101% in the colon. The anthocyanin content in the serum was about 15−21 and 52−67% in colon.[155]

Azzini et al.[156] studied the bioavailability of fresh strawberry (FS) and stored strawberry (SS) in human subjects. In the study, 13 healthy volunteers consumed 300 g each of FS and SS on two separate occasions. The study found that quercetin and anthocyanins were not found in the plasma, whereas coumaric acid, 4-hydroxybenzoic acid, pelargonidin-3-glucoside (Pel-glc), protocatechuic acid, and cyanidin-3-glucoside were detected in the plasma over a period of 8 h after ingestion of either FS or SS. Pelargonidin conjugates and pelargonidin aglycone peaked in the urine within 2 h of strawberry consumption, and after 24 h, the amount excreted was approximately 0.9% of the Pel-glc dose ingested. These results suggested that the content of phenolics in strawberry might influence the bioavailability of individual compounds. In raspberry, McDougall et al.[157] studied polyphenol bioavailability as influenced by different food matrices. The study showed that bioavailability patterns varied when raspberry was codigested with commonly combined foodstuff such as bread, breakfast cereal, ice cream, and cooked minced beef. Co-digestion with ice cream and cereal seemed to decrease phenolic bioavailability, bread had no effect, and minced beef caused an increase in phenolic availability. Anthocyanin bioavailability was either unaffected or increased by co-digestion with foodstuff, suggesting that food matrices may protect them from degradation during digestion.

Torabian et al.[158] demonstrated that bioavailability of polyphenols was linked with associated reduction in plasma lipid peroxidation and increased antioxidant capacity following consumption of almond. The study reported significant increase in plasma total phenolic content 30 min after the consumption of 91 g of almond (blended in water), whereas no changes were observed following an isocaloric control meal.

Numerous advances in the assessment of polyphenol bioavailability using both in vitro and in vivo approaches have been made, but there is room for more studies to enable consumers to benefit from the abundant polyphenolic compounds in Rosaceous fruits.

## BIOFORTIFICATION OF PHENOLICS IN THE ROSACEAE

Nutritionists, food scientists, and consumers have become increasingly interested in dietary polyphenols due to their role in human health and nutrition. A huge body of research now exists that supports the role of polyphenols in the prevention of degenerative diseases, including cancers, cardiovascular, and neurodegenerative disorders.[8−11,159] Thus, improving the composition as well as the concentration of phenolic compounds in foods originating from plants would be a great benefit to human health through dietary intervention. Plant geneticists have attempted to improve phytochemical levels through traditional breeding or through bioengineering of PAL, leading to secondary metabolite accumulation. To the best of our knowledge, there is limited systematic or concerted effort in the Rosaceae to increase or decrease the concentrations of particular bioactive compounds or a group of compounds related to human health. Although there are various approaches for biofortification, breeding would appear to provide a more systematic and sustainable enrichment. We believe that initial studies on genetic improvement will perhaps focus on understanding the heritability of these compounds such as has been done in strawberry[160] and blueberry.[161] Although other methods such as genetic modification may seem plausible, they still have a major issue with public acceptance. At this stage, the technology could at best be used in the laboratory for testing gene function. Another potential approach is the exploitation of biotic and abiotic stress factors, including optimization of growth conditions such as light, temperature, and soil fertility, for actualization of genetic potential of a particular cultivar or genotype. Although it is possible to increase the content of these compounds by manipulating the physiology of plants using different agronomic treatments, it is important to consider their effects on other quality parameters including yield and organoleptic properties such as color, bitterness, astringency, and texture. To achieve this goal through breeding, gene technologies that are increasingly being used to accelerate breeding progress and increase efficiency would be essential. The use of metabolomic approaches in the identification of quantitative trait loci (QTL) is a promising novel area. For example, metabolite analysis coupled with QTL mapping will offer an unprecedented opportunity to investigate and map hundreds of metabolic features simultaneously. These analyses will yield knowledge of the inheritance of complex economic traits such as polyphenols and their health-promoting compounds in relation to specific metabolites. Mapping key metabolites to molecular markers will give a detailed understanding of the genetic basis of these traits to facilitate incorporation into elite cultivars through marker-assisted breeding.

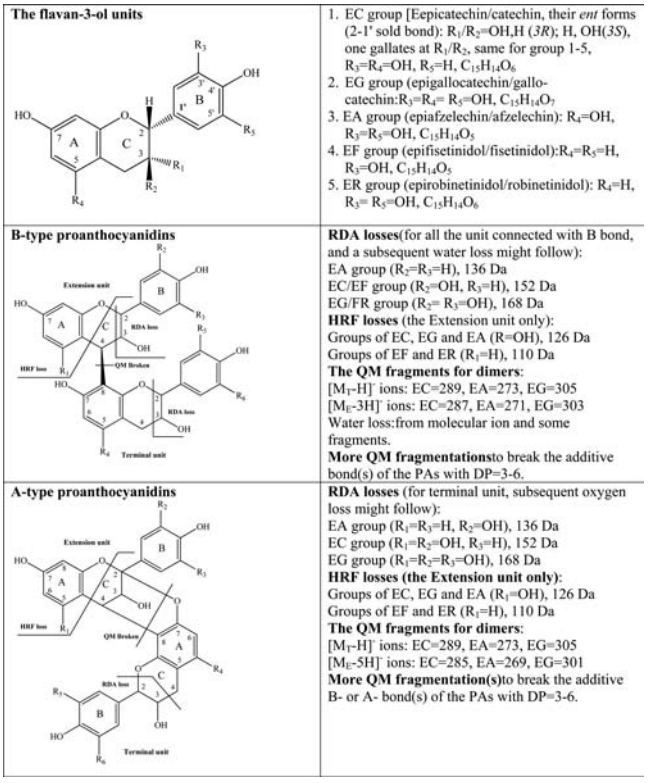

**Figure 1.** Structures of flavan-3-ol units and common fragmentation patterns for proanthocyanidins.

mixtures has also been used for quantification of PAs.[1−4,6,10−12] However, direct quantification of the different PAs comprising each oligomeric class is still problematic due to the difficulty of separation and the lack of standards.[1−4]

As a part of a project to systematically identify and quantify food phenolic compounds, a standardized HPLC-PDA-ESI/MS method was developed for the identification and quantification of food polyphenols, including some PAs.[24] Quantification was based on UV absorbance and molar relative response factors (MRRFs).[25] This method has been upgraded and now uses ultrahigh-performance liquid chromatography−photodiode array detection−high-resolution mass spectrometry operated in the tandem mode (UHPLC-PDA-ESI/HRMS$^n$).[26] In the current study, this method was employed to identify nearly 300 oligomeric PAs in selected plants (fruit pericarps of litchi and mangosteen), extracts (from grape seed and cranberry), and food samples (jujube, Fuji apple, and chocolate) and to quantify PAs in grape seed extract. The main PAs in each of the oligomeric classes were quantified.

## MATERIALS AND METHODS

**Chemicals.** Formic acid, HPLC grade methanol, and acetonitrile were purchased from VWR International, Inc. (Clarksburg, MD, USA). HPLC grade water was prepared from distilled water using a Milli-Q system (Millipore Laboratory, Bedford, MA, USA).

**Standards.** (+)-Catechin, (−)-epicatechin, (−)-gallocatechin-3-*O*-gallate, (−)-epigallocatechin-3-*O*-gallate, procyanidin $B_1$, procyanidin $B_2$, procyanidin $C_1$, and procyanidin $A_2$ were obtained from Chromadex, Inc. (Irvine, CA, USA). The standards were vacuum-dried using a vacuum drying box (National Appliance Co., Portland, OR, USA) at 110 °C until a constant weight was reached (about 24 h). These dried standards were used to determine the MRRF that were used for calibration.[25]

**Plant Materials and Extraction.** Fresh fruits of jujube (*Ziziphus jujuba* Mill), Fuji apple (*Malus domestica* Borkh cv. Fuji), litchi (*Litchi chinensis* Sonn.), and mangosteen (*Garcinia mangostana* Linn.) were purchased from local food stores. Dark chocolate was purchased from a local Trader Joes store in Maryland, USA. The extracts of grape seed and cranberry were kindly supplied by Triarco Industries, Inc. (Paterson, NJ, USA). The fruit pericarps of litchi and mangosteen and the skins of fresh jujubes and apples were lyophilized, and the dried materials were powdered.[24−26]

Each of the powdered fruit samples (250 mg) was extracted with 5.000 mL of a methanol/water (60:40, v/v) solvent using sonication for 60 min at room temperature. The slurry mixture was centrifuged at 2500 rpm for 15 min. The supernatant (4.000 mL) was taken from the tube and filtered through a 17 mm (0.45 μm) PVDF syringe filter (VWR Scientific, Seattle, WA, USA) for injections.[24−26] A second extraction using acetone/methanol/water (2:2:1, v/v/v, 4.000 mL) was treated in the same way to check the extraction efficiency of the general extraction method. The result showed that >95% of the mass for each main compound was extracted from the plant material by the first extraction.

Powdered chocolate samples (2000 mg) were extracted with 40 mL of the same aqueous methanol and treated as described above, and the supernatant was taken to dryness under vacuum at 40 °C. The approximately 30 mg of the residue was dissolved in water (1 mL) and passed through Sep-PakVac RC (500 mg) $C_{18}$ cartridge (Waters Corp., Milford, MA, USA). After washing with water (5 mL), the PAs were eluted with methanol (5 mL) and again taken to dryness under vacuum. The residue was dissolved in 1.000 mL of the methanol/water solvent and filtered for injection.

The grape seed (10.80 mg) and cranberry (10.20 mg) extracts were dissolved in the same aqueous methanol (1.0 mL) and filtered. Triplicate injections (1 μL) of each solution were used to determine the average concentration and the relative standard deviation for each of the PAs in the extract. Dried catechin was used as the external calibration standard; 4 mg was placed in a 10 mL volumetric flask, dissolved in the methanol/water (60:40, v/v) solvent, and brought to volume. This stock solution was diluted 1:4 and 1:16. The stock and each dilution were injected onto the column three times and used to construct a calibration curve.

**UHPLC-PDA-ESI/HRMS$^n$ Conditions.** The UHPLC-HRMS system used consisted of an LTQ Orbitrap XL mass spectrometer with an Accela 1250 binary pump, a PAL HTC Accela TMO autosampler, a PDA detector (ThermoScientific, San Jose, CA, USA), and a G1316A column compartment (Agilent, Palo Alto, CA, USA). The separation was carried out on a U-HPLC column (200 mm × 2.1 mm i.d., 1.9 μm, Hypersil Gold AQ RP-$C_{18}$) (Thermo- Scientific) with an HPLC/UHPLC precolumn filter (UltraShield Analytical Scientific Instruments, Richmond, CA, USA) at a flow rate of 0.3 mL/min. The mobile phase consisted of a combination of A (0.1% formic acid in water, v/v) and B (0.1% formic acid in acetonitrile, v/v). The linear gradient was from 4 to 20% B (v/v) at 40 min, to 35% B at 60 min, and to 100% B at 61 min and held at 100% B to 65 min. The PDA recorded spectra from 200 to 700 nm and provided real-time monitoring at 280 and 330 nm.[26]

The HRMS was operated in the negative ionization mode using the following conditions: sheath gas at 70 (arbitrary units), aux and sweep gas at 15 (arbitrary units), spray voltage at 4.8 kV, capillary temperature at 300 °C, capillary voltage at 15 V, and tube lens at 70 V. The mass range was from $m/z$ 50 to 2000 with a resolution of 15000, FTMS AGC target at 2e5, FT-MS/MS AGC target at 1e5, isolation width of 1.5 amu, and maximum ion injection time of 500 ms. The most intense ion was selected for the data-dependent scan to provide $MS^2$ to $MS^5$ product ions with a normalized collision energy at 35%.[26] The selective ion monitoring (SIM) mode was used to select the molecular ions of the isomers from each of the PA groups in grape seed extract for their quantification.

Table 1. Computed High-Resolution Mass, Molecular Weight, Molecular Ions, and Composition of Common Oligomeric PAs[a]

[a]Composition is used for the numbers of the atoms of carbon, hydrogen, and oxygen of the molecular formula and the numbers of the flavan-3-ol units, A-type bonds, and galloyls. Abbreviations: DP, degree of polymerization; G, galloyl; EC, EA, EG, epicatechin, epiafzelechin, and epigallocatechin, respectively; C, H, O, carbon, hydrogen, and oxygen.

## RESULTS AND DISCUSSION

**Exact Masses and Molecular Formula for Proanthocyanidins.** Chemically, each flavan-3-ol unit of a PA has two stereogenic (or chiral) centers (Figure 1), which can result in four (or $2^2$) stereoisomers, that is, (2*R*,3*S*)-catechin or (+)-C, (2*R*,3*R*)-epicatechin or (+)-EC, (2*S*,3*R*)-catechin, or (−)-C, and (2*S*,3*S*)-epicatechin or (−)-EC. In this paper, EC will be used to represent all four isomers in the text, tables, and figures. Similarly, the abbreviations for epiafzelechin (EA), epigallocatechin (EG), epifisetinidol (EF), and robinetinidol (ER) will be used to represent their isomers in PAs. In this paper, the PAs formed with only EA, EC, or EG units are called propelargonidin, procyanidin, or prodelpeinidin, whereas those formed from two different units are called proanthocyanidins.

The B-type PA dimers have two flavan-3-ol units (i.e., four chiral centers) and an additional asymmetric center at C4.

[a]Abbreviations: A, apple; C, cranberry extract; D, dark chocolate; G, grape seed extract; J, jujube; L, litchi; M, mangosteen; AL, all tested plants (the number of similar peaks in the sample is listed in parentheses); $B_1$, $B_2$, $A_2$, and $C_1$, procyanidin B-type dimers $B_1$, $B_2$, A-type dimers $A_2$, and trimer $C_1$;

**Table 2. continued**

DP, degree of polymerization; g, galloyl; EC, EA, EG, and EF, epicatechin, epiafzelechin, epigallocatechin, and epifisetinidol, respectively. The signal $unit_1 \rightarrow unit_2$ or $unit_1 \rightarrow A \rightarrow unit_2$ expresses the units bonded by B-type (4,8- or 4,6-) bond or A-type (plus additional $C_2-O-C_7-$ or $C_2-O-C_5-$) bond, respectively.

Thus, it is possible for them to be connected in two ways, through a $C_4-C_8$ or $C_4-C_6$ linkage, providing 64 (i.e., $2^6$) possible isomers.[1−4,10−23] The formation of B-type trimers and tetramers leads to an exponential increase in the possible number of isomers, which makes the separation and quantification of such complex PA isomers an enormous challenge.[1−4]

UHPLC columns (with 1.9 $\mu$m or smaller particles) provide much better separation of the PA isomers than HPLC columns.[1,20−23] In addition, the molecular ions detected by HRMS provide high-resolution molecular weight (HRMW) and exact molecular formula (MF). The HRMW, MF, and singly and multiply charged ions for different PAs are related to the DP, the flavan-3-ols (EC, EA, EF, EG, and ER) in the oligomer, the number of galloyls, and the number of type A bonds as described in the equations

$$\begin{aligned} \mathrm{HRMW} = {} & 12.0000 \times (15n + 7c) + 1.0078 \\ & \times (12n + 2 + 4c - 2d) + 15.9949 \\ & \times (6n + 4b - a + b) \end{aligned} \quad (1)$$

$$\mathrm{MF} = C_{15n+7c}H_{12n+2+4c-2d}O_{6n-a+b+4c} \quad (2)$$

$$\begin{aligned} [\mathrm{M} - \mathrm{H}]^- = {} & 12.0000 \times (15n + 7c) + 1.0078 \\ & \times (12n + 1 + 4c - 2d) + 15.9949 \\ & \times (6n + 4c - a + b) \end{aligned} \quad (3)$$

$$[\mathrm{M} - 2\mathrm{H}]^{2-} = (\mathrm{HRMW} - 2 \times 1.0078)/2 \quad (4)$$

$$[\mathrm{M} - 3\mathrm{H}]^{3-} = (\mathrm{HRMW} - 3 \times 1.0078)/3 \quad (5)$$

where $n$ = degree of polymerization, $a$ = number of ECs that were replaced by EAs or EFs (as regioisomers), $b$ = number of ECs replaced by EGs, $c$ = number of galloyls, and $d$ = number of A-type bonds; 12.0000, 1.0078, and 15.9949 are the accurate masses of carbon, hydrogen, and oxygen, and 15, 12, and 6, and 7, 4, and 4 are the numbers of carbon, hydrogen, and oxygen atoms for each EC (or its regioisomer ER) and galloyl unit, respectively. The equations can be easily modified to accommodate the PAs that contain acyl, glycosyl, or phloroglucinol adducts.[1,19]

Low-resolution ions are usually expressed to two decimal places in most cases and can be obtained directly from the high-resolution $[M - H]^-$ values. Formulas have been described for computing the PA molecular ion metal adduct values (in low resolution) from MALDI-TOF-MS, but the PA mass values can be obtained only after the mass of the metal has been subtracted.[11−13,20] Thus, eqs 1−5, for PA mass, are easier to use.

Table 1 presents the HRMW and deprotonated molecule ($[M - H]^-$) ($m/z$) for most of the PAs (DP = 2−10) detected in common foods in this laboratory and described in the literature.[1,4] For each oligomer, the nongalloylated B-type procyanidins (in bold) have the simplest formulas ($a = b = c = d = 0$), indicating that the PAs have no EC units replaced by EA, EF, or EG and do not contain any galloyls and A-type bonds. To be as systematic as possible, for each oligomer class, the related propelargonidins and proanthocyanidin-containing EA units are listed above the procyanidins, whereas the related prodelphinidins containing EG units are listed below the procyanidins. Similarly, all of the A-type PAs for each oligomer are listed above the B-type PAs and the galloylated PAs are listed below.

The data in Table 1, calculated from eqs 1−5, were found to agree well with experimentally determined $[M - H]^-$ values with an error of <3 ppm in most cases. Consequently, Table 1 can be used to provide the PA structure based on experimental high-resolution $[M - H]^-$ values. For example, trace ions recorded in grape seed extract were easily identified as galloylated procyanidin tetramers (1305.2698, error < 3 ppm), pentamers (1441.3250), hexamers (1729.3898), and their gallates (1593.3354 and 1881.4033). Thus, a detailed analysis of plant PAs can be achieved easily without using purified PA or PA-enriched samples.

The data in Table 1 permit a detailed PA oligomeric profile of a sample to be obtained from a single chromatogram using HRMS. Although identification of specific PAs based on the recorded HR $[M - H]^-$ values is putative, they are all correctly identified as PAs. It should be noted that nominal MS (typically masses to two decimal places) cannot positively identify them as PAs. The data in Table 1 also provide the opportunity to fully identify interesting or minor PAs (i.e., to specify the flavan-3-ol units and their connectivity) by selecting specific ions for fragmentation as described below.

**Identification of Proanthocyanidins in Foods.** The UHPLC-PDA-ESI-HRMS$^n$ profiling method provides retention time, UV, $[M - H]^-$, and $MS^{2-5}$ product ions for the PAs. Consideration of the product ions, especially $MS^2$ ions, permits easy putative identification of PAs. Table 2 lists 247 proanthocyanidins in 90 isomeric groups from 7 food materials, their plant sources, single-parent ions, formulas, and diagnostic and main $MS^2$ productions. The number of the isomers identified in each sample is in parentheses following the plant name. Approximately 130 of the PAs were detected in the grape seed and mangosteen extracts, and the rest were detected in the other five samples (Fuji apples, cranberry extract, dark chocolate, jujube, and litchi). Many of the PAs were detected in these plants for the first time.

It was noted that catechin and epicatechin showed the same product ions and very similar ratios at $MS^2$ [245 (100%), 205 (35%), and 179 (11−12%)], $MS^3$ [227 (28−30%), 203 (100), and 187 (20−25%)], and even at $MS^4$ [185, (20−37%), 175 (100%), 161 (28−42%)]. Similarly, dimeric procyanidins $B_1$ (EC-4$\beta$-8-C) and $B_2$ (EC-4$\beta$-8-EC) have very similar $MS^2$ [451 (27−37%), 425 (100%), 407 (41−47%), 289 (17−26%), and 287 (7−8%)], $MS^3$ [407 (100%) and 273 (6−8%)], $MS^4$ [285 (100%), 283 (36−43%), 389 (29−36%), 297 (27−37%), and 255 (17−27%)] and $MS^5$ [257 (100%) and 213 (4−7%)] fragments.

These data indicate that the slight differences in the relative ratio among the fragments might be caused by the stereochemistry of the monomers. However, there are insufficient data to predict the effect of the linkages and the positions of the PA flavan-3-ol units on product ion formation and relative abundance. At present, LC-MS$^n$ methods are not able to

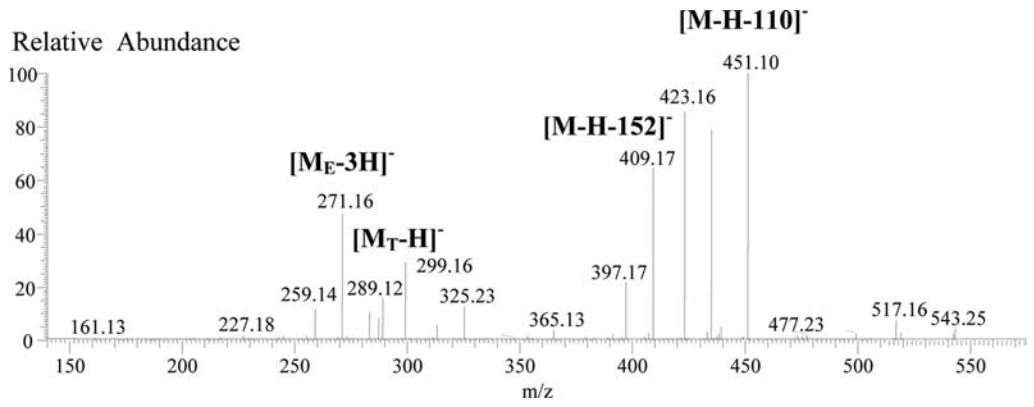

**Figure 2.** $MS^2$ spectrum of the EF−EC dimer with retention time at 26.98 min.

discriminate between the regioisomeric forms of the PAs or the related stereoisomeric forms.

As shown in Figure 1, the most important $MS^2$ fragments of B- and A-type PA dimers are formed by quinone methide (QM) fission, that is, breaking of the interflavan bond between the monomers to form $[M_T - H]^-$ and $[M_E - 3H]^-$ ions for B-type PAs and $[M_E - 5H]^-$ ions for A-type PAs, where E = extension unit and T = terminal unit. Other typical PA fragments were formed by retro-Diels−Alder (RDA) fission (loss of the whole B-ring with $C_2$−$C_3$ part of the C-ring, i.e., loss of 152, 136, and 168 Da for EC, EA, and EG, respectively) and by heterocyclic ring fission (HRF) of the extension unit (loss of the A-ring, i.e., loss of 126 Da for EC, EA, or EG and loss of 110 Da for EF or ER). Product ions formed by the loss of water (−18 Da), O (−16 Da), CO (−28 Da), HC≡CH (−26 Da), HC≡COH (−42 Da), and HC≡CH—CO (−54 Da) were also observed.[4,13,14,19−23,27] For PAs with DP ≥ 3, further fragmentation can occur from repeated QM breaks of interflavan bonds connecting the flavan-3-ols of the extension units. These product ions were also frequently used to identify the PAs. Information obtained from the analysis of thiolytic degradation products of the PAs from similar plants has proven useful for the identification of PAs.[1,4,13,14,19−23,27−30]

In this study, 247 PAs were identified in 7 tested materials (Table 2) using only the most intense ions among the coeluted ions (each peak) as the target ions. However, the identified PAs can be enhanced by selecting more target ions, such as the second and third most intense ions of each peak. The PAs are denoted as combinations of EC, EA, EG, and EF, and A-type bonds are designated by placing an "-A-" between the flavan-3-ols. Although there are numerous isomers in each oligomeric class, only one isomer was selected to represent all of the remaining isomers (each having the same $MS^2$ base and main fragments). There was no correlation between the PAs found in the different samples. Positive identification was achieved for only some of the PAs in Table 2 based on direct comparison to reference PAs (procyanidins $B_1$, $B_2$, $C_1$, $A_2$) or PAs positively identified in other studies.[1,4]

Procyanidins with DP = 2−5 have been previously reported in common foods.[4,19−23,27] Consequently, special attention was paid to PAs containing different flavan-3-ol units or A-type bonds because these features lead to more regioisomers. For example, 13 PA dimers ($[M - H]^-$ at 561.1388) contained two different flavan-3-ols. One of the three detected in mangosteen had $MS^2$ fragments at $m/z$ 435 (−126 Da, HRF from EA or EC), 409 (−152 Da, RDA from EA or EC), 287 ($[M_E - 3H]^-$), and 273 ($[M_T - H]^-$), suggesting it to be EC-EA, a PA dimer containing an EA unit as the terminal unit. The other two in mangosteen had $MS^2$ fragments at $m/z$ 289 ($[M_T - H]^-$, 100%), 435 (−126 Da), 425 (−136 Da), 407 [−(136 + 18) Da), and 271 ($[M_E - 3H]^-$), corresponding to EA-EC, the isomers containing EA as extension unit (Figure 1).

Another 10 interesting dimers were detected in grape seed extract. Three had $MS^2$ fragments at $m/z$ 451 (HRF loss of 110 Da, $C_6H_6O_2$ for the deoxy-A-ring of EF or ER, 100%), 423 [−(110 +28), 91−98%], 409 (−152 Da, RDA loss, 29−60%), 289 ($[M_T - H]^-$, 12−18%), and 271($[M_E - 3H]^-$, 20−48%) (Figure 2). Five had the same $MS^2$ fragments but with different intensities; one at $m/z$ 423 (100%), 451 (around 50%), 409 (28−64%), 289, and 271. The remaining two had $MS^2$ fragments at $m/z$ 435 (100) and 451 (40−50%). These fragments suggested that all might be proanthocyanidin dimeric isomers (EF-EC). To date, the PAs containing an EF unit have only been reported to exist in plant woods, such as quebracho (*Schinopsis balansae* var. *chaqueno*) wood, but rarely in common foods, such as grapes.[1,28−31]

A PA dimer ($[M - H]^-$ at 593.1279 Da) detected in grape seed extract had mass fragments at $m/z$ 441 (−152, RDA) and 305 ($[M_T - H]^-$), suggesting it was an EC-EG isomer. A PA trimer containing two EAs ($[M - H]^-$ at $m/z$ 833.2083) was found in mangosteen with $MS^2$ fragments at $m/z$ 543 (100%, $[M_E - 3H]^-$), 707, and 289 ($[M_T - H]^-$) and $MS^3$ fragments at $m/z$ 271 (100%, the second $[M_E - 3H]^-$), 417, and 407, indicating that two EA units were formed the extension units and that the EC was the terminal unit. Two PA trimers found in mangostenn and litchi with $[M - H]^-$ of 847.1860 Da had one A-type bond, $MS^2$ fragments at $m/z$ 557, 411, and 289, and a $MS^3$ base fragment at $m/z$ 285. This suggested that EA was the extension unit with the A-type bond connected to one of the two ECs and that the remaining EC was the terminal unit.

Nineteen PA trimers (9 in mangosteen and 10 in grape seed extract) had $[M - H]^-$ fragments at 849.2030 Da indicating EA or its constitutional isomer EF. Of these, 5 had $MS^2$ fragments at 577 (−272 Da, 100%) and 559 (−290 Da around 40−50%), 1 had $MS^2$ fragments at $m/z$ 561 (−288 Da), and the others had $MS^2$ fragments at 559 (−290 Da), 723 (−126 Da), 697 (−152 Da), and 831 (−18 Da). All of these PAs might be EA-EC-EC isomers. The two detected in grape seed extract (expressed as EF-EC-EF in the last line for this oligomeric class) had a $MS^2$ fragment at $m/z$ 739 (−110 Da, ∼20%) and might have EF instead of EA as the extension unit.

Fourteen procyanidin trimers ($[M - H]^-$ at 863.1800 Da) contained one A-type bond. Ten of them (6 from mangosteen, 3 from litchi, and 1 from cranberry) had $MS^2$ fragments at $m/z$

[a]Abbreviations: L, litchi; M, mangosteen (number of similar peaks in the sample is listed in parentheses). The value was taken from one of the PA and close to those of the remaining ones.

575 (−288 Da, 21−100%), 711 (42−100%), and 289 (20−89%), indicating they were EC-EC-A-EC isomers. Others (two from litchi and two from cranberry) had $MS^2$ fragments at $m/z$ 573 (−290 Da, 35−62%), 411 (43−100%), and 711 (91−100%) to suggest they were EC-A-EC-EC isomers.

One A-type PA tetramer in litchi ($[M - H]^-$ at 1135.2472) contained one EA and one A-type bond and had $MS^2$ fragments at $m/z$ 847 (−288 Da, 100%), 983 (−152 Da, 36%), 845 (−290 Da, −30%), 693 [−(152 + 290) Da, 26%], and 557 [−(288 + 290) Da, 22%]. This suggested it might be an EC-EA-A-EC-EC or EC-EC-A-EA-EC isomer.

Seven PA tetramers in mangosteen ($[M - H]^-$ at 1137.2450) contained one EA. Three had $MS^2$ fragments at $m/z$ 865 (−272 Da, 100%), 847 (−290 Da, 30%), and 577 [−(288 + 272) Da, 46%]. Another three had $MS^2$ fragments at $m/z$ 847 (−290 Da, 100%) and 575 [−(288 + 274 or 290 + 272) Da]. The remaining tetramer had $MS^2$ fragments at $m/z$ 1011, 985, 967, 849 (−288 Da), 847, and 577 [−(290 + 274) Da]. These fragments indicated EA was a part of the extension unit with two ECs and might be the final extension unit.

Four procyanidin tetramers (three from Litchi and one from cranberry) with $[M - H]^-$ at 1149.2280 had two A-type bonds and $MS^2$ fragment at $m/z$ 575 (80−100%) {−(288 + 286) Da for $[M_T - H]^-$} and 573 (75−85%) {−(2 +286 × 2) Da for $[M_E - 3H]^-$}, indicating that the A-type bonds were between the first and second and between the third and fourth flavan-3-ols. Ten procyanidin tetramers (9 from Litchi and 1 from cranberry) with $[M - H]^-$ at 1151.2415 had one A-type bond. Three (group 1) had $MS^2$ fragments at $m/z$ 863 (100%) (−288 Da for $[M_E - 3H]^-$) and 573 (41%) indicating the A-type bond was between the second and third flavan-3-ols. Five (groups 2−4) had $MS^2$ fragments at $m/z$ 861 (84−100%) (−290 Da for $[M_T - H]^-$) and 573 (49−59%) {−(2 +286 × 2) Da for $[M_E - 3H]^-$} indicating an A-type bond between the first and second flavan-3-ols. Two (groups 4 and 5) had $MS^2$ fragments at $m/z$ 863 (57−86%), 575 (48%) {−(288 + 286) Da for $[M_T - H]^-$ }, or 577 (38%) and 573 (57%) indicating an A-type bond between the third and fourth flavan-3-ols.[14,19] Similarly, the PA pentamers in eight groups (1−8) have one A-type bond, and the PAs of the first six groups (1−6) showed main fragment at $m/z$ 863 (50−100%), indicating the A-type bond between the fourth and fifth flavan-3-ols. The PS of the last group (8) showed the main fragment at $m/z$ 861 (50%), indicating the A-type bond between second and third flavan-3-ols, whereas the remaining one in group 7 showed fragments at $m/z$ 863 and 573 to suggest that this compound might have its A-type bond between the third and fourth flavan-3-ols.[14]

Ten galloylated dimers and 11 trimers were detected in grape seed extract. The existence of a galloyl connected to a PA with DP ≥ 2 provides the possibility of forming regioisomers; for example, EC-ECg and ECg-EC and EC-EC-ECg, EC-ECg-EC, and ECg- EC-EC. Unfortunately, the ECg position cannot be deduced from the mass fragments because gallate was very easy to lose. Thus, they were expressed as (EC-EC)g or (EC-EC-EC)g, respectively.

Jujube fruit was analyzed because PAs (DP = 2, 3, 5, and 7) consisting of both EA and EG have been isolated from jujube leaves and bark.[32] These PAs have the same molecular weight and formula as those of their related procyanidins, but can be easily distinguished from the procyanidins by the noticeable difference in their fragments. For example, the dimers of EA and EG will have QM (271 and 305 Da for EA-EG or 303 and 273 Da for EG-EA) and RDA fragments formed by the loss of 136 Da from EA and 168 Da from EG, whereas the related procyanidin dimers should have QM (289 and 287 Da) and RDA fragments formed by the loss of 152 Da. A careful check confirmed that all 30 of the detected PAs in jujube consisted of EC units only.

**Identification of Highly Polymerized PAs Based on the Doubly and Triply Charged Molecular Ions.** Negative

dx.doi.org/10.1021/jf501011y | J. Agric. Food Chem. 2014, 62, 9387−9400

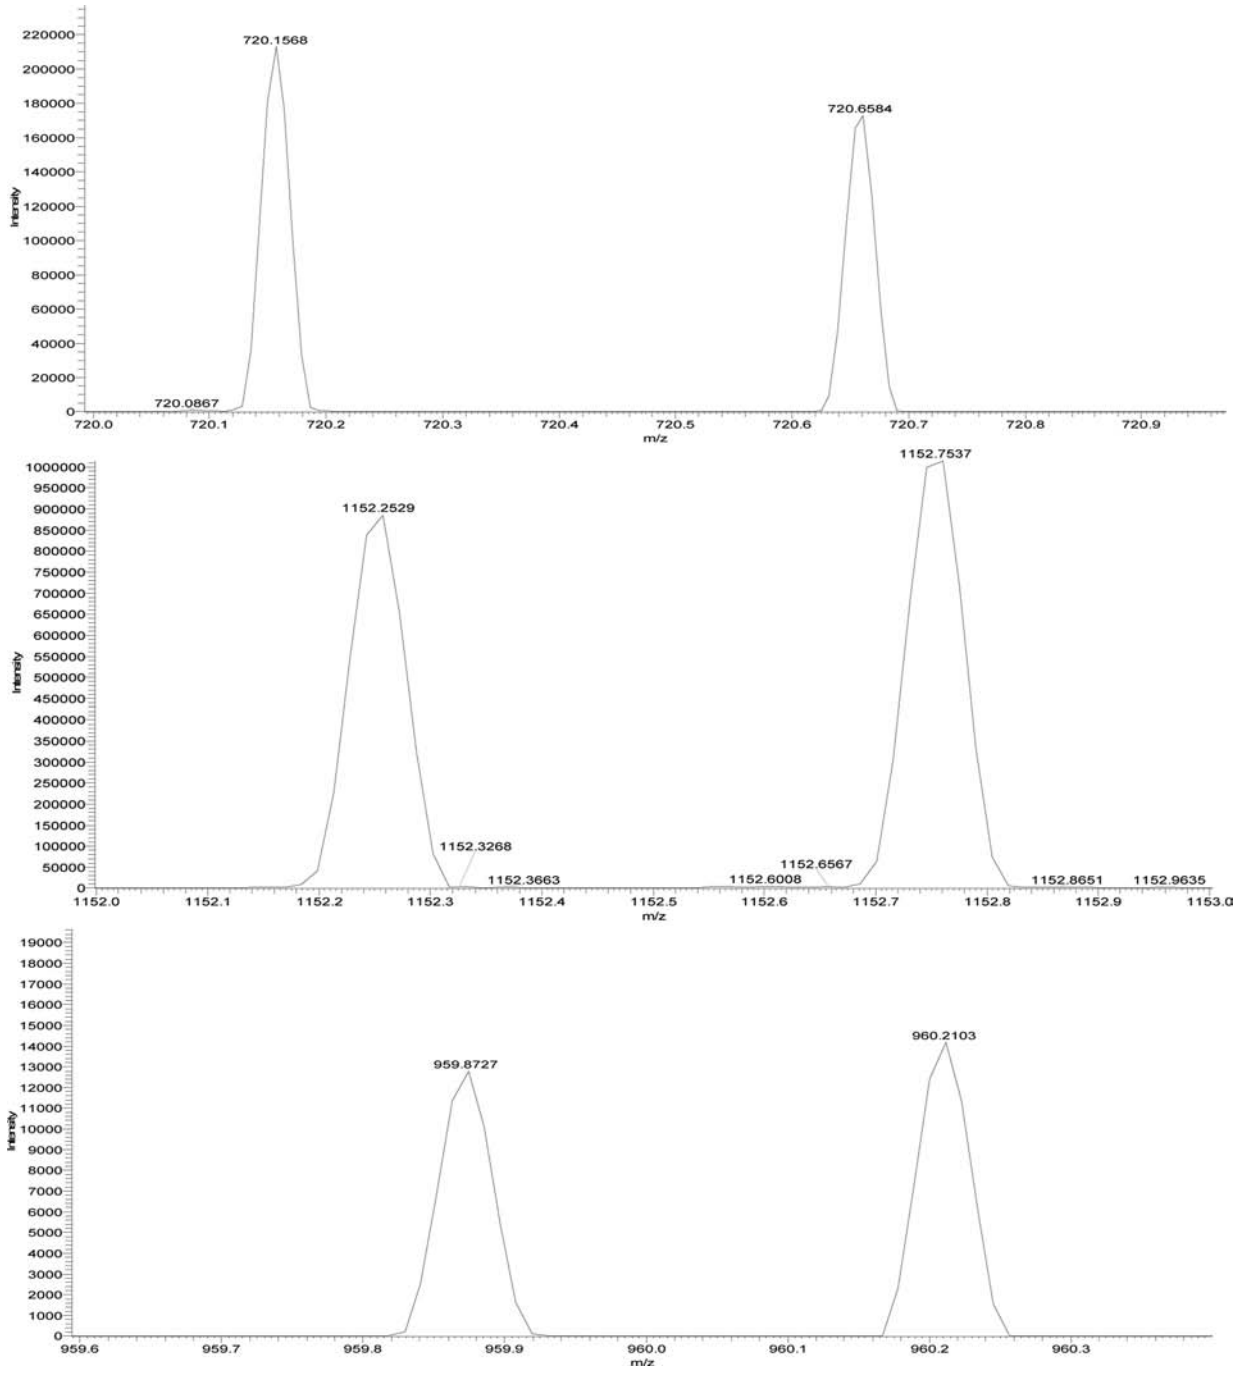

**Figure 3.** Accurate $^{12}C$ and $^{13}C$ isotope ion peaks for $[M - 2H]^{2-}$ of $m/z$ 720 and 1152 and for $[M - 3H]^{3-}$ of $m/z$ 960.

ionization of many highly polymerized PAs (DP ≥ 5) produces multiply (mainly doubly and triply) charged molecular ions. To date, several dozen multiply charged molecular ions have been reported and used to identify PAs with DP = 7−25.[1,4,13−19] With nominal resolution MS, these ions were recognized as doubly or triply charged molecules on the basis of the distance between the $^{12}C$ and $^{13}C$ isotope ions. As the charge increases from 1 to 2 to 3, the distance between the isotopes will decrease from 1 to 0.5 to 0.33 amu.[17,18] It was noted that the ion masses for PA isotopes were always slightly different.[1,4,13−20] This was attributed to the differences in the relative abundances of the $^{12}C$ and $^{13}C$ isotopes.

Table 1 contains the accurate $[M - 2H]^{2-}$ and $[M - 3H]^{3-}$ values for PAs with DP = 5−10, which matched the $[M - 2H]^{2-}$ or $[M - 3H]^{3-}$ of around 50 proanthocyanidins detected in mangosteen and litchi extracts (Table 3). The $^{12}C$ and $^{13}C$ isotope ions of each proanthocyanidin were easily found by examining the distance between the two isotopic ion peaks. For example, in mangosteen the main $[M - 2H]^{2-}$ ions were found at $m/z$ 720.1566, 856.1928, 864.1863, 1000.2235, 1008.7217, and 1152.7537 (Figure 3; Tables 1 and 3). The first four values were taken from the $^{12}C$ isotope ion and perfectly matched (error < 3 ppm) the listed $[M - 2H]^{2-}$ data in Table 1 for the B-type procyanidin pentamer and hexamer, the B-type propelargonidin hexamer containing one EA unit, and the B-type propelargonidin heptamer containing two EAs. The values of the $^{13}C$ isotope were $m/z$ 0.500 more than that from $^{12}C$ isotope (Table 3). However, the last two values, $m/z$ 1008.7217

dx.doi.org/10.1021/jf501011y | J. Agric. Food Chem. 2014, 62, 9387−9400

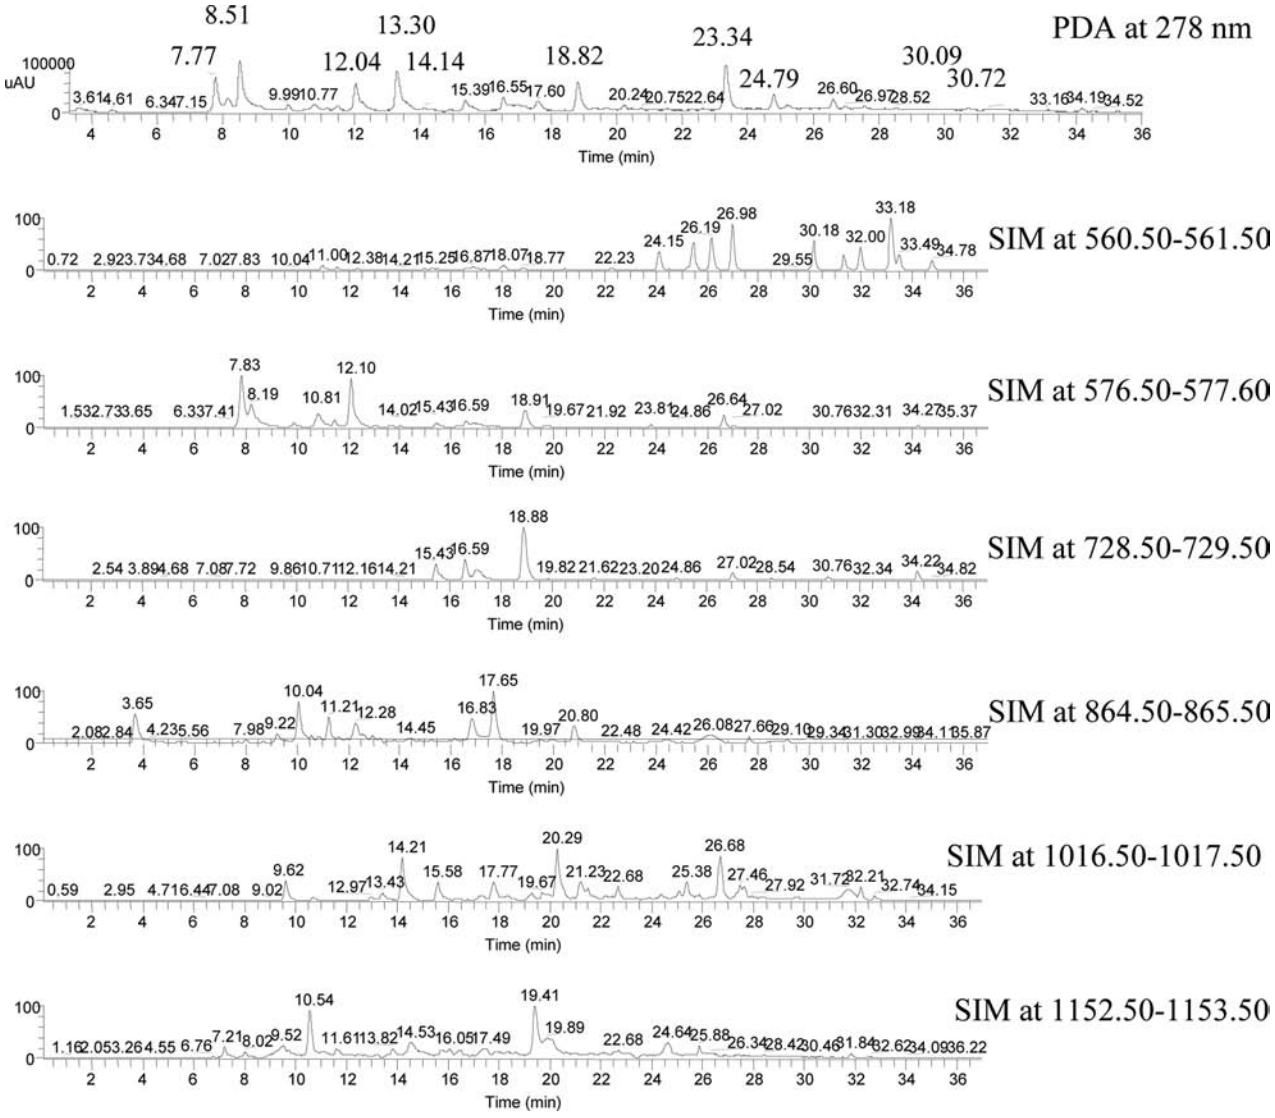

**Figure 4.** PDA (at 278 nm) and SIM chromatograms of grape seed extract.

and 1152.7537, were taken from the $^{13}C$ isotope ions of B-type procyanidin heptamer and octamer, respectively, so these masses were larger than the listed $[M - 2H]^{2-}$ values for the $^{12}C$ isotope ion by 0.50 amu.

Checking the distance between isotopes led to the detection of several minor PA ions in the TIC chromatogram of mangosteen extract. For example, the ions at $m/z$ 1296.2828, 1007.2120, 1136.2540, and 1288.2840 were close matches to the listed values for doubly charged B-type procyanidin octamers, A-type procyanidin heptamers with one A bond, B-type propelargonidin octamers with two EA, and B-type propelargonidin nonamers with one EA (Tables 1 and 3), respectively.

Similarly, checking for $^{12}C$ and $^{13}C$ isotopes with a 0.33 amu distance led to the discovery of several $[M - 3H]^{3-}$ ions. However, only one of them (in mangosteen) was for a PA with a DP $\leq$ 10. As shown in Table 3 and Figure 3, the HRMS values for this PA for the $^{12}C$ and $^{13}C$ isotope ions were 959.8727 and 960.2103 (Figure 3), respectively. To date, only five multiply changed ions have been reported in the pericarps of mangosteen.[12] This is the first report to use the high-resolution isotope ion values for accurate identification of multiply charged PAs based on the use of $^{12}C$ and $^{13}C$ isotope ions.

**Quantification of Proanthocyanidin Oligomers.** The extraction efficiency of the standardized method for PAs in plant materials was determined by a follow-up extraction using acetone/methanol/water (2:2:1, v/v/v), a solvent frequently used for PA extraction in other studies.[2−4,21,22] No additional material was found in the follow-up extractions as determined by the lack of detectable peaks. This indicated that the general extraction method was suitable for the quantification of PAs in jujube, Fuji apple, litchi, and mangosteen.

The UV absorbance of phenolic compounds is widely used for the quantification of PAs.[2−4,7,19,20,22] The MRRF of flavan-3-ol (catechin and epicatechin) monomers, dimeric procyanidin $B_1$, $B_2$, and $A_2$, and trimeric procyanidin $C_1$ at 274−280 nm were found to be proportional to the DP number in our previous study.[25] This established that, in molar units, the response of the monomers was additive. The MRRF values for catechin, gallocatechin, and gallic acid were determined to be 1.00, 0.31, and 2.8.[25] Thus, the MRRF for EC-EC is 2.0, that for EC-EC-A-EC is 3.0, and that for EC-EC-ECg is 4.8. There were no commercial standards for afzelechin or fisetinodol, so an

MRRF value of 1.00 was assigned to each. The additivity of the molar absorption coefficient makes it possible to quantify most of the PAs using (+)-catechin as a standard with the MRRF values listed above.

Unfortunately, even with UHPLC, only a few PAs were well separated and could be quantified on the basis of their UV peak area. Most PAs, when viewed with UV or TIC, had peaks that overlapped (coeluted) with other PAs. Selected ion monitoring (SIM) and multiple reaction monitoring (MRM) are the only methods that allow deconvolution of the overlapping peaks, that is, isolation of the ions of interest.[33,34] Consequently, concentrations had to be computed on the basis of ion counts obtained from SIM or MRM as reported in previous studies[19,22] The few well-separated absorbance peaks were used to equate the peak area in absorbance to integrated counts of specific ions. In other words, MRRF values based on absorbance were converted to MRRF values based on integrated ion counts. This approach allowed catechin and the MRRF values reported above to be used for computing PA concentrations.

Use of MRRFs based on ion counts assumes constant ionization efficiency for all PAs. Unlike absorbance, the ion count of a PA isomer can be expected to be dependent on its structural ionization sensitivity and the mobile phase. The SIM peak intensity might change with the solvent ratio at different retention times, the isomer concentration, and the presence of coeluting PAs (Figure 4). Tests performed with flavan-3-ol monomers and procyanidins $B_1$ and $B_2$ showed the variation in ionization efficiency to be <±10%. Further testing with PAs with DP = 3−5, A-type bond, or galloyls is needed but must wait on the availability of suitable standards.

The PA concentrations in dry weight percent (%) and milligrams per 100 g of dry plant material were calculated using the formulas

$$C\ (\%, w/w) = [100A_x \times MW_x \times V_s \times M_s \times W_s] / [A_s \times MW_s \times W_x \times V_x \times MRRF] \quad (6)$$

$$C\ (mg/100\ g) = [1000A_x \times MW_x \times W_s \times V_s] / [A_s \times MW_S \times V_x \times W_x \times MRRF] \quad (7)$$

where $A_x$, $MW_x$, $W_x$, and $V_x$ and $A_s$, $MW_s$, $W_s$, and $V_s$ are the peak area, molecular weight, sample weight, and volume of the extract for the sample and standard, respectively.

As shown in Table 4 for grape seed extract, at least one PA in each of the oligomers was found to have a well-separated peak (no coeluting compounds) that could be used to equate absorbance with ion counts from SIM. The concentrations of monomers, dimers, trimers, and tetramers as percent dry weight were 16.63 ± 0.67, 17.44 ± 0.70, 14.24 ± 0.57, and 0.47 ± 0.20%, respectively. The concentration for PAs with DP > 4 was negligible. The total concentration of PAs was 48.79 ± 1.95%.

Highly accurate masses can be computed for PAs on the basis of the degree of polymerization, the specific flavan-3-ol components, the number of A-type bonds, and the number of galloyls. PAs can be identified by comparing experimentally obtained high-accuracy masses to the computed masses. Identifications can be further confirmed by the analysis of fragments from tandem MS. Conversion of MRRF values from UV absorbance to ion counts with SIM was used for the quantification of individual PAs. Thus, this standardized UHPLC-PDA-ESI/HRMS$^n$ profiling method was able to offer identification and quantification of oligomeric PAs in plant-derived foods.

Several methods are available to detect EVOO adulteration with HO, targeting different chemical markers such as free fatty acids,[4,18,19] triacylglycerols,[20,21] sterols,[22] volatile organic compounds (VOC)[23] and, in particular, filbertone,[24] a ketone absent in olive oils. Filbertone determination is generally performed by liquid or gas chromatography (L-GC) coupled to mass spectrometry.[25] However, this marker becomes useless in the case of adulteration of EVOO with refined HO, because it undergoes a partial or full degradation during the refining process.[26] Recently, a method based on hydrophilic interaction chromatography (HILIC) microsolid phase extraction ($\mu$SPE) coupled to matrix assisted laser desorption ionization (MALDI) time-of-flight (ToF) mass spectrometry (MS) for the detection of the polar components in hazelnut and olive oil has been developed.[27] Consecutive analysis by tandem mass spectrometry allowed the identification of lysophosphatidylcholines as HO markers. More recently, phospholipids were confirmed[28] to be promising markers of EVOO adulteration with HO by a MALDI-MS approach involving an ionic liquid[29,30] (tributylamine-CHCA) as matrix.

However, existing literature dealing with the direct determination of HO residual proteins in EVOO, in order to get an immediate evaluation of the allergenic potential, is poor, and the attention is mainly focused toward intact proteins rather than peptides. Furthermore, MALDI-MS has never been applied on this topic—regardless, this technique has widely demonstrated its great potential on similar analytical problems[31,32] due to its rapidity and sensitivity.

A recent study[17] developed a biosensor immunoassay for residues of hazelnut proteins in olive oil, whereas Arlorio et al.[5] set up a simulation of olive oil adulterated with hazelnut oils to identify possible risks for allergic consumers, demonstrating the presence of hazelnut proteins in solvent-extracted hazelnut oil.

Further approaches, based on DNA and immunoassays analysis, are also available in the literature, and they now include an array of platforms. The fundamental principle of this approach is that the amount of DNA remaining in processed foods is sufficient for analytical purposes to obtain traceability, to detect the presence of both genetically modified organisms and allergens.[33−37]

Some of these methods are routinely used by industry and administration agencies even if they lack accuracy and robustness, especially in the case of processed foods.[38,39]

In this work, we tested different approaches for the extraction of residual proteins from various hazelnut oils. The resulting extracts were in-solution digested and analyzed by MALDI-MS. The most efficient extraction protocol was based on cold-acetone protein precipitation. The whole procedure is rapid and simple and facilitated the detection of hazelnut marker peptides in both HO and EVOO adulterated with HO.

## MATERIALS AND METHODS

**Reagents.** Acetone, water, chloroform ($CHCl_3$), acetonitrile (ACN), and methanol (MeOH) were LC-MS grade; hexane and *tert*-butyl methyl ether were HPLC grade. Trichloroacetic acid (TCA), trifluoroacetic acid (TFA), Trizma hydrochloride (Tris-HCl), sodium chloride (NaCl), all the reagents for the tryptic digestion (dithiothreitol (DTT), iodoacetamide, ammonium bicarbonate ($NH_4HCO_3$), urea, porcine trypsin), ACTH 18−39 fragment, angiotensin I, and renin were obtained from Sigma-Aldrich (St. Louis, MO). $C_{18}$Zip Tips were from Millipore (Billerica, MA). Tris-Glycine buffer, Laemmli buffer, 4−15% Mini-PROTEAN TGX precast gels, molecular weight marker "Precision Plus Protein Standards Dual Color", Mini-PROTEAN II electrophoresis cell, were acquired from Bio-Rad Laboratories (Hemel Hempstead, Hertfordshire, U.K.). $\alpha$-Cyano-4-chlorocinnamic acid (CClCA), obtained as a synthetic product, was recrystallized four times before use.

**Samples.** Different hazelnut oils were analyzed: two Italian (Monferrato, Piedmont), cold-pressed, from roasted and raw hazelnuts, respectively; one German, cold-pressed, from roasted hazelnuts; one Turkish, refined, from raw hazelnuts; one Greek, refined, from raw hazelnuts (the last two were seized by Italian Customs agencies). Commercial (five brands) and raw Italian extra-virgin olive oils (homemade by various Apulia cultivars) were analyzed. EVOO was intentionally adulterated by cold-pressed HO at different percentages (50/50 and 80/20, w/w). Each experiment was performed in triplicate.

**Protein Extraction Methods from Oils.** Experimental protocols available in the literature were applied with slight modifications.

**Cold Acetone Precipitation.**[10] To 5 g of pure hazelnut oil and pure olive oil, 12.5 mL of cold acetone (4 °C) was added, the mixture was shaken vigorously, kept for 1 h at 4 °C, and shaken every 10 min; then it was centrifuged at 4200*g* for 1 h, and the precipitate was washed twice with 1 mL of cold acetone. The pellet obtained from extraction was dried at 40 °C for 5 min in a vacuum concentrator.

**Hexane/Acetone Precipitation.**[10] To 5 g of pure hazelnut oil or pure olive oil, 12.5 mL of cold hexane/acetone (1:1, v/v) was added, the mixture was shaken vigorously, kept for 1 h at 4 °C, and shaken every 10 min; then it was centrifuged at 4200*g* for 1 h, and the precipitate was washed twice with 1 mL of cold hexane/acetone. The pellet obtained from extraction was dried at 40 °C for 5 min in a vacuum concentrator.

**Diethyl Ether/Trichloroacetic Acid Precipitation.**[5] Ten milliliters of *tert*-butyl methyl ether was added to 10 g of pure hazelnut oil and pure olive oil, and the mixtures were maintained at 18 °C for 30 min. Then, 10 mL of 20% w/v trichloroacetic acid (4 °C) was added, the mixture was transferred to a separating funnel, and the extraction was repeated three times. The three aqueous phases were collected and washed twice with 10 mL of *tert*-butyl methyl ether to remove lipids. The aqueous fractions were partially concentrated and centrifuged at 28 000*g* for 20 min at 4 °C. The supernatant was discarded; the pellet was washed twice with 1 mL of acetone and finally dried.

**Ammonium Hydrogen Carbonate.**[40] Hazelnut oil (7.5 mL) was extracted with 3.5 mL of ammonium hydrogen carbonate (0.2 M, pH 7.8) on a shaker for 2 h at room temperature. The mixture was centrifuged at 11 180*g* for 20 min at 4 °C, and the aqueous layer was dried in a vacuum concentrator.

**TBS Extraction.**[41] Tris-buffered saline (TBS) was prepared with 40 mM Tris-HCl and 300 mM NaCl. In particular, to 2 g of hazelnut oil, 5 mL of TBS was added. Extraction was done at 60 °C for 20 min under shaking. The extract was centrifuged at 4200*g* for 20 min, defatted by extracting twice with *n*-hexane, and dried under a nitrogen stream.

**Bligh−Dyer Extraction.**[42] $CHCl_3$/MeOH (1:2, 1.87 mL) was added to 0.5 mL of hazelnut oil or olive oil followed by vigorous vortex-mixing. Then, 0.62 mL of $CHCl_3$ was added, and the solution was vortexed again. Afterward, 0.62 mL of $H_2O$ was added, and the solution was vortexed again. Finally, the solution was centrifuged for 5 min at 4200*g*, and the

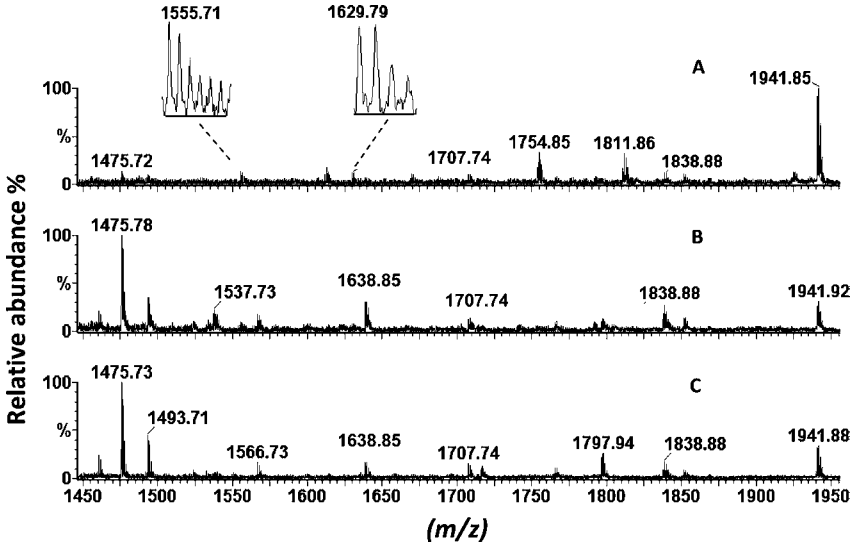

**Figure 1.** MALDI mass spectra relevant to the in-solution tryptic digests of hazelnut oil extracts obtained using Bligh−Dyer (A), diethyl ether/trichloroacetic acid (B), and hexane/acetone (C) protocols, respectively. The two peaks shown in figure (A), at *m/z* 1555.71 (RAESEGFEWVAFK) and 1629.79 (ALPDDVLANAFQISR), were attributed to Cor a 9.

aqueous upper layer, containing the proteins, was collected, divided in several aliquots, and dried under a stream of nitrogen. This aqueous extract was used for the following analysis steps.

**In-Solution Tryptic Digestion.** The pellets obtained from the different extraction methods were digested in solution following a reported protocol.[32] Dried pellets were resuspended in 40 $\mu$L of 400 mM $NH_4HCO_3$ in 8 M urea. Five microliters of DTT (50 mM) was added, and the mixture was incubated for 40 min at 60 °C and chilled at room temperature. Next, 5 $\mu$L of iodoacetamide (150 mM) was added, followed by an incubation in the dark at room temperature for 45 min. water (120 $\mu$L) and 20 pmol of porcine trypsin were added, and the solution was incubated overnight at 37 °C. The digestion was stopped with 10% TFA. The tryptic digests were mixed 1:1 (v/v) with the matrix $\alpha$-cyano-4-chloro-cinnamic acid (5 mg/mL), and then 1 $\mu$L of the sample/matrix solution was spotted, dried, washed at least once on target, and analyzed by MALDI-TOF-MS. In some cases, due to the low concentration of hazelnut derived peptides in the samples, a procedure of desalting and preconcentration using $C_{18}$Zip Tips was employed.

**SDS-PAGE.** As a reference, a roasted hazelnut protein extract was separated on SDS-PAGE gel. The extract for SDS-PAGE was prepared according to Sheoran et al.[43] with slight modifications. To 0.03 g of hazelnut powder, 1 mL of Tris-HCl buffer (50 mM) was added, and the mixture was kept at 4 °C for 30 min and then centrifuged at 16 000*g* for 20 min at 4 °C. The supernatant was collected, the pellet re-extracted, and the supernatants pooled. The proteins were precipitated with 5 vols (v/v) of 100% acetone and incubated at −20 °C for 2 h. After centrifugation at 4000*g* for 40 min, the pellet was washed twice with acetone, dried for 5 min at 40 °C, and suspended in Laemmli buffer (1:1, v/v). Then, 1 $\mu$L of DTT 50 mM was added and the samples were reduced at 90 °C for 5 min. Twenty microliters were loaded onto the gel, and electrophoresis was carried out at two different voltages—50 V to compact the proteins in the stacking gel and 80 V until the end of the run.

**In-Gel Digestion of Hazelnut Proteins.** The protein bands were cut and digested by porcine trypsin using a specific protocol. At first, the bands were cut in small pieces that were covered with 200 $\mu$L of 200 mM $NH_4HCO_3$ in 40% of ACN, and the samples were incubated at 37 °C for 30 min in a thermo shaker. The step was repeated until the gel pieces were decolorized. The gel fragments were dried in a speed vacuum for 15 min. Porcine trypsin (0.05 $\mu$g/$\mu$L) and 50 $\mu$L of 40 mM $NH_4HCO_3$ in 9% ACN were added, and the samples were incubated at 37 °C overnight. After the incubation, the liquid fraction, containing peptides, was collected and acidified with TFA before MALDI analysis.

**MALDI-ToF-MS.** MALDI-ToF-MS analyses were performed on a Micromass M@LDI - LR time-of-flight mass spectrometer (Waters MS Technologies, Manchester, U.K.) equipped with a nitrogen UV laser (337 nm wavelength), reflectron optics, and a fast dual microchannel plate (MCP) detector.

Positive ion spectra were acquired in reflectron mode. The following voltages were applied: pulse, 2610 V; source, 15 000 V; reflectron, 2000 V; MCP 1900 V. The laser firing rate was 5 Hz, and, unless otherwise specified, 50 laser shots were used for each well. The 50 resulting spectra were averaged, background subtracted, and smoothed by a Savitzky−Golay algorithm.

For peptide analysis, the explored mass range was 800−4000 *m/z*, and mass calibration was performed using a peptide mixture composed of angiotensin I, ACTH 18−39, and renin substrate tetradecapeptide porcine.

**Database Search.** For the attribution of hazelnut tryptic peptides, FindPept was employed as a main tool (www.expasy.org). The set parameters were the following: cysteines treated with iodoacetamide as a fixed modification and oxidation of methionines as a variable modification for in-solution digestion and in-gel digestion. A mass tolerance of 0.1 Da was set. Another useful tool was PeptideMass (http://web.expasy.org/peptide_mass/), accepting up to three missed cleavages.

ClustalO software was used for alignment study and the sequences of hazelnut, and avena 11S globulins, in FASTA format, were provided as an input.

## RESULTS AND DISCUSSION

**Methodology Development on Pure Hazelnut Oil.** At first, different protein extraction approaches were tested on

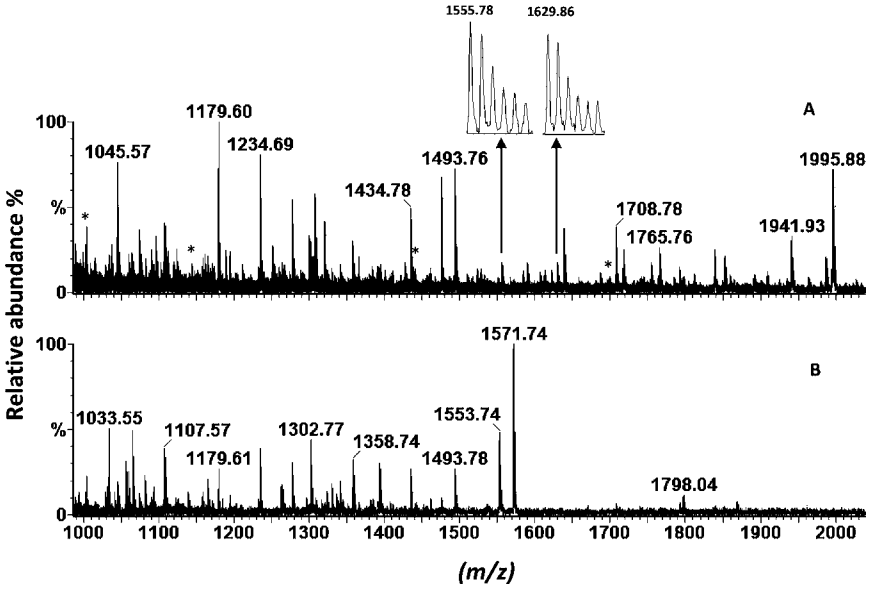

**Figure 2.** MALDI mass spectra (range 1000 to 2000 $m/z$) relevant to the in-solution tryptic digests of hazelnut oil extracts obtained using TBS (A) and ammonium hydrogen carbonate (B) protocols, respectively. In figure (A), the isotopic profiles of the peaks at $m/z$ 1555.78 and 1629.86 from Cor a 9 were magnified, and peptides from the same protein at $m/z$ 1002.53, 1144.54, 1440.76, and 1698.82 were marked with an asterisk.

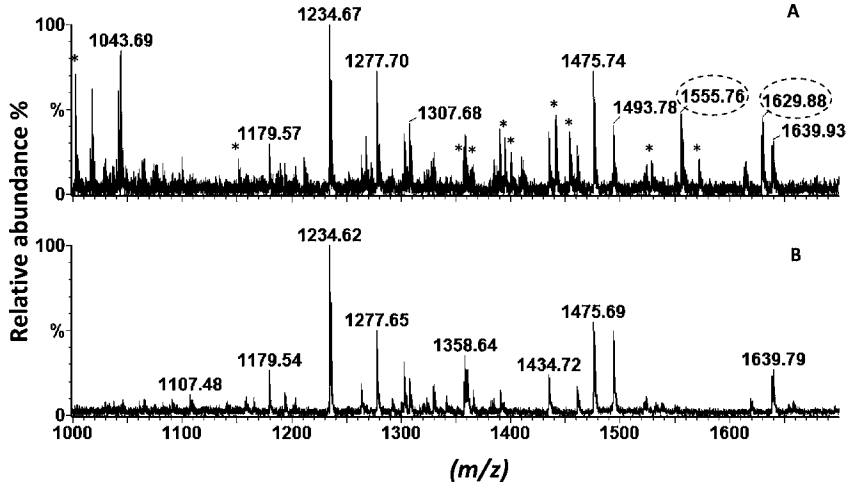

**Figure 3.** MALDI mass spectra (range shown 1000 to 1700 $m/z$) relevant to the in-solution tryptic digests of (A) an Italian cold-pressed hazelnut oil extract and (B) an extra-virgin olive oil extract, obtained using the cold acetone protocol. In 3(A), the two main peptides of Cor a 9 (at $m/z$ 1555.76 and 1629.88) were encircled. The peptides at $m/z$ 990.52, 1151.57, 1356.71, 1394.70, 1399.71, 1440.81, and 1571.84 from Cor a 9, 1528.67 from Cor a 1, 1363.73 from Cor a 11 and 1453.89 most likely from Cor a 14, were marked with an asterisk.

various raw hazelnut oil samples; it is worth noting that a very low quantity of oil (5−10 g) was used if compared to the usually employed amount (100 g).[5,10,40,41] After the extraction, all samples were in-solution digested and analyzed by MALDI-MS. Eventually, the best method was selected on the basis of the simplicity, rapidity, and reproducibility of the procedure and according to the number of detected hazelnut peptides. Because of the sample complexity and the high number of existing allergen isoforms, their identification was achieved by using a combination of literature data[5,8,44−46] and two different informatics tools, that is, the classic peptide mass fingerprint and FindPept (in the latter, proteins are individually compared with a reference list of hazelnut proteins).

Figure 1 reports the MALDI mass spectra relevant to the in-solution tryptic digests of hazelnut oil extracts obtained using Bligh−Dyer (A), diethyl ether/trichloroacetic acid (B), and hexane/acetone (C) protocols, respectively. Only two peptides at $m/z$ 1555.71 and 1629.79, originating from the hazelnut protein ***Cor a 9***, were observed in the MALDI spectrum relevant to the Bligh−Dyer extract (Figure 1A), although no peptides arising from hazelnut proteins were detected by using the other two extraction procedures (diethyl ether/TCA and hexane/acetone). Here, due to the very low protein content in the oil extracts, the level of background proteins introduced during sample preparation (in the form of dust or contaminated chemicals) might mask the presence of the target proteins; indeed, the spectra of Figure 1B,C were dominated by intense signals attributable to human keratins (for instance, the $m/z$ ions 1475.78, 1707.74, and 1638.85).

Then, protein extraction was carried out by using different buffers; the first method was based on the use of ammonium hydrogen carbonate, successfully applied by Rigby et al.[40] in the extraction of proteins from soybean oil, whereas the second protocol was based on the use of TBS as reported by Poms et

dx.doi.org/10.1021/jf504007d | J. Agric. Food Chem. 2014, 62, 9401−9409

**Table 1. List of Hazelnut Peptides Identified in HO by Using Different Protein Extraction Methods**

| protein extraction method | number and related $m/z$ ratios of identified hazelnut peptides |
|---|---|
| Bligh−Dyer | 2:1555.71, 1629.77 |
| diethyl ether/TCA | - |
| hexane/acetone | - |
| TBS | 8:990.51, 1002.53, 1144.54, 1440.76, 1555.75, 1629.83, 1695.84, 1698.82 |
| ammonium hydrogen carbonate | - |
| cold acetone (100% hazelnut oil) | 13:990.52, 1002.52, 1151.57, 1356.71, 1363.73, 1394.70, 1399.71, 1440.81, 1453.89, 1528.67, 1555.76, 1571.84, 1629.88, 1934.87 |
| cold acetone (50% hazelnut oil) | 11:1002.52, 1356.71, 1363.73,1394.70, 1399.71, 1440.79, 1453.85, 1528.72,1555.74, 1571.80, 1629.83, 2643.44 |
| cold acetone (20% hazelnut oil) | 11:1002.52, 1151.57, 1356.71, 1363.73, 1394.70, 1399.71, 1440.78, 1453.84,1528.72, 1555.74, 1571.83, 1698.76 |

al.[41] in the case of peanut proteins. Figure 2 shows the MALDI spectra (range 1000 to 2000 $m/z$) relevant to the in-solution tryptic digests of hazelnut oil extracts obtained using TBS (A) and ammonium hydrogen carbonate (B) protocols, respectively. The inset in Figure 2A reports the close-up image of two ***Cor a 9*** peptides ($m/z$ 1555.75 and 1629.83), whereas the other peptides of the same protein at $m/z$ 1002.53, 1144.54, 1440.76, 1698.82 have been marked with an asterisk. On the contrary, by using ammonium hydrogen carbonate as extraction buffer (Figure 2B), no hazelnut peptides were detected.

After replicating the procedure on other oils, it was possible to confirm that the most recurrent hazelnut peptides were at $m/z$ 1555.75, 1629.83, 1002.53, 1440.76, 1698.82.

Finally, protein precipitation was carried out by using the cold acetone protocol described by Martin-Hernandez et al.[10] The MALDI spectrum (range shown 1000 to 1700 $m/z$) relevant to the in-solution tryptic digest of an Italian cold-pressed hazelnut oil extract is reported in Figure 3A. Despite the intense signals arising from human keratins ($m/z$ ions 1234.67, 1277.70, and 1475.74), typical hazelnut peptides at $m/z$ values 1555.76, 1629.88, 990.52, 1151.57, 1356.71, 1394.70, 1399.71, 1440.81, 1571.84 (*Cor a 9*), 1528.67 (*Cor a 1*), 1363.73 (*Cor a 11*), and 1453.89 (most likely *Cor a 14*), were detected (marked with an asterisk). Of course, the peptide at $m/z$ 1528.67 attributed to Cor a 1 arises[7] from the isoform Cor a 1.0401−1.0404.

When replicating the whole strategy on other oils, the number of recognized peptides was between 10 and 15, even if the stable markers found in all the replicates were at $m/z$ 1002.53, 1151.57, 1356.71, 1394.70, 1440.76, 1555.75, 1629.83, and 1698.82.

The same procedure was then applied to extra virgin olive oil samples; the relevant MALDI spectrum is shown in Figure 3B. As expected, no peptides arising from hazelnut proteins were detected. Moreover, even peptides attributable to EVOO proteins were not observed probably due to their very low concentration (10−50 $\mu$g/100 g).[47] It was noted that the pellets obtained after cold-acetone protein precipitation of the EVOO samples investigated were not observable. On the contrary, in the case of hazelnut oil samples, visible pellets were obtained; their estimated protein concentration, determined by the Bradford method,[48] was in the range 20−100 $\mu$g/mL.

The cold acetone protocol proved to be the most efficient method for protein extraction and detection and was used for further experiments.

**Methodology Application on Adulterated Samples.** The cold acetone protocol was applied to the analysis of EVOO samples adulterated by cold-pressed hazelnut oil (50/50 and 80/20, w/w). Figure 4 shows the MALDI spectra relevant to the in-solution tryptic digests of EVOO extracts adulterated with 50% (A) and 20% (B) of HO obtained from roasted hazelnuts; only the most informative $m/z$ range was reported. The detected $m/z$ ions belong to ***Cor a 9*** ($m/z$ 1394.70, 1440.79, 1555.74, 1571.80, 1629.83), ***Cor a 1*** (1528.72 $m/z$), and ***Cor a 14*** (1453.85 $m/z$); Table 1 depicts the most significant hazelnut peptides showed in the spectra of Figure 4 (three replicates of the whole procedure were performed). It is worth noting that, among the various peptides detected in this work, the one at 1440.81 $m/z$ (INTVNSNTLPVLR) was recently included[46] in a list of the most stable peptide markers for hazelnut detection in processed food, because it does not contain amino acids susceptible to oxidation.

dx.doi.org/10.1021/jf504007d | J. Agric. Food Chem. 2014, 62, 9401−9409

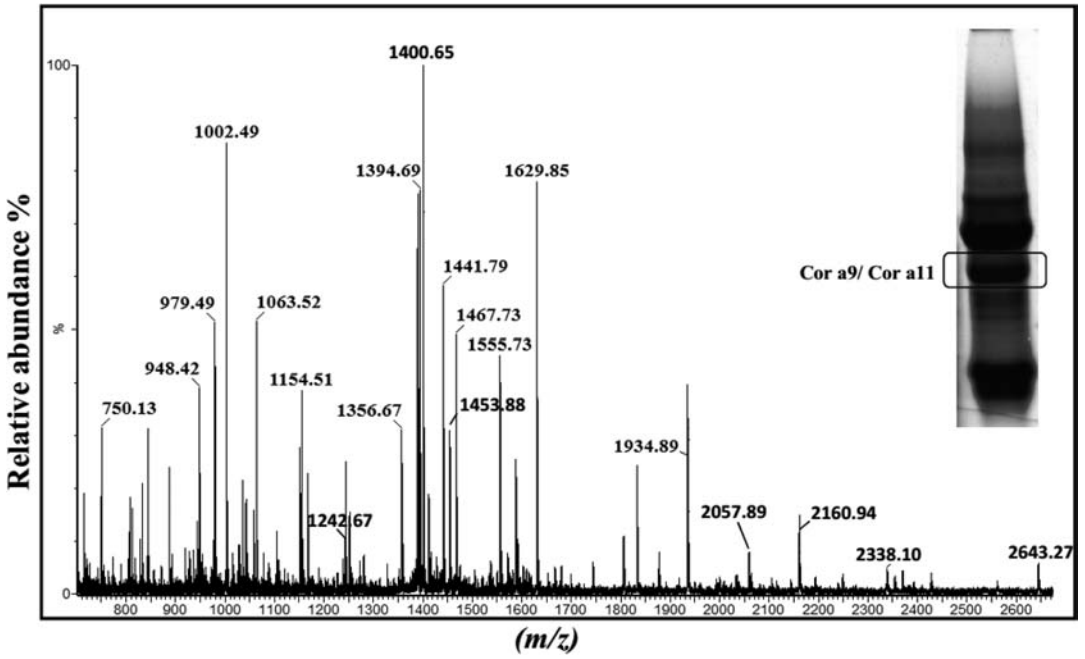

**Figure 5.** SDS-PAGE of a hazelnut kernels protein extract (inset) and MALDI mass spectrum relevant to the in-gel digestion of the band at 55 kDa.

The procedure was subsequently applied to different kinds of hazelnut oils of different origin (see experimental section), obtained from raw and roasted hazelnuts. Similar results were obtained for all samples, even if, as already reported,[17] the amount of extracted protein was always higher in the case of raw hazelnut oils.

As clearly stated in the introduction, the objective of the present work was the detection of hidden hazelnut allergens in EVOO samples. In general, the lowest dose of allergens that provokes a reaction is called LOAEL or lowest observed adverse effect level. Recent clinical studies[49,50] reported that the most sensitive patients had a LOAEL eliciting objective signs after the ingestion of only 1 mg of hazelnut protein, whereas the dosage eliciting reaction in a 10% of the food-allergic population is 133.8 mg. The present approach permitted the assessment of a total protein concentration in the range 20−100 $\mu$g per mL of hazelnut oil; then, 1 mL of EVOO adulterated with 20% of HO would contain a total protein concentration between 4 and 20 $\mu$g. It means that this method was able to reach detection limits well below the LOAEL value.

Thus, the present strategy allowed fast detection of a very low hazelnut protein content in complex matrices as edible oils by recurring to a simple acetone precipitation and in solution tryptic digestion.

**SDS PAGE for Confirming Hazelnut Proteins Attribution.** A more conventional approach, based on SDS-PAGE followed by in gel tryptic digestion, was then applied to a hazelnut kernels protein extract, with the aim to create a small reference database. All the bands obtained (see gel in the inset of Figure 5) were eventually analyzed by MALDI-MS. It should be noted that a univocal identification of these proteins is difficult to achieve, in particular by using a monodimensional gel, due to the presence of different isoforms, multiple glycoforms, and post-translational protease-cleaved subunits.[51] In fact, some peptides attributable to Cor a 9 and Cor a 11 were detected in all the processed bands at different molecular weights. Considering that hazelnut proteins are present as high molecular weight complexes (300−450 kDa) of minor subunits linked by noncovalent disulfide bridges, these weak bonds can be broken during the extraction processes, thus originating lower molecular weight units.

For instance, in the MALDI spectrum shown in Figure 5, relevant to the in gel digestion of the band at 55 kDa, the most intense peak was attributed to Cor a 9 even if some Cor a 11 peptides were also present. The complete attribution of the main peaks observed in the spectrum of Figure 5 is reported in Table 2. Other significant $m/z$ ions (750.13, 1154.51, 1242.67, 1400.65, 1453.88, 1467.73, 2057.89, and 2160.94) were not attributable with any known identification tool. Only the $m/z$ ions 1400.65 and 1453.88 were identified as the alkaline and immunogenic subunit of a new hazelnut allergen, an isoform of Cor a 9, recently identified by Nitride et al.[8]

Furthermore, by using FindPept and ClustalO (UniProt), it was possible to propose an attribution for the $m/z$ ion 1242.67 by homology with similar proteins. Indeed, from the in-silico digestion of the Avena globulin 11S (*Avena sativa*), a peptide at 1242.66 $m/z$ is generated. Then, aligning the sequences of *Avena sativa* globulin 11S (Q38780) and *Corylus avellana* 11S globulin-like protein (Q8W1C2), a similarity of 70% between the peptide QEARNLKNNR from *Avena s.* and the peptide EEARRLKYNR from *Corylus a.* was found suggesting an attribution as possible protein variants (Figure 6). Of course, de novo sequencing is needed to confirm this hypothesis and suggest possible protein variants.

In the present study, a cold-acetone protein precipitation followed by in-solution tryptic digestion and MALDI-MS analysis was applied for the first time for the direct determination of hidden hazelnut oil proteins in extra virgin olive oil.

The method, applied on oils of different geographical origin, showed to be reproducible and independent from oil processing and cultivars. In fact, contrary to usual markers (fatty acids, triacylglycerols, volatile compounds, and tocopherols) that are affected by the environmental conditions of plant growth, proteins, being more stable and species-specific, could

comparison to ESI, APCI is a less soft ionization technique that generates more fragment ions relative to the parent ion. Furthermore, the quadrupole time-of-flight (Q-TOF) analyzer is a suitable tool for screening for known and unknown SGs, whereas triple quadrupole (QqQ) is advisible only for monitoring targeted SGs.[13] Previously, Wewer et al. reported quantification of SGs by nanospray direct infusion by Q-TOF MS/MS experiments.[14] However, no chromatographic separation was conducted in that study prior to MS analysis, which makes the differentiation between isomers impossible. Rocio et al.[15] used HPLC-TOF-MS, and Van Gerpen et al.[16] used MALDI-TOF-MS for identification of SGs; however, MS-based quantification was not performed. With regard to chromatographic techniques, ultraperformance liquid chromatography (UPLC) is the newest state-of-the-art technology providing higher resolution, optimized signal-to-noise ratio, and shorter run times as compared to HPLC. To the best of our knowledge, no UPLC methods for SGs have been published so far.

In this study, the highly efficient separation af single, intact SG species by RP-UPLC was combined with detection by a Q-TOF analyzer, which led to high mass accuracy. The UPLC-Q-TOF-MS method was developed, optimized, and validated to enable rapid, mass accurate, and highly sensitive SG detection as the sodiated adduct of the molecular ion. Furthermore, the applicability of the validated method was demonstrated for selected foods (oat bran and whole wheat) with various SG amounts and profiles and including consideration of the matrix effect.

## MATERIALS AND METHODS

**Reagents.** Acetone, acetic acid, ammonium acetate, formic acid of LC-MS grade, and cholesterol $\beta$-D-glucoside (≥97% purity) were purchased from Sigma-Aldrich (Buchs, Switzerland). LC-MS grade acetonitrile, isopropanol, methanol, and water were from Biosolve (Dieuze, France). The commercial mixture of steryl glycosides (>98% purity) used as reference substances was from Matreya Inc. (Pleasant Gap, PA, USA) containing approximately 56% sitosteryl glucoside, 25% campesteryl glucoside, 18% stigmasteryl glucoside, and 1% $\Delta^5$-avenasteryl glucoside. HPLC grade hexane and isopropanol used for sample extraction were from Fluka (Buchs, Switzerland).

**Instrumentation and Chromatographic Conditions.** The UPLC system was a Waters Acquity UPLC System equipped with an Acquity UPLC BEH C18 column (50 mm × 2.1 mm, i.d., 1.7 $\mu$m). The MS system (Synapt G2) was composed of an electrospray ionization source and a Q-TOF analyzer (Waters Corp., Milford, MA, USA).

*Selection of the Mobile Phase and Additive.* The mobile phases for method development in positive mode consisted of acetonitrile, methanol, or a mixture of 50% acetonitrile and 50% isopropanol combined with water to which either 0.1% (v/v) acetic acid or formic acid was added, leading to suitable acidic conditions for positive mode (see Table 2). Less acidic conditions obtained by a buffered solution with 0.1% (v/v) acetic acid and 1 mM ammonium acetate solved in water and acetonitrile on the other hand allowed measurements in both positive- and negative-ion modes. Another advantage of the buffered system is an increased solubility of ammonium acetate in acetonitrile.[17] The resolution and sensitivity were assessed by extracted ion chromatograms (EIC) of sodiated ions of the two isomers stigmasteryl glucoside and $\Delta^5$-avenasteryl glucoside, with equal masses ($m/z$ 597.4131 as $[M + Na]^+$), that occur in the SG standard (Figure 2). For better comparability, the same ESI parameters and mobile phase gradient were used for all measurements in positive mode.

For the optimization of the UPLC mobile phase composition, 5 $\mu$L of the SG standard with a concentration of 9 $\mu$M (calculated on the basis of the mass of sitosteryl glucoside) dissolved in the same solvent as the organic mobile phase was injected in partial loop mode. All measurements for method development were carried out with the same UPLC gradient from 30% water + additive (A) and 70% organic solvent + additive (B) to 100% B in 3 min, followed by isocratic condition of 100% B for 2 min (total run time = 5 min). Column temperature was maintained at 40 °C with a flow rate of 0.3 mL/min. Each run was followed by re-equilibration period of 3 min with a mobile phase composition of 30% A and 70% B.

*UPLC Gradient Used for Food Analysis.* For a more precise injection volume, 10 $\mu$L of the sample was injected in full loop mode. The analysis was performed using the following gradient elution: 50% water + 0.1% (v/v) formic acid (A) and 50% methanol + 0.1% (v/v) formic acid (B) for 1 min changing to 87.5% B during 2 min. During the next 2 min, B was increased to 90% and finally during the next 2 min to 100%, which was kept for 3 min. The total run time was 10 min. The flow rate was 0.3 mL/min and the column temperature, 40 °C. Each run was followed by a re-equilibration period of 3 min with 50% B.

**MS Conditions.** *Optimization of Ionization Parameters by Direct Infusion and in Combination with LC.* For optimization of the ionization parameters a standard mixture of SG (3 $\mu$M, concentration calculated on the basis of the mass of sitosteryl glucoside) was injected by direct infusion into the MS using ESI. For ESI positive-ion mode the voltages of capillary, sample cone, and extraction cone were set at 3000, 60, and 4 V, respectively. The desolvation gas flow rate was 900 L/h at 550 °C. Source temperature was 130 °C. Cone gas flow was 10 L/h. For ESI negative-ion mode the voltages of capillary, sample cone, and extraction cone were set at 2000, 30, and 4.5 V, respectively. The desolvation gas flow rate was 950 L/h at 500 °C. Source temperature was 130 °C. Cone gas flow was 20 L/h.

APCI was performed using ESCI multi-mode ionization source. This mode switched between ESI and APCI at a high speed and, thus, made it possible to measure both ionization modes within the same chromatographic run. The ionization parameters were adopted from ESI with the addition of a corona current of 5 $\mu$A. Nitrogen served as desolvation gas and as cone gas for both ESI and APCI measurements.

Full scan mass spectra were acquired from $m/z$ 50 to 1200 at a scan rate of 0.5 s. EIC of sodium adducts and $[M - H + Hac]^-$ were used for method evaluation (Table 1). Peaks were identified on the basis of the mass-to-charge ratio ($m/z$) of the compounds and comparison of the relative retention time to cholesteryl glucoside. Each chromatographic peak was integrated using Mass-Lynx 4.1 software (Waters) without smoothing. Data evaluation was conducted with a mass range window of 0.02 Da (equivalent to approximately 33 ppm for sodiated SG adducts).

**Table 1. Mass-to-Charge Ratio $m/z$ of Targeted SGs as $[M + Na]^+$ in Positive and as $[M - H + Hac]^-$ in Negative Scan Mode**

| compound | $[M + Na]^+$ | $[M - H + Hac]^-$ |
|---|---|---|
| cholesteryl glucoside | 571.3975 | 607.4210 |
| campesteryl glucoside | 585.4131 | 621.4366 |
| $\Delta^5$-avenasteryl glucoside | 597.4131 | 633.4366 |
| $\Delta^7$-avenasteryl glucoside | 597.4131 | 633.4366 |
| stigmasteryl glucoside | 597.4131 | 633.4366 |
| sitosteryl glucoside | 599.4288 | 635.4523 |

*ESI Conditions Used for SG Analysis in Foods.* The final optimized conditions used for the validation and analysis of samples were all carried out in positive ionization mode. The voltages of capillary, sample cone, and extraction cone were set at 3000, 60, and 4.5 V, respectively. The desolvation gas flow rate was 850 L/h at 520 °C. The source temperature was 130 °C. Cone gas flow was 20 L/h. Full scan mass spectra were acquired from $m/z$ 350 to 1200 at a scan rate of 0.5 s.

**Internal Standard Preparation and Method Validation.** A stock solution of the internal standard cholesterol glucoside was prepared at a concentration of 4.8 $\mu$g/mL in methanol. The seven-

dx.doi.org/10.1021/jf501509m | J. Agric. Food Chem. 2014, 62, 9410−9419

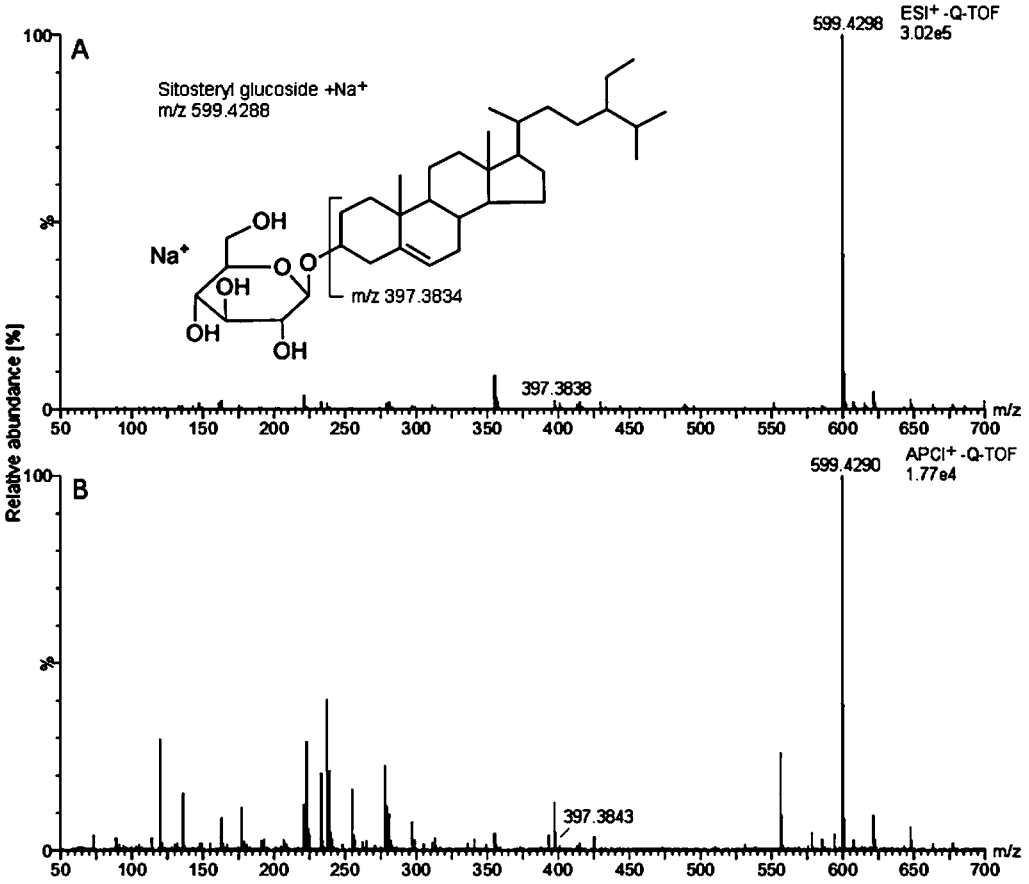

**Figure 1.** ESI (A) and APCI (B) mass spectra of sitosteryl glucoside ($[M + Na]^+ = m/z$ 599.4288, $[\text{aglycone} + H - H_2O]^+ = m/z$ 397.3834) in SG standard solution measured in one UPLC-MS analysis run using ESCI multi-mode ionization and MeOH/water gradient + 0.1% (v/v) formic acid acquired in positive scan mode.

point calibration curve of cholesteryl glucoside in 100% methanol was determined at the following levels: 14.4, 43.2, 72.0, 108.0, 144.0, 180.0, and 216.0 ng/mL, each measured in triplicate with an injection volume of 10 $\mu$L. The calibration curve was weighted by $1/x$, and the point of origin was excluded from the equation. To determine the interday and intraday variabilities, five repetitive analyses of quality control samples containing 54 and 90 ng/mL cholesteryl glucoside were performed on three different days. The limit of detection (LOD) and the limit of quantification (LOQ) were defined as 3 and 10 times the noise signal in the region of cholesteryl glucoside in the chromatogram, respectively. The determination of the LOD and LOQ was based on a calibration curve with lower cholesteryl glucoside levels (0.72, 1.44, 2.88, 5.76, and 14.40 ng/mL) all run in triplicate. For quantification of the SGs in food samples the lowest point of the calibration curve (14.4 ng/mL) was used as the LOQ.

**Sample Preparation for the Analysis of Steryl Glycosides Extracted from Foods.** Whole wheat flour was bought from a local grocery store, and oat bran (Oatwell 28%) was obtained from DSM Nutritional Products Ltd. (Kaiseraugst, Switzerland). For sample preparation the method described by Nyström et al. was used with small adaptions.[2] First, accelerated solvent extractor (ASE) was performed to extract the lipids. Afterward, 5 and 10 mL of the internal standard stock solution of 4.8 $\mu$g/mL were added to the wheat and oat extract, respectively. Next the extracts were evaporated to dryness and redissolved in a hexane/isopropanol mixture at a ratio of 95:5. To separate SGs from other sterols and neutral lipids, a fractionation by solid phase extraction (SPE) was performed with hexane and isopropanol. After evaporation under a gentle nitrogen stream at 50 °C of the SG fraction, the residue was dissolved in methanol.

**Determination of Matrix Effect Profile by Postcolumn Infusion.** First, the impact of the matrix effect on different SG species was evaluated by postcolumn infusion according to the method of Stahnke et al. with small adaptions.[18] In short, the matrix effect was defined as the alteration of the signal intensity of the target analyte (postcolumn infusion) caused by injected food compounds compared to an injected reference sample. Therefore, SGs extracted from oat and wheat as well as a reference sample (pure methanol) were measured in triplicates with the final UPLC-Q-TOF-MS method while a SG solution (2.4 $\mu$g/mL cholesteryl glucoside and 2.8 $\mu$g/mL SG standard solution with 8.2 ng/mL sodium acetate and 0.1% (v/v) formic acid) was continuously postcolumn infused. As the food samples naturally contained SG, they were additionally measured without postcolumn infusion, and the signal intensities were subtracted from the detected signal intensities of the infused SGs. The calculation of the matrix effect profile of particular sample matrices including smoothing of the data ($f = 0.6$) was performed according to the method of Stahnke et al.[18]

Second, the matrix profile of the wheat and oat samples was evaluated by postcolumn infusion using cholesterol glucoside as monitor substance. The infused solution was composed of 2.4 $\mu$g/mL cholesteryl glucoside in methanol, 8.2 ng/mL sodium acetate, and 0.1% (v/v) formic acid. The matrix effect profile of wheat was determined for 1 g per 500 mL and per 25 mL, whereas oat was measured at the concentrations of 1 g per 1000 mL and per 100 mL.

The four most common SGs (sitosteryl, campesteryl, stigmasteryl, and $\Delta^5$-avenasteryl glucoside) and $\Delta^7$-avenasteryl glucoside were identified on the basis of the relative retention times to cholesteryl glucoside and their $m/z$ (extracted ion chromatograms of $[M + Na]^+$). The SG contents of oat bran and whole wheat were quantified on the basis of the internal standard including matrix effect compensation at the retention time of each analyte of interest. Because the peak width had to be included, the mean of the 11 data points around the retention time of each analyte was used for the calculation.

Data acquisition and processing was performed using Mass-Lynx and Quan-Lynx software with automatic Savitzky−Golay smoothing (smoothing parameters were iterations = 1 and width = 2). A mass range window of 0.02 Da was used with a scan time of 0.5 s. For the matrix effect evaluation and application on food samples, all data points were considered, whereas for graphical illustration only one-fourth of the data were used.

**Statistical Analysis.** All experiments were carried out in triplicates. Results were presented as mean values ± standard deviation. For data analysis SPSS 20.0 statistical software was used. One-way ANOVA, together with Tukey's test, was performed using a confidence interval of 95%.

## RESULTS AND DISCUSSION

To optimize the methodology for the analysis of SG using UPLC-MS, we evaluated a range of conditions and their effects on the separation and ionization efficacy of the SG species. First, the ESI and APCI parameters were modified to reach the highest signal intensity of intact SG, using sitosteryl glucoside, campesteryl glucoside, and the three isomers stigmasteryl, $\Delta^5$-avenasteryl, and $\Delta^7$-avenasteryl glucoside as the target analytes. Second, the mobile phase and the additive were selected for UPLC separation, and the whole method was optimized, validated, and used to analyze SG contents and profiles in foods.

**Optimization of Ionization Parameters To Detect the Intact Steryl Glycosides.** We observed that the ESI parameters, assessed by direct infusion of the SG standard solution, had a significant impact on ionization efficiency, as shown by the varying intensities of the targeted ion species. Before optimization, SG ion species with the highest intensity were the aglycone ions $[\text{aglycone} + H - H_2O]^+$, the sodiated adducts $[M + Na]^+$, and the potassiated adducts $[M + K]^+$, as well as $[2\ M + Na]^+$ (in decreasing order of intensity), when experiments were performed with lower sample cone voltage (40 V), lower desolvation temperature (200 °C), and lower source temperature (100 °C) than the final optimized ionization parameters. A high intensity of the molecular ion of SG was targeted; however, $[M + H]^+$ was not formed in high abundance under any conditions tested. Thus, the ionization conditions were optimized to obtain the highest abundance of sodiated ion species $[M + Na]^+$. Formation of $[M + Na]^+$ in SG analysis was also reported by Yamauchi et al.[12] when using positive mode APCI analyzing bell pepper samples and by Van Gerpen et al.[16] measuring purified biodiesel residue with MALDI in positive mode. The advantage of adducts is their stability toward high ionization voltage, whereas nonadduct ion species are less stable and, thus, eliminated at high energy input. This makes quantitative analysis more reliable and increases reproducibility. In this study, high formation of sodiated SG adducts $[M + Na]^+$ was accomplished by increasing the cone voltage to 60 V, and the respective aglycone $[\text{aglycone} + H - H_2O]^+$ was detected only at a small intensity (Figure 1A). This was a major improvement compared to previous reports of APCI and nanospray ionization methods for SG, which have mainly enabled the detection of the aglycone ions, but not the respective molecular ions.[8,12,19] Although Strobl[20] demonstrated an improved signal for SG molecular ions with APCI using a QqQ analyzer, a high percentage of aglycone still occurred. The advantage of measuring the intact SG is the possibility of identifying the type of sugar attached, given the fact that both hexoses and pentoses have been identified in SGs.[21] Furthermore, SGs exist not only as monoglycosides but also as other oligoglycosides as reported, for instance, in rice and adzuki beans.[21−23]

In this study, we were able to show that different SG species have the same ionization behavior, which allows evaluation of only one ion species while enabling calculation of SG content. The $[\text{aglycone} + H - H_2O]^+$ signal was between 0.5 and 6% compared to the $[M + Na]^+$ signal for the different investigated SGs (sitosteryl, campesteryl, stigmasteryl, $\Delta^5$-avenasteryl, cholesteryl, and $\Delta^7$-avenasteryl glucoside). This led to the conclusion that different SG species demonstrate the same ionization behavior under the conditions applied.

The most abundant ion species of SGs and their respective $m/z$, in positive and negative mode, are listed in Table 1. $[M + Na]^+$ was the predominant ion species observed in positive mode. Earlier studies, by Schrick et al.[11] using ESI and by Wewer et al.[14] using nanospray, have reported the formation of $NH_4^+$ adducts. They both used direct infusion without chromatographic separation and enhanced the $[M + NH_4]^+$ formation by adding ammonium acetate to the sample. In the present study, $[M - H + Hac]^-$ was the most abundant ion species in negative mode.

**Comparison of APCI to ESI for the Analysis of Steryl Glycosides.** The usage of APCI for the analysis of SGs was shown to be inferior when compared to ESI. With APCI (Figure 1B), 10 times lower intensity of $[M + Na]^+$ and more fragment ions were obtained than with ESI (Figure 1A). APCI was used by Rudell et al.,[19] Yamauchi et al.,[12] and Rozenberg et al.,[8] who all detected the aglycone ion as the predominant ion species. In our study, APCI was harsher and caused more fragmentation, whereas ESI was shown to be milder. Therefore, ESI was the method of choice for the analysis of intact SG and led to higher intensity of targeted species and, thus, provided higher sensitivity.

Furthermore, a major benefit of the Q-TOF MS system used in this study was the high mass accuracy. In ESI and APCI modes, the mass accuracies of the sodiated SG were 1.7 and 0.3 ppm, respectively, and 1.0 and 2.3 ppm, respectively, for the aglycone ion (Figure 1). The mass accuracy of the method on average was 1.3 ppm (equivalent to approximately 0.76 mDa) for SG detection. Thus, our method was shown to be highly reliable for the identification of SGs based on their elemental composition.

**Effect of Mobile Phase and Additive of Sodiated Steryl Glycoside Ion Separation.** To compare the effects of different mobile phases and additives on sensitivity and resolution, a solution of purified SG standard mixture was used. In addition to the four SGs declared by the distributor, another SG with $m/z$ 597 was detected. This peak was tentatively identified as $\Delta^7$-avenasteryl glucoside, on the basis of the observations of Breinhölder et al.[9] on relative retention time (RRT) order of the SGs used in this study, also using a C18 column. Additionally, the retention time of cholesteryl glucoside was identified on the basis of the standard compound. Thus, the order of elution using the UPLC BEH C18 column was $\Delta^7$-avenasteryl glucoside (RRT = 0.99), cholesteryl glucoside (RRT = 1.00), $\Delta^5$-avenasteryl glucoside (RRT = 1.00), campesteryl glucoside (RRT = 1.03), stigmasteryl glucoside (RRT = 1.03), and sitosteryl glucoside (RRT = 1.06). All SGs were separated, except for stigmasteryl and campesteryl glucosides, $\Delta^5$-avenasteryl, and cholesteryl glucosides, which coeluted, but which could still be distinguished by their $m/z$ values.

**Table 2. Mobile Phases and Additives Evaluated for UPLC-QTOF-ESI-MS Analysis[a]**

| | ion mode | mobile phase A | mobile phase B | additive added to phases A + B[b] | area of peak c[c] | peak c/noise[c] | resolution[c] (b:c) |
|---|---|---|---|---|---|---|---|
| A | positive | $H_2O$ | IPA/ACN[d] | 0.1% FA | 973 ± 43a | 106 ± 35c | 2.5 ± 0.1e |
| B | positive | $H_2O$ | ACN | 0.1% FA | 1645 ± 116a | 286 ± 143c | 4.6 ± 0.3f |
| C | positive | $H_2O$ | MeOH | 0.1% FA | 20126 ± 2328b | 1880 ± 696d | 0.7 ± 0.1g |

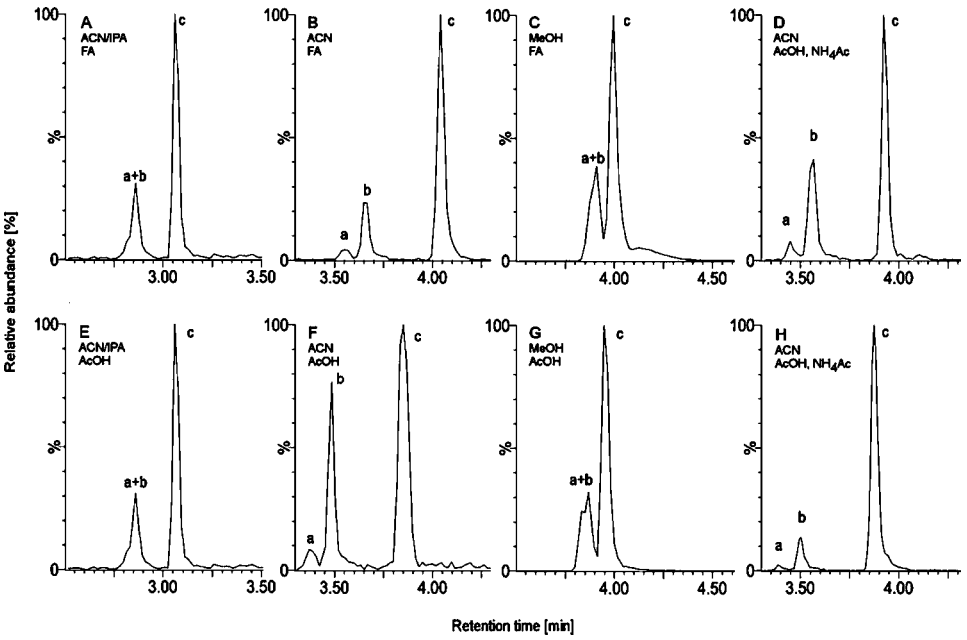

**Figure 2.** Extracted ion chromatograms (EIC) of $m/z$ 597.4131 (A–G) as $[M + Na]^+$ in ESI positive mode and $m/z$ 633.4366 (H) as $[M - H + Hac]^-$ in negative mode using different mobile phase compositions. Details of mobile phase compositions A–H are described in Table 2. The SG standard solution used contained three isomeric SGs: (a) $\Delta^7$-avenasteryl glucoside; (b) $\Delta^5$-avenasteryl glucoside; (c) stigmasteryl glucoside. No smoothing applied. ACN, acetonitrile; FA, formic acid; IPA, isopropanol; MeOH, methanol.

The separation and sensitivity of SGs were highly affected by the composition of the mobile phase (Table 2; Figure 2). The shortest retention time for stigmasteryl glucoside (3.07 min) was obtained with and isopropanol/acetonitrile mixture as the organic mobile phase at a flow rate of 0.3 mL/min. This mixture has a high eluting strength, whereas SGs were more retained with methanol. Selection of the mobile phase, and in the case of acetonitrile in positive mode, choice of the additive, had a significant influence on the resolution. The highest resolutions of 4.3–5.3 between the two isomers stigmasteryl glucoside and $\Delta^5$-avenasteryl glucoside were achieved using an acetonitrile/water gradient. $\Delta^5$-Avenasteryl glucoside and stigmasteryl glucoside were baseline separated, and a third peak, tentatively identified as $\Delta^7$-avenasteryl glucoside, eluted prior to $\Delta^5$-avenasteryl glucoside. Moreover, with the buffered system of acetic acid and ammonium acetate, an improvement in resolution and peak shape was observed as compared to those from formic acid or acetic acid. These improvements of the buffered system have been previously reported for HPLC-ESI-MS measurements of peptides.[17]

$[M - H + Hac]^-$ was the most abundant ion species in negative mode in this study (Table 1). Analysis of SGs in negative mode did not lead to any improvement when compared to the methods that showed best results with regard to resolution and sensitivity.

The sensitivity obtained using a methanol/water gradient was superior to that of the other systems tested. The area of the stigmasteryl glucoside peak in methanol/water systems was >10 times higher and the peak-to-noise ratio >6 times higher than with other eluents. These high values imply that detection and quantification of lower concentrations of SG are possible with methanol-based eluents. The improvement of LOD of the analytes with methanol has been previously reported for LC-ESI measurements of peptides.[24] In that study, the signal-to-noise ratio with methanol was 2.2–6.9 times higher than with acetonitrile. We detected an even greater increase, specifically 6.6–41.2 times higher with methanol compared to acetonitrile. Due to this advantage, methanol was chosen as the organic mobile phase component. Water and methanol were also used as mobile phases in other studies for SG analysis using HPLC combined with UV, ELSD, or MS detection.[8,12,16,25] The

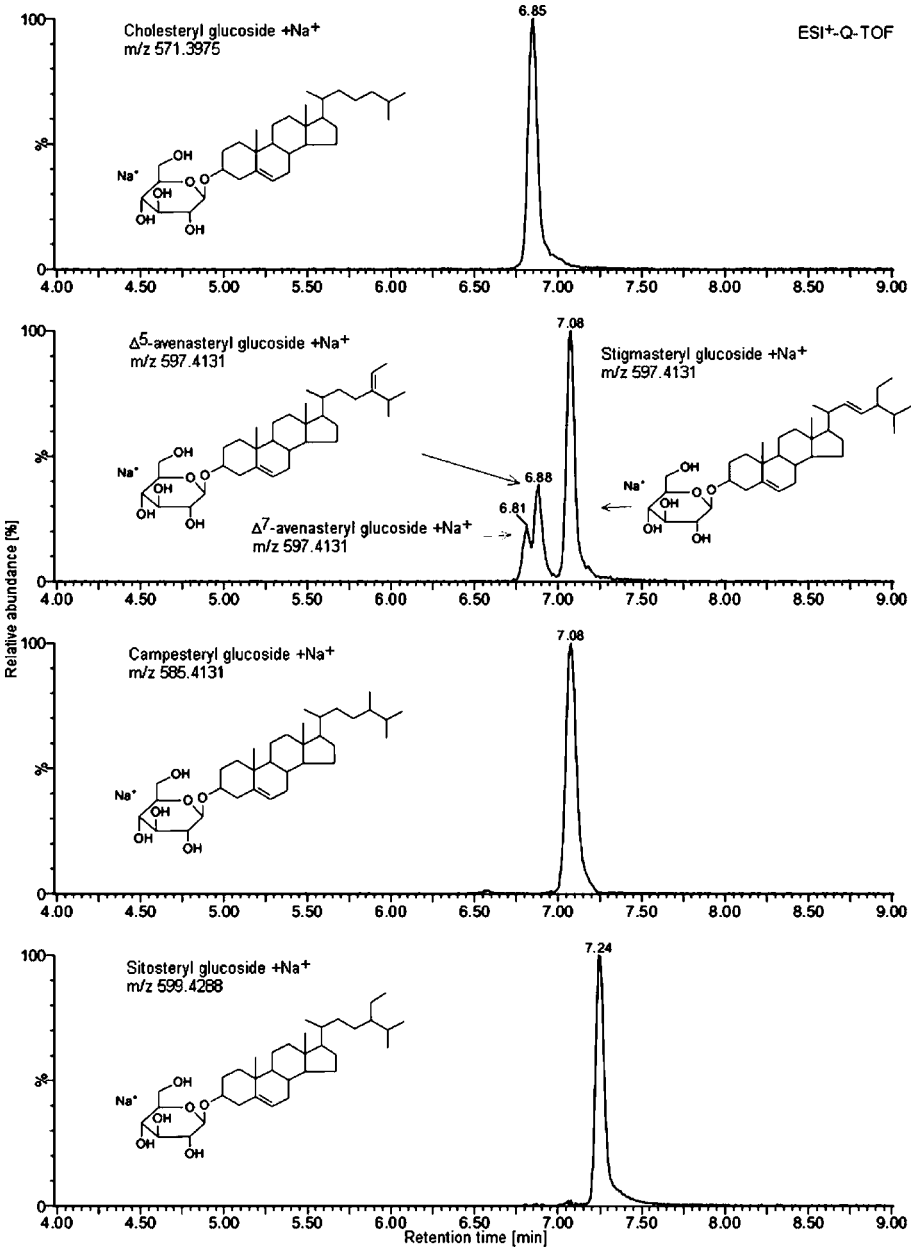

**Figure 3.** UPLC separation of targeted compounds as $[M + Na]^+$ obtained by measuring SG standard solution (sitosteryl glucoside, campesteryl glucoside, stigmasteryl glucoside, $\Delta^5$-avenasteryl glucoside, and $\Delta^7$-avenasteryl glucoside) and cholesteryl glucoside detected by Q-TOF-MS in positive ESI mode, obtained with optimized method (MeOH/water gradient + 0.1% (v/v) formic acid, BEH C18 column, total run time = 10 min). Savitzky−Golay smoothing was applied (iteration = 1 and width = 2).

addition of formic acid and acetic acid did not lead to significantly different results, and of these two, formic acid was chosen for further experiments.

**UPLC-Q-TOF-MS Method Optimization and Validation.** Peaks were assigned with respect to the $m/z$ of the compounds and the relative retention times to cholesteryl glucoside. Extracted ion chromatograms for the five SGs occurring in the SG standard mixture obtained under final UPLC-Q-TOF-MS conditions are shown in Figure 3. With adjusted gradient and run time, the resolution between $\Delta^5$-avenasteryl glucoside and stigmasteryl glucoside increased from 0.7 to 1.4. This provided suitable resolution for quantification using peak area, although the peaks were not baseline separated. Furthermore, the asymmetric factor $A_s$ (10% height) was improved from 3.1 to 2.0, and the tailing factor $T_f$ (5% height) was improved from 3.9 to 1.7 by method optimization. The major benefit of this UPLC method is that efficient separation was obtained with only 10 min runs, thus being far more rapid than conventional HPLC methods, which require 30 min per run.[8,19]

The calibration curve ranging from 14.4 to 216 ng/mL showed linear behavior with a correlation coefficient $R^2$ >0.993. The LOD and LOQ were 1 and 3 ng/mL, respectively. These values improved on earlier results, by >500-fold, where the LOD achieved by GC-FID or by HPLC-ELSD was in the lower micrograms per milliliter range.[25−28] However, it should be mentioned that the LOD was determined using methanol solutions without any sample matrix. The LOQ determined in this study was even lower than the LOQ of 27.4 ng/mL achieved by Q-TOF MS/MS.[14]

**Table 4. Total SG Content, Percentage SG Composition, and IS Recovery of More and Less Concentrated Wheat and Oat Bran SG Extracts with and without Inclusion of Matrix Effect Compensation**

| | wheat | | oat | |
|---|---|---|---|---|
| | − matrix effect[a] | + matrix effect[a] | − matrix effect[a] | + matrix effect[a] |
| total SGs (μg/g DM) | 164.9* ± 1.8 | 184.4* ± 3.2 | 310.9 ± 17.4 | 330.7 ± 8.9 |
| sitosteryl glucoside (%) | 74.2* ± 0.1 | 75.5* ± 0.1 | 52.7* ± 0.9 | 59.0* ± 0.8 |
| campesteryl glucoside (%) | 16.7* ± 0.4 | 15.3* ± 0.4 | 10.3* ± 0.3 | 7.5* ± 0.3 |
| stigmasteryl glucoside (%) | 2.1* ± 0.2 | 3.3* ± 0.3 | 2.1* ± 0.3 | 1.6* ± 0.2 |
| $\Delta^5$-avenasteryl glucoside (%) | 5.5* ± 0.2 | 4.6* ± 0.1 | 31.0* ± 0.4 | 28.8* ± 0.4 |
| $\Delta^7$-avenasteryl glucoside (%) | 1.5 ± 0.2 | 1.2 ± 0.1 | 3.9* ± 0.3 | 3.1* ± 0.2 |
| recovery less concentrated[b] (%) | 93.3* ± 2.8 | 110.7* ± 3.2 | 96.7 ± 13.1 | 102.8 ± 13.8 |
| recovery more concentrated[c] (%) | 36.8* ± 1.6 | 67.1* ± 2.9 | 56.6* ± 1.8 | 105.6* ± 5.8 |

[a]Mean values ± standard deviation ($n$ = 3). *, statistically significant difference between with and without ME compensation. [b]Per g/500 mL (wheat) and g/1000 mL (oat). [c]Per g/25 mL (wheat) and g/100 mL (oat).

The accuracy and precision of the method were determined by an intra- and interday variation test of two QC samples containing 54 and 90 ng/mL of cholesteryl glucoside. The accuracies of the detected concentrations were always >94%, and the highest standard deviations were 4.51% for interday and 2.75% for intraday measurements (Table 3). Therefore, good reproducibility and high accuracy of the investigated method were demonstrated.

**Quantification of Steryl Glycosides Extracted from Food Samples.** In a final step, the optimized and validated method was applied to analyze SG in whole wheat and oat bran samples. Although glycosylated cholesterol can occur in plant samples,[10,23,29] cholesteryl glucoside was selected as internal standard (IS) because it is essentially the only single SG commercially available as pure standard. To demonstrate the applicability of the IS for food samples with different SG profiles, containing high or low SG concentrations and containing cholesteryl glucoside or not, food samples of whole wheat and oat bran were selected. Wheat was found to contain low SG concentrations, and cholesteryl glucoside was detected only in traces. Oat bran contained a high concentration of SGs and cholesteryl glucoside in significant amounts, and therefore sample spiking was performed.

When the SG content in extracts of wheat and oat bran was analyzed, the recovery of the IS was only between 36 and 97% due to ion suppression produced by coeluting matrix compounds. This matrix effect is a well-known limitation of MS methods. Usually this effect can be reduced or eliminated by improved extraction and sample cleanup or by chromatographic separation of the investigated analytes from the food matrix compounds.[30] However, the matrix effect is time-dependent and therefore varies for different SGs. Due to a lack of pure standards, the reduction of the ion suppression cannot be evaluated for individual SG. Hence, another strategy, including matrix effect quantification and application to data as a correction, was chosen. Therefore, the matrix effects of our samples were assessed by permanent postcolumn infusion of cholesteryl glucoside and of the SG standard based on the method by Stahnke et al.[18] In this way, the matrix effect profile was detected throughout the whole run time and the re-equilibration period. The various SG species were similarly suppressed or enhanced, allowing the usage of a single monitoring substance representing other SGs (Figure 4A). Even though the postcolumn infused SG standard consists of SGs at different concentrations, they showed similar signal inhibitions. Thus, the matrix effect was independent of the abundance of the individual SGs in the sample (Figure 4A).

For wheat and oat bran, two different dilutions were selected for quantification of the SG content, and two different matrix effect profiles were produced, as the profile is highly dependent on the matrix concentration.[31] Therefore, cholesteryl glucoside, used as monitor substance, was infused postcolumn to the more concentrated (Figure 4B) and less concentrated (Figure 4C) oat and wheat samples. As expected, the more diluted samples showed less ion suppression, with inhibition between 3 and 25% around SG elution from the column, whereas in the less diluted samples the signal suppression was between 30 and 68%. The two different food samples generated different matrix effect profiles as a result of their different matrix compositions. Furthermore, it was also observed that some background matrix compounds were still eluting during the re-equilibration period, as ion suppression continued to occur between 10 and 13 min (Figure 4).

The SG composition and the IS recovery in wheat and oat samples were calculated with and without matrix effect correction (Table 4). By including compensation for the matrix effect, the IS recovery rates of the concentrated extracts experiencing higher matrix effect were increased from 36.8 and 56.6 to 67.1 and 105.6% in wheat and oat bran, respectively. Thus, ion suppression could be compensated, and inclusion of the matrix effect was highly necessary for concentrated samples. Furthermore, time dependence of the matrix effect was observed. The ionization of the early eluting $\Delta^7$-avenasteryl glucoside was inhibited by 39%, whereas the later eluting stigmasteryl glucoside signal was reduced 68% by the matrix in the concentrated wheat sample. Due to the variation of suppression of the different SGs, the SG composition changed significantly by inclusion of matrix effect correction. Furthermore, applying compensation for the matrix effect increased the total SGs quantified in wheat by about 12% from 164.9 to 184.4 μg/g DM.

With consideration of the matrix effect, the total SG content in whole wheat was 184.4 μg/g DM and was composed of 75.5, 15.3, 4.6, 3.3, and 1.2% of sitosteryl, campesteryl, $\Delta^5$-avenasteryl, stigmasteryl, and $\Delta^7$-avenasteryl glucosides, respectively. Compared to the results of our earlier study, the proportions of different sterols were similar, but in the current study more than double the amount of total SGs was detected.[2] Sugawara et al. detected 54 μg/g total SGs in wheat by HPLC-ELSD, which is only a third of what we measured.[26] These differences may, however, be due to analytical variability because Ruibal-Mendieta et al. measured steryl glycosides (SG + ASG) in winter wheat at a similar concentration to this study by HPLC-MS.[32]

The total SG content of oat bran under consideration of the matrix effect was 330.7 μg/g DM, demonstrating that the oat bran analyzed is a better source for SGs than whole wheat. Oat bran SGs consisted of 59.0, 7.5, 28.8, 1.6, and 3.1% of sitosteryl, campesteryl, $\Delta^5$-avenasteryl, stigmasteryl, and $\Delta^7$-avenasteryl glucosides, respectively. Kesselmeier et al. measured SGs in oat seed samples by HPLC-UV.[10] They found that sitosteryl glycoside and $\Delta^5$-avenasteryl glycoside are the two most abundant glycosylated sterols (in SG + ASG). These two accounted for 82% of the total SG content, which is in great accordance with our result (sitosteryl and $\Delta^5$-avenasteryl glucoside contributing 81% of the total SG content in oat). A mild analysis method, like the one developed in this study, is important for the analysis of oat SGs because $\Delta^5$-avenasteryl glycoside is a labile SG that is easily degraded or isomerized by the acidic hydrolysis included in several GC procedures.

To conclude, we developed a rapid, highly sensitive, and accurate UPLC-ESI-MS method for the detection of molecular ions of SGs as sodiated adducts. The possibility to separate SGs on the basis of different polarities, in combination with high sensitivity and mass accurate detection, makes this method a powerful tool for full screening of SG profiles in foods and other biological samples, even those with low SG content. Furthermore, we demonstrated that evaluation of the matrix effect is extremely important for accurate quantification of SGs in complex food samples.

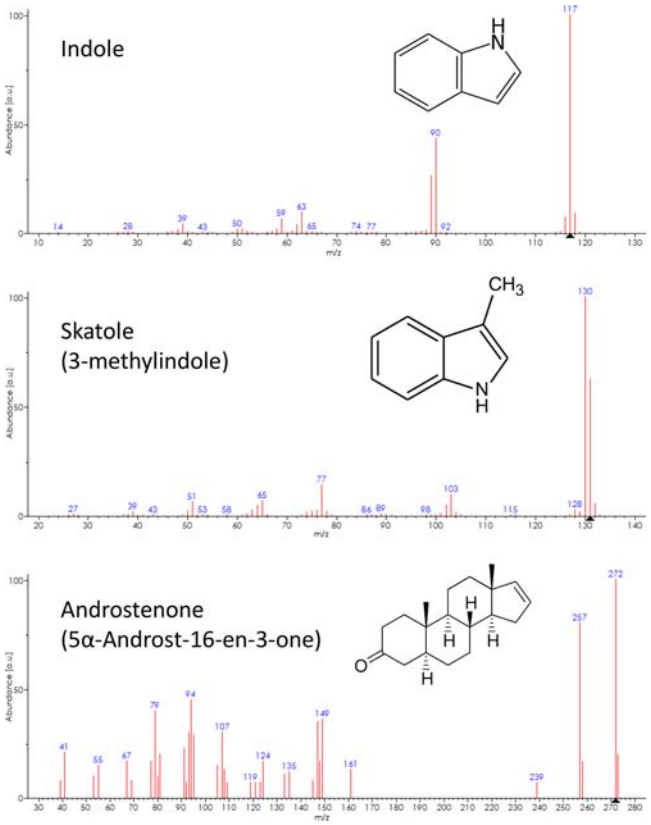

**Figure 1.** Electron ionization (EI) mass spectra at 70 eV for each of the three structures of (a) indole, (b) skatole, and (c) androstenone. (Mass spectral data were taken from the NIST 11 Mass Spectral Database, Gaithersburg, MD, USA.)

is homogenized (by mechanical means or by melting) and thoroughly mixed with methanol.

More recently, Fischer et al.[29] have reported a novel combination of internal labeled standards and headspace sampling and have achieved a LOQ of 0.7 ng/g for indole, 3.1 ng/g for skatole, and 64 ng/g for androstenone using gas chromatography, which makes their combined work very attractive for reference analysis of fat samples. In this method approximately 14 min is spent on manual sample preparation, approximately 60 min is spent on headspace sampling, and 35 min is spent on the GC run (times stated per sample).

The ideal abattoir situation is an absolute quantification of the relevant boar-taint compounds at the full processing speed of the carcasses. In modern abattoirs, this will require sampling as fast as 3 s per carcass and the measurement result and decision preferably in less than 20 min. However, if discrete risk levels can be accepted, the detection method does not need to produce results with high quantitative accuracy. A method that can discriminate carcasses in a low-, medium-, or high-risk group will be adequate if the method is quick, reliable, and applicable to the minimally equipped and staffed laboratories often found in slaughterhouses. Such a method calls for a very high degree of automation and, preferably, with no human involvement in the sample processing at all.

While the method described here is not an online method, it facilitates the use of high-throughput at-line GC-MS analysis in an industrial setting by simplifying the sample preprocessing and the chromatographic requirements. This method presumes that the industrial users in everyday evaluation of production carcasses do not need very high absolute accuracy, but that high accuracy can be compromised for faster analysis. This work exploits how far the envelope of chromatographic parameters can be pushed, and how crude the sample preparation can be performed while retaining reliable results for industrial boar-taint detection. The method developed is based on the use of dynamic headspace sampling (DHS) via thermal adsorption/desorption and gas chromatography−mass spectrometry directly on pure fat samples for the prediction of the risk for the meat to emit boar taint at human detectable levels.

## MATERIALS AND METHODS

The method development was made primarily through two experiments described as follows:

(I) Construction of a response calibration curve for each of the three compounds indole, skatole, and androstenone in order to map the response of the detector system to the actual masses of analytes presented to the system. This experiment is also used to define the basic chromatographic behavior of the three compounds and how the chromatography can be accelerated.

(II) Method validation on a set of samples from slaughter boars which are measured both with the new method and by a reference measurement obtained by liquid chromatography.[27] The method is evaluated by its ability to quantify and discriminate tainted samples.

**Experiment I: Direct Injection of Standards.** Methanolic standard solutions for each of the three compounds skatole, indole, and androstenone (all Sigma-Aldrich, Munich, Germany) were prepared in the laboratory. The analytes were weighed, placed into 20 mL vials, and capped (after a nitrogen fill to avoid oxidation), followed by addition of methanol (Sigma-Aldrich) to reach 1.0 and 0.1 μg of analyte/(μL of solution). The concentrations were used to prepare a series of sorbent tubes (Markes International Ltd., Llantrisant, U.K.), each loaded with 200 mg of Tenax TA (Sigma-Aldrich) in different concentrations as outlined in Table 1, by injection on a standard solution loading rig (Markes), in a $N_2$ (ALPHAGAZ 2, Air Liquide, Taastrup, Denmark) flow of 50 mL/min allowing for analyte adsorption in 5 min postinjection at 20 °C. Separate syringes (Sigma-Aldrich Hamilton GASTIGHT syringes, 10 and 25 μL) were kept for each of the six standard vials to avoid cross-contamination. The syringe needles were cleaned with methanol after each septum

**Table 1. Analyte Levels in Sorbent Tubes**

| | analyte added (ng) | |
|---|---|---|
| tube no. | skatole and indole | androstenone |
| 1 | 4.9 | 4.9 |

penetration. Following standard injection the tubes were sealed using brass storage caps and PFTE (poly-tetrafluoroethylene) ferrules (Markes), and kept refrigerated at 5 °C until analysis. The tubes were prepared in duplicates, one series at a time over two separate days. The instrument response for duplicates was averaged for further analysis. Standard deviation for the instrument response of the duplicates is provided in Table 3.

A second set of tubes was manufactured similarly, each prepared with 0.5 μg of indole, 0.5 μg of skatole, and 1.0 μg of androstenone. These tubes were used to identify retention times and chromatographic properties for various temperature and flow profiles (not shown).

**Experiment II: Analysis of the Natural Fat Matrix.** Tainted fat (backfat) samples were made available from an experiment conducted by The Danish Pig Research Center (Copenhagen, Denmark),[14] including reference values determined by LC-MS.[27] The samples were cut from the carcass loin neck region and individually vacuum packed and labeled. The collection of samples has been stored at −18 °C until its use in this experiment. A total of 25 samples were selected from this experiment so that the LC-MS reference values of each of the boar-taint compounds spans the minimum to maximum levels observed. The 25 samples and their analyte levels are listed in Table 2.

**Table 2. Analyte Concentrations for Selected Natural Fat Samples Used in Experiment II**

| | indole (ng/g) | skatole (ng/g) | androstenone (ng/g) |
|---|---|---|---|
| min | 28 | 37 | 344 |
| max | 543 | 1415 | 12348 |
| mean | 161.1 | 508.8 | 4946.6 |

For each sample approximately 2 g were removed from the cut and placed into a 10 mL headspace vial, which was weighed before and after fat addition. Samples were processed as coarsely as possible—from the cut-out piece of tissue, skin and meat were removed and an approximately 2 g piece of the remaining fat was cut and added to the vial. The headspace vial was filled with $N_2$ before capping with an airtight septa using a manual crimp tool. After preparation, the samples were labeled and stored at 5 °C until analysis (total storage time < 3 days). The cut, fill, purge, and crimp procedure was in average of less than 45 s.

**Instrumentation.** All experiments have been conducted on an Agilent 6890 gas chromatograph and Agilent 5973N mass spectrometer (Agilent, Hannover, Germany) with electronic ionization source. Data were collected in Agilent MSD Chemstation version E.01.01.335. A Markes International UNITY thermal desorber (Markes) was connected to the GC EPC inlet pneumatic module via the EPC carrier feed gas and EPC septum purge connections to enable GC control of a constant column flow. To supply the UNITY through the EPC pneumatic controls, the EPC inlet was configured with the heater set to off, in splitless mode, without split venting. Based on findings in refs 5 and 28 a Phenomenex Zebron ZB-5MSi low-polarity capillary was selected with dimensions 30 m × 0.25 mm o.d. × 0.25 μm i.d. The column was connected to the thermal desorber through a Phenomenex Zebron Z-Guard guard column (5 m × 0.25 mm o.d.), acting as a transfer line, and merged with the capillary column in the oven using a glass union secured with a high-temperature polyamide resin. The unity desorber was fitted with a Tenax cold trap (Markes). In experiment I, the sorbent tubes were loaded manually in the oven of the UNITY desorber. For experiment II, dynamic headspace sampling was achieved through a Markes International U-inlet direct sampling accessory replacing the sorbent tube in the UNITY flow line. The U-inlet accessory was modified to have sharp tips for easy insertion in the sample vials through the vial septa. The exhaust line was intentionally kept 2 cm longer than the intake line in order to avoid excessive looping of the exhaust gas when inserted into the sample vial. Furthermore, the U-inlet accessory was complemented with approximately 10 mm loosely packed fine glass wool acting as a filter to avoid excessive amounts of the fat matrix to enter the heated valve of the UNITY. Heating of the vials was achieved by using a CTC-PAL heated agitator. Hydrogen was supplied to the equipment using an in-laboratory hydrogen generator (PEAK Scientific, Inchinnan, Scotland, U.K.).

**Analytical Procedure.** A compromise between speed and chromatographic resolution was investigated in several separate experiments, where flow rates, temperatures, trap breakthrough volumes, and run times were tested (not shown here) in order to optimize recovery of the three analytes from the biological samples and to reduce the total analysis time. For all tests, evaluations were made on how the chromatographic method was able to return reproducible and quantifiable peaks for the three compounds. As shown in Figure 1, indole and skatole, with mass weights 117 and 131 g $mol^{-1}$, respectively, have relatively simple mass spectra, in that they show a low degree of fragmentation, and only target ions with $m/z$ 117 and (for skatole the more abundant) $m/z$ 130 were necessary to include obtaining a proper quantification. Androstenone, however, has two significant mass targets of $m/z$ 257 and 272. It was found that androstenone could be efficiently quantified by accounting for $m/z$ 257 alone (see Results and Discussion). Emphasis was given to identify proper temperatures where all three analytes become volatile enough for transport in the flow system and on the other hand not break apart into smaller components. In addition, the amount of vaporized fat present in the headspace of the sample vials for experiment II should be as low as possible, requiring that the equilibration and sample temperature of the sample vials should be kept as low as possible as well.

These experiments led to the following final analytical configuration: a constant column flow of 1.4 mL/min, with an oven program of 130 °C for 1 min, 30 °C/min to 250 °C, held for 1 min, which

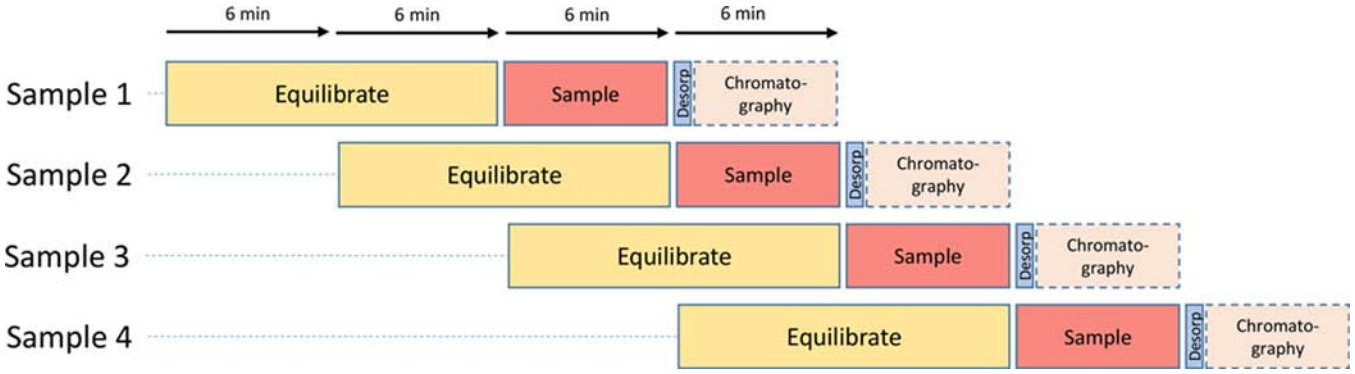

**Figure 2.** Sequence diagram of the analytical procedure. If sequenced by a multipurpose sampler robot, the analytical procedure can be arranged into a front-to-back sample mode of the GC-MS. If each step is kept in multiples of 6 min, the shown sample configuration could be achieved: a result delivered every 6 min, with a 24 min processing time for delivery of the first result.

combined gives a total analysis time of 6 min. The end temperature of 250 °C is relatively low (the ZB5-MSi column used has a maximum temperature of 350 °C), but was found sufficient for keeping the column clean between runs (experiment conducted but not shown), and advantageous for keeping the GC oven cool-down time postrun to a minimum. This 6 min chromatographic run time was subsequently imposed on the sample preparation steps; i.e., the fat sample processing should have equilibration and sample times in multiples of 6 min. The final measurement setup used is shown in Figure 2, where the processing sequence of the first four samples is shown. Each sample is set to equilibration of the sample/headspace concentration for 12 min, followed by a 6 min headspace purge. When the purge is complete, the 6 min chromatographic run is started. A multipurpose sample robot attached to the GC-MS equipment could be programmed to execute this sequence and, accordingly, allow the method to produce a chromatogram every 6 min.

The transfer line between the GC and the UNITY desorber and the desorber heated valve were kept at 220 °C throughout all experiments. The sorbent tube oven was operated at 250 °C during desorption/sampling. The UNITY cold trap was kept at −10 °C during primary desorption/sampling, elevated to 300 °C at the maximum heating rate (>40 °C/s) during cold trap fire, and held high for 45 s. The cold trap and sample tube was purged of atmospheric air at 0.5 min prior to desorption with carrier gas. Although previous experiments have established that the stated temperatures and times do not leave any analyte in the system to be observed as carryover between samples, empty tubes were run at regular intervals to test for carryover (data now shown).

In experiment I, an inlet split of 2:1 was achieved by enabling a split flow of 50 mL/min against a desorption flow of 50 mL/min, and was further split by enabling the split flow during trap desorption, resulting in an outlet split of 37.5:1. Hence, in total, the sample was split 75:1 and transferred to the column.

In experiment II, a vial purge flow of 20 mL/min was used to sample the vial headspace for 6 min at 150 °C. Prior to headspace sampling, the vial headspace was equilibrated in 12 min at 150 °C, while being shaked at 250 rpm for 30 s and then having a 10 s pause (and rotation direction reversal). During desorption, a split flow of 100 mL/min was enabled, resulting in a sample split of 72.4:1 (transferred to the column).

The MS temperatures were set to 230 °C for the ion source, 280 °C for the foreline and 150 °C as the quadropole temperature. The MS was operated in scan mode (scan range, 50−300 $m/z$). For quantification of the analyte concentration from the chromatograms, abundances of the target ions with $m/z$ 117 ± 0.5 for indole, $m/z$ 130 ± 0.5 for skatole, and $m/z$ 257 ± 0.5 for androstenone were accumulated for all MS samples in retention time windows of 1.5−3.5 min for indole and skatole and 4.5−5.5 min for androstenone. MS target ion samples with abundances less than 5000 au were rejected as noise and were not included in the accumulation. All processing of the chromatograms was performed in Matlab R2013b using a script developed for the purpose (a source code listing for the script can be obtained from the authors). MS data were loaded into Matlab through a CDF data export from Chemstation. The accumulated abundance results are corrected with the sample split ratios (as listed previously) and averaged for two separate series of sorbent tubes.

**Calibration of Response Regressions.** When chromatograms and $m/z$ abundances were accumulated for all target ions for all analyte levels, a calibration was made to allow for prediction of analyte mass from the instrument response. Assuming linearity between the analyte mass and measured accumulated peak abundance, the relationship between a concentration mass, $m_a$, and its corresponding accumulated instrument target ion response area, $r_a$, can be formalized as shown in

$$m_a = \beta r_a + \beta_o \quad (1)$$

where the regression coefficient $\beta$ is used to project the instrument response onto the analyte mass with an offset $\beta_o$. A regression vector $\mathbf{b} = [\beta_o \beta]$ can be determined in a least-squares sense[30] as in

$$\mathbf{b} = (\mathbf{R}^T\mathbf{R})^{-1}\mathbf{R}^T\mathbf{m}_a \quad (2)$$

from vectors of the $n$ known analyte masses $\mathbf{m}_a = [m_{a_1}\ m_{a_2}\ m_{a_3}\ \ldots\ m_{a_n}]$ and corresponding accumulated target ion instrument responses $\mathbf{r}_a = [r_{a_1}\ r_{a_2}\ r_{a_3}\ \ldots\ r_{a_n}]$. The matrix $R$ in eq 2 is the column-wise collation of and numerical ones *and* $\mathbf{r}_a$ (eq 3).

$$\mathbf{R} = [\mathbf{1}\mathbf{r}_a] \quad (3)$$

Having determined $\mathbf{b}$, a prediction $\mathbf{p}_a = [p_{a_1}\ p_{a_2}\ p_{a_3}\ \ldots\ p_{a_n}]$ (eq 4) of the known analyte masses $\mathbf{m}_a$ is used to summarize the prediction accuracy into a RMSE (root-mean-square error)[31] estimate (5).

$$\mathbf{p}_a = \beta \mathbf{r}_a + \beta_o \quad (4)$$

$$\mathrm{RMSE} = \sqrt{n^{-1}\sum_{i=0}^{n}(p_{a_i} - m_{a_i})^2} \quad (5)$$

## RESULTS AND DISCUSSION

**Experiment I: Direct Injection of Standards.** An example total ion chromatogram of a sorbent tube run is shown in Figure 3A. Three peaks, corresponding to the analytes, are observed at retention times 1.8, 2.1, and 5.0 min for indole, skatole, and androstenone, respectively. Despite the fact that the sorbent tube in Figure 3A is loaded with the same mass of each compound, large differences in peak areas are observed between the two indoles and the androstenone. However, the areas of the two indoles are comparable for the different runs. Figure 3B shows a plot of the relationship between the sorbent tube loading mass and the accumulated response area for the selected ions (detailed correlations of the relationships are listed in Table 3 for different decade ranges of the concentration masses). No response was recorded for indole and skatole of masses less than or equal to 10 ng and for

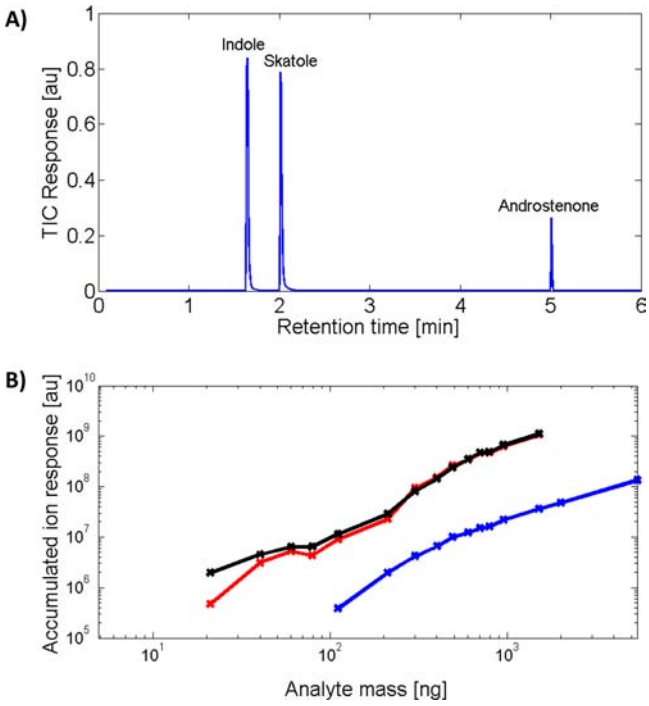

**Figure 3.** (A) Chromatogram showing the three analytes. (B) Prediction of analyte mass from instrument response using least-squares fit model. Black curve, skatole ($m/z$ = 130) with $R^2$ = 0.96; red curve, indole ($m/z$ = 117) with $R^2$ = 0.98; blue curve, androstenone ($m/z$ = 257) with $R^2$ = 1.00.

| 1−10 | <2 | 0.837 | 0.94 | | 0.74 | 0.86 | | 61.7 | 70.6 | |
| 10−100 | <1 | 0.994 | 0.99 | 0.99 | 0.98 | 0.98 | 0.99 | 48.9 | 56.1 | 19.1 |
| 100−1000 | <0.8 | | | 0.99 | | | 0.99 | | | 35.8 |

[a]Standard deviation is expressed for all three analytes per range and is expressed as percentage of the mean of the duplicate.

androstenone levels equal to or less than 79 ng. The detection limit of the method (i.e., the minimum masses distinguishable from background) was estimated to 21 ng for the indoles and 110 ng for androstenone.

As can be observed from Figure 3B, some nonlinearity is present in the relationship of the indoles for the low mass abundances of masses less than 90 ng. In contrast, no nonlinearity was observed for the androstenone quantification to analyte abundance relationship. Moreover, Figure 3B shows that the quantification areas of the indoles are highly similar in the high range of analyte concentrations but deviate slightly in the lower part of the concentration range. The androstenone area was a factor of 10−15 lower for the same analyte concentrations.

Statistics of the calibration performed in this experiment is given in Table 3. It is noticeable that the model provides a poorer fit for the 1−10 ng response range than for the 10−100 ng range for the indoles, which indicates that the system's LOQ is near the 1−10 ng range.

**Experiment II: Analysis of the Natural Fat Matrix.** A total ion chromatogram of a natural fat sample is shown in Figure 4. The fgure includes excerpts of assignments of the most abundant peaks (see also Table 4). The compounds observed are mainly a mix of intact free fatty acids (octadecanoic acid, caprylic acid, decanoic acid, palmitic acid, and others not annotated) and the aliphatic tails of fatty acids broken into varying sizes from the thermal transfer of the fat (heptane, nonanal, dodecane, undecane, and heptadecane). In addition, the presence of aldehydes (nonanal) is a typical product of fat oxidation, here occurring during the sampling procedure. Some volatile aroma compounds, including furan and (*E*,*E*)-2,4-nonadienal, also appear in the chromatogram, and these types of compounds may contribute to an altered perception of the odor profile of the fat when heated. Especially the short fatty acid caprylic acid (C8:0), reported to have an odor profile labeled "pungent, sour and rancid",[32] can potentially provide this effect. These observations were not pursued further in this work. The relatively broad peaks of indole and skatole indicate that either other compounds may be coeluting with the two analytes or that the chromatographic procedure used is not optimal for the two analytes. However, as the calibration method uses a single quantification ion (or by MS single ion monitoring (SIM) scanning) accumulated over a retention time gap, reliable quantifications can be made from the chromatogram. The peak area of androstenone in Figure 4 is visibly disproportional to other peaks representing compounds more abundant in the sample (fatty acids and so on) and is the combined effect of column polarity, the sampling method, and the difference in vaporization points for the various compounds.

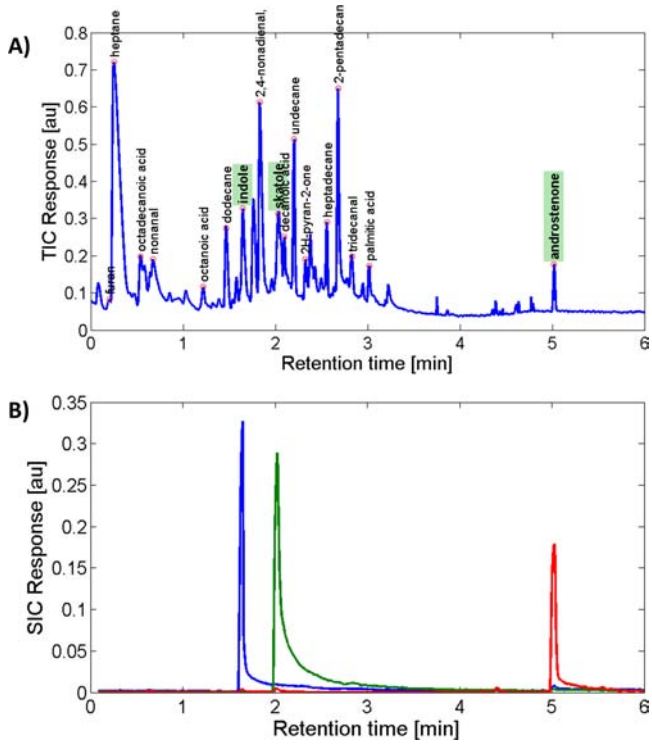

**Figure 4.** (A) Total ion chromatogram of a fat sample with annotated compounds (excerpt of full list). (B) Single ion chromatograms of the three analytes. Blue curve, indole ($m/z$ = 117 ± 0.5); green curve, skatole ($m/z$ = 130 ± 0.5); red curve, androstenone ($m/z$ = 257 ± 0.5).

In order to validate the ion and the retention-time-window selection, blank samples were run on fat determined with the LC method to have no noticeable boar-taint compounds (not shown). No instrument response could be accumulated on these samples, showing that the selected ions and window does target the three analytes.

The calibrations obtained in experiment I were used to predict analyte concentration levels from the chromatographic response, and to study how the analytes in the fat matrix are released compared to the directly injected standards. As the analyte concentrations in the biological samples previously have been determined using a high-performance LC (HPLC) reference method,[14] the relationship between the predicted and known levels can be expressed as in Figure 5A for the three analytes. Overall, the curves show a strong linear trend, and the minor deviations of the curves can be explained by variations in the biological sample material or by method sensitivity to (unrecorded) variations in the sampling procedure. The absolute level of the predicted masses in the fat matrix is lower than for the directly introduced standards, which indicate

**Table 4. Excerpts of the List of Compounds Tentatively Identified in Fat Chromatogram Using the NIST 11 Database[a]**

| retention time (min) | compound name |
|---|---|
| 0.20 | furan |
| 0.25 | heptane |
| 0.54 | octadecanoic acid |
| 0.68 | nonanal |
| 1.22 | octanoic acid |
| 1.47 | dodecane |
| 1.65 | indole |
| 1.83 | (*E*,*E*)-2,4-nonadienal |
| 2.03 | skatole |
| 2.10 | decanoic acid |
| 2.20 | undecane |
| 2.33 | 2*H*-pyran-2-one |
| 2.56 | heptadecane |
| 2.68 | 2-pentadecanone |
| 2.83 | tridecanal |
| 3.02 | palmitic acid |
| 5.02 | androstenone |

[a]Only compounds with high accuracy are shown.

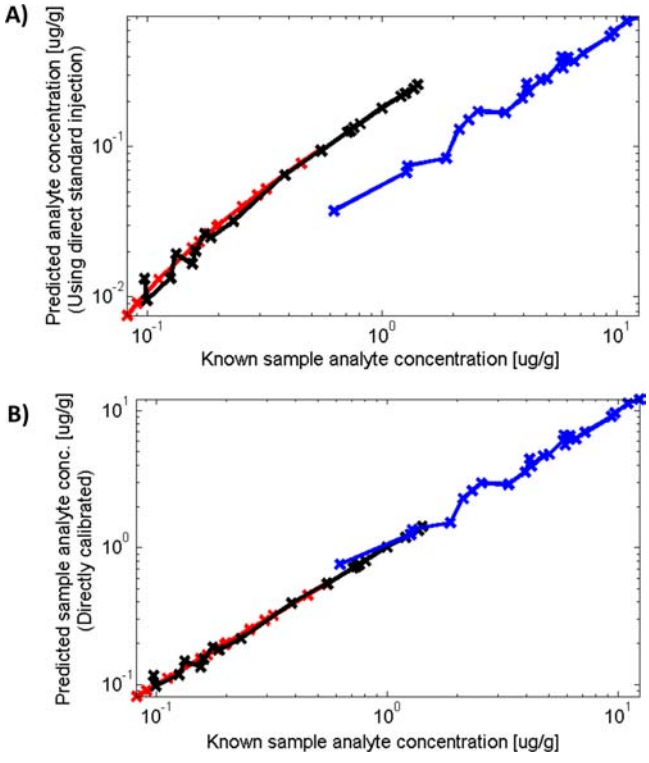

**Figure 5.** (A) Prediction of analyte concentration from instrument response using calibration obtained from the direct introduction of standards. Red curve, indole, $R^2$ = 1.00; black curve, skatole, $R^2$ = 0.99; blue curve, androstenone, $R^2$ = 0.98. (B) Prediction of known analyte concentration directly from instrument response to biological samples. Red curve, indole; black curve, skatole; blue curve, androstenone.

that the total analyte mass stored in the fat matrix was not released into the headspace during equilibration or sampling but rather is a function of temperature and time. However, the strong linear relationship observed shows that the released amount of analyte is quantifiable and reflects the known amount present in the sample.

In the recorded chromatograms no response (LOD) was recorded for fat samples with indole concentrations lower than 82 ng/g (backfat concentration), skatole concentrations lower than 97 ng/g, and androstenone concentrations lower than 623 ng/g. These levels are higher than for the directly introduced standards (experiment I), which may be explained by the fact that a lower concentration of analyte exists in the headspace of the fat samples and accordingly the actual mass concentration reaching the column is lower.

Finally, a direct calibration approach was examined in which the known analyte concentrations are predicted directly from the chromatographic response to the biological samples. The obtained calibration is shown in Figure 5B, and the corresponding statistics are listed in Table 5. This calibration yields on average prediction errors (LOQ) of RMSE = 96 ng/g for indole, 94 ng/g for skatole, and 331.3 ng/g for androstenone.

**Perspective.** *Boar-Taint Risk Assessment.* While the method presented here does not provide for the high prediction accuracy in absolute terms compared to existing laboratory reference methods (the produced results are one order of magnitude lower in precision than the used LC reference method), it does allow for discrete classifications. Based on the human olfactory response levels, a classification flowchart (decision tree) for a sample predicted to have analyte concentrations of $p_i$, $p_s$, and $p_a$, and quantification errors of $e_i$, $e_s$, and $e_a$, for indole, skatole, and androstenone, respectively, is proposed in Figure 6. The flowchart classifies the sample into three groups—a high-risk, intermediate-risk, or low-risk group. The high-risk group is selected if the predicted amount plus the quantification error is higher than thresholds $i_h$, $s_h$, or $a_h$. If this is not the case, the intermediate group is selected for indole and skatole if a prediction is found higher than the quantification error—as analyte definitely *is* present. In order to accommodate for the wider range of androstenone detection levels, an intermediate class is defined if the quantified mass plus its quantification error is higher than a threshold $a_l$. If none of the preceding conditions are fulfilled, the sample is categorized as being low risk. The decision tree may be extended with more nodes (checks and thresholds), if necessary, and the threshold limits should be determined so that they apply to a particular product or general abattoir screening procedure. This use of a decision tree provides possibilities for different actions to concentration levels of different compounds. If the thresholds $i_h$ and $i_s$ are set to the agreed-upon response level of 0.1 $\mu$g of analyte/(g of fat), the sample will be marked high-risk if this occurs—independent of the androstenone level. The androstenone level has two thresholds, a high, $a_h$, and low, $a_l$, in order to take into account the different perception levels as previously described. The decision tree also takes into account that the indole and androstenone levels are uncorrelated in real samples. The method can be used in highly automated setups, using already commercially available equipment. Several samples can be queued for processing with the method, yielding a result every 6 min, where the maximum time from measurement to result delivery limits the queue length. Considering a practical queue length, the method is suitable for verification of premium products for small abattoirs or for overnight batch verification in an abattoir laboratory setting.

*Calibration.* Because the method relies on calibration on known standard samples, the calibration should be maintained frequently to reflect changes in the desorber system (cold trap performance), chromatographic performance (column degra-

[a]Samples included in statistics. For indole: 10−100 ng/g, 2 samples; 100−1000 ng/g, 11 samples. For skatole: 10−100 ng/g, 2 samples; 100−1000 ng/g, 11 samples; 1000−10000 ng/g, 4 samples (all below 2000ng). For androstenone: 100−1000 ng/g, 1 sample; 1000−10,000 ng/g, 21 samples; 10,000−100,000 ng/g, 2 samples (both below 12,000 ng). [b]Only two samples included. [c]Only one sample included.

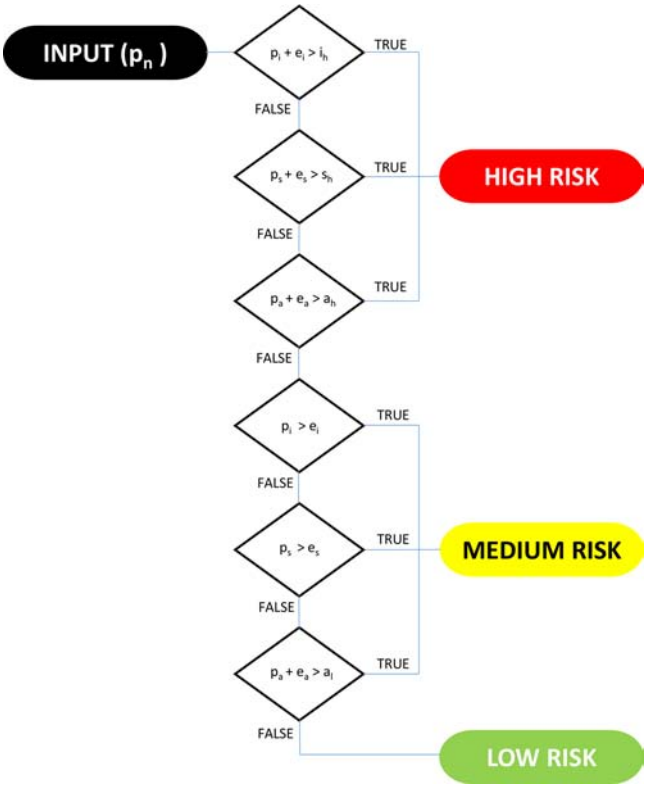

**Figure 6.** Proposed structure to perform classification of fat sample taint risk. Symbols: $p_i$, predicted indole mass; $e_i$, indole mass prediction error; $i_h$, indole high-risk detection threshold mass level; $p_s$, predicted skatole mass; $e_s$, skatole mass prediction error; $s_h$, skatole high-risk detection threshold mass level; $p_a$, predicted androstenone mass; $e_a$, androstenone mass prediction error; $a_h$, androstenone high-risk detection threshold mass level; $a_i$, androstenone intermediate-risk detection threshold mass level.

dation), and mass spectrometer tune changes. For this purpose, laboratory-produced samples of fat spiked with analytes—a high and low concentration—should be measured at daily intervals and the calibration adjusted accordingly (not shown). If a linear relationship between analyte concentration level and instrument response is assumed, a simple bias/slope correction of the instrument response would be sufficient to correct for changes in the chromatographic system. It is suggested that these steps are collected in a software system that maintains the classification and calibration algorithms, so that calibration can be made automatically on the spiked standard samples measured and analyzed in-sequence of the real samples. To avoid degradation of the system performance, it is recommended that a standard sample is run at regular intervals, for instance every 20 samples, with a suitable check against relevant acceptance criteria for the method.

*Comments on the Method and Suggestion for Further Work.* The GC-MS data presented in this work have been obtained using a mass spectrometer in scan mode in order to retain information on other components present in the released gas stream. It is possible and advisible to use the targeted SIM which will increase scan speed and provide a higher accuracy. For the quantification of androstenone, reliable calibration results were obtained by including only the $m/z$ 257 ion instead of separately accumulating instrument response for both $m/z$ 257 and $m/z$ 272. However, it is recommended that both ions are used for quantification. For the purpose of method development, a 30 m column with i.d. 250 $\mu$m was used for the GC results presented here. Since the complexity of the compounds coeluting with the analytes of interest is now known, a shorter column may be used to further reduce run time, just as the film thickness could be reconsidered. However, given the back-to-back nature of the method, an increase in overall analysis speed can only be gained if the desorption and equilibrate phases of the methods are reduced as well.

This work only examines quantification of androstenone to prove the principle of operation. Other similar steroids, also described to have boar-taint odor profiles, should also be examined. Moreover, the material available limited the number of samples for some analyte ranges (Table 5) wherefore a more complete range should be examined before implementation of the method.

[a]All samples were screened with the described method.

using species-specific marker peptides.[17] Based on this method, we present here an optimized approach for the detection of specific horse meat and pork marker peptides in different processed food samples.

## MATERIALS AND METHODS

**Chemicals.** LC-MS grade methanol (MeOH) and acetonitrile (ACN) were purchased from Sigma-Aldrich. Formic acid (FA) was purchased from Grüssing (Filsum, Germany). Water ($H_2O$) was prepared on a Milli-Q Gradient A10 system by Millipore (Schwalbach, Germany) and used for all buffers and other solutions including HPLC eluents.

**Commercially Available Samples.** All samples were purchased from German or Dutch supermarkets, butcher shops and farmer's markets, and directly stored at −20 °C in Corning (Amsterdam, Netherlands) 50-mL plastic centrifuge tubes. For self-made samples, pure beef, pork, and horse meat were bought as whole pieces to avoid contamination. Sample details are given in Table 1 for in-house prepared samples and in Supporting Information (SI) Table 1 for commercially available samples.

**Preparation of In-House Processed Samples.** The meat was cut into slices and minced using an electric meat grinder. The minced meat was formed to meat loafs, and frikadeller, a common European product similar to a fried hamburger patty, or meatballs. The meat loaf was placed in a porcelain tray and heated in a conventional kitchen oven to 200 °C until a core temperature of 100 °C was reached. Frikadeller were fried in a Teflon-coated pan until a brown crust typical for this dish was formed. The meatball was cooked in gently boiling water until a core temperature of 100 °C was reached.

For all in-house processed meat products no ingredients other than meat were used.

Products were cooled to room temperature and were precrushed in a freezing bag. The precrushed pieces were frozen in liquid nitrogen until the liquid nitrogen stopped boiling. Frozen pieces were ground at 8000 rpm for about 5 min in a Fritsch Pulverisette 14 rotor mill (Idar-Oberstein, Germany) with a 2-mm sieve. The powdered samples were stored at −20 °C in 50-mL plastic centrifuge tubes.

**Preparation of Sample Mixtures.** Samples containing more than one meat species were either prepared by weighing different amounts of ground pork or horse meat in ground beef followed by extraction of the mixture or by mixing desalted peptide solutions of relevant species (for details see Results and Discussion).

Powdered samples that contained at least 1.0 mg of pork or horse meat as contamination were prepared directly by weighing the different meat species directly in a 50-mL Corning tube on an analytical scale and were further prepared as described under sections "Extraction", "Digest", and "Desalting".

Samples that contained below 1.0 mg pork or horse meat (absolute amounts) were prepared by mixing desalted peptide solutions of respective species. In this case, pure beef (matrix) or either pork or horse meat (contamination) were processed as described below. A defined amount of the resulting, desalted pure beef peptide solution was spiked with either pure, desalted pork or horse meat peptide solution.

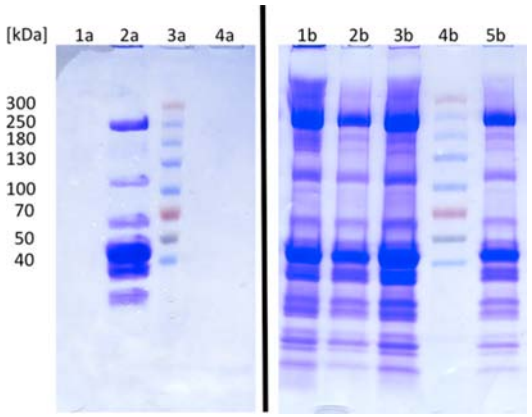

**Figure 1.** SDS-PAGE Gel showing the previously used extraction method (0.3 M KCl, 0.15 M $KH_2PO_4$, and 0.15 M $K_2HPO_4$) for meat samples (left gel, lanes marked #a) and the newly developed extraction method (6 M urea, 1 M thiourea, and 50 mM Tris-HCl) for processed samples (right gel, lanes marked #b). Loading scheme (in brackets volume of sample extract); all samples were made from pure pork; 1a: meatball (8 μL); 2a: raw (8 μL); 3a: marker; 4a: frikadeller (4 μL); 1b: raw (4 μL); 2b: meatball (2 μL); 3b: meatball (4 μL); 4b: marker; 5b: frikadeller (2 μL).

**Preparation of Commercial Processed Samples.** Salamis, sausages, meatballs, canned meat, and Frikandeln (Dutch convenience product similar to sausages) were diced to approximately 2 cm length with a kitchen knife.

Pasta sauce was removed from products by washing them with water on a lab sieve. The residue consisting of small meat and vegetable pieces was homogenized using an Ultra Turrax T-25 basic (ika, Staufen, Germany) with a 10 N dispersing element.

In the case of frozen lasagna and chilled pasta, Bolognese noodles and sauce were removed and the residual samples were also homogenized.

**Extraction.** Approximately 1 g of sample material was weighed in 50-mL plastic centrifuge tube, and 10 mL of extraction buffer (6 M urea, 1 M thiourea, and 50 mM TRIS-HCl (all Carl Roth, Karlsruhe, Germany) adjusted to pH 8) were added. For samples with a low overall meat content in the sample, this amount was slightly increased to approximately 1.4 g.

All samples were vortexed for 20 s and extracted using an Ultra Turrax T-25 (ika, Staufen, Germany) with a 10 N dispersing element. Samples with a higher content of connective tissue, e.g. salami, were dispersed for 30 s at 9500 rpm, followed by 40 s at 13 500 rpm and finally 40 s at 20 500 rpm. For all other sample types, the last step at 20 500 rpm was omitted. Finally, all samples were vortexed again for 20 s.

Following extraction, samples were centrifuged for 60 min at 4 °C at 12 000*g*. A 100-μL aliquot of the supernatant was transferred into a 1.5-mL Eppendorf reaction tube (Hamburg, Germany)

**Sodium Dodecyl Sulfate Polyacrylamide Gel Electrophoresis.** Precast 4−20% gradient gels (Mini-Protean TGX, Bio-Rad, München, Germany) were used to asses extraction efficiency. Running

dx.doi.org/10.1021/jf503468t | J. Agric. Food Chem. 2014, 62, 9428−9435

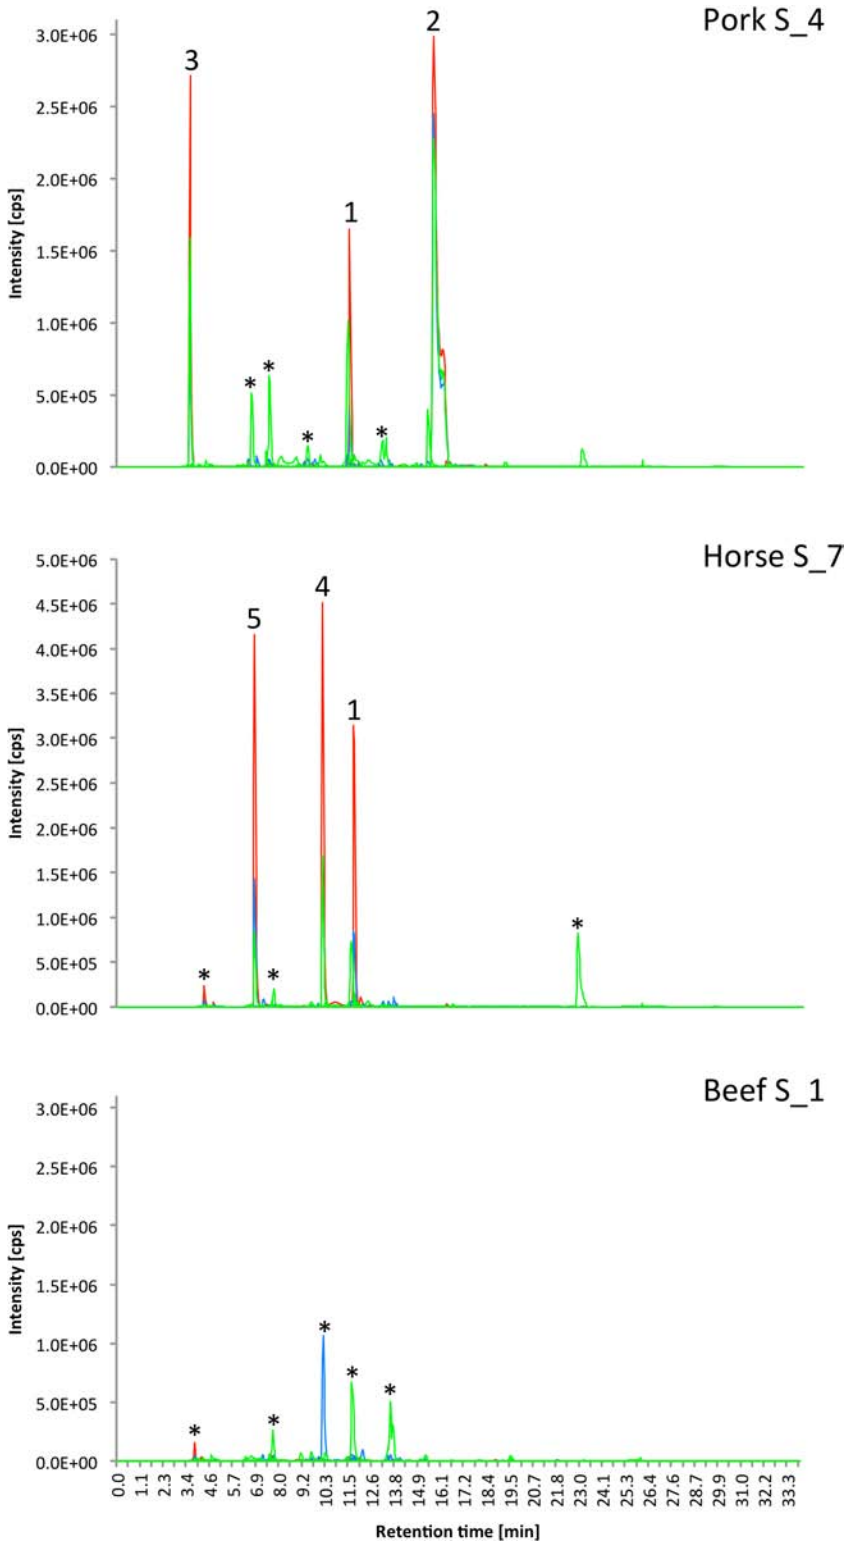

**Figure 2.** HPLC-MS/MS chromatograms of frikadeller samples made from pure pork, beef, or horse meat. To reduce complexity, only the three most intense MRM traces are shown for every peptide. The most intense transition is given in red, 2nd most intense is in blue, and 3rd most intense is in green. Unspecific signals are marked with asterisk. Markers are numbered according to Table 2 (for MS and HPLC parameters see SI Table 2).

buffer and sample buffer were prepared according to Lämmli.[18] SDS, Glycin, and TRIS-HCl were purchased from Roth in Bufferan quality. The protein molecular weight standard used was the Spectra Multicolor High Range Protein Ladder (Thermo Fisher Scientific, Rockford, IL, USA)

Briefly, samples were diluted with water and sample buffer, denatured at 95 °C for 5 min. Following sample application, SDS-gels were focused for 20 min at 100 V and then run at 140 V until the bromophenol blue front reached the end of the gel. Gels were fixed and stained using Coomassie brilliant blue dye for 25 min and destained. Gel pictures were taken on a standard flatbed scanner for personal computers.

**Digest.** An aliquot of the extract of the processed meat samples was subjected to tryptic digest following a standard protocol.[14] For each

dx.doi.org/10.1021/jf503468t | J. Agric. Food Chem. 2014, 62, 9428−9435

**Table 2. Characteristic Marker Peptides for Horse and Pork[a]**

| marker | species | name | uniprot accession | sequence | AA position |
|---|---|---|---|---|---|
| 1 | pig/horse | troponin T/uncharacterized protein | Q75NG7/F6 × 010 | YDIINLR | 239−245/185−191 |
| 2 | pig | myosin-4 | Q9TV62 | TLAFLFAER | 619−627 |
| 3 | pig | myosin-1 and -4 | Q9TV61/Q9TV62 | SALAHAVQSSR | 1331−1341/1329−1339 |
| 4 | horse | myosin-2 | Q8MJV1 | EFEIGNLQSK | 1086−1095 |
| 5 | horse | myosin-1 | Q8MJV0 | LVNDLTGQR | 1272−1280 |

[a]Markers 1, 2, and 4 are the most sensitive and are displayed in the subsequent figures. AA position: Position of the biomarker peptide in the sequence of the identified protein.

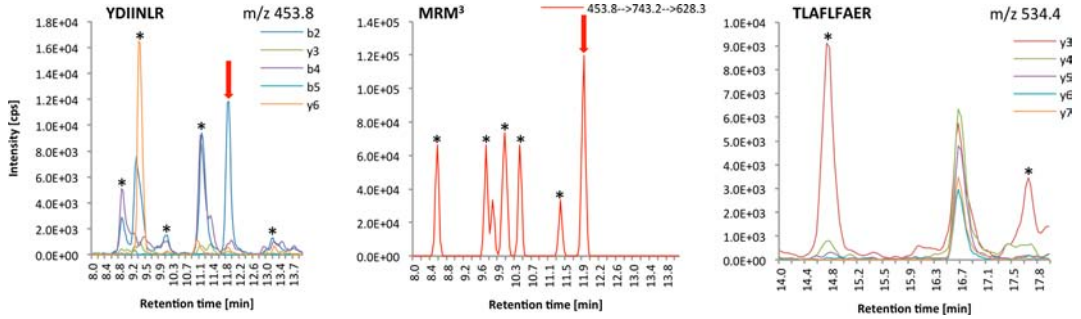

**Figure 3.** HPLC-MS/MS and MRM$^3$ chromatograms of a beef frikadeller spiked with 0.51% of pork frikadeller (mixed peptide solutions). Shown are the horse/pork-specific marker 1 (YDIINLR) and the pork-specific marker 2 (TLAFLFAER). For marker 1, four MRM transitions are detectable, but the s/n for y6 is only 3. However, the MRM$^3$ signal was detectable, showing a huge improvement for the sensitivity. For marker 2, all MRM transitions, but with a low overall intensity defining the LOD for this marker, were detectable. Unspecific signals have been marked with asterisks.

sample, an aliquot of 100 μL containing about 1.5 mg of protein was reduced, alkylated, diluted 1:10 with $H_2O$, and supplemented with 20 μg of Promega Sequencing grade modified trypsin (Promega, Mannheim). To allow complete digest, samples were incubated in a thermo shaker at 37 °C under slow shaking for at least 12 h.

**Desalting.** Digested samples were diluted 1:2 with $H_2O$ and desalted using Phenomenex (Aschaffenburg, Germany) Strata-X 33u polymeric reversed phase cartridges filled with 30 mg/mL RP material. Cartridges were washed and activated using 1 mL of MeOH followed by equilibration with 1 mL of 1% FA according to the manual. The samples were loaded onto the cartridge and washed with 1 mL of 5% MeOH/1% FA. Finally, peptides were eluted with 1 mL of ACN/$H_2O$ (90/10, 0.1% FA) and the eluate was collected in Eppendorf reaction tubes prefilled with 6 μL of dimethyl sulfoxide (DMSO) purchased from Roth (Karlsruhe, Germany).

**Preparation for HPLC.** After desalting, the solvent was removed under vacuum at 39 °C using an S-Concentrator BA-VC-300H purchased from H. Saur Laborbedarf (Reutlingen, Germany). DMSO is not removed during this procedure, which prevents peptides from sticking to the vessel surface and enhances peptide recovery. The samples were redissolved in ACN/$H_2O$ (3/97; 0.1% FA) and analyzed.

**MS/MS.** All samples were analyzed using a QTrap 5500 LC-MS/MS system (AB SCIEX, Darmstadt, Germany) with a VWR Hitachi HPLC (Pump L-2160U; autosampler L-2200U and column oven L-2300) and a Phenomenex Kinetex 2.6 u C18 100 Å (100 × 2.10 mm) column (Phenomenex, Aschaffenburg, Germany). A Turbo V ESI source was used. For details on HPLC gradient, source, and MS parameters see SI Table 2.

Data were evaluated using Analyst Software Version 1.5.2.

To survey retention time stability and relative intensity of MRM transitions, control samples of respective species were routinely analyzed accordingly.

A more detailed and basic description of the MS experiments is given directly after SI Table 2.

## RESULTS AND DISCUSSION

One of the most critical steps for the analysis of processed samples in targeted proteomics is efficient sample extraction. In our previous publication, we applied mild extraction conditions to reduce complexity of the extracted proteome and to focus on the readily soluble and highly abundant proteins of the myofibrillar and sarcoplasmic fraction in raw sample material.[17] Although target proteins in raw meat are soluble in low molar salt buffers (0.3 M KCl, 0.15 M $KH_2PO_4$, and 0.15 M $K_2HPO_4$)(Figure 1, lane 2a), heat treatment such as frying or boiling strongly reduced solubility for different meat products and led to lack of solubility of target proteins (Figure 1, lanes 1a and 4a). To overcome this problem, 11 different buffer compositions in combination with different extraction protocols such as vigorous shaking, vortexing, or the use of Ultra Turrax were assessed concerning efficiency of extraction and comparability with downstream sample preparation (data not shown) and best results were observed with 6 M urea, 1 M thiourea, and 50 mM Tris-HCl (see Materials and Methods for details). This extraction buffer gives excellent results for raw and for different processed samples as can be seen from the right gel in Figure 1 (lanes 1b−5b). In addition, the extraction time was strongly reduced to only approximately 2 min and a simple 10-fold dilution of the extract is sufficient to reduce urea and thiourea concentrations to allow tryptic digest.

It has, however, to be kept in mind that sample complexity is increased after processing and harsher extraction. We therefore assessed specificity and sensitivity of biomarker peptides under the modified conditions using pure, in-house processed beef, pork, and horse meat. Figure 2 and Table 2 give an overview of the five previously described[17] most important pork and horse meat biomarker peptides, demonstrating excellent specificity of the modified method. As expected, the specific horse and pork markers were not detectable in the beef sample. Though unspecific single MRM transitions occur, the specific marker peptides are only observed in the according samples and show retention time match, as well as matching MRM signal ratios and the full spectrum of MRM transitions. (See SI Table 3 for MRM Transitions and MS conditions). Similar results were observed for all in-house processed sample types (data not

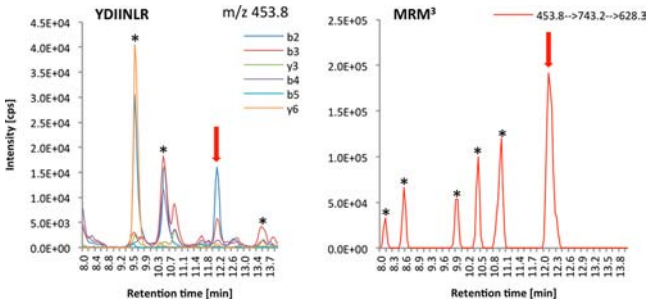

**Figure 4.** HPLC-MS/MS and MRM$^3$ chromatograms of a beef meatball spiked with 0.25% of horse meat ball (mixed peptide solutions). Shown is the most sensitive marker, the horse/pork-specific marker 1 (YDIINLR) and its corresponding MRM$^3$ experiment. Compared to Figure 3 it is obvious that the meatball matrix is less complex resulting in better overall intensities at lower concentration. Unspecific signals have been marked with asterisks.

shown), indicating that heat processing in general does not interfere with critical steps of our method (extraction, tryptic digest, MS analysis).

We next analyzed the sensitivity of the modified method using in-house processed samples containing trace amounts of pork and horse meat, respectively. At present, no official thresholds levels are in place for undeclared meat species. We therefore used the threshold level of 0.9% for genetically modified organisms (GMO) issued in Regulation (EC) 1830/2003 of the European Union[19] as orientation for "technically unavoidable" contaminations and the minimal performance level of our method.

Figure 3 shows results for a fried frikadeller containing 0.51% pork in beef. Marker 1 (YDIINLR) is still detectable with four MRM transitions. In addition, MRM$^3$ experiments provide a significant improvement of the signal-to-noise ratio and further improve specificity. In addition, all 5 MRM transitions for marker 2 (TLAFLFAER) were detected, demonstrating the specific detection of pork in this sample. However, we noted the increase in unspecific signals (as marked by asterisk) in MRM and MRM$^3$ experiments for highly processed samples. Fried meat products had a deep brown surface due to pronounced Maillard reaction and respective peptide solutions showed a yellow to brown color indicative for complex modification of the protein matrix.

As expected, for milder processing techniques such as boiling sensitivity was increased compared to fried samples. Figure 4 shows the results for boiled meatballs at a concentration of 0.24% horse in beef matrix. This concentration was achieved by mixing peptide solution of pure horse and beef samples. At this concentration, only marker 1 (YDIINLR) was detectable in MRM and MRM$^3$ experiments. Again, four MRM transitions were detectable and MRM$^3$ improved s/n and specificity (Figure 4). Similarly, for respective samples containing 0.24% of pork, we identified marker 1 as most sensitive marker but not the other pork-specific peptides (data not shown).

**Measurement of Commercially Available Processed Samples.** We next assessed the applicability of the detection method on a broad range of commercially available processed products obtained from supermarkets and a local farmers market (see SI Table 1 for details). All samples were prepared and analyzed with the described method.

Figure 5 shows the results for frikadeller (sample C_12 in SI Table 1) that was labeled to contain only pork meat. All MRM transitions from all specific peptides (see SI Table 3 for details) expected for pork were found in this sample and none of the marker peptide markers for horse, demonstrating excellent specificity for this processed sample.

An example of a more complex food matrix is given in Figure 6 (sauce Bolognese, sample C_11, see details in SI Table 1). The total meat content of the sample was declared with 3% pork and 7% beef. Detection of YDIINLR and TLAFLFAER (markers 1 and 2) confirmed the pork meat content of the product. As expected, no horse-specific markers (EFEIGNLQSK and LVNDLTGQR) were detected in this product (Figure 6). An overview of the results of the 23 different commercial samples

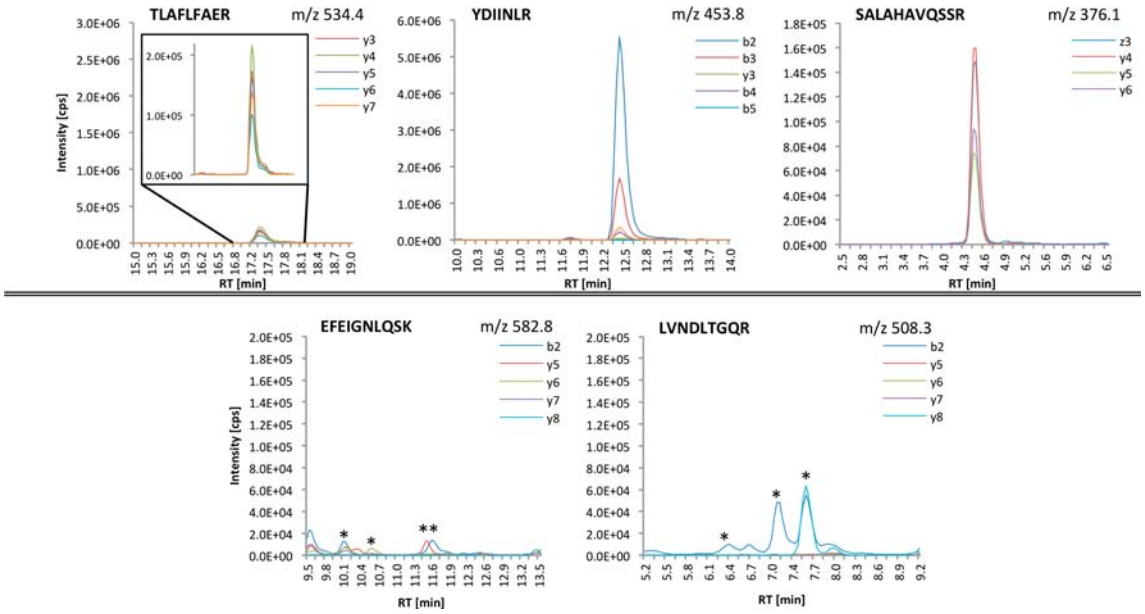

**Figure 5.** HPLC-MS/MS chromatograms of a commercial frikadeller (C_12) declared as pure pork. Shown are the horse/pork-specific marker 1 (YDIINLR), the pork-specific markers 2 (TLAFLFAER) and 3 (SALAHAVQSSR), and the horse-specific markers 4 (EFEIGNLQSK) and 5 (LVNDLTGQR). It is obvious that the sample C_12 contains pork and no horse was detected. Unspecific signals have been marked with asterisks.

[a]Match = MRM transitions were detectable at expected retention time with good intensities; n.d. = no MRM transitions were detectable.

analyzed in this study is given in Table 3 (sample details found in SI Table 1). Results of species identification and labeling was consistent for all analyzed samples except one corned beef sample (C_1, see Table 3). This sample was labeled to contain only beef material, but we detected horse-specific peptide markers using MRM and MRM$^3$ experiments, indicating unlabeled amounts of horse meat in this sample (Figure 7, upper chromatograms). We confirmed this result by the analysis

dx.doi.org/10.1021/jf503468t | J. Agric. Food Chem. 2014, 62, 9428−9435

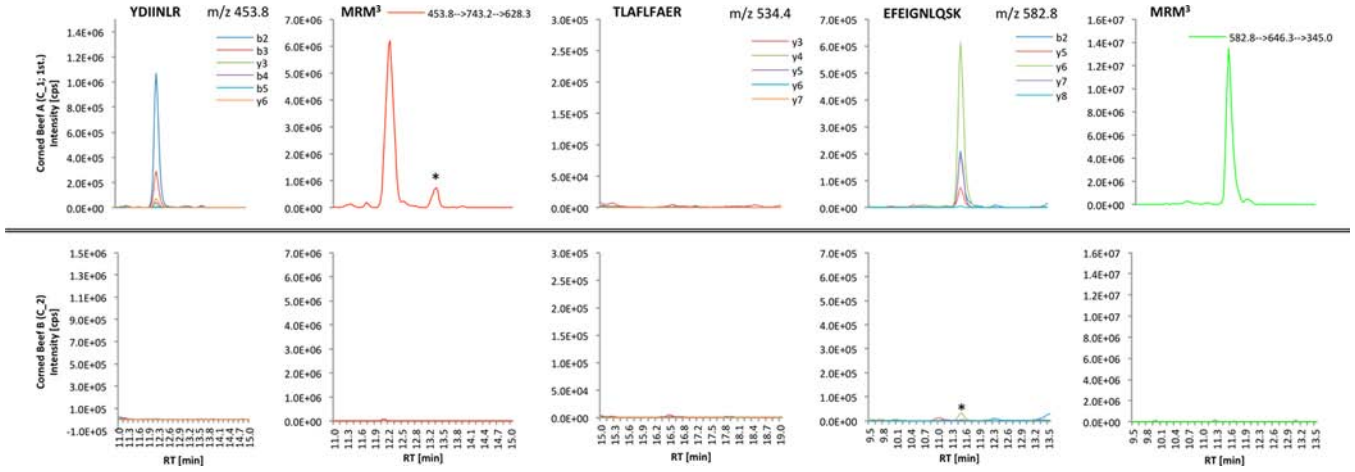

**Figure 7.** HPLC-MS/MS and MRM³ chromatograms of corned beef (C_1) declared as a pure beef. Shown are the horse/pork-specific marker 1 (YDIINLR) with its corresponding MRM³ experiment, the pork-specific marker 2 (TLAFLFAER), and the horse-specific marker 4 (EFEIGNLQSK) with its corresponding MRM³ experiment. It is obvious that sample C_1 contains horse meat because marker 1 and marker 4 both with corresponding MRM³ experiments were detectable. In sample C_2 (lower chromatograms), as declared, no horse or pork was detectable. Unspecific signals have been marked with asterisks.

of a biological replicate and analyzed two additional corned beef samples to rule out matrix effects of this sample material. As an example, results for corned beef sample C_2 are given in Figure 7 (lower chromatogram). Neither pork nor horse meat marker peptides were detectable, indicating that this sample contained only beef meat and that detection of horse in sample C_1 was not due to unspecific matrix effects (Figure 7). This was further underlined by use of droplet digital PCR to confirm the detection of horse meat in sample C_1 with a second analytical technique.

Taken together, we present in this study an optimized method for the specific detection of horse and pork meat in processed and highly processed food samples. Using MRM and the novel MRM³ detection of specific marker peptides, we were able to detect down to 0.24% horse or pork in a beef meat matrix. When necessary, a further reduction of sensitivity (approximately factor 3−4) can be achieved by the application of microLC systems instead of high flow LC as shown previously.[18] We were able to demonstrate that the identified marker peptides are sufficiently stable to resist thermal processing of different types of meat products and thus allow specific and sensitive detection also in processed food. The optimization of protein extraction had major impact on method performance, as demonstrated by the systematic evaluation of different extraction protocols. Optimal results were achieved by use of high molar urea and thiourea buffer systems. In addition, streamlining of extraction and sample preparation allowed us to drastically reduce extraction time to 20 s up to 2 min, depending on sample type. It is one of the huge advantages of this method that no special proteomics infrastructure such as 2D-PAGE or offgel-fractionation is necessary for prefractionation of samples and that separation and detection is performed on conventional C18 RP-columns and triple quadrupole instumentation. The protocol can therefore easily be implemented in routine analysis of laboratories without specific proteomics knowledge.

tea germplasms.[1,6,7] However, there are no comprehensive investigations about the catechin content of Chinese tea germplasms. Variations of the total catechins (TC) content of 119 accessions have been reported by the CNGTR.[7] However, the catechin compositions of Chinese tea germplasms were not clarified. To understand tea germplasms better and to use them effectively for breeding and production, the present study had the following main objectives: (1) to clarify the variation and profile of major catechins in tea germplasms of China, (2) to investigate the variability in catechin content of tea varieties and, (3) to understand the diversity of catechins of tea germplasms from main tea-producing regions of China.

## MATERIALS AND METHODS

**Materials.** A total of 403 accessions of representative tea germplasms were sampled for analysis. Having been introduced as cuttings or seedlings from 15 tea-growing provinces in China, they are currently preserved as genetic resources in the CNGTR (120°10′ E, 30°18′ N, 50 m in altitude) at Hangzhou, China, and are maintained through similar horticultural practices. Their geographic origins are shown in Figure 1. Among them, 320 accessions were *C. sinensis* var. *sinensis* (*sinensis* variety), 21 were *C. sinensis* var. *assamica* (*assamica* variety), 30 were *C. sinensis* var. *pubilimba* Chang (*pubilimba* variety), 8 were *C. taliensis* (W. W. Smith) Melchior, 4 were *C. crassicolumna* Chang, 3 were *C. tachangensis* F. C. Zhang, 1 was *C. gymnogyna* Chang, and 16 were uncategorized germplasms. All belong to the section *Thea* (L.) Dyer genus *Camellia* L. To analyze the main catechin components, 20−60 g of one bud and two leaves young shoots of the first flush in spring were harvested from individual plant of 403 accessions of tea germplasms in 2010 and 2011. All samples were immediately fixed with air at 120 °C for 5 min to deactivate polyphenol oxidase and then dried at 70 °C by a 1.1 kW drying machine (Zhejiang Chunjiang Tea Machinery Co., Hangzhou, China). The dried samples were stored in polyethylene bags and then kept frozen (−20 °C) until analysis. At the time of analysis, the frozen samples were ground and sifted through a 0.5 mm screen. Samples were analyzed in triplicate and results were averaged. Analysis of tea germplasms was performed over the course of two years. Because the difference in catechin content between two years was not significant ($P \geq 0.05$) (data not shown), data analysis utilized the mean catechin content of each tea accession in 2010 and 2011.

**Figure 1.** Sampling size and distribution of tea germplasms in China. Abbreviations represent different provinces. AH: Anhui, CQ: Chongqing, FJ: Fujian, GD: Guangdong, GX: Guangxi, GZ: Guizhou, HeN: Henan, HuB: Hubei, HuN: Hunan, JS: Jiangsu, JX: Jiangxi, SC: Sichuan, TW: Taiwan, YN: Yunnan, and ZJ: Zhejiang. A total of 403 accessions of tea germplasms were obtained.

**Chemicals and Standards.** The standard substances EGCG (97% purity), ECG (98% purity), EGC (95% purity), EC (98% purity), GC (98% purity), C (98% purity), and (−)-gallocatechin gallate (GCG) (98% purity) were bought from Sigma-Aldrich Chemicals Co. (St. Louis, MO, U.S.A.). Other chemicals were obtained from Huadong Medicine Co., Ltd. (Hangzhou, China).

**Sample Preparation and HPLC Conditions.** The isolation and detection of tea catechins, by high performance liquid chromatography (HPLC), was performed according to the International Standards Organization (ISO) ISO 14502-2-2005(E) procedure[25] with minor modifications. The powdered tea sample (0.2 g) was extracted by intermittent shaking with 5 mL of 70% (v/v) methanol at 70 °C, and the mixture was centrifuged at 1400*g* for 10 min. The supernatant was decanted into a 10 mL volumetric flask, and the extraction steps were repeated until a final volume of 10 mL was reached. The extracts were filtered through a 0.45 μm Millipore filter into autosampler vials. The sample injection volume was 10 μL. Tea extracts were analyzed for catechins. A Waters e2695 series HPLC system (Waters Co., Milford, MA, U.S.A.) with a reversed-phase C12 column (4 μm, 250 mm × 4.6 mm, Phenomenex) and a C12 guard column was utilized for analysis. The columns were maintained at 30 °C. The mobile phases were 0.5% (v/v) formic acid in double-distilled water (eluent A) and acetonitrile (eluent B). The flow rate was 1 mL/min. The gradient program was as follows: 0−16 min, linear gradient from 6.5% to 16% B; 16−20 min, linear gradient to 25% B; 20−25 min, 25% B; 25−26 min, linear gradient to 6.5% B; 26−30 min, 6.5% B. Corresponding changes in A were made. The eluate was monitored at 280 nm. Chromatographic peaks were identified by UV spectra using diode array detector, and retention times were compared with those of reference compounds. Figure 2 shows chromatograms of the standards and of a typical tea sample. Quantification was carried out by using the external standard method, and standard curves were constructed by linear regression analyses. The regression equations, linear ranges, and correlation coefficients of seven standards are summarized in Supporting Information Table S1. Recovery experiments were repeated three times. The samples were spiked with known amounts of the standards during the extraction. Mean values for the recoveries of EGCG, ECG, EGC, EC, GC, C, and GCG were 97.5% ± 2.6%, 96.9% ± 2.2%, 98.8% ± 4.1%, 97.3% ± 2.6%, 95.2% ± 6.5%, 96.4% ± 3.3%, and 93.1% ±

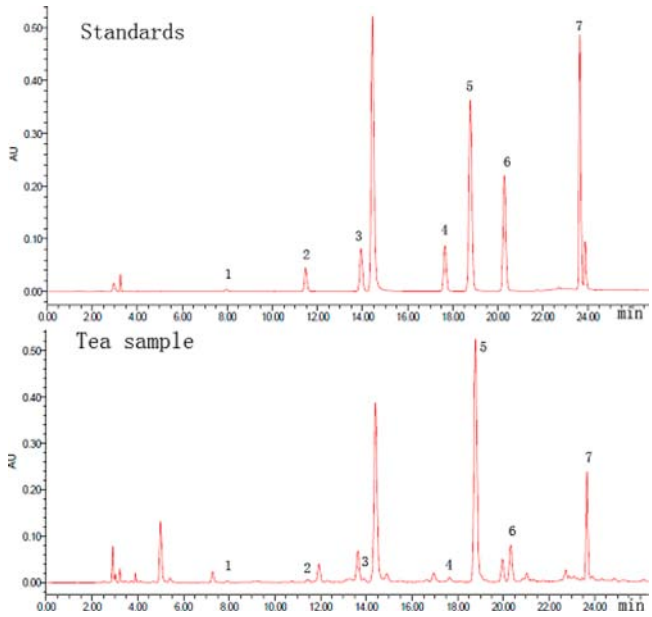

**Figure 2.** Chromatograms of standards and of a typical tea sample. 1, (+)-gallocatechin (GC); 2, (−)-epigallocatechin (EGC); 3, (+)-catechin (C); 4, (−)-epicatechin (EC); 5, (−)-epigallocatechin gallate (EGCG); 6, (−)-gallocatechin gallate (GCG); and 7, (−)-epicatechin gallate (ECG).

[a]The catechin content of each accession was the mean of two years. C, (+)-catechin; EC, (−)-epicatechin; ECG, (−)-epicatechin gallate; EGC, (−)-epigallocatechin; EGCG, (−)-epigallocatechin gallate; GC, (+)-gallocatechin; GCG, (−)-gallocatechin gallate; TC, total catechins; min, minimum value; max, maximum value; SD, standard deviation; CV, coefficient of variation; and $H'$, diversity index.

1.9%, respectively. The TC content was calculated as the sum of the above seven individual catechins.

**Statistical Analysis.** The results were analyzed by using SPSS 13.0 (SPSS Inc., Chicago, U.S.A.) statistical software. Differences among means were evaluated using Tukey's test. Factor analysis was performed using the method of principal component extraction to derive the factor matrix. The structure of the original factor matrix was simplified using Varimax rotation. A scatter plot of the first two factors was prepared to bring out their distribution in the factor space represented by these two factors.[26] The overall entry mean ($X$) and standard deviation ($\sigma$) for the parameters examined in this study were used to subdivide the accession values ($x_i$) into ten frequency classes ranging from class 1 (if $x_i < X - 2\sigma$) to 10 (if $x_i > X + 2\sigma$), with class interval of $0.5\sigma$.[27] The diversity of each parameter was estimated by using the Shannon−Weave index ($H'$),[28] expressed as $H' = -\Sigma\, P_i \ln P_i$, where $P_i$ is the proportion of the total number of entries in the $i$th class.

## RESULTS

**Variation in Catechin Content among Different Germplasms.** The variation and distribution for catechins contents of the 403 accessions are summarized in Table 1. Wide variation and diversity of the Chinese tea germplasms were observed. The average TC content was 154.5 ± 18.1 mg/g, varying from 56.6 to 231.9 mg/g, and that of the 396 accessions ranged from 120.0 to 200.0 mg/g (Tables 1 and 2). EGCG was the most abundant catechin (60.9%), its amount averaging 94.1 ± 14.6 mg/g; ECG, EGC, EC, GC, C, and GCG were next in abundance.

Table 2. Variation in Total Catechin Content among Tea Germplasms in China

| catechins (mg/g) | accessions | percent (%) |
|---|---|---|
| <120 | 4 | 1.0 |
| 120.1−140.0 | 80 | 19.9 |
| 140.1−160.0 | 178 | 44.2 |
| 160.1−180.0 | 106 | 26.3 |
| 180.1−200.0 | 32 | 7.9 |
| >200.1 | 3 | 0.7 |
| total | 403 | 100 |

Levels of TC, EGCG, ECG, EC, and EGC in the 403 accessions had a normal distribution and their $H'$ values were high (>1.85) (Table 1). In contrast, minor components such as GC, C, and GCG did not have a normal distribution and their $H'$ values were lower, although their coefficient of variation (CV) was higher. Through this study, several valuable transnormal tea germplasms were found in the 403 accessions, including one low-TC (<60 mg/g) and three high-TC (>200.0 mg/g) accessions.

**Variations in Catechin Content among the Three Varieties of *C. sinensis*.** Average values of the TC content of *sinensis*, *assamica*, and *pubilimba* varieties of *C. sinensis* (L.) O. Kuntze were 152.9 ± 16.2 mg/g, 162.8 ± 22.3 mg/g, and 165.1 ± 21.3 mg/g, respectively (Table 3). The TC content of the *assamica* and *pubilimba* varieties was significantly higher than that of the *sinensis* variety. Data in Table 3 clearly illustrate that there were statistically significant differences ($P < 0.05$) in the catechin content among the three varieties. The *assamica* variety had the highest levels of ECG and EC and the lowest levels of EGCG and GCG, whereas the *pubilimba* variety had the highest levels of EGCG, GC, C, and GCG and the lowest levels of EGC and EC. In particular, the GCG content of the *pubilimba* variety was 6−9 times higher than that of the other two varieties (Table 3). The CI value of the *assamica* variety was significantly higher ($P < 0.05$) than those of the *pubilimba* and *sinensis* varieties. The CI value of more than half of the accessions for the *assamica* variety was higher than 0.45.

Table 3. Catechin Profile of Three Varieties of *C. sinensis*[a]

| | var. *sinensis* ($n$ = 320) | var. *assamica* ($n$ = 21) | var. *pubilimba* ($n$ = 30) |

All units except those for CI are in mg/g. [a]Values are mean ± SD. Means within each line that are followed by the same letter are not different at $P \geq 0.05$, based on Tukey's honestly different significance test.

On the basis of the 9 catechin patterns of 371 tea accessions of *C. sinensis*, factor analysis was performed. The percentage variances explained by the first three factors are given in Table 4. These three factors together accounted for 81.9% of the total variance. GC, C, and GCG largely influenced the first factor, ECG, and CI dominated the second factor, while the third factor was largely associated with EGCG and TC. Spatial

distribution of 371 tea accessions of *C. sinensis* in relation to first two factors is presented in Figure 3. Most of the accessions from the *sinensis*, *assamica*, and *pubilimba* varieties were in groups I, II, and III, respectively.

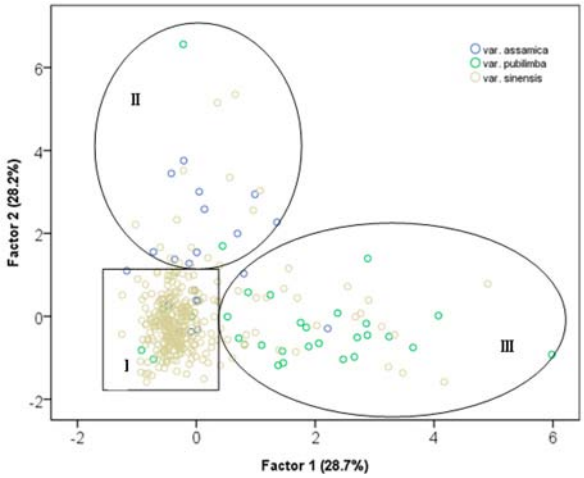

**Figure 3.** Spatial distribution of 371 accessions of *C. sinensis* in relation to the first two factors.

**Variation in Catechin Content of Germplasms from Different Geographical Origins.** The levels of main catechin constituents in the germplasms collected from various provinces were significantly different ($P < 0.05$, Table 5). Catechin levels were affected by the geographical origin of the tea plant. Germplasms from Henan province had the highest mean TC content (167.0 ± 14.6 mg/g), and those from Jiangsu had the lowest (141.6 ± 10.6 mg/g) (Table 5). The TC content of samples tended to decline from the southern to the northern provinces, with the exception of Henan. Henan had the highest average EGC and EGCG content, and the lowest mean ECG content. The highest mean ECG and combined EC and C contents were observed in germplasms from Yunnan. The CI value of genetic resources from Yunnan was significantly higher ($P < 0.05$) than that of the others (Table 5).

To survey the differentiation level of catechins among germplasms from the different provinces, 10 provinces with large number of accessions were selected for statistical analysis and comparison (Figure 4). Because of the differences in sample sizes, the calculation was based on a random selection of 18 accessions from each province. This selection was repeated three times for comparison. Samples from Yunnan province showed the highest differentiation level ($H' = 1.89$, CV = 15.6%), and those from Guangxi province had next highest level ($H' = 1.87$, CV = 13.5%). Those from Zhejiang and Fujian provinces had the lowest $H'$ (1.39) and CV (7.5%), respectively. These results indicate that tea germplasms from the southern provinces had higher differentiation levels of TC.

## DISCUSSION

There were significant differences in the composition of catechins among the three varieties of *C. sinensis*. The CI value, a measure of the difference in catechin composition, has been proven to be affected by the genetic background.[22−24] The CI value of the *assamica* variety was significantly higher ($P < 0.05$) than those of the *pubilimba* and *sinensis* varieties. C and GC are mainly derived from leucocyanidin through a reaction catalyzed by leucoanthocyanidin reductase (LAR) instead of anthocyanidin reductase, as in the case of EC, ECG, EGC, or EGCG.[29,30] The higher GC and C content of the *pubilimba* variety might be attributed to changes in the LAR activity. Factor analysis result based on the catechins as phenetic markers shows that it is basically consistent with morphological classifications, and catechins can be utilized for quantitative data to determine the characteristics of tea plant.

Catechins are converted from nonesterified to esterified derivatives during flavan-3-ol biosynthesis.[31] Catechol or dihydroxy derivatives of catechins such as EC and C are found mostly in primitive tea plants.[31,32] The present study showed that Yunnan germplasms had the highest sum of EC and C contents, suggesting that these are more primitive than those from the other provinces. The genetic diversity decreased from the central region (Yunnan and Guangxi provinces) toward the northern and eastern regions, as revealed by expressed sequence tags based on simple sequence repeat (EST-SSR) markers.[1] Among the 10 provinces investigated, those from the southwestern provinces Yunnan and Guangxi had the highest differentiation level of TC, whereas those from Fujian and Zhejiang had the lowest differentiation level. Results for TC differentiation level show a similar tendency for the genetic diversity.

Depending on the type of processing, which mainly differ in the oxidization degree of the catechins, tea is generally divided into green, white, oolong, black, yellow, and dark varieties. Each tea variety has a unique character, taste, and chemical profile.[33] Different tea cultivars are suitable for different types of tea, and catechins are important factors for the quality of tea.[16−19] This study provides comprehensive information on the catechin content of Chinese tea germplasms, as well as useful guidance for tea manufacturing. Germplasms with high catechin content have been used as commercial raw materials for extracting functional components. Their extraction ratio is higher than that of conventional materials.[7] The TC content increased by ~40 mg/g or 26% from spring to autumn (data not shown). Therefore, autumn tea leaves might be of greater potential use in the extraction of natural catechins. Among the genetic resources of tea with varied catechin contents, germplasms with high catechin content are useful as breeding materials for black and green tea.[34] For black tea, the target individuals might be selected from progenies resulting from crosses between accessions with high catechin content and cultivars of *assamica*

possess fewer hydroxyl groups on the B ring.[17] Although the detailed molecular mechanisms underlying the inhibitory effects of flavonoids remain unclear, these results suggest that differences in hydroxyl groups contained within the flavonoid structure may influence the formation of hydrogen bonds between A$\beta$ and its hydroxyl arms, and is possibly the key determinant of antiamyloidogenic activity.[17]

Many of the currently investigated small-molecule inhibitors act as general antiamyloid agents, which affect a range of amyloidogenic proteins.[18−20] Although the property of non-specificity is typically not desirable for drug design, it can offer the possibility of broad-spectrum therapeutics, but only provided there is no effects on functional human fibrous proteins such as those that constitute the cytoskeletal system. Currently myricetin has been demonstrated as exhibiting antiamyloidogenic activity against A$\beta$, $\alpha$-synuclein, IAPP.[17,21,22] We sought to assess further the general nature of inhibitory activity by investigating whether myricetin could inhibit fibril formation *in vitro* of hen egg white lysozyme. HEWL has two domains, $\alpha$ and $\beta$, and each consists of four $\alpha$-helices and an antiparallel $\beta$-sheet. Its structure is highly homologous to human lysozyme, which is responsible for the formation of systemic amyloidosis.[23]

In this study, thioflavin T (ThT) fluorescence assays and transmission electron microscopy (TEM) were used to detect and assess the inhibitory activity of myricetin upon fibril formation by HEWL. Additionally, the interaction between myricetin and the monomeric form of HEWL was investigated using a combination of anilinonaphthalene-8-sulfonic (ANS) and intrinsic fluorescence assays coupled with *in silico* simulations.

## MATERIALS AND METHODS

**Proteins and Reagents.** HEWL was purchased from Solarbio (Beijing, China). ThT, ANS, myricetin, and quercetin were purchased from Sigma-Aldrich (St. Louis, MO, USA).

**HEWL Sample Preparation.** A stock solution of myricetin (50 mM) was prepared in dimethyl sulfoxide (DMSO). HEWL sample solutions were prepared by dissolving 1 mg of HEWL powder in 1 mL of 50 mM glycine−hydrochloric acid buffer (pH 2.0) with or without an aliquot of myricetin solution. The final concentration of DMSO in HEWL sample solution is 0.2%, of which we confirmed that 0.2% DMSO had no obvious effect on fibrillar structure and ThT fluorescence. Incubation was carried out with constant agitation at 140 rpm at 65 °C during the course of aggregation.

**Thioflavin T Fluorescence Assay.** Phosphate buffer (50 mM $Na_2HPO_4$, 50 mM $NaH_2PO_4$, pH 7.0) was used to dissolve ThT to a stock concentration of 1 mM. Aliquots of HEWL samples taken at different times were diluted with phosphate buffer (pH 7.0), followed by the addition of an aliquot (30 $\mu$L stock solution) of ThT stock solution. ThT fluorescence measurement was conducted by exciting the sample at 440 nm and recording the emission intensity at 485 nm over 120 s. The measurement was carried out using a Cary Eclipse fluorescence spectrophotometer (Varian, Palo Alto, CA, USA).

**Intrinsic Fluorescence Assay.** Steady state intrinsic fluorescence spectrum was measured with a Cary Eclipse fluorescence spectrophotometer (Varian) using a quartz cuvette with a path length of 1 cm. HEWL samples (30 $\mu$L) with or without myricetin were diluted to a final volume of 3 mL and then subjected to analysis. The sample was excited at 280 nm, and the spectrum was recorded between 300 and 500 nm.

**ANS Fluorescence Assay.** A stock solution of ANS (0.4 mM) was prepared by dissolving ANS in phosphate-buffered saline (PBS; pH 7.0). The ANS stock solution was stored at 4 °C. Aliquots of HEWL solution with or without myricetin taken at different times were mixed with an aliquot of ANS solution, followed by the addition of PBS (pH7.0) to a final of volume of 3 mL. After incubation in the dark for 30 min at room temperature, the samples were subjected to fluorescence assay using a Cary Eclipse fluorescence spectrophotometer (Varian). The samples were excited at 380 nm, and fluorescence was recorded between 400 and 600 nm. Both the ANS fluorescence intensity and the average emission wavelength were recorded to account for the changes in intensity and spectrum. We confirmed that myricetin had no obvious effects on ThT, ANS, and intrinsic fluorescence.

**Transmission Electron Microscopy.** HEWL samples with and without myricetin were diluted 5-fold, and 10 $\mu$L of each sample was dispensed onto a coated copper-mesh grid. The grid was negatively stained with 1% (w/v) phosphotungstic acid and then observed with a Hitachi H-7650 transmission electron microscope with an accelerating voltage of 80 kV.

**Molecular Dynamic Simulations and Docking Studies.** All molecular dynamics (MD) simulations were carried out using the GROMACS 4.0.7 software package.[24] The crystal structure of HEWL (PDB entry 1GXV) was downloaded from the Protein Data Bank (PDB).[25] The GROMOS96 43a1[26] force field was adopted in all simulations in this study. The monomer model was solvated in a water box containing 10,124 simple point-charge water molecules[27] and neutralized by adding eight $Cl^-$ counterions. The linear constraint solver method[27] was used to constrain the bond length, allowing for integration time steps of 2 fs throughout the whole simulation. Electrostatic interactions were calculated with the particle-mesh Ewald algorithm.[28] A cutoff of 9 Å was used for all calculations. The solvated and neutralized systems were then energy-minimized for 20,000 steps to remove bad contacts. Then the side chains and solvent were allowed to move unrestrained for 40 ps, with the backbone atoms of the structure fixed. To investigate the structural fluctuation of HEWL under amyloid fibril forming conditions, MD simulations at 338 K and pH 2.0 were carried out. For the control, a physiological condition of 310 K and pH 7.0 was used. After equilibration, two independent simulations were carried out for 20 ns.

Docking studies were performed using Autodock 4.2.5.1. The 3D structure of myricetin was obtained from TCM Database@Taiwan.[29] Prior to autodocking the HEWL molecule and myricetin were prepared using AutoDockTools 1.5.4, including addition of polar hydrogen atoms and setting the charges of HEWL residues using Kollman charges and adding Gasteiger charges to myricetin.

The docking grids were carried out with a default spacing value of 0.375 Å and a grid volume of 60 × 60 × 60 points covering the entire surface of HEWL. The protein molecule was set to be rigid while the ligand molecule was considered to be flexible. In the docking simulation, a Lamarckian geneti algorithm was used to generate 50 binding models, each of which was individually selected as the lowest binding energy (calculated using the Autodock scoring function) among a maximum of 2,500,000 evaluations. These 50 complexes were clustered according to their root-mean-square deviation (RMSD) values and binding energies in order to distinguish the preferred binding model.

**Statistical Analysis.** All experiments were performed at least three times, and all data are presented as means ± standard deviations (SDs). Comparisons between groups were tested by one-way ANOVA analysis. Statistical significances of data were considered at the $P < 0.05$ level.

## RESULTS

**Analysis of HEWL Fibril Formation Using ThT Fluorescence.** HEWL is a model protein for amyloid research as it is known to readily form fibrils under conditions of low pH and elevated temperature, when coupled with mechanical agitation.[30] By monitoring the kinetics of HEWL fibril formation by fluorescence spectroscopy, we found that the relative fluorescence of HEWL increased with extended incubation times (Figure 2A), which is in agreement with previous studies.[31] The consistent increase in ThT fluorescence intensity observed when HEWL was incubated alone, demonstrates that formation of amyloid fibrils proceeded rapidly and without a lag phase (Figure 2A). The inhibitory effect exerted on the formation of HEWL fibril by the addition of myricetin (100 $\mu$M) into the assay resulted in a strong inhibition of HEWL fibril formation (Figure

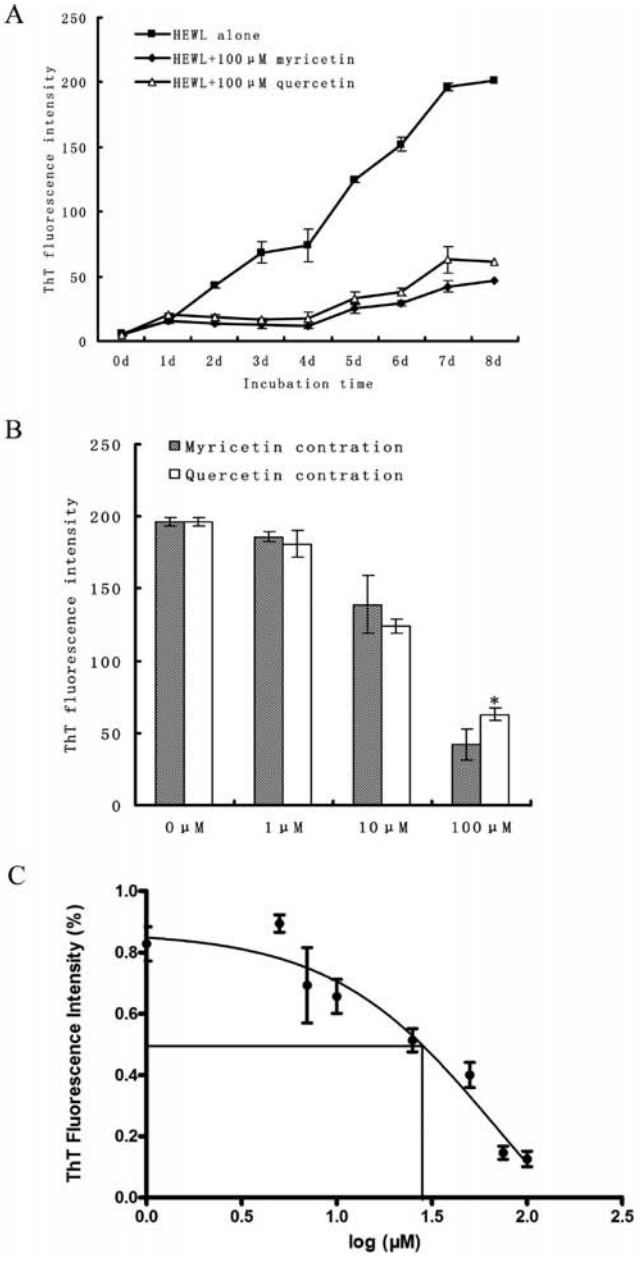

**Figure 2.** Effects of myricetin and quercetin on amyloid formation by HEWL: (A) the kinetics of HEWL fibril formation in the absence (filled squares) or the presence of myricetin (filled diamonds) or quercetin (filled upward triangles) as monitored by ThT fluorescence; (B) dose-dependent inhibitory capacity of myricetin and quercetin on amyloid formation by HEWL 7 days after incubation; (C) dose–response curve plotting the plateau value of the ThT fluorescence intensity of the HEWL sample against myricetin concentration.

2A). Compared to quercetin-containing HEWL samples (the positive control group), myricetin showed a reproducible moderately stronger inhibition.

To determine an effective concentration range of myricetin for inhibiting HEWL fibril formation, varying aliquots of myricetin were mixed with HEWL to final concentrations of 1, 10, and 100 $\mu$M; at these concentrations we did not observe significant toxic effects of myricetin on cell survival (data not shown) and the ThT fluorescence intensity measured (Figure 2B). Myricetin (and quercitin control) was observed to exhibit a dose-dependent effect on HEWL fibril formation (Figure 2B). Although fibril inhibition was observed up to a concentration of 10 $\mu$M, major inhibitory effects were only observed at a concentration of 100 $\mu$M, indicating effective fibril inhibition occurs between these two concentrations. Importantly, at 100 $\mu$M the inhibitory effect of myricetin on HEWL fibril formation was significantly stronger ($p$-value = 0.037626 < 0.05) than that previously obtained with quercetin (Figure 2B), the positive control.

By calculating the percentage of protection from the ThT curve of HEWL alone and fitting a logarithmic concentration–response curve, myricetin inhibited HWEL fibril formation with a median effective concentration (IC50 value) of 28.2 $\mu$M (Figure 2C).

**Assessing Structural Changes during HEWL Fibril Formation.** ANS is a fluorescencent dye that has high affinity for the hydrophobic surfaces of proteins. Upon binding to the hydrophobic regions of a protein surface, the intensity of the light emission is increased, with the emission maximum showing a blue shift.[32] This technique allows changes in the hydrophobic core and the stability of a whole protein to be monitored during the course of aggregation. As shown in Figure 3A, a significant

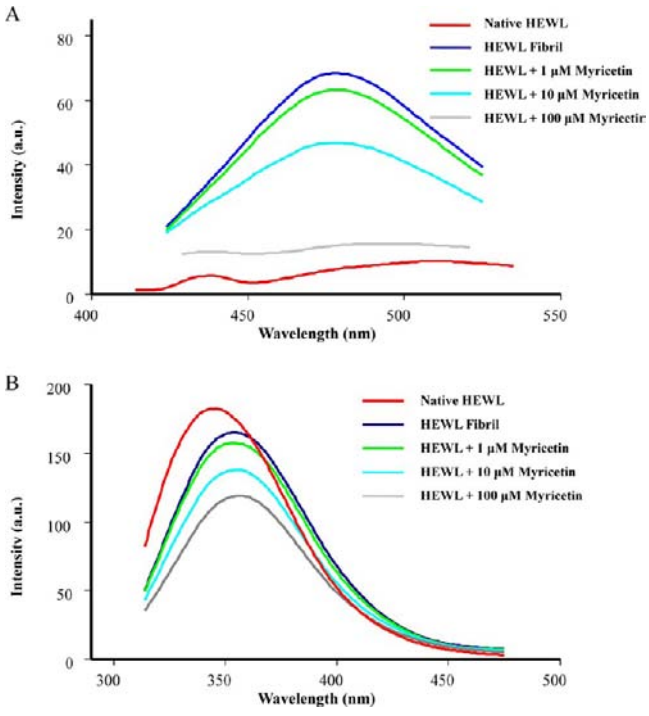

**Figure 3.** (A) ANS fluorescence emission spectra of HEWL fibril incubated with (pink) or without (red) myrecetin after incubation for 7 days. (B) Intrinsic fluorescence emission spectra of HEWL fibril in the absence (red) and presence (purple) of myricetin after incubation for 7 days.

blue shift from 515 to 473 nm and increase in intensity of ANS fluorescence, compared to native HEWL, is caused by HEWL fibril formation. The addition of 100 $\mu$M restores HEWL fibril ANS intensity to levels comparable with the native protein.

Variation in the microenvironment of tryptophan residues and monitoring the intrinsic fluorescence of a protein allow assessment of structural characteristics.[33] To further probe the effect of myricetin on the conformation of HEWL, the intrinsic fluorescence of HEWL in the absence or presence of myricetin was measured. A decreased intensity in intrinsic fluorescence of

dx.doi.org/10.1021/jf5025449 | J. Agric. Food Chem. 2014, 62, 9442–9449

HEWL fibril group with a shift from 344 to 355 nm was observed compared to the native HEWL group (Figure 3B). This indicated that tryptophan in HEWL became more accessible to solvent during the process of fibril formation, resulting in the quenching of fluorescence by water.[34,35] However, the presence of myricetin significantly reduced the fluorescence intensity during fibril formation (Figure 3B). The quenching of intrinsic fluorescence may possibly result from the interactions between aromatic residues of myricetin and the aromatic residues of target proteins.[36,37]

**Physical Analysis of HEWL Fibril formation.** Direct information on the formation of fibril by HEWL as well as by the antifibrillogenic activity of myricetin was obtained using TEM. The morphology of HEWL fibers and/or aggregates in the absence or presence of myricetin is shown in Figure 4A–G. In the absence of myricetin or quercetin, HEWL displayed straight and regular premature or mature amyloid fibril structures with typical diameters ranging from 2 to 20 nm and several micrometers in length (Figure 4A,E). The presence of quercetin (Figure 4B) clearly resulted in reduced amounts of HEWL fibrils. In contrast, the presence of myricetin resulted in formation of amorphous aggregates, with virtually no HEWL fibrils being observed (Figure 4C). This result provides further evidence that myricetin exhibits a stronger inhibition against fibril formation by HEWL compared to quercetin. To elucidate the physical nature of myricetin fibril inhibition, by using TEM we also examined HEWL fibril formation and myricetin inhibition with prolonged incubation time and found 25 $\mu$M myricetin (close to IC50 value) incubated with HEWL resulted in a reduced amount of amyloid fibril after 12 days incubation (Figure 4G). In contrast, the presence of 100 $\mu$M myricetin resulted in formation of amorphous aggregates, with virtually no HEWL fibrils being observed (Figure 4D). Taken together, we concluded that the physical nature of fibril inhibition is determined by the concentration of myricetin. We also confirmed that the TEM images of myricetin at 100 $\mu$M show only the deposition of the compound alone and no fibril structure was found (Figure 4H).

**Computational Analysis of HEWL Fibril Formation.** Based on the spectrometric and electron microscopy data, it can be inferred that myricetin inhibition of amyloid fibrils formation of HEWL mainly occurs at a very early stage in the process. To better understand the process of amyloid fibril formation by HEWL as well as the interaction of myricetin with lysozyme at the atomic level, we carried out MD simulations (see Materials and Methods).

Figure 5A compares the degree of conformational changes that occur in HEWL under two different MD simulation conditions, one favoring amyloid fibril formation (338 K and pH 2.0) and the other under normal cellular physiological parameters (310 K and pH 7.0). The backbone RMSD trajectory in fibril-forming condition (represented by the red trace) has a higher value, indicating a less stable state than that in physiological conditions (black trace). The root-mean-square fluctuation (RMSF) of each residue (Figure 5B) revealed a major contribution of the $\beta$-domain (residues from 36 to 87) toward the instability of HEWL under fibril-forming conditions. This is consistent with the dramatic changes of $\beta$-sheet content in the $\beta$-domain observed during the 20 ns MD simulation, particularly the major difference in stability observed after 15 ns compared to changes seen under physiological conditions (Figure 5C). In contrast, the $\alpha$-domain maintained much of the native conformation with the content of $\alpha$-helix being constant (data not shown). From the superposition of the final conformational state following the 20 ns MD simulation, the clear disruption in the $\beta$-domain could be directly observed (Figure 5D).

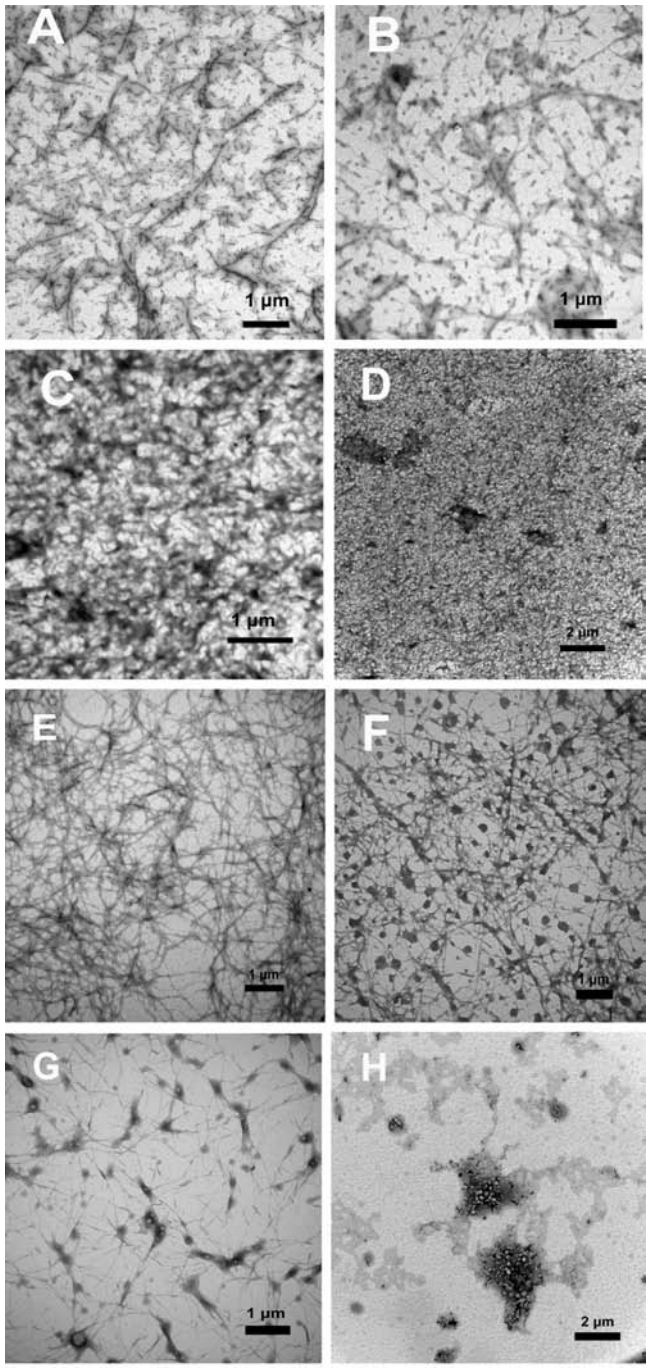

**Figure 4.** Transmission electron microscopic images of HEWL fibrils formed in the absence or presence of myricetin or quercetin, after incubation at 65 °C and pH 2.0 for 7 days or 12 days: (A) HEWL fibril after incubation for 7 days; (B) HEWL fibril in the presence of 100 $\mu$M quercetin; (C) images of HEWL in the presence of 100 $\mu$M myricetin after incubation for 7 days; (D) images of HEWL in the presence of 100 $\mu$M myricetin after incubation for 12 days; (E) HEWL fibril after incubation for 12 days; (F) images of HEWL in the presence of 10 $\mu$M myricetin after incubation for 12 days; (G) images of HEWL in the presence of 25 $\mu$M myricetin after incubation for 12 days; (H) images of 100 $\mu$M myricetin after incubation for 12 days. Scale bars represent 1 and 2 $\mu$m.

To investigate how myricetin may affect the conformation of HEWL, we carried out docking simulations between these two

molecules. According to the docking results, myricetin was located in an area between the $\alpha$-domain and the $\beta$-domain (Figure 6A). The predicted binding site for myricetin on HEWL was clustered around many residues, such as Asn44, Asn46, Asp52, Asn59 and Glu35, Ala107, Val109, and Trp62 and Trp63. The interactions between myricetin and these residues were through van der Waals interactions and hydrogen bonding. Of particular note are the interactions with residues Trp62 and Trp63 in the $\beta$-domain, which could explain the quenching of intrinsic fluorescence (Figure 6B).

## DISCUSSION

Amyloid diseases are either sporadic or familial in their nature. Usually, in the sporadic forms of the diseases the aggregated peptides/proteins display wild-type sequences, while in rarer early onset familial forms of the diseases the aggregation results from genetic mutations that exhibit a greater propensity for aggregation.[38] A major risk factor for most sporadic amyloid diseases is aging.[39] In older people, the age-related decline in cellular proteostasis includes the unfolded protein response, the ubiquitin proteasome system, autophagy, and the encapsulation of damaged proteins in aggresomes, all of which lead to the accumulation of protein aggregates.[40−43] Progression of the aging process means that most kinds of amyloid diseases occur undetected in their early stages. However, an increasing number of research investigations suggest that the intake of diets containing natural small molecules with inhibitory activities toward amyloid fibril formation may help to prevent such diseases or at least delay early onset.[44−46]

Myricetin is a cell-permeable flavanoid often used in inflammatory, diabetes, and cancer studies, since it has a variety of pharmacological properties such as antioxidant activity and an ability to reduce blood sugar levels.[47,48] High-throughput screens for small molecules exhibiting antiamyloidogenic activity demonstrated that myricetin could prevent amyloid fibril formation of A$\beta$, $\alpha$-synuclein, and IAPP. To further develop and characterize myricetin as a potential antiamyloid therapeutic agent, we assessed the ability of this small molecule to inhibit amyloid fibril formation by the model protein HEWL.

The inhibitory effect exerted by myricetin on HEWL fibril formation, as assessed by ThT fluorescence, was greater than the well-characterized polyphenol quercetin (Figure 2A). However,

dx.doi.org/10.1021/jf5025449 | J. Agric. Food Chem. 2014, 62, 9442−9449

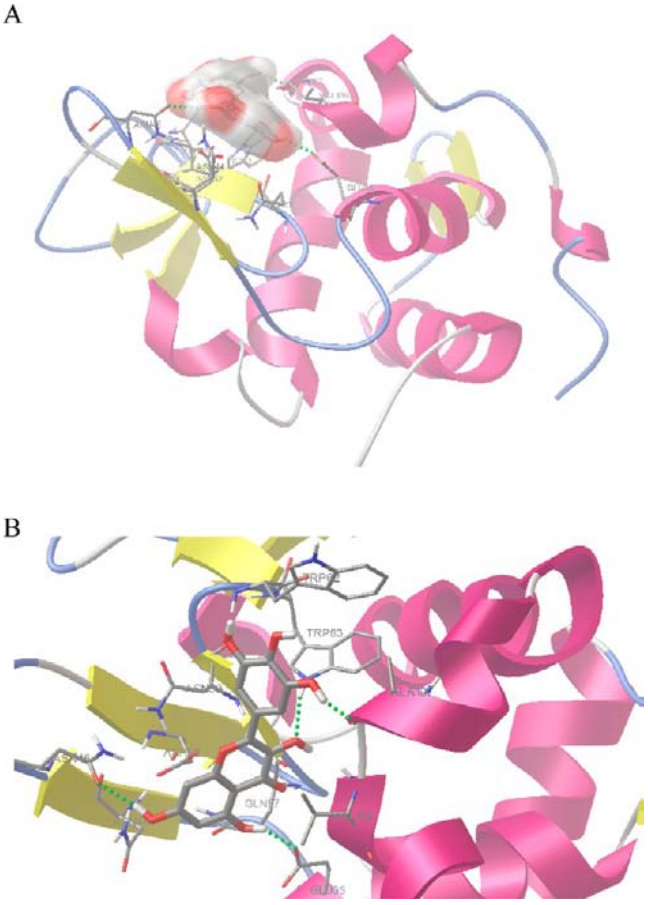

**Figure 6.** (A) Panoramic view showing the mode of binding between myricetin and HEWL. (B) Close-up view of the complex showing the binding between myricetin and HEWL, with hydrogen bonding marked as a green dotted line.

since ThT fluorescence induction can be biased by the presence of exogenous compounds,[49] we also assessed the physical nature of myricetin fibril inhibition using TEM. Incubation of myricetin with HEWL resulted in the formation of amorphous aggregates, with little or no fibrils being observed (Figure 4C,D). This was in contrast to incubation of HEWL in the presence of quercetin, which resulted in a reduction of amyloid fibril formation, but no formation of amorphous aggregates (Figure 4B). The results from the TEM analysis therefore are in agreement with the ThT assay and clearly demonstrate that myricetin inhibits HEWL fibril formation more effectively than quercetin. While these experiments reveal the inhibitory potential of myricetin against amyloid fibrils, they do not provide any information regarding the potential molecular mechanisms underlying this activity. In an attempt to gain insight into the molecular nature of fibril inhibition we turned to well-developed computational approaches.

Previous studies demonstrated that amyloidogenic variants of human lysozyme such as I56T and D67H, undergo transient and local cooperative unfolding in the $\beta$-domain region of the protein, a process that occurs at the early stage of amyloid fibril formation and under physiologically relevant conditions (pH and temperature).[50,51] Furthermore, the local unfolding of $\beta$-domain is considered to be the main trigger for fibril formation. Consistent with previous studies, we observed a similar phenomenon during MD simulations carried out using wild-type HEWL; that is, the localized unfolding of $\beta$-domain appeared to be the key event in inducing fibril formation (Figure 5A–D).

According to Sugimoto and colleagues,[52] a peptide located in the $\beta$-domain of HEWL referred to as K peptide (consisting of residues 54–62 GILQINSRW) was found to act as a core for aggregation and subsequent amyloid fibril formation. Likewise, Lara et al. recently found the shorter peptide sequence ILQINS to be highly amyloidogenic at room temperature.[53] This region of the protein is partially embedded inside the HEWL structure as a pocket in the junction connecting the $\alpha$-domain and the $\beta$-domain. Combined with results from previous studies, our findings in this work indicated that the stability of this region in the $\beta$-domain directly determines the aggregation fate of the entire protein, dictating whether it proceeds to form amorphous aggregates or amyloid fibril. Further understanding of the early events in conformation changes that occur in HEWL unfolding will not only allow a better understanding of the process of HEWL fibril formation but may also enable development of effective ways to inhibit amyloid fibril formation by reducing the ability of HEWL to form locally unfolded intermediates.

Computational approaches to studying how molecules interact are well-established.[54,55] Applying computational docking studies allowed the exploration of the mechanism of myricetin-induced inhibition of HEWL fibril formation. The smaller blue shift and reduced fluorescence intensity observed by ANS fluorescence assay, an indicator of a less hydrophobic core exposed to solvent, suggested that myricetin could stabilize the whole conformation of HEWL even though it was subjected to fibril-forming conditions (Figure 4A). The docking study revealed that the HEWL binding site for myricetin is located in the region that partly includes the K peptide located between the $\alpha$-domain and the $\beta$-domain (Figure 6A), the key region associated with amyloid fibril formation. A plausible explanation for the inhibitory action of myricetin is a reduction of locally unfolded intermediates, which in turn will reduce the propensity for amyloid fibril formation. In this binding mode, myricetin may be acting as an adhesive via hydrogen bonding and van der Waals interaction to glue the aggregation-prone region of the $\beta$-domain with the otherwise stable $\alpha$-domain, consequently resulting in a reduced population of transiently $\beta$-domain unfolded intermediates. Thus, no formation of amyloid fibril would occur under this condition. However, further biophysical experimentation is required to fully address the mechanism of fibril inhibition.

Support for the authenticity of the binding site for myricetin, derived from the docking study, is supported by the experimental data from the intrinsic fluorescence assay. Results from the intrinsic fluorescence assay showed that the interaction between the aromatic residues of myricetin and HEWL could account for the quenching of intrinsic fluorescence (Figure 3B). The normalized fluorescence changes versus the different incubation time appeared almost the same for the emission spectra obtained from excitation at 280 and 295 nm (data not shown), indicating that the quenching of fluorescence can be attributed to Trp residues. Taken together with the fact that Trp62 is one of the two dominant emitters (the other is Trp108),[56] the binding site which is located close to Trp62, identified by the docking study, is very likely to be the real scenario. This is consistent with previous investigations in which certain small molecules with inhibitory activity toward HEWL fibril formation, such as EGCG, EUK-8, and EUK-134 (two kinds of salen–manganese complexes) were also suggested to bind to Trp62 and Trp63 in docking studies.[10,57,58] Taken together, our findings provided a plausible rationale by which fibril formation by HEWL could be

dx.doi.org/10.1021/jf5025449 | J. Agric. Food Chem. 2014, 62, 9442–9449

inhibited by small molecules by targeting the aggregation-prone regions in monomers of this amyloidogenic protein.

Human lysozyme is a bacteriolytic enzyme. According to the Phillips mechanism,[59] the amino acid side chains glutamic acid 35 (Glu35) and aspartate 52 (Asp52) have been found to be critical to the activity of this enzyme. Our docking study predicted that the binding site for myricetin on HEWL was clustered around many residues, such as Asn44, Asn46, Asp52, Asn59 and Glu35, Ala107, Val109, and Trp62 and Trp63. Thus, it is possible that myricetin docking with lysozyme could inhibit its physiological functions to some extent; however, detailed inhibitory studies need to be carried out to determine at what concentration of myricetin is safe and efficient for dietary flavonol consumption or as a drug candidate. It is important to note that fibrillar tangles as well as amorphous aggregates can be cytotoxic;[60,61] also, a recent study on HEWL amorphous aggregates has demonstrated that Cu(II) directs formation of toxic amorphous aggregates resulting in inhibition of HEWL fibrillation under alkaline-salt-mediated conditions.[62] The potential cytotoxicity of amorphous aggregates of HEWL needs to be assessed in detail to fully appreciate the potential of myricetin as a drug candidate.

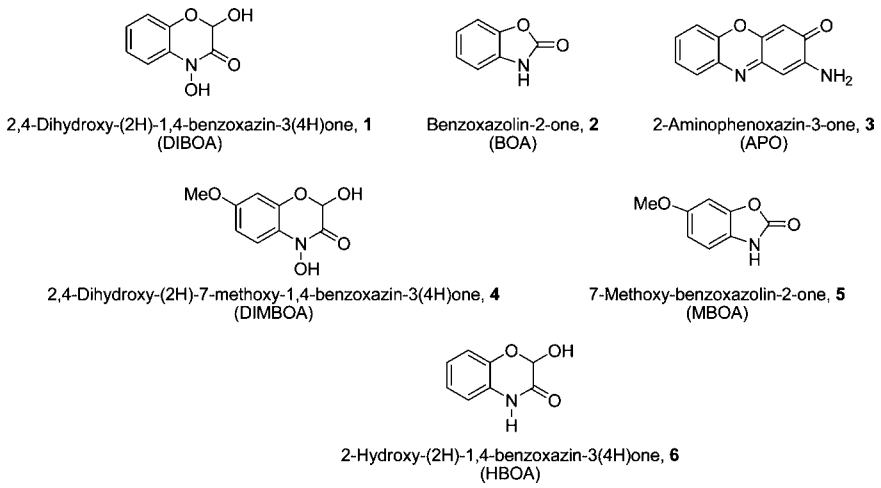

**Figure 1.** Structures of the compounds under discussion.

or their degradation products, as characterized inside the target plant. All of the analyses were conducted in a single bioassay involving a coculture of both species in order to ensure direct and mutual interactions between the donor and target plant. The dynamic character of the different determinations performed adds the value of a real-time description of the various processes that are involved in the allelopathic phenomenon.

The study focused on the interaction of rye (*Secale cereale* L.), as a strategic crop, with one of its most common weeds (wild oat, *Avena fatua* L.). This interaction is mediated by benzoxazinone allelochemicals, and we propose a relevant role for the degradation products on the basis of the experimental results.[9] *S. cereale* is well-known as a producer of 2,4-dihydroxy-(2*H*)$^{-1}$,4-benzoxazin-3(4*H*)one (DIBOA, **1**) (Figure 1). Extensive research has been performed on the phytotoxic effects of this compound and its degradation products benzoxazolin-2-one (BOA, **2**) and 2-aminophenoxazin-3-one (APO, **3**),[10,11] as well as the fate of allelochemicals[12,13] and the physiological aspects of the mode of action.[14−16] (2*H*)-1,4-Benzoxazin-3(4*H*)-ones have been isolated from Poaceae, Acanthaceae, Ranunculaceae and Scrophulariceae plants. Indeed, degradation in different systems, such as aqueous solutions,[7,11,17] microbial biotransformation,[18] or crop soils,[7,11,19,20] has been widely studied along with the dynamics of these systems. In addition, these compounds have shown a wide spectrum of biological activities,[21−24] as have some of their degradation products[25,26] and a wide variety of synthetic analogs.[27] Compounds such as 2,4-dihydroxy-(2*H*)-1,4-benzoxazin-3(4*H*)-one (DIBOA, **1**) and its 7-methoxy analog (DIMBOA, **4**) have been described as chemicals with relevant roles in chemical ecology for the last 50 years.[9] The levels of DIBOA (**1**), BOA (**2**), and APO (**3**) were monitored in *S. cereale*, culture medium, and *A. fatua*, and the results were correlated with the phytotoxic effects observed.

## MATERIALS AND METHODS

**Statistical Analysis.** Data for the lengths of root and shoot were statistically analyzed using Welch's test, with significance fixed at 0.01 and 0.05. The results are represented in bar charts as percentages from the control. Thus, zero represents the control, positive values represent stimulation of the studied parameter, and negative values represent inhibition. The fresh weights of seedlings were determined in triplicate, and the mean and standard deviation were calculated. A similar procedure was followed for endogenous (root and shoot content) and exogenous (exudate content) contents of the different metabolites. The quantitation of DIBOA (**1**), BOA (**2**), and APO (**3**) was carried out in quintuplicate using calibration curves and outlying values were discarded (values out of the range of the spiked value ±20%).

**Bioassays.** *S. cereale-A. fatua Pregermination.* The seeds used for the coculture experiment were surface-sterilized by soaking for 30 min in calcium hypochlorite 75 g/L (Merck, Darmstadt, Germany) with traces of Tween 20 (Sigma-Aldrich, St. Louis, MO, U.S.A.) followed by rinsing with sterilized deionized water. The sterilized seeds were placed in Petri dishes (8.5 mm diameter) containing a semisolid culture medium from Sigma-Aldrich (Agar-agar 7 g/L, Hoagland No. 2 basal salt mixture, pH 5.7). Petri dishes were placed in a growth chamber Celsius 2000 (Memmert, Duesseldorf, Germany) for a 16 h photoperiod at 25 °C, 70% relative humidity, with cold white light (standard illuminant D65; 6500 K). The activities were assessed under sterile conditions.

*S. cereale-A. fatua Coculture.* The bioassay substrate was designed by considering two criteria: an accurate simulation of the field interaction conditions and ease of monitoring the exuded chemicals. Glass perlite (3 mm diameter, 200 g) was placed in a glass flask (2.5 L) and culture solution (Hoagland No. 2 basal salt mixture, pH 5.7, 300 mL) was added. Glass perlite was chosen due to its negligible interference on the analysis by adsorption or absorption of the test solution and also because it minimizes the sample conditioning operations required prior to analysis. In this respect, a simple filtration was sufficient, and this avoided the need for extraction processes with organic solvents. Minimization of the absorption or adsorption of chemicals also enhances their bioavailability. Seedlings of *A. fatua* (3 d old) and *S. cereale* (6 d old) were placed inside the flasks, and they were allowed to grow for 6 d. The number of *A. fatua* seedlings was fixed at 4 and the number of *S. cereale* seedlings was set up according to the following donor/target plant ratios: 1:1, 2:1, 3:1, 7:1, 10:1, and 20:1. These donor/target proportions were optimized for maximum effect by performing bioassays under identical culture conditions. *A. fatua* and *S. cereale* monocultures, prepared under analogous conditions, were used as controls for phytotoxicity and DIBOA (**1**) production measurements.

*Phytotoxicity Parameters.* Phytotoxicity on *A. fatua* was measured by comparing its root length, shoot length, and shoot fresh weight after exposure to *S. cereale* seedlings under the experimental conditions described above. In addition, potential effects of *A. fatua* on *S. cereale* were studied and described in terms of root length, shoot fresh weight, and DIBOA (**1**) content.

**Analytical Method.** DIBOA (**1**), BOA (**2**), and APO (**3**) levels in culture solution were recorded using the previously described HPLC-DAD method.[28] Quantitation was performed using a method with an external standard. BOA (**2**) was purchased from Fluka Chemika Co.

dx.doi.org/10.1021/jf503840d | J. Agric. Food Chem. 2014, 62, 9450−9457

(Sigma-Aldrich, St. Louis, MO, U.S.A.). DIBOA (**1**) and APO (**3**) standards were obtained by the previously described methodology.[29] Compounds were identified by comparison of retention times and UV/vis spectra at two wavelengths, namely 253 and 264 nm (95% confidence), using external and internal standards. A single analysis therefore provided a description of the chemical situation of the whole system at a given time, and subsequent repetition of the analysis provided a complete description of the chemical evolution in terms of production and exudation by the donor plants (*S. cereale*), assimilation by the target plant (*A. fatua*) and degradation or retention by the environment.

**DIBOA Detection and Quantitation in *A. fatua*.** These experiments were performed on a Inova 600 NMR spectrometer (Varian, Palo Alto, CA, U.S.A.) equipped with an interchangeable triple-resonance microflux probe (Varian $^{1}H[^{13}C/^{15}N]$ 3 mm pulsed-field gradients PFG, 60 $\mu$L active volume) and connected to a Varian HPLC-UV/MS system (Varian 1200L quadrupole mass spectrometer, Varian HPLC-UV system). The UV/vis outlet was connected to the NMR equipment by means of a Rheodyne sampling unit. Stop-flow experiments were performed by using a Valco stop-flow valve. This valve was controlled by the LC-NMR software, considering the UV/vis and NMR detector delay. Liquid chromatography was carried out using an analytical column 150 mm × 4.6 mm i.d., 5 $\mu$m Gemini 110A RP-18 (Phenomenex, Torrance, CA, U.S.A.) with a guard column SecurityGuard Cartridges Gemini RP-18 (Phenomenex, Torrance, CA, U.S.A.) under reverse phase and isocratic conditions with a mixture of MeOH (1% TFA):$H_2O$ (1% TFA) (7:3). Gradient separation was performed using (A) MeOH;1% TFA and (B) $H_2O$;1% TFA with the following elution pattern: $t_0$ = 30% B; $t$ = 40 min, 100% B. The system was operated at room temperature and the eluent flow was set to 0.8 mL/min. $^{1}H$ NMR spectra were recorded under on-flow and stop-flow conditions for standard solutions and *A. fatua* tissue extracts, respectively. Solvent suppression was performed by using the WET2 method. Thirty-two NMR accumulations were used for standards and 256 for samples. The spectral width was set to 10 000 Hz in all experiments. WETG-COSY spectra were acquired using 48 accumulations, 128 and 2 K increments with a 10 000 Hz spectral width in both dimensions and a 1 s relaxation time. $CD_3OD$ was used as the solvent and the residual MeOH peak ($\delta$ 3.30 ppm) was used as a reference. A 10 $\mu$L injection of an equimolecular mixture of DIMBOA (**4**), DIBOA (**1**), BOA (**2**), and MBOA (**5**) (standard solution) was carried out. *A. fatua* methanol extracts were used for allelochemical detection and these were injected at a concentration of 3 mg/mL.

## RESULTS AND DISCUSSION

**Experimental Design.** The overall objective of this study was to characterize completely the allelopathic pathway with living plants and real exudates. To achieve this aim, we developed an experimental design that balances two factors: to model the real phenomenon under laboratory conditions and to mimic the real situation as closely as possible. The design allowed us to record the following information: the release of allelochemicals into the culture substrate in bioactive concentrations, monitorization of the degradation phenomena, identification of the final products, detection of the uptake of the "bioactive cocktail" by the target plant, and, finally, a beneficial or detrimental effect described using appropriate parameters. The experimental design was optimized by fixing the following elements: allelochemicals, donor plant, target plant, and substrate.

**Donor Plant Selection.** Wheat, rye, and maize have shown allelopathic effects, and they produce benzoxazinones. Farmers have taken advantage of these properties by employing them for crop rotation and by using their residues to treat the soil.[30] The activities of some mulches have also been tested. The effects of soil-incorporated wheat on the germination of 12 different weed species have been studied.[31] These allelochemicals have two desirable features for the present study: first, it is possible to measure accurately their concentrations in the donor plant, target plant, and the environment in which they grow; second, their degradation products are known and can be measured simultaneously with the initially released allelochemicals. Fortunately, a great deal of research has been focused on the bioactivity and biodegradability of these compounds and this has led to one of the most in-depth studies published to date.[27]

A key point in the selection of the donor plant is the stability of the allelochemicals present. Thus, the persistence of DIBOA (**1**) in soil and other environments is much higher than that of DIMBOA (**4**). The half-life of DIBOA (**1**) is 62 h in soil, 48 h in water and 12 h in bioassay media,[7] whereas the corresponding values for DIMBOA (**4**) are 31 min, 18 and 8 h, respectively.[11] Wheat and rye both produce DIMBOA (**4**) and DIBOA is also produced in the case of wheat. A higher level of activity was found in *S. cereale* and the major benzohydroxamic acid produced for this species is the more stable DIBOA (**1**).[32] These facts led us to select *S. cereale* as the donor plant.

**Target Plant Selection.** It has been reported that the following plant species, among others, are sensitive to DIBOA (**1**): *Lepidium sativum*, *Eruca sativa*, *Lactuca sativa*, *Sinapis alba*, *Vicia hirsute*, *Spinacia oleracea*, *Raphanus sativus*, *Brassica rapa* var. *oleifera*, *Lolium rigidum*, *Brassica rapa* var. *esculenta*, *Avena fatua*, and *Echinochloa crus-galli*. Exploratory bioassays were performed in order to select the target species and *Avena fatua* was found to be the optimal model for several reasons: this weed has rapid growth and biomass development (which facilitates extraction and analysis) and it has been used for phytotoxicity tests under field conditions for *Secale cereale* and *Triticum aestivum*. Finally, this species interacts in the field with Gramineae crops and is classified as one of the most problematic weed species.

**Influence of Seedling Density on the Experimental Design.** Phytotoxicity data recorded on *A. fatua* for the different *S. cereale* seedling densities are shown in Figure 2.

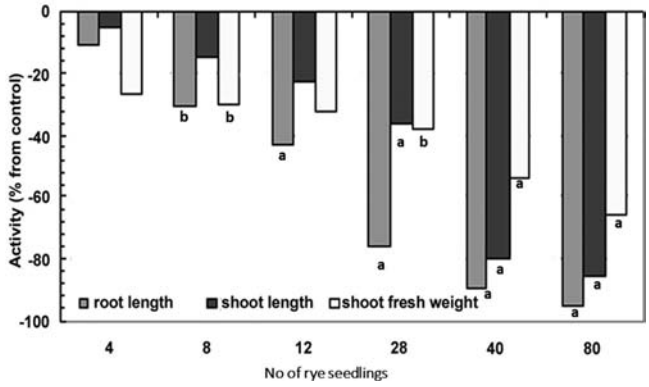

**Figure 2.** Phytotoxic activity on *A. fatua* seedlings in coculture bioassay with *S. cereale*.

Dose–response effects could be observed and mathematically treated (Figure 3). The presence of 14 *S. cereale* seedlings caused 50% inhibition of root length, whereas 35 seedlings were needed to cause the same level of toxicity when measured on shoot length. The growth parameters and the DIBOA (**1**) levels were evaluated for the donor plant, as some interaction caused by the organism chosen as the target could also take place. In

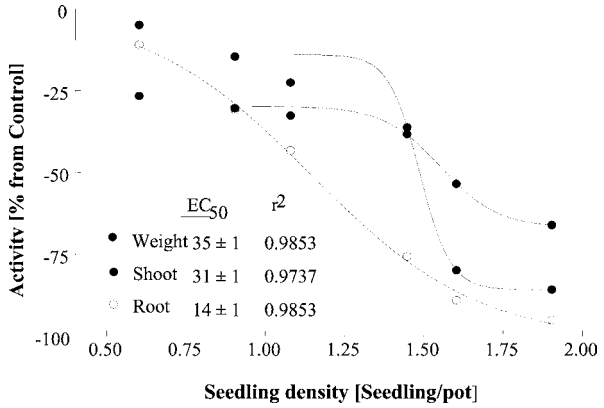

**Figure 3.** Dose–response curves for *A. fatua* growth vs *S. cereale* ratios.

control samples, the number of seedlings of the target species was replaced by the same number of rye seedlings.

The effects on weight, length, and the accumulation of DIBOA (**1**) for *S. cereale* in coculture with *A. fatua* are shown in Figure 4. In general, growth inhibition was very low, with the highest effect at around 12%. As can be observed, at lower donor seedling densities the growth parameters were inhibited to a greater extent. This trend is consistent with a detrimental effect caused on the donor plant. In addition, endogenous DIBOA (**1**) production decreased when the proportion of the target plant was decreased. This result is consistent with production of the defense metabolite being triggered by the presence of the target organism. The mutual character of the allelopathic interaction was therefore clearly displayed, and the plants chosen as donor and target played their expected roles under the selected experimental conditions.

The study of the chemical interference between two species continued with the detection of the allelochemicals in the donor plant exudates. Chromatograms were obtained for exudates at three ratios of donating seedlings in the coculture and the amounts of DIBOA (**1**), BOA (**2**), and APO (**3**) were also determined. In general, the levels of DIBOA (**1**) are similar to those obtained without target species although they do tend to be slightly lower in the latter case. A progressive increase in the amounts of DIBOA (**1**) in the media was observed on increasing the density of donating seedlings. This trend was less marked in the cases of BOA (**2**) and APO (**3**). In terms of concentration units, defined by the volume of initial nutrient solution, the highest concentration of DIBOA (**1**) in the system was 0.3 mM. Under these experimental conditions, the exudation, absorption, changes in solution volume, and degradation generated a phytotoxic concentration gradient that affected the target organism rather than a fixed concentration. These conditions are much more similar to an environmental allelopathic interaction than those used in most dose–response bioassays, in which there is a fixed concentration of a potentially active substance.

Once we had dynamically determined the donor plant exudation potential, degradation phenomena led to changes in the composition of the culture solution. In addition to the chemicals identified, DIMBOA (**4**) and the lactam HBOA (**6**) were detected (Figure 5). The presence of DIMBOA (**4**) in

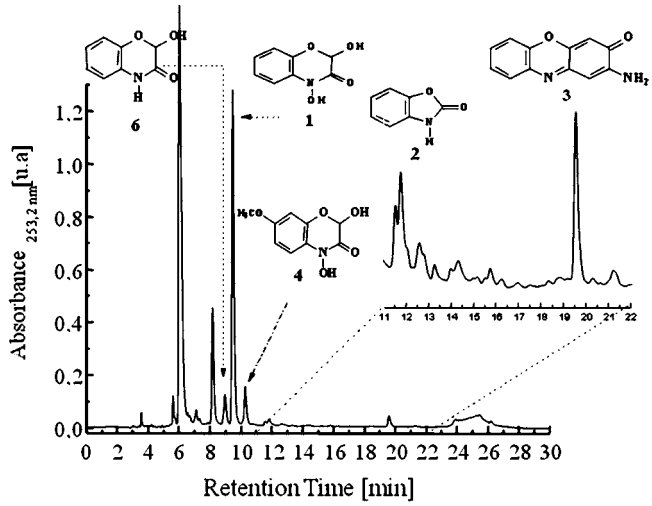

**Figure 5.** Chromatographic profile of the growth medium in coculture of *S. cereale* and *A. fatua*. Conditions: 300 seedlings, 12 d of growth from germination.

roots of rye and its exudates has been discussed. The production of this compound by seedlings seems to be dependent upon genetic and environmental factors as well as the bioassay design. In addition, secondary metabolites, and particularly the production of benzoxazinones in crops, have been characterized as highly accession-dependent, as indicated

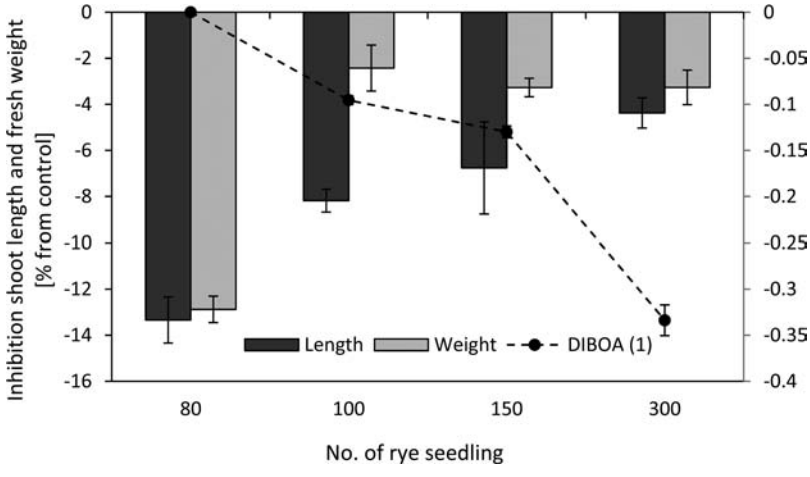

**Figure 4.** Effects on growth and accumulation of DIBOA (**1**) in the *S. cereale* bioassay.

dx.doi.org/10.1021/jf503840d | *J. Agric. Food Chem.* 2014, 62, 9450–9457

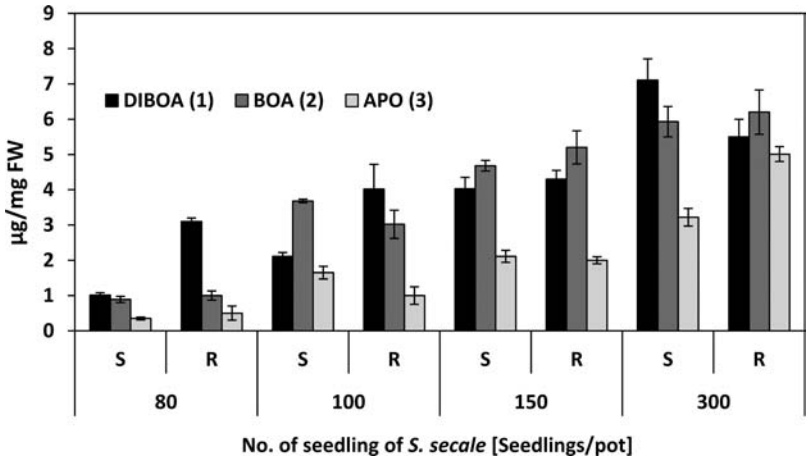

**Figure 6.** Levels of DIBOA (**1**), BOA (**2**), and APO (**3**) in shoot and root of *A. fatua* for different densities of *S. cereale*.

by a particular study on benzoxazinones from wheat.[33] Thus, in this case the phytotoxic effects on the target plant must correspond partly to the action of DIBOA (**1**), DIMBOA (**4**), and HBOA (**6**). Nevertheless, qualitatively it is evident that the DIBOA (**1**) concentration in the exudates was much higher than those of DIMBOA (**4**) and HBOA (**6**). Moreover, the phytotoxicity of DIBOA (**1**) to *A. fatua* was found to be much higher than that found for the other two benzoxazinones.[34] Therefore, DIBOA (**1**) and related compounds should be the most relevant molecules in considering phytotoxic effects and, consequently, the analysis was focused on these compounds.

DIBOA (**1**) and its degradation products BOA (**2**) and APO (**3**), present in the culture medium were studied inside the target plant tissue. The results of this study provided information on the contribution of each chemical to the observed phytotoxicity and confirmed their previously suspected[35] contribution to the interaction phenomena mediated by chemicals.

**Time Dependence.** As mentioned above, the concentrations of allelochemicals in the culture medium depended on the exudation rate, changes in the solution volume during the bioassay, and degradation of the primary products released by the donor plant. Thus, the degradation processes affected the amount of allelochemical by diminishing its concentration, whereas the consumption of nutritient solution caused an increase in the concentration in the system. These findings are not unique to this particular bioassay. In nature, it has been estimated that the concentrations of compounds are also in a gradient, with maximum and minimum values defined by the dynamics of the exudation phenomenon and the transformation processes.[36,37] This phenomenon was also studied in some detail by considering culture solution consumption for a density of 50 seedlings during 12 d of growth. It was found that a volume of 10 mL was sufficient for regular plant development. In the present bioassay, 60 mL of culture solution was used. This approach allowed us to infer that 10 mL of solution must still remain at the end of the bioassay with 300 seedlings (12 d).

**Unambiguous Identification.** The identification criteria in the analysis of DIBOA (**1**) in the nutrient solution were based on the commonly used chromatographic methodologies: retention time, addition of standard to the sample, recording of the ultraviolet spectrum, and comparison with pure standards. The unambiguous determination of the compound in target plant extracts was ensured by combining liquid chromatography with UV/vis spectrophotometry, mass spectrometry, and nuclear magnetic resonance spectroscopy. A full analytical system based on these techniques was designed and this provided the UV/vis spectrum, mass spectrum, and $^{1}$H NMR and $^{1}$H—$^{1}$H 2D WET-gCOSY NMR spectra. All of the techniques were standardized and optimized for the analysis of mixtures prepared from pure standards of DIBOA (**1**), BOA (**2**), and MBOA (**5**). The spectra (UV/vis, NMR, and MS) obtained from the sample were identical to those of the extracts, thus confirming the presence of the allelochemicals generated by the donor plant in the tissue of the target species and verifying the absorption of potentially allelopathic compounds from one species to another in the vicinity.

Once the structures of the compounds had been confirmed as DIBOA (**1**), BOA (**2**), and APO (**3**), their concentrations were determined by HPLC-DAD. An increase in the level of the detected compound in the target plant was observed when the population of donor species was increased. It should be pointed out that the amounts of DIBOA (**1**), BOA (**2**), and APO (**3**) in roots were similar to those in shoots, except for the lowest density, in which DIBOA (**1**) root levels were higher (Figure 6). Absorption through the root is a process that is governed by several factors, both biotic and abiotic. These factors include concentration in the medium. The metabolic effects caused by the compounds taken up can modify the absorption capacity, which would then vary with time. This phenomenon is related to the capacity for translocation of the chemicals from roots to shoots and the ability to metabolize and detoxify them.

With regard to the molecules to be taken up, their physical properties play a fundamental role in their absorption by roots. The molecular weights and functional groups of these compounds modify their solubilities and are among the determining factors. DIBOA (**1**), BOA (**2**), and APO (**3**) have different solubilities and their different structures also influence the molecular interactions, transport within the plant, and the final access to their molecular target sites of action for phytotoxicity. In the present case, APO (**3**) is absorbed the least and DIBOA (**1**) the most. This fact can be positively correlated with their concentrations in the test environment. However, considering that APO (**3**) has the lowest solubility in water of the compounds in question, it is not surprising that it has a lower concentration in the target plant.

**Phytotoxic Effect on the Target Plant.** Once the presence of the allelochemicals in the target plant had been

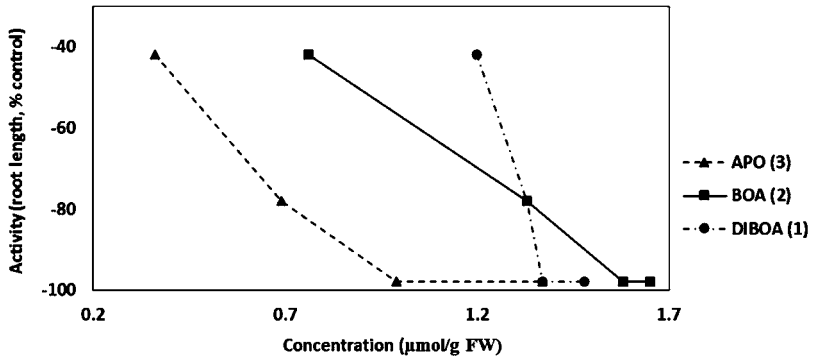

**Figure 7.** Levels of DIBOA (**1**), BOA (**2**), and APO (**3**) in *A. fatua* (μmol/PFW) roots and activity on the root growth parameters.

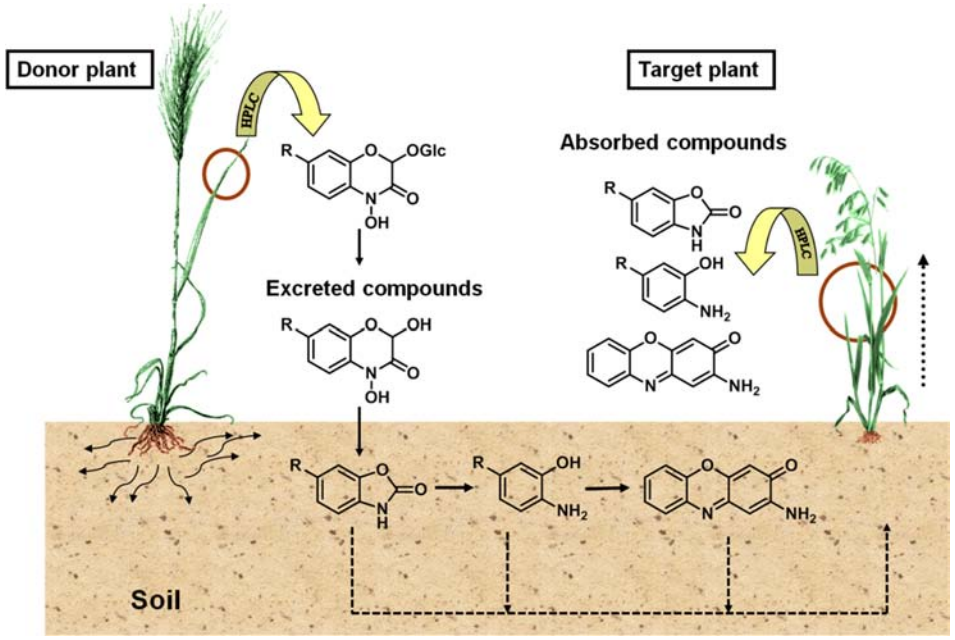

**Figure 8.** Proposed representation for the allelopathic pathway in the coculture of *S. cereale* and *A. fatua*.

confirmed, the dependence on the donor plant density from which they originate had to be described along with their bioactivity. A greater phytotoxic effect was observed as the amounts of allelochemicals found in the target plant tissue increased (Figure 7). The concentration of each chemical inside the plant, along with the resulting phytotoxic effect, followed a typical dose−response relationship. This correlation was observed for the three analyzed compounds DIBOA (**1**), BOA (**2**), and APO (**3**). All of the compounds were found in shoots and roots, albeit at different concentrations. Under these conditions, the higher concentration of DIBOA (**1**) could indicate that this is the compound that contributes most to the observed effects. Nevertheless, the higher phytotoxicity of APO (**3**) on *A. fatua*[29] implies that this compound would require a lower concentration to achieve the same effect. This result clearly establishes these chemicals as the agents responsible for the phytotoxic effects observed.

In summary, this is the first allelopathy study in which the mediators of the allelopathic phenomenon have been detected in all plant species under investigation and also in the environment in which they were grown (Figure 8). Since this experiment was conducted with living plants and real exudates, the system could capture multicompound interactions that influence the bioavailability of allelochemicals, effects that are otherwise obscured in allelopathy research.[38]

The results provide valuable information for the study of the allelopathic phenomenon and shed light on the role of benzoxazinones and their related chemicals in Gramineae crop-weed interactions. The production, transformation, and degradation processes that occur concomitantly have been fully characterized for the biocommunication process between *S. cereale* and *A. fatua*. Although the process reported here is a specific example of allelopathy, the results allowed us to show the complexity of this phenomenon, especially in terms of the dynamic nature of exudation, uptake, and degradation processes. The route of the allelochemicals from donor to target plant was fully characterized and the role of benzoxazinones and their degradation products on the interaction was confirmed. We suggest that exudation and uptake dynamics, together with degradation products, are factors that must be considered in studies aimed at the characterization of allelopathic phenomena.

The dynamics of the processes involved in allelopathy are extremely complex and gaining knowledge and understanding requires an in-depth investigation. For example, all experimental variables are time-dependent, from allelochemical structures to concentrations. Allelochemicals should be released

dx.doi.org/10.1021/jf503840d | J. Agric. Food Chem. 2014, 62, 9450−9457

to the environment and, as a consequence, data on their concentrations within the donor plant are not sufficient to characterize the process. Additionally, degradation products could be more active than the released compound and allelochemicals should also be incorporated into the target plant. This dynamic situation cannot be elucidated by simply recording macroscopic growth effects and analysis of the target plant is also required.

The experimental design described here eliminates the need to consider the soil system as a variable. However, with a view to the possible application of this approach in a field situation, one should consider the role of sorption in the soil and the resulting modification of the bioavailability of components in complex allelochemical mixtures.[39] Consideration of the experimental results in a field community and at the ecosystem level is crucial in understanding the ecological role of allelochemicals in plant interference.[40]

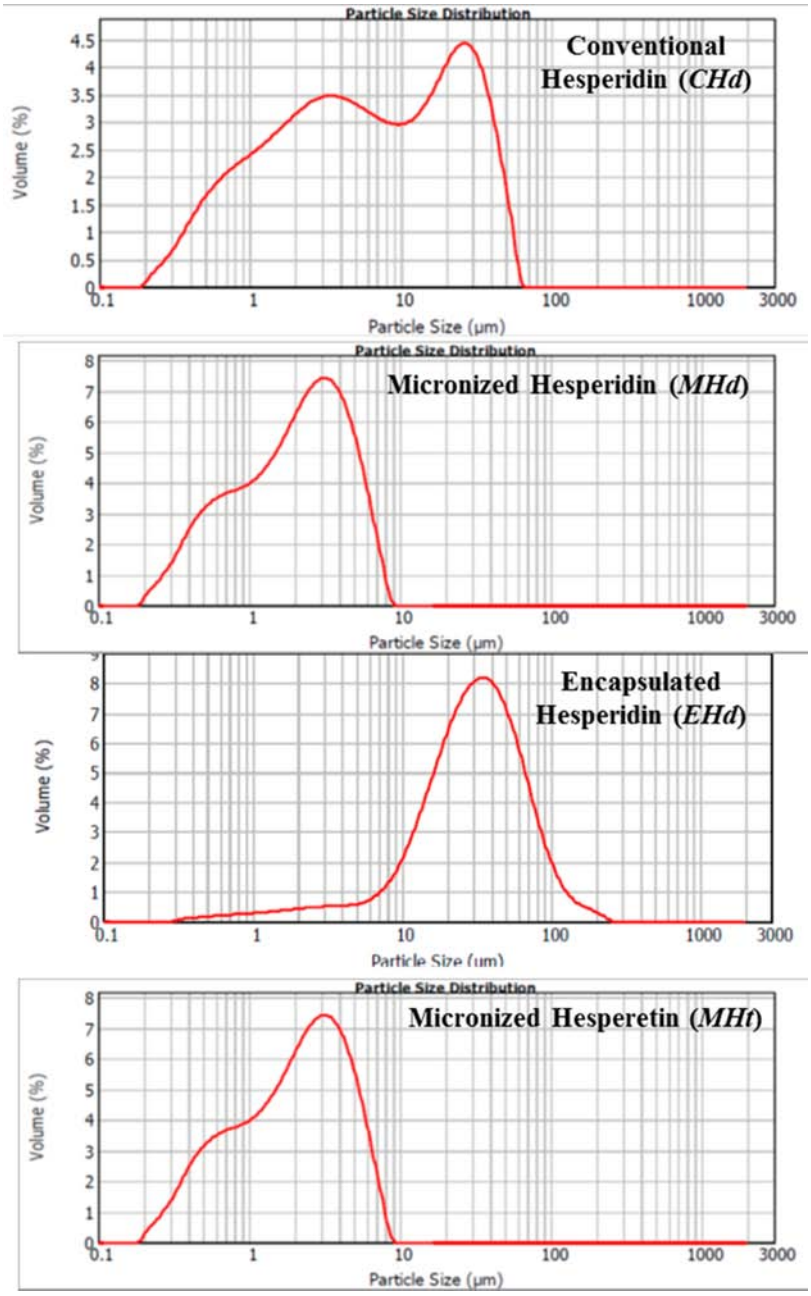

**Figure 1.** Representative particle size distribution of the four treatments after encapsulation and micronization processes.

Arabic as solubilizing agent. It has a $d(0.9)$ particle size of 74.2 $\mu$m. Conventional hesperidin (CHd), the standard hesperidin that has not been subjected to treatments to enhance its solubility, served as a control. It has a $d(0.9)$ particle size of 32.8 $\mu$m. Micronized hesperidin (MHd) is conventional hesperidin that has been micronized to a $d(0.9)$ particle size of 5.1 $\mu$m. Micronized hesperetin (MHt) is the aglycone that has been micronized to a $d(0.9)$ particle size of 5.1 $\mu$m.

**Sampling Procedure. Quantitative Analysis of Flavanones in the Beverages.** Flavanone formulations were UHPLC analyzed on a 1260-DAD single-quadrupole (Agilent 6100 series). Ten milligrams of each sample was weighed and dissolved in 1 mL of water. Samples were vortexed for 5 min and centrifuged using an Eppendorf centrifuge at 10000 rpm (Eppendorf 5804R, Hamburg, Germany). The supernatant was filtered through a 0.45 $\mu$M PVDF Millex filter (Millipore, Tokyo, Japan) and directly analyzed. The pellet was dissolved in 2 mL of dimethyl sulfoxide/methanol (50:50) by vortexing and then filtered through a 0.45 $\mu$M Nylon Millex filter (Millipore, Tokyo, Japan). One hundred microliters of dissolved pellet were diluted with 1900 $\mu$L of methanol and finally HPLC analyzed.

A Poroshell 120 C18 column (100 × 3.0 mm i.d., 2.7 $\mu$m) from Agilent (Palo Alto, CA, USA) was used at room temperature, and the injected volume was 5 $\mu$L. Gradient elution was carried out using water/formic acid (99:1, v/v) and acetonitrile at a constant flow rate of 0.5 mL/min. The gradient started with the following proportions (v/v) of acetonitrile [$t$ (min), % acetonitrile]: 0, 1; 10, 40; 12, 90; and 15, 1. Quantification was achieved using an external standard of hesperidin, and it was performed using UV detection set at 290 nm.

**Design of the Human Intervention Study.** This was a crossover study with 18 healthy volunteers (10 males and 8 females) between 25 and 50 years old. Volunteers were healthy, nonsmokers, non-vegetarians, without a history of gastrointestinal disease, and apparently without any hematological alterations, cardiovascular disease, or chronic diseases and had not been following body-weight-loss diets. Before the intervention study begun, the participants were informed of the background, objectives, methodology,

advantages, and risks of the experiment, as well as the benefits and results that were expected to come out of the study. Participants were required to sign informed consent to be enrolled in the study. The volunteers avoided any intake of both citrus- and tomato-derived foods prior to and during the experiment, starting 7 days before the first day and including the wash-out periods between the intakes. In the same way they had restricted the consumption of fruits and plant-derived food products such as chocolate, tea, beer, wine, and fruit juices. The intake of these products was forbidden starting the day before every assay. Meals were not strictly controlled, but during the whole study, the volunteers wrote down in a notebook any food intake. Thus, breakfast, lunch, and dinner were checked. In addition, the protocol of the study was approved by the UCAM (Universidad Católica S. Antonio de Murcia) Ethics Committee before the start of the study.

The ingested flavanone dose was calculated as hesperetin equivalents for all of the flavanone beverages assayed in order to supply similar amounts as those given with the intake of 200 mL of fresh orange juice. A hesperetin equivalent of 90 mg added to 200 mL of a colored and non-flavanone-containing beverage was ingested on the same day of the week and at the same time over the 4 weeks of the study (Table 1).

As has been widely described in the literature, the interindividual variation observed was high, and therefore the percentages of excretion among volunteers were rather different. Therefore, volunteers were stratified into three categories, high (flavanone excretion values >10% of the ingested flavanones), medium (excretion values between 5 and 10%), and low excretors (excretion values <5%).[6] The percentage of flavanone excretion in individual volunteers is usually very stable, and therefore their respective classifications as high, medium, or low excretors are regularly maintained.[6]

**Sampling Procedure of Urine Samples. Analysis of Flavanone Metabolites by UPLC-QqQ.** Urine samples were processed following a previously developed protocol.[6] Optimization of both mass spectometer parameters and metabolite calibration curves has been previously reported.[6] Flavanone glucuronides and sulfates were previously synthesized by Villapharma (Murcia, Spain), and quantification in urine samples was completed using an UPLC-QqQ method.[6]

The limit of detection (LOD) was determined as the concentration of analytes with a signal-to-noise ratio of at least 3, and the limit of quantification (LOQ) was the lowest standard with a signal-to-noise ratio of at least 10. LOQs were 80 nM for hesperetin, 50 and 80 nM for hesperetin 7- and 3′-glucuronides, respectively, and finally 40 and 50 nM for hesperetin 7- and 3′-sulfates, respectively. LODs were 30 nM for hesperetin, 20 and 30 nM for hesperetin 7- and 3′-glucuronides respectively, and finally 15 and 20 nM for hesperetin 7- and 3′-sulfates, respectively.

The intraday repeatability of the UPLC-QqQ method was assessed from 10 consecutive chromatographic runs using a standard solution with 2.5 $\mu$M of every standard in MeOH/0.1% (v/v) formic acid. The interday repeatability of the method was assessed by analyzing the same standard solution for two consecutive days. The relative standard deviation (RSD) for peak area was in the range of 0.5−4.7% in the intraday test and 1.3−3.5% in the case of the interday test.

**Statistical Analysis.** Analysis of variance (ANOVA) was carried out, and means were separated by Duncan's test ($p < 0.05$%).

## RESULTS

**Assessment of the Effect of Encapsulation and Micronization on Flavanone Absorption.** The analysis of the urine samples after the intake of hesperidin beverages shows that, as a general rule, among the different hesperetin phase II metabolites found, either hesperetin 7-sulfate or hesperetin 7-glucuronide was the most abundant (depending on each individual). Their isomers in the 3′-position, however, were found in smaller concentrations (between 2 and 5 times). Hesperetin sulfoglucuronide was also present in smaller amounts, and hesperetin diglucuronide was a minor metabolite. These results are consistent with those found in studies of flavanone pharmacokinetics after orange juice intake.[12,13]

Hesperidin encapsulation (EHd) and micronization (MHd) led to a significant impact on hesperetin bioavailability because it was clearly increased, between 2 and 3 times, compared with that of conventional hesperidin (CHd) (Figure 2). This increase was also observed when the equivalent dose of micronized hesperetin (MHt) was supplied. However, no clear differences were observed between the three different treatments (encapsulation, micronization, and hydrolysis to render hesperetin) (Table 1; Figure 2). The total excretion percentage expressed as hesperetin equivalents ranged between 2.2 and 5.9% for CHd and MHt, respectively (Table 1).

The percentage of hesperetin equivalents excreted after the intake of encapsulated hesperidin (EHd) (5.4%) was 11% higher than the excretion value recently reported after the intake of an ultrahomogenized orange juice with a $d(0.5)$

dx.doi.org/10.1021/jf502933v | J. Agric. Food Chem. 2014, 62, 9458−9462

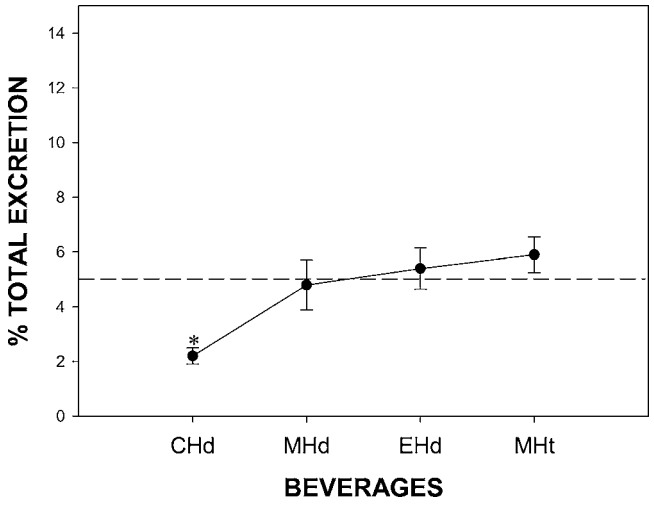

**Figure 2.** Urinary excretion of hesperetin after the intake of encapsulated and micronized hesperdin beverages in all volunteers ($n$ = 18): conventional hesperidin (CHd), micronized hesperidin (MHd), encapsulated hesperidin (EHd), and micronized hesperetin (MHt). Error bars are standard errors. Values are percentage of the total hesperetin intake excreted in urine. (*) $p < 0.05$ significantly different according to Duncan's test.

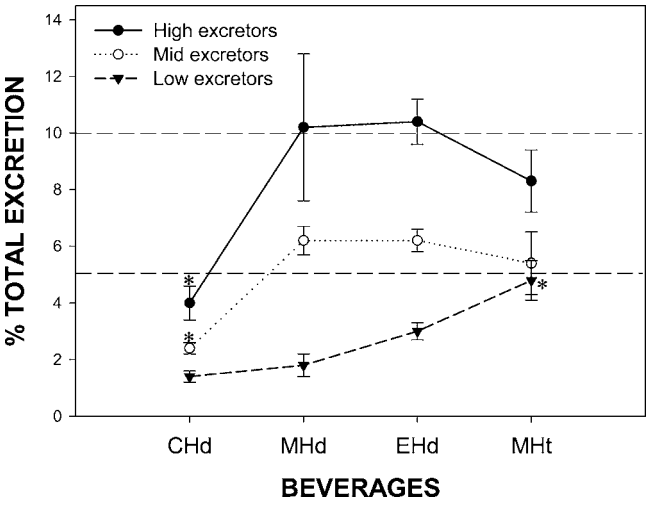

**Figure 3.** Urinary excretion of hesperetin after the intake of encapsulated and micronized hesperidin beverages in volunteers stratified as high ($n$ = 4), medium ($n$ = 7), and low ($n$ = 7) excretors: conventional hesperidin (CHd), micronized hesperidin (MHd), encapsulated hesperidin (EHd), and micronized hesperetin (MHt). Error bars are standard errors. Values are percentage of the total hesperetin intake excreted in urine. (*) $p < 0.05$ significantly different according to Duncan's test.

particle size of 61.6 $\mu$m for the same volunteers used in this study.[6]

However, in absolute terms the micronized aglycone (MHt) was the most bioavailable flavanone, reaching therefore the highest excretion values, deserving a particular comment. Its absorption at the small intestine level explains the marked increment of urinary excretion in volunteers with low excretion capabilities, because the rhamnosidases from gut microbiota are no longer determinant factors for absorption. Furthermore, among the 18 volunteers, there were 14 medium and low excretors in which the supply of the micronized aglycone (MHt) improved the final excretion value of hesperetin compared with that observed after the intake of micronized hesperidin (MHd).

**Stratification of Volunteers.** When volunteers were stratified into high, medium, and low excretors, the results showed additional evidence from that observed when all volunteers were considered together (Table 1; Figure 3). Thus, with a focus on high excretors (subjects with the appropriate microbiota to hydrolyze efficiently hesperidin to hesperetin),[14] percentages of excretion of both encapsulated (EHd) and micronized (MHd) hesperidin were clearly increased, reaching values above 10% of the total hesperetin equivalents intake due to the efficient metabolic activity of colon gut microbiota rhamnosidase activity. However, the micronized aglycone (MHt) reached a lower excretion in high excretors, although with no significant differences with hesperidin (Table 1; Figure 3). Different polymorphisms in intestinal transporters could also be involved in the absorption of flavanones and might explain the significantly higher excretion percentage reached by high excretors with respect to medium and low excretors after supply of the micronized hesperetin (MHt) beverage (Figure 3).

In the case of medium excretors, encapsulated (EHd) and micronized (MHd) hesperidin reached similar hesperetin excretion values, and those were slightly higher than those observed after the intake of the micronized aglycone (MHt) (Table 1). This higher bioavailability of micronized hesperidin than of micronized hesperetin could be explained by the higher solubility of hesperidin versus hesperetin in the gut environment (from 3.5- to 7-fold higher for hesperidin) as previously reported.[15,16]

Opposite to high and medium excretors, the bioavailability of micronized hesperetin (MHt) in low excretors was significantly higher (38 and 63%) than that of encapsulated hesperidin (EHd) and micronized hesperidin (MHd), respectively (Table 1). This clearly shows that low excretors do not have the proper gut microbiota to hydrolyze rutinosides (the appropriate rhamnosidases), and therefore a significant increase in bioavailability is observed when hesperetin is ingested.

As a summary, high excretors showed an efficient biovailability of orange flavanones as they harbor gut microbiota with rhamnosidase activity, as well as proper absorption and phase II metabolism as revealed by the highest excretion values even after the intake of conventional (nontreated) orange flavanone beverages. Thus, although conventional hesperidin was the less bioavailable form, high excretors were able to maximize conventional hesperidin metabolism and absorption with values up to 40 and 65% higher than those observed in medium and low excretors, respectively (Table 1).

No gender differences were observed in this study, in agreement with previous trials on flavanone excretion after orange beverages intake.[6]

To increase flavanone biovailability in low excretors, two strategies can be envisaged: (i) to fortify orange juice with micronized hesperetin or (ii) to encapsulate hesperidin, which enhanced flavanone excretion up to 3% of the intake, which is a value similar to that observed after the intake of fresh orange juice by the same volunteers in a previous study.[6]

stirred with water (1000 mL) and then centrifuged (6000 rpm) for 10 min to remove the sediment. The supernatant was then lyophilized (at −80 °C for 12 h) to obtain the MWEs and stored at −20 °C.

**High-Performance Liquid Chromatography (HPLC).** Using a Hewlett-Packard Vectra 436/33N system and a diode array detector, the components of the MWEs were determined by HPLC analysis[28] employing a 5 μm RP-18 column (4.6 × 150 mm inner diameter). After filtering through a 0.22 μm filter disk, the MWEs (25 mg/mL) were injected into the column. Two systems of mobile phase (A, 2% acetic acid/water; B, 0.5% acetic acid in water/acetonitrile) were used. The peak purity was confirmed with chromatography at 280 nm and ultraviolet (UV) spectra. The total phenolic compound content was measured according to the Folin−Ciocalteu method. The samples (20 μL/1.6 mL of water) were added in 100 μL of Folin−Ciocalteu reagent (Sigma, St. Louis, MO) and 300 μL of sodium carbonate (20%), then mixed, and incubated at 40 °C for 40 min. Absorption at 725 nm was measured.

**Animals and Diet.** A total of 30 male New Zealand white rabbits weighing 2000−2500 g (Animal Center of Chung Shan Medical University) were used in this study. They were individually housed in metal cages under the standard laboratory conditions (22 ± 2 °C, 55 ± 5% relative humidity, and 12 h light/12 h dark cycle) with free access to food and water. According to a suitable pharmacological dose of MWE for humans in a daily diet, five groups ($n = 6$) of animals were described as follows: group I, standard chow; group II, standard chow with 1% MWEs in the daily diet; group III, high-cholesterol diet (HCD) (containing 95.7% standard Purina chow (Purina Mills, Inc., Gray Summit, MO), 3% lard oil, and 1.3% cholesterol) for 10 weeks; and groups IV and V, HCD with 0.5 and 1.0% MWEs, respectively, in the daily diet. During the experimental period, all of the animals were handled according to the guidelines of the Institutional Animal Care and Use Committee of Chung Shan Medical University. After 10 weeks, the rabbits were sacrificed by exsanguination after deep anesthesia with pentobarbital (30 mg/kg intravenous) via the marginal ear vein. Serum was stored at −80 °C prior to serum lipid analysis and measurement of serum values. The aortic arch and thoracic aortas were carefully removed to protect the endothelial lining, collected, and freed of adhering soft tissue.

**Evaluation of Atherosclerotic Lesions.** Sudan IV is a fat-soluble dye often used for staining triglycerides, lipids, and lipoproteins present in cells and tissues. Aortic arches were rapidly dissected and stained with Sudan IV and then kept at −80 °C or in 10% neutral-buffer formalin. The sections of the aortic arch were stained with hematoxylin and eosin or α-smooth muscle actin antibodies (Santa Cruz Biotechnology, Inc., Dallas, TX) by immunohistochemistry.

**Cell Cultures.** Thea rat A7r5 thoracic aorta smooth muscle cells, obtained from American Type Culture Collection (ATCC, CRL-1444, Manassas, VA), were maintained in Dulbecco's modified Eagle's medium supplemented with 10% fetal bovine serum (FBS), 1% glutamine, 1% penicillin−streptomycin, and 1.5 g/L sodium bicarbonate (all from Gibco/BRL, Gaithersburg, MD) at 37 °C in a humidified atmosphere of 5% $CO_2$. The medium was changed every 2 or 3 days, and the cells were subcultured when confluence was achieved.

**Wound Healing.** The $1 \times 10^6$/mL A7r5 cells were cultured in 6-well plates for 48 h. A line was drawn on the underside of the well with a yellow P200 pipet tip. These lines served as fiducial marks for the wound areas to be analyzed. The non-adhering cells were washed out with phosphate-buffered saline (PBS), and the remaining cells were treated with MWEs (0.05−1.0 mg/mL). Under a 40× lens, images of the linear wounds were taken in nine fields per well at 0, 12, 24, 36, 48, 60, 72, 84, and 96 h. The migrated cells were counted per well, and the counts were averaged.[29]

**MMP Gelatin Zymography.** The levels of MMP-2 and MMP-9 released in the cultured medium were assayed by gelatin zymography as described previously.[30] MWE-treated A7r5 cells were plated onto 6-well culture plates ($5 \times 10^5$/well) and incubated with 1 mL of 0.5% FBS in Dulbecco's modified Eagle's medium for 24 h. The culture medium was prepared with a 5× loading buffer containing 0.01% sodium dodecyl sulfate (SDS) without β-mercaptoenthanol and subjected to electrophoresis with 8% SDS polyacrylamide gels containing 0.1% gelatin. Following electrophoresis, the gels were washed twice with 2.5% Triton X-100 on a gyrating shaker for 30 min at room temperature to remove SDS. The gels were then incubated in 50 mL of reaction buffer (40 mM Tris-HCl, 10 mM $CaCl_2$, and 0.01% $NaN_3$) at 37 °C overnight on a rotary shaker, stained with Coomassie Brilliant Blue R-250, and destained with methanol/acetic acid/water (50:75:87.5, v/v/v). Gelatinolytic activities were detected as horizontal white bands on a blue background.

**Western Blot Analysis.** Analysis of TIMP-2, VEGF, FAK, integrin-$\beta_3$, c-Raf, Src, Ras, PI3K, Akt, Cdc42, RhoA, RhoB, Rac1, p-FAK, IκB, and NF-κB (all from Santa Cruz Biotechnology, Dallas, TX), PI3K (Becton-Dickinson, San Jose, CA), and p-Akt and β-actin (Sigma, St. Louis, MO) was performed using western blot analysis.[31]. After the indicated treatment with MWEs (0−2.0 mg/mL) for 48 h, the cells were lysed and equal amounts of cell lysates (50 μg of protein) were separated by electrophoresis on 8−12% SDS polyacrylamide gels and transferred to nitrocellulose membranes (Millipore, Bedford, MA). The membranes were incubated with Tris-buffered saline containing 1% (w/v) nonfat milk and 0.1% (v/v) Tween-20 for 1 h to block non-specific binding, washed with Tween-20 for 30 min, incubated with the appropriate primary antibody for 2 h, incubated with horseradish-peroxidase-conjugated second antibody (Sigma, St. Louis, MO) for 1 h, developed using enhanced chemiluminescence (ECL, Millipore, Bedford, MA), and analyzed by densitometry using AlphaImager Series 2200 software. The results were representative of at least three independent experiments.

**Immunoprecipitation Assay.** Approximately 0.5 mg of the lysate protein was immunoprecipitated[32] using monoclonal anti-integrin-$\beta_3$ (Santa Cruz Biotechnology, Dallas, TX) antibodies. Immune complexes were harvested with protein-A-conjugated sepharose beads. After centrifugation at 2500 rpm, the eluates were analyzed by immunoblotting against FAK, Src, Ras, and PI3K antibodies.

**Electrophoretic Mobility Shift Assay of NF-κB.** An electrophoretic mobility shift assay[33] was performed using a Lightshift kit from Promega. A total of 10 μg of nuclear protein was mixed with the binding reaction buffer containing 10 mM Tris, 50 mM KCl, 1 mM dithiothreitol (DTT), 5 mM $MgCl_2$, 2 μg poly(dI·dC), and 2 pmol of oligonucleotide probe and incubated for 20 min at room temperature. Specific binding was confirmed using a 200-fold excess of unlabeled probe as a specific competitor. Protein−DNA complexes were separated by 6% non-denaturing acrylamide gel electrophoresis and then transferred to positively charged nylon membranes and cross-linked in a Stratagene cross-linker. Gel shifts were visualized with streptavidin−horseradish peroxidase, followed by chemiluminescent detection.

**Visualization of the F-Actin Cytoskeleton.** A7r5 cells ($5 \times 10^4$ cells/well) were treated with 0.1−1.0 mg/mL MWEs for 48 h, then fixed in 4.6% formaldehyde in PBS for 10 min, and permeabilized in 0.2% Triton X-100/PBS for 5 min. The cells were stained with phalloidin−fluorescein isothiocyanate (FITC, A12379, Invitrogen, Grand Island, NY) to visualize polymerized F-actin microfilaments under a Nikon upright fluorescence microscope (100× objective)[34] (red color). Then, they were extensively washed with PBS, briefly counterstained with 1 mg/mL 4′,6-diamidino-2-phenylindole (DAPI) to visualize the nuclei, and photographed (blue color).

**Reverse Transcription Polymerase Chain Reaction (RT-PCR) Analysis.** Total RNA was isolated from cells using a RNA Isolation Kit (Ultraspec, Biotecx, Houston, TX) according to the instructions of the manufacturer and quantified spectrophotometrically. For reverse transcription, total RNA (4 μg) was used as templates in the raction buffer containing oligo dT primer and 4 units/μL RTase (MMLV) in an Applied Biosystems GeneAmp PCR system 2700 at 42 °C for 60 min and then at 99 °C for 5 min to inactivate the RT. PCR master mix containing 1 mM deoxyguanosine triphosphate, 1 mM deoxyadenosine triphosphate, 1 mM deoxycytidine triphosphate, 1 mM deoxythymidine triphosphate, Dyna PCR buffer II, 2 units/μL AmpliTaq DNA polymerase, and the following primers was added at a 0.5 μM concentration: murine MMP, upstream primer (5′-ACACCCAG-TACTCATTCCCTG-3′) and downstream primer (5′-GTCCTGAC-CAAGGATATAGCC-3′); VEGF, upstream primer (5′-TGCACC-CACGACAGAAGGGGA-3′) and downstream primer (5′-

TCACCGCCTTGGCTTGTCACA-3′); GADPH, upstream primer (5′-ACCACAGTCCATGCCATCAC-3′) and downstream primer (5′-TCCACCACCCTGTTGCTGTA-3′). The complementary DNAs (cDNAs) in the samples were amplified for 30 cycles as follows: 1 min at 94 °C as an initial step, followed by 30 thermal cycles of 60 s at an annealing temperature and 2 min at 72 °C, and finally 20 min at 72 °C. The RT-PCR products were analyzed by agarose gel electrophoresis, and the intensity of the bands corresponding to MMP-2, VEGF, and GADPH were measured using Fujifilm Image Gauge software (version 3.1, Fujifilm Co., Ltd., Tokyo, Japan).[35]

**Statistical Analysis.** Data were shown as the means (standard deviation) of three independent experiments. Statistical comparisons were evaluated by one-way analysis of variance (ANOVA). A $p$ value of less than 0.05 was considered to be statistically significant.

## RESULTS

**Polyphenolic Compounds of MWEs.** The main polyphenolic constituents of MWEs have been identified as gallic acid (0.31%), protocatechuic acid (2.92%), catechin (0.54%), epigallocatechin gallate (2.68%), caffeic acid (1.10%), epicatechin (1.21%), $p$-coumaric acid (0.35%), rutin (3.22%), ferulic acid (0.27%), gossypin (0.26%), hesperetin (0.34%), resveratrol (0.35%), quercetin (0.50%), naringenin (0.52%), and hydroxyflavin (0.58%) (Table 1). The other constituents include protein (1.77%), fat (4.40%), polysaccharide (24.83%), and unknown components without standards (data not shown).

**Table 1**

| HPLC assay | | MWEs (%) | retention time (RT) (min) |
|---|---|---|---|
| polyphenolic compound | gallic acid | 0.31 ± 0.05 | 7.85 |
| | protocatechuic acid | 2.92 ± 0.45 | 15.17 |
| | catechin | 0.54 ± 0.03 | 23.49 |
| | epigallocatechin gallate | 2.68 ± 0.20 | 23.95 |
| | caffeic acid | 1.10 ± 0.24 | 26.08 |
| | epicatechin | 1.21 ± 0.17 | 27.27 |
| | $p$-coumaric acid | 0.35 ± 0.04 | 31.57 |
| | rutin | 3.22 ± 1.01 | 33.44 |
| | ferulic acid | 0.27 ± 0.01 | 34.00 |
| | gossypin | 0.26 ± 0.02 | 41.72 |
| | hesperetin | 0.34 ± 0.10 | 42.85 |
| | resveratrol | 0.35 ± 0.23 | 45.17 |
| | quercetin | 0.50 ± 0.07 | 51.83 |
| | naringenin | 0.52 ± 0.17 | 56.28 |
| | hydroxyflavin | 0.58 ± 0.12 | 57.44 |
| | total | 15.13 ± 0.93 | |

**MWEs Inhibited Proliferation of VSMCs and the Expression of SMA, Ras, and MMP-2 in Neointima.** Histological analysis was performed on a representative atherosclerotic lesion from a HCD-fed rabbit after treatment with 0.5−1% MWEs for 10 weeks. As shown in Figure 1, hematoxylin and eosin staining showed that the MWEs dose-dependently inhibited HCD-fed-induced intimal hyperplasia of vessel walls. After immunohistochemical staining, the expressions of SMA, Ras, and MMP-2 in the VSMCs were also found to be dose-dependently inhibited after MWE treatment.

**MWEs Effectively Inhibited VSMC (A7r5 Cell) Migration.** Monolayers of growth-arrested A7r5 cells treated with or without different concentrations of MWEs (0.1−1.0 mg/mL) were scraped, and the number of cells in the denuded zone (i.e., wound) were analyzed at the indicated times (0−96 h) under light microscopy and Boyden chamber assay. Both panels A and B of Figure 2 show that MWEs could effectively dose-dependently inhibit migration of the VSMCs.

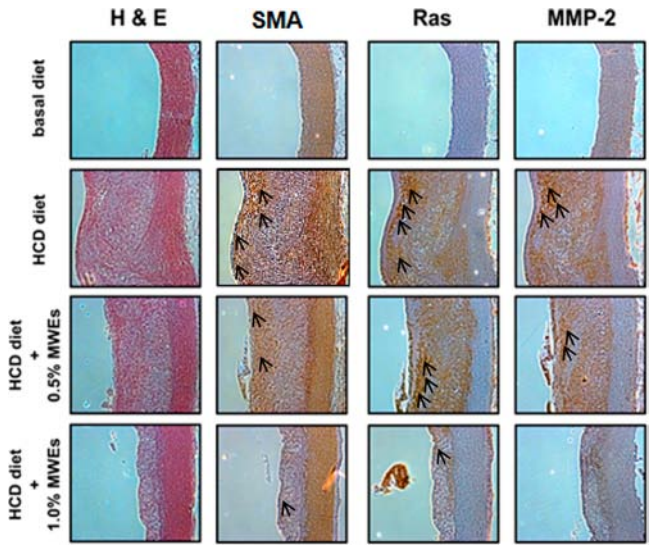

**Figure 1.** Histological analysis of a representative atherosclerotic lesion from HCD-fed rabbits treated for 10 weeks with 0.5 and 1% MWEs. The same group of slices were from the same area of the artery and stained with different antibodies. Primary antibodies were detected with $\alpha$-actin, Ras, and MMP-2. Semi-quantitative computer-assisted image analysis of the atherosclerotic lesion was performed on six randomly selected 400× magnified images of slides from individual animals.

**MWEs Inhibited MMP Activity and VEGF Secretion of the A7r5 Cells.** A7r5 cells were treated with or without MWEs for 0−48 h. The 0.5% FBS starvation medium of the A7r5 cells was changed after treatment with MWEs, and gelatin zymography was then performed to analyze the activities of MMP-9 and MMP-2. Figure 3A shows that more MMP-2 was secreted by the A7r5 cells than MMP-9. After treatment with MWEs, the activities of MMP-2 and MMP-9 decreased time-dependently. In time-dependent assays, A7r5 cells were treated with 1.0 mg/mL MWEs at the indicated times. Cell lysates (50 $\mu$g) were prepared and subjected to western blot analysis. Proteins were detected by TIMP-2 and VEGF antibodies, and albumin and $\beta$-actin were used for equal loading. The activity of TIMP-2 was time-dependently increased after MWE treatment (Figure 3B), and the activity of VEGF was time-dependently decreased (Figure 3C).

**MWEs Inhibited the Activities of FAK and Akt in A7r5 Cells.** Cultured cells were treated with MWEs (0.5−2 mg/mL) for 48 h. A7r5 cells were treated with MWEs (1.0 mg/mL) for 0−48 h, and cell lysates (50 $\mu$g) were prepared and subjected to western blot analysis. Proteins were detected by phospho-FAK, integrin-$\beta_3$, PI3K, Akt, and GSK3$\beta$ antibodies, and $\beta$-actin was used for equal loading. As shown in panels A and B of Figure 4, the activities of FAK-p, PI3K, Akt-p, GSK3$\beta$-p, and c-Raf were dose- and time-dependently decreased by MWE treatment. Total cell lysates were then immunoprecipitated with anti-integrin-$\beta_3$ antibodies, and the precipitated complexes were examined by immunoblotting with anti-FAK, Src, Ras, and PI3K antibodies. MWE treatment dose-dependently decreased the activities of Src, Ras, and PI3K (Figure 4C).

**MWEs Inhibited the Activity of NF-κB in A7r5 Cells.** A7r5 cells were treated with MWEs (0−1.5 mg/mL) for 48 h, and cultured cells were treated with MWEs (1.0 mg/mL) for 0−48 h. Cell lysates (50 $\mu$g) were prepared and subjected to western

dx.doi.org/10.1021/jf502942r | J. Agric. Food Chem. 2014, 62, 9463−9471

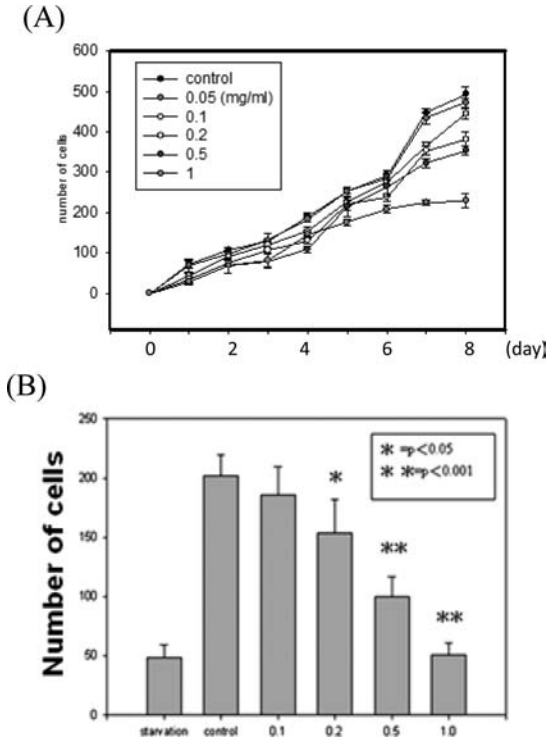

**Figure 2.** Effect of MWEs on the migration of A7r5 cells. Monolayers of growth-arrested A7r5 cells treated with or without different concentrations of MWEs (0.1−1.0 mg/mL) were scraped, and the number of cells in the denuded zone (i.e., wound) was analyzed at the indicated times (0−96 h) under (A) light microscopy and (B) Boyden chamber assay. Quantitative assessment of the mean number of cells at the indicated times in the denuded zone represents the average of three independent experiments ± standard deviation.

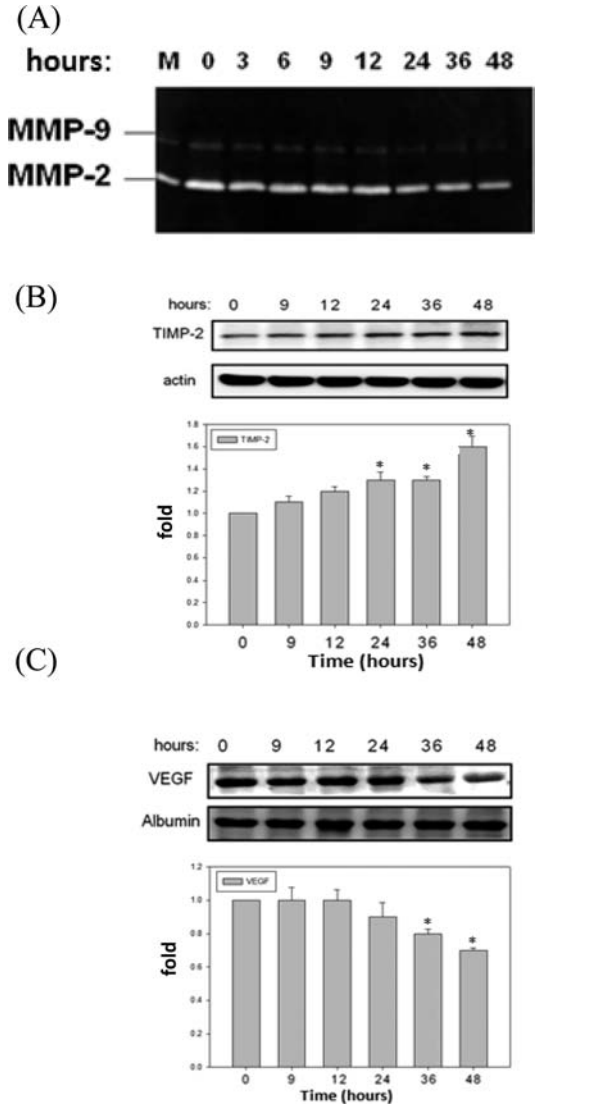

**Figure 3.** Effects of MWEs on MMP activity and VEGF secretion of A7r5 cells. A7r5 cells were treated with or without MWEs for 0−48 h. The 0.5% FBS starvation medium of the A7r5 cells was changed after treatment with MWEs, and (A) gelatin zymography was then performed to analyze the activities of MMP-9 and MMP-2 as described in the Materials and Methods. In time-dependent assays, A7r5 cells were treated with 1.0 mg/mL MWEs at the indicated times. Cell lysates (50 $\mu$g) were prepared and subjected to western blot analysis. Proteins were detected by (B) TIMP-2 and (C) VEGF antibodies. Albumin and $\beta$-actin were used for equal loading. The results from three separate experiments were similar.

blot analysis. As shown in panels A and B of Figure 5, MWE treatment dose- and time-dependently decreased the activity of NF-$\kappa$B and increased the activity of I$\kappa$B. The cell lysates were then immunoprecipitated with anti-NF-$\kappa$B and immunoblotted with anti-I$\kappa$B. $\beta$-actin was used for equal loading. MWE treatment dose-dependently increased the combination of I$\kappa$B and NF-$\kappa$B (Figure 5C). Thereafter, the A7r5 cells were treated with or without MWEs for 12 h, and then nuclear extracts were prepared. C23 was used as a nuclear control. NF-$\kappa$B DNA binding activity was analyzed by an electrophoretic mobility shift assay. MWE treatment dose-dependently inhibited the activity of NF-$\kappa$B in nuclei (Figure 5D). Finally, total RNA was extracted. Expressions of MMP-2 and VEGF mRNA were analyzed by RT-PCR with GAPDH as the loading control. Figure 5E shows that the mRNA expressions of MMP-2 and VEGF were dose-dependently decreased by MWE treatment.

**MWEs Inhibited the Expressions of Small G Proteins and Cytoskeletal F-Actin in A7r5 cells.** A7r5 cells were treated with MWEs (0−2 mg/mL) for 48 h. The A7r5 cells were then treated with MWEs (1.0 mg/mL) for 0−48 h. Cell lysates (50 $\mu$g) were prepared and subjected to western blot analysis. Proteins were detected by specific antibodies (Cdc42, Ras, RhoA, and Rac1), and $\beta$-actin was used for equal loading. As shown in panels A and B of Figure 6, MWE treatment dose- and time-dependently decreased the expressions of Ras, RhoA, cdc42, and Rac-1 and increased the activity of RhoB. Finally, cultured cells were treated with different concentrations of MWEs or without MWEs for 48 h. The cells were fixed and labeled for F-actin with phalloidin−TRITC (red) and for nucleic acid with DAPI (blue). Immunofluorescence microcopy of phalloidin (F-actin)- and DAPI (nuclei)-stained A7r5 cells revealed a marked increase in phalloidin staining in the control group (medium with FBS) compared to the starvation group (medium without FBS) (Figure 6C). After MWE treatment in the control group, the phalloidin staining decreased significantly again and was similar to that of the starvation group. Taken together, these results demonstrate that MWEs are a positive regulator of actin organization.

## DISCUSSION

*Nelumbo nucifera* leaf extracts, which contain a large amount of phenolic acids and flavonoids, including gallic acid, rutin,

dx.doi.org/10.1021/jf502942r | J. Agric. Food Chem. 2014, 62, 9463−9471

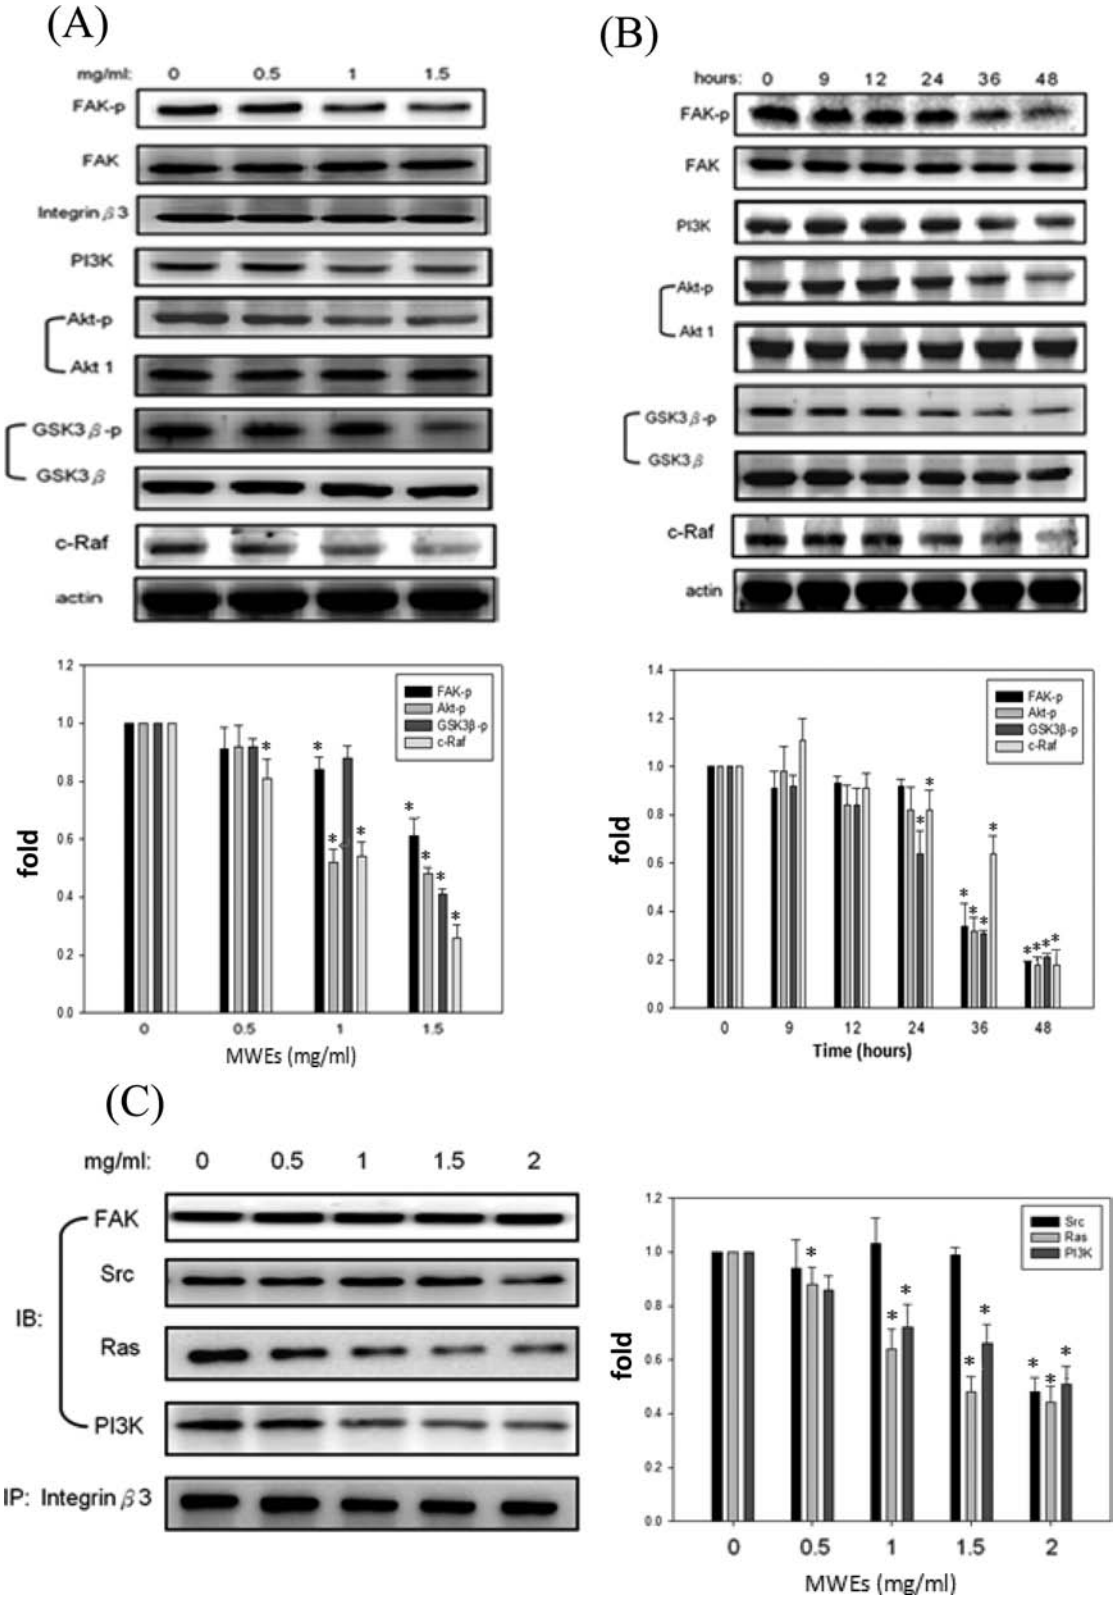

**Figure 4.** Effect of MWEs on the activities of FAK and Akt in A7r5 cells. (A) Cultured cells were treated with MWEs (0.5−2 mg/mL) for 48 h. (B) A7r5 cells were treated with MWEs (1.0 mg/mL) for 0−48 h. Cell lysates (50 $\mu$g) were prepared and subjected to western blot analysis. (C) Proteins were detected by phospho-FAK, integrin-$\beta_3$, PI3K, Akt, and GSK3$\beta$ antibodies. $\beta$-actin was used for equal loading. Total cell lysates were immunoprecipitated with anti-integrin-$\beta_3$ antibodies, and the precipitated complexes were examined by immunoblotting with anti-FAK, Src, Ras, and PI3K antibodies. The results from representative experiments were normalized to immunoprecipitated integrin-$\beta_3$ expression. The results from three separate experiments were similar.

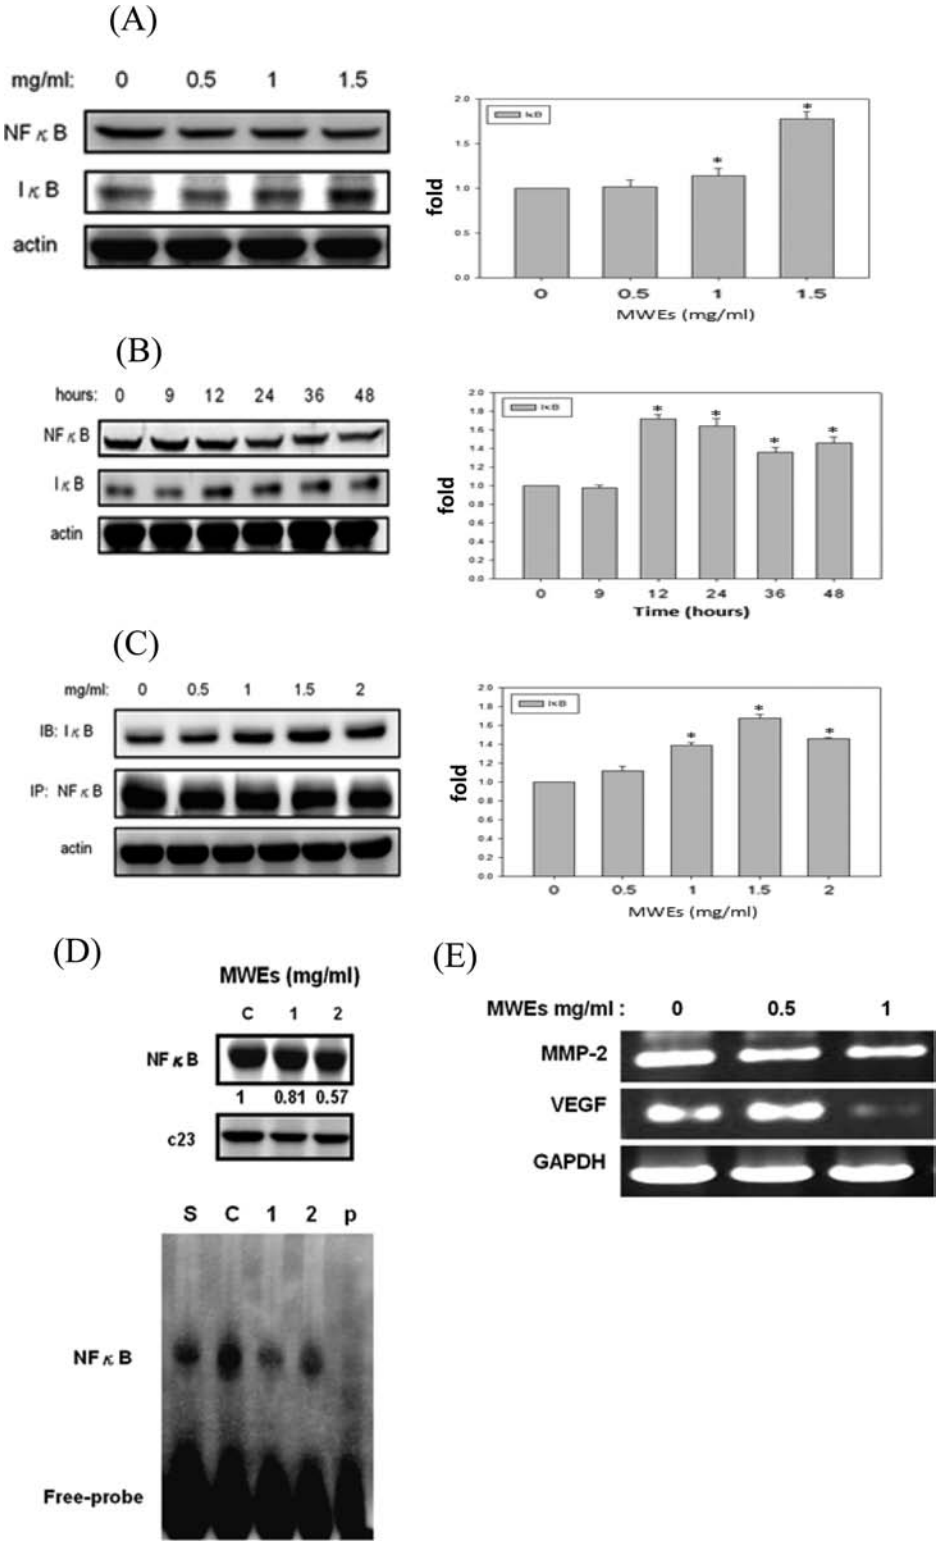

**Figure 5.** Effect of MWEs on the activity of NF-κB in A7r5 cells. (A) A7r5 cells were treated with MWEs (0−1.5 mg/mL) for 48 h. (B) Cultured cells were treated with MWEs (1.0 mg/mL) for 0−48 h. Cell lysates (50 μg) were prepared and subjected to western blot analysis. (C) Cell lysates were also immunoprecipitated with anti-NF-κB and then immunoblotted with anti-IκB. β-actin was used for equal loading. (D) A7r5 cells were treated with or without MWEs for 12 h, and then nuclear extracts were prepared. C23 was used as the nuclear control. NF-κB DNA binding activity was analyzed by an electrophoretic mobility shift assay as described in the Materials and Methods. "S" represented starvation, and "P" represented nuclear extracts incubated with unlabeled oligonucleotides (free probe), to confirm the specificity of binding. (E) Total RNA was extracted. Expressions of MMP-2 and VEGF mRNA were analyzed by RT-PCR. GAPDH served as the loading control. The results from three separate experiments were similar.

quercetin, catechin, epicatechin, and epigallocatechin gallate, have been reported to inhibit neointimal hyperplasia through modulation of smooth muscle cell proliferation and migration.[36] A previous study showed that red wine polyphenolic compounds

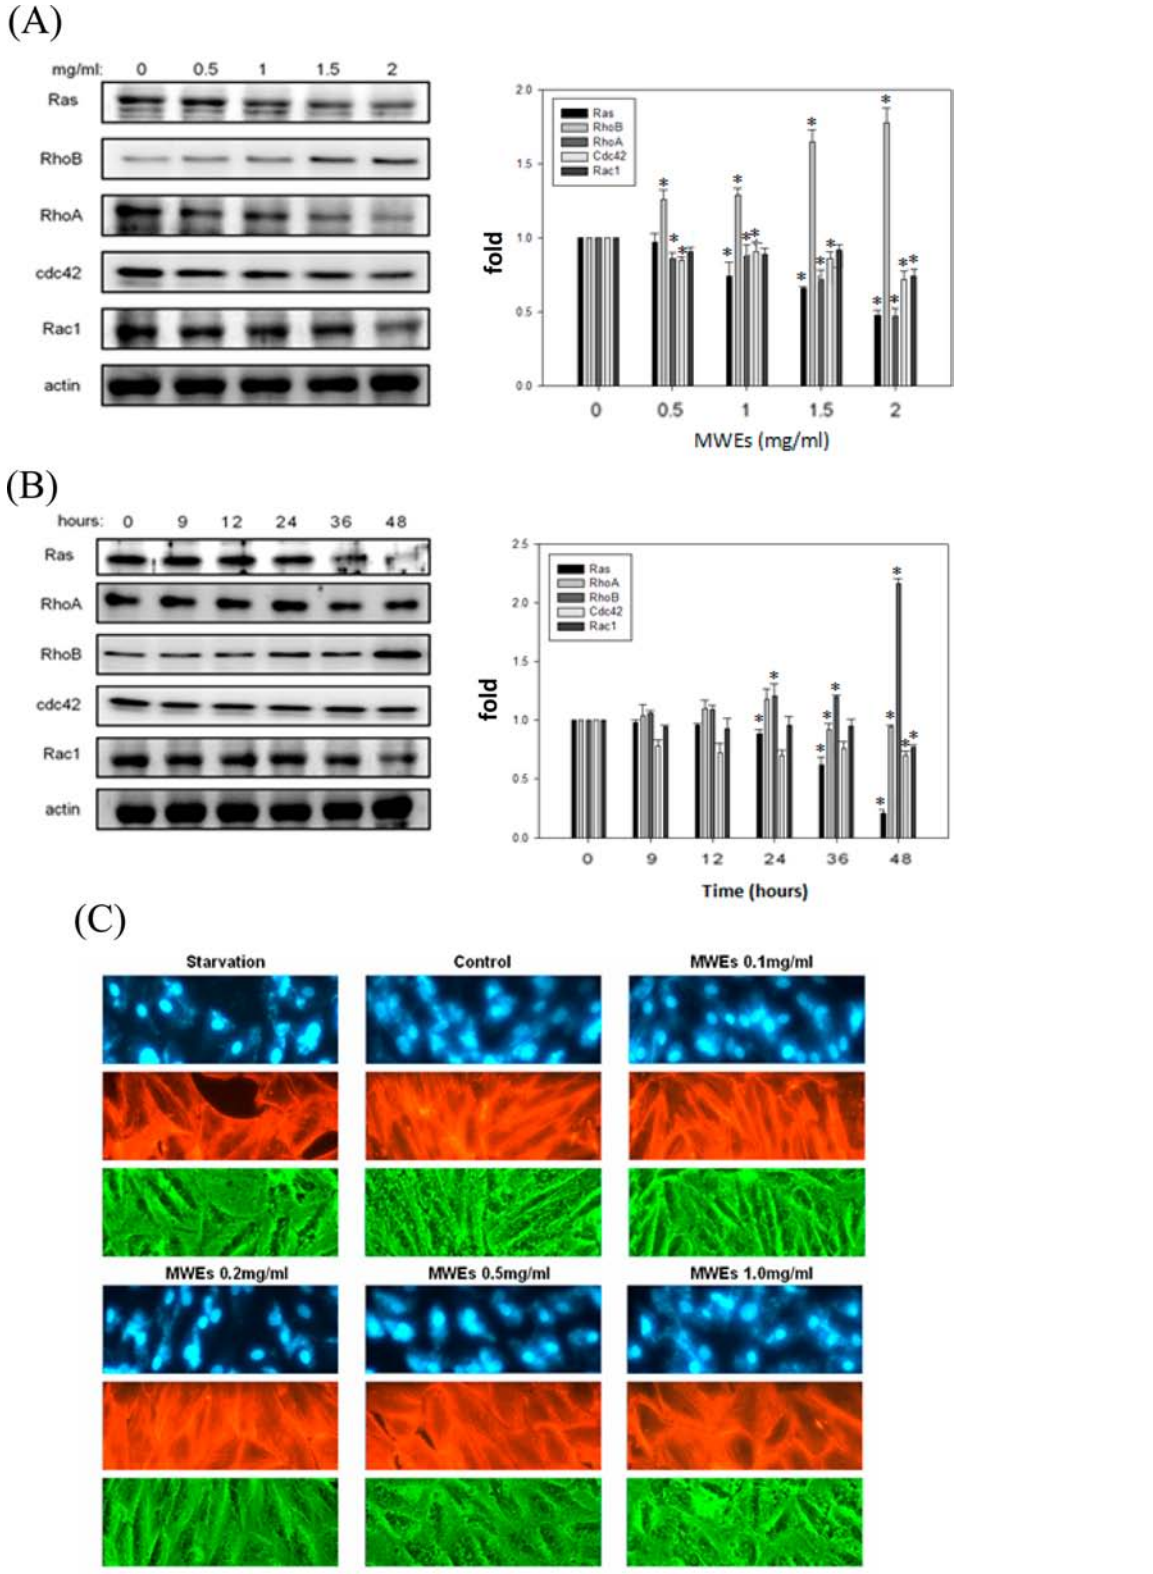

**Figure 6.** Effect of MWEs on the expressions of small G proteins and cytoskeletal F-actin in A7r5 cells. (A) A7r5 cells were treated with MWEs (0−2 mg/mL) for 48 h. (B) A7r5 cells were treated with MWEs (1.0 mg/mL) for 0−48 h. Cell lysates (50 $\mu$g) were prepared and subjected to western blot analysis. Proteins were detected by specific antibodies (Cdc42, Ras, RhoA, and Rac1). $\beta$-actin was used for equal loading. (C) Cultured cells were treated with different concentrations of MWEs or without MWEs for 48 h. The cells were fixed and labeled for F-actin with phalloidin−TRITC (red) and for nucleic acid with DAPI (blue).

and green tea polyphenols are able to inhibit the proliferation and migration of VSMCs and the expressions of VEGF and MMP-2.[37] Gallic acid has been reported to have a hypolipidemic effect on high-fat-diet-fed mice, and the antioxidative properties of protocatechuic acid has been reported to contribute to its suppression of platelet-derived growth factor (PDGF)-induced

dx.doi.org/10.1021/jf502942r | J. Agric. Food Chem. 2014, 62, 9463−9471

migration and proliferation in VSMCs.[38] Catechins have been reported to be able to suppress VSMC proliferation and migration via the inhibition of $\beta$PDGF receptors.[39] Quercetin, catechin, epicatechin, and epigallocatechin gallate have also been reported to inhibit the activity of xanthine oxidase, thereby reducing oxidative stress on vascular walls.[40] Quercetin has also been reported to inhibit the proliferation and migration of VSMCs by suppressing the phosphorylation of mitogen-activated protein kinase.[41] In addition, quercetin 3-*O*-$\beta$-D-glucuronide has been shown to inhibit PDGF-induced migration of rat aortic smooth muscle cells by suppression of PDGF-induced c-Jun N-terminal kinase (JNK) and Akt activations.[42] MWEs are also rich in phenolic acids and flavonoids, including gallic acid, caffeic acid, protocatechuic acid, catechin, epigallocatechin gallate, epicatechin, rutin, quercetin, and naringenin. As we know, protein, fat, and polysaccharide were not reported to have an antiatherosclerotic effect before. Therefore, the inhibitory effect of MWEs on VSMC migration may be attributed to the polyphenol compounds in MWEs.

We found that 0.5−1.0% MWEs effectively reduced HCD-fed-induced intimal hyperplasia in rabbits (Figure 1), which is consistent with the results of our previous study.[26] This further suggests that 2.5−5.0 g/day of MWEs may be enough to prevent atherosclerosis in humans. In the present *in vivo* and *in vitro* studies, we found that MWEs effectively inhibited migration of A7r5 VSMCs (Figure 2), which is important to prevent neointima formation in atherosclerosis. It is known that MMP and VEGF are vital regulators of VSMC migration and angiogenesis, and our results showed that MWEs could time-dependently decrease the activities of MMP-2, MMP-9, and VEGF (Figure 3). On the other hand, the activity of TIMP-2 (a MMP inhibitor) was time-dependently increased after MWE treatment. These results indicate that MWEs can effectively inhibit the activities of MMP-2, MMP-9, and VEGF and thereby inhibit VSMC migration and angiogenesis. Previous reports have shown that PI3K can induce the activation of Akt, thus mediate the phosphorylation of GSK3$\beta$, and inhibit its activity, thereby preventing migration. The FAK/Src complex plays a role in integrin signaling and actin cytoskeleton rearrangement. In addition, Ras-related small GTPases of the Rho family are involved in the regulation of the actin cytoskeleton, and Raf is an important downstream effector of Ras. Our results showed that the activities of FAK-p, PI3K, Akt-p, GSK3$\beta$-p, Src Ras, c-Raf, and integrin-$\beta_3$ were all decreased after MWE treatment (Figure 4), which suggests that MWEs can inhibit VSMC migration via inhibition of the FAK, PI3K/Akt, and Ras pathways. Previous studies have reported that NF-$\kappa$B may regulate angiogenesis via MMP induction and that I$\kappa$B is an inhibitor of NF-$\kappa$B. Our results showed that MWEs dose- and time-dependently decreased the activity of NF-$\kappa$B and increased the activity of I$\kappa$B (Figure 5). In addition, the combination of I$\kappa$B and NF-$\kappa$B was increased after MWE treatment. MWEs also dose-dependently inhibited the activity of NF-$\kappa$B in nuclei. These results indicate that MWEs inhibit VSMC migration via the NF-$\kappa$B pathway. Previous reports have also shown that NF-$\kappa$B is activated by RhoA, Rac1, and cdc42 and inhibited by RhoB. Rho and Rho kinase can also mediate VSMC migration, and RhoA has been reported to regulate the actin cytoskeleton. Our results showed that the activities of Ras and Ras-related small GTPases, including RhoA, cdc42, and Rac, were all significantly decreased after MWE treatment (Figure 6); however, the activity of RhoB was increased after MWE treatment. These results indicate that MWEs can inhibit VSMC migration via Ras and Ras-related small GPTase pathways. We also found that MWEs were a positive regulator of actin organization. In conclusion, MWEs inhibit VSMC migration via reducing the interactions between the integrin-$\beta_3$ and FAK complex and downregulating GSK3$\beta$ and NF-$\kappa$B signaling.

>97%), chlorogenic acid (purity >95%), nordihydroguaiaretic acid (purity >97%), syringic acid (purity >95%), dihydrocaffeic acid (purity >98%), and tyrosinase (from mushroom) were obtained from Sigma-Aldrich (St. Louis, MO). Vanillic acid (purity >96%) was purchased from Wako Pure Chemicals (Osaka, Japan). Kaempferol (purity >97%), taxifolin (purity >96%), and 5,5′-dithiobis(2-nitrobenzoic acid) were obtained from Funakoshi (Tokyo, Japan). All organic solvents (extra pure grade or HPLC grade) were obtained from Nacalai Tesque. Distilled water produced by a water-distilling instrument (SA-2100E, EYELA, Tokyo, Japan) was used for all experiments. NMR spectra were obtained from an ECS-400 spectrometer (JEOL, Tokyo, Japan) using the manufacturer's pulse sequences. High-resolution mass spectrometric data were obtained using a XEVO QtofMS spectrometer (Waters Japan, Tokyo, Japan) in negative ESI mode. A PU-2089 low-pressure gradient system (JASCO, Tokyo, Japan) equipped with an MD-2018 photodiode array detector (PDA) was employed for analytical HPLC. PDA data were analyzed using ChromNAV ver. 1.8 (JASCO). An LC-6AD system (Shimadzu, Kyoto, Japan) equipped with a UV-970 detector (JASCO) was used for preparative HPLC.

**Preparation of MetMb.** The MetMb solution was prepared from a stock solution of $MbO_2$, which was prepared using a method reported previously.[8] Potassium hexacyanoferrate(III) (2 mg) was added to a solution of $MbO_2$ (120 μmol/L) in a phosphate buffer (50 mmol/L, pH 7.4, 3 mL) at 23 °C. After gentle stirring for 0.5 min, the solution was desalted three times at 14 000*g* for 6 min, at 4 °C, with an Amicon Ultra-0.5, Ultracel-10 ultrafiltration membrane (Merck Millipore, Cork, Ireland) using phosphate buffer. The final residual solution (≈0.5 mL) was diluted with buffer, yielding 120 μmol/L of the MetMb solution (3 mL). The purity and concentration of the MetMb solution were confirmed using a UVmini 1240 UV/vis spectrometer (Shimadzu).[12]

**Measurement of MetMb Reduction to $MbO_2$.** Briefly, 50 mmol/L of phosphate buffer (pH 7.4, 100 μL), 120 μmol/L of MetMb (150 μL, in the same buffer), test samples (polyphenols) dissolved in DMSO (18 or 9 mmol/L, 10 μL), and cysteine dissolved in water (4.5 or 2.3 mmol/L, 40 μL) were subsequently added to a 96-well microplate. The microplate was then incubated at 37 °C in a Multiskan GO microplate reader (Thermo Fisher Scientific, Yokohama, Japan) for 2 h, and absorbance was measured at 500 and 582 nm. The $MbO_2$ and MetMb concentrations in the wells were calculated using the following equation[8] $MbO_2$ (μmol/L) = $89.7A_{582} - 32.9A_{500}$, where $A_{500}$ and $A_{582}$ refer to absorbance at 500 and 582 nm, respectively. The reductive conversion efficiency from MetMb to $MbO_2$ was expressed as a percentage by calculating the $MbO_2$ concentration relative to the initial concentration (60 μmol/L) of MetMb.

**HPLC and LC−MS Analyses of Caffeic Acid during MetMb Reduction.** For caffeic acid analysis, 10 μL of caffeic acid in DMSO (18 mmol/L), 40 μL of cysteine in water (4.5 mmol/L), and 120 μL of MetMb buffer solution were added to 150 μL of a phosphate buffer (50 mmol/L, pH 7.4) in a microplate well. After shaking the plate, it was incubated at 37 °C in a Multiskan GO microplate reader. At 1 h intervals, an aliquot (5 μL) was removed from the above-mentioned reaction, and the reaction products were analyzed under the following conditions: column, a 250 mm × 4.6 mm i.d., 5 μm, Cosmosil $5C_{18}$-AR-II (Nacalai Tesque); flow rate, 1.0 mL/min; solvent A, 1% acetic acid in water; solvent B, acetonitrile; gradient conditions: linear gradient of 5−100% solvent B (40 min); detection, absorbance at 280 nm. The concentrations of the caffeic acid and its derivative in the reaction mixture were measured by an external standard method and calculated using calibration curves, which were made from the peak areas of several concentrations of authentic samples. The MS data for each product were obtained by performing LC−MS. An additional aliquot (5 μL) was also withdrawn after 2 h for analyzing the compounds of peaks 1 and 2, and the analyses were carried out under the following conditions: column, a 250 mm × 4.6 mm i.d., 5 μm, Cosmosil $5C_{18}$-AR-II (Nacalai Tesque); flow rate, 0.5 mL/min; solvent A, 1% acetic acid in ultrapure water (Wako Pure Chemicals), solvent B, acetonitrile (LC−MS grade) (Merck, Darmstadt, Germany); gradient conditions, linear gradient of 5−100% solvent B (80 min). MS conditions: mode, negative ESI; capillary voltage, 2.4 kV; cone voltage, 40 V; source temperature, 150 °C; desolvation temperature, 500 °C; cone gas flow rate, 50 L/h; desolvation gas flow rate, 1000 L/h, $MS^E$ low collision energy, 6 V; $MS^E$ high collision energy, 20−30 V. The elemental composition of each peak compound was calculated from the high-resolution MS data of the deprotonated molecular ion by using MassLynx software v. 4.1 (Waters).

**Quantitative Analysis of Cysteine and Cystine during MetMb Reduction.** Quantitation of cysteine in the reaction was carried out by using a modified Ellman's method.[13,14] Briefly, at 1 h intervals, an aliquot (20 μL) was withdrawn from the above-mentioned reaction mixture. To the aliquot were subsequently added 30 μL of phosphate buffer (50 mmol/L, pH 7.4), 200 μL of distilled water, and 50 μL of 5,5′-dithiobis(2-nitrobenzoic acid) (0.4 mmol/L). After stirring for 5 min at 23 °C, 10 μL of the solution was withdrawn and the generated 5-hydrosulfuryl-2-nitrobenzoic acid was analyzed via HPLC under the following conditions: column, a 150 mm × 3.0 mm i.d., 3 μm, Cosmosil $3C_{18}$-EB (Nacalai Tesque); flow rate, 0.3 mL/min; solvent A, 0.1% phosphoric acid in water; solvent B, acetonitrile; gradient conditions, linear gradient of 0−100% of solvent B (30 min), detection at 330 min, with a retention time of 10.5 min. The quantitation of the cysteine in the incubating solution was performed using a calibration curve obtained by analyzing the reaction using known concentrations of cysteine.

The quantitation of cystine was carried out by using the method of Mizuta and Sakai[15] with a slight modification.[16] Briefly, 2 or 3 h after the start of incubation, an additional aliquot (20 μL) was withdrawn from the reaction mixture, and 10 μL of benzoyl chloride (8 mmol/L in $CH_3CN$) and 10 μL of triethylamine (8 mmol/L in $CH_3CN$) were added to the aliquot at 0 °C with stirring. After keeping the mixture for 1 h at 0 °C, 10 μL of the reaction mixture was analyzed by HPLC under the following conditions: column, a 250 mm × 4.6 mm i.d., 5 μm, Cosmosil $5C_{18}$-AR-II (Nacalai Tesque); flow rate, 0.5 mL/min; solvent A, 0.1% trifluoroacetic acid in water; solvent B, acetonitrile; gradient conditions, linear gradient of 10−100% of solvent B (50 min); detection, absorbance at 254 nm. The concentration of cystine was determined using a calibration curve, which was derived from the analytical data of authentic cystine.

**Preparation of Cysteinylcaffeic Acids.** 2′- and 5′-*S*-cysteinylcaffeic acids were synthesized enzymatically. Tyrosinase (2 mg) was added to a mixture of caffeic acid (50 mg) and cysteine (68 mg) in 10 mL of a phosphate buffer (50 mmol/L, pH 6.8). After keeping the mixture for 0.5 h at 23 °C, the mixture was concentrated to ≈10 mL in vacuo. The solution was then purified by a preparative HPLC as follows: column, a 250 × 20 mm i.d., 5 μm, Cosmosil $5C_{18}$-AR-II; solvent, $CH_3OH$−1% acetic acid in $H_2O$ (15:85, v/v); flow rate, 8.0 mL/min; detection, 280 nm. 5′-*S*-Cysteinylcaffeic acid (**5**) (7 mg) and 2′-*S*-cysteinylcaffeic acid (**4**) (38 mg) showing peaks at the retention times of 33 and 48 min, respectively, were collected.

*5′-S-Cysteinylcaffeic Acid.* HR-ESIMS (*m*/*z*) $[M - H]^-$ calcd for $C_{12}H_{12}NO_6S$ 298.0385, found 298.0374; $^1H$ NMR (DMSO-$d_6$) δ 8.30 (1H, brs), 7.25 (1H, d, *J* = 15.6 Hz), 6.95 (1H, d, *J* = 1.6 Hz), 6.83 (1H, d, *J* = 1.6 Hz), 5.88 (1H, d, *J* = 15.6 Hz), 2.95 (1H, dd, *J* = 14.8 and 4.0 Hz), 2.90−2.75 (2H, m).

**Statistical Analysis.** Data obtained from the experiments in triplicate are presented as mean ± standard deviation (SD). The differences between means were evaluated using the Student's *t*-test. Statistical significance was considered at $p < 0.05$.

## RESULTS AND DISCUSSION

**MetMb Reduction by Polyphenols in the Presence of Cysteine.** In the previous investigation, the effect of various kinds of polyphenols and the related phytophenols on MetMb reduction was examined (Figure 1). Most of the polyphenols

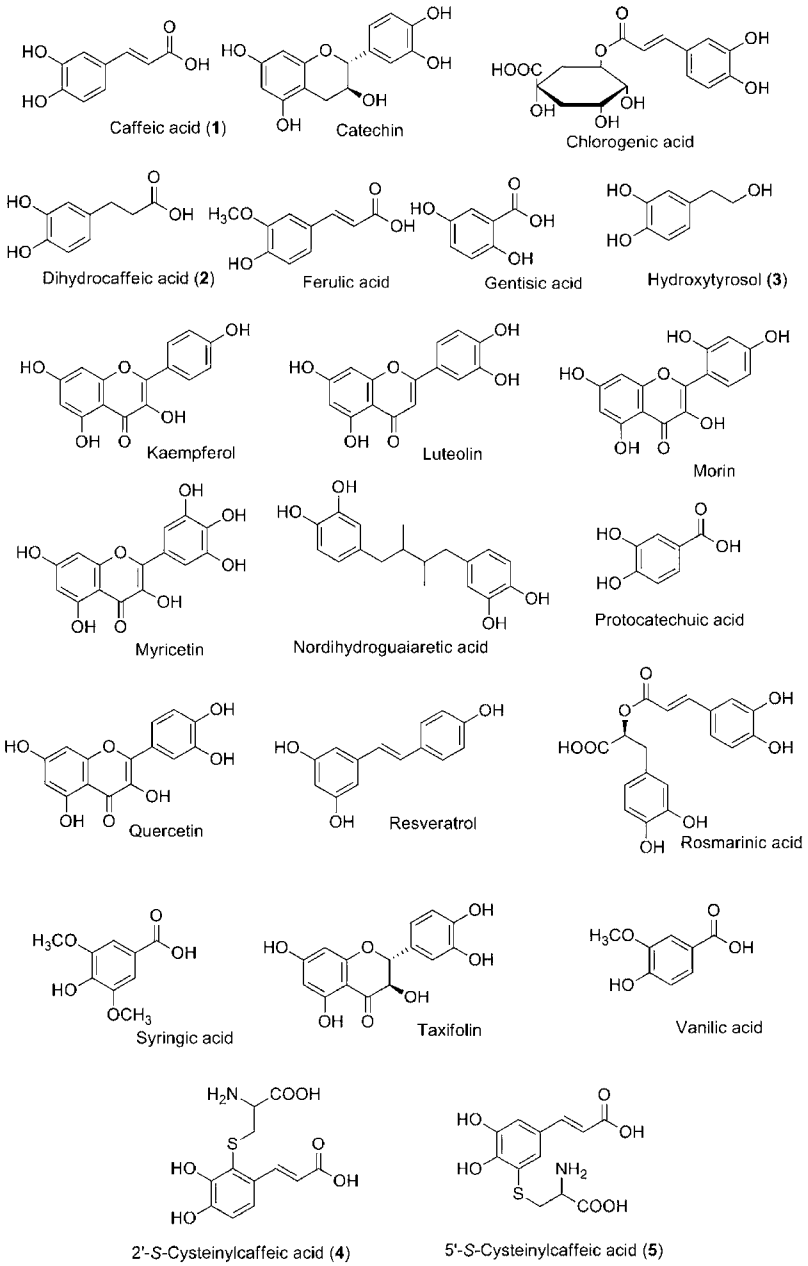

**Figure 1.** Chemical structures of the polyphenols and related phenols investigated for MetMb reduction in the presence of cysteine and two synthesized cysteinylcaffeic acids.

did not show sufficient reducing activity for MetMb, as compared to ascorbic acid. Although cysteine shows no reducing activity toward MetMb, it was expected that cysteine would facilitate the polyphenol-mediated MetMb reduction. Figure 2 shows the results of MetMb reduction in air and the polyphenol-mediated $MbO_2$ formation (concentrations of polyphenols 600 or 300 $\mu$mol/L) in the presence or absence of cysteine (600 or 300 $\mu$mol/L). The data are expressed as a percentage of the ratio of $MbO_2$ produced in air to the total amount of myoglobins (MetMb + $MbO_2$), which was calculated on the basis of the previously reported equation.[8] The figure shows that the reducing activity of most polyphenols was remarkably enhanced by the presence of cysteine, whereas the activity of cysteine itself was extremely weak. In particular, the activity of caffeic acid (**1**), dihydrocaffeic acid (**2**), and hydroxytyrosol (**3**) increased significantly in the presence of cysteine. Caffeic acid, dihydrocaffeic acid, and hydroxytyrosol are powerful antioxidants[17−19] and also have a strong reducing ability.[20,21] Both activities are dependent on their catechol substructures. The catechol structure is readily oxidized to orthoquinone, which may interact with $MbO_2$ to stimulate its oxidation to MetMb. When cysteine is present, the nucleophilic thiol group reacts with quinone to afford more stable polyphenolic derivatives as a result. Further investigation for elucidating the mechanism was carried out using the highly potent caffeic acid.

**Concentration Effect of Caffeic Acid and Cysteine on the Reduction of MetMb.** Two concentration levels, 600 or 300 $\mu$mol/L, of polyphenols and cysteine for carrying out the experiment on MetMb reduction were employed, according to the method reported in a previous study.[8] These above-mentioned concentrations of polyphenols and cysteine are

dx.doi.org/10.1021/jf5039508 | J. Agric. Food Chem. 2014, 62, 9472−9478

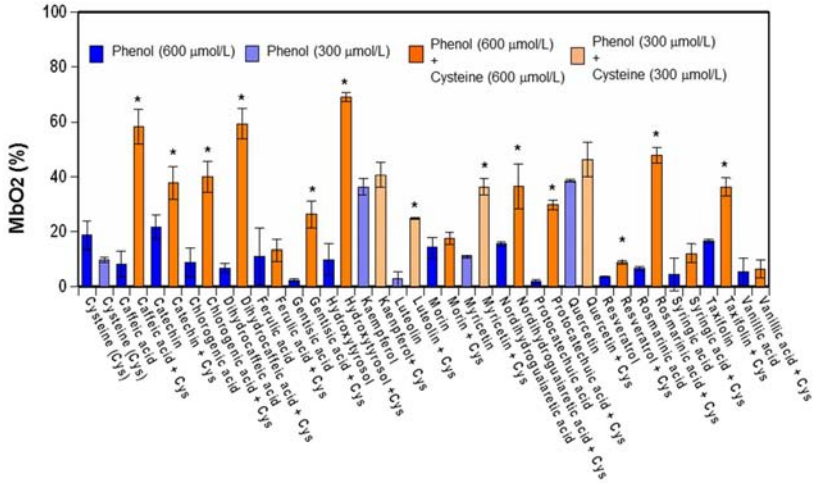

**Figure 2.** Effects of phenols (600 or 300 $\mu$mol/L) on MetMb reduction in the presence of cysteine (600 or 300 $\mu$mol/L). Results are expressed as mean ± standard deviation (SD) ($n$ = 3) and * signifies significantly different data against data from the corresponding experiment in the absence of cysteine ($t$-test, $p < 0.05$).

much higher than the concentration of MetMb (60 $\mu$mol/L). Therefore, we initially examined the concentration effects of not only caffeic acid but also cysteine on the MetMb-reducing reaction, using a microplate method. The obtained matrix data are shown in Figure 3. Pure caffeic acid and cysteine

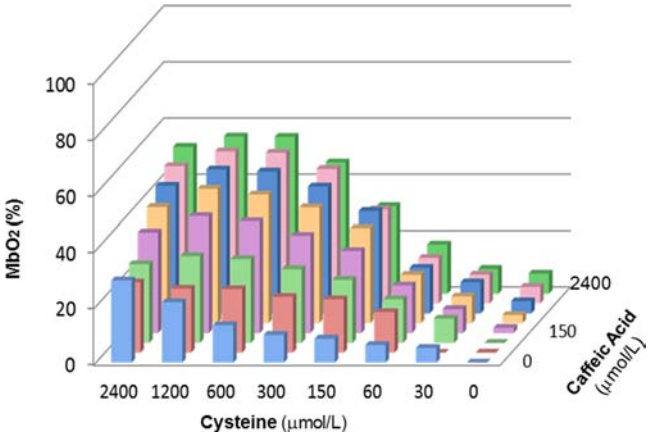

**Figure 3.** Matrix data of the various concentrations of caffeic acid and cysteine used for MetMb reduction. Reducing activity of MetMb is expressed as a percent of the formed $MbO_2$, from the MetMb in the air. All data were presented as mean values of two independent experiments.

independently showed a concentration-dependent activity up to 2400 $\mu$mol/L, but these activities were not very significant. On the other hand, the mixtures of caffeic acid and cysteine showed a remarkable reducing activity. The optimal concentrations of caffeic acid and cysteine were between 600 and 2400 $\mu$mol/L for caffeic acid and 600 $\mu$mol/L for cysteine, 2 h after the reaction commenced. In general, higher concentrations of active compounds are expected to result in an increased efficiency. However, in this case, higher concentrations of cysteine did not show the expected linear concentration-dependent effect. Tang et al.[22] have reported that glutathione, a biothiol related to cysteine, accelerated the oxidation of $MbO_2$ to MetMb at pH 7.2 and 37 °C. This could be the reason why a higher concentration of cysteine (>600 $\mu$mol/L) prevented $MbO_2$ formation.

**HPLC Analysis of MetMb Reduction in the Presence of Caffeic Acid and Cysteine and Identification of the Reaction Products.** We carried out the HPLC analysis of the MetMb-reducing reaction of caffeic acid (600 $\mu$mol/L) in the presence of cysteine (600 $\mu$mol/L). In the HPLC profile, 2 h after the initiation of reaction (Figure 4), two noticeable

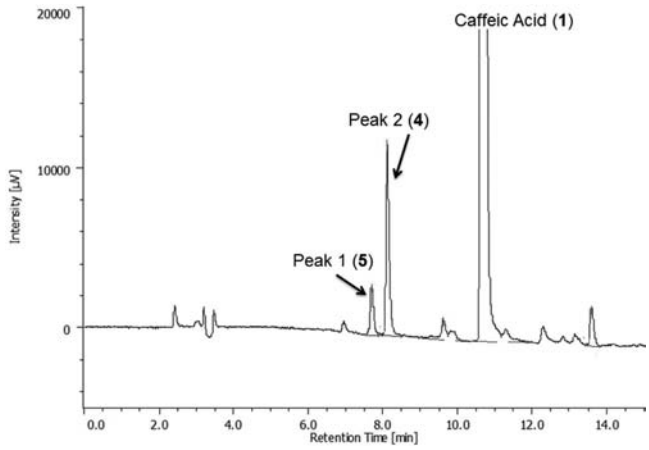

**Figure 4.** HPLC analytical profile for the reaction products from caffeic acid in the presence of cysteine, during the reducing reaction of MetMb at 2 h.

product peaks were observed at the retention times of 7.6 and 8.1 min, respectively, in addition to a large peak corresponding to caffeic acid (10.7 min). To obtain the structure information corresponding to these two peak compounds, they were subjected to MS analysis using LC−TOFMS. High-resolution MS data for peak 1 ($m/z$ 298.0384 $[M - H]^-$) and peak 2 ($m/z$ 298.0400 $[M - H]^-$) indicated that the molecular formula of both peak compounds was $C_{12}H_{13}NO_6S$. From the molecular formula, peaks 1 and 2 were thought to be the isomeric coupling products of an equimolar amount of caffeic acid and cysteine. In our previous study,[10] the radical oxidation of caffeic ester in the presence of a cysteine derivative afforded 2′-*S*-substituted caffeic ester as the main product, which was produced by the addition of cysteinyl thiol to a quinone derivative of the caffeic ester. Therefore, we prepared a similar

dx.doi.org/10.1021/jf5039508 | J. Agric. Food Chem. 2014, 62, 9472−9478

quinone derivative of caffeic acid and then added cysteine to the quinone. A quinone of caffeic acid was synthesized with the help of tyrosinase oxidation, and cysteine was then reacted to obtain the two products, whose structures were fully determined as 2′-*S*-cysteinylcaffeic acid (a major product) and 5′-*S*-cysteinylcaffeic acid (a minor product) by performing MS and NMR. These synthetically obtained cysteinylcaffeic acids were identical to the peak compounds by comparison of the retention times of the HPLC and MS data. Therefore, the structures of the compounds giving peaks 1 and 2 were determined to be 5′-*S*-cysteinylcaffeic acid (**5**) and 2′-*S*-cysteinylcaffeic acid (**4**), respectively. (Figure 1)

**Time Course Analysis of Caffeic Acid and Cysteine and the Oxidation Products during MetMb Reduction.** The time-course analytical results of the formation of two cysteinylcaffeic acids (2′-*S*-cysteinylcaffeic acid and 5′-*S*-cysteinylcaffeic acid) and the decrease of caffeic acid and cysteine in the MetMb-reducing solution are summarized in Figure 5A–C. Figure 5C shows that both the coupling products

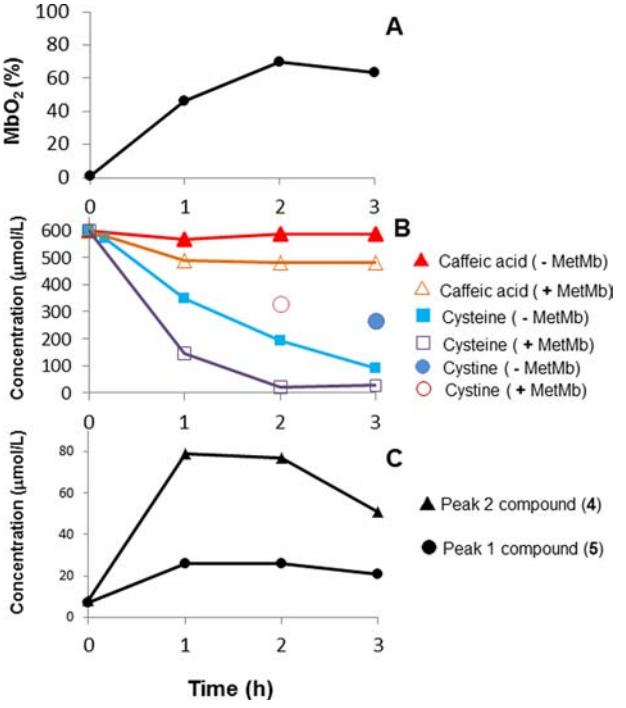

**Figure 5.** Time-course analytical data for $MbO_2$ (A); caffeic acid, cysteine, and cystine (2 or 3 h data only) (B); and reaction products (C) in the reducing reaction of MetMb. All the analytical experiments were performed in duplicate, and the data are expressed in terms of the corresponding mean values.

(2′-*S*-cysteinylcaffeic acid and 5′-*S*-cysteinylcaffeic acid) increased during the first 2 h. During this period, $MbO_2$ was continuously accumulated from the reduction of MetMb, as shown in Figure 5A. The amount of caffeic acid was partially decreased at 2 h, as shown in Figure 5B. Figure 5B also shows that cysteine decreased drastically during this time period. This decreased cysteine was oxidatively converted to cystine owing to the corresponding cystine concentration measured in the 2 h reaction. During the MetMb-reducing reaction, cysteine was completely oxidized. However, Romero et al.[23] reported that the reducing activity of cysteine toward MetMb was negligible. It should be noted that cysteine was unstable under the alkaline aerobic conditions. Therefore, we measured reaction rate of the same concentration of cysteine and caffeic acid without MetMb, and the corresponding results are shown in Figure 5B. Figure 5B shows that the reaction rate of cysteine in the absence of MetMb was lower than that in the presence of MetMb. Moreover, caffeic acid did not decrease during the same time period. These results indicated that MetMb primarily oxidized caffeic acid and then produced two cysteinylcaffeic acids from a subsequent coupling reaction of the remaining cysteine and the oxidized caffeic acid (quinone of caffeic acid). In our previous study,[3] high concentrations of caffeic acid were found to promote the oxidation of $MbO_2$ to MetMb. This $MbO_2$ oxidation may be attributed to interaction between $MbO_2$ and the electrophilically oxidized polyphenols such as caffeic quinone.[24,25] When cysteine was present in the solution, the caffeic quinone that was derived by the oxidation of caffeic acid quickly reacted with the cysteine to form cysteinylcaffeic acids. The cysteinylcaffeic acids might not stimulate $MbO_2$ oxidation because of the absence of any reactive quinone structures.

**Effect of Cysteinylcaffeic Acid on the Redox States of Mb.** During the reduction of MetMb, caffeic acid was oxidized to a corresponding quinone derivative. However, the coexisting cysteine quenched the quinone to produce cysteinylcaffeic acids. Next, we examined the redox activities of the cysteinylcaffeic acids on Mb. Cysteinylcaffeic acids were synthesized with tyrosinase oxidation, and the major product obtained (2′-*S*-cysteinylcaffeic acid) was used for this assessment. The MetMb-reducing activity and $MbO_2$-oxidizing activity of 2′-*S*-cysteinylcaffeic acid were measured. The corresponding results are shown in parts A and B of Figure 6, respectively. Figure 6A shows that 2′-*S*-cysteinylcaffeic acid

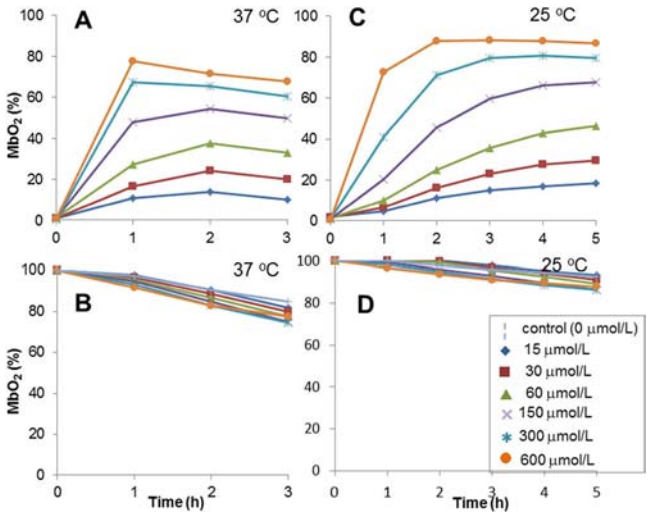

**Figure 6.** Concentration effect of 2′-*S*-cysteinylcaffeic acid on MetMb reduction (A and C) and $MbO_2$ oxidation (B and D) at 37 and 25 °C, respectively. Redox values of MetMb and $MbO_2$ were expressed as the $MbO_2$ percent of Mbs in the reaction. All the analytical experiments were performed in duplicate, and the data are expressed as mean values.

exhibited a potent MetMb-reducing activity in a concentration-dependent manner, but the same concentrations of 2′-*S*-cysteinylcaffeic acid did not show any oxidation activity of $MbO_2$ as compared to the control experiment, as shown in Figure 6B. These results were also observed clearly at lower temperature conditions corresponding to 25 °C as an ambient temperature (Figure 6C,D). At that temperature, $MbO_2$ was

dx.doi.org/10.1021/jf5039508 | *J. Agric. Food Chem.* 2014, 62, 9472–9478

stable until 5 h, and 2′-*S*-cysteinylcaffeic acid did not affect the stability of $MbO_2$ during this time period (Figure 6D). However, 2′-*S*-cysteinylcaffeic acid had a slower but more effective reducing activity for the conversion of MetMb to $MbO_2$, as shown in Figure 6C. It is known that sulfur substitutions in polyphenols alter their redox properties.[10,26] Substituted cysteinyl sulfur can modulate the pro-oxidant activity of caffeic acid and make it nonreactive toward $MbO_2$, while still retaining the powerful reducing activity of the caffeic acid. One of the objectives of the current study[3,8] was the development of a polyphenol-based technology for the preservation of fresh meat color. The cysteine-modified polyphenols may thus provide a novel alternative for the prevention of changes of meat color.

From the results obtained in this study, some highly antioxidative polyphenols produced bright red $MbO_2$ in the presence of cysteine by reducing brown MetMb at pH 7.4. The mechanism is thought to be a combination of the potent reducing activity of polyphenols and the preventive effect of cysteine on the expression of the pro-oxidant property of polyphenols by nucleophilic addition of cysteinyl thiol to oxidized polyphenols, as illustrated in Figure 7. Cysteinylcaffeic acid, a thiol-substituted polyphenol, exhibited no oxidation-stimulating property toward $MbO_2$ after the reduction of MetMb. These results show that the polyphenols were indeed useful in retaining the bright red color of $MbO_2$, with support from biothiols such as cysteine. The bright red color of meat is very important in the food industry. These findings in this investigation should contribute not only to meat science but also to the chemistry of meat products.

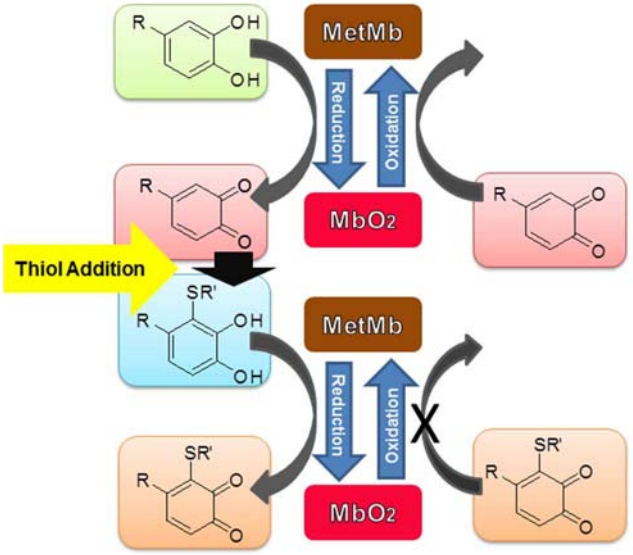

**Figure 7.** Proposed mechanism for redox change between MetMb and $MbO_2$ by polyphenols in the presence of thiols.

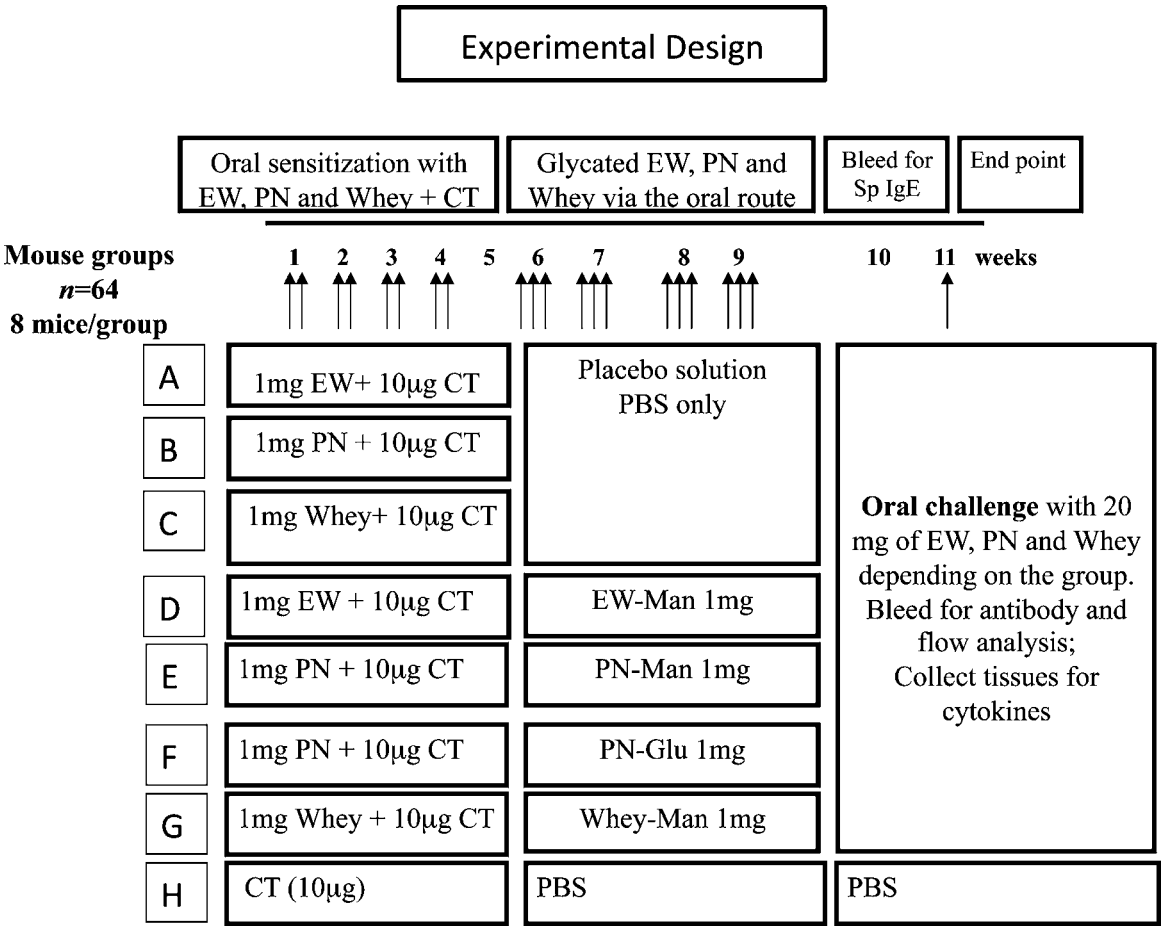

**Figure 1.** Experimental design. Mice were sensitized with 1 mg of egg white (EW), peanut (PN), and whey proteins and 10 $\mu$g of cholera toxin (CT) for 4 weeks, twice a week, followed by a 4 week treatment with mannosylated EW, PN, and whey proteins. The glucosylated PN group was used as a positive test group, and the negative control group received PBS. Clinical signs of allergy were recorded post oral challenge (0−30 min), and all mice were euthuanized for collection of blood and spleen. Both blood and spleen were pooled within groups such that $n$ = 4.

earlier research that mannosylation of OVA did have a potential impact on DCs and antigen recognition and uptake and in reducing allergenicity in vivo in mice. With this background we proposed to study different mannosylated glycoforms of major food allergens such as egg white (EW), peanut (PN), and whey proteins on tolerance induction in vivo in mice. It would be of interest to know under "the glycation allergen concept" if mannosylation influences different allergens in a similar fashion as observed with OVA with regard to reducing allergy or otherwise.

## MATERIALS AND METHODS

**Chemicals.** Carbohydrates such as D-mannose and D-glucose were obtained from Sigma (Oakville, ON, Canada). All antibodies used in the experiments were purchased from BD Biosciences (Pharmingen, San Diego, CA, USA), Sigma (Sigma-Aldrich, Oakville, ON, Canada), or eBioscience (eBiosciences, San Diego, CA, USA).

**Glycation of Common Allergens.** Egg white, PN, and whey proteins were all in-house-extracted and partially purified according to methods previously described.[15−17] Maillard reaction or glycation was performed as described in a previously established method with slight modifications.[11] In brief, mannose (Sigma-Aldrich, St. Louis, MO, USA) was added to the three proteins at a ratio of 1:1 (w/w protein/mannose), mixed into a solution, freeze-dried, and incubated at 55 °C for 3 days (72 h) at 65% relative humidity using saturated potassium iodide solution in a laboratory incubator. Native proteins were treated in a similar manner without mannose and regarded as the native, nonmodified form. All samples were dialyzed (5 kDa cutoff, Millipore, Bedford, MA, USA) with PBS to get rid of the nonconjugated saccharides. As an additional test group, PN proteins were glycated with glucose to be used as a positive control, on the basis of our earlier results that OVA conjugated to glucose did not alleviate allergic signs in mice.[11]

**Determination of Molar Binding Ratios.** Total carbohydrate (CHO) content was determined by the phenol/sulfuric acid colorimetric method at 490 nm with D-mannose as standard.[18] Protein concentration was measured using the standard bicinchoninic acid method.[19] Due to complex total proteins used, conjugation binding ratios for binding of CHO to total protein were calculated on the basis of the concentration using the following formula: concentration of CHO/concentration of total protein.

**SDS-PAGE.** Glycation was also confirmed with running the conjugated samples on sodium dodecyl sulfate−polyacrylamide gel electrophoresis (SDS-PAGE) gel. Each of the samples was mixed with 2× sample loading buffer and incubated for 10 min at 65 °C prior to SDS-PAGE on a 12% polyacrylamide separating gel with a 5% stacking gel. Electrophoresis was performed at a constant current of 30 mA using a mini Protean apparatus (Bio-Rad). The gel was placed into Coomassie Blue stain solution for 1 h postelectrophoresis and then destained in distilled water for 1 h and photographed.

**Mice and Sensitization.** All animal use protocols were based on Canadian Council for Animal Care guidelines and approved by the University of Guelph Animal Care Committee (eAUP No-1567). Briefly, 64 female Balb/c mice were randomly divided into eight groups ($n$ = 8/group). Mice were orally sensitized with 1 mg of EW, PN, and whey proteins adjuvanated with 10 $\mu$g of cholera toxin (CT;

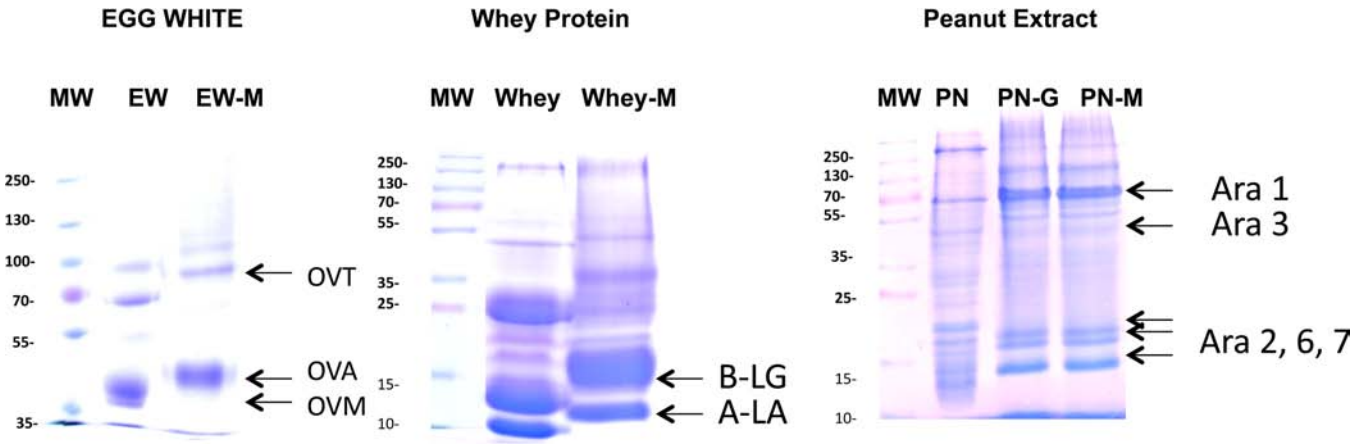

**Figure 2.** Coomassie staining of SDS-PAGE patterns of native and glycated allergens. EW represents egg white, and EW-M represents mannosylated EW. PN represents peanut proteins, PN-M represents mannosylated PN, and PN-G represents glucosylated PN. Whey-M represents mannosylated whey. MW in all panels represents molecular weight markers (kDa).

List Biologicals, Campbell, CA, USA) for 4 weeks (twice a week) as presented in Figure 1. Mice were further treated with mannosylated and glucosylated antigens (1 mg) for 4 weeks (three times/week). At week 11 mice were orally challenged with 20 mg of each antigen and monitored for clinical signs of allergy as described earlier.[11] Clinical scores were assigned in a blind fashion by three experienced observers. Total scores for each animal were obtained by adding scores for each individual sign. Blood was collected for measurement of histamine, antibody activity, and flow cytometry, and all samples were centrifuged for 20 min at 2000*g* and kept at 4 °C to obtain sera. All samples were stored at 20 °C until further analysis. Spleens were collected for measuring cytokines.

**Measurement of Serum Histamine and Mouse Mast Cell Protease.** Concentration of serum histamine post oral challenge was determined using an enzyme immunoassay kit (Labor Diagnostika Nord, Nordhon, Germany) according to the manufacturer's instructions. The mouse mast cell protease enzyme (MMCP) concentration was determined by ELISA as recommended by the manufacturer (eBioscience).

**Measurement of Allergen-Specific IgG, IgE, IgG1, and IgG2a.** Serum allergen-specific IgE, IgG1, and IgG2a were detected by an indirect sandwich-type enzyme-linked immunosorbent assay (ELISA) using standard protocols as described earlier.[11,15−17] In brief, 96-well microtiter plates (Costar, Corning Inc., NY, USA) were coated with 100 μL of EW, PN, and whey antigens (50 μg/mL in 50 mM carbonate buffer; $NaHCO_3/Na_2CO_3$, pH 9.6) for 24 h at 4 °C. Rabbit anti-mouse IgG conjugated to alkaline phosphatase was used for the detection of IgG, and rat monoclonal anti-mouse IgE was used for IgE followed by streptavidin−HRP conjugate. For IgG1 and IgG2 rat monoclonal anti-mouse IgG1 and IgG2a were used followed by streptavidin−HRP conjugate. In brief, plates were washed and blocked with 2% bovine serum albumin/phosphate-buffered saline (PBS) at 37 °C for 1 h. Serum samples (diluted 1:10 for IgE measurement, 1:100 for IgG, IgG1, or IgG2a) in PBS containing 0.05% Tween 20 (PBS/Tween) were added and incubated for 2 h at room temperature in duplicates. Plates were again washed, and the bound antibodies were detected by adding respective detection antibodies at room temperature for 1 h. Specific binding activity was detected by the addition of 100 μL/well of 3,3′,5,5′-tetramethylbenzidine substrate (Sigma). The reaction was terminated with 2 N $H_2SO_4$ after 30 min, and absorbance at 415 nm was measured by a microtiter reader (Bio-Rad 550, Hercules, CA, USA). The data were expressed as percentage of positive control in optical density units. Percentage of positive control activity = (mean test OD/mean positive control serum OD) × 100.

**Determination of Specific IgA in Mouse Fecal Pellets.** Antigen-specific IgA was measured in mouse fecal pellets collected freshly on a weekly basis at weeks 9, 10, and 11 and was processed as described earlier.[11] Indirect ELISA procedure for measuring specific IgA was followed as described earlier[11] except for the coating antigens replaced with EW, PN, and whey (10 μg/100 μL/well of antigens).

**Quantification of Specific Cytokines in Splenocytes.** Post oral challenge, mice from each group were euthanized, and individual spleens were aseptically removed and minced. After erythrocyte lysis, spleen cells were resuspended in complete medium (RPMI 1640 containing 10% fetal bovine serum, 2 mM L-glutamine, 25 mM Hepes, 100 IU/mL penicillin, 100 mg/mL streptomycin). Spleen lymphocytes from individual mice were used in further analysis of cytokine measurements. Splenocyte suspensions at a concentration of $2.5 \times 10^6$ cells/well were daily stimulated with 50 μg/well of EW, PN, and whey antigens, respectively, for 72 h, whereas splenocytes from the mice treated with CT were added with 50 μL of saline as controls (unstimulated). The plates were covered and incubated at 37 °C in a 5% $CO_2$ incubator with 95% humidity, and after 72 h, the aliquots were stored at −80 °C until further use. Concentrations of cytokines IFN-γ, IL-4, IL-10, IL-12, and TGF-β were determined using commercially available ELISA kits according to the manufacturer's instructions as described earlier.[11]

**Flow Cytometry.** Flow cytometry was done using whole blood collected postchallenge from individual mice and pooled in duplicates ($n$ = 4/group). Staining protocols were carried out as recommended by the manufacturer (BD Bioscience, San Jose, CA, USA). Samples were stained with 100 μL of FITC-conjugated anti-mouse CD25 antibody (558642; BD Bioscience) and phycoerythrin (PE)-conjugated anti-mouse Foxp3 (clone FJKS-16; eBioscience) measured via a fluorescence activated cell sorter (FACScan Flow cytometer; BD Bioscience). After forward-scatter versus side-scatter gating, fluorescence channels were analyzed and thresholds were set on isotype controls. Analysis was done using FCS Express 4 Plus software, and results were presented as percentage of double-stained $CD25^+$ $Foxp3^+$ cells.

**Statistical Analyses.** All data were analyzed using GraphPad Prism software version 5.0 (GraphPad Software, San Diego, CA, USA). All data were expressed as means ± SEM and subjected to ANOVA analyses followed by post hoc multiple comparison using Tukey's test. Comparison of all the end point differences with a level of $p < 0.05$ was considered significant.

## RESULTS

**SDS-PAGE.** Modifications of proteins due to the Maillard reaction in the presence or absence of CHO were observed as evidenced by the electrophoretic pattern. Figure 2 presents the SDS-PAGE pattern of the common allergens (EW, PN, and whey) before Maillard reaction (native, nonmodified protein) and after heating with allergen in the presence of mannose. All proteins heated in the presence of CHO appeared to be more

stable and were detected with a molecular weight slightly higher than that of the native protein, indicating occurrence of glycosylation. Moreover, slight aggregate formation was observed with PN and whey proteins, which was manifested by its presence at the boundary of the resolving and stacking gel. Nonglycated fractions were not visible, confirming negligible amounts of intact proteins in the glycated fractions. The binding ratios of the glycated fractions are given in Table 1.

**Table 1. Binding Ratio of the Conjugates**

| glycated protein | CHO concn/protein concn ratio (w/w) |
|---|---|
| EW-M | 3.85 |
| PN-M | 6.67 |
| PN-G | 6.67 |
| whey-M | 8.00 |

**Attenuation of Allergic Phenotype.** Both clinical signs and clinical scores were less severe and frequent in the mannosylated EW group (Figure 3A; $p < 0.05$). Histamine concentration was significantly reduced in the mannosylated EW group (Figure 3B; $p < 0.05$), and MMCP concentration (Figure 3C; $p < 0.05$) was significantly reduced in both mannosylated EW and PN groups. All other groups did not differ significantly ($p > 0.05$).

**Immunoglobulin Isotype-Related Antibody Activity.** Specific IgG, IgG1, and IgE isotypes were significantly different in the mannosylated EW group (Figure 4; $p < 0.05$). Specific IgG2 did not differ between groups ($p > 0.05$). Also, specific IgA as observed with glucosylated and mannosylated PN groups was less as compared to the native PN ($p < 0.05$) group. Specific IgA did not differ for the EW and whey groups ($p > 0.05$).

**Cytokine Concentration.** Concentrations of type-1 cytokines IL-12 and IFN-$\gamma$, type-2 cytokine IL-4, regulatory cytokines IL-10 and TGF-$\beta$, and pro-inflammatory cytokine IL-17A were measured. There was a significant decrease (Figure 5; $p < 0.05$) in IL-4 and a significant increase (Figure 5; $p < 0.05$) with IL-10 cytokines measured with the mannosylated EW group. Other groups did not differ significantly for the measured cytokines ($p > 0.05$).

**Proportion of T-Regulatory Cells.** The proportion of blood T-regs was measured, and there was a significant increase in the percentage of $CD25^+$ $Foxp3^+$ cells as measured in the mannosylated EW group (Figure 6; $p < 0.05$). All other groups treated otherwise did not differ significantly ($p > 0.05$). A representative image for each treatment group is shown in Figure 6.

## DISCUSSION

Structural changes of proteins that evolve due to conjugation of proteins with reducing sugars through the Maillard reaction are an effective way of improving the functionality of the protein, and this also seems to be a promising method for masking food protein allergenicity. We have for the first time, to the best of our knowledge, established that mannosylated EW plays a

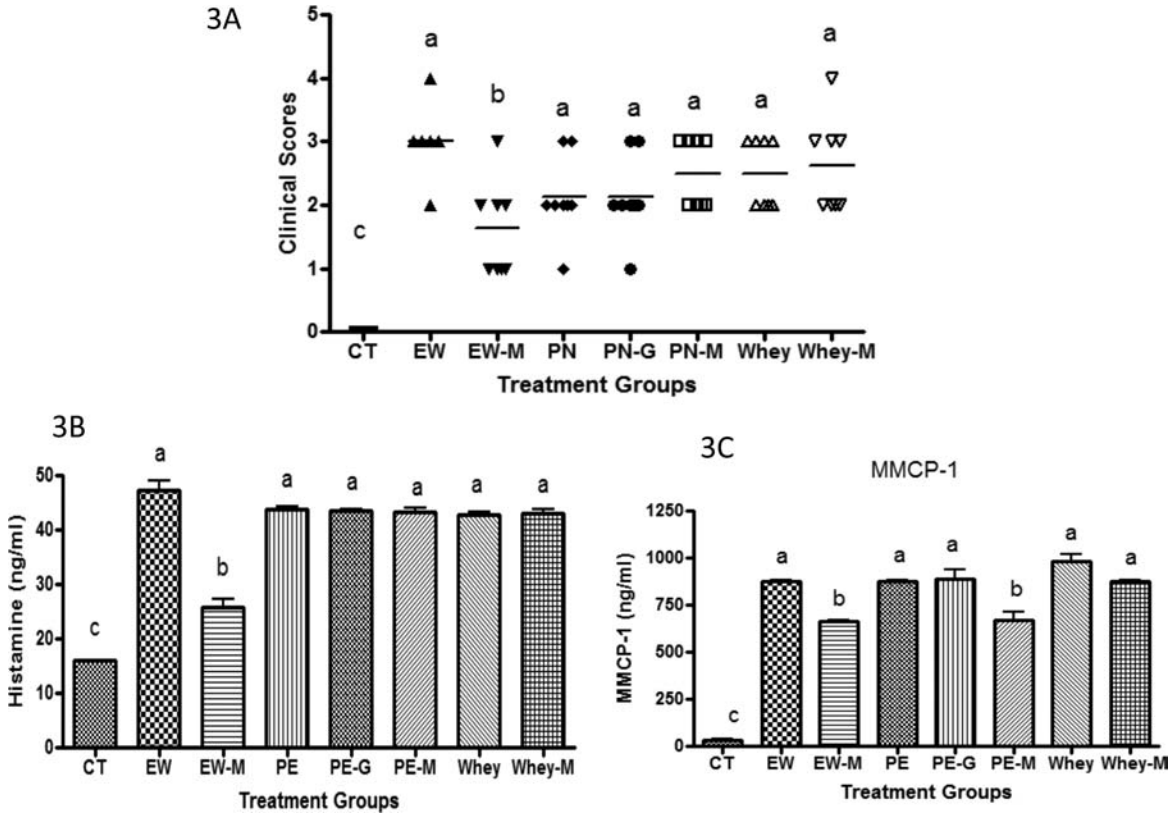

**Figure 3.** (A) Clinical scores for individual mice. Total clinical scores for each mouse post oral challenge on week 11 were calculated. Average scores were assigned by three independent observers in a blind fashion. Treatment groups differed significantly ($p \leq 0.05$; GraphPad Instat) in frequency of mice expressing allergic signs. (B) Serum histamine concentration. Data for serum histamine concentration are presented as mean ± standard deviation ($n = 4$ pooled sera). (C) Mouse mast cell protease (MMCP) concentration. Data for MMCP concentration are presented as mean ± SD. Different letters indicate statistically significant differences ($p < 0.05$) between groups of mice.

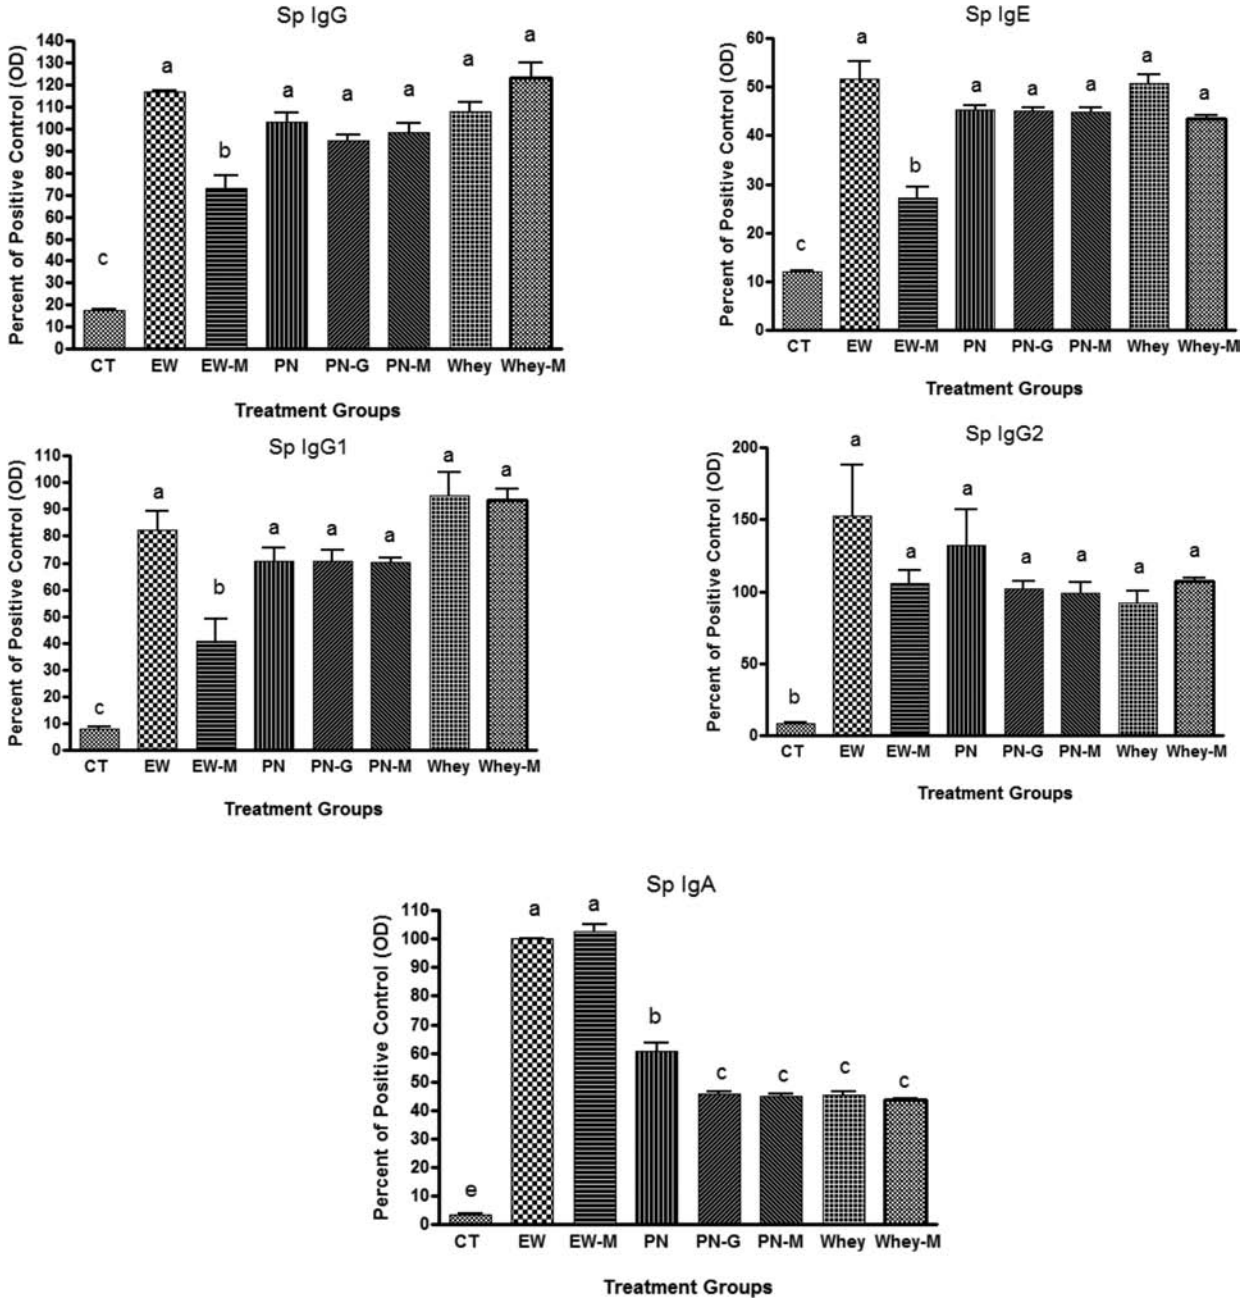

**Figure 4.** Antigen-specific IgG, IgE, IgG1, IgG2, and IgA-related antibody activity. Antigen-specific serum antibody activity was measured by ELISA in triplicates for each sample. Rabbit anti-mouse IgG conjugated to alkaline phosphatase was used for the detection of IgG, and rat monoclonal anti-mouse IgE was used for IgE followed by streptavidin−HRP conjugate. For IgG1 and IgG2 rat monoclonal anti-mouse IgG1 and IgG2a were used followed by streptavidin−HRP conjugate. IgA was detected from pooled fecal samples collected during weeks 9−11 using biotinylated rat monoclonal anti-mouse IgA antibody followed by avidin−HRP conjugate. Data are presented as percentage of positive control (sera from mice that had high Ovm-specific IgG) activity, calculated as [optical density (OD) of test serum]/(OD of positive control serum − OD of negative control) × 100%. Significance was taken at $p \leq 0.05$. Different letters indicate statistically significant differences.

critical role in attenuating the development of allergic sensitization. Mice were significantly protected against most of the aspects of allergic inflammatory response for the biomarkers tested. There was a significant difference in the IR phenotype measured with the mannosylated EW group, such that the mice had reduced clinical scores, histamine, and MMCP. Mice also had less specific IgG and IgE as compared to the EW group. Cytokine profiles revealed that the mannosylated EW group had less IL-4 and more IL-10. The proportion of T-regs differed significantly from those of the native EW group. It may be postulated that structural changes to mannosylated EW may have affected the stability and uptake of the protein, thereby altering its digestability and absorption, and this may have resulted in reduction of its allergenic potential.

Mannosylated PN and whey did not attenuate allergic signs, indicating that these proteins do not functionally interact to augment inhibition of the effector phase of the allergic inflammatory response and did not appear to be important determinants of modulating the outcomes of allergic signs. It

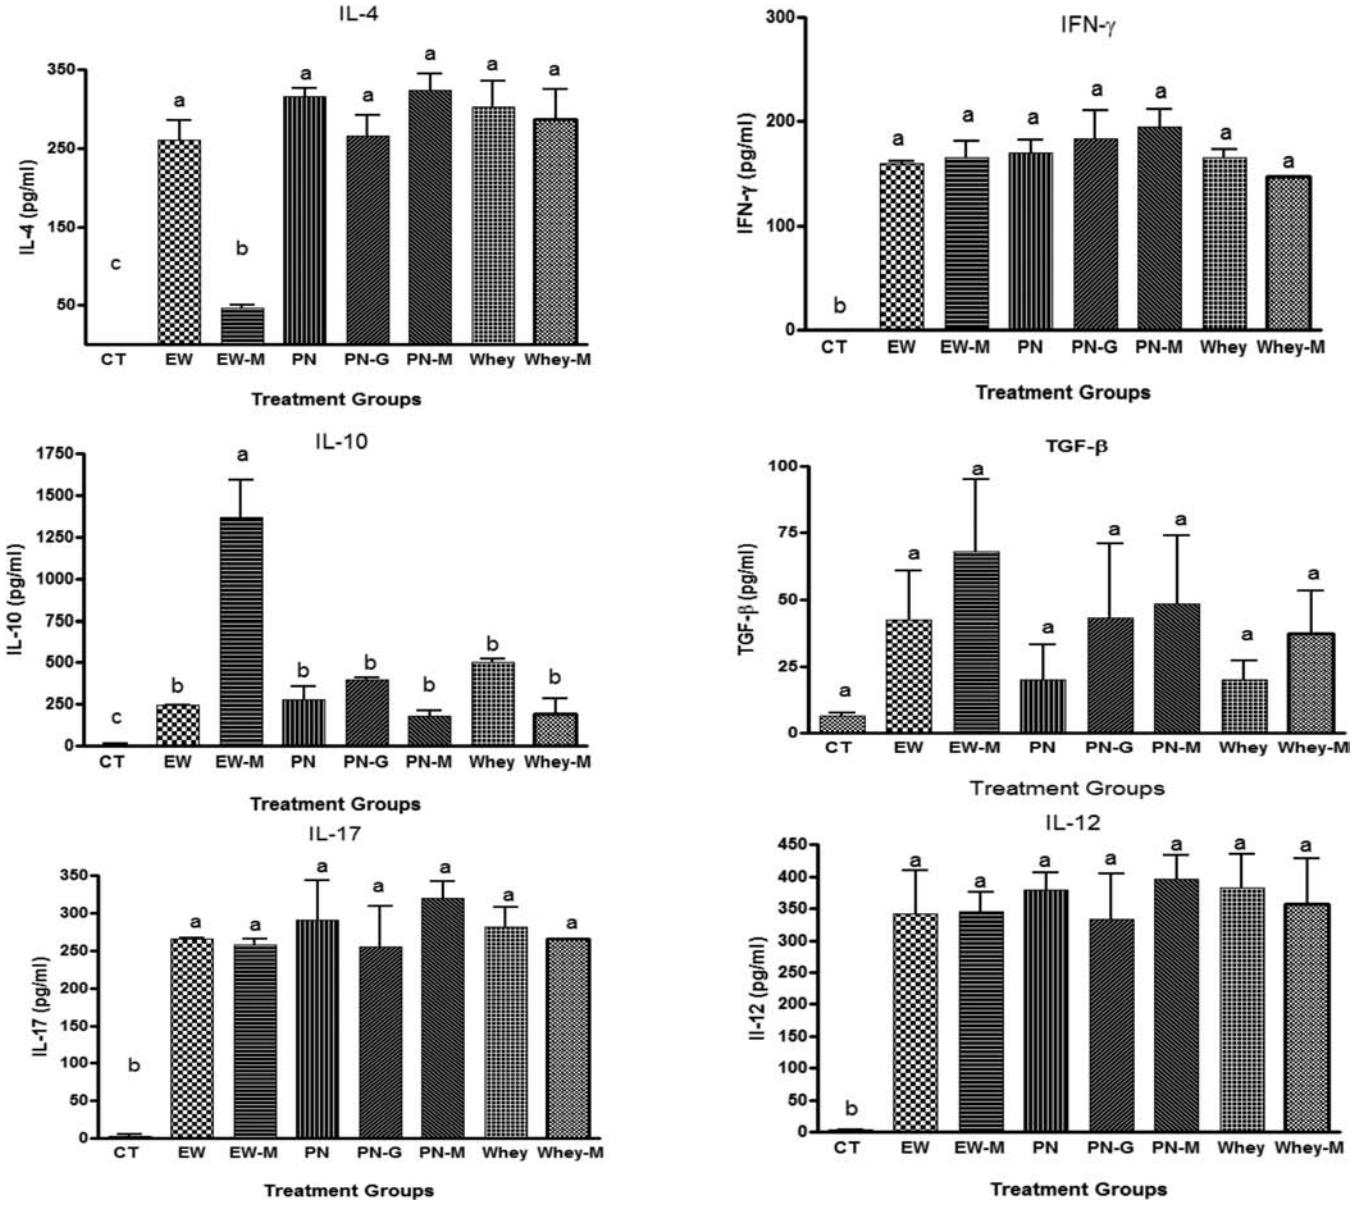

**Figure 5.** Cytokine concentration. Spleens were collected from each mouse and pooled within groups ($n$ = 4), and splenocytes were isolated and cultured at $2.5 \times 10^6$ cells/mL concentration of cells in triplicate wells as unstimulated (control) or stimulated with 50 $\mu$g/well each antigen for 72 h. The cytokine concentration of cell culture supernatants for IL-4, IFN-$\gamma$, IL-12, IL-10, TGF-$\beta$, and IL-17 was determined by ELISA. Different letters indicate significant difference between groups for each cytokine. Significance was taken at $p \leq 0.05$.

was earlier demonstrated that extracts from roasted PN were shown to bind higher IgE levels than extracts from raw PN,[20] and other studies have supported a role of advanced glycated products in enhancing IgE binding.[21] This is in good agreement with the study conducted here that both glucosylated and mannosylated PN did not alleviate clinical signs of allergy in Balb/c mice. Most of the biomarkers tested for allergy did not differ significantly as compared to the native PN antigen group, except for reduced MMCP concentration as observed in the mannosylated PN group. MMCPs under normal/unprovoked conditions are sequestered within the MC granule, and degranulation of MC leads to the massive release of fully active MC proteases.[22] An inhibitory allergic effect may result from reduced concentration of MMCP; however, in this case, although protein mediator releasing capacity was low with MMCP, it is unclear what contibuted to overall allergic signs of the mannosylated PN group, so this hypothesis requires further studies.

Effects of heat treatment on whey protein isolate (WPI) were reported earlier by Bu et al.,[23] and they showed that the antigenicity of WPI increased with increasing temperature from 50 to 90 °C. However, antigenicity remarkably decreased above 90 °C. This was similar to the observation in this study that whey protein incubated at 55 °C for 3 days did not decrease allergenicity in vivo. It may be possible that Maillard reaction may have led to the exposure of allergenic whey protein epitopes of the native molecule due to the unfolding of conformational structure. New epitopes may have emerged as a result of the conjugation process and led to the exposure of the hydrophobic region. On the other hand, effects of Maillard reaction of WPI with glucose were investigated earlier using response surface methodology, and the results demonstrated that the conjugation of WPI with glucose effectively reduced

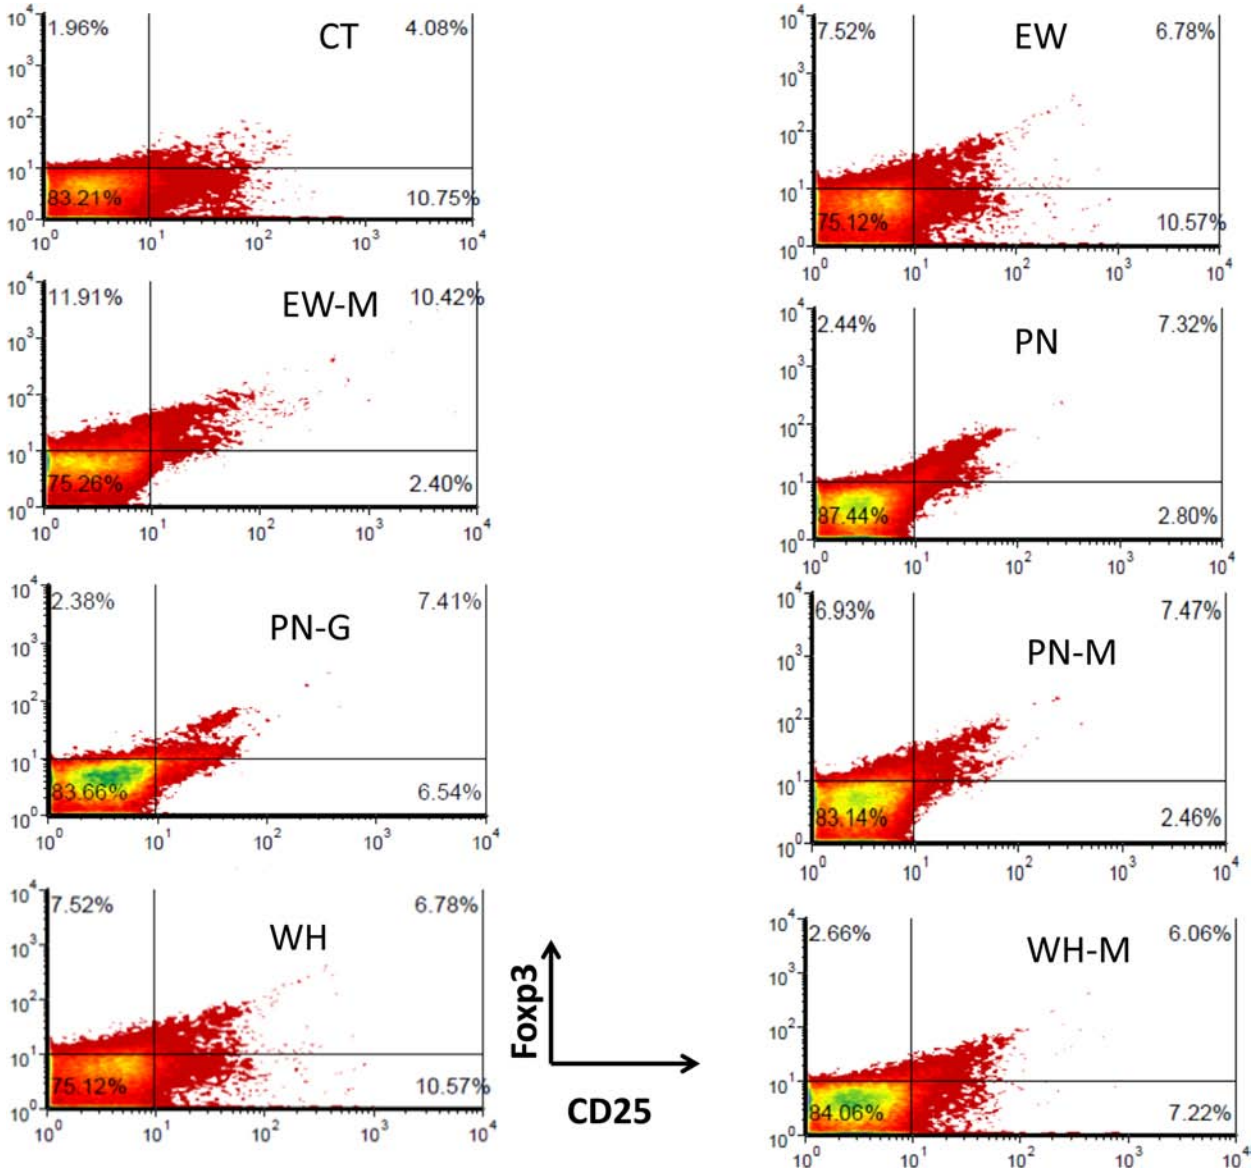

**Figure 6.** Flow cytometry. Percentage of $CD25^+$ $Foxp3^+$ cells was determined by FACS from whole blood of mice collected post oral challenge. A representative image of $CD25^+$ $Foxp3^+$ cells for each group and respective percentage of cells for each quadarant are shown.

the antigenicity.[24] It was also shown earlier that that the antigenicity of $\beta$-lactoglobulin and bovine serum albumin, major allergens in WPI, were significantly reduced by glycation with maltopentaose (MP) or glycation and phosphorylation, respectively.[25,26]

Several studies have earlier demonstrated that antigen mannosylation or mannosylated Ag delivery systems, such as mannosylated liposomes, could enhance not only MHC class II- but also MHC class I-restricted Ag presentation and T cell stimulation by targeting mannose receptors on Ag-presenting cells.[27,28] It was also shown that oligomannose-coated liposome ameliorates allergic signs in OVA-sensitized allergic mice.[29] In this study, the Maillard reaction induced changes in mannosylated EW allergic functionality. We speculate that the loss of secondary structure may have led to the destruction of conformational epitopes and thus to a decreased IgE binding capacity, and this may have had an effect on EW allergenicity. Also, mannosylation may have reduced the digestibility and absorption of the EW allergen in mouse. It was earlier reported that glycation of EW with MP reduced antiovomucoid and anti-OVA antibody response, and glycation and phosphorylation of EW by dry-heating overall improved the functional properties of EW protein.[30] We had demonstrated earlier via mannosylation of OVA that a change in secondary structure and processing via dendridic cell uptake and T cell activation led to alleviated allergic signs in mice.[11] However, circular dichroism for measuring secondary structure of EW, PN, and whey was not performed here due to the complex nature of the proteins. It was earlier shown that the transfer of $CD25^+$ T regs suppresses Th2-dependent reactions to allergens in vivo by an IL-10-mediated pathway and is thus able to reduce airway hyper-reactivity in a mouse model.[31] It is also known that the skew from type-2 allergic response to T reg predominance and influence of T reg-derived IL-10 response are known to strongly suppress allergen-specific IgE production.[32] Work done here confirms this and supports the concept that T reg-derived IL-10 may have used a similar molecular pathway to suppress allergen-specific IgG, IgG1, and IgE with mannosy-

dx.doi.org/10.1021/jf503109r | J. Agric. Food Chem. 2014, 62, 9479−9487

lated EW. Also, Aoki et al. have earlier confirmed that attachments of mannose to Cry j 1 allergen increased the colocalization of antigen with immune cells, such as dendritic cells, which have a mannose receptor, and it is expected that Cry j 1−mannnose conjugate is presented to antigen-presenting cells, such as dendritic cells, by mediation of a mannose receptor, leading to sequent antigen presenting to regulatory T cells.[33] This may be one of the possible mechanisms occurring here for increased frequency of T reg cells in the EW-M group.

Overall, this study reveals that mannosylated EW effectively suppressed orally induced allergic IR in mice. Several pieces of mechanistic evidence as derived from this study suggest that mannosylated EW modifies numerous surrogate clinical markers of allergy and validates a practical approach to cure egg allergy. Nevertheless, it also concludes that this approach does not seem to apply to any given allergen such as PN or whey. These results could have important implications for therapeutic use and potentially be targeted as a valid strategy for the effective treatment of egg allergy.

handling of fish was licensed by the Government of the Hong Kong Special Administrative Region and endorsed by the Animal Experimentation Ethics Committee of The Chinese University of Hong Kong.

SU5416 (1,3-dihydro-3-[(3,5-dimethyl-1*H*-pyrrol-2-yl)methylene]-2*H*-indol-2-one), a selective vascular endothelial growth factor (VEGF) receptor-2 inhibitor, was from Sigma.

**Cell Culture.** Human umbilical vein endothelial cells, HUVEC-C (CRL-1730, ATCC) at early passages (passages 8−15) were cultured in Dulbecco's modified Eagle's medium/Ham's nutrient mixture F12 (1:1) (DMEM/F12) (Gibco, catalog no. 12400-024) supplemented with 10% fetal bovine serum (Gibco, Gaithersburg, MD, USA), 0.1 mg/mL heparin (Sigma, catalog no. H3393), 0.03 mg/mL endothelial cell growth supplement (ECGS) (Sigma, catalog no. E2759), and 1% penicillin−streptomycin. Cells were incubated at 37 °C under 5% $CO_2$.

**Sample Preparation.** Samples of sclerotium were lyophilized before they were pulverized into powders to pass through a screen with a 0.5 mm sieve using a cyclotech mill (Tecator, Höganäs, Sweden). The milled powders (400 g) were extracted with 4 L of 60% ethanol three times at room temperature for 24 h, and the extract was centrifuged and filtered through no. 2 filter paper (Whatman International Ltd., Maidstone, Kent, UK), and concentrated in a rotary evaporator (Rotavapor R-200; Buchi, Postfach, Swizerland).

**Folin−Ciocalteu Assay.** The total phenolic content of EE was determined by using the Folin−Ciocalteu method with some modifications.[17] One milliliter of EE solution (1 mg/mL) was mixed with Folin−Ciocalteu reagent (1 mL). After 3 min of incubation at room temperature, 1 mL of saturated $Na_2CO_3$ (35% aqueous solution) was added to the mixture and adjusted to 10 mL with distilled water. The mixture was kept in the dark for 90 min, followed by the absorbance being read at 725 nm. Gallic acid was used to prepare the standard curve (0.01−0.4 mM). The total phenolic content of EE was expressed as gallic acid equivalents (GAE) as the amount of gallic acid (mg) per gram of extract.

**DPPH Radical Scavenging Assay.** The DPPH radical scavenging activity of EE was assayed according to the method described previously[18] with some modifications. Various concentrations (0.05−2 mg/mL) of EE or negative control (60% ethanol) (0.5 mL) were mixed with 1.0 mL of 0.1 mM DPPH radical solution. The mixture was vortex-mixed and left to stand for 30 min in the dark, the reduction of DPPH radical was determined by measuring the absorbance at 520 nm. *tert*-Butylhydroquinone (TBHQ) (1.5 g/mL) was used as standard.

The DPPH radical scavenging activity (%) was calculated by using the following equation:

$$\text{scavenging activity (\%)} = [1 - (\text{Abs}_{520\text{nm, sample}}/\text{Abs}_{520\text{nm, control}})] \times 100$$

The $IC_{50}$ value (mg/mL) refers to the effective concentration to scavenge the DPPH radicals by 50%.

**$ABTS^+$ Radical Scavenging Assay.** The $ABTS^+$ scavenging potency of EE was assayed according to the method described previously[19] with some modifications. Five milliliters of 7 mM ABTS was mixed with 88 μL of 140 mM potassium persulfate and kept for 12−16 h at room temperature in the dark to allow the completion of radical generation. The reagent was diluted with 95% ethanol to give an absorbance of 0.70 ± 0.05 at 734 nm. Then 1 mL of ABTS solution was mixed thoroughly with 10 μL of EE solution of different concentrations, and the absorbance was recorded at 734 nm at 6 min after the initial mixing, using the ethanol as blank. Trolox, with a concentration range of 0.5−2 mM, was prepared as a standard. The percentage scavenging effect was calculated as

$$\text{scavenging rate (\%)} = [1 - (\text{Abs}_{734\text{nm, sample}}/\text{Abs}_{734\text{nm, control}})] \times 100$$

The antioxidant activity of sample was expressed as Trolox equivalent antioxidant capacity (TEAC), which represented the concentration (mM) of Trolox, having the same activity as 1 mg of sample.

**Hydrogen Peroxide Scavenging Assay.** The scavenging activity of hydrogen peroxide was measured using a commercial kit (PeroXOquant Quantitative Peroxide Assay Kits, Pierce, catalog no. 23280) according to the manufacturer's instruction. Working reagent was prepared by mixing reagent A (25 mM ammonium ferrous(II) sulfate, 2.5 M $H_2SO_4$) with reagent B (100 mM sorbitol, 125 M xylenol orange in water) (1:100, v/v). EE at various concentrations (0.02−2 mg/mL) was mixed with 0.1 mM $H_2O_2$ (Wako, catalog no. 080-01206) for 15 min before assay, whereas standard was prepared by diluting 30% $H_2O_2$ to various concentrations (0−1000 μM) with water. An aliquot (20 μL) of sample or standard and 200 μL of working reagent were added into a 96-well plate. The plate was then incubated at room temperature for 20 min for the reaction. The absorbance was read at 595 nm. The concentration of $H_2O_2$ present in the sample was determined by interpolating from the sample absorbance value using the standard curve. The hydrogen peroxide scavenging activity (%) was calculated by using the following equation:

$$\text{scavenging activity (\%)} = \{1 - ([H_2O_2]_{\text{in sample}}/[H_2O_2]_{\text{in control}})\} \times 100$$

**HPLC-UV-ESI/MS Analyses.** Thirteen phenolic compound standards including flavonoids (quercetin) and phenolic acids (ellagic acid, sinapic acid, gallic acid, protocatechuic acid, chlorogenic acid, caffeic acid, syringic acid, cinnamic acid, ferulic acid, folic acid, salicylic acid, and coumaric acid) were purchased from Sigma-Aldrich (St. Louis, MO, USA). The standard stock solutions (30.3, 100, and 1000 μM) were made with the appropriate HPLC grade solvents. All standard calibration curves showed high degrees of linearity ($R^2$> 0.99) (data not shown). Sample compounds were identified on the basis of the retention times, UV spectrum, and MS spectrum of standard compounds and were quantified by comparing their peak areas with those of standard curves.

The FT-ICR MS analysis was performed using the Apex Ultra 7.0 Hybride Qh-FTMS (Bruker Daltonics Inc., USA) equipped with an Apollo II ion source and Dionex Ultimate 3000 2D Nanoflow LC system (Bruker Daltonics Inc., USA).

EE was redissolved in 60% aqueous methanol (HPLC grade) (J. T. Baker, Phillipsburg, NJ, USA) and filtered through a 0.45 μm nylon membrane filter (TITAN, Rockwood, TN, USA). A 3 μL filtrate was loaded on the HPLC and FT-MS system. Separation was achieved on an analytical (2.1 × 150 mm) C18 column (5 μm) (XBridge, Waters, Dublin, Ireland). The system was connected to two solvents used as mobile phases: Solvent A was 0.1% formic acid in Milli-Q water, and solvent B was 100% acetonitrile (Scharlau, catalog no. AC03402500). Table 1 shows the elution profile. The flow rate was 0.3 mL/min, and the temperature of the column was kept at 30 °C.

**Table 1. Elution Profile Used in the HPLC and LC-MS Analyses**

| time (min) | % formic acid (%) | 100% acetonitrile (%) |
|---|---|---|
| 0 | 95 | 5 |
| 40 | 70 | 30 |
| 45 | 50 | 50 |
| 65 | 30 | 70 |
| 70 | 30 | 70 |
| 71 | 95 | 5 |

**MTT Assay.** The MTT (3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide) assay was used to evaluate the cytotoxicity of EE on normal cell growth. In brief, cells were seeded in a 0.1% gelatin-coated 96-well plate at 2 × $10^4$ cells/well overnight. After incubation with various concentrations of EE solution for 24 h, 20 μL of 5 mg/mL MTT in phosphate-buffered saline (PBS) was added, and incubation was continued for another 4 h at 37 °C. The culture

medium was removed, and DMSO (100 $\mu$L/well) was added. Then, after complete dissolution, absorbance was detected at 570 nm.

$$\text{cell viability expressed as \% of control vehicle} = (\text{Abs}_{570\text{nm, sample}}/\text{Abs}_{570\text{nm, control vehicle}}) \times 100\%$$

**Lactate Dehydrogenase (LDH) Toxicity Assay.** The LDH release assay was performed using a cytotoxicity detection kit plus (LDH) (Cayman) according to the manufacturer's instructions. In brief, HUVECs were seeded in a 96-well plate at a density of $2 \times 10^5$ cells/well. After incubation with various concentrations of EE solution for 24 h, cell supernatants were collected and analyzed. The absorbance of formazan formed was read at 490 nm.

**Wound-Healing Assay.** The wound-healing method was performed according to protocols reported previously[20] with some modifications. In brief, cells were seeded in a 24-well plate at a density of $3 \times 10^5$ cells/well overnight. After two washings with PBS, the cells were then scraped away horizontally in each well using a sterilized P100 pipet tip. After two washings with PBS, the cells were treated with 300 $\mu$L of various concentrations of EE (cotreated with 20 ng/mL VEGF) or 20 ng/mL VEGF only (serving as vehicle control) for 24 h. Three random views along the line were selected and photographed using an inverted microscope (Nikon ECLIPSE TS-100F) at 0 h. After 24 h, another set of images were taken by using the same method.

Image analysis for determining the extent of migration was performed by ImageJ software (NIH, Bethesda, MD, USA). The percentage of wound size after 24 h was calculated using the following equation (wound size was expressed as % of wound area when it was made):

$$\text{wound area (\%)} = [\text{wound area } (t = 24\text{ h})/\text{wound area } (t = 0\text{ h})] \times 100$$

**Transwell Culture Insert Assay.** Cell invasion properties was carried out in a modified Boyden chamber (Transwell, Corning, NY, USA) with a poly(ethylene terephthalate) filter inserted coated with a Matrigel matrix in 24-well plates containing 8 mm pores. In brief, $1 \times 10^4$ cells suspended in 100 $\mu$L of starved medium were seeded on the upper chamber followed by filling the lower chamber with 600 $\mu$L of medium with or without EE under VEGF-induced migration. After 6 h of incubation, the nonmigrated cells on the upper side of the membrane were carefully removed by cotton swab. The migrated cells on the bottom side of the membrane were fixed with methanol for 20 min and then stained with 0.1% crystal violet for 10 min. Four randomly selected fields under 10× magnification of each well were scored for migrated cells. The quantification of the invaded cells was made by submerging the chambers in 1% SDS and measuring the absorbance of the solution at 570 nm. The mean of triplicate assays for each experimental condition was calculated, and values were normalized to the untreated cells.

$$\text{invasiveness expressed as \% of control vehicle} = (\text{Abs}_{570\text{nm, sample}}/\text{Abs}_{570\text{nm, control}}) \times 100$$

**Endothelial Tube Formation Assay.** The tube formation assay was performed according to previous protocols[21] with some modifications. Cells ($1 \times 10^4$ cells/well) were seeded on a layer of Matrigel (BD Biosciences, catalog no. 354234) and exposed to various concentrations of EE with 20 ng/mL VEGF in starved medium or with starved medium only (served as vehicle control) .

After incubation for 6 h in 37 °C, images of three randomly selected fields were captured using the inverted microscope.

**Measurement of Reactive Oxygen Species.** The 2′,7′-dichlorofluorescein diacetate (DCFH-DA, Sigma) assay was used to determine the scavenging activity of ROS in HUVECs following the exposure to EE as previously described.[22] After exposure to different concentrations of EE with 20 ng/mL VEGF in starved medium or with starved medium only (serving as vehicle control) for 24 h, endothelial cells (ECs) were then incubated in DCFH-DA (0.5 $\mu$g/mL) at 37 °C for 30 min. Cells were washed with PBS three times to remove DCFH-DA that had not entered into cells. The fluorescence was measured immediately by a fluorescent plate reader ($\lambda_{ex}$ = 485 nm, $\lambda_{em}$ = 535 nm).

**RT-PCR Study for mRNA Expression.** Total RNA was isolated by using an SV Total RNA Isolation System according the manufacturer's protocol (Z3100, Promega, Madison, WI, USA) followed by reverse transcription (cDNA synthesis). Real-time qPCR was performed on the ABI7500 real-time PCR detection system in a volume of 20 $\mu$L containing 10 $\mu$L of SYBR Premix Ex *Taq*II (2×), 0.4 $\mu$L of ROX reference Dye II (50×), 2 $\mu$L of cDNA, 6 $\mu$L of $dH_2O$, and 0.8 $\mu$L of each 10 $\mu$M primer. The primers of all tested genes are listed in Table 2. The reaction mixture was subjected to denaturation at 95 °C for 2 min followed by 40 cycles of denaturation at 95 °C for 5 s, annealing at 60 °C for 15 s, and elongation at 72 °C for 35 s. A melt-curve analysis was performed at the end of the reaction consisting of 40 cycles. The relative expression levels of the mRNAs of the target genes were normalized using the $\beta$-actin internal standard.

**Quantitative Endogenous Alkaline Phosphatase Assay on Zebrafish Embryo.** During zebrafish development, the stage between 48 and 72 h past fertilization (hpf) has the highest angiogenic activity,[23] and a quantitative endogenous alkaline phosphatase (EAP) assay was performed as previouly described.[24] In brief, embryos (24

hpf) was arrayed in a 96-well plate (one embryo per well) and incubated with 100 μL of embryo water per well containing various concentrations of EE, whereas only 100 μL of embryo water without samples was set as control. After further incubation at 28.5 °C for 48 h, the medium in each well was removed, and embryos were treated with 70% ethanol (100 μL) at room temperature for 15 min and then with 100% ethanol (100 μL) at −20 °C for 30 min for dehydration purposes. The embryos were washed three times with 1× diethanolamine buffer (Pierce, Rockford, IL, USA). Then, 100 μL of staining solution was added to each well. After staining, 50 μL of the 2 M NaOH was added to stop the reaction. The optical density was determined at the wavelength of 405 nm. SU5416, a known effective inhibitory compound on angiogenesis, was chosen to conduct the parallel experiments.[24]

Vessel growth was presented as percentage formation of vessels in optical density compared to control:

$$\%\text{vessel formation} = (OD_{405nm,\ sample,\ day\ 3} - OD_{405nm,\ sample,\ day\ 1}) / (OD_{405nm,\ control,\ day\ 3} - OD_{405nm,\ control,\ day\ 1}) \times 100$$

**Microscopic Imaging.** The embryos from the Tg (fli1a: EGFP) y1 zebrafish line were used to further evaluate the antiangiogenic effect of EE. The enhanced green fluorescent protein-expressing ECs of the subintestinal vessel plexus (SIVs) were observed and recorded at 72 hpf using an Olympus IX71S8F-2 inverted microscope (Olympus, Tokyo, Japan).

**Statistical Analysis.** All experiments were performed at least three times. All data are presented as means ± SEM, and all statistics were performed using GraphPad Prism 5.0 software. Differences between means were determined by one-way analysis of variance (ANOVA) or Student's *t* test. Differences were considered to be statistically significant at $p < 0.05$.

## RESULTS

**Amount of Total Phenolics in EE and HPLC-UV-ESI/MS Analysis.** The total phenolic content (TAC) was measured and expressed in terms of gallic acid equivalents (GAE; mg/g of GAE). The amount of total phenolics in EE from sclerotium of *PTR* was 420 ± 0.33 μg/mg extract, indicating that EE contained a substantial amount of phenolic compounds.

At least five phenolic acids (including protocatechuic, chlorogenic, syringic, ferulic, and folic acid) were positively identified and quantified in EE by HPLC-UV-ESI/MS on the basis of their chromatographic characteristics and absorption spectra with reference to standard compounds (Figure 1) and confirmed by mass analysis. The results are summarized in Table 3.

**Antioxidant Activity of EE.** Three methods were utilized to analyze the antioxidant activity of EE. The results on DPPH free radical scavenging activity of EE are shown in Figure 2A. EE inhibited DPPH radicals in a dose-dependent manner with an $IC_{50}$ at about 1 mg/mL. Furthermore, EE also had demonstrated both $ABTS^+$ radical scavenging activity (13.54 ± 2.51% at 5 mg/mL) (Figure 2B) and hydrogen peroxide scavenging activity (30.82 ± 4.28% at 5 mg/mL).

The above results suggested that EE demonstrated scavenging activity toward DPPH radical, $ABTS^+$ radical, and hydrogen peroxide, which might be related to its high phenolic content.

**Cytotoxicity Evaluation of EE on HUVECs.** MTT results showed that EE did not significantly affect the viability of the HUVECs when they were cultured in normal cell culture medium (DMEM/F12 supplemented with 10% FBS) at a concentration below 200 μg/mL (Figure 3A). The MTT

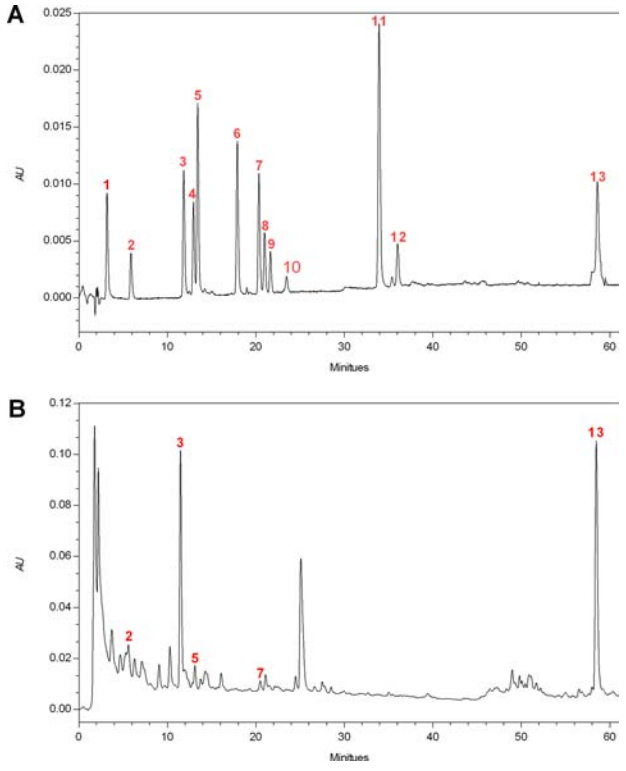

**Figure 1.** Chromatogram of phenolic compound analysis by HPLC: (A) standard mixture of 13 phenolic compounds (peaks: 1, gallic acid; 2, protocatechuic acid; 3, chlorogenic acid; 4, caffeic acid; 5, syringic acid; 6, coumaric acid; 7, ferulic acid; 8, sinapic acid; 9, ellagic acid; 10, salicylic acid; 11, cinnamic acid; 12, quercetin; 13, folic acid); (B) phenolic prolile of 60% ethanol extract from sclerotium of *PTR*.

results were further confirmed by the LDH release assay (Figure 3B). Therefore, a concentration range of EE from 3.125 to 200 μg/mL was chosen for the following cell culture experiments.

**Effects of EE on VEGF-Induced HUVEC Migration.** To find out the effects of EE on HUVEC migration, the scratch wound healing assay was performed. After scratching the monolayer HUVEC cells using a scraping tool, a denuded area was produced with the same width (red arrow shown in Figure 4A,a). Because activated motile ECs could move randomly in the direction of the angiogenic factors across a horizontal surface, the size of the wound could indicate the extent of wound closure and, therefore, the rate of cell migration.

Figure 4 illustrates the wound size of the monolayer HUVEC cells in different treatment groups after 24 h. The inhibitory effect on wound healing was increased in a dose-dependent manner after 24 h of treatment of EE. At the highest concentration of 200 μg/mL (Figure 4A,f), the percentage of wound size at 24 h was 40.90 ± 2.59%, which was significantly larger than that of the control (2.88 ± 1.76%, $p < 0.001$) (Figure 4A,c).

It was noted that quantification of the wound healing test was only arbitrary, and there were difficulties to ensure the consistency of identical growth conditions of confluence and the scraped area between control and different treatment groups.[25] Therefore, an alternative type of 2-D migration assay, the transwell culture insert method, was also performed to further confirm the inhibitory effect of VEGF-induced HUVECs migration by EE.

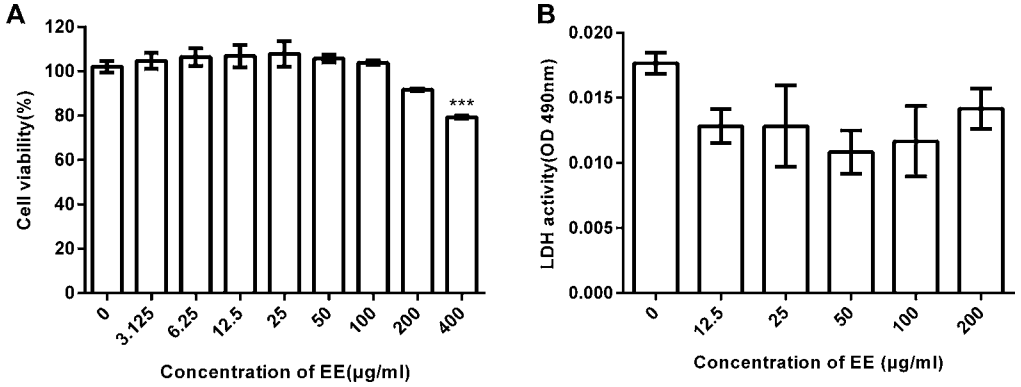

**Figure 3.** Cell viability (mean ± SD $n = 6$) after treatment with 60% ethanol extract from sclerotium of *PTR* by MTT assay (A) and LDH release activity (B) from HUVECs after treatment with 60% ethanol extract from sclerotium of *PTR*. Statistical significance was assessed by one-way ANOVA (Student's *t* test). (**) $p < 0.01$ compared with the control group.

As marked by red arrows in Figure 5, the stimulation of VEGF (20 ng/mL) could strongly promote cell migration. In contrast, co-incubation with VEGFR2 inhibitor SU5416 (4 μM) could strongly inhibit HUVEC migration by 15.02 ± 2.23%. Similarly, with the addition of various concentrations of EE, this VEGF-induced cell migration was suppressed significantly in a dose-dependent way (Figure 5C−E). When the concentration of EE reached 25 μg/mL, the number of cells migrating from the upper to the lower chamber was similar to that of the positive control (SU5416, 4 μM) (Figure 5F). These values were significantly lower ($p < 0.001$) than that of the control, indicating EE could effectively inhibit VEGF-induced HUVEC migration.

**EE Inhibit VEGF-Induced HUVEC Tube Formation.** Under normal culture conditions, ECs cultured on a Matrigel matrix could form tube-like structures within 6 h (Figure 6A), which could be further promoted by VEGF treatment (Figure 6B).

However, when treated with EE at various concentrations (6.25−200 μg/mL), this formation of a mesh of tubes on Matrigel could be inhibited dose-dependently (Figure 6C−F). The tube formation pattern of HUVECs treated with 25 μg/mL (Figure 6E) of EE was similar to that in the control group (Figure 6A), whereas those treated with 200 μg/mL (Figure 6F) mostly remained dotted on the Matrigel without extensive network of tube formation.

**Effects of EE on Intracellular ROS Level in HUVECs.** ROS derived from NADPH oxidase, which is the major source of ROS in ECs,[26] could enhance VEGFR2 autophosphorylation by inactivating protein tyrosine phosphatases (PTPs) and subsequently mediates related gene expression or signal pathways activities, such as the MMP family, angiopoetin family, Tie, PI3-kinase/Akt, and ERK1/2, and leads to the angiogenic responses including EC proliferation and migration.[27,28] We also detected the ROS levels by the DCFH-DA assay. The results indicated that VEGF (20 ng/mL) induced an 80% increase in ROS formation in untreated HUVECs after 24 h of exposure as compared to the control (Figure 7). Such an increase was alleviated after exposure to EE at a concentration of 3.125−50 μg/mL. However, when the concentration of EE was ≥100 μg/mL, the ROS level was similar to that of the control (Figure 7). This could be due to the possible activation of cell apoptosis, causing an up-regulation of the ROS level.[29]

**EE Suppress Angiogenesis-Related Gene Expression in HUVECs.** To investigate how EE could attenuate the progression of angiogenesis, the expression of the genes

dx.doi.org/10.1021/jf5031604 | J. Agric. Food Chem. 2014, 62, 9488−9498

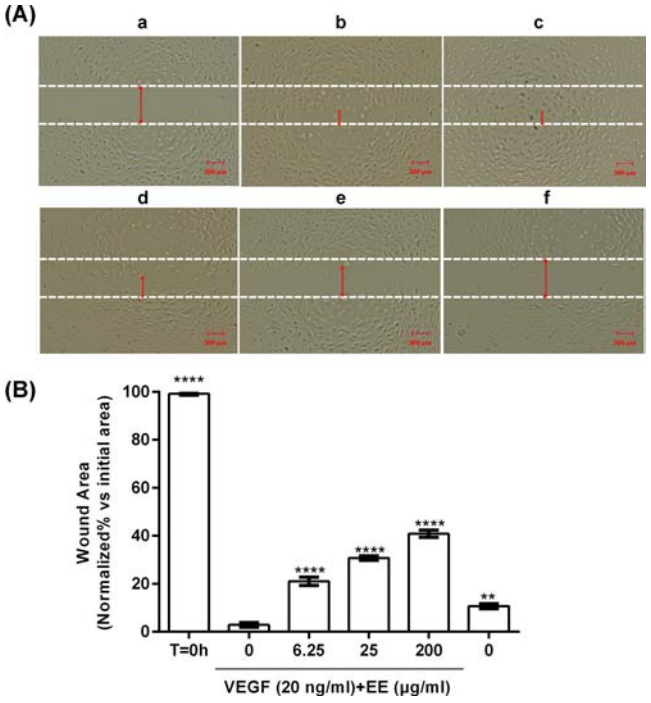

**Figure 4.** Inhibition of VEGF-induced HUVECs migration by 60% ethanol extract from sclerotium of *PTR* in wound healing assay: (A,a) microscopic image of wound size at 0 h; (A,b) without VEGF at 24 h; (A,c) with VEGF at 24 h; (A,d–f) with VEGF and 6.25, 25, and 200 $\mu$g/mL of 60% ethanol extract from sclerotium of *PTR* at 24 h (length between arrowheads indicates wound length); (B) graph of healing effect in percent wound area of EE (mean ± SEM $n = 6$) on VEGF-induced HUVECs motility (statistical significance was assessed by one-way ANOVA (Student's $t$ test); (**) $p < 0.01$; (****) $p < 0.001$ compared with VEGF-stimulated group).

involved in this process was evaluated. It was found that EE significantly decreased VEGF-induced FGF, ANG-Tie, and MMP gene expression as well as VEGFR at the mRNA level (Figure 8) in HUVECs treated with EE in a dose-dependent manner. These results indicated that the VEGF–VEGFR signal pathway was inhibited in the presence of EE in HUEVCs, which provides a critical link between the bioactive compounds in EE and VEGF-mediated activation of angiogenesis. Taken together, these results suggested that EE could regulate the angiogenesis-related signal transduction pathway and suppress the expression of angiogenesis regulation genes.

**EE Inhibits Vessel Formation in Zebrafish Embryos.** The above observations were also further examined in a zebrafish model. Quantitative EAP assay was used to measure the formation of blood vessels in the animal. It showed that incubation with 50 $\mu$g/mL EE significantly inhibited vessel formation at around 21.84 ± 0.24% in wild-type zebrafish embryos, which was similar to the positive control SU5416 at 4 $\mu$M (Figure 9).

Further experiments were conducted using transgenic zebrafish embryos [Tg (fli1a: EGFP)y1], which provides higher resolution and more definitive results. The Tg (fli1a:EGFP)y1 zebrafish contains the enhanced green fluorescent proteins (EGFP) cDNA under control of the fli1 promoter, which is expressed in all ECs of the vasculature.[30] Therefore, the ECs of the vasculature in the SIVs could be observed more clearly at 72 hpf through a fluorescent microscope on the basis of their EGFP.

The microscopic imaging results clearly showed that the control group (Figure 10A,B) treated with 0.1% DMSO had normal vessel formation, the SIVs developed normally as a smooth basket-like structure with approximately 5–6 arcades (Figure 10A,B), whereas in the transgenic zebrafish treated with 100 $\mu$g/mL EE, the development of SIVs was clearly inhibited (highlighted in arrows) (Figure 10C,D).

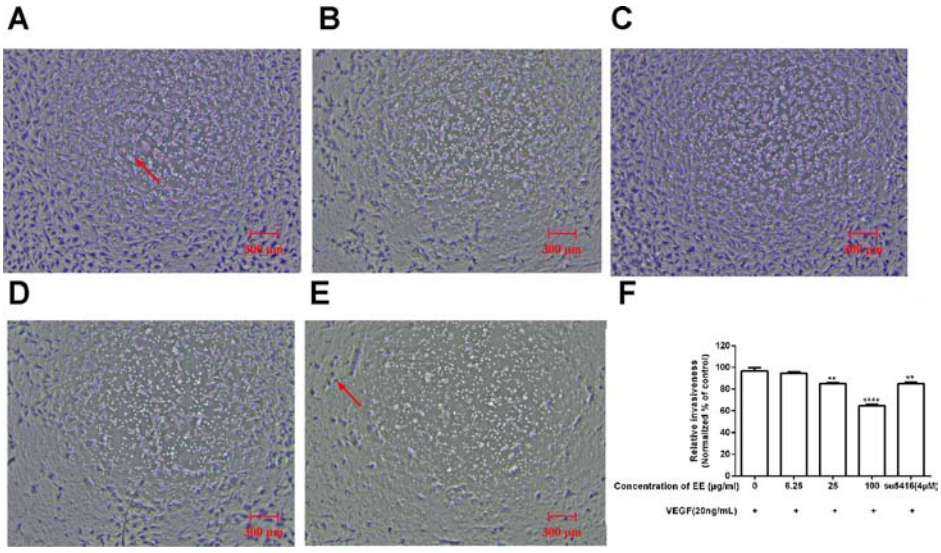

**Figure 5.** Effect of 60% ethanol extract from sclerotium of *PTR* on VEGF-induced HUVEC migration measured by transwell culture insert method: (A) microscopic image of HUVEC migration induced with 20 ng/mL VEGF; (B) with 20 ng/mL VEGF and SU5416 (4 $\mu$M); (C–E) with 20 ng/mL VEGF and 6.25, 25, and 100 $\mu$g/mL 60% ethanol extract from sclerotium of *PTR*; (F) graph shows percent invasion of 60% ethanol extract from sclerotium of *PTR* (mean ± SEM $n = 6$) on VEGF-induced HUVECs migration. Statistical significance was assessed by one-way ANOVA (Student's *t* test). (**) $p < 0.01$ and (***) $p < 0.001$ compared with VEGF-stimulated group.

## DISCUSSION

*PTR* has been reported for its high nutritive value and use as a functional food,[31] although the present study is the first to report the antioxidant and antiangiogenic activities of extract from the sclerotium of *PTR*. In this study, the 60% ethanol extract of *PTR* enriched with phenolic compounds had demonstrated strong antioxidant activity and inhibition of the VEGF-induced HUVECs angiogenesis in vitro and in vivo. Three different antioxidant assays confirmed that EE could significantly scavenge free radicals (DPPH, $ABTS^{+}$, and hydrogen peroxide), implying its powerful antioxidant activity. Phenolic compounds from plants have been reckoned as the main source of antioxidants, which have beneficial implications for cancer treatments.[32,33,34] It has also been suggested that the antioxidant activities of mushrooms are contributed by their phenolic compounds.[35,36] Several studies suggested a strong correlation between the total phenolic content in mushrooms and their antioxidant activity.[19] In the present study, the HPLC-UV-ESI/MS analysis confirmed the presence of phenolic compounds in EE, of which five known phenolic acids had been identified and quantified. Not surprisingly, these identified phenolic compounds had also been reported in other mushroom species, including protocatechuic acid in *Lepista nuda* and *Ramaria botrytis*[37] and chlorogenic acid in *Flammulina Velutipes* and *Pleurotus ostreatus*.[38] It was also noted that there were other phenolics or nonphenolic compounds present in EE, which could also act as antioxidants and need to be further studied.

Several research studies have investigated the effects of polyphenolic compounds on VEGF expression and angiogenesis process. Oak et al.[39] reported that the red wine polyphenolic compounds (RWPCs) with their antioxidant properties could significantly inhibit the $PDGF_{AB}$-induced expression of VEGF, which was associated with the prevention of the ROS formation. In addition, epigallocatechin-3-gallate (EGCG) has also been shown to inhibit the expression of subunits of NADPH oxidase, which plays a pivotal role in producing superoxide in endothelial cells, namely, $p47^{phox}$ induced by angiotensin II (Ang II) in human umbilical vein endothelial cells.[40] Meanwhile, EGCG could also decrease VEGF production in head and breast carcinoma cells by inhibiting epidermal growth factor receptor-related pathways of signal transduction.[41] Meanwhile, as one of the main compounds identified in EE, folic acid has been shown to inhibit EC proliferation through activating the cSrc/ERK 2/NF-$\kappa$B/p53 pathway mediated by folic acid receptor;[42] besides, it was also found to inhibit EC migration through inhibiting RhoA activity mediated by activating the folic acid receptor/cSrc/p190RhoGAP-signaling pathway.[43] Considering the strong link between antioxidant and antiangiogenesis reported previously,[28,44] the antiangiogenic effects of EE on HUVECs were evaluated. In the present study, our findings demonstrated that VEGF-induced HUVEC migration, tube formation, and intracellular ROS level were significantly reduced after EE treatment. However, in the presence of VEGF, EE seemed to be less effective in its antiangiogenic effect when applied at a high concentration (100 $\mu$g/mL) and could even up-regulate the ROS level. This might be explained by the possible triggering of cell apoptosis due to the high concentration of phenolics. Previous studies demonstrated that high concen-

dx.doi.org/10.1021/jf5031604 | J. Agric. Food Chem. 2014, 62, 9488−9498

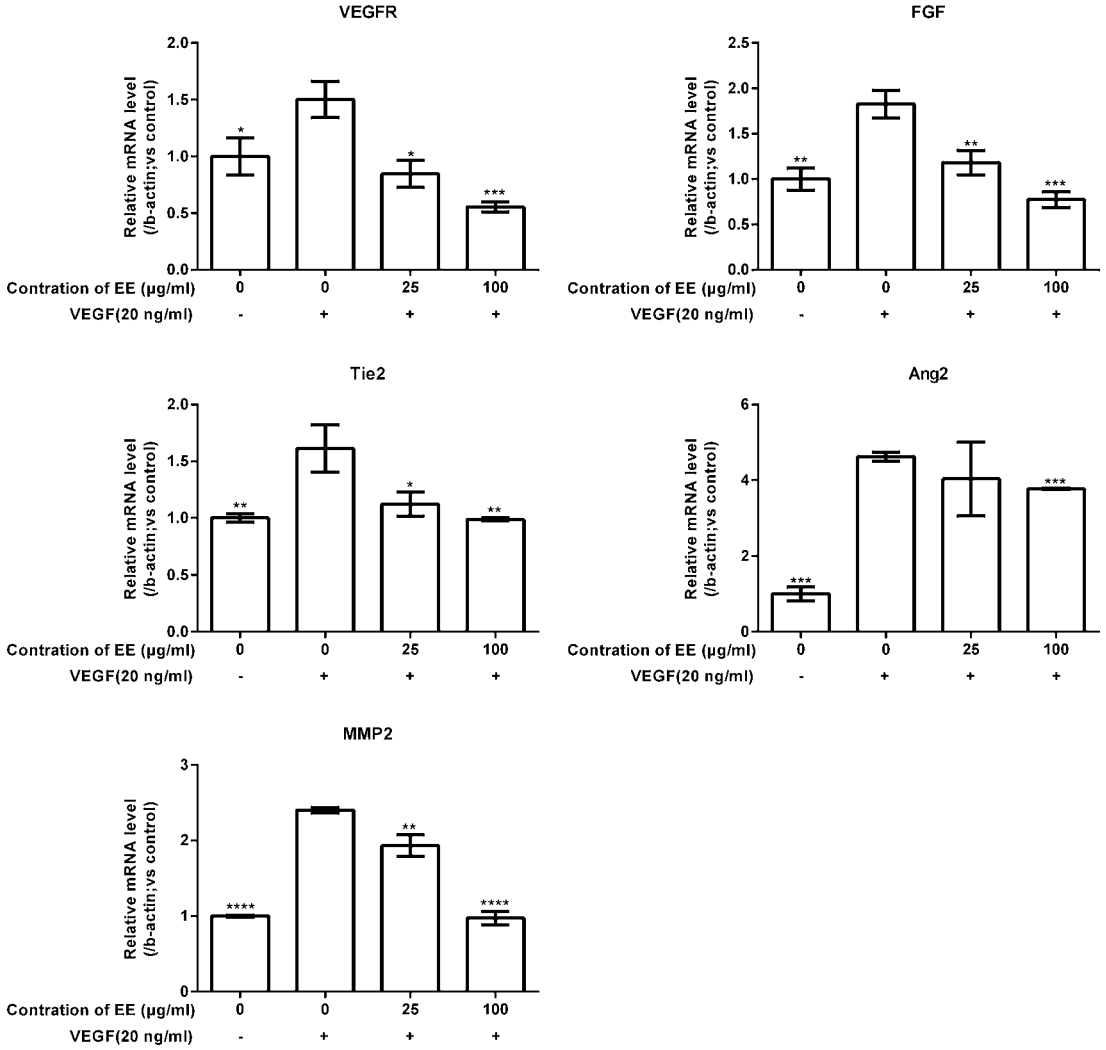

**Figure 8.** Effect of 60% ethanol extract from sclerotium of *PTR* on mRNA levels (mean ± SEM $n = 3$) of related intracellular genes (VEGFR, FGF, ANG2, Tie2, and MMP2) determined by RT-PCR. Total RNAs and cDNAs were prepared from HUVECs that had been treated with increasing concentrations of 60% ethanol extract from sclerotium of *PTR* for 7 h. Statistical significance was assessed by one-way ANOVA (Student's *t* test). (**) $p < 0.01$ and (***) $p < 0.001$ compared with VEGF-stimulated group.

tration of an apple extract rich in polyphenols increased the formation of ROS in HT-29 cells.[45] On the basis of these results, it is possible that the antiangiogenic effect observed in EE might be partly due to its phenolic compounds and is mediated by its antioxidant effect.

Angiogenesis is a process regulated by complex enzymatic and signal transduction pathway. Among the known mediators networks, VEGFA-VEGFR and angiopoietin (angpt)-Tie are two most widely studied signaling pathways involved in angiogenesis;[46−48] VEGF is the best characterized angiogenic cytokine and the most important angiogenic factor in sustaining tumor growth[49] by inducing proliferation, migration, and tubule formation of ECs.[50−52] There is much evidence suggesting that overexpression of VEGF in most hematologic malignancies is responsible for increased angiogenesis found in the malignancies.[53] Furthermore, VEGF stimulation could increase ROS production via activation of Rac1-dependent NADPH oxidase in HUVECs[54,55] and subsequently evoke the redox signaling pathway leading to angiogenic responses such as EC proliferation and migration. Many researchers[56,57] have shown that ROS are involved in VEGF-induced VEGFR2 autophosphorylation in ECs. In this research, we found EE from *PTR* could significantly decrease VEGF-induced ROS up-regulation, which was presumed to be mediated by its antioxidant activity and contribute to its antiangiogenic activity through ROS scavenging. Another important stimulator of angiogenesis is the fibroblast growth factors (FGF), first identified in 1975[58] and subsequently demonstrated to play an important role in modulating the angiogenesis process.[59] VEGF receptor signals for the effects in ECs include migration, proliferation, cell survival, and expression of downstream genes. MMP2 is also an important enzyme that degrades components of the extracellular matrix to allow the progression of angiogenesis to occur.[60] These major molecules participating in angiogenesis including VEGFR, FGF, and MMP2 were thus investigated after the HUVECs treated with EE. Indeed, mRNA expression of these angiogenic biomarkers was down-regulated by EE in a dose-dependent manner (Figure 8), suggesting a stronger effect of EE on migration and tube formation of HUVEC can be reflected in a decreased level of these angiogenic biomarkers. Besides, two other endothelial cell-specific surface receptors (Tie-1 and Tie-2) with tyrosine kinase activity are known so far and are found to hold unique functions in vascular biology as revealed by gene knockout experiments.[61] Tie-2 is present on

dx.doi.org/10.1021/jf5031604 | J. Agric. Food Chem. 2014, 62, 9488−9498

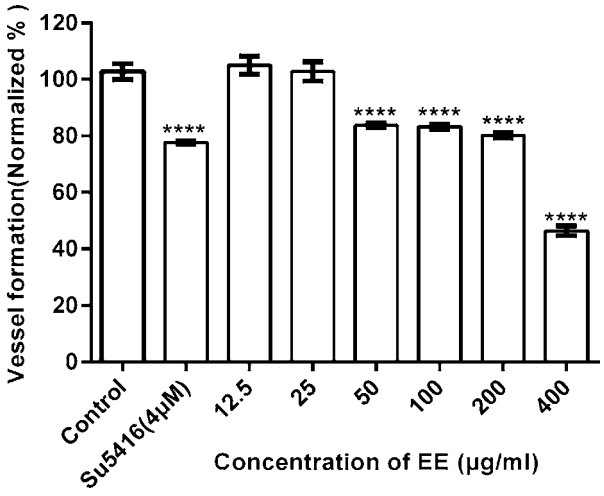

**Figure 9.** Antiangiogenic activities of 60% ethanol extract from sclerotium of *PTR* (mean ± SEM $n = 3$) in zebrafish through EAP assay. Effects were assessed by measuring the vessel formation of samples as compared to the control using the quantitative EAP assay. ECs in human glioblastoma tissues,[62] suggesting a connection to tumor angiogenesis. Its activation has been related to EC migration.[63] Our results showed that EE inhibited HUVEC migration, which might be due to its down-regulation effect on Tie2 expression (Figure 8). Besides, angiopoietin-2 (Ang2) exhibits broad expression in the remodeling vasculature of human tumors but has very limited expression in normal tissues, making it an attractive candidate target for antiangiogenic cancer therapy.[64] Our results also revealed that Ang2 gene expression was decreased after treatment with EE (Figure 8).

It has been well recognized that all successful tumors must undergo neovascularization (angiogenesis) to acquire adequate nutrients and oxygen for continuous growth.[65] To further ascertain the effect of EE on inhibiting angiogenesis, studies were then conducted in the zebrafish, which has been successfully used previously as the model system for evaluating antiangiogenic agents.[66] Many researchers[67−69] have shown that embryonic, young, and growing zebrafish are ideal animal models to observe blood vessel formation. The zebrafish vasculature system is highly characteristic in the developing zebrafish embryo. The small molecules added directly to the fish culture media could diffuse into the embryo and induce observable angiogenesis effect.[70] Besides, the blood vessel formation through angiogenic sprouting requires the same proteins that are necessary for blood vessel growth in mammals.[71] Here, our results clearly demonstrated that EE exposure altered the development of SIVs in zebrafish. More importantly, EE exposure did not induce apoptosis in zebrafish, which was in agreement with the toxicity assay in normal cells. This paper further demonstrated that the zebrafish model is a very promising platform not only for screening antiangiogenic compounds but also for delineating the drug action mechanism when incorporated with the use of powerful genetic tools and other molecular techniques.

In conclusion, to our knowledge, this is the first study reporting the profile of phenolic compounds and the antioxidant and antiangiogenic activities of ethanol extract (EE) isolated from the sclerotium of *PTR*. The antiangiogenic effect of EE was demonstrated by the inhibition of EC migration and tube formation. The mechanism underlying this inhibitory effect might be due to a decrease in both the ROS production and the mRNA expression of angiogenic biomarkers (such as VEGF, FGF, MMP2, Tie2, and Ang2). These antiangiogenic effects of EE were also clearly observed in the zebrafish model.

Therefore, our findings strongly suggest that the phenolics-enriched extract obtained from the sclerotium of *PTR* might be a potential target for further investigation of its antiangiogenic effect in cancer treatment. Mushroom phenolic antioxidants might be potential anticancer agents to target tumor angiogenesis, tumor development, and metastasis.

**Figure 10.** Lateral view of Tg (fli 1a: EGFP) y1 zebrafish embryos at 72 hpf: (A, B) control (live fluorescence microscopy highlights EGFP expressing subintestinal vessel plexus (SIVs), which appears as a smooth basket-like structure with five to six arcades); (C, D) treatment with 100 μg/mL (60% ethanol extract from sclerotium of *PTR*) (development of SIVs was inhibited after treatment). The arrow represents the regression of the SIVs. Treatments were done in triplicate. Sample size $n = 30$. The data represented were pooled from the experiments.

## ■ ABBREVIATIONS USED

EAP, endogenous alkaline phosphatase assay; ECs, endothelial cell; EE, ethanol extract of sclerotium from *Pleurotus tuber-regium*; GAE, gallic acid equivalents; Hpf, hour past fertilization; HUVEC, human umbilical vein endothelial cells; LDH, lactate dehydrogenase; *PTR*, *Pleurotus tuber-regium*; SIVs, subintestinal vessel plexus; TBHQ, *tert*-butylhydroquinone

and does not exist as free GSH in plasma, but was deposited into red cells or liver for future uses.

The objective of this work was to examine whether intact glutathione (GSH) can be transported across the intestinal epithelium and to characterize its uptake, as well as to determine the fate of orally administered GSH in animal models.

## MATERIALS AND METHODS

**Materials.** GSH was kindly provided by Kohjin Life Science Ltd., Tokyo, Japan. $^{13}$C-GSH was synthesized by a conventional liquid-phase method via $^{13}$C-GSSG using the disulfide bond as a thiol-protecting group. L-Cystine containing 1,1′-$^{13}$C isotopes (L-cystine-1,1′-$^{13}C_2$, Sigma-Aldrich, St. Louis, MO, USA) was converted into the corresponding *N*,*N*′-*tert*-butyloxycarbonyl (Boc) protected $^{13}$C-cystine using di-*tert*-butyl dicarbonate. The crude $^{13}$C-GSH was purified using reversed-phase HPLC on a Nakalai Tesque C18 column (COSMOSIL 5C18-AR-II, 20 × 250 mm). The final product was characterized by reversed-phase HPLC using a TSKgel ODS-100S (3.0 × 150 mm; Tosoh, Tokyo, Japan) and electrospray ionization time-of-flight mass spectrometry (ESI-TOFMS) with a Hitachi NanoFrontier LC-MS system (Tokyo, Japan). MS (ESI) *m*/*z*: 308.99 $[M + H]^+$ (calcd 309.09) (data not shown).

**In Vitro Transport of GSH across Human Intestinal Epithelial Cell Monolayers.** In vitro transport experiments were performed using Caco-2 or HT-29 human intestinal epithelial cells (ATCC). Caco-2 or HT-29 cell monolayers were grown in Costar transwell inserts (1.0 cm$^2$, 0.4 μm pore size) (Corning, Cambridge, MA, USA) in Eagle's minimal essential medium (MEM) (Invitrogen, Burlington, ON, Canada) containing 2 mM L-glutamine, 1 mM sodium pyruvate (Invitrogen), 0.1 mM nonessential amino acids (Invitrogen), 50 U/mL penicillin−streptomycin (Invitrogen), and 20% FBS (HyClone) (Fisher Scientific, Ottawa, ON, Canada). The cells were seeded at a density of 0.6 × 10$^5$ cells/cm$^2$, and the culture medium was changed every second day until confluent monolayers with transepithelial electrical resistance (TEER) values >500 Ω·cm$^2$ were obtained. TEER values were measured using a Millicell-ERS Volt-Ohm Meter (Millipore, Bedford, MA, USA). Cell monolayers were rinsed with Hanks' balanced salt solution (HBSS) adjusted to pH 7.4 with 10 mM HEPES, and the same buffer was added to both apical and basolateral chambers. After equilibration in buffer for 30 min, GSH (1 mM) was added to the apical chamber. Cells were incubated at 37 °C, and aliquots were removed from the basolateral chamber at the indicated time points. Apparent permeability coefficients ($P_{app}$) were calculated using the formula

$$P_{app} = V_R/A \times C_0 \, dC/dt$$

where $V_R$ is the volume in the basolateral chamber, $A$ is the filter surface area, $C_0$ is the initial GSH concentration in the apical chamber, and $dC/dt$ is the slope of the curve of basolateral GSH concentration versus time. To examine the effect of pH on GSH uptake, 1 mM GSH was prepared in HBSS buffer adjusted to pH 6.0 with 10 mmol/L MES and was added to the apical chamber.

To examine if GSH could be transported intact, Caco-2 cells were first incubated with 0.25 mM Acivicin (AT-125; Santa Cruz Biotechnology, Santa Cruz, CA, USA) for 30 min and/or 0.5 mM buthionine sulfoximine (BSO) (Sigma-Aldrich), to inhibit GSH degradation and synthesis, respectively. Probenecid (PB) (Sigma-Aldrich) (1 mM), a known organic anion transport inhibitor and inhibitor of GSH transport, was added 30 min before the addition of GSH.

**Cell Viability Assay.** Viability of the treated cells was measured using the WST-1 Cell Proliferation Reagent (Roche Applied Sciences, Laval, Quebec, Canada) according to the manufacturer's instructions. Briefly, 20 μL of WST-1 was added to the basolateral chamber, and cells were incubated for 1−2 h. Absorbances were read at 450 nm and converted to percent viability relative to untreated control cells.

**Ex Vivo Transport of GSH across Rat Intestinal Epithelial Tissue.** Sections of small intestine were removed from 8-week-old male Sprague−Dawley rats (SPF/VAF Crj:SD; Charles River Japan., Kanagawa, Japan) and mounted into an Ussing chamber for transport. Krebs−Ringer bicarbonate (KRB) buffer, adjusted to pH 6.0 and 7.4, was added to apical and basolateral chambers, respectively. After equilibration for 30 min, 10 mM GSH was added to the apical chamber, and transport was allowed to proceed for 60 min. After the 60 min incubation, the intestinal tissue membrane was removed and frozen using powdered dry ice. The frozen tissue was cryosectioned by a cryostat (Leica) with 12 μm thickness to prepare cross sections of intestinal wall and thaw-mounted to an indium−tin oxide (ITO)-coated glass slide followed by drying under $N_2$ gas for analysis by mass spectrometry.[17]

**In Vivo Supplementation with $^{13}$C-GSH in Mice.** Six 8-week-old female BALB/c mice (16−20 g) (Charles River Laboratories Inc., Montreal, Quebec, Canada) were group housed on a 12 h light−dark cycle and allowed unrestricted access to standard mouse chow and water. All animal studies were approved by the University of Guelph Animal Care Committee and carried out in accordance with the Canadian Council on Animal Care Guide to the Care and Use of Experimental Animals. Balb/c mice were administered $^{13}$C-GSH (10 mg/mouse) by oral gavage. Control mice received vehicle alone. The dose of 10 mg $^{13}$C-GSH per mouse was determined on the basis of in vitro assay and actual human subject trial in the past. Mice (5 mice/group) were euthanized at the time points indicated, and blood and liver samples were collected. Liver samples were flash-frozen (−80 °C) for further analysis. Blood samples were immediately flushed with $N_2$ gas under heparin-treated clinical tube (Fisher Sci) and centrifuged at 4 °C (3500*g* for 10 min). The red blood cells (RBCs) were treated by lysate buffer (Sigma-Aldrich) and subjected to further analysis. The plasma and RBC samples were immediately subjected to GSH and GSSH measurement. A reference GSH was used to confirm that GSH was not converted to GSSG during these sample pretreatments (data not shown).

**Enzymatic Detection of Transported GSH.** GSH was quantified in the Caco-2 cells and HT-29 basolateral chamber using an enzymatic assay for the detection of GSH/GSSG, according to the manufacturer's instructions (Oxford Biomedical Research, Rochester Hills, MI, USA). Briefly, a GSH/GSSG assay was designed to measure total, reduced, and oxidized glutathione using an Ellman's reagent (DTNB) and glutathione reductase (GR). This method can be used to measure oxidized (GSSG) by using a specific protocol, which first scavenges all GSH with 1-methyl-2-vinylpyridinium triflate. GSH concentrations were calculated from a GSSG standard curve, and results are expressed as micromolar total GSH ($GSH_t$) in the basolateral solution. The total GSH, reduced GSH, and GSSG in mouse plasma, red cells, and liver were quantified using the same protocol.

**Detection of GSH and $^{12}$C-GSH by Mass Spectrometry.** To confirm transport of intact GSH across Caco-2 monolayers, basolateral solutions were analyzed by LC/TOF-MS for the presence of GSH or GSH degradation products. Samples were derivatized using ThioGlo3 reagent (Covalent Associates, Inc., Corvallis, OR, USA) by incubating 20 μL of basolateral solution with 20 μL of 0.2 mM reagent and incubating for 1 h at room temperature. LC-MS was carried out using a Cosmosil 5$C_{18}$-MS-II column (i.d. 2.0 mm × 150 mm, Nacalai Tesque, Kyoto, Japan) with a linear gradient of 0−100% methanol containing 0.1% formic acid at a flow rate of 0.2 mL/min. MS conditions were as follows: mode, negative-low, expert mode; nebulizer, 1.6 bar; dry gas, 8.0 L/min; mass range, 100−1000; hexapole RF, 200 Vpp; dry temperature, 200 °C.

Detection of $^{12}$C-GSH transported by rat small intestine was carried out using matrix-assisted laser desorption/ionization time-of-flight imaging mass spectrometry (MALDI-IMS) as described by Hong et al. with modifications.[17] Briefly, the matrix reagent and ionization enhancer (20 mg/mL 2,4,6-trihydroxyacetophenone (THAP) with 10 mM diammonium citrate) were dissolved in 50% ACN/0.1% TFA and uniformly sprayed using an ImagePrep automatic matrix sprayer (Bruker-Daltonics, Tokyo, Japan). MALDI-MS imaging was preformed using autoflex III equipped with smart beam (Bruker-Daltonics) with the following analytical parameters: mode, positive; ion source 1, 20.00 kV; ion source 2, 18.80 kV; lens, 7.50 kV; pulsed ion extraction, 0 ns; mass range, 120−1000 Da; laser frequency, 200.0 Hz; number of shots, 500 shots/spot; spatial resolution (spot distance), 50 μm; laser attenuator, 1 minimum; laser power, 100%.

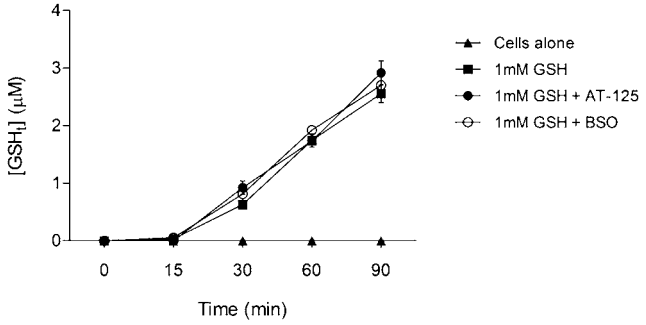

**Figure 1.** Time-dependent transport of 1 mM GSH across Caco-2 cell monolayers in the presence or absence of 0.25 mM AT-125 or 0.5 mM buthionine sulfoximine (BSO).

**Table 1. Apparent Permeability Coefficients (*Papp*) for the Transport of 1 mM GSH across Caco-2 Cell Monolayers in the Presence or Absence of 0.25 mM AT-125 or 0.5 mM Buthionine Sulfoximine (BSO)**

| treatment | $P_{app} \times 10^{-6}$ (cm/s) |
|---|---|
| 1 mM GSH | 1.28 ± 0.11[a] |
| 1 mM GSH + AT-125 | 1.23 ± 0.35[a] |
| 1 mM GSH + BSO | 1.20 ± 0.15[a] |

[a]Similar letters following entries indicate no statistically significant difference.

**Determination of $^{13}$C-GSH and $^{13}$C-GSSG by Liquid Chromatography–Tandem Mass Spectrometry (LC-MS/MS).** The concentrations of $^{13}$C-GSH and $^{13}$C-GSSG in the blood, red cells, and liver samples were determined with a slight modification of a previously reported $^{13}$C-stable isotope labeled dipeptide detection method.[18] Sample preparation followed the method described by Nakashima et al.[18] To prevent oxidation of GSH, all samples were flushed by $N_2$ gas at 4 °C. The derivates of GSH were prepared by the same method described above using ThioGlo3 reagent. A chromatographic separation was performed on a Biosuite C18 PA-A column (Waters, Milford, MA, USA), and a mobile phase of $CH_3CN$-water containing 0.1 FA) and a flow rate (0.20–0.30 mL/min) were applied. LC-MS/MS was performed as described above. Three separate replicates of $^{13}$C-GSH with different concentrations between 0.1 and 5.0 ng/mL were conducted for obtaining the calibration curve. We detected about 7% of endogenous $^{13}$C-GSH against $^{12}$C-GSH in vehicle mouse tissue samples (data not shown); therefore, we determined the actual exogenous $^{13}$C-GSH by subtracting the endogenous one. The $^{13}$C-GSSG and reduced $^{13}$C-GSH were quantified on the basis of a combination of the LC-MS/MS and an enzymatic assay.

**Statistical Analysis.** Data are expressed as means ± SEM. Statistical analyses were performed with GraphPad Prism version 5.0 (GraphPad, San Diego, CA, USA) using one-way ANOVA followed by Tukey's multiple-comparison test. Student's *t* test was used when comparisons between only two groups were carried out. Differences were considered significant when $p < 0.05$.

## RESULTS AND DISCUSSION

Several mechanisms may be involved in the uptake and utilization of luminal GSH by brush-border membrane enzymes in the intestine, including (1) cleavage of GSH into cysteinyl glycine, γ-glutamyl amino acids, or its constituent amino acids (Glu, Cys, Gly) by γ-glutamyltransferase, followed by their transport and intracellular GSH synthesis; and (2) transport of intact GSH directly by specific transporters.[19] GSH transport systems have been identified in the membranes of various tissues and organs, including renal cells, pulmonary alveolar

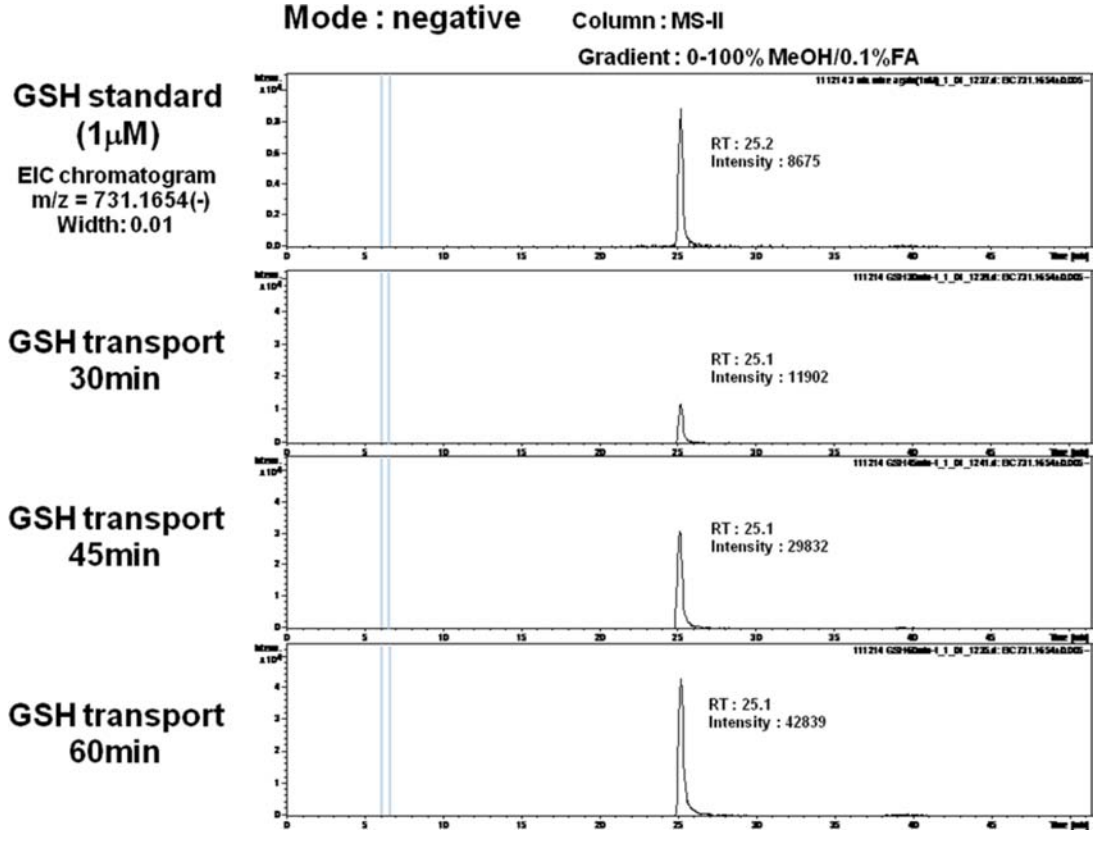

**Figure 2.** LC-MS analysis of transported GSH over 60 min. Transported samples were compared to a known GSH standard (top panel).

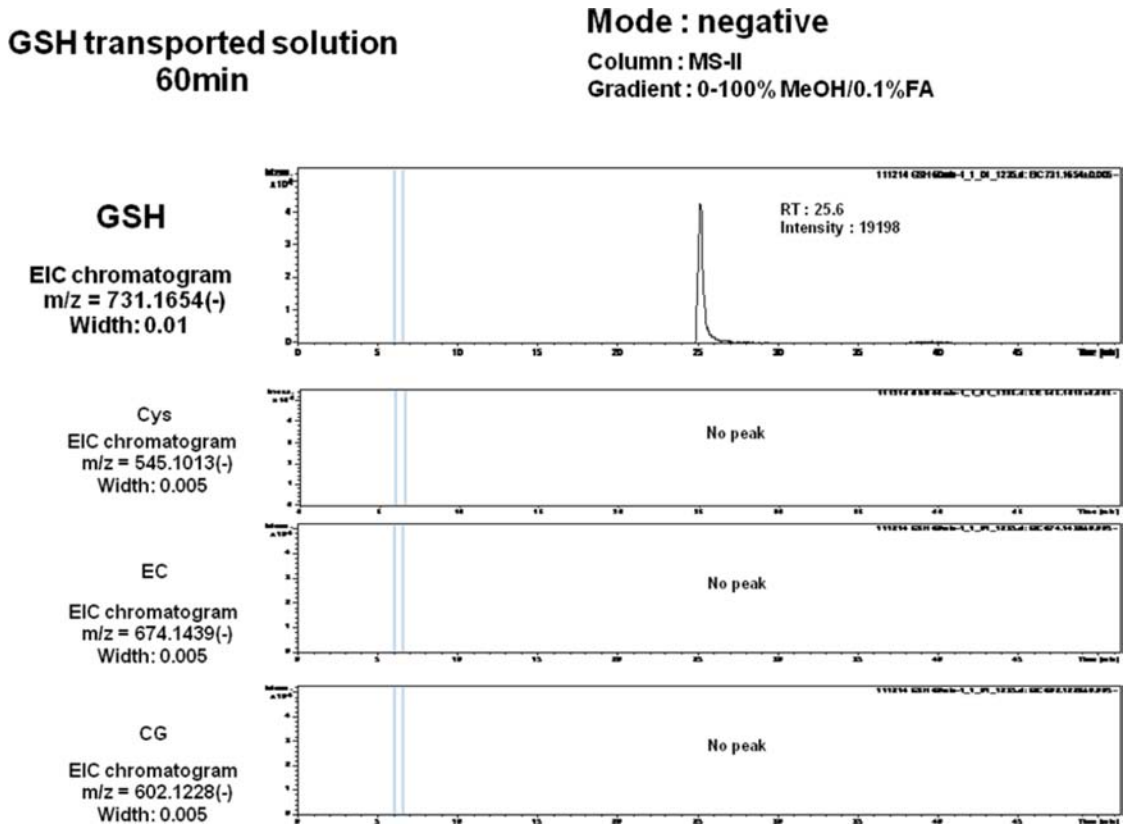

**Figure 3.** LC-MS analysis of transported GSH (top panel), showing absence of GSH degradation products.

cells, retinal pigment epithelial cells, brain endothelial cells, but less is known about its transport across the intestinal epithelium. Several studies examining GSH uptake in the intestine have been carried out using different animal species and techniques including pig and rabbit intestinal brush-border membrane vesicles (BBMV),[5,11,20,21] vascularly perfused rat small intestine,[8] and rat intestinal epithelial cells.[22] However, little is known regarding GSH transport across intestinal epithelial cells. Here, the transport of intact GSH across human intestinal epithelial cells was examined in vitro using Caco-2 cell monolayers. GSH was detected in the basolateral transport chamber of the cell monolayers using a GSH/GSSG enzyme assay and the structure of intact GSH confirmed by mass spectrometry (LC-MS).

Caco-2 cell monolayers were treated with exogenous GSH (1 mM), and the amount of GSH present in the basolateral transport chamber of Caco-2 cell monolayers was measured at different time points using a GSH/GSSG enzyme assay. To confirm that the GSH detected in the basolateral chamber was not as a result of GSH degradation by brush-border membrane enzymes and subsequent resynthesis within the cells, cells were treated with Acivicin (AT-125) and/or buthionine sulfoximine (BSO). AT-125 can prevent GSH degradation by irreversibly inhibiting $\gamma$-glutamyltransferase, and BSO can prevent GSH synthesis through inhibition of $\gamma$-glutamylcysteine synthetase. To test whether intact GSH is transported across Caco-2 cell monolayers, cells were pretreated with AT-125 or BSO, and GSH concentration in the basolateral chamber was measured as a function of time during incubation with 1 mM exogenous GSH.

Transported GSH was measured at various time points (Figure 1), and the apparent permeability coefficients, $P_{app}$, were calculated. There was no significant difference between the concentration of GSH detected in the presence or absence of the inhibitors AT-125 or BSO, indicating that the GSH present in the basolateral chamber was likely due to the uptake/transport of intact GSH across the Caco-2 monolayers, and not GSH resynthesis. No GSH was detected from untreated control cells (cells alone). Likewise, there was no difference in the permeability ($P_{app}$) of GSH in the presence or absence of either inhibitor (Table 1). Cell viability did not appear to be affected by the treatments (data not shown). Analysis by LC-MS confirmed that the detected sample was indeed intact

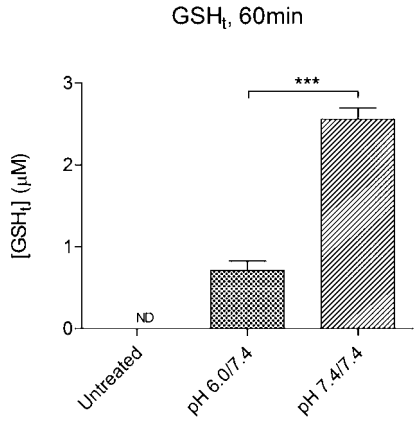

**Figure 4.** pH-dependent uptake of 1 mM GSH across Caco-2 cell monolayers in the presence of 0.25 mM AT-125 after 60 min at pH 6.0/7.4 indicates an apical pH of 6.0 and a basolateral pH of 7.4. pH 7.4/7.4 indicates apical and basolateral pH values of 7.4. ND, none detected. (***) $P < 0.001$. Untreated denotes 60 min of incubation in the absence of GSH at pH 7.4.

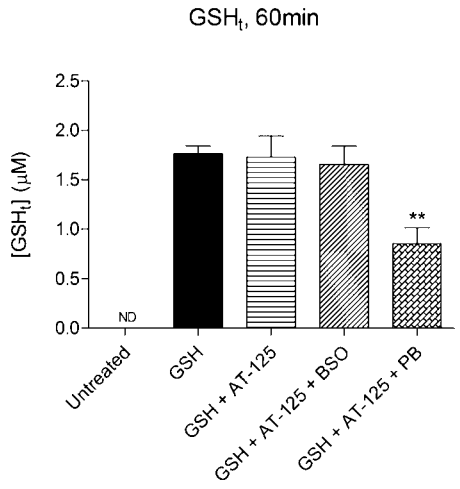

**Figure 5.** Uptake of 1 mM GSH across Caco-2 cell monolayers in the presence or absence of 0.25 mM AT-125 and 0.5 mM buthionine sulfoximine (BSO) or 1 mM Probenecid (PB) after 60 min. ND, none detected. (**) $P < 0.01$ relative to GSH, GSH + AT-125, and GSH + AT-125 + BSO. Untreated denotes 60 min of incubation in the absence of GSH at pH 7.4.

GSH by comparison to a known GSH standard (Figure 2). Moreover, no products of GSH degradation (e.g., cysteine, cysteinyl-glycine) were observed in the transported samples (Figure 3). These results indicated that intact GSH can cross intestinal epithelial cells without degradation, in contrast to previous reports.[14−16] Previously, it was speculated that intestinal epithelial cells also have the same mechanistic transport of GSH with other tissues of renal cells, pulmonary alveolar cells, retinal pigment epithelial cells, and brain endothelial cells,[19] whereas no-one has reported clearly with direct evidence until the current work. This is the first study to demonstrate direct uptake of GSH using human intestinal epithelial cells.

To examine whether GSH uptake is pH dependent or not, we carried out a proton-dependent study using different pH gradients at apical and basolateral sides (both apical and basolateral pH values of 7.4 or an apical pH of 6.0 and a basolateral pH of 7.4, typical of proton-dependent transporters such as the di/tripeptide transporter PepT1). The amount of GSH detected in the basolateral solution was significantly higher when an apical pH of 7.4 was used when compared to an apical pH of 6.0 (Figure 4), suggesting that GSH uptake is not proton-dependent. These results are in line with previous reports that uptake of GSH into brush-border membrane vesicles was not proton-driven and occurred optimally around pH 7.5.[21] To further characterize GSH uptake across the Caco-2 monolayers, transport was carried out in the presence of the inhibitor Probenecid (PB), a known organic anion transport inhibitor and inhibitor of GSH transport in basolateral membrane vesicles.[23] The amount of GSH detected in the basolateral solution of PB-treated cells was significantly reduced when compared to all other samples (Figure 5), suggesting transport of intact GSH.

It was notable when we used HT-29 cell monolayer, which does not express the human PepT1 transporter with the same conditions. We observed similar results (data not shown) and

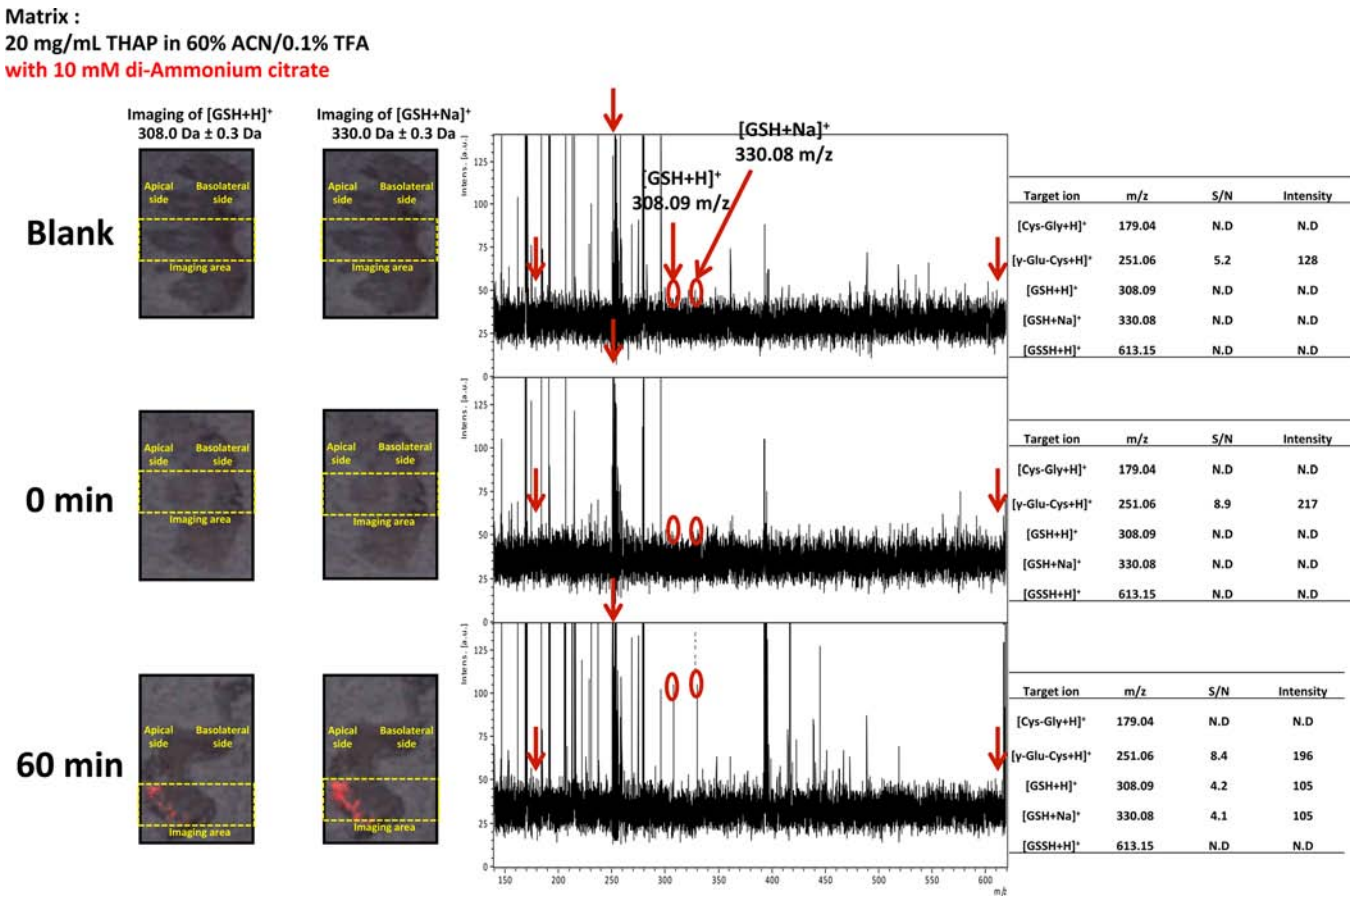

**Figure 6.** MALDI-MS imaging and spectra of transported GSH using rat intestinal membrane.

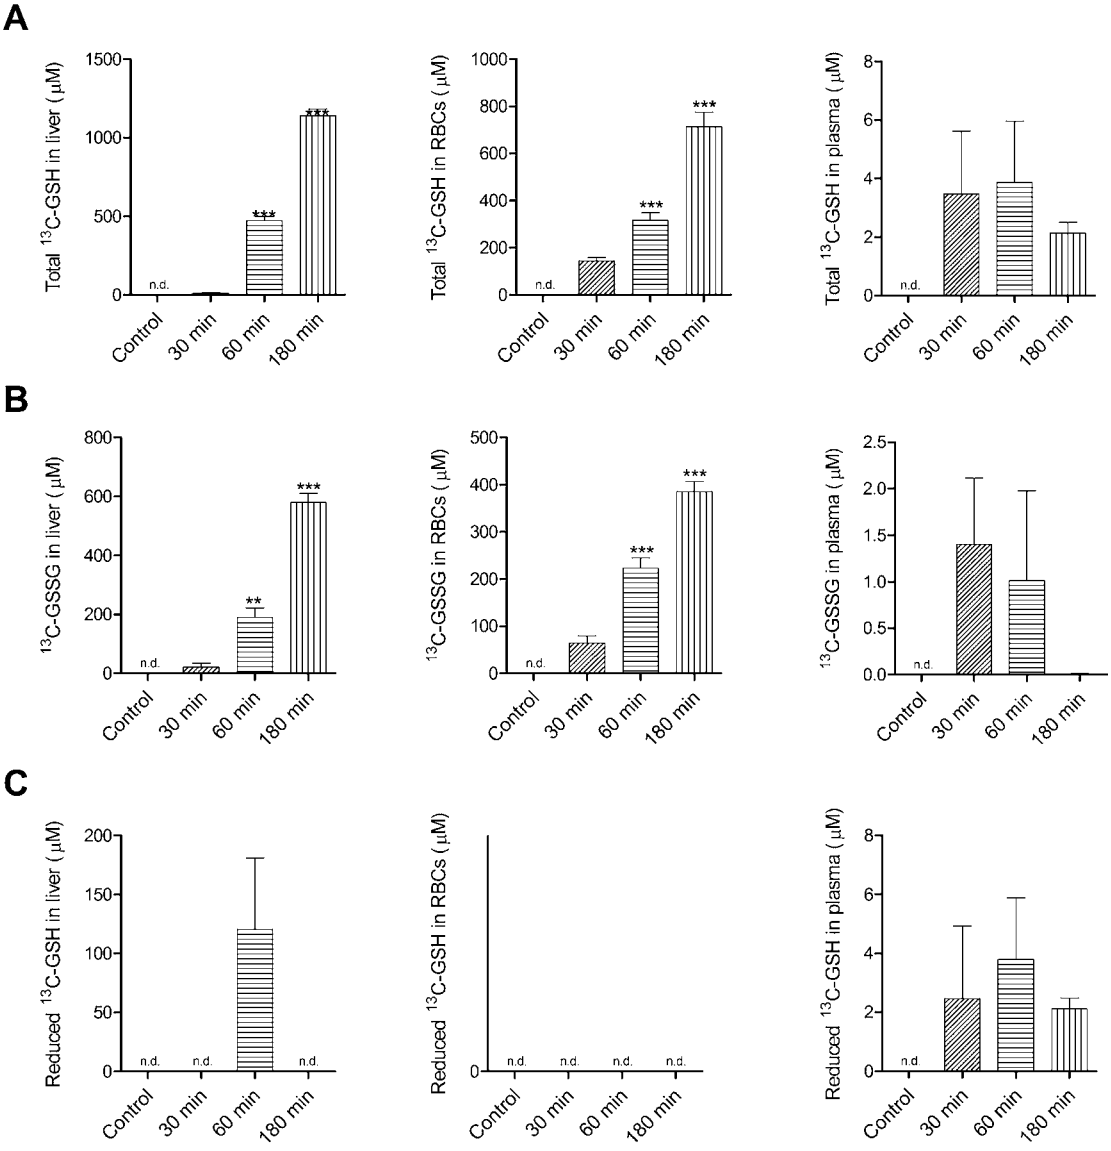

**Figure 7.** Measurement of (A) total $^{13}$C-GSH, (B) $^{13}$C-GSSG, and (C) reduced $^{13}$C-GSH in liver, red blood cells (RBCs), and plasma of mice orally administered 10 mg of $^{13}$C-GSH. n.d., none detected. (**) $P < 0.01$ and (***) $P < 0.001$ relative to vontrol.

could confirm that intact GSH is likely being taken up or transported across the HT-29 monolayers, and not GSH resynthesis. GSH transportation across human epithelial cells is not PepT1-mediated transport. The GSH-specific transport system in human small intestine epithelial cells was reported as a $Na^+$-independent transport system[24] or $Na^+$-coupled GSH transport.[25] However, its detailed transport mechanism is still not well understood. Further characterization of GSH transport may be required, including using the Caco-2 BB (C2BBe1) cell line or examining the effect of mono- and bivalent cations on GSH uptake, and using a more sensitive detection method to detect GSH uptake at earlier time points to gain a better understanding of uptake kinetics as from the literature it would appear that the initial uptake of GSH into cells is a rapid process.[20,21]

Rat intestinal epithelial tissues were treated with exogenous GSH, and transported $^{12}$C-GSH was visualized using MALDI-IMS, which has been similarly used to detect small transportable peptides in rat small intestine.[17] MALDI-MS imaging of GSH in the intestinal tissue sections showed clear localization of transported $^{12}$C-GSH as $[GSH + H]^+$ and $[GSH + Na]^+$ in the apical side of the intestinal wall after 60 min of incubation with 10 mM GSH (Figure 6). The presence of endogenous GSH in the intestinal tissue was not visualized in blank intestinal wall subjected to 60 min of incubation with KBR buffer without GSH. Neither endogenous nor transported GSSH (oxidized form of GSH), Cys-Gly, or γ-Glu-Cys was visualized in any of the intestinal samples tested (blank, 0 and 60 min GSH treated intestines). The absence of GSH on the apical surface of intestinal tissue after 0 min (actually ∼10 s of incubation) of incubation with GSH would strongly suggest that the visualized GSH after 60 min of transport showed localization of intact GSH inside the intestinal wall. To our knowledge, this is the first report of visualized intact GSH in the intestinal wall and demonstrates its presence in the tissues with intact form. Matrix-assisted laser desorption/ionization time-of-flight imaging mass spectrometry (MALDI-IMS) has been developed to visualize the target molecules in tissues, and this technique is a powerful tool for bioactive metablomics study. However, it was limited for only biological compounds with molecular weight of 1−50 kDa, and no small bioactive peptides (<500 Da) were visualized. Recently,

dx.doi.org/10.1021/jf503257w | J. Agric. Food Chem. 2014, 62, 9499−9506

there has been much attention to the study of small di/tripeptides metabolomics, and we reported a new technique of small peptide MALDI-IMS.[17] The current MALDI-IMS visualization of GSH in intestinal wall can provide new insights of intestinal absorption behavior of bioactive small compounds as foods and drugs and omics analysis of small metabolites in various tissues.

To determine the fate of orally ingested GSH, mice were supplemented with $^{13}$C-GSH (10 mg/mouse), and total $^{13}$C-GSH, $^{13}$C-GSSG, and reduced $^{13}$C-GSH in liver, RBCs, and plasma were quantified. Total $^{13}$C-GSH in liver and RBCs was significantly elevated 60 min after ingestion when compared to control mice, but no change in plasma total GSH was observed (Figure 7A). Interestingly, we found that ingested $^{13}$C-GSH was rapidly converted to GSSG and accumulated in RBCs and liver, but was not present in plasma (Figure 7B). Reduced $^{13}$C-GSH was low or negligible in all samples tested (Figure 7C), suggesting that $^{13}$C-GSH was predominantly deposited in the form of GSSG in the red cells and liver tissues after ingestion of GSH. Previously, it has been reported that dietary GSH does not increase serum GSH level after ingestion and its bioavailability is low, but increases only liver cysteine originating from the breakdown of ingested GSH in the gut.[14−16] This is in line with orally ingested GSH not altering plasma total, GSSG, and reduced GSH level from the current work as reported previously. However, the previous study overlooked analyzing GSH or GSSG level from red cells and liver. In this study, we found mostly orally ingested GSH was immediately converted into GSSG and deposited into red cells and predominantly carried into liver tissues. We speculate some of the ingested $^{13}$C-GSH could be degraded during the circulation of intact GSH into γ-glutamyl amino acid, cysteine, and glycine or γ-glutamyl cysteine by endogenous enzymes. However, the current LC-MS/MS technique could not detect notable degradation of ingested GSH. This must be further clarified in the future by developing a more sensitive method. Our recent small-scale work on human subjects indicated that there was no significant change of plasma GSH after ingestion of GSH. However, the GSH contents in the protein-bound fraction of plasma significantly ($P < 0.01$) increased from 15 to 120 min after GSH supplementation.[26] This is a very unique biological system because reduced GSH has a free thiol group (−SH) in cysteine, and an excess presence of reduced GSH in the plasma or tissues might have some harmful effects for the body due to the potential risk of reactive oxygen species (ROS) generation. If ingested GSH is deposited in circulating red cells or liver tissue as a GSSG form, it could be safer and used for detoxification in the body or liver.

GSH is the major intracellular nonprotein thiol compound and plays a major role in the protection of cells and tissue structures.[12] GSH allows the detoxification of free radicals and oxygen-reactive species involved in such diseases as atherosclerosis, rheumatoid arthritis, adult respiratory distress syndrome, or reoxygenation injury; consequently, its concentration decreases in such diseases.[27] Hepatic GSH concentrations have been observed in alcoholic[2829] and nonalcoholic[30,31] liver diseases. Plasma GSHt concentrations also decrease in such diseases. Therefore, supplemental ingested GSH can benefit the treatment of these diseases and increase liver GSH concentration for detoxification. The ingested GSH has potent nutraceutical benefits for human health to improve oxidative stress and defense in humans. These data indicated that there are several unknown pathways for GSH deposit in the circulating system and transfer into the liver. Further studies will unveil the exact mechanisms of orally administered GSH transport pathway and biological roles in the body.

without any side effects. The antiobesity effects of Oolong tea polyphenols may be produced by interacting with and inhibiting α-amylase, then reducing the carbohydrate digestibility.[25−27] However, the potential mechanisms of Oolong tea polyphenols in preventing obesity are complicated. Therefore, there is practical significance for development of α-amylase inhibitors through understanding the inhibitory effects and potential mechanisms of Oolong tea polyphenols, EGCG, and EGCG3″Me against α-amylase.

In this study, Oolong tea polyphenols, EGCG and EGCG3″Me were prepared from Oolong tea and their inhibitory effects against α-amylase were investigated. Furthermore, ultraviolet (UV) absorption spectroscopy and fluorescence emission spectroscopy were applied to analyze the nature of binding interaction of α-amylase with Oolong tea polyphenols, EGCG and EGCG3″Me.

## MATERIALS AND METHODS

**Materials.** Oolong tea was purchased from a local market in Guangdong province of China. Toyopearl HW-40S and polyamide resins for column chromatography were purchased from Tosoh Corp. (Tokyo, Japan) and Qingdao Ocean Chemical Co., Ltd. (Qingdao, China), respectively. Standards of EGCG, ECG, EGC, and EC were purchased from Funakoshi Co., Ltd. (Tokyo, Japan), and standards of EGCG3″Me, (−)-catechin gallate (CG) and (−)-gallocatechin gallate (GCG) were prepared according to our reported method.[28] 3,5-Dinitrosalicylic acid (DNS) and porcine pancreatic α-amylase were purchased from Sigma Chemical Co., Ltd. (St. Louis, MO, U.S.A.). Folin-Ciocalteu reagent was purchased from Kayon Biological Technology Co., Ltd. (Shanghai, China). All solvents used for chromatographic purposes were grade of high performance liquid chromatography (HPLC).

**Preparation of Oolong Tea Polyphenols, EGCG and EGCG3″Me.** The preparation of Oolong tea polyphenols, EGCG and EGCG3″Me was performed according to the reported methods[7,28,29] with some modifications. Briefly, 100.0 g of Oolong tea was extracted with distilled water (1600 mL) at 96 °C for 40 min. The extract was centrifuged at 4500*g* for 15 min, and the resulting insoluble residue was treated again as described above. The supernatants were combined, concentrated and dissolved with deinoized water. The resulting solution was filtered through 0.45 μm microfiltration membrane and applied to a polyamide resin column (30 × 1.6 $cm^2$). The column was first washed with 2 times bed volume (BV) of distilled water, and then was eluted with 4 times BV of ethanol solution (80%, v/v). The elution of ethanol solution was collected, concentrated and freeze-dried by a Freeze-Dry System (Labconco, Kansas City, MO, U.S.A.), affording Oolong tea polyphenols.

Part of the Oolong tea polyphenols was dissolved with distilled water and loaded onto a Toyopearl HW-40S column (30 × 1.6 $cm^2$). The column was eluted with 80% ethanol solution at a flow rate of 2.5 mL/min, and the elution was autocollected (10 mL/tube). The eluted fractions were analyzed by HPLC with diode array detector (HPLC-DAD), and the fractions containing EGCG and EGCG3″Me were collected, concentrated, and freeze-dried, affording EGCG and EGCG3″Me, respectively. The structures of resulting EGCG and EGCG3″Me were characterized by HPLC, electrospray ionization time-of-flight mass spectrometry (ESI-TOF-MS) and $^1$H nuclear magnetic resonance (NMR) spectrometry.

**Determination of Contents of Oolong Tea Polyphenols, EGCG, and EGCG3″Me.** The total polyphenols content in sample of Oolong tea polyphenols was determined by the Folin-Ciocalteu method according to the reported procedure.[30] The contents of EC, ECG, CG, GCG, EGCG, and EGCG3″Me were determined according to the reported method[28] by using an Agilent 1100 series HPLC-DAD system (Agilent Technologies Inc., St. Clara, CA, U.S.A.). The separation was achieved on a TSKgel ODS-100Z column (4.6 × 150 $mm^2$, 5 μm; Tosoh Corp., Tokyo, Japan) with a gradient mobile phase consisted of formic acid solution (A, pH 2.5) and methanol (B) at a flow rate of 1.0 mL/min. The linear gradient was as follows: mobile phase A from 82% to 40% in 15 min. The injection volume was 20 μL. The temperature of column oven was set at 40 °C. The wavelength of detector was set at 280 nm.

**Assay of α-Amylase Inhibition.** The determination of α-amylase inhibition was carried out according to the reported method[26,31] with slight modifications. First, α-amylase was dissolved in phosphate buffer saline (PBS, 0.02 mol/L, pH 6.8) at a concentration of 0.1 mg/mL. Various concentrations of Oolong tea polyphenols, EGCG, and EGCG3″Me solutions (0.25 mL) were mixed with α-amylase solution (0.25 mL) and incubated at 37 °C for 5 min. Then the reaction was initiated by adding 0.5 mL 1.0% (w/v) starch substrate solution to the incubation medium. After incubation at 37 °C for 3 min, the reaction was stopped by adding 0.5 mL DNS reagent (1% DNS, 0.2% phenol, 0.05% $Na_2SO_3$, and 1% NaOH in aqueous solution) to the reaction mixture and boiling at 100 °C for 8 min. After cooling to room temperature, the absorbance (Abs) at 540 nm was recorded by a spectrophotometer. The inhibition percentage was calculated by the following equation:

$$\text{inhibition rate } (\%) = [(\text{Abs}_1 - \text{Abs}_2)/\text{Abs}_1] \times 100$$

where $Abs_1$ and $Abs_2$ represent Abs at 540 nm without and with inhibitor, respectively. The half inhibitory concentration ($IC_{50}$) was calculated from inhibition curve.

**Determination of Inhibition Types and $V_{max}$ and $K_m$ Values.** The inhibition types of Oolong tea polyphenols, EGCG, and EGCG3″Me against α-amylase and values of maximum reaction velocity ($V_{max}$) and Michaelis constant ($K_m$) were determined by using the Lineweavere-Burk plots from the relevant Michaelis−Menten equations according the reported method.[32] The substrate solutions at concentrations of 6.0, 8.0, 10.0, 12.0, 14.0, and 16.0 mg/mL were reacted with α-amylase with or without inhibitor, respectively. The concentrations of α-amylase and inhibitor were 0.06 and 0.4 mg/mL, respectively, while distilled water was used as a control. The $V_{max}$ and $K_m$ values were obtained from the least-squares regression lines of the double reciprocal plots of the tested sample (inhibitor) concentration versus the reciprocal of reaction rate.

**UV Absorption Spectroscopy.** The general procedure to probe the interaction relationship between α-amylase and polyphenols by UV absorption spectroscopy was to mix the sample and enzyme solutions, incubate for 3−5 min and then determine the absorption spectrum in the range of 200−300 nm with a UV-2600 spectrophotometer (Shimadzu Corp., Kyoto, Japan). The concentration of α-amylase was 1.0 mg/mL, and the concentrations of Oolong tea polyphenols, EGCG and EGCG3″Me varied from 0.06 to 1.00 mg/mL. The control treatment was carried out without inhibitor.

**Fluorescence Emission Spectroscopy.** Fluorescence spectra were recorded with a Spectra Max Gemini XS spectrofluorometer (Molecular Devices, Sunnyvale, CA, U.S.A.) according to the reported method[33] with some modifications. Briefly, 3D fluorescence spectrum of α-amylase (0.1 mg/mL) was scanned under 20 °C and pH 6.9, the excitation wavelength ($\lambda_{ex}$) and emission wavelength ($\lambda_{em}$) were determined, respectively. Under the same conditions, the solutions of different concentrations of Oolong tea polyphenols, EGCG and EGCG3″Me were added into α-amylase solution and reacted for 3 min, respectively, then the relative fluorescence intensities were determined at excitation wavelength of 340 nm and emission wavelength of 280 nm.

**Statistical Analysis.** The results obtained were analyzed by SPSS version 16.0 (SPSS Inc.; Chicago, IL, U.S.A.). Any significant difference was determined by one-way analysis of variance (ANOVA) followed by the Tukey test for multiple comparisons at $P < 0.05$ level.

## RESULTS AND DISCUSSION

The water extract of Oolong tea was first separated by polyamide column chromatography to afford Oolong tea polyphenols that the total polyphenols content was 83.92%. As shown in Figure 2B, the main components in Oolong tea

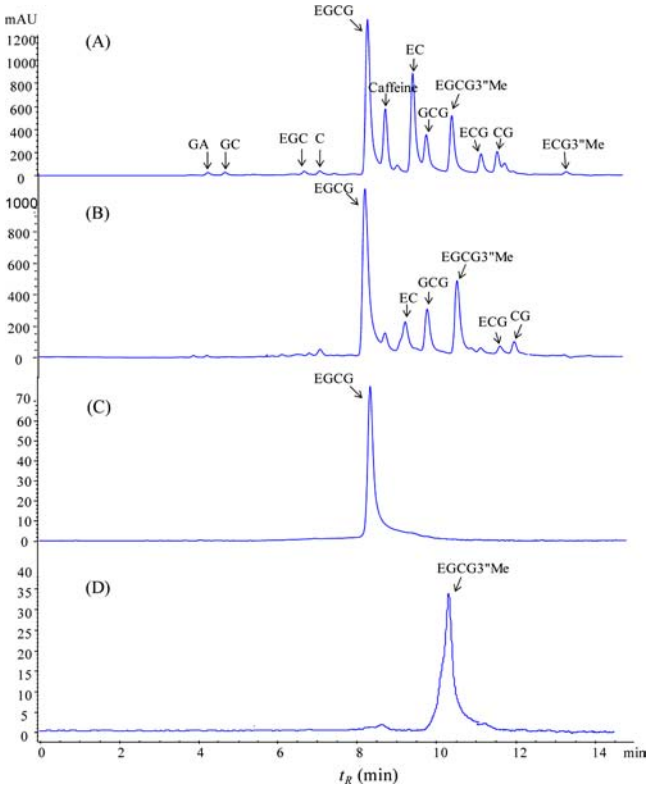

**Figure 2.** HPLC chromatograms of Oolong tea extract (A), Oolong tea polyphenols (B), purified EGCG (C), and purified EGCG3″Me (D).

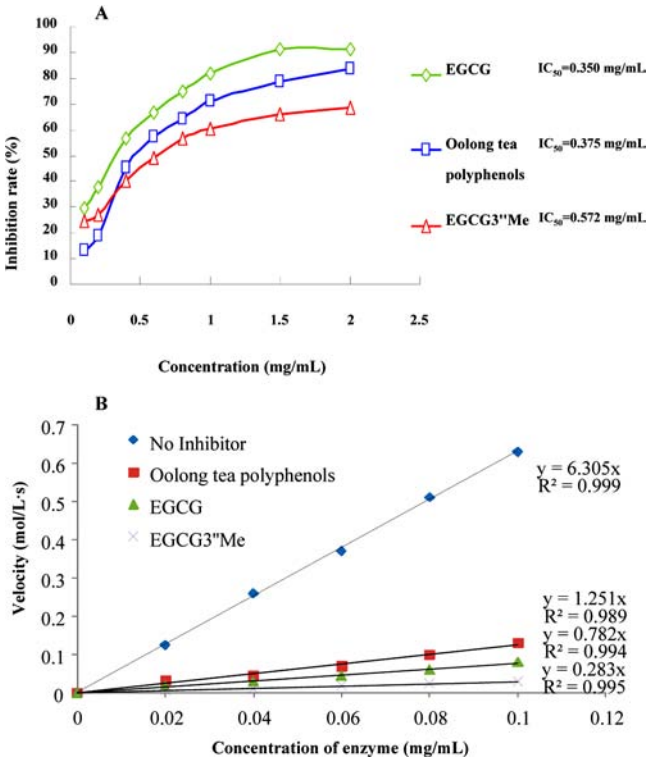

**Figure 3.** Inhibitory effects (A) and inhibition types (B) of Oolong tea polyphenols, EGCG, and EGCG3″Me on α-amylase.

polyphenols were EGCG (27.58 ± 1.73%), EGCG3″Me (14.30 ± 0.32%), GCG (9.28 ± 0.18%), EC (7.83 ± 0.11%), ECG (4.21 ± 0.29%), and CG (3.72 ± 0.17%). Notably, EGCG and EGCG3″Me occupied about 42% of the total polyphenols. The resulting Oolong tea polyphenols were separated by column chromatography of Toyopearl HW-40S, affording high purity of EGCG (98.00%, Figure 2C) and EGCG3″Me (96.68%, Figure 2D). By comparison with reported data,[16,34,35] their chemical structures were confirmed to be EGCG and EGCG3″Me by HPLC, ESI-TOF-MS, and $^1$H NMR.

**Inhibition of Oolong Tea Polyphenols, EGCG, and EGCG3″Me on α-Amylase.** The inhibitory effects of Oolong tea polyphenols, EGCG and EGCG3″Me against α-amylase were investigated. As shown in Figure 3A, the $IC_{50}$ values of Oolong tea polyphenols, EGCG and EGCG3″Me were 0.375, 0.350, and 0.572 mg/mL, respectively. EGCG exhibited relative lower $IC_{50}$ value, indicating its relative higher inhibitory potency in comparison with Oolong tea polyphenols and EGCG3″Me. It is consistent with reported results that the inhibitory effects of C, EC, EGC, and EGCG on α-amylase are in the following order: EGCG > EC > EGC > C.[27,36] The results also suggested that EGCG should be one of the main inhibitory compounds against α-amylase in Oolong tea polyphenols. However, EGCG3″Me showed the highest $IC_{50}$ value, indicating its relative weaker inhibitory effect on α-amylase. The inhibitory difference between EGCG and EGCG3″Me might be due to the difference in their structures. It has been reported that polyphenols interacted with α-amylase primarily through noncovalent interactions, such as hydrophobic interaction and hydrogen bonding between the hydroxyl groups of polyphenols and the catalytic residues of binding site in α-amylase, forming the polyphenols−enzyme complex.[27,37] Thus, the substitution of 3-OH in D ring of EGCG (Figure 1) by methoxy group might be the possible reason for relative weaker inhibitory effect of EGCG3″Me on α-amylase.[25,38] However, it has been reported that the methylation of polyphenols could greatly improve the transport through biological membranes and increase the oral bioavailability.[39,40] Thus, the in vivo inhibitory effect of EGCG3″Me is worthy of further study due to its relative higher bioavailabilty in vivo than EGCG.[41]

To explore the inhibition types of Oolong tea polyphenols, EGCG and EGCG3″Me against α-amylase, the kinetic reactions of α-amylase were investigated with different concentrations of α-amylase. As shown in Figure 3B, it was found that the lines obtained from the Lineweaver−Burk plots were all passed through the origin point (0, 0) of the coordinates, indicating that the inhibition types of Oolong tea polyphenols, EGCG, and EGCG3″Me against α-amylase were all reversible inhibition. To further investigate the inhibitory characteristics, Lineweaver−Burk double reciprocal plots were performed. As shown in Figure 4, the Lineweaver−Burk plots for Oolong tea polyphenols and EGCG showed the same intersection on *Y*-axis, indicating that the inhibition on α-amylase by Oolong tea polyphenols and EGCG were competitive. In contrast, EGCG3″Me had an intersection on *X*-axis, suggesting that EGCG3″Me inhibited α-amylase in a noncompetitive fashion. The difference of inhibition types of EGCG and EGCG3″Me, being worthy of further study, might also be due to the structural difference between EGCG and EGCG3″Me. Furthermore, kinetic inhibition parameters on α-amylase were calculated according to Lineweaver−Burk plots, and the results are shown in Table 1. In the presence of EGCG3″Me, $V_{max}$ value for α-amylase decreased, while the value of $K_m$ remained unchanged. In contrast, $K_m$ value for α-

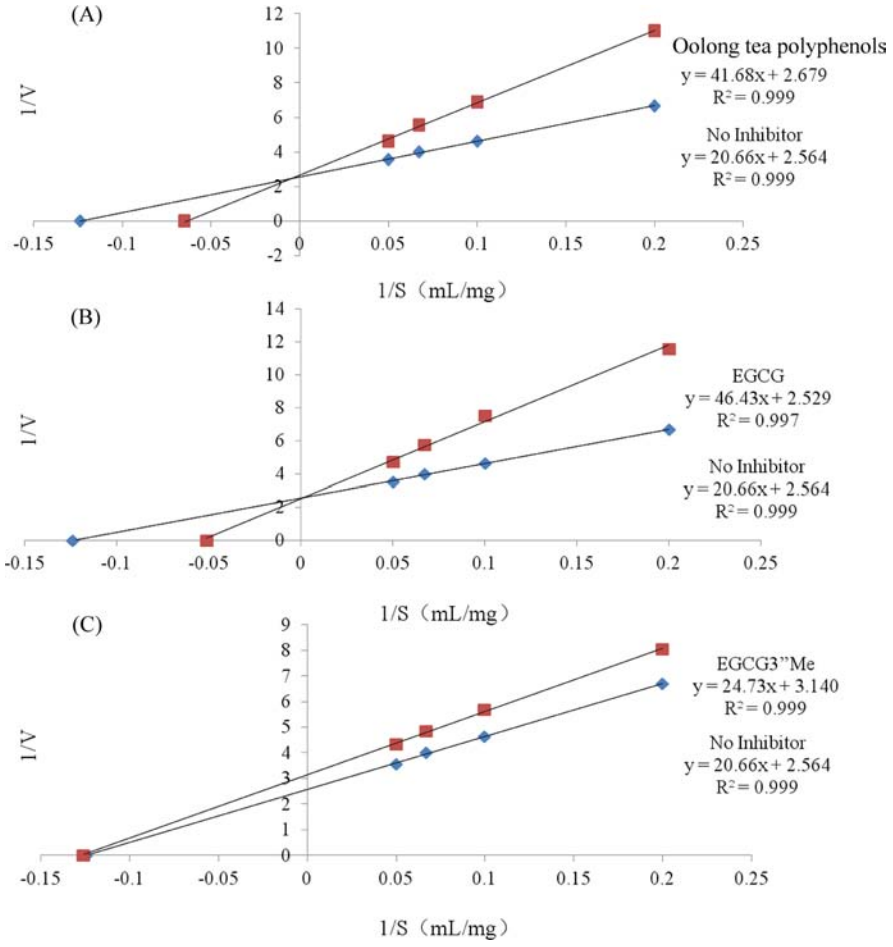

**Figure 4.** Lineweaver–Burk plots of the reaction of α-amylase in the presence of Oolong tea polyphenols (A), EGCG (B), and EGCG3″Me (C).

**Table 1. Kinetic Results of Inhibition against α-amylase by Oolong tea Polyphenols, EGCG, and EGCG3″Me**

| | $K_m$ (mg/mL) | $V_{max}$ (mg/mL·min) | inhibition type |
|---|---|---|---|
| no inhibitior | 8.06[a] | 0.39[a] | |
| Oolong tea polyphenols | 15.38[b] | 0.38[a] | competitive inhibition |
| EGCG | 18.51[c] | 0.39[a] | competitive inhibition |
| EGCG3″Me | 7.94[a] | 0.32[b] | noncompetitive inhibition |

amylase increased while $V_{max}$ value remained unchanged in the presence of Oolong tea polyphenols or EGCG. Such results are consistent with their inhibitory characteristics.

**Changes of α-Amylase UV Spectra Induced by Oolong Tea Polyphenols, EGCG or EGCG3″Me.** α-Amylase has an absorption peak at 270 nm due to the presence of tryptophan (Trp) and tyrosine (Tyr) aromatic heterocyclic residues, thus, the change of microenvironment of the aromatic amino acid residues would cause the change of α-amylase absorption wavelength. As shown in Figure 5, changes in UV spectra of α-amylase were observed after the addition of Oolong tea polyphenols, EGCG, and EGCG3″Me. With the increase of sample concentration, a red-shift for α-amylase was found, but there was no significant difference among the samples. It has been reported that the main mechanism of polyphenols-enzyme binding was considered to be noncovalent interactions, including hydrogen bond and hydrophobic association.[42−44] Interaction of polyphenols and α-amylase was conducive to intermolecular and intramolecular agglomeration effects of enzyme, which made the residues of Trp and Tyr within the aromatic heterocyclic and hydrophobic groups surrounded by α-amylase exposed, led to the microenvironmental change of the aromatic amino acid residues in the spatial structure and caused the conformational change of protein. However, the composition and quantity of the polar groups in the enzyme protein may affect the formation and stability of hydrogen bonds between polyphenols and α-amylase.[27,37] Thus, with the increase of sample concentration, the protein (enzyme) peptide bond extension phenomenon occurred, hydrophobic interaction enhanced slightly, and then absorption peak and red-shift amplitude increased correspondingly.

**Quenching of α-Amylase Fluorescence Spectra by Oolong Tea Polyphenols, EGCG, or EGCG3″Me.** Fluorescence quenching measures the decrease of the quantum yield of fluorescence from a fluorophore induced by a variety of molecular interactions with a quencher molecule. It is a useful approach to investigate intermolecular interactions. In the present study, therefore, the interaction between polyphenols and α-amylase was investigated from the changes of the fluorescence emission spectra of α-amylase in the absence and presence of polyphenols. From 3D fluorescence spectrum of α-amylase (Figure 6A), it was found that α-amylase had two absorption peaks at excitation wavelength of 340 nm, whereas Oolong tea polyphenols did not show any interference (Figure

dx.doi.org/10.1021/jf5032907 | J. Agric. Food Chem. 2014, 62, 9507−9514

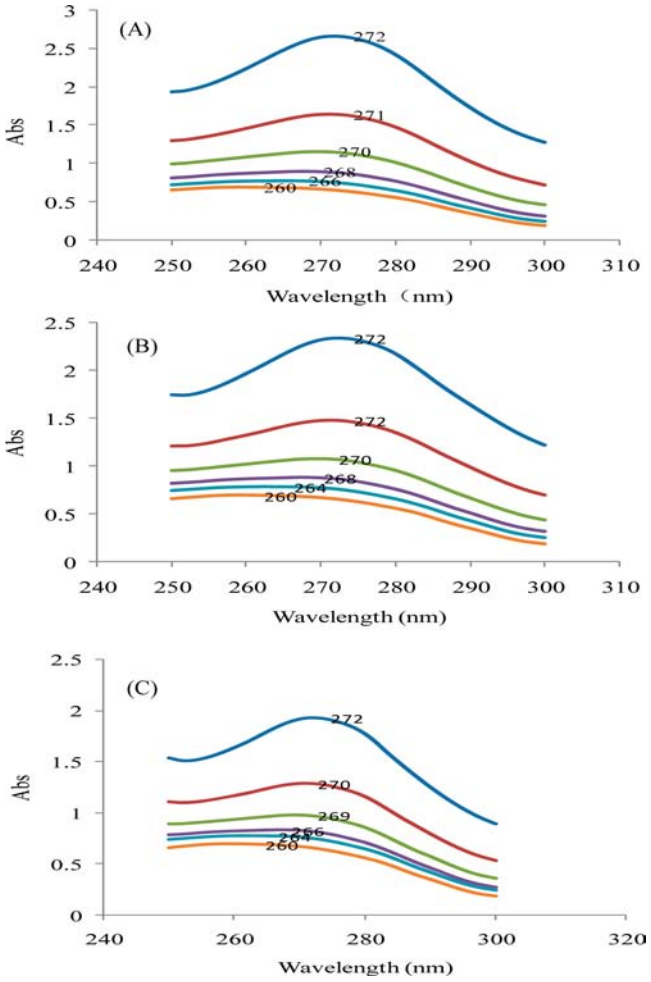

**Figure 5.** UV absorption spectra of $\alpha$-amylase in the presence of different concentrations of Oolong tea polyphenols (A), EGCG (B), and EGCG3″Me (C). From top down, 1.00, 0.500, 0.25, 0.13, 0.06, and 0.00 mg/mL for sample concentration.

6B). With the addition of Oolong tea polyphenols, EGCG, or EGCG3″Me, the fluorescence emission intensity of $\alpha$-amylase decreased (Figure 6C−H), indicating that Oolong tea polyphenols, EGCG, and EGCG3″Me could quench the intrinsic fluorescence of $\alpha$-amylase. The reason might be due to the fact that polyphenols bind to $\alpha$-amylase, which leads to the unfolding of $\alpha$-amylase fluorescent amino acid residues and causes quenching of the inherent fluorescence property. The observed spectral changes of $\alpha$-amylase reflected direct or indirect interactions of polyphenols with the hydrophobic and hydrophilic regions located in the vicinity of Trp and Tyr and induced conformational changes of $\alpha$-amylase. As Brayer et al.[5] reported, inhibitors may directly contact with the side chains of Asp197, Glu233, and Asp300 of $\alpha$-amylase. Computational ligand docking indicates that the inhibitory activity of EGCG on $\alpha$-amylase depends on hydrogen bonds between the hydroxyl groups of EGCG and the catalytic residues of the binding site and formation of a conjugated $\pi$-system that stabilizes the interaction with active site.[37,45,46]

As shown in Figure 6C−H, Oolong tea polyphenols, EGCG, and EGCG3″Me exhibited different quenching effects on $\alpha$-amylase. The absorption characteristics of Oolong tea polyphenols and EGCG with $\alpha$-amylase was roughly the same, but it was significantly different from that of EGCG3″Me. The difference in quenching effects between EGCG and EGCG3″Me might be due to the difference of their structures: hydroxyl group for EGCG and methoxy group for EGCG3″Me at C-3 of D ring (Figure 1). The interaction between polyphenol and $\alpha$-amylase was reported to depend on the structures of polyphenols and $\alpha$-amylase.[27,37] Some researchers also explored the structure−activity relationship of inhibitors with $\alpha$-amylase and possible mechanisms by molecular docking and other measurements, such as the binding of flavonols, flavones, and EGCG with human salivary $\alpha$-amylase.[6,38,47] On the basis of the present results and some previous reports, thus, we conclude that Oolong tea polyphenols, EGCG, and EGCG3″Me may act as antiobesity factor, in terms of their inhibitory effects on $\alpha$-amylase, due to the cooperative effects of hydrophobic association and hydrogen bond formation between polyphenols and $\alpha$-amylase.

The relationship between fluorescence quenching intensity and concentration of quencher can be described by following Stern−Volmer equation.[46,48]

$$F_0/F = 1 + k_q\tau_0[Q] = 1 + K_{sv}[Q]$$

$F_0$ and $F$ are the fluorescence intensities in the absence and presence of quencher, respectively. $k_q$ is the bimolecular quenching constant, $\tau_0$ is the native lifetime of the fluorophore, and $[Q]$ is the concentration of quencher. $K_{sv}$, the Stern−Volmer quenching constant, is given by $k_q\tau_0$. A linear Stern−Volmer plot is generally indicative of a single class of fluorophore in a protein, all equally accessible to the quencher. Here, the following modified Stern−Volmer equation was applied to analyze the fluorescence quenching.

$$\frac{F_0}{F_0 - F} = \frac{1}{fK[Q]} + \frac{1}{f}$$

where $f$ is the fraction of fluorophore accessible to the quencher and $K$ is the modified Stern−Volmer quenching constant which is very close to the binding constant. The plot of $F_0/(F_0 - F)$ versus $1/[Q]$ yields $1/f$ as the intercept and $1/fK$ as the slope. Thus, from the intercept and slope, the $f$ and $K$ can be obtained. The fluorescence quenching parameters are list in Table 2. On the basis of the fluorescence quenching parameters ($K_{sv}$ and $K_q$), we could verified that Oolong tea polyphenols and EGCG had almost the same binding ability on $\alpha$-amylase, which further proved that EGCG was one of the main inhibitory ingredients in Oolong tea polyphenols against $\alpha$-amylase as mentioned above. Besides, the lower $K$ value for EGCG3″Me indicated a lower affinity interaction between $\alpha$-amylase and EGCG3″Me compared to EGCG. EGCG-$\alpha$-amylase complex was reflected to have more exposure of Trp residues and unfolding of protein structure than EGCG3″Me-$\alpha$-amylase. It has been reported that the binding constants for the larger polyphenol-protein complexes are larger than those of smaller polyphenol−protein adducts, which can be due to the presence of more hydroxyl groups associated with the polyphenols.[49] Due to the tightening of protein structure through intramolecular interactions such as hydrogen bonds, polyphenol−$\alpha$-amylase complexes might induce Trp residues in a more hydrophobic environment. We could speculate that, therefore, hydroxyl but not the methoxy group in polyphenols played the main role in the binding process.

Fluorescence quenching can be dynamic (resulting from collisional encounters between fluorophore ($\alpha$-amylase) and quencher) or static (resulting from formation of a ground state

dx.doi.org/10.1021/jf5032907 | J. Agric. Food Chem. 2014, 62, 9507−9514

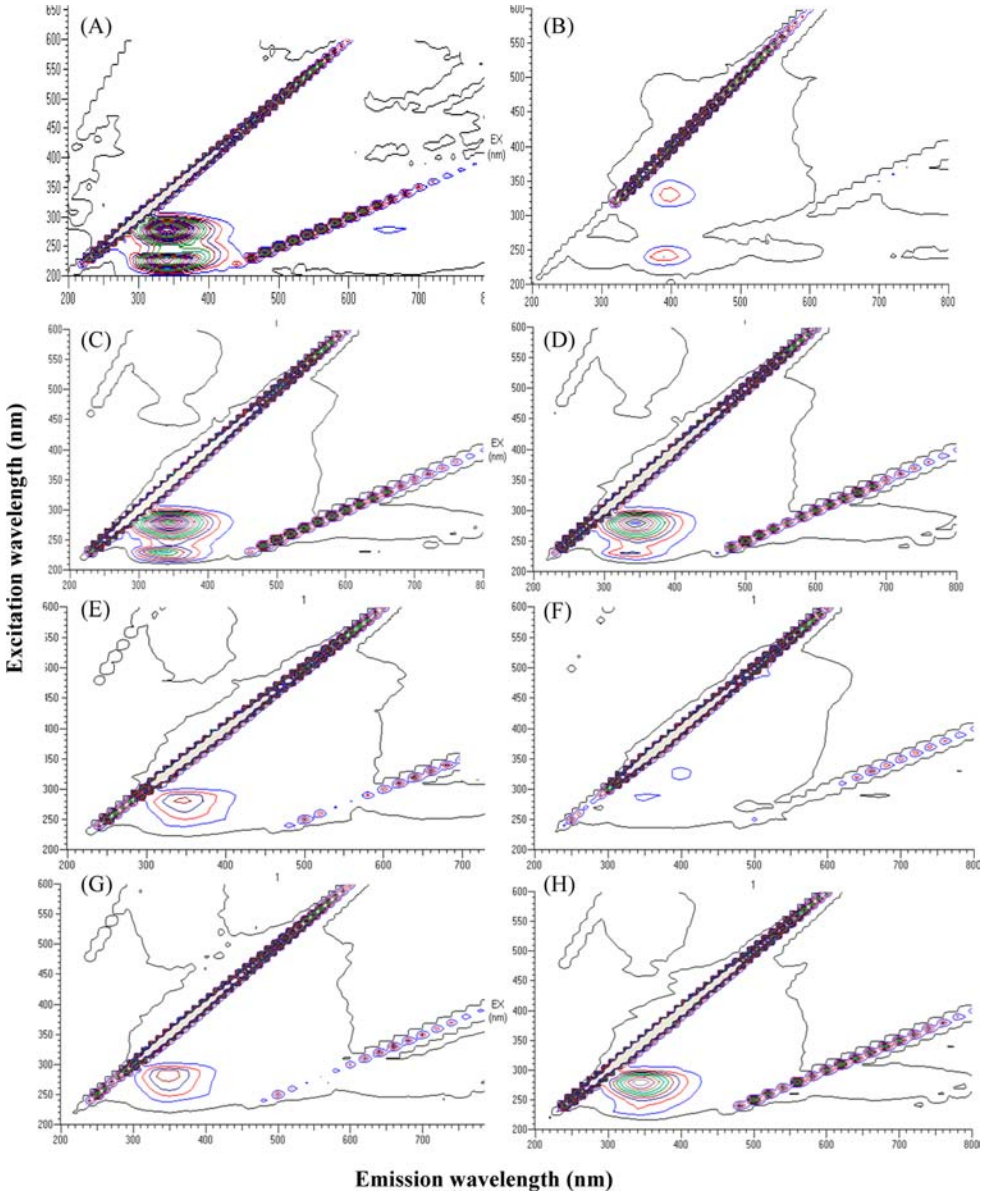

**Figure 6.** 3D Fluorescence spectra of $\alpha$-amylase (A) and Oolong tea polyphenols (B) and fluorescence quenching effects on $\alpha$-amylase by Oolong tea polyphenols (C, D, E, and F at concentrations of 10, 40, 100, and 200 $\mu$g/mL, respectively), EGCG (G, 100 $\mu$g/mL), and EGCG3″Me (H, 100 $\mu$g/mL).

**Table 2. Fluorescence Quenching Parameters for the Interactions of Oolong Tea Polyphenols, EGCG, and EGCG3″Me with $\alpha$-Amylase**

| | $K_{sv}$ (L·g$^{-1}$) | $K_q$ ( × 10$^{12}$ L·g$^{-1}$·s$^{-1}$) | $K$ (L·g$^{-1}$) |
|---|---|---|---|
| Oolong tea polyphenols | 53177.0[a] | 5.318[a] | 23684.1[a] |
| EGCG | 53174.4[a] | 5.317[a] | 39272.0[b] |
| EGCG3″Me | 61542.0[b] | 6.154[b] | 33746.0[b] |

between fluorophore and quencher).[50] Dynamic quenching is related to diffusion, and the rising of the temperature will increase the diffusion coefficient, thus increase the bimolecular quenching constant. Conversely, if it is static quenching, the temperature rise will improve the stability of the complexes, quenching constant will diminish.[51] As shown in Figure 7, the quenching constant slope increased slightly with the increase of temperature. Hence, the fluorescence quenching of Oolong tea polyphenols, EGCG, and EGCG3″Me on $\alpha$-amylase was determined to be dynamic one.

In conclusion, the inhibitory effects on $\alpha$-amylase of Oolong tea polyphenols, EGCG, and EGCG3″Me, prepared from Chinese Oolong tea, were investigated in the present study. EGCG appeared to be one of the main compounds in Oolong tea polyphenols for the inhibitory effects against $\alpha$-amylase. The differences of inhibitory effect and inhibition type between EGCG and EGCG3″Me might be due to substitution of the hydroxyl group in EGCG by methoxy group. In addition, it is speculated that Oolong tea polyphenols, EGCG, and EGCG3″Me exhibited their inhibitory effects against $\alpha$-amylase through the cooperative effects of hydrophobic association and hydrogen bond formation between polyphenols and $\alpha$-amylase. Further works on inhibitory effect in vivo and possible action mechanisms of EGCG3″Me are in progress.

containing 1:1:1 methanol, acetone, and ethanol. The mixture was stirred for 30 min and filtered through cheesecloth, and the remaining solids were re-extracted twice under the same conditions. Following a final filtration through no. 4 Whatman filter paper, the solvents were evaporated under reduced pressure at 45 °C, and the concentrate was brought up to 15 mL in water acidified with 0.01% HCl. Insoluble solids were removed by centrifugation prior to filtration through a Whatman 0.45 $\mu$m PTFE membrane for HLPC-MS characterization.

Additional isolation and concentration were deemed necessary to characterize minor compounds in mango pulp and were accomplished by extracting 1 kg of fruit as previously described.[9] Phytochemicals were partitioned from 10 g $C_{18}$ Sep Pak cartridges. Columns were preconditioned with 10 column volumes of methanol followed by 10 column volumes of water. Extracts were loaded onto the column and eluted with 100% methanol. $C_{18}$ nonretained compounds were further extracted by liquid−liquid partition with 2 volumes of ethyl acetate with a solvent to sample ratio of 1:1. The solvent fractions were pooled for evaporation and likewise dissolution in 0.01% HCl water.

**Characterization and Quantitation of Phytochemicals with HPLC-MS.** Polyphenolics were characterized and quantified using a Thermo Finnigan LCQ Deca XP Max $MS^n$ ion trap mass spectrometer equipped with an ESI source. Separations were in reversed phase using a Finnigan Surveyor HPLC coupled to a Surveyor PDA detector, and gradient separations were performed using a Dionex Acclaim (Bannockburn, IL, USA) $C_{18}$ column (250 × 4.6 mm, 5 $\mu$m) at room temperature. Injections were made into the column by use of a 25 $\mu$L sample loop. Mobile phase A was 0.1% formic acid in water, and mobile phase B was 0.1% formic acid in methanol run at 0.4 mL/min. A gradient was run of 0% phase B for 3 min and changed to 21% phase B in 20 min, from 21 to 35% phase B in 30 min, from 35 to 49% phase B in 50 min, and from 49 to 70% phase B in 70 min before returning to initial conditions. The electrospray interface worked in negative ionization mode. Source and capillary temperatures were set at 300 °C, source voltage was 3.50 kV, capillary voltage was set at −42 V, and collision energy for MS/MS analysis was set at 35 eV. The instrument operated with sheath gas and auxiliary gas ($N_2$) flow rates set at 40 and 5 units/min, respectively. In addition to chromatographic separations, the mango concentrate was infused to capture $MS^n$ fragmentation patterns of poorly ionized compounds using instrument tuning specific to gallic acid, methyl gallate, and pentagalloylglucose.

All compounds were quantified at 280 nm with their corresponding aglycones. If an aglycone standard was lacking, concentrations were measured with the use of gallic acid as a standard. As the majority of the compounds were tentatively identified and lacked standards, results of this study represent a relative concentration of polyphenols in 'Keitt' mango pulp.

**Commercial Enzyme Hydrolysis.** Cell wall active enzymes were applied to a 'Keitt' mango puree at a uniform rate of 0.05% v/w to simulate an average commercial application rate of the enzyme and to evaluate their effects on mango chemistry. Enzymes included Validase TRL (Val), a mixed-function enzyme with predominantly cellulase activity (6800 U/g) with side activities as a pectinase and hemicellulase; Crystalzyme 200XL (Cz), an enzyme with predominantly pectinase activity (200,000 depectinizing units/g); and Rapidase AR 2000 (Rap), a pectinase with approximately 25% $\beta$-glucosidase side activity (>4000 U/g). Enzyme and mango puree mixtures were incubated at 50 °C for up to 4 h under a blanket of nitrogen. Following incubation, an aliquot of the fruit pulp was placed in boiling water for 3 min to inactivate the enzyme and immediately cooled on ice. Prior to analysis, both control and enzyme-treated pulps were centrifuged at 2000*g* to separate solids from the supernatant, which was further filtered through a 0.45 $\mu$m PTFE filter and quantified under the same conditions as the characterized mango.

**Statistics.** Semiquantifications were evaluated in triplicate in independent reaction vessels. Data for commercial enzyme application represent the mean of triplicate analyses using ANOVA (analysis of variance) followed by each pair Student's *t* test using the JMP statistics software package, which provided corresponding probability ($p < 0.05$) values to indicate significant differences between treatments.

## RESULTS AND DISCUSSION

**Phytochemicals in 'Keitt' Mango.** The phytochemical composition in mango pulp, mostly phenolic acids, is poorly characterized in the literature. Like most fruits, mango chemistry and resultant bioactivity can differ on the basis of variety and postharvest handling,[15,16] yet all varieties with reported phytochemical characterizations have identified GA and derivatives of GA in the form of hydrolyzable gallotannins. In addition to derivates of GA, mango pulp contains a variety of low molecular weight compounds that are present in relatively low concentrations, yet these compounds may be critical for understanding the benefits of mango consumption. For the first time, tentative identification and semiquantification of many polyphenols and apocarotenoids were accomplished in 'Keitt' mango pulp using UV spectroscopic evaluations, mass fragmentation patterns, comparison to other reports of compound identity, and resultant changes following hydrolysis. (Figures 1−3; Table 1).

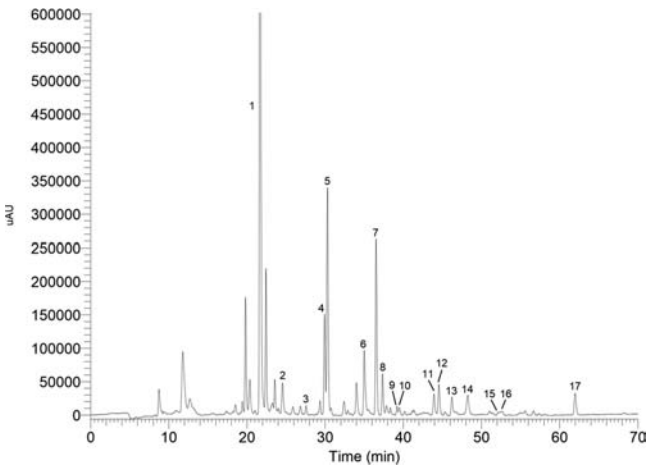

**Figure 1.** HPLC chromatogram of compounds present in mango (*Mangifera indica* L. cv. 'Keitt') pulp at 280 nm. Peak assignments are shown in Table 1.

**Hydroxybenzoic Acids.** Peaks 1 and 4 were tentatively identified as isomers of mono galloyl glucoside (MGG) as each compound showed a parent ion of $m/z$ 331.2 and a secondary ion fragment with a loss of 162 Da (Da) indicating the loss of a glucosyl to the base aglycone GA. Compound **1** additionally had a $m/z$ 271.1 fragment consistent with the loss of a 60 Da unit from the dissociation of a C6 sugar that resisted fragmentation in relation to compound **4** that exhibited characteristic losses of 162 and 206 Da [M − H − 162 − 44] from losses of both glucose and carboxylic acid. Therefore, these fragmentation patterns indicated that the glucose moiety of compound **1** was linked to an ester bond via the carboxylic acid of GA and that the glucose moiety of compound **4** was ether linked to a hydroxyl group of GA (Figure 2). Additional confirmation of these linkages was confirmed by alkali hydrolysis, which has been shown to preferentially hydrolyze ester bonds after brief exposure.[17] Within 5 min of exposure to pH 10 conditions, the complete hydrolysis of compound **1** to GA was observed, whereas compound **4** remained unchanged after 15 min. The ester-linked MGG accounted for 50% of the quantified phytochemicals at 37.7 mg/kg compared to only 3.82 mg/kg for the ether-linked species. The type of linkage between GA and glucose may be important for human

bioavailability because the ester linkage is more susceptible to hydrolysis in the high-pH environment of the human intestine,[18] whereas the ether bonds would require the action of $\beta$-glucosidase.[19]

Compound **2** was identified as free GA on the basis of comparison to a standard. Compound **2** had a $\lambda_{max}$ of 271 nm, a $m/z$ of 169.2, and the subsequent loss of $CO_2$ under MS/MS conditions to yield pyrogallol at $m/z$ 125.3. Compound **3** was also a GA derivative with a pseudomolecular ion of $m/z$ 493.4 with secondary ionization showing fragments of $m/z$ 313.2 [M − H − 180] and 169.2 [M − H − 324] corresponding to the loss of two glucose moieties from galloyl diglucoside, a compound previously reported in longan seed.[20] Compound **5** was characterized as a hydroxybenzoic acid glycoside (HBG) at $m/z$ 299.1 with a six-carbon sugar esterified to its carboxylic acid similar to ester-linked MGG. Secondary ionization produced fragments ($m/z$ 239, 209, and 179) typical of an acid-resistant glycosidic bond corresponding to the ring fission

dx.doi.org/10.1021/jf5031554 | J. Agric. Food Chem. 2014, 62, 9515–9521

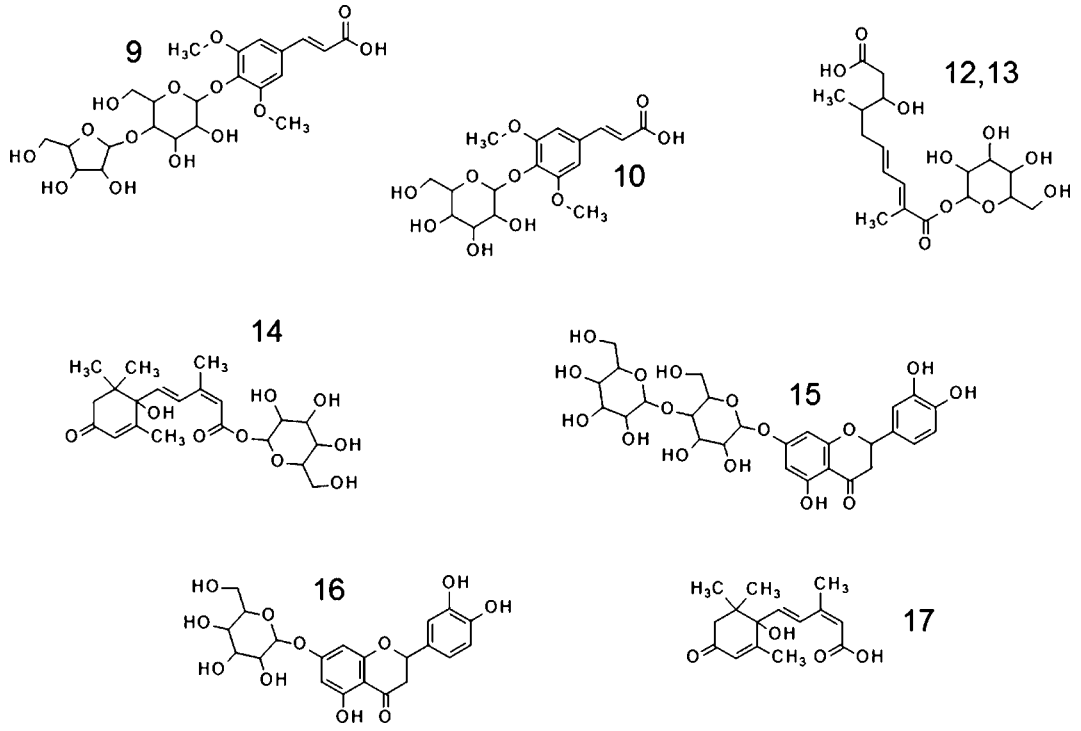

**Figure 3.** Tentative chemical structures for compounds **9**, **10**, and **12**−**17**.

of glucose that produced 60, 90, and 120 Da neutral fragments as previously reported for C-linked glycosides.[21] The corresponding aglycone at $m/z$ 137 corresponded to a *p*-hydroxybenzoic acid on the basis of its characteristic UV spectral bands at 256 and 299 nm as compared to a standard of *p*-hydroxybenzoic acid used for quantification.

**Cinnamic Acids.** Compounds **6** and **8**−**10** were characterized as cinnamic acid derivatives on the basis of their typical diode array absorbance patterns between 300 and 320 nm. These compounds were present in relatively low concentrations (<1.6 mg/kg) and were a strong indication that metabolic equilibrium is greatly shifted toward hydroxybenzoic acid production in mango pulp. Specifically, compound **6** was characterized as a coumaric acid glycoside with a pseudomolecular ion of $m/z$ 324.8 and a corresponding fragment of $m/z$ 163.2 indicating the loss of a C6 sugar moiety resulting in free coumaric acid. Compound **8** was characterized as a ferulic acid hexoside, $m/z$ 355.0 with a ferulic acid ion detected in $MS^2$, with an $m/z$ of 193.2 as well as the decarboxylated ferulate ion at $m/z$ 149 [M − H − 162 − 44]. Compounds **9** and **10** (Figure 3) were both identified as glycosylated sinapic acids. Compound **9** presented three UV spectral bands at 251, 283, and 328 nm and had a parent mass of $m/z$ 517.1. In the $MS^2$ scan event, fragments of $m/z$ 385.1 [M − H − 132] corresponded to the loss of a pentoside; $m/z$ 205.3 [M − H − 132 − 162 − 18] corresponded to the loss of a pentoside, a hexoside, and water; and $m/z$ 223.3 [M − H − 132 − 162] corresponded to sinapic acid. A similar sinapic acid pentoside−hexoside compound was previously reported in both eucalyptus and jocote fruits.[22] Compound **10** at $m/z$ 385.1 similarly produced fragments of $m/z$ 223.0 [M − H − 162] and 205.3 [M − H − 180], and the compound was identified as a sinapic acid hexoside. The cinnamic acids in 'Keitt' mango pulp were all glycosylated species, inconsistent with previous studies for which only aglycones were reported using HPLC-PDA.[6,7,10,23]

**Flavonoids.** Flavonoids such as quercetin and kaempferol have been previously reported in mango peel, seed kernel, and leaves[3,23] but are not commonly found in mango pulp and were not identified in 'Keitt' mango pulp in this study. However, the flavonoids eriodictyol-*O*-dihexoside and eriodictyol-*O*-hexoside (compounds **15** and **16**) were found in trace amounts and tentatively identified on the basis of the observed parent masses at $m/z$ 611.4 and 449.3, respectively. Identification was based on fragmentation patterns similar to those reported in tomato juice.[24]

**Apocarotenoids.** Mango pulp is known to be a rich source of C40 carotenoids[25] that contribute to the color and physical attractiveness of the fruit. Through oxidative cleavage of carotenoids, apocarotenoids are produced, which are utilized by plants to form various volatile compounds and are a source of important plant hormones.[26] 'Keitt' mango pulp contained six identifiable water-soluble apocarotenoids and many more related compounds hypothesized to exist in the fruit that are not characterized herein. Compounds **7**, **11**, **14**, and **17** all shared similar UV spectral properties ($\lambda_{max}$ 265 nm) and similar MS fragmentation patterns indicating structural similarities. Compound **14** was identified as an abscisic acid (ABA) glycoside with $m/z$ 425.0 that ionized under MS/MS to give a fragment of $m/z$ 263.0. The fragment of $m/z$ 263.0 when further ionized produced a fragment of $m/z$ 219.2. This pattern was also observed in the ionization of compound **17**, ABA, with a $m/z$ at 263.2 and MS/MS fragment of $m/z$ 219.2 confirming the structure of compound **14**. ABA is a known phytohormone responsible in part for mango ripening along with ethylene,[27,28] but derivatives of ABA have not been reported in the phytochemical composition of mango pulp. Additionally, compounds **7** and **11** both produced pseudomolecular ions of $m/z$ 443.5, the former with fragments of $m/z$ 237.0 [M − H − 162 − 44], $m/z$ 219.1 [M − H − 162 − 44 − 18], and $m/z$ 425.3 [M − H − 18], and were tentatively identified as dihydrophaseic acid (DPA) glycosides.[29] DPA is a known

dx.doi.org/10.1021/jf5031554 | J. Agric. Food Chem. 2014, 62, 9515−9521

product of endogenous abscisic acid metabolism[30] and serves a role in the regulation of ABA.[31] Lastly, compounds **12** and **13** were characterized as isomers each with a molecular ion of $m/z$ 403.2 that was tentatively identified as $^{12}$C dicarboxylic acid derivatives. The fragments $m/z$ 241.0 [M − H − 162], $m/z$ 343.0 [M − H − 60], and $m/z$ 197.2 [M − H − 162 − 44] were identical to those reported for the compound (2*E*,4*E*)-8-hydroxy-2,7-dimethyl-2,4-decadiene-1,10-dioic acid 6-*O*-$\beta$-D glucopyranosyl ester previously identified in walnuts.[32] The presence of a $^{12}$C dicarboxylic acid derivative would be expected in plants known to synthesize oxygenated carotenoids and is derived from a similar biosynthetic pathway as ABA with violaxanthin serving as the precursor molecule.[33,34] Violaxanthin is the predominate carotenoid in ripe mango pulp with *all-trans*-violaxanthin alone compromising almost 50% of pulp carotenoids by weight in some varieties.[35]

**Gallotannins.** Tannins are historically difficult to resolve by reversed phase chromatography, and numerous reports have attempted to elucidate and quantify gallotannins with varied results due to the coelution of the polymers and extensive band broadening.[36,37] The concentration of gallotannins in mango pulp differs extensively among varieties, with concentrations in 'Keitt' reported to range from 500 to 1000 mg/kg.[6] In this study, gallotannins were present in 'Keitt' mango pulp in relatively low concentrations and were not found during routine quantification, likely due to interactions with native proteins during sample preparation and poor chromatographic resolution. However, more concentrated extracts revealed gallotannin polymers ranging from 4 to 12 galloyl groups as both single- and double-charged ions in the total ion current from 42 to 70 min.

**Commercial Cell Wall Active Enzymes.** The activity of commercial cell wall degrading enzymes Val, Cz, and Rap was investigated for their role in modifying the phenolic acid composition of 'Keitt' mango pulp, specifically, the potential for these enzymes to possess side activities such as $\beta$-glucosidase that could have a major impact on the resultant chemistry and potential bioactive properties of processed mango. The changes in concentration observed for GA, ester-linked MGG, ether-linked MGG, and HBG after 4 h of enzyme incubation at 50 °C are reported in Figure 4. Among the enzymes, a complete loss of the ether-linked MGG was observed after incubation with Rap and Val, suggesting a strong $\beta$-glucosidase side activity, and served as additional support for the type of glycosidic linkage present for compound **4**. The hydrolysis of ether-linked MGG could be a good predictor for the capacity of hydrolysis to occur in vivo by cytosolic $\beta$-glucosidases,[38] which would internally produce aglycones, which are known to be better absorbed in the small intestine compared to their glycosylated counterparts.[39,40]

Cz was shown to have significant ester glucosidase side activity with 66 and 75% losses of ester-linked MGG and HBG observed, respectively. This further confirmed the ester glycosidic linkage observed for compounds **1** and **5** because the use of Rap and Val caused no significant reduction in ester-linked MGG, signifying that the glucose moiety was not ether linked. The hydrolysis of both ester and ether MGG led to overall changes in the free GA concentration and increased GA from 10.36 to 11.71, 18.38, and 29.76 mg/L for Rap, Val, and Cz, respectively. The use of Cz significantly increased the amount of free GA compared to the control ($p < 0.001$) and created a processed pulp that was higher in GA than MGG. The in vitro hydrolysis of ester-linked MGG could be useful for aiding absorption of its aglycone GA if hydrolysis is limited in the small intestine.

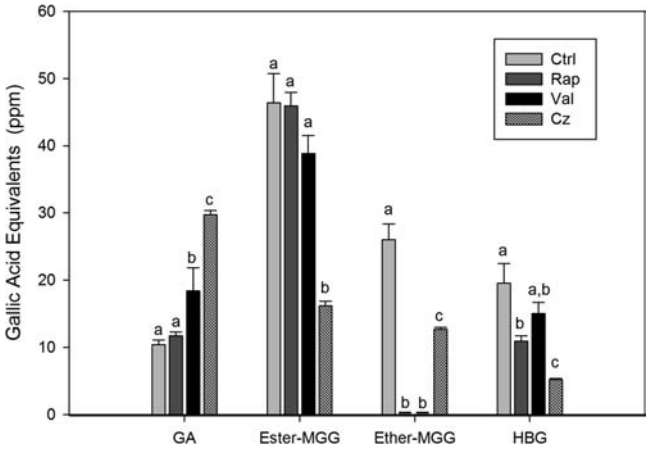

**Figure 4.** Quantity of free gallic acid (GA), ester-linked mono galloyl glucoside (Ester-MGG), ether-linked mono galloyl glucoside (Ether-MGG), and hydroxybenzoic acid glycoside (HBG) in mango pulp after enzymatic incubation of 0.05% Rapidase AR 2000 (Rap), Validase TRL (Val), and Crystalzyme 200XL (Cz) at 50 °C for 4 h. Different letters within groupings of the same compound are significantly different ($p < 0.05$).

Benefits of mango consumption have been attributed to its phytochemical composition, which largely includes polyphenols. The presence of glycosides on a polyphenol has been shown to affect in vivo stability and absorption. In general, deglycosylated polyphenols have higher absorption rates, but are more prone to degradation at physiological pH compared to their glycosylated counterparts.[41] Therefore, consumption of a fruit product that contains an altered phytochemical composition due to glycoside hydrolysis could potentially have different in vivo properties compared to an equivalent consumption of the whole fruit. Additional studies are needed before a conclusion can be reached regarding the in vivo differences of consuming a polyphenol glycoside or its respective aglycone. Therefore, phytochemical characterization both before and after any processes is crucial to understanding any potential health benefits due to the different mechanisms of absorption and metabolism with various phytochemical chemistries. This study found that the use of any of the tested enzyme preparations would significantly affect the phenolic acid composition of a 'Keitt' mango product compared to the unprocessed fruit and could potentially alter the bioactivity compared to that of the whole fruit.

For the first time, a detailed characterization and semi-quantification of phenolic acids and other minor phytochemicals was accomplished for 'Keitt' mango pulp, leading to the identification of five hydroxybenzoic acids, four cinnamic acids, two flavonoids, and six apocarotenoids in the pulp extract. The phenolic acid composition of the pulp was affected by the side activity of cell wall degrading enzymes. Addition of Cz reduced the amount of ester-linked MGG by 66%, indicating strong esterase side activity, and both Rap and Val showed $\beta$-glucosidase activity by the complete hydrolysis of ether-linked MGG. Phytochemical composition is critical in understanding the bioefficacy of any fruit or vegetable, and any changes are sure to affect the health-promoting properties.

**Table 1. Characteristics of Belgian Special Beer Samples**

| type | beer | alcohol (%) | original extract (g extract/100 g wort) | characteristics |
|---|---|---|---|---|
| blond | BL1 | 8.5 | 16.3 | Pilsen malt, unfiltered, bottle refermentation |
| | BL2 | 7.5 | 14.9 | Pilsen malt, organic beer (organic version of BL1), unfiltered, bottle refermentation |
| | BL3 | 6.3 | 14.4 | Pilsen malt,[a] POF(+) yeast, centrifuged, flash pasteurization |
| | BL4 | 7.5 | 16.8 | Pilsen malt,[a] POF(+) yeast, unfiltered, bottle refermentation, flash pasteurization |
| dry-hopped Trappist | TR1 | 6.2 | 13.3 | caramel malt,[a] POF(+) yeast, *Brettanomyces* for secondary fermentation and bottle refermentation, dry hopping, unfiltered |
| amber | AM1 | 12.0 | 20.8 | caramel malt, filtered |
| | AM2 | 4.5 | 10.93 | caramel malt,[a] POF(+) yeast, filtered |
| | AM3 | 5.4 | 12.77 | caramel malt, filtered |
| brown | BR1 | 8.0 | 19.8 | torrefied malt (7%),[a] POF(+) yeast, light filtration, bottle refermentation |
| | BR2 | 6.5 | 15.58 | torrefied malt,[a] POF(+) yeast |
| | BR3 | 5.2 | 12.71 | torrefied malt (12%), bottle refermentation |
| white Belgian | W1 | 4.9 | 11.8 | Pilsen malt and wheat, spices (orange peels, coriander),[a] POF(+) yeast, centrifuged |

[a]The POF(+) yeast descriptor is given only for yeasts that have been previously investigated in our laboratory for the PAD1 phenotype.[32]

**Malt Samples.** Five commercial barley malts (*Hordeum vulgare* L.) were provided by the Malterie du Château (Beloeil, Belgium): Pilsen malt (5 EBC), caramel malts (Cara 50 °EBC and coffee 500 °EBC; final kilning temperature = 125 and 180 °C, respectively), and torrefied malts (chocolate 900 °EBC and black 1500 °EBC; final roasting temperature = 225 °C).

**Chemicals.** Methanol (99.9%) and dichloromethane (99.9%, redistilled twice prior to use) were purchased from Romil (Prosan, Belgium). Ultrapure water (Milli-Q water purification system, Millipore, Bedford, MA, USA) was used. 2-Methoxy-4-vinylphenol (4-vinylguaiacol, 98%), dodecane (external standard for vanillin glucoside extraction, 99.9%), decane (external standard for phenol extraction, 99.9%), naphthol (internal standard for phenol extraction, 99.5%), guaiacol (98%), 4-methylguaiacol (97%), 4-ethylguaiacol (98%), 4-vinylphenol (solution 10% in propylene glycol), 4-ethylphenol (98%), 4-hydroxy-3-methoxy-$\alpha$-methylbenzyl alcohol (apocynol, 97%), diethyl ether (99,9%), octyl-$\beta$-D-glucopyranoside (internal standard for vanillin glucoside extraction, >98%), and $\beta$-glucosidase from almond were obtained from Sigma-Aldrich (Bornem, Belgium). *p*-Cresol (4-methylphenol, 99%) came from Acros Organics (Geel, Belgium). Vanillin (99%), sodium sulfate (99%), sodium chloride (99.5%), chloroform (99%), and potassium hydroxide (85%) were from Merck (Darmstadt, Germany). Hydrochloric acid (37%) was purchased from Fisher Scientific (Leicestershire, UK). Amberlite XAD-2 resin (Supelco, Bellefonte, PA, USA) (with a pore size of 9 nm and a specific area of 330 $m^2/g$) was sequentially washed with methanol and diethyl ether (each for 4 h) in a Soxhlet and stored in methanol at 4 °C.

**Wort Production.** Laboratory congress worts were produced in an LB 8 electronic normal-version mashing unit (Lochner, Germany) according to European Brewery Convention procedures (EBC Analytica 1998, method 4.5.1). Fifty grams of finely ground malt was added to 200 mL of water at 46 °C. The temperature was kept at 45 °C under constant stirring for 30 min. The caramel malts (Cara 50 and coffee 500) and torrefied malts (chocolate 900 and black 1500) were used with Pilsen malt at the ratio of 50:50 w/w (quantitations given for 100% specialty malt). The temperature was raised to 70 °C at 1 °C/min, then 100 mL of water was added, and the temperature was kept for 1 h at 70 °C with constant stirring before the mixture was cooled to room temperature and the weight to 450 g with water. After paper filtration (MN 614 × 32 cm diameter; Macherey-Nagel GmbH), the wort samples were stored at −32 °C until extraction.

**Samples Aging.** All beers were stored in a dark room at 20 °C before analysis.

**Phenol-Specific Liquid−Liquid Extraction Procedure.** All extractions were carried out in duplicate, according to a procedure derived from Callemien.[25] First, 50 mL of beer, 100 $\mu$L of IST (50 mg/L naphthol; 100 $\mu$g/L in beer), 1 mL of 37% hydrochloric acid, and 6.45 g of sodium chloride were mixed. After complete salt dissolution, 150 mL of chloroform/methanol (3:1, v/v) was added and the mixture stirred for 10 min at 1500 rpm. The lower organic phase was retained, whereas the aqueous phase was extracted a second time in the same manner. The collected 300 mL of organic phase was then shaken with 50 mL of 10% potassium hydroxide solution for 10 min at 1500 rpm. The upper aqueous phase (pH 13) was recovered and the lower organic phase extracted once again. The pH of the aqueous phase was then adjusted to pH 9.0 with hydrochloric acid and extracted twice with 25 mL of dichloromethane after stirring for 10 min at 1500 rpm. The combined organic phase was dried with anhydrous sodium sulfate, and 0.1 mL of EST (50 mg/L decane) was added to the extract before concentration to 0.5 mL in a Danish-Kuderna apparatus at 45 °C (total concentration factor = 100). The final extracts were stored at −81 °C and analyzed by GC-FID, GC-MS (Figure 1), and GC-O.

**Vanillin Glucoside Enzymatic Extraction Procedure.** First, 150 mL of BR1, 500 $\mu$L of IST (1 g/L octyl-glucopyranoside; 3.3 mg/L in beer), and 6 g of Amberlite XAD-2 resin thoroughly rinsed with Milli-Q water (approximately 400 mL) were poured into a 250 mL Schott flask. Samples were shaken in a dark room for 2 h and then poured into a glass column for separation. Aqueous eluate from the XAD-2 resin was drained, and 50 mL of water and 25 mL of diethyl ether were consecutively poured for washing. Glucosides were finally eluted with 25 mL of methanol. The extract was evaporated to dryness and resuspended in 25 mL of acetate buffer (pH 5). Enzymatically treated samples and controls were incubated at 35 °C for 2 h, with or without $\beta$-glucosidase (14 mg). Both were extracted three times with 15 mL of diethyl ether (10 min, 1000 rpm). The combined organic phase was dried with anhydrous sodium sulfate, and 0.5 mL of EST (20 mg/L dodecane) was added to the extract before concentration to 0.5 mL in a Danish-Kuderna apparatus at 39 °C. The final extracts were stored at −81 °C and semiquantitatively analyzed by GC-MS (just using the area ratio to the IST and the IST concentration; relative recovery factors and molar response coefficients fixed at 1).

**Gas Chromatography Hyphenated to Mass Spectrometry (GC-MS).** Electronic impact (EI) mass spectra were recorded at 70 eV on a ThermoFinnigan Trace MS mass spectrometer connected to a ThermoFinnigan Trace GC 2000 gas chromatograph equipped with a splitless injector (250 °C; opened 0.8 min after injection of 1 $\mu$L) and an apolar CP-Sil 5 CB MS capillary column (50 m × 0.32 mm i.d., 1.2

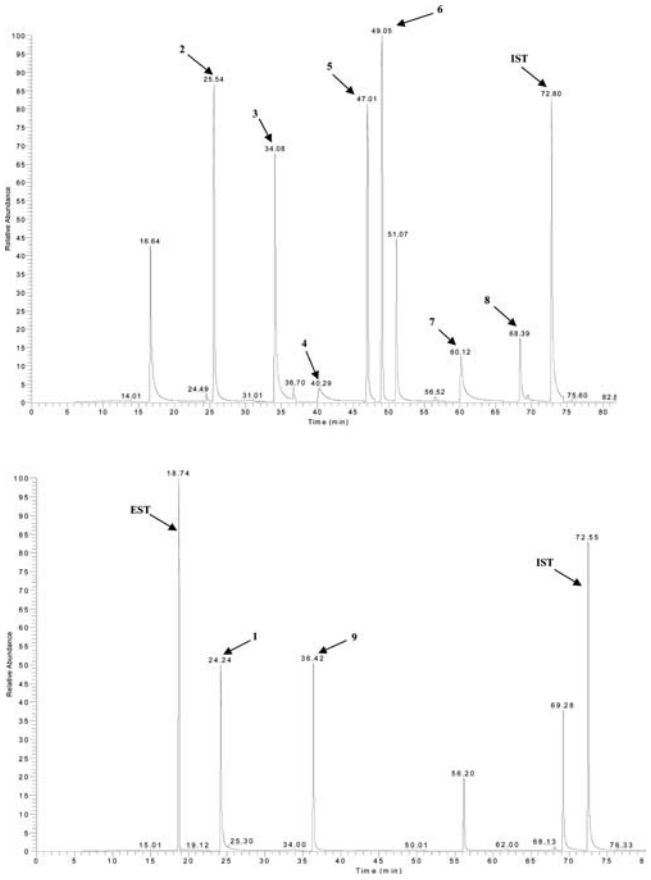

**Figure 1.** GC-MS-SIM chromatograms of our nine phenols spiked (20 mg/L) into a beer extract.

$\mu$m film thickness). The carrier gas was helium, and the pressure was set at 100 kPa. The oven temperature was raised from 36 to 85 °C at 20 °C/min, then to 145 °C at 1 °C/min, and finally to 250 °C at 3 °C/min. For all compounds, the single ion monitoring (SIM) mode was applied (selected $m/z$ given in Table 2). As depicted in Figure 1, two separate SIM programs were used to analyze our nine phenols. Xcalibur software was used for spectral recording throughout the chromatographic separation. The mass spectra obtained were compared to those of commercial standards and to the NIST library.[26] Quantification of phenols was done by standard addition to beer or to wort.

**Gas Chromatography−Olfactometry (GC-O).** Beer extracts (1 $\mu$L) were analyzed on a Chrompack CP9001 gas chromatograph equipped with a splitless injector maintained at 250 °C and opened 0.5 min postinjection. The carrier gas was nitrogen at a flow rate of 1 mL/min. Compounds were analyzed with a wall-coated open tubular (WCOT) apolar CP-Sil 5 CB capillary column (50 m × 0.32 mm i.d., 1.2 $\mu$m film thickness). The oven temperature was programmed to rise from 36 to 85 °C at 20 °C/min, then to 145 °C at 1 °C/min, and finally to 250 °C at 3 °C/min. This temperature was maintained for 30 min. To assess the olfactory potential of the extract, the column was connected to a GC-O port (Chrompack) maintained at 250 °C. The effluent was diluted with a large volume of air (20 mL/min) prehumidified with an aqueous copper(II) sulfate solution. The extracts of three beers (BL1, TR1, and BR1) were analyzed by aroma extract dilution analysis (AEDA)[27] to estimate the relative impact of each odorant. According to the AEDA method, the extracts were diluted stepwise with dichloromethane (1 + 2 by volume). The flavor dilution (FD) factor is defined as the highest dilution at which the compound can still be detected (FD = $3^n$, where $n$ + 1 is the number of dilutions applied to the extract until there was no detection by GC-O).

**Statistical Analyses.** Analyses were carried out in duplicate, and Student−Newman−Keuls tests were performed with SAS software version 9.2 (SAS Institute, Inc., Cary, NC, USA) to compare the means. Values sharing no common letter are significantly different ($p$ < 0.05).

**Table 2. Phenolic Concentrations ($\mu$g/L) in Fresh Belgian Special Beers Determined by GC-MS[a]**

| N° | RI CP-Sil5 | Substance | Structure | Odor (GCO) | Threshold in beer (µg/l) | Selected $m/z$ | BL1 | BL2 | BL3 | BL4 | TR1 | AM1 | AM2 | AM3 | BR1 | BR2 | BR3 | W1 |

## RESULTS AND DISCUSSION

**Volatile Phenols in Fresh Belgian Special Beers.** Specific phenolic extraction enabled us to quantify eight volatile phenols (**1**−**8**) in fresh beers (Table 2). Identification was confirmed by mass spectrometry (coincidence of the main $m/z$ values with those of commercial references and entries in the NIST library), capillary column (CP-Sil 5 CB MS) retention indices, and odors. All of the phenols were perceived at the sniffing port in the three beers investigated by AEDA, with descriptors such as burned, dentist, roasted, coffee, clove, vanilla, and smoked. Analytical results revealed different phenolic profiles according to the style of beer.

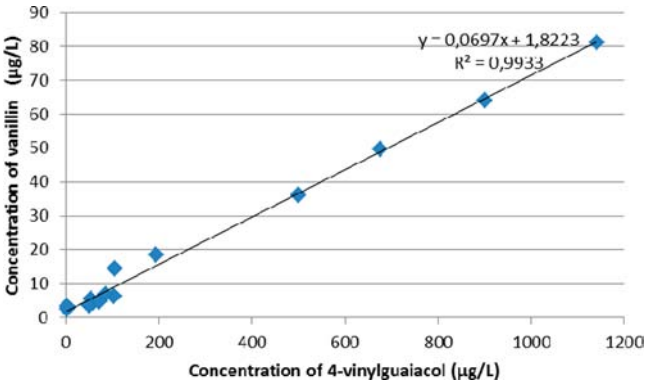

**Figure 2.** Correlation between the 4-vinylguaiacol and vanillin concentrations ($\mu$g/L) in fresh beers.

*4-Vinylphenol, 4-Vinylguaiacol, Vanillin, and Apocynol.* As shown in Table 2, the level of 4-vinylguaiacol and its analogues was not linked to the style of beer but rather to the yeast strain used (POF+ phenotype confirmed in Table 1 when data available). For instance, the blond BL1 and its organic version, BL2 (fermented with the same yeast), as well as W1 (a traditional Belgian white beer) proved to contain large amounts of all ferulic and coumaric acid-derived phenols. Up to 504.8 $\mu$g/L 4-vinylphenol, 1724.6 $\mu$g/L 4-vinylguaiacol, and 113.8 $\mu$g/L vanillin were evidenced, to be compared with the odor thresholds determined as 170, 125, and 50 $\mu$g/L, respectively. Among the amber beers investigated, AM2 reached 330.9 $\mu$g/L 4-vinylphenol, 375.8 $\mu$g/L 4-vinylguaiacol, and 27.4 $\mu$g/L vanillin, whereas AM3 gave rise to very low levels (8.2, 18.7, and 2.3 $\mu$g/L, respectively). One brown beer (BR2) was also characterized by high concentrations of 4-vinylphenol and 4-vinylguaiacol (570.3 and 700.6 $\mu$g/L, respectively). A nice correlation was observed between the 4-vinylguaiacol and vanillin concentrations in the different beers, suggesting that vanillin could arise through 4-vinylguaiacol oxidation (Figure 2). Apocynol, which results from the addition of a water molecule on 4-vinylguaiacol, was detected only as traces in all

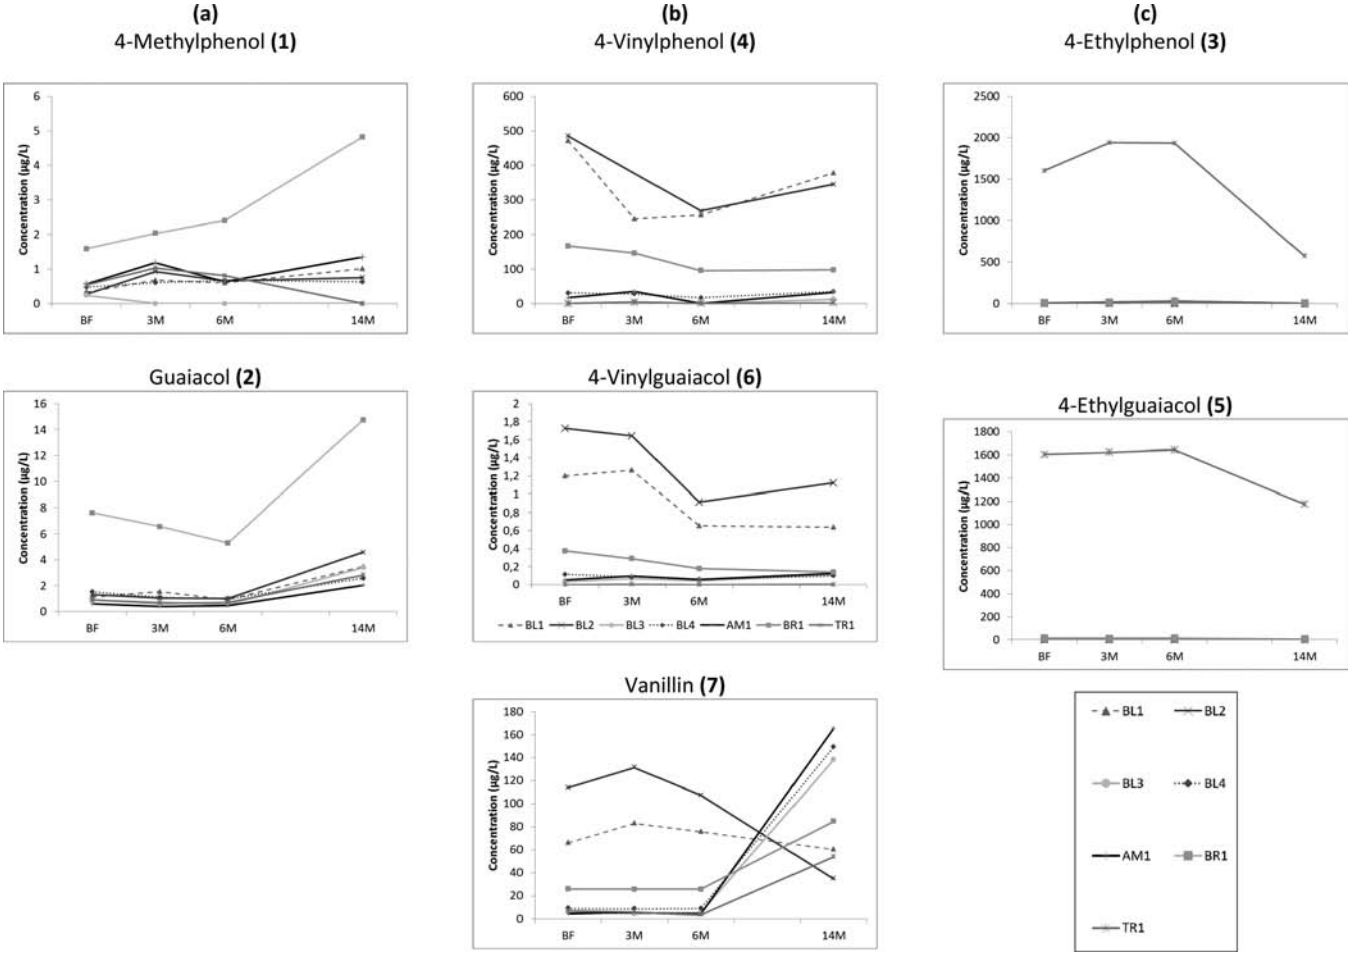

**Figure 3.** Fate of (a) 4-methylphenol and guaiacol, (b) 4-vinylphenol, 4-vinylguaiacol, and vanillin, and (c) 4-ethylphenol and 4-ethylguaiacol ($\mu$g/L) during beer aging.

beers. 4-Vinylguaiacol and vanillin were detected at the highest concentrations in BL2, for which organic malts were used. Very recently, Melotte et al.[28] found organic malts to contain higher amounts of ferulic acid (not true for cinnamic acid and its decarboxylated analogue, vinylphenol).

*4-Ethylphenol and 4-Ethylguaiacol.* Only TR1 showed high levels of 4-ethylphenol (1601 $\mu$g/L) and 4-ethylguaiacol (1603 $\mu$g/L) (Table 2). After hydroxycinnamic acid decarboxylation to vinylphenols (use of POF(+) yeasts for primary fermentation), the vinylphenol reductase activity of *Brettanomyces* yeasts (added only for secondary fermentation and bottle refermentation) allowed biotransformation of 4-vinylguaiacol and 4-vinylphenol. The residual 4-vinylguaiacol concentration was 0.5 $\mu$g/L in TR-1 and above 18 in all 11 other beers. The key role of *Brettanomyces* for reducing 4-vinylguaiacol into 4-vinylphenol was recently confirmed by Collin et al.,[29] who found only traces of 4-ethylguaiacol in TR1 before secondary fermentation ($\leq$2 $\mu$g/L). It steadily increases, in the presence of *Brettanomyces*, during the second part of maturation and through bottle refermentation, according to the pitching rate.

*Guaiacol and 4-Methylphenol.* The brown beers BR1, BR2, and BR3 contained the highest amounts of guaiacol (3.5−9.7 versus 0.4−0.9 $\mu$g/L in amber beers) and 4-methylphenol (1.1−3.8 versus 0.2−0.6 $\mu$g/L). Chocolate malts were used for all three of these beers, characterized by typical roasted and chocolate odors.[30,31]

**Volatile Phenols in Aged Belgian Special Beers.** The fate of phenols was monitored in seven beers for 14 months.

Guaiacol, described above as particularly relevant in fresh brown special beers made with chocolate malts, showed a significant concentration rise in all beers after 6 months (reaching 14 $\mu$g/L in BR1 after 14 months, Figure 3a). To a lesser extent, this was also the case of 4-methylphenol, which reached 4.9 $\mu$g/L in brown beer BR1 after 14 months. With their respective individual odor thresholds of 70 and 20 $\mu$g/L, guaiacol and 4-methylphenol could affect the organoleptic properties of aged dark beers. Acid hydrolysis of glycosides is suspected to gradually release these two compounds.

In contrast, 4-vinylphenol and 4-vinylguaiacol proved to be degraded over the first 6 months of storage (Figure 3b), particularly in BL1 and BL2. Oxidation of the double bond to

dx.doi.org/10.1021/jf5015654 | J. Agric. Food Chem. 2014, 62, 9522−9528

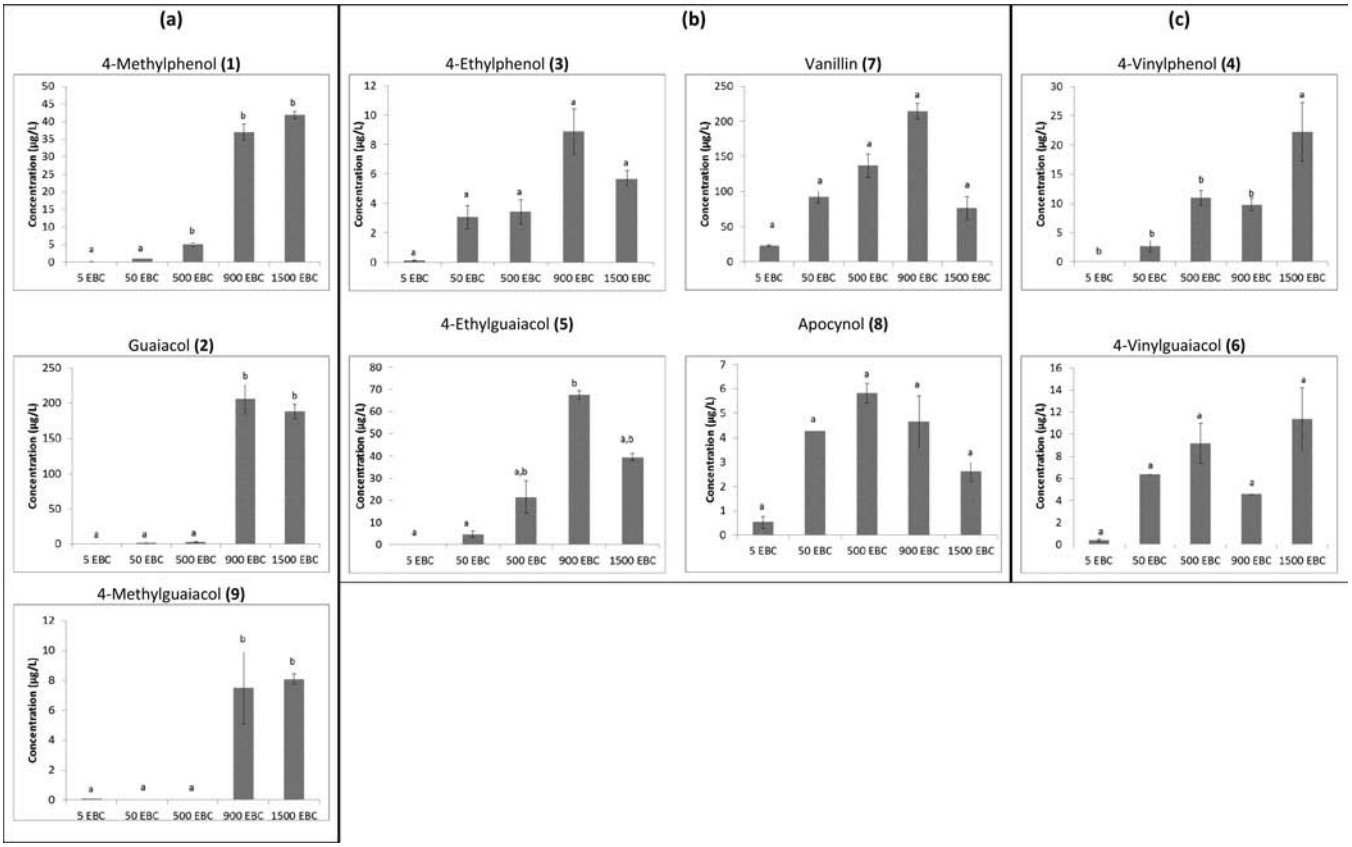

**Figure 5.** Concentrations ($\mu$g/L) of (a) 4-methylphenol, guaiacol, and 4-methylguaiacol; (b) 4-ethylphenol, 4-ethylguaiacol, vanillin, and apocynol; and (c) 4-vinylphenol and 4-vinylguaiacol in EBC laboratory worts, according to the color. Values sharing no common letter are significantly different ($p < 0.05$).

aldehyde might partly explain this evolution, as suggested in five beers by the strong increase in vanillin concentration between 6 and 14 months (Figure 3b). Yet vanillin degradation was observed in sample BL2, characterized by higher levels of both 4-vinylguaiacol and vanillin before aging. Hence, hydrolysis of glycosides most probably also partly contributes to the strong increase in vanillin concentration in BL3, BL4, AM1, BR1, and TR1 (up to 180 $\mu$g/L). From a sensory standpoint, these five beers reached the vanillin threshold value only after aging, whereas in BL2 the level of this active constituent of fresh beer fell below its threshold value during storage. BL1 was the only sample in which aldehyde oxidation was nearly balanced by 4-vinylguaiacol oxidation and/or glycoside hydrolysis.

To roughly assess if malt or hop vanillin glucosides could survive through the brewing process to be further hydrolyzed in beer (lower pH than wort), an enzymatic assay was applied on a fresh beer (BR1). As depicted in Figure 4, a $\beta$-glucosidase treatment applied on the XAD-2 glucoside extract did release 0.2 mg/L IST equivalent of vanillin. Complementary analyses will be needed to correlate the accurate concentrations of vanillin glucoside in each beer to the amount of free vanillin released through aging. The assay could be also optimized to quantify traces of other suspected glucosides (e.g., guaiacol and 4-methylphenol).

The hydrogenated derivatives 4-ethylphenol and 4-ethylguaiacol found in TR1 were also degraded between 6 and 14 months of aging (Figure 3c). Due to the presence of *Brettanomyces* yeasts in this Trappist bottled beer, 4-ethylphenol was, however, still synthesized during the first 3 months of storage (vinylphenol bioreduction).

**Volatile Phenols in EBC Laboratory Worts Produced with Five Different Malts.** The origin of guaiacol and 4-methylphenol in dark beers was investigated by analyzing worts produced with five differently colored malts (color ranging from 5 to 1500 °EBC; laboratory worts brewed with 50% special malts; values given for 100%). As depicted in Figure 5a, our results confirmed that high levels of 4-methylphenol (37−42 $\mu$g/L) and guaiacol (188−205 $\mu$g/L) are specific to the use of torrefied malts ($\leq$5 $\mu$g/L 4-methylphenol and $\leq$3 $\mu$g/L guaiacol for all other worts). The high temperatures applied during roasting (>250 °C) most probably allow thermal degradation of either free hydroxycinnamic acids or lignins. Also to be mentioned is the presence of 7−8 $\mu$g/L 4-methylguaiacol in both worts made with roasted malts only. Taking into account that <10% of torrefied malts are usually used by brewers for special beers, the concentration of this compound was logically too low to be detected in the above-described commercial beers (compound **9** in Table 2). The other phenols are not necessarily found in higher amounts in congress worts made with torrefied malts. Figure 5b shows a similar pattern for four phenols (4-ethylphenol, 4-ethylguaiacol, vanillin, and apocynol): a very low level in pale malt, a maximum concentration in malts of intermediate color, and again a lower level in 1500 °EBC malt. In the case of 4-vinylguaiacol, caramel and torrefied malts can bring similar concentrations (e.g., 500 and 900 °EBC in Figure 5c). For 4-vinylphenol, only the black malt shows a significantly higher concentration.

In conclusion, because guaiacol and 4-methylphenol were always found under 3 $\mu$g/L in EBC laboratory worts made with

dx.doi.org/10.1021/jf5015654 | J. Agric. Food Chem. 2014, 62, 9522−9528

caramel malt or pale malts, we suggest that these compounds, especially guaiacol, might be used as markers of torrefied malts.

enzymes extracted from apple are suspected to have activity in reducing higher alcohols of alcoholic drinks in acid condition. In this study, we prepared crude enzymes from five different apple varieties and optimized the conditions of Fuji sodium alginate-immobilized enzyme powder (SA-IEP), then applied this new product to treat three Chinese liquors in which ethanol content was from 45 to 56% (v/v). The results are hoped to demonstrate an enzymatic method to reduce higher alcohols in high ethanol content liquors.

## MATERIALS AND METHODS

**Apples and Chemicals.** Fresh apple fruits of five different cultivars (*Malus domestica* Borkh. cv. Fuji, Gala, Golden Delicious, Red Star, and Jonagold) were bought from the local market of Yangling city, Shaanxi province, China. Three liquors with different ethanol contents (45% Xifeng, 50% Taibai, and 56% Erguotou) were bought from the local supermarket and used to test the effect of apple enzymes on reducing higher alcohols in these products.

Acetone, 50% glutaraldehyde, citric acid, sodium citrate, and anhydrous calcium chloride were purchased from Bodi Chemical Ltd. (Tianjin, China). Ammonium sulfate was bought from Zonghengxing Industrial and Trading Co., Ltd., Chemical Reagent Branch (Tianjin, China). MD25 dialysis tubing was purchased from Sigma (St. Louis, MO, USA). Chitosan was obtained from Wolsen Biotechnology Co., Ltd. (Xi'an, China). Sodium alginate of food grade was obtained from Ming Yue Seaweed Group Co., Ltd. (Qingdao, China). All of these chemicals were of analytical grade.

**Preparation of Crude Enzymes.** Crude enzymes were prepared using a previously developed method described by Zhu et al.[27] In brief, apple peels (about 4 mm thick) were prepared as dry, fluffy, and white powders containing crude enzymes after removal of pigments and other ester-soluble impurities with cold acetone (−30 °C). A sample of 1 g of the prepared crude enzyme powder was extracted into 25 mL of citrate buffer (0.1 mol/L, pH 4.0) after extraction for 30 min at 4 °C with continuously gentle agitation. The liquid phase containing crude enzymes was obtained after a centrifugation at 4000 rpm and 4 °C for 30 min in an ALC PK121R refrigerated benchtop centrifuge (ALC International S.r.l., Cologno Honzese, Italy). The obtained supernatant was used as crude enzyme solution. Protein content in the prepared enzyme powder (EP) and enzyme solution (ES) was estimated using the method developed by Bradford.[28]

**Preparation of Immobilized Enzymes.** The prepared EP and ES were immobilized using the methods reported by Yen and Wang.[29,30] In brief, sodium alginate solution was prepared by dissolving 0.4 g of sodium alginate in 10 mL of distilled water, and then 0.125 g of EP or 2.5 mL of ES was added, in which protein contents were equal. After thorough mixing, the mixture was dropped into 10 mL of 20 g/kg $CaCl_2$ solution at a speed of 20 drops per minute using an injector to form beads containing enzymes. The enzyme beads were kept at 4 °C for 2 h to enhance the mechanical stability and then washed three times with distilled water, 20 mL per time. The obtained immobilized EP and ES were designated SA-IEP and SA-IES, respectively.

Chitosan was also used to prepare immobilized enzymes according to the method described by Jin et al.[31] Briefly, 0.565 g of chitosan polymer was dissolved in 3.75 mL of a 500 mL/L glutaraldehyde solution and then kept statically for 3 h to activate chitosan. After that, the treated chitosan powder was collected and thoroughly rinsed with sterilized water 10 times to remove the surplus glutaraldehyde and then mixed with 2.5 mL of ES for 1 h to get immobilized enzymes. The obtained powder was chitosan-immobilized enzyme solution and designated CTS-IES in the following text.

For the treatments as control, EP and SA-IEP were replaced with equivalent inactive EP and SA-immobilized inactive EP, respectively. ES, SA-IES, and CTS-IES were replaced with equivalent citrate buffer (0.1 mol/L, pH 4.0), SA, and chitosan-immobilized citrate buffer (0.1 mol/L, pH 4.0), respectively. Inactive EP was obtained by heating EP in boiling water for 1 h.

**Effect of Enzymes on Higher Alcohol Content in Taibai Liquor.** All prepared enzymes were preheated at 37 °C for 30 min. For all enzymes prepared from the five different apple varieties, samples of 0.125 g of EP, 2.5 mL of ES, SA-IEP prepared from 0.125 g of EP, SA-IES prepared from 2.5 mL of ES and, CTS-IES prepared from 2.5 mL of ES were added into 20 mL of Taibai liquor (50% ethanol by volume). The treatment was carried out at 37 °C for 1 h according to the method reported by Zhu et al.[32] The corresponding inactive enzyme preparations were used at the same time as control. All treatments were carried out in triplicate.

**Optimization of the Conditions for Preparing Immobilized Fuji Enzyme Powder Using SA.** The single-factor design was used to investigate the influence of enzyme dosage, sodium alginate concentration, calcium chloride concentration, and immobilizing time on higher alcohol degradation.

In enzyme dosage effect tests, 10 mL of a 40 g/L sodium alginate solution was mixed with Fuji EP at different dosages of 0.1, 0.3, 0.5, and 0.8 g, dropped into 10 mL of a 20 g/L $CaCl_2$ solution, and kept at 4 °C for 2 h to get the immobilized enzymes.

In sodium alginate concentration effect tests, sodium alginate solutions with different concentrations (25, 30, 35, 40, and 45 g/L) were separately mixed with 0.3 g of Fuji EP, dropped into 10 mL of a 20 g/L $CaCl_2$ solution, and kept at 4 °C for 2 h to get the immobilized enzymes.

In $CaCl_2$ solution concentration effect tests, 40 g/L sodium alginate solution was mixed with 0.3 g of Fuji EP and then dropped into 10 mL of a $CaCl_2$ solution with different concentrations (15, 20, 25, 30, and 35 g/L) and kept at 4 °C for 2 h to get the immobilized enzymes.

In immobilizing time effect tests, 40 g/L sodium alginate solution was mixed with 0.3 g of Fuji enzyme powder, dropped into 10 mL of a 20 g/L $CaCl_2$ solution, and then kept 4 °C for different times (1.25, 2, 2.75, 3.5, and 4.25 h) to get immobilized enzymes.

All of the obtained SA-IEPs were used to treat Taibai liquor (50% ethanol by volume) as described above, and their activities in degrading higher alcohols were measured using gas chromatography (GC) analysis.

Response surface methodology was also used to test the comprehensive effect of different factors on the higher alcohol degradation by SA-IEP, and Box−Behnken central composite design was used to design the experiments. Enzyme dosage, sodium alginate concentration, and $CaCl_2$ concentration were selected as independent variables, and their levels and codes are listed in Table 1. Immobilized time (2 h) and temperature (4 °C) were set as the fixed conditions. Design expert 8.0.5 software (Stat-Ease, Inc., Minneapolis, MN, USA) was used to perform the experimental design and data analysis.

**Table 1. Factors and Their Levels of the Parameters Used in Box−Behnken Design**

| | factors | | |
|---|---|---|---|
| level | sodium alginate A (g/L) | calcium chloride B (g/L) | enzyme powder C (g) |
| −1 | 35 | 15 | 0.2 |
| 0 | 40 | 20 | 0.3 |
| 1 | 45 | 25 | 0.4 |

**Effect of the Optimized SA-IEP Made from Fuji on Higher Alcohols of Different Liquors.** Xifeng (45% ethanol v/v), Taibai (50% ethanol v/v), and Erguotou (56% ethanol v/v) were used here. To evaluate the effect of the optimized SA-IEP made from Fuji on liquor flavor, 20 mL of all liquors was sampled after treatment with SA-IEP for 1 h and gas chromatography−mass spectrometry analysis (GC-MS). The liquors without any treatment were used as control. All treatments were carried out in triplicate.

**Activity of the Optimized SA-IEP Made from Fuji in Continuous Treatments.** The optimized SA-IEP was continuously used to treat Taibai liquor (containing 50% ethanol) eight times, 20 mL per time. For each time, the treatment was carried out at 37 °C for 1 h using preheated SA-IEP containing 0.3 g of enzyme powder. After each treatment, SA-IEP was collected by filtration, and 20 mL of new liquor was added again. This operation was repeated until a total of

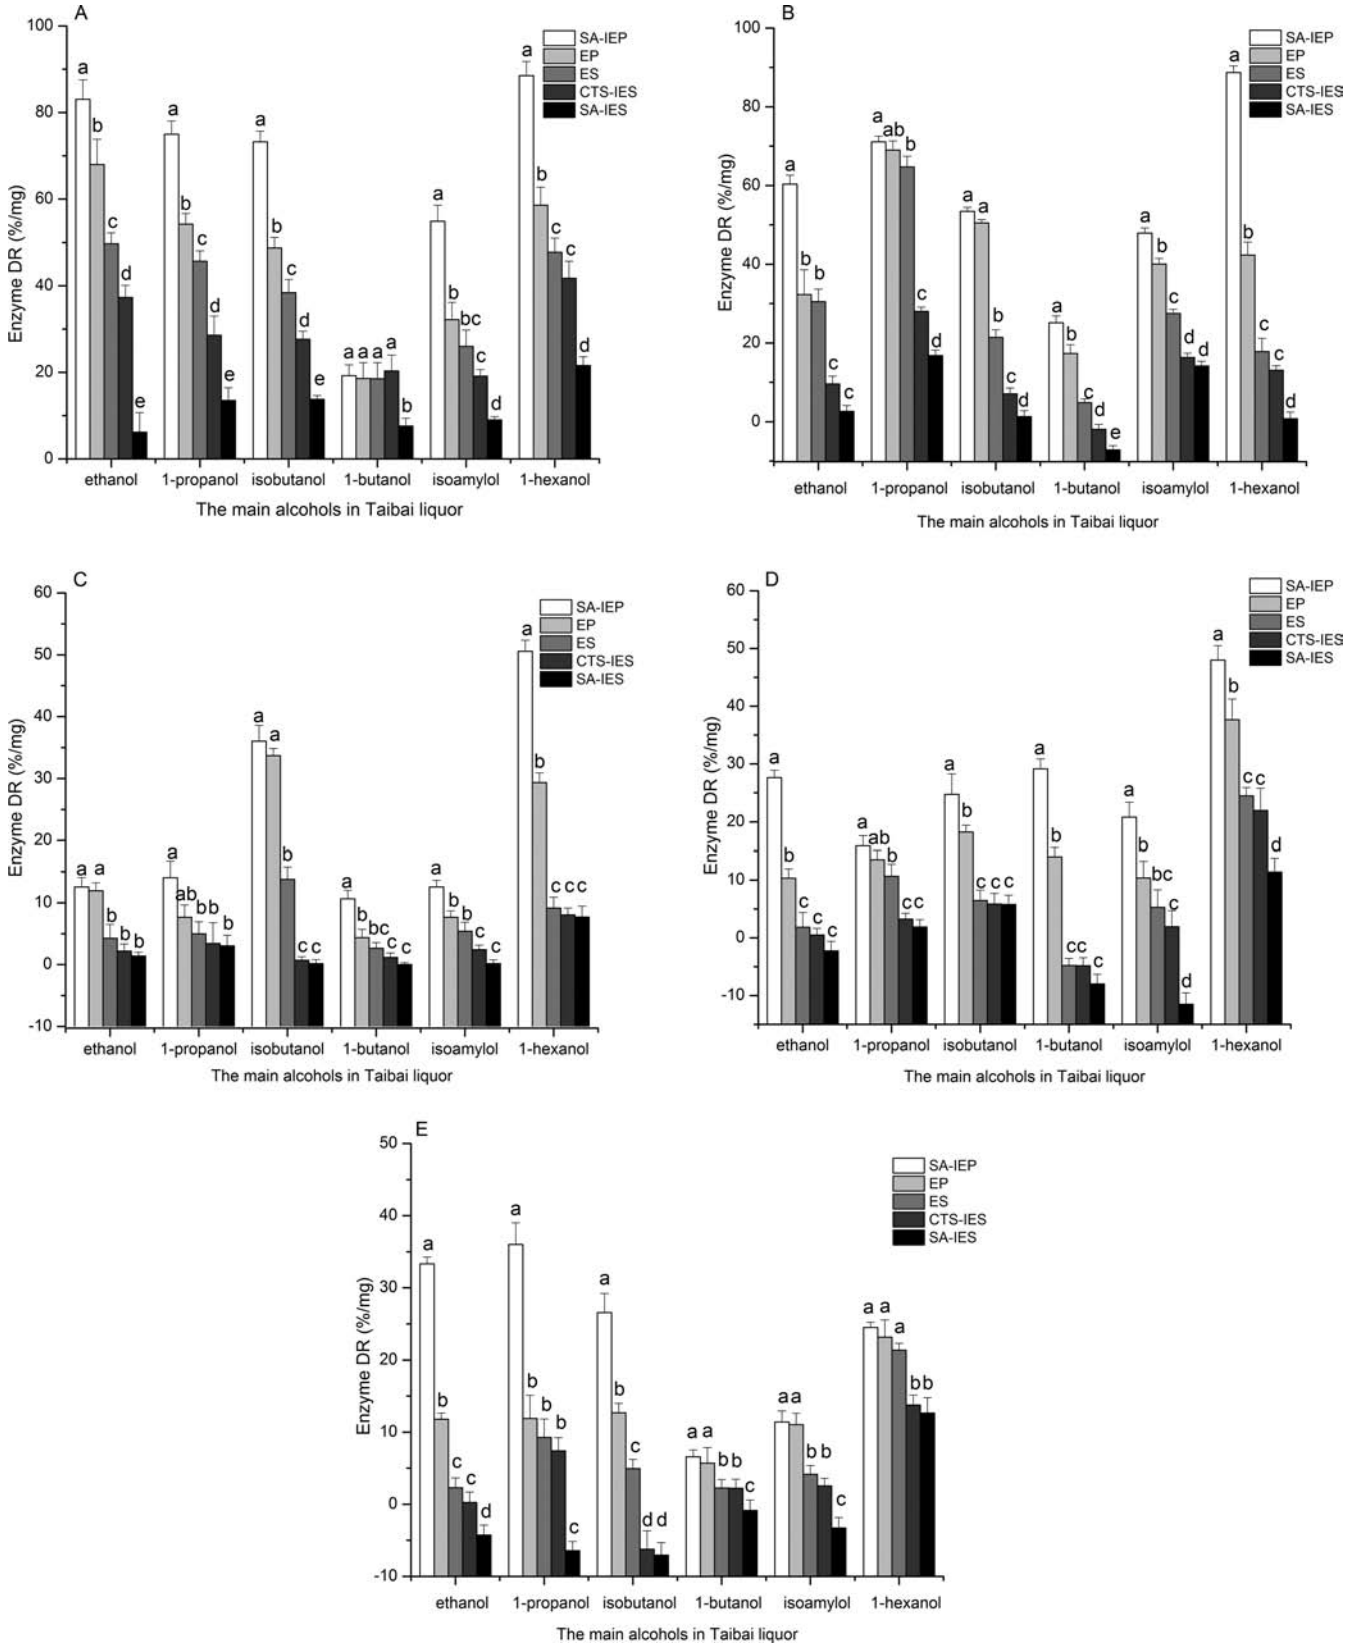

**Figure 1.** Degradation rates of different alcohols in Taibai liquor (50% ethanol v/v) using crude enzyme preparations made from Fuji (A), Golden Delicious (B), Jonagold (C), Red Star (D), and Gala (E). SA-IEP, sodium alginate-immobilized enzyme powder; SA-IES, sodium alginate-immobilized enzyme solution; CTS-IES, chitosan-immobilized enzyme solution; EP, enzyme powder; ES, enzyme solution. The bars show standard deviation of triplicate. Different letters in the same group indicate significant difference at the $P < 0.05$ level, according to ANOVA and Tukey's difference test.

dx.doi.org/10.1021/jf5018862 | J. Agric. Food Chem. 2014, 62, 9529−9538

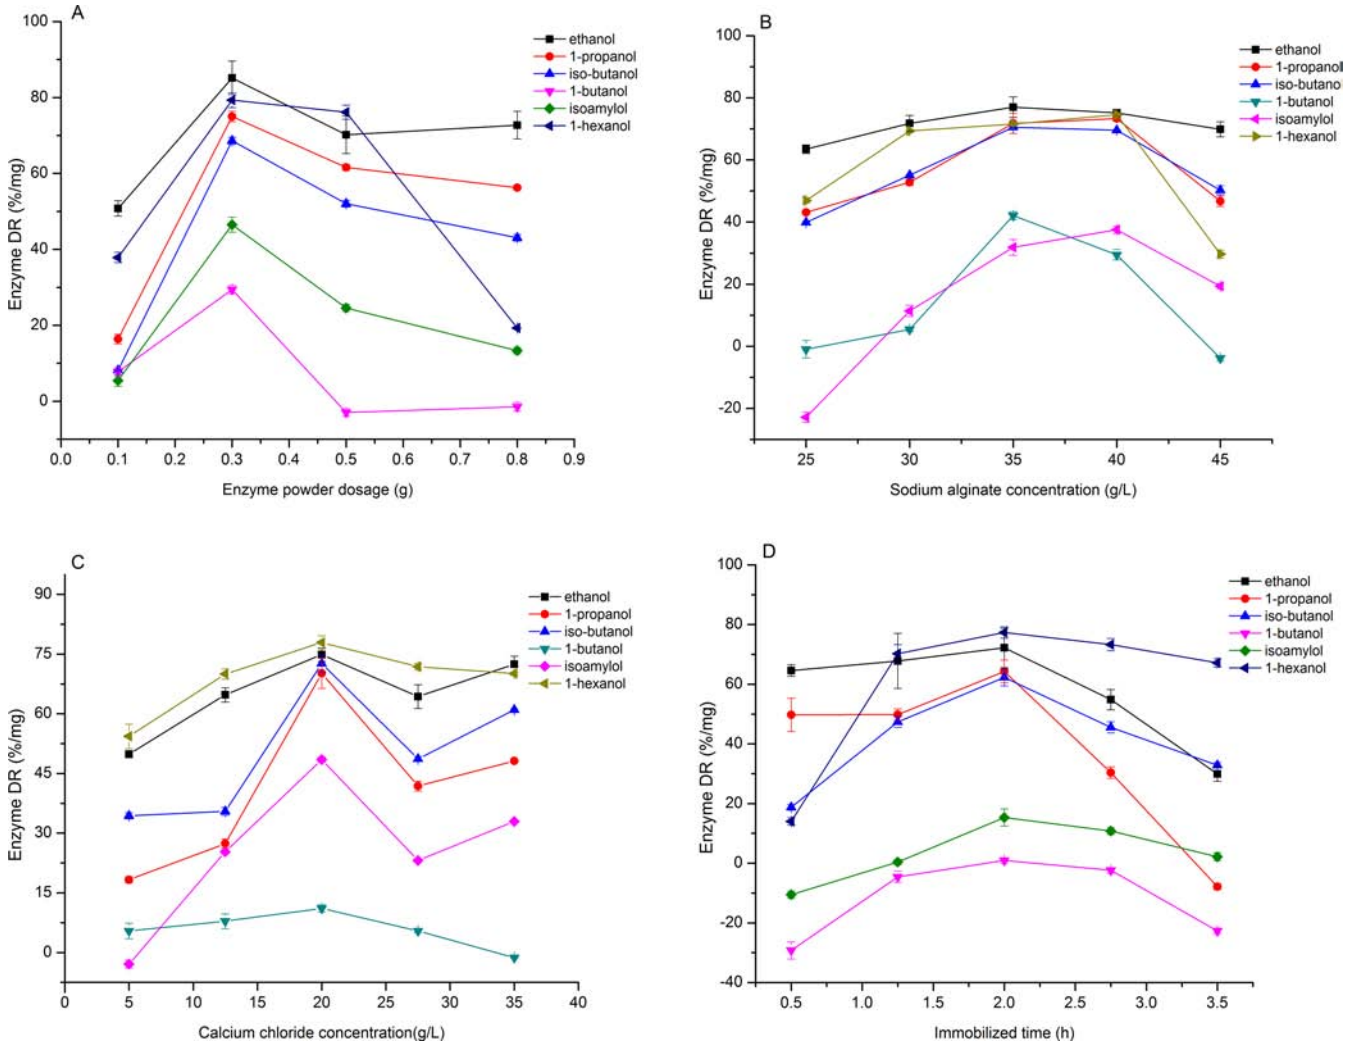

**Figure 2.** Degradation rates of different alcohols in Taibai liquor (50% ethanol v/v) using Fuji SA-IEP prepared under different levels of enzyme powder (A), sodium alginate concentration (B), calcium chloride concentration (C), and immobilization time (D). Bars show standard deviation of triplicate.

160 mL of liquor was treated. Measurement of the residue higher alcohols in the liquor was carried out by GC after each treatment.

**Measurement of Higher Alcohol Degradation Rate.** After each treatment, 3 mL of treated liquor was injected into an 8 mL GC vial together with 60 $\mu$L of internal standard (5% 4-methyl-2-pentanol/acetone g/v) and sealed immediately for measurement. The measurement was carried out in a gas chromatograph (GC-17A/FID, Shimadzu, Japan) combined with a SupelcoWax 10 capillary column (30 m × 0.32 mm i.d. × 0.25 $\mu$m film thickness; Bellefonte, PA, USA). Nitrogen was used as carrier gas with a linear flow rate of 30 mL/min. The column temperature was programmed as follows: 55 °C for 3 min, increasing to 200 °C at a rate of 5 °C/min, held at 200 °C for 3 min. Before determination, all samples were kept at 60 °C for 30 min in a water bath and subsequently injected to the GC system at a sample volume of 300 $\mu$L.

Volatile profiles of the liquors with and without treatment of Fuji SA-IEP were also tested using headspace solid phase microextraction coupled to gas chromatography spectrometry (HS-SPME-GC-MS) in a gas chromatograph−mass spectrometer equipped with a capillary column DB-WAX (3 m × 0.25 mm i.d. × 0.25 $\mu$m film thickness; Agilent, USA). Before measurement, the samples were kept at 60 °C for 30 min to release the volatiles from the liquid phase to the headspace. In measurements, 8 mL of the liquor sample was mixed together with 2.5 g of NaCl and 40 $\mu$L of an 8.00 mg/L 2-octanol solution (used as internal standard) and then was put into a 20 mL SPME vial. The SPME procedure and chromatographic conditions were the same as those detailed by Rodríguez Bencomo et al.[33] The flow rate of carrier gas (He) was 1 mL/min. The oven temperature program was set from 40 °C (2.5 min) to 200 °C (5 min) at an increasing rate of 5 °C/min. Data acquisition was made in different segments with electronic impact mode. The transfer line was kept at 230 °C and fed into an electron ionization (EI) source with an emission current of 100 $\mu$A. The masses in the range of $m/z$ 34−350 were tested. The volatile compounds were identified by comparing their mass spectra and retention indices with standards and from NIST 2002.

Measurement of 3 mL of untreated liquors was also carried out as control. Each assay was performed in duplicate.

The enzyme degradation rate (DR) of each higher alcohol by per milligram of crude enzyme was calculated according to eqs 1, 2, and 3:

$$\text{DR of treated sample (\%)} = \left(1 - \frac{T_1 \times S_0}{T_0 \times S_1}\right) \times 100 \quad (1)$$

$$\text{DR of control (\%)} = \left(1 - \frac{C_1 \times S_0}{C_0 \times S_1}\right) \times 100 \quad (2)$$

[a]Fifteen runs were carried out, including 12 factorial experiments and 3 central experiments to estimate error.

$$\text{enzyme DR (\%/mg)} = \text{DR of treated sample} - \text{DR of control} = \left(\frac{C_1 \times S_0}{C_0 \times S_1} - \frac{T_1 \times S_0}{T_0 \times S_1}\right) \times 100/M \quad (3)$$

$M$ is the protein concentration of the used enzyme, $S_1$ is the relative area of alcohol in the original liquor, $S_0$ is the relative area of internal standard in the original liquor, $T_1$ is the relative area of alcohol in the treated liquor, $T_0$ is the relative area of internal standard in the treated liquor, $C_1$ is the relative area of alcohol in the control, and $C_0$ is the relative area of internal standard in the control.

**Statistical Analysis.** The statistical analyses were performed using the Statistic Package for Social Sciences (SPSS version 13.0, IBM, Armonk, NY, USA) for Windows and Design expert 8.0.5 software (Stat-Ease, Inc., Minneapolis, MN, USA).

## RESULTS

**Degradation of Higher Alcohols by the Enzymes Prepared from Different Apple Varieties.** Figure 1 shows enzyme preparations made from five apple varieties had degrading activity toward ethanol and the tested higher alcohols, such as 1-propanol, isobutanol, 1-butanol, isoamylol, and 1-hexanol, in Taibai liquor (containing 50% ethanol). However, the degradation rate (DR) of the tested alcohols varied greatly depending on the apple varieties used, alcohols tested, and enzyme preparations. Generally, DR of SA-IEP was the highest for all apple varieties and all tested alcohols, followed by EP, ES, CTS-IES, and SA-IES in decreasing order at different degrees of significance. This demonstrated that enzyme powder was more efficient than enzyme solution in degrading alcohols, indicating that enzymes prepared in solid phase had higher activity than those in liquid phase in liquors. High DR of EP and immobilized EP might also be due to the absorption effect of solid materials in the enzyme preparations. In most cases, CTS-IES and SA-IES resulted in lower DR values than ES, manifesting the operation of immobilization lowered the enzyme activities, which is more serious when SA was used.

Figure 1A shows SA-IEP prepared from Fuji had DR values >80% for ethanol and 1-hexanol, >70% for 1-propanol and isobutanol, around 52% for isoamylol, and only 20% for 1-butanol, indicating high efficiency of Fuji SA-IEP in degrading most alcohols. SA-IEP prepared from Golden Delicious had DR values >80% for 1-hexanol and DR values <30% for 1-butanol, indicating better substrate specificity. However, the DR value of ethanol was still up to 60% when Golden Delicious SA-IEP was used (Figure 1B). Jonagold SA-IEP showed good substrate specificity for different alcohols with DR >50% for 1-hexanol, around 35% for isobutanol, but only 15% for ethanol (Figure 1C). SA-IEP made from Red Star had DR values about 28% for ethanol, 48% for 1-hexanol, and 15−28% for other higher alcohols (Figure 1D). SA-IEP made from Gala had DR values 33% for ethanol, 35% for 1-propanol, and <30% for other higher alcohols, showing low degrading efficiency and uncompetitive substrate specificity to ethanol and higher alcohols (Figure 1E).

Comparatively, Fuji enzymes were the most efficient in reducing ethanol and higher alcohols. So they had potential application in getting rid of drunken symptoms caused by alcoholic drinks. Jonagold enzymes were more suitable to selectively reduce higher alcohols in liquors with slight reduction of ethanol content. Therefore, they had potential in selectively reducing higher alcohols in liquors. For practical purposes, however, the application of the latter enzyme would be difficult to deploy into the processing of liquor-making in China. Thus, we would focus on Fuji enzymes in this study and designed the experiments as follows.

**Optimization of Conditions for Preparing SA-Immobilized Enzymes.** To optimize the conditions for preparing immobilized Fuji enzymes, the single-factor design and response surface methodology were used. Figure 2 shows the DR values of different Fuji SA-IEPs obtained at different conditions designed by the single-factor experiment. All tested factors showed significant effect on the activity of SA-IEP in reducing alcohols in Taibai liquor (50% ethanol v/v), following a similar trend that first increased and then decreased for all tested alcohols (Figure 2). Comparatively, the highest DR values of both ethanol and most higher alcohols were obtained at conditions of 0.3 g enzyme dosage (Figure 2A), 35−40 g/L sodium alginate concentration (Figure 2B), 20 g/L $CaCl_2$ concentration (Figure 2C), and 2 h immobilization time (Figure 2D). Therefore, these levels were selected as the central point in the surface response design. Results of the DRs of

dx.doi.org/10.1021/jf5018862 | J. Agric. Food Chem. 2014, 62, 9529−9538

different alcohols obtained in the surface response design are shown in Table 2.

After multiple regression analyses and optimization, five equations were obtained between DR values of different alcohols and coded condition factors (sodium alginate concentration, $CaCl_2$ concentration, enzyme dosage). They were as follows:

$$\mathrm{DR\ (ethanol)} = 82.66 - 0.36A + 1.19B - 2.72C + 2.28AB + 2.21BC - 3.51B^2 - 5.85C^2$$

$$\mathrm{DR\ (1\text{-}propanol)} = 75.55 - 1.46A + 3.17B - 3.97C + 4.85BC - 5.11B^2 - 8.27C^2$$

$$\mathrm{DR\ (isobutanol)} = 72.94 - 0.49A + 1.12B - 3.92C + 1.64AB + 1.84BC - 2.12B^2 - 5.69C^2$$

$$\mathrm{DR\ (1\text{-}butanol)} = 19.23 - 0.76A + 2.81B - 6.22C + 5.42AB - 1.32AC + 2.75BC - 7.96A^2 - 8.60B^2 - 15.80C^2$$

$$\mathrm{DR\ (isoamylol)} = 54.87 - 1.21A + 3.40B - 8.38C + 5.04AB + 6.83BC - 4.58A^2 - 12.97B^2 - 17.69C^2$$

$$\mathrm{DR\ (1\text{-}hexanol)} = 87.60 - 1.77A + 3.96B - 8.16C + 3.87AB + 6.74BC - 5.36B^2 - 13.30C^2$$

$A$ is sodium alginate concentration, $B$ is $CaCl_2$ concentration, $C$ is enzyme dosage, and DR is the degradation rate of alcohols.

One-way ANOVA (Table 3) shows the obtained equations were extremely significant ($P < 0.01$). The lack of fit $F$ value and the associated $P$ value of each obtained model were >0.05, which indicated that the lack of fit was not significant and the model fitted the data well. Sodium alginate ($A$) had no significant influence on all results. Enzyme dosage ($C$), quadratic term of $CaCl_2$ concentration ($B^2$), enzyme dosage item ($C^2$), and the interaction of $CaCl_2$ and enzyme dosage ($BC$) had significant influence on all results. Except for 1-propanol, the interaction between sodium alginate concentration and calcium chloride ($AB$) had significant influence on DRs of other higher alcohols as well. The quadratic term of sodium alginate ($A^2$) had a remarkable effect on the degradation of 1-butanol and isoamylol.

By solving the equations, the best condition for preparing Fuji SA-IEP with highest DRs for all alcohols was obtained at enzyme dosage 0.3 g, sodium alginate concentration 40 g/L, $CaC1_2$ concentration 20 g/L, and immobilization time 2 h. Under these optimal conditions for preparing SA-IEP, DR of each alcohol was predicted to be 82.66, 75.55, 72.94, 19.23, 54.87, and 87.60% for ethanol, 1-propanol, isobutanol, 1-butanol, isoamylol, and 1-hexanol, respectively. The difference between the theoretical value and the practical value was <1%.

**Application of Fuji SA-IEP in Different Liquors.** In all tested liquors, Fuji SA-IEP showed significant degradation of ethanol and higher alcohols and generated some new substrates, such as ethyl hexanoate and ethyl heptanoate (Table 4). Interestingly, we found other esters (i.e., ethyl acetate, ethyl butyrate, ethyl valerate), aldehydes, and acids were degraded by Fuji SA-IEP or could not be detected, which demonstrated ethyl hexanoate and ethyl heptanoate might be the products of alcohol degradation in terms of the law of conservation. Furthermore, the conclusion of our laboratory's previous study further proved some apple enzymes had the same ability with alcohol dehydrogenase. In this way, the enzyme possibly had catalyzed the synthesis of esters with alcohols and acids. In all liquors, DR of 1-hexanol was the highest (>84%) among the degraded higher alcohols. In Erguotou (56% ethanol v/v), DRs of 1-propanol, isobutanol, isoamylol, and hexanol reached >80%, illustrating high efficiency of Fuji SA-IEP in reducing multiple higher alcohols. It was also found that, except for 1-butanol, DRs of ethanol and other higher alcohols increased with the ethanol content in liquors from Xifeng (45% ethanol v/v) to Erguotou (56% ethanol v/v). This might be due to higher alcohol contents increased with the ethanol content in liquors. Thus, Fuji SA-IEP was very effective in reducing higher alcohols in high ethanol content liquors. This is acceptable in practice.

**Table 4. Degradation Rates of Higher Alcohols in Three Liquors Treated with Fuji SA-IEP**

| | degradation rate (%) | | |
|---|---|---|---|
| compound | Xifeng (45% ethanol) | Taibai (50% ethanol) | Erguotou (56% ethanol) |
| ethanol | 68.06 | 80.29 | 82.02 |
| 1-propanol | 43.30 | 67.67 | 80.89 |
| isobutanol | 37.29 | 70.01 | 82.29 |
| 1-butanol | 31.42 | 10.59 | 27.71 |
| isoamylol | 55.37 | 75.69 | 80.33 |
| hexanol | 84.33 | 88.59 | 88.24 |
| ethyl hexanoate | 47.54 | 69.83 | −62.65 |
| heptanoate | −70.35 | −11.40 | 29.97 |

**Activity of Fuji SA-IEP in Continuous Treatments.** When SA-IEP prepared from Fuji was continuously used to treat Taibai liquor (50% ethanol), DRs of all alcohols generally decreased with the increase of liquor volume (Figure 3). This

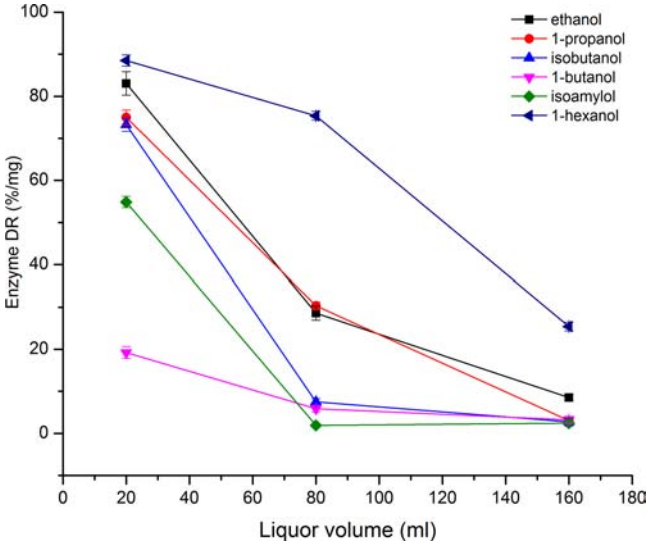

**Figure 3.** Degradation rates of different alcohols in Taibai liquor (50% ethanol v/v) during continuous treatment with Fuji SA-IEP. Bars show standard deviation of triplicate.

dx.doi.org/10.1021/jf5018862 | J. Agric. Food Chem. 2014, 62, 9529−9538

might be caused by the decrease of enzyme activity or the release of enzyme from the immobilizing material to liquid phase during the separation of SA-IEP from treated liquor. The decrease of 1-hexanol DR was comparatively much lower than that of other alcohols, illustrating 1-hexanol degrading enzymes were more stable than other alcohol-degrading enzymes. When 100 mL of liquor was treated with 0.3 g of enzyme, DR of 1-hexanol was still >70%, whereas DRs of other alcohols were <30%. When liquor volume increased to >100 mL, DR of 1-hexanol also decreased greatly. Therefore, the reasonable liquor to enzyme ratio should be 100 mL to 0.3 g of enzyme in batch treatment to produce acceptable higher alcohol degrading efficiency. To sum up, Fuji SA-IEP showed good stability in continuous treatments and it would be a novel and prospective way to reduce higher alcohols and improve flavors of alcoholic products.

## DISCUSSION

Enzyme preparations used in the study were all made of apple peels. SA-IEP and EP obtained in the study had high efficiency in degrading alcohols in liquors, implying the potential of apple pomace in improving liquor quality. SA-IEP and EP were made from apple peel that is the main constituent in apple pomace. Apple pomace is the waste of fresh apple processing, and its disposal is a major environmental problem. Many efforts have been made to process apple pomace into value-added products, such as solid state fermentation, extraction, and so on.[34,35] In the study, apple peels were extracted and prepared as solution and powder containing fiber. The latter showed higher efficiency in degrading alcohols. Therefore, it is possible to use apple pomace in Chinese liquor-making, which is carried out in solid state fermentation. In addition, enzyme preparations made from apple peels also showed significant degradation of higher alcohols in market liquors that have been separated from solid material by distillation. It is applicable and reasonable to use these enzyme preparations during or after the period of aging to enhance liquor quality, because the treatment and separation would be easily done when immobilized enzymes were used. However, it should be mentioned that the obtained results could not be used directly because they did not indicate the influence of apple ripeness and growing place on the treatment efficiency. Furthermore, ethanol was also degraded by the enzyme preparations in the study, indicating purification might be needed to increase substrate specificity of the obtained apple enzymes. In any case, the study provided useful information and proposed a new way to reduce higher alcohols in liquor and application of apple peel in this processing.

The enzyme preparations made in the study were more efficient than previously reported enzymes in higher alcohol degradation. Some enzymes have been previously used to treat alcoholic drinks. Kłosowski et al.[36] used pullulanase and proteolytic enzymes to reduce higher alcohols in maize wine during the fermentation, but the DRs were only 8.29 and 43.64%, respectively. Armada et al.[37] found that when maceration enzyme, clarificant enzyme, and the mixture of enzymes were separately added into Albariño wines, maceration enzyme reduced methanol and isobutanol, clarificant enzyme reduced 1-propanol, and the mixture of enzymes reduced 1-butanol. In this paper, all crude enzymes prepared from the five different apple varieties showed significant degradation of most alcohols, including ethanol and higher alcohols. In our previous studies, the enzyme that has activity on degrading 1-hexanol was identified as NADH-dependent hexanol-degrading enzyme.[27] It was different from all of the previously reported enzymes used in alcoholic drinks. More important, most enzymes prepared in this study had DRs of >60% to one or more higher alcohols.

The influence of the adsorption effect caused by immobilizing materials was excluded in the study by using enzyme degradation rate, which excluded the blank control that represented the used immobilizing materials without enzymes. For all apple varieties, SA-IEP and EP had higher efficiency than CTS-IES, SA-IES, and ES in most cases, indicating the carriers keeping solid state of the enzyme preparation might contribute to the enhancement of enzyme activities.[38] However, in some instances, immobilization would cause a decrease of enzyme activity, for example, the activities of CTS-IES and SA-IES were lower than that of ES. The Ehrlich mechanism indicated that the overall formation of higher alcohols was extremely complex.[39]

The obtained results showed the overall activity of crude enzymes extracted from apples. The enzymes that exactly contributed to the degradation of the alcohols might be different from each other. 1-Hexanol was comparatively easier to be degraded by most enzyme preparations extracted from four apple varieties, except of Gala. According to the results reported by Zhu et al.,[27] the hexanol-degrading enzyme extracted from Fuji also had activity to 1-propanol, isobutanol, and isoamylol, but not toward methanol and ethanol. However, the crude enzymes extracted from Fuji had significant degradation of ethanol as well, indicating the enzyme contributing to the degradation of ethanol was different from the reported hexanol-degrading enzyme. Alcohol dehydrogenase (ADH) has been reported to play an important role in alcohol degradation.[40] ADH and aldehyde dehydrogenase (ALDH) are responsible for the metabolism of alcohol to aldehyde and finally oxidizing to acid, in which NAD or NADP are indispensable.[41,42] The obtained GC-MS results showed that Fuji SA-IEP generated ethyl hexanoate in liquor (Xifeng and Taibai, 45 and 50% ethanol v/v) and heptanoate in liquor (Erguotou, 56% ethanol v/v), consistent with the characteristics of ADH. However, further study is still needed to identify the enzymes in apples that contribute to the degradation of each alcohol and confirm their corresponding substrates by purification and optimization of the conditions of GC-MS. After treatment, we invited an expert from the College of Enology of our school to evaluate the quality of the liquors. Her conclusion was that there was less pungent smell of alcohols in the liquor treated by Fuji SA-IEP and it tasted good. Later, we will expand the reaction system and carry on the normal sensory evaluation.

[a]Three productions of all almond beverages were performed. Analyses were made by triplicate. [b]Letters indicate the existence of statistically significant differences ($p < 0.05$) in the total tocopherol contents between the different UHPH treatments applied. [c]<LOD, below the limit of detection (0.02 mg/L).

(Frigomat, Milan, Italy) for 20 min with recirculation in a colloidal mill (E. Bachiller B. S.A, Barcelona, Spain). The pulp was separated by filtration using a 0.10 mm steel sieve to collect the almond beverage base product (BP) for further processing by UHPH. One hundred milliliters of BP had the following composition: 1.08 ± 0.10 g of protein; 2.04 ± 0.10 g of fat; 1.29 ± 0.08 g of carbohydrates; 4.53 ± 0.11 g of dry matter; 0.12 ± 0.02 g of ash; and a mean pH value of 7.20 ± 0.03.

To study the effect of the UHPH in almond beverage, six different treatments from each production were conducted. Then, BP was treated at 200 MPa with 55, 65, or 75 °C inlet temperature ($T_{in}$) and at 300 MPa with 55, 65, or 75 °C $T_{in}$.

During the pressurization operation, almond beverage experienced an adiabatic heating in the high pressure (HP) valve during approximately 0.7 s. Then, the temperature at the exit of the HP valve was 103.5 ± 0.9, 109.7 ± 3.9, and 114.3 ± 7.2 °C in the case of samples treated at 200 MPa with 55, 65, or 75 °C $T_{in}$ and 124.3 ± 7.5, 127.7 ± 9.7, and 129.3 ± 12.6 °C in the case of samples treated at 300 MPa with 55, 65, or 75 °C $T_{in}$, respectively. The temperature after cooling the liquid was between 28 and 31 °C for all treatments. Samples of BP and UHPH-treated almond beverages were stored in amber sterile bottles at −30 °C until analysis.

**Methods.** *Tocopherol Determination.* Sample preparation was carried out following the method described by Alves et al.,[16] slightly modified. Briefly, samples were lyophilized with a freeze-dryer (Telstar, Terrassa, Spain). Then, almond beverage powder (0.2 g) was dissolved in 1.25 mL of deionized water and spiked with 20 μL of α-tocopherol acetate (1000 mg/L) as internal standard, 0.125 mL of ascorbic acid (100 mg/L) as an antioxidant for prevention of tocopherol oxidation during the extraction procedure, and 2.5 mL of methanol. After mixing, extraction was performed three times with 1.5 mL of *n*-hexane/ethyl acetate (90:10). The organic phases collected were combined and taken to dryness under a nitrogen stream. The residue was resuspended in 750 μL of dichloromethane/methanol (2:1) for chromatographic analysis. All operations were performed in the absence of light and using amber glassware.

Determination of α-, γ-, and δ-tocopherol (Sigma S.A., St. Louis, MO, USA) was performed by ultra-high-performance liquid chromatography with fluorescence detection (UPLC) (Waters Acquity System, Milford, MA, USA) with a diode array detector (Waters 2996) following the method described by Moltó-Puigmartí et al.[17] Analysis was made by triplicate.

*Polyamines Determination.* An aliquot of 5−10 g of sample was mixed with 10 mL of 0.6 M perchloric acid in a magnetic stirring plate (JP Selecta, Barcelona, Spain) for 20 min to precipitate the proteins. Thereafter, the mixture was centrifuged at 5600*g* at 4 °C for 20 min. The liquid was filtered and adjusted to a final volume of 25 mL with 0.6 M perchloric acid. Polyamines, spermidine (SPM), and spermine (SPD) (Sigma S.A.) were determined by a UPLC system (Waters Acquity System) following the method described by Latorre-Moratalla et al.[18] Analyses were made by triplicate.

*Phytosterol Determination.* Samples were lyophilized with a freeze-dryer (Telstar). Then, fat was extracted from almond beverage powder three times with 10 mL of a chloroform/methanol mixture (2:1 v/v) with 5% acetic acid. The extracts were combined and evaporated to dryness under vacuum at room temperature with a rotary evaporator. Phytosterols were determined from 100 mg of the extracted fat according to the European Pharmacopoeia (01/2008:20423).[19] An aliquot of 20 μL of 5-α-colestane (1000 mg/L) (Sigma S.A.) as internal standard and 30 mL of 2 M alcoholic potassium hydroxide were added to the extracted fat and heated on a water bath for 1 h. Once cooled to a temperature below 25 °C, the unsaponifiable matter was extracted three times with 30 mL of hexane. The extracts were combined and evaporated to dryness under vacuum at room temperature with a rotary vapor. Derivatization of phytosterols was carried out with 150 μL of bis(trimethylsilyl)-trifluoroacetamide for 30 min at 150 °C. Then, the mixture was evaporated to dryness under a nitrogen stream, and the residue was resuspended in 400 μL of hexane prior to chromatographic determination.

Campesterol, stigmasterol, stigmastanol, fucosterol, $\Delta^5$-avenasterol, and β-sitosterol (Sigma S.A.) were determined by gas chromatography using a Thermo Trace GC Ultra system (Thermo Scientific, Waltham, MA, USA) equipped with a BD-5 MS column (30 m × 0.25 mm i.d. × 0.25 μm film thickness) operating with helium as carrier gas, coupled to a Thermo ITQ 900 mass spectrometer (MS). The GC injector was operated in a pulsed splitless mode. The volume of injection was l μL. Injector temperature was 270 °C, and the GC oven was programmed to hold at 70 °C for 0.5 min; the temperature was then raised at 20 °C/min to 210 °C, which was held for 0.5 min, and then temperature was again raised at 3 °C/min to 300 °C, which was held for 10 min. The MS was operated in electron impact at 70 eV with the ion source at 200 °C, scanning from $m/z$ 50 to 550 at 3 scans per second. Analyses were made by triplicate.

**Statistical Analysis.** Nonparametrical statistics Kruskal−Wallis analysis was performed because the data did not meet the assumptions of homoscedasticity and normality. The least significant difference test was employed to determine differences between means at a 5% significance level. Results were analyzed using the Statistical Software Package for Windows PASW Statistic 20.0 (SPSS, Chicago, IL, USA).

## RESULTS AND DISCUSSION

**UHPH Effect on the Tocopherols of Almond Beverage.** There are no previous studies on how the UHPH treatment affects the contents and profile of tocopherols in almond beverages. In contrast, in soy milk, a decrease in the total tocopherols was reported upon UHPH treatment at the same combinations of pressure and temperature as in the current work.[14] Total tocopherols were affected in UHPH-treated almond beverages (Table 1). Losses in the tocopherol contents were from 80 to 95% of the BP depending on the intensity of the UHPH treatments. α-Tocopherol was the predominant chemical form that represented >90% of the total tocopherols determined in BP, followed by δ-tocopherol and, to a lesser extent, γ-tocopherol (Table 1). These results are in accordance with the tocopherol distribution in almonds, in which α-tocopherol is the main tocopherol.[20] In comparison

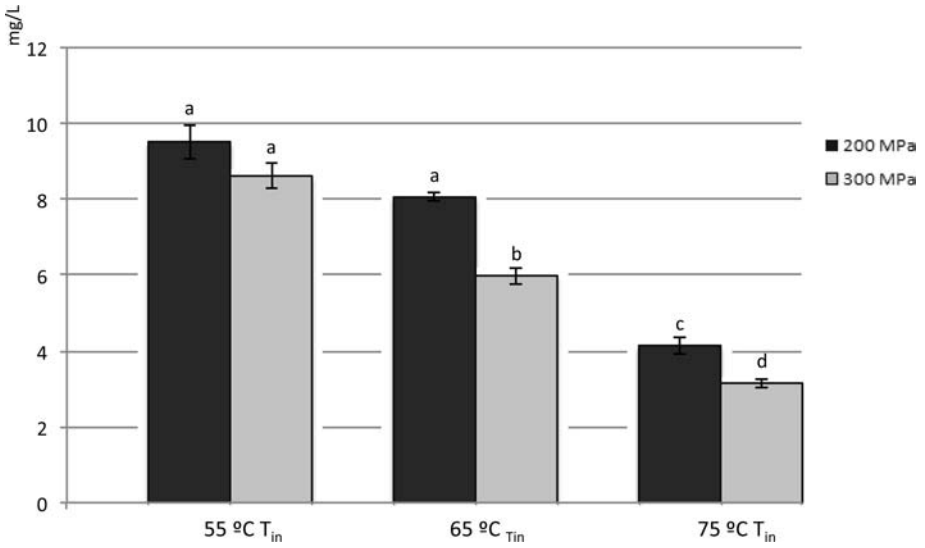

**Figure 1.** Total tocopherols (mg/L) in UHPH-treated almond beverage samples. Three productions of all almond beverages were performed. Analyses were made by triplicate. Letters indicate the existence of statistically significant differences ($p < 0.05$) in the total tocopherol contents.

**Table 2. Mean (Standard Deviation) $\beta$-Sitosterol, Avenasterol, Campesterol, Stigmasterol, and Stigmastanol Contents in Base Product and UHPH-Treated Almond Beverage Samples[a]**

| | phytosterol contents (mg/L) | | | | | | |
|---|---|---|---|---|---|---|---|
| | base product | 200 MPa, 55 °C $T_{in}$ | 200 MPa, 65 °C $T_{in}$ | 200 MPa, 75 °C $T_{in}$ | 300 MPa, 55 °C $T_{in}$ | 300 MPa, 65 °C $T_{in}$ | 300 MPa, 75 °C $T_{in}$ |
| $\beta$-sitosterol | 13.52 (0.66) | 15.13 (0.98) | 15.94 (1.41) | 16.37 (0.75) | 16.75 (0.61) | 18.00 (0.85) | 18.30 (0.88) |
| $\Delta^5$-avenasterol | 5.11 (0.31) | 5.77 (0.21) | 5.72 (0.44) | 6.79 (0.55) | 6.27 (0.41) | 7.90 (0.52) | 8.26 (0.41) |
| campesterol | 1.46 (0.04) | 2.31 (0.14) | 1.99 (0.25) | 1.71 (0.01) | 2.17 (0.55) | 1.05 (0.03) | 1.02 (0.05) |
| stigmaterol | 1.10 (0.05) | 1.52 (0.04) | 1.77 (0.11) | 1.33 (0.22) | 0.95 (0.03) | 1.24 (0.16) | 1.05 (0.02) |
| stigmastanol | 0.89 (0.04) | 1.23 (0.08) | 0.89 (0.06) | 1.05 (0.05) | 1.30 (0.05) | 0.78 (0.05) | 0.90 (0.04) |
| total[b] | 22.08 (1.34)a | 25.96 (1.32)b | 26.32 (1.48)b | 27.24 (0.78)b | 27.45 (1.04)bc | 28.97 (1.08)bc | 29.54 (1.17)c |

[a]Three productions of all almond beverages were performed. Analysis was made by triplicate. [b]Letters indicate the existence of statistically significant differences ($p < 0.05$) in the total phytosterol contents. Fucosterol was not detected.

with BP, only 10−20% of $\alpha$-tocopherol remained in all samples, whereas $\delta$-tocopherol was not found in any sample. On the contrary, 100% of the $\gamma$-tocopherol of BP sample was found in almond beverages treated at 200 MPa with 55 °C $T_{in}$ and at 300 MPa with 55 °C $T_{in}$, and 60% remained in the sample treated at 200 MPa with 65 °C $T_{in}$ (Table 1). Therefore, $\gamma$-tocopherol was the most resistant to the UHPH treatment at the mildest conditions of temperature. $\gamma$-Tocopherol is also more stable to heat than $\alpha$-tocopherol.[21]

These antioxidant compounds decreased as the temperature increased at the same pressure level, and they also decreased to a lesser extent as the pressure increased at the same temperature, suggesting that both temperature and pressure affected the tocopherol contents (Figure 1). In a previous work, tocopherols decreased by 20% in the soy milk treated at the mildest conditions of pressure and temperature of UHPH compared to untreated sample and by 50% in the soy milk treated at the strongest conditions.[14] In this work, tocopherols in almond beverages were less stable to UHPH treatments than those in soy milks. It is known that tocopherols are affected by conventional heat treatments, such as pasteurization or UHT.[22] Moreover, some authors reported no significant changes or even an increase in the total tocopherol content upon isostatic HP processing at low temperatures in different food matrices.[23,24] In the case of isostatic HP processing, pressure is uniformly and instantly applied throughout the liquid. Pressure induces some compression, but there is no shearing effect or biomolecule covalent bond compression in the food area. In the dynamic HP homogenization, also called UHPH, high pressure is applied for a few seconds in the pressure intensifier, generating intense mechanical forces through the HP valve. Besides, during UHPH treatments, samples through the HP valve gap are accompanied by short-life heating phenomena, that in the case of our samples represent temperatures from 103 to 129 °C (with a total jump in temperature by 17−21 °C per 100 MPa). Probably this temperature reached in the UHPH treatments could be responsible for the high tocopherol losses. Our results suggest that, to minimize tocopherol degradation in the almond beverages, the UHPH conditions should be as mild as possible. It is important to maintain the tocopherols in the almond beverages because of their recognized role as antioxidants.

**UHPH Effect on the Polyamines of Almond Beverage.** Polyamines have a recognized role as antioxidant compounds especially against the cellular oxidative stress.[25,26] As the capacity for the endogenous synthesis of SPD and SPM decreases with age, enhancing the intake of SPD and SPM appears to have a positive effect on health as people become older.[6] Thus, an increased intake of SPD and SPM is involved in decreasing the risk of cardiovascular diseases and age-

dx.doi.org/10.1021/jf503324f | J. Agric. Food Chem. 2014, 62, 9539−9543

associated pathologies.[27] There are no previous studies about the effect of UHPH treatment on the stability of the polyamines in almond beverages. However, polyamines were stable in all soy milks treated at the same UHPH conditions as in the current work.[14]

The polyamine SPD was found in all samples; meanwhile, SPM was not detected in any samples. The occurrence of SPD and SPM was expected because they are natural polyamines in plants and animal tissues. The SPD level is commonly higher than the SPM level in vegetable foods.[28] It has been reported that almonds contain 30 mg/kg SPD and 10 mg/kg SPM.[29] SPM was not detected, which can be ascribed to the low raw almond content used for the elaboration of the almond beverages. SPD mean contents were very low, 0.79 ± 0.04 mg/L. Consequently, because almond beverage is not a polyamine-rich food product, it is intriguing that the conditions of high pressure and temperature applied maintained the low amount of polyamines.

**UHPH Effect on the Phytosterols of Almond Beverage.** No studies have reported the effect of UHPH treatment on the phytosterols in almond beverages; however, an increase in the total phytosterol compounds was previously reported in soy milk treated by using the same UHPH conditions as in this work.[14] In almond beverages, total phytosterols were 22.08 ± 1.34 mg/L determined in BP, and they ranged from 25.96 ± 1.32 to 31.54 ± 1.69 mg/L in UHPH-treated almond beverages (Table 2). The total phytosterols determined in BP were significantly lower than UHPH-treated samples; therefore, the combination of pressure/temperature in the UHPH treatment applied resulted in an increase in the total phytosterols extractability in almond beverage. Among the UHPH-treated almond beverage samples, the highest extraction of phytosterols was found at 300 MPa, independent of the temperature conditions. Table 2 shows that total phytosterol content in samples treated at 300 MPa with 75 °C $T_{in}$ was statistically higher than those in samples treated at 200 MPa with 55, 65, and 75 °C $T_{in}$. Results indicate that the strongest conditions of UHPH favor the better extraction of phytosterols.

In all samples, the main phytosterol was $\beta$-sitosterol, which corresponded to >50% of total phytosterols, followed by $\Delta^5$-avenasterol, which represents almost 30% of the total. No data on the phytosterol composition in almond beverage were found in the literature. However, similar profiles were reported for phytosterol composition in almonds by Phillips et al.[30]

Phytosterols are integral lipid components of plant cell membranes. During the UHPH treatment several mechanical forces, shear stresses, turbulence, shocks, and cavitation phenomena occurring through the high-pressure valve could induce mechanical disruption and/or at least alteration of cell membranes.[31,32] The disruption of plant cell membrane by the UHPH treatment could release the phytosterols, which can explain the increase in total phytosterol content observed in the UHPH-treated samples.

Although phytosterols undergo oxidation, they are relatively stable in pure state and also when heated alone at temperatures ≤100 °C.[33] However, some degradation has been described under strong conditions of temperature and heating time.[34−36] Despite the temperatures reached during UHPH treatments being close to those that affect the phytosterols, the combination of pressure and short-time heating in the current work seemed not to affect phytosterol stability.

Phytosterols, which are structurally similar to cholesterol, play an important role in the control of cholesterol serum levels lowering total and LDL cholesterol.[8] Consequently, an adequate intake of these health-related compounds is strongly recommended to prevent cardiovascular diseases.

To summarize, UHPH treatment using the combination of the highest pressure and temperature would be optimum to increase the total phytosterols in almond beverage. On the contrary, UHPH treatment using the combination of the lowest pressure and temperature would be better to minimize tocopherol losses in almond beverage. UHPH treatments could be useful to increase the extractability of phytosterols from a vegetal matrix and, thereby, have a potential application in the food industry.

## AUTHOR INFORMATION

### Corresponding Author

*(M.C.V.-C.) Phone: +34 934033785. Fax: +34 934035931. E-mail: mcvidal@ub.edu.

### Funding

We thank the Direcció General de Recerca of the Generalitat de Catalunya (2014-1438 SGR) for their support and for a grant from the Ministerio de Educación y Ciencia (Spain) to Ph.D. student N.T.-F. This work was also supported by the Interministerial Commission for Science and Technology (CICYT) of the Ministerio de Educación y Ciencia (Spain) through Project AGL-2008-05430-C02-02.

### Notes

The authors declare no competing financial interest.

## ACKNOWLEDGMENTS

We thank the Centre Especial Planta de Tecnologia dels Aliments (CERPTA) for providing the almond beverage samples and especially Dr. Victoria Ferragut for her technological support.
