**Sampling.** *Feed for Farmed Fish.* Twenty samples of fish feed were purchased from Valencian hatcheries. Feed samples analyzed included, as nutrient composition, crude protein (36−49%), crude fat (18−26%), ashes (7−10%), crude fiber (1−4% as cellulose), and total phosphorus (1−2%). Their composition included vegetable products (21%), such as roasted soybeans, decorticated sunflower meal, soy protein concentrate, colza oil, and vegetable protein extract; cereal products (28%), such as corn and wheat gluten and wheat flour; fish and fish products (14%) such as fishmeal, fish oil, fish protein concentrate (14%), molluscs, and crustaceans (6%); algae (19%); and eggs and egg products (1%).

*Fish Samples.* Twenty fish (*Dicentrarchus labrax* ($n$ = 10) and *Sparus aurata* ($n$ = 10)) were purchased from different supermarkets located in Valencia (Spain), all of them from hatcheries. These species were selected for the study because they are two of the most important farmed Mediterranean fish species.[31] The origins of the sea bass and sea bream samples were Spain (Cartagena, Murcia) and Greece (Argolis). The nutrient compositions of both are similar, but the fat contents (concentrated mainly in liver) differ (1.3 g/100 g of edible portion in sea bass and 2.7 g/100 g of edible portion in sea bream).[32] These contents can differ between wild and farmed species and can also differ between seasons in wild species. Thus, cultured sea bass and sea bream contain higher lipid content than their wild counterparts (3 and 2 times higher in cultured fish, respectively).[33,34]

For the analysis, all samples were stored in a dark and dry place at −20 °C until analysis. After their packages had been opened, they were put into specific glass food containers and analyzed the same day.

**Mycotoxin Extraction.** *Extraction with Ultra-Turrax.* For feed samples, a 5 g aliquot was homogenized with 50 mL of acetonitrile during 5 min using an IKA T18 basic Ultra-Turrax (Staufen, Germany).The extract was centrifuged at 3540*g* for 15 min at 5 °C. The supernatant was purified using $C_{18}$ cartridges (Waters, Milford, MA, USA) by applying a slight vacuum. Cartridges were previously conditioned with 5 mL of MeOH and 5 mL of deonized water, washed with 5 mL of water, and then vacuum-dried for 5 min. Finally, mycotoxins were eluted with 5 mL of AcN/MeOH 50:50 v/v (MeOH with 20 mM ammonium formate). The extract was evaporated to dryness at 30 °C using a Büchi Rotavapor R-200 (Flawil, Switzerland). Then, the solution was reconstituted with 10 mL of AcN/MeOH 50:50 v/v (MeOH with 20 mM of ammonium formate) and evaporated to dryness at 30 °C using a multisample Turbovap LV Evaporator (Zymark, Hopkinton, MA, USA). The solution was reconstituted in 1 mL of AcN/MeOH 50:50 v/v (MeOH with 20 mM of ammonium formate) and filtered through a 13 mm/0.22 μm nylon filter prior injection into the LC-MS/MS-LIT system. The samples were extracted in triplicate.

*Extraction with Ultrasonic Bath.* For fish samples, a 10 g aliquot was homogenized with 50 mL of acetonitrile for 30 min at 30 °C using a Branson 5200 ultrasonic bath (Branson Ultrasonic Corp., Danbury, CT, USA). The extract was centrifuged at 3540*g* for 15 min at 5 °C. The supernatant was purified using $C_{18}$ cartridges (Waters) by applying a slight vacuum. Cartridges were previously conditioned with 5 mL of MeOH and 5 mL of deonized water, washed with 5 mL of water, and then vacuum-dried for 5 min. Finally, mycotoxins were eluted with 5 mL of AcN/MeOH 50:50 v/v (MeOH with 20 mM ammonium formate). The extract was evaporated to dryness at 30 °C using a Büchi Rotavapor R-200. The solution was reconstituted in 10 mL of AcN/MeOH 50:50 v/v (MeOH with 20 mM of ammonium formate) and transferred to a 15 mL conical tube to be evaporated to dryness at 30 °C using a multisample Turbovap LV Evaporator (Zymark). After solvent evaporation, the solution was reconstituted with 1 mL of AcN/MeOH 50:50 v/v (MeOH with 20 mM of ammonium formate) and placed again in the ultrasonic bath (30 min, 30 °C). Then, the solution was washed with hexane to eliminate fat particles in liver and viscera samples and filtered through a 13 mm/0.22 μm nylon filter (Membrane Solutions) prior to injection into the LC-MS/MS-LIT system. The samples were extracted in triplicate.

*Extraction with Microwave.* Fish samples (5 g) were extracted with 50 mL of acetonitrile during 3 min at 250 W using a microwave Saivod WP700P17-2 (Manisa, Turkey). The extract was centrifuged at 3540*g* for 15 min at 5 °C. The supernatant was purified using $C_{18}$ cartridges (Waters) by applying a slight vacuum. Cartridges were previously conditioned with 5 mL of MeOH and 5 mL of deonized water, washed with 5 mL of water, and then vacuum-dried for 5 min. Finally, mycotoxins were eluted with 5 mL of AcN/MeOH 50:50 v/v (MeOH with 20 mM ammonium formate). The extract was evaporated to dryness at 30 °C using a Büchi Rotavapor R-200. Then, the solution was reconstituted with 10 mL of AcN/MeOH 50:50 v/v (MeOH with 20 mM of ammonium formate) and evaporated to dryness at 30 °C using a multisample Turbovap LV evaporator (Zymark). The solution was reconstituted in 1 mL of AcN/MeOH 50:50 v/v (MeOH with 20 mM ammonium formate) and filtered through a 13 mm/0.22 μm nylon filter (Membrane Solutions) prior to injection into the LC-MS/MS-LIT system. The samples were extracted in triplicate.

**Instrumental and Chromatographic Conditions.** LC-MS/MS-LIT analyses were conducted on a system consisting of an Agilent

1200 chromatographic system (Agilent Technologies, Palo Alto, CA, USA) coupled to a 3200 QTRAP mass spectrometer (AB Sciex, Foster City, CA, USA) equipped with a turbo electrospray ionization (ESI) interface. The QTRAP analyzer combines a fully functional triple-quadrupole and a linear ion trap mass spectrometer within the same instrument. Separation of analytes was performed using a Gemini-NX LC-column (Phenomenex, Aschaffenburg, Germany) (150 mm × 4.6 mm, 5 $\mu$m of particle size) preceded by a guard column utilizing the same packing material. The flow rate was set to 0.8 mL $min^{-1}$, and the oven temperature was 40 °C, with eluent A water (mobile phase A) slightly acidified with 0.1% formic acid and 5 mM ammonium formate and eluent B (mobile phase B) methanol with 5 mM ammonium formate and 0.1% formic acid. The elution gradient started with 0% of eluent B, increased to 100% in 10 min, decreased to 80% in 5 min and, finally, decreased to 70% in 2 min. During the subsequent 6 min, the column was cleaned, readjusted to the initial conditions, and equilibrated for 7 min. The volume of the injections was 20 $\mu$L.

The analyses were performed using the Turbo V ionspray in positive ionization mode (ESI+). Nitrogen served as the nebulizer and collision gas. The operating conditions for the analysis were the following: ion spray voltage, 5500 V; curtain gas, 20 (arbitrary units); GS1 and GS2, 50 and 50 psi, respectively; probe temperature (TEM), 450 °C. MRM experiments were performed to obtain the maximum sensitivity for the detection of target molecules.

## RESULTS AND DISCUSSION

**Method Validation of the LC-MS/MS-LIT Analysis.** Before the MS/MS conditions were optimized, full scan and daughter scan under positive and negative mode have been used. In addition, each compound was also characterized by the retention time. The criteria adopted for accepting the analysis was a retention time deviation <2.5% compared to the standard.

The optimization of MS parameters as declustering potential (DP), collision energy (CE), and collision cell entrance potential (CEP) was performed by flow injection analysis for each standard mycotoxin; entrance potential (EP) and collision cell exit potential (CXP) were set at 10 and 4 V, respectively, for all analytes (Table 1). The MS was operated in multiple reaction monitoring (MRM) mode and with the resolution set to unit resolution for $Q_1$ and $Q_3$.

Method validation was carried out according to the guidelines established by the European Commission.[35] The method validation included the determination of linearity, limits of detection (LODs), limits of quantification (LOQs), recoveries, repeatabilities (intraday precision), reproducibilities (interday precision), and matrix effects.

Good sensitivity was obtained for selected mycotoxins when the ESI+ mode was applied: the base peak observed was $[M + NH_4]^+$ for all of the mycotoxins studied. Table 1 shows the optimum parameter values for each analyte and the two most relevant MRM transitions: the first transition was used for quantification purposes, whereas the second transition was used to confirm the presence of target compounds in the sample.

To determine the linearity, calibration curves for each studied mycotoxin were constructed from the standards prepared in methanol and from the standards prepared in the extract of blank sample (fish from extractive fishing). All mycotoxins exhibited good linearity over the working range (10LOQ and 100LOQ), and the regression coefficient of calibration curves was >0.992. For the evaluation of matrix effects, a mixture of blank extracts of different fish was prepared as blank sample. A suppression of the signal for all mycotoxins was observed (ranging from 7 to 40%). Therefore, to minimize these matrix effects and for a selective and reliable mycotoxin quantification in different fish samples, the employment of liquid chromatography coupled to mass spectrometry with linear ion trap (LC-MS/MS-LIT) required matrix-matched calibration standards prepared with fish samples.

**Table 1. Product Ions Obtained in Product Ion Scan Mode for Selected Mycotoxins and Multiple Reaction Monitoring Optimized Parameters**

| mycotoxin[a] | retention time (min) | precursor ion | product ions[b] | DP[c] (V) | CE[d] (V) | CXP[e] (V) |
|---|---|---|---|---|---|---|
| ENA | 16.4 | 699.4 | $210^{Q}$ | 76 | 35 | 14 |
| | | | $228^{q}$ | 76 | 59 | 16 |
| $ENA_1$ | 15.7 | 685.4 | $210^{Q}$ | 66 | 37 | 8 |
| | | | $214^{q}$ | 66 | 59 | 10 |
| ENB | 14.9 | 657.3 | $196^{Q}$ | 51 | 39 | 8 |
| | | | $214^{q}$ | 51 | 59 | 10 |
| $ENB_1$ | 15.5 | 671.2 | $214^{Q}$ | 66 | 61 | 10 |
| | | | $228^{q}$ | 66 | 57 | 12 |
| BEA | 15.3 | 801.2 | $784^{Q}$ | 116 | 27 | 10 |
| | | | $244^{q}$ | 116 | 39 | 6 |

[a]ENA, enniatin A; $ENA_1$, enniatin $A_1$; ENB, enniatin B; $ENB_1$, enniatin $B_1$; BEA, beauvericin. [b]Product ions. "Q" indicates quantification transition, and "q" indicates qualification transition. [c]DP, declustering potential. [d]CE, collision energy. [e]CXP, collision cell exit potential.

The LODs and LOQs were estimated from an extract of a blank sample, fortified with decreasing concentrations of the analytes. Additions were performed from three different blank samples ($n$ = 18), to the estimated concentrations for each mycotoxin. The LODs and LOQs were calculated using the criterion of S/N ≥ 3 or S/N ≥ 10 for LOD and LOQ, respectively (Table 2).

The recoveries, intraday precisions, and interday precisions were evaluated by spiking different levels of standard analyte to samples at two spiked levels (10 times LOQ and 100 times LOQ) (Table 2). According to Commission Decision (2002), recoveries were within the relative standard deviation (<20%).[35]

**Extraction Procedures.** For the optimization procedure, different parameters depending on the extraction method were tested. All experiments were carried out in triplicate using blank sample of fish fillet (hake from extractive fishing) spiked at two levels (10LOQ and 100LOQ) of ENs and BEA. The extraction efficiency was evaluated in terms of recovery. In Table 2 are shown the results for the parameters tested.

Ultra-Turrax extraction was used for feed samples. However, this method could not be used for fish sample extraction. For this reason, two extraction methods (ultrasonic and microwave extraction) were tested for fish samples.

**Ultra-Turrax Optimization.** This extraction method was employed only for feed samples. Critical parameters tested were the nature of the solvent, the volume of solvent (10, 20, 50 mL), and the weight of sample (2, 5, 10 g). Solvents tested with different polarities were AcN, a mixture of AcN/MeOH 50:50 v/v (MeOH with 20 mM ammonium formate), and ethyl acetate (EtOAc). Using the mixture of AcN/MeOH 50:50 v/v (MeOH with 20 mM ammonium formate), mean recoveries were not acceptable for ENA, $ENA_1$, and BEA (<70%) (data not shown). Mean recoveries for all mycotoxins when EtOAc was used as extraction solvent were lower than AcN ones. Recoveries obtained with 50 mL of AcN and 5 g of feed sample were acceptable

Table 2. Analytical Parameters Obtained in the Validation of the Method: Limits of Detection (LODs), Limits of Quantification (LOQs), Matrix Effects (ME), Recoveries, and Intraday and Interday Precisions for Feed (Ultra-Turrax Extraction) and Fish (Ultrasonic Bath Method), Both with AcN

[a]RSD, standard deviation (calculated by injecting samples in triplicate).

(ranging from 80 to 92%) according to the European Commission Decision.[35] For recovery assay a sample of feed destinated to other species (but with similar composition as feed for farmed fish) was used because all samples analyzed were positive for all mycotoxins analyzed in this study. The results obtained are presented in Table 2.

This extraction method is efficient and quick; however, it is not possible to use it for fish samples because fish tissue filaments were trapped in the Ultra-Turrax, eliminating the correct mixture and contact between the solid and liquid phases.

**Microwave Optimization.** Critical parameters tested were the time, potency, and nature of the extraction solvent. This study was performed with three solvents: AcN, a mixture of AcN/MeOH 50:50 v/v (MeOH with 20 mM ammonium formate), and MeOH. EtOAc was discarded due to its high volatility. The temperature applied was as low as possible because $ENA_1$ presents a melting point lower (66−67 °C) than those of the other ENs.[7] In fact, when the extraction was performed using high potency (500−1000 W), temperature was higher than the solvent boiling point, so a continuous potency of 250 W was used for the extraction procedure. The solvent volume was determined according to results previously described for Ultra-Turrax optimization, but the weight of sample was 10 g. Recoveries obtained with 10 g of sample and 50 mL of AcN were acceptable (ranging from 70 to 89%); however, the extracts were not clean, probably due to increased solubility of several compounds during the thermal treatment.

**Ultrasonic Bath Optimization.** Critical parameters tested were the nature of the extraction solvent, the temperature, and time of sonication. The best recoveries were obtained when the temperature applied was 30 °C (to prevent mycotoxin melting) and the sonication time applied was 30 min. As discussed above, solvents tested were AcN, a mixture of AcN/MeOH 50:50 v/v (MeOH with 20 mM ammonium formate), and EtOAc. The tested solvent with the best result was AcN: the extract was clear, the amount of fat in the extract was easy to eliminate, and recoveries were the highest. Results are presented in Table 2 and Figure 2. It can be observed that samples containing a large

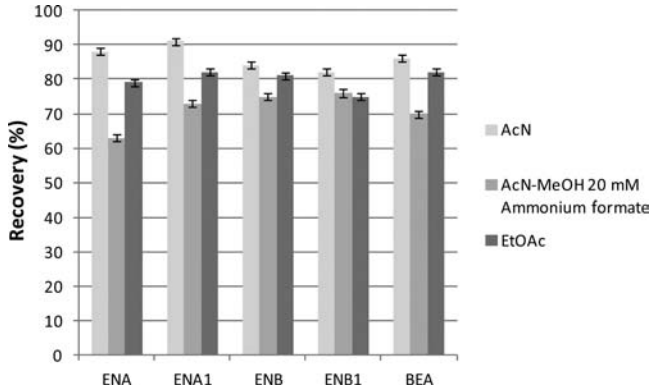

**Figure 2.** Recoveries with different solvents tested for fish samples by ultrasonic extraction. ENA, enniatin A; $ENA_1$, enniatin $A_1$; ENB, enniatin B; $ENB_1$, enniatin $B_1$; BEA, beauvericin. AcN, acetonitrile; MeOH, methanol with 20 mM ammonium formate; EtOAc, ethyl acetate. Standard deviation was obtained by analysis performance in triplicate.

fraction of AcN are appropriate for the extraction of most of the analytes. With regard to the results, this extraction method was selected for fish samples.

**Optimization of Liver and Viscera Preparation Conditions.** For animal origin samples, lipids may cause the main interference in the analysis of low-polarity contaminants in biological materials. Thus, the presence of lipids in the extracts must be avoided or reduced as much as possible to improve detection and quantification limits.[36] The main difference between edible muscle and liver is the lipid content, concentrated mainly in the liver, as mentioned under Materials and Methods. For this reason, for liver and viscera sample preparation, some variations were necessary: before the concentration on the turbovap evaporator, the extract was reconstituted with 3 mL of *n*-hexane (the third part of the total volume) and 6 mL of MeOH (total volume = 9 mL) and ultrasonicated for 30 min at room temperature. Two different phases appeared: the lipidic and the methanolic. The lipidic phase was discarded, and the methanolic phase was collected and evaporated. This procedure was carried out in triplicate. Finally, samples were reconstituted in 1 mL of AcN/MeOH 50:50 v/v (MeOH with 20 mM of ammonium formate) and filtered through a 13 mm/0.22 $\mu$m nylon filter (Membrane Solutions) prior to injection. Recoveries obtained were acceptable (ranging from 72 to 88%).

**Cleanup Procedure.** To obtain maximum extraction recoveries and to reduce the presence of compounds that may interfere in the determination, the extract purification was performed with cartridges with different types of dispersing agent to evaluate cleanup efficiency. Dispersing agents tested for fish samples were $C_8$, silica, and $C_{18}$. Results are shown in Figure 3. The best dispersing agent for obtaining the best performances in fish samples was $C_{18}$. Cartridges were previously conditioned with 5 mL of MeOH and 5 mL of deonized water, washed with 5 mL of watern and then vacuum-dried for 5 min. Finally, mycotoxins were eluted with 5 mL of AcN/MeOH 50:50 v/v (MeOH with 20 mM ammonium formate).

**Occurrence of ENs and BEA in Analyzed Samples.** *Feed for Farmed Fish.* All of the samples analyzed were contaminated with emerging *Fusarium* mycotoxins. Results are shown in Table 3. Concentrations in positive samples ranged from 0.19 to 3.40 $\mu$g/kg for ENA, from 0.24 to 6.50 $\mu$g/kg for $ENA_1$, from 0.11 to 3.20 $\mu$g/kg for ENB, from 0.15 to 10 $\mu$g/kg for $ENB_1$, and from 0.13 to 6.60 $\mu$g/kg for BEA.

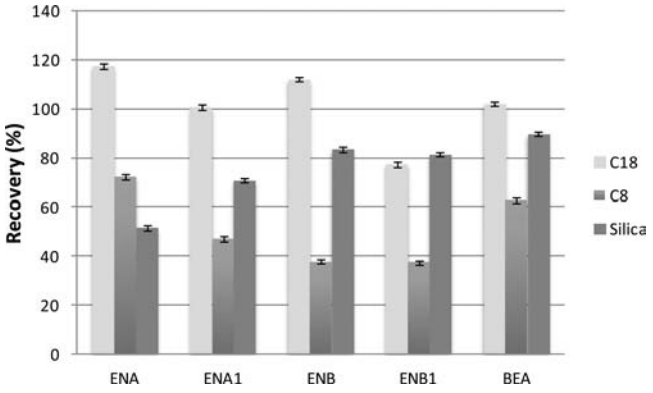

**Figure 3.** Recovery assays with different dispersing agents ($C_{18}$, $C_8$, silica) tested in fish samples by ultrasonic extraction with acetonitrile. Standard deviations were obtained by analysis of performance in triplicate.

The results obtained in this work are according to contents reported in different feed studies: in a study conducted by Warth et al.[37] in 10 feed samples from Burkina Faso and Mozambique, ENB and $ENB_1$ showed the highest contents (2.2−114 and 0.1−94.4 $\mu$g/kg, respectively), and BEA was present in 100% of the samples analyzed (3.3−418.4 $\mu$g/kg). Contents for ENA ranged from 0.6 to 7.9 $\mu$g/kg and for $ENA_1$, from 3.4 to 43.9 $\mu$g/kg.

These results are also according to those reported by Jurjevic et al.,[38] in which BEA was present in 19 of 209 corn samples and with those reported by Lee et al.[39] about the occurrence of *Fusarium* mycotoxin BEA in animal feeds from Korea: 27% of feed ingredients were contaminated with BEA at levels of 10−1800 $\mu$g/kg (mean = 480 $\mu$g/kg). The mean concentration of BEA was higher in bran feeds, followed by vegetable protein feeds, and grain feeds. In compound feeds, 33% of samples were contaminated with BEA at levels of 10−4660 $\mu$g/kg. BEA was not found in any of the 19 animal byproduct feed samples (fat meal, fish meal, and fish soluble) analyzed.

[a]nd, not detectable.

dx.doi.org/10.1021/jf5036838 | J. Agric. Food Chem. 2014, 62, 12462−12470

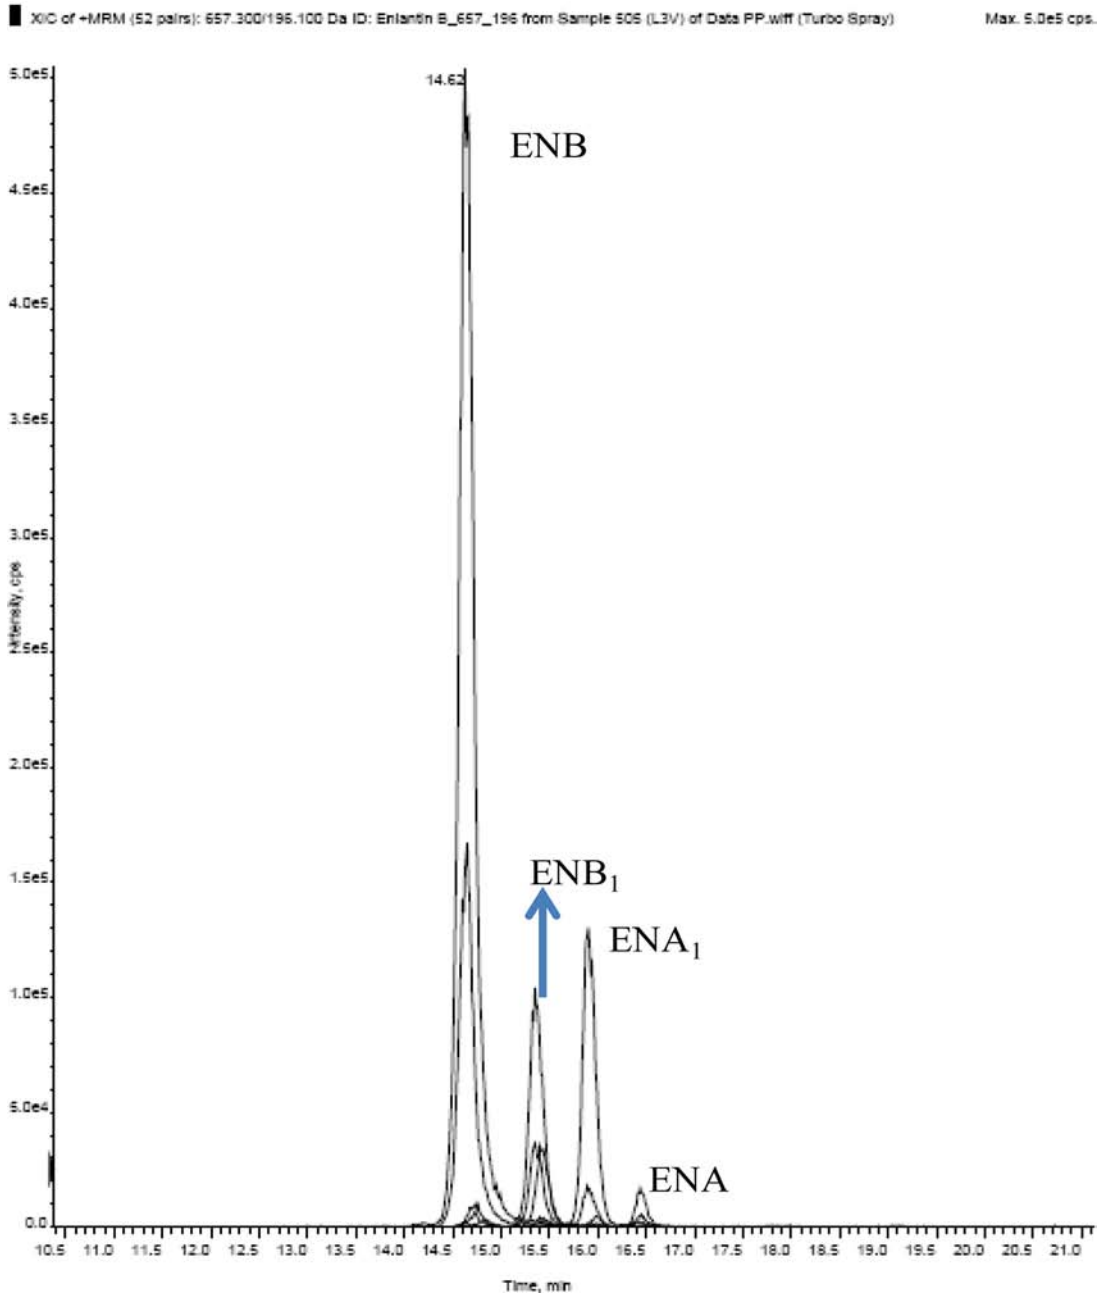

**Figure 4.** Chromatogram obtained from a sea bass tissue sample analyzed (contents were as follows: ENA, trace levels; $ENA_1$, 7 $\mu$g/kg; ENB, 7 $\mu$g/kg; and $ENB_1$, 18 $\mu$g/kg). BEA retention time = 15.3 min.

Mycotoxins can be present in processed feed due to the their resistance to treatments applied in feed processing (heat, chemical and mechanical extraction, and dehydration). These processes eliminate most of the original contaminating mycoflora; however, fungi spores and heat-stable toxins present in spores and mycelium can remain until more favorable conditions are reached.[40]

*Farmed Fish.* To determine the differences in mycotoxin contents in different fish tissues, samples were separated into four parts (liver, viscera, tissue, and head) and analyzed separately. Results are shown in Table 3.

The incidence of positive samples was lower than the incidence in feed, but the contents obtained were higher. These results suggest that contents depend on the time of withdrawal of the toxins from the diet. In this way, in a study conducted by Wu,[41] mycotoxin concentration in tissues decreased by 95−99% within 3 days after withdrawal of $AFB_1$ and OTA. In a pilot toxicokinetic study of $ENB_1$ in pigs, Devreese et al.[42] observed that $ENB_1$ is rapidly absorbed after oral administration and rapidly distributed and eliminated. The absolute oral bioavailability is high.

For the total fish samples analyzed, the highest incidence was obtained in muscle samples: 65% of samples (9 sea bass and 4 sea bream) were positive for ENB, 50% of samples (7 sea bass and 3 sea bream) were positive to $ENB_1$, and 40% of samples (5 sea bass and 3 sea bream) were positive for $ENA_1$. Thus, the highest incidence was found for ENB. The results obtained showed that the incidences for $ENA_1$, ENB, and $ENB_1$ in muscle samples were higher for sea bass samples than for sea bream samples. Figure 4 shows a chromatogram of a positive sea bass sample (tissue).

For $ENA_1$, the highest incidence was found in muscle and liver samples (40 and 20% of positive sample, respectively), whereas

dx.doi.org/10.1021/jf5036838 | J. Agric. Food Chem. 2014, 62, 12462−12470

Table 4. Estimated Daily Intake (EDI) of $ENA_1$, ENB, and $ENB_1$ for Spanish Fish Consumers

| mycotoxin | mean levels (nd = LOD[a]) (μg/kg) | mean levels (positive samples) (μg/kg) | EDI (μg/kg bw/day) | |
|---|---|---|---|---|
| | | | mean levels (nd = LOD) | mean levels (positive samples) |
| $ENA_1$ | 2.000 | 4.201 | 0.003 | 0.005 |
| ENB | 8.803 | 13.500 | 0.011 | 0.016 |
| $ENB_1$ | 5.100 | 10.902 | 0.006 | 0.013 |
| co-occurrence (sum of ENs) | 15.903 | 28.603 | 0.020 | 0.034 |

[a]nd, not detectable; LOD, limit of detection.

for ENB and $ENB_1$, the highest incidence was found in muscle (65 and 50%, respectively) and head samples (25%).

In the head samples analyzed, the percentages of positive samples were 20% for $ENA_1$ and 25% for ENB and $ENB_1$. In liver, 20% of samples analyzed were positive for $ENA_1$, whereas 15% of samples were positive for ENB and $ENB_1$. In viscera, 15% of samples were positive for ENB and $ENB_1$, whereas only 10% of samples were positive for $ENA_1$.

The mean contents obtained in muscle samples were higher in sea bream than in sea bass. This suggests differences in the mycotoxin intake and/or mycotoxin metabolism. Contents obtained for sea bass were similar in the four parts analyzed. However, for sea bream, higher contents were found in muscle and lower contents were obtained in viscera (Table 3).

With respect to different parts analyzed in sea bass and sea bream, in analyzed samples of sea bass head, the percentage of positive samples were 20% for $ENA_1$ and 30% for ENB and $ENB_1$, whereas for sea bream samples, the percentages were 20% for $ENA_1$, ENB, and $ENB_1$. In sea bream samples, the highest content was found for ENB (15.9 μg/kg). However, for sea bass, $ENB_1$ showed the highest content (75.4 μg/kg).

In liver samples of sea bass, 30% of analyzed samples were positive for $ENA_1$, whereas 20% of samples were positive for ENB and $ENB_1$. With regard to sea bream samples, only 10% of them were positive for $ENA_1$, ENB, and $ENB_1$. Only one sample of sea bass liver was positive for ENA, with 84.0 μg/kg. The highest content in both species analyzed was detected for ENB (17.7 and 13.4 μg/kg for sea bass and sea bream, respectively).

In viscera samples of sea bass, 30% of samples were positive for $ENB_1$ and 20% of samples were positive for ENB and $ENA_1$. The highest content was obtained for $ENB_1$ (119.0 μg/kg). In viscera samples from sea bream, only one sample was positive for ENB (1.9 μg/kg).

No more data are available for the toxicokinetic and bioavailability of the emerging mycotoxins in fish, but in the literature consulted is reported the presence of other mycotoxins in fish tissues. In this way, results of this survey are according to those reported by El Sayed and Khalil,[43] who reported 4.2 ± 0.8 μg/kg of $AFB_1$ in edible muscle of sea bass, and Nomura et al.[44], who reported $AFB_1$ concentrations in liver higher than in muscle, suggesting that AFs from feed were more highly accumulated in liver than in muscle. Deng et al.[45] reported that no detectable $AFB_1$ residues were found in muscle, whereas quite high residues were determined in liver.

*Daily Intake Estimation for Mycotoxins.* To determine an approximation to exposure assessment related to the intake of ENs and BEA in the Spanish adult population, the estimated daily intake (EDI) was calculated by relating the presence of mycotoxins in samples analyzed with the consumption data of fish by the Spanish population (26.84 kg per capita from January to December 2013).[46]

From these consumption data and the mean concentrations obtained (only from muscle samples analyzed), the estimated daily intake for Spanish consumers was calculated. Table 4 shows the mean concentration data for all samples (positives and negatives, criteria of nd = LOD) and only for positive samples and the EDI for each mycotoxin and also the sum of ENs (co-occurrence), because the obtained results are considered as the total exposure to mycotoxins found in samples analyzed at the same time.

With the data evidenced it is not possible to confirm that ENs represent a risk for the Spanish population, because a provisional maximum tolerable daily intake (PMTDI) has been not established by the Joint Expert Committee on Food Additives (JECFA). For this reason, approximation to the risk assessment was carried out according to the safety guidelines established for other *Fusarium* mycotoxins. In this way, results obtained were compared with the PMTDI values established for nivalenol (NIV) (1 μg/kg bw/day), DON (0.7 μg/kg bw/day), the sum of HT-2/T-2 toxins (0.1 μg/kg bw/day), and the sum of $FB_1$ and $FB_2$ (2 μg/kg bw/day).[47] It can be observed that the calculated EDIs for fish at mean levels (for positive samples and for all samples) were lower than the tolerable daily intakes (TDIs) for NIV, DON, $FB_1$/$FB_2$, and HT-2/T-2.

Although more information about toxicological data is necessary, special attention should be paid to these results, because some authors reported that DON cytotoxicity was not significantly different from that of ENs and BEA. These results indicated that ENs may have an underestimated toxic potential.[6]

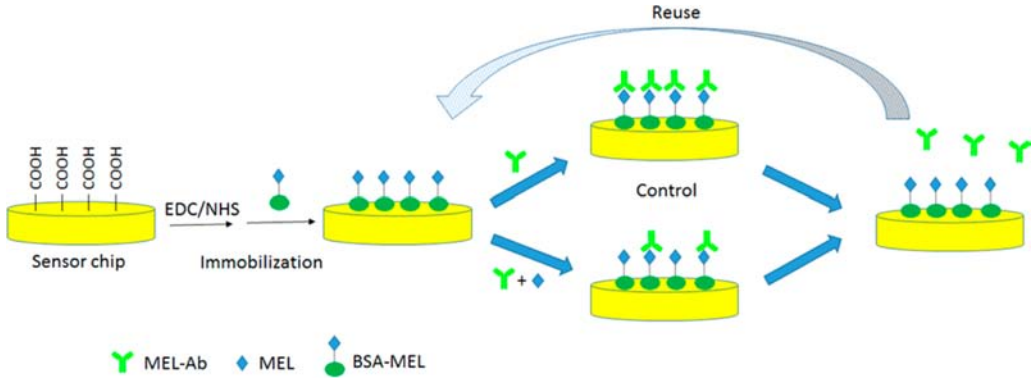
**Scheme 1. Schematic Illustration of the SPR Sensor for Detecting MEL**



triazin-2-yl)methyl)thio)propanoic acid, with BSA. MEL−Ab was generated against MEL hapten−ovalbumin (OVA) immunogen.

**Instrumentation.** The GE BIAcore X100 and the sensor chips (CM-5, which contain a carboxymethylated dextran matrix on a thin gold surface) were purchased from GE Healthcare (Tianjin, China). A BIAcore X100 system contains two flow cells in a sequential array. One of the cells was used for the test, and another one was treated as a blank cell. A centrifugal machine (Sigma, 3-30K) and an ultrafine filter (Sartorius, Germany) were used for sample preparation.

**Sensor Platform Preparation.** The MEL−BSA conjugates were immobilized onto the sensor chip using the EDC/NHS method. Briefly, a CM 5 sensor chip was activated by injecting 170 $\mu$L of 0.4 mol/L EDC and 0.1 mol/L NHS (1:1, v/v) into the flow cell at a flow rate of 30 $\mu$L/min. After a rinse with HBS at 30 $\mu$L/min (5 min), 175 $\mu$L of MEL−BSA (9 $\mu$g/mL) in acetate buffer, pH 4.5, was injected into the flow cell for immobilization. Any unreacted sites were deactivated by applying 126 $\mu$L of ethanolamine solution (61.08 mg/mL, pH 8.5) on the sensor surface. Finally, the chip surface was rinsed and stored at 4 °C before use.

**Preparation of MEL and Its Analogue Standards.** Standard stock solutions of MEL and its analogues (cyanuric acid, cyanuric chloride, and atrazine) were prepared by dissolving an appropriate amount of each chemical in HBS buffer to make a final concentration of $1.0 \times 10^3$ $\mu$g/mL. For atrazine, methanol was utilized to enhance the dissolution and make the refraction index changes (RIU). The individual stock solutions were stored in glass amber vials at 4 °C. The working standards were prepared by diluting the stock solutions in the assay buffer just before use.

**Measuring Procedure of MEL.** One hunder and ninety microliter MEL working standards at different concentrations (0, $0.5 \times 10^{-3}$, $1 \times 10^{-3}$, $5 \times 10^{-3}$, 0.01, 0.05, 0.10, 0.15, and 0.20 $\mu$g/mL) were prepared in HBS and incubated with 10 $\mu$L of MEL−Ab (100 $\mu$g/mL) for 10 min. Following this, 200 $\mu$L of each MEL/MEL−Ab mixture was injected into the flow cell (30 $\mu$L/min) for 3 min individually to allow the un-MEL-bound antibodies to bind with the immobilized MEL−BSA conjugates. The schematic diagram is shown in Scheme 1.

**Sensor Regeneration.** Gly−HCl, NaOH, SDS, and HCl at different concentrations and pH were tested to disassociate the combination of the antibody−analyte without removing the MEL−BSA conjugates from the sensor surface. After the each detection, 60 $\mu$L of the tested solution above was injected into the flow cell at 30 $\mu$L/min and rinsed with HBS.

**Cross-Reactivity.** The specificity of the assay was evaluated using selected structurally related MEL analogues in the concentration range of 0−0.20 $\mu$g/mL. These were cyanuric chloride, cyanuric chloride, cyanuric acid, cyromazine, and atrazine. Percent cross-reactivity (% CR) was calculated at $IC_{50}$:

$$\text{cross-reactivity (\%) at } IC_{50} = \left( \frac{IC_{50}\ \text{MEL}}{IC_{50}\ \text{test compound}} \right) \times 100$$

$IC_{50}$ is defined as the concentration of a test compound at which the corresponding absorbance is equal to half of the maximum absorbance.

**Sample Preparation and Spiking Method.** The milk products and pet food samples were obtained from a local supermarket and known to be MEL free.

*Full-Cream Milk.* Ten milliliters of milk sample was spiked with MEL stock solution to make final concentrations of 0.5, 2.0, and 10.0 $\mu$g/mL. After centrifugation (14243*g*, 30 min), the supernatant was 10-fold diluted and ultrafiltered. Finally, the supernatant was collected and diluted another 10 times with HBS buffer before it was loaded on the SPR sensor.

*Skim Milk Powder.* A 1.53 g sample of the skim milk powder was spiked with MEL and left overnight before it was dissolved into 10 mL of ultrapure water. The final concentrations of MEL were 0.5, 2.0, and 10.0 $\mu$g/mL. After centrifugation (14243*g*, 30 min), the supernatant was ultrafiltered and 10-fold diluted with ultrapure water for ultrafiltration. The diluted sample was ultrafiltered and diluted another 10 times with HBS buffer before use.

*Infant Formula.* Similarly to skim milk powder, the infant formula (1.53 g) was spiked with MEL. After overnight incubation, the spiked samples were dissolved into 10 mL of ultrapure water to make final concentrations of 0.5, 2.0, and 10.0 $\mu$g/mL. The samples were centrifuged (14243*g*, 30 min) to collect the supernatant. Following this, the supernatant was 10-fold diluted with ultrapure water and ultrafiltered before another 10-fold dilution with HBS.

*Cat Food and Dog Food.* In the spiking experiment, the cat food (or dog food) sample was crushed with triturator, then 1.0 g of sample was spiked with MEL stock solution and allowed to stand at room temperature overnight. Following this, the spiked sample was homogenized and immersed in 10 mL of ultrapure water to final concentrations of MEL at 0.5, 2.0, and 10.0 $\mu$g/mL. After being sonicated for 30 min, the sample was centrifuged (14243*g*, 15 min) and the supernatant was collected and diluted 100-fold with HBS before the SPR analysis.

## RESULTS AND DISCUSSION

**Fabrication of the Immunosensor Surface.** The immobilization strategy was to covalently bind MEL−BSA with activated carboxyl dextran using the EDC/NHS method. In this study, the acetate buffer at different pH values (4.0, 4.5, 5.0, and 5.5) was used to prepare MEL−BSA solution at the concentration of 9.0 $\mu$g/mL for optimizing the MEL−BSA conjugate immobilization condition. The MEL−BSA stock solution ($1.0 \times 10^{-3}$ $\mu$g/mL) was diluted to 9.0 $\mu$g/mL and injected into the flow cell at the rate of 30 $\mu$L/min for 3 min.

All of the immobilization process was performed by the instrument and is demonstrated in Figure S1 in the Supporting Information. In the immobilization pH-scouting procedure, MEL−BSA diluted in coupling buffer with different pH values was immobilized onto the sensor surface using electrostatic adsorption. The amount of immobilized MEL−BSA increased as the buffer pH decreased during the immobilization process

(Supporting Information, Figure S2). The relative response at pH 5.0 was only one-third of that at pH 4.5. The reason was that when the pH of the coupling buffer was in the range of 3.5−4.7 (the isoelectric point of BSA), the dextran on the sensor surface was negatively charged and the MEL−BSA conjugate was positively charged, causing MEL−BSA to favor covalent immobilizatiom on the sensor surface. However, at pH 4.0, a saturation point was observed, which implied the amount of MEL−BSA conjugate was overloaded; even the relative response was much higher than the one under pH 4.5. Therefore, by comparison of all the results of regeneration conditions, the acetate buffer at pH 4.5 was selected as the coupling buffer for the further experiment.

**Optimization of the Regeneration Procedure.** Regeneration is the process of removing bound MEL−Ab from the chip surface without damaging the MEL−BSA layer after one sample analysis in preparation for the next analysis cycle. The regeneration procedure was optimized in this study to improve the stability and reusability of the sensor.

Different regeneration conditions were tested including 0.01 mol/L Gly−HCl (pH 1.5, 2.0, and 2.5), the NaOH solution (0.05, 0.04, 0.03, and 0.02 mol/L), 5% SDS, and 0.1 mol/L HCl. The change of baseline response and response after immobilization of MEL−BSA (sample response) were compared (Supporting Information, Figure S3).

In the Gly, SDS, and NaOH condition, the baseline was continuously growing, whereas the sample response was decreasing under the influence. This indicated that the bound MEL−Ab was hardly removed from the sensor surface by these regeneration solutions. However, when HCl was used, there was no significant change in baseline and sample response, indicating there was no damage to the MEL−BSA layer. Thus, 0.1 mol/L HCl was selected as the regeneration solution for the chip.

The reusability of the sensor was evaluated by several replicate analyses in 1 month. With 5 $\mu$g/mL MEL−Ab injected in the flow cell, the relative response was reduced only <5% after 500 analysis cycles, which showed the high stability and reusability of the sensor surface.

**Detection of MEL by SPR Immunosensor.** The principle for detecting MEL was based on the inhibition assay. Briefly, 5 $\mu$g/mL of MEL−Ab was mixed with different concentrations of MEL (0, $0.5 \times 10^{-3}$, $1 \times 10^{-3}$, $5 \times 10^{-3}$, 0.01, 0.05, 0.10, 0.15, and 0.20 $\mu$g/mL), respectively. After 10 min of inhibition, the mixture was injected into the sensor chip by series system from channel 2 to channel 1. Channel 1 was used as blank to reduce the nonspecific adsorption and control the bulk effects, which may be caused by the different refractive indices of the instrument buffer and the sample solution.

The standard curve for MEL is illustrated in Figure 1. Under the optimal condition, the linearity region for measuring MEL had a wide range of $1.40 \times 10^{-3}$−0.1729 $\mu$g/mL. The LOD at a signal-to-noise ratio of 3.0 (S/N = 3.0) and the limit of quantitation (LOQ, S/N = 10.0) were $1.40 \times 10^{-3}$ and $2.32 \times 10^{-2}$ $\mu$g/mL, respectively. Higher sensitivity of MEL was achieved by SPR sensor than the reported measurement methodologies.[28]

**Specificity Research.** To validate the specificity of the sensor, percent cross-reactivity (%CR) for MEL was tested using four MEL analogues (cyanuric acid, cyromazine, atrazine, and cyanuric chloride). Table 1 exhibits the %CR of the SPR sensor calculated at $IC_{50}$ values.

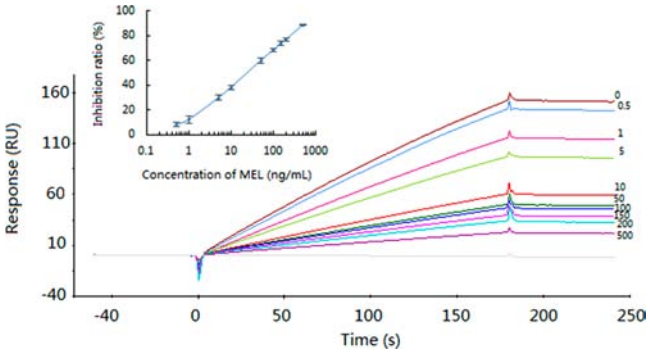


**Figure 1.** Response results corresponding with MEL−Ab mixed with different concentrations of MEL and the standard curve of SPR for MEL.

%CRs for most of the MEL analogues (cyanuric chloride, cyanuric acid, and atrizine) were <0.01% except cyromazine, which was up to 599%. This result was similar to that in a previous study.[29] The electronic configuration to MEL and the MEL hapten were more similar. The extra lone pair of electrons from the hydroxyl group in ammeline was able to inhibit binding with MEL−Ab.[29] However, because MEL was the major metabolite of cyromazine, the high %CR was not a detrimental feature of the assay.[30]

**Matrix Effect.** Matrix interferences such as pigment, protein, fat, and excess salt or sugar in foods can cause false positives by interfering with the antigen−antibody interaction.[31] For the milk products and pet food samples that contain protein and fat, the matrix interference could be simply minimized by the centrifugation, dilution, and ultrafiltration. The standard curves in the HBS buffer and the food samples shown in Figure 2 were overlapped, indicating there was no sample matrix effect. The sensitivities of the assay in full-cream milk, skim milk powder, infant formula, dog food, and cat food were higher than in the other studies,[28,32,33] which were $2.57 \times 10^{-2}$ $\mu$g/mL, $2.32 \times 10^{-2}$ $\mu$g/kg, $2.51 \times 10^{-2}$ $\mu$g/kg, $2.66 \times 10^{-2}$ $\mu$g/kg, and $2.68 \times 10^{-2}$ $\mu$g/kg, respectively. They were much lower than the MRLs for MEL set by the U.S. Food and Drug Administration (FDA) (1.0 mg/kg for infant formula and 2.5 mg/kg for normal milk, milk products, and animal feed).

**Recovery Studies of Food Samples.** Full-cream milk sample was spiked to $5 \times 10^{-3}$, 0.02, and 0.1 $\mu$g/mL MEL. Infant formula, skim milk powder, cat food, and dog food were spiked to $5 \times 10^{-3}$, 0.02, and 0.1 $\mu$g/kg MEL. The data shown in Table 2 represented the recoveries of MEL: 76.4−105.0% for full-cream milk, 97.9−99.9% for skim milk powder, 79.0−113.5% for infant formula, 86.0−113.3% for dog food, and 73.5−109.4% for cat food. In general, most of the recoveries were within a reasonable range of 73.5−113.5%. The recovery result in skim milk powder was better than the others. The reason may be that the residual fat may have a little influence on the responses of the SPR sensor. As above, the SPR method used to detect samples in milk products and pet food was feasible with precise quantitative and qualitative analysis by a simple preparation.

In summary, a SPR biosensor based on competitive format with MEL−BSA immobilized onto a gold surface was developed to monitor MEL in food samples. The optimized assay was proved to detect MEL with high rapidity, sensitivity, and stability. The cycle of sample detection could finish in 15 min including binding of 180 s and regeneration of 60 s. A good

Table 1. CR of SPR Sensor Calculated at $IC_{50}$ Values[a]

| compound | structural formula | $IC_{50}$ (ng/mL) | cross-reactivity (%) |
|---|---|---|---|
| MEL hapten |  | - | - |
| MEL |  | 23.2 | 100 |
| cyanuric chloride |  | >1000 | <0.01 |
| cyanuric acid |  | >1000 | <0.01 |
| atrizine |  | >1000 | <0.01 |
| cyromazine |  | 3.87 | 599 |

analysis cycles. The recovery results for infant formula, skim milk powder, full-cream milk, dog food, and cat food using this SPR assay ranged from 73.5 to 113.5%. On the basis of the SPR assay, the proposed method was found to have wide potential applications and rapid detection of various contaminants in food safety.

investigation has been conducted to identify chemical triggers for the enhanced lipid accumulation in *C. cohnii*.

In this study, we first evaluated effects of two antioxidant chemical triggers on lipid accumulation in *C. cohnii*. The results showed a differential effect of different antioxidants on lipid accumulation in *C. cohnii*, with BHA enhancing lipid content by 8.80%, while another antioxidant propyl gallate (PG) inhibiting lipid accumulation in *C. cohnii*. Currently, little is known about mode of action (MOA) of antioxidants on lipid production in microalgae, although various possible biological effects, such as modulation of photooxidative stress pathways and therefore enhance photosynthetic efficiency, have been proposed.[14] To determine the MOA, we first applied a metabolomics approach integrating both GC-MS and LC-MS to reveal time-series responses of *C. cohnii* to the antioxidant BHA. As a measurement and study of the small-molecule metabolites that constitute biochemical networks, metabolomics has recently been applied to studies of various microalgae[15−17] and was demonstrated as a valuable tool in analyzing cell metabolism.[18] Second, we constructed a metabolic network using a weighted gene coexpression network analysis (WGCNA)[19] to reveal metabolic modules and hub metabolites significantly associated with BHA supplementation. The study provided an overview of the metabolomics basis of the BHA stimulation effect of lipid accumulation in *C. cohnii*.

## MATERIALS AND METHODS

**Chemicals.** Antioxidant BHA and PG were purchased from Sigma-Aldrich (Taufkirchen, Germany) and stored at 4 °C until use. A stock solution of 10 mM BHA or PG in dimethyl sulfoxide (DMSO) was made in amber glass vials and stored in the dark at −20 °C.

**Strains and Cultivation.** *Crypthecodinium cohnii* ATCC 30772 was obtained from American Type Culture Collection (ATCC) and grown in 50 mL of basal medium (pH 6.5) consisting of 9 g/L glucose, 2 g/L yeast extract (OXOID, Basingstoke, UK), and 25 g/L sea salt (Sigma-Aldrich, USA) in 250 mL Erlenmeyer flasks at 25 °C and 180 rpm. The seed cultures were cultivated for 2 days after reaching exponential growth phase and then used to inoculate the fermentation flasks at an inoculum size of 10% (v/v). Two control cultures, one with 0.4% DMSO (v/v) and another without DMSO, were established in parallel with the chemical-spiked cultures. Varying concentrations of chemicals in 0.4% DMSO (v/v) were added at the beginning of the cultivation. Three biological replicates were established for each concentration. Cell density was measured on a UV-1750 spectrophotometer (Shimadzu, Japan) at $OD_{490}$. Cell number was determined by direct counting under microscope.

**Lipid Analysis and Extraction.** Two methods were used to determine the lipid accumulation under various chemicals in *C. cohnii* cells. The first protocol involves fluorescence intensity measurements at 510/585 nm after Nile Red staining.[20−22] A fluorescence spectrophotometer (F-2700FL, HITACHI) was used for the assay. The second protocol involves direct lipid extraction using a modified method described previously.[23] Briefly, *C. cohnii* cells were collected at 72 h by centrifugation (3500*g*) and then freeze-dried to generate a lyophilized algal powder. For lipid extraction, 15−25 mg of lyophilized algal powder was used for extraction using a chloroform/methanol solution (2:1, v/v). The extraction process was repeated three to four times, and then all organic solvents were combined and dried using a vacuum concentrator system (ZLS-1, Hunan, China).

**GC-MS and LC-MS Based Metabolomic Analysis.** All chemicals used for metabolome isolation and GC-MS and LC-MS analyses were obtained from Sigma-Aldrich (Taufkirchen, Germany). For metabolomic analysis, cells were collected by centrifugation at 8,000*g* for 10 min at 4 °C (Eppendorf 5430R, Hamburg, Germany) at three time points (i.e., 24, 48, and 72 h corresponding to exponential, transition, and stationary phases). The cell pellets were immediately frozen in liquid nitrogen and then stored at −80 °C before use. GC-MS metabolomic analysis was preformed according to methods described previously.[24,25] Briefly, the protocol included (i) metabolome extraction with cold 10:3:1 (*v*/*v*/*v*) methanol/chloroform/$H_2O$ solution (MCW); (ii) sample derivatization according to the two-stage technique;[26] (iii) GC-MS analysis on a GC-MS system-GC 7890 coupled to an MSD 5975 (Agilent Technologies, Inc., Santa Clara, CA) equipped with a HP-5MS capillary column (30 m × 250 mm id); (iv) data processing and statistical analysis using the automated massspectral deconvolution and identification system (AMDIS) to identify the compounds by matching the data with Fein Library and the mass spectral library of the National Institute of Standards and Technology (NIST). All metabolomic profile data were first normalized by the internal control and the cell numbers of the samples, and then subjected to partial least-squares-discriminant analyses (PLS-DA) using software SIMCA-P 11.5.

LC-MS metabolomic analysis was performed according to a previous publication with minor modifications.[27] Briefly, the protocol included: (i) Metabolome extraction by quenching quickly and methanol extraction;[28] (ii) LC-MS analysis using an Agilent 1260 series binary HPLC system (Agilent Technologies, Waldbronn, Germany) coupled to an Agilent 6410 triple quadrupole mass analyzer equipped with an electronic spray ion (ESI) source. A Synergi Hydro-RP (C18, 150 mm × 2.0 mm I.D., 4 μm 80 Å particles, Phenomenex, Torrance, CA) column was used for the separation of metabolites. Mobile phase A (MPA) was an aqueous 10 mM tributylamine solution adjusted to pH 4.95 with acetic acid, and Mobile phase B (MPB) was 100% HPLC grade methanol. Constant flow rate was maintained at 0.2 mL/min; (iii) Data processing and statistical analysis using Agilent Mass Hunter workstation LC/QQQ acquisition software (version B.04.01) and analyzed using Agilent Mass Hunter workstation qualitative analysis software (version B.04.00). The MS was operated in negative mode for multiple reaction monitoring (MRM) development, method optimization, and sample analysis. Injected sample volume for all cases was 10 μL; capillary voltage was 4000 V; and nebulizer gas flow rate and pressure were 10 L/min and 50 psi, respectively. Nitrogen nebulizer gas temperature was 300 °C. Metabolomic data was normalized by interior control and cell number, and then submitted to principal component analysis (PCA) using SIMCA-P 11.5.[29] A heatmap were created using MultiExperiment Viewer software available publically at http://www.tm4.org/.

**WGCNA Network Construction.** A metabolic correlation network was constructed from the metabolomic data, first by calculating weighted Pearson correlation matrices corresponding to metabolite abundance, and then by following the standard procedure of WGCNA to create the networks.[19,30] Hierarchical clustering based on topological overlap (TO) was used to group metabolites with highly similar correlation relationships into modules. The associated modules with correlation coefficient $r > 0.6$ and a statistical significance $p$-value less than 0.05 were extracted for further analysis. Hub metabolites were screened by high connectivity with other metabolites (≥5) in the modules strongly associated with phenotype.

## RESULTS AND DISCUSSION

**Screening Chemical Enhancers for Lipid Accumulation.** Based on previous results of antioxidant effects on lipid accumulation,[13] two antioxidant chemicals, BHA and PG were selected for evaluation of their effects on lipid accumulation in *C. cohnii*. In a previous study, BHA has been found to be an efficient lipophilic antioxidant in plants.[31] The roles of PG in lipid accumulation is not clearly defined yet, with one early study showing that PG can inhibit lipid accumulation in *C. cohnii*,[32] while another study showing that it can enhance lipid accumulation in *N. salina*.[14] Since both BHA and PG were dissolved in DMSO, two control cultures were established: one with 0.4% DMSO and another without. In the screening process, we determined the changes of growth and lipid content in cells, first in 96-well cultivation plates with Nile Red staining and then confirmed in 250 mL flask cultivation with

lipids extracted for more accurate quantitation. Multiple concentrations were evaluated for each chemical. The results showed that neither antioxidant of BHA and PG was found to affect cell growth under the tested conditions (Supporting Information, Figure S1); meanwhile, both antioxidants were found affecting lipid accumulation in *C. cohnii* (Table 1 and Supporting Information, Figure S2). Interestingly, BHA had positive effects on lipid accumulation at a concentration range of 40 nM to 30 $\mu$M, while PG issued no visible effect at low concentration but negative effects at high concentration (>30 $\mu$M) on lipid accumulation (Supporitng Information, Figure S2), consistent with the early study.[32] In addition, cell morphology of *C. cohnii* under various chemicals was also compared using microscopic analyses, and no significant difference was observed between treatments and controls (data not shown). Moreover, the opposite roles of antioxidant BHA and PG on lipid accumulation in *C. cohnii* found in this study suggested that the mechanisms in which antioxidants are involved in microalgae may be more complicated than previously proposed.[14] Finally, quantitative determination of DHA in the lipid was also conducted, and the results showed that although BHA can enhance total lipid content, it did not change the proportion of DHA in the total lipid (data now shown).

**Table 1. Lipid Content under Different BHA Concentrations**

| BHA concn | lipid content (mean) (%) | increasing proportion (%) |
|---|---|---|
| 40 $\mu$M | 46.11 | 0.72 |
| 30 $\mu$M | 49.81 | 8.80 |
| 4 $\mu$M | 49.17 | 7.40 |
| 400 nM | 48.79 | 6.57 |
| 40 nM | 48.34 | 5.59 |
| $C_{DMSO}$ | 46.25 | 1.03 |
| control | 45.78 | 0.00 |

**LC-MS Metabolomics Analysis.** Considering its low cost,[14] BHA could be a very useful chemical enhancer for lipid accumulation in large-scale fermentation of *C. cohnii*, so it is worth further investigating its enhancement mechanism on lipid accumulation. In the experiments, *C. cohnii* was cultivated with or without BHA for 3 days, and samples were collected at 24, 48, and 72 h, which correspond to exponential, transition, and stationary phases of the batch cultures, respectively. To exclude possible effects of DMSO since the BHA was dissolved and introduced as a DMSO solution, additional controls were also established for *C. cohnii* supplemented with 0.4% DMSO only. We then applied LC-MS based metabolomics to quantify the time series changes of selected metabolites related to central carbohydrate and energy metabolism in the *C. cohnii* cells with and without 30 $\mu$M BHA. Using the optimized protocol modified from a previous method for photosynthetic cyanobacteria,[26] reproducible analyses of 24 selected intracellular metabolites was achieved for *C. cohnii*, including acetyl coenzyme A (Ac-CoA), NADPH, NADP, NADH, NAD, ADP, UDP, ATP, ADP, Coenzyme A hydrate (CoA), AMP, D-fructose 1,6-bisphosphate (FBP), D-ribulose 1,5-bisphosphate (RuBP), D-fructose 6-phosphate (F6P), D-glucose 6-phosphate (G6P), D-ribose 5-phosphate (R5P), D-3-phosphoglyceric acid (3PG), dihydroxyacetone phosphate (DHAP), DL-glyceraldehyde 3-phosphate (GAP), phosphor-(enol)-pyruvic acid (PEP), L-glutamic acid (Glu), $\alpha$-ketoglutaric acid (AKG), oxaloacetic acid (OXA), and fumarate dibasic (FUM), mostly of which are unstable metabolites (Supporting Information, Table S1). Quantitative analyses of these targeted intracellular metabolites in samples collected at three time points (i.e., 24, 48, and 72 h) were conducted, each with three biological replicates and two analytical replicates, which led to time-series metabolomic profiles of *C. cohnii* with or without BHA. The quality of the LC-MS analysis was demonstrated from the following aspects (Figure 1): (i) all 24 metabolites were successfully detected in replicate samples of all time points and treatments; (ii) a PCA analysis of all samples showed an obvious clustering pattern for cell samples of the same time point and condition; (iii) samples of time points (i.e., 24, 48, and 72 h) were well separated; in addition, a clear moving trend of metabolomic profiles along the time courses was observed, suggesting the gradual change of the metabolic status; moreover, the analysis suggested that growth time may be a key distinguishing component which

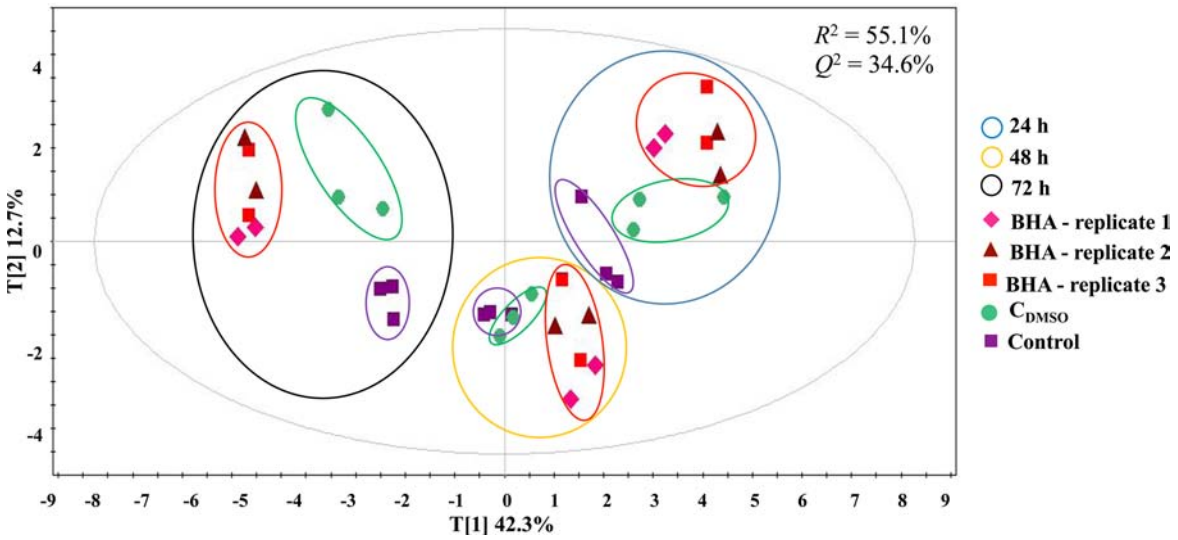

**Figure 1.** PCA analysis of LC-MS metabolomic profiles. Score plot of cell samples collected at 24, 48, and 72 h. BHA represents a microalgal cell sample grown in media supplemented with 30 $\mu$M BHA in 0.4% (v/v) DMSO. $C_{DMSO}$ represents a microalgal cell sample grown in media supplemented only with 0.4% (v/v) DMSO. Control represents a microalgal cell sample grown in media without DMSO or BHA.

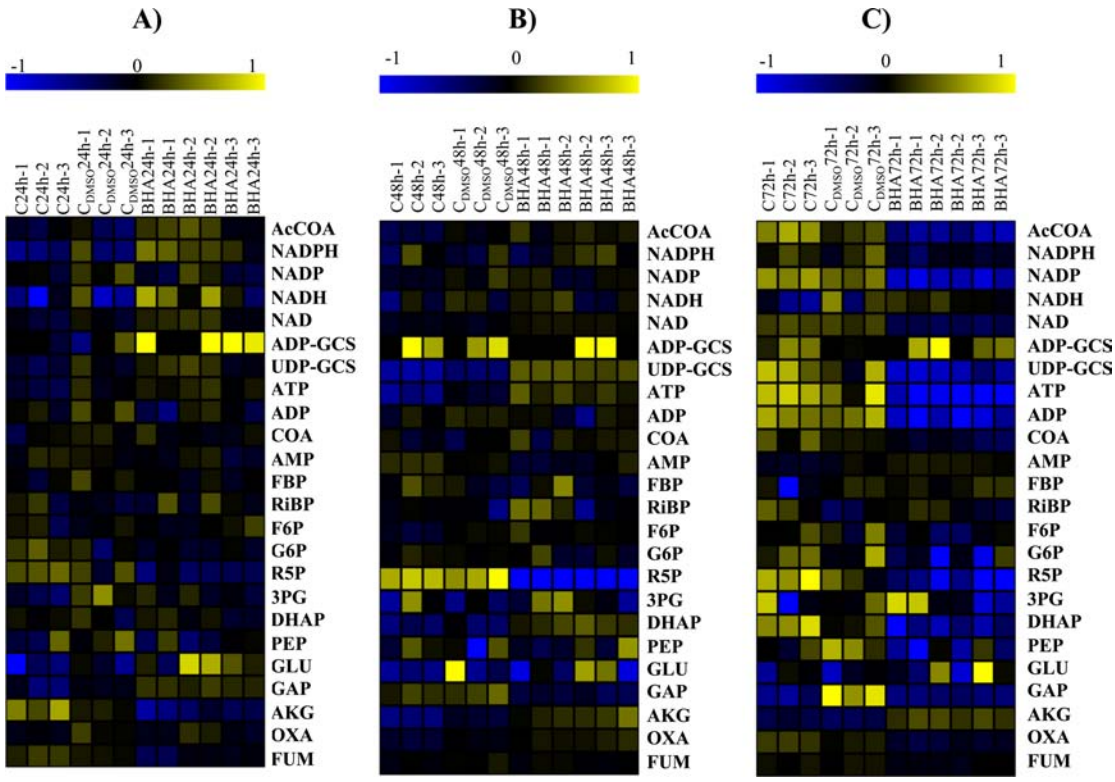

**Figure 2.** Heat maps of LC-MS metabolomic profiles. C represents control media, D represents media supplemented only with 0.4% (v/v) DMSO, and B represents BHA-spiked media. The number represents biological replicates. (A) 24 h; (B) 48 h; and (C) 72 h.

contributed significantly to the difference between samples; (iv), the samples with or without BHA can also be separated at any time point, suggesting differential metabolic changes in cells with or without BHA. Overall, the results demonstrated that the LC-MS methodology used in the study provided a good analytical resolution to distinguish various samples (Figure 1). In addition, variation of detected metabolites among biological replicates was also calculated, and a reasonably small variation was also observed, suggesting in general good quality of the LC-MS metabolomic analysis (Supporting Information, Table S2).

Heat maps of 24 metabolites in the cells with or without BHA treatment at 24, 48, and 72 h were generated (Figure 2). In the analysis, ratio of a given metabolite was calculated between the concentration of the metabolite in a given condition and the average concentration of the metabolite in all samples; a similar approach has been successfully applied in transcriptomic analysis.[33] Although the fold changes were relatively small, the results showed a clear up-regulation of ADP, NADH, NADPH, and PEP at 24 h and ATP, UDP, and GAP at 48 h. Among the BHA-induced metabolites, NADPH is an essential reducing agent for fatty acid biosynthesis, for example, it is estimated that the formation of one C18 fatty acid requires 54 NADPH from oxygenic photosynthesis in a microalgal *Phaeodactylum tricornutum*.[34] In addition, the NADPH supply has been found crucial for the DHA production in *Schizochytrium* sp. HX-308, where a reinforced acetyl-CoA and NADPH supply increased DHA content of total fatty acids from 35 to 60%.[35] Moreover, biochemical studies with the *N. salina* indicated that lipid accumulation is controlled by the availability of NADPH.[36] However, no significant increase of NADPH was observed at late stages after BHA treatment, suggesting that the effects may be related to fast growth of the cells. Interestingly, our LC-MS analysis showed that acetyl-CoA, which was considered as the major precursor for fatty acid biosynthesis, was not significantly regulated in BHA-treated samples, suggesting that the enhanced lipid synthesis by BHA may not be directly due to improved supply of the precursor acetyl-CoA.

Heat maps showed that AKG was down-regulated at 24 h but up-regulated at 72 h; and R5P was down-regulated at all three time points. Meanwhile, at 72 h of the stationary phase, most of the metabolites except AKG, PEP, and ADP, were significantly down-regulated, consistent with the slowed central carbohydrate and energy metabolisms in the aging cells. AKG is an important microbial metabolic intermediate in the citric acid cycle, a key node connecting the intracellular carbon−nitrogen metabolism.[37] Previous studies showed that in the oleaginous yeast *Yarrowia lipolytica*, AKG can behave as potent inhibitors of the malic enzyme that has been suggested as a key path to generate NADPH.[38] The down-regulation of AKG at the early phases (i.e., 24 h) and the up-regulation of AKG at the later phase (i.e., 72 h) may thus be consistent with the increased NADPH at the early phase, and the decreased NADPH at the later phase, respectively. R5P is an intermediate of the pentose phosphate pathway. In a recent study examining induction of lipid accumulation by nitrogen starvation in the green microalga *Chlamydomonas reinhardtii*, the pentose phosphate pathway was found down-regulated after lipid accumulation started.[39]

**GC-MS Metabolomic Analysis.** GC-MS based metabolomics has become a popular approach in recent years since it can achieve good coverage of polar metabolites and allow analysis of a wide range of chemical metabolite classes in a single run.[40,41] In the previous study, we developed an optimized protocol characterizing the time-series metabolic

responses for metabolite isolation and MS analysis, and achieved identification of more than 65 and 60 chemically classified metabolites from *Escherichia coli*[23] and *Synechocystis* sp. PCC 6803,[42] respectively. In this study, we first evaluated the protocol for *C. cohnii* and found that more than a hundred metabolites can be identified with good reproducibility (Supporting Information, Table S3), demonstrating that the GC-MS metabolomics approach can be applied to the study of *C. cohnii*. Following the same experimental design as LC-MS analysis described above, cells with or without 30 $\mu$M BHA treatments were collected 24, 48, and 72 h, and an extra control of only DMSO was also established as described above. Each condition carried three biological replicates, generating a total of 24 samples for GC-MS analysis. The results showed that a good separation of intracellular metabolites was achieved on the GC column, and further MS analysis allowed the chemical classification of 96 intracellular metabolites in all *C. cohnii* samples, including large number of amino acids, sugars, and organic acids (Supporting Information, Table S3). The metabolites were excluded from the list if it was detected in only one out of three replicates. The number of metabolites identified in *C. cohnii* is almost double that detected in *E. coli* and *Synechocystis*,[23,42] indicating possibly more abundant metabolites in *C. cohnii* cells. Supervised PLS-DA plots were applied to evaluate the similarities and differences between a total of 24 metabolomic profiles (Figure 3). Within each time point, BHA-treated samples were well separated from the controls at all time points. In addition, most biological replicate samples tended to be clustered together, demonstrating an overall good reproducibility.

**WGCNA Correlation Network Construction.** To further decipher mode of action of BHA in *C. cohnii*, we applied a WGCNA network analysis to the GC-MS metabolomic data sets. WGCNA is a correlation-based and unsupervised computational method to describe and visualize correlation patterns of data points[18] and was successfully applied to metabolomic data to define metabolic modules.[23,43] Following the standard protocol, we constructed unsigned networks using the GC-MS metabolomic data sets of three time points (i.e., 24, 48, and 72 h) and then localized the correlated metabolites into various metabolic modules; in addition, the association of each distinguished metabolic module with BHA treatment was also determined, as highly associated modules indicated on the plots (Figure 4). Setting a minimal number of metabolites in any module greater than 3, a cutoff of correlation coefficients ($r$ value) between module and treatment condition greater than 0.6 and their statistical confidence ($p$ value) less than 0.05, the WGCNA analysis identified 4, 2, and 2 distinct metabolic modules highly associated with BHA at 24, 48, and 72 h, respectively (Figure 4). Member metabolites clustered into each of the BHA-responsive modules are provided in Table 2. Among all eight BHA-responsive modules, it worth noting that only three modules were positively associated with BHA treatment (i.e., module M-24 h-4 at 24 h and module M-48 h-1 and M-48 h-2 at 48 h), and no module positively associated with BHA was found at 72 h. Analysis of the metabolites within the three modules showed a similar trend of high content of amino acids and sugar, such as alanine, glycine, glyceric acid, isoleucine, proline, isomaltose, lactose, maltose L-sorbose, and D-lyxose (Table 2). It may be worth further investigating whether these metabolites directly contribute to the enhanced lipid accumulation in *C. cohnii*.

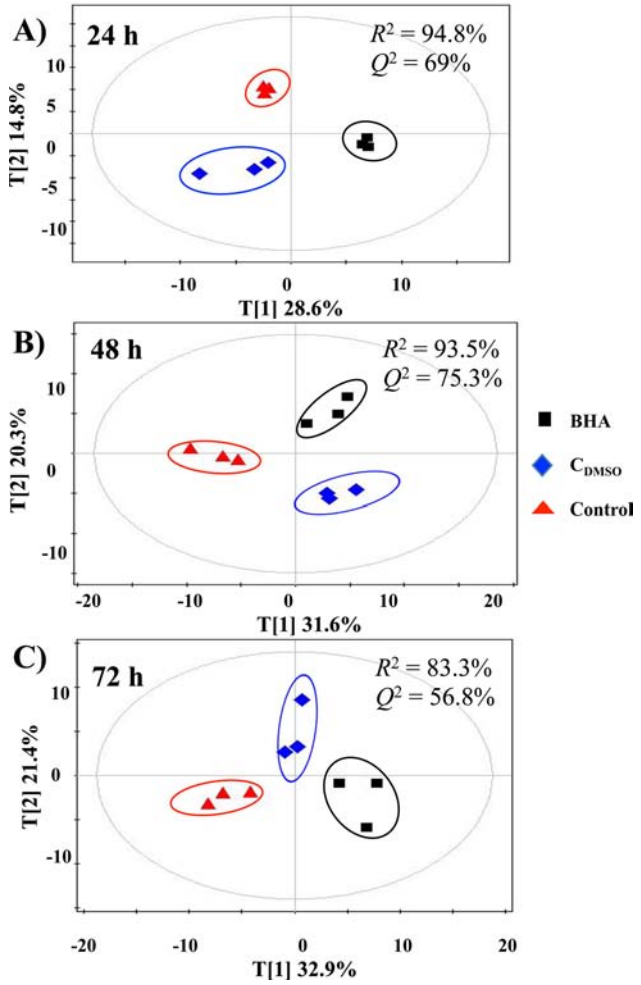

**Figure 3.** PLS-DA of GC-MS metabolomic profiles. (A) 24 h; (B) 48 h; and (C) 72 h. Each dot represents one biological sample, while the dots of the same color are biological replicates. Three conditions: control, DMSO control, and BHA treatment are indicated by different colors.

Hub metabolites have a high degree of connectivity in biological interaction networks and are thus supposed to have high biological importance.[44] Assuming hub metabolites with connectivity greater than 5, from the WGCNA network we were able to identify 3, 5, and 1 hub metabolites significantly associated with BHA at 24, 48, and 72 h, respectively (Figure 4). At 24 h, the first hub metabolite, isomaltose, was located in module M-24 h-1 negatively associated with BHA treatment ($r$ = −0.67, $p$ = 0.05); and adenosine and hydroquinone were located in module M-24 h-2 negatively associated with BHA treatment ($r$ = −0.89, $p$ = 0.002). At 48 h, three hub metabolites, 3-hydroxypropanoic-acid, L-isoleucine, and L-proline, were located in module M-48 h-1 positively associated with BHA treatment ($r$ = 0.89, $p$ = 0.001). Although never reported for any role in microalga, a chemical analogue of 3-hydroxypropanoic-acid, 2-hydroxypropanoic-acid extracted from grass *Lolium multiflorum*, was found increasing the lipid accumulation in 3T3-L1 cells.[45] At 48 h, two hub metabolites, methylmyristate and methyloleate were located in module M-48 h-2 positively associated with BHA treatment ($r$ = 0.67, $p$ = 0.05), which may be consistent with their roles as free fatty acids that can be incorporated into lipids.[46] At 72 h, one hub metabolite, malonic acid, was located in module M-72 h-2

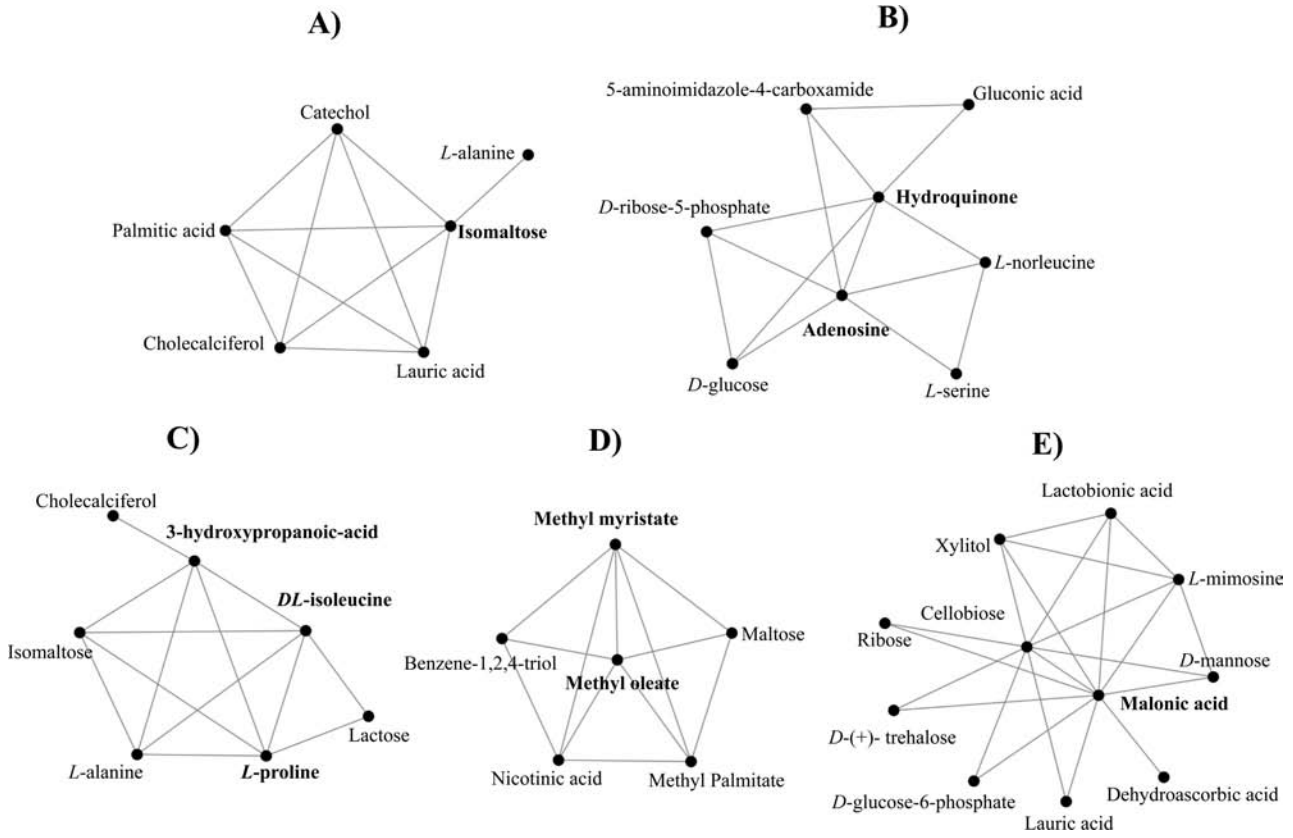

**Figure 4.** Hub metabolites and their metabolic profiles as represented by a node and edge graph. (A) Hub metabolites and associated network from module M-24 h-1; (B) hub metabolites and associated network from module M-24 h-2; (C) hub metabolites and associated network from module M-48 h-1; (D) hub metabolites and associated network from module M-48 h-2; (E) hub metabolites and associated network from module M-72 h-2.

**Table 2. Member Metabolites Clustered into Each of the BHA-Responsive Modules**[a]

| module | association | *p* value | metabolites |
|---|---|---|---|
| M-24 h-1 | $r = -0.67$ | $p = 0.05$ | catechol, cholecalciferol, L-alanine, L-allothreonine, isomaltose, nicotinic acid |
| M-24 h-2 | $r = -0.89$ | $p = 0.002$ | 3-hydroxypyridine, 5-aminoimidazole-4-carboxamide, adenosine, D-glucose, D-ribose-5-phosphate, DL-isoleucine, gluconic acid, hydroquinone, L-(+)-lactic acid, L-leucine, L-norleucine, maltose, urea |
| M-24 h-3 | $r = -0.74$ | $p = 0.02$ | benzoic acid, methyl laurate, nicotinamide, tagatose, uracil |
| M-24 h-4 | $r = 0.85$ | $p = 0.004$ | D-lyxose, ribose, glyceric acid, glycine, squalene |
| M-48 h-1 | $r = 0.89$ | $p = 0.001$ | 3-hydroxypropanoic acid, cholecalciferol, DL-isoleucine, L-alanine, L-proline, lactose, isomaltose |
| M-48 h-2 | $r = 0.67$ | $p = 0.05$ | benzene-1,2,4-triol, Maltose, L-sorbose, methyl myristate, methyl oleate, methyl palmitate, nicotinic acid |
| M-48 h-3 | $r = -0.64$ | $p = 0.06$ | D-ribose-5-phosphate, methyl-beta-D-galactopyranoside, L-alanine, linoleic acid |
| M-72 h-2 | $r = -0.87$ | $p = 0.002$ | catechol, cellobiose, dehydroascorbic acid, dioctyl phthalate, D-(+)-trehalose, D-mannose, D-glucose-6-phosphate, hydroquinone, itaconic acid, glycolic acid, lactobionic acid, lactose, lauric acid, L-mimosine, malonic acid, maltose, nicotinic acid, ribose, sucrose, uracil, xylitol |

[a]GC-MS metabolomic data set was used for this analysis.

negatively associated with BHA treatment ($r = -0.87$, $p = 0.002$). The coenzyme A derivative of malonic acid, malonyl-CoA, is an important precursor in lipid biosynthesis, and a previous study has found that malonic acid can enhance astaxanthin accumulation in *Haematococcus pluvialis*.[47] It is thus unexpected that malonic acid was negatively associated with BHA treatment, although another plausible explanation was that malonic acid is a well-known competitive inhibitor of succinate dehydrogenase and TCA cycle.[48] This negative association at 72 h may be due to cell aging and death occurring in the same phase.

A recent study demonstrated that the lipid accumulation in several microalga could be increased by antioxidant molecules in nanomolar concentration.[13] In this study, we studied the effects of selected antioxidants on lipid accumulation in *C. cohnii*. The efforts led to the discovery of an antioxidant BHA that could increase lipid content by 8.80% at a final concentration of 30 $\mu$M. To further explore the enhancing mechanism, we employed an integrated LC-MS and GC-MS metabolomic approach to determine the metabolic changes in cells treated with BHA, which allowed identification of 24 and 96 intracellular metabolites from the *C. cohnii* cells, respectively. In addition, analysis of metabolic networks constructed using a WGCNA approach uncovered eight distinguished metabolic modules and nine hub metabolites highly associated with BHA treatment. The metabolomic overview of cellular status under BHA treatment could be a useful knowledge base to further understand the molecular mechanisms of BHA and to discover relevant chemical enhancers for lipid accumulation in *C. cohnii*. Finally, as the first metabolomic study of DHA-producing *C.*

*cohnii*, the study demonstrated that the technology is a powerful tool in deciphering mode of action of chemical enhancers and could be useful in guiding optimization of lipid and DHA production in microalgae.

Editorial Advisory Board (EAB) members have been aimed at increasing the visibility of *JAFC*. We are soliciting and receiving many more Reviews and Perspectives than in the past, increasing our impact factor, and we now offer a fast-track Letters category for publishing urgent work with a focused, brief format.

The categories that define the scope of *JAFC* have been streamlined and modernized. This is a continuing and evolving task.

Improvements have been made to solidify our leadership position, given that there are now several new journals in agricultural and food sciences. Food, the science behind food, and its importance to good health have caught the attention of the research community as well as the public. Strong chemistry has been at the core of what *JAFC* is about, and it will continue to be a distinguishing feature. The chemistry related to antioxidants has been a major theme since about 1990, so much so that Associate Editor John Finley once quipped that we should change the name of the journal to "Journal of Antioxidant and Food Chemistry".

We have aimed to position *JAFC* for the research challenges of the present and future. The agricultural chemistry behind biofuels and biobased products is an example, as well as increasing focus on biopesticides and nanomaterials. The very recent development of commercial-scale cellulosic ethanol facilities was made possible by research, published in *JAFC* and other outlets. *JAFC* has been a leader in metabolomics, proteomics, and genomics applied to agriculture and food. Nanotechnology is a current focus area for *JAFC*, following on publication by *JAFC* of an ACS Selects on this topic earlier in 2014. This effort to expand coverage of emerging topics while maintaining strength in traditional areas is an ongoing challenge.

I leave the position of Editor-in-Chief with many good feelings toward all in the *JAFC* family, particularly our Associate Editors, EAB members, office staff in Davis (Loreen and Ann), and colleagues in the ACS Publications Division and ACS Divisions of AGFD and AGRO as well as our many authors and reviewers worldwide. I thank USDA's Agricultural Research Service for allowing me to be a federal Senior Executive Service Center Director and also editor of a major journal. The two appointments added value to the work conducted in each area. I look forward to continuing with teaching and service in related areas in my home department at the University of California, Davis, Environmental Toxicology.

The *Journal* will be in good hands with incoming Editor-in-Chief Dr. Thomas Hofmann, and the continuing efforts of our incredibly dedicated and knowledgeable Associate Editors and EAB members. I offer my support to Thomas and the Associate Editor team as they move forward. The *Journal* will continue to pursue excellence in publishing the research of agricultural and food chemistry, building upon a 60 year legacy, made possible by the efforts of thousands of authors, coauthors, and reviewers who share their time and intellect to advance the knowledge of applied chemistry.

**Jim Seiber,** Editor

## AUTHOR INFORMATION

### Notes

Views expressed in this editorial are those of the author and not necessairly the views of the ACS.

*brevibacter ruminantium* cells and of partially purified methyl-CoM reductase with the aim to obtain additional information on the inhibitor's molecular target.

## MATERIALS AND METHODS

Please see the Supporting Information.

## RESULTS AND DISCUSSION

The impact of 2-bromoethanesulfonate on methane production was determined using cultures of *Methanobrevibacter ruminantium* growing in 50 mL serum vessels using a complex medium as described in the Supporting Information and an atmosphere containing 80 mol % of $H_2$ and 20 mol % of $CO_2$ at an initial pressure of 210 kPa. Individual culture vessels were doped with the inhibitor at concentrations extending from 3 nM to 30 $\mu$M. The methane concentration in the overhead space was determined by gas chromatography after incubation for 3 days. The semilogarithmic plot in Figure 1A shows a sigmoidal, essentially symmetrical curve. Evaluation using the software package Dynafit (Biokin) affords an $IC_{50}$ value of 0.8 ± 0.2 $\mu$M.[19]

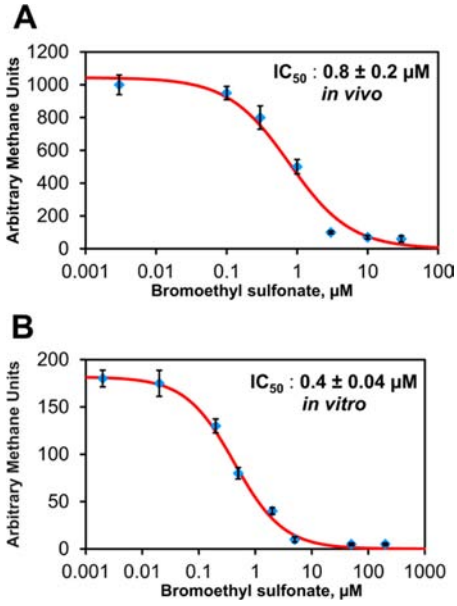

**Figure 1.** Inhibition of methyl-CoM reductase by 2-bromoethanesulfonate: (A) in vivo methane formation at different inhibitor concentrations; (B) in vitro methane formation at different inhibitor concentrations; (blue diamonds) mean of three independent measurements (error bars indicate standard deviation); (red curve) line of best fit.

To measure the in vitro impact of 2-bromoethanesulfonate on methyl-CoM reductase, we cultured *Methanobrevibacter ruminantium* to late log phase under an atmosphere containing 80 mol % of $H_2$ and 20 mol % of $CO_2$ in 1 L Schott flasks. The cells were harvested under anaerobic conditions and were disrupted by sonication. SDS-PAGE analysis of the crude extract revealed prominent bands at 59.8, 47.1, and 28.7 kDa most likely visualizing the $\alpha$, $\beta$, and $\gamma$ subunit types, respectively, of methyl-CoM reductase (not shown). The specific activity of the peak fraction was 6 nmol/mg·min.

The crude cell extract was placed on a column of Sepharose Q that was kept under anaerobic conditions and developed with a gradient of 0.4−1.0 M NaCl in 100 mM MOPS, pH 7.2. Fractions were analyzed for in vitro methane production using methyl-CoM and coenzyme B as substrates (Figures 2 and 3).

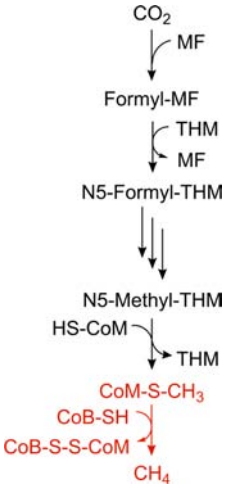

**Figure 2.** Methanogenesis in *Methanobrevibacter ruminantium*; methyl-CoM reductase reaction shown red. MF, methanofuran; THM, tetrahydromethanopterin.

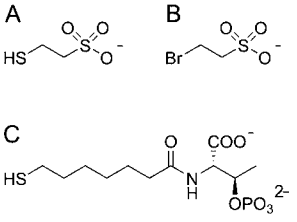

**Figure 3.** (A) Coenzyme M (CoM); (B) 2-bromoethanesulfonate; (C) coenzyme B (CoB).

Under these specific conditions, one molecule of methyl-CoM and one molecule of coenzyme B gave rise to one molecule of methane plus one disulfide (CoM−CoB complex). In vivo, this CoM−CoB complex is subject to reductive cleavage conducive to the regeneration of coenzymes B and M. Because our in vitro assay did not include any enzyme for coenzyme recycling, the mixed disulfide was the final product. Using this assay, active methyl-CoM reductase was shown to be eluted from the column with a retention volume of 30−40 mL. All three subunit types of methyl-CoM reductase were confirmed in the partially purified (about 90%) enzyme preparation as revealed by mass spectrometry.

In line with observations reported for *Methanothermobacter thermoautotrophicus*, the enzyme was subject to rapid activity loss under in vitro conditions.[20] Hence, inhibition assays were carried out immediately after the purification procedure. Figure 1B demonstrates the impact of 2-bromoethanesulfonate on the in vitro formation of methane by the partially purified enzyme. The semilogarithmic plot shows a sigmoid curve with $c_2$ symmetry. Evaluation with the software package Dynafit assigned an $IC_{50}$ of 0.4 ± 0.04 $\mu$M. Thus, methyl-CoM reductase from *Methanobrevibacter ruminantium* appears to be more sensitive to 2-bromoethanesulfonate inhibition than the enzyme from *Methanothermobacter thermoautotrophicus*, for which an $IC_{50}$ of 4 $\mu$M has been reported.[21] Notably, the $IC_{50}$ values obtained with *Methanobrevibacter ruminantium* cultures and with the partially purified *Methanobrevibacter ruminantium* enzyme are numerically similar. This is well in line

dx.doi.org/10.1021/jf505056g | J. Agric. Food Chem. 2014, 62, 12487−12490

with the hypothesis that the terminal enzyme of methanogenesis is the actual target of the inhibitor, which is a structural analogue of coenzyme M. Methyl-CoM reductase has been identified as a potential target for inhibition of methanogenesis.[10] The results of our study unequivocally support this hypothesis and confirm the relevance of using 2-bromoethanesulfonate as a model compound to test the effects of reduced methanogenesis in complex ecosystems such as the rumen or as a positive control to develop compounds working according to the same mode of action while benefiting from more favorable toxicological profiles.

Whereas methyl-CoM reductase from *Methanobrevibacter ruminantium* is not well suited for high-throughput screening, due to the limited storing options, it is, however, possible to directly test potential new inhibitors in our in vivo system. Currently, we are downsizing the required culture volume with the scope to run growth studies in 1.5 mL GC vials.

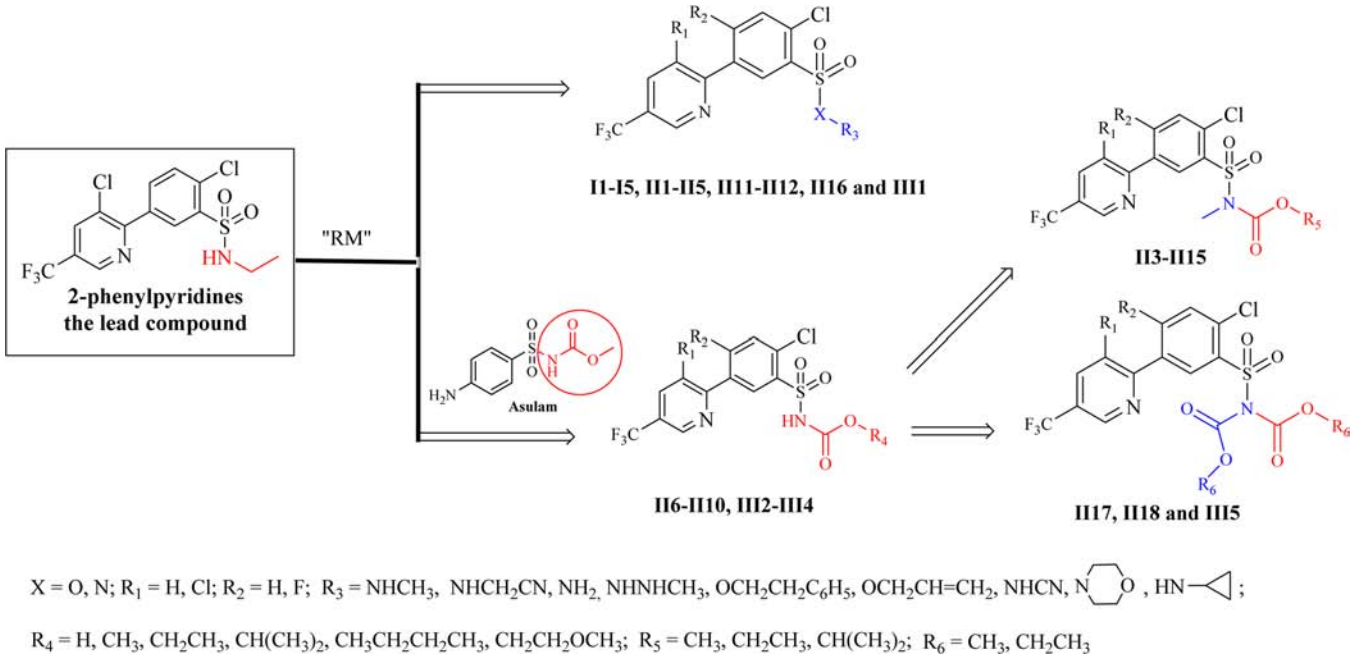

**Figure 1.** Design of 3-(pyridin-2-yl)benzenesulfonamide derivatives. "RM" means "terminal group replacement method".

dimethoxyethane and 550 mL of water were refluxed for 4 h. The mixture was then acidified to pH 4−5 with dilute hydrochloric acid, and dimethoxyethane was removed by distillation. The remaining aqueous phase was extracted with methylene chloride. The combined methylene chloride phased was washed with water, dried over sodium sulfate, and evaporated. The residue was stirred with a little cold *n*-hexane, filtered off with suction, and dried.

*2-(4-Chlorophenyl)-5-(trifluoromethyl)pyridine (**a1**).* Yield: 60% of colorless crystals of melting point 89−90 °C. $^1$H NMR (300 MHz, $CDCl_3$) $\delta_H$ (ppm) = 7.47 (d, *J* = 8.3 Hz, 2H), 7.73 (d, *J* = 8.4 Hz, 2H), 8.04 (d, *J* = 8.5 Hz, 1H), 8.05 (d, *J* = 8.3 Hz, 1H), 8.83 (s, 1H).

*3-Chloro-2-(4-chlorophenyl)-5-(trifluoromethyl)pyridine (**a2**).* Yield: 70% of colorless crystals of melting point 72−74 °C. $^1$H NMR (300 MHz, $CDCl_3$) $\delta_H$ (ppm) = 7.47 (d, *J* = 8.4 Hz, 2H), 7.73 (d, *J* = 8.4 Hz, 2H), 8.04 (s, 1H), 8.83 (s, 1H).

*3-Chloro-2-(4-chloro-2-fluorophenyl)-5-(trifluoromethyl)pyridine (**a3**).* Yield: 76% of colorless crystals of melting point 34−35 °C. $^1$H NMR (300 MHz, $CDCl_3$) $\delta_H$ (ppm) = 7.32 (dd, *J* = 8.3, 2.2 Hz, 2H), 7.43 (d, 1H), 8.05 (s, 1H), 8.86 (s, 1H).

**Synthesis of Intermediate b.** The intermediate **a** (0.033 mol) was added dropwise to chlorosulfonic acid at 0−5 °C, and the mixture was heated at 130 °C for 8 h.[25] The reaction mixture was then cooled to room temperature and was poured into crushed ice with ethyl acetate (3 × 60 mL). The combined extract was washed with water and saturated brine and dried over anhydrous magnesium sulfate, and then filtered and concentrated under reduced pressure to give a pale yellow liquid.

*2-Chloro-5-(5-(trifluoromethyl)pyridin-2-yl)benzene-1-sulfonyl Chloride (**b1**).* Yield: 90%. $^1$H NMR (300 MHz, $CDCl_3$) $\delta_H$ (ppm) = 7.73 (d, *J* = 8.3 Hz, 1H), 7.92 (d, *J* = 8.4 Hz, 1H), 8.05 (d, *J* = 8.3 Hz, 1H), 8.32 (d, *J* = 8.4 Hz, 1H), 8.80 (s, 1H), 8.99 (s, 1H).

*2-Chloro-5-(3-chloro-5-(trifluoromethyl)pyridin-2-yl)benzene-1-sulfonyl Chloride (**b2**).* Yield: 90%. $^1$H NMR (300 MHz, $CDCl_3$) $\delta_H$ (ppm) = 7.68 (d, *J* = 8.4 Hz, 1H), 7.96 (d, *J* = 8.4 Hz, 1H), 8.08 (s, 1H), 8.52 (s, 1H), 8.87 (s, 1H).

*2-Chloro-5-(3-chloro-5-(trifluoromethyl)pyridin-2-yl)-4-fluorobenzene-1-sulfonyl Chloride (**b3**).* Yield: 91%. $^1$H NMR (300 MHz, $CDCl_3$) $\delta_H$ (ppm) = 7.40 (d, *J* = 8.3 Hz, 1H), 8.05 (s, 1H), 8.25 (d, 1H), 8.86 (s, 1H).

**Synthesis of Substituted 3-(pyridin-2-yl)-benzenesulfonamide Compounds.** *2-Chloro-5-(5-(trifluoromethyl)pyridin-2-yl)benzenesulfonamide (**I1**).* The intermediate **b1** (0.01 mol) in 20 mL of THF was added dropwise to $NH_3 \cdot H_2O$ at 0−5 °C, and the mixture was stirred at room temperature. Then the mixture was concentrated under reduced pressure to obtain a pale yellow solid. Yield: 85%. Melting point: 163−165 °C. $^1$H NMR (300 MHz, $CDCl_3$) $\delta_H$ (ppm) = 8.97 (s, 1H), 8.76 (d, *J* = 2.3 Hz, 1H), 8.28 (d, *J* = 8.4 Hz, 1H), 8.04 (s, 1H), 7.93 (s, 1H), 7.70 (d, *J* = 8.3 Hz, 1H), 5.17 (s, 2H). Anal. Calcd (%) for $C_{12}H_8ClF_3N_2O_2S$: C, 42.80; H, 2.39; N, 8.32. Found: C, 42.81; H, 2.42; N, 8.35.

*2-((2-Chloro-5-(5-(trifluoromethyl)pyridin-2-yl)phenyl)sulfonyl)-acetonitrile (**I2**).* 2-amino acetonitrile (3 mmol), the intermediate **b1** (1.5 mmol), and triethylamine in 15 mL of THF were stirred at room temperature. Then the mixture was concentrated under reduced pressure to get the target compound. Yield: 40% of yellow solid of melting point 158−160 °C. $^1$H NMR (300 MHz, $CDCl_3$) $\delta_H$ (ppm) = 8.99 (s, 1H), 8.81 (s, 1H), 8.33 (d, *J* = 8.3 Hz, 1H), 8.05 (s, 1H), 7.93 (d, *J* = 7.9 Hz, 1H), 7.74 (d, *J* = 8.5 Hz, 1H), 5.52 (s, 1H), 4.12 (d, *J* = 6.7 Hz, 2H). Anal. Calcd (%) for $C_{14}H_9ClF_3N_3O_2S$: C, 44.75; H, 2.41; N, 11.18. Found: C, 44.76; H, 2.43; N, 11.16.

**II1**-**II5**, **II11**, **II12**, **II16**, and **III1** were synthesized using the synthetic method of **I2**

*Methyl ((2-Chloro-5-(3-chloro-5-(trifluoromethyl)pyridin-2-yl)-phenyl)sulfonyl)carbamate (**II6**).* Synthesis of 2-chloro-5-(3-chloro-5-(trifluoromethyl)pyridin-2-yl)benzenesulfonamide. The intermediate **b2** (0.01 mol) in 20 mL of THF was added dropwise to $NH_3 \cdot H_2O$ (0.02 mol) at 0−5 °C, and the mixture was stirred at room temperature for 2 h. Then the mixture was concentrated under reduced pressure to obtain a pale yellow solid. Yield: 81%. Melting point: 166−168 °C. $^1$H NMR (300 MHz, $CDCl_3$) $\delta_H$ (ppm) = 5.17(2H, s), 7.69(1H, d), 7.96(1H, d), 8.09(1H, s), 8.57(1H, s), 8.86(1H, s). Synthesis of methyl ((2-chloro-5-(3-chloro-5-(trifluoromethyl)pyridin-2-yl)phenyl)sulfonyl)carbamate. 2-Chloro-5-(3-chloro-5-(trifluoromethyl)pyridin-2-yl)benzenesulfonamide (0.6 g, 1.6 mmol), $K_2CO_3$ (0.31 g, 2.26 mmol), and methyl chloroformate (0.2 g, 1.67 mmol) in 15 mL of acetone were refluxed for 6 h. The mixture was concentrated under reduced pressure. Then the crude product was purified by column chromatography with a mixture of ethyl acetate and petroleum ether (1:3) to get 0.25 g of target compound. Yield: 31% of yellow solid of melting point 144−146 °C. $^1$H NMR (300 MHz, $CDCl_3$) $\delta_H$ (ppm) = 8.90 (s, 1H), 8.77 (d, *J* = 2.2 Hz, 1H), 8.12 (s, 1H), 8.07 (dd, *J* = 8.3, 2.2 Hz, 1H), 7.89 (s, 1H), 7.72 (d, *J* = 8.3 Hz, 1H), 3.75 (s, 3H). $^{13}$C NMR (75 MHz, $CDCl_3$) $\delta$ 156.42, 150.51, 144.57, 144.52, 144.47, 135.76, 135.71, 135.63, 134.27, 133.95, 133.44, 131.81, 127.32, 53.87. $C_{14}H_9Cl_2F_3N_2O_4S$: C, 39.18; H, 2.11; N, 6.53; Found: C, 39.19; H, 2.15; N, 6.52.

**II7**–**II10**, **II13**–**II15**, **II17**, **II18**, and **III2**–**III5** were synthesized using the synthetic method of **II6**.

**Herbicidal Activity Assay.** *Herbicidal Activity Assay in Glasshouse Tests.* All plant materials were obtained from the Agrochemical Discovery Department in Shenyang Research Institute of Chemical Industry. Plants were grown in plastic flowerpots containing loamy sand with about 3.0% humus as substrate. The seeds of the test plants were sown separately according to species.

The test plants were grown to a height of 3–15 cm, depending on the species, and only then treated with the active ingredients

[a]YOApost-, VELpost-, FOXpost- and BYG post- mean youth-and-old age (*Zinnia elegans Jacq.*), velvet leaf (*Abutilon theophrasti Medic.*), foxtail (*Setaria glauca (L.) Beauv*), and barnyard grass (*Echinochloa crus-galli (L.) Beauv*), respectively.

suspended or emulsified in water. For this purpose, the test plants were either sown directly or grown in the same vessels or they were germinated separately and transplanted into the test vessels a few days before the treatment. The application rate for postemergence treatment was 600, 150, and 37.5 g/ha active substance.

The plants were kept at 10−25 °C or 20−35 °C depending on the species. The test lasted 2−4 weeks during which the plants were tended and their reaction to the individual treatments was evaluated.

Evaluation was on a scale from 0 to 100, where 100 means no emergence of the plants or complete destruction of at least the above-ground parts and 0 means no damage or normal growth.

The plants used in the glasshouse tests comprised the following species: velvet leaf (*Abutilon Theophrasti Medic.*), youth-and-old age (*Zinnia Elegans Jacq.*), barnyard grass (*Echinochloa crus-galli(L.) Beauv.*), and foxtail (*Setaria Glauca(L.) Beauv.*).

*Herbicidal Activity Assay in Field Tests.* The experiment of the field tests was operated on the basis of field efficacy trials of Chinese pesticide standards (a) GB/T17980.40-2000. The test weeds in rice field were at 2−4 leaf stage. The controlling weeds comprised the following species: dayflower (*commelina tuberosa*) and nightshade (*disambiguation*) in Liaoning and arrowhead (*sagittarian trifolia*) in Heilongjiang. The application rate for treatment was 30 and 60 g/ha active substance. The application rate for treatment of bentazon[46]-(48%, water dispersible granule) which was used as the control in Liaoning was 1440 g/ha active substance, while 24% oxyfluorfen EC was used as the control in Herlongjiang.

Formulas used in these tests are as follows: Control effect (%) = (the number of live weeds in the control area − the number of live weeds in the treated area)/the number of live weeds in the control area × 100%.

## RESULTS AND DISCUSSION

**Chemistry.** The designed substituted 3-(pyridin-2-yl)-benzenesulfonamide compounds were synthesized through critical intermediates (**b**) as shown in Scheme 1. The reactions of the intermediates **b1**, **b2**, and **b3** via the amino compounds and triethylamine using THF as the solvent afforded series I, series II, and series III in considerable yield, respectively. The 28 target compounds and intermediates were characterized by $^1$H NMR and elemental analyses. All spectral and analytical data were consistent with the assigned structures.

**Herbicidal Activity.** The 28 target compounds were evaluated for their herbicidal ability to control the unwanted plants using postemergence treatment in the glasshouse and the field tests. For postemergence treatment in the glasshouse, the designed substituted 3-(pyridin-2-yl)benzenesulfonamide compounds were compared to the lead compounds which were disclosed by researchers at BASF Aktiengesellschaft,[26] saflufenacil[47] and sulcotrione.[48] As shown in Table 1, series **I** compounds which were synthesized through intermediates **b1** could not control unwanted plants at the 600 g/ha active substance, and most compounds of series II and III could efficiently control velvet leaf, youth-and-old age, barnyard grass, and foxtail. Especially, **II6**, **II7**, **II8**, **II9**, **II10**, **II11**, **III2**, **III3**, **III4**, and **III5** showed higher activity than the lead compound which showed detective values of 20, 15, 10, and 10 for velvet leaf, youth-and-old age, barnyard grass, and foxtail at the 37.5 g/ha active substance, respectively. The activity of **II6**, **II7**, **III2**, and **III4** proved roughly equivalent to the saflufenacil and better than 95% sulcotrione at the same concentration. Meanwhile, the other compounds of series **II** and **III** did not show exciting activity.

By comparison of activity of series **I**, series **II**, and series **III**, it may be seen that substituent site $R_1$ is a critical active group, and it could clearly improve the activities once $R_1$ is chlorine. Hydrogen and fluorine were designed to infer the preliminary structure−activity relationship of substituent site $R_2$; **II6** and **III3** which have the same structure except $R_2$ showed similar excellent activity for velvet leaf, youth-and-old age, barnyard grass, and foxtail. However, the activities of **II5** and **III1** differ significantly. **II5** of which $R_2$ is hydrogen could obviously control target weeds, while **III1** of which $R_2$ is fluorine loses the ability to control weeds. Therefore, more compounds should be synthesized to get the structure−activity relationship at site $R_2$. Moreover, it is evident that introduction at substituent position Q of methyl carbamate (**II6**), ethyl carbamate (**II7**), isopropyl carbamate (**II8**), buty carbamate (**II9**) and 2-methoxyethyl carbamate (**II10**) could improve the herbicidal activity, and it seems that the ability to control barnyard grass and foxtail may decrease with the increase in number of carbon of carbamic acid ester.

In order to compare activity of these highly reactive compounds (**II5**, **II6**, **II7**, **II10**, **III2,** and **III4**), a parallel experiment was executed in glasshouse. As shown in Table 2, **II6** and **II7** could excellently control youth-and-old age, velvet leaf, foxtail, and barnyard grass at 18.5 g/ha active substance. **II5**, **II10**, **III2**, and **III4** showed detective values of 100 for youth-and-old age and velvet leaf at 18.5 g/ha active substance and not good enough for foxtail and barnyard grass at low concentration.

Herbicidal activity results in field test (Table 3) showed that **II7** at 60 g/ha active substance showed roughly the same activity with bentazon (48%, water dispersible granule) at 1440 g/ha active substance. The detective value of control effect of **II7** at 60 g/ha active substance is 70% after 7 days treatment and 60% after 15 days treatment. Especially, 10% **II7** OF (oil miscible flowable concentrate) could excellently control arrowhead and showed better activity than 24% oxyfluorfen EC (emulsifiable concentrate). As shown in Table 4, the control effect of 10% **II7** OF showed 95, 100, and 100 at 150

**Table 3. Herbicidal Activity of II7 in Field Tests (Liaoning, China)**

| compd | concn g(a.i./ha) | control effect to dayflower and nightshade (%) | |
|---|---|---|---|
| | | 7 days | 15 days |
| II7 | 30 | 40 | 40 |
| | 60 | 70 | 60 |
| bentazon | 1440 | 70 | 70 |

**Table 4. Herbicidal Activity of II7 in Field Tests (Heilongjiang, China)**

| compd | concn g(a.i./ha) | control effect to arrowhead (%) | | | control effect to rice (%) | | |
|---|---|---|---|---|---|---|---|
| | | 15 days | 30 days | 45 days | 15 days | 30 days | 45 days |
| 10% II7 OF | 100 | 95 | 97 | 95 | 0 | 0 | 0 |
| | 150 | 95 | 100 | 100 | 0 | 0 | 0 |
| 24% oxyfluorfen EC | 180 | 31 | 68 | 69 | 0 | 0 | 0 |

g(a.i./ha) after 15 days, 30 days, and 45 days treatment, respectively, while 24% oxyfluorfen EC showed detective values of 31, 68, and 69 for arrowhead at 180 g(a.i./ha) after 15 days, 30 days, and 45 days treatment, respectively. Meanwhile, **II7** and oxyfluorfen could not control rice and showed high security to rice.

In summary, a series of novel substituted 3-(pyridin-2-yl)benzenesulfonamide compounds were designed and synthesized by intermediate derivatization methods. The compounds (**II6**, **II7**, **II8**, **II9**, **II10**, **II11**, **III2**, **III3**, **III4**, and **III5**) showed higher activity than the lead compound at the 37.5 g/ha active substance using herbicidal activity assay in glasshouse tests, and the activity of **II6**, **II7**, **III2**, and **III4** proved roughly equivalent to the saflufenacil and better than 95% sulcotrione at the same concentration. The result of the herbicidal activity assay in field tests in Liaoning showed that **II7** could effectively control dayflower and nightshade. The activity of **II7** at 60 g/ha active substance proved roughly equivalent to bentazon at 1440 g/ha active substance. Meanwhile, the herbicidal assay in field tests in Heilongjiang showed 10% **II7** OF could excellently control arrowhead. Compound **II7** excited better activity than oxyfluorfen and security to rice. Our results suggest that **II7** may be a novel compound candidate for potential herbicide. This study will be useful for the design of new herbicides for weed control.

## EXPERIMENTAL PROCEDURES

**Materials.** Sodium hydroxide (AR), acetonitirile (HPLC), methanol (GC), ethyl acetate (GC), isopropyl alcohol (AR), silver chloride, and nitric acid were purchased from Loba Chemie. Commercially available P25-$TiO_2$ (size = 30−50 nm, anatase phase = 70%, rutile phase = 30%, surface area = 50 $m^2$ $g^{-1}$) and imidacloprid were obtained from Degussa Corp., Germany, and Ravi Organics Pvt. Ltd. (Mumbai), India, respectively. Standard $CO_2$ gas (200 ppm) with $N_2$ as a base was obtained from Centurion Scientific Pvt. Ltd., New Delhi, India. Sodium nitrite, sodium nitrate, and sodium chloride were used as standards of nitrite, nitrate, and chloride ions, respectively, and were obtained from Sigma-Aldrich. All of the chemicals were used without further purification.

**Synthesis, Characterization, and Photoactivity of Bare and Ag-Loaded TNT.** TNT were prepared through the hydrothermal route using P25-$TiO_2$ as reported[7,8] by our group. Surface modification of TNT by Ag loading (0.2−1.0 wt %) was carried out by irradiating (125 W Hg arc lamp) the deaerated solution (50% v/v isopropyl alcohol) of TNT and $AgNO_3$ (equivalent to 0.2, 0.5, and 1.0 wt % of Ag) as reported[7,8] recently by our group. Catalysts thus obtained are termed 0.2-Ag-TNT, 0.5-Ag-TNT, and 1.0-Ag-TNT, respectively.

The photocatalytic activity of the as-prepared catalysts was carried out in a test tube (rubber capped) by taking 5.0 mg of catalysts and 5 mL (50 ppm) of aqueous solution of imidacloprid under UV light irradiation for various time intervals. The reaction solution was analyzed by HPLC (Agilent-LC1120) equipped with a UV detector (at $\lambda$ = 270 nm) having a C-18 column (BDS, Qualigens) of dimensions 250 mm × 4.6 mm and particle size of 5 $\mu$m using acetonitrile : water :: 80:20 as mobile phase (1 mL/min), at ambient temperature, using a 20 $\mu$L injection volume. The $CO_2$ evolution was determined by injecting 1 mL of gaseous mixture from the reaction vessel (gastight test tube) into a gas chromatograph (GC, NUCON-5765) using a Propak-Q column with nitrogen as carrier gas (30 mL/min) and thermal conductivity detector. The column oven was maintained at 40 °C, whereas the injector and detector were at 70 and 80 °C, respectively. Identification of the intermediates formed during photooxidation of IMI was carried out using a gas chromatograph (45X-GC)−mass spectrometer (MS-Scion-45P), by injecting 1 $\mu$L of extracted sample (Supporting Information, Scheme 1) on a HP-5MS column (15 m × 0.25 mm × 0.25 $\mu$m), with helium gas (1 mL/min) as a carrier. The oven was programmed from 60 °C (5 min hold) to 240 °C at 6 °C/min, whereas the transfer line and injector were kept isothermally at 250 and 275 °C, respectively, and the identified intermediates are termed I-1−I-8 hereafter. The formation of inorganic anions (nitrate, nitrite, and chloride) has been quantitatively estimated by injecting 100 $\mu$L of the sample into an ion chromatograph equipped with a Waters 501 pump, a Waters 431 conductivity detector, and an ion pack (50 mm × 4.6 mm, Metrhom) column using methanol : water :: 60:40 as mobile phase at 0.6 mL/min.

## RESULTS AND DISCUSSION

Morphological analysis of TNT (Figure 1) reveals the formation of open-ended straw-like nanotubes having length (L) = 80−115 nm and diameter (D) = 8−13 nm and has been reported by our group.[7,8] The Ag nanoparticles of narrow size (3−5 nm) distribution at the surface of many TNT particles can be distinctly noted for the 0.5-Ag-TNT sample.

The time course PCA of bare and Ag-loaded TNT in relation to P25 is shown in Figure 2. It is observed that TNT exhibited

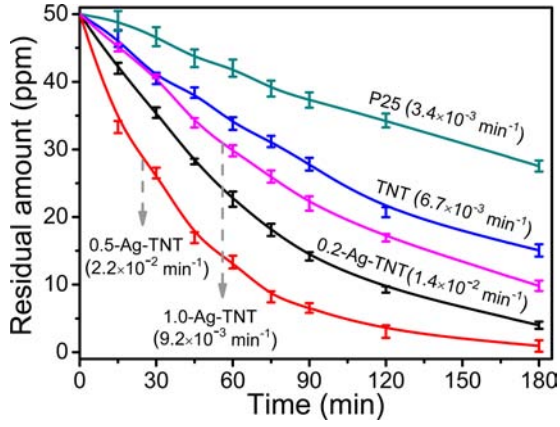

**Figure 2.** Time course study and pseudo-first-order decay constants for photocatalytic degradation of imidacloprid using various catalysts. Error bars represent standard deviation from three replicate experiments.

higher activity than P25 and is consistent with our[7,8] and other previous papers.[3−5] However, Ag-loading increases the activity of TNT up to 0.5 wt % for the degradation of IMI, and thereafter its activity decreases. Photooxidation of IMI was found to follow pseudo-first-order kinetics (Supporting Information, Figure S1) with the highest value of apparent rate constant ($k$) of 2.2 × $10^{-2}$ $min^{-1}$ for 0.5-Ag-TNT catalyst, and the half-life of IMI found (Supporting Information, Table 1) was ∼32 min, notably much lower in relation to that of TNT (∼103 min) or P25 (∼204 min) catalysts, under similar reaction conditions.

Time course GC-MS (Figure 3) analysis showed a gradual decrease in peak height for IMI along with the appearance of some new peaks, each belonging to a different intermediate. Some of these intermediates were identified by their mass spectra (Figure 4). There is a complete disappearance of peak

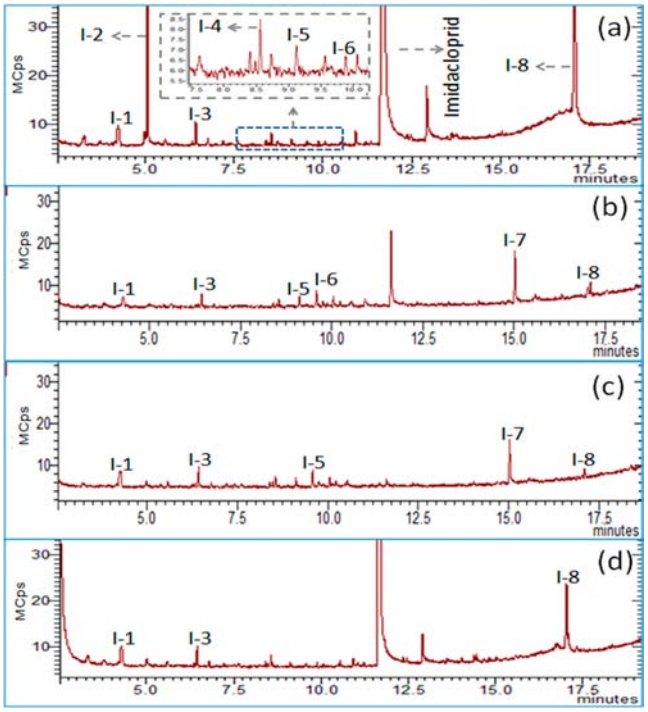

**Figure 3.** Gas chromatograms for identified intermediates (I-1−I-8) obtained after photocatalytic degradation of imidacloprid using 0.5 wt % Ag-photodeposited sodium titanate nanotubes after (a) 30 min, (b) 120 min, and (c) 180 min in comparison to (d) bare sodium titanate nanotubes after 180 min. (Inset) Corresponding enlarged view.

corresponding to IMI (at retention time ($R_t$) = 11.2 min, Figure 3) after 180 min of its photooxidation in the presence of 0.5-Ag-TNT catalyst; however, its presence was observed when studied with bare TNT under similar experimental conditions, confirming the improved activity of the former catalyst.

The quantitative estimation for $CO_2$ formation (Figure 5) during degradation of IMI by various catalysts was found to follow trends similar to those of its photooxidation. The highest amount of $CO_2$ formation (Supporting Information, Table 2) by 0.5-Ag-TNT catalyst with highest ($2.4 \times 10^{-3}$ $min^{-1}$) pseudo-first-order rate constant (Supporting Information, Table 3) corresponds to ∼70% of its actual mineralization despite its complete oxidation. This incomplete mineralization of IMI is because of the existence of some intermediates found (Figures 3 and 4) even after 180 min of its photooxidation.

Investigation for the fate of heteroatoms showed that the amounts of inorganic ions formed (Supporting Information, Figure S2) by 0.5-Ag-TNT are higher than those for P25 (Figure 6). Moreover, the amount of inorganic ions increases with increase in the time of irradiation, again confirming the mineralization of IMI during its photodegradation.

The chemical equation (eq 1) obtained from these results is found to deviate from stoichiometrically balanced eq 2, evidencing incomplete mineralization of IMI. The increase in the amount of nitrate ion formation with irradiation time is probably due to mineralization of the imidazole or pyridine-substituted ring(s). These results are in correlation with a previous study[27] for the dissipation of cyrpoconazole, where the nitrogen atoms present in the triazole moiety were found to decompose to nitrate and ammonium ions.

$$C_9H_{10}N_5O_2Cl + \frac{5}{2}O_2 \xrightarrow[h\nu\ (180\ min)]{0.5\ wt\%\ Ag\text{-}TNT} 2.88CO_2 + 0.04NO_2^- + 0.62NO_3^- + 0.6Cl^- + {}^{\bullet}intermediates \quad (1)$$

$$C_9H_{10}N_5O_2Cl + \frac{33}{2}O_2 \rightarrow 9CO_2 + 5NO_3^- + Cl^- + 6H^+ + 2H_2O \quad (2)$$

The PCA of TNT with Ag depositions was enhanced remarkably, certainly with an optimum amount (0.5 wt %) of the silver. With a greater amount of Ag photodeposition, the metal would rapidly become the recombination center for electron/hole ($e^-/h^+$) pairs and consequently diminish the PCA. Moreover, Ag being a plasmonic[28] nanostructure supports the formation of resonant surface plasmons in response to a photon flux that in turn could yield a high concentration of $e^-/h^+$ pairs in Ag-TNT samples. The formation of such plasmonic nanostructures also allows the selective formation of $e^-/h^+$ pairs at the interface of Ag-TNT, which could readily separate these carriers from each other and easily migrate[28−30] to the surface, where they can carry out PCA. Loaded Ag is well-known[28,31] to improve the adsorption capacity of $TiO_2$ for molecular oxygen; therefore, it can scavenge more conduction band electrons by the formation of highly oxidative superoxide radicals, whereas $h^+$ reacts with absorbed surface −OH groups and/or $H_2O$ molecules to form hydroxyl radicals possessing high oxidizability and causing the improved PCA of Ag-loaded TNT nanoparticles.

The formation of a variety of intermediates during the photooxidation of IMI suggests various possible attack positions for the hydroxyl radical leading to the formation of intermediates (Figure 7). The primary attack sites by the hydroxyl radical during photooxidation of IMI yielded I-2 and I-4 by cleavage of the N−N bond between the N1 and N2 positions and of the C−N bond at the C-1 position. The intermediate I-2 thus formed could be degraded to I-6 via attack of the hydroxyl radical on the C−N bond of the $-CH_2-N-$ moiety. On the other hand, intermediate I-4 (primary alcohol) is oxidized to the corresponding acid (I-5). The formation of carboxylated compounds has been observed during the photocatalytic degradation pesticides such as for cyproconazole[33] (fungicide) that has triazole and chlorobenzene moieties in its structure. Alternatively, hydrolysis, which is often reported[34−36] during the photocatalytic degradation of pesticides, could result (Scheme 1a) in the formation of intermediate I-8. The successive oxidation of I-8 on the methyl group at the C-2 position of the imidazole ring could lead to the formation of I-3. The formation of intermediate I-6 is proposed to be via fragmentation of I-3 and is reported to be an intermediate product[26] of IMI photooxidation. Interestingly, I-7, formed (Scheme 1b) by the removal of Cl and $NO_2$ radicals from IMI, has been identified in the present study using Ag-loaded TNT samples. This could be attributed to the facts that (i) the I-7 intermediate formed remained below the detection limit of GC-MS and (ii) it may have formed/consumed/transformed into some other product during the photooxidation. The formation of I-7 via the proposed radical mechanism is also suggested by Donald et al.[37] during the gas phase fragmentation of IMI. Because there is evolution of $CO_2$ and formation of inorganic ions during the photooxidation of IMI, it is possible that intermediates might further oxidize to

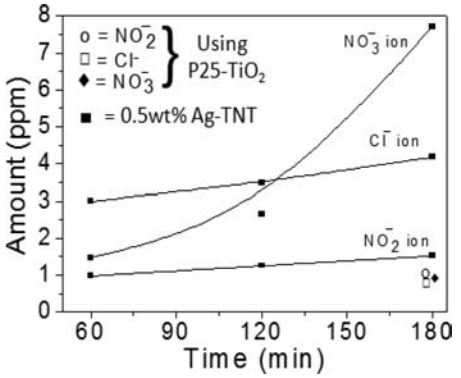

**Figure 6.** Evolution of inorganic ions during photooxidation of imidacloprid by 0.5 wt % Ag-photodeposited TNT and bare P25.

smaller compound(s) and eventually become mineralized. Similar to identified intermediates, previous studies also identified these intermediates[26] during the photooxidation of IMI using P25. However, the extent of IMI mineralization was 14−29%[32] and is 1.7 times less than in the present study, revealing the improved efficiency of as-prepared catalysts relative to P25.

The proposed mechanism is further supported by kinetic analysis of the intermediates (Figure 8) and by relating the ratio of peak area at any time ($area_{(t)}$) to the maximum peak area ($area_{(max)}$), due to the unavailability of authentic intermediates. Intermediates I-2, I-4, and I-8 appear promptly, and the concentration becomes maximum after 30 min before being degraded, whereas their corresponding transformed intermediates, namely, I-1, I-5, I-3, and I-6, were found to be at their maximum level after 15−30 min of photooxidation of I-2, I-4, and I-8 intermediates, respectively. Afterward, intermediates start disappearing and within 180 min of photooxidation are almost leveled off, except for I-2 and I-5. The existence of heteroatoms containing intermediates (I-2 and I-5) even after complete degradation of IMI signifies their stability in the reaction medium and is believed to be a cause for the incomplete mineralization for IMI. The results of the present are also supported by the results of Lhomme et al.[33] and

dx.doi.org/10.1021/jf5041614 | J. Agric. Food Chem. 2014, 62, 12497−12503

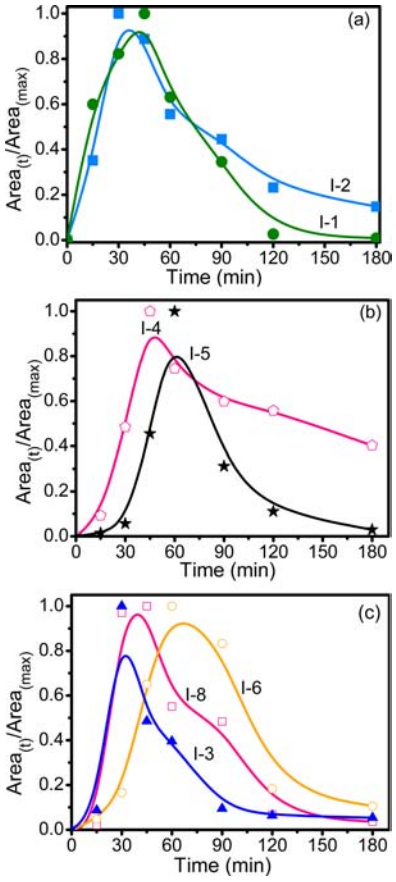

**Figure 8.** (a–c) Time evolution for the intermediates formed during the photooxidation of imidacloprid.

leveling off the intermediates with time during the photocatalytic degradation of cyproconazole and fenhexamid, respectively, in the presence of $TiO_2$.

Thus, Ag-photodeposited TNT is an efficient catalyst for the decomposition of IMI to $CO_2$ and inorganic ions, and it notably reduces the half-life of IMI to that found by most photoactive P25-$TiO_2$. Although structural parameters of TNT were found to play a vital role in the improved decay constants, a detrimental influence of sodium atoms was not observed in the present study. The formation of a number of intermediates identified revealed the complexity of the photocatalytic process, suggesting the existence of various oxidation routes and nonspecific attack of hydroxyl radicals that resulted in multistep and interconnected pathways for decomposition of IMI. The fate of heteroatoms suggests the partial mineralization to inorganic ions and is manifested by the presence of heteroatoms containing persistent intermediates even after the complete degradation of IMI.

Recently, we developed a novel emulsion and biomimetic dual-templating approach to synthesize oil-core silica-shell nanocapsules with tunable shell thickness.[29] Bifunctional SurSi peptide (Ac-MKQLAHSVSRLEHARKKRKKRKKRKKGGGY-$CONH_2$) was designed by modularizing a surface active peptide sequence (Sur module, MKQLAHSVSRLEHA) with a sequence for biosilicification (Si module, RKKRKKRKKR KKGGGY). Typically, oil-in-water (O/W) nanoemulsions are formed with a pharmaceutically safe oil, Miglyol 812, dispersed in the SurSi aqueous solution. Then a silica precursor tetraethoxysilane (TEOS) is added to facilitate the biosilicification at the O/W interfaces forming the oil-core silica-shell nanocapsules under room temperature, and at nearly neutral pH without use of any toxic chemicals. In contrast to the chemical methods mentioned above, our method is more biocompatible and environmentally friendly. An additional advantage of using peptide biosurfactant is the ability to be produced renewably at large scale and relatively low cost using biological expression.[30,31] Furthermore, our dual-templating approach offers easy preloading of active components by simply dissolving in the oil phase with a high loading capacity. It has been demonstrated that fipronil saturated in Miglyol 812 (at 10 $mg{\cdot}mL^{-1}$) was easily encapsulated in silica nanocapsules by a preloading technique and without the need for template removal.[29]

Fipronil (5-amino-1-[2,6-dichloro-4-(trifluoromethyl)-phenyl]-4-[(trifluoromethyl)sulfinyl] pyrazole-3-carbonitrile) is a systemic insecticide commonly used as soil treatment, seed coating, or baits[32] due to its nonrepellent property, broad-spectrum activity against agricultural, forest, pastoral, domestic and veterinary pests,[33] and high specificity for insect pests over mammalians.[34] The biochemical mode of action of fipronil is by blocking $\gamma$-aminobutyric acid (GABA) receptor of the GABA-gated chloride channel, thereby disrupting central nervous system activity and, at a sufficient dose, causing death.[34] It has low water solubility (~2 $\mu g{\cdot}mL^{-1}$ at 25 °C) and low Henry's constant ($6.6 \times 10^{-6}$ $m^3{\cdot}atm{\cdot}mol^{-1}$ at 25 °C), suggesting low volatility, and its soil organic carbon partition coefficient ($K_{oc}$) of 727 indicates low mobility in soil and, hence, low potential for groundwater contamination.[32,35]

In this study, sustained release of fipronil *in vitro* and *in vivo* from biocompatible oil-core silica-shell nanocapsules were investigated and compared. Fipronil-encapsulated silica nanocapsules with different shell thicknesses were synthesized using the dual-templating approach aforementioned. The *in vitro* release of fipronil was studied in water. The efficacy of the fipronil-encapsulated silica nanocapsules was evaluated by conducting *in vivo* laboratory tests, i.e., direct- and feeding-treatments, against economically important subterranean termites (i.e., *Coptotermes acinaciformis*). Subterranean termites cause substantial damages to cultivated plants, wooden structures, pastures, forests and other agricultural crops.[36] Based on the sales estimation of insecticides in 2010, the worldwide annual control and repair costs can reach US$40 billion with subterranean termites accounted for 80% of the costs.[37] This study would thus be expected to bring significant impact in agricultural fields.

## MATERIALS AND METHODS

**Chemicals.** SurSi peptide (Ac-MKQLAHSVSRLEHARKKRKK RKKRKKGGGY-$CONH_2$, $M_w$ 3632 $g{\cdot}mol^{-1}$) was custom synthesized by Peptide 2.0 Inc. (Chantilly, VA, USA) with purity >95% and was lyophilized prior to use. Fipronil in a powder form ($C_{12}H_4Cl_2F_6N_4OS$, $M_w$ 437.15 $g{\cdot}mol^{-1}$, mp 196−201 °C, and $d$ 1.55 $g{\cdot}cm^{-3}$) was of analytical standard obtained from Sigma-Aldrich. Miglyol 812 was purchased from AXO Industry S.A. (Wavre, Belgium) and was passed through heat-activated silica gel (Sigma-Aldrich) prior to use. Termidor (9.1% fipronil in a form of suspension concentrate) was obtained from BASF Australia Ltd. Water with >18.2 MΩ·cm resistivity was obtained from a Milli-Q (Millipore, Australia) system with a 0.22 $\mu$m filter. Other chemicals were of analytical grade purchased from either Sigma-Aldrich or Merck and used as received.

**Synthesis.** Oil-core silica-shell nanocapsules were synthesized using an emulsion and biomimetic dual-templating approach as we previously reported.[29] Briefly, fipronil was dissolved in Miglyol 812 oil at a concentration of 0.05 $mg{\cdot}mL^{-1}$ or 1 $mg{\cdot}mL^{-1}$, and then the fipronil-loaded oil was added into a solution of SurSi peptide (400 $\mu$M) containing $ZnCl_2$ (800 $\mu$M) in sodium 4-(2-hydroxyethyl)-1-piperazine ethanesulfonate (HEPES) buffer (25 mM, pH 7), and the mixture was sonicated at 10 W (Branson Sonifier 450 ultrasonicator) to obtain O/W nanoemulsions which were dialyzed against HEPES buffer (25 mM, pH 7.5) at 4 °C for 20 h to remove residual peptide in the bulk solution. Then the nanoemulsions (pH 7.5) were mixed with tetraethoxysilane (TEOS) at a concentration of 16 $\mu$mol, 32 $\mu$mol or 96 $\mu$mol under stirring at room temperature for 30 h to form fipronil-encapsulated silica nanocapsules having three different shell thicknesses. Subsequently, the nanocapsules were dialyzed against water at 4 °C for 20 h to remove the residual TEOS and prevent further growth of the silica shell.

**Characterization.** *Encapsulation Efficiency.* The suspensions of fipronil-encapsulated silica nanocapsules were freeze-dried for 20 h, subsequently mixed with water and sonicated at 20 W (Branson Sonifier 450 ultrasonicator) for 60 s to finely disperse the nanocapsules. Subsequently, acetonitrile was added into the suspensions with final acetonitrile concentration of 60 v/v%, and vigorously stirred at room temperature for up to 72 h. At different time intervals, the supernatants were collected by centrifugation, then fresh acetonitrile (60 v/v%) was added to the pellets to repeat the release of fipronil from the nanocapsules until no residual fipronil in the supernatants was detected via reversed-phase high-performance liquid chromatography (RP-HPLC).

*Reversed-Phase High-Performance Liquid Chromatography (RP-HPLC).* Concentrations of fipronil were assayed by RP-HPLC using a Shimadzu system equipped with a Jupiter C18 column (5 $\mu$m, 300 Å, 150 mm × 4.6 mm). Mobile phase A was water containing 0.1 v/v% phosphoric acid, while phase B contained 90 v/v% acetonitrile and 0.1 v/v% phosphoric acid. The elution gradient was increased from 50% B to 70% B over 20 min at a monitoring wavelength of 220 nm. The concentration of fipronil was determined based on the peak area at retention time of approximately 14.5 min according to calibration curve obtained from standard solution of fipronil in acetonitrile solution (60 v/v%).

*Fourier Transform-Infrared (FT-IR) Spectroscopy.* Silica nanocapsules without and with fipronil in the oil cores were prepared as described previously. The nanocapsules were washed twice with water and subsequently freeze-dried. FT-IR spectra of lyophilized SurSi peptide and the nanocapsules were determined by using a PerkinElmer Spectrum 100 FT-IR Spectrometer equipped with a universal attenuated total reflection (ATR) attachment. Spectra data were collected in the transmission mode by averaging 135 scans over wavenumber range 4000−600 $cm^{-1}$ at a spectral resolution of 4 $cm^{-1}$.

*Dynamic Light Scattering (DLS).* Size distributions of nanoemulsions and nanocapsules were determined by DLS using Malvern Zetasizer Nano ZS (Malvern Instrument Ltd., UK) at a scattering angle of 173° and a temperature of 25 °C. Samples were diluted by a factor of 100 prior to the measurements to avoid multiple scattering effects.

*Transmission Electron Microscopy (TEM).* Morphology of the fipronil-encapsulated silica nanocapsules was characterized by depositing the suspension (2 $\mu$L) onto Formvar-coated copper grids (ProSciTech Pty Ltd., Australia) and was then visualized via TEM (JEOL 1010, accelerating voltage of 100 kV). Size of the nanocapsules was analyzed using iTEM software (version 3.2, Soft Imaging System

GmbH) equipped with the TEM. Structure of the silica shell was determined using selected area electron diffraction (SAED) technique via high-resolution (HR) TEM (JEOL 2100, accelerating voltage of 200 kV).

***In Vitro* Release Study of Fipronil into Water.** Silica nanocapsules with three different shell thicknesses encapsulating 1 mg·mL$^{-1}$ fipronil in Miglyol 812 were used to study the release profile of fipronil *in vitro*. The releases of fipronil from the silica nanocapsules to water were carried out by stirring the suspensions at room temperature for up to 142 h. At different time intervals, aliquots were taken, replaced with fresh water and centrifuged to obtain clear supernatants which were then analyzed using RP-HPLC.

***In Vivo* Study against Termites.** Termites (*C. acinaciformis*) were collected from field site in Esk (Queensland, Australia). Plastic containers filled with moist wood were inverted (lid off) onto a timber-filled trench known to contain termite infestation, and each container was then covered with insulating material secured with soil. After harvesting, actively moving termites were carefully selected from the containers for *in vivo* tests.

*Direct Treatment.* Six samples, including water, nanoemulsions, silica nanocapsules (encapsulating 0.05 mg·mL$^{-1}$ fipronil in Miglyol 812) with three different shell thicknesses (8, 25, and 44 nm), and Termidor were used in the direct treatment, and they all contained the same final fipronil concentration except for the water sample. Water was used as control, and nanoemulsion was used as nanocapsules with zero silica-shell thickness. All six samples were used in five replicates for the direct treatment. Prior to the treatment, termites were placed in a group of ten termites in a Petri dish (92 mm × 16 mm), and incubated at 2 °C for 2 min to slow their movement. Each of the fipronil formulations or water (5.5 μL) was topically applied on the dorsal thorax of the worker termite. The termites were then transferred to clean Petri dishes containing a filter paper (42.5 mm, Whatman). The Petri dishes were placed into a controlled-environment chamber (65 cm × 47 cm × 37.5 cm) containing a thermometer, a lid and a 11.5-L metal container with water and heater to maintain the temperature at 28 ± 1 °C and high humidity, and, once covered with insulating material, total darkness (except during observation). At different time intervals, the Petri dishes were removed from the chamber, and the lids were opened with the least possible disturbance in order to examine termite response (mortality). A termite was considered dead when it was on its back or side (not supported by legs) and not able to move even after prodding with a soft brush.

*Feeding Treatment.* Silica nanocapsules (encapsulating 1 mg·mL$^{-1}$ fipronil in Miglyol 812) with the thickest shell (44 nm) were used in the feeding treatment. Termidor with the same final fipronil concentration and water were used as controls. Each fipronil formulation and water samples were used in four and two replicates for the feeding treatment, respectively. To mimic natural environment of termite colonies, a 750 mL container was filled with *Nasutitermes magnus* mound material (150 g) which was roasted (200 °C, 60 min), ground and mixed with water (50 g) prior to use. A clear vinyl tubing (150 mm × 6 mm) was connected from the container to a 70 mL feeding vial containing α-cellulose (20 g) bait with a moisture content of 70 w/w%. Then termites (7.5 g ≈ 1500 worker and soldier termites) were placed into the container. Each of the assembled feeding devices was placed into a controlled-environment chamber having dimensions and conditions similar to that in the direct treatment (described above). The termites in the ten assemblies were allowed to acclimatize to these conditions for 4 days and began feeding on the baits as indicated by the presence of enclosed tunnels and chambers built in the baits. Then, 0.5 mL of the sample (water, Termidor or the nanocapsule) was transferred into each feeding vial. The assemblies were removed from the chamber and observed daily with the least possible disturbance in order to detect movement of living termites using a TermatracT3i device (Termatrac Pty Ltd., Australia). Lack of movement indicated 100% mortality of termites and inspections in the containers were conducted to confirm. During the treatment, termite groups in one container connected to Termidor-treated bait and in two containers connected to nanocapsule-treated baits remained alive for up to 8 days as the tube entrances to the vials were blocked with mud built by the termites. These containers were not considered for further study. Therefore, three treatment results were included in the analysis for the Termidor-treated baits and two treatment results for the nanocapsule-treated baits. The termites in two containers connected to water-treated baits survived throughout the study.

## RESULTS AND DISCUSSION

**Encapsulation of Fipronil in Silica Nanocapsules.** Fipronil was easily dissolved in Miglyol 812 due to its high solubility in the oil (i.e., 10 mg·mL$^{-1}$).[29] The fipronil-loaded oil was emulsified in the presence of SurSi peptide via sonication, and nanoemulsions with narrow droplet size distribution were obtained due to the presence of the surface active Sur module[29] (Figure 1) in the emulsifying peptide. Following addition of the

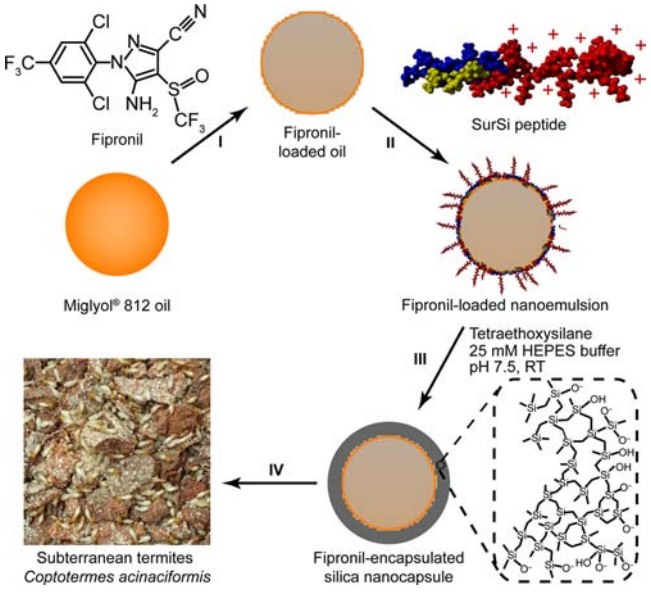

**Figure 1.** Illustration of the synthesis of fipronil-encapsulated silica nanocapsules formed using an emulsion and biomimetic dual-templating approach for sustained-release agroformulations against termites. Step (I), solubilization of fipronil in Miglyol 812 oil; step (II), sonication of the oil in SurSi peptide solution to form fipronil-loaded nanoemulsions; step (III), addition of tetraethoxysilane (TEOS) in the nanoemulsions to form a silica shell encapsulating the nanoemulsion core; step (IV), *in vivo* efficacy tests of the fipronil-encapsulated silica nanocapsules against economically important subterranean termites.

silica precursor tetraethoxysilane (TEOS) to the nanoemulsions, silica shell encasing the nanoemulsion core was formed at near-neutral pH and room temperature without using any toxic chemicals. The biosilicification process at the oil–water interface was due to the catalytic role of densely packed cationic arginine (R) and lysine (K) residues of Si module (RKKRKKRKKRKKGGGY) as well as polar residues of Sur module exposed toward the bulk aqueous solution that could induce hydrolysis of TEOS and interfacial polycondensation of the hydrolysis products i.e., silanol (≡Si–OH) and negatively charged silanolate (≡Si–O$^-$)[29] (Figure 1).

In this study, fipronil dissolved in Miglyol 812 oil at a concentration of 0.05 mg·mL$^{-1}$ or 1 mg·mL$^{-1}$ was encapsulated in silica nanocapsules and used for the sustained release study *in vitro* and *in vivo*. The amount of fipronil encapsulated in silica nanocapsules was determined based on the lethal dose of

fipronil sufficient to eliminate a termite for the *in vivo* tests. It has been reported that the lethal dose of fipronil for *Coptotermes* spp. is in the range of 2−10 ng per termite.[38,39] Based on this consideration, the encapsulated fipronil which was dissolved in Miglyol 812 at concentrations of 0.05 mg·mL$^{-1}$ and 1 mg·mL$^{-1}$ was equivalent to 1 ppm and 20 ppm in the silica nanocapsule suspensions and, at an applied volume, would give fipronil dose of around 6 ng/termite in the direct- and feeding treatments, respectively.

The encapsulation efficiencies (%*EE*) of fipronil in silica nanocapsules were determined by monitoring the concentration of fipronil released in acetonitrile solution (60 v/v%) over a period of time compared to initial concentration of fipronil dissolved in Miglyol 812 oil. Higher solubility of fipronil in acetonitrile (60 v/v%) i.e., 71.5 mg·mL$^{-1}$ than in Miglyol 812 i.e., 10 mg·mL$^{-1}$ promotes easy partition of the fipronil and its diffusion out of the silica nanocapsules. The results of practical encapsulation efficiencies of fipronil were calculated using eq 1:[29]

$$\%EE = \frac{\sum_{j=1}^{n} (C_f V_f)_j}{C_i V_i} \times 100\% \quad (1)$$

where $C_f$ (mg·mL$^{-1}$) and $V_f$ (mL) are the fipronil concentration released in acetonitrile solution and volume of the acetonitrile solution, respectively, $C_i$ (mg·mL$^{-1}$) and $V_i$ (mL) are the initial fipronil concentration in Miglyol 812 and volume of the Miglyol 812, respectively, and $n$ is the number of repeated-release of fipronil. At an initial fipronil concentration of 0.05 mg·mL$^{-1}$, %*EE* of fipronil in silica nanocapsules obtained at reactions with 16 $\mu$mol, 32 $\mu$mol and 96 $\mu$mol of TEOS were 72.8%, 73.2%, and 73.6%, respectively, while similar %*EE* of 71.6%, 72.2%, and 72.9%, respectively, were obtained when initial fipronil concentration of 1 mg·mL$^{-1}$ was used. The encapsulation of fipronil in the silica nanocapsules demonstrated high encapsulation efficiency which is suitable for agricultural applications.

**Characterization of Silica Nanocapsules Containing Fipronil.** To determine the molecular components of fipronil-encapsulated silica nanocapsules, SurSi peptide and silica nanocapsules without and with fipronil in the oil cores were analyzed using Fourier transform-infrared (FT-IR) spectroscopy, and the results were compared in Figure 2. For SurSi peptide, four characteristic peaks of the peptide backbone were observed (Figure 2a) which are assigned to amide A (N−H stretch), amide B (N−H stretch), amide I (C═O stretch), and amide II (C−N stretch and N−H in-plane bend) at 3284, 3071, 1648, and 1542 cm$^{-1}$, respectively.[40] The functional groups of peptide side chains can also be identified (Figure 2a) i.e., peak at 1298 cm$^{-1}$ corresponds to O−H deformation of hydroxyl group of serine (S), shoulder at 1248 cm$^{-1}$ and doublet at 837 and 800 cm$^{-1}$ are associated with C−O stretch and phenyl ring of tyrosine (Y), respectively, and doublet at 1180 and 1130 cm$^{-1}$ can be attributed to $NH_3^+$ rocking of lysine (K).[40,41] FT-IR spectrum of the silica nanocapsules without fipronil (Figure 2b) shows a broad signal centered at 3330 cm$^{-1}$ which reflects the vibration of O−H stretching of silanol group Si−OH. A strong absorption band at about 1060 cm$^{-1}$, with a shoulder at 1160 cm$^{-1}$, and a band at 780 cm$^{-1}$ correspond to asymmetric and symmetric Si−O−Si stretching vibrations of siloxane group, respectively. An absorption shoulder at 960 cm$^{-1}$ arises from the Si−O$^-$ stretching of Si−OH. The major peaks of N−H stretch of peptide and other peptide side chains are

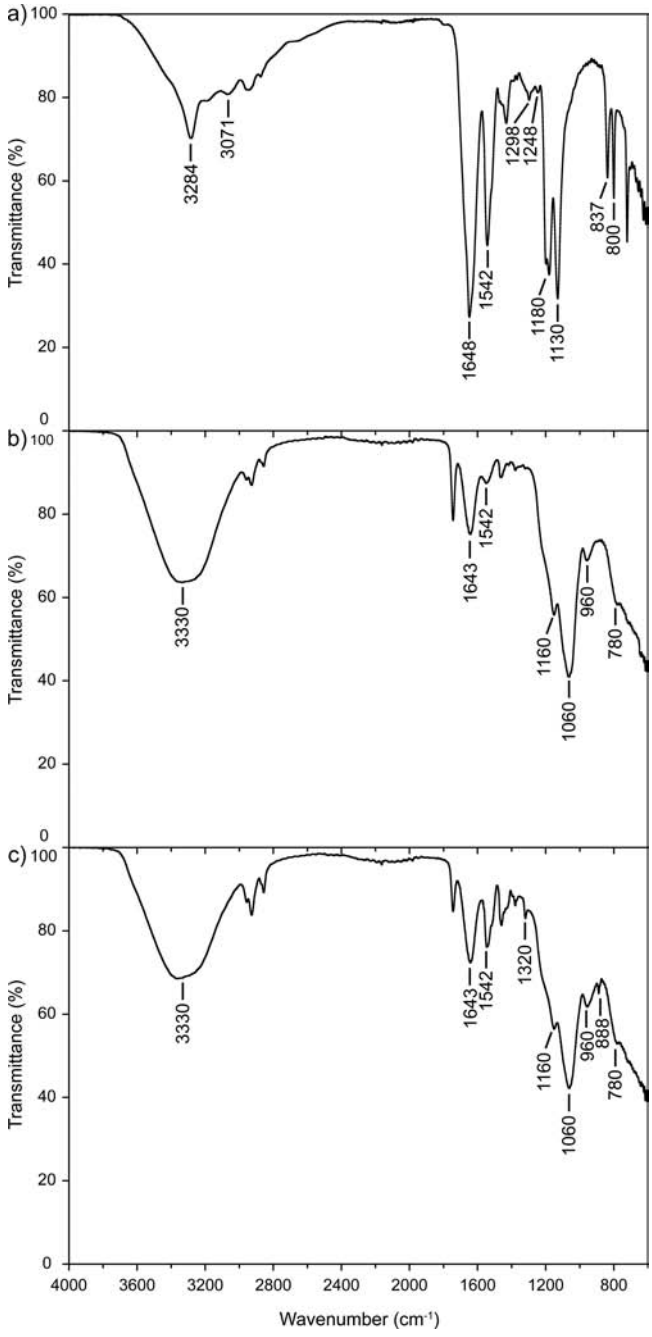

**Figure 2.** FT-IR spectra of (a) SurSi peptide, (b) silica nanocapsules without fipronil in the oil cores, and (c) fipronil-encapsulated silica nanocapsules.

overlapped by the characteristic bands of silica and thus are unobserved (Figure 2b). However, the presence of peptide in the silica nanocapsules can still be characterized by the absorption bands of amide I and amide II although the intensities are significantly reduced. The FT-IR spectrum of fipronil-encapsulated silica nanocapsules (Figure 2c) retained most of the major peaks of the silica nanocapsules without fipronil (Figure 2b). Additionally, new absorption bands appear and are clearly discernible at 1320 and 888 cm$^{-1}$ which can be attributed to $-CF_3$ stretching of trifluoromethyl group and C−H out-of-plane bending of benzene ring[42] of the fipronil molecule, respectively (Figure 2c). These vibrational frequen-

cies further verify the incorporation of fipronil into silica nanocapsules.

Morphology of silica nanocapsules can be visualized by using TEM without the need for staining or cryo-preservation. The TEM images showed morphology of a core−shell structure of fipronil-encapsulated silica nanocapsules having three different shell thicknesses (Figure 3a−c). In contrast, fipronil-loaded

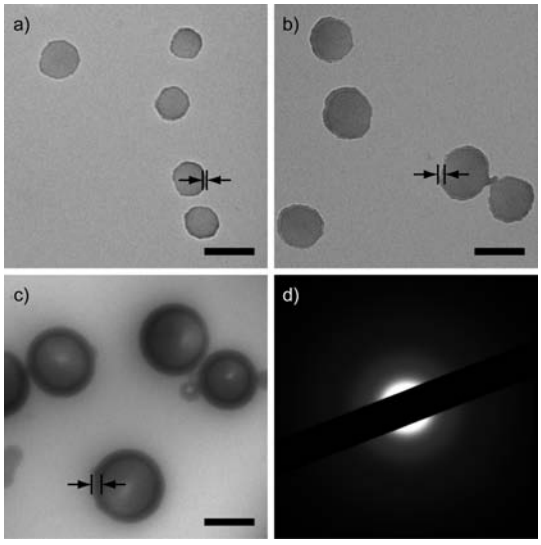

**Figure 3.** Fipronil-encapsulated silica nanocapsules with tunable shell thickness. (a−c) Representative transmission electron microscopy (TEM) images of fipronil-encapsulated silica nanocapsules having (a) 8 nm, (b) 25 nm, and (c) 44 nm shells. Scale bars are 200 nm. Arrows indicate the boundary of the silica shell. (d) Representative selected area electron diffraction (SAED) pattern of silica nanocapsules confirmed the amorphous state of the silica shell.

nanoemulsion having no silica shell was hardly observed in TEM as its structure was prone to disintegrate under high vacuum and electron beam irradiation (data not shown). The measured shell thicknesses, as determined by using TEM, of silica nanocapsules obtained at TEOS concentrations of 16 $\mu$mol, 32 $\mu$mol and 96 $\mu$mol were 8 nm, 25 nm, and 44 nm, respectively, while the outer diameters were 140 nm, 198 nm, and 288 nm, respectively. These values are consistent with our previously reported silica nanocapsules that encapsulated fipronil at concentration of 10 mg·mL$^{-1}$ in Miglyol 812.[29] Additionally, the representative selected area electron diffraction (SAED) of silica nanocapsules shows diffuse ring pattern (Figure 3d), indicating the amorphous structure of the silica shell. The formation of amorphous silica via peptides has also been reported for natural biogenic silica[43,44] and biomimetic silica.[45]

Dynamic light scattering (DLS) confirmed a size increase for silica nanocapsules in comparison with the nanoemulsion template (Figure 4). Furthermore, increasing TEOS concentrations corresponded to an increase in number-averaged diameters of the nanocapsules (Figure 4a−c). The number-weighted size distribution results showed that silica nanocapsules having 8, 25, and 44 nm shells have narrow size distributions (polydispersity index, PDI < 0.350).

**Fipronil Release Study *in Vitro*.** The release profiles of fipronil *in vitro* from silica nanocapsules with three different shell thicknesses encapsulating 1 mg·mL$^{-1}$ fipronil in Miglyol 812 i.e., 1F-NC8, 1F-NC25 and 1F-NC44 are shown in Figure

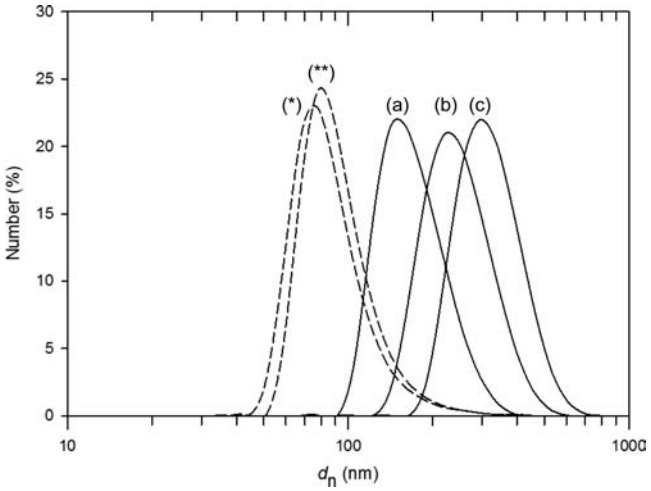

**Figure 4.** Number-weighted size distributions of fipronil-encapsulated silica nanocapsules and the nanoemulsion template. The measured number-averaged diameters ($d_n$) include silica nanocapsules having (a) 8 nm, (b) 25 nm, and (c) 44 nm shells, (*) fipronil-loaded nanoemulsions before reaction with TEOS, and (**) control fipronil-loaded nanoemulsions incubated over the reaction period.

5. The concentration of fipronil released in the water phase was normalized against the saturated concentration of fipronil in

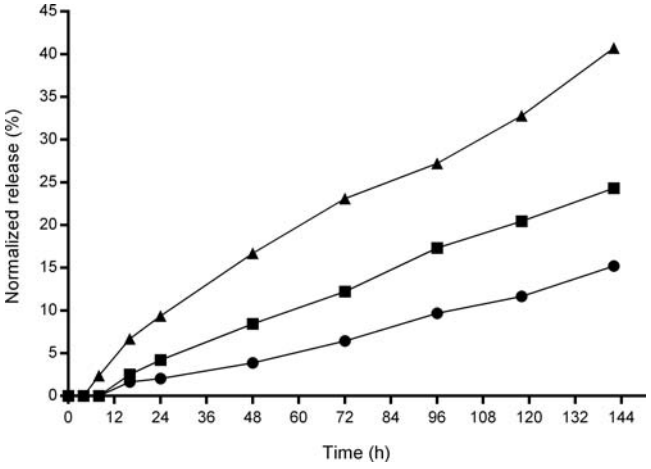

**Figure 5.** *In vitro* release profile of fipronil from silica nanocapsules having 8 nm (1F-NC8, ▲), 25 nm (1F-NC25, ■), and 44 nm (1F-NC44, ●) shells into water.

water considering the low solubility of fipronil in water (2 $\mu$g·mL$^{-1}$). The release of fipronil from 1F-NC8 was detected after 8 h of release study at 2.4%, while a longer lag time of 16 h was observed for fipronil released at 2.5% and 1.6% from silica nanocapsules having thicker shells i.e., 1F-NC25 and 1F-NC44, respectively (Figure 5). After 142 h, fipronil was released at percentages of 40.7%, 24.3% and 15.2% from 1F-NC8, 1F-NC25 and 1F-NC44, respectively. The rates of fipronil released in water show the order of 1F-NC8 > 1F-NC25 > 1F-NC44, demonstrating that increasing shell thickness resulted in an increased diffusion pathway and hence enhanced barrier to diffusion of fipronil across the silica shell, thus the slower release of fipronil.

**Fipronil Release Study *in Vivo*.** Sustained release of fipronil from silica nanocapsules was also investigated *in vivo*

against termites. Two experiments were carried out, including direct treatment and feeding treatment.

Direct treatment was demonstrated by topical application of six different formulations including water, Termidor, nanoemulsions (0.05F-NE), silica nanocapsules with three different shell thicknesses of 8 nm (0.05F-NC8), 25 nm (0.05F-NC25) and 44 nm (0.05F-NC44), on the dorsal thorax of worker termite *C. acinaciformis* (Figure 6). Rapid mortality was

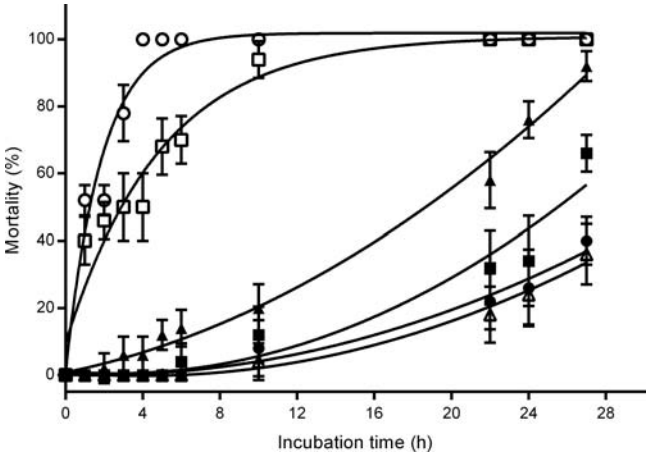

**Figure 6.** *In vivo* efficacy test via topical application on the dorsal thorax of worker termites. Fipronil-encapsulated silica nanocapsules having 8 nm (0.05F-NC8, ▲), 25 nm (0.05F-NC25, ■), and 44 nm (0.05F-NC44, ●) shells are tested in comparison with fipronil-loaded nanoemulsions without silica shells (0.05F-NE, □), Termidor (○), and water containing no fipronil (control, Δ). The lines are drawn to assist in reading the trends.

observed when termites were treated with commercial Termidor or fipronil-loaded nanoemulsions having no silica shells (0.05F-NE). The fipronil penetrated through the cuticle layer on the body surface of worker termites and eventually caused death depending the fipronil doses.[39] Termidor gave burst release of fipronil resulting in 50% mortality within the first hour and 100% mortality at 4 h (Figure 6). Fipronil-loaded nanoemulsions having no silica shells (0.05F-NE) exhibited a two-step release profile; a significant initial burst effect, with mortality of almost 50% within the first 4 h, and then more sustained release over 22 h (Figure 6). In contrast, silica nanocapsules showed sustained release as a result of the silica shell. First mortality was at 4 h (6%), 6 h (4%), and 10 h (8%) for silica nanocapsules having 8 nm (0.05F-NC8), 25 nm (0.05F-NC25) and 44 nm (0.05F-NC44) shells, respectively (Figure 6). Further, the termite mortality gradually increased in a way dependent on shell thickness suggesting that the silica shell provided an effective barrier for the controlled diffusion of the encapsulated fipronil, which corresponds well with the *in vitro* release study. The lag time, which was also observed in *in vitro* experiments, prior to termite mortality in the topical applications of silica nanocapsules strongly evidenced the sustained release of fipronil from the nanocapsules with no indication of burst release. Fipronil-encapsulated silica nanocapsules having 44 nm shell demonstrated the most significant delay in termite mortality and thus was chosen for the subsequent *in vivo* test.

We further evaluated the sustained release performance of fipronil-encapsulated silica nanocapsule having 44 nm shell (1F-NC44) *in vivo* by remote feeding treatment against *C. acinaciformis*. Prior to the treatment, groups of orphaned worker and soldier termites (≈1500) were allowed to adapt to the living conditions maintaining their biological activities in a container filled with nutritious materials at set temperature.[46] Food in the form of α-cellulose was supplied in peripheral feeding vials which were accessible through clear vinyl tubes. After 4 days, we observed that termites built mud and cellulose surrounding the interior space of the connector tubes as well as galleries within the baits, indicating that termites were responding to the α-cellulose. The α-cellulose in the feeding vials was then treated with water containing no fipronil, Termidor or 1F-NC44. As termites foraged in the feeding vials, they acquired and carried the α-cellulose back to the container, and inadvertently transferred it to other termites within the groups. These interactions could be through trophallaxis in which foraging worker termites feed other termites that do not or cannot forage on their own including soldier termites due to their anatomical and behavioral specializations.[47] Termidor-treated α-cellulose caused 100% mortality to termite groups after 3 days, whereas more delayed 100% mortality (6 days) was observed after treatment using nanocapsule-treated α-cellulose (Figure 7). The α-cellulose treated with water

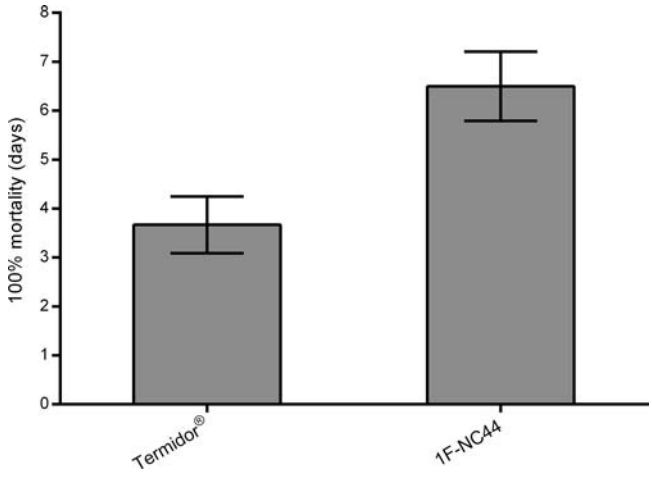

**Figure 7.** *In vivo* efficacy test via feeding treatment against groups of ≈1500 worker and soldier termites. The delayed 100% mortality of the termite groups caused by fipronil-encapsulated silica nanocapsules having a 44 nm shell (1F-NC44) is presented as compared to Termidor.

containing no fipronil in the feeding vials caused negligible termite mortality during the 8 days of the test. The feeding experiment results further confirmed the sustained release property of silica nanocapsules as a result of the presence of silica shell which plays a role as barrier to diffusion of fipronil.

Dead and decaying bodies of termites can elicit avoidance behavior of other termites,[48,49] and consequently any transmission through those termites is ineffective.[39] Therefore, the sustained release property of the fipronil-encapsulated silica nanocapsules is important to ensure constant exposure of fipronil to the termites in the colony until 100% mortality of the colony can be achieved. Furthermore, the more delaying insecticidal effect demonstrated by the silica nanocapsules as compared to the commercial fipronil formulation would be highly desirable, as it increases the likelihood of horizontal transfer of fipronil, hence allowing improved areawide control of larger populations of termite colonies.

## CONCLUSION

Biocompatible oil-core silica-shell nanocapsules synthesized using an emulsion and biomimetic dual-templating approach under environmentally friendly conditions were investigated as nanocarriers for the sustained release of fipronil insecticide. *In vitro* release studies of fipronil showed decreased release rate with increasing the shell thickness. *In vivo* direct treatment experiments using silica nanocapsules with three different shell thicknesses (8, 25, and 44 nm) against worker termites demonstrated that the time interval between the application of the nanocapsules and the occurrence of the termite mortality could be prolonged in a way dependent on silica-shell thickness as compared to the commercial formulation Termidor and fipronil-loaded nanoemulsions having no silica shells. The *in vivo* efficacy of 44-nm-shell nanocapsules against orphaned groups of ≈1500 worker and soldier termites by dispersing the nanocapsules in $\alpha$-cellulose feeding bait proved that the silica nanocapsules could be taken up from the bait vials by foraging workers, transmitted to recipient termites in the groups probably through horizontal transfer, and eventually caused 100% mortality of the termite groups in 6 days after the application, which was 3 days longer than the commercial Termidor. Both the *in vitro* and *in vivo* fipronil-released studies presented in this paper demonstrated the effectiveness of a pesticide delivery system having biocompatibility, high encapsulation efficiency, and sustained release property, which open potential utilities of the silica nanocapsules for other agricultural applications.

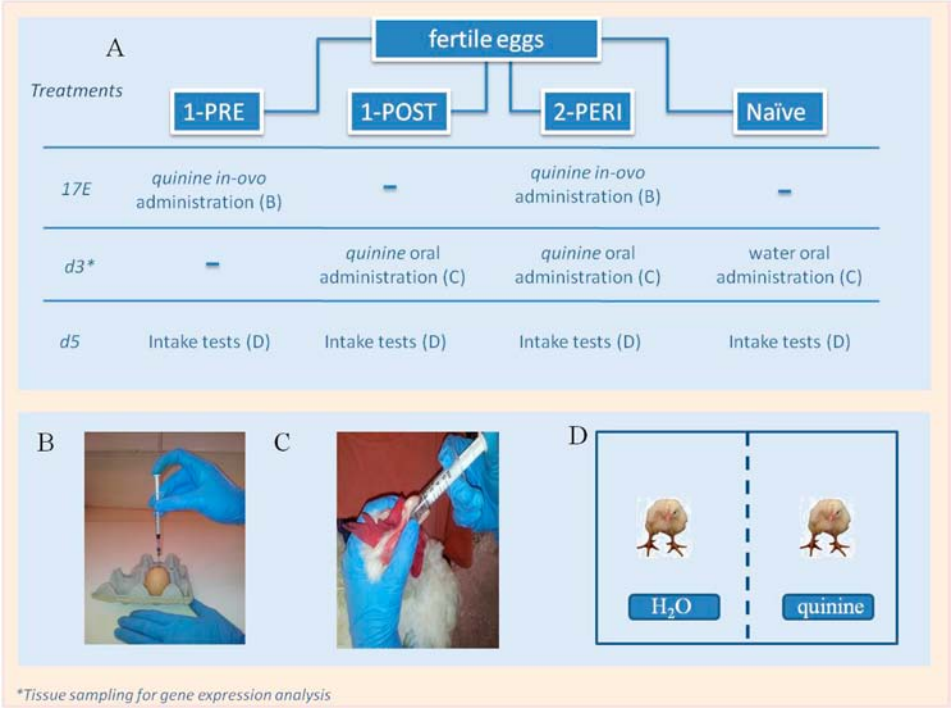

**Figure 1.** Quinine administration procedures and intake taste tests. (A) Groups in the experiment were 1-PRE, 0.6 mL of 2 mM quinine administered prenatally (0.04 μmol quinine/g BW); 1-POST, 1.3 mL of 2 mM quinine administered postnatally (0.04 μmol quinine/g BW); 2-PERI, two perinatal administrations (pre- and postnatal) of 2 mM (in both 0.04 μmol quinine/g BW) quinine and naïve. Intake tests to evaluate bitter tastant consumption were performed for all treatments on day 5. (B) Illustration of in ovo prenatal administration procedure in chicken embryos on embryonic day 17 (E17) delivers the quinine solution into the amnion. (C) Illustration of postnatal administration to chickens into the oral cavity. (D) Illustration of the no-choice intake test, where each chick is offered either water or quinine solution. (*) On day 3 palate and duodenum tissues were removed from all treatment groups for gene expression analysis.

## MATERIALS AND METHODS

**Chemicals.** Quinine (Sigma-Aldrich) was used at 2 mM (dissolved in distilled water) and 30 μM (dissolved in C1 buffer).

C1 buffer consisted of 130 mM NaCl, 5 mM KCl, 10 mM *N*-2-hydroxyethylpiperazine-*N*′-2-ethanesulfonic acid, 2 mM $CaCl_2$, and 10 mM glucose (pH 7.4).

**Functional Expression Procedures.** The expression constructs of chicken ggTas2r1, ggTas2r2, and ggTas2r7, containing the full length coding cDNA of the receptors flanked by an upstream located sequence coding for an sst3-tag and a downstream located sequence coding for a herpes simplex virus glycoprotein D (hsv)-epitope in the vector pcDNA5FRT (Invitrogen) were available from a previous study.[24] For functional analysis, HEK 293T cells stably expressing the G-protein chimera Gα16gust44[25] were transiently transfected with the expression constructs using Lipofectamine2000 (Invitrogen) as detailed before.[8,24] For a negative control, cells were transfected with empty vector (mock). About 24 h after transfection, cells were washed, loaded with the calcium-indicator dye Fluo4-AM in the presence of 2.5 mM probenecid, and subjected to calcium imaging analysis as described previously.[8,24] After automatic application of the stimulus (30 μM quinine in buffer C1), changes in fluorescence were monitored using a fluorometric imaging plate reader (FLIPR, Molecular Devices). The traces of identically treated cells were averaged using the program ScreenWorks 3.1 and exported to the graphics software Corel Photo-Paint X3 to create an overlay picture.

**Birds and Procedures.** Fertile broiler eggs ($n$ = 150; Cobb) were obtained from a maternal flock (32 weeks in lay; Brown Ltd., Hod Hasharon, Israel). The eggs were incubated under standard conditions at the Department of Animal Sciences of the Hebrew University (Rehovot, Israel). The eggs were divided into four groups ($n$ = 30) depending on time of quinine administration (prenatal or postnatal) and number of times administered (once or twice): (1) one prenatal administration (1-PRE); (2) one postnatal administration (1-POST); (3) two administrations, pre- and postnatally (perinatally) (2-PERI); (4) control (naïve). A concentration of 2.0 mM quinine (0.04 μmol/g BW) was chosen on the basis of previous reports of quinine aversion thresholds in chicken.[17] Administration of the bitter quinine molecule to the GIT of animals from the different treatment groups was as follows (see Figure 1): (a) 1-PRE, administration into the amniotic fluid of the embryo on E17 using a 21-gauge needle and 0.6 mL per embryo of sterile 2.0 mM quinine solution by in-ovo feeding procedure, which delivers nutrients to the GIT;[26] (b) 1-POST, oral administration at 3 days of age of 1.3 mL of 2.0 mM quinine per chick (0.04 μmol/g BW) using a 2 mL syringe; (c) 2-PERI, two administrations, on E17, with sterile 2.0 mM quinine solution (0.6 mL/embryo) by in-ovo feeding procedure and oral administration at 3 days of age with 2.0 mM quinine (1.3 mL/chick) using a 2 mL syringe; (d) naïve, oral administration of 1.3 mL of water at 3 days of age using a 2 mL syringe per chick. In addition, a water-injected control was used ($n$ = 30) to assess injection effects as an internal control (not shown). Ages for 1-PERI, 1-POST, and 2-PERI (E17 and day 3) were chosen on the basis of the following previous findings: between E16 and E20 the embryo orally consumes the amniotic fluid;[27] on E17, the embryo's taste buds are already visible, and on E19, they are fully developed and functioning; the number of taste buds peaks on E19 and then remains constant.[11]

**Treatment Procedure.** All eggs from all treatment groups were taken out of incubation (including the naïve group) and kept in a 37 °C room (similar to incubation temperature) during the in-ovo procedure. The eggs (which contained the embryos) were sprayed with 75% ethanol before and after the in-ovo procedure and were placed in hatching trays until hatch. Hatchability was 90% for in-ovo-administered groups (1-PRE and 2-PERI) and 93.3% for 1-POST and naïve. After hatch, chicks were placed in pens in a brooding house (27−28 birds/pen) for the 5 day trial period. Post hatch feed, which was formulated to meet National Research Council (1994) requirements as appropriate, was offered ad libitum, and water was freely

[a]gg, *Gallus gallus*; PLCβ2, phospholipase Cβ2; TRMP5, transient receptor potential melastatin 5; B2M, microglobulin; Cyc A, cyclophilin A. [b]VanHerch et al.[31] [c]Yadgary et al.[54]

available until the intake test was performed. Body weights and intestinal weights were recorded at day of hatch for all treatment groups including water injection group; no significant differences were found. Mortality was recorded and was negligible (1 bird per 100). All experimental procedures followed established guidelines for animal care and handling and were approved by the Hebrew University Institutional Animal Care and Use Committee (OPRR-A01-5011).

**Intake Experiments.** An individual no-choice intake taste test based on Gentle[28] was conducted on all treatment groups following quinine administration experiments (Figure 1). The tests were conducted on day 5 to separate them from the administrations by at least 24 h, thereby avoiding effects of the administrations themselves. One bird from each treatment group, chosen on the basis of the weight-average of all treatment groups, was placed in a separate pen. A water tray filled with either water or 2.0 mM quinine in water was weighed and placed in the pen for 10 min. Then the trays were reweighed and intake was calculated (evaporation was recorded and included in the final calculation). Four repeats (four different birds) were performed for each treatment group.

In all intake experiments, all groups were subjected to restricted water intake and ad libitum feeding for 6 h prior to the intake experiments.[17,28]

**Tissue Sampling and RNA Extraction.** For reverse transcription (RT)-PCR, the upper palate, tongue, and the three segments of small intestine, duodenum, jejunum, and ileum, were removed from a chicken (broiler; day 25) and kept in RNA Save (Biological Industries, Beit Haemek, Israel) according to the manufacturer's instructions.

For real-time PCR, following the 3 day postnatal administrations (in the appropriate treatment groups), four chicks from each treatment group, chosen on the basis of average weight of each treatment group, were terminated. Two tissues, palate and duodenum, were selected for real-time analysis based on (RT)-PCR results with highest expression levels. Upper palate and duodenum were removed and kept in RNA Save (Biological Industries) according to the manufacturer's instructions until RNA isolation. Total RNA for RT-PCR and real-time PCR was isolated from the upper palate and intestinal segments using an Animal Tissue RNA Purification Kit (Norgen Biotek Corp., Ontario, Canada), which includes on-column DNase digestion for elimination of genomic (g)DNA. Fifteen chicks remaining from each treatment group were used for DNA extraction for future studies.

**Primer Design and RT-PCR.** cDNA was synthesized using 1.0 μg total RNA and a Verso RT-PCR Kit (Thermo Fisher Scientific, Waltham, MA, USA) following the manufacturer's protocol. To assess the relative mRNA abundance of *ggTas2r1*, *ggTas2r2*, *ggTas2r7*, *α-gustducin*, *PLCβ2*, *TRPM5*, and the housekeeping gene *β-actin* gene-specific primers were used according to the published cDNA sequences (Table 1). Primers were either designed with the aid of Primer-BLAST[29] or taken from previous work[30,31] and are specified in Table 1. Because *Tas2rs* are exon-only sequences, we used a combination of controls to exclude gDNA contaminating cDNA samples; no-RT (−RT) negative controls were used, as well as chicken gDNA purified from intestinal segments using the GeneJET Genomic DNA purification column and collection tube (Thermo Fisher Scientific) as a negative control with either exon-spanning or intron-including primers (when possible). All PCR products were validated by running samples on a 1.5% agarose gel, excising bands of the correct size for purification using the Gel/PCR DNA Fragment Extraction Kit (Geneaid Biotech, Bade City, Taiwan), and sequencing (at the Weizmann Institute of Science, Rehovot, Israel).

**mRNA Abundance by Real-Time PCR.** Real-time PCR was performed on a Stratagene (Amsterdam, The Netherlands) MX3000P instrument. Specific primers for SYBR green detection were generated as described above for *ggTas2r1*, *ggTas2r2*, *ggTas2r7*, *α-gustducin*, *PLCβ2*, and *TRPM5* according to the published cDNA sequences (Table 2). The PCR mixture consisted of 3.0 μL of cDNA sample diluted 1:5, 200 nM of each primer, and 10 μL of Platinum SYBR Green qPCR super mix-UDG (Invitrogen, Carlsbad, CA, USA) in a final volume of 20 μL. All PCRs were performed in duplicate in ABgene PCR plates (Thermo Fisher Scientific) closed with optically clear flat QPCR caps (Thermo Fisher Scientific) under the following conditions: 50 °C for 2 min, 95 °C for 2 min, and 40 cycles of 95 °C for 30 s and 60 °C for 1 min. In addition, to ensure amplification of a single product, a dissociation curve was determined under the following conditions: 95 °C for 1 min, 55 °C for 30 s, and 95 °C for 30 s. To control for false positives, a nontemplate control was run for each template and primer pair. Single bands with the predicted product size for each gene tested were confirmed by gel electro-

phoresis, excising for purification using a Gel/PCR DNA Fragment Extraction Kit (Geneaid Biotech) and sequencing (Weizmann Institute of Science). Calculations of threshold cycles, amplification efficiencies, and $R_0$ values (the starting fluorescence value, which is proportional to the relative starting template concentration) were performed using the Data Analysis for Real-Time PCR Excel Workbook.[32] The raw fluorescence data for each of the examined genes were exported to the workbook, and the efficiency ($E$) of each individual reaction was determined using linear regression analysis of the fluorescence data from the exponential phase of each amplification. One-way ANOVA detected no significant difference in amplification efficiencies among samples within treatment groups; therefore, the average $E$ value (arithmetical mean of $E$ values of all samples) for each of the genes was used for the $R_0$ calculation in each sample. The $R_0$ values of two housekeeping genes, $\beta$2 microglobulin (*B2M*) and cyclophilin A, were not significantly different ($P > 0.05$) among the different treatments and, therefore, mRNA abundance was normalized for RNA loading to the geometric average of B2M and cyclophilin A as the internal control ([$R_0$ target gene/$R_0$ AVRHKs (geometric average of housekeeping genes)] × 100).

**Statistical Analysis.** Differences among solution intake in the intake test results (Figure 3A) were calculated using Student's $t$ test (results are the mean ± SEM; differences among means between water and quinine intake within each treatment group are marked by the letters a and b). Differences between the Δ consumption (Figure 3B) were subjected to one-way ANOVA, and the mean ± SD for each treatment group was calculated. Differences between means were calculated using the Tukey–Kramer test. Gene-expression data were subjected to one-way ANOVA. Prior to ANOVA, the mean ± SD for each data set was calculated. Heterogeneity of variance (expressed as an increase in SD with the mean) was observed between treatments for *ggTas2r1*, *ggTas2r2*, *ggTas2r7*, *α-gustducin*, *PLCβ2*, and *TRPM5*, and therefore logarithmic (ln) transformation was carried out for these genes' data. Differences among means were tested by Tukey–Kramer HSD (differences in means marked by the letters a and b) and within treatment group contrasts using Student's $t$ test (differences in means marked by *). For log-transformed data, values are presented as the back-transformed mean ± SEM. All statistical analyses were carried out using JMP 7 software (SAS Institute, 2006, Cary, NC, USA).

## RESULTS

**Functional Calcium Imaging.** To verify the activation of the three chicken bitter taste receptors, functional calcium imaging assays were conducted. As evident from our calcium imaging experiments, all three chicken receptors respond to quinine stimulation. The signal amplitudes of cells transfected with chicken Tas2r1and Tas2r2 were similar and higher compared to Tas2r7 transfected cells (Figure 2), in agreement with previously published results.[24]

**Intake of Quinine versus Water.** To evaluate the chicken's behavioral response to the bitter tastant following administration experiments, individual water or quinine solution (2.0 mM) no-choice intake experiments were conducted (Figure 1A,D) on day 5. In the naïve group, a decreasing trend with no significant differences ($P = 0.1049$) was apparent between water and quinine intake weights (7.8 ± 1.0 and 5.2 ± 0.7 g, respectively; Figure 3A). However, the difference in intake was significant for all treated groups: in the 1-PRE group, water-intake weight was 8.8 ± 0.6 g and quinine-intake weight was significantly lower ($P = 0.01$) at 4.6 ± 0.95 g; in the 1-POST group, water-intake weight was 8.8 ± 1.35 g and quinine-intake weight was significantly lower ($P = 0.0031$) at 3.9 ± 0.3 g. In the 2-PERI group, water-intake weight was 9.2 ± 1 g and quinine-intake weight was significantly lower ($P = 0.0049$) at 4.6 ± 1.6 g. The Δ consumption, which represents the difference between water and quinine consumptions during the intake test, was calculated as well and is represented in Figure 3B. No significant differences were found in the Δ consumption between the treatment groups and the naïve group.

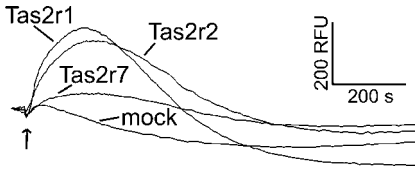

**Figure 2.** Chicken bitter taste receptors respond to quinine. HEK 293T Gα16gust44 cells transiently transfected with expression constructs coding for chicken Tas2r1, Tas2r2, and Tas2r7 respond to stimulation with 30 μM quinine. Traces of fluorescence signals corresponding to changes in intracellular calcium levels after quinine stimulation (arrow) are shown and labeled. Scale: $y$-axis, 200 relative fluorescence units (RFU); $x$-axis, 200 s.

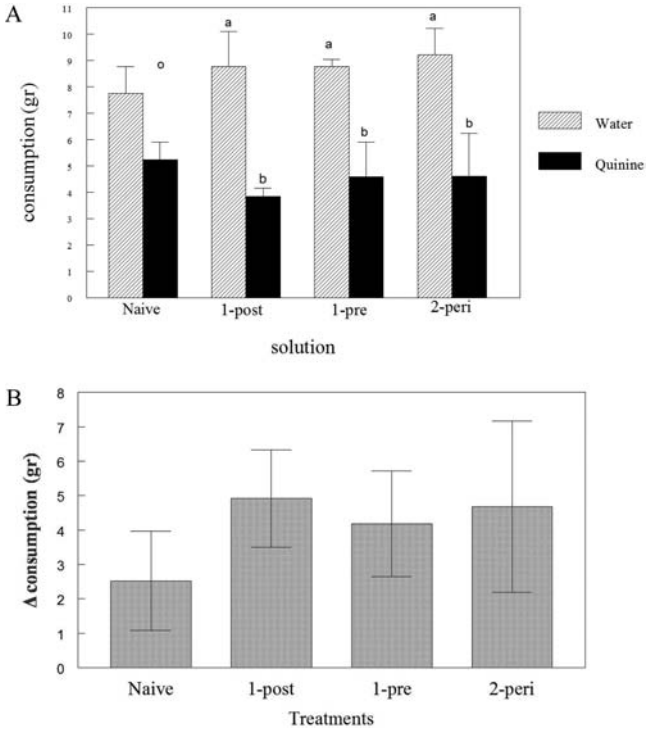

**Figure 3.** No-choice individual intake test following quinine administration. (A) Effect of quinine administration on individual no-choice intake of water or quinine solution. Values are presented as the mean ± SEM intake during 10 min for each treatment group: naïve (control, no quinine administration); 1-PRE (0.6 mL of 2 mM quinine administered prenatally, 0.04 μmol quinine/g BW); 1-POST (1.3 mL of 2 mM quinine administered postnatally, 0.04 μmol quinine/g BW); 2-PERI (two perinatal administrations, pre- and postnatal, of 2 mM quinine). For all treatment groups, $n = 8$ (4 water and 4 quinine solution). Means without a common letter (a, b) differ significantly ($P < 0.05$); o, means differ at $P = 0.1$. (B) Effect of quinine administration on the Δ consumption between water and quinine solution. Values are presented as the mean Δ consumption ± SEM in 10 min for each treatment group, where Δ consumption is (water consumption − quinine solution consumption in g) per each repeat. Treatments were as described for panel A.

***ggTas2rs* and Downstream Signal Transduction Molecules Are Expressed in the Chicken GIT.** RT-PCR analysis was used to determine the gene expression of the three

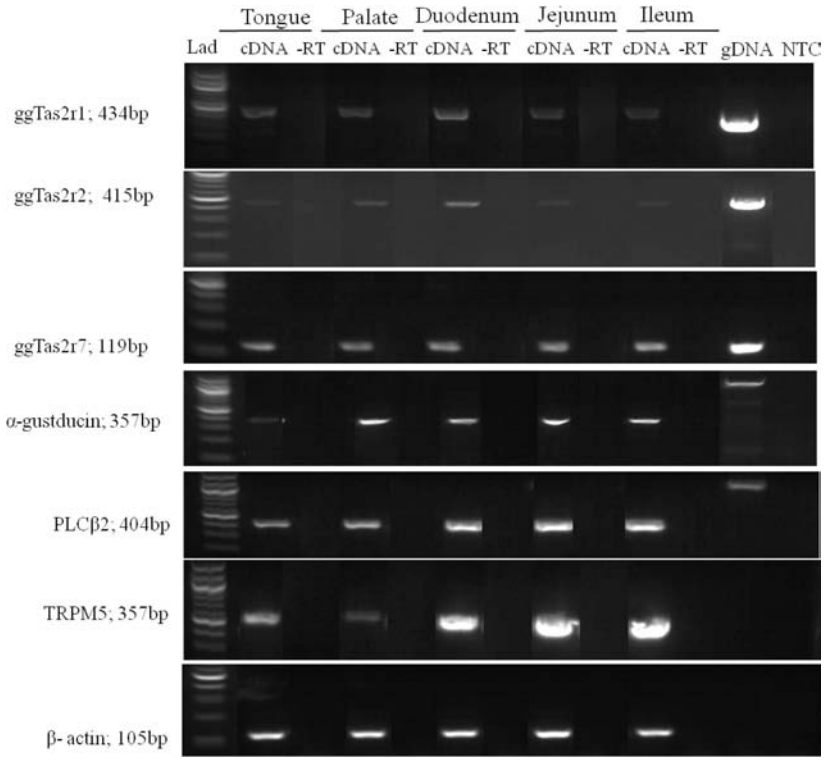

**Figure 4.** RT-PCR demonstrating taste receptors and taste transduction molecules in the chicken GIT. Templates were cDNA prepared from RNA isolated from tongue, palate, duodenum, jejunum, and ileum, as well as a chicken gDNA control. cDNA-amplified products of the expected sizes were obtained for *ggTas2r1* (434 bp), *ggTas2r2* (415 bp), *ggTas2r7* (119 bp), *α-gustducin* (357 bp), *PLCβ2* (404 bp), *TRPM5* (357 bp), and the housekeeping gene *β-actin* (105 bp). RT, negative control reactions without reverse transcriptase. Primers for α-gustducin and PLC*β*2 were designed as intron-inclusion primers (both >1000 bp). Primers for TRPM5 and *β*-actin were designed as exon-spanning, and therefore no product is seen in the gDNA control. PLC*β*2, phospholipase C*β*2; TRMP5, transient receptor potential melastatin 5; NTC, no template control.

chicken *Tas2rs* and three of the downstream effectors, *α*-gustducin, PLC*β*2, and TRPM5, in chicken gustatory tissue (tongue and palate) and extra-gustatory tissue (small intestinal segments duodenum, jejunum, and ileum). All three chicken (*G. gallus*) *Tas2r* genes, *ggTas2r1*, *ggTas2r2*, and *ggTas2r7*, and genes for taste-signaling proteins *α-gustducin*, *PLCβ2*, and *TRPM5*, were found to be expressed in the chicken tongue, palate, and small intestinal segments (Figure 4). Although not quantified, results showed different apparent expression levels of the tested genes among the different sampled tissues.

**ggT2RGene Expression on Day 3.** To test for possible effects of perinatal administration of a bitter tastant on bitter taste related gene expression, real-time PCR was conducted with all treatment groups in comparison to naïve chicks. Overall, and regardless of the treatment, *ggTas2r1* and*ggTas2r7* gave, respectively, 4.0- and 4.6-fold higher relative mRNA abundance values than *ggTas2r2* in the chicken palate and 2.5- and 1.5-fold higher relative mRNA abundance values in the duodenum (Figure 5). In addition, *TRPM5* showed 28-fold higher relative mRNA abundance in the duodenum than in the palate (Figure 6).

Following bitter tastant administration, all treated groups exhibited a trend toward elevated ggTas2rmRNA abundance in the palate on day 3 (Figure 5A). Providing quinine once postnatally caused a significant elevation in *ggTas2r1* and *ggTas2r7* mRNA abundance (6.5- and 4.5-fold, respectively) compared to naïve chicks, and providing quinine twice perinatally caused a significant 4.8-fold elevation in *ggTas2r1* compared to the naïve group.

However, in the duodenum, increasing trends in *ggTas2r* relative mRNA abundance were found in the 1-POST group, but decreasing trends were found in the 2-PERI group, although there were no significant changes in the mRNA abundance levels of the *ggTas2r* genes compared to the naïve group. Within treatment groups, a significant difference was found between 1-POST (higher expression) and 2-PERI (lower expression) for all three *ggTas2rs*.

**Downstream Signal Transduction Gene Expression on Day 3.** In the palate, diverse expression trends were found on day 3 (after quinine administration; Figure 6). Whereas*PLCβ2* relative mRNA abundance decreased significantly in the 1-POST and 2-PERI groups compared to the naïve group (7.2- and 8.2-fold decreases, respectively), *TRPM5* mRNA abundance was significantly elevated in 1-POST (by 3.36-fold) and showed a trend toward elevation in 1-PRE and 2-PERI compared to naïve.

In the duodenum, *α-gustducin* expression was significantly decreased in the 2-PERI compared to naïve and 1-POST groups (by 3.7- and 3.6-fold, respectively). On the other hand, no significant changes were demonstrated in *PLCβ2* and *TRPM5* gene expressions in any of the treatment versus naïve groups.

## DISCUSSION

Expression of *Tas2rs* and taste-signaling components in the GIT was first identified over a decade ago.[33,34] Over the years, *Tas2rs* and downstream signaling components have been identified along the GIT in a variety of different species[35,36] and found to be located in brush cells and enteroendocrine

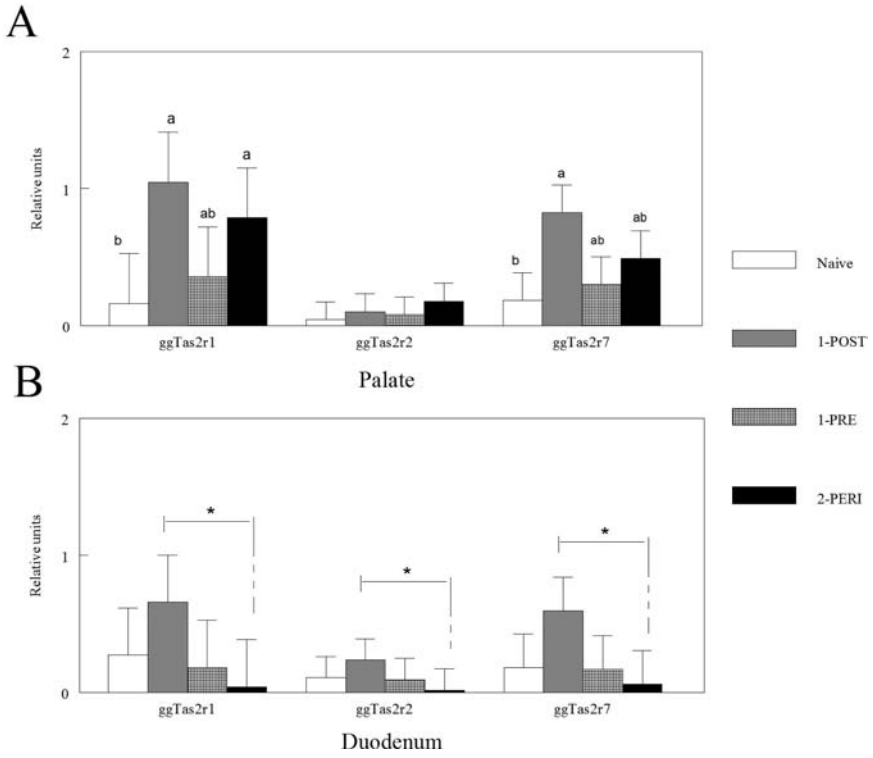

**Figure 5.** Effect of quinine administration on mRNA abundance of the three chicken taste receptors, *ggTas2r1*, *ggTas2r2*, and *ggTas2r7*, in chicken palate (A) and duodenum (B) as shown by relative mRNA abundance in naïve ($n$ = 4), 1-POST ($n$ = 4), 1-PRE ($n$ = 4), 2-PERI ($n$ = 4) treatment groups. Values are presented as back-transformed means (after normalization of RNA loading to the geometric average of B2M and cyclophilin A) ± SEM. Means without a common letter (a, b) differ significantly ($P < 0.05$) between treatments. (*) Means differ significantly when compared individually using each paired Student $t$ test. 1-PRE, 0.6 mL of 2 mM quinine administered prenatally (0.04 μmol quinine/g BW); 1-POST, 1.3 mL of 2 mM quinine administered postnatally (0.04 μmol quinine/g BW); 2-PERI, two perinatal administrations (pre- and postnatal) of 2 mM quinine.

cells[37] as well as in a subset of colonic goblet cells.[38] The exact role of these bitter taste-related genes in the GIT remains unclear, although they have been suggested to be involved in metabolic regulation and feed intake.[39−41] It is only in the past few years that the effect of bitter tastants on these genes' expression and its relationship to bitterness sensitivity and acceptance have begun to be investigated.[42]

The current study provides molecular evidence of gustatory and GIT (extra-gustatory) expression of the three bitter-taste receptors *ggTas2r1*, *ggTas2r2*, *ggTas2r7* and the signaling components *α-gustducin*, *PLCβ2*, and *TRPM5* in chicken, as indicated by RT-PCR; the activation of the three chicken bitter taste receptors by quinine stimuli was illustrated in vitro. Intake tests demonstrate that even a single exposure to quinine during early development (before or after hatch) significantly decreases its intake compared to water, whereas in the naïve group only a trend toward decrease in quinine consumption was evident ($P$ = 0.1). Real-time PCR results indicate that exposure to quinine at an early age affects the later expression of bitter taste transduction genes in both the palate and the duodenum of chicks.

**Quinine-Intake Taste Tests.** Using no-choice intake taste tests, we examined the chicken's behavioral responses to the administration of the bitter tastant quinine following prenatal, postnatal, and perinatal quinine administration treatments. No-choice intake taste tests were chosen for evaluating the animal response because in broiler feeding interface and broiler production, the animals have a no-choice diet.

The individual no-choice taste tests indicated intake in naïve animals encountering the bitter tastant for the first time demonstrated a decrease trend of quinine intake compared to water ($P$ = 0.105). Early exposure to quinine (either prenatally, postnatally, or both) decreases its intake significantly compared to water ($P$ values < 0.05).

Many studies dealing with flavor learning and programming in mammals during the perinatal period make use of repetitive exposure to the aversive tastants during early developmental stages, often leading to adaptation and improved acceptance.[43−47] In the current study, the no-choice taste test results did not indicate adaptation. Rather, the results may suggest a trend toward sensitization to the bitter tastant following early exposure. This can also be seen in Figure 3B, where the Δ consumption (the difference in intake between water and quinine solution) in the three treatment groups does not decrease (rather showing a trend of increase) compared to the Δ consumption of the naïve group.

**Gene Expression.** *ggTas2r1*, *ggTas2r2*, and *ggTas2r7* and the signal transduction components *α-gustducin*, *PLCβ2*, and *TRPM5* were expressed in the tongue, palate, and the three segments of the small intestine, duodenum, ileum and jejunum (Figure 4), as determined by RT-PCR. To the best of our knowledge, the only previous evidence of bitter taste perception-related gene expression in chicken is the expression of *α-gustducin* in taste buds located in the oral cavity.[48]

An important question is the relationship between bitter tastant consumption and bitter taste-related genes' expression. Does administration of quinine also affect the expression of bitter taste-related genes and is there an association between quinine intake and the related genes' expression in the chick GIT?

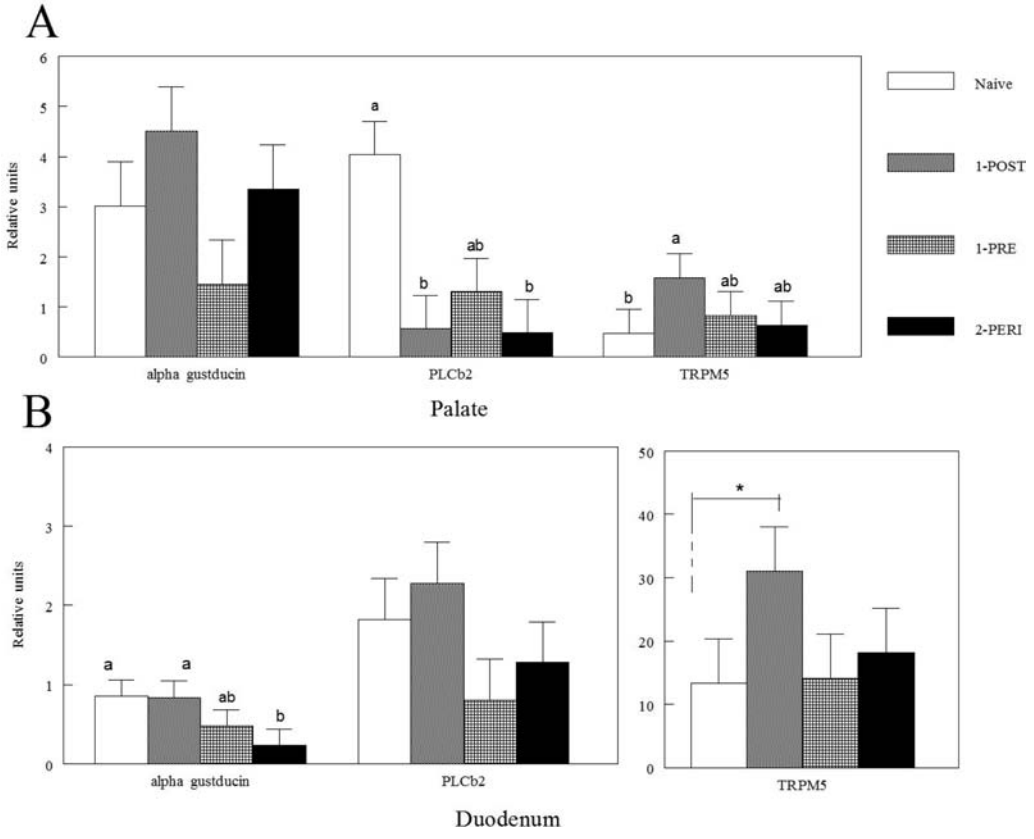

**Figure 6.** Expression of signal transduction molecule-encoding genes following quinine administration in chicken palate (A) and duodenum (B) by real-time PCR as shown by relative mRNA abundance in naïve ($n$ = 4), 1-POST ($n$ = 4), 1-PRE ($n$ = 4), and 2-PERI ($n$ = 4) treatment groups. Values are presented as back-transformed means (after normalization of RNA loading to the geometric average of B2M and cyclophilin (A) ± SEM. Means without a common letter (a, b) differ significantly ($P < 0.05$) between treatments. (*) Means differ significantly when compared individually using each paired Student $t$ test. 1-PRE, 0.6 mL of 2 mM quinine administered prenatally (0.04 $\mu$mol quinine/g BW); 1-POST, 1.3 mL of 2 mM quinine administered postnatally (0.04 $\mu$mol quinine/g BW); 2-PERI, two perinatal administrations (pre- and postnatal) of 2 mM quinine. PLC$\beta$2, phospholipase C$\beta$2; TRMP5, transient receptor potential melastatin 5.

Indeed, exposure to the bitter tastant quinine affects expression in the chicks' palate and duodenum. Our results demonstrate that in the palate, *ggTas2rs* expression is elevated following quinine administration, whereas in the duodenum,*ggTas2rs* and *α-gustducin* response to quinine was treatment-dependent: the one-time postnatal (1-POST) administration caused an increasing trend in all duodenal *ggTas2rs*, whereas two-time perinatal (2-PERI) administration resulted in a decreasing trend for all duodenal*ggTas2rs* (with expression in 1-POST being significantly higher than that in 2-PERI; Figure 5).

The increase in expression change in the palate following administration (all treatment groups showed elevated *ggTas2r1* and *ggTas2r7* expression compared to naïve) is in correlation with lowered quinine intake results. This is not surprising, because in chicken the palate is the major gustatory tissue responsible for bitter sensing.[49] Our findings are in accord with recent studies in humans: Hirai et al.[50] investigated mRNA expression and its association with taste sensitivity and perception and reported that increased T2R expression is related to human taste disorders involving increased bitter taste sensation. More recent research has shown a correlation between human bitter perception and mRNA expression of *TAS2R38*, one of the human bitter taste receptors, in the human fungiform papilla located in the tongue.[42]

Interestingly, gene expression patterns in the duodenum varied between the different treatment groups. The difference seen in the duodenum in *ggTas2r* and *α*-gustducin expression between 1-POST and 2-PERI may be a result of the number of times the chicken was exposed to the tastant (once versus twice). Changes in expression levels of taste transduction genes in the duodenum, following the different treatments, suggest possible extra-gustatory roles for these genes. Previous reports in mammals have also reported expression of *Tas2rs* and the downstream molecules *α-gustducin*, *PLCβ2*, and *TRPM5* located in the mouse GIT,[51] although their expression was not analyzed following bitter tastant administration. The precise participation of taste-signaling genes in these intestinal pathways is yet unclear. Studies performed in rodents suggest that the assumed surveillance of the luminal contents of the GIT by bitter taste receptor signaling may serve roles in metabolic control[52] and satiety regulation,[40] as well as defensive functions.[38,41,53] Following up on this result may help unravel the molecular mechanisms involved in intestinal tastant sensing.

In summary, the results of the present study demonstrate the expression of bitter taste related genes in the chicken's gustatory and extra-gustatory (GIT) tissues. Early developmental stage exposure to a bitter tastant prenatally, postnatally, or both, changes taste related genes' expression in the palate and duodenum and leads to a decreased bitter tastant intake. Our

results pave the way for studying the roles of GIT taste signaling machinery in poultry.

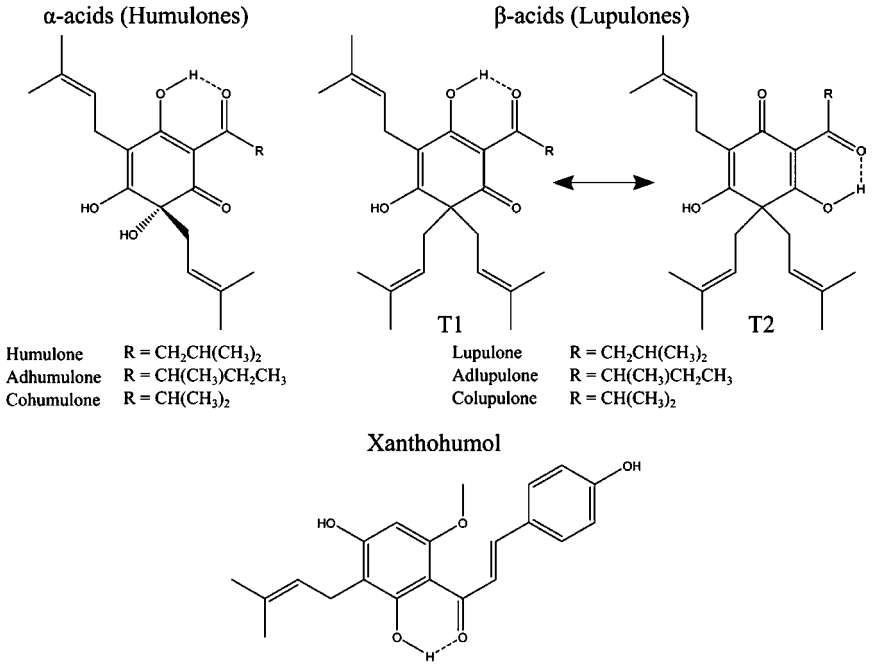

**Figure 1.** Structures of hops bitter acids and xanthohumol.

data, which means that a single spectral matrix can be successively tuned to different reference data using PLS-R.[28] This approach is particularly relevant to hops, where quantitation of the structurally similar $\alpha$- and $\beta$-acids in addition to the bioactive xanthohumol is desirable.

PLS-R has recently been successfully applied to quantitation of iridoid glycosides from *Verbena* by IR and NIR,[24] aspalathin in green rooibos by Raman,[23] and caffeine in roasted coffee beans by NIR.[29] As suggested by these examples, studies generally use only one or two vibrational spectroscopy techniques, a practice that risks missing the most suitable technique. Analysis by all three techniques results in complementary data sets that can be appraised relative to one another and in the context of their performances for a given application. In some cases, analytical challenges have been overcome using "fused" spectroscopic data sets.[30]

To better understand the PLS-R models, cohumulone, colupulone, and xanthohumol were isolated, their Raman and IR spectra were measured, and the vibrational bands were assigned using density functional theory (DFT) calculations. These assignments allowed the interpretation of LVs in the generated PLS-R models, which in turn permitted a more insightful understanding of model performances.

## MATERIALS AND METHODS

**Plant Material.** Hops were grown at Motueka, South Island, New Zealand (41°6′ S, 172°58′ E) in Riwaka silt loam. Advanced selections (139 individual plants encompassing 39 genetic varieties) from hops breeding trials were harvested in March 2013. Hops cones were kiln-dried at ∼60 °C for 8 h followed by determination of residual water content. Subsamples, ∼5 g of cones, were pulverized under $N_2$ (l) and stored at −20 °C prior to the analyses.

**Isolation of Hops Bitter Acids.** An aliquot of the hops International Calibration Extract (ICE-3) was purchased from the American Society of Brewing Chemists (ASBC). A solution containing ∼100 mg mL$^{-1}$ of ICE-3 in MeOH was filtered before it was injected onto an Agilent 1260 Infinity semipreparative HPLC system equipped with a Phenomenex Luna (5 $\mu$) C18 column (10 × 250 mm) with UV detection at 210 nm. Injections (50 $\mu$L) were eluted over 18 min in 87.9:12:0.1 MeOH:$H_2O$:formic acid, with a flow rate of 5 mL min$^{-1}$. Fractions were collected at retention times of 7.3, 8.4, 10.8, and 12.9 min and identified by $^1$H NMR as cohumulone, a mixture of humulone/adhumulone, colupulone, and a mixture of lupulone/adlupulone, respectively, by comparison to published spectra.[6] Using the same methodology, xanthohumol was isolated from a MeOH extract of hops inflorescences. This compound had a retention time of 5.5 min. The compound was identified by $^1$H NMR by comparison to published spectra.[31]

**Quantitation of Bitter Acids by UV Spectrophotometry.** Hops cones (10 g) were added to 100 mL of toluene for extraction in an Omni mixer. Over a 10 min period, samples were sequentially blended and rested for 30 s periods. Samples were filtered, and 50 $\mu$L was diluted to 25 mL with alkaline MeOH. The UV absorbances at 275, 325, and 355 nm were recorded using a UV spectrophotometer, with 50 $\mu$L of toluene in alkaline MeOH (25 mL) as a blank. This was adapted from a standard industry method.[10]

**Quantitation of Bitter Acids and Xanthohumol by HPLC.** Hops were extracted as described above, and 3 mL was transferred to a 50 mL volumetric flask and made to volume with MeOH. Ten $\mu$L of this solution was injected onto a Shimadzu SCL10Avp HPLC system equipped with a 250 mm × 4.6 mm, 5 $\mu$m Kinetix C18 column at 30 °C at a flow rate of 1.5 mL min$^{-1}$. The mobile phase was MeOH:$H_2O$:phosphoric acid:0.1 M EDTA (1700:350:5:1) with UV detection at 270 nm. Run time was 18 min. This was adapted from a standard industry method.[9]

**IR Analysis.** Hops powder (∼10 mg) was deposited directly onto the ATR crystal and compressed by the anvil mechanism. Spectra were acquired using a Bruker ALPHA Platinum Fourier transform infrared (FT-IR) spectrometer equipped with a diamond attenuated total relection (ATR) crystal. Spectra were recorded from 376−4000 cm$^{-1}$ with a spectral resolution of 4 cm$^{-1}$ and were the average of 32 scans. Prior to acquisition of each spectrum, the crystal and anvil were thoroughly cleaned, and a background spectrum was acquired to account for any environmental changes throughout the analysis. Spectral acquisition time was ∼1 min per sample.

**Raman Analysis.** Hops powder (∼50 mg) was packed into aluminum divots for analysis. Spectra were acquired using a FRA 106/5 Bruker Equinox FT-Raman spectrometer equipped with a Nd:YAG laser emitting at 1064 nm, Equinox 55 interferometer, and a germanium detector cooled with $N_2$ (l). The Raman Stokes shift was recorded from 200−3500 cm$^{-1}$ with a spectral resolution of 4

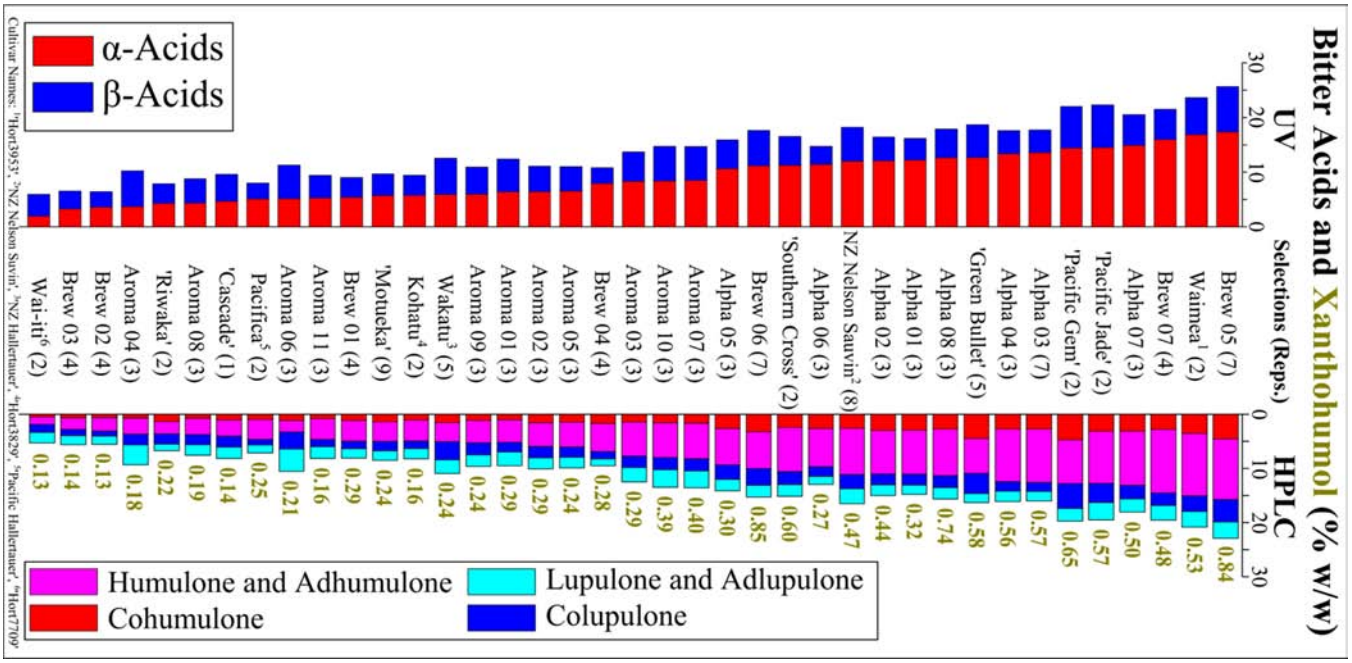

**Figure 2.** Concentrations of $\alpha$-acids, $\beta$-acids, and xanthohumol by HPLC and UV spectrophotometry.

**Table 1. Comparison of Hops Analyses by Vibrational Spectroscopy with UV and HPLC Analyses Using Partial Least-Squares Regression (PLS-R)**

$cm^{-1}$, spot size of 0.3 mm, and laser power of 120 mW. Spectra were the average of 256 scans, and the acquisition time was ~8 min per sample. Raman analysis with excitation at 830 and 785 nm could not distinguish Raman bands from raised baselines due to emission. These Raman systems have previously been described in detail.[21]

**NIR Analysis.** Hops powder (~1 g) was added to a sample cup, and the surface was smoothed with gentle compression. Background spectra, consisting of diffusely reflected light from a reflective surface, were taken prior to each sample acquisition. Diffuse reflectance infrared Fourier transform (DRIFT) spectra were recorded using a FRA 106/5 Bruker FT-NIR spectrometer equipped with an Equinox 55 interferometer and germanium detector cooled with $N_2$ (l) from 4000−10000 $cm^{-1}$, with a resolution of 8 $cm^{-1}$ in Kubelka−Munk units. Spectral acquisition time was ~1 min per sample.

**Portable NIR Analysis.** Hops powder (~1 g) were presented to the MicroNIR spectrometer (JDS Uniphase Corporation) in clear, 4 mL glass vials, and reflectance spectra were acquired through the base of the vial. A spectral acquisition time of 1 s was used, and analysis was performed in triplicate by shaking the vial between acquisitions. Two tungsten filaments were used to produce polychromatic radiation, and diffusely reflected light was dispersed with a linear variable filter onto a 128-pixel uncooled InGaAs photodiode array detector. Spectra were recorded from 4545−8696 $cm^{-1}$ (1150−2100 nm) with a spectral resolution of 32 $cm^{-1}$.

**Density Functional Theory Calculations.** The molecular geometries of xanthohumol, cohumulone, and both colupulone conformers (Figure 1) were optimized with DFT using the 6-31+G(d) basis set. A correction factor of 0.960 was applied to the predicted vibrational frequencies to correct for their systematic overestimation.[32−34] The mean absolute deviation between the calculated and experimental vibrational bands was 13 $cm^{-1}$. Quantum chemical calculations were performed using Gaussian 09 and, where possible, initiated from published crystal structures.[31,35]

**Regression Modeling.** *Quantitative IR Spectroscopy.* The IR spectrum of each sample was imported into the multivariate software "The Unscrambler®". A standard normal variate (SNV) transformation was applied to each spectrum to compensate for scattering effects that arise from experimental factors such as varying optical path lengths, sample inhomogeneity, and background effects.[36] Models were generated from the spectral region from 850−1700 $cm^{-1}$ (the spectral region below 850 $cm^{-1}$ and from 1810−2700 $cm^{-1}$ were omitted since IR spectra of purified bitter acids (Figure 3a) did not contain any distinct or intense vibrational bands in these regions, and the spectral region above 2700 $cm^{-1}$ was also omitted because the C−H and O−H stretching vibrations of many biological compounds contribute intensity in this region). One-third of the sample spectra was selected at random to be used as a test set for model validation. The remaining two-thirds were used as a calibration set to generate PLS-R models (noniterative, PLS1[27]) that relate the selected spectral regions to the reference values from the UV and HPLC analyses (Figure 2). This independent "test-set" validation methodology is considered robust.[37] Models were used to predict test-set values from their IR spectra with selected results in Table 1. The number of LVs selected was the optimum for predicting values in the independent validation test set. Data for all models are included in Table S1 of the Supporting Information.

*Quantitative Raman Spectroscopy.* The spectral region from 1050−1750 $cm^{-1}$ was used to generate PLS-R models that relate Raman spectra to UV and HPLC reference values (Figure 2). This spectral region was selected by comparison to the spectra of purified bitter acids (Figure 3b). The same validation methodology was used with the same samples comprising the calibration and test sets. Selected results of the test set analyses are shown in Table 1. Data for all models are included in Table S1 of the Supporting Information.

*Quantitative NIR Spectroscopy.* PLS-R models were generated from 4000−7300 $cm^{-1}$ from the DRIFT NIR spectra. This spectral region was chosen based on visual inspection and correlation loadings, which suggested that the noisy spectral region from 7300−10000 $cm^{-1}$ could not effectively be related to the reference data. For the NIR spectra measured with the portable NIR spectrometer, regression models were generated from the entire spectral range acquired (4545−8696 $cm^{-1}$). In both cases, spectra were subjected to SNV and used to generate PLS-R models relating them to UV and HPLC reference data (Figure 2). The calibration and test sets comprised the same samples used for in the Raman and IR analyses, and selected model performances are presented in Table 1. Data for all models are included in Table S1 of the Supporting Information.

## RESULTS AND DISCUSSION

Thirty-nine hops varieties, with one−nine replicate samples each (139 total) were used in this study, including both well-known commercial varieties and genetically novel selections chosen to encompass broad chemotypical differences. The novel selections were designated sequentially based on their associated breeding trials, that is, Alpha, Aroma, and Brewing (Brew) (Figure 2).

**Reference Analyses.** Bitter acid concentrations for all 139 hops samples were determined by the standard industry methods of HPLC[9] and UV spectrophotometry.[10] The average $\alpha$-acid and $\beta$-acid concentrations for each variety by UV are shown in Figure 2 in addition to HPLC results for the concentrations of the $\alpha$-acids cohumulone and the coeluting adhumulone and humulone, the $\beta$-acids colupulone and the coeluting adlupulone and lupulones, and the chalcone xanthohumol (Figure 1). $\alpha$-Acid concentrations were 2−17% w/w, and $\beta$-acid concentrations were 2−8%, which is close to the full range of values reported for wild and domesticated hops varieties.[17,38] Xanthohumol concentrations of 0.1−0.8% (Figure 2) also covered almost the full reported range.[3]

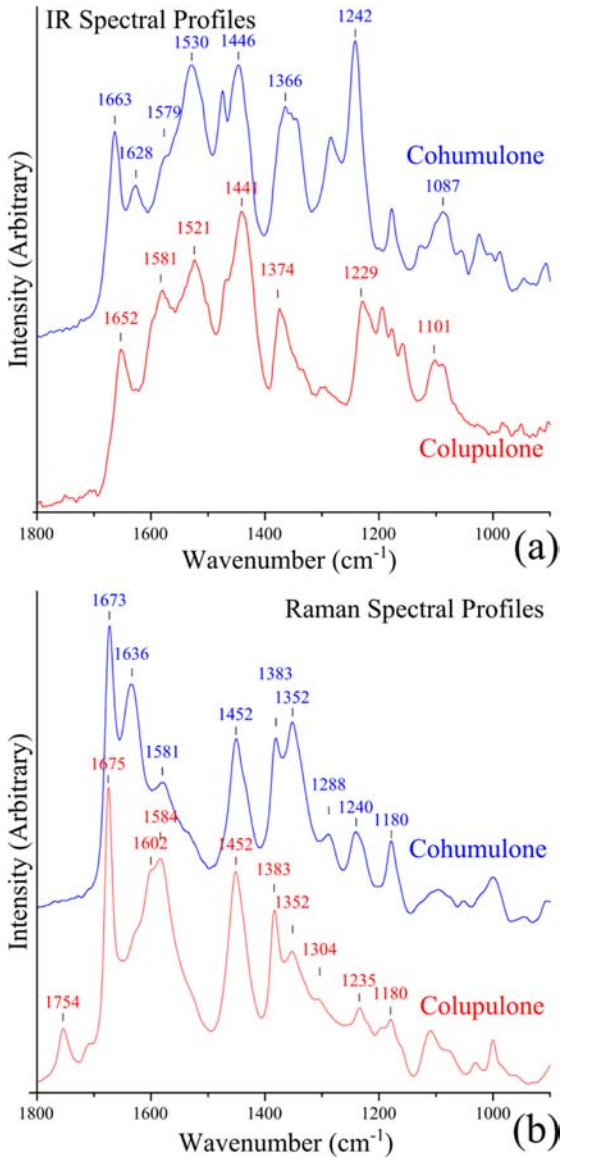

**Figure 3.** IR and Raman spectral profiles of pure cohumulone and colupulone.

Total $\alpha$-acids and total $\beta$-acids measured by the HPLC and UV methods showed good agreement between the results of both analyses, with correlation coefficients of 0.99 and 0.95, respectively. However, the absolute values for $\alpha$- and $\beta$-acids by UV spectrophotometry were, on average, 10% larger than values from HPLC analyses. It has been reported that the UV analysis method is subject to interference from bitter acid oxidation products, which absorb at analytically relevant wavelengths and cause this discrepancy.[39] Total $\alpha$-acid concentrations did not correlate strongly with total $\beta$-acid concentrations: $r^2$ = 0.36 (UV) and 0.39 (HPLC). Likens et al. found that $\alpha$-acid concentrations were negatively correlated to $\beta$-acid concentrations in lupulin from different hops varieties

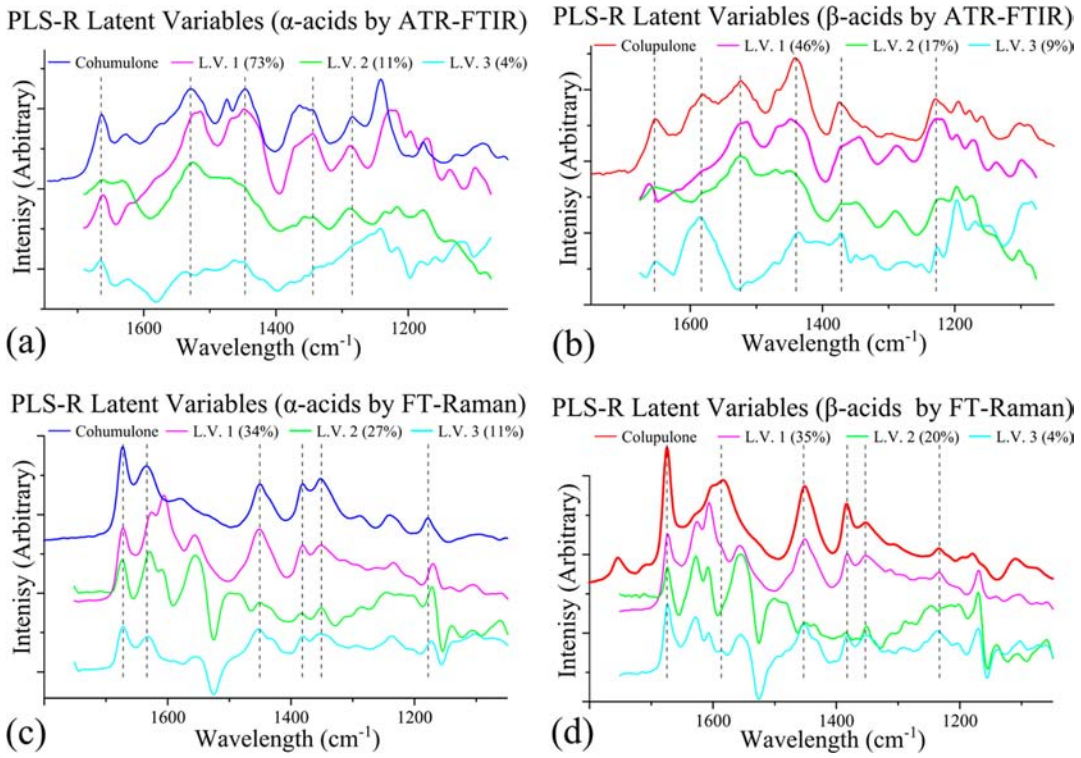

**Figure 4.** Overlay of spectral profiles of the pure bitter acids with latent variables from the Raman and IR PLS-R models predicting $\alpha$-acids (a and b) and $\beta$-acids (c and d) by UV spectrophotometry. Traces are scaled for ease of comparison. Dashed lines highlight discussed bands.

but that the variation in lupulin content between hops varieties confounded this correlation.[39] The key quality indicators for breeding selections, that is, total $\alpha$-acids, total bitter acids ($\alpha$ plus $\beta$), and cohumulone concentrations, were strongly correlated to one another. The correlations for the HPLC results were: total $\alpha$-acids versus total bitter acids, $r^2$ = 0.95; total $\alpha$-acids versus cohumulone, $r^2$ = 0.82. The $\alpha$-acids were the main bitter acids in most hops varieties, and the proportion of cohumulone in the $\alpha$-acids was 17−40% in these varieties (Figure 2).

**Vibrational Spectroscopic Analyses.** These same 139 hops samples were analyzed by the different vibrational spectroscopy techniques of IR, Raman, and NIR (two instruments) to assess which was best suited to the application of rapid screening of bittering hops. PLS-R models were generated, which related spectral matrixes to each of the UV and HPLC reference data, and these models were categorized using the ratio of prediction to deviation (RPD) methodology described by Williams (Table 1).[40] "Prediction" refers to the standard error of prediction (SEP) of the test-set values predicted by the calibration model, and "deviation" refers to the standard deviation of the corresponding reference data. The scale is used to broadly categorize PLS-R models by their fitness for purpose and was useful for our data set, which contained an unwieldy number of models with a large range of performances. The RPD scale defines models with values of $\geq$ 3.1 as suitable for quantitative screening applications.[40] Details of hops models that met this criterion are shown in Table 1. These models predicted the concentrations of the most important chemical values for breeding selections, that is, total $\alpha$-acids, cohumulone, total bitter acids ($\alpha$ plus $\beta$), and the bioactive xanthohumol. Results from the other models can be found in the Supporting Information (Table S1).

The RPD values (Table 1) showed that spectra from all three vibrational spectroscopy techniques could be used to predict total $\alpha$-acids and total bitter acids as determined by industry standard UV analyses. However, the portable NIR analysis, which had a RPD value of 3.0 for total $\alpha$-acids, fell just short of the suitability criterion. The spectroscopic techniques could also be used to predict total $\alpha$-acids and total bitter acids as determined by HPLC analyses, with the exception of the IR models, which fell short of the criterion. The IR spectra could be used to predict concentrations of the minor $\alpha$-acid cohumulone, as could Raman spectra, but NIR spectral analyses failed (Tables 1 and S1).

We had expected that xanthohumol would be readily quantifiable by Raman spectroscopy as the compound was predicted to show strong Raman scattering. However, the RPD values suggested that both Raman and IR spectra would not be appropriate for quantitative analysis (Table 1), which highlights the difficulty of predicting which vibrational spectroscopic technique will be most suitable and illustrates how different vibrational techniques can be appropriate for different analytes. Models that predict total and individual $\beta$-acids failed for all spectroscopic techniques (RPD values 1.0−2.4), but these components are not considered critical for the screening of hops varieties (Table S1, Supporting Information).

**Assignment of IR and Raman Spectra of Bitter Acids and Xanthohumol.** DFT calculations were used to predict the optimized geometries of cohumulone, colupulone, and xanthohumol. The predicted IR and Raman vibrational modes were compared to the experimental IR (Figure 3a) and Raman (Figure 3b) spectra of cohumulone and colupulone. Calculated values were in good agreement with the experimental, with a mean absolute deviation value of 13 $cm^{-1}$ for the assigned bands.

Most of the IR spectral differences occurred in the region from 1700−1000 $cm^{-1}$ (Figure 3a). The ring carbonyl band occurred at 1663 $cm^{-1}$ in cohumulone and at 1652 $cm^{-1}$ in colupulone. These were in good agreement with the DFT calculations, which predicted the bands at 1663 and 1660 $cm^{-1}$, respectively. A medium-intensity band was observed as a shoulder in cohumulone at 1579 $cm^{-1}$, and an equivalent colupulone band was observed at 1581 $cm^{-1}$. These bands were assigned to the keto−enol carbonyl stretching vibration, predicted at 1603 and 1608 $cm^{-1}$ for cohumulone and colupulone, respectively. The relatively low frequencies of these carbonyl bands were consistent with previous vibrational spectroscopic and DFT studies performed on compounds bearing similar intramolecularly hydrogen-bonded groups.[41,42] The intense band at ∼1525 $cm^{-1}$ in both compounds was due to a conjugated mode that involved large displacement of the intramolecularly bonded proton. Lastly, a number of overlapping C−H bending modes gave rise to a strong band at ∼1440 $cm^{-1}$ in both compounds.

Selected regions of the Raman spectra of cohumulone and colupulone are shown in Figure 3, panel b. The prenyl alkene stretching vibration at 1674 ± 1 $cm^{-1}$ was prominent in the spectra of both compounds (predicted at 1681 ± 1 $cm^{-1}$). The cohumulone and colupulone spectra deviated from one another in the region from 1660−1500 $cm^{-1}$ (Figure 3b). Four bands were predicted for each compound in this region with variable intensities. The vibrations are complex and involve displacement throughout the conjugated backbones of the molecules. The bands were loosely assigned at their maxima as diene stretches. The predicted spectrum of the colupulone tautomer (T2) (Figure 1) had no intense vibrational modes in this region, which implied that the lower energy (T1) structure (Figure 1) was abundant in the solid state of the compound. This was consistent with a published crystal structure.[35] The other noteworthy bands in the Raman spectra occurred at 1452, 1383, and 1352 $cm^{-1}$ in both cohumulone and colupulone. These were in good agreement with the calculations for overlapping C−H twisting, wagging, and bending modes.

**IR PLS-R Models Predicting UV Reference Data.** The PLS-R models that predicted total $\alpha$- and $\beta$-acid concentrations (by UV) from IR and Raman spectral data were interpreted visually by comparing the first three LVs of each model to the relevant bitter acid spectra (Figure 4). When a LV is similar to spectra of the pure compound, this implies that the model is spectrally meaningful, but when the LVs no longer contain the features of the analyte, the model may no longer be extracting spectrally relevant information, and overfitting becomes a consideration.[43] This approach complements the standard approach for model interpretation based on statistical data, that is, the validation data (Tables 1 and S1).

In Figure 4, panel a, the IR spectrum of cohumulone is overlaid with the first three LVs from the PLS-R model for $\alpha$-acids by IR spectroscopy. The first LV explained 73% of the reference value variance and was almost identical to the profile of cohumulone—a sure indication of effective modeling. Successive LVs described less variance and deviated increasingly from the spectrum of the pure compound. In Figure 4, panel b, LVs from the IR $\beta$-acids models are overlaid with colupulone. In this case, the first LV did not mimic the colupulone spectrum and explained only 46% of the reference data variance. In particular, one of the key lupulone bands, at 1580 $cm^{-1}$, was almost absent, which made the profile more similar to that of cohumulone. Subsequent LVs related more specifically to $\beta$-acid concentrations and the third LV, which explained 9% of the variance in the reference data, had high loading coefficients around 1580 $cm^{-1}$. This inspection of LVs implied that the $\alpha$-acids, which were nearly always present in greater concentrations (Figure 2), were interfering with chemometric quantitation of $\beta$-acids, which explains the poor performance of these models (Table S1, Supporting Information).

**Raman PLS-R Models Predicting UV Reference Data.** The Raman PLS-R LVs are compared to the relevant IR and Raman spectra in Figure 4, panels c and d. The first LV in the $\alpha$-acid model had high loading coefficients around 1673, 1452, 1382, and 1352 $cm^{-1}$ (Figure 4c). These bands were all observed in the spectrum of cohumulone (Figure 3b), which suggests that the model was extracting spectrally relevant data. However, the first LV also had high loading coefficients around 1608 and 1626 $cm^{-1}$ that were not observed in the spectrum of cohumulone (Figure 3b). Xanthohumol, the conjugated chalcone responsible for the yellow color of lupulin (Figure 1), had intense Raman bands at both of these frequencies (Figure 5) and was present in the hops samples at concentrations ranging from 0.13−0.85% (by HPLC, Figure 2). Despite its relatively low concentration, the contribution of xanthohumol to the Raman spectrum of hops was pronounced due to the large and highly polarizable $\pi$-conjugated system that makes the compound extremely Raman active (Figure 1). The relative intensities of xanthohumol and cohumulone (intensity ×10) are shown in Figure 5 and highlight the extreme Raman activity of the bioactive chalcone. Figure 5 also shows the vibrational displacement vectors of the most intense xanthohumol bands, which highlights the complexity and delocalization of these vibrations.

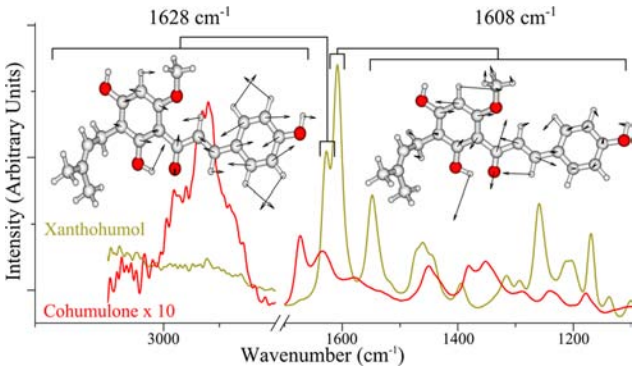

**Figure 5.** Raman spectra of xanthohumol and cohumulone (intensity ×10) with the DFT predicted vibrational displacement vectors of the most intense xanthohumol modes inset (lengths of arrows are proportional to predicted displacements).

After initial studies, it was feared that these intense xanthohumol bands would interfere with PLS-R models and prohibit the use of Raman spectroscopy for the analysis of hops bitter acids. This did not prove to be the case, as evidenced by the performance metrics in Table 1. This was not altogether surprising given the fact that xanthohumol concentrations were correlated to $\alpha$-acids ($r^2$ = 0.68) and total bitter acids ($r^2$ = 0.73). In the case of $\beta$-acids models, xanthohumol had a more detrimental effect since concentrations of these components were poorly correlated to one another ($r^2$ = 0.46). This, in tandem with the interfering $\alpha$-acids, which were more concentrated in nearly all varieties, could explain the poor

performance of the Raman PLS-R models for β-acids (Table S1, Supporting Information).

We have shown that NIR, IR, and Raman spectroscopy could be used to quantitatively screen for the key hops components α-acids, total bitter acids, and cohumulone. It has also been shown that portable NIR technology could be used for this purpose. Some of the limitations of these techniques are also reported, including the fact that quantitation of β-acids is unlikely to be achieved using this approach. Although some analytical challenges have been overcome using "fused" spectroscopic data sets,[30,44] our preliminary investigation suggested that this approach did not improve the performance of the reported models. The spectroscopic techniques required less sample preparation and, in most cases, greatly reduced analysis times compared to traditional analyses. Solvent use was also eliminated. Some vibrational features of cohumulone, colupulone, and xanthohumol have been assigned. Finally, the PLS-R LVs have been related to the pure spectra of the compounds for which they predict, which allows for a more insightful appraisal of the generated PLS-R models.

was to develop a quality control method for goji berry that could be applied in the industry to give fast and reliable results.

## MATERIALS AND METHODS

**Fruits and Sample Preparation.** Nine commercial samples of dried fruits of *L. barbarum* were used (S1−S9) along with five juices (S10−S15) and one jam (S16). Samples S1−S3 were of Chinese origin (S1-Shroeger, lot 950276; S2-Hebei Meiwei Chinese Herb, lot 110313; S3-Shenzhou, lot 0040, art. no MEDBOOM 30177; S4−S9 were purchased on the Italian market (herbalists'shops, pharmacies, supermarkets) and consisted of the entire dried fruits. The juices (samples S10−S15) were concentrated juice obtained from the fresh fruits and in some cases with the addition of other juices (pear, acer, etc.).

**Optimized Extraction of Carotenoids from the Dried Fruit.** Ten grams of each sample of goji was weighed and ground with a mortar and pestle in liquid $N_2$. Approximately 500 mg of the ground fruits was ultrasonicated with 50 mL of distilled water for 15 min. The sample was centrifuged, and the supernatant was discarded. The samples were washed with 20 mL of absolute ethanol and centrifuged, and the supernatant was again discarded. The residue was ultrasonicated for 15 min with 20 mL of hexane/acetone 50:50 and centrifuged, and the supernatant was collected. The procedure was repeated until the supernatant remained colorless (four to five times in total). The extracts were combined, concentrated partially under vacuum (at 20 °C), and adjusted to 50.0 mL using hexane/acetone 40:60. The solutions were filtered and immediately injected.

**Extraction of Carotenoids from Juices.** Ten milliliters of a well-shaken juice was added in a volumetric flask of 50 mL, and the volume was adjusted with distilled water. Two milliliters of this solution was transferred to a separator funnel, a small quantity of NaCl was added, and the aqueous phase was extracted with hexane/EtOAc until the upper layer was colorless (three to five times, depending on the sample). Extracts were combined, concentrated partially under vacuum (at 20 °C), and adjusted to 10.0 mL using hexane/acetone 40:60. The samples were filtered and immediately injected.

**Chemicals.** All solvents used for HPLC analysis were of HPLC grade; $CH_3CN$ and MeOH for HPLC were purchased from Sigma-Aldrich (Amersham, Sweden). Water was purified by a Milli-Qplus system from Millipore (Bedford, MA, USA). All laboratory chemicals used in this study in the isolation protocol were of reagent grade. Sephadex LH-20 was purchased from Sigma-Aldrich. The Sep Pak C18 cartridge (Vac35 $cm^3$) was from Waters (Milford, MA, USA). Nylon filters (0.45 $\mu$m pore size) were from Agilent (Agilent Technologies, Palo Alto, CA, USA).

**Standards.** $\beta$-Carotene (98% purity) was purchased from Extrasynthèse (Genay, France). About 5 mg of $\beta$-carotene was accurately weighed and dissolved in 25 mL of hexane 100%. This stock solution was kept at −20 °C. A series of dilutions was prepared in acetone 100% each time immediately before analysis.

**Preparation of Zeaxanthin Dipalmitate Enriched Extract and Isolation of Zeaxanthin Dipalmitate (Figure 1).** The above-described extraction scheme was employed using a higher amount of herbal drug (5−10 g). The extract was subjected to size exclusion chromatography on Sephadex LH-20 (15 × 3 cm) using MeOH/acetone 50:50 as elution solvent and afforded 10 fractions. Fractions were monitored using HPLC-DAD and combined accordingly. The fraction containing zeaxanthin dipalmitate was then subjected to a fast RP column chromatography on Sep Pak using mixtures of acetone/MeOH of descending polarity. The fraction obtained with 70% acetone contained zeaxanthin dipalmitate 85% pure. This fraction was used to perform the precision and accuracy of the HPLC method. The zeaxanthin dipalmitate enriched extract was obtained as above without the use of Sep Pak. Fractions containing zeaxanthin dipalmitate were combined to afford the enriched extract. This extract was used to estimate the accuracy of the overall method, as matrix spike. The protocol described above was fast to ensure minimum exposure of the carotenoid to light and heat.

**Instrumentation.** The centrifuge used was a Hermle Labortechnik Z323 K operating at 5 °C, and 5000 rpm. A Bandelin Sonorex RK 100 H (Germany) sonicator was operated at a medium operating frequence of 35 kHz.

**HPLC-DAD-MS Analysis Instrumentation.** Analysis was carried out using an Agilent 1200 liquid chromatograph equipped with a DAD detector and an Agilent 6410 triple-quadrupole equipped with dual mode APCI-electrospray source operated in APCI mode and managed by Masshunter software (Agilent Technologies). The column was a Luna RP-C18 (150 mm × 4.6 mm) with a particle size of 5 $\mu$m (Phenomenex) maintained at 20 °C. An isocratic system was used, acetone/MeOH 55:45 (v/v) with a flow rate of 1.4 mL/min. After the DAD detector, the flow was split 1:4 to meet the flow requirements for maximal sensitivity of the dual mode source. The injected volume of the samples was 5 $\mu$L. The UV−vis spectra were recorded between 220 and 650 nm, and the chromatographic profiles were registered at 350, 430, 450, and 480 nm. Carotenoids were detected by positive ionization mode, scan spectra from $m/z$ 100 to 1500; fragmentors were 135 and 200 V, gas temperature was 350 °C, nitrogen flow rate was 12 L/min, nebulizer pressure was 30 psi, quadrupole temperature was 100 °C, and corona needle voltage was 4000 V.

**Linearity, LOD, LOQ, Precision, and Accuracy of the HPLC Method.** The linearity range of responses of the standard was determined on six concentration levels with three injections for each level. Calibration graphs for HPLC were recorded with sample amounts ranging from 2.6 ng to 0.35 $\mu$g. Stock solutions of the standards (LOQ included) were prepared at different concentrations ranging from $0.18 \times 10^{-3}$ $8.9 \times 10^{-3}$ mg/mL and were injected into HPLC (injection volumes varying from 2 to 20 $\mu$L). The limits of detection (LOD) and quantification (LOQ) under the chromatographic conditions were determined by injecting a series of standard solutions until the signal-to-noise (S/N) ratio was 3 for LOD and 10 for LOQ. To evaluate the repeatability of the HPLC method on real sample (S3 sample), extracts were analyzed at three different concentration levels (200, 100, and 50%) in the range of the calibration curve. For the intraday variability test, the sample was analyzed in six replicates within 1 day. For the interday variability test, the sample was examined in triplicate for three consecutive days. The contents of zeaxanthin dipalmitate were evaluated to calculate the relative standard deviation (RSD). For the accuracy test of the HPLC method, the spiking method was applied. A known amount of freshly prepared standard solution (zeaxanthin dipalmitate of 85% purity) in three different concentration levels (in the range of the calibration curve) was added into a certain amount of sample. The samples were measured in triplicates, and the amount of the standards added was calculated by subtraction (in total, 12 injections).

**Precision and Accuracy of the Overall Method (Including Extraction Process).** To check the repeatability of the method over a broad range of concentrations, amounts of herbal drug corresponding to 150 100, and 50% (750, 500, and 250 mg) of the expected analyte were analyzed. Six different extracts for each concentration level were prepared according to the method described above and injected twice in the HPLC. The mean, standard deviation, and relative standard deviation were calculated on the basis of zeaxanthin dipalmitate. Results are expressed as RSD. For the accuracy study of the overall

method the recovery experiment was modified as described previously in the literature.[18] As the amount of the purified zeaxanthin dipalmitate was too little to perform this analysis, an enriched extract was prepared and used as a matrix spike solution. Different stock solutions of this extract were prepared and added (2, 1 mL) to 500 mg of herbal drug in to obtain three different concentration levels (120, 140, and 200%) of the main analyte. Samples were left for a few minutes under $N_2$ to dry and were extracted according to the method. Extractions were repeated three times for each concentration level, and samples were injected twice. Results are presented in Table 4.

**Qualitative and Quantitative Determination of Zeaxanthin Dipalmitate.** Identification of zeaxanthin dipalmitate was done by HPLC-APCI-MS ($m/z$ 1045.8 $[M + H]^+$, 789.6 $[M -$ palmitoyl $+ H]^+$). Due to the presence of triglycerides in the fruits, suppression of the ionization was observed in the positive ion mode.[19] For the quantitative determination of zeaxanthin dipalmitate, the method of external standard was applied using $\beta$-carotene as standard. The regression curve was obtained by measuring each point in triplicate. Measurements were performed at 450 nm, which is the maximum absorbance for $\beta$-carotene and zeaxanthin dipalmitate. Results were adjusted using a molecular weight correction factor (molecular weight of zeaxanthin dipalmitate 1045.8 vs 536.8 for $\beta$-carotene).

## RESULTS AND DISCUSSION

The fruits of *L. barbarum* have been the subject of many phytochemical and analytical investigations, which have given evidence to a wide variety of secondary metabolites and nutritive elements. Besides polysaccharides, which are responsible for the significant nutritive value and antioxidant activity of goji berry,[4−6] the fruits contain glycerogalactolipids, carotenoids, simple phenolics, flavonoids, and considerable amounts of vitamins, most importantly vitamin C.[15,20,21] Furthermore, the fruit contains free amino acids and especially nonproteinogenic amino acids such as taurine, $\gamma$-aminobutyric acid, and betaine.[2,22] Taurine has been claimed to be responsible for the protective role of goji berry on diabetic retinopathy.[23] All of these groups of constituents cover a wide range of polarity and molecular weight so as to require analytical methods specific for each case. Several analytical protocols have been developed accordingly, which include classic phytochemical separations, enzymatic hydrolysis, HPLC-UV-MS, capillary electrophoresis, size exclusion chromatography, thin layer densitometry characterization by NMR, and IR.[4,5,8,9,15,20−22] A literature survey makes evident that quality control of the fruit cannot be achieved by a single analytical protocol. The methodology described in the current study targeted the carotenoids and especially zeaxanthin dipalmitate. The solvent system used was specific for the extraction of this type of constituent, and other types of constituents were not extracted as observed in our analyses.

**Development of the HPLC Methodology.** Preliminary analyses of the *L. barbarum* fruit nonpolar extracts (hexane/acetone 50:50) showed the predominance of one main constituent, which was identified by its UV and MS data as zeaxanthin dipalmitate. By applying the normalization method at 450 nm, the content of zeaxanthin dipalmitate was estimated to be >80% of total carotenoids. Therefore, the developed assay was based solely on this active/marker constituent.

A typical C18 column was chosen (Luna, 150 × 4.6 mm, 5 $\mu$m) with spherical particles, end-capped, and high carbon load. Due to the nonpolar nature of the main metabolite, mixtures of methanol/acetonitrile or acetonitrile 100% did not provide adequate elution strength. An isocratic mixture of acetone/MeOH 55:45 instead resulted in a well-separated peak of zeaxanthin dipalmitate and afforded pseudomolecular ion in the HPLC-MS analysis. Due to the well-reported low stability of carotenoids, the temperature during the analysis was kept at 20 °C.

**Preparation of the Samples: Sampling−Grinding−Extraction.** Analysis of carotenoid presents many problems that are linked to the uneven distribution of carotenoids within the berry and nature of the matrix in the preparations, instability of carotenoids under light, high temperature, oxygen, metal exposure, and stability in the presence of solvents ($H_2O$, acetone, dichloromethane).[24] Generally, an extraction protocol should be fast and simple and respect the physical and chemical properties of the tested constituents. In the case of goji berry, besides the carotenoid instability, two other issues had to be taken into consideration: the gluey nature of the fruits, which makes their handling difficult, and the variability of the fruits in the same package in terms of different sizes and moisture levels. The first step of this study was to develop a practical and efficient method to overcome these problems.

Due to the gluey nature of the fruits, grinding is very difficult, and during any grinding process the temperature is increased and aggregates are afforded. Therefore, classical mill pulverization is not feasible, whereas a lyophilization step prior to milling does not resolve the problem. The use of a sieve to refine and homogenize the ground material is also not feasible due to the sticky behavior of the grinded pieces. Both methods were tested in our laboratory without success. Zhao et al.[17] described a method during which the fruits are ground together with silica gel micropowder or anhydrous sodium sulfate. This method, however, suffers from low repeatability. Peng et al.[16] succeeded in grinding the material after extraction with water and air-drying. This methodology was also excluded in the present paper due to the long total analysis time (not reported by the authors), which makes the assay not practical over a large number of samples. Instead, liquid $N_2$ with the use of a mortar and pestle was a fast way to reduce the material to smaller pieces of berry, maintaining the samples at low temperature, preserving carotenoids. With this method it is also possible to grind a higher amount of fruits (10 g or more), obtaining a representative and homogenized sample.

The next step was the choice of the most suitable extraction solvent and the method of extraction. Maceration with HEAT (hexane/ethanol/acetone/toluene 10:6:7:7, v/v/v/v) followed or not by saponification in one extraction cycle was reported in the literature.[15,17] When this method was performed in our laboratory without the saponification step, the material was not discolored, and further extraction steps afforded intense yellow extracts, suggesting that the carotenoid extraction is not complete. This extraction protocol along with the extraction solvent mixture was excluded because of the toxicity of toluene. Ultrasonication instead of the previously reported maceration[15,25] gave better results (extracts monitored by LC-UV). Ultrasonication is a fast and efficient way of extracting, favoring the penetration of solvent in plant tissues, and might be useful especially in the case of carotenoids, which are located inside the plant tissues. To avoid raising the temperature during ultrasonication, ice was added into the sonication bath.

Preliminary experiments with goji had shown that the main constituent, zeaxanthin dipalmitate, is more soluble in nonpolar organic solvents, such as petroleum ether and hexane. Therefore, the extraction protocol was designed aiming at the exhaustive extraction of this lipophilic compound. Previously described[24] solvent systems for carotenoids such as THF/methanol or ethanol 100% are not suitable for *L. barbarum*.

Mixtures with hexane such as ethanol/hexane 4:3 or combinations of partition between ethanol and hexane[26] were tested along with a series of mixtures of acetone/hexane and dioxane/hexane (0:100, 25:75, 50:50, 75:25, 100:0, respectively). Acetone is considered a good solvent for its capacity to penetrate the solid matrix and dissolve the range of carotenoids present in the samples. Indeed, mixtures of hexane/acetone gave better results than mixtures of dioxane/hexane. Among different mixtures of hexane/acetone, the best results (controlled by UV-DAD) were obtained using the combination 50:50. It is noteworthy that in all of these experiments no discoloration of the herbal drug was observed, indicating that the extraction was not exhaustive. This fact was attributed to the high content of polysaccharides in the fruits, which form a layer and do not favor the extraction of the carotenoids from the pericarp.[26] A step of ultrasonication with water prior to extraction with our solvent system removed efficiently the polysaccharides, and after four to five cycles of extraction (ultrasonication), the residue had become visually colorless as a sign of the exhaustive extraction of carotenoids (Supporting Information, Figure S1). At this point an additional extraction step was necessary to remove water and because mixtures of acetone/hexane are not miscible with water and carotenoids can be oxidized under humidity. To achieve this, acetone 100% and absolute ethanol were tested as suitable solvent. Six independent experiments were carried out using acetone or ethanol for the water removal, and the amounts of zeaxanthin dipalmitate were calculated. The repeatability of the extraction was better (<5%) when absolute ethanol was used, probably because this solvent removes water without solubilizing the nonpolar zeaxanthin dipalmitate. Quantification of the ethanol fractions obtained with this method showed only a small loss of zeaxanthin dipalmitate ranging from 0.05 to 0.1%.

Other issues taken into consideration during the preparation of the samples were evaporation of solvents in the rotary evaporator and the final adjustment of volume in the volumetric flask. Experiments were carried out in subdued light using amber glassware, and the evaporation was carried out at 20 °C to avoid degradation of carotenoids. Furthermore, the extracts were not evaporated to dryness to avoid adhesion of carotenoids on glassware, whereas the final adjustment of volume was done using hexane/acetone 40:60, instead of acetone 100%, as in this solvent degradation of carotenoids has been reported.[24] Indeed, degradation of zeaxanthin dipalmitate was observed on the second day (Figures S2 and S3 in the Supporting Information) when acetone 100% was used, whereas it remained stable after 1 week (in each case samples kept at 4 °C) when a mixture of hexane/acetone 40:60 was added in the volumetric flask, in complete accordance with Taungbodhitham et al.[27]

**Analysis of the Fruits.** Nine samples of goji fruits were analyzed for their content in zeaxanthin dipalmitate. Results are shown in Table 2. Quantitative differences among samples are linked to the status of conservation and time of harvest. On the basis of these results the mean content of zeaxanthin dipalmitate in fruits of goji is 0.3−0.4% compared to the 0.1−0.2% that is reported in the literature. This difference is attributed to the exhaustive extraction of carotenoids of the developed assay and confirms the method's efficiency. In all samples studied zeaxanthin dipalmitate represents >85% of the total carotenoid content. Quantitative results showed a big variance among investigated samples, which might be due to different sources of the fruits and different harvest times, manufacturing processes, and storage conditions.[28−30] Comparison of our results with those reported in the literature is also not feasible. Besides the variances of the samples, the methodology reported in the literature is completely different, aiming at the whole range of carotenoids, especially when saponification is applied. Nevertheless, from the results given in this study the high content of zeaxanthin dipalmitate in goji berry might be due to the efficient extraction.

According to our results, the amounts of zeaxanthin dipalmitate vary from 28 to 54 mg/10 g of edible portion. Compared to other fruits or vegetables of our daily diet,[31] it can be concluded that goji berry contains remarkable amounts of zeaxanthin dipalmitate and is a rich source of carotenoids. What is more important is that the esterified zeaxanthin has a better solubility and bioavailability in comparison to zeaxanthin alone.[32,33]

**Analysis of Products Based on Goji Berry.** Although the scope of this study was to develop a quality control assay for Fructus Lycii, other types of commercial samples were tested for comparison reasons. Because juices contained residues of the fruit, it was not feasible to filter the samples and inject them as such in the HPLC. Therefore, a small extraction (partition) using hexane/EtOAc was necessary to obtain a zeaxanthin dipalmitate fraction. HPLC analyses showed a great variability in the content of zeaxanthin dipalmitate among juices depending on the source or manufacturing process and probably from the addition of other juices (acer syrup, black cherry juice, pear juice, apple juice, carrot juice). As to the quality of the juices available in the market, some of them showed a high content of zeaxanthin dipalmitate, but the HPLC-DAD analyses clearly indicated that in the aqueous environment of the juice the main carotenoid was isomerized,

**Table 1. Calibration Equations, LOD, LOQ, and Repeatability Calibration Curve for β-Carotene**

| calibration eq | correl coeff | LOD (ng) | LOQ (ng) | repeatability (RSD %) ($n$ = 3) |

[a]Zeaxanthin dipalmitate expressed as β-carotene and after application of a molecular weight correction factor.

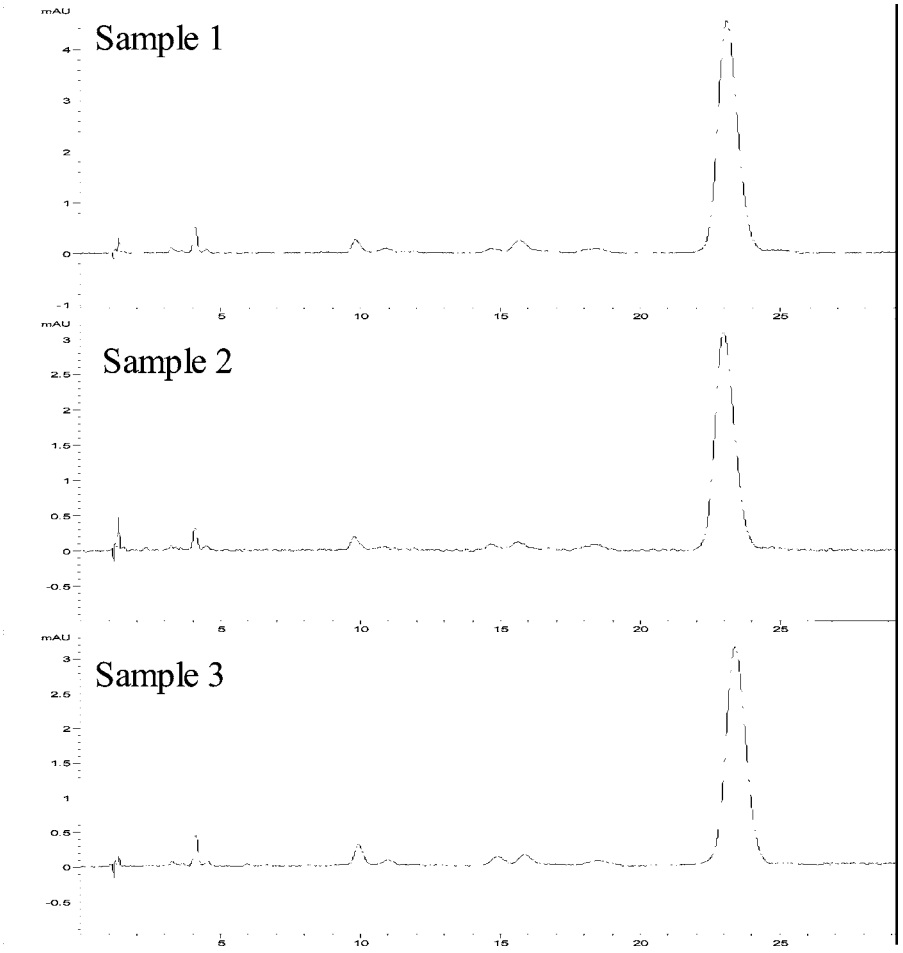

**Figure 2.** Representative chromatograms of the goji berry extracts (samples S1−S3) at 450 nm. Experimental conditions: column, Luna RP-C18 (150 × 4.6 mm); particle size, 5 $\mu$m (Phenomenex) at 20 °C; eluents, isocratic acetone/MeOH 55:45 (v/v); flow rate, 1.4 mL/min; injected volume, 5 $\mu$L solution. Zeaxanthin dipalmitate is the main carotenoid.

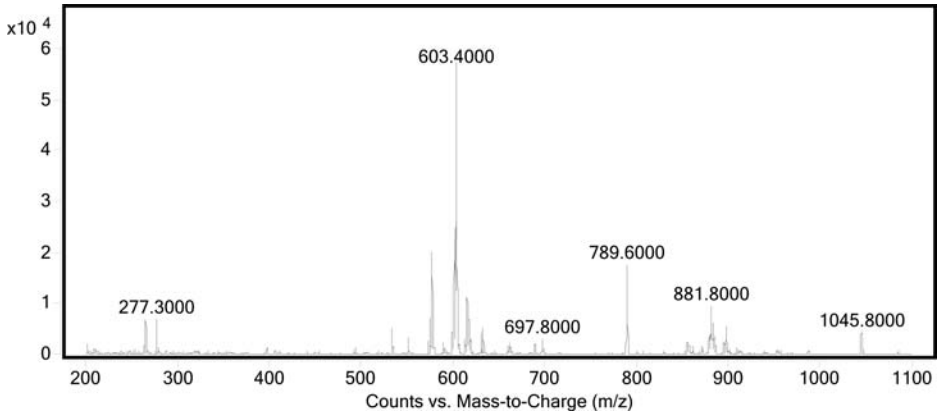

**Figure 3.** Mass spectra (APCI-positive mode) of zeaxanthin dipalmitate. Fragments 881.8 and 603.4 correspond to triglycerides. Fragments $m/z$ 1045.8 $[M + H]^+$ and 789.6 $[M - \text{palmitoyl} + H]^+$ correspond to zeaxanthin dipalmitate.

giving broad peaks in the chromatograms (Figure 2 and Supporting Information, Figure S4).

**Validation Data.** *Linearity, Repeatability on Real Sample, LOD, LOQ, Precision, and Accuracy of both HPLC and Overall Method.* The method had good linearity with $r^2$ value for zeaxanthin dipalmitate of 0.9986 (regression curve: $y = 0.0008x - 0.0052$) (Table 1). The repeatability on real sample was calculated on three individual extracts corresponding to nine different samples. Each was analyzed by HPLC, and the relative standard deviation (% RSD) of the contents of the major constituents was calculated (Table 2). RSD values ranged between 1.71 and 5.01%, 5.01% being calculated only in one sample. Although in some sample RSD values seem to be a little high (4−5%), this is still acceptable if the matrix is taken into consideration. Many of the packages tested had a heterogeneous aspect: fruits of different sizes and moisture

Table 4. Precision and Accuracy Data of the Overall Method Based on Zeaxanthin Dipalmitate

| precision | | | | accuracy | | | |
|---|---|---|---|---|---|---|---|
| amount of herbal drug (%) | % mg ± SD | mean (RSD, %) ($n$ = 6) | concn level | added ($\mu$g) | found ($\mu$g) | recovery (%) | RSD (%, $n$ = 3) |
| 150 | 0.4151 ± 0.0160 | 3.86 | high (200%) | 4.2130 | 4.1730 | 99.11 | 1.21 |
| 100 | 0.4215 ± 0.0178 | 4.13 | medium (140%) | 1.6181 | 1.5362 | 94.94 | 1.92 |
| 50 | 0.4243 ± 0.0166 | 3.81 | low (120%) | 0.8426 | 0.9047 | 107.37 | 1.84 |

contents, factors that deeply affect the extraction yield.[26] More robust fruits contain more carotenoids, are well preserved (limited carotenoid loss during the manufacturing process), and have a moisture content that favors efficient extraction. Being highly lipophilic, carotenoids are distributed internally in the tissues. When the water content of the herbal drug is high, the tissues are softer, solvents penetrate more easily into the material, and the whole extraction process is simplified, affording a better and more repeatable result. Samples that had a better macroscopic aspect (bigger, more robust, or less dry) were those that gave the lowest RSD values.

The HPLC method was validated for intra- and interday variation using purified zeaxanthin dipalmitate at three different concentration levels (50, 100, and 200%) in six replicates for the intraday and in three replicates for the interday. For each concentration level mean, standard deviation and RSD were calculated. The accuracy of the HPLC method was also evaluated using the purified zeaxanthin dipalmitate solution, which was spiked to one sample with known content. RSD values were less than 0.72 and 1.97, respectively. Results are displayed in Table 3.

Finally, the overall method (extraction step included) was tested for repeatability (in six independent replicates) and for accuracy at three different concentration levels of the main analyte. Results are displayed in Table 4. The method afforded good repeatability with acceptable RSD (<5%). For the accuracy test a recovery experiment was carried out. It has been stated that the analyte added to a substrate may behave differently from an endogenous analyte, and because it is not protected by plant tissues, it may be more easily extracted, giving an artificially high recovery.[24] This is true in the case of goji berry, for which even after the removal of polysaccharides repeated extractions are needed to obtain a colorless material, indicating distribution of carotenoids in the internal parts of the tissues. In such cases a recovery experiment is of little importance, and it may serve only as a measure of losses (degradation) during analysis. With this concept, a recovery test was carried out at three different concentration levels. The values obtained were between 94 and 107% (with RSD values <2%), which are within the acceptable limits (80−120%) for matrix spike.

It is noteworthy that the assay is based solely on zeaxanthin dipalmitate, but it is very suitable as marker constituent for the quality assays because it represents ≥85% (based on our extraction method) of the total carotenoids, and there are numerous studies in the literature confirming the increased stability of esterified carotenoids compared to their free analogues.[34,35] Therefore, a quality control method based on this constituent provides consistent results. Furthermore, the isocratic system in the HPLC enables work with a single channel, and given the fact that the solvents employed are volatile, it permits a more stable and repeatable HPLC chromatogram throughout the whole analysis period.

noncompetitive indirect ELISA (iELISA) for the detection of horse meat, this approach is again applicable only to raw meats.

The objective of this study was, therefore, to (1) develop horse selective monoclonal antibodies (mAbs) using thermally stable horse muscle proteins as the immunogen and, consequently, (2) develop a suitable mAb-based ELISA for the quantitative detection of horse meat in both raw and heat-processed ground meat samples.

## MATERIALS AND METHODS

**Materials.** Hydrogen peroxide, $\beta$-mercaptoethanol, 2,2′-azinobis(3-ethylbenzthiazoline-6-sulfonic acid (ABTS), and EZblue gel staining reagent were purchased from Sigma-Aldrich Co. (St. Louis, MO, USA). The alkaline phosphates (AP) conjugate substrate kit, goat anti-mouse IgG (H + L) AP (anti-Ig-AP) conjugate, Tris-buffered saline (TBS), 0.5 M Tris-HCl buffer (pH 6.8), 1.5 M Tris-HCl (pH 8.8), *N*,*N*,*N*′,*N*′-tetramethyl-ethylenediamine (TEMED), Precision Plus Protein Kaleidoscope Standards, 30% acrylamide/bis solution, Tris/glycine buffer, Tris/glycine/SDS buffer, supported nitrocellulose membrane (0.2 $\mu$m), and thick blot paper were purchased from Bio-Rad Laboratories Inc. (Hercules, CA, USA). All other chemicals, reagents, filter paper (Whatman no. 1 paper), egg albumin, nonfat dry milk, and polystyrene microplates were purchased from Fisher Scientific (Fair Lawn, NJ, USA). All chemicals and reagents were of analytical grade, and solutions were prepared using distilled deionized pure water (DD water) from a NANOpure DIamond ultrapure water system (Barnstead International, Dubuque, IA, USA). Meat samples, including beef eye of round roast, pork loin, lamb shoulder, whole chicken, whole duck, whole goose, turkey breast, bison, and frozen dressed rabbit were purchased from a local supermarket. Horse meat was obtained from the College of Veterinary Medicine, Auburn University (Auburn, AL, USA). Deer, elk, and African buffalo steak meats were provided by the Fats and Proteins Research Foundation (Bloomington, IL, USA). Porcine and bovine gelatins were provided by GELITA USA Inc. (Sioux City, IA, USA). Kosher fish gelatin, whey protein concentrate (80%), and soy powder were provided by Custom Collagen (Addison, IL, USA), Davisco Foods International, Inc. (Le Sueur, MN, USA), and Soylink (Oskaloosa, IA, USA), respectively.

**Production of mAbs.** Horse meat samples trimmed of visible fat were cut up and ground twice using a household meat grinder. A portion (100 g) of the ground horse lean meat was autoclaved at 121 °C for 1 h at 1.2 bar using the SterileMax benchtop steam sterilizer (Barnstead International) and the autoclaved meat mashed into fine particles. One hundred milliliters of extraction buffer [10 mM phosphate buffer solution containing 0.5 M NaCl (pH 7.0), PB-salt solution] was added to the mashed sample and the mixture homogenized for 2 min at 11000 rpm using the ULTRA-TURRAX T25 basic homogenizer (IKA Works Inc., Wilmington, NC, USA) and kept overnight at 4 °C. The mixture was then centrifuged at 4 °C for 1 h at 3220*g* (Eppendorf 5810R centrifuge, Brinkman Instruments Inc., Westbury, NY, USA), and filtered through Whatman no. 1 filter paper. The filtrate [comprising thermally stable soluble proteins (TSPs)] was dialyzed in 10 mM phosphate-buffered saline (PBS) for 24 h with frequent changes and the dialyzed extract used as the immunogen. The protein concentration of the immunogen was determined by the Bradford method using a protein assay kit (Bio-Rad). The immunization and subsequent hybridoma procedures were performed as previously described.[18] Only those clones secreting the IgG class of antibodies were selected, and mAbs were obtained from the supernatants of the propagated cell cultures. The isotype of each selected mAb was determined using a mouse mAb isotyping kit (ISO-2 1 kit, Sigma) according to the manufacturer's protocol.

**Sample Preparation.** *Meat Extracts.* Lean meat samples (horse, beef, pork, lamb, bison, African buffalo, deer, elk, chicken, turkey, goose, duck, and rabbit) trimmed of visible fat and connective tissues were ground twice, and 5 g of each sample was weighed into a sampling bag. Twenty-five milliliters of PB-salt solution was added to each, and the mixture was blended for 2 min using the Lab-Blender 400 stomacher (Tekmar Co., Cincinnati, OH, USA). Two other sets of 5 g meat samples that had been cooked (immersed in boiling water for 15 min) or autoclaved for 15 min at 121 °C and 1.2 bar using a SterileMax benchtop steam sterilizer (Barnstead International) were mashed into fine particles, 10 mL of PB-salt solution was added, and the mixtures were homogenized (using the ULTRA-TURRAX T25 basic homogenizer) for 2 min. The raw and heat-treated mixtures were then centrifuged and filtered as described above to obtain raw, cooked, and autoclaved meat extracts. The clear extracts were aliquoted into 1.5 mL small tubes and stored at −20 °C until use.

*Spiked Sample Extracts.* Sampling beakers containing 9 g of either ground pork or ground beef with 1 g of ground horse meat were prepared to obtain 10% (w/w) horse meat spiked ground pork or beef samples. These spiked meat samples were then placed in sampling bags, and 50 mL of PB-salt solution was added, after which the mixtures were blended (using the stomacher) and centrifuged as described above to obtain extracts of the 10% (w/w) raw horse meat in either ground pork or beef. A further set of 10% (w/w) horse meat in ground pork or beef in separate beakers was cooked as described above. The cooked samples were mashed, 20 mL of PB-salt solution was added, and the mixture was homogenized, centrifuged, and filtered as described above to obtain extracts of the 10% (w/w) cooked horse meat in either ground pork or beef. Ten percent (w/w) autoclaved horse meat in ground pork and beef extracts was similarly prepared as described for the spiked cooked samples except that the heating involved autoclaving the samples at 121 °C for 15 min at 1.2 bar. The resulting 10% (w/w) spiked samples were mixed with appropriate amounts of the respective unspiked (0%) beef or pork extracts (described above) to obtain 0.1, 0.3, 0.5, 1, and 3% (v/v) concentrations of spiked samples. All of these spiked samples were analyzed immediately.

*Food Protein Extracts.* Extracts of common food proteins (nonfat dry milk, soy powder, whey protein concentrate, bovine serum albumin, egg albumin, porcine gelatin, bovine gelatin, and fish gelatin) were prepared as previously described.[19]

**SDS-PAGE and Western Blot.** Western blot analysis was performed to reveal the approximate molecular weight of the antigenic protein recognized by the raised mAbs. Briefly, soluble proteins (3 $\mu$g of protein in 10 $\mu$L of sample buffer per lane) from the samples were loaded on 5% stacking gel and separated on a 12% polyacrylamide separating gel (at 200 V using the Mini-Protein 3 Electrophoresis Cell, Bio-Rad) in accordance with the method by Laemmli.[20] The separated proteins were transferred electrophoretically (1 h at 100 V, using the Mini Trans-Blot Electrophoretic Transfer Cell, Bio-Rad) as described by Towbin and others,[21] and the membrane was blocked with 1% BSA in TBS, incubated with raised mAbs diluted 1:4 (v/v) in TBST (TBS containing 0.05% (v/v) Tween-20) and secondary antibody (goat anti-mouse IgG (H + L)-AP conjugate diluted 1:3000 (v/v) in 1% BSA in TBST) in succession, and color was developed as previously described.[22] Precision Plus Protein Kaleidoscope standards were used for molecular weight estimation on gels and blots.

**Noncompetitive Indirect ELISA (iELISA).** The selectivity of raised mAbs was characterized using antigen coated iELISA as follows. One hundred microliters of sample extract appropriately diluted in 0.06 M carbonate buffer (pH 9.6) to contain 2 $\mu$g of protein was coated on the wells of a polystyrene microplate alongside controls and incubated at 37 °C for 2 h. The plate was then blocked for 1 h at 37 °C with 200 $\mu$L/well of blocking buffer [1% bovine serum albumin (BSA) in PBS]. Next, 100 $\mu$L of mAbs appropriately diluted in antibody buffer [1% BSA in PBST−PBS containing 0.05% (v/v) Tween 20] was added and the plate incubated for 2 h at 37 °C. At the end of this period, the plate was incubated with 100 $\mu$L of goat anti-mouse IgG (Fc-specific)−peroxidase conjugate diluted 3000 times in antibody buffer for 1 h at 37 °C. Finally, 100 $\mu$L of substrate solution (22 mg of ABTS and 15 $\mu$L of 30% hydrogen peroxide in 100 mL of 0.1 M phosphate−citrate buffer, pH 4.0) was added and the color developed for 20 min at 37 °C. The enzyme reaction was stopped at the end of 20 min by the addition of 0.2 M citric acid solution and the absorbance measured at 415 nm using the PowerWave XS microplate reader (Bio-Tek Instruments, Winooski, VT, USA). The microplate was washed between steps with PBST.

**Epitope Comparison.** The additivity test described by Friguet and others[23] was performed to determine whether pairs of mAbs bind to the same epitope or to different epitopes on the common antigenic protein. Briefly, saturation curves were first generated to determine the dilution of each antibody required to saturate the antigen (cooked horse meat) using iELISA as described above. To perform the additivity test, to one well containing 2 $\mu$g/100 $\mu$L of bound cooked horse meat was added 100 $\mu$L of mAb H3E3 so diluted to saturate the antigen as obtained from the saturation curve. To another well was added 100 $\mu$L of mAb H4E4 similarly diluted. To a third well was added 50 $\mu$L each of appropriately diluted H3E3 and H4E7. Secondary antibody, color substrate, and stop solution were added in succession as previously described, and the absorbance for well 1(mAb H3E3 alone), well 2 (mAb H4E7 alone), and well 3 (mAb H3E3 and mAb H4E7) was recorded as $A_1$, $A_2$, and $A_{1+2}$, respectively. The additivity index (AI) was calculated according to eq 1. AI values between 50 and 100% are deemed to indicate that the two antibodies bind cooperatively.

$$\mathrm{AI} = [(2A_{1+2})/(A_1 + A_2) - 1]\times 100 \quad (1)$$

*Competitive ELISA (cELISA).* The presence of horse meat in raw and cooked ground pork or beef was determined by testing ground meats (pork or beef) spiked with horse meat using cELISA. A series of experiments was utilized to select the optimum concentration of immobilized antigen (cooked horse meat extract) and sample extracts, dilutions of mAbs, and incubation times for antigen and antibody binding. One hundred microliters of cooked horse meat extract appropriately diluted in 0.06 M carbonate buffer to contain 0.5 $\mu$g of protein was coated on the wells of a polystyrene microplate and the plate incubated at 37 °C for 2 h. The plate was then blocked by adding 200 $\mu$L of blocking buffer, and the plate was incubated at 37 °C for 1 h. Next, 50 $\mu$L of undiluted sample extract (cooked horse meat, spiked samples, and common food proteins) was added to the wells alongside 50 $\mu$L of mAbs diluted 200 times in antibody buffer, and the plate was incubated at 37 °C for 2 h. Finally, the plate was incubated in succession with peroxidase-conjugated secondary antibody and substrate solution, and the color was developed and absorbance measured as described above. The microplate was washed between steps with PBST.

*Data Analysis.* All experiments were performed in triplicate and the results analyzed using Microsoft Excel 2007 or OriginPro 9 (OriginLab Corp., Northampton, MA, USA). One-way ANOVA using SPSS software 11.0 for Windows (SPSS Inc., Chicago, IL, USA) was used to compare means for difference among three or more treatment groups. Post hoc analysis was performed using Tukey HSD. Significance was accepted at $P < 0.05$.

## RESULTS AND DISCUSSION

**Production of mAbs.** Meat products may undergo heat processing ranging from mild to severe heat processes such as autoclaving (as in the case of canned meat). Accordingly, to increase the chances of selecting for mAbs that recognize their cognate antigen even when it has been subjected to excessive heat processes such as canning, autoclaved horse meat extract containing soluble heat-stable peptides was used as the immunogen. Although the use of a pure antigen increases the chances of obtaining the desired mAbs, there was no prior knowledge of potentially suitable species-specific and thermally stable horse meat proteins. Therefore, crude thermally stable protein extract of autoclaved horse meat was used as the immunogen to enhance the chances of getting mAbs with desired specificity as each protein in the extract had the potential to induce immune response for antibody production. Only hybridomas that secreted mAbs that reacted both with raw and autoclaved meat extracts were selected for further characterization studies.

**Specificity of mAbs.** Among approximately 80 positive hybridomas, 5 were selected for cloning due to their interesting reaction patterns. The preliminary screening of these five clones against the immunogen (protein extracts of autoclaved meats) showed that three (1A11, 2H5, and 7A2) cross-reacted with other species and only two (H4E7 and H3E3) exhibited a species specificity to horse meat alone. Their subclasses and reactivity patterns are listed in Table 1. On the basis of these results, the immunoreactivity of the two mAbs that demonstrated species specificity, H3E3 (IgG2b) and H4E7 (IgG2a), were examined against raw, cooked (100 °C for 15 min), and autoclaved (121 °C for 15 min at 1.2 bar) meat extracts from a broader range of animal species (horse, beef, pork, elk, deer, lamb, bison, African buffalo, rabbit, turkey, chicken, goose, and duck) using both iELISA and Western blot (WB) to confirm their suitability as probes for the detection of horse meat contamination.

**Table 1. Immunoreactivity of Five Selected Clones Determined by iELISA**

| antibody | subclass | species reactivity |
|---|---|---|
| 3E3 | IgG2b | reacts strongly to raw, cooked and autoclaved horse, and also reacts with raw poultry meats |
| 4E7 | IgG2a | |
| 1A11 | IgG1 | reacts strongly to all raw, cooked, and autoclaved meats |
| 2H5 | IgG1 | reacts strongly to all autoclaved meats; does not react to any cooked meat, but reacts slightly to raw meat |
| 7A2 | IgG1 | reacts strongly to all autoclaved meats but does not react to cooked or raw meats |

The iELISA results showed that both mAbs reacted strongly with raw, cooked, and autoclaved horse meat, with mAb H3E3 consistently exhibiting stronger immunoreactivity than mAb H4E7 (Figure 1). In the case of raw meat, both mAbs H3E3 and 4E7 also exhibited reactivity with raw poultry meat (turkey, chicken, duck, and goose) (Figure 1a). For the cooked and autoclaved meat extracts, both mAbs reacted solely with cooked (Figure 1b) and autoclaved (Figure 1c) horse meat extracts, with no cross-reactivity with other species of meat samples (beef, pork, elk, deer, lamb, bison, African buffalo, rabbit, turkey, chicken, goose, and duck). By comparison of the results for the raw and heat-treated samples, the absorbance readings ($A_{415\ \mathrm{nm}}$) for cooked horse meat for mAbs H3E3 and H4E7 were respectively 2.6 and 2.8 times stronger than those for raw horse meat. Likewise, the absorbance readings ($A_{415\ \mathrm{nm}}$) for autoclaved horse meat were 1.7 and 1.8 times stronger, respectively. In iELISA, antigens adsorbed onto the solid support (microplate) at high concentrations encourage high avidity and bivalent binding, leading to higher reaction signals.[24] The much stronger reaction with heat-treated compared to raw horse meat extracts may therefore be due to the higher concentrations of thermally stable antigens in the heat-treated samples because of insolubilization of most of the thermally labile soluble proteins in the raw extract.

The results from the Western blot analysis revealed that in raw meat samples both mAbs H3E3 (Figure 2a(i)) and H4E7 (Figure 2b(i)) reacted with a 32 kDa protein found not only in horse meat but also in all mammalian meats except beef and rabbit. However, several other higher molecular weight antigenic bands (35−150 kDa for mAb H4E7 and 50−150 kDa for mAb H3E3) that appeared as smeared bands were also present in the horse meat extracts. As was the case with iELISA, both mAbs also reacted with poultry meats, but compared with mammalian meats, the molecular weight for the antigenic

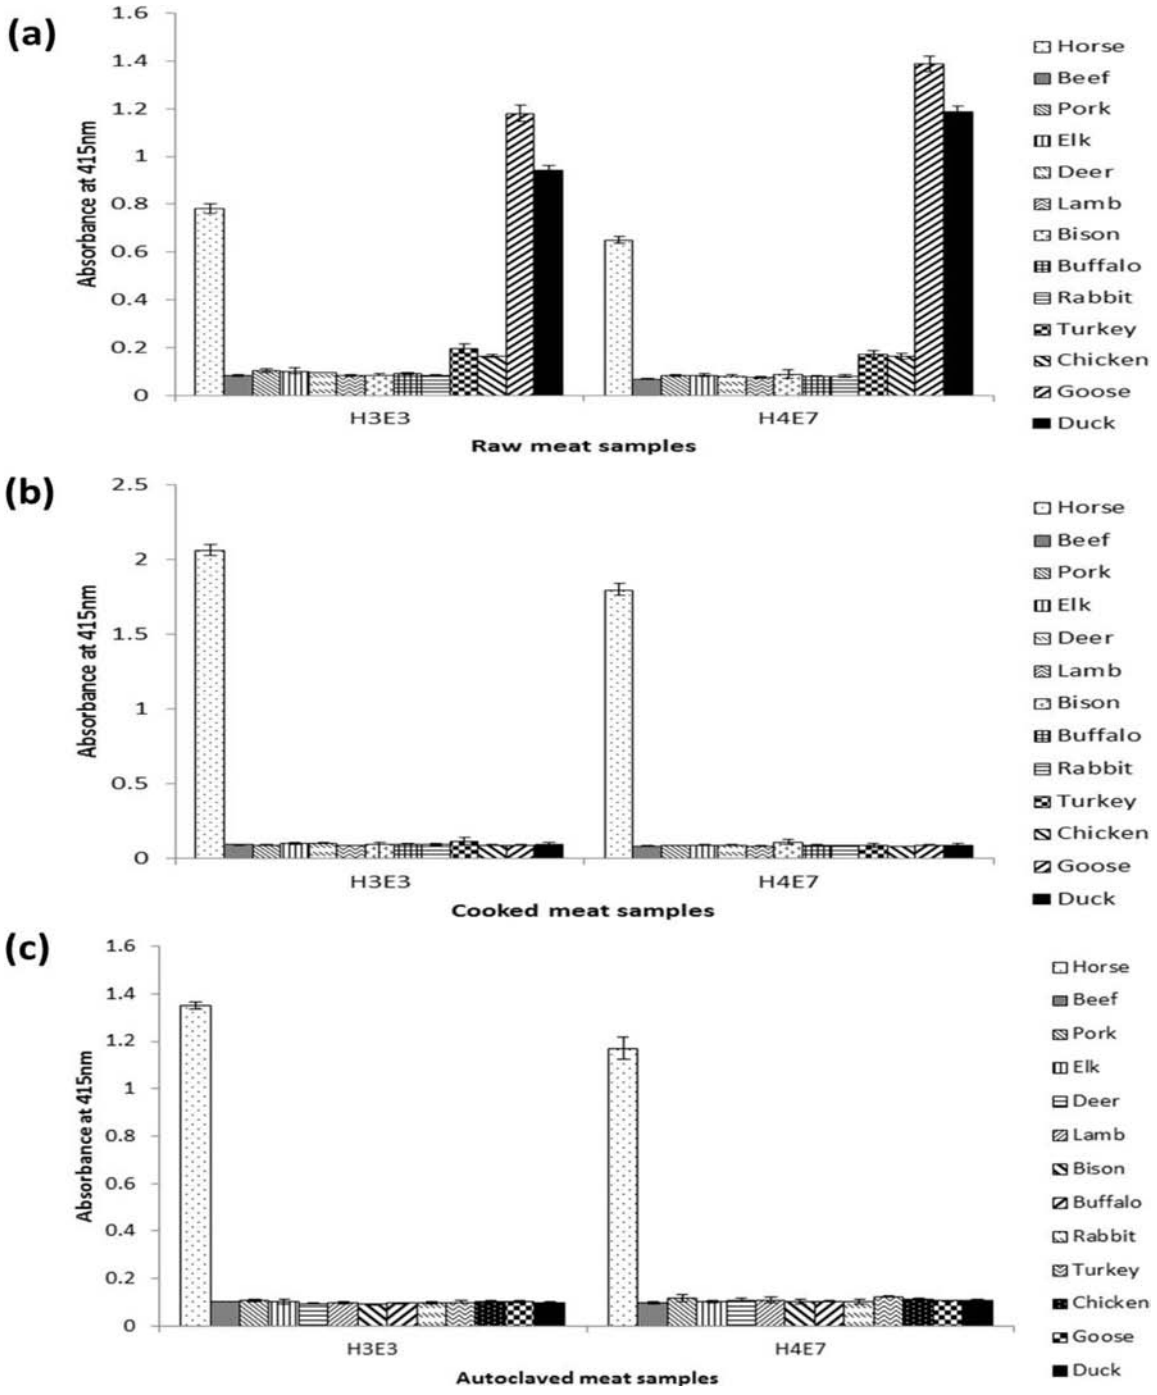

**Figure 1.** Species specificity of mAbs H3E3 and H4E7 with (a) raw, (b) cooked, and (c) autoclaved meats using indirect ELISA. Soluble proteins extracted from raw, cooked and autoclaved meat extracts were coated at 2 $\mu$g/100 $\mu$L. Results are expressed as $A_{415\ nm} \pm$ SD, $n = 3$.

protein in poultry meat had a higher estimated weight of 37 kDa. For the cooked and autoclaved samples, the Western blot analysis showed a positive reaction only with horse meat for both mAbs H3E3 (Figure 2a(ii)) and H4E7 (Figure 2b(ii)), although the bands were smeared as for the raw meat samples. For both antibodies, a 150 kDa band was visible in the cooked samples, but the bands were more smeared in autoclaved samples compared to the raw and cooked meat samples. SDS-PAGE, which involves a prior heat treatment that includes boiling for 5 min, may have denatured the proteins somewhat and hence caused the smeared bands for the raw samples. The progressive increase in the severity of the band smearing for cooked and autoclaved samples may similarly be due to the denaturation of proteins caused by the heat treatment of cooking (100 °C for 15 min) and autoclaving (121 °C for 15 min at 1.2 bar), respectively, and the additional presample treatment of boiling for 5 min.

Unlike the cooked and autoclaved samples, the Western blot results for the raw meat extracts did not agree completely with the results for iELISA, largely because there are many more types of soluble proteins present in raw meat than heated meat extracts. An antibody recognizes a specific feature on the antigen referred to as the epitope, which is usually composed of six to eight amino acids.[25] Epitopes may be either linear

dx.doi.org/10.1021/jf504032j | J. Agric. Food Chem. 2014, 62, 12536−12544

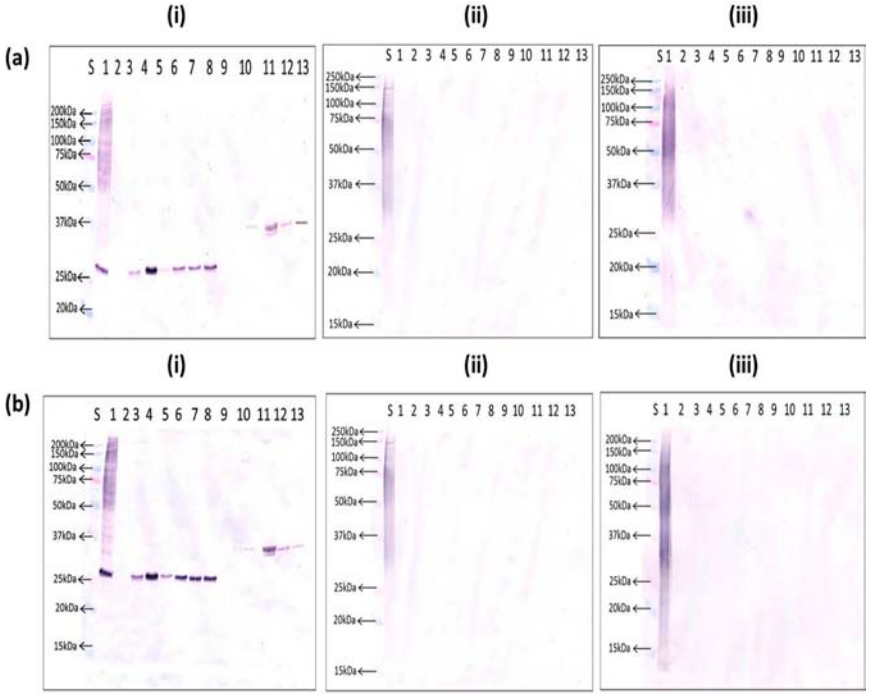

**Figure 2.** Western blot of soluble proteins extracted from (i) raw, (ii) cooked, and (iii) autoclaved meats using (a) mAb H3E3 and (b) mAb H4E7. Protein extracts were loaded at 3 $\mu$g/10 $\mu$L per lane alongside Precision Plus protein kaleidoscope prestained standards. Lanes: S, standard; 1, horse; 2, beef; 3, pork; 4, elk; 5, deer; 6, lamb; 7, bison; 8, African buffalo; 9, rabbit; 10, turkey; 11, chicken; 12, goose; 13, duck.

(formed by contiguous amino acid sequences) or conformational (formed by noncontiguous amino acid sequences).[26] In iELISA, the adsorption of proteins onto the solid support (wells of microplate) happens randomly and is therefore vulnerable to conformational changes that may either totally block or drastically reduce accessibility to the epitope such that recognition by its cognate antibody can be either hampered considerably or completely prevented.[27−29] This is not a factor in Western blot analysis, where the use of SDS ensures that the proteins or polypeptides that have been separated by SDS-PAGE assume a linear conformation,[26] thus exposing otherwise hidden epitopes. These differences in assay formats may explain why both antibodies failed to react with pork, elk, deer, lamb, bison, and African buffalo meat using iELISA but did react with these same meat samples when using Western blot, probably as a result of the exposure of hidden epitopes (in the case of iELISA) from specific or even nonspecific molecules due to the treatment with SDS in the Western blot analysis.

Because the epitopes recognized by antibodies are located in relatively small regions on the antigen, as mentioned above, sometimes antibodies find similar epitopes on related molecules, and this forms the molecular basis for cross-reaction.[24] This may explain why although horse meat extract was used as the immunogen, cross-reactions with raw poultry meat (using both iELISA and Western blot) and all mammalian meats except beef and rabbit (using Western blot) were observed. The lack of binding with heated poultry meat extracts using iELISA may occur because the antigenic protein (37 kDa) in poultry meat that is recognized by these two mAbs may be a different protein that is not as thermally stable as its counterpart in horse meat.

To test for the existence of additional cross-reactions that could lead to false positives, the two mAbs were also tested against extracts of proteins (nonfat dry milk, soy protein, whey protein concentrate, bovine serum albumin, egg albumin, gelatin, soy, whey, etc.) commonly used in food formulations using iELISA. Both mAbs failed to react with any of the proteins tested, producing absorbance readings ($A_{415\ nm}$) of <0.1 for all of the food proteins examined.

**Detection of Horse Meat in Ground Pork and Beef Using mAbs H3E3 and H4E7 Individually in cELISA.** Of all the ELISA formats, sandwich ELISA (sELISA) is often preferred because it is both sensitive and user-friendly. A requirement for developing a sELISA is that the two mAbs used (one as the capturing antibody and the other as the detecting antibody) must bind to different epitopes on the same antigenic protein without inhibiting each other's binding sites. The binding characteristics of these two mAbs were therefore examined for their suitability for use in a sELISA. The results of the additivity test performed as described by Friguet and others[23] to determine whether mAbs H3E3 and H4E7 bind complimentarily on the common antigenic protein revealed an additivity index of 0% (data not shown), indicating that these two antibodies completely inhibited epitope binding of each other on the antigenic protein and therefore were not suitable for use in a sELISA. However, although ruled out for sELISA, the two mAbs could be used individually as probes in cELISA for the quantitative detection of horse meat in raw, cooked, and autoclaved ground pork and beef samples.

In cELISA, an antigen in free form (here, the horse meat present in the spiked samples) competes with a known amount of a bound antigen (cooked extract of horse meat) such that the expected absorbance (OD) for the bound antigen in the absence of the competitor is reduced. This reduction is calculated as the percent inhibition in accordance with eq 2,[30] where 0 and 100% inhibition are controls representing the inhibitions calculated when the competitors are unspiked (0%) horse meat sample (raw, cooked, or autoclaved beef or pork meat) and a cooked horse meat sample (100% horse meat), respectively.

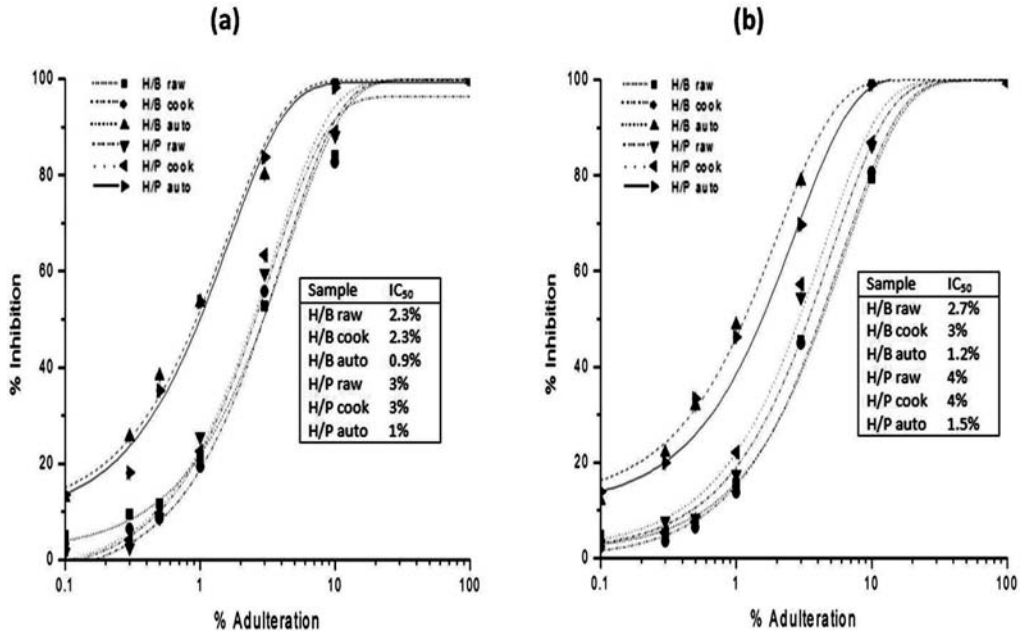

**Figure 3.** Inhibition curves with $IC_{50}$ values of raw, cooked, and autoclaved ground beef and pork adulterated with horse meat using cELISA with (a) mAb H3E3 and (b) mAb H4E7. H/B raw, horse meat in raw ground beef; H/B cook, horse meat in cooked ground beef; H/B auto, horse meat in autoclaved ground beef; H/P raw, horse meat in raw ground pork; H/P cook, horse meat in cooked ground pork; H/P auto, horse meat in autoclaved ground pork.

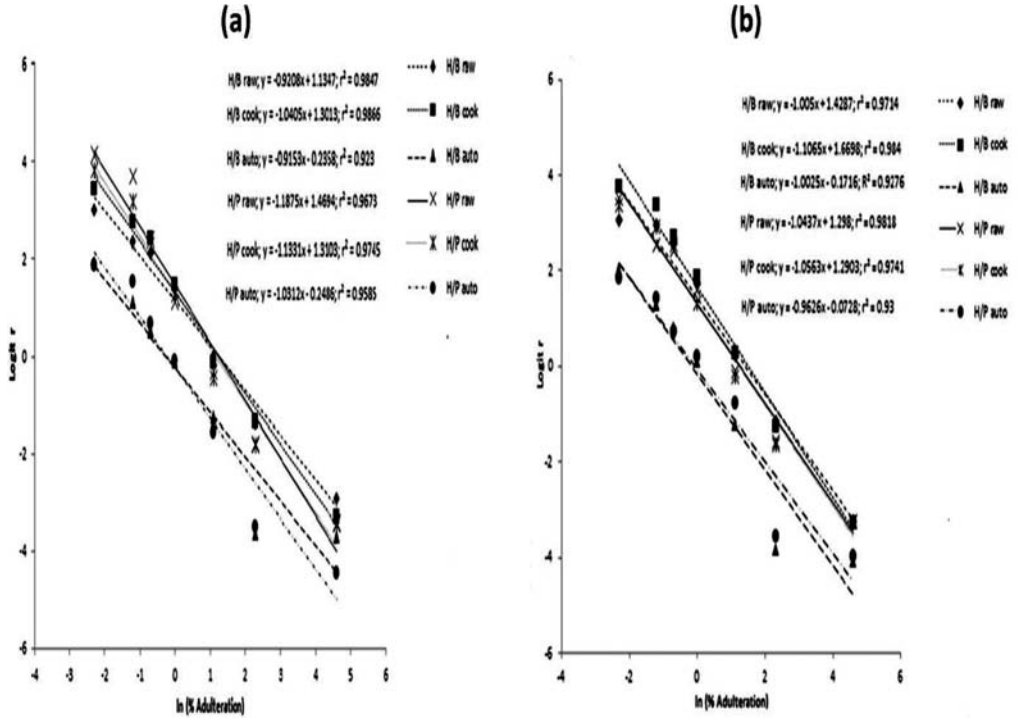

**Figure 4.** Logit-log transformed linear curves of raw, cooked, and autoclaved ground beef and pork spiked with ground horse meat as analyzed by (a) mAb H3E3- and (b) mAb H4E7-based cELISA. H/B raw, horse meat in raw ground beef; H/B cook, horse meat in cooked ground beef; H/B auto, horse meat in autoclaved ground beef; H/P raw, horse meat in raw ground pork; H/P cook, horse meat in cooked ground pork; H/P auto, horse meat in autoclaved ground pork.

$$\%\ \text{inhibition} = 100 - \frac{\text{sample OD} - 100\%\text{inhibition OD}}{0\%\text{inhibition OD} - 100\%\text{inhibition OD}} \times 100 \quad (2)$$

Because the degree of inhibition is proportional to the amount of freely competing antigen in a sample, a standard inhibition curve can be generated by plotting the percent inhibition against known concentrations of the antigen that can be used to quantify the amount of antigen present in an unknown sample. Using the spiked samples described above, six

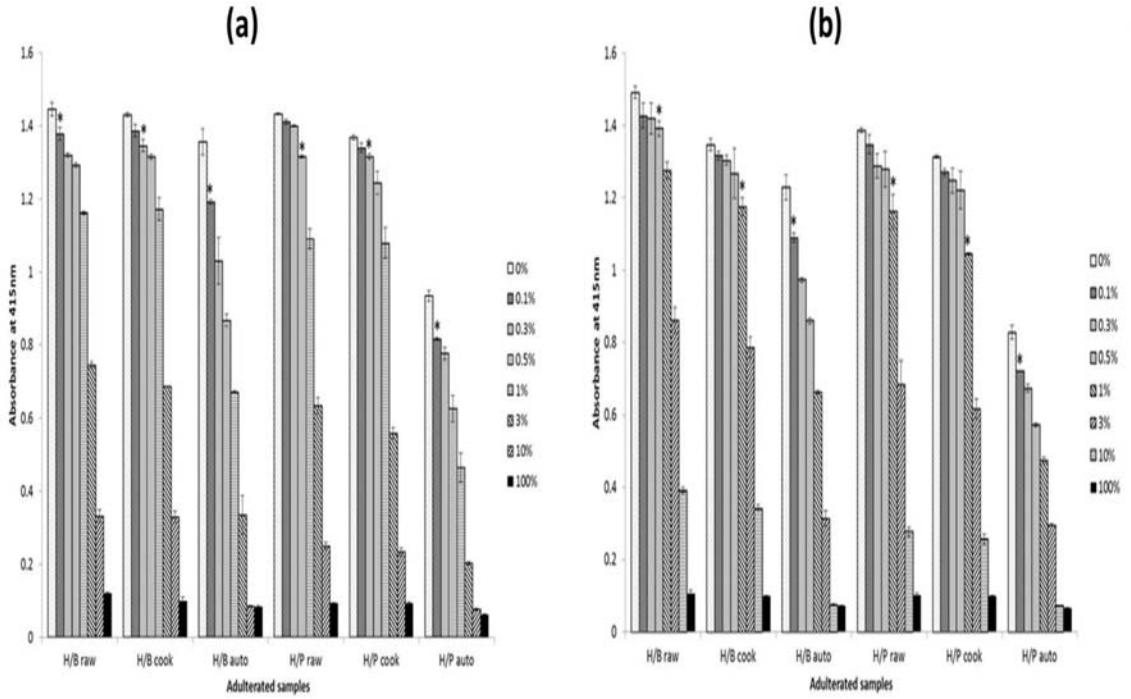

**Figure 5.** Detection limit for raw, cooked, and autoclaved ground beef and pork adulterated with horse meat using (a) mAb H3E3- and (b) mAb H4E7-based cELISA. H/B raw, horse meat in raw ground beef; H/B cook, horse meat in cooked ground beef; H/P auto, horse meat in autoclaved ground beef; H/P raw, horse meat in raw ground pork; H/P cook, horse meat in cooked ground pork; H/P auto, horse meat in autoclaved ground pork. Results are expressed as $A_{415\ nm} \pm SD$, $n = 3$. An asterisk indicates a significant difference ($P < 0.05$).

such inhibition curves were generated for each of the two mAbs, H3E3 (Figure 3a) and mAb H4E7 (Figure 3b), for the quantification of horse meat in test samples and the 50% inhibitory concentrations $IC_{50}$, the competitor concentration at which the OD is halved (50% inhibition) compared to the OD in the absence of a competitor (0% inhibition), determined for each mAb and each type of sample. For mAb H3E3, the $IC_{50}$ values were 2.3% (v/v) for horse meat in both raw and cooked beef and 0.9% (v/v) for horse meat in autoclaved beef (Figure 3a). For adulterated ground pork, the $IC_{50}$ values were 3.0% (v/v) for horse meat in both raw and cooked ground pork and 1.0% for horse meat in autoclaved ground pork (Figure 3a). In the case of the other mAb, H4E7, the $IC_{50}$ values were 2.7, 3.0, and 1.2% (v/v) for horse meat in raw, cooked, and autoclaved ground beef, respectively (Figure 3b). For adulterated ground pork, the $IC_{50}$ values were 4.0% (v/v) for horse meat in both raw and cooked ground pork and 1.5% (v/v) for horse meat in autoclaved ground pork (Figure 3b).

The issue of matrix interference in antigen−antibody interactions is usually determined by comparing the $IC_{50}$ values.[31] The differences in $IC_{50}$ between the two matrices (beef and pork) described above suggest that different matrices do indeed have an effect on the detectability of horse meat. Hence, for accurate quantification of horse meat in different matrices, corresponding matrix-matched sample standards must be analyzed simultaneously. $IC_{50}$ is also a measure of the sensitivity of the assay; the higher the $IC_{50}$ value, the lower the sensitivity of the assay and vice versa. This means that cELISAs using both mAbs will have a higher sensitivity for horse meat in ground beef than for horse meat in ground pork. Our iELISA results revealed that mAb H3E3 exhibited a consistently higher immunoreactivity than mAb H4E7, and these cELISA results also indicate that an assay based on mAb H3E3 will be more sensitive than one based on mAb H4E7, suggesting that mAb H3E3 may have an intrinsically higher affinity for the antigenic protein in horse meat than mAb H4E7.

To obtain a more accurate quantification of the target material (horse meat) in each sample, the dose−response standard inhibition curves were transformed into linear relationships using logit-log transformations for both mAbs H3E3 (Figure 4a) and H4E7 (Figure 4b), as previously described.[32] Both assays exhibited a good linear response over a wide concentration range (0.1−100%) for all of the horse meat spiked samples, with high correlations ($r^2$ = 0.9276−0.9818 for H4E7-based cELISA; $r^2$ = 09230−0.9866 for H3E3-based cELISA) between the horse meat concentrations and ELISA responses. These linear curves can thus serve as a useful standard curve for the quantification of horse meat in different matrices over a wide range of horse meat contaminated samples.

The limit of detection, defined as the smallest amount of the analyte (horse meat) that could be significantly ($P < 0.05$) differentiated from unadulterated samples (0%), was also determined for both assays. The detection limits for the mAb H3E3-based cELISA were 0.1, 0.3, and 0.1% (v/v) for horse meat in raw, cooked, and autoclaved ground beef, respectively; and 0.5% (v/v) for horse meat in both raw and cooked ground pork and 0.1% (v/v) in autoclaved ground pork (Figure 5a). For the mAb H4E7-based cELISA, the detection limits were 0.5% (v/v) for horse meat in raw ground beef, 1% (v/v) for horse meat in cooked ground beef, 0.1% (v/v) for horse meat in autoclaved ground beef, 1% for horse meat in both raw and cooked ground pork, and 0.1% for horse meat in autoclaved ground pork (Figure 5b). The detection limits for the mAb H3E3-based cELISA were lower than for the mAb H4E7-based cELISA for all of the horse meat spiked samples except for

those that had been autoclaved, indicating a higher sensitivity for the former.

For both cELISAs, the detection limit was generally lower for the spiked beef samples compared to those for the corresponding spiked pork samples, indicating a higher sensitivity to horse meat in beef than in pork, which agreed with the $IC_{50}$ values. The observed detection limit for both the new assays was lower than the 5% of horse meat in raw ground beef reported by Lopez-Andreo and others[15] and either comparable to (in the case of mAb H4E7-based cELISA) or lower than (in the case of mAb H3E7-based cELISA) the 1% horse meat in raw ground pork reported by the same group[15] using PCR. The mAb H3E7-based cELISA also performed better than the detection limit of 1% horse meat in raw ground pork and beef reported by Martin and others[16] using a polyclonal antibody-based sELISA. The detection limits of the new assays were, however, higher than the 0.05 and 0.1% horse meat in raw and cooked ground pork and beef achieved by the PCR methods of Xu and others[14] and Kesmen and others,[11] respectively, although both suffered from problems due to an inability to detect amplified fragments with increasing heating temperature or time[14] or guarantee that the assay could be effective against samples cooked to an internal temperatures above 72 °C.[11] In contrast, the new cELISAs reported here were able to detect horse meat down to 1% or lower in ground meat samples that had been boiled for 15 min and to as low as 0.1% for autoclaved samples, which were not considered in either of the earlier studies.

In conclusion, two mAbs (H3E3 and H4E7) were selected from a panel of mAbs raised against partially purified protein in autoclaved horse meat extract to detect the presence of horse meat in cooked and autoclaved samples without exhibiting any cross-reactivity with other meat or food proteins. These two mAbs were used individually to develop cELISAs for the quantitative determination of horse meat content in raw, cooked, and autoclaved beef and pork samples. Although the mAb H3E3-based cELISA was the more sensitive of the two, the cELISA based on mAb H4E7 could detect ≤1% of horse meat in raw and cooked ground beef or pork and down to 0.1% of horse meat in autoclaved ground beef or pork, thus easily satisfying the 1% detection limit required by the European Union. The cELISA based on either mAb H3E3 or mAb H4E7 is therefore expected to become a valuable analytical tool for monitoring horse meat adulteration in meat products to address many health, ethical, and economic issues associated with horse meat contamination in meat products for human consumption. In situations involving raw poultry, the cross-reactivity of these mAbs with raw poultry can be readily eliminated by heating the samples prior to analysis to avoid possible false-positive results.

All other solvents were of analytical reagent grade. Potassium hydroxide, phenolphthalein, ethyl alcohol, acetic acid, isooctane, soluble starch, potassium iodide, sodium thiosulfate, and *p*-anisidine were of analytical grade.

**Measurements of Acid Value (AV), Peroxide Value (POV), and *p*-Anisidine Value (*p*-AV).** AOCS official methods were used to determine acid value (method Cd 3d-63), peroxide value (method Cd 8-53), and *p*-anisidine value (method Cd 18-90) of oil samples.

Total oxidation value (TOTOX) was calculated as follows:[17]

$$\text{TOTOX} = 2\text{POV} + p\text{-AV}$$

**Tocopherols Analysis by HPLC.** The concentration of tocopherols in oil samples was determined according to the method reported by Hu et al.[18] Approximately 1 g of oil sample was put into a volumetric flask and made up to 10 mL with HPLC grade hexane. After filtering through a 0.45 μm filter, 3 μL of sample was directly injected into an Agilent 1100 series HPLC system equipped with a fluorometric detector. The excitation wavelength was set at 295 nm, and the emission wavelength was set at 325 nm. The column was a Hypersil ODS2 C18 column (4.6 mm × 15 cm, 5 μm, Elite, Dalian, China). The mobile phase was methanol/water (98:2, v/v), and the flow rate was 0.8 mL/min. The corresponding standards (α-, β-, γ-, and δ-tocopherol) for identification and quantification were prepared separately in a 100 mL volumetric flask with hexane, and the final concentrations of α-, β-, γ-, and δ-tocopherol were 100, 20, 15, and 80 μg/mL, respectively. Then they were serially diluted to different concentration gradients for generating the standard curves.

**Fatty Acids Analysis by GC.** Fatty acid compositions of vegetable oils were analyzed by gas chromatography. Samples were methylated as described by Cruz-Hernandez et al.[19] The FAMEs were identified using a capillary column of fused silica (100 m × 0.25 mm × 0.20 μm) coated with 100% cyanopropyl polysiloxane (CP-Sil 88, Chrompack, Agilent Technologies, Shanghai, China) equipped with a flame ionization detector. Hydrogen was used as the carrier gas at a flow rate of 30 mL/min. The oven temperature program (86 min in total) was as follows: The initial temperature was set at 45 °C for 4 min, increased to 175 °C at a rate of 13 °C/min, maintained for 27 min, further raised to 215 °C at a rate of 4 °C/min, and finally kept at 215 °C for 35 min.[20] The injector and detector were kept at 250 °C. Analysis of all peaks was accomplished by comparison of their retention time with FAME standards. Area under each fatty acid peak relative to the total area of all fatty acid peaks was used to quantify the fatty acids identified,[21,22] and the obtained results are reported as percentage of fatty acid.

**Accelerated Oxidation Assay.** A Schaal oven test was used to accelerate the oxidation process in different vegetable oils.[23] The modified protocol followed AOCS (1998) Recommended Practice Cg 5-97 (AOCS cg 5-97). In total, 500 g of oils was weighed into 500 mL glass bottles that were loosely capped. Bottles were kept randomly inside an oven maintained at 62 ± 1 °C without light to accelerate the oxidation (WGS201, Hongzhan Products Inc., Shanghai, China). After intervals of 7 days of heating, samples were removed into bottles. Then they were topped immediately with nitrogen, capped tightly, and kept frozen (−20 °C) until analysis. Analyses were conducted on the same day for some sensitive indices such as POV, *p*-AV, and secondary oxidative products or for other indices within 2 days of removal from the oven.

**Synthesis of DNPH Derivatives.** DNPH derivatives of aldehyde/ketone products in oxidized oils were synthesized as follows: Oil sample (0.1−1.0 g) was put into a 10 mL volumetric flask, and the flask was filled to volume with isopropanol containing DNPH (3 g/L) and hydrochloric acid (3%).[8,24] The test tube was shaken and kept at 40 °C for 1 h to accelerate derivatization reaction. Then it was cooled in water and centrifuged at 4200 rpm for 5 min. The sample was then filtered through a 0.22 μm membrane syringe filter and injected into the HPLC column.

**Isolation and Identification of DNPH Derivatives by HPLC-ESI-QqQ-MS.** An Agilent 1260 series HPLC system equipped with a diode array detector (DAD) was used to analyze samples. Separation of DNPH derivatives was achieved on a Zorbax Edipse plus-C18 column (4.6 mm × 25 cm, 5 μm, Agilent Technologies, Shanghai, China). The column was thermostatically controlled at 30 °C. The flow rate was set to 1 mL/min, and the injection volume was 5 μL. The mobile phase consisted of two solvents: methanol (A, 100%) and Milli-Q water (B, 100%). The solvent gradient in volumetric ratios was set as follows: 0−15 min, 70−75% A; 15−45 min, 75−100% A; and held at 100% A for an additional 2 min. There was a 3 min postrun,

which brings it back to the starting condition. The ultraviolet (UV) absorbance values of the peaks were collected between 200 and 620 nm using a DAD and monitored at wavelengths of 360 nm.

A triple-quadrupole mass spectrometer (6430 QqQ LC/MS system; Agilent Technologies) equipped with an orthogonal electrospray ionization (ESI) source was used to identify the derivatives. Negative ion mode was selected for data collection.[25,26] MS parameters were set as follows: sheath gas was nitrogen and collision gas was helium; drying gas flow rate, 11.0 L/min; drying gas temperature, 300 °C; nebulizing gas pressure, 15 psi; capillary voltage, 4 kV. Some of the ketones, alkanals, alkenals, and alkadienals were identified by using standards. Others were tentatively identified according to their retention times, mass spectra, and matching with mass spectra by the software MassHunter Acquisition B.03.01, Qualitative Analysis B.03.01 and Quantitative Analysis B.03.02 (Agilent Technologies).

**Quantification of Carbonyls.** To have a more complete picture of the carbonyls present in the four oils and of their evolution with heating time, their quantification was expressed as peak area per gram of oil acquired by HPLC chromatogram.

**Statistical Analysis.** Data are expressed as the mean value ± standard deviation. One-way ANOVA was used to compare the differences between mean values. A level of probability at $p < 0.05$ was set as statistically significant. Regression analysis was used to determine the correlation of two data sets. All of the data were performed with SPSS 13.0 software for Windows (SPSS Inc., Chicago, IL, USA).

## RESULTS AND DISCUSSION

**Initial Properties of Oils.** Initial fatty acid composition, tocopherol content, acid value, peroxide value, and *p*-anisidine value of oil samples are shown in Table 1. These oils contained the typical proportions of fatty acids: palm oil contained higher percentages of palmitic acid (38.23%) and oleic acid (43.05%); camellia oil was rich in oleic acid (80.14%), whereas sunflower oil and perilla oil were rich in linoleic acid (55.24%) and linolenic acid (54.37%), respectively.

The analysis of tocopherols showed that sunflower oil contained the highest concentration of total tocopherols (the sum of $\alpha$-, $\beta$-, $\gamma$-, and $\delta$-tocopherols), at 1113 mg/kg. Palm, camellia, and perilla oils contained a similar amount of total tocopherols (193.4, 198.7, and 185.0 mg/kg, respectively). Additionally, palm, camellia, and sunflower oils had high proportions of $\alpha$-tocopherol (>98%), whereas perilla oil had 69% of $\gamma$-tocopherol and only 20% of $\alpha$-tocopherol.

Before accelerated oxidation assay, analysis of AV, POV, and *p*-AV showed that the four oil samples were so-called fresh oils. All complied with the legal dietary requirements of China. The maximal AV was 0.72 mg KOH/g in perilla oil, and maximal POV and *p*-AV were 5.11 mequiv $O_2$/kg and 4.07 in palm oil.

**Changes of Total Oxidation Value during Oxidation.** The TOTOX is often used to estimate oxidative deterioration of lipids, as it has the advantage of combining the amounts of primary oxidation products (hydroperoxides) with secondary products (principally alkenals and alkadienals) in fats or oils.[17] As shown in Figure 1, the highest increment of TOTOX at 62 °C with limited air for 35 days was found in sunflower oil (814), rising from 8.12 to 822, followed by camellia oil (247) and perilla oil (223). Palm oil gave rise to the lowest increment of TOTOX, only 155. That means the order of oxidation stability was sunflower oil < camellia oil < perilla oil < palm oil.

**Comparison of Carbonyl Products Generated in Oils.** Identification of carbonyls in these oils heated at 62 °C with limited air for 35 days (Figure 2) showed that camellia oil (20 types), sunflower oil (19 types), and palm oil (19 types) contained numerous nonpolar carbonyl compounds, whereas

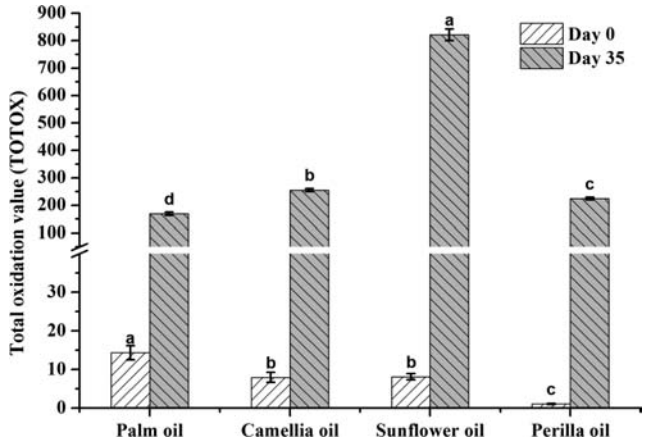

**Figure 1.** Initial and final total oxidation value (TOTOX) for four oils heated at 62 °C with limited air for 35 days. TOTOX = 2POV + *p*-AV. Data are mean values ± SD, $n = 3$. Values followed by the same letter in each set are not significantly different ($p < 0.05$).

perilla oil (14 types) lacked some types of compounds. Twenty carbonyls identified in camellia oil were ranked as retention time of peak: ethanal, 2-propenal, acetone, propanal, pentanal, 2-hexenal, hexanal, 2-hexanone, 2,5-dimethylbenzaldehyde, 2-heptenal, heptanal, 2-octenal, octanal, octanone, 2-nonenal, nonanal, 2-nonanone, 2-decenal, decanal, and decanone, respectively. The above 19 types of nonpolar carbonyls, except 2-decenal, were also detected in palm oil. Sunflower oil contained the most similar components of nonpolar carbonyls to palm oil, but acetone was not detected in sunflower oil and 2,4-decadienal was not detected in palm oil. Fourteen types of carbonyls identified in perilla oil were ethanal, acetone, propanal, butanal, 2-pentenal, 2-hexenal, hexanal, 2,4-heptadienal, 2,5-dimethylbenzaldehyde, 2,4-nonadienal, 2-octenal, octanal, 2-nonenal, and nonanal. These compounds represented groups of secondary oxidation products resulting mainly from the oxidative deterioration of unsaturated fatty acids.[3]

Although the four oil samples contained the most similar components of nonpolar carbonyls, 2-decenal was detected only in camellia oil, and 2,4-decadienal was found only in sunflower oil. Butanal, 2-pentenal, 2,4-heptadienal, and 2,4-nonadienal were observed only in perilla oil. Guillén and Uriarte[5] reported that aldehydes and relative carbonyls generated in lipids during oxidation were substantially different in quantity and type depending on the composition of the lipid matrix. Hence, it was estimated that 2-decenal might be derived mainly from oleic acid, and 2,4-decadienal might be from linoleic acid. Linolenic acid might be the parent fatty acid of butanal, 2-pentenal, 2,4-heptadienal, and 2,4-nonadienal. Similar results have been reported by other researchers.[11,27] For example, there were high levels of 2-decenal in high-oleic rapeseed oil[4] and high-oleic sunflower oil.[28]

The distribution of nonpolar carbonyls in four vegetable oils is shown in Figure 3. Ketones, alkanals, and alkenals were identified in camellia and palm oils during the whole experimental period. Alkanals were the major compounds in camellia oil on the 35th day (72% of total carbonyls), followed by ketones (15%). Both alkanals and alkenals were the main carbonyls in palm oil (49 and 24%) and sunflower oil (45 and 41%). For perilla oil, the major products were alkanals (44%), followed by alkenals (19%) and alkadienals (16%). These carbonyl compounds with different double bonds in samples

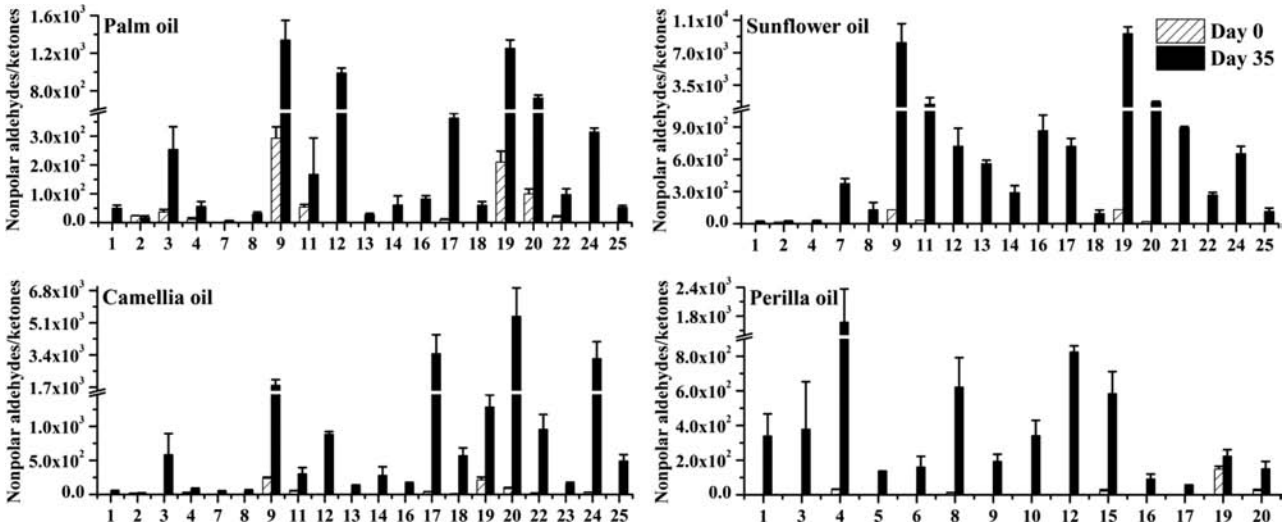

**Figure 2.** Initial and final nonpolar aldehydes/ketones (peak area/g oil) identified for four oils heated at 62 °C with limited air by HPLC-QqQ-MS. 1, ethanal; 2, 2-propenal; 3, acetone; 4, propanal; 5, butanal; 6, 2-pentenal; 7, pentanal; 8, 2-hexenal; 9, hexanal; 10, 2,4-heptadienal; 11, 2-hexanone; 12, 2,5-dimethylbenzaldehyde; 13, 2-heptenal; 14, heptanal; 15, 2,4-nonadienal; 16, 2-octenal; 17, octanal; 18, octanone; 19, 2-nonenal; 20, nonanal; 21, 2,4-decadienal; 22, 2-nonanone; 23, 2-decenal; 24, decanal; 25, decanone. They were ranked as retention time of peak. The identification or quantification was done according to the retention times and the $m/z$ ratio reported in the author's previous paper.[41] Data are mean values ± SD, $n$ = 3.

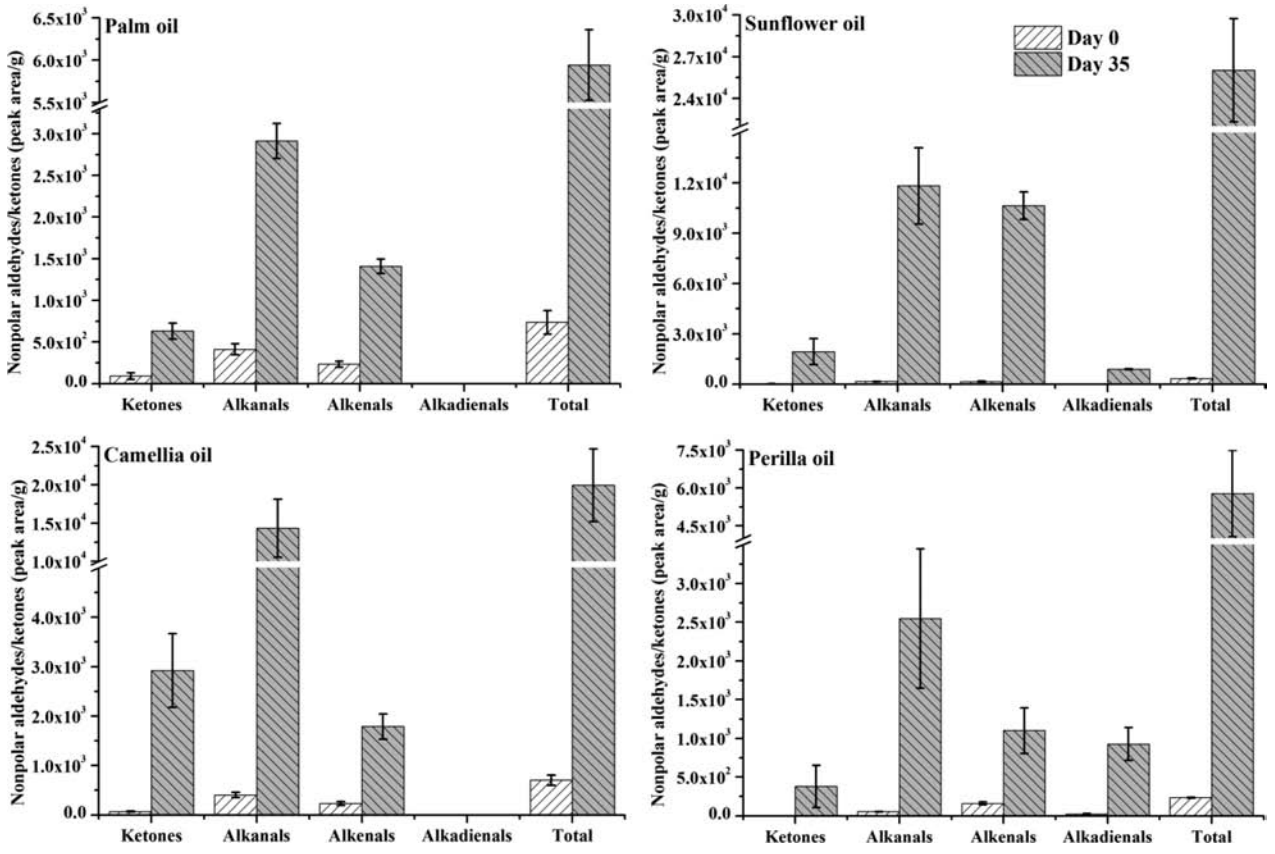

**Figure 3.** Distribution of nonpolar aldehydes/ketones (peak area/g oil) in four oils heated at 62 °C with limited air. Data are mean values ± SD, $n$ = 3.

were mainly owing to the fatty acid chains with different double bonds.[27]

**Possible Pathways of Fatty Acid Decomposition and Aldehyde/Ketone Formation.** The autoxidation of lipid or the reaction of free radical chain mainly includes three steps: initiation, propagation, and termination.[1] Hydroperoxides as the primary oxidation products are first formed. However, they are unstable and rapidly decomposed to a variety of volatile compounds, including aldehydes, ketones, hydrocarbons, and other secondary products.[29,30] Aldehydes, either saturated or

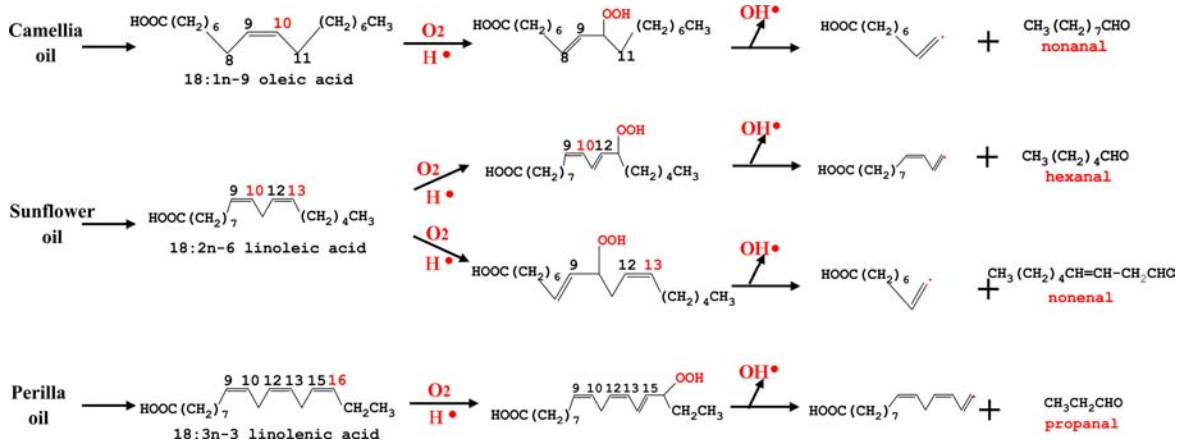

**Figure 4.** Nonanal, hexanal, nonenal, and propanal, from oleic, linoleic, and linolenic acyl group oxidation, identified in the HPLC-QqQ-MS after derivatization.

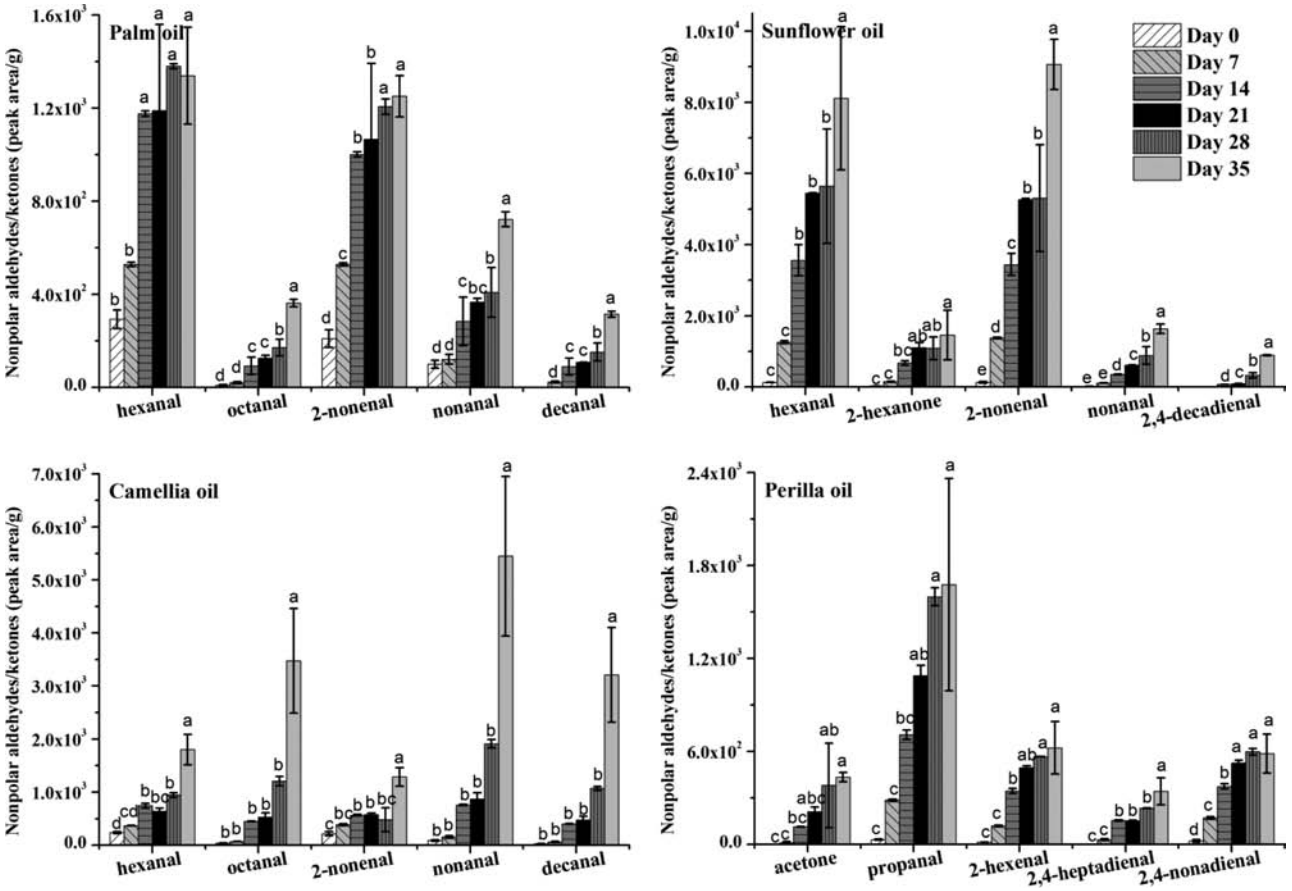

**Figure 5.** Oxidative volatile profiles obtained for four oils by plotting the content of five major carbonyl compounds (chosen from Figure 2) versus time of thermal treatment at 62 °C with limited air. unsaturated, are considered as the main volatile secondary compounds formed in any oil oxidation process.[6] Vegetable oils are rich in unsaturated fatty acids, especially oleic, linoleic, and linolenic acids, which are the main causes of deterioration. It was reported that the relative oxidation rates of methyl oleate, linoleate, and linolenate were 1:10.3:21.6.[31] Different types of unsaturated fatty acids would generate various types of hydroperoxides and aldehydes/ketones.[32,33] Possible formation pathways of nonanal, propanal, hexanal, and 2-nonenal are shown in Figure 4. Nonanal is produced probably by breakdown of oleate 10-OOH; hexanal and 2-nonenal are probably from linoleate 13- and 10-OOH; propanal is probably by decomposition of linolenate 16-OOH. Additionally, decanal, 2-decenal, and octanal from oleate 8-, 9-, and 11-OOH, heptanal, 2-octenal, and pentanal originated by decomposition of linoleate 11- and 13-OOH; 2-hexenal and 2,4-heptadienal from linolenate 13- or 12-OOH were also produced.[32]

The breakdown of acyl group chains in unsaturated fatty acids was the main formation pathway of aldehydes/ketones. According to the distribution of aldehydes/ketones shown in

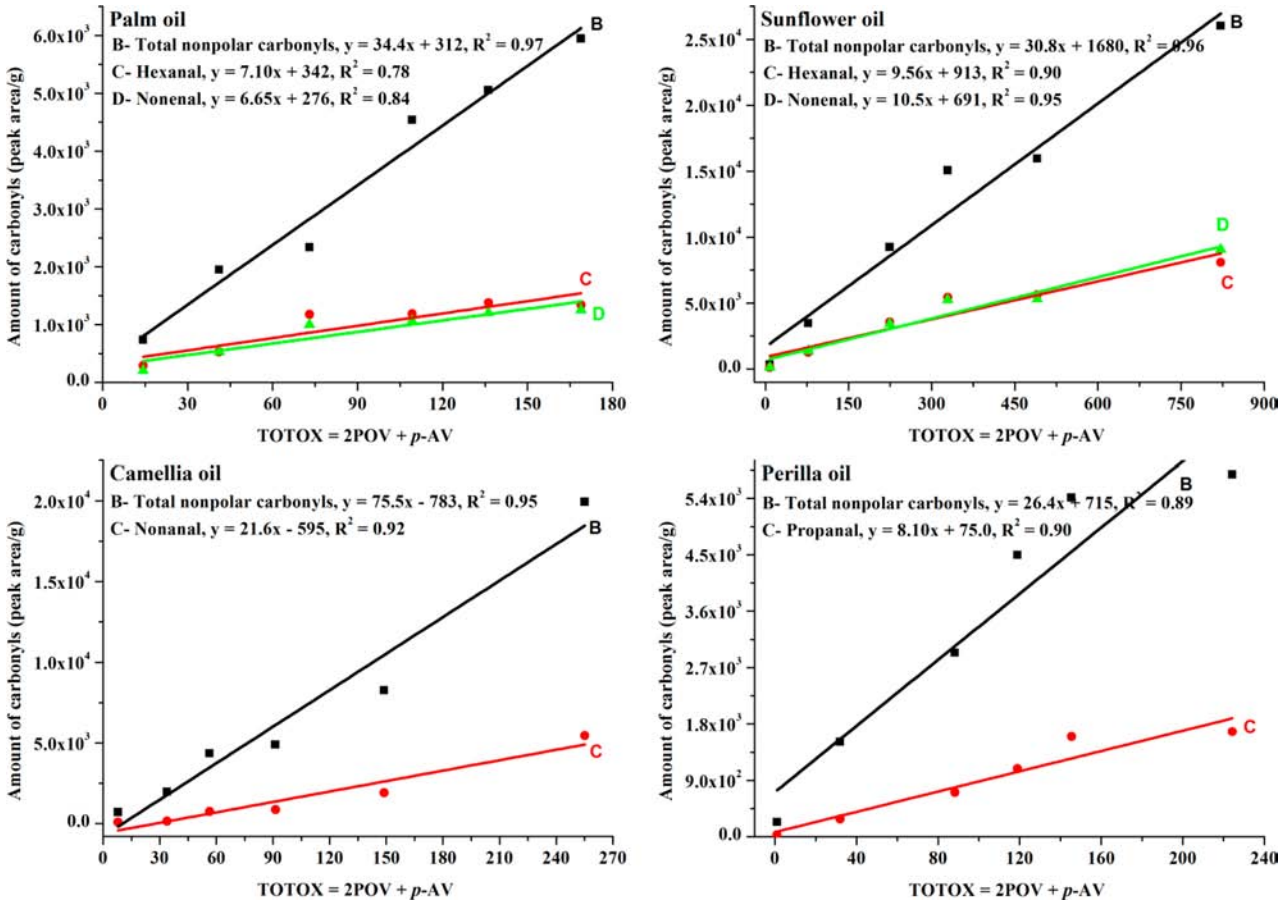

**Figure 6.** Linear correlations of TOTOX versus carbonyl compounds (peak area/g oil) during 35 days of accelerated oxidation at 62 °C.

Figures 2 and 3, these carbonyls derived from linoleic acyl groups showed the highest abundances, followed by those derived from oleic acyl and much lower proportions of those derived from linolenic acyl. Similar results were also found in the studies of many other studies on oil oxidation.[6,34] Additionally, the formation of all secondary products depends not only on the intrinsic property of lipid but also on the conditions under which the process takes place, such as temperature, amount of air, and type of bottle.[35,36]

**Changes of Carbonyls during Oxidation.** Before oxidation assay (day 0), only 10 types of carbonyl compounds in camellia oil and 9 types in palm oil were found, and sunflower and perilla oils showed a lower number of carbonyls, 6 and 5 types, respectively (Figure 2). It is well-known that the thermoxidative degradation of unsaturated fatty acids may result in the presence of many other secondary products, and their concentrations increased with time. As shown in Figure 3, the highest increment of total carbonyls (the sum of all detected aldehydes and ketones) measured as area count during 35 days of oxidation was detected in sunflower oil ($2.57 \times 10^4$) from $3.33 \times 10^2$ to $2.60 \times 10^4$, followed by camellia oil ($1.92 \times 10^4$). By contrast, there were lower increments in perilla oil ($5.54 \times 10^3$) and palm oil ($5.21 \times 10^3$). That means the order of oxidation stability was sunflower oil < camellia oil < perilla oil < palm oil. Interestingly, the order was the same as that in comparison of TOTOX of samples.

Figure 5 shows oxidative volatile profiles obtained for four oils by plotting five major carbonyl compounds' content (chosen from Figure 2) versus time of thermal treatment at 62 °C with limited air. It is very obvious that oil samples with different fatty acid compositions had their characteristic carbonyl compounds. For camellia oil (oleic acid mainly), nonanal was the most abundant carbonyl on the 35th day, followed by octanal and decanal. For sunflower oil (linoleic acid mainly), 2-nonenal and hexanal (measured as area count) showed the highest increments during 35 days of oxidation assay, increasing by $8.93 \times 10^3$ and $7.97 \times 10^3$, respectively. Hence, the two carbonyls might be good oxidation indicators for evaluating the oxidation state of sunflower oil. For perilla oil (linolenic acid mainly), propanal showed a more remarkable growth compared with other products, which might be also the key oxidation marker. Although 2-nonenal and hexanal were the most abundant carbonyls in palm oil, they showed slow increases after 14 days of oxidation. On the other hand, the concentration of nonanal was sharply increased after 14 days of oxidation and showed a high level on the 35th day. The increment tendency of nonanal, octanal, and decanal in palm oil had the same patterns as that in camellia oil. These results indicated linoleic acid was first oxidized and generated 2-nonenal and hexanal and then oleic acid was oxidized and formed nonanal (octanal and decanal) in palm oil.

The changes of the above characteristic carbonyls also played an important role in the evaluation of oil deterioration. By choosing 2-nonenal or hexanal as the oxidation indicators for palm and sunflower oils, nonanal for camellia oil, and propanal for perilla oil, it was found that sunflower oil had the highest indicator increment ($8.93 \times 10^3$ or $7.97 \times 10^3$), followed by camellia oil ($5.36 \times 10^3$), perilla oil ($1.65 \times 10^3$), and palm oil

($1.04 \times 10^3$ or $1.05 \times 10^3$). The order of oxidation stability was sunflower oil < camellia oil < perilla oil < palm oil. Hence, the yield of indicator could be used to demonstrate the oxidation state of oil. Meanwhile, the correct choice of oxidation indicator was necessary.

**Regression Analysis.** As shown in Figure 6, good linear correlations were observed between the total nonpolar carbonyl amount ($y$) and TOTOX ($x$) during 35 days of accelerated oxidation: palm oil ($y = 34.4x + 312$, $R^2 = 0.97$), camellia oil ($y = 75.5x - 783$, $R^2 = 0.95$), sunflower oil ($y = 30.8x + 1680$, $R^2 = 0.96$), and perilla oil ($y = 26.4x + 715$, $R^2 = 0.89$). These linear trends suggested that the amount of nonpolar carbonyls could be used to estimate oxidative deterioration of oils as TOTOX. To our knowledge, this is the first report on this linear relationship between nonpolar carbonyl amount and TOTOX during lipid oxidation. TOTOX was calculated by POV and *p*-AV, and also linear correlations were found between nonpolar carbonyl amount and POV in the four oils ($R^2 = 0.92-0.97$; Supporting Information, Figure S1). In a sense, generation of carbonyl compounds may be closely related to the production of hydroperoxides. Richards et al.[37] established a model relating ln[POV] to the volatile oxidation products: $\ln[\text{POV}] = -2.50 + 0.308 \times \ln[\text{hexanal}] + 0.229 \times \ln[\textit{trans,trans}\text{-2,4-heptadienal}]$, but $R^2$ was much lower (only 0.26). Hence, the total amount of nonpolar carbonyls was a good index for oxidation assessment, despite their difficult and time-consuming determination.

Generally, POV, *p*-AV, and TBARS are the common and foundational oxidation indices in lipid analysis. Actually, hexanal has become a well-known indicator owing to its being a major secondary oxidation product in lipid.[38−40] However, the profile of carbonyl compounds may be closely linked to the fatty acid composition of lipid. In our previous study, we found that oleic, linoleic, and linolenic acids had their characteristic carbonyl compounds during accelerated oxidation.[41] Thus, it is necessary and significant to choose corresponding oxidation indicators for oil samples with different fatty acids.

It was found that both hexanal and 2-nonenal were good oxidation indicators for sunflower and palm oils, as both had good linear relationship with TOTOX (Figure 6): hexanal = 7.10 TOTOX + 342, $R^2 = 0.78$, and nonenal = 6.65 TOTOX + 276, $R^2 = 0.84$ for palm oil; hexanal =9.56 TOTOX + 913, $R^2 = 0.90$, and nonenal = 10.5 TOTOX + 691, $R^2 = 0.95$ for sunflower oil. For camellia oil, nonanal was a good indicator because of the good linear correlation (nonanal = 21.6 TOTOX − 595, $R^2 = 0.92$). Propanal was a good indicator for perilla oil, and also a good linear relationship was found between the amount of propanal and TOTOX: propanal = 8.10 TOTOX + 75.0, $R^2 = 0.90$. Hence, the yield of the indicator was a key index for evaluating the oxidation state of vegetable oil.

In summary, in this work, palm, camellia, sunflower, and perilla oils were selected in oxidation assays in consideration of their typical fatty acid compositions. Camellia (20 types), sunflower (19 types), and palm (19 types) oils were found to have more types of nonpolar carbonyls than perilla oil (14 types) on the 35th day. Besides, alkanal contained a higher proportion of nonpolar carbonyl than alkenal and alkadienal in the four oils. Interestingly, the four oils had their own characteristic carbonyl products, which could be used as markers to monitor the oxidation state of oils. Nonanal was a good oxidation indicator for camellia oil (oleic acid mainly); hexanal and nonenal were good oxidation indicators for sunflower oil (linoleic acid mainly) and palm oil (palmitic and oleic acids mainly); propanal was a good oxidation indicator for perilla oil (linolenic acid mainly). In addition, these indicators had good linear correlations with their corresponding TOTOX and the amounts of total nonpolar carbonyls in oils ($R^2 > 0.8$) during 35 days of accelerated oxidation. According to the change patterns of POV, TOTOX, total nonpolar carbonyls, and oxidation indicator, the corresponding order of oxidation stability was uniformly sunflower oil < camellia oil < perilla oil < palm oil. Hence, the yield of indicator was a key index for evaluating the oxidation state of vegetable oil. In addition, the determination of indicator was a novel approach to monitor oil oxidation. They played an important role as TOTOX or POV in the oxidation assessment of lipid.

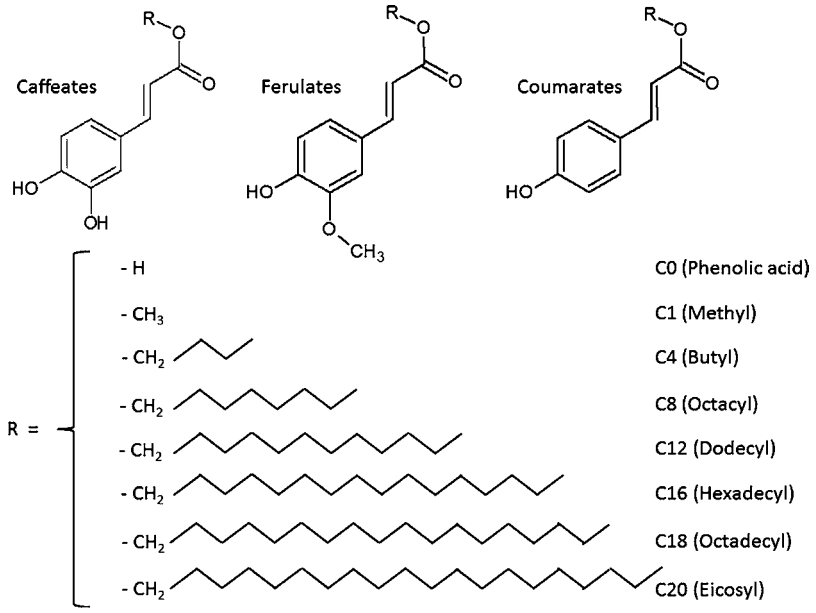

**Figure 1.** Molecular structure of caffeic, ferulic, and coumaric acids and synthesized alkyl caffeates, ferulates and coumarates.

The aim of the study was to evaluate the antioxidant properties of hydroxycinnamic acids with very similar structures and their alkyl esters (phenolipids) using different *in vitro* antioxidant assays. Moreover, the efficacy of the antioxidants was evaluated in a microemulsion using the conjugated autoxidizable triene (CAT) assay. The phenolics selected only differ in one chemical group on the phenolic ring (Figure 1). Caffeic acid has an *o*-dihydroxyl (catechol) group, ferulic acid has a hydroxyl and a methoxyl group, and coumaric acid has one hydroxyl group substituted to the benzene ring. It is hypothesized that the structure will impact antioxidant efficacy and critical chain length for the different phenolipids: caffeates, ferulates, and coumarates.

## MATERIALS AND METHODS

**Materials.** Phenolic acids (caffeic, ferulic, and coumaric), alcohols, Amberlite IR-120H, and molecular sieves were purchased from Sigma-Aldrich (Saint Quentin, France). All solvents used were of HPLC or analytical grade and were purchased from Sigma (Saint Quentin, France). Silica columns for flash chromatography were purchased from Acros organics (Geel, Belgium). Tung oil (872 g/mol), Brij 35 (a nonionic polyoxyethylene surfactant, estimated Mw 1198 g/mol), AAPH (2,2′-azobis-2-methyl-propanimidamide, dihydrochloride), phosphate buffer solution (PBS, pH 7.2), alumina, BHT (butylated hydroxytoluene), and trolox were purchased from Sigma-Aldrich (Steinheim, Germany). EDTA (Titriplex, ethylenedinitrilo-tetraacetic acid disodium salt dehydrate) was purchased from Merck (Darmstadt, Germany).

**Synthesis of Caffeates, Ferulates, and Coumarates (Phenolipids).** Esterification of caffeic, ferulic, and coumaric acids was catalyzed by acid either added as the strongly acidic sulfonic resin Amberlite IR-120H or as pure sulfuric acid to the reaction medium. The composition of the reaction mixtures depending on catalyst applied is described below. Molecular sieves (3 Å, 4−8 mesh, 40 mg/mL, Aldrich, St. Louis, MO, USA) were added to the reaction mixtures to remove water generated during reaction. The reaction mixtures were stirred in an orbital shaker (250 rpm, 55 °C) during the whole reaction time. Samples (20 μL) from the reaction mixtures were regularly withdrawn, mixed with methanol (980 μL), filtered (0.45 μm syringe filter Millex-FH, Millipore Corp., Bedford, MA, USA), and analyzed by reverse phase HPLC with UV detection at 328 nm.

*Methyl Caffeate, Methyl Feulate, and Methyl Coumarate Synthesized with Amberlite IR-120H.* Phenolic acid (3 g, caffeic acid (16.7 mmol), ferulic acid (15.4 mmol), and coumaric acid (18.3 mmol)) were solubilized in methanol (150 mL, 3.7 mol) in a dark, sealed bottle in an orbital shaker. The reaction between phenolic acid and methanol was catalyzed by adding 5% sulfonic resin Amberlite IR-120H (w/w of total weight of both substrates, dried 4 h at 103 °C).

*Phenolipids Synthesized with Sulfuric Acid.* Phenolic acid (caffeic, ferulic, and coumaric acids) was solubilized in THF (tetrahydrofuran) in a dark, sealed bottle in an orbital shaker. THF was applied as a solubilization medium due to the poor solubility of phenolic acids in longer chain alcohols (lipophilic medium). Alcohol was added to the phenolic acid-THF solution in a mole ratio of 1 mol phenolic acid to 3−5 mol of alcohol. Excess of alcohol was reduced as much as possible due to difficulties in the purification of synthesized phenolipids. The purification difficulties were due to the similarity in polarity of synthesized phenolipids and unreacted alcohols. Pure sulfuric acid (5% v/v of total volume of alcohol and THF) was added to the reactants in THF.

**Purification of Synthesized Phenolipids.** Methyl esters were purified one way, and all other phenolipids were purified in different ways depending on the phenolic acid from which they were synthesized. The different ways applied to purify the synthesized phenolipids are described below. The purity of the purified phenolipids was evaluated quantitatively by HPLC-MS[13] and qualitatively by TLC. The HPLC-MS analysis of the synthesized compounds revealed a purity ≥95%.

*Purification of Methyl Caffeate, Ferulate, and Coumarate.* When the reaction was completed (>90% conversion), the reaction was stopped by removal of Amberlite IR-120H and molecular sieves in a centrifugation and filtration step. Then THF and unreacted methanol were evaporated, the mixture was diluted in ethyl acetate, and unreacted phenolic acid was removed by washing the ethyl acetate solution with two different saturated salt solutions (sodium bicarbonate (3 times), sodium chloride (2 times)), and water (2 times). To remove traces of water, the ethyl acetate solution was dried over sodium sulfate. Finally, the purified methyl ester was obtained by evaporating off ethyl acetate.

*Purification of Butyl, Octyl, Dodecyl, Hexadecyl, Octadecyl, and Eicosyl Esters.* When the reaction was completed (>90% conversion), molecular sieves were removed from the reaction mixture in a centrifugation and filtration step. Then, THF was evaporated, and the reaction mixture was diluted in ethyl acetate. To neutralize the reaction mixture in ethyl acetate, this solution was washed with water

several times and dried over sodium sulfate to remove traces of water. Then, the remaining alcohol and phenolic acid were eliminated by flash chromatography (CombiFlash Companion system, Teledyne Isco Inc., Lincoln, NE, USA). Separation was carried out on a silica column (pore size 60 Å, Acros organics, Geel, Belgium) using an elution gradient of two solvents with different polarities. Because of the different polarities of the phenolic acids and their alkyl esters, a different elution gradient was applied for caffeates (chloroform and methanol, 0−100%), ferulates, and coumarates (dichloromethane and ethyl acetate, 5−100%), respectively. For some phenolipids, alcohol was still present after flash chromatography. In these cases, preparative TLC with different migration solvents was applied (caffeates, 96% chloroform and 4% methanol; ferulates, 95% dichloromethane and 5% ethyl acetate; and coumarates, 90% dichloromethane and 10% ethyl acetate).

**Antioxidant Properties.** The antioxidative properties of the phenolic acids and their synthesized alkyl esters were evaluated using three different *in vitro* antioxidant assays: radical scavenging (DPPH), iron chelating activity, and reducing power. All antioxidants were evaluated in 4 concentrations (final concentrations: 50, 100, 200, and 400 $\mu$M) and were measured in triplicate ($n$ = 3). The concentrations were selected based on earlier antioxidant property analysis and storage experiments with similar compounds.[14]

*Radical Scavenging.* Antioxidants were solubilized in methanol in different concentrations, and BHT was included in this assay as a positive control in the same concentrations. The antioxidant solution (150 $\mu$L) was diluted 1:1 (v/v) with 0.1 mM DPPH in ethanol (96%, 150 $\mu$L). Then, 200 $\mu$L of this mixture was transferred to a well in the microplate.[15] The absorbance at 517 nm was measured after 30 min (RT, darkness) in a microplate reader (Synergy 2 BioTek, Winooski, VT, USA). Results are expressed as inhibition percentages.

$$\text{Inhibition } [\%] = \left(1 - \frac{A_s - A_0}{A_b}\right) \times 100$$

where $A_s$ is the measured absorbance after the antioxidant-DPPH reaction, $A_0$ is the measured absorbance of antioxidant in ethanol without DPPH (sample control), and $A_b$ is the absorbance measured of DPPH without the antioxidant added.

*Reducing Power.* Antioxidants were solubilized in methanol in different concentrations, and ascorbic acid was included in this assay as a positive control in the same concentrations. Antioxidant methanolic solutions (200 $\mu$L) were transferred to test tubes, and 0.2 M phosphate buffer (200 $\mu$L) and 1% potassium ferricyanide (200 $\mu$L) were added. These mixtures were incubated at 50 °C for 20 min. After incubation, 10% TCA (trichloroacetic acid, 200 $\mu$L) was added and mixed. This reaction mixture (228 $\mu$L) was transferred to an Eppendorf tube and mixed with an equal amount of water (228 $\mu$L). Ferric chloride (0.1%, 46 $\mu$L) was added to the reaction mixture, and it was incubated for 10 min at RT. After incubation, the reaction mixtures (200 $\mu$L) were transferred to the wells in the microplate,[15] and absorbance was measured at 700 nm in a microplate reader (Synergy 2 BioTek, Winooski, VT, USA). Results are shown relative to ascorbic acid ($Abs_{Sample}/Abs_{Ascorbic\ acid}$).

*Iron Chelating Ability.* Antioxidants were solubilized in warm water in different concentrations. Because of solubility problems with long alkyl chain phenolipids, only caffeic acid, ferulic acid, coumaric acid, and their methyl esters were evaluated for their chelating ability of ferrous chloride. EDTA was included in this assay as a positive control in the same concentrations as the phenols and phenolipids. For further details, refer to Sørensen et al.[14] The absorbance was measured at 562 nm (UV-1800 Shimadzu, Columbia, MD, USA), and results are expressed as chelating activities.

**Antioxidant (Hydroxycinnamic Acids and Their Alkyl Esters)−Iron Interactions.** Interactions between iron and the antioxidant were evaluated using a spectrophotometer according to the method developed by Sørensen et al.[9] Methanolic solutions of caffeic acid, ferulic acid, coumaric acid, and their methyl esters were diluted in a buffer solution: 10 mM sodium acetate−imidazole (pH 7). Moreover, methanolic solutions of caffeic acid and methyl caffeate were also diluted in PBS (pH 7.2). The final concentration of antioxidant was 100 $\mu$M. Iron, as $FeSO_4$, was solubilized in 0.50 M HCl and buffer (1:1, v/v) and added to pure buffer and to the antioxidant−buffer solution. The final concentration of iron was 100 $\mu$M. Each solution was measured using a spectrophotometer (UV-1800, Shimadzu Scientific Instruments, Columbia, MD, USA), and a spectrum was recorded in the UV−vis region (200−800 nm).

**Conjugated Autoxidizable Triene (CAT) Assay.** Stock solutions of the different hydroxycinnamic acids, their alkyl esters, and trolox were prepared in methanol. Various volumes of these antioxidant methanolic solutions were added to 1.8 mL of PBS (pH 7.2) and then filled up to 2 mL with pure methanol. These buffered solutions with antioxidant (50 $\mu$L) were transfered into a microtiterplate, (UV-Star 96-well microplate, Greiner, Frickenhausen, Germany). The microplate was then preheated (37 °C) and stirred in the microplate reader (Synergy 2, BioTek, Winooski, VT, USA) for 5 min at medium speed. Brij 35-PBS (34 $\mu$M, 25 mL) was added to 5 mg of stripped tung oil in a brown glass bottle. Brij 35−PBS−tung oil was premixed for at least 10 s using a vortex apparatus before the mixture was homogenized with a POLYTRON PT1200E (Kinematica AG, Lucerne, Switzerland) at high speed for 4 min. Each well was then filled with 100 $\mu$L of the tung oil-in-PBS microemulsion; the plate was again preheated and stirred for 1 min. The oxidation of tung oil was initiated by adding 50 $\mu$L of 4 mM AAPH in PBS. Finally, each microplate well contained 200 $\mu$L of the following mixture: 115 $\mu$M stripped tung oil, 17 $\mu$M Brij 35, 1 mM AAPH, and various concentrations of phenolics, phenolipids, or trolox (0.2−0.8 $\mu$M). The progress of lipid oxidation was immediately followed by measuring the decrease in absorbance at 273 nm. Measurements were performed each minute for 6 h at 37 °C with 5 s stirring before each measurement. Each antioxidant concentration was measured in triplicate on the plate and via independent measurements (three different microplates), $n$ = 9. Results were expressed as CAT value (mean ± SD). This method was developed by Laguerre et al.[16] For further details about the calculations, see refs 7 and 16 by Laguerre et al.

**Removal of Tocopherols from Tung Oil.** Tung oil was stripped from tocopherols using an alumina packed glass column. A glass column was packed with 25 g of alumina oxide in hexane. The excess of hexane was removed. Tocopherols were removed from the tung oil by passing 25 mL (200 mg/mL) of tung oil in hexane through the packed column. Pure hexane (50 mL) was then loaded to the column to get the loaded tung oil through the column. After passing the tung oil through the column, hexane in the stripped tung oil was removed using a vacuum rotary evaporator. Finally, a trace of hexane in the stripped tung oil was removed under nitrogen. The stripped tung oil was bottled (5 mg/bottle) in brown glass tubes, flushed with nitrogen, and stored at −80 °C until use (CAT Assay). Furthermore, the absence of tocopherols in the stripped tung oil was checked by HPLC according to the AOCS method.[17]

**Data Treatment.** All measurements were performed in triplicate and reported as average ± SD. In the separate method descriptions, calculations are described, or there are references to data treatment.

*Statistics.* The obtained results were analyzed by one-way ANOVA (GraphPad Prism, version 4.03, GraphPad Software Inc.). Bonferroni multiple comparison post-test was used to test differences between samples. For statistics, a significance level of $p < 0.05$ was used. When a significant difference was observed between samples, they are denoted with different lowercase letters in the text, table and figures.

## RESULTS

**Antioxidant Properties.** All the synthesized antioxidants were evaluated for different antioxidant properties as radical scavenger (DPPH), reducing power, and iron chelation in *in vitro* assays.

*Radical Scavenging Properties.* The phenolics and synthesized phenolipids were all able to scavenge free radicals measured by the DPPH assay (Figure 2A−C). Caffeic acid and caffeates had similar radical scavenging activities in the

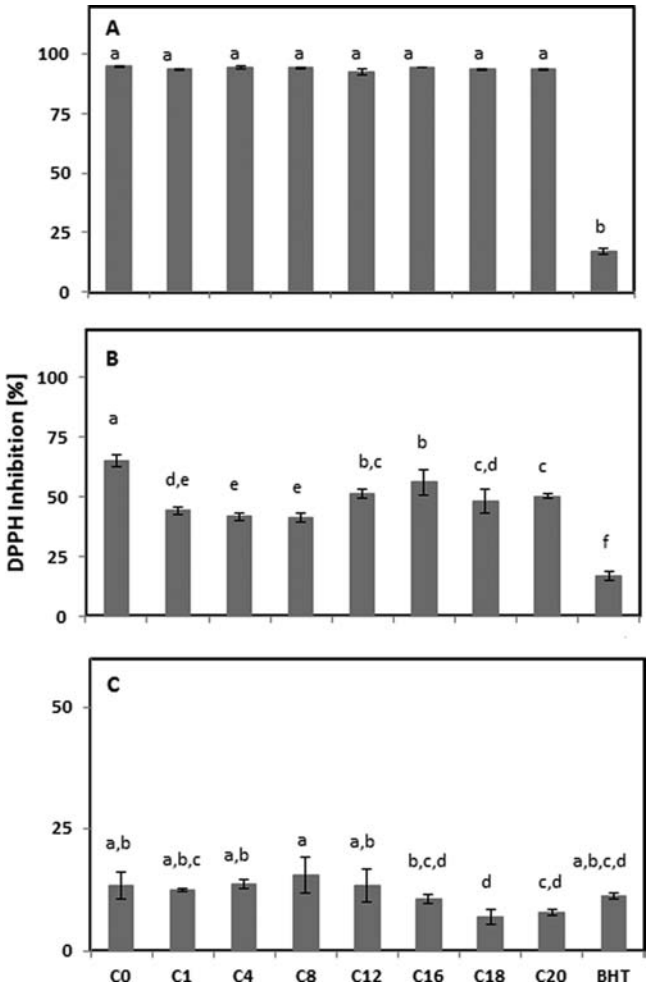

**Figure 2.** Radical scavenging properties of hydroxycinnamic acids and their alkyl esters at 100 $\mu$M calculated as DPPH inhibition [%]. (A) Caffeic acid and caffeates, (B) ferulic acid and ferulates, and (C) coumaric acid and coumarates. BHT was included as a positive control in this assay. C0 is phenolic acid, and C1 to C20 indicate the length of the alkyl chain grafted to the phenolic acids (phenolipids). Error bars indicate the standard deviation ($n$ = 3). Significant differences between different compounds are denoted with different lowercase letters (significance level was $p < 0.05$).

concentration range (50−400 $\mu$M) evaluated (Supporting Information, Figure A). The DPPH inhibition was >85%, and the lowest inhibition was observed for caffeic acid (95%) and caffeates (87−92%) at the lowest concentration (50 $\mu$M) evaluated. At this low concentration, a significantly different DPPH inhibition was observed, although the differences in inhibition were small. In the concentration range of 100−400 $\mu$M, the DPPH inhibition of caffeic acid and alkyl caffeates was not significantly influenced by the applied concentration, and no significant effects of the chain length were observed. Caffeic acid and all alkyl caffeates were more efficient in scavenging DPPH than BHT irrespective of the concentration applied. Ferulic acid appeared to have the highest DPPH inhibition followed by long chain alkyl ferulates > medium, short chain alkyl ferulates, and BHT (Figure 2B). BHT had significantly lower DPPH inhibition than ferulic acid (~1.5−4 fold) and alkyl ferulates (~1.4−3 fold) at the different concentrations, but significant differences in DPPH inhibition between ferulic acid and alkyl ferulates were more unclear. The ranking of ferulic acid and alkyl ferulates was independent of their concentration in the evaluated range (50−400 $\mu$M, Supporting Information, Figure A). Coumaric acid and alkyl coumarates had low DPPH inhibition <25% in the evaluated concentration range (50−400 $\mu$M, Supporting Information, Figure A. Depending upon the concentration evaluated, coumaric acid (50 $\mu$M) or octyl coumarate (100 $\mu$M, Figure 2C) had the highest DPPH inhibition. For high concentrations (200 and 400 $\mu$M), BHT showed significantly higher inhibition percentages compared to those of coumaric acid (~1.5−2-fold) and coumarates (~2.5−3.7-fold). Overall, caffeic acid and alkyl caffeates had the highest radical scavenging activity followed by ferulic acid and alkyl ferulates, whereas coumaric acid and alkyl coumarates were least efficient.

*Reducing Power.* The ability of hydroxycinnamic acids and their alkyl esters to reduce ferric ions ($Fe^{3+}$) to ferrous ions ($Fe^{2+}$) is shown in Figure 3 (100 $\mu$M) and Figure B in the Supporting Information (50−400 $\mu$M). For alkyl caffeates and ferulates, the same trend was observed (Figure 3A and B). Caffeic acid and ferulic acid had the highest reducing power, and an increase in alkyl chain length for caffeates and ferulates significantly decreased the reducing power. The reducing power observed for coumaric acid and alkyl coumarates was different (Figure 3C). At low concentration (50 $\mu$M), coumaric acid had the highest reducing power. Whereas, at 100 $\mu$M and higher concentrations dodecyl coumarate appeared to have the highest reducing power. Its effect was significantly higher than the other alkyl coumarates only at the highest concentration (400 $\mu$M). Overall, the highest reducing power was obtained with caffeic acid and its alkyl esters followed by ferulic acid and its alkyl esters. Lowest reducing effect was observed for coumaric acid and its alkyl esters. As shown in Figure 3, results were calculated relative to ascorbic acid. Increments in concentration of ascorbic acid resulted in increased reducing power (50−400 $\mu$M). Since, the reducing power of coumaric acid and coumarates decreased slightly with increased concentrations, their reducing power increased to a lower extent with increasing concentrations than that of ascorbic acid. In contrast, increasing the concentration of caffeic acid and ferulic acid to 400 $\mu$M resulted in a higher increase in reducing power than that measured for ascorbic acid (Supporting Information, Figure B).

*Iron Chelation Ability.* This assay measured the ability of the antioxidant to chelate iron, and the obtained results are shown in Table 1. Because of decreased solubility in water with increasing alkyl chain length, only the hydroxycinnamic acids and their methyl esters were evaluated in this assay. EDTA is known as a strong iron chelator and was included as a positive control. At all concentrations (50−400 $\mu$M) evaluated, EDTA had significantly higher iron chelating ability than the hydroxycinnamic acids and their methyl esters. For all compounds evaluated, the iron chelating activity increased with increasing concentrations. In general, the structure with two hydroxyl groups in ortho position (a catechol group), i.e., caffeic acid and methyl caffeate, were the most efficient among the evaluated hydroxycinnamic acids and methyl esters followed by ferulic acid and methyl ferulate (Table 1). The least efficient was coumaric acid, which only had minor activity (<5%). However, the esterification of coumaric acid significantly increased its iron chelating ability at concentrations of 200 (~10-fold) and 400 $\mu$M (~6-fold) (Table 1).

*Antioxidant−Iron Interactions.* Interactions between ferric ions ($Fe^{2+}$) and different antioxidants were determined by spectrophotometry. The spectra obtained for iron−caffeic acid

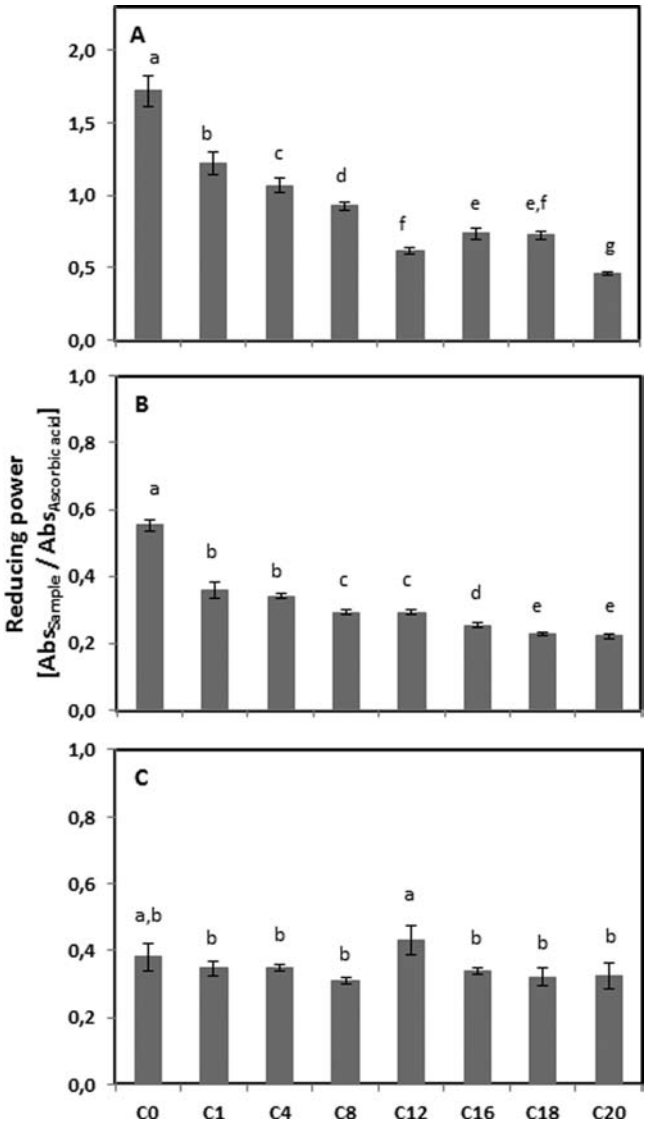

**Figure 3.** Reducing power properties of hydroxycinnamic acids and their alkyl esters at 100 $\mu$M calculated relative to ascorbic acid (positive control in the assay). (A) Caffeic acid and caffeates, (B) ferulic acid and ferulates, and (C) coumaric acid and coumarates. C0 is phenolic acid, and C1 to C20 indicates the length of the alkyl chain grafted to the phenolic acids (phenolipids). Error bars indicate the standard deviation ($n$ = 3). Significant differences between different compounds are denoted with different lowercase letters (significance level was $p < 0.05$).

and iron−methyl caffeate in two different buffers are shown in Figure 4. The absorbance measured was different for the two different buffers used. When either caffeic acid and iron or methyl caffeate and iron were solubilized in phosphate buffer, no absorbance was observed in the visible area, 400−800 nm (Figure 4A and B). In contrast, when the other buffer, sodium acetate−imidazole (10 mM), was used, both the combination of caffeic acid and iron or methyl caffeate and iron resulted in low absorbances in the visible area of the spectrum (Figure 4C and D). Moreover, these solutions changed from no color to blue or black color when iron was added. Phosphate buffer with caffeic acid and with and without iron added had peaks at the same wavelengths; however, when iron was added the absorbance was slightly higher in the UV area than that without iron added (Figure 4A). When methyl caffeate was solubilized in phosphate buffer, the spectra changed when iron was added compared to that when no iron was present (Figure 4B). This may indicate other types of interactions with iron. Furthermore, when iron was added to phosphate buffer without antioxidant, the spectrum changed, whereas iron added to sodium acetate−imidazole buffer did not alter the spectrum (Figure 5). Thus, phosphate buffer may also participate in interactions with the iron added. The other compounds evaluated, ferulic acid, methyl ferulate, coumaric acid, or methyl coumarate solubilized in sodium-acetate imidazole buffer, were not influenced by the addition of iron since similar absorbance spectra were obtained with and without iron addition (data not shown). This indicates that a catechol structure is needed to form a complex with iron, while a monophenol (coumaric acid-like structure) or a monophenol combined to a methoxyl group in ortho position (ferulic acid-like structure) does not allow the formation of such an iron complex. The possible interactions between iron and caffeates will be discussed in more detail later.

**Antioxidant Activity Evaluated by the CAT Assay (o/w Emulsion).** The antioxidant effect of the hydroxycinnamic acids and their alkyl esters was evaluated in the CAT assay. In the CAT assay, lipid oxidation and the effect of the tested antioxidants are evaluated from the decrease in conjugated trienes over time. The results for the three series of homologues are shown in Figure 6. Similar to the other assays evaluated, the highest antioxidant effect was obtained with alkyl caffeates followed by alkyl ferulates with CAT values of 1.3−5.0 and 0.2−1.5, respectively. Coumarates had close to zero antioxidant effect due to the low CAT values measured (0.05−0.36). For caffeic acid and alkyl caffeates, an increase in antioxidant capacity with increasing alkyl chain length up to octyl caffeate ($C_8$) was observed, whereas further increase in the alkyl chain length resulted in a decreased antioxidant

**Table 1. Iron Chelating Ability [%] of Caffeic Acid, Ferulic Acid, Coumaric Acid, and Their Methyl Esters (50−400 $\mu$M)[a]**

| | concentration [$\mu$M] | | | |

| methyl coumarate | 0.80 ± 0.35 d | 5.93 ± 0.57 d | 14.7 ± 1.03 e | 26.9 ± 3.16 e |
| EDTA | 65.5 ± 3.26 a | 94.2 ± 2.29 a | 99.3 ± 0.80 a | 100 ± 0.04 a |

[a]EDTA was included as a positive control. The analyses were performed in triplicate ($n$ = 3). When a significant difference was observed between samples (within each column, i.e., concentrations), it is denoted with different lowercase letters (significance level was $p < 0.05$).

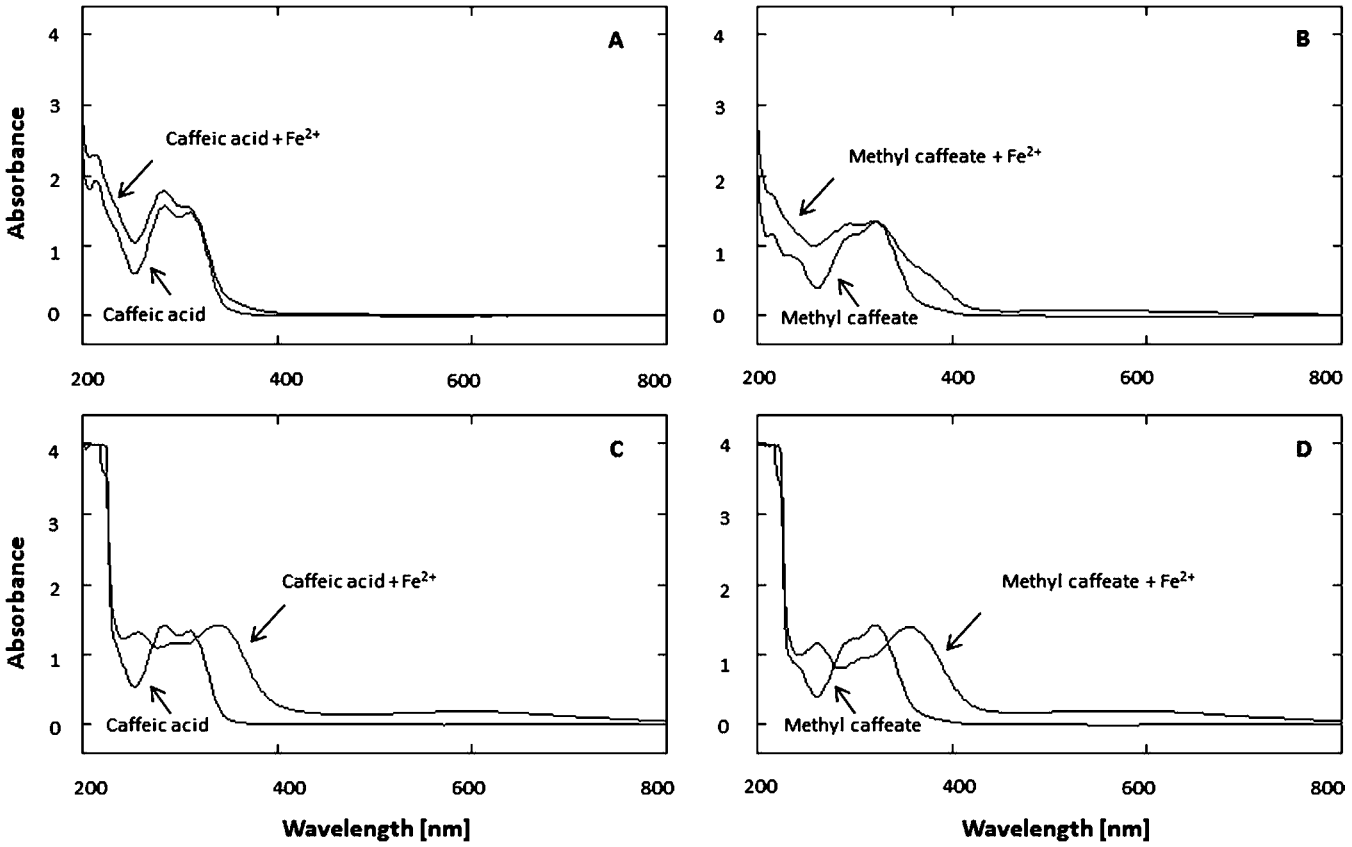

**Figure 4.** UV−vis spectra (200−800 nm) recorded for caffeic acid and methyl caffeate solubilized in different buffers with and without iron addition. (A) Phosphate buffer (pH 7.2), caffeic acid (100 $\mu$M) and ± Fe (100 $\mu$M), (B) phosphate buffer (pH 7.2), methyl caffeate (100 $\mu$M) and ± Fe (100 $\mu$M), (C) sodium acetate−imidazole buffer (10 mM, pH 7.0), caffeic acid (100 $\mu$M) and ± Fe (100 $\mu$M), and (D) sodium acetate−imidazole buffer (10 mM, pH 7.0), methyl caffeate (100 $\mu$M), and ± Fe (100 $\mu$M).

capacity (Figure 6). Thus, the most efficient antioxidant among the alkyl caffeates was octyl caffeate followed by dodecyl caffeate (not significantly different), and a cut-off effect was observed with $C_8$−$C_{12}$ as critical chain length. Octadecyl caffeate and eicosyl caffeate were significantly less efficient antioxidants than caffeic acid. The same clear cut-off effect as that for alkyl caffeates, with octyl caffeate being the best of the homologues series, was not observed for alkyl ferulates and alkyl coumarates, even though a global nonlinear tendency was observed between the CAT values and the alkyl chain lengths. The ranking of the alkyl ferulates was as follows: $C_{12}{}^{a} = C_8{}^{a} = C_4{}^{a} \geq C_1{}^{a,b} \geq C_0{}^{b} = C_{16}{}^{b}$ (Figure 6). Alkyl coumarates had limited antioxidant efficacy in this assay. The most efficient antioxidant among the alkyl coumarates was dodecyl coumarates, and the ranking of the alkyl coumarates according to their antioxidant efficiency was as follows: $C_{12}{}^{a} \geq C_8{}^{a,b} = C_4{}^{a,b} \geq C_0{}^{b} = C_{16}{}^{b} = C_1{}^{b}$ (Figure 6). Even though the antioxidative effects of coumaric acid and alkyl coumarates were limited, an improvement in the efficacy was observed with esterification. Dodecyl coumarate had approximately 5.6 times higher CAT value than coumaric acid.

## DISCUSSION

**Antioxidant Properties and Molecular Structure.** Antioxidant properties depend upon the molecular structure of the compounds.[18] Apart from the different degrees of lipophilization (alkyl chain length), three different molecular structures were evaluated: caffeic acid, ferulic acid, and coumaric acid (Figure 1). The antioxidant activity of phenolic compounds is primarily due to resonance stabilization of the phenoxyl radical and various substitutions, e.g., electronegative hydroxyl groups may increase radical stability. Thus, di- and trihydroxyl substitutions have greater antioxidant activity than monohydroxyl substitution due to greater resonance stabilization.[18,19] Moreover, Dueñas et al.[20] have evaluated antioxidant activities of O-methylation of the catechol group in quercetin and catechins using the FRAP assay (ferric reducing power) and ABTS$^{\bullet+}$ assay (radical scavenging). The O-methylation of one of the hydroxyls in the catechol group reduced the antioxidant activity compared to that of the parent compounds.[20] Thus, destroying the catechol structure lowered the antioxidant activity of the compound. Therefore, the efficacy based on radical scavenging and reducing power assays of the evaluated antioxidants is expected to be highest for caffeic acid followed by ferulic acid and coumaric acid. The obtained results confirmed this ranking in activity of the evaluated hydroxycinnamic acids (Figures 2 and 3). Moreover, Kikuzaki et al.[21] have also reported that caffeic acid had the highest DPPH scavenging activity followed by ferulic acid and coumaric acid. This ranging of the three types of alkyl ester is also observed in another study where short saturated alkyl esters of caffeic and ferulic acids were evaluated.[22] In addition, ester of sinapic acid has shown antioxidant activities in between those of alkyl caffeates and ferulates.[23] In the DPPH assay, caffeic acid and alkyl caffeates showed similar activities, whereas ferulic acid and coumaric acid showed higher activities than their alkyl esters (Figure 2). However, among the alkyl esters there was no clear pattern with respect to the effect of the chain length on the DPPH

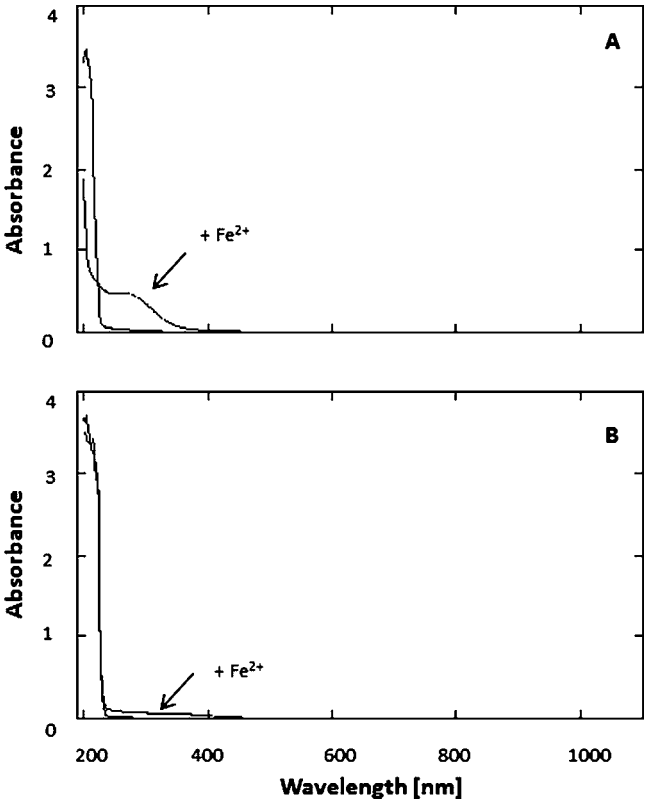

**Figure 5.** Spectra (200−800 nm) recorded for different buffers with and without iron addition. (A) Phosphate buffer (pH 7.2) ± Fe (100 $\mu$M) and (B) sodium acetate−imidazole buffer (10 mM, pH 7.0) ± Fe (100 $\mu$M).

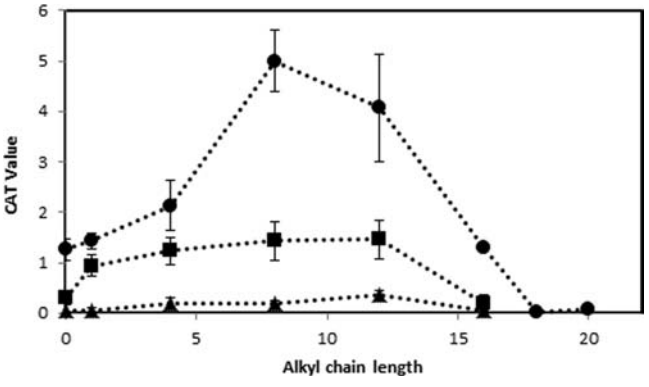

**Figure 6.** Influence of the alkyl chain length of phenolic alkyl esters on their antioxidant activity in stripped tung oil-in-water microemulsions oxidized by AAPH at 37 °C (CAT assay). Symbols: ●, caffeic acid and caffeates; ■, ferulic acid and ferulates; and ▲, coumaric acid and coumarates. Error bars indicate the standard deviation ($n$ = 3).

radical scavenging activity. These findings are similar to observations reported by Garrido and co-workers,[22] who had measured the $IC_{50}$ for different short chain saturated alkyl esters (methyl, ethyl, propyl, and butyl) of caffeic and ferulic acids using the DPPH assay. They reported similar $IC_{50}$ values for caffeic acid (16.6 $\mu$M) and caffeates (13.5−14.5 $\mu$M), whereas ferulic acid (44.6 $\mu$M) was reported with lower $IC_{50}$ than ferulates (56.3−74.7 $\mu$M). For the two evaluated alkyl esters, the efficiency was as follows for caffeates and ferulates: ethyl (lowest $IC_{50}$) > methyl > butyl > propyl and butyl > propyl > ethyl > methyl.[22] In contrast, in the reducing power assay, caffeic and ferulic acids had higher activities than their alkyl esters, and the activities decreased with increasing alkyl chain lengths for alkyl caffeates and alkyl ferulates (Figure 3). However, this is contrary to findings reported by Garrido et al.[22] who used the FRAP assay to measure reducing power, which was similar to the $IC_{50}$ findings, i.e., compounds with low $IC_{50}$ had high reducing power.

Phenylethanoid glycosides are ester derivatives of phenolic acids and are widely distributed in nature. These phenylethanoid glycosides are more lipophilic compounds compared to phenolic acids. Interestingly, some phenylethanoid glycosides of caffeic and ferulic acids, namely, acyl derivatives, have shown lower (∼2-fold) $IC_{50}$ values than those of their corresponding phenolic acid,[24] whereas alkyl esters of caffeic acid showed similar $IC_{50}$ values as those of caffeic acid.[22] Thus, some of these alkyl and glycoside esters of phenolic compounds may serve as good antioxidants in emulsions or other complex systems due to increased lipophilicity, which is important in multiphases systems.

Both antioxidant assays in this study are homogeneous systems; whereas the DPPH assay is measured in ethanol, the reducing power assay is measured in distilled water. Thus, solubility may influence the results obtained. The evaluated compounds are more soluble in solvent than water, i.e., less polar. Therefore, the reduced activity with increased alkyl chain length in the reducing power assay can at least partly be explained by the reduced solubility of the more lipophilic alkyl esters in water. In the DPPH assay, the ethanolic medium did not influence the solubility of the more lipophilic alkyl esters. Additionally, the results obtained in the DPPH assay are in accordance with results obtained earlier by Kikuzaki et al.[21] In their study, ferulic acid also had higher scavenging activity than alkyl ferulates, and no dependency in lipophilicity and antioxidant activity of the different alkyl ferulates was observed.[21] Thus, these data confirm the earlier assumption regarding solubility issues that the ethanolic solution does not have the same impact on the solubility of the more lipophilic alkyl esters as the water solution. In addition, the lower activity observed for alkyl ferulates and alkyl coumarates than their corresponding acids in the DPPH and reducing power assays has also been reported earlier for other phenolipids, namely, dihydrocaffeates[25] and rutin esters.[26] These findings may indicate that the esterification site for the alkyl chain play an active role for the antioxidant properties measured in these assays. Additionally, López-Giraldo et al.[27] have evaluated the kinetics of the reaction of chlorogenic acid and its alkyl esters with the DDPH radical. For the different compounds, strong differences were observed. Hence, pathways of DPPH stabilization were suggested to be different for chlorogenic acid and its alkyl esters, which were confirmed by LC-MS characterization of the reaction products obtained.

Another antioxidant property is chelation of transition metal irons, which are prooxidants. Therefore, if they are chelated their interactions with the lipid substrate or lipid hydroperoxides is supposed to be inactivated.[28] The iron chelating assay can thus reveal the ability of the compounds to chelate iron. This assay is, like the reducing power assay, a homogeneous solution of water wherein the antioxidants are solubilized. Solubility was indeed an issue for this assay. It seemed like the methanolic stock solutions of the different antioxidants interfered with the assay since the results obtained were not reproducible. The assay was repeated with the antioxidant solubilized only in water. Only caffeic acid, ferulic

acid, coumaric acid, and their methyl esters were evaluated. It is known that phenolic compounds containing a catechol group are able to chelate iron in the form of an iron-phenolic complex. Only caffeic acid and its esters contain a catechol group in their molecular structure. Nevertheless, all the evaluated hydroxycinnamic acids and their methyl esters had iron chelating activity (Table 1). UV−vis spectra (200−800 nm) of caffeic acid and methyl caffeate in sodium acetate−imidazole buffer revealed different absorbance patterns when iron was added (Figure 4). Furthermore, absorbance was detected in the visible area when iron was added. Change in the absorbance at 587 and 680 nm has been reported to correspond to iron−gallyl and iron−catechol complexes, respectively.[29] Thus, the obtained spectra indicated the formation of an iron−catechol complex with caffeic acid and methyl caffeate. Moreover, the absorbance spectra for these compounds changed in the area of 250−400 nm upon iron addition. The absorbance spectra in the area of 250−400 nm are characterizing the ring substitutions. Similar results have been reported by Andjelković et al.[30] who evaluated the formation of a complex between caffeic acid and iron in Tris buffer. When EDTA was added to the iron−caffeic acid complex, the absorbance spectrum changed again and was similar to that obtained for caffeic acid solubilized in Tris buffer without iron.[30] On the basis of the results reported by Andjelković et al.[30] with caffeic acid, iron, and EDTA and the fact that the catechol group was a part of the complex formed with iron, the changes in this area of the spectra were due to the formed complex.

Ferulic acid, methyl ferulate, and methyl coumarate had chelating ability but no change in their UV−vis spectra when iron was added. None of these compounds has a catechol or gallyl group. Therefore, the similar spectra obtained with and without iron were expected. The chelating ability measured for those compounds is therefore suggested to be due to other types of interactions with iron. Earlier findings support this suggestion since both caffeic acid and coumaric acid were shown to form nanoparticles in the presence of iron.[9]

Moreover, the complex formed between iron and the catechol group in caffeic acid and methyl caffeate were not formed when sodium acetate−imidazole buffer was substituted with phosphate buffer. A change in the UV region of the spectrum with phosphate buffer upon iron addition was also observed. Thus, this indicated interaction between phosphate and iron that impeded the complex formation between iron and the catechol group. A similar observation for phosphate buffer and iron has also been reported by Andjelković et al.[30] when they evaluated the interaction with iron and different phenolics. Therefore, the choice of buffer is crucial when evaluating the chelating ability of different compounds[30] due to the changed reactivity with different buffers.

Studies have shown that the most efficient antioxidants in limiting lipid oxidation in food emulsions during storage are not always comparable to antioxidant properties measured in *in vitro* antioxidant assays.[31,32] Hence, these antioxidant assays are only indicators of the properties of the compound studied and do not provide information about the efficiency of the antioxidants in emulsions or complex food systems.

**Antioxidant Activity in Emulsions.** In contrast to the above-discussed antioxidant assays, emulsions are heterogeneous systems. In general, the efficacy of antioxidants in food emulsion is dependent on their reactivity, properties, and partitioning in the emulsion.[33,34] These factors are not included in the simple antioxidant assays. Moreover, several components present in the emulsions may interfere with the antioxidants and thus alter their efficacy.

The CAT assay developed by Laguerre et al.[17] measures the antioxidant activity in a microemulsified system with AAPH used as a peroxyradical initiator. This assay gave different results than those obtained with the DPPH (radical) assay. In the CAT assay, there was an effect of the alkyl chain length grafted to caffeic acid, which was not observed in the DPPH assay. The difference between the results obtained with the CAT assay and the DPPH assay is suggested to be due to the influence of the antioxidant partitioning in the microemulsion. However, the influence of the phenolic structure was similar to the findings with the DPPH assay; caffeic acid was the most efficient antioxidant followed by ferulic acid and then with less activity coumaric acid.

For the three homologues series of antioxidants, the trend was that the antioxidant efficiency was highest for the phenolipids with medium chain length. However, only alkyl caffeates showed significant differences between the different chain lengths. Other reported results from the CAT assay have also shown that the CCL was obtained for medium chain length phenolipids. For alkyl chlorogenates and rosmarinates, the antioxidant efficiency was highest with a chain length of 12 and 8 carbon atoms, respectively.[7,11] Moreover, the antioxidant efficiency of alkyl rosmarinates is 3−5 times higher than that of alkyl chlorogenates and caffeates. This is suggested to be due to the substituted groups in the ring structure. Rosmarinic acid has two catechol groups, whereas chlorogenic acid and caffeic acid only have one.

The most efficient alkyl caffeate in the CAT assay was octyl caffeate. Recent studies with alkyl caffeates in food emulsions have shown that the effect of the chain length depended upon the system it was added into. In milk emulsion, the most efficient alkyl ferulate was methyl ferulate (C1),[35] and the most efficient alkyl caffeates were methyl caffeate (C1) and butyl caffeate (C4), whereas in mayonnaise the most efficient were butyl caffeate (C4), octyl caffeate (C8), and dodecyl caffeate (C12).[36] Similarly, the CCL for alkyl rosmarinates has also been shown to be influenced by the different emulsion systems. Despite this, the CCL for alkyl chlorogenates in emulsion and fibroblasts was similar , dodecyl chlorogenate (C12).[37]

In addition, a study reported by Anselmi et al.[38] shows that ferulic acid lipophilized with different saturated unbranched and branched alkyl chain lengths resulted in different three-dimensional structures. Different anchorages of the phenolic with the different alkyl chains were observed, which resulted in a specific folding of some of the alkyl esters. This structure resulted in the highest antioxidative capacity of these molecules (octyl ferulate and dodecyl ferulate) in rat liver microsomes. It was assumed that it was due to the orientation of the phenoxy group outside the membrane surface, which may have favored the radical scavenging in the microsomes.[38] In milk emulsion, octyl and dodecyl ferulate were reported to be intermediate to strong prooxidants.[35] Unfortunately, the three-dimensional structure of the molecules was not analyzed. However, if the alkyl chain has folded toward the ethylenic protons as reported by Anselmi et al.,[38] this is not a favorable structure in milk emulsions due to their prooxidative effects. Hence, CCL can be a variable parameter dependent upon the molecule and its three-dimensional structure, as well as the structure and composition of the emulsion system. Therefore, the effect of

antioxidants has to be studied in each emulsion system where antioxidant protection is needed.

In conclusion, the evaluated hydroxycinnamic acids and their alkyl esters showed antioxidant properties and activity. The antioxidant properties were affected by the molecular structure. Caffeic acid was a stronger iron chelator than ferulic acid and coumaric acid due to its ability to form complexes with iron. Moreover, caffeic acid also had higher radical scavenging activity and reducing power than the other hydroxycinnamic acids. The CCL in the CAT assay was C8−C12 for alkyl caffeates.

Additionally, esterification of caffeic acid with saturated short alkyl chains (methyl, ethyl, propyl, and butyl) was shown to improve the cell protective activity against oxidative stress, whereas caffeic acid, ferulic acid, and alkyl esters of ferulic acid were not able to protect the cells.[22] Moreover, esters of caffeic and ferulic acids have also shown excellent inhibition of tumor cell proliferation.[39]

Thus, the lipophilicity of phenolic compounds is a crucial factor that can determine their efficiency as antioxidants in multiphase systems such as food emulsions and cellular systems.

Hence, the synthesized phenolipids may serve as good antioxidants in food emulsions, especially alkyl caffeates, due to their free radical scavenging properties and antioxidant efficacy. However, their activity will also depend upon the partitioning of the antioxidant in the food emulsion as well as the interaction with other compounds present in the food emulsion. Our present and previous findings seem to suggest that the effect of alkyl esterification on the antioxidant activity may differ from one phenolic compound to another. Thus, antioxidant protection has to be further studied in each specific food emulsion with the different phenolic compounds.

The use of organogel as a delivery system is possibly a good choice to enhance the stability of the products. However, its use in water-rich systems may be inconvenient because of its high hydrophobicity. Emulsification of organogel may offer additional benefits and increase its application versatility. To date, the use of modern delivery systems, such as organogel-based nanoemulsions, to encapsulate a hydrophobic compound is very limited. However, Yu and Huang[35] developed a novel curcumin organogel-based nanoemulsion by ultrasonication. The authors have reported that the organogel-based nanoemulsion has contributed to the improvement of the bioavailability of curcumin by enhancing its water solubility. This finding result may give evidence that these systems are very useful in terms of improving the solubility of hydrophobic compounds.

The objective of the current study was to prepare a D-limonene organogel-based nanoemulsion by high-pressure homogenization and investigate the influence of the type and concentration of organogelators and emulsifiers, homogenization pressure, and number of cycles on the formation and stability of the formulation.

## MATERIALS AND METHODS

**Chemicals.** D-Limonene was obtained from Florida Worldwide Citrus Products Group, Inc. (Bradenton, FL). Monostearin and stearic acid were purchased from Aladdin Reagents Co., Ltd. (Shanghai, China). Non-ionic surfactants (Tween 20, 40, 60, 80, and 85) were purchased from the Sinopharm Chemical Reagent Co., Ltd. (Beijing, China). The Tween surfactant structures were composed of a polyoxyethylene headgroup and fatty acid tail group of various lengths, with the two moieties being connected together via a sorbitol molecule. Medium-chain triglyceride (MCT oil) was purchased from Sigma-Aldrich (Shanghai, China).

**Preparation of D-Limonene Organogel and Organogel-Based Nanoemulsion.** D-Limonene organogel was prepared as described by Yu and Huang,[35] with some modifications. Briefly, D-limonene, MCT oil, and stearic acid or monostearin were mixed together followed by heating to ensure complete dissolution of the organogelator. The mixture was set at room temperature, and organogel was formed within a few minutes. D-Limonene organogel-based nanoemulsion preparation was carried out by a high-pressure homogenization procedure. D-Limonene organogel was used as the oil phase, and Milli-Q water containing different types of Tween surfactants was used as the aqueous phase. The organogel-based nanoemulsion formation was performed by mixing the water phase together with the oil phase. Then, the two phases were mixed by a high-blending homogenizer at 24 000 rpm for 5 min to form a coarse emulsion, followed by high-pressure homogenization to form D-limonene organogel-based nanoemulsion. Using the above procedure, several batches were established by varying the organogelator, surfactant type and concentration, homogenization pressure, and cycles to study their effect on the formation and stability of the formulation.

**Particle Size Measurements.** The average particle diameters and particle size distributions of the organogel-based nanoemulsions were determined using dynamic light scattering at 25 °C (Zetasizer Nano-ZS90, Malvern Instruments, Malvern, U.K.). The measurements were carried out at a scattering angle of 90°. Each measurement was recorded in an average of 10 scans. The samples were diluted approximately 1000-fold with Milli-Q water. The particle size of the emulsions was described by the mean particle size diameter, and the size distribution was described by the polydispersity index (PdI).

**Turbidity Measurements.** The turbidity was determined using an ultraviolet−visible (UV−vis) spectrophotometer at 600 nm (Ultraspec 2450, Shimadzu, Ltd., Japan). Distilled water was used as a reference to the blank cells.

**Storage Stability.** The prepared formulations were placed in amber bottles and stored at 4 or 28 °C. The stability was determined by measuring the change of the droplet sizes every 3 days for 2 weeks.

**Statistical Analysis.** All experiments were carried out in triplicate. The data were recorded as the mean ± standard deviation (SD) for the measurements. The data were analyzed by the statistical package (SPSS, version 12.0, for Windows, SPSS, Inc., Chicago, IL).

## RESULTS AND DISCUSSION

**Effects of Organogelators on the D-Limonene Organogel-Based Nanoemulsion Formation.** To investigate the impact of the organogelator type and concentration on the formation of nanoemulsions with small droplet sizes, a series of organogel-based nanoemulsions with a fixed surfactant content and homogenization conditions (10% Tween 80, 10 cycles, and 30 MPa) was prepared using two kinds of organogelators (stearic acid or monostearin) at different concentrations. As shown in Table 1, a large decrease on the mean droplet size was observed, following the addition of the organogelator into the oil phase. The average diameter decreased from $d$ = 133.8 ± 2.03 to 112.8 ± 1.17 and 122.8 ± 1.06 nm, following the addition of 5% stearic acid or monostearin, respectively. This can give evidence that the organogelator has contributed to the decrease of the droplet diameters. In addition, there was a minor change on the droplet diameters after increasing the amount of the organogelators, which means that the amount of the organogelators did not influence the formation of the D-limonene organogel-based nanoemulsion. In comparison of the mean droplet diameters of the formulations prepared by stearic acid or monostearin, stearic acid organogel-based nanoemulsion exhibited the smallest droplet size. Possible reasons are the difference on physicochemical proprieties between this two organogelators or the low molecular weight of stearic acid compared to monostearin. On the other hand, the increase on the stearic acid amount (5, 10, and 15% for $d$ = 112.2, 110.4, and 110.8 nm, respectively) did not contribute to a large change on the mean droplet diameters. For this reason, 5% stearic acid was used as the structuring agent of D-limonene organogel preparation for the following experiments.

**Table 1. Impact of the Organogelator Type and Concentration on the Mean Droplet Formation**

| organogelator type | content of the organogelator in the organogel (%) | mean droplet diameter[a] ($z$ average) |
|---|---|---|
| stearic acid | 0 | 133.8 ± 2.03[b] |
| | 5 | 112.2 ± 1.17[c] |
| | 10 | 110.4 ± 0.95 |
| | 15 | 110.8 ± 1.32 |
| monosearin | 5 | 122.8 ± 1.06[d] |
| | 10 | 125.9 ± 1.65 |
| | 15 | 127.5 ± 0.72 |

**Effects of the Surfactant Type and Concentration on D-Limonene Organogel-Based Nanoemulsion Formation.** *Effect of the Surfactant Type on the Particle Size.* In this part, a series of organogel-based nanoemulsions with fixed homogenization conditions (10 cycles and 30 MPa) was

formulated using a series of non-ionic surfactants (Tween 20, 40, 60, 80, and 85). Figure 1 shows the particle size parameters

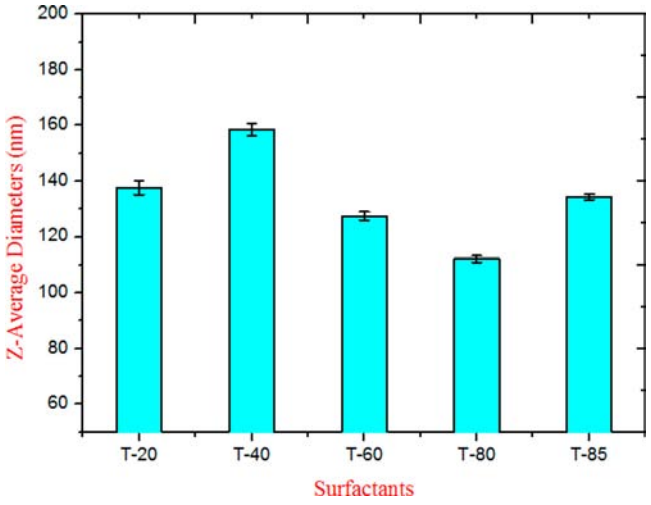

**Figure 1.** Effect of the surfactant type on the mean droplet diameter of D-limonene organogel-based nanoemulsion. Surfactants were Tween 20, 40, 60, 80, and 85, from the left to the right (data shown are the mean ± SD).

of organogel-based nanoemulsion prepared at 10% (w/w) with different Tween surfactants. The mean droplet diameters of the colloidal dispersions were arrayed between 112 and 158 nm with the PdI being in the range of 0.148−0.229. This can give evidence that D-limonene organogel-based nanoemulsions can be formulated using all tested surfactants, with the dispersed droplets in the nanometer scale. Among the five different surfactants tested, Tween 80 produced the smallest mean droplet size ($d$ = 112.2 ± 1.17 nm) with a slightly turbid shape, as presented in panels A and B of Figure 2. In contrast, the largest droplets were produced in the systems prepared by Tween 40 ($d$ = 158.5 ± 2.15 nm). The difference of the mean droplet diameters is maybe due to the hydrophilic−lipophilic balance (HLB) of the surfactants, which is a very important factor for the selection of surfactants having the ability to form

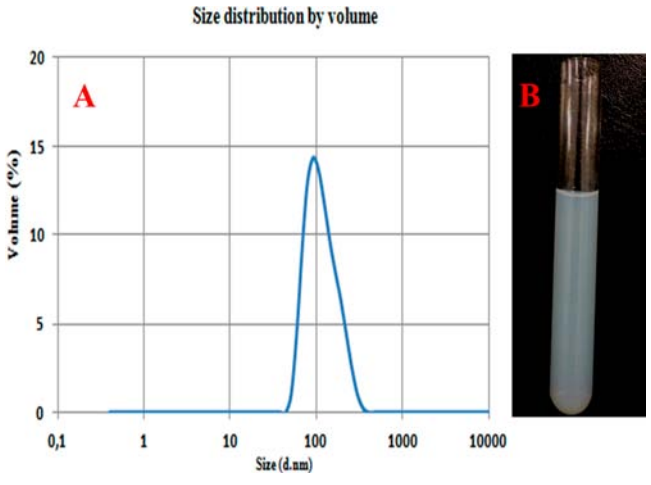

**Figure 2.** (A) Profile of the particle size distribution of D-limonene organogel-based nanoemulsion prepared with Tween 80 at a final concentration of 10% (w/w), 30 MPa, and 10 cycles and (B) its typical picture.

and stabilize the emulsions.[36,37] Surfactants with high HLB values, such as Tween 20 and 40 (HLB = 16.7 and 15.6, with $d$ = 137.7 and 158.5 nm, respectively) or a low HLB value, such as Tween 85 (HLB = 11.0, with $d$ = 134.4 nm) were not able to form D-limonene organogel-based nanoemulsion with the smallest droplet sizes. However, surfactants with a medium HLB value, such as Tween 60 and 80 (HLB = 14.9 and 15.0, with $d$ = 127.5 and 112.2 nm, respectively) could form organogel-based nanoemulsion with the smallest particle sizes. Furthermore, Tween 60 and 80 both have approximately the same HLB value of ≈15, but they have given colloidal dispersions with different droplet size diameters ($d$ = 112.2 and 127.5 nm, respectively). This is maybe due to the molecular geometry of the surfactants, which is known to play an important role in the emulsion production and stability.[38] There is thus far a prominent similarity between the geometric structures of both Tween 60 and 80 (polar headgroup and nonpolar tail), making their HLB approximately the same. However, the nonpolar tails of Tween 60 are saturated, but those of Tween 80 are unsaturated. Those saturated tails may affect the packaging of the surfactant at the oil phase interface, which may cause a disturbance in the formation of small droplets when the oil phase (organogel) and the water phases are mixed together. Moreover, many researchers have reported that the presence of unsaturation on the non-ionic surfactant structures may favor the tiny droplet formation.[36,39]

In the following experiments, Tween 80 was chosen as the appropriate surfactant because it contributes to the formation of an organogel-based nanoemulsion with the smallest mean droplet size diameter.

*Effect of the Surfactant Concentration on the Particle Size Formation.* The effect of the surfactant concentration on the mean droplet size formation and distribution was also investigated. D-Limonene organogel-based nanoemulsions were prepared by Tween 80 at different concentrations with a fixed homogenization condition (30 MPa and 10 cycles). The surfactant concentrations were varied from 2.5 to 20% (w/w). As shown in Figure 3, the surfactant concentration seems to play an efficient role on the formation of the droplets. The mean droplet sizes were found to decrease by increasing the content of surfactant. For example, at 2.5% Tween 80, the mean

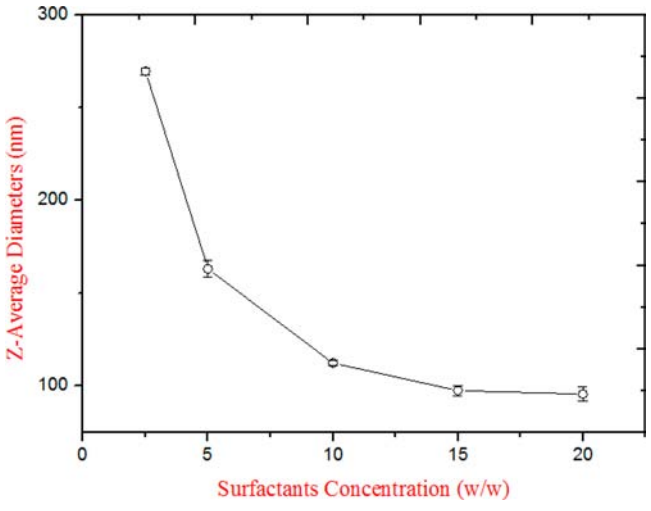

**Figure 3.** Effect of the Tween 80 concentration on the mean droplet diameter of D-limonene organogel-based nanoemulsion (data shown are the mean ± SD).

dx.doi.org/10.1021/jf5032108 | J. Agric. Food Chem. 2014, 62, 12563−12569

droplet size was large ($d$ = 269.7 ± 2.02 nm). In contrast, the amount of surfactant was increased, the droplet size diameters decreased ($d$ = 163.3 ± 4.5, 112.4 ± 1.17, 97.44 ± 2.85, and 95.6 ± 4.03 nm at 5, 10, 15, and 20%, respectively). Our results are in agreements with a previous study reported by Yuan et al.,[40] who found that the droplet sizes of $\beta$-carotene nanomulsions prepared by the high-pressure homogenization method decreased by increasing the amount of surfactant. These results can be explained by a greater amount of Tween 80 being able to completely dissolve the dispersed phase (D-limonene organogel) into the dispersing phase (water). On the other hand, Tween 80 can also form a layer between the two phases, leading to the formation of a minimum interfacial tension, hence promoting the formation of a tiny droplet size with a narrow distribution. It is already known the use of a high amount of surfactants on the nanoemulsion preparation is costly and may have an undesirable taste in commercial formulations. Thus, an intermediate amount of surfactant is maybe more suitable for the preparation of stable nanoemulsions. In this regard, we found it necessary to use 10% Tween 80 in the following experiments.

*Effects of the Homogenization Pressure and Number of Cycles on the Proprieties of D-Limonene Organogel-Based Nanoemulsion.* It is well-known that the homogenization pressure and number of cycles significantly influence the mean droplet size formation and particle distributions.[41] In this part, the influence of the homogenization pressure and number of cycles on the average droplet diameter of D-limonene organogel-based nanoemulsion was investigated (Figure 4).

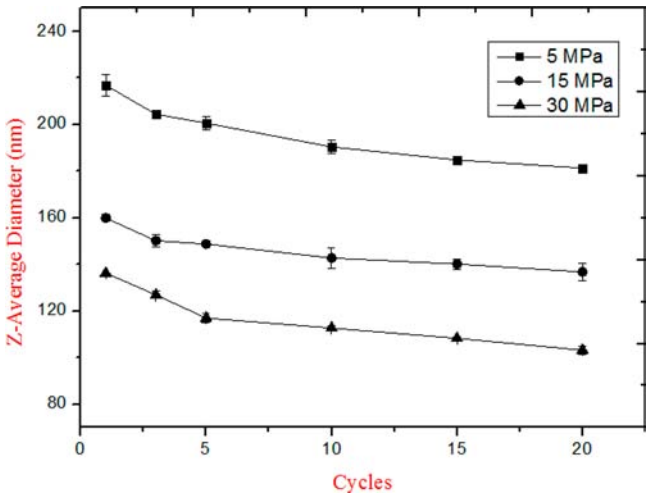

**Figure 4.** Effect of the high-pressure homogenization pressure (5, 15, and 30 MPa) and number of cycles (1, 3, 5, 10, 15, and 20) on the mean droplet diameter of D-limonene organogel-based nanoemulsion (data shown are the mean ± SD).

The mean droplet diameter was decreased by increasing the homogenization pressure and number of cycles. These results are in agreement with previous studies reported by many researchers.[40,42,43] A large decrease of the mean droplet diameter was observed when the coarse emulsions were passed through the high-pressure homogenizer at all pressures studied. For example, the average droplet size decreased from 1340 ± 340 nm before homogenization to 216.9 ± 4.6, 160 ± 1.61, and 136.3 ± 0.45 nm after passing 1 cycle through the high-pressure homogenizer system working at 5, 15, and 30 MPa, respectively. These results showed that organogel-based nanoemulsion can be formed using a high-pressure homogenizer method, and this technique is efficient for preparing organogel-based nanemulsions with small droplet sizes. The average particle size of the organogel-based nanoemulsion continued to decrease by increasing the number of cycles, but the decrease was modest in a certain stage. Organogel-based nanoemulsion prepared at 30 MPa showed the lowest average of the particle size, as it was decreased from 136.3 ± 0.45 after 1 cycle to 103.2 ± 1.84 after 20 cycles. It should be noted that the average particle sizes did not mainly change after about 10 cycles. Therefore, we found it necessary to use this value as a processing condition for our experiments.

*Storage Stability of D-Limonene Organogel-Based Nanoemulsion.* For most commercial applications, it is very important that nanoemulsion-based delivery systems remain physically stable during their shelf life (i.e., there is little change in their particle size diameter during storage). The change on the turbidity of D-limonene organogel-based nanoemulsion was investigated in this part during a storage time of 2 weeks at 4 or 28 °C. As shown in Figure 5, the turbidity of D-limonene organogel-based nanoemulsion increased rapidly throughout the first 6 days and the increase was slight for the remaining storage time.

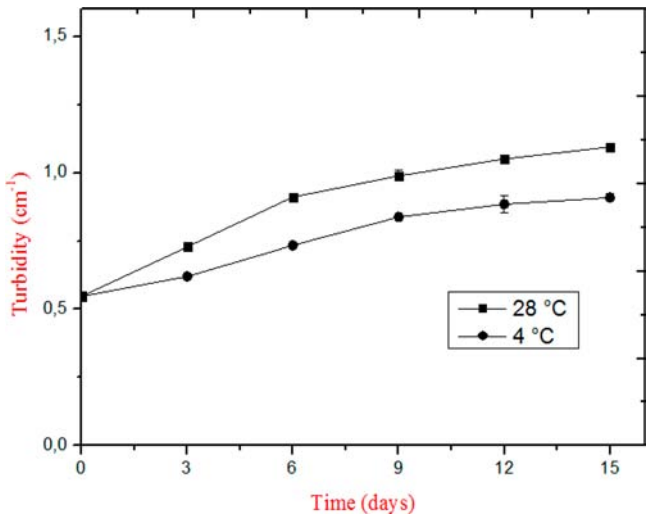

**Figure 5.** Storage turbidity of D-limonene organogel-based nanoemulsion at 4 and 28 °C (data shown are the mean ± SD).

The droplet diameter and size distribution are important parameters affecting nanoemulsion stability.[44] The change of the nanoemulsion droplet sizes is due to numerous physiochemical processes, which include coalescence, flocculation, gravitational separation, and Ostwald ripening.[28] We therefore investigated the influence of the storage time at 4 and 28 °C on the stability of D-limonene organogel-based nanoemulsion for 2 weeks of storage. There was a slight increase in the mean droplet diameters for all samples stored at 4 and 28 °C, respectively (Figure 6). This increase is maybe due to the movement of the dispersed droplet throughout the dispersing phase, which increased the opportunities of droplet collisions.[45] In comparison to conventional emulsions, nanoemulsions are endowed with good stability against phase separation, creaming, and sedimentation because of their small droplet sizes. However, many researchers have reported that Ostwald ripening and/or coalescence are the main mechanisms causing the instability of nanoemulsions.[46] Ostwald ripening

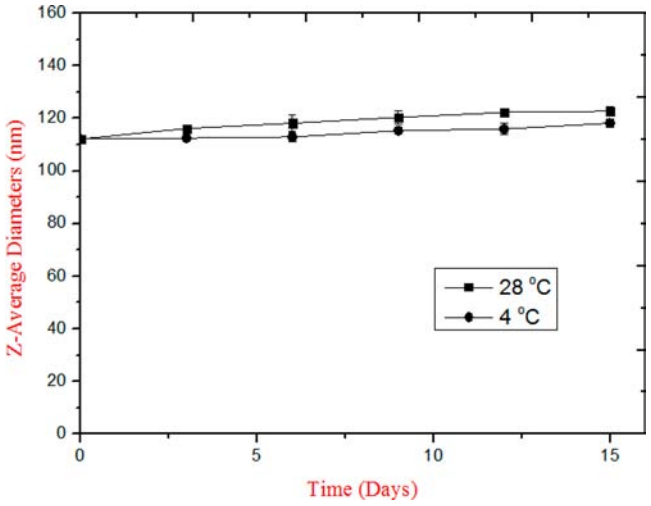

**Figure 6.** Storage stability of D-limonene organogel-based nanoemulsion at 4 and 28 °C (data shown are the mean ± SD).

can occur because of the difference in the chemical potential of the oil phase between the droplets.[47] In this phenomenon, larger droplets grow at the expense of smaller droplets, which is caused by the molecular diffusion through the dispersing phase. In other words, the small droplets become smaller and the larger droplets become bigger. D-Limonene has a slight solubility in water around 13.8 g/L.[48,49] This can increase the susceptibility to the Ostwald ripening process of the nanoemulsion made from it. As demonstrated previously, the Ostwald ripening can be inhibited by incorporating a highly water-insoluble oil into a relatively water-insoluble oil prior to nanoemulsion formation,[50,51] because of the entropy of the mixing effect. Li and Chiang[11] prepared D-limonene nanoemulsion and reported that the main destabilization mechanism of the system was Ostwald ripening. In addition, the droplet growth of the nanoemulsion was large through the storage period of 98 days. In another study, Li et al.[20] reported that Ostwald ripening was also the major destabilization mechanism for D-limonene nanoemulsion. Furthermore, they have mentioned that the growth of the particle size increased at a relatively higher rate to 128 nm at 4 °C and 67 nm at 28 °C during a storage period of 2 weeks, whereas, in our study, the increase of the particle size was 10 nm at 28 °C and 6 nm at 4 °C during a storage period of 2 weeks. In comparison to their results, D-limonene organogel-based nanoemulsion showed an ameliorated stability with a slight increase on the droplet size diameter at the same storage conditions. This improvement is maybe due to the incorporation of D-limonene into the organogel prior to nanoemulsion preparation, which contributed to the decrease of the D-limonene polarity, thereby increasing the stability of the nanoemulsion.

Coalescence is the process in which two or more droplets merge together when they colloid.[52,53] A higher amount of essential oils may lead to the droplet coalescence acceleration, which is caused by the low interfacial tension and the relatively high polarity of this kind of oil.[54] In addition, the polarity of the oil may play an efficient role in the rate of droplet coalescence (i.e., nanoemulsions containing more polar oils occur more rapidly than the nonpolar oils), and this phenomenon is maybe due to the influence of the oil phase proprieties on the optimum curvature.[55,56] The incorporation of D-limonene on the organogel (MCT oil and monostearin) and the preparation conditions seem to have a good benefit on both nanoemulsion formation and storage stability by decreasing the polarity and increasing the interfacial tension, thereby acting as Ostwald ripening and/or coalescence.

In the current study, D-limonene organogel-based nanoemulsion was successfully prepared by high-pressure homogenization technology. The type and concentration of organogelators and emulsifiers, homogenization pressure, and number of cycles on the formation and stability of the nanoemulsions were investigated. It was found that stearic acid was the most suitable structuring agent for small droplet formation. In addition, among the non-ionic emulsifiers tested, Tween 80 at 10% (w/w) was appropriate for the formation of D-limonene organogel-based nanoemulsion with the smallest mean droplet size. The optimum conditions of high-pressure homogenization emulsification of the nanoemulsion were 30 MPa and 10 cycles. The prepared formulation showed good stability in terms of Ostwald ripening and/or coalescence through the storage period at the two different temperatures tested. In summary, our results may have a valuable implication for the design and use of organogel-based nanoemulsion as a delivery system in food and other industries.

lactate/40% water, Lincolnshire, IL); and anhydrous dibasic sodium succinate was obtained from Spectrum Chemical Corp. (Gardena, CA). A Wheaton Potter−Elvehjem grinder tube with polytetrafluoroethylene pestle, RNase-free D-sucrose, and lactic acid were obtained from Fisher Scientific (Fair Lawn, NJ). Ethylene glycol-bis(β-aminoethyl ether)-N′-N′-N′-N′-tetraacetic acid (EGTA) was obtained from MP Biomedicals (Solon, OH). A Kontes Duall tissue grinder glass tube with polytetrafluoroethylene pestle and centrifuge tubes (DNase, RNase, and endotoxin free) were obtained from VWR (Suwanee, GA). A heavy-duty mechanical drill driver purchased locally was used to drive the pestles for the tissue-grinding procedures.

**Beef Homogenate Preparation and Color Measurements.** A total of 25 g (devoid of fat and connective tissue) of minced bovine skeletal muscle from strip loin ($n$ = 3) was homogenized with 4 times (weight by volume) of 0.04 M MOPS buffer solution containing either 2% (w/v) lactate or 2% (w/v) succinate or only buffer as the control. Samples were homogenized at 5000 rpm with a variable-speed PowerGen homogenizer (model 35, Fisher Scientific, Pittsburgh, PA) for 60 s, and visible lumps of connective tissue were removed. The pH of the homogenate was adjusted to 5.6 ± 0.1, and the homogenate was poured into sterile polystyrene Petri plates (60 × 100 mm, Fisher Scientific, Pittsburgh, PA) and covered with a clear, snug-fitting lid. To this, 200 ppm of ferrous and/or ferric ions was added to achieve the final concentration of RRI between 0 and 60 ppm in the homogenate. The homogenates were gently stirred with a clean glass rod, and the Petri plates were incubated at 37 °C for 30 min.

Post-incubation, the homogenates were stirred and color parameters CIE $L^*$, $a^*$, and $b^*$ and reflectance from 400 to 700 nm using A/10 illuminant (d/8°, LAV, 25 mm port) from HunterLab Miniscan EZ portable spectrophotometer (Hunter Associates Laboratory, Inc., Reston, VA) were measured. The CIE $L^*$, $a^*$, and $b^*$ values and reflectance measurements were recorded in duplicate and averaged for statistical analysis. The relative percent of the Mb redox forms were determined using the absorption and scattering index ($K/S$) values specific to isosbestic wavelengths as described in the American Meat Science Association (AMSA) Meat Color Guidelines.[22]

**Mitochondrial Isolation.** A briefly modified procedure by Tang and colleagues was followed for mitochondrial isolation and oxygen polarographic measurements.[23] Briefly, 50 g of cardiac muscle, free of visible connective tissue and fat was excised and washed twice in the wash solution before mitochondrial isolation. The lean meat was minced and suspended in 200 mL of isolation buffer while being gently stirred with a magnetic stirrer. Bacterial nagarse protease (25 mg/50 g of tissue) was added to this suspension, and the pH was maintained between 7.2 and 7.4. After 20 min of proteolysis, the suspension was allowed to stand and the supernatant was gently decanted. The protease-treated cardiac tissue was washed twice with the isolation buffer to remove the residual protease and resuspended in 500 mL of isolation buffer. This suspension was given three passes each of Kontes Duall grinder and the Wheaton Potter−Elvehjem grinder. The resulting suspension was centrifuged at 1200$g$ for 20 min. The supernatant was filtered through two layers of ultrapure water-washed cheese cloth. This clear solution was further centrifuged at 20000$g$ for 20 min (Sorvall RC 6 centrifuge, Thermo Fisher Scientific, Waltham, MA). The resulting pellets were washed twice with suspension buffer and resuspended in the same. The temperature of the entire mitochondrial isolation operation was maintained between 0 to 4 °C. The protein concentration of the mitochondrial suspension was measured using the Bicinchoninic acid assay (BCA, bicinchoninic acid kit, Sigma-Aldrich, St. Louis, MO).

**Oxygen Consumption of Isolated Mitochondria.** The mitochondrial oxygen consumption was measured using a Clark electrode attached to a model 20 controller (Rank Brothers, Cambridge, U.K.) and PicoLog ADC 20 USB data logger. The data logger was attached to a computer for real-time data acquisition and storage. The temperature of the electrode cell was maintained at 25 °C using a circulating water bath. A 1 cm magnetic flea stirrer was used to keep the cell suspension agitated during oxygen consumption measurements. Iron solutions of suitable concentrations to obtain final concentrations of 5 or 60 nm of iron/mg of mitochondrial protein were added to 1 mL of incubation buffer in the electrode chamber, and it was sealed with a stopper. These levels represent the normal iron concentration and exceptionally high concentration of mitochondrial iron reported in viable cells suffering from mitochondrial dysfunction as in the case of Friedreich's ataxia, respectively.[24] Although iron accumulation of such a high level in beef muscle mitochondria is unlikely, the level was tested as a realistic extremity to understand the iron-mediated changes in mitochondrial respiration.

Additions of mitochondrial suspension, substrates (lactate and succinate), and ADP solutions were made to the electrode cell using Hamilton syringes through the port in the stopper while being continuously stirred. The mitochondrial suspension was added until the protein concentration in the cell chamber achieved 1 mg/mL, which is sufficient to exhibit measurable oxygen consumption. The state IV oxygen consumption rate was calculated as the rate of consumption of atomic oxygen per mg of mitochondrial protein per minute in the presence of substrate alone, and the state III oxygen consumption rate was calculated as the rate of consumption of atomic oxygen per mg of mitochondrial protein per minute in the presence of both the substrate and ADP. The respiratory control ratio (RCR) was calculated as the ratio of state III to state IV oxygen consumption rates. The time of calculation of the slopes varied according to the response given by mitochondria to the substrate and ADP additions.

**Design of Experiments and Statistical Analysis.** For the experiments on beef homogenate, the experimental design was a balanced factorial with three levels of substrate treatment (control, succinate, and lactate) and five levels each of $Fe^{2+}$ and $Fe^{3+}$ ion concentrations (3 × 5 × 5 = 75 × 3 replications = 225 total samples). Data were collected in duplicate samples, and the experiment was repeated 3 times ($n$ = 3) at three different occasions. Type-3 tests of fixed effects were performed using the MIXED procedure of SAS (SAS Institute, Inc., Cary, NC). Least-square means for $F$ tests ($p < 0.05$) were separated using the diff option (least significant differences) and were considered significant at $p < 0.05$.

For the mitochondrial experiments, a complete randomized block design was used. Experimental replication was performed 3 times ($n$ = 3) on three separate occasions. The treatments were applied on the isolated mitochondria within a heart; duplicate samples were used for each treatment application; and data were averaged for statistical analysis. Fixed effects for experiment included a two-way treatment structure consisting of treatments lactate, succinate, and combination of different RRI concentrations. Type-3 tests of fixed effects were performed using the MIXED procedure of SAS (version 9.1, SAS Institute, Inc., Cary, NC). Least-square means were separated using the Pdiff option of SAS and were considered significant at $p < 0.05$. The results were expressed as the least-square mean values of three independent trials.

## RESULTS AND DISCUSSION

**Instrumental Color.** The $a^*$ values of samples containing metabolic substrates in the absence of RRI were higher ($p < 0.05$) than those with added RRI (Figure 1). The addition of lactate and succinate with RRI resulted in a decrease ($p < 0.05$) of $a^*$ values compared to the control. The $a^*$ values did not differ ($p > 0.05$) between samples containing RRI with added lactate and added succinate. However, in the absence of added RRI, the $a^*$ values were higher ($p < 0.05$) for added lactate compared to succinate and the control. The $a^*$ value decreased as concentrations of $Fe^{2+}$ ions ($p < 0.05$) and $Fe^{3+}$ ions ($p < 0.01$; Figure 2) increased.

Lindahl et al.[25] found that the overall pigment content and fraction of MMb were most important in explaining the variation of the $a^*$ value in pork *longissimus dorsi* and *biceps femoris* muscles. Metabolic substrates, lactate and succinate, increase MMb reducing activity by generating NADH and increasing the oxygen consumption, respectively, which reduce MMb to DMb. When exposed to oxygen, DMb is oxygenated

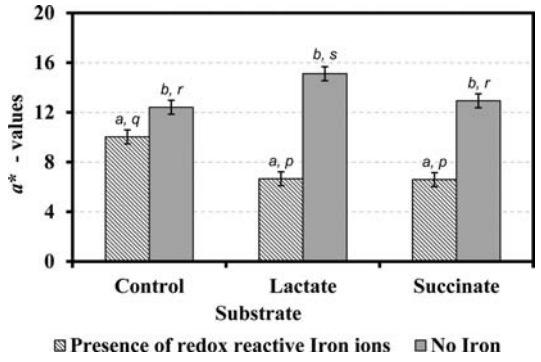

**Figure 1.** Variation of $a^*$ with metabolic substrates, with and without the presence of redox iron ions ($n = 3$). In the absence of redox iron ions, the $a^*$ of lactate-added homogenates was higher ($p < 0.05$) than that of succinate and control. In the presence of redox iron ions, the $a^*$ was lower ($p < 0.05$) for homogenates with added succinate and lactate. Values are expressed as least-square means with standard error of the mean (SEM) = 0.56. Means within a substrate treatment with different letters a and b are different ($p < 0.05$). Means across the substrate treatment with different letters p, q, r, and s are different ($p < 0.05$).

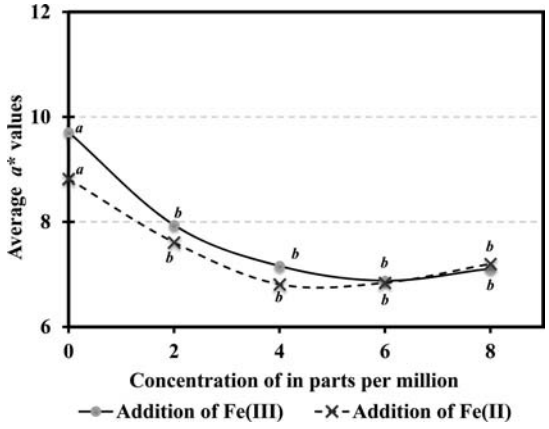

**Figure 2.** Effects of RRI (ferrous or ferric ions) concentration interaction with lactate and succinate on beef skeletal muscle homogenate $a^*$ values. The $a^*$ values of the beef homogenate was measured after the addition of increasing cocentrations of RRI forms (ferrous or ferric) in the presence of either lactate or succinate. Increasing $a^*$ values indicate a redder color, whereas a lower value indicates a less red color with some discoloration. Values are expressed as least-square means with SEM = 0.47. Means not sharing common letters a and b across the iron concentration are different ($p < 0.05$).

to OMb, which gives the desired bright cherry red color appearance to meat.[18,26] In this study, the $a^*$ values for the beef homogenate treated with lactate and succinate, in the absence of added RRI, were higher than that of the control, which was expected because of the color-stabilizing effect of metabolic substrates. However, in the presence of RRI, the homogenates with added lactate and those with added succinate had lower $a^*$ values than that of the control. This reduction in $a^*$ values may be due to oxidation of OMb directly or through other mechanisms, such as lipid oxidation, which might also contribute to reducing the redness indirectly.

Of the two RRI forms used in this work, $Fe^{2+}$ ions are pro-oxidants with well-documented roles in lipid peroxidation in raw muscle foods. This leads to a series of detrimental qualitative changes.[26] $Fe^{3+}$ ions are not soluble at post-mortem meat pH, which is approximately pH 5.6 or more. In the presence of reducing agents, such as ascorbate, NADPH, or cysteine, which are commonly present in raw meat[17] and in an aerobic environment, ferric ions are reduced to ferrous ions. This reaction contributes to lipid peroxidation through reactions 1−3, where AH is an arbitrary reducing agent.

$$Fe^{3+} + AH \rightarrow Fe^{2+} + A^{\bullet} + H^{+} \quad (1)$$

$$Fe^{2+} + O_2 \rightarrow Fe^{3+} + O_2^{\bullet -} \quad (2)$$

$$Fe^{2+} + ROOH \rightarrow Fe^{3+} + RO^{\bullet} + OH^{-} \quad (3)$$

In an acidic environment, the superoxide radicals also combine to form hydrogen peroxide through reaction 4, which further reacts with RRI ions to generate hydroxyl radicals through Fenton reactions 5 and 6. The hydrogen peroxide can further knock out iron from porphyrin in Mb, increasing the inorganic iron content. Overall, the oxidation reactions are self-catalyzing.

$$2O_2^{\bullet -} + 2H^{+} \rightarrow H_2O_2 + O_2 \quad (4)$$

$$Fe^{2+} + H_2O_2 \rightarrow Fe^{3+} + HO^{\bullet} + OH^{-} \quad (5)$$

$$Fe^{3+} + H_2O_2 \rightarrow Fe^{2+} + HO^{\bullet} + HOO^{\bullet} + OH^{-} \quad (6)$$

**Variation in Mb Redox Forms.** The interaction effect of the $Fe^{2+}$ concentration and substrate affected the OMb content ($p < 0.01$; Figure 3). For homogenate samples with added

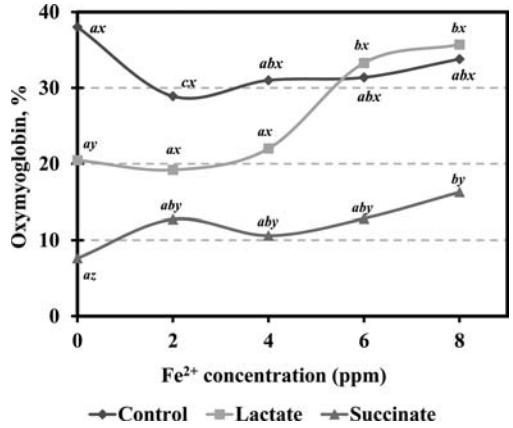

**Figure 3.** Variation of the OMb content with the ferrous ion concentration and different substrates ($n = 3$). The interaction effect between the ferrous ion concentration and substrate was significant ($p < 0.05$). For both lactate- and succinate-added homogenates, the OMb content increased with the ferrous ion concentration ($p < 0.05$). Values are expressed as least-square means with SEM = 6.31. Means not sharing common letters a, b, and c within a substrate are different ($p < 0.05$). Means not sharing common letters x, y, and z across the substrates are different ($p < 0.05$).

lactate and succinate, the OMb content increased ($p < 0.05$) with the ferrous ion concentration. However, the OMb content reduced with the ferrous ion concentration in the absence of lactate or succinate. The ferric ion concentration directly influenced ($p < 0.05$) the relative content of all three Mb redox forms in the homogenate system (Figure 4). The relative DMb and OMb contents decreased ($p < 0.01$) with the $Fe^{3+}$ concentration, and the relative MMb content increased ($p < 0.01$) with $Fe^{3+}$ addition.

A previous study of a buffered model system containing microsomes, purified Mb, and redox iron ions has shown that redox iron along with membranal lipid oxidation causes most

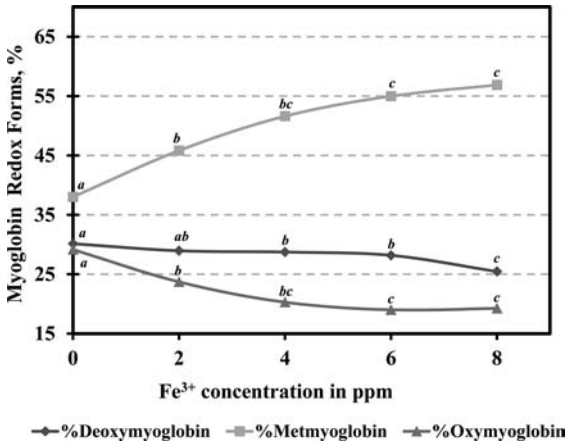

**Figure 4.** Variation in the relative contents of Mb redox forms with the ferric ion concentration ($n$ = 3). With the increase of the ferric ion concentration, the relative MMb content increased ($p$ < 0.05) and DMb and OMb contents decreased ($p$ < 0.05). Values are expressed as least-square means with SEM (DMb, 1.5; OMb, 3.6; and MMb, 3.15). Means not sharing common letters a, b, and c across $Fe^{3+}$ ion concentrations are different ($p$ < 0.05).

oxidation of OMb to MMb. However, the oxidation activity attributed to redox iron alone was very small.[27] The present study involved beef homogenate containing the cell membrane lipids as well as other components inherent to skeletal muscle, which can have both pro- and antioxidant activities. The relative percentage of OMb decreased ($p$ < 0.05) with the ferric concentration (Figure 4), while the percentage of MMb increased ($p$ < 0.05) with the ferric concentration. The results of this study suggest that the extent of OMb oxidation increased with the ferric ion concentration, possibly by the following reaction:

$$\mathrm{Mb{-}Fe^{2+}{-}O_2\ (OMb) + Fe^{3+} \rightarrow Mb{-}Fe^{3+}\ (MMb) + Fe^{2+} + O_2} \quad (7)$$

However, increasing the ferric ion concentration may lead to increased ferrous ion production via reaction 1. This can possibly lead to the formation of hydrogen peroxide, hydroxyl radicals, and perhydroxyl radicals (reactions 2 and 4−6). These can oxidize ferrous Mb through reactions 8 and 9.

$$\mathrm{Mb{-}Fe^{2+} + H_2O_2 \rightarrow Mb{-}Fe^{4+}{=}O + H_2O} \quad (8)$$

$$\mathrm{Mb{-}Fe^{2+} + OH^{\bullet} \rightarrow Mb{-}Fe^{3+} + OH^{-}} \quad (9)$$

Hence, it is difficult to pinpoint the exact route of action of ferric ions on oxidation of DMb and OMb. The underlying presence of either lactate or succinate in this experiment may be significant in the reactions of ferrous ions. Also, it would be worth investigating how RRI ions affect lactate dehydrogenase and succinate dehydrogenase in the beef skeletal muscle environment.

**Mitochondrial Oxygen Consumption.** In the absence of RRI, the addition of succinate to mitochondria isolated from the fresh beef hearts resulted in a much greater ($p$ < 0.05) state III consumption rate (oxygen consumption in the presence of substrate and ADP) than that for lactate, as seen in Table 1. Tang and colleagues[23] have reported that RCR above 2.2 is indicative of functional integrity and active respiration of beef heart mitochondria. In the absence of RRI, the RCR for both succinate (2.87) and lactate (2.38) addition indicated that the mitochondria isolated during the present experiments were functional and actively respiring. Loading with inorganic iron has been reported to negatively influence mitochondrial function, possibly by causing oxidation of cell membrane polyunsaturated fatty acids, loss of activity in thiol-dependent enzymes, and increased fragility of lysosomes.[27−30] When

**Table 1. Effect of Inorganic Iron and Metabolic Substrates on the Oxygen Consumption Rates and Respiratory Control Ratios of Beef Heart Mitochondria, Observed at pH 7.2 and 25 °C ($n$ = 3)[a]**

[a]The iron ion concentrations are expressed as nanomoles of iron per milligram of mitochondrial protein. [b]State IV OCR is the oxygen consumption rate of mitochondria in the presence of substrate alone. The oxygen consumption rates are expressed in nanomoles of atomic oxygen per milligram of protein per minute. [c]State III OCR is the oxygen consumption rate in the presence of both substrate and ADP. The oxygen consumption rates are expressed in nanomoles of atomic oxygen per milligram of protein per minute. [d]RCR is the ratio of state III OCR divided by state IV OCR. Each combination of ferrous and ferric ions is considered as a level of treatment. [e]Within a substrate, values in each column not sharing common letters a−e are significantly different ($p$ < 0.05). Within an iron ion concentration across the two substrates, values in each column not sharing common letters x and y are significantly different ($p$ < 0.05).

succinate was added to the isolated mitochondria treated with 5 nmol/mg of ferrous ions, either alone or in combination with 5 nmol/mg of ferric ions, RCRs near unity were obtained. A similar RCR was observed for 60 nmol/mg of ferrous treatment and succinate. A low RCR of near 1 indicates that the mitochondria are structurally compromised and unresponsive to ADP addition, which would otherwise increase oxygen uptake (i.e., the state III oxygen consumption rate).[23]

For lactate-supported mitochondrial respiration, either ferrous or ferric ions at 60 ppm alone or ferrous and ferric ions together at 60 ppm had a similar effect on both state III and state IV oxygen consumption rates. The three treatments reduced the RCR with respect to the lactate control, although the value was greater than 1, indicating that the mitochondria were actively respiring. Ferric ions at 5 ppm level reduced ($p < 0.05$) the state III OCR and RCR, indicating structural and functional compromise to mitochondria.[23]

The treatment combination of succinate with 60 ppm each of ferrous and ferric ions on mitochondria exhibited RCR greater than 2. Also, a RCR greater than 2 was observed with a combination of lactate with 5 ppm of both ferrous and ferric ions. Both of the treatments, however, reduced ($p < 0.05$) the state III and IV oxygen consumption rates compared to their respective controls.

Lactate as a metabolic substrate has been reported to support mitochondrial activity, because it can enter mitochondria through monocarboxylate shuttles. Mitochondria also contain an isoform of lactate dehydrogenase, which can oxidize lactate to generate NADH. NADH participates in the electron transfer chain and, thus, leads to oxygen consumption.[31,32] The mitochondrial oxygen consumption rates obtained with lactate and succinate fuelled respiration in the absence of iron addition, are similar to those reported in the literature.[33]

Mb and active mitochondria compete for dissolved oxygen in the tissue. Oxygen uptake because of mitochondrial respiration leads to reduction of oxygen partial pressure, causing conversion of OMb to MMb. Through metabolite-mediated enzymatic reduction, MMb can be further reduced to DMb via mitochondrial MMb reduction pathways,[34] thus offering better color stability. Because both lactate and succinate support mitochondrial respiration, their addition would lead to MMb reduction in post-mortem skeletal muscle. Mitochondria have been reported to be actively respiring for up to 45 days post-mortem at refrigeration temperatures.[35] Thus, they can participate in MMb reduction when supplied with suitable substrates. RCR values of near unity for mitochondria treated with inorganic iron are indicative of their compromised structure and function. This seems to indicate that inorganic iron would be detrimental to color stability of raw beef products.

The inorganic iron concentrations employed in this work represented those associated with storage, ingredient addition, and processing of fresh beef. A combination of inorganic ferrous and ferric ions (also termed redox reactive inorganic iron) was observed to reduce redness in raw beef homogenates. Ferric ions showed a concentration-dependent increase in MMb content, resulting in discoloration of the beef homogenates. Mitochondrial respiration was adversely affected by RRI. These findings provide evidence of the detrimental role of inorganic RRI on the color and color stability of raw beef. Specific iron-mediated targeting of mitochondrial components in raw beef skeletal muscles merits further research.

## MATERIALS AND METHODS

**Subjects.** Healthy subjects, 12 men and 12 women, were selected to participate in this study. Subjects' characteristics were 27 ± 6 years old, weight 68.3 ± 11.7 kg, and body mass index (BMI) 24 ± 3 kg $m^{-2}$. The subjects were non-smokers and non-vegetarians, and were not currently using hormones or nutritional supplements or taking medication for any gastrointestinal or metabolic diseases. The subjects did not regularly consume alcohol or perform intensive physical exercise. Systolic and diastolic blood pressures were 118 ± 11 and 70 ± 10 respectively, and the levels of triglycerides, total cholesterol, high density lipoprotein cholesterol, glucose and insulin were within normal ranges. The study was approved by the Ethics Committee of the School of Pharmaceutical Sciences, São Paulo State University, and an informed written consent was obtained from each participant before entering the study (protocol no. 00558712.5.0000.5426, The Ministry of Health, Brazil).

**Study Design.** The study was a crossover trial where the subjects received a sequence of two types of orange juice, (1) FOJ and (2) POJ, on two different days separated by a washout period of 30 d. The subjects agreed to refrain from consuming citrus fruits in any form for 3 d before each treatment and to follow a citrus flavonoid free diet. They were given a list of allowed and prohibited foods. Clinical data (anthropometric and blood pressure) were collected on the day before the first treatment.

The fasted subjects arrived at 8 a.m. on each day of the experiment, and a blood sample of 10 mL was collected (time point zero). The subjects were given 11.5 mL/kg body weight of orange juice, FOJ or POJ, in a 10 min period, and after 30 min they had a flavonoid-free standard breakfast. Blood samples of 10 mL were collected at 3, 4, 5, 6, 7, 8, and 24 h after each treatment with a catheter installed in a vein of the arm, and blood was sampled into heparinized vacuum tubes. At 4 h after ingestion of the orange juice the subjects were provided a lunch consisting of skinless chicken breast, rice and beans. After collection of the 7 h blood sample the subjects were provided with a snack similar to breakfast. Water was freely available during the entire day.

The first urine sample was discarded, and the subsequent urine samples were collected in plastic bottles containing 1 g of ascorbic acid, and kept at 4 °C. The subjects were asked to avoid eating any foods that contained polyphenols until after the last time point blood sampling. The subjects returned the following morning and the last blood sample was collected 24 h after ingestion of the orange juice.

**Orange Juices.** Two standard boxes of fresh oranges (Pera Rio sp) and 20 L of commercially extracted processed orange juice (POJ), made from the same batch of fruits, were provided by Citrosuco, Matao, Brazil. The fresh-squeezed orange juice (FOJ) was prepared from fruit extracted with a commercial fresh fruit juicer (MJ-20 Basic, Mulligan Associates, Inc., Jupiter, FL, USA) in the morning 2 h before starting the procedure for each subject. Remaining portions of the FOJ were frozen immediately after administration to the subjects. The POJ was pasteurized at 95 °C for 15 s, frozen, stored in 1 L bottles at −20 °C, and thawed under refrigeration the day before the experiment.

**Extraction of Flavonoids in Orange Juice.** FOJ and POJ were thawed and mixed, and triplicate samples (35 g) were centrifuged at 27000*g* at 4 °C for 30 min. Supernatants were collected and pellets were suspended with 35 mL of deionized water and centrifuged. The final pellets were vacuum-dried for 24 h at 55 °C. Prior to analysis, supernatant samples (1.0 mL) were spiked with 5.4 μg of mangiferin as an internal standard and analyzed without further processing. The vacuum-dried samples were ground to fine powder under liquid nitrogen for sample preparation. The ground pellet (100 mg) was extracted with 3 mL of dimethyl sulfoxide by shaking for 18 h with a platform shaker at 110 rpm at 25 °C. The extracts were centrifuged at 7500*g* for 15 min to remove any solid particulates. The supernatant (1.0 mL) was placed in a vial containing 5.4 μg of mangiferin (internal standard) prior to analysis by high-performance liquid chromatography−mass spectrometry (HPLC-MS).

Analyses of the orange juice flavonoids were done with a Waters 2695 Alliance HPLC (Waters, Medford, MA) connected in parallel with a Waters 996 PDA detector and a Waters/Micromass ZQ single-quadrupole mass spectrometer equipped with an ESI source. Compound separations were achieved with a Waters XBridge C8 column (5 μm, 4.5 × 150 mm) with linear gradients of acetonitrile and 0.5% aqueous formic acid with a flow rate of 0.75 mL/min. Identifications of compounds were done by absorbance and mass spectrometry, and by comparison of retention times of samples and authentic standards (narirutin, hesperidin, didymin, and vicenin-2). Quantitations of the flavanone glycosides and hydroxycinnamates were performed with UV peak integrations at 285 and 330 nm, respectively. The PMFs were quantified using both MS and UV absorbance detection and calibration curves with authentic standards (sinensetin, nobiletin, heptamethoxyflavone, and tangeretin). MS parameters were as follows: ionization mode, positive ESI; capillary voltage, 3.0 kV; extractor voltage, 5 V; source temperature, 100 °C; desolvation temperature, 225 °C; desolvation gas flow, 465 L/h; cone gas flow, 70 L/h; scan range, *m*/*z* 100−900; rate, 1 scan/s; cone voltages, 20 and 40 V. Quantification of flavonoids was done by external calibration curves obtained by injecting different amounts of stock solution containing the internal standard and all the compounds of interest.

**Plasma and Urine Samples Preparation.** Blood samples were collected in heparinized tubes and stored for a maximum of 15 min before centrifugation at 10000*g* for 4 min. Plasma was recovered and stored at −80 °C until processed. Plasma samples (200 μL) were combined with methanol (600 μL), thoroughly mixed, and centrifuged at 10000*g* for 4 min at room temperature. The supernatants were collected and reduced to dryness under vacuum with a Speedvac centrifugal evaporator (Savant, Holbrook, NY). Total urine samples collected in the flasks were homogenized and a 200 mL sample was withdrawn from each bottle. Five C18 Sep Pak (360 mg of resin/cartridge) (Waters, Milford, MA) were series connected and were preconditioned with methanol and water. The metabolites were absorbed onto the Sep Pak cartridges, and then eluted with 80% methanol. The recovered metabolites were dried under vacuum with a Speedvac centrifugal evaporator. Plasma and urine metabolite samples were dissolved in 1.0 mL of methanol/dimethyl sulfoxide (1/1 v/v), and 5.4 μg of mangiferin as internal standard was added.

**Analyses of Flavanone Metabolites in Human Plasma and Urine.** The flavanone metabolites in human plasma and urine samples were analyzed by HPLC-ESI-MS, with a Waters 2695 Alliance HPLC connected in parallel with a 996 photodiode array (PDA) detector and a Micromass ZQ single-quadrupole mass spectrometer equipped with an ESI source. Post-column split to the PDA and mass ZQ detector was 10:1. Compound separations were achieved with a Waters Atlantis dC18 column (2.1 × 100 mm) using linear gradients of aqueous 0.5% formic acid/acetonitrile, initially composed of 90:10 (v/v), and increased in acetonitrile content to 85:15, 80:20, 70:30, 30:70, 30:70 and then decreased to 90:10 (v/v) at 5, 7, 12, 20, 23, and 25 min, respectively, at a flow rate of 0.45 mL/min. Data handling was done with Mass Lynx software ver. 4.1 (Micromass, Division of Waters Corp., Beverly, MA). MS parameters were as follows: ionization mode, negative ESI; capillary voltage, 3.0 kV; extractor voltage, −4 V; source temperature, 100 °C; desolvation temperature, 250 °C; desolvation $N_2$ flow, 550 L/h; cone $N_2$ flow, 100 L/h; cone voltage, 40 V.

Detection and identifications of the metabolites were based on their characteristic UV spectra, molecular masses, and fragmentation patterns as described previously.[20,28] Hesperetin glucuronides were identified by ions at *m*/*z* 477 and 301, hesperetin sulfates at *m*/*z* 381 and 301, mixed sulfo/glucurono hesperetin conjugates at *m*/*z* 301, 477, and 557, and naringenin glucuronides with *m*/*z* ions at 477 and 271. Quantifications of the metabolites in the plasma and urine samples were made with peak area (PA)/μg conversion factors of authentic metabolite standards using integrated mass-extracted peak areas (PA) obtained either in the scan mode (100−900 amu) or in the single ion response (SIR) mode at the $[M-H]^-$ *m*/*z* for each compound. Standards for hesperetin-7-*O*-*β*-glucuronide (product no. HD322), hesperetin-3′-*O*-*β*-glucuronide (HD324), hesperetin-7, 3′-di-*O*-*β*-glucuronide (HD326), and naringenin-7-*O*-*β*-glucuronide (ND329) were obtained from LC Scientific Inc. (Concord, Ontario, Canada). Conversion factors (SIR PA $\mu g^{-1}$) of the metabolite standards were linear over the concentrations in the test urine samples.

**Plasma Metabolite Pharmacokinetics Analysis.** The plasma metabolites' data were plotted versus time (24 h), and the area under curve was calculated by the trapezoidal rule (AUC):

$$\mathrm{AUC} = \frac{1}{2}\sum_{i=1}^{n-1}(m_{i+1} - m_i)(H_{i+1} + H_i)$$

where $m_i$ is the $i$th hour, $H_i$ is the $i$th available concentration value, and $n$ is the number of hours. Plasma bioavailability of metabolites was from 0 to 24 h, and the secondary outcomes were $C_{max}$, i.e., maximum concentration, and $T_{max}$, i.e., time after treatment when reaching $C_{max}$. The pharmacokinetic parameters (AUC, $C_{max}$, and $T_{max}$) were calculated using Microcal Origin (version 6.0).

**Statistical Analysis.** Clinical characteristics were documented by descriptive statistics. All results are expressed as mean ± SD or SEM. The data distributions were tested for normality, and subsequently, a paired $t$ test or Wilcoxon test was applied using Sigma Stat version 3.11 (Systat Software Inc., USA).

## RESULTS

**Phenolic Compounds in FOJ and POJ.** The flavonoids in orange juice occur mainly as flavanone and flavone glycosides and polymethoxylated flavones,[29,30] although other phenolic compounds such as hydroxycinnamates and phenolic alkaloids also occur.[31−33] The concentrations of the main flavonoids in the juices used in this study are summarized in Table 1. Three

**Table 1. Concentrations of Flavanone Glycosides and Polymethoxylated Flavones (μg/mL) in Pasteurized Orange Juice (POJ) and Fresh-Squeezed Orange Juice (FOJ)**

| flavonoids | POJ | FOJ |
|---|---|---|
| Flavanone Glycosides | | |
| narirutin (NR) | 36.5 ± 5.5 | 5.5 ± 0.91 |
| hesperidin (HSP) | 154.6 ± 47.2 | 47.2 ± 4.03 |
| isosakuranetin rutinoside (ISR) | 10.5 ± 4.3 | 4.27 ± 1.34 |
| Polymethoxylated Flavones | | |
| sinensetin (SIN) | 0.60 ± 0.03 | 1.77 ± 0.07 |
| nobiletin (NOB) | 0.84 ± 0.04 | 2.36 ± 0.19 |
| tetramethylscutellarein (TMS) | 0.35 ± 0.03 | 0.86 ± 0.07 |
| 3,5,6,7,8,3′,4′-heptamethoxyflavone (HMF) | 0.35 ± 0.03 | 1.18 ± 0.10 |
| tangeretin (TAN) | 0.11 ± 0.02 | 0.45 ± 0.04 |

of the main flavanone glycosides, hesperidin, narirutin, and isosakuranetin rutinoside (didymin) (Figure 1) were identified by their elution times and characteristic UV and mass spectra matching those of authentic standards. The results show that 3.5 times higher total flavanone glycoside concentrations occurred in the POJ than in the FOJ. The average POJ and FOJ samples (786 ± 135 mL) consumed in this study contained 121.5 ± 37.1 and 37.1 ± 3.1 mg of hesperidin, respectively. For narirutin the average doses contained 28.7 ± 4.3 and 4.3 ± 0.7 mg in the POJ and FOJ, respectively. In sharp contrast, the polymethoxylated flavones occurred at concentrations 2−3 times higher in the FOJ than in the POJ. In the average sample of FOJ the total polymethoxylated flavone content was 4.73 ± 0.18 mg, but only 1.76 ± 0.30 mg in the average sample of POJ. The polymethoxylated flavones occur in orange juice as constituents of the peel oil introduced into the juice by the fruit extraction methods, and consistent with this were differences in the peel oil levels (estimated by limonene content) of the FOJ (0.080 ± 0.004%) and POJ (0.028 ± 0.037%).

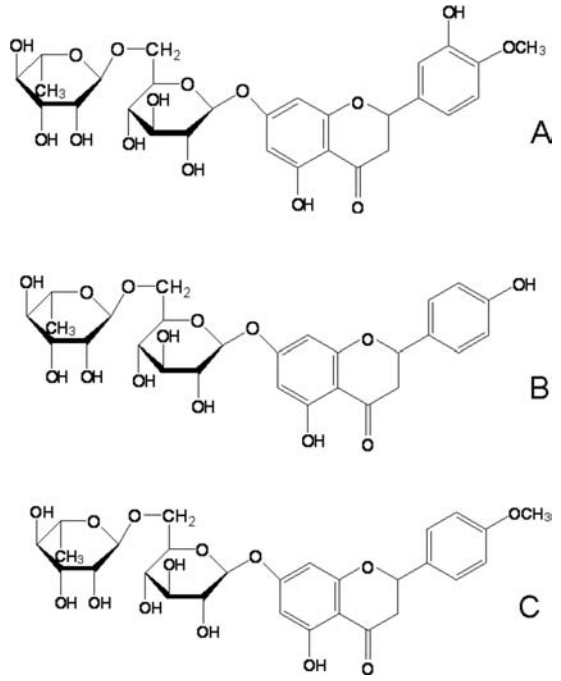

**Figure 1.** Main flavanone glycosides: (A) hesperidin, (B) narirutin, and (C) isosakuranetin rutinoside.

The levels of additional juice compounds in the POJ and FOJ were also analyzed. Concentrations of vicenin-2 (6,8-di-*C*-glucosylapigenin) and feruloylputrescine were 4.5 and 3.3 times higher in the POJ than in the FOJ, respectively (data not shown). Concentrations of the total hydroxycinnamic acids, ferulic, *p*-coumaric, and sinapinic acids in the POJ and FOJ released after saponification of the juices are shown in Table 2.

**Table 2. Contents of Hydroxycinnamic Acids (μg/mL) in Pasteurized Orange Juice (POJ) and Fresh-Squeezed Orange Juice (FOJ) after Saponification**

| hydroxycinnamic acids | POJ | FOJ |
|---|---|---|
| *p*-coumaric acid | 13.1 ± 1.0 | 20.5 ± 0.6 |
| ferulic acid | 66.2 ± 3.1 | 42.1 ± 2.1 |
| sinapinic acid | 15.1 ± 0.6 | 16.0 ± 0.3 |

These compounds occur in orange juice mainly as hydroxycinnamates with glucaric acids.[34] The levels of ferulic and sinapinic acids were nearly the same in POJ compared to FOJ, while the levels of *p*-coumaric acid were higher in FOJ (20.5 ± 0.6 ppm) than in the POJ (13.1 ± 1.0 ppm).

In addition to the differences in total concentrations of the main flavanone glycosides and polymethoxylated flavones in the POJ compared to the FOJ, there were also important differences in the distributions of these compounds occurring soluble in the juice serum or precipitated in the juice cloud. The average flavonoid content (μg) of pellets and sera of POJ and FOJ, along with percent averages in parentheses are listed in Table 3. In the FOJ 98.6% of the hesperidin occurred soluble in solution, whereas in the POJ only 28.6% of the total hesperidin remained soluble. The remaining 71.4% of the hesperidin in the POJ was precipitated in the juice cloud. Similar properties were observed for isosakuranetin rutinoside. In the FOJ 99% of the narirutin occurred soluble in solution and 62.4% soluble in solution for POJ. In this latter aspect, narirutin differed from

**Table 3. Average Flavonoid Content (μg) of Precipitated Pellets and Serum in 35 g of Pasteurized Orange Juice (POJ) and Fresh Orange Juice (FOJ)[a]**

| flavonoids | POJ | | FOJ | |

[a]Values are reported as mean ± standard deviation. Asterisk (*) indicates that values are significantly different ($P < 0.05$). [b]$t_R$, retention time. [c]AUC, area under the curve. [d]$C_{max}$, maximum concentration. [e]$T_{max}$, time at $C_{max}$. [f]Hesperetin-7-*O*-glucuronide. [g]Hesperetin-3′-*O*-glucuronide. [h]Naringenin-7-*O*-glucuronide. [i]nd, not detected.

hesperidin and isosakuranetin rutinoside which occurred mostly in the juice clouds of the POJ. The polymethoxylated flavones also occurred soluble in the serum and precipitated in the juice cloud. Unlike the flavanone glycosides, there were no clear trends in these distributions for these compounds resulting from the different juice extraction methods. An exception was sinensetin, which occurred mainly soluble in the FOJ (63.3%), but mainly precipitated in the juice cloud of the POJ (62.8%).

**Plasma and Urine Metabolites.** Previous reports have shown that metabolites of hesperidin and narirutin in humans occur as glucuronic acid and/or sulfate conjugates of the hesperetin and naringenin aglycones.[20,28] In the present study, the relative bioavailabilty and uptake of hesperidin and narirutin in the POJ and FOJ were studied by HPLC-ESI-MS analyses of extracts of blood plasma and urine samples obtained over a 24 h period for each human subject. Analyses of the plasma and urine samples showed no evidence of the original flavanone glycosides, rather, in plasma, two main metabolites (**B** and **C**) exhibited mass ions at $m/z$ 301 and 477 (Table 4), and in urine two additional minor metabolites (**A** and **D**) also exhibited these mass ions (Table 5). Metabolites **B** and **C** were identified as hesperetin-7-*O*-glucuronide and hesperetin-3′-*O*-glucuronide, respectively, by comparisons with authentic standards. The neutral losses of 176 atomic mass units (amu) associated with these compounds were attributed to cleavages of glucuronic acid units from the $m/z$ 477 deprotonated molecular ions. Two other metabolites (**E** and **G**) also exhibited $m/z$ 477 and 301 ions and also an $m/z$ 557 ion. The 80 amu neutral loss between the 557 and 477 $m/z$ ions was attributed to cleavages of sulfate units from these metabolites. An additional metabolite, **H**, exhibited mass ions at $m/z$ 301 and 381, suggestive of a hesperetin-sulfate conjugate. Two metabolites (**J** and **K**) in the plasma, along with two other minor metabolites (**I** and **L**) in the urine (Table 5) are tentatively attributed to naringenin glucuronide conjugates. Metabolite **K** was identified as naringenin-7-*O*-glucuronide, based on peak overlaps and spectroscopic comparisons with an authentic standard.

**Plasma Kinetic Data.** The pharmacokinetic parameters—area under the curve (AUC), maximum concentration ($C_{max}$), and time of $C_{max}$ ($T_{max}$)—for the hesperidin and narirutin metabolites in the human plasma are listed in Table 4, and the average kinetic curves of the plasma metabolites obtained from the intake of the FOJ and POJ samples are presented in Figure 2. Concentrations of the flavanone metabolites in the blood plasma of subjects consuming POJ were higher than in the plasma of subjects consuming FOJ, with the exception for the tentatively identified naringenin glucuronic acid metabolite **J** (Table 4). In addition, the tentatively identified hesperetin-sulfate metabolite **H** was detected only after POJ intake. Plasma concentrations of the flavanones metabolites started to increase after the ingestion of orange juice and reached maximum

[a]Values are reported as mean ± standard deviation. Asterisk (*) indicates that values are significantly different ($P < 0.001$). [b]$t_R$, retention time. [c]Hesperetin-7-*O*-glucuronide. [d]Hesperetin-3′-*O*-glucuronide. [e]Naringenin-7-*O*-glucuronide. [f]nd, not detected.

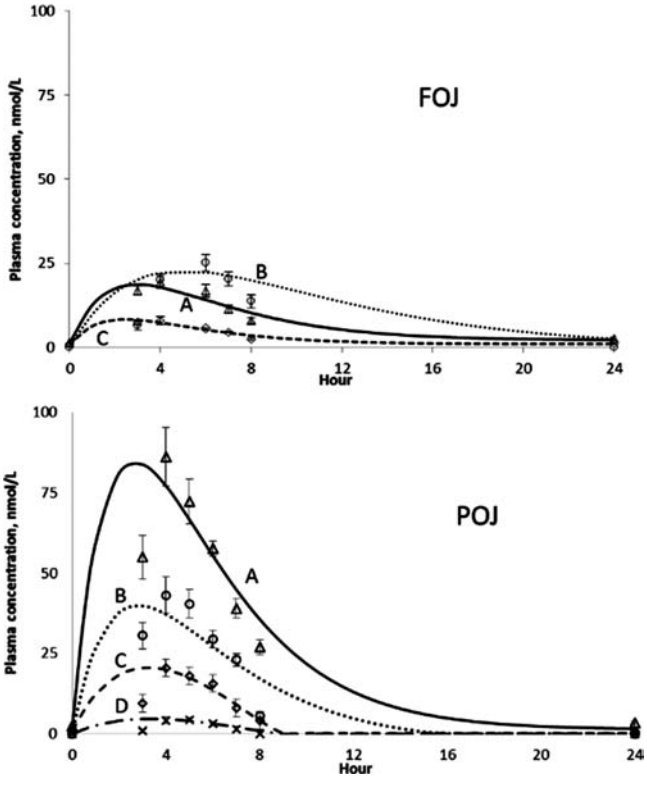

**Figure 2.** Plasma concentrations versus time of flavanones metabolites: (A) hesperetin-7-*O*-glucuronide (13.1 min), (B) hesperetin glucuronide sulfate (11.2 min), (C) naringenin glucuronide (10.6 min), and (D) hesperitin sulfate (15.0 min) after ingestion of FOJ and POJ. Values are expressed as mean ± standard deviation ($n = 24$).

concentrations between 3.7 and 6.3 h ($T_{max}$), and then returned to base values 24 h after orange juice consumption.

The average maximum concentrations ($C_{max}$) of the majority of the metabolites in the plasma were higher after the intake of POJ than after the intake of FOJ. As shown in Table 4, naringenin glucuronide metabolite **K** was 9 times higher in the plasma of subjects consuming the POJ than those consuming the FOJ; the hesperetin glucuronide metabolites **B** and **C** were 4 and 1.8 times higher, respectively, in the plasma of subjects consuming the POJ than those consuming the FOJ; and the hesperetin glucuronide sulfate metabolite **G** was 3.1 times higher in the plasma of subjects consuming the POJ than those consuming the FOJ. The areas under the concentration−time curve (AUC = 0−24) values for the plasma metabolites **K**, **G**, and **B** were 2.4, 2.6, and 4.1 time higher, respectively, for subjects consuming the POJ than for subjects consuming the FOJ. Only the metabolite tentatively identified as a naringenin glucuronide (**J**), was 2.4 times higher in the plasma measurements following intake of FOJ than following the intake of POJ.

**Urine Metabolites.** Analyses of the flavonoid metabolites in the urine samples obtained from the subjects after the consumption of both types of juices showed high concentrations of glucuronic acid and sulfate conjugates (Table 5), and numerous similarities occurred between the plasma and urine metabolite profiles. The metabolite **E**, tentatively identified as a hesperetin glucuronide sulfate was detected in the urine of subjects after consuming POJ, but not after consuming FOJ. Similarly assigned metabolites **F** and **G** were 11 and 2.4 times higher in the urine of subjects consuming the POJ compared to subjects consuming FOJ. The $m/z$ 381 metabolite **H** was detected at 2.5 times higher values in the urine of subjects consuming the POJ compared to subjects consuming FOJ. The naringenin glucuronide metabolites **I**−**L** were present respectively at 1.7, 1.7, 2.3, and 2.7 times higher after ingestion of POJ compared to the ingestion of FOJ. The hesperetin glucuronide metabolite **A** was detected in the urine after intake of POJ, but not after intake of the FOJ. Hesperetin-7-*O*-glucuronide (**B**) and hesperetin-3′-*O*-glucuronide (**C**) were present, respectively, at 2.3 and 2.5 times higher after ingestion of the POJ than after the ingestion of the FOJ. The percent urine excretion and absorption values for the combined hesperetin and naringenin metabolites are shown in Tables 6 and 7, respectively. Also included in Tables 6 and 7 are comparisons of the AUC, $C_{max}$, and $T_{max}$ values of the plasma metabolites reported in this current study as well as other previously reported studies. For our current study, the percent absorptions of the ingested hesperetin doses, measured by the combined urinary hesperetin metabolites were 0.8 and 0.9% after consumption of the POJ and FOJ, respectively (Table 6). The percent urine excretions were 4.13 ± 3.33 and 3.76 ± 2.19% for the POJ and FOJ, respectively. For the narirutin doses, the percent naringenin absorptions were 1.05 and 5.95% after consumption of the POJ and FOJ, respectively (Table 7).

## DISCUSSION

Orange juice has long been known to play important roles in healthy diets, contributing to daily intakes of folic acid, vitamin C, potassium, calcium, and other minerals. Particular benefits of orange juice consumption now focus on cardiovascular health, where orange juice has recently been shown to improve lipid profiles in humans by decreasing low-density lipoprotein cholesterol in hypercholesterolemic subjects, and by improving lipid transfer to high-density lipoprotein.[35−37] Additionally, in spite of its high sugar content, orange juice triggers no inflammatory oxidative responses in humans, rather, the

consumption of orange juice has been shown to prevent the induced oxidative and inflammatory responses caused by high-fat meals.[38,39] Although complete understandings of the modes of action for these beneficial effects are lacking, results from in vitro and animal trials suggest that the flavonoids in orange juice are at least partly responsible for these effects. In vitro cell culture studies with hesperidin and narirutin provide evidence for the roles of metabolites of the main orange juice flavonoids in cardiovascular protective effects.[40−43]

Many of the orange juice flavonoids, including hesperidin and narirutin, occur both soluble in solution and precipitated in the juice cloud, and a number of studies have now shown that these distributions are influenced by commercial juice processing and storage techniques.[23,24,26,27] In commercially processed orange juice the majority of the flavanone glycosides occur precipitated in the juice cloud.[22] Also associated with the juice cloud are major portions of the polymethoxylated flavones.[26] Under the physiological conditions of the gastrointestinal tract, a high percentage of the flavanones occurs as precipitated chalcones,[24] and the uptake and pharmacokinetics of these compounds are thought to be influenced by the relative distributions of soluble and cloud-precipitated forms. Hand squeezing of the fruit provides a higher content of soluble and permeable hesperidin than industrial extraction, while freezing and cold storage of processed juice decreases hesperidin solubility.[24] No effects on hesperidin solubility were seen with juice pasteurization and concentration.

The orange juices in our study were prepared by commercial industrial processing techniques and by a commercial fresh-squeezed method, and the differences in the flavonoid contents of the juices were consistent with earlier studies. The POJ contained higher total concentrations of the flavanone glycosides than the FOJ, and most occurred precipitated in the cloud fraction. In contrast, nearly all the flavanone glycosides in the FOJ occurred in the soluble form. Preparation of the FOJ introduced a high content of peel oil with a resultant higher polymethoxylated flavone content than in the POJ. These two styles of juices provided very different doses of flavonoids to the human subjects participating in this current study, and were valid systems to test for the influences of precipitated and soluble states of the flavanone glycosides on their absorption and pharmacokinetics in humans.

The metabolites of hesperidin and narirutin detected in the blood plasma and urine of the subjects that consumed the FOJ and POJ agreed with those detected in previous studies. Vallejo et al.[20] reported the detection of naringenin-7-*O*-glucuronide, naringenin-4′-*O*-glucuronide, naringenin and hesperetin sulfates, and hesperetin-7-*O*-glucuronide and hesperetin-3′-*O*-glucuronide as major constituents in human plasma. Other minor-occurring naringenin and hesperetin diglucuronides and sulfoglucoronides were also detected in human plasma.[20,21,28] Similar metabolites have been reported in urine of human subjects post orange juice consumption. We report the detection of hesperetin-7-*O*-glucuronide (**B**), hesperetin-3′-*O*-glucuronide (**C**), two hesperetin-sulfoglucuronides (**E** and **G**), a hesperetin sulfate (**H**), and naringenin-7-*O*-glucuronide (**K**) in the human plasma extracts (Table 4). Additional sulfo/glucurano-metabolites were detected in the concentrated extracts of the human urine samples (Table 5). The above metabolites have also been reported elsewhere.[20,21,28,44] Further metabolism of these compounds by colon microbiota leads to the ring fission of the main flavanone structures, leading to conjugated forms of ferulic and *m*-coumaric acids, phenyl propionic acids, benzoic acids, hippuric acid, and others.[45]

Glucuronic acid conjugates of these metabolites were detected, but not quantified, by Vallejo et al.[20] Similar compounds were detected in our current study, and further analyses of these compounds in the plasma and urine samples are in progress. It is possible that some of these metabolites are also produced from the hydroxycinnamates in the juices consumed in this study.

The bioavailabilities of orange juice flavanones were shown in a previous study to be influenced by the soluble levels of the flavanones, but independent of the total hesperidin (soluble plus precipitated) concentrations in the juices.[20] Yet the pharmacokinetics in our study show that the AUC and $C_{max}$ values, when corrected for differences in dose amounts were not influenced by the soluble/precipitate ratios. Juices with contrasting flavanone profiles were analyzed in our study, where the profiles of these compounds in the POJ appeared to match several of the commercial juices and pulp-enriched juice analyzed by Vallejo et al.[20] The hesperidin in the latter juices contained 78% in the precipitated form in comparison to 71% in our POJ (Table 3). The FOJ analyzed in our study contained less than 2% precipitated hesperidin, and thus contrasted sharply with any of the juices analyzed in the previous study.[20] An important feature of the juices tested in our study was that the levels of soluble hesperidin in the FOJ and POJ were nearly identical at 46.5 and 44.2 $\mu$g/mL, respectively. Yet, the total AUC values for the three main plasma flavanone metabolites in Table 4 (**B**, **G**, and **K**) of subjects consuming the POJ was 848 nmol·h/L, in contrast to 255 nmol·h/L for subjects that consumed FOJ. The difference in these values reflect the differences in total flavanones in these juices (Table 1), and not the soluble flavanone concentrations, as discussed above. Furthermore, the percent hesperidin urinary excretion values measured in the POJ and FOJ trials (Table 6) show no statistically significant difference, thus providing additional evidence that the absorption of the orange juice flavanones was not appreciably influenced by the distributions of soluble and precipitated forms. As shown in Tables 6 and 7, these percent urinary excretion values were similar to values reported in other previous orange juice consumption studies. Hence, while the different styles of orange juices produced different blood plasma concentrations of the main flavanone metabolites, the qualitative aspects of the pharmacokinetics of this metabolism in humans remain similar for the two juices.

However, other factors may also influence flavanone metabolism and bioavailability from orange juice, including differences in the colon microbiota that are essential to flavonoid metabolism. Multiple pathways may exist that produce the abundant flavanone ring-fission products that occur in addition to the intact flavanone metabolites.[45,46] What influence the physical state of flavanones have in controlling these pathways is unknown, although further influences of the colon microbiota on orange juice flavanone bioavailability were recently studied by Navarro et al.[27] in human subjects exhibiting either high (>10% flavanone intact), medium (5−10%), or low (>5%) urinary hesperidin excretion capabilities. Subjects with high capabilities of urinary hesperidin excretion exhibited better absorption of hesperidin from juices with smaller juice cloud particles in contrast to the medium and low capacity hesperidin urinary excretors. Navarro et al.[27] proposed that these differences arise from differences in colon microbiota

and intestinal transporters capable involved in flavanone release and uptake. It is possible, therefore, that differences in colon microbiota may greatly expand the influences of hesperidin solubility and juice cloud interactions on flavanone bioavailability in many individuals.

trients.[25,26] However, available information on cooking and the effects on phytochemicals and antioxidant properties of lentil is rather scarce. Hence, the present study was conducted to deliver a comprehensive investigation on the effects of domestic boiling without presoaking, as is recommended by Pulse Canada,[27] on phytochemical compositions (in both lipophilic and hydrophilic fractions) and antioxidant activities of lentils.

## MATERIALS AND METHODS

**Plant Materials.** Four lentil cultivars and breeding lines received from Saskatchewan Pulse Growers (Canada) on September 26, 2012, were selected for this study. The four selected lentils included two red lentil cultivars, Blaze and Maxim, and two green cultivars, Greenland and Sovereign. The four cultivars used in the present study were cultured at the same time and location. The whole raw lentil samples were used for cooking or ground into fine powder and stored in sealed plastic bags at −4 °C prior to analysis.

**Domestic Cooking Process.** Whole raw lentils (150 g) were rinsed in a strainer with cold running water for 1 min and then shaken for 30 s to remove excess water. The rinsed lentils were transferred to a pot and boiled with 450 mL of deionized water (seed/water, 1:3, w/v) on a Cimarec hot plate (Fischer Scientific Inc., Waltham, MA, USA). The hot plate was set at 500 °C until boiling and then lowered to 280 °C to simmer the lentils with the pot covered. The lentils were tested for firmness after 30 min of cooking by squeezing lentils between two fingers. Lentils are considered cooked when the seeds have little or no resistance to squeezing. The cooked lentils were allowed to cool and then lyophilized with the boiling water. The cooked lentil samples were ground into fine powder and stored in sealed plastic bags at −4 °C prior to analysis.

**Chemicals and Reagents.** 2,2-Diphenyl-1-picrylhydrazyl radical (DPPH), fluorescein disodium (FL), 2,2′-azobis(2-methylpropionamidine) dihydrochloride (AAPH), Folin−Ciocalteu reagent, gallic acid (GA), catechin, and 6-hydroxy-2,5,7,8-tetramethylchroman-2-carboxylic acid (Trolox) were purchased from Sigma (St. Louis, MO, USA). All standards used in this study were purchased from Sigma. Sodium acetate, ferric chloride hexahydrate, sodium phosphate monobasic, sodium phosphate dibasic, and HPLC grade solvents, including methanol (MeOH), methyl *tert*-butyl ether (MTBE), hexane, isopropanol, formic acid, and hydrochloric acid (HCl) were purchased from Caledon Laboratories (Georgetown, ON, Canada). All other chemical reagents used were of analytical grade.

**Sequential Extraction of Raw and Cooked Lentils.** The lipophilic fraction of lentils was extracted from 1 g of the finely ground raw or cooked samples by using hexane/isopropanol (3:2, v/v) as described in our recent publication.[12] The lipophilic extract was then evaporated under nitrogen stream at room temperature, redissolved in 1 mL of DMSO, and stored at −20 °C before use for different analyses. Subsequently, the residue from lipophilic extraction was air-dried under room temperature and extracted with aqueous methanol to obtain the hydrophilic extractable fraction. In brief, the dried residue was extracted with 20 mL of 70% methanol in 0.1% HCl (v/v) overnight (ca. 15 h) at room temperature with constant rolling on a rotary shaker (Scientific Industries Inc., Bohemia, NY, USA) at 150 rpm and then re-extracted two more times each with 10 mL of the same solvent. The supernatants were combined after centrifugation (Eppendorf centrifuge 5810R, Brinkman Instruments Inc., Westbury, NY, USA), topped up to 40 mL, filtered through a 0.2 μm PTFE membrane filter (VWR International, ON, Canada), and analyzed for extractable hydrophilic phenolics. The resulting residue from this extraction was dried under nitrogen and then hydrolyzed with 2 M NaOH (20 mL) at room temperature overnight on a rotary shaker at 150 rpm. The solution was then acidified to pH 2 with concentrated HCl (ca. 37%, w/w; 12 M) and extracted three times each with 20 mL of ethyl acetate/ethyl ether (1:1, v/v). The organic layer was combined, evaporated to dryness under nitrogen, dissolved in 1 mL of methanol, and analyzed for bound phenolics.

**Fatty Acid Analysis by Gas Chromatography.** The fatty acid compositions of the lipophilic fraction of both raw and cooked lentils were analyzed according to the method described in our recent publication.[12] Fatty acid methyl esters (FAME) were prepared using base-catalyzed reactions. Briefly, 10 mg of lipophilic extract was placed in a 15 mL glass tube equipped with Teflon-lined screw cap and dissolved in 80 μL of toluene. One milliliter of $NaOCH_3$/methanol (0.5 N) was then added for methylation at 50 °C for 30 min. After cooling to room temperature, 1 mL of water was added to the solution, and the esters were extracted with 2 mL of hexane.

**Total Phytochemical Contents by Colorimetric Assays.** *Total Carotenoid Content (TCC).* TCC in the raw and cooked lentil extract was determined according to the method described in our previous publication.[12] In brief, the absorbance of extract diluted appropriately and serial dilutions of lutein standard (0.5−10 μg/mL) were measured at 450 nm using a UV−vis plate reader (EL 340, Bio-Tek Instruments Inc., Winooski, VT, USA). The purity of the lutein standard was based on the manufacturer's information and has not been measured in the present study. The TCC was calculated on the basis of authentic lutein, which is the main carotenoid in lentil, and expressed as micrograms of lutein equivalent per gram of dry weight (DW) of sample.

*Total Phenolic (TPC), Flavonoid (TFC), and Condensed Tannin Content (CTC).* The contents of total phenolics, flavonoids, and condensed tannins in raw and cooked lentil extracts were determined according to our previously reported method.[28] Briefly, TPC was measured using Folin−Ciocalteu's phenol reagent and expressed as milligrams of gallic acid equivalent (GAE) per gram of dry weight of lentil (mg GAE/g DW). TFC was measured by the aluminum chloride ($AlCl_3$) assay by reading the absorbance at 510 nm, and result was expressed as milligrams of catechin equivalents (mg CAE) per gram of DW. CTC was determined according to the vanillin−HCl procedure by reading the absorbance at 500 nm, and the result was expressed as milligrams of catechin equivalents (mg CAE) per gram of DW.

**Phytochemical Composition by HPLC.** *Carotenoids and Tocopherols.* All-*trans*-carotenoids, *cis*-isomers, and tocopherols were separated by HPLC using the method described in our recent publication.[12] Identification of these lipophilic compounds was based on matching retention time, UV−vis spectra, and similarity in elution order with the available commercial standards, as well as by comparison with reported data in the literature.

*Phenolic Compounds.* The phenolic compositions of hydrophilic extracts (extractable and bound) in raw and cooked lentils were analyzed according to a previously reported HPLC method.[28] Briefly, HPLC separation was done in a Kinetex phenyl-hexyl column (100 × 4.60 mm, 2.6 μm) (Phenomenex Inc., Torrance, CA, USA) with a binary mobile phase consisting of 5% formic acid in water (v/v) (solvent A) and 95% methanol/5% acetonitrile (v/v) (solvent B). The gradient program was set as follows: 0−12 min, 0−20% B; 12−25 min, 20% B; 25−50 min, 20−80% B; 50−55 min, 80−100% B; 55−60 min, 100−0% B. The flow rate was 0.7 mL/min, and the data were collected at 280 nm for phenolic compounds. At least 21 phenolic compounds were identified in the lentil hydrophilic extract, all of which were quantified using individual standard curves of external standards or similar compounds of the same phenolic subgroup generated by plotting HPLC peak areas against the concentrations. For instance, catechin glucoside, catechin gallate, procyanidins, and related flavonoid derivatives were expressed as catechin equivalents; epicatechin glucoside and epicatechin gallate were expressed as epicatechin equivalents. Kaempferol glycosides and quercetin glycosides were quantified with the calibration curve of kaempferol and quercetin, respectively.

**Antioxidant Assays.** *DPPH Assay.* The antioxidant activities of both lipophilic and hydrophilic extracts (including extractable and bound phenolics) were estimated by DPPH assay.[12,28] Briefly, aliquots of 200 μL of methanolic solution of DPPH (350 μM) were mixed with 25 μL of the lipophilic lentil extract diluted 5-fold with methanol or the hydrophilic lentil extract or with a series of Trolox standard solutions (62.5−1000 μM) in a 96-well plate and allowed to react for 6 h at room temperature before the absorbance was recorded at 517 nm. Both lipophilic (DPPH-L) and hydrophilic (DPPH-H) DPPH antioxidant activities were calculated as micromoles of Trolox equivalent per gram of dry weight of lentil (μmol TE/g DW).

*Oxygen Radical Absorption Capacity Assay for Lipophilic Extract (ORAC-L).* The ORAC-L assay was conducted according to existing

**Table 1. Effect of Domestic Cooking on the Lipophilic Phytochemical Contents ($\mu$g/g DW) of Lentil Cultivars[a]**

protocols described by Li et al.[29] Briefly, samples and Trolox standard were prepared in 7% (w/v) randomly methylated $\beta$-cyclodextrin (RMCD) to ensure the solubility of the lipophilic antioxidants in the reaction mixture. Twenty-five microliters of blank, Trolox standard, or the lipophilic extract was mixed with 200 $\mu$L of fluorescein (0.0868 nM) and incubated for 30 min at 37 °C and then added to 25 $\mu$L of AAPH (153 mM). The fluorescence (excitation wavelength, 485 nm; emission wavelength, 528 nm) was measured every minute for about 120 min until it reached zero in a Bio-Tek fluorescence spectrophotometer equipped with an automatic thermostatic holder (PLX 800, Bio-Tek Instruments, Inc.). The results were expressed as micromoles of Trolox equivalent (TE) per gram of dry weight of sample ($\mu$mol TE/g DW).

*ORAC Assay for Hydrophilic Extract (ORAC-H).* The ORAC assay for the hydrophilic extracts (both extractable and bound fractions) of lentil (ORAC-H) was conducted according to the method of Li et al.[29] The protocol was the same as that described above for the ORAC-L assay except that a phosphate buffer (75 mM, pH 7.4) instead of 7% (w/v) RMCD was used.

**Statistical Analysis.** All assays or tests were conducted in triplicate, and data are expressed as the mean ± standard deviation (SD). One-way analysis of variance (ANOVA) was used to compare the means. Differences were considered significant at $p < 0.05$. All statistical analyses were performed using Statistix for Windows version 9.0 (Analytical Software, Tallahassee, FL, USA).

## RESULTS AND DISCUSSION

**Effect of Domestic Cooking on Lipophilic Phytochemicals.** Concentrations of total and individual lipophilic antioxidants, namely, carotenoids and tocopherols, in tested lentils before and after cooking are summarized in Table 1. The TCC varied from 7.24 to 16.28 $\mu$g/g DW in raw lentils and significantly increased ($P < 0.05$) to 12.26−24.50 $\mu$g/g DW after cooking (increases of 37.37−103.18%). The cooking process also caused significant increases in individual carotenoids; for example, increases of 12.04−60.70% were found for the major carotenoid all-*trans*-lutein among the four varieties after cooking. Another measure for total carotenoids is total carotenoid index (TCI), which is the sum of the concentrations of all detected carotenoids by HPLC. Similar to TCC, TCI also had a 21.80−37.62% increase in cooked lentils as compared with all tested raw samples (Table 1). These results are the first to be reported for lentils but consistent with findings in other carotenoid-rich foods. For instance, the carotenoid content of tomato was found to be markedly higher after thermal processing.[30]

Because tocopherols are considered as one of the most effective lipophilic natural antioxidants, changes in concentration of individual and total tocopherols in lentils before and after cooking were determined by analyzing all tocopherol isomers by HPLC. $\gamma$-Tocopherol was the predominant isomer in lentils, which accounted for 96.38−97.78% of the total tocopherol content, followed by $\alpha$- and $\delta$-tocopherols among all tested raw lentils. Cooking caused the largest increase in $\alpha$-tocopherol level by 187.52−381.78%. Significant increases ($P < 0.05$) in $\gamma$-tocopherol and total tocopherols, but not in $\delta$-tocopherol level, were also observed after cooking (Table 1). This observation,

however, is contrary to what was found by others. For instance, Kalogeropoulos et al. reported a 1−2 orders of magnitude decrease in $\alpha$- and $\gamma$-tocopherols realtive to uncooked legumes including lentils.[31] These discrepancies could be attributed to different cooking protocols. Kalogeropoulos et al. removed soaking water before cooking and drained excess water after cooking, which is believed to cause significant loss of tocopherols. However, presoaking is not a normally followed cooking practice for lentil. The present study was carried out according to the cooking protocol recommended by Pulse Canada,[27] that is, one without presoaking and draining of the boiling water. This suggests that the recommended protocol retains the majority of tocopherols and other bioactive phytochemicals.

Results of the present study also suggest that thermal processing such as domestic cooking by boiling can significantly enhance the bioaccessibility of lipophilic bioactives of lentil. Heating is considered to cause cell membranes and cell walls to disrupt, releasing the lipophilic components such as carotenoids and tocopherols from the lentil matrix, thus leading to increased extraction efficiency.[30]

**Effect of Domestic Cooking on Fatty Acid Compositions.** Although lentils contain only 1.5−3% oil, its fatty acid composition had a very favorable omega-3 to omega-6 ratio (1:4).[12] Heating can potentially cause degradation of fatty acids, especially the essential fatty acids.[32,33] The effect of boiling on the fatty acid composition of lentils was investigated, and the results are summarized in Table 2. The lipophilic extracts from raw lentils mainly contained unsaturated fatty acids (UFA) (80.93−84.38%) including monounsaturated fatty acids (MUFA) (17.08−30.58%) and polyunsaturated fatty acids (PUFA) (52.24−63.85%), and an insignificant amount of saturated fatty acids (SFA). Cooking caused significant increases ($P < 0.05$) in SFA in all tested lentils, but had no significant effect on MUFA and PUFA. In terms of individual fatty acids, however, the predominant fatty acid 18:2n-6 decreased significantly ($P < 0.05$), whereas 18:3n-3 decreased only slightly without any statistical significance ($P > 0.05$) upon cooking. The concentration of the major MUFA 18:1 was markedly higher in cooked lentils ($P < 0.05$). These results indicate that the majority of PUFA in lentils remain relatively stable after cooking. Possible explanations may include the relatively low temperature of boiling as compared to other thermal processing techniques that can cause lipid oxidation. It may also be due to the coexistence of tocopherols, which can prevent lipid peroxidation by acting as peroxyl radical scavengers that terminate chain reactions in membranes and lipoprotein particles.[34]

**Effect of Domestic Cooking on Hydrophilic Phytochemicals.** *TPC, TFC, and CTC in Extractable and Bound Phenolic Extracts.* Table 3 shows the total phenolic content, total flavonoid content, and condensed tannin content in the extractable (TPC-E, TFC-E, and CTC-E) and bound phenolic (TPC-B, TFC-B, and CTC-B) fractions from raw and cooked lentils. Significant ($P < 0.05$) decreases in TPC-E and CTC-E were found in the extractable fraction of cooked lentils, whereas no significant change in TFC-E was observed in the same sample. Decreased TPC-E and CTC-E contents in cooked lentils suggest that losses of condensed tannin might be the contributing factor. The losses of condensed tannin could be well explained by the interactions between tannins and starch molecules. Barros et al. recently reported that condensed tannins could interact with starch (forming insoluble complexes) during cooking, particularly with amylose, thus resulting in significant decreases in extractable phenolic content.[35] Interactions between condensed tannins and starch molecules could, however, increase resistant starch content and decrease starch digestibility, thus providing benefits to human health.

Bound phenolics in lentils, both raw and cooked, were low compared to extractable phenolics. As shown in Table 3, bound phenolics (TPC-B, TFC-B, and CTC-B) represented only roughly 5% of the respective extractable phenolic fraction. TPC-B, TFC-B, and CTC-B varied significantly among tested lentils, ranging from 0.18 to 0.29 mg GAE/g DW, from 0.03 to 0.22 mg CE/g DW, and from 0.02 to 0.10 mg CE/g DW in cooked lentils, respectively. Bound phenolics, especially in TFC-B and CTC-B, were significantly higher in tested red lentil cultivars (Blaze and Maxim) than in the tested green cultivars (Greenland and Sovereign), despite the similar concentrations of extractable phenolics. Results that lentils had only a small portion of bound phenolics do not agree with those reported by Han et al., who found concentrations of bound phenolics were higher than extractable phenolics and the former to be the main contributor to total antioxidant activity in pulse seeds including lentils.[20] The discrepancy could be attributed to the different extraction protocol, as well as the genotype of tested lentils. Similar to the extractable phenolics, cooking also significantly decreased the

bound phenolics including TPC-B, TFC-B, and CTC-B in all tested lentils (Table 3). Oxidative degradation of phenolic compounds, including enzymatic browning during cooking process, may promote losses of these phenolics.[36]

*Individual Phenolic Compounds in Extractable and Bound Phenolic Extracts and Effect of Cooking.* Twenty-one phenolic compounds were found in the extractable phenolic fraction, with the majority being flavonoids including kaempeferol glycosides and catechin/epicatechin glucosides. These phenolic compounds were identified by matching the retention times, UV spectra, and mass spectrometric data with those of the corresponding standards as described in our recent paper.[28]

Concentrations of the individual phenolic compounds in the extractable fraction of raw and cooked lentils are summarized in Table 4. Flavonols, mainly kaempferol glycosides, were the major extractable phenolic compounds of the tested raw lentils, with the tetraglycoside and triglycoside having the highest concentrations ranging from 214.72 to 302.14 μg/g DW and from 91.42 to 137.49 μg/g DW, respectively, followed by flavanols including catechin glucoside (119.46− 141.72 μg/g DW), catechin gallate (50.26−78.15 μg/g DW), and epicatechin glucoside (39.42−82.48 μg/g DW). Several phenolic acids including *trans*-*p*-coumaric acid, syringic acid, and *p*-hydroxybenzoic acid were also detected in the extractable fraction of raw lentils, but in much lower amounts. These results indicate that the majority of extractable phenolics in tested raw lentils are flavonoid glycosides. The total phenolic indices (TPI-E) defined as the sum of concentrations of all phenolic compounds detected in extractable fraction of lentils were between 627.18 and 943.48 μg/g DW, much lower than the corresponding TPC-E indices (Table 3). This can be attributed to incomplete quantification of all peaks in the HPLC method and to the extractable but conjugated phenolic compounds, which may be bound to soluble components such as small peptides or oligosaccharides,[28,37,38] but not separated and detected in HPLC. Potential interferences from other nonphenolic substances such as vitamin C and proteins, as well as Maillard reaction (nonenzymatic browning) and caramelization products, may also cause positive reactions in the Folin−Ciocalteu assay.[39,40] Cooking led to significant increases in the concentrations of individual flavonols such as kaempferol and quercetin glycosides, as well as in phenolic acids, but significant losses in flavanols (catechin/epicatechin glucoside, catechin gallate, and oligomeric procyanidins) ($P < 0.05$). The net result as expressed in TPI-E suggests no significant overall change by cooking, probably due to cancellation between the gains and losses of these two groups of extractable phenolics (Table 4). The exact reason as to how certain subgroups of polyphenols are increased and others are decreased during cooking is unclear, although it is well-known that heat-induced breakdown of cellular constituents and cell walls can lead to enhanced release of certain food bioactives[41] and that oxidative degradation and reaction with starch molecules may reduce the release.[35]

From the bound TPC-B, TFC-B, and CTC-B data, it was clear the phenolic contents in both raw and cooked lentils were extremely low compared to the extractable TPC-E (Table 3). This was also shown by the HPLC profile of the individual phenolic compounds. Figure 1 shows typical HPLC chromatograms of the bound phenolic extracts of raw and cooked lentil (Maxim). Five phenolic compounds (peaks 1, 2, 4, 7, and 9) including gallic acid, protocatechuic acid, catechin, epicatechin, and 3-hydroxycinnamic acid, respectively, were positively identified in both raw and cooked extracts by comparing their

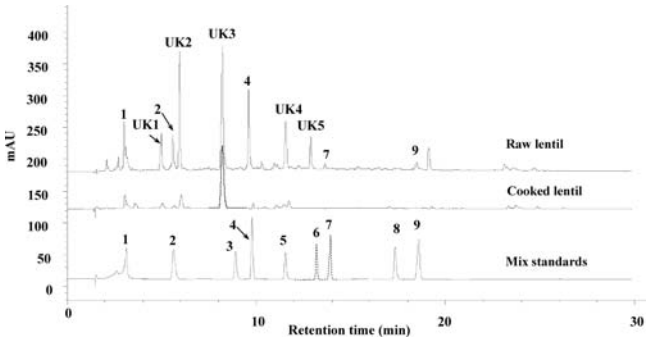

**Figure 1.** HPLC chromatograms of bound phenolics extract of a typical lentil cultivar (Maxim) before and after cooking and a standard mixture monitored at 280 nm. Peaks: UK, unknown; 1, garlic acid; 2, protocatechuic acid; 3, *p*-hydroxybenzoic acid; 4, catechin; 5, caffeic acid; 6, syringic acid; 7, epicatechin; 8, ferulic acid; 9, 3-hydroxycinnamic acid.

retention time and UV spectra with those of the corresponding commercial standards. The identified bound phenolic compounds (peaks 1, 2, 4, 7, and 9) were mainly flavonoids and phenolic acids, among which catechin at 14.19−71.04 μg/g DW in raw lentils, was the major phenolic compound, followed by gallic acid (8.54−19.18 μg/g DW), protocatechuic acid (6.39−11.09 μg/g DW), epicatechin (7.70−9.72 μg/g DW), and 3-hydroxycinnamic acid (2.03−2.82 μg/g DW). These bound phenolic compounds were all aglycones, and their concentrations in cooked lentils were significantly lower individually and collectively ($P < 0.05$), suggesting cooking negatively affected the release of bound phenolic compounds (Table 4). In addition, catechin levels in the tested red lentil cultivars, both raw and cooked, again were significantly higher than those of the respective tested green lentils (Table 4). This is consistent with the above result on bound TFC-B and CTC-B (Table 3).

Apart from the above five identified bound phenolic compounds, several unknown peaks (UK1−5) were detected from bound phenolic extracts of both raw and cooked lentils (Figure 1). None of these peaks matched the retention time or UV−/vis spectrum of the aglycones or glycosides detected in the extractable fraction or any known phenolics commonly found in lentils (Figure 1). Literature on phenolic contents (particularly bound phenolics) in both raw and cooked lentils is scarce, and data are sometimes contradictory. Phenolic acids (sinapic acid, chlorogenic acid) in the extractable fraction and 2,3,4-trihydroxybenzoic acid as bound fraction were found to be the main phenolics in lentils by Xu and Chang,[42] as opposed to the flavonols (kaempferol glycosides) in the extractable and flavanol (catechin) in the bound fractions found in the present study (Table 4). Whereas genetics and environmental conditions may affect the phytochemical compositions, other factors such as extraction and analytical methods used in different laboratories may also cause misidentification of targeted compounds and thus lead to such discrepancies. Currently, there is no available information on the composition and identity of bound phenolics of either raw or cooked lentils. Further studies using LC-MS or NMR are required to accurately report on the concentration and identity of the bound phenolics in lentils. However, what is clear from the present study is that these unknown bound phenolics were at much lower concentrations in cooked lentils. The UV−vis absorption spectra of the five unknown bound phenolics are shown in Figure S1 (Supporting Information), and quantification of these five unknown peaks was done using the calibration

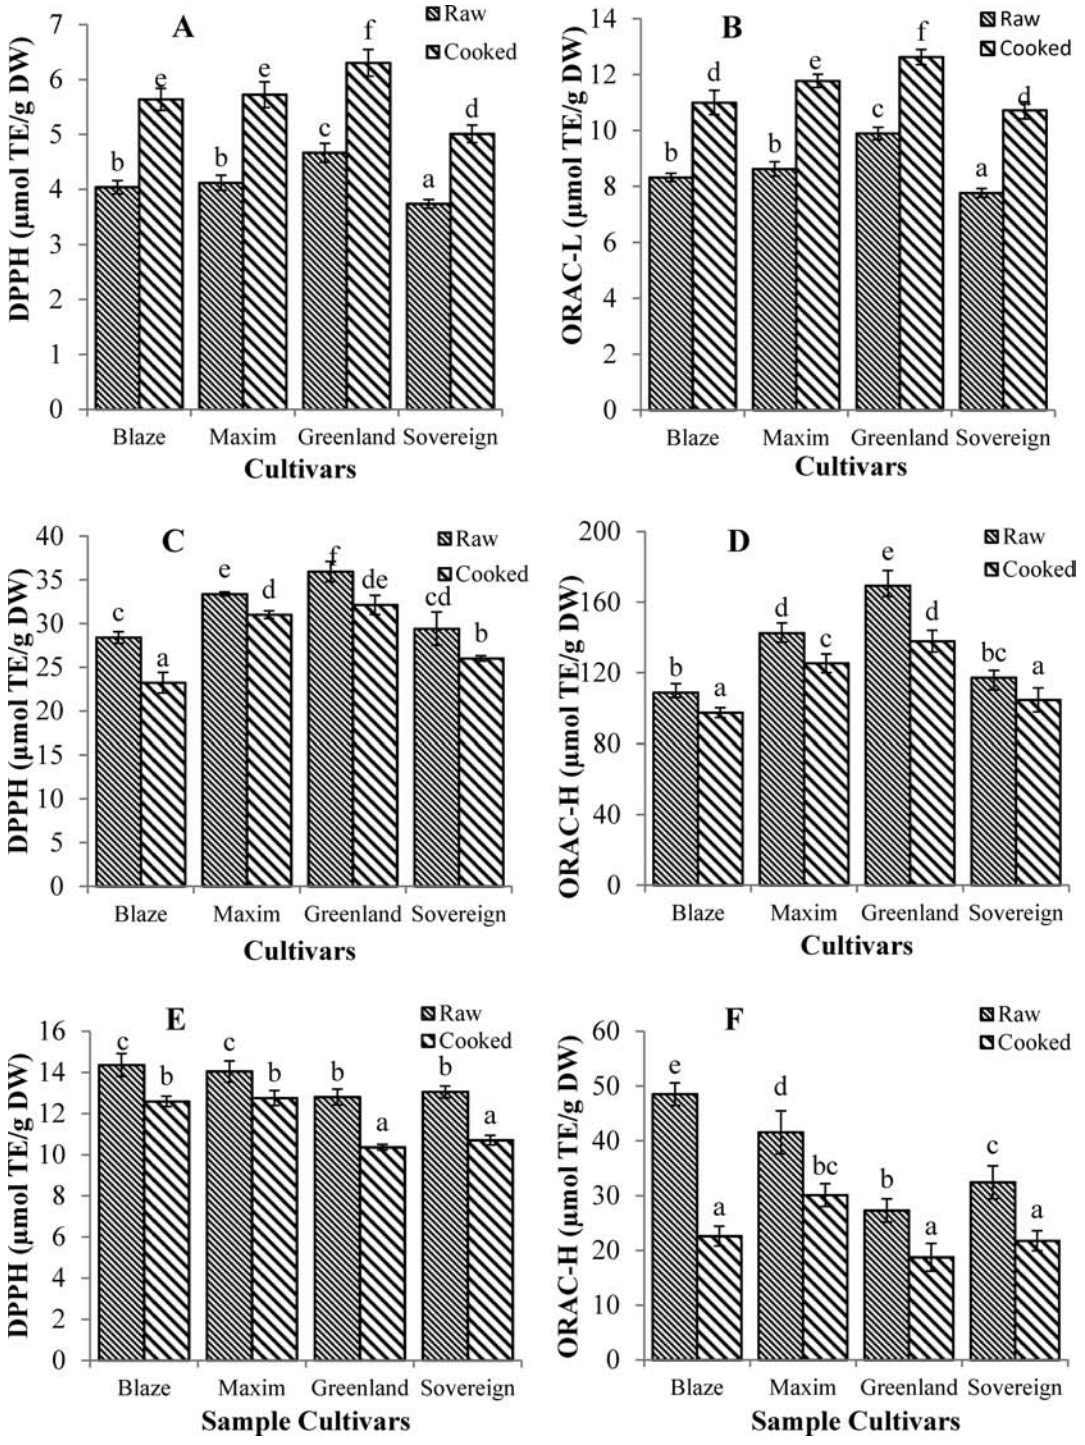

**Figure 2.** Antioxidant activities of the lipophilic fractions (A, B) and extractable (C, D) and bound (E, F) phenolic fractions of raw and cooked lentils as measured by DPPH and ORAC assays. DPPH and ORAC values are expressed as micromoles Trolox equivalent per gram DW lentil (μmol TE/g DW). Values are means ± SD, $n = 3$. Values followed by the same letter in the same assay are not significantly different ($p < 0.05$).

curve of gallic acid standard and expressed as micrograms of GAE per gram of DW in Table 4.

**Effect of Domestic Cooking on Antioxidant Activities.** The total antioxidant activities of lentil extracts were evaluated using DPPH and ORAC assays. Whereas DPPH was used for both the lipophilic and hydrophilic extracts, two protocols, ORAC-L and ORAC-H, were used for the two types of extracts, respectively.[43] The antioxidant activities of the lipophilic extracts (containing mainly carotenoids and tocopherols) of raw lentils were 3.74−4.67 and 8.32−9.89 μmol TE/g DW as assessed by DPPH and ORAC-L assays, respectively (Figure 2A,B). The antioxidant activities of hydrophilic extractable and bound fractions of raw lentils ranged from 28.40 to 35.94 μmol TE/g DW and from 12.80 to 14.36 μmol TE/g DW by the DPPH assay, respectively (Figure 2C,E) and from 108.78 to 169.27 μmol TE/g DW and from 27.29 to 48.52 μmol TE/g DW by ORAC-H, respectively (Figure 2D,F). These results are similar to those found by Xu et al. in lentils, but significantly higher than

in other pulses.[25,44,45] From the Trolox equivalent antioxidant activities, it was clear that the hydrophilic extracts containing mainly phenolics, especially the extractable phenolics, were stronger antioxidants and are perhaps the main contributors to the overall antioxidant activities of raw lentils (Figure 2). The same can be said for the cooked lentils; however, cooking itself showed different effects on the antioxidant activities of the lipophilic and hydrophilic extracts. Cooked lentils showed significantly higher antioxidant activity in both DPPH and ORAC-L assays for the lipophilic extract ($P < 0.05$), but significantly lower activity in both DPPH and ORAC-H for both extractable and bound phenolics ($P < 0.05$) (Figure 2). This is in agreement with the changes in concentration of the antioxidants of lentils; that is, the increased antioxidant activity of the lipophilic extract after cooking may be due to the increased carotenoid and tocopherol contents, whereas reduction in the antioxidant activity of the hydrophilic extracts may be due to significantly lowered phenolic contents in both extractable and bound forms as a result of cooking (Table 3).

In conclusion, lentils are an excellent source of phytochemical antioxidants such as carotenoids, tocopherols, and phenolics. The domestic cooking process significantly affects not only the phytochemical contents of both lipophilic and hydrophilic compounds but also the antioxidant activities associated with these components. Cooking caused significant increases in total and individual carotenoid and tocopherol levels and led to elevated antioxidant activity in the lipophilic fraction, whereas minimum effect was found on the fatty acid composition including PUFA. Total and individual phenolics were mainly in the extractable form as opposed to bound phenolics, and they are the main contributors to the antioxidant activities. Cooking significantly reduced the antioxidant activity of both extractable phenolic and bound fractions due to lowered total phenolic contents, whereas no or less effect was found in individual phenolic concentrations. More specifically, cooking was found to favor the release of flavonols (kaempferol glycosides) but led to losses of flavanols (monomeric and condensed tannin). Whereas reduced flavanols and other phenolic compounds may have negatively affected the antioxidant activity, other components, especially the lipophilic antioxidants, were increased. In general, the present study suggests that a properly designed cooking protocol will not cause significant loss of the phytochemical antioxidants and thus will retain the potential health benefits of lentils when incorporated into the diet.

## MATERIALS AND METHODS

**Materials.** Wine pomaces from red winemaking were kindly supplied by seven different wineries located in the Burgos region. Wine pomaces from all wineries were well mixed and dehydrated to achieve a final water content of <10%.

Three products were obtained from the dry material: one from the global or whole wine pomace, termed "whole wine pomace product" (WWPP); another from the seed-free WP, termed "skins wine pomace product" (SkWPP); and the third from the isolated seeds, termed "seeds wine pomace product" (SdWPP). The dried materials were milled and sieved, and powdered products with particle sizes of <0.250 (SkWPP and WWPP) and 0.355 mm (SdWPP) were used to carry out this study. Ultraviolet (UV-C, 254 nm) and thermal (90 °C) treatments were applied to inactivate the microbial flora present in the products obtained. Different heat and UV treatment times (15, 30, 60, 90, and 120 min) were tested to reach the optimum microbial inactivation.

**Analytical Methodologies.** *Main Composition Analysis.* The moisture content was evaluated by the difference in the sample weight before and after drying at 105 °C to constant weight. The fat content was determined after Soxhlet extraction using petroleum ether (Lab-Scan, Gliwice, Poland) as extraction solvent in a Buchi B-811 extraction system (Buchi, Flawil, Switzerland). The protein content was determined using the Kjeldahl method, which measures the total nitrogen content after digestion with boiling sulfuric acid. A conversion factor of 6.25 was used to convert nitrogen into protein values. The total dietary fiber content was evaluated using the kit provided by Sigma (St Louis, MO, USA) according to the manufacturer's instructions based on AOAC method 985.29. Total $SO_2$ was determined using the enzymatic kit developed by R-Biopharm AG (Darmstadt, Germany) according to the manufacturer's instructions.

*Mineral Content.* The ash content was determined by incineration of the samples at 525 °C in a furnace (P-selecta, Barcelona, Spain). Sodium and potassium contents were determined according to the dry ashing method proposed by AOAC[10] using flame photometry (Flame Photometer 410, Corning, UK), whereas the calcium content was measured in the same acid solution using a polarized Zeeman atomic absorption spectrophotometer Z-8200 (Hitachi; Japan). Phosphorus determinations were conducted by reaction of the acid solution with vanadate−molybdate reagent (Panreac, Barcelona, Spain).[11]

*Main Phenolic Families.* Previously rehydrated powders were extracted in methanol/HCl (97:3) for 24 h. The resulting extract was centrifuged and filtered. The content of four phenolic groups was determined: total polyphenol content (TPC) was determined by reaction with Folin−Ciocalteu reagent (Merck, Darmstadt, Germany) and expressed as milligrams per gram of gallic acid;[12] total catechin content (TCC) was determined by treatment with vanillin reagent (Sigma) and expressed as milligrams per gram of D-catechin;[13] total anthocyanin content (TAC) was quantified by measuring the difference in the absorbance (525 nm) of the sample diluted in 1 N HCl and in phosphate citrate buffer (pH 3.5)[14] and the results expressed as milligrams of malvidin-3-glucoside per gram; and total proanthocyanidin content (TPAC) was measured after acid hydrolysis at 95 °C for 40 min and expressed as milligrams of procyanidin B1 per gram.[15]

*Antioxidant Capacity. (1) ABTS$^{\bullet+}$ Method.* The radical scavenger activities of the powdered products were studied by measuring the decrease in absorbance at 734 nm after incubation of methanolic extracts with a solution of 2,2′-azinobis(3-ethylbenzothiazoline-6-sulfonic acid) (ABTS). The ABTS radical solution was prepared by mixing ABTS and $K_2O_8S_2$ in water (1:1).[16]

*(2) Fat Oxidation Inhibition Capacity.* The ability of the extracts to protect fats against oxidation was evaluated using the Rancimat test, which was performed using a Rancimat 743 instrument (Metrohm, Switzerland). The air flow rate and temperature were set at 20 L/h and 110 °C, respectively. The tests were conducted in triplicate on commercial olive oil and melted pork lard. Controls and fats with 2% (w/w) of the different wine pomace products (WPPs) under study were conducted. The Rancimat test evaluates the conductivity caused by the short-chain fatty acids produced during lipid oxidation. Although this test has been criticized due to the use of high temperatures, which may affect the mechanism of lipid oxidation,[17] it remains a valuable tool for predicting the protection exerted by an antioxidant in real food systems. The results were expressed as protection factor, which was calculated by dividing the induction period of the WPPs with that for controls (fat without WPPs).

*Microbial Analysis.* Samples were weighed in a Stomacher bag, decimally diluted with Ringer solution (Oxoid, Basingstoke, Hampshire, UK) under sterile conditions, and homogenized in a laboratory blender (Stomacher 400, Colworth, London, UK). Total aerobic mesophilic bacteria (TAMB) and total yeasts and molds were evaluated on plate count agar (PCA) (Merck) and Sabouraud agar with chloramphenicol (Pronadisa, Madrid, Spain) respectively. PCA plates were incubated at 30 °C for 72 h and Sabouraud plates at 25 °C for 7 days.

*Antimicrobial Potential of Products.* The antimicrobial capacity was measured using meat homogenates, which were prepared by homogenizing commercially available beef in sterile water (1:3). A comparative study was carried out using homogenates of control meat (additive-free), meat with 2% of each WPP, and meat with 300 ppm of $SO_2$. Homogenates were incubated while stirring for 32 h in an incubator (New Brunswick Scientific, Edison, NJ, USA) at 37 °C. For each sample, decimal dilutions were prepared in Ringer solution and plated onto the appropriate culture medium. TAMB were determined using pour plates on PCA after incubation at 30 °C for 72 h. Lactic acid bacteria (LAB) were enumerated using de Man−Rogosa−Sharpe agar (MRS) (Oxoid) after incubation at 25 °C in an atmosphere of 5% $CO_2$ for 5 days. Those colonies that reacted positively to the catalase test were not counted. Enterobacteriaceae counts were determined using a double layer of violet red bile glucose agar (Pronadisa) incubated at 37 °C for 24 h. Antimicrobial experiments were repeated three different times with duplicate homogenates each time.

**Statistical Analysis.** Statistical analysis was performed using StatGraphics Centurion XVI. Fisher's least significant difference (LSD) test was performed to identify significant differences.

## RESULTS AND DISCUSSION

WP presents a sufficiently high water content to promote both microbial growth and enzyme-related degradation; therefore, a dehydration process was required to obtain a raw material that remains stable until final transformation into the desired powder products. Thermal drying was chosen over freeze-drying for the following reasons. Previous studies have suggested that, in contrast to freeze-drying, oven-drying does not affect total extractable polyphenols and condensed tannins as long as the temperature does not exceed 60 °C.[18] Tseng and Zhao[19] reported that freeze-dried products had the lowest stability during storage, probably due to their higher porosity and higher exposure to oxygen. Furthermore, the cost of freeze-drying, which is estimated to be 4−8 times more expensive than thermal drying,[20] was also considered. WP was dehydrated to a water content of <10%.

Particle size determines the use and application of different ingredients in food manufacture.[21] The handling safety of the ingredient, palatability of the resulting foodstuff, and release of active compounds are some of the factors involved in this aspect. Furthermore, stability of products and manufacturing costs need to be considered. The likelihood of oxidative reactions and microbiological contamination increases with the reduction of particle size. Besides, the manufacturing costs also increase, due to the longer manufacturing times and higher energy levels required to obtain smaller particle size. To balance the advantages and drawbacks of a very small particle size, SkWPP and WWPP were milled and sieved through a mesh

with a size of 0.250 mm, whereas SdWPP was milled and sieved through a mesh with a size of 0.355 mm. The reason for choosing a higher particle size in SdWPP was the low yield obtained using a size of 0.250 mm. This could be explained by the caking and sticking of the seed powder as a consequence of the high fat content of grape seeds. These phenomena are commonly found for dairy-based powders with high lipid contents. Surface fat may melt during the grinding process due to the temperature increase, which leads to the formation of fatty bridges between particles. When the temperature drops, the fat solidifies, forming bridges between particles and resulting in a lumpy product.[22,23] Furthermore, the tough structure of grape seed endosperm[24] could also contribute to the low yield obtained.

**Characterization of the Products Obtained.** The three products obtained showed significant differences in terms of composition (Table 1). Dietary fiber was the main component

**Table 1. Proximate Composition of Skin Wine Pomace Product (SkWWP), Whole Wine Pomace Products (WWPP), and Seed Wine Pomace Product (SdWPP)[a]**

| parameter | SkWPP | WWPP | SdWPP |
|---|---|---|---|
| moisture (%) | 6.78 ± 0.43 a | 7.12 ± 0.25 ab | 7.57 ± 0.09 b |
| total dietary fiber (% DM) | 48.6 ± 0.7 a | 49.4 ± 0.9 a | 58.9 ± 0.5 b |
| total lipid (% DM) | 3.69 ± 0.07 a | 10.61 ± 0.18 b | 16.99 ± 0.18 c |

in all three products, with the highest content being found for SdWPP (±59%) (Table 1), probably due to the presence of lignin in the seeds. These results agree with those of Saura-Calixto et al.[25] and Tseng and Zhao,[19] who indicated that WP mainly contains insoluble fiber and, more specifically, Klason lignin. WP fiber is associated with a high amount of antioxidants, thus making it a valuable source of dietary antioxidant fiber.[26] Similar protein contents were found for SkWPP and WWPP (±14 and 13%, respectively), with the value for SdWPP (12%) being slightly lower due to the higher fiber and lipid contents. Protein values were comparable to those obtained by other authors.[26,27] Similar differences in the content of the various components of WP (mainly between skins and seeds) have been described previously.[19,27,28]

SkWPP showed the highest ash content (±14%), with the values obtained being similar to those reported for Spanish grape pomaces by Saura-Calixto,[26] thus indicating a high mineral content in grape skins. Potassium was the predominant macroelement, especially in the products derived from raw material containing grape skins (±43 mg/g), which correlates with the well-known high potassium content usually found in grape skins. It is widely accepted that during grape ripening, potassium accumulates in the skin and forms both soluble and insoluble salts with organic acids.[29] Seeds are considered to be the strongest sinks for calcium and phosphorus in grape berry, which explains the higher content of these minerals observed in SdWPP in comparison to SkWPP.[30] The low sodium levels detected also agree with the lack of accumulation of these mineral during grape ripening.[30]

The incorporation of sulfating agents is widespread in wineries due to the microbial and oxidative stability provided by them. However, sulfites were not detected in any of the WP products obtained.

The phenolic composition of the products obtained (Table 2) agrees with the well-known fact that grape seeds are a richer

[a]Different letters (a–c) denote significant differences (LSD test and $P < 0.05$) among treatments. Values are means ± standard deviation of three replicate determinations. SkWPP, skin wine pomace product; WWPP, whole wine pomace product; SdWPP, seed wine pomace product.

source of polyphenols, especially catechins and proanthocyanidins, than grape skins and that only grape skins contain a relevant amount of anthocyanins.[31,32] It should be noted that the values obtained are lower than those reported in grapes[33] but are in agreement with the quantity of phenolic compounds transferred from grapes to wine during red winemaking.[34]

Control of the microbial load of the products obtained was considered both convenient and necessary to obtain the safe products required by the food industry. Despite their wide range of applications, the microbiological contribution of WP-derived ingredients to foodstuffs has been underestimated as it has been assumed that the drying process is sufficient to ensure the safety of the powdered products.[35] However, other agricultural products with similar water contents and water activities, such as herbs and spices, have been involved in different outbreaks of food poisoning caused by the presence of pathogens.[36] Moreover, it is also important to consider that fungi are able to produce mycotoxins even at low water activities.[37]

Our results showed that SkWPP had the highest microbial load, most likely due to the higher degree of manipulation and exposure to microbial contamination (Table 3). Although the microbial load observed is usually considered to be acceptable in spices,[38] microbial inactivation is recommended to ensure the quality of the powdered products obtained.

**Table 3. Microbial Load of Untreated, UV-Treated, and Thermally Treated Wine Pomace Products[a]**

| | product | untreated | UV-treated | thermally treated |
|---|---|---|---|---|
| total aerobic mesophilic bacteria | SkWPP | 4.65 ± 0.06 | 3.49 ± 0.17 | nd |
| | WWPP | 4.00 ± 0.09 | 3.95 ± 0.06 | nd |

[a]Results are expressed as log CFU/g of each product. Values are means ± standard deviation of three replicates. SkWPP, skin wine pomace product; WWPP, whole wine pomace product; SdWPP, seed wine pomace product; nd, not detected.

Two inactivation methods were conducted: thermal treatment and UV treatment. Although thermal treatment is the most common means of inactivating microorganisms, the low thermal stability of phenolic compounds may limit its application in WP products. Ultraviolet radiation has been mainly applied in liquid foods, although its use has also been proposed in powdered products.[39] In addition, it has successfully been used in leafy vegetables and is a clean and relatively inexpensive alternative.[40,41] As such, it may be a valuable option for WP products.

Preliminary studies were conducted to establish the most efficient conditions for thermal and UV treatments. First, the efficiencies of different UV treatment times were tested. The differences between the microbial load of untreated and UV-treated WWPP and SdWPP were not significant (Table 3). The highest effectiveness of UV treatment was observed for SkWPP. These differences in effectiveness could be due to the difference in the particle size of each type of product.[42] A progressive reduction in microbial load of SkWPP was observed from 15 to 60 min of treatment, whereas no significant reduction was observed during the second hour (from 60 to 120 min) of UV treatment. Thus, after 60 min of UV treatment, SkWPP showed reductions of 1.16 and 1.26 log CFU/g in the counts of TAMB and yeasts and molds, respectively (Table 3). The thermal treatment at 90 °C produced a progressive reduction in the microbial load of the three products under study. The complete inactivation of the studied microbial flora was achieved after 90 min of treatment.

UV and thermally treated products showed main compositions similar to those of the untreated ones, although some differences in phenolic composition were detected (Table 2). WWPP showed the highest decrease in TPC (16% in UV-treated and 6% in thermally treated), whereas the TPC of SkWPP was affected similarly by both treatments. In contrast, only UV treatment affected the TPC of SdWPP. The cause of this higher decrease in UV-treated samples might be the photodimerization and isomerization of phenolic compounds induced by UV radiation.[43] Furthermore, UV radiation may also promote the formation of new linkages between hydroxycinnamic acids and lignin units,[39] thereby decreasing their extractability. As far as thermal processing is concerned, previous studies found no significant decrease after heating to 100 °C for 250 min and even a significant increase at 150 °C.[44] This fact can be explained by the degradation of cell-wall polysaccharide structures, thus facilitating polyphenol release and extractability from the matrix structure.[45] Similarly, Chamorro et al.[46] found no significant decrease in TP after thermal treatment at 100 °C for 1 h.

Catechin was one of the groups most affected by treatments (26% after UV treatment and 17% after thermal treatment). Epimerization and autoxidation seem to be the most likely mechanisms for catechin degradation. The observed degradation agrees with the rates reported by Volf et al.[47] Thermal treatment produced the highest degradation in TAC (27% in WWPP and SkWPP), which may be explained by the well-known thermal lability of anthocyanins.[48] Sólyom et al.[44] reported degradation rates of 75% in similar thermal treatments of nondehydrated WP. Water availability plays a key role in anthocyanin degradation, and the low water activity of the studied products may explain the relatively limited degradation of anthocyanins observed in this study.[49,50] UV treatment did not decrease the TAC of either WWPP or SkWPP. Thermal and UV treatments produced similar decreases in the TPAC for all products studied (approximately 15%). Previous literature data in this regard are contradictory. Significant reductions in TPAC levels were reported by Khanal et al.[51] for grape pomace after thermal treatment at temperatures of ≥60 °C. These authors observed degradation of the oligomeric procyanidins in WP upon increasing the temperature from 60 to 125 °C. In contrast, Chamorro et al.[46] found no significant reductions after heating grape pomace at 100 °C for 60 min. Overall, thermal treatment produced less intense reductions in TPC, TCC, and TPAC than UV treatment, whereas it affected TAC more extensively. These reductions can be considered acceptable because the WPPs obtained retain the vast majority of their phenols and their safety is markedly improved. Consequently, thermal treatment was selected as the best option, and thermally stabilized products were used in the subsequent study of antioxidant and antimicrobial activities.

**Properties of Interest for Food Industry Applications.** In addition to use of the products obtained as a source of fiber, antioxidant, and possibly some minerals, such as potassium, WPPs exhibit other properties of interest to the food industry. In this regard, antioxidant and antimicrobial properties were considered to be of particular importance for application as natural food preservatives.

The ABTS method was used to evaluate the global antioxidant capacity of the products studied from among the large number of possibilities available due to its simplicity and the complete information provided by it.[16] All WP products showed interesting antioxidant capacities but with statistically significant differences. SdWPP exhibited the highest antioxidant activity (141.99 ± 2.09 μmol/g), followed by WWPP (103.29 ± 0.23 μmol/g) and SkWPP (75.65 ± 1.98 μmol/g). ABTS results were positively and strongly correlated with TPC, TCC, and TPAC, as indicated by Pearson correlation coefficient, which showed values of 0.9951, 0.9968, and 0.987, respectively. This fact agrees with the attribution of antioxidant activity to the phenolic composition of WP. For example, Bonilla et al.[52] reported that gallic acid exerted the highest protection among all of the phenols extracted from crushed grape pomace when added at the same concentration. Lafka et al.[53] also concluded that catechins and gallic acid contents are the main factors that determine the antioxidant activity of WPPs.

Considering the importance of preventing fat oxidation in the food industry, the ability of the products obtained to protect against fat oxidation was evaluated using the Rancimat method. Two fat systems with different oxidation sensitivities (olive oil and pork lard) were used. Olive oil mainly contains

unsaturated fatty acids, which are more susceptible to oxidation than the saturated fatty acids found in pork lard. However, olive oil also contains polyphenols and tocopherols with antioxidant activity,[54] whereas metals with pro-oxidant activity can be found in pork lard.[55] Furthermore, both fats can be considered as good representatives of the different types of fat used in the food industry (plant and animal fats).

Olive oil and pork lard gave average induction times of 26.07 and 14.65 h, respectively. The three products studied delayed the onset of lipid oxidation in both types of fats (Table 4).

**Table 4. Protection Factor of Wine Pomace Products in Olive Oil and Pork Lard Measured by Rancimat Method[a]**

| | SkWWP | WWPP | SdWPP |
|---|---|---|---|
| olive oil | 1.087 ± 0.028 b | 1.061 ± 0.026 ab | 1.024 ± 0.016 a |
| pork lard | 1.145 ± 0.028 b | 1.086 ± 0.036 ab | 1.052 ± 0.010 a |

[a]Values are means ± standard deviation of three replicate determinations. Protection factor = induction time of fat with product under study/induction time of control fat. Different letters (a, b) denote significant differences (LSD test and $P < 0.05$) among products. SkWPP, skin wine pomace product; WWPP, whole wine pomace product; SdWPP, seed wine pomace product.

These results could be correlated to the global antioxidant capacities of the products, most likely to the phenol content. The protection exerted by SdWPP was significantly lower than that exerted by SkWPP despite their higher TPC, TCC, and TPAC values. These findings are in agreement with the findings of Shaker,[56] who reported a higher inhibition for grape skin extracts in comparison to grape seed extracts when added to sunflower oils at the same polyphenol concentration. The data obtained appear to indicate a key role for anthocyanins in the protection against lipid oxidation.[57] These same authors found that grape skin anthocyanins present a higher protective capacity against lipid oxidation than catechin and $\alpha$-tocopherol at the same concentration. Although anthocyanins are not soluble in fat, their protective properties could be associated with their excellent ability to scavenge the free radicals formed during fat oxidation. Wine anthocyanins showed a particularly intense hydroxyl radical scavenging capacity, which was similar to their superoxide radical scavenging activity.[58] Furthermore, the possible lipid oxidation of seed fat during the production and storage of SdWPP and WWPP should be also considered, due to the fact that the presence of oxidized fatty acids may initiate oil and fat oxidation,[59] counteracting the antioxidant effects of polyphenols.

Antimicrobial activities were studied in meat homogenates because meat is a good system for studying spoiler growth. The inhibitory effect of the WP products on the growth of potential spoilage microorganisms was studied and compared with the antimicrobial effect of sulfites (Figure 1), a standard and well-known antimicrobial food additive, as control. The antimicrobial activity of sulfites appears to be related to their ability to induce changes in protein structures. Other antimicrobial mechanisms of sulfites include blockage of transport, inhibition of glycolysis, nutrient destruction, and inhibition of microbial metabolism.[60]

First, it is worth noting that the incorporation of SdWPP did not affect the initial load of homogenates, whereas addition of SkWPP, WWWP, and sulfites produced an immediate decrease in TAMB and LAB counts. This finding suggests that the WP products obtained were in optimal conditions for use as food additives. Significant protective effects were detected for all three products studied, with these effects being very similar for all three assays performed.

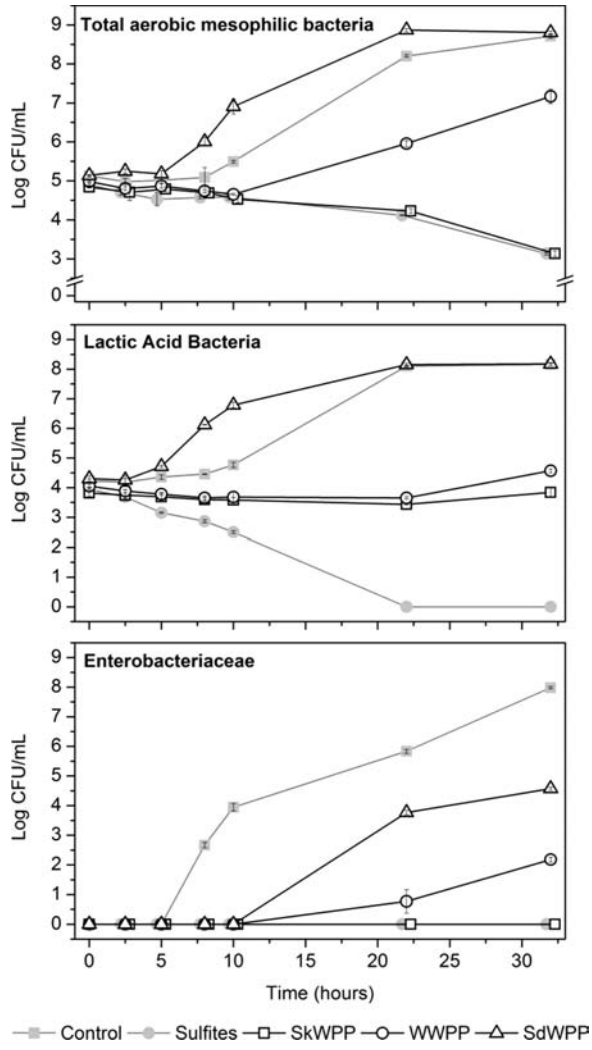

**Figure 1.** Effect of incorporation of sulfites, skin wine pomace product (SkWPP), whole wine pomace product (WWPP), and seed wine pomace product (SdWPP) on the total aerobic mesophilic bacteria, lactic acid bacteria, and Enterobacteriaceae counts of beef homogenates incubated at 37 °C.

Meat homogenates incubated with sulfites exhibited a significant decrease in TAMB count, a complete inactivation of LAB after 32 h of incubation, and no Enterobacteriaceae growth. SkWPP produced inhibitions of TAMB and Enterobacteriaceae growth similar to those produced by sulfites. The decrease in TAMB and LAB counts in the meat incubated with SkWPP suggests its bactericidal capacity. The addition of WWPP delayed the onset of TAMB and LAB growth (by 15 and 22 h, respectively), thereby confirming its bacteriostatic activity against spoilage flora. Moreover, addition of WWPP delayed Enterobacteriaceae growth and decreased the final counts in comparison with controls. These results could be correlated with the phenolic compounds present in SkWPP and WWPP. The effect of grape polyphenols on the growth of different meat spoiler microorganisms, such as LAB, has been widely studied and appears to depend on the polyphenol concentration, medium, and species (or even strains) under study.[61−63]

The antimicrobial effects of plant materials containing phenolic compounds have been associated with different mechanisms of action,[3] such as the ability to inhibit cell wall synthesis, thereby producing cell membrane alterations and the consequent loss of crucial intracellular material; the ability to chelate essential metals such as iron; and the ability to bind polysaccharides and proteins, thereby producing compounds that cannot be metabolized by microorganisms.[64] Furthermore, Friedman[65] reported the ability to bind vital components in the cell, such as enzymes and cell transport proteins. Previous studies have shown an ability to increase the microbial stability of meat products but using grape pomace extracts. For instance, Sagdic et al.[66] observed the inhibitory effect of ethanolic grape pomace extract on the spoiler growth of beef patties. The incorporation of high levels of grape pomace extracts (10%) led to the complete inactivation of spoilage flora, whereas the addition of 1% grape pomace extract delayed the onset of microbial growth. The microbial results obtained with WWPP were worse than those obtained with SkWPP but better than those observed for SdWPP. The incorporation of SdWPP promoted the growth of TAMB and LAB and reduced their lag phases. These results were surprising in light of the higher phenolic content of this product. However, they are in agreement with the stimulatory role of grape seed extract on *Lactobacillus acidophilus* growth[67] and with the improved growth caused by gallic acid and catechin in *Lactobacillus hilgardii*.[68] Alberto et al.[69] have suggested that polyphenols may improve sugar metabolism in LAB, thereby stimulating proliferation. The results obtained are satisfactory and novel.

From a microbial stability and spoilage protection point of view the best product was SkWPP, although WWPP also showed good results. Moreover, the results obtained upon addition of SdWPP were also interesting, especially considering that the promoting effect on LAB could result in an increase in the production of certain bacteriocins with antimicrobial activity against pathogens.[70] In addition, it has been found that the bacteriocins produced by gallic acid and catechin adapted LAB are particularly potent inhibitors of the growth of some foodborne pathogens such as *Staphylococcus aureus* and *Salmonella enterica*.[71]

In conclusion, wine pomace can be readily transformed into a series of products that meet the requirements of the food industry, namely, cheap, environmentally friendly, and natural and with good antioxidant and antimicrobial abilities. Furthermore, these products can be used as a natural source of fiber, antioxidants, and potassium. The bactericidal activity of SkWPP, which is similar to that for sulfites, suggests the possibility of using this product as a sulfite substitute, thereby reducing the allergenic risk. The ability of the products studied to inhibit fat oxidation also suggests potential applications in fatty food with a high tendency to rancidity, thereby extending their shelf life.

U/mg of protein) and pancreatin from porcine pancreas (4× USP specifications) were obtained from Sigma-Aldrich (Shanghai Branch, Shanghai, China).

**Isolation of Polyaspartic Acid According to Molecular Weight.** PAA (50 g) with a molecular weight of 5−150 kDa was dissolved in 5 L of water. From this aqueous solution, PAA samples of 10−30, 30−50, and 50−100 kDa were isolated. Four hundred milliliters of the aqueous solution was filtered using a 400 mL Millipore/stirred cell 8400 (Millipore, Bedford, MA, USA) equipped with a 10 kDa ultrafiltration membrane to remove the molecules of <10 kDa, yielding PAA of 10−150 kDa (3.4 g, dry weight). The PAA (10−150 kDa) was dissolved with 400 mL of water and filtered through a 30 kDa ultrafiltration membrane to afford PAA of 30−150 kDa (2.7 g, dry weight) and a solution of 10−30 kDa PAA, which was evaporated and dried under reduced pressure at 60 °C to give 0.6 g of 10−30 kDa PAA. The PAA of 30−150 kDa was subjected to the above procedure, using 50 and 100 kDa ultrafiltration membranes consecutively, to produce 1.2 g of 30−50 kDa PAA and 0.8 g of 50−100 kDa PAA.

**Preparation of CS−PAA Nanoparticles.** CS−PAA nanoparticles were prepared from chitosan of molecular weight 3−5, 14−22, or 50−150 kDa and polyaspartic acid with a molecular weight of 10−30, 30−50m or 50−100 kDa. The molecular weight of each component was varied to find the composition that would obtain the ideal particle size. The weight ratio of CS to PAA was 1:1. CS−PAA nanoparticles were prepared by mixing a positively charged CS/acetic acid solution with a negatively charged PAA solution at room temperature. Briefly, PAA (20 mg) was thoroughly dissolved in 10 mL of deionized water, and CS (20 mg) was fully dissolved in 10 mL of 1% acetic acid solution by magnetic stirring. The CS solution (10 mL) was added dropwise to the PAA solution (10 mL) at a flow rate of 1 mL/min using an injection pump and mixed by magnetic stirring at a speed of 500 rpm to form a dispersion of CS−PAA nanoparticles. After the optimal molecular weight of CS and PAA was determined, the effect of the CS/PAA ratio on the particle size and zeta potential of the nanoparticles was investigated.

**Trial Preparation of EGCG−CS−PAA Nanoparticles.** EGCG−CS−PAA nanoparticles were prepared by mixing a positively charged CS acetic acid solution containing EGCG (2 mg/mL) and a negatively charged PAA solution at room temperature. The preparation process was similar to that of CS−PAA nanoparticles. To harvest the nanoparticles, the nanoparticle solution was centrifuged under 15000*g* for 20 min, following which the precipitate was immediately dispersed in 0.5% aqueous acetic acid (10 mL) and freeze-dried. The freeze-dried powder was tested to determine the EGCG loading amount, release, and stability in simulated body fluids.

**Characterization of the EGCG−CS−PAA Nanoparticles.** The average diameter and size distribution of particles were determined by dynamic light scattering (DLS) using a Zetasizer Nano-ZS analyzer (Malvern Instruments, Worcestershire, UK). All DLS measurements were done at 25 ± 0.1 °C and at a scattering angle of 90°. The particle size distribution was produced from the volume measurement, in which the relative percentage of particles in each size class is based on the volume they occupy. The zeta potential was measured with laser Doppler velocimetry (LDV) using the same Zetasizer Nano-ZS analyzer. The morphology of the EGCG−CS−PAA nanoparticles was performed on a transmission electron microscope (TEM, Hitachi H-600) after the nanoparticles had been mounted onto a carbon-coated copper grid.

**Determination of Entrapment Efficiency and Loading Amount of EGCG in the Nanoparticles.** The solution of EGCG−CS−PAA nanoparticles (2 mL) was transferred into an Amicon Ultra-3K centrifugal filter device (Millipore Corp. Billerica, MA, USA) made up of a centrifuge tube and a filter unit with a low-binding Ultracel membrane (3000 MWCO). After centrifugation at 4000*g* for 30 min, EGCG−CS−PAA nanoparticles remained in the filter unit and free EGCG and salts penetrated through the Ultracel membrane into the centrifuge tube. The free EGCG was determined by high-performance liquid chromatography (HPLC). The EGCG−CS−PAA nanoparticles in the filter unit were freeze-dried, and part of the lyophilized powder was extracted with methanol for EGCG determination by HPLC. The HPLC analysis were performed on a Shimadzu HPLC system (Shimadzu, Kyoto, Japan) composed of two LC-10A pumps, an SIL-10Avp autosampler, an SPD-M10Avp UV detector, and a Symmetry C18 (5 $\mu$m, 4.6 mm × 250 mm) column. The elution employed a linear gradient system with mobile phase A (water/acetic acid 98:2) and mobile phase B (acetonitrile) at a flow rate of 1 mL/min at 40 °C. The chromatogram was recorded at 280 nm. The entrapment efficiency (%) of EGCG in the nanoparticles and the loading amount (mg/g) were calculated from the results of HPLC analysis.

**Stability of EGCG−CS−PAA Nanoparticles at Different pH Values.** EGCG−CS−PAA nanoparticles were prepared by mixing a solution of positively charged CS in acetic acid, containing EGCG, with a solution of negatively charged PAA at room temperature. The nanoparticle dispersion was centrifuged at 15000*g* to harvest the nanoparticles. The collected nanoparticles were dispersed in 0.5% aqueous acetic acid and freeze-dried to form a lyophilized powder. This powder was tested to determine the PDI and particle size of the EGCG−CS−PAA nanoparticles at different pH values (2.5, 3.5, 4.5, 6.6, 7.0, and 7.4) to evaluate the stability of the nanoparticles.

**Release of EGCG from EGCG−CS−PAA Nanoparticles.** The release profile of EGCG from test nanoparticles was investigated in different media (pH 2.5, 4.0, 6.6, 7.0, and 7.4) in the presence of the reducing agents ascorbic acid (20 mM) and tris[2-carboxyethyl]-phosphine hydrochloride (13 mM) to prevent EGCG from oxidation in alkaline environments.[19] Briefly, 5 mg of the EGCG−CS−PAA nanoparticles was dispersed in 20 mL of pure water by ultrasonic process and then incubated in a water bath at 37 °C under magnetic agitation (100 rpm). At given time intervals, samples (1.0 mL) were taken out and centrifuged, and the supernatants were analyzed by HPLC. The amount of EGCG released was expressed as a decrease in the percentage of EGCG in the nanoparticles, which was obtained from the EGCG concentration in the supernatants after centrifugation of the nanoparticle solutions.

**Stability Evaluation of EGCG in Nanoparticles under Simulated Digestion and Adsorption Conditions in Vitro.** The simulated digestion condition was PBS buffer with pH 2.1 containing pepsin (simulated gastric fluid, SGF), and the simulated adsorption condition was PBS buffer at pH 7.2 containing pancreatin−bile salts (simulated intestinal fluid, SIF).[23] The amount of EGCG remaining in EGCG−CS−PAA nanoparticles in SGF and SIF after 0−4 h was determined according to the study of Krook and Hagerman.[12] Briefly, EGCG−CS−PAA nanoparticles were added to SGF or SIF, to a final EGCG concentration of 0.25 mg/mL (0 h), and then incubated in a water bath at 37 °C under magnetic agitation (100 rpm). After 1, 2, 3, and 4 h of incubation, 1 mL of the incubated solution was removed and the EGCG concentration in this aliquot was determined by HPLC as described above. The amount of EGCG remaining after the incubation reflects the stability of EGCG in nanoparticles during digestion and adsorption in vitro.

**Preparation of EGCG−CS−PAA Nanoparticles for Animal Experimentation.** PAA (2 g) was thoroughly dissolved in 1 L of deionized water. CS (2 g) was fully dissolved in 1 L of 1% acetic acid solution by stirring; 2 g of EGCG was then added to this solution. The CS−EGCG solution was added to the PAA solution (1 L) at a flow rate of 10 mL/min using a BT100-1F peristaltic pump (Konap Peristaltic Pump Co., Ltd., Chongqing, China) and mixed by an ultrasonic processor (FS-1800N, Shanghai Sonxi Ultrasonic Instrument Co., Shanghai, China) to form a solution of EGCG−CS−PAA nanoparticles. The sizes of the nanoparticles in the solution and in the trial preparation were compared by DLS. This solution was centrifuged under 13000*g* for 20 min to harvest the nanoparticles; the pellet was dispersed in 0.5% aqueous acetic acid (500 mL), ultrasonicated, and freeze-dried. The freeze-dried powder was used in the animal experiments.

**Effectiveness of EGCG−CS−PAA Nanoparticles on Rabbit Atherosclerosis.** Thirty male New Zealand white rabbits (Animal Center of Zhejiang Academy of Medical Sciences) weighing 1.92−2.11 kg were randomly divided into six experimental groups. They were

Table 1. Mean Diameter, Polydispersity Index, and Zeta Potential of the Nanoparticles (CS−PAA NP) Prepared with Chitosan (CS) and Polyaspartic Acid (PAA) of Various Molecula Weight[a]

[a]Mean ± SD, $n = 3$. Values in a column followed by different letters are significantly different ($p < 0.05$).

housed individually in metal cages in an air-conditioned room (22 ± 2 °C, 55 ± 5% humidity) and maintained on a 12 h light/12 h dark cycle with free access to food and water. Water was allowed ad libitum, and 150 g/day of food was provided. One group of rabbits was used as a control. Experimental rabbits (five groups) were fed for 5 weeks with a high-fat diet (HFD) containing 93.75% standard rabbit chow (Jiangsu Synergistic Bioengineering Co. Ltd., Nanjing, China) supplemented with 1.0% cholesterol, 5% lard oil, and 0.25% sodium cholate to provoke atherosclerosis. Four of the groups were orally treated with EGCG−CS−PAA nanoparticles (EGCG NP), EGCG, blank CS−PAA nanoparticles (blank NP), or simvastatin (positive control). In the EGCG NP-fed group, each rabbit was daily given 350 mg of EGCG NP (7 mL of 0.5% aqueous acetic acid) containing 100 mg of EGCG, whereas each rabbit in the EGCG group was given 100 mg of EGCG (7 mL of 0.5% aqueous acetic acid). Each rabbit in the blank NP-fed group was given 250 mg of blank NP (7 mL of 0.5% aqueous acetic acid) per day, and each rabbit in the positive control was given 5 mg of simvastatin (5 mg/tablet, Shanghai Xinyi Wanxiang Pharmaceutical Co. Ltd., Shanghai, China) per day. For EGCG NP and blank NP, the sample was dispersed in water solution via ultrasonication, and then the solution was provided to the rabbit by oral administration.

The daily EGCG dose was selected according to the suitable pharmacological dose for humans. All animal experiments were performed according to the protocols approved by the Animal Care Center of the Zhejiang Academy of Medical Sciences and complied with the guidelines for the care and use of laboratory animals. Five weeks after commencement of the HFD, the rabbits were sacrificed by exsanguination via the marginal ear vein after deep anesthesia with pentobarbital (30 mg/kg iv). Serum was stored at −80 °C until serum lipid analysis and measurements of serum values were conducted. The thoracic arteries with arches were carefully excised to avoid damaging the endothelial lining, and the adhering soft tissue was trimmed off. Thoracic arteries with arches were rapidly dissected, opened longitudinally, and stained with Oil Red. Photographs of the inner surface were taken and copied onto graph paper with magnification (×2), and athermanous plaques were delineated. The number of small squares surrounded by the line was counted on the graph paper and the percentage of the area of athermanous plaque was calculated. Serum and lipoprotein levels of cholesterol and triglyceride were measured by enzymatic colorimetry using commercial kits (Boehringer, Mannheim, Germany). Quantitative data were expressed as the mean ± SD and analyzed by one-way ANOVA. Multiple comparisons between the groups were performed using the Student−Newman−Keuls (SNK) method. Statistical significance was set at a level of $p < 0.05$.

## RESULTS AND DISCUSSION

**Formation of Chitosan−Polyaspartic Acid Nanoparticles.** Nanoparticles can form from self-assembly of polyelectrolytes such as chitosan and poly-γ-glutamic acid.[24] In the present study, we tested the preparation of nanoparticles by self-assembly of chitosan and polyaspartic acid because PAA is less expensive than poly-γ-glutamic acid. Table 1 shows the mean diameter, polydispersity index (PDI), and zeta potential of the CS−PAA nanoparticles prepared with CS−PAA (1:1, w/w) prepared from various molecular weights of CS and PAA. The zeta potential and particle size increased as the molecular weights of CS and PAA increased, which suggests that long-chain CS and PAA form large particles with high stability, and short-chain CS and PAA form small particles with low stability. Furthermore, the values of PDI increased when the difference in the molecular weights of CS and PAA molecules was increased. Considering that the parameters for best stability and uptake in cellular systems are zeta potential >30 mV or < −30 mV[25] and particle size near 75 nm,[26] the optimal nanoparticles in the present study were self-assembled from PAA 30−50 kDa and CS 3−5 kDa and had a diameter of 92.6 nm and a zeta potential of 31.5 mV. These nanoparticles were selected for further experiments.

Further study showed that changing the CS/PAA ratio in the self-assembled nanoparticles could change their size and stability (Table 2). As the CS/PAA ratio increased, the values of both nanoparticle size and zeta potential increased. When the CS/PAA ratio was 0.75, the particle size decreased to 84.7 nm, but the particles (zeta potential = 22.3 mV) were less stable than those in which the ratio of CS/PAA was 1.0. On the basis of the above results, we decided to use the nanoparticles that were self-assembled from PAA 30−50 kDa and CS 3−5 kDa at a ratio of 1:1 for loading EGCG.

Table 2. Mean Diameter, Polydispersity Index and Zeta Potential of the Nanoparticles (CS−PAA NP) Prepared with Various Ratios of Chitosan (MW 3−5 kDa)/Polyaspartic Acid (MW 30−50 kDa)[a]

| CS/PAA (w/w) | particle size (nm) | PDI | zeta potential (mV) |
|---|---|---|---|
| 0.75 | 84.7 ± 3.2 a | 0.206 ± 0.004 | 22.3 ± 0.2 a |
| 1 | 93.3 ± 2.1 b | 0.205 ± 0.006 | 31.8 ± 0.2 b |
| 1.5 | 100.4 ± 2.5 c | 0.242 ± 0.009 | 40.5 ± 0.4 c |
| 2 | 126.3 ± 1.9 d | 0.307 ± 0.015 | 44.2 ± 0.1 d |
| 2.5 | 136.4 ± 3.8 e | 0.318 ± 0.017 | 45.5 ± 0.3 d |

[a]Mean ± SD, $n = 3$. Values in a column followed by different letters are significantly different ($p < 0.05$).

**EGCG−CS−PAA Nanoparticles.** EGCG was loaded into self-assembled CS−PAA nanoparticles by adding EGCG into a

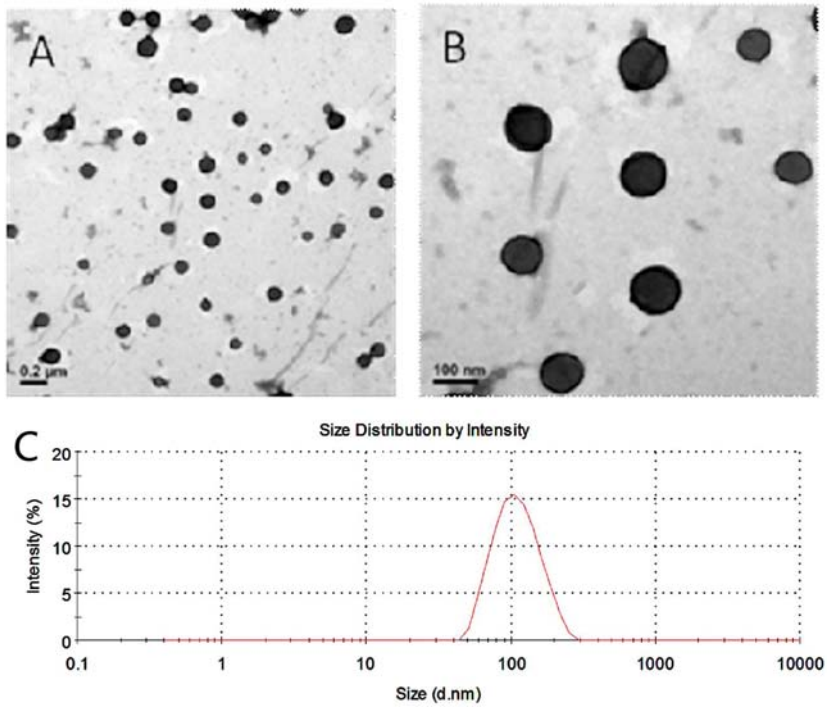

**Figure 1.** TEM micrographs of CS−PAA−EGCG nanoparticles: (A) 50000× magnification; (B) 150000× magnification; (C) particle size determination by DLS.

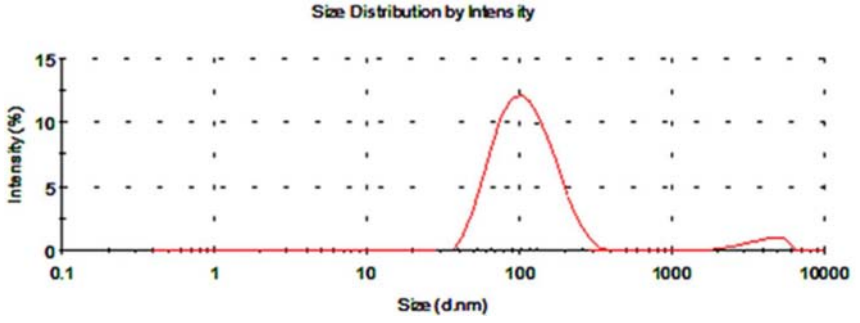

**Figure 2.** DLS measurement of the particle size in the dispersion prepared by reconstituting the freeze-dried nanoparticles.

CS solution, which was mixed with a PAA solution under magnetic stirring at room temperature. The mean particle diameter, PDI, and entrapment efficiency (EE) of nanoparticles prepared with a 1:1 ratio of CS/PAA were determined. The prepared EGCG−CS−PAA nanoparticles exhibited a particle size of 102.4 ± 5.6 nm, PDI = 0.224, and EE = 25.0 ± 2.1%. The EE value was greater than that of nanoparticles self-assembled from CS and the same mass amount of poly-γ-glutamic acid as PAA.[24] Because the PAA molecule is shorter than γ-glutamic acid, PAA contains more carboxyl groups for forming hydrogen bonds with EGCG. The zeta potential of the nanoparticle solution was 33.3 ± 0.2, which indicates excellent stability.

TEM images (Figure 1) showed that the EGCG−CS−PAA nanoparticles were spherical and about 100 nm in diameter (Figure 1). The diameters determined by TEM were consistent with those determined via DLS. This demonstrated that DLS was an effective method to determine the size of the prepared nanoparticles. After the nanoparticles were harvested by centrifuging and freeze-drying, HPLC showed that the concentration of EGCG in the nanoparticles was 34.4%. Dispersing the freeze-dried nanoparticles in 0.5% aqueous acetic acid yielded a sample whose particle size was similar to that of the original system before freeze-drying (Figure 2).

**Stability of EGCG−CS−PAA Nanoparticles in the Solutions at Different pH Values.** The stability of the EGCG−CS−PAA nanoparticles in the solutions at different pH values was evaluated from the PDI and particle diameter (Table 3). At pH 3.5, the original pH when the nanoparticles were prepared, the EGCG−CS−PAA nanoparticles were stable after 2 h at room temperature. At pH 2.5, no significant change in the nanoparticles was observed after 2 h. As the pH was increased from 4.5 to 7.4, the PDI and particle diameter rapidly increased, which means that small nanoparticles aggregated or reassembled into larger nanoparticles. This result is similar to that obtained via TEM observation of CS/poly-γ-glutamic acid nanoparticles.[24]

**Release of EGCG from EGCG−CS−PAA Nanoparticles at Different pH Values.** Release of EGCG from EGCG−CS−PAA nanoparticles at different pH values was investigated because the pH in the digestive system varies widely between gastric and intestinal fluid. The typical pH in the stomach is

**Table 3. Polydispersity Index and Diameter of the EGCG−CS−PAA Nanoparticles after 2 h at Different pH Values[a]**

| treatment | pH | PDI | mean particle size (nm)[a] |
|---|---|---|---|
| original solution | | | |
| 0 h | 3.5 | 0.213 ± 0.008 | 103.7 ± 2.5 a |
| 2 h | 3.5 | 0.228 ± 0.008 | 102.9 ± 2.1 a |
| 2 h after adjusting pH | 2.5 | 0.224 ± 0.013 | 106.3 ± 3.5 a |
| | 4.5 | 0.288 ± 0.021 | 134.2 ± 5.2 b |
| | 6.6 | 0.323 ± 0.035 | 200.4 ± 9.5 c |
| | 7.0 | 0.403 ± 0.039 | 443.1 ± 16.5 d |
| | 7.4 | 0.651 ± 0.051 | 856.6 ± 24.6 e |

[a]Mean ± SD, $n = 3$. Values in a column followed by different letters are significantly different ($p < 0.05$).

from 2.0 to 4.0 depending on the species and food intake.[27] The pH in the duodenum is 6.0−6.6, and in the jejunum and proximal ileum the pH is 6.6−7.0, whereas the pH is about 7.4 in the distal ileum and in the body fluid filling intercellular spaces between enterocytes.[28] The present study determined the release of EGCG from EGCG−CS−PAA nanoparticles in dispersions at pH 2.5 (0−1 h), 4.0 (1−2 h), 6.6 (2−3 h), 7.0 (3−4 h), and 7.4 (4−5 h), conditions similar to those encountered in food ingestion. Figure 3 shows the release of

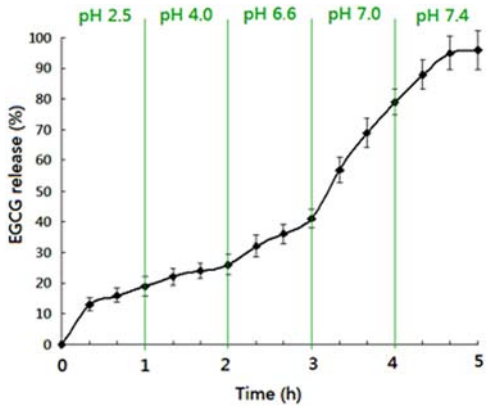

**Figure 3.** EGCG release profiles of EGCG−CS−PAA nanoparticles at pH 2.5, 4.0, 6.6, 7.0, and 7.4.

EGCG from the nanoparticles at the various pH conditions. At pH 2.5 and 4.0 (simulating the stomach), the release of EGCG in 0−2 h was about 25% of the total EGCG amount in the nanoparticles. At pH 6.6 (simulating the duodenum), the release rate increased and the amount released reached 41% of the total. At pH 7.0 (simulating the jejunum and the proximal ileum) and pH 7.4 (simulating the distal ileum and the intercellular body fluid), the release rate showed a rapid increase, which implies that the nanoparticles became unstable and quickly disintegrated to release EGCG. The stability of the nanoparticles in the stomach, combined with the rapid release in the intestine, may improve the uptake of EGCG in the intestine.

**Stability of EGCG−CS−PAA Nanoparticles in Simulated Gastric and Intestinal Conditions.** Loading EGCG into nanoparticles improves its stability in gastric and intestinal conditions. In SGF (pH 2.1), the loss of EGCG in EGCG−CS−PAA nanoparticles was about 10−15% less than that of the free EGCG regardless of the presence of pepsin (Figure 4). In SIF (pH 7.2) EGCG was more unstable than in SGF. Encapsulation with CS and PAA clearly protected EGCG. Upon addition of the nanoparticles to SIF in the presence of pancreatin−bile salts, the amount of EGCG lost was 41, 71, 92, and 93% after 1, 2, 3, and 4 h, respectively. For nanoparticles in SIF without pancreatin−bile salts, smaller amounts of EGCG were lost at the same time intervals: 39, 81, 83, and 90%, respectively. Increasing the stability of compounds in the human stomach and intestine can improve their uptake. Therefore, loading EGCG in CS−PAA nanoparticles may improve the effectiveness of EGCG against diseases such as atherosclerosis.

**EGCG−CS−PAA Nanoparticles (EGCG NP) for Animal Experiments.** EGCG NP for animal experiments were prepared according to a modified process in which ultrasonication replaced magnetic agitation because the amount was scaled up from milligrams to grams. The product exhibited the same properties, that is, particle size = 100.6 ± 4.2 nm, PDI = 0.215 ± 0.008, zeta potential = 33.9 ± 0.5 mV, and EGCG loading amount = 348.1 ± 12.4 mg/g, dry weight.

**Effectiveness of EGCG NP against Atherosclerosis.** The inner surfaces of the rabbit arteries are shown in Figure S1 in the Supporting Information. The control rabbit artery was covered with opaque atherosclerotic lesions in its inner surface (Figure 5a). The HFD-fed rabbits showed severe lipid deposition in their inner surface artery on which the average ratio (%) of lipid deposit area to intimal surface area (without artery arch) was 69.0 ± 9.6% (Figure 5b). The blank NP-fed rabbits exhibited an average ratio (%) of lipid deposit area of 65.3 ± 10.8% (Figure 5c), which suggests no significant difference in lipid deposition between the HFD-fed rabbits and the blank NP-fed rabbits. Compared to the HFD-fed rabbits, the EGCG NP-fed rabbits and EGCG-fed rabbits exhibited

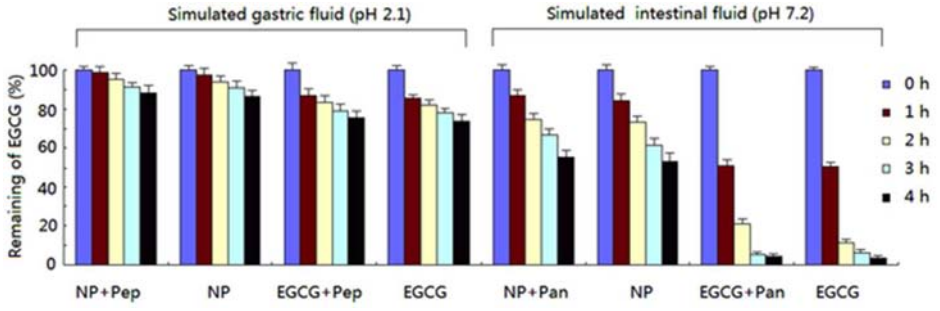

**Figure 4.** Amount of EGCG remaining in SGF and SIF after 0, 1, 2, 3, and 4 h. NP+Pep, EGCG−CS−PAA nanoparticles in the presence of pepsin; NP, EGCG−CS−PAA nanoparticles alone; EGCG+Pep, EGCG in the presence of pepsin; EGCG alone; NP+Pan, in the presence of pancreatin−bile salts; EGCG+Pan, EGCG in the presence of pancreatin−bile salts.

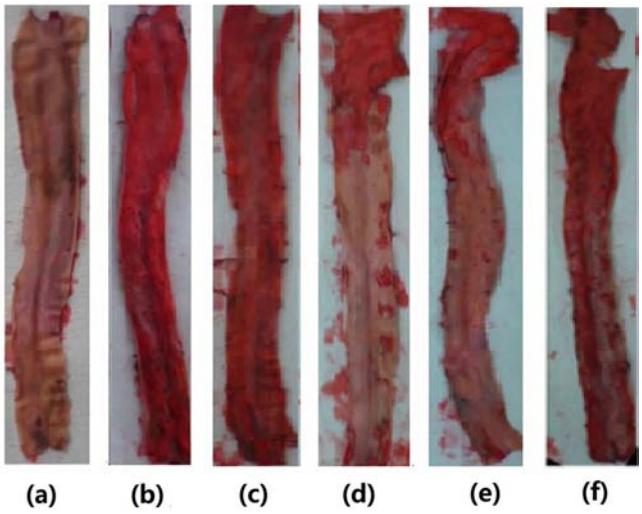

**Figure 5.** Extent of atherosclerosis lesion development in rabbits after feeding with the experimental diets: (a) normal group; (b) HFD-fed group; (c) blank NP-fed group; (d) simvastatin-fed group (2.5 mg/kg); (e) EGCG NP-fed group, 175 mg/kg (corresponding to 50 mg EGCG/kg); (f) EGCG-fed group (50 mg/kg).

significantly less lipid deposition. The average ratios of lipid deposit area for EGCG NP-fed rabbits and EGCG-fed rabbits were 16.9 ± 5.8 and 42.1 ± 4.0%, respectively, which showed that the EGCG NP were much more effective against atherosclerosis compared with EGCG alone ($p < 0.01$). The effect of EGCG NP against rabbit atherosclerosis was close to that of simvastatin (Figure 5d, percent average ratio of lipid deposit area, 15.6 ± 4.1%), which is a clinical treatment for atherosclerosis. It should be mentioned that no difference was seen in the body weight of the EGCG NP-fed group and the normal-fed group (Table 1S), which suggests that the nanoformulation EGCG did not trigger toxic reactions in the rabbits.

**Effect of EGCG NP and EGCG on Blood Lipid Levels.** The serum levels of total cholesterol (TC) and LDL cholesterol (LDL-C) of HFD-fed rabbits were 10−20 times those of normal rabbits, whereas the levels of triglyceride (TG) and HDL cholesterol (HDL-C) were increased but to a lesser degree (Table 4). After administration of EGCG NP and EGCG, the levels of TG, TC, HDL-C, and LDL-C decreased by 52, 55, 27, and 65% and 19, 26, 23, and 33%, respectively. It is clear that EGCG NP decreased the blood lipid levels of rabbits to a much greater extent than EGCG. Meanwhile, no significant changes in the levels of TG, TC, HDL-C, and LDL-C were found between the HFD-fed and the blank NP-fed groups. The results demonstrate that the reduction of the blood lipid levels in the EGCG NP and EGCG groups fully correspond to the reduction in lipid deposition.

The effectiveness of EGCG in humans is relatively low because EGCG is unstable at the pH conditions of body fluids.[18] It is known that EGCG undergoes significant metabolism and conjugation during absorption in the small intestine and the colon. In the small intestine EGCG is degraded to smaller phenolic acids and valerolactones.[29] To improve the effectiveness of EGCG, various methods have been investigated by loading EGCG in vehicles such as liposomes, ethosomes, or other nanoparticles, which can protect EGCG by delayed release, act to target the release of EGCG, or protect it from unstable circumstances such as body fluids with various pH values.[30] The present study provides a nanoformulation of EGCG to improve its effectiveness.

In conclusion, EGCG-loaded nanoparticles with a mean diameter ca. 100 nm were prepared from 30−50 kDa PAA and 3−5 kDa CS. The nanoparticles were pH-responsive and demonstrated different EGCG release profiles in simulated gastrointestinal tract media. Compared to EGCG alone, this nanoformulation of EGCG demonstrated higher stability in body fluids and showed greater activity against atherosclerosis.

lipids to perform their roles in assuring plant quality and safety.[11,12] Although $\alpha$-tocopherol has been considered to be the main contributing isoform to vitamin E activity, $\gamma$-tocopherol exhibits the greatest antioxidant activity.[12−14] Thus, it is necessary to assess the composition of all vitamin E isoforms in quinoa and amaranth leaves. Carotenoids, as pro-vitamin A and/or antioxidants, have not been carefully examined in the leaves of either quinoa or amaranth. Our recent study, however, has revealed that lipophilic phytochemicals including carotenoids in quinoa and amaranth leaves can be present at even higher concentrations than some commonly consumed cereal grains and pulses. Detailed results are reported in the present paper.

Evaluation and comparison of the nutritional quality of a large number of foods or feeds are often difficult. Major nutritional components, such as the lipophilic nutrients carotenoids, tocopherols, and fatty acids, in a food or feed have been assessed separately.[15,16] However, there is a lack of an evaluation system for the overall lipophilic quality attributes in samples of this nature.

The objectives of this study were to carry out a comprehensive examination on the lipophilic bioactive components in leaves of quinoa and amaranth, including the fatty acids, tocopherols, and carotenoids, and to evaluate the possible roles of these compounds in antioxidant and potentially other health promoting activities. This study is part of our current effort in assessing the economic and nutritional values of whole plants of both quinoa and amaranth in Ontario, Canada. A total of 14 amaranth and 6 quinoa cultivars were included in this study to help garner accurate information on the profile of lipophilic bioactives in the leaves and to explore the possibility of using quinoa leaves as healthy vegetables or even functional food ingredients.

## MATERIALS AND METHODS

**Leaf Materials.** Leaves of 14 amaranth and 6 quinoa cultivars were sampled from a farm near Campbellville, Ontario, Canada, in July 2013 (Table 1). Heads (with at least 4−5 fully opened leaves) of at least 5 plants per cultivar were handpicked, pooled and lyophilized in a 12-L bulk tray dryer (Labconco, Kansas City, MO) at 0.110 mbar and −40 °C prior to grinding with a commercial coffee blender (particle sizes 400−800 $\mu$m). The fine powder was stored in polyethylene tubes at −80 °C until extraction for the various analyses.

Lutein, zeaxanthin, $\beta$-carotene, and $\beta$-cryptoxanthin standards were purchased from Indofine (Hillsborough, NJ). 2,2-Diphenyl-1-picrylhydrazyl (DPPH), Trolox, 1,3,5-tri(2-pyridyl)-2,4,6-triazine (TPTZ), L-ascorbic acid, fluorescein, 2,2′-azobis(2-methylpropionamidine) dihydrochloride (AAPH), randomly methylated-$\beta$-cyclodextrin (RMCD), and $\alpha$-, $\beta$-, $\gamma$-, and $\delta$-tocopherols were from Sigma−Aldrich (Oakville, ON, Canada). Standards of fatty acid methyl esters (FAMEs) were obtained commercially (mixture 463, Nu-Chek-Prep, Inc., Elysian, MN). All solvents were of HPLC grade and obtained from Caledon Laboratories Ltd. (Georgetown, ON, Canada).

**Sample Extraction.** The powdered samples were accurately weighed then extracted with methyl *tert*-butyl ether/tetrahydrofuran (MTBE/THF, 1:1 v/v) on a Soxtec extraction system (Soxtec System 2050, Tecator AB, Hdganas, Sweden). In this system, the sample was first immersed in the boiling solvent for 30 min and then continuously rinsed by refluxing solvent from the condenser for 80 min. The solvent recovery lasted 30 min and predrying was for 2 min. During the extraction, solvents were heated to 155 °C. After cooling, ca. 5 mL of hexane each was used to wash the lipid extracts in the container three times. The oil yield was determined by the difference in mass of the container before and after the extraction. The extract was stored at −80 °C until analysis. All extraction tubes were covered with aluminum foil and the experiment was conducted under dim light in order to avoid sample degradation by photooxidation during the extraction period.

**Analysis of Fatty Acids by Gas Chromatography−Mass Spectrometry.** A 1 mL aliquot of the lipophilic extract was dried under a gentle stream of $N_2$ to remove hexane, methylated with anhydrous HCl/methanol (5% w/v), and dried over anhydrous sodium sulfate, and finally the FAMEs were analyzed by gas chromatography (GC; model 6890, Hewlett-Packard, Palo Alto, CA) on a CP-Sil 88 WCOT fused silica column (100 m × 0.25 mm i.d. × 0.2 $\mu$m film thickness; Chrompack, Middleburg, The Netherlands). The column was operated at 45 °C for 4 min and then temperature-programmed at 13 °C/min to 175 °C, held for 27 min, programmed at 4 °C/min to 215 °C, and finally held for 31 min; total run time was 86 min.[15] A flame ionization detector (FID) was used. GC−mass spectrometry (MS) analysis was performed on a Varian Saturn 2000 system running in default electron ionization mode (4 V axial bias and 1400 V multiplier) according to the method described by Karimi et al.[17] Samples were injected into the GC−MS system via split injection at 1:10. The injection volume was 1 $\mu$L. The mass spectrometer (5975C MSD) was equipped with an electron impact ion source (EI). All experiments were carried out in positive-ion mode. The source temperature was set at 230 °C, and the energy was 70 eV. The multiplier voltage was set to 900 V without solvent delay.

**Analysis of Tocopherols, Tocotrienols, and Carotenoids by HPLC.** Tocopherols from the extracts were separated and analyzed following a published procedure with slight modification on an Agilent Technology 1100 series HPLC system equipped with a Phenomenex silica column (250 × 4.6 mm, 5 $\mu$m, Torrance, CA), a diode array detector (DAD), and a fluorescence detector. $\alpha$-Tocopherol equivalents ($\alpha$-TE) was an expression based on the activity relative to the most active form of vitamin E. $\alpha$-TE is calculated from the formula $\alpha$-TE = ($\alpha$-T) + 0.5($\beta$-T) + 0.1($\gamma$-T) + 0.03($\delta$-T) + 0.3($\alpha$-T3) + 0.05($\beta$-T3) + 0.01($\gamma$-T3), where T = tocopherol and T3 = tocotrienol.[18]

Carotenoids in the extracts were identified and quantified by the same Agilent Technology 1100 series HPLC system as mentioned above, following the same method used by Zhang et al.[15] Separation was on a YMC C30 carotenoid column (250 × 4.6 mm, 5 $\mu$m) (Waters, Mississauga, ON) at 35 °C, and peaks were detected by DAD at 452 nm. The carotenoids were tentatively identified on the basis of matching retention time, similarity in elution order, and UV/vis spectra with those of the standards and data reported in the literature. All carotenoids were quantified on the basis of corresponding curves of lutein, zeaxanthin, $\beta$-carotene, and $\beta$-cryptoxanthin standards.

**Structural Identification and Confirmation by Liquid Chromatography–Mass Spectrometry.** Carotenoids tentatively identified as described above were confirmed by liquid chromatography (LC)–MS on a Dionex UHPLC UltiMate 3000 liquid chromatograph interfaced to an amaZon SL ion trap mass spectrometer (Bruker Daltonics, Billerica, MA).[19] UV/vis data were collected at 190–800 nm and the electrospray positive ionization (ESI + ve) mass spectrometric data were scanned from $m/z$ 50 to 1200. The capillary temperature was 220 °C and the source voltage was 4.50 kV. The chromatographic separation conditions for LC–MS were the same as those described for the HPLC-DAD analyses.

The MS conditions for vitamin E were the same as described for carotenoids. Selected ion monitoring (SIM) acquisition mode was used to help in the quantification of tocopherols, and the ions monitored were as follows: $m/z$ 429 for $\alpha$-tocopherol, $m/z$ 415 for $\beta$- and $\gamma$-tocopherol, and $m/z$ 401 for $\delta$-tocopherol.[20]

**Antioxidant Activity Assays.** The lipophilic extracts were dried under a nitrogen stream and then dissolved in 7% (% w) RMCD in acetone/water (1:1 v/v). The DPPH assay was carried out according to the procedures used by Zhang et al.[15] with minor modification: appropriately diluted samples or Trolox solutions were placed in wells of a 96-well plate (flat bottom, Nalge Nunc International, Denmark) and read at 517 nm by use of a Multiskan Spectrum microplate reader (EL 340, Bio-Tek Instruments Inc., Winooski, VT). The DPPH radical scavenging activity of extracts was calculated from the standard curve of Trolox ($r^2$ = 0.999) and expressed as micromoles of Trolox equivalents (TE) per gram dry weight of sample.

The ferric reducing antioxidant power (FRAP) assay followed procedures reported by Li et al.[21] Briefly, a total of 10 $\mu$L of properly diluted samples or L-ascorbic acid solutions (62.5, 125, 250, 500, 750, and 1000 $\mu$M) and 300 $\mu$L of freshly prepared FRAP reagent were added in a 96-well plate and incubated at room temperature throughout the reaction period. After 120 min, the absorbance was read at 593 nm against a reagent blank. The antioxidant activities were expressed as micromoles of ascorbic acid equivalent (AAE) per gram dry weight of sample ($r^2$ = 1.000).

Lipophilic oxygen radical absorbance capacity (ORAC) assay was conducted according to Zhang and others[15,22] with slight modifications. The lipophilic extracts and Trolox solutions were dissolved in RMCD solution as discussed before. The fluorescence (excitation/emission wavelength = 485/528 nm) was read every minute for 120 min or until it reached zero in a fluorescence plate reader equipped with an automatic thermostatic holder (PLX 800, Bio-Tek Instruments, Inc., Winooski, VT). A calibration curve was constructed by plotting the calculated differences of area under the fluorescein decay curve between blank and sample. The results were expressed as micromoles of Trolox equivalent per gram dry weight of quinoa sample ($r^2$ = 0.998).

**Statistical Analysis.** Results were expressed as mean value ± standard deviation of three independent extractions. One-way analysis of variance (ANOVA) was used to compare the means by use of Duncan's posthoc test. Comparison of assays was made by correlation and linear regression analysis. Differences were considered as significant at $p \leq 0.05$. All statistical analyses were performed with Statistics from SPSS (version 18.0, Chicago, IL).

## RESULTS AND DISCUSSION

**Fatty Acids.** The oil content and composition of the major fatty acids of quinoa and amaranth leaves are shown in Table 2. The oil yields of the quinoa leaves ranged from 3.95% to 4.18%, which was higher than that in amaranth leaves (2.13–3.59%). Fatty acids were over 80% in unsaturated form, mainly the two essential fatty acids C18:3n-3 ($\alpha$-linolenic acid), ranging between 35.1% in QL1 and 49.43% in AL12, followed by C18:2n-6 (linoleic acid, 11.36–18.38%), C16:0 (palmitic acid, 9.28–16.44%), and C18:1(9c) (oleic acid, 5.11–11.22%) in both quinoa and amaranth leaves. C16:1 (palmitoleic acid) and C18:0 (stearic acid) were present in relatively low levels compared to the foregoing fatty acids. This is different from the fatty acids in seeds of quinoa and amaranth, which contained more C18:2n-6 (33.56–52.0%) than C18:3n-3.[3,23]

Food data generated throughout the 20th century indicates that the ratio of $\omega$-3 to $\omega$-6 fatty acids has decreased from 1:1 to 1:30, much lower than the recommended ratio (1:2.3 to 1:4).[24,25] Diets having higher $\omega$-6 fatty acids such as C18:2n-6 have been linked to increased risk of prostate cancer, cardiovascular disease, and other chronic diseases,[26] whereas $\omega$-3 fatty acids such as C18:3n-3 have been shown positive effects on various cardiac disorders and many chronic illnesses.[27] Consequently, foods rich in $\omega$-3 fatty acids, such as fish oils and certain plant oils, are considered a healthier diet. The $\omega$-3/$\omega$-6 ratios of quinoa and amaranth leaves averaged 2.28–3.89, which is severalfold higher than the ideal ratio and much better than most vegetable oils.[28] Incorporation of these leaves into a diet can therefore compensate the unhealthy $\omega$-3/$\omega$-6 ratio.

**Carotenoids.** Leafy green vegetables and fruits have generated interest worldwide as they exhibit multiple benefits for the health of humans, particularly as a source of dietary vitamin A in developing countries.[29] The present study showed that carotenoid compositions in amaranth and quinoa leaves were similar but concentrations varied significantly among different cultivars of the same plant.

$\beta$-Carotene is an important lipid-soluble antioxidant that functions to protect cellular membranes by scavenging free radicals and as a photosensitizer by quenching triplet oxygen in biosynthesis.[30,31] As shown in Table 3, $\beta$-carotene was the primary carotenoid in both quinoa (302.97–484.86 $\mu$g/g DW) and amaranth leaves (115.19–394.31 $\mu$g/g DW). Lutein was the second dominant carotenoid in all of the samples, with amaranth leaves containing an average of 67.03 $\mu$g/g DW (33.31–136.78 $\mu$g/g DW) and quinoa leaves containing a higher average lutein content (83.65 $\mu$g/g DW) in a narrower range (65.93–103.39 $\mu$g/g DW). A similar trend was found for violaxanthin: quinoa leaves had a higher level at 67.34–93.20 $\mu$g/g DW than the amaranth leaves, which ranged between 21.24 and 80.78 $\mu$g/g DW. $\alpha$-Carotene was also found in both quinoa and amaranth leaves, albeit the average concentrations were 42.29 and 28.82 $\mu$g/g DW, respectively, ca. $^1/_9$ of that of $\beta$-carotene. Leaves richer in $\beta$-carotene were also found to have higher $\alpha$-carotene. Minor carotenoids including $\beta$-cryptoxanthin and zeaxanthin were also found in most quinoa and amaranth cultivars at much lower concentrations (Table 3).

Carotenoids play essential roles in human health. Carotenes such as $\alpha$- and $\beta$-carotenes are provitamin A nutrients, and xanthophylls such as lutein, zeaxanthin, and violaxanthin are strong antioxidants and provide significant protection against macular degeneration and other light-induced eye and skin damages.[32] The total carotenoid concentration as measured by HPLC and expressed in total carotenoid index (TCI) was 496–738 $\mu$g/g DW for quinoa leaves and 189–676 $\mu$g/g DW for amaranth leaves (Table 3), which were similar to those estimated by spectrophotometric methods.[3,1,33,34] Concentrations of individual carotenoids including $\beta$-carotene, lutein, violaxanthin, antheraxanthin, and $\beta$-cryptoxanthin in amaranth leaves have been studied; however, there was a lack of similar information for quinoa leaves, and the present study is the first report of compositional information for individual carotenoids.[30,35] It is also worth mentioning that the total and individual carotenoid concentrations in quinoa and amaranth leaves of the present study are similar to or even higher than many widely consumed leafy vegetables such as spinach and

kale.[30,36,37] Our results confirm that both quinoa and amaranth leaves are excellent source of carotenoids, richer than in their own seeds.[3,38]

**Tocopherols.** All four tocopherol isomers (α, β, γ, and δ) but no tocotrienols were detected in quinoa and amaranth leaves (Table 4). The average total tocopherol content of both quinoa and amaranth was around 65 μg/g DW, similar to what was reported by others.[39] However, in addition to α-tocopherol, we also found β-, γ-, and δ-tocopherol in quinoa and amaranth leaves. The tocopherol profiles in amaranth and quinoa leaves were generally similar, with α-tocopherol being the predominant isomer (75.38% and 71.93% of total tocopherols on average in quinoa and amaranth, respectively), followed by β-, γ-, and δ-tocopherol. The concentration of α- and β-tocopherol in quinoa leaves was generally higher than in the leaves of amaranth, while γ-tocopherol was at lower levels in quinoa compared with amaranth. Even within the amaranth leaves, a few cultivars such as AL2, AL8, AL4, and AL6 showed exceptionally high γ-tocopherol content compared with all other plants. Both quinoa and amaranth leaves had low concentration of δ-tocopherol averaging from 1.61 to 1.68 μg/g DW. In terms of the α-TE values, the present results suggested that nearly all vitamin E activity of quinoa and amaranth leaves was from α-tocopherol (Table 4).

It is also worth mentioning that quinoa leaves had completely different tocopherol profiles than their respective seeds. Quinoa seeds contained overwhelmingly γ-tocopherol (>85%) and ca. 10% α-tocopherol, whereas the primary tocopherol in quinoa leaves was α-tocopherol followed by β-tocopherol (Table 4).[4] Similarly the tocopherol profile of amaranth leaves was different from that of amaranth seeds, which have been found to vary significantly from study to study.[3,39] As a source of vitamin E, quinoa and amaranth leaves contained nearly twice as much total tocopherols as those high-tocopherol grains, although compared to other common vegetable leaves, the concentration is lower.[12,20,30,40]

**Overall Evaluation.** Fatty acids, carotenoids, and vitamin E are three important lipophilic parameters to be evaluated for fruits, vegetables, and grains for their overall nutritional quality. However, these parameters have only been discussed separately in previous studies.[3,10,12,30] Food lipids are generally reported to include oil yield and major groups of saturated fatty acids (SFA), monounsaturated fatty acids (MUFA), and polyunsaturated fatty acids (PUFA), while carotenoids are mainly discussed under pro-vitamin A (β-carotene) and xanthophylls (lutein).[40] In terms of vitamin E, four tocopherols and four tocotrienols have been reported to have vitamin E activity, and α-tocopherol equivalency (α-TE) has been recently used as a measure for evaluation of the overall vitamin E activity of foods containing different vitamin E isoforms.[18,41]

Evaluation of the overall nutritional quality of the lipophilic components of a particular food or feed has been attempted by assessing the nutrients separately.[15,16] Such an attempt, however, lacks the cohesiveness that integrates all three lipophilic parameters; thus it is difficult to assess and compare the overall nutritional quality of different foods. A novel approach was then taken in the present study to establish a unified protocol for evaluation of the nutritional quality (NQ) of all lipophilic contents from the original data. Because the original data of the total carotenoids, α-TE and ω-3/ω-6 ratio were in different units, a linear scale transformation method was used to first transform all data to an arbitrary unit between 0 and 1 by use of the following equation:

$$\mathrm{NQ} = \frac{\mathrm{NQ}_i}{3\mathrm{NQ}_{\max}} \times 100$$

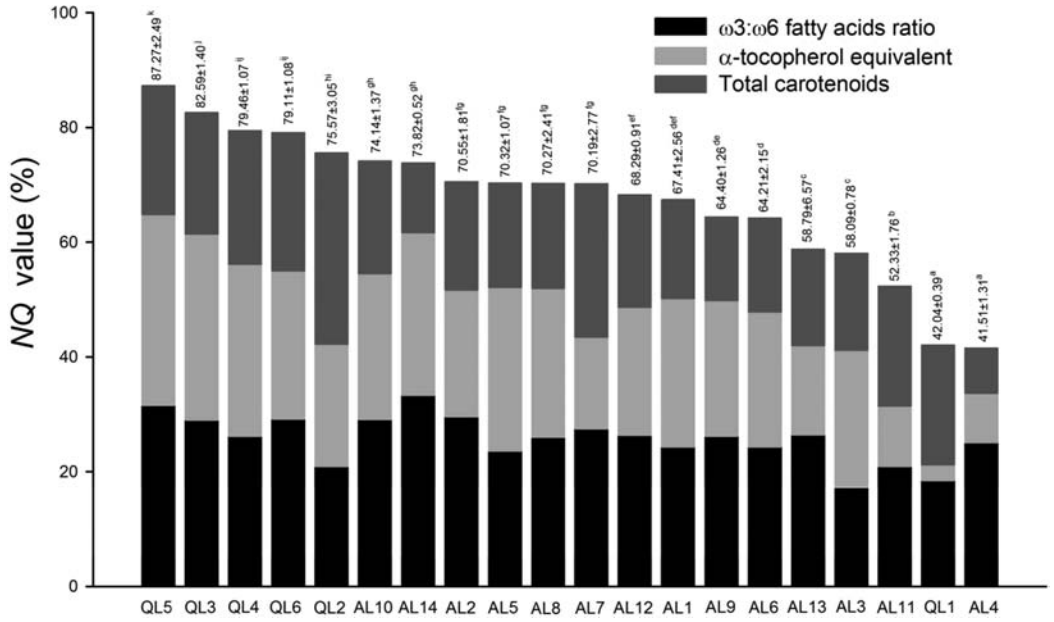

**Figure 1.** Nutritional quality (NQ) value of lipophilic extract from quinoa and amaranth leaves. Values with different letters are significantly different from each other. Values are given as mean ± SD, $n = 3$, $p \leq 0.05$.

where $NQ_{max}$ is the highest value of total carotenoids, $\alpha$-TE, or $\omega$-3/$\omega$-6 ratio and $NQ_i$ is the individual value of total carotenoids, $\alpha$-TE, or $\omega$-3/$\omega$-6 ratio of a particular sample. Three is the number of lipophilic parameters used for normalizing so that the final value can be presented as a percentage.

Figure 1 shows the ranking of overall nutritional quality by use of the above-mentioned method. The $\omega$-3/$\omega$-6 ratio was relatively consistent among all quinoa and amaranth samples, whereas the total carotenoids and $\alpha$-TE varied significantly. The overall nutritional quality was better in quinoa leaves than in amaranth. QL5 and QL3 ranked as the top two among all quinoa and amaranth leaves samples, while AL10 and AL14 had the highest NQ values among amaranth samples. No individual parameter among the three can represent the overall nutritional quality of a sample, and because of the inconsistency, no single individual nutrient group can therefore be used to evaluate or to rank the overall nutritional quality of the samples. Our approach overcomes this dilemma and provides a standardized method for assessment of the lipophilic merits of food.

**Antioxidant Activities.** The antioxidant activities of the lipophilic compounds in quinoa and amaranth leaves were assessed by DPPH, FRAP, and ORAC methods. In general, quinoa leaves had higher antioxidant activity than amaranth leaves (Figure 2). Due to the different mechanisms of in vitro antioxidant assays and the existence of different groups of lipophilic components of food, correlations between the concentration of individual nutrient groups and the different antioxidant activities have not been consistent.[10,15] For example, in a study on the lipophilic antioxidants of lentils, the total carotenoids correlated well with the antioxidant activity in the photochemiluminescence assay (PCL) but not with DPPH activity, whereas total tocopherols had a relatively good correlation with DPPH but no correlation with PCL activity. Studies on quinoa seeds also showed that different lipophilic components showed different degrees of correlation with different antioxidant activities.[5,15] In the present study, the correlation coefficients ($r^2$) between the $\omega$-3/$\omega$-6 ratio and DPPH, FRAP, or ORAC values were 0.594, 0.639, and 0.674, respectively; the $r^2$ values for $\alpha$-TE were 0.700, 0.741, and 0.786, respectively; and for carotenoids, they were all low at 0.428, 0.391, and 0.418, respectively. The $r^2$ values, however, were significantly improved by use of NQ value as an overall marker for food nutritional quality of lipophilic components. The overall NQ value of quinoa and amaranth leafy samples showed a strong positive correlation with all antioxidant activities, with $r^2$ = 0.848, 0.874, and 0.927, respectively, for DPPH, FRAP and ORAC activities.

Quinoa and amaranth seeds are emerging as the latest healthy foods on the market, and the demand for these pseudocereal grains has increased in recent years. As a result of the current effort being made to produce quinoa and amaranth seeds in Canada, additional value from the whole plants of these two crops has become an interesting subject of research. The present study examined the lipophilic bioactives in leaves of quinoa and amaranth plants. Three major lipophilic nutrients were analyzed, essential fatty acids, tocopherols, and carotenoids, and the total and individual compounds were identified and quantified for the first time. While the oil yield was only 3−4% of the leaves, both plants contained high-quality fatty acids with 50.97−62.32% PUFA which consisted of almost entirely 18:3n-3 and 18:2n-6. The ratio of these two essential fatty acids, that is, the $\omega$-3/$\omega$-6 ratio, ranged between 2.13 and 4.11, which was more favorable than other plant oils in terms of potential contribution to health benefits. Pro-vitamin A (mainly $\beta$-carotene and $\alpha$-carotene) and xanthophylls (mainly lutein and violaxanthin) were considered the major contributors to the carotenoids in leafy samples of both quinoa and amaranth. Different from the seeds, the tocopherols in quinoa and amaranth leaves were primarily $\alpha$- and $\beta$-tocopherol. A new approach to establishing a unified standard evaluation method for the overall nutritional quality of the lipophilic bioactives was proposed. This novel method calculates the NQ value of each sample by combining the relative quantities of the three major bioactive groups: carotenoids, $\alpha$-TE, and $\omega$-3/$\omega$-6 ratio. The NQ value correlated strongly with all antioxidant activities as measured by DPPH, FRAP, and ORAC assays, thus

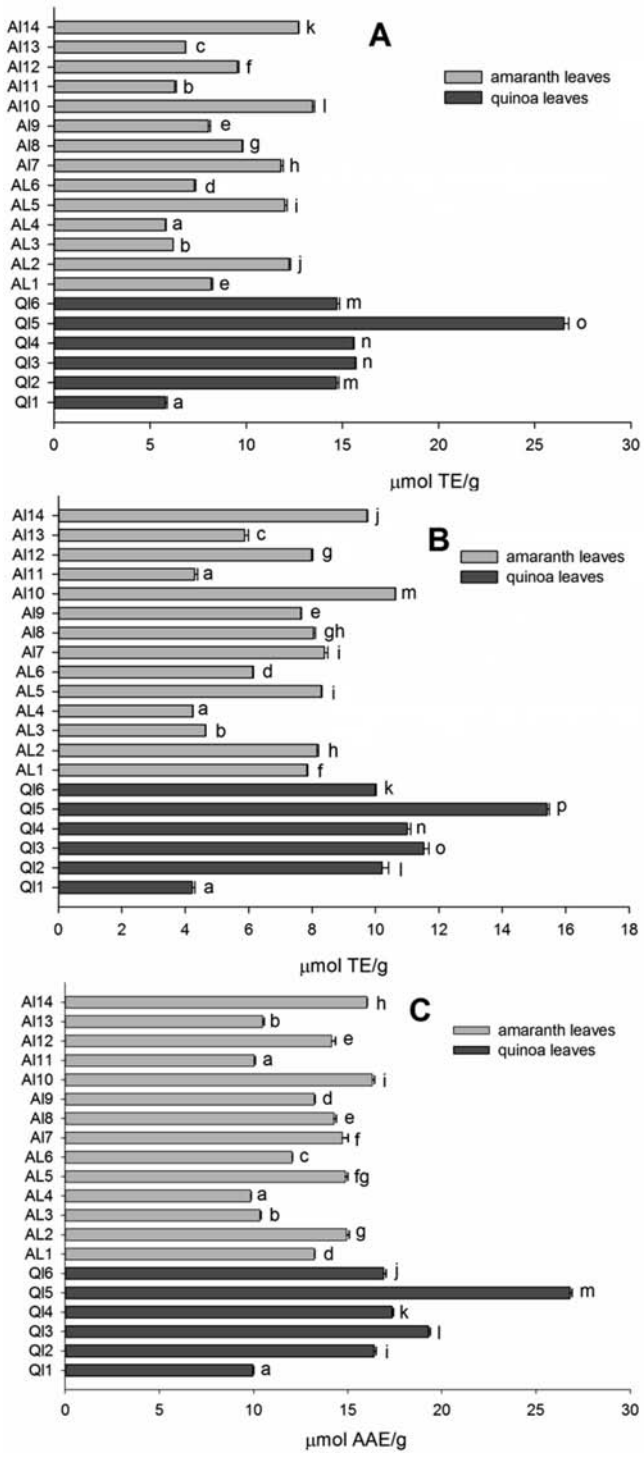

**Figure 2.** Antioxidant activities as measured by DPPH assay [A, top; micromoles of Trolox equivalent (TE) per gram dry weight], FRAP assay [B, middle; micromoles of ascorbic acid equivalent (AAE) per gram dry weight], and ORAC assay [C, bottom; micromoles of Trolox equivalent (TE) per gram dry weight]. Values with different letters are significantly different from each other. Values are given as mean ± SD, $n = 3$, $p \leq 0.05$.

overcoming the inconsistency between an individual group of bioactives, such as carotenoids alone, and the potential nutritional attribute, such as antioxidant activities. The NQ value is a better descriptor for nutritive quality of the lipophilic component of quinoa and amaranth leaves and can be potentially applied to all other foods. This new approach and the NQ value can be used for more precise comparison of the nutritive quality of lipophilic bioactives in foods. Information obtained in this study will aid the selection process of quinoa and amaranth cultivars adaptable to Ontario climate, and how the whole plant instead of the seeds can be used for the development of value-added products such as nutraceuticals and functional foods.

the amount of cholesterol absorbed and transported to the blood.[20] Furthermore, the conformation and aggregation state of pectin in aqueous solutions may be altered due to its interactions with certain gastrointestinal components, which leads to changes in solution rheology that might affect lipid digestion, for example, by altering gastric emptying times or the mass transport of digestive enzymes.[3] Pectin may also directly interact with other components in the gastrointestinal tract such as $CaCl_2$, NaCl, and digestive enzymes.[9,21−23] Finally, pectin is known to promote depletion flocculation of lipid droplets, which may reduce lipid digestion by protecting them from attack by lipolytic enzymes.[24,25]

Pectin ingredients obtained from different natural sources using different isolation and processing methods may vary widely in their molecular and physicochemical characteristics, such as backbone length, electrical charge, hydrophobicity, surface activity, conformation, self-association, viscosity, and binding capacity.[17] In addition, the molecular and functional characteristics of pectins may be altered appreciably in response to changes in solution and environmental conditions such as pH, composition, ionic strength, and temperature.[14,15,18,19] For this reason, the study of the nature of the interactions that pectin may have with the components of the gastrointestinal tract is important in understanding the effect of pectin on digestive processes. An improved understanding of the origin and nature of these interactions would lead to the design of functional foods with improved nutritional, physicochemical, and sensory properties.

In this study, isothermal titration calorimetry (ITC) was used to study the interactions between pectin and gastrointestinal components (bile salts, pancreatic lipase, $CaCl_2$, and NaCl). ITC measures the heat absorbed or evolved when one solution is titrated into another solution.[26−28] Previous studies have shown that ITC is an extremely valuable tool for studying chemical interactions of polysaccharides with other molecules because it provides valuable data concerning binding enthalpies, critical aggregation concentrations, and binding stoichiometries.[29,30] In addition, electrophoresis, turbidity, and microstructural observations were used to provide additional information about the nature of the interactions between pectin and gastrointestinal components. The results of this study may aid the rational design of functional foods designed to improve human health and wellness by controlling lipid digestion within the gastrointestinal tract.

## MATERIALS AND METHODS

**Chemicals.** Corn oil was purchased from a commercial food supplier (Mazola, ACH Food Co. Inc., Memphis, TN, USA) and stored at 4 °C until use. The manufacturer reported that this oil contained approximately 14, 29, and 57% (w/w) of saturated, monounsaturated, and polyunsaturated fatty acids, respectively. Commercial powdered high-methoxyl pectin (Genu Pectin (Citrus), USP/100) was kindly donated by CP Kelco (Lille Skensved, Denmark) and was used without further purification. The manufacturer reported that the powdered pectin ingredient contained 6.9% moisture, 89.0% galacturonic acid, and 8.6% methoxyl groups, with a degree of esterification of approximately 62%. The average molecular weight was reported to be 200 kDa. Lipase from porcine pancreas (type II, L3126, triacylglycerol hydrolase EC 3.1.1.3), bile extract (porcine, B8631), mucin from porcine stomach (type II, M2378, bound sialic acid ≤ 1.2%), and pepsin A from porcine gastric mucose (P7000, endopeptidase EC 3.4.23.1, activity ≥ 250 units/mg solid) were purchased from Sigma-Aldrich Chemical Co. (St. Louis, MO, USA). The supplier reported that the lipase activity was 100−400 units/mg protein (using olive oil) and 30−90 units/mg protein (using triacetin) for 30 min of incubation (1 unit of lipase activity was defined as the amount of enzyme required for the release of 1 μequiv of fatty acid from either triacetin (pH 7.4) or olive oil (pH 7.7) in 1 h at 37 °C). The composition of the bile extract was reported as 49% (w/w) total bile salt (BS), containing 10−15% glycodeoxycholic acid, 3−9% taurodeoxycholic acid, 0.5−7% deoxycholic acid, 1−5% hyodeoxycholic acid, and 0.5−2% cholic acid; 5% (w/w) phosphatidylcholine (PC); $Ca^{2+}$ ≤ 0.06% (w/w); critical micelle concentration of bile extract 0.07 ± 0.04 mM; and mole ratio of BS to PC being around 15:1. All other chemicals were purchased from Sigma-Aldrich Chemical Co. Double-distilled water was used to prepare all solutions.

**Simulated Gastrointestinal Studies.** *Solution and Emulsion Preparation.* Pectin stock solution (4% w/w) was prepared by dispersing 4 g of powdered pectin into 96 g of 5 mM phosphate buffer solution (pH 7.0). The resulting solution was stirred at 800 rpm for 12 h (overnight) at room temperature to ensure complete dispersion and dissolution. Pectin stock solution was then adjusted to pH 7 and equilibrated for 10 min before analysis.

A stock emulsion was prepared by mixing 20% (w/w) corn oil and 80% (w/w) buffered emulsifier solution (5 mM phosphate buffer, pH 7, containing 2.5% (w/w) Tween 80) together for 5 min using a biohomogenizer (speed 2, model MW140/2009-5, Biospec Products Inc., ESGC, Switzerland). The resulting coarse emulsion was then passed five times through a high-pressure homogenizer (microfluidizer M-110L processor, Microfluidics Inc., Newton, MA, USA) operating at 11000 psi (75.8 MPa) to reduce the particle size further.

Pectin−emulsion mixtures were then prepared by mixing stock emulsion (containing 20% (w/w) corn oil) with pectin stock solution (containing 4% (w/w) pectin) to obtain systems of various compositions: 2% (w/w) corn oil and 0.2−3.6% (w/w) pectin. The pectin−emulsion mixtures were then stirred with a high-shear mixer (Fisher Steadfast Stirrer, model SL-1200, Fisher Scientific, Pittsburgh, PA, USA) at 1000 rpm and stored overnight at room temperature. The pectin−emulsion mixtures were characterized to obtain the initial phase, prior to subjection to the in vitro gastrointestinal model.

*Simulated Gastrointestinal Tract Model.* Each emulsion sample (initial phase) was passed through a simulated in vitro gastrointestinal tract that consisted of oral, gastric, and intestinal phases. This method is based on a static model utilized in previous studies.[31,32]

Simulated saliva fluid (SSF, pH 6.8) containing 3% (w/w) mucin was prepared according to the composition shown in Table 1. Each emulsion (initial phase) was mixed with SSF (ratio 1:1 w/w) to obtain a mixture containing 1% (w/w) corn oil and 0.1−1.8% (w/w) pectin. The simulated oral phase consisted of a conical flask containing an emulsion−SSF mixture incubated at 37 °C with continuous shaking at 100 rpm for 10 min in a temperature-controlled air incubator (Excella E24 Incubator Shaker, New Brunswick Scientific, New Brunswick, NJ, USA). The mixture resulting from processing of the initial emulsions in the oral phase (bolus) was used in the gastric phase.

**Table 1. Chemical Composition of Simulated Saliva Fluid (SSF) Used To Simulate Oral Conditions**

| compound | chemical formula | concentration[a] (g/L) |
|---|---|---|
| sodium chloride | NaCl | 1.594 |
| ammonium nitrate | $NH_4NO_3$ | 0.328 |
| potassium dihydrogen phosphate | $KH_2PO_4$ | 0.636 |
| potassium chloride | KCl | 0.202 |
| potassium citrate | $K_3C_6H_5O_7{\cdot}H_2O$ | 0.308 |
| uric acid sodium salt | $C_5H_3N_4O_3Na$ | 0.021 |
| urea | $H_2NCONH_2$ | 0.198 |
| lactic acid sodium salt | $C_3H_5O_3Na$ | 0.146 |
| porcine gastric mucin (type II) | | 30 |

[a]The SSF was prepared in double-distilled water and then pH 6.8 was adjusted.

Simulated gastric fluid (SGF) was prepared by adding 2 g of NaCl, 7 mL of concentrated HCl (37% w/w), and 3.2 g of pepsin A (from porcine gastric mucose, 250 units/mg) to a flask, then diluting the mixture with double-distilled water to a volume of 1 L, and finally adjusting the pH to 1.2 using 1 M HCl. Samples from the oral phase (bolus) were mixed with SGF (ratio 1:1 w/w) so that the final mixture contained 0.5% (w/w) corn oil and 0.05−0.9% (w/w) pectin. This mixture was then adjusted to pH 2.5 using 1 M NaOH and incubated at 37 °C with continuous shaking at 100 rpm for 2 h. The mixture resulting from processing of the emulsions in the gastric phase (chyme) was used in the intestinal phase.

Samples obtained from the gastric phase (20 mL) were incubated for 2 h at 37 °C in a simulated small intestine fluid (SIF) consisting of 2.5 mL of pancreatic lipase (24 mg/mL), 3.5 mL of bile extract solution (54 mg/mL), and 1.5 mL of salt solution containing 0.25 M $CaCl_2$ and 3 M NaCl, to obtain a final composition in the reaction vessel of 0.36% (w/w) corn oil and 0.05−0.65% (w/w) pectin. The free fatty acids (FFA) released were monitored by determining the amount of 0.1 M NaOH needed to maintain a constant pH 7.0 within the reaction vessel using an automatic titration unit (pH stat titrator, 835 Titrando, Metrohm USA, Inc.). All components were dissolved in 5 mM phosphate buffer solution (pH 7) before use. Lipase addition and initialization of the titration program were carried out only after the addition of all predissolved ingredients and balancing the pH to 7. The volume of 0.1 M NaOH added to the emulsion was recorded over time and used to calculate the FFAs generated by lipolysis. The amount of FFAs released was calculated using the equation

$$\mathrm{FFA\ (\%\ w/w)} = 100 \times \left( \frac{V_{\mathrm{NaOH}}\ \mathrm{(L)} \times C_{\mathrm{NaOH}}\ \mathrm{(M)} \times \mathrm{MW_{lipid}\ (g/mol)}}{2 \times w_{\mathrm{lipid}}\ \mathrm{(g)}} \right) \quad (1)$$

where $C_{\mathrm{NaOH}}$ is the concentration of the sodium hydroxide (0.1 M), $\mathrm{MW_{lipid}}$ is the average molecular weight of corn oil (872 g/mol), $w_{\mathrm{lipid}}$ is the initial weight of corn oil in the intestinal phase (0.1 g), and $V_{\mathrm{NaOH}}$ is the volume of NaOH (L) titrated into the reaction vessel to neutralize the FFA released, assuming that all triacylglycerols are hydrolyzed in two molecules of FFA and one molecule of monoacylglycerol. Titration blanks were performed by inactivating lipase in boiling water for 15 min prior to initialization of the titration program.

*Creaming Stability Measurements of Initial Emulsions.* Ten milliliters of emulsions (initial phase) was transferred into a test tube (internal diameter = 15 mm, height = 125 mm), tightly sealed with a plastic cap, and then stored at room temperature for 24 h, after which appreciable phase separation into an opaque layer at the top, a turbid layer in the middle, and a transparent layer at the bottom was observed in some of the systems. We defined the serum layer to be the sum of the turbid and transparent layers. The total height of the emulsion ($H_E$) and the height of the serum layer ($H_S$) were measured using a laser vertical profiling system (Turbiscan Classic MA2000, Formulaction, Wynnewood, PA, USA). The extent of creaming was then characterized by the creaming index (CI), defined as $\mathrm{CI} = 100 \times (H_S/H_E)$. The creaming index provided indirect information about droplet aggregation, because an increase in particle size (e.g., due to flocculation) leads to faster creaming (provided the droplet concentration is not too high).

**Interaction of Pectin with Gastrointestinal Components.** *Solution Preparation.* Stock solutions of 0.9% (w/w) pectin, 2.7% (w/w) bile salts, and 1.1% (w/w) lipase were individually prepared by dispersing them in 5 mM phosphate buffer solution (pH 7) at room temperature for 12 h (overnight), to ensure their complete dispersion and dissolution. Salt solutions consisting of 55 mM $CaCl_2$ or 545 mM NaCl were prepared freshly before each experiment. A stock solution containing a mixture of all the above components at the same initial concentrations as in their individual solutions was also prepared. This stock solution was referred to as having a relative concentration of "100%" of the digestive components. A series of mixtures containing lower amounts of the digestive components was prepared by diluting the stock solution with buffer solution.

To establish the interaction of pectin with specific gastrointestinal components, individual solutions of $CaCl_2$, NaCl, lipase, bile salts, and the mixture of all components were titrated into either buffer solution (blank) or pectin solution at 37 °C. Twenty-nine 100 μL aliquots of individual solutions containing 2.7% (w/w) bile salts, 1.1% (w/w) lipase, 55 mM $CaCl_2$, 545 mM NaCl, or the mixture of all components (100% relative concentration) were added sequentially into a test tube containing 14.5 mL of either buffer (5 mM phosphate buffer, pH 7) or 0.9% (w/w) pectin solutions. Turbidity, ζ-potential, and microstructure (observed by optical microscopy) of these solutions were then characterized throughout the titration process.

*Solution Characterization.* Optical turbidity of the solutions was determined by measuring their absorbance at 600 nm ($\Delta\tau = A_{600\ \mathrm{nm}}$) using a UV−visible spectrophotometer (Ultrospec 3000 pro Pharmacia Biotech, Biochrom Ltd., Cambridge, UK) at 37 °C. The samples were contained within 1 cm path length optical cells, and buffer solution was used as a control. The change in turbidity was defined as $\Delta\tau = \tau_{\mathrm{pectin}} - \tau_{\mathrm{buffer}}$. Triplicate measurements of turbidity were carried out on each sample.

The electrical charge (ζ-potential) of the solutions was determined using a particle microelectrophoresis instrument (Zetasizer NanoSeries, Malvern Instruments Ltd., Worcestershire, UK). Solutions were injected into the measurement chamber and equilibrated for 120 s, and then the ζ-potential was determined by measuring the direction and velocity that the particles moved in the applied electric field. Each individual ζ-potential measurement was calculated from the average of 20 continuous readings made per sample. The ζ-potential was recorded at each pH after 60 s of equilibrium.

The microstructure of the solutions was characterized by optical microscopy. An optical microscope (C1 Digital Eclipse, Niko, Tokyo, Japan) with a 60× objective lens was used to capture images of the solutions. Solutions were gently stirred to form a homogeneous mixture without introducing any air bubbles. A small aliquot of the solutions (5 μL) was then transferred to a glass microscope slide and covered with a glass coverslip. The coverslip was fixed to the slide using nail polish to avoid evaporation. A small amount of immersion oil (type A, Nikon, Melville, NY, USA) was placed on the top of the coverslip. All optical images were taken using a digital camera and then characterized using the instrument software (EZ CS1 version 3.8, Nikon).

*Isothermal Titration Calorimetry Measurements.* An ITC instrument (Microcalorimeter VP-ITC, MicroCal Inc., Northampton, MA, USA) was used to measure the enthalpy ($\Delta H$) resulting from titration of individual solutions of $CaCl_2$, NaCl, lipase, bile salts, and a mixture of all components (100% relative concentration) into either buffer solution (blank) or pectin solution. Twenty-nine 10 μL aliquots of individual solutions of 2.7% (w/w) bile salts, 1.1% (w/w) lipase, 55 mM calcium chloride, 545 mM sodium chloride, or a mixture of all components (100% relative concentration) were injected sequentially into a 1450 μL titration cell initially containing either buffer (5 mM phosphate buffer, pH 7) or 0.9% (w/w) pectin solutions. The range of concentrations of pectin and gastrointestinal components used was selected to approximately mimic the concentrations in the small intestinal phase of the gastrointestinal tract. Each injection lasted 24 s, and there was an interval of 240 s between successive injections. The temperature of the solution in the titration cell was 37 °C, and the solution was stirred at a speed of 315 rpm throughout the experiments. Triplicate measurements of enthalpy profiles were carried out on each sample, and they were reproducible to better than 5%.

**Data Analysis.** All measurements were performed at least three times using freshly prepared samples. Averages and standard deviations were calculated from these triplet measurements.

## RESULTS AND DISCUSSION

**Properties of Initial Emulsion−Pectin Mixtures.** Initially, the properties of the initial emulsions used to prepare the emulsion−pectin mixtures were characterized (5 mM

phosphate buffer, pH 7). The initial emulsions had a relatively small mean particle diameter immediately after preparation ($d_{32}$ = 200 ± 10 nm), which did not change during the course of the experiments.[33] This can be attributed to the relatively strong steric repulsion between the nonionic surfactant-coated lipid droplets resulting from the polyoxyethylene headgroups on the Tween 80 molecules.[34] The lipid droplets initially had a small negative charge ($\zeta$ = −5.8 ± 0.2 mV), even though they were stabilized by a nonionic surfactant, which can be attributed to anionic impurities in the oil or surfactant ingredients (such as free fatty acids) or to preferential adsorption of hydroxyl ions from water ($OH^-$).[35,36] The droplets in the initial emulsions containing no pectin were stable to creaming throughout the experimental time frame (Figure 1), which is due to the fact that the droplets were small and did not associate with each other.[37]

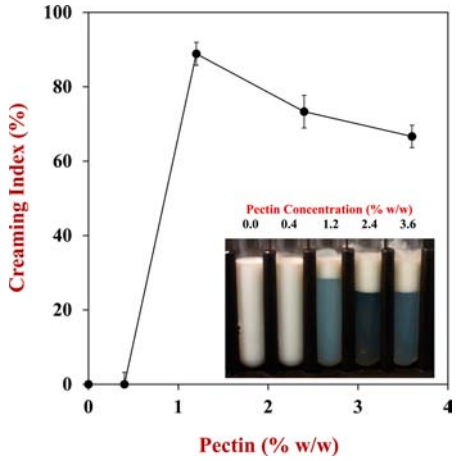

**Figure 1.** Influence of pectin concentration on creaming stability of 2% (w/w) corn oil-in-water emulsions stabilized with 0.2% (w/w) Tween 80 before the digestion process.

Emulsions containing relatively low levels of added pectin (≤0.4% w/w) were still observed to be stable to gravitational separation; that is, they maintained a uniform white appearance (Figure 1). They also had good stability to droplet aggregation with the mean particle diameter ($d_{32}$) increasing only from around 200 to 210 nm when the pectin concentration was increased from 0 to 0.2% (w/w). However, emulsions containing higher levels of pectin clearly separated into a creamed layer and a serum layer, indicating that the droplets moved upward due to gravity. The origin of this effect is depletion flocculation induced by the presence of nonadsorbed pectin molecules within the aqueous phase.[24,38] There was an appreciable increase in mean particle diameter in the samples in which depletion flocculation occurred, for example, $d_{32}$ = 350 nm in the sample initially containing 2.4% (w/w) pectin. This effect can be attributed to the fact that the droplets were pushed together in the flocs due to the depletion attraction, which promoted coalescence. Pectin molecules should not be attracted to the surfaces of the nonionic surfactant-coated lipid droplets because of electrostatic and steric repulsion effects (the carboxyl groups of pectin are completely dissociated at pH 7 because its $pK_a$ is ∼3.5). There is therefore a narrow region around each lipid droplet (approximately equal to the radius of hydration of the pectin molecules) from which the pectin molecules are excluded.[39] Consequently, there is a pectin and water concentration gradient between this exclusion zone and the surrounding bulk aqueous phase, which leads to an osmotic pressure. This osmotic pressure generates an attraction between the lipid droplets (depletion force) because when they come into close contact, the volume of the thermodynamically unfavorable exclusion zone is reduced.[25] At low pectin concentrations, the osmotic attraction is not large enough to overcome the various repulsive forces in the system (e.g., steric and electrostatic), and so the emulsion remains stable to droplet aggregation. However, once a critical pectin concentration is exceeded (∼0.5% w/w), the attractive forces exceed the repulsive forces and droplet flocculation occurs.[24] It should be noted that the main thermodynamic driving force for depletion flocculation is entropy.[40,41] The reason that the thickness of the creamed layer increases (CI decreases) as the pectin concentration increases above the critical flocculation concentration (Figure 1) is that the depletion attraction is higher and so the droplets are held more strongly into a particle gel network.[42] In summary, these measurements showed that the degree of droplet flocculation in the initial emulsion−pectin mixtures depended on the amount of pectin present in the system.

**Influence of Pectin on Lipid Digestion.** In a recent study, we examined the influence of pectin addition on the

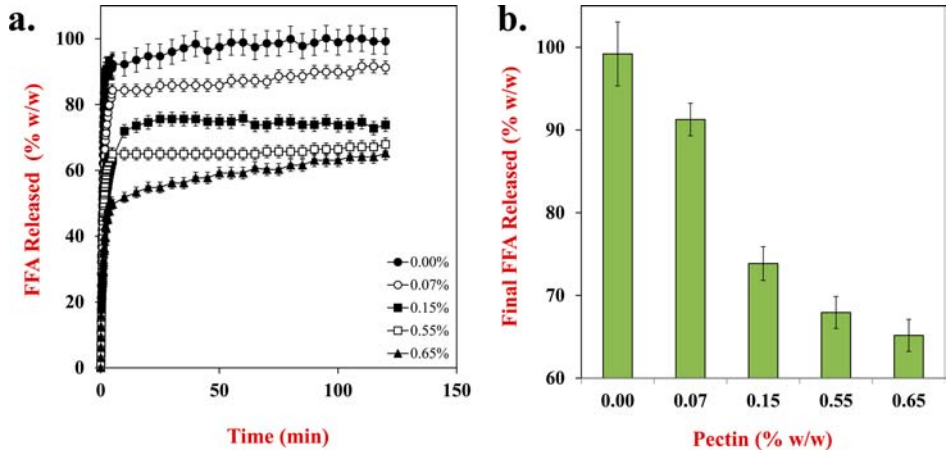

**Figure 2.** Influence of pectin concentration on free fatty acids (FFA) released during lipid digestion process (pH stat): (a) kinetics; (b) FFA released after 2 h. Pectin concentrations refer to those present in the intestinal phase.

gastrointestinal fate of emulisified lipids.[33] This study showed that pectin influenced the aggregation state of the lipid droplets in different regions of the simulated gastrointestinal tract (mouth, stomach, and small intestine). It also showed that pectin addition reduced the rate and extent of lipase-catalyzed lipid digestion in the small intestine phase. In the current study, the same pH-stat method was used to measure the influence of pectin on lipid digestion so that we could directly compare these results with the studies of pectin interactions with various gastrointestinal components using the same constituents.

In general, the amount of FFAs produced increased rapidly during the first few minutes of digestion and then increased more slowly at longer times, until a relatively constant value was reached after 25 min of digestion (Figure 2a). The final amount of FFAs produced at the end of the 2 h digestion period decreased with increasing pectin concentration (Figure 2b), which is in good agreement with our earlier study.[33]

The ability of pectin to decrease the rate and extent of lipid digestion in corn oil-in-water emulsions could be due to several physicochemical and physiological mechanisms. Pectin may have interacted with calcium ions and formed a highly viscous solution or gel network that impeded the diffusion of GIT components (such as lipase or bile salts), thereby retarding the lipid digestion process.[43−45] Pectin−calcium interactions may also have inhibited lipid digestion due to the important role that calcium ions play in removing FFAs from lipid droplet surfaces.[46] Calcium ions normally form insoluble soaps with long-chain FFAs that help remove the FFAs from the lipid droplet surfaces and thereby allow the lipase to keep working.[47] If the calcium ions are tightly bound to pectin molecules, then the FFAs may accumulate at the lipid droplet surfaces, thereby inhibiting further digestion. Pectin may also have bound to bile salts or phospholipids and so prevented them from adsorbing to lipid droplet surfaces or from solubilizing lipid digestion products.[10,18,44] The solubilization of long-chain FFAs in mixed micelles is another important means of removing them from the lipid droplet surfaces and thereby allowing lipase to keep functioning.[34] The adsorption of bile salts and phospholipids to lipid droplet surfaces often facilitates the subsequent adsorption of lipase molecules. Pectin may also be able to alter lipid digestion by interacting directly with lipase molecules.[21,48] Finally, the presence of pectin in the system may alter the aggregation state of the lipid droplets through either depletion or bridging flocculation.[49] The digestion of highly flocculated lipid droplets is often less than that of nonflocculated ones because the lipase molecules have to diffuse through the flocs before they can reach the lipid droplets in their interiors.[23,50] Clearly, the potential influence of pectin on the lipid digestion process within the GIT is complex because pectin is able to interact with many constituents within the GIT fluids.

The purpose of the current study was to provide further insights into the potential origin of these effects by studying the interactions between pectin and specific gastrointestinal components.

**Interactions of Pectin with Mixed Gastrointestinal Components.** In this series of experiments, we used ITC, electrophoresis, turbidity, and microstructure measurements to examine the interactions of pectin with a solution containing a mixture of all the major GIT components: sodium, calcium, bile salts, and lipase. The microstructure of the emulsion−pectin mixtures changed appreciably after exposure to the mixed gastrointestinal components (Figure 3). In the absence of pectin (control), the individual lipid droplets were too small to be observed by optical microscopy, but confocal microscopy images have shown that they are evenly distributed throughout the system.[33] After digestion, there were clearly some large aggregates in the control samples, which may have been lipid digestion products or remnants from the various GIT components (such as calcium, sodium, bile salts, and lipase). In the presence of pectin, the lipid droplets were trapped within large clusters prior to digestion, which can be attributed to depletion flocculation induced by nonadsorbed pectin molecules (Figure 3).[25] After digestion, there were a relatively high number of large aggregates (undigested lipid droplets) remaining in the samples containing pectin, which could have been due to interactions of the pectin molecules with various components in the simulated GIT fluids.

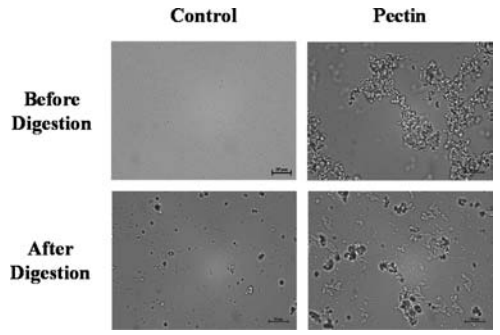

**Figure 3.** Influence of pectin on the microstructure (observed by optical microscopy) of emulsions before (initial phase) and after (intestinal phase) of lipid digestion. The initial emulsions contained 2% (w/w) corn oil, 2% (w/w) Tween 80, and 0 or 2.4% (w/w) pectin. The scale bar corresponds to 20 $\mu$m.

Turbidity ($\Delta\tau$), $\zeta$-potential, and enthalpy change ($\Delta H$) were measured when increasing amounts of mixed GIT fluids (0 to 100% of mixture) were titrated into a pectin (0.9% w/w) solution at pH 7 (Figure 4). The 100% GIT fluids contained the levels of the NaCl, $CaCl_2$, bile salts, and lipase in the final simulated small intestinal fluids. There was a progressive increase in the turbidity when the amount of mixed GIT fluids titrated into the pectin solution increased (Figure 4a). The $\zeta$-potential of the mixed system moved from highly negative (−19 mV) to less negative (−2 mV) as increasing amounts of GIT fluids were added (Figure 4a), which may have occurred due to electrostatic screening effects induced by the presence of salts or due to binding of cations in the GIT fluids to anionic pectin molecules.[51] There was also an appreciable difference in the enthalpy profiles of samples with either buffer or pectin solutions (Figure 4b). In the absence of pectin, the enthalpy change was relatively low and may be attributed to heat of dilution effects associated with the various molecules and/or particles moving further apart when the GIT fluids were injected into the reaction cell.[22,27,30] In the presence of pectin, there was a large exothermic enthalpy change when the first few aliquots of the mixed GIT fluids were injected into the reaction cell containing the pectin solution. The enthalpy change became progressively less exothermic when 0−20% of the GIT fluids was added, until it eventually reached a relatively constant endothermic value at higher GIT levels (∼40%). These results suggest that the pectin molecules interacted with some of the components in the GIT fluids, possibly through electrostatic interactions, and formed aggregates that were large enough to scatter light strongly.

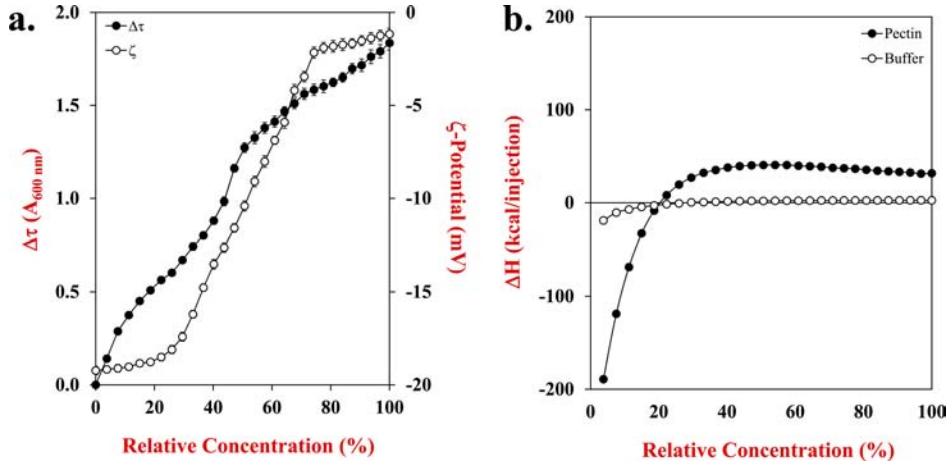

**Figure 4.** Influence of relative concentration (0−100%) of simulated gastrointestinal fluids on (a) optical turbidity ($\Delta\tau = A_{600\ nm}$) and $\zeta$-potential and (b) interaction enthalpy ($\Delta H$) of solutions containing either buffer solution or an initial concentration of 0.9% (w/w) pectin. The initial simulated gastrointestinal fluids (100%) contained 0.45% (w/w) bile salts, 0.18% (w/w) lipase, 9 mM $CaCl_2$, and 91 mM NaCl. Optical turbidity ($\Delta\tau$) was defined as $\Delta\tau = \tau_{pectin} - \tau_{buffer}$.

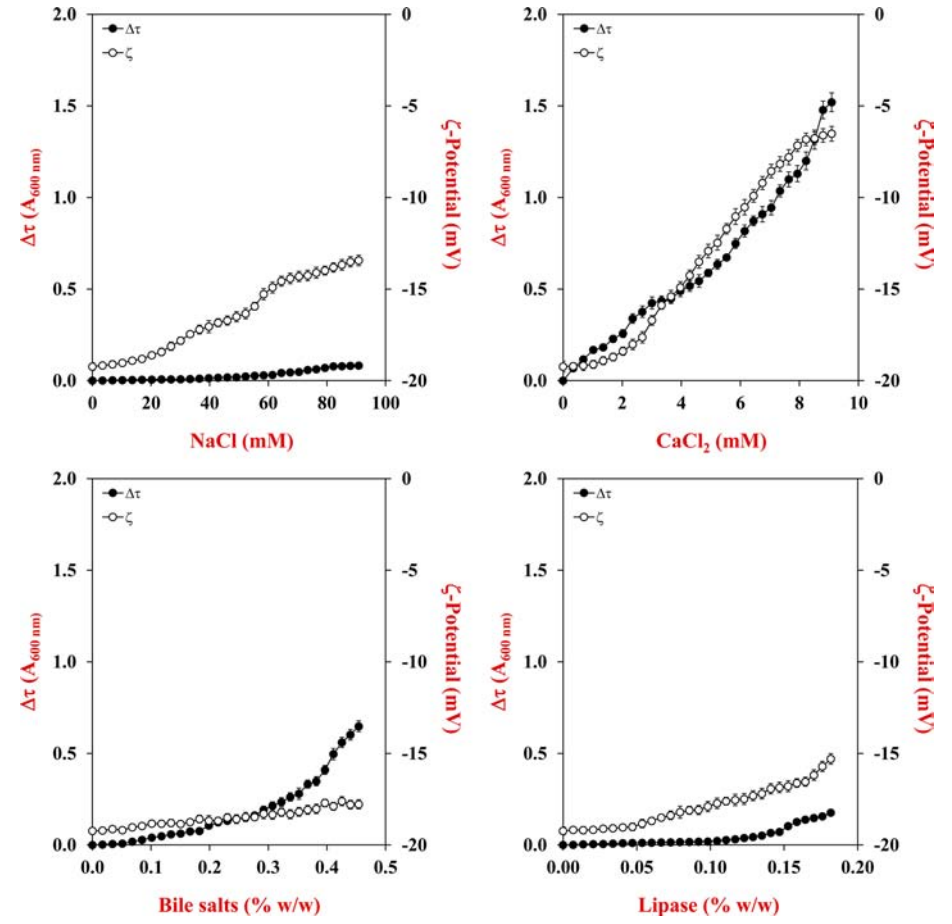

**Figure 5.** Influence of the concentrations of NaCl, $CaCl_2$, bile salts, and lipase on optical turbidity ($\Delta\tau = A_{600\ nm}$) and $\zeta$-potential of solutions containing an initial concentration of 0.9% (w/w) pectin.

**Interactions of Pectin with Specific Gastrointestinal Components.** In this series of experiments, ITC, electrophoresis, turbidity, and microstructure measurements were used to characterize the interactions of pectin with specific GIT components (NaCl, $CaCl_2$, bile salts, or lipase). Measurements were made as increasing amounts of GIT components were individually added to a pectin solution (0.9% w/w) (Figure 5). In addition, the turbidities and $\zeta$-potentials reached at the end of these titrations were reported so that different samples could be compared more easily (Figure 6).

*NaCl.* Addition of increasing amounts of NaCl to the pectin solutions caused an appreciable decrease in the magnitude of the $\zeta$-potential of the pectin solutions (Figure 5, NaCl), which can be attributed to electrostatic screening effects, that is,

dx.doi.org/10.1021/jf504829h | J. Agric. Food Chem. 2014, 62, 12620−12630

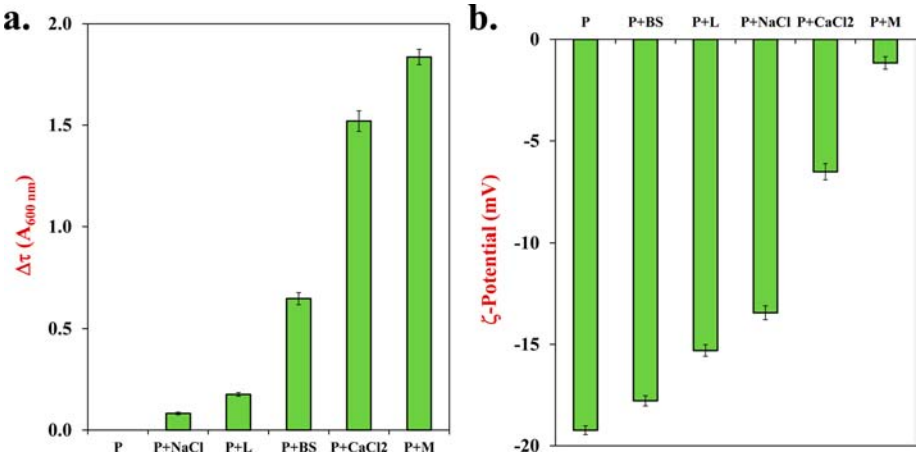

**Figure 6.** Influence of 91 mM NaCl, 9 mM $CaCl_2$, 0.45% (w/w) bile salts (BS), 0.18% (w/w) lipase (L), and a mixture of all components (M, 100% relative concentrations) on optical turbidity ($\Delta\tau = A_{600\ nm}$) (a) and $\zeta$-potential (b) of solutions containing an initial concentration of 0.9% (w/w) pectin (P).

accumulation of sodium ions around the negative groups on the pectin molecules.[51] There was no evidence of an increase in aggregate formation within the microstructure images (Figure 8, NaCl), and there was little change in the general appearance (Figure 7, NaCl) and optical turbidity (Figure 5, NaCl) of these

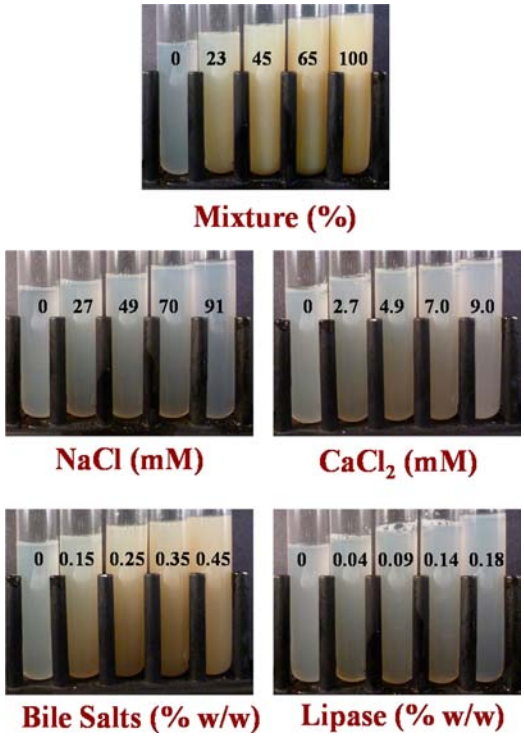

**Figure 7.** Influence of the concentrations of NaCl, $CaCl_2$, bile salts, lipase, and a mixture of all components (% relative concentrations) on the turbidity of solutions containing an initial concentration of 0.9% (w/w) pectin.

samples upon NaCl addition. We did observe a slight increase in the turbidity at the highest NaCl levels used, which suggested that the NaCl may have caused a slight amount of pectin aggregation, presumably through screening of the electrostatic interactions.[52] The ITC measurements indicated that there was not a strong interaction ($\Delta H = -102$ kcal) between the pectin

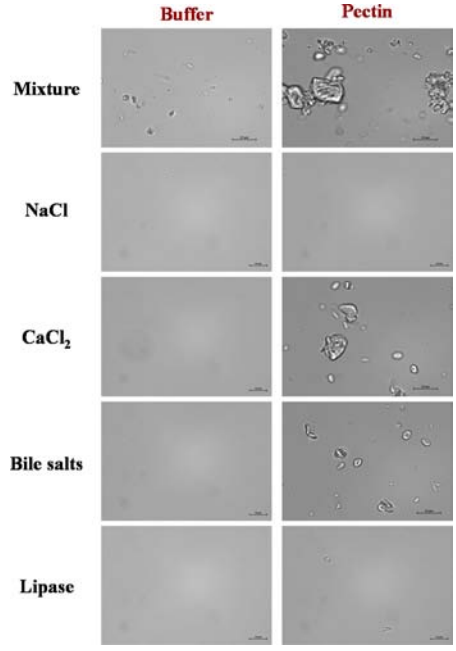

**Figure 8.** Influence of 91 mM NaCl, 9 mM $CaCl_2$, 0.45% (w/w) bile salts (BS), 0.18% (w/w) lipase (L), and a mixture of the previous components (100% relative concentrations) on the microstructure (observed by optical microscopy) of solutions prepared on either buffer solution or 0.9% (w/w) pectin. The scale bar corresponds to 20 $\mu$m.

and the NaCl (Figure 9, NaCl), because the enthalpy versus salt concentration profiles were fairly similar. Overall, these results suggest that pectin did not have a major interaction with the NaCl in the GIT fluids.

*$CaCl_2$.* Addition of $CaCl_2$ to the pectin solutions had a more pronounced influence on their physicochemical properties than NaCl addition. Addition of increasing amounts of $CaCl_2$ caused the $\zeta$-potential of the pectin solutions to go from around −19 mV to around −6 mV (Figure 5, $CaCl_2$), which can be attributed to electrostatic screening and ion binding effects.[51] Multivalent counterions are more effective at screening electrostatic interactions than monovalent ones, and they have a greater tendency to bind strongly to oppositely charged groups.[53] The change in the $\zeta$-potential with calcium addition

dx.doi.org/10.1021/jf504829h | J. Agric. Food Chem. 2014, 62, 12620−12630

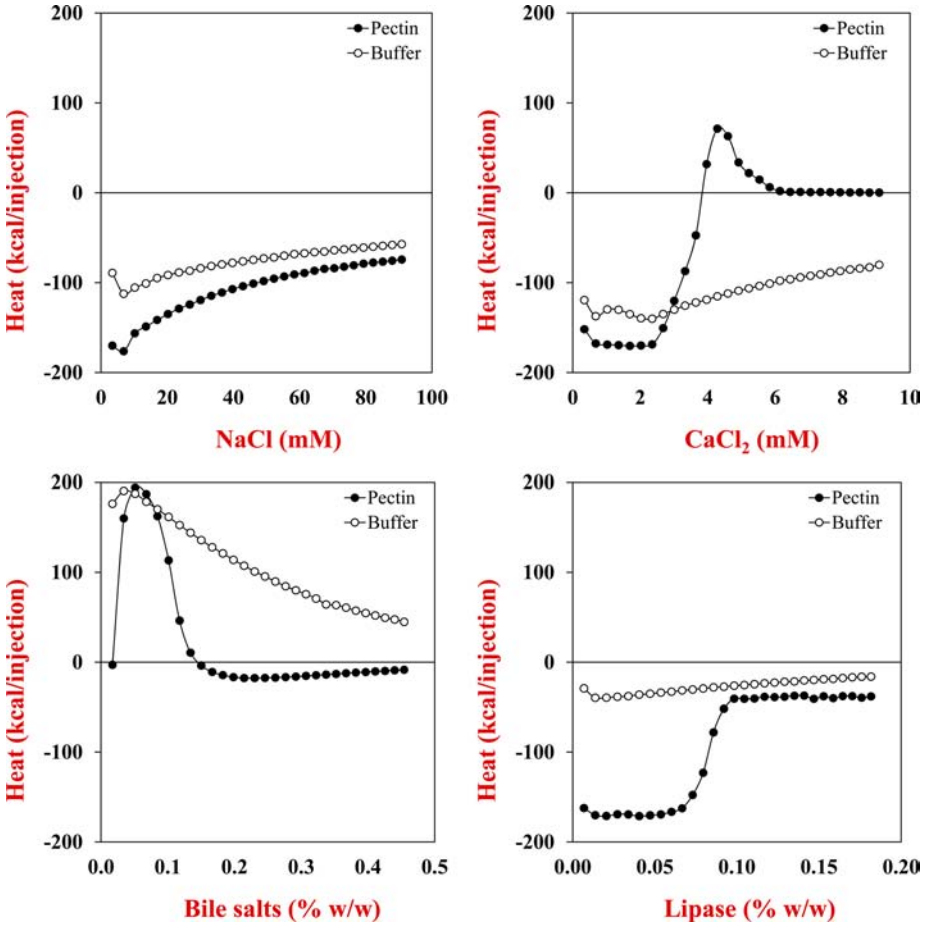

**Figure 9.** Influence of the concentrations of NaCl, $CaCl_2$, bile salts, and lipase on interaction enthalpy ($\Delta H$) of solutions containing either buffer solution or an initial concentration of 0.9% (w/w) pectin.

was fairly similar to that observed with the addition of the mixed GIT solution (Figure 6b), which suggests that calcium ions play an important role in determining the overall electrical interactions. The ITC measurements also indicated that there was a strong interaction ($\Delta H$ = −241 kcal) between the calcium ions and pectin (Figure 9, $CaCl_2$). When calcium ions were injected into buffer solution, there was an exothermic enthalpy change that decreased in magnitude with increasing $CaCl_2$ concentration, which can be attributed to heat of dilution effects.[22] However, when calcium ions were injected into pectin solution, there was initially a strong exothermic reaction (from 0 to 4 mM), then a relatively strong endothermic reaction (from 4 to 6 mM), followed by an enthalpy change close to zero after 6 mM $CaCl_2$ (Figure 9, $CaCl_2$). The shape of the ITC curve suggests that there may have been several events occurring sequentially, such as calcium binding, pectin conformational changes, and/or pectin aggregation. Nevertheless, it is not possible to determine the molecular origin of these events from ITC measurements alone because they provide only the overall enthalpy change.

The addition of calcium ions to the pectin solutions caused a large increase in their optical turbidity (Figures 5 ($CaCl_2$) and 6a), which can be attributed to the appearance of large aggregates, as observed within the optical microscopy images (Figures 7 and 8, $CaCl_2$). We postulate that these aggregates were microgels formed by pectin in the presence of calcium.[43,45] The calcium ions may have cross-linked the anionic pectin molecules through electrostatic bridging.[13] As mentioned earlier, the binding of calcium ions to pectin may be important for a number of reasons. First, pectin−calcium microgels may trap lipid droplets inside, thereby restricting the access of lipase to the lipid substrates.[23] Second, the formation of these electrostatic complexes may prevent the calcium ions from forming insoluble soaps with long-chain FFAs at the lipid droplet surfaces, thereby preventing the lipase from functioning properly.[47] In practice, there will be other types of salts in the gastrointestinal fluids that may alter the interactions of calcium with pectin through electrostatic screening or binding effects. It should be noted that there may have been some sodium or calcium present in the ingredients used in this study (such as pectin), and these ions could also contribute to the observed electrostatic interactions.

*Bile Salts.* The addition of bile salts to the pectin solutions had a limited influence on their physicochemical properties. Addition of increasing amounts of bile salts caused only a relatively small decrease in the negative charge on the pectin molecules (Figure 5, bile salts), which can probably be attributed to electrostatic screening effects.[7,9] There was an appreciable increase in the optical turbidity of the pectin solutions when bile salts were added (Figures 5 (bile salts) and 6a), and the solutions appeared visibly cloudier (Figure 7, bile salts). These effects can be attributed to the formation of large aggregates within the bile salts−pectin solutions as observed by optical microscopy (Figure 8, bile salts). The ITC measurements also indicated that the bile salts interacted with the pectin molecules. In the absence of pectin, there was a relatively

large endothermic enthalpy change ($\Delta H$ = 204 kcal), which progressively decreased with increasing bile salt concentration (Figure 9, bile salts). This effect may have been due to the breakdown of bile salt micelles within the reaction chamber, resulting in the exposure of a greater number of nonpolar groups to water.[54] In the presence of pectin, there was a large endothermic peak (from 0.05 to 0.15% w/w) followed by a value that was close to zero at higher bile salt concentrations (after 0.2% (w/w), Figure 9, bile salts). The large difference between the two curves suggests that there was an interaction between pectin and bile salts; for example, bile salt micelles may have bound to pectin molecules and/or promoted their aggregation.[55]

One might not expect a strong interaction between bile salts and pectin molecules because they are both usually negatively charged at neutral pH. However, bile salts may be able to interact with pectin molecules through hydrophobic interactions.[56] In general, the hydrophobic interactions of pectin with bile salts are known to increase with the degree of esterification of pectin molecules (by increasing its hydrophobicity) and the molecular weight (viscosity) of the pectin molecules.[20] These experiments clearly show that bile salts can interact with pectin molecules, which may have important implications for the effects of pectin on lipid digestion observed in Figure 2. If the bile salts form microgel particles with pectin, then they may not be available to absorb to the surfaces of the lipid droplets or to solubilize lipid digestion products, as discussed earlier. In addition, if any lipid droplets are trapped inside the microgels, then the rate of digestion may be decreased because the lipase molecules cannot easily reach the lipid droplet surfaces.[9]

*Lipase.* Finally, we examined the influence of lipase addition to the pectin solutions on their overall physicochemical properties. The addition of increasing amounts of lipase caused a slight change in the $\zeta$-potential of the pectin (Figure 5, lipase), which may have been due to some binding of lipase molecules to the pectin molecules. In addition, there was an appreciable difference between the ITC curves of the control and the system containing pectin (Figure 9, lipase), which also suggests that some form of interaction occurred ($\Delta H$ = −129 kcal).[21] In the absence of pectin, there was a relatively large exothermic change observed when the lipase solution was titrated into the buffer solution. This effect can probably be attributed to the heat of dilution associated with salts in the lipase solution. In the presence of pectin, there was a large exothermic change observed at low lipase levels (0−0.1 w/w %), followed by a much smaller exothermic change at higher lipase levels. The large difference between the curves in the presence and absence of pectin suggests that there was a strong interaction between the lipase and the pectin, although again the molecular origin of this effect cannot be established from the ITC measurements. There was a slight increase in the optical turbidity of the lipase−pectin solutions when high levels of lipase were added (Figure 5, lipase), but there was little change in their overall visual appearance (Figure 7, lipase) or their microstructure (Figure 8, lipase). These results suggest either that any interactions between the lipase and pectin did not lead to extensive aggregation or that the lipase−pectin complexes formed were soluble in buffer solution.

For simple systems involving the binding of a ligand to another molecule, ITC is a powerful tool for determining thermodynamic properties, such as the number and strength of binding sites and the nature of the enthalpy change ($\Delta H$) associated with the interaction (endothermic or exothermic). For more complex systems, the interpretation of ITC data is more difficult because many different molecular and physicochemical events contribute to the overall enthalpy changes, such as binding, conformation changes, and aggregation. Consequently, it is not possible to establish the precise nature of the different contributions to the measured ITC signal. Nevertheless, ITC measurements do still provide valuable information, because they indicate that one or more types of interaction are taking place between two molecules, and they show the range of concentrations over which these intearctions occur. Typically, ITC measurements should be combined with other techniques to provide a more detailed understanding of the nature of the interactions involved, such as chromatography, scattering, spectrometry, or spectroscopy methods.

The purpose of this study was to investigate the interaction of pectin molecules with some of the major constituents within gastrointestinal fluids, that is, NaCl, $CaCl_2$, bile salts, and lipase. Our measurements have shown that a number of these components interact strongly with pectin, which may have important implications for understanding the influence of pectin on lipid digestion. In particular, calcium ions and bile salts appear to promote the formation of pectin microgels that can lead to flocculation of lipid droplets in the gastrointestinal tract, decreasing the ability of emulsified lipids to be accessed by gastrointestinal lipases and thereby inhibiting digestion. If appreciable amounts of calcium and bile salts are trapped within these microgels, then they will not be able to remove long-chain fatty acids from lipid droplet surfaces, which would inhibit lipid digestion. In addition, if lipid droplets are trapped within pectin microgels, then it may be more difficult for lipase molecules to access the surfaces of the lipid substrate, again delaying lipid digestion. These results have important implications for the rational design of dietary fiber-based functional foods that may modulate lipid digestion within the gastrointestinal tract.

stage), stage III (pileus-growing stage), stage IV (gill-growing stage), and stage V (mature stage) (Figure 1).

**Figure 1.** *P.eryngii* fruiting bodies at five stages of maturity: SI (bud-forming stage), SII (stipe-growing stage), SIII (pileus-growing stage), SIV (gill-growing stage), and SV (mature stage).

**Proximate Analysis.** The proximate compositions of mushrooms, including moisture, crude ash, crude fiber, crude protein, and crude fat, were determined according to the methods of AOAC (1990, 15th).[18] The nitrogen factor used for crude protein calculation was 4.38.[19] The carbohydrate content was calculated by subtracting the other proximate compounds from 1 g of dry sample.

**Isolation of Crude Polysaccharide-Proteins, Crude Polysaccharides, and Ethanol Extracts.** The crude polysaccharide-protein fraction in the harvested *P. eryngii* fruiting body at five maturity stages was extracted as described previously.[20,21] Briefly, 500 g of fruiting body was blended with distilled water (500 mL) for 1 min and then continuously stirred for 2 h to obtain homogeneous slurry, respectively. The slurry was stored at 4 °C for 24 h and centrifuged at 5000*g* for 20 min to collect the supernatant. Solid ammonium sulfate was added to the supernatant to reach 80% saturation and then stored at 4 °C overnight. The precipitate collected by centrifugation (12000*g*, 20 min) was dissolved, dialyzed against distilled water, and freeze-dried to obtain the crude polysaccharide-protein extract.

For extracting polysaccharide fraction, the fruiting body was homogenized and mixed with distilled water (w/v 1:2) at 100 °C for 4 h. The supernatant was concentrated and precipitated with a final concentration of 80% ethanol for 12 h at 4 °C. The precipitation was collected by centrifugation (12000*g*, 10 min), washed twice with absolute ethanol, dialyzed (cutoff 3500 Da) against distilled water, and freeze-dried to obtain the crude polysaccharide extract.

For obtaining the ethanol extract of *P. eryngii*, the fruiting body (100 g) at five maturity stages was extracted with 1 L of 60% ethanol at 25 °C for 2 h with an ultrasonic bath (SB-5200DTS, Scientz Biotechnology, Ningbo, China) of 40 kHz. After filtration, ethanol was removed by a rotary evaporator (RE-2000B, Yarong Shenghua, Shanghai, China). The ethanol extract was then preserved at −20 °C before further use.

**Analysis of *P. eryngii* Extracts.** Protein content in the polysaccharide and polysaccharide-protein fractions was analyzed by Bradford Protein Assay Kit (Beyotime Institute of Biotechnology, Shanghai, China) using bovine serum albumin as the standard. Carbohydrate content in the polysaccharide and polysaccharide-protein fractions was determined by the phenol−sulfuric acid method using glucose as the standard.

Phenolic content in the ethanol extracts was estimated by a colorimetric assay based on procedures described by Adom et al.[22] Gallic acid was used to calculate the standard curve, and the results were expressed as milligrams of gallic acid equivalents (GAEs) per gram of extract. Flavonoid content was determined by a colorimetric method described by Jia et al.[23] with some modifications. The dried ethanol extract was dissolved in 2 mL of 60% ethanol and mixed with 0.5 mL of a 5% $NaNO_2$ solution. Then 0.5 mL of a 10% $Al(NO_3)_3$ solution was added, followed by adding 4 mL of 4% NaOH and 3 mL of 60% ethanol to make up the total volume to10.0 mL. After incubation at room temperature for 30 min, the absorbance of the reaction mixture was measured at 510 nm. The flavonoid content was calculated using a standard calibration of rutin solution and expressed as micrograms of rutin equivalents (RE) per gram of sample. The quantitative analysis of the total saponins in the ethanol extract was done by the vanillin−perchloric acid colorimetric method described by Wang et al.[24] Ginsenoside Rg 1 was used as a reference standard, and the content of total saponins was expressed as Ginsenoside Rg 1 equivalents (GR1 mg/g extract).

**Assay of Cytotoxical Activity.** The cytotoxical activity of each crude extract from *P. eryngii* fruiting body at five maturity stages was evaluated with the MTT colorimetric assay method.[25] The human gastric cancer cell line SGC-7901, human liver carcinoma cell line HepG-2, and normal human liver L-02 were obtained from American Tissue Culture Collection (ATCC, Rockville, MD, USA) and Shanghai Cell Biology Institute (Shanghai, China). The cells were maintained in 5% $CO_2$ at 37 °C in RPMI-1640 (Gibco, NY, USA) containing 10% fetal bovine serum (FBS) supplemented with 100 U/mL penicillin and 100 $\mu$g/mL streptomycin. Cells ($5 \times 10^5$) in their exponential growth phase were seeded into each well of a 96-well plate and incubated for 24 h before addition of the samples with the different concentration. Incubation was carried out for another 24/48 h, and MTT was added to cells for another 4 h to produce formazan. The absorbance of each well was read at 490 nm in the microplate reader (Multiskan GO, Thermo Labsystems, Beverly, MA, USA) after addition of 150 $\mu$L of dimethyl sulfoxide (DMSO) and shaking for 10 min. The cell viability was used for expressing the cytotoxicity of samples and calculated as follows:

$$\text{cell viability (\%) of control} = \mathrm{OD}_{490\mathrm{nm}}(\text{sample})/\mathrm{OD}_{490\mathrm{nm}}(\text{control}) \times 100.$$

**Amino Acid Composition and Monosaccharide Composition of Polysaccharide-Protein Fractions.** Determination of amino acid composition followed the description by Su et al.[26] Briefly, each polysaccharide-protein fraction was subjected to hydrolysis under vacuum in 6 M HCl at 110 °C for 24 h. The hydrolysate was analyzed with a Sykam S433D/S433 automatic amino acid analyzer (Sykam, Munich, Germany).

Monosaccharide compositions and their ratios were determined by a previously described method.[21] Briefly, 30 mg of each polysaccharide-protein fraction was hydrolyzed, filtered, and applied to the monosaccharide composition in a 6890N GC (Agilent Technologies, Santa Clara, CA, USA) with capillary column (30 m × 0.32 mm) with L-rhamnose, D-arabinose, D-mannose, D-galactose, and D-glucose as the standards.

**SDS-PAGE and Native-PAGE of polysaccharide-protein fractions.** SDS-PAGE with a 12% resolving gel was used for qualitatively analyzing the protein changes in polysaccharide-protein fractions at each stage.[27] The main components and primary molecular mass determination were estimated by comparing the electrophoresis mobility with those of standard molecular weight markers. Native-PAGE with a 12% resolving gel and bromophenol blue as the tracking dye was further applied to estimate the purity.[28]

**Further Purification of the Polysaccharide-Protein Fractions.** The crude polysaccharide-protein fraction was applied to a column (2.5 × 25 cm) DEAE-Sepharose Fast Flow anionic resin (GE Healthcare, Uppsala, Sweden) equilibrated with 10 mM PBS buffer (pH 7.4). Then the column was eluted with a discontinuous gradient of PBS, 0.1, 0.3, and 0.5 M NaCl in PBS, and the eluate was collected with fraction tubes (8 mL per tube). The carbohydrate content of the eluates was determined by measuring the absorption at 490 nm using the phenol−sulfuric acid method. The protein concentration was determined spectrophotometrically at 280 nm. Four fractions, PEG-0, PEG-1, PEG-3, and PEG-5, were collected, dialyzed, and freeze-dried for analyzing the cytotoxical activity with the MTT assay.

Table 1. Proximate Composition of *P. eryngii* Fruiting Body Harvested at Five Maturity Stages[a]

| component | content (%) | | | | |
|---|---|---|---|---|---|
| | stage I | stage II | stage III | stage IV | stage V |
| moisture | 90.80 ± 0.35 | 92.18 ± 0.26 | 90.13 ± 0.35 | 90.49 ± 0.57 | 93.09 ± 0.69 |
| dry matter | 9.20 ± 0.35 | 7.82 ± 0.26 | 9.87 ± 0.35 | 9.51 ± 0.57 | 6.91 ± 0.69 |
| carbohydrate | 50.55 ± 0.45 | 50.95 ± 0.57 | 51.06 ± 0.30 | 51.49 ± 0.21 | 51.71 ± 0.51 |
| crude ash | 7.50 ± 0.34 | 7.78 ± 0.65 | 6.51 ± 0.18 | 6.10 ± 0.14 | 6.77 ± 0.21 |
| crude fat | 3.55 ± 0.18 | 3.56 ± 0.01 | 3.21 ± 0.412 | 2.81 ± 0.51 | 2.62 ± 0.71 |
| crude fiber | 20.70 ± 0.82 | 20.40 ± 0.23 | 21.32 ± 0.20 | 20.80 ± 0.03 | 19.79 ± 0.18 |
| crude protein | 17.70 ± 0.42 | 17.31 ± 1.09 | 17.90 ± 0.31 | 18.80 ± 0.14 | 19.11 ± 0.40 |

[a]Moisture and dry matter are presented based on fresh weight; other data are presented based on dry weight. Each value is expressed as mean ± SD ($n$ = 3).

Table 2. Carbohydrate and Protein Content of Both Polysaccharide-Protein Fractions and Polysaccharide Fractions[a]

| component (%) | crude polysaccharide-proteins | | | crude polysaccharides | | |
|---|---|---|---|---|---|---|
| | yield | carbohydrate content | protein content | yield | carbohydrate content | protein content |
| stage I | 0.89 ± 0.03 | 3.37 ± 0.06 | 39.12 ± 0.11 | 3.12 ± 0.04 | 75.33 ± 0.32 | 12.13 ± 0.19 |
| stage II | 1.84 ± 0.06 | 6.70 ± 0.07 | 42.51 ± 0.13 | 3.68 ± 0.06 | 60.45 ± 0.24 | 21.36 ± 0.08 |
| stage III | 1.56 ± 0.05 | 3.94 ± 0.05 | 39.90 ± 0.09 | 3.43 ± 0.05 | 86.11 ± 0.38 | 13.51 ± 0.07 |
| stage IV | 1.55 ± 0.08 | 4.89 ± 0.04 | 45.36 ± 0.05 | 3.47 ± 0.07 | 88.06 ± 0.21 | 1.67 ± 0.05 |
| stage V | 1.56 ± 0.05 | 4.28 ± 0.04 | 55.66 ± 0.08 | 4.85 ± 0.05 | 57.07 ± 0.26 | 11.21 ± 0.17 |

[a]Each value is expressed as mean ± SD ($n$ = 3).

**In-Gel Tryptic Digestion of Polysaccharide-Protein Fraction PEG-1.** According to the MTT assay results, polysaccharide-protein fraction PEG-1 had the highest cytotoxical activity compared to the other three fractions. The in-gel tryptic digestion was conducted for mass spectrometric characterization of PEG-1.[29] The bands of PEG-1 in SDS-PAGE were excised, rinsed with double distilled water, and destained with 200 μL of destaining solution (25 mM $NH_4HCO_3$, 50% $CH_3CN$), respectively. Then the gel slices were vacuum-dried and incubated with a trypsin solution at 37 °C overnight. After the reaction cooled down to room temperature, the supernatant was collected and saved. The gel was subsequently extracted twice with 20 μL of 0.1% TFA in 50% ACN by gentle mixing and incubation at 60 °C for 10 min. Both the supernatant and extract solution were freeze-dried for further MALDI-TOF analysis.

**Mass Spectrometry and Protein Identification.** MALDI-TOF mass spectrometric analysis was performed on AB 5800 MALDI-TOF (AB SCIEX, Foster City, CA, USA) following a previously described method.[21] Spectra were accumulated until a satisfactory S/N had been obtained. The peptide mass fingerprinting of glycoprotein was acquired and processed using Mass-Lynx V4.1 software (Waters, Milford, MA, USA) and was converted to PKL files by the Protein-Lynx 2.2.5 software (Waters, Milford, MA, USA). The PKL files were analyzed using the MASCOT search engine. The search parameters were defined as follows: database, NCBInr; taxonomy, *Homo sapiens*; enzyme, trypsin; and allowance of one missed cleavage.

**Statistical Analysis.** Each experiment was repeated three times using duplicate samples. The results were expressed as means ± standard deviations. Statistical comparisons were made by one-way analysis of variance (ANOVA), followed by Duncan's multiple-comparison test. Differences were considered significant when the $p$-values were <0.05.

## RESULTS AND DISCUSSION

**Effect of Maturity Stage on Proximate Compositions in *P. eryngii* Fruiting Body.** The moisture contents of *P. eryngii* were in the range of 90.13−93.09% based on fresh weight (Table 1). Based on dry weight, other proximate compositions were listed in the following order: carbohydrate (50.55−51.71%) > crude fiber (19.79−21.32%) > crude protein (17.31−19.11%) > crude ash (6.10−7.78%) > crude fat (2.62−3.56%). It could be concluded that *P. eryngii* had high contents of carbohydrate, fiber, and protein and was low in ash and fat, which was in agreement with the previous study by Li et al.[30]

The carbohydrate and protein contents in *P. eryngii* slightly increased with the development of fruiting body maturity from stage I to stage V, respectively, while fat content decreased. Different phenomena have been observed: the maturity of *Agaricus bisporus* increased the carbohydrate and fat contents and decreased the protein content from 27.0% to 21.7%.[31] Interestingly, the maturating processes of *L. deliciosus* and *L. piperatus* fruiting bodies decreased the carbohydrate contents and increased protein contents.[32]

The fiber content of *P. eryngii* reached the highest value of 21.32% at stage III and declined to 19.79% at stage V, which showed a similar trend with *Agaricus bisporus* with a peaked fiber content of 23.3% at stage III.[31]

**Effect of Maturity Stage on Carbohydrate and Protein Contents in Polysaccharide and Polysaccharide-Protein Fractions.** The *P. eryngii* polysaccharide and polysaccharide-protein fractions at each stage were obtained by water extraction at 100 or 4 °C followed by ethanol or $(NH_4)_2SO_4$ precipitation. The carbohydrate and protein contents in these polysaccharide and polysaccharide-protein fractions were determined and are summarized in Table 2.

The polysaccharide fractions at each stage were carbohydrate-predominate with high carbohydrate contents ranging from 57.07% to 88.06% and low protein contents from 1.67% to 21.36%. The maturity development from stage I to stage IV led to the increase of carbohydrate content and decrease of protein content. Overgrowth appeared to decrease the carbohydrate content to 57.07% at stage V.

The polysaccharide-protein fractions extracted at 4 °C with $(NH_4)_2SO_4$ precipitation showed the protein-predominate characteristic with the increased high protein content from 39.12% to 55.66% with the maturation. The maturity development showed the fluctuation of carbohydrate content in the polysaccharide-protein fractions from 3.37% to 6.70%.

**Effect of Maturity Stage on Phenols, Flavonoids, and Saponin Contents in Ethanol Extracts of *P. eryngii*.** Table

Table 3. Phenol, Flavonoid, and Saponin Contents in Ethanol Extracts of *P. eryngii* at Five Maturity Stages[a]

| contents(mg/g) | stage I | stage II | stage III | stage IV | stage V |
|---|---|---|---|---|---|
| phenols | 19.11 ± 0.11 | 20.70 ± 0.05 | 18.72 ± 0.09 | 15.15 ± 0.13 | 14.85 ± 0.08 |
| flavonoids | 24.77 ± 0.09 | 22.47 ± 0.03 | 21.08 ± 0.06 | 20.16 ± 0.07 | 20.62 ± 0.09 |
| saponins | 7.41 ± 0.06 | 7.75 ± 0.08 | 6.71 ± 0.05 | 6.83 ± 0.08 | 6.13 ± 0.06 |

[a]Each value is expressed as mean ± SD ($n$ = 3).

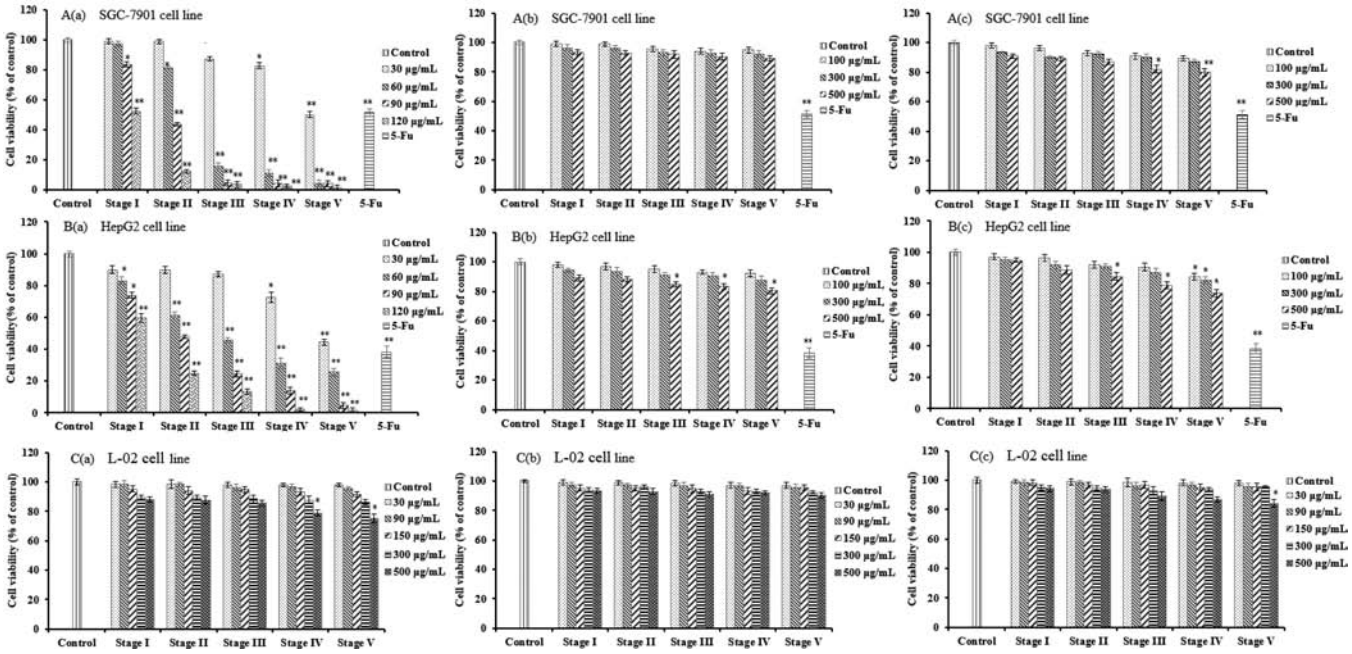

**Figure 2.** (A) Effect of crude polysaccharide-proteins (A(a)), crude polysaccharides (A(b)), and ethanol extracts (A(c)) from *P. eryngii* fruiting bodies of five maturity stages on the cell viability of SGC-7901 cells incubated with at 37 °C for 24 h and 5-Fu (20 μg/mL) as the positive control. (B) Effect of crude polysaccharide-proteins (B(a)), crude polysaccharides (B(b)), and ethanol extracts (B(c)) from *P. eryngii* fruiting bodies of five maturity stages on the cell viability of HepG-2 cells incubated with at 37 °C for 24 h and 5-Fu (20 μg/mL) as the positive control. (C) Toxicity of crude polysaccharide-proteins (C(a)), crude polysaccharides (C(b)), and ethanol extracts (C(c)) from *P. eryngii* fruiting bodies of five maturity stages on normal human liver L-02 cells. Data are presented as mean ± SD of three independent experiments. *$P$ < 0.05 compared to control group, **$P$ < 0.01 compared to control group.

3 presents the phenol, flavonoid, and saponin contents in ethanol extracts from 5-stage *P. eryngii* fruiting bodies. The early stages (stage I and II) gave the higher contents of phenol, flavonoid, and saponin. From stage III, all the contents of phenol, flavonoid, and saponin began to slightly decrease with the prolonged maturity stage. These phenomena were in agreement with the results with the low content of bioactive compounds such as total phenol and flavonoid at the mature stage (cap diameter higher than 7 cm) compared to those in immature (cap diameter less than 4.5 cm) *L. piperatus* fruiting bodies.[33]

**Effect of Maturity Stage on the Cytotoxical Activity of Polysaccharide and Polysaccharide-Protein Fractions and Ethanol Extracts of *P. eryngii*.** Figure 2 presents the antiproliferative effect on SGC-7901 and HepG-2 cells of polysaccharide fractions, polysaccharide-protein fractions, and ethanol extracts at five *P. eryngii* fruiting body maturity stages. The polysaccharide fraction (Figure 2A(b) and Figure 2B(b)) of *P. eryngii* fruiting body seemed to have a slight inhibition effect on SGC-7901 cells and HepG-2 cells with the cell viability of over 80.39% at concentration even up to 500 μg/mL. Generally, high purity or content of bioactive polysaccharides will benefit the antitumor activity in vitro with lower dose. For example, the purified polysaccharide PEPE-3 from *P. eryngii* residue showed highest growth-inhibitory activity to HepG-2 cells with the cell viability of 27.56% at 400 μg/mL.[34] However, most mushroom polysaccharides could not directly kill the tumor cells in vitro while exerting their antitumor action through activating the host immune systems.[20,35] The commercial D-fraction from the fruiting body of *Grifola frondosa* was a β-1,6-glucan exhibiting its antitumor activity via increase of cytokine level in NK cells, T cells, and spleen/lymph node cells.[36−38] The purified polysaccharide from *P. eryngii* fruiting body also acted as the potent immunomodulator to activate the immune response in tumor-bearing mice.[39]

The ethanol extract showed weak inhibition to SGC-7901 and HepG-2 cells with cell viability of 79.86% and 73.79%, respectively, even at a concentration of 500 μg/mL. Similar results were also found that the *Pleurotus ferulae* ethanol extracts had the higher cell viability of 67.94% at 800 μg/mL after 48-h treatment.[40]

Compared to polysaccharide fraction and ethanol extract, all the polysaccharide-protein fractions at five stages possessed higher cytotoxical activity against SGC-7901 and HepG-2 cells with a cell viability of less than 52.26% and 61.05% at a concentration of 120 μg/mL, respectively. These results correspond to the existing evidence that polysaccharide-protein complexes could kill the tumor cells directly in vitro by arresting the cell cycle and/or inducing the apoptosis of tumor

[a]Each value is expressed as mean ± SD ($n$ = 3). [b]Not determined.

cells.[41] The typical examples included that the polysaccharide-protein HM-3A from mushroom *Hypsizygus marmoreus* and glycoprotein PCP-3A from golden oyster mushroom *Pleurotus citrinopileatus* showed a human leukemic U937 cell growth inhibition rate of over 74.6% at 100 μg/mL and 97.7% at 50 μg/mL, respectively.[42,43]

Interestingly, the polysaccharide-protein at the same concentration had increased cytotoxical activity with growing maturity of *P. eryngii* fruiting body. For example, after the treatment of polysaccharide-proteins from stage I to V at a concentration of 90 μg/mL, the SGC-7901 and HepG-2 cell viabilities decreased from 83.76% to 3.88% and 75.37% to 4.7%, respectively, which also motivated us to further elucidate the structural and maturity stage-specific features of the *P. eryngii* polysaccharide-protein fractions.

Toxicity of polysaccharide-protein fraction, polysaccharide fraction, and ethanol extracts from *P. eryngii* fruiting bodies of five maturity stages was evaluated by using normal human liver L-02 cells. As shown in Figure 2C, there was no significance between the polysaccharide fraction treated groups with control ($P > 0.05$). As for the polysaccharide-protein fractions, samples at mature stage (IV, V) showed significant inhibition of L-02 cell growth at over 500 μg/mL ($P < 0.05$), which indicated that the polysaccharide-protein fractions from *P. eryngii* fruiting bodies were relatively safe to the normal human liver L-02 cells.

**Effect of Maturity Stage on Amino Acid Composition in *P. eryngii* Polysaccharide-Proteins.** Table 4 shows the amino acid compositions/contents in the polysaccharide-protein fractions at stages I–V. The most abundant amino acids (present at 7.5 mass % or higher) among stages I–V were Asp, Glu, and carnosine. Furthermore, the low content amino acids (present at 2.2 mass % or lower) were Cys, Met, His, and Orn. Dundar et al. also found that Asp and Glu had high contents and Met and His had low contents in *Pleurotus eryngii* cultivated on the wheat stalk.[44] However, Li et al. determined that Arg, Ala, Glu, and Gln had high contents while the contents of D,L-α-aminoadipic acid, γ-aminobutyric acid, β-alanine, Cys, and $NH_3$ were low in the fresh *P. eryngii* harvested at the mature stage.[30] The differences in the amino acid composition and contents were mainly due to different *Pleurotus* materials or determination methods used.

Contents of three amino acids, Asp, Thr, and Glu, kept increasing in relative abundance while Val and Leu decreased with the development of *P. eryngii* maturation. Additionally, the

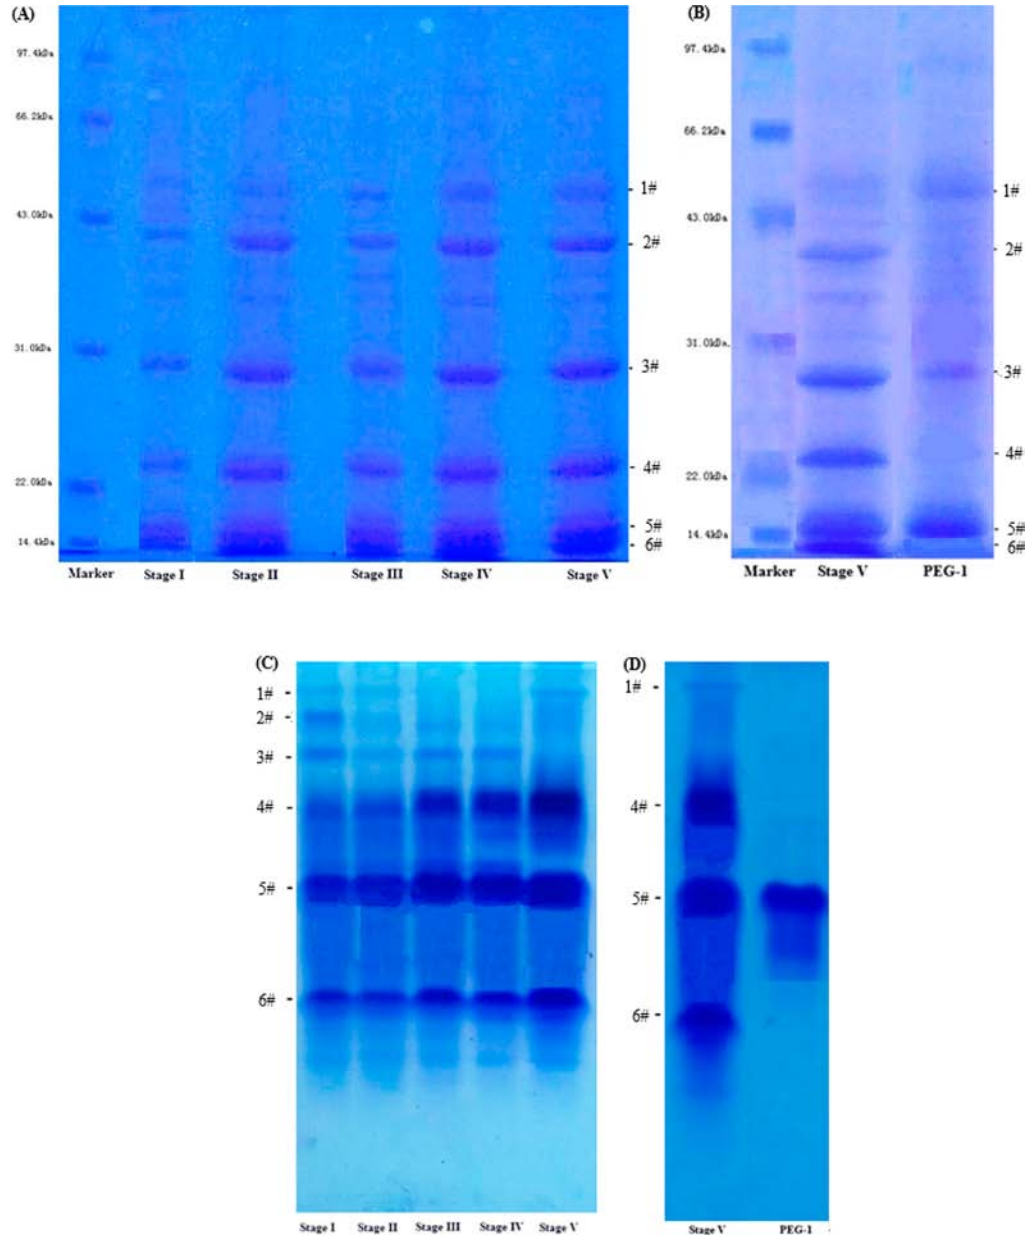

**Figure 3.** SDS-PAGE (A, B) and Native-PAGE (C, D) of crude polysaccharide-proteins from *P. eryngii* fruiting bodies at five stages and PEG-1 purified from crude polysaccharide-protein at stage V.

increase of acidic amino acids (Asp and Glu) with the *P. eryngii* maturation indicated that the assembled polysaccharide-protein fractions possibly showed acid properties with low p*I* value. Some polysaccharide-proteins (lectins), such as MAL from *Mycoleptodonoides aitchisonii*, were acid protein (p*I* value, 4.3–4.5) with a high content of acidic amino acid (12.1% of AsX).[45]

**Effect of Maturity Stage on Monosaccharide Composition in *P. eryngii* Polysaccharide-Proteins.** Table 5 showed monosaccharide compositions of crude polysaccharide-proteins from *P. eryngii* fruiting bodies harvested at five maturity stages. L-Rhamnose, D-xylose, D-glucose, D-mannose, and D-galactose were detected in the crude polysaccharide-proteins of *P. eryngii* fruiting body, which indicated that the polysaccharide-protein contained a heteropolysaccharide chain. The monosaccharide compositions in *P. eryngii* are related to the extraction methods, material suppliers, and different parts of the fruiting body. Some polysaccharide fractions extracted with high temperature (100 °C) from *Pleurotus ostreatus* and *Pleurotus eryngii* are from fruiting bodies composed of glucose and indentified as the glucans.[9] *P. eryngii* fruiting body supplied from Xi'an city (China) contained no D-arabinose,[46] while those produced in Seoul (Korea) or Shanghai BaixinBio-Tech Co. Ltd. (China) had no D-fructose.[47,48]

D-Glucose was the main sugar with a content of over 42.46% while D-galactose was lowest (<3.00%) in all stages. The content of D-glucose increased from stage I to stage III, and then began to decrease during stages III–V. On the contrary, the content of D-xylose decreased with stages I–III and increased with stages III–V with the lowest content of 12.80% at stage III. Similarly, the content of D-mannose decreased with stages I–IV and increased with stages IV and V with the lowest level of 7.66% at stage IV. Maturation seemed to have a slight effect on the contents of L-rhamnose and D-galactose. However, fiber-associated galactose in *Agaricus bisporus* (white button and

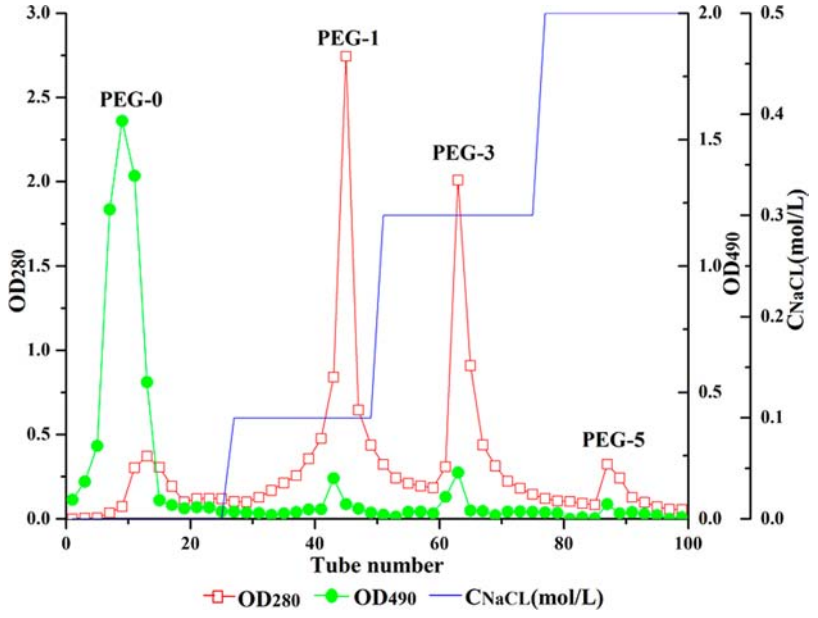

**Figure 4.** Anion-exchange chromatography of crude polysaccharide-protein from *P. eryngii* fruiting bodies at stage V on DEAE-Sepharose Fast Flow column (2.5 cm × 20 cm).

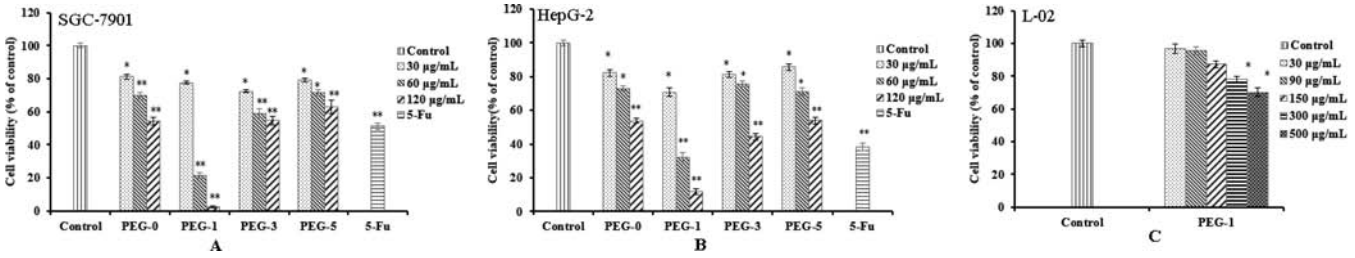

**Figure 5.** Effect of polysaccharide-protein fractions purified from *P. eryngii* fruiting bodies at stage V on the cell viability of SGC-7901 cells (A) and HepG-2 cells (B) incubated at 37 °C for 24 h and 5-Fu (20 μg/mL) as the positive control. (C) Toxicity of polysaccharide-protein fractions purified from *P. eryngii* fruiting bodies at stage V on normal human liver L-02 cells. Data are presented as mean ± SD of three independent experiments. *$P$ < 0.05 compared to control group, **$P$ < 0.01 compared to control group.

crimini) and *Lentinus edode* decreased with aging process.[13] These observed changes might be due to the energetic roles of monosaccharides during fungal growth.[49]

**SDS-PAGE, Native-PAGE, Mass Spectrometry, and Protein Identification of *P. eryngii* Polysaccharide-Proteins.** To find which polysaccharide-protein possibly possesses the cytotoxical activity in the crude samples extracted from *Pleurotus eryngii* fruiting body, SDS-PAGE and Native-PAGE were conducted, and the results are shown in Figure 3. Six distinct SDS protein bands were obviously observed in SDS-PAGE results of all the crude polysaccharide-proteins in 5 stages (Figure 3A). These SDS protein bands had differentiated molecular weights approximately as follows: band 1#, 50 kDa; band 2#, 40 kDa; band 3#, 30 kDa; band 4#, 23 kDa; band 5#, 15 kDa; and band 6#, 14 kDa. Among these bands, band 1# had increased width and intensity with the fruiting bodies' maturation. Other bands were weak in stages I and III and increased the width and intensity in stages II, IV, and V.

The Native-PAGE figure (Figure 3 C) showes that Native band 1# had the low intensity at stages I and II, disappeared in stages III and IV, and appeared in mature stage (V). The intensity of Native band 2# decreased gradually with the development of fruiting body and disappeared in stage V, while Native bands 4#, 5#, and 6# showed significant increase of intensity with fruiting body development. According to the increased cytotoxical activity and the intensity changes of crude polysaccharide-proteins with the fruiting body maturation, the polysaccharide protein with the cytotoxical activity would be targeted to the one or more samples in Native bands 4#, 5#, and 6#.

Further purification steps were applied to narrow the target polysaccharide-protein with cytotoxical activity. The purification with DEAE-Sepharose Fast Flow chromatography (Figure 4) of the crude polysaccharide-proteins in stage V resulted in four fractions as PEG-0, PEG-1, PEG-3, and PEG-5. The cell viabilities of SGC-7901, HepG-2, and L-02 cells influenced by each fraction are shown in Figure 5. At a concentration of 120 μg/mL, PEG-1 inhibited the SGC-7901 cell viability to 2.53% while residual cell viabilities in PEG-0, -3, and -5 treated groups were 54.41%, 54.70%, and 63.11% after 24 h treatment, respectively. Similar trends were found in HepG-2 cell treated with four fractions. PEG-1 showed the highest inhibitory effect with cell viability of 11.83% after 24 h treatment. PEG-1 also had no significant inhibition of normal human liver L-02 cells at a concentration of <300 μg/mL ($P$ > 0.05). Increased PEG-1 concentrations to over 300 μg/mL resulted in the decreased cell viability of 77.9%, which also verified the conclusion that

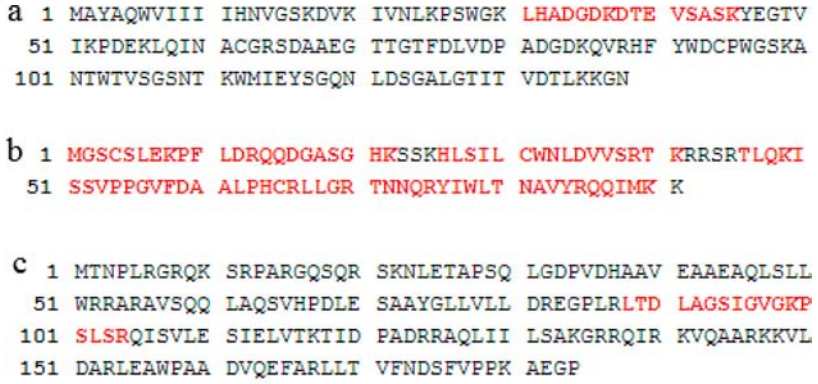

**Figure 6.** Peptide mass fragments of SDS protein bands confirmed by a NCBI blast search of mass spectrometry: (a) SDS protein band 1#, (b) SDS protein band 3#, (c) SDS protein band 5#.

the polysaccharide-protein had selectivity on cancer and normal cells.

The SDS-PAGE result of PEG-1 (Figure 3 B) showed three bands corresponding to bands 1#, 3#, and 5# with molecular weight of approximately 50 kDa, 30 kDa, and 15 kDa, respectively. However, Native-PAGE of PEG-1 (Figure 4 D) had a single band which was at the same position with Native band 5#, which indicated that the purified PEG-1 possibly had three subunits.

The three bands of purified PEG-1 on the SDS-PAGE were applied to the MALDI-TOF-MS and NCBI BLAST search for analyzing its partial sequences. The mass spectra of peptides of PEG-1are shown in Figure 6. From the sequence search, the band 1# subunit was similar to the Pe. Pleurutolysin A [*Pleurotus eryngii*] (gil543583497) of 15181 Da with a high score of 110 and 10% sequence coverage (Figure 6a); the band 3# subunit had a similar peptide sequence to the hypothetical protein Y032_0223g2652 [*Ancylostoma ceylanicum*] (gil 597840512) of 10590 Da with a low score of 63 and 91% sequence coverage (Figure 6b), while the band 5# subunit was similar to the hypothetical protein [*Acaricomes phytoseiuli*] (gil 516862670) of 20111 Da with a low score of 60 and 9% sequence coverage (Figure 6c). Hence, it could be concluded that the cytotoxical polysaccharide-protein PEG-1 from *P. eryngii* fruiting body at least contained the identified peptide sequences shown in red (Figure 6). However, the total amino acid sequence of polysaccharide-protein PEG-1 needs to be further elucidated by using molecular cloning such as genome walking PCR, or column affinity chromatography and crystallization.

In summary, our study first reported the changes of macromolecular compositions in *P. eryngii* and their contents and cytotoxical activity with the development of the fruiting bodies' maturity. The polysaccharide-protein fractions had the highest antiproliferative effect on the SGC-7901 and HepG-2 cells in vitro compared with polysaccharide fractions and ethanol extract, and the increased cytotoxical activity with growing maturity of *P. eryngii* fruiting body. The polysaccharide-protein PEG-1 with three subunits was identified as the possible target cytotoxical component. Further investigations would focus on finding the fine structure of PEG-1 including protein sequence and polysaccharide chain, and its physiological role during growth and development of *P. eryngii* fruiting body.

microsphere design due to its good stability at various pH and moisture levels.[25,26] Drug-loaded beeswax microspheres demonstrated the absence of drug release at pH 1.2, proving the suitability for its use as a gastric-resistant material.[27]

The present research investigated the role of SCMC cross-linked with aluminum ions (AlCMC) and AlCMC−beeswax composites as the coating materials on the gelatin microcapsules for controlling essential oil release in simulated swine gastrointestinal fluid. Holy basil essential oil (HBEO) from *Ocimum sanctum* Linn., which has received significant attention as a natural substitute for AGP,[28] was used in this study. It contains several secondary metabolites with the major components being 42.6% methyleugenol, 26.9% $\beta$-caryophyllene, 10.7% eugenol, and 6.00% $\beta$-elemene.[29] The physicochemical properties of the microcapsules that were relevant to HBEO release and HBEO release kinetics were also examined.

## MATERIALS AND METHODS

**Chemicals.** HBEO was supplied by Thai-China Flavours and Fragrances Industry Co., Ltd. (Phra Nakhon Si Ayutthaya, Thailand). Gelatin from porcine skin (300 Bloom, type A) and NaCMC (medium viscosity) were purchased from Sigma-Aldrich (St. Louis, MO, USA). Sodium dodecyl sulfate (SDS) and Tween 80 were obtained from Ajak Finechem (NSW, Australia). Glutaraldehyde was provided by Merck (Darmstadt, Germany). Stearic acid was obtained from Laboratory Reagents & Fine Chemicals (Mumbai, India). White beeswax (pharmaceutical grade) was purchased from Paramelt BV (Heerhugowaard, The Netherlands). Porcine bile extract, pancreatin, and lipase from porcine pancreas and pepsin from porcine gastric mucosa were purchased from Sigma (Hampshire, UK). All chemicals were of analytical grade.

**Preparation of HBEO-Loaded Gelatin Microcapsules.** HBEO-loaded gelatin microcapsules were prepared using simple coacervation via glutaraldehyde cross-linking.[29] HBEO was dispersed into a gelatin solution (11.75% (w/v) gelatin and 0.1% (w/v) SDS) with stirring at 450 rpm and 40 °C for 25 min. Then, sodium sulfate solution (20% w/v) was added dropwise with continuous stirring at 550 rpm for phase separation. The temperature was subsequently decreased to 5 °C. Next, a glutaraldehyde solution consisting of 25% (v/v) glutaraldehyde, acetone, and distilled water was introduced into the mixture. This was followed by increasing the temperature to 40 °C with continuous stirring for 60 min. The microcapsules were washed twice with 0.3% (v/v) Tween 80 and were filtered through an 11 $\mu$m filtration Whatman membrane under vacuum. They were collected and dried at 60 °C until a constant dry weight was obtained. The finished microcapsules were stored in a hermetically sealed glass bottle at room temperature.

**Coating of HBEO-Loaded Gelatin Microcapsules with AlCMC and AlCMC−Beeswax Composites.** The HBEO-loaded gelatin microcapsules (UC) were coated with AlCMC or AlCMC−beeswax (1:1, w/w) composites, respectively named CC and CB. For the CC microcapsules, 20 g of UC was added into 200 mL of 1% (w/v) NaCMC solution, which contained 1% (w/v) glycerol as a plasticizer and 1% (w/v) stearic acid as an emulsifier. The mixture was shaken at 100 rpm and 30 °C. This was followed by the addition of 200 mL of 0.05 M aluminum chloride solution as a cross-linking agent with continuous stirring. To prepare the composite coating, the NaCMC solution was mixed with melted beeswax with stirring at 1200 rpm. Next, 20 g of UC was transferred into 200 mL of the composite, and the mixture was shaken at 100 rpm and 30 °C. Finally, to obtain CB microcapsules, NaCMC cross-linking was performed as previously described. The CC and CB microcapsules were filtered under vacuum and were stored at 4 °C until further analysis.

**Determination of HBEO Content and Encapsulation Efficiency.** The HBEO content was determined using a Thermo Spectronic Helios $\gamma$ UV−vis spectrophotometer (Cambridge, UK) at 289 nm, which is the wavelength of maximum absorbance of eugenol, the most powerful antioxidant and antimicrobial component of HBEO.[29] Briefly, the microcapsules (80 mg) were dissolved in dichloromethane to a final volume of 1 mL, and their concentration was calculated using the calibration curve shown in eq 1 ($R^2$ = 0.998)

$$y = 1.8082x + 0.0662 \quad (1)$$

where $y$ is the HBEO concentration and $x$ is the absorbance. Then, the encapsulation efficiency was calculated according to eq 2

$$\text{encapsulation efficiency} = (W_O/W_I) \times 100 \quad (2)$$

where $W_O$ is the mass of HBEO in the microcapsule and $W_I$ is the initial mass of HBEO added for the encapsulation.

The HBEO content was determined using eq 3

$$\text{HBEO content} = (W_O/W_M) \times 100 \quad (3)$$

where $W_M$ is the mass of the microcapsule.

**Determination of Antioxidant Activity.** Antioxidant activity was estimated using the 2,2-diphenyl-2-picrylhydrazyl (DPPH) radical assay as previously described with minor modifications.[30] The microcapsule solution (1 mL) in dichloromethane was mixed with 1 mL of 0.2 mM DPPH radical solution in methanol. The mixture was then shaken vigorously and left to stand for 20 min in the dark. The decrease in absorbance was measured at 517 nm against a blank sample. All samples were analyzed in triplicate. The DPPH radical scavenging activity was calculated according to eq 4

$$\text{DPPH radical scavenging activity} = [A_O - (A_M - A_S)]/A_O \times 100 \quad (4)$$

where $A_O$ is the absorbance of the control, $A_M$ is the absorbance of the DPPH solution mixed with the samples, and $A_S$ is the absorbance of the samples without DPPH.

**Particle Size Analysis.** The area-volume mean diameter ($D[4,3]$) was measured using a Mastersizer 2000 particle size analyzer (Malvern, Worcestershire, UK) equipped with a Hydro 2000 MU (A) wet dispersion unit and 0.3% Tween 80 as the dispersion medium.

**Scanning Electron Microscopy (SEM) Studies.** The microcapsules were fixed using 2% (v/v) osmium tetroxide for 1 h and were rinsed twice with distilled water. Then, they were dehydrated using a graded ethanol series (30, 50, 70, 95, and 100% (v/v)) three times for 10 min. Preparation of a microcapsule cross section was performed by cutting the sample with a razor blade. The samples were consecutively dried using a critical point dryer and were fixed on an aluminum stub using double-sided adhesive tape. This was followed by gold coating using an ion sputtering coater (IB2, Giko Engineering, Japan). The microcapsule surface morphology was characterized using SEM (JSM-5600, JEOL, Tokyo, Japan) at an accelerating voltage of 15 kV.

**Confocal Laser Scanning Microscopy (CLSM) Studies.** Fluorescence imaging with CLSM (LSM 5 Pascal, Carl Zeiss GmbH, Jena, Germany) was used to visualize the HBEO distribution in gelatin. HBEO was labeled with Nile blue dye prior to encapsulation, and the microcapsules were stained with Rhodamine B dye to localize gelatin. All fluorescence pictures were obtained using a ×10 objective (Plan-Neofluar, Carl Zeiss) and a 0.3 numerical aperture. Confocal illumination of HBEO and gelatin was provided using a multiline argon laser (488 nm excitation) and a helium/neon laser (543 nm excitation), respectively.

**Fourier Transform Infrared Spectroscopy (FTIR) Studies.** The FTIR spectra of UC, CC, CB, gelatin, beeswax, and HBEO were recorded using a TENSOR series FTIR spectrometer (Bruker Optics, Ettlingen, Germany) in ATR mode. The samples were scanned in transmission mode from 4000 to 500 $cm^{-1}$ with a resolution of 4 $cm^{-1}$.

**X-ray Diffraction (XRD) Studies.** The crystal structures of UC, CC, CB, and beeswax were determined using an XRD diffractometer (Philips model X'Pert MPD, Almelo, The Netherlands) equipped with Cu K$\alpha$ radiation (wavelength 1.5406 Å, 40 kV, and 30 mA). The samples were scanned along a 2$\theta$ range of 5−50° at a rate of 2.4°/min.

**Differential Scanning Calorimetry (DSC) Studies.** The thermal properties of UC, CC, CB, the physical mixture of HBEO and gelatin powder, and beeswax as well as HBEO were determined using a DSC-

1 *STAR*$^e$ *System* (Mettler Toledo, Switzerland) calibrated with indium. Accurately weighed samples (5 mg) were placed in a 40 $\mu$L aluminum pan and heated at a programmed rate of 10 °C/min in the temperature range from −80 to 300 °C.

**HBEO Release under Simulated Swine Gastrointestinal Conditions Experiments.** HBEO release studies were performed using a previously published method with slight modifications.[31] One percent (w/v) microcapsules were added into simulated gastric fluids (SGF) consisting of 3 g/L NaCl, 1.1 g/L KCl, 0.15 g/L $CaCl_2$, 0.6 g/L $NaHCO_3$, 3 g/L SDS, 0.21 g/L pepsin, and 0.25 g/L lipase. The pH was adjusted to 6.0, 3.5, 3.0, 2.5, and 2.0 at 0, 5, 30, 120, and 180 min, respectively, using 1 M HCl. The experiment was performed at 39 ± 0.5 °C with a stirring speed of 100 rpm. The absorbance of the sample at 289 nm was measured at 0, 5, 10, 20, 30, 40, 60, 80, 100, 120, 180, 210, and 240 min, and the electrolytes were replaced with fresh solution. CLSM observations were performed to verify HBEO diffusion after 10 min of incubation in SGF. After 240 min, 1 mL of trypsin solution (2 mg/mL), 14 mL of bile solution (40 mg/mL), 7.5 mL of pancreatic solution, and 7.5 mL of small intestinal electrolyte solution (0.6 g/L KCl, 5.0 g/L NaCl, 0.23 g/L $CaCl_2{\cdot}2H_2O$, and 3 g/L SDS) were mixed with SGF. Then, the pH of the simulated intestinal fluid (SIF) was increased to 5 and 6.5 at 240 and 300 min, respectively, by adding 1 M $NaHCO_3$. A 1 mL sample was collected from the medium to measure absorbance, and the electrolytes were replaced with fresh SIF at predetermined time intervals for 4 h.

The HBEO in vitro release data were analyzed to describe the release kinetics by fitting the data into various release kinetic models. The zero-order model describes a system in which the release rate is independent of concentration (eq 5). The first-order model describes a system in which the release rate is concentration dependent (eq 6). The Higuchi model (eq 7) describes the release from an insoluble matrix system as the square root of a time-dependent process based on Fickian diffusion. The Hixson and Crowell model (eq 8) describes the release by dissolution with a change in the surface area and the diameter of a particle. The Korsmeyer−Peppas model (eq 9) describes the release from a polymeric system. The kinetic model that best fits the release data was selected on the basis of the correlation coefficient ($R^2$) value for each model

$$Q = K_0 t \tag{5}$$

where $Q$ is the amount of HBEO released in time $t$ and $K_0$ is the zero-order release constant. To study the release kinetics, the release data were plotted as a cumulative percentage of HBEO release versus time

$$\log C = \log C_0 - (K/2.303)t \tag{6}$$

where $K$ is the first-order rate constant, $C_0$ is the initial concentration of HBEO, and $C$ is the concentration of HBEO at time $t$. The HBEO release data were plotted as the log cumulative percentage of the HBEO remaining versus time

$$Q = K_H t^{1/2} \tag{7}$$

where $K_H$ is the Higuchi dissolution constant. The HBEO release data were plotted as the cumulative percentage of HBEO release and the square root of time

$$W_0^{1/3} - W_t^{1/3} = K_{HC} t \tag{8}$$

where $W_t$ is the amount of HBEO released in time $t$, $W_0$ is the initial amount of HBEO in the microcapsule, and $K_{HC}$ is the rate constant. The HBEO release data were plotted using the cube root of the HBEO percentage remaining in a matrix and time

$$M_t/M_\infty = kt^n \tag{9}$$

where $M_t/M_\infty$ is the fraction of the HBEO released at time $t$, $k$ is the release rate constant, and $n$ is the release exponent. The calculations of $k$ and $n$ were measured up to the initial 60% release of HBEO. The value of $n$ characterizes the release mechanism of the HBEO. For spheres, values of $n$ lower than 0.45 indicate a diffusion-controlled system, and values of $n$ between 0.45 and 0.85 indicate both diffusion-controlled release and swelling-controlled release (anomalous transport). Values above 0.85 indicate case II transport relating to polymer relaxation during gel swelling.

**Statistical Analysis.** A completely randomized design was used in this experiment. The statistical analysis was performed using one-way ANOVA. The experiments were performed in triplicate. The data are presented as the mean value ± standard deviation. Statistical significance was evaluated using Duncan's multiple-range test at the 95% confidence level.

## RESULTS AND DISCUSSION

HBEO was encapsulated in gelatin using simple coacervation and was cross-linked with glutaraldehyde to serve as a health enhancers for swine-raising. To delay HBEO release in the gastrointestinal tract, the microcapsule was successively coated with AlCMC or AlCMC−beeswax composites. Due to the acid resistance of AlCMC and the highly hydrophobic nature of beeswax, a delayed HBEO release was possible. The AlCMC layer was formed on the surface of the microcapsule by dispersing the microcapsules in a SCMC solution. Complex coacervation between SCMC and gelatin occurred due to the electrostatic attraction between the negatively charged SCMC carboxyl group and the positively charged gelatin amide group.[32] In addition to electrostatic attraction, the interaction between SCMC and gelatin was partially driven by hydrophobic interactions as well as hydrogen bond and van der Waals forces.[33] To produce a stable layer in the water-insoluble AlCMC gel, SCMC was consecutively cross-linked with aluminum ions. For the AlCMC−beeswax composite coating, a homogeneous dispersion emulsification was performed comprising beeswax in SCMC. Then, the microcapsules were added into the emulsion and were subsequently cross-linked with $AlCl_3$. The preparation of the emulsion composite film using the emulsification technique is simple and feasible. Additionally, the obtained film had adequate structural cohesion due to the long-chain polymer and hydrorepellency imparted by the lipids.[22] The physicochemical properties of the microcapsules were characterized in subsequent experiments.

**Encapsulation Efficiency, HBEO Content, and Antioxidant Activity.** The encapsulation efficiency of all samples was calculated on the basis of the HBEO weight in the microcapsule and the HBEO weight used initially. The encapsulation efficiency was found to be 95.4 ± 0.17%, which suggested that HBEO was effectively encapsulated using our simple coacervation procedure. UC, CC, and CB microcapsules contained 67.7 ± 0.16, 67.1 ± 0.13, and 66.7 ± 0.26% HBEO and exhibited 96.5 ± 0.20, 95.8 ± 0.18, and 94.3 ± 0.27% DPPH radical scavenging activity, respectively, which were significantly different for both values ($p \leq 0.05$). The radical scavenging activities of the CC and CB microcapsules were slightly weaker than that of the UC microcapsules. This result may be attributed to the increased weight of the microcapsule and HBEO loss after coating. However, with regard to their high antioxidant activity, all microcapsule samples could be potentially useful as feed additives.

**Size and Surface Morphology.** The microcapsule coating was also expected to have an influence on the size and surface morphology of the microcapsules. The volume moment mean diameter of the UC microcapsules was 392 $\mu$m, which was slightly smaller than those of the CC and CB microcapsules (407 and 414 $\mu$m, respectively). This increase in size indicates the presence of the coating layer on the outer surface of the microcapsule. In addition, the incorporation of beeswax, a long

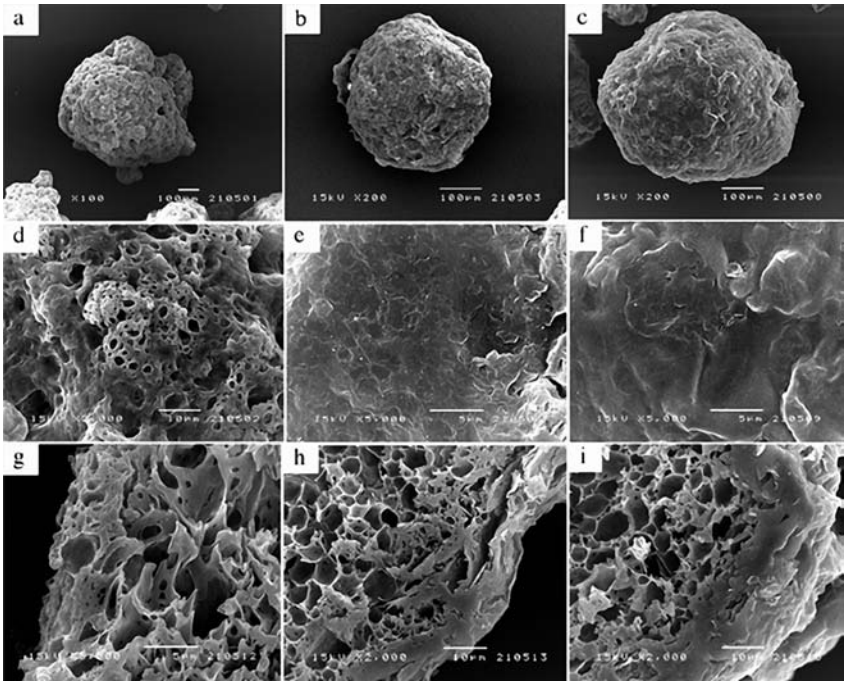

**Figure 1.** SEM images of UC, CC, and CB microcapsules: (a) whole UC; (b) whole CC; (c) whole CB; (d) external surfaces of UC; (e) external surfaces of CC; (f) external surfaces of CB; (g) inner edges of UC; (h) inner edges of CC; (i) inner edges of CB.

carbon chain molecule of $C_{16}$–$C_{95}$[34] in the AlCMC matrix results in an increase in the coating thickness.

SEM was used to characterize the internal and external surface morphology of the microcapsules. The UC microcapsules were almost spherical in shape (Figure 1a). After coating, the CC (Figure 1b) and CB (Figure 1c) microcapsules were more spherical. At high magnification, the UC microcapsule images revealed the highly porous sponge-like structure of the external surface (Figure 1d), and those of the CC (Figure 1e) and CB (Figure 1f) microcapsules were denser. The beeswax was markedly dispersed in the AlCMC matrix, resulting in a bumpy appearance. The cross-section view image showed a highly porous honeycomb-like internal morphology of the gelatin matrix (Figure 1g) as previously reported.[35,36] A large number of micropores on the multiwalls of the microcapsule were also observed. The cross-section images of the CC (Figure 1h) and CB (Figure 1i) microcapsules showed the compact outer coating layer covering the honeycomb-like inner microcore and, with the presence of beeswax, the coating layer appeared to be thicker.

**FTIR Spectra.** FTIR was used to confirm the successful coating and to reveal the interactions between each component that are possibly associated with the oil release properties. All of the characteristic peaks of gelatin (Figure 2a) and HBEO (Figure 2b) appeared in the UC microcapsule spectrum (Figure 2c). The N—H stretching vibrations of the amide groups, representing the amide A, appeared at 3351 $cm^{-1}$. The carbonyl C═O stretching vibrations, with minor contributions from the out-of-phase C—N stretching vibrations of the amide I, occurred at 1638 $cm^{-1}$. The out-of-phase combination of the N—H in-plane bending and the C—N stretching vibrations of the amide II were at 1568 and 1455 $cm^{-1}$. The peak at 1235 $cm^{-1}$ belonged to the in-phase combination of the N—H bending and the C—N stretching vibrations of amide III. The characteristic peaks of the main components of HBEO, methyleugenol, eugenol, and caryophyllene, were also observed

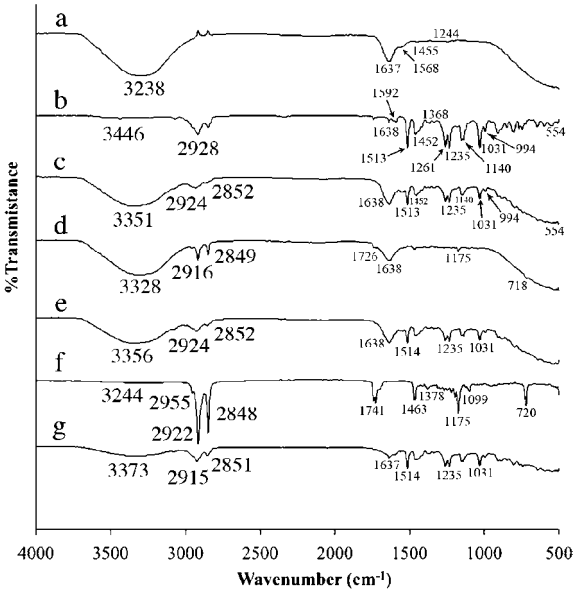

**Figure 2.** FTIR spectra of (a) gelatin, (b) HBEO, (c) UC, (d) NaCMC solution mixed with glycerol, (e) CC, (f) beeswax, and (g) CB.

in the UC microcapsule spectrum. The asymmetric and symmetric C—H stretching vibrations in $-CH_2-$ were observed at 2924 and 2852 $cm^{-1}$. The peaks in the region of 1638–1513 $cm^{-1}$ were assigned to the alkene/aromatic −C═C− stretching vibrations. The $=CH_2$ scissor bends occurred at 1463 $cm^{-1}$. The asymmetric and symmetric C—H bending vibrations in $-CH_3$ were observed at 1452 and 1368 $cm^{-1}$. There was also C−H bending of the alkene/aromatic groups in the range of 994–554 $cm^{-1}$. A comparison of the HBEO spectrum with the microcapsule spectrum revealed the chemical

dx.doi.org/10.1021/jf5019438 | J. Agric. Food Chem. 2014, 62, 12641–12648

stability of the encapsulated HBEO; therefore, its antioxidant and antimicrobial properties should remain intact.

After coating the UC microcapsules with AlCMC, the presence of AlCMC was evaluated by comparing the FTIR spectra of UC (Figure 2c) and SCMC (Figure 2d) with CC (Figure 2e). The SCMC spectrum had a peak at 3328 $cm^{-1}$ that was assigned to O−H stretching vibrations. The asymmetric and symmetric stretching vibrations of the aliphatic C−H were observed at 2916 and 2849 $cm^{-1}$, respectively. The peak at 1638 $cm^{-1}$ was attributed to the absorbed water molecules in cellulose. The bands at 1175, 1099, and 718 $cm^{-1}$ indicated the C−O−C (glycosidic linkage) stretching vibrations. As the characteristic peaks of SCMC were observed in the spectrum of the CC microcapsules, successful coating was achieved.

The beeswax incorporation into the AlCMC matrix as the coating material for the microcapsule was confirmed using FTIR. The beeswax FTIR spectrum (Figure 2f) had the characteristic peaks of its primary components, which consisted of a mixture of esters of fatty acids and fatty alcohols, long-chain hydrocarbons, and free fatty acids. O—H stretching was observed at 3244 $cm^{-1}$. The peak at 2955 $cm^{-1}$ was assigned to asymmetric C—H stretching vibrations. The peaks at 2915 and 2848 $cm^{-1}$ corresponded to the asymmetric and symmetric $C—H_2$ stretching vibrations of the fatty acid chains, respectively. The C═O stretching vibrations of the ester were observed at 1741 $cm^{-1}$. The symmetric $CH_2$ scissoring vibrations appeared at 1463 $cm^{-1}$. The peak at 1378 $cm^{-1}$ indicated the symmetric $CH_3$ bending vibrations. The band at 1175 $cm^{-1}$ was assigned to the $CH_2$ wagging vibrations. The peak at 1099 $cm^{-1}$ was due to the symmetric C—C stretching vibrations. The band at 720 $cm^{-1}$ represented the $CH_2$ rocking vibrations of the long-chain hydrocarbons.

The CB microcapsule spectrum contained most of the characteristic peaks of UC, AlCMC, and beeswax, indicating the successful coating of AlCMC−beeswax composites on the surfaces of the gelatin microcapsules. However, when compared with the CC spectrum, a significant decrease in the intensities of the aprroximately 3351 and 1638 $cm^{-1}$ peaks was observed, indicating that beeswax may interfere with the electrostatic attractions between the $Al^{3+}$ and $COO^-$ of SCMC.

**XRD Analysis.** XRD was used to evaluate the effect of AlCMC and beeswax on the structure of the microcapsule. The UC XRD pattern revealed an amorphous structure due to the amorphous nature of HBEO and the $\beta$-sheet conformation of gelatin (Figure 3a). In addition, an examination of the amorphous pattern also possibly indicated that amorphous HBEO is molecularly dispersed in the amorphous gelatin matrix. For the CC microcapsules, a flat and broad contour was observed (Figure 3b), suggesting that the presence of AlCMC decreased the crystallinity of the gelatin microcapsule. This result is attributed to the significant hydrogen bonding interactions between AlCMC and gelatin. With the incorporation of beeswax, the CB microcapsules had a semicrystalline structure composed of both crystals and amorphous structures (Figure 3c). The crystalline nature of beeswax was detected at $2\theta$ = 21° and 23° (Figure 3d) as previously observed.[34,37] Therefore, the XRD pattern demonstrates the successful incorporation of beeswax in the AlCMC layer. As a result of the semicrystalline structure of the AlCMC−beeswax composite, the release characteristics of the CB microcapsules may be different from those of UC and CC, which requires further investigation.

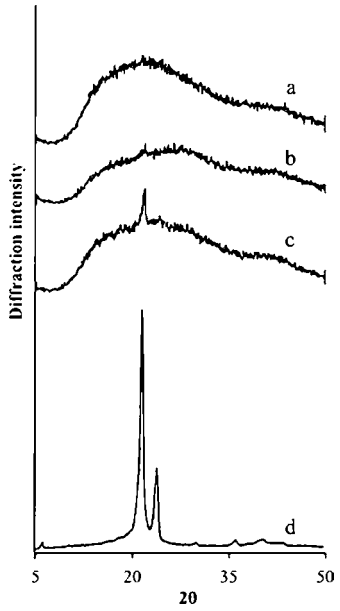

**Figure 3.** XRD patterns of (a) UC, (b) CC, (c) CB, and (d) beeswax.

**DSC Analysis.** DSC was used to monitor the physical state and thermal behavior of the samples. When HBEO was physically mixed with gelatin, its thermal analysis indicated three endothermic phase changes at 121, 220, and 251 °C, signifying the gelatin melting, HBEO vaporization, and gelatin degradation, respectively (Figure 4a). The characteristic

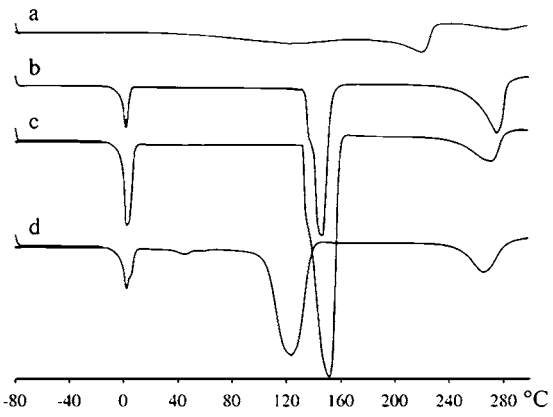

**Figure 4.** DSC thermograms of (a) physical mixtures of HBEO and gelatin powder, (b) UC, (c) CC, and (d) CB.

thermogram of the UC microcapsules (Figure 4b) was noticeably different from that of the physical mixture. The first absorption peak was around −1 °C, attributed to the melting endotherm of HBEO. The next sharp endothermic peak at 143 °C was associated with the melting of the microcapsule. The shift of the melting peak toward a higher temperature (from 121 to 143 °C) indicated the effect of cross-linking on the physical properties of the gelatin. The final phase transition showed the decomposition of the microcapsule. However, the DSC profile of the microcapsule did not clearly show the HBEO vaporization peak. This result suggests that HBEO is highly dispersed in the amorphous gelatin. Another possibility for this result is that HBEO vaporization occurs simultaneously with the decomposition of the microcapsule in that temperature range. In addition, the lack of any visible

exothermic peak confirmed that there was no chemical interaction between HBEO and gelatin. A comparison of the absorbed energy during the decomposition process between the microcapsule and the physical mixture also revealed the effect of cross-linking.

The DSC thermogram of the CC microcapsules (Figure 4c) was also composed of three endothermic events. The first peak, around −1 °C, corresponded to the melting temperature of HBEO. The sharp peak at 148 °C and the broad peak in the 250−280 °C temperature range represented the melting and decomposition of the microcapsule, respectively. The CC melting temperature (148 °C) was slightly higher than that of the UC microcapsules (143 °C), indicating the interaction between AlCMC and gelatin. Therefore, the DSC thermograms confirmed the FTIR spectrum data, demonstrating the presence of the intermolecular hydrogen bonds between AlCMC and gelatin.

The presence of beeswax in the AlCMC network and its effect on the thermal behavior of the microcapsule was also determined. The DSC thermogram of the CB microcapsules (Figure 4d) showed four endothermic peaks with one peak at 60 °C, representing the beeswax melting peak.[37] Moreover, the broadening of the melting peak and the decline in the melting temperature and melting enthalpy compared with the CC thermogram can be attributed to the colloidal beeswax due to its large surface-to-volume ratio properties.

**Release Characteristics of Microencapsulated HBEO in SGF.** The previous physicochemical analysis suggested a possible role for the microcapsule in controlling HBEO release. Therefore, the final study examining in vitro release was conducted. All of the microcapsules had a two-step biphasic HBEO release that was characterized by an initial burst, followed by a sustained release (Figure 5). Initially, the UC

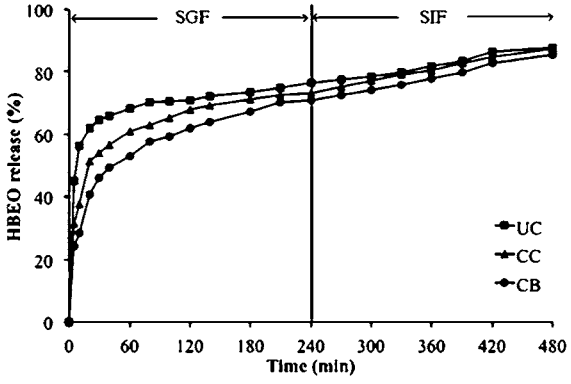

**Figure 5.** HBEO release profiles of UC, CC, and CB microcapsules in simulated swine gastrointestinal fluids.

microcapsules exhibited the highest burst release, followed by the CC and CB microcapsules, respectively. For example, within the first hour of incubation, the UC microcapsules released 69% of HBEO compared with 61% for the CC microcapsules and 50% for the CB microcapsules. The SGF penetration into the microcapsule leads to chain relaxation, microcapsule swelling, and finally HBEO release. Moreover, pepsin degrades the amide linkage in the gelatin chain,[38−40] resulting in microcapsule erosion and burst release. The HBEO release rate decreased after coating with AlCMC, which may be because AlCMC has a lower quantity of polar groups per monomeric unit.[41] As a result, the passage of the SGF through the CC microcapsules is slower. The slowest HBEO release rate was observed for the CB microcapsules. Because beeswax is highly hydrophobic, it has a low affinity for water. This potentially slows HBEO diffusion out of the microcapsules. In addition, the dispersed beeswax particle in the AlCMC matrix increases the diffusional path length of the HBEO, ions, and water, consequently hindering their transport across the composite layer as illustrated in Figure 6.

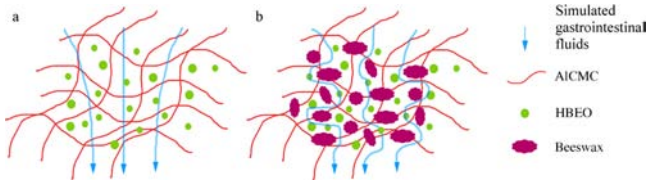

**Figure 6.** Schematic diagrams of SGF traversing (a) AlCMC and (b) AlCMC−beeswax composite coated on HBEO-loaded gelatin microcapsules.

Under simulated intestinal conditions, all of the microcapsules demonstrated sustained release. The physical and chemical disintegration of the UC microcapsules continuously occurred due to microcapsule swelling and gelatin hydrolysis by pancreatin and trypsin. AlCMC only experienced the physical disintegration induced by the polymer chain relaxation and swelling. In the CB microcapsules, the beeswax cannot retain its structural integrity because its ester bond is cleaved by the lipase found in pancreatin.[42]

The experimental results determined that the coating layer, particularly the AlCMC−beeswax composite, decreased the initial HBEO burst release in the SGF. The AlCMC−beeswax composite enhanced HBEO stability against acid denaturation and preserved antioxidant activity, which prevents free radical-induced damage and suppresses oxidative stress. The cumulative amounts of HBEO released in the SGF were 77.9, 74.7, and 70.5%, and the amounts released in the SIF were 11.6, 15.8, and 21.1% for the UC, CC, and CB microcapsules, respectively. Because antimicrobial activity depends on concentration, the CB microcapsules should exhibit the strongest activity in the intestine. In our in vitro studies, HBEO demonstrated high antimicrobial activity against pathogenic bacteria found in the intestine of swine, *Salmonella* Typhimurium, *Escherichia coli* O157, and *Staphylococcus aureus* (unpublished data). In our experiment, all types of microcapsules, particularly CB, released HBEO at concentrations greater than its minimal inhibitory concentration (the lowest concentration of an antimicrobial that can inhibit the growth of a microorganism) in the intestine. Therefore, HBEO encapsulation is a method for achieving HBEO release at desirable sites in the intestinal tract, rather than being almost completely absorbed in the stomach and the proximal intestine within 2 h after oral administration.[8]

To understand the mode of HBEO release and determine a suitable release kinetic model, the HBEO release data were fitted to various kinetic models. The model that provided the highest correlation coefficient ($R^2$) value was considered the optimal model for describing the release kinetic data. The results indicated that the in vitro HBEO release kinetics were best described by the Korsmeyer−Peppas model for all microcapsule preparations (Table 1). The HBEO release mechanism for the UC microcapsules followed the anomalous transport mechanism, which is controlled by diffusion and

**Table 1. Correlation Coefficients, Rate Constants, and Release Exponents for Different HBEO Release Kinetic Models for UC, CC, and CB Microcapsules**

| release kinetic model | | microcapsule formulations | | |
|---|---|---|---|---|
| | | UC | CC | CB |
| zero order | $R^2$ | 0.84 | 0.80 | 0.84 |
| | $K_0$ | 0.07 | 0.09 | 0.10 |
| first order | $R^2$ | 0.95 | 0.94 | 0.86 |
| | $K$ | 0.002 | 0.002 | 0.002 |
| Higuchi | $R^2$ | 0.92 | 0.92 | 0.95 |
| | $K_H$ | 1.72 | 2.34 | 2.72 |
| Hixson–Croswell | $R^2$ | 0.90 | 0.90 | 0.89 |
| | $K_{HC}$ | 0.002 | 0.002 | 0.002 |
| Korsmeyer–Peppas | $R^2$ | 0.97 | 0.97 | 0.97 |
| | $k$ | 3.52 | 3.64 | 3.30 |
| | $n$ | 0.51 | 0.30 | 0.30 |

swelling. These results confirmed the initial HBEO burst release from the gelatin. However, the HBEO release mechanism of the CC and CB microcapsules showed Fickian diffusion, indicating a diffusion-controlled release system due to the chemical potential gradient. As HBEO diffused through the water-filled pores, because CC and CB were denser than UC, the diffusion rate of HBEO from the coated microcapsules was lower.

**Stability of Microencapsulated HBEO during SGF Exposure.** CLSM was used to visualize and identify the location of HBEO in the microcapsule before and after exposure to SGF for 10 min. Figure 7a represents the nonhomogeneous distribution of large amounts of HBEO throughout the gelatin matrix in the UC microcapsules before incubation. The difference in fluorescence intensity was attributed to the difference in the HBEO amounts, which are directly related to the gelatin pore sizes. CLSM detected the gelatin matrix (Figure 7b), but it was not able to provide information on the shape of the gelatin pores. Nevertheless, the image shown in Figure 7c confirmed the multicore structure of the microcapsule with distinct gelatin walls, as previously observed by SEM. In addition, HBEO was almost entirely entrapped inside the microcapsule; nonencapsulated oil was barely detected on the outer surface.

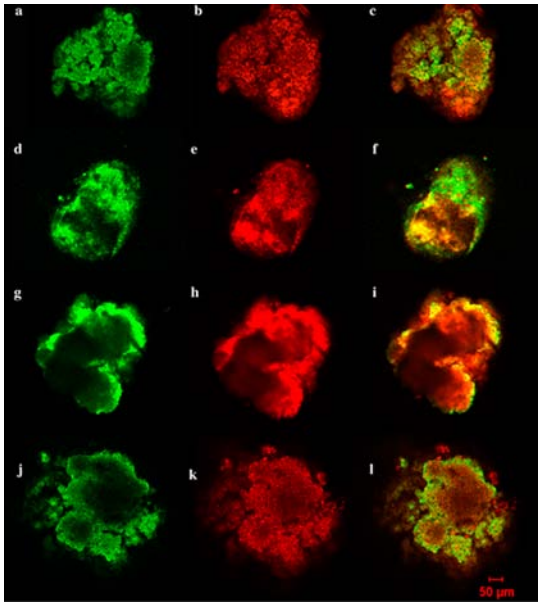

**Figure 7.** CLSM images of microcapsules before and after exposure to SGF: (a–c) UC before exposure; (d–f) UC after exposure; (g–i) CC after exposure; (j–l) CB after exposure. HBEO was colored with Nile blue dye (a, d, g, and j). Gelatin was colored with Rhodamine B dye (b, e, h, and k). Red and green represent gelatin and HBEO, respectively (c, f, i, and l).

The information obtained in this study can be used to indicate the protective ability of microcapsules and HBEO stability during SGF exposure. Panels d–f of Figure 7 show that HBEO was released from the UC microcapsules after incubation in the SGF for 10 min at pH 3 due to the degradation of the gelatin network by pepsin. Conversely, large amounts of HBEO were retained on the edge of the CC (Figure 7g–i) and CB microcapsules (Figure 7j–l); HBEO was not able to traverse the coated layers. These results confirmed that higher amounts of HBEO were released from the UC microcapsules.

In summary, microcapsules for the controlled release of HBEO in swine gastrointestinal fluid were developed. The analysis of physicochemical properties confirmed the successful coating of AlCMC and AlCMC–beeswax composite on the gelatin microcapsule. The coating material, particularly the AlCMC–beeswax composite, inhibited HBEO burst release in the SGF and promoted HBEO release in the SIF of swine over an extended period of time. Therefore, the encapsulation method proposed in the present study is an effective process for improving HBEO efficacy for pathogen reduction in the distal region of the intestine.

up applications in bioreactors. Moreover, this study quali−quantitatively characterized five main IF constituents (calycosin-7-*O*-*β*-D-glucoside, ononin, astraisoflavan-7-*O*-*β*-D-glucoside, calycosin, and formononetin) from *A. membranaceus* HRCs (AMHRCs), followed by the evaluation of antioxidant activities of AMHRC extracts. We conclude that AMHRCs were more efficient for production of isoflavonoids compared to field grown roots (AMFGRs) of *A. membranaceus*.

## MATERIALS AND METHODS

**Plant Materials and Reagents.** Mature *A. membranaceus* seeds were generously provided by Heilongjiang University of Chinese Medicine (Harbin, China). Standard compounds including calycosin-7-*O*-*β*-D-glucoside (CAG), ononin (ON), astraisoflavan-7-*O*-*β*-D-glucoside (ASG), calycosin (CA), and formononetin (FO) were purchased from Weikeqi Biological Technology Co. Ltd. (Sichuan province, China). Ascorbic acid (VC), 2,2-diphenyl-1-picryl-hydrazyl-hydrate (DPPH), linoleic acid, butylated hydroxytoluene (BHT), and *β*-carotene were obtained from Sigma-Aldrich Co. (Steinheim, Germany). *A. rhizogenes* LBA9402 strain was obtained from the Key Laboratory of Forest Plant Ecology, Ministry of Education, Harbin, China. The bacterial culture was maintained at 25 ± 1 °C on yeast mannitol broth (YMB) medium. Other reagents of either analytical or optical grade were purchased from Beijing Chemical Reagents Co. (Beijing, China). Ultrapure water was prepared from a Milli-Q system at 18.3 MΩ resistance (Millipore, Bedford, MA).

**Induction and Establishment of Hairy Roots.** Young leaves of 3 week old aseptic plantlets were used as explants for hairy root induction. The excised leaf segments were preincubated on half-strength Murashige and Skoog (MS/2) solid medium for 2 days prior to the following infection. After that, the explants were immersed into overnight grown bacterial suspensions of *A. rhizogenes* LBA9402 strain ($OD_{600nm}$ = 0.6−0.8) for 10 min, dry-blotted on sterile filter paper, and incubated in the dark at 25 ± 1 °C on MS/2 solid medium supplemented with acetosyringone (100 *μ*M). After 2 days of cocultivation, the explants were transferred to the hormone-free MS solid medium containing sodium cefotaxim (500 mg/L) to eliminate the residual bacteria. Putative transgenic hairy roots were observed emerging from the wound sites of explants within 13 days of incubation. During subculture every other week, the concentration of antibiotic was gradually decreased and finally omitted, until the bacteria were completely eliminated. Eventually, eight lines (AMHRL I−VIII) among 62 established AMHRLs were selected for the present study.

**Molecular Characterization of Hairy Roots.** Integration of T-DNA responsible for hairy root formation was confirmed by PCR analysis using *rol*B, *rol*C, *aux*1, and *vir*D specific primers (see Supporting Information Table S1) as suggested by previous reports.[20,21] Genomic DNA was isolated from AMHRL II using a DNeasy Plant Mini Kit (Tiangen, China) following the manufacturer's instructions. PCR amplification of *rol*B, *rol*C, *aux*1, and *vir*D genes was performed by a S1000 thermal cycler (Bio-Rad, Hercules, CA) according to the following program: initial denaturation at 94 °C for 5 min, followed by 30 cycles of denaturation at 94 °C for 30 s, annealing at 59 °C for 50 s, and extension at 72 °C for 50 s, and final extension at 72 °C for 7 min. PCR products were analyzed by electrophoresis on a 2.5% (w/v) agarose−ethidium bromide gel along with 1000 bp DNA marker. Additionally, genomic DNA isolated from *A. membranaceus* aseptic plantlets and Ri-plasmid (pRi) DNA from *A. rhizogenes* LBA9402 strain were used as negative and positive controls, respectively.

**Optimization of Culture Conditions.** Once the highly productive AMHRL was identified, a certain amount of hairy roots was transferred into 250 mL Erlenmeyer flasks containing 150 mL of MS liquid medium (pH 5.8) supplemented with 1% casein hydrolysate without $NH_4NO_3$, and further incubated on a rotary shaker (100 rpm) at an appropriate temperature in the dark. AMHRCs were harvested by filtration after a certain period of cultivation and dried in a vacuum drier at 60 °C until achieving constant weight. Thereafter, biomass DW and total IF (TIF) content (sum amount of CAG, ON, ASG, CA, and FO) were measured and determined, respectively.

In order to obtain optimal biomass production and IF accumulation during the culture process, a Box−Behnken design (BBD) was applied to investigate the effects of four independent key variables (culture temperature 24−32 °C, sucrose concentration 2−4%, inoculum size 1−2%, and harvest time 20−40 days) on dependent variables (biomass DW and TIF content). The inoculum size was calculated based on the fresh weight (FW) of hairy roots. Regression analysis was carried out to evaluate the response function as a quadratic polynomial:

$$Y = \beta_0 + \sum_{j=1}^{k} \beta_j X_j + \sum_{j=1}^{k} \beta_{jj} X_j^2 + \sum \sum_{i<j} \beta_{ij} X_i X_j \quad (k = 4)$$

where $Y$ is the predicted response; $\beta_0$, $\beta_j$, $\beta_{jj}$, and $\beta_{ij}$ are regression coefficients for intercept, linearity, square and interaction, respectively; $X_i$ and $X_j$ are independent coded variables; and $k$ represents the number of variables. The actual and coded levels of independent variables used in the experimental design are summarized in Table 1. The experiment data were statistically analyzed with Design-Expert 7.0 (State-Ease, Inc., Minneapolis MN). Analyses of variance (ANOVA)

[a]AMHRL II in full strength MS liquid medium (pH 5.8) supplemented with 1% casein hydrolysate. [b]CT is expressed as the culture temperature (°C). [c]SC is expressed as the sucrose concentration (%, g/L). [d]IS is expressed as the inoculum size (%, g/L). [e]$t$ is expressed as the harvest time (days).

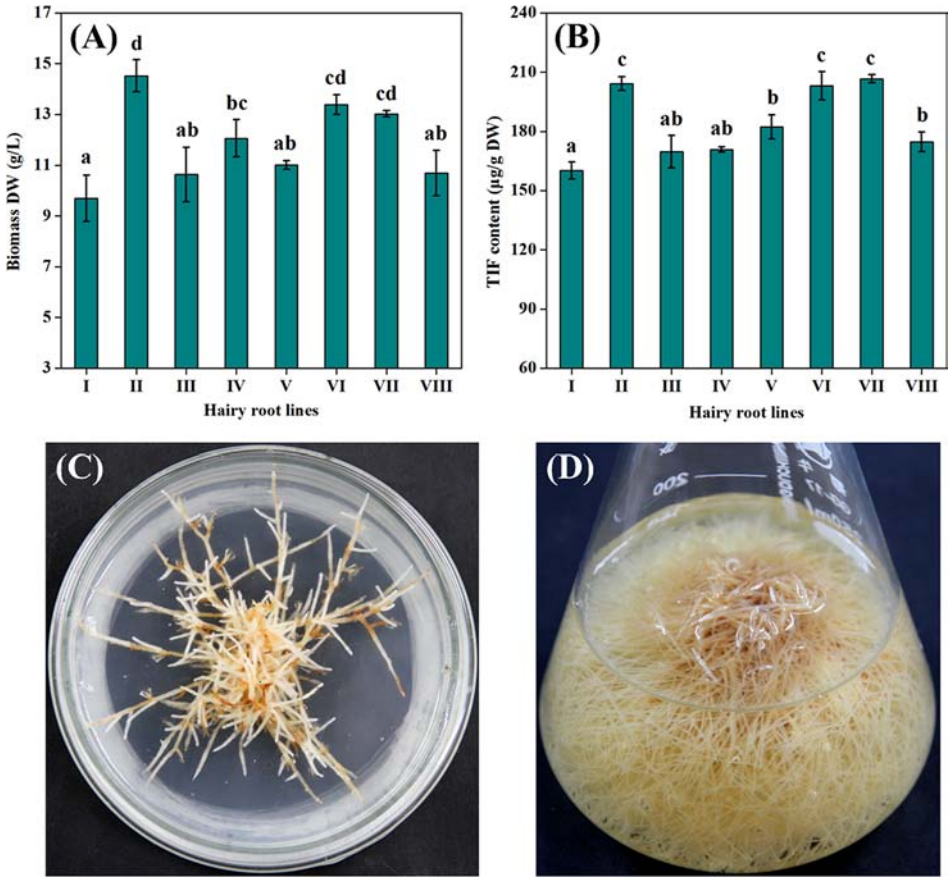

**Figure 1.** (A) Biomass production and (B) IF accumulation of eight representative AMHRL (I–VIII) after 4 weeks of cultivation in MS liquid medium (culture temperature 25 °C, sucrose concentration 3%, and inoculum size 1.25%). (C) Cultivation of AMHRL II on MS solid medium and (D) its growth in MS liquid medium. Mean ± SD values not sharing the same lowercase letters are significantly different ($P < 0.05$).

was performed to calculate and simulate the optimal values of the tested parameters.

**Extraction of IF.** Powders (0.5 g DW) of hairy roots and 3 year old field grown roots were extracted with 70% ethanol solution (25 mL) in an ultrasonic bath for 120 min. For complete extraction, the above procedure was repeated for three cycles. Subsequently, the supernatant extracts were combined and dried at 45 °C using a rotary evaporator under vacuum with oil pump. The resulting extracts were redissolved in 25 mL of methanol (HPLC grade) and then filtered through a 0.45 μm membrane for LC–MS/MS analysis.

**LC–MS/MS Analysis.** An Agilent 1100 series HPLC (Agilent, San Jose, CA, USA) coupled to an API 3000 triple tandem quadrupole MS (Applied Biosystems, Concord, Ontario, Canada) with a Phenomenex Gemini C18 110A reversed-phase column (250 mm × 4.6 mm i.d., 5 μm) was applied for the analysis of IF. The binary mobile phase consisted of acetonitrile (A) and 0.01% formic acid aqueous solution (B) using the following gradient program: 0–5 min, 45–50% A; 5–7 min, 50–65% A; 7–12 min, 65% A; 12–13 min, 65–45% A; and 13–15 min, 45% A. The column temperature was maintained at 30 °C. The flow rate was 1.0 mL/min, and the injection volume was 10 μL.

Mass spectral analyses were performed in the selected reaction monitoring (SRM) transitions with an electrospray ionization source in the negative ion mode. The universal parameters were set as follows: nebulizing gas (NEB) 12 au; curtain gas (CUR) 10 au; collision gas (CAD) 6 au; ion source temperature (TEM) 300 °C; ion spray voltage (IS) −4500 V; focusing potential (FP) −75 V; and entrance potential (EP) −10 V. To obtain the highest response for each analyte, the specific parameters for acquiring the optimal precursor/product ion combinations were optimized, e.g., declustering potential (DP), collision energy (CE) and collision cell exit potential (CXP) (Supporting Information Table S2). The content of each target compound was calculated by corresponding calibration curves and expressed as micrograms per gram based on the DW of roots.

**Determination of Antioxidant Activities.** Antioxidant activities of extracts from AMHRCs and AMFGRs were assessed using the DPPH radical-scavenging assay and β-carotene/linoleic acid bleaching test. Scavenging activities of samples toward DPPH radicals were determined according to the previously reported method.[22] Lipid antioxidant activities of samples toward β-carotene/linoleic acid were evaluated in accordance with the method described by Wu et al.[23] VC and BHT were used as the synthetic antioxidants. Antioxidant activities of samples were reported as $IC_{50}$ values, which were calculated using logarithmic regression curves for DPPH radical scavenging ratio or β-carotene bleaching inhibition percentages (%) versus the concentrations of samples (mg/mL).

**Statistical Analysis.** Results were expressed as means ± standard deviations. The data were statistically analyzed using the SPSS statistical software (version 17.0, SPSS Inc., Chicago, IL, USA). Differences between means were determined by analysis of variance (ANOVA) with Tukey's HSD post hoc test at a level of significance of $P < 0.05$.

## RESULTS AND DISCUSSION

**Screening the High-Productive Hairy Root Line.** Generally, hairy roots carry the *aux* and *rol* genes in their genome as a result of the transfer of the plasmidic T-DNA from *A. rhizogenes*, and the genetic integration is inherently stable.[12−19] *Aux* genes are responsible for the auxin synthesis in hairy roots leading to unlimited proliferation.[12,13,17] *Rol* genes can affect growth and development of transformed roots,[17,19] and induce secondary metabolite synthesis through a

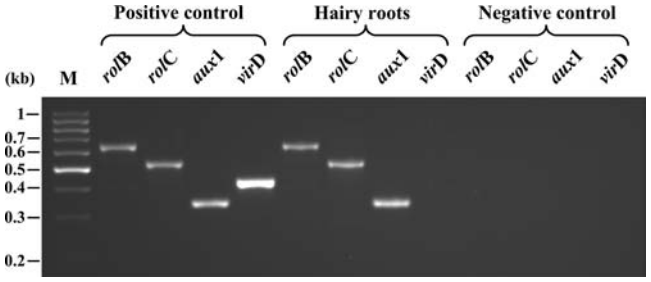

**Figure 2.** PCR analysis of *rol*B (670 bp), *rol*C (534 bp), *aux*1 (350 bp), and *vir*D genes (438 bp) in AMHRL II, positive control (*A. rhizogenes* LBA 9402 strain), and negative control (aseptic *A. membranaceus* plantlets).

variety of signal transduction pathways (for reviews on functions and applications of *rol* genes in plant secondary metabolism, see Nopo-Olazabal et al.,[15] Sharma et al.,[19] Shkryl et al.,[24] Bulgakov,[25] and Bulgakov et al.[26]). In fact, HRCs are a self-induction system for secondary metabolite biosynthesis due to the effects of *rol* genes. The presence of *rol* genes makes HRCs a self-sufficient system to induce the secondary metabolic pathways (SMPs) at a significant level without a selection mechanism.[19] Consequently, HRCs with inherently induced SMPs are an ideal experimental system for the consistent expression of secondary metabolites without a driving force.

**Table 2. ANOVA Results of the Quadratic Models for Biomass Production and IF Accumulation**

| | biomass DW (g/L) | | TIF content ($\mu$g/g) | |
|---|---|---|---|---|
| source | *P*-value[a] | significance[b] | *P*-value | significance |
| model | <0.0001 | significant | <0.0001 | significant |
| lack of fit[c] | 0.3013 | not significant | 0.2428 | not significant |
| $R^2$ | 0.9652 | | 0.9406 | |

[a]Probability of observing *F*-value, if the null hypothesis is true. [b]*P*-value less than 0.05 indicates that model term is significant. [c]Variation of the data around the fitted model.

Owing to the uncertainty of T-DNA integration into the host plant genome, various derived hairy root lines often show considerable variation in growth rates and diverse biosynthesis patterns of secondary metabolites.[27−29] Therefore, it was essential for the selection of an appropriate hairy root line in the present study. Based on the results of preliminary experiments, AMHRL I−VIII were determined as candidate lines for comparing their abilities of biomass production and IF accumulation. As shown in Figure 1, panels A and B, AMHRL II, VI, and VII were categorized as highly productive lines in terms of biomass DW (13.03−14.52 g/L) and TIF content (203.22−206.75 $\mu$g/g DW) as compared to the others. However, AMHRL II exhibited the best capability for biomass production in spite of no significant differences regarding the TIF content among them. AMHRL II was used as optimal hairy

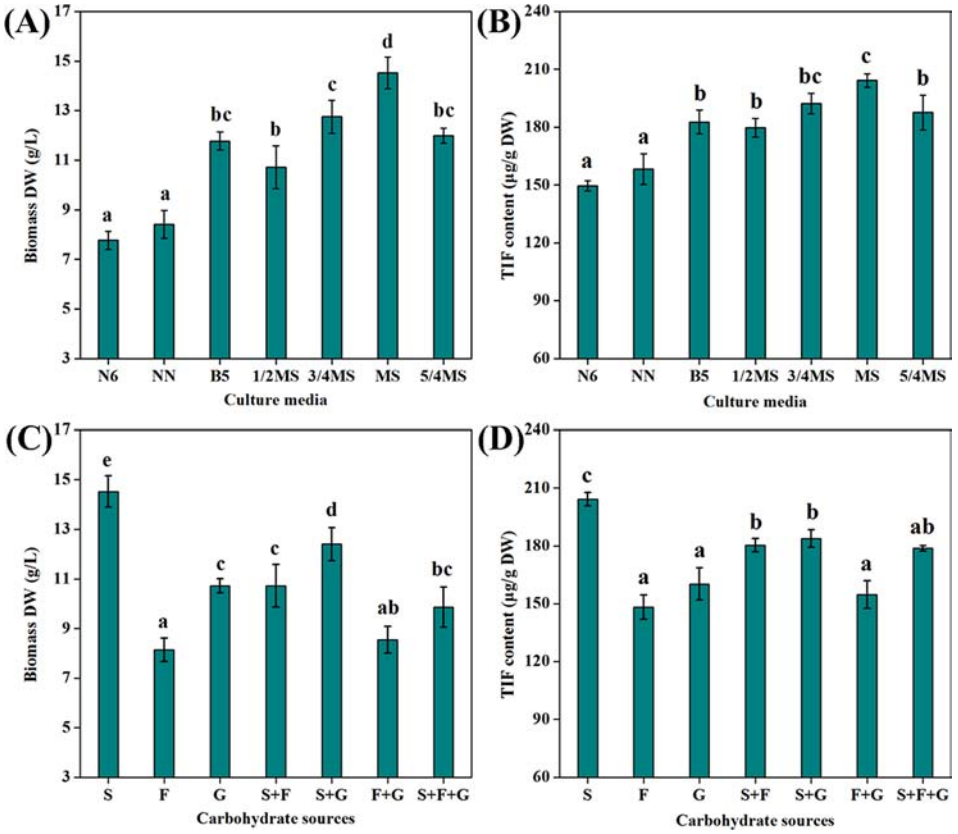

**Figure 3.** Effect of different culture media on (A) biomass production and (B) IF accumulation of AMHRL II after 4 weeks of cultivation (culture temperature 25 °C, sucrose concentration 3%, and inoculum size 1.25%). Effect of different carbohydrate sources on (C) biomass production and (D) IF accumulation of AMHRL II after 4 weeks of cultivation (MS medium, culture temperature 25 °C, inoculum size 1.25% and sugar concentration 3%). S: Sucrose. F: Fructose. G: Glucose. Mean ± SD values not sharing the same lowercase letters are significantly different ($P$ < 0.05).

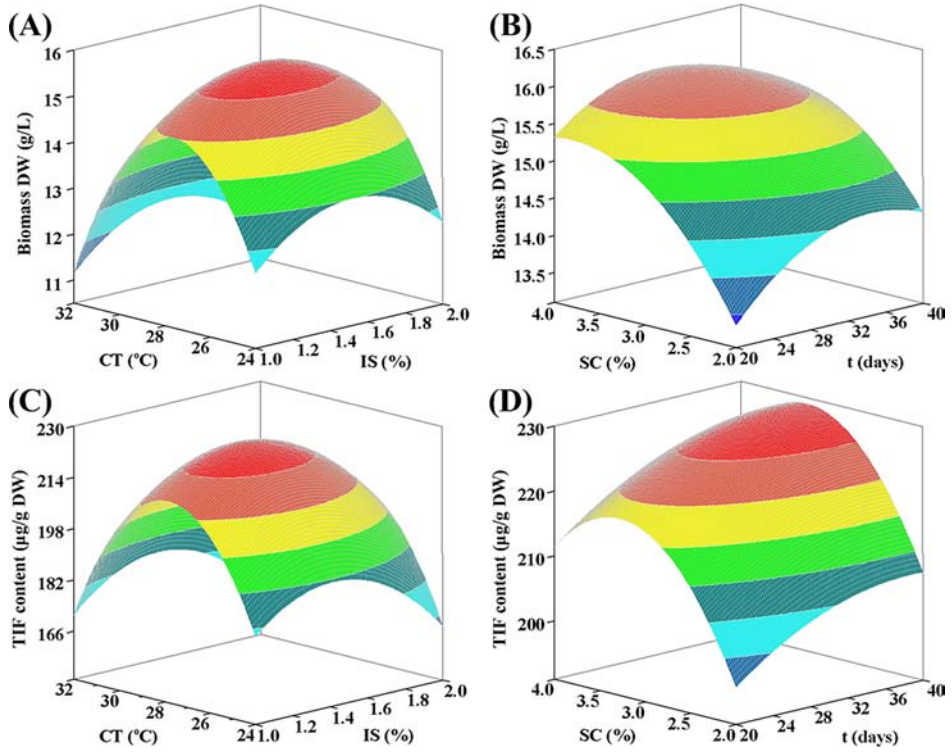

**Figure 4.** Response surfaces for biomass production and IF accumulation of AMHRCs in MS liquid medium: varying culture temperature and inoculum size on (A) biomass DW and (C) TIF content; varying sucrose concentration and harvest time on (B) biomass DW and (D) TIF content.

root line used for subsequent experiments. The cultivation of AMHRL II on MS solid medium and its growth in MS liquid medium are presented in Figure 1, panels C and D, respectively.

**Confirmation of Hairy Roots by PCR.** PCR-based analyses of *rol*B, *rol*C, *aux*1, and *vir*D genes were performed to confirm the genetic transformation of AMHRL II. The *rol*B and *rol*C genes (located at the pRi TL-DNA segment) and the *aux*1 gene (located at the pRi TR-DNA segment) were used to validate the presence of these fragments in the genomic DNA of AMHRL II. In order to prevent interference, the *vir*D gene (located outside the pRi T-DNA segment) served to verify the complete absence of *A. rhizogenes* in AMHRL II. Moreover, aseptic *A. membranaceus* plantlets and *A. rhizogenes* LBA 9402 strain were utilized as negative and positive controls, respectively. As shown in Figure 2, the coexistence of *rol*B, *rol*C, and *aux*1 genes as well as the absence of *vir*D gene were observed in the established hairy root line, indicating that the pRi T-DNA fragments of *A. rhizogenes* were successfully integrated into the genome of AMHRL II without bacterial residues.

**Optimization of Culture Conditions.** As shown in Figure 3A,B, the full strength MS liquid medium was found to be superior compared to other media for both biomass production and IF accumulation. Moreover, sucrose was found to be the ideal carbohydrate source for hairy root growth and IF biosynthesis (Figure 3C,D). Due to the tedious process, the number of experiments necessary for optimizing culture conditions can be reduced by statistical experimental designs. Therefore, the remaining key parameters such as culture temperature, sucrose concentration, inoculum size, and harvest time were systematically optimized by BBD combined with RSM. The experimental design matrix and all relevant data are illustrated in Table 1.

**Fitting Mathematical Models.** ANOVA results of established quadratic models are presented in Table 2. The high significance levels of the models ($P < 0.0001$), nonsignificance "lack of fit" ($P > 0.05$), and desirable determination coefficients ($R^2 \geq 0.9406$) suggested that the built mathematical models were precise and applicable. The second-order polynomial models were applied to express biomass production and IF accumulation:

$$Y_{bio} = 15.74 - 0.49X_1 + 0.77X_2 + 0.078X_3 + 0.027X_4 - 0.27X_1X_2 - 0.002X_1X_3 + 0.33X_1X_4 - 0.013X_2X_3 - 0.19X_2X_4 - 0.86X_3X_4 - 2.98X_1^2 - 0.6X_2^2 - 1.04X_3^2 - 0.51X_4^2$$

$$Y_{TIF} = 225.82 - 2.47X_1 + 7.33X_2 - 4.07X_3 + 5.42X_4 - 0.2X_1X_2 + 1.21X_1X_3 + 0.53X_1X_4 - 1.58X_2X_3 - 1.81X_2X_4 + 2.63X_3X_4 - 39.06X_1^2 - 13.21X_2^2 - 16.03X_3^2 - 3.14X_4^2$$

where $Y_{bio}$ and $Y_{TIF}$ were the biomass DW (g/L) and TIF content ($\mu$g/g DW), respectively; $X_1$ was the culture temperature (°C); $X_2$ was the sucrose concentration (%), $X_3$ was the inoculum size (%), and $X_4$ was the harvest time (days).

**Analysis of Response Surfaces.** As shown in Figure 4A,C, both culture temperature and inoculum size exhibited significant effects on biomass production and IF accumulation. At a fixed inoculum size, the biomass DW and TIF content increased with raising temperature from 24 to 28 °C, because growth and metabolic activities of hairy roots were enhanced with increasing temperature. However, higher temperature (30−32 °C) resulted in irreversible damage of proteins in root

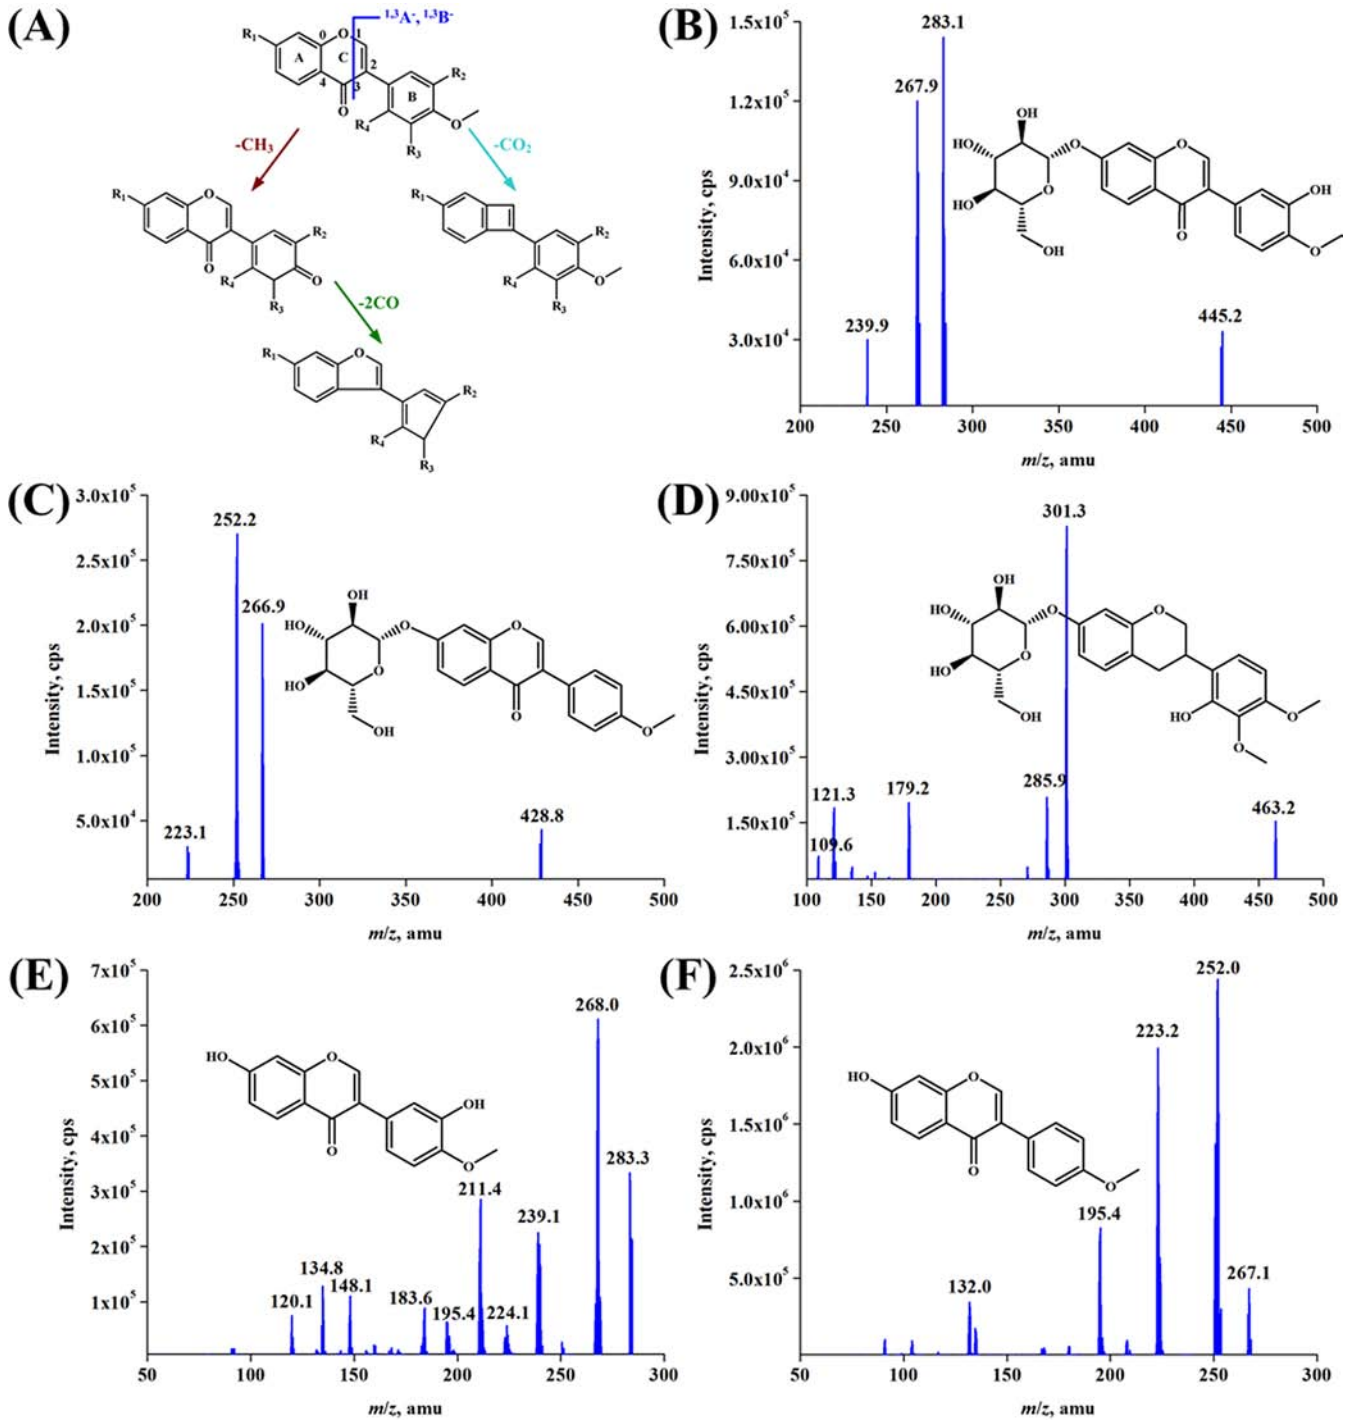

**Figure 5.** (A) The main fragmentation pathways of IF, and ESI−MS/MS analysis of (B) CAG, (C) ON, (D) ASG, (E) CA, and (F) FO originating from AMHRCs.

tissues,[30] leading to a decrease in biomass DW and TIF content. Additionally, the biomass DW and TIF content increased with the extension of inoculum size from 1% to 1.6% at a given culture temperature, but decreased gradually afterward. The restriction of root growth and IF biosynthesis under higher inoculum size (1.6−2.0%) was ascribed to the limitation of nutrients, oxygen levels, and volume of culture flasks.[31] Moreover, a sucrose concentration around 3.5% favored biomass production and IF accumulation at a fixed harvest time (Figure 4B,D). Generally, sucrose has a dual role as carbon source and osmotic agent in plant cell/organ culture media.[28] Higher consumption of sucrose favored the growth of hairy roots and the biosynthesis of metabolites. However, the osmolality of culture media increased with raising sucrose concentration, which caused the loss of cell viability by dehydration and promoted the diffusion of phytochemicals from tissues into media. This led to low biomass production and IF accumulation in AMHRCs. Furthermore, at a given sucrose concentration, the biomass DW and TIF content initially increased with extended time, but nearly stabilized beyond 32 days, which might be due to the depletion of medium nutrients and the liquid mass-transfer limitations.[32]

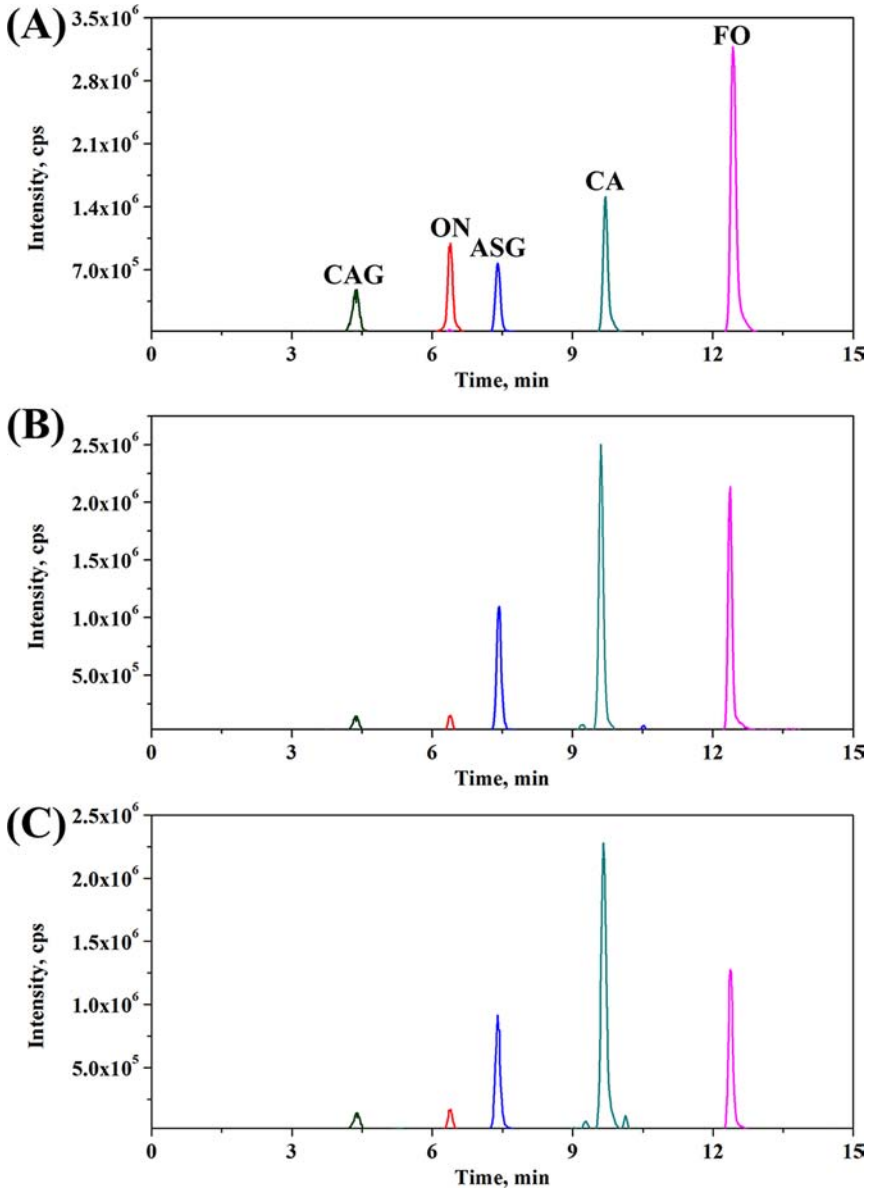

**Figure 6.** Representative LC−MS/MS with SRM total ion chromatograms of (A) standards and extracts from (B) 34 day old AMHRCs and (C) three year old AMFGRs.

**Verification of Predictive Models.** Based on the above mathematical models, the optimal operational conditions were obtained as follows: culture temperature 27.78 °C, sucrose concentration 3.39%, inoculum size 1.44%, and harvest time 34.09 days. Considering the actual operation, culture temperature and harvest time were modified to 27.8 °C and 34 days, respectively. To validate the reliability of these predictive parameters, six sequential experiments adopting AMHRL II were performed using the above optimized conditions. The optimal values of biomass DW (15.74 ± 0.49 g/L) and TIF content (234.77 ± 4.27 μg/g DW) were very close to those (15.98 g/L and 228.62 μg/g DW) forecast by theoretical models. Therefore, the culture conditions achieved by BBD combined with RSM were reliable and practical.

**LC−MS/MS analysis of IF.** In the present study, an accurate LC−MS/MS method was developed for simultaneous quali−quantitative determination of CAG, ON, ASG, CA, and FO from AMHRCs. The ESI-MS/MS analysis of each compound originating from AMHRCs was initially performed, and the main fragmentation pathways are displayed in Figure 5A. As shown in Figure 5B, CAG (retention time 4.37 min) produced a precursor ion of $m/z$ 445.2 ($[M - H]^-$), which fragmented into the primary product ions of $m/z$ 283.0 $[M - H - \text{glucose}]^-$ and 267.9 $[M - H - \text{glucose} - CH_3]^-$. Likewise, the MS fragmentation patterns of ON, ASG, CA, and FO are presented in Figure 5, panels C, D, E, and F, respectively. All MS information on these compounds was consistent with the reported data[3,33−35] as well as that of standard compounds, which confirmed that the established AMHRCs could indeed produce CAG, ON, ASG, CA, and FO. Additionally, LC−MS/MS analysis with SRM mode was applied for quantification of five target analytes in AMHRCs and AMFGRs. The representative chromatograms are presented in Figure 6.

In this study, AMHRCs (34 days old) yielded 9.22 ± 0.23 μg/g DW of CAG, 4.04 ± 0.16 μg/g DW of ON, 66.42 ± 2.53 μg/g DW of ASG, 94.85 ± 1.99 μg/g DW of CA, and 60.25 ± 3.34 μg/g DW of FO, which were comparable to or greater

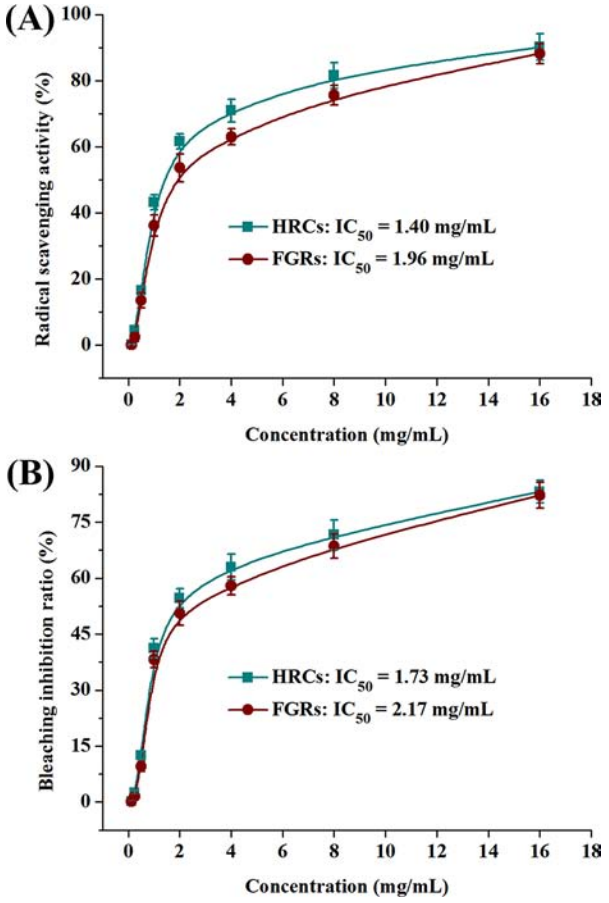

**Figure 7.** Antioxidant activities of extracts from AMHRCs and AMFGRs as assessed by (A) DPPH radical scavenging assay and (B) $\beta$-carotene/linoleic acid bleaching test.

than those from 3 year old AMFGRs (8.87 ± 0.44 $\mu$g/g DW of CAG, 4.50 ± 0.62 $\mu$g/g DW of ON, 51.92 ± 3.34 $\mu$g/g DW of ASG, 89.35 ± 7.21 $\mu$g/g DW of CA, and 32.75 ± 3.02 $\mu$g/g DW of FO). The TIF content of AMHRCs was 234.77 ± 4.27 $\mu$g/g DW, which was significantly higher than that of AMFGRs (187.38 ± 7.25 $\mu$g/g DW). It is evident that the phytochemical production in HRCs is often affected by the incorporation of T-DNA in the host genome, in which the *rol* genes can induce and enhance the biosynthesis of various secondary metabolites with the *rol*B gene probably being the most powerful inducer followed by the *rol*C gene.[15−17,19,21,24−26] From this point of view, the existing *rol*B and *rol*C genes (Figure 2) are likely to be the stimulators for the activation of IF accumulation in AMHRCs.

**Antioxidant Activities of AMHRC Extracts.** The intake of IF is associated with a broad variety of health benefits to humans, and it is generally believed that the beneficial properties of IF (e.g., prevention of cardiovascular disease, cancer, and inflammation) might be related to their antioxidant activities.[36] Therefore, another aim of this study was to evaluate the antioxidant properties of AMHRC extracts and hypothesize their possible uses in pharmaceutical, cosmetic nutritional, and nutraceutical applications. In this work, the DPPH radical-scavenging assay was used to measure antiradical activities, while the $\beta$-carotene/linoleic acid bleaching test was applied to determine antilipid peroxidation capacities. As shown in Figure 7A,B, the antioxidant activities of extracts from AMHRCs and AMFGRs obviously appeared as dose-dependent relationships. However, AMHRC extracts exhibited superior efficacies in terms of antiradical ($IC_{50}$ value of 1.40 mg/mL) and lipid peroxidation inhibition ($IC_{50}$ value of 1.73 mg/mL) as compared to those of AMFGRs ($IC_{50}$ values of 1.96 and 2.17, mg/mL, respectively). Additionally, the $IC_{50}$ values of VC (the reference in DPPH radical-scavenging assay) and BHT (the reference in $\beta$-carotene/linoleic acid bleaching test) were 0.067 and 0.025, mg/mL, respectively.

Although antioxidant activities of AMHRC extracts were quite moderate as against those of synthetic antioxidants, the main focus of this study was on the evaluation of antioxidant properties from AMHRCs as compared to AMFGRs. Due to the presence of phenolic hydroxyls, CAG, ASG, CA, and FO were the primary antioxidant contributors of *A. membranaceus*, which can act as hydrogen/electron donors to neutralize peroxyl free radicals, shown in several in vitro antioxidant assays.[3,37−39] In this study, AMHRC extracts exhibited better antioxidant activities than AMFGRs, which can be partly explained by their higher levels of ASG, CA, and FO as compared to AMFGRs. However, one essential difference of traditional Chinese herbal medicines from synthetic drugs is that their therapeutic effects are due to the joint contribution of multiple components, not only a few ones. Possible synergistic effects of the multiple constituents in AMHRC extracts should therefore be taken into consideration. Overall, the antioxidant activity screening results are indicative of AMHRCs as potentially more effective medicaments compared with naturally occurring roots in food and pharmaceutical industries.

**Predominance of AMHRCs.** The aforementioned results clearly indicated that the highly productive AMHRC system was capable of synthesizing and accumulating IF (34 day old) in higher yield and quality comparable to those of 3 year old AMFGRs. Additionally, AMHRC extracts were more effective in scavenging radicals and inhibiting lipid peroxidation as compared to those of AMFGRs. Moreover, the proposed AMHRC system exhibits several potential advantages as follows: (1) The desired IF products with uniform quality can be harvested anywhere in the world, meeting the stringent criteria of the Good Manufacturing Practice (GMP) guidelines (e.g., absence of agrochemicals). (2) The AMHRC system represents a continuous and reliable production system independent of climate or ecology-related problems and constraints. (3) The system's growth cycle can be measured in weeks rather than years of intact plants grown in fields.

Overall, this study provided the generation of an attractive alternative source for the efficient production of IF. It is assumed that this system will meet the worldwide demand for IF and issues associated with *A. membranaceus* cultivation on account of its prolonged seed dormancy and extensive period from planting to harvest (3−5 years). The present investigation highlighted the importance of optimizing AMHRC growth and culturing conditions to better predict and define IF biosynthetic capacity as precondition for industrial processes. Furthermore, the genetic and biochemical stability of the established AMHRC as well as its high productivity offers an effective platform for further studies on the biosynthetic pathways of IF.

Table 1. Oligonucleotide Sequences Used in Amplification, Immobilization, and Hybridization Experiments Specific for *Staphylococcus aureus* (EF529607.1)

| target | accession no. | oligonucleotide | sequence (5′−3′) | length (bp) | amplicon size (bp) |
|---|---|---|---|---|---|
| *Aeromonas hydrophila* | M84709 | forward primer | 5′-CCAATATGTCGGTGAAGA-3′ | 18 | 161 |
| | | reverse primer | 5′-CATGTTTGAAGCTGTCAG-3′ | 18 | |
| *Staphylococcus aureus* | EF529607.1 | forward primer | 5′-GCTATCAGTAATGTTTCG-3′ | 18 | 151 |
| | | reverse primer | 5′-GCACTATATACTGTTGGA-3′ | | |
| *Staphylococcus aureus* | EF529607.1 | capture probe | 5′-AGTAGCTCAGCAAATGCA-SH-3′ | 18 | |
| | | detection probe | 5′-$NH_2$-CACAAACAGATAACGGCG-3′ | | |

detection of pathogens, such as those incorporating the use of nanoparticles for DNA detection.[15] They allow continuous, fast, sensitive, and selective detection of DNA hybridization, and they can also be reused.[16] These systems usually rely on the immobilization of a single-stranded DNA (ssDNA) probe onto a surface to recognize its complementary DNA target sequence by hybridization.[16] Transduction of hybridization of DNA can be measured electronically.[17] The electrochemistry relies on the use of different inorganic-colloid nanoparticles (zinc sulfide, cadmium sulfide, and lead sulfide) to differentiate the target DNA signals in connection with a sandwich hybridization and highly sensitive stripping voltammetry of the corresponding targets. DNA hybridization biosensors play an important role in pharmaceutical, clinical, and forensic applications. Some techniques have been successfully applied to the development of genosensors based upon the combination of a suitable transducer.[18]

The use of nanomaterials and nanotracers in biosensors allows new transduction technology and application of a bismuth layer on glass carbon electrodes to detect heavy metals in samples showing an alternative material to substitute toxic mercury.[5,19−21] The main advantages of bismuth are the high capacity to form fused alloys with metals, which are less affected by dissolved oxygen. However, it fails to detect low amounts of analyte due to its poor conductivity,[10,22] but applied multiwall carbon nanotubes−bismuth modified on glassy carbon electrodes showed increased sensitivity in the detection of trace metals.

In the present work, a sensitive and selective electrochemical DNA biosensor for the rapid detection of *S. aureus* was measured. Signalizing probe DNA was connected with lead sulfide nanoparticles coated with 5′-($NH_2$) oligonucleotide using 1-ethyl-3-[3-(dimethylamino)propyl]carbodiimide hydrochloride (EDC) as a cross-linker. The fixing probe (fDNA) was another complementary sequence of DNA with thiol modification, which strongly adsorbed on the gold electrode surface (GE). After hybridization, the sandwich structure was dissolved in 1 M $HNO_3$ to release $Pb^{2+}$, which was electrodeposited on the glass carbon electrode (GCE) surface decorated with MWCNT−Chi−Bi. Finally, the signal was measured by differential pulse voltammetry (DPV).

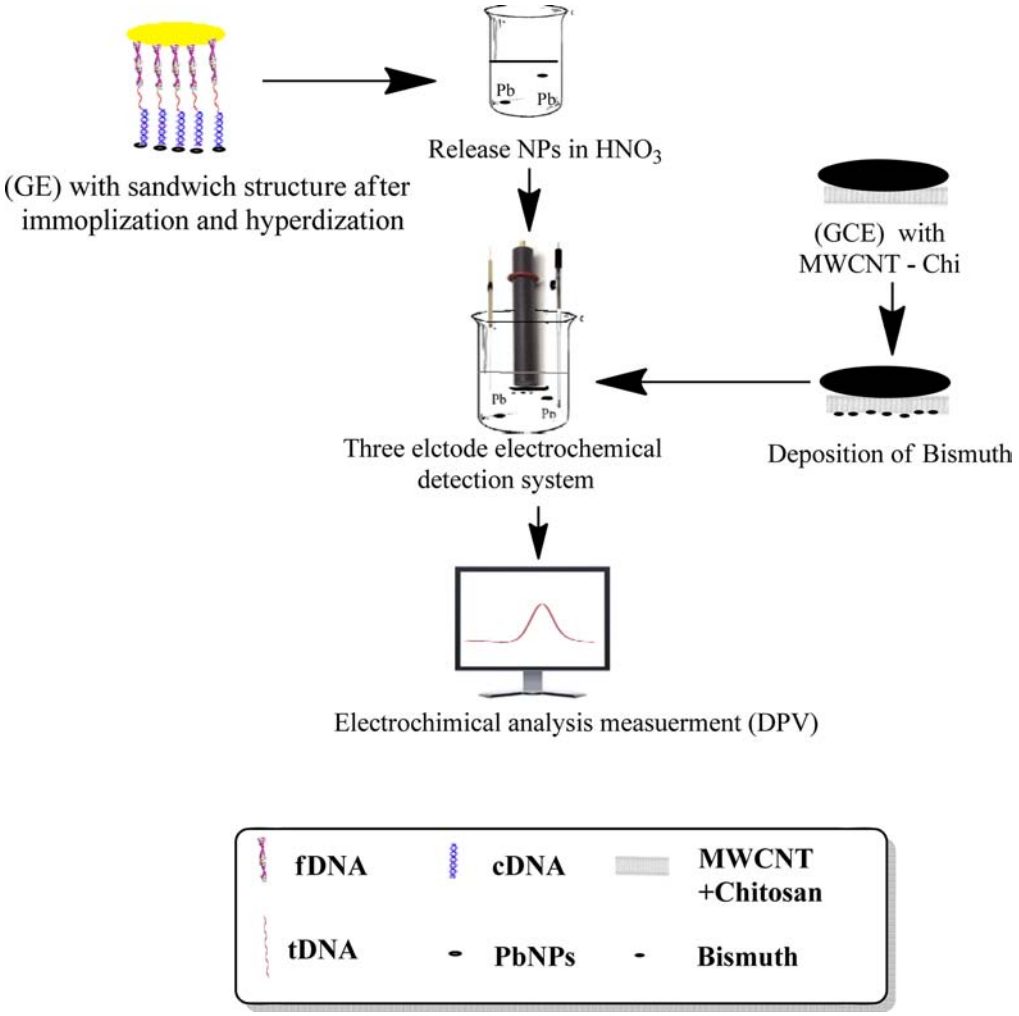
## EXPERIMENTAL PROCEDURES

**Reagents and Materials.** Lead nitrate $Pb(NO_3)_2$, sodium sulfide ($Na_2S$), sodium hydroxide (NaOH), and 3-mercaptoacetic acid $C_2H_4O_2S$ (used as a stabilizer for the NPs) were used for the synthesis of lead sulfide nanoparticles (PbS NPs). EDC, salmon sperm DNA, and buffers were used for the conjugation of the carboxylic group on NPs, and an amine group on the capture probe was obtained from Sigma Aldrich. 6-Mercapto-1-hexanol was purchased from Tokyo Chemical Industry Co. Ltd. (Tokyo, Japan). Hybridization buffer PBS (potassium phosphate buffer with NaCl, pH 7.4), washing buffer Tris-HCl (pH 8.0) with Tween-20, and sodium dodecyl sulfate (SDS) were used to remove the unhybridized DNA. Multiwalled carbon nanotubes were obtained from Nanjing Xianfeng Nanomaterials Technology Co. Ltd. (Nanjing, China). Chitosan was put on the surface of the electrode to increase the sensitivity. A PCR kit was set up to purify the DNA products after PCR amplification was purchased from Sangon Biotech Co. (Shanghai, China). Bismuth nitrate in nitric acid 0.5 mol/L obtained from Scharlau Chemie S.A. (Spain) was deposited on the GCE surface prior to electrochemical processing. All of the solutions were prepared using ultrapure water from a Millipore Milli-Q system. All oligonucleotides used in the sensors were purchased from Takara Co. (Dalian, China) and Sangon Biotechnology Co., Ltd. (Shanghai, China) with HPLC purification and working solutions prepared by dilution in PBS buffer.

**Apparatus.** The morphology and characterization of lead nanoparticles were studied by transmission electron microscopy (TEM) (JEM-2100, JEOL, Japan). An incubator for the hybridization reaction, magnetic stirrer, and vortex mixer were used to conjugate the carboxylic group on PbS NTs and the amine group on the capture probe. A centrifuge (5804 R Eppendorf, Hamburg, Germany) was used to separate the nanoparticles and extract the DNA. Nanodrop (Thermo Scientific, Ashville, NC, USA) was used to measure the concentration and purity of DNA. Gel electrophoresis was performed using a Bio-Rad electrophoresis instrument (Powerpac Universal, Bio-Rad, USA). The three electrode electrochemical detection system consisted of a GCE (working electrode), an Ag/AgCl reference electrode (saturated KCl), and platinum wire as counter electrode. The gold electrode, GCE (working electrode) and silver/silver chloride electrode (counter and reference electrodes) were purchased from (Chenhua, Shanghai, China). A gold electrode (diameter = 2 mm) was used to make sandwich structures and a GCE (diameter = 2.5 mm) was used for measuring target DNA. Electrochemical measurements were performed with an electrochemical station analyzer (Shanghai CH Instruments Co., China).

**Bacteria Culture and Genomic Extraction.** *S. aureus* (accession no. EF520720.1) was obtained from Zhangjiagang Entry-Exit Inspection and Quarantine Bureau (Suzhou, Jiangsu province, China), and *A. hydrophila* (accession no. M84709) was obtained from Fresh Water Fisheries Research Center (Wuxi, China). The nucleotide sequences submitted with these accession numbers were used in designing primers and probes for targeted gene amplification and detection. Other strains were collected and preserved at Jiangnan University laboratories. Pure cultures of *A. hydrophila* were grown in ampicilin starch agar phenol red, and *S. aureus* was grown in *Staphylococcus* selective agar (CM 310) and obtained from Beijing Land Bridge Technology Co., Ltd., China. Inoculum media were incubated at 37 °C for 24 h, in duplicate aerobiosis. Colonies were purified by streaking on the same media and incubating at 37 °C for 24 h. This treatment step was repeated several times to obtain a pure culture. Genomic DNA was extracted by slightly modified boiling methods[23,24] from tubes after incubation for 18 h in tryptic soy broth media (TSB). Briefly, the culture was heated in a water bath for 10 min to kill all surviving bacteria, and one portion of each broth was centrifuged at 13000 rpm for 5 min at 4 °C. The pellet was suspended in 500 μL of sterile distilled water (DD water) and vortexed

**Scheme 1. Steps of Representation of Sandwich Structure and GCE with MWCNT−Chi**



vigorously. The bacterial suspensions were boiled in a water bath for 15 min, then rapidly cooled at −20 °C for 10 min to shock the cells, and then centrifuged again at 12000 rpm for 3 min to precipitate the debris. The supernatant containing genomic DNA was harvested into a clean tube and used as the DNA template for PCR amplification.

**Oligonucleotides.** The primers were designed to provide PCR amplification, and the probe was complementary to part of the fragment, allowing it to hybridize with the PCR product. The probes were designed with modification (3′SH and 5′$NH_2$) and purification by HPLC to allow the detection of the PCR product using National Center for Biotechnology Information (NCBI) databases using Basic Local Alignment Tool (BLAST) software (http://www.ncbi.nlm.nih.gov/).[24] DNA calculators from Sigma-Aldrich to specify the primer sequences were further verified using software (http://www.sigmagenosys.com/calc/DNACalc.asp). All oligonucleotides used in the sensors were obtained from Takara Co. and Sangon Biotechnology Co., Ltd., and the reverse and forward primers were diluted to 0.4 μM. The sequences of the oligonucleotides are shown in Table 1.

**PCR Conditioning.** A fragment (151 bases) of the *S. aureus* (accession no. EF529607.1) gene was amplified using the forward and reverse primers. PCR was performed in a reaction solution with a total volume of 25 μL containing (2.5 μL) PCR buffer and (2 μL) deoxynucleoside triphosphate (dNTP) mixture obtained from Takara. Mixed together were 1 μL of each primer (0.4 μM), 1 μL of template DNA, 0.25 μL of Taq DNA polymerase, and 17.25 μL of sterile double-distilled water (DDW) to obtain the reaction mixture. Specificity of the primer amplifications was performed and verified using strains of *S. aureus* (EF529607) as target DNA and *A. hydrophila* (ATCC 7966) as the negative control. Amplification conditions were carried out using the following protocol: initial denaturation at 94 °C for 2 min followed by 30 cycles of denaturation at 94 °C for 30 s, annealing at 46 °C for 30 s, and an extension at 72 °C for 1 min, followed by a final extension at 72 °C for 5 min, and finally a hold at 4 °C. All amplification reactions were carried out in a thermal cycler (Takara, Gradient PCR). PCR products (5 μL) with a loading buffer were visualized by electrophoreses through 2% agarose gel in TAE buffer and stained with Andy Safe DNA gel stain (BioProbes, USA). A DNA molecular ladder (100 bp) obtained from (Takara) was included in each gel as a molecular weight marker. The gels were photographed under ultraviolet light using a Bio-Rad Gel doc 1000 molecular imager.

**Genome Purification and Dilution.** The PCR product was purified by using a PCR purification kit, from Shanghai Sangon Bioengineering Ltd. Co., according to the manufacturer's instructions, and then stored at −20 °C until use. Then, it was diluted serially with PBS buffer, and PCR product quantification and concentration were measured with a nanodrop spectrophotometer and used as DNA samples for the experiments.

**Synthesis of Lead Sulfide Nanoparticles.** All glassware used in the following procedure was carefully cleaned by soaking in a bath of freshly prepared aqua regia solution 1:3 $HCl/HNO_3$ over 24 h followed by rinsing thoroughly in twice-distilled water and dried in an oven. The pH values of all nanoparticle solutions prepared were recorded using a pH meter (Mettler-Toledo instruments, Delta 320, Shanghai, China). All steps of the synthesis were performed at room temperature and ambient conditions. For the preparation of lead sulfide nanoparticles (PbS NPs), $Pb(NO_3)_2$ and $Na_2S$ solutions were filtered through a nylon syringe filter (25 mm × 0.22 μm) (ANPEL Scientific Instrument, Shanghai, China) prior to use. PbS NPs were

prepared according to the literature.[25,26] Briefly, 9.22 μL of thioglycolic acid ($C_2H_4O_2S$) used as a stabilizer was added to 50 mL of 0.4 mmol $L^{-1}$ Pb $(NO_3)_2$ solution under vigorous stirring, and then the pH was adjusted to 7.0 with 0.5 mol $L^{-1}$ NaOH. The solution was bubbled with nitrogen for 30 min, then 50 mL of 1.34 mmol $L^{-1}$ $Na_2S$ was added dropwise to the mixture solution. The reaction was carried out for 24 h under nitrogen bubbling, and gradually a brown colloid was formed. The colloid was stable for 3 weeks in a brown bottle at 4 °C.

**Characterization of Nanoparticles.** A JEOL JEM-2100 (HR) transmission electron microscope (TEM) from Electronic Inc. Co., Japan, was used to observe the morphology and particle size distribution in PbS NPs solution. Samples were prepared by dropping aliquots of the colloidal solution onto holey copper-coated grids, which were then dried at room temperature.

**Preparation of Multiwalled Carbon Nanotubes−Chi.** The MWCNT−Chi matrix was used to increase the sensitivity of GCE. Before mixing with chitosan, MWCNT was treated with concentrated $HNO_3$ for 2 h and dried in a vacuum at 30 °C. Then, 10 mg of treated MWCNT was mixed with 20 mL of (2%) acetic acid and 2.5 mg of chitosan, followed by ultrasonification for 2 h. The prepared MWCNT−Chi was stored at room temperature until further use.[22,27]

**Immobilization of Probe DNA.** Immobilization of capture probe DNA was performed according to the literature[26,28,29] with slight modifications. The sequences of the probe oligonucleotides used in this study are shown in Table 1. According to the literature,[26,29] the most critical step in the preparation of a DNA biosensor is the immobilization of the DNA probe on the surface of the sensing device such as an electrode. Prior to use, the gold electrode was first heated in a Piranha solution (3:7 $H_2O_2$/concentrated $H_2SO_4$) for about 10 min and then subsequently hand polished thoroughly with 0.03 μm and 0.05 nm alumina slurries, respectively, and a microfiber pad to a mirror-like finish. This was followed by cleaning for 5 min in ethanol and water, respectively, to remove all residual alumina powder and other possible contamination. The electrode was then electrochemically cleaned in 0.5 M of $H_2SO_4$ to ensure complete removal of contaminants from the electrode surface and finally dried in a stream of nitrogen gas.

The fixing probe was diluted by using 10 mM TCEP with a 1:1 ratio and incubated at room temperature for 1 h. The probe was then dropped in the electrode and incubated at 4 °C overnight to form chemisorption of the thiol groups onto the gold surface. The gold electrode was washed with 0.1 M, pH 8.0, Tris-HCl containing 0.05% Tween-20 to remove excess fixing probe and then immersed in a 1 mM MCH solution for 1 h to obtain a well-aligned DNA monolayer and for 30 min in 125 μg/mL salmon sperm DNA to block specific binding and 2% BSA in 0.1 M, pH 8.0, Tris-HCl to make DNA straight line.

**Hybridization of Probes and PCR Amplified Target DNA.** Prior to use, the purified PCR product (*S. aureus*) was denatured for 10 min at 95 °C and immediately put in −20 °C, and then target denatured PCR product was diluted to the desired concentration[30] to measure different concentrations in the sensor. A gold electrode content fixing probe was immersed into the denatured DNA and incubated for 1 h at 45 °C to make the first hybridization. The hybridized electrode was then immersed into 0.1% sodium dodecyl sulfate (SDS) for 10 min to remove the unhybridized DNA and any nonspecific adsorption of DNA. The second hybirdization was done by immersing the electrode into a solution of 200 μL (PBS buffer) containing the PbS NPs−capture DNA probe for 1 h at 45 °C to form a sandwich structure as fix DNA−target DNA−detective DNA−PbS NPs and then washed three times with a 0.1% SDS phosphate buffer (pH 7.3) to remove the unhybridized DNA probes.[28,29] After hybridization, the carrier containing nanoparticles was immersed into a cell containing 1.0 M nitric acid solution for 5 min to dissolute the sandwich structures. Scheme 1 shows the steps of immobilization and hybridization.

**Electrochemical Analysis.** The GCE and DNA detection procedures are illustrated in Figure 1. Prior to use, the GCE for the experiment was cleaned and dried according to the literature.[28,31] Then 10 μL of MWCNT−Chi was dropped onto the surface of the GCE and dried, then immersed into a solution containing 0.1 M acetate buffer solution (pH 4.5) and 100 μL of bismuth ions. The bismuth films were formed by deposition on the carbon electrode containing MWCNT−Chi, and the deposition was performed in a separate solution prior to measurement of lead and dried. After the hybridization reaction, the gold electrode with sandwich structure (fDNA−tDNA−cDNA−PbS NPs) was immersed in 150 μL of 1.0 mol $L^{-1}$ $HNO_3$ solution for 5 min to dissolve the PbS NPs fixed on the surface of the electrode. All of the experiments were carried out at room temperature. Every test was replicated at least three times. All curves were the average of three test results.

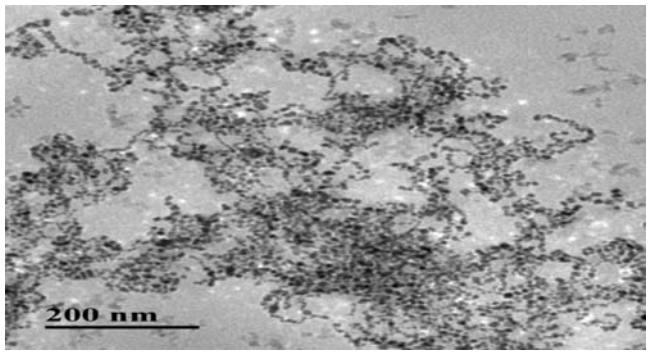


**Figure 1.** Transmission electron micrographs of the synthesized lead nanoparticles (PbS NPs).

**Detection of Target DNA in Artificial Contaminated Beef Meat.** Fresh beef was collected from a local supermarket (Wuxi, Jiangsu province, China), and the meat was removed from the carcasses and transported immediately to the laboratory in an ice box. Prior to inoculation, the samples were treated according to the literature[32] with slight modifications. Briefly, samples were divided into 10 g pieces using a knife that was sterilized under UV radiation. Then, each piece was transferred into sterilized Petri dishes with 100 μL of different concentrations of bacteria ($10^5$−$10^1$ CFU/mL) used as inocula. Aliquots of each dilution were spread onto the surface of the beef samples and stored at 4 °C for 4 h. A sterilized sample without inoculation was used as a negative control. Then, the samples were transferred into a sterilized 250 mL Erlenmeyer flask, and 90 mL of tryptic soy broth (TSB) medium was added immediately with homogenized shaking for 10 min at 200 rpm, inoculation of samples on Petri dishes, and enumeration after 24 h at 37 °C. The samples in the Erlenmeyer flask were incubated overnight at 37 ± 1 °C. A 1.5 mL rinse fluid was taken from the sample Erlenmeyer flask and placed in a sterile 2 mL microcentrifuge tube for DNA extraction. DNA of the pellet was extracted using the boiling methods (described above), and the PCR, purification kit, and electrochemicistry were done as above.

## RESULTS AND DISCUSSION

**Characterization of Nanoparticles.** The colloid chemistry route offers a simple means to synthesize lead sulfide nanoparticles as it uses inexpensive inorganic starting materials and has a good control over the particle sizes and, more importantly, the size distributions. In this study, PbS NPs were chosen as an alternative to oligonucleotide labels. Lead is a good semiconductor due to its electronic and optical properties such as $Pb^{2+}$ ion selective sensors, and lead sulfide nanoparticles are an important direct band gap semiconductor material with a small band gap.[26,33] The structure and morphology of the synthesized nanoparticle product PbS NPs were studied (TEM). Figure 1 shows a TEM image of the synthesized nanoparticles. TEM images of PbS NPs showed a spherical shape with a 4−6 nm diameter.[18] The difference in size depended on many different factors during synthesis but most importantly the pH, temperature, and time of nitrogen flow

based on tests using different experimental conditions. The PbS NPs were stable and did not aggregate after 1 month.

**PCR Amplification.** Figures 2 and 3 show the PCR amplification of target DNA *S. aureus* and negative control *A. hydrophila* for the pure cultures, respectively. The length of primer used in this study was 18 bp, and the results showed that the primer pair was high specific for bacteria in the final product performance PCR reaction. The results indicated that each primer pair was specific for the corresponding target organisms, and it used the amplification reactions for PCR detection of the target genes of *S. aureus* at 151 bp, whereas the *A. hydrophila* band appeared at 161 bp,

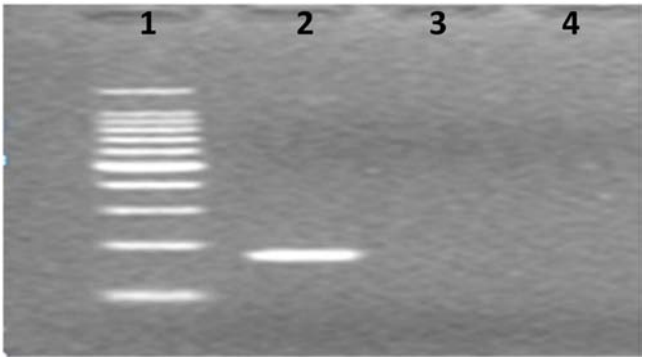

**Figure 2.** Agarose gel electrophoresis analysis (2%) of PCR amplicon. Lanes: 1, molecular marker (100 bp); 2, positive test sample *Staphylococcus aureus* (EF529607.1); 3, negative control containing PCR mixture with *Aeromonas hydrophila* (ATCC 7966); 4, negative control containing PCR mixture with *Escherichia coli* (JX206444.1).

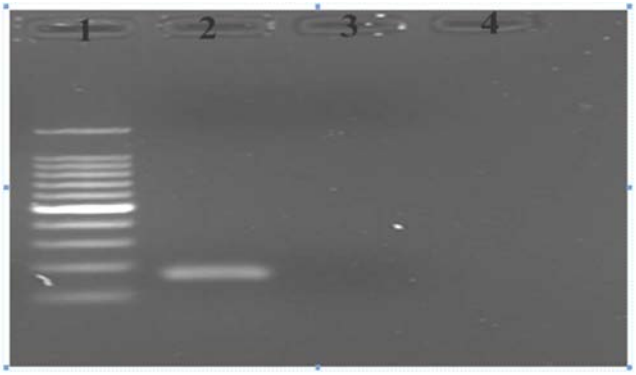

**Figure 3.** Agarose gel electrophoresis analysis (2%) of PCR amplicon. Lanes: 1, molecular marker (100 bp); 2, positive test sample *Aeromonas hydrophila* (ATCC 7966); 3, negative control containing PCR mixture with *Staphylococcus aureus* (EF529607.1).

**Cyclic Voltammetry (CV) and Impedance Spectroscopy.** DNA immobilization and hybridization on the films were studied by CV. CV on a ferricyanide ($K_3$ Fe $(CN)_6$ solution) is a valuable tool to monitor the barrier of the modified electrode. CV is recorded by a three-electrode system, which consists of a working electrode (WE), a reference electrode (RE), and a counter electrode (CE). These electrodes are inside the analyte and connected to an electrochemical station analyzer.[34] The current between the working and the counter electrodes is measured and plotted versus the applied potential between the working and reference electrodes. CV measurements look at redox processes of an analyte in solution $Fe^{3+}$ that converts to $Fe^{2+}$ and then converts again back to $Fe^{3+}$. Figure 4 shows the evolution of the cyclic voltammogram. First the bare electrode was measured, and then the surface was covered with MWCNT−Chi. After that, the deposition of bismuth was optimal after 150 s at −1.4 V. The results showed that signal increased significantly. When the electrode was first treated with fixing probe, a small increase in peak current was observed as the target DNA was deposited on the electrode.

**Impedance Spectroscopy (EIS).** Impedance techniques are useful to monitor changes in electrical properties arising from biorecognition events at the surfaces of modified electrodes. EIS is a powerful tool to monitor the whole procedure in preparing modified electrodes and can provide useful information on various properties including electrode impedance.[35] EIS can also give further information on the impedance changes of the electrode surface during the modification process. EIS measurements were carried out using ferricyanide (1 mM $K_3Fe(CN)_6$ solution) in three electrodes. In EIS, the semicircle diameter equals the electron-transfer resistance. This resistance controls the electron-transfer kinetics of the redox probe at the electrode interface. This is also a powerful and sensitive tool for studying the charge-transfer processes occurring in electrode solutions or modified electrodes.[9,36] Figure 5 shows the EIS at different stages, which was used to test the immobilization of the probe DNA on the electrode.When the immobilized probe DNA was hybridized with its complementary target DNA, the peak increased further. The bare Au electrode exhibited an almost straight line, which was characteristic of a diffusion-limited electron-transfer process, after the electrode was treated by the immobilization of fixing probe peak and remarkably increased. This can be attributed to physical coverage by the oligonucleotides and repulsive electrostatic interaction between the negatively charged phosphate backbone of the single-strand nucleic acid and ferricyanide anion.[35,36] The function of MCH was employed to force the tethered DNA strands to "stand up" on the electrode surface and reduce its nonspecific adsorption on the surface through hydrophobic and electrostatic interactions.[37] The impedance initially increased due to interaction of the fixing probe and immobilization target DNA. The reason behind this observation was the increase in conductivity, followed by an impedance decrease in sandwich structure step. The nanoparticles were conjugated to form a complete sandwich structure onto the modified electrode surface. EIS possesses the ability to study any intrinsic material property or specific processes that could influence the conductivity/resistivity or capacity of an electrochemical system.

**Electrochemical Analysis.** In this study MWCNT was mixed with chitosan and then the bismuth was deposited in the GCE surface. They were used to increase the sensitivity of GCE and to help to improve the stability and sensitivity of the modified electrode. The fixing and capture DNA probes were modified by thiol and amino groups, respectively. The thiol group binds strongly with the gold electrode, and it was complementary with specific target sequence (*S. aureus*). Thiol−metal interactions are frequently used to bind biomolecules covalently onto gold surface biosensors.[16] Amino groups were bound with the PbS NPs and possessed specific target sequences to build the sandwich structure. The probe oligonucleotides (probe DNA) had a thiol modification at the 5′ end to covalently bond to the gold surface. The anchor group (SH unit) was responsible for the chemical link with the gold surface. After immobilization and hybridization, the

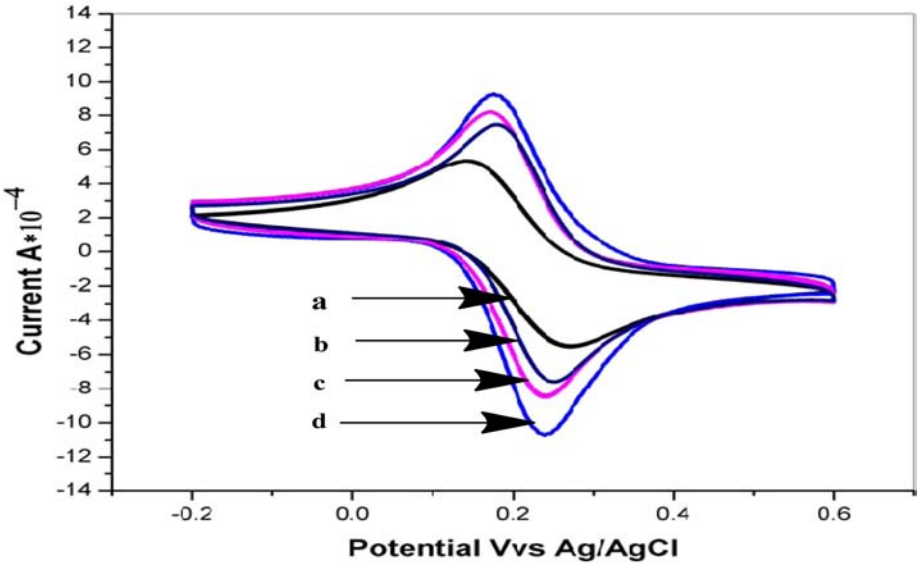

**Figure 4.** Cyclic voltammogram (CV) of the electrode at different stages, responses of 1 mM $K_3Fe(CN)_6$ on (a) clean GCE, (b) GCE with carbon nanotube, (c) GCE with carbon nanotube and bismuth, and (d) GCE with carbon nanotube, bismuth, and NPs.

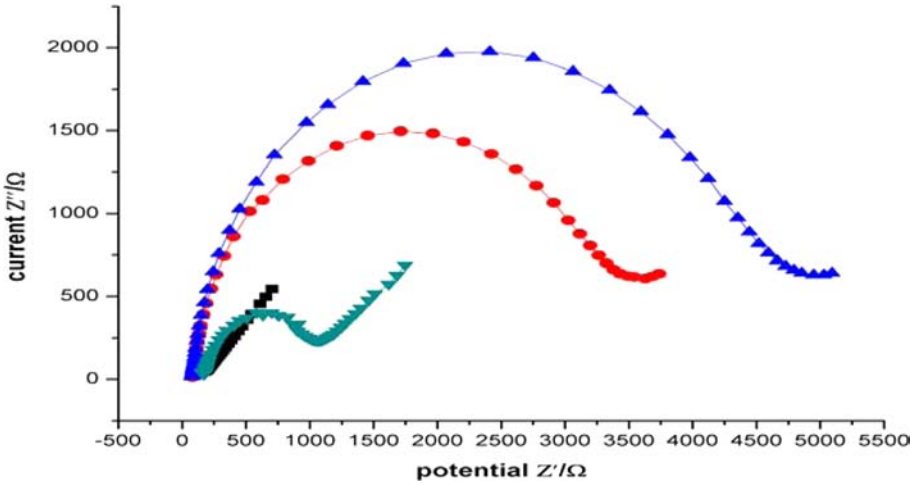

**Figure 5.** EIS of the electrode at different stages (different film-modified electrodes) in otassium ferricyanide [$K_3OFe(CN)_6$] on (Black) the bare gold electrode surface, (Green) gold electrode and fixing probe, (Red) gold electrode, fixing probe, and tDNA, (Blue) gold electrode, fixing probe, tDNA, and capture probe.

sandwich structure (fDNA−tDNA−cDNA−PbS NPs) was formed. The immobilization step for the DNA probe was essential to develop a range of biosensors,[16] after which it was released in 1 M nitric acid and the PbS NPs ions were measured. A potentiostat controlled the voltage, according to a preselected voltage−time program between the working electrode and the counter electrode to maintain the potential difference between the working and the reference electrodes.

Figure 6 shows the DPV measurements performed with target DNA from pure culture bacteria obtained for the detection of DNA using different concentrations of target DNA. As the concentration of the complementary target DNA sequence continuously increased, the concentration of dissolved $Pb^{2+}$ was quantified by DPV. A significant amplification for the detection of target DNA was observed. The DPV signal of the target DNA concentration was $3.87 \times 10^{-14}$−$1.22 \times 10^{-15}$ M, and the limit detection was $3.17 \times 10^{-14}$ M. The voltammetric response increased with target concentration. The peak current of various tDNA concen-

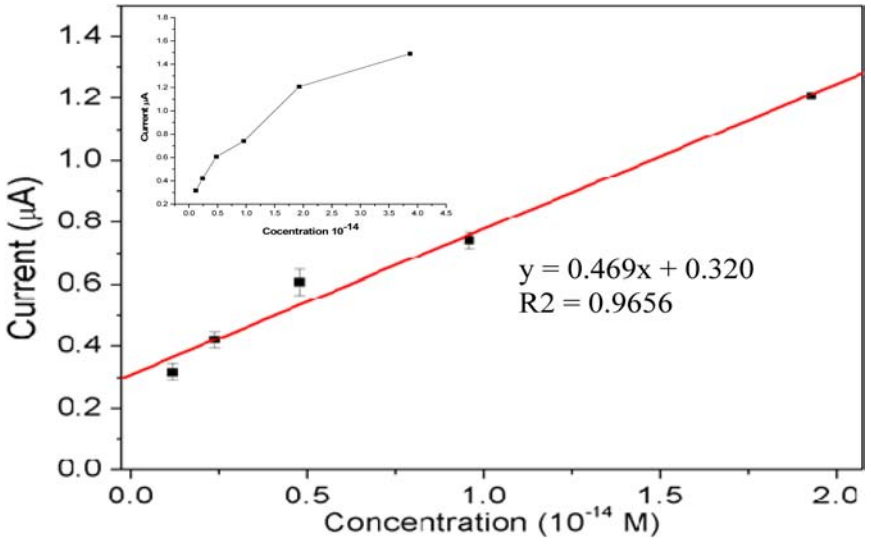

**Figure 7.** Corresponding calibration plots of peak current versus the concentration of *Staphylococcus aureus* genomic DNA detection. The presented values are an average of triplicates with standard deviation.

**Table 2. Limit of Detection of Different Studies Including This Study**

| target | method | detection limit | ref |
|---|---|---|---|
| nopaline synthase (NOS) terminator gene sequences of GMOs | DNA genosensor electrochemical DNA detection with CdS nanoparticle labels | $2.75 \times 10^{-12}$ mol $L^{-1}$ | 28 |
| synthesized oligonucleotides | DNA sandwich electrochemical biosensor based on the amplification of magnetic microbeads and Au nanoparticles | $5.0 \times 10^{-15}$ M | 30 |
| *Mycobacterium* sp. | DNA electrochemical biosensor | 0.25 ng/mL | 29 |
| *Salmonella* invA gene | electrochemical DNA sensor | 0.5 pM | 35 |
| *Staphylococcus aureus* nuc gene | chitosan−$Co_3O_4$ nanorod−graphene | $4.3 \times 10^{-13}$ M | 38 |
| *Staphylococcus aureus* | electrochemical DNA biosensor based on MWCNT−Chi and bismuth | $2.44 \times 10^{-14}$ M | this study |

trations increased with increasing concentration. The equation for the resulting calibration plot was $Y = 0.469x + 0.320$ ($R^2 = 0.965$) as shown in Figure 7. To test the analytical performance of the assay, a calibration experiment was conducted using target DNA. All results shown in this study are the means of a minimum of triplicate measurements. The system was highly sensitive, selective, and efficient in comparison with other DNA biosensors. Table 2 shows the DNA biosensor for this study compared with other studies.

**Detection in Artificially Contaminated Samples.** The present system tested for enumeration of bacteria, and in the six dilutions, the counts ranged from $(4.31 \pm 2.15) \times 10^2$ to $(5.86 \pm 0.74) \times 10^4$ CFU/mL, for *S. aureus*. There were significant growth increases for the different dilutions. Table 3 shows the enrichment for bacteria inoculated into the beef samples, followed by extract and amplification of the DNA. Figure 8 shows the amplification of six different dilutions where the reliability of the PCR amplification was satisfactory. Figure 9 shows the curves of target DNA from beef samples after incubation for 24 h. DPV measurements were performed at −0.2 V versus Ag/AgCl. The calibration curve of DPV peak current increased with different concentrations of target DNA. The results showed that the efficiency was influential in the detection of different concentrations ($10^1$ −$10^5$) of target pathogenic bacteria. The results also showed a gradual increase

**Table 3. Enumeration of *Staphylococcus aureus* on Fresh Beef and after Samples Had Been Inoculated[a]**

| dilution factor | *S. aureus* ± SD (CFU/mL) |
|---|---|
| $10^1$ | $(5.86 \pm 0.74) \times 10^4$ |
| $10^2$ | $(1.82 \pm 0.67) \times 10^4$ |
| $10^3$ | $(1.65 \pm 0.26) \times 10^4$ |
| $10^4$ | $(5.50 \pm 0.54) \times 10^3$ |
| $10^5$ | $(4.31 \pm 2.15) \times 10^2$ |

[a]The number was counted after incubation for 24 h at 37 °C. Data are expressed as the mean ± standard deviation (average of three replications for *S. aureus*). PCR analysis was carried out after overnight culture.

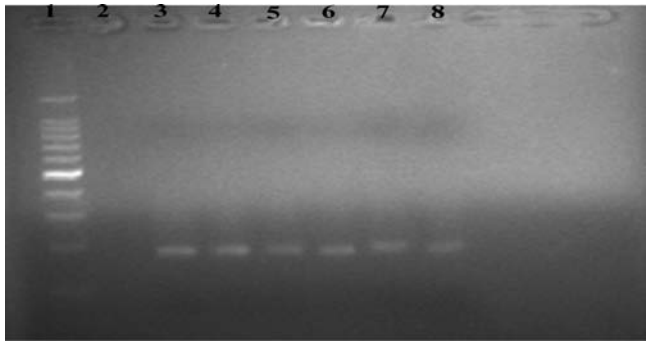

**Figure 8.** Agarose gel electrophoresis analysis (2%) of PCR amplicon extraction from fresh beef. Lanes: 1, molecular marker (100 bp); 2, negative control containing PCR mixture with *Aeromonas hydrophila* (ATCC 7966); 3−6, positive test sample *Staphylococcus aureus* (EF529607.1) in different concentrations.

## MATERIAL AND METHODS

**Chemicals.** The norbixin sample was a commercial Annatto WS28 product containing 2.8% w/w norbixin in aqueous alkaline (pH 12) solution from DD Williamson, LLC (Port Washington, WI, USA). GA and other chemicals were purchased from Fisher Scientific (Pittsburgh, PA, USA).

**Preparation of Norbixin−Gum Arabic Dispersions with or without $Fe^{2+}$.** GA was dissolved at 2% w/v in 150 mL of distilled water. After stirring at room temperature (21 °C) for 30 min, the sample was filtered through a Millex-HN nylon clarification kit with a pore size of 0.45 μm (Fisher Scientific). Subsequently, 2 mL of norbixin aqueous solution (2.8% w/w, pH 12.0) was added to the GA solution and adjusted to pH 5.0 using 1.0 N HCl. For treatments with $Fe^{2+}$, 29.1 mg of ferrous chloride was additionally added into the GA−norbixin mixture, corresponding to a norbixin/$Fe^{2+}$ molar ratio of 1:1.56. After stirring for 30 min, the mixture solution was diluted 10 times in distilled water, and the pH was adjusted to 3.0, 4.0, and 5.0 using 1.0 N HCl. Controls with the same concentrations of norbixin and ferrous chloride as GA−norbixin−$Fe^{2+}$ solutions were prepared by diluting the alkaline norbixin solution in distilled water directly and adjusting the pH to 5.0, followed by the addition of ferrous chloride and pH adjustment as above. To simulate representative pasteurization and sterilization temperatures,[20−22] all samples were heated at 90 or 126 °C for 30 min and cooled in a 21 °C water bath before following analyses within 48 h.

**Color Assay of Norbixin Dispersions.** Color analyses of norbixin dispersions followed the procedures in our recent study.[14] The $L^*$, $a^*$, and $b^*$ values of 5 mL samples were measured using a MiniScan XE Plus Hunter colorimeter (Hunter Associates Laboratory, Inc., Reston, VA, USA). The absorbance of samples at 460 nm was additionally determined using an Evolution 201 UV−vis spectrophotometer (Thermo Scientific, Waltham, MA, USA).

**Fluorescence Spectroscopy.** Fluorescence spectroscopy experiments were conducted according to a previous method.[23] The instrument was an RF-1501spectrofluorometer (Shimadzu Corp., Tokyo, Japan). The excitation wavelength was set at 330 nm, and the emission spectra were recorded from 300 to 600 nm with the background fluorescence calibrated using distilled water.

**Particle Size Assay.** Particle sizes of dispersions were determined at room temperature (21 °C) according to the method in the literature.[24] Samples were diluted 10-fold using distilled water and adjusted to pH 3.0−5.0. The instrument was a Delsa Nano-Zeta Potential and Submicron Particle Size Analyzer (Beckman Coulter Inc., Brea, CA, USA).

**Zeta-Potential Assay.** Zeta-potential was measured according to a recent method[25] with a slight modification. GA and norbixin−GA dispersions with and without $Fe^{2+}$ were diluted 100-fold in distilled water and adjusted to pH 3.0, 4.0, and 5.0. The instrument was the above Zeta Potential and Submicron Particle Size Analyzer.

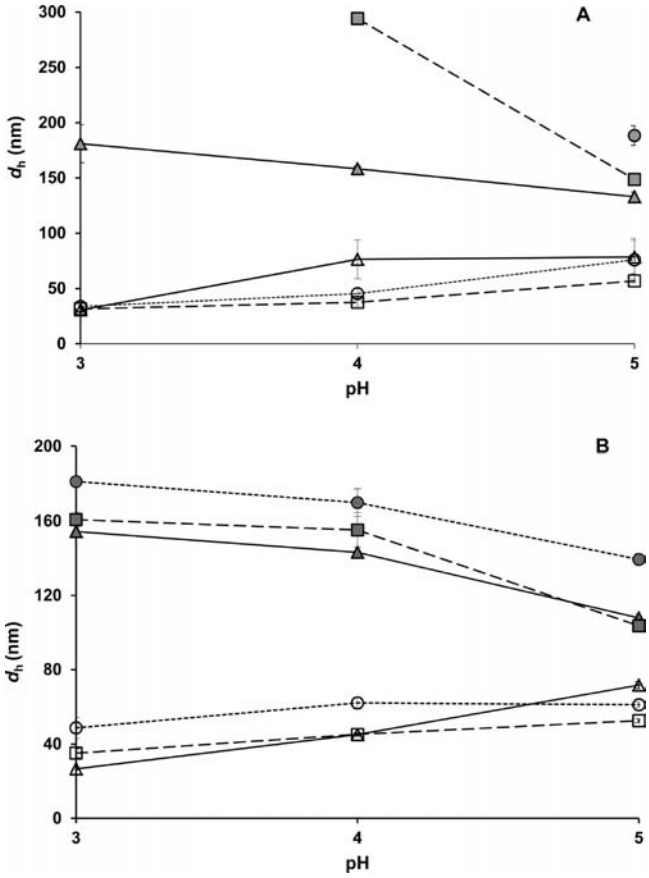

**Figure 1.** Hydrodynamic diameter ($d_h$) of gum arabic (open symbols) and norbixin−gum arabic dispersions (solid symbols) without (A) and with (B) $Fe^{2+}$ before (21 °C, triangles) and after heating at 90 °C (squares) or 126 °C (circles) for 30 min. The pH 3 and 4 samples after heating at 90 °C and the pH 4 sample after heating at 126 °C are not presented in plot A because the measurements exceeded the instrument detection limit. Error bars are standard deviations from triplicates.

**Atomic Force Microscopy (AFM).** AFM imaging was conducted as in our recent work.[25,26] Samples with and without thermal treatments were diluted 10 times in deionized water and readjusted to pH 3.0−5.0. Two microliters of the diluted sample was spread on a freshly cleaved mica sheet with an area of ∼1.8 $cm^2$ and dried at room temperature for 6 h in a fume hood. Topography images were collected at

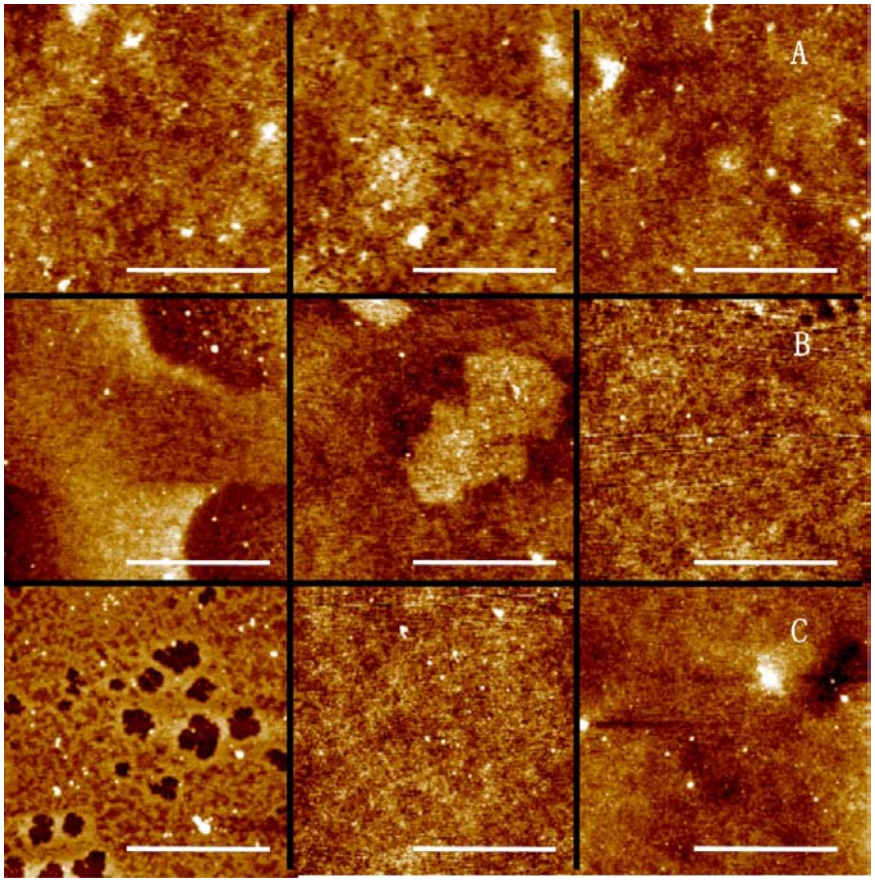

**Figure 2.** AFM topographic images of gum arabic dispersions at pH 3.0 (left), pH 4.0 (center), and pH 5.0 (right) before (A) and after heating at 90 °C (B) or 126 °C (C) for 30 min. Bar = 1 $\mu$m.

the tapping mode using a nanoprobe cantilever tip (BrukerNanoprobe, Camarillo, CA, USA) driven at a frequency of 50−100 kHz on a Multimode Nanoscope IIIa microscope (Veeco Instruments, Inc., Plainview, NY, USA). Images were analyzed using the AFM instrument software (version 5.30r3, Digital Instruments, Inc., Tonawanda, NY, USA).

**Statistical Analysis.** All experiments were carried out in triplicate. Means and standard deviations of the data were calculated for each treatment. Analysis of variance (ANOVA) was carried out to determine any significant differences between treatments ($p < 0.05$) using SPSS 16.0 software (SPSS Inc., Chicago, IL, USA).

## RESULTS AND DISCUSSION

**Color Stability of Norbixin.** Photographs of samples before and after heating are presented in Figure S1 of the Supporting Information. Norbixin precipitated at pH 3.0 and 4.0, as reported previously.[3,14] GA prevented the precipitation of norbixin before heating, but precipitates were observed after heating the pH 3 sample at 90 °C and the pH 3 and 4 samples at 126 °C for 30 min. The addition of $Fe^{2+}$ alone did not prevent the precipitation of norbixin at pH 3 and 4 before and after heating. However, no precipitation was observed for norbixin−GA dispersions with added $Fe^{2+}$ before and after heating at 90 and 126 °C for 30 min. Therefore, GA can improve the acid stability of norbixin, whereas GA and $Fe^{2+}$ can synergistically improve the heat stability of norbixin. Multivalent cations were observed previously to form coordinate bonds within GA.[27] The results suggest that norbixin forms complexes with GA to provide acid and heat stability and that $Fe^{2+}$ strengthens the complexes to provide additional heat stability. Physicochemical properties of the samples are further characterized below.

When color parameters (Table 1) were compared, slight changes were observed in the $L^*$ value of norbixin solutions at pH 5.0 with and without GA and $Fe^{2+}$. The stabilization of norbixin by GA at pH 3.0 and 4.0 enabled $L^*$, $a^*$, and $b^*$ values similar to those at pH 5.0. After heating, the reduction of the $a^*$ value of norbixin was significantly improved after the addition of both GA and $Fe^{2+}$ ($p < 0.05$) but not individually ($p > 0.05$). Conversely, the $b^*$ value of norbixin after heating was improved by GA alone and was further improved by additional $Fe^{2+}$. The solubility of norbixin enabled by carboxylate groups affects its orange color.[28] The protonation of carboxylate groups reduces the solubility of norbixin at lowered pH and causes its precipitation, which becomes more significant after thermal treatment. The results in Table 1 indicate that addition of GA or $Fe^{2+}$ did not change the clarity of norbixin solutions and that GA and $Fe^{2+}$ synergistically improved the stability of redness and yellowness of norbixin solutions after thermal treatments. As discussed previously, this likely is due to the complex formation between norbixin and GA, further strengthened by $Fe^{2+}$.

To further study the thermal stability of norbixin, the absorbance at 460 nm ($A_{460}$) before and after heating was further compared (Supporting Information, Table S1). Like $a^*$ and $b^*$ values, $A_{460}$ of the norbixin sample at pH 5 was significantly reduced after heating, which was insignificantly improved by adding $Fe^{2+}$ alone. The addition of GA maintained the $A_{460}$ after heating at pH 5.0, with and without $Fe^{2+}$. Furthermore,

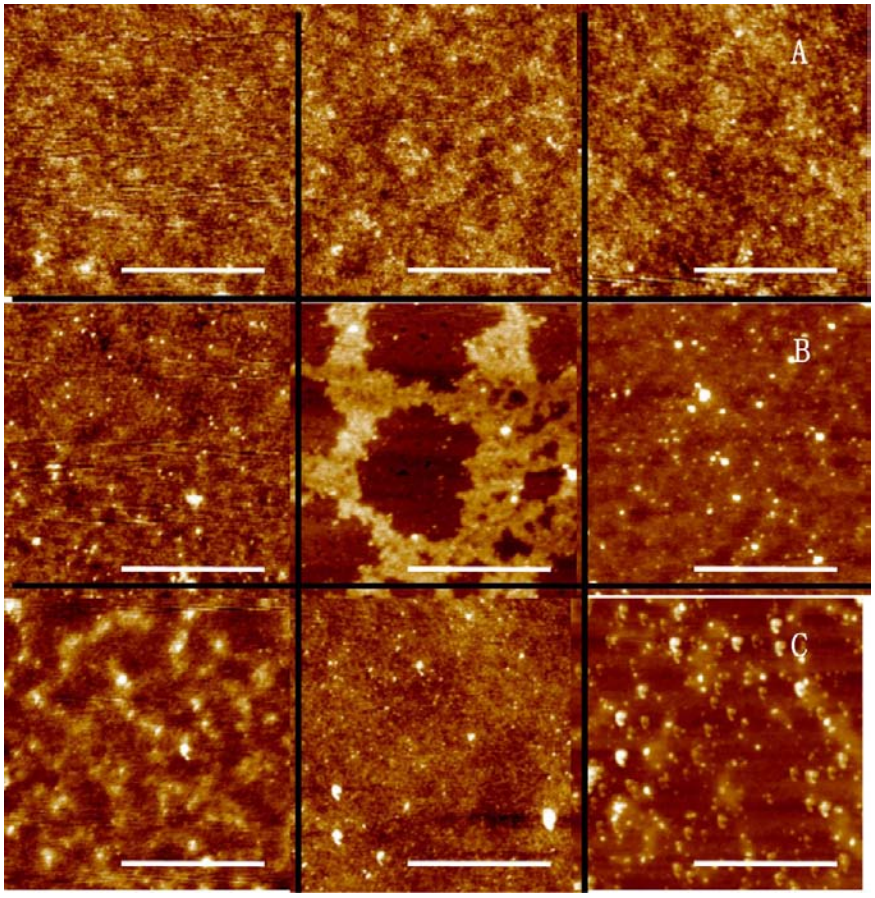

**Figure 3.** AFM topographic images of gum arabic dispersions with $Fe^{2+}$ at pH 3.0 (left), pH 4.0 (center), and pH 5.0 (right) before (A) and after heating at 90 °C (B) or 126 °C (C) for 30 min. Bar = 1 $\mu$m.

the $A_{460}$ at pH 3.0 and 4.0 was lower than that at pH 5.0 and was stabilized by GA, with and without $Fe^{2+}$, after heating.

The $A_{460}$ is due to the conjugated structures of norbixin molecules and is affected by the delocalization of $\pi$-electrons along the polyene backbone.[28,29] During heating, hydrolysis of the polyene backbone of norbixin in aqueous solutions can lead to the breakup of conjugated double bonds and therefore the reduction of $A_{460}$.[30] Degradation of 9′-*cis*-bixin in model solutions to aromatic products such as toluene and *m*-xylene was previously proposed to be responsible for color changes of annatto after heating.[31] In actual food products such as cheeses, the thermal degradation of norbixin, however, was much reduced.[31] In the present study, the hydrolysis of the polyene backbone of norbixin was likely inhibited by GA and $Fe^{2+}$, which resulted in the maintained $A_{460}$ after heating. Additionally, ferrous ions can be oxidized during heating, but the addition of GA can inhibit this oxidation (Supporting Information, Figure S2). Therefore, GA provided the chemical degradation of norbixin at the studied conditions. This agrees with reports that GA can effectively prevent the oxidation of compounds containing polyene structures such as linoleic acid,[32] monoterpenes,[33] and carotenoids.[34] $Fe^{2+}$ was also shown to protect anthocyanins from oxidative degradation.[35]

**Molecular Binding between Gum Arabic and Norbixin with and without $Fe^{2+}$.** The fluorescence spectrum is a convenient tool to study binding between biomolecules. The quenching of fluorescence intensity due to binding by another molecule (quencher) can result from dynamic and static mechanisms, with the former due to intermolecular collision and the latter due to complex formation.[14] The fluorescence quenching data can be further analyzed by the Stern−Volmer model (eq 1).[14] For dynamic quenching, the maximum quenching constant ($k_q$) of various quenchers is $2.0 \times 10^{10}$ $M^{-1}$ $s^{-1}$.[36]

$$\frac{F_0}{F} = 1 + k_q \tau_0 [Q] \quad (1)$$

$F_0$ and $F$ are the fluorescence intensities without and with a quencher, respectively, [Q] is the concentration of the quencher (M), $k_q$ is the biomolecular quenching constant, and constant $\tau_0$ (= $10^{-8}$ s) is the lifetime of the fluorophore in the absence of a quencher.[37]

The $k_q$ values of the GA−$Fe^{2+}$, norbixin−GA, and norbixin−$Fe^{2+}$−GA dispersions calculated from fluorescent spectra (not shown) according to eq 1 are compiled in Table 2. The $k_q$ values of the GA−$Fe^{2+}$ dispersions were from $7.44 \times 10^{12}$ $M^{-1}$ $s^{-1}$ at pH 5.0 to $9.24 \times 10^{12}$ $M^{-1}$ $s^{-1}$ at pH 3.0 before heating and reduced to $(5.04-6.04) \times 10^{12}$ $M^{-1}$ $s^{-1}$ after heating at 90 °C for 30 min. Heating at 126 °C for 30 min did not significantly reduce the $k_q$ values further. The $k_q$ value of the GA−norbixin dispersion was $(41.71-43.18) \times 10^{12}$ $M^{-1}$ $s^{-1}$ before heating and was decreased significantly to $(1.01-8.27)$ and $(0.91-4.40) \times 10^{12}$ $M^{-1}$ $s^{-1}$ after heating at 90 and 126 °C for 30 min, respectively. Dispersions of GA−norbixin with $Fe^{2+}$ had the highest $k_q$ values, which were $(21.86-34.72)$ and $(13.29-18.65) \times 10^{12}$ $M^{-1}$ $s^{-1}$ after heating at 90 and 126 °C for 30 min, respectively, and the reductions after heating were much less than those for GA dispersions with only norbixin or $Fe^{2+}$.

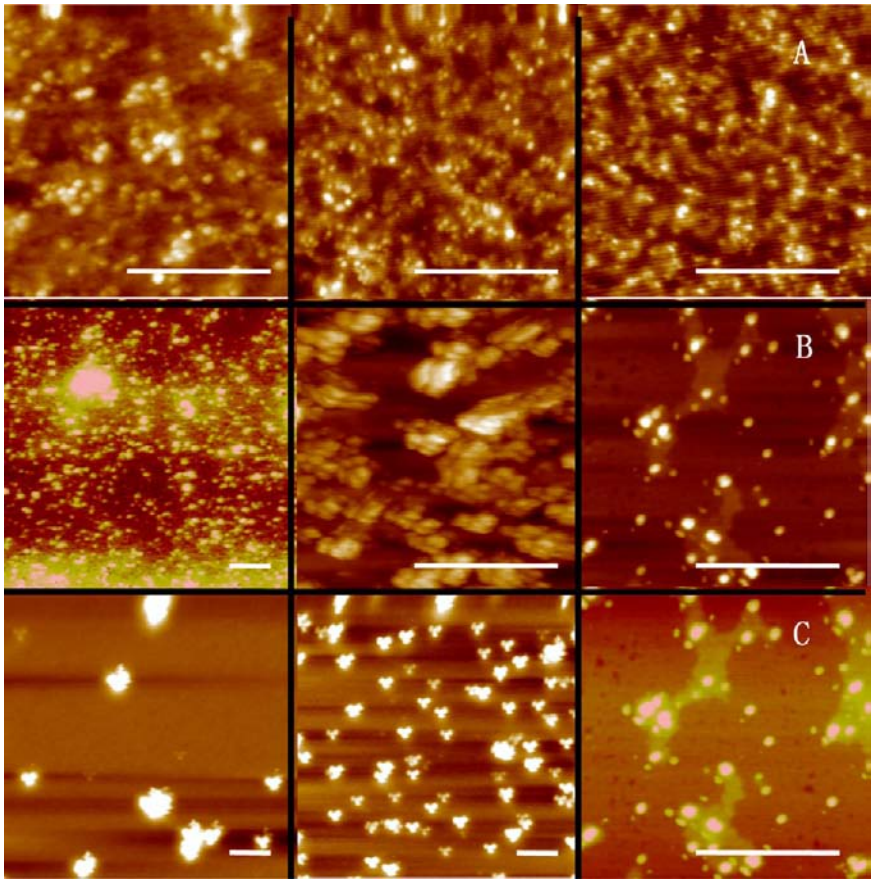

**Figure 4.** AFM topographic images of gum arabic−norbixin dispersions at pH 3.0 (left), pH 4.0 (center), and pH 5.0 (right) before (A) and after heating at 90 °C (B) or 126 °C (C) for 30 min. Bar = 1 $\mu$m.

The $k_q$ values of all GA dispersions before and after heating at 90 and 126 °C for 30 min were at least 2 orders of magnitude higher than $2.0 \times 10^{10}$ $M^{-1}$ $s^{-1}$, which indicated that GA formed complexes with $Fe^{2+}$ and norbixin at pH 3.0−5.0. Moreover, the higher $k_q$ values of GA−norbixin than those of $Fe^{2+}$−GA dispersions before heating suggest the greater ability of complex formation between norbixin and GA. After heating, the reductions of $k_q$ values of GA−$Fe^{2+}$ dispersions were less than those of GA−norbixin dispersions. These results imply that complexes formed between norbixin and GA were not thermally stable and the degradation of norbixin and decoupling of complexes after heating caused the significant reduction of the $k_q$ values. The decoupling of complexes was evidenced by the precipitation of norbixin (Supporting Information, Figure S1) and implied that the coordinate bonds between norbixin and GA complexes weakened during heating. The synergism in GA, $Fe^{2+}$, and norbixin complexation increased the extent of static quenching (highest $k_q$ values in Table 2), suggesting the formation of stronger and more stable complexes.[38] This likely resulted from ionic bridges formed between anionic groups of GA and possibly norbixin and $Fe^{2+}$ that effectively prevented the decoupling of norbixin−GA complexes, inhibited the norbixin precipitation, and maintained the $k_q$ values to a greater extent after heating (Table 2).

As for the pH effects (Table 2), no significant changes were found in $k_q$ values for $Fe^{2+}$−GA mixture at pH 3−5 before and after heating, indicating the formation of stable complexes. For the norbixin−-GA system, $k_q$ values were similar ($p > 0.05$) before heating but $k_q$ was significantly larger at a higher pH from 3 to 5 after heating at 90 and 126 °C for 30 min. The latter was due to the smaller amount of precipitation (decoupling) of norbixin after heating at a higher pH, as presented above. The $k_q$ values of norbixin−$Fe^{2+}$−GA mixtures were similar before heating and became bigger at a higher pH after heating at 90 °C for 30 min, which were opposite to the data after heating at 126 °C for 30 min. The exact mechanisms causing different trends after heating at these two temperatures were unclear. One possible explanation may be that decoupling (precipitation) of norbixin from complexes, more significant at a lower pH, was the dominant factor affecting the binding in complexes during heating at 90 °C, whereas decomposition of norbixin, more significant for the more soluble form (at a higher pH), was also significant during heating at 126 °C.

**Particle Size of Complexes before and after Heating.** Hydrodynamic diameters ($d_h$) of GA with and without $Fe^{2+}$ and norbixin at pH 3.0, 4.0, and 5.0 are shown in Figure 1. In the absence of norbixin, the $d_h$ of GA solutions with and without $Fe^{2+}$ was <80 nm before and after heating and was overall smaller at a lower pH between 3 and 5, which likely is due to the reduced number of charges due to protonation of carboxylate groups with $pK_a$ of 1.8−2.2,[39] reducing the effective dimension of GA. The weakened electrostatic repulsion at a lower pH can cause the aggregation of GA to increase the $d_h$, which was not observed. This indicates that the steric hindrance of polysaccharide chains prevented intermolecular aggregation of GA at acidic conditions.[19,40]

The addition of norbixin significantly increased the $d_h$, which further increased significantly after heating at 90 and 126 °C for 30 min. The $d_h$ was about 300 nm after heating the

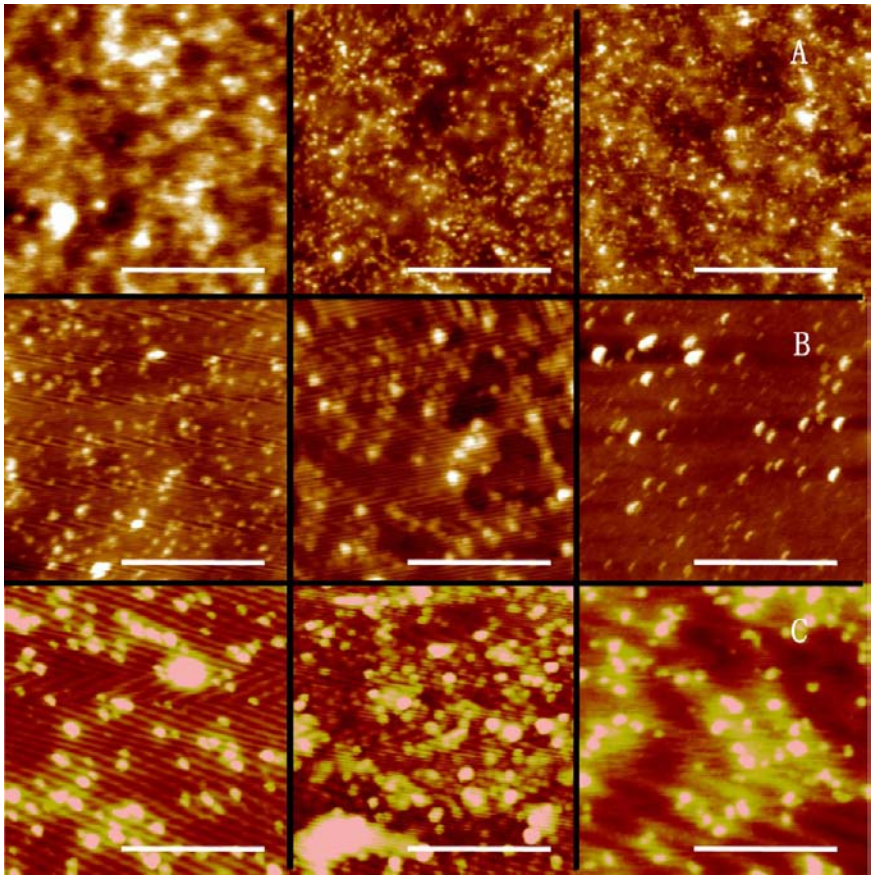

**Figure 5.** AFM topographic images of gum arabic−norbixin dispersions with $Fe^{2+}$ at pH 3.0 (left), pH 4.0 (center), and pH 5.0 (right) before (A) and after heating at 90 °C (B) or 126 °C (C) for 30 min. Bar = 1 $\mu$m.

norbixin−GA dispersion at pH 4.0 and 90 °C for 30 min and exceeded the detection limit of the particle size analyzer (~3 $\mu$m) after heating the pH 3.0 dispersion at 90 °C for 30 min and the pH 3.0 and 4.0 dispersions at 126 °C for 30 min (Figure 1A). The addition of $Fe^{2+}$ in norbixin−GA dispersions did not significantly change the $d_h$ before heating. The norbixn−GA dispersions with $Fe^{2+}$ did not show significant changes in $d_h$ after heating at 90 °C for 30 min, and the $d_h$ increased by only 20−40 nm, from about 104−161 to 139−181 nm, after heating at 126 °C for 30 min.

Similar $d_h$ values of GA with and without $Fe^{2+}$ indicated that ionic bridges were intramolecular and did not change the dimension of GA and cause the flocculation of GA. Similar $d_h$ of GA dispersions with and without $Fe^{2+}$ before and after heating suggested the thermal stability of GA and ionic bridges. The significant increase in $d_h$ of GA dispersions after the addition of norbixin suggested the complex formation between norbixin and multiple GA molecules. After heating the GA dispersions with norbixin, the dramatic increases of $d_h$ of treatments without $Fe^{2+}$ should have resulted from the instability of norbixin−GA complexes and the precipitation of norbixin that was more significant at a lower pH (Supporting Information, Figure S1) because of the reduced norbixin solubility when the carboxylate groups are protonated. Further addition of $Fe^{2+}$ improved the thermal stability of norbixin−GA complexes to effectively prevent the leaking out and precipitation of norbixin, which provides physical interpretation of the synergism of $Fe^{2+}$ and GA in improving the heat and acid stability of norbixin.

**Morphology of Dispersion Particles before and after Heating.** AFM was used to study the morphology of GA dispersions with and without norbixin and $Fe^{2+}$ before and after thermal treatments, with the topographical images shown in Figures 4−7 and the measured particle heights shown in Table 3. No large aggregates were observed for GA dispersions without (Figure 2) and with (Figure 3) $Fe^{2+}$ before and after thermal treatments at 90 and 126 °C for 30 min. The results agreed with the above analyses based on particle size (Figure 1), showing good heat stability of GA dispersions without norbixin. The height of GA with and without $Fe^{2+}$ (Table 3) is in agreement with that (1−3 nm) of monomeric GA measured in aqueous solutions.[41]

For the norbixin−GA dispersions (Figure 4), aggregated structures were observed after heating the pH 4.0 dispersion at 90 °C for 30 min, and much larger aggregates were present after the pH 3.0 dispersion was heated at 90 °C for 30 min and the pH 3.0 and 4.0 dispersions were heated at 126 °C for 30 min. Aggregated structures also showed significant increases in particle height (Table 3). AFM results (Figure 4) were in good agreement with the particle size data (Figure 1). For the GA dispersions with both norbixin and $Fe^{2+}$, structural changes were insignificant after heating at 90 °C for 30 min but were noticeable after heating at 126 °C for 30 min (Figure 5), but the changes were much less than those of the GA−norbixin dispersions without $Fe^{2+}$ (Figure 4). This was further verified by particle heights in Table 3. The AFM results again agreed with more significant increases in $d_h$ after the GA−norbixin−$Fe^{2+}$ dispersions were heated at 126 °C than at 90 °C (Figure 1).

**Zeta Potential of Complexes before and after Heating.** Zeta-potential results in Figure 6 showed that GA had more

**Table 3. AFM Height of Particles in Dispersions at pH 3.0−5.0 with Gum Arabic (GA), $Fe^{2+}$, and/or Norbixin before (21 °C) and after Heating at 90 or 126 °C for 30 min[a]**

negative charges at a higher pH between 3.0 and 5.0, as discussed above due to deprotonation of carboxyl groups.[42] Similar to $d_h$ (Figure 1), the zeta potential of GA alone did not change significantly after heating (Figure 6A), which confirmed the heat stability of GA. No significant changes of zeta potential were observed for GA after mixing with $Fe^{2+}$, but the zeta-potential magnitude of the mixture decreased significantly after heating. This may result from the binding between $Fe^{2+}$ and GA being insignificant at room temperature but becoming significant and irreversible after heating.

After mixing norbixin with GA dispersions, the zeta potential became significantly more negative (Figure 6A). Further addition of $Fe^{2+}$ decreased the zeta-potential magnitude of the GA−norbixin dispersions (Figure 6B). For the GA−norbixin dispersions, heating at 90 and 126 °C did not show a significant impact on the zeta potential ($p > 0.05$). Conversely, the GA−$Fe^{2+}$−norbixin dispersions became significantly more negative after heating, and the two heat treatment temperatures of 90 and 126 °C did not affect zeta-potential changes differently ($p > 0.05$)

On the basis of the above information, the proposed GA−norbixin−$Fe^{2+}$ complex structure is presented in Figure 7. On the basis of $d_h$, complex formation between norbixin and GA involves multiple GA molecules (Figure 1), forming a core of norbixin and a shell of GA. At pH 3−5, the protein/polypeptide moiety of GA likely has cationic amino acid residues[19] and is included in the complex center. When the complex is measured for zeta potential, the complex surface with negatively charged polysaccharide fractions is measured, resulting in the higher magnitude of negative zeta potential for complexes of norbixin−GA than that of GA alone. After addition of $Fe^{2+}$, coordinated ionic bridges form mostly between GA−norbixin and ferrous ions within or near the core at the studied conditions. After heating, some complexes are dissociated and re-formed as bigger structures (Figure 1), which results in a greater number of surface anionic polysaccharides in each complex, corresponding to the increased magnitude of the zeta potential. The ionic bridges within the complexes are heat stable, but binding between norbixin molecules and that between norbixin and GA may not be thermally stable but play a minor role in overall complex structure. This results in overall good stability of GA−norbixin−$Fe^{2+}$ complexes that effectively

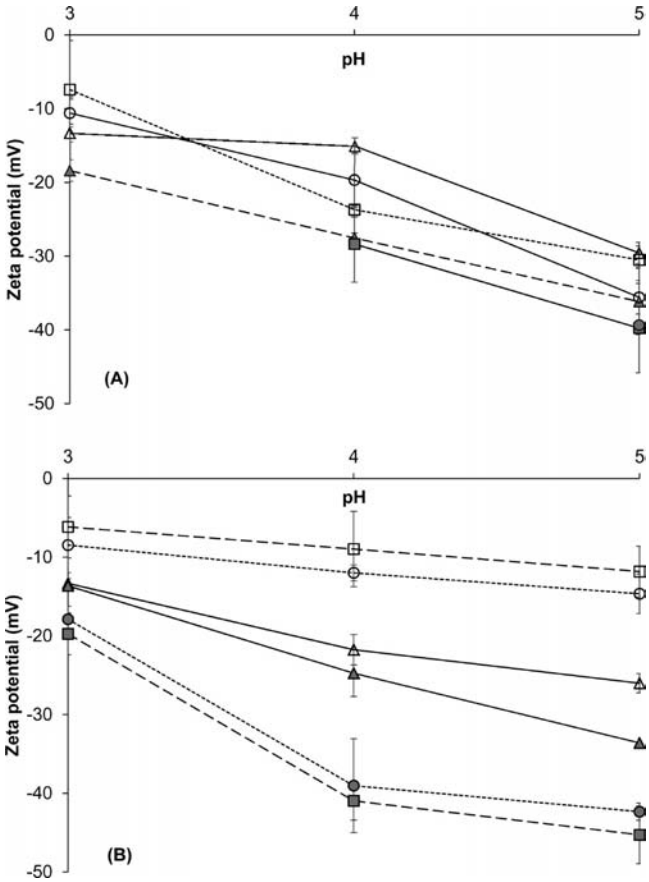

**Figure 6.** Zeta potential of gum arabic (open symbols) and norbixin−gum arabic dispersions (solid symbols) without (A) and with (B) $Fe^{2+}$ before (21 °C, triangles) and after heating at 90 °C (squares) or 126 °C (circles) for 30 min. Error bars are standard deviations from triplicates.

provided the macroscopically good thermal and acid stabilities of norbixin. The improvement of norbixin stability is to be verified in specific food matrices and their processing conditions.[31]

In summary, GA and/or $Fe^{2+}$ can significantly improve the stability of norbixin in aqueous dispersions at pH 3.0−5.0

dx.doi.org/10.1021/jf5037799 | J. Agric. Food Chem. 2014, 62, 12668−12677

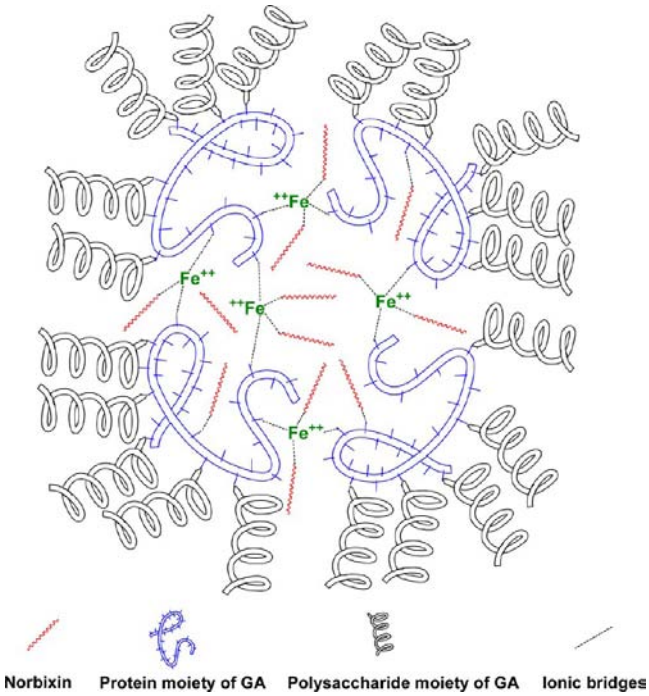

**Figure 7.** Proposed complex structure formed with gum arabic, norbixin, and $Fe^{2+}$.

before and after thermal treatment at 90 and 126 °C for 30 min. The acid stability was enabled by complex formation between norbixin and GA involving multiple GA molecules. $Fe^{2+}$ further strengthened the GA–norbixin complexes by forming coordinated ionic bridges. The strengthened complexes reduced the decoupling of norbixin from complexes and effectively prevented the aggregation of norbixin during heating, forming particles that were sufficiently small to prevent noticeable turbidity. Therefore, GA and $Fe^{2+}$ can be dissolved in transparent beverages utilizing norbixin as a pigment to ensure its stability after thermal treatments.

In this study, we prepare nanoparticles from β-conglycinin, conjugates of β-conglycinin−dextran (CDC), and conjugate hydrolysates of β-conglycinin−dextran at DH 2.2% (CDCH) by a desolvation method. The structure and morphology of the nanoparticle samples were characterized by dynamic light scattering (DLS), transmission electron microscopy (TEM), and small-angles X-ray scattering (SAXS). The interfacial properties of the nanoparticle samples at the oil−water interface were investigated using interfacial dilatational rheological measurement.

## MATERIALS AND METHODS

**Materials.** β-Conglycinin were prepared from defatted soybean flakes (Xinjiahua Industrial and Commercial Co. Ltd., Shandong Province, China) according to the method of Nagano et al.[22] Protein content of β-conglycinin (91.21%, dry weight basis, N × 5.71) was determined by the Dumas combustion method (Elemental Analyzer rapid N cube, Hanau, Germany). Trypsin and dextran (67 kDa) were purchased from Sigma Co. (St. Louis, MO, USA). Other chemicals (ethanol, glutaraldehyde, etc.) were of analytical grade.

**Preparation of Conjugates of β-Conglycinin−Dextran.** β-Conglycinin and dextran powders (1:1, w/w) were dissolved in a sodium phosphate buffer solution (10 mM, pH 6.8) for 2 h at 25 °C and adjusted to pH 6.8 with the addition of 0.1 M HCl and then freeze-dried. The freeze-dried powders were incubated under 79% relative humidity at 60 °C for 6 days in a glass desiccator (diameter 30 cm, Shanghai Shupei Experimental Installation Co., Ltd., China) containing over-saturated potassium bromide. After incubation, the samples were dissolved in deionized water for 2 h at 25 °C and then centrifuged at 10000*g* for 15 min to dislodge insoluble substances. The supernatant was then freeze-dried, and the resultant substances (conjugates of β-conglycinin−dextran, CDC) were kept at 4 °C prior to use. The obtained conjugates of β-conglycinin−dextran were simply defined as CDC in this study.

**Hydrolysis of Conjugates of β-Conglycinin−Dextran.** The obtained conjugates of β-conglycinin−dextran were redissolved in distilled water with a protein concentration of 1.0% (w/v), stirred for 2 h at 25 °C, and then stored at 4 °C overnight. The solution was adjusted to pH 8.0 and then equilibrated at 40 °C for 30 min in a magnetically stirred water bath (HH-J1, Jiangsu Jinda instrument Co., Ltd., China). Trypsin solution was added to the above-mentioned solution and incubated at 40 °C with gentle stirring. The pH and DH were regulated by the pH-stat method using a 888 Titrino (Metrohm ion analysis, Herisau, Switzerland).[23] The enzyme concentration was 3 units of per gram protein to obtain a DH value of 2.2%. The pH of the sample solution was maintained at 8.0 during hydrolysis with 0.1 M NaOH. The enzymatic hydrolysis was terminated with the addition of 1 mM phenylmethanesulfonyl fluoride and 2-propanol solution when the DH value of 2.2% was reached. The resulting hydrolysates of β-conglycinin−dextran conjugates at DH 2.2% (CDCH) were freeze-dried and stored at 4 °C. The obtained conjugate hydrolysates of β-conglycinin−dextran at DH 2.2% were defined as CDCH in this study.

**Preparation of Nanoparticles.** A desolvation method was used for preparing nanoparticles according to the method of Ko et al. with modifications.[1] β-Conglycinin, CDC, and CDCH was dispersed in sodium phosphate buffer solutions (pH 7.0, 10 mM) to achieve a protein content of 1% (w/v). Subsequently, these sample solutions were adjusted to pH 9.0 with 0.1 M NaOH. While the sample solutions were kept stirring at 500 rpm using a magnetic stirrer (Color squid digital, IKA, Germany), ethanol was added at a rate of 1 mL/min into the sample solutions until the ethanol ratio achieved 80% (v/v). After desolvation, 16 μL of 2.5% (v/v) glutaraldehyde−ethanol solution was added to cause intraparticle cross-linking. The solutions were stirred at 500 rpm and 25 °C for 3 h. Subsequently, the solutions of these nanoparticles were centrifuged at 100000*g* (Hitachi CS150NX ultracentrifuge, Tokyo, Japan) for 30 min. The resulting pellets were redispersed to a certain volume of sodium phosphate buffer solutions (10 mM, pH 7.0) using a stick-type ultrasonicator (Sonic Ruptor 400, The Homogenizer Co., Kennesaw, GA, USA). Protein concentrations of the nanoparticle solutions were estimated according to the method of Lowry and his co-workers,[24] and bovine serum albumin was used for obtaining a standard calibration curve. The resulting nanoparticles were stored in sodium phosphate buffer solutions (10 mM, pH 7.0) at 4 °C. The nanoparticles prepared from β-conglycinin, CDC, and CDCH were named CN, CDCN, and CDCHN, respectively.

**Surface Hydrophobicity ($H_0$).** The $H_0$ of protein and nanoparticles was measured using 8-anilino-1-naphthalenesulfonic acid ammonium salt (ANS), according to the method of Haskard and Li-Chan.[25] Samples were dispersed into the buffer solutions (10 mM, pH 7.0) to achieve different protein concentrations of 0.02−0.5 mg/mL. Four milliliters of each sample solution were added with ANS stock solution (20 μL, 8 mM) and then mixed for about 5 s in a vortex mixer. Fluorescence intensity was determined at 390 nm (excitation) and 470 nm (emission) using a fluorescence spectrophotometer (F7000, Hitachi Co., Tokyo, Japan), with 5 nm of constant excitation and emission slit. Linear regression analysis was used to calculate the initial slope of the fluorescence intensity versus protein concentration plot, which was used as an index of $H_0$.

**Determination of Particle Size of Nanoparticles.** The *Z*-average hydrodynamic diameter and particle size distribution of the nanoparticles were determined by DLS technique using a Nanosizer ZS (Malvern Instruments, UK). The sample dispersions were diluted with 10 mM sodium phosphate buffer (pH 7.0) to the protein concentration of 0.5% (w/v) and poured into cuvettes (PCS8501). A cumulant analysis of the autocorrelation function was used to calculate the *Z*-average hydrodynamic diameter. In all cases, the particle size distributions were reported on the basis of volume frequency. All measurements were carried out at 25 °C, and three replications of each measurement were made.

**Determination of Nanoparticle Microstructure by Transmission Electron Microscopy.** The specimens of these nanoparticles were observed using a TEM (Fei Tecnai $G^2$ 12, FEI, USA). The preparation process of these samples was as follows: a carbon-coated copper grid was respectively dropped in 5 μL of nanoparticle sample solutions, and a filter paper was used to remove the excess solution after 30 s. After that, the nanoparticle samples were stained by 5 μL of 1% (w/v) phosphotungstic acid and dried at 25 °C for 72 h before examination by TEM. Image acquisition was performed at 200 kV.

**Small-Angle X-ray Scattering.** A SAXSess camera (Anton-Paar, Graz, Austria) was used to collect the SAXS data. An X-ray generator (PW3830) with a glass X-ray tube (PANalytical, Almelo, The Netherlands) was performed at 40 kV and 50 mA. The intense monochromatic primary beam (Cu K$\alpha$, $\lambda$ = 0.1542 nm) was provided by a block collimator and a focusing multilayer optics. Sealed quartz capillaries (1 mm in diameter) was used to load the samples with a protein content of 1.0% (w/v), which were placed in a temperature-controlled sample hold unit (TCS 120, Anton Paar) along the line-shaped X-ray beam in the evacuated camera housing. The distance between sample and detector was 261.2 mm, and the temperature was set at 26.0 °C. The 2D images were read out by a Cyclone storage phosphor system (PerkinElmer, Waltham, MA, USA), and they were corrected by taking into account the detector dark noise and found to be isotropic. The subtraction of the scattering of the pure solvent (water) was used to correct the curves of $I(q)$ versus $q$ ($q = 4\pi \sin\theta/\lambda$, where $2\theta$ is the scattering angle) resulting from the 360° azimuthal integration of the 2D patterns, and the curves were also fitted by using a spherical copolymer model.[26] Thirty minutes was used to collect data for each measurement. All $I(q)$ data were normalized because transmission calibration demanded the uniform primary intensity at $q = 0$. The radius of gyration ($R_g$) was calculated as follows: $I(q) = I(0)\exp(-R_g^2 q^2/3)$, where $I(0)$ is the scattering intensity at $q = 0$ and $I(q)$ is the scattering intensity.

**Interfacial Dilatational Properties.** The dynamic interfacial properties of the samples at corn oil−water interface were measured by recording temporal evolution of interfacial dilatational parameters using an optical contact angle meter (OCA20, Dataphysics, GmbH, Germany) equipped with an ODG-20 oscillating drop accessory. The

sample solutions with protein concentrations of 0.01, 0.1, and 1% (w/v) were placed in the syringe, respectively, and a drop of the sample solution (10 μL) was then delivered to a cuvette containing corn oil and kept for 3 h to adsorb sample to the oil−water interface. According to the oscillating drop methodology, sinusoidal expansion and compression were carried out by increasing and decreasing the drop volume with 10% of deformation amplitude, and the frequency was 0.1 Hz. Details of this experiment were described elsewhere.[27]

The protein adsorption process was described, and the change in the interfacial pressure with time was correlated by a modified form of the Ward−Torday equation,[28] which was defined as $\pi = 2C_0KT(D\theta/3.14)^{1/2}$, where $D$ is the diffusion coefficient, $K$ is the Boltzmann constant, $T$ is the absolute temperature, and $C_0$ is the bulk concentration in the aqueous phase. When the diffusion of protein at the interface dominates the adsorption process, a plot of $\pi$ versus $\theta^{1/2}$ will be presented for linear, and the slop of the plot will be the diffusion rate ($K_{dif}$). The change in interfacial tension $\gamma$ (dilatational stress) and interfacial area $A$ (dilatational strain) derived the interfacial dilatational modulus $E$, which might be described by the equation[29] $E = d\gamma/(dA/A) = -d\pi/d\ \ln A = E_d + iE_v$, where $\pi = \gamma_0 - \gamma$ is the interfacial pressure, $\gamma$ is the interfacial tension of the sample solution, and $\gamma_0$ is the interfacial tension of the pure oil−water interface. The dilatational modulus indicates two contributions of a dissipative part and the elastic part. The dissipative part accounts for energy lost through relaxation processes (loss modulus, $E_v$), and the elastic part illuminates the recoverable energy stored in the interface (storage modulus, $E_d$).

**Statistical Analysis.** All experiments were performed at least three times using freshly prepared samples. An analysis of variance (ANOVA) of the data was carried out, and the means were compared by a least significant difference (LSD) with a confidence interval of 95%. Values are shown in means ± standard deviations (SD).

## RESULTS AND DISCUSSION

**Detection of CDC and Their Hydrolysates by SDS-PAGE.** In our previous study, we indicated the formation of conjugates between β-conglycinin and dextran molecules by SDS-PAGE according to the method of Laemmli[30] and also confirmed that the distributions of molecular weight in CDC products decreased by enzymatic hydrolysis.[21] The covalent bond between β-conglycinin and dextran was not breached after trypsin hydrolysis of CDC.[21]

**Surface Hydrophobicity.** An important parameter indicative of hydrophobic groups on the surface of the proteins is surface hydrophobicity ($H_0$), which was usually used to identify the structural changes of the proteins.[31] The $H_0$ values of various samples are presented in Table 1. The $H_0$ of CDC was 326.30 ± 12.11, lower than that of β-conglycinin (465.01 ± 12.53). This might be because the conjugation of hydrophilic chain of dextran increased hydrophilicity on the molecule surface. However, CDCH exhibited higher $H_0$ (613.61 ± 15.33) than β-conglycinin and CDC. This might be because controlled enzymatic hydrolysis could expose hydrophobic groups from the hydrophobic core of the protein molecules. Dextran was conjugated to β-conglycinin, the hydrophilic chains of dextran could increase the hydrophilicity of the protein, and controlled enzymatic hydrolysis could improve the hydrophobicity of the protein; thus, CDCH could possess amphiphilic structures. Furthermore, the $H_0$ of each control protein sample was lower than its nanoparticle sample (Table 1), and the $H_0$ of CDCHN was the highest (1363.63 ± 20.85), followed by CN (863.87 ± 11.42) and CDCN (523.54 ± 4.26). This might be because ethanol could induce protein unfolding and the exposure of hydrophobic regions to the exterior during nanoparticle formation,[32,33] which led to an increase in $H_0$ of the nanoparticles.

**Table 1. Surface Hydrophobicity ($H_0$) of Proteins (β-Conglycinin, CDC, CDCH) and Their Nanoparticles (CN, CDCN, CDCHN) at pH 7.0**

| | surface hydrophobicity ($H_0$) | | |
|---|---|---|---|
| sample | β-conglycinin | β-conglycinin−dextran conjugates | conjugates DH 2.2% |
| control | 465.01 ± 12.53 | 326.30 ± 12.11 | 613.61 ± 15.33 |
| nanoparticles | 863.87 ± 11.42 | 523.54 ± 4.26 | 1363.63 ± 20.85 |

**Particle Size Distribution of Nanoparticles.** The particle size distribution of β-conglycinin, CDC, and CDCH and their nanoparticles is shown in Figure 1. Table 2 further illustrates the Z-average hydrodynamic diameter of the control and nanoparticle samples. After desolvation, the particle size distribution of β-conglycinin nanoparticles (CN) indicated a shift to larger sizes compared to that of control β-conglycinin (Figure1). The Z-average hydrodynamic diameters of β-conglycinin and β-conglycinin nanoparticles (CN) were 27.58 ± 0.16 and 49.64 ± 0.56 nm, respectively (Table 2). This could be attributed to the high content of ethanol (80%, v/v) benefiting the exposure and interaction of hydrophobic groups on protein molecules, which formed protein aggregates.[34] Similar observations were reported for human serum albumin nanoparticles.[5] However, the change of Z-average hydrodynamic diameter in control CDC and CDCN (from 95.78 ± 0.46 to 102.70 ± 0.88 nm) was less than that in β-conglycinin and CN (from 27.58 ± 0.16 to 49.64 ± 0.56 nm). This could be because the hydrophilic chain of dextran lowered the $H_0$ of CDC and suppressed the aggregation of the molecules during the desolvation process. For CDCH and its nanoparticles, the Z-average hydrodynamic diameters were 50.80 ± 0.44 and 117.64 ± 0.76 nm, respectively (Table 2).

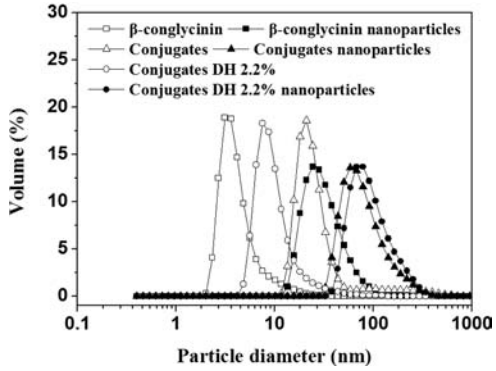

**Figure 1.** Particle size distribution of β-conglycinin, conjugates of β-conglycinin−dextran (CDC), conjugate hydrolysates of β-conglycinin−dextran at DH 2.2% (CDCH), and their nanoparticles (CN, CDCN, CDCHN).

**Table 2. Z-Average Hydrodynamic Diameter of Proteins (β-Conglycinin, CDC, CDCH) and Their Nanoparticles (CN, CDCN, CDCHN)**

| | Z-average hydrodynamic diameter (nm) | | |
|---|---|---|---|
| sample | β-conglycinin | β-conglycinin−dextran conjugates | conjugates DH 2.2% |
| control | 27.58 ± 0.16 | 95.78 ± 0.46 | 50.80 ± 0.44 |
| nanoparticles | 49.64 ± 0.56 | 102.70 ± 0.88 | 117.64 ± 0.76 |

When nanoparticles were prepared from CDCH by the desolvation method, the increase degree of the *Z*-average hydrodynamic diameter from CDCH to its nanoparticles was higher than that of *β*-conglycinin and CDC. This was probably because amphiphilic CDCH had higher $H_0$ compared with *β*-conglycinin and CDC, which could enhance hydrophobic interactions between hydrophobic groups of unfolded polypeptides and cause aggregation of protein molecules, inducing a greater degree of increase in particle size.

**Microstructural Observation of Nanoparticles.** The microstructures of the nanoparticles were investigated using TEM, as presented in Figure 2. All of the nanoparticles were shown to form a spherical shape. Figure 2a shows CN with a number of small spherical particles and trended toward aggregation on the observation grid, but they retained their stability in solution. The average particle diameter of CN analyzed by TEM was 55.22 ± 3.14 nm, which was very similar to the *Z*-average hydrodynamic diameter (49.64 ± 0.56 nm) determined from DLS (Table 2). The microstructures of CDCN and CDCHN are given in panels b and c of Figure 2, respectively. The globular proteins were often stained dark, and the hydrophilic chains of dextran were stained light via the negative staining of phosphotungstic acid. CDCN was stained lighter than CN, and it might be suggested that the CDCN was composed of the complex coacervate of *β*-conglycinin with dextran. However, the TEM image revealed that CDCHN had a spherical and obvious core−shell structure (Figure 2c). The shell was in light color, and the core was in dark color. On the basis of the steric stability of dextran and the negative staining of protein by phosphotungstic acid, we assumed that the shell was made up of the conjugated dextran segments and the core consisted of the colloidal particles of *β*-conglycinin. These results demonstrated that the amphiphilic graft copolymers of CDCH were likely to form nanoparticles with a core−shell structure during the desolvation process. In addition, the average particle diameters of CDCN and CDCHN measured from TEM were 125.01 ± 8.04 and 141.03 ± 6.32 nm, respectively, all slightly higher compared to the DLS data (102.70 ± 0.88 and 117.64 ± 0.76 nm, respectively) (Figure 2b,c and Table 2), which might be because of dehydration aggregation of the nanoparticles during the process of samples preparation for TEM experiments.

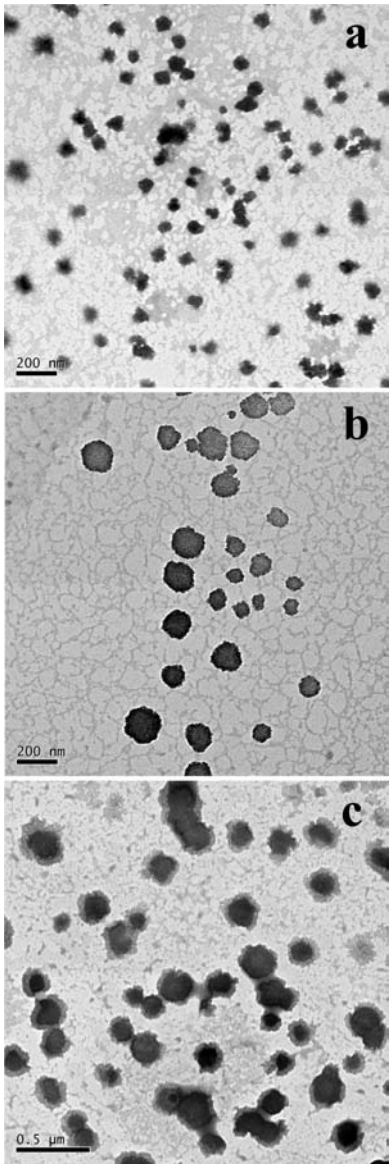

**Figure 2.** TEM micrographs of the nanoparticle samples: (a) *β*-conglycinin nanoparticles (CN); (b) nanoparticles prepared from conjugates of *β*-conglycinin−dextran (CDCN); (c) nanoparticles prepared from conjugate hydrolysates of *β*-conglycinin−dextran at DH 2.2% (CDCHN).

**Structure Analysis of Nanoparticles.** Besides DLS and TEM analysis, the SAXS technique was carried out to investigate the shape, structure, and size of the nanoparticles. Table 3 shows the scattering data of the samples including scattering intensity of zero scattering angle, $I(0)$, and the gyration radius, $R_g$, and also provided the hydrodynamic radius, $R_h$, measured by DLS. The values of $R_g$ and $R_h$ represent the particle size of the nanoparticles. $R_g$ characterizes the particle size or compactness, whereas $I(0)$ is relevant to the molecular mass of the particle.[35] Both $R_g$ and $I(0)$ of the control samples were lower than those of their nanoparticle samples as shown in Table 3, which indicated that hydrophobic interactions of the unfolded protein led to aggregation during the desolvation process for preparing nanoparticles. Furthermore, the $R_h$ values of the control samples were also lower than that of the nanoparticle samples. The result further confirmed that aggregation happened during the desolvation process. Additionally, the increased values of both $R_g$ and $I(0)$ from CDCH to its nanoparticles were greater than that of *β*-conglycinin and CDC (Table 3), which suggested that the aggregation degree of CDCHN was higher than that of CN and CDCN. This demonstrated that the amphiphilic CDCH was beneficial in the formation of larger aggregates during the desolvation process.

Figure 3 shows the Kratky plots ($q^2 \times I(q)$ versus $q$) of control protein samples and their nanoparticles. The Kratky plots are usually used to describe the conformational characteristics of the polypeptide chain and are often applied in polymer science.[36] A typical bell-shaped scattering curve in the Kratky plot indicated a compact globular structure, whereas the typical random coil structure with untight packed core exhibited a plateau at large angle or a curve of Kratky plot with no clear maximum.[36] Therefore, the Kratky plot can distinguish ordered or molten globule state conformation. The Kratky curves for all of the control protein samples and their nanoparticles exhibited the typical bell shape (Figure 3), which suggested that globular nanoparticles could be formed

**Table 3. Structural Parameters Obtained from SAXS and DLS Data of Protein and Nanoparticle Samples**

| sample | | $I(0)$ | $R_g$ (SAXS) (nm) | $R_h$ (DLS) (nm) |
|---|---|---|---|---|
| control | $\beta$-conglycinin | 1.89 ± 0.01 | 3.67 ± 0.02 | 13.79 ± 0.08 |
| | CDC | 3.92 ± 0.03 | 6.73 ± 0.04 | 47.89 ± 0.23 |
| | CDCH | 2.68 ± 0.02 | 6.07 ± 0.03 | 25.40 ± 0.22 |
| nanoparticles | CN | 4.54 ± 0.06 | 6.96 ± 0.07 | 24.82 ± 0.28 |
| | CDCN | 6.37 ± 0.10 | 11.37 ± 0.11 | 51.35 ± 0.44 |
| | CDCHN | 8.68 ± 0.13 | 12.97 ± 0.10 | 58.82 ± 0.38 |

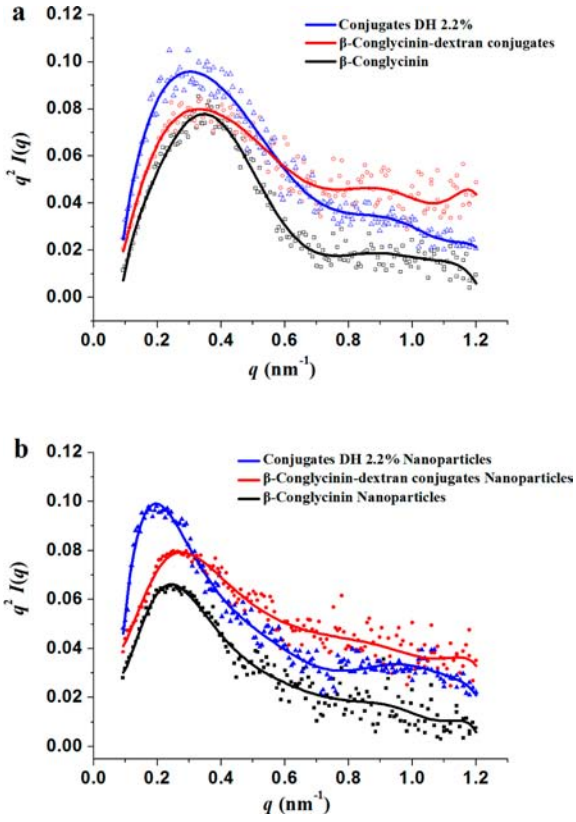

**Figure 3.** Kratky plot scattering curves of $\beta$-conglycinin, conjugates of $\beta$-conglycinin−dextran (CDC), conjugate hydrolysates of $\beta$-conglycinin−dextran at DH 2.2% (CDCH), and their nanoparticles (CN, CDCN, CDCHN).

from the control protein samples using the desolvation method. The results were in keeping with the TEM images (Figure 2).

**Interfacial Dilatational Properties of Nanoparticles.** *Adsorption Kinetics.* The adsorption of proteins on the oil−water interface may be analyzed by detecting the changes of interfacial pressure, which may serve as parameters for adsorption kinetics.[37] Conformational change of protein molecules could occur because of the interaction with the interface or surmounting energy barrier to adsorption during the adsorption process.[37] The adsorption kinetics of protein can be divided into three stages including the diffusion of protein from the principal part to the interface, the adsorption of protein to the oil−water interface, and the interfacial aggregation and recomposition of adsorbed protein on the interface.[38] The adsorption kinetics of the samples with protein concentrations of 0.01, 0.1, and 1% (w/v) by measuring the interfacial pressure ($\pi$) over adsorption time ($\theta$) are shown in Figure 4. All of the protein and nanoparticle samples conduced an increase of $\pi$ values with the increase of adsorption time, which indicated that the samples' adsorption occurred at the

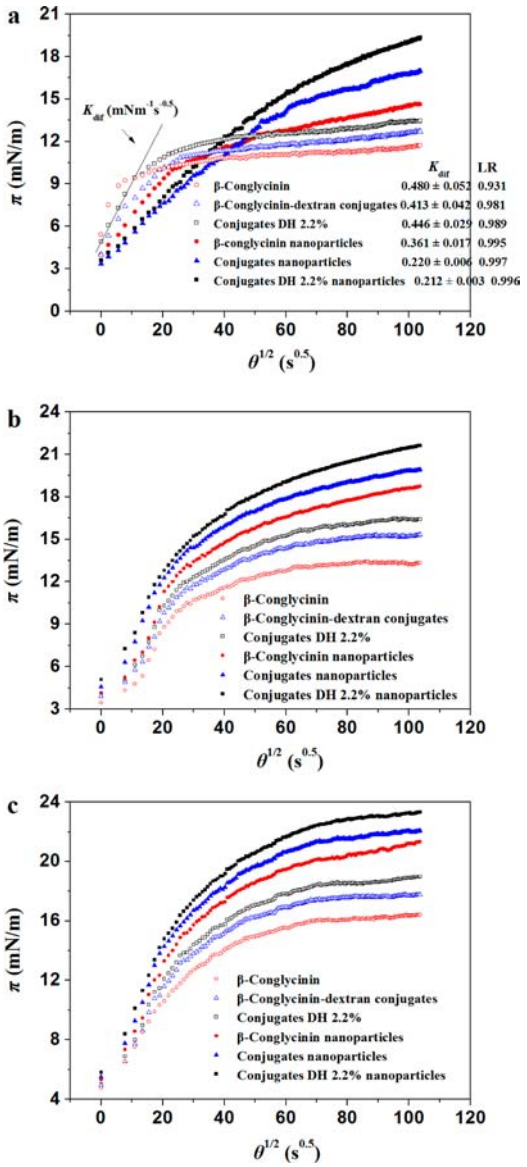

**Figure 4.** Interfacial pressure ($\pi$) changes during adsorption time at the corn oil−water interface for the samples of $\beta$-conglycinin, conjugates of $\beta$-conglycinin−dextran (CDC), conjugate hydrolysates of $\beta$-conglycinin−dextran at DH 2.2% (CDCH), and their nanoparticles (CN, CDCN, CDCHN). The protein concentrations in aqueous phase were (a) 0.01%, (b) 0.1%, and (c) 1% (w/v). The diffusion rate ($K_{dif}$) and linear regression coefficient (LR) are inserted in the figure.

interface. The diffusion of proteins on the oil−water interface may dominate the adsorption when the protein concentration is lower (0.01%, w/v).[27] The diffusion rate ($K_{dif}$) will be the slop of plot of $\pi$ against $\theta^{1/2}$, and the plot may be linear.[28] The

dx.doi.org/10.1021/jf504173z | J. Agric. Food Chem. 2014, 62, 12678−12685

$K_{dif}$ values of the protein samples of $\beta$-conglycinin, CDC, and CDCH were higher than those of nanoparticles (Figure 4a), which might be due to the difference of molecular weight between protein samples and nanoparticles, and the protein samples with lower molecular weight were easier to diffuse to the interface. The $K_{dif}$ values of CDCN and CDCHN were lower than that of CN (Figure 4a). This phenomenon might be interpreted by nanoparticle diffusion resistance because of the formation of conjugation of dextran with $\beta$-conglycinin. Dextran is a highly hydrophilic polysaccharide with high molecular weight, thus resulting in a low diffusion rate of CDCN and CDCHN to the interface.[39]

At longer adsorption times, the $\pi$ values of CDCHN were higher than that of CDCN, and the $\pi$ values of CN were the lowest. The $K_{dif}$ value of CN was higher than that of CDCN and CDCHN (Figure 4a), which indicated a fast absorption of CN to the interface. The steric hindrance effects of the fast absorption of CN could inhibit the CN unfolding at the interface; thus, the effective reduction of the interfacial tension was restrained. However, the $K_{dif}$ value of CDCN was lower than that of CN (Figure 4a), which could result in CDCN unfolding more effectively at the interface; therefore, the decrease in the interfacial tension of CDCN was greater than that of CN. Furthermore, the adsorption of surfactants on the oil−water interface was identified as a process of dynamic balance between surfactant adsorption and desorption, in which the molecular weight of the surfactants was one of the main factors for surfactant adsorption and desorption.[40] The lower molecular weight surfactants could make the surfactant desorption from the interface more likely to occur; otherwise, the surfactants with higher molecular weight tended to show considerably slower desorption than those surfactants of lower molecular weight.[40] The molecular mass of CN was lower than that of CDCN (Table 3), which could make CN desorption from the interface happen more easily than that of CDCN, thus resulting in a lower interfacial pressure of CN compared with CDCN at long absorption times. Moreover, the interfacial pressure ($\pi$ value) of CDCHN was higher than that of CDCN during long-term absorption (Figure 4). The faster increase of the interfacial pressure of CDCHN after diffusion stage could be attributed to its higher $H_0$ (Table 1), which might favor adsorption of nanoparticles to the oil−water interface.

The adsorption process of proteins would not be controlled by diffusion effect at the high concentration of protein (0.1−1%, w/v).[41] With the increase of adsorption time ($\theta$), the interfacial pressures ($\pi$) of nanoparticles were higher than their control protein samples; this may be because of higher surface hydrophobicity of nanoparticles (Figure 4b,c and Table 1). In addition, the interfacial pressures ($\pi$) of CDCHN were the highest among all of the samples, and this might be beneficial for them to adsorb to the oil−water interface; thus, the $\pi$ values rapidly increased.

*Interfacial Dilatational Rheological Properties.* A deformation of the interfacial area can be denoted by dilatational rheology, and the technique is impressible to the intermolecule interactions and adsorption at the interface.[42] Dynamic dilatational modulus ($E$) versus interfacial pressure ($\pi$) was used to further investigate the extent of intermolecule interactions and the capacity of protein adsorbed to the interface.[42] Figure 5 shows the $\pi$ dependence of $E$ in the interfacial layer for the adsorption of the nanoparticle and its control protein samples. For all of the samples at the contents of 0.01, 0.1, and 1% (w/v), the $E$ increased with increasing $\pi$,

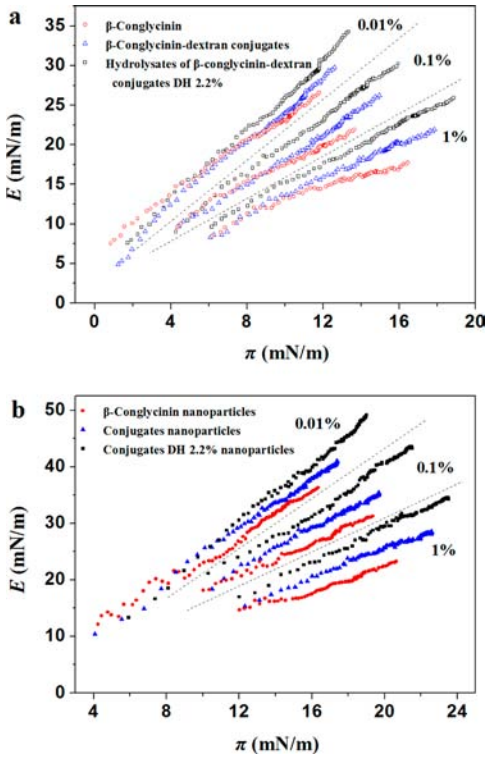

**Figure 5.** Interfacial pressure ($\pi$) dependence of interfacial dilatational modulus ($E$) for $\beta$-conglycinin, conjugates of $\beta$-conglycinin−dextran (CDC), and conjugates hydrolysates of $\beta$-conglycinin−dextran at DH 2.2% (CDCH) and their nanoparticles (CN, CDCN, CDCHN) adsorption to the oil−water interface: (a) protein samples; (b) nanoparticle samples.

and the $E$ values of control protein samples were all lower than its nanoparticle samples (Figure 5). This might be because the $H_0$ values of nanoparticles were all higher than its control protein samples, and the hydrophobic interaction of nanoparticles adsorbed on the oil−water interface was higher than that of the control protein samples. The values of $E$ for all samples were maximal at the concentration of 0.01% (w/v) and decreased with the decline of sample concentration. This might be because compact membrane was formed after the samples adsorbed to the oil−water interface, and this would inhibit the adsorption and intermolecular interactions of protein and nanoparticles samples at the oil−water interface.[41]

The $E$ value of CDCN increased more quickly than that of CN (Figure 5b). This might be attributed to the existence of the conjugated dextran in the adsorbed CDCN, which could protrude outward into the aqueous phase and increase the thickness of the interfacial layer, thus leading to a faster increase of dynamic dilatational modulus ($E$) at the oil−water interface.[43] However, the $E$ values of CDCN increased at a slower rate than that of CDCHN (Figure 5b). This result indicated that the enhancement of interactions between CDCHN, which might be due to its highest surface hydrophobicity, could benefit intermolecular interactions inside the oil−water interface.

In conclusion, nanoparticles of $\beta$-conglycinin, CDC, and CDCH were successfully prepared using a desolvation method. All of the nanoparticle samples showed spherical structures determined by TEM and SAXS, and nanoparticles prepared from amphiphilic graft copolymer (CDCH) exhibited the highest $H_0$, interfacial pressure, and dilatational modulus at long

**Figure 6.** Schematic illustration of nanoparticles prepared from amphiphilic graft copolymer and its application in stabilizing oil–water interface.

absorption times among all of the samples. The enhanced $H_0$ of the nanoparticles prepared from amphiphilic graft copolymer might favor thir adsorption and intermolecular interaction inside the oil–water interface (Figure 6). These properties of the nanoparticles synthesized from amphiphilic graft copolymer may have potential for application in drug delivery systems, and the release properties on the nutrient materials should be investigated.

[a]Restriction sites are underlined.

(BMGY), and buffered methanol complex medium (BMMY) for *P. pastoris* growth and induction, respectively, were prepared according to the manual of the *Pichia* Expression kit (Invitrogen).

The DNA purification kit and Genome Walking kit were purchased from TaKaRa (Otsu, Japan). Restriction endonucleases and T4 DNA ligase were supplied by New England Biolabs (Hitchin, UK). The Fungal DNA Mini kit was purchased from Omega Bio-Tek (Norcross, GA, USA). D-(+)-Galacturonic acid, digalacturonic acid, trigalacturonic acid, polygalacturonic acid, and citrus pectin of different methyl esterification degrees (34% for P9311, 70% for P9436, and 85% for P9561) were purchased from Sigma-Aldrich (San Diego, CA, USA). All chemicals were of analytical grade and commercially available.

**Cloning of the Endo-polygalacturonase Gene (*pg7fn*).** The core region of the polygalacturonase gene from strain XZ7 was amplified by degenerate primers GH28nF and GH28nR,[6] which were designed on the basis of the conserved motifs of endo-polygalacturonases of glycoside hydrolase (GH) family 28. The genomic DNA of strain XZ7 was used as a template for polymerase chain reaction (PCR) amplification. The resulting PCR products were gel purified and ligated into the pEasy-T3 vector and then transformed into *E. coli* Trans1-T1 for sequencing. The 5′ and 3′ flanking regions of the core region were obtained using fusion primer and nested integrated (FPNI)-PCR.[20] The nested insertion-specific primers (Table 1) for FPNI-PCR were named up special primers (usp) 1−3 and down special primers (dsp) 1−3.

Mycelia of strain XZ7 were collected after 3 days of growth and immediately ground to a fine powder in liquid nitrogen. Total RNA was extracted using the SV Total RNA Isolation System (Promega). cDNA was synthesized according to the protocol of Ace-$\alpha$-TM kit (TOYOBO, Osaka, Japan). The full-length cDNA of endo-polygalacturonase gene *pg7fn* was amplified using the specific primers PG7fn-F and PG7fn-R (Table 1) with an annealing temperature of 63 °C. The specific PCR product was ligated into the pEasy-T3 vector for sequencing.

**Sequence and Structure Analysis.** Sequence assembly and analysis were conducted by Vector NTI Advance 10.0 software (Invitrogen). DNA and protein sequences were aligned using BLASTx and BLASTp programs (http://www.ncbi.nlm.nih.gov/BLAST/), respectively. The presence of signal peptide was predicted using SignalP 4.0 (http://www.cbs.dtu.dk/services/SignalP/). The potential N-glycolysation sites were predicted using the NetNGlyc 1.0 Server (http://www.cbs.dtu.dk/services/NetNGlyc/). Alignment of multiple protein sequences was accomplished using ClustalW program (http://www.ebi.ac.uk/clustalW/). The three-dimensional structure model of PG7fn was built with Discovery Studio 2.5 MODELER (Accelrys, San Diego, CA, USA; http://www.accelrys.com) using the crystal structure of endo-polygalacturonase CluPG1 from *Colletotrichum lupini* (2IQ7_A, 78% identity) as the template. To remove steric clashes, the constructed model was subjected to an energy minimization process in a vacuum by using the steepest descent method for about 5000 iterations in Gromacs 4.5.5. The quality of the homology model was evaluated by PROCHECK and Verify3D.[21,22] The results were visualized using the PyMOL program (The PyMOL Molecular Graphics System, Delano Scientific, Portland, OR, USA).

**Heterologous Expression of PG7fn in *P. pastoris*.** The cDNA fragment of *pg7fn* without the signal peptide-coding sequence was amplified with primers PG7fn-pF and PG7fn-pR (Table 1). The PCR products were digested with *Eco*RI and *Not*I and then cloned into pPIC9 vector in-frame fusion of the $\alpha$-factor signal peptide to generate recombinant plasmid pPIC9-*pg7fn*. The positive recombinant plasmids were identified by restriction digestion and DNA sequencing, linearized with *Bgl*II, and transformed into *P. pastoris* GS115 competent cells by electroporation (Bio-Rad, Hercules, CA, USA). The positive transformants were screened on the basis of their enzymatic activities in shake tubes, and those exhibiting the highest activities were selected for fermentation in 1 L conical flasks as described by Tu et al.[6] using polygalacturonic acid as the substrate.

**Purification and Deglycosylation of Recombinant PG7fn.** All purification steps were carried out at 4 °C, and McIlvaine buffer (200 mM $Na_2HPO_4$ and 100 mM citric acid, pH 6.5) was used for dialysis unless otherwise specified. The induced cultures were centrifuged at 12000*g* for 10 min at 4 °C to remove cell debris and undissolved materials. The cell-free culture supernatant was concentrated by ultrafiltration with a Vivaflow 200 membrane of a 5 kDa molecular weight cutoff (Vivascience, Hannover, Germany) and desalted on a 5 mL HiTrap desalting column (GE Healthcare, Uppsala, Sweden) in 20 mM McIlvaine buffer (pH 6.5). The desalted sample was loaded onto a HiTrap SP XL 5 mL FPLC column (GE Healthcare) that was pre-equilibrated with the same buffer. A linear gradient of NaCl (0−1.0 M) in buffer A was used to elute the proteins.

Sodium dodecyl sulfate−polyacrylamide gel electrophoresis (SDS-PAGE) was carried out with a 5% stacking gel and a 12% separation gel. The protein concentration was measured by a Protein Assay kit (Bio-Rad). To remove any N-glycosylation, the purified PG7fn (5 $\mu$g) was treated with 250 U of endo-$\beta$-*N*-acetylglucosaminidase H (Endo H) at 37 °C for 1 h according to the manufacturer's instructions (New England Biolabs, Ipswich, MA, USA) and then analyzed by SDS-PAGE.

**Biochemical Characterization of Recombinant PG7fn.** The enzymatic activity was determined using the 3,5-dinitrosalicylic acid (DNS) method with D-(+)-galacturonic acid as the standard as described by Tu et al.[5,23] One unit of polygalacturonase activity was defined as the amount of enzyme that released reducing sugars equivalent to 1 $\mu$mol of D-(+)-galacturonic acid per minute under standard conditions (pH 5.0, 60 °C, 10 min). All reactions were performed in triplicate.

Both glycosylated and deglycosylated enzymes (PG7fn and d-PG7fn) were subjected to enzyme characterization, and 0.33% (w/v) polygalacturonic acid was used as the substrate. The pH optima were determined at 60 °C for 10 min in McIlvaine buffer (pH 3.0−8.0). The temperature optima were determined at optimal pH for 10 min at 0−80 °C. To estimate the pH stability, the enzymes were preincubated in the buffers of pH 3.0−8.0 without substrate at 37 °C for 1 h, and the residual activities were estimated under standard conditions (pH 5.0, 60 °C, 10 min). Thermostability of the enzymes was investigated after

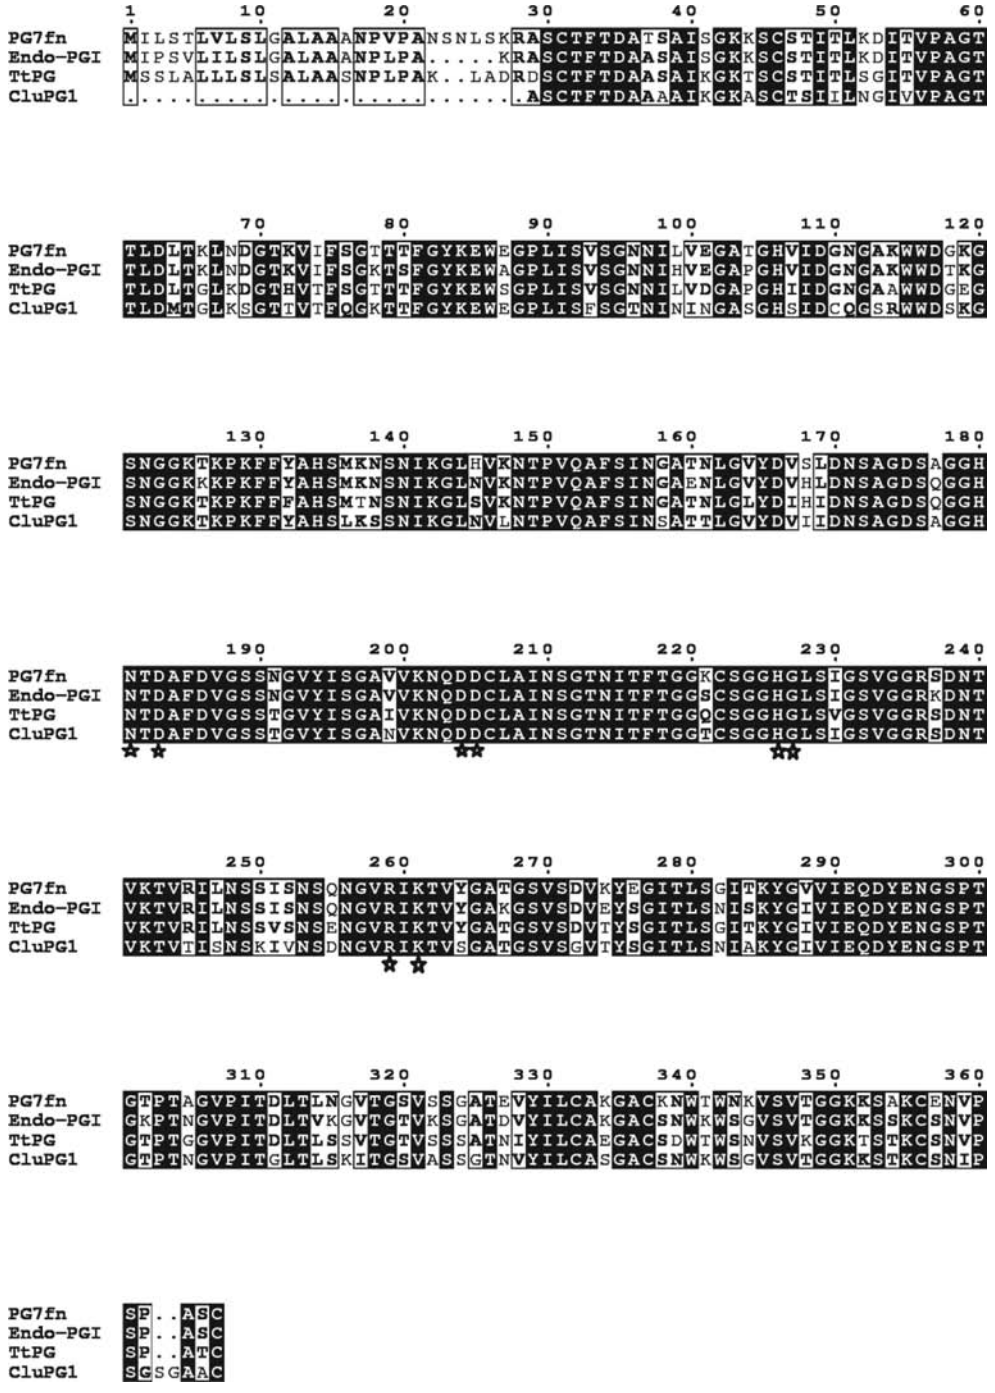

**Figure 1.** Multiple alignment of the deduced amino acid sequence of PG7fn from *T. arenaria* XZ7 with other fungal counterparts from *Achaetomium* sp. Xz8 (Endo-PGI, AGR51994.1), *T. terrestris* NRRL 8126 (TtPG, XP_003657319.1), and *C. lupini* (CluPG1, PDB 2IQ7_A). Identical and similar amino acids are indicated with solid black boxes. Putative conserved residues involved in enzyme catalysis are indicated with asterisks.

preincubation of the enzyme at 40, 50, 60, or 70 °C without substrate for various periods. Then, the residual enzyme activities at specific time points were measured at 60 °C and pH 5.0 for 10 min.

To determine resistance to proteolysis, purified PG7fn was incubated with either pepsin in 100 mM glycine-HCl (pH 2.0) or trypsin in 100 mM Tris-HCl (pH 7.0) at 37 °C for different periods using a protease/PG7fn (w/w) ratio of 0.1:1. Protease resistance was assessed by measuring the residual enzyme activities under standard conditions (pH 5.0, 60 °C, 10 min) following protease treatment.

The effects of various metal ions and chemical reagents on the enzyme activities of PG7fn and d-PG7fn were determined in the presence of 1 mM of various metal ions and chemical reagents ($Na^+$, $K^+$, $Li^+$, $Ag^+$, $Ca^{2+}$, $Co^{2+}$, $Ni^{2+}$, $Mn^{2+}$, $Cu^{2+}$, $Mg^{2+}$, $Zn^{2+}$, $Pb^{2+}$, $Cr^{3+}$, $Fe^{3+}$, SDS, $\beta$-mercaptoethanol, or EDTA). The system without any additive was used as control. The residual enzyme activity was determined as described above.

The substrate specificities of PG7fn and d-PG7fn were determined by measuring the enzyme activities in McIlvaine buffer (pH 5.0) containing polygalacturonic acid and pectin of various degrees of methyl esterification under standard conditions. Enzyme kinetic assay was performed in McIlvaine buffer (pH 5.0) containing 0.1−20 mg/mL polygalacturonic acid at 40 or 60 °C for 5 min. The experiments were repeated three times, and each experiment included three replicates. The $K_m$ and $V_{max}$ values were plotted according to the Lineweaver−Burk method.

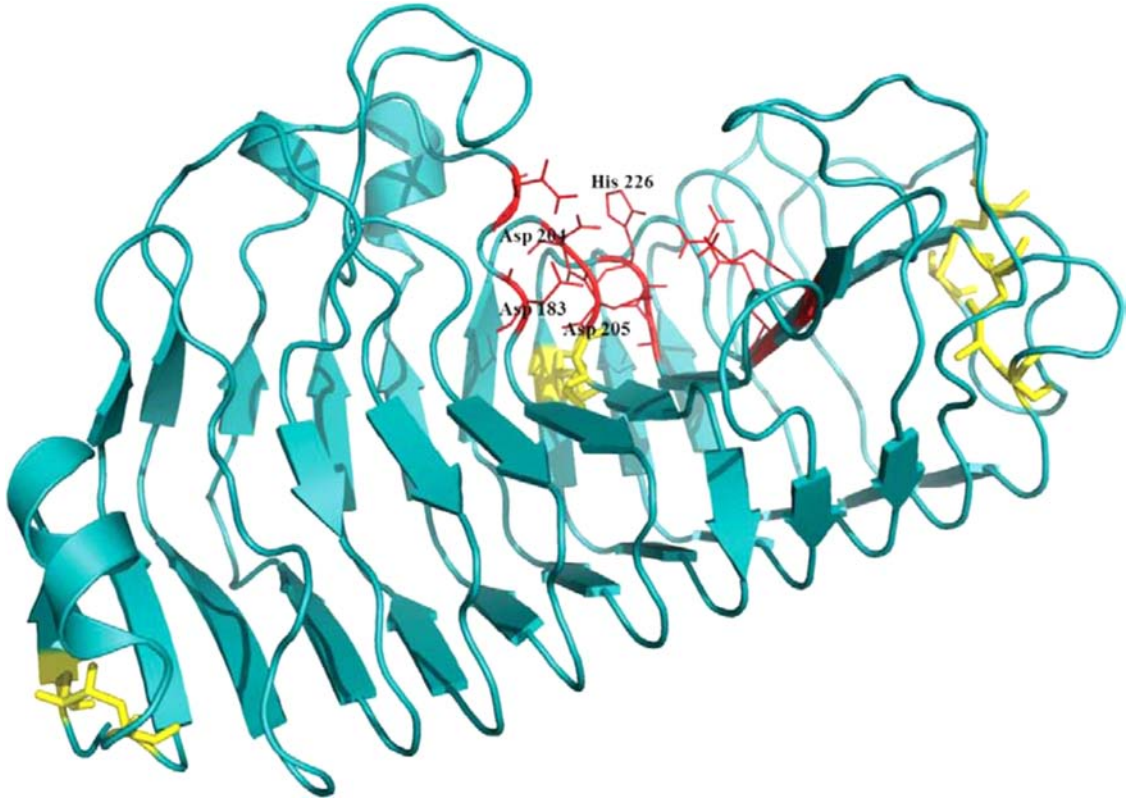

**Figure 2.** Homology modeling of PG7fn with CluPG1 from *C. lupini* (2IQ7_A, 78% identity) as the template. Putative conserved residues involved in enzyme catalysis and cysteine residues forming disulfide are indicated in red and yellow, respectively.

**Analysis of Hydrolysis Products.** The reactions containing 100 U of PG7fn or d-PG7fn and 0.2% (w/v) of polygalacturonic acid in McIlvaine buffer (pH 5.0) were incubated at 37 °C for 12 h. The excess enzyme was removed by ultrafiltration using a 3 kDa cutoff membrane after hydrolysis, and the hydrolysates were analyzed by using high-performance anion-exchange chromatography (HPAEC). Samples were diluted 100-fold in $ddH_2O$, and 25 $\mu$L of each sample was injected into a model 2500 HPAEC system (Dionex, Sunnyvale, CA, USA) equipped with a Carbo-Pac PA200 column (3 × 250 mm). NaOH (600 mM) was used to elute the oligosaccharides at the flow rate of 0.45 mL/min. Galacturonic acid, digalacturonic acid, and trigalacturonic acid were used as standards.

**Digestion Trial in Vitro.** The in vitro digestion trial was conducted to evaluate the hydrolytic effects of PG7fn on soybean meal, the main protein feedstuff. The contents of total pectin and water-soluble pectin were measured by using the carbazole colorimetry method with galacturonic acid as the standard.[24,25] Four grams of soybean meal was boiled for 15 min in 40 mL of McIlvaine buffer (pH 5.0), cooled to room temperature, and treated for 1 h with 100 $\mu$L of enzyme(s) (0, 2, 4, 6, 8, or 12 U of PG7fn) at 60 °C. The mixtures were then boiled for enzyme inactivation, followed by centrifugation at 12000*g* for 10 min at 4 °C. After drying at 35 °C for 24 h, the insoluble residues were added to 30 mL of hot absolute ethanol, heated for 10 min in a boiling water bath, and centrifuged at 12000*g* for 10 min at 4 °C. The insoluble residues were dried again at 35 °C for 24 h to obtain alcohol insoluble solids (AIS). Aliquots of AIS (5 mg) were added in a 25 mL volumetric flask containing 2 mL of concentrated sulfuric acid; distilled water was then added to 25 mL for the measurement of total pectin content. For determination of soluble pectin contents, 80 mg of AIS was directly mixed with 100 mL of distilled water, followed by centrifugation at 12000*g* for 10 min at 4 °C. The supernatants were subjected to pectin content measurement. Reaction systems consisting of 2 mL of supernatant and 12 mL of sulfuric acid (98%, w/w) were boiled for 10 min and cooled using running tap water followed by the addition of 0.5 mL of carbazole ethanol solution. After cooling to room temperature, its absorption at 530 nm was measured. All of the experiments were performed in triplicate. Data regarding total pectin and water-soluble pectin were subjected to analysis of variance (ANOVA), and a *t* test was used to identify significant differences at $p < 0.05$ (SPSS 16.0).

**Nucleotide Sequence Accession Number.** The nucleotide sequence of the endo-polygalacturonase gene (*pg7fn*) from *T. arenaria* XZ7 CGMCC6544 was deposited in the GenBank database under accession no. KM067135.

## RESULTS

**Gene Cloning and Sequence Analysis.** Strain XZ7 exhibited significant endo-polygalacturonase activity of 678.1 ± 48.6 U/mL in the culture supernatants after 72 h of growth at 45 °C. With genomic DNA of strain XZ7 as the template, a partial endo-polygalacturonase gene (252 bp) was amplified by PCR using degenerate primers GH28nF and GH28nR. The 5′ and 3′ flanking regions were obtained by FPNI-PCR and assembled with the core region to generate a full-length 1290 bp gene, termed *pg7fn*. Three introns (53, 71, and 68 bp, respectively) interrupt the coding sequence, and the cDNA sequence of *pg7fn* is 1098 bp in length. The N-terminal 16 amino acids were predicted to be a putative signal peptide by using SignalP 4.0. The mature protein contains 349 residues with a calculated molecular mass of 35.8 kDa and a p*I* value of 8.78. Further sequence analysis indicated that PG7fn has two putative N-glycosylation sites (Asn24 and Asn214).

The deduced amino acid sequence of *pg7fn* shares the highest identity of 88% with the experimentally verified GH28 endo-polygalacturonase (endo-PG I) from *Achaetomium* sp. Xz8 (AGR51994.1) and of 84% with a putative protein of GH28 from *T. terrestris* NRRL 8126 (XP_003657319.1). Multiple sequence alignment analysis with other endo-

polygalacturonases revealed that PG7fn is a typical endo-polygalacturonase of GH28 (Figure 1). Eight residues, Asn181, Asp183, Asp204, Asp205, His226, Gly227, Arg259, and Lys261 (in PG7fn numbering), were found to be strictly conserved.[26] The tertiary structure of PG7fn was predicted by homology modeling with minor modification through energy minimization. Modeled PG7fn folds into a right-handed parallel $\beta$-helix structure consisting of 10 complete turns (Figure 2), which is typical of pectinases. Putative catalytic residues (Asp183, Asp204, Asp205, and His226) are located on the bottom of the cleft, and four disulfide bridges conserved in all *Aspergillus niger* endo-polygalacturonases are also identified.[3] Two disulfide bonds at the terminal regions (Cys31−Cys46 and Cys356−Cys365) ensure the "capping" of the core of the $\beta$-helix, and the others, Cys206−Cys222 and Cys332−Cys337, connect two adjacent $\beta$-helical turns in the middle of the putative active site cleft and the ends of the T1 loop to stabilize the protein structure, respectively.

**Expression and Purification of Recombinant PG7fn.** The gene fragment coding for mature PG7fn without the signal peptide-coding sequence was expressed in *P. pastoris*. Positive transformants were screened on the basis of endo-polygalacturonase activity in shaker flask culture, which was subject to high-cell density fermentation. Before the induction phase, no endo-polygalacturonase was detected in the culture supernatant. Upon methanol induction, the endo-polygalacturonase activity in the supernatant increased to 1080 ± 50 U/mL after 72 h. The crude enzyme was separated into two parts. One was directly purified to electrophoretic homogeneity by a one-step cation exchange chromatography with the final yield of 31.6%, and the other was treated with Endo H followed by purification (with the final yield of 28.8%) as described above. Purified PG7fn migrated two bands of ∼40.0 and 38.0 kDa on SDS-PAGE (Figure 3), which are higher than the calculated molecular mass. The molecular mass of deglycosylated PG7fn, termed d-PG7fn, was 35.8 kDa, which is in agreement with the calculated molecular weight. The result indicates that different levels of N-glycosylation occurred in recombinant PG7fn during heterologous expression in *P. pastoris*.[5,6,27]

**Properties of Purified PG7fn and d-PG7fn.** The enzymatic properties of glycosylated and deglycosylated PG7fn were compared. PG7fn and d-PG7fn were both optimally active at pH 5.0 and exhibited >70% of the maximal activities at pH 4.0−5.5 (Figure 4A). The enzymes were very stable over a wide range of pH, retaining ∼90% of the maximum activity after incubation at pH 3.0−8.0 for 1 h at 37 °C (Figure 4B). PG7fn and d-PG7fn had optimal temperature of 60 °C at pH 5.0 (Figure 4C) and retained ∼50% of the activities even at 70 °C. Although deglycosylated d-PG7fn showed similar pH and temperature profiles as the glycosylated counterpart, its thermostability is much worse. Both enzymes were much stable at temperatures of 40 °C and below, but PG7fn showed better thermostability at higher temperatures (Figure 4D). It retained >85% of the initial activity after 1 h of incubation at 50 °C and >60% activity at 60 °C for 30 min.

The effects of various metal ions and chemical reagents at a final concentration of 1 mM were also investigated on the activity of glycosylated and deglycosylated PG7fn (data not shown). Except for $Ca^{2+}$, SDS, and $Ag^{+}$ that partially or completely inhibited the activity, other chemicals had little or no effect. The result indicates that perturbation of N-glycosylation has no detectable effect on the surface charge of PG7fn.

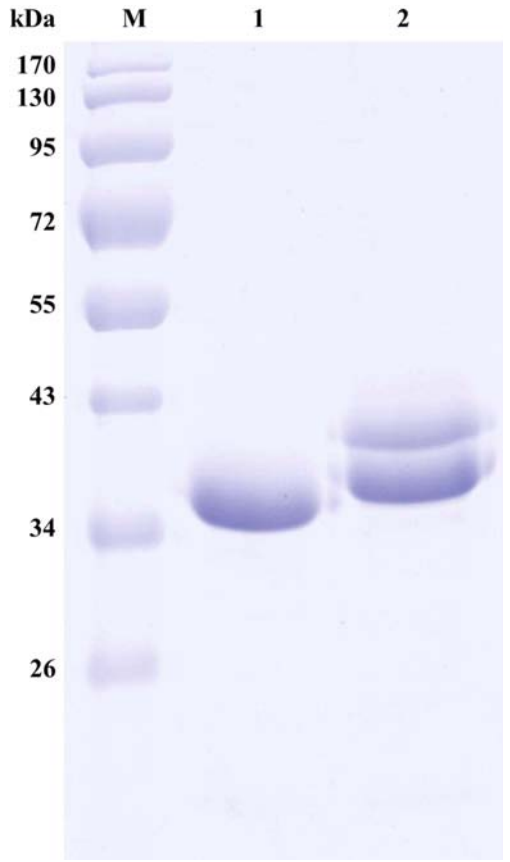

**Figure 3.** SDS-PAGE analysis of purified recombinant PG7fn. Lanes: M, standard protein molecular weight markers; 1, purified recombinant PG7fn after N-deglycosylation with Endo H (d-PG7fn); 2, purified recombinant PG7fn by one-step cation exchange chromatography.

**Substrate Specificity and Kinetic Parameters.** Demethylated pectin is the best substrate for purified recombinant PG7fn and d-PG7fn. It showed highest activity toward polygalacturonic acid (defined as 100%), followed by pectin of different methyl esterification levels. The enzyme activity decreased along with the increased level of methyl esterification. PG7fn and d-PG7fn exhibited relative activities of 62, 31, and 7% and 53, 26, and 6% toward 34, 70, and 85% methyl-esterified pectin, respectively.

Under standard conditions (pH 5.0, 60 °C, 10 min), the specific activities of PG7fn and d-PG7fn toward polygalacturonic acid were 34382 ± 351 and 26760 ± 108 U/mg, respectively. The enzymes had similar $V_{max}$ (50000 ± 1067 and 50000 ± 1768 $\mu$mol/min/mg) and $k_{cat}$ (29817 ± 636/s and 29817 ± 1054/s) values, but their $K_m$ values varied, 1.5 ± 0.03 mg/mL for PG7fn and 2.0 ± 0.07 mg/mL for d-PG7fn, respectively. Besides the higher substrate affinity, PG7fn had higher catalytic efficiency ($k_{cat}/K_m$) than d-PG7fn (19878 ± 473 vs 14908 ± 527 mL/mg/s). Their kinetic values were also determined at 40 °C using polygalacturonic acid as the substrate. The $K_m$, $V_{max}$, and $k_{cat}$ values of purified PG7fn and d-PG7fn were 2.0 ± 0.06 and 2.8 ± 0.04 mg/mL, 32000 ± 915, and 30000 ± 362 $\mu$mol/min/mg and 19082 ± 546/s and 17890 ± 216/s, respectively. These results indicated that glycosylation improves the substrate affinity of PG7fn and correspondingly its catalytic efficiency.

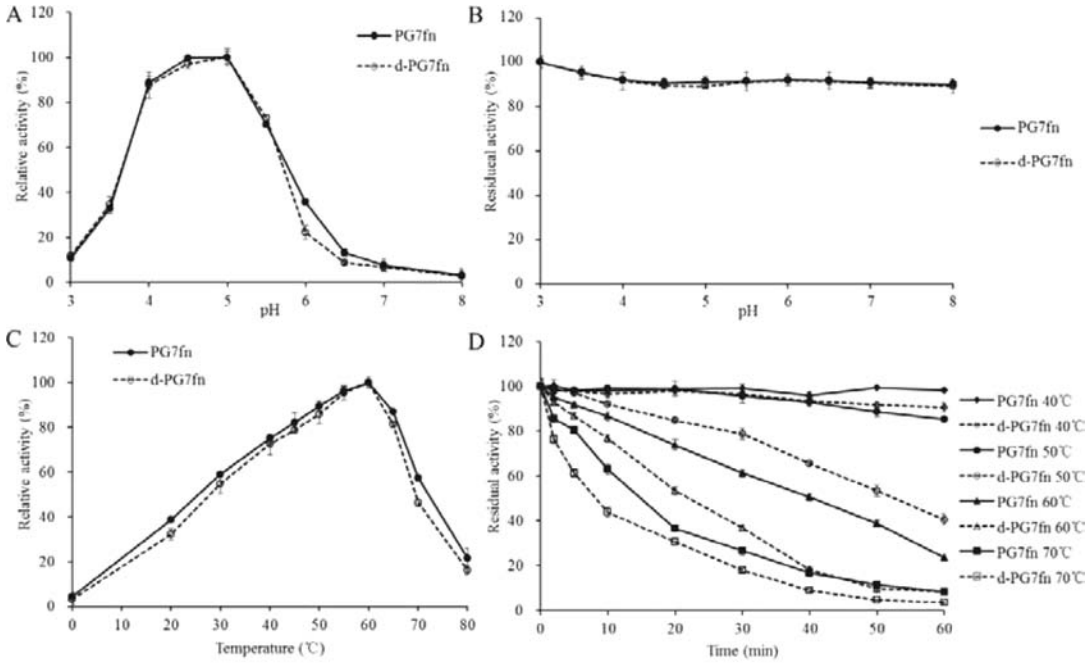

**Figure 4.** Characterization of the purified recombinant PG7fn with and without N-glycosylation. (A) Effect of pH on PG7fn and d-PG7fn activities. The polygalacturonase activity assay was performed at 60 °C in buffers of various pH values for 10 min. (B) pH stability of PG7fn and d-PG7fn at 37 °C for 1 h at pH 3.0−8.0. The residual activities were measured in McIlvaine buffer (pH 5.0, 60 °C, 10 min). (C) Effect of temperature on PG7fn and d-PG7fn activities measured in McIlvaine buffer (pH 5.0) for 10 min. (D) Thermostability of PG7fn and d-PG7fn. The enzymes were preincubated at 40, 50, 60, or 70 °C in McIlvaine buffer (pH 5.0) for various periods, followed by enzyme activity assay under pH 5.0 and 60 °C for 10 min. Each value in the panel represents the mean ± SD ($n$ = 3).

**Composition of Hydrolysis Products.** Similar to endo-PG I from *Achaetomium* sp. Xz8,[5] the hydrolysis end-products of PG7fn and d-PG7fn are mainly galacturonic acid, digalacturonic acid, trigalacturonic acid, and small amounts of unidentified oligosaccharides, but the hydrolysis of PG7fn is more complete. After 12 h of incubation, the major products by PG7fn hydrolysis were 40.74 ± 0.54% galacturonic acid, 18.01 ± 0.14% digalacturonic acid, and 8.59 ± 0.16% trigalacturonic acid. Under the same conditions, the products of d-PG7fn consisted of 34.51 ± 0.69% galacturonic acid, 14.54 ± 0.03% digalacturonic acid, and 14.28 ± 0.48% trigalacturonic acid.

**Resistance to Pepsin and Trypsin.** PG7fn was strongly resistant to pepsin and trypsin digestion (Figure 5). After treatment with pepsin and trypsin at 37 °C for 120 min, the enzyme retained 45 and 67% activity, respectively. SDS-PAGE analysis indicated that PG7fn was not degraded by these proteases (data not shown), suggesting its application potential in the food and feed industries.

**Soybean Meal Degradation.** The total pectin content of soybean meal was determined to be 6.41%, similar to the results of Malathi and Devegowda (6.16%).[28] PG7fn has great capacity to remove pectin from soybean meal (Table 2). After 1 h of incubation with PG7fn, the pectin contents in soybean meal were decreased. The greatest degradation rate (19.33%) was observed with the addtion of the dosage of 1000 U/kg.

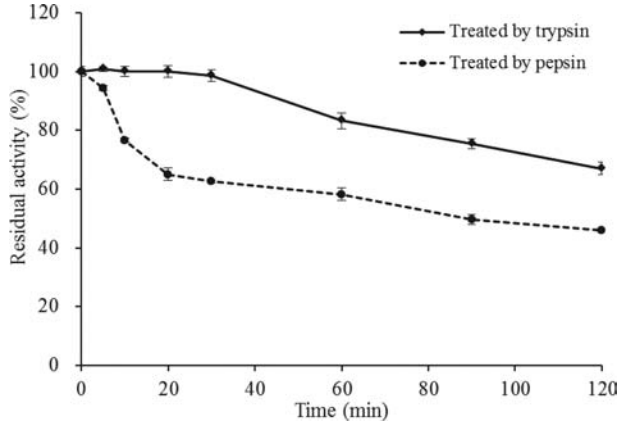

**Figure 5.** Effect of proteases on the endo-polygalacturonase activity of PG7fn. The enzymes were preincubated with pepsin in 100 mM glycine-HCl (pH 2.0) or trypsin in 100 mM Tris-HCl (pH 7.0) at 37 °C for different periods and subjected to enzyme activity assay under pH 5.0 and 60 °C for 10 min. Each value in the panel represents the mean ± SD ($n$ = 3).

## ■ DISCUSSION

Thermophilic fungi are liable to manipulation using classical and molecular genetics as representing a potential reservoir of thermostable enzymes.[13] To our best knowledge, only a few fungal endo-polygalacturonases have activities at ≥55 °C (Table 3). Compared with other characterized thermophilic endo-polygalacturonases and its close homologue endo-PG I from *Achaetomium* sp. Xz8,[5] PG7fn has a higher temperature optimum (60 °C) and greater specific activity (34382 ± 351 U/mg) toward polygalacturonic acid. Furthermore, PG7fn shows a lower acidic pH optimum (5.0 vs 6.0), better stability at pH 3.0 (100 vs ∼60%), higher temperature optimum (60 vs 45 °C), and better thermostability (50 vs 40 °C). These properties make PG7fn favorable for applications in various industries.

N-glycosylation is one of the most common posttranslational modifications in protein biosynthesis or in the methylotrophic yeast,[31] which has an effect on secretion, activity, stability, and biosynthesis.[31−34] Most fungal endo-polygalacturonases are

**Table 2. Effect of PG7fn on the Degradation of Soybean Meal Pectin[a]**

| enzyme level (U/kg) | total pectin contents (%) | soluble pectin contents (%) | soluble/total pectin (%) | degradation rate (%) |

[a]Specific activities were determined using polygalacturonic acid as the substrate except for special cases. [b]nd, not determined.

glycoproteins with at least one N-glycosylation site.[3,26,35] Our result showed that N-glycosylation has effects on enzyme activity; thus, a thorough comparative analysis of glycosylated and deglycosylated PG7fn was performed to determine its effect on other enzyme properties. Abrogation of N-glycosylation has no detectable effect on the temperature optimum and pH properties of d-PG7fn, but the protein showed worse thermostability. It has been reported that glycoproteins are more stable than their corresponding unglycosylated counterparts.[6,36,37] N-linked glycans may facilitate the overall stability of the protein by enhancing the reversibility of the unfolding process or enabling some specific functions performed around the attached site by reducing the disorder of the unfolded protein.[34,38] Elimination of N-linked glycans showed no change in the temperature optimum as to thermostability. The reason might be that N-glycosylation has no effect on the structure of protein, and N-linked glycan only makes glycosylated enzyme more resistant to thermal inactivation. In addition, PG7fn had higher catalytic efficiency ($k_{cat}/K_m$) than d-PG7fn. It has been reported that the biological activity of protein is affected by attaching a long glycan chain to the Asn residue.[31] The results of kinetic parameters indicate that N-glycosylation plays a role in the substrate affinity of PG7fn and catalytic efficiency. Without N-glycosylation, the protein structure of d-PG7fn might be looser and, thus, lose strong affinity to substrate.[39] According to the hydrolysis products analysis, N-glycosylation makes PG7fn more efficient and complete in hydrolysis.

Pectinase is an important feed additive that can reduce feed viscosity and increase nutrient absorption.[40] Besides pectinase, other carbohydrate-active enzymes (CAZymes) such as phytase, xylanase, glucanase, mannanase, and cellulase are commonly supplemented in animal feed for the improvement of nutrient bioavailability.[28,41] A necessary requirement of feed enzyme is strong resistance to protease. PG7fn has such a good property. In contrast to the endo-polygalacturonase (endo-PGA1) from *Bispora* sp. MEY-1 that retained only 40% of its initial activity after a 10 min trypsin treatment,[42] PG7fn retained 45 and 67% activity, respectively, after treatment with pepsin and trypsin at 37 °C for 120 min. On the other hand, soybean meal is the major protein source of animal feed. PG7fn has the capacity to degrade soybean meal pectin, increasing the pectin bioavailability by 19.33% at 1 U/g dosage. In comparison with the commercial compound pectinase (including polygalacturonases, pectin lyases, and methylesterases) commonly added in animal feed in China, the amount of PG7fn used in this study is a little higher (1 vs 0.5 U/g based on polygalacturonase activity). Considering the complex composition of pectin, PG7fn in combination with other pectinases will be more efficient in pectin degradation in the food and feed industries.

In summary, the efficacy of feed enzymes depends on their substrate specificity, activity, and stability. In this study, a highly active thermophilic endo-polygalacturonase, PG7fn, was identified in *T. arenaria* XZ7 and successfully expressed in *P. pastoris*. A thorough comparative analysis of the enzymatic properties of glycosylated and deglycosylated PG7fn indicated

that N-glycosylation improved enzyme thermostability, substrate affinity, and catalytic efficiency. The high specific activity, good stabilities over a wide pH range and high temperature, and great catalytic efficiency make PG7fn a good enzyme candidate for applications in the food and feed industries.

in a 20 μL RT mixture. The RT reaction was allowed to proceed for 60 min at 37 °C in the presence of a recombinant ribonuclease inhibitor (RNaseOUT from Invitrogen) at a concentration of 2 units/μL. The reverse transcriptase was inactivated by incubating the reaction mixture at 95 °C for 5 min. The RT product was either used immediately as a template in PCR or stored at −80 °C for future use.

Primers I (5′-caccgtgaacagatcggtggtatgtcgtggcagcagtacgtc-3′) and II (5′-cctctcgagttacagaccctgctcgataaggta-3′) were designed based on a published Pru du 4 sequence (GI:24473793)[19] to amplify the coding region of Pru du 4. The underlined portion of primer I was added to facilitate a second round PCR to join the Pru du 4 coding sequence with that of the sumo. The sumo sequence was previously synthesized commercially with codon optimization for *E. coli* expression. Primer III (5′-ccggatcctgggaagttaaaccggaaaccc-3′) and primer IV (which is complementary to primer I) were used to amplify the synthesized sumo coding sequence. The two PCR products were mixed and used as template for a second round PCR using primers III and II. The final PCR product was inserted into the cloning vector pBluescript II SK with blunt-end ligation to make pBlue-SPrudu4. The ligation product was transformed to *E. coli* strain dH5α, and the plasmid prepared from the isolated colonies was sequenced to confirm correct insertion of the sumo-Pru du 4 fusion. pBlue-SPrudu4 was digested with *Bam*HI and *Xho*I to release the sumo-Pru du 4 coding sequence which was then ligated with the pRSFdeut-1 vector prepared with the same enzymes to generate pRSF-SPrudu4.

Primers V (5′-cctcatgagccacgtgcatcaccatcatcaccacggatcctttaaaatcgaagaggtaaac tggtaatc-3′) and VI (5′-ccagatcttacgtaagtctgcgcgg-3′) were used in a PCR with pMAL-c2 as template to amplify the MBP coding sequence. The underlined sequences in the primers were added to incorporate enzyme recognition sites and a His-tag coding sequence. The PCR product was inserted into Bluescript II SK as described above. The MBP coding sequence was confirmed with DNA sequencing. It was released with *Bsp*HI and *Bgl*II and ligated with the pRSF-SPrudu4 plasmid prepared with *Nco*I and *Bam*HI to generate pRSF1MS-SPrudu4. The sequence-confirmed pRSF1MS-SPrudu4 plasmid was then transformed into the *E. coli* strain BL21(DE3)* (Invitrogen) for protein expression. The transformed bacteria were grown in 1 L batches of LB medium containing 50 mg/L kanamycin (Gold Biotechnology, St. Louis, MO) at 37 °C until the $OD_{600}$ of the culture reached 1.0. IPTG (Gold Biotechnology) was then added to the medium to a final concentration of 1 mM, and the expression of Pru du 4 fusion protein was allowed for 5 h. The cells were collected by centrifugation, and the cell pellets were stored at −80 °C for future use.

**Purification of the Fusion Protein.** The cell pellet was thawed on ice and resuspended in 50 mL of a His-binding buffer (buffer HB, 20 mM imidazole, pH 8.0, 500 mM NaCl) containing 1 mM benzamidine. The bacteria were lysed by sonication for 9 min in a beaker surrounded by a mixture of ice and water using a Model 450 Digital Sonifier (Branson, Danbury, CT). The cell lysate was centrifuged at 20 000g for 40 min at 277 K. The supernatant was loaded onto a 5 mL HisTrap FF Crude column (GE Healthcare, Piscataway, NJ). The column was washed with 7 bed volumes of buffer HB and then eluted with a His-elution buffer (buffer HE, 300 mM imidazole, pH 8.0).

The main peak of the HisTrap elution was diluted with buffer QB (10 mM Tris-HCl, pH 7.9) to 50 mL. The sample was then loaded onto an 8 mL Source15 Q column (GE Healthcare). The column was washed with 7 bed volumes of buffer QB and eluted with QB plus a linear NaCl gradient of 0−1 M (over 10 bed volumes). The main peak of the elution was confirmed later to contain the target fusion protein.

**Removal of the Fusion Tag.** The elution fractions of the main peak from the anion exchange column were pooled, and aliquots of the pooled sample were used to optimize the conditions for the removal of the fusion tag by a recombinant sumo protease rULP which also contained a His-tag and was expressed and purified in-house. The scaled up rULP digestion was in 50 mL of a buffer containing 10 mM Tris, pH 7.9, 250 mM NaCl, 18 mg of His-MBP-sumo-Pru du 4, and 18 μg of rULP. The digestion was carried out at 20 °C for 12 h. The digested sample was passed through a 5 mL HisTrap FF Crude column, and the flow-through was collected and concentrated to a final volume of 15 mL using an Amicon Ultra centrifugal filter device with 3 kDa molecular weight cutoff for proteins (Millipore, Bedford, MA). The concentrated sample was further purified with size exclusion chromatography (SEC) using an XK 26/70 Superdex-75 column (GE Healthcare) pre-equilibrated with buffer SC (10 mM Tris-HCl, pH 7.9, 200 mM NaCl) and eluted with the same buffer. Determination of the concentrations of the purified protein samples was based on $OD_{280}$ using the theoretical molecular mass and molar extinction coefficient using the program SPHERE (http://www.fccc.edu/research/labs/roder/sphere/).[20] All chromatographic steps were carried out at room temperature using an FPLC system (GE Healthcare).

Samples of the target protein after each step of purification were boiled in an SDS sample buffer for 5 min and separated by electrophoresis with 4−20% gels and stained using the Colloidal Coomassie G-250 Staining protocols.[21] The image of the stained gel was taken with a Nikon digital camera.

**N-terminal Sequencing.** The final recombinant Pru du 4 was subjected to SDS-PAGE using 8−25% gradient gels in a PhastSystem (GE Healthcare) and electrophoretically transferred (0.35 A at 25 °C) to a Problott membrane (Applied Biosystems, Foster City, CA) in a transfer buffer [10 mM 3-(cyclohexyl-amino)-1-propanesulfonic acid containing 10% methanol, pH 11.0]. The blot was stained with Coomassie Brilliant Blue, and the protein band was excised and subjected to N-terminal amino acid sequencing by Edman degradation using a Shimadzu PPSQ-33A Protein Sequencer (Shimadzu, Columbia, MD).

**Determination of the Mass of the Purified Protein.** The purified Pru du 4 was subjected to reverse-phase HPLC using an Easy nLC II (Thermo Fisher Scientific, San Jose, CA) with a PicoChip column packed with 3 μm Reprosil-Pur (New Objectives, Woburn, MA) and a flow rate of 250 nL/min. MS data were collected on an Orbitrap Elite operated at 15 000 mass resolution. Data across chromatographic peak were averaged with Thermo Excalibur software and subsequently deconvoluted with MagTran software.[22]

**Circular Dichroism (CD).** The buffer of the purified protein was changed to a buffer containing 20 mM phosphate (pH 7.0) and 200 mM NaCl by repeated concentration-and-dilution using an Amicon Ultra centrifugal filter device with 3 kDa molecular weight cutoff for proteins (Millipore). CD spectroscopy was used to study the secondary structure content of recombinant Pru du 4. Far-UV spectra were collected in the 195−260 nm region using a J-815 CD spectrometer (Jasco, Tokyo) and a quartz cuvette with a light path length of 2.0 mm. Wavelength scans were performed with a speed of 50 nm/min at 20 °C. The spectra were averaged for 10 scans.

**Guanidinium Hydrochloride (GuHCl) Denaturation.** Two stock solutions of recombinant Pru du 4 were prepared. Both solutions (pH 7.0) contained 2 μM of the protein, 10 mM of phosphate, and 200 mM of NaCl. One of them additionally contained 6.923 M of GuHCl. Thirty samples were prepared with various ratios of the two stock solutions to obtain samples at 0.187 M intervals of GuHCl concentration from 0 to 5.43 M. A 6 M GuHCl sample was also made by mixing the two stock solutions at the right ratio. The samples were thoroughly mixed and equilibrated at room temperature for 24 h. The CD signals at 220 nm of these samples were measured at 20 °C for half a minute with data collected every second. The free energy of denaturation was calculated by fitting the data to a two-state transition using Origin Pro9 software (OriginLab Corp., Northampton, MA).

## RESULTS

**Isolation and Expression of Pru du 4.** The mRNA sequence of Pru du 4 could be found in the Genbank that also contained the 5′- and 3′-untranslated regions (GI:24473793). On the protein level, it has 100% sequence identity with the Japanese apricot profilin (GI:645226637) and 99% (GI:596206424)−100% (GI:27528309) to the peach profilin allergen Pru p 4.[23] Using primers designed based on the available Pru du 4 mRNA sequence, the coding sequence for

the Nonpareil almond profilin isolated in this study was identical to that of the Pru du 4 in the GenBank. When Pru du 4 was expressed without an expression tag in *E. coli*, only minimal expression could be achieved. This is also true when expressed with a sumo tag (data not shown). We sought to use sumo as an enzyme recognition site and produce Pru du 4 with a protocol depicted in Figure 1. Despite of its size, using sumo

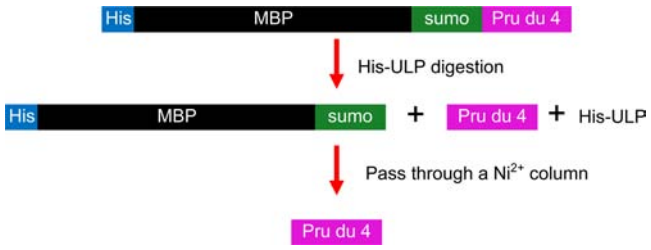

**Figure 1.** Producing Pru du 4 with sumo as a peptidase recognition site.

as a peptidase recognition site had no negative effect on the enhancement of the expression of Pru du 4 by MBP fusion (Figure 2, lane 1, and data not shown). Sumo can be used as a peptidase recognition site at least in the combination of MBP-sumo and Pru du 4.

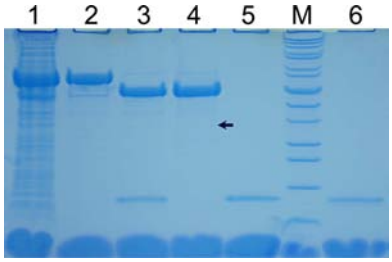

**Figure 2.** SDS-PAGE analyses of recombinant Pru du 4. Samples loaded in lanes 1−6 are (1) supernatant of the lysate of *E. coli* expressing Pru du 4, (2) sample after ion exchange purification, (3) product of ULP digestion, (4) unwanted proteins removed from the protease digestion product, (5) recombinant Pru du 4 after tag-removal, (6) the final Pru du 4 sample after SEC. The molecular masses (in kDa) of the protein standard in the maker (lane M) are 200, 150, 120, 100, 85, 70, 60, 50, 40, 30, 25, 20, 15, and 10, respectively. The arrow line close to lane 4 indicated the position of the ULP band that is barely detectable in lanes 3 and 4.

**Purification of Pru du 4.** The expressed His-MBP-sumo-Prudu4 was highly soluble in aqueous solutions. The fusion protein was purified with immobilized metal affinity chromatography using a $Ni^{2+}$ column. The purity of the sample was >90%, high enough to start fusion tag removal. To facilitate downstream purification, a second step of purification (anion exchange chromatography) was performed. In the ion exchange step, the sample eluted at ~200 mM NaCl. This step also eliminated imidazole from the sample. High concentration of imidazole is undesirable for removing the expression tag from the sample after protease digestion. Recombinant ULP produced in our lab was used to cleave the fusion tag. After optimization, a peptidase/substrate ratio of (w/w) 1:1000 was used. The reaction was carried out at 20 °C overnight, and it was almost complete without nonspecific digestions (Figure 2, lane 3). The undigested fusion protein, the cleaved fusion tag, and the recombinant ULP were successfully removed by passing the digestion product through a $Ni^{2+}$ column (Figure 2, lane 4). The flow-through seemed to contain homogeneous recombinant Pru du 4 (Figure 2, lane 5). Gel filtration was used to further purify the recombinant Pru du 4 to ensure high purity. The yield for the final product was at least 8 mg/L. Twenty cycles of N-terminal amino acid sequencing of the sample confirmed the expected N-terminal sequence (MSWQQYVDDHLMCDIDGNRL) of Pru du 4, except for Cys13 for which no major signal was obtained as is the case usually for a Cys residue. In addition, the total mass of the protein was determined to be 14060.8 Da (Figure 3). This is consistent with the calculated isotope averaged mass of 14061.10 for the protein (using the ExPASy server at http://web.expasy.org/cgi-bin/compute_pi/pi_tool). Additionally, the mass spectrometry method also detected minor populations of the protein with Pyruvoyl-(Serine) or oxidized residues that are most likely at its methionine residues.

**Chemical Stability of Pru du 4.** Far-UV CD spectrometry studies indicated that the spectrum of recombinant Pru du 4 is typical of a protein with mixed $\alpha$-helix and $\beta$-sheet secondary structures (Figure 4). Chemical denaturation is widely used as a way to assess the stability of native proteins. The folding−unfolding equilibrium of Pru du 4 was studied by measuring the GuHCl-induced transitions of the protein. In the present study, the equilibrium between unfolded and folded Pru du 4 at various concentrations of GuHCl was studied by measuring the CD signal at 220 nm (Figure 5). The data points seemed to follow a sigmoidal shape, indicative of a two-state transition between folded and unfolded states of Pru du 4 without a measurably populated stable intermediate. The method for finding the free energy of unfolding of a protein has been described in many comprehensive reviews (see, e.g., ref 24). The concentrations of the protein in the unfolded [U] and folded [F] states vary with the change of the denaturant concentration. The Gibbs free energy of the equilibrium transition, $\Delta G = \ln([U]/[F])$, changes accordingly. To the first approximation, the free energy of transition is a line function of the denaturant concentration

$$\Delta G = \Delta G_0 - mC$$

where $C$ is the concentration of the denaturant, $\Delta G_0$ is the free energy of the transition when there is no denaturant, and $m$ is a constant. At the midpoint of the transition (when $C = C_m$), the folded and unfolded states are equally populated and $\Delta G = 0$. Thus, $m$ equals to $\Delta G_0/C_m$. Generally, the CD signals of a protein in its folded and unfolded are both a linear function of the concentration of the denaturant. The measured CD signal is the sum of those of the folded and unfolded protein. Thus, $\Delta G_0$, $m$, and $C_m$ can be found by nonlinear fitting of the CD data. The results of the curve fitting are shown in Table 1. The transitions occurred with a midpoint concentrations of 1.38 ± 0.02 M. The free energy of unfolding, $\Delta G_0$, in the absence of denaturant was 5.4 ± 0.6 kcal/mol.

## DISCUSSION

Profilin is considered to be a panallergen. Almond profilin is known to be a food allergen. Unlike the 2S albumin, 7S vicilin, and 11S legumin allergens, the amount of profilin, including almond allergen Pru du 4, in plant seeds is minute. Expression of Pru du 4 in *E. coli* without an expression tag was unsuccessful though untagged expression of peanut profilin Ara h 5 was successful.[25] Its expression with an MBP-tag was reported, and the recombinant protein was used in immunological analyses.[19]

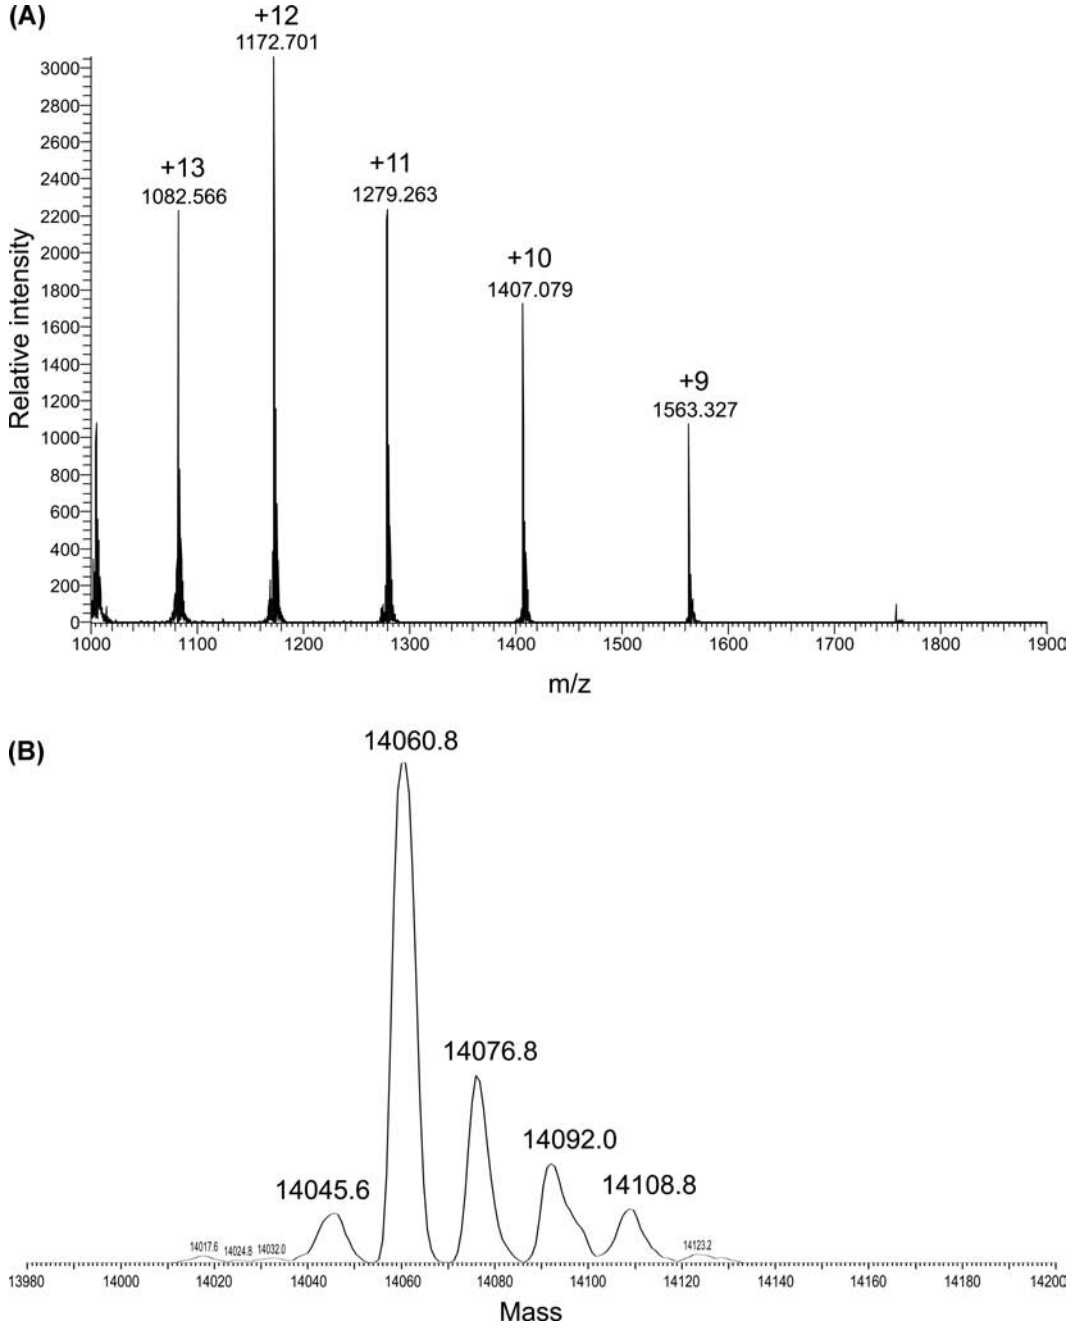

**Figure 3.** Mass determination of the purified Pru du 4. The sample was eluted from a Reprosil-Pur column coupled with an Easy nLC II mass spectrometer for accurate mass measurement. Panel A shows the mass spectrum of purified Pru du 4. Panel B shows the deconvolution result of the spectrum. The main peak indicated the measured mass of the protein is within 0.3 mass units of its calculated mass based on it peptide sequence.

In dot blot and ELISA studies, the recombinant protein and Pru du 4 purified from almond extract were recognized by IgE in patient sera differently. Some of the patient sera recognize Pru du 4 from almond, but not the recombinant Pru du 4.[19] N-terminal amino acid sequencing of Pru du 4 purified from almond indicated that no signal peptide was removed post-translationally (ref 19 and above). One of the reasons for the differences in the IgE recognition of the two versions of the allergen might be that the recombinant Pru du 4 used in the reported study had eight extra amino acids at its N-terminus after removing the expression tag with thrombin (or factor Xa) cleavage. These residues might block the conformational epitopes for IgE association.

To understand the relative importance of linear and conformational IgE epitopes in food allergy, native allergens are needed. As the amounts of a number of the allergens in foods are very low, it is desirable to obtain the native allergen with recombinant technology. In addition, an available system for producing native allergen in *E. coli* will make it possible to study the allergenicity of food allergens with site-directed mutagenesis technologies. Thus, we decided to use a highly specific peptidase for removing the expression tag without leaving any extra amino acids in the final product. Most of the widely used protease recognition sites that have been incorporated in varies DNA vectors designed for protein expression are short peptides with just a few amino acids. To

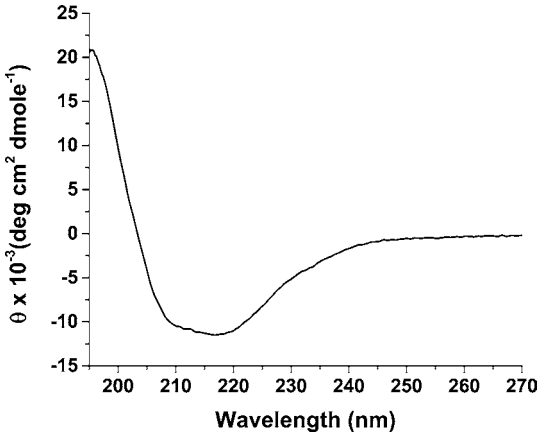

**Figure 4.** CD spectrum of recombinant Pru du 4. The residue molar ellipticity is shown as a function of wavelength.

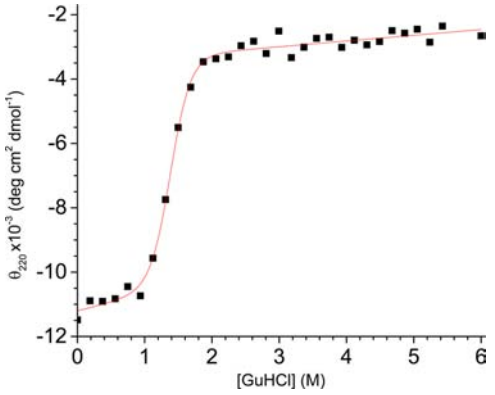

**Figure 5.** Folding–unfolding equilibrium of Pru du 4 in the presence of GuHCl. The data were fitted according to the equations shown in the text.

**Table 1. Equilibrium Parameters for GuHCl-Induced Unfolding of Pru du 4**[a]

| $\Delta G_0$ (kcal mol$^{-1}$) | $C_m$ (M) | $m$ (kcal mol$^{-1}$ M$^{-1}$) | $R^2$ |
|---|---|---|---|
| 5.4 ± 0.7 | 1.38 ± 0.02 | 3.9 ± 0.5 | 0.996 |

[a]Measured by CD at 220 nm in 10 mM sodium phosphate, pH 7.00, 20 °C.

our knowledge, the use of a protein, such as sumo, as a protease recognition site has not been reported, other than when sumo itself was used as an expression/solubility enhancement tag. Our results showed that by using sumo for peptidase recognition, the tag could be removed from almost 100% of the fusion protein without nonspecific cleavage of the target protein or the fusion tag. In our experience, this is a better system than using other proteases such as enteropeptidase which also does not leave any extra residues to the target protein. We expect that sumo as a protease recognition site can be used to conveniently obtain a wide variety of proteins. This may become the recognition site of choice especially when extra residues at the N-terminal of the target protein become problematic.

Profilin is considered as a panallergen.[11,12] Celery allergen Api g 4, which is also a profilin, was reported to lose its association with patient serum IgE after it was heated at 100 °C.[26] Strong allergenicity of cherry allergens was reported to be related to high stability against thermal processing and digestion.[27] The $\Delta G_0$ value obtained for Pru du 4 was 5.4 ± 0.7 kcal/mol. This is similar to the free energy of the folding–unfolding transitions of other globular proteins in the ProTherm Database.[28] The database currently consists of more than 3000 entries of the thermodynamic parameters for wild-type proteins obtained by studying the chemically induced changes in the folding–unfolding equilibrium of the proteins. While the stability is considered a contribution factor for the allergenicity of food proteins, information on the stabilities of food allergens derived from careful biochemical studies is limited. Additional comparative studies of the thermodynamic parameters of food allergens are required to understand the relationship between the chemical, physical, and biological stability of food allergens and their allergenicity. Currently, a well-characterized IgE or IgG antibody that recognizes only the native Pru du 4 is not available although immunoblotting experiments with such antibodies might give additional indication on the immunological equivalence of the recombinant protein and the protein purified from almond. Thus, the development of well-characterized antibodies is also desired for better understanding of the allergenicity of food proteins.

action.[17] Therefore, inhibiting nitrite formation from nitrate reduction, as well as enhancing nitrite reduction, can be efficient to decrease the final nitrite content. The aim of this study is to lower the TSNA content of tobacco leaves during the air-curing process using a high nitrite reductive strain with low nitrate reduction capability.

## MATERIALS AND METHODS

**Samples and Chemicals.** Tobacco leaves and involved rhizosphere soil samples were collected from Shiyan, Enshi, and Wuhan of Hubei Province in China for strain isolation. The standard substances of NNN, NNK, NAB, and NAT were purchased from Sigma-Aldrich Co. LLC (St. Louis, MO, USA). The deuterated equivalents of NNN-D4, NNK-D4, NAB-D4, and NAT-D4 were bought from C/D/N Isotopes Inc. (Pointe-Claire, Quebec, Canada). All other chemicals were purchased from Sinopharm Chemical Reagent Co., Ltd. (Shanghai, China).

**Isolation of the Nitrite Reductive Strain.** The tobacco and soil samples were added into the liquid screening medium ($NaNO_2$ 0.5 g/L, $MgSO_4{\cdot}7H_2O$ 0.2 g/L, $K_2HPO_4$ 0.5 g/L, $KNaC_4H_4O_6{\cdot}4H_2O$ 20.0 g/L, pH 7.2), cultured at 37 °C and 180 rpm for 48 h. The cultures were then diluted, and spread onto the solid screening medium containing 15 g/L agar, and incubated at 37 °C for another 24 h. The single clone was then inoculated in the nitrate medium ($NaNO_3$ 1 g/L, peptone 10 g/L, yeast extract 5 g/L, NaCl 10 g/L, pH 7.2) and nitrite medium ($NaNO_2$ 0.5 g/L, peptone 10 g/L, yeast extract 5 g/L, NaCl 10 g/L, pH 7.2), respectively. After culture at 37 °C and 180 rpm for 12 h, the concentrations of nitrate and nitrite in the medium were determined. The high nitrite reductive strain with low nitrate reduction ability was selected.

**Fermentation of Tobacco Leaves.** The isolated nitrite reductive strains were cultured in LB liquid medium (peptone 10 g/L, yeast extract 5 g/L, NaCl 10 g/L, pH 7.2) at 37 °C and 180 rpm for 12 h, and subcultured for 24 h. The cells were collected by centrifugation at 7656*g* for 10 min and diluted with sterile distilled water to obtain the suspension of bacteria ($1 \times 10^8$ CFU/mL). The suspension of bacteria was sprayed onto the Burley tobacco (Eyan 6) leaves and incubated at 30 °C with 30% moisture content and 80% relative humidity. After incubating for 5 days, the contents of nitrite and various TSNA compounds (NNN, NNK, NAB, and NAT) were determined.

**Identification of the Strain.** The isolated nitrite reductive strain was identified by physiological, biochemical, and 16S rDNA sequence analysis. The traditional physiological and biochemical experiments were performed based on *Bergey's Manual of Systematic Bacteriology*.[18] The 16S rDNA sequence analysis was carried out according to our previous report.[19] The 16S rDNA sequence was amplified using the primers of 27f (AGAGTTTGATCMTGGCTCAG) and 1492r (GGTTACCTTGTTACGACTT), and the PCR was performed as follows: 95 °C for 5 min; 95 °C for 45 s, 54 °C for 45 s, 72 °C for 1.5 min, 28 cycles; 72 °C for 10 min; and 4 °C for 10 min. The DNA products were then purified, recovered, and sequenced by the BGI Tech Solutions Co., Ltd. (Shenzhen, China). The sequence similarity analysis was carried out by the Blastn program (http://blast.ncbi.nlm.nih.gov/Blast.cgi), and the phylogenetic tree was constructed using MEGA 4.0.[20]

**Batch Culture.** The selected strain was inoculated into the LB liquid medium, cultured at 37 °C and 180 rpm for 12 h as the seed cultures. With 3% (v/v) inoculum size, the seed cultures were transferred into the initial fermentation medium (glucose 20 g/L, $NH_4Cl$ 10 g/L, corn steep liquor 10 g/L), incubated at 37 °C and 180 rpm for 36 h, and the medium components as well as culture conditions were optimized for maximum cell growth. After culture at the optimized fermentation parameters, the cells were collected by centrifugation at 7656*g* for 10 min, and applied in the air-curing process of tobacco.

**Microbial Treatment of Tobacco Leaves during the Air-Curing Process.** The cells collected from batch culture were diluted to $2 \times 10^8$ CFU/mL, and 30 mL cell suspensions were sprayed onto 300 g of fresh Burley tobacco (Eyan 6) leaves for air-curing treatment. Leaves sprayed with the same volume of sterile distilled water were used as the control. The fresh leaves (0 day) and the leaves at different air-curing stages (7, 20, and 45 day) were collected, and the concentrations of total cells, nitrate, and TSNA compounds (NNN, NNK, NAB, and NAT) were determined.

**Determination of Nitrate and Nitrite.** Nitrate was determined by the salicylic acid method.[21] In brief, 0.1 mL of sample and 0.4 mL of salicylic acid solution (5%) were mixed and added into 9.5 mL of NaOH solution (8%). The reaction mixture was incubated for 20 min and determined for its absorbance at 420 nm. $NaNO_3$ was used as the standard substance. For determination of the nitrite, 4 mL of sulfanilamide solution (1%) was mixed with 2 mL of sample solution in the test tube, supplied with 4 mL of $\alpha$-naphthylamine solution (0.02%), and maintained at 25 °C for 30 min. The absorbance of the sample was determined at 540 nm with $NaNO_2$ being used as the standard.[22]

**Analysis of the TSNA Concentration.** The tobacco leaf samples were dried at 45 °C to reach constant weight, smashed, and sieved. 0.25 g of tobacco powder was placed into an erlenmeyer flask and combined with 0.2 mL of internal standard solution (5000 ng/mL) and of 19.8 mL ammonium acetate solution (100 mM). The mixture was shaken at 150 rpm for 1 h, filtered, and collected for analysis of the contents of TSNA compounds by an LC−MS/MS system (Agilent Technologies Corporate, Santa Clara, CA, USA). The HPLC was carried out on an Agilent 1290 system using an Agilent ZORBAX XDB-C18 column (Agilent Technologies, Santa Clara, CA, USA). The column temperature was set as 65 °C with an injection volume of 5 $\mu$L. 0.1% acetic acid water solution and 0.1% acetic acid methanol solution were used as the mobile phases A and B respectively. The gradient elution conditions were programmed as follows: 0.0−0.5 min, 60−70% B; 0.5−1.0 min, 70% B; 1.0−1.5 min, 70−90% B; 1.5−2.3 min, 90−60% B; 2.3−2.5 min, 60% B. MS/MS was performed using the Agilent 6460 triple quadrupole tandem mass spectrometer (Agilent Technologies Corporate, Santa Clara, CA, USA), and the conditions were controlled as follows: ESI ion source, positive ion mode, 4000 V voltage, 35 psig nebulizer pressure, 10 L/min gas flow rate, and 350 °C vaporizer temperature. The deuterated equivalents of NNN-D4, NNK-D4, NAB-D4, and NAT-D4 were used as the internal standard to determine the contents of NNN, NNK, NAB, and NAT, and the total TSNA contents were calculated by summing the NNN, NNK, NAT, and NAB.

**Statistical Analyses.** Each experiment was carried out at least in triplicate, and *t* test was performed to analyze the difference in means at the 95% confidence level using Statistica 6.0 software package.

## RESULTS AND DISCUSSION

**Isolation of the TSNA-Decreasing Strain.** Various microbes coexist with the tobaccos,[23,24] and thus the leaves and rhizosphere soils of tobaccos were collected for strain isolation. In this work, we isolated 304 clones from different tobacco and rhizosphere soil samples, and those strains were cultured in nitrite and nitrate selection medium. Among those strains, eight strains had high nitrite reducing capabilities. As shown in Figure 1, the degradation efficiencies of three strains (DA9, 1-4, and CH3) were higher than 30%, while the strain DA9 had the lowest nitrate degradation capability (11%). Due to the unique feature of high nitrite reductivity and low nitrate reductivity, the strain DA9 was selected for further verification by fermentation of tobacco leaves. As shown in Table 1, the nitrite concentration after fermentation with DA9 decreased 39% compared with the control, and the total TSNA content decreased 56% accordingly. Further analysis revealed the significant difference of each individual TSNA compound, and the NNN, NNK, NAT, and NAB content decreased by 57%, 69%, 46%, and 52%, respectively. The results indicated that the strain DA9 had the potential to lower the TSNA content in tobacco leaves.

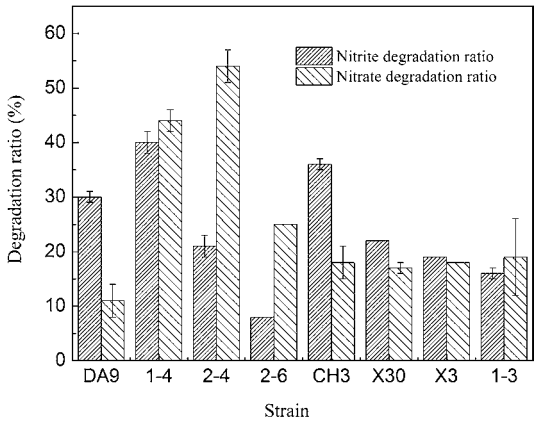

**Figure 1.** Degradation ratios of different strains on nitrite and nitrate. The isolated strains were cultured in the nitrate medium and nitrite medium at 37 °C and 180 rpm for 12 h respectively, and then the concentrations of residual nitrate and nitrite in the medium were determined to calculate corresponding degradation ratios.

**Identification of the Strain.** The strain DA9 was identified by morphological, physiological, biochemical, and 16S rDNA sequence analysis. After culturing in LB agar medium, white colonies with rough surface and irregular edge were observed. Under the microscope, the bacterial cells showed rod shape with strong motility. The physiological and biochemical characteristics of DA9 strain (Table 2) indicate that DA9 belonged to the *Bacillus* genus.[18] The 16S rDNA sequence of 1423 bp was obtained from DA9, aligned with the sequences in GenBank using the Blastn program, and revealed 100% identity to that of the *Bacillus amyloliquefaciens* LFB112 (CP006952).[25] The phylogenetic tree constructed on the basis of the 16S rDNA sequences shows that the DA9 clustered with *B. amyloliquefaciens* (Figure 2). Collectively, the above results indicate that the strain DA9 belonged to *B. amyloliquefaciens*. In a separate report, *Bacillus* and *Pseudomonas* were reported to be the two dominant genera, of which *B. amyloliquefaciens* was also found in the flue-cured tobacco leaves.[14] The 16S rDNA sequence of DA9 was submitted into the GenBank database (Accession number KM272942), and this strain was preserved in China Center for Type Culture Collection (CCTCC M2014252).

**Optimization of Fermentation Parameters.** To maximize the growth of the isolated *B. amyloliquefaciens* DA9, we optimized the medium components for this strain including glucose, corn steep liquor, $NH_4Cl$, $MnSO_4$, $KH_2PO_4$, and $MgSO_4$. Based on the preliminary screening results (data not shown), three key components, glucose (A), $NH_4Cl$ (B), and corn steep liquor (C), were identified as the factors with significant effects on the cell growth, therefore, these three medium compositions were further optimized using three-factor-three-level orthogonal design. As shown in Table 3, range analysis results were observed as $R(C) > R(A) > R(B)$, indicating that the influential effects of the three components were ranged as corn steep liquor (C) > glucose (A) > $NH_4Cl$ (B). The $k$ value analysis showed that the optimal factor levels were glucose (A3), $NH_4Cl$ (B1), corn steep liquor (C2). Based on the above results, the optimized medium components were determined as glucose 40 g/L, $NH_4Cl$ 4 g/L, corn steep liquor 8 g/L, $MnSO_4$ 0.01 g/L, $KH_2PO_4$ 1.0 g/L, $MgSO_4$ 0.3 g/L. The culture conditions were also investigated follwing the medium optimization. It was found that the combined conditions of initial pH 7.0, inoculum age 6 h, inoculum size 3%, and temperature 37 °C were optimal for cell growth (data not shown). Under those optimized parameters, the DA9 cells were cultured, and the maximum cell dentisity reached $1.2 \times 10^9$ CFU/mL at 36 h. Those cells were then collected for applying to the tobacco leaves during the air-curing process.

**Table 2. Physiological and Biochemical Characterization of the Strain DA-9[a]**

[a]The experiments were performed using three-factor-three-level orthogonal design. The $R$ value indicates the range, and the $k$ value represents the average biomass of each factor level.

**Effects of Microbial Treatment with DA9 on the Contents of Nitrite and Total TSNA in the Tobacco Leaves.** The *B. amyloliquefaciens* DA9 cells were sprayed onto the tobacco leaves; the same volume of distilled water was also sprayed onto the leaves as control. After the air-curing process, the nitrite content of the control increased from 10.20 μg/g to 17.77 μg/g (Figure 3A). The nitrate reductases of tobaccos and their symbiotic microbes can mediate the nitrate reduction action during the air-curing process,[7] which may be the main reason for the increased nitrite formation. By treating the leaves with DA9 cells, however, the maximum nitrite content just reached 12.06 μg/g, and such an increment was significantly lower than the control (Figure 3A). For the control, the native strain number changed from $9.33 \times 10^5$ CFU/g to $1.05 \times 10^5$ CFU/g after air-curing of tobacco leaves for 45 d, while the DA9 treated tobacco leaves had bacterial counts ranging from $8.71 \times 10^8$ CFU/g to $1.32 \times 10^8$ CFU/g, much higher than that of the control. As the dominant microflora, the DA9 cells inhibited the growth of other native bacteria and, thus, lowered those bacteria's capability of nitrate reduction. This feature, together with the strong nitrite reduction ability, makes the DA9 strain an ideal strain for decreasing nitrite during the tobacco air-curing process.

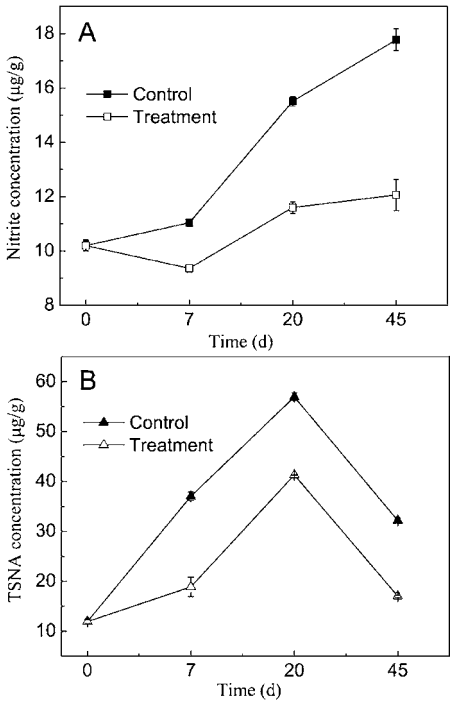

**Figure 3.** Effects of microbial treatment on the nitrite (A) and tobacco specific nitrosamine (TSNA) (B) concentrations of the tobacco leaves during the air-curing process. 30 mL cell suspensions ($2 \times 10^8$ CFU/mL) were sprayed onto 300 g of fresh Burley tobacco leaves for air-curing treatment. At 0, 7, 20, and 45 days, the control without treatment and the tobacco leaves treated with DA9 cells were sampled to determine the concentrations of nitrite and total TSNAs.

It has been reported that nitrite was the direct precursor for TSNA synthesis.[5] Therefore, decreased nitrite content inhibited TSNA formation. As shown in Figure 3B, the total TSNA concentration in the control increased before 20 d, which is in agreement with a previous report.[26] However, the maximum TSNA concentration reached 56.94 μg/g at 20 d, while the content decreased to 32.19 μg/g at 45 d, which is a little higher than previous reports.[6,27] The Burley tobaccos have higher TSNA levels than other tobacco lines, such as flue-cured and oriental tobaccos.[6] Moreover, the average TSNA content of air-cured Burley tobacco from Hubei Province is much higher than that of Sichuan, Yunnan Province, and USA.[8] The TSNA contents are significantly affected by processing techniques,[6] cultivation conditions,[7] tobacco lines, and producing areas,[8] which may result in the high TSNA levels of air-cured tobacco in Hubei Province. Figure 3B also shows that, after treatment with DA9, the total TSNA content of tobacco leaves was much lower than that of the control at each stage. The final TSNA content at 45 d reached 17.03 μg/g (Figure 3B), which was 47% lower than the control. The above results indicate that treatment by *B. amyloliquefaciens* DA9 was an efficient way to lower the nitrite and TSNA contents of air-cured Burley tobacco.

**Effects of Microbial Treatment on the Contents of NNN, NNK, NAT, and NAB.** The individual compounds of TSNA, i.e., NNN, NNK, NAT, and NAB, were further analyzed. As the direct substrate, nornicotine shows positive correlation with NNN formation.[9] Among the alkaloid precursors of TSNA, nornicotine was most abundant, and thus the NNN preponderated among the four kinds of TSNA. Similar to previous results,[6] the NNN contents detected were much higher than those of other TSNA components (Figure 4), and thus the change trend of NNN agreed with that of total TSNA contents (Figure 3B). After microbial treatment with DA9, the NNN content was 15.53 μg/g at 45 d, a 48% decrease compared to the control (Figure 4A). Meanwhile, similar inhibitory effects were observed for NNK and NAT, which decreased by 12% and 35% after 45 d (Figure 4B and Figure 4C), while no significant difference was found in NAB contents (Figure 4D). NAT and NAB show little biological activity, while NNN and NNK are the main carcinogens.[1] In summary, our results show that microbial treatment with DA9 can efficiently lower the contents of the main carcinogens of TSNA in Burley tobacco. Tobacco leaves treated with DA9 have the potential to be applied in cigarette as the filler, which may help to decrease the probability of smoking-related cancer. The health implications of smoking tobacco leaves treated with *B.*

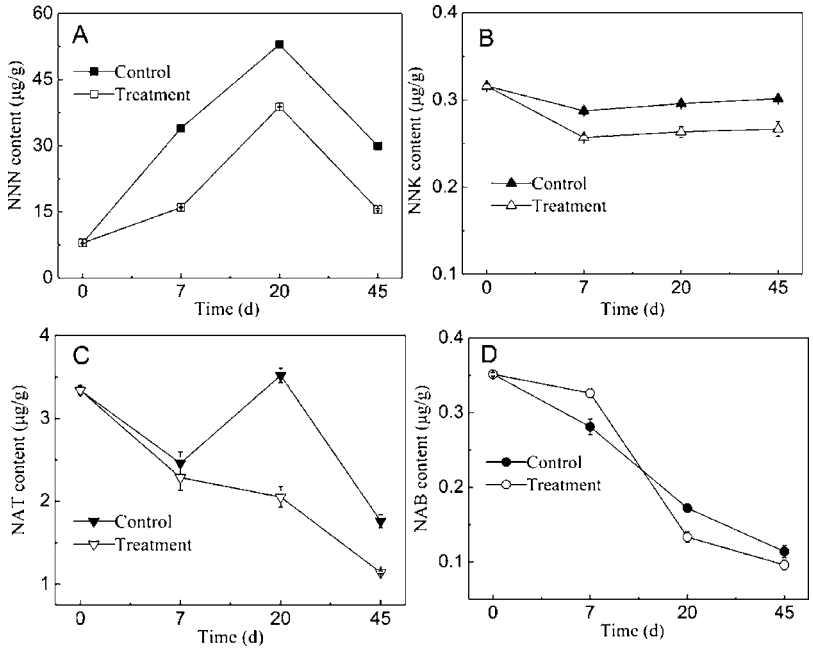

**Figure 4.** Effects of microbial treatment on the concentrations of *N*-nitrosonornicotine (NNN) (A), 4-(methylnitrosamino)-1-(3-pyridyl)-1-butanone (NNK) (B), *N*-nitrosoanatabine (NAT) (C), and *N*-nitrosoanabasine (NAB) (D) of the tobacco leaves during the air-curing process. The DA9 cell suspensions ($2 \times 10^8$ CFU/mL) were sprayed onto the fresh Burley tobacco leaves and air-cured for 0, 7, 20, and 45 days, and then the concentrations of NNN, NNK, NAB, and NAT were determined.

*amyloliquefaciens* DA9 are very important before commercial application, and the toxicity and sensory characteristics will be evaluated in further study. Meanwhile, the detailed mechanism for decreased TSNA in tobacco leaves treated with DA9 will be further investigated in a future study.

concentrations of ergovaline and lolitrem B in endophyte-infected perennial ryegrass strongly varied with time, and the maxima were observed at different periods of the year.[30] High rainfall in spring−summer accompanied by dry warm conditions in late summer−autumn were observed in the years when severe outbreaks of toxicosis occurred.[31]

The purpose of this study was thus to investigate ergovaline and lolitrem B levels in the symbiotic association *E. festucae* var. *lolii*/*L. perenne*, which is known to produce high concentrations of alkaloids. Alkaloid levels were investigated in the leaves, base, and inflorescence. The stage of maturity of the plant and the temperature and rainfall over the three-year study of plant growth were investigated as factors responsible for variations in ergovaline and lolitrem B contents.

## MATERIALS AND METHODS

**Experimental Pastures.** Perennial ryegrass seeds *L. perenne* cv. 'Grasslands Samson' with a seedling infection rate of 70% measured using a Phytoscreen immunoblot kit (Agrinostics Ltd., Watkinsville, GA, USA) were obtained from RAGT 2n SAS (Rodez, France). Sowing (27 kg seeds/ha) was done in September 2009 after conventional soil preparation in Saint-Affrique (Aveyron, France). The plot (0.75 ha) slopes gently toward a small river, the soil is a sandy clay loam, red brown, little humus, with gravel and angular fragments of sandstone and mudstone of polyhedral structure. Each year the plot was mowed in June to avoid dissemination. Nitrogen fertilization was done in 2011 with urea (70 and 50 U/ha on March 9 and April 13, respectively). Rainfall was recorded at the Saint-Affrique site, whereas maximum and minimum daily air temperatures were measured at the Montlaur site (9 km from Saint-Affrique). The Biologische Bundesanstalt Bundessortenamt and Chemische Industrie (BBCH) scale was used to monitor the perennial ryegrass growth.[32] Cumulative degree-days (average daily temperature above 0 °C) was calculated from February to mowing.[33,34]

**Plant Material.** Levels of ergovaline and lolitrem B were measured once a week from April to June and once or twice a month the rest of the year. Whole plants, cut just above the ground, were collected on each sampling occasion, whereas inflorescence (after heading), leaves (stem and leaf blade), and base (stem and leaf sheath) were collected from the heading stage to the fully ripe stage. On each sampling occasion, five samples of around 100 g of fresh material were harvested to be representative of the plot. Samples were dried for 24 h at 60 °C in a ventilated oven and then ground to 0.5 mm in a Cyclotech 1093 grinding mill (Foss, Hogande, Sweden). The ground material was pooled and stored at room temperature until analysis.

**Ergovaline and Lolitrem B Analysis.** All reagents and chemicals, HPLC grade, were from Sigma Chemical Co., (St. Louis, MO, USA). Ergovaline standard was kindly provided by G. E. Rottinghaus (College of Veterinary Medicine, University of Missouri). Lolitrem B standard was purchased from AgResearch Limited Ruakura Research Centre (Hamilton, New Zealand). Ergovaline and lolitrem B concentrations were detected by fluorescence after purification on homemade Ergosil columns and HPLC separation according to the methods of Rottinghaus et al.[24] and Gallagher et al.[36] with slight modifications.[23,35] Percentage recovery was 83% for ergovaline and 86% for lolitrem B. The limits of quantitation were 20 and 50 μg/kg of dry matter (DM) for ergovaline and lolitrem B, respectively.

**Statistical Analysis.** Statistical analysis was performed using R version 2.11.1 (R Foundation for Statistical Computing, Vienna, Austria). Comparison of ergovaline and lolitrem B levels in plants depending on the year of analysis was done using one-way ANOVA. The slopes of accumulation of the alkaloids in the base, leaves, and inflorescence plotted according to the BBCH stage were compared using ANCOVA. Correlation between ergovaline and lolitrem B concentrations in whole plant across the three years of study was analyzed using Pearson's test. Two-way ANOVA was used to reveal the effects of year of analysis (factor 1) and cumulative degree-days or cumulative rainfall (factor 2) on ergovaline and lolitrem B concentrations (dependent variable). Pearson's test was used to reveal correlations between cumulative degree-days or cumulative rainfall and ergovaline or lolitrem B concentrations in whole plant.

## RESULTS AND DISCUSSION

**Effect of Time.** Perennial ryegrass (*L. perenne*) infected with *E. festucae* var. *lolii* contains ergovaline and lolitrem B that are toxic for livestock (Figure 1). Samson cultivar was used because no endophyte-infected perennial ryegrass was commercialized in France. The ergovaline and lolitrem B concentrations measured in the seeds sown in the experimental pasture were 8950 and 5100 μg/kg DM, respectively. These levels were within the ranges of those observed in wild perennial ryegrass.[7] Ergovaline and lolitrem B concentrations in whole plants were monitored from April 2010 to June 2012 (Figure 2). The ergovaline level increased from the middle of heading (weeks 20, 70, and 124 in 2010, 2011, and 2012, respectively) to reach its maximum at the fully ripe stage, 5 weeks later. Maximum values varied considerably with the year, with mean concentrations at mowing of 526, 2322, and 604 μg ergovaline/kg DM, in 2010, 2011, and 2012, respectively. Two other ergovaline peaks of 377 and 216 μg/kg DM were observed at the end of September 2011 (week 91) and at the beginning of January 2012 (week 105), respectively. Between-years comparison of ergovaline from the beginning of grass growth to the emergence of the inflorescence (from February to April) revealed no significant difference (ANOVA). The mean concentration of ergovaline was 35 ± 21 μg/kg DM. By contrast, comparison of the level of ergovaline from the emergence of the inflorescence to the fully ripe stage (from May to June) revealed significant differences between years. Ergovaline was higher in 2011 than in 2010 and 2012 (ANCOVA, $P$ = 0.049 and 0.003, respectively), but did not differ between 2010 and 2012.

Concentrations of lolitrem B in the whole plant increased earlier, at the beginning of March, but maximum levels were also reached at the fully ripe stage. Only slight differences between years were observed at the fully ripe stage, with mean concentrations of 1871, 1500, and 1296 μg lolitrem B/kg DM, in 2010, 2011, and 2012, respectively. Only one other peak of lolitrem B was observed in the middle of October (week 93/94) with a mean lolitrem B level of 819 μg/kg DM. A between-year comparison of the level of lolitrem B in the whole plant from February to June revealed no significant difference.

Vegetative stage is a main factor to take into consideration when ergovaline contents in whole plant are compared. The highest contents measured in tall fescue in France were observed at the fully ripe stage, and two other peak ergovaline concentrations were measured in fall and winter.[23] Studies in perennial ryegrass showed peak ergovaline concentrations in spring during flowering.[4,22,37−39] Another peak of ergovaline has also been reported in the fall, sometimes higher than the value observed in the spring.[4,22,38,39] In Australia, the maximum ergovaline concentration in ryegrass pastures was observed in March, which corresponds to fall in the northern hemisphere.[19,30] Differences in when peak ergovaline concentrations were observed can be explained by the hemisphere in which the study was conducted and also by climate, which can affect plant maturation. The peak of ergovaline observed in the fall corresponded to plant regrowth ("regain"), whereas the peak observed in winter corresponded to the maximum senescence of the plant.

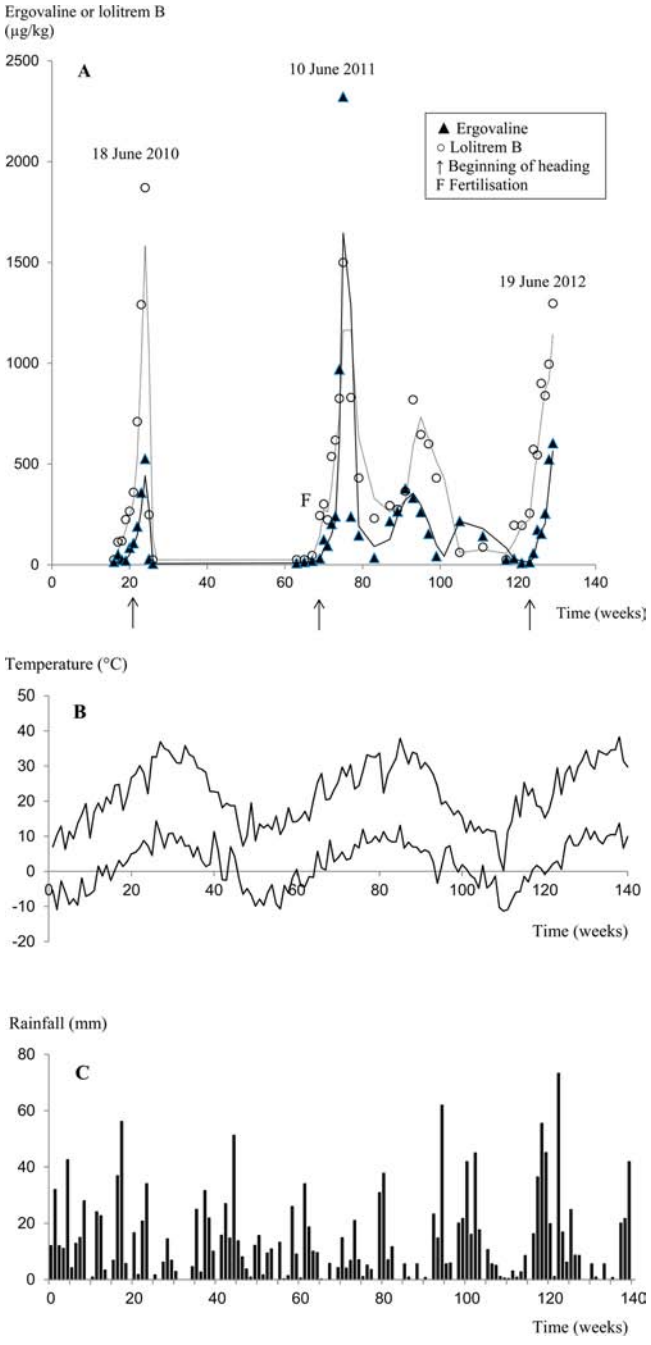

**Figure 2.** Ergovaline (solid line) and lolitrem B (dashed line) concentrations in whole endophyte-infected perennial Samson ryegrass sown in September 2009 in Saint-Affrique (Aveyron, France) according to (A) the week of measurement, (B) the minimum and maximum temperatures, and (C) the cumulative rainfall per week. Week 1 corresponds to the first week in the year 2010.

The range of lolitrem B concentrations in the whole plant was smaller than the range observed in the field in Australia.[19,31] The concentration of lolitrem B generally paralleled the concentration of ergovaline in terms of seasonal accumulation patterns. This observation is in agreement with data from Australia and New Zealand, even if peak concentrations were not observed at the same period of the year.[19,31,38] In this study the highest concentration of lolitrem B was observed at the fully ripe stage, in agreement with data obtained in Germany and France, at least in some ecotypes.[21,22] In other ecotypes in France, Germany, and New Zealand, the highest lolitrem B level was observed later, in October in Europe and in January/February in New Zealand.[21,22,38−40] Finally, the peak lolitrem B concentration observed in the fall appeared to vary in intensity and was sometimes higher than the concentration observed in the spring.[4,22,38] The toxic threshold of lolitrem B in livestock ranges from 1800 to 2000 µg/kg depending on the species.[2,3] In this study, this level was reached only one time, at week 24 in 2010. There is no toxic threshold of ergovaline in endophyte-infected perennial ryegrass, but a toxic threshold of 300−400 µg/kg was reported in endophyte-infected tall fescue.[2,3] This concentration in whole plant was reached at weeks 23−24, 74−75, 91−93, and 128−129.

**Relationship between Ergovaline and Lolitrem B Concentrations.** Correlation between lolitrem B and ergovaline concentrations in the whole plant across the three years of study was investigated (Figure 3). The correlation between the two variables was high (Pearson's test, $P < 0.0001$), lolitrem B level in whole plant being around 2-fold higher than ergovaline. The lolitrem B to ergovaline ratio of concentration has interest with regard to the respective threshold of toxicity of these compounds in livestock.[2,3] Studies conducted in endophyte-infected ryegrass straw in Oregon have shown that the concentration of lolitrem B was around 10-fold higher than that of ergovaline.[20] By contrast, a study conducted over 6 months on pastures in two ecotypes of endophyte-infected perennial ryegrass in Australia revealed that the concentration of lolitrem B was 1−2-fold higher than the concentration of ergovaline.[30] In Europe, higher ergovaline levels than lolitrem B levels have previously been reported in endophyte-infected ryegrass.[7,11] The origin of the ecotypes explains in part the differences in the respective concentrations of ergovaline and lolitrem B observed, some ecotypes being able to produce high ergovaline level in plants, whereas others were unable.[22] Also, the culture of New Zealand cultivar of endophyte-infected *L. perenne* under German conditions revealed that the environ-

[a]B, base; L, leaves; I, inflorescence. [b]Week 69 of study began on April 25, 2011, and week 123 of study began on May 7, 2012.

mental conditions during plant growth have a strong influence on lolitrem B concentration.[21]

**Distribution within the Plant.** In 2011 and 2012 the ergovaline and lolitrem B levels were measured in the base, leaves, and inflorescence (Table 1). From the heading stage to the fully ripe stage, the highest concentrations of the toxin were always observed in the inflorescence at the fully ripe stage. Whatever the part of the plant analyzed, the levels of the toxin at the fully ripe stage did not appear to be linked to those observed at the beginning of heading. A comparison of the slope of ergovaline accumulation revealed variations in bases and leaves depending on the year (ANCOVA, $P = 0.001$ and 0.017, respectively), whereas no significant difference was observed in the inflorescences. By contrast, no significant difference between years was observed in the level of lolitrem B, whatever the part on the plant analyzed. From the middle of heading to the fully ripe stage (weeks 70 and 124 and weeks 75 and 129, respectively), the levels of ergovaline in bases ranged from 160 to 362 μg/kg in 2011 and from 26 to 33 μg/kg in 2012. During the same period of time, the levels of ergovaline in inflorescences ranged from 316 to 6241 μg/kg and from 253 to 3933 μg/kg. This result demonstrates that ergovaline accumulates in the inflorescence of perennial ryegrass, as it does in the inflorescences of endophyte-infected tall fescue.[23] At the same stage of plant maturity, the concentrations of lolitrem B in bases ranged from 588 to 1383 μg/kg in 2011 (weeks 70 and 74, respectively) and from 887 to 1147 μg/kg in 2012 (weeks 124 and 128, respectively). In the inflorescences, lolitrem B ranged from 322 to 2392 μg/kg in 2011 (weeks 70 and 129, respectively) and from 725 to 3046 μg/kg in 2012 (weeks 124 and 129, respectively). This suggests that, even if the inflorescences are highly contaminated by lolitrem B, its accumulation in bases is stronger than that of ergovaline, in agreement with data demonstrating that lolitrem B accumulates in the oldest leaves, which is not the case for ergovaline.[18,41] In the present study in 2011, nitrogen fertilization conformed to the usual recommendations for this kind of pasture.[42] Comparison of alkaloids in the different parts of the plant revealed that the ergovaline level was significantly higher in 2011, with fertilization, than in 2012 without fertilization. By contrast, no difference was observed in the level of lolitrem B. Although factors other than nitrogen input in the pasture could explain these differences, the increase in ergovaline content after fertilization agrees with previous data obtained on endophyte-infected tall fescue.[23−25] Data concerning the effect of fertilization on alkaloid contents in endophyte-infected ryegrass are less numerous. Most data were obtained under controlled conditions, with high nitrogen input that led to a decrease in the level of endophyte in the plant. In these conditions, fertilization decreased alkaloid contents.[43,44]

**Climatic Factors.** The concentrations of ergovaline and lolitrem B in the whole plant were plotted as a function of cumulative degree-days measured each year, from February to the ripe stage (Figure 4). When cumulative degree-days were below 900 °C, the concentration of ergovaline was low and did not differ between years (Figure 4A). By contrast, the concentration of ergovaline increased when cumulative degree-days exceeded 900 °C. This increase was linear in the years 2010 and 2012, but exponential in 2011. Two-way ANOVA revealed a strong effect of cumulative degree-days on the ergovaline level ($P < 0.001$), whereas the effect of the year was not significant. Correlation between the cumulative degree-days and the ergovaline content across all three years was highly significant (Pearson's test, $P = 0.00015$). This result agrees with what was observed in endophyte-infected tall fescue; cumulative degree-days higher than 900 °C were also necessary to increase ergovaline content.[23] The concentration of lolitrem B in the whole plant also correlates with cumulative degree days across all three years of study (Pearson's test, $P < 0.0001$). Two-way ANOVA revealed a significant effect of cumulative degree-days on lolitrem B level ($P < 0.001$), whereas the effect of year was not significant. The cumulative degree-days necessary to observe an increase of lolitrem B concentration in whole plant ranged from 300 to 600 °C (Figure 4B).

The cumulative rainfall per week from the beginning of February to the ripe stage was 326, 172, and 329 mm in 2010, 2011, and 2012, respectively (Figure 2C). Comparison of rainfall showed that 2011 was the driest (ANOVA, $P = 0.006$), whereas 2010 and 2012 did not differ. Two-way ANOVA revealed no significant effect of cumulative rainfall or of the year of analysis on the ergovaline level. Also, correlation between the cumulative rainfall and the ergovaline content across the three years from the beginning of February to the ripe stage was not significant (Pearson's test). This result agrees with what was

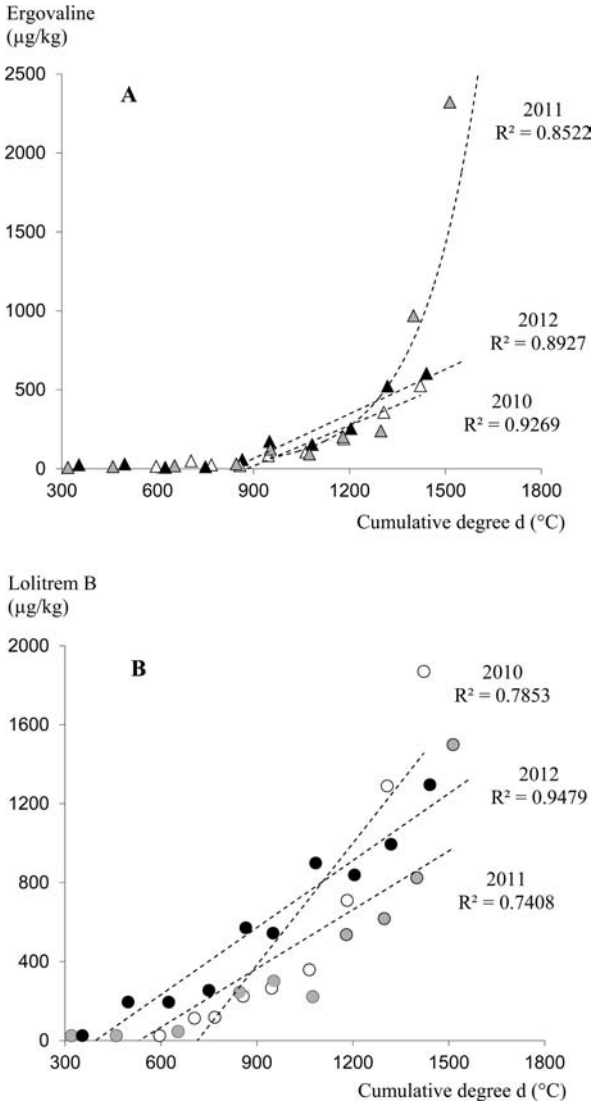

**Figure 4.** Plot of the concentrations of ergovaline (A) and lolitrem B (B) observed in whole endophyte-infected perennial Samson ryegrass from the beginning of February to the fully ripe stage over three years of culture according to the cumulative degree-days.

observed on endophyte-infected tall fescue.[23] By contrast, two-way ANOVA revealed a significant effect of cumulative rainfall on the lolitrem B level ($P < 0.001$), whereas the year of measure had no effect. Correlation between the cumulative rainfall and the lolitrem B level was highly significant (Pearson's test, $P = 0.0001$). Interestingly, outbreaks of perennial ryegrass toxicosis were observed in Australia when high rainfall was observed in spring–summer, but the concentrations of lolitrem B in the whole plant was not greater than the one recorded in earlier season.[31]

In conclusion, measurement of ergovaline and lolitrem B contents in endophyte-infected Samson perennial ryegrass sown in southern France revealed that the lolitrem B levels in whole plant were lower than those required to produce staggers in livestock, whereas high ergovaline concentrations were observed. Analysis of the factors influencing alkaloid concentrations revealed that the stage of maturity of the plant is a determining factor, with the highest levels observed at the fully ripe stage. Over the three year study period, concentrations of lolitrem B did not vary with year, whereas concentrations of ergovaline varied significantly. Positive correlations were observed between cumulative degree-days and ergovaline and lolitrem B concentrations, with an increase in lolitrem B in the whole plant at lower temperatures than ergovaline. Taken together, these results suggest that abiotic factors do not have the same influence on the levels of ergovaline as on lolitrem B in endophyte-infected ryegrass sown in southern France.
