[a]Numbers or text in bold font and underlined indicates ionization form or charge state for data processing or quantification. [b]Exact mass or measured accurate mass was used for quantification. The electron mass (0.000549 amu) is subtracted when exact mass is calculated. [c]Bold and underlined indicate pesticides with recoveries not in the range of 81−110%. [d]Bold and underlined indicate pesticides with intermediate precision >20%. [e]Bold and underlined indicate pesticides MU > 50%. [f]For data in red font, the method performance was based on three spike levels, i.e., 90.0, 240.0, and 400.0 μg/kg, due to its poor sensitivity. For data in blue font, the method performance was based on two spike levels, i.e., 240.0 and 400.0 μg/kg, due to its poor sensitivity. [g]Column number.

problem is liquid chromatography−mass spectrometry (LC-MS), which has been widely used to quantify LC-amenable (or thermally labile) pesticides and to confirm their identities in fruits and vegetables at low parts-per-billion (ppb) concentration levels.[7,8]

Liquid chromatography coupled with quadrupole tandem mass spectrometry with electrospray ionization (LC/ESI-MS/MS) as an interface is the most commonly used LC-MS system for pesticide residue analysis. This system configuration allows for increased selectivity and sensitivity when operated in multiple-reaction monitoring (MRM) mode. Current advances in mass spectrometers have made it possible to determine hundreds of targeted pesticides in a single analysis. However, LC-MS/MS requires extensive compound-dependent parameter optimization. Alternatively, an LC can be coupled to full scan mass spectrometers such as Orbitrap and time-of-flight (TOF) mass spectrometers. These types of MS have been increasingly used for quantification, identification, characterization, and structural elucidation of pharmaceuticals, pesticides, veterinary drugs, unknown contaminants, and their transformation or degradation products in foods and environmental samples.[9−12] The Orbitrap and TOF mass spectrometers (recently advanced models) offer high resolution (>20000 fwhm), accurate mass measurement (<5 ppm), excellent full MS scan sensitivity, and complete mass spectral information. The full MS scan data allow for the screening of targeted analytes, quantification of selected compounds, confirmation of positive findings, identification of unknowns or metabolites, and retrospective analysis even when appropriate standards are not available at the time of analysis.[13,14] Currently, a quadrupole Orbitrap (Q-Orbitrap) can easily achieve a resolving power >70000 fwhm for routine practice and still be sensitive enough to quantify at trace ppb concentration levels. The resolving power and accurate mass measurement capability of the Q-Orbitrap (<5 ppm) provide confidence in differentiating analytes of interest from coeluting compounds in complex matrices for both quantification and identification. Moreover, Q-Orbitrap MS/MS and QqTOF MS/MS, which have their quadruople filter function and collision cell enabled, can provide product-ion spectra with accurate mass measurements that permit unequivocal identification for compounds of interest. In routine practice, Orbitrap and TOF mass spectrometers operated in full MS scan mode have been favored for multiresidue screening purposes. If any incurred analytes are found, they are further identified using Q-Orbitrap MS/MS and QqTOF MS/MS.

This paper discusses the development and validation of a method that can rapidly quantify and accurately identify 451 pesticides in fruits and vegetables at low (∼10) ppb concentration levels using an UHPLC/ESI Q-Orbitrap along with the QuEChERs extraction procedure. The UHPLC/ESI Q-Orbitrap MS operated in full MS scan mode for screening and quantification was evaluated, and the UHPLC/ESI Q-Orbitrap Full MS/dd-$MS^2$ (i.e., data-dependent scan) mode for identification was demonstrated. The UHPLC/ESI Q-Orbitrap mass spectrometer proved to be a very promising and powerful tool for the determination of pesticide residues in fruits and vegetables. This is the first validated UHPLC/ESI Q-Orbitrap method to quantify 451 pesticide residues in fruits and vegetables. The method proved to be robust and sensitive enough to determine pesticide residues at low ppb concentration levels. The sample extraction was also quick and simple enough to allow for high-throughput testing of routine samples, which will greatly benefit monitoring programs while satisfying regulatory purposes.

## MATERIALS AND METHODS

**Materials and Reagents.** Five fruit and five vegetable blank samples were obtained from either local markets or previous years' sample monitoring program. Fruits included apple, banana, grape, orange, and strawberry. Vegetables included carrot, potato, tomato, broccoli, and lettuce. All samples were homogenized using a food processor, and 2 kg of each sample was prepared and kept in −20 °C. Pierce LTQ ESI positive ion calibration solution (10 mL) was purchased from ThermoFisher Scientific (Rockford, IL, USA). The calibration solution, which includes *n*-butylamine (*m*/*z* 74), caffeine (*m*/*z* 195 and its fragment *m*/*z* 138), Ultramark 1621 (*m*/*z* 1022, 1122, 1222, 1322, 1422, 1522, 1622, 1722, and 1822), and MRFA (*m*/*z* 524), was used to tune and calibrate the Q-Orbitrap. Ammonium acetate (reagent grade), formic acid (LC-MS grade, ∼98%), ammonium formate (for mass spectrometry, >99.0%), and LC-MS acetonitrile (Chromasolv, 2.5 L) were purchased from Sigma-Aldrich Corp (Canada). ENVIRO CLEAN MYLAR pouches (6.0 g of anhydrous magnesium sulfate ($MgSO_4$) and 1.5 g of anhydrous sodium acetate) and ENVIRO CLEAN extraction columns (900 mg of $MgSO_4$, 150 mg of $C_{18}$, and 300 mg of primary−secondary amine (PSA), 15 mL centrifuge tubes) were purchased from United Chemical Technologies, Inc. (Bristol, PA, USA). Acetic acid (glacial acetic acid, reagent grade, 99.7%), acetonitrile (distilled in glass), and methanol (distilled in glass) were obtained from Caledon Laboratories

Ltd. (Canada). Water (18.2 MΩ·cm) used for reagent and sample preparation was obtained from a Barnstead Nanopure system (Thermo Scientific, USA). Pesticide standards (Table 1, column 1) were obtained from EQ Laboratories Inc. (USA), Riedel-de Haen AG (Germany), or Chem Service (USA). Internal standards carbendazim-$d_4$ and carbofuran-$d_3$ were purchased from EQ Laboratories Inc. (USA), and thiabendazole-$d_4$ was from Chemical Synthesis Services (Northern Ireland). LC vials were Mini-UniPrep syringeless filter devices with polypropylene housing and PVDF 0.45 μm membrane (Whatman Inc., USA).

**Preparation of Standard Solutions.** Individual pesticide standard stock solutions were generally prepared at a concentration of 4000.0 μg/mL in methanol/acetonitrile (50 + 50, v/v). Due to their poor solubility in methanol, carbendazim was prepared at 200.0 μg/mL, and some pesticides were prepared at 1000.0 or 2000.0 μg/mL. Intermediate pesticide standard mix working solutions were prepared at 10.0 or 15.0 μg/mL in methanol/acetonitrile (50 + 50, v/v), from stock solutions. Because of the large number of pesticides (>450), intermediate solutions were prepared in separate 200 mL (15 μg/mL, including 210 stocks) and 250 mL (10 μg/mL, including 241 stocks) volumetric flasks. Stock and intermediate solutions were stored at −20 °C. A six-level pesticide standard mix working solution was prepared by transferring 0.15, 0.75, 3.0, 6.0, 9.0, and 15.0 mL of 10.0 μg/mL and 0.1, 0.5, 2.0, 4.0, 6.0, and 10.0 mL of 15.0 μg/mL intermediate working solution into six separate 50 mL volumetric flasks for their respective concentration levels and then making up to volume with methanol. The resulting concentrations were 0.03, 0.15, 0.60, 1.20, 1.80, and 3.00 μg/mL, which were used to construct the matrix-matched standard calibration curves. Four-level sample spike pesticide standard working solutions were prepared by transferring 1.5, 13.5, 36.0, and 60.0 mL of 10.0 μg/mL and 1.0, 9.0, 24.0, and 40.0 mL of 15.0 μg/mL intermediate working solution into four separate 100 mL volumetric flasks and making up to volume with methanol for their respective concentration levels. The resulting concentrations were 0.15, 1.35, 3.60, and 6.00 μg/mL, which were used for sample fortification. Internal standard working solutions (5.0 and 0.5 μg/mL) including carbofuran-$d_3$, carbendazim-$d_4$, and thiabendazole-$d_4$ were prepared in a mixture of methanol/acetonitrile (50 + 50, v/v). All working solutions were stored at 4 °C.

**Preparation of Reagent Solutions.** Acetonitrile/acetic acid (99 + 1, v/v) was prepared by mixing 990 mL of acetonitrile with 10 mL of acetic acid. Ammonium acetate (0.1 M) was prepared by weighing 7.7 g of ammonium acetate and dissolving it in 800 mL of water. After transfer into a 1000 mL volumetric flask, the solution was made up to volume with water. Solvent buffer was a mixture of 0.1 M ammonium acetate and methanol (50 + 50, v/v).

**UHPLC/ESI Q-Orbitrap Parameters.** The UHPLC/ESI Q-Orbitrap system consisted of an Accela 1250 LC pump and an Accela open autosampler coupled with a Q Exactive mass spectrometer (ThermoFisher Scientific, Germany). The system was controlled by Xcalibur 2.2 software.

*(a). UHPLC.* UHPLC mobile phase A was 4 mM ammonium formate and 0.10% formic acid in water, and mobile phase B was 4 mM ammonium formate and 0.10% formic acid in methanol. The UHPLC column utilized was a Hypersil Gold, 100 mm × 2.1 mm, 1.9 μm column (Thermo Scientific, USA). The UHPLC guard column was an Accucore aQ 10 × 2.1 mm, 2.6 μm Defender cartridge (Thermo Scientific, USA). The UHPLC gradient profile and flow rate are shown in Figure 1. The column oven temperature was set at 45 °C, and the autosampler temperature was set at 5 °C. The injection volume was 5 μL, and the total run time was 14 min.

*(b). Q-Orbitrap Parameters.* The Q-Exactive ion source was equipped with a heated electrospray ionization (HESI) probe, and the Q-Orbitrap was tuned and calibrated using positive LTQ calibration solution once a week. The Q-Exactive was operated in either full MS-SIM or full MS/dd-MS$^2$ positive mode. In full MS-SIM, the Q-Oritrap performed full MS scan without high-energy collision dissociation (HCD) fragmentation. The full MS scan range was set from $m/z$ 80 to 1100 (0−12.0 min). The mass resolution was set to 70000 fwhm at $m/z$ 200, and the instrument was tuned for maximum ion throughput.

B

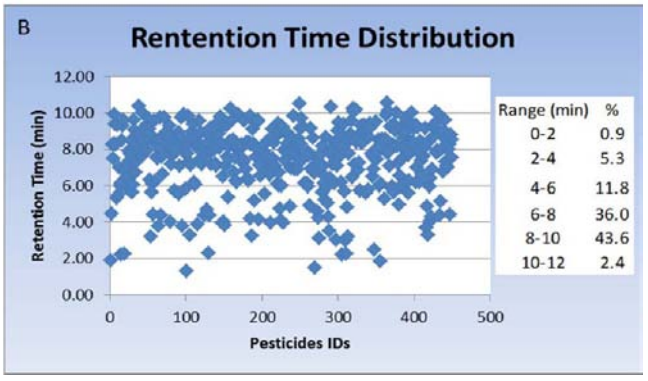

**Figure 1.** UHPLC gradient profile and 451 pesticides elution distribution.

AGC (automatic gain control) target or the number of ions to fill C-Trap was set at 1.0 × 10$^6$ with a maximum injection time (IT) of 250 ms. All quantitative data in this study were acquired using full MS-SIM mode.

Targeted identification was achieved by full scan MS, and if a targeted pesticide was present, its precursor ion scan, provided by an inclusion list, triggered a data-dependent MS$^2$ (dd-MS$^2$) scan. During full MS scan, the mass resolution was set at 70000 fwhm, AGC target at 1.0 × 10$^6$, maximum IT 250 ms, and scan range from $m/z$ 80 to 1100. If the targeted compound was detected within the 10 ppm mass error window and achieved by a designated intensity threshold (i.e., setting of 1.7 × 10$^5$), the precursor ion in the inclusion list was then isolated by the quadrupole and sent to the HCD collision cell for fragmentation via the C-trap. The inclusion list consists of precursor ions that are of interest for targeted identification and is provided in Table 1, columns 3−5. The precursor ion was fragmented with stepped normalized collision energy (NCE) to generate the resulting dd-MS$^2$ product ion spectrum. At this stage, the mass resolution of the Orbitrap analyzer was set at 35000 fwhm, AGC target at 2 × 10$^5$, maximum IT at 120 ms, and isolation window at 1.0 $m/z$, NCE at 40 ± 50%, underfill ratio at 10%, intensity threshold at 1.7 × 10$^5$, apex trigger at 2−4 s, and dynamic exclusion at 10.0 s. Other Q-Exactive generic parameters were sheath gas flow rate set at 60, Aux gas flow rate at 30, sweep gas flow rate at 2, spray voltage (kV) at 3.50, capillary temperature (°C) at 350, S-lens level at 55.0, and heater temperature (°C) at 350.

**Sample Preparation and Extraction Procedure.** Sample extraction and cleanup procedures followed the buffered QuEChERS[14] or AOAC Official Method 2007.01[15] with a slight modification. For the fortification experiment, fruit and vegetable samples (15.0 g/sample) were weighed into individual 50 mL polypropylene centrifuge tubes (VWR International, Canada). One milliliter per four-level sample spike pesticide standard working solution(s) was added into four centrifuge tubes to provide 10.0, 90.0, 240.0, and 400.0 μg/kg of pesticide equivalent in samples, followed by the addition of 300 μL of 5.0 μg/mL internal calibration standard working solution (100.0 μg/kg equivalent in samples). The centrifuge tubes were capped, mixed, and left to stand for 15 min at room temperature. Then, 14 mL of acetonitrile/acetic acid (99 + 1, v/v) mixture was added to individual samples and mixed for 45 s, followed by adding 1.5 g of anhydrous sodium acetate and 6.0 g of anhydrous magnesium sulfate from an ENVIRO CLEAN MYLAR pouch. One milliliter of organic solvent (methanol/acetonitrile, 50 + 50, v/v), resulting from the addition of the pesticide standard working solutions, was accounted for and added

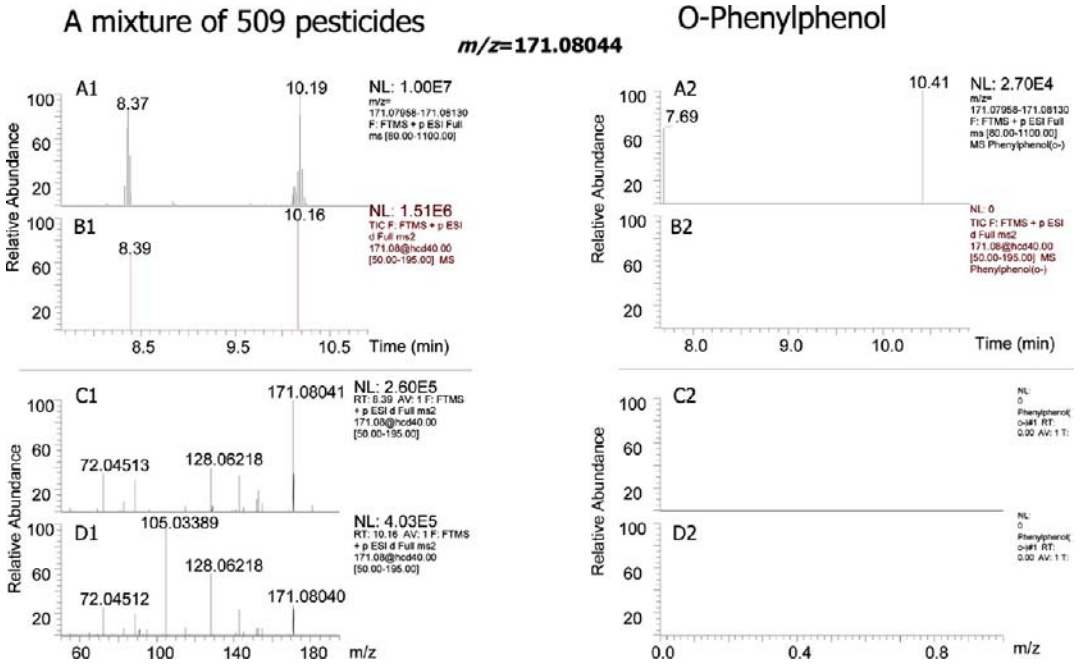

**Figure 2.** UHPLC/ESI Q-Orbitrap Full MS/dd-MS$^2$ chromatograms and product ion spectra. A mixture of 509 pesticides (50 $\mu$g/L in solvent buffer) and single O-Phenylphenol (50 $\mu$g/L in solvent buffer) were injected and analyzed: (left) Mixture of 509 pesticides; (right) O-Phenylphenol; (A1, A2) extracted ion chromatograms of $m/z$ 171.08044 with a mass tolerance of 5 ppm, if detected; (B1, B2) dd-MS$^2$ chromatograms of $m/z$ 171.08044, if detected; (C1, C2) dd-MS$^2$ product ion spectra of $m/z$ 171.08044, if triggered at 8.39 min; (D1, D2) dd-MS$^2$ product ion spectra of $m/z$ 171.08044, if triggered at 10.16 min.

up to a total of 15 mL organic solvent for extraction. The centrifuge tubes were capped, shaken at 1500 rpm using a Geno/Grinder 2010 (SPEX SamplePrep, USA) for 1 min, and then centrifuged at 3000 rpm (~2100$g$) for 3 min using an Allegra 6 centrifuge (Beckman Coulter Inc., USA). Supernatants were transferred (7 mL/sample) into individual 15 mL polypropylene centrifuge tubes or ENVIRO CLEAN extraction columns that contain 900 mg of $MgSO_4$, 150 mg of $C_{18}$, and 300 mg of PSA for cleanup. The centrifuge tubes were capped, shaken by hand for 45 s, and centrifuged at 3000 rpm (~2100$g$) for 3 min. Ninety microliters of each sample extract and 410 $\mu$L of solvent buffer were transferred into separate Mini-UniPrep vials (Whatman Inc., USA). The vials were capped, vortexed for 30 s, and pressed to filter the solution. Sample extracts were ready for UHPLC/ESI Q-Orbitrap injection.

**Preparation of Matrix-Matched Calibration Standards and Calculation.** Matrix-matched calibration standards were prepared by adding standards and internal standards to blank sample extracts after sample extraction and cleanup. A blank fruit or vegetable sample (15.0 g/sample) was weighed into a 50 mL centrifuge tube, and the sample was processed through the extraction procedure as described above (but using 15 mL of acetonitrile/acetic acid (99 + 1, v/v) mixture for extraction). After 90 $\mu$L of blank sample extracts and 377 $\mu$L of solvent buffer had been transferred into each of six Mini-UniPrep vials (Whatman Inc., USA), 15 $\mu$L of each six-level pesticide standard mix working solution and 18 $\mu$L of 0.50 $\mu$g/mL internal calibration working solution were added to the individual vials, providing 5.0, 25.0, 100.0, 200.0, 300.0, and 500.0 $\mu$g/kg per standard and 100.0 $\mu$g/kg per internal standard equivalent in samples. The vials were capped, vortexed for 30 s, and pressed to filter the solution. Sample extracts were ready for UHPLC/ESI Q-Orbitrap injection.

Matrix-matched standard calibration curves for each individual pesticide were constructed using TraceFinder 3.1 (optimized for Environmental and Food Safety) software. Concentration ($\mu$g/kg (ppb)) versus the ratio (analyte area/IS area) of each individual pesticide was plotted. Deuterium-labeled standards carbendazim-$d_4$, carbofuran-$d_3$, and thiabendazole-$d_4$ were used as internal standards for their respective native compounds for quantification. Other pesticides used carbofuran-$d_3$ as an internal standard for quantification. In general, a quadratic function was applied to the calibration curves based on the line of best fit. Occasionally, linear regression may be used for quantification. The $1/x$ weighting was used to improve the accuracy for quantification of pesticides at low concentrations. Responses for the unknown concentration or fortified samples were compared to the curves to calculate the amount of pesticide residues ($\mu$g/kg (ppb)) in samples. Matrix-matched calibration standards were prepared fresh for each batch of samples.

**Experimental Design and Method Validation.** The method was validated according to the nested experimental design, which was described elsewhere.[16] The main factors of variances associated with the method performance or measurement uncertainties of an in-house validated method were concentrations or spiked levels of analytes, matrix effects, day-to-day variation, and within-day variation of the method. The last two factors are designated the intermediate precision. In this study, there were a total of five fruits (i.e., apple, banana, grape, orange, and strawberry) and five vegetables (i.e., carrot, potato, tomato, broccoli, and lettuce). For each matrix, samples were spiked at 10.0, 90.0, 240.0, and 400.0 $\mu$g/kg, in triplicate. Spike experiments were repeated on two different days or by two analysts. Overall recovery, intermediate precision, and measurement uncertainty were calculated using a combined computer program that consisted of SAS codes (SAS Software release 9.3, SAS Institute Inc., USA) along with a Microsoft Excel (Microsoft Office 2010) workbook.

## RESULTS AND DISCUSSION

**QuEChERs.** Pesticides were extracted from fruits and vegetables (15 g/sample) following the buffered QuEChERS method[14] or AOAC Official Method 2007.01.[15] The whole procedure consisted of two steps including (1) extraction with acetonitrile containing 1% acetic acid, $MgSO_4$, and sodium acetate or (2) cleanup by dispersive solid-phase extraction (d-SPE) using $MgSO_4$, PSA, and $C_{18}$. Previous methods used ChloroFiltr, a polymeric-based sorbent used in the cleanup of chlorophyll-rich matrices such as lettuce and broccoli.[14] To simplify the method and avoid confusion, the d-SPE that

[a]Number or text in bold font and unerlined indicates ionization form or charge state for data processing or quantification. [b]Exact mass or measured accurate mass was used for quantification. The electron mass (0.000549 amu) is subtracted when exact mass is calculated. [c]Bold and underlined indicate pesticides with recoveries not in the range of 81−110%. [d]Bold and underlined indicate pesticides intermediate precision >20%. [e]Bold and underlined indicate pesticides MU > 50%. [f]For data in red font, the method performance was based on three spike levels, i.e., 90.0, 240.0, and 400.0 μg/kg, due to its poor sensitivity. For data in blue font, the method performance was based on two spike levels, i.e., 240.0 and 400.0 μg/kg, due to its poor sensitivity. [g]Column number.

contained 900 mg of $MgSO_4$, 150 mg of $C_{18}$, and 300 mg of PSA was used for all matrices in the cleanup step for this method. An experiment (data not shown) proved that no obvious differences regarding matrix effects were observed between d-SPEs with or without ChloroFiltr. In addition, sample extracts were diluted 5.56 times (90 μL of extracts + 410 μL of solvent buffer). The Mini-UniPrep vials, consisting of a polyvinylidene difluoride (PVDF) membrane, filtered some of the light green coextractives or precipitates in the final extracts after sample extract dilution prior to UHPLC/ESI Q-Orbitrap injection. Therefore, the QuEChERS method without ChloroFiltr proved to be a simple, practical, and fast extraction procedure to achieve UHPLC/ESI Q-Orbitrap quantification of pesticide residues at trace level in fruits and vegetables.

**UHPLC.** Four hundred and fifty-one pesticides and three isotopically labeled standards (Table 1, column 1) were chromatographically separated within 12 min under a gradient profile (Figure 1A) using a Hypersil Gold (100 mm × 2.1 mm, 1.9 μm) column with methanol and water, each containing 4 mM ammonium formate and 0.10% formic acid, as mobile phases. Initially, a Waters Acquity UPLC BEH $C_{18}$ (100 mm × 2.1 mm, 1.7 μm) column with acetonitrile and water (10 mM ammonium acetate)[14] was chosen for the study. However, higher detection limits were observed for some of the compounds. To improve sensitivity, different LC methods were compared, and then an UHPLC method, which used Hypersil Gold (100 mm × 2.1 mm, 1.9 μm) column, was adopted.[17] The Hypersil Gold (100 mm × 2.1 mm, 1.9 μm) column generally provided better chromatographic resolution

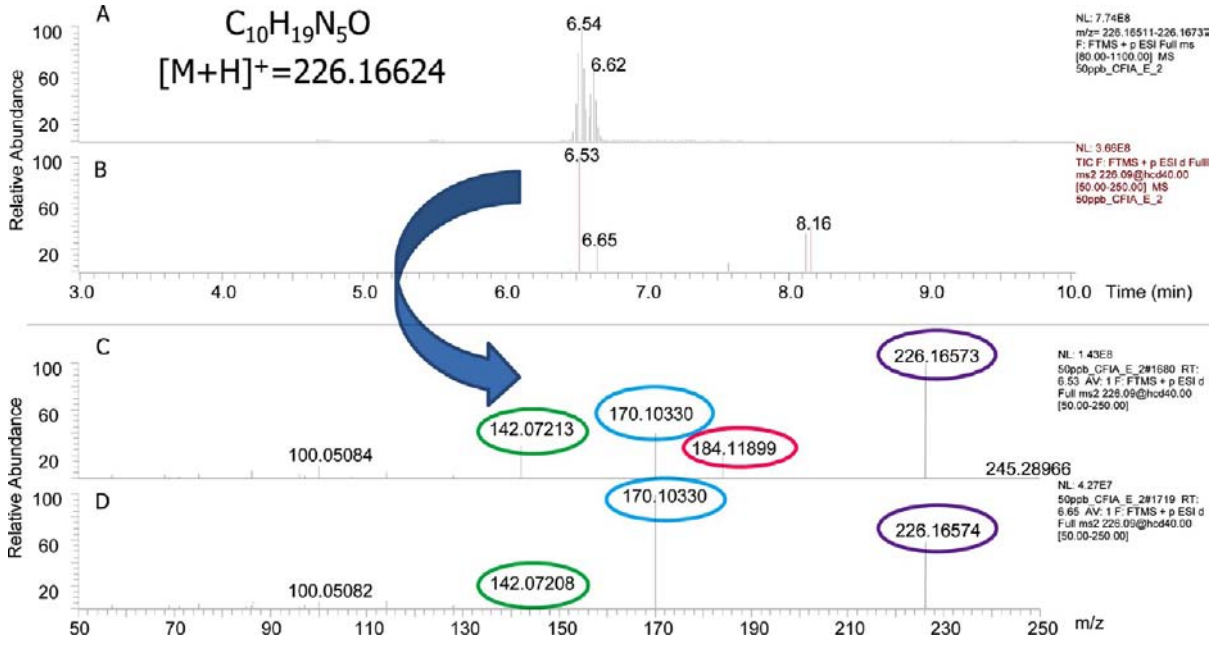

**Figure 3.** UHPLC/ESI Q-Orbitrap Full MS/dd-MS$^2$ chromatograms and product ion spectra. A mixture of 451 pesticides (50 $\mu$g/L in solvent buffer) was injected and analyzed: (A) extracted ion chromatogram of $m/z$ 226.16624 with a mass tolerance of 5 ppm; (B) dd-MS$^2$ chromatogram of $m/z$ 226.16624; (C) dd-MS$^2$ product ion spectrum of $m/z$ 226.16624 at 6.53 min; (D) dd-MS$^2$ product ion spectrum of $m/z$ 226.16624 at 6.65 min.

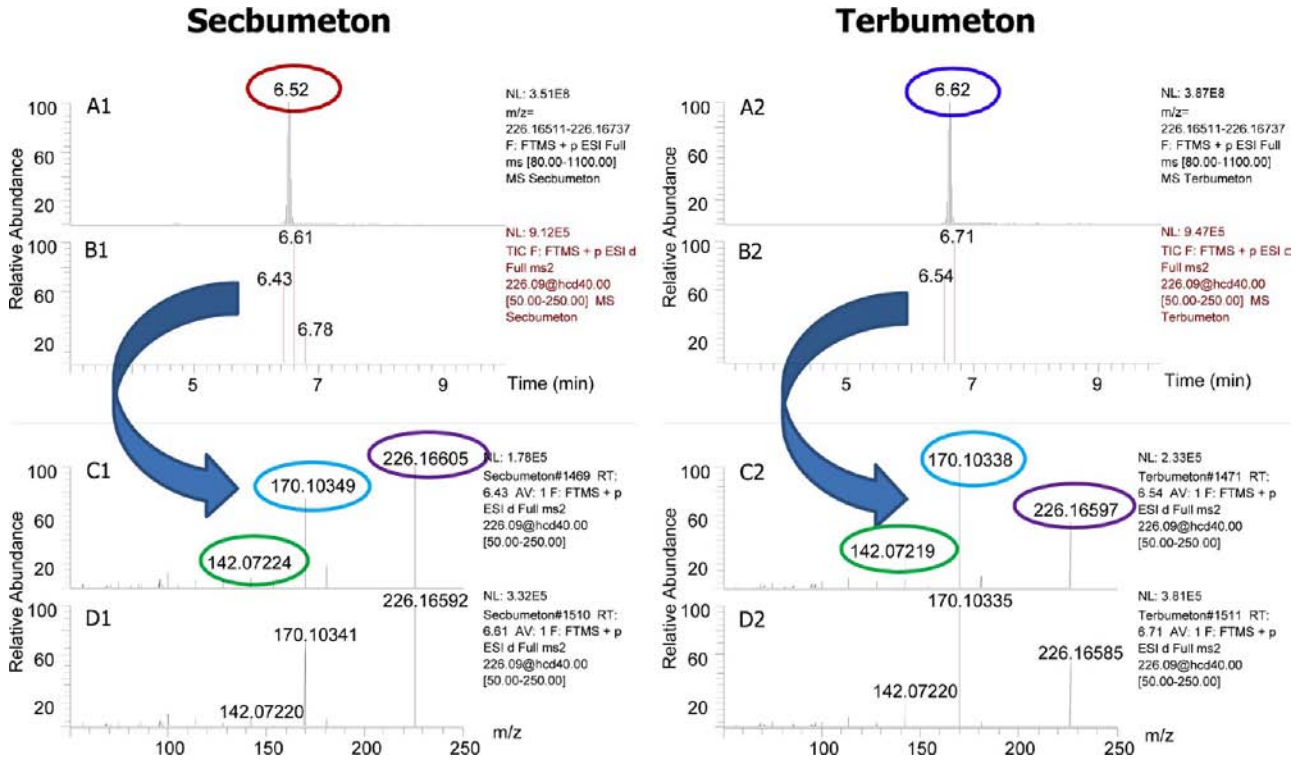

**Figure 4.** UHPLC/ESI Q-Orbitrap Full MS/dd-MS$^2$ chromatograms and product ion spectra. Individual secbumeton or terbumeton (50 $\mu$g/L in solvent buffer) was injected and analyzed: (left) secbumeton; (right) terbumeton; (A1, A2) extracted ion chromatogram of $m/z$ 226.16624 with a mass tolerance of 5 ppm; (B1, B2) dd-MS$^2$ chromatogram of $m/z$ 226.16624; (C1, C2) dd-MS$^2$ product ion spectra of $m/z$ 226.16624 at 6.43 and 6.54 min, respectively; (D1, D2) dd-MS$^2$ product ion spectra of $m/z$ 226.16624 at 6.61 and 6.71 min, respectively.

and higher responses compared to an Acquity UPLC BEH $C_{18}$ column for improved sensitivity. The gradient profile also was modified so that the elution of pesticides was optimized over the 12 min run time (Figure 1B). Under the modified gradient profile, 79.6% of pesticides were eluted between 6 and 10 min or 91.4% between 4 and 10 min. The span of the retention time distribution reduced the number of concurrent pesticides and provided sufficient time for the dd-MS$^2$ experiment between full MS scans.

Under most circumstances, an extracted ion presented as a single LC peak or baseline separation from other peaks, which was a result of superior resolving power of both UHPLC and

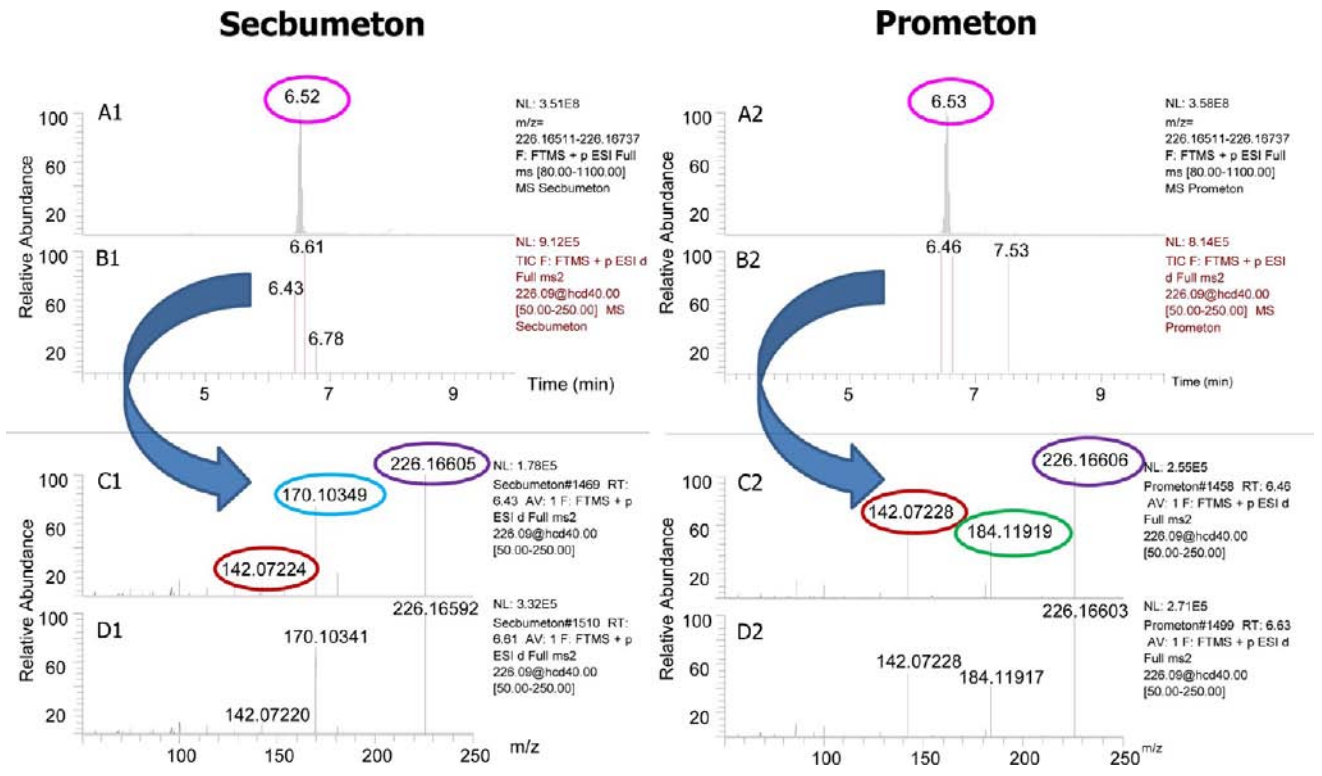

**Figure 5.** UHPLC/ESI Q-Orbitrap Full MS/dd-MS$^2$ chromatograms and product ion spectra. Individual secbumeton or prometon (50 $\mu$g/L in solvent buffer) was injected and analyzed: (left) secbumeton; (right) prometon; (A1, A2) extracted ion chromatograms of $m/z$ 226.16624 with a mass tolerance of 5 ppm; (B1, B2) dd-MS$^2$ chromatograms of $m/z$ 226.16624; (C1, C2) dd-MS$^2$ product ion spectra of $m/z$ 226.16624 at 6.43 and 6.46 min, respectively; (D1, D2) dd-MS$^2$ product ion spectra of $m/z$ 226.16624 at 6.61 and 6.63 min, respectively.

Q-Orbitrap MS, with the exception of coeluting isomeric compounds. Pesticides were eluted between 1.0 and 11.0 min, and their peak shapes were of Gaussian distribution with a baseline peak width of 5−10 s. The retention times were reproducible under ±0.2 min within and between batches for most of the pesticides. The scan rate of 3 Hz with the resolution, set at 70000 fwhm at $m/z$ 200, is more than adequate to generate sufficient data points for quantification. For example, at least 18 data points across the chromatographic peak were generated with a 6 s (0.1 min) baseline peak width.

**Q-Orbitrap MS.** When operated in its full MS-SIM mode in a range from $m/z$ 80.0 to 1100.0 with 70000 fwhm at $m/z$ 200, the Q-Orbitrap acquired full MS scan data for the screening and quantitation of the 451 pesticides listed in Table 1. When operated in full MS/dd-MS$^2$ mode, the Q-Orbitrap acquired product ion spectra with accurate mass measurement for identification according to a list of targeted exact masses (Table 1, columns 3−5). In the current study, "stepped" normalized collision energy (NCE) was used for dd-MS$^2$ fragmentation. The Q-Orbitrap performed a three-step 40 ± 50% NCE (i.e., the center energy 40 NCE; plus one above, 60 NCE; and one below, 20 NCE) fragmentation on the precursor ion. All fragments created in the three steps were collected sequentially in the HCD and sent together to the Orbitrap analyzer for single-scan detection. Stepped NCE worked for most but not all of the pesticides because some pesticides are not optimally fragmented in the 40 ± 50% NCE range.

At the initial stage of method development, we prepared a mixture of 509 pesticides and injected it into the system. It was thought that individual pesticides in the mixture would have been identified simply on the basis of high mass-resolving power and accurate mass measurement in conjunction with UHPLC chromatographic resolution. However, this assumption did not account for impurities present in the mixture, which possibly led to false identification, and therefore the injection of each individual pesticide became necessary. Figure 2 showed an example of potential misidentifications when a mixture of pesticides was injected into the system during the method development stage. O-Phenylphenol has a $m/z$ 171.08044, if protonated. In full MS scan, two peaks were found at 8.37 and 10.19 min (Figure 2A1), respectively, for $m/z$ 171.08044 with a mass tolerance of 5 ppm, and dd-MS$^2$ was triggered twice at 8.39 and 10.16 min (Figure 2B1), resulting in product ion spectra as shown in Figure 2C1,D1. To identify the O-Phenylphenol peak, its neat standard (50 ppb in solvent) was injected into the system. No peaks were detected to trigger dd-MS$^2$ for O-Phenylphenol (Figure 2A2,B2,C2,D2), indicating the peaks were results of chemical impurities. Therefore, it was required that individual pesticide standards were injected in full MS/dd-MS$^2$ mode to obtain both retention times and product ion spectra during the method development stage. This step proved to be critical because it provided data for the identification of individual pesticides in a mixture or sample matrices and for generating exact mass spectral library in future.

Another challenge was to identify or differentiate isomeric compounds in the mixture of pesticides. Table 2 lists 22 pairs or groups of isomers among 451 pesticides that required both LC retention times (LC resolution) and dd-MS$^2$ product ion spectra (MS fragmentation) for identification and differentiation. For example, secbumeton, terbumeton, and prometon are isomers and share the same precursor ion ($[M + H]^+$) with $m/z$ 226.16624. When a mixture of standards was injected, the three compounds eluted at 6.54 and 6.62 min (Figure 3A), and dd-MS$^2$ was triggered twice at 6.53 and 6.65 min,

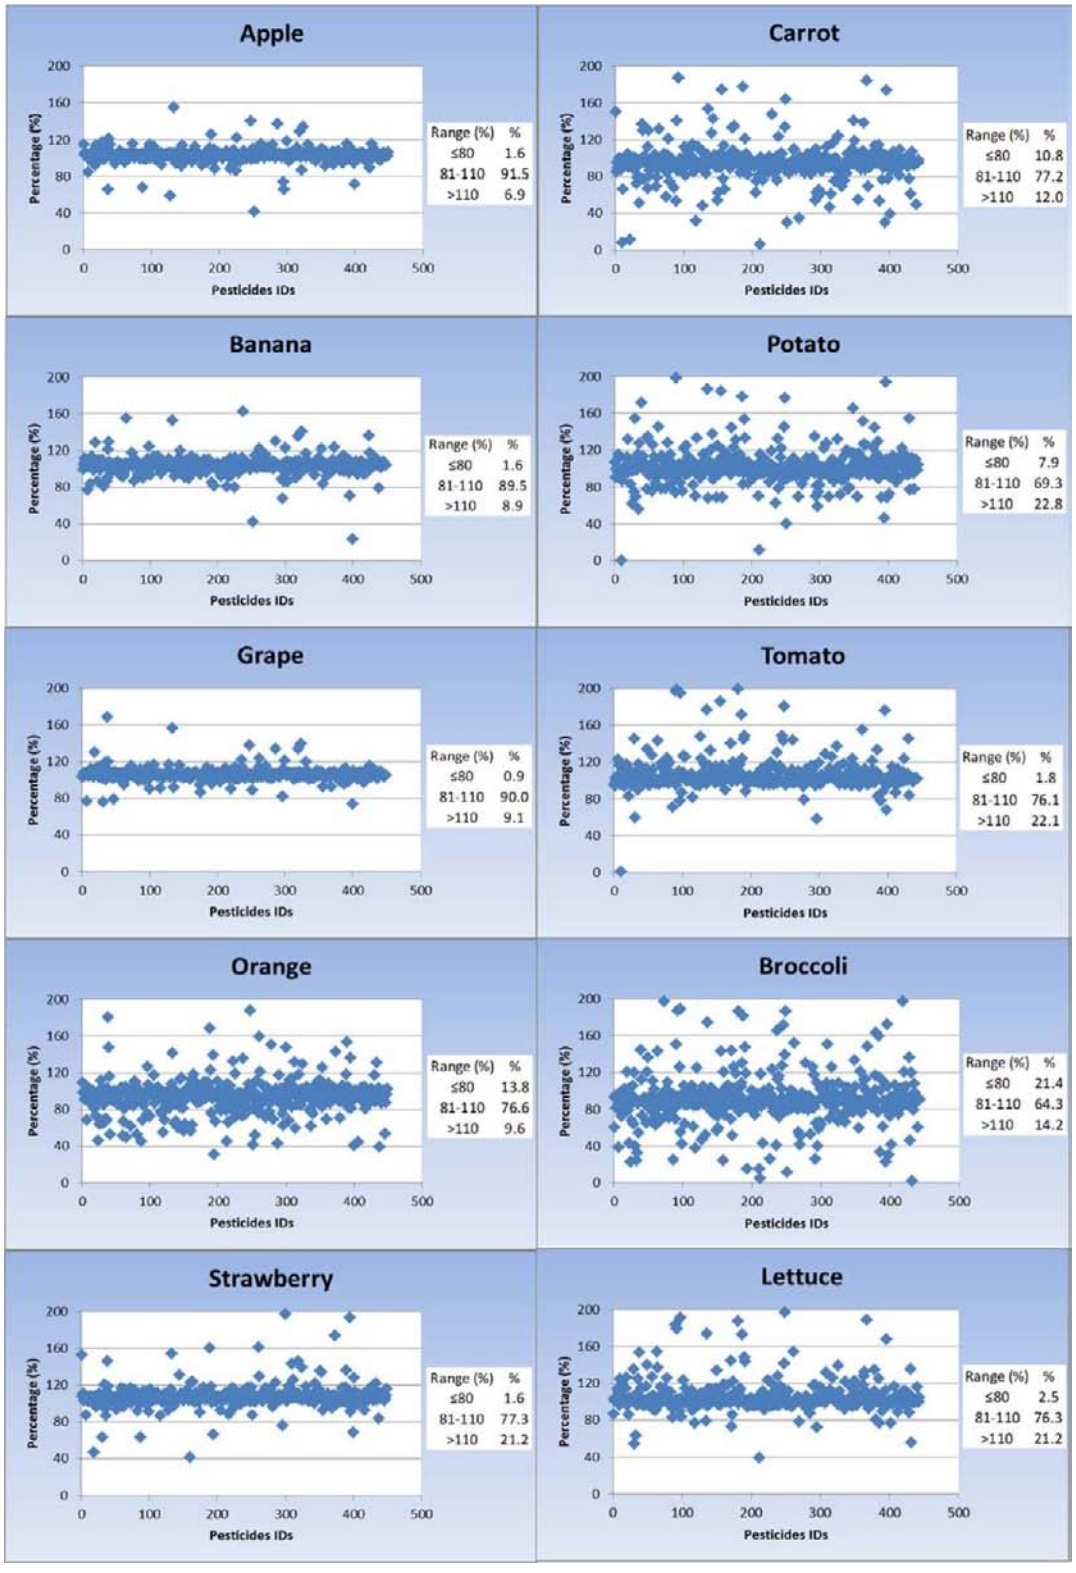

**Figure 6.** UHPLC/ESI Q-Orbitrap MS matrix effects. The 451 pesticides were prepared in sample extracts (a total of 10 matrices) and solvent buffer at a concentration of 100 $\mu$g/kg equivalent in sample: (left) fruits; (right) vegetables.

respectively (Figure 3B). The corresponding product ion spectra are shown in Figure 3C,D, and the observed differences revealed a product ion at $m/z$ 184.11899 and relative ion intensities. To identify and differentiate the three compounds, individual standards were injected, and chromatograms and mass spectra are shown in Figures 4 and 5. Secbumeton (6.52 min) and terbumeton (6.62 min) were chromatography resolved (Figure 4A1,A2) but shared the same major fragment ions with different relative intensities (Figure 4C1,D1,C2,D2). Secbumeton (6.52 min) and prometon (6.53 min) coeluted (Figure 5A1,A2) but possessed different fragment ions ($m/z$ 170.10349 and 184.11919, Figure 5, panels C1 and D1 and C2

dx.doi.org/10.1021/jf503778c | J. Agric. Food Chem. 2014, 62, 10375−10391

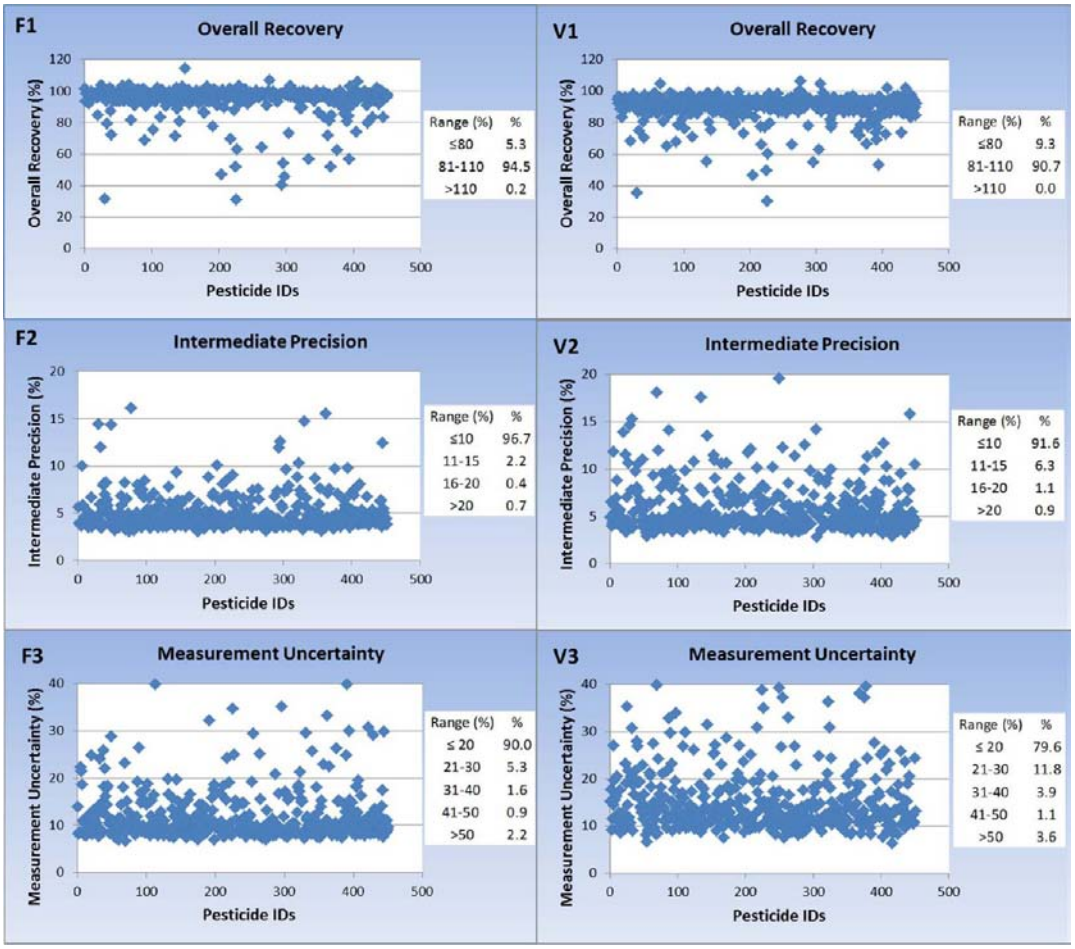

**Figure 7.** UHPLC/ESI Q-Orbitrap MS method performance for analysis of 451 pesticides in fruits and vegetables: (left) fruits; (right) vegetables; (A) overall recovery; (B) intermediate precision; (C) measurement uncertainty.

and D2, respectively). Prometon (6.53 min) and terbumeton (6.62 min) were chromatographically resolved (Figures 4A2 and 5A2) and possessed different fragment ions ($m/z$ 184.11919 and 170.10338, Figures 5C2,D2 and 4C2,D2, respectively). Therefore, dd-$MS^2$ was required to differentiate between secbumeton and prometon. Among the 22 pairs or groups of isomers, only 5 pairs were not chromatographically resolved, and dd-$MS^2$ was necessary for identification when detected in full MS mode.

**Matrix Effects.** Sample matrix could either enhance or suppress the ionization of pesticides; its effects might vary from sample to sample and ultimately affect the UHPLC/ESI Q-Orbitrap MS quantitative results. To evaluate matrix effects, the responses of pesticides in sample extracts were compared to those pesticide standards prepared in solvent buffer at 100 $\mu$g/kg equivalent in sample. In fruit matrices (Figure 6), pesticides experienced fewer matrix effects in apple, banana, and grape than in orange and strawberry. About 90% pesticides had ion suppression <20% or ion enhancement ≤10% in apple, banana, and grape, but only 77% of pesticides fell into the same range in orange and strawberry. More pesticides were subjected to ion suppression in orange or ion enhancement in strawberry. In vegetable matrices (Figure 6), pesticides generally experienced both ion suppression and enhancement. For example, >20% of pesticides in potato, tomato, and lettuce were subjected to ion enhancement (≥10%), whereas >10% of pesticides in carrot and broccoli experienced ion suppression (>20%).

Matrix-matched standard calibration curves along with isotopically labeled standards were required to compensate for matrix effects and were used to assess the UPLC/ESI Q-Orbitrap MS quantitative accuracy. Three commercially available deuterium-labeled standards, that is, carbendazim-$d_4$, carbofuran-$d_3$, and thiabendazole-$d_4$, were used as internal standards for quantifying their respective native compounds, and carbofuran-$d_3$ was utilized for all other pesticides. The calibration curves were observed to be linear or quadratic with coefficient of determinations ($R^2$) ≥ 0.97. Because of matrix effects, ion source contamination, or other unidentified factors, the responses of some pesticides either decreased or increased slightly over time. To average out the response changes during the course, the matrix-matched standard calibration curves were constructed on the basis of the two injections, that is, before and after spike samples, so as to improve the method performance.

**Quantification and Method Performance.** The UHPLC/ESI Q-Orbitrap MS method was validated according to a nested design, reported elsewhere, to evaluate the method performance characteristics including accuracy expressed as overall recovery, intermediate precision, and measurement uncertainty (MU).[16] Four factors, concentrations or spiked levels of pesticides, matrix effects, day-to-day variation, and within-day variation, were considered for the evaluation, and the experimental details were described under Materials and Methods. Data were grouped into two sets, that is, fruits and

vegetables, so that statistics were valid. The method performance results are summarized in Tables 1 and 2 and are illustrated in Figure 7. Depending on the type of sample matrices, about 94.5% of the pesticides in fruits or 90.7% in vegetables had recoveries between 81 and 110%; 99.3% of the pesticides in fruits and 99.1% of the pesticides in vegetables had an intermediate precision ≤20%; and 97.8% of the pesticides in fruits or 96.4% of the pesticides in vegetables showed measurement uncertainty ≤50%, which was a recommended default value in EU Document No. SANCO/12495/2011 for pesticide analysis and enforcement decisions (MRL exceedances).[18] Although five pairs of isomeric compounds that were not chromatographically resolved (Table 2) had very good method performance, they needed to be quantified separately when found in samples. Overall, the UHPLC/ESI Q-Orbitrap MS can serve as a liable and practical tool for quantification.

**Pesticide Identification.** The identification of any pesticides using UHPLC/ESI Q-Orbitrap mass spectrometry was based on mass accuracy and chromatographic retention time. SANCO/12495/2011[18] required ≥2 diagnostic ions (preferably the precursor ion and its product ion) with mass accuracy <5 ppm along with retention time tolerance of ±0.2 min for identification. The UHPLC/ESI Q-Orbitrap provided a measured mass accuracy <5 ppm and retention time tolerance within ±0.2 min. Full MS/dd-MS$^2$ was able to obtain product ion spectra that included both precursor and product ions with accurate masses. Currently, this identification was achieved using the system software. Further study will be to expand existing or develop new software to build a searchable exact mass spectral library or chemical compound database that can be used for efficient screening and identification.

**Method Sensitivity.** The lowest concentration levels (LCL) of individual pesticides, which indicated the method sensitivity, were determined according to the recommended default LC peak height value, that is, $1.0 \times 10^4$, reported elsewhere for Orbitrap.[19,20] To ensure the peaks were real, the peak areas were taken into account by calculating a ratio of peak height and peak area. If the ratio were >1.5, then the condition was satisfied and LCL by peak height can be determined. The signal-to-noise (S/N) ratio approach was not used because it was not practical as a result of a lack of background present in high mass resolution chromatograms. Approximately 85% of the pesticides could be detected and quantified at ≤5 μg/kg. The method proved to be sensitive enough to quantify most of the pesticides at 10 μg/kg, which is a default concentration for pesticides with no MRLs.

In conclusion, UHPLC/ESI Q-Orbitrap proved to be a powerful tool for the determination of up to 451 pesticide residues in fruits and vegetables. The UHPLC/ESI Q-Orbitrap MS, that is, full MS scan, provided superior method accuracy, repeatability, and sensitivity for quantification. Generally, about 94.5% of the pesticides in fruits or 90.7% in vegetables had recoveries between 81 and 110%; 99.3% of the pesticides in fruits and 99.1% of the pesticides in vegetables had an intermediate precision ≤20%; and 97.8% of the pesticides in fruits or 96.4% of the pesticides in vegetables showed measurement uncertainty ≤50%. UHPLC/ESI Q-Orbitrap dd-MS$^2$ provided product ion spectra with accurate mass measurement that allowed identification of pesticides. Overall, UHPLC/ESI Q-Orbitrap along with QuEChERs offers a practical tool for pesticide residue analysis in routine monitoring programs for food safety.

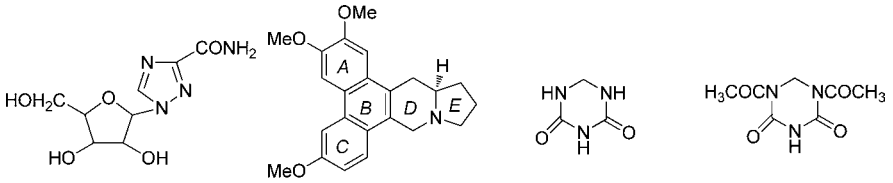

**Figure 1.** Chemical structures of ribavirin, antofine, DHT, and DADHT.

$GF_{254}$ with detection by UV. Melting points were determined using an X-4 binocular microscope melting point apparatus (Beijing Tech Instruments Co., Beijing, China), and the thermometer was uncorrected. $^1$H NMR spectra were obtained by using Bruker AV 400 and Varian Mercury plus 400 MHz spectrometers with $CDCl_3$ or DMSO-$d_6$ as solvent. Chemical shifts ($\delta$) were given in parts per million (ppm) and were measured downfield from internal tetramethylsilane. $^{13}$C NMR spectra were recorded by using a Bruker AV 400 (100 MHz) with $CDCl_3$ or DMSO-$d_6$ as solvent. Chemical shifts ($\delta$) were reported in parts per million using the solvent peak. High-resolution mass spectra were obtained with an FT-ICR MS spectrometer (Ionspec, 7.0 T).

**General Synthetic Procedure for Alcohols 45−47.** To a mixture of $LiAlH_4$ (0.03 mol) in 150 mL of THF at 0 °C was added corresponding acids **42−44** (0.02 mol) in portions. The solution was refluxed for an additional 2 h, then brought back to 0 °C, at which point 10 mL of EtOAc was added dropwise, followed by 10 mL of 2 N HCl. The solution was stirred and filtered, and the solvent was removed by rotary evaporation to give corresponding alcohols **45−47**.

*(3,6,7-Trimethoxyphenanthren-9-yl)methanol (**47**):* yield, 94%; white powder; mp, 161−162 °C (lit.[25] mp, 157−158 °C); $^1$H NMR (400 MHz, $CDCl_3$) $\delta$ 7.85 (s, 1H), 7.79 (s, 1H), 7.74 (d, $J$ = 8.7 Hz, 1H), 7.56 (s, 1H), 7.50 (s, 1H), 7.17 (d, $J$ = 8.7 Hz, 1H), 5.06 (s, 2H), 4.09 (s, 3H), 4.04 (s, 3H), 4.00 (s, 3H), 1.78 (s, 1H); $^{13}$C NMR (100 MHz, $CDCl_3$) $\delta$ 158.4, 149.4, 148.8, 131.4, 131.2, 130.2, 125.8, 125.5, 124.8, 124.6, 115.4, 104.8, 103.9, 103.7, 64.7, 56.0, 55.9, 55.5.

**Synthetic Procedure for 1.** Alcohol **45** (10 mmol) was dissolved in 200 mL of $CHCl_3$ and cooled to 0 °C. A solution of $PBr_3$ (15 mmol) in 40 mL of $CHCl_3$ was added dropwise under nitrogen. The solution was then stirred at room temperature for 4 h and poured over ice, and the two layers were separated. The organic phase was dried over anhydrous $Na_2SO_4$, filtered, and concentrated in vacuo to afford **48** as a white solid. Bromide **48** was then redissolved in 120 mL of DMF.

To the solution of $Me_2NH$ (14.2 mmol) in DMF (80 mL) was added $(i\text{-Pr})_2$NEt (15.6 mmol), and the mixture was stirred for 10 min. Then the above solution of bromide **48** was added. The mixture was stirred at 90 °C for 3 h and then cooled to room temperature. Then 300 mL of $H_2O$ was added, followed by 300 mL of $CH_2Cl_2$. The product was partitioned between $CH_2Cl_2$ and $H_2O$. The organic layer was dried over anhydrous $Na_2SO_4$, filtered, and concentrated to obtain a crude product. The crude product was purified by flash column chromatography to give compound **1** (2.8 g, 80%) as a white powder: mp, 157−159 °C; $^1$H NMR (400 MHz, DMSO-$d_6$) $\delta$ 8.01 (s, 1H), 7.98 (s, 1H), 7.68 (s, 1H), 7.52 (s, 1H), 7.37 (s, 1H), 4.02 (s, 3H), 4.02 (s, 3H), 3.90 (s, 3H), 3.90 (s, 3H), 3.76 (s, 2H), 2.24 (s, 6H); $^{13}$C NMR (100 MHz, DMSO-$d_6$) $\delta$ 149.0, 148.7, 148.6, 148.0, 130.1, 125.4, 125.2, 125.0, 124.6, 123.9, 108.4, 106.1, 103.9, 103.7, 62.7, 55.9, 55.8, 55.3, 55.1, 45.1; ESI-HRMS ($m/z$), calcd for $C_{21}H_{26}NO_4$ $[M + H]^+$ 356.1856, found 356.1853.

**General Synthetic Procedure for Compounds 24, 27, 30, 33, 36, 39, and 40.** Corresponding alcohols **45−47** (10 mmol) were dissolved in 200 mL of $CHCl_3$ and cooled to 0 °C. A solution of $PBr_3$ (15 mmol) in 40 mL of $CHCl_3$ was added dropwise under nitrogen. The solution was then stirred at room temperature for 4 h and poured over ice, and the two layers were separated. The organic phase was dried over anhydrous $Na_2SO_4$, filtered, and concentrated in vacuo to afford corresponding bromides **48−50**, which were then redissolved in 120 mL of DMF.

To the solution of corresponding alkylamines (3 mmol) in DMF (80 mL) was added $(i\text{-Pr})_2$NEt (12 mmol), and the mixture was stirred for 10 min. Then the above solution of bromide **48** was added. The mixture was stirred at 90 °C for 3 h and then cooled to room temperature. Then 300 mL of $H_2O$ was added, followed by 300 mL of $CH_2Cl_2$. The product was partitioned between $CH_2Cl_2$ and $H_2O$. The organic layer was dried over anhydrous $Na_2SO_4$, filtered, and concentrated to obtain a crude product. The crude product was purified by flash column chromatography to give compounds **24**, **27**, **30**, **33**, **36**, **39**, and **40**.

*Methyl 6-(bis((2,3,6,7-tetramethoxyphenanthren-9-yl)methyl)-amino)hexanoate (**24**):* yield, 60%; white powder; mp, 191−192 °C; $^1$H NMR (400 MHz, $CDCl_3$) $\delta$ 7.74 (s, 2H), 7.74 (s, 2H), 7.56 (s, 2H), 7.48 (s, 2H), 7.17 (s, 2H), 4.11 (s, 6H), 4.07 (s, 6H), 4.06 (s, 4H), 4.03 (s, 6H), 3.58 (s, 3H), 3.49 (s, 6H), 2.61 (t, $J$ = 8.0 Hz, 2H), 2.10 (t, $J$ = 8.0 Hz, 2H), 1.78−1.69 (m, 2H), 1.48−1.39 (m, 2H), 1.22−1.16 (m, 2H); $^{13}$C NMR (100 MHz, $CDCl_3$) $\delta$ 174.0, 149.1, 148.9, 148.8, 148.4, 130.6, 126.9, 126.1, 125.9, 124.9, 124.3, 108.1, 106.1, 103.0, 102.8, 59.6, 56.1, 56.0, 55.9, 55.4, 54.5, 51.4, 33.9, 27.1, 27.0, 24.7; ESI-HRMS ($m/z$), calcd for $C_{45}H_{51}NO_{10}Na$ $[M + Na]^+$ 788.3405, found 788.3405.

*2-(Bis((2,3,6,7-tetramethoxyphenanthren-9-yl)methyl)amino)-ethanol (**38**):* yield, 58%; white powder; mp, 246−248 °C; $^1$H NMR (400 MHz, $CDCl_3$) $\delta$ 7.76 (s, 2H), 7.74 (s, 2H), 7.58 (s, 2H), 7.29 (s, 2H), 7.18 (s, 2H), 4.16 (s, 4H), 4.11 (s, 6H), 4.06 (s, 6H), 4.03 (s,

6H), 3.64 (s, 2H), 3.41 (s, 6H), 2.86 (s, 2H); $^{13}$C NMR (100 MHz, $CDCl_3$) $\delta$ 148.4, 148.0, 147.9, 147.9, 128.5, 126.7, 124.7, 124.1, 123.6, 107.2, 104.0, 102.3, 101.8, 58.6, 57.9, 55.1, 55.0, 54.9, 54.6, 54.2; ESI-HRMS ($m/z$), calcd for $C_{40}H_{43}NO_9Na$ $[M + Na]^+$ 704.2830, found 704.2823.

**Synthetic Procedure for 2,3,6,7-Tetramethoxyphenanthrene-9-carbaldehyde (51).** A mixture of alcohol **45** (5 g, 15.23 mmol), silica (10 g), and pyridinium chlorochromate (PCC, 9.85 g, 45.69 mmol) in $CH_2Cl_2$ (150 mL) was stirred at room temperature for 10 h and then filtered. The filtrate was concentrated by rotary evaporation and purified by flash column chromatography to give compound **51** (4.02 g, 80%) as a yellow powder: mp, 227−228 °C (lit.[27] mp, 210−214 °C); $^1$H NMR (400 MHz, $CDCl_3$) $\delta$ 10.27 (s, 1H), 8.98 (s, 1H), 8.07 (s, 1H), 7.80 (s, 1H), 7.78 (s, 1H), 7.35 (s, 1H), 4.17 (s, 3H), 4.14 (s, 3H), 4.11 (s, 3H), 4.07 (s, 3H).

**Synthetic Procedure for Methyl 6-(((2,3,6,7-Tetramethoxyphenanthren-9-yl)methyl)amino)hexanoate (2).** A mixture of aldehyde **51** (1.2 g, 3.68 mmol), $Et_3N$ (0.42 g, 4.12 mmol), AcOH (5 drops), and methyl 6-aminohexanoate hydrochloride (0.74 g, 4.05 mmol) in $CH_2Cl_2$ (40 mL) was refluxed for 6 h. The solution was cooled to room temperature and concentrated in vacuo. The resulting solid was dissolved in MeOH (30 mL), followed by the addition of AcOH (5 drops) and $NaBH_3CN$ (0.47 g, 7.40 mmol). The solution was stirred at room temperature for 3 h and concentrated in vacuo. To the resulting mixture were added $CH_2Cl_2$ (30 mL), $H_2O$ (20 mL), and saturated $NaHCO_3$ solution (10 mL), and the two layers were separated. The organic phase was dried over anhydrous $Na_2SO_4$, filtered, concentrated, and purified by flash column chromatography to give compound **2** (1.14 g, 68%) as a yellow powder: mp, 104−106 °C; $^1$H NMR (400 MHz, $CDCl_3$) $\delta$ 7.75 (s, 1H), 7.67 (s, 1H), 7.58 (s, 1H), 7.42 (s, 1H), 7.18 (s, 1H), 4.16 (s, 2H), 4.08 (s, 3H), 4.07 (s, 3H), 4.06 (s, 3H), 4.02 (s, 3H), 3.64 (s, 3H), 2.79 (t, $J$ = 8.0 Hz, 2H), 2.28 (t, $J$ = 8.0 Hz, 2H), 1.71−1.65 (m, 2H), 1.64−1.57 (m, 2H), 1.40−1.33 (m, 2H); $^{13}$C NMR (100 MHz, $CDCl_3$) $\delta$ 174.1, 149.3, 149.0, 148.9, 148.8, 130.1, 126.0, 125.1, 125.0, 124.8, 124.3, 108.3, 104.7, 103.4, 102.8, 56.1, 56.0, 56.0, 55.9, 51.7, 51.5, 49.2, 33.9, 29.2, 26.8, 24.7; ESI-HRMS ($m/z$), calcd for $C_{26}H_{33}NO_6Na$ $[M + Na]^+$ 478.2200, found 478.2208.

**Synthetic Procedure for 6-(((2,3,6,7-Tetramethoxyphenanthren-9-yl)methyl)amino)hexan-1-ol (3).** A procedure similar to that used for the preparation of compounds **26**, **29**, **32**, **35**, and **38** was used: yield, 89%; white powder; mp, 83−85 °C; $^1$H NMR (400 MHz, DMSO-$d_6$) $\delta$ 8.02 (s, 1H), 7.98 (s, 1H), 7.60 (s, 1H), 7.58 (s, 1H), 7.34 (s, 1H), 4.34 (s, 1H), 4.13 (s, 2H), 4.03 (s, 3H), 4.02 (s, 3H), 3.92 (s, 3H), 3.90 (s, 3H), 3.40−3.36 (m, 2H), 2.67 (t, $J$ = 6.8 Hz, 2H), 1.56−1.47 (m, 2H), 1.44−1.39 (m, 2H), 1.35−1.28 (m, 4H); $^{13}$C NMR (100 MHz, $CDCl_3$) $\delta$ 149.1, 148.9, 148.8, 148.6, 130.8, 126.0, 125.1, 125.0, 124.3, 124.1, 108.2, 104.6, 103.3, 102.7, 62.7, 56.0, 56.0, 55.9, 52.1, 49.7, 32.7, 29.8, 27.1, 25.7; ESI-HRMS ($m/z$), calcd for $C_{25}H_{34}NO_5$ $[M + H]^+$ 428.2431, found 428.2440.

**General Synthetic Procedure for Compounds 6, 9, 10, and 13−21.** A mixture of compound **3** (0.18 g, 0.40 mmol) and NaH (0.03 g, 1.20 mmol) was stirred at room temperature for 30 min, and then corresponding bromides or iodides (0.60 mmol) were added. The solution was stirred for a further 3 h, followed by the addition of $H_2O$ (150 mL) and $CH_2Cl_2$ (100 mL), and the two layers were separated. The organic phase was dried over anhydrous $Na_2SO_4$, filtered, concentrated, and purified by flash column chromatography to give corresponding compounds **6**, **9**, **10**, and **13−21**.

*Methyl 6-(methyl((2,3,6,7-tetramethoxyphenanthren-9-yl)methyl)amino)hexanoate (**6**):* reaction with $CH_3I$, yield, 89%; yellow powder; mp, 128−129 °C; $^1$H NMR (400 MHz, DMSO-$d_6$) $\delta$ 8.00 (s, 1H), 7.98 (s, 1H), 7.77 (s, 1H), 7.51 (s, 1H), 7.36 (s, 1H), 4.02 (s, 3H), 4.02 (s, 3H), 3.90 (s, 6H), 3.81 (s, 2H), 3.55 (s, 3H), 2.43 (t, $J$ = 8.0 Hz, 2H), 2.22 (t, $J$ = 8.0 Hz, 2H), 2.13 (s, 3H), 1.56−1.52 (m, 2H), 1.48−1.41 (m, 2H), 1.31−1.26 (m, 2H); $^{13}$C NMR (100 MHz, $CDCl_3$) $\delta$ 173.1, 148.1, 147.9, 147.8, 147.4, 124.9, 124.0, 123.3, 107.2, 104.9, 102.0, 101.8, 56.7, 55.1, 55.0, 54.9, 54.8, 50.5, 40.9, 32.9, 26.1, 26.0, 23.8; ESI-HRMS ($m/z$), calcd for $C_{27}H_{35}NO_6$ $[M + Na]^+$ 492.2357, found 492.2361.

*Methyl 6-(butyl((2,3,6,7-tetramethoxyphenanthren-9-yl)methyl)amino)hexanoate (**9**):* reaction with BuI, yield, 80%; yellow powder; mp, 96−98 °C; $^1$H NMR (400 MHz, $CDCl_3$) $\delta$ 7.97 (s, 1H), 7.81 (s, 1H), 7.79 (s, 1H), 7.50 (s, 1H), 7.20 (s, 1H), 4.13 (s, 6H), 4.04 (s, 6H), 3.94 (s, 2H), 3.62 (s, 3H), 2.52−2.42 (m, 4H), 2.18 (t, $J$ = 7.2 Hz, 2H), 1.56−1.46 (m, 6H), 1.31−1.20 (m, 4H), 0.84 (t, $J$ = 7.2 Hz, 3H); $^{13}$C NMR (100 MHz, $CDCl_3$) $\delta$ 174.1, 149.0, 148.8, 148.7, 148.2, 131.4, 126.1, 126.1, 125.7, 124.9, 124.2, 108.2, 106.5, 102.9, 102.8, 59.3, 56.1, 56.0, 55.9, 53.9, 53.5, 51.4, 34.0, 29.4, 27.0, 26.7, 24.8, 20.7, 14.1; ESI-HRMS ($m/z$), calcd for $C_{30}H_{42}NO_6$ $[M + H]^+$ 512.3007, found 512.3012.

*2-(Bis((2,3,6,7-tetramethoxyphenanthren-9-yl)methyl)amino)-propane-1,3-diol (**23**):* a procedure similar to that used for the preparation of compound **24** was used; yield, 69%; yellow powder; mp, 152−154 °C; $^1$H NMR (400 MHz, $CDCl_3$) $\delta$ 7.75 (s, 2H), 7.73 (s, 2H), 7.59 (s, 2H), 7.23 (s, 2H), 7.16 (s, 2H), 4.40 (s, 4H), 4.12 (s, 4H), 4.11 (s, 6H), 4.06 (s, 6H), 4.02 (s, 6H), 3.42 (s, 6H), 3.30−3.23 (m, 1H), 2.36 (s, 2H); $^{13}$C NMR (100 MHz, $CDCl_3$) $\delta$ 149.4, 149.0, 149.0, 148.9, 129.5, 128.1, 125.7, 125.7, 125.14, 124.5, 108.2, 104.8, 103.4, 102.8, 59.7, 56.1, 56.0, 55.9, 55.1, 54.6, 45.7; ESI-HRMS ($m/z$), calcd for $C_{41}H_{45}NO_8Na$ [M + Na]$^+$ 734.2936, found 734.2941.

**Synthetic Procedure for $N^1$,$N^1$-Dimethyl-$N^2$,$N^2$-bis((2,3,6,7-tetramethoxyphenanthren-9-yl)methyl)ethane-1,2-diamine (41).** A mixture of aldehyde **51** (0.38 g, 1.17 mmol), *N*,*N*-dimethylethylenediamine (0.049 g, 0.55 mmol), $NaBH_3CN$ (0.11 g, 1.65 mmol), AcOH (5 drops) in MeOH (30 mL), and $CH_2Cl_2$ (15 mL) was refluxed for 6 h. Then the mixture was cooled to room temperature, concentrated, and purified by flash column chromatography to give compound **41** (0.15 g, 39%) as a yellow powder: mp, 138−140 °C; $^1$H NMR (400 MHz, $CDCl_3$) $\delta$ 7.73 (s, 2H), 7.72 (s, 2H), 7.58 (s, 2H), 7.45 (s, 2H), 7.17 (s, 2H), 4.10 (s, 6H), 4.07 (s, 10H), 4.03 (s, 6H), 3.52 (s, 6H), 2.85 (t, $J$ = 6.8 Hz, 2H), 2.62 (t, $J$ = 6.8 Hz, 2H), 2.13 (s, 6H); $^{13}$C NMR (100 MHz, $CDCl_3$) $\delta$ 148.2, 147.9, 147.8, 147.5, 129.1, 125.9, 124.9, 124.8, 123.9, 123.3, 107.1, 105.0, 102.0, 101.7, 58.9, 56.2, 55.1, 55.0, 54.9, 54.5, 51.2, 44.3; ESI-HRMS ($m/z$), calcd for $C_{42}H_{49}N_2O_8$ [M + H]$^+$ 709.3483, found 709.3482.

**Antiviral Biological Assay.** *Phytotoxic Activity.* Growing 5−6-leaf stage tobaccos (*Nicotiana tabacum* var. Xanthi nc) were selected. The compound solution (500 $\mu$g/mL) was smeared on the leaves. The local lesion numbers were then counted and recorded 3−4 days later.

*Purification of Tobacco Mosaic Virus.* Using Gooding's method,[21] the upper leaves of *N. tabacum* L. inoculated with TMV were selected and ground in phosphate buffer and then filtered through a double-layer pledget. The filtrate was centrifuged at 10000*g* for 15 min, treated with polyethylene glycol (PEG) twice, and centrifuged again. The whole experiment was processed at 4 °C. Absorbance value was estimated at 260 nm by ultraviolet spectrophotometer.

$$\text{virus concn} = (A_{260} \times \text{dilution ratio})E^{0.1\%,260\text{nm}}_{1\text{cm}}$$

*Antiviral Activity of Compounds against TMV in Vitro.* The in vitro activity of the synthesized compounds against TMV was evaluated by using the conventional half-leaf method.[22] Fresh leaf of the growing 5−6-leaf stage tobacco (*N. tabacum* var. Xanthi nc) mechanically inoculated (concentration of TMV = 10 $\mu$g/mL) was cut into halves along the main vein. The halves were immersed into the solution of 500 $\mu$g/mL of the compounds and double-distilled water for 20 min, respectively, and then kept still at 25 °C for 72 h. Each compound was replicated at least three times.

*Protective Effect of Compounds against TMV in Vivo.*[23] Growing 5−6-leaf stage tobaccos (*N. tabacum* var. Xanthi nc) were selected. The compound solution was smeared on the left side, and the solvent serving as control was smeared on the right side of growing tobacco (*N. tabacum* var. Xanthi nc) leaves of the same ages. The leaves were then inoculated with the virus after 12 h. A brush was dipped in TMV of 10 $\mu$g/mL to inoculate the leaves, which were previously scattered with silicon carbide. The leaves were then washed with water and rubbed softly along the nervature once or twice. The local lesion numbers appearing 3−4 days after inoculation were counted. There are three replicates for each compound.

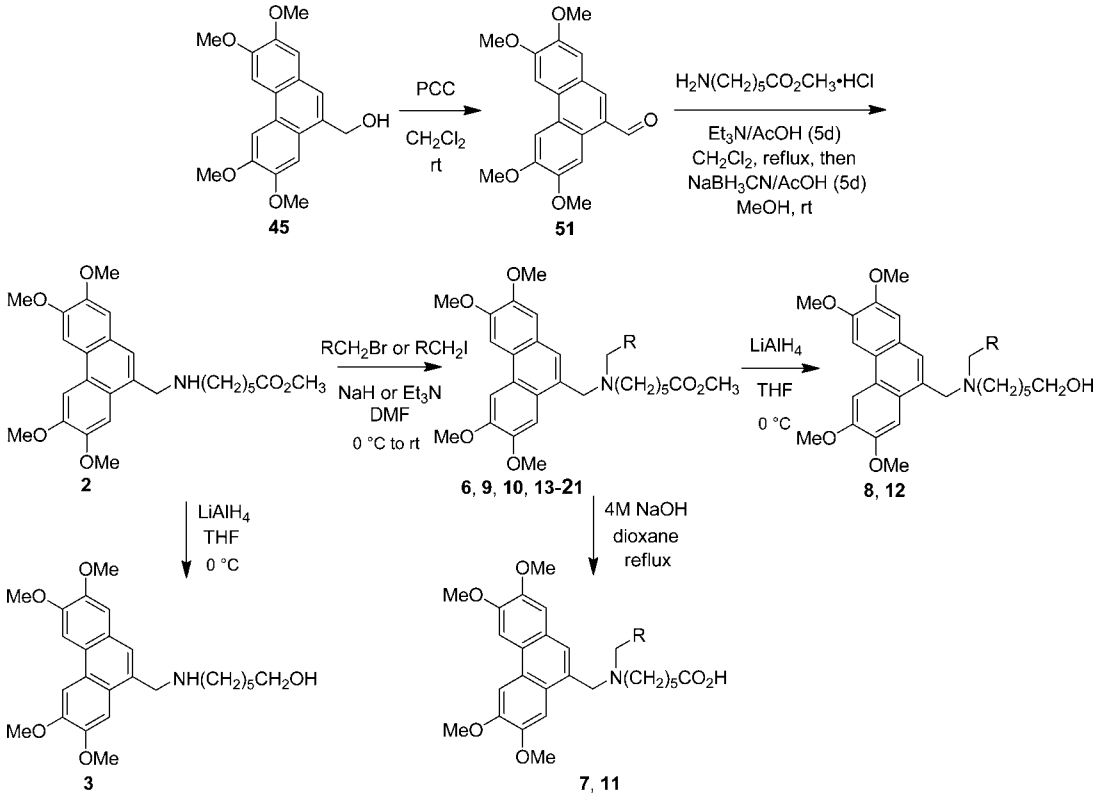
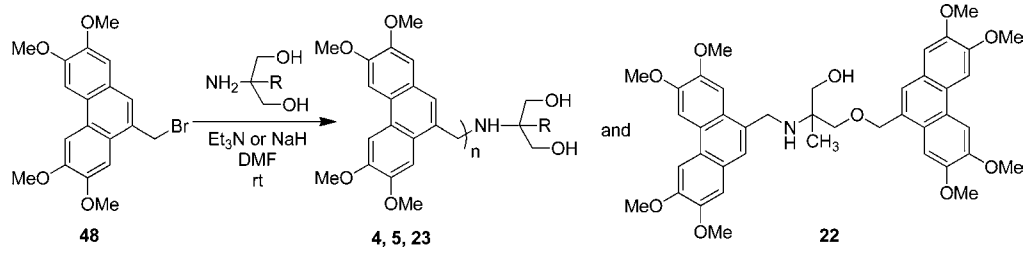
**Scheme 2. Synthesis of Compounds 2, 3, and 6−21**



**Scheme 3. Synthesis of Compounds 4, 5, 22, and 23**



*Inactivation Effect of Compounds against TMV in Vivo.*[23] Growing 5−6-leaf stage tobaccos (*N. tabacum* var. Xanthi nc) were selected. The virus of 10 μg/mL was inhibited by mixing with the compound solution at the same volume for 30 min. The mixture was then inoculated on the left sides of the leaves, whereas the right sides of the leaves were inoculated with the mixture of solvent and the virus for control. The local lesion numbers were recorded 3−4 days after inoculation. There were three replicates for each compound.

*Curative Effect of Compounds against TMV in Vivo.*[23] Growing 5−6-leaf stage tobaccos (*N. tabacum* var. Xanthi nc) were selected. TMV (concentration = 10 μg/mL) was dipped and inoculated on the whole leaves. Then the leaves were washed with water and dried. The compound solution was smeared on the left side, and the solvent was smeared on the right side for control. The local lesion numbers were then counted and recorded 3−4 days after inoculation. There were three replicates for each compound.

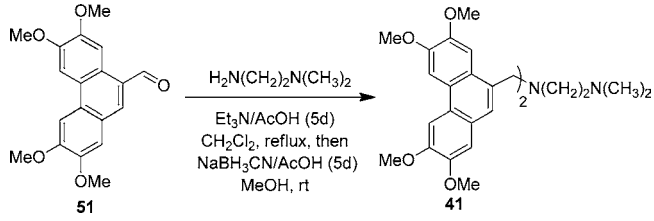
The in vitro and in vivo inhibition rates of the compound were then calculated according to the following formula ("av" means average, and controls were not treated with compound):

$$\text{inhibition rate (\%)} = [(\text{av local lesion no. of control} - \text{av local lesion no. of drug-treated}) / \text{av local lesion no. of control}] \times 100\%$$

## RESULTS AND DISCUSSION

**Chemistry.** Reduction of acids **42**−**44**[24] with $LiAlH_4$ gave alcohols **45**−**47**, which were treated with $PBr_3$ to afford bromides **48**−**50**. Coupling of **48**−**50** with corresponding amines gave the antofine derivatives **1**, **24**, **27**, **30**, **33**, **36**, **39**, and **40**. Treatment of **24**, **27**, **30**, **33**, and **36** with 4 M NaOH solution gave acids **25**, **28**, **31**, **34**, and **37**. Reduction of **24**, **27**, **30**, **33**, and **36** with $LiAlH_4$ afforded alcohols **26**, **28**, **32**, **35**, and **38** (Scheme 1).

**Scheme 4. Synthesis of Compound 41**



As shown in Scheme 2, oxidation of alcohol **45** with pyridiniumchlorochromate (PCC) gave aldehyde **51**, which was

[a]All results are expressed as means ± SD.

coupled with methyl 6-aminohexanoate hydrochloride to give compound **2**. Reduction of **2** with $LiAlH_4$ afforded alcohol **3**. Coupling of **2** with corresponding bromides or iodides gave the antofine derivatives **6**, **9**, **10**, and **13**−**21**. Treatment of **6** and **10** with 4 M NaOH solution gave acids **7** and **11**. Reduction of **6** and **10** with $LiAlH_4$ afforded alcohols **8** and **12**.

Coupling of bromide **48** with corresponding alkamines gave the antofine derivatives **4**, **5**, **22**, and **23** (Scheme 3). It is worth mentioning that reaction of **48** with excess alkamine gave only N,O-dialkylation compound **22**. Using a similar procedure for the preparation of derivatives **1**, **24**, **27**, **30**, **33**, **36**, **39**, and **40** could not afford **41** due to the presence of *N*,*N*-dimethyl. As an

alterative method, compound **41** was prepared by coupling of **51** with excess amine (Scheme 4).

**Bioactivities and the Structure−Activity Relationship.** *Phytotoxic Activity.* The antofine derivatives **1**−**41** were first tested for their phytotoxic activity against *N. tabacum* var. Xanthi nc, and the results indicated that these natural product-based compounds showed no phytotoxic activity at 500 μg/mL.

*Antiviral Activity in Vitro and in Vivo.* To make a judgment of the antiviral potency of the antofine derivatives **1**−**41**, the precursor antofine and commercial plant virucide vibavirin were used as controls.

The first in vitro anti-TMV bioassay indicated that all of the tested compounds displayed good antiviral activity, of which compounds **1**, **2**, **6**, **10**, **18**, **19**, **33**, **38**, and **40** exhibited higher inhibition than ribavirin (Table 1). Therefore, these compounds were bioassayed further to investigate their antiviral activity in vivo.

As shown in Table 1, the antofine derivatives **1**−**41** also exhibited good to excellent in vivo anti-TMV activity; especially compounds **10**, **18**, and **19** displayed higher antiviral activity than the precursor antofine and commercial plant virucide ribavirin, thus emerging as new lead compounds.

Among the phenanthrenyl methyl amines **2**−**5**, long-chain containing compounds **2** and **3** exhibited better antiviral activity, and the ester group is favorable for activity (antiviral effect, **2** > **3**). It is worth mentioning that dimethyl amine compound **1** showed a higher antiviral effect than compounds **2**−**5**, and compound **6** displayed better activity than **2**, which indicated that the hydrogen on the N atom is unfavorable for antiviral activity. To further investigate the substituents on the long chain, compounds **6**−**8** and **10**−**12** were prepared. The bioassay results indicated that the ester group is more suitable than acid and hydroxy groups (antiviral effect, **6** > **7**, **8**; antiviral effect, **10** > **11**, **12**). The main difference between compounds **6**, **9**, and **10** lies in the substituents on the N atom. Compounds **6** and **9** displayed similar good antiviral activities, which are lower than that of compound **10**. The results indicated that the replacement of methyl with *n*-butyl is tolerant, and benzyl is more suitable for antiviral activity than an alkyl group. To investigate the substituents on benzyl, compounds **13**−**21** were prepared. Only compounds **18** and **19** maintained good antiviral activity (antiviral effect, **10** ≈ **18** ≈ **19**). The results indicated that the benzyl lies in a sensitive area for antiviral activity.

In previous work, we have found that the presence of nitrogen in the tertiary amine and the phenanthrene ring are essential for high antiviral activity.[18,19] The increase of phenanthrene ring may raise the interaction between small molecular compound and TMV RNA. On the basis of the above hypothesis, a series of two phenanthrene rings containing compounds **22**−**41** were synthesized and evaluated for their antiviral activity. Unfortunately, most of these compounds exhibited only moderate antiviral activity. Only compounds **22**, **38**, and **40** maintained good antiviral activity (antiviral effect, **22** ≈ **38** ≈ **40** ≈ **6**). The results indicated that phenanthrene is important for these compounds, but not the more the better.

In summary, on the basis of our previous structure−activity relationship and antiviral mechanism studies, a series of phenanthrene and alkylamine chain containing antofine derivatives **1**−**41** were prepared and systematically evaluated for their antiviral activity against TMV. The bioassay results indicated that most of these compounds exhibited good to excellent anti-TMV activity, of which compounds **10**, **18**, and **19** displayed higher activity than the precursor antofine and commercial ribavirin, thus emerging as potential inhibitors of plant virus. The D and E rings of antofine were proved to be not indispensable. Phenanthrene is important for these compounds, but not the more the better. The novel concise structure provides another new template for antiviral studies, which may have different mechanisms of action. Further studies on structural optimization and mode of action are currently underway in our laboratories.

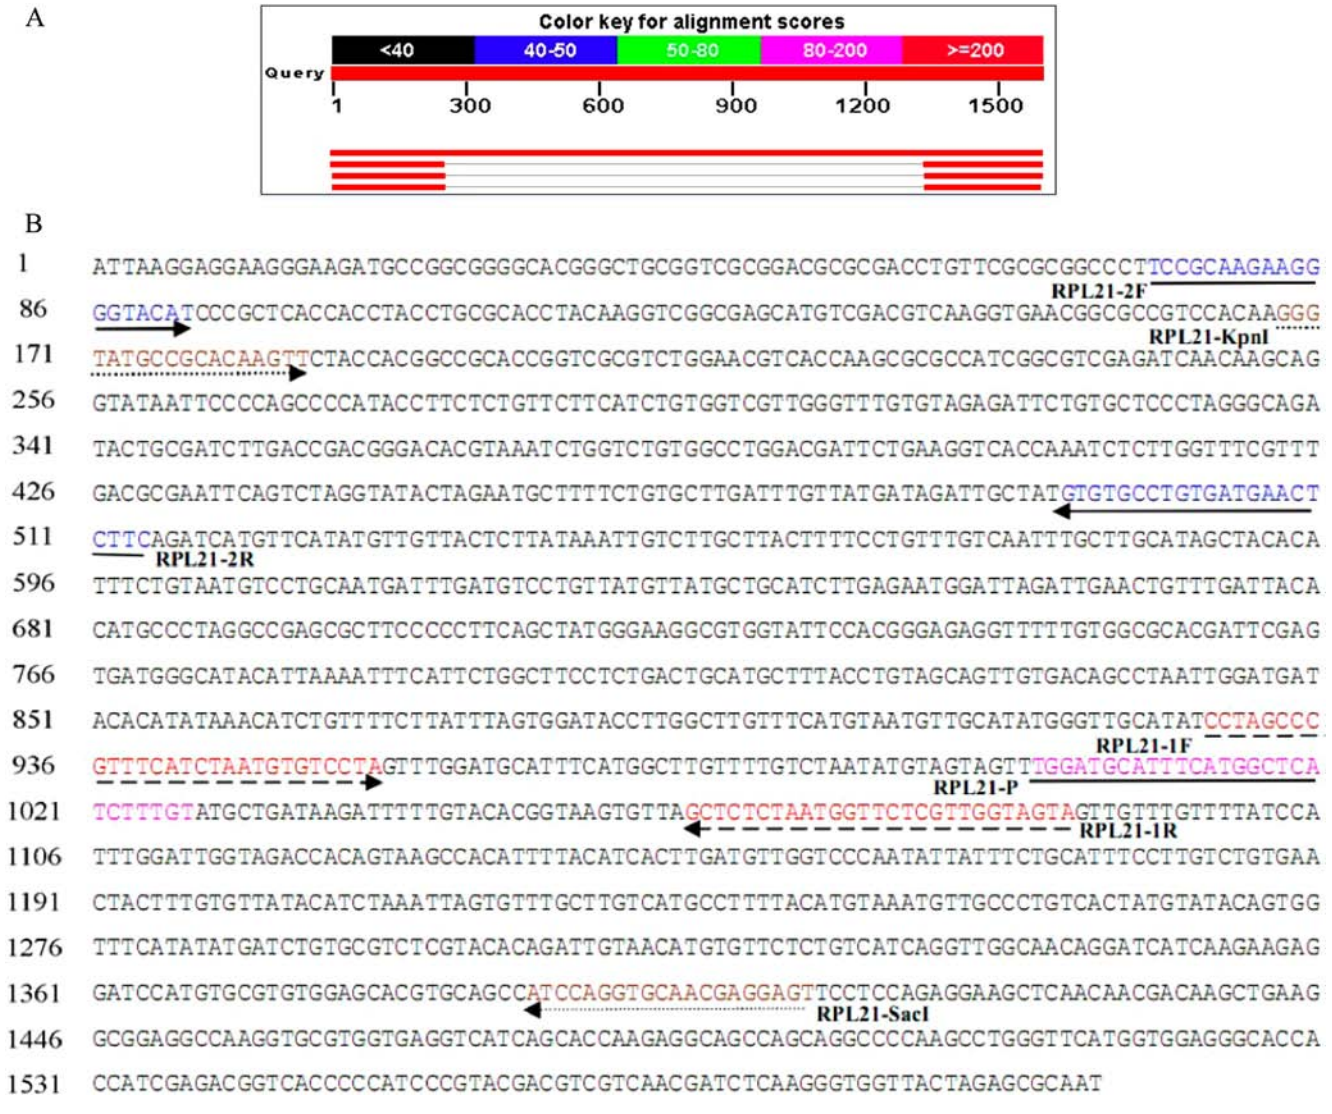

**Figure 1.** Homology analyses of the wheat *RPL21* gene and its sequence and positions for annealing by primers. (A) BLAST analysis of wheat *RPL21* based on the nucleotide collection database. (B) Primers and their annealing positions are indicated by underlines and labels.

lines, and the *Waxy-D1* gene assay was validated to be useful in establishing qualitative and quantitative PCR analyses of GM wheat.[26] However, some Chinese wheat landraces were null *Waxy-D1* mutants.[27,28] Moreover, none of these endogenous reference genes was verified for detecting GM wheat contents with GM wheat materials.

In the present work, we investigated whether the wheat *ribosomal protein L21* (*RPL21*) gene encoding 60S ribosomal protein L21 was a good candidate to serve as a wheat endogenous reference gene for a GM wheat assay. *RPL21* was found by searching database sequences. We designed species-specific primers based on this gene and developed conventional and quantitative real-time PCR systems. Furthermore, we developed the construct-specific real-time PCR method using *NPR1* GM wheat, and seven mixed *NPR1* GM wheat samples

of known content were also quantitatively analyzed using the developed real-time PCR method.

## MATERIALS AND METHODS

**Plant Materials.** A total of 17 plant species were used for the specificity test of the designated primers: barley (*Hordeum vulgare* L.), maize (*Zea mays* L.), rye (*Secale cereale* L.), tomato (*Lycopersicon esculentum* Mill.), common bean (*Phaseolus vulgaris* L.), rapeseed (*Brassica napus* L.), Chinese cabbage (*Brassica campestris* L. ssp. *pekinensis*), cotton (*Gossypium hirsutum* L.), soybean (*Glycine max* L. Merr.), mung bean (*Phaseolus vulgaris* L.), *Arabidopsis* [*Arabidopsis thaliana* (L.) Heynh.], cucumber (*Cucumis sativus* L.), sweet potato [*Ipomoea batatas* (L.) Lam.], pea (*Pisum sativum* L.), rice (*Oryza sativa* L.), sunflower (*Helianthus annuus* L.), and sorghum (*Sorghum bicolor* L. Moench). All samples were obtained from local stores.

A total of 18 common wheat (AABBDD) varieties from different ecological regions in China, including hard winter wheat, hard spring wheat, soft winter wheat, and soft spring wheat, were stored in our laboratory or kindly provided by Professor Jun Yin from Henan Agricultural University (Zhengzhou, Henan, China). *Triticum urartu* (AA), *Aegilops speltoides* (BB), and *Aegilops tauschii* (DD) were kindly provided by Professor Jizeng Jia from the Institute of Crop Science, the Chinese Academy of Agriculture Sciences, China. The *NPR1* (non-expressor of PR genes) GM wheat line R4 was developed in our laboratory.[29]

**DNA Extraction.** Total genomic DNA from seedlings of the 17 plant species, 18 common wheat varieties, 3 diploid wheat species, and dry flour of common wheat was extracted using the cetyltrimethylammonium bromide (CTAB) protocol.[30] The concentration and quality of the purified DNA samples were measured and evaluated using a Shimadzu UV-1800 spectrophotometer (Shimadzu Corporation, Kyoto, Japan), and the DNA quality was further checked by 1% (w/v) agarose gel electrophoresis in 0.5× TBE with ethidium bromide staining.

**Oligonucleotide Primers and Probes.** Oligonucleotide primers and probes used in this study were designed with Primer Premier 5 (PREMIER Biosoft, Palo Alto, CA) and are listed in Table 1. Primers RPL21-1F/1R, RPL21-2F/2R, and RPL21-*Kpn*I/*Sac*I were designed on the basis of the wheat *RPL21* gene sequence (GenBank HM138481.1). The annealing sites of these primers are shown in Figure 1. The primer pair NPR1-1F/1R was designed according to the sequence of the *A. thaliana NPR1* gene (GenBank NM_105102.2), which was integrated into an elite wheat cultivar Yangmai11.[29] The TaqMan probes were labeled on the 5′ end with the 6-carboxyfluorescein (FAM) reporter dye, and 6-carboxytetramethylrhodamine (TAMRA) quencher dye was attached to the 3′ end. All of the primers and probes were synthesized by Sangon (Shanghai, China). The probe for southern blot was a fragment derived from 74 to 514 of the wheat *RPL21* sequence (Figure 1B) amplified with primer pair PRPL21-2F/2R (Table 1) using a Takara random primer DNA labeling kit, version 2 (TaKaRa, Dalian, China).

**Southern Blot Analysis.** Aliquots of 15 μg of DNA from young leaves of common wheat culture Yangmai11 were digested with 60 units of restriction enzymes *Hind*III and *Nde*I (TaKaRa) overnight and electrophoresed on 0.8% agarose gels. DNA fragments were transferred onto a nylon membrane (Hybond-$N^+$, Amersham, Buckinghamshire, U.K.) and hybridized with an $\alpha$-[$^{32}$P]-dCTP-labeled DNA fragment derived from the *RPL21* sequence amplified with primer pair RPL21-2F/2R (Figure 1). Autoradiography was conducted using a Fujifilm imaging plate and cassette, which was analyzed with a Fuji BAS1800-II system (Fujifilm, Tokyo, Japan).

**Sequencing Analysis of the *RPL21* Gene.** The specific DNA fragments were amplified with the primer pair RPL21-*Kpn*I/*Sac*I from the common wheat variety Yangmai11 and three diploid ancestral species, *T. urartu* (AA), *A. speltoides* (BB), and *A. tauschii* (DD), employing the KOD Plus DNA polymerase PCR kit (TaKaRa). The amplified DNA fragments were cloned into pBluescript SK(−) vector and analyzed with the ABI Prism 3730 genetic analyzer (Invitrogen Co., Ltd., Shanghai, China). The sequences obtained were aligned using DNAMAN software (Lynnon Biosoft, Quebec, Canada).

**Conventional PCR Conditions.** Conventional PCR assays were carried out in a 25 μL final volume on a thermal cycling instrument (MyCycler, Bio-Rad, Hercules, CA). Each reaction mixture contained the following reagents: 10× EasyTaq buffer (TransGen Biotech, Beijing, China), 2 units of EasyTaq polymerase (TransGen), 120 μM dNTPs (TaKaRa), 1 μL of template (about 50 ng), 0.5 μM of each primer, and double-distilled water (dd$H_2O$). Conventional PCR programs were as follows: 5 min of predenaturation at 94 °C, followed by 35 cycles of 30 s at 94 °C, 30 s at 60 °C, and 30 s at 72 °C, and a final extension of 10 min at 72 °C. The PCR-amplified products were analyzed by 1% (w/v) agarose electrophoresis in 0.5× TBE with ethidium bromide staining. As for PCRs used to test the limit of detection (LOD), wheat genomic DNA was serially diluted to 6250, 1250, 250, 50, 10, 2, and 1 initial template copies of the haploid genome based on the DNA content of 17.3 pg/haploid genome in common wheat;[24] these dilutions were used in PCRs with the primer pair RPL21-1F/1R under the conditions described above.

**Quantitative Real-Time PCR.** Quantitative real-time PCR reactions were performed in a 20 μL final volume containing 50 ng of sample DNA, 10 μL of FastStart Universal Probe Master (Roche Applied Science, Indianapolis, IN), 0.5 μM each of the forward and reverse primers, and 0.2 μM FAM/TAMRA-labeled oligonucleotide probe. Real-time PCR reactions were run on a Roche LightCycler 480 (Roche, Mannheim, Germany) using the following program: 95 °C for 10 min, 40 cycles of denaturation at 95 °C for 20 s each, followed by annealing at 60 °C for 40 s. For the generation of standard curves of the two genes *RPL21* and *NPR1*, extracted genomic DNA from GM wheat line R4 was diluted 5-fold to final copy numbers of 5000, 1000, 200, 40, and 8 per reaction. All of the quantitative PCRs were repeated 3 times, each with three replicates. The resulting data were analyzed, and standard curves were constructed with the LightCycler 480 software release 1.5.0 (Roche).

## RESULTS AND DISCUSSION

**Selection of Wheat Endogenous Reference Gene.** The application of an endogenous reference gene makes the detection of plant species more practical and precise. Reference genes must be species-specific and have a low and consistent copy number in different varieties of the same species.[11] To choose a suitable reference gene in common wheat, large amounts of gene information were collected from GenBank and several candidates were evaluated. After BLAST and homology analyses, the 60S ribosomal protein L21 (RPL21) in the common wheat genome (accession number HM138481.1) was found to have low homology with the sequences from other non-wheat species. The homologue in *Arabidopsis* to this chloroplast ribosomal protein L21 is required for chloroplast development and embryogenesis,[31] whereas the exact biological function of the *RPL21* gene in wheat is not yet known.

Sequence alignment analyses indicated that a region of the wheat *RPL21* sequence from 257 to 1322 nucleotides displayed no homology with other known sequences in the database (Figure 1A). Subsequently, primers specific to this region were designed, and a specificity analysis for each primer was performed by a BLAST search for each primer against several public and genetically modified organism (GMO) DNA sequence databases, such as NCBI. Any primer showing homology with non-relevant DNA sequences was discarded. Finally, we designed the primer pair RPL21-1F/1R, which spanned a sequence of 161 base pairs (bp) within the region of 257−1322 nucleotides and was wheat-specific (Table 1 and Figure 1B). The specificity of the primers was further tested in both qualitative and quantitative assays.

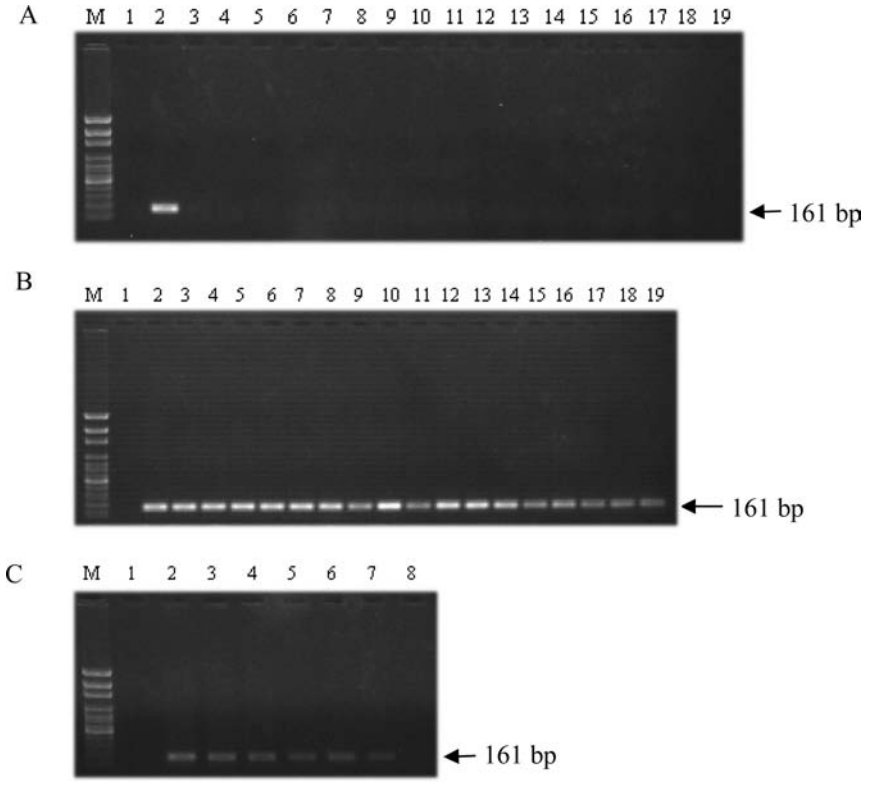

**Figure 2.** Agarose gel electrophoresis of conventional PCR products amplified with the RPL21-1F/1R primer pair. (A) PCR-amplified products with DNA from wheat and other plant species: (1) no DNA template control, (2) common wheat, (3) barley, (4) maize, (5) rye, (6) tomato, (7) bean, (8) rapeseed, (9) Chinese cabbage, (10) cotton, (11) soybean, (12) mung bean, (13) *Arabidopsis*, (14) cucumber, (15) sweet potato, (16) pea, (17) rice, (18) sunflower, (19) sorghum and (M) 100 bp ladder size standard. (B) PCR-amplified products with DNA from (2−19) 18 different varieties of common wheat, (1) no DNA template control, and (M) 100 bp ladder size marker. (C) PCR-amplified products with serial dilutions of common wheat DNA: (1) no DNA template control, (2) 6250 copies, (3) 1250 copies, (4) 250 copies, (5) 50 copies, (6) 10 copies, (7) 2 copies, (8) 1 copy, and (M) 100 bp ladder size standard.

**Specificity, Allelic Stability, and Sensitivity of *RPL21* Systems in Conventional Qualitative PCR.** To assess the specificity of the *RPL21* gene-based PCR system using the primer pair RPL21-1F/1R, qualitative PCRs were performed using 50 ng of genomic DNA extracted from 17 plant species that are either closely related to common wheat or frequently consumed plant materials. A single 161 bp DNA fragment was amplified only from wheat, whereas no product was amplified from any of the other 16 plant species (Figure 2A), demonstrating that the *RPL21* gene is wheat-specific.

To examine whether an allelic variation of the *RPL21* gene is present in wheat, genomic DNA isolated from 18 common wheat varieties collected from different ecological regions in China was tested by PCR with the primer pair RPL21-1F/1R. As shown in Figure 2B, all of the varieties contained one DNA fragment of identical size (161 bp) and similar intensity, indicating the presence of the same amplicon in those wheat genotypes. Thus, the RPL21 fragment has no allelic variation among the wheat varieties.

To further evaluate the sensitivity of the primer pair, known amounts of wheat genomic DNA isolated from Yangmai11 were assayed by conventional PCR. A series of wheat genomic DNA dilutions containing approximately 6250, 1250, 250, 50, 10, 2, and 1 initial template copies of the haploid genome was used in PCRs with the primer pair RPL21-1F/1R to test its LOD. The expected 161 bp amplicon was obtained in all of the dilutions, except for the level of 1 copy and water (Figure 2C), indicating that the LOD of the primer pair RPL21-1F/1R was as low as about 2 copies of common wheat haploid genome. This level of sensitivity was similar to that of a wheat *ALMT1* system (2.3 copies) and better than that of *Waxy-D1* system (7 copies).[24,25]

**Copy and Amplicon Number of the Wheat *RPL21* Gene.** The copy number of an endogenous reference gene is critical for GMO quantification. Targeting a gene sequence with a single or stably low copy number should result in stable real-time PCR assays.[25] To estimate the copy number of the *RPL21* gene in the common wheat genome, we designed another primer pair RPL21-2F/2R to amplify a 441 bp DNA fragment used as a probe for southern blot analysis. Wheat genomic DNA from Yangmai11 digested with *Hind*III and *Nde*I was hybridized with the 441 bp DNA fragment derived from the *RPL21* gene (Figure 1B), revealing three hybridizing bands in both enzyme-digested DNA samples (Figure 3). Among the three bands, one had stronger signal intensity than the other two bands, which had similar intensities in both digests. These results suggest that the stronger band was the sequence from the AA genome nearly identical (about 98% identity) to the probe, whereas the weak bands were the sequences from the BB and DD genomes, respectively, which have low similarity to the probe (see Figure S1 of the Supporting Information). Therefore, the *RPL21* gene may have 3 copies or 1 copy in the common wheat genome. In the *Waxy-D* system, two hybridizing bands were detected in southern blots, suggesting the presence of 1 or 2 copies,[25] whereas the copy numbers of

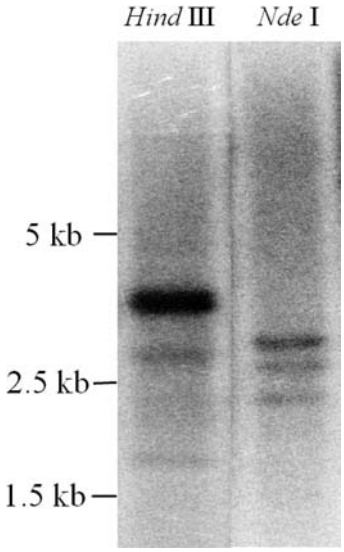

**Figure 3.** Estimation of the copy number of a wheat *RPL21* gene as illustrated by genomic southern blot of common wheat (Yangmai11) genomic DNA digested with *Hind*III and *Nde*I, separately, and hybridized to a 441 bp probe of the *RPL21* gene amplified with primer pair RPL21-2F/2R.

other endogenous reference genes from wheat have not been confirmed.[12,18,24]

Common wheat is a hexaploid species with the genome constitution of AABBDD originating from three diploid ancestral species: *T. urartu* (AA), *A. speltoides* (BB), and *A. tauschii* (DD).[32] Allopolyploidization leads to the generation of duplicated homeologous genes (homeologs). Therefore, most genes in hexaploid wheat are present as triplicate homeologs.[33]

To obtain information on the amplicon number generated by the primer pair RPL21-1F/1R from ancestral wheat species, the primer pair RPL21-*Kpn*I/*Sac*I was used to amplify fragments (about 1242 bp) from *T. urartu*, *A. speltoides*, and *A. tauschii*. The alignment of the four amplified sequences (see Figure S1 of the Supporting Information) showed that the annealing sites of the primer pair RPL21-1F/1R were only present in the A genome but not in the B or D genomes, thus generating only one amplicon in common wheat (Figure 4). Conventional PCRs with the primer pair RPL21-1F/1R confirmed that one expected 161 bp DNA fragment was amplified from *T. urartu* (AA) and common wheat (AABBDD), but no amplicon was obtained from *A. speltoides* (BB) or *A. tauschii* (DD) (data not shown). Thus, the *RPL21* gene was apparently evolutionarily derived from diploid *T. urartu*, and the primer pair RPL21-1F/1R generated only one amplicon from the A genome of common wheat.

**Quantitative Assay Based on LOD and Limit of Quantification (LOQ).** When quantifying a nucleotide sequence by real-time PCR, LOD and LOQ are the most important parameters, referring to the lowest quantity of target that can be reliably detected and quantified with a probability of ≥95%.[34,35] The absolute limit is the lowest number of initial template copies that can be detected and quantified. To determine LOD and LOQ of the established method based on the primer pair RPL21-1F/1R by real-time PCR, six serial dilutions of common wheat DNA containing approximately 5000, 1000, 200, 40, 8, and 1.6 haploid genomes were prepared and tested in seven replicates per dilution. As shown in Table 2,

**Table 2. Amplification Data Used To Determine the Absolute LOD and LOQ**

| estimated template copies | signal rate (number of positive signals) | mean $C_p$ values | SD | RSD (%) |
|---|---|---|---|---|
| 5000 | 7/7 | 24.27 | 0.14 | 0.57 |
| 1000 | 7/7 | 26.68 | 0.14 | 0.53 |
| 200 | 7/7 | 28.89 | 0.16 | 0.56 |
| 40 | 7/7 | 31.12 | 0.25 | 0.83 |
| 8 | 7/7 | 33.45 | 0.37 | 1.12 |
| 1.6 | 4/7 | 35.81 | ND | ND |
| 0 | 0/7 | >45 | ND | ND |

the ability to detect *RPL21* decreased with the reduction of genomic DNA copy number, and 1.6 copies of wheat genomic DNA were detected 3 times in the seven replicates, indicating that the LOD value was about 2 copies. This value is in accordance with that determined by the conventional PCRs. A LOD of 2 haploid genome copies was reported for the wheat *Waxy-D1*, *acc1*, and *ALMT1* systems,[12,24,25] and a LOD of 5 genome copies was reported for the *PKABA1* system.[18]

The LOQ values were calculated on the basis of the crossing point ($C_p$) values and confidence intervals.[12] The results showed that approximately 8 initial template copies were required to obtain reliable quantification results with 95% confidence under ideal conditions (Table 2), indicating that the LOQ of the RPL21-1F/1R-based real-time PCR assay was about 8 copies of haploid genome.[36,37] This value is 2.5−4-fold lower than that of the *ALMT1* (20 copies) and *acc1* (30 copies) systems, respectively.[12,24] No such information is available for the *Waxy-D* and *PKABA1* systems.

**Construct-Specific Qualitative PCR Detection of *NPR1* in Transgenic Wheat.** To validate the applicability and sensitivity of the developed *RPL21* system with transgenic

**Figure 4.** Sequence alignment of a portion of the wheat *RPL21* gene containing the region amplified with the primer pair RPL21-1F/1R with DNA from *T. aestivum* (AABBDD, GenBank accession number HM138481.1), *T. urartu* (AA), *A. speltoides* (BB), and *A. tauschii* (DD). The sequences in the red boxes were the region annealed with the primer pair RPL21-1F/1R.

wheat materials, we selected a stably transgenic wheat line R4 that contained a *NPR1* gene from *A. thaliana*.[29] To detect the content of *NPR1* in wheat line R4 through quantitative real-time PCR, the sensitivity and specificity of the construct-specific sequence of *NPR1* were first evaluated using qualitative PCR. The construct-specific primer pair NPR1-1F/1R (Table 1) was designed on the basis of the *NPR1* sequence to establish the construct-specific conventional PCR assay. As shown in Figure 5A, a 148 bp DNA fragment was amplified only from

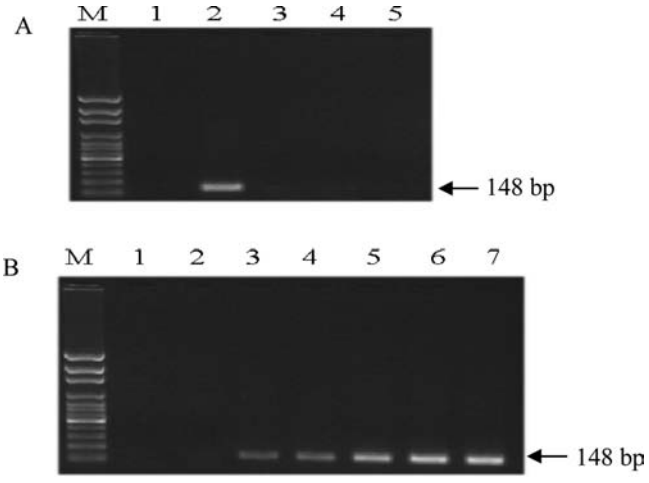

**Figure 5.** Agarose gel electrophoresis of conventional PCR products with the primer pair NPR1-1F/1R. (A) PCR-amplified products from *NPR1* transgenic wheat line R4 and some non-GM wheat varieties: (1) no DNA template control, (2) transgenic wheat line R4, (3) Yangmai11, (4) Zhenmai9023, (5) Yangmai158, and (M) 100 bp ladder size standard. (B) PCR-amplified products with DNA from a non-GM wheat mixed with serial dilutions with GM wheat line R4: (1) no DNA template control, (2) 0%, (3) 0.2%, (4) 1%, (5) 0.5%, (6) 2.0%, (7) 5.0%, and (M) 100 bp ladder size standard.

*NPR1* transgenic wheat and not from other non-GM wheat varieties and no template control, indicating a high specificity of this primer pair.

To test the LOD of the established construct-specific PCR assay, pure dried wheat flour from transgenic line R4 was mixed at proportions of 0, 0.2, 0.5, 1.0, 2.0, and 5.0% with flour from non-transgenic wheat variety Yangmai11 and subjected to DNA isolation and PCR analyses. In conventional PCR assays, an aliquot of 50 ng of genomic DNA was used as the template per reaction. The results showed that the expected 148 bp target DNA fragment of *NPR1* gene was generated from all levels of transgenic wheat flour, except for 0% and no template control, indicating that the LOD of the conventional PCR assay is at least 0.2%. This level corresponds to about 6 copies of wheat haploid genome (AABBDD = 6; Figure 5B), confirming that the construct-specific PCR assay is highly specific and sensitive for practical detection of *NPR1* transgenic wheat samples.

**Establishment of Standard Curves.** To establish a method to estimate the contents of transgenic wheat, two standard curves (one for endogenous gene *RPL21* and the other for transgenic gene *NPR1*) through five 5-fold serial dilutions (corresponding to 5000, 1000, 200, 40, and 8 copies of the wheat haploid genome per reaction) were performed in transgenic wheat line R4, in which an *A. thaliana NPR1* gene was integrated into wheat variety Yangmai11.[29] The calculated $C_p$ values were plotted versus the log copies of total DNA of each starting quantity. The correlation coefficients ($R^2$) of the standard curves were 0.993 and 0.997, respectively (Figure 6), indicating a good linearity for both assays. On the basis of the equation $E = 10^{-(1/\text{slope})} - 1$, the PCR efficiency can be calculated and the ideal slope should be −3.32 for 100% PCR efficiency.[38] Slopes in the range from −3.1 to −3.6 are acceptable, indicating PCR efficiency from 90 to 110%. The two efficiencies were 101.3% for endogenous *RLP21* and 97.4% for *NPR1* in the standard dilutions, indicating that the PCR efficiencies were acceptable. The acceptable PCR reaction efficiencies and the good linearity between the logarithm of initial DNA quantities and $C_p$ indicated that the established real-time PCR systems of *RLP21* and *NPR1* are suitable for quantitative analysis.

**Quantification of the Samples with Known Transgenic Wheat Content.** Seven samples with 0.5, 1, 2, 5, 20, 50, or 100% of GM wheat contents were prepared by mixing pure dried wheat flour of transgenic line R4 with non-GM dried wheat flour on a w/w basis, from which DNA was extracted. An aliquot of 50 ng of DNA from each sample was used as a template in each reaction, and GM contents were calculated on the basis of the standard curves using the relative quantification method. The quantitative results of these seven samples were 0.45, 0.85, 1.90, 4.56, 17.37, 48.17, and 108.26%, respectively (Table 3). The quantified biases (mean tested value versus true value) of tested samples ranged from 4.88 to 15.22%, and the relative standard deviation (RSD) values ranged from 5.19 to 10.63%. All variations from the samples were below 25%, the accepted level for GMO quantification.[38] These findings suggest that the *RPL21* gene can be used as the wheat endogenous reference gene for quantifying GM wheat food contents, and the established construct-specific PCR systems are suitable for the quantification of practical samples derived from *NPR1* transgenic wheat. A previous study used a *PKABA1*-based system to test 10 samples of food and feed and showed that 8 of the analyzed samples presumably contained wheat contents, and on the basis of that, the authors stated that *PKABA1* could be used for the detection of GM wheat.[18] However, no previous study has quantified genuine GM wheat contents using an endogenous reference gene system. The *RPL21* system developed in this study can quantify GM wheat contents as little as 0.5%, satisfying the labeling regulations in the European Union and many other countries.[5−7] To our knowledge, this is the first study to detect the contents of GM wheat using a reference gene system with quantitative real-time PCR.

In conclusion, the wheat *RPL21* gene used as an endogenous reference gene was validated for GM wheat detection and quantification with qualitative and real-time quantitative PCR assays. Southern blot with common wheat DNA and sequence analyses of common wheat together with its three diploid ancestral species congruently indicated that the primer pair RPL21-1F/1R had only one amplicon in common wheat. The LOD of conventional PCR was 2 copies of wheat haploid genome. The LOD and LOQ of real-time PCR were 2 and 8 copies of wheat haploid genome, respectively. Furthermore, two standard curves of *RPL21* and *NPR1* were established using *NPR1* transgenic wheat, and seven mixed samples with known content of *NPR1* GM wheat were relatively accurately quantified using the established real-time PCR method. All of these results demonstrate that the *RPL21* gene is a suitable endogenous reference gene for GM wheat detection, and the developed *RPL21* system will facilitate the enforcement of GMO labeling for wheat in the near future.

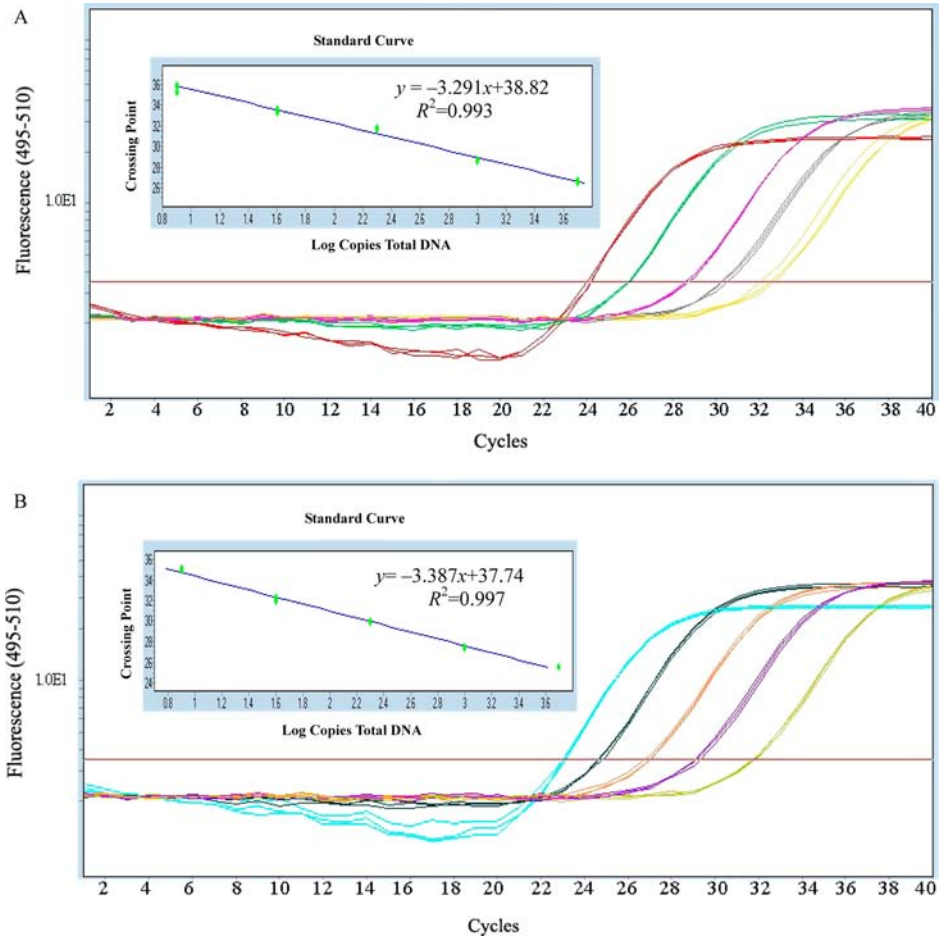

**Figure 6.** Real-time PCR assay of the logarithmic plots resulting from the amplification of five 5-fold serial dilutions (corresponding to 5000, 1000, 200, 40, and 8 copies of the wheat haploid genome per reaction) of DNA from GM wheat line R4 and its relative standard curve obtained with the crossing point ($C_p$) value versus the log of each initial total DNA for (A) *RPL21* gene and (B) *NPR1* gene.

development of heterogeneous catalysts for the interesterification reaction in an environmentally friendly manner has become an area of great importance particularly from the green chemistry point of view.

The interesterification reaction involves as least two oils with different FA compositions. Due to the complex compositions in the oils, it is hard to evaluate quantitatively the interesterification process. For the optimization of the catalyst preparation conditions, in the current study, soybean oil and methyl stearate were used as reactants, and the incorporation of stearoyl groups into TAGs was determined by gas chromatography (GC) techniques.[22] Besides, the interesterification reaction between soybean oil and lard was also carried out to investigate the properties of the interesterified products.

Alumina has attracted much interest as a heterogeneous catalyst support, due to its high surface area, simple structure and availability.[23] Thus, in the present study, $KNO_3/Al_2O_3$ catalysts with different $KNO_3$ loadings were prepared using alumina as a catalyst support, and then were tested in the interesterification reaction. The prepared solid catalysts were characterized by using Hammett titration method, power X-ray diffraction (XRD), scanning electron microscopy (SEM), and nitrogen adsorption−desorption techniques. The effect of calcination temperature and $KNO_3$ loading was investigated with the interesterification of soybean oil with methyl stearate in terms of stearoyl incorporation into the TAGs. By using this solid base catalyst, the interesterification reactions of soybean oil and lard blends were carried out in a batch reactor, and the properties of the interesterified products were investigated by gas chromatography (GC), high-performance liquid chromatography (HPLC), and confocal laser scanning microscopy.

## MATERIALS AND METHODS

**Materials.** Refined soybean oil and lard used in this study were purchased from the local supermarket. Methyl stearate (≥98%) was obtained from Sinopharm Chemical Reagent Corporation (Shanghai, China). The alumina used as a support, with a surface area of 123 $m^3/g$, was obtained from Tianjin Chemical Reagent Factory. Porcine pancreatic lipase (EC 3.1.1.3, Type II; PPL) used for the analysis of FA profiles at the *sn*-2 position of the interesterified TAGs, was purchased from Sigma-Aldrich Corporation (St. Louis, U.S.A.). All the other materials used were of analytical or chromatographical grades.

**Catalyst Preparation.** The potassium-doped alumina catalysts ($KNO_3/Al_2O_3$), with different loadings of $KNO_3$ over the alumina support, were prepared by the conventional incipient-wetness impregnation method with an aqueous solution of $KNO_3$ using commercial alumina as a support. In a typical preparation, the required amount of alumina was placed into the aqueous $KNO_3$ solution. The resulting suspensions were stirred for 24 h at room temperature, and water was then evaporated at 80 °C under reduced pressure. The concentration of initial $KNO_3$ solution was changed to prepare the solid catalyst with different $KNO_3$ loadings. After impregnation the white solid obtained hereby was dried overnight and was finally calcined under an air flow at 500−900 °C for 6 h prior to the catalytic tests. The solid catalysts prepared with various $KNO_3$ loadings of 30, 35, 40, and 45 wt %, were expressed as $30\%KNO_3/Al_2O_3$,$35\%KNO_3/Al_2O_3$, $40\%KNO_3/Al_2O_3$, and $45\%KNO_3/Al_2O_3$, respectively.

**Catalyst Characterization.** Powder X-ray diffraction (XRD) patterns of selected samples were obtained with a Bruker-AXS NanoSTAR instrument. Nickel filtered K$\alpha$ radiation of copper was used at 40 kV and 30 mA. The data were analyzed with the DiffracPlus software, and the phases were identified using the powder diffraction file database (JCPDS, International Centre for Diffraction Data)

Basic strengths of the solid catalyst (H_) were determined by using various Hammett indicators. For this purpose, about 300 mg of the sample was placed into 1 mL Hammett indicator solution diluted with 10 mL of methanol and allowed to equilibrate for 2 h. The basic strength is quoted as being stronger than the weakest indictor that shows a color change, and weaker than the strongest indicator, which exhibits no color change. The basicity of the solid catalyst was measured by the method of Hammett indicator involving the benzene carboxylic acid (0.02 mol/L methanol solution).[17]

Scanning electron microscope (SEM) measurements were performed with a field-emission microscope (JEOL, JSM-6390LV) using an accelerating voltage of 15 kV. The nitrogen adsorption−desorption isotherms at −196 °C were measured using a Quantachrome NOVA 1000e instrument. The Brunauer−Emmett−Teller (BET) method was used to calculate the specific surface area. The total pore volume and pore size distribution were estimated according to the Barrett−Joyner−Halenda (BJH) method based on the adsorption isotherm.

**Interesterification Procedures.** The interesterification of soybean oil and methyl stearate was carried out in a 50 mL round-bottom flask. Prior to each reaction, a mixture of 20 g of soybean oil and 41 g of methyl stearate was dried in the reactor under reduced pressure at 80 °C. By adding 10 wt % of the solid catalyst, the heterogeneous reaction mixture was allowed to proceed under reduced pressure at 200 °C. Constant stirring at 750 rpm was used to minimize mass transfer limitations. After 4 h of reaction time, the reactor was cooled to room temperature. Thereafter, the catalyst was recovered from the reaction mixture by simple filtration, and the filtrate was then used for subsequent analysis.

Soybean oil and lard were blended in different proportions of 80:20, 60:40, 40:60, 20:80 ratios (w/w), and then the binary blends were interesterified in batch reactors. In order to avoid oil oxidation, the interesterifications were carried out in a nitrogen atmosphere. Portions (100 g) of the blends were initially heated under vacuum at 80 °C to remove air and moisture. When the reaction mixture had reached a reaction temperature of 100 °C, 5 wt % of the solid catalyst was added in a batch reactor, and the blends were stirred vigorously. The interesterification reaction of different blends of soybean oil and lard was performed under reduced pressure at 100 °C in a 150 mL stoppered flask with magnetic stirring (∼750 rpm) for a time frame of 5 h. At the end of the reaction, the interesterified product was filtered, and then employed for subsequent analysis.

**Analytical Methods.** The FA compositions of triacylglycerols were analyzed by a gas chromatography (GC) according to AOAC method.[24] After complete conversion of FA residues into fatty acid methyl esters (FAMEs), the methylated FA residues were determined using an Agilent 6890 N gas chromatograph (Santa Clara, CA. U.S.A.) equipped with a flame-ionization detector, an auto injector and a fused silica capillary column (60 m × 0.25 mm) coated with 0.25 $\mu$m of BPX-70 (SGE, Australia). Nitrogen was used as a carrier gas at flow rate of 1.2 mL/min with a split ratio of 1:20. The temperatures of injector and detector were set at 260 and 300 °C, respectively. The initial temperature of the program was increased to 160 °C and then held for 5 min. This temperature was finally increased to 200 °C at a rate of 5 °C/min, and held isothermally for another 42 min at the final temperature. The FAME composition was identified by comparison with the relative retention time of FAME standards. The FAME content was obtained by area normalization and expressed as mass percentage.[25]

For the interesterification of soybean oil with methyl stearate, the triacylglycerol was separated from the reaction mixtures by thin-layer chromatography (TLC) on a silica gel 60G plate. The interesterified blends were spotted on TLC silica gel plates, and then developed with petroleum ether/ethyl ether/acetic acid (90:10:1,v/v/v). The developed TLC plates were sprayed with 2% 2,7-dichlorofluorescein in methanol. Bands corresponding to triacylglycerols, which were identified using triolein as the standard, were scraped from the silica plates, extracted with *n*-hexane, and subsequently analyzed for the FA profiles. The progress of the interesterification reaction was followed by the determination of stearoyl incorporation into the TAGs.

The FA profiles at the *sn*-2 position of triacylglycerols were measured by using pancreatic lipase according to the method described in the literature.[25] The pancreatic lipase can be applied to

hydrolyze selectively FAs at sn-1,3 positions of TAGs, producing 2-monoacylglycerol and FAs. The formed 2-monoacylglycerol was separated by TLC plates, and the *sn*-2 positional analysis of FA residues in the TAGs was carried out by GC techniques after 2-monoacylglycerol was totally converted to FAMEs as described previously.

For the interesterification of soybean oil with lard, the variation of TAG compositions occurred during the reaction was assessed using high-performance liquid chromatography (HPLC) fitted with commercially packed Genesis C18 column (150 mm × 4.6 $mm^2$).[25] Each sample was dissolved in chloroform (10 mg/mL), and 20 $\mu$L of the dissolved sample was injected into the HPLC system. The elution solvent consisted of dichloromethane and acetonitrile (HPLC grade) at a gradient composition from 35% acetonitrile increasing to 55% dichloromethane in 45 min. The column temperature was held at 40 °C. The TAG species were detected by an evaporative light scattering detector (Alltech 500). Individual TAG species were identified tentatively by comparing the relative retention time with those of TAG standards and according to the literature.[26,27]

The iodine value (IV) for the interesterified product was measured according to the AOCS Official Method Cd 1c-85 (AOCS, 2009).[25]

Slip melting point (SMP) was determined according to the AOCS Official Method *Cc* 3−25 (AOCS, 2009) using the open capillary tube method,[25] The capillary tubes filled with 1 cm high column of the samples were stored in a refrigerator for 16 h prior to the measurements in a beaker of cold water. Thereafter, the sample tube was heated gradually, and the temperature at which the sold fat in the tube began to rise, was considered to be the SMP. This measurement was performed in triplicate, and the reported SMPs were the average of the determinations.

The crystal morphology of the interesterified product was observed using a XP-203 polarized light microscopy fitted with a digital video camera. The samples were first heated at 70 °C in a water bath and maintained at this temperature for 30 min to eliminate all crystal nuclei. Afterward, about 10 mg of melted sample was placed on a preheated microscope slide, cooled to 25 °C and then held for 20 h. The crystal morphology was taken at room temperature.

## RESULTS AND DISCUSSION

**Catalyst Characterization.** A Hammett indicator method was employed to evaluate the basic properties.[17] The alumina support was acidic and could change the color of dimethylaminoazobenzene (H_= 3.3) from yellow to red, and in consistent with this, the transesterification did not proceed when the alumina support was acted as a catalyst. However, as the $KNO_3$ was loaded and subsequently calcined at 700 °C, the thus-obtained solid base catalyst showed the basic strength values (H_) of 15 < H_18.4, and the basicity of 35% $KNO_3/Al_2O_3$ catalyst was determined to be 6.97 mmol/g. Owing to the basicity, the solid catalyst displayed comparable activities to the reaction as expected.

Figure 1 gives the XRD patterns of the $KNO_3/Al_2O_3$ catalysts prepared at different conditions. As can be seen, the XRD pattern of uncalcinated $KNO_3/Al_2O_3$ sample exhibited the characteristic peaks of $Al_2O_3$ and $KNO_3$ (curve a in Figure 1).[28] Besides, there were other minor peaks, which could not be unequivocally identified. In the XRD pattern of 35%$KNO_3/Al_2O_3$ catalyst calcined at 500 °C, in addition to the XRD peaks associated with alumina, only three peaks of $KNO_3$ was observed (curve c in Figure 1). As the calcination temperature increased beyond 700 °C, the number of the XRD peak corresponding to $KNO_3$ phase was found to further decrease, indicating the decomposition of loaded $KNO_3$ during the calcination processes. In the case of 30% $KNO_3/Al_2O_3$ catalysts calcined at 700 °C (curve b in Figure 1), the diffraction lines of $Al_2O_3$ were visible; however the $KNO_3$ phases were decreased

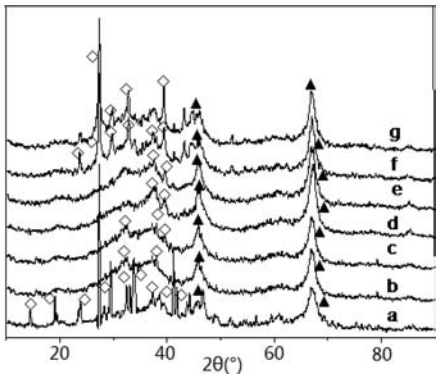

**Figure 1.** Power X-ray diffraction patterns for samples: (a) uncalcined 35%$KNO_3/Al_2O_3$; (b) 30%$KNO_3/Al_2O_3$ calcined at 700 °C; (c) 35% $KNO_3/Al_2O_3$ calcined at 500 °C; (d) 35%$KNO_3/Al_2O_3$ calcined at 700 °C; (e) 35%$KNO_3/Al_2O_3$ calcined at 800 °C; (f) 40%$KNO_3/Al_2O_3$ calcined at 700 °C; and (g) 45%$KNO_3/Al_2O_3$ calcined at 700 °C. (◇),$KNO_3$; (▲), $Al_2O_3$.

in number when compared with the uncalcined sample. With increasing the $KNO_3$ loading beyond 35%, the diffraction peaks attributed to $KNO_3$ phases were observed to increase both in intensity and in number, mostly due to the overloading of $KNO_3$ that saturated the alumina surface. At these $KNO_3$ loadings, the dispersion of excess potassium compound could mask the active base sites that serve as active sites for the interesterification reaction. However, no obvious peak for $K_2O$ phase was clearly registered in the XRD patterns. The catalytically active phase such as $K_2O$ might have been present in an amorphous state, which was not detected by XRD techniques. By drawing on the results, it is reasonable to state that the surface basicity and the subsequent catalytic activity are resulted from the decomposition of impregnated $KNO_3$ and the formation of $K_2O$ and Al—O—K groups that can act as active sites for the interesterification reactions.[18,20]

SEM techniques can be used to investigate the morphology feature of the solid catalyst. The typical SEM micrograph of alumina support and solid catalyst is illustrated in Figure 2. As can be seen, the support was presented as irregular shaped agglomerations of alumina particles with clear edges, with particle size ranging from approximately 2−5 $\mu$m. As evidenced in Figure 2, no significant morphological change was found between the alumina support and the solid base catalyst. After loading with the potassium compounds, the alumina cluster or agglomeration with clear demarcation into regions could also be observed. This observation suggested that the alumina retained its structure during the catalyst preparation process, and there was a homogeneous distribution of potassium compounds on alumina supports, which were important for catalysis.

The nitrogen adsorption−desorption isotherms of the alumina support and the prepared catalyst are presented in Figure 3. The two samples exhibited the type IV isotherm according the IUPAC classification with a obvious hysteresis loop of type H4, implying the existence of micropores with narrow pore size distributions. Clearly, a significant reduction in the adsorbed volume was observed after impregnation of alumina support with potassium compounds, mostly likely owing to the pores obstruction of the active sites in the support, evidencing the incorporation of potassium compounds into the alumina support.

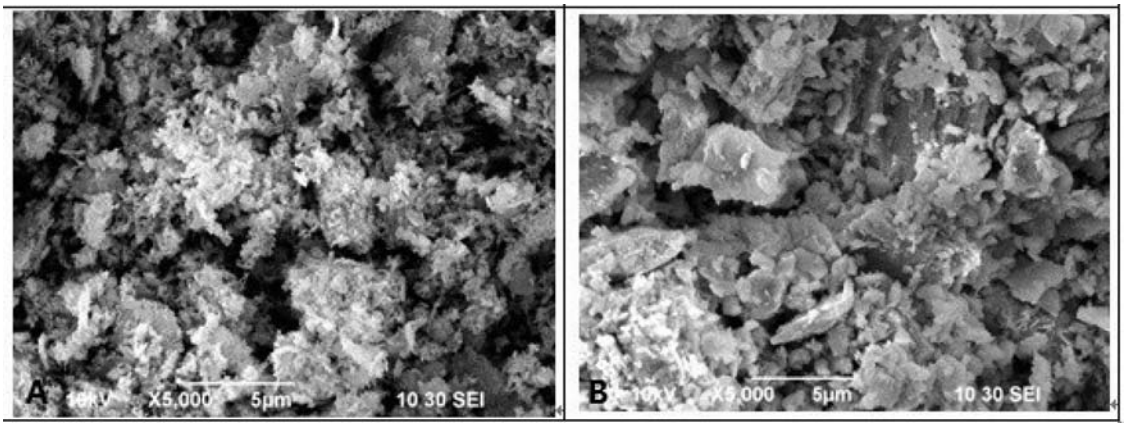

**Figure 2.** Scanning electron micrographs of samples: (a) $Al_2O_3$ and (b) 35%$KNO_3$/$Al_2O_3$ catalyst.

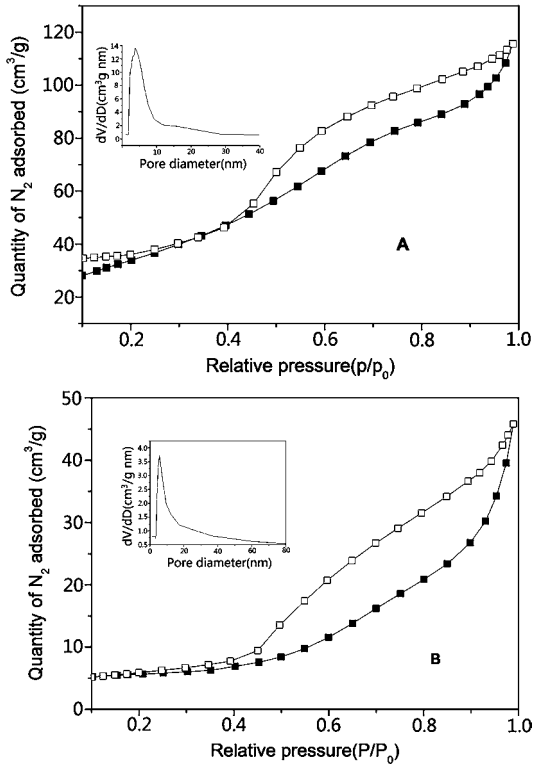

**Figure 3.** Nitrogen adsorption/desorption isotherms and pore size distribution profiles of samples: (a) $Al_2O_3$ and (b) 35%$KNO_3$/$Al_2O_3$ catalyst.

The textural properties of the solid base catalyst are shown in Table 1. The alumina support gave a surface area of 123 $m^2$/g, and an mean pore size of 5.8 nm, In the case of the solid catalyst, the surface area calculated from the $N_2$ adsorption−desorption isotherm was decreased to 19 $m^2$/g, while the pore size was decreased to 3.8 nm. Anyway, an obvious decrease of the surface area occurred after $KNO_3$ was impregnated and calcined at a higher temperature. Moreover, a decrease in the pore size and pore volume was also observed. Such results further demonstrated the potassium compounds on the alumina support were formed by the decomposition of potassium nitrates at a higher calcination temperature.

**Influence of Catalyst Preparation Conditions on the Catalytic Activities.** In the current study, the interesterification of soybean oil and methyl stearate was chosen to investigate the effect of catalyst preparation conditions on the catalytic activity. To optimize the $KNO_3$ loading, different loading amounts of $KNO_3$ were employed for the preparation of the catalyst. Table 2 shows the evolution of stearoyl incorporation on the solid catalyst with different $KNO_3$ loadings. As can be seen, the stearoyl incorporation achieved at the $KNO_3$ loading of 20% was 30.8%, and then increased to the maximum value of 50.6% with increasing the $KNO_3$ loading up to 35%. However, with subsequent increase in the $KNO_3$ loading, the stearoyl incorporation remained nearly unchanged. In light of the results, the suitable $KNO_3$ loading is determined to be 35%.

**Table 2. Different Catalyst Preparation Conditions and the Results of the Interesterification between Soybean Oil and Methyl Stearate Catalyzed by the Heterogeneous Catalyst**

| entry | loading amount of $KNO_3$ (h) | calcination temperature (°C) | stearoyl incorporation (%) |
|---|---|---|---|
| 1 | 35 | 500 | 0 |
| 2 | 35 | 600 | 0 |
| 3 | 35 | 650 | 0 |
| 4 | 35 | 700 | 50.6 |
| 5 | 35 | 750 | 46.1 |
| 6 | 35 | 800 | 38.2 |
| 7 | 20 | 700 | 30.8 |
| 8 | 25 | 700 | 37.6 |
| 9 | 30 | 700 | 46.7 |
| 10 | 40 | 700 | 48.2 |
| 11 | 45 | 700 | 45.3 |

In order to assess the effect of calcination temperature on the catalytic activity of the solid catalyst, the calcination temperature was set from 500 to 800 °C. The experimental results are also included in Table 2. As observed, the catalyst did not exhibit any activity in the transesterification reaction as the calcination temperature was below 700 °C. The maximum

stearoyl incorporation of 50.6% was achieved at a calcination temperature of 700 °C. However, when the calcination temperature was further increased beyond 700 °C, there was an obvious decline trend in stearoyl incorporation to be observed. Accordingly, the best calcination temperature is 700 °C.

**Fatty Acid Composition and Iodine Value.** The interesterification of lard and soybean oil was carried out using the solid catalyst prepared at a calcination temperature of 700 °C with a $KNO_3$ loading of 35%. Table 3 shows the total FA compositions and the iodine values (IV) of lard, soybean oil and their binary blends before and after the interesterification. The total FA profile of lard was oleic acid (38.7%), palmitic acid (26.5%), linoleic acid (17.2%), stearic acid (12.3%) and palmitoleic acid (2.5%), with the IV of 67.2. The predominant FAs in the lard were accounted to be about 40% of long-chain saturated FAs, and accordingly at room temperature the lard was usually in solid state. As shown in Table 3, soybean oil had predominantly the following FA profiles: linoleic acid (55%), oleic acid (22.2%) and palmitic acid (11.9%), with small amounts of linolenic acid (7.6%) and stearic acid (3.4%). The IV of the soybean oil was determined to be 134.5. Owing to large amounts of mono- and polyunsaturated FAs, soybean oil always exhibited a liquid state at room temperatures. The total FA profile and IV of lard and soybean oil are in agreement with those reported in the literature.[29]

As indicated in Table 3, there was no significant change in the total FA profile to be observed for the different blends of lard and soybean oil after the interesterification reaction. Moreover, the IV of the binary blends before and after the CIE reaction remained almost constant, implying that the interesterification did not affect the degree of saturation. Besides, the *trans* FAs were not detected in the interesterified blends catalyzed by the solid base catalyst, and the interesterification did not cause conjugation during the interesterification process. These results revealed that the total FA compositions of the binary blends were not significantly altered between the initial blend and the interesterified product. In spite of this, at the present study, the distribution pattern of FAs in the TAGs can influence the physicochemical and nutritional properties.

The FA compositions at *sn*-2 position for the 60:40 blend, before and after the CIE catalyzed using the solid catalyst, were investigated. The interesterification reaction did not occur without catalyst under the reaction conditions employed here. It was shown that palmitic acid, stearic acid, oleic acid, linoleic acid at *sn*-2 position for the 60:40 blend of lard and soybean oil were varied from 29.5%, 21.6%, 25.5% and 22.8% to 33.9%, 16.1%, 20.3% and 29.1%, respectively, after the CIE reaction. As a consequence, the FA compositions on the glycerol backbone were changed obviously after the interesterification reaction, and thus the solid catalyst was demonstrated to be active for the interesterification of soybean oil with lard.

**Triacylglycerol Composition.** The TAG compositions of lard, soybean oil as well as their blends before and after the interesterification, are presented in Table 4. As observed, the main TAG compositions of lard were POO (22.8%), PLL (13.7%), PStO (12.8%), PPO (9.7%), POL(8.9%), PPL (8.6%), and StOL (4.7%). The soybean oil contained a wide range of unsaturated TAG species such as PLL (20.8%), LLL (17.2%), OLL (16.3%), OOL (14.5%), POL (12.4%), and POO (4.7%). As illustrated in Table 4, for different mass ratios of lard to soybean oil, different TAG species of the reaction mixtures were obtained. Moreover, the interesterification of the blends could result in a noticeable change in the TAG species as compared to their physical blends. For example, when the 60:40 blend of lard and soybean oil was interesterified, the interesterified product showed a reduced amount on POO, POL, OLL, LLL, OOL, and StOL from 16.5%, 10.5%, 8.7%, 7.6%, 6.6%, and 3.5% to 13.2%,7.6%,5.6%,6.4%, 4.8%, and 2.8%, respectively, but an increased amount of PLL, PStO, PPO,PPL, StOL, and PPSt from 15.3%, 9.5%, 6.3%,5.2%, and 0.8% to 18.7%,12.8%,8.7%,7.8%, and 1.8% was observed as a result of the CIE reaction. Similar phenomena were also reported previously.[27] Indeed, it is difficult to evaluate quantitatively the progression of the interesterification process due to the complex compositions in the reaction mixture. According to the method described by De Clercq et al.,[30] the degree of interesterification (DI) could be evaluated on the basis of TAG composition in the interesterified product. For the 80:20, 60:40, 40:60, and 20:80 blends of lard and soybean oil, the DI for the interesterification reaction was calculated to be 47.4%,76.8%, 81.4% and 43.6%, respectively. These obtained results suggested that the solid catalyst could efficiently catalyze the interesterification reaction.

In the present investigation, to avoid hydrolysis reaction, free water was totally removed from the reaction mixture under reduced pressure prior to the interesterification process. Moreover, the acid value (AV) of the feedstocks was lowered below 0.1 mg KOH/g, since the free fatty acid could result in the deactivation of the solid base catalyst. Therefore, after the interesterification reaction, the undesirable byproducts, such as free fatty acids, monoglycerides, and diglycerides formed by the hydrolysis reaction, were not detected by TLC techniques. However, in the enzymatic interesterification catalyzed by immobilized lipase, such byproducts were formed during the reaction as water is essential to maintain the activity of enzyme.[31]

**Slip Melting Point.** In general, the melting properties vary with the TAG composition in the interesterified product, and the slip melting points (SMPs) of the samples are associated with their TAG compositions. The interesterification reactions between solid fat and liquid oil were conducted to obtain fat mixtures with better melting behavior. The SMP was determined by the open capillary tube method, and the results are presented in Table 5. It was shown that the SMPs of the physical blends and the interesterified blends were significantly different, and the proportion of lard to soybean oil had significant effect on the SMP. As observed, these physical blends showed SMPs ranging from 26.2 to 44.1 °C, and the SMP was decreased with an increase in the proportion of soybean oil in the blends mostly due to the increase of the unsaturated FAs. Notably, the interesterified blends possessed lower SMPs for all samples when compared with their physical blends, which could be regarded as another evidence for the catalyst activity. The interesterified fat had an SMP below 37 °C, showing that it could melt almost completely at body temperature. This observation has demonstrated that the heterogeneous interesterification could give an attractive method for producing new tailored-fats with desired melting profiles that meet consumer preferences.

**Table 5. Slip Melting Point of Binary Soybean Oil and Lard Blends before and after Interesterification Reaction**

| LA/SO | SMP (°C) | |
|---|---|---|
| | before CIE | after CIE |
| 80:20 | 44.1 ± 0.1 | 38.6 ± 0.1 |
| 60:40 | 39.3 ± 0.1 | 34.5 ± 0.1 |
| 40:60 | 33.4 ± 0.1 | 30.4 ± 0.0 |
| 20:80 | 26.2 ± 0.0 | 23.1 ± 0.1 |

**Crystal Structure and Crystal Morphology.** Crystal properties can greatly influence the consistency and acceptability of the final product. Small crystals result in firmer products, whereas large crystals yield a sandy mouthfeel.[32] Figure 4 shows the crystal microstructures of the selected samples. As can be seen, soybean oil displayed no any distinct crystal at a temperature of 25 °C, while lard contained a dense network of nearly globular collections of clustered crystals. For the physical blend of lard and soybean oil, the sample exhibited small spherulite and needle-shaped like structure with no evident regular pattern, which was probably resulted from a dilution of the lard microstructure. Compared with the physical blend, the interesterified sample showed a very small crystal size, less aggregation, no large crystals, and a more homogeneous distribution of the crystals. As a result, the interesterification of soybean oil with lard led to not only a decrease in the size of the crystal, but also a change in the morphology with a network of small crystal. Small crystals are necessary for margarine fats and shortenings, owing to their stabilization of air bubbles to food products. The change in textural properties can be explained by the variation in TAG compositions observed for the interesterification. The TAG composition can be responsible for arrangement of different kinds of crystals, which strongly influences the product texture.

In conclusion, an environmentally friendly catalyst based on alumina impregnated with potassium was prepared by the conventional incipient-wetness impregnation method. The prepared solid catalyst was demonstrated to be an efficient solid base catalyst for the interesterification reactions. The HPLC analysis of the TAGs and analysis of the *sn*-2 positional FA compositions showed that the CIE reaction could lead to the rearrangement of FAs in the TAGs. After the interesterification, the SMPs and crystal morphology of the interesterificated products were varied substantially. The solid catalyst has several advantages of green or sustainable chemistry for

to distinguish liquors belonging to similar flavor types or forged liquors produced by diluting industrial alcohol with water.[13] In view of reliability, accuracy, and reproducibility, the most efficient analytical methods undoubtedly depend on large equipment, including headspace solid-phase microextraction gas chromatography,[14] ambient glow discharge ionization mass spectrometry,[15] headspace solid phase microextraction−mass spectrometry,[3,16] gas chromatography−mass spectrometry (GC-MS),[1,6] and infrared spectroscopy.[17−19] However, unavoidable drawbacks such as complicated pretreatment, time-consuming procedures, requirement for professional operation, and also high cost,greatly hinder their application for in situ real-time measurements.[7,15,20] Furthermore, due to the complicated composition of ingredients in the liquor, it is rather difficult to realize an accurate recognition of the overall characteristics of hundreds of Chinese liquors through component-by-component analysis of individual sample. Hence, it is of great significance to develop a rapid and reliable method to realize convenient evaluation of the authenticity of Chinese liquor as well as easy characterization of the unique personality of each liquor sample.

Analysis methods based on sensory techniques, commonly referred to as electronic nose or electronic tongue, have offered a powerful alternative to analyze foodstuffs in the recent years.[20,21] Treating the complicated mixed sample as a single analyte, they are able to give a combined sensor response to the target and thus achieve fast yet efficient discrimination of those mixtures.[13,22] The challenge is that those sensors require relatively complicated post pattern recognition methods to collect feature information and can hardly avoid signal overlap of closely similar samples because they usually lack chemical discrimination.[22−24] In view of those shortcomings, the colorimetric sensor array stands out as a good candidate to address the above-mentioned problems.[25] Inspired by the mammalian gustatory and olfactory systems, such a sensor can give unique visible fingerprints to the complex analytes in either the liquid phase or the headgas.[26,27] Successful application of colorimetric sensor arrays has been reported to distinguish drinks including beers,[28] soft drinks,[26] coffees,[29] and also Chinese liquors.[12,23] However, the high concentration of ethanol and water in high-alcoholic Chinese liquors might not only mask the response of other compounds, which contain more individual information on the liquor rather than alcoholic strength, but also shorten the sensor life.[30] Besides, as most of the sensitive dots in the sensor array rely on nonspecific interactions such as van der Waals interaction, Lewis acid−base interaction, $\pi-\pi$ interaction, and physical adsorption, efficient discrimination of liquor samples that are similar in flavor and composition remains a big challenge.

In the present study, we fabricated a new colorimetric sensor array based on volatile markers determined by GC-MS to characterize Chinese liquor. In total 17 volatile markers were selected by applying factor analysis to fabricate a 4 × 5 sensor array sensitive to different groups of markers. Data analysis was performed by principal component analysis (PCA) and hierarchical clustering analysis (HCA) to distinguish 12 base liquor samples and 15 commercial liquors. The main focus of this study is to develop a reliable sensor to discriminate high-alcoholic liquors and to identify different commercial Chinese liquors of different brands and flavor types. This effort develops a simple method that may prove to be useful for the quality control of Chinese liquors in the market and even in mass production.

## MATERIALS AND METHODS

**Chemicals and Stock Solution Preparation.** All 12 base Chinese liquors (listed in Table S1 of the Supporting Information (SI)) were kindly provided by Luzhou laojiao Co. Ltd. (Luzhou, China), and 15 commercially available Chinese liquors (listed in SI Table S2) were purchased from a local supermarket in Chongqing city, China. 5,10,15,20-Tetraphenylporphine, 5,10,15,20-tetraphenylporphine indium, 5,10,15,20-tetrakis(pentafluorophenyl)porphyrin iron(III) chloride, and 5,10,15,20-tetraphenylporphine zinc were obtained from Frontier Scientific (Logan, UT, USA). All other indicator dyes (see SI Table S3) were supplied by Sigma-Aldrich (St. Louis, MO, USA). 2,4-Dinitrophenylhydrazine (DNPH) and ammonium ceric nitrate were purchased from Aladin Reagent (Shanghai, China). Hydrochloric acid (HCl), sulfuric acid ($H_2SO_4$), NaOH, potassium persulfate, nitric acid, absolute ethanol, and other reagents of analytical purity were all obtained from Chuandong Reagent (Chengdu, China). Porous hydrophilic membrane used for dye staining was bought from Shanghai Minglie Chemical Engineering Science Co. Ltd. (Shanghai, China). Ultrapure water was generated by a Millipore Direct-Q Water system (Molsheim, France). A PHS-3C pH detector (Shanghai Jingke Equipment, Shanghai, China), ultrasonic atomizer apparatus (Shanghai Yuyue Medical Equipment Co., Shanghai, China), and Media microwave oven were used in the study.

DNPH solution was prepared according to our previous study.[31] To be specific, 0.4 g of DNPH was added to a mixed solution of 3 mL of water and 10 mL of ethanol, and then 2 mL of concentrated sulfuric acid was added dropwise. The solution was stirred for 10 min and then went through filter paper to obtain a yellow DNPH store solution. The prophyrin solutions were prepared using DMF solution and stored in a dark place before use. Marker solutions used for sensitive dot selection were freshly prepared using a mixed solution of absolute ethanol and deionized water (60:40) upon detection. All other solutions without specification were prepared using deionized water.

**Analysis of Volatile Components in Base Liquors Using GC-MS.** An Agilent 5975I GC-MS with a 7683B automatic sampler was coupled with a FID detector to analyze the volatile components in the 12 base Chinese liquors. Using a cross-linked silica capillary column (30 mm length, 0.25 mm inside diameter, and 0.25 $\mu$m coating thickness), the initial column temperature was set at 40 °C, held for 2 min, and then heated to 80 °C at a rate of 5 °C/min; this temperature was held for 2 min and then raised to 260 °C at a heating rate of 10 °C/min and held for 10 min. High-purity nitrogen was applied as eluant gas using split sampling with a split ratio of 30:1. The sample volume for GC was 1 $\mu$L and 2−5 $\mu$L for MS. Resultant data about the volatile components were analyzed using SPSS (version 18.0) software.

**Fabrication of the Sensor Array.** After determination of the volatile markers, sensitive dyes were subsequently selected for each group of markers. A virtual library of possible combinations for different markers was first constructed according to former studies and our previous study. Practically, taking the selection of sensitive dots for acidic markers as an example, acetic acid solutions with a concentration of 0.4 g/L (average concentration of 12 base liquor samples) were prepared using 60% ethanol (in deionized water) as standard simulated samples. Because the pH of all the base liquors was detected between 3.1 and 4.1, Congo red and bromophenol blue were selected as responsive dyes. The mixture of dyes was kept in ultrasonic agitation for 10 s, and then a quartz capillary was used to deliver approximately 0.1 $\mu$L of solution onto the surface of a porous hydrophilic membrane to fabricate a selection-oriented sensor array (Figure 1A). Once printed, the arrays were placed in a 500 mL beaker saturated in nitrogen atmosphere for 30 min and subsequently dried in a 60 °C oven for 24 h, after which the oven temperature was reduced to 35 °C and the arrays were left for another 24 h.

The image of the sensor array was captured before detection; 5 mL of standard simulated sample atomized with an ultrasonic atomizer apparatus was then sprayed upon the array sealed with preservative film in Petri plate (8 cm in diameter) and held for at least 5 min before its image was taken finally. Comparing the images of the array before and after exposure to the sample, color change profiles were automatically obtained. The detailed working principle of the sensory system and data process can be found in our former study.[32] By analyzing resultant color change (RGB) and the relative standard error of parallel dots, the combination and concentration of the dyes in the sensitive dots were subsequently optimized. After optimization of all the sensitive dots, the 4 × 5 sensor array (see Figure 1B) was fabricated finally. The sensor arrays were subjected to the above-mentioned preparing procedure, and the arrays were stored in a nitrogen-flushed dark environment before use.

**Discrimination of the Liquor Samples.** After fabrication of the sensor array, 12 base liquor samples and 15 commercial Chinese liquors were analyzed subsequently. Briefly, 5 mL of liquor sample was atomized with an ultrasonic atomizer apparatus and then sprayed upon the array sealed with preservative film in a Petri plate (8 cm in diameter) and then held for 1 min. Then, it was placed in the microwave oven and treated for 2 min (400 W, 60 °C). Data acquisition was performed with a routine procedure mentioned in our previous experiments and finally analyzed using the SPSS software. It should be noted that the detection of each sample, both liquor samples and simulated ones, was performed repeatedly at least five times, and the average images were used for follow-up data analysis.

## RESULTS AND DISCUSSION

**Selection of Markers.** The composition of the volatile components analyzed by GC-MS of 12 base liquors is listed in Table 1. There were more than 30 volatile compounds in those liquors, and their concentrations varied significantly in different samples. To simplify data analysis, factor analysis method was first applied to find the principal components (PCs). Table 2 summarizes the eigen values of the correlation matrices. As can be seen from the table, the first 10 components covered >99.8% of accumulative contribution rate dominated by the first three

**Table 2. Results of Factor Analysis Using the Concentrations of Principal Volatile Components**

| component | eigen value | contribution rate (%) | accumulative contribution rate (%) |
|---|---|---|---|
| **1** | 12.918 | 40.369 | 40.369 |
| **2** | 9.217 | 28.804 | 69.173 |
| **3** | 6.213 | 19.415 | 88.589 |
| **4** | 1.262 | 3.945 | 92.534 |
| **5** | 0.876 | 2.737 | 95.271 |
| **6** | 0.758 | 2.368 | 97.639 |
| **7** | 0.283 | 0.883 | 98.522 |
| **8** | 0.195 | 0.608 | 99.131 |
| **9** | 0.158 | 0.495 | 99.626 |
| **10** | 0.064 | 0.199 | 99.852 |

PCs. Then maximum orthogonal rotation of the factor loading matrices was performed using a varimax method to find the relationship between the volatile compounds and the first three principal components. It was found that the first PC had a closer positive relationship with acetaldehyde, furfural, acetal, isoamylol, 2-butyl alcohol, *n*-propyl alcohol, isobutanol, *n*-butanol, and isoamyl acetate. Those compounds were normally regarded as the origin of taste (or mouthfeel) of Chinese liquors. Because ester compounds (ethyl acetate, ethyl butyrate, ethyl valerate, ethyl hexanoate, and ethyl lactate), which are important substances constituting the flavor of Chinese liquors,[33,34] exhibited a higher contribution rate to the second PC than other compounds, we can assume that the second component mainly depends on the flavor composition. For the third principal component, organic acids including acetic acid, butyric acid, isopropylacetic acid, and caproic acid dominated its cumulative load value (Table 3). As a result, in total 17 kinds of compounds were selected to serve as markers in the base liquors, those being acetaldehyde, furfural, acetal, isoamylol, 2-butyl alcohol, *n*-propyl alcohol, isobutanol, *n*-butanol, acetic acid, butyric acid, isopropylacetic acid, caproic acid, ethyl acetate, ethyl butyrate, ethyl valerate, ethyl hexanoate, and ethyl lactate. We subsequently reanalyzed the 12 base liquors (each with 5 control samples) using only the concentration information on the selected markers to confirm whether it can discriminate the 60 base liquor samples. As expected, PCA and HCA all showed correct discrimination of the liquors directly using the concentration information on the selected 17 markers (Figure 2B,C). Most importantly, the factor analysis result resembles closely that obtained from all of the volatile compounds, which again demonstrated the feasibility of the selected 17 volatile compounds to distinguish the base liquor samples.

**Fabrication of the Sensor Array.** Successful discrimination of Chinese liquors using sensory techniques has been reported by our group and other groups previously.[7,12,20] Because those studies rely on either complex post data analysis or nonspecific interaction between sensing materials and liquor samples, it remains a big challenge to realize in-depth recognition of each kind of Chinese liquor with respect to raw materials in production, brewing techniques, and even storage methods. In view of these problems, we endeavored to develop an easy yet efficient sensor to discriminate Chinese liquor using volatile makers selected for the base liquors. Despite the complexity of the selected 17 markers, they can be classified into 4 groups, including alcohol, acid, ester, and aldehyde, so it is not unreasonable to discriminate those liquors on the basis of

responsive materials sensitive to organic alcohol, acid, ester, and aldehyde. Considering that all of the sensitive dots are selected and fabricated in a similar way, we here choose dot, D12 (specific to alcohol), to illustrate the procedure to fabricate individual sensitive dots. Typically, when certain combinations of the dyes were selected, it was used to make a selection-oriented sensor array, which was then used to test simulated standard samples. We use Euclidean distance change (root of the sum of $\Delta R^2$, $\Delta G^2$, and $\Delta B^2$ of each sensor dot) to measure the response. As can be seen from Figure S1A (SI), different combinations of the dyes showed varied responses, and higher responses were observed when the ratios were set at 4:1 and 3:1. We finally chose 3:1 as the optimized ratio to obtain high stability of the resultant sensitive dot because it showed the lowest RSD (SI Figure S1B). Finally, in total 20 combinations were selected as sensor dots (see Table S3 (SI) for detailed information). Specifically, D11−D15 were specific to organic alcohols, D21−D23 were specific to esters (catalyzed by microwave), D24, D25, and D31 were specific to acid via acid−base reactions (see Figure S2 (SI)), and the rest were specific to aldehydes, the detection mechanism of which was explained in detail in our former study.[31]

**Discrimination of the Base Liquors with High Alcoholic Strength.** Sixty base wine samples (5 controls for each kind of

base Chinese liquor) were then selected to test the recognition ability of the newly developed colorimetric sensor array. We first studied the time-dependent response of the sensor after its interaction with the liquor samples. Figure 3 shows that the

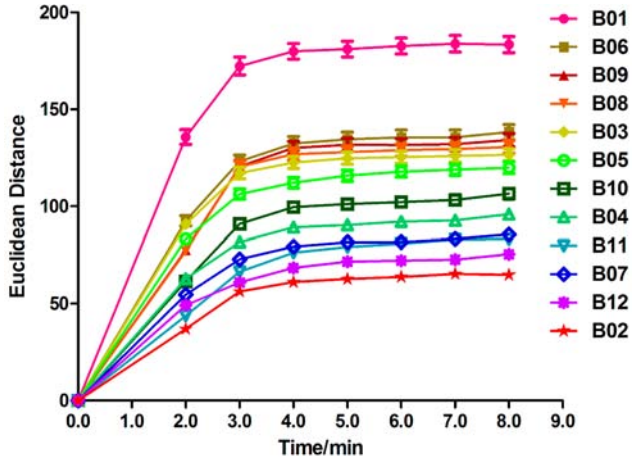

**Figure 3.** Time-dependent responses of the sensor array upon interaction with 12 base liquor samples.

Euclidean distance of all the samples increased until they reached equilibrium in 4 min. This indicates that 4 min is long enough for the interaction to establish an equilibrium. The colorful profiles of the base liquors in Figure 4A demonstrated that different base liquors showed significant difference, which can even be differentiated by the naked eye. When analyzing individual sensor dots, we found that samples BL-4 (72% in alcoholic strength) and BL-5 (72.1% in alcoholic strength) exhibited similar colorimetric responses in D11 and D12, specific to alcohols with low molecular weight (mostly ethanol), but completely different responses in other sensitive dots. This suggested that a difference in alcoholic strength did not conceal the colorimetric response of the sensor array. Besides, the responses of D11 and D12 in BL-4 and BL-5 were clearly different from other samples (even BL-10 with an alcoholic strength of 71.4%), indicating that the sensor had fine discrimination of alcoholic strength.

Statistical analysis of the data was applied to get a further understanding of the interaction between the sensor and the base liquors. The cumulative load values of individual dots for the first three principal components, which cover >70% of the cumulative contribution rate, are listed in Table S4 in the SI. The results suggested that the first one mainly relied on the discrimination of esters, the second relied on aldehydes, and the third relied greatly on organic acids, which is partly consistent with analysis by GC-MS. Results of the first two principal components are plotted in Figure 4B; the successful classification of different base liquor samples is indicative of the good discrimination ability of the sensor array. Moreover, correct clustering of the 60 samples by HCA further proved the sensor to have excellent performance in screening among different base liquors (Figure 4C), and it also realized almost the same grouping of the samples as that by GC-MS analysis (Figure 2C), demonstrating its discriminating ability comparable with that of GC-MS to some extent. Therefore, we can conclude that the colorimetric sensor developed in the present study has good performance in distinguishing different base Chinese liquors and that the recognition is based on the combination of specific affinity of individual sensitive dots to volatile markers, which constitute the specificity of different liquors, including alcohols, esters, acids, and aldehydes.

**Discrimination of 15 Commercial Liquors.** Lastly, the colorimetric sensor was applied to common Chinese liquors

that are commercially available in the supermarket. The colorimetric maps of 15 selected kinds of Chinese liquors are shown in Figure 5A. It can be seen from the figure that different brands of Chinese liquors exhibited different responses in the sensor array and the differences can also be distinguished by the naked eye. Similar to the base liquors, liquor samples of the same alcoholic strength showed analogous colorimetric responses in D11 and D12 and were hardly alike in other dots, which is again verified that it is immune to high ethanol interfering. A plot of the first two principal components is shown in Figure 5A, demonstrating again the good recognition of the commercial Chinese liquors. PCA study also suggested that the first PC mostly relied on discrimination of esters and aldehydes. The second one mainly relied on organic acids and the third greatly on alcohols, which is slight different from base liquors. Moreover, the cumulative contribution rate (65.6%) of the first three principal components for the commercial liquor was lower than that of the base liquors. This might result from the change of marker compounds in liquor aging process of the commercial Chinese liquor by base liquor as well as its storage.[35]

A HCA study was also used to analyze the data (R, G, and B valued of each dot and Euclidean distance) obtained from colorimetric reaction. It was found that control samples of the same brand clustered together without any misclassification, and different liquors of the same flavor type grouped together first, then with others. However, samples of the same alcoholic strength did not cluster close with each other in the dendrogram. Those results suggested that discrimination of the Chinese liquors by the sensor array was dominated by the flavor types, relying on esters and aldehydes, instead of alcoholic strength. Moreover, we also compared the colorimetric response of the present sensor with that depending on cross-responsive mechanism by non-specific interactions in former studies (Figure 6). This showed that the present one exhibited significantly better response to selected Chinese liquor samples, and the Euclidean distances were much higher than in the former, despite the former having more sensitive dots.

In summary, facile discrimination of 12 high-alcoholic Chinese base liquors from Luzhou Co., Ltd., and 15 commercial Chinese liquors of different brands and flavor types was achieved with a freshly developed colorimetric sensor array. On the basis of 17

volatile markers determined by GC-MS analysis and subsequent factor analysis including acetaldehyde, furfural, acetal, isoamylol, 2-butyl alcohol, *n*-propyl alcohol, isobutanol, *n*-butanol, acetic acid, butyric acid, isopropylacetic acid, caproic acid, ethyl acetate, ethyl butyrate, ethyl valerate, ethyl hexanoate, and ethyl lactate, the sensor realized correct identification of both base liquors with high alcoholic volume and commercial liquors within the same flavor type just by comparison of the color change profiles. Statistical analysis including PCA and HCA suggested that no misclassification was observed for both liquor samples, and the discrimination had a close relationship with the characteristic flavor compounds (esters, aldehydes, and acids) and alcoholic strength in the liquors. Because the response of the sensor array improved significantly in comparison with those that rely on nonspecific interactions and its discrimination ability was partly comparable with GC-MS, we can envisage its potential application for quality surveillance of Chinese liquors in the market and even in mass production.

Two of the most commonly used methods for the determination of phenolic acids are (1) a total phenolic acids method in which the substrate is subjected directly to base hydrolysis in the presence of EDTA and ascorbic acid[9] and (2) extraction and separation of soluble (free, conjugated) and insoluble bound phenolic acids followed by hydrolysis in the absence of absorbate and EDTA.[10] In the present study, we carried out a direct comparison of these two methods in refined and whole wheat flours of three wheat varieties. We subsequently investigated the effects of the major processes in refined and whole wheat breadmaking by evaluating the phenolic acid and composition in each of the three wheat varieties utilizing the total phenolic acids method. Phytochemicals were analyzed in flour (F), mixed dough (MD), proofed dough (PD), bottom crust (BCT), crumb (CM), and upper crust (UCT) fractions of all wheat varieties.

## MATERIALS AND METHODS

**Wheat and Bread Samples.** Three spring wheat cultivars representing three wheat classes, 'Westbred 936' (hard red), 'Alpowa' (soft white), and 'Blanca Grande' (hard white), were grown as previously described.[11] Grain was tempered and milled to approximately 70% extraction (refined white flour) on a Bühler MLU-202 flour mill. The particle size of bran and shorts mill streams was reduced with a pin mill so that ≥70% passed through a 180 μm sieve; reduced fractions were then blended with the refined wheat flour to produce whole wheat flour. Flour samples were stored at −20 °C prior to processing.

Bread was prepared from refined and whole wheat flours of each variety following the 100 g straight-dough pan bread test (90 min fermentation and 33 min proof are used, then doughs are baked for 21 min at 218 °C).[12,13] Dough and bread fractions were made as follows: a dough sample was frozen immediately after mixing, referred to as "mixed dough", and another dough sample was frozen after proofing, referred to as "proofed dough". After baking, the loaves were divided into the following three components: "upper crust", which represented that part of the loaf exposed directly to oven temperatures; "bottom crust", representing that part of the crust in contact with the loaf pan; and "crumb", which was everything except crust fractions. The crust components were scraped to remove the adhering crumb component. Each fraction was lyophilized and stored at −20 °C. Each flour sample was also tested as the "starting point". Dried samples were broken up with a mortar and pestle and ground in a Tecator Cemotec 1090 burr mill set at the finest setting and stored at −20 °C. Prior to analysis, each fraction was further ground to a particle size of 40 mesh using a Micromill manufactured by Bel Art Products (Pequannock, NJ, USA).

**Chemicals and Reagents.** Phenolic acid (vanillic, caffeic, syringic, *p*-coumaric, ferulic, and sinapic acids) standards and ascorbic acid were purchased from Sigma-Aldrich (St. Louis, MO, USA). Sodium hydroxide and all solvents (ethyl ether, ethyl acetate, and methanol) were obtained from Fisher Chemicals (Fair Lawn, NJ, USA). All chemicals and solvents were of either analytical grade or HPLC grade and were used directly without further purification. Ethylenediaminetetraacetic acid (EDTA) was purchased from EMD Chemicals (Gibbstown, NJ, USA). Polyvinylidene difluoride (PVDF) syringe filters with a pore size of 0.45 μm were purchased from National Scientific Co. (Duluth, GA, USA).

**Comparison of Two Phenolic Acid Methods.** Flour samples from the three wheat varieties were hydrolyzed separately by two common methods. Method A allowed separation of soluble (free and conjugated) and bound insoluble phenolic acids,[10] and method B involved direct hydrolysis of the total phenolic acids in the sample in the presence of EDTA and ascorbic acid.[14] Briefly, the ground sample was extracted with acetone/methanol/water (7:7:6, v/v/v) first to obtain the soluble supernatant and residue. Soluble free and conjugated phenolics were first acidified (pH 2) by hydrochloric acid; free phenolics were extracted by ethyl ether and ethyl acetate (1:1, v/v), and then conjugated phenolics were hydrolyzed with 2 N sodium hydroxide and acidified with 6 N HCl. Free phenolic acids were extracted with diethyl ether and ethyl acetate (1:1, v/v). The residue was stored overnight at room temperature and hydrolyzed with 2 N sodium hydroxide, acidified by hydrochloric acid, and then extracted with ethyl ether and ethyl acetate (1:1, v/v) for analysis of insoluble bound phenolic acid. After evaporation of the organic phase under nitrogen, the residue was redissolved in methanol/water (75:25, v/v) and filtered through a 0.45 μm membrane filter. The filtered extract was analyzed for phenolic acid quantification by HPLC. In method B, the ground flour sample was mixed with 2 N NaOH containing 10 mM EDTA and 1% ascorbic acid for 30 min at 40−45 °C.[15] The reaction mixture was acidified with 6 N HCl and then extracted with ethyl acetate. The organic phase was dried, and the residue was redissolved in methanol/water (75:25, v/v). Then, the extract was filtered through a 0.45 μm membrane filter and analyzed by HPLC. Four replicate base hydrolyses, extractions, and analyses of each fraction were carried out.

**Analysis of Phenolic Acids by HPLC-ESI-MS.** Quantification of phenolic acids from all samples was carried out using an Agilent 1290 Infinity LC system coupled to diode array (DA) and mass spectrometry (MS) detectors from Agilent Technologies (Palo Alto, CA, USA). Identification of phenolic acids was achieved by comparison of mass and ultraviolet spectral data as previously reported and by comparison of retention time with authentic commercial phenolic acid standards.[9,14] Briefly, separation of phenolic acids was achieved using a reversed phase C18 Luna column (150 × 4.6 mm; particle size = 5 μm) from Phenomenex (Torrance, CA, USA) at ambient temperature (between 22 and 27 °C) as previously described.[9] Separation was achieved using a binary gradient with two solvents. Solvent A was 0.1% (v/v) formic acid in water, and solvent B was 0.1% (v/v) formic acid in methanol. The flow rate was set to 1 mL $min^{-1}$. Twenty microliters was used for injection. The linear gradient consisted of 5−30% B for 25 min, followed by 30% B for 35 min, then ramped from 30 to 100% B for 10 min, and held at 100% B for 5 min. The mobile phase concentration was returned to 5% B and held for 10 min before the next injection. The mass spectral data were collected in both positive and negative ion modes at low and high fragment voltages (70 and 250 V). The instrument was set to scan from 100 to 750 mass units. The temperature of the drying gas was 300 °C at a flow rate of 12 L $min^{-1}$; the capillary voltage for both positive and negative ion modes was adjusted at 3000 V and a nebulizer pressure of 50 psi. The LC system was directly connected to a mass spectrometer with no stream splitting.

**Statistical Analysis.** Data were reported as means ± standard deviations (SD) for four replicate treatments. One-way analysis of variance (ANOVA) and Tukey's tests were performed using SPSS (SPSS for Windows, version 10.0.5, SPSS Inc., Chicago, IL, USA). Correlation analyses were performed using a two-tailed Pearson correlation test. Statistical significance was declared at $P < 0.05$.

## RESULTS AND DISCUSSION

**Comparison of Two Methods for Phenolic Acid Hydrolysis and Extraction.** There are two chemical methods commonly used for extraction of phenolic acids. Method A allowed the separation of soluble (free and conjugated) and insoluble bound phenolic acids, whereas method B directly extracted phenolic acids after base hydrolysis of the plant matrix in the presence of EDTA and ascorbic acid.[15] The results using method A (Figure 1A,B) showed that most (>82%) of the phenolic acids in all three varieties exist in insoluble bound form. These results were similar to those previously published in a study from our group and by other researchers.[10,11,16] Ferulic acid was the most abundant phenolic acid present in soluble and insoluble bound forms for all three wheat varieties. It accounted for about 64.1−67.9% of total soluble phenolic acids and for between 84.4 and 85.6% of total insoluble bound phenolic acids (Figure 1C,D). Whent et al.[11] also found that ferulic and *p*-coumaric acids were primarily in the insoluble

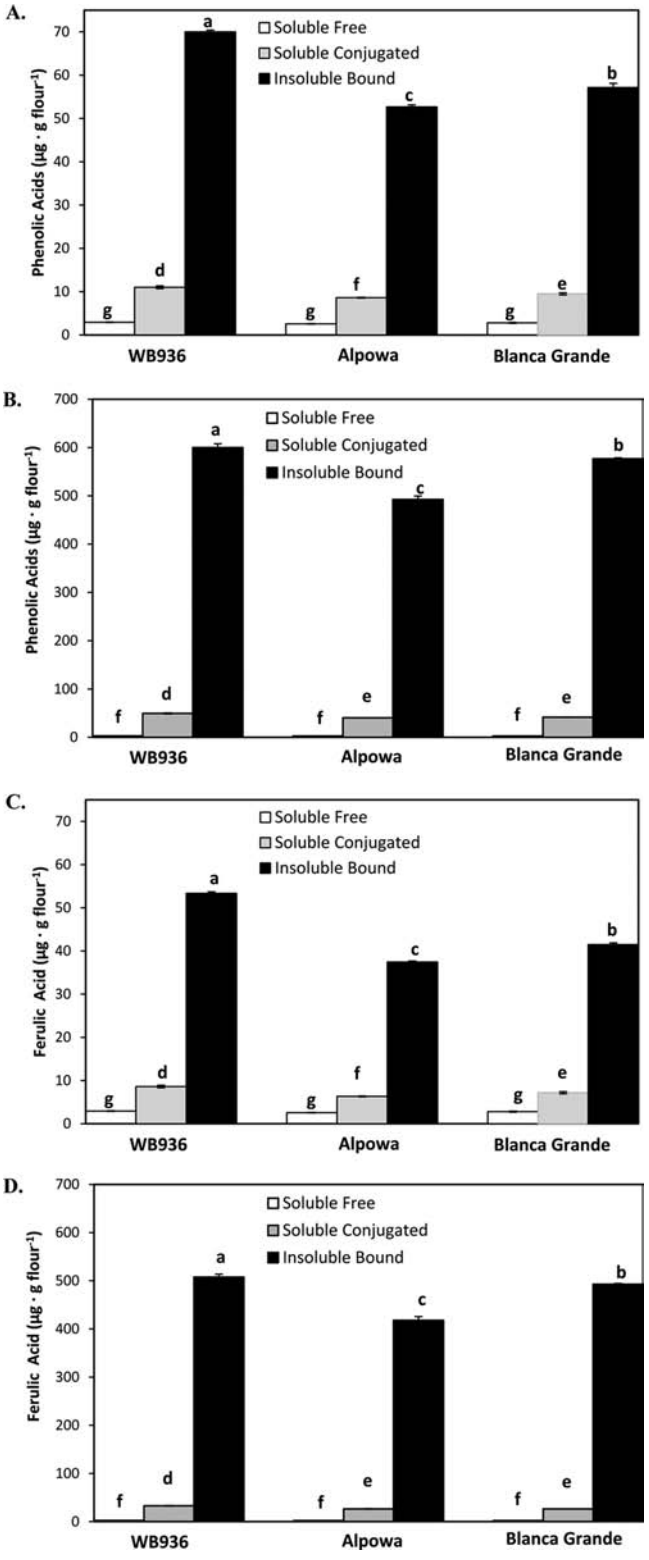

**Figure 1.** Soluble (free and conjugated) and insoluble bound phenolic acids of (A) refined wheat (RF) and (B) whole wheat (WW) flours of three wheat varieties. Soluble (free and conjugated) and insoluble bound ferulic acid of (C) refined wheat (RF) and (D) whole wheat (WW) flours of three wheat varieties. The same letter indicates no statistical difference, whereas different letters stand for significant statistical difference ($P > 0.05$).

bound form in flour samples from five wheat varieties. A similar high concentration (89.2−94.6%) of the insoluble bound form of ferulic acid has been reported in a previous study by Moore et al.[10]

The amounts of total phenolic acids quantified in all three wheat varieties using method B hydrolysis and extraction were significantly higher than those of method A ($P < 0.05$). This is primarily due to the presence of additional antioxidant ascorbic acid and chelating agent EDTA. However, method A provided useful information on the soluble and insoluble bound phenolic acids that may also have importance in the determination of the bioavailability of the bioactive phenolic acids. In the present study, method B (base hydrolysis in the presence of EDTA and ascorbic acid) was used for comparison of phenolic acids content in refined and whole wheat fractions.

**Comparison of Phenolic Acids in Refined versus Whole Wheat Fractions.** The quantities of total phenolic acids extracted from the refined flour samples were significantly lower than those from the whole wheat flour samples (Figure 2). This is in agreement with previously published papers in

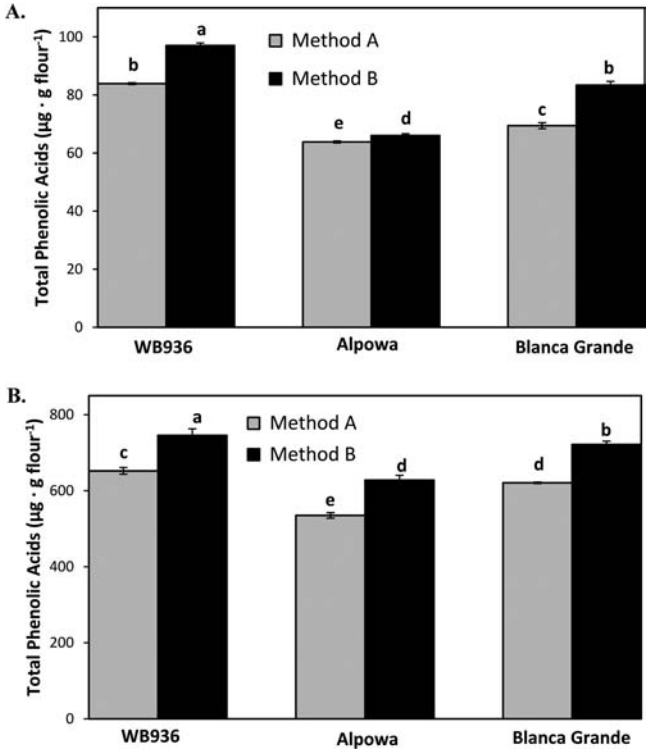

**Figure 2.** Total phenolic acids of (A) refined wheat (RF) and (B) whole wheat (WW) flours of three wheat varieties by using two extraction methods. Method A involves separation of soluble (free and conjugated) and insoluble bound phenolic acids, whereas method B allows only determination of total phenolic acids in the presence of EDTA and ascorbic acid. The same letter indicates no statistical difference, whereas different letters stand for significant statistical difference ($P > 0.05$).

which authors observed only about $^{1}/_{10}$ of the total phenolic acids content in wheat flour as compared to the whole grain flour.[17−19]

The phenolic acid composition and content in refined (RF) and whole wheat (WW) flour (F), mixed dough, proofed dough, bottom crust, crumb, and upper crust are presented in Tables 1, 2, and 3. In terms of overall abundance, FA was the most abundant phenolic acid, accounting for a mean of 59% (range from 51 to 68%) of TPA among RF fractions and a

mean of 81% (range from 76 to 86%) among WW fractions. Sinapic acid was the second most abundant phenolic acid, accounting for means of 13 and 8.5% of TPA in RF and WW fractions, respectively. Among the fractions evaluated, TPA ranged from 5.5- to 9.8-fold greater in WW fractions than in RF fractions (Tables 1−3). All individual phenolic acids were also higher in WW than in RF fractions (Tables 1−3). The greatest increases came from FA and sinapic acid, which had 11.5- and 5.5-fold increases, respectively, in WW compared to RF when averaged across fractions and varieties. Our results are consistent with previous studies demonstrating that total phenoilc acids were around 10-fold greater in whole wheat than in refined wheat products and are also consistent with our additional work on two other varieties.[19,20] In addition, Baublis et al.[21] reported that antioxidant activity was better in whole wheat than in refined wheat products.

The dramatic increase in FA in WW compared to RF fractions was correlated with previously demonstrated higher levels (8.4−15.5-fold) of FA in rye bran than in RF flour.[22] Ferulates were also far more abundant (ca. 100-fold) in the outer tissues of the wheat kernel, including aleurone and pericarp, compared to the starchy endosperm tissue; ferulate ester and ether cross-linkages were most abundant in the outer pericarp.[4] The latter observations indicate that FA is far lower in the endosperm, consistent with our observation that FA is far lower in RF compared to WW fractions.

**Comparison of Processing Fractions within Each Variety.** In comparison of the phenolic acid compositions among the six RF fractions, the upper crust fraction had the highest TPA of all fractions in all three varieties. RF upper crust also had the highest FA content in 'WB936' and 'Alpowa' (Tables 1−3). However, in 'Blanca Grande', FA content in the upper crust did not stand out among the fractions. Among the three RF bread fractions, the crumb fraction had the lowest TPA levels in 'WB936' and 'Blanca Grande', but in 'Alpowa' the bottom crust TPA was lower than that of the crumb. Both mixed and proofed dough fractions generally had slightly lower TPA and FA than bread fractions. However, the two dough fractions were similar, suggesting that fermentation had little effect on FA and TPA contents. When the effect of processing

of RF fractions on the minor phenolic acids, that is, those other than FA, was examined, some trends were noted. In two of three varieties, the highest levels of vanillic, caffeic, and sinapic acids were seen in the RF upper crust, similar to the trends noted above for FA and TPA. Also, the lowest levels of vanillic, caffeic, and *p*-coumaric acids were seen in the RF flour of all three varieties, suggesting the possibility that the availability to hydrolysis or chemistry of these phenolic acids may be altered during processing.

The TPA trends among WW and RF fractions were similar as the upper crust, bottom crust, and flour fractions were generally higher than crumb, mixed dough, and proof dough fractions. TPA and FA in the dough fractions were, on average, similar to those in the crumb fraction. As in RF fractions, the TPA and FA levels were generally similar in the two WW dough fractions. No consistent trends were observed in examination of the effect of processing on the minor phenolic acids of WW fractions.

It is a safe generalization that, in our study, the total process of preparing bread did not decrease TPA, FA, and other phenolic acids. Similarly, Mattila et al.[19] found that baking did not significantly reduce the concentration of phenolic acids. In both RF and WW fractions we generally observed a slight decrease in TPA and FA in preparing dough fractions from flour. Accordingly, decreases in individual insoluble bound phenolic acids during dough preparation have also been reported by Abdel-Aal and Rabalski.[8] Similarly, Han and Koh[23] found an approximately 40% decrease in antioxidant activity in dough compared to flour samples.

The decrease generally observed in dough preparation was more than compensated for by an increase in TPA and FA in baked bread fractions. The increase during baking appeared to be correlated with temperature, because the upper crust (highest temperature) most often had the highest TPA and FA levels. It is possible that intense heat rendered phenolic acids more physically accessible or chemically more susceptible to the hydrolysis process. Similar increases in phenolic acid levels and antioxidant activity during baking were reported in two other studies[8,22] and in our own evaluations in two other wheat varieties.[20]

**Comparison of Wheat Varieties.** When RF fractions for the three varieties were compared, TPA and FA contents were always highest in 'WB936', intermediate in 'Blanca Grande', and lowest in 'Alpowa' (Tables 1−3). In the WW fractions, TPA and FA contents for 'Alpowa' were consistently lowest as expected, but there was no consistent trend in the relative levels of TPA or FA when 'WB936' and 'Blanca Grande' were compared. Specifically for the WW flour fraction, however, FA content was greatest in 'WB936', intermediate in 'Blanca Grande', and lowest in 'Alpowa' (Tables 1−3), as previously reported.[11]

**Conclusions.** We investigated the effect of the breadmaking process and wheat varieties on the quantities of phenolic acids of refined and whole wheat fractions. Two commonly used base hydrolysis methods for the analysis of phenolic acids were tested. Method A provided information on the soluble (free and conjugated) and insoluble bound phenolic acids, which may have significantly different bioavailabilities and nutritional properties. Using method A, insoluble phenolics were far more abundant than soluble formsm but both soluble and insoluble phenolics were several times more abundant in WW flour than in RF flour (Figure 1A,B). Using both methods A and B, FA was the predominant phenolic acid present in both soluble and bound insoluble forms for all three wheat varieties. In method B, the whole sample was directly hydrolyzed in the presence of ascorbic acid and EDTA and showed 5−17% higher yields of TPA than method A (Figure 2).

The effects of processing and varieties on phenolic composition in RF and WW fractions were evaluated using method B. FA was the most abundant phenolic acid, accounting for means of 59 and 81% of TPA among all RF and WW fractions, respectively. All phenolic acids measured were more abundant in WW than in RF fractions (Tables 1−3). The greatest increase came from FA, which had an 11.5-fold increase in WW compared to RF when averaged across fractions and varieties.

Evaluation of the effects of the processing steps revealed that TPA and FA tended to decrease slightly in both RF and WW doughs compared to flour. However, the two dough fractions generally had similar TPA and FA levels, indicating that

fermentation had little effect. The decrease generally observed in preparing dough was more than compensated for by an increase in TPA and FA in both RF and WW bread fractions. The increase during baking appeared to be related to temperature, because the upper crust, exposed to the greatest heat, generally had the highest TPA and FA levels. It is possible that intense heat rendered phenolic acids more physically accessible or chemically more susceptible to the hydrolysis process.

When RF fractions for the three varieties were compared, TPA and FA contents were always highest in 'WB936', intermediate in 'Blanca Grande', and lowest in 'Alpowa' (Tables 1−3). In the WW fractions, TPA and FA contents for 'Alpowa' were consistently lowest as expected, but there was no consistent trend in the relative levels of TPA or FA when 'WB936' and 'Blanca Grande' were compared.

In summary, we observed slightly higher TPA yields when samples were directly hydrolyzed in the presence of ascorbate and EDTA (method B) than when a procedure that omitted these reagents (method A) was used. Among the three varieties evaluated, 'WB936' and 'Blanca Grande' consistently had higher TPA levels than 'Alpowa'. The effects of processing on phenolic acid composition were evaluated using direct hydrolysis (method B). TPA generally decreased slightly in dough compared to flour, but increased during baking, which was especially notable in the upper crust fraction, which was exposed to the most intense heat. Results clearly indicated that the phenolic acids measured do not decrease, and may even increase slightly, when bread is prepared from RF and WW flour.

straw bound more of the hydrolytic enzymes (*Trichoderma reesei* Cel7A and Cel7A-core) compared to the non-pretreated analogues.[16] This indicates that chemical changes that are detrimental to the saccharification process take place within the lignin structure during the SE process. Several studies regarding the impact of SE on the lignin structure have been reported. The major effects are the decrease in the level of $\beta$-O-4′ units and an increase in the level of C−C condensed structures and other interunit linkages ($\beta$-1′ and $\beta$-5′) formed via radical coupling reactions.[17−19] Dependent upon the SE conditions, the formation of higher molecular weight lignins has been observed, explained by competing depolymerization and repolymerization reactions.[19]

The aim of the present study was to elucidate the chemical changes within the enzymatic mild acidolysis lignin of wheat straw structure, caused by the SE process. NMR techniques using state-of-the-art pulse variations [quantitative 2D $^1$H−$^{13}$C HSQC, 2D $^1$H−$^{13}$C HMBC, and one-dimensional (1D) $^{31}$P NMR]

have been applied for the structural characterization of the lignins. Density functional theory calculations have been used to support the proposed routes in which coupling reactions are followed by homolytic cleavage of the $\beta$-O-4′ linkages. The structure of lignin in wheat straw has been elucidated previously. Also, the incorporation of tricin in the lignin via $\beta$-O-4 in G units has been reported.[3] In this study, quantitative data about the removal of tricin during SE were obtained by a novel $^{31}$P NMR method. Homolytic cleavage of $\beta$-O-4 substructures in the lignin during SE was also elucidated using theoretical calculations, and a comparison was carried out using model systems (G−O−G, G−O−S, and G−O−T).

## MATERIALS AND METHODS

**Lignins and Lignin Model Compounds.** Lignins were isolated from raw wheat straw (MTT Agrifood Research, Jokioinen, Finland) before and after SE treatment, employing the enzymatic mild acidolysis lignin (EMAL) isolation method.[20,21] The milled wheat straw sample was pretreated with steam at 200 °C using a 10 min residence time, and the treatment was terminated by fast release of pressure. Isolation of EMAL lignin from non-treated and SE treated wheat straw involved the following four main steps: extraction of acetone-soluble material, ball milling, enzymatic hydrolysis of cell wall carbohydrates, and lignin extraction with a mildly acidic dioxane/water mixture. The lignin isolation procedure is explained in more detail in the literature.[16] 4′,5,7-Trihydroxy-3′,5′-dimethoxyflavone (tricin) was purchased from SelectLab Chemicals GmbH (Bönen, Germany) and used as received.

**2D $^1$H−$^{13}$C HSQC and HMBC NMR Measurements.** For the 2D $^1$H−$^{13}$C HSQC and HMBC experiments, 50 mg of the lignin sample was dissolved in 1 mL of dimethyl sulfoxide (DMSO)-$d_6$, and the experiments were carried out at 30 °C on a 600 MHz Bruker Avance III NMR spectrometer equipped with a CPQCI cryoprobe. The quantitative HSQC spectra were acquired using echo/anti-echo time proportional phase incrementation (TPPI) selection, and matched sweep adiabatic pulses optimized for $^{13}$C sweep width of 200−50 ppm were used for all 180° $^{13}$C pulses to compensate for the differences in the $^1J_{CH}$ coupling constants.[22] The HMBC experiments were optimized for 8 Hz (62.5 ms) long-range couplings. Matrices of 2048 × 256 (HSQC) or 2048 × 512 (HMBC) data points were collected and

[a]Signal identification was carried out according to the literature.[3,25]

zero-filled once in F1, and a $\pi/2$-shifted squared sine bell weighting function was applied in both dimensions prior to the Fourier transformation.

**$^{31}$P NMR Measurements and Size-Exclusion Chromatography (SEC) Analyses.** For $^{31}$P NMR analyses, the lignin samples and tricin were phosphorylated and the freshly prepared samples were measured with $^{31}$P NMR at room temperature. The experimental procedure has been explained in detail previously.[23] A 500 MHz Bruker Avance III NMR spectrometer equipped with 5.0 mm broadband observe (BBO) probe was used for the measurements. Chemical shifts are relative to the reaction product of water with tetramethyldioxaphospholane, which gives a sharp signal in pyridine/$CDCl_3$ at 132.2 ppm. The following NMR parameters were used: scans, 512; pulse delay, 5 s; Lorentzian line broadening, 4 Hz.

SEC analyses were carried out using a HPLC system (Waters Corp., Milford, MA) equipped with 8 × 3000 mm MCX 1000 and 100 000 Å columns (Polymer Standard Services, Mainz, Germany) and a Waters 2998 UV detector (Waters Corp., Milford, MA) set at 280 nm using 0.1 M NaOH eluent (0.5 mL/min flow rate). For the SEC analysis, lignins were dissolved in 0.1 M NaOH (1 mg/mL) solutions overnight, followed by filtration through a 0.45 $\mu$m polytetrafluoroethylene (PTFE) syringe filter. Results were calculated relative to polystyrenesulfonate sodium salt standard using Waters Empower 3 software.

**Table 2. Amount of Main Interunit Linkages and Structural Characteristics Detected in Wheat Straw before (EMAL) and after the SE Treatment from the Integration of $^{1}H-^{13}C$ Correlation Signals in HSQC NMR Spectra**

[a]Expressed as the number per 100 $C_9$ units ($0.5S_{2,6} + G_2$). [b]$H_\beta$–$C_\beta$ correlation signal integral.

**Density Functional Calculations.** All calculations were performed with Gaussian 09, C.01 using the facilities of the Alabama Supercomputer Center in Huntsville, AL. All structures were optimized at the M06-2X level of theory, using the 6-311++G(d,p) basis set and the fine grid consisting of 75 radial shells and 302 angular points per shell. Frequency calculations were performed on the stationary points identified. Bond dissociation enthalpies were determined as the difference between the enthalpy of the reactant and products.

## RESULTS AND DISCUSSION

The amounts of the lignin units and the detected interunit linkages in wheat straw EMALs before and after steam explosion treatment were determined by 2D $^{1}H-^{13}C$ HSQC NMR experiments (Figure 1). The lignin subunits detected are presented in Figure 2, and the spectroscopic assignments based on the literature are presented in Table 1.

The quantitation was based on the assumption that the $C_2$ position in G units and the $C_2$ and $C_6$ positions in the S units are not substituted. Thus, ($G_2 + S_{2,6}/2$) was used as an internal standard. The interunit linkages were determined by careful integration of the $H_\alpha$–$C_\alpha$ correlation signals in the HSQC NMR spectra (with the exception of $H_\beta$–$C_\beta$ in the $\alpha$-oxidized $\beta$-O-4′ structure) and comparing to the total $C_9$ unit integral. $H_\gamma$–$C_\gamma$ correlation signals originating from resinol structures were shown only as a trace in the HSQC NMR spectra. Calculated amounts of the main interunit linkages and structural characteristics are shown in Table 2. It was observed that the S-type $\beta$-O-4′ interunit linkages were cleaved preferentially (36% decrease), whereas no cleavage on $\beta$-O-4′ in the G type was observed. Recently, incorporation of tricin into the wheat straw lignin via $\beta$-O-4′ in the G unit has been reported.[3] Accordingly, also, these linkages were cleaved during the SE treatment, leading to significant loss of tricin

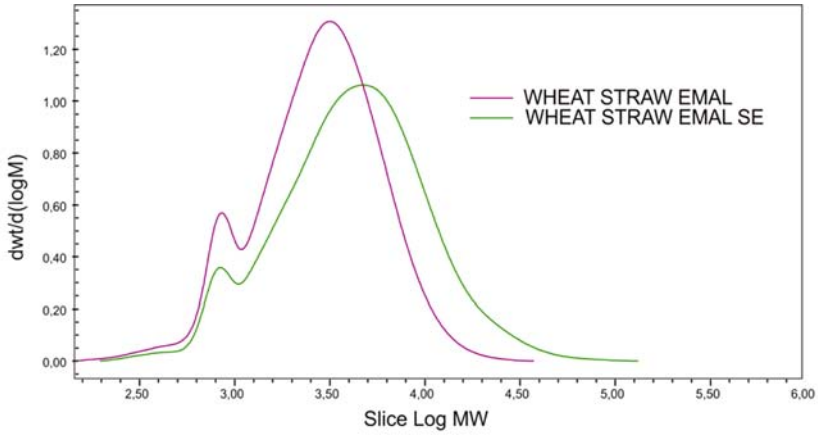
(85% decrease). The result is in accordance with the literature,[19] where the cleavage of $\beta$-O-4′ structures during SE is depicted as one of the most predominant depolymerization reactions in lignin. Our results show that various $\beta$-O-4′ substructures differ in the tendency to cleave.

The SE treatment also caused an increase in the average lignin molar mass ($M_w$) from 3600 to 6100 as measured with SEC (Figure 3).[16] This was contradictory with the observed rather high degree of cleavage of the aryl ethers but can be explained by competing repolymerization reactions.

From Table 2, it can be seen that SE alters the lignin structure in several ways. Besides the decrease in the content of $\beta$-O-4′, an increase in the amount of phenylcoumaran ($\beta$-5′) interunit linkages after the SE treatment was also detected. Upon heating lignin with water, rearrangement from alkyl-aryl ether ($\beta$-O-4′) to phenylcoumaran ($\beta$-5′) has been previously reported.[24] It has been proposed that this rearrangement is initiated by the homolytic cleavage of $\beta$-O-4′, followed by the formation of the new linkage. To evaluate if the conclusions made based on the NMR analyses are sound from the theoretical point of view, calculations were performed to elucidate the thermodynamic feasibility of the rearrangement reaction.

The results also indicated that the SE treatment of wheat straw caused a substantial decrease of cinnamic acids, particularly *p*-coumaric acid, which acylates a portion of $\gamma$-OH of the lignin side chain in grasses, and may thus be hydrolytically cleaved during the autocatalytic SE treatment. The higher levels of the *p*-coumarates (11 per $C_9$) in comparison to the value presented in the literature [4% in milled wood lignin (MWL) wheat straw] may be explained by the milder hydrolytic conditions applied in the EMAL process compared to MWL isolation.

The wheat straw lignin samples were analyzed by $^{31}$P NMR to obtain more information on the hydroxyl groups on lignin. Because the lignin was known to contain tricin, it was necessary to apply a model compound for signal verification in the $^{31}$P NMR spectrum. As a consequence, a novel quantitative



| Sample | Mn | Mw | PD |
|---|---|---|---|
| WHEAT STRAW EMAL | 2 100 | 3 600 | 1.7 |
| WHEAT STRAW EMAL SE | 2 700 | 6 100 | 2.2 |

**Figure 3.** Calculated SEC results of wheat straw lignins before (purple) and after (green) the SE treatment. Both $M_n$ and $M_w$ of the wheat straw lignin increased after the SE treatment, alongside with the polymerization degree (PD).

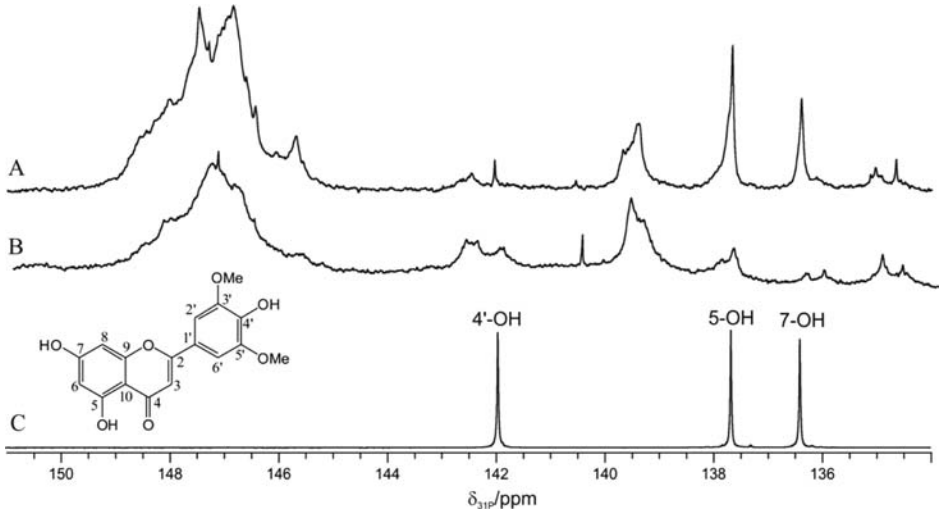


**Figure 4.** (A) $^{31}$P NMR spectrum of wheat straw EMAL, (B) $^{31}$P NMR of SE-treated wheat straw EMAL, and (C) structure of tricin with $^{31}$P NMR showing three different −OH groups in the molecule.

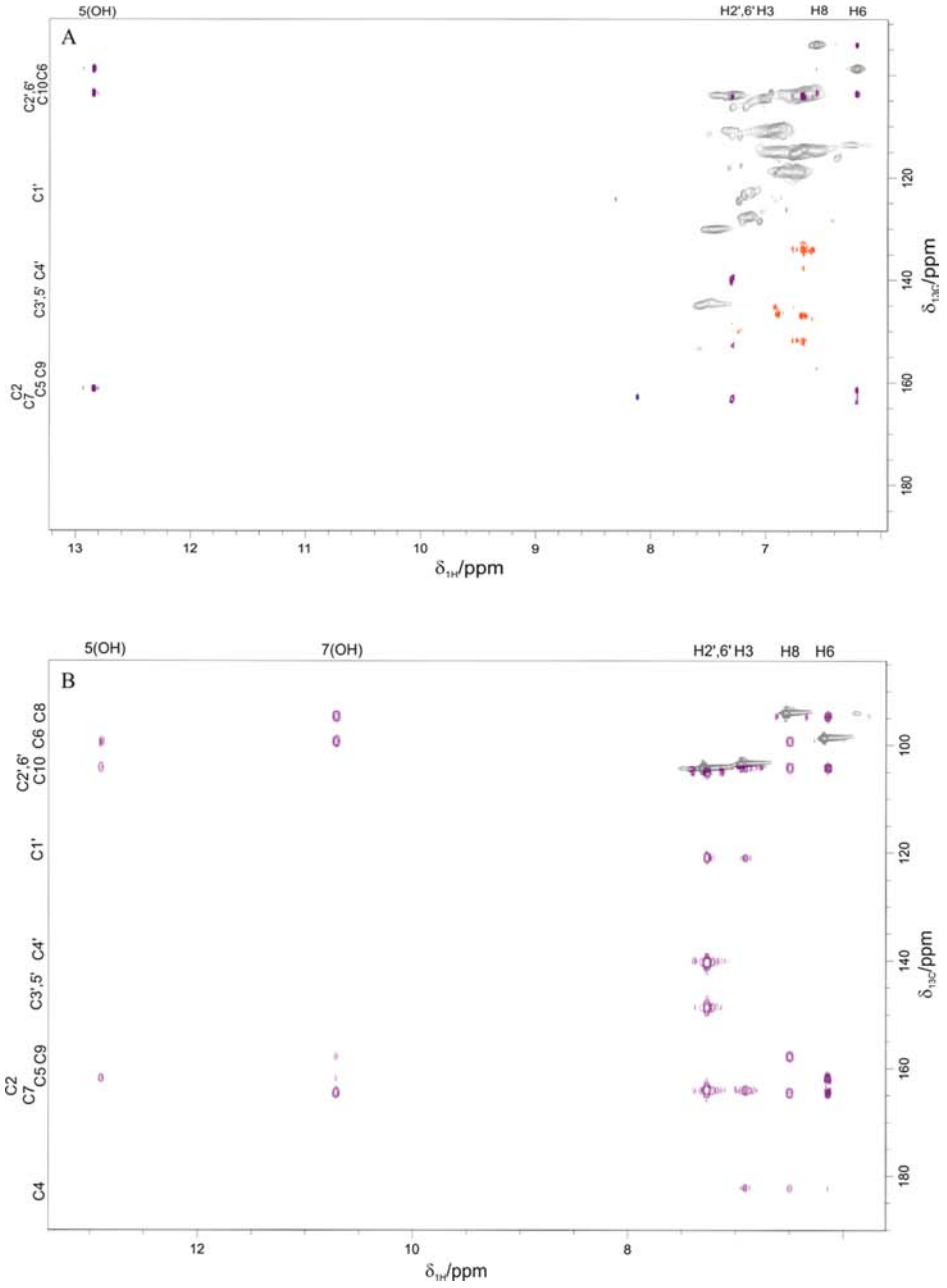

**Figure 5.** (A) Stacked HSQC (gray) and HMBC (violet) NMR spectra of wheat straw EMAL and (B) stacked HSQC (gray) and HMBC (violet) NMR spectra of the tricin model compound, showing the main long-range correlations recorded with Δ = 62.5 ms. Long-range correlation signals not originating from tricin are shown in orange.

method for tricin was developed. In addition, a comparison of the model compound and the wheat straw lignin showed evidence of 4′-OH of tricin being the linking site to lignin. The $^{31}$P NMR spectra of the phosphitylated lignins before and after SE pretreatment along with a pure tricin model compound sample are shown in Figure 4.

As seen from the $^{31}$P NMR spectrum (Figure 4C), the pure tricin (4′,5,7-trihydroxy-3′,5′-dimethoxyflavone) molecule shows three distinct chemical shifts at 136.40, 137.67, and 141.96 ppm. We have tentatively assigned these to 7-OH, 5-OH, and 4′-OH hydroxyl groups, respectively. In the literature, the chemical shift at 136.40 ppm has been previously detected and reported as phenol hydroxyl in unknown structures.[25]

The tricin signals found in the wheat straw EMAL lignin $^{31}$P NMR spectrum (Figure 4A) are much more intense in the sample before the SE treatment, confirming the presence of tricin in wheat straw lignin and its partial cleavage in the SE pretreatment. The quantitative results of tricin contents prior to and after the SE treatment are 0.15 and 0.02 mmol/g of lignin, respectively, determined using the tricin peak of $C_7$−OH for quantitation. Furthermore, the signal of the 4′-OH group was significantly less intense than the two others, indicative of its role in linking to lignin. Tricin incorporation into the lignin network through $\beta$-O-4′ ether linkages was thus confirmed both by $^{31}$P NMR and based on the tricin $C_{4'}$ carbon chemical shift ($\delta_{^{13}C}$, 139.6 ppm).

Figure 5 presents the long-range $^{13}$C−$^{1}$H correlations of the tricin moiety between the wheat straw EMAL sample and the tricin model compound. Interestingly, $C_7$−OH correlation ($\delta_{^{1}H}$, 10.7 ppm in model compound) is missing in the wheat straw

dx.doi.org/10.1021/jf504622j | J. Agric. Food Chem. 2014, 62, 10437−10444

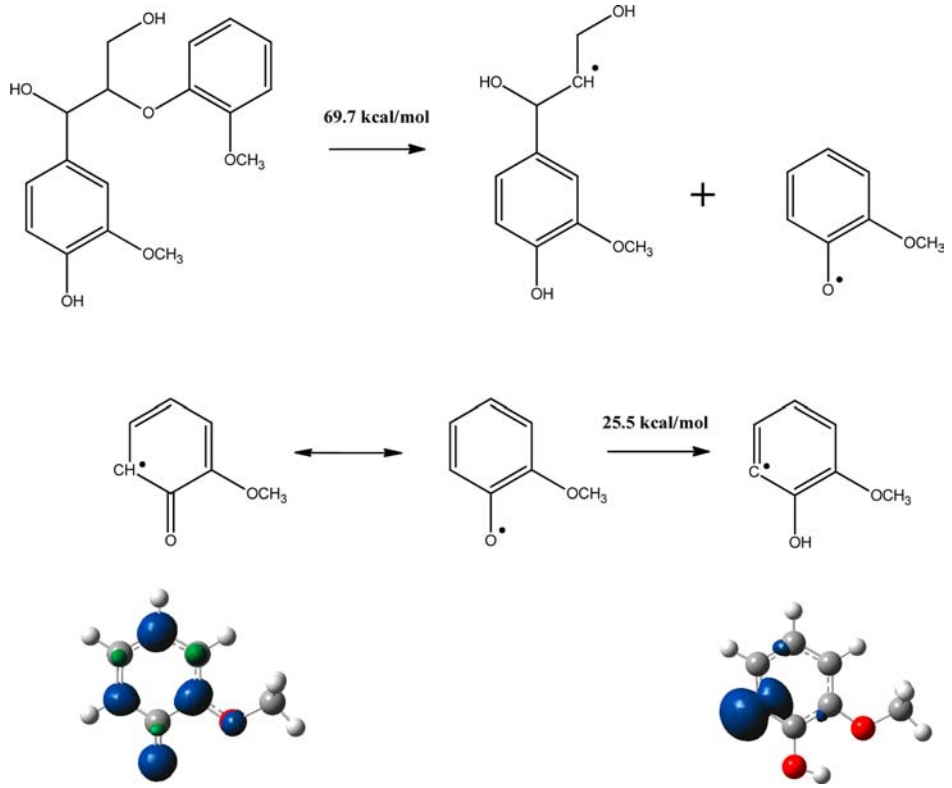

**Figure 6.** Homolytic $\beta$-O-4 cleavage reaction in G−O−G with formed phenoxy radical tautomers. The illustrations represent spin densities.

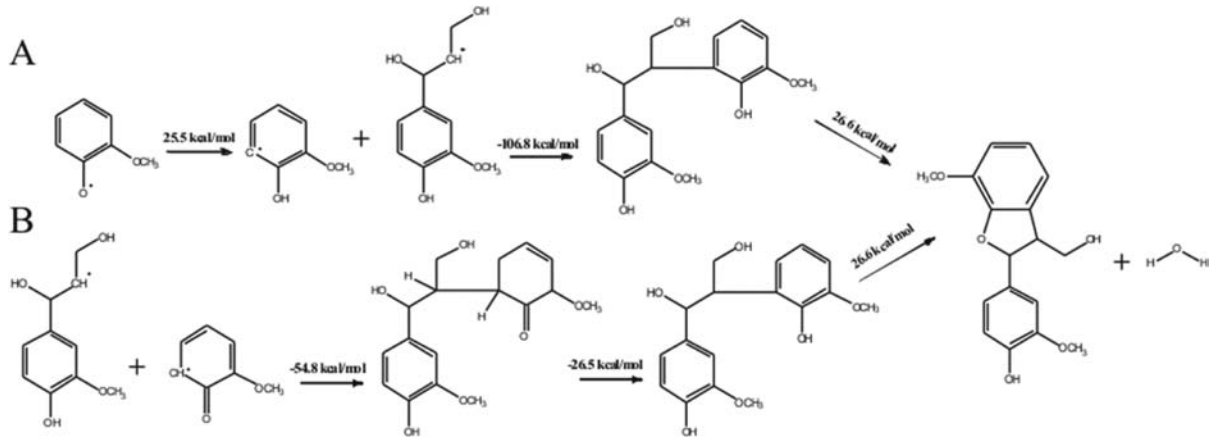

**Figure 7.** Schematic presentation of two routes (A and B) for the $\beta$-O-4 to $\beta$-5 transformation.

EMAL spectrum, even though $C_5$−OH ($\delta^1_H$, 12.9 ppm in wheat straw and model compound) is easily detectable. This may be due to higher acidity of $C_7$−OH. Some of the long-range correlations of the tricin are also missing from the wheat straw EMAL spectrum, indicating the impact of the presence of lignin and carbohydrates toward the visibility of long-range correlations. We also noticed that the tricin T8 $^1H-^{13}C$ correlation signal ($\delta_C/\delta_H$, 94.1/6.56) shows a small shift upfield ($\delta_C/\delta_H$, 93.8/6.38) after SE treatment, whereas the T6 signal was not shifted.

The feasibility of the postulated lignin reactions during the SE treatment were evaluated by comparing the bond dissociation energies. The $\beta$-O-4 bond dissociation energies for the homolytic cleavage reactions were calculated for G−O−G-, G−O−S-, and G−O−T-type $\beta$-O-4 structures. G−O−G showed the highest dissociation energy (69.7 kcal/mol); G−O−S showed intermediate dissociation energy (68.4 kcal/mol); and G−O−T showed the lowest dissociation energy (67.9 kcal/mol). These values are in accordance with the 2D NMR data (Table 2), which indicated the order of stability of $\beta$-O-4′ structures to be G−O−G > G−O−S > G−O−T.

Figure 6 presents an example of the homolytic $\beta$-O-4 cleavage, including G−O−G moieties with relevant tautomerization of the phenoxy radical and including the spin densities of the alternative radical forms.

The feasibility of possible reaction routes leading to the homolytic $\beta$-O-4 cleavage was evaluated on the basis of their energetic requirements. Two possible reaction routes (A and B) for the cleavage, followed by transformation to the $\beta$-5 substructure are presented in Figure 7.

The first route (A) requires and includes the formation of a tautomer from the phenoxy radical, while the second route (B)

dx.doi.org/10.1021/jf504622j | J. Agric. Food Chem. 2014, 62, 10437−10444

couples the phenoxy radical and β-O-4 radical without the need for tautomerization. Altogether, the transformation from β-O-4 to β-5 (+water) substructure requires energy of around 15 kcal/mol, which could be adequately provided by the SE process. It is worth pointing out that the β-5 dilignol is actually a more stable form than the original β-O-4 dimer by 11.6 kcal/mol.

In conclusion, homolytic cleavage of the β-O-4 linkages and recoupling to β-5 linkages were identified as the main reaction types of lignin in SE treatment. The β-O-4 bond dissociation energies for the homolytic cleavage reactions were calculated for G−O−G (69.7 kcal/mol), G−O−S (68.4 kcal/mol), and G−O−T (67.9 kcal/mol) type β-O-4 structures. This was confirmed by 2D $^{1}H-^{13}C$ HSQC and $^{1}H-^{13}C$ HMBC NMR data, indicating nearly complete removal of tricin and significant reduction of G−O−S units. We also postulated means to identify and measure the amount of tricin in the lignin sample with the aid of a 1D $^{31}P$ NMR experiment.

The development of biomass pretreatment methods in the field of biorefinery is of vital importance for generating value-added biomaterials and chemicals. The presence of tricin as part of the lignin structure may generate more diversity in the use of lignin as a feedstock for value-added products. The cleavage of tricin from lignin may also enhance saccharification, even if the mechanism for this cannot be explained on the basis of the present results.

In this study, we aimed to develop new types of substrates consisting of monolayer graphene, gold film, and/or AuNRs structures. The performance of these substrates was evaluated in SERS measurement for the detection of three types of pesticides. Multivariate statistical analysis such as partial least-squares (PLS) was used in data analysis for the quantification of the analytes, and the detection limits of the target analytes were obtained and evaluated.

## MATERIALS AND METHODS

**Preparation of Chemicals.** Cetyltrimethylammonium bromide (CTAB), silver nitrate, ascorbic acid, and $HAuCl_4$ were purchased from Sigma-Aldrich (St. Louis, MO, USA). Silicon wafers were purchased from Ted Pella (Redding, CA, USA). Two OP pesticides (azinphos-methyl and phosmet) and one CB pesticide (carbaryl) were purchased from Fisher Scientific (Pittsburgh, PA, USA). All of the glassware was carefully washed with aqua regia freshly prepared before experiments.

Pure pesticide solutions of 100 ppm (w/v) stock solutions of azinphos-methyl, phosmet, and carbaryl were prepared in volumetric flasks using a mixed solvent system (acetonitrile/$H_2O$ = 1:1, v/v). Solutions of 0.01, 0.1, 0.5, 1, 10, and 50 ppm pesticides were prepared by serial dilutions from the 100 ppm solution. The solvent without pesticides was used as the control.

**Gold Film Silicon Substrate.** A thin layer of gold was deposited on a silicon wafer or monolayer graphene substrate (Graphene Supermarket, NY, USA) in a desktop sputter coater (Quorum Technologies K650X, UK). Samples were grown with an argon pressure of 0.06−0.09 mbar. The thickness of gold film was measured by a quartz crystal microbalancer.

**Synthesis of Gold Nanorods.** AuNRs were synthesized using a seed-mediated method. Seed solution was prepared by adding 120 $\mu$L of a freshly prepared ice-cold solution of 10 mM sodium borohydride into 0.1 mL of 0.1 M CTAB and 0.1 mL of 5 mM $HAuCl_4$ aqueous solution at 25 °C. The resulting pale brown solution was vortexed for 2 min and then stored at 25 °C for 1 h in the dark. Growth solution was prepared by mixing 42.5 mL of 0.1 M CTAB, 1.35 mL of 10 mM $HAuCl_4$, 0.27 mL of 10 mM silver nitrate, and 0.65 mL of 0.1 M ascorbic acid. The solution was homogenized by gentle stirring, and to the resulting colorless solution was added 0.075 mL of freshly prepared seed solution followed by gentle stirring for 20 s. The reaction mixture was set aside in the dark at 28 °C for 24 h. The solution turned from colorless to greenish brown or reddish brown. Finally, the AuNR solution was centrifuged at 4293*g* for 10 min (Eppendorf MiniSpin) to remove excess CTAB and redispersed in Milli-Q water (18.2 MΩ cm). The centrifugation procedure was repeated at 1073*g* for 10 min to obtain purified AuNRs. The purified AuNRs were dispersed in 100 $\mu$L of Milli-Q water and sonicated (45 kHz) for 30 min.

**Fabrication of SERS Substrates.** Purified AuNRs were dispersed in Milli-Q water (1 mL of AuNR solution pellet in 20 $\mu$L of water). Then 10 $\mu$L of AuNR solution was cast on (1) a monolayer graphene silicon slide (G-AuNR), (2) a gold film (40 nm thickness)−monolayer graphene−silicon slide (G-Au-AuNR), and (3) a gold film (40 nm thickness)−silicon (Au-AuNR). All of the prepared substrates were placed in Petri dishes that were sealed by adhesive tape and put in a humidity chamber (humidity of ∼30%) at 25 °C. The drops on the silicon surface were finally dried after 3 h of evaporation. Figure 1 describes the structure of each type of substrate.

**SERS Measurements.** A volume of 0.2 $\mu$L of the pure pesticide solution was transferred onto the surface of a substrate using a micropipet. The substrate, which was fixed on a glass slide, was then placed on a hot plate and heated at 40 °C until the solvent completely evaporated. A Renishaw RM1000 Raman spectrometer system (Gloucestershire, UK) equipped with a Leica DMLB microscope (Wetzlar, Germany) was used in this study. This system is equipped with a 785 nm near-infrared diode laser source. During the measurement, light from the high-power (maximum at 300 mW) diode laser was directed and focused onto the sample on a microscope

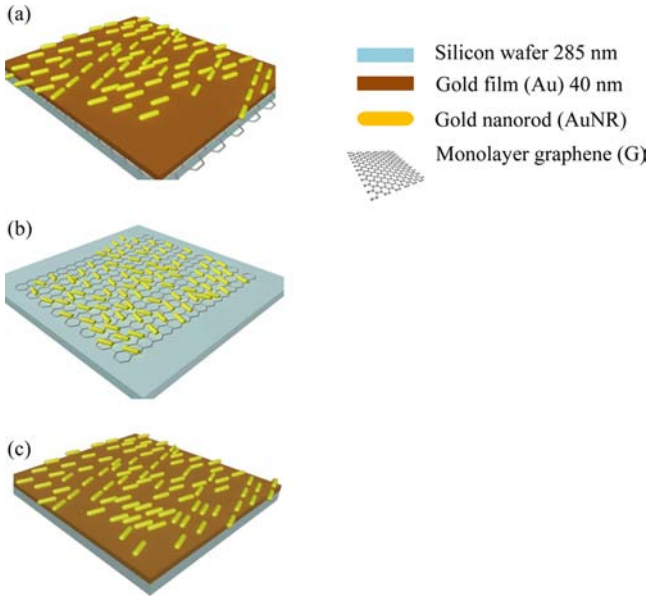

**Figure 1.** Structures of substrates: (a) graphene−AuNR (G-AuNR); (b) graphene−Au−AuNR (G-Au-AuNR); (c) Au-AuNR.

stage through a ×50 objective. Raman scattering signals were detected by a 578 × 385 pixel charge-coupled device array detector. The size of each pixel was 22 × 22 $\mu$m. Spectral data were collected by WiRE 3.2 software (Gloucestershire, UK). In this study, the spectra of samples were collected using a ×50 objective with 10 s exposure time, 0% focus, and ∼20 mW laser power in the extended mode. Detection ranges for each pesticide were 500−1800 $cm^{-1}$ for all of the pesticides. The detection range was determined in a way that the range was as narrow as possible, but no obvious signals were missed.

**Data Analysis.** The software Delight version 3.2.1 (D-Squared Inc., LaGrande, OR, USA) was used for data analysis. SERS spectral data were analyzed following our previously published methods.[2] Briefly, data preprocessing algorithms including polynomial subtract were employed to adjust the baseline shift. The PLS model, a multivariate statistical regression model, was constructed to predict analyte concentrations in tested samples. The number of PLS latent variables was optimized on the basis of the lowest root-mean-square error of prediction (RMSEP) values to avoid overfitting of spectral data. In this study, spectral data were smoothed with a Gaussian function at 4 $cm^{-1}$ followed by a second-derivative transformation with a 12 $cm^{-1}$ gap before PLS was conducted.

$$\mathrm{RMSEP} = \sqrt{\frac{\sum_i^n (\hat{c}_i - c_i)^2}{n}} \quad (1)$$

In this equation, $n$ is the number of samples, $\hat{c}_i$ is the predicted pesticide concentration (ppm), and $c_i$ is the actual pesticide concentration (ppm). The correlation coefficient ($R$) and RMSEP were used to evaluate the model. The higher the $R$ value or the lower the RMSEP value is, the better predictability the model has.

The limit of detection (LOD) with 99.86% confidence interval can be calculated from the PLS calibration curve based on characteristic peaks in SERS spectra using the formula

$$\mathrm{LOD} = 3\sigma/m \quad (2)$$

in which $\sigma$ is the standard error of predicted concentration and $m$ is the slope of the calibration curve. In a PLS model, $\sigma$ equals RMSEP.

## RESULTS AND DISCUSSION

The SPR of synthesized AuNRs displays two adsorption features as shown in Figure 2. This result is in agreement with several previous paper[23−25] that showed a strong feature at 778 nm of AuNRs due to the resonant propagation of surface

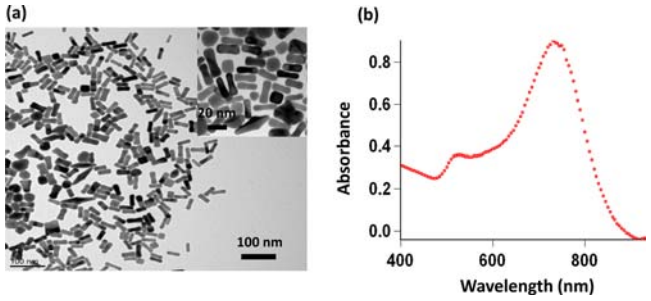

**Figure 2.** TEM image of AuNRs (a) and UV−vis spectrum of purified AuNRs (b).

plasmons along the longitudinal axis. A weak peak at 540 nm is a characteristic peak of the impurities of spherical gold nanoparticles. Overall, the long AuNRs are dominant in the purified AuNR solution, which can be used for SERS measurement with a 785 nm excitation source. In addition, the UV−vis absorption spectrum in Figure 2b shows a narrow absorption band, indicating a highly monodispersed substrate morphology. TEM imaging demonstrates that AuNRs are rod shaped with a width and length of 119.87 and 50.69 nm, respectively. The aspect ratio (length/width) of AuNRs is ~2.36 (Figure 2a). The TEM image also shows that there was a small amount of cubic and spherical nanoparticles on the TEM grids.

To investigate whether G-Au-AuNR, G-AuNR, and Au-AuNR substrates can be used as effective SERS substrates in the detection of pesticides, a droplet of each pesticide solution was deposited on the surface of the substrate. As shown in Figure 3a, no visible Raman signals of azinphos-methyl were observed on the G-AuNR substrate, whereas obvious SERS peaks of azinphos-methyl were obtained on the G-Au-AuNR and Au-AuNR substrates. The same results were also obtained for carbaryl (Figure 3b) and phosmet (data not shown). The band assignments of the peaks are consistent with previous studies.[2] A strong peak at 1380 $cm^{-1}$ is due to symmetric vibration of the naphthalene ring, and a peak at 1440 $cm^{-1}$ arises from an unspecified vibration of this ring. Interestingly, we found that Raman signals of all three types of pesticides on G-Au-AuNR substrate are much stronger than those on G-AuNR and Au-AuNR substrates. To calculate the contribution of enhancement from graphene, we chose the SERS intensity of carbaryl on these three substrates at two selected characteristic peaks (1380 and 1440 $cm^{-1}$). As shown in Figure 3c, the SERS intensity of these two peaks of carbaryl on G-Au-AuNR substrate are 2 times higher than that of Au-AuNR and hundreds of times higher than that of G-AuNR substrate.

There are two widely accepted mechanisms for SERS enhancement: electromagnetic mechanism (EM) and chemical mechanism (CM). EM is considered the main enhancement, resulting from the large increase of the local electric field caused by SPR on roughened metal surface, such as gold or silver. Several recent studies suggested that SERS enhancement can be not only from the gold nanostructure (AuNR and Au film) but also from the monolayer graphene.[20,26−29] The enhancement mechanism of graphene is believed to be from the partial contribution of high thermal conductivity of graphene. Xu et al. observed that the morphology of the metal film changed after a relatively large laser power exposure if there was no graphene layer present, whereas it remained stable for the G-Au film

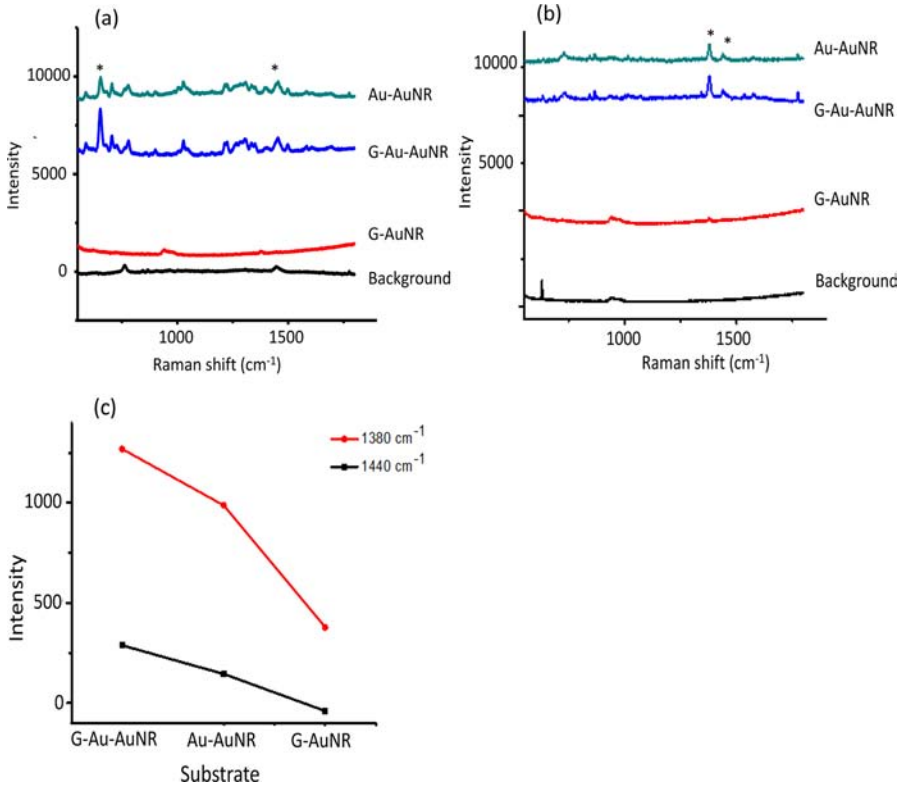

**Figure 3.** Raman spectra of (a) 100 ppm of azinphos-methyl and (b) 100 ppm of carbaryl on Au-AuNR, G-Au-AuNR, and G-AuNR substrate. The peaks marked by an asterisk (*) are the characteristic band of pesticides. (c) Intensity of two characteristic peaks of carbaryl on three kinds of substrate.

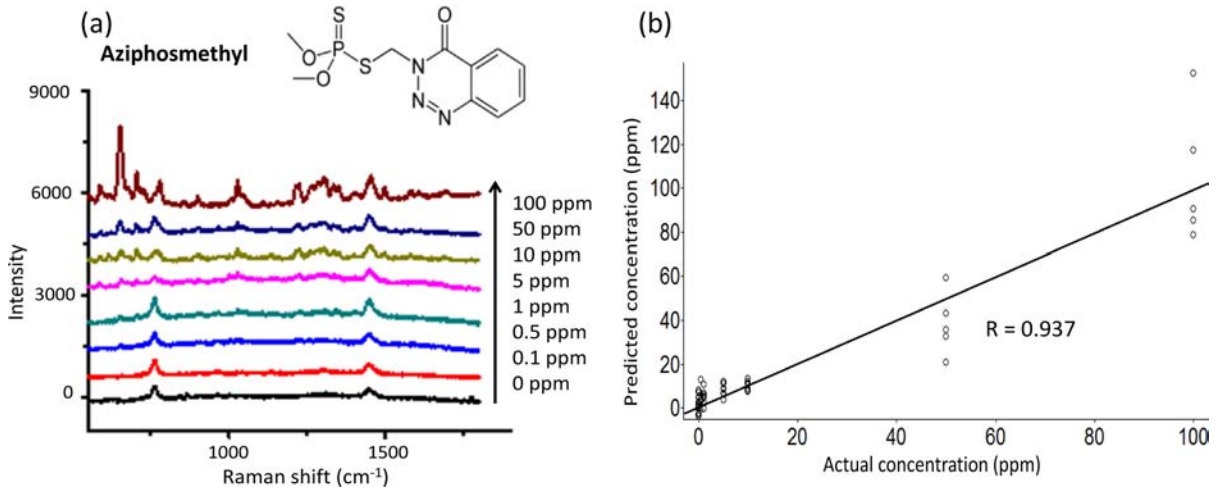

**Figure 4.** (a) SERS spectra of azinphos-methyl on G-Au-AuNR substrate. (b) Calibration curve of predicted azinphos-methyl concentration (ppm) versus actual concentration (ppm) using the PLS models: smoothing at 4 $cm^{-1}$, baseline adjustment by subtracting a first-order polynomial function; six latent variables; spectral region, 500−1800 $cm^{-1}$; spectral number ($n$ = 58).

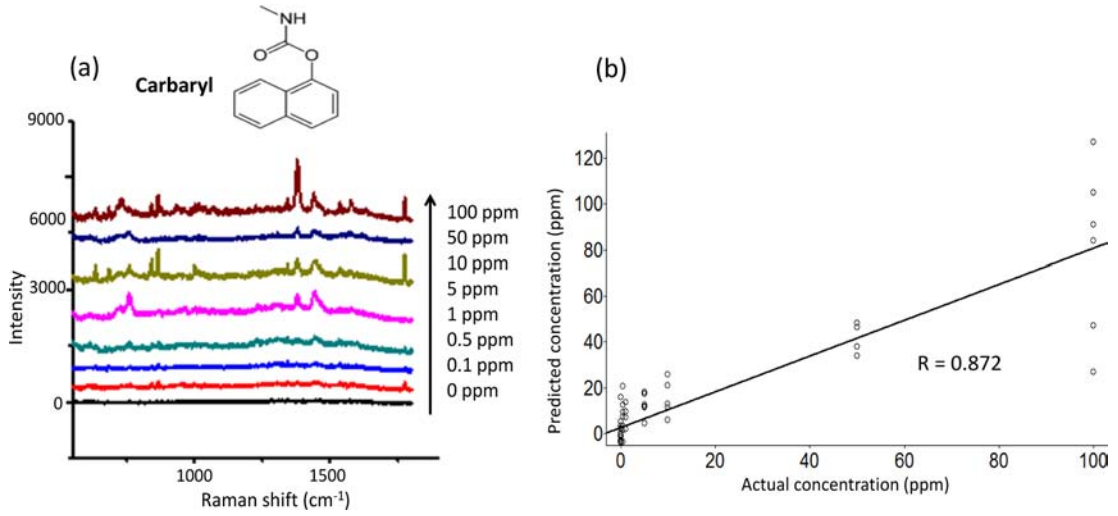

**Figure 5.** (a) SERS spectra of carbaryl on G-Au-AuNR substrate. (b) Calibration curve of predicted carbaryl concentration (ppm) versus actual concentration (ppm) using the PLS models: smoothing at 4 $cm^{-1}$, baseline adjustment by subtracting a first order polynomial function; three latent variables; spectral region 500−1800 $cm^{-1}$; spectral number ($n$ = 52).

substrate.[22] Although SERS signals on Au-AuNR substrate were much stronger than those on G-AuNR, the Raman intensity of characteristic peaks of azinphos-methyl was slightly weaker than that of G-Au-AuNR.

Schedin et al. studied SERS measurement using graphene patterned with a square array of Au nanodisks on $SiO_2$(300 nm)/Si and implied that both G and 2D bands of graphene at 633 nm were significantly enhanced.[27] The authors found that the graphene scales combined with the nanoparticle cross section, the 4th power of the Mie enhancement, are inversely proportional to the 10th power of the separation between graphene and the nanoparticle. The grown AuNRs significantly enhanced Raman signals of reduced graphene oxide (rGO) by 34-fold at the tip of the long AuNRs, which is the highest Raman enhancement of rGO by gold nanostructures ever reported.[27] Ling et al. used graphene as a substrate for Raman enhancement.[26] By coupling or not coupling with gold nanoparticles (AuNPs) or silver nanoparticles (AgNPs), the Raman signals of the molecules on monolayer graphene are clearer, stronger, and more reproducible than that on the $SiO_2$/Si substrate, indicating a clear SERS effect on the atomically flat surface of monolayer graphene. Additionally, the authors also found that graphene makes the SERS system more stable and that the graphene−SERS (G-SERS) process does not require special sample preparation. Their results showed that the enhancement factor of G-SERS was even slightly higher than those of normal SERS for most of bands and that the presence of the graphene layer did not cause the localized EM field to decay observably in its vicinity and possibly led to additional chemical enhancement.[26]

Kim et al. obtained Raman spectra of a single-layer graphene sheet placed in different gold substrates in the context of SERS. The difference in the enhancement factors among various gold substrates is explained with a model based on the spatial distribution and polarization of the local field and the orientation of inserted graphene sheet.[29] Besides graphene, its other two derivatives, graphene oxide (GO) and rGO, have also been studied as promising substrates for SERS. A study used GO-based SERS substrate to acquire Raman spectra of rodamine, melamine, and cephalexin,[21] but the results showed

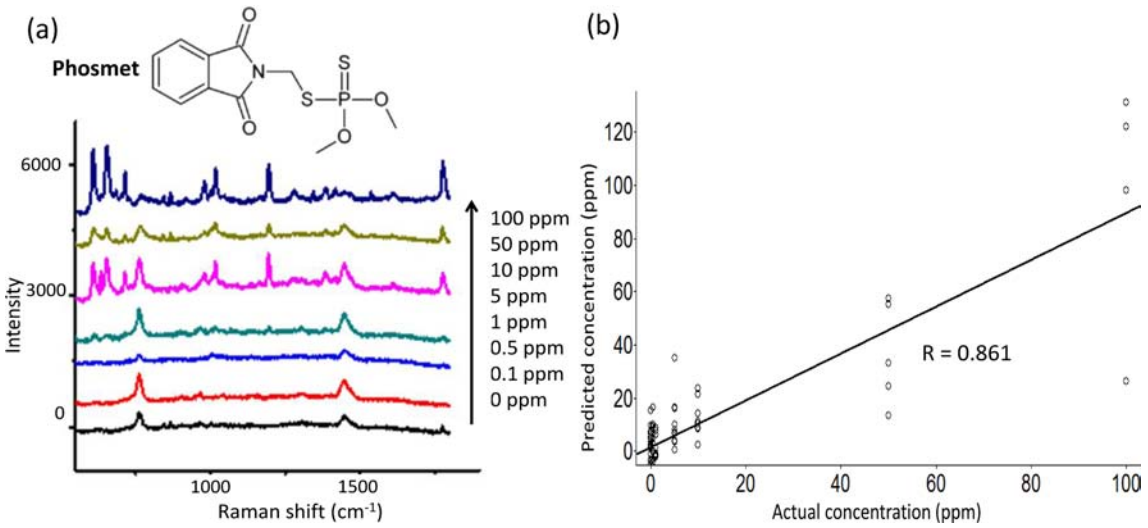

**Figure 6.** (a) SERS spectra of phosmet. (b) Calibration curve of predicted phosmet concentration (ppm) versus actual concentration (ppm) using the PLS models: smoothing at 4 $cm^{-1}$; baseline adjustment by subtracting a first-order polynomial function; five latent variables; spectral region, 500−1800 $cm^{-1}$; spectral number ($n$ = 75).

a weak enhancement of SERS due to CM of graphene.[21] This same conclusion was also reached in another study by Yu et al.[28] In our study, we observed that the main SERS enhancer still relied on the EM of noble metal nanostructures. This is consistent with another study[30] using fabricated Ag or AuNPs-decorated rGO on Si substrate as an efficient SERS substrate to detect aromatic molecules with a low detection limit at the nanomolar level. Due to the combination of AuNPs and graphene, the Raman signals of the dye were dramatically enhanced by this novel substrate.[30] In summary, this line of studies demonstrates that G-Au-AuNR substrate is a promising SERS substrate for the detection of various analytes.

Most commercial SERS substrates either are in the form of a colloidal solution containing metal nanoparticles or are silicon chip-based flat substrates with a thin layer of metal deposited on top. The main drawback of colloidal SERS substrates is that a surfactant is needed to stabilize the solution and prevent or reduce the aggregation and precipitation of metallic nanoparticles. The surfactant may affect the SERS measurement, and the reproducibility of colloidal SERS substrates is low.[31,32] In addition, target molecules have to be mixed with colloidal SERS nanoparticles, which complicates the sample preparation step and limits the application of colloidal SERS substrates. In contrast, chip-based SERS substrates are more stable and have good reproducibility. Sample solution can be easily transferred onto a substrate using a micropipet.

In addition, we studied the reliability of G-Au-AuNR substrate in the characterization and quantification of pesticides. Figure 4 shows the average SERS spectra of different concentrations of azinphos-methyl, and a linear calibration curve was constructed by monitoring the intensity of the peaks in a selected region (500−1800 $cm^{-1}$). Similar results were provided for carbaryl (Figure 5) and phosmet (Figure 6). The band assignments are shown in Table 1. PLS analysis was conducted to obtain the RMSEP values from the PLS models of each pesticide. The lowest RMSEP value was achieved and used to construct the PLS prediction model. Figure 4b illustrates the plot between the predicted concentration and actual concentration of pesticides ($R$ = 0.87; RMSEP = 15.87 × $10^{-5}$). For carbaryl (Figure 5) and phosmet (Figure 6), $R$ values are 0.87 and 0.84 and RMSEP values are 16.08 × $10^{-5}$ and 21.21 × $10^{-5}$, respectively. These results demonstrate that the SERS method coupled with PLS can be used as a reliable method to quantify pesticides.

[a]References 2 and 26−28.

The LODs of azinphos-methyl, phosmet, and carbaryl of G-Au-AuNRs substrate were calculated by using eq 2. The calibration curve of azinphos-methyl is shown in Figure 7. As compared to the maximum residue limits of the three pesticides in fruits (apples) of FAO/WHO and English standard (Table 2), the LOD of the SERS method coupled with this substrate meets the requirement for carbaryl and phosmet. However,

more studies are needed to improve the results of this method for testing azinphos-methyl.

In summary, a simple, fast, and efficient method was developed to fabricate new SERS substrates by coating an AuNR-decorated graphene sheet on Si substrate. This substrate exhibits strong Raman enhancement due to the unique properties of graphene and the deposited AuNRs. The performance of this G-Au-AuNRs substrate was evaluated using three types of pesticides (azinphos-methyl, carbaryl, and phosmet). The LODs of carbaryl and phosmet meet the maximum residue limits set by the FAO/WHO and the European Union. These results demonstrate that there is a great potential to use graphene and gold materials for food safety applications. More research is needed to improve the performance of SERS substrates using different materials and use them to test real food products.

deposited at the Chrysler Herbarium, Rutgers University, New Brusnwick, NJ, USA.

**Preparation of the Extract.** Dry seeds were ground into powder, and the seed powder (2 g) was extracted in 95% ethanol (20 mL) for 24 h at room temperature with continuous agitation provided by a platform shaker. After extraction, the sample was filtered and the solvent removed by rotary evaporation, yielding 40.25 mg (2%). The extract was dissolved in 95% ethanol to appropriate concentrations for in vitro assays, chemical characterization, and bioactivity-guided fractionation.

**COX-2 in Vitro Assay.** Grains of paradise extract was dissolved in 95% ethanol at a concentration of 1 mg/mL. The activity of the extract was tested with a colorimetric COX (ovine) inhibitor screening assay (catalog no. 760111, Cayman Chemical, Ann Arbor, MI, USA). The screening assay measures the peroxidase activity of cyclooxygenase by monitoring the appearance of oxidized *N*,*N*,*N*′,*N*′-tetramethyl-*p*-phenylenediamine (TMPD) at 590 nm as previously described.[12] A relatively higher TMPD concentration corresponds to a greater absorbance at 590 nm, a greater peroxidase activity, and a greater COX-2 activity (i.e., less inhibition of COX-2 activity). The assays were performed according to the manufacturer's instructions.

**Bioassay-Guided Purification of the Extract.** Purification and isolation of compounds were carried out using a preparatory HPLC from Waters Corp. (Milford, MA, USA) consisting of a W717 plus autosampler, a W600E multisolvent delivery system, a W600 controller, a W490E multiwavelength detector, and a Waters fraction collector. A Waters liquid chromatography−mass spectrometry (LC-MS) Integrity system consisting of a solvent delivery system with a W616 pump and a W600S controller, a W717 plus autosampler, a W996 PDA detector, and a Waters TMD Thermabeam electron impact (EI) single-quadrupole mass detector with fixed ionization energy of 70 eV was used for analysis. Data were collected and analyzed with the Waters Millennium v. 3.2 software, linked with the sixth edition of the Wiley Registry of Mass Spectral Data, containing 229,119 EI spectra of 200,500 compounds.

**Gene Expression: Macrophage Cell Culture.** The mouse monocyte/macrophage cell line RAW 264.7 (ATCC TIB-71 obtained from American Type Culture Collection, Manassas, VA, USA) was maintained in Dulbecco's modified Eagle medium (DMEM; Invitrogen Inc., Carlsbad, CA, USA) supplemented with 100 U/mL penicillin, 100 $\mu$g/mL streptomycin, and 10% heat-inactivated fetal bovine serum (Sigma-Aldrich Co.). The cells were kept in a 37 °C incubator with 5% $CO_2$. Cells were subcultured by scraping when plates reached 90% confluence with a 1:5 ratio in fresh medium.

Cells were seeded at a density of $4 \times 10^5$ cells per well (viable cell counts were carried out by trypan blue staining using a hemocytometer) in 24-well plates 12 h prior to treatment. The cells were then treated with test compounds dissolved in dimethyl sulfoxide (DMSO) at predetermined doses (based on MTS assays) for 2 h before elicitation with bacterial endotoxin lipopolysaccharide from *Escherichia coli* serotype 055:B5 (LPS) (Sigma-Aldrich Co.) at 1 $\mu$g/mL for an additional 6 h. For every experiment one positive control (cells treated only with LPS and vehicle) and one negative control (cells treated with vehicle only) were included. Three replicates were made for both treatments and the controls. Final concentration of DMSO in cells was 1%. The same concentration was used as vehicle control. At the end of the treatment period, cells were harvested in Trizol reagent for subsequent cellular RNA extraction.

**Gene Expression: Cell Viability Assay and Dose Range Determination.** A Cell Titer 96 MTS assay kit (Promega Corp., Madison, WI, USA) was used to determine the relative number of viable cells remaining after incubation with treatments. The assay has been performed according to the manufacturer's protocol and a previously described method.[18]. In short, the assay was performed by treating cells with different extract concentrations, followed by adding 20 $\mu$L of reagent 3-4,5-(dimethylthiazol-2-yl)-5-(3-carboxymethoxyphenyl)-2-(4-sulfophenyl)-2*H*-tetrazolium/phenazine methosulfate (MTS/PMS) directly to culture wells and incubating for 3 h at 37 °C. Plates were read using a microplate reader (Molecular Devices, Sunnyvale, CA, USA) at 490 nm. For dose range studies, the highest nontoxic concentrations for respective compound/extract were selected.

**Gene Expression: Quantitative Polymerase Chain Reaction (qPCR) and Data Analysis.** The synthesized cDNAs were diluted 4-fold. Two microliters of each diluted sample was added to 0.5 $\mu$L of gene-specific primers (6 $\mu$M, oligos synthesized by IDT Inc., Coralville, IA, USA) and 12.5 $\mu$L of Brilliant SYBR green PCR master mix (2×) (Stratagene, La Jolla, CA, USA) containing green jump-start Taq ready mix, and the final volume was brought to 25 $\mu$L by adding sterile distilled water. Carboxy-X-rhodamine (ROX) was used as an internal dye. To avoid interference due to genomic DNA contamination, only intron-overlapping primers were selected using Primer Express vers. 2.0 software (Applied Biosystems, Foster City, CA, USA) as shown in Table 1. PCR amplifications were performed on a MX3000p system (Stratagene, La Jolla, CA, USA) as described in ref 19. RNA expressions for genes of interest, normalized with respect to the expression of housekeeping $\beta$-actin gene, were analyzed using the $\Delta\Delta$Ct method.[19]

**Carrageenan-Induced Rat Paw Edema.** Groups of Long Evans-derived male rats with body weights of 150 ± 10 g were housed six animals per cage in a room kept at 22−23 °C with 60−70% humidity and a 12 h light/dark cycle for 1 week prior to the start of the study. Access to standard laboratory chow and water was ad libitum. All aspects of this work including housing, experimentation, and disposal of animals were performed in general accordance with the International Guiding Principles for Biomedical Research Involving Animals (CIOMS Publication ISBN 9290360194, 1985), and the protocol was approved by MDS Pharma (King of Prussia, PA, USA). The animals were fasted overnight prior to use.

Grains of paradise extract and pure compounds ([6]-paradol, [6]-shogaol, [6]-gingerol) were administered per os (extract at 1000 and 500 mg/kg and pure compounds at 150 mg/kg) suspended in 0.2% Tween-80/10% ethanol 1 h before right hind paw injection of carrageenan (0.1 mL of 1% suspension intraplantar, TCI, Tokyo, Japan). Aspirin (150 mg/kg, Sigma-Aldrich Co.) was used as a reference compound (positive control). The severity of the hind paw edema as a measure of inflammation was recorded 3 h after carrageenan administration using a plethysmometer (Ugo Basile, Comerio, VA, Italy) with water cell (25 mm diameter). Reduction of edema was calculated by comparison with vehicle control. The anti-inflammatory activity is expressed as a percentage of edema reduction.

**Statistical Analysis.** Statistical comparisons were performed between the vehicle control and treated groups. For the in vitro and in vivo assays, the results are presented as the mean ± standard deviation (SD) The statistical analysis was calculated by using the analysis of variance (ANOVA) test and followed by post hoc analysis using Tukey's multiple-comparison test.

## RESULTS AND DISCUSSION

In a search for novel anti-inflammatory compounds we evaluated ethanolic extract of grains of paradise (*A. melegueta*) for inhibition of COX-2 enzyme activity, inhibition of pro-inflammatory genes expression (in vitro), and anti-inflammatory activity in rat paw edema assay (in vivo), and the active compounds from the extract were characterized.

**COX-2 Enzyme Inhibitory Activity and Active Compound Characterization.** At an initial concentration of 1 mg/mL, the ethanolic extract demonstrated inhibitory activity against COX-2, similar to the drug Vioxx that was used as a positive control. The level of inhibition for the extract was 76% compared to 87% for Vioxx (Table 2). Biochemical analytical data indicated that the extract is a complex mixture of compounds. In order to identify compounds responsible for the observed activity, the extract was subjected to bioactivity guided fractionation with concurrent LC-MS analysis. Bioactivity guided fractionation was performed in the following manner:

Grains of paradise extract (1 g, obtained from a large-scale extraction) was dissolved in 95% ethanol (20 mL) and fractionated using a preparatory HPLC. For the initial purification, a Waters 19 × 300 mm symmetry preparative C8 reverse phase column was used. The mobile phases consisted of 100% acetonitrile ($CH_3CN$) and 0.5% of acetic acid in water (v/v). For the initial separation, a gradient from 5% $CH_3CN$ to 95% $CH_3CN$ over 35 min was used with a flow rate of 8 mL/min. Ten fractions (volume of 40 mL each) at 5 min intervals were collected and tested for COX-2 inhibitory activity. Fraction 8 (F8; yield = 360 mg) had the highest activity and was further purified using similar conditions as before except the gradient was run over 70 min. Four fractions were collected from F8, and they were subjected to the COX-2 assay. The most active fraction, F8-2 (4 mL volume, eluted at 59.2 min at 282 nm; yield = 90 mg), was then purified using a 10 × 250 mm Curacil-PFP column and an isocratic run with a mobile phase consisting of 0.5% acetic acid in water/methanol/$CH_3CN$ (2:3:5) at a flow rate 3 mL/min. Four fractions were collected from F8-2, and F8-2-3 (1.45 mL volume, eluted at 8.67 min, at 282 nm; yield = 49.5 mg) was found to have the highest inhibitory activity on COX-2 enzyme. This fraction was refractionated using the conditions described previously, with the exception of the flow rate, which was reduced to 1 mL/min. Three fractions were collected from F8-2-3, and F8-2-3-2 (1.48 mL volume, eluted at 25.29 min, at 282 nm; yield = 32.2 mg) had the highest inhibitory activity. This fraction was identified as [6]-paradol (95% purity) using LC-MS and $^1H$, $^{13}C$, and 2D

**Table 2. In Vitro COX-2 Enzyme Inhibition by the Ethanolic Extract of Grains of Paradise and Its Anti-inflammatory Components**[a]

| treatment | inhibition (%) ± SD |
|---|---|
| control[b] | 2 ± 2 |
| *A. melegueta* extract | 76 ± 6.7*** |
| [6]-gingerol | 7 ± 11.7 |
| [6]-shogaol | 68 ± 6.4*** |
| [6]-paradol | 91 ± 3.6*** |
| Vioxx | 87 ± 1.5*** |

[a]Data are shown as mean inhibition ± SD in %. Significance: ***, 0.1%. [b]All samples were tested at the concentration of 1 mg/mL. Control, celery extract at 1 mg/mL; whole extract, grains of paradise (*A. melegueta*) extract at 1 mg/mL; Vioxx (MW 314.36) at 1 mg/mL, 3.18 mM; [6]-gingerol (MW 294.38) at 1 mg/mL, 3.39 mM; [6]-shogaol (MW 276.37) at 1 mg/mL, 3. 62 mM; [6]-paradol (MW 278) at 1 mg/mL, 3.60 mM.

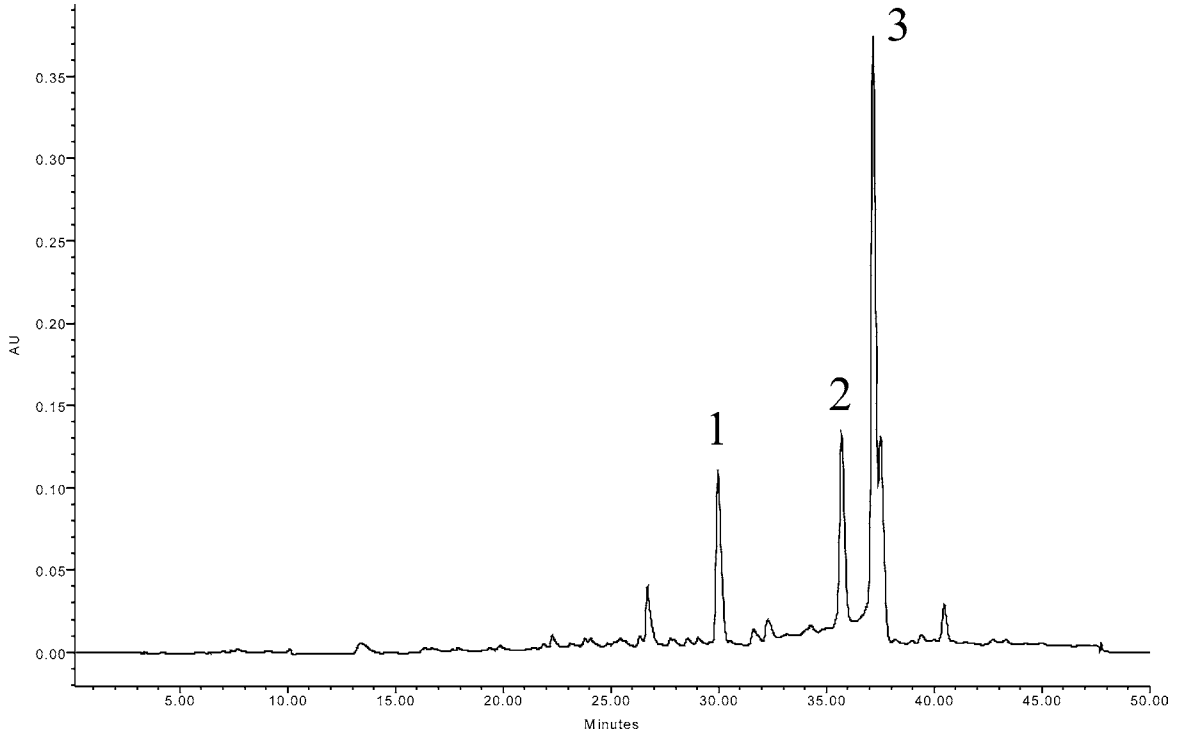

**Figure 1.** HPLC chromatogram of grains of paradise (*A. melegueta*) extract showing putative compounds. Peaks: 1, [6]-gingerol; 2, [6]-shogaol; 3, [6]-paradol.

NMR data.[20,21] The purification procedure was repeated multiple times to obtain sufficient amounts of [6]-paradol for in vitro and in vivo experiments.

Chemical analysis of the extract revealed three major peaks (Figure 1). The UV spectra and mass fragmentation patterns of these peaks matched the compounds of the gingerol family previously identified in *A. melegueta*[22] and in other members of Zingiberaceae.[23] The most abundant were putatively identified as [6]-gingerol, [6]-shogaol, and [6]-paradol at 1.0 mg/g [6]-gingerol, 0.53 mg/g [6]-shogaol, and 1.2 mg/g [6]-paradol per gram of the extract. All three compounds were assayed for COX-2 enzyme inhibitory activity at the same concentration (1 mg/mL) as the whole extract and Vioxx. [6]-Paradol was the most active with 91% inhibition, followed by [6]-shogaol (68%), and [6]-gingerol (7%) (Table 2). Paradol inhibitory activity was higher than those of Vioxx (87%) and the whole extract (76%), confirming it as the most active compound as found in the bioactivity-guided fractionation assay. [6]-Gingerol and [6]-shogaol were commercially purchased, and [6]-paradol was isolated by bioactivity-guided fractionation (as described above).

**Inhibition of Expression of Pro-inflammatory Genes (in Vitro).** In addition to inhibiting the pro-inflammatory COX-2 enzyme, the extract of grains of paradise was also tested for inhibition of pro-inflammatory genes. The genes tested were tumor necrosis factor alpha (TNF$\alpha$), interleukin-1beta (IL-1$\beta$), interleukin-6 (IL-6), COX-2, and inducible nitric oxide synthase (iNOS).

The in vitro experiments were designed to quantify the relative amount of transcripts for target genes (COX2, iNOS, TNF$\alpha$, IL6, and IL1$\beta$) within the total RNA in individual cell batches following treatments with the extract or its three major gingerols. All experiments were started with an equal number of cells for each treatment. For each assay, two control sets were monitored (Figure 2). The in vitro experiments showed that both ethanolic extract of grains of paradise extract and [6]-shogaol were inhibitory in a dose-dependent manner ($p < 0.05$ by ANOVA) on IL1$\beta$ (Figure 2) but not on other genes tested. The extract was significantly cytotoxic to macrophages at concentrations >20 $\mu$g/mL and hence could not be tested for gene expression inhibition beyond that concentration. [6]-Shogaol did not affect the transcription of other genes at 5 $\mu$g/mL, its highest nontoxic concentration. [6]-Paradol and [6]-gingerol did not show any significant inhibitory activities at the noncytotoxic concentration range up to 30 and 50 $\mu$g/mL, respectively (data not shown).

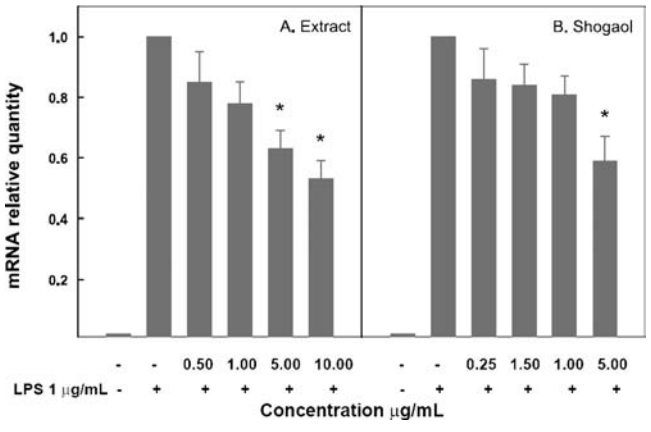

**Figure 2.** Effect of grains of paradise extract (A) and [6]-shogaol (B) on IL1$\beta$ gene expression in LPS-activated RAW macrophages measured by the mRNA quantity relative to the response to LPS activation only (positive control) that is normalized to a value of 1.00. Lower values represent greater inhibitory effects with 0.00 corresponding to a complete inhibition of the induced gene expression. Values are the mean ± SD. (*) $p < 0.05$ (compared with positive control).

**Anti-inflammatory Activity in Rat Paw Edema Assay (in Vivo).** To investigate whether the observed in vitro COX-2 enzyme and gene expression inhibitory properties translate into in vivo anti-inflammatory activity, we tested the extract in a rat paw carrageenan edema assay, which is commonly used for testing anti-inflammatory agents. Initially, two doses of the whole extract were given per os (orally) to the animals, 1000 and 500 mg/kg. Aspirin was used as a positive control at a 150 mg/kg dose. At 1000 mg/kg, the extract demonstrated anti-inflammatory effect, reducing edema by 49% (Table 3). At the lower dose (500 mg/kg) the extract exhibited a reduced anti-inflammatory effect (11% edema reduction). At the same time, aspirin reduced edema by 43% at 150 mg/kg. Therefore, grains of paradise extract does have in vivo anti-inflammatory activity, but it was not as effective as aspirin.

**Table 3. Inhibition of Carrageenan-Induced Rat Paw Edema by Grains of Paradise Ethanolic Extract and Its Main Components, [6]-Gingerol, [6]-Shogaol, and [6]-Paradol, with Aspirin as a Positive Control[a]**

| | treatment | dose | average paw difference ± SD | inhibition (%) |
|---|---|---|---|---|
| I | | | | |
| | vehicle | 10 mL/kg | 90 ± 3.5 | |
| | *A. melegueta* extract | 500 mg/kg | 80 ± 13.7 | 11 |
| | | 1000 mg/kg | 46 ± 4.2** | 49 |
| | aspirin | 150 mg/kg | 51 ± 5.1** | 43 |
| II | | | | |
| | vehicle | 10 mL/kg | 85 ± 3.3 | |
| | [6]-paradol | 150 mg/kg | 68 ± 6.7* | 20 |
| | aspirin | 150 mg/kg | 54 ± 8.5*** | 36 |
| III | | | | |
| | vehicle | 10 mL/kg | 79 ± 3.4 | |
| | [6]-shogaol | 150 mg/kg | 49 ± 5.4*** | 38 |
| | [6]-gingerol | 150 mg/kg | 59 ± 8.5** | 25 |
| | aspirin | 150 mg/kg | 50 ± 8.6*** | 37 |

[a]Test substances were administered orally 60 min before the right hind paw received an injection of carrageenan (0.1 mL of 1% suspension intraplantar). Hind paw edema was measured 3 h later; paw sizes were compared, and average paw difference (expressed in mL) established and inhibition were calculated relative to the vehicle-treated animals in the control group. Data are shown as the mean ± SD and percentages of inhibition. Significance levels: *, 5%; **, 1%; ***, 0.1%.

To analyze the anti-inflammatory activity of single compounds, the most active compound in the COX-2 enzymatic assay, [6]-paradol, has been isolated from the extract and tested in in vivo assay at the same dose level as aspirin (150 mg/kg), which was used as a positive control. At this dose it inhibited the rat paw edema by 20% and aspirin by 36%, respectively. Two other compounds from the extract, [6]-gingerol and [6]-shogaol, given at 150 mg/kg, inhibited edema by 25 and 38%, respectively. In the same assay aspirin given at 150 mg/kg inhibited the edema by 37%. Therefore, [6]-shogaol, the most active compound in the gene expression

assays, was also the most active compound in vivo and demonstrated anti-inflammatory activity similar to that of aspirin (Table 3).

Results of our study demonstrated the inhibitory activity of grains of paradise ethanolic extract in COX-2 in vitro enzymatic assay. The bioactivity-guided fractionation revealed that the [6]-paradol present in the extract is the most effective inhibitor of COX-2 enzymatic activity. [6]-Paradol and two other major compounds present in the extract, [6]-gingerol and [6]-shogaol, belong to the gingerol family of compounds. The results for the enzymatic inhibition support previous reports on gingerols as inhibitors of the arachidonic acid biosynthetic pathway. In one study, ginger rhizome extract (*Zingiber officinale* Roscoe, Zingiberaceae) was investigated for inhibition of COX-1 enzyme and antiplatelet aggregation activity. [8]-Paradol, a natural constituent of ginger, was the most active inhibitor and stronger than aspirin.[24] Similar studies on COX-2 enzyme inhibitory activity revealed that ginger constituents [8]-paradol and [8]-shogaol had strong inhibitory activity.[25] Additionally, structure−activity study on gingerols and COX-2 inhibition has shown that the paradols showed the highest affinity for COX-2 followed by the shogaols and then the gingerols.[26] Our data, together with the above-mentioned studies on compounds from ginger, suggest that compounds from the gingerol family are cyclooxygenase inhibitors. When the gingerols from the extract were tested for the inhibition of expression of pro-inflammatory genes (COX2, iNOS, TNF$\alpha$, IL6, and IL1$\beta$), the whole extract and [6]-shogaol exhibited inhibitory activity on IL1$\beta$ gene expression, whereas other genes have not been affected.

To evaluate how these in vitro activities at enzyme and gene level transpond into in vivo activity, we used the cyclo-oxygenase-dependent carrageenan-induced paw edema assay,[27] a standard model to reproduce acute inflammation in vivo. The ethanolic extract of grains of paradise exhibited anti-inflammatory activity in this assay. This also confirmed the anti-inflammatory activity reported earlier for the aqueous extract of grains of paradise.[5,12] Additionally, the three major gingerols present in the extract were also effective in reducing the inflammation with [6]-shogaol at a level comparable to that of aspirin.

Because grains of paradise ethanolic extract and major gingerols present in it showed in vitro inhibition of COX-2 enzyme activity and ethanolic extract and [6]-shogaol reduction in expression of pro-inflammatory IL1$\beta$ gene, we could hypothesize that the extract may have a dual mode of action, at the gene and enzyme levels. Inhibition by [6]-paradol and other gingerols present in the extract of COX-2 enzyme activity and inhibition by [6]-shogaol of pro-inflammatory gene expression could impair prostaglandin (the end product of the cyclooxygenase pathway) production, thereby reducing the inflammatory process in vivo. Gingerols from ginger (*Z. officinale*) have been previously reported to inhibit prostaglandin biosynthesis.[28] However, to put more light on this, our extract and its compounds require further studies, especially on how the whole ethanolic extract and its three major isolated gingerols affect prostaglandin levels. In conclusion, this study with in vitro and in vivo assays has demonstrated that the ethanolic extract of grains of paradise and its major compounds have anti-inflammatory potential at the enzyme and in vivo levels, but they need to be further evaluated.

precise role of autophagy in the death of tumor cells, especially TMZ-treated glioblastoma cells, is not yet entirely clear.

Because previous studies have shown the potential anticancer effects of pine needle extracts, we performed this study to investigate the anti-glioblastoma effects as well as the bioactive compounds present in pine needle extracts. In particular, chrysin (5,7-dihydroxyflavone), a major phenolic compound in pine needle extract, may be responsible for the anticancer properties of pine needle extracts.[11] Chrysin exhibits antioxidant and antiviral activities, reduces blood lipids, and prevents mutagenesis. In one study, chrysin showed antitumor activities by suppressing tumor cell proliferation and inducing apoptosis.[12] However, studies on the effects of chrysin on human glioblastoma are rare. In this study, we showed that chrysin was the most active ingredient in pine needle extract that induced apoptosis and suppressed the migration and invasion of glioblastoma cell line GBM8901. Furthermore, chrysin markedly inhibited autophagy and reduced MGMT expression, which may contribute to TMZ chemoresistance. Taken together, our results suggested that pine needle extracts containing chrysin might provide potential beneficial effects against glioblastoma and attenuate resistance to TMZ in a synergistic behavior. This may help in developing anti-proliferative and anti-recurrence strategies by sensitizing glioblastoma cells resistant to TMZ.

## MATERIALS AND METHODS

**Materials.** Chrysin, TMZ, 4′,6-diamidino-2-phenylindole (DAPI), 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT), propidium iodide (PI), 3-methyladenine (3-MA), chloroquine (CQ), and rapamycin were purchased from Sigma-Aldrich (München, Germany). Caspase inhibitor zVAD-fmk was obtained from R&D Systems (Minneapolis, MN). Antibodies to β-actin, anti-pmTOR, anti-mTOR, beclin1, p62, and MGMT were obtained from Santa Cruz Biotechnology (Santa Cruz, CA). Cleaved PARP, cleaved caspase 3, anti-pAkt, and anti-Akt antibodies were obtained from Millipore (Bedford, MA). Anti-LC3, Atg5-Atg12, and Atg7 antibodies were purchased from Novus Biologicals (Littleton, CO). Acridine orange was obtained from Life Technologies (Rockville, MD).

**Sample Preparation.** Fresh leaves (pine needles) of *P. morrisonicola* Hayata were collected from Taiwanese mountains in Nantou county at elevations of 300−2300 m. The preparation of pine needle extracts for this study was modified from a previous report.[13] Briefly, pine needles were air-dried, homogenized, and ground. The obtained powder (200 g) was extracted with water, methanol, or ethanol at room temperature for 48 h. Next, the respective solutions were filtered and dried by evaporation of the filtrates in vacuum at 40 °C. The pine needle extracts of water, methanol, and ethanol were named pine water extract (PWE), pine methanol extract (PME), and pine ethanol extract (PEE), respectively. The dried samples were stored at −20 °C until further use.

**Cell Culture and Viability Assay.** GBM8901 human glioblastoma cells, EOC 13.31 glia cells, and Detroit 551 and NIH3T3 fibroblast cells were obtained from Bioresources Collection and Research Center (Hsinchu, Taiwan). GBM8901 cells were maintained in RPMI-1640 medium; Detroit 551 cells were maintained in minimum essential medium (MEM); and EOC 13.31 and NIH3T3 cells were maintained in Dulbecco's modified Eagle's medium (DMEM) (Gibco). Primary mixed glial cell cultures were established from neonatal rat brain tissue according to a previous protocol.[14] All cultures were supplemented with 10% fetal calf serum, 100 units/mL penicillin, 100 μg/mL streptomycin, and 2 mM L-glutamine and incubated at 37 °C in a humidified atmosphere of 5% $CO_2$. In the viability assay, the cells were seeded in 96-well plates at a density of $1 \times 10^4$ cells/well and were incubated overnight. Next, the cells were treated with indicated conditions. After 24 h, the tetrazolium salt MTT was added to the medium according to the instructions of the manufacturer. Only viable cells metabolized MTT to a purple product formazan, which was quantified spectrophotometrically at 550 nm. The cell viability was determined as the percentage of control cells treated with the vehicle alone.

**High-Performance Liquid Chromatography (HPLC) and Tandem Mass Spectrometry (MS/MS) Analyses.** Sample separation was performed using a HPLC system (JASCO model PU-2080, Tokyo, Japan). Isocratic chromatography was performed using separate reversed-phase (RP)-HPLC by employing the following conditions: fractionation in a LUNA C18 analytical column packed with 5 μm particles (250 × 4.6 mm, Phenomenex, Torrance, CA) and elution with a mobile phase (deionized water/methanol/formic acid = 79.1:20:0.1) at a flow rate of 1.0 mL/min that was monitored at a wavelength of 280 nm [SPD-10 AV ultraviolet−visible (UV−vis) detector, Shimadzu, Kyoto, Japan]. MS was performed using an API 3000 triple quadruple mass spectrometer equipped with a Turbo IonSpray interface operated in negative electrospray ionization (ESI, AB SCIEX, Framingham, MA). All quantitative and qualitative analyses were performed in a multiple reaction monitoring (MRM) scan.

**Western Blot Analysis.** GBM8901 cells were harvested and homogenized in lysis buffer [50 mM Tris−HCl at pH 8.0, 5 mM ethylenediaminetetraacetic acid (EDTA), 150 mM NaCl, 0.5% Nonidet P-40, 0.5 mM phenylmethylsulfonyl fluoride, and 0.5 mM dithiothreitol] for 30 min at 4 °C. Equal amounts of total cellular proteins (50 μg) were resolved by sodium dodecyl sulfate−polyacrylamide gel electrophoresis (SDS−PAGE), transferred onto polyvinylidene difluoride membranes (Millipore), and probed using primary antibodies, followed by horseradish-peroxidase-conjugated secondary antibodies. The immunocomplexes were visualized using enhanced chemiluminescence kits (Millipore).

**Nucleus Morphology.** Changes in cell nuclei morphology that were characteristic of apoptosis were examined using a fluorescence microscope (AXioskop 2, Zeiss) on cells grown on coverslips. For this, cells were fixed in 4% paraformaldehyde after 24 h of treatment with the indicated compound, permeabilized in ice-cold methanol, and incubated with 1 ng/mL 4′,6-diamidino-2-phenylindole (DAPI) staining under the fluorescence microscope for 15 min at room temperature.

**Apoptosis by Flow Cytometry.** Cells were cultured as described above. The percentage of sub-G1 apoptotic cells was examined by the propidium iodide (PI) technique using flow cytometry. Briefly, GBM8901 cells ($1 \times 10^6$/mL) were fixed in 70% methanol, resuspended in phosphate-buffered saline (PBS) incubated with 50 μg/mL PI for 0.5 h, and analyzed by FACScan (Becton Dickinson, San Jose, CA).

**Cell Migration and Invasion Assay.** The cell migration and invasion assays were performed in a 24-well Boyden chamber with an 8 μm pore size polycarbonate membrane (Corning, NY). For the migration assay, $1 \times 10^5$ cells in 200 μL serum-free medium were added to the upper compartment of the chamber; the lower compartment was filled with 600 μL of RPMI 1640 supplemented with 10% fetal bovine serum (FBS). After incubation at 37 °C for 24 h, GBM8901 cells remaining in the upper chamber were removed using swabs. The cells on the lower surface of the membrane were fixed with methanol, stained with 0.1% crystal violet, photographed, and counted using a light microscope. The invasion assay was performed using the same procedure, except that the membrane was coated with Matrigel (BD Biosciences) to form a matrix barrier and $3 \times 10^4$ GBM8901 cells were added to the upper compartment of the chamber.

**Acridine Orange Staining.** Acridine orange is a dye that specifically labels intracellular acidic vesicles. GBM8901 cells were treated with the indicated compounds for 24 h. The cells were then stained with 1 μg/mL acridine orange for 15 min, washed with RPMI 1640 medium, and examined under the fluorescence microscope.

**Protein Expression Knockdown by siRNA Technology.** The beclin1 and Atg7 siRNA gene silencer (human) dsRNA was obtained from Santa Cruz Biotechnology (sc-44286 and sc-41448). Neuroblastoma cells were transfected with dsRNAs using siRNA transfection reagent (Santa Cruz) and incubated for 6 h. Afterward, the cells were analyzed by immunoblot for protein expression.

**Statistical Analysis.** All data were obtained from at least three separate experiments and were expressed as the mean ± standard error of the mean (SEM). Statistical comparison of the differences among multiple groups was performed using one-way analysis of variation

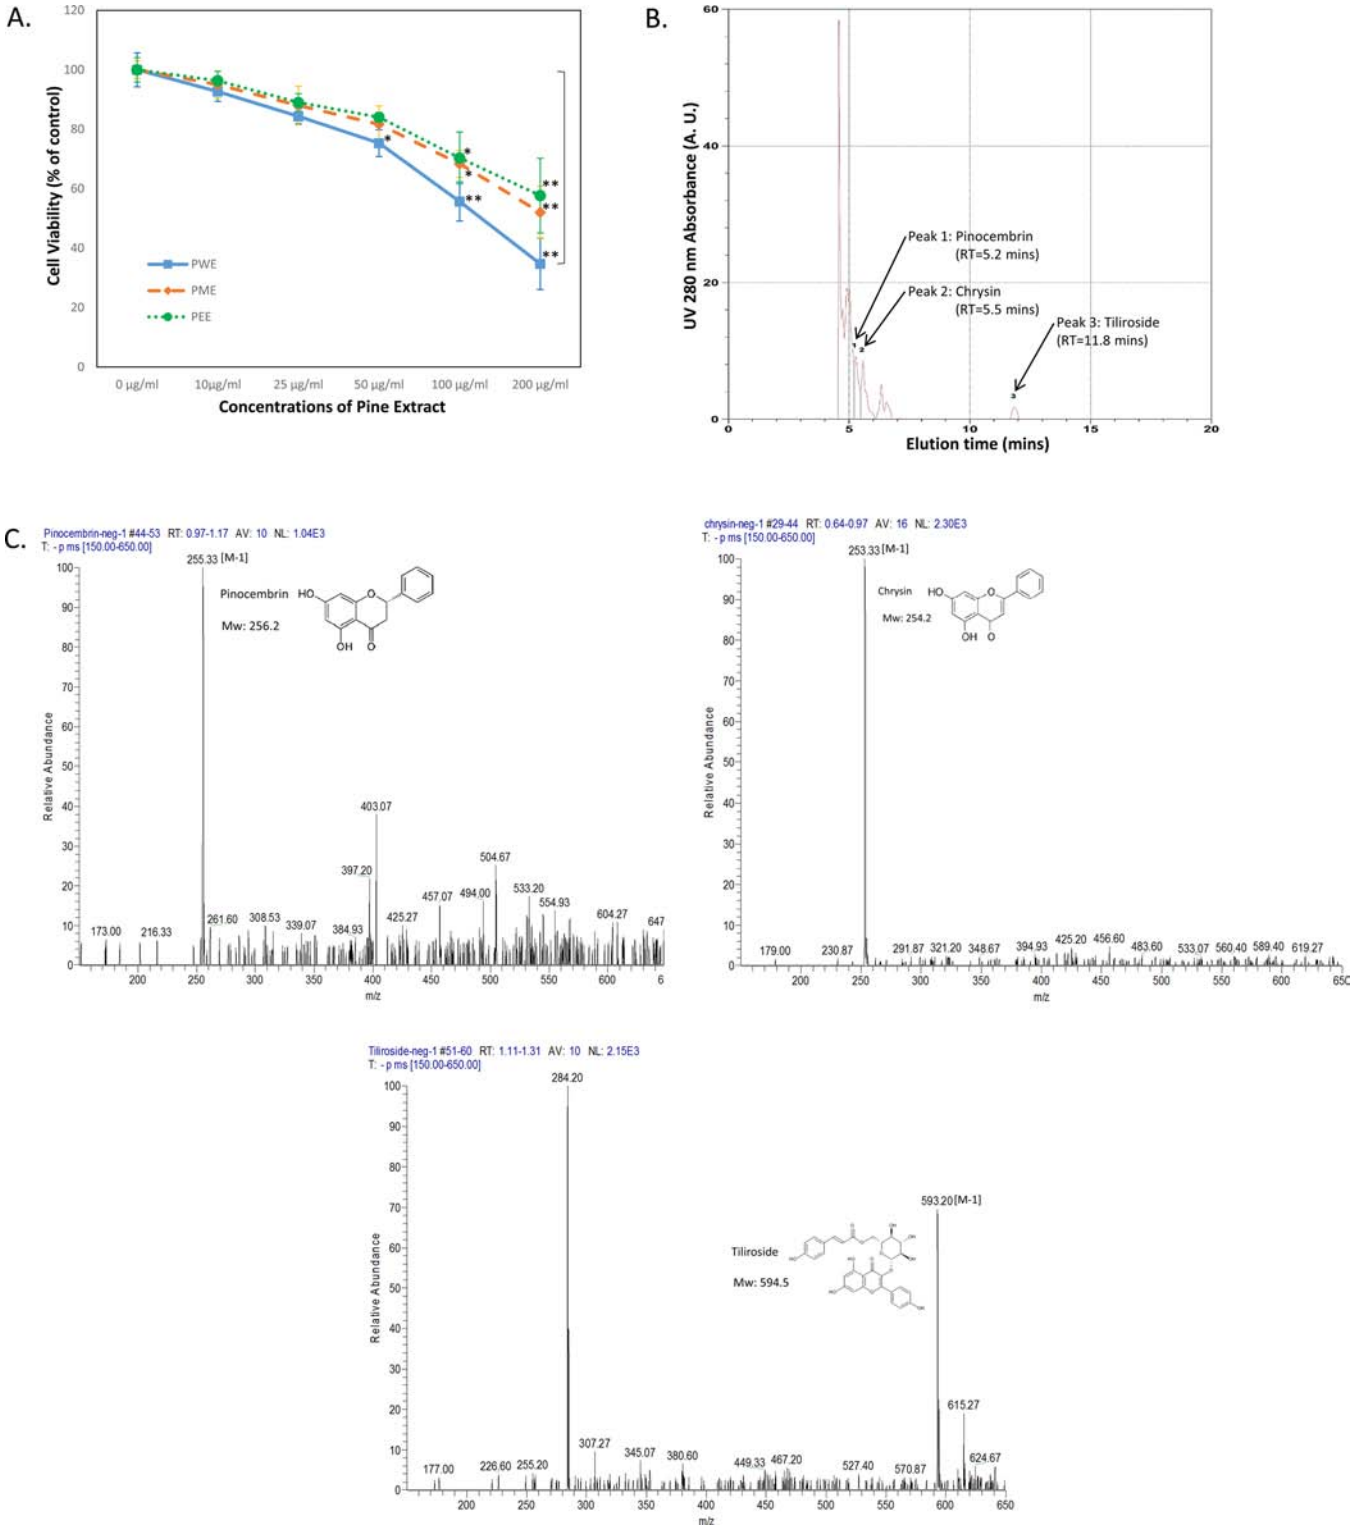

**Figure 1.** *P. morrisonicola* Hayata needle extracts have cytotoxic effects on GBM8901 cells. (A) Cytotoxic potential of the three solvent extracts. GBM8901 cells were incubated with 0−200 $\mu$g/mL pine extracts for 24 h. Cytotoxicity was measured using the MTT method, and the values are represented as the mean ± SEM of triplicates. PME, pine methanol extract; PEE, pine ethanol extract; PWE, pine water extract. (B) Major ingredients of PWE were identified by HPLC. Three compounds, pinocembrin [retention time (RT) = 5.2 min], chrysin (RT = 5.5 min), and tiliroside (RT = 11.8 min), were identified in the extracts. (C) MS/MS product ion profiles of pinocembrin, chrysin, and tiliroside. (∗) $p < 0.05$ and (∗∗) $p < 0.01$ when compared to non-treated cells using the one-way ANOVA test.

(ANOVA) tests, and differences between pairs of groups were compared using Student's $t$ test. Statistical significance was assumed when the $p$ value was ≤0.05. All of the statistical analyses were performed using the SPSS statistical software (SPSS, Inc., Chicago, IL).

## RESULTS

### Cytotoxic Effects of Various Solvent Extracts of *P. morrisonicola* (Hayata) on the GBM8901 Cell Line.

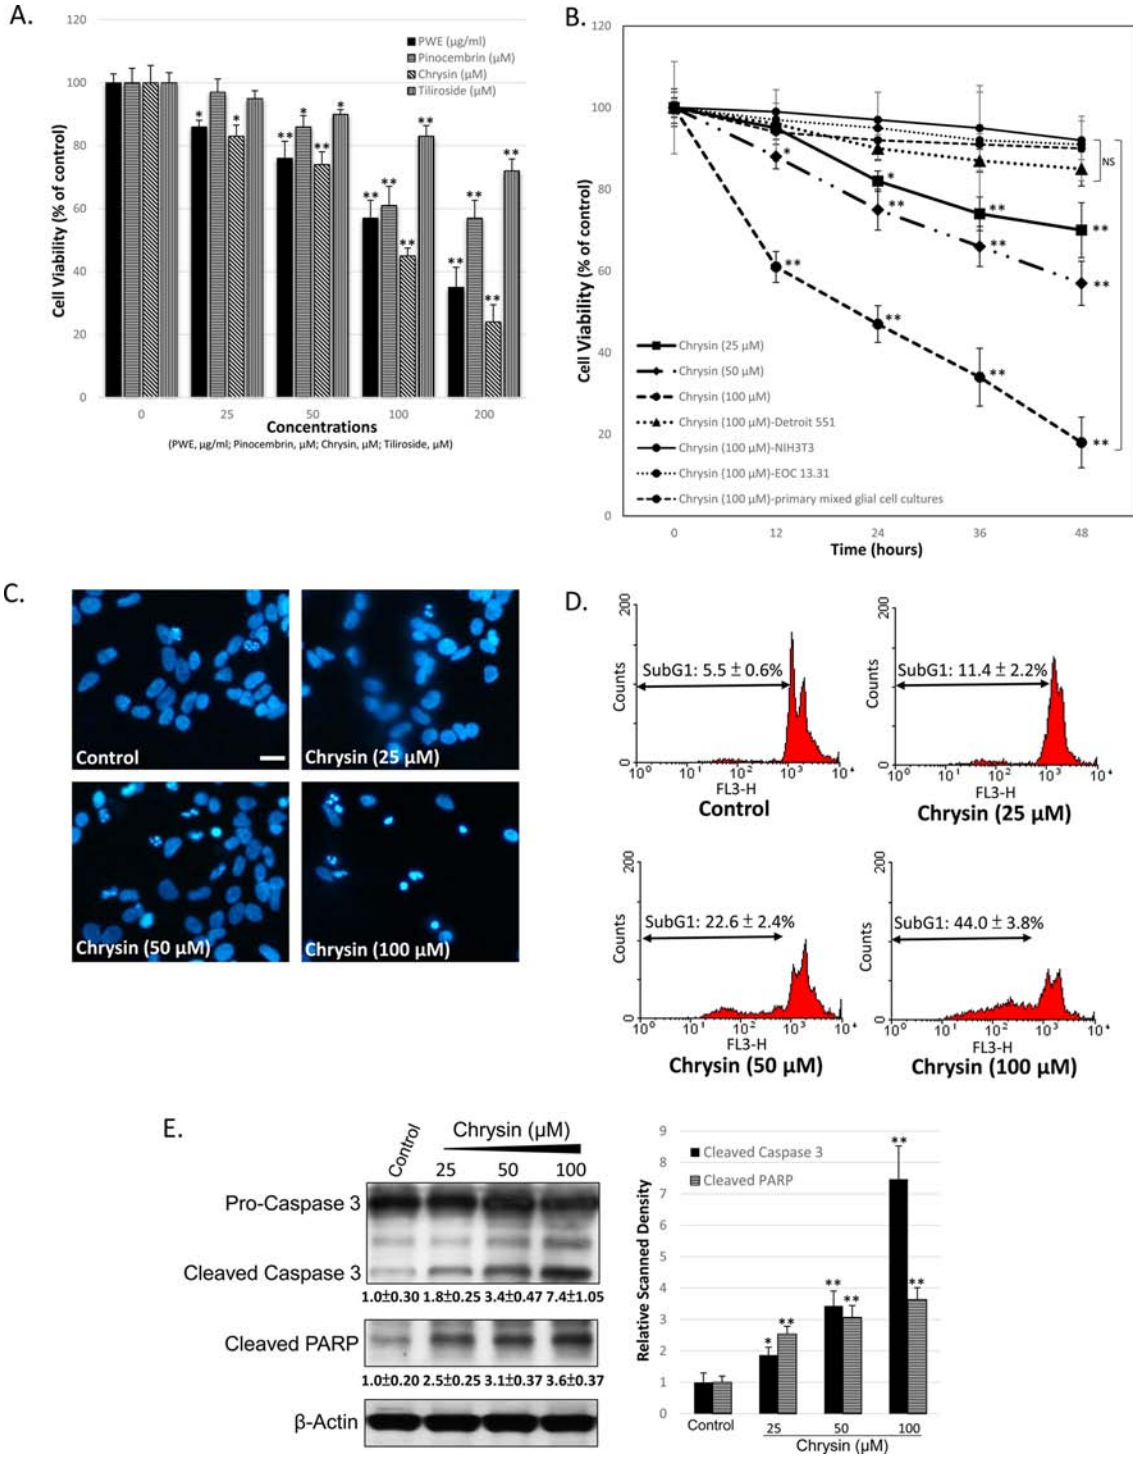

**Figure 2.** Chrysin-induced apoptosis in GBM8901 cells. (A) Effects of PWE, pinocembrin, chrysin, and tiliroside against GBM8901 cells after 24 h of treatment. Among these compounds, chrysin showed the most powerful anti-glioblastoma activity by reducing cell viability. (B) Chrysin exerted cytotoxicity in GBM8901 cells in a dose-dependent manner but only limited the effect in Detroit 551 human normal skin fibroblasts at a concentration of 100 $\mu$M. Measuring apoptosis by (C) fragmented nuclei stained and (D) flow cytometry analysis. (E) Caspase 3 and PARP activation were determined by immunoblotting and evaluated in chrysin-treated GBM8901 cells. Results are expressed as the mean ± SEM of three independent experiments performed in triplicates. (*) $p < 0.05$ and (**) $p < 0.01$ when compared to non-treated cells using the one-way ANOVA test. Proteins from three independent western blot experiments were quantified using densitometry and normalized to actin band intensity. The scale bar represents 50 $\mu$m.

Phenolic compounds are commonly present in pine and are reported to have multiple biological effects, such as growth suppression and death induction. To determine whether pine needle extracts have antiproliferative effects on glioblastoma cells, the ability of crude pine needle extracts to inhibit the viability of GBM8901 cells was examined. Figure 1A shows the cytotoxic effect of various solvent extracts of pine needles, including PME, PEE, and PWE. The $IC_{50}$ values of PWE, PME, and PEE were 121.0, 208.5, and 243.7 $\mu$g/mL, respectively. Of these different solvent extracts, the inhibitory effect of PME was

dx.doi.org/10.1021/jf501234b | J. Agric. Food Chem. 2014, 62, 10458−10467

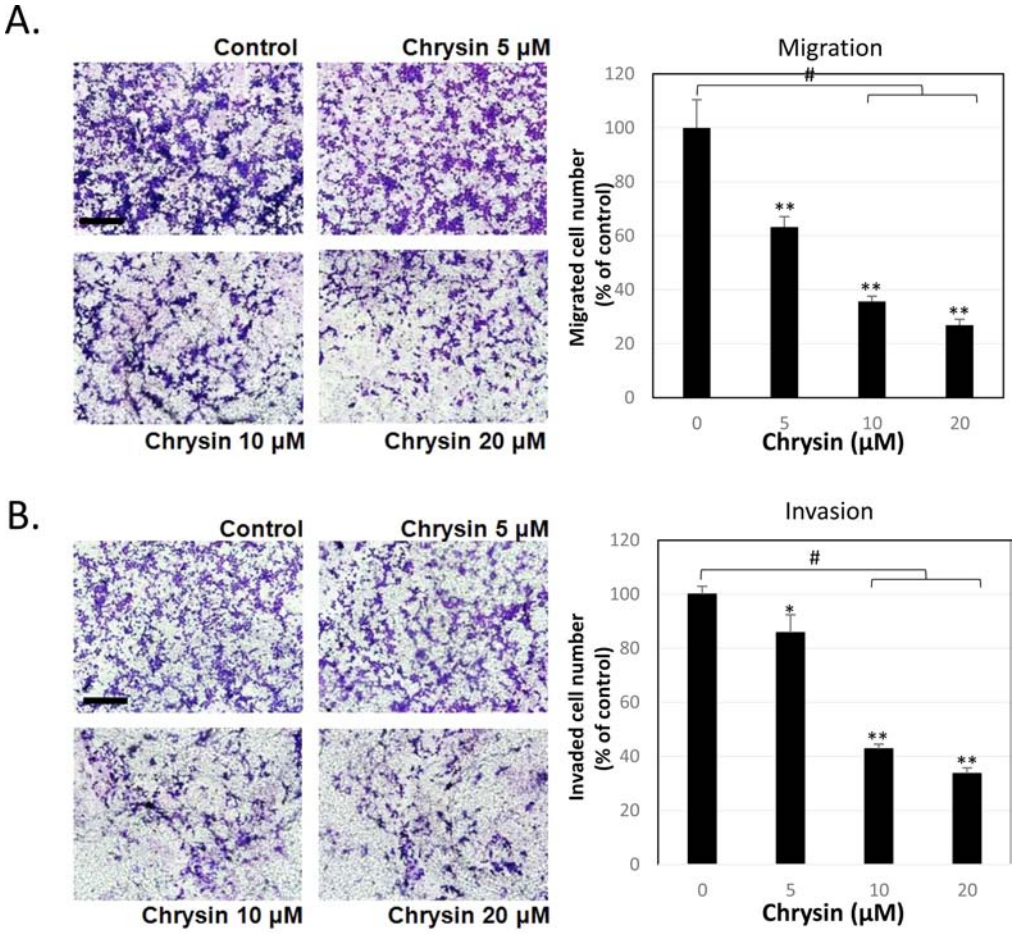

**Figure 3.** Chrysin inhibits the migration and invasion of GBM8901 cells. Transwell migration and Matrigel invasion assays showed that chrysin treatment resulted in a significant inhibition of (A) 74% in migration and (B) 68% in invasion. Experiments were performed in triplicates, and values are presented as the mean ± SEM. (#) $p < 0.05$ for one-way ANOVA or (∗) $p < 0.05$ and (∗∗) $p < 0.01$ for Student's $t$ test.

similar to that of PEE at a higher concentration. However, the $IC_{50}$ value of PWE on GBM8901 cell viability was the lowest. To determine the active ingredients on pine needle extracts that act against GBM8901 cells, the PWE was further analyzed using HPLC (Figure 1B). Using C18 column material and an acidic mobile phase, all of the major constituents of PWE were well-resolved within 20 min. HPLC signals were assigned by standard comparison of UV spectra and were then used directly for MS/MS studies to identify the specific compounds. Using these methods, three compounds were identified from the extract: pinocembrin, chrysin, and tiliroside. These results indicate that the three phenolic compounds were predominantly present in PWE and represented approximately 29% of the total flavonoid content.

**Chrysin Reduces the Proliferation and Induces Apoptosis in GBM8901 Cells.** To determine the most active component of PWE, the cytotoxicity of these pure individual compounds was examined. As shown in Figure 2A, all of the compounds inhibited the proliferation of GBM8901 cells significantly. However, chrysin showed the highest inhibitory activity against GBM8901 cells, indicating that chrysin has a greater anti-glioblastoma activity in PWE. Figure 2B shows that chrysin concentrations ranging from 25 to 100 $\mu$M inhibited the growth of GBM8901 cells in a time-dependent manner. The growth inhibition was approximately 50% at a concentration of 100 $\mu$M after 24 h. However, exposure of several normal cell lines, including Detroit 551, NIH3T3, EOC 13.31, and rat primary mixed glial cells, to 100 $\mu$M chrysin did not induce significant growth inhibition. These results confirmed that chrysin might inhibit the growth of glioblastoma cancer cells without significantly affecting normal cells. To determine further the relationship between growth inhibition and apoptosis, cells were stained with the nuclear staining cytochemistry dye DAPI to analyze the morphology of the nuclei. As shown in Figure 2C, observation of stained fragmented nuclei confirmed that chrysin induced apoptosis in GBM8901 cells. Apoptotic cells were simultaneously quantified by flow cytometry, and there was a significant increase in the percentage of cells in the sub-G1 phase after treatments of chrysin (Figure 2D). Apoptosis induction by chrysin was further examined by western blotting. Figure 2E shows a dose-dependent cleavage of caspase 3 and poly(ADP-ribose)-polymerase (PARP) in GBM8901 cells treated with chrysin. Thus, a higher concentration of chrysin (100 $\mu$M) induced apoptosis after 24 h of treatment.

**Chrysin Inhibits Migration and Invasion by GBM8901 Cells.** The above results showed that chrysin induced apoptosis in glioblastoma cells through caspase 3 and PARP pathways. However, a low concentration of chrysin (25 $\mu$M) did not show this strong apoptosis-inducing effect. Most studies have reported that glioblastoma is the most migratory and invasive brain tumor and is invariably fatal for affected patients.[15] Therefore, GBM8901 cells were treated with chrysin to determine their

dx.doi.org/10.1021/jf501234b | J. Agric. Food Chem. 2014, 62, 10458−10467

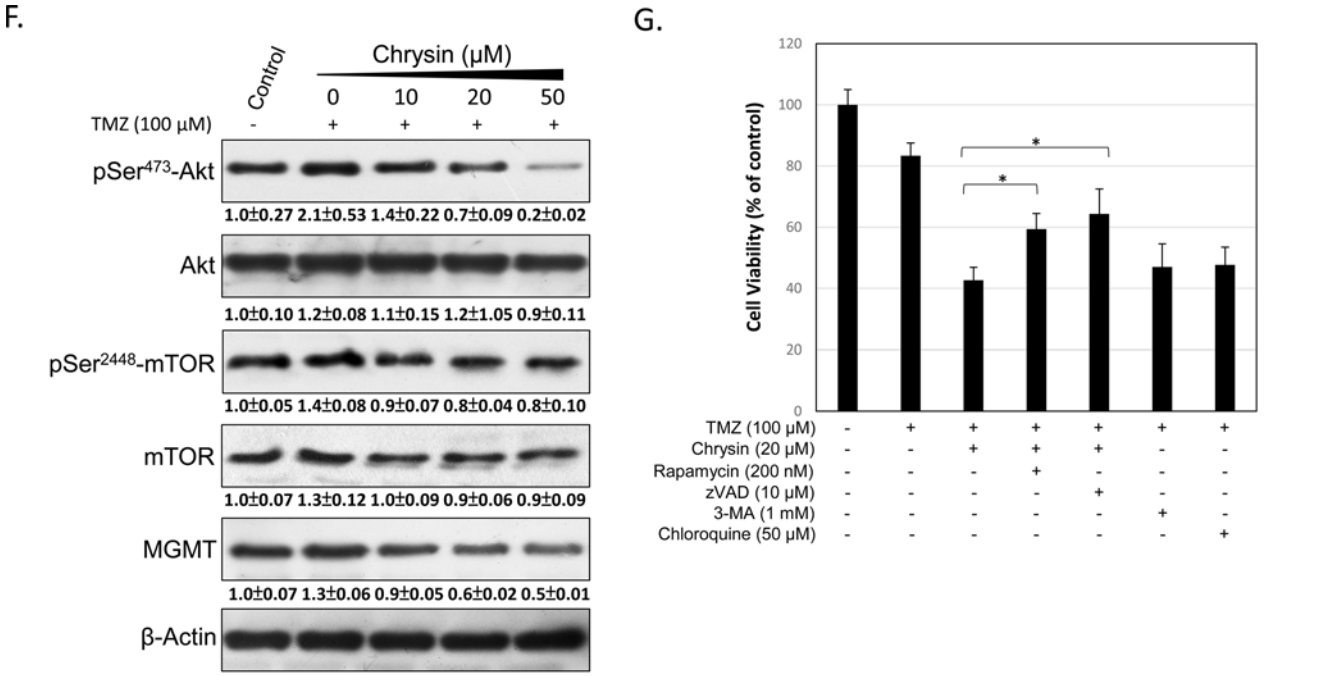

**Figure 4.** Chrysin sensitizes GBM8901 cells to TMZ-induced cytotoxicity. (A) Cells were treated for 24 h with the indicated concentrations of TMZ and chrysin (20 $\mu$M) or PWE (50 $\mu$g/mL). (*) $p < 0.05$ and (**) $p < 0.01$ when compared to TMZ-treated cells for the one-way ANOVA test. (B) Fluorescence microscopy analysis of GBM8901 cells treated with TMZ and chrysin (20 $\mu$M), PWE (50 $\mu$g/mL), 3-MA (1 mM), or CQ (50 $\mu$M) for 24 h, followed by acridine orange staining. The formation of acridine-orange-accumulating acidic vacuoles (orange−red fluorescence) in TMZ-treated cells was significantly suppressed by chrysin, PWE, and autophagic inhibitors 3-MA or CQ treatments. (C) Western blots showing autophagy induction by monitoring LC3, Atg12−Atg5 conjugate, Atg7, beclin1, and p62 levels in GBM8901 cells treated or not treated with TMZ (100 $\mu$M) alone or in combination with PWE (50 $\mu$g/mL), chrysin (20 $\mu$M), or 3-MA (1 mM) for 24 h. (D) Fluorescent microscopy analysis of cells LC3 treated with TMZ (100 $\mu$M) alone or combined with chrysin (20 $\mu$M) or rapamycin (200 nM) co-treatments for 24 h. (E) Beclin1 and Atg7 siRNA (20 nmol/L pool) knockdown was confirmed via western blot, and autophagy blockade was validated using LC3-II western blot. Enhanced apoptosis in response to TMZ (100 $\mu$M) was determined via PARP cleavage. (F) Western blot analysis showed p-Akt/Akt, p-mTOR/mTOR, and MGMT in GBM8901 cells alone or treated with increasing concentrations of chrysin in combination with TMZ (100 $\mu$M). (G) Both rapamycin (200 nM) and zVAD-fmk (10 $\mu$M) treatments for 24 h blocked chrysin-induced cell death significantly. However, 3-MA or CQ treatments enhance cell death similar to that in chrysin-treated groups. (*) $p < 0.05$ and (**) $p < 0.01$ when compared to cells treated with TMZ + chrysin for Student's $t$ test. The mean ± SEM of three independent experiments performed in triplicates is shown. Proteins from three independent western blot experiments were quantified using densitometry and normalized to actin band intensity. The scale bar represents 50 $\mu$m.

migratory and invasive capacities, which are the two most important features of malignant cells. As shown in Figure 3A, chrysin treatment remarkably suppressed the migration of GBM8901 cells by approximately 40−70% in a dose-dependent manner compared to that in control groups. Because cell migration is believed to be a fundamental step in tumor invasion, we next examined the effect of chrysin on the invasive capacity of GBM8901 cells. Treatment of Matrigel-coated wells with chrysin reduced cell invasion significantly in a dose-dependent manner. Because we used a lower dose of chrysin, the above anti-metastatic effects of chrysin were not mainly attributed to its cytotoxicity, as shown in Figure 2B. Our findings suggest that low levels of chrysin effectively inhibited cell migration and invasion by GBM8901 cells.

**Chrysin Sensitizes GBM8901 Cells to TMZ by Inhibiting Autophagy and Attenuating MGMT Expression.** Because TMZ therapy is the current standard of care for patients with malignant glioblastoma, we next examined whether TMZ can decrease cell growth of the GBM8901 cell line. As shown in Figure 4A, TMZ was unable to decrease the growth of GBM8901 cells even at concentrations of up to 200 $\mu$M. These results are consistent with the results of previous studies, which showed that GBM8901 cells are grade-IV GBM cells with an inherent tendency of drug resistance and recurrence.[16] In contrast, a combination of PWE (50 $\mu$g/mL) or chrysin (20 $\mu$M) with TMZ had synergistic cytotoxic effects on GBM8901 cells. This suggested that PWE or chrysin might be effective TMZ-sensitizing agents. Studies have been reported that therapeutic resistance of glioblastoma is attributed to the activation of drug-induced autophagy. Therefore, we first used acridine orange staining to examine whether acidic vacuoles were induced in GBM8901 cells after treatment with TMZ. After exposure to TMZ (100 $\mu$M) for 24 h, cells showed an increase in orange fluorescence, indicating the accumulation of acridine orange in the acidic compartments of TMZ-treated cells. However, co-treatment with PWE or chrysin significantly decreased the orange fluorescence (Figure 4B). Similar to PWE or chrysin, treated cells with the autophagy inhibitors 3-methyladenine (3-MA) and chloroquine (CQ) can both significantly reduce the number of detected orange acidic vesicles. To verify the obtained results, western immunoblotting was performed to probe the autophagy hallmark LC3. TMZ-induced autophagy was determined by the shift in the molecular weight of LC3 from LC3-I to LC3-II. On the other hand, PWE or chrysin markedly inhibited TMZ-induced LC3-II formation. Similar reduction was observed in Atg7, Atg12−Atg5 conjugate, beclin1, and p62. Besides, autophagy inhibition was accomplished using 3-MA, which caused similar effects compared to chrysin groups (Figure

4C). Furthermore, an increase of LC3 punctate dots was observed in TMZ-only groups but abolished by co-treating of chrysin (Figure 4D). In contrast, chrysin-induced autophagy blockade returned to levels similar to those of control for the rapamycin-treated cells. Thus, these independent approaches suggested that TMZ-induced autophagy in GBM8901 cells was inhibited by the co-administration of PWE or chrysin. To further confirm the observations, knockdown of the autophagy constituent, beclin1 and Atg7, was conducted using target-specific siRNAs and cells were treated with or without TMZ, as shown in Figure 4E. Both beclin1 and Atg7 knockdown resulted in pronounced GBM8901 cell apoptosis in response to TMZ treatment. One study reported that TMZ-induced autophagy in glioblastoma cells is dependent upon MGMT.[17] Because MGMT overexpression is a principle mechanisms contributing to TMZ resistance in glioblastoma cells, we examined whether chrysin regulated MGMT expression to increase sensitivity to TMZ. Immunoblotting results shown in Figure 4F indicated that GBM8901 cells expressed higher levels of MGMT, irrespective of TMZ treatment. However, application of chrysin markedly suppressed MGMT expression by inhibiting AKT signaling in a dose-dependent manner. Besides, the expression of phospho-mTOR ($Ser^{2448}$) was unaltered by chrysin, indicating chrysin-inhibited autophagy through a mTOR signaling-independent pathway. To further elucidate the impact of autophagy on chrysin-mediated cell death, GBM8901 cells were treated with autophagy inducers or inhibitors to determine cell viability. As shown in Figure 4G, 3-MA or CQ enhanced glioblastoma cell death similar to that in chrysin-treated groups. However, both rapamycin and zVAD-fmk treatments blocked chrysin-induced cell death, indicating that autophagy supported the viability of GBM8901 cells against chrysin-induced apoptosis. Taken together, these data showed that chrysin might sensitize GBM8901 cells to TMZ by attenuating MGMT expression and TMZ-induced autophagy simultaneously.

## DISCUSSION

Glioblastoma is the most malignant human brain tumor, characterized by increased growth and invasion. The standard therapy for glioblastoma is maximal resection, followed by radiotherapy and concurrent chemotherapy with drugs, such as TMZ. However, glioblastoma is still associated with poor prognosis because of high recurrence after TMZ chemotherapy. To enhance the benefit of TMZ in the treatment of aggressive glioblastoma, effective combination strategies that sensitize glioblastoma cells to TMZ are important to prevent the recurrence of these tumors. In this regard, natural products, such as flavonoids, have received considerable attention because of their lower side effects.[18] In this study, we evaluated the inhibitory effects of pine needle extracts on a malignant glioblastoma cell line GBM8901. Our results showed that chrysin, a major biologically active component in pine needle extracts, inhibited the growth and invasiveness of the glioblastoma cell line. We further observed that chrysin also suppressed TMZ-induced autophagy, which protects glioblastoma cells against chronic TMZ treatment. Signaling through both the Akt pathway and autophagy is frequently activated in glioblastoma cells.[19] Because autophagy is a prosurvival response that makes glioblastoma cells resistant to chemotherapy, our results suggested that use of the nutraceutical chrysin for inhibiting Akt activation and stress-induced autophagy may be a potential therapeutic approach for treating glioblastoma, especially in cases of TMZ-resistant tumor recurrence.

The therapeutic benefit of TMZ also depends upon its ability to alkylate/methylate the DNA in tumor cells. MGMT expression in glioblastoma cells is the most critical determinant of TMZ resistance.[20] MGMT counteracts the effects of TMZ by removing DNA methyl adducts, suggesting that downregulation of MGMT is effective for the management of TMZ-resistant glioblastoma.[21] To date, many clinical trials have aimed to modulate MGMT expression for increasing TMZ efficiency. In this regard, our present study showed that chrysin administration suppressed MGMT expression. Previous studies have suggested that Akt activation contributes to MGMT overexpression in glioblastoma.[22] These findings indicated that chrysin-inhibited Akt signaling may be a strong and selective approach against TMZ-resistant glioblastoma.[23] Logically, activation of Akt-mTOR signaling inhibits autophagy. However, our data indicated that mTOR phosphorylation was unaltered but phosphorylation of Akt at $Ser^{473}$ was significantly inactivated by chrysin treatment. This indicates chrysin-inhibited autophagy through an Akt-mTOR signaling-independent pathway. Interestingly, accumulating studies indicated that autophagy is mediated in many circumstances by negative modulation of apoptosis.[24] Moreover the autophagy-associated protein, LC3, and Akt were maintained during the treatment with TMZ, suggesting that glioblastoma cells escape from TMZ-induced cell death because of Akt signaling pathways.[25] Our results demonstrated that chrysin induces apoptosis and downregulates Akt of GBM8901 cells significantly, suggesting that chrysin-induced apoptotic signaling serves to inhibit autophagy. This result is consistent with those of previous studies, which have shown that pharmacologic inhibition of stress-induced autophagy was reported to promote chemotherapeutic response.[26] However, the mechanisms mediating the counter-regulation of apoptosis and autophagy are not yet fully understood. In addition, recent studies have reported that chrysin inhibits nuclear factor E2-related factor 2 (Nrf2) by downregulating the PI3K/Akt/Nrf2 pathway.[27] The Nrf2 signaling is known to activate autophagy-related genes independent of mTOR.[28] Thus, our data indicated that chrysin decreased the expression of Akt, which may have contribute to the inhibition of autophagy by a similar pathway in GBM8901 cells. However, these ideas remain to be examined further.

Chrysin, a natural, biologically active dietary flavonoid extracted from propolis and other plants, has various beneficial health effects. Chrysin exerts an anticancer effect through various mechanisms, including inhibition of the PI3K/Akt pathway and activation of mitogen/stress-activated kinase 1 (MSK1) signaling.[29,30] Chrysin also selectively sensitizes cancer cells to apoptosis via tumor necrosis factor-related apoptosis-inducing ligand (TRAIL) by inhibiting STAT3 and Mcl-1.[31] Moreover, chrysin decreases the expression of vimentin, suggesting that it attenuates epithelial−mesenchymal transition and suppresses metastases.[29] This results indicate the potential of chrysin in treating cancer and overcoming therapeutic resistance. In this study, we reported that chrysin is an active compound in pine needle extracts and potentially inhibits autophagy and MGMT expression, thus sensitizing glioblastoma cells to TMZ. Similar results were obtained by Markiewicz-Żukowska et al., who showed antiproliferative properties of chrysin-rich ethanolic extract of propolis in glioblastoma and its synergistic action with TMZ.[32] On the basis of these results, we proposed that chrysin may be a useful monotherapy to enhance brain tumor apoptosis and inhibit tumor migration/invasion or a component of combination therapy to overcome TMZ resistance and prolong

the survival of patients with malignant glioblastoma. Pine needle extracts and chrysin are reported to have various effects on the central nervous system (CNS),[13,33] suggesting that chrysin may have the ability to cross the blood−brain barrier (BBB). In fact, most flavonoids are amphipathic molecules that appears to be capable of passing the BBB and reaching the CNS.[34] However, further studies, especially in *in vivo* models, are needed to elucidate the efficacy of the anti-glioblastoma effects of chrysin.

In conclusion, we identified an efficient method to extract chrysin from pine needles and evaluated the anti-glioblastoma effects of chrysin, which could be potentially used as an efficacious component in functional food products. Our study also showed a novel role of chrysin in sensitizing glioblastoma cells to TMZ. These findings are consistent with those obtained from a model that simultaneously suppresses TMZ-induced autophagy and MGMT expression in TMZ-resistant glioblastoma, suggesting that modulation of the autophagic pathway may be a novel way to modify resistance to TMZ. Therefore, chrysin in combination with TMZ chemotherapeutic agent warrants further examination.

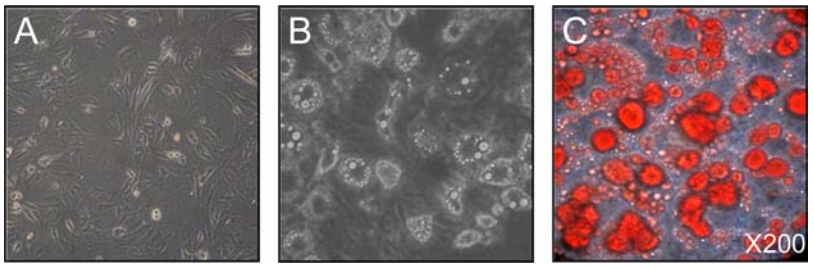

**Figure 1.** Morphology and oil red O staining of differentiated 3T3-L1 cells: (A) morphology of 3T3-L1 preadipocytes before differentiation; (B) morphology of differentiated 3T3-L1 cells at 10 day. (C) On 10 day after differentiation, the cells were stained with oil red O and viewed under a microscope.

kinase 1 (S6K1) and the mammalian target of rapamycin complex 1 (mTORC1) signaling pathway in adipose tissue, suggesting that this compound regulates diet-induced obesity.[19]

However, there has been no study on the effect of fisetin on the regulation of adipokines, particularly adiponectin, in terms of obesity and adiposity. Therefore, this study aimed to investigate the effect of fisetin on the regulation of adiponectin expression in association with other related regulators such as SIRT1 and PPARs using 3T3-L1 preadipocyte cells, which finally differentiate to mature adipocytes.

## MATERIALS AND METHODS

**Materials.** Fisetin, dexamethasone, 3-isobutyl-1-methylxanthine (IBMX), insulin, oil red O, and sirtinol were obtained from Sigma-Aldrich (St. Louis, MO, USA). PPAR$\alpha$ antagonist GW6471 was purchased from Tocris (Ellisville, MO, USA). PPAR$\gamma$ antagonist T0070907 was purchased from Cayman (Ann Arbor, MI, USA). Anti-adiponectin, anti-PPAR$\alpha$, anti-PPAR$\gamma$, anti-PGC-1, anti-acetyl-lysine, anti-AMPK, anti-phospho-AMPK (T172), and anti-$\beta$-actin antibodies were obtained from Santa Cruz Biotechnology (Santa Cruz, CA, USA). SIRT1 siRNA and scrambled control siRNA-A were also purchased from Santa Cruz Biotechnology. Anti-rabbit IgG light chain was purchased from Aviva Systems Biology (San Diego, CA, USA). A mouse adiponectin Quantikine ELISA kit was purchased from R&D Systems (Minneapolis, MN, USA).

**Cell Culture and Differentiation.** 3T3-L1 mouse preadipocytes were obtained from American Type Culture Collection (ATCC, Rockville, MD, USA). Preadipocytes were maintained under Dulbecco's modified Eagle's medium (DMEM) supplemented with 10% bovine calf serum (BCS) in a 37 °C humidified atmosphere containing 5% $CO_2$. Passage numbers of cells used were between 10 and 20. Two days after full confluence, cells were induced to differentiate by exposure to 1 $\mu$M dexamethasone, 0.5 mM IBMX, and 10 $\mu$g/mL insulin in DMEM with 10% FBS for 72 h. Cells were replaced with DMEM supplemented with 10% FBS and 10 $\mu$g/mL insulin. Another 2 days later, the medium was changed to DMEM with 10% FBS. Thereafter, cells were maintained by exchanging media every 2 days with DMEM with 10% FBS until used in the experiments 10−14 days after initiation of the differentiation protocol. The cells were used for experiments whenever 80−90% of the cells exhibited the adipocyte phenotype by accumulation of lipid droplets.

**Oil Red O Staining.** Cell medium was discarded from fully differentiated 3T3-L1 adipocytes. Cells were prefixed with 10% formalin for 5 min at room temperature. After prefix, formalin was discarded and the same volume of fresh formalin was added. Cells were incubated at room temperature for at least 1 h or more. The parafilm was wrapped over the plate to prevent drying. After fixing of the cells, formalin was discarded, and the cells were washed with 60% isopropanol. After cells were completely dried, oil red O staining working solution (Sigma-Aldrich) filtered at 0.2 $\mu$m pore size was added, and the cells were stained for 10−20 min. After staining, oil red O solution was removed and $dH_2O$ was added immediately. Cells were washed with distilled water four times. Cells were observed and photographed by using an Olympus CKX41 microscope (Olympus, Japan).

**Immunoblot Analysis.** Fisetin-treated differentiated cells were harvested and washed twice in ice-cold PBS. Samples were placed in ice-cold lysis buffer containing 40 mM HEPES (pH 7.5), 120 mM NaCl, 1 mM EDTA, 1% Triton, and EDTA-free protease inhibitor cocktail (Roche Diagnostics, Mannheim, Germany) for 30 min. Cell lysates were clarified by centrifugation (13000 rpm for 30 min). Protein concentrations were determined using a Bicinchoninic Acid Protein Assay Kit (Sigma-Aldrich). Proteins were separated in 8% or 12.5% SDS-PAGE and transferred onto polyvinylidene difluoride (PVDF) membrane (Millipore, Bedford, MA, USA). The membrane was blocked in 5% nonfat dry milk dissolved in Tris-buffered saline (TBS) for 1 h. After washing with TBS with 0.05% Tween-20, the membrane was incubated with primary antibodies and then incubated with horseradish peroxidase (HRP)-conjugated secondary antibodies. The bands were detected using the enhanced chemiluminescence (ECL) reagent (Santa Cruz Biotechnology).

**Immunoprecipitation.** After cell lysis, cell lysates were clarified by centrifugation. Cell extract (200−500 $\mu$g) was precleared with protein A/G agarose (Santa Cruz Biotechnology) on a rotating platform plate at 4 °C for 1 h. Then sample was incubated with antibody on a rotation platform plate at 4 °C for 2 h. After a washing with PBS, the sample was subjected to SDS-PAGE and immunoblot analysis.

**SIRT1 Activity Assay.** SIRT1 activity assay proceeded with a Deacetylase Fluorometric Activity Assay Kit (Enzo Life Sciences, Farmingdale, NY, USA), according to the manufacturer's instructions. Briefly, differentiated 3T3-L1 cells were treated with different concentrations of fisetin. Cells were extracted as described above, and then the protein concentration in the cell lysate was quantified with deacetylase buffer. Reactions with cell lysate were performed in the presence of 200 $\mu$M Fluor-de-Lys substrate. Then Fluor-de-Lys developer was treated for 30 min. Finally, the fluorescence was read using a fluorometric reader (Victor 3 Multilabel Plate Readers, PerkinElmer, Waltham, MA, USA) with excitation of 360 nm and emission at 460 nm. Negative controls were also included for normalization.

**RT-PCR Analysis.** Cells were harvested, and total RNA was isolated using QIAzol-Regent (Qiagen, Germany). An equal quantity of total RNA was reverse transcribed using Omniscript Reverse Transcriptase (Qiagen) and Oligo-dT primer. The cDNA was amplified using *Taq* DNA polymerase (Cosmo Genetech, Korea) and primer sets. The primer sequences were as follows: adiponectin primers, 5′-TGGAGAGAAGGGAGAGAAAGG-3′ and 5′-TGGTCG-TAGGTGA AGAGAACG-3′; GAPDH primers, 5′-CATGGCCTT-CCGTGTTCCTAT-3′ and 5′-CCTGCTTCACCACCTTCTTGA-3′. PCR products were separated by electrophoresis in agarose gel containing ethidium bromide.

**PPAR Activity Assay.** A PPAR Transcription Factor Assay Kit (Cayman) was used for the determination of PPAR$\alpha$ and PPAR$\gamma$ DNA binding and transcription activity. Briefly, cells were harvested and placed in hypotonic buffer on ice for 15 min. Nonidet P-40 (10%) was added and gently mixed. The turbid lysate were clarified by centrifugation at 4 °C. The supernatant was transferred to a new tube as cytosolic fraction. The pellet was also resuspended with ice-

cold complete nuclear extraction buffer and rocked vigorously for 45 min. The lysate was clarified by centrifugation at 4 °C, and the supernatant was collected as nuclear fraction. The nuclear fractions were added to consensus dsDNA-coated 96-wells as a quantitatively equal amount. After primary antibody (anti-PPAR$\alpha$ antibody or anti-PPAR$\gamma$ antibody) incubation, horseradish peroxidase-conjugated secondary antibody was added, and the optical density of each well was measured using a Multiskan plate reader (Thermo Scientific, Waltham, MA, USA) with 450 nm wavelength.

**Small Interfering RNA (siRNA).** For SIRT1 siRNA transfections, 3T3-L1 adipocytes, 2−3 days post differentiation, were transfected with Lipofectamine RNAiMAX (Invitrogen, Carlsbad, CA, USA), according to the manufacturer's protocol. Following 24 h of transfection with 40 nM siRNA, the protein level of SIRT1 was analyzed with anti-SIRT1 antibody.

**Statistical Analysis.** Data are expressed as means ± SE. Statistical comparisons were performed by using one-way analysis of variance and Student's $t$ test. Differences were considered significant at $p < 0.05$.

## RESULTS

**Fisetin Up-regulates Adiponectin Expression in Differentiated 3T3-L1 Cells.** Mouse 3T3-L1 preadipocytes were differentiated to mature adipocytes as described under Materials and Methods. Cell morphology showed that differentiated 3T3-L1 cells had many lipid droplets indicating lipid accumulation, whereas these were not observed in undifferentiated preadipocytes (Figure 1A,B). The oil red O staining was executed to confirm differentiation and lipid droplet formation with red pigments (Figure 1C). Differentiated 3T3-L1 cells were exposed to fisetin with range of concentration from 1 nM to 10 $\mu$M for 24 h. The culture media were collected and subjected to ELISA. Adiponectin was secreted from 3T3-L1 adipocyte cells in response to fisetin treatment in a concentration-dependent manner (Figure 2A). The adiponectin expression levels in fisetin-treated 3T3-L1 cells were also determined by immunoblot analysis. As shown in Figure 2B, protein expression levels of adiponectin were up-regulated upon the addition of fisetin in a similar pattern to adiponectin secretion. The mRNA levels of adiponectin were also up-regulated upon treatment with fisetin (Figure 2C).

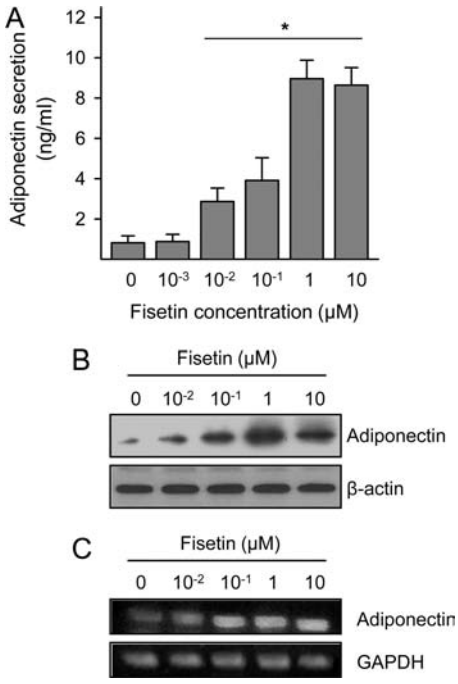

**Figure 2.** Effect of fisetin on adiponectin expression and secretion in 3T3-L1 adipocytes. Differentiated 3T3-L1 cells were treated with the indicated concentration of fisetin for 24 h. (A) Adiponectin levels released from 3T3-L1 cells were determined using adiponectin ELISA kit. (B) Protein levels of adiponectin in 3T3-L1 cell lysate were analyzed by immunoblot assay using anti-adiponectin antibody. (C) Total RNA was purified from 3T3-L1 cells and subjected to RT-PCR analyses using primers specific for adiponectin. (*) $p < 0.05$ by Student's $t$ test.

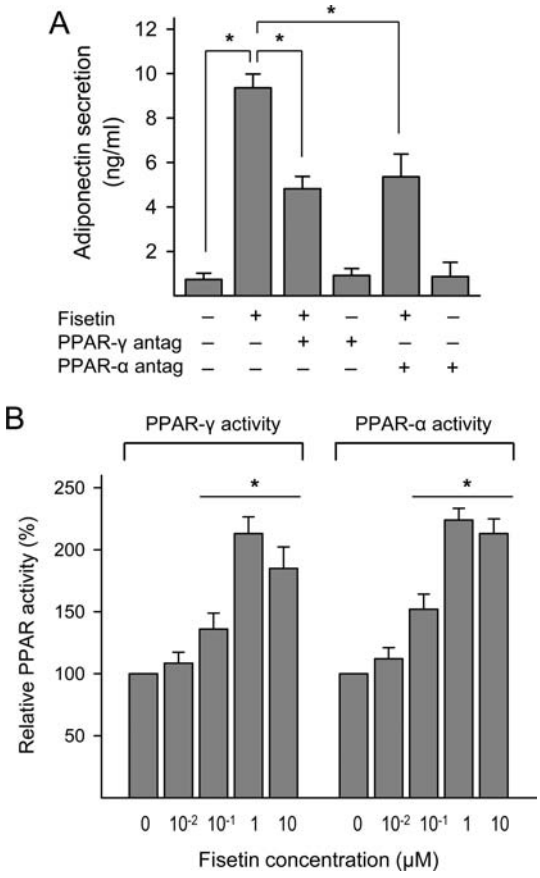

**Figure 3.** Effect of PPARs on fisetin-induced adiponectin up-regulation. (A) Differentiated 3T3-L1 cells were pretreated with PPAR-$\gamma$ antagonist (20 $\mu$M T0070907) or PPAR-$\alpha$ antagonist (20 $\mu$M GW6471) for 1 h and then treated with 1 $\mu$M fisetin for 24 h. Adiponectin levels released from cells were determined using adiponectin ELISA kit. (B) Differentiated 3T3-L1 cells were treated with the indicated concentration of fisetin for 24 h. PPARs activity was determined in nuclear extracts using a PPAR transcription factor assay kit. (*) $p < 0.05$ by Student's $t$ test.

**Fisetin Activates PPARs, Which Up-regulates Adiponectin Expression.** To assess the effects of PPARs on the adiponectin production induced by fisetin treatment in 3T3-L1 cells, we used two selective antagonists, T0070907, a PPAR-$\gamma$ antagonist, and GW6471, a PPAR-$\alpha$ antagonist. Differentiated 3T3-L1 cells were pretreated with T0070907 or GW6471 for 1 h and then treated with 1 $\mu$M fisetin for 24 h. As shown in Figure 3A, fisetin-induced adiponectin production was significantly inhibited by both antagonists. In addition, fisetin induced the activation of the PPARs in a concentration-dependent manner, reaching a maximum at 1 $\mu$M (Figure 3B).

**Fisetin Induces SIRT1 Activation.** To determine whether SIRT1 is involved in fisetin-induced adiponectin production,

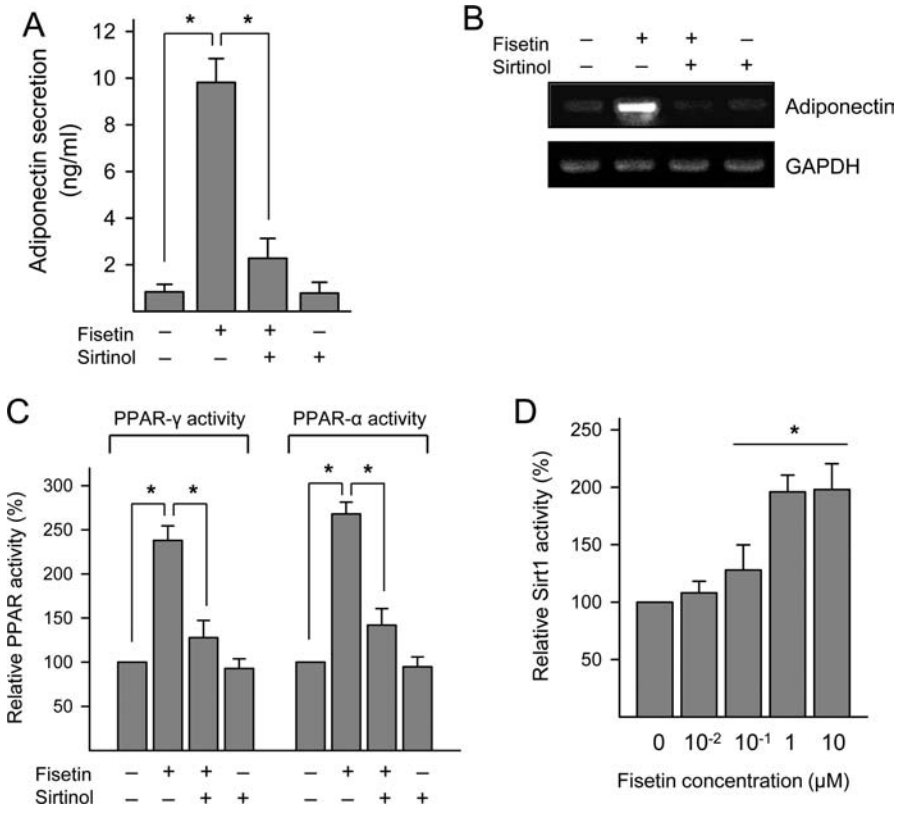

**Figure 4.** Effect of SIRT1 on fisetin-induced adiponectin up-regulation. Differentiated 3T3-L1 cells were pretreated with SIRT1 inhibitor (60 $\mu$M sirtinol) for 1 h and then treated with 1 $\mu$M fisetin for 24 h. (A) Adiponectin levels released from 3T3-L1 cells were determined using adiponectin ELISA kit. (B) Total RNA was purified from 3T3-L1 cells and subjected to RT-PCR analyses using primers specific for adiponectin. (C) PPAR-$\gamma$ and PPAR-$\alpha$ activities were determined in nuclear extracts using PPAR transcription factor assay kit. (D) Differentiated 3T3-L1 cells were treated with the indicated concentration of fisetin for 24 h. SIRT1 activity was determined with a deacetylase fluorometric activity assay kit. (*) $p < 0.05$ by Student's $t$ test.

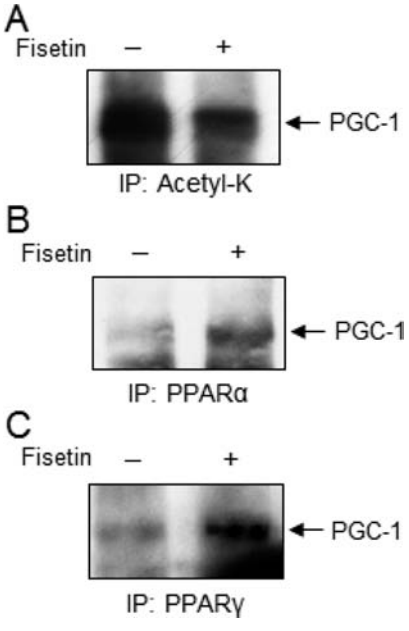

**Figure 5.** Interaction between PPARs and PGC-1. Differentiated 3T3-L1 cells were treated with 1 $\mu$M fisetin for 24 h. Cell lysate was immunoprecipitated with antiacetyl-lysine antibody (A), anti-PPAR-$\alpha$ antibody (B), or anti-PPAR-$\gamma$ antibody (C). Then immunoprecipitant samples were analyzed by immunoblot assay with anti-PGC-1 antibody.

we examined the effect of treatment with a SIRT1 inhibitor, sirtinol, on fisetin-induced adiponectin expression and secretion in 3T3-L1 cells. Fisetin-induced adiponectin release was significantly suppressed by treatment with sirtinol (Figure 4A). RT-PCR data also showed that inhibition of SIRT1 leads to a significant decrease in expression level of adiponectin induced by fisetin (Figure 4B). Moreover, the SIRT1 inhibitor suppressed fisetin-induced PPAR activation (Figure 4C). To check whether fisetin affected SIRT1 activity, we measured the intracellular SIRT1 activity in fisetin-treated adipocytes. It was found that fisetin increased the SIRT1 activity in a concentration-dependent manner (Figure 4D).

**Fisetin Promotes PPARs–PGC-1 Interaction.** We examined whether fisetin treatment alters the acetylation level of PGC-1 and the interaction between PPARs and PGC-1 in 3T3-L1 cells. Fisetin-treated cell lysates were immunoprecipitated with anti-acetyl lysine antibody and immunoblotted with anti-PGC-1 antibody. As shown in Figure 5A, fisetin reduced the acetylation level of PGC-1. Also, an immunoprecipitation study using anti-PPAR antibodies showed that the interaction of PPARs and PGC-1 was significantly elevated in fisetin-treated cells (Figure 5B,C).

**Effects of SIRT1 Knock-Down on PPARs and PGC-1 in Fisetin-Treated Adipocytes.** To confirm the molecular mechanisms of SIRT1-mediated adiponectin expression in fisetin-treated adipocytes, we used siRNA to silence SIRT1 gene expression. The SIRT1 protein level was significantly decreased in the cells transfected with SIRT siRNA compared

dx.doi.org/10.1021/jf502849j | J. Agric. Food Chem. 2014, 62, 10468–10474

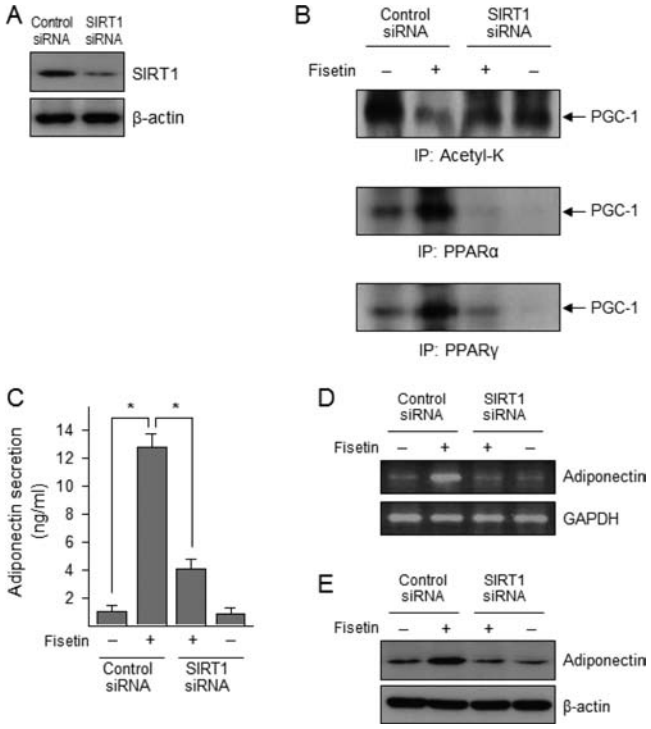

**Figure 6.** Effects of SIRT1 knock-down on PPARs−PGC-1 interaction and adiponectin production. (A) Differentiated 3T3-L1 cells were transfected with SIRT1 siRNA or control siRNA. After 24 h, SIRT1 levels were analyzed by immunoblot assay using anti-SIRT1 antibody. (B) After 24 h of transfection with SIRT1 siRNA, 3T3-L1 cells were incubated with 1 $\mu$M fisetin for 24 h. Cell lysate was immunoprecipitated with antiacetyl-lysine antibody, anti-PPAR-$\alpha$ antibody, or anti-PPAR-$\gamma$ antibody. Then immunoprecipitant samples were analyzed by immunoblot assay with anti-PGC-1 antibody. (C) Differentiated 3T3-L1 cells transfected with SIRT1 siRNA were treated with 1 $\mu$M fisetin for 24 h. Adiponectin levels released from cells were determined using an adiponectin ELISA kit. (D) Expression of adiponectin was determined by RT-PCR analysis. (E) Protein levels of adiponectin in cell lysate were analyzed by immunoblot assay using anti-adiponectin antibody. (*) $p < 0.05$ by Student's $t$ test.

to control siRNA (Figure 6A). We found that SIRT1 knockdown led to a decrease in deacetylation of PGC-1 in fisetin-treated cells (Figure 6B). Knockdown of SIRT1 also largely decreased fisetin-induced interaction of PPARs and PGC-1 (Figure 6B). To check the changes of adiponectin production by SIRT1 knockdown, we measured the secreted adiponectin in the culture medium. Fisetin-stimulated adiponectin production was significantly blocked by SIRT1 knockdown (Figure 6C), and there was a high correlation with mRNA expression and protein level in the cells (Figure 6D,E).

## ■ DISCUSSION

This study shows that fisetin, a dietary flavonoid, significantly promoted the expression of adiponectin through the activation of SIRT1-deacetylase and PPARs in adipocytes. In this study, we found increased expression and secretion of adiponectin in 3T3-L1 cells upon treatment with fisetin in a concentration-dependent manner. The activities of PPARs and SIRT1 were also increased by the stimulation of fisetin. In addition, fisetin-induced adiponectin secretion was inhibited by PPARs antagonists. The up-regulation of adiponectin and the activation of PPARs by fisetin were also prevented by SIRT1 inhibitor and knockdown with SIRT1 siRNA. Furthermore, fisetin promoted the deacetylation of PGC-1 and its interaction with PPARs. We also confirmed an important role of SIRT1-mediated deacetylation in regulating the PPARs−PGC-1 interaction and adiponectin production induced by fisetin. This is the first study showing the beneficial effect of fisetin on the adipokine regulation in adipocytes, thereby being considered to contribute to the modulation of the pathogenesis of obesity-linked metabolic disorders and vascular diseases.

Previous studies demonstrated that several polyphenols and bioactive natural products promoted the expression and secretion of adiponectin in adipocytes.[12−14] According to Yen et al., polyphenolic compounds (i.e., resveratrol, quercetin, and *p*-coumaric acid) increased the levels of secreted adiponectin and antioxidant enzymes and inhibited the production of cytokines and intracellular reactive oxygen species in the tumor necrosis factor receptor-stimulated 3T3-L1 adipocytes.[12] In this study, we also found that fisetin, one of flavonoids, increased adiponectin gene expression and its secretion in 3T3-L1 cells. Fisetin is a naturally occurring flavonoid, commonly found in strawberries and other fruits, that belongs to the flavonoid groups of plant polyphenols.[17−20] Fisetin was reported to exert a wide range of biological activities such as anti-inflammatory,[21] antioxidant,[22] and anticancer activities.[23] Also, Lee and Bae reported an antiadiposity effect of fisetin, which suppressed preadipocyte proliferation at early stages of differentiation, partly mediated by cell cycle arrest during adipogenesis.[24] We also tested several fisetin analogues for adiponectin production using ELISA in differentiated 3T3-L1 cells. However, the other compounds including apigenin did not exhibit considerable adiponectin production (data not shown).

Adiponectin is the most abundantly secreted adipokine, particularly derived from the adipocytes, which is involved in a variety of pathophysiological processes such as obesity, diabetes, and CVDs and exerts various beneficial effects as an antidiabetic, antiatherogenic, and anti-inflammatory.[6−9] Various studies reported that PPAR$\alpha$ and PPAR$\gamma$ are important transcription factors involved in adipogenesis and adipokine expression.[25−27] The initiation of adiponectin gene promotion was known to require the formation of PPAR$\gamma$ and retinoid X receptor (RXR) or PPAR$\alpha$−RXR complex,[28] thereby the complex binding with adiponectin promoter region for the activation. As an essential initiation condition for its activity, PPAR−RXR complexes were reported to require PGC-1 to bind with the complex itself to invoke transcriptional activation, which up-regulates adiponectin gene expression.[28,29] In addition, the deacetylation of SIRT1, a family of sirtuins that are characterized as its deacetylase activity against nonhistone protein, was reported to participate in the regulation of various transcription factors, for example, PGC-1, forkhead box-type O transcription factors, liver X receptor, RXR p53, mammalian target of rapamycin complex 1, and insulin receptor substrate 2.[30−34] According to recent studies, SIRT1 binds with PGC-1 and deacetylases PGC-1 to restore its activity to work as a PPAR coactivator, thereby binding with the PPAR$\gamma$−RXR or PPAR$\alpha$−RXR complex.[35−37]

In our study, PPARs and SIRT1 were significantly activated by fisetin treatment in 3T3-L1 cells, and fisetin-induced adiponectin secretions were inhibited by PPAR antagonists and SIRT1 inhibitor. Fisetin-induced PPAR activations were also prevented by SIRT1 inhibition and knockdown, and the deacetylation of PGC-1 and its interaction with PPARs were promoted by fisetin. Therefore, our data suggested that fisetin can up-regulate adiponectin expression by increasing SIRT1-

deacetylase activity, which catalyzes PGC-1 deacetylation, leading to an increase in the interaction with PPAR complex and ultimately to transcriptional activation. Our findings may have clinical importance given that adiponectin has multiple beneficial effects on obesity-related medical complications.[38] Moreover, fisetin is thought to prevent adipocyte differentiation, thereby maintaining preadipocytes in an undifferentiated state,[24] whereas in certain conditions such as differentiated state, cells can encounter the different responses that are activated to promote adiponectin production with another physiological signal under fisetin treatment. Hence, fisetin could have potential applications in the prevention and treatment of diseases, alternative medicine, and other therapeutic approaches by modulating the concentration or improving the bioavailability.

In summary, this study showed that fisetin, a dietary flavonoid, increased adiponectin gene transcription by inducing SIRT1-deacetylase activity. The activation of SIRT1 by fisetin may be connected to PGC-1 deacetylation, which increases its interaction with PPAR complex, which triggers up-regulation of adiponectin promoters. This is the first report of the beneficial effect of fisetin on the regulation of adipokine derived from adipocytes. The discovery of fisetin as an up-regulator of adiponectin expression that functions to enhance insulin sensitivity, suppress inflammation, and increase energy expenditure may exert its beneficial biofunction, thereby fisetin being considered as a contributor for modulating the pathogenesis of obesity-linked metabolic disorders.

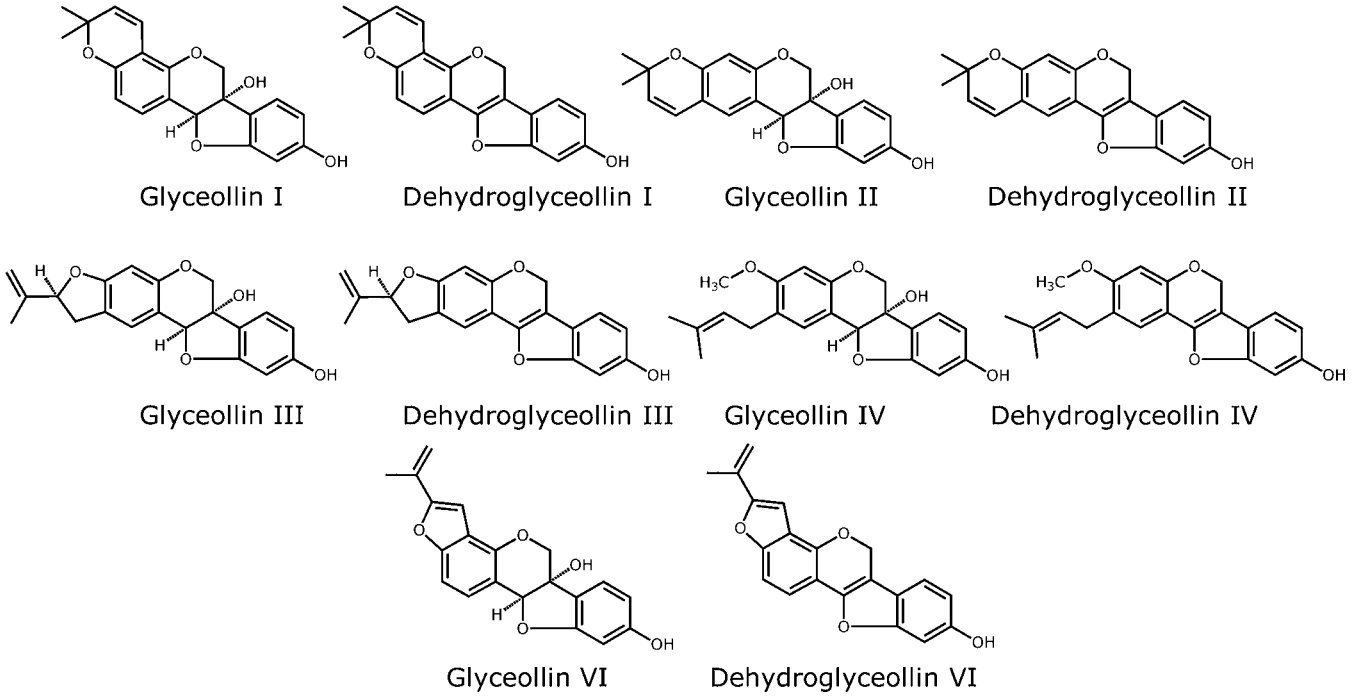

**Figure 1.** Structures of glyceollins and dehydroglyceollins assigned in soy extracts.

## MATERIALS AND METHODS

**Materials.** Soybeans, *Glycine max* (L.) Merrill, were provided by Frutarom (Londerzeel, Belgium). Acetic acid (HOAc) (HPLC grade), daidzein, genistein, coumestrol, L-leucine, L-histidine, sodium hydroxide (NaOH) pellets, and 17$\beta$-estradiol ($E_2$) were purchased from Sigma-Aldrich (St. Louis, MO, U.S.A.). Ethanol (100%, analytical grade), D-(+)-glucose (dextrose), ammonium sulfate and dimethyl sulfoxide (DMSO) were purchased from Merck (Darmstadt, Germany) and yeast nitrogen base without amino acids and without ammonium sulfate, and agar were obtained from Becton-Dickinson (Franklin Lakes, NJ U.S.A.). HOAc (ULC/MS grade), acetonitrile (ACN) (ULC/MS and HPLC-R grade), silica gel (60 Å, 70−230 mesh), water (ULC/MS grade), ethyl acetate (LC-MS grade), and methanol (ULC/MS grade) were purchased from Biosolve BV (Valkenswaard, The Netherlands). Water for other purposes than UHPLC was prepared using a Milli-Q water purification system (Millipore, Molsheim, France). The reporter yeast strain was provided by RIKILT (Wageningen, The Netherlands).

***Rhizopus*-Challenged Germination and Extraction of Soybean Seedlings.** Soybeans, *Glycine max* (L.) Merril, were germinated and challenged with the fungus *Rhizopus microsporus var. oryzae* (LU581) as previously described.[7] After germination and challenging, the soybean sprouts were freeze-dried and milled with a Retsch Ultra centrifugal mill ZM (Haan, Germany), using a 0.5 mm sieve. Soybeans were defatted by hexane. Next, isoflavonoids were extracted with ethanol and subsequent drying was performed as described elsewhere.[7] The dried extract containing the isoflavonoids is referred to as soy extract.

**Heat Treatment of Soy Extract.** The soy extract was suspended in either 0.56 M HOAc or water to a concentration of 10.7 mg/mL. The suspension was heated in a water bath of 100 °C, during three independent experiments. Samples were taken after 20, 30, 40, 50, 60, and 70 min in experiment 1; after 10, 30, 60, and 120 min in experiment 2; after 1, 5, 30, 60, 180, and 240 min in experiment 3. After the heat treatment, ethanol (EtOH) was added to obtain a 70% (v/v) EtOH concentration. Solubilisation was enhanced in a water bath of 40 °C for 5 min followed by sonification at 25 °C for 10 min. Finally, the samples were centrifuged (18.500*g*; 5 min; RT) and the supernatant was stored at −20 °C.

**RP Flash Chromatography.** For Flash chromatography, the untreated soya extract and a modified soy extract (0.56 M HOAc, 70 min at 100 °C) were used. Solvents were evaporated under vacuum, frozen and lyophilized. A Grace Reveleris Flash system was used to obtain fractions enriched in glyceollins or dehydroglyceollins. The untreated and treated soy extract (52.2 mg DW) were solubilized in methanol acidified with 0.1% (v/v) HOAc to a concentration of 5 mg/mL (5 min in a water bath of 40 °C, followed by 10 min sonication at 25 °C). This solution was added to 3 g silica and the soy extract was coated onto silica particles by using a rotary evaporator. The soy extract-coated silica was transferred into an empty 5 g cartridge and closed with a plunger. The cartridge was placed upstream of a 12 g Reveleris C18 RP column (particle size 38.6 $\mu$m) (Grace Davison Discovery Science, Columbia, MD, U.S.A.). Water (Milli-Q) acidified with 0.1% (v/v) HOAc (HPLC grade) + 1% (v/v) ACN (HPLC-grade), eluent A, and ACN (HPLC-grade) acidified with 0.1% (v/v) HOAc (HPLC grade), eluent B, were used as eluents. The flow rate was 30 mL/min and the experiment was performed at room temperature. The following elution profile was used: 0−5 min, linear gradient from 0 to 40% B; 5−9 min, linear gradient from 40 to 50% B; 9−14 min, isocratic on 50% B; 14−19 min, linear gradient from 50 to 60% B; 19−24 min, linear gradient from 60 to 70% B; 24−27 min, linear gradient from 70 to 80% B; 27−28 min, linear gradient from 80 to 84% B; 28−33 min, linear gradient from 84 to 96% B; 33−35 min, linear gradient from 96 to 100% B. Absorption was measured at 280 nm. During the entire run, fractions of 10 mL were collected. All fractions were analyzed with UHPLC-MS. Fractions containing similar glyceollins or dehydroglyceollins were pooled. Solvents from pools containing dehydroglyceollins were evaporated under vacuum, frozen, and lyophilized. Ethyl acetate was added to the pools containing glyceollins in a ratio 3:1 (v/v). This liquid−liquid partitioning was performed three times. The pooled ethyl acetate fractions were evaporated under vacuum, frozen, and lyophilized. The pools were resolubilized in 70% (v/v) ethanol for analysis with UHPLC-MS and resolubilized in DMSO to determine the estrogenicity.

**RP-UHPLC-ESI-MS Analysis.** Samples were analyzed on an Accela ultra high performance liquid chromatography (RP-UHPLC) system (Thermo Scientific, San Jose, CA, U.S.A.) equipped with a pump, autosampler and PDA detector. Samples (5 $\mu$L for the soy extract and 1 $\mu$L for isoflavonoid-enriched pools) were injected on an Acquity UPLC BEH Shield RP18 column (2.1 × 5 mm$^2$, 1.7 $\mu$m particle size)

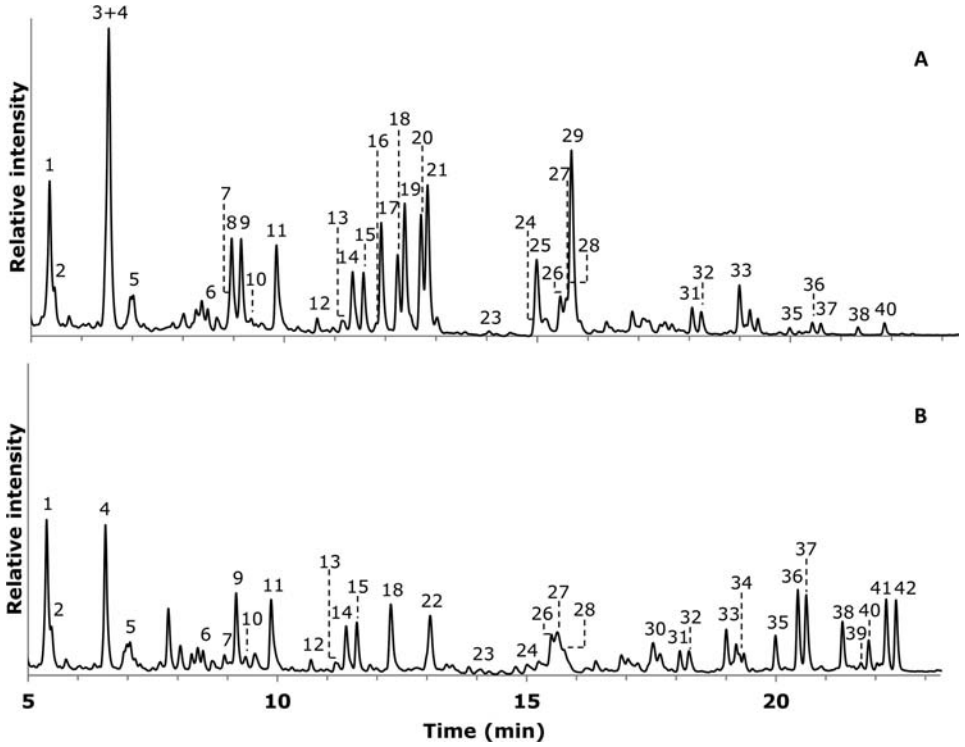

**Figure 2.** RP-UHPLC-UV profile of untreated (A) and heat (60 min)/acid treated (B) soy extract. Peak numbers refer to compounds in Table 1.

with an Acquity UPLC Shield RP18 Vanguard guard-column (2.1 × 5 $mm^2$, 1.7 $\mu$m particle size; Waters, Milford, MA, U.S.A.). Water acidified with 0.1% (v/v) HOAc + 1% (v/v) ACN, eluent A, and ACN acidified with 0.1% (v/v) HOAc, eluent B, were used as eluents. The flow rate was 300 $\mu$L/min, the column temperature was controlled at 35 °C, and the PDA detector was set to measure 200−400 nm. The following elution profile was used: 0−1 min, isocratic on 9% B; 1−3 min, linear gradient from 9 to 25% B; 3−10 min, linear gradient from 25 to 50% B; 10−13 min, isocratic on 50% B; 13−23 min, linear gradient from 50 to 100% B; 23−25 min, isocratic on 100% B; 25−26 min, linear gradient from 100 to 9% B; 26−31 min, isocratic on 9% B.

Mass spectrometric (MS) data were obtained by analyzing samples on a LTQ-Velos (Thermo Scientific) equipped with a heated ESI-MS probe coupled to the RP-UHPLC. Nitrogen gas was used as sheath and auxiliary gas. Data were collected over a $m/z$ range of 150−1500 in both positive (PI) and negative (NI) mode. Data-dependent $MS^2$ analysis was performed with a normalized collision energy of 35%. Most settings were optimized via automatic tuning using "Tune Plus" (Xcaliber 2.1, Thermo Scientific). The system was tuned with genistein in both PI and NI mode. For the PI an NI mode, the source voltage were 4.50 kV and 3.50 kV, respectively. In both ionization modes the ion transfer tube (ITT) temperature and the probe temperature were 400 and 50 °C, respectively.

The identification of isoflavonoids was based on UV and MS spectra using the approach reported earlier.[6,7,12] The quantification of isoflavonoids was performed based on their absorption at 280 nm by means of Xcalibur (version 2.1.0, Thermo Scientific). As for many compounds no commercial standards were available, the amounts of isoflavonoid were expressed as mg daidzein equivalents per gram challenged soybean seedling extract, in which daidzein was used as a generic standard to make a calibration curve with five data points (0.001−0.01 mg/mL, $R^2$ = 0.996).

**Determination of Molecular Characteristics.** Molecular structures were evaluated using the software program ChemBio3D Ultra 12 (Cambridgesoft, Waltham, MA, U.S.A.) after MM2 molecule minimization.

**Determination of Estrogenic Activity.** Estrogenicity was determined as described elsewhere[13] with slight modifications. Cultures of the yeast estrogen biosensor with either ER$\alpha$ or ER$\beta$ were grown overnight at 30 °C and 200 rpm. At the late log phase, both cultures were diluted in minimal medium supplemented with either L-leucine (ER$\alpha$) or L-histidine (ER$\beta$) to an optical density value at 630 nm ($OD_{630}$) of 0.045 ± 0.005 and 0.200 ± 0.005 for ER$\alpha$ and ER$\beta$, respectively. For determination of ER agonism, 200 $\mu$L aliquots of diluted yeast cultures were combined with 2 $\mu$L of test compound or isoflavonoid fraction in a 96-well plate. Dilution series of each sample were prepared in DMSO ranging from 0.0001−10 $\mu$g/mL. The final concentration of DMSO in the assay did not exceed 1% (v/v). Each sample concentration was assayed in triplicate. Exposure was performed for 6 or 24 h for the ER$\beta$ or ER$\alpha$ assay, respectively, at 30 °C and orbital shaking at 200 rpm. Fluorescence and OD were measured at 0 and 24 h for the ER$\alpha$ and at 0 and 6 h for the ER$\beta$ in a Tecan Infinite F500 (Männedorf, Switzerland), using an excitation filter of 485 nm (bandwidth, 20 nm) and an emission filter of 535 nm (bandwidth, 35 nm). The fluorescence signals of the samples were corrected with the signal obtained with the diluted yeast suspension at $t$ = 0. In order to verify the viability of the yeast in each well, the absorbance was measured at 630 nm. Cytotoxicity occurred when the yeast growth was inhibited for more than 30% during the incubation and these incubations were not further considered. DMSO (blank) and control samples containing 17$\beta$-estradiol (E2) dissolved in DMSO were included in each experiment. The $EC_{50}$ values for 17$\beta$-estradiol in the ER$\alpha$ and ER$\beta$ bioassay were 0.66 nM and 0.18 nM, respectively, and were in line with those reported previously.[13] $EC_{50}$ calculations were performed in Sigma Plot (8.02, SPSS Inc., Chicago, IL, U.S.A.). The relative estrogen potency (REP) of a compound was determined by dividing the $EC_{50}$ of E2 by the $EC_{50}$ of the compound. The $EC_{50}$ values could not be calculated in all cases, due to toxicity of the compounds toward the yeast. To be consistent for all compounds, the REP was determined by thresholds, i.e., the threshold of $E_2$ divided by the threshold of the compound. The threshold value was defined as the value where the slope was >0.4 units relative absorbance per log difference in concentration. The threshold values for 17$\beta$-estradiol in the ER$\alpha$ and ER$\beta$ bioassay were 5.44 × $10^{-8}$ and 2.45 × $10^{-8}$ mg/mL, respectively. For the determination of ER antagonism, the yeast cells were exposed to 2 $\mu$L of $EC_{70}$ (ER$\alpha$) or $EC_{90}$ (ER$\beta$) of 17$\beta$-estradiol in combination with 2 $\mu$L of different dilutions of test compound or

fraction (measured in triplicates). For antagonism, the decrease of the maximal response in percentages was determined.

## RESULTS

**Identification of Isoflavonoids in Untreated and Heated Soy Extracts.** Comparison of the chromatograms of the 60 min acid/heat treated and untreated soy extract showed that a number of compounds were acid/heat unstable (Figure 2). In total, 42 peaks were distinguished using UV, MS, and $MS^2$ in negative and positive mode (Table 1), many of which were annotated in our previous studies.[6,7] Peaks 22, 30, 34−38, and 40 were new. They seemed to be formed upon acid/heat treatment at the expense of peaks 3, 8, 17, 19−21, 25, and 29, which all represented 6a-hydroxy-pterocarpans. The newly formed compounds had molecular masses minus 18 Da compared to the original 6a-hydroxy-pterocarpans. Moreover, the newly formed compounds showed a second absorption maximum between 330 and 364 nm, besides the one at around 280 nm (Table 1). This indicated that these newly formed compounds have a larger conjugated system than the 6a-hydroxy-pterocarpans. Taken together, this might suggest that the 6a-hydroxy-pterocarpans were converted into 6a,11a-pterocarpenes. Formation of 6a,6-pterocarpenes seems unlikely as these compounds have a less extensive conjugated system, consistent with their lower $\lambda_{max}$ of 302 nm.[14] For 6a,11a-pterocarpenes, other than those from soybean, absorption maxima between 330 and 350 nm have been reported, similar to those observed in the present study.[15]

*MS and $MS^2$ NI Mode.* Compound **22** with an $m/z$ value of 253 in NI mode produced fragment ions $m/z$ 209 $[M - H - CO_2]^-$, 225 $[M - H - CO]^-$, and 235 $[M - H - H_2O]^-$. It was tentatively assigned as dehydroglycinol. Compound **30** was tentatively assigned as dehydroglyceofuran based on a $m/z$ of 335 in NI mode and fragment ions with a $m/z$ of 291 $[M - H - CO_2]^-$, and 307 $[M - H - CO]^-$. Compound **34** was tentatively identified as dehydroglyceollidin II with a $m/z$ of 321 in NI mode. In NI $MS^2$ mode fragment ions $m/z$ 265 $[M - H - 2CO]^-$, 277 $[M - H - CO_2]^-$, and 306 $[M - H - CH_3]^-$ were formed. Compounds **35**−**37** were tentatively assigned as dehydroglyceollin I, II, and III, as these compounds have a $m/z$ of 319 in NI mode. They produced the fragment ions $m/z$ 291 $[M - H - CO]^-$ and 275 $[M - H - CO_2]^-$ in NI $MS^2$ mode. Assuming that compounds **35**−**37** had the same elution order as their corresponding glyceollins, peak **35** was tentatively annotated as dehydroglyceollin III, peak **36** as dehydroglyceollin II, and peak **37** as dehydroglyceollin I. Compound **38** was tentatively annotated as dehydroglyceollin IV with a $m/z$ of 335 in NI mode. In NI, $MS^2$ a loss of a methyl radical was observed. This is indicative for the presence of a methoxy group.[16] Compound **40** had a $m/z$ of 317 in NI mode and was tentatively identified as dehydroglyceollin VI, with neutral losses of CO (28 Da) and $CO_2$ (44 Da). In this study, only traces of *retro*-Diels−Alder fragments were observed in NI $MS^n$ for the compounds described above. Such MS behavior was also found in other studies performed with pterocarpenes and coumestans.[15,17] Both these subclasses of isoflavonoids have a relatively large conjugated system. This results in small neutral losses and no apparent A-ring or B-ring fragment ions, due to the resistance against cleavage of the C-ring or D-ring.

*MS and $MS^2$ PI Mode.* Additional data for confirmation that the prenylated compounds after the treatment were formed at the expense of the 6a-hydroxy-pterocarpans came from PI MS analysis, which allowed prediction of the type of prenylation.[18] For compounds **34**−**38** and **40** neutral losses of 42 and 56 Da were observed in PI $MS^2$. The ratio (42:56) was <1 for compound **34** and **38**, which suggested that these compounds had a prenyl chain. This ratio was >1 for compounds **35** and **36**, indicative for a pyran ring. Compounds with a furan ring are known to show a different behavior.[17] Glyceollin III has a 2″-isopropenyl-dihydrofuran-group and the ratio (42:56) is >1. However, glyceollin VI has a 2″-isopropenyl-furano-group and the ratio is <1. Upon fragmentation of compounds **35** and **40**, which were probably formed from glyceollin III and glyceollin VI, respectively, it was observed that the ratio for compound **35** was >1 and that for compound **40** was <1. This is in line with the corresponding 6a-hydroxy-pterocarpans. On the basis of UV data, $MS^n$ data in negative and positive mode the compounds were tentatively annotated as 6a,11a-pterocarpenes. It seems that the 6a-hydroxyl group of the original 6a-hydroxy-pterocarpans was first protonated, followed by dehydration and formation of a double bond during the heat treatment. This resulted in a more extensive conjugated system than the original 6a-hydroxy-pterocarpan. These findings are in accordance with previous data.[11] They suggest that the 6a-hydroxy-pterocarpan glyceollin I forms the thermodynamically more stable 6a,11a-pterocarpene dehydroglyceollin I upon water loss.[11] Structures of the main prenylated 6a-hydroxy-pterocarpans and 6a,11a-pterocarpenes are shown in Figure 1. Note that the nomenclature of glyceollins and dehydroglyceollins is ambiguous in literature, as elaborated in the footnote of Table 1.

Peaks **39**, **41**, and **42** appeared only after 20 min of acid/heat treatment. They all had a $m/z$ value in NI mode of 277.2169, corresponding to the molecular formula of $C_{18}H_{30}O_2$. Similar $m/z$ values suggest that compounds **39**, **41**, and **42** were isomers. Despite the fact that the amount of these compounds increases and the amount of dehydroglyceollin I, II, and III decreases after longer duration of incubation, it is unlikely that there is a relationship between these compound groups, considering the molecular formulas of dehydroglyceollins ($C_{20}H_{16}O_4$) and compounds **39**, **41**, and **42**.

**Stability of 6a-Hydroxy-Pterocarpans Compared to Other Soy Isoflavonoids.** The soy extract contained different subclasses of isoflavonoids (Table 1). Before heating, 6a-hydroxy-pterocarpans comprised 45% of the total area at 280 nm of all isoflavonoids, coumestans 10%, isoflavones 43%, and pterocarpenes 1%. After a 60 min combined heat/acid treatment all 6a-hydroxy-pterocarpans were converted. Now, 29% of the total area of isoflavonoids belonged to the subclass of pterocarpenes, 20% corresponded to coumestans, and 51% to isoflavones. The compositions were expressed as percentages of the total peak area, as molecular extinction coefficients were not known for all compounds. Comparing the total peak area of the untreated soy extract and the treated soy extract (60 min 100 °C + 0.56 M HOAc), it can be calculated that a loss of 45% of the total isoflavonoids occurred during acid/heat treatment (Figure 2). When only heat was applied a loss of 19% was observed (data not shown). Considering the scope of this study, this loss of isoflavonoids was not further elaborated. The conversion of isoflavonoids when heated with and without acid at different time points can be seen in Figure 3. The 6a-hydroxy-pterocarpans were converted for 23% after 5 min, and for 53% after 20 min; within 180 min at 100 °C all 6a-hydroxy-pterocarpans were converted. This transition was accelerated with acid: after 5 min 32% was converted and within 20 min all 6a-hydroxy-pterocarpans were converted. This is in agreement

[a]The nomenclature of glyceollins and dehydroglyceollins is ambiguous. The nomenclature in this article is based on Simons et al. and Aisyah et al.[6,7] Glyceollin VI in this article is sometimes also referred to as clandestacarpin in the literature. Dehydroglyceollin III in this article is also referred to as glyceollin VI in the literature. In the current work, "glyceollin" always refers to prenylated 6a-hydroxy-pterocarpans, whereas "dehydroglyceollin" always refers to prenylated 6a,11a-pterocarpenes. [b]Only peaks with a relative intensity of 4% or higher were considered, with a maximum of the four most abundant product ions. [c]The $[M + H - H_2O]^+$ dominated in the $MS^1$ compared to the $[M + H]^+$.

**Figure 3.** Conversion of 6a-hydroxy-pterocarpans in time with (○) or without acid (●) and the conversion of other isoflavonoids in time with (□) or (■) without acid.

with a previous study, showing that glyceollin I was unstable at temperatures above 40 °C and at pH values below 4.[11] The other three subclasses of isoflavonoids showed little conversion (~15%) and acid did not accelerate this conversion. This suggests that the 6a-hydroxyl group of 6a-hydroxy-pterocarpans in particular is susceptible to acid. This is in line with a thermal degradation study, in which daidzein and genistein did not degrade after 3 h of heating at 150 °C, whereas a minimal degradation of glycitein was seen after 1 h of heating.[19] In contrast, it has also been shown[20] that degradation of daidzein and genistein, occurred at 120 °C and pH 7 and 9.

**Preparative Enrichment of Prenylated 6a-Hydroxy-Pterocarpans and 6a,11a-Pterocarpenes.** In order to compare the estrogenic properties of glyceollins and dehydro-glyceollins, the (treated) soy extracts were fractionated using Flash chromatography, with a fairly good separation considering the particle size of the column material (Figure 4). All fractions were analyzed by RP-UHPLC-MS, and it was seen that the first 20 fractions contained unprenylated isoflavonoids (data not shown). The subsequent fractions contained prenylated isoflavonoids and the compositional analysis of these fractions is shown in Figure 5. Different prenylated isoflavonoids could be separated and different pools were made based on this compositional analysis (Figure 4). Fractions 28−29 and 33−36 contained the prenylated 6a-hydroxy-pterocarpans, mainly present before the treatment. Fractions 28 and 29 were combined to obtain pool 1, and 97% of this pool comprised of the 6a-hydroxy-pterocarpans glyceollin I, II, and III. Pool 2 (fractions 33−36) contained 74% glyceollin IV and VI. Fractions 58−66 and 71−75 contained the prenylated 6a,11a-pterocarpenes, obtained in high quantities after the heat/acid treatment. Fractions 58−66 were combined to obtain pool 3, which consisted of 88% dehydroglyceollin I, II, and III. Pool 4 (fractions 71−75) contained 89% dehydroglyceollin IV and VI (Table 2 and Supporting Information (SI) Figure S1). It should be noted that the sample used for Flash chromatography was dried at slightly elevated temperatures, which resulted in a larger proportion of 6a,11a-pterocarpenes than in the untreated sample shown in Figure 2A. This sample is further referred to as "mildly treated". The treated sample used for Flash chromatography had a further increased proportion of 6a,11a-pterocarpenes (pool 3 and 4) compared to the untreated sample, at the expense of 6a-hydroxy-pterocarpans (pool 1 and 2) (data not shown).

**Change in Estrogenic Activities upon Heating.** The different pools were tested for their estrogenic activities (Figure 6). Agonistic activities were expressed as relative estrogen

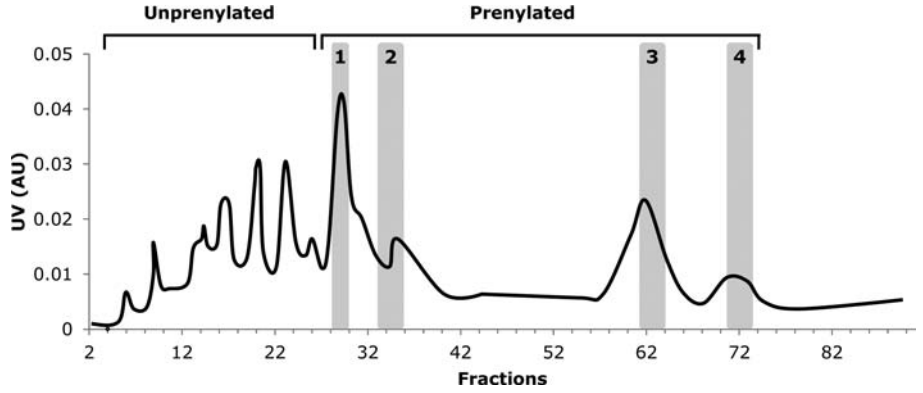

**Figure 4.** Flash chromatography UV profile of the mildly treated soy extract. Gray areas refer to the four different pools collected.

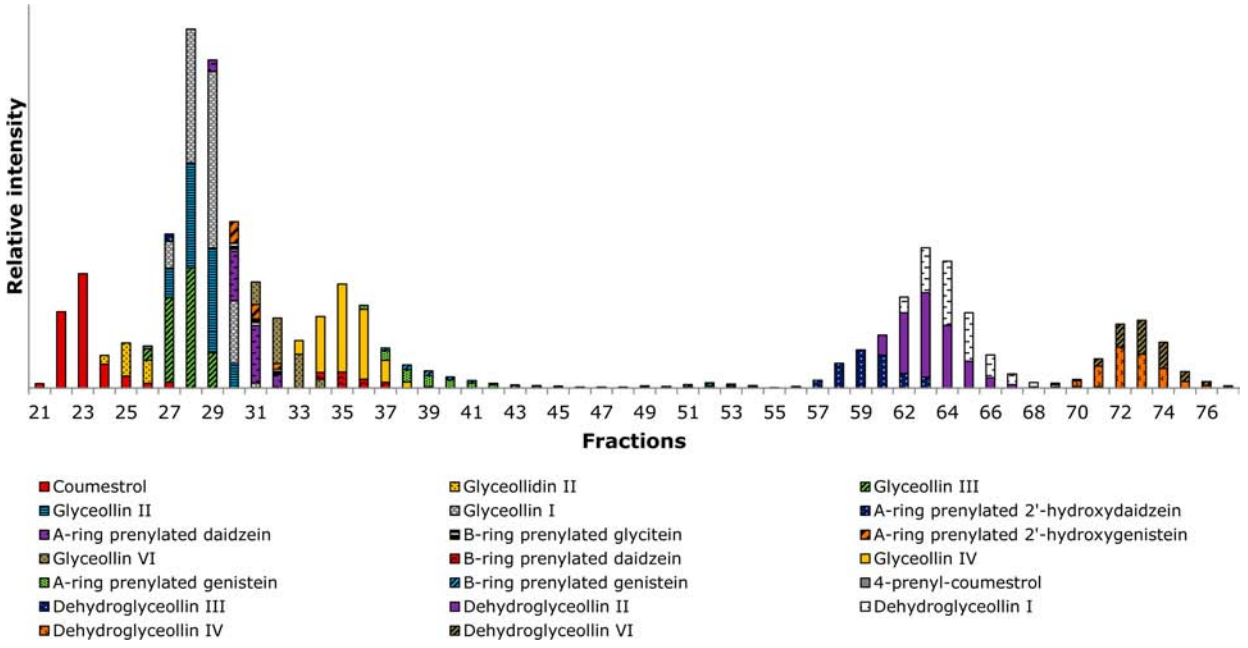

**Figure 5.** Content of Flash chromatography fractions of the mildly treated soy extract determined by RP-UHPLC-MS.

**Table 2. Quantitative Analysis Of Prenylated Isoflavonoids In The Enriched Pools**

| pool | identification | area 280 nm (%) |
|---|---|---|
| 1 | Glyceollin III | 15.3 |
| | Glyceollin II | 31.1 |

| | Other | 10.9 |

potencies (REPs) based on the threshold values, and antagonistic activities were expressed as the decrease of the maximal response in percentages. Pool 1 (glyceollin I–III) showed a slight ER agonistic activity toward ER$\alpha$ (REP 1.1 × $10^{-5}$) and a clear agonistic activity toward ER$\beta$ (REP 1.2 × $10^{-4}$). No antagonistic properties of pool 1 could be established toward both receptors (Figure 6A,C). Estrogenic activity of glyceollin I–III seemed ambiguous, as it was previously shown that glyceollin I, II, and III could act as agonist and antagonist toward estrogen receptors.[8−10] Taken together, the present results and those from previous studies[8−10] indicated that glyceollin I, II, and III might act as SERMs. Pool 2, containing glyceollin IV and VI, showed a slight agonistic activity toward ER$\alpha$ (REP 1.1 × $10^{-5}$), a clear agonistic activity toward ER$\beta$ (REP 1.0 × $10^{-4}$), and slight antagonistic activities toward ER$\alpha$ and ER$\beta$ (34% and 24%, respectively) (Figure 6A,C), indicating that glyceollin IV and VI are partial agonists or can act as SERMs.[21] Other assays, e.g., proliferation assays based on human breast cells or U2-OS based ER-CALUX bioassays, are needed to conclude on the exact estrogenic classification. Figure 6B,D shows the estrogenic activities of the corresponding dehydroglyceollins (pools 3 and 4). Figure 6B showed that the dehydroglyceollins had clear antagonistic properties toward ER$\alpha$, i.e., 78% decrease with pool 3 (dehydroglyceollin I, II, and III) and 26% decrease with pool 4 (dehydroglyceollin IV and VI), whereas no ER$\alpha$ agonistic activity was observed (Figure 6B). Toward ER$\beta$, dehydrogly-

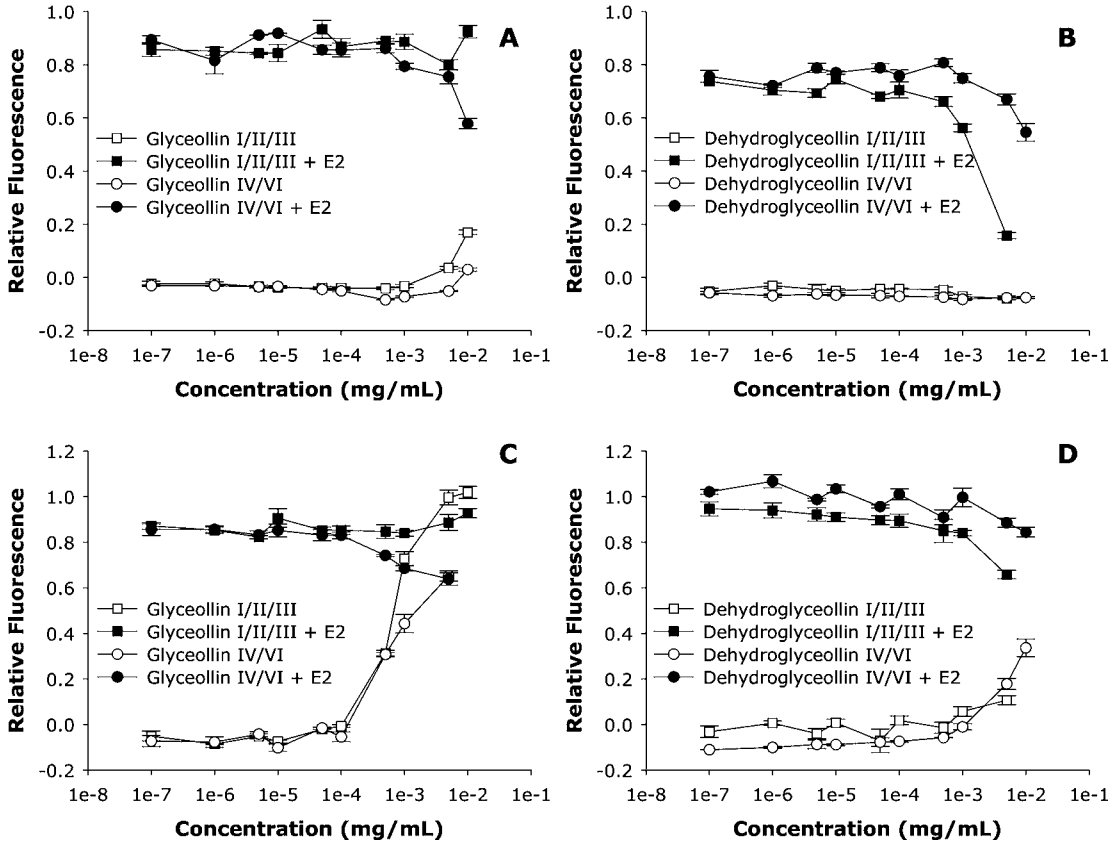

**Figure 6.** Transcriptional activation by ER$\alpha$ (A and B) and ER$\beta$ (C and D) in response to pools 1−4.

ceollins seemed to have both agonistic and antagonistic properties (Figure 6D), indicating that these compounds could act as partial agonists or as SERMs. No agonistic response was detected for dehydroglyceollin I−III, whereas the REP value of dehydroglyceollin IV/VI was $9.8 \times 10^{-5}$. The antagonistic effects resulted in a 28% decrease in estrogenic activity for dehydroglyceollin I−III and 15% for dehydroglyceollin IV/VI. In summary, glyceollins showed higher agonistic activity toward ER$\beta$ than toward ER$\alpha$, which is in line with literature.[2] In particular, the response toward ER$\alpha$ changed from agonistic for glyceollin I−III to full antagonistic for dehydroglyceollins I−III. Toward ER$\beta$ a decrease in agonistic activity was observed after heating.

## DISCUSSION

Compounds are considered estrogenic when they activate the ER at concentrations below $10^4$ times that of estradiol.[22] Thus, REP values $\geq 1 \times 10^{-4}$ indicate that compounds (or pools) have clear estrogenic properties, which was not always the case with the pools tested in the present study. Intriguingly, the estrogenic properties of glyceollins and their corresponding dehydroglyceollins were different.

After heat/acid treatment, the dehydroglyceollins that were formed from 6a-hydroxy-pterocarpans showed full antagonistic properties toward ER$\alpha$ and lower agonistic activities toward ER$\beta$. It has been suggested[23] that the removal of the 6a-hydroxyl group with the concomitant extra planarity of the dehydroglyceollins might increase the binding to the estrogen receptor. This was not observed in the present study. Nevertheless, our results clearly showed that dehydroglyceollins had different mode of action toward both receptor types compared to the 6a-hydroxy-pterocarpans. The natural ligand 17$\beta$-estradiol has two hydroxyl groups, each on one side of the molecule. These are required for binding to the estrogen receptor, the distance of which is important for binding. When the geometry of glyceollins and dehydroglyceollins is compared (Figure 7), it is apparent that the length of the two compounds

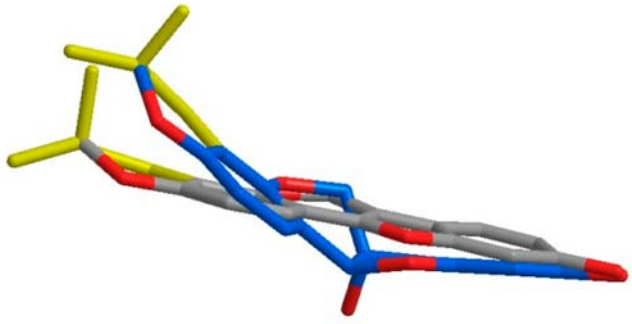

**Figure 7.** Molecular structures of glyceollin I (blue) and dehydroglyceollin I (gray). Prenyl group is indicated in yellow.

is different. With the increased planarity of the dehydroglyceollins, the distance between the two hydroxyl groups of dehydroglyceollins becomes larger than that in glyceollins. Furthermore, the orientation of the prenyl group changes between the two compounds as a result of the planarity. This might affect binding in the ligand-binding domain of the receptor, turning the agonistic response observed for glyceollins into the antagonistic response observed for dehydroglyceollins in case of ER$\alpha$, and into a decreased agonistic response observed for dehydroglyceollins in case of ER$\beta$.

Glyceollins showed agonistic activities to both estrogen receptors. This gives the opportunity to use these glyceollins of elicited soy sprouts in food supplements to prevent menopausal complaints. It is known that dietary agonistic estrogens, like soy isoflavones, are helpful to counteract the drop in endogenous estrogen levels in postmenopausal women.[4,24] The present results show that care should be taken during processing (e.g., when soy glyceollins are processed into food supplements) or isolation, because 6a-hydroxy-pterocarpans are prone to transformation upon which estrogenic characteristics can change, i.e., drop in estrogenic activity or switch from agonistic to antagonistic behavior.

Alternatively, heat and acid might be used to modulate estrogenicity of elicited soy sprouts in a relatively simple way. After the treatment, the dehydroglyceollins showed full antagonistic activity toward ER$\alpha$. Full antagonistic compounds, like fulvestrant and RU 58668, are well-known molecules in treatment of patients with breast cancer.[21,25,26] Full antagonists are rare, and dehydroglyceollins might represent a new class of ER$\alpha$ antagonists, although further verification of their in vitro antiestrogenic potency by other bioassays and their in vivo activity remain to be established.

chemical structures isolated from fungal pathogens belonging to *Diplodia*, *Didymella*, *Phoma*, *Pyrenophora*, and *Seiridium* genera on the seed germination and radicle growth of four major broomrape species. This work was designed to investigate the ability of metabolites isolated from the above cited plant and fungi to either stimulate suicidal seed germination or inhibit germination induced by a germination-inducing factor on four broomrape species *Orobanche crenata*, *Orobanche cumana*, *Orobanche minor*, and *Phelipanche ramosa*. Their effect on the radicle growth and their potential as lead compounds to develop new classes of bioherbicides was also evaluated and discussed.

## MATERIALS AND METHODS

**Fungal Sources and Tested Metabolites.** Sphaeropsidin A, **4**, sphaerospidone, **5**, and *epi*-sphaeropsidone, **3**; cyclopaldic acid, **1**; and *epi*-epoformin, **2** (Figure 1), were purified,

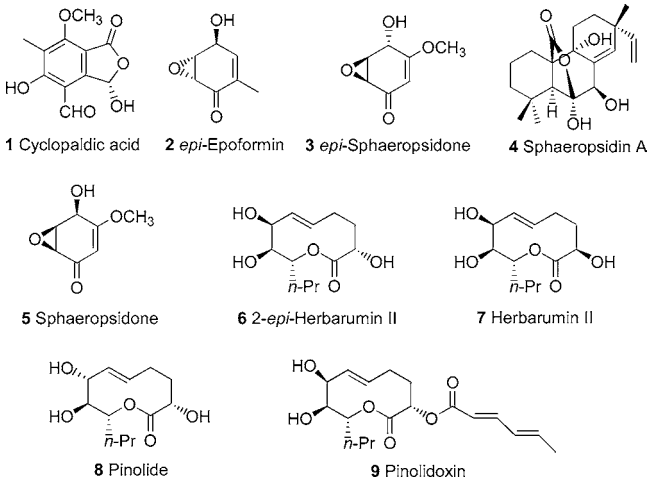

**Figure 1.** Phytotoxins isolated from *Seiridium cupressi* and *Diplodia* spp.—cyclopaldic acid, *epi*-epoformin, *epi*-sphaeropsidone, sphaeropsidin A, and sphaeropsidone (**1**–**5**)—and from *Didymella pinodes*—*epi*-herbarumin II, herbarumin II, pinolide, and pinolidoxin (**6**–**9**).

respectively, all as white needles from the culture filtrates of *Diplodia cupressi*,[17,18] *Seiridium cupressi*,[19] and *Diplodia quercivora*.[20] Pinolidoxin, **9**; pinolide, **8**; herbarumin II, **7**; and *epi*-herbarumin II, **6** (Figure 1), were isolated from the culture filtrates of *Didymella pinodes*.[21] Cavoxin, **10**, and cavoxone, **11**, and chenopodolin, **12**; chenopodolan C, **13**; and 6-hydroxymellein, **14** (Figure 2), were isolated, respectively, from the culture filtrates of *Phoma cava*[22] and *Phoma chenopodiicola*.[23,24] Cytochalasins A, **15**, and B, **16**, and deoxaphomin, **17** (Figure 2), were isolated from the solid culture of *Pyrenophora seminiperda*.[25] All the above cited fungal metabolites were freshly isolated from the fungal cultures according to the protocols reported in the literature and were identified by $^1$H NMR and electrospray ionization mass spectrometry (ESI MS), comparing these data with those previously described. Finally, fusaric acid, **21** (Figure 3), was purchased from Sigma (St. Louis, MO).

**Plant Source and Tested Metabolites.** Inuloxins A, **19**, and C, **20**, and $\alpha$-costic acid, **18** (Figure 3), were freshly isolated from the aerial part of *Inula viscosa* according to the previously reported protocol[16] and were identified by $^1$H NMR and ESI MS, comparing these data with those previously described.

**Induction of *Orobanche* Seed Germination by Fungal and Plant Metabolites.** The biological activity of the metabolites (Figures 1–3) isolated from *Diplodia* spp., *Didymella pinodes*,

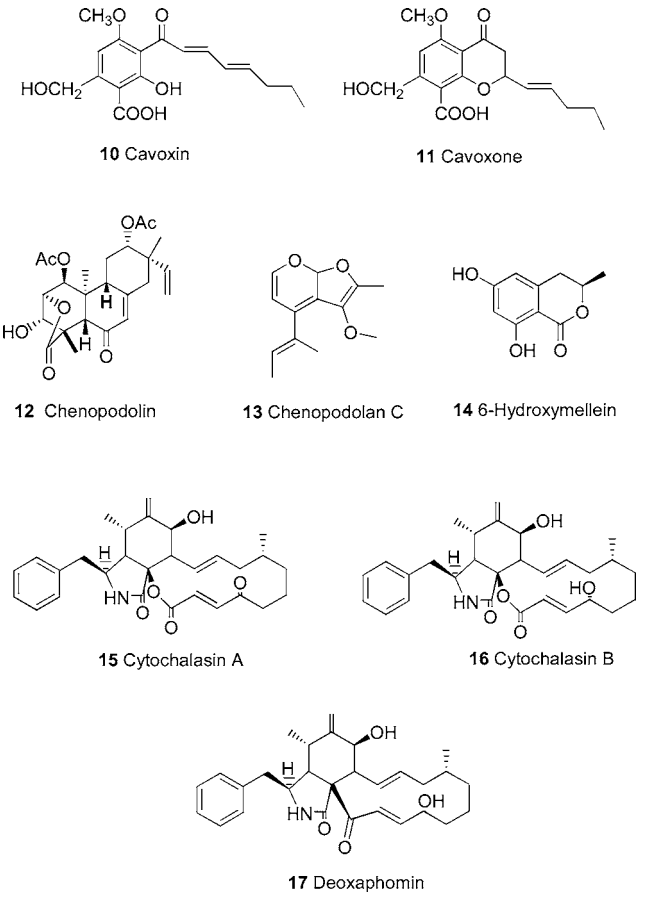

**Figure 2.** Phytotoxins isolated from *Phoma* spp.—cavoxin, cavoxone, chenopodolin, chenopodolan C, and 6-hydroxymellein (**10**–**14**)—and from *Pyrenophora seminiperda*—cytochalasins A and B and deoxaphomin (**15**–**17**).

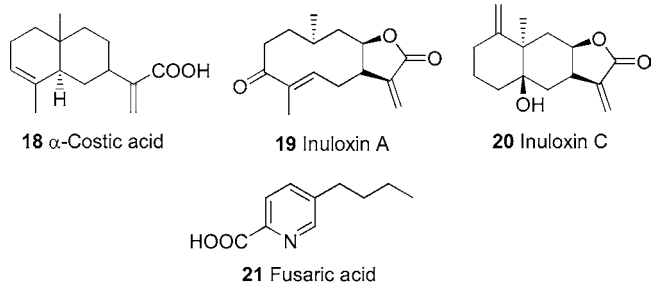

**Figure 3.** Phytotoxins isolated from *Inula viscosa*, $\alpha$-costic acid and inuloxins A and C (**18**–**20**). Fusaric acid (**21**).

*Phoma* spp., *P. seminiperda*, *S. cupressi*, and *I. viscosa* was assayed on *O. crenata*, *O. cumana*, *O. minor*, and *P. ramosa* seeds. For this purpose, seeds were surface sterilized by immersion in 0.5% (w/v) NaOCl and 0.02% (v/v) Tween 20, were sonicated for 2 min, were rinsed thoroughly with sterile distilled water, and were dried in a laminar air flow cabinet. Approximately 100 seeds of each broomrape species were placed separately on 9 mm diameter glass fiber filter paper disks (GFFP) moistened with 50 $\mu$L of sterile distilled water. Subsequently, GFFP disks were placed inside sterile 10 cm Petri dishes, were sealed with parafilm, and were kept for 10 days in the dark at 22 °C to allow seed conditioning. GFFP disks were transferred inside laminar flow cabinet to sterile filter paper to remove excess water, and then they were transferred to a new 10 cm sterile Petri dish.

dx.doi.org/10.1021/jf504609w | J. Agric. Food Chem. 2014, 62, 10485–10492

Tested samples, dissolved in methanol, were diluted with sterilized distilled water to a final concentration of $10^{-4}$ M. The final concentration of methanol was adjusted to 0.70% (v/v). Each disk containing conditioned seeds was treated with 50 $\mu$L aliquot of the respective test solution. Each treatment was replicated three times. Seeds treated with distilled water (containing 0.70% methanol) or the synthetic strigolactone GR24[26,27] at 0.6 and 0.06 mM were included as controls for comparison. The seeds were incubated in the dark at 22 °C for 7 days prior to examination for germination. Seeds with an emerged radicle were scored as germinated using a stereoscopic microscope at 30 × magnification, and the percentage of germination was established for each dish.

**Inhibition of *Orobanche* Seed Germination and Radicle Growth by Fungal and Plant Metabolites.** The inhibitory activity of the various above metabolites (Figures 1−3) on seed germination and radicle growth of *O. crenata, O. cumana, O. minor,* and *P. ramosa* was assayed as reported previously.[28] A solution of the GR24 ($10^{-6}$ M) was prepared in sterile distilled water. Immediately before use, stock solutions of each toxin prepared in methanol were diluted in the GR24 solution to $10^{-4}$ M of each toxin while keeping constant the GR24 concentrations and methanol in order to allow comparisons. Broomrape seeds were surface sterilized and conditioned as described above. GFFP disks containing conditioned broomrape seeds were transferred inside a flow laminar cabinet to a sterile sheet of filter paper to remove excess moisture and were transferred to a 10 cm diameter Petri dish. Fifty microliter aliquots of each toxin-GR24 were applied to each GFFP disk containing the seeds. Petri dishes were sealed with Parafilm and were stored in the dark at 22 °C for 7 days to promote germination and radicle growth. Then, seeds were observed under stereoscopic microscope in order to score levels of allelopathic-mediated inhibition of broomrape seed germination and radicle growth.

**Statistical Analysis.** All the bioassays were performed twice with at least three replicates. Percentage data were approximated to normal frequency distribution by means of angular transformation $\{180/\pi \times \text{arcsine}(\text{sqrt}[\%/100])\}$ and were subjected to analysis of variance (ANOVA) using SPSS software for Windows, version 21.0 (SPSS Inc., Chicago, Illinois, U.S.A.). The significance of mean differences between each treatment against its respective control was evaluated by the two-sided Dunnett test. Null hypothesis was rejected at the level of 0.05.

## RESULTS AND DISCUSSION

Phytotoxins isolated from plant pathogenic fungi as well as those produced by an allelopathic plant were used in a bioactivity screening on seed germination and radicle growth of *O. crenata, O. cumana, O. minor*, and *P. ramosa*, four major broomrape species constraining production of major agricultural crops worldwide.

The phytotoxins belong to different classes of natural compounds as sphaeropsidin A, **4** (Figure 1), and chenopodolin, **12** (Figure 2), which are tetracyclic pimarane diterpenes, and as *epi*-epoformin, **2**; *epi*-sphaeropsidone, **3**; and sphaeropsidone, **5** (Figure 1), which are cyclohexene epoxide. *epi*-Herbarumin II, **6**; herbarumin II, **7**; pinolide, **8**; and pinolidoxin, **9** (Figure 1), are nonenolides, while cytochalasins A, **15**, and B, **16**, and deoxaphomin, **17** (Figure 2), are 24-oxa[14] and [13] cytochalasans, respectively. Cavoxin, **10**; cavoxone, **11**; chenopodolan C, **13**; and 6-hydroxymellein, **14** (Figure 2), are a chalcone, a chromanone, a furopyran and a hydroxymellein. $\alpha$-Costic acid, **18**, and inuloxins A, **19**, and C, **20** (Figure 3), are bi- and tricyclic sesquiterpenes. Finally, cyclopaldic, **1** (Figure 1), and fusaric acid, **21** (Figure 3), are a substituted benzofuranone and a substituted pyridinic acid, respectively.

**Phytotoxin Activity as Stimulators of Broomrape Suicidal Germination.** The stimulation activity of these metabolites on broomrape seed germination was tested on four broomrape species—*O. crenata, O. cumana, O. minor,* and *P. ramosa*. All metabolites belonging to bi- and tricyclic sesquiterpenes class (inuloxins A and C and $\alpha$-costic acid) induced significant germination on seeds of *O. cumana* (Figure 4A). The effect of inuloxin A, **19**, and $\alpha$-costic acid, **18** (Figure 3), was stronger than inuloxin C, **20** (Figure 3). Interestingly, *O. cumana* seeds that germinated with inuloxin C showed short radicles with light brown patches, symptoms that were not observed in seedlings germinated with inuloxin A and $\alpha$-costic acid. In addition to bi- and tricyclic sesquiterpenes, cyclopaldic acid, **1** (Figure 1), a substituted benzofuranone, induced significant germination of *O. cumana* seeds (Figure 4A). The rest of the metabolites tested did not induce any germination in *O. cumana* seeds except for the positive control. *P. ramosa* seeds were induced to germinate when exposed to inuloxin A and $\alpha$-costic acid but not when exposed to inuloxin C or cyclopaldic acid (Figure 4B). In addition, *epi*-sphaeropsidone, **3** (Figure 1), a cyclohexene epoxide, induced significant germination on *P. ramosa* but not in the rest of the broomrape species tested (Figure 4B). *O. crenata* and *O. minor* seeds did not germinate when exposed to any of the compounds tested except for the positive control (data not shown).

**Phytotoxin Activity as Inhibitors of Broomrape Germination and Radicle Growth.** In addition to germination-inducing activity, each compound was also tested as potential inhibitor for broomrape development by inhibiting its germination (Figure 5) and its radicle growth (Figure 6). Each metabolite was mixed with the germination factor GR24 and was applied to conditioned seeds of *O. crenata, O. cumana, O. minor,* and *P. ramosa*. *epi*-Epoformin, **2**, and sphaeropsidin A, **4** (Figure 1), significantly inhibited germination of *O. crenata* and *O. cumana* seeds (Figure 5A and B). Inhibition of *O. minor* and *P. ramosa* seed germination was induced by sphaeropsidin A but not by *epi*-epoformin (Figure 5C and D). All cytochalasans, **15**−**17** (Figure 2), inhibited the germination of *P. ramosa* seeds (Figure 5D), but germination of *Orobanche* species was not inhibited by this class of compounds except that deoxaphomin, **17** (Figure 2), induced inhibition of *O. crenata* germination (Figure 5A).

Regarding inhibition of radicle growth, all cyclohexene oxides (**2**, **3**, and **5**, Figure 1) and cytochalasans (**15**−**17**, Figure 2) induced a strong and significant reduction on broomrape radicle length when compared with control radicles (i.e., radicles emerged from seeds induced only with GR24, Figures 6 and 7). This is very significant from a parasitic weed control point of view, as broomrape radicles have limited growth length and constitute the organ that establishes host contact and carries the attachment and penetration organ in its tip. Despite the similar effect on radicle growth inhibition performed by cyclohexene oxides and cytochalasans, there were important differences in the appearance of the radicles treated with each class of compound. While radicles of all broomrape species exposed to cytochalasans quickly turned brown and necrotic (Figure 7B), radicles exposed to cyclohexene oxides although much shorter than the control radicles had a healthy appearance (Figure 7C). In addition, *O. crenata* and *O. cumana* radicles exposed to cyclohexene epoxides developed a dense layer of papilla-like structures at the tip of the radicle

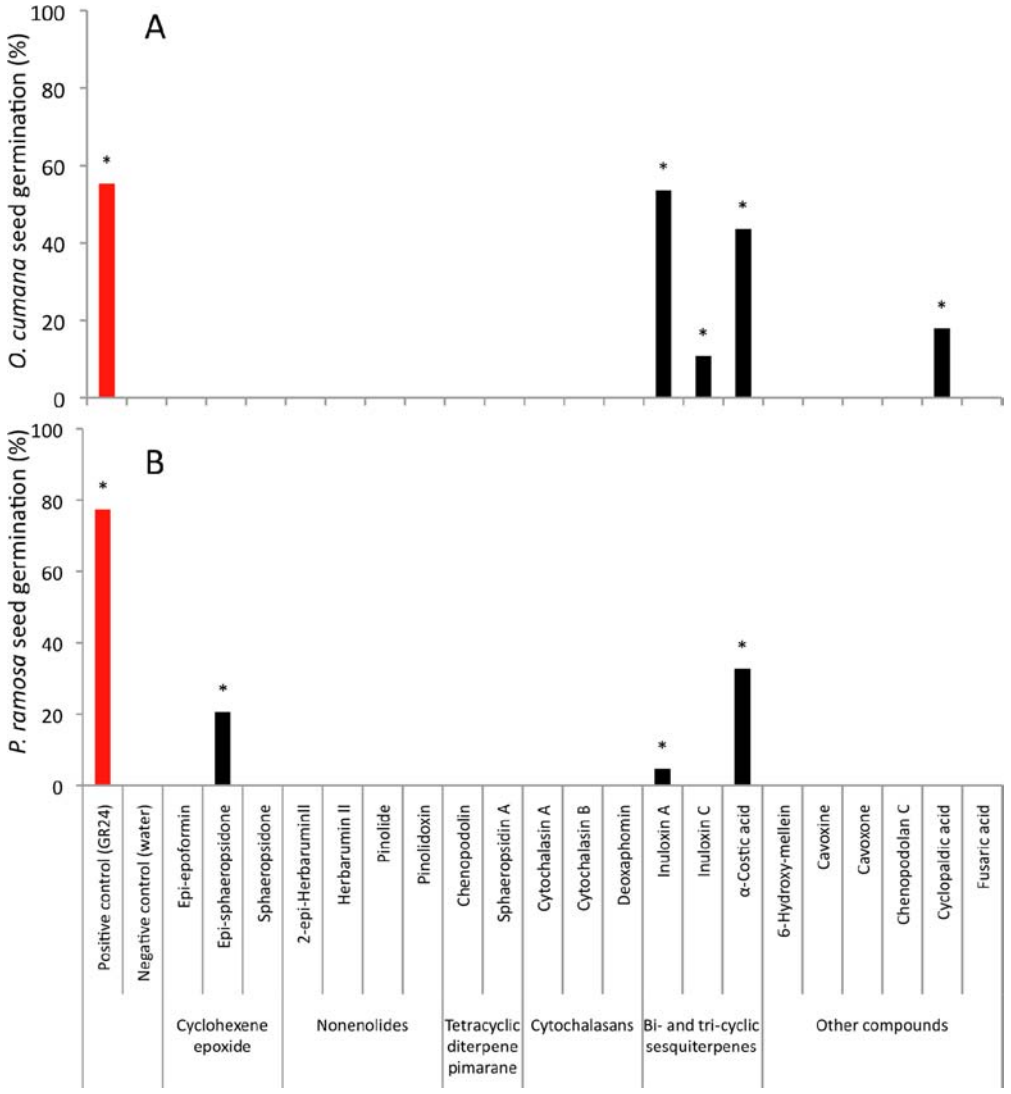

**Figure 4.** Stimulatory effect on (A) *O. cumana* and (B) *Phelipanche ramosa* seed germination of the tested phytotoxins. The asterisk (*) indicates differences at the 0.05 level compared with the negative control (seeds treated with water).

(Figure 7C). The papilla layer was not observed in radicles exposed to any other compound in this work.

The tetracyclic pimarane diterpene, sphaeropsidin A, **4** (Figure 1), showed a strong phytotoxic effect on all broomrapes species tested inducing inhibition of both germination and radicle growth. Radicles of broomrape exposed to sphaeropsidin A quickly turned brown and necrotic.

Inuloxin C, **20** (Figure 3), did not significantly inhibit broomrape germination, and its inducing effect on suicidal germination, in absence of germination-inducing factor GR24, was low and restricted to *O. cumana* (Figure 4A). Despite this stimulatory activity observed in *O. cumana*, when broomrape seeds were exposed to a mixture of GR24 and inuloxin C, germinated seedlings developed radicles that were shorter than those in the controls, and this effect was observed in seeds of all the broomrape species tested. In addition, *O. crenata* and *O. cumana* radicles exposed to inuloxin C showed light brown patches (Figure 7D), which could point to a cytotoxic effect although this fact needs further investigation. This combined activity allows differentiating inuloxin C from the other sesquiterpenes tested regarding its potential for agronomical use. Inuloxin C, rather than being a good candidate for suicidal germination-based herbicide, like inuloxin A and $\alpha$-costic acid, would be a better candidate for broomrapes post-germination herbicide reducing the parasitic capability of attacking the host crop by reducing the attachment organ length.

Some structure−activity relationships could be evaluated within the same class of the natural compounds. The different activity showed on broomrape germination by *epi*-epoformin, **2** (Figure 1, strong inhibitor of *O. cumana* seed germination), and *epi*-sphaeropsidone, **3** (Figure 1, stimulant of *P. ramosa* seed germination), and sphaeropsidone, **5** (Figure 1, practically inactive), which have the same carbon skeleton, should be due to the different stereochemistry of the epoxy ring and that of the hydroxy group at C-5. On the other hand, common structural features such as the 5-hydroxycyclohexenone-1,6-oxide group in these three compounds induced radicle growth cessation in all broomrapes tested and induced the differentiation of a papillae layer in the radicle tip of *O. crenata* and *O. cumana*. No reports have been previously published on these effects on broomrape development mediated by these chemical structures.

Sphaeropsidin A, **4** (Figure 1), showed a strong phytotoxic effect by inhibiting both germination and radicle growth on all the broomrapes species tested while chenopodolin, **12** (Figure 2),

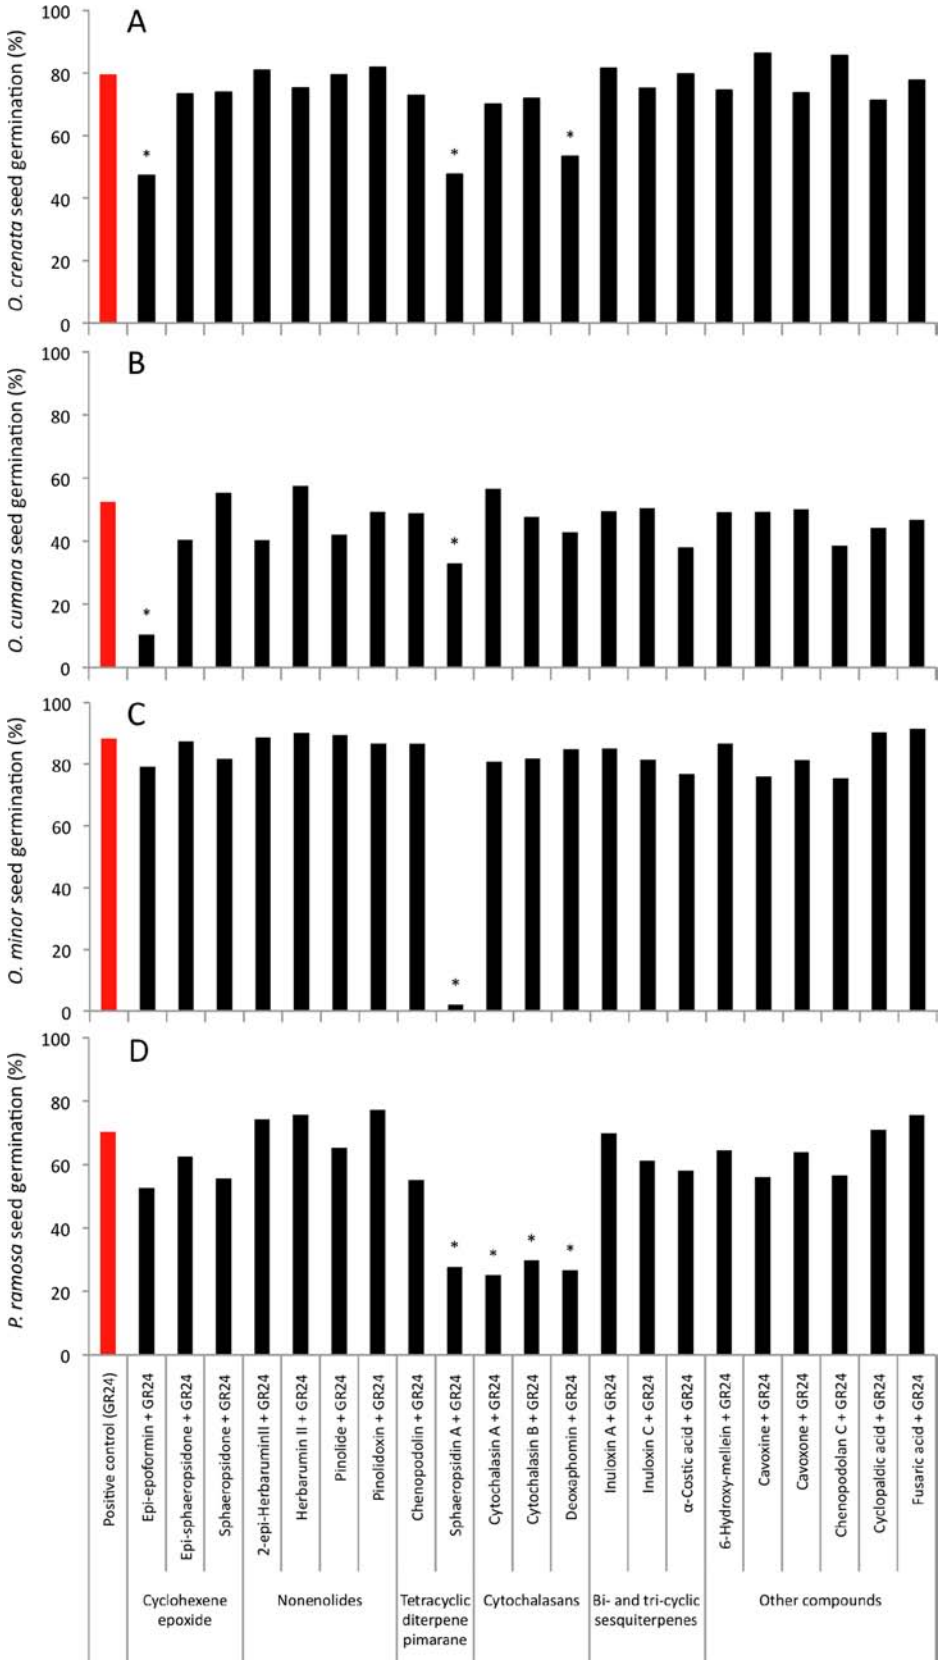

**Figure 5.** Inhibitory effect on (A) *Orobanche crenata*, (B) *O. cumana*, (C) *O. minor*, and (D) *Phelipanche ramosa* seed germination of the tested phytotoxins. The asterisk (*) indicates differences at the 0.05 level compared with the positive control (seeds induced to germinate with GR24).

is inactive. Both are tetracyclic pimarane diterpenes but strongly differ in the junction between γ-lactone ring and phenanthrene ring system and in the functionalities of the latter.

The different biological activity observed between the three sesquiterpenes tested, with α-costic acid and inuloxins A inducing *O. cumana* and *P. ramosa* germination and inuloxin C displaying

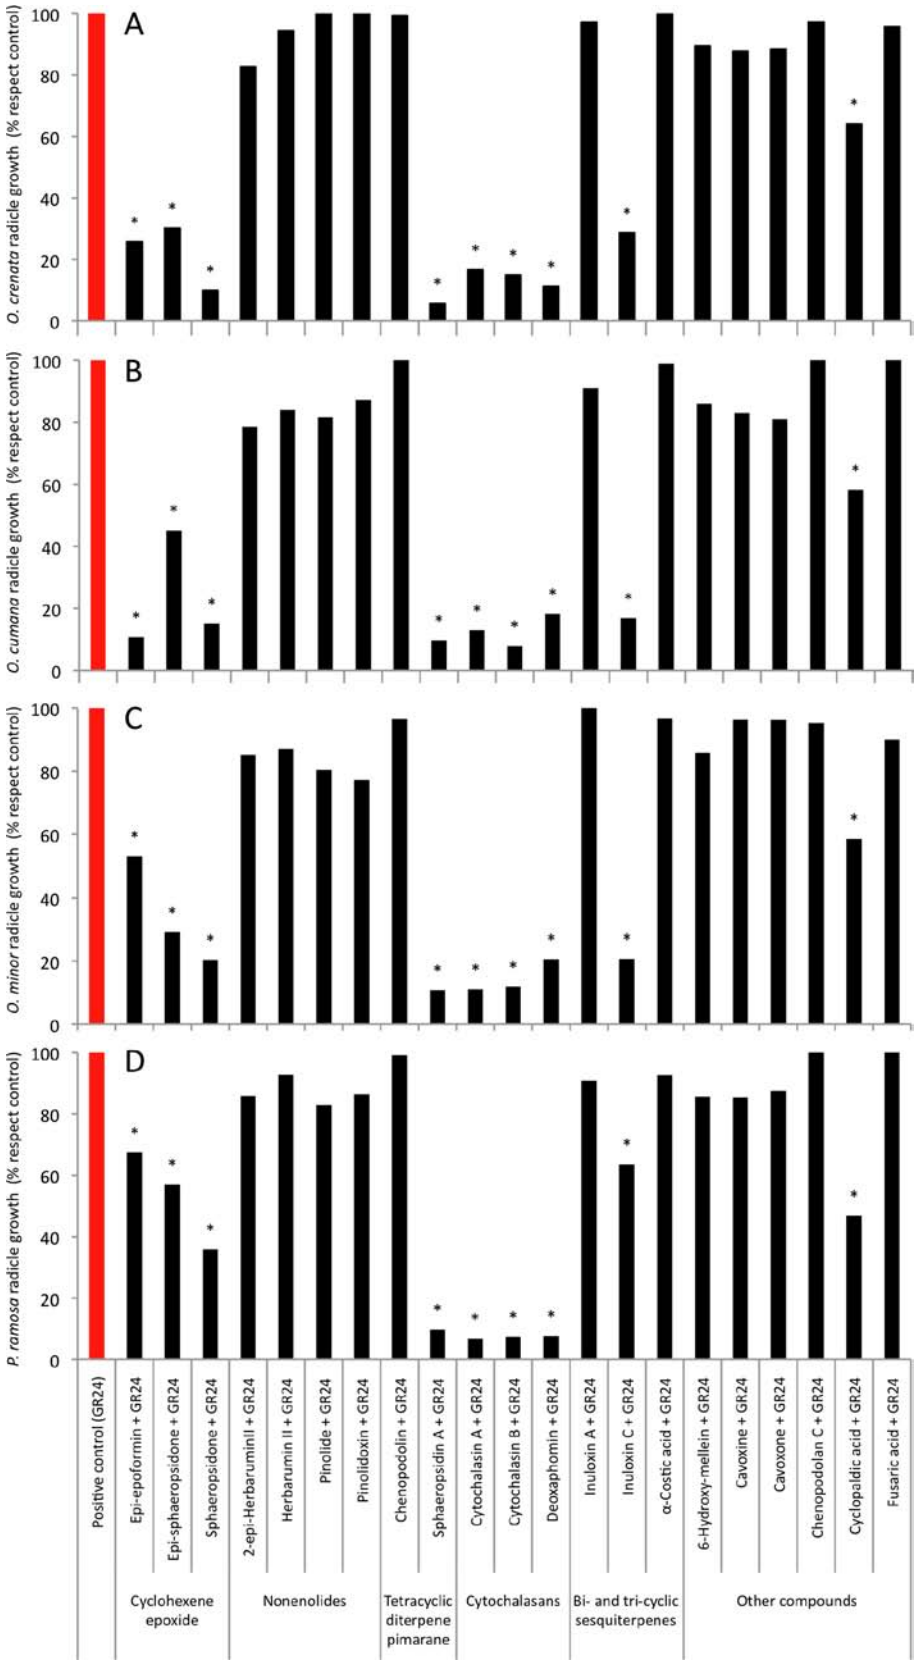

**Figure 6.** Inhibition of broomrape radicle growth induced by the tested phytotoxins. The broomrape species tested were (A) *Orobanche crenata*, (B) *O. cumana*, (C) *O. minor*, and (D) *Phelipanche ramosa*. The asterisk (*) indicates differences at the 0.05 level compared with the positive control (seeds induced to germinate with GR24).

mainly a phytotoxic effect, was due to the different organization of the carbon skeleton and also to their different functionalities and stereochemistry. These results were in agreement with those reported previously testing the same compounds on *O. crenata*.[16]

dx.doi.org/10.1021/jf504609w | J. Agric. Food Chem. 2014, 62, 10485−10492

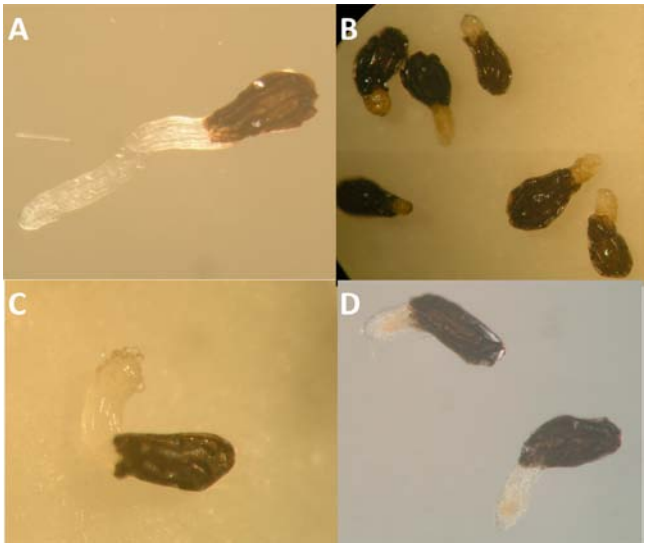

**Figure 7.** Radicle growth modification by fungal and plant toxins observed at 7 days after GR24 aplication. (A) *Orobanche* control radicle, (B) cytochalasin-treated *Orobanche* radicle, (C) cyclohexene epoxide-treated *Orobanche* radicle, and (D) inuloxin C-treated *Orobanche* radicle.

The structural differences between the three cytochalasans tested did not lead to differences in biological activities for broomrape germination and radicle growth. All of them similarly induced phytotoxic effects on broomrape by inhibiting seed germination and radicle growth inhibition and toxicity in radicles. Herbicidal effects mediated by deoxaphomin, cytochalasin A, and cytochalasin B inducing necrosis in tissues of other weeds have been previously reported,[29] but this effect was never tested in broomrape germination and radicle growth. Previously, cytochalasins E and B were tested on *Striga* seed germination, and of them, only cytochalasin E inhibited *Striga* germination by 50%, cytochalasin B being noninhibitory.[30] Unfortunately, these authors did not evaluate the effect of the toxic effects in *Striga* radicles. We have found that cytochalasans inhibit germination only in the *Phelipanche* species but not in the *Orobanche* species. In addition, we observed a strong toxic effect in radicles of all broomrape species tested by inhibiting their growth and inducing darkening in the radicle. The germination bioassays widely conducted on broomrape research are based on the quantification of seeds with emerged radicle through the seed coat. A seed with emerged radicle is counted as germinated. However, in bioassays where the herbicide tested is inducing such a strong reduction on seedling development as that in this work by cytochalasans, it is difficult to discern between inhibition of the strict germination process and inhibition of initial seedling development. Seed germination is a complex physiological process where the seed transforms from dormant to metabolically active, and this process begins with perception of dormancy breaking/germination inducing signals and ends with the beginning of radicle emergence through the seed coat. In the present study, lack of visible radicle in *P. ramosa* induced by cytochalasans does not mean strictly germination inhibition as the toxins could have allowed germination triggered by GR24, but the seedling development could be inhibited so strongly that the radicle did not make it through the seed coat. Cytochalasan-treated *P. ramosa* seeds showed either no radicle visible or such a short radicle that it was extending in length very little from the seed cover. Inhibitory effect of cytochalasans on *P. ramosa* germination may be confounded with strong inhibition of initial seedling development because of the radicle remaining inside the seed coat.

In conclusion, 21 phytotoxins belonging to different classes of natural compounds isolated from different pathogenic fungi and an allelophatic plant were tested on four different broomrape species. The discovery of the negative effect on radicle growth exerted by sphaeropsidin A and compounds belonging to cyclohexene epoxides and cytochalasans is the first step that paves the way for the development of herbicides promoting the interruption of parasitic life cycle before host attachment and crop resource withdrawal by the parasite. Further studies on these compounds could lead to the development of a new and unexplored strategy for broomrape control. In addition to radical growth inhibition, some compounds induced the inhibition of germination in the presence of parasitic plant germination-factor GR24. *epi*-Epoformin, **2**; sphaeropsidin A, **4** (Figure 1); and cytochalasans caused the strongest inhibition of seed germination, and this effect adds to the effect of radicle growth inhibition to strengthen the potential of these substances as candidates for broomrape seedbank management in agricultural soils cultivated with susceptible crop species. Interesting species-specific activity was discovered for some of the compounds tested inducing broomrape seed germination. *P. ramosa* seed germination was induced by *epi*-sphaeropsidone, **3**, and cyclopaldic acid, **1** (Figure 1), and inuloxin A, **19** (Figure 3), while germination of *O. cumana* was only induced by sesquiterpenes. Seeds from the *O. crenata* and *O. minor* species did not germinate in the presence of any of the compounds tested except for the positive control. This specificity is important from a point of view of parasitic plant germination biology because the unresponsive broomrape species and particularly *O. minor* are broomrape species with high sensitivity to a broad range of compounds and root exudates.[31,32] The strong effect induced by inuloxin A and $\alpha$-costic acid on *O. cumana* opens new research addressing broomrape control through a suicidal germination strategy for this broomrape species. Among the rest of the active compounds as broomrape germination inductors, *epi*-sphaeropsidone and cyclopaldic acid are probably too weak in their current structural form to have practical applications for field delivery as suicidal germination-inducing herbicides; however, as described before, the report of this activity is important because of the special evolutionary strategy of parasitic plants that allows them to germinate in the presence of host-derived factors. The germination biology of parasitic plants is far from completely elucidated, and it has been suggested that combination of compounds may confer specific host recognition patterns. Metabolites promoting low germination inducing activity may have a role on modulation of host recognition in a species-specific manner. In addition, those compounds that showed activities can be subjected to structural modifications in order to increase the intensity of germination-inducing activities. The results represent important findings for further studies on new compounds as tools to be used in the design of new approaches for parasitic weed control such as nature-inspired herbicides or engineering resistant crops by enhancing expression of allelochemicals or phytotoxins against parasitic weed germination and development.[33]

potential molecular protein networks. To the best of our knowledge, this is the first proteomics study to report the antidepressive mechanism of WGE.

## MATERIALS AND METHODS

**Material Extraction and Composition Determination.** WGE was provided by Koda Pharmaceutical Company (Taoyuan, Taiwan). To obtain WGE, 700 g of dried rhizome of GE was boiled twice with 6 and 4.8 L of water for 1 h, respectively. Then, the extract was filtered, freeze-dried, and stored until utilization. Fluoxetine was obtained from Eli Lilly Company (Taiwan).

An LC-NET II/ADC (JASCO, Easton, MD, USA) high-performance liquid chromatography (HPLC) system, which consisted of a pump (PU-2089-PLUS) and a UV detector (UV-2075-PLUS), with a Phenomenex Luna $C_{18}$ column (250 × 4.6 mm, 5 $\mu$m, Torrance, CA, USA) and Chrompass analyzing program, was used for analyzing the composition of WGE. An acetonitrile−water solution (10:90, v/v) was used as the mobile phase at 1 mL/min flow rate. The mobile phase was filtered using 0.45 $\mu$m Millipore filters, the UV detector was set at 220 nm, and the oven was set at 35 °C to maintain the column temperature. The injected sample volume was 20 $\mu$L.

**Animal and Treatments.** Male Sprague−Dawley rats (4 weeks old) were purchased from BioLasco Taiwan Company (Taipei, Taiwan) and housed individually at controlled day/night cycle (12 h light/dark), temperature (23 ± 2 °C), and humidity (60 ± 10%). Free access to food and water was provided and recorded every day. Rats were randomly separated into three groups (7 rats/group): control (CTL), WGE, and fluoxetine (FLX). After 2 weeks of habituation, oral administration was initiated and continued for 21 days with ultrapure water, fluoxetine (20 mg/kg body weight), and WGE (500 mg/kg body weight) to CTL, FLX, and WGE groups, respectively. The dosage was based our preliminary studies. Animal protocol was reviewed and approved by the Institutional Animal Care and Use Committee of National Taiwan University, Taiwan (Approval Number: NTU-IACUC-96-56). The protocol complied with guidelines described in the "Animal Protection Law", amended on June 29, 2011, Hua-Zong-(1)-Yi-Tzi-10000136211, Council of Agriculture, Executive Yuan, Taiwan.

**Forced Swimming Test.** The protocol of the FST was described previously.[12] This method followed the procedure developed by Porsolt et al.[14] The behavior of rats during the FST was video recorded. Films were analyzed by ForcedSwimScan software (CleverSys, Reson, VA, USA) for calculating the duration of immobility.

**Sacrifice and Protein Extraction.** After the FST, rats were deeply anesthetized by $CO_2$ and decapitated, and the frontal cortex and hippocampus were dissected from the brain immediately. The dissected tissues were frozen at −80 °C until further analysis. The frozen tissues were ground into a powder with liquid nitrogen and dissolved with lysis buffer containing 7 M urea, 2 M thiourea, 65 mM DTT, 4% CHAPS, and a cocktail of proteinase and phosphatase inhibitors (Roche, Rotkreuz, Switzerland). The samples were centrifuged at 12000$g$ for 2 h, and the precipitates were discarded. Protein extracts were quantified by the Bradford protein assay (Bio-Rad, Hercules, CA, USA).

**Proteomics and Bioinformatics Analysis.** Due to the limitations in the sampling of the 2-DE system, three replicates from CTL and WGE, which had the most opposite duration of immobility in the FST, were further analyzed by 2-DE. Protein extracts were loaded onto the Immobiline DryStrip 18 cm pH 3−10 nonlinear gel strips (GE Healthcare, Pittsburgh, PA, USA) with 350 $\mu$L of rehydration buffer (lysis buffer plus 0.5% IPG buffer). The voltage−time program of isoelectric focusing was set at 50 V for 12 h and 100, 250, 500, 1000, 3000, and 5000 V for 1 h, respectively, and 8000 V for a total of 56 000 V × h. Prior to the second dimension, strips were equilibrated for 15 min in buffer (6 M urea, 30% glycerol, 2% SDS, 50 mM Tris-HCl, 0.002% bromophenol blue, and 0.02% w/v DTT), then soaked for 15 min in the same buffer (replacing DTT with 0.025% IAA). Then the second dimension separation was performed using 10 mA/gel electrophoresis for 18 h on 10−18% polyacrylamide gels at 4 °C by using the PROTEAN II xi Multi-Cell 2-D electrophoresis system (Bio-Rad). The gels were fixed (10% methanol, 7% acetic acid solution for 30 min) and stained with Sypro Ruby dye (Life Technologies, Grand Island, NY, USA). After the destaining process, a Typhoon scanner 9200 (GE Healthcare) was used to scan the gels (100 $\mu$m). PDQuest Basic 2-D analysis software version 8.0 (Bio-Rad) was used for protein spot analysis. The spots on the gel were automatched by PDQuest and manually corrected based on their relative location. Only the significantly expressed spots were selected and subjected to in-gel tryptic digestion.

**In-Gel Tryptic Digestion.** The protein spots that differed significantly were picked up from 2-D gels manually using a UV light box. Then, the gels of the spots were washed with 50% acetonitrile (ACN)−25 mM $NH_4HCO_3$ at room temperature for 20 min, and the solution was replaced by 100% ACN. After washing, gel pieces were dried by a SpeedVac concentrator (Savant, Holbrook, NY, USA). Then, the dried gel plugs were crushed and incubated with 1% trypsin (Promega, Madison, WI, USA) in 25 mM $NH_4HCO_3$ at 37 °C for 16 h. Peptides were extracted subsequently by 50% ACN−5% trifluoroacetic acid (TFA) from gel crushes and then dried with a SpeedVac concentrator. The dried pellets were rehydrated, resuspended with 0.1% TFA, and then concentrated with a C18 ZipTip (Millipore). After washing the C18 ZipTip with 0.1% formic acid (FA), the peptides were eluted with 75% ACN−0.1% FA.

**Peptide Sequence Analyses.** The matched protein spots of the frontal cortex (loading protein: 400 $\mu$g) and hippocampus (loading protein: 400 $\mu$g) were subjected to concerted matrix-assisted laser desorption ionization (MALDI) with time-of-flight (TOF) to operate peptide mass fingerprinting (PMF) and CID MS/MS mass spectrometry. In order to catch more possible proteins, the proteins of the hippocampus were loaded as 450 $\mu$g into the 2-DE system again, and the spots were submitted to a liquid chromatography electronic spray ionization (LC-ESI)-quantitative-TOF Ultima API (Micromass) instrument. The peptide sequencing analyses were performed by the Core Facilities for Protein Structural Analysis located at the Institute of Biological Chemistry, Academia Sinica, Taiwan. The protocols of LC-ESI-Q-TOF and MALDI-TOF were announced on the Web site of the Core Facilities (http://cfpsa.sinica.edu.tw/eng_04_filedownload.php#F3, material and method of mass analysis section). MS and MS/MS data were submitted to the Mascot protein online search program (Matrix Science, Boston, MA, USA) based on Swissprot and the NCBI database to identify proteins by PMF and MS/MS ion search.

**Bioinformatics Analysis.** Metacore (Thomas Reuters, New York, NY, USA), a systemic bioinformatics software, was employed to evaluate the function of proteins, relationship and interactions between proteins, and the potential signaling maps, based on a huge database. In Metacore, the "GeneGo Process Network" shows the cooperative relationships between identified proteins and the "GeneGo Pathway Maps" provides related signaling cascades. All of the candidates in the lists were ranked by −log($p$ value) table. A higher −log($p$ value) indicated by Metacore suggested a higher possibility for its occurrence.

**Western Blot (WB).** The protein extracts were solubilized individually in sample buffer (62.5 mM Tris-HCl, 10% glycerol, 2% SDS, and 0.01% bromophenol blue), heated at 95 °C for 10 min, and subjected to one-dimensional SDS polyacrylamide gel electrophoresis (SDS-PAGE). Following SDS-PAGE, proteins were transferred onto a polyvinylidene fluoride membrane (Millipore, Billerica, MA, USA). Following transfer, 5% bovine serum albumin (BSA) in Tris-buffered saline with 0.1% Tween-20 (TBS-T) was used to block the membranes. Then, the membranes were incubated with TBS-T-diluted primary antibodies. The primary antibodies were Slit1 and Slit2 (Genetex, Irvine, CA, USA), Robo1 and Robo2 (Genetex), RhoA (Cell Signaling, Danvers, MA, USA), PFN1 (Cell Signaling), CRMP2 (Cell Signaling), and GAPDH (Genetex). The corresponding secondary antibodies (Cell Signaling) were added for 1 h at room temperature. Membranes were soaked in ECL solution (PerkinElmer, Santa Clara, CA, USA), and the images were obtained using a UVP Autochemi system. Finally, ImageJ software (National Institutes of Health, USA) was utilized for quantification.

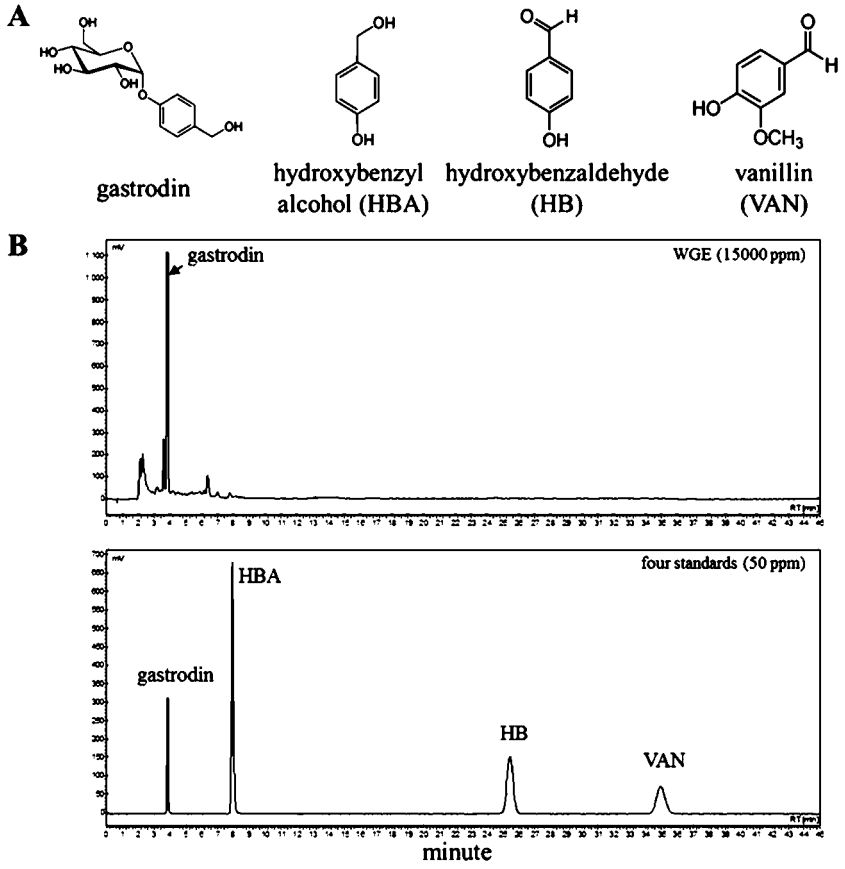

**Figure 1.** (A) Chemical structure of four major active compounds in *Gastrodia elata* Blume. (B) Chromatogram of the water extract of *G. elata* Blume (WGE). Different concentrations of WGE and standard were analyzed by HPLC: WGE (top, 15 000 ppm), standards (bottom, 50 ppm).

**Statistical Analysis.** The results are represented as mean ± SD. Student's unpaired *t* test (2-DE spots comparison and WB) and one-way ANOVA with Duncan's multiple test (body weight, daily intakes, and FST) were employed. $p < 0.05$ (body weight, daily intakes, FST, bioinformatics analysis, and WB) and at least $p < 0.1$ (2-DE spots comparison) were considered statistically different.

## RESULTS

**Active Compounds in WGE.** We determined gastrodin, HBA, HB, and VAN, which are considered to be the major active compounds in GE, by HPLC using a $C_{18}$ column. Similar to gastrodin standard, a signal appeared at 4 min after injection. This peak was further confirmed as gastrodin by MS/MS analysis (data not shown). After quantification, WGE composed with 2.48% gastrodin. However, three other compounds could not be detected in WGE by the HPLC system (Figure 1).

**Animal Behavior and Daily Intakes.** Figure 2 shows the significant difference after FST between each group. CTL demonstrated a higher duration (100.4 ± 23.3 s) of immobility behavior than that of WGE (63.2 ± 19.1 s) and FLX (32.8 ± 5.8 s). In addition, FLX and WGE significantly increased the duration of swimming in comparison to CTL (CTL: 97.04 ± 27.4 s, WGE: 134.2 ± 19.7 s, FLX: 128.2 ± 20.4 s). The duration of struggling behavior was elevated after administration with WGE but was not significant compared to CTL. During experiment, FLX influenced food and water intake and hindered body weight gain. In contrast, WGE administration did not interfere with body weight gain and water intake; even food intake was only slightly affected (Table 1).

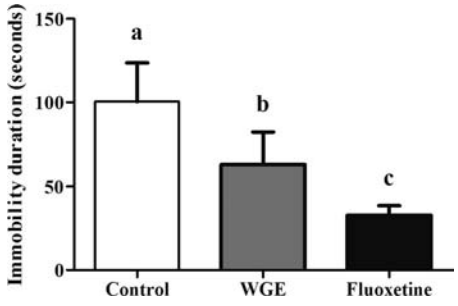

**Figure 2.** Effect of water extract of *Gastrodia elata* Blume on the immobility behavior in rats in the forced swimming test. [abc] indicate significant differences between one another in each group ($p < 0.05$) analyzed by ANOVA and Duncan's multiple range test.

**2-DE and Protein Identification.** Forty-six spots had significant differences out of the 316 matched spots in the frontal cortex (loading protein 400 μg, fold change ≥2, at least $p < 0.1$). Among 46 spots, 30 proteins were identified by MALDI-TOF. In the hippocampus, 29 spots were significantly different in similar conditions to that of the frontal cortex, and 17 proteins were identified. However, 17 protein identities may not be adequate for bioinformatics analyses. To address this issue, we further loaded more proteins (450 μg) for the hippocampus into the 2-DE system and switched to a higher sensitivity MS system (LC-ESI). Finally, 25 proteins, which were not included in the list of 17 proteins from the initial matching, were identified from the 39 differentially expressed spots in the second separation (fold change ≥2, at least $p < 0.1$). Thus,

[a]The capital letters represent the significant differences in the specific group in different weeks. The lower case letters symbolize the significant differences between different treatment groups in the same week. All of the results were subjected to ANOVA with Duncan's post hoc analysis ($p < 0.05$). [b]W0: the habituation period, W1−3: the first to the third week.

42 total proteins were identified from the hippocampus. The information on identified proteins such as protein name, peptide matching percentage, and fold change is shown in Tables 2 and 3 for the frontal cortex and hippocampus, respectively. The zoom-in spot images on 2-DE gel and quantitative charts of specific identified proteins are shown in Figure 3.

**Bioinformatics Analysis.** To elucidate the mechanism underlying the antidepressive-like activity of WGE, the identified proteins were uploaded to Metacore. A cytoskeleton-related process emerged with a high ranking in the analysis of functional classifications based on the GeneGo Process Network (Figure 4A). Furthermore, Slit−Robo signaling emerged with the highest score in the predicted pathways analyzed by the GeneGo Pathway Map of Metacore (Figure 4B). The gel images of these identified proteins related to cytoskeleton remodeling and the Slit−Robo pathway are shown in Figure 3. Besides, we found similar results when the two regions were assessed individually (data not shown). Therefore, the Slit−Robo pathway probably mediates the antidepressive-like activity of WGE. The proteins shown on the Slit−Robo signaling map were built using the Metacore database (Figure 5). The tubulin and actin subunits, actin-related protein 3 (ARP3), dihydropyrimidinase-related protein 2 (DPYL2; also named CRMP2), and profilin1 (PFN1), which were identified in 2-DE, are presented with a "ratio bar (WGE compared to CTL)" on the upper right corner of the symbols.

**Western Blot.** WB was employed to validate the expression of the proteins associated with Slit−Robo signaling, which emerged with the highest score for the predicted pathways. In addition to CRMP2 and PFN1 identified in 2-DE, Slit1, Slit2, Robo1, Robo2, and RhoA were also analyzed (Figure 6). The result showed that Slit1 was markedly down-regulated in both regions after WGE administration. However, the expression of Slit2 was not equally down-regulated. WGE did not influence the expression of Robo1 and Robo2, the receptors of Slits. The down-regulation of the negative regulator RhoA was discovered in the WGE group. In contrast, incremental changes in the expression of CRMP2 and PFN1 were observed.

## DISCUSSION

Previously, we found that *G. elata* Blume reduced depressive-like behavior and influenced the monoaminergic neurotransmitters of the frontal cortex, hippocampus, amygdala, and striatum of rats subjected to FST, a common behavior model for evaluating the antidepressive activity of medicine. To exclude the influence on animal locomotion of treatments, an open field test was performed. During a 5 min observation for the open field test, the travel distance and velocity of rats were not affected by administrations (data not shown). This result indicates that the influence of the behaviors in the FST was not coming from the change of locomotion.

In the present study, we detected the composition of WGE in order to realize the active components that could be responsible for the antidepressive effect of WGE. The HPLC fingerprint indicated that among the four candidates only gastrodin could be detected in the WGE (Figure 1). This profile was similar to Zhang's study.[15] In contrast, HBA, HB, and VAN could be detected in the diethyl ether fraction of a methanolic extract of GE.[16] Zhang's research indicated that gastrodin ameliorated depressive-like behavior and up-regulated the expression of brain-derived neurotrophic factor (BDNF).[17] In addition, the reduction of glutamate-induced apoptosis in differentiated PC12 cells via regulating CaMKII/ASK-1/p38 and MAPK/p53 signals by gastrodin had been noticed.[18] However, the blood brain barrier hinders compounds acting on the central nervous system (CNS), which is the difficulty in drug development for mood disorders. Pharmacokinetic studies showed that gastrodin could be detected in plasma after gavage with WGE[15] and quickly appeared in brain microdialysates after gastrodin administration in rats.[19,20] Furthermore, gastrodin could be absorbed via glucose transporters 1 (GLUT1) that are distributed in the brain and intestine, on the basis of its glycoside structure.[21] These findings suggested that WGE could be absorbed and directly act on the CNS, implying that gastrodin is the major active compound of WGE. Thus, gastrodin was surmised to be the major potential active component for the antidepressive-like effect of WGE.

The relationship between neurocytoskeletal remodeling, neuroplasticity, and depression has been discovered.[22,23] In addition to the original pharmaceutical designs, many antidepressants not only influenced the level of neurotransmitters but also stimulated neurocytoskeletal rearrangement and elevated neuroplasticity.[24−26] In the present study, many cytoskeleton-related proteins were up-regulated by 2−5-fold after chronic administration with WGE. According to the network analysis, the detection of cytoskeleton rearrangement with the highest score in bioinformatics analysis indicated the potential interaction between identified proteins (Figure 4A). Hence, WGE could enhance neurocytoskeletal rearrangement and be associated with

[a]These proteins were differentially expressed in the water extract of *Gastrodia elata* Blume (WGE) and control (CTL) groups and were detected by MALDI-TOF mass spectrometry. [b]The SSP is the serial number assigned by the gel image analysis software. [c]N/D means that the spot was not detected by MS or MS/MS. [d]The protein identities were identified from MS and/or MS/MS method in the Mascot protein online search program. [e]All the protein identities that were matched successfully from the Mascot protein online search program are presented (more than one protein was identified from one spot). [f]Asterisk represents the significance of the spot comparing between WGE and CTL (***$p < 0.01$, **$p < 0.05$, *$p < 0.1$).

neuroplasticity and an antidepressive-like effect. On the basis of the bioinformatics analysis, the identified proteins that were associated with actin filament, microtubule, and neurofilament processes will be discussed in the following section.

Actin remodeling is facilitated by dendritic branching and synaptogenesis during neuronal growth. We discovered that actin, actin-related protein 3 (APR3), cyclase-associated protein 2 (CAP2), and profilin1 (PFN1), which were related to actin

[a]These proteins were differentially expressed between the water extract of *Gastrodia elata* Blume (WGE) and control (CTL) groups. [b]The SSP is the serial number assigned by the gel image analysis software. [c]N/D means that the spot was not detected by MS or MS/MS. [d]Total loading protein was 400 $\mu$g, and the spots were analyzed by MALDI-TOF mass spectrometry. [e]Total loading protein was 450 $\mu$g, and the spots were analyzed by LC-ESI mass spectrometry. [f]The protein identities were identified from MS and/or MS/MS method in the Mascot protein online search program. [g]Asterisk represents the significance from spot comparing between WGE and CTL (***$p < 0.01$, **$p < 0.05$, *$p < 0.1$). [h]All the protein identities that were matched successfully from the Mascot protein online search program are presented (more than one protein was identified from one spot; more than one spot was identified as the same protein).

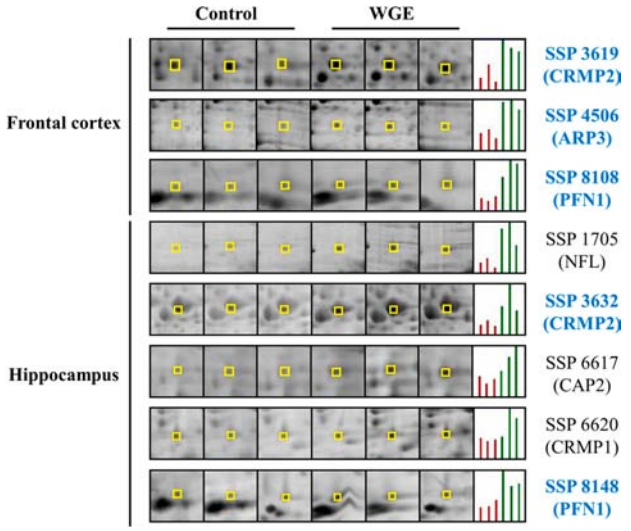

**Figure 3.** Magnified gel images and quantification of differentially expressed proteins related to cytoskeleton remodeling in the frontal cortex and hippocampus. The matched spots are located in the center of each zoom-in gel image with yellow squares. The charts beside the gel images show the quantification results. The red and green bars represent respectively the expressed density of the matched spots for each of three replications of the control and WGE. The protein name in blue signifies that protein is involved in the Slit−Robo pathway. CRMP2, dihydropyrimidinase-related protein-2; ARP3, actin-related protein 3; PFN1, profilin-1; NFL, neurofilament light chain; CAP2, adenylyl cyclase-associated protein 2; CRMP1, dihydropyrimidinase-related protein-1.

processes, were up-regulated in the WGE group. ARP2 and ARP3 form an ARP 2/3 complex and control the dependent branch function of actin filaments in rapidly developed neuronal regions such as lamellipodia and filopodia. These molecular effects have also been reported in pharmacological studies of antidepressants such as nortriptyline in rats.[24] Actin dynamic programs include the CAP family. According to Peche et al., CAP1 abundantly exists in many tissues, but CAP2 is specifically highly expressed in brain, heart, and skeletal muscle.[27] The cooperative model between CAP, actin, and cofilin in the promotion of actin dynamics and synaptogenesis was established.[28] In the same study, Moriyama et al. also noted that the functions of CAP1 and CAP2 are analogous. However, research indicated that a defect in CAP is correlated with mood disorders.[29] Similar to CAP and ARP, the expression of PFN1 was also increased in the WGE group. PFN1 regulates the mechanisms related to fixing actins on the phosphoinositide of the plasma membrane and assists in the formation of actin filaments during neuronal growth. Thus, PFN1 was shown to be an essential factor for neuronal differentiation, synaptic plasticity, and stabilizing the dendritic spine morphology.[30] In contrast, actin-related genes were down-regulated in the mice that are sensitive to depression and the post-mortem cerebrum of mood disorder victims.[29] In our study, we showed that WGE stimulates the expression of proteins associated with actin processes (Tables 2 and 3), which in turn facilitates its antidepressive-like effect.

Like the roles of actin during neuronal growth, microtubules are polymerized to elongate the axon and dendritic trunk. In the present study, we found that the essential factor, CRMP2, was up-regulated in both the frontal cortex and hippocampus. However, dysfunction of CRMP2 has a strong correlation with psychiatric disorders. Recent proteomics data indicated that CRMP2 is down-regulated severely in rats with depressive-like behavior induced by UCMS.[31] Post-mortem research also noted a reduction in the expression of CRMP2 in the frontal cortex of patients with MDD and bipolar disorder.[32] Hence, CRMP2 is considered to be a potential biomarker for MDD. Another CRMP protein, CRMP1, was also up-regulated in the

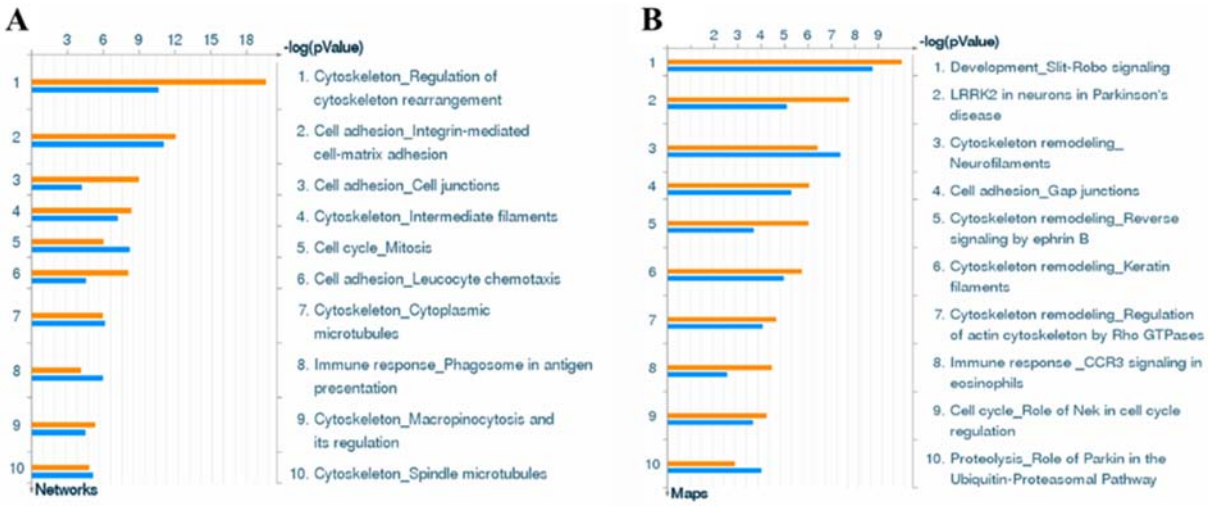

**Figure 4.** Metacore-analyzed results presented as −log($p$ value) chart of matched protein identities for potential molecular networks and pathways. A higher value in the chart represents a higher correlation and possibility. (A) GeneGo Process Network; (B) GeneGo Pathway Maps (orange chart: frontal cortex; blue chart: hippocampus).

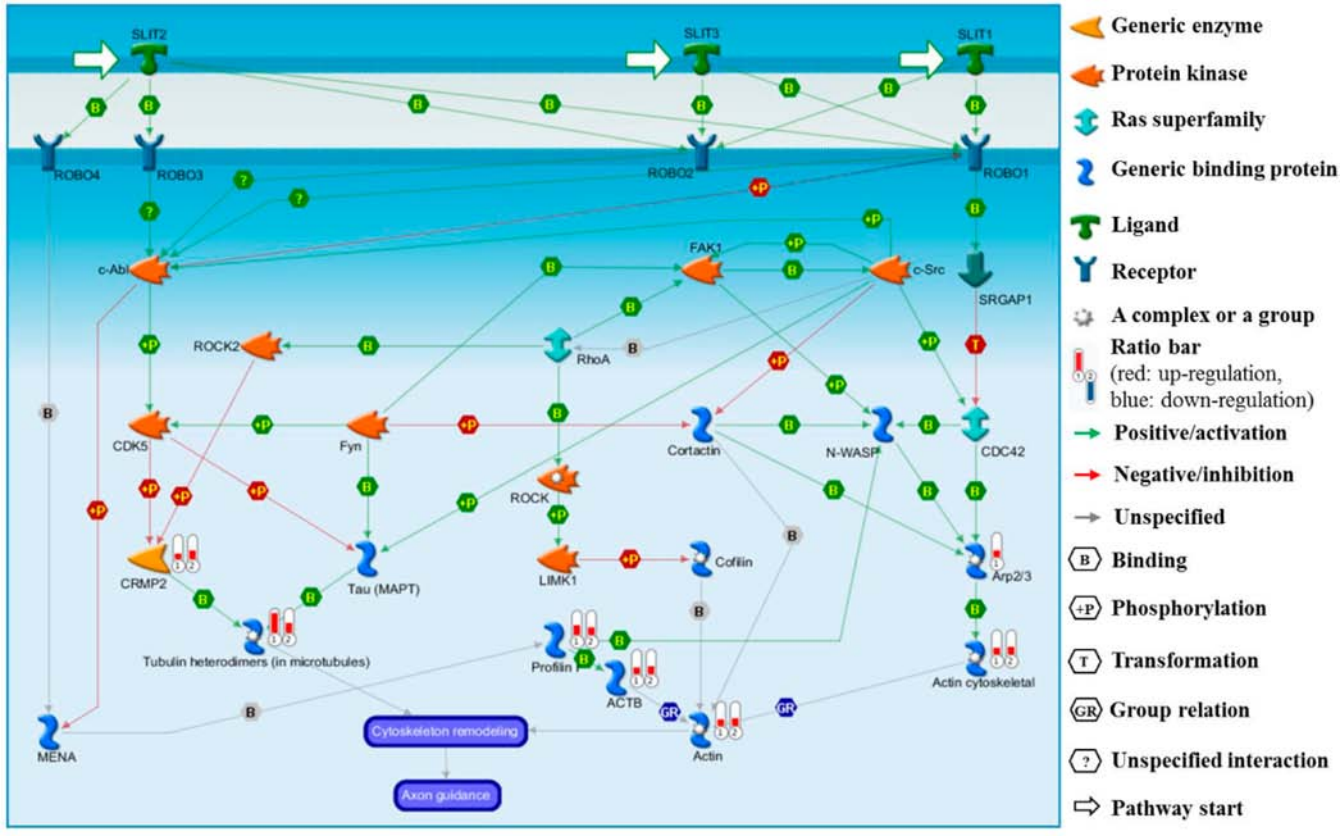

**Figure 5.** Pathway map for Slit−Robo signaling and the downstream factors. Proteins labeled with "1" and "2" represent the proteins identified from 2-DE of the frontal cortex and hippocampus, respectively. The ratio bars on the upper right corner of the symbols represent the expression ratio between the water extract of *Gastrodia elata* Blume (WGE) and the control (CTL) (WGE/CTL). c-Abl, c-Abl nonreceptor tyrosine kinase; CDK5, cyclin-dependent kinase 5; ROCK, Rho-associated protein kinase; CRMP2, dihydropyrimidinase-related protein-2; Arp 2/3, actin-related protein 2/3 complex; RhoA, Ras homologous member A; c-Src, Proto-oncogene tyrosine-protein kinase Src; CDC42, cell division cycle 42; N-WASP, neural Wiskott−Aldrich syndrome protein; FAK1, focal adhesion kinase 1.

hippocampus. The function of CRMP1 is similar to CRMP2, which stimulates neuronal pathfinding and axon elongation. Research has proved that a deficiency of CRMP1 also leads to a defect in neuronal development.[33] In contrast, antidepressants up-regulate the expression of CRMP proteins and tubulin-based processes.[34] Hence, up-regulation of CRMP1 and -2 reflect the activation of microtubule-dependent activity in the brain after WGE administration.

Neurofilament light chain (NFL), which forms intermediate filaments and composes the axon structure with medium

dx.doi.org/10.1021/jf503132c | J. Agric. Food Chem. 2014, 62, 10493−10503

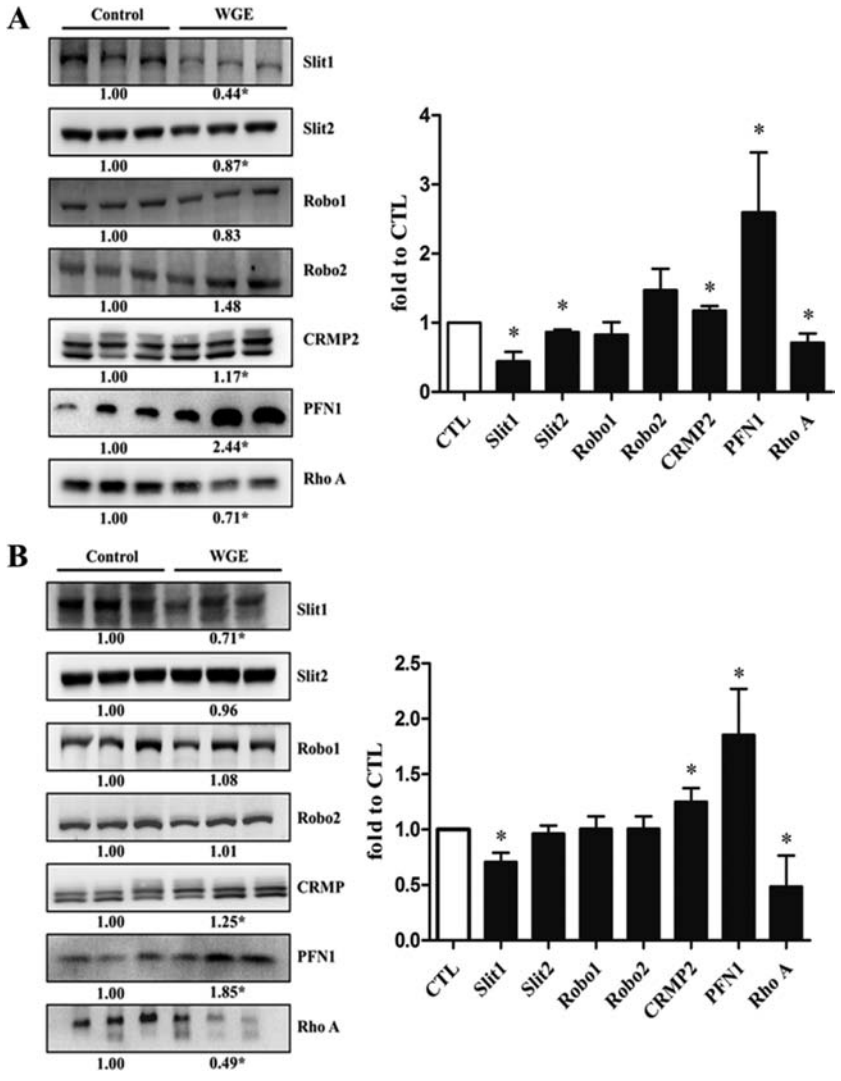

**Figure 6.** Western blot analysis of the regulators in the Slit−Robo pathway in the (A) frontal cortex and (B) hippocampus. The value on the bottom of each group and the chart images represent the ratio of expressed levels, which were normalized with the expression of GAPDH and relative to the control group. * indicates significant difference between control and WGE ($p < 0.05$) analyzed by Student's unpaired $t$ test.

(NFM) and heavy chains (NFH), was highly up-regulated after WGE administration (Table 3). Studies have showed that, similar to other cytoskeletal units, negative regulation of neurofilaments is possibly related to neurodegenerative diseases.[35] Foot-shock-induced depressive-like behavior in rats presented with lower expression of NFL but not NFM and NFH in the hippocampus.[36] Moreover, antidepressants enhanced the expression of NFL and synaptic remodeling.[37] Thus, incremental increase in the expression of NFL may be related to cytoskeleton remodeling and a neuroplasticity-stimulating effect of WGE.

The Slit−Robo pathway emerged with the highest score in the bioinformatics analysis of the predicted mechanisms for the antidepressive-like effects of WGE (Figure 4B). During neuronal growth, the axon is elongated and guided to another target neuron by the attractive and repulsive activities of Netrin and Slits, respectively. These actions involve excited cytoskeletal remodeling. The repulsive property of Slits includes the deactivation or down-regulation of positive regulators such as CRMP2 and PFN1 and activation of negative factors such as Ras homologous member A (RhoA). This program operates especially in the embryo, so that axons grow and allow the neural plate to construct the networks. Thus, the Slit−Robo signal is generally regarded as an essential process for embryonic neuronal development. Interestingly, *slit* and *robo* are not only expressed in the embryonic developmental phase but maintain a high level in postnatal stages and adults.[38] Marillat et al. also demonstrated that the expression of *slit1* and *robo2* changes in the hippocampus from postnatal day 10, the stage when synapses are rapidly generated. It seems that Slit−Robo signaling has some other activities in addition to mediating embryonic neuronal development. In fact, some research revealed that Slit−Robo may suppress neuroplasticity. Lin et al. discovered that dopaminergic neuronal extension and neurite growth are restricted by Slits and stimulated by Netrin.[39,40] Furthermore, this phenomenon was also validated in a stem cell-derived neuron mode.[40] In addition, a negative regulator, RhoA, is also involved in the Slit−Robo pathway. Down-regulation of RhoA correlates to neuronal growth. Cheng et al. observed that BDNF down-regulated the expression of RhoA, which stimulated neuronal growth.[41] Besides, L-glutamate (L-Glu), an excitatory transmitter, promotes and stabilizes dendritic growth and spine formation, results in neuroplasticity, and is correlated with Rac1/Cdc42 activation

dx.doi.org/10.1021/jf503132c | J. Agric. Food Chem. 2014, 62, 10493−10503

and reduction of RhoA activity.[42] According to these studies, down-regulation of the Slit−Robo pathway plays a potential role in neuroplasticity.

The WB results validated the expression of mediators involved in Slit−Robo signaling, which was matched by Metacore (Figure 6). To the best of our knowledge, there was no study indicating the potential relationship between the Slit−Robo pathway, pathology, and pharmacology for depression. In this study, based on the bioinformatics analyses and validation processes, stimulating neurocytosekeletal remodeling and enhancing neuroplasticity due to down-regulation of the Slit−Robo pathway might be one of the mechanisms to achieve the antidepressive-like activity of WGE.

growing season are reported. All phenolic compounds were confirmed using a mass spectrometer with an electrospray interface (ESI) operating in negative ion mode. The results provide information on the advantages of grafted eggplant fruit, which are recognized in the outer and inner quality parameters and are important from the point of view of the consumer as well as the vegetable producer. Knowing the effect of grafting on important fruit quality traits, especially changes in the phenolic profile, could also be very helpful for rootstock breeders, who have stressed the market value of fruits of grafted plants as a focus of most rootstock breeding efforts.[7]

## MATERIALS AND METHODS

**Plant Material.** Fruits were collected from three commercial varieties of eggplant, Blackbell F1 (BB), Epic F1 (EC), Galine F1 (GA), and landrace Domači srednje dolgi (DSD), which had been grafted onto tomato rootstock Beaufort F1 (BE) (and self-grafted plants were used as a control) using the cleft procedure described by Lee[30] and were grown in experiments from May until September in 2010 and 2011, on the experimental field (latitude 46°2′, longitude 14°28′, 298 m asl) of the Biotechnical Faculty in Ljubljana, Slovenia. The main characteristics of each of the varieties are presented in Table 1.

Successfully grafted plants were transplanted on May 24 in both years at a planting density of 0.8 × 0.8 $m^2$ (plant density of 12 500 plants $ha^{-1}$) in an unheated three-span greenhouse with flap ventilation at the ridge and roll-up ventilation at the side walls. Each span was 6 m wide and 25 m long and covered with a transparent polycarbonate Lexan corrugated sheet (LCS100, SABIC Innovative Plastics, Netherlands), with 89% visible light transmittance and <3% UV transmission. On the side walls, polyethylene film was used for roll-up ventilation. In both years, a completely randomized block design was used, with four eggplant varieties and two rootstocks (BE and self-grafted), four replicates per each grafted combination and 6 plants per replicate, making a total of 24 plants per treatment (scion/rootstock combination) and 192 plants for each experiment.

The soil of the experimental site is classified as gleyic fluvisol and endogenic fluvisol containing 24 g $kg^{-1}$ soil organic matter in the 0−0.3 m soil layer. At the beginning of the season, the average initial soil nitrate content was 5.2 mg $kg^{-1}$ for the same depth, soil assimilable P and K was 22 and 28 mg $kg^{-1}$, respectively, on the basis of which application rates of macronutrients were calculated according to the Regulations on Integrated Production of Vegetables. One day before transplanting, granulated mineral fertilizers were incorporated on the plots at a rate of 70 kg N $ha^{-1}$, 50 kg P $ha^{-1}$ and 235 kg K $ha^{-1}$, and 20 kg Ca $ha^{-1}$ as calcium ammonium nitrate, super phosphate, and potassium sulfate, respectively. The remaining N and Ca (150 and 184 kg $ha^{-1}$) were applied via fertigation with the water-soluble fertilizer (WSF) calcium nitrate (Multi-Cal, Haifa Chemicals, Israel). Irrigation was applied as required through a drip tape (T-tape TSX 500 model, T-systems International) beneath the plastic mulch. Diseases were managed with applications of Vertimec (Syngenta Agro d.o.o., Ljubljana, Slovenia) (0.05% on July 11, 2010 and on July 4, 2011) and Calipso SC 480 (Bayer Ag., Leverkusen, Germany) (0.03% on July 27, 2011).

**Weather Conditions.** Average daily temperature and total daily solar irradiation (presented in Table 2) during the experimental period from May to September of 2010 and 2011 were taken from the meteorological station on the experimental field of the Biotechnical Faculty in Ljubljana, Slovenia. It can be assumed that the environmental conditions in the greenhouse were very similar to those in the open field but, on the basis of experience from previous years, 3−4 °C higher. The weather during the experimental period in 2010 was comparable to the long-term average, but the average daily temperatures were slightly above the long-term average, with the highest positive deviation in June (by 2.5 °C) and in July (by 3 °C), while the average daily temperature in September fell below the long-term average daily temperature by 0.8 °C. The year 2011 was comparable to the long-term average in terms of temperature. Higher temperatures compared to the long-term average (more than 3 °C higher) were measured in May, August, and September.

More solar radiation compared to the long-term average was measured in all months during the experimental period in both years. The highest monthly averages of total daily solar radiation in 2010 were in June and July, 27 and 15% above the long-term average, respectively. Higher than average solar radiation was recorded in 2011, being highest in May (58%), August (45%), and September (55%).

**Fruit Sampling.** Fruit harvesting began 56 days after transplanting in 2010 and 60 days in 2011. Commercially mature fruit were harvested weekly; in the first year there were 12 pickings altogether and 11 in the second year of trials. Carpometric characteristics were measured in fruits of all scion/rootstock combinations, which were harvested in the middle of the harvesting period, 86 and 94 days after transplanting in the first and second year, respectively. For each scion/rootstock combination and each of four replications, six eggplant fruits were randomly selected from among marketable and undamaged fruits. Variation of carpometric characteristics [fruit weight (g), fruit length (cm), fruit width (cm), fruit length/width, and calyx prickles (0 = none; 9 = very many) (>30)], as well as color measurement and polyphenolic content, was studied on these samples.

**Color Measurements.** Skin color measurements were conducted to confirm skin color uniformity within individual varieties and among them in order to eliminate the effect of skin color as a factor that could influence the chemical composition of anthocyanins. Skin color was measured on the equatorial region of the fruits using a Minolta CR 300 Chroma portable colorimeter (Minolta Co., Osaka, Japan) with C illuminant for each fruit, and an average for individual varieties was calculated. Fruit chromaticity was expressed in $L^*$, $a^*$, $b^*$ color space coordinates (CIELAB). Color was described by the CIRG index, specifically intended for the evaluation of the external color of violet-colored fruits[31] and calculated as $(180 - h)/[L^* + \sqrt{(a^2 + b^2)}]$, where $h$ represents the hue angle.

**Determination of Browning.** Fruit flesh color was measured using the same colorimeter (Minolta CR 300) to determine the lightness of fruit pulp by measuring the $L^*$ value (0 = black, 100 = white). Fruit was cut transversally at the midpoint between the blossom and stem ends, and measurements were made on the surface immediately after being cut, 10 min later, and after 30 min, when maximum browning was achieved.

The oxidation potential was estimated using the method of Larrigaudiere et al.[32] with a slight modification as suggested by Concellon et al.[25,33] A colorimeter was used to measure the color parameter $L^*$ on the section obtained, as described earlier. Measurements obtained immediately after cutting were marked $L_0$, those obtained after 10 min were marked $L_{10}$, and those after 30 min were marked $L_{30}$. The browning potential was expressed as $\Delta L_{10} = (L_0 - L_{10})$ and $\Delta L_{30} = (L_{30} - L_0)$.

**Chemicals.** The standards used to determine the phenolic compounds in samples were chlorogenic acid (5-caffeoylquinic acid) and quercetin 3-O-rutinoside from Sigma-Aldrich and (−)-epicatechin, (+)-catechin, delphinidine, quercetin 3-*O*-rhamnoside, quercetin-3-*O*-galactoside, and quercetin 3-*O*-glucoside from Fluka Chemie (Buchs, Switzerland). Methanol for extraction of phenolics was acquired from Sigma-Aldrich. The chemicals for the mobile phases were HPLC−MS-grade acetonitrile and formic acid from Fluka. Water for the mobile phase was double distilled and purified with the Milli-Q system (Millipore, Bedford, MA)

**Extraction and HPLC−MS/MS Identification of Phenolic Compound.** The eggplant fruits were peeled with a mechanical peeler and the peel was separated from the pulp. The extraction of fruit samples (peel and pulp separately) was done as described by Mikulic-Petkovsek et al.[34] with some modification. Fresh eggplant samples were ground to a fine powder in a mortar chilled with liquid nitrogen. The samples of 10 g of pulp or 5 g of peel were extracted with 10 mL of methanol containing 3% (v/v) formic acid and 3% (w/v) 2,6-di-*tert*-butyl-4-methylphenol (BHT) in a cooled ultrasonic bath for 1 h. BHT was added to the samples in order to prevent oxidation. After extraction, the fruit extracts were centrifuged for 7 min at 10 000 rpm. The supernatant was filtered through a Chromafil AO-45/25 polyamide filter produced by Macherey-Nagel and transferred to a vial prior to injection into the HPLC system. The individual phenolic compounds were analyzed using the Thermo Finnigan Surveyor HPLC system (Thermo Scientific, San Jose, CA) with a diode array detector at 280 nm (flavanols, cinnamic acid derivatives), 350 nm (flavonols), and 530 nm (anthocyanins). A Phenomenex (Torrance, CA) HPLC column C18 (150 × 4.6 mm, Gemini 3 $\mu$m) protected with a Phenomenex Security guard column and operated at 25 °C was used for the separation of phenolic compounds. The injection volume was 20 $\mu$L and the flow rate was maintained at 1 mL min$^{-1}$. The elution solvents were aqueous 1% formic acid and 5% acetonitrile (A) and 100% acetonitrile (B). The samples were eluted according to the linear gradient described by Marks et al.:[35] 0−5 min, 3−9% B; 5−15 min, 9−16% B; 15−45 min, 16−50% B; 45−50 min, 50% isocratic mixture. This step was followed by washing and reconditioning of the column. Compound identification was achieved by comparing the retention times and their UV−vis spectra from 200 to 600 nm, as well as by the addition of an external standard.

The identity of the phenolic compounds was confirmed using a mass spectrometer (Thermo Scientific, LCQ Deca XP MAX) with electrospray ionization (ESI) operating in positive (for anthocyanins) and negative (other phenolic groups) ion modes.

Full-scan data-dependent MS scanning from $m/z$ 115 to 2000 was used for the analyses. Quantification was achieved on the basis of the concentrations of the corresponding external standard. For compounds lacking reference compounds, related compounds were used as standards for quantification. Delphinidin 3-rutinoside-5-galactoside, delphinidin 3-rutinoside-5-glucoside, and delphinidin 3-rutinoside were therefore quantified in equivalents of delphinidin. The concentrations of phenolic compounds were expressed in mg kg$^{-1}$ of fresh weight (FW).

**Statistical Evaluation.** The experiment was treated as a two-factorial experiment in four randomized replications. The first factor (eggplant variety) had four levels: BB, EC, GA, and DSD, while the second factor (rootstock) had two levels (BE, self-grafted plants). Results were analyzed using the Statgraphics Plus 4.0 program (Manugistics. Inc., Rockville, MD). Prior to the Anova test, Levene's test for equality of variances was performed. Data from all of the analyses were tested for any differences among scion/rootstock combinations within each year using two-way analysis of variance (ANOVA). The differences were tested using the Duncan test with a significance level of 0.05. The means and the standard errors for variety, treatment, and the interaction V × T, which were taken from the ANOVA table, are presented.

The average three-part composition of anthocyanins expressed by absolute amounts was analyzed using multivariate analysis of variance (MANOVA) and a further separate ANOVA test for three variables (D-3-rutinoside, D-3-rutinoside-5-galactoside, and D-3-rutinoside-5-glucoside).

## RESULTS

Data for yield, expressed as the number of fruits per plant, and other visible fruit traits, such as fruit weight, color, and shape, as well as fruit calyx prickles, for the eggplant varieties grafted onto tomato rootstock are presented in Table 3. For the number of fruits per plant, both main effects (rootstock and variety) were significant ($p = 0.001$) in both years, while the interaction between them ($p = 0.01$) was significant only in 2011. In 2010, grafting significantly increased the number of fruits per plant for all varieties, while in 2011 the same effect of grafting was found with two varieties and landrace but not with GA. The significant effect of variety on fruit yield was also confirmed by ANOVA ($p = 0.001$), with a significantly higher number of fruits per plant for all commercial varieties compared to landrace DSD.

For the average fruit weight, ANOVA showed a significant impact of variety ($p = 0.001$) in 2010, while in 2011 both main effects were significant, as was also their interaction. In the first year, heavier fruits were recorded with BB and DSD compared to EC and GA, while between them no significant differences were found (Table 2). In the second year, grafting increased the average fruit weight with GA, EC, and DSD compared to self-grafted plants, but the differences were significant only with landrace DSD ($p = 0.01$).

For the color index CIRG, ANOVA showed a significant impact of varieties in both years, and in 2011 the V × T

[a]Different letters in rows denote significant differences in treatment (Duncan test, $p < 0.05$). [b]The significance is designated by asterisks as follows: *statistically significant differences at *P*-value below 0.05; **statistically significant differences at *P*-value below 0.01; ***statistically significant differences at *P*-value below 0.001. [c]SE = standard error for significant term.

interaction was also significant ($p = 0.01$). The CIRG index ranged from 6.5 to 7.1 in 2010 and from 5.3 to 8.6 in 2011, which indicated a very dark-violet skin of the eggplant fruit. According to Carreño et al.,[36] a CIRG index of 5 indicates red-dark violet skin, 5.7 indicates red-black fruit skin, and higher than 6 indicates blue-black fruit skin. In 2010, the darkest fruit skin was recorded with variety EC, with a CIRG index of 7.0, while the CIRG indexes of other varieties were lower than 6.9. In 2011, grafting significantly increased the darkness of the fruit peel with indexes for BB from 6.5 (self-grafted plants) to 8.6 (plants grafted onto BE), while with EC darkness decreased from 7.1 (self-grafted plants) to 5.5 (plants grafted onto BE).

The length/width ratio of fruit was significantly influenced by variety ($p = 0.001$) in 2010. Although ANOVA did not confirm a significant effect of grafting on fruit shape in 2010, we found more elongated shapes with self-grafted plants of all varieties, with a higher length/width ratio compared to fruits from plants grafted onto rootstock. A significant effect of varieties on fruit shape was expected, since fruit shape is highly genetically controlled.[37] EC had the most elongated fruits among all tested varieties. In 2011, the significant impact of the V × T interaction ($p = 0.001$) indicated that fruits of BB and landrace DSD plants grafted onto BE were more elongated than the fruits of self-grafted plants; with EC and GA, the opposite effect was recorded.

Finally, an important visible trait of eggplant fruit is calyx prickles, which is an undesirable trait for handling eggplant fruits. In both years, ANOVA confirmed the significant impact of grafting on decreasing the amount of calyx prickles, since the scores of this trait for fruits from grafted plants were lower than those from self-grafted plants. A significant effect of variety on calyx prickles was reflected in the highest scores for it in fruits from landrace DSD, in both years, compared to those of other commercial varieties.

The lightness of the fruit pulp immediately after cutting ($L_0$) was similar in grafted and self-grafted plants, with values

between 80 and 82.0 and with no significant impact of grafting in either the central or lateral parts of the pulp surface (Table 4). Differences were significant among varieties, in both years. DSD and GA showed whiter pulp, both laterally and centrally, while fruits from BB had the darkest pulp. The effect of grafting combination on the browning potential was assessed by measurements of the lightness of the fruit pulp 10 min ($L_{10}$) and 30 min ($L_{30}$) after slicing, and the difference with $L_0$ was calculated as the index of browning potential.[38] ANOVA showed a significant effect of rootstock ($p$ = 0.01) on the browning potential only 10 min after cutting ($L_{10}$) in 2010 and of varieties ($p$ = 0.001) in both years. Browning was more evident in the peripheral part of the fruit section, both 10 and 30 min after cutting. In 2010, the effect of grafting on changes of browning pulp tissues was recorded in lower browning potential ($\Delta L_{10}$ was 2.8) on the lateral part of the pulp of grafted fruit compared to the fruits of self-grafted plants ($\Delta L_{10}$ was 4.8). After 30 min no significant differences regarding the grafting effect on browning potential were found, and the same effects were also recorded in 2011. In 2011 grafting did not affect the browning potential of eggplant pulp 10 and 30 min after cutting. In relation to varieties, a higher browning potential after 30 min was found in the lateral section of BB in 2010 and DSD and GA in 2011. The variety with the lowest browning potential in the lateral section after 30 min was DSD in 2010 and BB and EC in 2011.

In the four eggplant varieties that were grafted onto BE tomato rootstock, we identified and quantified 13 phenolics (Tables 5−7) belonging to four groups: hydroxycinnamic acids, flavonols, flavanols, and anthocyanins. Compounds of the first three groups were identified in eggplant pulp, while anthocyanins were identified in the eggplant peel. Great differences in relation to variety and grafting treatment were found in the individual phenolic groups between the years. These results are in accordance with data reported by Lata et al.,[39] who observed up to 70% differences in phenolics between seasons.

In the fruit pulp we found the following hydroxycinnamic acids: chlorogenic, caffeic, *p*-coumaric, and ferulic acids. Hydroxycinnamic acids were the highest represented group of phenolics in the eggplant fruit of all four varieties, ranging from 25 to 45% in 2010 and from 34 to 51% in 2011. For total hydroxycinnamic acids, ANOVA showed a statistically significant effect of variety ($p$ = 0.001) in 2010 and the interaction V × T in both years. In 2010, fruits of BB (from grafted and self-grafted plants) had the highest total hydroxycinnamic acid contentration, and no significant differences were found between them. The effect of grafting on hydroxycinnamic acid content was recorded with DSD, where grafting onto BE caused their increase in comparison with the fruits from self-grafted plants and with GA and EC, where the opposite effect was found. In 2011, grafting had no effect on changes in total hydroxycinnamic acid content in fruits of commercial varieties while for DSD a significant decrease was found (Tables 6 and 7).

In terms of quantity, quercetins are a minor phenol group in eggplant fruits, ranging from 1 to 4% of the total analyzed phenolic concentration. The analysis of flavonols covered four types of quercetin glycoside: quercetin 3-rhamnoside accounted for approximately 75−90% of total flavonol concentration, followed by quercetin 3-rutinoside (4−17%), quercetin 3-glucoside (2−8%) and quercetin 3-galactoside (1−2%). Total flavonols were significantly influenced by variety and interaction of V × T in 2010 and by both main factors and their interaction in 2011. In 2010, grafting on rootstock significantly increased the total

[a]Anthocyanins were obtained in positive ion mode and other phenolics in negative ion mode.

flavonols in fruits of the landrace DSD and decreased in GA. A more consistent impact of grafting on total flavonol concentrations was observed in 2011, where grafting increased their concentration in fruits of EC and GA (Tables 6 and 7).

Within flavanols, monomeric catechin and epicatechin were analyzed in eggplant pulp. Catechin was a more abundant individual flavanol in the eggplant fruits than epicatechin, representing 50−80% of the total flavanol concentration. Their concentrations ranged from 30 to 45% in 2010 and from 25 to 40% in 2011 of the total phenolic concentration. Significant changes in total flavanols were observed only in 2010, for which ANOVA showed a significant impact of variety and interaction V × T. Fruits of grafted EC and GA had significantly lower total flavanol concentrations than fruits from self-grafted plants. The opposite effect, with significantly higher total flavanol concentration was found in grafted fruits from DSD compared to self-grafted fruits.

In terms of quantity, anthocyanins were the third most represented phenolic group in eggplant fruits after hydroxycinnamic acids and flavanols. Their concentration ranged from 15 to 30% of the total analyzed phenolic concentration. In the fruit peel we identified and quantified the following anthocyanins: delphinidin 3-rutinoside, delphinidin 3-rutinoside-5-galactoside, and delphinidin 3-rutinoside-5-glucoside. Delphinidin 3-rutinoside was found in the highest mean concentrations in all the samples and represented 90−95% in 2010 and 83−92% in 2011 of the total anthocyanin concentration. Delphinidin 3-rutinoside-5-galactoside was the second most represented, ranging from 2 to 7% in 2010 and from 7 to 13% in 2011. Delphinidin 3-rutinoside-5-glucoside was found in the lowest mean concentrations, ranging from 1 to 3% in both years. ANOVA confirmed a significant effect of grafting ($p = 0.01$) on total anthocyanin concentration only in 2010, when grafting decreased the total anthocyanin concentration in the peel of eggplant fruits with all tested varieties.

## DISCUSSION

In recent years, a high quality of vegetable fruits is even more important than total fruit yield, due to the benificial role of vegetables in the human diet.[11] External quality described by visual traits such as fruit size, shape, color, and calyxs prickles are important criterion in making purchasing decisions of eggplant fruits.[1] Among many strategies, such as genetic selection, optimization of the environmental conditions, and agricultural practices, grafting represents an efficient technological tool where a scion/rootstock combination plays an important role in the achievement of the established tasks.[5,7,10] It is well-known that scion variety mainly affects the final yield and quality traits of fruit in grafted plants,[40] but rootstock effects can alter these characteristics,[1,3,4] possibly due to changes in vigor and concentration of growth regulators induced by the rootstocks.[8] Further, differences in the requirements for assimilating mineral nutrients between tomato (rootstock) and eggplant (scion) also altered the quality of fruit yield.[41] In our study, higher yield and the changes of visual characteristics of fruits from grafted and self-grafted plants could be explained by the successful adoption by the scion of the main rootstock's characteristics, already described in Table 1. The lower presence of calyx prickles, observed in fruits from grafted plants, may indicate more vigorous and balanced growth[41] of grafted plants than self-grafted ones, since the prickles in the eggplant calyx are probably caused by biotic or abiotic stresses.[17]

Eggplant has a high antioxidant capacity, mainly attributed to its high content of phenolic compounds.[14] First evaluations of phenolic acid constituents in eggplant fruit from different accessions and varieties were reported by Stommel and Whitaker[12] latter in phytochemical investigations, and the impact of different cultivation systems, grafting techniques, and methods of sample preparation on phenolic constituents were examined.[3,8,28,42] In accordance with the above-mentioned studies, the analyzed composition, and the content of the main phenolic groups (hydroxycinnamic acids, flavonols, flavanols, and anthocyanins) in eggplant pulp and peel showed high dependence not only on variety but also on rootstock, as well as on environmental conditions, since the phenolic profile varied during the two growing periods. In 2010, less solar radiation and lower mean daily temperatures (Table 2) led to less favorable environmental conditions for growth and development of eggplant fruits. It seems that higher vigor of grafted plants of commercial varieties is more expressed under such temperate environmental conditions, where rootstock hastened plant growth and development, which resulted in higher yield. We picked a significantly higher number of fruits per plant (7.5−8) from plants of grafted commercial varieties compared to the grafted landrace (Table 3).

On the other hand, it could be expected that fruits from grafted commercial varieties had not reached physiological maturity at harvesting, because they grew faster than self-grafted plants and we picked them at a younger maturity stage. At physiological maturity, the contents of sugars, ascorbic acid,

and polyphenols are the highest in eggplant fruits and then significantly decreased.[48] Our assumption was partly confirmed by the chemical analysis of phenolic constituents in eggplant fruits, which showed a lower concentrations of all phenolic constituents in grafted fruits in comparison with the fruits from self-grafted plants. The opposite effect was found for the landrace/rootstock combination, where we harvested only five fruits per plant in that year, which indicates that fruits from the landrace grew more slowly; thus, they could reach their physiological maturity by harvest date, which was confirmed also with an increase of the phenolic contents in grafted plants compared to self-grafted ones.

Anthocyanins are the most important group within flavonoids for the production of a dark red or purple color of the eggplant peel.[21] The composition of anthocyanins in fruits from our study was relatively similar to those observed by Sadilova et al.[21] and Wu and Prior.[43] On the other hand, the composition of anthocyanins is largely conditioned by eggplant variety and growth conditions.[2,23,38,44] This could be one of the reasons why our results differed from the data reported by Azuma et al.,[45] who identified an acylated anthocyanin, known as nasunin, as the prevailing anthocyanin in Japanese eggplant varieties. In our study, the concentrations of anthocyanins, which were analyzed in eggplant peel in 2010, showed high dependence on grafting. Their concentration significantly decreased in fruits from grafted plants compared to the fruits from self-grafted plants. This response was probably a consequence of more shaded fruits, since grafted plants had a higher habitus with much bigger leaves (data not shown), with which the fruits were covered. Since accumulation of anthocyanins is strongly light-exposure-dependent,[29,46] it could be additionally suggested that, in order to produce fruits with a higher anthocyanin concentration and thus with higher nutritional value, grafted eggplant plants should properly be pruned and illuminated.

As eggplant is ranked among the top 10 vegetables in terms of antioxidant activity, mainly due to the fruit phenolic constituents, the high browning potential of the fruit pulp could be expected.[1,28,18] Browning appears on cutting, when disruption of cellular structures leads to release of the enzyme polyphenol oxidase (PPO), which oxidizes phenolics, and in the presence of oxygen, *o*-quinones are polymerized, causing brown-colored pigments.[18] Eggplant varieties differed in their extents of postcut browning, which could be due to variations in the PPO activity or level of soluble phenolics.[7,17,18] In contrast to the findings of Gisbert et al.[8] and Moncada et al.,[3] who reported that little or no effect of grafting on fruit phenolics content was found, in our study grafting decreased the phenolics concentration in fruits of commercial varieties in 2010, while the landrace/rootstock combination gave a significant increase (in 2010) and decrease (in 2011) of phenolics concentration. Higher phenolic concentration in grafted DSD eggplant pulp in 2010, in addition to the lowest fruit yield among the grafted treatments (Table 3), may be an additional indicator of the stress in this scion/rootstock combination, since stress conditions induce an accumulation of phenolics.[1,47] An inverse effect of grafting in DSD in the next year of the study probably indicated a higher diversity among landrace plants compared to the plants of the other commercial hybrid varieties, for which a very similar pattern of phenolic concentration changes were observed in both years. An interesting result of our study is that the fruits from the same landrace/rootstock grafted combination behaved differently during the two growing season, which could be explain with findings reported by Hanson,[2] who suggest that environmental factors, above all light, temperature and water management, influenced the types or levels of phenolic compounds in eggplant fruits. During the growing seasons in our study, weather conditions were very similar, with temperatures slightly above the long-term average in both years, but with a little lower solar radiation in 2010 than in 2011, which contributed to less suitable growing conditions for eggplants in that year.

In accordance with the studies on the impact of different factors on browning potential of eggplant fruit pulp,[17,18,33] the browning potential in our study showed high dependence on variety and partly on grafting combination. As regards the different correlations between phenolic contents and browning potential (positive for EC and GA and negative for the landrace DSD), the importance of other main antioxidants, such as reduced ascorbate, could be evidenced.[18,38] The content of ascorbic acid, which has antibrowning properties because it reduces enzymatically formed *o*-quinones to their precursor diphenols, is also genetically, developmentally, and environmentally dependent;[17] therefore, variations of its content in fruits from our treatments could be expected. The syntheses of sugars, ascorbic acid, and polyphenols are developmentally conditioned and reached their maximum values about 6 weeks from eggplant fruit set. This fact emphasizes the importance of considering this point for determination of the physiological maturation stage of the fruit,[48] in order to harvest eggplant fruits with higher nutritional value. There are also some other variety-dependent factors, like intracellular pH, which affects the activity of the polyphenol oxidase enzyme, or cellular factors, such as cell size, which may have a role in browning and color evaluation of the fruit pulp.[25]

In conclusion, the impact of grafting commercial eggplant varieties and landrace onto tomato rootstock on internal and external eggplant fruit characteristics is not equal and is largely conditioned by scion/rootstock combination and environmental conditions. For all tested varieties data indicated a positive effect of grafting on yield and visual traits of eggplant fruits. Grafted plants were more vigorous than self-grafted plants and gave higher yield. For some varieties grafting influenced also fruit shape and size and for all varieties decreased the presence of calyx prickles. Higher vigor of grafted plants negatively influenced the concentration of anthocyanins; therefore, pruning of grafted plants to improve the color and phenolics concentration in eggplants peel should be performed during the growing period. For some of the commercial varieties grafted onto tomato rootstock, a decrease of the phenolic content in eggplant pulp was found, compared to self-grafted plants. The effect of grafting eggplant landrace onto tomato rootstock showed an inconsistent trend in the phenolics content of eggplant samples, which indicated that the synthesis of phenolics in landrace fruit is probably dependent also on environmental factors, especially on light conditions. With additional analysis with which a higher presence of reducing antioxidants in eggplant fruits could be confirmed, our results would become more promising and useful, especially when grafted varieties showed better characteristics and as such deserve more attention by rootstock breeders. Further research work should focus on the evaluation of the complete chemical profile of eggplant fruits picked from the different scion/roostock combinations and on the observation of their growth and development. With this knowledge, appropriate criteria for the determination of the physiological maturity stage of fruits can be define in order to get

the eggplant with higher content of substances responsible for flavor, nutritional value, and sensorial characteristics of eggplant fruits.

extract (GSE) could reduce plasma TC, with focus on the interaction of dietary GSE with the gene expressions of hepatic SREBP2, LXR$\alpha$, HMG-CoA-R, LDL-R, and CYP7A1 as well as intestinal NPC1L1, ACAT2, MTP, and ABCG5/8.

## MATERIALS AND METHODS

**Diet.** Three diets were prepared as previously described with minor modifications.[14] The control diet (CTL) was prepared by mixing the following powdered ingredients (g/kg): cornstarch, 507; casein, 242; lard, 50; sucrose, 119; mineral mix, 40; vitamin mix, 20; gelatin, 20; DL-methionine, 1; and cholesterol, 1. Two GSE diets were similarly prepared by adding 0.5% GSE (L-GSE) or 1.0% GSE (H-GSE) into the control diet. All three diets contained 0.1% cholesterol by weight and had 68.2, 26.4, and 5.4% energy from carbohydrate, protein, and fat, respectively. A 0.1% cholesterol diet in this study could induce plasma cholesterol concentration to about 240 mg/dL or 6.2 mM, which is borderline for the diagnosis of human hypercholesterolemia. The rationale for adding 0.5 and 1.0% GSE into diet was that the recommended dose of dietary supplements, for example, phytosterols, is 2−3 g per day to decrease plasma LDL-cholesterol, translating to a dose of 0.8−1.2 g plant sterol esters/1000 kcal provided that humans daily consume about 2500 kcal of energy. In the present study, GSE was added in diets at two doses of 0.5 and 1.0%, which were equivalent to 0.8 and 1.6 g per 1000 kcal for humans, respectively.

**Hamsters.** Thirty male Golden Syrian hamsters (aged 2.5 months) were randomly divided into three groups ($n$ = 10 each) and fed one of the three diets for 6 weeks. Hamsters were housed in an animal room at 23 °C with a 12/12 h light−dark cycle. Food consumption was measured daily, and the fecal outputs from each hamster were collected weekly. Blood samples were collected from the retro-orbital sinus under light anesthesia using a mixture of ketamine, xylazine, and saline (v/v/v; 4:1:5) at weeks 0, 3, and 6 after overnight fasting. At the end of week 6, hamsters were sacrificed under carbon dioxide anesthesia. Organs were removed, washed with saline, weighed, and frozen in liquid nitrogen. The first 5 cm of duodenum was discarded, and the remaining 30 cm of the small intestine was kept. All samples were stored in a −80 °C freezer before analysis. The whole experimental protocol was approved and performed under the guidelines of the Animal Experimental Ethical Committee, The Chinese University of Hong Kong.

**HPLC Analysis of Gingerols and Shogaols.** GSE was obtained from Sabinsa Corp. (Piscataway, NJ, USA). Individual gingerols and shogaols were separated and quantified using an HPLC-ECD system (ESA, Chelmsford, MA, USA), which consists of an ESA model 584 HPLC pump, an ESA model 542 autosampler, an ESA organizer, and an ESA electrochemical detector (ECD) coupled with two ESA model 6210 four sensor cells.[15,16] A Gemini C18 column (150 mm × 4.6 mm, 5 $\mu$m; Phenomenex, Torrance, CA, USA) was used for chromatographic analysis at a flow rate of 1.0 mL/min. The mobile phases consisted of solvent A (30 mM sodium phosphate buffer containing 1.75% acetonitrile and 0.125% tetrahydrofuran, pH 3.35) and solvent B (15 mM sodium phosphate buffer containing 58.5% acetonitrile and 12.5% tetrahydrofuran, pH 3.45). The gradient elution had the following profile: 20% B from 0 to 3 min; 20−55% B from 3 to 11 min; 55−60% B from 11 to 12 min; 60−65% B from 12 to 13 min; 65−100% B from 13 to 40 min; 100% B from 40 to 45 min; and then 20% B from 45.1 to 50 min. The cells were then cleaned at a potential of 1000 mV for 1 min. The injection volume of the sample was 10 $\mu$L. The eluent was monitored by the Coulochem electrode array system (CEAS) with potential settings at −100, 0, 100, 200, 300, 400, and 500 mV. Data for Figure 1 were from the channel set at 300 mV of the CEAS. Individual gingerols and shogaols were identified by comparing the retention times of authentic standards. HPLC analysis found that GSE mainly consisted of 29.4% 6-gingerol, 4.5% 8-gingerol, 5.3% 10-gingerol, 4.3% 6-shogaol, 0.5% 8-shogaol, and 1.8% 10-shogaol (Figure 1).

**Analysis of Plasma Lipids.** Commercial enzymatic kits from Infinity (Waltham, MA, USA.) and Stanbio Laboratories (Boerne, TX, USA) were used to determine the plasma TC, HDL-C, and TG, respectively. Non-HDL-C was calculated by deducting HDL-C from TC.

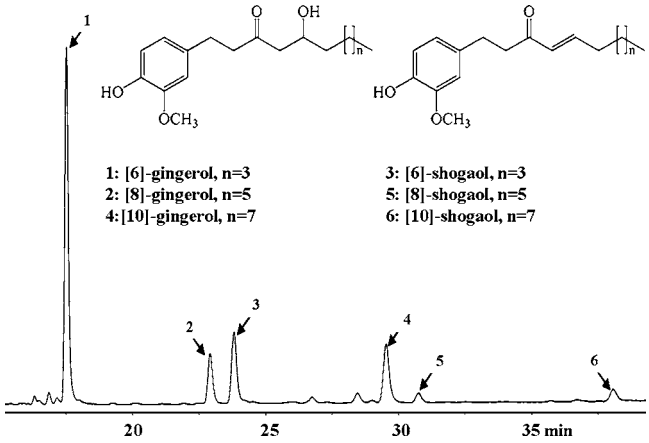

**Figure 1.** HPLC chromatogram of gingerol- and shogaol-enriched ginger extract (GSE). Peaks: 1, 6-gingerol; 2, 8-gingerol; 3, 6-shogaol; 4, 10-gingerol; 5, 8-shogaol; 6, 10-shogaol.

**Analysis of Hepatic Cholesterol.** Total cholesterol in the liver was determined using a gas chromatograph (GC) method as we previously described.[14] In brief, total lipids were extracted from the liver into a solvent mixture of chloroform/methanol (2:1, v/v) with the addition of 5$\alpha$-cholestane (1.0 mg) as an internal standard. The total lipids were saponified, followed by the conversion of cholesterol to its trimethylsilyl ether (TMS) derivative. Cholesterol-TMS derivative was determined using a Shimadzu GC-14B gas chromatograph equipped with a fused silica capillary column (SAC-5, 30 m × 0.25 mm, i.d.; Supelco, Inc., Bellefonte, PA, USA) and a flame ionization detector.

**Analysis of Atherosclerotic Plaque.** The severity of atherosclerosis in the endothelial layer of the aorta was measured as previously described.[17] In brief, aortas were cut open vertically, stained with saturated oil red for 30 min, and washed with 2-propanol three times and then distilled water twice before scanning with a table scanner (Epson 1220 perfection, Epson Co., Tokyo, Japan). The area of atherosclerotic plaque was analyzed by a computer images analyzing program (Sigma Scan Pro 5.0, SPSS, Inc., Chicago, IL, USA).

**Analysis of Hepatic and Fecal Lipids.** In brief, total lipids from 100 mg of liver or 300 mg of feces were extracted with the addition of heptadecanoic acid (0.9 mg) as an internal standard by chloroform/methanol (2:1, v/v). The solvents were evaporated under a gentle stream of nitrogen, and the lipids were then methylated with 14% BF3 in methanol. The resultant total fatty acid methyl esters (FAME) were analyzed on a Shimadzu GC 2010 equipped with a flame ionization detector and a HP Innowax capillary column (30 m × 0.5 $\mu$m, i.d. = 0.32 mm). The temperature was increased from 150 to 200 °C at a rate of 15 °C/min, further increased to 25 °C at a rate of 2 °C/min, and finally kept at 250 °C for 15 min. Injector and detector temperatures were set at 250 and 270 °C, respectively. Helium was used as a carrier gas at a rate of 1.5 mL/min.[18]

**Analysis of Fecal Sterols.** Total fecal outputs from each hamster at weeks 1 and 6 were freeze-dried, ground, and thoroughly mixed before analysis. Both fecal neutral and acidic sterols were measured according to the previous method.[19] In brief, 300 mg fecal samples were weighed with the addition of 5$\alpha$-cholestane (0.5 mg) as an internal standard for neutral sterols and hyodeoxycholic acid (0.3 mg) as an internal standard for acidic sterols. The fecal samples were first saponified, followed by extraction of the total neutral sterols with cyclohexane. The fecal neutral sterols were then converted to their TMS derivatives before GC analysis. Similarly, the acidic sterols in the aqueous phase were extracted, converted to their corresponding TMS derivatives, and subjected to GC analysis.

**Real-Time PCR.** mRNA of intestinal NPC1L1, ACAT2, MTP, and ABCG5/8 and hepatic SREBP2, HMG-CoA-R, LDL-R, LXR$\alpha$, and

USA). Reverse transcription was conducted in a thermocycler (Gene Amp PCR system 9700, Applied Biosystems), and the synthesized cDNA was stored at −20 °C. A fast real-time PCR system 7500 (Applied Biosystems) was used to analyze RT-PCR of small intestinal and hepatic genes. SYBR green was used as a fluorophore for RT-PCR analysis of small intestinal NPC1L1, ACAT2, MTP, ABCG5/8, and cyclophilin, whereas primers and TaqMan probes were used for RT-PCR analysis of liver SREBP2, HMG-CoA-R, LDL-R, LXR$\alpha$, CYP7A1, and GAPDH. Data were analyzed using Sequence Detection software version 1.3.1.21 (Applied Biosystems).

**Western Blotting.** Total liver proteins were extracted and separated on a 7% sodium dodecyl sulfate polyacrylamide gel, followed by transfer to polyvinylidene difluoride membranes according to the previous method with modifications.[14] The membranes were blocked in 3% nonfat milk (dissolved in Tris-buffered saline with Tween-20) for 1 h, followed by incubation overnight at 4 °C in the same solution consisting of anti-SREBP2 antibody (Santa Cruz Biotechnology, Santa Cruz, CA, USA), anti-HMG-CoA-R (Upstate USA, Lake Placid, NY, USA), anti-LDL-R antibody (Santa Cruz Biotechnology), anti-LXR$\alpha$ (Santa Cruz Biotechnology), or anti-CYP7A1 (Santa Cruz Biotechnology). After incubation at 4 °C for another hour in diluted horseradish peroxidase-linked goat anti-rabbit IgG, donkey anti-rabbit IgG, or goat anti-mouse IgG, membranes developed with ECL enhanced chemiluminescence agent were subjected to autoradiography on SuperRX medical X-ray film. Densitometry was analyzed by using Bio-Rad Quantity One (Bio-Rad Laboratories, Hercules, CA, USA), and protein concentrations of SREBP2, HMG-CoA-R, LDL-R, LXR$\alpha$, and CYP7A1 were normalized with $\beta$-actin (Santa Cruz Biotechnology).

**Statistical Analysis.** Values from each measurement were expressed as the mean ± standard deviation (SD), $n = 10$. All data were analyzed using one-way analysis of variance (ANOVA) followed by Fisher's LSD test. A simple linear regression analysis was carried out in SPSS to assess the dose-dependent activity of GSE.

## RESULTS

**Food Intake and Body and Organ Weights.** All three groups had a similar daily food intake of 11−12 g with similar body weight gain during the experimental period. No differences in relative organ weights of heart, kidney, testes, and perirenal fat pad were seen among the three groups (data not shown).

**Plasma TC, TG, HDL-C, and Non-HDL-C, Liver Cholesterol, and Aortic Atherosclerotic Plaque.** Plasma lipoprotein cholesterol was measured at weeks 1, 3, and 6. At week 0, similar levels of plasma TC, TG, HDL-C, and non-HDL-C were observed in the three groups of hamsters (Table 1). In response to the switch from the chow diet to the high-cholesterol diets, plasma TC in all three groups increased at week 3 compared with that in week 0. When the experiment approached the end of week 3, hamsters fed the two GSE diets began to show a marked decline in plasma TC compared with the control group. At the end of week 6, plasma TC concentrations in the control, L-GSE, and H-GSE groups were 259.4, 240.6, and 209.1 mg/dL, respectively, demonstrating that GSE decreased plasma TC in a dose-dependent manner ($P < 0.01$). However, dietary GSE had no effect on plasma TG. Like its effect on plasma TC, dietary GSE could decrease hepatic cholesterol concentration and atherosclerotic plaque (Table 1).

**Hepatic and Fecal Lipids.** Dietary GSE significantly affected the fatty acid profile of liver and fecal lipids (Table 2). To be specific, it decreased total fatty acids in the liver by 15%. This was characterized by a proportional decrease in saturated fatty acids (SFAs), monounsaturated fatty acids (MUFAs), and polyunsaturated fatty acids (PUFAs). In contrast, dietary GSE increased the excretion of fecal total fatty acids by 26−48% in a dose-dependent manner. Similarly, dietary GSE could increase the excretion of all individual fecal fatty acids by 15−83%.

**Fecal Sterols and Apparent Cholesterol Absorption.** Some cholesterol in the liver is metabolized to primary bile acids mainly as cholic and chenodeoxycholic acids and secreted via the bile duct into the intestinal lumen, where they emulsify and help absorb fats or are excreted into the large intestine. In the intestine, cholesterol is converted to it metabolites by microbial bioconversion, with coprostanol and dihydrocholesterol as the main products. Dietary GSE increased the excretion of primary bile acids by 65−200%, whereas it increased the excretion of secondary bile acids (lithocholic and deoxycholic acids) by 20−138%. Dietary GSE at a high dose increased the excretion of fecal cholesterol by 65%. As a whole, dietary GSE could decrease the excretion of total neutral sterols by 38−97% (Table 3). By using the equation described previously,[14] apparent cholesterol absorption (%) = [(cholesterol intake −

total fecal neutral sterols − total fecal acidic sterols) ÷ cholesterol intake] × 100, it was found that dietary GSE could dose-dependently decrease cholesterol absorption (CTL group, 73.20%; L-GSE group, 56.21%; H-GSE group, 33.28%, $p < 0.001$, Table 3).

**Results of Real-Time PCR and Western Blot Analyses.** Real-time PCR results showed that dietary GSE down-regulated mRNA of intestinal NPC1L1, ACAT2, MTP, and ABCG5 in a dose-dependent manner; however, it had no significant effect on mRNA of ABCG8 (Figure 2). We were not able to measure the protein mass of intestinal NPC1L1, ACAT2, MTP, and ABCG5/8 because they are commercially unavailable. With regard to its effect on the target genes in the liver, dietary GSE up-regulated the gene level of hepatic SREBP2; however, it had no effect on the protein mass of SREBP2 (Figures 3 and 4). Similarly, dietary GSE down-regulated the mRNA LXR$\alpha$ with its protein mass being unaffected. In contrast, dietary GSE caused a nearly 2.0-fold increase in not only the mRNA but also the protein level of hepatic CYP7A1 (Figures 3 and 4).

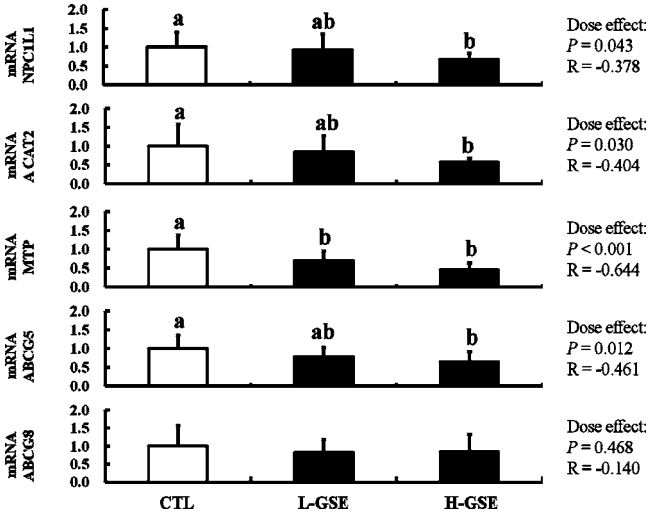

**Figure 2.** Effect of gingerol- and shogaol-enriched ginger extract (GSE) on mRNA levels of intestinal Niemann−Pick C1-like 1 (NPC1L1), acyl coenzyme A:cholesterol acyltransferase 2 (ACAT2), microsomal triacylglycerol transport protein (MTP), and ATP binding cassette transporters (ABCG5 and ABCG8) in hamsters fed the control (CTL) and the two experimental diets containing 0.5% GSE (L-GSE) and 1.0% GSE (H-GSE). *R* is the coefficient of correlation for the regression analysis on the dose-dependent effect of GSE on target sterols. Bars with different letters differ significantly, $p < 0.05$.

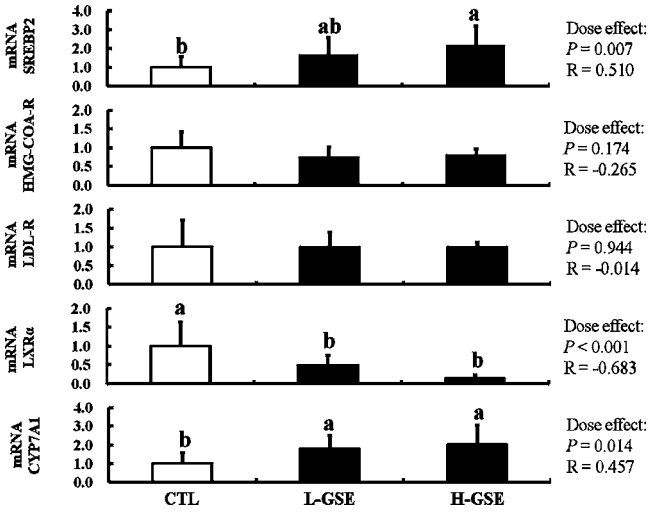

**Figure 3.** Effect of gingerol- and shogaol-enriched ginger extract (GSE) on mRNA levels of hepatic sterol regulatory element-binding protein 2 (SREBP2), 3-hydroxy-3-methylglutaryl-CoA reductase (HMG-CoA-R), LDL receptor (LDL-R), liver X receptor-alpha (LXR$\alpha$), and cholesterol-7$\alpha$-hydroxylase (CYP7A1) in hamsters fed the control (CTL) and the two experimental diets containing 0.5% GSE (L-GSE) and 1.0% GSE (H-GSE). *R* is the coefficient of correlation for the regression analysis on the dose-dependent effect of GSE on target sterols. Bars with different letters differ significantly, $p < 0.05$.

## DISCUSSION

The present study examined the hypocholesterolemic activity of dietary GSE and the underlying mechanism using hamsters as an animal model. In general, results regarding the effect of GSE on plasma TC were consistent with published data in rats,[6] mice,[10] rabbits,[8,9] and broilers.[20] The major observations in the present study were that dietary GSE could reduce plasma TC by 6−18%, atherosclerotic plaque by 57%, hepatic cholesterol by 20%, and total liver lipids by 15%, confirming dietary GSE was effective in treating not only hypercholesterolemia but also non-alcohol-induced fatty liver disease.[21] The present study was the first to systematically investigate the underlying mechanisms by which dietary GSE reduced plasma TC concentration.

Two possible mechanisms associated with the cholesterol-lowering activity of dietary GSE were explored. The first mechanism was that that dietary GSE reduced plasma TC by increasing the excretion of fecal neutral sterols via inhibiting cholesterol absorption with the following supportive evidence. First, fecal sterol analysis found that dietary GSE increased the excretion of fecal cholesterol by 65% and total fecal neutral sterols by 38−97%. Second, real-time PCR analysis affirmed that dietary GSE down-regulated the gene expression of transporters and enzymes involved in cholesterol absorption. Intestinal NPC1L1 is a sterol transporter responsible for taking the cholesterol from the intestinal lumen to enterocytes, whereas ACAT2 in the enterocytes catalyzes an essential reaction that esterifies free cholesterol to cholesteryl ester (CE) before it can be packed into chylomicrons. At the final step of cholesterol absorption, MTP assembles CE into chylomicrons, which are transported into the blood vial the lymph system. ABCG5/8 are also sterol transporters that shuttle the unabsorbed cholesterol in the enterocytes back to the intestinal lumen for excretion. The present study clearly demonstrated that dietary GSE could down-regulate the mRNA of intestinal NPC1L1, ACAT2, MTP, and ABCG5 (Figure 2). At a molecular level, dietary GSE favorably modulated the plasma lipoprotein profile, largely mediated by increasing cholesterol excretion via down-regulation of the target proteins involved in cholesterol absorption.

Excessive cholesterol in the liver is eliminated by converting cholesterol to bile acids. The second mechanism underlying GSE's cholesterol-lowering activity was that it could modulate the cholesterol homeostasis in a way enhancing the bile acid synthesis. This mechanism was supported by the observation that dietary GSE significantly enhanced the excretion of bile acids, leading to 63−147% increases in the excretion of fecal total acidic sterols (Table 3). This was accompanied by up-regulation of hepatic CYP7A1, a key enzyme in bile acid

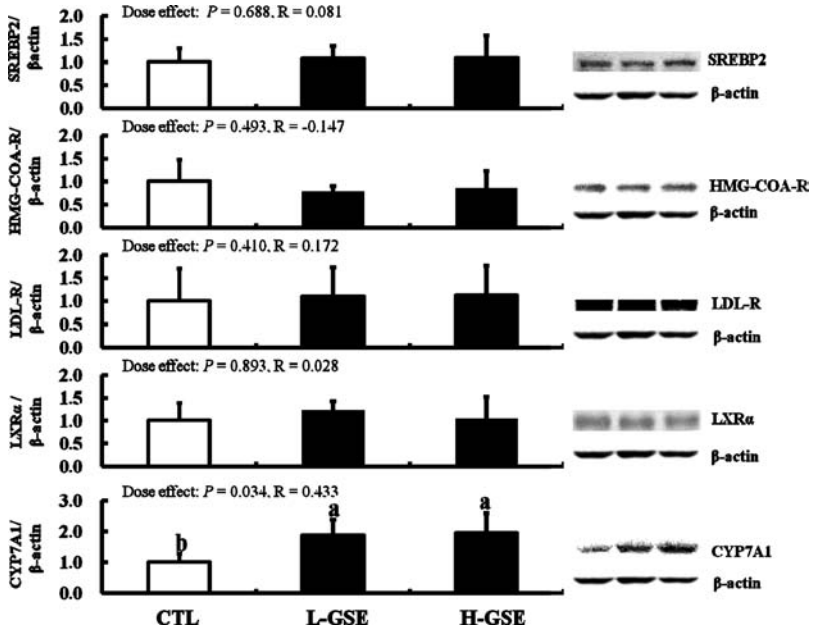

**Figure 4.** Effect of gingerol- and shogaol-enriched ginger extract (GSE) on protein mass of hepatic sterol regulatory element-binding protein 2 (SREBP2), 3-hydroxy-3-methylglutaryl-CoA reductase (HMG-CoA-R), LDL receptor (LDL-R), liver X receptor-alpha (LXR$\alpha$), and cholesterol-7$\alpha$-hydroxylase (CYP7A1) in hamsters fed the control (CTL) and the two experimental diets containing 0.5% GSE (L-GSE) and 1.0% GSE (H-GSE). *R* is the coefficient of correlation for the regression analysis on the dose-dependent effect of GSE on target sterols. Bars with different letters differ significantly, $p < 0.05$.

synthesis in the liver, and down-regulation of hepatic LXR$\alpha$, a cholesterol sensor in the liver (Figures 3 and 4). When CYP7A1 was up-regulated, cholesterol in the liver was subsequently converted to bile acids, leading to a reduction of cholesterol concentration in the liver and consequently a reduction in plasma TC. In fact, the present study found that dietary GSE was able to decrease hepatic cholesterol by 20% and plasma TC by 19%. As a cholesterol sensor in the liver, down-regulation of mRNA LXR$\alpha$ was expected (Figure 3). The present study clearly demonstrated the cholesterol-lowering activity of dietary GSE was mediated not only by inhibition on cholesterol absorption but also by enhancing the production of bile acids in the liver and their excretion in the intestine. HMG-CoA-R is a regulating enzyme in cholesterol synthesis in the liver, whereas LDL-R is responsible for the removal of plasma LDL cholesterol from circulation into the liver. Although dietary GSE could up-regulate mRNA of SREBP2, it had no effect on mRNA and protein mass of hepatic HMG-CoA-R and LDL-R, suggesting that plasma TC-lowering activity of GSE was unlikely mediated by modulating cholesterol removal and synthesis.

In summary, we systematically studied the effect of dietary GSE on plasma TC and gene expression of intestinal NPC1L1, ACAT2, MTP, and ABCG5/8 as well as hepatic SREBP2, HMG-CoA-R, LDL-R, LXR$\alpha$, and CYP7A1 in hamsters fed a high-cholesterol diet. It was clear that GSE could decrease plasma TC concentration via the combination of two mechanisms, inhibition of cholesterol absorption and enhancement of bile acid excretion, leading to substantial reductions in the apparent cholesterol absorption from 73.20% in the control to 56.21 and 33.28% in the L-GSE and H-GSSE groups, respectively. This was accompanied by up-regulation of hepatic CYP7A1 and down-regulation on the genes of intestinal NPC1L1, ACAT2, and MTP.

## MATERIALS AND METHODS

**Plant Materials.** Five 5-year-old Chinese bayberry (*Myrica rubra* Sieb. and Zucc.) trees were chosen for these experiments from commercial orchards in Zhejiang Province, China. Two types of varieties, 'Biqi' (BQ) and 'Dongkui' (DK), were obtained from the Cixi (30°12′N, 121°24′ E) and Xianju (28°85′N, 120°61′E), respectively. Fruit were collected at five developmental stages from 57 to 113 days after flower bloom (DAFB) with an interval of 14 days from May 1 to July 31 in 2013. At each stage, 10 fruit on each branch and 2 fruiting branches from each bayberry trees were selected. All of the samples were healthy and uniformly distributed around the tree. There were 10 fruit on each tree used to measure fruit diameter during different developmental stages (see Supporting Information S1). After transportation to laboratory in 2 h, 20 fruit from each variety were selected for color measurement. All samples were immediately frozen in liquid nitrogen, and then stored at −81 °C until use.

**Total Anthocyanin Content Determination.** To prepare the fruit extract, 1 g samples from each replicate were homogenized with 5 mL of precooled acidified water (3% formic acid), and after centrifugation at 10 000*g* for 15 min (4 °C), another 5 mL of precooled acidified water was used to extract the residue again. The supernatant was combined to make the final volume of 25 mL for analysis. Total anthocyanin content of bayberry extract was measured using the pH differential method.[9] Absorbance was measured at 510 and 700 nm, respectively, in different buffers at pH 1.0 and 4.5, using $A = [(A510 - A700)\ \mathrm{pH1.0} - (A510 - A700)\ \mathrm{pH4.5}]$ with a molar extinction coefficient of cyanidin 3-glucoside (Cy-3-Glu) of 29 600. Results were expressed as milligrams of Cy-3-Glu equivalents per gram of fresh weight. All analysis was repeated three times using three biological replicates

**Sugars Extraction and HPLC Determination.** The extraction of sugars from bayberries was modified from a method described by Eyéghé-Bickong et al.[10] Briefly, 80 mg of frozen homogenized bayberry tissue from each replicate was weighed off into 800 μL of $dH_2O$ containing 5% (w/v) insoluble PVPP and vortexed for 5 min to homogenize. An equal volume of chloroform was added to the mixture, and the biphasic solvent was vortexed for 5 min to mix and incubated at 50 °C for 30 min with continuous shaking. After incubation, the microfuge tube was centrifuged at 12 000*g* for 10 min at room temperature to recover the upper aqueous phase containing the sugars. The supernatant was passed through a 0.22 μm membrane filter (Millipore Corp., Bedford, MA) for HPLC analysis. All analysis was repeated three times using three biological replicates

Chromatographic analysis of sugars was carried out on a Waters 2695-series HPLC system (Waters Corp., Milford, MA) equipped with a refractive index detector and Empower 3 software. A COSMOSIL Sugar-D column (4.6 mm i.d. × 250 mm) and COSMOSIL Sugar-D guard column (4.6 mm i.d. × 10 mm) both from NacalaiTesque Inc. (Kyoto, Japan) were used. The mobile phase was HPLC grade acetonitrile/water (65:35, v/v) with a flow rate of 1.0 mL/min at 35 °C, and sample volume injected was 20 μL. A refractive index detector maintained at 35 °C was used for detection purposes. The column was equilibrated for 10 min at the starting conditions before each injection. The sugars were identified on the basis of comparison of their retention times with those of pure standards and quantified using standard calibration curves.

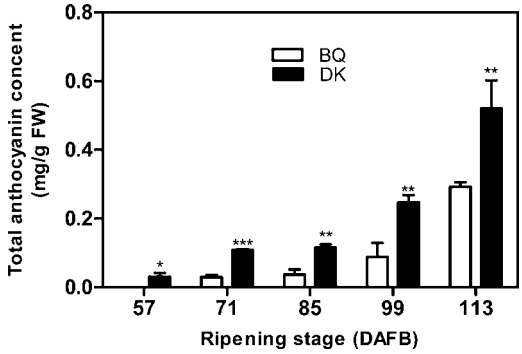

**Figure 1.** Changes of total anthocyanin content in Chinese bayberries during fruit development. Values are the means ±SE. Vertical bars represent the standard errors of the means. Asterisks indicate significant differences between 'Dongkui' and 'Biqi' samples (Duncan's multiple range test; $^*P < 0.05$, $^{**}P < 0.01$, and $^{***}P < 0.001$).

**Total RNA Extraction and cDNA Synthesis.** Total RNA was isolated using a Plant Total RNA Extraction Kit (Genotheramics, Suzhou, China) according to the manufacturer's instructions. Extracted RNA was purified with amplification grade RNase-free DNase I (Omega, Norcross, GA) to remove any DNA contamination prior to cDNA synthesis. Reverse transcription (RT) was carried out using 2 μg of total RNA and the SuperRT First Strand cDNA Synthesis Kit (CWBIO, Beijing, China), following the manufacturer's instructions.

**Quantitative Real-Time PCR (qPCR).** qRT-PCR was conducted using a total volume of 12.5 μL reaction containing 0.5 μL of the synthesized cDNA, 0.25 μL of 10 μM each forward and reverse primers, 6.5 μL of the SYBR Green PCR Master Mix (Thermo Scientific, Pittsburgh, PA), and 5 μL of RNase-free water. Amplifications were performed using Mx3000P qRT-PCR System (Agilent Stratagene, Santa Clara, CA). The amplification program consisted of an initial denaturation step of 95 °C for 7 min, followed by 40 cycles of 15 s at 95 °C, and combined with each primer specific annealing temperature ranged from 50 to 60 °C for 30 s. Melting curve analysis was performed at the end of 40 cycles to ensure proper amplification of target fragments. *MrACT* (GenBank accession no. GQ340770) was used to

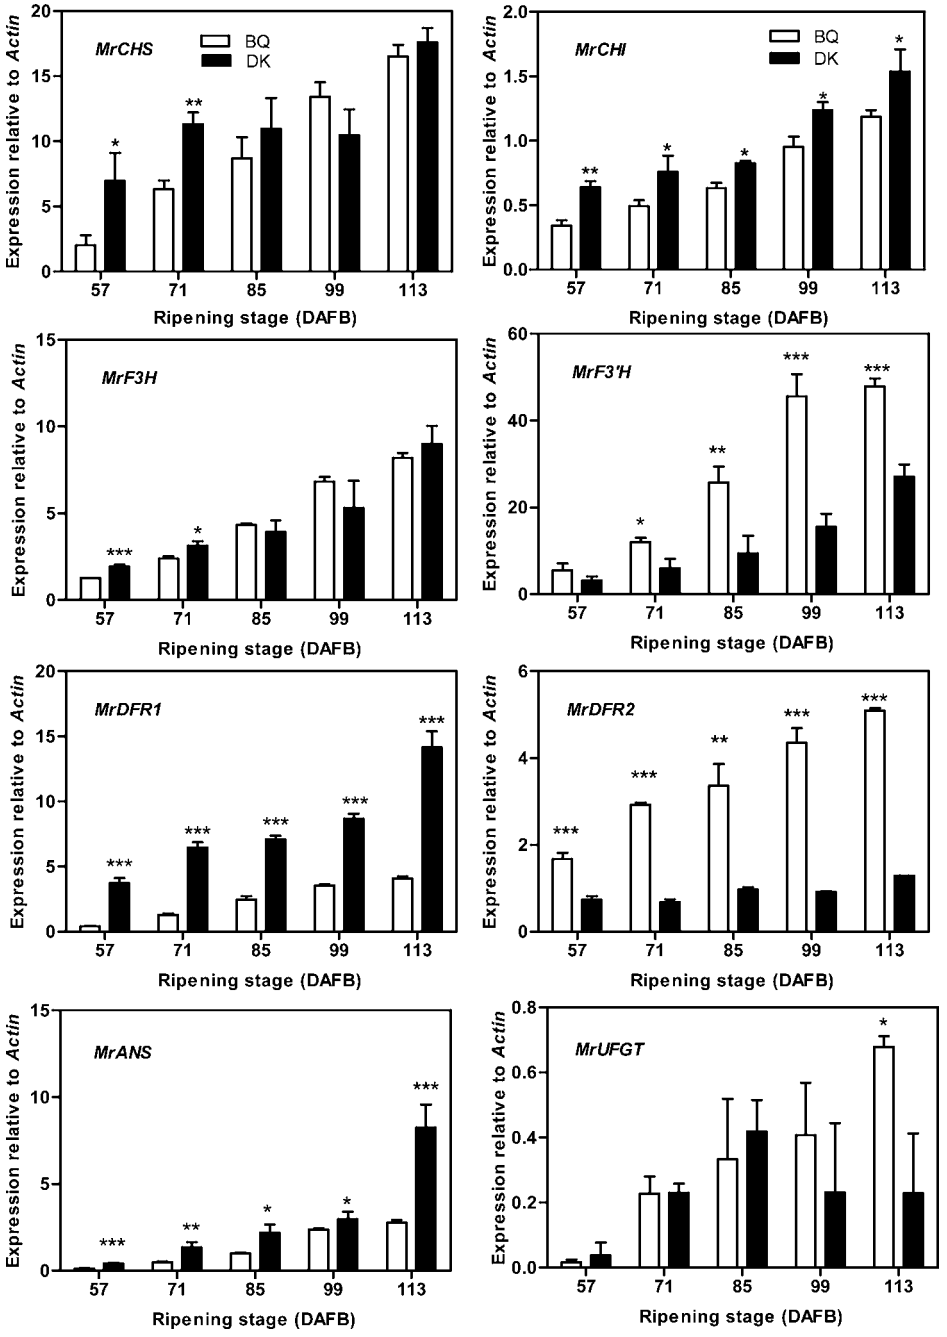

**Figure 2.** Expression of anthocyanin biosynthetic genes in Chinese bayberries during fruit development. Values are the means ±SE. Vertical bars represent the standard errors of the means. Asterisks indicate significant differences between 'Dongkui' and 'Biqi' samples (Duncan's multiple range test; $*P < 0.05$, $**$ $P < 0.01$, and $***P < 0.001$).

normalize as endogenous reference, and transcripts were quantified using the standard curve method. All analysis was repeated three times using three biological replicates, and primer sequences used for real time PCR are listed in Table 1.

**Statistical Analysis.** All values are shown as the mean ±SE. Statistical analysis was performed using the SPSS package program version 16.0 (SPSS Inc., Chicago, IL). Student's unpaired *t* test was used to compare the means at $P < 0.05$.

## RESULTS

**Changes of Total Anthocyanin Content During Fruit Development.** The total anthocyanin content in 'DK' and 'BQ' bayberries increased continuously during fruit development (Figure 1). Generally, 'DK' fruit had higher levels of anthocyanins than 'BQ' fruit, and the content in 'DK' fruit was nearly 2 times that in 'BQ' fruit at 113 DAFB. No anthocyanin was detected in 'BQ' fruit at 57 DAFB.

**Expression of Anthocyanin Biosynthetic Genes During Fruit Development.** As shown in Figure 2, transcript levels of biosynthetic genes *MrCHS*, *MrCHI*, *MrF3H*, *MrF3′H*, *MrDFR1*, and *MrANS* increased throughout fruit development in both bayberry cultivars. Expression of *MrDFR2* and *MrUFGT* in 'DK' fruit showed a gradual increase with ripening, but no significant change was observed in *MrDFR2* transcript level in 'BQ' fruit. Transcript abundance of *MrUFGT* in 'BQ' fruit increased with fruit development from 57 to 85 DAFB and then declined toward to maturity. As compared to 'BQ' fruit, 'DK' fruit experienced

dx.doi.org/10.1021/jf503317k | J. Agric. Food Chem. 2014, 62, 10522−10528

higher expression of *MrCHI*, *MrDFR1*, and *MrANS*, whereas the transcript levels of *MrF3′H* and *MrDFR2* were significantly lower during fruit development. Higher expression levels of *MrCHS* and *MrF3H* were found in 'DK' fruit from 57 to 71 DAFB, but there was no significant difference between the two cultivars from 85 to 113 DAFB. Meanwhile, a significant higher *MrUFGT* was observed in 'DK' fruit at the end of fruit development.

**Expression of *MrMYB1* During Fruit Development.** Transcript abundance of *MrMYB1* increased gradually during bayberry fruit development. Expression of *MrMYB1* was higher in 'DK' fruit than that in 'BQ' fruit (Figure 3).

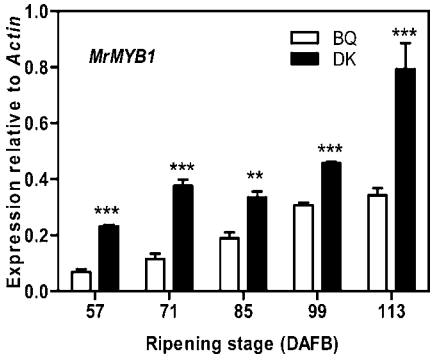

**Figure 3.** Expression of *MrMYB1* in Chinese bayberries during fruit development. Values are the means ±SE. Vertical bars represent the standard errors of the means. Asterisks indicate significant differences between 'Dongkui' and 'Biqi' samples (Duncan's multiple range test; $*P < 0.05$, $** P < 0.01$, and $***P < 0.001$).

**Changes of Glucose, Fructose, and Sucrose During Fruit Development.** The changes of glucose, fructose, and sucrose differed from the two bayberry cultivars (Figure 4). In 'DK' fruit, levels of glucose and fructose accumulated at early development stage and showed the first peak at 71 DAFB, followed by the second peak at 99 DAFB (Figure 4A,B), whereas sucrose content increased with fruit development from 57 to 99 DAFB, and then decreased slightly toward maturity (Figure 4C). However, all of the three soluble sugars in 'BQ' fruit accumulated throughout fruit development. Significantly higher levels of glucose, fructose, and sucrose were observed in 'DK' fruit compared with that in 'BQ' fruit (Figure 4).

**Expression of Sucrose Phosphate Synthase and Sucrose Invertase Genes During Fruit Development.** Both of the bayberry cultivars experienced a similar expression patterns in SPS genes during fruit ripening (Figure 5). No significant change in expression level was observed for *MrSPS1*, whereas the transcript abundance of *MrSPS2* showed a slight increase during fruit development. The transcript level of *MrSPS3* increased with fruit development from 57 to 85 DAFB and then decreased slightly toward maturity. A significantly higher expression level of these three SPS genes was observed in 'DK' fruit than 'BQ' during fruit development.

Three INV genes, *MrINV1*, *MrINV2*, and *MrINV3*, showed similar expression patterns in 'DK' fruit (Figure 5). Transcript levels of these three INV genes decreased with fruit development from 57 to 71 DAFB, and then increased gradually from 71 to 99 DAFB followed by a decline toward maturity. In 'BQ' fruit, the expression levels of *MrINV2* and *MrINV3* were detected only at an early stage of fruit development from 57 to 71 DAFB. Moreover, no expression of *MrINV1* was detected in this cultivar. 'DK' fruit showed remarkably higher expression of these

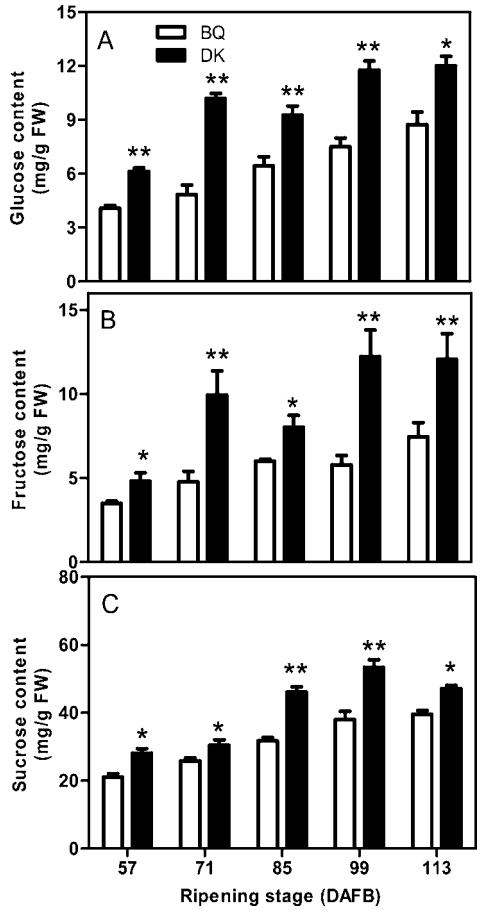

**Figure 4.** Changes of glucose (A), fructose (B), and sucrose (C) in Chinese bayberries during fruit development. Values are the means ±SE. Vertical bars represent the standard errors of the means. Asterisks indicate significant differences between 'Dongkui' and 'Biqi' samples (Duncan's multiple range test; $*P < 0.05$, $** P < 0.01$, and $***P < 0.001$).

three INV genes compared to 'BQ' fruit throughout the fruit development.

**Correlation between Total Anthocyanins and Levels of Glucose, Fructose, and Sucrose.** A common positive linear correlation was observed between anthocyanin and soluble sugars such as glucose, fructose, and sucrose in Chinese bayberry fruit. The corresponding correlation coefficients were 0.79, 0.79, and 0.72, respectively (Figure 6). From this linear function, threshold values of glucose, fructose, and sucrose (3.64, 2.74, and 18.5 mg/g FW, respectively), above which bayberries were stimulated to accumulate anthocyanins, could be obtained.

## DISCUSSION

In Chinese bayberry fruit, changes in the levels of anthocyanin accumulation have been well-known to occur during fruit ripening.[8,11] The results of our study indicated a progressive increase of anthocyanin accumulation as the bayberry fruit developed which was in agreement with the previous report.[12] However, fruit pigmentation differed significantly between the two tested cultivars. The maturation led to a more favorable red color in 'DK' fruit, in which higher anthocyanin content was observed compared to that in 'BQ' fruit. However, according to Niu et al.,[8] 'DK' fruit was red whereas 'BQ' was dark red-purple which was due to a higher content of anthocyanins than 'DK'. In our study, we observed that 'BQ' presented a 2-fold reduction

dx.doi.org/10.1021/jf503317k | J. Agric. Food Chem. 2014, 62, 10522−10528

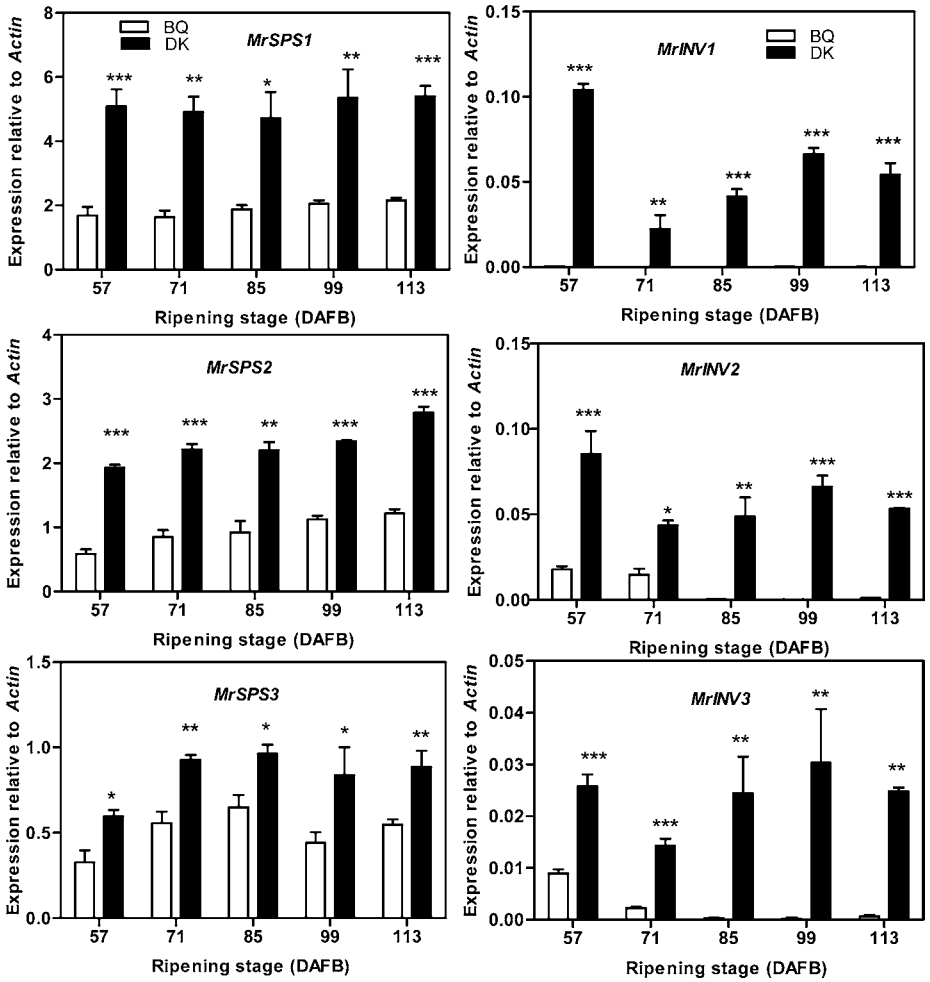

**Figure 5.** Expression of sucrose phosphate synthase and sucrose invertase genes in Chinese bayberries during fruit development. Values are the means ±SE. Vertical bars represent the standard errors of the means. Asterisks indicate significant differences between 'Dongkui' and 'Biqi' samples (Duncan's multiple range test; $^{*}P < 0.05$, $^{**}P < 0.01$, and $^{***}P < 0.001$).

in anthocyanins when compared to 'DK'. The difference in terms of anthocyanins in the two varieties between the published paper and our studies was associated with the temperature difference in the two different places where the fruit was picked (see Supporting Information S2).

Expression of flavonoid genes has been shown to be correlated with anthocyanin accumulation during fruit development in apple, grape, pear, and Chinese bayberry.[8,11,13,14] Therefore, the transcription of genes in the anthocyanin biosynthesis pathway was investigated by qPCR in present study. All of the biosynthetic genes studied were expressed in all the samples from the two cultivars taken at the different developmental stages. Expression of these genes in bayberry fruit increased during ripening, regardless of the cultivars. In particular, the higher transcript levels of *MrCHI*, *MrDFR1*, and *MrANS* in 'DK' fruit was in parallel to its higher anthocyanin concentration during fruit development. These data suggested that these three genes might be the key regulatory genes in the process of anthocyanin biosynthesis in Chinese bayberries. However, inconsistent with its anthocyanin content, 'BQ' fruit also exhibited higher expression of *MrF3′H* and *MrDFR2* at each fruit development stage in comparison with 'DK' fruit. In grapes, Boss et al.[13] reported that samples without anthocyanins expressed all major anthocyanin biosynthesis genes except *UFGT*, and they suggested that these genes were associated with the other biosynthesis pathways, notably those involved in the biosynthesis of aurones, flavones, flavonols, iosflavonoids, and proanthocyanindins. These specific expression patterns of *MrF3′H* and *MrDFR2* in Chinese bayberries were likely related to these other pathways, because phenolic compounds such as catechin and epicatechin, present in bayberries, are synthesized by proanthocyanindin biosynthesis pathway. *MrMYB1* is a known activator of the bayberry anthocyanin pathway.[8] In accord with anthocyanin content, 'DK' fruit was associated with higher *MrMYB1* transcription than 'BQ'. Overall, anthocyanin and transcript quantifications in Chinese bayberry fruit performed in this study suggested a possible mechanism controlling pigment patterns in bayberry fruit. We have found that less red-colored fruit 'BQ' were related to lower anthocyanin accumulation, which was explained by reduced transcript levels of several antho cyanin pathway genes evaluated, including the structural genes in the pathway, and *MrMYB1*, a transcription factor which regulates them.

Sugar is a common regulator for the expression of genes encoding metabolic enzymes and proteins involved in photosynthesis, carbohydrate metabolism, pathogenesis,[15] and anthocyanin biosynthesis.[16,17] Glucose and fructose are primarily derived from the hydrolysis of the imported sucrose via invertase. Our data clearly suggested that the metabolism of sugars in bayberries varied from different cultivars and development stages.

dx.doi.org/10.1021/jf503317k | J. Agric. Food Chem. 2014, 62, 10522−10528

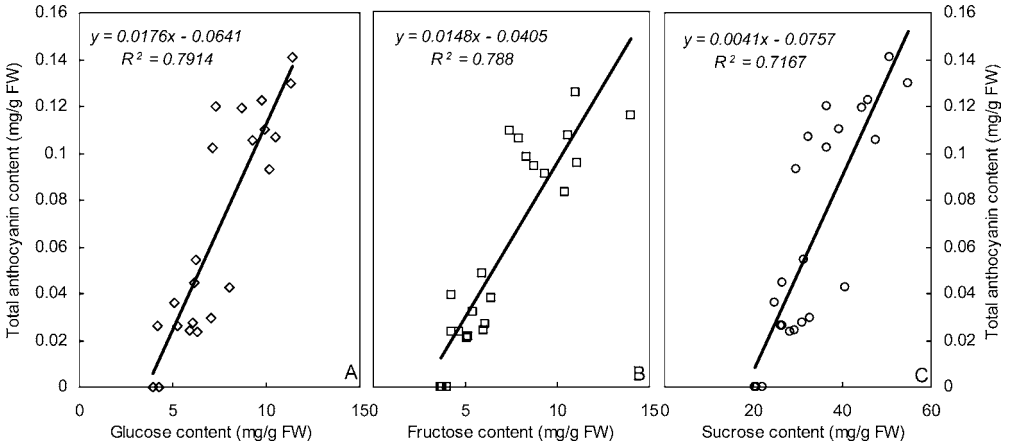

**Figure 6.** Correlation between total anthocyanins and levels of glucose (A), fructose (B), and sucrose (C) in both cultivars.

'DK' fruit experienced significantly higher expression of INV genes than 'BQ', indicating more glucose and fructose were produced and available for accumulation. However, it must be pointed that, being different from 'BQ', contents of glucose and fructose in 'DK' showed two peaks in relation to the expression pattern of INV genes. At the early stage of fruit development (57 DAFB), relatively higher expression of INV genes found in this study matched the first peak of glucose and fructose accumulation at 71 DAFB. Subsequently, the increased expression of these three INV genes from 71 to 99 DAFB indicated that the generation of glucose and fructose increased toward maturity. There are two sources of sucrose for accumulation: the imported sucrose that has not been metabolized and newly synthesized sucrose. In our present study, sucrose content in bayberries accumulated during fruit ripening regardless of the cultivars. However, the high transcript levels of SPS genes and very low expression of INV genes suggested that newly synthesized sucrose via SPS contributed significantly to the total sucrose level. The higher expression levels of SPS genes in 'DK' fruit toward maturity were consistent with faster accumulation of sucrose during this period. Therefore, taking into account all the expression studies involved in sugar metabolism, sucrose accumulation in bayberry fruit during ripening is of SPS type according to the categorization of mechanisms controlling sugar accumulation in fruit by Yamaki,[18] as in strawberry, apple, and melon.[19−21] A direct correlation between sucrose accumulation and SPS transcript levels has also been demonstrated in banana, melon, and apple fruit.[20−22]

Many studies have revealed the stimulatory effects of sugars on anthocyanin accumulation in a variety of plant species, of which sugars seem to not only be general carbohydrate sources, but also act as signal molecule to activate/repress the reactions.[2,17] For example, in flowers, sugar levels increase during petal development. Corollas cultured *in vitro* without sucrose do not elongate or show color.[2] Anthocyanin accumulation in grape berries commenced at veraison and sugar accumulating began, and continued throughout berry ripening,[4] which can be promoted by sucrose in grape cell suspensions and intact detached grape.[23,24] Similarly, sugars enhanced anthocyanin biosynthesis in radish hypocotyls.[5] In our experiment, during bayberry development, anthocyanin accumulation was consistent with the levels of glucose, fructose, and sucrose. Also, the correlation analysis revealed a significant relationship between levels of anthocyanin and sugars. A few studies demonstrated that this regulation is mediated by the expression of genes involved in anthocyanin synthesis.[6,25,26] In an *Arabidopsis* mutant impaired in phloem unloading and thereby having an accumulation of high sugar levels, anthocyanin accumulated in the leaves as a result of sucrose-induced expression of anthocyanin biosynthesis-related genes.[25] In sliced grape berries, sucrose up-regulated *VvF3H* expression, coinciding with enhanced anthocyanin levels.[6] In our study, increased expression of anthocyanin biosynthetic and regulatory genes has been observed with the accumulation of glucose, fructose, and sucrose during bayberry ripening regardless of the cultivars. In addition, the transcripts of *MrF3H*, *MrANS*, and *MrMYB1* in 'DK' fruit were dramatically higher than that in 'BQ', which was in compliance with the higher sugar levels. These results suggested that the accumulated sugars in Chinese bayberry fruit may play an important role in inducing expression of anthocyanin biosynthetic and regulatory genes, which was largely responsible for the pigmentation in bayberries.

In conclusion, we demonstrated a close correlation between the production of anthocyanins and the amount of sugars such as glucose, fructose, and sucrose during fruit ripening in Chinese bayberry fruit. The data presented confirm a specific role of high sugar levels in the promotion of the synthesis of specific secondary metabolites. However, the direct evidence that sugars enhance anthocyanin accumulation is still unknown because the study of the effects of sugars on bayberries still attached to intact plants is very challenging due to the large size of plant, interplant, intercluster, and interberry variability. Recently, an *in vitro* culture system that enabled long-term culture covering the whole ripening processes was developed in grapes in order to reveal the synthesis of anthocyanin in response to sugar levels.[23] A similar model system that enables easy modulation of the sugar status in Chinese bayberry fruit is therefore desirable to decipher the biochemical and molecular mechanisms of this regulation, which needs further investigation.

working volume of 3 L of the production liquid medium including (g/L) 80.0 g of sucrose, 6.0 g of $K_2HPO_4$, 0.9 g of yeast extract, 0.5 g of $MgSO_4$, 4.0 g of NaCl, and different concentrations of $(NH_4)_2SO_4$. The fermentor loaded with 3 L of the production culture medium was autoclaved at 121 °C for 15 min. A total of 150 mL of the seed culture medium was transferred to the production culture medium. The pullulan fermentation was performed at 28 °C and 300 rpm with an aeration rate of 3 L/min. The pH was maintained at 6.5 by the addition of either 2 M NaOH or 2 M HCl.

**Determination of Pullulan Production and Biomass.** Properly distilled water was added to the fermentation liquor to dilute. The broth was heated at 80 °C in a water bath for 30 min and then centrifuged at 10000*g* for 20 min to separate the biomass and insoluble debris. Two volumes of precooling 95% (v/v) ethanol was added to the supernatant and stirred and placed at 4 °C for 24 h to deposit the exopolysaccharide thoroughly. The sediment was isolated by centrifugation at 15000*g* for 20 min, washed with ethanol again, and dried at 80 °C until the weight was constant. The biomass sediment from the initial centrifugation was washed three times with distilled water by centrifugation at 10000*g* for 5 min and dried at 80 °C until the dry cell weight (DCW) was constant. Pullulan production and DCW were expressed as grams per liter.

**$(NH_4)_2SO_4$ Concentration.** For residual $(NH_4)_2SO_4$ concentration determination, a revised indophenol method was used.[13] The fermentation liquor (2 mL) was centrifuged at 4000*g* to separate microorganisms and other precipitates. Hundred-fold distilled water was added to the supernatant to dilute and then adjusted to pH 7.0. Next, 25 mL of sample was mixed with 10 mL of phenol nitroprusside buffer. To this mixture was added 15 mL of hypochlorite reagent, and the mixture was held at room temperature for 45 min for color development. The absorbance of the solution was measured at 290 nm.

**Protein Preparation for 2-DE.** Cells were harvested by centrifugation at 15000*g* for 20 min at 4 °C and washed three times with ultrapure water by centrifugation at 10000*g* for 5 min. Cells were ground in liquid nitrogen after freeze-drying. The fine powder was suspended in acetone including 0.07% (w/v) dithiothreitol (DTT) and 10% (w/v) trichloroacetic acid (TCA) and incubated at −20 °C overnight. The suspension was centrifuged at 15000*g* for 15 min at 4 °C, and the sediment was washed three times with precooling acetone including 0.07% (w/v) DTT. The sediment was dried and redissolved in rehydration solution [7 M urea, 2 M thiourea, 2% (w/v) CHAPS, 1.8 mM DTT, 0.5% (w/v) Pharmalyte 3−10] and then centrifuged at 15000*g* for 20 min at 4 °C. The limpid supernatant including the soluble proteins was stored in aliquots at −80 °C. The method of Bradford was used to determine protein concentration with bull serum albumin as standard.[14]

**2-DE.** The protein extracts (250 μg/gel) were loaded for 2-DE as follows. The 24 cm strips (Immobiline Drystrip) covering a nonlinear pH 3−11 (GE Healthcare) were rehydrated in 450 μL of rehydration solution for 16 h at room temperature. Isoelectric focusing was operated by the Ettan IPGphor (GE Healthcare) with a ceramic tray manifold at 20 °C. Each strip was limited to a maximum current of 50 μA. The isoelectric focusing electrophoresis program followed the protocol rehydration at 50 V for 12 h (step), 500 V for 1 h (step), 1000 V for 1 h (step), 10000 V for 1 h (gradient), and 11000 V for 10 h (step).

The strip is taken from the strip holder. The redundant oil and protein solutions were absorbed by filter paper. The IPG gel strips were respectively incubated in an equilibration solution [50 mM Tris-HCl, pH 8.8, 6 M urea, 30% (v/v) glycerol, 2% (w/v) SDS, and 0.002% bromophenol blue] with 1% DTT and 2.5% iodoacetamide for 15 min. Then the equilibrated gel strips were put on a 1.5 mm 12.5% polyacrylamide gel and sealed with agarose sealing solution [25 mM Tris-base, 192 mM glycine, 0.1% (w/v) SDS, 0.5% agarose, and 0.002% (w/v) bromophenol blue]. The second-dimensional separation was performed by the ETTAN DALTsix (GE Healthcare) in a cold chamber at 15 °C. SDS-PAGE was operated at a constant voltage of 100 V for 45 min and at 200 V for 6−8 h until the bromophenol blue arrived at the bottom of the gel. After SDS-PAGE, the separated proteins were visualized by silver staining as previously described.[15]

**Image Analysis.** Silver-stained gels were scanned using an Image Scanner (Amersham Biosciences). Date analysis was carried out utilizing Image Master 2D Platinum 5.0 software (Amersham Biosciences). For each treatment, three gels from three independent treatments were studied. Gel spots were automatically tested and manually edited and deleted when necessary. Evidently spots were marked by calibrating and matching the gel. Next, the three replicate gels were compared to each other and merged into a master gel, containing the spots distributed on the three gels for every independent experiment. To quantify and contradistinguish the protein spots, standardization of the volume ratio was performed. The significantly changed spots were chosen with at lowest a 0.2-fold decrease and a 5.0-fold increase in the normalized volume ratio.

**In-Gel Digestion.** The differentially expressed protein spots were excised for digestion. The gel spot was washed and the destained solution removed. Fifty percent acetonitrile (ACN) and 100% ACN were successively added for 5 min. The samples were rehydrated in 2−4 μL of mass spectroscopy grade gold trypsin (Promega, Madison, WI, USA) solution (20 μg/mL in 25 mM $NH_4HCO_3$) for 30 min. Then, 20 μL of cover solution (25 mM $NH_4HCO_3$, 10% ACN) was added for digestion for 16 h at 37 °C. The supernatant was shifted to another tube, and the gel was extracted with 50 μL of extraction buffer [67% ACN and 5% trifluoroacetic acid (TFA)]. The supernatant of the gel spot and the peptide extracts were combined and freeze-dried for mass spectrometry.

**Mass Spectrometry Analysis.** The freeze-dried power was suspended with 5 μL of 0.1% TFA and then mixed with a saturated solution of α-cyano-4-hydroxy-*trans*-cinnamic acid in 50% ACN and 0.1% TFA, at the ratio of 1:1. One microliter of the mixture was spotted on a stainless steel sample target board. Peptide MS and MS/MS were performed on an ABI 5800 MALDI-TOF/TOF Plus mass spectrometer (Applied Biosystems, Foster City, CA, USA). Data were obtained in a positive MS reflector using a CalMix5 standard to adjust the instrument (ABI5800 Calibration Mixture). The integrated MS and MS/MS data were disposed by the GPS Explorer V3.6 software (Applied Biosystems, USA) with default parameters. On the basis of the combination of MS and MS/MS spectra, proteins were successfully identified in the standard of 95% or higher confidence interval of their scores in the Mascot V2.3 search engine (Matrix Science Ltd., London, UK), using the search parameters as follows: NCBInr-Funji database; trypsin as the digestion enzyme; one missed cleavage site; fixed modifications, carbamidomethyl (C); partial modifications, acetyl (protein N-term), deamidated (NQ), dioxidation (W), oxidation (M); 100 ppm for precursor ion tolerance and 0.5 Da for fragment ion tolerance.

## RESULTS AND DISCUSSION

**Effect of Different $(NH_4)_2SO_4$ Concentrations on Pullulan Fermentation.** The effect of various concentrations of $(NH_4)_2SO_4$ on cell growth and pullulan production by *A. pullulans* CGMCC1234 is shown in Figure 1. The results acquired at different $(NH_4)_2SO_4$ concentrations proved that the $(NH_4)_2SO_4$ played a vital role on pullulan formation. The carbon flux from merging into fungal cell material to pullulan synthesis was dependent on $(NH_4)_2SO_4$ concentration. When 0.6 g/L of $(NH_4)_2SO_4$ was added into the medium, pullulan concentration achieved the maximum and the production was 37.72 g/L. A higher concentration of $(NH_4)_2SO_4$ brought about the higher level of biomass but reduced the pullulan production. Just 9.45 g/L of pullulan was obtained when 1.5 g/L $(NH_4)_2SO_4$ was added; meanwhile, 12.31g/L DCW was obtained. The possible reason was that excess $(NH_4)_2SO_4$ could not be entirely expended until the end of the fermentation stage, which led to the growth of cell biomass and reduced pullulan production. However, insufficient nitro-

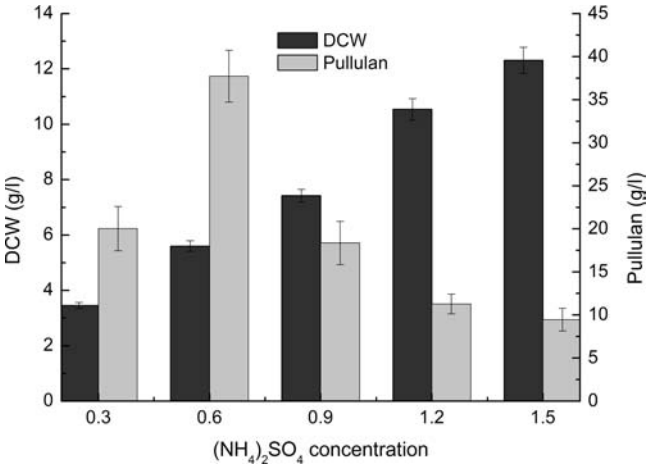

**Figure 1.** Effect of $(NH_4)_2SO_4$ concentration on DCW and pullulan production of *A. pullulans* CGMCC1234 during culture development in a 5 L stirred tank fermentor. Values are given as means ± standard deviation ($n$ = 3).

gen source sparked off the reduction of both biomass and pullulan. When 0.3 g/L $(NH_4)_2SO_4$ was added to the culture medium, just 20.03 g/L pullulan was obtained.

Comparison of the fermentation parameters of *A. pullulans* CGMCC1234 with 0.6 and 1.2 g/L $(NH_4)_2SO_4$ is shown in Figure 2. With 0.6 g/L $(NH_4)_2SO_4$ addition, the biomass growth was apparently inhibited after 36 h. In the meantime, $(NH_4)_2SO_4$ was consumed almost at 36 h. Nevertheless, 1.2 g/L $(NH_4)_2SO_4$ was exhausted until 84 h and the biomass constantly increased through the end of the fermentation. Interestingly, compared to the 1.2 g/L $(NH_4)_2SO_4$ group, the pullulan formation of the 0.6 g/L $(NH_4)_2SO_4$ group was more quickly increased during the 4 days of cultivation. The production of pullulan under nitrogen limit was 3.3-fold as compared to the nitrogen-replete group. Providing excess nitrogen could induce the promotion of cell biomass, but not increase pullulan production.[16]

Nitrogen metabolism was a strictly conducted process in fungi; therefore, fungi had the capacity to exploit finite nitrogen source for cell growth. Effective supervision of the nitrogen metabolism process possibly endowed fungi with the ability to utilize varieties of ecological niches.[17] For *A. pullulans* CGMCC1234 in the nitrogen-limited condition, the medium with 0.6 g/L $(NH_4)_2SO_4$ group displayed sensitivity to pullulan formation. Excess nitrogen source would impel carbon flux flow toward biomass production. The depletion of nitrogen induced exopolysaccharide accumulation of *A. pullulans* fermentation.

**Protein Identification.** In previous studies, we found that exopolysaccharide accumulation was not tightly related to cell growth. When *A. pullulans* cells reached a stationary phase and the cell growth was limited, pullulan could be synthesized more as a secondary metabolite.[18] To search for differences in physiological metabolism and its administration between the cell biomass growth and secondary metabolite pullulan biosynthesis in *A. pullulans* CGMCC1234 cells in the presence of high and low levels of nitrogen source, proteins extracted from the cells of culture medium with 0.6 and 1.2 g/L $(NH_4)_2SO_4$ group at 60 h were subjected to proteome analysis. The representational gel maps of the proteins separated from the *A. pullulans* cells cultivated in the nitrogen-limited medium and the nitrogen-replete medium are shown in Figure 3. As

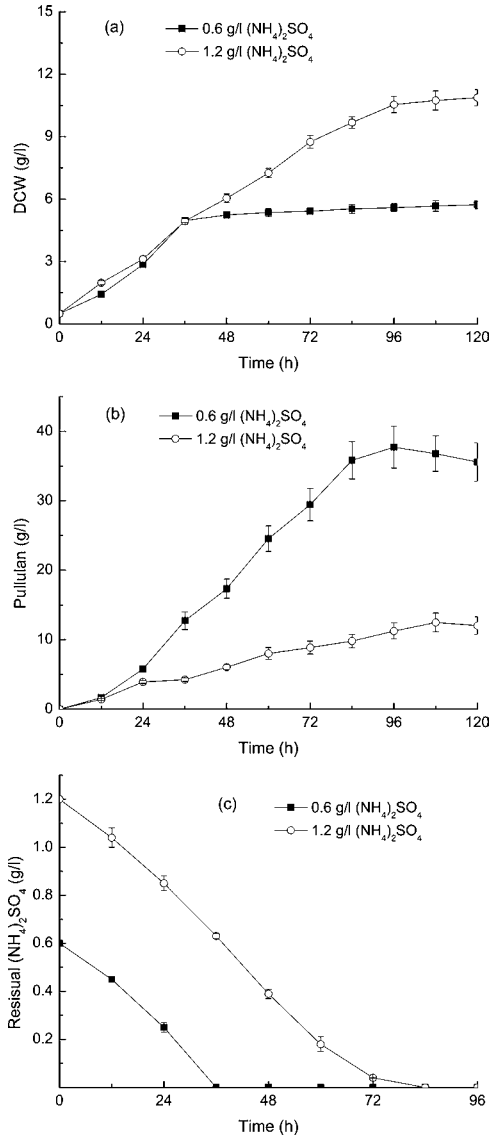

**Figure 2.** Effect of nitrogen-limited cultivation with 0.6 g/L $(NH_4)_2SO_4$ and nitrogen-replete cultivation with 1.2 g/L $(NH_4)_2SO_4$ on the DCW (a), pullulan production (b), and residual $(NH_4)_2SO_4$ concentration (c) of *A. pullulans* CGMCC1234 during culture development in a 5 L stirred tank fermentor. Values are given as means ± standard deviation ($n$ = 3).

analyzed through Image Master, approximately 1100 visualized spots were found on the gels.

After comparison and analysis the gel images, altogether 19 protein spots from the whole cell protein gels were excised and subjected to MALDI-TOF/TOF. The successfully identified proteins were marked on the 2-DE gel maps (Figure 3), and more detailed information about identified proteins is shown in Table 1. Among the 19 protein spots cut for MALDI-TOF/TOF analysis, 12 protein spots were successfully identified, achieving a 63% identification rate. Meanwhile, the identified proteins were matched to known proteins from the fungus species and other microorganisms. Of the 12 protein spots identified, 7 were up-regulated under the nitrogen repletion and 5 were up-regulated under the nitrogen limitation (Table 1). The up-regulated proteins in the nitrogen-replete sample contained nascent polypeptide-associated complex subunit $\beta$, peroxiredoxin-6, $\alpha$-glucan branching enzyme, fructose-bisphos-

[a]The 19 chosen protein spots showed significant difference in expression level between the nitrogen-limited and the nitrogen-replete conditions of culture as analyzed by 2D eletrophoresis. Of the 19 protein spots excised for MALDI-TOF/TOF analysis, 12 proteins were identified.

phate aldolase, arginase, enolase, and hypothetical protein ARB_01037. In comparison, five identified proteins, including putative cyanate hydratase protein, mitochondrial peroxiredoxin-1, hypothetical protein SMAC_07435, ATP synthase subunit $\beta$, and Hsp70-like protein, revealed up-regulation in the nitrogen-limited sample.

**Proteome Changes.** Fructose-bisphosphate aldolase (spot 9 in Figure 3 and Table 1) and enolase (spot 11 in Figure 3 and Table 1) were two proteins involved in the glycolytic pathway. Fructose-bisphosphate aldolase, generally referred to as aldolase, was an enzyme responsible for the catalysis of fructose 1,6-bisphosphate to glyceraldehyde 3-phosphate (G3P) and dihydroxyacetone phosphate (DHAP). Aldolase could also catalyze sedoheptulose 1,7-bisphosphate and fructose 1-phosphate to generate DHAP.[19] Glycolysis, a catabolic pathway, used the forward reaction. Enolase, also called phosphopyruvate hydratase, was a metalloenzyme catalyzing a reversible reaction of the conversion of phosphoenolpyruvate (PEP) to 2-phosphoglycerate (2-PG), the penultimate step of glycolytic pathway. Aldolase and enolase both belonged to the class lyase. These two enzymes could catalyze the reverse reaction, according to the environmental concentrations of substrates.[20] Increasing evidence has revealed that enolase had mutiple capabilities and played an important part in the transcriptional regulation of glycolysis flux. For instance, enolase participated in adjusting and controlling glycolysis flux through induction of the expression of Rag1 glucose permease in *Kluyveromyces lactis*.[21] It was obvious that more $(NH_4)_2SO_4$ up-regulated fructose-bisphosphate aldolase and enolase protein, leading to the carbon flux toward glycolic pathway for the growth of biomass.

$\alpha$-Glucan branching enzyme (spot 8 in Figure 3 and Table 1) was an essential enzyme that catalyzed the development of the $\alpha$-1,6-glucosidic linkages in glucan chains by scission of an $\alpha$-1,4-linked oligosaccharide from growing $\alpha$-1,4-glucan chains and the subsequent attachment of the oligosaccharide to the $\alpha$-1,6 position. It was involved in the biosynthesis of both glycogen and capsular $\alpha$-D-glucan.[22] Excess nitrogen source might accelerate the biosynthesis of intracellular glycogen but reduce the pullulan production. Simon et al. found that pullulan synthesis was increasing while glycogen production was decreasing during growth, so it should be possible that the kinetics of production of these two kinds of polysaccharides were inversely correlated.[23]

Arginase (spot 10 in Figure 3 and Table 1) was a manganese-containing enzyme and ubiquitous to all domains of life. Arginase catalyzed the hydrolysis of L-arginine into L-ornithine and urea. This reaction was the initial step in catabolism of

arginine and the terminal step in anabolism of urea.[24] Excess nitrogen source stimulated amino acid biosynthesis and metabolism in *A. pullulans* CGMCC1234 cells.

Nascent polypeptide-associated complex subunit $\beta$ (spot 6 in Figure 3 and Table 1) was part of the nascent polypeptide-associated complex (NAC). A component of the NAC was a dynamic ribosomal transport corridor. It protected the newly formed polypeptides from interaction with other cytoplasmic proteins to guarantee suitable nascent protein targeting. Furthermore, the NAC could effectively enhance the interaction of ribosome and the membrane of mitochondria and also prevent improper interaction of nonsecretory nascent polypeptides translated from ribosome and translocation sites in the endoplasmic reticulum membrane. Hence, the NAC could efficiently improve the import of mitochondrial protein.[25−27] Numerous proteins were synthesized when *A. pullulan* cells rapidly multiplied in sufficient nitrogen source. The up-regulation of nascent polypeptide-associated complex was conducive to protein transport and transcription regulation.

The 70 kDa heat shock proteins (Hsp70) (spot 5 in Figure 3 and Table 1) belonged to a family of widespread heat shock proteins. Proteins with similar structures were found in almost all organisms. Hsp70 played a crucial role in protein folding in the cells and meanwhile helped to protect the cells from environmental pressure. Hsp70 seemed to be involved in treating defective and damaged proteins. Hsp70 could be able to protect protein from aggregating through close connection to fractional synthesized peptide sequences.[28] As the nitrogen source was consumed, the environment outside the cells became rigorous; the expression of more Hsp70 could protect *A. pullulans* cells from oxidative stress, which generally hurts proteins, leading to aggregation and partial unfolding.

ATP synthases (spot 4 in Figure 3 and Table 1) were membrane-bound enzymes existing in mitochondrial inner membrane and vacuoles. The basic function of ATP synthases was to synthesize ATP using an electrochemical ion gradient. Some ATP synthases worked in reverse, using the energy from the hydrolysis of ATP to create a proton gradient. Studies suggested that pullulan synthesis involved UDP-glucose, required ATP, and proceeded through lipid intermediates.[29] It was obvious that nitrogen-limited cells generated more ATP necessary for metabolism including polymerization of precursor to form pullulan and excretion of pullulan to the culture broth.

In this work, the fermentation results obtained showed that proper concentration (0.6 g/L) of $(NH_4)_2SO_4$ was important for pullulan biosynthesis. Excess nitrogen source would enhance the accumulation of biomass, but decreased the pullulan production. Nitrogen limitation in *A. pullulans* CGMCC1234 seemed to influence the flux change of carbon flux flow toward exopolysaccharide accumulation. The proteomic results revealed that the expression of antioxidant-related enzymes and energy-generating enzymes and the depression of the enzymes concerning amino acid biosynthesis, glycogen biosynthesis, glycolysis, protein transport, and transcriptional regulation under nitrogen limitation, caused a conversion of metabolic flux from the glycolysis pathway to the pullulan biosynthesis pathway. This research supplies a new perspective into the understanding of the mechanism of pullulan biosynthesis and will apply practical significance for the improvement of pullulan production from *A. pullulans*.

storage protein diversity and of the relationships between the considerable numbers of inbred lines should aid in the development of breeding programs that efficiently utilize the available rye germplasm. The high resolution and separation efficiency of the presented CZE method facilitated the rapid identification of the rye HMW-SS compositions in the lines. The qualitative compositions of the rye HMW-SS in the inbred lines determined by CZE in this study were then compared with SDS-PAGE data.

## MATERIALS AND METHODS

**Plant Materials.** The experiment was performed on 68 inbred lines of winter rye (*S. cereale* L.) from generation $S_{20}$, which were obtained by self-pollination and from the selection of 14 rye cultivars and two inbred forms (Table 1). Simultaneously grains from six rye cultivars (cv., accession number, origin country (Everest, 30206, FRA; Buriatskaya, 30308, RUS; Lekkeroggen, 30660, GER; Ponsi, 31004, SWE; Radosinska Record, 30143, SVK; Stel, 31032, SWE)) obtained from the National Centre for Plant Genetic Resources, Radzików, Poland and three standard triticale cultivars Binova (2*/13 + 16/5.1r + 6.4r), Eldorado (1/7 + 8/2r + 5.3r), and Titan (2*/7 + 18/1.2r + 6.5r) were analyzed.

The inbred rye lines were obtained by self-pollination of the individual plants and of the sisters bred within the cultivars and the bred forms for 11 years. For this purpose, two ears from each plant and one ear from each of the two plants of a given variety or form were placed under a tomophane isolator. In the wax maturity phase, the isolators containing ears were cut off and the grains from the ears were manually collected. In the subsequent year, the seeds from the isolated plants from a given variety and a bred form were sown separately. This cycle was repeated for 5 years to obtain phenotypically equalized inbred lines of winter rye, which were subjected to self-pollination and selection for the subsequent 5 years. Using this approach, we obtained individual inbred lines of winter rye of genetically defined morphological features. Then, sets of 100 kernels from each of the selected inbred lines were sown every second year in plots of 1 $m^2$.

Prior to flowering, the plants were protected with canvas sheets that were spread on metal frames, which were then removed from plants representing a given line after flowering. The ears were manually cut at full maturity and were threshed in a laboratory threshing machine. Then, the seed germination energies and abilities were evaluated on the basis of observations of 100 kernels from each line sown in three batches. If the ability of the kernels to germinate was greater than 80% for a given inbred line, the seeds were dried to a moisture content of 7−8% in a chamber containing air with approximately 20% relative humidity and at 20 °C. Finally, the seeds from a given line were cleaned and sealed under a vacuum in laminated foil sheets. The samples of seeds representing the studied lines were stored in this form at −25 °C.

**Reagents and Chemical Materials.** Iminodiacetic acid (IDA), (hydroxylpropyl)methylcellulose (HPMC), acetonitrile (AcN), poly(vinylpyrrolidone) (PVP; $M_r \sim 360{,}000$), dithiothreitol (DTT), urea, and *N*-dodecyl-*N*,*N*-dimethyl-3-ammonio-1-propanesulfonate (lauryl sulphobetaine, SB3-12) were purchased from Sigma (St. Louis, MO, USA). Poly(ethylene oxide) (PEO) with a molecular weight of 8,000,000 Da and acrylamide were acquired from Aldrich (Milwaukee, WI, USA). Sodium phosphate monobasic and dibasic, potassium phosphate monobasic, and sodium hydroxide were the products of J. T. Baker (Phillipsburg, NJ, USA). All chemicals were of electrophoresis or analytical grade.

All solutions were prepared in deionized 18 MΩ·m water using a Milli-Q system (Millipore, Bedford, MA, USA). The solutions were filtered through a 0.5 μm Millipore membrane filter before being injected into the capillary.

**Apparatus.** The CZE experiments were performed on a Beckman Coulter P/ACE system MDQ capillary electrophoresis instrument. The system was equipped with a high-voltage power supply, diode array detector, and 32 Karate ver. 8.0 software (Beckman Coulter) for system control and data handling. The separations were performed using uncoated fused-silica capillaries (Polymicro Technologies, Phoenix, AZ, USA) with internal diameter of 50 μm and 31.2 cm in total length (detection at 10.2 cm from the capillary outlet). The temperature was maintained at 40 °C during all runs.

**Extraction of HMW Secalin Subunits from Rye Flour.** HMW secalin subunits were extracted from 50 mg of rye flour. First, twice preextraction was performed with 0.5 mL of 0.4 M NaCl and 0.067 M $HKNaPO_4$ (pH 7.6) at room temperature to remove the albumins and globulins (mixing each time on a vortex mixer for 10 min and centrifuging for 5 min at 12500*g*). The 40 kDa γ- and ω-secalins were removed by two 10 min extractions using 70% (v/v) ethanol, followed by centrifugation at 15000*g* for 10 min. Then, the HMW-SS and 75 kDa γ-secalins were isolated from the sediment by an extraction for 30 min with 0.05 M Tris buffer (titrated by HCl to pH 7.5) containing 50% (v/v) 1-propanol, 2 M urea, and 1% (w/v) DTT at 60 °C under

nitrogen. This mixture was then centrifuged at 13000*g* for 15 min. The obtained supernatant was aliquoted between two tubes, and half of the volume of the reduced proteins was alkylated with 4-vinylpyridine at 60 °C for 30 min. Then, the alkylated and nonalkylated HMW proteins were precipitated by the addition of 1-propanol to a final concentration of 60% (v/v), and the samples were stored at 4 °C overnight. The precipitated HMW-SS were collected after centrifugation for 8 min at 15000*g*. Next, the HMW-SS precipitates were redissolved in 75 μL of a solution containing 40% (v/v) AcN + 0.1% (v/v) trifluoroacetic acid (TFA) and 2 M urea, vortexed for 30 min at 60 °C, and centrifuged again for 10 min at 15000*g*. All samples were used for SDS-PAGE and CZE analyses within 24 h of extraction.

**Separation of Rye HMW-SS by SDS-PAGE.** The alkylated HMW secalin subunits that were obtained from the rye samples and the triticale cultivars (as protein standards) were separated by electrophoresis on a vertical SDS-PAGE gel using a Protean II xi cell unit (Bio-Rad, Hercules, CA, USA) and the discontinuous Tris-HCl−glycine buffer system of Laemmli.[27] A 10 μL aliquot of a protein sample was loaded onto the upper 4.5% gel, and separation was performed on 12.0% (m/v; 1.35% C) polyacrylamide in resolving solution at 240 V for 45 min after the tracking dye migrated off the gel. The gels were stained overnight with Coomassie Brilliant Blue G-250. The designation of the rye HMW-GS in the inbred lines was performed according to McIntosh et al.[28]

**Separation of Rye HMW-SS by CZE.** The HMW protein separations were conducted according to Salmanowicz[29] with some modifications. A solution containing 75 mM IDA (pH 2.7), 0.15% PEO with a molecular weight of 8,000,000 Da, 26 mM SB3-12, and 15% (v/v) AcN was used as the separation buffer. A buffer containing 0.1 M IDA, 0.2% (m/v) PVP with a $M_w$ of $0.36 \times 10^6$, 0.05% (m/v) HPMC, and 20% (v/v) ACN was used to dynamically coat the capillary wall. Conditioning comprised a rinsing sequence of 1.0 M NaOH, ultrapure water, 0.1 M HCl, ultrapure water, and buffer (all at 275.7 kPa and for 2 min). For the first use on a day, the capillary was additionally flushed with 1 M HCl for 20 min, followed by a 5 min rinse with Milli-Q water and 15 min with separation buffer. The separations were performed with a constant voltage of 10 kV at 40 °C. The samples were injected hydrodynamically under low pressure (3.45 Pa) for 10 s into the anodic end. The separation buffer and dynamic coating of the capillary wall solution were stored in a refrigerator at 4 °C after being degassed with a vacuum system in an ultrasonic tank. Proteins were detected by UV absorbance measurements at 200 nm. The HMW-SS extracts were filtered through a 0.20 μm PVDF syringe filter prior to CZE analysis. The particular HMW-SS were identified through comparisons of single and mixed samples and the results obtained from the SDS-PAGE separations. Three protein separations were performed by CZE for each analytical assay.

**Statistical Analysis.** The resolution was calculated using the half-width method. The mean differences were compared using an unpaired Student's *t* test. All statistical analyses were performed using Statistica software (version 10.0 PL, StatSoft Polska).

## RESULTS AND DISCUSSION

**SDS-PAGE Analysis of Rye HMW-SS.** Alkylated rye HMW protein extracts from 68 inbred lines were used for the identification of allelic variation of HMW-SS compositions by one-dimensional SDS-PAGE. Figure 1A shows the electrophoretic patterns of the rye HMW secalin subunits detected in the selected inbred lines and two standard triticale cultivars. The presented patterns revealed wide variability in the qualitative composition of these subunits. Also earlier conducted analysis of storage proteins in 11 inbred lines showed a difference in the number of bands and their molecular masses.[30]

The SDS-PAGE gel patterns for the particular inbred lines showed two major protein bands for the rye HMW-SS: a more slowly moving x-subunit and a more quickly moving y-subunit. A total of 59 analyzed lines appeared to show genetic homogeneity, while the remaining 9 lines were found to be heterogeneous. It was difficult to make exact identifications of

the subunits because of the very similar electrophoretic mobilities of the rye HMW-SS in the SDS-PAGE gel. The nomenclature commonly used for wheat was used to mark the protein bands in the separating gels: numeration of the bands in the order of their migration in the gel in reference to the bands of the standard wheat HMW glutenin subunits using Arabic numerals with the letter "r" at the end. In the analyzed lines, 9 tentative HMW-SS compositions were detected. Six rye HMW-SS isoforms have similar electrophoretic mobilities, as previously described isoforms from triticale cultivars,[29] and four of them were marked as x-type (2r, 5.1r, 5.2r, and 5.3r), and two as y-type (6.4r and 6.5r). Moreover, three new x-type (1.9r, 2.1r and 6.1r) rye HMW-SS isoforms and four new y-type (5.4r, 6.6r, 7r, and 7.2r) subunits were detected in the gels. In 30 analyzed rye inbred lines, the triticale HMW-SS composition 5.1r + 6.4r was identified (Table 1). A majority of these lines (25 lines) had been selected from the 4 initial rye cultivars (cvs Pancerne, Dańkowskie Selekcyjne, Jeleniec, and Smolickie).

**Optimization of CZE Separation Conditions.** The HMW fraction from the inbred line D855/1 containing the composition 5.1r + 6.4r was used as a model protein mixture for the development of the CZE separation method. Until now, an isoelectric buffer system composed of IDA in conjunction with 0.3 M PEO, 26 mM SB3-12, and 30% AcN has been applied as the running buffer for the separation of the triticale HMW-SS together with wheat HMW glutenin subunits in uncoated fused-silica capillaries.[30] Good solubility of rye HMW-SS in low-concentration 15% (v/v) AcN in conjunction with 2 M urea in comparison with 40% AcN used earlier for redissolution of the mixture of the wheat and rye HMW proteins in triticale cultivars[29] enabled the development of a more efficient method of separation of these classes of proteins. The resolution was determined to be optimum at a concentration of 80 mM IDA in the running buffer containing 0.15% PEO, 26 mM SB3-12, and 15% AcN. This modified procedure maintained satisfactory peak shapes and separation efficiencies for the major peaks of wheat HMW-GS at $(4.6-6.8) \times 10^5$ plates/m. The alkylated rye HMW-SS isoforms migrated in the capillary faster than the nonalkylated isoforms ($t_m$ of major x-type peaks, 10.8 and 12.5 min, respectively), but the reproducibilities and separation efficiencies of the individual protein peaks were less satisfactory (not presented). The relative standard deviation (RSD) values for the migration times ($t_m$) of peaks representing the major x-type and y-type peaks of the alkylated subunits ranged from 1.04% to 1.66%, whereas those of the nonalkylated subunits ranged from 0.49% to 0.84%.

**Detection of Rye HMW Secalin Subunits in Inbred Lines by CZE.** In contrast to the challenging rye HMW-SS identifications on the SDS-PAGE gels due to the very similar electrophoretic mobilities and molecular masses of the particular subunits, the CZE separation of these subunits enabled the correct identification of the specific subunits on the basis of their peak migration times within 16 min. The CZE profiles of nine selected inbred rye lines with detected various HMW-SS compositions are presented in Figure 2A–I. The presented electropherograms of the nonalkylated proteins indicated satisfactory separation of all rye HMW-SS isoforms. The HMW-SS that were isolated from the homogeneity inbred lines were separated into two individual peaks representing x- and y-type subunits, with the exception of two lines that contained only an x-type subunit (Figure 2E). In most cases, a

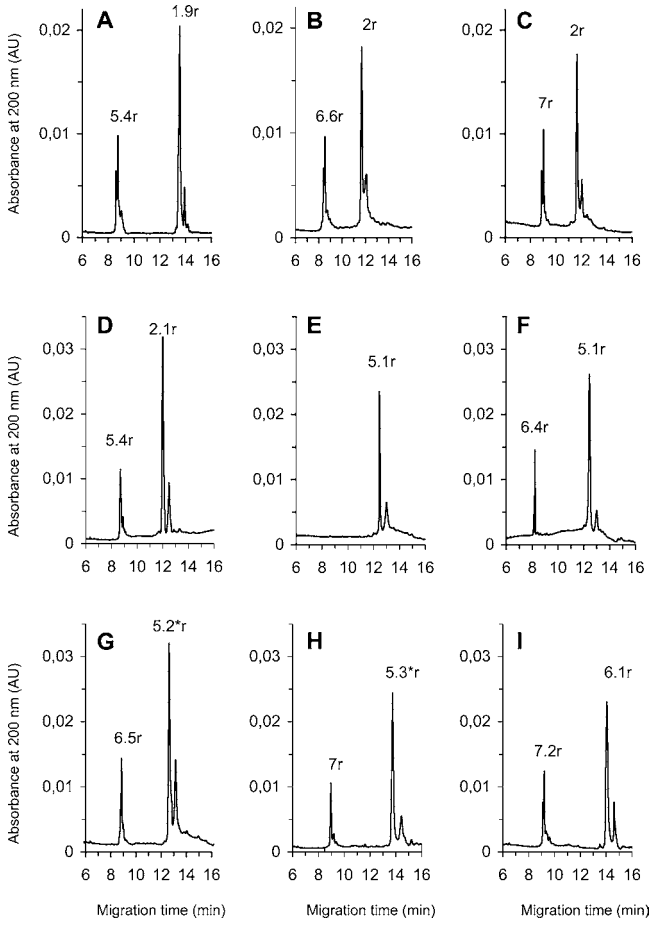

**Figure 2.** CZE electropherograms of nonalkylated rye HMW-SS from selected inbread lines with different subunits compositions: (A) L427 (1.9r + 5.4r), (B) L260/94 (2r + 6.6r), (C) Ch2/99 (2r + 7r), (D) L127bk/97 (2.1r + 5.4r), (E) L228 (5.1r), (F) H9/3 (5.1r + 6.4r), (G) L298/97 (5.2*r + 6.5r), (H) L59 (5.3*r + 7r), and (I) lo segr (6.1r + 7.2r). Proteins were separated at 10.0 kV and 40 °C with a 75 mM isoelectric IDA buffer, containing of 0.15 M PEO, 26 mM SB3-12, and 15% AcN. Prior to the separation, the capillary was rinsed with 0.1 M IDA solution containing 0.2% PVP, 0.05% HPMC, and 20% AcN.

major peak and one or two minor peaks for each HMW-SS were observed. The multiple detected CZE peaks for individual HMW-SS indicated various posttranslational modifications of these subunits. Additionally, the multiple peaks for wheat HMW-GS and triticale HMW-SS have previously been detected via CZE[25,26,29,31] and capillary isoelectric focusing.[32] The migration order of the rye HMW-SS in the capillaries differed from the relative electrophoretic mobilities in the SDS-PAGE gels. The differences in the identifications of the HMW-SS compositions determined by SDS-PAGE and CZE methods could be caused by the various intensities following the staining of the individual HMW secalin bands in SDS-PAGE gels, owing to considerable quantitative differences in these subunits revealed by CZE analysis. Moreover, rye HMW-SS possess similar molecular masses, which makes the identification of particular subunits on the basis of SDS-PAGE patterns in comparison with CZE profiles very difficult. In total, seven x-type and six y-type HMW-SS were designated via the CZE method (Table 1). The rye HMW-SS were separated in the capillary within two time ranges, namely, the y-type subunits with shorter migration times (8.21–9.18 min) and the x-type subunits with longer migration times (11.68–14.06 min)

**Table 2. Means of Migration Times ($t_m$) of Individual x- and y-Type HMW Secalin Subunits in Rye Inbred Lines Determined by CZE Method**

| x-type | 1.9r | 2r | 2.1r | 5.1r | 5.2*r | 5.3*r | 6.1r |
|---|---|---|---|---|---|---|---|
| *n* | 1 | 13 | 2 | 32 | 7 | 3 | 1 |
| $t_m$ (min) | 13.53 ± 0.15 | 11.64 ± 0.12 | 12.01 ± 0.11 | 12.33 ± 0.13 | 12.63 ± 0.10 | 13.74 ± 0.16 | 14.06 ± 0.18 |

| y-type | 5.4r | 6.4r | 6.5r | 6.6r | 7r | 7.2r |
|---|---|---|---|---|---|---|
| *n* | 3 | 30 | 7 | 6 | 10 | 1 |
| $t_m$ (min) | 8.74 ± 0.10 | 8.21 ± 0.08 | 8.84 ± 0.09 | 8.46 ± 0.06 | 8.98 ± 0.06 | 9.18 ± 0.09 |

(Table 2). Both the detected rye x-type and y-type HMW-SS migrated in the capillary with time ranges similar to those of the triticale HMW glutenin subunits (HMW-GS), whereas the typical rye HMW-SS exhibited a wider range of migration times than the triticale HMW-SS.[26,29] The lack of considerable distinction between the rye HMW-SS migration times from the European triticale cultivars,[33] from which they earlier were obtained, can only be demonstrated based on the limited utilization of rye germplasm for the creation of this synthetic species.

Generally, the x-type rye HMW-SS in the analyzed lines were more abundant than the y-type subunits. Seven x-type HMW-SS were distinguished on the basis of their CZE migration times (Table 1). Using the SDS-PAGE electrophoretic mobilities of wheat HMW-GS bands as points of reference,[26] the following names were assigned to the rye HMW-SS: 1.9r, 2r, 2.1r, 5.1r, 5.2*r, 5.3*r, and 6.1r. Only two x-type subunits earlier identified in the triticale rye cultivars, 2r and 5.1r, were also detected in the presented CZE study. However, the remaining five rye subunits were new and had not been described before. New subunits 5.2*r and 5.3*r possessed SDS-PAGE electrophoretic mobilities that were similar to those of the earlier detected triticale subunits 5.2r and 5.3r,[29] respectively, but they had considerably different migration times using CZE analysis. The relative migration order of the x-type rye HMW-SS encoded by genes on the *Glu-R1* locus was 6.1r > 5.3*r > 1.9r > 5.2*r > 5.1r > 2.1r > 2r (from the slowest to the fastest). In summary, the presented CZE data did not fully confirm the classification of the specific encoded HMW-SS alleles based on the SDS-PAGE analysis.

Six rye y-type HMW-SS were distinguished in the analyzed material based on their migration times via the CZE method, of which four were new and had not been previously described (Table 1). According to their relative electrophoretic mobilities in the SDS-PAGE gels, the following names were assigned to these subunits: 5.4r, 6.4r, 6.5r, 6.6r, 7r, and 7.2r. The y-type subunits 7r and 7.2r, the smallest of the subunits as determined by SDS-PAGE, exhibited the longest migration times, 8.98 and 9.18 min, respectively (Table 2). Additionally, most analyzed rye samples contained y-type subunit 6.4r, which possessed the shortest $t_m$ of 8.21 min. The relative migration order of the y-type rye HMW-SS encoded by genes on the *Glu-R1* locus was 7.2r > 7r > 6.5r > 5.4r > 6.6r > 6.4r (from the slowest to the fastest).

The following eight new HMW secalin subunit pairs 1.9r + 5.4r (*Glu-R1h*), 2r + 6.6r (*Glu-R1i*), 2r + 7r (*Glu-R1j*), 2.1r + 5.4r (*Glu-R1k*), 5.1r + Null (*Glu-R1l*), 5.2*r + 6.5r (*Glu-R1m*), 5.3*r + 7r (*Glu-R1n*), and 6.1r + 7.2r (*Glu-R1p*) were identified on the basis of the CZE analysis performed in this study and after regarding the nomenclature for rye allelic variants (pairs of x + y). The rye HMW-SS allelic compositions 5.1r + 6.4r and 2r + 7r were the most frequently identified (41.1% and 10.3%, respectively) in the analyzed inbred lines, whereas the compositions 1.9r + 5.4r and 6.1r + 7.2r occurred very rarely (at 1.5%).

**Detection of HMW Secalin Subunits in Rye Cultivars.** The separation of rye HMW secalin subunits from six cultivars was performed using SDS-PAGE and CZE methods. The SDS-PAGE patterns of the rye HMW-SS obtained from four selected single grains descending from three cultivars are shown in Figure 1B. The obtained SDS-PAGE electropherograms revealed considerable genetic variations in the rye HMW-SS and resulted in highly diverse subunit band patterns. The majority of the lanes in the SDS gel showed four protein bands (two x-type and two y-type subunits) with different protein staining intensities. The correct identification of particular x + y HMW-SS subunit pairs was therefore not possible. The presence of two x-type and two y-type HMW-SS on SDS-PAGE gels for the individual rye cultivars has also been presented before in other works.[10,17,25,34] The occurrence of two to four inbred lines that were selected earlier from individual initial rye cultivars differing in their HMW-SS compositions confirmed the high level of rye polymorphism (Table 1).

The CZE analysis of the rye HMW secalin fraction from single grains of six cultivars fully confirmed the works of other authors[11,23,24] who identified the multilines (mixtures of genotypes) of most rye cultivars. Generally, the HMW-SS fractions from the analyzed rye cultivars were separated into four major peaks representing two x- and two y-type subunits (Figure 3A,B). Moreover, there often occurred considerable quantitative differences in the peak areas for the particular x + y subunit pairs. Although certain single seeds of the rye cultivars presented very characteristic CZE profiles of the HMW-SS, generally the high levels of heterogeneity and heterozygosity made cultivar identification very difficult, which is in contrast to

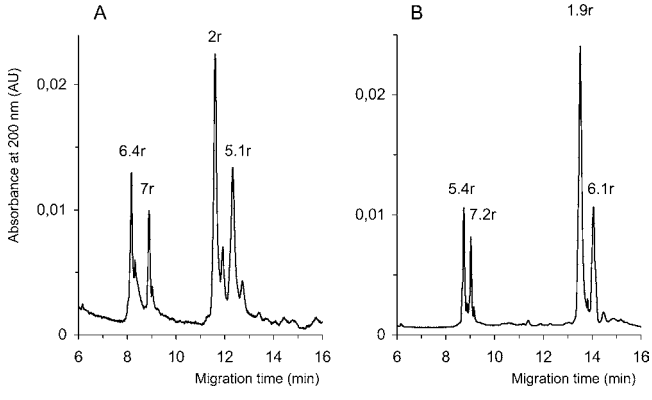

**Figure 3.** CZE electropherograms of rye HMW-SS from two selected cultivars: (A) cv. Lekkeroggen (5.1r + 6.4r and 2r + 7r) and (B) cv. Buriatskaya (1.9r + 5.4r and 6.1r + 7.2r). Separation conditions were as described in Figure 2.

the case of identifying cultivars of wheat, triticale, and barley.[35,36]

In conclusion, it has been proven that HMW secalin subunits from rye inbred lines can be rapidly (below 15 min) separated via CZE method with both high resolution and good reproducibility. Using selective preparation of HMW proteins precipitated by addition of 1-propanol to a final concentration of 60% (v/v), 75 kDa γ-secalins from HMW protein extract were eliminated, which have migration times similar to those of HMW-SS during the CZE separation. The HMW-SS were separated into two major peaks (x-type and y-type subunits), with the exception of two lines that contained only the x-type subunit. The CZE analysis of rye HMW secalin fraction fully confirmed the occurrence of the mixture of genotypes in single grains of rye cultivars. A knowledge of the HMW secalin subunit composition of the particular rye samples enables breeders the utilization of rye germplasm in a wider range for the creation of new genotypes of triticale and wheat species with desirable properties. Fast and more accurate characterization of rye HMW-SS by CZE is an efficient alternative to identification of these proteins by the standard SDS-PAGE analysis.

[a]Peak numbers correspond to peaks in Figure 1. [b]Recorded during LC-DAD-MS analysis using a Waters Acquity UPLC instrument. [c]sh, shoulder. [d]Accurate mass determined experimentally. [e]Data acquired in MS/MS mode. [f]Typical flavanone shoulder at ca. 330 nm not detected due to low concentration.

and problematic integration due to background absorption. The same problems were observed for *C. subternata* analyzed using the "generic" HPLC method.[18]

The present paper therefore describes the development and application of a validated HPLC method using diode array detection (DAD) suitable for the qualitative and quantitative analysis of *C. maculata* aqueous extracts. Mass spectrometry (MS) was applied to confirm peak purity and the identity of known compounds and to tentatively identify additional compounds. Extracts were prepared from the unfermented plant material of a large number of wild-harvested and cultivated seedling plants to understand the extent of batch-to-batch variation that could be expected when using this species for the production of nutraceutical extracts. Variation in extract composition was assessed in terms of the content of individual phenolic compounds and chemometric analysis of the chromatographic fingerprints, using similarity analysis and principal component analysis (PCA). The major compounds present in extracts of fermented *C. maculata* plant material were also analyzed to assess changes in quantitative composition with "fermentation" as this type of extract is also used by the food industry as an ingredient.

## MATERIALS AND METHODS

**Chemicals.** All chemicals were of analytical grade and sourced from either Sigma-Aldrich (St. Louis, MO, USA) or Merck Chemicals (Darmstadt, Germany); HPLC gradient grade acetonitrile was purchased from Merck. Authentic reference standards with purity >95% were obtained from Sigma-Aldrich (hesperidin and scolymoside), Extrasynthese (Genay, France; mangiferin, eriocitrin, and eriodictyol-7-*O*-glucoside), Phytolab (Vestenbergsgreuth, Germany; vicenin-2), and Chemos (Regenstauf, Germany; isomangiferin). Iriflophenone-3-*C*-glucoside (purity ≥94%), isolated from *Cyclopia genistoides*,[19] was obtained from the Post-Harvest and Wine Technology Division, ARC Infruitec-Nietvoorbij (Stellenbosch, South Africa). Deionized water, prepared using an Elix water purification system (Millipore, Milford, MA, USA), was further purified to HPLC grade using a Milli-Q Academic water purification system (Millipore).

**Plant Material and Extract Preparation.** Two sets of plant material were used in the present study. All plants were identified by M. Joubert, a honeybush cultivation expert from the ARC Honeybush Breeding Program (Cultivar Development Division, ARC Infruitec-Nietvoorbij, Stellenbosch, South Africa) on the basis of the classification of Schutte.[20] Plant material for sample set 1 comprised nine batches of plant material, harvested during summer (December 2009) from bushes forming part of the same natural population growing in marsh land on Welgedacht farm (Riversdale, South Africa). The shoots from two to three bushes made up a batch. Each plant material batch ($n$ = 9) was processed as follows: Thick stems with little or no side stems were removed, and the plant material was mechanically shredded (≤3 mm), mixed, and divided into two sub-batches for preparation of unfermented and fermented plant material ($n$ = 9 each). The unfermented plant material was prepared by drying one sub-batch without delay in a cross-flow drying tunnel at 40 °C for 6 h (<10% moisture content). The dried plant material was then sieved for 90 s to obtain the fraction <1.4 mm (12 mesh) using a SMC Mini-sifter (JM Quality Services, Cape Town, South Africa). Sifting removed mostly coarse pieces of stems. The other sub-batch was "fermented" (oxidized) by adding tap water to the cut plant material to

achieve a moisture content of ca. 60−65%, followed by heating at 90 °C for 16 h. Drying and sieving were performed as described above.

Plant material for sample set 2 comprised shoots of individual seedlings ($n$ = 40; 2 years old) grown in pots at ARC Infruitec-Nietvoorbij (Stellenbosch, South Africa) and harvested during winter (June 2011). The seeds for the pot trial were collected from a natural population, also growing in marsh land on Welgedacht farm. Thick stems were removed, and the remaining plant material was dried intact at 40 °C in a drying tunnel to ca. 8−10% moisture content. The dried plant material was ground to a powder with a Retsch mill (1 mm sieve; Retsch GmbH, Haan, Germany).

A freeze-dried extract of each plant material sample was prepared as described by de Beer et al.[21] Extracts were reconstituted by dissolving them in deionized water (ca. 6 mg/mL), and aliquots were frozen at −20 °C until analysis.

**HPLC-DAD Method Development and Validation.** All HPLC-DAD analyses were performed on an Agilent 1200 series HPLC instrument, consisting of an in-line degasser, quaternary pump, autosampler, column oven, and DAD, controlled by Chemstation software (Agilent Technologies Inc., Santa Clara, CA, USA). The following columns were evaluated using the solvent gradient as reported by de Beer and Joubert:[18] a Zorbax SB-C18 (100 × 4.6 mm; 1.8 μm; 80 Å) and a Zorbax Eclipse XDB-C18 (150 × 4.6 mm; 5 μm; 80 Å) from Agilent Technologies (Waldbronn, Germany); a Kinetex C18 (150 × 4.6 mm; 2.6 μm; 100 Å) with core−shell technology and a Gemini-NX C18 (150 × 4.6 mm; 3 μm; 110 Å) from Phenomenex (Santa Clara, CA, USA). A randomly selected pair of unfermented and fermented extracts were employed for method development to allow for expected profile differences introduced by fermentation. For optimization of separation conditions on the selected column, acetic acid and formic acid as aqueous phases (solvent A) and acetonitrile and methanol as organic modifiers (solvent B) were evaluated as mobile phases. Furthermore, scouting gradients, using 2% acetic acid (A) and acetonitrile (B), were evaluated at different temperatures. The final method, subjected to validation, entailed separation on the Gemini-NX C18 column at 30 °C and 1 mL/min flow rate using 2% acetic acid (A) and acetonitrile (B). The mobile phase gradient profile was as follows: 0−2 min, 8% B; 2−31 min, 8−38% B; 31−32 min, 38−50% B; 32−33 min, 50% B; 33−34 min, 50−8% B; 34−44 min, 8% B. The extracts used for method development and a standard calibration mixture were used for method validation. This entailed determination of the linearity of response, compound stability over a 24 h period, and intra- and interday precision, as previously described.[18] The specificity of the method was evaluated by assessing the purity of peaks based on UV−vis and MS spectra.

**Identification of Phenolic Compounds.** LC-MS analyses were conducted on a Waters Acquity UPLC equipped with a binary pump, in-line degasser, autosampler, column oven, and DAD (Waters, Milford, MA, USA), which was coupled to a Synapt G2 Q-TOF mass spectrometer (Waters) with an electrospray ionization (ESI) source. Data acquisition and analysis were performed using MassLynx v.4.1 (Waters). The LC method used was the same as described for the validated HPLC-DAD method except for the following modifications: gradient time delayed by 0.2 min (each step); percentage of solvent B increased by 0.5% at each time interval; and temperature increased by 2 °C. These alterations were necessary to obtain similar separations on the Waters UPLC as on the Agilent HPLC instrument.

UV−vis spectra were recorded from 235 to 450 nm. Prior to introduction into the ionization chamber, the eluent was split in a ratio of 3:2. MS and $MS^E$ data were attained in both positive and negative ESI modes using a 3 μL injection volume. Mass ranges of 200−1500 and 50−1500 Da were used for MS and $MS^E$ acquisition modes, respectively. A collision energy ramp from 25 to 60 V was used for $MS^E$. Leucine enkephalin was used as lock mass, and the instrument was calibrated using a sodium formate solution. The MS ionization parameters were as follows: desolvation temperature, 275 °C; source temperature, 120 °C; nitrogen flow rate, 650 L/h; capillary voltage, 2500 V; cone voltage, 15 V. In the case of LC-MS/MS analysis (for compound **3**), a scan range of 50−875 Da was used with a collision trap energy of 30 V.

**Quantification of Phenolic Compounds using HPLC-DAD.** UV−vis spectra were recorded from 200 to 550 nm for all samples. The xanthones (mangiferin and isomangiferin) and the flavone (vicenin-2) were quantified using peak areas at 320 nm, whereas the flavanones (eriocitrin, an eriodictyol-*O*-hexoside (**8**; Table 1) and hesperidin) and benzophenones (iriflophenone-3-*C*-glucoside and maclurin-3-C-glucoside) were quantified using peak areas at 288 nm. Seven-point calibration curves were constructed with the available authentic standards by dilution of the stock solutions in water. Due to the small quantity available, iriflophenone-3-*C*-glucoside was not included in the calibration series and was quantified using a response factor (1.1511) previously determined relative to hesperidin. Furthermore, maclurin-3-*C*-glucoside and eriodictyol-*O*-hexoside were quantified as iriflophenone-3-*C*-glucoside and eriocitrin equivalents, respectively, due to the unavailability of authentic reference standards. Calibration curves were developed to accommodate the expected concentration range (μg injected) of the compounds in the extracts, namely, mangiferin (0.02−4.9 μg), isomangiferin (0.005−1.3 μg), eriocitrin (0.007−1.8 μg), hesperidin (0.009−2.3 μg), and vicenin-2 (0.01−1.0 μg).

**Data Analysis.** *Analyis of Variance (ANOVA).* Quantitative data were subjected to univariate ANOVA using SAS, version 9.2 (SAS Institute, Cary, NC, USA). The Shapiro−Wilk test was performed to test for normality. Student's $t$ test was used to calculate the least significant difference (LSD) at the 5% level to facilitate a comparison of mean values.

*Pretreatment of Chromatograms for Fingerprint Analysis.* The recorded absorbance matrices for the duplicate injections of each extract (wavelengths × time) of *C. maculata* ($n$ = 98) were exported from ChemStation software (Agilent) as *.csv files for the wavelength range from 220 to 500 nm (2 nm bandwidth) and from 0 to 40 min using a ChemStation macro, export3D (available in the Agilent user contribution library). The *.csv files were each changed to comma delimited format in Microsoft Excel (2010) and then imported into MATLAB R2012b (The MathWorks, Natick, MA, USA). All matrices contained 12000 time (data) points and were averaged to individual absorbance vectors (absorbance × time). These new vectors were arranged into a new matrix, with dimensions of 98 × 12000 (duplicate extracts × time). Peak alignment was conducted by means of correlation-optimized warping (COW)[22] using MATLAB code freely available from www.models.life.ku.dk/DTW_COW, followed by background elimination by means of the penalized asymmetric least-squares (PALS) method.[23] Normalization[24] to a constant sum was then performed by dividing each signal value for each sample by the sum of all signal values for that specific sample. The time axis of the matrix was shortened to remove irrelevant data. The final dimensions of the new matrix were 98 × 5381.

*Similarity Analysis.* Similarity analysis of the extracts was conducted by determining the correlation coefficients between fingerprints of the extracts. The similarity analysis conducted in this study was based on the Pearson product-moment correlation coefficient, $r$.[25]

$$r(\mathbf{x}_1, \mathbf{x}_2) = \frac{\mathrm{cov}(\mathbf{x}_1\mathbf{x}_2)}{s_{x1}s_{x2}} = \frac{\sum_{j=1}^{q}(x_{1j} - \bar{x}_1)(x_{2j} - \bar{x}_2)}{\sqrt{\sum_{j=1}^{q}(x_{1j} - \bar{x}_1)^2 \sum_{j=1}^{q}(x_{2j} - \bar{x}_2)^2}} = \frac{(\mathbf{x}_1 - \bar{x}_1)(\mathbf{x}_2 - \bar{x}_2)}{\|\mathbf{x}_1 - \bar{x}_1\| \|\mathbf{x}_2 - \bar{x}_2\|} \quad (1)$$

This coefficient was calculated between each pair of fingerprints, $\mathbf{x}_i$, where $i$ = 1, 2, ..., $p$ are the samples evaluated, and each fingerprint comprises absorbance measurements at $j$ = 1, 2, ..., $q$ time points. In each case $\mathbf{x}_1$ and $\mathbf{x}_2$ are the individual fingerprints or vectors that were considered; $x_{1j}$ and $x_{2j}$ are the absorbances that were measured for each fingerprint at the specific $j$th time point, and $x_1$ and $x_2$ are the mean values of the respective absorbances of each fingerprint. Furthermore, cov is the covariance of the fingerprints and $s_{xi}$ is the standard deviation of the fingerprints.

*Principal Component Analysis.* PCA was conducted on the same data as for similarity analysis after mean centering to determine whether any relevant information could be extracted from the data.

$$X = TP^t + E \quad (2)$$

The data matrix was decomposed into a product of two matrices where **T** is the score matrix, **P** is the loading matrix, $\mathbf{P}^t$ is the transpose of **P**, and **E** is the matrix of residuals.

## RESULTS AND DISCUSSION

**HPLC-DAD Method Development and Validation.** The method described in de Beer et al.[21] was not suitable for the analysis of *C. maculata* extracts, due to minor unidentified compounds, which were not present in *C. subternata*, coeluting with mangiferin and isomangiferin. Column performance was therefore assessed with regard to the separation of mangiferin and isomangiferin from the unidentified coeluting compounds. Of the four columns evaluated, the Gemini-NX C18 column provided the best separation, as observed for *C. subternata*.[21] However, the gradient differed from that used for *C. subternata* to allow adequate resolution in this case. Separation at 30 °C provided the lowest degree of coelution for hesperidin, eriocitrin, and iriflophenone-3-*C*-glucoside, while also maintaining optimal resolution for mangiferin and isomangiferin. The HPLC-DAD chromatograms of green and fermented *C. maculata* extracts using the optimized conditions are illustrated in Figure 1.

To determine the suitability of the developed method for the routine analysis of the major phenolic compounds in green and fermented *C. maculata* extracts, method validation was conducted (data summarized in Supporting Information Tables S1–S3). The linearity of the standard calibration curves was excellent ($r^2$ = 1.000) (Table S1). The stability (Table S2) of the compounds in the standard calibration mixture and extracts and the intra- and interday precision (Table S3) of the method were good (%RSD values <4 and <5%, respectively, except for vicenin-2, which had a +5.9% change over 24 h).

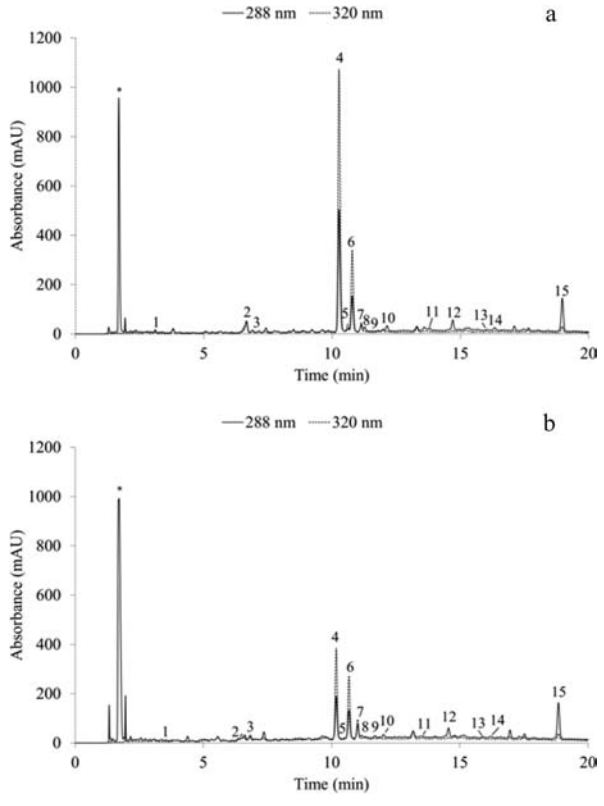

**Figure 1.** HPLC-DAD chromatograms (Agilent 1200 HPLC system) of aqueous extracts prepared from (a) green and (b) fermented *Cyclopia maculata* plant material using the optimized method (∗, ascorbic acid peak; see Table 1 for identity of numbered peaks).

**Identification of Phenolic Compounds.** LC-MS analysis was conducted on paired green and fermented *C. maculata* aqueous extracts ($n$ = 1 each) in both positive and negative ESI modes. LC-MS and -$MS^E$ data of each peak in negative ionization mode were used in combination with comparison of the relative retention times and UV–vis spectra with those of the authentic reference standards, where available, to identify the compounds (Table 1). LC-MS and -$MS^E$ data obtained in positive ionization mode are presented in the Supporting Information (Table S4) as further evidence of compound identification. The presence of iriflophenone-3-*C*-glucoside (**2**), mangiferin (**4**), isomangiferin (**6**), vicenin-2 (**7**), eriocitrin (**12**), scolymoside (**13**), and hesperidin (**15**) was confirmed in both the green and fermented extracts using authentic reference standards. Of these, vicenin-2 (**7**) was identified for the first time in *C. maculata*. Additional compounds were tentatively identified by comparison to published data (Table 1); these will be discussed in more detail in the sections below with respect to their MS fragmentation patterns, retention behavior, and UV–vis spectra. Compound structures, including proposed structures for tentatively identified compounds, are shown in Figure 2.

*Xanthones.* Two additional xanthones (**5** and **9**), with UV–vis spectra similar to those of mangiferin and isomangiferin, were detected at retention times 8.84 and 10.20 min, respectively. Both compounds displayed pseudomolecular ions at $m/z$ 437 ($[M - H]^-$), and a molecular formula of $C_{19}H_{18}O_{12}$ ($[M - H]^-$) is proposed. Both compounds also displayed major fragment ions at $m/z$ 317 ($[M - H - 120]^-$) and $m/z$ 347 ($[M - H - 90]^-$), indicating C-glycosidic structures.[26] Furthermore, compounds **5** and **9** differ from isomers **4** and **6** by 16 amu. These data suggest possible hydroxylated derivatives of mangiferin and isomangiferin. The principal $MS^E$ fragments confirm that the additional hydroxyl group is attached to the aglycone moiety in both cases. According to their relative elution order, compounds **5** and **9** are presumably the hydroxylated derivatives of mangiferin (**4**) and isomangiferin (**6**), respectively. They eluted slightly later than compounds **4** and **6**, respectively, which was somewhat surprising in view of the additional OH group. Hydroxylation most likely occurs at position 5 or 8 (indicated by $R_3$ or $R_4$) on the B ring (Figure 2), although this could not be confirmed on the basis of the available MS data. These compounds have not been reported previously in *Cyclopia* species.

Compound **3**, with the proposed molecular formula of $C_{40}H_{39}O_{22}$ ($[M - H]^-$), had a retention time of 6.26 min and a molecular ion at $m/z$ 871 $[M - H]^-$. This compound seems to be a derivative of mangiferin (**4**) or isomangiferin (**6**), because it contains fragments identical to these compounds at $m/z$ 421 ((iso)mangiferin molecular ion), $m/z$ 331 ($[M - H - 90]^-$), and $m/z$ 301 ($[M - H - 120]^-$). The much higher molecular weight of compound **3** appears to indicate a dimeric derivative of (iso)mangiferin,[27,28] although the lower retention time is not consistent with this and rather points to a highly glycosylated derivative. High molecular weight fragments also indicate the presence of more than one *C*-glycosidic group, for example $m/z$

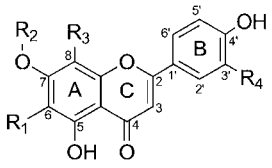
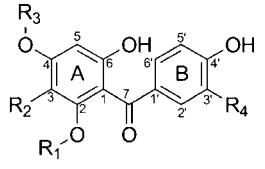
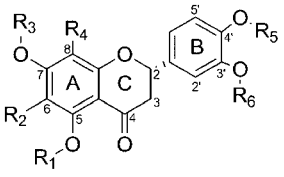
*Xanthones*
Mangiferin (**4**): $R_1$ = glucosyl; $R_2$, $R_3$, $R_4$ = H
Isomangiferin (**6**): $R_2$ = glucosyl; $R_1$, $R_3$, $R_4$ = H
Hydroxymangiferin (**5**) *: $R_1$ = glucosyl; $R_2$ = H; $R_3$ or $R_4$ = OH or H
Hydroxyisomangiferin (**9**) *: $R_2$ = glucosyl; $R_1$ = H; $R_3$ or $R_4$ = OH or H



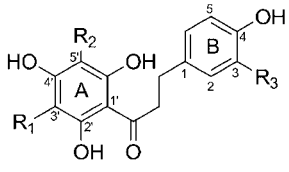
*Flavones*
Apigenin-6,8-di-*C*-glucoside (Vicenin-2) (**7**): $R_1$, $R_3$ = glucosyl; $R_2$, $R_4$ = H
Scolymoside (**13**): $R_1$, $R_3$ = H; $R_2$ = rutinosyl; $R_4$ = OH



*Benzophenones*
Maclurin-3-*C*-*β*-glucoside (**1**): $R_1$, $R_3$ = H; $R_2$ = glucosyl; $R_4$ = OH
Iriflophenone-3-*C*-*β*-glucoside (**2**): $R_1$, $R_3$, $R_4$ = H; $R_2$ = glucosyl



*Flavanones*
Eriodictyol-*O*-hexoside (**8**, **10**) *: $R_1$ or $R_3$ = hexosyl or H; $R_2$, $R_4$, $R_5$, $R_6$ = H
Eriocitrin (**12**): $R_3$ = rutinosyl; $R_1$, $R_2$, $R_4$, $R_5$, $R_6$ = H
Hesperidin (**15**): $R_3$ = rutinosyl; $R_5$ = $CH_3$; $R_1$, $R_2$, $R_4$, $R_6$ = H



*Dihydrochalcones*
3-Hydroxyphloretin-3′,5′-di-*C*-hexoside (**11**): $R_1$, $R_2$ = hexosyl; $R_3$ = OH
Phloretin-3′,5′-di-*C*-glucoside (**14**): $R_1$, $R_2$ = glucosyl; $R_3$ = H

**Figure 2.** Structures of phenolic compounds identified in freeze-dried aqueous extracts of green and fermented *Cyclopia maculata* (∗ indicates that the positions of hexosyl or hydroxyl moieties are not certain).

751 ($[M - H - 120]^-$), *m/z* 691 ($[M - H - 2 \times 90]^-$), *m/z* 601 ($[M - H - 120 - 150]^-$), and *m/z* 571 ($[M - H - 2 \times 150]^-$) (Supporting Information, Figure S2). This compound needs to be investigated further, as no structure could be proposed with certainty on the basis of currently available data.

*Benzophenones.* Compound **1**, with a retention time of 3.38 min, had a pseudomolecular ion at *m/z* 423 ($[M - H]^-$), and a molecular formula of $C_{19}H_{19}O_{11}$ $[M - H]^-$ is proposed on the basis of accurate mass data. Its relative retention, UV−vis spectrum, and MS fragmentation pattern are consistent with those of maclurin-3-*C*-*β*-glucoside, a compound present in the leaves of *Mangifera indica* L.[29,30] and *C. genistoides*.[31] Maclurin-3-*C*-*β*-glucoside has not been reported previously in *C. maculata*.

*Dihydrochalcones.* Compounds **14** and **11** had retention times of 14.18 and 11.78 min, respectively. Molecular formulas of $C_{27}H_{33}O_{15}$ ($[M - H]^-$) and $C_{27}H_{33}O_{16}$ ($[M - H]^-$) are proposed for compounds **14** and **11**, respectively. The UV−vis spectra, retention behavior, and $MS^E$ fragments of the two compounds correspond to phloretin-3′,5′-di-*C*-glucoside (**14**)[32] and its hydroxylated derivative, 3-hydroxyphloretin-3′,5′-di-*C*-hexoside (**11**), as discussed in de Beer et al.[21] Phloretin-3′,5′-di-*C*-glucoside has previously been identified in an aqueous extract of green *C. maculata* using LC-MS.[6] 3-Hydroxyphloretin-3′,5′-di-*C*-hexoside is identified here for the first time in *C. maculata*.

*Flavanone O-glycosides.* Compounds **8** and **10**, with similar pseudomolecular ions at *m/z* 449 ($[M - H]^-$) and fragments at *m/z* 287 ($[M - H - 162]^-$) and *m/z* 151, eluted at retention times of 9.61 and 10.39 min, respectively. Their UV−vis spectra were characteristic of flavanones. On the basis of these data and the major fragment ion corresponding to eriodictyol, compounds **8** and **10** were tentatively identified as eriodictyol-*O*-hexosides. An eriodictyol-5-*O*-glucoside and eriodictyol-7-*O*-glucoside were previously isolated from *C. intermedia* and identified by means of nuclear magnetic resonance (NMR).[10] However, both compounds **8** and **10** showed earlier retention times compared to an authentic reference standard of eriodictyol-7-*O*-glucoside. Similar retention behavior has been noted for the 5-*O*-glucosides of quercetin and apigenin compared to their 7-*O*-glucoside counterparts.[33] Consequently, these compounds may be the (*R*)- and (*S*)-diastereomers of eriodictyol-5-*O*-glucoside, which can be separated by reversed phase LC.[34] No eriodictyol-hexosides have been reported previously in *C. maculata*.

**Quantitative Phenolic Composition of Green and Fermented *C. maculata* Extracts.** Fermentation conditions employed in the current study were based on those used by industry. The validated HPLC-DAD method was used to quantify the major xanthones (mangiferin and isomangiferin), flavanones (hesperidin, eriocitrin, and an eriodictyol-*O*-hexoside), benzophenones (iriflophenone-3-*C*-*β*-glucoside and maclurin-3-*C*-*β*-glucoside), and a flavone (vicenin-2) (Table 2). Maclurin-3-*C*-*β*-glucoside, iriflophenone-3-*C*-*β*-glucoside, and the eriodictyol-*O*-hexoside could not be quantified in fermented extracts due to their substantially lower levels

dx.doi.org/10.1021/jf5028735 | J. Agric. Food Chem. 2014, 62, 10542−10551

[a]Standard deviation. [b]Relative standard deviation as percentage of mean. [c]Different letters indicate significant ($p$ < 0.05) differences between green and fermented extracts.

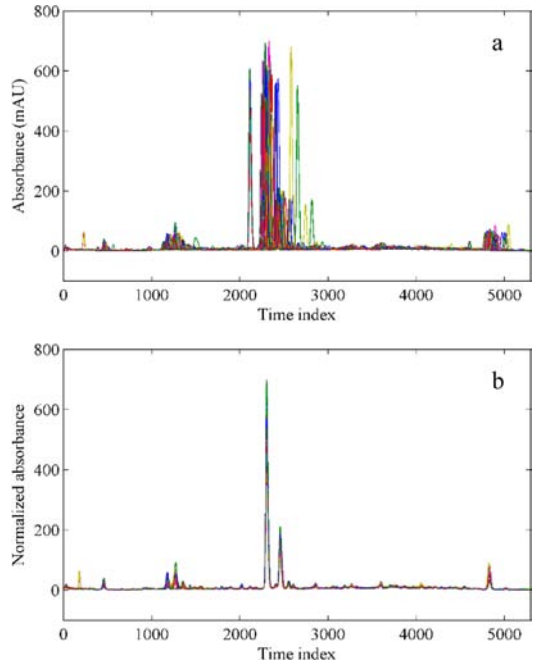

**Figure 3.** Overlay of *Cyclopia maculata* chromatographic fingerprints ($n$ = 49) (a) before and (b) after pretreatment.

compared to green extracts and poor resolution with other minor compounds. Mangiferin, isomangiferin, eriocitrin, and hesperidin levels decreased by 80, 57, 52, and 42%, respectively, following fermentation. Positioning of the sugar moiety on the dibenzo-$\gamma$-pirone structure clearly affects stability as exemplified by the difference in the stabilities of mangiferin and isomangiferin. Hesperidin has been shown to be more thermally stable than other flavanones, such as narirutin, during pasteurization treatments of citrus juice.[35−37] Vicenin-2 remained stable during fermentation.

*C. maculata*, compared to other species analyzed to date, including *C. subternata*, *C. sessiliflora*, *C. intermedia*, and *C. genistoides*,[18,21] appears to have a less complex chromatographic profile, where only a few compounds are present in significant amounts for quantification purposes. Mangiferin and isomangiferin contents of extracts from green *C. maculata* were lower than those of *C. genistoides*, which to date had the highest mangiferin content of the species analyzed.[12,17,33] *C. maculata* extracts, however, contain more mangiferin than those of *C. subternata*, *C. intermedia*, and *C. sessiliflora*[18,21,38] and thus have potential for further development as a food ingredient extract with high mangiferin content, considering the interest in mangiferin as a nutraceutical compound.[13]

**Assessment of Genotypic Variation Using Chemometric Analysis.** To investigate the genotypic variation of *C. maculata*, the quantitative data for individual phenolic compounds and the complete chromatographic fingerprints of aqueous extracts were analyzed. The data from unfermented extracts of sample set 1 (wild-harvested; $n$ = 9) were combined with those of sample set 2 (cultivated; $n$ = 40) to provide a larger sample set.

*Data Pretreatment for Development of Fingerprints.* Before chemometric analysis of chromatographic fingerprints could be performed, a number of pretreatment steps were essential. The chromatograms of the *C. maculata* extracts before any pretreatment are shown in Figure 3a. From this figure it is clear that peak alignment was needed due to extreme shifts in peak retention times. These shifts could be due to column aging and general experimental variation,[17] as analyses were performed over a period of 4 months. Pretreatment, therefore, started with peak alignment, which was achieved by means of COW. This method was chosen because it is an efficient and popular method among chemometricians[15,25,39] and MATLAB code is freely available. COW consists of piecewise linear alignment of chromatograms toward a target chromatogram by means of stretching and compressing of segments using dynamic programming.[22] Peak alignment entails a trial-and-error-based selection of the best input parameters to obtain the optimal alignment toward a target chromatogram.[22] The latter chromatogram was selected as the one showing the highest correlation with all of the chromatograms in the sample set.[40] The optimal number of segments for alignment of the data set was between 60 and 100, whereas the optimal slack size was between 20 and 30 data points.

After peak alignment, the background was removed from the data set to further improve the relevance of the data for analysis.[23] A value of $10^4$ for the lambda ($\lambda$) input parameter for smoothing (usually between $10^2$ and $10^9$) was deemed optimal after visual inspection of the results.[41] The first derivatives of the signals were used to determine the signal smoothness. To account for differing HPLC injection volumes due to inevitable small instrumental variations and experimental weighing errors, normalization was applied to each vector (injection) to scale them to the same unit. Figure 3b shows the chromatograms after acceptable pretreatment was achieved. The chromatograms were shortened after pretreatment of the data, by removing the elution time representing the dead volume and the ascorbic acid peak from the start, and the time required for the re-equilibration of the column from the end of the chromatogram. The removal of these chromatogram sections was necessary to exclude all information that would not represent relevant data. Consequently, the dimensions of the new matrix were 98 × 5381.

*Comparison of Chromatographic Fingerprints and Quantitative Data.* The similarity of the fingerprint of each

sample extract to those of all other extracts was evaluated by calculating the Pearson product-moment correlation coefficients ($r$). For similar fingerprints, the correlation is high when $r$ is close to 1.[17] The results are presented in the form of a heat map indicating $r$ values for each pair of fingerprints by means of colors (Figure 4). Fingerprints for duplicate injections were

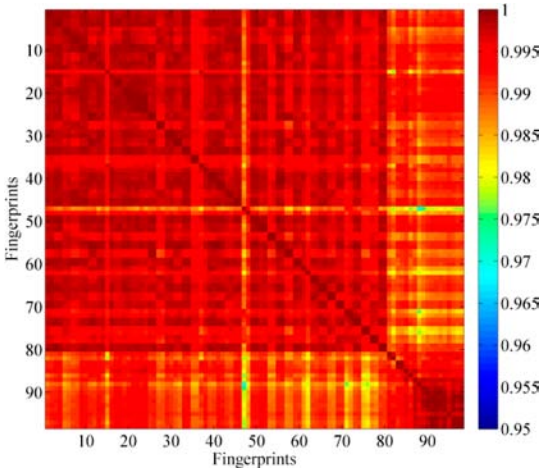

**Figure 4.** Heat map of correlation coefficients between fingerprints of *Cyclopia maculata* ($n$ = 98) after pretreatment (duplicate injections are shown as separate measurements).

extremely similar, confirming that pretreatment was effective. The similarity analysis showed that all of the extracts were surprisingly similar, with $r$ values ranging between ca. 0.97 and 1.00 (Figure 4). These high correlation values may, in part, be attributed to the simplicity of the chromatogram, which comprises only two large- and three medium-intensity peaks and many minor peaks. The high level of mangiferin in the samples, relative to the other compounds, limits the quantities injected so that detector response for the minor peaks is low. The fingerprints of the extracts prepared from wild-harvested (set 1) and cultivated (set 2) plants were very similar with regard to $r$ values. The wild-harvested plants were from the same wild population that provided the seeds for cultivated plants.

PCA was also performed on the combined data matrix of sample sets 1 and 2 after mean centering of the fingerprints to further explore the genotypic variation of the phenolic profile of *C. maculata*. On the basis of the first two principal components (PCs), the wild-harvested samples (set 1; $n$ = 9; no. 81−98) were clearly separated from the rest of the samples (set 2; $n$ = 40; no. 1−80) in the bottom right quadrant (Figure 5a). As indicated by the loadings (Figure 5b,c), this clustering of the wild-harvested samples is associated to a large extent with mangiferin and isomangiferin contents, whereas the samples from set 2 are associated with the remaining compounds. Quantitative data (Tables 2 and 3) showed that the mangiferin and isomangiferin contents of wild-harvested samples were slightly lower than those of the cultivated samples. On the other hand, the extracts of the wild-harvested samples contained only about half of the levels of hesperidin, maclurin-3-C-glucoside, and iriflophenone-3-C-glucoside compared to the extracts of set 2; this is likely the reason for the differentiation of the samples observed in Figure 5a. The lower hesperidin content for set 1 samples is attributed to the sieving process that removed the coarse pieces of stem. Analysis of *C.*

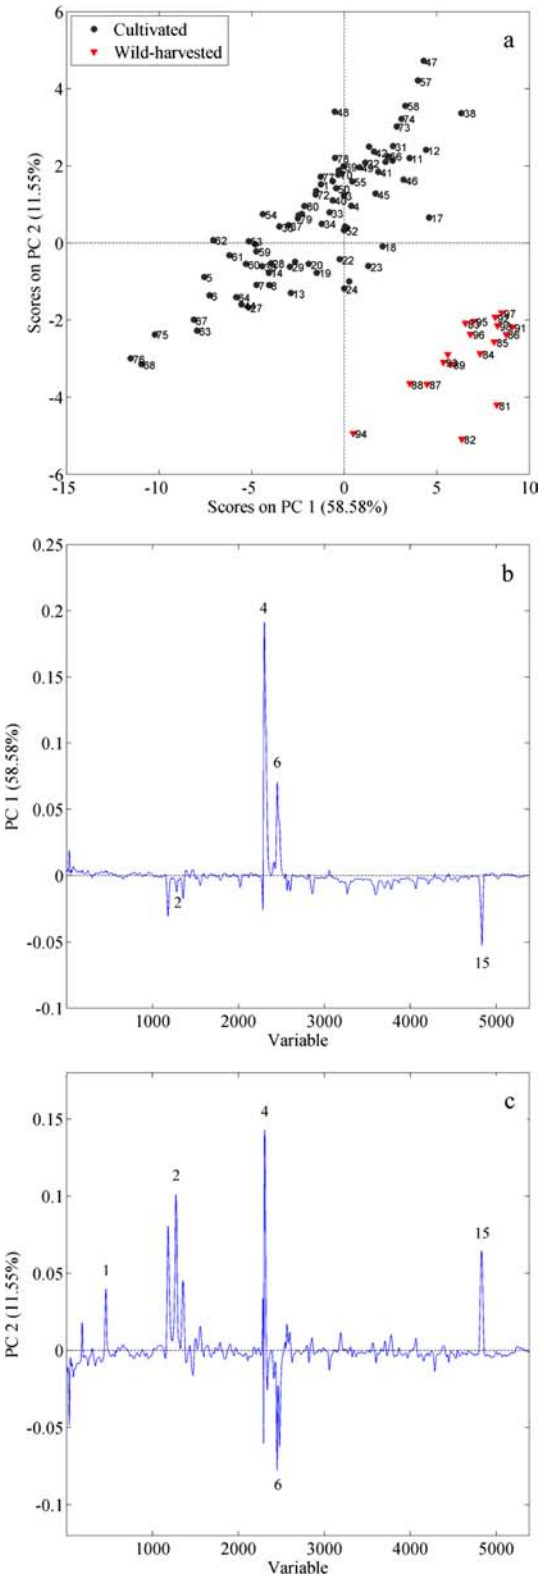

**Figure 5.** (a) PCA scores plot of PC1 versus PC2 for fingerprints of *Cyclopia maculata* samples ($n$ = 98) and loadings plots of (b) PC1 and (c) PC2.

*maculata*[42] and *C. subternata*[21] leaf and stem plant material showed that hesperidin is mostly concentrated in the stems. However, this does not explain the lower iriflophenone-3-C-glucoside and maclurin-3-C-glucoside concentrations in the wild-harvested samples. Other differences between the sample

**Table 3. Quantitative Data from Aqueous Extracts of Unfermented (Green) *C. maculata* (Cultivated) ($n$ = 40; Set 2)**

| compound | content (g/100 g soluble solids) | | | | |
|---|---|---|---|---|---|
| | mean | min | max | SD[a] | %RSD[b] |

[a]Standard deviation. [b]Relative standard deviation as percentage of mean.

sets include growing conditions and harvest season: wild-harvested plants grew in marshy conditions and were harvested in summer, whereas the cultivated plants were irrigated and harvested in winter. Joubert et al.,[43] investigating *C. genistoides*, showed that environmental factors could affect levels of these compounds.

For PC3 of the fingerprint data ($n$ = 98) of the extracts, more information was revealed and sample duplicates 47 and 48 were separated from the other samples (Figure 6a). Upon further investigation (Figure 6b), it was determined that the chromatograms of this sample contained a peak (peak a) that none of the other samples contained (Supporting Information, Figure S3). According to the quantitative data this "atypical" sample also had the highest quantity of hesperidin (data not shown). The loadings of PC3 also indicate that hesperidin contributes to this differentiation (Figure 6b). PC4 and PC5 did not reveal any further information of interest.

If similarity analysis were performed using a fixed cutoff of 0.95 for $r$, the "atypical" sample would still be considered as similar to the other samples, despite its having the lowest overall correlation with the other samples. Additional exploratory analysis (PCA) was useful to identify a unique feature while indicating some basis for differentiation from the other samples. It is therefore advisible that similarity analysis should not be used in isolation. Overall, the variation between the fingerprints of the different *C. maculata* extracts was relatively small, except for the clear differences in hesperidin content based on the stem-to-leaf ratio and the presence of an "atypical" extract. Quantitative data for selected compounds in the cultivated seedlings (Table 3) indicated relatively low variation, with %RSD values ranging from 12.5 to 16.3% for mangiferin, isomangiferin, vicenin-2, and hesperidin. The other compounds varied substantially more (%RSD values between 23.0 and 40.3%). Variation of the latter compounds in the wild-harvested seedlings was less than observed for the cultivated seedlings. In the case of wild-harvested seedlings, shoots of two to three bushes comprised a batch (i.e., sample) to obtain sufficient plant material for processing into paired unfermented and fermented plant material. The low variation in the xanthone content of *C. maculata* extracts would simplify production of extracts standardized on xanthone content. Previous research demonstrated large variation in the levels of the xanthones in *C. subternata* seedlings (%RSD > 30%),[21] one of the *Cyclopia* species used to prepare honeybush food ingredient extract that is standardized on mangiferin content.[2]

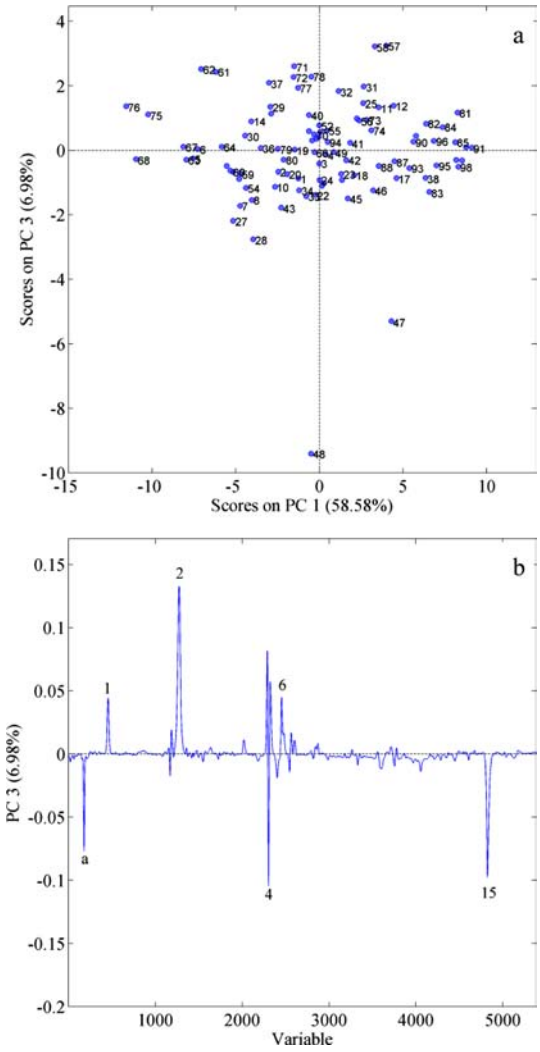

**Figure 6.** (a) PCA scores plot of PC1 versus PC3 for fingerprints of *Cyclopia maculata* samples ($n$ = 98) and (b) loadings plot of PC3.

In conclusion, the validated HPLC-DAD method proved suitable for the quantification of the major phenolic compounds present in aqueous *C. maculata* extracts and construction of chromatographic fingerprints. Several new compounds were tentatively identified for the first time in *C. maculata,* as well as in *Cyclopia* species, by means of LC-DAD hyphenated with high-resolution MS. The fermentation process decreased the concentrations of the phenolic compounds (except for vicenin-2), with the most notable effect on the xanthones mangiferin and isomangiferin. Quantitative data for individual phenolic compounds and fingerprint analysis of the complete chromatogram revealed that *C. maculata* shows very low genotypic variation, making this *Cyclopia* species ideal for the production of standardized food ingredient extracts.

sugared water at 37 °C for 20 min and added to the remaining six containers at a concentration of 25 g of yeast/hL, as suggested by the manufacturer. In both cases, the yeast inoculum was mixed with marc and spread at the bottom, middle, and top of the containers to ensure its homogeneous distribution in the pomace. Then the containers were hermetically closed and the fermentation and storage were performed at room temperature until distillation.

**Distillation.** Each 50 kg fermentation tank was divided in two equal portions, which were distilled separately by one method or the other. Six distillations per yeast were performed in both distillation systems.

*Alembic Distillations.* Fermented Albariño grape pomace (22−23 kg) was distilled in a 50 L copper charentais alembic. The base of the boiler was heated by direct fire, with natural gas as a heating source, and tap water was used to cool the total condenser. The heating power was set to obtain an initial average distillation rate in the range 1.3−1.8 L/h. On the basis of sensorial analysis, distillation products were separated into three fractions: head, heart, and tail. The head fractions were defined as the first 220 mL; the following 2320 and 1740 mL were collected as heart fraction for L1 and L2 distillates, respectively; and the following 600 and 880 mL were collected as tail fraction for L1 and L2 distillates, respectively.

*Packed-Column Distillations.* Fermented grape pomace of Albariño variety (22−23 kg) was distilled in a packed column with a 50 L copper boiler, previously described by Garcia-Llobodanin et al.[23] The base of the boiler was heated by direct fire, and the heating and partial condenser cooling rates of the distillation column were adjusted to obtain a distillate flow rate of 1.03 L/h. The first 240 and 280 mL was collected as head fraction for L1 and L2 distillates, respectively; the heart fraction was defined as the following 2320 and 2290 mL for L1 and L2 distillates, respectively; and the tail fraction was defined as the following 210 and 310 mL for L1 and L2 distillates, respectively.

**Microbiological Control.** Samples from grape pomace before fermentation and from each container before distillation were taken for yeast isolation. Twenty grams of marc was randomly collected from each container, dispersed in 100 mL of YEPD, and incubated in a rotary shaker at 28 °C for 2 h. Then the appropriate decimal dilutions in sterile water were spread on WL nutrient agar (Scharlau Microbiology, Barcelona, Spain) supplemented with 100 μg/mL chloramphenicol to inhibit bacterial growth. The plates were incubated at 28 °C until visible colonies appeared. After counting, 20 colonies from each sample were randomly selected, isolated as pure cultures on fresh YEPD plates, and stored in the same medium with 15% (v/v) glycerol at −70 °C for further characterization. All isolated colonies were plated on lysine agar medium (Scharlau Microbiology, Barcelona, Spain) to distinguish between *Saccharomyces* and non-*Saccharomyces* yeasts. *Saccharomyces* yeasts do not grow in this medium.

Yeast isolates were characterized at species level by polymerase chain reaction (PCR) amplification of the 5.8S rRNA gene and the two ribosomal internal transcribed spacers (ITS) and subsequent restriction analysis with the endonucleases *Hin*fI, *Hae*III, and *Cfo*I.[29] PCR products and their corresponding restriction fragments were separated on 2% and 3% agarose gels in 1× Tris−acetate−ethylenediaminetetraacetic acid (TAE) buffer, respectively. After staining with ethidium bromide (0.5 μg/mL), the DNA pattern bands were visualized under UV light and photographed with a Gelprinter Plus system (TDI).

Additionally, PCR amplification and sequencing of D1/D2 region of 26S rDNA gene were used to confirm yeast identification. The D1 and D2 domains were amplified by use of the primers NL-1 and NL-4 as described by Kurtzman and Robnett.[30] PCR products were purified by use of the PCR Extract Mini kit (5PRIME) according to the supplier's instructions. The same primers were used for sequencing with a BigDye Terminator v3.1 cycle sequencing kit (Applied Biosystems) and a 3130xl genetic analyzer (Applied Biosystems). Sequence similarities were obtained by use of GenBank BLASTN search facilities.[31] The identification was considered as correct when the identity of gene sequences was 98% or higher.

Those yeasts identified as *S. cerevisiae* were characterized at strain level by analysis of mitochondrial DNA restriction fragment length polymorphism (mtDNA-RFLP). Total DNA was obtained as described by Querol et al.[32] DNA samples were digested with the restriction endonuclease *Hin*fI (Promega) and the fragments obtained were separated by electrophoresis on 0.8% (w/v) agarose gels and visualized as described above.

**Chemical Analysis of Distillates.** Ethanol content (%, v/v) was measured by electronic densimetry according to the official method.[33]

Chemical composition of heart fractions was determined by gas chromatography coupled with flame ionization detector (GC-FID), with direct injection of the distillate, previously adjusted to 40% (v/v). Analyses were carried out on two different columns. Macroconstituents (methanol, higher alcohols, acetaldehyde, 1,1-diethoxyethane, ethyl acetate, ethyl lactate, 1-hexanol, isobutyraldehyde, ethyl formate, methyl acetate, 2-propenal, 2-butanol, and allylic alcohol) were determined on a capillary column CP WAX-57 CB (Varian) (50 m × 0.32 mm i.d. × 0.2 μm film thickness) on an Agilent 6890 chromatograph (Agilent Technologies, Waldbronn, Germany) equipped with a split/splitless injector following the methodology reported by López-Vázquez et al.[9] Separation of the remaining compounds was done on a Supelcowax 10 capillary column (30 m × 0.32 mm × 0.25 μm film thickness; Supelco Inc., Bellefonte, PA) in a Varian CP3900 GC chromatograph as described by López-Vázquez et al.[34] Samples were analyzed in triplicate.

**Sensory Analysis.** Evaluation of the distillates was carried out in two steps: first a ranking preference test and then a descriptive analysis. All distillates (heart fractions) were diluted with Milli-Q-treated water (Millipore Corp., Bedford, MA) to an ethanol content of 40% (v/v). The samples were served at room temperature in Association Française de Normalisation (AFNOR) glasses labeled with random numbers.

The first evaluation was carried out by a group of 10 females and 27 males, 18−60 years old (potential consumers) but not trained in specific evaluation of distillates. They were asked to rank by preference the distillates, evaluating separately aroma and taste of the spirits. The results were analyzed by the Friedman statistical test.

The second evaluation was a descriptive sensory analysis performed by a trained panel (five people) with experience in distillates assessment. Previously, the most representative descriptive attributes of the distillates were defined in an initial tasting session according to the method described in the ISO 13299:2003 standard.[35] The chosen attributes were aroma and taste descriptors. This test consisted of a preliminary round-table discussion, where the panelists defined the terms: 11 aroma descriptors (floral, fruity, vegetal/herbaceous, spicy, positive general impression, solvent, rancid, oxidized, pungent, burnt/smoky, negative general impression) and eight taste descriptors (astringency, mellowness, sweet, harmony, alcoholic, persistence, prickling, and general quality in mouth). Then an individual smelling and tasting of the samples was carried out by the panelists in order to qualify the distillates. The intensities of the descriptors were rated on a discontinuous scale from 0 to 5. A score of 0 indicated that a descriptor was not perceived, and a score of 5 indicated the highest intensity.

**Statistical Analysis.** One-way analysis of variance (ANOVA) was applied to the data obtained from the GC analysis. The aim was to ascertain whether the distillation system and/or yeast strain led to any significant differences (at 5% level) in volatile composition of the spirits. The variables that showed significant differences were used for principal component analysis (PCA). All statistical analyses were performed with the SPSS statistical package (version 17.0).

## RESULTS AND DISCUSSION

**Microbiological Control.** Albariño grape pomace presented a yeast population of $2.3 \times 10^5$ colony-forming units (cfu)/mL before inoculation and fermentation. This value was similar to that described by Bovo et al.[14] for Italian marcs but lower than the counts reported in more recent studies.[12,15] The distribution of yeast species is the following: *Metschnikowia pulcherrima* and *Hanseniaspora uvarum* were the predominant species found, at 43.5% and 52.2%, respectively, whereas *S.*

[a]Different letters before the comma in the same row indicate a significant difference ($p \leq 0.05$) with respect to the distillation system (within the same yeast strain). Different letters after the comma in the same row indicate a significant difference ($p \leq 0.05$) with respect to the yeast strain (within the same distillation system). [b]$\sum$ 1-propanol, 2-Methyl-1-propanol, 1-butanol, 2-butanol, allylic alcohol, 2-methyl-1-butanol, and 3-methyl-1-butanol.

*cerevisiae* was not detected. An isolate of *Pichia kluyveri* was also identified at 4.3%. These results partially agree with those reported by Bovo et al.[14] for Italian marcs. They found that *Hanseniaspora* sp. and *M. pulcherrima* were the main yeasts, although their distribution was different, with dominance of the apiculate yeasts, and *S. cerevisiae* was present below the detection limits. Other yeast species have been reported in Prosecco marcs[14] and marcs from Portugal.[13]

After inoculation, Albariño pomace was allowed to ferment, and then it was stored until distillation. In order to evaluate the prevalence of the added yeast strain for fermentation and during the storage period, pomace samples from each container were taken before distillation. The presence of both bacteria and yeast was found in almost all samples, although only yeast isolates were characterized. The results showed that in all *S. cerevisiae* L1 fermentations except for L1-5, the inoculated strain was the dominant yeast even after the storage period. In L1-5, a different strain of *S. cerevisiae* (strain IV) was isolated. In addition, a non-*Saccharomyces* yeast species appeared with a frequency higher than *Saccharomyces*. The later was characterized as *Pichia membranifaciens*, a film-forming yeast that has oxidative activity,[36] suggesting that anaerobic conditions were not adequately kept in this container. This yeast is considered a common food spoilage species,[37] and its presence has been also reported at the end of fermentations of Prosecco marc.[14] On the basis of microbiological results, L1-5 was not considered for chemical analysis and ethanol yield, to avoid misleading conclusions.

The commercial yeast L2 did not show the same ability to ferment and survive in Albariño pomace as the native EVEGA strain. It only appeared as the leader strain in four out of the six fermentations performed; in one of them, L2-5, it was isolated as the dominant strain (frequency 93%), but in the remaining containers it fermented in codominance with indigenous strains from pomace, reaching frequencies close to 50%. These findings confirm the suitability of L1 for grape pomace fermentation, since this strains is able to control fermentation when added as starter and also in spontaneous processes.[38] The ability of inoculated yeast strains to prevail over the autochthonous microorganisms during grape marc fermentation and storage has also been reported for grappa production.[15] All L2 fermentations were considered for chemical analysis and ethanol yield determination.

**Distillation.** *Ethanol Yield.* Table 1 summarizes the yield of ethanol recovery and the alcoholic strength for alembic and column distillations. For packed-column distillation, the heart-fraction ethanol yield was higher than that for alembic distillation for both yeast strains. Moreover, packed-column distillates also showed higher alcoholic strength of heart fraction (between 13.9% and 24.4% v/v) than alembic distillates. In addition, with the yeast strain L1 a higher heart-fraction ethanol yield was obtained, mainly when the alembic was used.

*Major Volatile Compounds in Albariño Grape Pomace Distillates.* Table 2 summarizes the average concentrations of macroconstituents and the ANOVA test results for the Albariño heart distillates grouped according to yeast strain and distillation system. From this table, differences in some components of the different distillates are revealed. The methanol content of the distillates obtained from pomace inoculated with L2 yeast was 34−40% higher than those obtained from pomace fermented with L1 regardless of the distillation system employed. No differences in methanol content were found between distillation systems, and its concentration remained under the legal limits of 1000 g/hL p.a.[2] in all cases. Although methanol formation depends on plant enzymes,[39] it was reported that differences in yeast growth might affect the conditions for pectin methyl esterase activity[16] and to the evolution of the volatiles compounds of the marc during the process of storage.[40] Our results support these findings. The concentration of ethyl acetate was almost 2-fold higher in the L1 distillates (mean value of 221.00 g/hL p.a.) than in the L2 ones (mean value 126.43 g/hL p.a.) when alembic distillation was used, whereas no differences were found according to yeast strain when packed-column distillation was used (mean values around 105−110 g/hL p.a.). In all cases, the values of this compound were within the permitted maximum concentration (250 g/hL) by the Regulation of the Geographic Indication of the Spirits and Traditional Liqueurs from Galicia and Its Regulating Council.[3] Acetaldehyde and 1,1-diethoxyethane are the major aldehydes in grape marc distillates, accounting for more than 90% of total aldehydes.[41] The values of acetaldehyde obtained in this study were low (ranging between 21 and 32 g/hL) and within the orujo regulation limits (150 g/hL), indicating that the grape marc has been properly stored and distilled. No effect of yeast strain and/or distillation system on the concentration of acetaldehyde and 1,1-diethoxyethane was found. Similarly, no significant differences were found for the concentration of higher alcohols among the distillates, though their contents were slightly higher in alembic distillates (Table 2). The lower concentration is due to dilution by the higher recovery performance of ethanol in the heart fraction with packed-column distillation, since the recovery of higher alcohols is similar for both distillation systems (Table 1). From this group, the only compound that showed significant differences among yeasts was 1-propanol, being higher in L2 distillates (Table 2). The concentration of 2-butanol was below 2.0 g/hL p.a. in all cases, indicating a minimum presence of bacteria in the pomace; their activity did not affect the distillate quality. When the total sum of higher alcohols was compared with those reported for spontaneously

fermented grape pomace distillates,[9,34] higher values were obtained in this study. This confirmed the fact that the amount of fusel alcohols is higher in inoculated fermentations.[16] The concentration of 1-hexanol was mainly influenced by the distillation system, with alembic distillates having the highest values (around 7.5 g/hL p.a.), although none surpassed the level (10−15 g/hL p.a) at which it can contribute negatively to the flavor of wine distillates.[42] The content of ethyl lactate, a typical tail compound, was significantly higher in heart fractions of distillates from alembic than those from packed columns (Table 2). No effect of the yeast strain was observed. The values obtained in this study were lower than 150 g/hL p.a, indicating no spoilage by lactic acid bacteria during fermentation, and the distillates obtained could have favorable characteristics, since ethyl lactate is able to stabilize and soften the harsh flavours of distillates.[43,44]

*Minor Volatile Compounds in Albariño Grape Pomace Distillates.* Tables 3 and 4 summarize the average concentrations of microconstituents and ANOVA test results for the Albariño heart distillates grouped according to yeast strain and distillation system. Among the minor volatile compounds identified, the low molecular weight ethyl esters (C6−C12) were the most influenced by both distillation system and yeast strain (Table 3). Distillates fermented with L1 yeast and distilled with a packed column had the highest concentration values. Previous studies also reported similar results comparing distillations of fruits via batch column and alembic.[23,45,46] It is interesting to note that the concentration of C6−C12 ethyl esters obtained with L1 yeast, independent of the distillation system used, was higher than those obtained for L2 distillates, and the values were also higher than those reported for grape pomace distillates.[9,34] This yeast strain (L1) has already been reported to produce higher amounts of ethyl esters and fatty acids than other yeast strains in Albariño wines.[26] Similar behavior was observed in the sum of acetates of higher alcohols; higher values were obtained for the L1 and packed-column distillates in comparison with the L2 and alembic ones, although this difference was not significant when the distillation system is compared. These compounds are of fermentative origin and contribute fruity (banana and apple) notes to distillates.[47,48] In contrast, a clear effect was not found on the total amount of high molecular weight ethyl esters (C14−C18) with respect to distillation system and yeast strain. However, within this group, ethyl hexadecanoate was significantly higher in packed-column distillates independent of the yeast strain used (mean values of 3.63 and 4.38 g/hL p.a. for L1 and L2, respectively). The concentration of isoamyl esters was low (<0.13 g/hL p.a.) in all distillates; significant differences were found for isoamyl octanoate according to yeast strain. These compounds are produced by yeast during fermentation[49] and have been identified with fruity aroma in grappa from Moscato.[50] The levels of isoamyl esters referenced in other varieties of grape pomace were lower than the detection limits;[34] thus our results suggest that L1 yeast may increase these values in less aromatic varieties.

Regarding minor alcohols (Table 4), no differences were appreciated between strains, except for *trans*-2-hexen-1-ol, whose concentration was higher for L1 distillates. In contrast, differences were observed in the sum of linear alcohols (C7−C10) according to distillation system; benzyl alcohol, 2-phenylethylethanol, and 3-ethoxy-1-propanol concentrations were higher in alembic distillates. As shown in Table 4, the overall concentration of monoterpenols, typical varietal compounds that impart fruity notes to distillates, was similar in all distillates (ranged between 1.67 and 1.21 g/hL p.a.). Significant differences were found only for linalool according to distillation system, being higher when alembic was used.

On the other hand, diethyl succinate (Table 3), a compound linked to the intensity of the tail-fraction aroma, ranged from 2.33 to 4.86 g/hL p.a., showing higher levels in the distillates from the alembic than in those obtained with the column. This result is in accordance with those found for other typical tail-fraction compounds (ethyl lactate, 2-phenylethanol, and benzyl alcohol). Other minor compounds detected were less affected by yeast strain or distillation system; however, from Table 4 it is possible to observe that L1 yeast produced a higher concentration of benzaldehyde and a lower concentration of furfuraldehyde than L2, although the difference was significant only for one of the two distillation systems (alembic for benzaldehyde and packed column for furfuraldehyde).

**Principal Component Analysis.** Those compounds that showed significant differences among systems and/or yeasts were considered for principal component analysis (PCA), except for those influenced by cut supervision at the distillation process like 2-phenylethanol, diethyl succinate, ethyl lactate, and benzyl alcohol. To simplify the analysis, the concentration of ethyl esters C6−C12, acetates of higher alcohols, and linear alcohols were grouped as family sums. Two principal components were obtained (PC1 and PC2), which explained 73.75% of the variance (Table 5). These components are shown in Figure 1, in which the separation of samples according to yeast and distillation system used can be clearly seen. PC1 accounts for 38.70% of the total variance and clearly differentiates the spirits according to yeast strain. L1 distillates were located on the positive side of PC1, whereas those from L2 where plotted on the negative side of this component. L1 distillates were characterized by higher concentrations of ethyl esters C6−C12, isoamyl octanoate, *trans*-2-hexenol, and acetates of higher alcohols than L2 ones. On the contrary, L2 distillates were defined by a higher content of methanol and 1-propanol. PC2 accounts for 35.05% of the total variance and differentiates the spirits according to distillation system. Alembic distillates (top) were characterized by higher levels of linear alcohols, linalool, 1-hexanol, and 3-ethoxy-1-propanol,

**Table 5. Principal Component Analysis Results for Volatile Compounds Analyzed in Heart Fractions of Different Distillates**

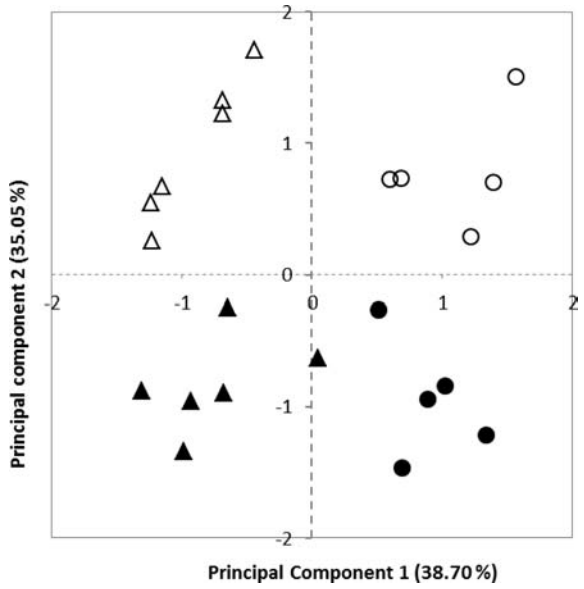

**Figure 1.** Principal component analysis of volatile composition of Albariño grape pomace distillates (heart fraction): L1 yeast (circles) and L2 yeast (triangles); alembic spirits (open symbols) and packed-column spirits (solid symbols).

whereas column distillates (bottom) were characterized by higher concentrations of ethyl hexadecanoate.

**Sensory Analysis.** The preference test did not show any significant taste and aroma difference (Friedman test $p < 0.05$) among the distillates according to the distillation system and yeast strain. In contrast, a noticeable difference according to the distillation system and/or yeast strain is observed for results obtained from the descriptive test (Figure 2). For aroma (Figure 2A), the distillates obtained from column and L1 yeast were scored with the highest PGI (positive general impression) and described by fruity character. This could be related to ethyl esters C6−C12 and acetates of higher alcohols, which were present in higher concentrations in these distillates (Table 3). The distillates obtained from alembic and L2 yeast received the lowest scores in some aromas (fruity, herbaceous, and spicy). However, the distillates obtained from L1 and distilled in alembic had the highest punctuation in oxidized and solvent attributes, which may be due to the fact that this distillate was the only one with concentrations of acetaldehyde (31.96 g/hL) and ethyl acetate (221 g/hL) close to the perception thresholds (30−50 and 180 g/hL, respectively).[51,52] It also can be noted in Figure 2 that distillates obtained with alembic had higher concentration of compounds associated with floral nuances (1-linalool and linear alcohol). However, the difference in these concentrations was not large enough (Table 1) for the panel to be able to differentiate the distillates according to this characteristic.

The panel of experts was able to differentiate the distillation system by taste (Figure 2B) but not the yeast. Distillates obtained from alembic (independent of the yeast strain) were characterized by the highest scores in astringency and the lowest scores in positive attributes (sweet, harmony, mellowness, and general quality in mouth). This result may be attributed to the interactions of the different compounds present in the studied distillates.

In summary, a packed column is an excellent option to produce orujo distillates, which are characterized by positive sensations in mouth and reduced intensity of negative aromas

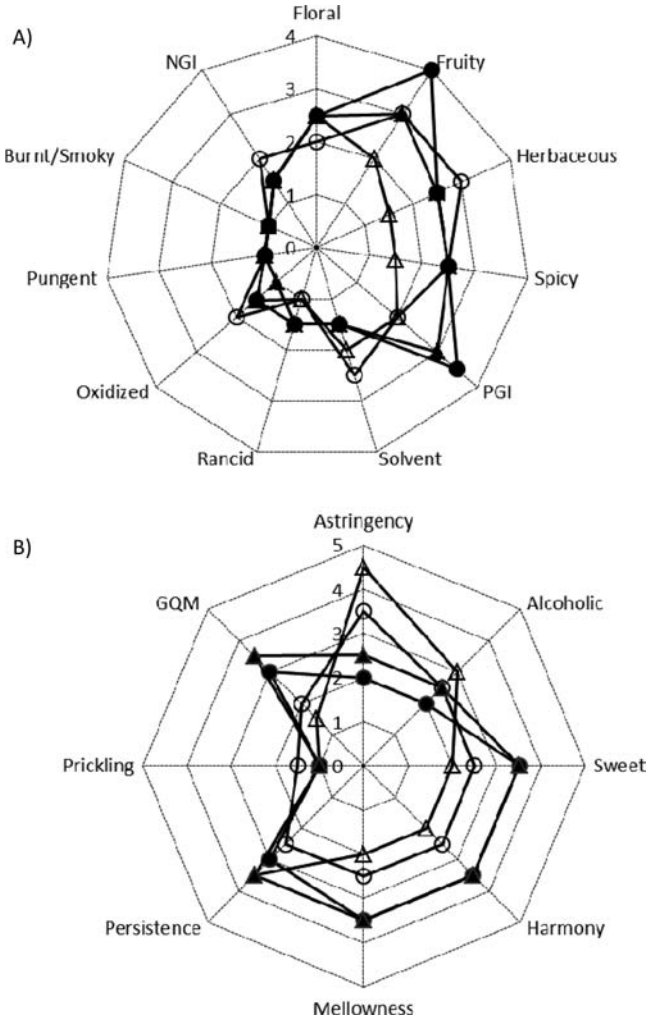

**Figure 2.** Spider diagram of descriptive sensory analysis for Albariño grape pomace distillates (heart fraction): (A) aroma profile and (B) taste profile. L1 yeast (circles) and L2 yeast (triangles) and alembic spirits (open symbols) and packed column (solid symbols) are shown. PGI, positive general impression; NGI, negative general impression; GQM, general quality in mouth.

(oxidized, solvent). Combined with an adequate yeast strain (L1 in this case), packed-column distillates present fruity notes attributable to their high concentrations of alcohols, acetates, and C6−C12 ethyl esters. Moreover, packed-column distillation combined with L1 fermentation resulted in higher ethanol yields and produced orujo distillates with low methanol concentration.

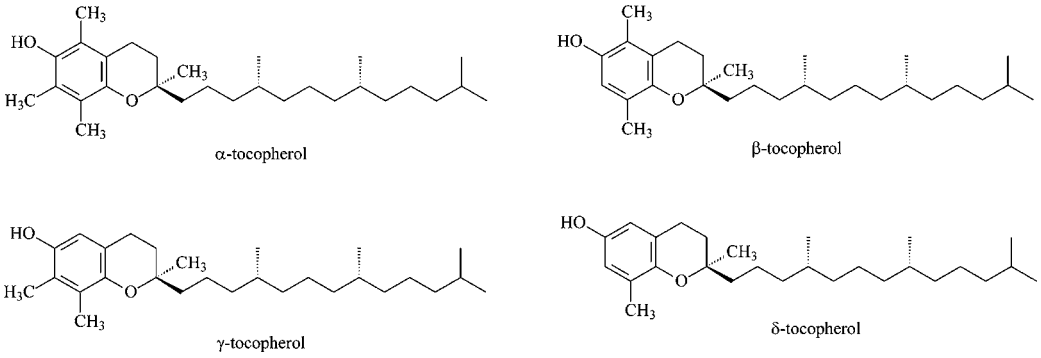

**Figure 1.** Structures of tocopherol homologues used in this study.

often explained by their differences in polarity.[12] Huang and coworkers[13] reported that the more polar $\gamma$-tocopherol was a more effective antioxidant than $\alpha$-tocopherol in corn O/W emulsions. Also, it was found that antioxidant activity of more polar $\delta$-tocopherol was better than $\alpha$-tocopherol in menhaden O/W emulsions, while in bulk menhaden oil, $\alpha$-tocopherol was a more effective antioxidant than $\delta$-tocopherol.[12] The physical location of antioxidants in O/W emulsions can be influenced by surfactant micelles, which can increase aqueous-phase antioxidant concentrations 2.3−7.5-fold.[14,15] In this study, we proposed to determine the effect of the Tween 20 concentration on the partioning behavior of $\alpha$-, $\gamma$-, and $\delta$-tocopherols and investigate how partitioning impacted the antioxidant activity of $\alpha$- and $\delta$-tocopherol in O/W emulsions. To accomplish this goal, the location of tocopherols in O/W emulsions was determined by high-performance liquid chromatography (HPLC), and antioxidant activity was determined by monitoring the formation of lipid peroxides and headspace hexanal.

## MATERIALS AND METHODS

**Chemicals and Materials.** Soybean oil was purchased from a local retail store in Hadley, MA. Iso-octane, 2-propanol, methanol, 1-butanol, *n*-hexane hydrochloric acid, and sodium phosphate dibasic were purchased from Fisher Scientific (Fair Lawn, NJ). Ethylenediaminetetraacetic acid (EDTA) was purchased from Chempure Ultra (Houston, TX). Silicic acid (100−200 mesh), activated charcoal (100−400 mesh), polyoxyethylene (20) sorbitan monolaurate (Tween 20), sodium phosphate monobasic, barium chloride dihydrate, ammonium thiocyanate, iron(II) sulfate heptahydrate, cumene hydroperoxide, hexanal, (±)-$\alpha$-tocopherol, (+)-$\gamma$-tocopherol, and (+)-$\delta$-tocopherol were purchased from Sigma-Aldrich (St. Louis, MO). The solvents were HPLC-grade, and all other chemicals were analytical-grade. Double-distilled and deionized water were used throughout the study. Glassware was incubated in 2 M HCl overnight to remove metals, followed by rinsing with double-distilled water before use.

**Preparation of Stripped Soybean Oil (SSO).** SSO was prepared according to the method by Boon et al.[16] and was used in all experiments. Briefly, silicic acid (100 g) was washed 3 times with a total of 3 L of distilled water and activated at 110 °C for 20 h. The activated silicic acid (22.5 g) and activated charcoal (5.63 g) were suspended in 100 and 70 mL of *n*-hexane, respectively. A chromatographic column (3.0 cm internal diameter × 35 cm height) was then packed sequentially with silicic acid, followed by activated charcoal, and then another layer of silicic acid. A total of 30 g of soybean oil was dissolved in 30 mL of *n*-hexane and passed through the column by eluting with 270 mL of *n*-hexane. To retard lipid oxidation during stripping, the collected soybean oil was held in an ice bath and covered with aluminum foil. After complete elution, *n*-hexane was removed with a vacuum rotary evaporator (model RE 111, Buchi, Flawil, Switzerland) at 37 °C, and traces of the remaining solvent were evaporated under a nitrogen stream. The SSO was flushed with nitrogen and stored at −80 °C until use. Removal of tocopherols in SSO was verified by HPLC.

**Emulsion Preparation.** O/W emulsions were prepared using 1.0 wt % SSO in a 10 mM phosphate buffer solution (pH 7.0). Tween 20 was used as an emulsifier at a 1:10 emulsifier/oil ratio. SSO, Tween 20, and phosphate buffer were added to a beaker, and a coarse emulsion was made by blending with a hand-held two-speed homogenizer (model M133/1281-0, Biospec Products, Inc., Bartlesville, OK) at the high speed setting for 2 min. The coarse emulsion was then homogenized with a microfluidizer (model M-110L, Microfluidics, Newton, MA) at a pressure of 9 kbar for three passes. During homogenization, ice was used to cover the homogenizer chamber and coil, to maintain the emulsion temperature at <25 °C.

After O/W emulsion was prepared, samples were mixed with 0, 0.1, 0.5, and 1.0 (w/w) Tween 20 and stirred by an electronic stirrer (model 2008, Thermo Fisher Scientific, Inc., Raleigh, NC) at 500 rpm for 1 h at room temperature. The emulsions (1 mL) were then transferred into 10 mL GC vials, capped with aluminum caps with polytetrafluoroethylene (PTFE)/silicone (tetrafluoroethylene) septa, and stored at 37 °C in the dark.

Particle size distributions of the final emulsions were measured using a dynamic light scattering instrument (Zetasizer Nano-ZS Malvern Instruments, Ltd., Worcestershire, U.K.). Samples for particle size distribution measurements were diluted into 10 mM phosphate buffer solution (pH 7.0) at an emulsion/buffer ratio of 1:50 to prevent the multiple scattering effects. Each measurement was determined in triplicate at room temperature. The average emulsion droplet size was 193.8 ± 14.4 nm, and there was no significant change in the droplet size of each emulsion over the course of studies (data not shown).

**Determination of Antioxidant Partitioning.** The physical location of $\alpha$-, $\gamma$-, and $\delta$-tocopherols in the emulsions were determined according to the procedure described by Panya et al.[15] Emulsions with various added Tween 20 concentrations (0, 0.1, 0.5, and 1.0, w/w) were prepared with 10 mM phosphate buffer, including 200 $\mu$M EDTA, to minimize oxidation of the antioxidants during analysis. $\alpha$-, $\gamma$-, and $\delta$-tocopherols in methanol were added to the emulsions at a final concentration of 100 $\mu$M. The emulsions were centrifuged at 162102*g* (46 000 rpm) for 1 h at 4 °C using a PTI F65L-6 × 13.5 rotor with a Sorvall WX Ultra 80 centrifuge (Thermo Fisher Scientific, Inc., Asheville, NC). After centrifugation, the aqueous phase was carefully collected with a needle and syringe. The aqueous phase (0.5 mL) was dried using a vacuum centrifuge drier and stored at −80 °C prior to further analyses. Aqueous-phase samples were dissolved in 200 $\mu$L of methanol, and tocopherol concentrations were determined by HPLC (Shimadzu, Kyoto, Japan) using a C18 reversed-phase column (150−4.6 mm, 5 $\mu$m, Beckman Coulter) equipped with a security guard column (C18, 4 × 3.0 mm, Phenomenex, Torrance, CA). An isocratic elution was carried out using methanol with a flow rate of 1 mL/min. Tocopherol homologues were detected with a fluorescence detector (scanning fluorescence detector, Waters 474, Milford, MA) at an excitation wavelength of 290 nm and emission wavelength of 330 nm. The concentration of tocopherols was calculated using a standard curve made from each tocopherol dissolved in methanol.

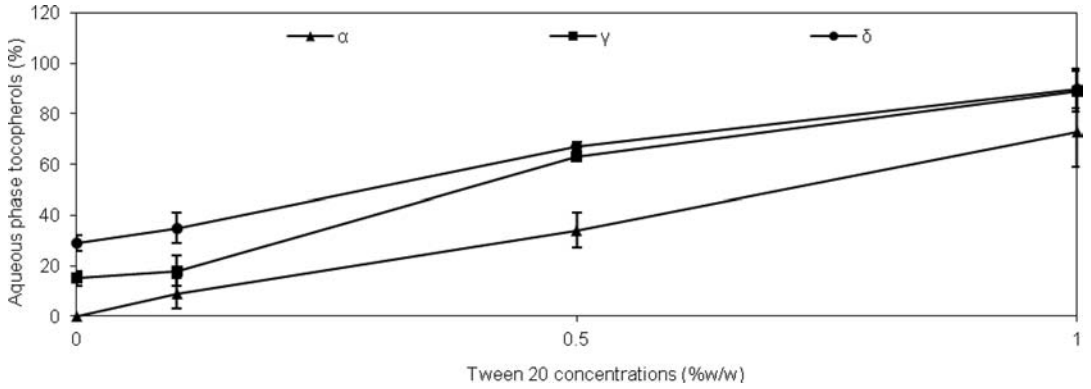

**Figure 2.** Effect of added Tween 20 (0, 0.1, 0.5, and 1%) on the partitioning of $\alpha$-, $\gamma$-, and $\delta$-tocopherols (100 $\mu$M) into the aqueous phase of 1% stripped soybean O/W emulsions. Data points and error bars represent means ($n$ = 3) ± standard deviations.

**Front-Face Fluorescence Measurements.** Front-face fluorescence of $\alpha$-tocopherol in O/W emulsions was determined by steady-state emission measurements recorded with a PTI spectrofluorometer (Photon Technology International, London, Ontario, Canada). Emulsions were prepared as described above with the addition of 30 $\mu$M $\alpha$-tocopherol. Final emulsions (1.5 mL) were transferred into triangular Suprasil cuvettes, and they were held in a sample holder at 25 °C. Emission was observed at 90° to the incident beam, that is, 22.5° with respect to the illuminated cell surface. The emission of $\alpha$-tocopherol was measured at 330 nm using an excitation wavelength of 299 nm. Spectral bandwidth for both excitation and emission slits was 2.0 nm; integration time was 1 s; and the wavelength increment was 2.5 nm. The intensity of the spectra of $\alpha$-tocopherol was determined as the emission signal intensity (counts per second) measured by means of a photomultiplier. The intensity ratio ($I_o/I$), where $I_o$ is the fluorescence intensity of $\alpha$-tocopherol, was plotted versus the concentrations of emulsifiers.

**Lipid Oxidation Studies.** For the lipid oxidation studies, $\alpha$- and $\delta$-tocopherols were added to the emulsions at a final concentration of 35 and 10 $\mu$M, respectively. Samples with methanol but without the addition of tocopherols were used as control samples. Lipid hydroperoxide formation was determined using the method adapted from Shanta and Decker.[17] Emulsion samples (0.3 mL) were mixed with 1.5 mL of isooctane/2-propanol solution (3:1, v/v) and vortexed (10 s, 3 times). The mixed solution was centrifuged at 3400$g$ for 10 min (Centrific centrifuge, Thermo Fisher Scientific, Inc., Fairlawn, NJ). The upper organic layer (0.2 mL or less according to the oxidation state) was mixed with 2.8 mL of methanol/butanol solution (2:1, v/v), followed by the addition of 15 $\mu$L of 3.94 M ammonium thiocyanate and 15 $\mu$L of $Fe^{2+}$ solution. The clear $Fe^{2+}$ solution was prepared freshly from the supernatant of a mixture of equal amounts of 0.132 M $BaCl_2$ (in 0.4 M HCl) and 0.144 M $FeSO_4$. The solution was vortexed, and after 20 min of incubation at room temperature, the absorbance of the samples were measured at 510 nm using an ultraviolet−visible (UV−vis) spectrophotometer (Genesys 20, Thermo Fisher Scientific, Inc., Waltham, MA). Hydroperoxide concentrations were determined using a standard curve prepared from cumene hydroperoxide.

Headspace hexanal was measured according to the method described by Panya et al.[18] using a gas chromatograph (GC, model GC-2014, Shimadzu Co., Tokyo, Japan) equipped with an autoinjector (model AOC-5000, Shimadzu Co., Tokyo, Japan). Emulsions (1 mL) in 10 mL glass vials capped with aluminum caps with PTFE/silicone septa were heated at 55 °C for 10 min in the autosampler heating block before measurements. A 50/30 $\mu$m divinylbenzene/carboxen/polydimethylsiloxane (DVB/carboxen/PDMS) stable flex solid-phase microextraction (SPME) fiber (Supelco Co., Bellefonte, PA) was then inserted into the vial headspace for 2 min to absorb volatiles. The fiber was transferred to the GC injector port (250 °C) for 3 min. The injection port was operated in split mode, and the split ratio was set at 1:7. Volatiles were separated on a fused-silica capillary Equity-1 Supelco column (30 m × 0.32 mm inner diameter × 1 $\mu$m) coated with 100% polydimethylsiloxane (PDMS) at 65 °C for 10 min. A flame ionization detector was used at a temperature of 250 °C. Hexanal concentrations were determined from peak areas using a standard curve made from authentic hexanal.

**Statistical Analysis.** All data shown represents the mean value ± standard deviation of triplicate measurements. The data obtained were analyzed by analysis of variance (ANOVA) using SPSS version 21 (SPSS, Inc., Chicago, IL). The differences between mean values were compared using Duncan's multiple-range test with a level of significance of $p < 0.05$.

## RESULTS AND DISCUSSION

**Impact of the Tween 20 Concentration on the Partitioning Behavior of Tocopherols in Stripped Soybean O/W Emulsions.** In this study, the effect of the surfactant concentration on the location of different tocopherol homologous in 1% stripped soybean O/W emulsions was determined by adding 0.1, 0.5, and 1.0% Tween 20 to the emulsions (Figure 2). The addition of all concentrations of Tween 20 increased the aqueous-phase concentration of all of the tocopherol homologues. Because the tocopherols are essentially insoluble in water,[19] the ability of Tween 20 to solubilize the tocopherols into the aqueous phase means that Tween 20 was forming comicelles with the tocopherols.

When the aqueous-phase concentration of the different forms of tocopherols were compared, they were in the order of $\delta$- > $\gamma$- > $\alpha$-tocopherols at all of the Tween 20 concentrations tested. At 1.0% Tween 20, the amount of $\alpha$-, $\gamma$-, and $\delta$-tocopherols in the aqueous phase was 73, 89, and 90%, respectively (Figure 2). $\delta$-Tocopherol is the most polar and most surface-active[20] of all of the tocopherols tested, which could explain why its solubilization into the aqueous phase by Tween 20 was greatest. Other researchers have reported that antioxidants in the emulsion droplet can migrate to the aqueous phase in the presence of surfactants. Richards et al.[14] found that Brij 700 was able to solubilize propyl gallate and butylated hydroxyltoluene out of emulsion droplets, with the more polar propyl gallate partitioning into the aqueous phase to a greater extent. Laguerre et al.[8] found that Brij 35 solubilized cholorogenic acid fatty acid esters out of emulsion droplets. Panya et al.[15] reported that Tween 20 solubilized rosmarinic acid esters out of the oil droplets, but in this case, the more nonpolar 20 carbon ester partitioned into the aqueous phase more than the 4 carbon ester.

It should be noted that the concentration of tocopherols in the presence of no added Tween 20 was in the order of $\delta$- > $\gamma$-

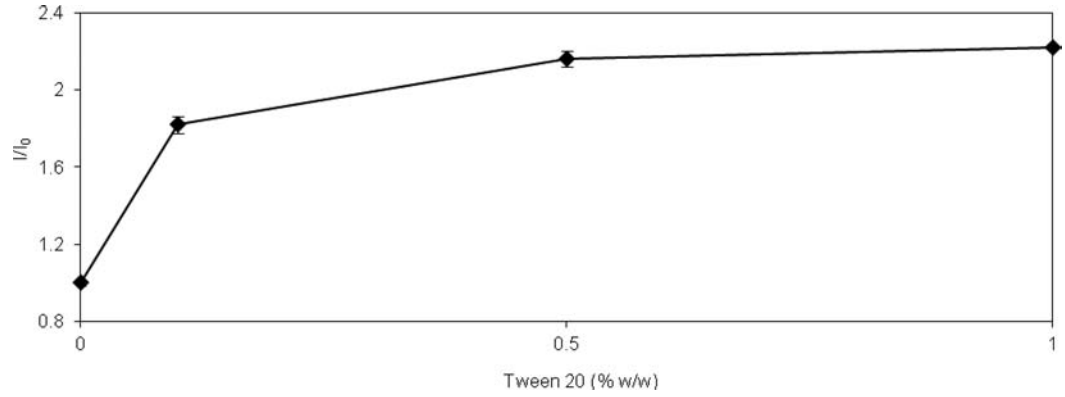

**Figure 3.** Front-face fluorescence measurements ($\lambda_{ex}$, 299; $\lambda_{em}$, 330) of 30 $\mu$M $\alpha$-tocopherol in 1% stripped soybean O/W emulsions with varying Tween 20 concentrations. Data points and error bars represent means ($n$ = 3) ± standard deviations.

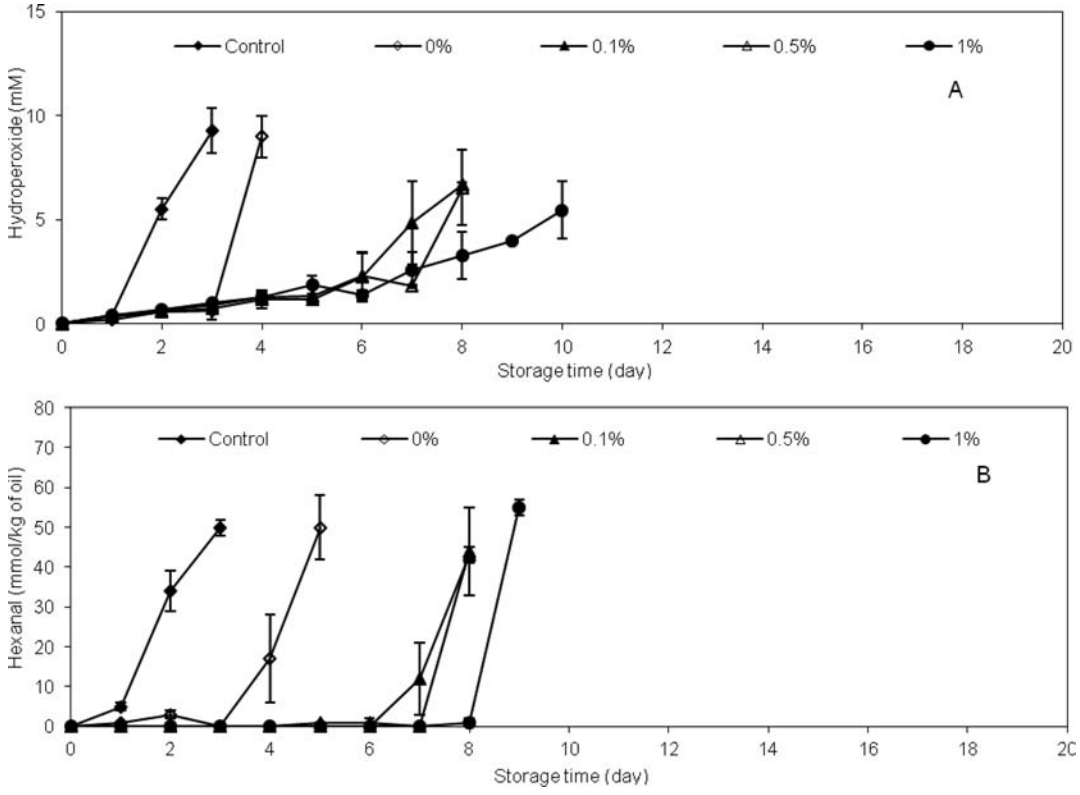

**Figure 4.** (A) Lipid hydroperoxide and (B) hexanal formation in 1% SSO−Tween 20 emulsions in the absence (control) or presence of $\alpha$-tocopherol (35 $\mu$M) as a function of added Tween 20 (0, 0.1, 0.5, and 1.0%, w/w) during storage at 37 °C. Data points and error bars represent means ($n$ = 3) ± standard deviations.

> $\alpha$-tocopherols at 0.1% Tween 20. All three tocopherol homologues are listed in the Merck Index as not being soluble in water.[21] During emulsion preparation, surfactants will concentrate at the droplet surface until the surface is saturated with the remaining surfactant partitioning into the aqueous phase.[14] Tween 20 has a low critical micelle concentration (cmc; <0.1 mM at 21 °C).[22] It is likely that Tween 20 present in the aqueous phase used in this study was at concentrations above the cmc, and these micelles were able to solubilize the tocopherols.

The process of measuring aqueous-phase antioxidant concentrations is time-consuming because of the need to separate the aqueous phase from the emulsion droplets by centrifugation. Therefore, we determined the possibility of measuring aqueous-phase tocopherol concentrations in the emulsions directly by fluorescence. In bulk oils, it is difficult to measure $\alpha$-tocopherol by fluoresce because of self-quenching.[5] However, if the tocopherols are present in the aqueous phase in surfactant micelles, this self-quenching could be decreased by physically separating the tocopherols into numerous micelles. The fluorescence intensity of $\alpha$-tocopherol with varying Tween 20 concentrations (0.1, 0.5, and 1.0%) as determined by front-faced fluoresce is shown in Figure 3. Increasing Tween 20 concentrations caused higher fluorescence intensity as $\alpha$-tocopherol was solubilized into the aqueous phase. Fluorescence intensity was 1.0-, 1.8-, 2.2-, and 2.2-fold higher in the presence of 0, 0.1, 0.5, and 1.0%, respectively. While the front-face fluorescence could detect the solubilization of $\alpha$-tocopherol into the aqueous phase, the increases in fluorescence did not strongly correspond to the aqueous-

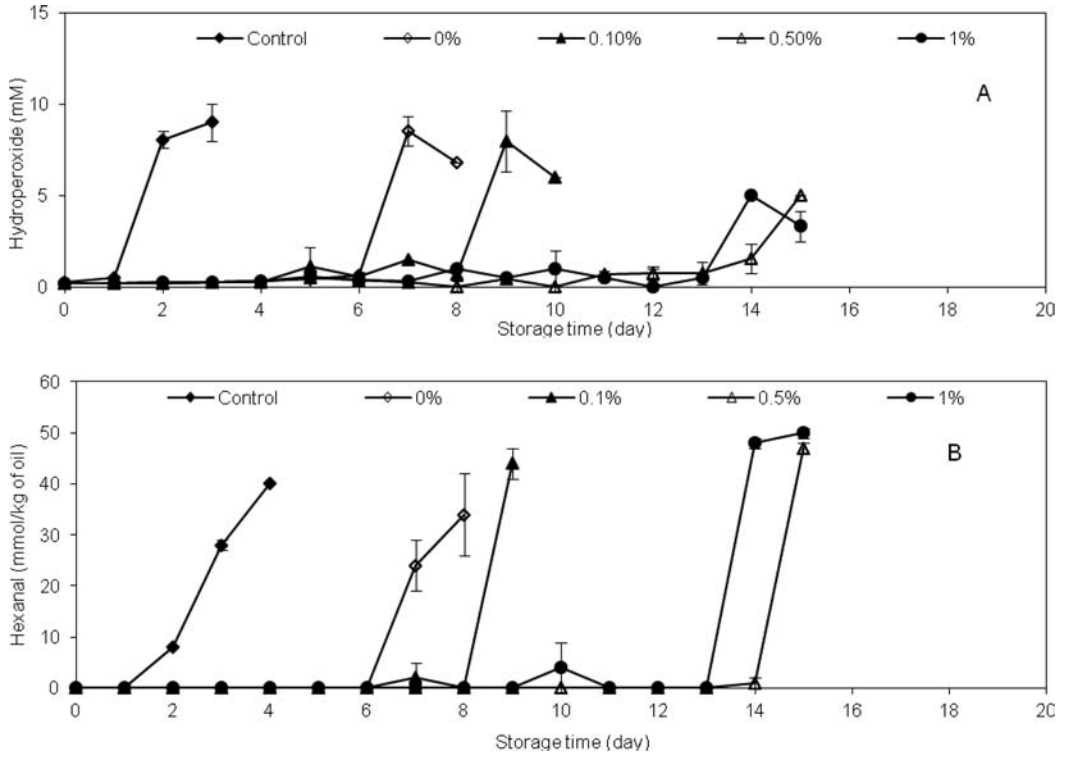

**Figure 5.** (A) Lipid hydroperoxide and (B) hexanal formation in 1% SSO−Tween 20 emulsions in the absence (control) or presence of $\delta$-tocopherol (10 $\mu$M) as a function of added Tween 20 concentrations (0, 0.1, 0.5, and 1.0%, w/w) during storage at 37 °C. Data points and error bars represent means ($n$ = 2) ± standard deviations.

phase concentrations determined by HPLC. For example, at 0.1% added Tween 20, fluorescence increased by over 80%, while actual aqueous-phase concentrations increased by less than 5%. Therefore, the front-faced fluorescence technique was not used for further studies.

**Impact of Partitioning on the Antioxidant Activity of Tocopherols.** The impact of the increasing concentrations of Tween 20 (0, 0.1, 0.5, and 1%) and, thus, the physical location of tocopherols on oxidative stability of 1% stripped soybean O/W emulsions were determined during incubation in the dark at 37 °C. Lipid oxidation rates of stripped soybean O/W emulsions with $\alpha$-tocopherol at a concentration of 35 $\mu$M were evaluated by lipid hydroperoxide and hexanal as indicators of primary and secondary oxidation products (panels A and B of Figure 4). The stripped soybean O/W emulsion without $\alpha$-tocopherol was used as a control. Lipid oxidation occurred rapidly in the absence of $\alpha$-tocopherol (control) with a lag phase of lipid hydroperoxide and hexanal formation of 1 day. The addition of 35 $\mu$M $\alpha$-tocopherol increased the lag phase for both lipid hydroperoxide and hexanal to 3 days. Increasing Tween 20 concentrations from 0.1 to 1.0% enhanced the antioxidant activity of $\alpha$-tocopherol in a concentration-dependent manner. The lag time of lipid hydroperoxide formation increased to 6−7 days, and hexanal formation improved oxidative stability to 6−9 days.

A similar trend was observed in O/W emulsions with $\delta$-tocopherol. In these experiments, $\delta$-tocopherol was added to the O/W emulsions at a concentration of 10 $\mu$M because preliminary studies showed that its activity was greater than $\alpha$-tocopherol. This was consistent with the study by Wagner et al., who reported that $\delta$-tocopherol was a better antioxidant in O/W emulsions than $\alpha$-tocopherol.[23] Huang et al. also reported that the more polar $\gamma$-tocopherol was more effective than $\alpha$-tocopherol in O/W emulsions.[13] As observed in the previous study, the lag phase of lipid hydroperoxide and hexanal formation in the control (without $\delta$-tocopherol) was 1 day (Figure 5). In the presence of 10 $\mu$M $\delta$-tocopherol, the lag phase for lipid hydroperoxide and hexanal increased to 6 days. Similar to $\alpha$-tocopherol, the activity of $\delta$-tocopherol was also enhanced by the presence of Tween 20 in the aqueous phase of the O/W emulsion. However, unlike $\alpha$-tocopherol, Tween 20 dramatically increased the ability of $\delta$-tocopherol to inhibit both lipid hydroperoxide and hexanal formation. The addition of 0.1% Tween 20 to the O/W emulsion increased the lag phase from 6 to 8 days. In the presence of 0.5 and 1.0% Tween 20, the activity of $\delta$-tocopherol was more than doubled, with lag phases of lipid hydroperoxide and hexanal formation of 14 and 13 days. Overall, the increased impact on $\delta$-tocopherol was not that unexpected; at both 0.5 and 1.0% Tween 20, the aqueous phase concentration of $\delta$-tocopherol was higher than $\alpha$-tocopherol (Figure 2).

This research and others[8,15] have found that increasing the concentration of hydrophobic antioxidants into the aqueous phase of O/W emulsions by surfactant micelles increases antioxidant activity. The reason for this phenomenon is currently unclear but has been proposed to be due to the ability of surfactant micelles to solubilize the antioxidant out of the emulsion droplet core, where they are ineffective antioxidants. However, this is contrary to the antioxidant polar paradox,[4] which states that the most effective antioxidants in lipid dispersions are those that remain in the emulsion droplet. The ability of surfactant micelles to increase the activity of hydrophobic antioxidants might be related to the hypothesis that antioxidants are most effective when they are at the interface of emulsion droplets.[7,15] Surfactant micelles can rapidly exchange lipid components between the micelles and

emulsion droplets.[24] Therefore, it is possible that the Tween 20−tocopherol comicelles could form a reservoir of tocopherols that could replace oxidized tocopherols in the emulsion droplets to maintain an optimum level of antioxidants. Alternately, it could be possible that reactive oxygen species could exist in the aqueous phase of the O/W emulsion, and the presence of the Tween 20−tocopherol comicelles could scavenge these radicals before they could oxidize the fatty acids in the oil droplets. This seems less likely because water-soluble antioxidants are often ineffective in O/W emulsions.[25]

This research highlights that tocopherols naturally occurring in refined oils are not reaching their maximum potential and could be made more effective in O/W emulsions if they can be solubilized into the aqueous phase by surfactant micelles. Unfortunately, this could be difficult in food emulsions because synthetic surfactant are not accepted by many consumers and many surfactants have unpleasant flavors. Therefore, more research is needed to gain a better understanding of how surfactant−antioxidant micelles impact the activity of antioxidants and how different surfactants effect antioxidant partitioning and activity, so that alternative strategies can be developed to increase the activity of tocopherols that are already present in the refined oils used in food emulsions.

inflammation mediators (e.g., IL-1$_\beta$, IFN-$\gamma$, TNF-$\alpha$, and IL-8) is considered a good approach to ascertain the status of the inflammation processes. Moreover, TNF-$\alpha$ released by monocytes/macrophages plays a key role in initiating the cascade of other pro-inflammatory cytokines, including IL-1$_\beta$, IL-6, and IFN-$\gamma$, which are important biomarkers in gastroenteric inflammation.[13] C-reactive protein[16] and fecal calprotectin[17,18] have been used widely as noninvasive markers of gut inflammation, including active IBD.

The aim of this study was to investigate the possible effects of moderate wine consumption on the gut immune status of healthy people through the study of a wide spectrum of fecal immune parameters, including several immunoglobulins, cytokines, chemokines, and growth factors. Possible relationships between contents of these immune parameters and of phenolic metabolites present in feces as a consequence of wine consumption were explored.

## MATERIALS AND METHODS

**Red Wines.** Initially, different enological parameters and practices, including grape variety and time of contact with seeds and skins, were optimized at the winery, with the aim of obtaining a red wine with especially high polyphenol content (data not shown). Finally, a young red wine (Pinot noir, vintage 2010) with a total phenolic content of 1758 mg of gallic acid equivalents/L and 12% ethanol was selected for the intervention study. Ethanol, pH, total acidity, and volatile acidity were determined in the wine according to the methods of the OIV (International Organization of Vine and Wine, 1990). The results were as follows: wine pH, 3.52; alcohol degree, 13.8% v/v; total acidity, 6.45 g/L tartaric acid; and volatile acidity, 0.56 g/L acetic acid. Wine phenolic composition determined by UPLC-ESI- MS/MS is shown in Table 1.

**Human Fecal Samples.** Fecal samples collected in a controlled and randomized human intervention study carried out at the CIAL-Institute of Food Science Research (CSIC-UAM) according to a computer-generated random-number table[19] involving 42 "healthy" volunteers (34 case and 8 control subjects; 23 women and 19 men; age range of 20−65 years) were selected for the present study. The participants were not suffering from any disease or intestinal disorder and were not receiving antibiotics or any other medical treatment for at least 6 months before the start of the study or during the study (including the washout period). All of the participants were fully informed about the study and gave written informed consent. The study was carried out according to the rules and approval of the Bioethics committee of Hospital "Ramón y Cajal" (Madrid, Spain).

The intervention study was divided into two consecutive periods: (a) an initial washout period of 2 weeks (baseline) during which the volunteers did not consume any wine or any other alcoholic beverage and followed a low-polyphenol diet and (b) a period of 4 weeks during which the case volunteers consumed a daily intake of red wine (250 mL) of red wine over 28 days (intervention period), divided into two doses. During this latter period, participants also maintained the restrictions for any other alcoholic beverages and followed a low-polyphenol diet. The control group ($n$ = 8) followed the same pattern as the case group ($n$ = 34), with the exception that no wine was ingested during this 4 week period.

Each participant provided samples of feces at two points: (a) after the washout period and (b) at the end of the study. Feces were immediately frozen and stored at −80 °C, no longer than 6 months, awaiting analysis. Only one freezing/thawing cycle was performed prior to the analysis and, after thawing, samples were kept on ice to prevent protease activity.

**Preparation of Fecal Solutions for Analysis of Immune Compounds.** Fecal samples (~0.1 g) were suspended in 1 mL of PBS. After homogenization, the samples were centrifuged (14000$g$, 15 min, 4 °C) and the supernatants (~200 $\mu$L) were collected.

**Detection and Quantification of Immune Compounds in the Fecal Samples.** Fecal concentration of immunoglobulins (Ig) Ig G1, Ig G2, Ig G3, Ig G4, Ig M, and Ig E, cytokines, chemokines, and growth factors, including interleukins (IL) 1$_\beta$, 2, 4, 5, 6, 7, 8, 10, 12(p70), 13, and 17, interferon-gamma (IFN-$\gamma$), tumor necrosis factor-alpha (TNF-$\alpha$), growth-regulated oncogene-alpha (Gro-$\alpha$), monocyte chemoattractant protein-1 (MCP-1), macrophage inflammatory protein-1$_\beta$ (MIP-1$_\beta$), granulocyte colony-stimulating factor (G-CSF), and granulocyte macrophage colony-stimulating factor (GM-CSF), were determined in fecal solutions by using the Bio-Plex Pro Human Isotyping assay and the Human Cytokine group I and II assay kits (Bio-Rad Laboratories, Hercules, CA, USA), following the manufacturer's protocol, in a Bioplex 200 system instrument (Bio-Rad Laboratories). Sample determinations were carried out in duplicate. Standard curves of each analyte were performed from triplicates of each assayed concentration on each plate, with the Bio-Plex Manager 6.0 software (Bio-Rad Laboratories). The variation coefficient for the standard curves between plates was <10%.

The concentration of Ig A in the fecal solution supernatants was determined using a specific enzyme-linked immunosorbent assay (ELISA) kit (Cusabio Biotech Co., Ltd., Wuhan, China), according to the manufacturer's instructions.

[a]Significant difference in the median values after intervention (nonparametric Wilcoxon test).

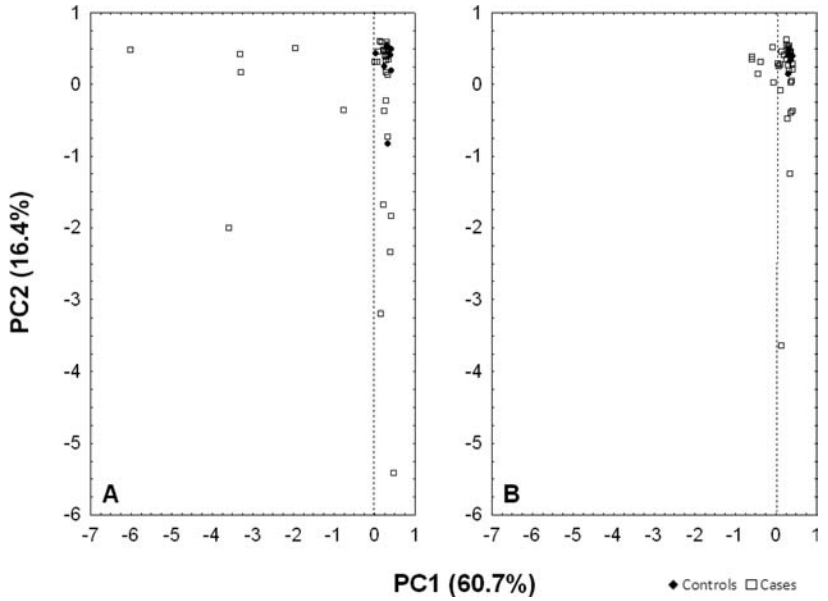

**Figure 1.** Representation of the volunteers (squares) and controls (rhombus), before (A) and after (B) intervention, in the plane defined by the two principal components.

**Quantification of Calprotectin.** Fecal calprotectin values were determined using a commercially available enzyme-linked immunosorbent assay (ELISA) Kit (Calpro, Lysaker, Norway). The standard curve of calprotectin was obtained from triplicates of each assayed concentration and fit to a four-parameter curve model according to the manufacturer's recommendations.

**Analysis of Phenolic Metabolites.** Phenolic metabolites were determined in the fecal samples as previously reported,[19] although in this paper data are arranged in a different manner according to the groups resulting from the analysis of immune compounds. Briefly, fecal samples were thawed at room temperature, homogenized, and weighed (1.0 g) in 15 mL sterile conical tubes. Ten milliliters of sterile saline solution (NaCl 0.9%, Fresenius Kabi, Spain) spiked with the internal standard (4-hydroxybenzoic-2,3,5,6-$d_4$ acid, Sigma-Aldrich, St. Louis, MO, USA) was added, vortexed, and centrifuged (10 min, 10000 rpm, 4 °C) twice. The supernatant (fecal solution) was filtered (0.22 $\mu$m) and diluted with acetonitrile (1:4, v/v, acetonitrile/fecal solution). Two microliters of sample was injected onto the chromatographic system. Fecal samples were analyzed by an UPLC-ESI-MS/MS method validated for the screening of >60 microbial-derived phenolic metabolites including phenols, valerolactones, and mandelic, benzoic, hippuric, phenylacetic, phenylpropionic, valeric, and cinnamic acids. The chromatographic conditions and MS/MS parameters (cone voltage, collision energy, and MRM transition) of the phenolic compounds targeted in our study were previously reported.[20] Fecal samples were analyzed in duplicate.

**Statistical Analysis.** The statistical analysis was performed using STATISTICA program for Windows, version 7.1 (Statsoft Inc., 2005,

[a]Median values, before intervention, with different letters are significantly different ($P < 0.05$) between groups (Mann−Whitney $U$ test). [b]Significant difference in the median values after intervention (nonparametric Wilcoxon test).

www.statsoft.com). As the data were not normally distributed, medians and interquartile ranges (IQR) were calculated for all of the groups. Principal component analysis (PCA) was used for exploration of the data and tentative classification of the case volunteers. For assessing significant differences between low- and high-cytokines-values subgroups before intervention, the nonparametric Mann−Whitney $U$ test was performed. For assessing significant differences before and after the intervention period for both the intervention group, either as a whole group ($n$ = 34) or divided into low-cytokines-values ($n$ = 28) and high-cytokines-values ($n$ = 6) subgroups, and the control group ($n$ = 8), the nonparametric Wilcoxon test was applied. In both cases, a value of $P$ = 0.05 was fixed for the level of significance of the tests. Finally, Pearson's correlation coefficients among the different immune parameters and between immune parameters and the total content of phenolic metabolites were calculated.

## RESULTS

**Changes in the Concentration of the Immune Parameters after Wine Consumption.** Without doubt, selection of the red wine for the intervention study is a key step in achieving maximum effects of wine active compounds in vivo. The wine used in this study was especially rich in flavan-3-ols, a class of compounds that represented 60% of the phenolic compounds identified (Table 1). Total flavan-3-ol content (270 mg/L) in this wine was relatively higher in comparison to that of other red wines.[21] After the wine intervention study, fecal samples from all of the subjects included in the intervention trial ($n$ = 42) were available for the immune parameters study. A high interindividual variability in the fecal concentration of the immune compounds analyzed in this study was observed either before or after the wine intervention (Table 2). Globally, no statistically significant differences in any fecal immune parameter were observed before or after wine consumption, except for IL-13 ($P$ = 0.044), when the whole intervention group ($n$ = 34) was considered (Table 2).

PCA was applied to all samples (before and after the intervention period), from both the intervention and control groups, to obtain a possible grouping of the volunteers according to their immune compound values. The first principal component (PC1) explained 60.7% of the total variance, whereas the second principal component (PC2) explained only 16.4% of the total variance (Figure 1). PC1 was highly correlated with the cytokine variables: G-CSF (−0.99326), IL-2 (−0.98931), IL-4 (−0.98626), TNF-$\alpha$ (−0.98531), IL-6 (−0.98453), IL-12(p70) (−0.98369), IFN-$\gamma$ (−0.98039), GM-CSF (−0.97632), IL-17 (−0.96915), IL-10 (−0.96162), IL-8 (−0.94341), MCP-1 (−0.93860), and IL-5 (−0.93454). Interestingly, the PCA representation allowed the detection of a volunteers' subgroup within the intervention group, which was characterized by significantly high concentrations for most of the cytokines before starting wine consumption (Figure 1A; Table 3), a fact that was in agreement with their low PC1 values. As a consequence, these six volunteers exhibiting high fecal cytokine values before intervention were considered as a subset (high-cytokines-values subgroup) clearly differentiated from the rest (low-cytokines-values subgroup, $n$ = 28) of the intervention group. The high-cytokines-values subgroup was formed by five men (age range 30−50 years) and one woman (age 50 years), all exhibiting BMI values within the normality (18.5−25). Then, the concentration of calprotectin in the samples of the six volunteers of the high-cytokines-values subgroup was determined to detect a potential intestinal inflammation. Results revealed that all of the volunteers from the high-cytokines-values subgroup exhibited normal fecal calprotectin values (2.07−37.73 mg/kg feces)[22,23] and inflammatory diseases were dismissed.

When the values obtained at the beginning and at the end of the study were compared, no significant differences in the concentrations of either immunoglobulins (data not shown) or cytokines, chemokines, and growth factors (Table 3) were found for the low-cytokines-values subgroup ($n$ = 28) or for the control group ($n$ = 8). However, significant differences were found for 16 of the 24 analyzed immune compounds (IL-2, IL-

4, IL-5, IL-6, IL-8, IL-10, IL-12(p70), IL-13, IL-17, IFN-$\gamma$, Gro-$\alpha$, MCP-1, MIP-1$_\beta$, TNF-$\alpha$, G-CSF, and GM-CSF) in the samples of the high-cytokines-values subgroup, after wine consumption (Figure 2; Table 3). Interestingly, among them, the medians of TNF-$\alpha$, IL-6, and IFN-$\gamma$ decreased 90-, 58-, and 30-fold, respectively, after the intervention period (Table 3).

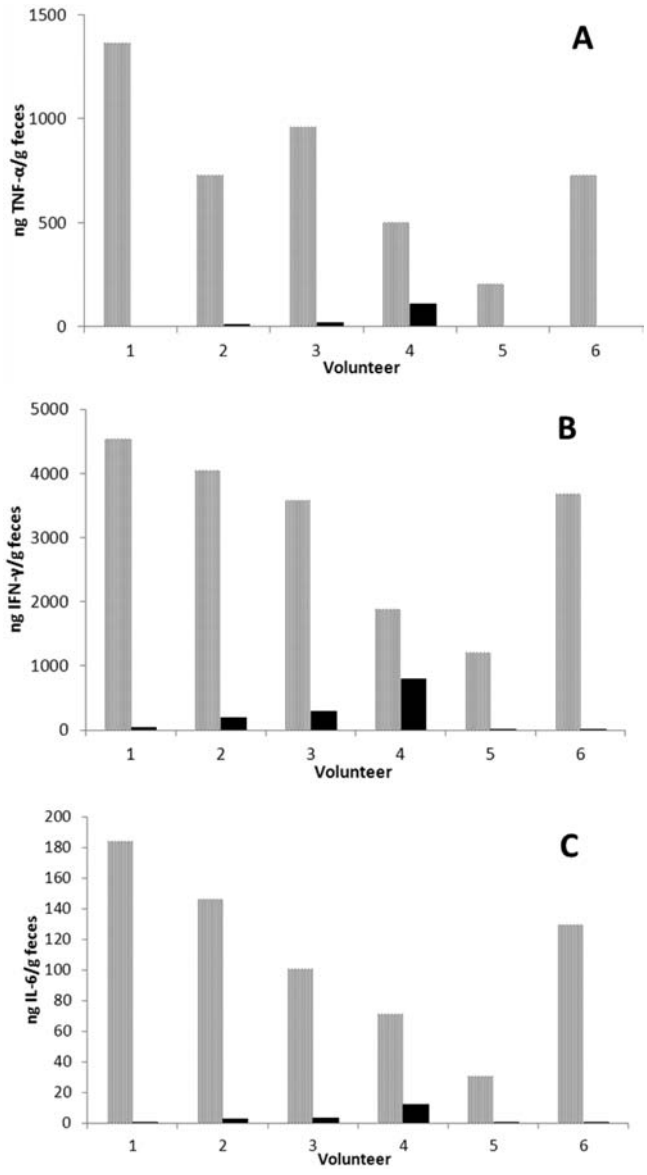

**Figure 2.** Line plots of variables TNF-$\alpha$ (A), IFN-$\gamma$ (B), and IL-6 (C) before (gray bars) and after (black bars) wine intervention in the high-cytokine-value subgroup.

**Relationships among Immune Compounds.** Pearson's correlation coefficients for cytokine values were determined for the samples of the two subgroups in which the case population was classified. Positive and significant correlations ($P < 0.01$) among the different cytokines were found for both the high- and low-cytokines-values subgroups before intervention (data not shown). In the high-cytokines-values subgroup, the highest correlations were established among the pro-inflammatory cytokines IL-2, IL-6, and IL-8 and also among IL-2, IL-4, and C-GSF. Correlations among cytokines in the low-cytokines-values subgroup were notably lower (data not shown). In both subgroups the cytokines with the lowest correlations were IL-1$_\beta$ and IL-7.

**Relationships between Immune Compounds and Fecal Phenolic Metabolites.** A total of 35 phenolic metabolites including mandelic acids, benzoic acids, phenols, hippuric acids, phenylacetic acids, phenylpropionic acids, valeric acids, valerolactones, and cinnamic acids were found in the fecal samples used in this study.[19] To better summarize changes after wine consumption and investigate a possible relationship with immune compounds, the sum of the concentration of all metabolites (total phenolic metabolite content) was calculated considering the subgroups exhibiting high and low cytokine content before wine intervention. For both groups, the range of variation (minimum−maximum interval) for the total fecal phenolic slightly moved forward after wine intake: from 122.2−501.1 to 169.2−864.6 $\mu$g/g (before and after wine intake, respectively) for the high-cytokines-value subgroup ($n = 6$) and from 46.2−1307.9 to 111.8−1364.5 $\mu$g/g (before and after wine intake, respectively) for the low-cytokines-values subgroup ($n = 27$, after excluding one volunteer not considered in our previous study[19]). Pearson's correlation coefficients between the content of immune parameters and the content of fecal phenolic were calculated separately for both the high- and low-cytokines-values subgroups, before and after wine consumption. For the high-cytokines-values subgroup and for data before the wine intervention, negative and significant correlations ($P < 0.05$) were found between the total content of phenolic metabolites and the immune markers IFN-$\gamma$ ($r = -0.892$), IL-8 ($r = -0.892$), and IL-6 ($r = -0.876$) (Figure 3). Interestingly, after wine intake, no significant correlations were found for any of these immune parameters, except for IL-8 ($r = 0.832$), but this fact was attributed to the high value obtained for the subject V25 in comparison to the rest of the group (Figure 3A). For the low-cytokines-values subgroup, no significant correlation between any cytokines and total phenolic metabolite content was found either before or after wine consumption (see Figure 3 for data corresponding to IFN-$\gamma$, IL-8, and IL-6).

## DISCUSSION

During recent years, the potential immunomodulatory and anti-inflammatory effects of wine have been investigated. These studies carried out so far have been performed in serum as biological fluid. Chiva-Blanch et al.[4] studied the seric concentrations of some inflammatory-related molecules after administration of red wine, dealcoholized red wine, or gin to high-cardiovascular-risk male volunteers and found that IL-6 concentration was significantly lower after the intake of wine or dealcoholized wine in comparison to that of gin. This finding suggested that wine compounds other than ethanol would be responsible for the IL-6 decrease. Another human intervention study with 35 healthy women who consumed white or red wine (~20 g ethanol/day) during two periods of 4 weeks also reported decreases in serum inflammatory biomarkers, such as C-reactive protein, and in IL-6 and MCP-1 after wine consumption.[24]

To our knowledge, this is the first paper to investigate the effects of wine in vivo on intestinal immunomodulation and inflammation in healthy volunteers. Our experimental design tried to assess changes in as many immune markers as possible to have the most complete overview of the immune status. The results of the study showed that moderate wine consumption for 4 weeks resulted in a significant decrease in the concentration of several cytokines among the volunteers of

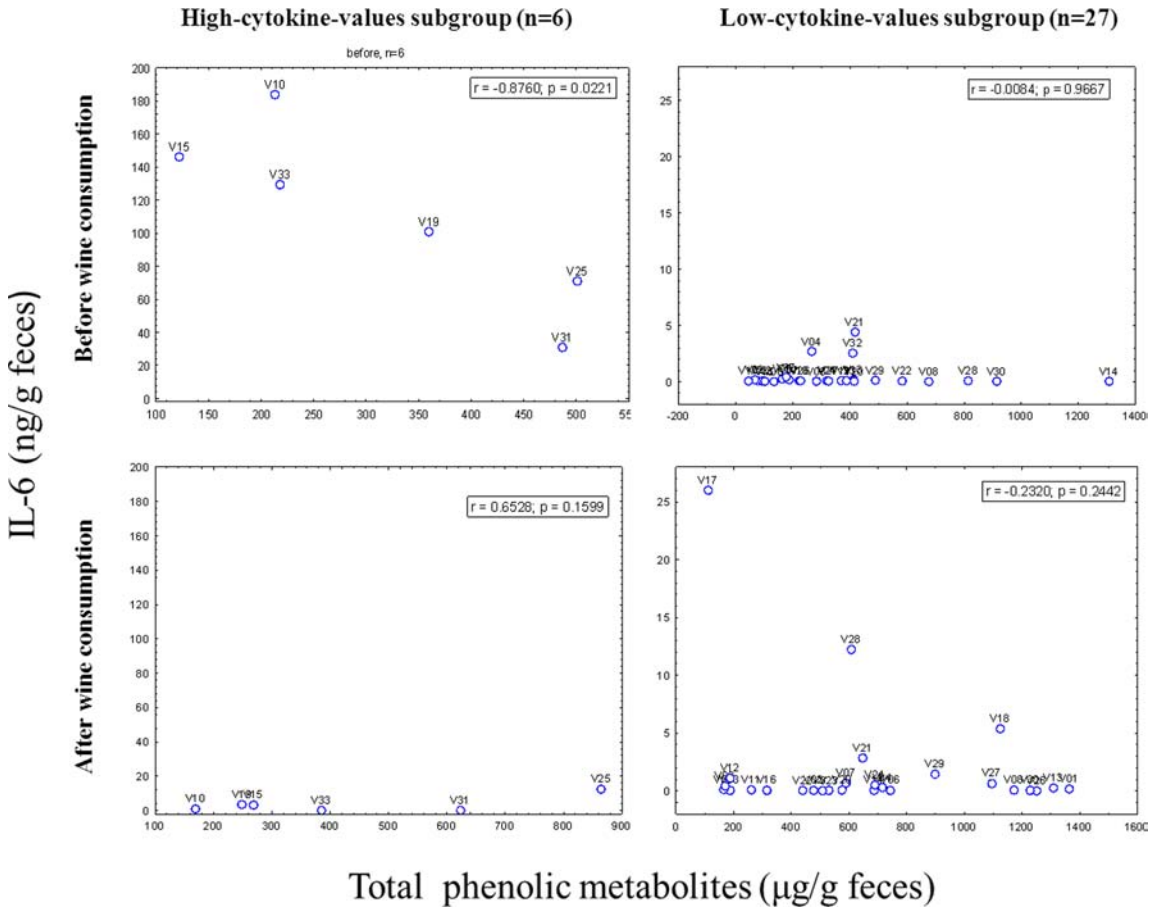

**Figure 3.** Correlation plots between contents of the immune compounds IFN-$\gamma$, IL-8, and IL-6 and of phenolic metabolites present in feces before and after wine intervention for both the high- and low- cytokine-value subgroups.

the subgroup that exhibited high cytokine values before the intervention (Table 3; Figure 2). No significant differences in the cytokine values were observed among the rest of the intervention volunteers after wine intake (Table 3; Figure 2). None of the control group's volunteers (no wine intake) exhibited high cytokine values in their initial samples, which could be due to its low number ($n$ = 8) in comparison to that of the intervention group ($n$ = 34).

Previous studies have shown anti-inflammatory effects of wine extracts in colonic cell models.[6,9,25] Nunes et al.[9] studied the effect of a red wine extract on a cytokine-stimulated HT-29 cell model and demonstrated that the extract significantly reduced the cytokine-induced overproduction of IL-8 in a dose-dependent manner. Angel-Morales et al.[26] used a red wine extract on an LPS-induced inflammation model of human colon CCD-18Co fibroblast cells and observed a decrease in the LPS-induced production of the pro-inflammatory cytokines IL-6 and TNF-$\alpha$. Another study assessed the effects of polyphenols on intestinal inflammation by using a Caco-2 Transwell model, and results confirmed that polyphenols from different sources, including red wine polyphenols, moderately modulate intestinal inflammation.[27] As red wine polyphenols comprise a great diversity of compounds, including phenolic acids, flavan-3-ols, and anthocyanins, studies with individual wine phenolic compounds have also been performed to specifically study the influence of the chemical structure on their anti-inflammatory properties. Bognar et al.[5] studied the anti-inflammatory effect of malvidin, a major red wine polyphenol, in an inflammation cell model and concluded that this compound was responsible, at least partially, for the positive effects of moderate red wine consumption on inflammation-mediated chronic maladies such as obesity, diabetes, hypertension, and cardiovascular disease. Other authors have studied the effect of polyphenols from different sources on experimentally induced gut inflammation in vitro and in vivo. Sergent et al.[11] tested different representative dietary phenolic compounds on an in vitro model of inflamed human intestinal epithelium and demonstrated that genistein and (−)-epigallocatechin-3-gallate provoked a decrease in IL-6 and IL-8 overproduction. Larrosa et al. and Sánchez-Fidalgo et al.[28,29] found significant reductions in the expression of IL-1$_\beta$, IL-8, IFN-$\gamma$, and TNF-$\alpha$ or IL-1$_\beta$ and TNF-$\alpha$, respectively, when administering hydrocaffeic acid or resveratrol, respectively, to the Dextran sulfate sodium (DSS)-treated rats used as a colitis model. Although most of these studies were conducted with the original phenolic forms present in wine or food, their derived metabolites may exhibit similar or enhanced anti-inflammatory properties.[28] In this context, a parallel study, focused on the phenolic metabolites present in the same set of fecal samples assayed in this paper, has revealed a great variability among subjects in the fecal content of phenolic metabolites (including benzoic, mandelic, hippuric, phenylacetic, phenylpropionic, cinnamic and valeric acids, phenols, valerolactones, and others).[19] Red wine phenolic content might be directly associated with the decrease observed in several cytokines after wine intake by the volunteers showing a high-

concentration cytokine profile before the intervention, because a significant increase of phenolic metabolites in the fecal profile was found after wine consumption. In this work, we demonstrated negative and significant correlations among the cytokines IFN-$\gamma$, IL-8, and IL-6 and the total content of phenolic metabolites for the high-cytokines-values subgroup before wine intake. This negative correlation between the content of certain cytokines and the content of phenolic metabolites at initial stages of gut inflammation (i.e., for the high-cytokine-value subgroup) suggested an anti-inflammatory action by phenolic metabolites at the epithelial level. In accordance with our findings, Chun et al.[30] found that intake of total flavonoid and also individual flavonol, anthocyanidin, and isoflavone intakes were inversely correlated with serum C-reactive protein in a large study ($n$ = 8335). Also, in another study with apparently healthy subjects ($n$ = 2115), Lanberg et al.[31] examined the association between the intake of total and six flavonoid subclasses as well as flavonoid-rich food sources in relation to plasma biomarkers of inflammation (including IL-6, IL-18, and C-reactive protein among others) and found negative correlations between several flavonoid classes and the pro-inflammatory cytokine IL-18. Cytokines play a key role in regulating the intestinal immune response and inflammation that is characterized by the loss of the physiological equilibrium between pro- and anti-inflammatory cytokines.[12] In our study, there was a significant decrease in the concentration of most of the tested cytokines after wine intake by the volunteers' subgroup characterized by high cytokines concentration in the initial sample. The decrease was especially noticeable in relation to those cytokines (TNF-$\alpha$, IL-6, and IFN-$\gamma$) that promote initial inflammation. Elevated values of fecal IFN-$\gamma$ and TNF-$\alpha$ have been observed in fecal samples from patients with bacterial diarrhea,[32] whereas increased concentrations of some pro-inflammatory cytokines, mainly TNF-$\alpha$, IL-1$_\beta$, and IL-6, have also been detected in feces of IBD patients.[33]

In summary, this study with healthy hosts showed, for the first time, that moderate consumption of a phenolic-rich red wine modulates the intestinal inflammatory response in vivo. This effect that could be attributed, at least partially, to the phenolic metabolites derived from wine polyphenols may be particularly beneficial for hosts with an initial (and still nonsymptomatic) stage of gut inflammation. These results will be the basis of further studies of wine consumption by patients affected by IBD.

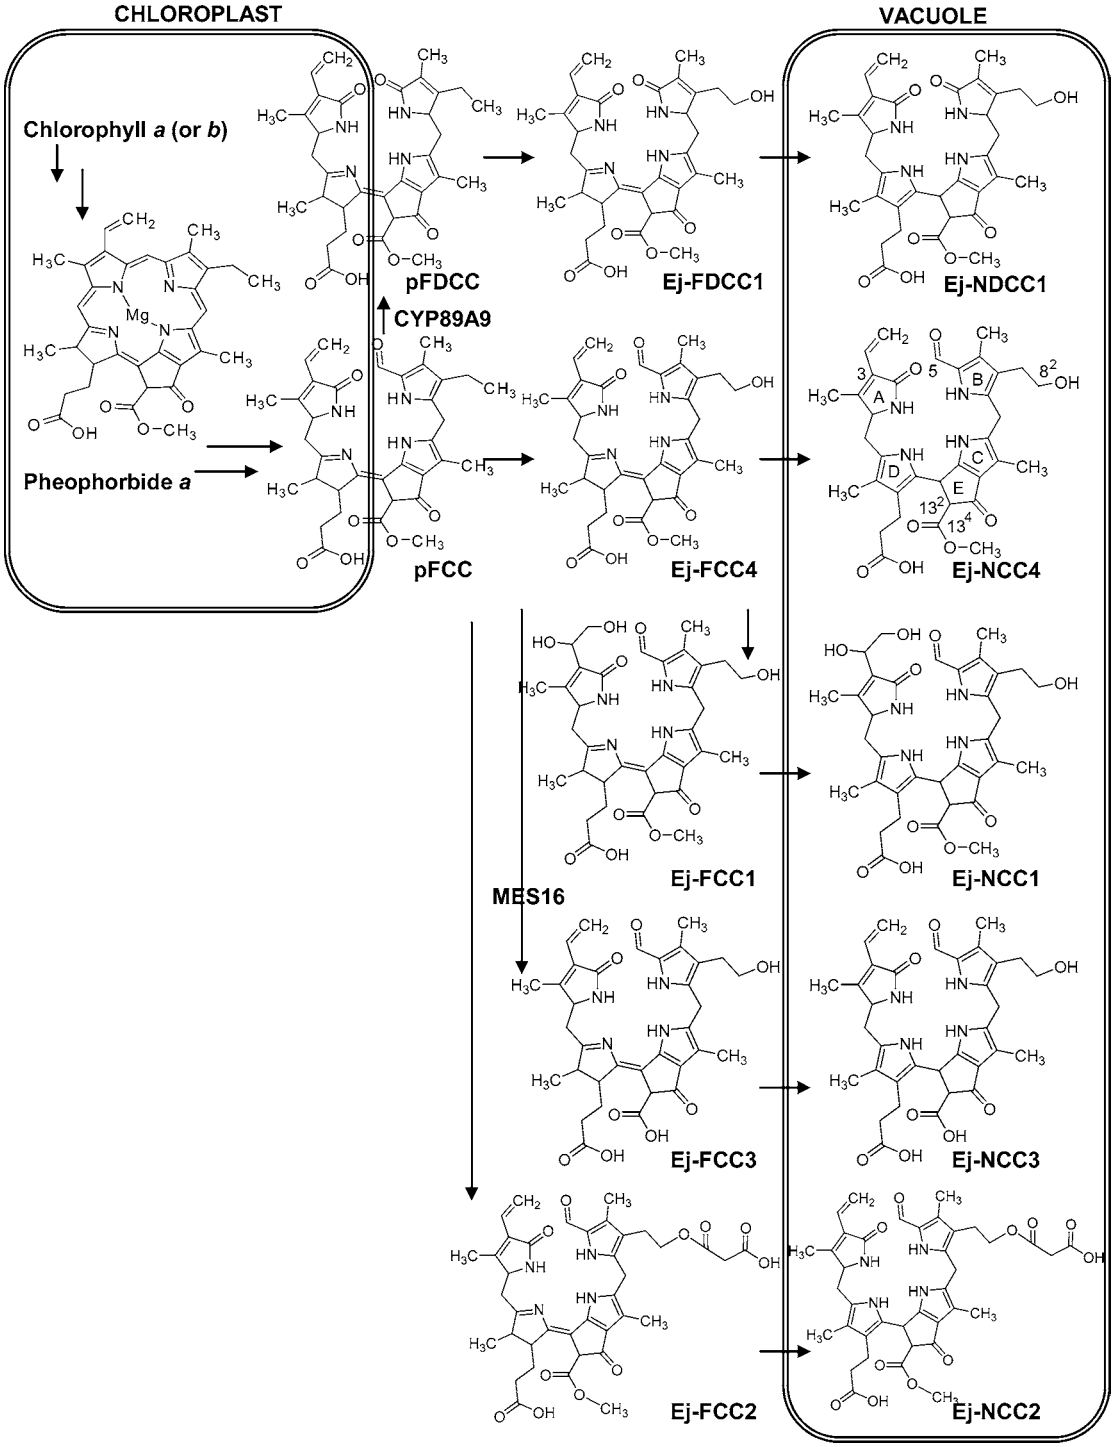

**Figure 1.** Proposed chlorophyll degradation pathway in senescent loquats fruits (*Eriobotrya japonica* Lindl.).

with electrospray ionization and mass spectrometry (HPLC–ESI–MS) with a couple of NCC/NDCC ratios equal to the catabolites identified in senescence leaves of maize (*Zea mays* L.) and barley (*Hordeum vulgare* L.), respectively, and a duo of two new structures.[13]

Autumn or early winter is time for loquats (*Eriobotrya japonica* Lindl.) to flower, and fruits are ripe in the market in late winter or early spring when few competitive fruits are available, so loquat fruits can be sold at higher prices.[14] The scientific literature describes the phenolics and antioxidative potential of loquat fruits,[15,16] but in relation to the chlorophyll fraction, only one publication[17] studied it considering its bioactive potential with medical purposes. Currently, numerous scientific studies point to tetrapyrroles as significant bioactive components related to cancer prevention, antioxidant and antimutagenic activity, mutagen trapping, modulation of xenobiotic metabolism, and induction of apoptosis.[18] Measurement of antioxidant capacity of NCCs brought new insights for the assignment of functionality to these molecules. It has been shown that NCCs display a similar antioxidant capacity to that of bilirubin, which points to a possible role of NCCs, to soften the stress induced by senescence.[11] This hypothesis is even

dx.doi.org/10.1021/jf503619s | J. Agric. Food Chem. 2014, 62, 10576–10584

more significant once it was shown that NCCs are resistant to digestion and absorbed by human intestinal epithelium.[19] The aim of this work was to determine NCCs/NDCCs profile in loquat fruits, a perennial species that may present an intricate process of chlorophyll catabolism, and produce a heterogeneous catabolites profile in comparison to the regular profile described in deciduous plant fruits described to date. To achieve this aim, a high-performance liquid chromatography coupled with electrospray ionization ion trap and quadropole time-of-flight mass spectrometry (HPLC/ESI-IT/qTOF-MS) method was applied to reach a high specificity for description of those already known NCCs and also to screen new structural rearrangements to expand knowledge of the chlorophyll breakdown route.

## MATERIALS AND METHODS

**Plant Material.** *Eriobotrya japonica* Lindl. trees (ca. 10 years old) were cultivated in an open field with a Mediterranean climate (Seville, Spain). Determination of the NCC profile was performed in naturally yellow fruits. Leaves of spinach (*Spinacea oleracea* L.) were bought at local market, and they were allowed to senescence by dark-incubation in distilled water in Petri dishes at 25 °C for 5−7 days.[20]

**Reagents.** Potassium phosphate was provided by Sigma-Aldrich Chemical Co. (Madrid, Spain). HPLC LC/MS grade solvents were supplied by Panreac (Barcelona, Spain). The deionized water used was obtained from a Milli-Q 50 system (Millipore Corp., Milford, MA, U.S.A.). Na (NaCOOH) (10 mM NaOH in 300 $\mu$L of formic acid) was used for calibration.

**NCCs Extraction.** Fresh material (ripened loquat fruits and senescent leaves of spinach) was homogenized in liquid nitrogen and extracted into four volumes of 20 mM potassium phosphate buffer (KPi), pH 7.0/methanol (1:3, v/v). The extract was centrifuged at 14 000 × *g* for 5 min, and the supernatant was concentrated[21] by a $C_{18}$ column (Bakerbond SPE, 500 mg/6 mL, J.T. Baker, Deventer, Holland). The SPE column was activated with two volumes of water and two volumes of methanol. Then, the extract, previously diluted to 80% with water, was applied to the column. The SPE with the sample was cleaned with four volumes of water for desalting, and the NCCs fraction was eluted with 1 mL of 20 mM KPi pH 7.0/methanol (1:9, v/v).[19]

**Liquid Chromatography/Electrospray Ionization Ion Trap/Time-of-Flight Mass Spectrometry.** The liquid chromatograph system was Dionex Ultimate3000RS U-HPLC (Thermo Fisher Scientific, Waltham, MA, U.S.A.). Chromatographic separation was performed as described earlier[22] but with modifications as follows. The eluent components were 0.1% (v/v) formic acid in water (A) and 0.1% (v/v) formic acid in methanol (B). The proportion of B was increased from 20% to 32% in 10 min, to 40% in 15 min, to 60% in 30 min, to 100% in 10 min, and held at 100% for 18 min. Initial conditions were reached in 2 min, and the equilibrium time was 10 min. The injection volume was 30 $\mu$L, and the flow rate was 1 mL/min. A stainless steel column (20 cm × 0.46 cm i.d.), packed with 3 $\mu$m $C_{18}$ Spherisorb ODS-2 (Teknokroma, Barcelona, Spain), was used. A split postcolumn of 0.4 mL/min was introduced directly on the mass spectrometer electrospray ion source. The HPLC/ESI-qTOF operated for mass analysis using a micrOTOF-QII High Resolution Time-of-Flight mass spectrometer (UHR-TOF) with qQ-TOF geometry (Bruker Daltonics, Bremen, Germany) equipped with an ESI interface. The HPLC/ESI-IT system operated for $MS^2$ analyses and selected an ion of a particular $m/z$ value to obtain exclusively its daughter ions. In this case, the instrument was operated in positive ion mode using a scan range from $m/z$ 50−1200. Mass spectra were acquired in MS fullscan mode, and data were used to perform multitarget-screening using TargetAnalysis 1.2 software (Bruker Daltonics, Bremen, Germany). $MS^2$ spectra were acquired in auto-$MS^2$ mode (data-dependent acquisition) and were used for structural confirmation of the compounds detected. Collision energy was estimated dynamically based on appropriate values for the mass and stepped across a ± 10% magnitude range to ensure good quality fragmentation spectra. The instrument control was performed using Bruker Daltonics HyStar 3.2.

**Data Analysis.** An in-house mass database created ex professo comprised monoisotopic masses, elemental composition, and, if known, retention time and characteristic product ions for 13 NCCs and the five NDCCs.[10,11,13,21−31] Additionally, elemental composition of new NCCs/NDCCs not described so far was included in the database. These new chlorophyll catabolites were generated holding two rules: (1) only those substituents already described in literature are allowed to enter in the basic NCC/NDCC structure and in the same carbon atom positions; and (2) dioxobilin-type chlorophyll catabolites are generated from all NCC structures (both known and new ones) by deformylation at C6 in ring B. Thus, some of the new NCC structures were the de-esterified form of *Nr*-NCC1 and the esterifed form of Bn-NCC1. Data evaluation was performed with Bruker Daltonics DataAnalysis 4.0. From the HPLC/TOF-MS acquisition data, an automated peak detection on the extracted ion currents (EICs) expected for the protonated molecule of each compound in the database was performed with Bruker Daltonics TargetAnalysis 1.2 software. The software performed the identification automatically according to mass accuracy and in combination with the isotopic pattern in the SigmaFit algorithm. This algorithm provides a numerical comparison of theoretical and measured isotopic patterns and can be utilized as an identification tool in addition to accurate mass determination. The calculation of mSigma values includes generation of the theoretical isotope pattern for the assumed protonated molecule and calculation of a match factor based on the deviations of the signal intensities. Only those hits with mass accuracy and mSigma values within the tolerance limits, which were set at 5 ppm and 50, respectively, are included in the final report list that was carried out using a Microsoft EXCEL-based script. This software has been successfully applied for screening of some other phytochemicals.[32,33] The interpretation of the $MS^2$ spectra was performed using the SmartFormula3D module included in the DataAnalysis software. This module includes an algorithm that estimates whether a formula for a product ion is a subset of a formula for the precursor ion. On the basis of expected chemistry, the elements carbon, hydrogen, oxygen, nitrogen, bromine, and iodine were allowed. Sodium and potassium were also included for the calculation of adduct masses. The number of nitrogen atoms was limited to an upper threshold of ten. The number of rings plus double bonds was checked to be chemically meaningful (between 0 and 50). For each NCC/NDCC detected in the sample, the module shows the original MS and $MS^2$ data as peak lists. From all possible formulas for the precursor ion, only one should fit with the elemental composition expected for the protonated molecule and satisfy thresholds for mass accuracy and mSigma values. Once the correct formula is selected, the module displays the formulas and neutral losses in the $MS^2$ spectrum fitting to the boundary conditions for the precursor ion, and they should be consistent with the $MS^2$ data peak list. The SmartFormula3D checks the consistency and highlights the monoisotopic peaks with formula suggestion and the related isotopic peaks. On the basis of this combined data evaluation, a fragmentation pattern for each NCC/NDCC can be generated to support its identification in the sample.

Mass Frontier 4.0 is a software package for the management, evaluation, and interpretation of mass spectra, including the automated generation of possible fragments and rearrangement mechanisms, starting from a user-supplied chemical structure. With this feature of the software, we can check the consistency between a chemical structure and its mass spectrum and recognize the structural differences between spectra of closely related compounds. The program generates a fragmentation scheme for the drawn molecular structure using fragmentation rules of mass spectrometry known in the literature as well as the selected ionization mode and the number of fragmentation steps. The program parameters used in this study were ESI ionization method, inductive cleavage, and five as the maximum number of reaction steps. The fragmentation reactions were selected to include hetero- and homolytic cleavage, neutral losses, and hydrogen rearrangements. Other parameters were left as their default values.

**Semipreparative HPLC Isolation of NCC Product(s).** To obtain enough quantity of *Ej*-NCC4, this catabolite was isolated from a NCC concentrated sample of loquat by semipreparative HPLC (injection volume, 500 $\mu$L; flow rate, 4.5 mL/min). Solvent A, 0.1% formic acid in water; solvent B, methanol; solvent composition (A/B) as a function of time (0−180 min), 0−5, 80:20; 5−120, 80:20 to 35:65; 120−180, 35:65 to 0:100. A stainless steel column (25 cm × 1 cm i.d.) packed with 3 $\mu$m C18 Spherisorb ODS-2 (Thermo Scientific Easy, Barcelona, Spain) was used. A split postcolumn of 0.30 mL/min was introduced directly on the mass spectrometer electrospray ion source using the same acquisition conditions described above. Three consecutive semipreparative HPLC runs were performed, and fractions containing *Ej*-NCC4 were collected at 59−61 min. For desalting, the aqueous solution was applied to a $C_{18}$ SPE column (Bakerbond SPE, 1 g/12 mL, J.T. Baker, Deventer, Holland) activated with two column volumes of methanol and preconditioned with two column volumes of water, washed with 20 mL of $H_2O$, and eluted with 4 mL of MeOH. The solvents were removed using a rotary evaporator.

**Chemical Derivatization of *Ej*-NCC4 Product.** Isolated compound was subjected to chemical derivatization for the identification of functional groups. Specific methylation of the hydroxyl function at the propionic acid group was performed with diazomethane.[34] An aliquot of the sample was dried with nitrogen and redissolved in methanol. Fresh diazomethane was generated from an ethereal solution of *N*-methyl-*N*-nitroso-*p*-toluene-sulfonamide in the presence of KOH and MeOH. A gentle stream of $N_2$ was bubbled from the reaction vessel, where diazomethane is generated, to the one containing the *Ej*-NCC4 solution to achieve the methylation reaction upon development of a light yellow color of the solution. For silylation, an aliquot of the isolated compound was dried with nitrogen and redissolved in 200 mL of bis(trimethylsilyl)trifluoroacetamide (BTSFA) in pyridine; the solution was heated at 90 °C for 20 min. Afterward, the final volume was evaporated with a nitrogen stream to 10 $\mu$L of MeOH for analysis by MS.[35]

## RESULTS AND DISCUSSION

**NCCs/NDCCs Profile in Senescent Fruits of Loquat.** Figure 2 depicts the HPLC 320 nm chromatogram obtained

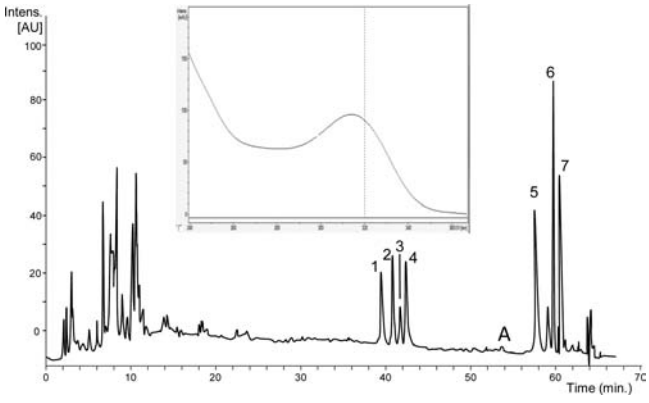

**Figure 2.** HPLC chromatogram of loquat senescent fruit extract acquired at 320 nm, showing the target compounds described in Table 1. Inserts correspond to UV spectrum of *Ej*-NCC4 (peak 9). A, artifact peak.

from the extract of ripened fruits of loquat and shows the NCCs/NDCCs identified through the application of the data-processing procedure from the acquired HPLC/ESI-TOF-MS data. Additionally, the UV−vis spectrum of the major NCC found (peak 9, *Ej*-NCC4) is included with the characteristic maximum absorbance peak at 320 nm as a consequence of the $\alpha$-formyl pyrrole moiety at ring B.[22] In ripened fruits of loquat, the nonfluorescent chlorophyll catabolite profile contains four different molecular formulas corresponding to NCCs and one to NDCC. Following the nomenclature convention (initials from latin species name followed by a number that indicates order in HPLC chromatogram),[36] these catabolites are designed as *Ej*-NCC1−*Ej*-NCC4 and *Ej*-NDCC1. Table 1 contains the mass spectroscopic characteristics of the NCC/NDCC detected in senescent fruits of loquat. Considering the elution order, *Ej*-NCC1 (peaks 1 and 3 in Figure 2) is the first NCC present in loquat fruits with a predicted elemental composition equal to $C_{35}H_{42}N_4O_{10}$, and with an experimental $m/z$ value equal to 679.2990 and 679.2974 for the protonated molecule (peaks 1 and 3, respectively). This compound should be equivalent to *So*-NCC2 described in senescent leaves of spinach,[22] and the results obtained for the standard *So*-NCC2 in our HPLC−MS system. The same elution time (39.4 min) with identical UV spectra and showing the same elemental composition and an experimental $m/z$ value equal to 679.2989 for the protonated molecule confirmed the hypothesis. Additionally, the characteristic product ions of *Ej*-NCC1 and *So*-NCC2 obtained by IT−$MS^2$ are the same. A signal at $m/z$ 647 corresponds to the product ion $[M+H-CH_3OH]^+$, $m/z$ 591, and $m/z$ 522 $[M+H\text{-ring A}]^+$. The high resolution ESI−TOF−$MS^2$ analysis of *So*-NCC2 from an extract of spinach senescent leaves and of its equivalent in loquat fruits confirms the consistency of the elemental composition and formulas of all product ions, which obtained positive records in all cases for both compounds. Consequently, *Ej*-NCC1 is the equivalent of *So*-NCC2 in loquat ripened fruits, which means a dihydroxylation in the vinyl group at C3, hydroxylation at $C8^2$, and keeps the esterification at $O13^4$ (Figure 1) .

*Ej*-NCC3 is the third NCC compound in elution order (57.7 min and 58.4 min, peaks 7 and 8, Figure 2) with an accurate mass for the protonated molecule of $m/z$ 631.2775 and 631.2762 and a predicted molecular formula of $C_{34}H_{38}N_4O_8$, identical to that of *So*-NCC3. The IT−$MS^2$ fragmentations of *Ej*-NCC3 are replicated in the corresponding analysis of the standard *So*-NCC3 in spinach extracts[22] and detailed in Table 1. Signals at $m/z$ 625 and 613 corresponding to the loss of $H_2O$ and that at $m/z$ 508 corresponding to the loss of ring A (both from the protonated molecule) were observed for *Ej*-NCC3 and *So*-NCC3. In addition, the elemental composition and formulas of all product ions were checked with the SmartFormula3D algorithm by high resolution ESI−TOF−$MS^2$ analysis of the *Ej*-NCC3 observed in loquat fruits and *So*-NCC3 in spinach, which obtained positive records for all fragments in both cases. The structure proposed for *Ej*-NCC3 maintained the vinyl group at C3, was hydoxylated at $C8^2$ and de-esterified at $O13^4$ (Figure 1).

The last chlorophyll NCC detected in loquat fruits was *Ej*-NCC4 (59.0 min and 60.4 min, peaks 8 and 9, Figure 2). The protonated molecule of this product was observed at $m/z$ 645.2910 in the high resolution ESI−qTOF−MS, with an elemental composition ($C_{35}H_{40}N_4O_8$) that fits with that of *So*-NCC4. The high resolution ESI−qTOF−MS data analysis of *So*-NCC4 showed the same predicted elemental composition as did *Ej*-NCC4 and an experimental $m/z$ value equal to 645.2918 for the protonated molecule (data not shown). The observed characteristic IT−$MS^2$ product ions for *Ej*-NCC4 and *So*-NCC4 were the same and are detailed in Table 1. The most prominent product ion was the one representing the loss of ring A, a characteristic fragmentation in the mass spectra of NCCs as well as the loss of methanol moiety from the protonated molecule that indicates the presence of a methyl

group at O13[4] as it has been previously described.[13,24,29] An additional product ion was observed corresponding to the loss of the propionic moiety at C17 ($m/z$ 571). This fragmentation has been described for chlorophyll derivatives[37] but not for NCCs so far. It is logical to assume that the fragmentation pattern of chlorophylls and their derivatives (NCCs) may display common product ions as in this case. To be sure that the signals obtained in the $MS^2$ analyses correspond to the predicted fragments, we checked the elemental composition and formulas of all product ions with the SmartFormula3D algorithm. Consistency of the monoisotopic peaks and the related isotopic peaks was determined by high resolution ESI−qTOF−$MS^2$ analyses, which obtained positive records for all fragments. The structure of *Ej*-NCC4 (and *So*-NCC4) is the simplest possible since it only implies the hydroxylation at C8[2], which maintains the vinyl group at C3 and the esterification at O13[4].

In addition, a chromatographic peak of the HPLC analysis (Rt: 55.8 min) of ripened fruits of loquat showed spectroscopic properties that match with those of a NCC (Supporting Information, S2). The MS spectrum of this "new" NCC indicated an elemental composition of $C_{36}H_{42}N_4O_9$, which means a molecular weight of 674.2951. The $MS^2$ spectrum, obtained by ESI−qTOF−MS to guarantee the interpretation with SmartFormula3D (Supporting Information, S3), shows two fragments corresponding to neutral losses of one or two molecules of methanol from the protonated molecule at $m/z$ 643.2762 $[M\text{-}CH_3OH+H]^+$ and at $m/z$ 611.2515 $[M\text{-}2 \times CH_3OH+H]^+$, respectively. In addition, the characteristic product ions corresponding to NCCs were also present, including the product ion at $m/z$ 552.2337 ($[M\text{-ring A}+H]^+$) and the product ion at $m/z$ 520.2105 $[M\text{-ring A-}CH_3OH+H]^+$ ion. With these data, the new NCC structure was tentatively assigned to the one presented in S3 of the Supporting Information. The compound derives from *Ej*-NCC4, to which a methoxy function was added at the C8[2] position. To confirm that the new NCC is an artifact produced during solvent extraction of the plant material from *Ej*-NCC4, ripened fruits of loquat were extracted with ethanol, and the HPLC gradient composition was changed by acetonitrile. A new compound was formed, with a protonated molecule at $m/z$ 689.3181, that is, the derivatization of *Ej*-NCC4 with ethanol; therefore, the new NCC is really an artifact produced during solvent extraction of the plant material. An FCC artifact formed during solvent isolation was reported recently[12] in banana fruits (*Musa acuminata* Colla) consisting of a trans-esterification by methanol at the propionic group. Special attention should be paid to the proper identification of noncolored chlorophyll catabolites since it seems they are prone to experiment modifications during solvent extraction.

**New NCC/NDCCs in Senescent Loquat Fruits.** Screening was not the sole strategy for NCC/NDCC determination; by exploiting the capabilities of this new methodology, we included in the target database elemental composition of new possible structures of NCCs/NDCCs not described so far. Of all of the plausible enzymes implicated in the modifications of FCCs (and consequently NCCs/NDCCs), only MES16, a methylesterase has been described, and taking into account that in loquat senescent fruits most NCCs (*Ej*-NCC1 and *Ej*-NCC4) are esterified, the ratio of esterified/de-esterified should be important in senescent fruits of loquat. Consequently, new theoretical structures were designed in base of de-esterifying or esterifying alternatives in already identified NCCs (not described to date). The methyl ester at the C13[2] form of *Bn*-NCC1 ($m/z$ 730.2850, $C_{38}H_{42}N_4O_{11}$) and the de-esterified forms of *Hv*-NDCC, *Zm*-NCC1, and *Nr*-NCC1 at C13[2], corresponding to the following masses and elemental compositions: $m/z$ 652.2744, $C_{33}H_{40}N_4O_{10}$; $m/z$ 826.3273, $C_{40}H_{50}N_4O_{15}$; and $m/z$ 878.3222, $C_{43}H_{50}N_4O_{16}$, respectively (Supporting Information, S1), were also included in the target database. Two positive matches (40.1 min and 42.2 min) with NCC UV absorption spectra were detected during the postprocessing procedure, both with an exact mass determined by high resolution ESI−TOF−MS of $m/z$ 731.2880 and 731.2878, corresponding to $C_{38}H_{42}N_4O_{11}$. Taking into account the structure of an NCC and the functional groups described, such an elemental composition could correspond to the ester form of *Bn*-NCC1, which means a vinyl group at C3, esterified at O13[4], and a malonyl group at C8[2] (Figure 1). Table 1 reports chromatographic characteristics of this NCC, designed as *Ej*-NCC2, following the nomenclature convention.[36] The $MS^2$ spectrum analyzed by IT−MS of *Ej*-NCC2 is shown in Figure 3, panel A. Besides the signal of the protonated molecule ion ($m/z$ 731), two signals of characteristic product ions of *Bn*-NCC1[20] are detected, one at $m/z$ 552 and the other at $m/z$ 522, corresponding to the $[M\text{-ring A-malonyl} +H]^+$ ion.

Within this strategy of including new possible structures in the target database of elemental composition for the screening

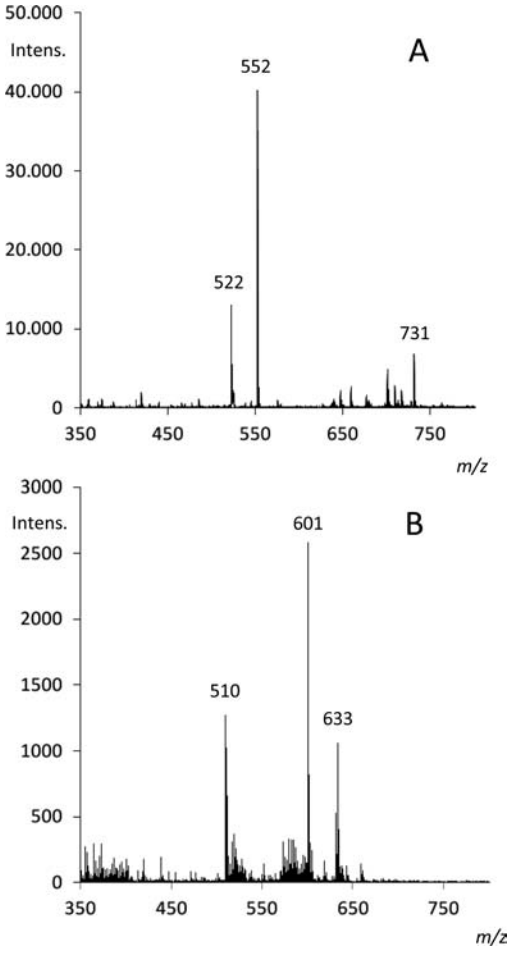

**Figure 3.** $MS^2$ spectra of (A) *Ej*-NCC2 and (B) *Ej*-NDCC1. The protonated molecule ion and the main product ions are shown.

procedure we also added the NDCCs theoretical alternatives that can be obtained from all the NCC structures described so far. NDCCs are generated from all NCC structures (both known and new ones) by deformylation at C6 in ring B. The screening showed the occurrence of *Ej*-NDCC1 (50.4 min and 50.8 min, peaks 5−6, Figure 2), both with the typical UV absorption spectrum of a NDCC[10,27] with broad bands near 237 nm and 274 nm. The only NDCCs detected in loquat fruits present in the high resolution ESI−TOF−MS a protonated molecule ion at *m/z* 633.2882 and 633.2919, both with a predicted elemental composition of $C_{34}H_{40}N_4O_8$. The $MS^2$ spectrum obtained by IT−MS (Figure 3B), besides the signal of the protonated molecule, showed two prominent signals of product ions, one at *m/z* 601 that corresponds to the neutral loss of methanol $[M\text{-}CH_3OH+H]^+$ and the other at *m/z* 510 in response to the ring A loss, $[M\text{-ring A}+H]^+$. Both losses are characteristics of NDDC MS fragmentation.[27] On the basis of previous configurations of NDCCs, the elemental composition of *Ej*-NDCC1 corresponds to the structure proposed in Figure 1, a vinyl group at C3, hydroxylated at $C8^2$, and keeping the esterification at $O13^4$. This means that *Ej*-NDCC1 is the NDCC that corresponds to *Ej*-NCC4. This compound has been identified previously in *Arabidopsis* MES16 mutant leaves,[31] a mutant that accumulates a different chlorophyll catabolite profile with novel and higher amounts of dioxobylins (FDCCs plus NDCCs, Figure 1). The results obtained show that at least *Ej*-NDCC1 is present as a consequence of a wild-type chlorophyll metabolism.

**Evidence for Tautomerism in NCCs Metabolism.** The description of the chlorophyll catabolites in extracts of fully developed loquat fruits shows a pair of isomers for each NCC/NDCC. For each catabolite, it detected a second product at a different retention time (see Table 1) with a feature UV-spectrum of NCC/NDCC, the same elemental composition, and an equivalent $MS^2$ fragmentation pattern. These compounds were assigned as isomers of *Ej*-NCC1, *Ej*-NCC2, *Ej*-NDCC1, *Ej*-NCC3, and *Ej*-NCC4. The possible effect of formic acid in the isomerization of NCCs was ruled out with a control experiment without formic acid in the HPLC gradient, which checked the presence of isomers in the control assay. This is not the first time that isomers of chlorophyll catabolites are described in senescent tissues. Four fractions of NDCCs produced by the activity of cytochrome P450 CYP89A9 have been described in *Arabidopsis* leaves,[30] and in senescent quince fruits, a pair of isomers for each NCC and two pairs for the NDCCs have been reported.[13] Although NCCs display three chiral centers at C1, $C13^2$, and C15, occurrence of different configurations is very constrained; thus, the possibility of epimerization at the chiral center C1 is excluded since this conformation is enzymatically originated and constant within the same vegetal species.[38] Structural configurations of the chiral centers $C13^2$ and C15 are *S* and *R*, respectively, for all NCCs described to date. This imposed spatial distribution is a sine qua non condition to carry out the spontaneous acid-catalyzed reaction of the FCC precursor to NCC in the weakly acidic vacuolar environment.[3] Consequently, few new structural rearrangements are available and hypothesized. One of those structural rearrangements to explain the NCC isomers is the keto−enol tautomerism at $C13^1$. This possible structural conformation is supported in the occurrence of enol forms of chlorophyll *a* and its derivatives at the isocyclic ring E. In fact, chlorophyll *a* keto−enol tautomerism was already evidenced by trapping the enol isomer as trimethylsilyl ether derivative.[39] By following the experimental approach that demonstrated keto−enol tautomerism in chlorophylls, the chemical derivatives of isolated *Ej*-NCC4 peaks (both isomers of the main NCC of loquat fruits) were obtained by semipreparative HPLC. To check the number of possible hydroxyl groups in the molecule(s) of *Ej*-NCC4 (two in the case of the keto tautomer, three for the enol configuration, Figure 4), a silylation reaction was performed with BSTFA, and the derivative compounds were analyzed by high resolution qTOF−MS. At 62.3 min, a derivative product was observed with a feature UV−vis spectrum of NCC, but regarding the original protonated molecule of *Ej*-NCC4, the atomic mass increased by 216 Da, which corresponds to the incorporation of three trimethylsilyl ether groups (TMSi) on the molecule (see Figure 4 for molecular rearrangement of *Ej*-NCC4 derivatives). At a different retention time the presence of di-TMSi derivative was also observed as shown in the table inserted in Figure 4 that contains retention time, elemental composition, and experimental atomic mass of the protonated molecules of the derivative products from *Ej*-NCC4 as well as the mass error and mSigma values from which the consistency of the isotopic pattern was ascertained. The incorporation of three TMSi groups to the *Ej*-NCC4 molecule is the hint for the presence of the enol isomer. The occurrence of the di-TMSi derivative should arise from the keto isomer. We also proceed to the specific methylation of the hydroxyl function from the

propionic group at C17 via diazomethane (see Figure 4), and then the silylation reaction was performed. In this case, we only observed the derivative products corresponding to the incorporation of one or two TMSi groups in the keto and enol isomer, respectively (see insert in Figure 4). Although specific analyses are required to definitively establish the structures of isomers found in senescent tissues, keto−enol tautomerism is a plausible possibility that should be elucidated in future research.

**Proposed NCC/NDCC Pathway in Loquat Senescent Fruits.** Figure 1 depicts a scheme for the structural rearrangements that originate the wide profile of FCCs in senescent loquat fruits by considering the pathway proposal outlined before.[22] It must be noted that the modification at C3, C8, and $C13^2$ takes place exclusively on the FCC/FDCC structure; however, FCC/FDCCs are very unstable, so we analyzed the NCC/NDCC structures.

The first structural modification of *p*FCC is the hydroxylation at the terminal carbon of the ethyl group at C8, which yields a secondary FCC (*s*FCC) that later is structurally modified by different catabolic enzymes,[6] which introduces new functions in the peripheral of the molecule and yields modified FCCs (*m*FCCs). In senescent loquat fruits, the major NCC is *Ej*-NCC4, which arises from a hydroxylation at $C8^2$ (resembles the rest of the structural features of FCC) and represents 80% of total NCCs. In parallel, three refunctionalization routes are available from *Ej*-NCC4.[22] First, the dihydroxylation at the vinyl group of ring A; second, the de-esterification process at ring E ($C13^2$). Certainly, esterified NCCs represent 95% of total NCCs in loquat senescent fruits. Remarkably, the only enzyme involved in the refunctionalization of NCCs that has been identified to date is MES16,[6] a member of the methylesterase protein family, which localizes to the cellular cytosol and specifically demethylates FCCs. It could be hypothesized that senescent fruits of loquat do not display a significant activity of MES16 as do some other vegetal species including *Zea mays* L., although no enzymatic determination has been developed. A third and new level of structural modification is the conjugation of the hydroxyl group at the $C8^2$ position with malonyl directly from *Ej*-NCC4, which means a complement to a previous proposal.[22] This new compound formed, *Ej*-NCC2, has a noncommon refunctionalization on $C8^2$ in plants, since the only vegetal species in that has been identified at the moment is *Brassica napus*.[20] In fact, *Brassica napus*, L., has three different NCCs, two of them with the same modifications in $C8^2$ as in loquat fruits. Nevertheless, no data are available in relation to the esterases enzymes implicated in the FCC modifications at $C8^2$. At this point, the identification of the enzymes responsible of such modifications will be very important for a better understanding of chlorophyll catabolism.

An alternative pathway (Figure 1) is the deformylation at C6 from *p*FCC by CYP89A9[6], which originates *p*FDCC. The hydroxylation at $C8^2$ is the reaction responsible for the formation of *Ej*-FDCC1. The esterase responsible for such hydroxylation should be very potent in loquat fruits since it is the dominating reaction in the refunctionalization of NCCs (*Ej*-NCC4, also hydroxylated in $C8^2$ is the major NCC). Later, *Ej*-FDCC1 is imported to the vacuole, where the low pH isomerizes to *Ej*-NDCC1. In loquats, CYP89A9 activity seems to be not very active, FDCC formation is very low and consequently so is *Ej*-NDCC1. The ratio among the sum of the UV-absorbance areas of NCCs (at 320 nm) and the sum of the UV-absorbance areas of NDCC (at 250 nm) in loquat fruits is about 1500. Clearly, there are two types of senescent tissues under the point of view of chlorophyll degradation, the NCCs species (most of the species analyzed so far) and the NDCCs species (Norway maple and *Arabidopsis thaliana* leaves). Recently, NDCCs were described for the first time in fruits,[13] and it was found that quince fruits have a dominated NDCC metabolism. The results obtained for loquats demonstrate that their major chlorophyll metabolism yields to NCC and consequently that the existing divergence between NCC or NDCC dominant metabolism in senescent leaves is also a reality in ripened fruits. This fact is another parallelism between chlorophyll catabolism in fruits and leaves.

protein in the presence or absence of lactose. These findings were then related to heat-induced viscosity measurements (with the addition of fat) in model IMF systems over a range of DM contents.

## MATERIALS AND METHODS

**Materials.** Whey protein isolate (WPI; Isolac; 90% protein) was obtained from Carbery (Cork, Ireland). Phosphocasein (PCN; 80% protein) was obtained from Sachsenmilch (Leppersdorf, Germany). Edible lactose (L) was obtained from Glanbia (Kilkenny, Ireland). Sunflower oil (SO; Solesta, Warwickshire, UK) was obtained from a local supermarket. Mineral salts (>98% purity) were obtained from Sigma-Aldrich (Wicklow, Ireland).

**Basis.** Heat-induced changes in dispersions of IMF constituents (protein, lactose, and fat) were studied for individual components and in combinations. Dispersions were prepared to correspond to an IMF intended for newborn infant feeding. The ratios of total protein to lactose and whey to casein were 1.4 to 7.2 and 6.0 to 4.0, respectively. For each combination of ingredients (WPI, PCN, and L) four concentration levels were prepared in simulated milk ultrafiltrate (SMUF), which approximated DM contents at various processing stages during IMF manufacture (i.e., 25.8−58.2% DM; Table 1). For example, at the lowest concentration studied, WPI solutions contained 2.4 g of whey protein per 100 g of SMUF, whereas WPI-PCN contained 2.4 g of whey protein and 1.6 g of casein per 100 g of SMUF. Table 2 shows the whey protein concentration of whey-containing solutions/dispersions as a function of overall weight of formulations (% w/w). For viscosity measurements, SO was also used in the systems at a protein to oil ratio of 1.4 to 3.6 (see Homogenization). All dispersions and emulsions were prepared and analyzed in triplicate.

**Table 1. IMF Constituents in Dispersion/Emulsions**

| concn level | whey (g) | casein (g) | fat[a] (g) | lactose (g) | SMUF (g) | DM (%) |
|---|---|---|---|---|---|---|
| 1 | 2.4 | 1.6 | 10.3 | 20.6 | 100.0 | 25.8 |
| 2 | 4.8 | 3.2 | 20.6 | 41.1 | 100.0 | 41.1 |
| 3 | 7.2 | 4.8 | 30.9 | 61.7 | 100.0 | 51.1 |
| 4 | 9.6 | 6.4 | 41.1 | 82.3 | 100.0 | 58.2 |

| | % whey protein (w/w) | | | |
|---|---|---|---|---|
| concn level | WPI | WPI-L | WPI-PCN | WPI-PCN-L |
| 1 | 2.3 | 2.0 | 2.3 | 1.9 |
| 2 | 4.6 | 3.3 | 4.4 | 3.2 |
| 3 | 6.7 | 4.3 | 6.4 | 4.1 |
| 4 | 8.8 | 5.0 | 8.3 | 4.8 |

**Preparation of Dispersions.** SMUF was prepared using deionized water according to the method of Jenness and Koops.[17] Proteins, at levels stated in Table 1, were allowed to hydrate in SMUF overnight before use. The composition of SMUF was as follows: $KH_2PO_4$, 11.61 mM; $K_3$citrate·$H_2O$, 3.70 mM; $Na_3$citrate·$5H_2O$, 6.09 mM; $K_2SO_4$, 1.03 mM; $K_2CO_3$, 2.17 mM; KCl, 8.05 mM; $CaCl_2$·$2H_2O$, 8.98 mM; $MgCl_2$·$6H_2O$, 3.21 mM. Sodium azide (0.03% w/w) was added as a preservative. Dispersions and emulsions were standardized to pH 6.7 by the addition of 0.5 M NaOH. When necessary, lactose was added to dispersions at 25 °C and agitated for 2 h before use.

**Denaturation Temperature.** DSC was carried out using a Q2000 DSC (TA Instruments, New Castle, DE, USA). Samples (ca. 20 mg) were heated from 40 to 100 °C at a rate of 5 °C $min^{-1}$ in a nitrogen-purged environment. Heat flow to the sample was compared against an empty reference pan. The denaturation temperature ($T_d$) of $\beta$-lg was obtained using Universal Analysis 2000 software (TA Instruments), where $T_d$ was the temperature corresponding to the peak minimum of the denaturation endotherm.

**Fourier Transform Infrared Spectroscopy.** FTIR spectroscopy (Bruker Tensor 27, Bruker Optik GmbH, Germany) provided qualitative information on the physical state of proteins in dispersion. Attenuated total reflectance (ATR), mid-IR spectra were obtained using a thermally controlled BioATR cell II. Spectra used were an average of 300 scans at 4 $cm^{-1}$. Samples were measured, stepwise from 50 to 90 °C at 10 °C intervals, using fresh dispersions at each temperature. Background readings were taken against SMUF at each measurement temperature and subtracted automatically. Atmospheric corrections ($H_2O$ and $CO_2$ compensations), vector normalization, and Fourier self-deconvolution (Lorentzian shape with bandwidth and noise reduction factors of 20.31 and 0.36, respectively) of the amide I region (1700−1600 $cm^{-1}$) were carried out using OPUS 5.5 software.[18] FTIR measurements were carried out in triplicate at the highest whey protein concentration (9.6 g 100 $g^{-1}$ SMUF). In lactose-containing dispersions, the concentration of lactose (82.3 g 100 $g^{-1}$ SMUF) was present at levels greater than its theoretical solubility limit in water (42.4 g 100 $g^{-1}$ water at 49 °C[19]). Samples were centrifuged at 1000*g* for ca. 1 min to sediment crystalline lactose, and the supernatant was used for analyses.

**Viscosity.** Viscosity of dispersions/emulsions was monitored throughout heating using a starch pasting cell in a rheometer (AR 2000 rheometer, TA Instruments, New Castle, DE, USA). All samples (28 g) were heated from 40 to 95 °C at a rate of 22 °C $min^{-1}$ and then held at 95 °C for 5 min before cooling to 40 °C at a rate of 18 °C $min^{-1}$. During the measurement samples were sheared with the starch pasting cell impeller at a rate of 16.8 $s^{-1}$. For samples containing lactose, a solubilization step (60 °C for 30 min) was included prior to the heating ramp described above.

**Homogenization.** Emulsions were prepared (for viscosity experiments) by homogenizing mixtures of sunflower oil with dispersions (WPI, WPI-L, PCN, PCN-L, WPI-PCN, and WPI-PCN-L at each concentration level) prepared above. Homogenization was carried out at 65 °C using a two-stage, valve-type homogenizer, model NS2006H (Niro Soavi, Parma, Italy), employing a first-stage pressure of 15 MPa and a second-stage pressure of 5 MPa.

**Statistical Analysis.** Analysis of variance (ANOVA) was carried out using Minitab 15 (Minitab Ltd., Coventry, UK; 2007) statistical software. The significance of formulation type on heat-induced viscosity increase was estimated ($P < 0.05$).

Where the slope ($m$) of a regression line is reported, the 95% confidence limits associated with the slope are also specified ($m \pm t$ $SE_m$). The standard error of the estimated slope ($SE_m$) was calculated using Microsoft Excel's LINEST function. The confidence interval was then calculated as the product of $SE_m$ and $t$, the two-tailed $t$ value associated with $P = 0.05$ and $n - 2$ degrees of freedom.

## RESULTS AND DISCUSSION

**Denaturation Temperature.** Denaturation temperature ($T_d$) of $\beta$-lg was measured by DSC in the various dispersions, starting with WPI in deionized water, followed by the stepwise addition of the other constituents, mineral salts (SMUF), phosphocasein (PCN), and lactose (L). The effect of concentration was also studied; protein content of dispersions corresponded to concentrations found typically in IMF systems (Table 1). Figure 1 shows a representative trace of denaturation in a WPI solution. The shape of the thermograms is similar to those reported previously with the peak minimum corresponding to the $T_d$ of $\beta$-lg.[20,21] The $T_d$ of $\alpha$-lactalbumin was identified as a small shoulder occurring 10−15 °C lower than the $T_d$ $\beta$-lg on DSC thermograms but was detectable only at whey protein concentrations >8% w/w.

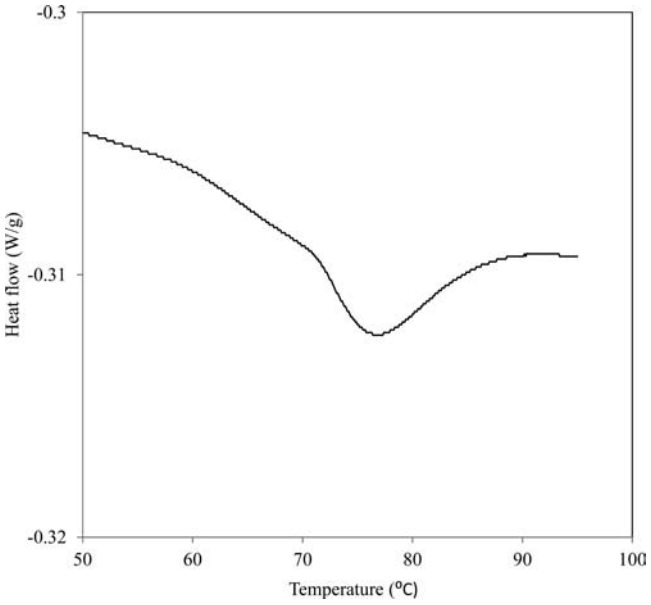

**Figure 1.** DSC thermogram of WPI solution (8.8% whey protein w/w in SMUF).

The $T_d$ of $\beta$-lg in WPI hydrated in deionized water and SMUF was within the range reported by previous studies, that is, 75−85 °C, depending on concentration, genetic variant of $\beta$-lg, scanning rate, etc.[22,23] In general, $T_d$ decreased with increasing protein concentration (Figure 2). Qi et al. reported

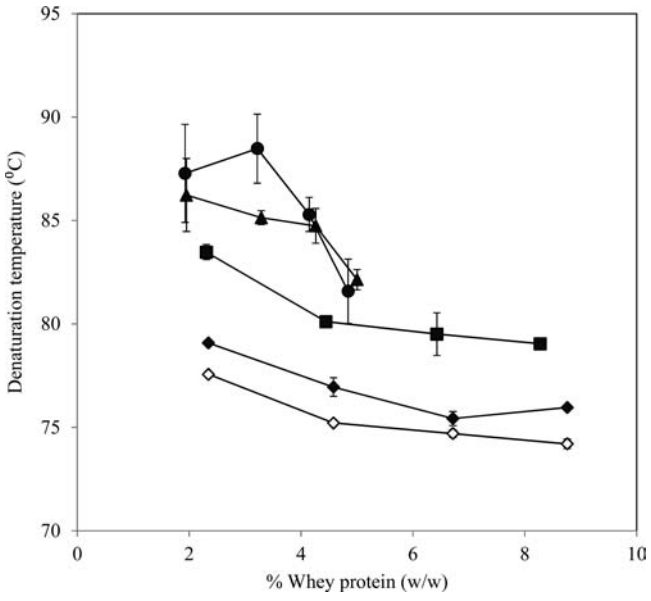

**Figure 2.** Denaturation temperature ($T_d$) in SMUF (solid symbols) and deionized water (open symbols), WPI (◇, ◆), WPI-PCN (■), WPI-L (▲), and WPI-PCN-L (●), at increasing protein concentrations. Error bars represent the standard deviation of three replicate trials.

that increasing the concentration of purified $\beta$-lg increased $T_d$.[23] $T_d$ values reported across a number of studies suggest that increasing protein concentration in nonpurified systems tends to decrease $\beta$-lg denaturation temperature.[20,22,24]

Hydrating WPI in SMUF, prior to DSC analysis, had the effect of increasing the $T_d$ of $\beta$-lg compared to that of WPI in deionized water (Figure 2) The effect of salts on denaturation temperature of proteins can be related to the Hoffmeister lyotropic series, according to which, ions are classified as chaotropic or kosmotropic, depending, respectively, on their destabilizing or stabilizing effects.[25] Chaotropes disrupt hydrophobic aggregation and promote unfolding of proteins and thereby reduce $T_d$. In contrast, kosmotropic agents promote hydrophobic interactions and lead to an increase in $T_d$.[26] The $T_d$ of $\beta$-lg in WPC has been shown to increase in the presence of NaCl and decrease in the presence of $MgCl_2$ or $CaCl_2$.[27,28] It appears from the present study that the net effect of the milk serum salts in SMUF is kosmotropic in nature; that is, the presence of mineral salts had the effect of increasing the $T_d$ of $\beta$-lg. These results show a clear effect of SMUF on $T_d$. Therefore, as SMUF plays an important role in stabilizing rehydrated PCN, all subsequent dispersions/solutions were hydrated in SMUF; this allowed comparisons to be made more easily between the various systems.

Addition of PCN to systems containing WPI increased the $T_d$ of $\beta$-lg (Figure 2). Casein micelles require a significant amount of water for hydration; extrapolating from previously reported data, casein micelles, at temperatures of 70−80 °C have a water content of approximately 2.2 g water $g^{-1}$ casein.[29] It could be argued that PCN increased the effective concentration of whey protein in the continuous phase due to the large voluminosity of casein micelles, rendering a significant proportion of solvation water unavailable to whey proteins. At the highest casein content of the present study (6.4 g 100 $g^{-1}$ SMUF) the propensity of casein micelles to hydrate and compete for water could decrease available water by ca. 14.1 g. On this basis, it might be expected that the addition of PCN should decrease $T_d$, given that increasing concentration of WPI dispersions resulted in a decrease in $T_d$. However, increased $T_d$ of $\beta$-lg in WPI-PCN dispersions suggests PCN had a stabilizing effect on whey protein denaturation. In previous studies, the effects of individual caseins ($\alpha$-, $\beta$-, $\kappa$-) on $T_d$ were inconsistent.[22,30,31] Imafidon et al.[22] found that $\kappa$-casein variants AB and BB decreased $T_d$, whereas variant AA increased $T_d$. Inconsistencies may be due to differences in buffer system source, genetic variants, and preprocessing of proteins used. Furthermore, these studies did not examine the effect of intact casein micelles on the $T_d$ of $\beta$-lg.

Addition of lactose to systems containing WPI resulted in an increase in $T_d$ of $\beta$-lg compared to lactose-free systems at equivalent protein concentrations (Figure 2). The stabilizing effect of sugars, including lactose, against whey protein denaturation has been well documented.[20,32−34] Interactions between sugars and the hydrophobic backbone of whey proteins are thermodynamically unfavorable.[35] As a result, sugars become preferentially excluded from the vicinity of the protein to minimize protein−carbohydrate contact.[36] Similarly, when heat is applied to whey protein, any potential interaction with a cosolvent sugar is unfavorable, which results in retention of the compact, native structure of the protein to higher temperatures. The stabilizing effect of lactose was least apparent at high protein levels, possibly due to low lactose solubility at high DM concentrations and particularly so in the presence of PCN.

**Fourier Transform Infrared Spectroscopy.** The amide I region (1700−1600 $cm^{-1}$) of FTIR spectra was examined in formulations equivalent to 58.2% DM (see Table 1). This region is associated with C═O and C—N stretching vibrations and is indicative of protein secondary structure.[18] Changes in

[a](○) no change from previous temperature; (+/++/+++) small/intermediate/large increase; (-/--/---) small/intermediate/large decrease. [b]Increased absorbance compared to lactose-free dispersion. Analysis based on three replicate trials.

amide I spectra, with respect to temperature, are summarized in Table 3. As expected, little effect of temperature was observed for PCN dispersions, due to a relative lack of secondary structure in casein proteins. In the case of WPI, however, increasing temperature from 60 to 90 °C resulted in significant changes in secondary structure, particularly decreases in intramolecular $\beta$-sheet (1630−1627 $cm^{-1}$) and $\alpha$-helix (1654 $cm^{-1}$) conformations. A concomitant increase in the absorbance spectra in the region of 1617 $cm^{-1}$ indicated the formation of aggregates with intermolecular $\beta$-sheet structures.[37,38] The greatest changes in secondary structure and intermolecular aggregate formation occurred between 60 and 70 °C. Qi et al.[10] also reported a significant reduction in $\alpha$-helix conformation over these temperatures, which, it was suggested, plays an important role in the exposure of the free thiol group, Cys-121. Exposure of this group is of particular significance to IMF manufacture as it is associated with potentially large increases in viscosity, due to whey protein aggregation following intermolecular thiol−disulfide interchange reactions.

At 50 °C, the secondary structure of WPI-PCN dispersions was similar to that of WPI. The presence of PCN delayed temperature-induced losses of $\beta$-sheet structure. A major decrease in intramolecular $\beta$-sheet structure was not observed until >70 °C, compared to >60 °C for WPI in the absence of PCN. Delayed loss of secondary structure correlated well with DSC analysis, where PCN caused an increase in $T_d$. Surprisingly, between 80 and 90 °C, where intramolecular $\beta$-sheet structure decreased, intermolecular $\beta$-sheet structure also decreased. Increases in turns/random coil structure (~1672 $cm^{-1}$) were also observed as the temperature increased. Overall, it is evident that PCN altered the effects of temperature on secondary structural changes in whey proteins.

Addition of lactose to SMUF had negligible effect on absorbance of SMUF buffers in the amide I region. Lactose, however, did influence the spectra of WPI solutions in the amide I region (Figure 3A). A notable difference between the spectra of WPI and WPI-L is the relatively large absorbance peak in the region from 1670 to 1640 $cm^{-1}$ in lactose-containing samples. Peaks in this region (1654 and 1645 $cm^{-1}$) have been associated previously with $\alpha$-helical and random coil conformations.[10,38] However, it is also possible that the presence of lactose altered the local structure of water, resulting in preferential hydration of proteins.[39] Another notable difference occurred at ~1617 $cm^{-1}$, an area associated with intermolecular aggregates, where WPI-L systems had a lower absorbance in comparison to WPI (Figure 3A). It is also possible that spectral changes of WPI in the presence of lactose were due to the Maillard reaction. Czerwenka et al.[40] reported that lactosylation of $\beta$-lg (over 120 h at 60 °C) resulted in approximately 1.6 molecules of lactose bound to each $\beta$-lg molecule. It is suggested that the extent of the Maillard reaction was limited over the time frame of FTIR measurements reported here (approximately 6 min per analysis). Schiff base intermediates have been reported to absorb at 1647 $cm^{-1}$;[41] in the current study, the intensity at 1647 $cm^{-1}$ diminished with increasing temperature. On the basis of the above, it appears unlikely that possible spectral interferences due to lactosylation were a confounding factor.

Heating from 50 to 60 °C increased the aggregation band (1617 $cm^{-1}$) of WPI-L (Table 3). An accompanying reduction in the 1670−1640 $cm^{-1}$ region indicated that some of the additional secondary structure, due to the presence of lactose, was lost upon heating. Intramolecular $\beta$-sheet structure was preserved to a higher temperature in WPI-L solutions (Table 3), where no loss was observed until >70 °C, compared to

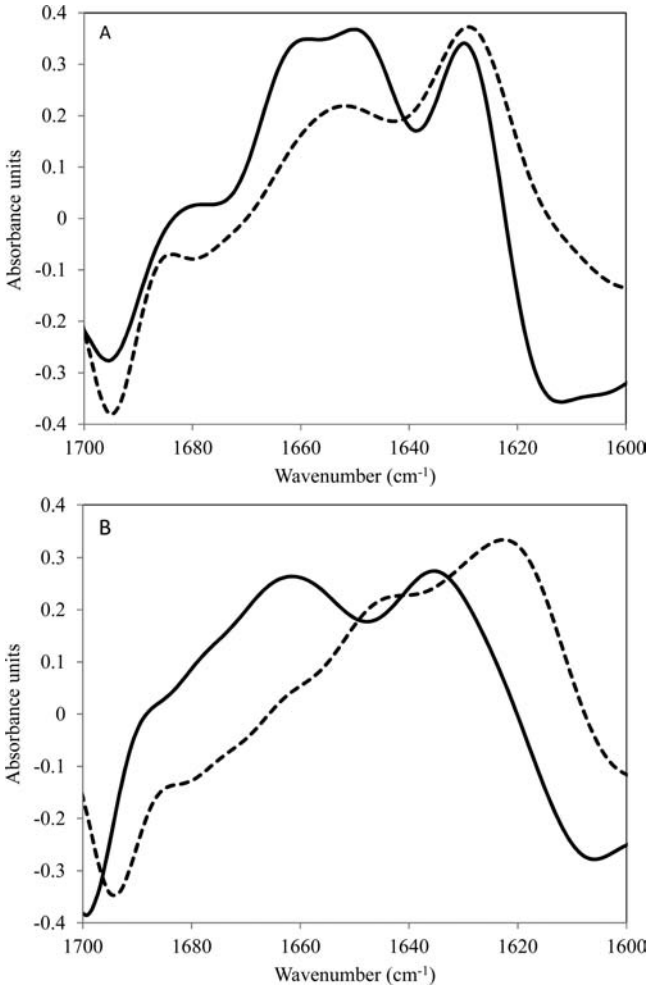

**Figure 3.** FTIR spectra of WPI (dashed line) and WPI-L (solid line) at 50 °C (A) and 80 °C (B).

>60 °C in the absence of lactose. Spectra of WPI-L solutions heated from 50 to 80 °C did not change in the same manner as WPI alone (compare panels A and B of Figure 3), in which the main peak shifted from intramolecular (1630 $cm^{-1}$) toward intermolecular $\beta$-sheet structure (1617 $cm^{-1}$). Delayed loss of structure and aggregation were most likely due to the stabilization effect of lactose, which has previously been shown to delay aggregation in $\beta$-lg solutions, albeit to a lesser extent than other sugars.[42] The findings are consistent with the DSC results reported above, which showed that $T_d$ of WPI in the presence of lactose was higher than in its absence. Increased absorbance at 1672 $cm^{-1}$ indicated an increase in turns/random coil structure upon heating, which was similar to the effect of PCN upon WPI.

Lactose in WPI-PCN dispersions had a similar effect as lactose in WPI solutions; that is, a relatively large peak, compared to lactose-free dispersions, in the range of 1640–1670 $cm^{-1}$ was observed. As with WPI-L dispersions, a decrease was observed in $\alpha$-helix/random conformation between 50 and 60 °C, and intramolecular $\beta$-sheet structure remained intact until the temperature exceeded 70 °C (Table 3).

**Heat Treatment Experiments.** The effect of heat treatment on viscosity of IMF formulations was determined by heat treatment at 95 °C for 5 min. Samples were heated from 40 to 95 °C at a rate of 22 °C $min^{-1}$. During this temperature ramp, viscosity first decreased, before a critical temperature was exceeded ($T_v$) and viscosity increased exponentially (Figure 4). Measurement of $T_v$ provides practical

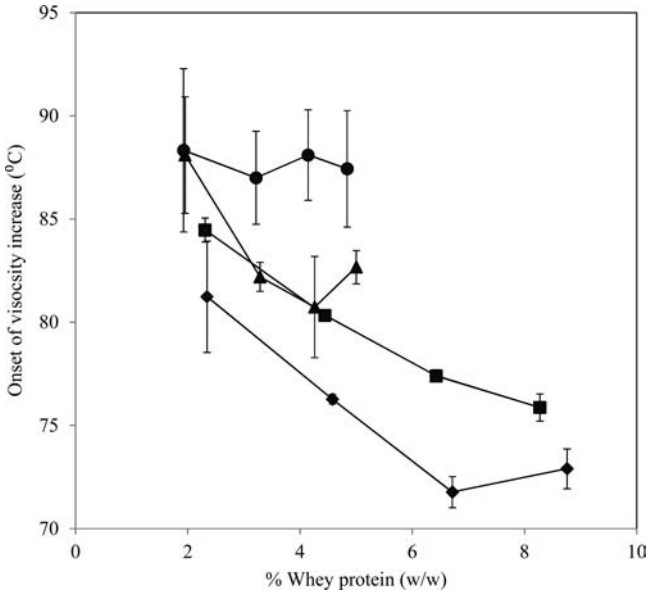

**Figure 4.** Onset of viscosity increase during heating, WPI (◆), WPI-PCN (■), WPI-L (▲), and WPI-PCN-L (●), at increasing protein concentrations. Error bars represent the standard deviation of three replicate trials.

information relevant to existing, industrial heat treatment scenarios, given that it was carried out under shear conditions and the rate of temperature increase was high (22 °C $min^{-1}$) compared to $T_d$ measurements. As observed by DSC and FTIR data reported above, $\beta$-lg in WPI is sensitive to heat denaturation and is highly reactive when unfolded due to the exposure of a free sulfhydryl (thiol) group.[11,12] During heat treatment, denatured and unfolded $\beta$-lg forms aggregates through self-association and association with other milk proteins.[43−46] Denatured whey proteins and aggregates have a greater hydrated volume than native proteins, which leads to significant increases in viscosity.[47,48] Therefore, it is not surprising that all WPI-containing systems increased in viscosity as the temperature approached $T_d$. The trends observed for $T_v$ were similar to those observed for $T_d$ (Figure 2); that is, addition of lactose and/or PCN increased $T_v$. In some cases it was observed that $T_v$ occurred prior to $T_d$, especially at higher whey protein concentrations. This could be explained by differences in heating and shearing rates between the rheometer and DSC methods. In the case of PCN and PCN-L dispersions viscosity did not increase due to the absence of whey protein.

The extent of viscosity change during heat treatment was calculated as the ratio of apparent viscosities (at 40 °C) after and before heating at 95 °C for 5 min (Figures 5 and 6). Heating for 5 min represents a more severe heat treatment than that generally applied during manufacture.[5,49] As a result, aggregates were observed in concentrated WPI-containing systems that would not be expected in an industrial process. The shearing action of the starch pasting cell ensured aggregates remained in suspension. Despite the severity of the treatment, it has the benefit of showing the potential for viscosity increase in a given system while providing indicative trends relevant to manufacture. Dispersions of PCN had lower viscosities following heat treatment (Figure 5). Viscosity in milk

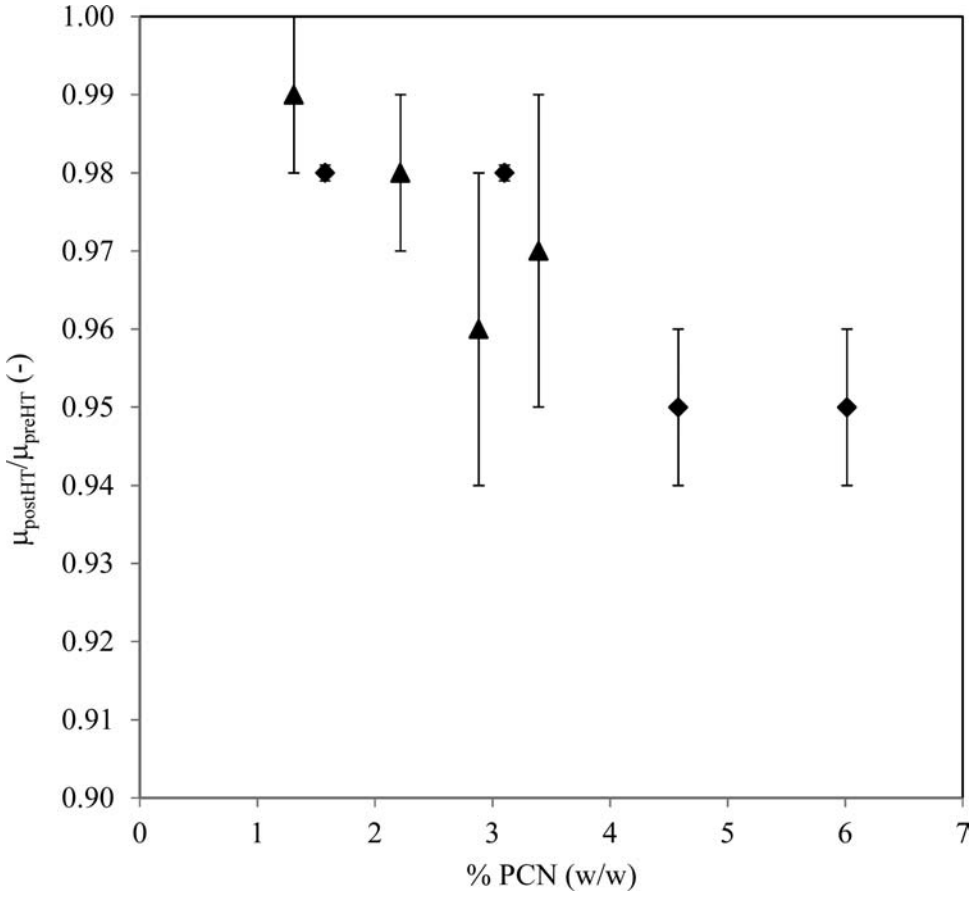

**Figure 5.** Ratio of apparent viscosity (40 °C; 16.8 $s^{-1}$) post ($\mu_{postHT}$) and pre ($\mu_{preHT}$) heat treatment (95 °C for 5 min) in PCN (◆) and PCN-L systems (▲). Error bars represent the standard deviation of three replicate trials.

protein dispersions is related to the hydrated volume of the micelle.[50] At higher temperatures the hydrophobic effect, responsible for much of the stability of the casein micelle, is greater, resulting in a "tightening" or deswelling of the micelle and a decrease in micellar hydration.[50] The lower viscosity of PCN dispersions after cooling is postulated to have been caused by high-temperature association of calcium phosphate with the micelles, which subsequently prevented reswelling of micelles upon cooling.[51]

Figure 6 shows the extent of viscosity increase in WPI containing dispersions/solutions as a result of heating. The large viscosity increases observed in systems containing WPI following heat treatment were related to the extensive water-holding capacity of denatured whey proteins and aggregates, an effect supported by the findings of O'Loughlin et al.[52] The extent of viscosity increase was a linear function of whey protein content (Figure 6). The 95% confidence intervals of both WPI and WPI-PCN dispersions overlap, suggesting there was no difference in extent of viscosity increase with whey protein concentration for these two systems. This was despite $T_d$ and $T_v$ occurring at higher temperatures in the presence on PCN; however, whey protein−casein interactions may also contribute to heat-induced increases in viscosity, depending on heating and solvent conditions and could explain the similar degree of viscosity increase.[13]

Lactose increased heat stability. The rate of change of viscosity increase per unit change in whey protein concentration (as indicated by the slope of regression lines in Figure 6) was lower for systems containing lactose; the 95% confidence intervals of the slopes did not overlap with those of lactose-free systems, suggesting lactose had a significant effect. Addition of lactose resulted in lower post heat treatment viscosity at higher DM content. For example, the most concentrated WPI solution had a DM content of 8.8% (w/w) compared to 47.9% (w/w) for the most concentrated WPI-L solution, yet the apparent viscosity of the former, post heat treatment, was twice that of the latter. Rich and Foegedding[16] found that the onset of WPI gelation was delayed in the presence of lactose and that subsequent gel strength was reduced.

As fat is a vital component in IMF, emulsions were also prepared and heat treated. In all cases addition of fat to formulations resulted in higher viscosities, post heat treatment, compared to corresponding oil-free systems. During homogenization, protein adsorbs to the oil−water interface and protects fat droplets from coalescence. Therefore, protein in emulsified systems can be divided into two classes: adsorbed and nonadsorbed. Despite this difference, the general trends observed upon heating of fat-free systems were reflected in emulsified systems. Major increases in viscosity were observed only in WPI-containing systems; PCN-stabilized emulsions were remarkably stable to heat treatment over the whole range of DM content studied. Lactose increased the heat stability of emulsions. Figure 7 shows the viscosity after heat treatment of the different formulations as a function of total DM content. In emulsified systems, a major increase in viscosity was observed between 25 and 35% DM (w/w) for lactose-free emulsions; similar viscosity increases were not observed before the DM

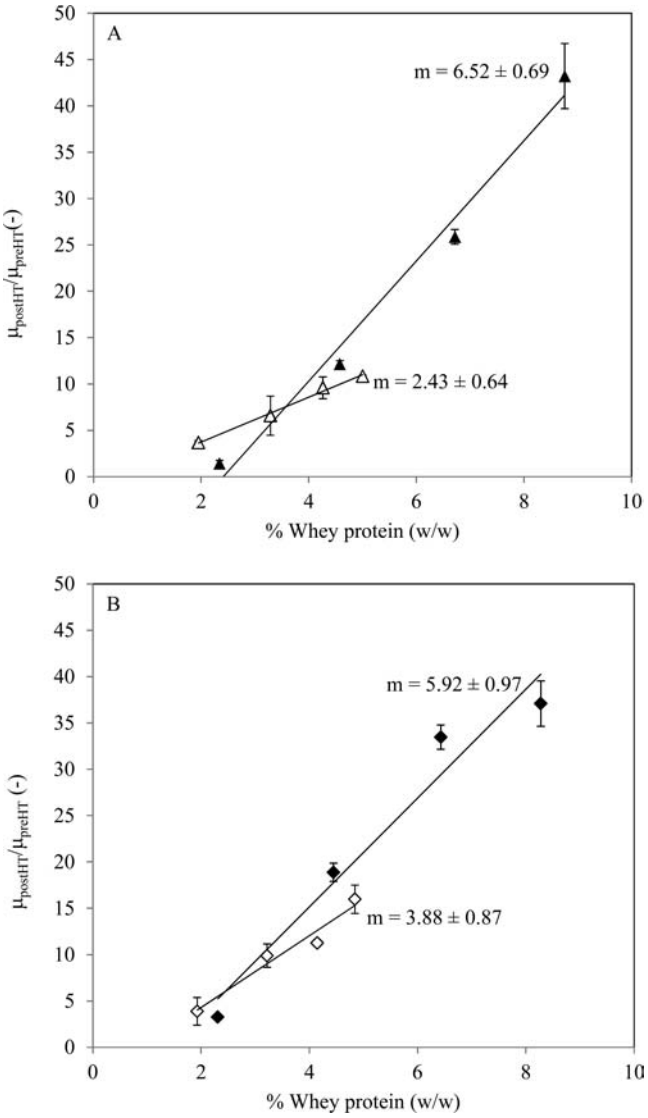

**Figure 6.** Ratio of apparent viscosity (40 °C; 16.8 $s^{-1}$) post ($\mu_{postHT}$) and pre ($\mu_{preHT}$) heat treatment (95 °C for 5 min) in WPI containing systems: (A) WPI (▲) and WPI-L (△); (B) WPI-PCN (◆) and WPI-PCN-L (◇). Error bars represent the standard devitation of three replicate trials. Slopes ($m$) are given ±95% confidence intervals.

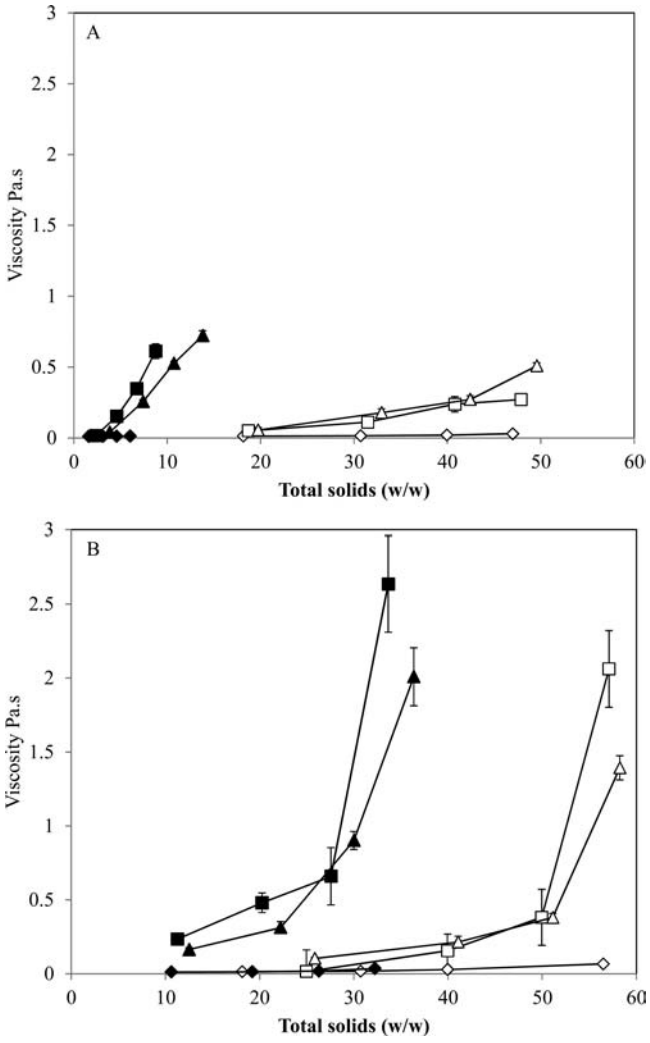

**Figure 7.** Apparent viscosities (40 °C; 16.8 $s^{-1}$) of oil-free (A) and homogenized oil-containing (B) IMF model systems after heat treatment (95 °C for 5 min). Solid symbols denote lactose-free dispersions/emulsions: PCN (◆), WPI (■), and WPI-PCN (▲). Open symbols denote lactose-containing dispersions/emulsions: PCN-L (◇), WPI-L (□), and WPI-PCN- L (△). Error bars represent the standard devitation of three replicate trials.

content reached 50% (w/w) in emulsions containing lactose. This is particularly relevant for ingredient/IMF manufacturers that produce lactose-depleted base powders with the intention of adding crystalline lactose at a later stage.[6] Maximizing DM content prior to heat treatment of lactose-depleted base mixtures could have a significant impact on the viscosity of concentrates, which in extreme cases causes problems such as inefficient atomization during spray-drying.[7] The extensive increases in viscosity following heat treatment of WPI-containing emulsions suggest that, during heat treatment, protein-stabilized oil droplets associated with nonabsorbed denatured whey proteins, and/or each other, to form a transient network of flocculated oil droplets, with an associated increase in volume fraction.[53] Such changes were sufficient to alter the viscoelastic properties of emulsions and confer a macro-structure with more "solid-like" properties.

The extent of whey protein structural changes and their influence on the viscosity of IMF dispersion/emulsions were significantly affected by their interactions with other macro-nutrient components. Lactose content, in particular, played an important protective role during the heat treatment of IMF, retarding and reducing viscosity increases in dispersions and emulsions alike. This is in keeping with the theory of preferential hydration of proteins in the presence of carbohydrates resulting in stabilization of the protein. Lactose content of wet-mixes should be a key consideration in the design of IMF manufacturing processes. PCN (micellar casein) also had a protective effect on $\beta$-lg denaturation. Despite increasing the denaturation temperature and delaying the onset of viscosity increase in WPI, in a manner similar (albeit diminished) to lactose, it seems that PCN interacted with WPI, during heating, in ways that led to similar levels of viscosity increase to that observed in WPI alone. Overall, this study provided insight into the relationships that exist between macronutrients as a function of concentration and temperature and should provide information of direct relevance to manufacturers of IMF.

[a]The codes (−1, 0, 1) in parentheses represent different levels of independent variables for optimization.

group; then, a new ester bond is formed by the reaction between the newly created hydroxyl group and the incoming new free fatty acid.

Besides that, the fatty acids at different positions of the TAG affect the absorption efficiency; different lengths of fatty acids also have different absorption rates and different functions. Clinical experiments reveal that long-chain fatty acids (LCFAs, $C_{14}$−$C_{22}$) were more slowly absorbed than medium-chain fatty acids (MCFAs, $C_6$−$C_{12}$).[13] An increase in chain length of saturated fatty acids reduced their absorbability as well increased the loss of energy intake and calcium. MCFAs were absorbed more efficiently than LCFAs in the gastrointestinal tract via the portal system and rapidly provide energy for the body.[14] It has also been reported that MCFAs had greater antiviral and antibacterial activities than LCFAs.[15] Due to the predominance of LCFAs in infant formula and human milk fats, the incorporation of MCFAs into HMFS has been suggested to provide a concentrated source of energy by many clinical nutrition experts.[16] Recently, a commercial product named Neobee consisting of MCFAs (caprylic and capric acids) has been developed as a functional food for patients. To our knowledge, in the literature, few data can be found regarding the enrichment of human milk fat substitutes with MCFAs.[17]

Lipozyme RM IM, which is an immobilized lipase from *Rhizomucor miehei*, is widely used as a catalyst in pharmaceutical and drug production and lipid modifications. It has the characteristics of substrate specificity, stereospecificity, and regioselectivity.[18] In a recent study, different strategies of lipase immobilization were investigated to improve enzyme properties by positive alterations of structure, which may enhance enzyme activity, specificity, or selectivity and increase its mechanical strength, hydrophobic or hydrophilic character, and regeneration.[19]

*Cinnamomum camphora* (Lauraceae), known as an evergreen tree, is largely distributed south area of the Yangtze River in China. In a previous study, it has been reported that the oil from *C. camphora* (Lauraceae) seeds has a unique fatty acid profile that mainly contains MCFAs (capric acid, C10:0, 53.27%; lauric acid, C12:0, 39.93%).[20] Liu et al.[21] have also confirmed that *C. camphora* seed oil (CCSO) is nontoxic with no side effects, which could be used as a woody edible oil for its further development and utilization. Recently, our research group has managed to use CCSO for the production of medium-chain triacylglycerol (MCT) enriched plastic fats.[22−24]

The aim of this work was to synthesize HMFS enriched with MCFAs through enzymatic acidolysis of CCSO and oleic acid using immobilized Lipozyme RM IM lipase as a catalyst. The effects of reaction conditions (time, temperature, enzyme concentration, and substrate mole ratio) on oleic acid incorporation were optimized by response surface methodology (RSM). Subsequently, scale-up trials were conducted to determine the feasibility of enzymatic modification of CCSO for the production of HMFS and the reusability of Lipozyme RM IM.

## MATERIALS AND METHODS

**Materials and Chemicals.** Oleic acid (≥85%) was purchased from a local oil market (Nanchang, China). CCSO was extracted from *C. camphora* seeds by the $CO_2$ supercritical fluid method as described in Hu et al.[20] Lipozyme RM IM, a commercial immobilized 1,3-specific lipase from *R. miehei*, was purchased from Novozymes A/S (Bagsvaerd, Denmark). The specific activity of Lipozyme RM IM was 150 IU/g, having 0.35−0.45 g/mL bulk density and 0.3−0.6 mm particle diameter. Carbon dioxide (99.9%) was provided by Wanli Gas Corp (Nanchang, China). Four hundred and sixty-three standard fatty acid methyl esters (FAMEs) containing methyl esters $C_8$−$C_{20}$ saturated fatty acid, methyl myristate, methyl palmitoleate, methyl oleate, methyl linoleate, methyl linolenate, and four positional conjugated linoleic acid isomers were purchased from Nu-Chek Prep Inc. (Elysian, MN, USA). Tocopherol ($\alpha$, $\gamma$, and $\delta$) standards were acquired from Sigma Chemical Co. (St. Louis, MO, USA). All other chemicals used were of analytical or chromatographic grade.

**Acidolysis Reaction of Small-Scale Sample.** CCSO (1 g each) was blended with oleic acid at substrate mole ratios of 1:2, 1:4, and 1:6. Lipozyme RM IM of 6, 10, and 14% (w/w total reactants) was added to the blend in 50 mL screw-capped flask. The acidolysis was performed under 200 rpm orbital shaking water bath, and temperature was set at 55, 60, and 65 °C for 20, 24, and 28 h of incubation. After reaction, RM IM lipases were separated from the mixture through a 0.45 $\mu$m polytetrafluoroethylene (PTFE) syringe membrane filter. The filtrate was stored at −18 °C until analysis.

**Experimental Design for RSM Study.** Enzyme-catalyzed acidolysis was influenced by reaction conditions such as water content, substrate mole ratio, enzyme concentration, temperature, and reaction time.[12] Before models were set up by RSM, single-factor experiments were carried out to detect the effects of these five conditions on oleic acid incorporation. Then, four of the five factors were selected as independent variables, and the optimal reaction conditions for the acidolysis reaction were established via RSM. RSM, a useful mathematical tool, has been widely applied to the optimization of reaction conditions for the production of HMFS in several studies.[25,26] In our experiment, a four-factor and three-level full factorial design called Box−Behnken design (BBD) was employed to generate factor combinations by using Design Expert 7.1 software (Stat-Ease Inc., Minneapolis, MN, USA). The four selected factors were substrate mole ratio ($A$), enzyme concentration ($B$), temperature ($C$), and reaction time ($D$), and three levels were substrate mole ratios of 1:2, 1:4, and 1:6, Lipozyme RM IM of 6, 10, and 14% (w/w total reactants), temperature of 55, 60, and 65 °C, and reaction time of 20, 24, and 28 h. To avoid bias, 29 runs including 16 factorial points, 8 axial points, and 5 center points were performed in a random order. Oleic acid incorporation was acted as response value. The independent variables ($A$, $B$, $C$, $D$) and exact experimental model are presented in Table 1. Experiments were run randomly, and duplicate reactions were performed at all design points.

**Fatty Acid Profile.** The fatty acid compositions of substrates and products were determined. Thin-layer chromatography (TLC) analysis was carried out for the separation of newly synthesized product. About 50 $\mu$L of product was applied to TLC plates coated with silica gel G. The developing solvent was hexane/diethyl ether/acetic acid (50:50:1, v/v/v). Then, the bands were sprayed with 0.2% 2,7-dichlorofluorescein in methanol and visualized under UV light. Finally, the TAG band was scraped off into a screw-capped test tube and dissolved in 2 mL of hexane for fatty acid composition analysis. The TAG sample was converted to FAMEs following the procedure of Zhu et al.[27] and then analyzed by a gas−liquid chromatograph (GLC) (model 6890N, Agilent Technologies, Santa Clara, CA, USA) equipped with an autoinjector, a fused-silica capillary column (CP-Sil 88, 100 m × 0.25 mm × 0.2 $\mu$m i.d.), and a flame ionization detector (FID) and operated in splitless mode. The injector and detector temperatures were maintained at 250 and 260 °C, respectively. The column temperature was held at 45 °C for 3 min and then programmed to 175 °C for 27 min at the rate of 13 °C/min. The temperature was then further increased to 215 °C at the rate of 4 °C/min and held for 35 min. The carrier gas was nitrogen, and the total gas flow rate was 52 mL/min. The injecting sample volume was 0.3 $\mu$L.

**Sn-2 Positional Analysis.** Composition of sn-2 FAs was analyzed by the pancreatic hydrolysis method as previously described.[28] Likewise, TLC was used to separate 2-monoacylglycerol (2-MAG) from the hydrolysate. The 2-MAG band was scrapped off, methylated, and analyzed by GLC as also described above.

**Identification of TAG Species.** The different species of TAGs of CCSO and HMFS were separated by reversed-phase high-performance liquid chromatograph (HPLC) with a Nova-Pak C18 column (150 × 3.9 mm; Waters, Milford, MA, USA) and an evaporative light-scattering detector (Alltech 2000ES, USA) operating at 55 °C and a gas flow rate of 1.5 L/min. Samples were dissolved in methanol and filtered by 0.45 $\mu$m PTFE syringe membrane filter. Twenty microliters of filtered sample was injected and eluted by acetonitrile (solvent A) and 2-propanol/*n*-hexane (1:1, v/v) (solvent B) at a flow rate of 1.8 mL/min with the following profile: 0−20 min, 30% B; 21−36 min, 60% B; 37−40 min, 100% B, and then back to the initial flow rate. Last, the separated TAGs were identified by comparing the retention time and equivalent carbon number (ECN). ECN = CN − 2DB, used to predict the elution order, where CN is the total carbon number except three carbons of glycerol in the TAG and DB is the total number of double bonds on the fatty acids.

**Urea Inclusion for Separation and Purification of HMFS.** The mechanism of urea inclusion is traditionally explained as follows: separation of mixed fatty acids by urea inclusion occurs in terms of different saturation degrees and carbon chain lengths of the fatty acids.[29] Urea/HMFS mixed with 50 mL of 95% (v/v) ethanol was put into a round-bottom flask. Under the nitrogen gas flow, the mixture was refluxed at 60 °C in a water bath until the solution became clear. Then, the product was cooled at room temperature for 1 h and placed at −4 °C for 24 h. The mixture was separated by suction filtration using a Buchner funnel to obtain urea inclusion compounds and non-urea inclusion compounds. The non-urea inclusion compounds containing PUFA and acylglycerol were transferred to a round-bottom flask, and ethanol was evaporated as much as possible. Acylglycerol was separated and analyzed by HPLC.

**Tocopherol Analysis.** About 1 g of CCSO or HMFS sample was weighed into a flask and fully dissolved in 10 mL of hexane. After filtration with a 0.45 $\mu$m PTFE syringe filter, 3 $\mu$L samples were injected into the Agilent 1100 series HPLC. Then, the contents of tocopherol in prepared sample were determined by reversed-phase HPLC equipped with Hypersil ODS2 column (5 $\mu$m, 4.6 × 150 mm, Agilent Technologies) and a fluorescence detector (FLD). The mobile phase was methanol/water (98:2, v/v) with a flow rate of 0.8 mL/min. Standards of $\alpha$-, $\gamma$-, and $\delta$-tocopherol dissolved in hexane were used for identification and quantification.[30]

**Physicochemical Characteristics.** The determinations of CCSO and HMFS chemical properties, such as acid value, peroxide value, saponification value, and iodine value, were conducted following AOAC (1990) standard analytical methods.[31]

**Scale-up Trial.** Model verification was carried out from RSM design. To verify the feasibility of the scaled up acidolysis, a batch reaction (50 times scaleup) in a 500 mL flask was carried out at optimum conditions. The incorporation of oleic acid and productivity of TAG were determined to evaluate the feasibility of the scale-up trial.

**Statistical Analysis.** The effects of different substrate mole ratio, enzyme concentration, temperature, and reaction time studied in this work and their interactions were analyzed by using Design Expert 7.1 software. Mean values and standard deviations of a single-factor experiment, contents of tocopherol, and physicochemical characteristics were analyzed by using Statistical Analysis System software (SAS 2000, Cary, NC, USA).

## RESULTS AND DISCUSSION

**Effect of Water Content.** The water content in any quantity cannot be neglected because lipases are activated by a small amount of water,[32] and it is required for a first breaking of the triglyceride;[12] however, too much water can make the lipase

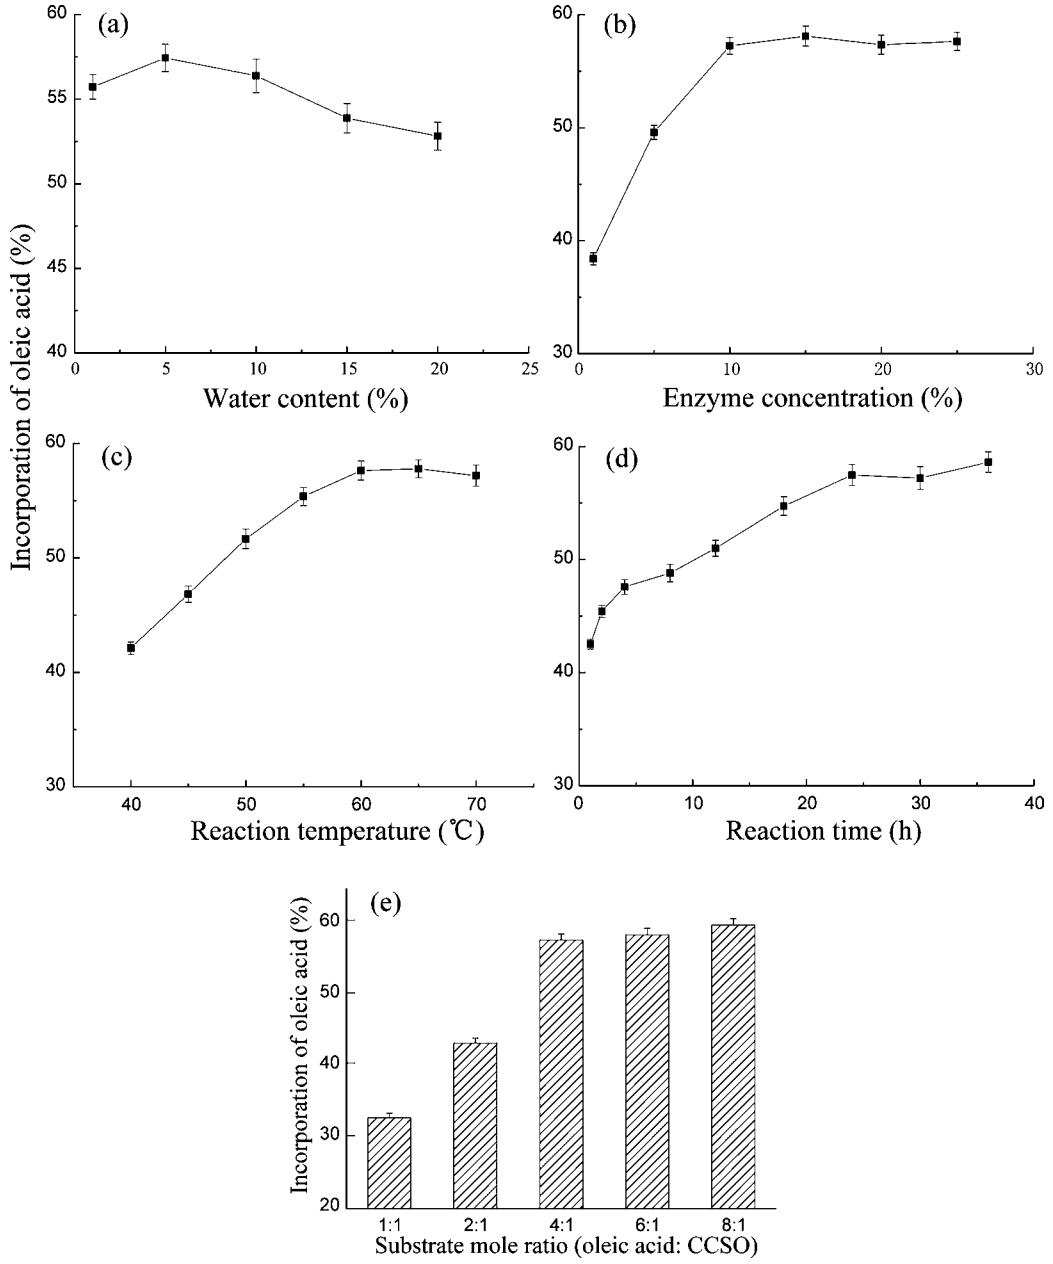

**Figure 1.** Effects of water content (a), enzyme concentration (b), reaction temperature (c), reaction time (d), and substrate mole ratio (oleic acid/CCSO) (e) on the incorporation of oleic acid.

unstable and have an adverse impact on activity, leading to a higher amount of byproducts.[33] Some authors reported that the optimum water contents were generally in the range of 0.2−3%;[34−36] however, a given enzymatic reaction depends on many factors (the selected enzyme, support, solvent, and quantities of substrates). Thus, it is necessary to optimize the water content in the reaction system. With enzyme of 10% (w/w total reactants), a 4:1 substrate mole ratio (oleic aid/CCSO), reaction temperature of 60 °C, and time of 24 h, the effects of water contents in the range of 1−20% (w/w total reactants) on the incorporation of oleic acid were studied (Figure 1a). The incorporation increased from 55.72 ± 0.31% to a maximum level of 57.44 ± 0.25% when the water content was increased from 1 to 5%. Then, a decrease to 52.81 ± 0.19% was observed when the water content was increased from 5 to 20%. Hence, we chose 5% water content for the ongoing study.

**Effect of Enzyme Concentration.** The effect of enzyme load, by varying from 1 to 25% (w/w total reactants) with constant substrate mole ratio of 4:1 and 60 °C reaction temperature after 24 h of incubation, on the oleic acid incorporation was also observed (Figure 1b). An increase in the catalyst percentage from 1 to 10% led to an incorporation increase from 38.41 ± 0.54 to 57.26 ± 0.75%. Further increase in the enzyme load from 10 to 25%, however, did not lead to further incorporation increase. This is possibly due to the saturation of the enzyme at the interface between CCSO and aqueous phase, in which an increase in enzyme concentration provided no significant changes on the incorporation.[37] Our results are similar to those reported by Rooney and Weatherley[37] and Raspe et al.[38] Considering the incorporation of oleic acid and the cost of Lipozyme RM IM, 10% (w/w total

reactants) enzyme concentration was chosen for the following optimization.

**Effect of Reaction Temperature.** Temperatures from 40 to 70 °C were evaluated in the present study. Substrate mole ratio (oleic acid/CCSO), water content, enzyme load, and reaction time were 4:1, 5%, 10%, and 24 h, respectively. Results are shown in Figure 1c. It can be noted that the increasing temperature in the range of 40−60 °C increased oleic acid incorporation from 42.11 ± 0.54 to 57.63 ± 0.83%. However, when the temperature further increased to 70 °C, the incorporation decreased to 57.19 ± 0.92%. This result is in good agreement with the results of Phuah et al.,[39] who investigated the effect of temperature on the hydrolysis of partial palm oil. It has been stated that enzyme activity and acyl migration are both increased by an increase in temperature until reaching the maximal rate.[40] Therefore, a higher temperature was not suggested. A temperature of 60 °C was suitable for further study.

**Effect of Reaction Time.** The reaction time was set from 1 to 36 h to investigate its influence on the incorporation. Substrate mole ratio (oleic acid/CCSO), water content, enzyme load, and reaction temperature were 4:1, 5%, 10%, and 60 °C, respectively. As shown in Figure 1d, the incorporation of oleic acid increased from 42.51 ± 0.43 to 57.48 ± 0.94% when the reaction time increased from 1 to 24 h. In 36 h, the oleic acid incorporation was 58.62 ± 0.90%. In a similar study the optimal reaction time was different depending on the use of enzyme and substrate.[41] Forty hours as the optimal reaction time was reported by Akoh et al. for the incorporation of EPA and capric acid into borage oil.[41]

**Effect of Substrate Mole Ratio (Oleic Acid/CCSO).** The effect of the molar ratio of oleic acid to CCSO on oleic acid incorporation was studied from 1:1 to 8:1 at a constant enzyme concentration (10%, w/w total reactants) and temperature of 60 °C for 24 h (Figure 1e). The incorporation increased from 32.75 ± 0.24 to 58.73 ± 0.13% as the substrate mole ratio changed from 1:1 to 4:1. Then, from 4:1 to 8:1, the incorporation increased until to 59.84 ± 0.26% was found. It was reported that the appropriate substrate molar ratio was in favor of the reaction equilibrium and increased the ratio of the collision between substrates and catalyst,[42] but higher substrate ratios were not desirable because a large amount of FFAs containing high levels of free or ionized carboxylic acid groups acidifies the enzyme layer, leading to absorption of water from the interface, which may decrease the activity of the enzyme.[43] Considering the stability of the enzyme and the cost of materials, a substrate mole ratio of 4:1 was chosen for further investigation.

**Experimental Design for RSM.** To find the optimal conditions of the greatest incorporation and also to see whether the reaction parameters have interactions on each other, RSM was used. According to the results of the single-fator experiment discussed above (Figure 1), the water content was set at constant 5% (w/w total reactants), and the substrate mole ratio (*A*, oleic acid/CCSO), enzyme load (*B*, w/w total reactants), temperature (*C*, °C), and reaction time (*D*, in hours) were chosen as the four optimizing factors. The experimental model is shown in Table 1.

**Model Fitting and Variance Analysis.** Quadratic models were well established by multiple regression and backward elimination using Design Expert 7.1 software. The model equation for the responses (% oleic acid incorporated) catalyzed by Lipozyme RM IM can therefore be written as

$$Y = 57.60 + 3.8A + 2.36B + 0.81C + 1.65D + 1.31AB - 0.82AC + 0.097AD - 0.012BC - 0.80BD - 0.54CD - 4.80A^2 - 1.80B^2 - 1.54C^2 - 0.51D^2$$

where *Y* is the oleic acid incorporation, *A* is substrate mole ratio, *B* is enzyme load, *C* is temperature, and *D* is reaction time.

The analysis of variance (ANOVA) of models for response variables is listed in Table 2. The very small *p* values (<0.0001) and nonsignificant lack of fit ($p = 0.0502$) from the ANOVA

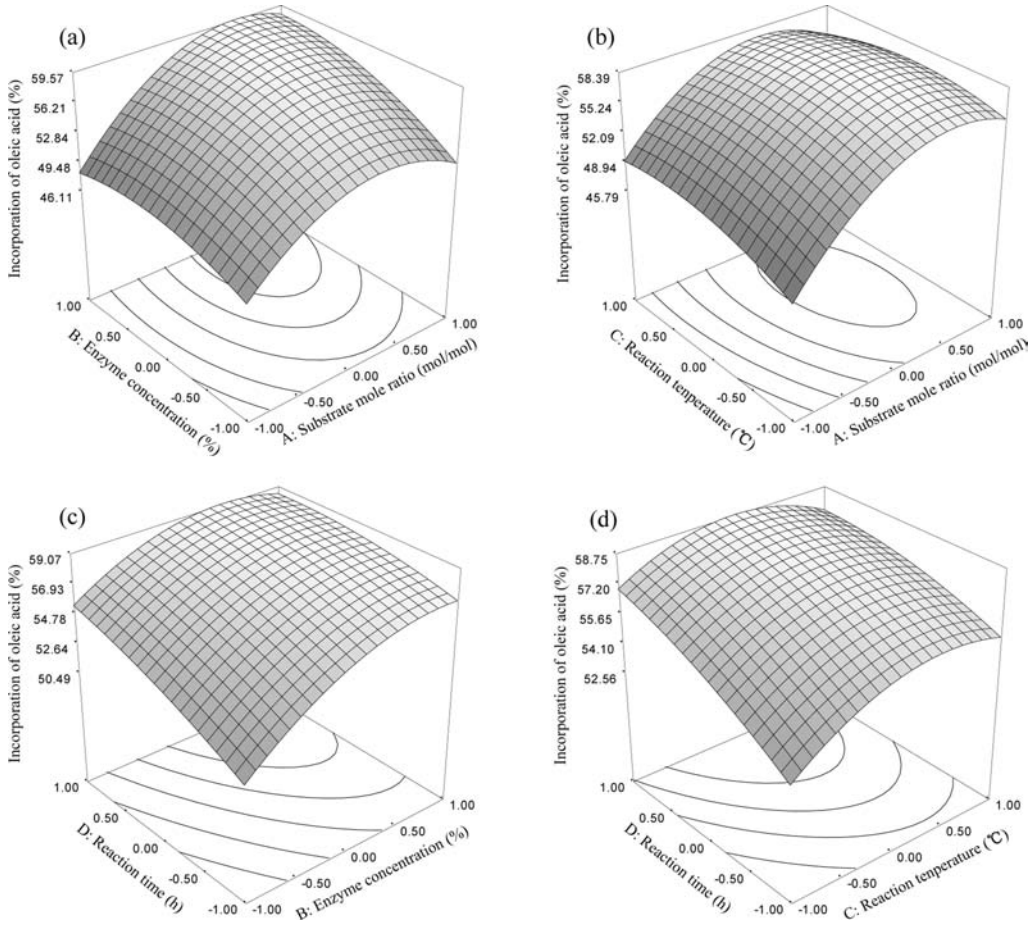

**Figure 2.** Response surface plots reflecting the pairwise interactive effects of the four selected factors on the acidolysis reaction catalyzed by RM IM.

indicated that the reduced cubic polynomial model was highly significant and sufficient to represent the actual relationship between responses (the incorporation of oleic acid) and the significant variables. The low pure error (0.055) demonstrated good reproducibility of the data. The high values of $R^2$ (0.9924) and adjusted $R^2$ (0.9847) showed a good agreement between the experimental results and predicted values, and the accuracy of the models was evaluated by coefficient of determination. The first-order parameters of substrate mole ratio ($A$, oleic acid/CCSO) had the greatest positive linear relation ($p < 0.01$) on the incorporation, followed by enzyme concentration ($B$), reaction time ($C$), and temperature ($D$), whereas the second-order parameters of $A^2$, $B^2$, and $C^2$ had significant quadratic relation. Interactions of $A$ and $B$, $A$ and $C$, $B$ and $D$, and $C$ and $D$ were found to be significant ($p < 0.05$) for the incorporation.

**Optimization.** The optimal conditions for the lipase-catalyzed synthesis of HMFS were predicted using the optimized function of the Design Expert Software. Figure 2a shows the predicted response surface of oleic acid incorporation as a function of enzyme concentration and substrate mole ratio, keeping the reaction temperature fixed at 60 °C and time at 24 h. An increase in oleic acid incorporation was observed by increasing the substrate mole ratio in an early stage of reaction. The trend was, however, reversed when the substrate mole ratio reached a certain value under the range of enzyme concentration in this work. At a fixed enzyme concentration of 10% and reaction time of 24 h, the effect of reaction temperature and substrate mole ratio on oleic acid incorporation is shown in Figure 2b. The elliptical contour plot showed that the interaction of substrate mole ratio and reaction temperature had a great influence on the incorporation. The oleic acid incorporation also increased as the increase of substrate mole ratio in an early stage of reaction and then decreased. The maximum increase of oleic acid incorporation was observed at a substrate mole ratio of 4:1 to 5:1 and a reaction temperature of 58−62 °C. Figure 2c shows the effect of varying enzyme concentration and reaction time on the oleic acid incorporation at a constant reaction temperature of 8 h with a substrate mole ratio of 4:1. The maximum increase of oleic acid was found at an enzyme concentration of 4:1−5:1 and time of 28 h. Figure 2d illustrates the effect of varying reaction temperature and time on the oleic acid incorporation at a constant enzyme concentration of 10% and substrate mole ratio of 4:1. The oleic acid incorporation increased from 55 to 62 °C and thereafter decreased with a dome shape observed. The effect of reaction time on the incorporation was more significant than reaction temperature. The maximum increase of oleic acid incorporation was found at a reaction temperature of 58−62 °C and time of 28 h.

**Model Verification.** By optimization, the optimum conditions yielding 60.19% of HMFS were as follows: a substrate molar ratio (oleic acid/CCSO) of 5:1, an enzyme concentration of 12.48% (w/w total reactants), a reaction temperature of 59.75 °C, and a reaction time of 28 h. To confirm the predicted results of this model, the experiment was done using optimized conditions with few modifications for the sake of experimental operating convenience. The modified conditions were as follows: a substrate molar ratio (oleic acid/

CCSO) of 5:1, an enzyme concentration of 12.5% (w/w total reactants), a reaction temperature of 60 °C, and a reaction time of 28 h. The incorporation of oleic acid from the experiments conducted according to the modified optimal conditions was 59.68%, which was in accordance with the predicted values and further verified the efficiency of the quadratic regression models.

**Fatty Acid Profile.** The fatty acid compositions of GC profiles of CCSO and HMFS are presented in Figure 3. The

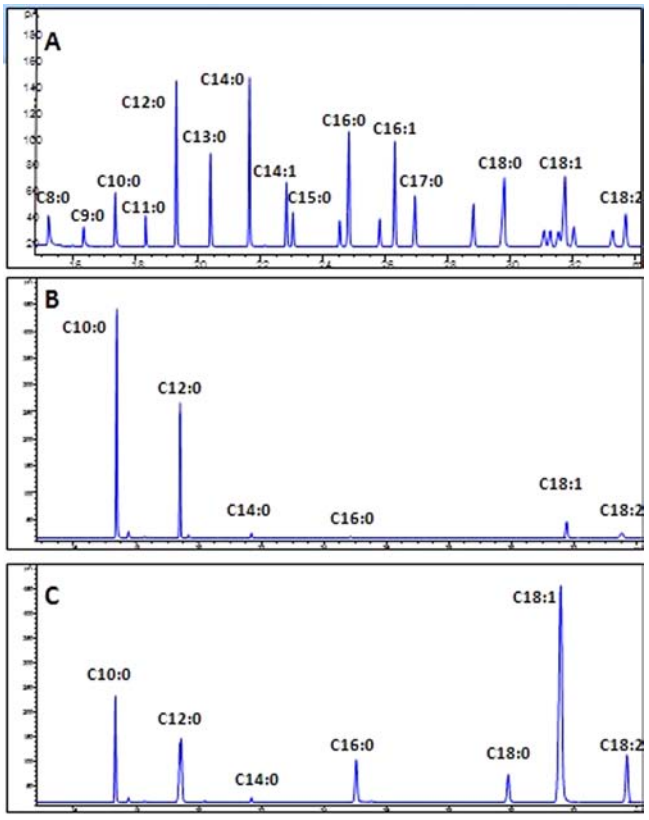

**Figure 3.** GC profile of fatty acid methyl esters of standards of glyceride (A), CCSO (B), and HMFS (C).

major fatty acids of CCSO were MCFAs including capric acid (C10:0, 54.76%, Table 3) and lauric acid (C12:0, 39.83%,

[a]Human milk fat substitutes (HMFS) were synthesized with the Lipozyme RM IM of 12.5% (of the total substrate) and a molar ratio of 5:1 (oleic acid/CCSO) at 60 °C for the reaction of 28 h. [b]Sn-1,3 (percentage of the area) = (3*T* − sn-2)/2, where *T* is total fatty acids.

Table 3). The unsaturated fatty acid accounted for only 2−3%, mainly oleic acid and linoleic acid. The content of MCFAs at the sn-2 position of CCSO was up to 96%, and the ratio of C10:0 to C12:0 was 2:1, but only 1:1 at the sn-1,3 position. Compared with CCSO, MCFAs at the sn-2 position of the final product HMFS possessed >70%, whereas oleic acid was predominantly esterified at the sn-1,3 position, accounting for 78.69%. It can be concluded that the configuration of synthetic TAG rich in MCFAs can be expressed as sn-USU (U, unsaturated; S, saturated), which is similar to mother's milk and has the potential to be added to infant formula milk powder, especially to be used as a dietary treatment for premature infants who suffer from fat-absorption abnormalities and infant patients who need rapid fat absorption and energy supply.

**Triacylglycerol Analysis.** The TAG species of CCSO and HMFS product are shown in Figure 4, and respective

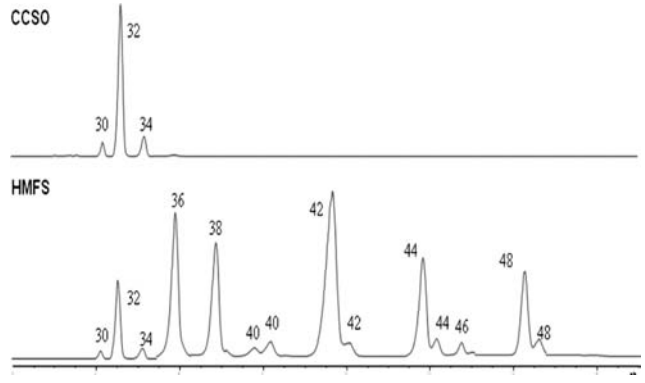

**Figure 4.** TAG of CCSO and HMFS (peak number represents ECN of the triacylglycerol group).

percentages are presented in Table 4. CCSO contained considerable amounts of LaCC/CLaC (82.21%), followed by MCC/LaLaC (11.82%) and CCC (5.97%). After acidolysis,

**Table 4. Triacylglycerol (TAG) Species (Area Percent) of CCSO and HMFS Product**

| ECN[a] | TAG[b] | CCSO | HMFS |
|---|---|---|---|
| 30 | CCC | 5.97 | 1.87 |
| 32 | LaCC/CLaC | 82.21 | 8.92 |
| 34 | MCC/LaLaC | 11.82 | 2.35 |
| 36 | CCO/LaCL | ND[c] | 14.94 |
| 38 | LaCO/LCL | ND | 13.58 |
| 40 | LaLaO/LaOLa | ND | 1.43 |
| 40 | SLaC/PCL | ND | 1.98 |
| 42 | COO/OCO | ND | 23.93 |
| 42 | PPC/PCP/PCO/SCL | ND | 1.82 |
| 44 | LaOO/OLaO | ND | 12.66 |
| 44 | PLaO/PLaP/SLaL | ND | 2.17 |
| 46 | LOO/OLO | ND | 1.64 |
| 46 | PLO/PLP/LLS | ND | 0.79 |
| 48 | OOO | ND | 11.13 |
| 48 | POO/OPO | ND | 2.14 |

[a]Equivalent carbon number (ECN) = CN − 2DB, where CN is carbon number of TAG and DB is total number of double bonds in TAG. [b]Abbreviations: C, capric acid; La, lauric acid; M, myristic acid; P, palmitic acid; S, stearic acid; O, oleic acid; L, linoleic acid. [c]Not detected under this analysis condition.

LaCC/CLaC was significantly reduced; however, COO/OCO, CCO/LaCL, LaCO/LCL, LaOO/OLaO, and OOO were observed as the major TAG species in HMFS accounting for 23.93, 14.94, 13.58, 12.66, and 11.13%, respectively. All five of these TAG species newly appeared in products compared to CCSO. This indicated that enzymatic acidolysis had taken place and HMFS rich in MCFAs were well synthesized. Considering that 70% of MCFAs are at the sn-2 position and 78.69% of oleic acid is at the sn-1,3 position in the final product of HMFS, we can speculate that OCO, CCO, LaCO, OLaO, OLaO, and OOO were the major TAG compositions in HMFS.

**Purification of HMFS Product.** Free fatty acid content in the raw product was higher, mainly of oleic acid and MCFAs, and the urea inclusion method was used to remove the saturated and unsaturated fatty acids. The determination of acid value and the content of TAG in non-urea inclusion compounds were used to evaluate the effect of different HMFS/urea ratios (1:1, 1:2, 1:3) on the purification. Relevant results are shown in Table 5. Acid values in the raw product were 51.47, 52.15, and 51.53 mg KOH/g respectively, higher than those in purified product (20.33, 2.46, and 2.94 mg KOH/g). When the HMFS/urea ratio was 1:2, the acid value lowered to the minimum (2.46 mg KOH/g), which showed that free fatty acids had been almost removed. By comparison of panels C and D of Figure 5, the purity of TAG improved, and the content of TAG improved to 77.28% when the HMFS/urea ratio was 1:2. Furthermore, the synthetic HMFS was a kind of light yellow liquid and its smell was the same as ordinary oil.

**Table 5. Acid Value and Triacylglycerol Content (Weight Percent) of Raw and Purified Products with Different Ratios of HMFS/Urea**

| | acid value (mg KOH/g) | | triacylglycerol (%) | |
|---|---|---|---|---|
| HMFS/urea | raw product | purified product | raw product | purified product |
| 1:1 | 51.47 | 20.33 | 38.49 | 52.96 |
| 1:2 | 52.15 | 2.46 | 38.12 | 77.28 |
| 1:3 | 51.53 | 2.94 | 39.04 | 61.42 |

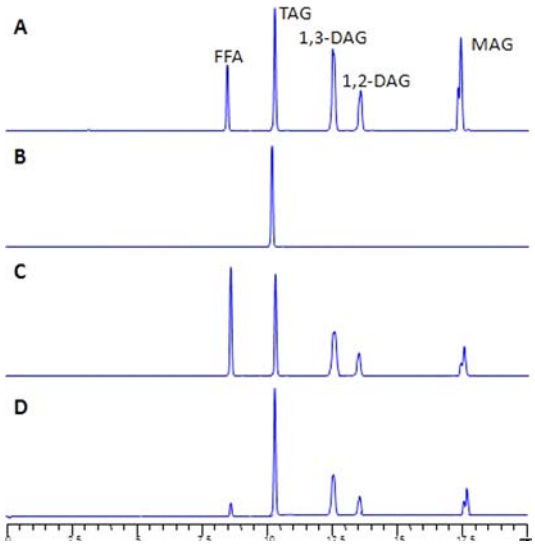

**Figure 5.** HPLC chromatograms of (A) glycerides standard, (B) CCSO, (C) raw product, and (D) purified product.

The urea inclusion product was of high purity and low damage; thus, the method was available for separation and purification of the product.

**Scale-up Trial and Physicochemical Properties.** To further verify the optimization model for mass production, a 50 times substrate (containg 50 g of CCSO) scale-up experiment was carried out under optimized condition, and the urea inclusion method was applied to purify the raw product. After purification, the incorporation of oleic acid was 58.36% as determined by GC analysis, and TAG were up to 76.95% by HPLC analysis. Table 6 shows the tocopherols content and physicochemical properties of the modified CCSO (HMFS) and CCSO. Tocopherols found naturally in vegetable oils function as antioxidants, having a physiological function of scavenging radicals in membrane and lipoprotein particles, thus preventing lipid peroxidation.[44] The contents of $\alpha$-tocopherol in CCSO and HMFS were 16.05 ± 0.62 and 5.86 ± 0.12 mg/100 g, respectively. Likewise, HMFS contained total tocopherols of 12.27 ± 0.19 mg/100 g, lower than that in CCSO (33.74 ± 1.15 mg/100 g). This indicated that the synthetic products contained a lower level of total tocopherols than the CCSO. This is a common phenomenon resulting from the acidolysis reaction and purification processes possibly due to the exposure to light and heat during these processes.[45] The acid value and peroxide value of HMFS were 1.46 ± 0.10 mg KOH/g oil and 1.87 ± 0.08 mmol/kg, respectively, higher than those of CCSO (0.21 ± 0.03 mg KOH/g oil, 0.25 ± 0.04 mmol/kg). This may be attributed to the lower level of total tocopherols in HMFS. The saponification value of HMFS (279.2 ± 2.40 mg KOH/g) was higher than that of CCSO (211.8 ± 1.70 mg KOH/g), illustrating the higher content of glyceride or fatty acid in HMFS per unit weight, which indicated that oleic acid was successfully incorporated into CCSO. The increased iodine value further proved the successful incorporation due to the inserted unsaturated oleic acid reducing the saturability of HMFS. This is in good agreement with Zhao's study.[24]

**Table 6. Contents of Tocopherol and Physicochemical Characteristics of CCSO and Human Milk Fat Substitutes (HMFS)[a]**

| | CCSO | HMFS[b] |
|---|---|---|
| tocopherol (mg/100 g) | | |
| $\alpha$-tocopherol | 16.05 ± 0.62 | 5.86 ± 0.12 |
| $\gamma$-tocopherol | 4.99 ± 0.24 | 1.73 ± 0.01 |
| $\delta$-tocopherol | 12.70 ± 0.29 | 4.68 ± 0.06 |
| total | 33.74 ± 1.15 | 12.27 ± 0.19 |
| physicochemical characteristics | | |
| acid value (mg KOH/g oil) | 0.21 ± 0.03 | 1.46 ± 0.10 |
| peroxide value (mmol/kg) | 0.25 ± 0.04 | 1.87 ± 0.08 |
| iodine value (g $I_2$/100 g oil) | 5.98 ± 0.23 | 54.52 ± 0.63 |
| saponification value (mg KOH/g) | 279.20 ± 2.40 | 211.8 ± 1.70 |

[a]Values presented as means of triplicates ± standard deviation. [b]Human milk fat substitutes (HMFS) was synthesized with the Lipozyme RM IM of 12.5% (of the total substrate) and molar ratio of 5:1 (oleic acid/CCSO) at 60 °C for the reaction of 28 h.

**Reusability of Lipozyme RM IM.** To investigate the reusability of Lipozyme RM IM, the modified optimal reaction conditions were used to detect the stability of the lipase. The activity was expressed as the incorporation of oleic acid in the produced HMFS. After each batch, the lipase was filtered and recovered. Ten batch cycles were conducted. The results

showed that the incorporation of oleic acid was maintained above 52% (87.13% of the first cycle oleic acid incorporation) at the 6th cycle, above 43% (72.05% of the 1st cycle oleic acid incorporation) at the 9th cycle, and about 38% (63.67% of the 1st cycle oleic acid incorporation) at the 10th cycle using Lipozyme RM IM (Figure 6). Therefore, Lipozyme RM IM could be reused 9 times without significant loss of activity.

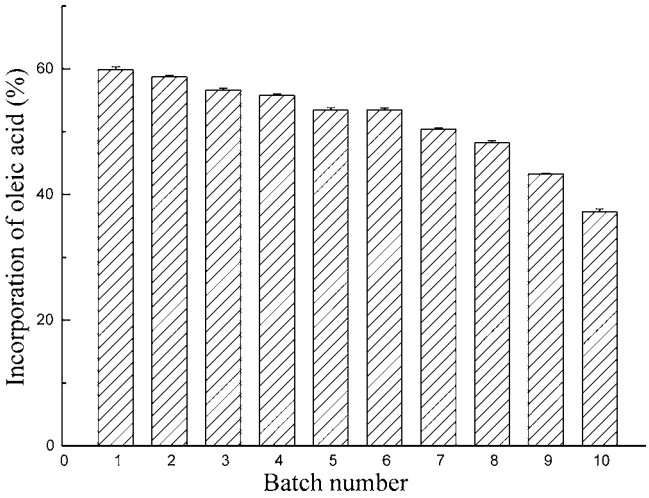

**Figure 6.** Stability of Lipozyme RM IM used for the acidolysis reaction after several usages.

**Conclusion.** This study has synthesized HMFS from CCSO with oleic acid by Lipozyme RM IM-catalyzed acidolysis in a solvent-free system, and the optimal reaction conditions were investigated by RSM and found to be a substrate molar ratio (oleic acid/CCSO) of 5:1, an enzyme concentration of 12.5% (w/w total reactants), a reaction temperature of 60 °C, and a reaction time of 28 h. Under these reaction conditions, the final product HMFS was achieved with >70% of MCFAs at the sn-2 position and 78.69% oleic acid at the sn-1,3 position. In a scale-up trial, the urea inclusion method can separate and purify the synthetic product to some extent, although it has limitations for production at the industrial scale. After purification, the contents of TAG and total tocopherols were 77.28% and 12.27 ± 0.19 mg/100 g, respectively. All of the physicochemical indices of product including acid value and peroxide value were within national standards. The present results showed that such HMFS enriched in MCFAs might have potential application in the infant formula industry, especially to be used as a dietary treatment for premature infants who suffer from fat-absorption abnormalities and infant patients who need rapid fat absorption and energy supply. All of these results may be further improved by the use of an immobilization-modified enzyme, which has enhanced stability and selectivity, and by the use of a better purification method such as molecule distillation for industrial production.

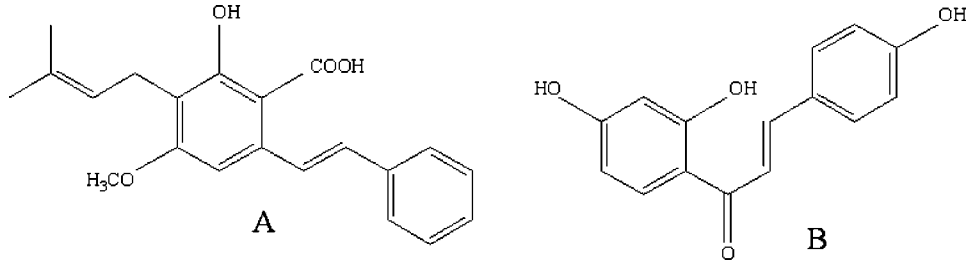

**Figure 1.** Chemical structures of (A) cajaninstilbene acid (CSA) and (B) isoliquiritigenin (ISL).

majority of drugs.[14,15] The activity alteration of these enzymes is the major cause of metabolic food−drug interactions.[16]

Hence, the aim of our study was to investigate the in vitro metabolism of CSA by human liver microsomes and recombinant human P450 enzymes to identify the CYP450 enzymes involved and evaluate potential CSA food−drug interactions.

## MATERIALS AND METHODS

**Chemicals and Reagents.** Cajaninstilbene acid (CSA, purity = 98%, HPLC grade) was isolated and purified in our laboratory. By comparing the IR, $^{1}H$ and $^{13}C$ nuclear magnetic resonance (NMR), and MS data with reported data,[17] we confirmed the structure of CSA. Isoliquiritigenin (ISL), paclitaxel, glucose 6-phosphate, glucose-6-phosphate dehydrogenase, NADPH- and CYP450-specific substrates, inhibitors, and inducers were purchased from Sigma-Aldrich (St. Louis, MO, USA). Human liver microsomes (pooled from 20 donors) and primary human hepatocytes (the human donor was a 47-year-old nonsmoking Chinese female with no known history of human immunodeficiency or virus exposure to hepatitis B or C) were purchased from iPhase Biosciences Co., Beijing, China. Recombinant human P450 enzymes (CYP1A2, CYP2A6, CYP2C9, CYP2C19, CYP2D6, CYP2E1, and CYP3A4) and human CYP-reductase coexpressed in *Escherichia coli*, supplemented with purified human cytochrome *b*5, were purchased from Cypex (Dundee, UK). All microsomal preparations were stored at −80 °C until used. The total P450 content, protein concentrations, and specific activity of each P450 isoform were supplied by the manufacturer. All other reagents and chemicals were of analytical grade. The chemical structures of CSA and ISL are shown in Figure 1.

**Incubations with Human Liver Microsomes for Metabolite Identification.** Incubation experiments were performed as described previously with slight modification.[18,19] Microsomal incubation mixture in phosphate buffer, pH 7.4 (0.1 mol/L), consisted of CSA (20 $\mu$M), 3 mM $MgCl_2$, 0.5 mg/mL microsomal protein, and the NADPH-regenerating system (0.5 mM $NADP^+$, 5 mM glucose 6-phosphate, and 0.5 unit of glucose-6-phosphate dehydrogenase/mL). Final volume was 500 $\mu$L. Samples were incubated at 37 °C for 5 min before the reaction was initiated by the addition of microsomal proteins. Thereafter, samples were carried out aerobically at 37 °C in a test tube placed on a temperature-controlled heating block for 60 min. To terminate the reaction, 500 $\mu$L of acetonitrile containing ISL (100 $\mu$L of 50 $\mu$M) was added. ISL was added as an internal standard to the incubation sample and vortexed for 3 min, and then the sample was extracted using 1 mL of ethyl acetate. The sample was centrifuged at 12000 rpm for 20 min at room temperature. The supernatant was then transferred to a separate tube and evaporated to dryness under nitrogen. The residues were dissolved in 0.1 mL of methanol and then vortex-mixed for 30 s and centrifuged at high speed for 5 min in an Eppendorf tube. All of the samples were injected into HPLC and LC-MS/MS for the analysis of CSA and its metabolites.

**Identification of P450s Involved in Metabolite Formation from CSA.** To determine the isozymes involved in metabolite formation in CSA, the chemical inhibitor and recombinant human P450 enzymes were used.

Formation rates of hydroxylation metabolites (M1, M2) from CSA were evaluated in the absence (control) and presence of known CYP450 isoform-specific inhibitors with pooled human liver microsomes. The inhibitors were 20 $\mu$M furafylline (CYP1A2 inhibitor), 50 $\mu$M pilocarpine (CYP2A6 inhibitor), 50 $\mu$M sulfaphenazole (CYP2C9 inhibitor), 5 $\mu$M ticlopidine (CYP2C19 inhibitor), 10 $\mu$M quinidine (CYP2D6 inhibitor), 50 $\mu$M diethylthiocarbamate (CYP2E1 inhibitor), and 5 $\mu$M ketoconazole (CYP3A4 inhibitor). The final concentration of acetonitrile in incubations was 0.1%. CSA (20 $\mu$M) was preheated for 5 min at 37 °C in an NADPH-generating system. Human liver microsomes (0.5 mg/mL) were added to initiate the reaction and incubated at 37 °C for 15 min. The inhibitors concentrations were chosen selectively for the respective CYP450 isoforms. Inhibition percent of metabolites' formation rate was calculated by comparing the inhibited activity with uninhibited controls (without inhibitors). Stock solutions of the chemical inhibitors were prepared in acetonitrile. Control solutions were prepared with the same amount of acetonitrile without inhibitors. The conditions for use of these inhibitors have been described in previous publications.[20−22]

The recombinant human P450 enzyme experiments were performed as described previously with slight modification,[23] The incubation system was the same as those applied to the liver microsomal incubations with the exception that microsomes were replaced by recombinant human P450 enzymes CYP1A2, 2A6, 2C9, 2C19, 2D6, 2E1, and 3A4. The enzyme concentration in the incubation system was 50 pmol/mL. The total volume of incubation was 500 $\mu$L. The incubation time was 60 min, and the sample treatment method was same as described under Incubations with Human Liver Microsomes for Metabolite Identification.

**Quantification and Chromatographic Analysis of Metabolites.** An LC-MS/MS analysis method was used to quantify CSA and its major metabolites M1 and M2. LC-MS/MS was carried out with an Agilent 1100 series LC system equipped with a UV detector (Agilent Technologies, Palo Alto, CA, USA). An HPLC system consisting of degasser G1379B, binary pump G1312B, a 7725i manual injector, and column thermostat G1316B was used. An HIQ Sil C 18 column (4.6 mm × 250 mm, KYA TEACH, made in Japan) was used. The mobile phase consisted of water and methanol (15:85, v/v) containing 0.1% formic acid. The flow rate was 1.0 mL/min, and the column eluate was monitored at a wavelength of 254 nm. The Agilent 1100 series LC system was series connected with an API5500Q trap triple-stage quadrupole mass spectrometer (Applied Biosystems, Concord, Canada) equipped with an electrospray ionization (ESI) source. The mass spectrometer was operated in negative ion mode with a capillary temperature of 300 °C and spray voltage of −4500 V. The nitrogen gas flow rate, collision energy, and declustering potential were adjusted to give maximum sensitivity for CSA (12 L/min, −25 V, −60 V, respectively).[9] The mass spectrometer was operated in multiple reaction monitoring (MRM) mode. For semiquantification of CSA and hydroxylation metabolites (M1, M2), ISL was added to each sample as internal standard and the following MRM transitions were selected on the basis of the fragmentation of $(M - H)^-$ ions (results observed in previous MS/MS analyses): 337.1/293.0 for CSA, 353.1/279.1 for M1, 353.4/253.9 for M2, and 255.1/119.3 for ISL.

An LC-MS/MS quantification method was used to quantify CYP450 enzyme activities in human liver microsomes and primary

Table 1. Experimental Conditions for Measuring Microsomal P450 Activity for Enzyme Inhibition Studies

| CYP isoform | substrate | substrate probe | parent ion | daughter ion | polarity | declustering potential (V) | collision energy (V) |
|---|---|---|---|---|---|---|---|
| 3A4 | testosterone | testosterone 6$\beta$-hydroxylation | 305.5 | 269 | ESI+ | 65 | 25 |
| 2D6 | dextromethorphan | dextromethorphan O-demethylation | 258.2 | 157 | ESI+ | 80 | 55 |
| 2C9 | tolbutamide | tolbutamide 4′-hydroxylation | 287.1 | 171.2 | ESI+ | 55 | 30 |
| 2A6 | coumarin | coumarin 7′-hydroxylation | 160.9 | 132.1 | ESI+ | 65 | 35 |
| 1A2 | phenacetin | phenacetin O-dealkylation | 151.9 | 110.1 | ESI+ | 60 | 25 |
| 2C19 | *S*-mephenytoin | *S*-mephenytoin 4 -hydroxylation | 233.4 | 190.2 | ESI− | −55 | −20 |
| 2E1 | chlorozoxazone | chlorozoxazone 6′-hydroxylation | 184 | 120.1 | ESI− | −40 | −15 |
| internal standard | | paclitaxel | 876 | 308.1 | ESI+ | −45 | −25 |

human hepatocytes. The ionization mode was electrospray, polarity positive. Electrospray jet stream conditions were as follows: capillary voltage, −4500 V; drying gas temperature, 300 °C; nebulizer pressure, 20 psi; sheath gas temperature, 350 °C. The mass spectrometer was operated in the MRM mode. MRM transitions, fragmentor voltage, and collision energy of the substrate probes are summarized in Table 1.

For structural identification, metabolites and major molecular ion peaks were determined using HPLC-MS, MS/MS, and MS/MS/MS spectra separately. Metabolites were identified on the basis of their accurate mass determination and fragmentation patterns in positive and negative modes.

**Enzyme Kinetic Analysis of CSA in Human Liver Microsomes and Recombinant Human P450 Enzymes.** The enzyme kinetics of CSA metabolism by pooled human liver microsomes and seven recombinant human P450 enzymes (CYP1A2, CYP2A6, CYP2C9, CYP2C19, CYP2D6, CYP2E1, or CYP3A4) was investigated. Kinetic constants were derived from incubations with the following CSA concentrations: 1, 2, 3.9, 7.8, 15.6, 31.3, 62.5, 125, 250, and 500 $\mu$M ($n$ = 3). Human liver microsomes and recombinant human P450 enzyme contents were 0.5 mg/mL and 50 pmol/mL, respectively. Incubation times were 30 and 15 min for human liver microsomes and recombinant human P450 enzymes, respectively. Reactions were stopped by adding 500 $\mu$L of protein precipitation/internal standard solution and were extracted as previously described. Incubation mixtures without NADPH incubated were used as controls.

**CSA Inhibition Study of CYP450 Enzymes.** The potential of CSA as an inhibitor of major drug-metabolizing CYP450 enzymes was evaluated with human liver microsomes using selective CYP450 probe substrates (Table1) in a reversible and time-dependent manner. Incubation in phosphate buffer, pH 7.4 (0.1 mol/L), was conducted at 37 °C, consisting of human liver microsomes, 0.5 mg/mL, and CYP450 probe substrate with the NADPH-regenerating system. In the assay of CSA inhibition in reversible manner, human liver microsomes were the last reagent added into the incubation system to initiate the reaction; after 10 min, the reaction was terminated by adding an equal volume of acetonitrile (v/v) containing paclitaxel as an internal standard. To examine CSA potential as a time-dependent inhibitor, CSA (20 $\mu$M) was preincubated at 37 °C with human liver microsomes and an NADPH-generating system for 30 min. After the preincubation period, the probe substrate was added, and the incubation was continued for 10 min to measure residual CYP450 activity. Reactions were terminated as described above. Samples were analyzed as described under Analytical Methods. The $IC_{50}$ value was determined by incubation of pooled human liver microsomes (0.5 mg/mL) with CYP450 probe substrates in the presence and absence of CSA (0.1−100 $\mu$M). The results were processed following a method described previously.[24]

**Analysis of CSA To Induce CYP450 Enzymes.** To investigate the potential of CSA to induce CYP450 enzymes, the enzyme activities of CYP1A2, CYP2A6, CYP2E1, CYP2C9, CYP2C19, and CYP3A4 in primary human hepatocytes were assessed. Primary human hepatocytes were treated with CSA (1, 10, and 30 $\mu$M) or one of three prototypical CYP450 inducers, omeprazole (100 $\mu$M), phenobarbital (750 $\mu$M), and rifampin (10 $\mu$M), as positive controls for 3 days. CSA and the positive controls were dissolved in DMSO, and hepatocytes treated with DMSO (final concentration = 0.1%, v/v) served as negative controls. Hepatocytes were harvested after 72 h of treatment, and microsomes were prepared from each culture, on the basis of the methods described previously.[25] The enzyme activity in microsomal samples was determined by incubating microsomal samples with probe substrates for 10 min at 37 °C. Microsomes were incubated with phenacetin (80 $\mu$M), tolbutamide (100 $\mu$M), coumarin (100 $\mu$M), chlorozoxazone (200 $\mu$M), *S*-mephenytoin (200 $\mu$M), and testosterone (250 $\mu$M) for various time periods (10−30 min). Then the activities of CYP1A2, CYP2A6, CYP2E1, CYP2C9, CYP2C19, and CYP3A4 were determined, respectively. Samples were analyzed as described under Quantification and Chromatographic Analysis of Metabolites. Hepatocytes' culture method and sample treatment method were described previously.[26]

**Data Analysis.** Nonlinear regression analysis, $V = V_{max}(S)/(K_m + (S))$, was used to describe the kinetics of biotransformation of CSA to M1 and M2 in human liver microsomes (GraphPad Prism 5.0).[27] $V$ is reaction rate, $(S)$ is substrate concentration, and $K_m$ is the Michaelis−Menten constant. The intrinsic clearance ($CL_{int}$) for formation of each CSA metabolite was calculated by $V_{max}/K_m$; it is a parameter commonly used for quantitative in vitro−in vivo allometric scaling.[28,29]

## RESULTS

**Identification of Metabolites Formed by Human Liver Microsomes.** When CSA was incubated with human liver microsomes in the presence of NADPH, two metabolites (M1 and M2) were detected by HPLC. The formation of the metabolites was dependent on the presence of NADPH, and the yield of metabolite appeared to be linear with respect to incubation time (up to 30 min). However, no metabolite could be clearly observed in the absence of NADPH. Typical chromatograms of CSA and its two main metabolites are shown in Figure 2. The HPLC retention times of metabolites, CSA, and the internal standard (ISL) were 6.8 (M1), 9.1 (M2), 15.7, and 3.9 min, respectively.

To characterize M1 and M2, LC-MS/MS and LC-MS/MS/MS methods were used. MS/MS and MS/MS/MS spectra of M1 and M2 are shown in Figure 3. First, precursor ion scanning identified two potential metabolites that exhibited 353.1 and 353.4 amu in the CSA microsomal incubates that consisted of human liver microsomes and NADPH system (but not in negative control experiments) in addition to the 337.3 amu of CSA. Second, to gain further structural information, MS/MS spectra of these potential metabolites were obtained by collision-induced dissociation of their molecular ions. The MS/MS spectra detected two major characteristic fragment ions for each potential metabolite: $m/z$ 309.1, 291.2, and 279.1 were obtained from $m/z$ 353.1; $m/z$ 309.3, 253.9, and 238.7 were obtained from $m/z$ 353.4. These transition ions were selected in the MRM modes for identification and quantification of the metabolites: The metabolite with 353.1 amu was measured with

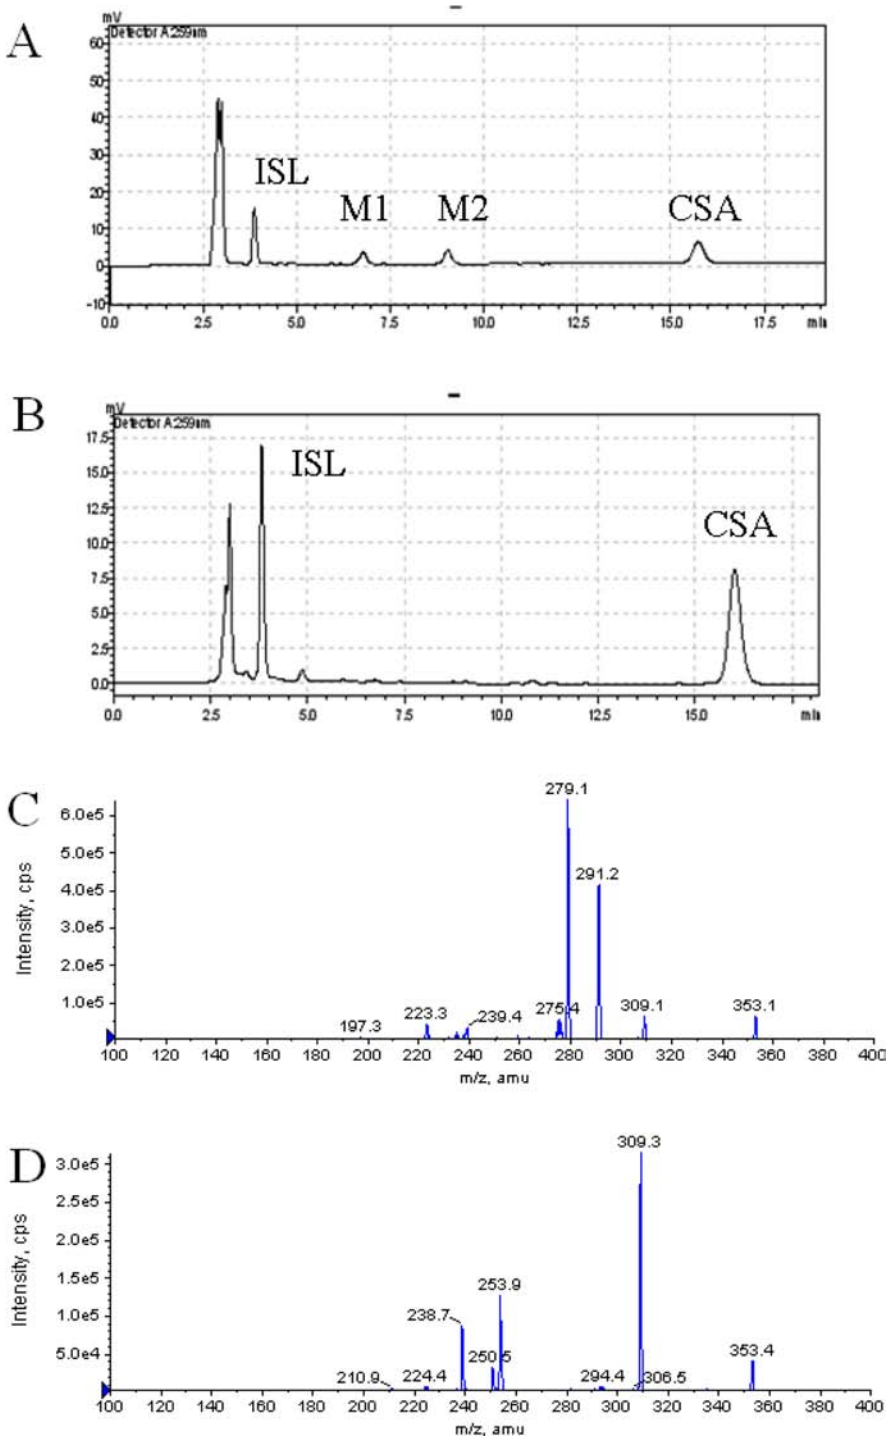

**Figure 2.** Representative chromatograms of CSA metabolites (M1 and M2) extracted from human liver microsomal incubates: (A) CSA incubated by human liver microsomes with NADPH-regenerating system; (B) CSA incubated by human liver microsomes without NADPH-regenerating system; MS/MS spectra of (C) M1 and (D) M2, the metabolite of CSA formed by human liver microsomes. ISL was used as an internal standard (IS). The retention times of M1, M2, CSA, and the internal standard (ISL) were 6.8, 9.1, 15.7, and 3.9 min, respectively.

the quantifier MRM $m/z$ 353.1/279.1 and confirmed with the qualifier MRM transition $m/z$ 353.1/291.2, and the metabolite with 353.4 amu was measured with the quantifier MRM $m/z$ 353.4/253.9 and confirmed with the qualifier MRM 353.4/238.7.

To determine the structures of M1and M2, the parent drug fragmentation pattern was used as a guide to identify CSA metabolites; metabolic pathways of CSA are shown in Figure 4. M1 and M2 showed the (M − H) ion at $m/z$ 353, which was 16 amu higher than that of the parent compound, suggesting that an oxygen atom was inserted into the molecule of CSA. To further confirm the structure of metabolites M1 and M2, MS/MS/MS experiments were performed. Fragment ions $m/z$ 309.1, 291.2, 279.1, and 239.4 from M1 and $m/z$ 309.3, 253.9, 250.5, and 238.7 from M2 were analyzed. The major fragment ions of $m/z$ 309.1, 291.2, 279.1, 239.4, 309.3, 253.9, 250.5, and 238.7 are shown in Figure 3. The fragment pathways of M1 and M2 are shown in Figure 5.

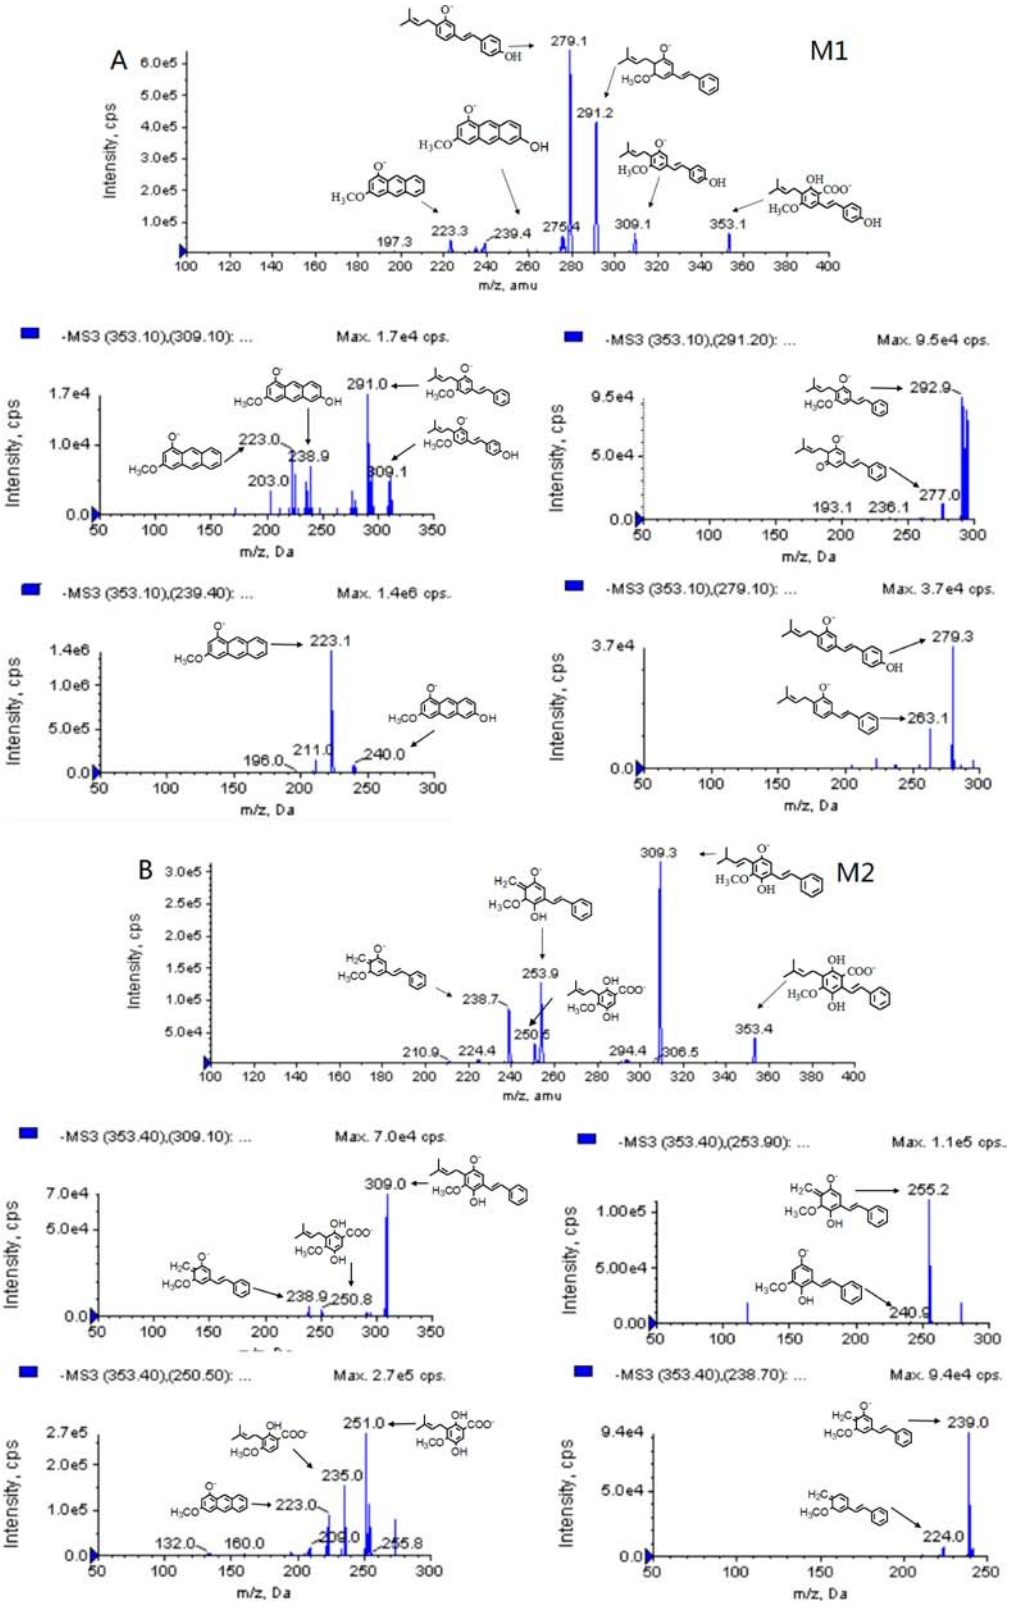

**Figure 3.** MS/MS and MS/MS/MS spectra of (A) M1 and (B) M2.

**Kinetic Analysis of CSA in Human Liver Microsomes.** Kinetic analysis for the formation of M1 and M2 was studied with pooled human liver microsomes. The formation rate of M1 and M2 revealed Michaelis−Menten saturation curves. A representative Michaelis−Menten plot for M1 and M2 formation in human liver microsomes is shown in Figure 6. The apparent $K_m$ values of M1 and M2 catalyzed by human liver microsomes are 28.8 and 23.6 $\mu$M, respectively (Table 2). $V_{max}$ (apparent) values were 141.6 and 122.7 pmol/mg/min, respectively. On average, the apparent intrinsic clearances ($Cl_{int}$) of M1 and M2 formation were 4.9 and 5.2 $\mu$L/mg protein/min, respectively.

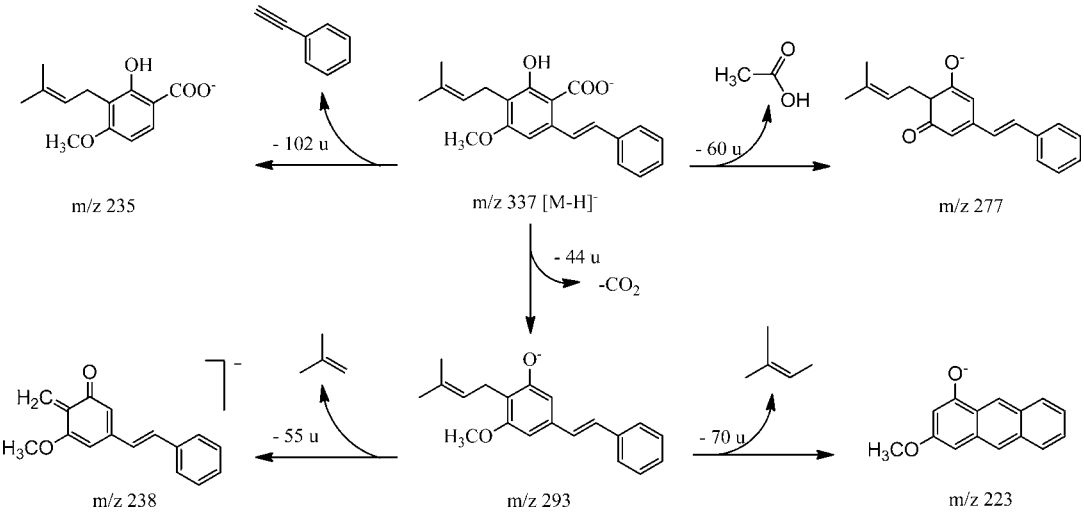

**Figure 4.** Formation and fragmentation pathways of CSA.

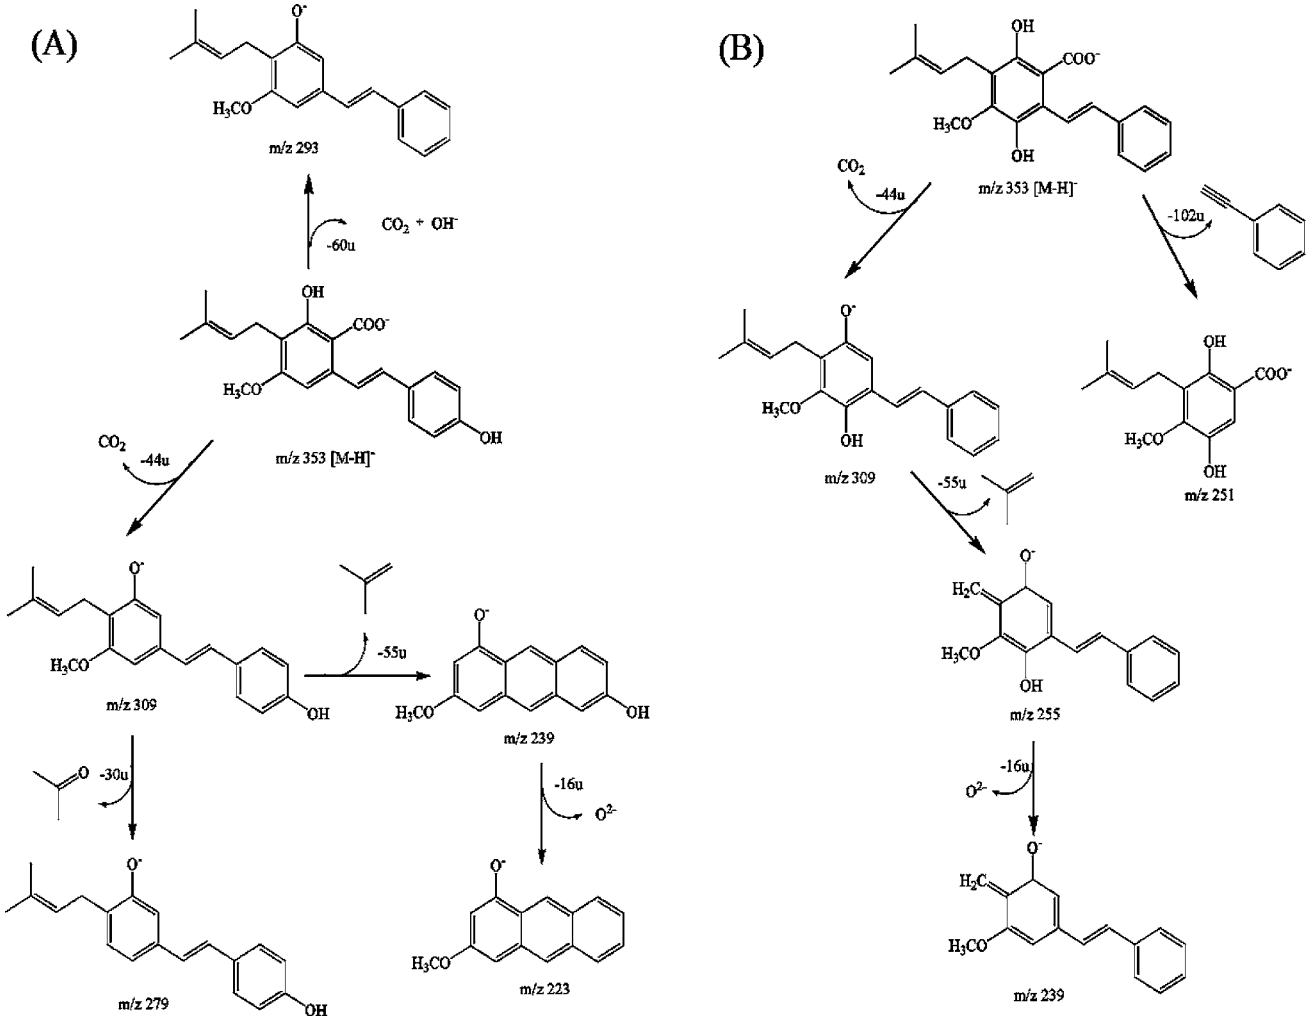

**Figure 5.** Formation and fragmentation pathways of (A) M1 and (B) M2.

**Metabolism of CSA by Recombinant Human P450 Enzymes.** Kinetic parameters of M1 and M2 from CSA are shown in Table 3. The formation rates of M1 and M2 revealed Michaelis–Menten saturation curves. The $K_m$ and $V_{max}$ of M1 formation from CSA were 5.9, 9.0, and 12.9 $\mu$M and 6.8, 15.0, and 28.9 pmol/mg/min for CYP1A2, CYP2C9, and CYP3A4, respectively. The $K_m$ and $V_{max}$ of M2 formation from CSA were 19.7 $\mu$M and 104.6 pmol/mg/min, respectively, for CYP2C9. To better assess the relative contribution of the individual P450 isoforms to the in vitro formation of CSA in human liver microsomes, the intrinsic clearances were calculated. The $CL_{int}$ values ($V_{max}/K_m$) for the formation of M1 by CYP1A2,

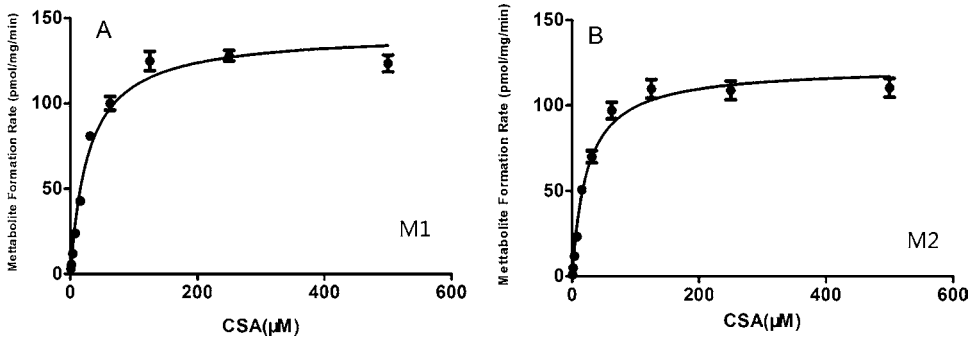

**Figure 6.** CSA concentration-dependent formation of (A) M1 and (B) M2 in the incubations with human liver microsomes. Data were fitted to a Michaelis–Menten substrate binding curve.

**Table 2. Kinetic Parameters for the Metabolism of CSA by Human Liver Microsomes**

| metabolite | pathway | $K_m$ ($\mu$M) | $V_{max}$ (pmol/mg/min) | $V_{max}/K_m$ ($\mu$L/mg protein/min) | kinetic model |
|---|---|---|---|---|---|
| M1 | phenyl hydroxylation | 28.8 | 141.6 | 4.9 | Michaelis–Menten |
| M2 | phenyl hydroxylation | 23.6 | 122.7 | 5.2 | Michaelis–Menten |

**Table 3. Kinetic Parameters for the Metabolism of CSA by Recombinant Human P450 Enzymes**

| metabolite | P450 | $K_m$ ($\mu$M) | $V_{max}$ (pmol/mg/min) | $V_{max}/K_m$ ($\mu$L/mg protein/min) | % of total $CL_{int}$ | kinetic model |
|---|---|---|---|---|---|---|
| M1 | CYP1A2 | 5.9 | 6.8 | 1.2 | 22.1 | Michaelis–Menten |
| | CYP2C9 | 9.0 | 15.0 | 1.7 | 31.7 | Michaelis–Menten |
| | CYP3A4 | 12.9 | 28.9 | 2.2 | 42.6 | Michaelis–Menten |
| M2 | CYP2C9 | 19.7 | 104.6 | 5.3 | 95.6 | |

CYP2C9, and CYP3A4 were 1.2, 1.7, and 2.2 $\mu$L/mg protein/min, respectively. The $CL_{int}$ value for the formation of M2 by CYP2C9 was 5.3 $\mu$L/mg protein/min.

**Chemical Inhibition Experiment.** Studies were conducted to evaluate the effect of CYP450 enzyme chemical inhibitors on the formation of M1 and M2 in pooled human liver microsomes (the concentration of CSA was 20 $\mu$M). According to the result above, M1 and M2 were identified as the metabolites derived from hydroxylation of CSA. Because of the very low yield of metabolites, they have not been separated or synthesized for technical reasons; metabolite formation was quantified by the loss of CSA relative to the internal standard (ISL) in each incubation sample on the basis of the MRM responses. Figure 7 presents the results of CSA biotransformation in the human liver microsome incubations after treatment with various inhibitors. Among seven kinds of inhibitors, ketoconazole (CYP3A4), sulfaphenazole (CYP2C9), and furafylline (CYP1A2) notably inhibited the formation of M1 from CSA. The percentages of inhibition of M1 formation by CYP1A2, CYP2C9, and CYP3A4 were 26.0, 35.5, and 38.5%, respectively. Sulfaphenazole showed significant inhibition to M2 formation, the percentage of inhibition reaching 97.8%. Percent inhibition of metabolite formation rate by isoform-specific inhibitors was calculated by comparing the inhibited activity with uninhibited controls (without inhibitors).

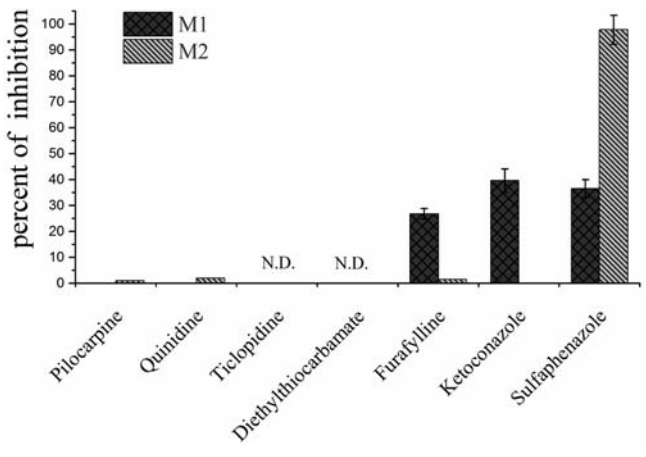

**Figure 7.** Inhibition percent of CSA with chemical inhibitor addition in the incubation system of human liver microsomes.

**CSA Inhibition Study of CYP450 Enzymes.** CSA (0.1–100 $\mu$M) was evaluated for its ability to inhibit CYP450 activity in pooled human liver microsomes using probe substrate. The results are presented in Table 4 and Figure 8. It is indicated that in a reversible manner CSA was an inhibitor of CYP3A4 and CYP2C9 ($IC_{50}$ values were 28.3 and 31.3 $\mu$M, respectively). CSA showed little or no inhibition to CYP1A2, 2A6, 2D6, 2C19, or 2E1 ($IC_{50} \geq 40$ $\mu$M).

**Table 4. CSA Inhibitory Activity against CYP1A2, CYP2A6, CYP2E1, CYP2C9, CYP2C19, CYP2D6, and CYP3A4 in Pooled Human Liver Microsomes**

| | $IC_{50}$ ($\mu$M) | |
|---|---|---|
| CYP isoform | 0 min of preincubation | 30 min of preincubation |
| 3A4 | 28.3 | 27.2 |
| 2D6 | >100 | >100 |
| 2C9 | 31.3 | 33.5 |
| 2A6 | >100 | >100 |
| 1A2 | >100 | >100 |
| 2C19 | >100 | >100 |
| 2E1 | 43.9 | 44.1 |

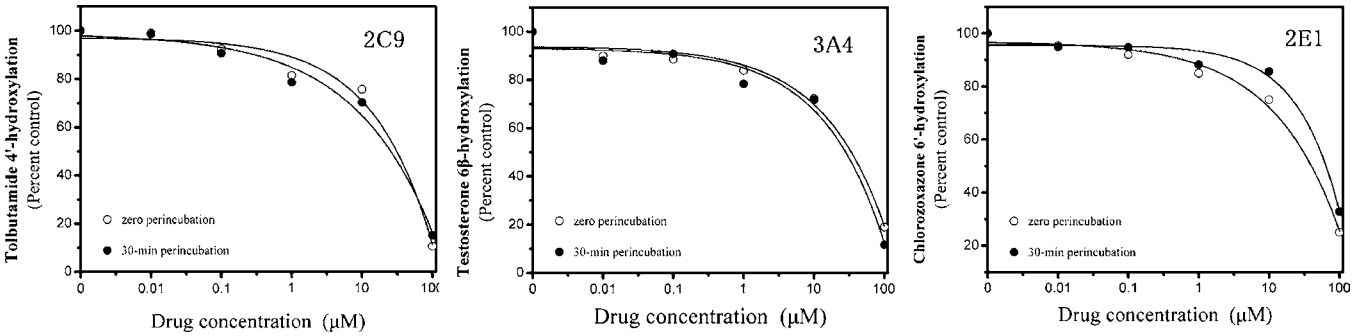

**Figure 8.** Effect of CSA on microsomal enzyme activity of CYP3A4, CYP2C9, and CYP2E1 with and without a 30 min preincubation with NADPH-fortified human liver microsomes.

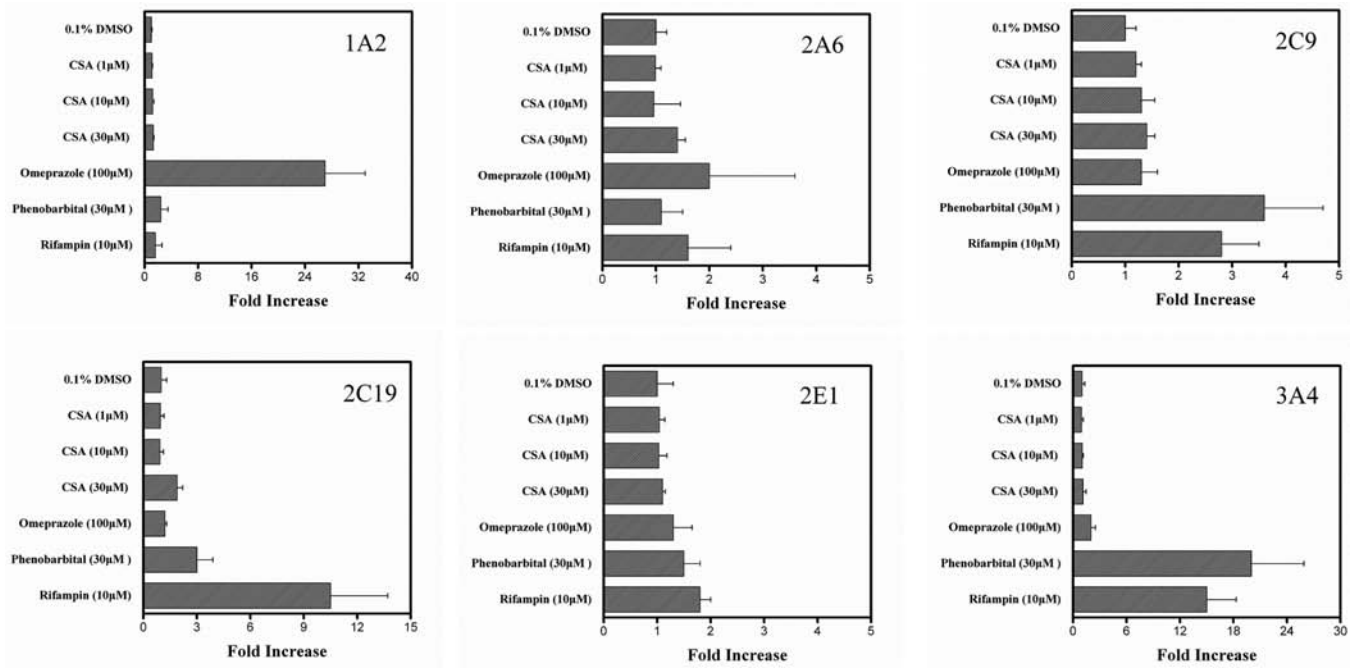

**Figure 9.** Effect of CSA or prototypical inducers on microsomal CYP450 activity in cultured human hepatocytes.

In the assay of time-dependent manner, the $IC_{50}$ values of CYP3A4 and CYP2C9 were 27.2 and 33.5 $\mu$M, respectively. $IC_{50}$ values of other enzymes were >40 $\mu$M.

**Analysis of CSA Potential To Induce CYP450 Enzymes.** To investigate the potential of CSA to induce the expression of CYP450 enzymes, freshly isolated and pretreated human hepatocytes were used. Three preparations of human hepatocytes were cultured and treated with CSA (1, 10, or 30 $\mu$M) or one of three prototypical enzyme inducers, omeprazole (100 $\mu$M), phenobarbital (750 $\mu$M), and rifampin (10 $\mu$M), once daily for 3 consecutive days. For the concentrations tested, CSA was not cytotoxic.

After treatment in all three preparations of human hepatocytes, prototypical CYP450 enzymes showed obviously sensitive to the inducers, as the result in Figure 9. Treatment with omeprazole produced a marked increase in CYP1A2 (27-fold), whereas it showed increases in CYP2C9 (3−4-fold), CYP2C19 (3−10-fold), and CYP3A4 (15−21-fold) after treatment with phenobarbital and rifampin. In the experiment of treatment with human hepatocytes for 3 consecutive days, with the concentration of CSA up to 30 $\mu$M, the activities of CYP1A2, CYP2A6, CYP2E1, CYP2C9, CYP2C19 , and CYP3A4 were almost not affected by CSA. The extent of enzyme activity induction did not reach significant levels, <2-fold increase (40% of the positive control).

## ■ DISSCUSSION

CSA has been shown to have effective antitumor, antioxidant, anti-inflammatory, and analgesic activities. However, up until now, the metabolism of CSA in vitro was unclear, and CSA metabolism in humans needs to be clarified. Therefore, metabolism of CSA with the CYP450 enzymes involved in vitro was identified in this study. Furthermore, experiments were conducted to explore the potential of CSA to cause food−drug interactions resulting from the inhibition or induction of the major human CYP450 enzymes.

LC-MS/MS, LC-MS/MS/MS, and parent drug fragmentation patterns were used as a guide to identify CSA metabolites. The fragmentation pathway of M1 was very similar to that of CSA. It was supposed that a hydroxyl group was conjugated on a simple benzene ring and dehydroxylation occurred easily. The most stable combination will occur at the para-position of the benzene ring, suggesting the structure of M1 was 12-hydroxycajaninstilbene acid. Fragment ions $m/z$ 250.5 and

dx.doi.org/10.1021/jf501635a | J. Agric. Food Chem. 2014, 62, 10604−10614

235.1 were found in fragment products of M2. It can be confirmed that $m/z$ 235.1 was obtained by styrene group removal on CSA according to the fragment pathway of CSA. $m/z$ 250.5 was 16 Da higher than $m/z$ 235.1, suggesting the hydroxyl occurred on $m/z$ 235.1 on the basis of MS/MS/MS results. Hence, it was supposed the hydroxyl was on the benzene ring that conjugated to isoprene, so the structure of M2 was 6-hydroxycajaninstilbene acid.

Hydroxylation to form metabolites M1 and M2 was the primary metabolic pathway of CSA in human liver microsomes. This indicates that CYP2C9 catalyzed the formation of all oxidative metabolites according to the results of incubations with recombinant human P450 enzymes and studies with human liver microsomes and selective P450 inhibitors, whereas CYP3A4 and CYP1A2 were only involved in the oxidization of CSA in the process of M1 formation.

The $CL_{int}$ values between human liver microsomes and recombinant human P450 enzymes indicated that CYP1A2, CYP2C9, and CYP3A4 were the predominant P450 enzymes forming M1. The $CL_{int}$ values for the formation of M1 by CYP3A4, CYP1A2, and CYP2C9 consistently were 1.2, 1.7, and 2.2 $\mu$L/mg protein/min, accounting for 22.1, 31.7, and 42.6% of the total $CL_{int}$. The inhibition effects of the chemical inhibitor toward M1 formation were consistent with the results of the contribution of each P450 involved in M1 formation. CYP1A2, CYP2C9, and CYP3A4 chemical inhibitors in human liver microsomes inhibited the formation of M1 by 26.0, 35.5, and 38.5%, respectively. This result was consistent with the $CL_{int}$ values of recombinant human P450 enzymes.

It is strongly suggested that M2 was primarily metabolized by CYP2C9 in human liver microsomes, on the basis of the present P450 reaction phenotype study. First, sulfaphenazole, a CYP2C9 specific inhibitor, significantly inhibited the formation of all major metabolites and the overall metabolism of M2; the inhibition rate was 97.8%. The chemical inhibitors selective to CYP1A2, CYP2A6, CYP2C9, CYP2C19, CYP2D6, and CYP2E1 showed little or no inhibitory effect on M2 formation. Second, recombinant CYP2C9 exhibited very high M2 oxidation activity, whereas other P450 isoforms had no or minimal M2 oxidation activity. The $CL_{int}$ values for the formation of M2 by CYP2C9 were 5.3 $\mu$L/mg protein/min, accounting for 95% of the total $CL_{int}$.

CYP2C9 was the only cytochrome P450 enzyme that converted CSA to M2, which raises the potential food−drug interactions. When two or more drugs competed for only one enzyme, and this enzyme catalyzing the metabolic reaction constitutes the major elimination pathway, a significant cytochrome P450 drug interaction may occur.[30,31] Compared with only one isozyme, three isozymes involved in the metabolism of CSA to M1 will reduce the potential food−drug interactions.

Inhibition studies were determined using the $(I)/K_i$ approach. $(I)$ is the maximum concentration of total drug at steady state $C_{max}$. $K_i$ wis the unbound inhibition constant determined in vitro. With a cutoff value of $(I)/K_i > 0.1$, drugs show an inhibition effect on enzymes. When $(I)/K_i < 0.1$, it is reasonable to assume that a drug had no clinically significant CYP450 inhibition. Although CSA metabolism studies in rats were reported recently,[9] there is no relative report of CSA metabolism in the human body until now. Herein, we assumed that $C_{max}$ is similar between rats and humans (with the addition of $IC_{50}$), and the potential of CSA in vitro food−drug interactions was evaluated using the $(I)/K_i$ approach. After 10 mg oral administration b.i.d. to rats, CSA resulted in a steady-state $C_{max}$ concentration of 2.03 $\mu$M (data not shown). The inhibitor concentration causing 50% inhibition ($IC_{50}$) was determined, and $K_i$ can be calculated as $IC_{50}/2$ by assuming competitive inhibition. Because $C_{max}/K_i$ was 0.14 for CYP3A4 and 0.13 for CYP2C9, it was possible for CSA to cause CYP3A4 and CYP2C9 inhibition. $C_{max}/K_i$ values were <0.1 for CYP1A2, CYP2A6, CYP2D6, CYP2C19, and CYP2E1, suggesting that CSA had a low tendency to inhibit these enzymes. CYP3A is the most abundant cytochrome P450 enzyme in humans, and it has been estimated that CYP3A4 is the major drug-metabolizing enzyme for nearly 50% of all currently marketed drugs.[32,33] A significant cytochrome P450 drug interaction may occur when two or more drugs compete for the same enzyme and when the metabolic reactions catalyzed by this enzyme constitute the major elimination pathway.[34] According to previous studies, resveratrol and naturally occurring stilbenes were suggested to be inhibitors of cytochrome P450 CYP3A4.[35−38] CSA belongs to the class of stilbene compounds, and our result showed its similar effect on CYP3A4, which was in accordance with results in the above references.

The preferred model for enzyme induction studies was primary human hepatocytes because primary human hepatocytes were mostly related to prediction of food−drug interactions.[39] The current study demonstrated that CSA was not an inducer of CYP1A2, CYP2A6, CYP2E1, CYP2C9, CYP2C19, or CYP3A4. CYP2D6 was not examined for its noninducible character recognized by the FDA (Draft Guidance for Industry: Drug Interaction Studies: Study Design, Data Analysis and Implications for Dosing and Labeling, 2006; http://www.fda.gov/downloads/Drugs/GuidanceComplianceRegulatoryInformation/Guidances/ucm072101). CSA did not cause more than a 2-fold induction in CYP1A2, CYP2A6, CYP2E1, CYP2C9, CYP2C19, or CYP3A4, and the relative response did not exceed 40% of the positive control.

In summary, major metabolism of CSA in human liver microsomes has been demonstrated. Of all the evaluated CYP450 isoforms, CYP3A4, CYP2C9, and CYP1A2 were the primary CYP450 enzymes responsible for the formation of these hydroxylation metabolites of CSA in human liver microsomes. These in vitro study results indicated that CYP3A4 and CYP2C9 were inhibited by CSA, which showed no inhibition for other CYP450 enzymes in a reversible manner. CSA did not show time-dependent inhibition potential on the CYP450 enzymes investigated here. In addition, the results of the present study suggested that CSA will not produce clinically significant induction of CYP450 enzymes.

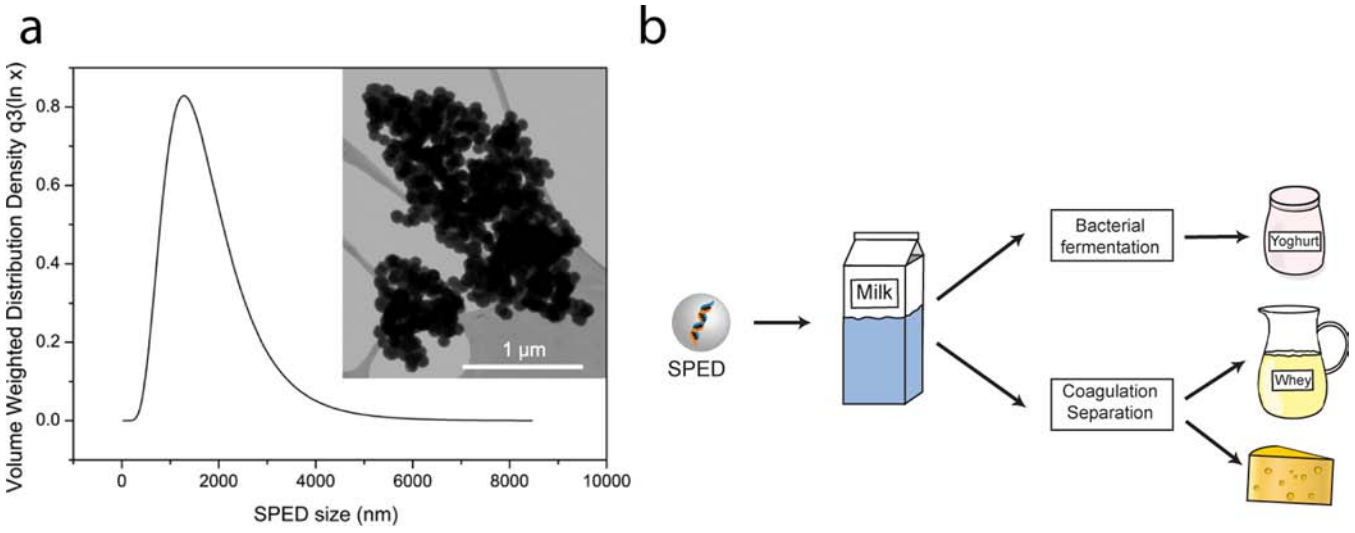

**Figure 1.** (a) Particle size distribution and a characteristic electron microscopy image of the applied Silica Particles with Encapsulated DNA (SPED). (b) Milk is complemented with SPED with a specific code and subsequently manufactured to yoghurt and cheese.

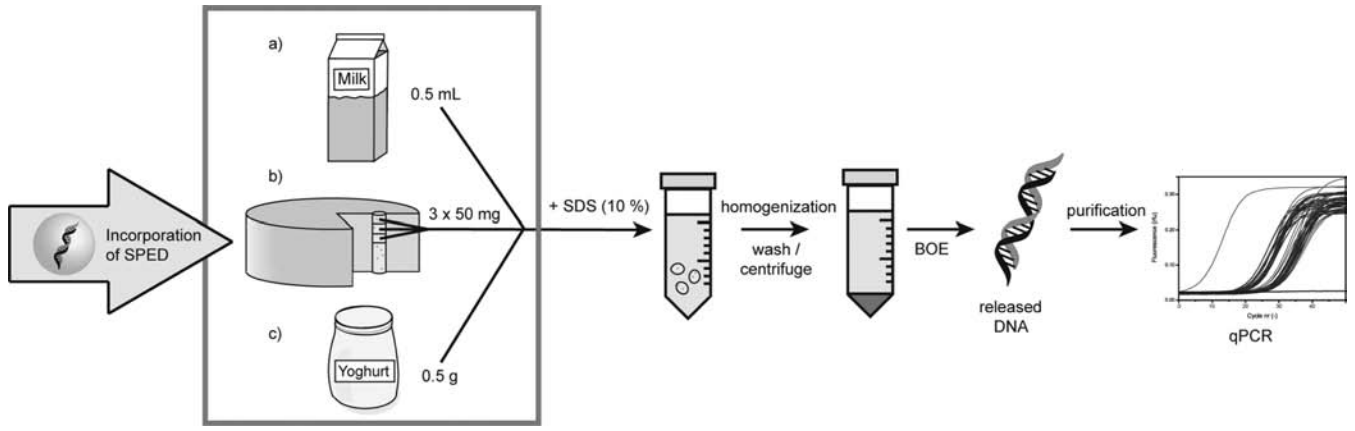

**Figure 2.** Flowchart for incorporation of SPED into milk, cheese, and yoghurt and subsequent extraction of the marker from the foodstuff by washing/centrifugation procedures for final analysis via qPCR.

solution (25 wt %), hydrogen peroxide ($H_2O_2$, 30 wt %), and ammonium hydrogen difluoride ($NH_4FHF$, pure) were purchased from Merck. Isopropanol (>99.8%), ammonium fluoride ($NH_4F$, puriss.), and ammonium hydroxide solution (25 wt %) were used as supplied from Sigma-Aldrich. Tetraethoxysilane (TEOS, ≥99.0%) was received from Aldrich, *N*-trimethoxysilylpropyl-*N*,*N*,*N*-trimethylammonium chloride (TMAPS, 50 wt % in methanol) from ABCR, L-ascorbic acid sodium salt (99%) from Acros Organics, and hexyltrimethoxysilane (>96%) from Tokyo Chemical Industry. Sodium dodecyl sulfate (SDS, >98%) was purchased from Sigma. Qubit dsDNA high-sensitivity (HS) assay was supplied by Invitrogen, QIAquick PCR purification kit from Quiagen, and EDTA disodium salt dihydrate (99%) from Biosolve. Ultrapure water (18.2 MΩ cm at 25 °C) was used. The double-stranded DNA solutions for the 116 base-pair (bp) amplicon MB1 and the 121 bp amplicon TOM1 (from tomato DNA sequence) as well as their corresponding primers were purchased from Microsynth. MB1 was used for the experiments with milk, yoghurt, cheese, and whey, while TOM1 was only used in one yoghurt experiment.

**Real-Time Quantitative PCR.** The qPCR was executed with a Roche Lightcycler 96. Based on the cycle of threshold (Ct), conclusions on the initial DNA concentration in the sample—and with that, the SPED concentration—can be drawn. The positive controls for the PCR were obtained by dissolving known SPED amounts directly in buffered oxide etch (BOE) solution. A PCR blank (no-template control) confirmed clean working conditions. Each sample well was filled with 5 µL of sample volume, 10 µL of master mix (Lightcycler 480 SYBR Green I Master, Roche), 3 µL of PCR-grade water, 1 µL of forward primer, and 1 µL of reverse primer (2 µM each). The qPCR consisted of a three-step amplification with 45 cycles. The samples were first heated to 95 °C for 15 s, then remained at 60 °C for 30 s, and last were held at 72 °C for 30 s. Each sample was analyzed in replicates (technical triplicates).

**Food Products.** Pasteurized milk (0.5 L, 3.9% fat, organic) and yoghurt (180 g, 4% fat, Naturaplan) were bought at Coop, ETH Hönggerberg. The rennet tablets were supplied by Swissmilk (Winkler AG, approximately 95% chymosin, 5% pepsin, salt as support material).

**DNA Codes.** Sequence *MB1* is a randomly generated DNA sequence, which was selected for good PCR amplification properties and checked for specificity using Basic Local Alignment Search Tool (BLAST):[26] (5′−3′) ATT GCA CCC TTA CCA CGA AGA CAG GTT TGT CCA ATC CCA TAT TGC GAC CTT GGC AGG GGG TTC GCA AGT CCC ACC CGA AAC GTT GCT GAA GGC TCA GGT TTC TGA GCG ACA AAA GC. Sequence *TOM1* is a short sequence taken from the tomato genome (species *Solanum lycopersicum*), Chromosome 1, NC_015438.1: (5′−3′) TGA AGG ACT GAA GCA ACA CGA AAC CTA TAC AAC TAA CTA GCA GAG CTC TCG ATT TTG CTA ATT CAT CAT AAC TCA TAC TAT GAG CAA AAA AGT AAA GGG AAA TTT TCG TGC ATG GTG TTG A.

dx.doi.org/10.1021/jf503413f | J. Agric. Food Chem. 2014, 62, 10615−10620

**Particle Synthesis.** To produce the SPED, the protocol of Paunescu et al.[22] was applied. Particles containing either the DNA sequence MB1 or the DNA sequence TOM1 were produced (for sequences, see above). Following their production, the SPED were tested on their radical treatment stability as previously described.[22] The particle structure was analyzed by scanning transmission electron microscopy (STEM, NovaNanoSEM 450, FEI) at 30 kV. The particle size was determined by volume-weighted sedimentation analysis (LUMiSizer, LUM GmbH).

**Labeling of Food.** *Milk.* SPED concentrations of 10, 1, and 0.1 ppb were prepared in milk. For every SPED concentration, ten 0.5 mL samples of pasteurized milk were labeled by adding a 5 $\mu$L of SPED dispersion at prediluted concentrations to give the final SPED concentration.

*Yoghurt.* The yoghurt was spiked with 100, 10, 1, and 0.1 ppb SPED containing the MB1 sequence. Additionally, yoghurt with 10 ppb SPED containing DNA code TOM1 was made. To produce 100 g of yoghurt, 87 g of pasteurized milk, 13 g of yoghurt, and 10 $\mu$L of prediluted SPED dispersion were used. After vortexing, the yoghurt was placed into an incubator at 42 °C for 5.5 h. Subsequently, the glasses were carefully transferred to a refrigerator ($T$ = 4−6 °C) and left there overnight. Experiments were performed in triplicates (three yoghurts for every concentration). From every yoghurt, two samples were analyzed. To ensure a representative sample, the yoghurt was stirred before sampling.

*Cheese.* For the cheese production, 5.8 g of yoghurt, 100 g of pasteurized milk, and a defined amount of SPED were mixed in a beaker. The mixture was added to 900 g of pasteurized milk. The detailed cheese recipe can be found in the Supporting Information.

**Label Extraction from Food.** *Milk.* For the extraction, the 0.5 mL sample was mixed with 1 mL of SDS solution (10 wt %) in a 2 mL Eppendorf tube (Figure 2). The sample was sonicated for 30 s using an ultrasonicator (Ultraschall-Prozessor UP50H, Huberlab) and then centrifuged for 3 min at 21500$g$. The supernatant was discarded, while 50 $\mu$L of ultrapure water was added to the pellet. The sample was vortexed for 1 min before 70 $\mu$L of the BOE solution was added. After the final purification with a QIAquick PCR Purification Kit, a qPCR was performed with a Roche Lightcycler 96. See Figure S5 in the Supporting Information for a flow diagram of the extraction method.

*Yoghurt.* To extract the SPED, 0.5 g of the yoghurt was mixed with 1 mL of SDS solution (10 wt %) in a 2 mL Eppendorf tube (Figure 2). After a quick vortex step, the sample was sonicated for 30 s. The tubes were centrifuged for 3 min at 21500$g$. The resulting supernatant was discarded, while 1 mL of SDS solution (10 wt %) was added to the pellet. One minute of vortexing was followed by another centrifugation step for 3 min at 21500$g$. The supernatant was discarded, while 50 $\mu$L of ultrapure water was given to the pellet. The sample was then vortexed for another minute. Finally, 70 $\mu$L of BOE solution was pipetted to the sample. As a last step, the QIAquick PCR Purification Kit was applied. The resulting liquid was directly used for qPCR analysis. See Figure S6 in the Supporting Information for a flow diagram of the extraction method.

*Cheese.* From the cheese, a cylindrical-shaped piece was cut out (Figure 2). From the cross section, three 50 mg samples from the cylinder's rind, core, and the space between the rind and the core were combined to a collective sample and placed into a 2 mL microtube. Next, 1.5 mL of SDS solution (10 wt %) and two speed mixing beads (chrome steel, $d$ = 6.35 mm) were added. The sample was then homogenized with a Mini-Beadbeater (Biospec Products) for 70 s at a speed of 4200 rpm. After the beads had been removed from the tubes, the latter were centrifuged for 7 min at 21500$g$. Following a repetition of the mechanical homogenization at the same conditions, the sample was washed twice with 1 mL of SDS solution (10 wt %) and once with ultrapure water, with intermediate centrifugation steps. After addition of 50 $\mu$L of ultrapure water, the sample was vortexed for 1 min, and 70 $\mu$L of the BOE solution was added. The sample was then shaken at 24 °C for 30 min before it was purified using the QIAquick PCR Purification Kit for qPCR analysis. See Figure S7 in the Supporting Information for a flow diagram of the extraction method.

**Statistical Analysis.** The validity of the SPED labeling method was proven. Please find the discussion on the necessary variables in the Supporting Information.

The experimental data were analyzed with Origin 8.6. The two-sample $t$ tests were based on a 5% significance level. One-way analysis of variance (ANOVA) was used to compare the sample means at different time points.

## RESULTS AND DISCUSSION

SPED are aggregated silica particles with a primary particle size of ∼140 nm and an agglomerate size of ∼1200 nm (see Figure 1a), much resembling the structure of commercial silica products (e.g., Aerosil, fumed silica, and precipitated silica). The particles are easily dispersed in water and can be directly mixed with aqueous liquids at various concentrations. The silica can be loaded with ∼0.1 wt % of DNA, and in this work both a random (MB1) and a naturally occurring (TOM1) DNA code were utilized. The DNA molecules are well encapsulated within the silica matrix, as proven by exposing the particles to aggressive radical oxygen species (stability >90%, see Table S2 in the Supporting Information).[23] Upon mixing with fluoride-containing solutions (e.g., buffered oxide etch (BOE), a pH-stabilized $NH_4F$ solution) the silica can be dissolved, releasing the DNA and allowing its analysis by qPCR without further treatment.[22] In the case of food products, the particles first have to be extracted from the complex matrix, as food components such as proteins and fats are known to interfere with PCR analysis. Therefore, for every food type, a processing procedure was elaborated (see Figure 2 and Figures S5−S7 in the Supporting Information). These processing procedures essentially include multiple SDS washing and particle centrifugation steps. In the case of the cheese, the semisolid matrix was first mechanically broken down utilizing a mini-bead-beater. Following the washing and centrifugation procedure, all cases resulted in (hardly visible) particle deposits in the tubes, without any visual residue of proteins or fat. The deposits were dissolved in BOE, and then the DNA was purified with commercial DNA purification kits and directly analyzed via qPCR using the corresponding primers. qPCR analysis was done in a traditional way, where the cycle was monitored (= Ct) at the point at which the fluorescence signal exceeded a given threshold (threshold computed automatically from signal-to-noise ratio by Lightcycler instrument). In this way the DNA, and by extension also the particles, could be detected down to 0.1 ppb for milk and yoghurt and down to 1 ppb for cheese (Figure 3 and Supporting Information). In comparison, the analysis of pesticide residues in fruit and vegetable samples with gas chromatography is possible to a limit of detection of 20 ppb.[27]

To investigate whether the DNA/particle detection method is quantitative, the foodstuffs under investigation were labeled with various SPED concentrations in the ppb range. Based on the exponential nature of the qPCR method, we did not expect to be able to measure small concentration differences, but rather concentrations on a logarithmic scale. Indeed, the Ct depended linearly ($R^2$ = 0.98 for yoghurt, $R^2$ = 0.99 for milk and cheese) on logarithmic particle concentration added to the individual foods (see Figure S1 and Table S1 in the Supporting Information). Additionally, in milk, yoghurt, and cheese, particle concentrations could be statistically discriminated on a log 10 scale, i.e., 0.1 ppb could be discriminated from 1 ppb, and 1/10 ppb samples were statistically different ($p$ < 0.05, Figure 3). Further control experiments (data not shown)

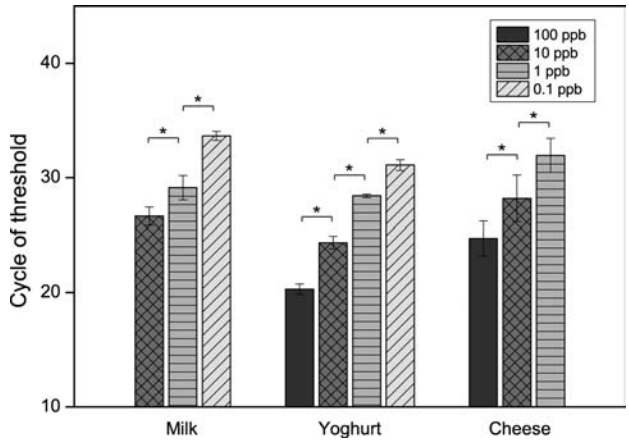

**Figure 3.** qPCR results (cycle of threshold, Ct) for the DNA within the particles detected at various particle loadings (ppb = $\mu$g particles per kg of food). *Denotes statistical significance at $p < 0.05$. The linearity of the Ct vs log particle concentration is shown in Figure S1 in the Supporting Information.

revealed that the particle concentration was independent of the sampling position in the cheese sample (yoghurt and milk samples were homogenized prior to particle extraction).

An additional aspect that is of importance with regard to quantitative analysis is the stability of the marker within the matrix over time. We have previously shown that, based on its encapsulation in silica, the DNA is protected from environmental decay over long storage times.[23] In order to display that this is true within the food products under investigation, additional tests were performed: SPED particles were added to cheese and yoghurt at 1 ppb and analyzed over time (2 weeks for yoghurt; 4 weeks for cheese). As visible in Figure 4, the

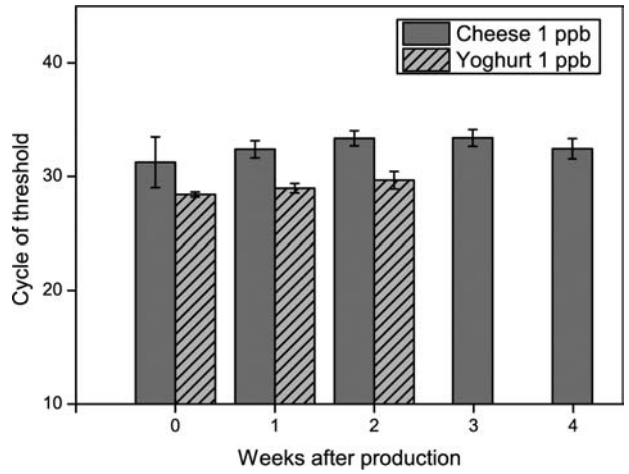

**Figure 4.** Cycle of threshold for cheese and yoghurt labeled with 1 ppb SPED. The samples remained stable over a course of 4 and 2 weeks for cheese and yoghurt, respectively.

qPCR readings (Ct values) did not increase over time, indicating that the DNA within the particles is unharmed during storage. This further shows that absolute quantification was feasible, even after several weeks of storage. Of course, for cheese, longer storage durations are of interest and are under current investigation.

The application of natural DNA as a unique sequence may be an advantage for consumer acceptance. For this reason we utilized a fragment (121 bp) of tomato DNA (species *Solanum lycopersicum*) as code. The sequence was selected from chromosome 1 of the tomato's DNA for optimal primers utilizing an online primer search algorithm (Primer3)[28] and tested for uniqueness using the Basic Local Alignment Search Tool (BLAST).[26] Yoghurt manufactured with 10 ppb of these particles could be identified by qPCR if the corresponding TOM1 primers were utilized (Ct = 28.77 ± 0.27). Utilizing the same procedure but analyzing with non-corresponding primers (MB1 primers) gave no significant PCR amplification (Ct = Ct(blank)), proving the selectivity of PCR analysis, which is well known and reported in medical diagnostics[29] and bacteria detection.[30]

The SPED labeling method is much more quantifiable compared to tagging approaches where a microbial cell with a DNA discriminable from the somatic cells of the milk was applied. Bacterial cells pass through a growth cycle with replication and decline. Their cell number and DNA amount is therefore not at all times the same. With our method, we could prove that the amount of DNA encapsulated in silica was stable over a course of several weeks. The SPED ensure, therefore, a more precise tagging than other methods do.

When silica particles loaded with the natural source DNA sequence (TOM1) are utilized to mark yoghurt at a particle loading of 1 ppb, a consumer eating 250 g of the yoghurt would consume 0.25 $\mu$g of silica and 0.25 ng of tomato DNA. This is equivalent to 0.0002% of the average daily dietary silica intake[31] and equivalent to the DNA present in 0.0001% of one fresh tomato.[32,33] Silica particles have a long history as food additives (E551) and are approved for several uses in European and U.S. markets. Based on the availability of billions of base-pair sequences from food sources, the use of naturally occurring DNA sequences as a coding tool can easily be envisioned. Combinations of mixtures of particles carrying several codes may further increase the variability of the code library.

In order to estimate the price of the DNA in silica food tagging technology presented here, we utilized currently available price data. The main cost driver of the technology is the synthetic DNA code, at a price of 9000 USD/g (as per commercial offer from Microsynth in March 2014; costs of additional raw materials are negligible). From 1 g of DNA, about 1 kg of particles can be produced (loading of ~1 $\mu$g/mg). If a SPED concentration of 10 ppb is applied to a food product, the labeling would cost 0.00009 USD per kg (i.e., 9¢ per ton) of food plus the labor costs, which will depend on the cost structure of the particle-producing company. This short calculation shows that in a potential application of the technology in tracing food, the cost of the DNA label is not critical.

From a purely technical and chemical point of view, above justification of material choice and cost estimation shows that the application of DNA in silica particles as a food-marking tool is of both low risk and low cost. Still, it will be evident to the reader that the ongoing public discussion on the risk of both DNA technology and nanotechnology (including discussions on the general use of amorphous silica as a food additive)[34] may slow down the application of these tracers in foodstuff. As with most new technologies, the potential risk of the additive must be balanced with the potential opportunity of uniquely tagging foodstuff. The answer to this question can only be the result of future discussions between many stakeholders, including consumers, producers, customs agencies, and local governments. In terms of food additive regulation, the use of an

additive as internal food label has not been addressed so far, so neither the Codex Alimentarius nor the European numbering system (EFSA) has a corresponding functional category.

This study shows that DNA-loaded silica particles can be utilized as tracers in milk, yoghurt, and cheese. The technology requires only marginal amounts of resources and has a broad range of label generation possibilities. While quantification has to be normalized for every food type (standard curve per food type), the result is quantitative on a logarithmic scale for tracer concentrations as low as 0.1 ppb (i.e., 0.1 $\mu$g of tracer per kg of foodstuff). The stability of the DNA tracer in the processing of milk to yoghurt and cheese shows the stability of the tracer over the production chain. The possibility of tracer read-out from food matrixes as complex as cheese and yoghurt displays the robustness of the method, and the applicability of the tracer to other food types is anticipated.

# Correction to Muscadine Grape (*Vitis rotundifolia*) and Wine Phytochemicals Prevented Obesity Associated Metabolic Complications in C57BL/6J Mice

Vishnupriya Gourineni, Neil F. Shay, Soonkyu Chung, Amandeep K. Sandhu, and Liwei Gu*

*J. Agric. Food Chem.* **2012**, *60* (31), 7674−7681. DOI: 10.1021/jf3013663

A recent review of the data related to this publication indicated several errors. Figure 3 and Table 5 in the original paper had typographical errors and should be replaced with the following.

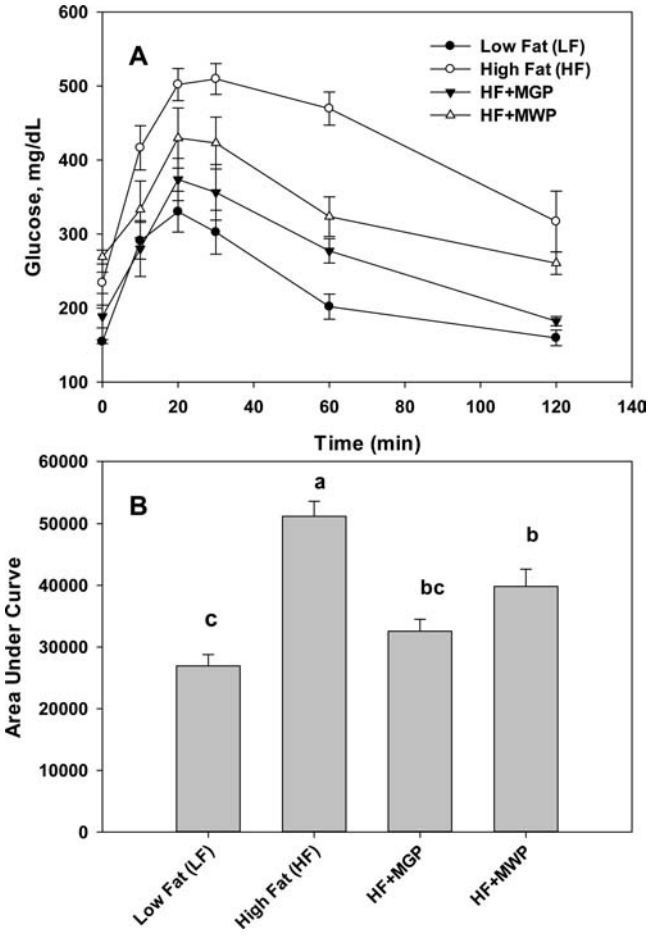

**Figure 3.** (A) Blood glucose levels in intraperitoneal glucose tolerance tests at week 12; (B) area under curve of blood glucose for 2 h after a glucose challenge ($n$ = 5).

Corrected Figure 3B shows that the AUC of glucose levels in the LF group was 47.4% lower ($p$ < 0.001) compared to HF controls. AUC levels in mice fed HF+MGP and HF+MWP were significantly lower than that of the HF group by 36.3 and 22.2%, respectively. AUC levels in mice fed HF+MGP were similar to those of mice receiving the low-fat diet. These data suggested that muscadine grape and wine phytochemicals improved glucose tolerance in mice fed a high-fat diet.

**Table 5. Effects of Muscadine Grape Phytochemicals (MGP) and Muscadine Wine Phytochemicals (MWP) on Plasma C-Reactive Protein (CRP) and Glutathione Peroxidase Activity**[a]

| group | plasma CRP (ng/mL) | plasma glutathione peroxidase activity (nmol/min/mL) |
|---|---|---|
| low fat (LF) | 23.2 ± 0.4 d | 1.1 ± 0.5 |
| high fat (HF) | 62.0 ± 0.2 a | 0.3 ± 0.07 |
| HF+MGP | 30.1 ± 0.6 c | 1.2 ± 0.3 |
| HF+MWP | 47.6 ± 0.8 b | 0.7 ± 0.2 |

[a]Values are the mean ± SEM $n$ = 9. Columns not sharing a common letter (a−d) are significantly different ($p \leq 0.05$).

Corrected values in Table 5 showed that muscadine grape or wine phytochemicals did not affect plasma glutathione peroxidase in mice; therefore, we cannot conclude that muscadine grape or wine phytochemicals alleviated oxidative stress.

Furthermore, there were, we believe, arithmetic errors in Table 4. Therefore, we withdraw the data in that table. As a result, we cannot conclude that muscadine grape or wine phytochemicals affect plasma insulin levels or insulin resistance in mice.

These corrections do not affect other conclusions in this paper.

disadvantages, and this new concept was quite different from previous studies.[16,17] Our aims were to (1) characterize the chemical and physical properties of biochars and investigate the mechanisms which led to these changes in properties; (2) investigate the heavy metal adsorption capacity of manure biochars, prepared with added straw feedstock using, as an example, Zn(II) adsorption; (3) assess the abilities of biochars prepared jointly from manures and plant materials as soil amendments, and suggest the appropriate proportions of straw addition and the pyrolysis temperature to suit different agronomic and environmental purposes.

## MATERIALS AND METHODS

**Preparation of Biochars.** The swine manure was obtained from a piggery in the suburbs of Hangzhou city, Zhejiang Province, China, where vegetables, corn, and wheat are provided as the diet of the pigs. The rice straw was collected from farmland near Zhejiang University, Zhejiang Province, China. The feedstocks were air-dried, crushed into pieces, and ground <0.154 mm. To change the properties of manure biochar, the straw was added to the manure feedstock at 3:1, 1:1, and 1:3 (w/w) manure/straw ratios respectively and then mixed thoroughly. The manure without straw addition and the straw without manure addition were regarded as the controls. The mixtures were placed in stainless steel bottles and pyrolyzed in a muffle furnace for 2 h without oxygen supply. The pyrolysis temperature was increased to the selected values of 300, 400, 500, 600, and 700 °C, respectively, at 26 °C/min. After cooling, all the biochars were ground, sieved <0.154 mm, and prepared for chemical and physical analysis. Throughout the paper, the biochars prepared from the feedstock mixtures at the ratio of 3:1, 1:1, and 1:3 (w/w) manure/straw are named "manure/straw 3:1 biochar", "manure/straw 1:1 biochar", and "manure/straw 1:3 biochar". The swine manure biochar and rice straw biochar are named "manure biochar" and "straw biochar" respectively.

**Chemical and Physical Analyses.** Yield (%) was calculated by the following equation: yield (%) = (weight of biochar)/(weight of feedstock) × 100. The ash content was determined as follows: 1.00 g of the ground biochar was heated at 700 °C for 2 h in a muffle furnace and the ash (%) calculated from ash (%) = (weight of ash)/(weight of biochar) × 100. The pH values of the biochars were determined in deionized water at the ratio of 1:10 w/w biochar/water with a pH meter. The total C, H, and N concentrations of the biochars were measured with a Flash EA 1112 elemental analyzer (Thermo Scientific, USA), and the total O concentration was determined by difference.[6] The exchangeable base cations (K, Na, Ca, and Mg) and heavy metal (Cu, Zn, and Fe) concentrations of the biochar samples were extracted by 1.0 mol/L ammonium acetate using a ratio of 1:25 w/v biochar/solution. The Ca, Mg, K, Na, Cu, Fe, and Zn concentrations were determined by a NovAA300 atomic absorption spectrometer (Analytikjena, Germany). The micropore area (MA), surface area (BET), total pore volume (TPV), average pore width (APW), and average particle size (APS) were measured using a Nova 2200e surface area analyzer (Quantachrome, USA) after degassing at 200 °C for 8 h.

**SEM-EDS, XRD, and FTIR Analyses.** A Sirion 100 thermal field emission scanning electron microscope (FEI, Netherlands) equipped with a Genesis 4000 X-ray energy dispersive spectroscope (EDAX, USA) (SEM-EDS) was used to determine the biochar morphology. X-ray diffraction (XRD) was used to observe the changes in mineral crystals in the biochars, using an X'Pert PRO computer-controlled diffractometer (PANalytical, The Netherlands). An Avatar370 Fourier transform infrared (FTIR) spectrometer with a Nicolet 380 spectrophotometer (ThermoNicolet, USA) was used to determine the functional groups on the biochar surface. The detail operations for the SEM-EDS, XRD, and FTIR analyses have been previously described.[5]

**Batch Zn(II) Adsorption Experiments.** Duplicate biochar samples of 0.1 g were added to 50 mL polypropylene tubes. The $Zn(NO_3)_2$ solutions were prepared with varying initial concentrations from 0 to 6.0 mM. The ionic strengths of the $Zn(NO_3)_2$ solutions

were adjusted to 10 mM $NaNO_3$. Then, 25 mL of Zn(II) solutions were added into each tube and mixed thoroughly. The mixtures were shaken at 160 rpm for 10 h at 25 °C, and the pH values of the suspensions in the tubes were adjusted to 5.0 before adsorption. After shaking, the suspensions were kept overnight and then centrifuged at 3500*g* for 10 min to separate the $Zn(NO_3)_2$ solutions from the biochar samples. The concentrations of Zn(II) were determined by atomic absorption spectroscopy, and the amount of Zn(II) absorbed by the biochars was calculated.

To investigate the Zn(II) adsorption capacity of the biochars, the Freundlich and Langmuir models were introduced to analyze the sorption isotherms data by the following equations:

$$\text{Freundlich: } q_e = K_F C_e^{\,n} \quad (1)$$

$$\text{Langmuir: } q_e = q_{max} C_e/(1/b + C_e) \quad (2)$$

where $q_e$ (mmol/kg) is the Zn(II) adsorbed by biochars at equilibrium; $C_e$ (mM) is the equilibrium Zn(II) concentration in the solution; $q_{max}$ (mmol/kg) is the maximum adsorption capacity; $n$ is the Freundlich constant without dimensions, which represents the degree of nonlinearity of the sorption isotherms; $K_F$ (mmol/kg)/(mmol/L)$^n$ and $b$ (mmol/L) are the adsorption constants of the Freundlich and Langmuir models, respectively.

**Statistical Analysis.** SPSS 18.0 software (SPSS Inc., Chicago, IL, USA) was used to perform statistical data analyses. Principal Components Analysis (PCA) was used to quantitate the relationships between biochar parameters and the differences in the biochar treatments.

## RESULTS AND DISCUSSION

**The Basic Properties of the Biochars.** The pH, total carbon, ash, and yield were all influenced by the pyrolysis temperature. Generally, as the pyrolysis temperature increased, the pH, ash, and C contents increased while the yield decreased (Figure 1), as previously reported.[5,18,19] The pH of the biochars is considered to be the most important parameter to correct soil acidity.[10,20] The formation of basic functional groups and carbonates or oxides of base cations (K, Na, Ca, and Mg) during the pyrolysis is the main mechanism for acidity correction, as these components can neutralize the $H^+$ in the soils. Thus, the temperature of 700 °C would be the best choice to increase the soil pH (Figure 1A). The total C in the biochars was divided into two pools: the aromatic portion and the aliphatic portion. The aliphatic portion, which can be readily mineralized, contributes to the biochar lability, whereas the aromatic portion, that is oxidized more slowly, can persist in the soils for thousands of years.[21,22] As the pyrolysis temperature increases from 300 to 700 °C, the aliphatic components will gradually be converted into aromatic components, as shown by the FTIR spectra (Figure 2), i.e., the peaks located in the region 2800−2950 $cm^{-1}$ associated with $CH_2$ and $CH_3$ disappeared. Thus, the biochar at 700 °C is an excellent material for soil C sequestration (Figure 1B). Similarly, the ash contents, which indirectly contribute to the soil nutrients, also reached the highest values when the temperature was 700 °C (Figure 1C). However, the yield rate markedly decreased as the pyrolysis temperature increased (Figure 1D), indicating that the more aliphatic fractions were evolved as methane, hydrogen, and carbon monoxide during pyrolysis. Thus, the yield rate should be also considered when selecting the most appropriate biochar with specific purposes for agronomic and environmental applications.

Compared with other straw amended biochars, manure biochar had the lowest pH and carbon content as well as the highest ash content and yield rate (Figure 1). The pH and C

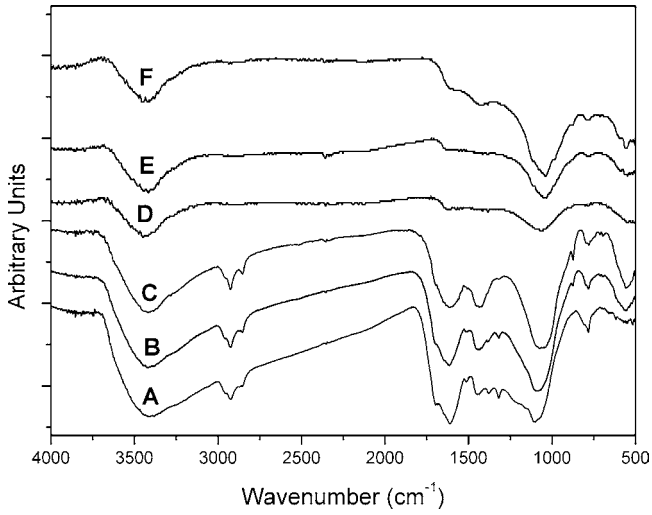

**Figure 2.** FTIR analyses of the biochars at pyrolysis temperature of 300 and 700 °C: (A) straw biochar-300 °C; (B) manure/straw 1:1 biochar-300 °C; (C) manure biochar-300 °C; (D) straw biochar-700 °C; (E) manure/straw 1:1 biochar-700 °C; (F) manure biochar-700 °C.

content increased consistently as the proportion of straw increased. For instance, the pH of manure biochar at 700 °C was 10.06, while the pH of the four other biochars (manure/straw 3:1, manure/straw 1:1, manure/straw 1:3, and straw biochars) were 11.12, 11.30, 11.41, and 11.48, respectively. This trend suggests that the added straw caused increases in pH and carbon content, giving the manure biochars the abilities to decrease soil acidity and soil C sequestration. However, with increased straw addition, the ash content and yield had the opposite trends (Figures 1C and 1D). This phenomenon indicated that the properties of manure biochar can be deliberately changed according to the different agronomic purposes required. To obtain higher yields from pyrolysis and to provide more nutrients for plant growth, the proportion of the straw added should be limited. However, to decrease soil acidity and to increase soil organic matter, increasing proportions of straw should be added. Normally, a soil which has a pH problem is always accompanied by other problems. Thus, the manure biochar blended with straw is probably the most comprehensive and effective soil amendment compared to the other biochars.

Measurements of physical parameters such as BET and micropore area of biochars are also essential to characterize their properties and to evaluate their agronomic and environmental potentials. From 300 to 500 °C, the BET and micropore area remained stable in all the biochars (except for straw biochar), at about 10 $m^2/g$ and 0 $m^2/g$, respectively (Figure 3). However, when the pyrolysis temperature increased to 600 and 700 °C, both the BET and micropore area increased rapidly, especially with the manure/straw 3:1, manure/straw 1:1, manure/straw 1:3, and straw biochars. For instance, the BET and micropore area in manure/straw 1:3 biochar at 700 °C were about 83 $m^2/g$ and 54 $m^2/g$, respectively, while the BET and micropore area in manure biochar at 700 °C were only 31 $m^2/g$ and 22 $m^2/g$, respectively (Figure 3). Normally, the biochars with high surface areas and more porous structures can provide large effective adsorption sites, for example as adsorbents for heavy metals and permanent organic pollutants.[23−25] This indicated that straw addition to the manure

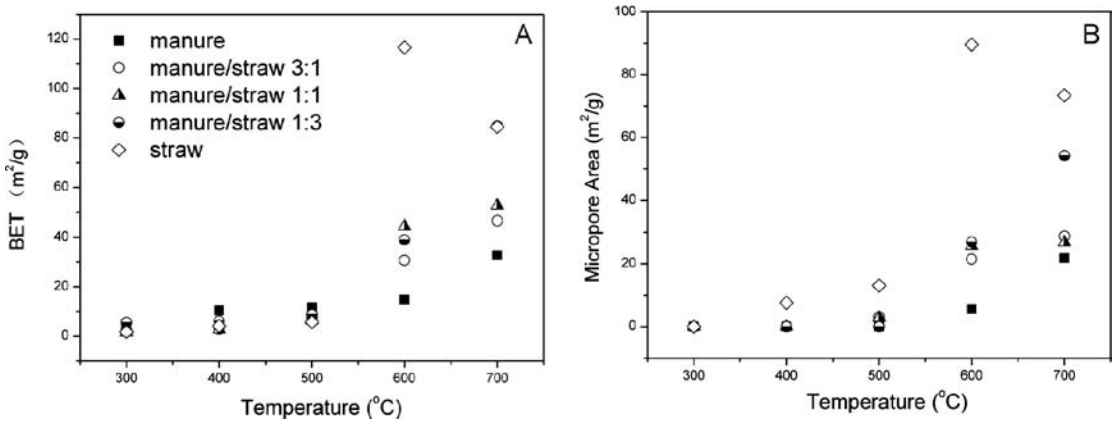

**Figure 3.** (A) BET and (B) micropore area of the biochars at five pyrolysis temperatures.

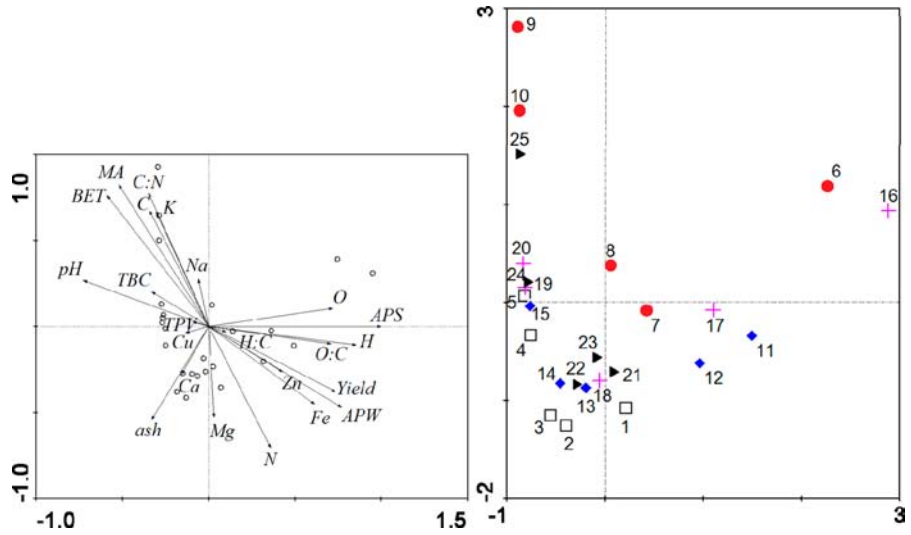

**Figure 4.** PCA analyses of the chemical and physical parameters in the biochars. 1, manure biochar-300 °C; 2, manure biochar-400 °C; 3, manure biochar-500 °C; 4, manure biochar-600 °C; 5, manure biochar-700 °C; 6, straw biochar-300 °C; 7, straw biochar-400 °C; 8, straw biochar-500 °C; 9, straw biochar-600 °C; 10, straw biochar-700 °C; 11, manure/straw 3:1 biochar-300 °C; 12, manure/straw 3:1 biochar-400 °C; 13, manure/straw 3:1 biochar-500 °C; 14, manure/straw 3:1 biochar-600 °C; 15, manure/straw 3:1 biochar-700 °C; 16, manure/straw 1:1 biochar-300 °C; 17, manure/straw 1:1 biochar-400 °C; 18, manure/straw 1:1 biochar-500 °C; 19, manure/straw 1:1 biochar-600 °C; 20, manure/straw 1:1 biochar-700 °C; 21, manure/straw 1:3 biochar-300 °C; 22, manure/straw 1:3 biochar-400 °C; 23, manure/straw 1:3 biochar-500 °C; 24, manure/straw 1:3 biochar-600 °C; 25, manure/straw 1:3 biochar-700 °C. MA, micropore area; BET, surface area; TPV, total pore volume; APW, average pore width; APS, average particle size.

during pyrolysis increased the manure biochar adsorption ability. Thus, the higher pyrolysis temperatures (600 and 700 °C) and the higher proportions of straw (1:1 and 1:3) would be the best choices to prepare the biochars for adsorption of pollutants, without consideration of production costs and yield rate. The porous structures are also supposed to be appropriate habitats for microbial growth and nutrient uptake.[26,27] However, the effects of pore numbers and sizes, and other factors (e.g., nutrient content, pH, labile organic carbon) of biochars, which may influence the microbial activity, remain unclear. Thus, the analyses of porous structure of the biochars provided valuable information for further studies of biochar effects on microbial growth and activity.

**The PCA of the Biochars.** To reach a conclusive interpretation of the effects of added straw to the manure, PCA was conducted to analyze the correlations between the biochar parameters, and determine the similarity and difference between the biochar samples. BET had a positive correlation with micropore area and total pore volume and a negative correlation with average pore width and average particle size (Figure 4), which is consistent with previous studies.[5,7] The H:C ratio was positively correlated with the O:C ratio and O concentrations, and negatively correlated with C concentrations. The results were attributed to the H and O loss (as $H_2$, $CH_4$, and CO) and the stable C formation during the pyrolysis process. In addition, the pH had a negative correlation with yield and had no correlation with ash content. Generally, some components of the ash (e.g., carbonates and bicarbonates) and functional groups ($-O^-$ and $-COO^-$) are both responsible for biochar pH. Thus, the ash content has no direct correlation with biochar pH because the functional groups also controlled the biochar pH and other components of ash are not alkaline. The first principal component was partially explained by the average particle size, total pore volume, O, and pH, whereas the second principal component was partially explained by K, Mg, Na, and ash.

The linear distances between two biochar samples demonstrated the degree of similarity between two biochars,

dx.doi.org/10.1021/jf504106v | J. Agric. Food Chem. 2014, 62, 10623−10631

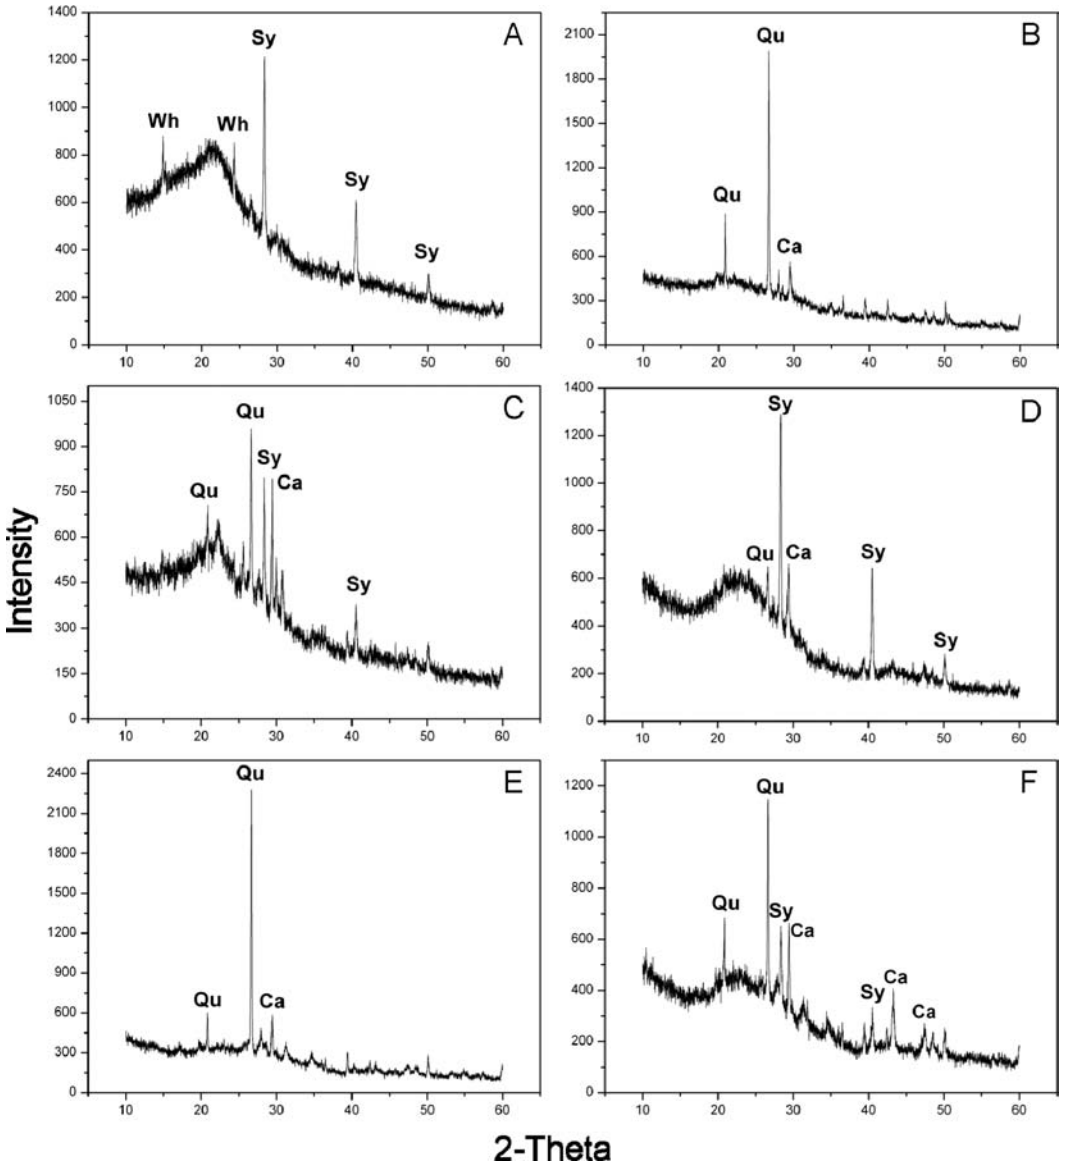

**Figure 5.** XRD analyses of the biochars at pyrolysis temperature of 300 and 700 °C: (A) straw biochar-300 °C; (B) manure biochar-300 °C; (C) manure/straw 1:1 biochar-300 °C; (D) straw biochar-700 °C; (E) manure biochar-700 °C; (F) manure/straw 1:1 biochar-700 °C. Sy, sylvite; Ka, kalicinite; Qu, quartz; Ca, calcite; Do, dolomite; Wh, Whewellite.

i.e., the larger the distance, the greater the difference (Figure 4). In most cases, the biochars at low pyrolysis temperatures (300 and 400 °C) had the most similar properties. When the temperature increased to 500 °C, the properties began to change slightly. At 600 and 700 °C, the properties were very different from those at the relatively lower temperatures (300, 400, and 500 °C), and the biochars at 600 and 700 °C only had small differences in the overall properties. In addition, at the same pyrolysis temperatures, the biochar properties gradually changed as the straw addition increased. For instance, the manure biochar had the largest differences with the manure/straw 1:3 and straw biochars. This statistical analysis indicates that the manure biochar can be adjusted to meet different agronomic and environmental purposes as a soil amendment, based on the pyrolysis temperatures and the proportion of straw added.

**XRD, FTIR, and SEM-EDS Spectra and Application Implications.** Based on results of the PCA analyses, the biochars from 300 to 500 °C and from 600 to 700 °C had similar properties, respectively (Figure 4). Thus, the typical biochars (manure, straw, and manure/straw 1:1 biochars) at 300 and 700 °C were selected for further analysis. The XRD spectra revealed the same mineral crystals in biochars at 300 and 700 °C, and the addition of straw had apparent influences on the mineral components in these biochars, i.e., the manure biochar at both 300 and 700 °C contained large quartz ($SiO_2$) and calcite ($CaCO_3$) concentrations, whereas the manure/straw 1:1 biochar at both 300 and 700 °C also contained some sylvite (KCl), which was from straw biochar (Figure 5). The mineral crystals, which can be detected by XRD, were the largest proportion of mineral components in the biochars and would play a great role in biochar applications, such as acidity correction and heavy metal adsorption. For instance, quartz and calcite can form silicate and calcite precipitates with some heavy metals in aqueous solutions,[15,28] and thus reduce their mobility and bioavailability. In addition, the calcite and sylvite, which are responsible for alkalinity, can also neutralize soil acidity and increase soil pH.

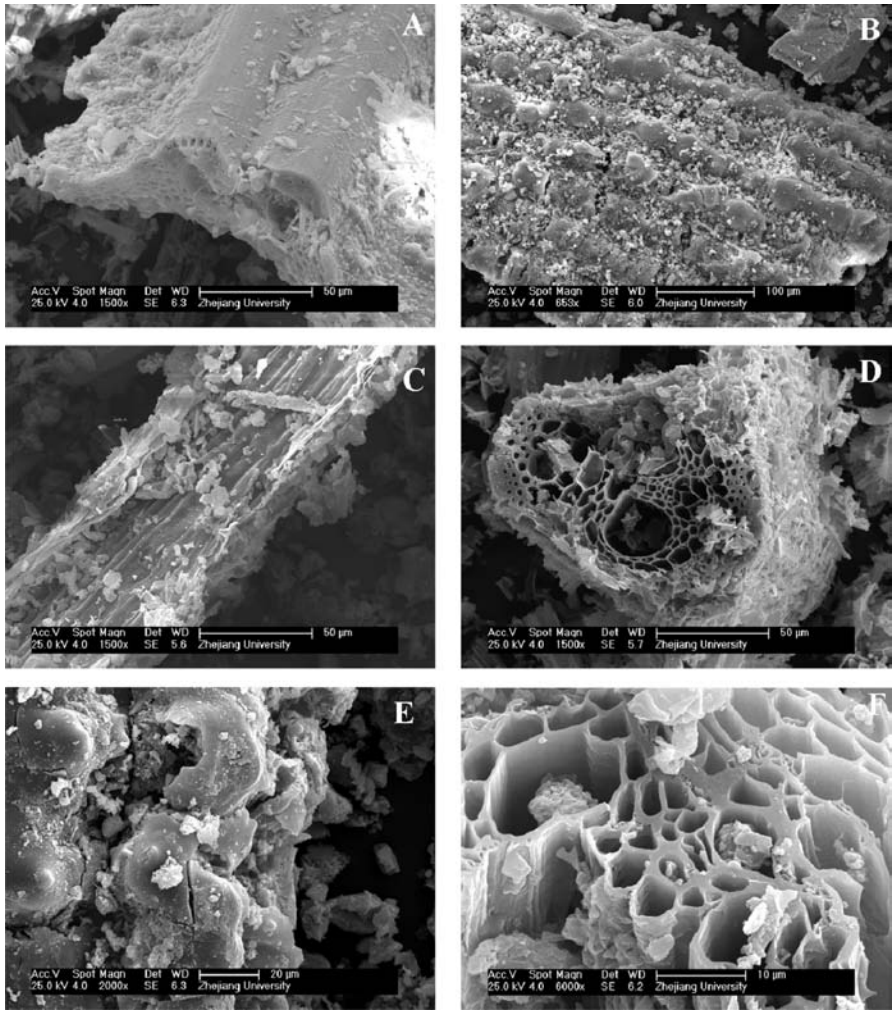

**Figure 6.** SEM analyses of the biochars at pyrolysis temperature of 300 and 700 °C: (A) straw biochar-300 °C; (B) manure biochar-300 °C; (C) manure/straw 1:1 biochar-300 °C; (D) straw biochar-700 °C; (E) manure biochar-700 °C; (F) manure/straw 1:1 biochar-700 °C.

The FTIR spectra of the biochars can indicate the changes in surface functional groups of the biochars (Figure 2). The biochars at 300 and 700 °C both had two big peaks, i.e., the peaks at 3418 $cm^{-1}$ and the peaks between 1000 and 1100 $cm^{-1}$. These two peaks were attributed to hydroxyl stretching and the aliphatic ether, alcohol C−O, or aromatic stretching, respectively.[29,30] Unlike the biochars at 700 °C, the peaks at 1614 and 1430 $cm^{-1}$ were detected in biochar at 300 °C, which were probably attributed to C═O stretching, respectively.[31] The oxygen functional groups, such as hydroxyl and carboxyl, can form complexes with heavy metals and thus increase the heavy metal adsorption ability of soil.[32] In addition, the carboxyl ($-COO^-$) and hydroxyl ($-O^-$) groups that can associate $H^+$ are the main contributions to the alkalinity of biochars[33] and play an important role in soil acidity correction.

The SEM images showed that both pyrolysis temperature and proportion of straw addition influenced the morphological structure of the biochars (Figure 6). At 300 °C, the manure biochar had few porous structures (Figure 6) and the lowest surface area (Figure 3). At 700 °C, the porous structure of manure biochar still had not been formed (Figure 6), which is consistent with the low values of BET and micropore area (Figure 3). However, the straw biochar and the manure/straw 1:1 biochar at 700 °C had large numbers of porous structures, in accordance with the larger surface area and porosity compared with the manure biochar. The reason was that the porous structures were more easily formed with the straw addition at the high pyrolysis temperature, due to the higher content of lignocellulose. However, at 300 °C, the straw biochar and the manure/straw 1:1 biochar also demonstrated low surface areas and porosities, suggesting that only high pyrolysis temperatures in combination with the straw addition can induce highly porous structures, not only providing large numbers of physical adsorption sites for heavy metals but also probably providing a suitable habitat for some specific microbes to colonize, reproduce, and grow. Therefore, the effects of the porous structure of biochar on microbial growth should be investigated further. The EDS images show the major elements in the biochars. The manure biochar contained more nutrients (K, P, Ca, and Mg) than the straw biochar, suggesting that a great number of minerals and nutrients adhered to the manure biochar surface. Overall, the biochars prepared from manure plus straw showed more comprehensive properties because of the increased ash from manure and the increased porous structure from straw. The proportion of the straw added should be carefully taken into account according to the results required for various agronomic and environmental applications.

**The Effect and Mechanism of Biochars on Zn(II) Adsoption.** The Zn(II) absorbed by all biochars at 300 °C decreased slightly as the proportion of straw addition increased

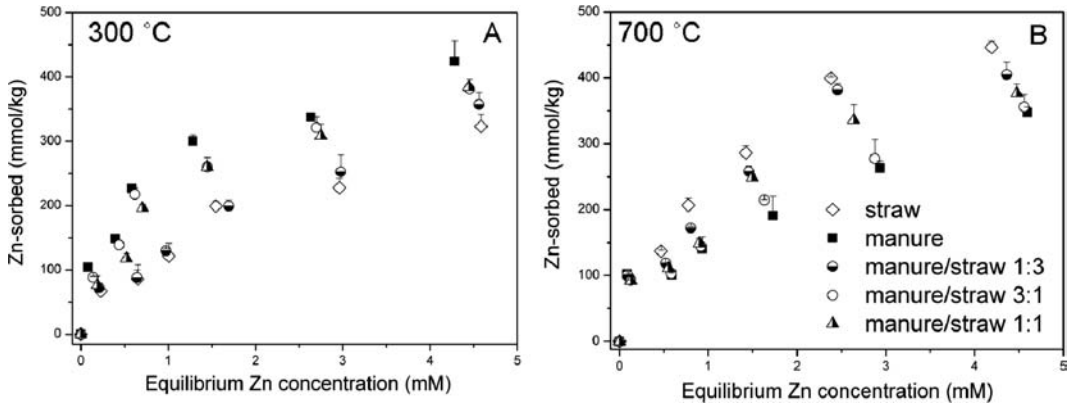

**Figure 7.** Adsorption isotherms of the biochars at pyrolysis temperature of (A) 300 and (B) 700 °C.

(Figure 7A). For instance, when the initial concentration of Zn(II) was 4 mM, the Zn(II) absorbed by biochars at 300 °C was 337, 321, 309, 253, and 228 mmol/kg with manure, manure/straw 3:1, manure/straw 1:1, manure/straw 1:3, and straw, respectively. However, the Zn(II) absorbed by biochars at 700 °C showed a trend opposite to that at 300 °C (Figure 7B). The Zn(II) absorbed by these biochars was 263, 277, 336, 382, and 400 mmol/kg for manure, manure/straw 3:1, manure/straw 1:1, manure/straw 1:3, and straw biochars, respectively, which suggests that the Zn(II) absorbed by biochars at 700 °C increased slightly as the proportion of straw addition increased.

The Freundlich and Langmuir models were introduced to fit the Zn(II) adsorption iostherms obtained from different biochars. The Freundlich model fitted the adsorption data better than the Langmuir model, with all correlation coefficients ($R^2$) being greater than 0.90, and mostly >0.94 (Table 1), and thus the Freundlich model could be used to explain the Zn(II) adsorption by biochars. At 300 °C, the Zn(II) adsorption capacity ($K_F$) decreased as the proportion of straw increased (except for straw biochar), i.e., 234, 210, 203, 136, and 146 (mmol/kg)/(mmol/L)$^n$ for manure, manure/straw 3:1, manure/straw 1:1, manure/straw 1:3, and straw biochars, respectively. However, At 700 °C, the Zn(II) adsorption capacity ($K_F$) increased as the proportion of straw increased, i.e., 139, 152, 174, 187, and 226 (mmol/kg)/(mmol/L)$^n$ for manure, manure/straw 3:1, manure/straw 1:1, manure/straw 1:3, and straw biochars, respectively. In addition, with the same proportion of straw added, the manure, manure/straw 3:1, and manure/straw 1:1 biochars at 300 °C had a larger Zn(II) adsorption capacity than that at 700 °C, whereas the manure/straw 1:3 and straw biochars had the opposite trend.

**Table 1. Constants and Correlation Coefficients of Freundlich and Langmuir Models for Zn(II) Adsorption by Feedstock Blending Biochars at 300 and 700 °C**

| | Freundlich | | | Langmuir | | |
|---|---|---|---|---|---|---|
| biochar | $K_F$ (mmol/kg) /(mmol/L)$^n$ | $n$ | $R^2$ | $q_{max}$ (mmol/kg) | $b$ | $R^2$ |
| straw-300 °C[a] | 146 | 0.52 | 0.97 | 324 | 1.08 | 0.95 |
| manure/straw 1:3[b]-300 °C | 136 | 0.62 | 0.95 | 595 | 0.29 | 0.88 |
| manure/straw 1:1-300 °C | 203 | 0.43 | 0.96 | 488 | 0.83 | 0.98 |
| manure/straw 3:1-300 °C | 210 | 0.44 | 0.96 | 377 | 2.07 | 0.94 |
| manure-300 °C | 234 | 0.38 | 0.99 | 410 | 1.75 | 0.96 |
| straw-700 °C | 226 | 0.63 | 0.99 | 683 | 0.58 | 0.94 |
| manure/straw 1:3-700 °C | 187 | 0.70 | 0.94 | 225 | 8.85 | 0.68 |
| manure/straw 1:1-700 °C | 174 | 0.58 | 0.90 | 580 | 0.46 | 0.90 |
| manure/straw 3:1-700 °C | 152 | 0.71 | 1.00 | 350 | 0.91 | 0.66 |
| manure-700 °C | 139 | 0.60 | 1.00 | 317 | 5.25 | 0.85 |

[a]The pyrolysis temperature at which biochars were prepared. [b]The ratio (w/w) of the swine manure and rice straw feedstocks.

Normally, the adsorption of heavy metals by biochars can be described by three main mechanisms: precipitation, cation exchange, and complexation.[34,35] In our study, the silicate and calcite from XRD in manure biochar, which can form the Zn-silicate and Zn-carbonate precipitates, were responsible for the higher Zn(II) adsorption in manure biochar at 300 °C. In addition, at 300 °C, as the proportion of straw increased, the EBC (sum of exchangeable K, Na, Ca, and Mg) decreased, resulting in less exchange with Zn(II). This is also the mechanism for the decrease in Zn(II) adsorption by the biochars with added straw compared to the manure biochar. At 700 °C, the adsorption capacity increased as the proportion of straw added increased, which was attributed to the large BET and micropore area (Figure 3). The large increases in BET and micropore area, especially with manure/straw 1:3 and straw biochars, provided more physical potential for adsorption sites, and the SEM images also showed the larger porous structures in manure/straw 1:3 and straw biochars. Overall, the biochars at 300 °C had greater Zn(II) adsorption capacities than 700 °C (except for the manure/straw 1:3 biochar and straw biochar), due to the high content of oxygen functional groups on biochar surfaces at low pyrolysis temperature (Figure 2). The −OH and −COOH, which can form complexes with Zn(II), were the main mechanism. Additionally, the extremely high number of adsorption sites in manure/straw 1:3 biochar and straw biochar at 700 °C caused higher Zn(II) adsorption capacities than at 300 °C.

**The Criteria To Select Biochars as Soil Amendments.** The criteria were to select biochars as soil amendments for varied purposes. It should be considered whether the soil can be improved by biochars for a specific purpose or not. For instance, biochars may have no positive effects on alkaline and calcareous soils,[36] which already have high pH values and organic matter. Second, the biochars should be classified into several groups based on the specific agronomic and environmental requirements. For instance, the properties of biochars used for heavy metal adsorption are quite different from those

required from biochars used for soil acidity correction. In our study, without considering the production costs, the manure/straw 3:1 biochar and manure biochar at 300 °C were suitable to absorb heavy metals such as Zn(II); the manure/straw 1:3 biochar and straw biochar at 700 °C can be used to correct soil acidity and increase soil carbon contents considerably; the manure/straw 3:1 biochar and manure biochar at 700 °C caused the largest increases in nutrients. In addition, the biochars prepared from two feedstocks may have more comprehensive and varied effects on soils rather than biochars prepared from a single feedstock. In conclusion, biochars prepared from manure plus straw had different physiochemical properties than the manure biochar. The addition of straw compensated for the disadvantages in the remedial effects of the manure biochar, while it decreased the advantages of the manure biochar. More detailed criteria should be established to prepare the most appropriate biochars as soil amendments for varied agronomic and environmental requirements, and the yield, production costs, and the long-term effects also should be taken into account.

sufficient to control white grubs during the later stages of the peanut-growing season. Fipronil and chlorpyrifos have different modes of action. Fipronil can be absorbed by roots and transported into plants whereas chlorpyrifos activity does not appear in plant tissues.[15] In this study, a microencapsulated mixture of fipronil and chlorpyrifos was applied through seed treatment to control white grubs in peanut fields, and the release kinetics and behaviors of the two active ingredients in the environment were investigated in comparison with those of the conventional formulation.

## MATERIALS AND METHODS

**Chemicals.** Technical-grade fipronil (95.0%) and chlorpyrifos (98.0%) were provided by the CAC Group Limited (Shanghai, China) and were used without further purification. Commercial-grade emulsifier 0203 (polyoxyethylene castor oil + calcium dodecylbenzenesulfonate, 1:1, w/w) and the NNO dispersant (2-naphthalenesulfonic acid) were purchased from Jiangsu GPRO Group Co. (Jiangsu, China). Xylene, melamine, acetonitrile, and a 37% formaldehyde solution were purchased from Sinopharm Chemical Reagent Beijing Co., Ltd. (Beijing, China). Hydroxyl poly(vinyl alcohol) (17-88) was purchased from Beijing Organic Chemical Plant (Beijing, China). PSA was purchased from Agela Technologies Inc. (Tianjin, China).

**Plant Material.** Peanut seeds (Jihua 4) were kindly supplied by the Cangzhou Seed Company (Cangzhou, China).

**Preparation of Microcapsules.** Microencapsulation was achieved using a modification of the in situ polymerization method.[16] Briefly, a mixture of 6.0 g of melamine and 11.6 g of 37% formaldehyde was adjusted to pH 8.5−9.0 with 10% $Na_2CO_3$ solution. The melamine−formalin precondensate was prepared by stirring the mixture at 70 °C until it became transparent. The temperature was then reduced to 40 °C. Simultaneously, an o/w emulsion was prepared by adding a mixture of 15.3 g of chlorpyrifos, 3.3 g of fipronil, 3.3 g of xylene, and 4.0 g of emulsifier 0203 to 26 g of water. The o/w emulsion was added to the melamine−formalin prepolymer. The reaction liquid was adjusted to pH 4.5 with 10% hydrochloric acid solution. The reaction system was then stirred at 70 °C for an hour.

The microcapsule slurry was centrifuged at $1.2 \times 10^4$ rev $min^{-1}$. The microencapsulated formulation for seed treatment was prepared by resuspending the sedimented material in an aqueous solution containing dispersant NNO (40 g $L^{-1}$) and poly(vinyl alcohol) (17-88) (10 g $L^{-1}$). The concentrations of chlorpyrifos and fipronil in this microencapsulated formulation for seed treatment were 150.0 g $L^{-1}$ and 30.0 g $L^{-1}$, respectively. The conventional formulation (flowable suspension for seed treatment) was prepared by milling 15.3 g of chlorpyrifos, 3.3 g of fipronil, 4.0 g of NNO, 1.0 g of 17-88, and 86.4 g of water using a Pulverisette 6 high-speed bead mill (Fritsch, Germany). The concentrations of chlorpyrifos and fipronil in the conventional formulation for seed treatment were the same as those in the microencapsulated formulation.

**Determination of Particle Sizes and Size Distribution.** The sizes of the microcapsule particle and their size distribution were determined using a BT-9300H laser particle-size analyzer (Dandong, China).

The encapsulation efficiency of the microcapsules was tested following a modification of the method of Asrar et al.[17] Briefly, 0.003 g of microcapsule formulation was mixed with 100 mL of 10% aqueous solution of methyl alcohol. The mixture was shaken for 1 min and was immediately filtered through a 0.45 μm PTFE filter, and then the amounts of fipronil and chlorpyrifos in the filtered solution were determined by HPLC using a VWD detector and a Hypersil ODS column (46 mm × 250 mm, 5 μm). The mobile phase was acetonitrile/water (90:10) flowing at a rate of 1.0 mL $min^{-1}$. The injected volume was 20 μL. Fipronil and chlorpyrifos were detected at wavelengths of 279 and 230 nm, respectively. The limits of quantification of fipronil and chlorpyrifos were 0.05 mg $L^{-1}$ and 0.04 mg $L^{-1}$, respectively. The filtered amount represented the REA, and the encapsulation efficiency was expressed as 100 − REA %.

**Field Experiments for Release Study.** Peanut seeds were coated with either the conventional formulation or the microencapsulated formulation. Each of the two formulations were applied to the seeds at rates of 1.8 g $kg^{-1}$ seed (fipronil:chlorpyrifos = 0.3 g:1.5 g) and 3.6 g $kg^{-1}$ seed (fipronil:chlorpyrifos = 0.6 g:3.0 g). All treatments were applied using the traditional method of stirring 100 g of seeds with a calculated dose of formulation after dilution with 1 mL of water. The untreated control seeds were stirred with 1 mL of tap water.

The treatments were arranged in a split-plot design and replicated three times in Cangzhou, China. Each subplot (45 $m^2$) consisted of 18, 5 m long rows spaced 0.5 m apart. The plants within the rows were spaced 0.3 m apart. There was 1.5 m spacing between the plots. Each planting hole was sowed with one coated peanut seed on May 13, 2012.

Five plants were randomly selected from each plot and dug out with approximately 200 g of soil adhering to the root zone at intervals of 15, 30, and 45 DAE. The sampled plants and adhering soil were stored at −20 °C for determining the dose dynamics of fipronil and chlorpyrifos. Thirty plants were randomly selected from each plot, and the plants and the adhering soil to a depth of 0.3 m were dug out at harvest to survey the white grub content.

**Field Experiments for Residual Analysis at the Time of Harvest.** The field experiments for the final residual analysis were conducted in Yongqing, Jinan, and Xiantao China in 2012. Table 1 lists the soil characteristics and climate information in three test locations. Peanut seeds were coated with the microencapsulated formulation at rates of 3.6 g $kg^{-1}$ seed and 5.4 g $kg^{-1}$ seed (fipronil:chlorpyrifos = 0.9 g:4.5 g). The untreated control seeds were treated with tap water. The insecticide-treatment and untreated-control plots were arranged randomly with three replications of each treatment. The area of each plot was 30 $m^2$.

Soil and plant samples were collected at harvest. The sampling method used was the same as that used for the release study in the field.

**Sample Preparation for Chemical Analysis.** The soil from each plot was pooled and sieved, and the extraneous matter, including stones and pieces of gravel, was removed. The sampled roots and pods were washed with water and were allowed to dry in the air. Afterward, 10 g of a sample (soil, roots, kernels, or pod hulls) was homogenized using a mortar. The homogenized sample was transferred to a centrifuge tube. Then, 20 mL of acetonitrile and 5 mL of 1% formic acid solution were added. The mixture was shaken for 1 h. Then, 3 g of NaCl was added, which was followed by vigorous shaking for 1 min. The mixture was centrifuged at $3.8 \times 10^3$ rev $min^{-1}$ for 5 min. A 6 mL aliquot of the supernatant was transferred to a 15 mL centrifuge tube containing 0.3 g of PSA. The sample was vigorously shaken for 1 min and then was centrifuged at $1.0 \times 10^4$ rev $min^{-1}$ for 3 min. A 1 mL aliquot of the supernatant was taken for fipronil analysis. Another 1 mL aliquot of the supernatant was transferred to a centrifuge tube containing 0.1 g of anhydrous $MgSO_4$ and then was vigorously shaken for 1 min. The sample was centrifuged at $1.0 \times 10^4$ rev $min^{-1}$ for 3 min. The supernatant was evaporated to dryness under a stream of

nitrogen. Finally, the residue was reconstituted using 1 mL of hexane prior to chlorpyrifos analysis.

**GC Analysis of the Chlorpyrifos Content.** The chlorpyrifos content was determined using an Agilent 7890A GC/FPD with an Agilent RTX-17 column (30 m × 0.25 mm × 0.25 $\mu$m) under the following conditions: column injector port temperature, 240 °C; injection volume, 1 $\mu$L with splitless mode; nitrogen as carrier gas at a flow rate of 1.0 mL min$^{-1}$; oven temperature program, 100 °C (1 min), increased at 20 °C min$^{-1}$ to 250 °C, and held for 3 min. The retention time of chlorpyrifos was 10.3 min. The limit of determination was 0.001 mg kg$^{-1}$. The recovery rates, relative standard deviations, and linearity of this method are provided in the Supporting Information (Table s1).

**LC−MS/MS Analysis of the Fipronil Content.** The fipronil content was determined using an Agilent 1200 HPLC system coupled online to an Agilent 6410 B LC-QQQ system. The LC separation was performed using an Agilent eclipse plus column (2.1 mm × 50 mm × 3.5 mm) at 30 °C. The mobile phase used was acetonitrile/water (containing 0.1% formic acid) (90:10) at a rate of 0.3 mL min$^{-1}$. The injected volume was 5 $\mu$L. For the mass spectrometric analysis, the ESI source was operated in the negative-ionization mode, and its parameters were as follows: gas temperature, 350 °C; gas flow, 8 L min$^{-1}$; nebulizer gas, 35 psi; and capillary voltage, 4000 V. Nitrogen gas served as the nebulizer, and argon gas was used as the collision gas. The MRM mode was selected to monitor the precursor-to-product ion transitions. The MRM parameters were the following: qualifying ion pair, 465/330 and 435/250; quantifying ion pair, 435/330; fragmentation voltage, 120 V; and collision energies, 8/25 eV. The retention time of fipronil was 0.64 min. The limit of determination was 0.001 mg kg$^{-1}$. The recovery rates, relative standard deviations and linearity of this method are provided in the Supporting Information (Table s1).

**Statistical Analysis.** Statistical analysis of the insecticide-efficacy values and the white-grub density values was conducted using SPSS 10.0 (SPSS Inc., Chicago, IL, USA) software at $\alpha = 0.05$. Fisher's least significant difference test was applied to compare the mean values, and $p < 0.05$ was accepted as significant. Before performing the statistical analysis, the values of white-grub density were transformed using $\log_{10} x$, and the efficacy of the insecticides was transformed using arcsine $\sqrt{x} \times 180/\pi$.

## RESULTS

**Characterization of the Microcapsules Containing the Mixture of Fipronil and Chlorpyrifos.** The size distribution of the microcapsules containing the mixture of fipronil and chlorpyrifos was found to be unimodal (Figure 1). The particle sizes ranged from 0.2 to 4.7 $\mu$m, with an average of 1.6 $\mu$m. The encapsulation efficiencies for fipronil and chlorpyrifos were 90.0% and 96.0%, respectively.

**Dynamic Changes in the Fipronil Concentration in the Soil and the Peanut Roots.** In the case of all of the treatments, fipronil was detectable in the soil and peanut roots during the experimental period. Microencapsulation effectively reduced the rate of fipronil degradation in the soil and peanut roots compared with that of the conventional formulation. As shown in Table 2, the fipronil concentration in the soil and the peanut roots of the microcapsule treatments at the same growth stage of the peanuts was higher than that of the conventional formulation treatments. The fipronil concentration in soil declined from 0.895 mg kg$^{-1}$ to 0.211 mg kg$^{-1}$ with the microencapsulated formulation, 2.5−4.9 times that of the conventional formulation when both were applied at a dose of 1.8 g kg$^{-1}$ seed and compared at the same peanut growth stage. When used at a dose of 3.6 g kg$^{-1}$ seed, this concentration decreased from 1.27 mg kg$^{-1}$ to 0.275 mg kg$^{-1}$ with the microcapsule formulation, 2.5−6.1 times that of the conventional formulation.

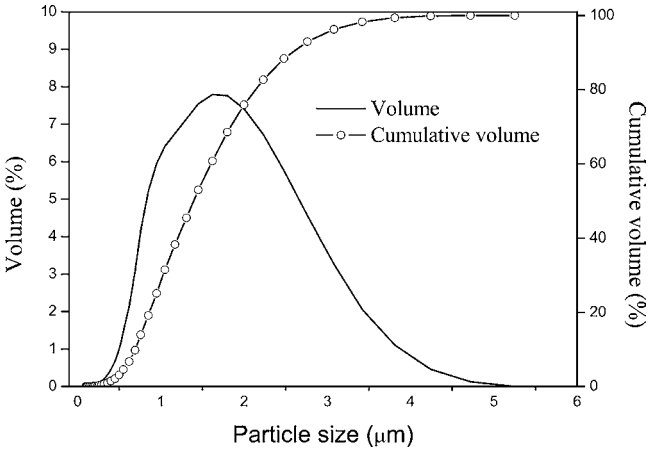

**Figure 1.** Size distribution of the microcapsules containing the mixture of fipronil and chlorpyrifos as determined using a BT-9300H laser particle-size analyzer.

The fipronil concentration in the peanut roots also declined gradually over the experimental period for both the microencapsulated and conventional formulations. These fipronil concentrations with the microencapsulated formulation were above 2.2 times that of the conventional formulation treatments when compared at the same peanut growth stage.

It was also observed that fipronil $C_r/C_s$ ratio for the conventional formulation declined gradually from 1.09 to 0.202 when applied at a dose of 1.8 g kg$^{-1}$ seed and from 1.36 to 0.273 when applied at a dose of 3.6 g kg$^{-1}$ seed. However, the fipronil $C_r/C_s$ ratio for the microencapsulated formulation peaked on 30 DAE.

**Dynamic Changes in the Chlorpyrifos Concentration in the Soil and Peanut Roots.** In contrast to fipronil, chlorpyrifos was detectable in both the soil and peanut roots on 15 DAE. After that point, it was detectable only in the soil (Table 3). Chlorpyrifos that was applied in microcapsules was effectively protected from degradation. On 15 DAE, its concentration for the microencapsulated formulation was 5.6 times that of the conventional formulation, and it increased to 10.3 times on 45 DAE when applied at a dose of 1.8 g kg$^{-1}$ seed. Similarly, the chlorpyrifos concentration for the microencapsulated formulation increased from 6.4 times that for the conventional formulation on 15 DAE to 28.1 times that for the conventional formulation on 45 DAE when applied at a dose of 3.6 g kg$^{-1}$ seed.

On 15 DAE, the $C_r/C_s$ ratio of chlorpyrifos for the conventional formulation was in the range of 2.55−2.80. For the microencapsulated formulation, that $C_r/C_s$ ratio was 2.48 when applied at a dose of 1.8 g kg$^{-1}$ seed, and 1.55 when applied at a dose of 3.6 g kg$^{-1}$ seed.

**Fipronil and Chlorpyrifos Residues in the Soil and Peanut Pods at Harvest.** As shown in Table 4, residues of fipronil were detectable in peanut kernels at harvest for all of the treatments, with the maximum residue level being 0.005 mg kg$^{-1}$, and the minimum residue level being 0.001 mg kg$^{-1}$. The amount of fipronil residue in the pod hulls and soil greatly varied depending on the location. The maximum residue level was found to be 0.040 mg kg$^{-1}$ in pod hulls and 0.059 mg kg$^{-1}$ in the soil when the formulations were applied at a dose of 5.4 g kg$^{-1}$ seed. Fipronil residues were also observed to be below the determination limit (0.001 mg kg$^{-1}$) in pod hulls and soil samples.

| | 5.4 | 0.001 ± 0.000 | ND | ND | 0.002 ± 0.002 | 0.008 ± 0.007 | 0.010 ± 0.001 |

[a]The results are presented as the mean values ± SD ($n$ = 3). [b]ND, not detectable.

As shown in Table 4, the level of chlorpyrifos residues in the soil were always above the determination limit (0.001 mg kg$^{-1}$). The maximum residue level found in the soil was 0.141 mg kg$^{-1}$ when the formulations were applied at a dose of 5.4 g kg$^{-1}$ seed in Jinan. However, chlorpyrifos was detectable in less than half of the samples of pod hulls and kernels.

**The Efficacies of the Insecticides against White Grubs in Peanut Fields.** Microencapsulation greatly improved the efficacy of the mixture of fipronil and chlorpyrifos to control white grubs. As shown in Table 5, when the formulations were applied at a rate of 1.8 g kg$^{-1}$ seed, the populations of white grubs in the conventional formulation treated plots were not significantly lower than those in the control plots. When the formulations were applied at a rate of 3.6 g kg$^{-1}$ seed, the populations of white grub in the conventional formulation treated plots were significantly reduced, but the efficacy of this treatment was only 44.4%. In contrast, the microencapsulated mixture of fipronil and chlorpyrifos significantly reduced the populations of white grubs in the test fields and the efficacies of this formulation were greater than 71% when applied at both of the tested doses.

Table 5. Densities (Mean Values ± SD Numbers Per 30 Plants) of White Grubs and Efficacies (%) of the Insecticides at Harvest Time after a Single Dose Application of Fipronil and Chlorpyrifos through Seed Treatment[a]

| formulation | rate (g kg$^{-1}$ seed) | white grub density | efficacy |
|---|---|---|---|
| conventional formulation | 1.8 | 31.0 ± 1.0 a | 13.9 ± 2.8 c |
| | 3.6 | 20.0 ± 2.6 c | 44.4 ± 7.3 b |
| microcapsule formulation | 1.8 | 10.3 ± 1.5 b | 71.3 ± 4.2 a |
| | 3.6 | 9.0 ± 2.6 b | 75.9 ± 6.4 a |
| untreated control | | 36.0 ± 4.6 a | |

[a]The results are presented as the mean values ± SD ($n$ = 3). Values in the same column followed by different letters are significantly different at $\alpha$ = 0.05.

## DISCUSSION

Chlorpyrifos is often applied as a granular treatment along the peanut rows at pegging to control soil pests.[18,19] However, most growers choose to apply chlorpyrifos through seed treatment prior to planting because it is a more labor-efficient practice. Although the trials in this study were conducted by applying chlorpyrifos at planting, treatments at pegging or at both planting and pegging are more effective in controlling soil pests.[4,19] Our study indicated that applying a single dose of the conventional mixture of chlorpyrifos and fipronil through seed treatment did not meet the demands of peanut producers for the control of white grubs. The efficacy of this conventional formulation was in the range of only 13.9−44.4%. To better control this pest, a higher application rate or repeated

applications of the insecticides would be required, which is the commonly accepted practice for agricultural production.[20,21] A single dose of the microencapsulated mixture of chlorpyrifos and fipronil effectively controlled the white grubs throughout one growing season of peanuts, proving that microencapsulation can reduce the dosage and frequency of application of the insecticides (Table 5).

The degradation of chlorpyrifos in natural soil results from hydrolytic and microbial processes that often work in tandem.[10,22,23] However, hydrolysis constitutes the major route of chlorpyrifos degradation in soil, and a higher level of soil moisture increases the dissipation rate.[24,25] In this study, the concentration of chlorpyrifos in the soil for the microencapsulated formulation was 5.6−28.1 times that of the conventional formulation, which demonstrated the ability of microencapsulation to stabilize chlorpyrifos against degradation in the environment. However, chlorpyrifos is a compound without systemic activity. But it can strongly adhere to plants and soil.[10] When crop roots contact soil containing chlorpyrifos, no uptake of chlorpyrifos occurs. Chlorpyrifos adheres to the surface of roots and other underground tissues. In our study, chlorpyrifos was detectable in both the roots and soil on 15 DAE but was detectable only in the soil later in the growing season. This finding can be explained by gradual diffusion into the soil, as the peanut plants grew, of the chlorpyrifos coated on the surface of the peanut seeds, so that the level of chlorpyrifos in the roots decreased with the increasing experimental time. Additionally, although chlorpyrifos can adhere to the surface of roots, a great deal of the adsorbed chlorpyrifos might be washed away during the preparation of the root samples. The amounts of final chlorpyrifos residues in the soil, kernels, and pod hulls taken from the three tested locations were consistent with this hypothesis. At harvest, the levels of the final residues of chlorpyrifos were detectable in all of the soil samples but were detectable in less than half of the samples of pod hulls and kernels. Taken together, these results revealed that although microencapsulating chlorpyrifos retards its rate of degradation in the soil and improves its residual activity, there is a low risk that chlorpyrifos will contaminate the underground edible tissues following seed treatment because this compound is not taken up by plants.

In contrast, fipronil exhibits systemic activity against certain susceptible pests. Following application via seed treatment, fipronil can be absorbed by roots and transported upward in the xylem of plants.[15] In agreement with this chemical property, fipronil was detectable in all of the samples of the roots and soil within 45 DAE. At harvest, fipronil was detectable in all of the kernel and pod hull samples from Yongqing and Jinan, as well as in the kernel samples from Xiantao. Similarly, Aajoud et al. found that a great amount of fipronil was present in the tissues of sunflowers throughout the experiment course following seed coating application, as determined using $^{14}$C-fipronil. Therefore, they suggested that slow release strategies should be adopted when formulating a seed coating mixture using fipronil to maintain its efficiency to control soil-dwelling pests and to limit the uptake and transport of fipronil by plants.[15] In our study, the fipronil $C_r/C_s$ ratio for the conventional formulation exhibited a downward trend during the experiment period. This downward trend was due to the initially high dose of fipronil directly contacting the roots and the subsequent uptake of fipronil by the peanut roots occurring more slowly than the water uptake.[15] However, the fipronil $C_r/C_s$ ratio for the microencapsulated formulation peaked on 30 DAE, which revealed that the slow rate of fipronil release by the microcapsules limited its direct contact with the roots.

Fipronil is widely used in unencapsulated conventional formulation to control soil-dwelling pests, and the fipronil residues were often found to be below the detectable levels in the soil and plant tissues at the time of harvest.[9,11,26] At least a 2.2-fold higher concentration of fipronil in the soil and peanut root tissues was found with the microencapsulated treatment compared with the conventional treatment, which indicated that microencapsulation prolonged it activity. Besides this advantage of prolonged activity, the controlled release of pesticides can also reduce the adverse effects of pesticides on the biological systems. Many pesticides have been encapsulated within polymer beads for safer application, such as neem seed oil, chlorpyrifos, cypermethrin, and fenvalerate.[27−31] However, another risk should be taken into consideration. In this study, the greater persistence of the microencapsulated fipronil may result in a higher risk of exceeding the MRLs set by governments worldwide. The concentration of its final residue in kernels was in the range of 0.001−0.005 mg kg$^{-1}$. The official MRL for fipronil in peanuts set by the European Union is 0.005 mg kg$^{-1}$, and that of the Japanese government is 0.01 mg kg$^{-1}$. The level of fipronil residues in some kernel samples reached the MRL set by the European Union, which indicated that a higher application rate or repeated application of the microencapsulated fipronil at the tested dosages would not be acceptable.

In conclusion, white grubs are difficult to control because they can damage peanut plants throughout their growing season. A microencapsulated mixture of fipronil and chlorpyrifos effectively controlled this insect pest after a single dose applied via seed treatment. Microencapsulation protected both fipronil and chlorpyrifos against degradation in the environment. In this formulation, chlorpyrifos has a low risk of exceeding the MRLs at harvest in the underground edible tissues following seed treatment. However, the fipronil residues in some kernel samples at harvest reached the statutory MRL set by the European Union, which indicated that a higher rate of application or repeated application of the microencapsulated fipronil would not be acceptable.

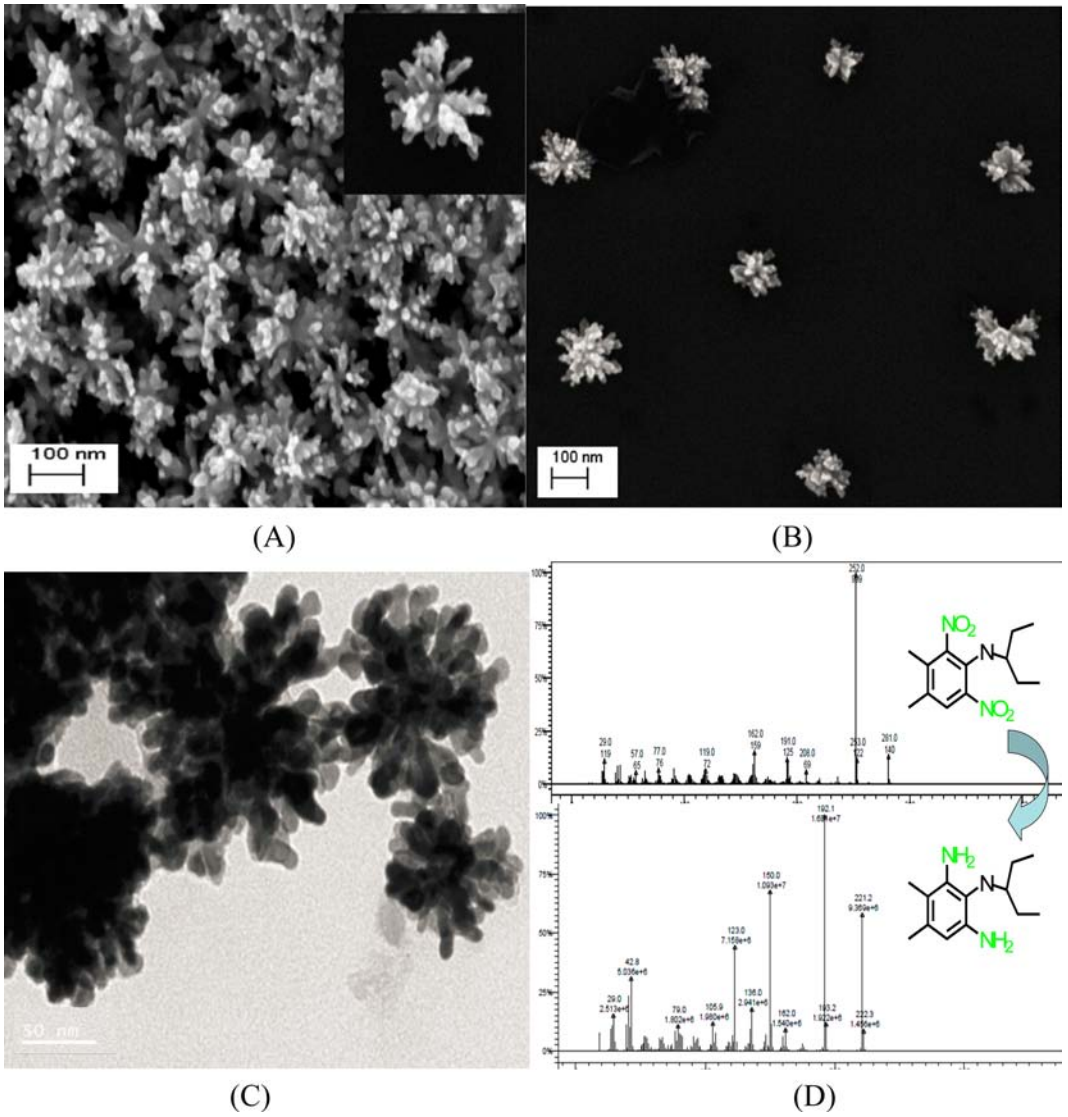

**Figure 1.** (A, B) SEM and (C) TEM images of gold nanoflower that were synthesized; Mass spectral data of (D) shows the process of degradation of pendimethalin (above) to *N*-(1-ethylpro-pyl)-2,6-diamino-3,4-xylidine (below).

the model contaminant due to its relatively long persistence in soil and its frequent use as a criterion for soil contamination by pesticide dealerships,[38] was effectively degraded by sodium borohydride. Pendimethalin is the common name for *N*-(1-ethylpro-pyl)-2,6-dinitro-3,4-xylidine, a representative member of the growing list of N-substituted 2,6-dinitroaniline herbicides used for selective control of most annual grasses and many annual broad-leaved weeds in several crops. Pendimethalin has approved uses in all countries of the European Union.[39] However, according to the label of pendimethalin, even in nanomolar concentration, it is toxic to aquatic organisms such as fish and may cause long-term adverse effects in the aquatic environment. What's more, pendimethalin has half-lives in soil usually ranging from a few days to several months.[40] Plieth and Boerner[41] reported approximately 10−15% remains of the 2.3 mg/kg pendimethalin 10 months after its application in the soil. Compared with previously reported ways of pendimethalin degradation, our method exhibited higher efficiency and faster reaction (within 5 min). In addition, degradation of pendimethalin in soil samples was performed to demonstrate enormous potential in the practical use of this platform. Furthermore, to verify the effectiveness of gold nanoflower as the catalyst in the degradation of nitroaromatic pesticides, additional experiments on trifluralin and *p*-nitrophenol, which are common nitroaromatic pesticides were carried out with satisfactory results.

## MATERIALS AND METHODS

**Chemicals and Apparatus.** Pendimethalin were purchased from Zouping Luda Pharmaceutical Co., Ltd. (Shandong, China). Trifluralin were purchased from Feng Shan Group Co., Ltd. (Jiangsu, China). *p*-Nitrophenol were purchased from Sinopharm Chemical Reagent Co.,Ltd. Two soil samples (A clay soil containing organic matter and sandy loam soil in absence of organic matter) came from Wuhan University. Other chemicals were of analytical grade and prepared with ultrapure water from a Millipore system (18.2 M resistivity).

The size distribution and structure of the Au nanoflower were probed by high-resolution transmission electron microscopy (HRTEM) using a JEM-2100 (HR) operated at an acceleration voltage of 200 kV and scanning electron microscope (SEM), respectively. Subsequently, gas chromatography−mass spectrometry (GC−MS) was used to ensure the product of degradation reaction. Finally, UV−vis absorption spectrometer (UV-2550, Hitachi Co. Ltd., Japan) was employed to record UV−vis absorption spectra.

**Synthesis of Au Nanoflower.** Modifications were made based on the literature[37,42] and Au nanoflower has been successfully synthesized with a simple, fast process without seeds and other surfactants. First, 50 $\mu$L of $HAuCl_4$ (wt 1%) aqueous solution was added to 2.5 mL of deionized water. Then, 10 $\mu$L of $NH_2OH$ (wt 50%) aqueous solution was injected into the solution with stirring, and after 1 min reaction, Au nanoflower dispersion was obtained. Finally, after half an hour standing, homogeneous Au nanoflower was obtained for use.

**UV−vis Spectra Measurements.** The color change was qualitatively measured by taking UV−vis spectra with 600 $\mu$L-optical-path-length quartz cuvettes at 1 min interval in the range of 200−700 nm. The rate constant of the degradation reaction of nitroaromatic pesticides was determined by the function of the measurement of the change of absorbance at the initially observed peak at 430 nm in relation to time. All experiments were reacted and measured at room temperature.

In order to investigate the feasibility of degrading pendimethalin by $NaBH_4$ in the presence of Au nanoflower (with stable particle size100 nm) as a degradation catalyst, three 2 mL test tubes (A,B,C) have been added into 500 $\mu$L of 2.34 mM pendimethalin aqueous solution. Then, pendimethalin aqueous solution in test A and test B was respectively mixed with 500 $\mu$L of 15 mM $NaBH_4$ aqueous solution and 500 $\mu$L ultrapure water was added into test C. 100 $\mu$L Au nanoflower was introduced into test A and 100 $\mu$L ultrapure water was added to test B and test C, respectively, to make each reaction solution 1100 $\mu$L. The final mixed solution was allowed to stand and react for 30 min at room temperature. The UV−vis absorption spectrum was measured at room temperature.

To save cost and time, kinetic analysis is necessary. A 500-$\mu$L portion of 2.34 mM pendimethalin aqueous solution was mixed with 500 $\mu$L of 15 mM $NaBH_4$ aqueous solution. After vibration, 100 $\mu$L Au nanoflower aqueous solution was added. The UV−vis absorption spectrum was measured at 1 min interval from zero to 10 min at room temperature. The rate constant of the degradation reaction of pendimethalin was determined by measuring the change in absorbance of the initially observed peak at 430 nm, for the pendimethalin, as a function of time.

The pH value is a very important factor to the reaction process. The pH value of pendimethalin aqueous solution was adjusted by 1 M HCl or 1 M NaOH aqueous solution and the final concentration was 2.34 mM. 500 $\mu$L of pendimethalin aqueous solution (2.34 mM) of different pH value (pH 1, 4, 7, 11, 14) were mixed with 500 $\mu$L 15 mM of $NaBH_4$ aqueous solution in 2.0 mL test tube respectively, and 100 $\mu$L Au nanoflower aqueous solution was added to make each solution 1.1 mL. Finally, these mixtures were detected by the UV−vis absorption spectrum at room temperature.

In order to optimize volume of Au nanoflower, 500 $\mu$L of 2.34 mM pendimethalin aqueous solution were mixed with 500 $\mu$L of 15 mM $NaBH_4$ aqueous solution. After vibration, different volumes (25−200 $\mu$L) of Au nanoflower solution were added in, respectively. Then appropriate aliquot of ultrapure water was introduced in to make each reaction solution 1.2 mL. Finally, the UV−vis absorption spectrum measurements were done at room temperature.

To verify the feasibility of this new platform for pendimethalin degradation in practical samples, two soil samples (clay soil containing organic matter and sandy loam soil in absence of organic matter) are applied to degrade pendimethalin. Two 10 g samples of air-dried soil were transferred to a 100 mL flask. Then 100 mL of water was added in and stirred for about 3 h; after the soil settled, the supernatant was filtered by 0.22 $\mu$m microporous membrane. Two 4.68 mM pendimethalin portions were diluted by two soil filtrates, and the final concentration was 2.34 mM. 500 $\mu$L 2.34 mM pendimethalin was mixed with 500 $\mu$L 15 mM $NaBH_4$ aqueous solution, then, 100 $\mu$L Au nanoflower aqueous solution was added into the mixtures. The UV−vis absorption spectrum measurements were done at room temperature.

To further explore the potential application of the platform in the practical samples, the development of new degradation platform was tested by other nitroaromatic pesticides, including trifluralin and *p*-nitrophenol. 500 $\mu$L of 1.43 mM trifluralin aqueous solution and 0.2 mM *p*-nitrophenol aqueous solution were mixed with 500 $\mu$L 15 mM NaBH4 aqueous solution respectively, then, 100 $\mu$L Au nanoflower aqueous solution was added into the mixtures. The UV−vis absorption spectrum measurements were done at room temperature.

## RESULTS AND DISCUSSION

**The Proposed Mechanism.** Gold-based catalysts have attracted intense interest in recent years following the discovery that small supported Au nanoparticles (NPs) can be effective catalysts for CO oxidation at low temperatures. They have been widely used and regarded as a new generation of catalysts to some reactions that are otherwise unfeasible. However, the properties of AuNPs depend strongly on their size and shape, which determine the surface structure of the particles.[29] In our experiment, Au nanoflower was synthesized through $NH_2OH$ reduction of $HAuCl_4$. To confirm the successful formation of Au nanoflower and its size and shape, the as-prepared Au nanoflower was characterized by SEM and HRTEM. As shown in Figure 1A−C, dendritic structures of Au nanoflower were synthesized, and the diameter of Au nanoflower was approximately 100 nm, exhibiting relatively narrow size distribution. Although reports of dendritic structure of gold nanoparticle are rarely seen,[37,42−44] dendritic nanostructures have often been reported in the synthesis of platinum nanocrystals.[45,46] According to diffusion-limited aggregation (DLA) model,[33,47] small Au nanoparticle has higher energy owing to a larger surface-to-volume ratio and of a higher collision frequency associated with their greater mobility, which leads to Au nanoparticle coalescence or attachment. The probability of finding a randomly diffusing AuNPs particle around the Au core is extremely low owing to the so-called screening effect. Due to the screening effect, the tips of most advanced branches of Au core can most effectively capture the incoming and randomly diffusing gold particles, forming particle coalescence, or attachment to the tips, thus homogeneous and stable gold nanoflower solution can be obtained in the end.

It can be observed that the yellow pendimethalin aqueous solution exhibited a large absorption peak at 430 nm without $NaBH_4$ and Au nanoflower. Upon the addition of aqueous solution of $NaBH_4$ (15 mM), the absorption peak at 430 nm of (B) and (C) remained unaltered and their solution color remained the same for a long duration, which indicated that the strong reducing agent $NaBH_4$ alone cannot degrade pendimethalin. Interestingly, the addition of an aliquot of Au nanoflower dispersion to the reaction system caused a fading and ultimate bleaching of the yellow color of pendimethalin in aqueous solution (A), suggesting the occurrence of the degradation reaction. The UV/vis spectra in Figure 2 unambiguously verifies this conclusion as well, as the absorption band of pendimethalin at 430 nm decreases and disappears in less than 5 min after the addition of Au nanoflower. To exclude the possibility that the degradation reaction could have been activated by the superfluous $NH_2OH$ instead of Au nanoflower, $NH_2OH$ alone was added into pendimethalin and $NaBH_4$ (15 mm) mixtures. No change in the color and position of the absorption band (at 430 nm) of pendimethalin was observed. Thus, the degradation of pendimethalin by $NaBH_4$ has been clearly demonstrated to be activated by the Au nanoflower. The samples of pendimethalin and degredation product were characterized using gas chromatography−mass spectrometry (GC−MS) for identification of compounds. The experimental results of mass spectrum (Figure 1 D) showed that the two

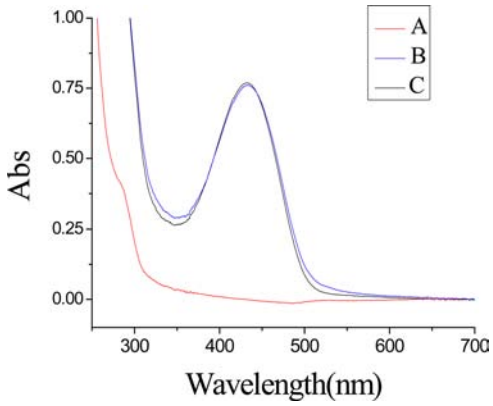

**Figure 2.** (A) UV−vis absorption spectra of degradation of pendimethalin catalyzed by Au nanoflower, (B) UV−vis absorption spectra during the reduction of pendimethalin by $NaBH_4$ without Au nanoflower, and (C) UV−vis absorption spectra of pendimethalin in aqueous solution.

nitro groups of pendimethalin were reduced to two amino groups of *N*-(1-ethylpro-pyl)-2,6-diamino-3,4-xylidine. On the basis of the above findings, a tentative reaction pathway for degradation of pendimethalin catalyzed by Au nanoflower processes is presented as follows (Scheme 1): in this process,

**Scheme 1. Reaction Pathway for Degradation of Pendimethalin Catalyzed by Au Nanoflower Processes**

the main oxidizing species is $H^-$ from $NaBH_4$. But $H^-$ is unstable in aqueous solution. Due to its large specific surface area and high specific activity, gold nanoflower could adsorb hydrogen anion ($H^-$) and provide places for the degradation of pendimethalin. Meanwhile, a large Fermi level shift caused the higher driving force of particle-mediated electron transfer from $BH_4^-$ ion to nitro compounds mediated by the Au nanoflower because that existing $H^-$ belong to highly electron-injecting species.[48] As seen from the principle above, pendimethalin are removed directly from the aqueous solution, leading to the formation of aromatic intermediates. Hence, this method is applicable to the degradation of all nitroaromatic pesticides rather than just a few particular nitrophenolic compounds.

**Kinetics for Pendimethalin Oxidation.** Hydrogen anion ($H^-$) from sodium borohydride ($NaBH_4$) is mainly used as a principal reducing agent in pendimethalin degradation. Hydrogen anion ($H^-$), as a nonspecific reductant, reacts with the target organic contaminants (pendimethalin) at rates close to diffusion rates in water. Thus, the kinetics for pendimethalin reducing by reduction of sodium borohydride catalyzed by Au nanoflower processes can be represented as follows:

$$dC(P)/dt = -k_P'C(P) \times C(NaBH_4) \quad (1)$$

A second-order rate equation can be applied to fit the data, where $C(P)$ is the concentration of pendimethalin, $C(NaBH_4)$ is the sodium borohydride concentration, and $k_P'$ is the second-order rate constant for the reaction. Since the concentration of $NaBH_4$ added in the system is much higher in comparison with that of pendimethalin, it is reasonable to assume that the concentration of $BH_4^-$ remains constant during the reaction. Equation 1 can be reduced to a pseudo-first-order rate equation:

$$dC(P)/dt = -k_PC(P) \quad (2)$$

where, $k_P$ is the pseudo-first-order rate constant. In case of Au nanoflower-catalyzed degradation processes, Au nanoflower remained almost constant during the experimental time and hence eq 2 was equated in evaluating the kinetics of pendimethalin during Au nanoflower-catalyzed degradation processes. When $t = 0$, $C(P)$ is equal to $C(P)_0$, and the solution of eq 2 becomes,

$$C(P) = C(P)_0 \exp(-k_Pt) \quad (3)$$

or

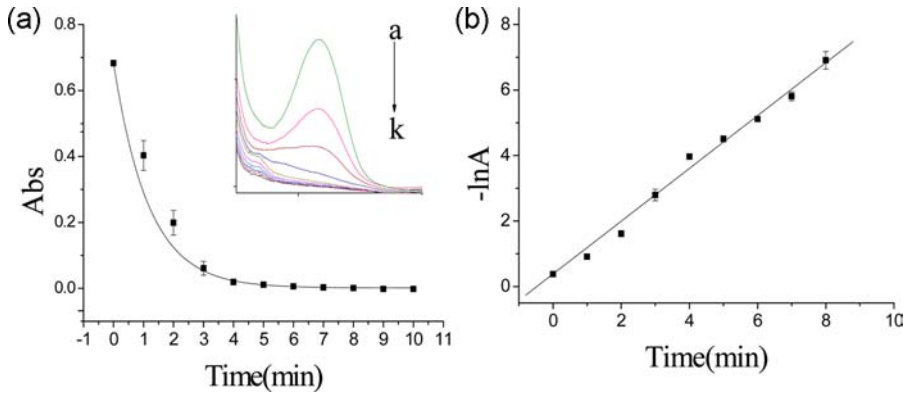

**Figure 3.** (a) Plot of absorbance (A) against time for the catalytic reduction of pendimethalin by Au nanoflower (the insets present the reaction kinetic graph for the degradation of pendimethalin catalyzed by Au nanoflower. (a–k): 0, 1, 2, 3, 4, 5, 6, 7, 8, 9, and 10 min) and (b) Plot of −ln(A) against time for the catalytic reduction of pendimethalin by Au nanoflower (conditions: 500 μL 2.34 mM pendimethalin + 500 μL 15 mM $NaBH_4$ + 100 μL Au nanoflower).

dx.doi.org/10.1021/jf5034015 | J. Agric. Food Chem. 2014, 62, 10638−10645

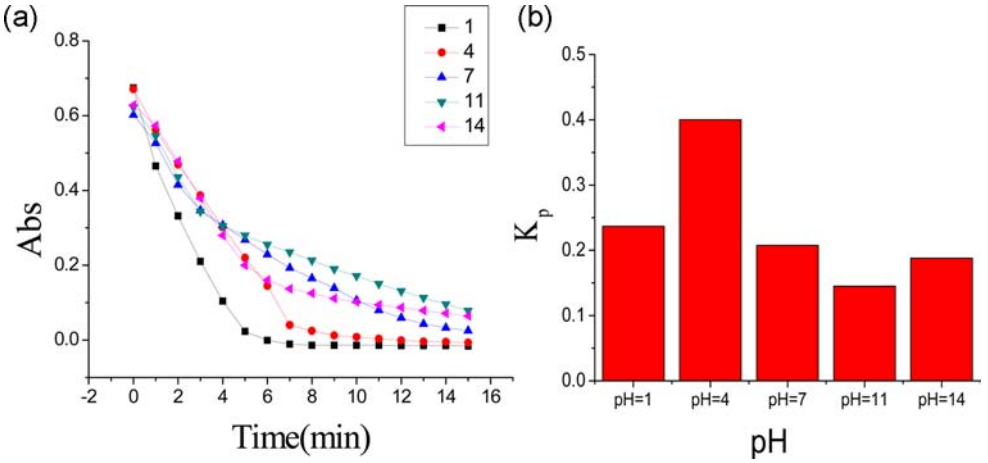

**Figure 4.** (A)Plot of the absorbance at $\lambda_{max}$ ($\lambda_{max}$ = 430 nm) of degradation pendimethalin versus time at different pH (B) Histogram of rate constant of degradation pendimethalin at different pH (pH 1, 4, 7, 11, and 14).

$$\ln[C(P)/C(P)_0] = -k_p t \quad (4)$$

On the basis of the above considerations, pseudo-first-order kinetics could be used to evaluate the kinetic reaction rate of the current catalytic reaction, together with the UV/vis absorption data in Figure 3. As expected, a good linear correlation of $\ln(A)$ versus time ($A$ is the absorption intensity of pendimethalin) was obtained (Figure 3), where $k$ is a kinetic reaction rate constant, $k$ = 0.8066 and $b$ = 0.3813. The linear fitting of the experimental data gives a linear correlation coefficient of 0.998 and standard deviation of 3.75. The equation is as follows:

$$-\ln A = kt + b$$

**Optimal pH Value.** We studied the effect of pH on the removal of pendimethalin because the degradation efficiency of the pendimethalin is pH dependent.[38] The changes of UV−vis absorption spectrum as a function of pH and time (Figure 4A) was taken into account. According to Figure 4A, when the pH value was increased from 1 to 11, the time of degradation was gradually prolonged, and the removal efficiency decreased. Despite the fact that velocity constant (Figure 4B) was improved slightly when the pH value was 14, it was accompanied by long degradation time and unsatisfactory removal efficiency. Under acidic conditions, protonation of nitrogen atoms of nitro of pendimethalin could easily be formed, giving them higher affinities with $H^-$ produced by $NaBH_4$. Nevertheless, $H^-$ is unstable in acidic solution because of the presence of $H^+$. Therefore, the degradation reaction was influenced by both the degree of protonation of nitrogen atom and the amount of $H^-$ existence. Under acidic conditions, nitrogen atoms of nitro of pendimethalin could achieve higher degree of protonation, while under alkaline conditions, $H^-$ is more stable. Due to redundant $NaBH_4$ in the designed system, the degradation reaction had little effect on $H^-$ under acidic condition. But under alkaline conditions, the reaction platform was largely influenced by the degree of protonation. Considering all these, pH under acidic condition, which is more conducive for pendimethalin degradation, was selected in the subsequent experiments, which is in accordance with the literature.[38] Since pendimethalin solution is naturally acidic (pH 4−5), no adjustments of pH were done in the experiments.

**Optimal Au nanoflower volume.** It is essential to carefully optimize the concentration of Au nanoflower due to its crucial role in the degradation of pendimethalin in aqueous solution and complex samples. A too low concentration of Au nanoflower could lead to low catalytic efficiency and longer time, while a too high concentration could have a slower effect on catalytic activity or cause a waste of the material. Both would result in bad rate of the degradation. Thus, the optimization of Au nanoflower concentration was performed (Figure 5). As shown in Figure 5, the degradation time decreased gradually with the increasing concentration of Au nanoflower, and a turning point of least degradation time was observed when the volume of Au nanoflower reached 150uL (Figure 5). Therefore, an optimized volume of 150 $\mu$L Au nanoflower was chosen in the experiments.

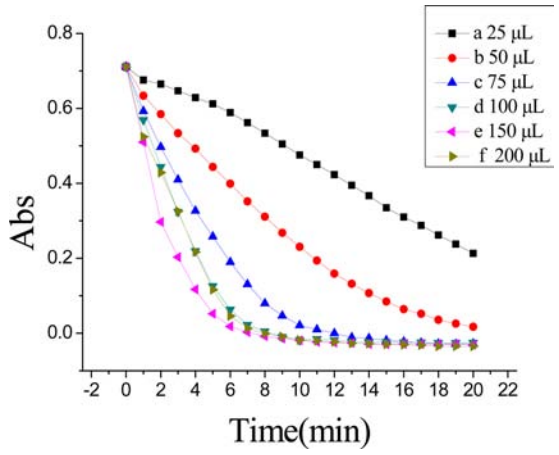

**Figure 5.** Plot of the absorbance at $\lambda_{max}$ of pendimethalin versus time at different volumes of Au nanoflower (a-f: 25, 50, 75, 100, 150, and 200 $\mu$L).

**Degradation of pendimethalin in soil.** To demonstrate the practical applicability of the designed strategy, we measured the UV−vis absorption spectra of soil diffusate containing pendimethalin at specific concentrations (Figure 6). It required about 7 min to complete the degradation of pendimethalin in the inorganic soil, and a little longer in organic soil yet within 10 min. Variations in pendimethalin removal efficiency between different soils were consistent with known effects from soil

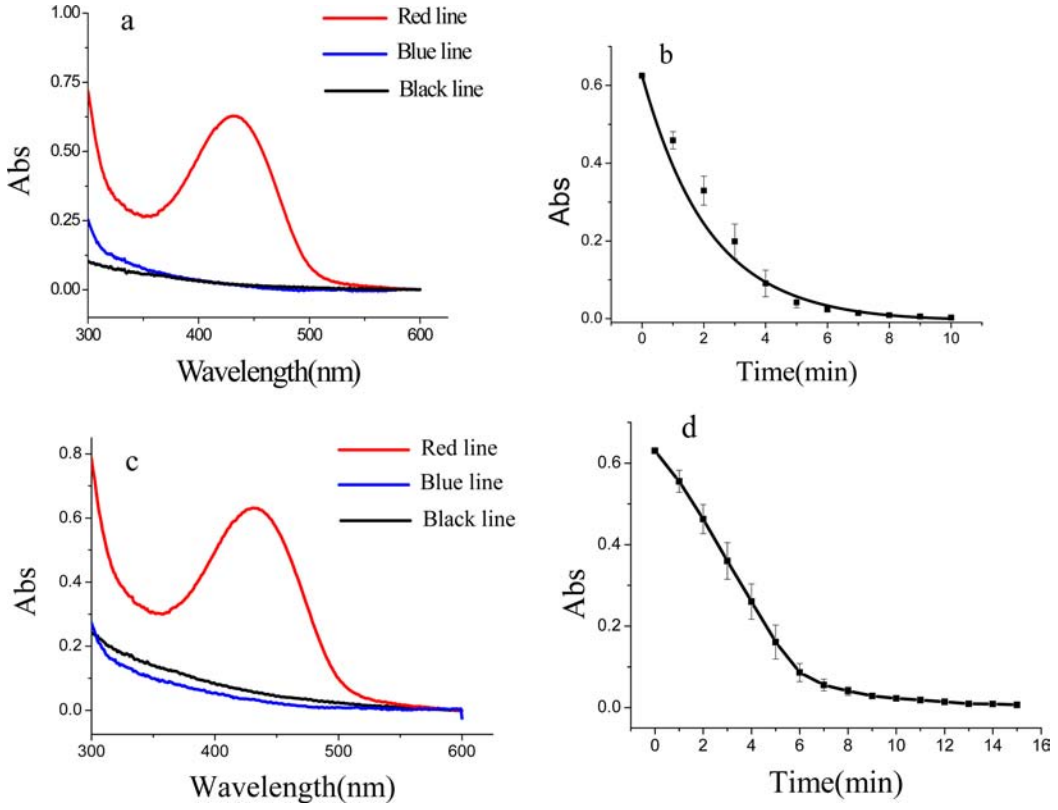

**Figure 6.** UV−vis spectrum of degradation pendimethalin in two soils (a) Red line is the UV−vis spectrum of sandy soil leachate containing pendimethalin. Blue line is UV−vis spectrum of sandy soil leachate. Black line is UV−vis spectrum of sandy soil leachate containing pendimethalin after reaction for about 10 min. (b) Plot of the absorbance at $\lambda$ max of pendimethalin degradation versus time in sandy soil. (c) Red line is UV−vis spectrum of organic soil leachate containing pendimethalin. Black line is UV−vis spectrum of organic soil leachate. Blue line is UV−vis spectrum of organic soil leachate containing pendimethalin after reaction about 10 min. (d) Plot of the absorbance at $\lambda$ max of pendimethalin degradation in organic soil versus time. Note: corresponding histograms with error bar (standard deviation from the mean, $n$ = 3).

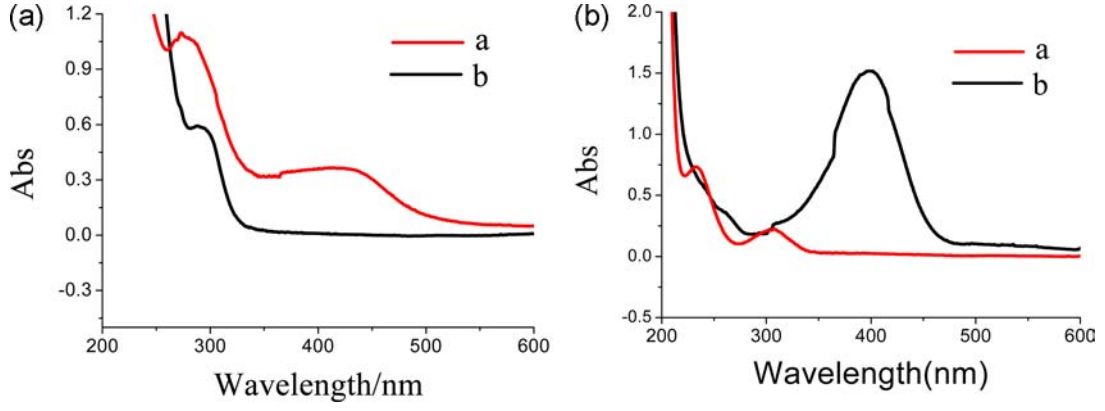

**Figure 7.** UV−visible spectra of (A) trifluralin and (B) *p*-nitrophenol during the reduction catalyzed by Au nanoflower, [$NaBH_4$] 2.34 mM and trifluralin 1.43 mM, *p*-nitrophenol 0.2 mM. Note: (a) is UV−vis spectrum before degradation reaction and (b) is UV−vis spectrum before degradation reaction. Corresponding histograms with error bar (standard deviation from the mean, $n$ = 3).

organic matter (i.e., removal efficiency decrease with organic content increase), which is in accordance with literature.[38] Delightfully, all pendimethalin could be degraded in a short time, hence achieving satisfactory contamination soil remediation. Therefore, this new degradation platform has a great potential in pendimethalin degradation in both organic and inorganic soil with interference.

**Degradation of Other Nitroaromatic Pesticides.** To exemplify the general applicability of our strategy to nitroaromatic pesticides, we applied the same principle and Au nanoflower to design a degradation platform targeting at trifluralin and *p*-nitrophenol. As expected, in the absence of Au nanoflower, this platform could not function and UV−vis absorption spectrum band (trifluralin at 425 nm and *p*-nitrophenol at 400 nm) did not change in a long duration (Figure 7); however, in the presence of Au nanoflower, the two solutions correspondingly changed from light yellow to transparency and a drop in UV−vis absorption spectrum band was observed (Figure 7). Amazingly, *p*-nitrophenol was degraded completely within 2 min and trifluralin within 10 min.

dx.doi.org/10.1021/jf5034015 | J. Agric. Food Chem. 2014, 62, 10638−10645

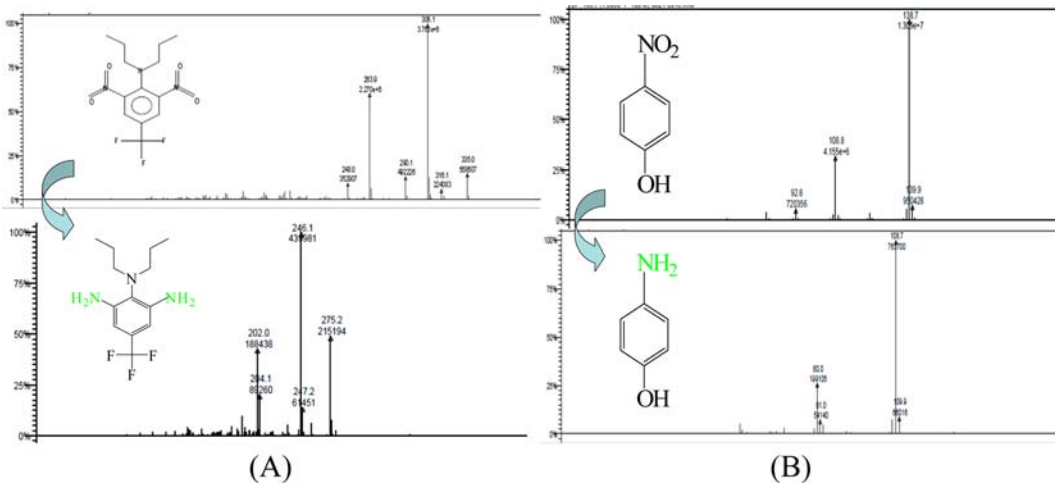

**Figure 8.** Mass spectral data of (A) shows the process of degradation of trifluralin (above) to 2,6-2-amino-*N*,*N*-2-4-propyl-3-fluorine methylanilines (below); Mass spectral data of (B) shows the process of degradation of *p*-nitrophenol (above) to *p*-aminophenol (below).

The degredation of the parent pesticide were confirmed by gas chromatography−mass spectrometry (GC−MS), Figure 8A,B shows that trifluralin and *p*-nitrophenol were reduced to 2,6-2-amino-*N*,*N*-2-4-propyl-3-fluorine methylanilines and *p*-aminophenol, respectively. Thus, when finished the degredation reaction, nitro groups of pesticides were reduced to amino groups of degredation product. The universality of the approach is achieved by virtue of catalyst of Au nanoflower without any change of the degradation platform structure.

In summary, we have developed a simple, rapid, facile, economically viable, and "green" growth approach without the use of seeds to synthesize branched gold nanocrystals which resemble the shape of a flower through $NH_2OH$ reduction of $HAuCl_4$. Under optimal conditions, the synthesized Au nanoflower can complete the degradation of pendimethalin in the presence of $NaBH_4$ within 4 min. In addition, the designed strategy is well applied not only to pendimethalin degradation in practical soil samples, but also to the degradation of common nitroaromatic pesticides including trifluralin and *p*-nitrophenol. We believe that this novel degradation platform can be very useful in the fields of environment protection, soil contamination remediation, and sewage treatment. It has also opened a window to the wide applications of synthesized Au nanoflower in pharmaceuticals, biomedicals, and biosensors in the future.

have exerted profound influences on the molecular design and interaction mechanism investigations of pesticides.[20−23] In the present study, the 3D structures of homopentamer of $GABA_ARs$ in representative insect (fruitfly Rdl) and fish (zebrafish $\beta3$) were established by the homology modeling method based on the open-state structure of an inhibitory glutamate-gated chloride channel[24] from *Caenorhabditis elegans*. The GluCl[24] showed high sequence similarity and was a good template for modeling the structures of the $GABA_ARs$, which was better than the nAChR and AChBP (acetylcholine binding protein) structures used in previous studies.[16−18] Finally, docking and molecular dynamics (MD) simulation studies were performed to explore the binding difference of fipronil with fruitfly Rdl and zebrafish $\beta3$ $GABA_ARs$.

## MATERIALS AND METHODS

**Homology Modeling.** The target sequences of fruitfly Rdl (UniProt ID P25123) and zebrafish $\beta3$ (UniProt ID E7EXG0) subunits were retrieved from UniProtKB (http://www.uniprot.org/). The sequences were subjected to template search using the BLAST program of the National Center for Biotechnology Information (NCBI) (http://www.ncbi.nlm.nih.gov/). Finally, the crystal structure of glutamate-gated chloride channel[24] (PDB ID 3RHW) was chosen as the template to build the 3D structures of both $GABA_ARs$.

As no intracellular portion of the Cys-loop receptor superfamily was resolved, the sequences of the long cytoplasmic loops of the intracellular domain were removed during homology modeling study. The ClustalW2 program[25−27] was used for sequence alignment. The identities of two $GABA_ARs$ of fruitfly and zebrafish with the same template were 40.6 and 37.6%, respectively. On the basis of the aligned sequences (Supporting InformationFigure S1), in which the blue squares stand for the conserved residues of extracellular loop A-F and the Cys-loop, the channel pore of $GABA_AR$ formed by the TM2 helices is magenta squares, and the rest of the TM helices are purple squares, the Build Homology Models Module encoded in the Discovery Studio 3.5 software package (Accelrys Inc., 2013) was applied to generate the $GABA_AR$ structures of fruitfly and zebrafish species. The quality of the established 3D structures was not only assessed by the PROCHECK[28] and the Profile-3D[29] approaches but also validated by the comparison between following docking investigations and the previous experimental mutation results within the TM2 domain.

**Ligand Docking.** Ligand docking was performed by the Glide approach integrated into Maestro 9.3 (Schrödinger, LLC, 2013), with default settings in standard precision mode. The binding site was set around the centroid of the −2′ and 2′ residues from five chains, with a size of 30 Å. In the docking run, 100 conformations were output and ranked by GlideScore. The superior pose with a reasonable binding orientation was selected as the initial binding conformation for further molecular dynamics (MD) simulation.

**Molecular Dynamics Simulation.** The obtained docking results of the fipronil−$GABA_AR$ complex were conducted for MD simulation using the GROMACS 4.5.5[30−32] package with the GROMOS53a6[33] force field for all atoms. The topology and other force field parameters for fipronil were obtained using the PRODRG beta server (http://davapc1.bioch.dundee.ac.uk/prodrg/).[34] The ESP partial atom charges were calculated at the B3LYP/6-31G(d,p) level using the Gaussian 09 package (Gaussian, Inc., Wallingford CT, USA; 2009) and determined using the Merz−Singh−Kollman scheme.[35,36] On the basis of the calculated electrostatic potential, the restrained electrostatic potential (RESP) charges were produced using the Antechamber module[37] of the Amber10 package. The fipronil−$GABA_AR$ complex structures were inserted into a pre-equilibrated 1-palmitoyl-2-oleylphosphatidylcholine (POPC) lipid bilayer using the "shrinking" method, where the shrinking cycles were performed with the InflateGRO script.[38] The bilayer structure used here was downloaded from Tieleman's Web site (http://moose.bio.ucalgary.ca/). The cubic periodic box comprising the simple point charge (SPC) water[39] model was built. The $Cl^-$ ions were inserted randomly into the solvent to preserve the electric neutrality in both systems.

The two systems were performed under the NPT ensemble, using the Nosé−Hoover thermostat[40,41] and Parrinello−Rahman barostat[42] to maintain the pressure at 1.02 bar, with the temperature maintained at 300 K. All bonds were constrained using the LINCS algorithm.[43] In the MD simulation, the cutoff distance was set to 1.2 nm for Lennard-Jones interactions. The long-range electrostatic interactions were handled using the particle-mesh Ewald (PME) method.[44,45] The time step of the simulation was set to 2 fs. Finally, the fruitfly and zebrafish $GABA_AR$ systems in the fipronil-bound state have 1695 and 1680 residues, 71635 and 71932 water molecules, 25 and 5 $Cl^-$ ions, and 502 POPC molecules, and the densities of the POPC lipid bilayers were 66.6 and 66.8 $Å^2$, respectively.

## RESULTS AND DISCUSSION

**Homology Models of $GABA_AR$s.** The modeled structure of $GABA_AR$ is depicted in Figure 1a, of which the $\beta$-sheets of extracellular region are shown in magenta and the $\alpha$-helices are in cyan. The channel pore of $GABA_AR$ was surrounded by five TM2 helices. The number for the residues of the TM2 region was indexed and is shown in Figure 1b for a convenient comparison between the two species. The interior residues in the TM2 channel of the $GABA_AR$ from fruitfly and zebrafish were −2′Pro (Ala), 2′Ala, 5′Val (Ile), 6′Thr, 9′Leu, and 20′Ala (Glu), which are shown as sticks in Figure 1c. Only three residues were different between the $GABA_AR$s of fruitfly and zebrafish, denoted −2′, 5′, and 20′, of which the 20′ residue was close to the extracellular region, the −2′ residue was near the intracellular domain, and 5′ was located in the lower part of the TM2 domain.

The quality of both modeled structures was evaluated by using the PROCHECK[28] and Profile-3D[29] approaches. In the fruitfly model, 99.3% residues were located in the allowed regions, and only 0.7% residues (Thr104 and Ser172 in the extracellular region) were located in the disallowed regions (Supporting Information Figure S2a). In the zebrafish model, 99.7% residues were observed in the allowed regions, whereas only 0.3% residues (Thr101 in the extracellular domain) were found in the disallowed regions (Supporting Information Figure S2b). The self-compatibility score by Profile-3D for the $GABA_AR$ structure of fruitfly was 543.87, which was close to the top score of 782.05. The corresponding score of the zebrafish $GABA_AR$ structure reached 546.56, which was also close to the top value of 775.07. Moreover, it could be seen that most residues were reasonable with positive score values; only a few residues far from the fipronil binding site, which located in the extracellular and TM3 regions, showed small negative profile-3D values (Supporting Information Figure S2c,d). The above results indicated that the homology models of fruitfly and zebrafish were reliable.

**Docking Results.** Docking studies were performed to explore the binding modes of fipronil with $GABA_AR$. The final docking pose was obtained by considering the GlideScore values and analyzing the binding mode, which is depicted in Figure 2. This showed that fipronil erected in both channels enclosed by the five TM2 helices, with the trifluoromethyl group of the benzene ring facing the intracellular domain, which was consistent with the previous modeling study by Cheng et al.[16] Also, the residues 2′Ala, 6′Thr, and 9′Leu were found to play important roles for the binding of fipronil (Supporting Information Figure S3), which was in accordance with the previously published investigations.[10−18,46−51] For example, Casida et al.[18] showed that the mutation of A2′C or A2′S and T6′C or T6′F, as well as L9′C or L9′S, in the human $\beta$3 homopentamer could abolish the binding sensitivity of NCAs.

The N−H···O H-bond between the amino group of fipronil and the side chain of 6′Thr was observed in both systems, which has been reported to be very important for binding by other researchers.[16−18] Moreover, it was found that the residues −2′Pro (Ala) and 5′Val (Ile) could also form interactions with fipronil (Supporting Information Figure S3). According to the docking results, both $GABA_AR$s showed favorable interactions with fipronil. All above docking analyses also confirmed that the modeled 3D structures of $GABA_AR$s were reasonable.

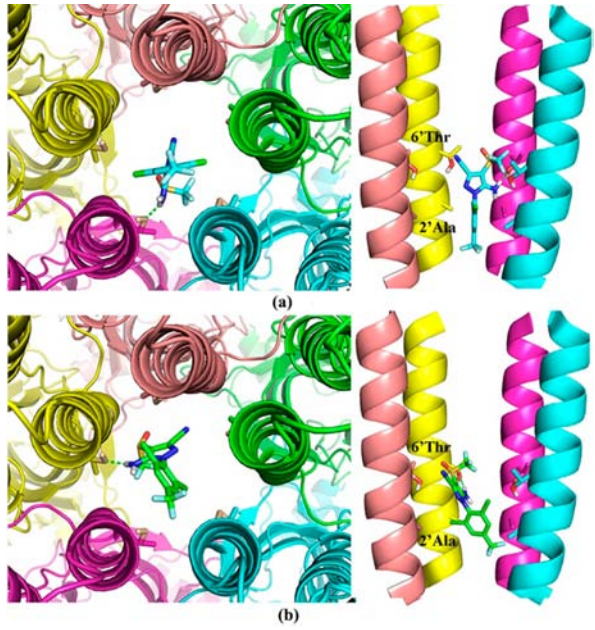

**Figure 2.** Docking poses of fipronil with fruitfly (a) and zebrafish (b) $GABA_AR$s. Dotted line, H-bond; stick, fipronil and the key residues.

**Molecular Dynamics Simulation.** *Root Mean Square Deviation (RMSD).* To evaluate the stability of the two systems during the MD simulation, the RMSD was plotted versus time. Figure 3 depicts the RMSD values for the backbone atoms of protein and ligand. The RMSD values for the backbone of fruitfly and zebrafish systems are colored in black and red, respectively; the two systems were stable after 16 ns simulations. However, during the last 14 ns of the simulations, the amplitude of the equilibrium deviation was slightly different in each trajectory. The RMSD values of the fruitfly system showed that the disruption of convergence was at about 0.46 nm, whereas the corresponding value was 0.43 nm for the zebrafish system. Meanwhile, the RMSD values of ligand atoms were also calculated and are depicted in Figure 3. The data indicated that the fipronil in both systems reached equilibrium states after a small fluctuation in the initial period of the simulation. The magnitude of fluctuations for ligand, together with the backbone of protein, led to the conclusion that the

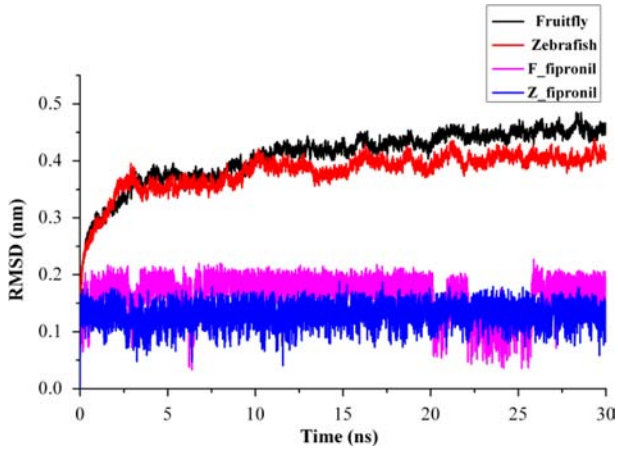

**Figure 3.** RMSD plots for the backbone of $GABA_AR$s and fipronil during MD simulation.

dx.doi.org/10.1021/jf503851z | J. Agric. Food Chem. 2014, 62, 10646−10653

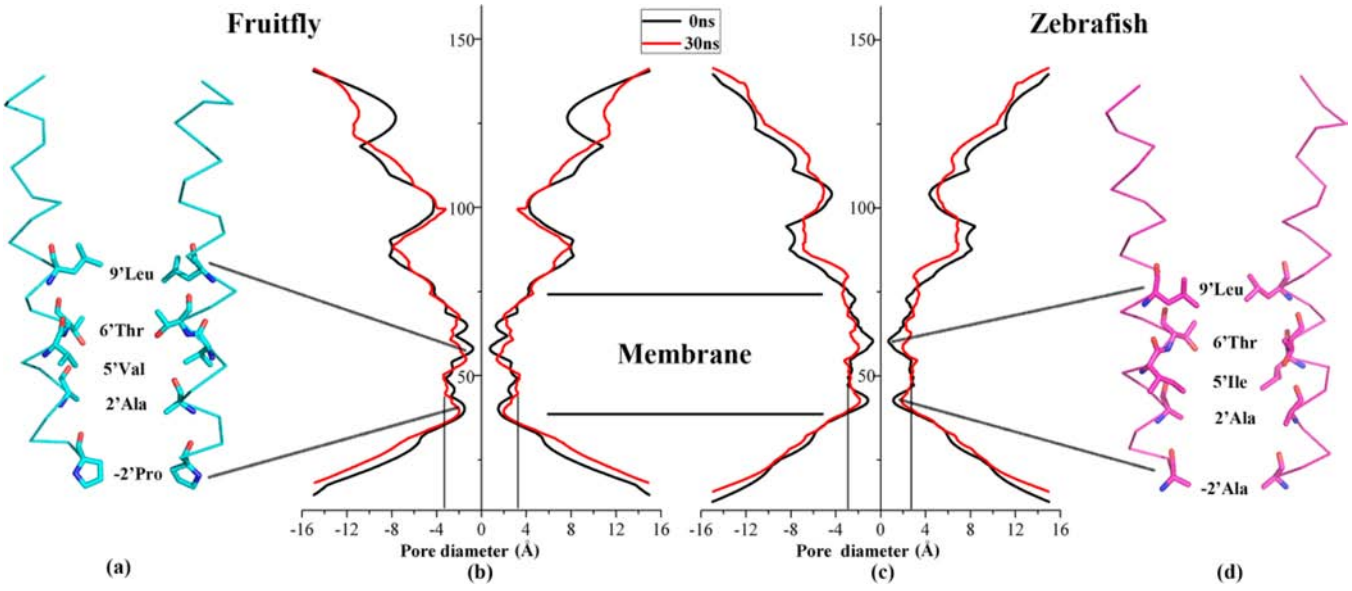

**Figure 4.** Pore diameter analysis at 0 and 30 ns snapshots of fruitfly (a, b) and zebrafish (c, d) systems: distance along the pore axis (Å) versus pore diameter. The key residues in the binding pocket from TM2 helices are shown as sticks.

simulation produced stable trajectories and provided a reliable basis for further analysis.

*Root Mean Square Fluctuation (RMSF).* With the aim of determining the mobility and flexibility of each residue in the MD simulation, the RMSF values were calculated. The RMSF values for the residues of TM domains were small, indicating that they were stable during the entire simulation (Supporting Information Figure S4a), whereas larger values were observed in the extracellular domain and the loops between TM3 and TM4, which implied that residues in these regions were flexible in the MD simulation. The fluctuating residues were observed far from the ligand binding site and might have weak influences on the interaction of fipronil with $GABA_AR$. For detailed analysis, the RMSF for the residues in ligand binding pocket within the TM2 domains is also depicted in Supporting Information Figure S4b. Clearly, the fruitfly system showed higher peaks around the fipronil binding pocket, compared with the zebrafish system, which indicated that such residues from the fruitfly system might undergo larger fluctuation than those from the zebrafish system. The smaller RMSF values in the zebrafish system also coincided with the above RMSD values.

*Pore Radius.* Ion channel radius is an important parameter to characterize the channel opening and closing, which has been widely used to measure the size of a channel pore. In the present study, the pore radius of the $GABA_AR$ was conducted using the HOLE program.[52−54] The pore radii at the 0, 5, 10, 20, and 30 ns snapshots, as well as on the average structure of the last 5 ns in the equilibrium state, have been calculated and analyzed (Supporting Information Figure S5). It could be observed that the pore radius variations were very similar at the 20 and 30 ns snapshots and on the average structure of the last 5 ns, especially in the region between the −2′Pro (Ala) and 9′Leu residues of the TM2 domain. The calculated pore diameters at 0 and 30 ns snapshots were analyzed and are depicted in Figure 4 to understand the changes of pore size after MD simulation.

The ion pores of both $GABA_ARs$ tilted radially from the extracellular domains down to the TM2 domain. The binding site of fipronil was located in the region between 9′Leu and −2′Pro (Ala) for both systems, where the side chain of 9′Leu defined the narrowest point in the middle of the two channels, whereas −2′Pro in the fruitfly system or −2′Ala in the zebrafish system determined the lowest narrow part of the channels. After a 30 ns simulation, the pore radius at 9′Leu that represented the top side of the binding pocket expanded for both systems, as well as the −2′Pro (Ala) that denoted the bottom of binding site. In the zebrafish system, no clear changes were found for the tunnel radius between 5′Ile and 2′Ala after simulation, whereas in the fruitfly system the corresponding radius between 5′Val and 2′Ala enlarged. It was also observed that the pore size between the 5′ and 2′ residues within the binding pocket of fruitfly system was wider than that in the zebrafish system, which might be a result of the smaller volume of 5′Val than of 5′Ile. Moreover, in the fruitfly system the pore radius defined by the 6′Thr narrowed, whereas in the zebrafish system the corresponding tunnel radius widened. The above differences in the binding pockets of the two systems might exert some influences on the binding modes of fipronil with the $GABA_ARs$ from the two species.

*Position and Orientation Changes of Fipronil during Simulation.* Figure 5a and b show the superposition for fipronil

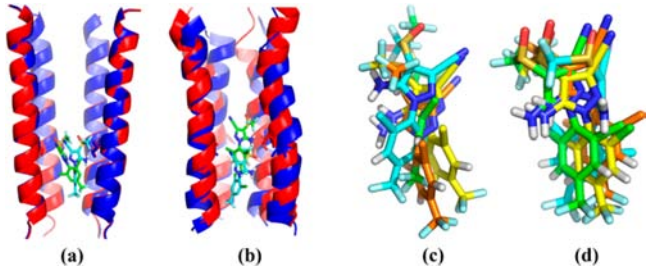

**Figure 5.** Alignment of the TM2 domain in the fruitfly (blue) and zebrafish (red) systems at 0 (a) and 30 ns (b). Cyan and green sticks represent the fipronil in fruitfly and zebrafish systems, respectively. Superimposition of the fipronil in fruitfly (c) and zebrafish (d) systems is shown as 0 ns (cyan), 10 ns (green), 20 ns (yellow), and 30 ns (orange) snapshots.

dx.doi.org/10.1021/jf503851z | J. Agric. Food Chem. 2014, 62, 10646−10653

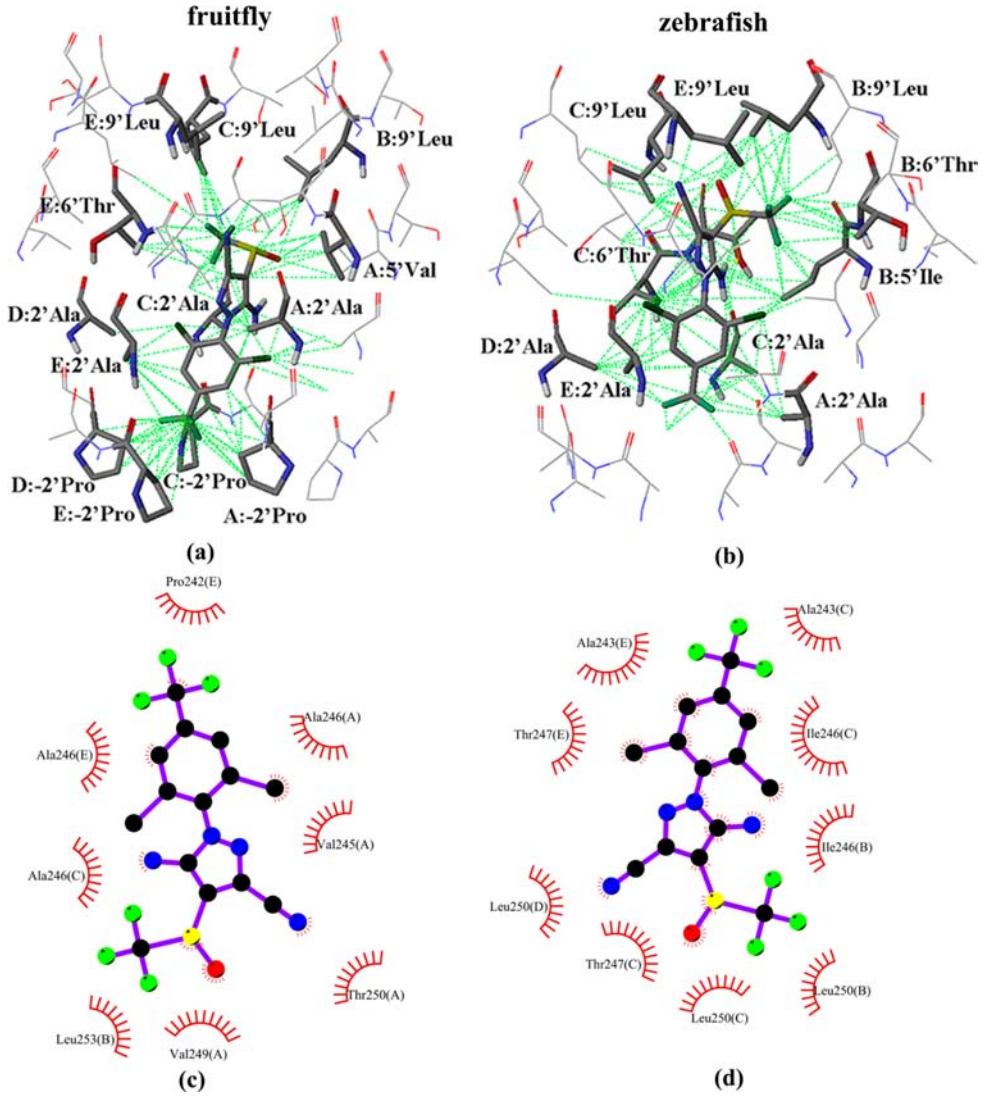

**Figure 6.** Interactions of fipronil with fruitfly (a) and zebrafish (b) $GABA_A$Rs at 30 ns snapshot after MD simulation: hydrophobic interactions between fipronil and the residues in fruitfly (c) and zebrafish (d) systems at the 30 ns snapshot.

and TM2 helices in the fruitfly and zebrafish systems at the snapshots of 0 and 30 ns of the simulation, respectively. Small position changes of fipronil were observed in the zebrafish system during the entire MD simulation, whereas the position of fipronil in the fruitfly system moved toward the lower part of the TM2 channel, as compared with its initial binding site. In other words, the binding site of fipronil in the fruitfly system was much closer to the intracellular domain than in the zebrafish system (Figure 5b).

Figure 5c and d display the superposition of fipronil in the snapshots at 0, 10, 20, and 30 ns in the MD trajectory from the fruitfly and zebrafish systems, respectively. It can be observed that fipronil went through large orientation changes in the fruitfly system relative to the zebrafish system. This might be a result of the different pore radius properties between the two systems. A wider tunnel dimension between 5′Thr and 2′Ala appeared in the binding pocket of the fruitfly system than in the zebrafish system, which might be an important reason for the observed larger position and orientation changes in the fruitfly system.

*Binding Difference of Fipronil with Fruitfly and Zebrafish $GABA_A$Rs.* To better understand the binding modes of fipronil with $GABA_A$Rs in fruitfly and zebrafish systems, the key residues for the binding of fipronil were fully analyzed on the structures at the equilibrium state. Panels a and b of Figure 6 depict the interaction between fipronil and the residues in the TM2 channel of $GABA_A$R at the 30 ns snapshots. The potential key residues displayed in sticks could also be observed in the 0, 5, 10, and 20 ns snapshots and in the average structure of the equilibrium state. It was found that residues 2′Ala, 6′Thr, and 9′Leu formed hydrophobic interactions with fipronil (Figure 6c,d), which were important for the binding of fipronil with both $GABA_A$Rs. The findings were in accordance with the previous modeling studies.[17,18] For example, Casida et al.[18] reported that 2′Ala, 6′Thr, and 9′Leu could form hydrophobic interactions with diverse antagonists, which had a critical influence on the recognition of NCAs. Moreover, in this study, the residue 5′Val (Ile) was observed forming hydrophobic interactions with fipronil in both.

Many researchers have reported that 6′Thr could form an H-bond with fipronil, which played key roles for the ligand−receptor recognition.[16−18] In the zebrafish system, an N−H···O H-bond was observed between the amino group of fipronil and the side chain of 6′Thr (Figure 7a). The distance between the

dx.doi.org/10.1021/jf503851z | J. Agric. Food Chem. 2014, 62, 10646−10653

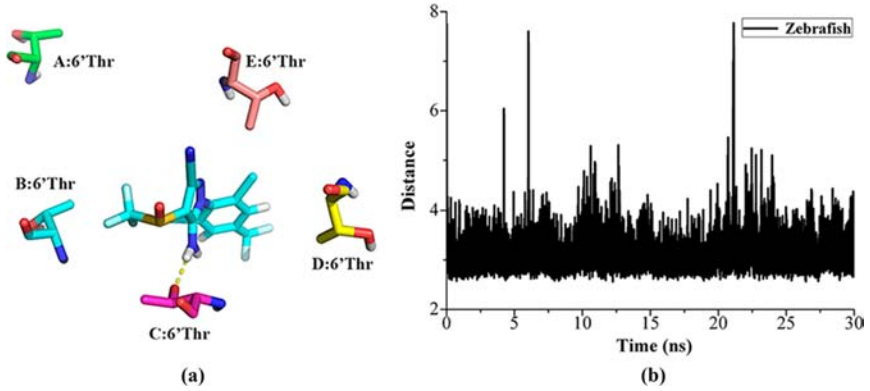

**Figure 7.** (a) N−H···O H-bond between fipronil and 6′Thr in zebrafish system; (b) N−H···O H-bond distance during the whole MD simulation.

N and O atoms versus the simulation time was monitored during the whole simulation (Figure 7b). It was found that the N−H···O H-bond was very stable, with an H-bond distance around 3.0 Å in the whole simulation. In the fruitfly system, the corresponding H-bond could be observed in the docking results and the initial snapshot of the simulation. However, it disappeared during the subsequent simulation. The detailed reasons for the disappearance of the N−H···O H-bond are still unclear. One of the reasons might be the above-mentioned large position and orientation changes of fipronil in the fruitfly system.

To gain detailed energy contributions of the key residues in the TM2 helices on the binding affinity of fipronil, a per-residue decomposition of the total energy was performed to evaluate the critical residues on the binding, using the Calculate Interaction Energy Protocol encoded in the Discovery Studio 3.5 software package (Accelrys Inc., 2013). The snapshots of two systems in the last 5 ns of MD simulation were extracted, respectively, for energy analysis. The residue-based energy decomposition results characterized the key residues in ligand binding and identified the contributions of different nonbonded interaction forces (van der Waals and electrostatic interactions). The energy contributions of each key residue are displayed in Table 1. They showed that 5′Val (Ile), 6′Thr, and 9′Leu were

**Table 1. Average Energy of Interaction between Individual Residues and Ligands for the Fruitfly and Zebrafish Systems**

| residue | fruitfly | zebrafish |
|---|---|---|
| 2′Ala | −1.05 | 1.01 |
| electrostatic term | −1.15 | 1.03 |
| 5′Val(Ile) | −1.19 | −1.54 |
| electrostatic term | −1.14 | −1.67 |
| 6′Thr | −0.82 | −1.94 |
| electrostatic term | −0.66 | −1.12 |
| 9′Leu | −0.67 | −1.23 |
| electrostatic term | −0.69 | −1.12 |

favorable for the binding of fipronil with both $GABA_A$Rs. Moreover, the average interaction energy between residue 2′Ala and fipronil, which was originated predominantly by the electrostatic interaction, was beneficial for complexation in the fruitfly system but unfavorable to binding in the zebrafish system. All of the data in Table 1 and Figures 6 and 7 indicated that residues 5′Val (Ile), 6′Thr, and 9′Leu played important roles for the binding of fipronil with both $GABA_A$Rs. Although the N−H···O H-bond between fipronil and 6′Thr could not be monitored during the MD simulation of the fruitfly system, the strong electrostatic interaction between 2′Ala and fipronil might compensate the binding force of fipronil with $GABA_A$R. Although 2′Ala and 6′Thr in the two systems, respectively, showed different roles in the recognition of fipronil, the favorable interactions enabled fipronil to erect steadily in both channels, which might contribute to the high toxicities to insects and fishes.

All of the data above indicated that residues 5′Val (Ile), 6′Thr, and 9′Leu played important roles in the binding of fipronil with both $GABA_A$Rs. Moreover, the H-bond between 6′Thr and fipronil in the zebrafish system was very stable during the whole MD simulations, which played a key role in the ligand−receptor recognition. However, such an H-bond was absent in the fruitfly system during simulation, although it could be observed in the docking results and the initial snapshot of the simulation. On the other hand, the electrostatic interaction between 2′Ala and fipronil was favorable to ligand recognition in the fruitfly system, but was detrimental to the binding in the zebrafish system. As a result, the observed strong electrostatic interaction between 2′Ala and fipronil compensated the absent contribution of the H-bond between 6′Thr and fipronil in the fruitfly system. The different roles of 2′Ala and 6′Thr marked the binding difference of fipronil with the $GABA_A$Rs of fruitfly and zebrafish, which might provide some clues for future design of new selective phenylpyrazole pesticides against insects over fishes.

investigated the mechanism of citrate exudation by following the effect of DM on the transcription of the gene OSFRDL4 coding for an anion channel protein believed to mediate citrate efflux in plants[15] in the presence or absence of anthracene-9-carboxylase (a specific anion channel inhibitor).

## MATERIALS AND METHODS

**Culture Conditions and Herbicide Treatment.** The sterilized Japonica rice seeds (*Oryza sativa* L. *japonica* cv. Xiushui 63) were germinated on filter papers at 30 °C in the dark for 2 d. The germinated seeds were then transferred onto a net floating on a culture medium containing 0.5 mM $CaCl_2$ (initial pH ≈ 5.7) at 25 °C in the dark for 4 d. For the DM exposure experiments, the seedlings were uniformly placed in an environmentally controlled growth room under a 12 h/12 h light/dark cycle. The rice seedlings were exposed for 24, 48, and 72 h to DM concentrations of 0, 5, and 50 μg/L (or 0, 14.7, and 147 nM), which were added to the $CaCl_2$ culture medium. Note that DM may rapidly hydrolyze in diclofop acid (DH) on a time scale of hours to days.[4] Because DH has a $pK_a$ of 3.57,[16] the unprotonated or negatively charged species ($D^{-1}$) of DH is then expected to predominate over the protonated species at the pH of the culture medium. The rice seedlings were thus exposed to a mixture of DM, $D^{-1}$, and a low concentration of DH. The toxicity of DM on root growth and various biochemical targets in root explants of *O. sativa* L. was then investigated after 48 h of exposure. The transcription of genes related to citrate production and incorporation in fatty acids, as well as the activity of citrate synthase, were, however, measured after 24, 48, and 72 h of exposure to DM.

**Root Growth Measurement, Microscopic Observation of Leaf Protoplasts and Root Tissue Section.** The degree of inhibition in root elongation due to DM was measured using a vernier caliper. In parallel, we also isolated protoplasts from the leaves of rice seedlings using cellulase and pectinase incubation according to the protocol described in our previous study, and tissue sections were prepared from the roots of rice seedlings by paraffin block embedding.[17] The leaf protoplasts and root tissue sections were then observed with a light microscope at 1000×.

**Quantitative Real-Time PCR (qRT-PCR).** Root tissues were ground with a mortar and pestle in liquid nitrogen, and total RNA was extracted in 1 mL of RNAiso reagent according to the manufacturer's instructions (TaKaRa Company, Dalian, China). Total RNA was treated with DNase. RNA (500 ng) was then reverse transcripted in cDNA using a M-MLV reverse transcript kit (TaKaRa Company, Dalian, China). cDNA was diluted 10 times and used for real-time quantitative RT-PCR (qRT-PCR) which was carried out on an Eppendorf MasterCycler ep RealPlex[4] (Wesseling Berzdorf, Germany) according to the manufacturer's instructions using primers specific to the DNA sequence of several genes (Supporting Information (SI) Table SI.1). The housekeeping gene *25S* rDNA was used as an internal standard. qRT-PCR was performed in 10-μL aliquots, containing 1 μL of cDNA, 0.2 μL of each primer (10 μM), 5 μL of 2× mix buffer (Master mix, TOYOBO), and supplemented with sterile distilled water, with the following program: 95 °C 1 min; 40 cycles of 95 °C 15 s, and 60 °C 1 min. Gene expression normalized to 25S rDNA was analyzed by the $2^{-\Delta\Delta Ct}$ method, where $C_t$ is the cycle number at which the fluorescent signal rises statistically above the background.[18] qRT-PCR was repeated with three independent replicates.

**Enzyme Activity and Lipid Peroxidation Analyses.** To extract the enzymes, root tissues were ground and homogenized with a mortar and pestle in 1.5 mL of 20 mM phosphate buffer (pH 7.4) in an ice bath. The homogenate was centrifuged at 10 000*g* for 10 min at 4 °C and the supernatant was used for the enzyme, protein, and malondialdehyde assays. The activity of citrate synthase (CS) was measured according to the method of Srere.[19] The activity of superoxide dismutase (SOD) was determined with a SOD kit (SOD kit, Sangon Company, China). Peroxidase (POD) activity was measured according to Andrews et al.[20] Lipid peroxidation level was determined by following the root malondialdehyde (MDA) content according to Zhang and Kirkham.[21] The activity of each enzyme was normalized to protein concentration, which was determined using the bicinchoninic acid (BCA) method (BCA protein kit, Sangon Company, China).

**Intracellular and Extracellular Citrate Analyses by HPLC.** After the DM exposures, the root tissues of rice seedlings were rinsed with distilled water and homogenized with a mortar and pestle in 1.2 mL of ice-cold 0.6 M $HClO_4$. The homogenates were transferred into Eppendorf tubes, which were centrifuged at 14 000*g* at 4 °C for 5 min. Eighty microliters of 5 M $K_2CO_3$ was added to the homogenates to neutralize the $HClO_4$. The intracellular concentration of citrate was measured by HPLC using an ion-exclusion column (Shodex Rspak Kc811, 300 mm × 8 mm) and a spectrophotometry detector at the wavelength of 210 nm. The mobile phase was perchloric acid solution (pH 2.1) with a flow rate of 0.8 mL/min.

The dissolved concentration of citrate in the culture medium was also analyzed according to the following procedure. The culture medium was collected to purify the organic acids exuded in solution by *O. sativa* L. The medium was then passed through a cation-exchange column (16 mm × 20 cm) filled with 5 g of Amberlite IR-120B resin ($H^+$ form) and an anion-exchange column (16 mm × 20 cm) filled with 2 g of Dowex 1 × 8 (100−200 mesh, formate form). The organic acid anions retained on the anion-exchange resin were eluted with 2 M HCl. The eluate was then dried in a 40 °C water bath, redissolved in 1 mL of Milli-Q water, and filtered through a 0.45-μm filter membrane. Determination of dissolved citrate exuded in the culture medium was done by HPLC according to the same method as that used for the measurement of intracellular citrate.

**Measurements of Polysaccharides and Uronic Acid in Root Cell Wall.** Root tissues were disrupted with a mortar and pestle in liquid nitrogen, and put in 75% (v/v) ethanol for 20 min in a cool water bath. The sample was then centrifuged at 12 000*g* for 10 min. After the supernatant was removed, the pellet was washed with acetone, methanol/chloroform (1:1), and methanol, for 20 min each. The remaining pellet, composed of cell wall materials, was freeze-dried for further use. Two mg of cell wall was dissolved in 1 mL of water, and the pectin fraction was extracted with a 1-h heating treatment (100 °C). The samples were again centrifuged at 14 400*g* for 10 min, and the supernatants were collected into the tube. The above two steps were repeated three times. The pellet was further extracted with 1 mL of 24% (w/v) KOH and 0.1% (w/v) $KBH_4$ for 12 h and centrifuged at 12 000*g* for 10 min. The hemicellulose (HCl) fraction was recovered in the supernatant. Pectin extracts (200 μL) were then incubated with 1 mL of 98% (v/v) $H_2SO_4$ containing 0.0125 M $Na_2B_4O_7{\cdot}10H_2O$ at 100 °C for 5 min. After cooling, 20 μL of M-hydro-diphenyl (0.15%, w/v) was added to the solution and let to react with the samples for 20 min. The uronic acid concentration in the pectin fraction was then measured spectrophotometrically by following the absorbance at 520 nm. Extraction of total polysaccharides in the hemicellulose fraction of the cell wall was performed using the phenol sulfuric acid method in which 200 μL of hemicellulose was incubated in 1 mL of 98% $H_2SO_4$ and 10 μL of 80% (v/v) phenol for 15 min, followed by incubation in boiling water for 15 min. The total polysaccharide content in the HCl fraction was finally measured spectrophotometrically using an absorbance wavelength set to 490 nm.

**Statistical Analyses.** Significant differences among the means of different treatments were evaluated by using analyses of variance (ANOVA). The conditions of ANOVAs (the normality and homogeneity of variance) were evaluated with the Kolmogrov−Smirnov test and the Levene test, respectively. If the test conditions were not validated, the data were transformed prior to the ANOVAs. Statistical analyses were performed using the program StatView. Differences among means were considered to be significant when the probability ($p$) was less than 0.05. All means and standard errors were calculated from three independent replicates.

## RESULTS

**Effect of DM on Root Growth.** After a 48-h exposure to 5 and 50 μg/L DM, the mean root growth was only about 31.2%

($p < 0.01$) and 15.6% ($p < 0.01$) of the control value, respectively (Figure 1). DM also affected the shape and color of

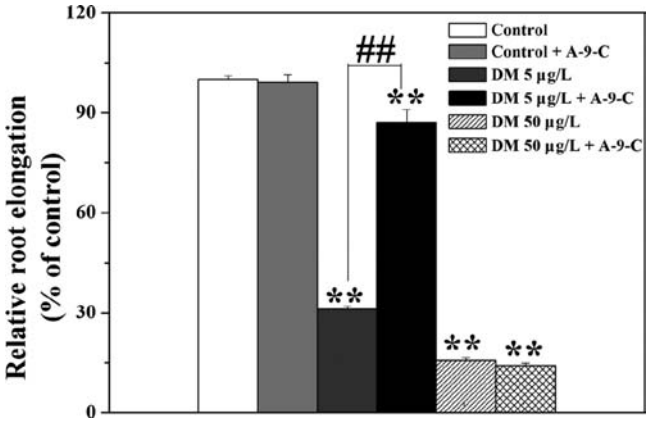

**Figure 1.** Relative root growth inhibition after a 48-h exposure to 5 and 50 $\mu$g/L DM in the presence or absence of the anion channel inhibitor anthracene-9-carboxylic acid (A-9-C). (*), (**) represent statistically significant differences relative to controls at $p < 0.05$ and at $p < 0.01$, respectively. (#), (##) show statistically significant differences due to the presence of A-9-C at $p < 0.05$ and at $p < 0.01$, respectively. Error bars represent the standard errors of three replicates.

cell walls and chloroplasts based on microscopic observations (SI Figure SI.1). Indeed, the root cell wall appeared darker and thicker after DM exposures (SI Figure SI.1). Moreover, at 50 $\mu$g/L DM, the chloroplasts could not be distinguished in the leaf protoplast and the green color of chlorophyll also weakened relative to that of the control (SI Figure SI.1).

**DM Effect on Cell Wall Composition.** Uronic acid and polysaccharides accounted for a relatively high proportion (>50%) of the pectin and hemicellulose fraction of the cell wall, respectively. The mean proportion of uronic acid significantly increased to a level 1.54-fold higher than that of the control after a 48-h exposure to 50 $\mu$g/L DM ($p < 0.01$) (SI Figure SI.2A). The proportion of polysaccharides in the cell wall also significantly increased by around 1.60-fold relative to that of the control after the 48 h exposure to 5 and 50 $\mu$g/L DM ($p < 0.01$) (SI Figure SI.2B). Furthermore, the transcription of five *pectin methylesterase* homologous genes was strongly induced by DM (SI Figure SI.2C). After the 48-h exposure to 50 $\mu$g/L DM, the transcripts of PME7, PME11, PME12, and PME22 significantly increased to levels 2.03-, 2.69-, 4.16-, and 3.10-fold higher than those of the control, respectively ($p < 0.01$ for PME11, PME12, PME22, but $p < 0.05$ for PME7) (SI Figure SI.2C). Gene transcription of PME29 was only significantly induced in response to the 5 $\mu$g/L DM treatment ($p < 0.05$), but did not change significantly at the highest DM concentration tested (50 $\mu$g/L) (SI Figure SI.2C). The microarray results also showed that the transcripts of many genes involved in the biosynthesis of cell wall can be induced in response to DM exposure (SI Table SI.2). The transcripts of phenylalanine ammonia-lyase (PAL) and peroxidases (PODs) were all induced by more than 2-fold in response to DM exposure.

**Effect of DM on Citrate Metabolism and Exudation.** Figure 2A shows that the transcript of ATP-cirate lyase (ACLY) already significantly decreased by 19.4% and 60.8% after 24 h of exposure to 5 and 50 $\mu$g/L DM, respectively ($p < 0.01$). Between 24 and 72 h, the transcript of ACLY continued to

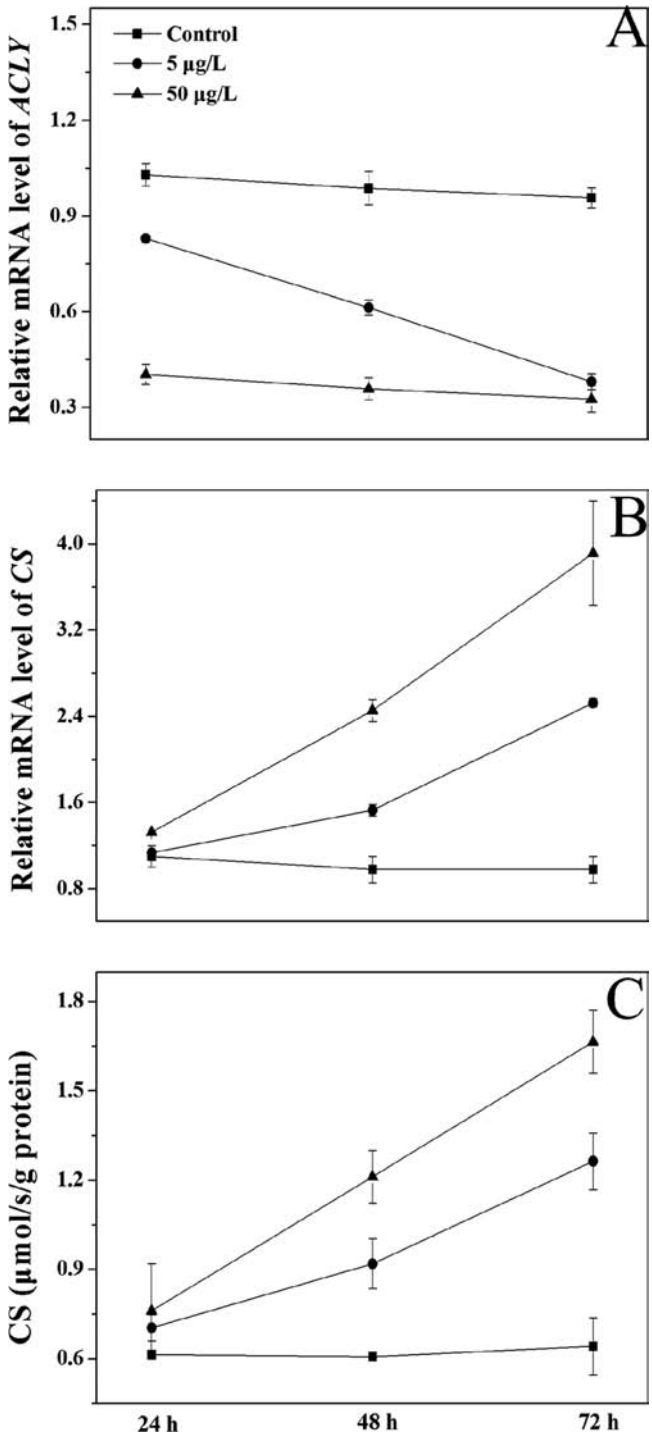

**Figure 2.** Effect of a 5 and 50 $\mu$g/L DM exposure for 24, 48, and 72 h on the transcription level of the citrate lyase (ACLY) gene (A) and the citrate synthase gene (B). Expression levels were normalized to that of the 25S rRNA gene. The effect of DM on CS activity (C). Error bars are the standard errors of three replicates.

decrease in the presence of 5 $\mu$g/L DM; at 72 h, the transcription of ACLY was inhibited by 63.0%. In contrast, at 50 $\mu$g/L DM, ACLY transcripts were inhibited by around 68% throughout the 72 h exposure ($p < 0.01$). The CS transcript level and CS enzyme activity both significantly increased in the presence of the two tested DM concentrations after 48 and 72 h exposure. After 72 h of exposure to 5 and 50 $\mu$g/L DM, CS

dx.doi.org/10.1021/jf503974t | J. Agric. Food Chem. 2014, 62, 10654−10660

enzyme activities reached levels 1.97- and 2.62-fold higher than those of the control, respectively (Figure 2B,C).

The citrate concentration in rice roots was not affected significantly after 24 h of exposure to 5 or 50 $\mu$g/L DM relative to control value, but significantly increased by approximately 15% after 48 h of exposure to 50 $\mu$g/L DM or 72 h of exposure to 5 or 50 $\mu$g/L DM. (Figure 3A). The amount of exuded

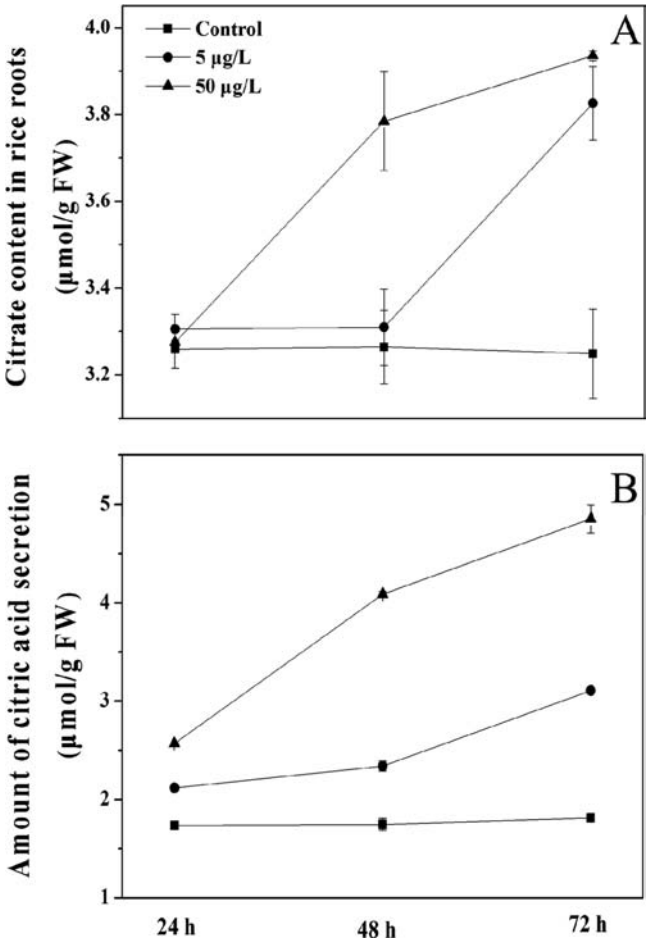

**Figure 3.** Citrate concentration in rice roots (A) and citrate concentration exuded in the medium normalized to root biomass (B) as a function of DM concentrations and time. Error bars are the standard errors of three replicates.

citrate in the culture medium normalized to root biomass showed a 1.79-fold increase after 72 h of exposure to 5 $\mu$g/L DM ($p < 0.01$) relative to that measured in control. The mean exudation of citrate increased by a factor of 1.48, 2.34, and 2.68 relative to control after 24, 48, and 72 h, respectively, of exposure to 50 $\mu$g/L DM (Figure 3B).

**Anion-Channel Inhibitor and Citrate Exudation.** Preliminary experiments demonstrated that 1 mg/L anthracene-9-carboxylic acid (A-9-C) did not affect the root growth of *O. sativa* L. over 48 h. In Figure 1A, we showed that addition of 1 mg/L A-9-C can even significantly decrease the toxicity of DM on root growth after 48 h of exposure to 5 $\mu$g/L DM, although 1 mg/L A-9-C did not affect significantly the toxicity of 50 $\mu$g/L DM. The results in Figure 4A shows that the transcription of *OsFRDL4* significantly increased in the presence of DM relative to control cultures without DM. Exposure of rice seedlings to 5 $\mu$g/L DM and 1 mg/L A-9-C

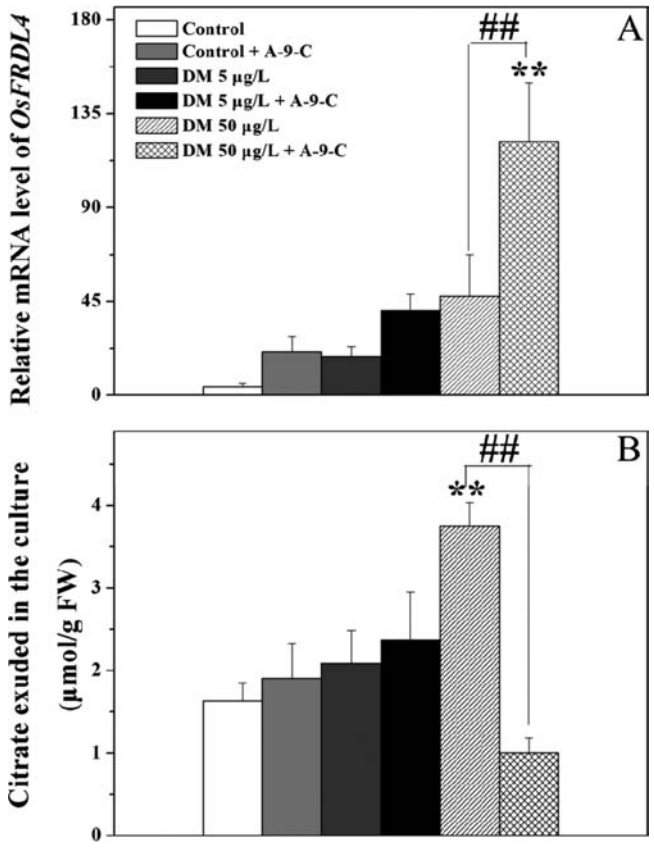

**Figure 4.** (A) Effect of a 5 and 50 $\mu$g/L DM exposure for 24, 48, and 72 h on the transcription level of the anion channel protein gene (OsFRDL4) normalized against 25S rRNA. The experiments in panel A were done in the presence or absence of the anion channel inhibitor Anthracene-9-carboxylic acid (A-9-C). B: Amount of citrate exuded in the culture medium normalized to root biomass. Error bars are the standard errors of three replicates. (*), (**) represent statistically significant differences relative to controls at $p < 0.05$ and at $p < 0.01$, respectively. (#), (##) show statistically significant differences due to the presence of A-9-C at $p < 0.05$ and at $p < 0.01$, respectively.

significantly increased the transcription of *OsFRDL4* relative to that measured after the exposure to 5 $\mu$g/L without A-9-C. In the presence of 50 $\mu$g/L DM and 1 mg/L A-9-C, the transcription of *OsFRDL4* was markedly induced by almost one order of magnitude with respect to its transcription at 50 $\mu$g/L DM without A-9-C (Figure 4A). A-9-C alone or combined with 5 $\mu$g/L DM did not affect significantly citrate exudation relative to control cultures, but addition of 1 mg/L A-9-C and 50 $\mu$g/L DM decreased citrate excretion by approximately 4-fold relative to that measured at 50 $\mu$g/L DM without A-9-C ($p < 0.01$)(Figure 4B).

**Antioxidant Enzymes and Oxidative Stress in Roots.** A 48-h exposure to 5 and 50 $\mu$g/L DM induced a significant increase in SOD activities relative to control values ($p < 0.05$ at 5 $\mu$g/L DM; $p < 0.01$ at 50 $\mu$g/L DM). In contrast, when 1 mg/L A-9-C was added in combination with DM, the SOD activity remained unaffected by the presence of DM (SI Figure SI.3A). The activity of total peroxidase (POD) also significantly increased in response to 5 or 50 $\mu$g/L DM ($p < 0.01$) and this stimulation of POD activity was less pronounced when A-9-C was added in combination with DM (SI Figure SI.3B). The malondialdehyde content in root tissues nearly doubled at 50 $\mu$g/L DM relative to control value, and the addition of A-9-C in

dx.doi.org/10.1021/jf503974t | J. Agric. Food Chem. 2014, 62, 10654−10660

combination with DM tended to decrease this effect, although this decrease was not statistically significant (SI Figure SI.3C).

## DISCUSSION

**DM Toxicity on Root Growth.** Residual low concentrations of the widely used herbicide diclofop-methyl have been shown to inhibit the growth of nontarget monocots and aquatic algae.[8,9,22] Qian et al.[9] have previously shown that exposures to 50 $\mu$g/L DM for 2 weeks significantly inhibited by around 50% the root growth of rice seedlings. Our results here show that DM toxicity on root growth of rice seedlings for a 48-h exposure period may be more important that that measured after a much longer exposure time of 2 weeks, indicating that DM toxicity may be particularly important in the first hours or days of exposure to DM (Figure 1A). This is consistent with a relatively rapid uptake of the hydrophobic DM species followed by a relatively rapid hydrolysis of DM in mostly deprotonated diclofop acid ($D^-$) (at pH of our culture medium).[4] Indeed, hydrophobic molecules such as DM (and perhaps DH) are typically taken up by living cells at a much higher rate compared to that of charged species (such as $D^-$).[12,23]

**Interaction between DM and Cell Wall Biosynthesis.** To exert its toxicity in plant cells, DM first needs to pass through the cell wall. Several studies have shown that both biotic stresses (e.g., bacteria, fungi, and virus) and abiotic stresses (metals, pesticide, UV−B, and temperature) may alter the composition of cell wall by inducing a thickening of cuticles or trichomes.[24,25] The present study confirms that the herbicide DM may strongly affect the cell wall of *O. sativa*. Our results show that a 48-h exposure to trace DM concentrations may increase the proportion of uronic acid and polysaccharides in cell wall fractions (SI Figure SI.2A, B) and induce the transcription of various genes involved in the biosynthesis of cell wall (*pectin methylesterase, pectinesterase, cellulose synthase, phenylalanine ammonia-lyase* genes) (SI Figure SI.2C; Table SI.1 and SI.2). Different hypotheses may explain this energy investment in cell wall biosynthesis: (1) The increased biosynthesis of cell wall components might be a toxic effect of DM with no cellular function per se. (2) If not accompanied by a net increase in the absolute amount of cell wall components, the DM-induced up-regulation of cell wall biosynthesis rate could be triggered to repair the cell wall damages caused by DM. (3) If accompanied by a net increase in the absolute amount of cell wall components, DM might trigger a cellular defense mechanism associated with the thickening of the cell wall, which could reduce DM or DH diffusive rate across the cell wall (depending on the cell wall porosity), as well as DM or DH uptake rate and its toxicity. Additionally, if the unprotonated diclofop acid species ($D^-$) could be internalized in cells of rice roots via a specific cell membrane transporter, then the increase in the activity of pectin methylesterase, which converts the methoxyl groups on the polygalacturonic acid chain of the cell wall into negatively charged carboxyl groups,[26] would decrease (to more negative values) the cell surface charge of plant cells, which could decrease the effective concentration of $D^-$ close to the cell surface and help decrease $D^-$ uptake rate. Further experiments are, however, needed to confirm or refute the above hypotheses stipulating that DM-induced cell wall thickening might decrease DM, DH, or $D^-$ uptake in rice roots.

**DM Toxicity on Fatty Acid Precursors.** The high toxicity of DM in monocots was previously shown to be due to the ability of DM to inhibit the activity of the enzyme acetyl-CoA carboxylase, which catalyzes the conversion of two acetyl-CoA molecules in one molecule of malonyl-CoA, the primary precursor for fatty acid biosynthesis in the chloroplast.[27] Another key enzyme upstream of the acetyl-CoA carboxylase that might also be affected by DM is the ATP-dependent citrate lyase (ACLY), which catalyzes the conversion of citrate and CoA in acetyl-CoA and oxaloacetate in the chloroplast.[28] This citrate comes from the mitochondrion matrix, where another important enzyme, citrate synthase (CS) produced citrate and initiates the tricarboxylic acid cycle. The present study shows that the activity and gene transcription of the enzyme CS increased in response to DM exposure, while DM decreased the gene transcription of the enzyme ACLY (Figure 2). This regulation pattern of CS and ACLY gene expression and enzyme activity will lead to an increase in citrate concentration in root cells as observed in Figure 3A.

**DM-Induced Citrate Exudation from Root Cells.** Our results show that the herbicide DM may increase citrate exudation from root cells since dissolved citrate concentrations increased over time in plant cultures exposed to DM (Figure 3B) as observed in the study of Ding et al.[10] who performed longer (2−3 weeks) DM exposure of rice seedlings.

Our data also show that the transcription level of *OsFRDL4* increased under DM exposure (Figure 4A) and that addition of the anion channel inhibitor A-9-C (at nontoxic concentration, Figure 1A) further increased the transcription of *OsFRDL4* (Figure 4A). Moreover, the amount of citrate exuded in the culture medium contaminated with 50 $\mu$g/L DM (but not with 5 $\mu$g/L DM) strongly decreased in response to the addition of the anion channel inhibitor A-9-C (Figure 4B). Together, the results strongly suggest that DM may up-regulate the synthesis of anion channel proteins in the plasma membrane of rice roots and may mediate the transport of excess intracellular citrate out of the cells (as shown in Figure 3B). However, this up-regulation of citrate channels and its associated increase in citrate exudation (only at 50 $\mu$g/L DM) caused by DM exposure did not decrease DM toxicity. Our results agree with those of previous reports showing that citrate exudation from plant roots probably involved a specific transport system in the plasma membrane.[14,29,30] The latter reports dealt with the effect of metals or phosphorus limitation, but, to our knowledge, the present study is the first showing that citrate exudation in the presence of an herbicide, DM, is mediated by an anion channel protein. Contrary to the protective effect of citrate exudation on Al toxicity,[14] our study shows that DM-induced citrate exudation did not protect rice roots against DM toxicity.

**DM Toxicity and Oxidative Stress.** Besides the toxicity of DM at the level of fatty acid biosynthesis, other studies of Shimabukuro et al.[31,32] have proposed that DM toxicity might be due to the DM-induced production of free radicals in plant cells. In the present study, we show that DM increased oxidative stress at the level of cell membranes (MDA production SI Figure SI.3C) in the roots of rice seedlings, and that the activity of two antioxidant enzymes may increase in response to this stress (SOD and POD) (SI Figure SI.3A,B). Furthermore, the addition of 1 mg/L A-9-C in cultures contaminated with 5 $\mu$g/L DM significantly decreased the level of oxidative stress in cell membrane (SI Figure SI.3C) as well as DM toxicity on root growth (Figure 1A). Then, our results are also consistent with a putative DM toxicity cellular mechanism based on the production of free radicals.

**Conclusions.** This study brings new insights into the key biochemical mechanisms leading to DM toxicity in rice. Here

we show that DM may increase the activity of CS and decrease the activity of ACLY, which increase the intracellular pool of citrate in rice roots. This cellular excess in citrate may be exuded by specific anion channels located in the cell membrane of root cells, but this DM-induced citrate exudation did not protect against DM toxicity on the root growth of rice seedlings. The exudation of citrate induced under DM stress is noteworthy since an increase in organic acid release in soils contaminated by residual herbicide concentrations may affect the chemistry of soil pore water (e.g., pH, organic carbon respiration) and the microbial community structure in the rhizosphere, which could in turn affect plant nutrition.

fatty acids (FFAs), peroxide value (PV), two UV absorption parameters ($K_{232}$ and $K_{268}$), 1,2-diacylglycerol content (DAGs), and pyropheophytins (PPPs)), some or all of which are considered by various national and international standards as quality or grade indicators of olive oil,[21−23] have been linked to results provided by trained sensory panelists to, in the end, be able to provide a quality assessment of blind olive oil samples.

## MATERIALS AND METHODS

**Olive Oil Samples.** Two hundred and twenty samples of extra virgin olive oil were collected before their best-before date during 2010−2012, when this information was included on labels; some samples did not have labels indicating such information. Samples were stored in an air-conditioned laboratory (20−25 °C) away from light. Nitrogen gas was used to displace air in the space above the oil.

Sampled olive oils are a blend of different olive varieties and came from various olive oil producing countries, such as Spain, Italy, Greece, Tunisia, and the United States.

**Chemical and Sensory Analyses of the Olive Oil Samples.** Six different chemical parameters were obtained from the 220 olive oil samples studied. They are FFA, PV, two UV absorption parameters ($K_{232}$ and $K_{268}$), DAGs, and PPP. These were selected as they have been linked in the past to olive oil quality evaluation by multiple national and international sources. Specifically, FFA, PV, and both UV absorption parameters are associated with olive oil grades by numerous relevant organizations like the International Olive Council (IOC)[22] and United States Department of Agriculture (USDA),[23] while DAGs and PPP are related to olive oil quality, for instance, by Australian Standards[21] or Guillaume et al. (2014).[24]

In addition, sensory analyses were carried out by a trained taste panel (IOC-certified Australian Oils Research Laboratory (AORL))[25] to attain a reliable olive oil grading of the samples. The reasons for the parameter selection, protocols followed, and equipment employed are described in the following subsections.

*Free Fatty Acids.* The FFA is linked to olive oil quality as it manifests the carefulness taken during the production process as well as the intrinsic quality of the employed fruit.[23] FFAs are formed when triacylglycerols in olive oils suffer hydrolysis during extraction, processing, distribution, and storage. For this reason, high levels of FFA can be linked to poor-quality olive oils.

FFA values were determined by the method of the American Oil Chemists Society (AOCS), Ca 5a-40, and expressed as a percentage of oleic acid.[26]

*Peroxide Values.* The PV of an olive oil is a crude measurement of its primary oxidation due to oxygen exposure. This oxidation leads to secondary oxidation products which give undesirable flavors and odors. In general, high PVs imply an oxidized oil and, therefore, a lower quality product.[23]

PVs were determined according to International Standard ISO 3960:2007 and expressed as meq $O_2$/kg.[27]

*Ultraviolet Absorption Measurements.* The information gathered from these tests offers evidence concerning quality, state of preservation, and modifications originated by the processing method.[23] Conjugated double bonds are formed from natural nonconjugated molecules in olive oil due to oxidation. This means that an elevated UV absorbance (high $K_{232}$ and $K_{268}$) is related to oxidized and low-grade oils.

Ultraviolet absorbance was determined using IOC method COI/T.20/Doc. 19.[28]

*1,2-Diacylglycerol Content.* DAGs have shown to be reliable markers of olive oil freshness and quality in the past and are employed by Australian Standards as a quality assessing parameter.[21] They are excellent indicators of initial poor-quality or low-grade olive oils, and high temperatures affect their values. High-quality and fresh olive oils contain a high level of 1,2-diacylglycerols.[24,29]

1,2-Diacylglycerols were determined using the method ISO 29822:2009.[30,31] A miniaturized chromatography column of silica gel 60 at 5% moisture was used to separate the isomeric diacylglycerols. The diacylglycerol profiles were determined by gas chromatography using a SGE BP5 capillary column (30 m, 0.25 mm, 0.25 μm film) and a flame ionization detector (FID).

*Pyropheophytin Quantification.* Determination of PPPs can also be used as an indicator of general quality and freshness of olive oil samples.[24] Comparable to DAGs, PPPs are utilized by Australian Standards for quality evaluation processes,[21] but in contrast, these are not influenced by the initial quality of the olive oil. In fact, cultivar or growing conditions do not affect PPPs either. High temperatures and light exposure are responsible for PPP amount alteration.[24] Their values increase upon thermal degradation of olive oil, thus being related to lower quality products.

Pyropheophytin A was measured using method ISO 29841:2009.[32,33] A miniaturized chromatography column of silica gel 60 at 5% moisture was used to separate the pheophytins. Separated sample was dissolved in 200 μL of acetone and analyzed by HPLC with a mobile phase of water:methanol:acetone/4:36:60 using a Phenomonex Luna 5 μ silica column (250 × 4.60 mm). Separated components were measured at 410 nm using a photodiode array detector, and data was analyzed with Waters Empower Pro version 5.00.

*Sensory Analyses.* The sensory profiles of the oils collected in the study were evaluated following official IOC procedures by the Taste Panel of the Australian Oils Research Laboratory (AORL).[25]

The sensory attributes which were rated under official IOC procedures were defects (fusty/muddy sediment, musty/humid/earthy, winey/vinegary/acid/sour, rancid, and other) and desirable attributes (fruity (green and ripe), pungent, and bitter). Olive oils were graded to either "EVOO" or other grades by the sensory taste panel.

**Artificial Neural Networks.** The mathematical model designed to classify olive oil samples according to their quality is based on nonlinear ANNs. These intelligent algorithms have been used to link chemical information from 220 olive oil samples, which came from different geographical origins and olive types with the sensory results provided by trained panelists to achieve a potential tool for accurate quality control. Of the 220 olive oil samples, the panelists considered 94 of them to be EVOOs.

The specific type of ANN that has been selected to fulfill the objective is a supervised multilayer perceptron (MLP), which relies on target data to be adequately optimized.[34] These particular ANNs have offered successful results in terms of accurate estimations and classifications in multiple fields such as chemistry or food technology.[11,19,35,36] It is important to note that these tools are designed to carry out accurate interpolations; in other words, they originate large errors when tests are done with data points outside the operational window of the ANN.[19] For this reason, the final optimized model will perform adequately with samples that possess the nature of some of those included into the training data set. This confers a great additional value to the vast analytical work carried out during sampling and to the wide variety of olive oil types found in the database assembled in terms of olive variety, geographic origin, and quality grade.

MLPs possess a layer topology. The first one is the input layer, which is formed by nodes that are used to introduce all the desired independent variables into the nonlinear model.[37] In this case, the inputs correspond to six chemical parameters (FFAs, PV, $K_{232}$, $K_{268}$, DAGs, and PPPs) from the olive oil samples. The second layer of the MLP contains neurons, which are the calculation centers of the ANN, and it is known as the hidden layer. The hidden neuron number (HNN) should be optimized appropriately to get the most out of the MLP (vide infra).[38] Finally, the third and last layer is the output layer, which is also formed by neurons. These define the dependent variables of the mathematical tool, which in the end allow evaluation of the statistical performance of the ANN.[35] In the designed model, the single output resembles the quality of the olive oil samples.

Every node from the input layer is connected to all the neurons from the hidden layer, while these last ones are also connected to each neuron from the output layer. Each individual connection is controlled by a specific weighted coefficient or weight, which initially is a random value but is optimized during the training phase of the MLP. This optimization is crucial because the final performance of the model (in

this case, correct olive oil classification percentage) will strictly depend on it.[39] Additionally, so it can take place, a suitable training function should be selected according to the database variables and size (vide infra).

Prior to training the model, and so its optimization can be successfully carried out, the initial database (220 data points) was randomly divided into two. This led to the appearance of training and verification data sets, which approximately possessed 85% and 15% of the data points, respectively. The training data set is comprised of the data that the MLP employs to modify the values of the weights in order to attain lower estimation or, in this case, classification errors. On the other hand, the role of the verification data set is to ensure that the system is not only able to correctly classify data points from the training data set but also capable of correctly classifying data outside it, which allows assessing the generalization and applicability range of the designed, and now optimized, ANN. This second data set is vital in order to avoid obtaining overfit models that are not accurate for samples outside the data used to train it because the mentioned second data set is never involved in the weight modification process.[19]

There are additional parameters, different from the weights, which should be optimized to get the best possible results. For instance, the HNN has been optimized following a heuristic approach,[35] testing possibilities from 10 to 25 neurons due to the size of the database. The HNN selected is the one that provides the most accurate model. This step is very important because ANNs with a low HNN will offer a poor learning capability, while an excessive one may lead toward overfit systems.[38] Moreover, other parameters that should be optimized are the Marquardt adjustment parameter (Lc), the decrease factor for Lc (Lcd), and the increase factor for Lc (Lci).[40] The Lc parameter acts like the learning coefficient in usual back-propagation algorithms. Its value is modified by Lcd and Lci up until the Lc changes originate a less accurate MLP.[38] These three parameters have been optimized following a "Box-Wilson Central Composite Design $2^3$ + star points" experimental design,[38] and, once again, the combination selected has been the one that provided the best statistical performance. The range analyzed for Lc and Lcd was between 0.001 and 1, while for Lci it was between 2 and 100.[35]

All of the ANN-related calculations have been completed using Matlab version 7.0.1.24704 (R14),[40] while experimental design has been carried out with Statgraphics Centurion 16.1.18.

## RESULTS AND DISCUSSION

**Selection and Optimization of Multilayer Perceptron Parameters.** Design of an ANN requires a series of steps that must be followed to attain the most accurate nonlinear model possible. First of all, the architecture or topology of the MLP must be defined by selecting the independent and dependent variables as well as optimizing the HNN. Furthermore, a well-suited training function must be chosen depending on the database, and a set of ANN parameters (Lc, Lcd, and Lci) should be optimized.

*Topology of the Model.* The independent variables, or MLP inputs, selected have been the six chemical parameters obtained from different measurements of all the olive oil samples. They are FFA, PV, $K_{232}$, $K_{268}$, DAG, and PPP. On the other hand, the single dependent variable, or output, of the ANN is the quality evaluation of the olive oil provided by trained panelists. The output was transformed into a qualitative response based on the results from the panel. Ones (1s) were assigned to the samples that were identified as EVOOs by the panelists, while zeroes (0s) were given to all other lower quality samples (VOO and OVOO) found in the database.

After testing all HNN possibilities between 10 and 25, it was observed that the accuracy of the model was stable throughout the whole range. For example, when physicochemical property estimation is the goal of the MLP, every different HNN provides different prediction errors.[35,38] However, when single-output classifications are attempted, as is the case, and estimations are converted into 1s or 0s, the different HNNs provide very similar results. In fact, all HNN tests offered the same exact accuracy in terms of percentage classification of olive oil samples according to their quality. HNN 10 was finally chosen in order to lower the required calculations and obtain a more manageable model. It is worth mentioning that the optimal threshold found was 0.64, and therefore, estimations >0.64 were turned into 1s and ≤0.64 into 0s.

In Figure 1, a schematic representation of the architecture of the designed and optimized MLP can be seen.

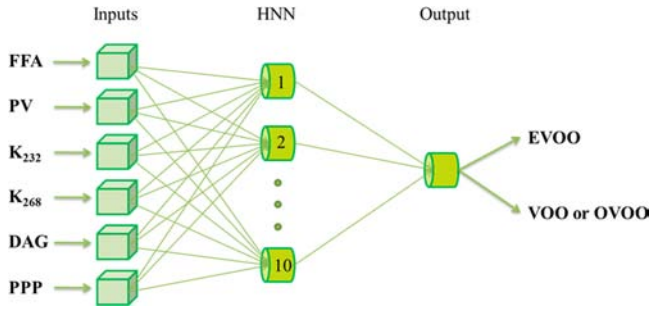

**Figure 1.** Schematic representation of the topology of the designed MLP. It is formed by six input nodes that correspond with chemical parameters measured from different olive oil samples, 10 hidden neurons, and a single output neuron, which classifies samples according to their quality.

*Training Function Selection.* Correct selection of a training function that is well suited for accomplishing the desired task is essential. Due to the database size and attempted goal, training function trainBR (Bayesian regularization function) has been designated. It is a modified version of the Levenberg–Marquardt training algorithm and employed to create MLPs that are able to generalize well, thus avoiding overfit systems. It reduces the difficulty of determining the optimum network topology and regularly updates the values of the weights turning trainBR into a compelling and an adaptable option.[41]

*Neural Network Parameter Optimization.* An experimental design based on a "Box-Wilson Central Composite Design $2^3$ + star points" was carried out in order to define the combination of Lc, Lcd, and Lci that offers the model with the highest accuracy (greatest correct classification rate). Nonetheless, similar to the HNN, the correct classification percentage did not practically vary with different values of these parameters due to the defined objective. Therefore, the following optimized values were selected: Lc = 0.005, Lcd = 0.1, and Lci = 10.

**Statistical Performance of the Model.** In order to evaluate the statistical performance of the designed and optimized MLP and to confirm that it is applicable for the entire database, a *K*-fold cross-validation ($K = 6$) was implemented so every data point is used to test the model (except for data points with the highest or the lowest values of any independent variable to limit the MLP to interpolations (vide supra); for this reason, only 203 out of 220 data points have been used to test the model).[35] The main and only difference between all six tests carried out is that the verification data set is completely different for each one of the ANNs (randomly divided into six). The role of these verification data sets is to permit the design of widely applicable models that can generalize well. They have been used to test each individual

system as well, due to the fact that they are not involved in the weight optimization process (vide supra), thus avoiding potential overfitting issues.[42] The results for all 6 tests can be found in Table 1.

**Table 1. Statistical Performance of the MLP Represented by the Results of the *K*-Fold Cross-Validation**

| | classification accuracy | |
|---|---|---|
| tests ($K$ = 6) | correctly classified | percentage of corrects (%) |
| 1 | 32/33 | 97.0 |
| 2 | 30/34 | 88.2 |
| 3 | 33/34 | 97.0 |
| 4 | 34/34 | 100 |
| 5 | 34/34 | 100 |
| 6 | 32/34 | 94.1 |
| total/average | 195/203 | 96.0 |

As shown, the MLP offers accurate results for every different data set employed to test the tool, proving its wide applicability range and generalization capability. It shows a correct classification rate of about 96% on average, verifying that the chemical information provided has a clear relationship with the results from the trained panelists.

Nevertheless, to further validate this statement, three blind tests were carried out. In this case, the database has been randomly divided into three data sets: training, verification, and simulation (or internal validation) data sets containing 80%, 10%, and 10% of the data points, respectively.[43] The MLP was optimized following the same procedure previously explained using the training and verification data sets. The only difference is that now the model was tested with the simulation data set, which has never been seen by the ANN for any purpose, instead of with the verification one. The results of these three internal validations are shown in Table 2.

**Table 2. Statistical Performance of the MLP for Three Independent Blind Tests**

| | classification accuracy | |
|---|---|---|
| blind tests | correctly classified | percentage of corrects (%) |
| 1 | 20/22 | 90.9 |
| 2 | 21/22 | 95.4 |
| 3 | 22/22 | 100 |
| total/average | 63/66 | 95.4 |

These results imply that the tool designed could be employed as an accurate quality control for diverse olive oil samples outside of the database employed in the present study. The tool could be set as a yes/no (EVOO/not EVOO) test for olive oil samples prior to being evaluated by trained panelists. This could allow lowering the amount of necessary tastings when the panelists are looking for only specific types of olive oil, classified by their quality, for sensory analysis.

The successful performance and accuracy of the MLP model corroborates that there is at least an indirect relation between the selected independent variables (six chemical parameters) and the results from the sensory analyses that can be adequately interpreted through nonlinear modeling. The manifestation of negatively affecting factors such as excessive amounts of fatty acids, peroxides, or PPPs, elevated absorption indices, and low quantities of 1,2-DAGs[21,23,24,29] can be related to low-quality grade olive oils which present one or more of the main sensory defects (vinegary, humid, fusty, and/or rancid). In other words, the appearance and emission of volatile organic compounds that characterize determined olive oil defects is nonlinearly correlated with the variables selected to train the MLP model presented.

It must be noted that ANNs are dynamic tools that can improve their performance and robustness with new data. In other words, tests carried out with new data points from more olive oil samples can be incorporated into the model leading to an enhanced version of the nonlinear model, with a greater applicability span. Ideally, in the end there will be enough data from such a wide variety of olive oils and panel results that the tool will be able to convert a subjective interpretation into an objective classification.

In summary, in the present article, a nonlinear model based on artificial neural networks has been designed and optimized to discriminate between extra virgin olive oil samples and other lower quality ones. The mathematical tool employs six chemical parameters (percentage of free acidity, peroxide value, two UV absorption parameters ($K_{232}$ and $K_{268}$), 1,2-diacylglycerol content, and pyropheophytins) as independent variables to accurately classify the olive oil samples. Two tests were carried out to determine the statistical performance of the model: (a) a *K*-fold cross-validation ($K$ = 6) that showed 96.0% of correct classifications and (b) three blind tests which provided 95.4% on average. These successful results prove the existence of a relationship between the six parameters utilized and the quality of the olive oil, leading to potential design of an objective evaluating method of the quality of diverse olive oil samples.

showed an average BaP content level of 1.62 μg/kg of chocolate sweet.[13] Representative analyses on the occurrence of PAH4 in cocoa, derived products, and chocolate products on the German market were not available at the start of this study.

The pertinent literature contains a plethora of analysis methods for detecting the various relevant PAH individual substances. These methods are based on gas chromatography measurement procedures[21−26] and detection procedures using UV, fluorescence,[14−19] and MS.[20] GC-MS is the method most frequently used to detect PAH.[27] HPLC coupled with mass spectrometry (LC-MS) is only seldom used due to the nonionic and unpolar property of PAH.[20,28]

Currently, the European cocoa and chocolate industry is aware of the recent discussion at the European level about the possibility of a review into how to express PAH levels detected in cocoa beans and derived products. The ongoing discussion was triggered by the results of a recent proficiency test carried out by the European Reference Laboratory (EU-RL).[29] This showed that the results obtained in laboratories are less favorable if the analyses are conducted on a fat basis rather than on a product basis. It seems that converting the analytical results obtained on a product basis into results on a fat basis leads to variations in the final results obtained. For this reason it is considered that the best approach to addressing this issue is to use a standardized "fat extraction method" for cocoa beans and derived products. The current study consistently sidestepped this issue by using only cocoa butter obtained from products by way of cold extraction for PAH analysis. This did away with the need to use an additional fat determination method.

The objective of this research work was to develop a suitable internal standard (ISTD) method of routine analysis for quantitating the relevant PAH in cocoa and cocoa products and to give a situation assessment of the occurrence of these substances in the tested products. Due to the entry into force on April 1, 2013, of Regulation (EU) No. 835/2011, amending the EU Contaminants Regulation with regard to "cocoa beans and derived products" and stipulating a maximum level of 5.0 μg/kg fat for BaP and 35 μg/kg fat for PAH4 (30 μg/kg fat for PAH4 as of 01.04.2015), the focus of analytical methods was especially placed on BaP and PAH4 levels in cocoa, derived products, and chocolate products. In addition, a combined pool of 218 samples was analyzed, composed of samples of cocoa butter, cocoa masses, and raw cocoa plus monitoring samples of finished cocoa and chocolate products from the German market. Specific examination of cocoa butter samples from various growing and harvest years was also aimed at tracing the development and pattern of PAH4 content levels from 1999 to 2012.

## MATERIALS AND METHODS

**Samples.** In the period from 2010 to 2012, a total of 218 samples were analyzed for PAH4: of these, 12 were raw cocoa beans, 22 were cocoa masses, 67 were cocoa butter samples, and 117 were cocoa and chocolate products. The cocoa beans and semifinished cocoa products (cocoa masses and butter) came from the main growing regions in Africa, Asia, and America, in the harvest period from 1999 to 2012. The cocoa products and chocolate products were purchased quarterly in retail shops in the period from 2009 to 2012.

Definitions of the cocoa and chocolate products we analyzed in our research work are as follows: **Cocoa beans** (including raw cocoa) are the unshelled, fermented, and dried seeds of *Theobroma cacao* L. They have a thin shell (**cocoa shell**, botanical description: seed shell consisting of testa and rest of pulp). **Cocoa nibs** (botanical description: seed leaves [cotyledons] without seed shell) are the roasted, unshelled, mostly already broken up cocoa kernels. **Cocoa mass** is made up of finely ground cocoa nibs; **cocoa powder** is the finely ground cocoa press cake, which, in addition to **cocoa butter**, is what remains after pressing out the **cocoa mass**.[30] Cocoa nibs, cocoa masses, cocoa powder, and cocoa butter are collectively referred to as **semifinished cocoa products**. The term **cocoa products and chocolate products** covers products defined under Annex 1 of the German Cocoa Regulation, such as whole milk chocolate, dark chocolate, and chocolate coating.[31] The term cocoa and cocoa products used in this research work is a collective term and implies all products defined in this section.

**Chemicals.** The solvents used were petroleum benzene, *n*-hexane, and ethanol for analysis, as well as dichloromethane and acetonitrile, both of HPLC grade (>99.9%). Other reagents and materials used were potassium hydroxide and Strata EPH (200 μ, 70 Å) 5 g/20 mL (part 8B-SO31_LEG), Giga tube. All of the solvents, reagents, and materials mentioned are commercially available from Phenomenex (Aschaffenburg, Germany), Sigma-Aldrich (Steinheim, Germany), and Merck (Darmstadt, Germany).

The following PAH standards were used for the identification and quantitation of the PAH4 present in the samples: benzo[*a*]anthracene, chrysene, benzo[*b*]fluoranthene, benzo[*a*]pyrene, and benzo[*b*]-chrysene, which was used as an internal standard. All standards were obtained from Dr. Ehrenstorfer (Augsburg, Germany) and LCG (Wesel, Germany).

**Methodology.** To extract the cocoa butter, the samples are first defatted; depending on the respective matrix, this means weighing 10−15 g (raw cocoa, cocoa nibs, cocoa mass, and chocolate) or 50 g (cocoa powder) into a 250 mL centrifuge tube. Seventy milliliters of petroleum benzene and a magnetic stir bar are added to the samples. This mixture is then stirred for 1 h and centrifuged. The supernatant is transferred via pipet into a 500 mL round flask. This process is repeated three times, and the combined petroleum benzene residues are removed via rotary evaporator. The isolated fat, which is dried overnight in a desiccator cabinet (at 50 °C), can subsequently be used for further PAH analysis. Cocoa butter samples are melted at approximately 50 °C and can be immediately used for PAH analysis without additional preparation.

For saponification, 2 g of cocoa butter was weighed, spiked with 5 ng of benzo[*b*]chrysene as internal standard, and incubated for 30 min. After the addition of 8 mL of ethanol and 2 mL of potassium hydroxide solution (10%), the solution was heated at 60 °C for 30 min in an ultrasonic bath. After saponification, 5 mL of demineralized water was added and, after cooling, 10 mL of hexane. After centrifugation (20 °C, 2000 rpm), the upper hexane phase was put on a Strata EPH Giga Tube (conditioned with 30 mL of hexane). This extraction procedure was repeated twice with 8 and 7 mL of hexane. PAH were eluted with 20 mL of dichloromethane, and the solvent was removed using a rotary evaporator and further evaporated to just dryness under a nitrogen stream. The residue was redissolved in 2 mL of acetonitrile and finally transferred into an autosampler vial for HPLC-FD-analysis.

For the identification and quantitation of PAH4, extracts were analyzed using HPLC coupled to a fluorescence detector (FD). The HPLC system consists of a gradient pump, a column oven, an autosampler, and a fluorescence detector (Dionex Ultimate 3000, Idstein, Germany). A Multosphere PAH-III column (250 × 4.6 mm i.d., CS-Chromatographie Service, Langerwehe, Germany) was used along with a precolumn filled with the same material (20 × 4 mm). Separation was performed using the following gradient: acetonitrile/water (85:15, v/v) for 13.5 min, followed by a 2 min ramp to 100% acetonitrile, this solvent being further maintained for 15 min. The total flow rate was 1 mL/min. The analytical column was placed in an oven, and the following temperature program was performed: 25 °C for 4 min, followed by direct heating to 45 °C. Detection was performed at selected excitation and emission wavelengths, programmed as follows: 0−8.3 min, 290/470 nm; 8.3−11 min, 270/390 nm; 11−11.5 min, 290/470 nm.

**Table 1. Validation Parameters Obtained for the Four Individual PAH**

| parameter | BaA | Chr | BbF | BaP |
|---|---|---|---|---|
| calibration range (μg/kg) | 0.02−15.57 ($r^2$ > 0.999) | 0.02−9.45 ($r^2$ > 0.999) | 0.13−36.32 ($r^2$ > 0.999) | 0.17−67.33 ($r^2$ > 0.999) |

## RESULTS AND DISCUSSION

**Method Validation.** The presented method was validated on the basis of the guidelines provided by Kromidas.[32] For this purpose a cocoa butter sample without detectable PAH4 content was spiked with a PAH4 solution, prepared in keeping

**Table 3. PAH4 Content Levels in Cocoa Butter Samples from Various Sample Years[a]**

with the method developed in this study, and analyzed. A series of validation data, such as calibration range, recovery rate, inter- and intraday precision, limit of detection (LOD), and limit of quantitation (LOQ), are compiled in Table 1. As a result, it is noted that the described method for analyzing the PAH4 shows linearity over a wide measuring range, has a good reproducibility, and is extremely sensitive (possessing an LOD of between 0.01 and 0.07 μg/kg). Regulation (EU) No. 836/2011 lays down the analytical performance criteria for the determination of PAH4 in food as recovery rates of 50−120%, LOD ≤ 0.30 μg/kg, LOQ ≤ 0.90 μg/kg, and $HORRAT_r$ < 2 for each of the four substances.[8] The method developed by the LCI optimally fulfills these requirements.

**PAH4 in Raw Cocoa and Semifinished Cocoa Products.** Using the successfully developed and validated analytical methods for determining PAH4, a selection of 101 samples of raw cocoa and semifinished cocoa products was examined. An overall view of the corresponding test results for PAH4 and the individual PAH benzo[*a*]anthracene (BaA), chrysene (Chr), benzo[*b*]fluoranthene (BbF), and benzo[*a*]-pyrene (BaP) is presented in Table 2. The analysis of PAH examinations of cocoa butter samples (*N* = 67) of various origins and treatments produced an overall mean for all cocoa butter samples of 12.44 μg PAH4/kg fat and 0.96 μg BaP/kg fat (median = 9.94 μg PAH4/kg fat and 0.66 μg BaP/kg fat) within a range of 2.09−92.53 μg PAH4/kg fat and <LOD−7.86 μg BaP/kg fat. This large range in PAH measurements is a result of the variation of the analyzed samples of different years from different origins.

The deodorized samples tended to show lower PAH4 content levels than the nondeodorized samples. The reason for this observation is the calcination of volatile compounds within the thermal treatment of the deodoration process.[10]

The maximum PAH4 content of 92.53 μg/kg fat was determined in a cocoa butter sample of unknown origin and treatment. The cocoa mass samples examined within the scope of this study (*N* = 22) contained a mean of 4.57 μg PAH4/kg fat and 0.32 μg BaP/kg fat (median = 3.80 μg/kg PAH4/kg fat and 0.26 μg BaP/kg fat) within a range of 2.59−9.29 μg PAH4/kg fat and <LOD−0.76 μg BaP/kg fat. The alkalized cocoa mass samples included in the examinations (*N* = 3) showed a low mean of 2.83 μg/PAH4/kg fat (median = 2.61 μg PAH4/kg fat). Our examinations for PAH4 of a comparatively small selection of raw cocoa samples (*N* = 12) produced an overall mean of 8.21 μg PAH4/kg fat and 1.28 μg BaP/kg fat (median =2.91 μg PAH4/kg fat and 0.24 μg BaP/kg fat) within a range of 0.88−44.28 μg PAH4/kg fat and <LOD−9.98 μg BaP/kg fat. One raw cocoa sample produced the maximum level measured in this category, showing a PAH4 content of 44.28 μg/kg fat.

All in all, however, among all of the examined product groups, we found a comparatively low contamination level in the 101 analyzed raw cocoa and semifinished cocoa products. Only two samples showed higher PAH content levels. This concerned one cocoa butter sample from the sample year 1999, showing a PAH4 content of 92.53 μg/kg fat, and a raw cocoa sample from the harvest year 2007 originating from Java, showing a PAH4 content of 44.28 μg/kg fat. All other samples were largely well below the legally stipulated maximum levels.

**Trend in PAH4 Content Levels Since 1999.** The cocoa butter samples analyzed for PAH4 during testing originated from various sample years. In particular, samples of cocoa butter stemming from the sample years 1999 and 2010 as well as 2011/2012 were examined. The results of these tests are compiled in Table 3 and Figure 1.

Given the trend in BaP and PAH4 content levels in the analyzed cocoa butter samples, a distinct decrease in these contaminants was observed throughout the sample years 1999−2012. This drop in contamination was particularly significant from 1999 to 2010, almost halving the PAH4 content levels determined in the samples we analyzed, falling from a mean of 17.12 μg/kg fat in 28 cocoa butter samples stemming from 1999 to a mean of 8.81 μg PAH4/kg fat in 26 cocoa butter samples originating from 2010.

The reason for the observed very significant decrease in PAH contents in cocoa butter samples over the years with respect to this project is of course a result of actions the cocoa producers applied, following the instructions of the "Code of Practice for the Reduction of Contamination of Food with PAH from Smoking and Direct Drying Processes" which was released by

Codex Alimentarius Commission in 2009.[33] This Code of Practice gives farmers in the cocoa-producing countries a very explicit toolset to avoid PAH contamination in cocoa beans within the postharvest process such as drying and fermenting.

**PAH4 in Cocoa and Chocolate Products.** In the final part of our research work, 117 samples taken from the food retail trade over the period 2009−2012 were analyzed for their PAH4 and BaP contents. Our test samples included milk chocolate and milk chocolate coatings, dark chocolate and dark chocolate coatings, cocoa-containing drink powders, and cocoa powder. The corresponding analysis results are compiled in Table 4 and Figure 2. It was observed that none of the analyzed samples exceeded the maximum levels set by Regulation (EU) No. 835/2011 of 5 μg/kg fat for BaP and 35 μg/kg fat for PAH4 (30 μg/kg as of April 1, 2015). Moreover, the data show that the samples of cocoa powder and cocoa-containing drink powders with a BaP mean of 1.07 and 1.00 μg/kg fat, respectively, had slightly higher content levels than the samples of milk chocolate and dark chocolate with BaP means of 0.70 and 0.57 μg/kg fat, respectively. However, contamination of the monitoring samples, showing an overall mean of 6.66 μg PAH4/kg fat and a median of 6.22 μg PAH4/kg fat, can be considered very low, particularly taking into account the maximum limits for cocoa beans and derived products set by Regulation (EU) No. 835/2011.

**Resume.** Within the scope of this research project it was shown that, for the period 1999−2012, raw cocoa and semifinished cocoa products (raw cocoa, cocoa masses, and cocoa butter) from various growing years and origins ($N$ = 218) underwent a steep downward trend in contamination with polycyclic aromatic hydrocarbons (PAH), especially in the years 1999−2010. Therefore, the assumption is suggested that the application of the "Code of Practice for the Reduction of Contamination of Food with PAH from Smoking and Direct Drying Processes" in the cocoa-producing countries since 2009 seems to be very successful.

No samples exceeding the maximum limits set by Regulation (EU) No. 835/2011 for cocoa beans and derived products have been found since the regulation came into effect.

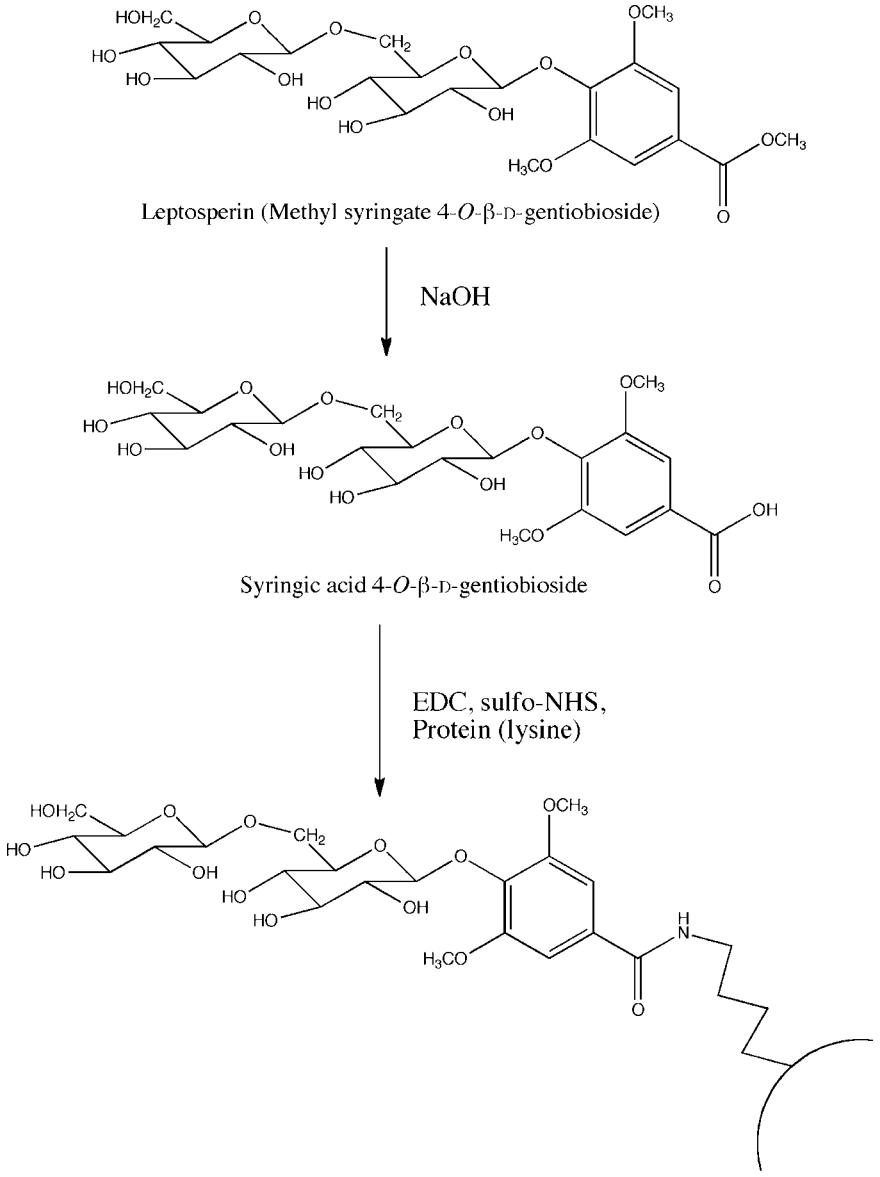

**Figure 1.** Scheme for the preparation of the immunogen to leptosperin. The methyl ester of leptosperin was hydrolyzed with a 1 M NaOH solution, and the successive syringic acid 4-*O*-*β*-D-gentiobioside was used as a hapten and conjugated with carrier protein, keyhole limpet hemocyanin (KLH), using carbodiimide through the carboxyl group of the hapten. Mice were immunized with the conjugated KLH, and monoclonal antibodies were then established.

HPLC or LC−MS/MS is much higher relative to that for an ELISA.

Recent studies have demonstrated the preparation and application of an antibody for the detection of phytochemicals or their derivatives.[6−10] Immunochemical approaches, in particular an ELISA, may allow the handling of multiple samples. The cost of an ELISA is much lower than that of HPLC or LC−MS/MS. For example, to quantify an antigen by an ELISA, only a microplate reader is needed.

In this paper, on the basis of the specific monoclonal antibody against leptosperin, we established an ELISA to quantify leptosperin levels in honey for the first time.

## EXPERIMENTAL PROCEDURES

**Materials and Methods.** Methyl syringate was purchased from Alfa Aesar, Johnson Matthey Co. (Ward Hill, MA). Maltose, sucrose, and glucose were obtained from Nacarai Tesque Inc. (Kyoto, Japan). 2-Methoxybenzoic acid and bovine serum albumin (BSA) were obtained from Sigma-Aldrich Japan (Tokyo, Japan). Syringic acid (4-hydroxy-3,5-dimethoxybenzoic acid), 5-hydroxymethyl-2-furaldehyde (HMF), and gentiobiose were purchased from TCI Co., Ltd. (Tokyo, Japan). 4-Hydroxyphenylacetic acid was purchased from Wako Pure Chemical Industries, Ltd. (Osaka, Japan). Sulfo-*N*-hydroxysuccinimide (sulfo-NHS), 1-ethyl-3-[3-(dimethylamino)propyl]carbodiimide (EDC), and keyhole limpet hemocyanin (KLH) were purchased from Pierce (Thermo Fisher Scientific K. K., Yokohama, Japan). Leptosperin was isolated from manuka honey as described previously.[2] Twenty certified honey samples were obtained from the Unique Manuka Factor Honey Association (UMFHA). Other kinds of honey samples were obtained from retail stores in Japan, China, Brazil, and New Zealand between 2011 and 2014.

**Preparation of the Immunogen.** Leptosperin was treated with a 1 M NaOH aqueous solution for 30 min at room temperature. After neutralization by the addition of Dowex 50W, the solution was centrifuged, and the modified leptosperin (syringic acid 4-*O*-*β*-D-gentiobioside, in the supernatant) was then purified by reversed-phase HPLC using a Combi-RP column (20 mm × 100 mm, Nomura Chemical Co. Ltd., Aichi, Japan) with a 0.1% acetic acid/$CH_3CN$

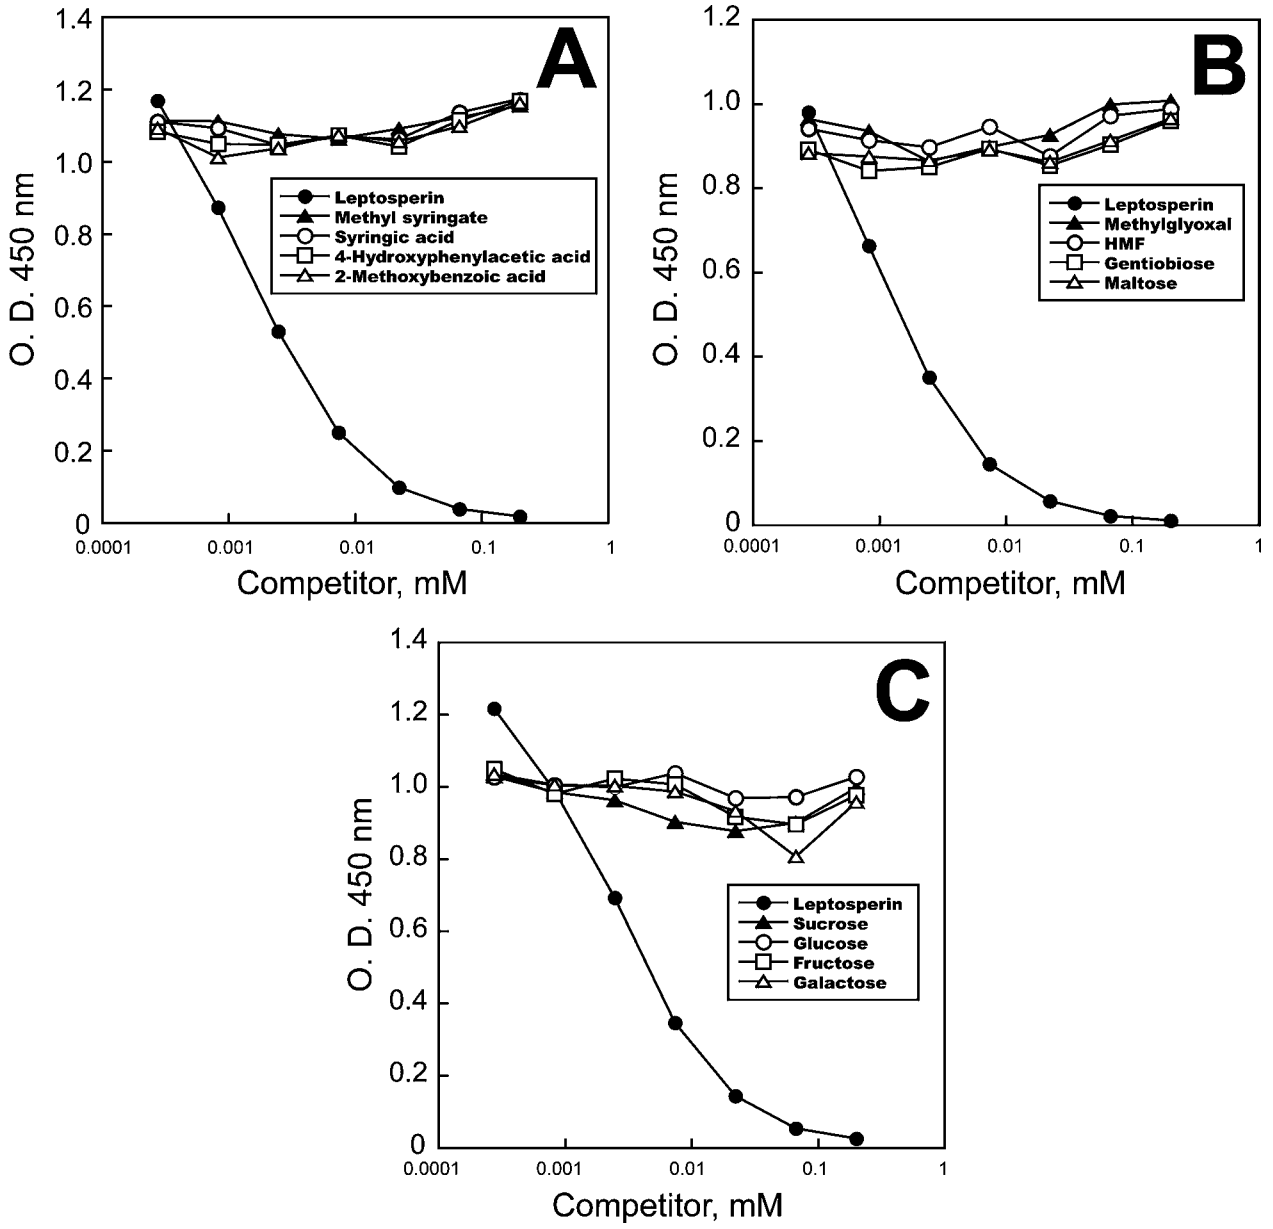

**Figure 2.** Characterization of monoclonal antibody 2H3 to leptosperin. The competitor and the antibody 2H3 were added to a well, which had been precoated with leptosperin-conjugated BSA. The antibody binding to the immobilized leptosperin-BSA was evaluated with a second antibody–peroxidase conjugate treatment. Each point represents the mean of duplicate determinations. (A) Cross-reactivity against phenolics: (●) leptosperin, (▲) methyl syringate, (○) syringic acid, (□) 4-hydroxyphenylacetic acid, and (△) 2-methoxybenzoic acid. (B) Cross-reactivity against aldehydes or disaccharides: (●) leptosperin, (▲) methylglyoxal, (○) HMF (5-hydroxymethyl-2-furaldehyde), (□) gentiobiose, and (△) maltose. (C) Cross-reactivity against saccharides: (●) leptosperin, (▲) sucrose, (○) glucose, (□) fructose, and (△) galactose.

mixture (85/15) at a flow rate of 5 mL/min. The modified leptosperin was then conjugated with KLH for an immunogen or BSA for a positive control antigen using EDC and sulfo-NHS. Briefly, 21 mg of modified leptosperin, 7.7 mg of EDC, and 8.7 mg of sulfo-NHS were dissolved in 700 μL of dimethylformamide, and then the mixture was incubated for 24 h at room temperature. Then, 350 μL of the reaction mixture reacted with KLH [8.5 mg/1.6 mL of 0.1 M phosphate buffer (pH 7.4)] for 4 h and then dialyzed against phosphate-buffered saline (PBS) for 3 days at 4 °C. The obtained leptosperin–KLH conjugate was stored at −80 °C until it was used. For the positive control antigen, BSA [13 mg/1.6 mL of 0.1 M phosphate buffer (pH 7.4)], instead of KLH, was mixed with 350 μL of reaction mixture and then dialyzed against PBS. The conjugation of leptosperin to BSA was confirmed by the loss of free amines by the reaction with 2,4,6-trinitrobenzenesulfonic acid (Thermo Scientific) according to the manufacturer's instructions and also an increase in absorbance at 262 nm, which was derived from absorption by the leptosperin moiety. The leptosperin–BSA antigen was used as the antigen for screening, cloning, and characterization by an ELISA.

**Preparation of the Monoclonal Antibody.** The monoclonal antibodies were prepared as described previously.[11] Three clones, 2H3, 2B5, and 1C10, which are all of the IgG1 class, were finally obtained. By simple characterization using culture media, the three antibodies showed strong reactivity against leptosperin and did not cross-react with gentiobiose, glucose, or methyl syringate. The 2H3 antibody from the clone was the most sensitive to leptosperin compared to the other two antibodies and then selected. The clone was cultivated, and the secreted antibody was purified from the cultured medium by a protein G column (HiTrap, Protein G HP, 1 mL, GE Healthcare) according to the manufacturer's instructions and then used for experiments.

**Characterization of the Antibody by an ELISA.** The leptosperin–BSA conjugate (5 μg/mL, 50 μL in PBS) was coated

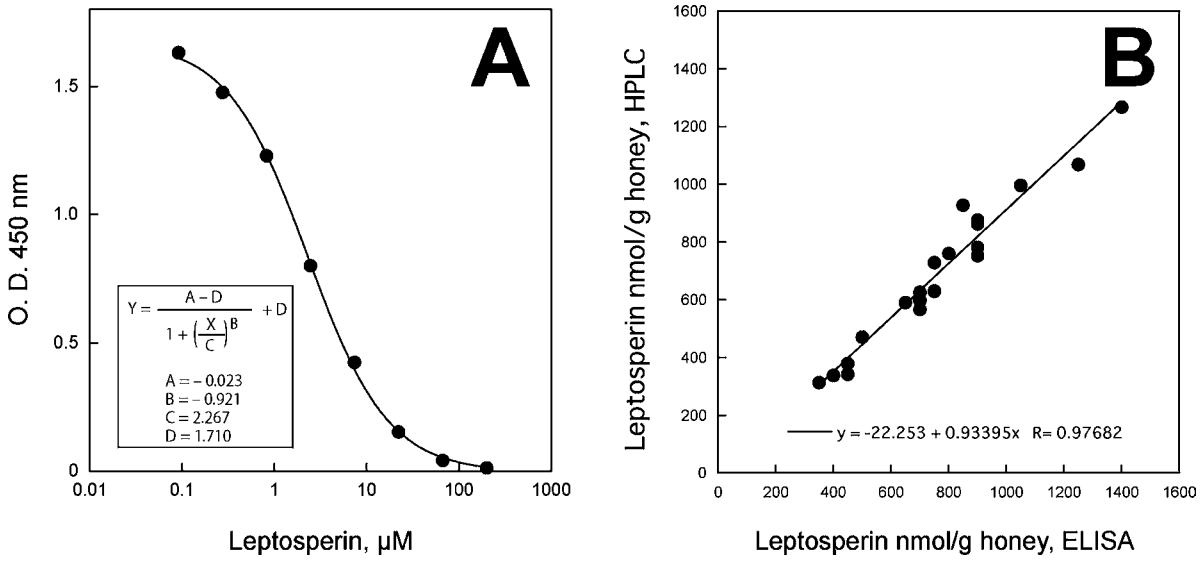

**Figure 3.** (A) Standard curve for an ELISA and (B) correlation between HPLC and ELISA. (A) A typical standard curve is shown with the equation (a four-parameter curve fitting). (B) The contents of leptosperin in the 20 certified manuka honey samples estimated by an ELISA significantly correlate with those determined by HPLC.[5] The ELISA for honey samples was performed four times, and the average was used.

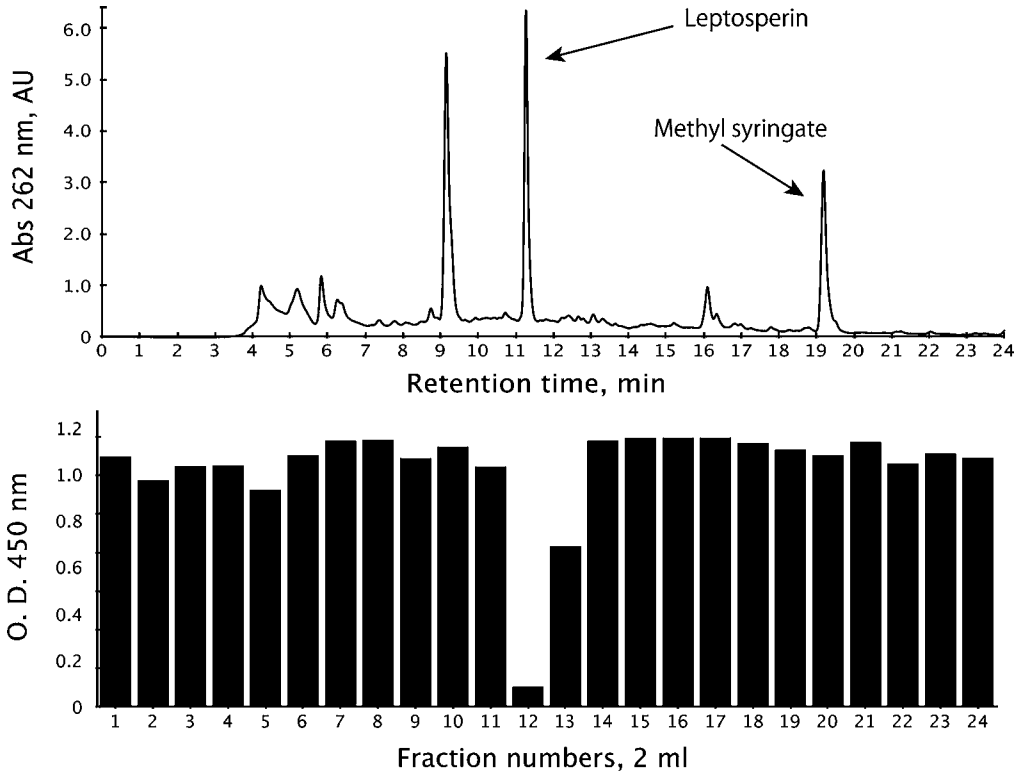

**Figure 4.** Fractionation and identification of antigen in manuka honey. An aqueous solution of manuka honey was injected into a semipreparative HPLC instrument, and the eluate was fractionated every minute (each 2 mL). The top panel shows the separation chromatogram with monitoring at an absorbance of 262 nm. The elution positions of leptosperin and methyl syringate are shown with arrows. The bottom panel indicates the immunoreactivity of fractionated samples estimated by a competitive ELISA.

on microtiter plate wells and kept overnight at 4 °C. The wells were washed with PBS containing 0.05% Tween 20 (PBST) and then blocked with 200 μL of 1% Block Ace (Dainihon Sumitomo Seiyaku, Osaka, Japan) for 1 h at 37 °C. Competitor (0−0.1 mM) or authentic leptosperin was mixed with the 2H3 antibody (0.02 μg/mL) in a well and further incubated for 2 h at 37 °C. The plate was washed and treated with 1/5000 diluted anti-mouse immunoglobulins labeled with peroxidase (DAKO) in PBST for 1 h at 37 °C. Color development was performed using 100 μL of 3,3′,5,5′-tetramethylbenzidine reagent (Popular, Nacalai Tesque) and terminated by the addition of 100 μL of 1 M aqueous phosphoric acid.

**Quantitation of Leptosperin in Honey Samples.** For an ELISA, manuka honey was dissolved in water at a concentration of 0.02 g/mL of water. Nonmanuka honey was dissolved at a concentration of 0.1 g/mL. The samples were centrifuged, and supernatants were then used. Authentic leptosperin (0−0.1 mM) and the honey samples (duplicate) were analyzed by an indirect competitive ELISA as described above. The concentration of

leptosperin was calculated by MPM-III software (version 6.0, Bio-Rad) with a four-parameter curve fitting. For analysis of 20 manuka honeys, an ELISA was performed four times and the averages were used. Commercial honeys were analyzed twice, and the averages were used. For chemical measurement of leptosperin, HPLC−PDA was used as described previously.[5]

**Fractionation of Honey by Semipreparative HPLC.** Manuka honey (UMF10+) was dissolved in water (1 g/mL of aqueous 10% $CH_3CN$) and then centrifuged. The supernatant (100 $\mu$L) of the sample was injected into a semipreparative HPLC instrument. The separation was achieved using a Develosil ODS-HG-5 column (8 mm × 250 mm, Nomura Chemical Co. Ltd.) and a 0.1% formic acid (A)/$CH_3CN$ (B) gradient system at a flow rate of 2 mL/min. The program was as follows: 90% A at 0 min, 70% A at 25 min, 90% A at 30 min, and 90% A at 55 min. The eluate was fractionated every minute (each 2 mL) in a test tube and dried with a centrifugal evaporator. The samples were dissolved in PBS, and 50 $\mu$L of the sample (duplicate) was then used for a competitive ELISA as described above.

**Statistics.** The relationship between two groups was calculated by IBM SPSS Statistics version 22 with Spearman's correlation.

## RESULTS

**Preparation of the Immunogen and Monoclonal Antibody.** The methyl ester (-$COOCH_3$) of leptosperin was hydrolyzed by alkali, and successive demethylated leptosperin was conjugated via carboxylic acid with a carrier protein, KLH, using a conventional carbodiimide method (Figure 1). To prepare a positive antigen, conjugation of demethylated leptosperin to BSA was simultaneously performed. The conjugation was confirmed by a 20% loss of the free amino moiety on the BSA, which was estimated by reactivity against trinitrobenzenesulfonic acid. The increase in absorption at 262 nm also indicated the adduction (data not shown). The immunogen was injected into mice, and hybridomas between spleen cells and myeloma cells were prepared by a typical polyethylene glycol method. Three clones (2H3, 2B5, and 1C10), which secreted the respective antibody to the immunogen, were obtained, and the 2H3 clone was then selected on the basis of simple characterization by an ELISA.

**Specificity of the Antibody to Leptosperin.** The detailed characterization of the 2H3 antibody was performed by a competitive ELISA. As shown in panels A and B of Figure 2, the antibody recognized leptosperin but not its component, methyl syringate or gentiobiose. Though manuka honey contains some characteristic compounds, HMF, 4-hydroxyphenylacetic acid, 2-methoxybenzoic acid, and methylglyoxal,[12−14] they did not cross-react with the 2H3 antibody. The antibody did not react with other saccharides such as glucose, fructose, sucrose, and galactose, which are the major components of honey (Figure 2C). These results suggest that the established antibody specifically reacts with leptosperin.

**Quantification of Leptosperin in 20 Certified Manuka Honey Samples.** Using the antibody, we established an ELISA method for the detection and quantitation of leptosperin. The range of quantitation was approximately 0.3−200 $\mu$M (Figure 3A). Twenty certified manuka honey samples were analyzed by an ELISA and then compared with previous data by HPLC.[5] As shown in Figure 3B, a significant correlation between the results of ELISA and HPLC was observed ($r = 0.97$; $p < 0.001$). An ELISA tended to produce a value higher than that produced by HPLC. The fitting equation (Figure 3B, inset; $y = -22 + 0.93x$) indicated that approximately 22 nmol of leptosperin per gram of honey should be calculated in manuka honey by an ELISA; even actual leptosperin was under the HPLC detection limit. This result suggested that some contaminants present in honey interfered with the assay. The amounts of leptosperin in the honey correlated with their nonperoxide-dependent antibacterial activities or the content of methylglyoxal.[2,5,12] The amount of leptosperin measured by an ELISA also correlated with this (data not shown). These results indicate that immunochemical quantification of leptosperin may be applicable for authentication of manuka honey.

**Identification of the Antigen as Leptosperin in Manuka Honey.** To confirm that the antigen in the honey was leptosperin, honey was fractionated by HPLC and the reactivities of the fractions with the antibody were then analyzed by a competitive ELISA. As shown in Figure 4, the antibody significantly reacted with fraction 12. Fraction 12 corresponded to a retention time of 11−12 min, which coincided with the elution time of leptosperin (11.5 min). This indicated that the antibody specifically reacts with leptosperin

[a]The calculated data are given in parentheses. [b]Data (for samples 18–34) determined by HPLC were acquired previously.[5] [c]Data (for samples 35–50) determined by HPLC were acquired previously.[2] [d]Not detected.

in manuka honey. In addition, syringic acid 4-*O*-β-D-gentiobioside (demethylated leptosperin) could not be detected.

**Application of the Determination of Leptosperin in Honey and Vodka by an ELISA.** Leptosperin has been found almost exclusively in manuka honey and jelly bush honey.[2,5,12,15] As shown in Table 1, leptosperin was detected in almost all manuka honey samples by an ELISA. The data for certified and noncertified manuka honey are fairly linear with respect to data determined previously by HPLC ($p < 0.001$).[2,5] There were no strong signals from non-manuka honey (Table 2), even if the honey was rich in methyl syringate (sample 36, from Sardinia, Italy).[16] After taking each datum into consideration, we decided that 70 nmol of leptosperin/g of honey was the detection limit for this ELISA. For reference, calculated data are given in parentheses in Table 2. In addition, leptosperin was also found (approximately 4 μmol/mL) in vodka to which manuka honey had been added. The concentration in vodka was almost identical to that measured by HPLC in our previous report.[5]

## DISCUSSION

The leptosperin levels in manuka honey correlated with the nonperoxide-dependent antibacterial activity of honey, which is used for authentication of manuka honey as UMF.[5] Because leptosperin is found exclusively in manuka honey,[2,12] the quantification of leptosperin could be an authentication marker for manuka honey. To detect the leptosperin, chemical methods are available, and these methods provide accurate measures of leptosperin levels.[5] Some products contain trace amounts of manuka honey, making it difficult to detect leptosperin using conventional HPLC–PDA (UV). However, mass spectrometry could resolve the problem. In contrast, immunochemical methods such as an ELISA can analyze many samples simultaneously; therefore, the cost of the required equipment, such as a conventional microplate reader, is lower than those required for chemical methods like HPLC–PDA (UV) or LC–MS/MS. Needless to say, a specific antibody is required for the construction of an ELISA.

There are several reports on antibodies to phytochemicals or their metabolites. Kawai et al. prepared antibodies to quercetin glucuronide and proved the localization of the metabolite in atherosclerotic plaques or the brain immunohistochemically.[7−9] Recently, a monoclonal antibody to liquiritin, a glucoside of liquiritigenin, has been developed to assist in the quality control of licorice products.[10] Antibodies developed specifically for a phytochemical may be useful for analyzing the metabolism of compounds and for the quality control of products. In this study, we aimed to obtain the antibody specific to leptosperin.

In preliminary experiments, we tried to prepare the antibody using an immunogen, which was prepared by conjugation of the carrier protein with leptosperin by a periodate oxidation method.[17] The obtained antibody recognized leptosperin; however, it also recognized its aglycone, methyl syringate (data not shown). In the study presented here, the methyl ester of methyl syringate in the leptosperin molecule was treated with a weak alkaline solution to expose the carboxyl moiety (-COOH); i.e., the methyl syringate moiety was transformed into a syringic acid moiety. Using the generated terminal COOH group, the leptosperin molecule was conjugated with a lysine residue of a carrier protein, KLH. The novel antibody that was obtained did not recognize gentiobiose, syringic acid, or methyl syringate (Figure 2). This result suggests that the antibody is highly specific for leptosperin.

We have found that the antigen in manuka honey completely coincides with the fraction containing leptosperin (Figure 4). Figure 3B and Tables 1 and 2 show good linearity between the data determined by HPLC and ELISA, indicating that the reliability of leptosperin analyses by an ELISA is sufficient for practical purposes.

The antibacterial activity is a key property of manuka honey, and this activity can be changed during storage, transport to a store, or its display at the store. A recent study showed that quantitation of leptosperin could identify falsified manuka honey or low-quality manuka honey[5] sold in the market. These findings suggest that the quantitation of leptosperin along with the measurement of antibacterial activity should be applicable for authentication of manuka honey. Immunochemical methods, such as an ELISA, using the antibody specific to leptosperin provide a simple method for novel immunochemical authentication of manuka honey.

identify the ligands isolated. Moreover, using a fluorescence quenching method and molecular docking, the binding affinity and potential interaction mechanism between the ligands and lipase were investigated.

## MATERIALS AND METHODS

**Reagents and Chemicals.** Dried lotus leaves were obtained from Sichuan province, China. $FeCl_3 \cdot 6H_2O$, $FeCl_2 \cdot 4H_2O$, and *N*,*N*-dimethylformamide (DMF) were purchased from Chengdu Tianhua Chemical Technology Co., Ltd. (Chengdu, China). *N*-Hydroxysuccinimide (NHS), 2-(*N*-morpholino)ethanesulfonic acid (MES), 1-(3-(dimethylamino)propyl)-3-ethylcarbodiimide hydrochloride (EDC·HCl), orlistat, 4-methylumbelliferyl oleate (4-MUO), and porcine pancreatic lipase (type VI-S, from porcine pancreas) were purchased from Sigma Chemical Co. (St. Louis, MO, USA). Tetraethyl orthosilicate (TEOS), succinic anhydride, and 3-aminopropyltrimethoxysilane (APTMS) were purchased from TCI (Tokyo, Japan). The acetonitrile used for HPLC was of chromatographic grade (J. T. Baker, Phillipsburg, NJ, USA). HPLC grade water was produced by a Milli-Q (18.2 MΩ) system (Millipore, Bedford, MA, USA). The other chemicals and solvents were all of analytical reagent grade. Sephadex LH-20 was from Amresco (Solon, OH, USA). D101 macroporous resin, which was a cross-linked polystyrene copolymer, was purchased from the Chemical Plant of Nankai University (Tianjin, China).

**Apparatus and Instruments.** A TSP HPLC system consisting of quaternary pump and DAD detector (Thermo Separation Products Inc., Waltham, MA, USA) was used for HPLC analysis and ultraviolet (UV) measurement. A Thermo-Quest Finnigan $LCQ^{DECA}$ system equipped with an electrospray ionization source (Thermo-Quest LC/MS Division, USA) was used for HPLC-MS/MS measurements. Fluorescence spectra were recorded by an RF-5301 spectrofluorometer equipped with a 150 W xenon lamp (Shimadzu, Japan). Thermo Scientific Varioskan Flash equipped with a 96-well microplate (Thermo, USA) was used for lipase inhibition assay of active compounds. Ligand fishing was performed in a constant-temperature incubator shaker (Zhengzhou Zhicheng Device Works, Zhengzhou, China). The pH values were measured with a pHS-3 digital pH-meter (Shanghai LeiCi Device Works, Shanghai, China). Preparative separation of active compounds was performed using a Waters 2545 HPLC on a C-18 preparative column (5 μm, 250 × 10 mm i.d.).

**Preparation of Lipase-Functionalized MNPs (LMNPs).** Lipase-functionalized MNPs were prepared following a previously reported process with a little modification.[18] Briefly, $Fe_3O_4$ nanoparticles (MNPs) were prepared by coprecipitation of $FeCl_2$ and $FeCl_3$ with ammonia water. Using TEOS and APTMS, the MNPs were first coated with $SiO_2$, and then the $SiO_2$ was terminated with amino groups. These amine-terminated MNPs were then treated with 10% succinic anhydride in DMF to obtain carboxyl group-terminated MNPs. Lipase-MNPs coupling was achieved by activating the carboxyl groups with EDC/NHS followed by covalently cross-linking the primary amino groups of the lipase amino acids. LMNPs were suspended in $NH_4OAc$ buffer and stored before use at −4 °C. The immobilized yield of lipase on the MNPs was measured as 50 mg/g MNPs.

**Ligand Fishing from Lotus Leaf Extract.** Air-dried, powdered lotus leaves (5.0 g) were refluxed with 80% ethanol at 80 °C for 90 min, three times. The extractions were filtered, and all of the filtrates were combined and concentrated to dryness in vacuum at 45 °C to give the crude extract (456.0 mg). The crude extract was suspended in water and fractionated with petroleum ether and ethyl acetate successively. The ethyl acetate fraction was absorbed with a D101 macroporous resin-packed column, washed with water and 30, 50, and 75% alcohol successively. The 50% alcohol eluent was concentrated in vacuum to dryness (named $S_0$) and used for the following ligand fishing experiment.

Ligand fishing was performed according to the method we reported previously.[11] A 1.0 mg/mL $S_0$ solution was prepared in ammonium acetate buffer (10 mM, pH 7.4). Twenty milligrams of LMNPs was added to the Eppendorf tube containing 1 mL of $S_0$ solution. The tube was shaken vigorously for 30 min at 25 °C before being placed on a magnet for 1 min to carry out magnetic liquid−solid separation. The LMNPs were washed three times using 3 × 1 mL buffer to remove nonspecifically bound compounds. Finally, LMNPs were eluted with 1 mL of 50% acetonitrile to release the active compounds. The eluent was stored as solution $S_5$. $S_0$ and $S_5$ were then analyzed with HPLC-MS/MS.

**HPLC-DAD-MS/MS Analysis and Compounds Identification.** A Tianhe Kromasil C18 column (5 μm, 250 mm × 4.6 mm) kept at 35 °C with a guard column (C18, 5 μm, 4.0 mm × 3.0 mm) was used for chromatographic analysis. The injection volume was 20 μL. The mobile phase was composed of 0.1% HAc (A) and acetonitrile (B), and the column was eluted with a gradient of 10−90% B for 0−50 min at a flow rate of 0.8 mL/min. The peaks were detected by a UV detector set at 280 nm. A Thermo-Quest Finnigan $LCQ^{DECA}$ mass spectrometer equipped with an electrospray ionization source (Thermo-Quest LC/MS Division, USA) was used for HPLC-MS/MS analysis, which gave information on the molecular weights and fragmentation patterns. The mass spectrometry detector parameters were set as follows: nebulizer sheath gas $N_2$ was 80 units; nebulizer auxiliary gas $N_2$ was 20 units; capillary temperature was 300 °C; spray voltage was 4.5 kV; capillary voltage was −13 V; and lens voltage was 18 V. All of the data were processed using Finnigan Xcalibur core data system rev. 2.0 (Thermo, USA). Identification of compounds **1**−**6** was realized by comparison of the retention time as well as MS/MS data with those of the known compounds reported previously.[19]

**Purification and Identification of the Active Compounds.** Five hundred grams of the powdered lotus leaves was extracted and processed according to the method described above. The 50% alcohol eluent fraction was concentrated and redissolved in 50% methanol aqueous solution to submit to Sephadex LH-20 column chromatography eluated with 50% methanol. Elution of fraction A-2 was evaporated under vacuum and recrystallized in methanol to afford compound **1** (15 mg). Elution of fraction B-2 was concentrated and separated by a preparative HPLC system eluated with 40% methanol to give compound **4** (38 mg). Although identified as described above, chemical structures of compound **1** and **4** were further confirmed by comparing the $^1H$ and $^{13}C$ NMR data with the published ones. The two isolated compounds were used for subsequent lipase inhibition assay and fluorescence quenching experiment.

**Lipase Inhibition Assay.** The two bioactive compounds fished out from lotus leaves and the crude extract ($S_0$) used for ligand fishing process were subjected to lipase inhibition assay with the well-known lipase inhibitor orlistat as positive control.[20] Samples were dissolved in water, whereas both lipase and 4-MUO were dissolved in a buffer containing 13 mM Tris-HCl, 150 mM NaCl, and 1.3 mM $CaCl_2$ (pH 8.0). Briefly, 50 μL of a 0.1 mM 4-MUO solution was mixed with 25 μL of the sample solution into the well of a 96-well microtiter plate, to which 25 μL of the lipase solution (50 U/mL) was added to start the enzymatic reaction. After incubation for 30 min at 25 °C, the enzymatic reaction was stopped by adding 0.1 mL of 0.1 M sodium citrate (pH 4.2). The product of the enzymatic reaction, 4-methylumbelliferone, was quantified with a fluorometric microplate reader (Thermo Scientific Varioskan Flash system) at 355 nm (excitation wavelength) and 460 nm (emission wavelength). All of the assays were performed in triplicate to calculate the mean ± standard deviation values.

**Fluorescence Quenching Measurements of Active Compounds with PPL.** In the fluorescence quenching experiment, 1.0 μM lipase solution was used. Series concentrations of compounds **1** and **4** (0.013−0.26 mM) were prepared in a buffer of DMSO/$H_2O$ (9:1). Each 0.25 mL of sample solution was added to a 3 mL lipase solution to give a sample concentration in the range of 0.001−0.02 mM. Each mixture was then incubated at 300 K for 0.5 h. The intensity of the fluorescence emission of each mixture at 340 nm was measured at the excitation wavelength of 280 nm, which was repeated three times. Neither compound **1** nor **4** gave out fluorescence emission around 340 nm (in the range of 300−450 nm) at the excitation wavelength. The fluorescence intensities were measured with a Shimadzu RF5301 spectrophotometer with 5.0 nm of excitation and emission slit widths.

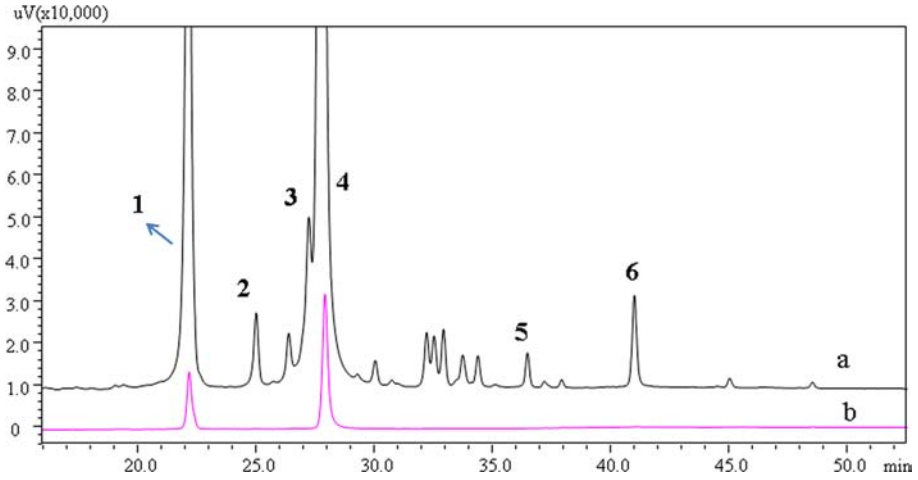

**Figure 1.** HPLC chromatograms obtained from (a) the extract of lotus leaf ($S_0$) and (b) the eluent from LMNPs after extraction ($S_5$). Peaks: 1, quercetin-3-*O*-*β*-D-arabinopyranosyl-(1→2)-*β*-D-galactopyranoside; 2, quercetin-3-*O*-rhamnopyranosyl-(1 → 6)-glucopyranoside; 3, quercetin-3-*O*-glucoside; 4, quercetin-3-*O*-glucuronide; 5, isorhamnetin 3-*O*-*β*-D-xylopyranosyl-(1→2)-*β*-D-glucopyranoside; 6, isorhamnetin 3-*O*-glucoside (**6**).

**Table 1. UV−Vis Absorption Maxima ($\lambda_{max}$) in HPLC and Main ESI-MS$^n$ Ions of Ingredients in Extracts of Lotus Leaves**[a]

| compd | identification | $t_R$ (min) | $\lambda_{max}$ (nm) | NI$^-$ | MS/MS |
|---|---|---|---|---|---|
| **1** | quercetin-3-*O*-*β*-D-arabinopyranosyl-(1→2)-*β*-D-galactopyranoside | 22.1 | 227, 254, 354 | 595 | 300 |
| **2** | quercetin-3-*O*-rhamnopyranosyl-(1→6)-glucopyranoside | 25.0 | 227, 254, 354 | 609 | 301, 150 |
| **3** | quercetin-3-*O*-glucoside | 27.2 | 227, 254, 354 | 463 | 300 |
| **4** | quercetin-3-*O*-glucuronide | 27.9 | 229, 254, 354 | 477 | 301 |
| **5** | isorhamnetin 3-*O*-*β*-D-xylopyranosyl-(1→2)-*β*-D-glucopyranoside | 36.4 | 234, 265, 354 | 609 | 299, 314 |
| **6** | isorhamnetin 3-*O*-glucoside | 41.0 | 236, 254, 354 | 477 | 314, 299 |

[a]Compound numbering is in accordance with peak numbering in Figure 1.

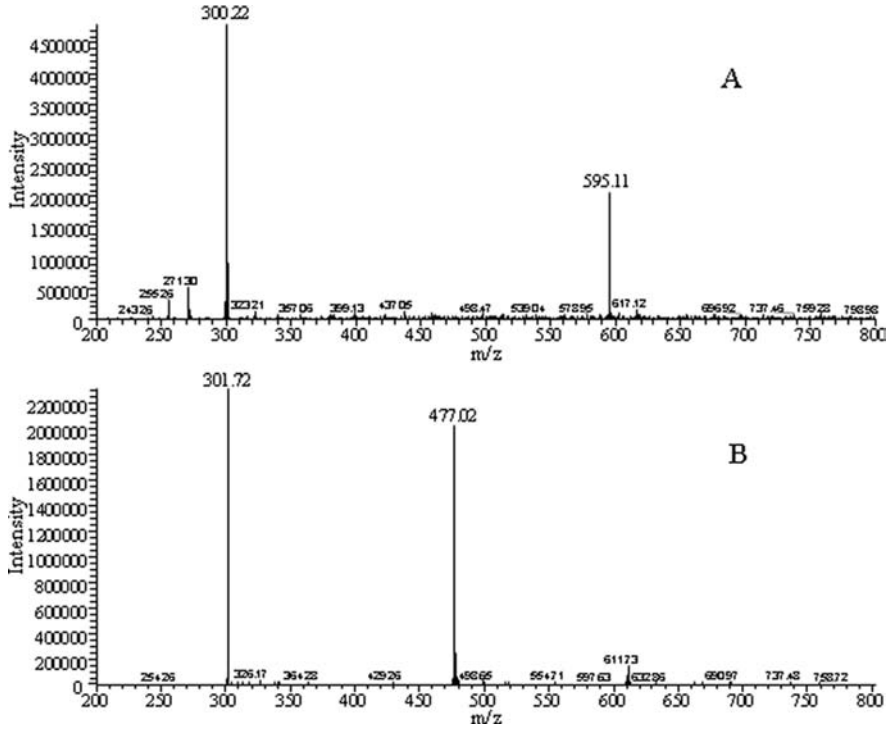

**Figure 2.** Negative ion CID mass spectra of the two compounds: (A) MS/MS of Qc-3-*O*-AraGal ($m/z$ 595); (B) MS/MS of Qc-3-*O*-Glu ($m/z$ 477).

In addition, synchronous fluorescence spectra of lipase ($T$ = 300 K, pH 7.4) were measured, and the range of synchronous scanning was $\Delta\lambda$ = 60 nm.

The quenching emission data were plotted as a Stern−Volmer plot of $F_0/F$ against [Q], and the quenching constant was calculated by linear regression. Binding constants ($K_a$) and binding sites ($n$) were calculated in static quenching by the following equation:

$$\lg[(F_0 - F)/F] = \lg K_a + n \lg[Q] \quad (1)$$

dx.doi.org/10.1021/jf503687e | J. Agric. Food Chem. 2014, 62, 10679−10686

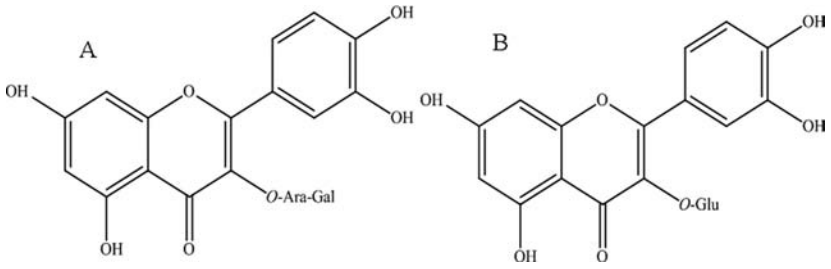

**Figure 3.** Chemical structures of the ligands isolated from the extract of *Nelumbo nucifera* leaves.

Thermodynamic evaluation of the active compounds with lipase was assessed according to a previously reported method.[20]

**Molecular Docking Studies.** To investigate the interactions between compounds **1** and **4** with porcine pancreas lipase (PPL), we tried to dock them onto the enzyme. Autodock Vina program was used for in silico molecular docking of the compounds in the active site of lipase.[17] Both compounds were drawn in mol2 format with all hydrogen atoms added, and then the energy was minimized using Hamiltonian-Force-Field-MMFF94x by Molecular Operating Environment (MOE) software. The partial charges were calculated, which were finally saved in pdbqt format. The X-ray crystallographic structure of PPL (Protein Data Bank, PDB entry code 1ETH, 2.80 Å resolution[21]) was downloaded from the Protein Data Bank and opened with Deep View software to check whether the amino acids of the protein were complete or not. Subsequently, all hydrogen atoms and the charges were added for the PPL and also saved as a pdbqt file.

The structure was complexed respectively with the two inhibitors by AutoDock Vina. The catalytic serine residue of the lipase was replaced by glycine residue, and docking runs were subsequently performed to enable the ligand to adopt a suitable position corresponding to the prebound intermediate before the nucleophilic attack in the lipase active site. To fit the active site cleft and allow nonconstructive binding, the appropriate box size for PPL was selected. Using the center of the bound compound, the center of the grid enclosing the box could be defined. The dimensions of the enclosing box were deduced according to the compound size Grid utility program within the Dock 4.0.1 to generate docking grid, which was calculated using box dimensions of 52.65, 45.404, and 123.331. Binding free energies of Qc-3-*O*-AraGal and Qc-3-*O*-Glu were also calculated.

## RESULTS AND DISCUSSION

LMNPs are shown in Figure 1. As in Figure 1a, the crude extracts ($S_0$) from lotus leaves possessed a complicated composition containing a variety of flavonoid compounds. The chromatographic and MS data of the main flavonoids from $S_0$ are listed in Table 1. By comparison of HPLC retention time, molecular weight, and MS/MS data with those reported in the literature previously,[19] six flavonoids were identified as quercetin-3-*O*-*β*-D-arabinopyranosyl-(1→2)-*β*-D-galactopyranoside (**1**), quercetin-3-*O*-rhamnopyranosyl-(1→6)-glucopyrano-

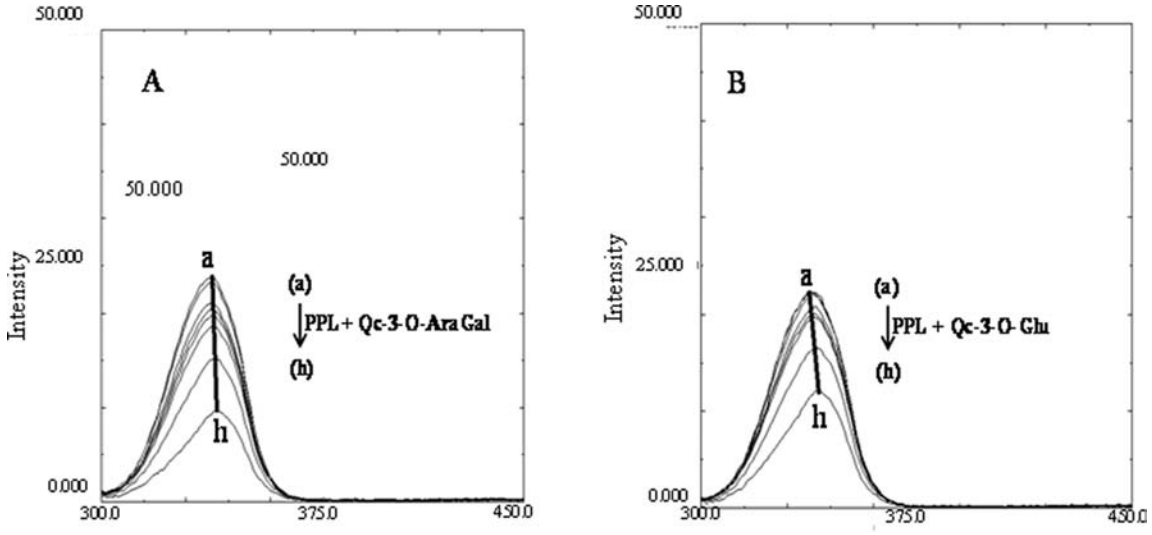

**Figure 6.** Synchronous fluorescence spectra of PPL at various concentrations of Qc-3-*O*-AraGal (A) and Qc-3-*O*-Glu (B) at 60 nm wavelength interval, $T$ = 310 K, $c$(PPL) = $1.0 \times 10^{-6}$ mol $L^{-1}$; $c$(Qc-3-*O*-AraGal), and $c$(Qc-3-*O*-Glu)/($10^{-6}$ mol $L^{-1}$) a–h: 0, 1, 2, 4, 6.5, 8, 10, 20, respectively.

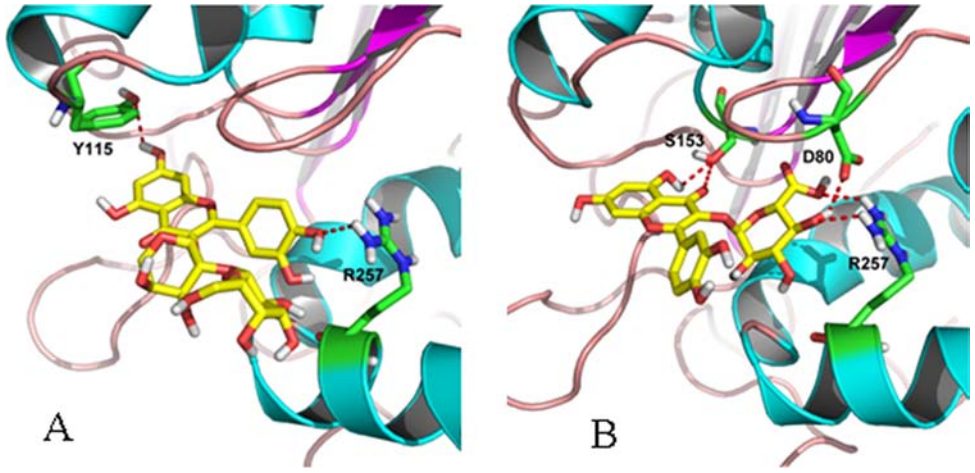

**Figure 7.** Superimposition of the top-scoring docking positions of (A) Qc-3-*O*-AraGal and (B) Qc-3-*O*-Glu in PPL active sites. Each inhibitor is represented in atom color-code sticks (oxygen, red). Structures were drawn with PyMOL Molecular Graphics System (version 1.3, Schrodinger, LLC), using the following PDB file: 1ETH for PPL.

side (**2**), quercetin-3-*O*-glucoside (**3**), quercetin-3-*O*-glucuronide (**4**), isorhamnetin 3-*O*-*β*-D-xylopyranosyl-(1→2)- *β*-D-glucopyranoside (**5**), and isorhamnetin 3-*O*-glucoside (**6**). Two compounds (**1** and **4**) were found in $S_5$ as shown in Figure 1b, indicating that there were only two lipase ligands in the lotus leaf crude extracts which can bind to LMNPs. They were isolated from the extracts for subsequent lipase inhibition assay and fluorescence quenching experiment, and their chemical structures were confirmed as following.

The UV absorption maximum ($\lambda_{max}$, nm) of both **1** and **4** were at ∼254 nm (Figure 2), which were consistent with those of quercetin type flavonoids.[22] Compound **1** has a molecular weight of 596 ($m/z$ 595, $[M - H]^-$). The radical aglycone ion at $m/z$ 300 $[A - 2H]^-$ in $MS^2$ (Figure 2A) indicated that the interglycosidic linkage between the two monosaccharides was C1→C2.[22] Therefore, this compound was identified as quercetin-3-*O*-*β*-D-arabinopyranosyl-(1→2)-*β*-D-galactopyranoside (Qc-3-*O*-AraGal). Compound **2** was found to have a molecular weight of 478 ($m/z$ 477, $[M - H]^-$). A significantly strong aglycone ion peak was observed at $m/z$ 301 $[A - H]^-$ in $MS^2$ (Figure 2B), indicating that it was a glucuronic acid glycoside. Therefore, compound **2** was identified as quercetin 3-*O*-D-glucuronide (Qc-3-*O*-Glu), which was the dominant flavonoid in lotus leaves.[19] Their chemical structures are shown in Figure 3.

It is worth noting that only two flavonoids (compounds **1** and **4**) were fished out from the mixture of many flavonoids present in the extract, and only these two exhibited potent binding ability to PPL. As all six identified flavonoids have the same aglycones, that is, quercetin or isorhamnetin, we speculated that it was the complicated conformation of the different sugar chains that caused such difference in lipase binding. This result corresponds largely to a previous study in which lipase immobilized on hollow fiber was used to select lipase inhibitors from lotus leaf.[23] The only difference is that, apart from compounds **1** and **4**, another kaempferol type flavonoid was extracted in the study. However, it showed significantly lower bioactivity and binding capacity compared with compounds **1** and **4**.

**Lipase Inhibition Assay.** The beneficial effects of lotus leaves have been mainly attributed to their high flavonoid contents. To our knowledge, this is the first screening of lipase

inhibitors from lotus leaves by LMNP-based ligand fishing. The PPL inhibitory activities of the two PPL-bound flavonoids, Qc-3-*O*-AraGal (**1**) and Qc-3-*O*-Glu (**2**), together with the crude extract of lotus leaves ($S_0$) were evaluated by a traditional PL inhibitor assay[20] with orlistat as the positive control. The lipase inhibitory activities of the samples were determined using 4-MUO as the substrate of the lipase-catalyzing reaction. They were determined by measuring the fluorescence intensity increment arising from the fluorescent product 4-methylumbelliferone (4-MU) at an excitation wavelength of 360 nm and an emission wavelength of 450 nm using a 96-well microplate reader. Compared to the $IC_{50}$ value of orlistat (1.53 ± 0.02 μM), those for compounds **1**, **4**, and $S_0$ were 52.9 ± 3.2 μg/mL (88.8 ± 5.4 μM), 17.1 ± 1.5 μg/mL (35.8 ± 3.1 μM), and 95.0 ± 5.1 μg/mL, respectively. The two active compounds (**1** and **4**) showed significantly stronger inhibitory effects than the crude extracts ($S_0$). These results indicate that both compounds fished out by this method are effective inhibitors of lipase. This finding is in agreement with a previous report.[24] Therefore, this method is expected to be useful for activity-guided separation of active compounds from natural products.

**Fluorescence Quenching Measurements of Active Compounds with PPL.** *Fluorescence Quenching Mechanism.* The intrinsic fluorescence is usually used to investigate the structure and dynamics of proteins; therefore, it is a good tool in the study of association reactions between proteins and bioactive compounds.[24] When the excitation wavelength was set at 280 nm, the fluorescence emission peaks of PPL (at 340 nm) mixed with a series concentrations of the quencher provided information on tryptophan residues, which are the main contributors to intrinsic fluorescence of proteins.[25] Fluorescence quenching can thus be used to measure binding affinity. Fluorescence quenching is described by the Stern−Volmer equation as follows:

$$\frac{F_0}{F} = 1 + k_q\tau_0[Q] = 1 + K_{SV}[Q] \quad (2)$$

$F_0$ and $F$ are the fluorescence intensity before and after quencher was added to PPL; $k_q$ is the quenching rate constant, $K_{SV}$ is the Stern−Volmer dynamic quenching constant, $\tau_0$ is the average lifetime of bimolecular fluorescence without quencher ($\tau_0 = 10^{-8}$ s), and [Q] is the concentration of the quencher. $K_{SV}$ was determined by linear regression of a plot of $F_0/F$ against [Q], and it is the slop of linear regression of eq 2. In this work, Stern−Volmer plots for PPL fluorescence quenching by Qc-3-*O*-AraGal and Qc-3-*O*-Glu are shown in Figure 4, and $K_{SV}$ and $k_q$ at pH 7.4 are summarized in Table 2. A linear Stern−Volmer plot usually indicates a single way of quenching, in which the fluorophores are all equally accessible to the quencher. On the other hand, when the fluorophores are quenched by both collision and complex formation with the quencher, the Stern−Volmer plot will exhibit an upward curvature, corresponding to the occurrence of both dynamic and static quenching. In this work, the plots of the two flavonoids were in good agreement with the linear Stern−Volmer plot, whereas no obvious deviation toward the *y*-axis was observed, indicating that either dynamic quenching or static quenching was predominant.[26]

The $k_q$ value reflects the efficiency of quenching or the accessibility of the fluorophores to the quencher and, thus, is used to judge whether the formation of a complex can lead to the quenching.[27]The $k_q$ value near $1 \times 10^{10}$ $M^{-1}$ $s^{-1}$ is typical for dynamic quenching mechanism. In this work, the $k_q$ values of Qc-3-*O*-AraGal and Qc-3-*O*-Glu were 200-fold ($2.157 \times 10^{12}$ L $mol^{-1}$ $s^{-1}$) and 250-fold ($2.521 \times 10^{12}$ L $mol^{-1}$ $s^{-1}$) higher than $1 \times 10^{10}$ $M^{-1}$ $s^{-1}$, respectively. This result suggested that both compounds formed a complex with PPL and both belonged to static quenching mechanism. Moreover, Qc-3-*O*-Glu showed higher fluorescence quenching effects on PPL than Qc-3-*O*-AraGal.

*Thermodynamic Parameters and the Characteristic of the Binding Forces.* The binding of ligands to proteins is mainly affected by noncovalent interactions including hydrogen bonds, van der Waals forces, electrostatic interactions, and hydrophobic interactions. These acting forces can be confirmed by thermodynamic parameters of the binding reaction. Therefore, the interaction of the two flavonoids with PPL identified by thermodynamic parameters dependent on temperature are calculated from van't Hoff equations:

$$\ln(K_2/K_1) = \left(\frac{1}{T_1} - \frac{1}{T_2}\right)\Delta H/R \quad (3)$$

$$\Delta G = \Delta H - T\Delta S = -RT\ln K \quad (4)$$

where $T$ is the experimental temperature, $\Delta H$ is the enthalpy change, $R$ is the gas constant, $\Delta S$ is the entropy change, $K_2$ and $K_1$ are the binding constants ($K_a$) at the corresponding $T$, and $\Delta G$ is the free energy change.

The values of $\Delta H$, $\Delta S$, and $\Delta G$ obtained are shown in Table 3. The negative value for $\Delta G$ indicated a spontaneous interaction process. For both Qc-3-*O*-AraGal (+93.270 J $mol^{-1}$ $K^{-1}$) and Qc-3-*O*-Glu (+116.867 J $mol^{-1}$ $K^{-1}$), from the point of water structure, the positive $\Delta S$ values reflected a hydrophobic interaction.[28] In particular, the specific positive $\Delta H$ and $\Delta S$ values indicated that hydrophobic interaction was the major acting force and the reaction was mainly driven by entropy. These interactions could proceed through aromatic rings and other hydrophobic groups of the two active compounds. In addition to hydrophobic forces, hydrogen bonding between OH groups and the side chain of amino acids was also involved in the interaction of the two active compounds with PPL at the molecular level.

*Numbers of Binding Sites (n) and Binding Constants ($K_a$).* For static quenching, the binding sites and constants were calculated according to the following double-logarithm equation:[29]

$$\lg\frac{F_0 - F}{F} = \lg K_a + n\lg[Q] \quad (1)$$

$F_0$ and $F$ are the fluorescence intensities of PPL in the absence and presence of both compounds; $K_a$ is the binding constant; $n$ is the number of binding sites; and [Q] is the concentration of the quencher. The dependence of $\lg[(F_0 - F)/F]$ on $\lg[Q]$ value was linear, the slope of which equals $n$, and intercept to $\lg[K_a]$. Plots of $\lg[(F_0 - F)/F]$ versus $\lg[Q]$ for Qc-3-*O*-AraGal and Qc-3-*O*-Glu to PPL are shown in Figure 5. The double-logarithm curves for both active compounds were obviously linear. The corresponding calculated $K_a$ ($n$) values between Qc-3-*O*-AraGal or Qc-3-*O*-Glu and PPL were $1.491 \times 10^5$ (1.176) and $10.926 \times 10^5$ (1.338) at 300 K, respectively. The active compound Qc-3-*O*-Glu showed an obviously stronger binding capacity than Qc-3-*O*-AraGal (Table 4).

*Characteristics of Synchronous Fluorescence Spectra.* To investigate the effect of active compounds on the structural change of PPL, synchronous fluorescence spectra of PPL with different concentrations of active compounds were measured by simultaneously scanning the excitation and emission mono-

chromators. Qc-3-O-AraGal and Qc-3-O-Glu were measured individually under the same condition to exclude the possible interruption. Because none of them showed signals, no background control was needed in the following experiment. The synchronous fluorescence spectra have advantages of reducing bandwidth and avoiding various perturbations. It shows only the characteristics of tyrosine and tryptophan residues of PPL under wavelength interval ($\Delta\lambda$) between 15 and 60 nm, respectively. The maximum excitation and emission wavelengths of the residues correlate to the polarity of the microenvironment and, thus, can be used to judge the conformational change of proteins.

The effect of the two active compounds on PPL synchronous fluorescence spectroscopy is shown in Figure 6. The emission maximum of tryptophan residues exhibited a significant red shift (from 338 to 342 nm) for both Qc-3-O-AraGal and Qc-3-Glu, indicating an increase of polarity around the tryptophan residues and a decrease of the hydrophobicity. The results showed the conformational change of PPL tryptophan microregion by addition of active compounds during the binding process.

*Molecular Docking.* In silico molecular docking provided additional explanation for the experimental inhibition activity of Qc-3-*O*-AraGal and Qc-3-*O*-Glu. The porcine pancreatic lipase possesses two domains. Its N-terminal domain is an $\alpha/\beta$ hydrolase fold, which contains the catalytic sites of Ser153, Asp177, and His264. The crystal structure of the ternary porcine lipase-colipase-tetraethylene glycol monooctyl ether showed that the overall position of the three catalytic sites is conservative in different species.[21] The crystal structure of PPL (1ETH) was determined at a resolution of 2.80 Å, and the lipase active site was fully accessible so that docking experiments with the two inhibitors could be carried out. The in silico docking experiment showed that Qc-3-*O*-AraGal mostly interacted with PPL through hydrogen bonding of Tyr115 with the 7-hydroxyl group on ring A and Arg257 with the 3′-hyroxyl group on ring B (Figure 7A). Docking of Qc-3-*O*-Glu to PPL also showed an apparent hydrogen-bonding network resulting from the interaction of the 5-hyrdoxyl group on ring A and carbonyl group on ring C with the PPL catalytic residue Ser153. Additionally, the carboxyl and hydroxyl moieties on the sugar residue together had strong hydrogen-bonding interactions with the side chain of the PPL catalytic residue Arg257; the hydroxyl group on the sugar residue also showed hydrogen-bonding interaction with PPL residue Asp80 (Figure 7B). The estimated binding energies were −9.2 kcal $mol^{-1}$ for Qc-3-*O*-Glu and −7.9 kcal $mol^{-1}$ for Qc-3-*O*-AraGal, respectively. The docking results suggested that the two compounds from the screen might be potential inhibitors of PPL. In addition, the different binding free energies of Qc-3-*O*-Glu and Qc-3-*O*-AraGal suggested that Qc-3-*O*-Glu had a higher affinity than Qc-3-*O*-AraGal for PPL, which was consistent with the results of the lipase inhibition assay in vitro and fluorescence quenching analysis.

In conclusion, an effective method based on ligand fishing was developed to screen lipase inhibitors from complex chemical mixtures. Pancreatic porcine lipase immobilized onto magnetic nanoparticles was used to bind the ligands from the complex mixtures, and then the bound ligands could be easily separated magnetically for HPLC-MS/MS analysis. This method was first employed in lotus leaf extract to identify two flavonoids that showed significant inhibitory effect toward lipase, and the mechanism of PPL inhibition of the two ligands was investigated by fluorescence quenching together with molecular docking. The result of this study adds to the understanding of the mechanism of health effects of lotus leaves, and the method proposed shows great potential in screening enzyme inhibitors from edible and medicinal plants.

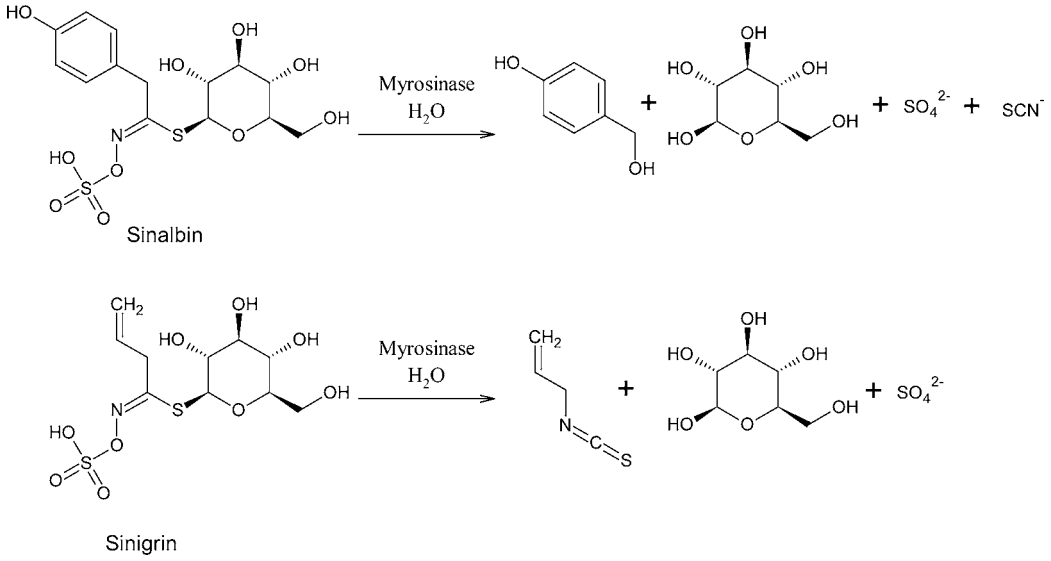

**Figure 1.** Myrosinase-catalyzed hydrolysis of mustard glucosinolates sinalbin and sinigrin.

quantification provides a measure of glucosinolate hydrolysis based on reaction stoichiometry. Thus, for *B. juncea*, sinigrin and $SO_4^{2-}$ can be quantified prior to seed meal application to predict biopesticidal potential.

Intact glucosinolates are ionic compounds that can be quantified by ion chromatography (IC) along with $SCN^-$ and $SO_4^{2-}$; however, there is no reported method for simultaneous analysis of mustard glucosinolates and their anionic hydrolysis products. Our objective was to develop and evaluate an IC method for the simultaneous quantification of sinigrin, sinalbin, $SO_4^{2-}$, and $SCN^-$ in mustard seed. The advantages of using IC for analysis include simplicity, selectivity, and relatively low cost. Ion chromatography is a commonly used technique in agricultural and environmental laboratories and, as such, a method that can be easily implemented in routine quality control analyses. The availability of a simple and inexpensive method of analysis is critical in encouraging the development of plant-derived biopesticides to improve agricultural sustainability.

## MATERIALS AND METHODS

**Materials.** Mustard seeds (*S. alba* and *B. juncea*) were obtained locally (Latah County, ID, USA). Two varieties of *B. juncea* (Pacific Gold and Kodiak) and one variety of *S. alba* (IdaGold) were used (Table 1). Oil contents of seeds and meals were analyzed gravimetrically after extraction with hexane. A sinigrin standard and sulfatase (EC 3.1.6) were purchased from Sigma-Aldrich (St. Louis, MO, USA). Glucolimnanthin (3-methoxybenzyl glucosinolate) and sinalbin were isolated from meadowfoam (*Limnanthes alba*) and *S. alba*, respectively, in our laboratory. Acetonitrile, water, methanol, and other solvents were of HPLC or LC/MS grade. Solvents and all other chemicals (at least of analytical grade) were purchased from Sigma-Aldrich or ThermoFisher (Pittsburgh, PA, USA).

**Table 1. Mustard Seeds and Seed Meals Used in IC Analysis**

| sample | species | variety | form | oil content[a] (%) |
|---|---|---|---|---|
| Sa_1 | *S. alba* | IdaGold | seed | 32 |
| Sa_2 | *S. alba* | IdaGold | seed | 41 |
| Sa_3 | *S. alba* | IdaGold | meal | 22 |
| Sa_4 | *S. alba* | IdaGold | meal | 29 |
| Sa_5 | *S. alba* | IdaGold | meal | 18 |
| Bj_1 | *B. juncea* | Pacific Gold | meal | 33 |
| Bj_2 | *B. juncea* | Kodiak | meal | 26 |
| Bj_3 | *B. juncea* | Pacific Gold | meal | 29 |
| Bj_4 | *B. juncea* | Pacific Gold | seed | 46 |
| Bj_5 | *B. juncea* | Kodiak | seed | 40 |

[a]Oil content was calculated on a weight basis.

**Extraction of Intact Glucosinolates.** Mustard seed and meal samples were ground and analyzed as schematically depicted in Figure 2. Prior to analysis, mustard samples were homogenized and milled

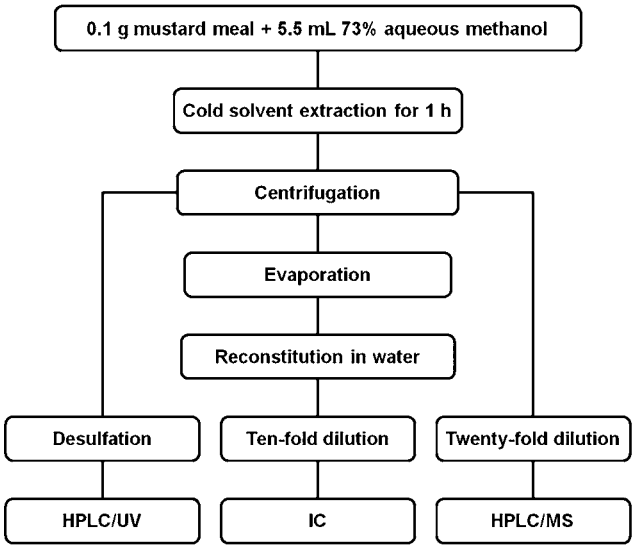

**Figure 2.** Scheme for optimization of the IC method for analysis of sinalbin and sinigrin in mustard seed meals.

with a coffee grinder to a fine powder. Seed meal (0.1 g) was extracted with 5.5 mL of 73% (v/v) methanol using an end-to-end shaker at room temperature for 1 h. To account for extraction recoveries, 1 mL of glucolimnanthin was added as an internal standard. Seed debris was separated by centrifugation at 2400 rpm for 20 min. An aliquot (1000 $\mu$L) of supernatant was (1) evaporated to dryness under a gentle stream of $N_2$ in a heating block at 60 °C, reconstituted in water, diluted 10 times with deionized water, and analyzed by IC; (2) diluted 20 times with deionized water and analyzed directly by HPLC/TOF MS; or (3) desulfated and analyzed by HPLC/UV.

**Desulfation of Glucosinolates for HPLC/UV Analysis.** Desulfation of intact glucosinolates was carried out according to the ISO 9167-1 procedure.[17] A 1-mL aliquot of the filtered methanol extract was transferred onto a column containing 500 mg of DEAE-Sephadex A-25 anion exchanger and allowed to drain freely. The column was washed twice with 1 mL of deionized water and finally with 1 mL of 0.1 M ammonium acetate buffer (pH 4.0). One hundred microliters of a 1 mg/L sulfatase enzyme (Sigma-Aldrich) solution was added to the column, the column was covered to prevent evaporation, and hydrolysis was allowed to continue for 12 h. Desulfated glucosinolates were eluted directly into 2-mL HPLC autosampler vials with two consecutive 1-mL volumes of deionized water.

**HPLC/DAD/TOF MS Analysis.** HPLC analysis was performed using an Agilent 1200 series HPLC with a diode array detection (DAD) system coupled to an Agilent G1969A TOF-MS equipped with an ESI source (Agilent, Santa Clara, CA, USA). Chromatographic separation of desulfated glucosinolates was conducted using a Phenomenex 4u Hydro-RP, 250 mm × 2 mm, 4 μm, column (Phenomenex, Torrance, CA, USA) maintained at 30 °C. The injection volume was 5 μL. The mobile phase consisted of water (solvent A) and acetonitrile (solvent B). The gradient elution program started with 2% B and followed a linear gradient to 30% B during a 30-min period, after which solvent B was increased to 70% in 1 min and held for 2 min; solvent B was then reduced to 2% at 32 min and held for 13 min. The flow rate was 0.25 mL/min. The UV signal was recorded at 229 nm with the reference set to 360 nm.

The chromatographic separation of intact glucosinolates was performed using a Zorbax XDB-C18, 50 mm × 4.6 mm, 1.8 μm, column (Agilent) maintained at 30 °C. The injection volume was 5 μL. The mobile phase consisted of 0.1% formic acid in water (solvent A) and 0.1% formic acid in methanol (solvent B). The gradient program started with isocratic elution using 5% B for 3 min, followed by a linear gradient to 70% B from 3 to 5 min, and then held at 70% B for 5 min; solvent B was then reduced to 5% at 10 min and held for 5 min. For the first 1.5 min of the analysis, the flow was diverted from the MS to prevent MS contamination and ion suppression with salts and other polar species. The flow rate was 0.4 mL/min, and spectra were recorded from 190 to 400 nm. Electrospray ionization was operated in the negative mode, and electrospray ionization potential was set at −3500 V. The collision-induced dissociation potential was set at 200 V. Gas temperature was 350 °C, drying gas ($N_2$) flow rate was 12 L/min, and nebulizer pressure was $2.4 \times 10^5$ Pa. Analyses were conducted in a profile mode with an $m/z$ range from 90 to 1000 amu. Quantification was performed using deprotonated molecules ($[M - H]^-$) with $m/z$ of 424.0378, 358.0272, and 438.0534 to quantify sinalbin, sinigrin, and glucolimnanthin, respectively.

**Ion Chromatographic Analysis of Intact Glucosinolates.** Ion chromatography was performed using Dionex Ion Analyzer (Dionex, Sunnyvale, CA, USA) equipped with a GP40 gradient pump, an ED40 electrochemical detector, and an AS40 autosampler. Three Dionex, 4 × 210 mm anion-exchange columns were tested: Ion-Pac AS11, Ion-Pac AS16, and Ion-Pac AS18. Sodium hydroxide (100 mM) was used as the mobile phase. Flow rate was varied from 0.5 to 0.9 mL/min. The detector stabilizer temperature was set at 30 °C with temperature compensation of 1.7% per °C. Anion suppressor current was set to 300 mA. The injection volume was 20 μL. The solution used for optimization included 1 mM sinigrin, 1.5 mM sinalbin, 1 mM glucolimnanthin, 0.1 mM $SO_4^{2-}$, and 0.25 mM $SCN^-$ in deionized water.

**Calibration Curves, Accuracy, and Precision.** Eight calibration standards (0.015625, 0.03125, 0.0625, 0.125, 0.25, 0.5, 1.0, and 2.0 mM) containing equimolar concentrations of sinigrin, sinalbin, $SO_4^{2-}$, and $SCN^-$ were included in calibration curves for glucosinolates and their hydrolysis products. Limits of detection (LOD) and limits of quantification (LOQ) for glucosinolates were determined under the optimized conditions for IC analysis based on a least-squares regression analysis as $3.3s_y/b$ and $10s_y/b$, respectively, where $b$ is the slope of the calibration curve and $s_y$ is the residual standard deviation of the regression line. The precision of the developed IC method was evaluated on the basis of intra- and interday reproducibility of analyses. The accuracy of the IC method for glucosinolate analysis was evaluated on the basis of statistical differences in IC concentrations compared to concentrations detected by the ISO 9167-1 HPLC/UV and HPLC/TOF MS methods.

**Matrix Effects, Analyte Recoveries, and Sample Stabilities.** The chemical compositions of the two mustard species are similar with the exception of the major glucosinolates. *B. juncea* contains sinigrin, but not sinalbin, and *S. alba* contains sinalbin, but not sinigrin. For evaluation of matrix effects, recovery, and sample stability, methanol extracts of *S. alba* (Sa_4) and *B. juncea* (Bj_5) were spiked with sinigrin and sinalbin, respectively, to yield a final glucosinolate concentration of 5 mM. Thus, for the evaluation of matrix effects on sinigrin, methanolic extracts of *S. alba* were used to prepare calibration standards. Similarly, methanolic extracts of *B. juncea* were used to evaluate matrix effects on sinalbin. Recoveries of analytes evaluated at three representative concentrations were expressed as percent of spiked concentrations in the extracts relative to concentrations of the same analytes prepared in water. Stabilities of the analytes were evaluated in *B. juncea* and *S. alba* extracts spiked with known amounts of sulfate, thiocyanate, and sinalbin or sinigrin, respectively. Analyte concentrations were quantified at 3, 6, 12, and 24 h after sample storage at room temperature.

Oil contents of mustard meals and seeds analyzed in the present study ranged from 18 to 46% (Table 1), thus potentially introducing additional matrix effects. To test for oil-introduced matrix effects, sinigrin in whole and defatted (DF) seed of Bj_5 and sinalbin in whole and DF seed of Sa_4 were quantified and respective samples of the same species compared.

A final concern was that the evaporation/reconstitution step included in the proposed IC method may cause glucosinolate loss (Figure 2). Sinigrin concentrations in three *B. juncea* samples (Bj_2, Bj_4, and Bj_5) were analyzed by HPLC/TOF MS to address this possibility. One set of extracts was evaporated and reconstituted in water as described previously under Extraction of Intact Glucosinolates (Figure 2), and another set of extracts were not evaporated, but diluted 20 times. Both sets of samples were analyzed using HPLC/TOF MS, and sinigrin concentrations in each respective sample were compared.

**Glucosinolate Hydrolysis in Solutions of Varied Methanol Concentrations.** For evaluation of sinalbin and sinigrin hydrolysis in methanol solutions, 0.1 g of seed (Sa_2 and Bj_4) was hydrolyzed for 1 h in 5.5 mL of solution containing 10, 40, or 70% methanol (v/v). Extracts were prepared and analyzed by IC as described under Ion Chromatographic Analysis of Intact Glucosinolates.

**Statistical Analysis.** All experiments were performed at least in triplicate and are presented as means ± one standard deviation. Calibrations were conducted both before and after the analysis of each sequence of samples. The accuracy of the proposed method was evaluated on the basis of statistical differences determined using one-way analysis of variance (ANOVA) with a $p < 0.05$ level of significance. Precision was evaluated using the relative standard deviations of standards at three representative concentrations as well as biological replicates. For evaluation of sample extract stability, mean values of peak areas for each analyte in freshly prepared samples were compared to corresponding peak areas at 3, 6, 12, and 24 h. Differences were assessed on the basis of Student's $t$-test. All analyses were performed using JMP software (version 10, SAS Institute Inc., Cary, NC, USA).

## RESULTS AND DISSCUSION

**Optimization of the IC Method.** IC conditions including anion-exchange column, mobile phase compositions, and the elution program were optimized to obtain baseline separation of mustard glucosinolates (sinigrin and sinalbin), their hydrolysis products ($SO_4^{2-}$ and $SCN^-$), and the internal standard (glucolimnanthin). All three Dionex anion-exchange columns evaluated for analyte separation were hydroxide-selective, cross-linked alkanol, quaternary ammonium-based columns. The Ion-Pac AS11 (45 μequiv) column has a low capacity, whereas Ion-Pac AS16 (170 μequiv) and Ion-Pac

AS18 (185 μequiv) columns have higher capacities. On the basis of preliminary results, conditions were initiated with 100 mM NaOH at a 0.5 mL/min flow rate.

The Ion-Pac AS11 column provided a good separation for inorganic anions; however, glucosinolates were not baseline separated under initial isocratic conditions (Table 2). When gradient elution (10−100 mM NaOH in 15 min) was used, the critical $SO_4^{2-}$/sinigrin pair could be valley separated, but not the glucolimnanthin/sinalbin pair. Glucolimnanthin and sinalbin have similar structures with comparable polarizabilities of 35.86 ± 0.5 × $10^{-24}$ and 37.83 ± 0.5 × $10^{-24}$ $cm^3$, respectively (calculated using ACDLabs 12, Advanced Chemistry Development Inc., Canada). Decreasing the gradient steepness from 6 to 4 mM NaOH/min resulted in unacceptable $SCN^-$ peak broadening and long run times. The use of Ion-Pac AS16 and Ion-Pac AS18 columns provided baseline separation of the five analytes under isocratic conditions (Table 2). Late-eluting sinalbin and $SCN^-$ peaks exhibited significant broadening on the Ion-Pac AS18 column (peak widths were 2.0 and 3.1 min, respectively), and their retention factors exceeded 20. The Ion-Pac AS16 column provided a reasonable run time as all five analytes were baseline separated in 13 min with retention factors ranging from 4.1 to 12.0 and resolutions ranging from 3.1 to 5.7. The Ion-Pac AS16 column was used for all subsequent analyses.

**Table 2. Performance Characteristics of Three Tested Anion-Exchange Columns for the Separation of Glucosinolates (Sinigrin, Sinalbin, and Glucolimnanthin) and Anionic Hydrolysis Products ($SO_4^{2-}$ and $SCN^-$)[a]**

| analyte | $t_r$ (min) | $T_f$ | $k$ | $N$ | $R_s$ |
|---|---|---|---|---|---|

[a]Separation was carried out in an isocratic mode with 100 mM NaOH at room temperature. $T_f$, tailing factor; $k$, retention factor; $N$, number of plates; $R_s$, resolution; $t_r$, retention time. [b]na, not applicable.

To increase throughput of the analysis, a series of runs with flow rates ranging from 0.5 to 0.9 mL/min were evaluated. An increase in flow rate of 0.1 mL/min resulted in a 10−12% decrease in retention time and a 6−14% decrease in peak width. Using a 0.9 mL/min flow rate, elution of the five analytes was achieved in 7.5 min with resolution and retention factors ranging from 2.4 to 5.4 and from 1.8 to 6.2, respectively. Thus, optimum conditions of the IC method were as follows: isocratic elution with 100 mM NaOH at a flow rate of 0.9 mL/min on a Dionex Ion-Pac AS16 column (Figure 3).

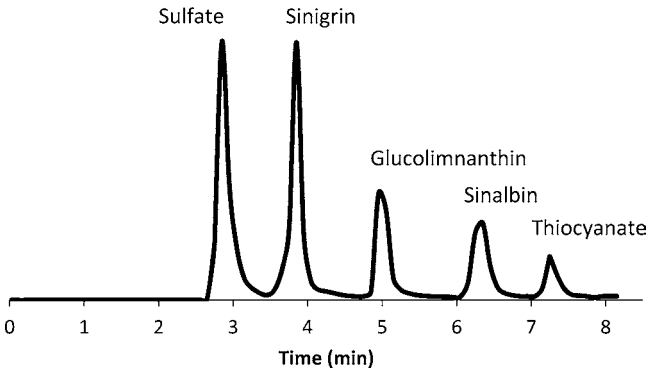

**Figure 3.** IC chromatogram for glucosinolates, $SCN^-$, and $SO_4^{2-}$ obtained using a 0.9 mL/min flow rate.

**Linearity and Detection and Quantification Limits of the IC Method.** Calibration curves for all analytes were linear for the entire calibration range (Table 3). Regression analysis of triplicates for each concentration level yielded correlation coefficients ($r$) of 0.9998 and 0.9986 for sinigrin and sinalbin, respectively. The LOD for sinigrin and sinalbin were 0.03 mM (Table 3). These LOD are comparable with those of the HPLC/UV method (0.06 mM) and up to 5 times higher than those of the HPLC/TOF MS method (0.01 mM).[20] The LODs for $SO_4^{2-}$ and $SCN^-$ were 0.02 and 0.04 mM, respectively. The LOQ for sinigrin, sinalbin, sulfate and thiocyanate were 0.09, 0.10, 0.07, and 0.09 mM, respectively.

When concentrations of sinigrin and sinalbin in the final solution are at the LOQ (0.09−0.10 mM), the corresponding concentrations in mustard meal would be 5.37 and 5.70 μmol/g meal (Table 3). The typical concentrations of glucosinolates in mustard meal are significantly higher and range from 60 to 220 μmol/g meal. Similarly, the concentrations of $SO_4^{2-}$ and $SCN^-$ in mustard hydrolysates are >200 times higher than the corresponding LOQ. Thus, the proposed IC method is sufficiently sensitive for the quantification of sinigrin and sinalbin concentrations in mustard meal. When concentrations of glucosinolates in mustard are expected to be low, 10-fold dilution of methanol extracts (Figure 2) can be omitted and more concentrated extracts can be analyzed.

**Precision.** Precision was evaluated by intraday and interday reproducibility of analysis. When standards were analyzed by the proposed method, intraday and interday relative standard deviations were 1.0−2.6 and 1.3−2.6%, respectively (Table 4 and Figure 4). The ranges of detected concentrations were 64−189 and 126−201 μmol/g in DF meal for sinigrin and sinalbin, respectively. The relative standard deviations for sinigrin were 2−9% and 2−6% for sinalbin. The precision of the IC method for both glucosinolates was comparable with those of the reference HPLC/UV method (1−7%) and the HPLC/TOF MS method developed in our laboratory (2−6%)[20] (Figure 4).

**Accuracy.** The accuracy of the proposed method was compared to that of the ISO HPLC/UV and HPLC/TOF MS methods for concentrations of sinigrin and sinalbin in the same respective samples (Figure 4). No differences in the concentrations of sinigrin and sinalbin detected by IC, HPLC/UV, and HPLC/TOF MS methods were observed.

**Matrix Effects and Analyte Recoveries.** When mustard meal is extracted, other compounds may be coextracted along

with glucosinolates including proteins, phenolics, and carbohydrates.[21,22] Whereas only anions are detected by IC, positively charged and neutral compounds may affect detected concentrations of target analytes. For example, if glucosinolates are strongly associated with other matrix components, they may not be quantified by IC.[23]

First, the effect of coextracted matrix components was evaluated (Table 4). Recoveries for all four analytes at three representative concentrations ranged from 83 to 102% as determined by comparing conductivity peak areas for each calibration standard spiked with mustard extracts containing the corresponding standard prepared in deionized water (Table 4).

The effect of oil content in mustard seed on method performance was then evaluated. Concentrations of sinigrin in whole mustard seed (sample Bj_5) with 40% oil content did not differ significantly from sinigrin concentrations in the same DF seed meal (155 ± 4 vs 152 ± 2 $\mu$mol/g DF meal, respectively). Concentrations of sinalbin in whole mustard seed (sample Sa_4) with 29% oil content did not differ significantly from sinigrin concentrations in the same DF seed meal (165 ± 3 vs 165 ± 2 $\mu$mol/g DF meal, respectively) (data not shown). These results demonstrate that the proposed method can be used for the analysis of mustard meals with a wide range of oil contents. The possibility of analysis with no required oil removal shortens overall analysis time.

Finally, the effect of methanol evaporation on glucosinolate concentrations was evaluated. The two most commonly used

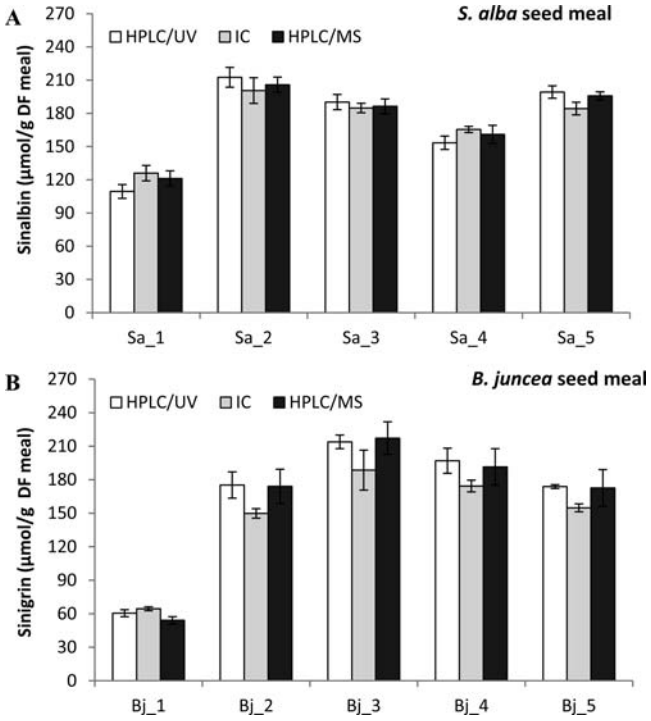

**Figure 4.** Concentrations of sinalbin in *S. alba* Sa_1−Sa_5 samples (A) and sinigrin in *B. juncea* Bj_1− Bj_5 samples (B) in mustard meal determined by the developed IC method as compared with ISO 9167-1 HPLC/UV and HPLC/TOF MS methods. Concentration is expressed as a mean value of three replicates with a verticle line representing the associated standard deviation for that mean.

procedures for the extraction of intact glucosinolates from mustard meals are extraction with boiling water and extraction with 73% aqueous methanol. High temperature and methanol prevent enzymatic hydrolysis of intact glucosinolates by myrosinase naturally present in mustard. When glucosinolates are extracted by boiling water, the filtered supernatant can be analyzed by IC with no additional sample preparation. However, during boiling extraction mustard meal can swell up to 400% by weight and a colloidal suspension may be formed. Also, a significant amount of protein (constituting up to 45% of mustard meal by weight) coextracted by boiling water may interfere with analysis and typically requires precipitation with lead acetate or barium acetate.[24] The use of methanol reduces the formation of colloids and minimizes coextraction of proteins. However, when aqueous methanol is used, methanol should be removed, and extracts require

reconstitution in water prior to IC injection. On the basis of the HPLC/TOF MS analysis of methanolic *B. juncea* extracts and corresponding evaporated and reconstituted in water extracts, no significant differences were found and, consequently, no loss of glucosinolates by evaporation was observed (Figure 5). The relative standard deviation for both sets of extracts did not exceed 8%.

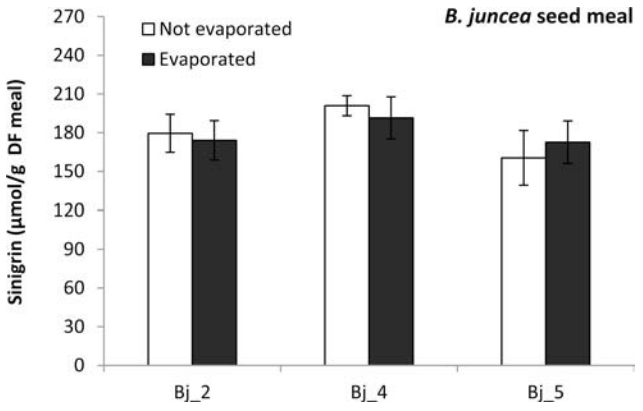

**Figure 5.** Effect of evaporation on sinigrin concentrations in *B. juncea* seed meal (Bj_2, Bj_4, and Bj_6 meal samples) as determined by the HPLC/TOF MS method. Concentration is expressed as a mean value of three replicates with a verticle line representing the associated standard deviation for that mean.

**Stability of Sample Extracts.** The stability of the extracts was evaluated during a 24 h time period, which is a reasonable time interval for sample preparation and analysis that includes a sample preparation time of <90 min and an analysis run time of 10 min (Figure 6). Samples of three representative concentrations (0.1, 0.5, and 1.0 mM) covering the expected concentration range of detected glucosinolates in mustard meal extracts were analyzed immediately after preparation and again at 3, 6, 12, and 24 h. On the basis of the results of Student's *t*-test, peak areas of all four analytes at the three representative concentrations were not significantly different from the corresponding peak areas of freshly prepared samples (Figure 6).

**Glucosinolate Hydrolysis in Solutions of Varied Methanol Concentrations.** One application for the proposed method is monitoring glucosinolate hydrolysis during extraction of biopesticidal compounds from mustard meal. To prepare extracts with the highest concentration of biologically active compounds, glucosinolate hydrolysis and recoveries of hydrolysis products are monitored. Intact glucosinolates are typically extracted with 70% methanol, whereas lower methanol concentrations result in partial glucosinolate hydrolysis and the associated production of multiple hydrolysis products. Thus, to demonstrate the applicability of the proposed IC method, we assessed the extent of glucosinolate extraction and hydrolysis in aqueous solutions containing 10, 40, and 70% methanol by quantifying sinigrin, sinalbin, $SCN^-$, and $SO_4^{2-}$ by the proposed IC method (Figure 7). On the basis of stoichiometric conversion of glucosinolates to $SO_4^{2-}$ (Figure 1), the mass balance was within 90% of that expected for both mustards (Figure 7). For *S. alba* seed, the use of $SCN^-$ or $SO_4^{2-}$ resulted in similar total moles of products. These results demonstrate the use of ion chromatography for simultaneous analysis of intact mustard glucosinolates and their anionic hydrolysis products, providing a technique with high utility for studies involving the hydrolysis of glucosinolates contained in mustard seed and seed meals.

The proposed method can be used for the fast analysis of intact glucosinolates in mustard seeds and meals for screening and quality control. The method may also be useful for

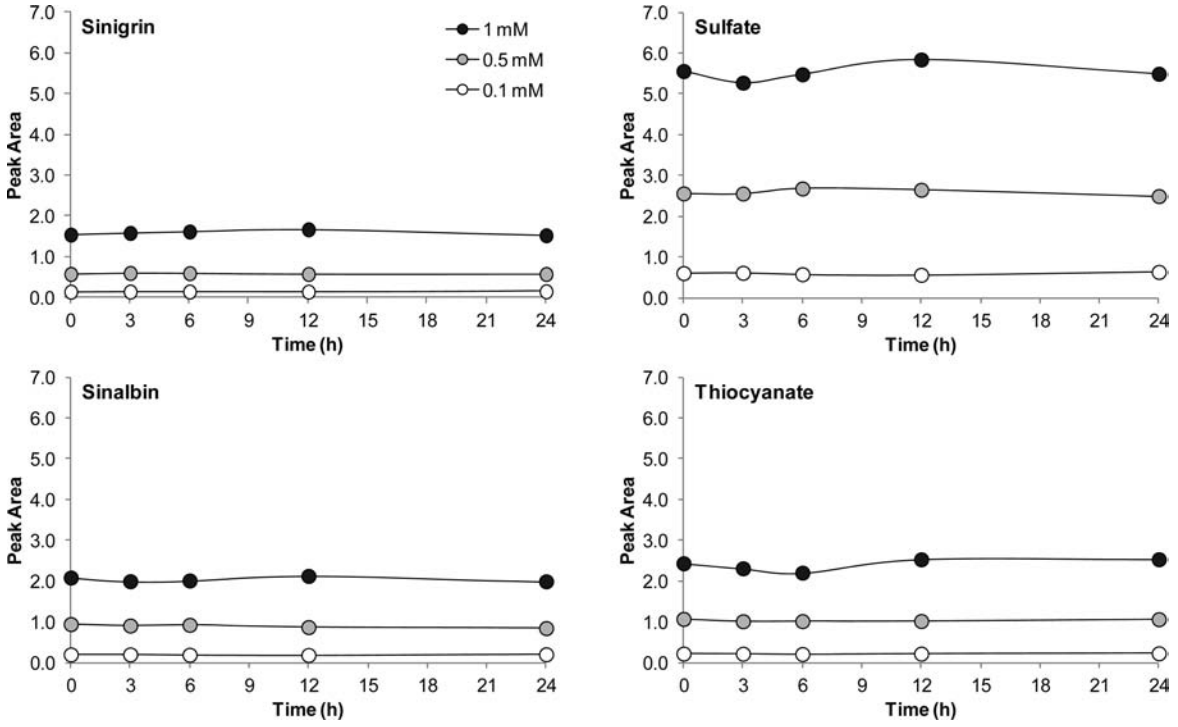

**Figure 6.** Stability of mustard glucosinolates $SO_4^{2-}$ and $SCN^-$ in sample extracts within 24 h of sample preparation. Peak areas are expressed as a mean value of three replicates. Standard deviations are smaller than the symbol for each respective mean and are therefore not shown.

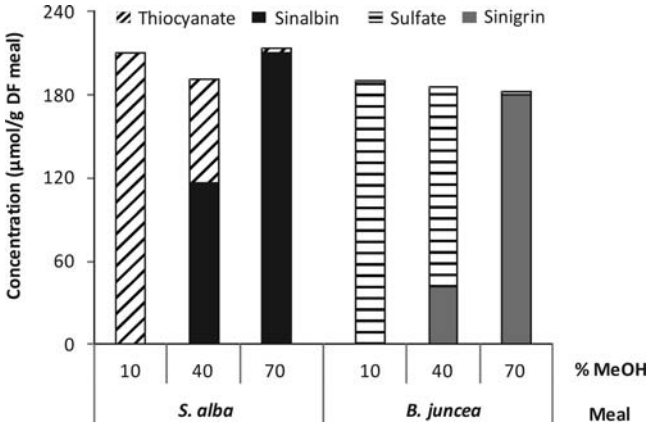

**Figure 7.** Concentrations (μmol/g DF meal) of intact glucosinolates and anionic hydrolysis products in *S. alba* and *B. juncea* hydrolysates with different methanol contents.

studying enzyme kinetics using glucosinolate−myrosinase systems. To the best of our knowledge, the proposed IC procedure is the only reported method that allows for simultaneously monitoring intact glucosinolates and their anionic hydrolysis products in the same sample extract in one chromatographic run.

and pancreatin were purchased from Wako Pure Chemical Industries Ltd. (Osaka, Japan). Phosphatidylcholine and lysozyme (Ly) were obtained from Kewpie Corp. (Tokyo, Japan).

**Animals, Diets, and Permanent Thoracic Lymph Duct Cannulation.** Seven-week-old male Sprague−Dawley rats (Kud:SD) were obtained from Kyudo (Kumamoto, Japan). The rats were housed individually in metal cages in a temperature-controlled room (21−23 °C) under a 12 h light/dark cycle. Experimental diets were prepared according to the recommendations of the AIN-93G[17] and contained the following ingredients (in weight, %): casein or EWP (20), $\alpha$-cornstarch (13.2), sucrose (10), cellulose (5), mineral mixture (3.5), vitamin mixture (1), choline bitartrate (0.25), soybean oil (7), cholesterol (0.5), cholic acid (0.125), *tert*-butylhydroquinone (0.0014), and $\beta$-cornstarch (39.4236). The rats were trained to consume the casein diet as a basal diet twice a day from 10:00 to 11:00 a.m. and from 4:00 to 5:00 p.m., respectively, for 5 days. On day 6, the rats were anesthetized using nembutal before permanent cannulation of the thoracic duct lymph, as described previously.[14,15] In brief, a cannula [SH silicon tube, 0.5 mm inner diameter (i.d.) and 1.0 mm outer diameter (o.d.), Kaneka Medics, Osaka, Japan] filled with heparinized saline was inserted into the thoracic duct and secured within the abdominal cavity. After surgery, the rats were returned to their cages and provided free access to isotonic glucose solution (139 mM glucose and 85 mM NaCl in distilled water). On days 7 and 8, the rats were provided with the casein diet twice a day, as described. On day 9, the rats were attached to a long polyethylene cannula (0.58 mm i.d. and 0.97 mm o.d.; Becton, Dickinson, and Co., Franklin Lakes, NJ, USA). The end of the cannula was 5−10 cm below the bottom of the cage to allow the lymph to drain. After a 20 min collection period, the rats were provided free access to the casein diet or the EWP diet for 30 min. Then, the lymph was collected every hour for 7 h. The rats had free access to deionized water throughout the feeding periods and during lymph collection. The collected lymph was maintained at 4 °C overnight before the fibrin was removed, and the samples were stored at −30 °C until lipid analysis. Following lymph collection, the rats were anesthetized with nembutal and sacrificed by exsanguination. This experiment was conducted according to the Guidelines for Animal Experiments of Kyushu University (Fukuoka, Japan) and the law (no. 105) and notification (no. 6) of the government of Japan. The authorization number was A19-195-0.

**Lymphatic Lipid Transport Measurement.** Total cholesterol, triacylglycerol (TAG), and phospholipid levels in the lymph were measured using commercial enzyme assay kits (T-CHO Kainos from Kainos Laboratories, Inc., Tokyo, Japan; Triglyceride E-Test and Phospholipid C-Test from Wako Pure Chemicals, Tokyo, Japan). If the lymphatic lipid levels exceeded the range of a standard curve, the lymph was diluted with physiological saline and retested.

**Preparation of Micellar Solutions.** Micellar solutions containing 6.6 mM sodium taurocholate, 0.6 mM phosphatidylcholine, 50 $\mu$M cholesterol, 1.0 mM oleic acid, 0.5 mM monoolein, and 132 mM NaCl in 15 mM sodium phosphate buffer (pH 6.8) were prepared by sonication. The micelles were passed through a 0.2 $\mu$m syringe filter (DISMIC-25CS, Toyo Roshi Kaisha Ltd., Tokyo, Japan) and maintained at 37 °C for 24 h for stabilization of the micelles.

**Preparation of Casein, EWP, and EWP Constituent Protein Hydrolysates.** Ten grams of casein, EWP, OA, OT, OM, and Ly was hydrolyzed by 400 mL of experimental gastric juice [0.1% (w/v) pepsin in 100 mM KCl] at pH 2.0 with HCl and 37 °C for 24 h.[18] The reaction mixtures were adjusted to pH 7.0 with 1 M KOH, freeze-dried, and powdered to obtain casein pepsin hydrolysate (C-ph), EWP pepsin hydrolysate (EWP-ph), OA pepsin hydrolysate (OA-ph), OT pepsin hydrolysate (OT-ph), OM pepsin hydrolysate (OM-ph), and Ly pepsin hydrolysate (Ly-ph). The degree of hydrolysis of casein and EWP was determined by SDS-PAGE. The protein content of casein, C-ph, EWP, and EWP-ph was determined according to the method discussed by Lowry et al.[19] The samples in the SDS-PAGE sample buffer were incubated at 95 °C for 5 min using a thermal cycler, and 5 $\mu$g of protein from each sample was then electrophoresed on a 5−20% gradient polyacrylamide gel. The gel was stained using a silver staining kit (Wako Pure Chemical Industries Ltd.).

**Micellar Solubility of Cholesterol in Vitro.** The micellar solubility of cholesterol was measured according to the method of Ikeda et al.[20] A solution containing C-ph, EWP-ph, ovalbumin, ovotransferrin, ovomucoid, or lysozyme was added to the micelles. In the experiments shown in Figure 3A,C, the samples were added at a final concentration of 10 mg/mL to the micelles. In the experiment shown in Figure 4A, the samples were added at a final concentration of 5 mg/mL to the micelles. In the experiment shown in Figure 4B, EWP-ph was added at a final concentration of 10 mg/mL to the micelles, whereas the reconstituted EWP-ph was added at a final concentration of 8 mg/mL to the micelles. In accordance with a previous study,[21] the reconstituted EWP-ph included 54% OA-ph, 13% OT-ph, 11% OM-ph, and 3.5% Ly-ph. The samples were incubated at 37 °C for 1 h and passed through the 0.2 $\mu$m syringe filter. In the experiment shown in Figure 3A, pancreatin was added at a final concentration of 0.15 mg/mL during the incubation time. After lipid extraction from the filtrate, cholesterol levels were measured by gas chromatography (GC).[20]

**Transfer of Cholesterol from the Bile Acid Micelle to Triolein.** The transfer rate of triolein to cholesterol was measured according to the method of Hamada et al.[22,23] One and a half milliliters of the micellar solution, 0.5 mL of triolein, and C-ph or EWP-ph (final concentration, 10 mg/mL) were placed in a plastic tube, which was flushed with $N_2$ and sealed. The tubes were incubated at 37 °C for 1 h with shaking. After incubation, the contents of each tube were transferred to a sealed tube, and the oil and aqueous phases were separated by centrifugation at 100000*g* for 1 h at 37 °C. The oil and micellar phases were collected, and the cholesterol levels in each phase were analyzed by GC using 5$\alpha$-cholestane as an internal standard.

**Water-Holding Capacities (WHCs) of Casein, EWP, and Its Pepsin Hydrolysate.** The WHCs of casein, EWP, C-ph, and EWP-ph were measured as described previously.[24] Samples (0.1 g) were placed on two filter papers fitted in a stainless steel container (hole diameter, 2.5 cm; diameter, 5 cm; height, 1.5 cm) with a polypropylene net. This weight was measured as dry weight. After being placed in a case with distilled water for 24 h at room temperature, the container was removed and weighed. The WHCs of casein, EWP, C-ph, and EWP-ph were evaluated by measuring the difference between the wet and dry weights. Each measurement was repeated three times.

**Settling Volumes (SVs) in Water of Casein, EWP, and Its Pepsin Hydrolysate.** The SVs of casein, EWP, C-ph, and EWP-ph were measured as described previously.[24] Samples (7 mg) were blended with 7 mL of distilled water in 10 mL graduated cylinders. The cylinders were left to stand for 24 h at room temperature. The SVs of casein, EWP, C-ph, and EWP-ph were evaluated on the basis of precipitation volume. Each measurement was repeated three times.

**Viscosities of Casein, EWP, and Its Pepsin Hydrolysate.** The viscosities of casein, EWP, C-ph, and EWP-ph were measured using an Ostwald viscometer (Sansyo Co., Ltd., Tokyo, Japan) with a 0.75 mm capillary diameter, as described previously.[24] Samples (1 g) were blended with distilled water. After being stored for 24 h at room temperature, 1% (v/v) suspending solutions were prepared in 100 mL volumetric flasks. The solutions were preheated at 37 °C for 15 min and the flow times determined. Each measurement was repeated three times. The viscosities of casein, EWP, C-ph, and EWP-ph were calculated relative to the viscosity of distilled water.

**Statistical Analysis.** All values are expressed as the mean ± standard error of mean (SEM). Comparisons between two groups were performed by Student's *t* test, whereas those among more than three groups were performed by using one-way ANOVA followed by the Tukey−Kramer multiple-comparison post hoc test. Differences were considered to be significant at $P < 0.05$. Statistical analysis was performed using StatView version 4.5 (Abacus Concept Inc., Berkeley, CA, USA).

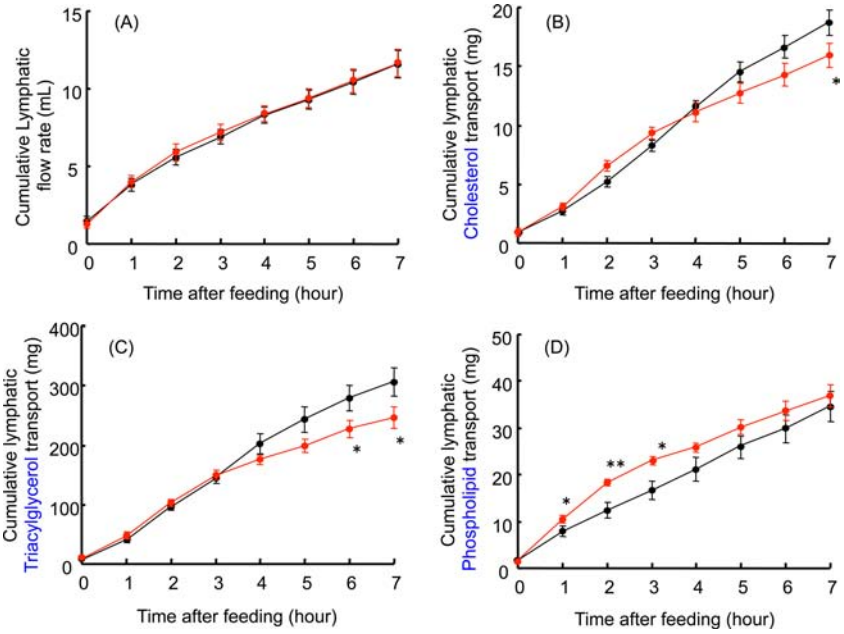

**Figure 1.** Cumulative lymph flow (A), lymphatic transport of cholesterol (B), triacylglycerol (C), and phospholipids (D) in rats fed diets containing casein (black circles) or EWP (red circles). Values are expressed as the mean ± SEM for six rats. (∗) $P < 0.05$ and (∗∗) $P < 0.01$ versus casein group by Student's $t$ test.

## RESULTS

**Effects of Dietary EWP on Lymphatic Lipid Transport.** The two groups of rats did not differ in final body weight (casein, 232.3 ± 3.7; EWP, 228.4 ± 6.5 g). The rats consumed the casein and EWP diets for 30 min (4.6 ± 0.3 and 4.4 ± 0.4 g, respectively). Figure 1 shows the cumulative lymph flow and lipid transport. There was no significant difference in lymph flow (Figure 1A). The lymphatic transport of total cholesterol at 7 h (Figure 1B) and TAG at 6 and 7 h (Figure 1C) after feeding was significantly decreased in the EWP group compared with that in the casein group. In addition, the lymphatic transport of phospholipids at 1, 2, and 3 h after feeding was significantly increased in the EWP group compared with that in the casein group (Figure 1D).

**Degree of Hydrolysis of Casein and EWP by Pepsin.** Figure 2 shows the degree of hydrolysis of casein and EWP by pepsin. Two bands were recognized in the gel. These bands were identified as ovalbumin (45 kDa) and lysozyme (14.3 kDa) in EWP-ph.[25] The casein was almost digested with pepsin.

**Effects of EWP Pepsin Hydrolysate and EWP Constituent Protein Pepsin Hydrolysates on the Micellar Solubility of Cholesterol.** EWP-ph significantly inhibited the micellar solubility of cholesterol to a greater extent than C-ph did (Figure 3A). There was no effect of pancreatin on micellar solubility (Figure 3A). The inhibitory effect of EWP-ph on micellar solubility was dose-dependent and reached a plateau at a final concentration of 10 mg/mL (Figure 3B). There was no effect of the presence of phosphatidylcholine in bile acid micelles on micellar solubility (Figure 3C). Compared with C-ph, EWP-ph, OA-ph, and OT-ph significantly inhibited micellar solubility (Figure 4A). Furthermore, there was no significant difference in micellar solubility between EWP-ph and reconstructed EWP-ph (Figure 4B).

**Effects of EWP on Transfer of Cholesterol from Micelles to Triolein.** EWP-ph significantly inhibited the transfer of cholesterol from micelles to triolein (Figure 5). That is, EWP-ph inhibited cholesterol monomer release from micelles.

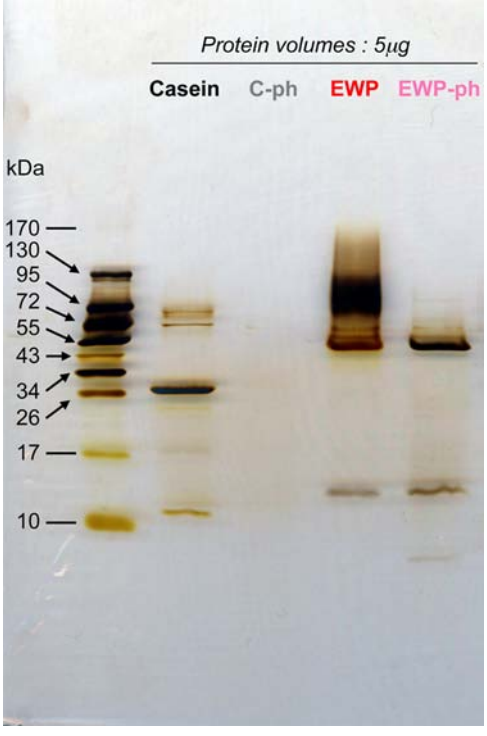

**Figure 2.** Results of electrophoresis of casein, EWP, and its pepsin hydrolysate.

**Effects of EWP and Its Pepsin Hydrolysate on Water-Holding Capacity, Settling Volume in Water, and Relative Viscosity.** Table 1 summarizes the effects of EWP and its pepsin hydrolysate on WHC, SV, and relative viscosity. There was no significant difference in WHC between casein and EWP. However, the WHC of EWP-ph was approximately

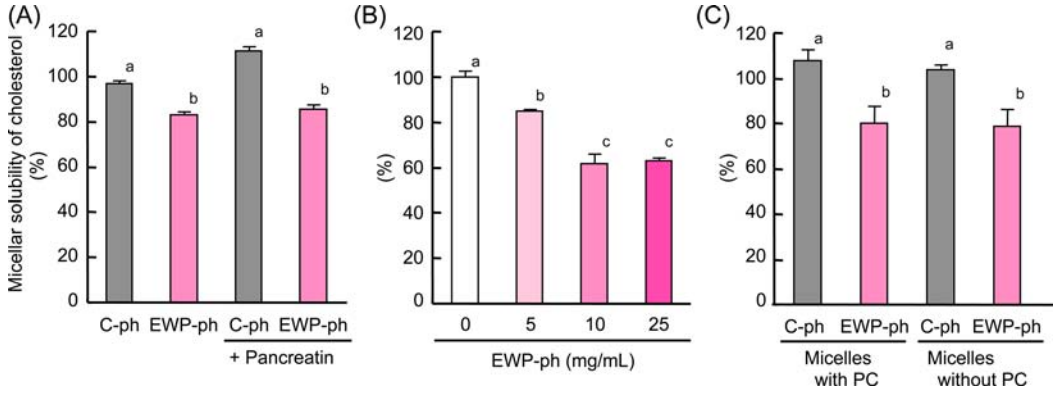

**Figure 3.** Effects of EWP hydrolysate on the micellar solubility of cholesterol in vitro: (A) effects of EWP pepsin hydrolysate or EWP pepsin + pancreatin hydrolysate; (B) dose-dependent effects of EWP pepsin hydrolysate; (C) effects of phosphatidylcholine containing the micelles. C-ph, casein pepsin hydrolysate; EWP-ph, egg white protein pepsin hydrolysate; PC, phosphatidylcholine. Data were calculated using the following formula: micellar cholesterol contents incubated with protein/micellar cholesterol contents incubated without protein × 100. Values are expressed as the mean ± SEM for three samples. Different letters (a–c) show a significant difference by the Tukey–Kramer test ($P < 0.05$).

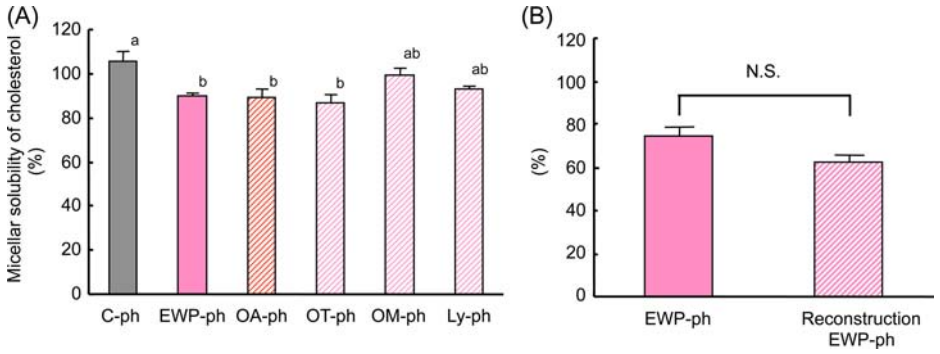

**Figure 4.** Effects of EWP constituent protein pepsin hydrolysates and reconstructed EWP-ph on the micellar solubility of cholesterol in vitro: (A) effects of EWP-ph and EWP constituent protein pepsin hydrolysates (each protein was added at a final concentration of 5 mg/mL); (B) effects of EWP-ph and reconstruction EWP-ph (reconstructed EWP-ph included 54% OA-ph, 13% OT-ph, 11% OM-ph, and 3.5% Ly-ph; EWP-ph was added at a final concentration of 10 mg/mL; reconstruction EWP-ph was added at a final concentration of 8 mg/mL). C-ph, casein pepsin hydrolysate; EWP-ph, egg white protein pepsin hydrolysate; OA-ph, ovalbumin pepsin hydrolysate; OT-ph, ovotransferrin pepsin hydrolysate; OM-ph, ovomucoid pepsin hydrolysate; Ly, lysozyme pepsin hydrolysate. Data were calculated using the following formula: micellar cholesterol contents incubated with protein/micellar cholesterol contents incubated without protein × 100. Values are expressed as the mean ± SE for three samples. Different letters(a–c) show a significant difference by the Tukey–Kramer test ($P < 0.05$).

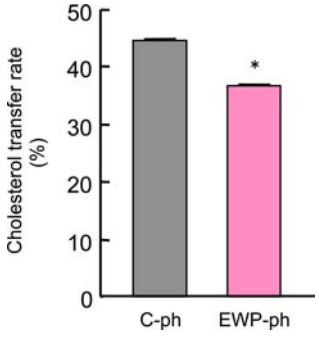

**Figure 5.** Effects of EWP-ph on the transfer of micellar cholesterol to triolein in vitro. Data were calculated using the following formula: cholesterol contents in the triolein phase/original micellar cholesterol contents × 100. Values are expressed as the mean ± SEM for three samples. (*) $P < 0.05$ versus casein group by Student's $t$ test.

7.6 times higher than that of C-ph. In addition, the SV of casein was higher than that of EWP, whereas the SV of EWP-ph was approximately 4.5 times higher than that of C-ph. In accordance with the behavior of SV, the relative viscosity of casein was higher than that of EWP, whereas that of EWP-ph was significantly higher than that of C-ph.

## DISCUSSION

We confirmed that dietary EWP inhibited intestinal cholesterol absorption in thoracic lymph duct-cannulated rats (Figure 1B). These data supported the serum and hepatic cholesterol-lowering action of EWP in our previous paper.[11] In that previous paper, evidence for the inhibition of cholesterol absorption was the fecal excretion of neutral steroids in rats fed the 20% EWP diet compared with that in rats fed the 20% casein diet. Most of the dietary lipids are absorbed in the proximal small intestine and then transported by the lymphatic system. We hypothesized that EWP hydrolysate by pepsin in the stomach may play a major contributing role to the inhibition of cholesterol absorption by EWP. To test the hypothesis, we prepared EWP-ph and then conducted the in vitro experiments. The results showed that EWP-ph inhibited the micellar solubility of cholesterol (Figures 3A–C and 4A) and cholesterol monomer release from micelles (Figure 5). In addition, there was no effect of pancreatin on the micellar solubility of cholesterol (Figure 3A).

Table 1. Water-Holding Capacities, Settling Volumes in Water, and Relative Viscosities of Casein, EWP, and Its Pepsin Hydrolysate[a]

| | casein | EWP | C-ph | EWP-ph |
|---|---|---|---|---|
| water-holding capacity [wet (g)/dry (g)] | 2.87 ± 0.03a | 2.87 ± 0.13a | 0.32 ± 0.09b | 2.11 ± 0.09c |
| settling volume (mL/g) | 4.14 ± 0.22a | 0.95 ± 0.13b | 1.80 ± 0.17b | 8.09 ± 0.34c |
| relative viscosity ($\eta$) | 1.115 ± 0.000a | 1.096 ± 0.001b | 1.054 ± 0.001c | 1.059 ± 0.001d |

[a]Different letters (a–d) show a significant difference by the Tukey–Kramer test. Mean ± SE of three samples.

The hypocholesterolemic manners of EWP resemble those of plant sterols, which have hypocholesterolemic activity.[12,23] The efficiency of lymphatic cholesterol transport inhibition by $\beta$-sitosterol, a major plant sterol, was 57% in thoracic lymph duct-cannulated rats administered lipid emulsions in the stomach.[12] The efficiency of a hypocholesterolemic effect of $\beta$-sitosterol in rats fed a 0.5% cholesterol-containing diet for 2 weeks was 21%.[26] According to a comparison of these calculated data, it was estimated that dietary $\beta$-sitosterol inhibited intestinal cholesterol absorption more strongly than dietary EWP did. However, the hypocholesterolemic effect of dietary plant sterol was similar to that of dietary EWP. To assess intestinal lipid absorption, the administration of two types of diets containing lipids and infusion lipid emulsions into the stomach or duodenum was used. The method that used lipid emulsions failed to consider the interaction of the lipid emulsion with other dietary components, particularly proteins and carbohydrates.[27] Therefore, differences in the methods of administration may contribute to the fact that the hypocholesterolemic effects of dietary plant sterols and EWP were similar. Otherwise, EWP may have other functions for the hypocholesterolemic effect. It has been reported that a commercially available EWP hydrolysate produced by microbial proteases, with an average molecular weight of approximately 1100, as well as EWP, have hypocholesterolemic effects in rats and mice.[28] In this study, the hypocholesterolemic effect of EWP through its physicochemical properties depended on its protein structure, which resisted protease digestion in the gut and inhibited intestinal cholesterol absorption. The commercial EWP hydrolysate primarily comprises peptides and amino acids. The hypocholesterolemic effect of the hydrolysate may be exerted on the intestinal mucosa after absorption as smaller size peptides except for the physiological properties of the hydrolysate described above.

Many studies have reported that other dietary proteins such as soy protein isolate[29] and whey protein[30] can provide several peptides that can exert a hypocholesterolemic effect. Therefore, some peptides derived from EWP may have a hypocholesterolemic effect inside animal bodies. In this study, the efficiency of the inhibition of lymphatic cholesterol transport was approximately 14%. In the previous study, the decrease in serum cholesterol levels in rats fed the EWP diet was approximately 17%.[11] The serum cholesterol-lowering activities of several dietary proteins compared with those of casein were found to depend on their amino acid compositions.[31] Serum cholesterol levels were found to be similar in rats fed a casein diet supplemented with cystine as an amino acid rich in EWP and those fed a casein diet, as described in the previous paper.[11] To exert the serum cholesterol-lowering action of EWP, protein structures, including the primary structure, may be important; however, the amino acid composition does not obviously. Further studies are needed to investigate whether a reconstructed amino acid mixture of the EWP amino acid composition has a hypocholesterolemic effect. Therefore, we concluded that the primary mechanism underlying the hypocholesterolemic effect of dietary EWP was the inhibition of dietary cholesterol absorption.[11] In addition, in this study, lymphatic cholesterol transport was decreased by dietary EWP (Figure 1B).

As shown in Figure 2, there were proteins that were resistant to pepsin in EWP. On the other hand, there was no band in the C-ph lane. Two major bands were recognized in the EWP lane after pepsin digestion (EWP-ph lane). These bands were individually identified as ovalbumin (MW 45 kDa) and lysozyme (MW 14.3 kDa). EWP contains 54% ovalbumin and 3.5% lysozyme.[21] Ovalbumin is the most abundant protein in EWP. Ovalbumin almost remained in EWP digestion by pepsin. We attempted to do a reverse experiment. A reconstructed EWP-ph was used; four pepsin hydrolysates of the EWP protein components were mixed with the EWP-ph while considering an intact ratio for the EWP composition, as described in Figure 4. The cholesterol micellar solubility was found to be similar for reconstructed EWP-ph and EWP-ph (Figure 4B). There was no ingredient in EWP that altered the solubility. According to the results of inhibition of cholesterol-micellar solubility, ovalbumin is responsible for the cholesterol-lowering activity. The solubility of EWP-ph was as low as that of OA-ph (Figure 4A). Ovalbumin may pass through the intestine, as evidenced by difficulty in its digestion according to the results of the in vitro protease digestion experiment (Figure 2). When EWP was the only dietary protein source in the rats fed the EWP diet, approximately half the dietary protein could not be absorbed. However, in the previous study, body weight gain in rats fed the EWP diet was not different from that in rats fed the casein diet.[11]

From the perspective of nutrition, the EWP diet supplemented with biotin did not cause growth inhibition in animal models, similar to that observed with egg white injury. It was reported that nitrogen excretion in the feces of rats fed EWP was not high.[32] Furthermore, EWP exhibits greater net protein utilization compared with other protein sources.[32] It has also been reported that EWP includes protease inhibitors.[33] Protease inhibition by EWP components or ovalbumin may be selective for proteases during gastric digestion. In this study, ovalbumin was resistant to stomach pepsin, but it may not be resistant to the other proteases in the intestine.

We newly observed that EWP inhibited lymphatic triacylglycerol (TAG) transport (Figure 1C). This observation reflected on serum and hepatic TAG levels from the previous study, where the efficiency of inhibition in rats fed the EWP diet for 3 weeks was 26 and 37%, respectively.[11] However, there were no significant differences in serum and hepatic TAG levels between the casein and EWP diets. These TAG-lowering effects were not observed in rats fed the EWP diet for 1 week; however, the hypocholesterolemic effect of EWP was evident. Ovalbumin has a pancreatic lipase inhibitory activity.[34] It is not digested by pepsin in the stomach because of its protease inhibitory activity as described above; it reaches the intestine to

act as a lipase inhibitor. Therefore, the intestinal absorption and lymphatic transport of TAG decreased and serum and hepatic TAG levels decreased. The difference in sensitivities for the inhibition of intestinal absorption of dietary cholesterol and TAG may rely on the feeding periods. The inhibition of cholesterol absorption may be more sensitive to its accumulation in the animal body compared with the inhibition of TAG.

As shown in Figure 1D, the mechanisms underlying temporal promotion of lymphatic phospholipid transport are not clear for the EWP diet without phospholipids. The rats may have temporarily experienced a condition of less intestinal phospholipid from 1 to 4 h after consuming the EWP diet. As shown in Figure 3C, there was no effect of the presence of PC in the bile acid micelles on the micellar solubility of cholesterol. Also, EWP-ph has better physicochemical properties of WHC, SV, and relative viscosity compared with casein and C-ph. These characteristics of EWP-ph are similar to those of water-soluble fibers such as guar gum.[24] Under alkaline conditions, fatty acids, water, and EWP combine in the intestine after ingestion, and EWP turns into a gel because of its physicochemical properties.[35−39] According to these results and information, the gel form of EWP may hold the micelles. Moreover, the gel mixture that contained EWP, fatty acids, and water may lead to inhibited fatty acid absorption. The time-dependent effect of dietary EWP on lymphatic transport of lipids was totally exerted after 3 h of feeding. In research on the effects of dietary protein on gastric emptying, compared to casein, gluten, and fish protein, whey protein delays gastric emptying time to suppress plasma FFA levels because of their controlling gastric hormone secretion and/or their physicochemical properties such as solubility of acidic solution.[40] Physicochemical properties and stimulation of gastric hormone secretion of dietary protein influence gastric emptying time, and then the influences reach intestinal absorption of nutrients. In fact, the protein form of EWP partly remained after the digestion (Figure 2). In the early phase of lipid transfer, EWP may stay in the stomach and the TAG and cholesterol may reach the duodenum more rapidly than EWP-ph. In the late phase, EWP-ph may exert effects of inhibition of intestinal lipid absorption. In this study, the lymphatic phospholipids may be derived from bile, intestinal mucosa exfoliation, bacterial flora, etc., but not from the diets and stomach. The lymphatic phospholipid transport may primarily suffer from the influence of phase shifting of gastric emptying. Taken together, the differences of the time course of lymphatic lipid transport may depend on the differences of gastric emptying time of protein. These mechanisms remain a hypothesis. Therefore, we have to organize acceptable plans for each dietary lipid in future studies.

The efficiency of intestinal cholesterol absorption is approximately 50%.[17,41] It assumes a one-to-one relationship between a passive diffusion process and a process through the Niemann−Pick C1-like 1 (NPC1L1) protein, a cholesterol transporter.[17,41] Possible findings about the effect of dietary EWP on NPC1L1 would be of great interest for future study, although none of the studies have shown that dietary components inhibit NPC1L1 protein. Further studies are also needed to investigate whether dietary EWP affects the assembly and secretion of chylomicrons.

In summary, dietary EWP inhibited dietary cholesterol absorption via decreased cholesterol passage in and out of the micelles and increased WHC, SV, and relative viscosity. Ovalbumin, a major protein in EWP, resisted protease digestion and may possess properties capable of exerting a hypocholesterolemic effect.

kaempferol 3-O-(2''-glucopyranosyl)-rutinoside kaempferol 3-O-(2''-xylopyranosyl)-rutinoside

**Figure 1.** Structures of two phytochemicals in fraction 3 from the methanol extracts of tea seed pomace from *Camellia tenuifolia*: kaempferol 3-*O*-(2″-glucopyranosyl)-rutinoside and kaempferol 3-*O*-(2″-xylopyranosyl)-rutinoside.

Given that it is an inexpensive and residual resource, we explored the potential beneficial health effects from the main biowaste, tea seed pomace, produced when tea seed from *C. tenuifolia* is processed. DPPH radical scavenging and total phenolic content assays were performed to evaluate the in vitro activities of the extracts. *C. elegans* was used as an in vivo model to evaluate the beneficial health effects, including antioxidant activity, delayed aging, and reduced amyloid-$\beta$ toxicity.

## MATERIALS AND METHODS

**Plant Materials.** All chemicals unless otherwise stated were purchased from Sigma-Aldrich (Poole, Dorset, UK). Tea seed pomace of *C. tenuifolia* was collected in October 2011 from the *Camellia* tree farm located in Taichung county, Taiwan. The species were identified by the Taiwan Forestry Research Institute.

**Tea Seed Pomace Extract Preparation and Identification of Compounds.** The dried samples (in triplicate 100 g batches) were incubated with water, hot water (100 °C), ethyl acetate (EtOAc), ethanol (EtOH), *n*-hexane (Hex), and methanol (MeOH) at room temperature for 1 h (sample/solvent = 1:5). The extracts were decanted, filtered under vacuum, concentrated in a rotary evaporator, and then lyophilized. The MeOH-soluble fraction was further divided into six fractions (1−6) by chromatography with a Diaion HP-20 column eluted with water/MeOH (gradient elution was performed by changing from 100/0 to 0/100).

The phytochemicals from fraction 3 were separated and purified by semipreparative high-performance liquid chromatography (HPLC) on an Agilent model 1100 pump equipped with a UV detector (Agilent 1100) and a 250 mm × 10.0 mm i.d., 5 $\mu$m, Luna RP-18 column (Phenomenex, Torrance, CA, USA). The mobile phase used was solvent A (ultrapure water) and solvent B (MeOH). Elution conditions were 0−5 min, 55% B (isocratic gradient); 5−20 min, 55−65% B (linear gradient); 20−30 min, 65−100% B (linear gradient). ESI-MS data were collected using a Finnigan LCQ mass spectrometer, and NMR spectra were recorded by a Bruker AVIII 500 MHz FT-NMR spectrometer. The structures of chemical compounds (as shown in Figure 1) were identified by ESI-MS and NMR, and the data were consistent with those reported in the studies.[16,17]

**1,1-Diphenyl-2-picrylhydrazyl (DPPH) Free Radical Scavenging Assay.** The DPPH free radical scavenging activities of MeOH extracts and their derived fractions were measured. Extracts with a series of concentrations were dissolved in EtOH (50 $\mu$L) and mixed with 1000 $\mu$L of 0.1 mM DPPH−EtOH solution and 450 $\mu$L of 50 mM Tris-HCl buffer (pH 7.4). EtOH (50 $\mu$L) was used as the control for this experiment. After 30 min of incubation at room temperature, the reduction of the DPPH free radical was determined by reading the absorbance at 517 nm. Ascorbic acid, a well-known antioxidant, was used as the positive control, and the inhibition ratio (%) was calculated as follows:

$$\%\ \text{inhibition} = [(\text{absorbance of control} - \text{absorbance of test sample})/\text{absorbance of control}] \times 100$$

Each test was repeated three times, and the results were averaged.

**Determination of Total Phenolic Contents.** Total phenolic contents were analyzed according to the Folin−Ciocalteu method, using gallic acid as a standard. The samples were dissolved in 10 mL of EtOH/water (50:50, v/v). Subsequently, the sample solution (0.5 mL) was mixed with 0.5 mL of 1 N Folin−Ciocalteu reagent and then incubated at room temperature for 5 min followed by the addition of 1 mL of 20% $Na_2CO_3$. After 10 min, the mixture was centrifuged for 8 min (12000*g*), and the absorbance of the supernatant was measured at 730 nm. The total phenolic contents were presented as gallic acid equivalents (GAE) in milligrams per gram of test sample. Each test was repeated three times, and the results were averaged.

***C. elegans* Strains and Culture Conditions.** *C. elegans* strains used in this study were Bristol N2 (wild-type) and CL4176 (smg-1ts [myo-3/A$\beta$1−42 long 3′-UTR]). *C. elegans* was maintained and assayed (unless otherwise stated) at 20 °C on nematode growth medium (NGM) agar plates carrying a lawn of *Escherichia coli* OP50. All chemicals in NGM plates and liquid are expressed as the final concentrations.

***C. elegans* Oxidative Stress Resistance Assays.** Oxidative stress assays were performed as previously described.[18−20] Briefly, synchronized wild-type L1 larvae were incubated in liquid S-basal containing *E. coli* OP50 bacteria at $10^9$ cells/mL in the presence or absence of tea seed pomace extracts (1 and 10 $\mu$g/mL) for 72 h at 20 °C followed by 250 $\mu$M juglone (5-hydroxy-1,4-naphthoquinone) (Sigma, St. Louis, MO, USA) exposure for 3 h and then scored for viability. The survival of worms was determined by touch-provoked movement as described.[21] Nematodes were scored as dead when they failed to respond to repeated touching with a platinum wire pick. The test was performed on at least three independent biological replicates.

***C. elegans* Intracellular Reactive Oxygen Species (ROS) Measurement.** *C. elegans* was pretreated with tea seed pomace extracts (1 and 10 $\mu$g/mL) as the oxidative stress assays. After 72 h at 20 °C, nematodes were washed with K-medium three times and then transferred to 500 $\mu$L of K-medium containing 100 $\mu$M CM-$H_2$DCFDA (Molecular Probes, Eugene, OR, USA) for 2.5 h at 20 °C. At least 20 randomly selected worms from each set of experiments were mounted onto microscope slides coated with 3% agarose, anesthetized with 2% sodium azide, and capped with coverslips. Epifluorescence images were captured with an epifluorescence

microscope (Leica, Wetzlar, Germany) using a suited filter set (excitation, 480 ± 20 nm; emission, 510 ± 20 nm) with a cooled charge-coupled device (CCD) camera. Total fluorescence for each whole worm was quantified by Image-Pro Plus software (Media Cybernetics, Bethesda, MD, USA).

***C. elegans* Lifespan Assays.** Lifespan analyses were performed in the same manner for all treatments at 20 °C. Synchronized eggs were placed on fresh NGM plates containing UV-inactivated *E. coli* OP50 in the absence or presence of tea seed pomace extracts (1 and 10 μg/mL), and nematodes were allowed to develop to adulthood. UV inactivation was used to avoid the effects of live *E. coli* on the conditions of tea seed pomace extracts examined in this study.[22] Surviving and dead worms were scored daily (starting on the first day of adulthood) until all nematodes had died. Nematodes that did not move when gently prodded (with a platinum wire) were judged to be dead. Nematodes suffering from internal hatch (a defect in egg laying) and those that crawled off the NGM plate were not included in the lifespan scores. During the reproductive period, adult nematodes were transferred to fresh NGM plates every day and then every other day thereafter. The test was performed on at least three independent biological replicates.

***C. elegans* Paralysis Assays.** Strain CL4176[23] maintained at 16 °C was egg-synchronized onto the NGM plates containing *E. coli* OP50 in the absence or presence of tea seed pomace extracts. At 50 h after egg laying, A$\beta$ transgene expression was induced by increasing the temperature from 16 to 23 °C and continued to the end of the paralysis assays.[23] Paralysis was scored at 2 h intervals until the last worm became paralyzed.[24] The definition of paralysis of worms in this study was that worms exhibited pharyngeal pumping, but failed to complete one sinusoidal turn within 5 s of being touched on the head and tail with a platinum wire.[24] The test was performed on at least three independent biological replicates.

**Statistical Analysis.** Statistical analysis was performed using SPSS Statistics 17.0 software (SPSS, Inc., Chicago, IL, USA; 2008). The results are presented as the mean ± standard errors of mean (SEM). Comparisons and $p$ value calculations were made between treated and untreated animals of the same strain using one-way ANOVA and the LSD post hoc test. Differences were considered significant at $p < 0.05$ (see figures). For the lifespan and paralysis assays, animal survival was plotted using Kaplan–Meier survival curves and analyzed by log-rank test using GraphPad Prism (GraphPad Software, Inc., La Jolla, CA, USA).

## RESULTS AND DISCUSSION

**Solvent Selection.** Direct extraction using various types of solvents is the most common technique employed to obtain extracts with high antioxidant activity from plants. To examine the extraction process of compounds with antioxidant properties from tea seed pomace of *C. tenuifolia*, tea seed pomace was initially extracted by various types of solvents, including $H_2O$ (room temperature), hot $H_2O$ (100 °C), EtOAc, EtOH, Hex, and MeOH.

*C. elegans* was used to investigate whether extracts from different solvents exert oxidative stress resistance. Wild-type N2 *C. elegans* was pretreated with different solvent extracts followed by exposure to juglone-induced oxidative stress. Figure 2 shows that pretreatments with extracts from $H_2O$, hot $H_2O$ (100 °C), EtOH, and MeOH significantly increased the survival of *C. elegans* exposed to juglone-induced oxidative stress (Figure 2). It is noted that the extracts from hot $H_2O$ (100 °C) showed a protective effect at lower dose (1 μg/mL), whereas the higher dose (10 μg/mL) did not. It is possible that the higher concentration of extracts from hot $H_2O$ might be toxic, alleviating the antioxidant effects on wild-type *C. elegans*. Therefore, it is likely that a linear dose–response curve was not observed. Moreover, MeOH extract exhibited the highest *C. elegans* survival against juglone-induced oxidative stress (Figure 2). Herein, we selected the extract from MeOH-extracted tea seed pomace for further investigation.

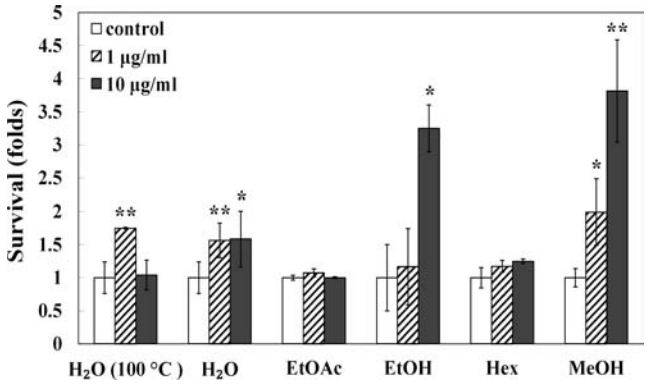

**Figure 2.** Protective effects of tea seed pomace extracts with different solvents extraction on wild-type *C. elegans* N2 under oxidative stress. Synchronized wild-type L1 larvae were pretreated with 1 and 10 μg/mL of different solvent extracts or with 0.1% DMSO as the solvent control for 72 h at 20 °C. Nematodes were then subjected to oxidative stress assays. Tea seed pomace extract-treated (1 and 10 μg/mL) and untreated control nematodes were exposed to 250 μM juglone for 3 h and then scored for viability. Solvents used for the extractions were water ($H_2O$, room temperature), hot water ($H_2O$, 100 °C), ethyl acetate (EtOAc), ethanol (EtOH), *n*-hexane (Hex), and methanol (MeOH). At least three independent biological replicates were performed, and approximately 60–80 worms were scored in each experiment. Data are normalized to the untreated control. Results are presented as the mean ± standard error of mean (SEM). Differences compared to the untreated control were considered significant at $p < 0.05$ (*) and $p < 0.01$ (**) by one-way ANOVA and LSD post hoc test.

**Fraction Selection from the Methanol Extract.** The MeOH extract was further fractionated by column chromatography with a Diaion HP-20 column, and six fractions (1–6) were obtained. For the in vitro assay, the DPPH radical scavenging activity of MeOH-soluble extract and the derived fractions of tea seed pomace were performed. DPPH contains a proton free radical, which significantly reduces on exposure to proton radical scavengers.[25] Therefore, the DPPH assay has been commonly used to examine in vitro antioxidant activity.[26] Figure 3A shows that the lowest $IC_{50}$ value (the concentration required to inhibit radical formation by 50%) was observed in fraction 3 ($IC_{50}$ = 49.5 μg/mL), whereas fraction 4 ($IC_{50}$ = 93.0 μg/mL) and the MeOH-soluble extract ($IC_{50}$ = 133.4 μg/mL) also exhibited good inhibitory effects.

The total phenolic contents were also examined as most plant phenolics are highly effective free radical scavengers and antioxidants. The total phenolics in the MeOH extract and their derived fractions were determined according to the Folin–Ciocalteu method and expressed as GAE. As shown in Figure 3B, fraction 3 showed the highest total phenolic contents (101.2 mg of GAE/g), followed by fraction 4 (99.9 mg of GAE/g) and the MeOH extract (50.1 mg of GAE/g). These results indicated that the free radical scavenging activity of the MeOH extract of tea seed pomace could be effectively enriched in fractions 3 and 4.

For the in vivo assay, the antioxidant activity of the MeOH-soluble extract and their derived fractions was examined in *C. elegans*. Wild-type N2 *C. elegans* was pretreated with 1 and 10 μg/mL of MeOH-soluble extract and their derived fractions. Figure 3C showed that pretreatment with fractions 1 and 3 significantly enhanced the survival of worms. Although fraction

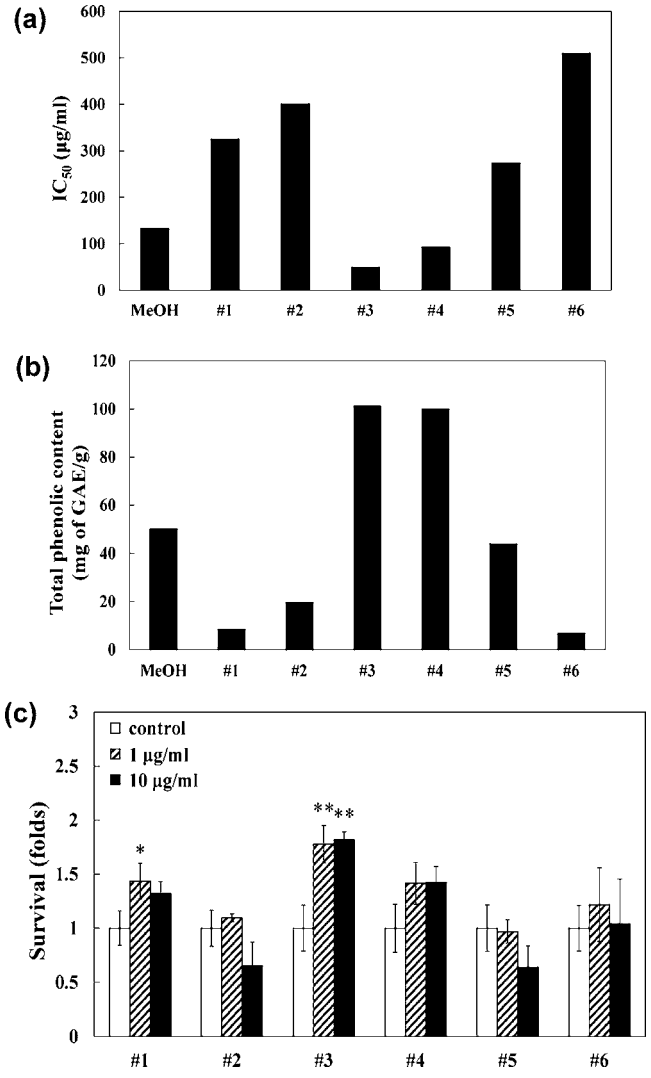

**Figure 3.** In vitro and in vivo antioxidant activity of different fractions from the methanol extracts of tea seed pomace. The MeOH-soluble extraction was divided into six fractions (1−6) by chromatography with a Diaion HP-20 column eluted with water/MeOH. (A) The DPPH scavenging activity of each test sample is presented as $IC_{50}$ values (μg/mL). Each test was repeated three times, and the results were averaged. (B) Total phenolic contents in each sample are expressed as gallic acid equivalent (mg of GAE/g of test sample). Each test was repeated three times, and the results were averaged. (C) Oxidative stress was performed as described above. At least three independent biological replicates were performed, and approximately 60−80 worms were scored in each experiment. Data are normalized to the untreated control. Results are presented as the mean ± standard error of mean (SEM). Differences compared to the untreated control were considered significant at $p < 0.05$ (*) and $p < 0.01$ (**) by one-way ANOVA and LSD post hoc test.

4 pretreatment did not show statistically increased survival of nematodes ($p = 0.0716$ for 1 μg/mL; $p = 0.053$ for 10 μg/mL), the observed protective effect to *C. elegans* against juglone-induced oxidative stress was obvious (Figure 3C). In contrast, fractions 2, 5, and 6 did not produce a significant increase in the survival of worms exposed to juglone-induced oxidative stress. Furthermore, it was observed that fraction 3 (both 1 and 10 μg/mL) exhibited the best performance in oxidative stress resistance in *C. elegans*.

Taken together, the aforesaid results suggested that the free radical scavenging effect of each fraction and their phenolic contents correlates closely with their oxidative stress resistance in *C. elegans*. Moreover, fraction 3 of the MeOH extract from tea seed pomace not only had the highest phenolic contents but also had the best antioxidant activity in both in vitro and in vivo tests (Figure 3). Accordingly, fraction 3 was selected for further investigation in the *C. elegans* model.

**Fraction 3 from the Methanol Extract of Tea Seed Pomace Reduces Intracellular ROS Production in *C. elegans*.** To gain insight into which fraction 3 from the MeOH extract suppresses the juglone-induced oxidative stress in *C. elegans*, intracellular ROS production in *C. elegans* after fraction 3 pretreatment was measured. Figure 4 shows that both 1 and

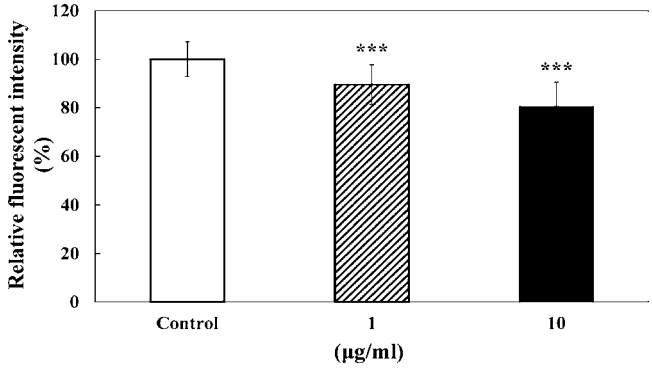

**Figure 4.** Effects of fraction 3 from the methanol extracts of tea seed pomace on intracellular ROS production in wild-type *C. elegans* N2. Synchronized wild-type L1 larvae were pretreated with fraction 3 from the methanol extracts (1 and 10 μg/mL) of tea seed pomace for 72 h at 20 °C. Subsequently, worms were treated with 100 μM CM−$H_2$DCFDA for 2.5 h at 20 °C, and intracellular ROS for adult animals was measured. Twenty randomly selected worms from each set of experiments were directly measured for the total GFP fluorescence for each whole worm and quantified by Image-Pro Plus software (Media Cybernetics, Bethesda, MD, USA). At least three independent biological replicates were performed. Data are normalized to the untreated control. Results are presented as the mean ± standard error of mean (SEM). Differences compared to the untreated control were considered significant at $p < 0.001$ (***) by one-way ANOVA and LSD post hoc test.

10 μg/mL of fraction 3 significantly inhibited the production of ROS compared to that in the untreated control ($p < 0.001$) (Figure 4). This suggests that pretreatment of fraction 3 from the MeOH extract may reduce juglone-induced toxicity as observed in Figure 3, by decreasing the levels of intracellular ROS in *C. elegans*.

**Fraction 3 from the Methanol Extracts of Tea Seed Pomace Significantly Prolongs *C. elegans* Lifespan.** Aging has been correlated to oxidative stress in *C. elegans*.[27] An increased lifespan was shown to be closely associated with increased survival under oxidative stress.[21,28] Therefore, we evaluated whether fraction 3 from the MeOH extract of tea seed pomace has an effect on the lifespan of *C. elegans* or not.

The lifespans of untreated (control) and fraction 3-treated wild-type nematodes were compared. Adult wild-type nematodes grown on control NGM plates and fed UV-killed bacteria at 20 °C have a median lifespan of 16 days with a maximum lifespan of 24 days (the age at death of the oldest animals). When nematodes grown on medium containing fraction 3 (1 and 10 μg/mL) were fed UV-killed bacteria at 20 °C, the

fraction 3-treated worms showed a statistically significantly increased lifespan compared to the untreated ones (log-rank, $p$ = 0.0372 for 1 $\mu$g/mL; $p$ = 0.0044 for 10 $\mu$g/mL, treated vs untreated control) (Figure 5). The median lifespans for both 1

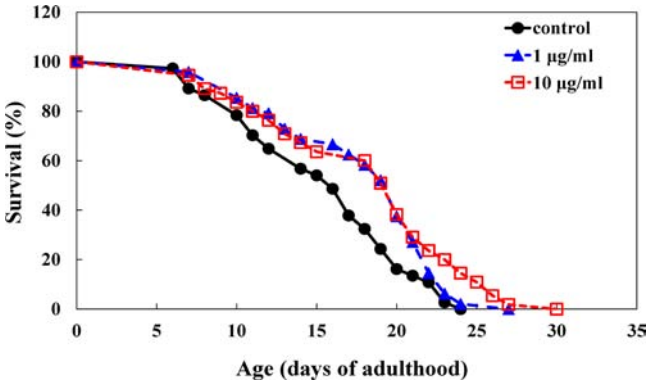

**Figure 5.** Effects of fraction 3 from the methanol extracts of tea seed pomace on the lifespan of wild-type *C. elegans* N2. Synchronized wild-type L1 larvae were incubated on NGM plates in the absence (control) or presence of fraction 3 (1 and 10 $\mu$g/mL), and worms were allowed to develop to adulthood. Surviving and dead animals were counted daily until all nematodes had died. Survival curves are of untreated control compared to fraction 3-treated worms. Day 1 refers to the first day of adulthood. At least three independent biological replicates were performed. Approximately 60 worms were scored in each experiment. Statistical significance of the difference between the curves (treated vs untreated control) was demonstrated by log-rank test using the Kaplan–Meier survival analysis. Differences at the $p < 0.05$ level were considered significantly different.

and 10 $\mu$g/mL fraction 3-treated worms are 20 days, respectively, with maximum lifespans of 27 days (1 $\mu$g/mL) and 30 days (10 $\mu$g/mL) (Figure 5). Taken together, the results suggest that fraction 3 from the MeOH extract of tea seed pomace has a beneficial effect on *C. elegans* in longevity.

**Fraction 3 from the Methanol Extracts of Tea Seed Pomace Delays Amyloid-$\beta$-Induced Paralysis in Transgenic *C. elegans* Expressing Human A$\beta$.** Production of oxidative stress by amyloid-$\beta$ (A$\beta$) is a possible cause for neurodegenerative diseases such as Alzheimer's disease (AD).[29,30] It has previously been shown that certain small molecules inhibit A$\beta$ oligomers, thereby reducing its toxicity.[31,32] However, most of these studies were conducted in vitro. In addition, it is time- and cost-consuming using a transgenic mice model of AD for pharmacological evaluation and mechanistic studies. Therefore, *C. elegans* has been increasingly used as a model of neurodegenerative diseases as it offers experimental advantages to address many basic cellular processes/functions that are conserved among animals.[33] *Ginkgo biloba* extract EGb 761 and aqueous coffee extracts were previously shown to associate A$\beta$ toxicity with A$\beta$-induced pathological behaviors in *C. elegans*.[24,34]

To examine whether fraction 3 has protective effects on AD, we investigated the effects of fraction 3 in a *C. elegans* model of A$\beta$ toxicity.[23] In the transgenic *C. elegans* strain CL4176 model, a temperature increase from 16 to 23 °C induced human A$\beta_{42}$ expression in body wall muscle of *C. elegans*, resulting in an A$\beta$-dependent paralysis phenotype.[23] In the present study, synchronized eggs from transgenic CL4176 worms were placed on *E. coli* OP50 food in the presence or absence of fraction 3 (1 and 10 $\mu$g/mL) for 50 h at 16 °C, and then the temperature was increased to 23 °C to induce A$\beta$ transgene expression. Figure 6 shows that A$\beta$-induced muscle paralysis was

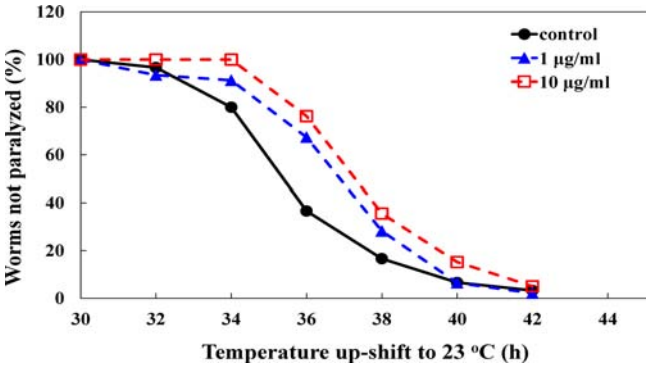

**Figure 6.** Effects of fraction 3 from the methanol extracts of tea seed pomace on A$\beta$-induced paralysis in transgenic *C. elegans* CL4176 strain. Strain CL4176 (muscle A$\beta$ strain) maintained at 16 °C was egg-synchronized onto the NGM plates with *E. coli* OP50 in the absence or presence of fraction 3 (1 and 10 $\mu$g/mL). At 50 h after egg laying, the temperature was shifted to 23 °C to induce A$\beta$ transgene expression. The paralysis phenotype was scored at 2 h intervals. Data are expressed as percentage of nonparalyzed worms from at least three independent assays of 100 worms in each set of experiments. Statistical significance of the difference between the curves (treated vs untreated control) was demonstrated by log-rank test using the Kaplan–Meier survival analysis. Differences at the $p < 0.05$ level were considered significantly different.

significantly delayed in nematodes fed fraction 3 (1 and 10 $\mu$g/mL) compared with the untreated controls (log-rank, $p$ = 0.008 for 1 $\mu$g/mL; $p < 0.001$ for 10 $\mu$g/mL, treated vs untreated control) (Figure 6). This suggests that fraction 3 from the MeOH extract has protective effects on *C. elegans* against A$\beta$ toxicity.

**Constituents of Fraction 3 from the Methanol Extracts of Tea Seed Pomace from *C. tenuifolia*.** Constituents of fraction 3 were further determined by the bioactivity-guided fractionation procedure. Semipreparative HPLC was employed to isolate phytochemicals in fraction 3 from the MeOH extracts of *C. tenuifolia* tea seed pomace. ESI-MS and NMR were applied to determine two constituents, namely, kaempferol 3-*O*-(2″-glucopyranosyl)-rutinoside (23 ± 0.11% of crude extracts) and kaempferol 3-*O*-(2″-xylopyranosyl)-rutinoside (20.65 ± 0.25% of crude extracts).

In Figure 3C, as low as 1 $\mu$g/mL fraction 3 from the MeOH extract showed good oxidative stress resistance in *C. elegans*. Thus, we further examined the antioxidant activity of kaempferol 3-*O*-(2″-glucopyranosyl)-rutinoside and kaempferol 3-*O*-(2″-xylopyranosyl)-rutinoside with 0.24 and 0.21 $\mu$g/mL, respectively, for the juglone-induced oxidative stress assays. The results showed that both phytochemicals exhibited higher *C. elegans* survival than the control (Figure 7).

In the present study, kaempferol derivatives were identified from *C. tenuifolia* tea seed pomace. Kaempferol triglycosides have been identified from a variety of plants.[35] The flavonoid kaempferol is commonly found in many edible plants and used in traditional medicine. Many studies have reported that kaempferol and some glycosides of kaempferol have a wide range of biological activities, including antioxidant, anti-inflammatory, antimicrobial, and anticancer activities.[35,36] In the *C. elegans* model, previous studies have shown that kaempferol decreases the intracellular ROS level, prolongs

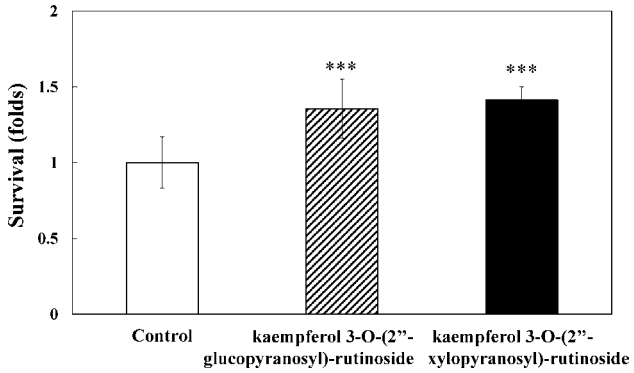

**Figure 7.** Antioxidant activity of kaempferol 3-*O*-(2″-glucopyranosyl)-rutinoside and kaempferol 3-*O*-(2″-xylopyranosyl)-rutinoside on wild-type *C. elegans* N2. Oxidative stress was performed as described above except that L1 nematodes were pretreated with kaempferol 3-*O*-(2″-glucopyranosyl)-rutinoside (0.24 μg/mL) and kaempferol 3-*O*-(2″-xylopyranosyl)-rutinoside (0.21 μg/mL). At least three independent biological replicates were performed, and approximately 60−80 worms were scored in each experiment. Data are normalized to the untreated control. Results are presented as the mean ± standard error of mean (SEM). Differences compared to the untreated control were considered significant at $p < 0.01$ (**) and $p < 0.001$ (***) by one-way ANOVA and LSD post hoc test.

lifespan, and attenuates amyloid-β-induced toxicity.[37−39] The aforesaid studies were in good agreement with our present findings (Figures 3−6). Therefore, the extracts from *C. tenuifolia* tea seed pomace are important and valuable and should be explored for further development of potential applications.

In conclusion, to the best of our knowledge, this is the first report demonstrating that the extracts from *C. tenuifolia* tea seed pomace exert multiple beneficial health effects in an intact organism. The MeOH extract of tea seed pomace from *C. tenuifolia* significantly decreases intracellular ROS level, prolongs *C. elegans* lifespan, and delays amyloid-β-induced paralysis in transgenic *C. elegans* expressing human $A\beta_{42}$. Aging is considered as one of the major risk factors in AD, and oxidative stress has been correlated to aging and amyloid-β toxicity. Therefore, the observed delay in aging and reduced amyloid-β toxicity by MeOH extract of tea seed pomace might be due to its antioxidant properties. Moreover, two phytochemicals, namely, kaempferol 3-*O*-(2″-glucopyranosyl)-rutinoside and kaempferol 3-*O*-(2″-xylopyranosyl)-rutinoside, were identified from the extract and exhibited excellent in vivo antioxidant activity. Our results showed that extracts of tea seed pomace from *C. tenuifolia* have multiple beneficial health effects, suggesting that biowaste might be valuable and should be explored for further development as nutraceutical products. Furthermore, the reuse of agricultural byproduct tea seed pomace also fulfills the environmental perspective.

HR62 allows more comprehensive understanding of the mechanisms involved in this biocontrol system. The objectives of this work were as follows: (1) to assess the capability of a new bioorganic fertilizer containing *B. amyloliquefaciens* HR62 to control bacterial wilt of tomato under greenhouse conditions and (2) to purify and to identify the antibacterial compounds produced by *B. amyloliquefaciens* HR62 that are responsible for the in vitro antagonism of *R. solanacearum*.

## MATERIALS AND METHODS

**Bacterial Strains and Culture Conditions.** HR62 was isolated from the rhizosphere soil of healthy tomato plants from a heavily wilt diseased field using dilution plate techniques. The strain was identified as *B. amyloliquefaciens* based on its biochemical characteristics and partial 16s rRNA.[23]

*B. amyloliquefaciens* HR62 was cultured on Luria−Bertani medium (LB) plates and stored at −70 °C in a mixture of LB liquid broth and 30% glycerol for further use. *R. solanacearum* QL-Rs1115 was provided by the Soil-Microbe-Interaction Laboratory at Nanjing Agricultural University in Nanjing, China.[11] The strain was maintained on KB plates supplemented with 0.005% triphenyltetrazolium chloride (m/v) for 2 days at 30 °C. A single colony was transferred into sterilized water for storage at room temperature.

For the production of antibiotics, *B. amyloliquefaciens* HR62 was grown in an optimized culture.[24]

**Preparation of Bioorganic Fertilizers.** The preparation of the bioorganic fertilizer (BIO62) followed the procedure described by Zhang et al.[36] The organic fertilizers (OF) consisted of a compost of pig manure and rice straw containing 33.7% OM (organic material), 2.51% N, 2.4% $P_2O_5$, 1.13% $K_2O$, and 22.3% $H_2O$ (Jiangsu Tianniang Agri-technology Ltd., Jiangsu, China) and an amino acid organic fertilizer containing a biologically hydrolyzed rapeseed cake with 44.2% OM, 8.0% amino acids, 4.4% N, 3.5% $P_2O_5$, 0.67% $K_2O$, and 28.5% $H_2O$[36] provided by Jiangsu Xintiandi Ltd. (Jiangsu, China). The two organic fertilizers were evenly mixed (1:1, w/w). *B. amyloliquefaciens* HR62 was incubated in 1 L of optimized culture in a 5 L fermentation tank on a shaker at 170 rpm at 30 °C for 36 h. The bacterial culture was centrifuged (at 10 000*g* for 10 min at 4 °C), and the collected cell pellets were resuspended in sterile water. The suspension of HR62 ($5.0 \times 10^9$ cfu $mL^{-1}$) was mixed with the OF mixture at a 1:5 (v/w) ratio. The final concentration of HR62 in the fortified organic fertilizer was approximately $10^9$ cfu $g^{-1}$ dry soil (ds).

**Design of the Pot Experiment under Greenhouse Conditions.** Tomato seedlings were grown in nursery cups (8.5 × 11 cm) containing 300 g of healthy nursery soil (i.e., soil that had been previously planted with tomato). One seedling was maintained in each cup. The seedlings were grown in a greenhouse, with temperatures ranging from 26 to 35 °C, until the seedlings had four true leaves. The seedlings were then transplanted to pots with 5 kg of *R. solanacearum*-infested soil. The following three treatments were included in the pot experiment: (1) CK treatment, where OF was applied to the soil; (2) HR62 treatment, where OF and a cell-free fermentation of HR62 was applied to the soil; and (3) BIO62 treatment, where BIO62 was added in the pot soil. The rate of the OF and BIO applications was 0.5% (dry weight basis). The OF and BIO applications were mixed separately into the soil prior to the transplantation of the tomato seedlings. Seedlings with four leaves were transplanted into the ceramic pots (5 kg soil per pot). One week after the transplantation, a 1 mL suspension of the *R. solanacearum* strain QL-Rs1115 ($5 \times 10^7$ cfu $mL^{-1}$) was poured into the soil to give a final bacterial concentration of $10^4$ cfu $g^{-1}$ ds. A total of 45 pots (15 pots with 30 plants for each treatment) were placed on a glasshouse bench in a completely randomized design and watered regularly. The experiment was repeated twice.

Disease development, expressed as disease incidence (DI), was based on a disease index (di) scale of 0−4,[25] where 0 = no wilting, 1 = 1−25% wilting, 2 = 26−50% wilting, 3 = 51−75% wilting, and 4 = 76−100% wilting or dead. The di was recorded daily for 28 days after pathogen challenge. The DI was calculated according to the following equation:[26]

$$DI = [\sum(\text{number of diseased plants in the index} \times \text{di})/(\text{total number of plants investigated} \times \text{highest di})] \times 100\%$$

To evaluate the *R. solanacearum* populations in the rhizosphere soils and crown sections, three tomato plants were uprooted from each treatment at 1, 7, 14, 21, and 28 days after pathogen challenge. Ten grams of rhizosphere soils or tomato crown sections was added to 90 mL of sterile water (crown sections were ground beforehand). The suspensions were shaken for 30 min on a rotary shaker at 200 rpm. Several 10-fold dilutions were made, and 0.1 mL aliquots were spread on the surface of M-SMSA medium.[27] After 2 days of incubation at 30 °C, colonies typical of *R. solanacearum* were counted. Colony forming units (cfu) were calculated per gram (dry weight) of soil and the values were log-transformed before statistical analysis was performed.

**Amplification of HR62 Antagonistic Genes.** The primers used to amplify the genes encoding bioactive compounds in HR62 were either used as previously described by Arguelles-Arias et al.[19] and Joshi and Gardener[28] or designed using Primer 5 software from Premier Biosoft based on consensus sequences of known *Bacillus subtilis* lipopeptide antibiotic genes that were deposited in GenBank (Table S1, Supporting Information).[29,30] PCR reactions were carried out in a 25 μL reaction volume containing 1 μL of genomic DNA, 2.5 μL of 10× PCR buffer, 20 mM $MgCl_2$, 0.2 mM of each dNTP, 0.5 μM of each primer, and 1.25 U of Taq DNA polymerase (Takara, Dalian). Amplification was performed using a PCR System DNA thermal cycler (Bio-Rad) programmed for one cycle of 94 °C for 5 min, followed by 30 cycles of 94 °C for 30 s, annealing for 30 s at 51 °C, extension for 1 min and 30 s, and a final extension at 72 °C for 10 min. A negative control without DNA was included in each PCR run. Each PCR reaction had three replicates. The amplified products were visualized by gel electrophoresis in 1% agarose gels; gels were stained with ethidium bromide. Expected PCR fragments were extracted using a gel extraction kit (Axygen, China). The obtained fragments were sequenced by Majorbio Co. (Shanghai, China). Nucleotide sequences were compared with those from GenBank using the BlastN software provided online by the National Center for Biotechnology Information.

**Isolation and Purification of Antibacterial Compounds from *B. amyloliquefaciens* HR62.** To select the best extractant, HR62 was incubated in an optimized culture (100 mL) for 36 h and extracted twice (for 1 h each) in an equal volume for five the following extractants: toluene, hexane, chloroform, ethyl acetate, and *n*-butyl alcohol. Among these, *n*-butyl alcohol was found to be the best extractant and was therefore used in subsequent experiments. Then, 5 mL of an overnight optimized culture of HR62 was used to inoculate 500 mL of fresh liquid optimized culture. The culture was then placed in an incubator shaker (at 170 rpm and 30 °C) for 36 h. The liquid culture was centrifuged at 10 000*g* for 10 min, and the supernatants were pooled together. Active compounds were extracted twice (for 1 h each) with an equal volume of *n*-butyl alcohol. The extract was concentrated using a rotary evaporator, and the residues were dissolved in 100 mL of distilled water. The sample was adjusted to pH 2.0 with 6 mol $L^{-1}$ HCl and stored overnight at 4 °C. The precipitate was recovered by centrifugation at 8000 g for 20 min. The pellet was washed twice with acidic deionized waster (pH 2.0) and extracted twice with methanol.[31] The solution was dried in a rotary vacuum evaporator, and the residue was dissolved in 10 mL of 0.01 mol $L^{-1}$ phosphate buffer solution (PBS) at pH 7.4.

A chloroform and methanol gradient (e.g., 100 mL of chloroform, 90 mL of chloroform + 10 mL of methanol, 80 mL of chloroform + 20 mL of methanol, and so on, up to 100 mL of methanol) was used to elute active compounds from a silica gel column (2 × 24 cm). Twenty-eight fractions (10 50-mL fractions and 18 30-mL fractions) were collected. The fractions were dried using a rotary evaporator and dissolved separately in 2 mL of PBS buffer. Active fractions were identified by an agar diffusion assay against *R. solanacearum* on KB plates; these fractions were then pooled and eluted further using a water and methanol gradient (e.g., 100 mL of water, 90 mL of water + 10 mL of methanol, 80 mL of water + 20 mL of methanol, and so on, up to 100 mL of methanol) in a Sephadex LH-20 column (2 × 24 cm). Active fractions were found using a bioassay and were then pooled. The pooled fractions were purified further using an HPLC device (1200 series, Agilent, Santa Clara, CA).

A 20 μL of sample was injected into an HPLC column (Eclipse XDB-C18, 4.6 × 250 mm, 5 μm, Agilent, Santa Clara, CA). Two conditions were applied. In condition 1, the temperature of the column was maintained at 30 °C throughout the experiment. The purification was performed using a solvent containing 40% A ($CH_3CN$) and 60% B [0.1% (v/v) $CH_3COOH$], with a flow rate of 0.6 mL $min^{-1}$ for 30 min. In condition 2, the temperature of the column was maintained at 35 °C throughout the experiment. The sample was eluted in 60−93% A ($CH_3CN$) and 40−7% B [0.1% (v/v) $CH_3COOH$] over 9 min. The ratio was then kept stable until the end of the experiment, with a flow rate of 0.84 mL $min^{-1}$ for 25 min. A standard sample of surfactin was also tested using condition 2. An ultraviolet (UV) detector was used to detect peaks at 210 nm. A fraction collector (Analyt FC, G1364C, Agilent, Santa Clara, CA) was used to collect the pure compounds; the fractions were collected using the time and peaks mode. The injections were performed repeatedly to allow for the collection of a sufficient quantity of antibiotics. The fractions were lyophilized, and the residues were dissolved in 500 μL of methanol. After an agar diffusion assay against *R. solanacearum* on KB plates, the active peaks were located.

**Mass Spectrometry Analysis.** The antibacterial material was subjected to a liquid chromatography/electrospray ionization-mass spectrometry (LC/ESI-MS) system (1200 series, Agilent, Santa Clara, CA, and ESI-MS, 6410 Triple Quad LC/MS, Agilent, Santa Clara, CA) with a C18 column (4.6 × 250 mm, 5 μm). Two conditions were used; these conditions were the same as those described for the purification in the HPLC section. For the MS analysis, the electrospray needle was operated at a spray voltage of 4.5 kV. The capillary temperature was 300 °C. The fractions eluted in condition 1 were measured in the both positive and negative ion modes to determine the accurate molecular weights of the antibiotics. The fractions eluted in condition 2 were measured in positive ion mode. The mass spectra were acquired in an *m*/*z* range of 100−2000 at a scan rate of 500 atomic mass units (amu)/s.

**Sensitivity of the Antibacterial Compounds to Temperature, pH, Enzymes, and Organic Solvents.** For the thermal stability test, the antibacterial compounds were exposed to temperatures of 30, 40, 50, 60, 70, 80, 90, and 100 °C for 1 h; 115 °C for 30 min; or 121 °C for 20 min. For the pH stability test, the antibacterial compounds were solubilized in a buffer containing 100 mM citrate and 200 mM phosphate buffer (pH 1−8), a buffer containing 100 mM phosphate and 100 mM HCl (pH 9−11), or a buffer containing 200 mM KCl and 200 mM NaOH (pH 12−14), followed by an incubation at 30 °C for 12 h. The residual antibacterial activity was assessed after neutralizing the samples to pH 7.0 with an appropriate weak base or weak acid. The sensitivity of the antibacterial compounds to various enzymes was tested. The enzymes used were as follows: pepsin (800−2500 U $mg^{-1}$; P8160, Solarbio), recombinant proteinase K (600−100 U $mg^{-1}$; 03115828001, Roche Applied Science), albumin fraction V (≥95% protein; A8020, Solarbio), and trypsin from bovine pancreas (≥2500 U $mg^{-1}$; 64008834, SCRS). All of the enzyme solutions were prepared in 25 mM phosphate buffer (pH 7.0). Each solution contained 1 mg $mL^{-1}$ of its respective enzyme. Solutions containing the antibacterial compounds were prepared by centrifuging the HR62 fermentation. The stock solutions of the antibacterial compounds and the enzymes were mixed at a 1:1 ratio (v/v) and incubated at 37 °C for 1 h before the residual antibacterial activity was measured using an agar diffusion assay against *R. solanacearum*. The sensitivity of the antibacterial compounds to the following organic solvents was tested: acetone, methanol, isopropyl alcohol, and ethanol. A 100 mL aliquot of cultured HR62 was centrifuged at 10 000*g* for 10 min, and the supernatants were added to the organic solvents in equal volumes. The mixture was then placed at room temperature for 4 h. The mixtures were dried using a rotary evaporator, and the residues were dissolved in 100 mL of PBS buffer. The resistance activity of the PBS solutions to *R. solanacearum* was determined using KB plates.

**Statistical Analysis.** The arcsin conversion was performed before the data were analyzed for percentages. Differences were assessed by one-way ANOVA. Duncan's multiple-range test was applied when one-way ANOVA revealed significant differences ($P < 0.05$). All statistical analyses were performed with SPSS 16.0 (SPSS Inc.) and SigmaPlot 11.0 (Systat Software Inc.).

## RESULTS

**Biological Control Assays against Bacterial Wilt of Tomato.** Treating plants with BIO62 resulted in reduced disease incidence (Figure 1). Disease symptoms were apparent 7 days after the pathogen challenge in all treatments. The BIO62-treated plants had significantly lower disease incidence compared with the control at 14, 21, and 28 days after the pathogen challenge. At the end of the experiment, the disease incidence in HR62- and BIO62-treated plants was reduced by 53% and 65%, respectively. The disease incidence in the control was 85%.

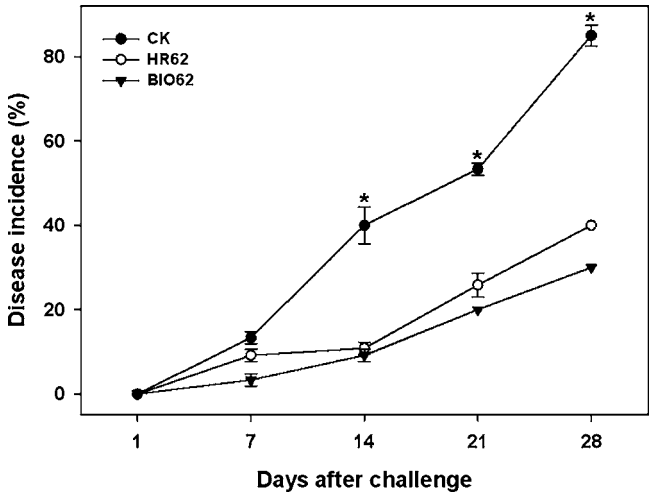

**Figure 1.** Effect of different treatments on bacterial wilt disease incidences at 1, 7, 14, 21, and 28 days after challenge. All values are means of three blocks with ten replicates per block. Bars show standard errors of the mean. An asterisk on the top of the bar represents significance at $P < 0.05$ (Duncan's multiple range test).

**Population Dynamics of *R. solanacearum* in the Rhizosphere Soil and Crown Sections of Tomato.** Populations of *R. solanacearum* in the rhizosphere soil of CK-treated tomatoes were significantly higher than those observed in HR62 and BIO62 treatments (Figure 2A) throughout the challenge period. The rhizosphere soil of BIO62-treated plants had the lowest population density at 8.04 log cfu $g^{-1}$ ds. For the CK treatment, the observed population density was 9.30 log cfu $g^{-1}$ ds at the end of experiment.

The same trend was observed in the dynamics of *R. solanacearum* among three treatments in the crown sections of tomatoes (Figure 2B). BIO62-treated plants had the lowest population density at 5.63 log cfu $g^{-1}$ fresh plant section (fps). For the CK treatment, the observed population density was 8.08 log cfu $g^{-1}$ fps at the end of experiment.

**Identification of Antibiotic Biosynthesis Genes from *B. amyloliquefaciens* HR62.** PCR was used to detect the genes involved in the biosynthesis of the six antibiotics reported to be produced by *B. amyloliquefaciens*. A total of 10 gene fragments of expected sizes correlated with biological control activities were efficiently amplified from HR62 (Figure S2, Supporting Information). The DNA sequences obtained from these amplifications confirmed the identity of these genes (Table 1). FenBF/FenBR and FNDF/FNDR primers amplified fragments with 99% and 96% homology, respectively, to the gene that encodes fengycin (synonymous with plipastatin) synthetase. The analysis of sequences amplified by the primers ituAF/ituAR, bamB1F/bamB1R, ituCF/ituCR, and ituD2F/ituD2R showed

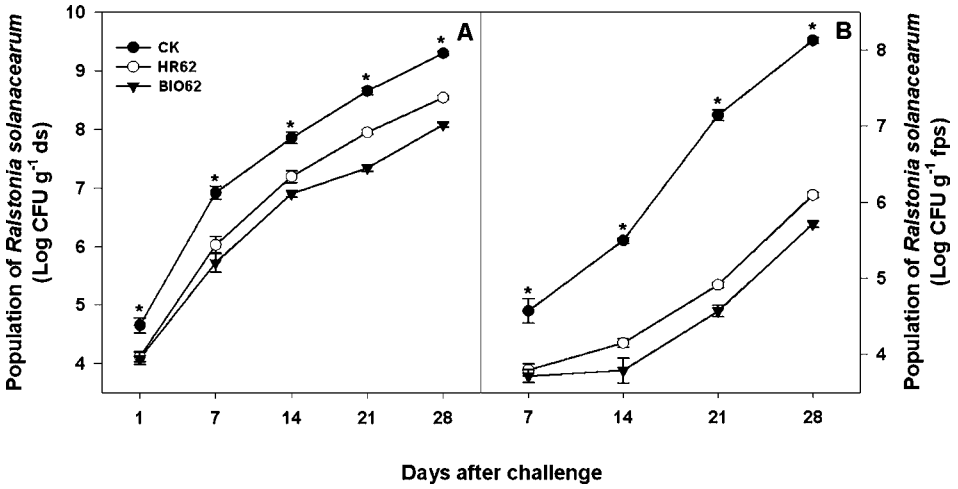

**Figure 2.** Populations of *R. solanacearum* in the rhizosphere soil (A) and crown section (B) of tomato plants were determined using the plate count method at 1, 7, 14, 21, and 28 days after challenge with *R. solanacearum* QL-Rs1115. Bars show standard errors of the mean. An asterisk on the top of the bar represents significance (Duncan's multiple range test, $P < 0.05$).

**Table 1. Genes Showing the Highest Similarity to the Sequenced Products Obtained from PCR Amplification of Biosynthetic Genes**

| primer names | isolate | match with proper genes by BlastN | GenBank accession numbers of matching genes | e value of BlastN | % identity of corresponding gene by BlastN |

97−99% identity with regions of genes encoding iturin synthetase or enzymes synthesizing closely related compounds in the iturin family. A sequence with 95% (e value = 8e-115) homology to the surfactin synthetase gene was detected in HR62 by the primer pair 110F/110R. BacF/BacR primers amplified a fragment similar to the Bacillorin operon with 98% homology. The Macrolactin gene cluster was amplified by mLn1F/mLn1R primers with 98% homology. Moreover, the analysis of sequences amplified by BACDF1/BACDR1 primers revealed 99% identity with the bacilysin synthetase gene cluster.

**Characterization of the Antibacterial Compounds from *B. amyloliquefaciens* HR62.** After the final purification with RP-HPLC, the fractions eluted at 4.740 and 5.808 min (Figure 3A) in condition 1 showed pathogen antagonism; these fractions were recorded as HR62-1 and HR62-2, respectively. To determine the molecular weight and molecular formula of the HPLC-purified antibiotics, the samples were subjected to HPLC analysis coupled with ESI-Q-trap MS. The data from the HPLC/ESI-MS analyses are shown in Figure 4. The spectra of HR62-1 revealed molecular masses of 401.3 $[M - H]^-$ in negative ion mode (Figure 4B) and 425.2 $[M + Na]^+$, 441.2 $[M + K]^+$, 385.2 $[M + H - H_2O]^+$, 367.2 $[M + 2K - 2H_2O]^{2+}$, and 349.1 $[M + 2K - 3H_2O]^{3+}$ in positive ion mode (Figure 4A). Therefore, HR62-1 contained macrolactin A, with a molecular weight of 402 Da.[16] The spectra of HR62-2 exhibited molecular masses of 435.5 $[M - OH - H_2O]^-$ in negative ion mode (Figure 4D) and 511.2 $[M + Na]^+$ and 367.2 $[M -$ malonic acid $- 2H_2O + H]^+$ in positive ion mode (Figure 4C). This fraction was identified as containing 7-*O*-malonyl macrolactin A, with a molecular weight of 488 Da.[16]

In addition, five fractions collected from sample HR62 showed antagonism to *R. solanacearum* QL-Rs1115. These fractions were collected at almost the same retention time as the standard surfactin sample (Figure 3B,C). The collection times were 14.385, 15.563, 17.476, 18.303, and 20.248 min (Figure 3B); the fractions were named HR62-1′, HR62-2′, HR62-3′, HR62-4′, and HR62-5′, respectively. The mass spectra of HR62-1′, HR62-2′, HR62-3′, HR62-4′, and HR62-5′ exhibited $m/z$ ratios of 516.8, 523.7, 530.9, 530.9, and 537.8, respectively. According to the already available information about surfactin, the molecular weight of surfactin is approximately 1000 Da. We deduced that the sample took two charges after ionization and analyzed the $m/z$ results as 516.8 $[M + K + H]^{2+}$, 523.7 $[M + K + H]^{2+}$, 530.9 $[M + K + H]^{2+}$, 530.9 $[M + K + H]^{2+}$, and 537.8 $[M + K + H]^{2+}$ in positive ion mode; these fractions were identified as surfactin with molecular weights of 994 ($C_{13}$), 1008 ($C_{14}$), 1022 ($C_{15}$), 1022 ($C_{15}$), and 1036 ($C_{16}$), respectively. The prominent masses from the HPLC/ESI-MS spectra and the molecular weights are listed in Table 2.

**The Effect of Temperature, pH, Organic Solvents and Enzymes on Antibacterial Activity.** The antibacterial

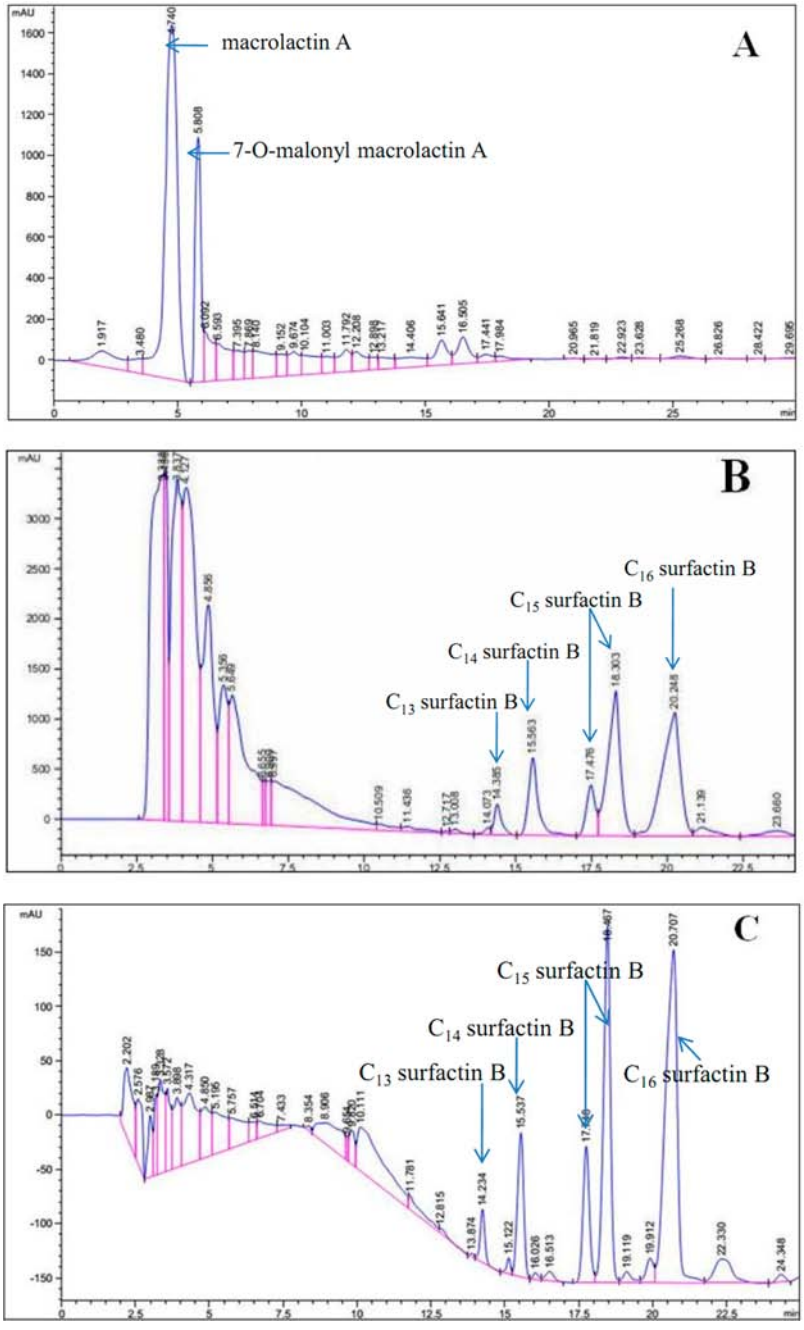

**Figure 3.** Reversed-phase HPLC chromatograms of antibiotics produced by *B. amyloliquefaciens* HR62 by condition 1 (A) and condition 2 [B and C (standard sample)]. Antibacterial activities were found in peaks located at 4.740 and 5.808 min (A) and at 14.385, 15.563, 17.476, 18.303, and 20.248 min (B).

compounds were stable at different temperatures (40, 50, and 60 °C) (Figure 5A) and at a pH range of 5−7 (Figure 5B). Antibacterial activities were decreased at 100, 115, and 121 °C. In addition, the antibacterial compounds were stable in methanol, ethanol, acetone, and isopropyl alcohol (Figure 5C). The enzymes pepsin (800−2500 U $mg^{-1}$; P8160, Solarbio), recombinant proteinase K (600−100 U $mg^{-1}$; 03115828001, Roche Applied Science), albumin fraction V (≥95% protein; A8020, Solarbio), and trypsin from bovine pancreas (≥2500 U $mg^{-1}$; 64008834, SCRS) were unable to degrade the antibacterial compounds (Figure 5D).

## DISCUSSION

Bacterial wilt of tomato was significantly suppressed by both of the treatments tested in the present study. The application of organic fertilizer and antagonists separately (treatment HR62) reduced the incidence of bacterial wilt disease by 53% (Figure 1), in agreement with the established effect of organic amendments and biocontrol agents such as *Bacillus* on soilborne diseases.[32−34] The application of BIO62 conferred a biocontrol efficacy of 65% (Figure 1). The combination of antagonists with a suitable organic fertilizer may provide sufficient nutrients to the antagonists to ensure high inoculum to the plants at the time of treatment, promote the root-colonization capacity of the antagonist, and prevent the invasion of the pathogen.[35,36]

Biomass yields of plants treated with HR62 and BIO62 were significantly higher than that of the control (Figure S1, Supporting Information). This result demonstrates that BIO62 not only reduced bacterial wilt of tomato but also promoted plant growth. This was most likely due to the beneficial contribution of the enriched microorganism community in the compost.[37] These results were in agreement with the report published by Wei et al.,[11] which indicated that the application of bioorganic fertilizers significantly reduced the incidence of bacterial wilt disease both in the greenhouse and in field conditions.

Several *B. amyloliquefaciens* strains have been used as biological control agents of plant diseases.[21,38,39] The most convincing antagonism properties are the broad-spectrum antibiotic and antimicrobial compounds synthesized by these microorgan-

dx.doi.org/10.1021/jf503136a | J. Agric. Food Chem. 2014, 62, 10708−10716

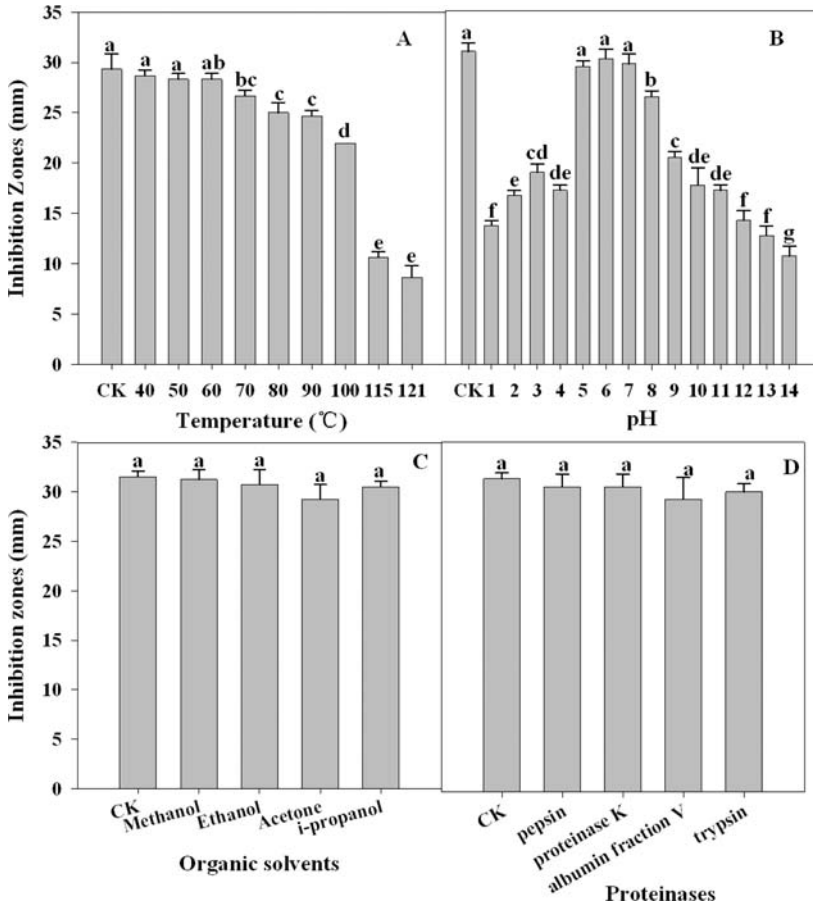

**Figure 5.** Sensitivities of antibacterial compounds produced by *B. amyloliquefaciens* HR62 to temperature (A), pH (B), organic solvents (C), and proteinases (D).

isms.[20] Antibiotics from *Bacillus* protect plants either by hampering the pathogens directly or by inducing systemic resistance in the host.[40,41] In the present study, *B. amyloliquefaciens* HR62 showed antagonism against seven soil-borne fungi pathogens (Table S2, Supporting Information). This result suggests that a large range of antibiotics may be secreted by HR62. Furthermore, PCR analysis of the HR62 genome revealed the existence of lipopeptide-synthetic genes encoding for surfactin, fengycin, iturin, and bacillicon; polyketide-synthetic genes coding for macrolactin; and dipeptide-synthetic genes encoding for bacilysin synthetase (Table 1). Therefore, *B. amyloliquefaciens* HR62 is an effective biocontrol agent. We focused on its antagonism to *R. solanacearum*, a causative agent of bacterial wilt of tomato, both in vitro and in vivo. In this study, we tried to isolate the antibiotics produced by HR62 to explain another biocontrol mechanism. After purification and characterization using extraction, precipitation, and purification using silica gel columns (Sephadex LH-20, RP-HPLC and LC−MS), two types of polyketides were identified, macrolactin A and 7-*O*-malonyl macrolactin A. One type of lipopeptide, surfactin B ($C_{13}$, $C_{14}$, $C_{15}$, $C_{15}$, and $C_{16}$), was observed and identified according to previous studies.[16,19,42]

Macrolactin, which consists of a 24-membered lactone ring, was first isolated from a deep-sea bacterium. Macrolactin was used in clinical antibiosis because of its selective antibacterial activities, its cytotoxicity against murine melanoma cancer cells, and its antiviral activities against Herpes simplex virus (HSV) and human immunodeficiency virus (HIV).[43,45] 7-*O*-Malonyl macrolactin A (MMA) has the same configuration as its parent molecule macrolactin A. MMA is a bacteriostatic antibiotic that inhibits a number of multidrug-resistant Gram-positive pathogens, such as *B. subtilis*, *Staphylococcus aureus*, and *Burkholderia cepacia*.[44,45] Dunlap et al.[46] identified and confirmed the presence of the PKS cluster that encodes the synthesis of macrolactin from antagonist *B. amyloliquefaciens* AS 43.3, which showed antagonism to *Fusarium* head blight. In this present study, we observed the inhibition activities of these compounds to the phytopathogen *R. solanacearum*; this activity was supported by the results published by Yuan et al.[16]

In the present study, the antibiotic surfactin was also shown to act as an antagonist to *R. solanacearum* QL-Rs1115. This compound is applied in an extremely wide variety of industrial processes involving emulsification, foaming, detergency, wetting, dispersing, and solubilization. Kim et al.[42] reported that surfactin isolated from *Bacillus polyfermenticus* KJS-2 showed antimicrobial activity to several Gram-positive and Gram-negative bacteria. Zhu et al.[47] tested the antagonism of lipopeptides produced by *B. amyloliquefaciens* XZ-173 to *R. solanacearum* QL-Rs1115; one of these lipopeptides was surfactin. Bacon et al.[48] reported that *Bacillus mojavensis* produce a considerable amount of surfactin A to inhibit of the maize mycotoxic fungus *Fusarium verticillioides*. Surfactin resists soil-borne pathogens by stimulating plant growth, increasing the adhesion of biocontrol agents to plant surfaces, inhibiting the formation of biofilms by pathogenic organisms, and activating systemic resistance in a wide range of plants.[24,49,50]

In this work, the combination of organic fertilizers with *B. amyloliquefaciens* HR62 significantly reduced the disease

incidence of bacterial wilt of tomato. Macrolactin and surfactin analogs were detected in an HR62 culture filtrate. Although these two compounds have been previously reported in the literature, here they were found in one strain that could inhibit *R. solanacearum* for the first time. Polyketide and lipopeptide production were pursued as another possible mechanism underlying the biocontrol of bacterial wilt disease by HR62. These data provide a theoretical basis for the development of commercial bioorganic fertilizers with different functional biocontrol agents.

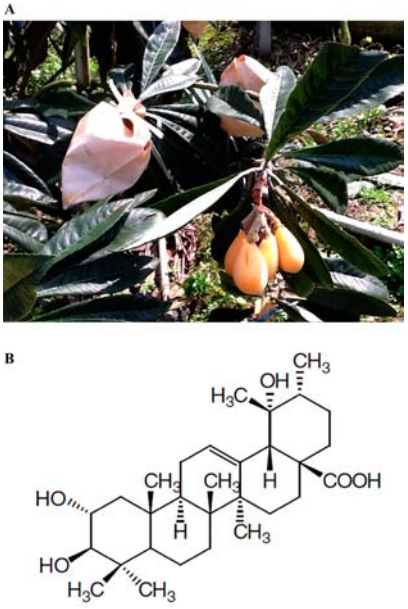

**Figure 1.** (A) The plant *Eriobotrya japonica* Lindl. (B) Structure of tormentic acid (PTA).

of loquat is reported to produce large amounts of triterpenes.[16] We have recently shown that loquat leaf extract as well as its cell suspension culture (which contains five main bioactive constituents including tormentic acid (PTA), see chemical structure in Figure 1B) could improve insulin sensitivity and hyperlipidemia;[17,18] we think it is possible that the five constituents act synergistically (a synergistic effect is one in which the combined effect of two chemicals is greater than the sum of the effect of each agent given alone) on diabetes and lipid. Nevertheless, the effect of single and pure PTA of antidiabetes and antidyslipidemia is still not fully understood. The aerial part of *Poterium ancistroides* Desf. contained tormentic acid and exhibited antidiabetic activity.[19] Tormentic acid has been shown to lower blood glucose in normoglycemic and glucose-induced hyperglycemic rats[19] and initiates insulin secretion by isolated rat islets of Langerhans.[20]

The mouse C57BL/6 model fed a high-fat (HF) diet could induce insulin resistance, obesity, hyperlipidemia, hyperinsulinemia, hyperleptinemia, and excess circulating free fatty acid.[21,22] Therefore, we conducted our animal study using HF diet-induced diabetic and hyperlipidemic states. AMPK activity is dependent on the phosphorylation of Thr 172 of $\alpha$ subunits.[23] This study also examined the effect of PTA on the expression or protein of genes involved in antidiabetes and lipogenesis, including GLUT4, Akt, AMPK, phosphoenol pyruvate carboxykinase (PEPCK), glucose-6-phosphatase (G6 Pase), sterol regulatory element binding protein-1c (SREBP-1c), peroxisome proliferator-activated receptor $\alpha$ (PPAR$\alpha$), and apolipoprotein C-III (apo-CIII).

## MATERIALS AND METHODS

**Chemicals.** GLUT4 was purchased from Santa Cruz Biotechnology (Santa Cruz, CA, USA); phospho-AMPK was purchased from Abcam Inc. (Cambridge, MA, USA); phospho-Akt, total AMPK, and total Akt were obtained from Cell Signaling Technology, Inc. (Danvers, MA, USA); the BCA protein assay kit was from Thermo Scientific (Rockford, IL, USA); and the ECL reagent kit was from GE Healthcare BioSciences (Buckinghamshire, UK). Secondary antibody anti-rabbit was from Jackson ImmunoResearch Laboratories, Inc. (West Grove, PA, USA). Structural proteins GAPDH and $\beta$-actin were from Santa Cruz Biotechnology.

**Isolation of Tormentic Acid.** PTA was obtained from Jen Li Biotech Co. Callus induction, suspension cultures, and extraction and isolation of tormentic acid from suspension cells of *E. japonica* were performed as previously described.[16,24] Briefly, sterilized seeds after callus induction were cultured in a bioreactor, and the cell suspension (ca. 844.5 g) was dried and extracted with ethanol and then concentrated to afford the white powder fraction (ca. 6.1 g).[24] The white powder (0.5 g) was chromatographed on a reverse silica gel column (LiChroprep RP-18, E. Merck, 40−63 $\mu$m) and then further purified by preparative high-performance liquid chromatography (PHPLC) to yield tormentic acid.[24] Tormentic acid (230.5 mg): $^1$H NMR (pyridine-$d_5$) $\delta$ 1.00 (H-25), 1.07 (H-24), 1.10 (H-26), 1.11 (H-30), 1.26 (H-23), 1.42 (H-29), 1.71 (H-27), 3.04 (H-18), 3.36 (H-3$\alpha$), 4.09 (H-3$\beta$), 5.58 (H-12). $^1$H NMR (400 MHz) spectra were measured by using a Bruker AMX-400 spectrometer as previously described.[24]

**Animals and Experimental Design.** Part 1, an oral glucose tolerance (OGTT), test was performed on 12 h fasted ICR mice ($n$ = 5) that were allowed access to 0.2, 0.4, and 0.8 g/kg PTA or an equivalent amount of vehicle (water), which were given orally 30 min before an oral glucose load (1 g/kg body wt). The control group was given glucose, whereas the normal group was not. Blood samples were collected from the retro-orbital sinus of fasted mice at the time of the glucose administration (0) and every 30 min until 120 min after glucose administration. The blood glucose level was monitored. For part 2, C57BL/6J mice (4 weeks old) were obtained from the National Laboratory Animal Breeding and Research Center. The mice were divided randomly into two groups after 7 days acclimation. The control (CON) group ($n$ = 9) was fed a low-fat diet (diet 12450B, Research Diets, Inc., New Brunswick, NJ, USA), whereas the experimental group was fed a 45% high-fat diet (diet 12451, Research Diets, Inc.) for 12 weeks.[18,25] The compositions of the experimental diets are given in previous studies.[18,25] After 8 weeks, the high-fat treated mice were randomly subdivided into four groups ($n$ = 9) including PTA (0.06, 0.12 g/kg/day) or rosiglitazone (Rosi; 1% methylcellulose, 10 mg/kg body weight) (GlaxoSmithKline) or vehicle and treated by oral gavage one time per day from the 9th to 12th weeks, while the mice were still on the high-fat diet, whereas the CON and high-fat control (HF) mice were treated with vehicle only. At the end, food was withheld from the animals (from 10 p.m. to 10 a.m.). The next day, the mice were sacrificed for blood and tissue collection and analysis. Livers, skeletal muscles, and white adipose tissues (WATs) (including epididymal, mesenteric, and retroperitoneal WAT) were weighed and excised, followed by immediate freezing, and kept at −80 °C for target gene analysis. Heparin (30 units/mL) (Sigma) was added to blood samples. Plasma samples were collected within 30 min by centrifugation at 1600$g$ for 15 min at 4 °C. Plasma was obtained for insulin and leptin assay.[18,25]

**Measurement of Body Weight, Body Weight Gain, and Food Intake.** Body weight was measured daily at the same time throughout the study. Body weight gain is defined as the difference between one day and the next day. The pellet food was weighed and placed in a food container. After 24 h, the remaining food was weighed, and the difference represented the daily food intake.

**Analysis of Blood Parameters.** Blood samples (0.8 mL) were collected from the retro-orbital sinus of fasted mice, and the glucose level was analyzed by the glucose oxidase method (model 1500; Sidekick Glucose Analyzer; YSI Inc., Yellow Springs, OH, USA).[18,25] Plasma triglycerides (TG), total cholesterol (TC), and free fatty acids (FFA) were measured using commercial assay kits according to the manufacturer's directions (Triglycerides-E test, Cholesterol-E test, and FFA-C test, Wako Pure Chemical, Osaka, Japan).[17,18] The levels of insulin and leptin in blood were analyzed by ELISA using a commercial assay kit according to the manufacturer's directions (mouse insulin ELISA kit, Sibayagi, Gunma, Japan; and mouse leptin ELISA kit, Morinaga, Yokohama, Japan).[18,25]

**Analysis of Histopathology.** Small pieces of epididymal WAT and liver tissue were fixed with formalin (200 g/kg) neutral buffered

**Table 1. Primers Used in This Study**

| gene | accession no. | forward and reverse primers | PCR product (bp) | annealing temp (°C) |

solution and embedded in paraffin. Sections (8 $\mu$m) were cut and stained with hematoxylin and eosin. For microscopic examination, a microscope (Leica, DM2500) was used, and the images were taken using a Leica Digital camera (DFC-425-C).[18]

**Analysis of Hepatic Lipids.** Hepatic lipids were extracted using a previously described protocol.[17] For the hepatic lipid extraction, 0.375 g liver samples were homogenized with 1 mL of distilled water for 5 min. Finally, the dried pellet was resuspended in 0.5 mL of ethanol and analyzed using a triglycerides kit as used for serum lipids.[18]

**Isolation of RNA and Relative Quantization of mRNA Indicating Gene Expression.** Total RNA from the liver tissue was isolated with a Trizol reagent (Molecular Research Center, Inc., Cincinnati, OH, USA) according to the manufacturer's directions. The integrity of the extracted total RNA was examined by 2% agarose gel electrophoresis, and the RNA concentration was determined by ultraviolet (UV) light absorbency at 260 and 280 nm (spectrophotometer U-2800A, Hitachi). Total RNA (1 $\mu$g) was reverse transcribed to cDNA with 5 $\mu$L of Moloney murine leukemia virus reverse transcriptase (Epicenter, Madison, WI, USA) as a previously described protocol.[17,25] The polymerase chain reaction (PCR) was performed in a final 25 $\mu$L containing 1 U of Blend Taq-Plus (TOYOBO, Japan), 1 $\mu$L of the RT first-strand cDNA product, 10 $\mu$M of each forward (F) and reverse (R) primer, 75 mM Tris-HCl (pH 8.3) containing 1 mg/L Tween 20, 2.5 mM dNTP, and 2 mM $MgCl_2$.[17,18,25] The primers are shown in Table 1. The products were run on 2% agarose gels and stained with ethidium bromide. The relative density of the band was evaluated using AlphaDigiDoc 1201 software (Alpha Innotech Co., San Leandro, CA, USA). All of the measured PCR products were normalized to the amount of cDNA of GAPDH in each sample.[17,18,25]

**Western Immunoblotting Analysis.** This follows a previous paper;[18,26,27] protein extractions and immunoblots for the determination of GLUT4, phospho-AMPK (Thr172), and phospho-Akt (Ser 473) proteins were carried out on frozen skeletal muscle and liver tissue from mice. Briefly, samples of liver tissue (0.1 g) were homogenized with lysis buffer (pH 6.4) and protease inhibitors. Forty micrograms of each homogenate was used for SDS-PAGE and immunoblotting as in a previously described protocol.[18,26,27] Additionally, GLUT4 was carried out on frozen skeletal muscle from mice, as briefly described: Skeletal muscle (1 g) was powdered under liquid nitrogen and homogenized for 20 s in buffer (pH 7.4). The total membrane fractions were collected with buffer and centrifuged as a previously described.[28,29] The protein contents of GLUT4, phospho-AMPK, phospho-Akt, total AMPK, and total Akt were detected by immunoblotting using a rabbit polyclonal antibody. The protein concentration in supernatant was determined with a BCA protein assay kit. The membranes were blocked with 5% skim milk in Tris-buffered saline (TBS) (Amersham BioSciences, Uppsala, Sweden) containing 0.05% Tween-20 (Bio-Rad, Hercules, CA, USA) and incubated overnight at 4 °C with anti-GLUT4, antiphospho-AMPK, and antiphospho-Akt at 1:200 dilution and anti-total-AMPK and anti-total-Akt at 1:1000 dilution. Subsequently, the membranes were washed three times with TBS containing 0.05% Tween-20 and incubated with secondary antibody anti-rabbit (1:1000) for 1 h. Immunoreactive bands were detected with ECL reagent kit. The density blotting was analyzed using Alpha Easy FC software (Alpha Innotech Corp., Randburg, South Africa). Structural proteins GAPDH and $\beta$-actin were obtained by stripping the nitrocellulose membrane proteins of liver and skeletal muscle, respectively.[18,26,27]

**Statistical Analysis.** All results are presented as the mean and standard error. Statistical significance is calculated by Dunnett's multiple-range tests, using SPSS software (SPSS Inc., Chicago, IL, USA).

## RESULTS

**OGTT Assay.** Administration of 0.2, 0.4, and 0.8 g/kg tormentic acid decreased the levels of blood glucose from 30 to 120 min following a glucose loading.

**Body Weight and Food Parameters.** Body weights of mice were measured at the end of the study. Feeding with a high-fat diet increased body weight and body weight gain, whereas the 4 week average food intake of the HF group was

[a]All values are means ± SE ($n$ = 9). #, $p < 0.05$; ##, $p < 0.01$; and ###, $p < 0.001$ compared with the control (CON) group. *, $p < 0.05$; **, $p < 0.01$; and ***, $p < 0.001$ compared with the high-fat + vehicle (distilled water) (HF) group. Tormentic acid (PTA) (PTA1:0.06 and PTA2:0.12 g/kg body wt); Rosi, rosiglitazone (0.01 g/kg body wt); BAT, brown adipose tissue; RWAT, retroperioneal white adipose tissue; MWAT, mesenteric white adipose tissue; visceral fat, sum of epididymal and retroperioneal WAT; FFA, plasma free fatty acid; TC, total cholesterol; TG, triglyceride. [b]Dose (g/kg/day).

decreased. Final body weight and food intake were unchanged between the PTA-treated groups and the HF group. The PTA1- and PTA2-treated groups decreased the body weight gain over 4 weeks of treatment (Table 2).

**White Adipose Tissue Fat Accumulation.** The final weights of epididymal, mesenteric and retroperitoneal WATs, and visceral fat of the HF group were increased. Administration of PTA1, PTA2, and Rosi reduced epididymal WAT, mesenteric and retroperitoneal WATs, and visceral fat weights (Table 2).

**Blood Parameter, Leptin, Insulin, and Liver Lipid.** HF-diet increased blood glucose, and administration of PTA1, PTA2, and Rosi lowered blood glucose levels (Figure 2B). High-fat diets caused increases in circulating TG, FFA, leptin, and insulin levels. The PTA1-, PTA2-, and Rosi-treated mice displayed decreased TG, FFA, leptin, and insulin. The PTA2- and Rosi-treated mice showed decreased TC levels. The HF diet increased the total lipids of liver and concentrations of triacylglycerol, whereas mice administrated PTA1, PTA2, and Rosi showed significant decreases in these phenomena.

**Pathological Diagnosis.** HF induced adipocyte hypertrophy (the average areas of adipocytes in the HF group and CON group were 6515.9 ± 495.1 and 2584.6 ± 205.8 $\mu m^2$, respectively), whereas mice administered PTA1 (2380.9 ± 108.6 $\mu m^2$) and PTA2 (2243.2 ± 100.9 $\mu m^2$) showed significantly lower hypertrophy. The average area of the Rosi-treated mice was 4574.4 ± 162.7 $\mu m^2$ (Figure 3A). According to a previous study,[30] designation of histological hepatocellular ballooning findings included grade 0, none; grade 1, a few cells; grade 2, many cells. The ballooning phenomenon in liver is visible on the HF diet (mean score = 1.7 ± 0.2). The ballooning phenomenon is lower in the PTA1-treated (1.0 ± 0.2), PTA2-treated (0.7 ± 0.2), and Rosi-treated (0.9 ± 0.2) mice (Figure 3B).

**Hepatic Target Gene Expressions.** The mRNA levels of PEPCK, G6 Pase, 11$\beta$-hydroxysteroid dehydrogenase 1 (11$\beta$-HDS1), diacyl glycerol acyltransferase 2 (DGAT2), PPAR$\alpha$, SREBP1c, fatty acid synthase (FAS), and apo C-III were increased in the HF group. Following treatment, the PTA1-, PTA2-, and Rosi-treated groups decreased the mRNA level of PEPCK, G6 Pase, DGAT2, 11$\beta$-HSD1, SREBP1c, FAS, and apo C-III. The PTA1- and PTA2-treated groups showed increased mRNA levels of PPAR$\alpha$ (Figure 4).

**Protein Contents of Phospho-AMPK (Thr172), GLUT4, and Phospho-Akt (Ser 473)/Total Akt in Different Tissues.** The protein contents of phospho-AMPK protein were decreased in the HF group, whereas the PTA1-, PTA2-, and Rosi- treated groups increased the protein contents of both hepatic and skeletal muscular phospho-AMPK. HF-induced the protein contents of GLUT4 and phospho-Akt decreased, whereas PTA1-, PTA2-, and Rosi-treated mice increased the protein contents of GLUT4 and phospho-Akt in skeletal muscle (Figure 5).

## DISCUSSION

The present results demonstrated that PTA is effective in lowering blood glucose and circulating triglyceride levels in HF-fed mice. We have previously shown that loquat leaf extract as well as its cell suspension culture (total contents of five triterpenes were 85.35% including tormentic acid, 44.30%; corosolic acid, 19.50%; maslinic acid, 14.65%; oleanolic acid, 1.60%; and ursolic acid, 5.30%),[18] could improve insulin sensitivity and hyperlipidemia.[17,18] Because the cell suspension culture contained 44.3% tormetic acid, it is possible that the five constituents act synergistically and exert a more potent effect on diabetes and lipid. Nevertheless, the effect of single and pure tormentic acid (PTA) on diabetes and dyslipidemia is still not fully understood; therefore, we hypothesized that the present

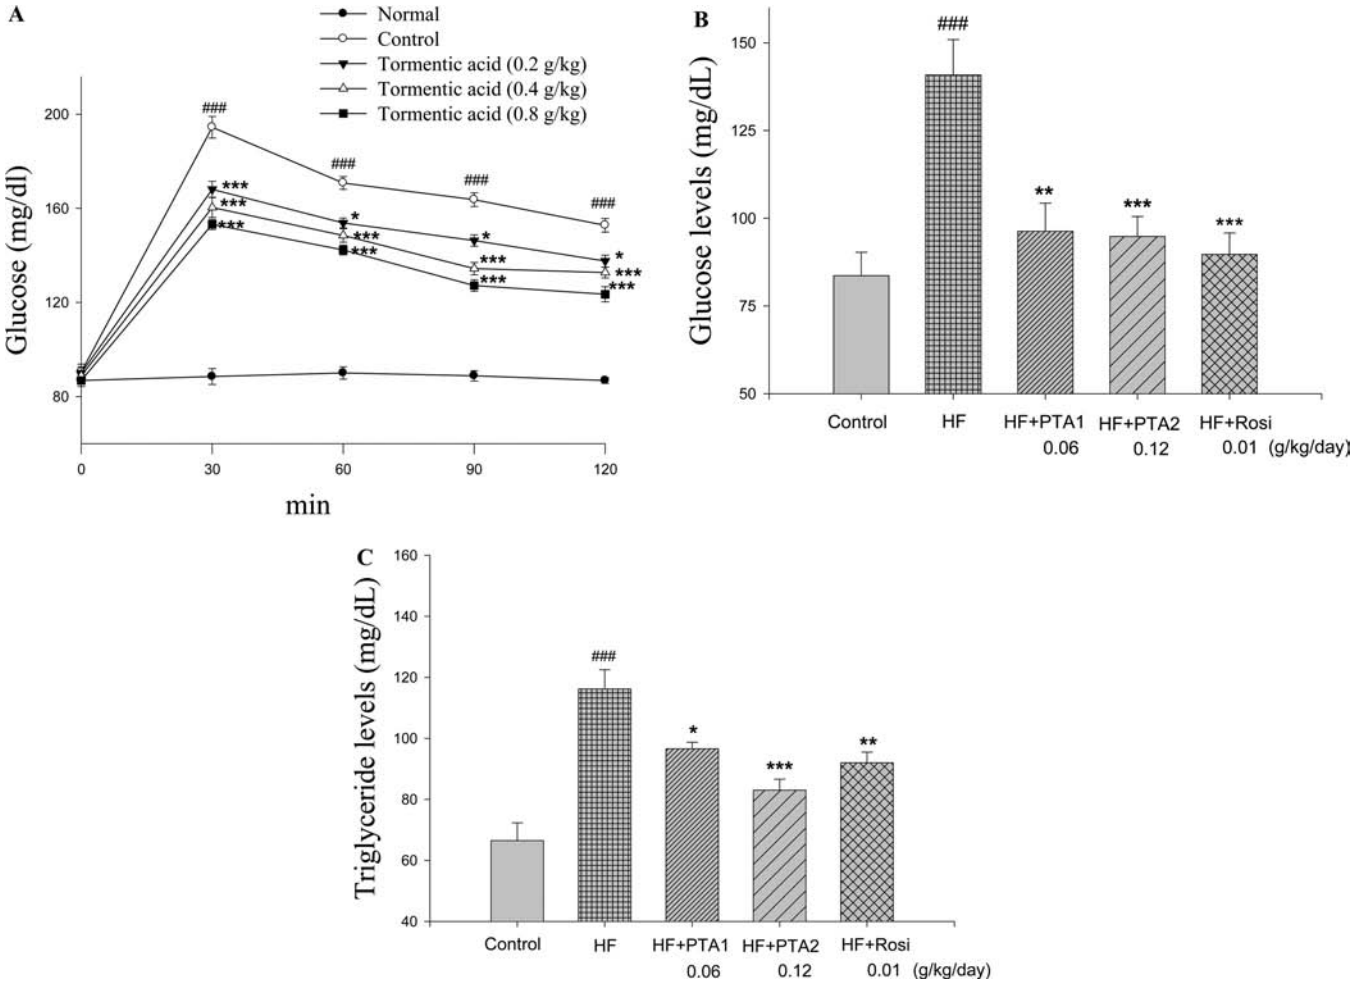

**Figure 2.** (A) Effects of tormentic acid on oral glucose tolerance test (OGTT) in normal mice. Animals in all groups received oral glucose 30 min after tormentic acid administration. Blood samples were collected and centrifuged at 3000 rpm for 10 min. Each point is the mean ± SE of five separate mice. (###) $p < 0.001$ compared with the control (CON) group; (∗) $p < 0.05$ and (∗∗∗) $p < 0.001$ were significantly different compared with the control group in the same time by ANOVA. (B, C) Effects of tormentic acid (PTA) on (B) blood glucose levels and (C) circulating triglyceride levels at week 12. Mice were fed a 45% high-fat diet (HF) or low-fat diet (CON) for 12 weeks. After 8 weeks, the HF mice were treated with vehicle or tormentic acid (PTA) or rosiglitazone (Rosi) accompanied by HF diet for 4 weeks. All values are means ± SE ($n = 9$). (#) $p < 0.05$, (##) $p < 0.01$, and (###) $p < 0.001$ compared with the control (CON) group; (∗) $p < 0.05$, (∗∗) $p < 0.01$, and (∗∗∗) $p < 0.001$ compared with the high-fat plus vehicle (distilled water) (HF) group by ANOVA. Tormentic acid (PTA1:0.06 and PTA2:0.12 g/kg body wt); Rosi, rosiglitazone (0.01 g/kg body wt); WAT, white adipose tissue; epididymal WAT+retroperitoneal WAT, visceral fat.

study of pure PTA could exhibit an effect in glucose control and lipid metabolism. Indeed, treatment with PTA displayed hypoglycemic and hypolipidemic effects.

C57BL/6J mice fed a high-fat diet is a mouse model to induce type 2 diabetes.[31] The HF-induced model had also elevated levels of triglycerides.[31] Therefore, this model was used in the present study for investigating PTA's effects on diabetes and dyslipidemia. In the present study, feeding C57BL/6J mice a HF diet induced hyperglycemia, obesity, hyperinsulinemia, hypertriglyceridemia, hyperleptinemia, and excess circulating free fatty acid, consistent with earlier observations.[31] Following treatment with PTA, blood glucose levels, circulating triglycerides, and visceral fat mass were lowered along with a reduction in free fatty acid and improved insulin resistance.

One of the difficulties in pursuing the mechanism of action of this compound is its limited availability, although at present PTA could be produced in great quantity. Therefore, PTA was first administered at concentrations of 0.2, 0.4, and 0.8 g/kg in OGTT by ICR mice. It was found PTA could lower blood glucose levels. Then, PTA was administered at concentrations of 0.06 and 0.12 g/kg in chronic HF-fed mice. On the basis of the few amounts of PTA and the duration of the 4 week chronic treatment experimental design, tormentic acid at a dosage of 30 mg/kg exerted an antihyperglycemic effect but did not act in rats with severe diabetes induced by an injection of streptozotocin,[19,20] so the concentration of PTA was lowered to 0.06 and 0.12 g/kg (duplicated or four times) in HF-fed mice; the daily dosage is expected to have a cumulative effect and a long-lasting effectiveness.

The primary aim is to investigate the antidiabetic mechanism of PTA, and we evaluate the GLUT4 protein content in the skeletal muscle. The present study showed that PTA2 caused marked increases of GLUT4 protein, and PTA1 displayed GLUT4 levels similar to those of Rosi, which is an antidiabetic agent and directly targets insulin resistance and increases peripheral glucose uptake (GLUT4), leading to improved glycemic control.[32] These findings are the first to reveal that PTA caused increased GLUT4 proteins as well as a direct relationship exhibiting antidiabetic activity. Thus, PTA

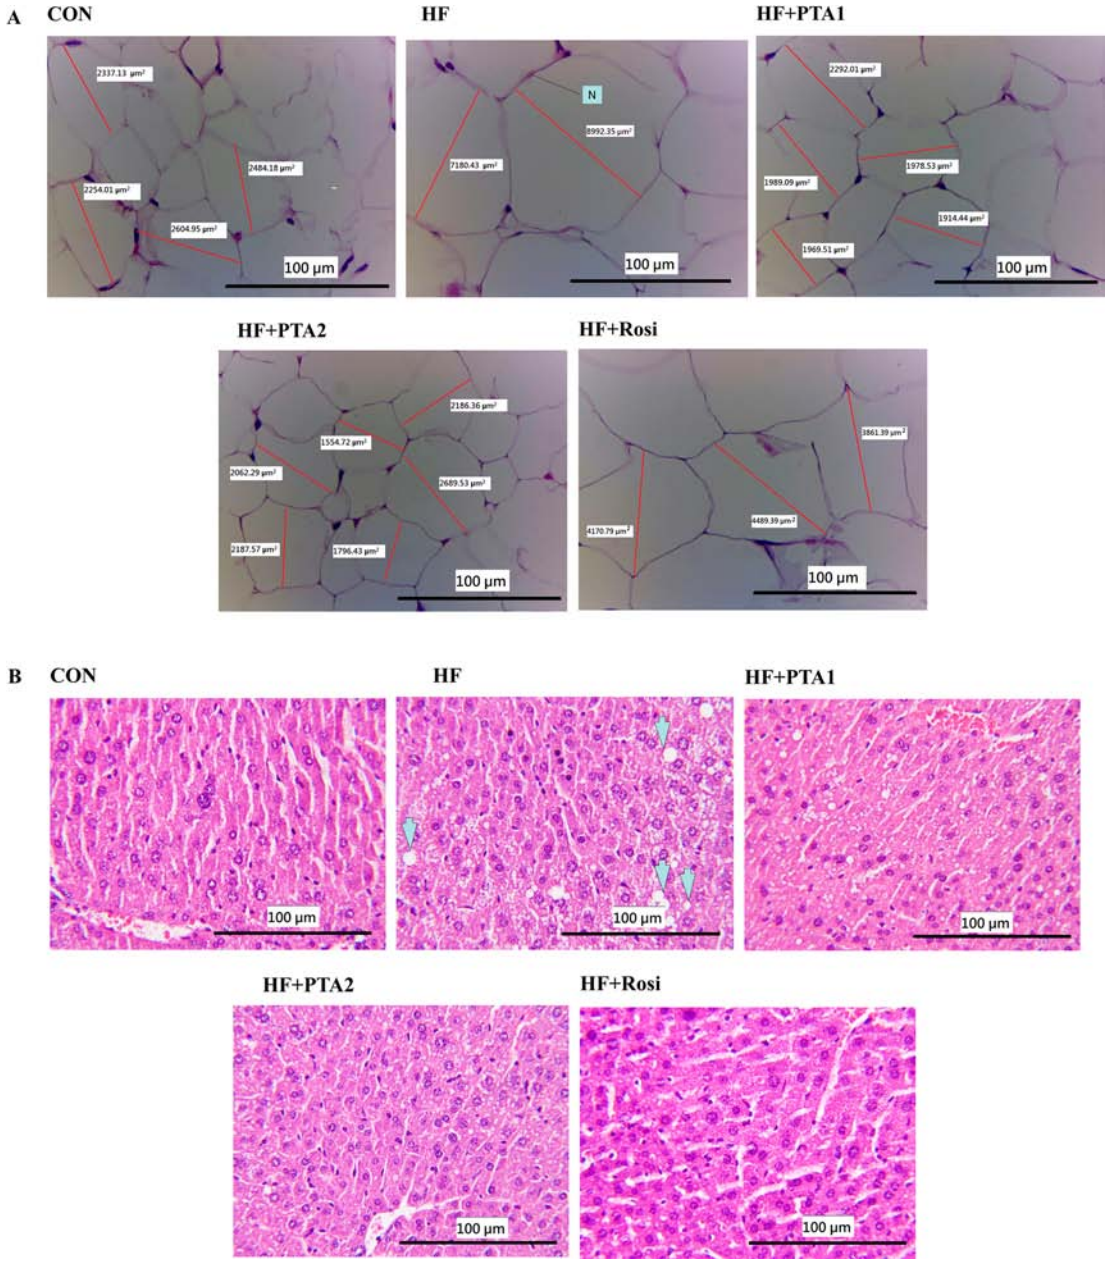

**Figure 3.** Effects of tormentic acid (PTA) on (A) epididymal WAT and (B) liver tissue morphology in the low-fat (CON), high-fat (HF), HF + PTA1, HF + PTA2, or HF + Rosi groups. Pictures of hematoxylin and eosin-stained sections of (A) mean area of adipocytes ($\mu m^2$) for epididymal WAT (magnification: 10 (ocular) × 20 (object lens)) from mice fed with PTA. The high-fat diet induced the hepatic ballooning degeneration in the HF group as compared with the CON group. The ballooning degeneration is a form of liver parenchymal cell death, and the nucleolus was squeezed into the other side named balloon (as the arrow indicates). This may be due to the heap of glycogen in the nucleus. The high-fat diet induced obesity and insulin resistance. Insulin levels affected the storage of hepatic glycogen. Treatment with PTA1 and PTA2 significantly decreased the degree of ballooning degeneration. Each presented is typical and representative of nine mice. Tormentic acid (PTA1:0.06 and PTA2:0.12 g/kg body wt); Rosi, rosiglitazone (0.01 g/kg body wt).

displayed a very marked enhancement of GLUT4 accompanied by ameliorated insulin resistance.

There are two pathways in regulated GLUT4 translocation including insulin signaling (those involving phosphatidylinositol 3′ kinase (PI3K)/Akt) and the AMPK pathway.[33] To monitor the mechanism of enhanced GLUT4 by PTA, we evaluated its effects on the phosphorylation of Akt in the skeletal muscle. The results demonstrated that PTA had a significantly increased effect on skeletal muscular phosphorylation of Akt, suggesting that PTA increased muscular GLUT4 contents are likely to be partly mediated by Akt phosphorylation; moreover, PTA enhanced Akt phosphorylation and increased insulin sensitivity.

Furthermore, it was evaluated that PTA acts on the phosphorylation of AMPK to the same effect as in people who exercise or take antidiabetic agents such as AICAR and metformin,[34,35] and rosiglitazone could activate AMPK. TZDs act as an AMPK activator, but differently from metformin, reduce liver fat accumulation, and ameliorate insulin resistance due to their effect on plasma adipocytokine (including adiponectin and leptin) and more AMPK activation.[36,37] Indeed, PTA increases skeletal muscular phosphorylation of

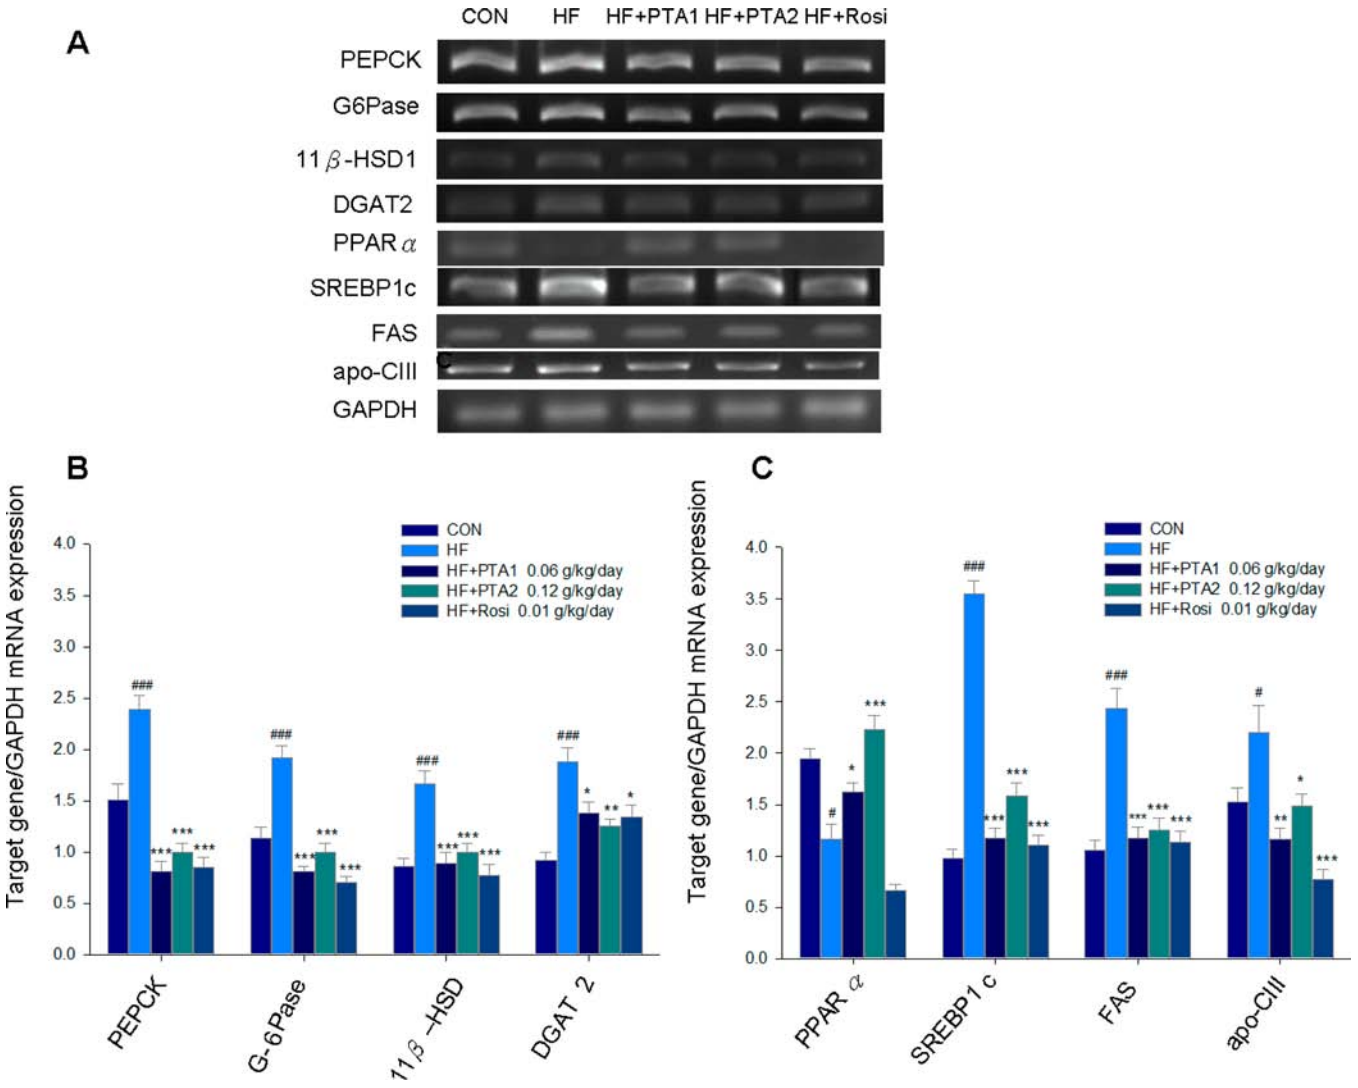

**Figure 4.** Semiquantative RT-PCR analysis on PEPCK, G6 Pase, 11$\beta$-HSD1, DGAT2, PPAR$\alpha$, SREBP1c, FAS, and apo C-III mRNA expression in liver tissue of the mice receiving oral gavage extracts of tormentic acid (PTA) for 4 weeks. All values are means ± SE ($n$ = 9). (#) $p < 0.05$ and (###) $p < 0.001$ compared with the control (CON) group; (∗) $p < 0.05$, (∗∗) $p < 0.01$, and (∗∗∗) $p < 0.001$ compared with the high-fat + vehicle (distilled water) (HF) group. Tormentic acid (PTA) (PTA1:0.06 and PTA2:0.12 g/kg body wt); Rosi, rosiglitazone (0.01 g/kg body wt). Total RNA (1 $\mu$g) isolated from tissue was reverse transcripted by MMLV-RT, and 10 $\mu$L of RT products was used as template for PCR. Signals were quantitated by image analysis; each value was normalized by GAPDH.

AMPK, suggesting that it is possibly partly responsible for increased GLUT4 translocation. Further study on the phosphorylation of AS160 is needed.

The liver is the organ responsible for the majority of hepatic gluconeogenesis.[38] A number of hormones regulate a set of genes (including PEPCK and G6 Pase) in the liver that modulates the rate of glucose synthesis. PEPCK is a rate-controlling step of gluconeogenesis in animals, and G6 Pase plays a vital role in glucose homeostasis.[39] Overexpression of the PEPCK enzyme in mice results in symptoms of type 2 diabetes. The hepatic G6 Pase activities of diabetic animals were increased.[40] PTA treatment reduced the expressions of PEPCK and G6 Pase. Therefore, the antidiabetic effect of PTA is due to down-regulation of PEPCK and G6 Pase. Furthermore, PEPCK is controlled by hormonal mechanisms including 11$\beta$-HSD1. 11$\beta$-HSD1 knockout mice fed a HF diet are protected from developing insulin resistance.[18,41] Therefore, compounds that down-regulate 11$\beta$-HSD1 might contribute to antidiabetic activities.[18] Besides PEPCK and G6 Pase, PTA-decreased hepatic 11$\beta$-HSD1 expressions also lead to enhanced insulin sensitivity.

AMPK activation is beneficial in the management of type 2 diabetes.[42] Metformin is a medication for the treatment of type 2 diabetes causing increased skeletal muscular glucose uptake and reduced gluconeogenesis in the liver.[20] HF-induced reduced phospho-AMPK in the liver, with increased in PTA- and Rosi-treated groups, indicates improved hyperglycemia by AMPK activation. Besides increasing muscular glucose uptake (GLUT4), PTA is likely to reduce hepatic glucose production by down-regulations of PEPCK and G6 Pase via AMPK.

To monitor the mechanism of PTA on antihyperlipidemia, we found that PTA increased PPAR$\alpha$ expressions. PPAR$\alpha$ ligands (such as fibrates) have been shown to reduce the expression of the apo C-III gene,[43] thus resulting in lowering fat values in the blood and liver and exhibiting a hypotriglyceridemic effect. We also measured DGAT2 expressions. DGAT2 catalyzes the final step in the synthesis of triglycerides.[18,44] It was found that PTA decreased circulating TG levels, and this

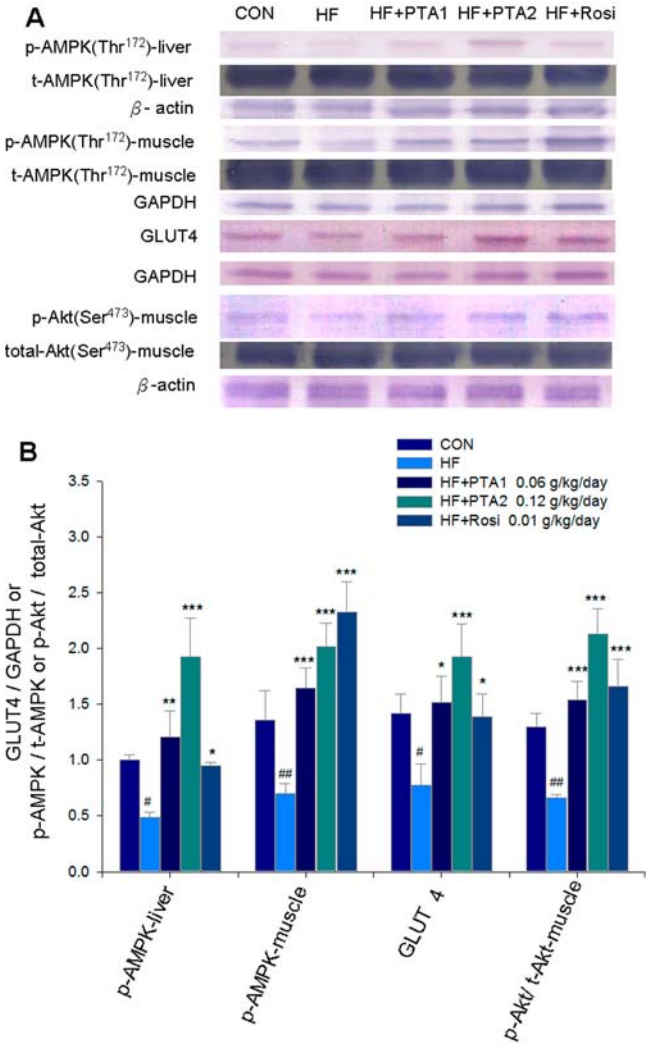

**Figure 5.** Protein contents of GLUT4 in skeletal muscle, the ratio of phospho-AMPK (Thr172) to total AMPK in liver tissue and skeletal muscle, and quantified results for the phosphorylation status of Akt (p-Akt normalized to total Akt (pAkt/Akt)) in skeletal muscle of the mice receiving tormentic acid (PTA) by oral gavage for 4 weeks. Protein was separated by 12% SDS-PAGE detected by Western blot. All values are means ± SE ($n$ = 9). (#) $p < 0.05$ and (##) $p < 0.01$ compared with the control (CON) group; (*) $p < 0.05$, (**) $p < 0.01$, and (***) $p < 0.001$ compared with the high-fat plus vehicle (HF) group. Tormentic acid (PTA) (PTA1:0.06 and PTA2:0.12 g/kg body wt); Rosi, rosiglitazone (0.01 g/kg body wt).

may be associated with decreased DGAT2 expressions. Previous study showed that leptin activated AMPK.[45] It is possible that PTA directly caused AMPK phosphorylation or altered leptin secretion by PTA, inducing AMPK activation. The blood leptin level is markedly reduced in PTA-treated mice, which is consistent with the reduced fat mass.[46] PTA significantly reduced SREBP1c, a key transcription factor controlling de novo lipogenesis.[47] Moreover, PTA suppressed the expression of FAS, which is a key enzyme in fatty acid synthesis. The glucose-induced SREBP1c and FAS mRNA levels were also down-regulated by AMPK.[48] The AMPK activator metformin has been shown to down-regulate FAS expression via AMPK activation.[7] Therefore, it is possible that PTA down-regulated these genes through AMPK activation.

The evidence for morphological analysis comes from the finding that treatment with PTA1 and PTA2 decreased the hypertrophy of adipocytes. The liver is a major organ metabolizing fat. The level of circulating TG fluctuates;[49] it is possible that PTA caused fat to move from adipose to liver tissue by increasing hepatic lipid catabolism, thus resulting in decreased size of adipocytes and almost the complete absence of liver lipid droplets.

In conclusion, this study demonstrated that PTA effectively lowers hyperglycemia and hypertriglycemia in HF-fed mice. PTA improves glycemic control primarily via increased skeletal muscular GLUT4 proteins to elevate glucose uptake but suppresses hepatic glucose production (down-regulations of PEPCK and G6 Pase). PTA enhanced AMPK phosphorylation both in skeletal muscle and in the liver. PTA enhanced skeletal muscular Akt phosphorylation and increased insulin sensitivity. PTA increased hepatic fatty acid oxidation (PPAR$\alpha$), but suppressed lipogenic enzyme expression (including SREBP1c and FAS), thus contributing to lowering triglyceride levels. Therefore, tormentic acid is effective on type 2 diabetes and hyperlipidemia in HF-fed mice.

in vivo of verbascose was evaluated by using animal models through the measurement of immune organ index, lysozyme activity, hemolysin level, and swelling rate of earlap in delayed-type hypersensitivity (DTH) reaction.

## MATERIALS AND METHODS

**Materials and Chemicals.** Mung beans were obtained from a local market (Nanjing, China). The RAW264.7 murine macrophage cell line was purchased from Nanjing University of Chinese Medicine (Nanjing, China). The Kunming mice (8 weeks old), grade of specific pathogen free (SPF) with body weights (BWs) of 20 ± 2 g, were purchased from the Experiment Animal Center of Academy of Military Medical Sciences (Beijing, China). Mulbecco's modified Eagle medium (DMEM), newborn calf serum, 4-(2-hydroxyethyl)-1-piperazine-ethane-sulfonic acid (HEPES), and trypan blue dye were purchased from Gibco/Invitrogen (Carlsbad, CA, USA). Sheep blood and guinea pig serum were purchased from Chuanxiang Biotechnology Co. (Shanghai, China). Lipopolysaccharide (LPS), neutral red, penicillin–streptomycin stock solution, and 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) were obtained from Sigma-Aldrich Chemical Co., Ltd. (St. Louis, MO, USA). Cyclophosphamide (CPA) was purchased from Jiangsu Hengrui Medcine Co. (Nanjing, China). Dinitrofluorobenzene (DNFB) was purchased from Xiya Reagent Co., Ltd. (Chengdu, China). Levamisole hydrochloride was purchased from Jinan Aodekai Pharmaceutical Co., Ltd. (Jinan, China). Lysozyme kit and NO kit, as well as IL-6, IL-1$\beta$, INF-$\alpha$, and INF-$\gamma$ ELISA kits were purchased from Nanjing Jiancheng Bioengineering Institute (Nanjing, China). Chromogenic TAL/TAL end point assay kit for determination of endotoxin was purchased from Chinese Horseshoe Crab Reagent Manufactory Co., Ltd. (Xiamen, China). All other reagents used were of analytical grade.

**Preparation of Verbascose from Mung Beans.** The preparation of verbascose from mung beans was carried out according to the reported method.[21] Full grains of pest-free mung beans were selected and crushed with a grinder, and the powder was extracted two times with 80% aqueous ethanol in a ratio of 10:1 (ethanol solution to material, mL/g) at 70 °C for 60 min. The extract was centrifuged at 2800*g* for 10 min. The supernatants of two extractions were combined and concentrated by using a rotary vacuum evaporator (Heidolph, Germany). The resulting residue was loaded onto a column (2.0 × 30.0 cm) of charcoal/Celite (1:1, w/w), and the column was successively eluted with a linear gradient of 0–50% aqueous ethanol. The fractions were collected (40 mL/tube) and screened by reaction with naphthoresorcinol, and those with sugars were further analyzed by using an Agilent 1100 series HPLC system (Agilent, USA) with a refraction index detector (RID). The separation of sugars was completed on a Sugar-D column (4.6 × 250 mm, Nacalai Tesque Inc., Kyoto, Japan) by using acetonitrile/water (75:25, v/v) as the mobile phase at a flow rate of 1.0 mL/min. Sugars were identified by comparing the retention times with those of standard sugars. The fractions containing verbascose only were combined, concentrated in vacuo, and further purified by gel filtration chromatography of Biogel P-2 (1.5 × 100.0 cm). The fractions (2.5 mL/tube) containing verbascose checked by HPLC were combined, concentrated/ and freeze-dried, affording high-purity verbascose. The structure of verbascose prepared was characterized by HPLC, mass spectrometry (Mariner system 5304 mass spectrometer, Applied Biosystems, Foster City, CA, USA), and nuclear magnetic resonance (NMR) spectroscopy. $^{1}$H and $^{13}$C NMR spectra of the sample, dissolved in deuterated water, were recorded on a Burker Avance DRX-500 spectrometer (Bruker, Karlsruhe, Germany) at a temperature of 298 K. Data for verbascose: $^{1}$H NMR (500 MHz, $D_2O$) $\delta$ 5.42 (d, 1H, $J$ = 3.7 Hz), 4.98 (t, 2H); $^{13}$C NMR (500 MHz, $D_2O$) $\delta$ 106.44, 100.98, 100.57, 100.41, 94.74, 83.98, 79.00, 76.64, 75.39, 73.90, 73.59, 72.14, 72.03, 71.88, 71.48, 71.30, 71.08, 70.91, 69.10, 68.95, 68.49, 65.12, 64.08, 63.80; MS $m/z$ 851.27 for $[M + Na]^+$ (calcd for $C_{30}H_{52}O_{26}$ $[M + Na]^+$, 851.2639).

**Determination of Endotoxin Contamination.** The concentration of endotoxin in the verbascose sample was measured by using a chromogenic TAL/TAL end point assay kit according to the manufacturer's instruction.

**Cell Culture.** The RAW264.7 cells cryopreserved in liquid nitrogen were rapidly thawed in a water bath at 37 °C, transferred to sterile tissue culture dishes, suspended in DMEM supplemented with 10% newborn calf serum, 100 IU/mL penicillin, and 100 IU/mL streptomycin, and incubated in a humidified 5% $CO_2$ incubator at 37 °C. When the cells spread to >80% of the bottom of the culture dishes, the adherent cells were kept for cell passage and used for further culture.

**Assay of RAW264.7 Cell Viability.** Measurement of RAW264.7 cell viability was done according to the MTT-based colorimetric method.[39] Briefly, the RAW264.7 cells, suspended at a density of 1 × $10^5$ cells/mL in DMEM supplemented with 10% newborn calf serum, 100 IU/mL penicillin, and 100 IU/mL streptomycin, were seeded into a 96-well flat-bottom plate (100 $\mu$L/well) and inoculated in a humidified 5% $CO_2$ incubator at 37 °C for 12 h. The nonadherent cells in the wells were removed by washing three times with DMEM. After that, a series of concentrations of verbascose solution (final concentrations of 25.0, 50.0, 100.0, 200.0, and 400.0 $\mu$g/mL) were added (100 $\mu$L/well). LPS (final concentration of 10.0 $\mu$g/mL) and complete DMEM alone were used as positive control and blank control, respectively. The cells were incubated as mentioned above for 12, 24, 36, and 48 h, respectively. After each incubation, 200 $\mu$L of MTT solution (0.5 mg/mL) was added to each well, and the plate was further incubated at 37 °C for 4 h. Finally, the reaction was stopped by adding 150 $\mu$L of DMSO to each well for the dissolution of formazan crystals. The absorbance (Abs) at 570 nm was determined by a Synergy 2 Multimode Microplate Reader (BioTeK Instruments, Inc., Winooski, VT, USA), and the cell viability rate was calculated according to the formula below:

$$\text{cell viability rate (\%)} = \text{Abs}_{\text{sample}}/\text{Abs}_{\text{control}} \times 100$$

**Assay of Phagocytosis of RAW264.7 Cells.** Phagocytosis of RAW264.7 cells was measured according to the reported method with modification.[40] The prior stage culture of RAW264.7 cells was done as previously described. The verbascose solutions with different concentration (25.0, 50.0, 100.0, 200.0, and 400.0 $\mu$g/mL) as well as a blank control (complete DMEM) and positive control (LPS, 10.0 $\mu$g/mL) were added to a 96-well plate (100 $\mu$L/well), and the plate was incubated at 37 °C in a 5% $CO_2$ incubator for 24 h. Subsequently, the neutral red solution at a concentration of 0.075% was added to each well (100 $\mu$L/well). After further incubation for 1 h, the cells were washed with phosphate-buffered saline (PBS) two times to remove excess neutral red. After that, a mixture of glacial acetic acid (0.1 M) and ethanol (1:1, v/v) was added to each well (100 $\mu$L/well), and the plate was incubated again overnight at 37 °C. Finally, Abs at 540 nm of each well was measured by using an ELISA plate reader. The phagocytosis index of devouring neutral red of peritoneal macrophages was calculated by using the following equation:

$$\text{phagocytosis rate (\%)} = \text{Abs}_{\text{sample}}/\text{Abs}_{\text{control}} \times 100$$

**Assay of NO and Cytokines.** The NO amount released by peritoneal macrophages was determined by measuring the nitrite level in the cell supernatant with Greiss reaction.[41] Briefly, the collected cell supernatant from the assay of phagocytosis of peritoneal macrophages was mixed in 96-well cell plates with Griess reagent (1% sulfanilamide and 0.1% *N*-1-naphthylethylenediamine dihydrochloride in 5% phosphoric acid) in equal volume and incubated at room temperature for 10 min. Abs at 492 nm was then measured by an ELISA plate reader by using sodium nitrite ($NaNO_2$) as a standard. The levels of cytokines (IL-6, IL-1$\beta$, IFN-$\alpha$, and IFN-$\gamma$) were measured by using an ELISA kit according to the manufacturer's protocol.

**Animal Grouping and Experimental Design.** All animals were treated according to the previously reported method,[42] and the procedures involving animals were conducted in strict accordance with the Chinese legislation on the use and care of latoratory animals. Briefly, female Kunming mice were housed in an air-conditioned animal room with constant temperature (21 ± 1 °C), 50–60% relative

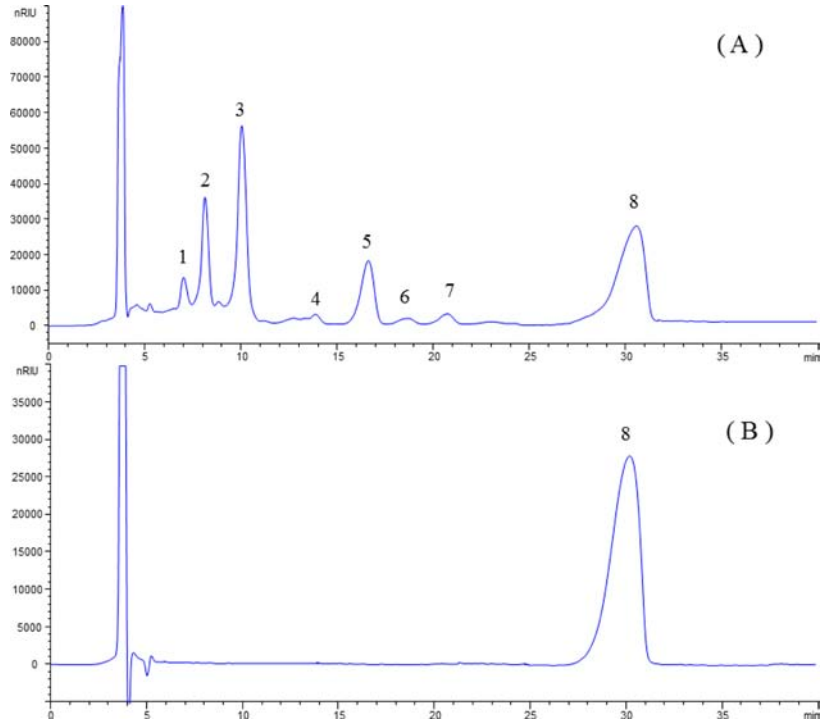

**Figure 1.** HPLC chromatograms of soluble sugars (A) and purified verbascose (B) from mung beans. HPLC conditions: column, Sugar-D (4.6 × 250 mm); mobile phase, acetonitrile/water (75:25, v/v); flow rate, 1.0 mL/min; detector, RID. Peaks: 1, fructose; 2, glucose; 3, sucrose; 4, melibiose; 5, raffinose; 6, unknown compound; 7, stachyose; 8, verbascose.

humidity, and a 12 h light/dark cycle with free acess to laboratory chow and water. After acclimatization for 7 days, the mice were randomly assigned to six groups (eight for each group). The mice in group I (normal control) were given a hypodermic injection of 0.9% NaCl once daily for 8 days. The mice in group II (model control group) were given a hypodermic injection of 0.9% NaCl once daily as well as a hypodermic injection of CPA (100 mg/kg BW) on days 2, 3, and 4. Group III was positive control, in which 0.9% NaCl was replaced with levamisole hydrochloride on the basis of group II. Groups IV–VI were verbascose treatment groups at doses of 30, 90, and 270 mg/kg BW, respectively. Different doses of verbascose were given for 8 consecutive days, and a hypodermic injection of CPA (100 mg/kg BW) was performed on days 2, 3, and 4. At 12 h after the last administration, all of the mice were sacrificed by using a cervical dislocation method and the spleen index, thymus index, swelling rate of earlap, lysozyme activity, and serum 50% hemolytic value ($HC_{50}$) were measured.

**Lymphoid Organ and Body Weights.** The BWs of mice in each group were measured during the experimental period. Furthermore, the weights of vital organs (spleen and thymus) were recorded after cervical dislocation of the mice. The viscera index was calculated as

$$\text{viscera index (mg/g)} = W_1/W_0$$

where $W_1$ is the weight of the spleen or thymus and $W_0$ is the BW of mouse.

**DTH Response.** DNFB solution was prepared with acetone and vegetable oil in a ratio of 1:1 (v/v) in advance. On the third day of inspection, abdomenal hair on the mice was cut off (3.0 × 3.0 cm), and 30 μL of 1% DNFB was smeared slowly on the shaved abdomen. After 7 days of treatment, both sides of the right ears of the mice were embrocated with 20 μL of 1% DNFB, whereas the left ears were not treated (as control). After cervical dislocation of the mice, a 6 mm diameter round ear piece was taken from each earlap by using a puncher. The swelling rate of the earlap was calculated as follows:

$$\text{swelling rate of earlap (\%)} = (W_{\text{right ear}} - W_{\text{left ear}})/W_{\text{left ear}} \times 100$$

**Assay for Serum Hemolysis to Sheep Red Blood Cell (SRBC).** On the fourth day of treatment, the mice were sensitized by intraperitoneal injection of 0.2 mL of 2% SRBC suspension. At 24 h after the last inspection, the serum was collected through the eye orbit of the mouse and diluted with normal saline. The diluted serum (200 μL) was taken into a centrifuge tube, and 200 μL of SRBC (2%) and 200 μL of guinea pig serum were added in sequence. The diluted serum was substituted with normal saline as a blank control. The mixtures were incubated at 37 °C for 30 min and then centrifuged at 10000*g* for 5 min. The Abs of the supernatant was measured at 540 nm ($Abs_{sample}$). In addition, the Abs at which SRBC reached the half hemolytic situation was measured ($Abs_{SRBC}$). Briefly, 2% SRBC (1.0 mL) was centrifuged and the sediment was diluted with distilled water to a volume of 950 μL. After 10 min, 17% NaCl solution (50 μL) was added to afford a 0.2% hemoglobin solution. To the resulting hemoglobin solution (50 μL), 50 μL of SRBC suspension and 400 μL of normal saline were added. Finally, the Abs at 540 nm of the supernatant from centrifugation was measured as $Abs_{SRBC}$. The content of serum hemolysin antibody was expressed by $HC_{50}$ as follows:

$$HC_{50} = Abs_{sample}/Abs_{SRBC}$$

**Determination of Lysozyme Activity in Spleen and Serum.** The spleen and serum were obtained as previously described. The lysozyme activity was measured by an ELISA kit according to the manufacturer's protocol.

**Statistical Analysis.** Data are expressed as means ± SD and subjected to one-way analysis of variance (ANOVA). Duncan's new multiple-range test was performed to determine the significant difference using SPSS 18.0 software (SPSS Inc., Chicago, IL, USA).

## RESULTS AND DISCUSSION

**Preparation of Verbascose.** As shown in Figure 1A, the soluble sugars extracted from mung bean were effectively separated by HPLC. According to the retention times of standard sugars, fructose, glucose, sucrose, melibiose, raffinose,

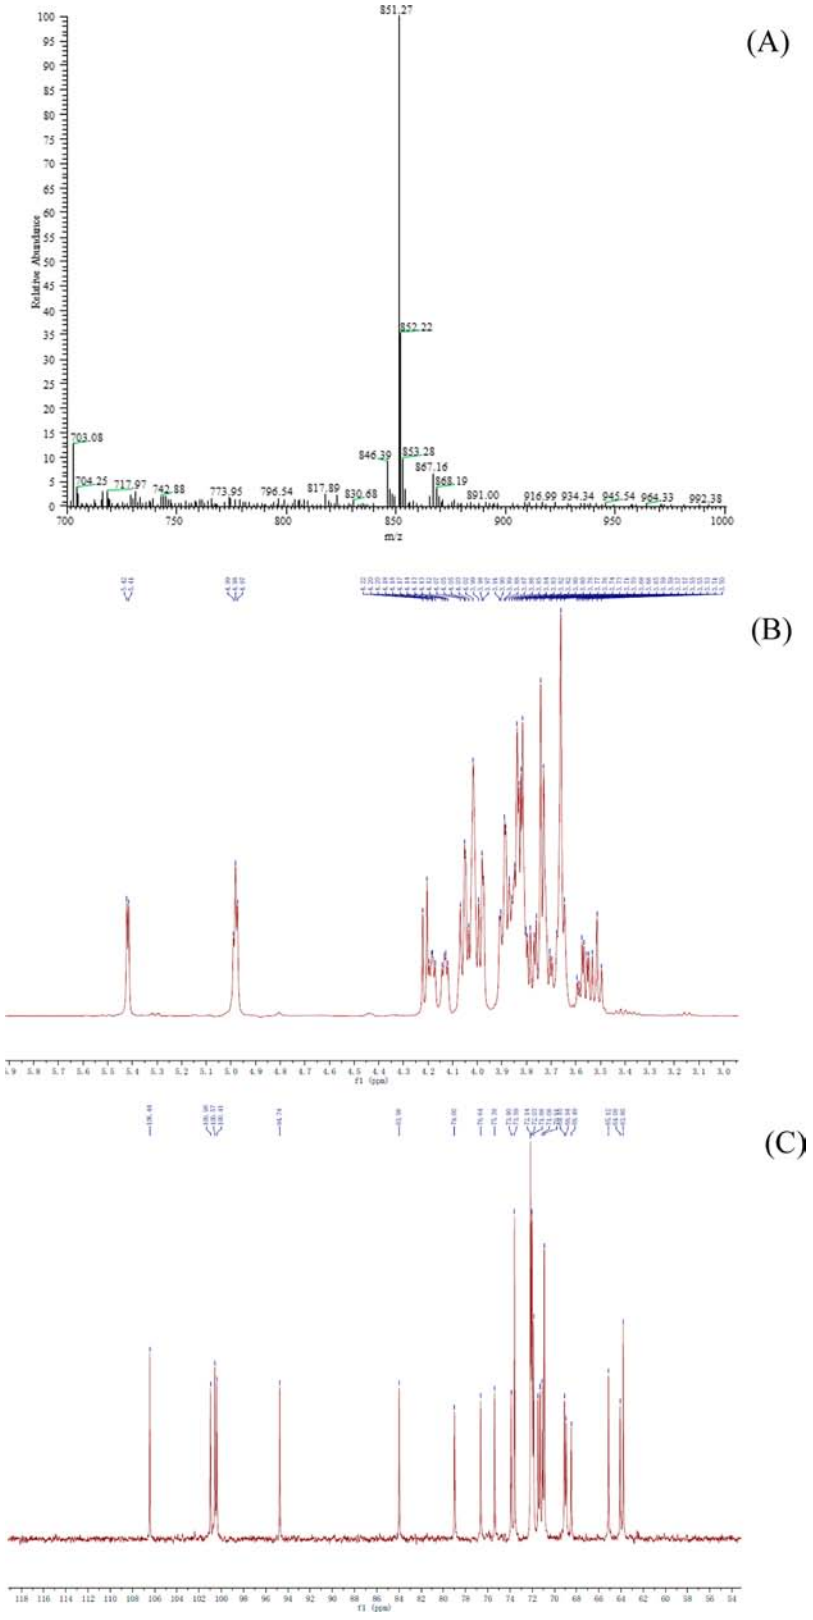

**Figure 2.** Mass spectrum (A) and $^{1}H$ (B) and $^{13}C$ NMR (C) spectra of verbascose prepared from mung bean.

stachyose, and verbascose were identified in mung beans. Notably, the three most abundant sugars were verbascose, sucrose, and raffinose, accounting for 41.8, 26.7, and 12.5% of the total soluble sugars in mung beans, respectively. The contents of monosaccharides and disaccharides including fructose, glucose, sucrose, and melibiose accounted for only 42.4% of the total soluble sugars, only slightly greater than the content of verbascose. Despite the low level of stachyose, $\alpha$-GOS still accounted for >50% of total soluble sugars. The results clearly demonstrate that nodigestible $\alpha$-GOS are the

[a]Different lower case letters represent a significant difference ($p < 0.05$) between different samples of the same time.

major oligosaccharides present in mung bean. Therefore, mung bean is one of the most suitable materials for verbascose preparation, which is consistent with the previous study.[20]

To prepare verbascose, the soluble sugars extracted from mung bean were separated by charcoal/Celite column chromatography combined with Biogel P-2 gel filtration chromatography. Charcoal/Celite column chromatography can isolate different carbohydrates mainly through their hydrophobic properties. However, stachyose and verbascose showed similar hydrophobicities, and both were eluted out by 15% aqueous ethanol in the present study. The mixture of stachyose and verbascose was further separated by Biogel P-2 gel filtration chromatography, due to the distinct difference in their molecular sizes. The data of MS and NMR (Figure 2) for the resulting fractions of verbascose clearly demonstrated that it was verbascose,[36] and the purity of verbascose obtained was 98.5% (Figure 1B).

**Endotoxin Contents.** Endotoxin, as a contaminant in biological preparations, has a capacity of immune stimulation. In the present work, we measured the endotoxin content in verbascose sample by TAL chromogenic method for the sake of endotoxin influence. As a result, the endotoxin contamination of verbascose sample was quite low (0.0056%), suggesting that the interference from endotoxin to the immunity could be ignored.

**Effects of Verbascose on RAW264.7 Cell Viability.** The viability of RAW264.7 cells is an indicator for further experiments of immune activation. The assay is dependent on the ability of viable cells to metabolize a water-soluble tetrazolium salt into a water-insoluble formazan product. Therefore, we investigated the effects of verbascose on the viability of RAW264.7 cells. As shown in Table 1, the viabilities of treatments by verbascose (100.0, 200.0, and 400.0 μg/mL) were significantly increased ($p < 0.05$) as compared with that of blank control after 12 h of incubation. However, after incubation for 24, 36, and 48 h, all of the doses of verbascose showed significant differences ($p < 0.05$) compared with the blank control, indicating that they all had positive influences on the viability of RAW264.7 cells. The cell viability increased with the increase of sample concentration and reached the maximum value at a concentration of 200.0 μg/mL. Furthermore, both treatments at concentrations of 200.0 and 400.0 μg/mL showed striking differences compared with the other treatments, but there was no significant difference between the two concentrations. The results suggested that the influence of verbascose on RAW264.7 cell viability was in a dose-dependent manner at lower concentrations. The treatments at 100.0, 200.0, and 400.0 μg/mL of verbascose with incubation time of 24 h exhibited the best effects on cell viability. Therefore, 24 h was selected for the cell culture time in the following experiments.

**Effects of Verbascose on Phagocytic Activity of RAW264.7 Cells.** Activated macrophage not only participates in both specific and nonspecific immune reactions but also is the "bridge cell" of these two kinds of immune reactions.[43] The increase in phagocytic activity is one of the most distinguished features of macrophage activation. Therefore, the neutral red phagocytosis assay was applied to evaluate the effects of verbascose on phagocytic activity of RAW264.7 cells, and the results are presented in Figure 3. The phagocytosis indices of

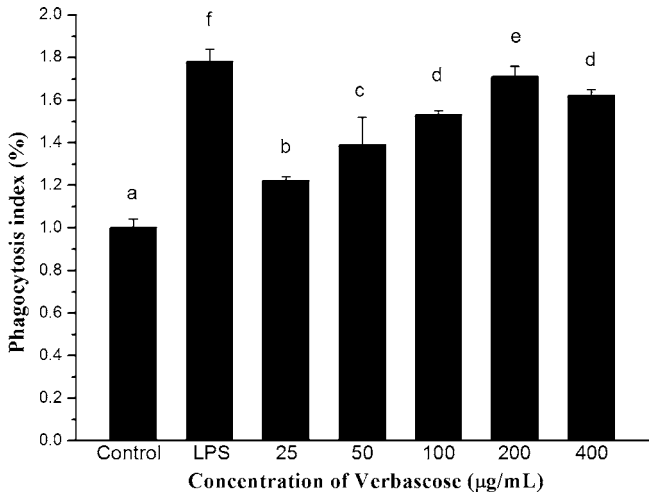

Figure 3. Effects of verbascose on phagocytosis of RAW264.7 cells. Letters a–f represent a significant difference ($p < 0.05$) between different concentrations of samples.

different doses of verbascose on devouring neutral red of peritoneal macrophages all exceeded 1.0, and all of the stimulating indices at different concentrations were comparable to that stimulated by LPS (positive control). The results demonstrated that verbascose had notable activity of promoting peritoneal macrophages to devour neutral red at a low dose. Furthermore, the promoting effects increased with the increases of sample concentration ranging from 25 to 200 μg/mL. Nevertheless, the phagocytosis index for treatment at 400 μg/mL was significantly lower ($p < 0.05$) than that of treatment at 200 μg/mL, which confirmed that verbascose exhibited its maximum activity of cell phagocytosis at a concentration of 200 μg/mL.

**Effects of Verbascose on NO and Cytokine Production.** Once activated, macrophages release a large number of cell factors, such as NO, INF, and $PGE_2$, to exert joint efficacy against microbial infections and cancer.[44] NO is a modulator of neurotransmission that can act as a vasorelaxant and defend against pathogens. It has been reported that the antitumor and antiviral activities, inflammatory reaction, and immune response

have a strong relationship with the release of NO.[45] Thus, we considered NO as an index to evaluate the immunomodulatory effects of verbascose. As shown in Figure 4, a minimum amount

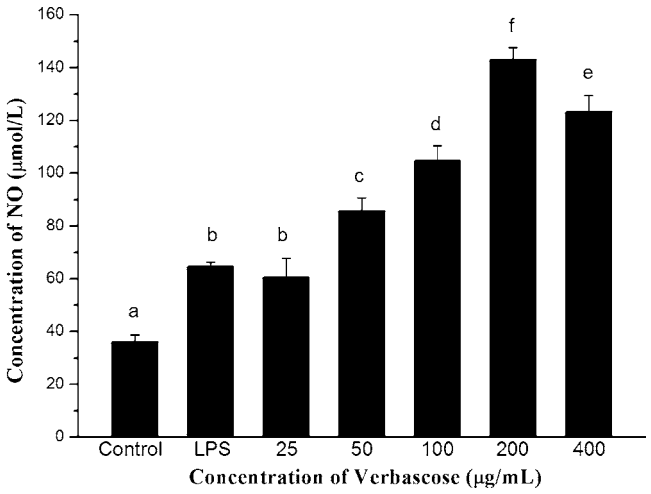

**Figure 4.** Effects of verbascose on nitric oxide level of RAW264.7 cells. Letters a–f represent a significant difference ($p < 0.05$) between different concentrations of samples.

of NO was produced in the blank control group, which might be due to the low expression of inducible NO synthase (iNOS) in static status RAW264.7 cells, whereas treatments with verbascose induced significant increases of NO production ($p < 0.05$), indicating that verbascose had the ability to activate macrophages to release NO. At concentrations of verbascose from 25.0 to 200.0 μg/mL, the levels of NO production showed a dose-dependent effect. In addition, between every two concentrations there was a significant difference ($p < 0.05$). It might be related to the expression of iNOS induced by verbascose.

Cytokines are small molecule proteins produced by immune cells with immunomodulatory and anti-inflammatory abilities. It is well-known that mature T cells, following antigen recognition, are induced to differentiate into three distinct functional subsets of Th1, Th2, and Th0 cells, which can be discriminated on the basis of the array of cytokines produced. Th1 cells secrete IL-2, IFN-$\gamma$, and TNF-$\beta$, and Th2 cells secrete IL-4, IL-5, and IL-6, whereas Th0 cells, having the capacity to produce both Th1 and Th2 cytokines, are believed to represent a stage of differentiation before commitment to the Th1 or Th2 lineage. Thus, the section of IFN-$\gamma$ and IL-6 may represent the function of mature T cells.[46,47] IL-1 (IL-1$\alpha$ and IL-1$\beta$) is the prototypic "multifunctional" cytokine, which affects nearly every cell type and often in concert with other cytokines or small mediator molecules. IFN-$\alpha$, produced by leukocytes, is mainly involved in innate immune response against viral infection.[34] Accordingly, the effects of verbascose on cytokine production (IL-1$\beta$, IL-6, IFN-$\alpha$, and IFN-$\gamma$) were investigated in the present study. Compared with those of the normal control group (Table 2), the concentrations of cytokines (IL-1$\beta$, IL-6, IFN-$\alpha$, and IFN-$\gamma$) secreted by RAW264.7 cells in all treatments of verbascose were significantly higher ($p < 0.05$). In the range of 25–200 μg/mL verbascose, the production of cytokines was enhanced in a dose-dependent manner, whereas there was no significant difference in the secretion of IL-6, IFN-$\alpha$, and IFN-$\gamma$ between the treatments of verbascose at concentrations of 400 and 200 μg/mL. The results indicated that verbascose could stimulate immune responses through the release of immune cell factors (IL-1$\beta$, IL-6, IFN-$\alpha$, and IFN-$\gamma$) as well as inflammatory mediators (NO).

**Effects of Verbascose on the Immune Organ Index.** Thymus decline is an important marker of immune system aging because the immune system degeneration is expressed as an aging process from center to periphery piloted by thymus involution. Thus, the immunomodulatory effect is closely related to the change of immune organ index.[48] CPA, a DNA alkylating agent with striking immunomodulatory properties being used as a chemotherapeutic and immunosuppression drug, may cause the decline of lymphocyte percent, peripheral blood leucocyte, macrophage phagocytosis, spleen index, thymus index, DTH earlap swelling, carbon clearance, and serum hemolysin. Therefore, it is often used to establish the immunosuppressed model.[49] In this study, the effects of verbascose on the thymus and spleen indices were investigated. Compared with the normal control group (Figure 5), significant decreases in indices of spleen and thymus were observed after treatment by CPA in model control group ($p < 0.05$). However, treatment of verbascose could improve the spleen index as compared with the model control group. Furthermore, the medium-dose treatment (90 mg/kg BW) exhibited the best effect (significant difference with the other treatments at $p < 0.05$), even though no significant difference was observed for medium-dose treatment and the normal group. For the thymus index, there were no significant difference between the treatment and model control group ($p > 0.05$), but the medium-dose treatment showed some improvements on the thymus index. The results suggested that verbascose was able to act against immunosuppression induced by CPA in vivo to some extent.

**Effects of Verbascose on DTH.** DTH is a protective localized cell-mediated immune response mediated by $CD4^+$ and $CD8^+$ T-cells, primarily against intracellular pathogens. In

Normal, normal control group, given a hypodermic injection of 0.9% NaCl once daily for 8 days; CPA-Model, model control group, given 0.9% NaCl once daily as well as a hypodermic injection of cyclophosphamide (CPA, 100 mg/kg body weight (BW)) on days 2, 3, and 4; Positive, positive control group, which replaced NaCl with levamisole hydrochloride on the basis of model control group; LVG-30, low dose of verbascose (30 mg/kg BW); MVG-90, medium dose of verbascose (90 mg/kg BW); HVG-30, high dose of verbascose (270 mg/kg BW).

the case of allergenic effect, T-lymphocyte may become sensitized lymphocyte and will generate a regional abnormal reactive inflammation when it encounters the allergen again. This allergic inflammation is delayed (starting after 12 h and peaking at 24−72 h) and characterized by cell degeneration and necrosis.[50] It has been reported that DNFB (a hapten) may become a complete antigen when binding with skin protein. It will then stimulate T-lymphocyte to form sensitized lymphocyte. After it is painted on the earlap of mice, regional earlap swelling would be observed 4−7 days later and the swelling rate of earlap is associated with the degree of DTH reaction. As shown in Figure 6, a significant decrease of earlap swelling rate was observed between the model control group compared and the normal control group ($p < 0.05$), which indicated the feasibilty of the present immunosuppressed model. When mice received positive drug or verbascose, they showed a significant DTH response in vivo ($p < 0.05$) compared with the normal control group. Compared with the positive control group, all of the treatments of different verbascose doses exhibited significant DTH responses. However, a notably significant immunological effect was observed for the treatment with the middle dose (90 mg/kg) of verbascose compared to the other two dose treatments ($p < 0.05$). The results suggested that verbascose might strengthen immune function by increasing DTH earlap swelling.

**Effects of Verbascose on Serum Hemolysin ($HC_{50}$).** Serum hemolysin antibody, secreted by B-lymphocytes when stimulated by a variety of antigens, is a reliable indicator reflected by the level of humoral immunity.[51] Therefore, we evaluated the levels of serum hemolysin antibody in response to SRBC in mice. As shown in Figure 7, the daily treatments of mice with 30 or 90 mg/kg doses of verbascose resulted in a significant enhancement of serum hemolysin level as compared with the model control group ($p < 0.05$). Particularly, there was no significant difference between the treatments of the middle dose of verbascose and positive control, and both treatments exhibited the best effects. However, the high-dose treatment (270 mg/kg BW) showed a sharp decrease in hemolysin level, indicating that the high-dose verbascose treatment might suppress the production of serum hemolysin to SRBC. From the above results, it was concluded that low-dose verbascose

treatment possessed the potential of immune-enhancing activity.

**Effects of Verbascose on Lysozyme in Serum and Spleen.** Lysozyme, also called muramidase or peptidoglycan *N*-acetylmuramoyl-hydrolase, existing extensively in animals, plants, and microorganisms, is considered to be a potent innate immunity molecule.[52] In vivo, lysozyme catalyzes the hydrolysis of the $\beta$-(1→4) glycosidic linkage between *N*-acetylmuramic acid and *N*-acetylglucosamine, alternates the sugar residues in the bacterial peptidoglycan, and causes bacterial cell lysis.[53] As a consequence, lysozyme occupies an important position in normal and nonspecific immunity. In the present study, the effects of verbascose on lysozyme activity in serum and spleen were evaluated, and the results are presented in Table 3.

**Table 3. Effects of Verbascose on Activity of Lysozyme in Mouse Spleen and Serum**[a]

| sample | lysozyme in serum (U/mL) | lysozyme in spleen (U/mg) |
|---|---|---|
| normal | 347.2 ± 19.14bcd | 142.96 ± 29.80d |
| CPA-model | 182.66 ± 25.91a | 77.23 ± 7.93a |
| levamisole | 486.15 ± 39.82d | 273.31 ± 15.08f |
| low dose of verbascose (30 mg/kg BW) | 272.69 ± 43.12abc | 90.68 ± 3.26b |
| medium dose of verbascose (90 mg/kg BW) | 427.63 ± 26.76cd | 146.91 ± 12.56e |
| high dose of verbascose (270 mg/kg BW) | 236.89 ± 20.35ab | 105.14 ± 15.19c |

[a]Different lower case letters represent a significant difference ($p < 0.05$) between different concentrations of samples.

Compared with the normal control group, the activities of lysozyme in the three doses of verbascose and positive drug were significantly enhanced ($p < 0.05$). In addition, it was found that treatment with a medium dose of verbascose (90 mg/kg BW) could significantly improve the activity of lysozyme compared with the other two treatment doses ($p < 0.05$) and restored the activity of lysozyme to normal level. The results suggested that verbascose could reinforce the immune function by raising the activity of lysozyme.

In conclusion, we demonstrated that verbascose could promote the proliferation in vitro of RAW264.7 cells, strengthen peritoneal macrophages to devour neutral red, and enhance the production of NO and cytokines (IL-1$\beta$, IL-6, IFN-$\alpha$, and IFN-$\gamma$). In in vitro experiments, treatment with 200 $\mu$g/mL verbascose exhibited the most significant immunomodulatory activity. As for in vivo experiments, the results demonstrated that verbascose could raise the spleen index, elevate the activity of lysozyme in serum, and increase the level of serum hemolysin and the swelling rate of earlap in DTH reaction. The results suggested that verbascose had potent immunostimulatory activity, and further works on its potential mechanisms are in progress.

## MATERIALS AND METHODS

**Plant Materials.** Two varieties of common legumes: lentil (*Lens culinaris* L., var. *Salmantina*) and kidney bean (*Phaseolus vulgaris* L., var. *Pinta*) were provided by Institute of Food Science, Technology and Nutrition (CSIC, Madrid). They were stored in dark and dry conditions under refrigeration.

**Processing Conditions.** Three batches of seeds (20 g of lentils and 50 g of beans) were sterilized in 1% NaClO solution for 30 min to reduce bacterial and fungal growth. Seeds were washed three times with distilled water and then soaked in distilled water for 5 h for seed hydration (ratio 1 g:20 mL, seed:water). They were germinated in an incubator (Construcciones Frigoríficas, Confri, S.L.) at 20 °C and 80% RH, illumination conditions of photoperiodic cycle (12 h light/12 h dark) and darkness (24 h dark) for 3, 6, and 8 days. Lentil and kidney bean sprouts were withdrawn, frozen in $N_2$, freeze-dried, and milled. Flours were passed through a 50-$\mu$m sieve and stored at 4−6 °C for further analysis.

**Melatonin Extraction and Quantification by HPLC-MS/MS.** Extraction was conducted according to Manchester et al.[22] and Ansari et al.[23] with some modifications. Briefly, lentil and kidney bean flours (2 g) were extracted with 10 mL of methanol (MeOH). Extracts were stored for 16 h at 4 °C in darkness. After a brief centrifugation at 2000*g* for 15 min at room temperature; the supernatants were filtered under vacuum by a filter (11 $\mu$m, Whatman) and they were evaporated to dryness under $N_2$ (g). The residues were resuspended in 2 mL of water, after a mild ultrasonic treatment for 2 min at room temperature; the reconstituted extracts were filtered using the solid phase extraction (SPE, cartridge C-18, Waters). The extracts obtained were evaporated to dryness by use of evaporator centrifuge (Speed Vac SC 200, Savant, USA). The residues were dissolved in MeOH/$H_2O$ (80:20; v/v) + 0.1% formic acid. Melatonin was determined by HPLC-ESI-MS/MS triple quadrupole (Varian 1200L with API-ES between 10 and 1500 Da range mass). Melatonin was recorded using multiple reaction monitoring (MRM) mode by selecting ion 233 ($M + H^+$) at the first quadrupole (Q1), fragmented in Q2 using Ar and analyzing resulting ion $m/z$ 130, 131, 159, and 174 at Q3, measuring at 174 (Figure 1). The system consisted of two pumps, Varian Prostar 210, and an Intensity Trio C18 (150 mm × 2.0 mm ID, S-3 $\mu$m, 12 nm BRYTC18032150) (Bruker) column, at a flow rate of 0.2 mL/min. Acetonitrile containing 0.1% formic acid (solvent A) and 0.1% formic acid in $H_2O$ (solvent B) as mobile phase were pumped with the following gradient: 5% solvent A (0−4 min), 5−100% solvent A (4−15 min), 100% solvent A (15−18 min), and 100−5% solvent A (18−25 min) to recover initial conditions. The injection volume was 50 $\mu$L. Quantification was performed using external standard method, using pure melatonin (Sigma-Aldrich Química, Spain) dissolved in MeOH/$H_2O$ (80:20; v/v) containing 0.1% formic acid, showing good regression coefficient ($R^2$ = 0.9989). Samples and standard solutions were analyzed in triplicate. Melatonin content was expressed as ng/g dry weight (DW).

**Phenolic Compounds Extraction and Determination.** Extraction of phenolic compounds was carried out following the Gou et al.[24] method with some modifications. Germinated flours (2 g) were blended using 30 mL of 80% chilled acetone (1:2, w/v) for 5 min and vortex for 10 min. The homogenates were then centrifuged at 2054*g* for 5 min. Supernatants were collected, and the extraction was repeated three times. All the supernatants were pooled and evaporated until 10% of the supernatants remained. The soluble phytochemical extracts were brought to 10 mL in water and were kept at −40 °C until analysis. For the extractions of bound phytochemicals, the residues from above soluble free extraction were flushed with $N_2$ and hydrolyzed directly with 20 mL of 4 M NaOH at room temperature for 1 h with shaking. The mixture was acidified to pH 2 with concentrated HCl, centrifuged at 2958*g* for 5 min, and extracted three times with ethyl acetate. The ethyl acetate fractions were evaporated to dryness, and were reconstituted into 1.5 mL of methanol and stored at −40 °C until analysis.

The phenolic compounds were determined by Folin−Ciocalteu colorimetric method according to Singleton et al.[25] using gallic acid (GAE) as standard. Phenolic compounds were expressed as mg GAE/100 g DW.

**Oxygen Radical Absorbing Capacity (ORAC) Assay.** The above methanol extracts were used for determining the radical absorbance activity by ORAC method using fluorescein as a fluorescence probe.[26] Briefly, the reaction was carried out at 37 °C in 75 mM phosphate buffer (pH 7.4) and the final assay mixture (200 $\mu$L) contained fluorescein (70 nM), 2,2-azobis (2-methyl-propionamidine)-dihydrochloride (12 mM), and antioxidant standard (Trolox [10−80 $\mu$M] or sample extracts). A Polarstar Galaxy plate reader (BMG Labtechnologies GmbH, Offenburg, Germany) was used to read fluorescence at wavelengths of 485 nm excitation and 520 nm emission. The equipment was controlled by the Fluostar Galaxy software version (4.31-0) for fluorescence measurement. Black 96-well untreated microplates (PS Balck, Porvair, Leatherhead, UK) were used. The plate was automatically shaken before preincubation, and the fluorescence was recorded every minute for 80 min. All reaction mixtures were prepared in duplicate and at least 3 independent runs were performed for each sample. Fluorescence measurements were normalized to the oxidation control (phosphate buffer) and stability control (no antioxidant). From the normalized curves, the area under the fluorescence decay curve (AUC) was calculated as

$$\mathrm{AUC} = 1 + \sum_{i=1}^{i=80} f_i/f_0$$

where $f_0$ is the initial fluorescence reading at 0 min and $f_i$ is the fluorescence reading at time $i$. The net AUC corresponding to a sample was calculated as follows:

$$\text{net AUC} = \text{AUC antioxidant} - \text{AUC blank}$$

The net AUC was plotted against the antioxidant concentration, and the regression equation of the curve was calculated. The ORAC

value was obtained by dividing the slope of the latter curve between the slopes of the Trolox curve obtained in the same assay. Final ORAC values were expressed as μmol of Trolox equivalents/g of dry sample (μmol TE/g DW).

**Statistical Analysis.** Each sample was analyzed in triplicate. Data were expressed as mean ± standard deviation (SD). The data were analyzed by one-way analysis of variance (ANOVA) and posthoc Duncan test. Differences were considered to be significant at $p < 0.05$. The statistical analysis was performed by SPSS 17.0.

## RESULTS AND DISCUSSION

**Germination Process.** The changes in biomass and percents of germination under different germination conditions are shown in Table 1. Legume biomass increased from 111% to 162% and lentil sprouts showed higher levels than bean sprouts at the same germination conditions. The highest rise was reached in lentil under eighth day 12 h light/12 h dark. The success of this processing exhibited good viability for both legumes, reaching 100% in case of bean sprouts at 12 h light/12 h dark on the eighth germination day. However, lentil exhibited lower germination percentage on the eighth day due to fungal growth. The parameter of development of radicle was different not only dependent on the kind of leguminous seeds, but also on process conditions (i.e., the presence of light and germination time). The length of bean radicle was higher than of lentils, irrespective of light conditions and germination time. These differences could be attributed to changes in bioactive compounds (melatonin) that promote vegetative plant growth.[12]

**Table 1. Changes in Seed/Seedlings Biomass and Percent of Germination at Different Illumination Conditions of Germination**[a]

| illumination conditions of germination | germination time (day) | % increase in fresh weight of seeds/ seedlings | % germination | development of radicle (cm) |
|---|---|---|---|---|
| | | Lentil | | |
| 12 h light/ 12 h dark | 3 | 137 ± 8 a | 92 ± 8 b | 1.4 ± 0.1 a |
| | 6 | 141 ± 9 a | 58 ± 5 a | 2.6 ± 0.1 b |
| | 8 | 162 ± 5 b | 59 ± 5 a | 4.5 ± 0.2 c |
| 24 h dark | 3 | 138 ± 5 a | 83 ± 7 b | 1.4 ± 0.1 a |
| | 6 | 150 ± 6 b | 83 ± 7 b | 4.1 ± 0.2 c |
| | 8 | 156 ± 10 b | 65 ± 6 a | 7.3 ± 0.2 d |
| | | Bean | | |
| 12 h light/ 12 h dark | 3 | 104 ± 6 a | 47 ± 3 a | 1.0 ± 0.1 a |
| | 6 | 126 ± 9 b | 84 ± 5 b | 3.7 ± 0.2 b |
| | 8 | 133 ± 9 c | 100 ± 4 c | 6.1 ± 0.4 d |
| 24 h dark | 3 | 90 ± 7 a | 46 ± 4 a | 1.9 ± 0.1 a |
| | 6 | 104 ± 8 a | 89 ± 5 b | 5.6 ± 0.2 c |
| | 8 | 111 ± 9 a | 96 ± 5 b | 10.6 ± 0.6 e |

[a]Results are reported as mean ± SD ($n = 3$). Mean values of each row of different illumination conditions followed by different superscript letter significantly differ when subjected to Duncan's multiple range test ($p < 0.05$).

**Melatonin.** Different methods have been developed for melatonin identification in plant extracts. Melatonin was detected in raw lentil and kidney beans varieties studied, and chromatograms are shown in Figure 2. From the results, kidney beans exhibited higher melatonin content than lentils (1.0 and 0.4 ng/g DW, respectively). These data explain the different elongation showed by legume sprouts that could be due to melatonin levels. This molecule exhibits auxinic activity in a way similar to indole-3-acetic acid (IAA).[12] In comparison to other plant foods, the results obtained were higher than those reported in other seeds such as sweet corn and rice,[27] indicating a good dietary melatonin source. The available scientific data of melatonin in foods are scarce because only a few food items have been analyzed. Melatonin levels are greatly variable among plant species, apart from seeds, fruits (12−36 pg/g WW), roots protected from light such as carrots and onions, or processed foods such as fermented drinks (0.1−35 ng/mL) and olive oil (108 pg/mL) are also natural sources of melatonin.[19]

Germination brought about a noticeable increase in melatonin ($p < 0.05$) and this effect was time-dependent in all seeds studied (Figure 3). Reports indicated higher melatonin levels at complete darkness[28] and relative increases in cucumber and red cabbage germinated seeds.[29,30] To our knowledge, the present work is the first report on the melatonin content of lentil and bean sprouts to improve the content of this bioactive compound. In this sense, melatonin content increased significantly in lentil sprouts during both germination processes, showing similar values under 12 h light/12 h dark and 24 h dark conditions (Figure 3a). In both illumination conditions, the highest contents were shown on the sixth germination day (2.3 and 2.5 ng/g DW under 12 h light/12 h dark and 24 h dark, respectively). After the sixth germination day, the levels of melatonin decreased in lentil sprouts, being more pronounced under 24 h dark (72% of decrease with respect to the sixth germination day). Similar behavior was found in bean sprouts (Figure 3b). On the sixth processing day, germination significantly influenced melatonin accumulation in both germination conditions, up to 2.4-fold at 12 h light/12 h dark and more accentuated, up to 9.4-fold at 24 h dark conditions. Finally, it is worth emphasizing that a sharp melatonin decrease (94%) from the sixth to eighth germination day was observed at 24 h darkness (0.6 ng/g DW) and less accentuated (38% of decrease) at 12 h light/12 h dark (1.5 ng/g DW). Thus, germination in darkness for 8 days did not cause melatonin increase either in lentils or beans. Our data were in agreement with those of Zielinski et al.,[31] who found contents of melatonin in lentil, vetch, and soybean seeds, as well as increases in melatonin during 7 days of germination. Hence, melatonin content in lentil showed maximum levels at sixth germination day either at 12 or 24 h dark, while melatonin content in bean reached the highest content at 24 h dark. From our results, melatonin was mainly influenced by photoperiods; darkness regimes led to more of this bioactive compound in kidney bean and these results were in agreement with those of Murch et al.[27]

The melatonin originated from these sprouts may play a role as a health promoting substance with clear antioxidant and anti-inflammatory properties; its genomic effects, and its capacity to modulate mitochondrial homeostasis, are linked to the redox status of cells and tissues.[16] From our results, the sprout intake, especially germinated beans, could be considered as a food source of dietary melatonin.

**Phenolic Compounds.** The free, bound (cell wall-associated), and total phenolic compounds (TPC) of lentil and bean sprouts are shown in Figure 4. TPC in raw lentil and bean seeds were 488 and 379 mg GAE/100 g DW, respectively. These legume seeds seem to be a good source of phenolic compounds and our results are within the range of previously reported data.[32−34] The predominant phenolic compounds in lentils and beans are catechins and procyanidins;[35,36] however, the phenolic composition of legume seeds may vary among

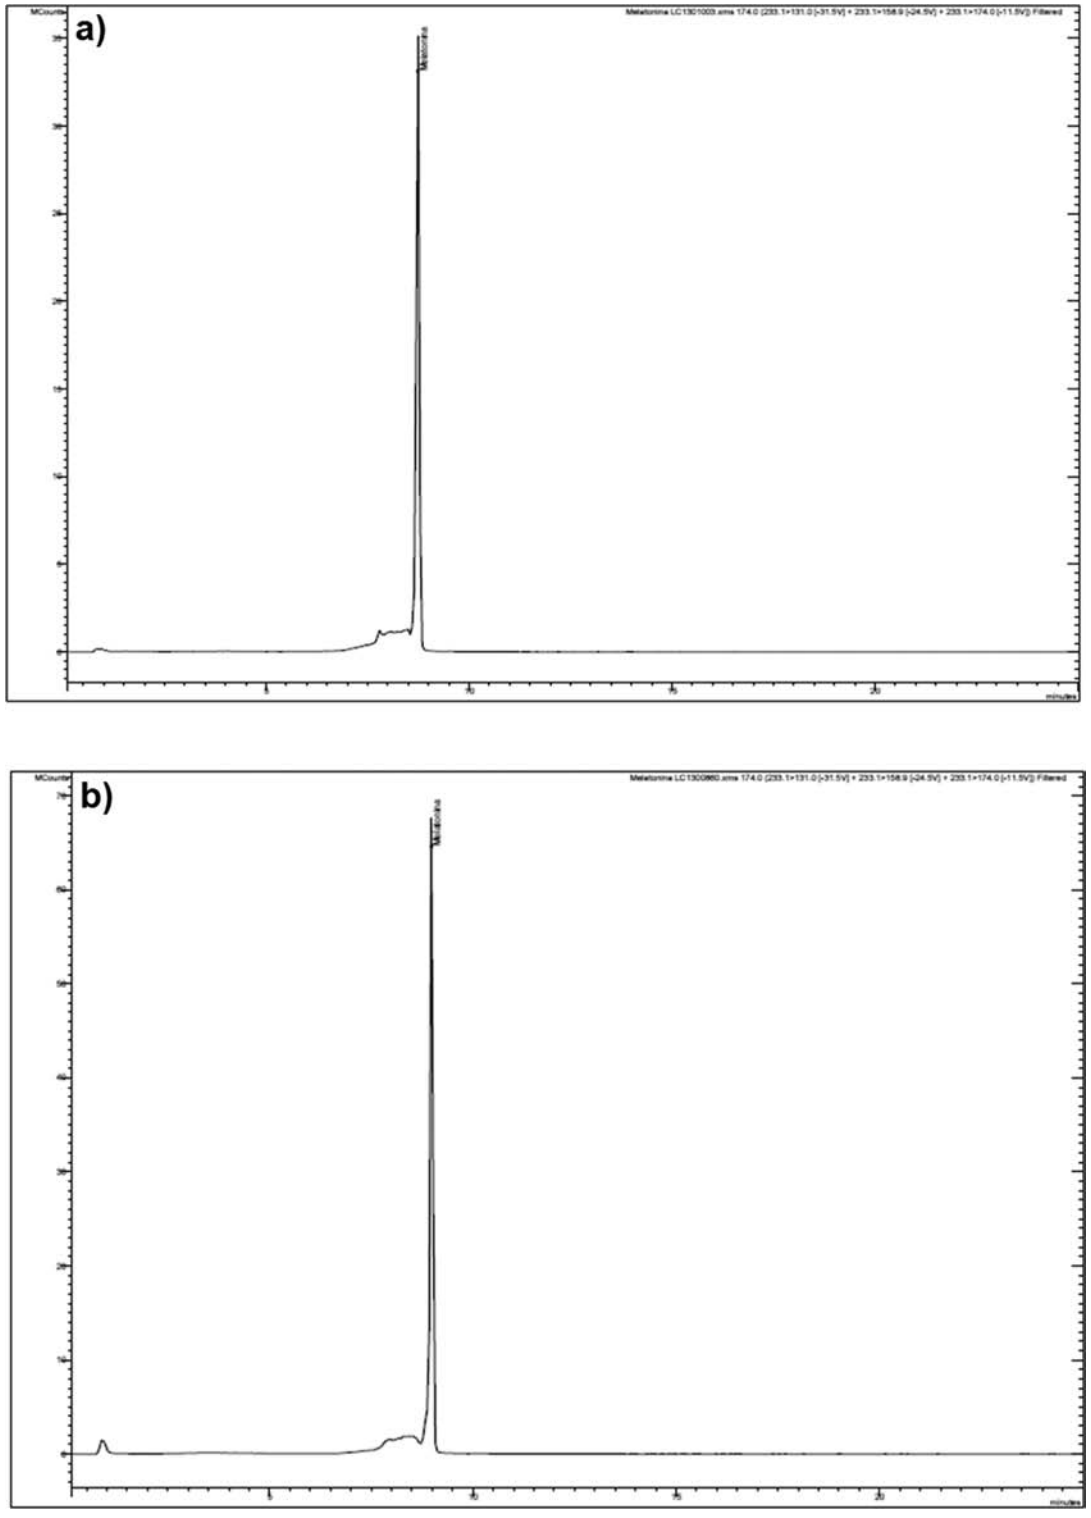

**Figure 2.** HPLC-MS/MS chromatograms of raw lentil (a) and raw kidney bean (b).

cultivars and genotypes. Differences among them may be attributed to differences in the color of the seed coat as has been reported in the literature,[32] lentil was darker than kidney bean. Lentil seeds showed 88% of free phenolic contents with respect to TPC (Figure 4a), while kidney bean seeds exhibited a higher percentage of free phenols (92%) and consequently, a lower percentage of bound phenols (8%) (Figure 4b). These results are in agreement with those found in other legume seeds.[24,37]

Our results exhibited that TPC decreased dramatically in lentil sprouts at both darkness germination conditions (12 and 24 h dark), while kidney bean sprouts exhibited relevant decreases at 12 h light/12 h dark but no relevant changes at 24 h dark germination conditions. These results are in agreement with the findings of Khandelwal et al.[32] and Troszyńska et al.[38]

With respect to lentil, decreases of phenolic compounds (total, free, and bound forms) were initiated at the third germination day and maintained during germination conditions

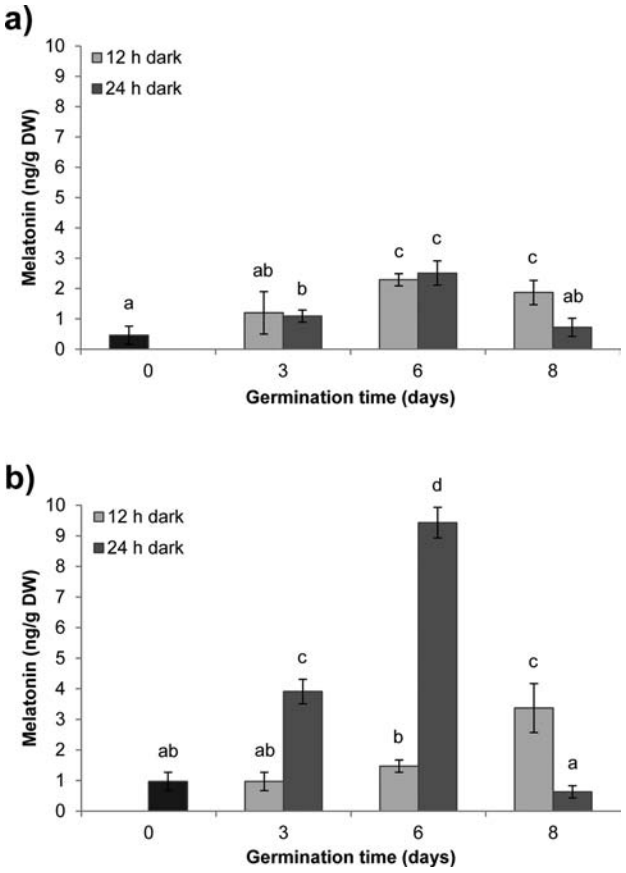

**Figure 3.** Melatonin content in raw and germinated lentils (a) and kidney beans (b).

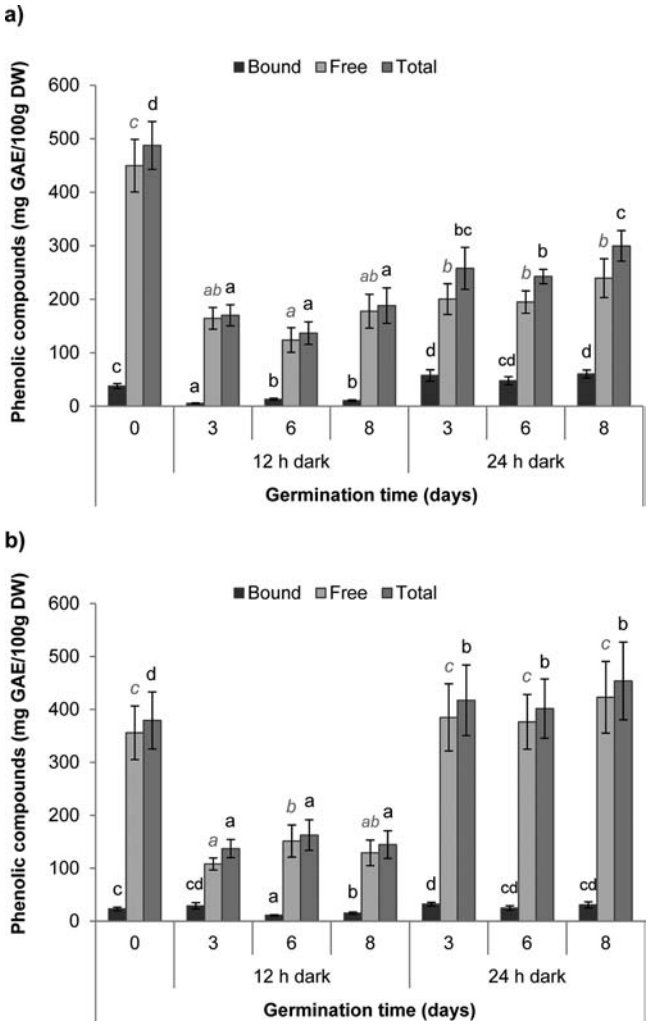

**Figure 4.** Bound, free, and total phenolic compounds in raw and germinated lentils (a) and kidney beans (b).

(12 and 24 h dark) (Figure 4a). The germination process of 12 h light/12 h dark reduces significantly up to 72% with respect to raw lentil on the sixth germination day, but any further process did not exhibit any significant changes ($p < 0.05$). In this sense, the concentration of free phenolic acids showed the maximum decrease on the sixth germination day (from 450 to 124 mg GAE/100 g DW). Decreasing tendency was also observed in bound phenols, being more accentuated on the third germination day (from 38 to 5 mg GAE/100 g DW). Regarding 24 h dark lentil germination, a similar trend was observed but lower reduction in TPC was detected (50% of decrease at the sixth germination respect to control). This may be due to the relative amounts of free phenolic compounds present in these sprouts and, also, the significant increases of bound phenolics (up to 1.6-fold respect to raw lentil seed) exhibited under 24 h darkness (Figure 4a). Although this fraction is hardly noticeable in both legumes, bound phenols are more likely glycoside flavonols, subjected to the action of colonic microflora, releasing aglycones that might be absorbed in a lesser extent and, probably, degraded to simpler phenolic derivatives and thus, they may play a special role on health.[39]

Concerning kidney beans, 12 h light/12 h dark led to a TPC reduction in a time-dependent manner (Figure 4b). The contents of free phenolic under 12 h light/12 h dark exhibited decreases (70% reduction at the third germination day as compared to raw bean) and contributed up to 93% of TPC of bean sprouts. Bean sprouts at 24 h dark exhibited an increase of TPC due to the increases either of free or bound phenol forms but these were not significant ($p < 0.05$) in a time-dependent manner. A similar trend was also observed in germinated black beans (*Phaseolus vulgaris* L.) with no significant difference of phenolic contents among them.[34] However, decreases in phenolic contents of legumes following germination have been reported by several authors.[32,40] These decreases may be attributed to the increases in the activity of enzymes responsible for the oxidation of endogenous phenolic compounds and other catabolic enzymes in raw and processed legumes. During germination, enzymes are activated, resulting in the hydrolysis of various components, including carbohydrate, protein, fiber, and lipid, as well as phenolic compounds.[32] Thus, the phytochemical quality of sprouts depends on many factors such as legume cultivar and germination conditions. This means that optimum germination conditions need to be defined for legume seeds to improve the functional quality of the sprout.

**Antioxidant Activity.** The antioxidant capacities of lentil and bean seeds (Figure 5) were similar (20.2 and 24.0 $\mu$mol TE/g DW, respectively). The results obtained were lower than those reported by Xu et al.[41] and Aguilera et al.,[35] but similar to those of Xu and Chang[37] and Guajardo-Flores et al.[34] in common beans. In general, germination brought about an enhancement of the antioxidant potential of legumes, in agreement with other studies.[7,10,34,42] Germination time directly affected the antioxidant activity of lentil and bean

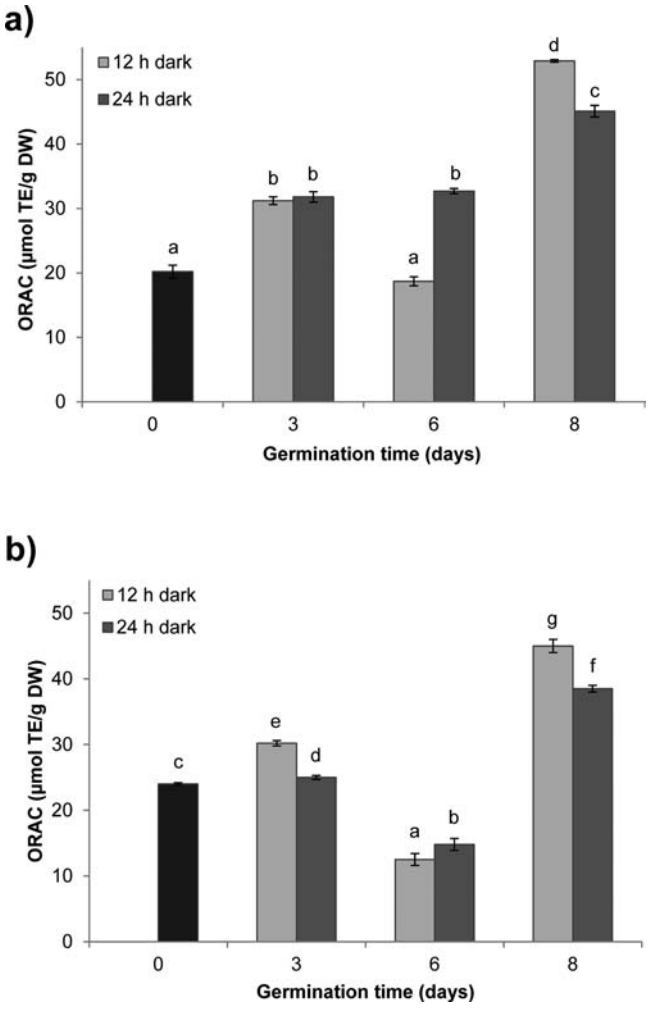

**Figure 5.** Antioxidant activity in raw and germinated lentils (a) and kidney beans (b).

sprouts. The antioxidant activity of both sprouts increased with longer germination time ($p < 0.05$), except at day 6. Among legume seeds, antioxidant activity also varied following different germination conditions. ORAC values were up to 2.4- and 2.2-fold higher after sprouting on the eighth germination day at 12 and 24 h dark for lentil sprouts, respectively. In general, lower increases were detected in bean sprouts (1.6- and 1.9-fold on the sixth germination day at 12 and 24 h dark, respectively). In addition, it should be pointed out that different light conditions during germination significantly influenced the antioxidant capacity of sprouts.[43] Among all of the sprouted legumes tested, it was noted that both samples germinated on the sixth germination day under 12 and 24 h dark showed the lowest antioxidant activities, with values ranged from 14.8 to 18.9 μmol TE/g DW. Interestingly, these samples corresponded to those exhibiting the lowest phenolic compound levels but the maximum contents of melatonin. In general, the antioxidant properties of melatonin and its ability to scavenge several radical species as part of its bioactivity have been described in the literature.[44,45] Melatonin has been found to neutralize the most toxic oxidizing agents generated within cells, such as hydroxyl radical (·OH) and peroxynitrite anion (ONOO−). In addition, melatonin reportedly scavenges singlet oxygen ($^1O_2$), superoxide anion radical ($O_2^{\bullet-}$), hydrogen peroxide ($H_2O_2$), nitric oxide (NO·), and hypochlorous acid (HClO).[46]

Finally, after the eighth germination day, a significant increase of antioxidant activity was also detected for both legume sprouts as mentioned before. Thus, this effect could be attributed to higher accumulation of compounds as melatonin degradation with radical scavenging activity. Longer application of germination resulted in further increment of antioxidant capacity, showing major ability of sprouts to prevent oxidative stress on the eighth germination day. The pronounced values of antioxidant capacity on day eight have an inverse correlation with values of melatonin in sprouts ($r = 0.61-0.75$, $p < 0.01$). This behavior may result from the indirect antioxidant properties of melatonin, as the activation of several antioxidant enzymatic cascades, including glutathione peroxidase, superoxide dismutase, and glutathione reductase, and the accumulation of degradation products, highly effective scavengers (AFMK, AMK, and cyclic 3-hydroxymelatonin),[46,47] bringing about the increased antioxidant capacity levels of bean sprouts on the eighth germination day.[48] Thus, the legume sprouts obtained in this study are valuable sources of natural antioxidants that most likely could positively influence the overall antioxidant status in humans.

Germination led to decreases in phenolic compounds and relative improvements in melatonin levels, bringing about significant increases of antioxidant activity in lentil and bean sprouts. Optimal germination conditions for melatonin levels seemed to be under 24 h dark at the sixth germination day for both sprouts, even though antioxidant activity increased on the eighth day. These germinated legume seeds with improved levels of melatonin might play a role because of the potential enhancement of the nutraceutical value of these seeds. Thus, considering the potent antioxidant activity of melatonin, these sprouts can be consumed as direct foods or adopted in the future consumer's food practices and be offered as preventive food strategies in combating chronic diseases through the diet.

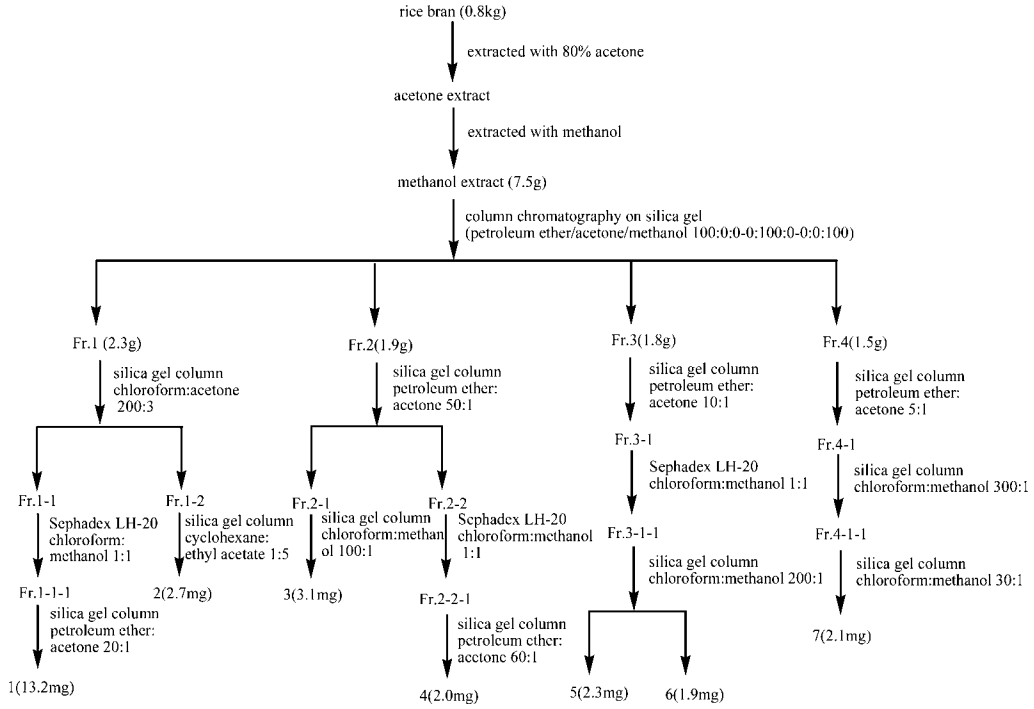

**Figure 1.** Extraction and separation process for the methanol extract of rice bran.

**Extraction and Isolation.** Rice bran (0.8 kg) was homogenized using a Polytron homogenizer before being extracted three times with 8 L of 80% acetone at ambient temperature for 24 h. The resulting mixture was then filtered after each extraction, and the filtrate was collected and concentrated under vacuum at 38 °C until approximately 90% of the solvent had been evaporated. The final solution was then extracted three times with equal volumes of methanol, and the combined extracts were concentrated under vacuum at 40 °C to give the crude methanol extract (7.5 g).

The crude methanol extract (7.5 g) was separated into four fractions (Fr. 1-4; Figure 1) by normal-phase silica gel CC (20 g of silica gel, 300−400 mesh) using a stepwise gradient elution of petroleum ether:acetone:MeOH (100:0:0 to 0:100:0 to 0:0:100, v/v/v).

Fraction 1 (2.3 g) was separated into two subfractions (Fr. 1-1 and Fr. 1-2) on a silica gel CC with a $CHCl_3$: acetone eluent (200:3, v/v). Fr. 1-1 was passed through a Sephadex LH-20 column with a $CHCl_3$:MeOH eluent (1:1, v/v) to give Fr. 1-1-1, which was purified over a silica gel CC using a petroleum ether:acetone eluent (20:1, v/v) to give **1** (13.2 mg). Fr. 1-2 was purified by CC over silica gel with a cyclohexane:ethyl acetate eluent (1:5, v/v) to give **2** (2.7 mg).

Fraction 2 (1.9 g) was purified over a silica gel CC with a petroleum ether:acetone eluent (50:1, v/v) to yield Fr. 2-1 and Fr. 2-2. Fr. 2-1 was then purified over a silica gel CC with a $CHCl_3$:MeOH eluent (100:1, v/v) to give **3** (3.1 mg). Fr. 2-2 was separated through a Sephadex LH-20 column with a $CHCl_3$:MeOH eluent (1:1, v/v) to yield Fr. 2-2-1, which was further purified on a silica gel CC using a petroleum ether:acetone eluent (60:1, v/v) to yield **4** (2.0 mg).

Fraction 3 (1.8 g) was also purified on a normal-phase silica gel CC using a petroleum ether:acetone eluent (10:1, v/v) to yield Fr. 3-1. Fr. 3-1 was purified over a Sephadex LH-20 column with a $CHCl_3$:MeOH eluent (1:1, v/v) to give Fr. 3-1-1, which was further purified on a silica gel CC using a $CHCl_3$:MeOH eluent (200:1, v/v) to give **5** (2.3 mg) and **6** (1.9 mg).

Fraction 4 (1.5 g) was subjected to CC over silica gel using a petroleum ether:acetone eluent (5:1, v/v) to yield Fr. 4-1. Fr. 4-1 was subsequently purified on a silica gel CC using a $CHCl_3$:MeOH eluent (300:1, v/v) to give Fr. 4-1-1, which was purified by CC over silica gel, eluting with $CHCl_3$:MeOH (30:1, v/v) to yield 7 (2.1 mg).

**Assay of $ABTS^+$ and DPPH Radical Scavenging.** Radical-scavenging activity against $ABTS^+$ was performed as described in the literature.[14] DPPH radical-scavenging assay was performed according to a previously reported protocol.[15] Vitamin C was employed as a positive control. The antioxidant activities of the test compounds were expressed as $IC_{50}$, with the $IC_{50}$ being defined as the concentration of the test compounds required to inhibit the formation of radicals by 50%.[16] All of the samples were analyzed in triplicate.

**Antimicrobial Bioassay.** The antimicrobial assay was carried out on the pure compounds using the disc diffusion method described in the literature.[17] The commercial antimicrobial agent, gentamicin (National Institute for the Control of Pharmaceutical and Biological products, Beijing, China), was employed as a positive control. Several test microorganisms were used, including *Escherichia coli* (*E. coli*; ATCC 25922), *Staphylococcus aureus* (S. aureus; ATCC 25923), *Bacillus subtilis* (B. subtilis; ATCC 6633), *Mycobacterium smegmatis* (*My. smegmatis*; CMCC 93321), *Clostridium perfringens* (*C. perfringens*; ATCC 13124), *Micrococcus tetragenus* (*Mi. tetragenus*; ATCC 35098), *Candida albicans* (*C. albicans*; CMCC 98001), and *Mycobacterium phlei* (*My. phlei*; AS 4.1180). The tested strains were incubated in Luria−Bertani (LB) agar plates for bacteria and in YPD agar plates for *C. albicans* at 37 °C. The minimal inhibitory concentrations (MICs) were determined. After an incubation period of 24 h, the zones of inhibition (millimeters in diameter) were recorded, and the MICs values were determined.

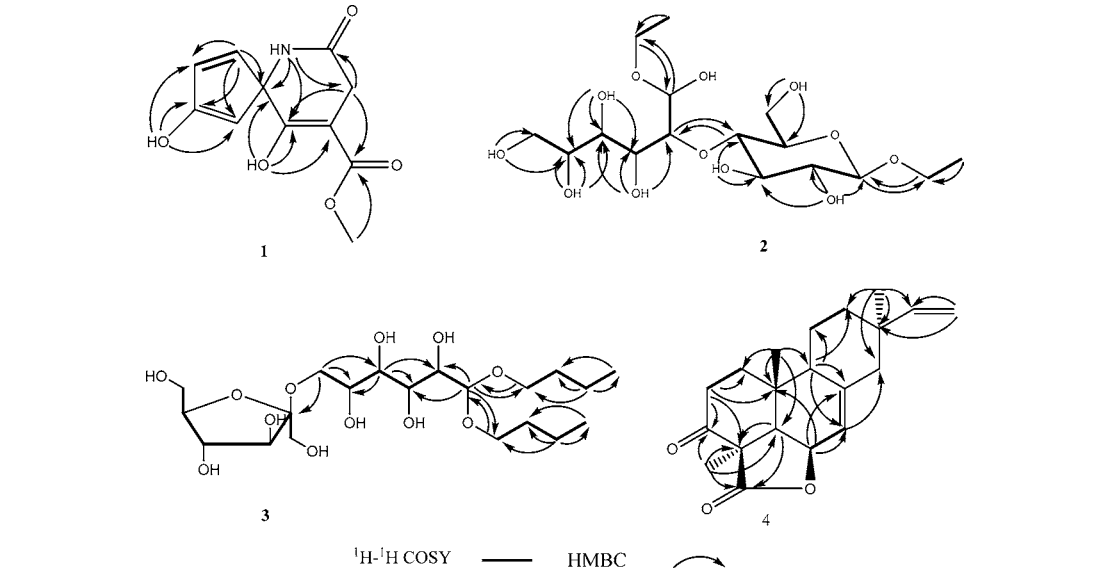

**Figure 2.** Key $^1$H−$^1$H COSY and HMBC correlations for compounds **1**, **2**, **3**, and **4**.

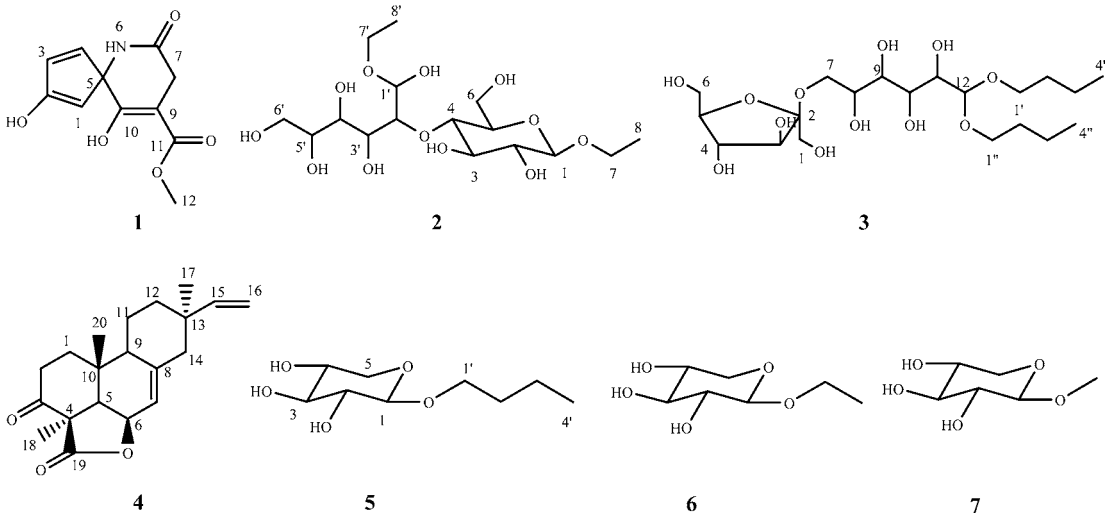

**Figure 3.** Structures of the compounds isolated from the methanol extract of rice bran.

**Statistical Analysis.** All of the data were analyzed according to Duncan's multiple comparison test ($p < 0.05$), using version 8.1 of the SAS software package. The resulting data were presented as mean ± SD.

## RESULTS AND DISCUSSION

**Structural Elucidation of the Isolated Compounds.** Compound **1** was isolated as a yellow amorphous powder. Its molecular formula was determined to be $C_{11}H_{11}NO_5$ based on HRESIMS analysis of the pseudomolecular ion peak at $m/z$ 260.0542 $[M + Na]^+$ (calcd 260.0535), indicating seven degrees of unsaturation. The UV spectrum of compound **1** revealed three strong absorption bands at 210, 265, and 320 nm. The IR spectrum displayed strong absorption bands at 3274, 1721, 1478, and 1204 cm$^{-1}$, which were attributed to hydroxyl, amide, ester carboxyl, and olefinic functionalities. The $^1$H NMR spectrum showed three exchangeable protons in the downfield at $\delta$ 10.01 (s, 1H), 9.01 (s, 1H), and 6.07 (s, 1H) corresponding to two hydroxyl group linked to C-10 and C-2, and an amide group at the position of 6-NH, respectively, these three functionalities were further confirmed by the key HMBC correlations (Figure 2) from 2-OH to C-1, C-2, and C-3, from 10-OH to C-5, C-9, and C-10, and from 6-NH to C-5, C-8, and C-10. The double bond at C-3 and C-4 was supported by COSY correlations between H-3 and H-4, as well as confirmed by the key correlation from H-4 to C-1, C-2, C-3, and C-5. The proton signal at $\delta$ 2.91 was assigned to C-8 on the basis of the results provided by the HSQC and HMBC spectra, respectively. A key correlation from H-12 to C-11was observed in the HMBC experiment, indicating that a methoxy at C-12 was connected to the carbonyl at C-11. Consequently, the structure of **1** was determined to be methyl 2,10-dihydroxy-7-oxo-6-azaspiro[4.5]deca-1,3,9-triene-9-carboxylate and named Oryzalactam (Figure 3).

Compound **2** was isolated as a white amorphous powder, and its molecular formula was determined to be $C_{16}H_{32}O_{12}$ based on HRESIMS analysis of the pseudomolecular ion peak at $m/z$ 415.1826 $[M - H]^-$ (calcd 415.1816). The UV spectrum of compound **2** revealed only one strong absorption band at 205 nm. The IR spectrum displayed strong absorption bands at 3416 and 1029 cm$^{-1}$ which are characteristic of glycosidic-type structures. The $^1$H NMR spectrum of **2** showed the presence of

dx.doi.org/10.1021/jf5037273 | J. Agric. Food Chem. 2014, 62, 10744−10751

two anomeric protons at $\delta$ 4.12 (d, $J$ = 7.77 Hz, 1H) and 4.63 (d, $J$ = 3.72 Hz, 1H), which was further supported by the chemical shift at $\delta$ 103.0 and 98.7 in the $^{13}$C NMR spectrum. Analysis of the $^{1}$H−$^{1}$H COSY, HSQC, and HMBC spectra (Figure 2) of compound **2** allowed for the complete assignment of the $^{1}$H and $^{13}$C NMR spectral data. The sequence from an anomeric proton H-1 to oxymethylene proton H-6 through oxymethine protons H-2, H-3, H-4, and H-5, as well as H-7 to H-8, was confirmed by $^{1}$H−$^{1}$H COSY. Similarly, the fragments from H-1′ to H-6′ and from H-7′ to H-8′ were also established. Three sets of mutual key long-range couplings from H-1 to C-7 and from H-7 to C-1, and from H-1′ to C-7′ and from H-7′ to C-1′, as well as from H-2′ to C-4 and from H-4 to C-2′, were observed in the HMBC experiments, indicating that two ethyl groups and another sugar unit in a ring-opening form were connected directly to the C-1, C-1′, and C-4 by ether linkages. The pyranosyl sugar units were identified as a $\beta$-glucopyranosyl group on the basis of its $^{3}J_{\text{H-1,H-2}}$ coupling constant of 7.77 Hz. On the basis of this evidence, the structure of **2** was characterized as shown Figure 3 and trivially named oryzasaccharide A.

Compound **3** was obtained as a white amorphous powder. Its molecular formula was established as $C_{20}H_{40}O_{12}$ by negative HRESIMS $[M - H]^-$ at $m/z$ 471.2451 (calcd 471.2444). The UV spectrum of compound **3** revealed only one strong absorption band at 205 nm. The IR spectrum displayed strong absorption bands at 3420 and 1033 cm$^{-1}$ which are typical of glycosidic-type structures. The 1D NMR data (Table 3) revealed the presence of a fructofuranose, a ring-opening pyranose moiety and two butyl group fragments. The $^{13}$C NMR of **3** revealed the presence of 20 carbon signals, with six of these signals being assigned to the fructofuranose, six to the ring-opening pyranose moiety, and the remaining eight to two butyl ether fragments. The chemical shifts of all of the protons and carbons belonging to these three parts were assigned using a combination of $^{1}$H−$^{1}$H COSY, HSQC, and HMBC analysis (Figure 2). Several key correlations in the HMBC spectra, including correlations from H-7 to C-2, and two mutual long-range couples from H-12 to C-1′ and H-1′ to C-12, and from H-12 to C-1″ and H-1″ to C-12, were observed, indicating that two butyl groups and the ring-opening pyranose moiety were connected directly to the C-1′, C-1″, and C-2 by three ether linkages, respectively. Taken together, these data were indicative of a typical sugar ether structure with unique ring-opening moiety and two butyl groups. Consequently, the structure of **3** was elucidated, as shown in Figure 3 and named oryzasaccharide B (Figure 3).

Compound **4** was isolated as a colorless needle. The molecular formula of the material was determined to be $C_{20}H_{26}O_3$ on the basis of its $^{1}$H and $^{13}$C NMR and ESI-MS data. ESI-MS analysis of the material revealed a peak at $m/z$ 337.2, corresponding to $[M + Na]^+$, indicating that the molecular weight of **4** was 314. The $^{1}$H NMR and $^{13}$C NMR spectra revealed the presence of three tertiary methyls at $\delta$ 0.94 (s, 3H), 1.58 (s, 3H), and 1.04 (s, 3H), three vinylic protons at $\delta$ 5.90 (dd, $J$ = 10.76, 17.48 Hz, 1H), 5.01 (d, $J$ = 17.48 Hz, 1H), and 4.98 (d, $J$ = 10.76 Hz, 1H), one oxygenated methane at $\delta$ 4.89 (t, $J$ = 5.12 Hz, 1H), and one trisubstituted olefinic protons at $\delta$ 5.76 (d, $J$ = 5.00 Hz, 1H), as well as one $\gamma$-lactone carbon at $\delta$ 174.5 and one carbonyl carbon at $\delta$ 205.3 in the molecule. The structure of **4** was further confirmed by the COSY and HMBC correlations (Figure 2) and by comparing the NMR data with those of momilactone A in the literature.[18] Compound **4** was consequently identified as momilactone A (Figure 3).

Compound **5** was isolated as a white amorphous powder. The molecular formula was determined to be $C_9H_{18}O_5$ on the basis of its $^{1}$H NMR, $^{13}$C NMR, and ESI-MS spectra. ESI-MS analysis gave $m/z$ values of 205.1 and 229.1, corresponding to $[M - H]^-$ and $[M + Na]^+$. The $^{1}$H and $^{13}$C NMR spectra of **5** were typical of a sugar ether compound. The $^{13}$C NMR spectrum revealed the presence of nine carbons corresponding to one xylopyranose unit and one butyl group, respectively. Analysis of the $^{1}$H−$^{1}$H COSY, HSQC, and HMBC spectra of compound **5** allowed for the complete assignment of the $^{1}$H and $^{13}$C NMR spectral data. From the $^{1}$H−$^{1}$H COSY spectrum, the molecular fragments from C-1 to C-5 and from C-1′ to C-4′ could be established. Key mutual correlations from H-1 to C-1′ and from H-1′ to C-1 were observed in the HMBC experiments, indicating that the xylopyranose unit and the butyl group were connected by ether linkages. The xylopyranose unit was identified as a $\beta$-xylopyranose group on the basis of its $^{3}J_{\text{H-1,H-2}}$ coupling constant of 6.90 Hz. Based on a comparison of these data with data published in the literature,[19] compound **5** was identified as butyl $\beta$-D-xylopyranose (Figure 3).

Compound **6** was isolated as a white amorphous powder, and its molecular formula was determined to be $C_7H_{14}O_5$ on the basis of its $^{1}$H and $^{13}$C NMR and ESI-MS spectra. ESI-MS analysis of the material gave $m/z$ values of 177.1 and 201.1, corresponding to $[M - H]^-$ and $[M + Na]^+$, respectively. A careful comparison of the $^{1}$H and $^{13}$C NMR spectra of **6** with those of **5** revealed the existence of a close structural relationship between the two compounds. Compared to the spectra of **5**, five ethyoxyl proton signals at $\delta$ 3.51 (m, 2H, H-1′), 1.25 (t, $J$ = 6.87 Hz, 3H, H-2′) in **6** instead of nine butyoxyl proton signals at $\delta$ 3.54 (m, 2H, H-1′), 1.61 (m, 2H, H-2′), 1.38 (m, 2H, H-3′), and 0.93 (t, $J$ = 7.35 Hz, 3H, H-4′) in **5** were observed in the $^{1}$H NMR spectrum. As expected, two methene carbon signals at $\delta$ 31.6 (C-2′) and 19.1 (C-3′) in **5** were missed in the $^{13}$C NMR spectrum of **6**. By a comparison with data available in the literature,[19] compound **6** was determined to be ethyl $\beta$-D-xylopyranose (Figure 3).

Compound **7** was isolated as a white amorphous powder. The molecular formula was determined to be $C_6H_{12}O_5$ on the basis of its $^{1}$H NMR, $^{13}$C NMR, and ESI-MS spectra. ESI-MS analysis gave $m/z$ values of 163.0 and 187.1, corresponding to $[M - H]^-$ and $[M + Na]^+$, respectively. The $^{1}$H and $^{13}$C NMR spectra for **7** and **6** are very similar, with the exception that an ethyoxyl group in **6** was replaced by a methoxy group in **7**. Based on a comparison of these data with information reported in the literature,[19] compound **7** was identified as methyl $\beta$-D-xylopyranose (Figure 3).

**Antioxidant Activities of the Pure Compounds Isolated from Rice Bran.** The antioxidant activities of the seven pure compounds were tested according to their ABTS$^+$ and DPPH radical-scavenging assay. The results of these experiments have been shown in Figure 4 and Figure 5. Only compound **1** showed 98.57% and 77.33% of ABTS$^+$ and DPPH radical-scavenging ability at the concentration of 100 $\mu$M, respectively (Figure 4A,B) and were comparable to that of positive control vitamin C; other compounds were inactive. Based on the data obtained, compound **1** was selected to further determine whether their ABTS$^+$ and DPPH radical-scavenging capacity was in a dose-dependent manner , and the results are shown in Figure 5. The ABTS$^+$ radical-scavenging activities for compound **1** and vitamin C were comparable and

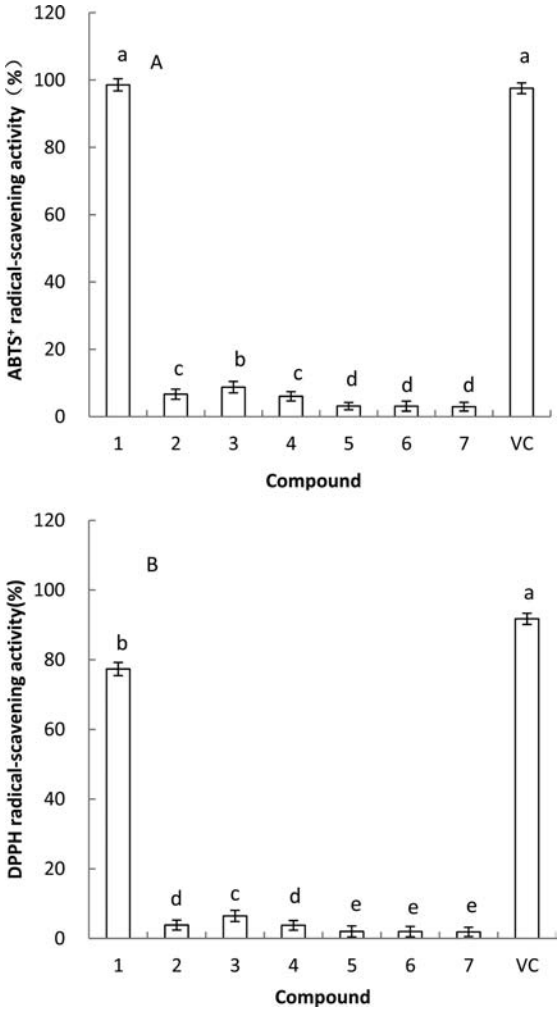

**Figure 4.** ABTS$^+$ radical-scavenging activity (A), DPPH radical-scavenging activity (B) of the isolated compounds. oryzalactam (**1**), oryzasaccharide A (**2**), oryzasaccharide B (**3**), momilactone A (**4**), butyl $\beta$-D-xylopyranose (**5**), ethyl $\beta$-D-xylopyranose (**6**), and methyl $\beta$-D-xylopyranose (**7**). Each value has been presented as the mean ± SD of three experiments. Note: a−e, results with a different letter differ significantly ($p < 0.05$).

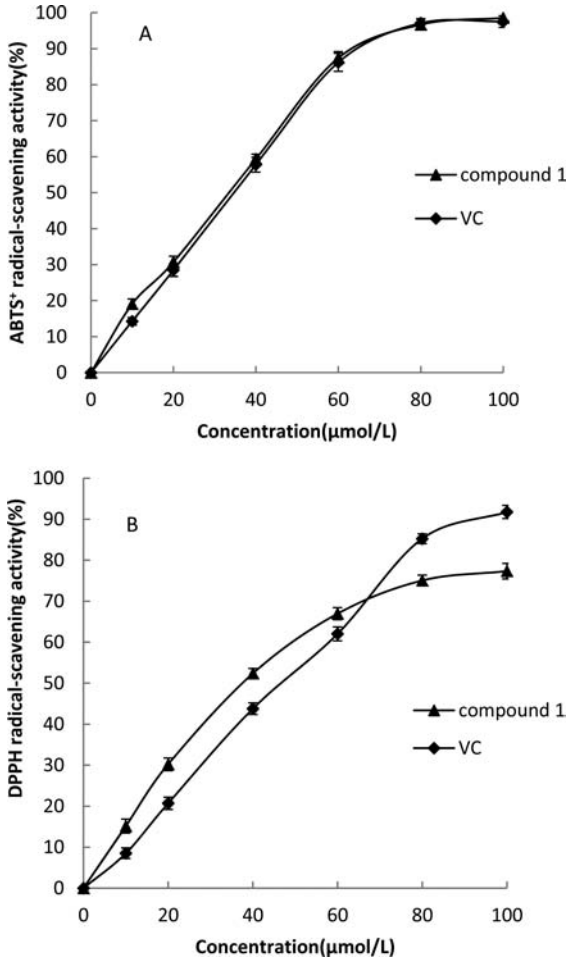

**Figure 5.** ABTS$^+$ radical-scavenging activity (A) and DPPH radical-scavenging activity (B) of compound **1** under different concentrations.

increased sharply with increasing concentration in a dose-dependent manner at the range of 0−80 $\mu$M, increased to maximal values of 96.70% and 97.10% ABTS$^+$ inhibitory effect at the concentration of 80 $\mu$M, and then were kept constant, and their $IC_{50}$ values were 33.38 ± 1.58 and 34.70 ± 1.19 $\mu$M, respectively. The results suggested that the ABTS$^+$ radical-scavenging activity of compound **1** was almost identical to that of vitamin C. Similarly, as shown in Figure 4B and Figure 5B, compound **1** and vitamin C showed antioxidant activity profiles that resembled one another and a dose-dependent manner in DPPH scavenging-radical assay, and their $IC_{50}$ values were 40.2 ± 1.34 and 47.59 ± 1.41 $\mu$M, respectively, indicating that the DPPH scavenging-radical activity of compound **1** was slightly weaker than that of Vitamin C.

**Antimicrobial Bioassay.** Seven pure compounds were tested for their antimicrobial activities against eight pathogenic strains. Only compound **4** exhibited a significant inhibition zone against *E. coli* with a MIC value of 5 $\mu$M, indicating that compound **4** possessed high levels of selectivity toward *E. coli*. All of the other compounds isolated were found to be inactive.

**NMR and ESI-MS Spectroscopic Data.** Oryzalactam (**1**). Yellow amorphous powder. $^1$H NMR and $^{13}$C NMR data, see Table 1. ESI-MS $m/z$ 260.0542 $[M + Na]^+$.

1.61 (m, 2H, H-2′), 1.38 (m, 2H, H-3′), 0.93 (t, $J$ = 7.35 Hz, 3H, H-4′). $^{13}$C NMR: $\delta$ 102.9 (C-1), 72.9 (C-2), 76.0 (C-3), 69.6 (C-4), 64.9 (C-5), 69.7 (C-1′), 31.6 (C-2′), 19.1 (C-3′), 13.8(C-4′). ESI-MS $m/z$ 205.1 $[M - H]^-$, 229.1 $[M + Na]^+$.

Ethyl $\beta$-D-xylopyranose (**6**). Colorless amorphous powder. $^1$H NMR (300 MHz, $CDCl_3$, TMS): $\delta$ 4.28 (d, $J$ = 6.84 Hz, 1H, H-1), 4.19 (m, 1H, H-5a), 3.94 (m, 1H, H-4), 3.51 (m, 2H, H-1′), 3.50 (m, 1H, H-3), 3.38 (m, 1H, H-2), 3.26 (m, 1H, H-5b), 1.25 (t, $J$ = 6.87 Hz, 3H, H-2′). $^{13}$C NMR: $\delta$ 102.9 (C-1), 72.9 (C-2), 76.0 (C-3), 69.6 (C-4), 65.4 (C-5), 65.3 (C-1′), 15.1 (C-2′). ESI-MS $m/z$ 177.1 $[M - H]^-$, 201.1 $[M + Na]^+$.

Methyl $\beta$-D-xylopyranose (**7**). Colorless amorphous powder. $^1$H NMR (300 MHz, DMSO-$d_6$, TMS): $\delta$ 3.99(d, $J$ = 7.5 Hz, 1H, H-1), 3.70 (m, 1H, H-5a), 3.41 (m, 1H, H-4), 3.34 (s, 3H, 1-$OCH_3$), 3.30 (m, 1H, H-3), 3.01 (m, 1H, H-2), 2.94 (m, 1H, H-5b). $^{13}$C NMR: $\delta$ 105.2 (C-1), 73.7 (C-2), 77.0 (C-3), 70.1 (C-4), 66.1 (C-5), 56.4 (C-1′). ESI-MS $m/z$ 163.0 $[M - H]^-$, 187.1 $[M + Na]^+$.

An investigation of the methanol extract of rice bran allowed for the isolation of a new screw lactam and two new oligosaccharide derivatives, oryzalactam (**1**), oryzasaccharide A (**2**), and oryzasaccharide B (**3**), as well as four known compounds, including momilactone A (**4**), butyl $\beta$-D-xylopyranose (**5**), ethyl $\beta$-D-xylopyranose (**6**), and methyl $\beta$-D-xylopyranose (**7**), and the structures of all seven of these compounds were elucidated using a combination of spectroscopic methods. To the best of our knowledge, this is the first report concerning the isolation of compounds **1**, **2**, **3**, **5**, **6**, and **7** from rice bran.

Oryzalactam is a new screw lactam and extremely rare. To date, there are no compounds with this particular skeleton have been isolated from natural sources. This compound exhibited strong antioxidant activity against $ABTS^+$ and DPPH radical and might represent a new potential natural antioxidant agent.

| 4″ | 0.97 (m, 3H) | 12.9 | C-2″ | |

It is worth mentioning, however, the bioactivities of this compound *in vitro* are not necessarily equal to its actual beneficial effects on human health. It is determined by the bioaccessibility and bioavailability of the compound *in vivo* where it is commonly mixed with different macromolecules such as carbohydrates, lipids, and proteins to form the food matrix.[20] Several factors interfere with the real effects of a compound, such as food source and chemical interactions with other phytochemicals and biomolecules present in the food matrix. Therefore, research concerning the bioaccessibility and bioavailability of a compound from rice bran are important, since a compound is only released from the food matrix by the action of digestive enzymes in the small intestine or bacterial microflora in the large intestine and then can be absorbed to exert their beneficial effects.[2] Oryzasaccharides A and B and the three other known compounds are carbohydrate derivatives with a diverse side chain. It has been reported that rice bran contains about 6.5% free sugars on a dry-weight basis, more than 50% of the sugar being simple saccharides (mainly glucose and sucrose); therefore, the current research indicated that the free sugar in the rice bran might exist in more complex forms. Momilactone A obtained in this study is one of the diterpenoid phytoalexins and originally isolated from the seed husk of rice. So far, three momilactones members (momilactone A–C) have been found from rice in all.[21,22] It has been reported that momilactones are accumulated in rice during vegetative growth and are released into the soil, causing growth inhibition of neighboring plants, and responding to UV irradiation and pathogenesis such as fungal invasion, suggesting that momilactones in rice also play a role in plant defense.[23,24]

In summary, the current study has effectively demonstrated that various compounds with antioxidant and antimicrobial activities are present in rice bran. Oryzalactam, in particular, has been identified as a new screw lactam and showed strong antioxidant activities. The results of the current study represent a useful addition to understanding the potential application and health benefits of rice bran and confirming the interesting potential of rice bran as natural antioxidant to the food industry, as well as enhancing our better understanding of the relationships between the individual component and human health in rice bran. Further studies should be carried out to assess the bioactivities to validate the real effects of the compounds on the prevention and therapy of some chronic human diseases in future, especially on antioxidant activities of the compounds isolated, e.g., bioaccessibility, bioavailability, and enrichment for developing a food by using these compounds, as well as possibilities of interactions with other biomolecules.

## MATERIALS AND METHODS

**Cells and Chemicals.** Human prostate cancer LNCaP, VCaP, and CWR22Rv1cells were obtained from the ATCC (Rockville, MD, U.S.A.). α-T, γ-T and δ-T were from Sigma Co. (St. Louis, MO, U.S.A.). A mixture of tocopherol γ-TmT was purchased from the Cogns Corp. (Cincinnati, OH, U.S.A.). The extracellular matrix Matrigel was obtained from Corning Co. (Tewksbury, MA, U.S.A.). The various human prostate cancer cells were maintained in RPMI-1640 culture medium as described in our earlier study.[17]

**Cell Viability.** Cell viability was determined by the trypan blue exclusion assay. At the end of the experiments, the cells were trypsinized. Trypan blue solution (0.4%) was mixed with cell suspension in a ratio of 1:4, and the mixtures were kept at room temperature for 2 min for the cells to be stained with the dye. The number of viable cells was counted under a microscope (Nikon Optiphot, Tokyo, Japan). Cells absorbed the dye were counted as dead cells. The cells that did not absorb the dye were counted as live cells.[18]

**Determination of Apoptosis.** Apoptotic cells were identified in propidium iodide (PI) stained cells by morphology.[19] At the end of the experiment, cells were spined to slides using a Shandon cytospin centrifuge (Thermo Scientific, Waltham, MA, U.S.A.) and fixed in a solution containing 50% acetone and 50% methanol. The cells were then stained with PI at a concentration of 1 μg/mL. A microscope (Nikon Optiphot, Tokyo, Japan) was used to identified apoptotic cells according to the morphological changes characteristic of apoptosis as described earlier.[19]

**Western Blotting.** After treatment, the cell lysates were prepared as described earlier.[20] Proteins were subjected to sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE) and transferred to nitrocellulose membrane. After blocking nonspecific binding sites with blocking buffer, the membrane was incubated overnight at 4 °C with PSA primary antibody (CBL-252, Millipore Co, Billerica, MA, U.S.A.). The β-actin was used as a loading control. Following removal of the primary antibody, the membrane was washed three times with TBS (PBS containing 0.05% tween 20) buffer at room temperature and then incubated with fluorochrome-conjugated secondary antibody (Santa Cruz Biotechnology Inc., CA, U.S.A.). The membrane was then washed with TBS three times. Final detection was done with an Odyseey infrared imaging system (Li-Cor Biotechnology, Lincoln, NE, U.S.A.).

**AR Luciferase Reporter Assay.** The CWR-22Rv1/AR cell line that stably expresses the AR-luciferase reporter gene was used in the present study.[21] CWR-22Rv1/AR cells were treated with dihydrotestosterne (DHT), α-T and δ-T for 24 h. After treatment, the cells were harvested in a reporter lysis buffer and the luciferase activities were measured using luciferase assay kits from Promega (Madison, WI, U.S.A.), as described in our recent study.[21]

**Subcutaneous LNCaP Tumors in SCID Mice.** SCID mice originally obtained from Taconic Farms (Germantown, NY, U.S.A.) were bred in the animal facility in the Susan Lehman Cullman Laboratory for Cancer Research. Eight-week old SCID mice were housed in microisolator cages. Human prostate cancer LNCaP cells ($2.0 \times 10^6$ cells/mouse) were suspended in culture medium and Matrigel (1:1) and injected subcutaneously into the back of the animals.[22] The mice were randomly assigned to 3 experimental groups in the same day of the tumor cell injection. Group 1 was the control and the mice in this group were fed AIN 93 M diet. Mice in group 2 received AIN 93 M diet containing 0.3% α-T. Mice in group 3 were fed 0.3% δ-T in AIN 93 M diet. There were 10 animals in each experimental group. The experimental duration was 48 days. The mice were examined every day for the formation of subcutaneous tumors. When the subcutaneous tumor formed, tumor length and tumor width were measured once every third day and calculated as tumor size (length × width, $cm^2$). The animal experiment was carried out under the Rutgers University Institutional Animal Care and Use Committee (IACUC)-approved protocol (RU02-001).

**Tumor Cell Proliferation and Apoptosis.** Proliferation of LNCaP tumor cell was measured by determining the number of mitotic cells, and apoptosis of the tumor cells was assessed by immunohistochemical staining for activated caspase-3. At the end of the experiment, tumors were excised from each mouse and weighted. Tumor tissues were fixed in buffered formalin for 24 h and then with ethanol for 48 h. Paraffin blocks of tumor tissues were prepared and paraffin sections of tumor tissues were processed for H&E staining. A microscope (Nikon Optiphot, Tokyo, Japan) was used to examine the tumor sections for mitotic cells. Activated caspase-3 was determined immunohistochemically using an anti activated caspase-3 antibody (#AF835, R&D Systems Ltd., Minneapolis, MN). Immunohistochemical staining was performed as described earlier.[23] The number of cells with positive staining of activated caspase-3 was counted and expressed as % caspase-$3^+$ cells.

**Statistical Analyses.** We used ANOVA (analysis of variance) and multiple comparison (Tukey-Kramer test) to perform statistical analyses in the present study. Differences in cell viability, apoptosis and AR activity in cells from different treatment groups were analyzed. Differences in tumor size and body weight between different treatment group in the in vivo study were also analyzed.

## RESULTS

**Effects of Different Tocopherols on Growth and Apoptosis of Human Prostate Cancer Cells.** In initial studies, the effects of α-T, γ-T, δ-T, and γ-TmT on growth and apoptosis in human prostate cancer LNCaP cells were determined. As shown in Figure 1A, the different tocopherols dose-dependently inhibited the growth of cultured LNCaP cells. δ-T had a stronger inhibitory effect on the growth of LNCaP cells than the other tocopherols (Figure 1A). Additional experiments showed that treatment of LNCaP

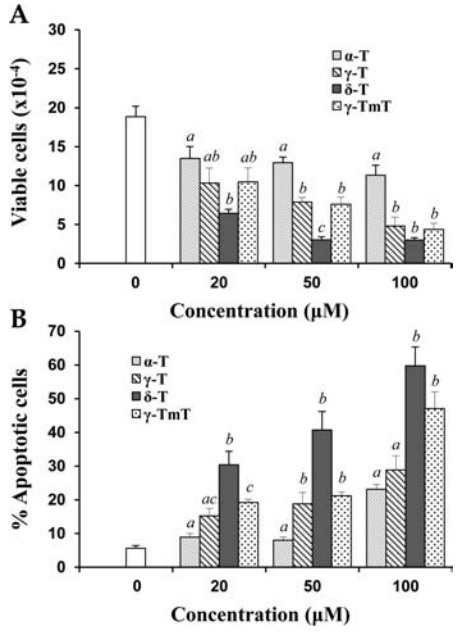

**Figure 1.** Inhibition of growth and induction of apoptosis in LNCaP cells by α-T, γ-T, δ-T, and γ-TmT. Human prostate cancer LNCaP cells ($0.5 \times 10^5$ cells/mL) were seeded in RPMI medium with 10% FBS and incubated 24 h to allow the cells attach to the dish. Then the cells were cultured in medium containing 1% FBS and treated with various concentrations of α-T, γ-T, δ-T, or γ-TmT. The treatment time was 96 h. The trypan blue exclusion assay was used to determine cell viability. Number of viable cells after treatment is shown in (A). Morphological assessment of PI-stained cells was used to determine apoptosis and the number of apoptotic cells is shown in (B). Different superscripts (*a*, *b*, and *c*) indicate statistical differences in the number of viable cells or percent apoptotic cells among different tocopherol isoforms ($p < 0.05$).

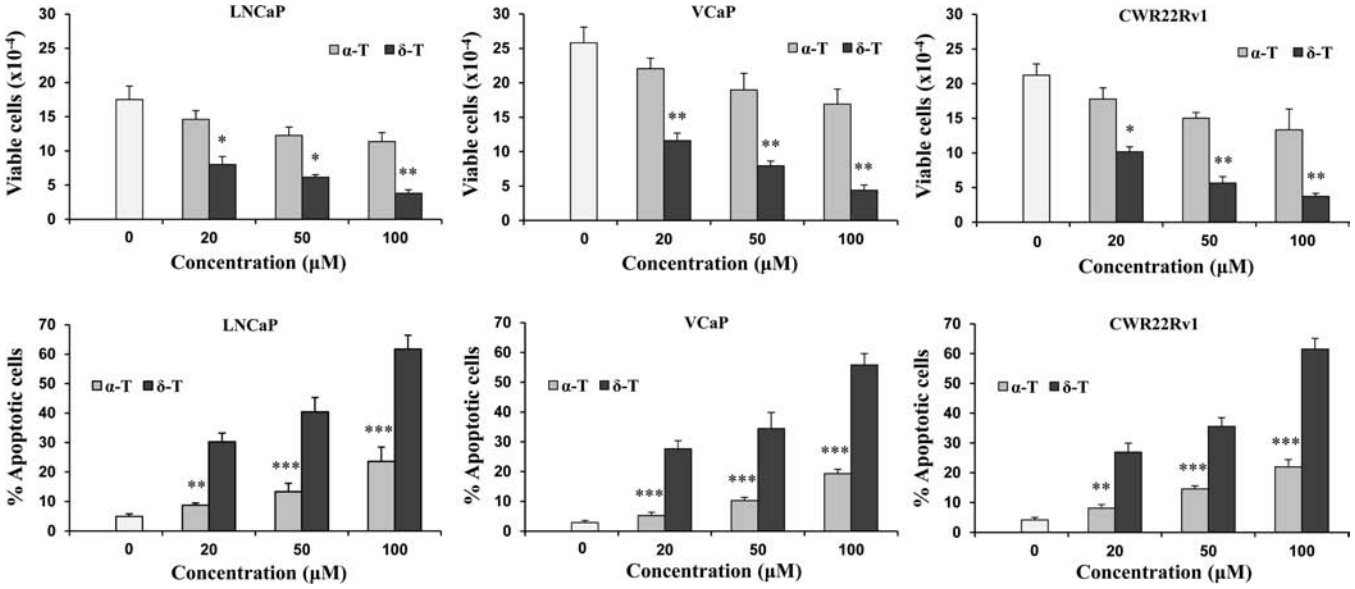

**Figure 2.** Effects of $\alpha$-T and $\delta$-T on growth (upper panel) and apoptosis (lower panel) of cultured human prostate cancer cells. LNCaP, VCaP, and CWR22Rv1 cells (all at $0.5 \times 10^5$ cells/mL) were seeded in RPMI medium containing 10% FBS. After 24 h incubation, the cells were cultured in medium containing 1% FBS and treated with $\alpha$-T or $\delta$-T. The treatment time was 96 h. Graphs in the upper panel show the number of viable cells as determined by the trypan blue exclusion assay. Graphs in the lower panel show the number of apoptotic cells determined by morphological assessment. Differences for the number of viable or apoptotic cells between the $\alpha$-T-treated group and the $\delta$-T-treated group at different concentrations were statistically analyzed. $^*p < 0.05$, $^{**}p < 0.01$, and $^{***}p < 0.001$.

cells with different tocopherols resulted in a concentration-dependent increase in apoptosis. As shown in Figure 1B, $\delta$-T had a more potent effect on inducing apoptosis in LNCaP cells than other tocopherols.

Since $\delta$-T had stronger effects on growth inhibition and apoptosis induction than other tocopherols tested, we subsequently determined the effects of $\delta$-T on different prostate cancer cells and compared its effects with $\alpha$-T, the most common form of vitamin E. As shown in the upper panel of Figure 2, treatment with $\delta$-T and $\alpha$-T inhibited the growth of cultured LNCaP, VCaP, and CWR22Rv1 prostate cancer cells in a dose-dependent manner. $\delta$-T had a stronger inhibitory effect on the growth of all three prostate cancer cell lines than $\alpha$-T (upper panel of Figure 2). Treatment of different prostate cancer cells with $\alpha$-T and $\delta$-T also induced apoptosis in a dose-dependent manner. As shown in the lower panel of Figure 2, $\delta$-T had a more potent effect on induction of apoptosis in different prostate cancer cells than $\alpha$-T.

**Effects of $\delta$-T and $\alpha$-T on AR Activity in CWR-22Rv1/AR Cells.** The effects of $\delta$-T and $\alpha$-T on AR activation was determined using the AR-luciferase reporter gene expression assay. AR activity in CWR-22Rv1/AR cells was stimulated by treatment with DHT and the inhibitory effect of $\delta$-T and $\alpha$-T on DHT-induced AR activation was determined. As shown in Figure 3, treatment with $\alpha$-T and $\delta$-T dose-dependently inhibited DHT-induced AR activation in CWR-22Rv1/AR cells. A stronger inhibitory effect of $\delta$-T on AR activation than $\alpha$-T was observed (Figure 3).

**Effects of $\delta$-T and $\alpha$-T on the Level of PSA in CWR-22Rv1 and LNCaP Cells.** To investigate whether decrease in AR activity by tocopherols leads to inhibition of AR signaling, we determined the level of PSA which is a down stream target of the AR signaling pathway. Treatment of CWR-22Rv1 and LNCaP cells with DHT caused an increase in the level of PSA (Figure 4). Treatment of the cells with $\delta$-T strongly inhibited the DHT-induced increase in PSA while $\alpha$-T only had small to

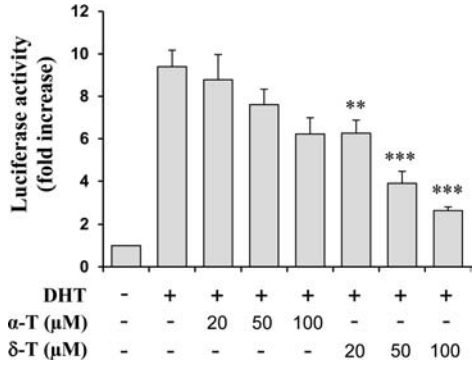

**Figure 3.** Effect of $\alpha$-T and $\delta$-T on AR reporter activity in CWR-22Rv1/AR cells. CWR-22Rv1/AR cells were seeded at a density of $0.5 \times 10^5$ cells/mL of medium for 24 h. The medium was then changed to RPMI supplemented with 1% FBS, and the cells were treated with vehicle (control), with DHT (10 nM) alone or in combination with $\alpha$-T or $\delta$-T (20, 50, or 100 $\mu$M) for 24 h. The luciferase activity and protein concentration of the CWR-22Rv1/AR cells were measured. Each value represents the mean ± SE from three separate experiments. Differences for the relative luciferase activities between the $\alpha$-T-treated group and the $\delta$-T-treated group were analyzed by ANOVA with the Tukey-Kramer Multiple Comparison Test $^{**}p < 0.01$, $^{***}p < 0.001$.

moderate effects (Figure 4). The Western blots were analyzed by optical density measurement and normalized for actin. In the Western blot with LNCaP cells, the level of PSA relative to control (1.00) was 1.97 ± 0.12 in cells treated with DHT, 1.46 ± 0.09 in cells treated with DHT + $\alpha$-T and 0.91 ± 0.08 in cells treated with DHT + $\delta$-T. In the Western blot with CWR22Rv1 cells, the relative level of PSA was 1.00 in control, 2.01 ± 0.15 in cells treated with DHT, 1.02 ± 0.05 in cells treated with DHT + $\alpha$-T and 0.48 ± 0.06 in cells treated with DHT + $\delta$-T. Statistical analysis showed that the differences for density measurement between DHT + $\alpha$-T and DHT + $\delta$-T groups are statistically significant ($p < 0.01$) in both LNCaP and

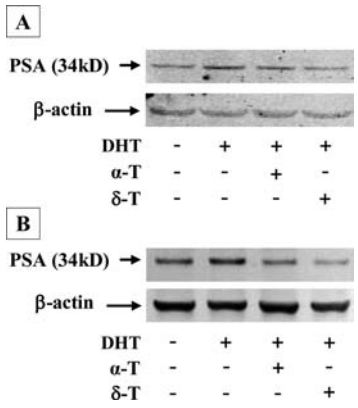

**Figure 4.** Effect of $\alpha$-T and $\delta$-T on the level of PSA in prostate cancer cells. CWR-22Rv1 and LNCaP cells were seeded at a density of $1 \times 10^5$ cells/mL of medium in 100 mm culture dishes (10 mL/dish) and incubated for 24 h. The medium was changed to RPMI supplemented with 1% FBS, and the cells were then treated with vehicle, with 10 nM DHT alone or together with $\alpha$-T (50 $\mu$M) or $\delta$-T (50 $\mu$M) for 48 h. PSA was determined by the Western blot analysis with anti-PSA antibody. The extent of protein loading was determined by blotting for $\beta$-actin. Representative blots for LNCaP (A) and CWR22Rv1 (B) cells are shown.

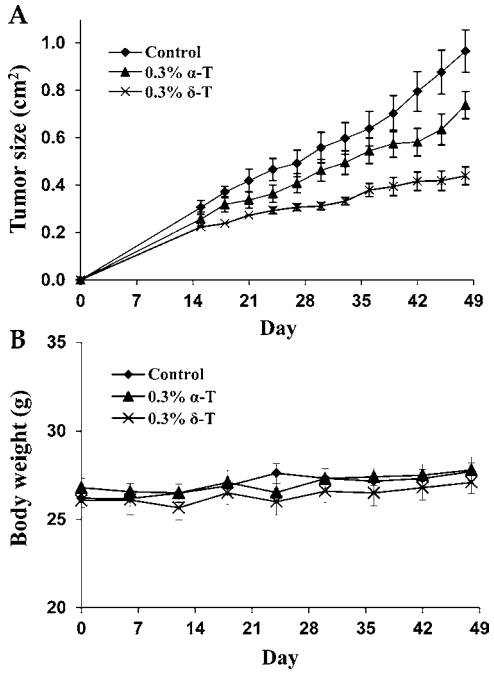

**Figure 5.** In vivo effects of $\alpha$-T and $\delta$-T. Human prostate cancer LNCaP cells were injected subcutaneously into male SCID mice. The mice received AIN93 M diet (10 mice), AIN93 M diet containing 0.3% $\alpha$-T (10 mice), or AIN93 M diet containing 0.3% $\delta$-T (10 mice) for 48 days. (A) Tumor growth curve (measured as tumor size; $cm^2$) in the control, 0.3% $\alpha$-T-treated, and 0.3% $\delta$-T-treated groups. (B) Body weight (g) of the mice in each group. Each value represents the mean ± SE.

CWR22Rv1 cells. The result indicates that $\delta$-T more potently inhibits activation of AR and its downstream target PSA as compared to $\alpha$-T.

**In Vivo Effects of $\delta$-T and $\alpha$-T.** SCID mice were injected subcutaneously with LNCaP cells and received 0.3% $\alpha$-T or 0.3% $\delta$-T in diet. The tumor take rate was 100% in the control group, 70% in the $\alpha$-T-treated group, and 50% in the $\delta$-T-treated group. This result indicates that $\delta$-T has a more potent inhibitory effect on the development of transplant prostate tumors than $\alpha$-T. Treatment with $\delta$-T also more potently inhibited the growth of LNCaP tumors than $\alpha$-T (Figure 5). As shown in Table 1, the average tumor size at the end of the experiment (day 48) in the $\delta$-T-treated group was significantly smaller than the $\alpha$-T-treated group ($p < 0.05$). The tumor weight (g) was also measured at the end of the experiment (day 48). A statistically significant difference ($p < 0.05$) in the tumor weight between the $\delta$-T-treated group and the $\alpha$-T-treated group was found (Table 1). As shown in Figure 5B, mice in different treatment group had similar body weight during the experiment period. No statistically significant difference in body weight between any two groups was found at the end of the experiment ($p > 0.05$).

**Decreased Proliferation and Increased Apoptosis in LNCaP Tumors by $\alpha$-T and $\delta$-T.** Tumor cell proliferation was measured by determining the number of mitotic cells in the xenograft tumors. We found that treatment of the mice with $\delta$-T in diet resulted in a strong inhibition of tumor cell mitosis (Table 2). The differences in % mitotic cells between the $\delta$-T-treated group and the control group, and between the $\delta$-T-treated group and the $\alpha$-T-treated group were statistically significant ($p < 0.001$). We found no statistically significant difference ($p > 0.05$) in % mitotic cells between the control group and the $\alpha$-T-treated group (Table 2). As shown in Table 2 and Figure 6, treatment with $\delta$-T also resulted in a strong increase in the number of caspase-$3^+$ cells. The differences in the percentage of caspase-$3^+$ between the $\delta$-T-treated group and the control group, and between the $\delta$-T-treated group and the $\alpha$-T-treated group were statistically significant ($p < 0.001$). Treatment with $\alpha$-T did not significantly increase the percentage of caspase-$3^+$ cells ($p > 0.05$).

**Table 1. Effects of $\delta$-T and $\alpha$-T on Tumor Growth and Body Weight of SCID Mice[a]**

| treatment group | tumor size ($cm^2$) | tumor weight (g) | body weight (g) |
|---|---|---|---|
| control | 0.97 ± 0.08 | 0.62 ± 0.05 | 27.7 ± 0.50 |
| 0.3% $\alpha$-T | 0.74 ± 0.05 | 0.54 ± 0.09 | 28.1 ± 0.74 |
| 0.3% $\delta$-T | 0.44 ± 0.04[b,d] | 0.28 ± 0.06[c,d] | 27.5 ± 0.64 |

[a]Human prostate cancer LNCaP cells were injected subcutaneously into SCID mice as indicated in the Materials and Methods. The mice were fed diet with 0.3% $\alpha$-T or 0.3% $\delta$-T. Tumor size ($cm^2$) and tumor weight (g) were measured at the end of the experiment. Each value is the mean ± SE. [b]Indicates $p < 0.001$ compared to the control. [c]Indicates $p < 0.01$ compared to the control. [d]Indicates $p < 0.05$ compared to the 0.3% $\alpha$-T-treated group.

**Table 2. Effects of $\delta$-T and $\alpha$-T on Tumor Cell Proliferation and Apoptosis[a]**

| treatment group | number of tumors | % mitotic cells | % caspase-$3^+$ cells |
|---|---|---|---|
| control | 10 | 0.88 ± 0.03 | 0.57 ± 0.03 |
| 0.3% $\alpha$-T | 7 | 0.78 ± 0.03 | 0.68 ± 0.05 |
| 0.3% $\delta$-T | 5 | 0.50 ± 0.02[b] | 1.01 ± 0.05[b] |

[a]The tumors from mice at the end of the experiment were analyzed for proliferation and apoptosis. Tumor cell proliferation was measured by determining mitotic cells. Apoptosis was measured by immunohistochemical staining with activated caspase-3. Each value is the mean ± SE. [b]Indicates $p < 0.001$ compared to the control or to the 0.3% $\alpha$-T-treated group.

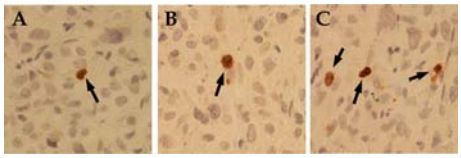

**Figure 6.** Effects of $\alpha$-T and $\delta$-T on expression of activated caspase-3 in prostate LNCaP xenograft tumors. Immunohistochemistry with an activated caspase-3 antibody was performed in paraffin sections of LNCaP tumors collected from the experiment described in Figure 5. Representative micrographs of caspase-3 immunostaining in LNCaP tumors from the control (A), $\alpha$-T-treated (B), and $\delta$-T-treated (C) mice are shown. Arrows indicate caspase-3 positive cells.

## DISCUSSION

In the present study, we demonstrated for the first time that $\delta$-T had a potent inhibitory effect on the growth of prostate cancer cells cultured in vitro and grown as subcutaneous xenograft tumors in SCID mice. In initial studies, we determined the effects of $\alpha$-T, $\gamma$-T, $\delta$-T, and a mixture of tocopherols on cultured prostate cancer cells and found that $\delta$-T had stronger effects on growth inhibition and apoptosis stimulation than $\alpha$-T, $\gamma$-T, and the tocopherol mixture. In subsequent studies, we found that $\delta$-T more potently inhibited the growth of LNCaP tumors in SCID mice than $\alpha$-T. Most of the previous studies on vitamin E have focused on $\alpha$-T. Studies on the effects of $\alpha$-T on prostate cancer reveal inconsistent results.[24−29] It has recently been shown by a number of laboratories that $\gamma$-T or a mixture of different tocopherols, $\gamma$-TmT, are more active than $\alpha$-T for inhibiting prostate cancer.[14,17,30−32] Accumulating evidence from experimental studies suggests that the $\alpha$-T used in clinical trials may not be the correct form of vitamin E for cancer prevention. The strong inhibitory effect of $\delta$-T on prostate cancer shown in our present studies indicates that $\delta$-T may be a good candidate for future clinical trial of prostate cancer prevention.

The mechanisms by which different tocopherols inhibit the growth and induce apoptosis in prostate cancer cells are still largely unknown. Although many studies investigated the mechanisms of action for $\alpha$-T and $\gamma$-T in cancer cells, there are very few studies for the mechanisms of anticancer activities of $\delta$-T. A previous study showed that combination of $\gamma$-T with $\delta$-T induced apoptosis in LNCaP cells by induction of cytochrome *c* release, activation of caspase-9 and caspase-3, and cleavage of poly-ADP-ribose polymerase.[30] Recent studies by our collaboration team demonstrated that suppression of lung tumorigenesis by $\delta$-T was associated with its ability to inhibit the formation of 8-OHdG, $\gamma$-H2AX, and nitrotyrosine, as well as to induce cell apoptosis.[33] In another study, $\delta$-T was found to induce PPAR-$\gamma$ and PTEN, and reduce pAkt levels in breast cancer cells.[34] The mechanisms for the effects of $\delta$-T on prostate cancer are not clear. It is known that the AR signaling pathway is important for growth and survival of prostate cancer cells. Earlier studies have shown that analogues of $\alpha$-T induced transcriptional repression of AR, inhibited AR activity and decreased the level of PSA.[35,36] However, the effect of $\delta$-T on AR signaling was not reported. In the present study, we demonstrated that $\delta$-T had a more potent inhibitory effect than $\alpha$-T on AR activation in prostate cancer cells as determined by the luciferase reporter gene expression assay. In addition, $\delta$-T more potently decreased the level of PSA than $\alpha$-T. Suppression of the AR signaling may be one of the mechanisms by which $\delta$-T inhibits the growth and induces apoptosis in androgen sensitive prostate cancer cells. Preliminary results from our recent studies showed inhibitory effect of $\delta$-T on the growth of PC-3 and Du145 cells (data not shown). This result indicates that $\delta$-T also inhibited androgen-independent prostate cancer cells and that mechanisms other than AR signaling may be involved. Further studies are needed to explore the mechanisms of action for $\delta$-T in androgen-independent prostate cancer cells.

Since $\delta$-T showed strong effects on growth inhibition and apoptosis in cultured prostate cancer cells, we used the xenograft prostate tumor model to determine the in vivo effect of this tocopherol. We found in our earlier studies that 0.3% of different tocopherols in diet were effective.[13−15] Therefore, 0.3% of $\alpha$-T and $\delta$-T in diet were used in our present in vivo study. Our study showed that treatment with 0.3% $\alpha$-T in diet decreased the number of mice that formed LNCaP tumors. However, $\alpha$-T administration did not significantly inhibit the growth of the tumors. Administration of 0.3% $\delta$-T in the diet strongly inhibited the formation and growth of subcutaneous LNCaP tumors. In a recent pilot study, we found low plasma levels of $\delta$-T (0.16−0.47 $\mu$M) in prostate cancer patients received 2 capsules of mix-tocopherol (containing 128 mg $\alpha$-T, 200 mg $\gamma$-T, and 71 mg $\delta$-T per capsule) for 7 or 14 days (data presented in the 2011 AACR annual meeting). The concentrations of $\alpha$-T and $\delta$-T to inhibit cultured prostate cancer cells are higher than the plasma levels of these compounds. It is possible that the in vivo effects of $\delta$-T were cumulative. In addition, $\delta$-T may interact with endogenous factors such as cytokines within tumor tissues leading to stronger anticancer effects. Mechanistic studies showed that treatment of mice with $\delta$-T inhibited proliferation as reflected by decreased mitosis, and stimulated apoptosis as reflected by increased caspase-3 in LNCaP tumors. This result indicates that the strong inhibitory effect of $\delta$-T on the growth of LNCaP tumors in SCID mice may be mediated by inhibition of proliferation and stimulation of apoptosis in the tumors. To our knowledge, this is the first report for an inhibitory effect of $\delta$-T on the formation and growth of human prostate tumors in a xenograft model.

In summary, the present study showed that $\delta$-T had more potent effects on inhibiting proliferation and inducing apoptosis in prostate cancer cells than $\alpha$-T. The strong activities of $\delta$-T were associated with suppression of AR activity and decreased level of PSA. Results from the in vivo study demonstrated a strong inhibitory effect of $\delta$-T on the formation and growth of LNCaP tumors in SCID mice without apparent toxicity. Clinical studies for determining the potential preventive efficacy of $\delta$-T on prostate cancer patients are warranted.

lignin could replace 55% of phenol in phenol−formaldehyde resins. Gromov and Pormale[10] performed hydrogenation of lignin directly during hydrotropic treatment with a nickel catalyst to obtain phenols. Kreicberg and Grabovskij[7] carried out nitrobenzene oxidation of aspen hydrotropic lignin in alkaline media and obtained aromatic aldehydes with a yield of 8.8% based on Klason lignin of the hydrotropic lignin. Another paper[11] describes oxidative degradation of aspen hydrotropic lignin with oxygen in an alkaline media in the presence of copper oxide. The yield of low molecular weight products was 39.3% based on Klason lignin of the hydrotropic lignin. The products were further fractionated into aldehyde, acidic, phenolic, and neutral fractions.[11]

All of these studies have shown that hydrotropic lignin is a valuable biobased polymer that can be used to produce chemicals and as a substituent of phenol in phenol−formaldehyde resins. Despite all of the research, there is no detailed information about the composition and chemical structure of this, rather novel, type of technical lignin. However, characterization of lignin has a great importance for the evaluation of its potential for various applications. In this study, hydrotropic lignin was isolated from industrial birch wood chips by conventional (reference) and modified hydrotropic treatments.[5] The difference between these two processes is that in the latter the hydrotropic solution was modified by the addition of formic acid and hydrogen peroxide. Such modification led to a better delignification, and the obtained pulp had higher cellulose content than the reference one; however, the modified process was more severe, which resulted in a lower yield of pulp with a lower viscosity.[5] Therefore, it was interesting to investigate how the modification of hydrotropic solution with hydrogen peroxide and formic acid would affect the chemical composition of lignin. The lignins were characterized with Fourier transform infrared spectroscopy (FTIR), pyrolysis−gas chromatography−mass spectrometry (pyrolysis-GC-MS), semi-quantitative $^{1}H-^{13}C$ HSQC NMR, $^{31}P$ NMR spectroscopy techniques, and size exclusion chromatography (SEC) to elucidate their structures and functional groups. The chemical and elemental compositions of the lignins were studied as well. We believe that the characterization of hydrotropic lignins presented will facilitate their utilization and promote the hydrotropic process in the pulp and biorefinery industry.

## MATERIALS AND METHODS

**Materials.** Birch wood chips collected from a Finnish pulp and paper mill were screened in the laboratory, and a 4−6 mm fraction was used for the hydrotropic treatments. Technical grade sodium xylenesulfonate having purity >90% (Sigma-Aldrich) was used as a hydrotropic agent. Other chemicals were obtained from commercial sources and were used without further purification.

**Isolation of Hydrotropic Lignins.** Hydrotropic lignins were extracted in a 10 L rocking digester using a 36% aqueous hydrotropic solution. Two treatments were performed, namely, a conventional reference method and one with the addition of formic acid and hydrogen peroxide. Lignins obtained with these treatments were designated R and M lignins, respectively. A dosage of hydrogen peroxide for the modified treatment was 2.5% based on wood, and the amount of formic acid was added to lower the pH to 3.5. The conditions of the extractions were the following: liquor-to-wood ratio, 4 (w/w); heating rate, 1.5 °C/min; dwell temperature, 170 °C; and dwell time, 120 min. The pH values of the prepared hydrotropic solutions were 9.2 and 3.5 for the reference and modified solutions, respectively. Prior to the extractions, the chips were vacuum-impregnated with the hydrotropic solutions at room temperature for 30 min using a water pump. The solid residues (or pulps) after the treatments were disintegrated and washed as described elsewhere[5] and screened in a Valmet TAP03 rotary screen using a 0.1 mm slit basket. The accepted fraction was used for the determination of residual lignin content.

Hydrotropic lignins from the collected spent solutions were precipitated by dilution with 10-fold (v/v) of hot distilled water. After addition of the hot water, the temperature of the diluted solution was around 75 °C. The precipitated lignin was separated by filtration through a glass filter funnel no. 2. At the beginning of the filtration, some amount of the filtrate was recirculated back onto the filter until the filtrate became free of lignin particles. The precipitate was further washed with around 8-fold (v/v, based on the volume of spent solution taken for precipitation) of hot distilled water. The temperature of the suspension during the washing was maintained at 75−80 °C. The washed lignins were freeze-dried and stored in a cold room at a temperature of 10 °C.

The amounts of dissolved, precipitated, and nonprecipitated lignins were calculated according to eqs 1−4.

dissolved lignin (or degree of delignification) based on lignin in wood, %

$$L_{dis} = (L_{wood} - L_{pulp} \times m_{pulp}/m_{wood})/L_{wood} \times 100 \quad (1)$$

precipitated lignin (lignin yield) based on wood, %

$$L_{precip/wood} = L_{precip\ ss} \times m_{ss}/m_{wood} \times 100 \quad (2)$$

precipitated lignin (lignin yield) based on the original lignin in wood, %

$$L_{precip/lignin} = L_{precip\ ss} \times m_{ss}/m_{lignin\ wood} \times 100 \quad (3)$$

nonprecipitated lignin based on the original lignin in wood, %

$$L_{nonprecip} = L_{dis} - L_{precip/lignin} \quad (4)$$

$L_{wood}$ and $L_{pulp}$ are lignin contents in birch wood and in pulp, %; $m_{pulp}$ and $m_{wood}$ are the amounts of pulp and wood, g; $L_{precip\ ss}$ is the amount of lignin precipitated from spent solution, g/g; $m_{ss}$ is the amount of spent solution calculated as a sum of hydrotropic solution, water in wood, and dissolved wood, g; $m_{lignin\ wood}$ is the amount of lignin in birch wood, g.

**Chemical Composition of Lignins.** Residual carbohydrates in the lignin samples were determined using acid methanolysis and gas chromatography (GC) as described elsewhere.[5] The analysis was carried out using an AutosystemXL (PerklinElmer, Norwalk, CT, USA) gas chromatograph. The columns used were 25 m × 0.200 mm i.d., 0.11 μm, HP-1 (Agilent Technologies, Santa, Clara, CA, USA) and 25 m × 0.199 mm i.d., 0.11 μm, HP-5 (Agilent Technologies). The operating parameters of the GC were the following: injection amount, 1 μL; split ratio, 1:25; injector temperature, 250 °C; temperature program of the oven, 100 °C, held for 1 min, increased at 4 °C/min to 170 °C and then at 12 °C/min to 300 °C, and, finally, held for 7 min. The temperature of the detector (flame ionization detector, FID) was 310 °C. Hydrogen was used as a carrier gas.

Extractives in lignins were analyzed by GC after silylation. The amount of samples weighed for the analysis was about 8 mg with the accuracy of 0.1 mg. Two milliliters of the internal standard containing 0.02 mg/mL cholesterol, heneicosanoic acid, 1,3-dipalmitoyl-2-oleoylglycerol, and cholesteryl heptadecanoate in methyl *tert*-butyl ether was added to the samples. The samples were mixed well with the internal standard and evaporated under a nitrogen flow at 50 °C. To ensure complete removal of the solvent, the samples were kept in a vacuum oven for 20 min at 40 °C. The dried samples were dissolved in 40 μL of pyridine and silylated with 80 μL of *N*,*O*-bis(trimethylsilyl)-trifluoroacetamide and 40 μL of trimethylchlorosilane at 70 °C for 45 min. After cooling at room temperature, the samples were transferred

into GC vials and analyzed by Clarius 500 (PerkinElmer) and AutosystemXL (PerkinElmer) gas chromatographs equipped with 6−7 m × 0.530 mm i.d., 0.15 μm, HP-1 (Agilent Technologies) and 25 m × 0.200 mm i.d., 0.11 μm, HP-1 (Agilent Technologies) columns, respectively. The injection parameters and temperature programs are described elsewhere.[12] The short column was used to analyze groups of components, whereas the long column was used for the analysis of individual substances (except for steryl esters and triglycerides). The identification and assignment of the peaks were done with the help of GC-MS.[13]

**Elemental Analysis.** Carbon, hydrogen, nitrogen, and sulfur contents of the lignins were measured with a Thermo Scientific Flash 2000 series elemental analyzer. The description of the analysis can be found elsewhere.[14] Oxygen content was calculated by subtracting the sum of C, H, N, and S from 100%. The elemental compositions of lignins obtained by the reference and modified treatments were as follows: carbon, 65.51 and 64.50%; hydrogen, 5.87 and 5.54%; nitrogen, 0.23 and 0.22%; sulfur, 0.16 and 0.39%; oxygen, 28.23 and 29.35%, respectively.

**Pyrolysis-GC-MS.** The mass ratios of the *p*-hydroxyphenyl (H), guaiacyl (G), and syringyl units (S) in the hydrotropic lignins as well as in the lignin in the wood were determined using pyrolysis-GC-MS. Before the analysis, the wood was ground using a cutting mill with a sieve cassette with 1 mm openings. After that, the wood meal was sieved to obtain a fraction <250 μm and freeze-dried.

The pyrolysis-GC-MS was done on a foil pulse Pyrola 2000 pyrolyzer (Pyrol AB, Lund, Sweden) connected to the GC-MS instrument.[13] The analyses were performed as described previously.[13] The tentative identification was mainly based on the mass spectra library created at the Laboratory of Wood and Paper Chemistry at Åbo Akademi University and partly on the Wiley 10/NIST 2012 mass spectral libraries. A sample amount of about 100 μg and one drop of acetone was applied onto the Pt filament, the sample was allowed to dry, and the analysis was started 2 min after the filament was added into the probe.

**FTIR.** The FTIR spectra were recorded in transmission mode using a Thermo Scientific Nicolet iS50 instrument. The concentration of lignin in a KBr pellet was about 1%. The number of scans was 32, and the resolution was 4 $cm^{-1}$.

**$^{1}H-^{13}C$ HSQC NMR.** Around 50 mg was dissolved in 1 mL of DMSO-$d_6$. NMR spectra were recorded at 25 °C on a Bruker AVANCE III 400 MHz instrument equipped with a 5 mm BBI probe (5 G/cmA). Heteronuclear single-quantum coherence (HSQC) experiments used Bruker's "hsqcetgpsi2" pulse program with spectral widths of 5000 Hz (from 10 to 0 ppm) and 20843 Hz (from 165 to 0 ppm) for the $^{1}H$ and $^{13}C$ dimensions. The number of collected complex points was 1024 for the $^{1}H$ dimension with a recycle delay of 1.5 s. The number of transients was 32, and 256 time increments were always recorded in the $^{13}C$ dimension. The $^{1}J_{CH}$ used was 145 Hz. Processing used squared cosine-bell apodization in both dimensions. Prior to Fourier transformation, the data matrices were zero-filled to 1024 points in the $^{13}C$ dimension. The central solvent peak was used as an internal reference ($\delta_C$ 39.5; $\delta_H$ 2.49). HSQC correlation peaks were assigned by comparison with the literature.[15−18] A semi-quantitative analysis[15] of the volume integrals (uncorrected) of the HSQC correlation peaks was performed using Mnova 7 processing software. In the aliphatic oxygenated region, the relative abundances of side chains involved in the various interunit linkages were estimated from the $C_\alpha-H_\alpha$ correlations to avoid possible interference from homonuclear $^{1}H-^{1}H$ couplings. In the aromatic/unsaturated region, $C_2-H_2$ and/or $C_6-H_6$ correlations from H, G, and S lignin units were used to estimate their relative abundances.

**$^{31}P$ NMR.** Hydroxyl and carboxyl functional groups were quantified by $^{31}P$ NMR after derivatization with 2-chloro-4,4,5,5-tetramethyl-1,3,2-dioxaphospholane. The detailed description of the analysis can be found elsewhere.[19]

**SEC.** Number-average ($M_n$) and weight-average ($M_w$) molar mass distributions and polydispersity were determined with alkaline SEC analysis according to the method of Gosselink et al.[19]

**Other Analysis.** Contents of lignin in the birch wood and in the wood residues (pulps) after the treatments were determined as described elsewhere.[5]

## RESULTS AND DISCUSSION

**Isolation of Hydrotropic Lignins.** As expected, the addition of hydrogen peroxide and formic acid to a hydrotropic solution resulted in a more efficient lignin removal from the wood in comparison with the reference process. The contents of residual lignins in the pulps were 4.5 and 1.7% for the reference and modified treatments, which corresponded to degrees of delignification of 91 and 97%, respectively. The yield of the residue after the modified treatment was also lower, 43 against 48% in the case of the reference treatment. Such a low yield of pulp from the modified process, besides the higher degree of delignification, can be attributed to a higher rate of carbohydrate degradation, mainly hemicelluloses, as has been shown previously.[5]

The yield of lignin from both treatments was 16.1% calculated on the dry wood basis or 160 kg of lignin from 1 t of wood. This amount corresponded to around 67.0% of the original lignin contained in the birch wood. Some amount of lignin did not precipitate upon dilution with water and, therefore, was not recovered. This fraction constituted 23.9 and 30.0% of the original lignin in birch for the reference and modified treatments, respectively. These numbers also include losses of lignin during the washing step. Similar behavior of lignin during precipitation was also described by Gromov and Odincov.[20,21] In their studies of hydrotropic treatment of aspen wood, the amount of nonprecipitated lignin fractions varied in the range from 10 to 50% based on the original lignin in the wood.[20] The authors assumed that this fraction was composed of low molecular weight lignin. In another study,[21] they partially isolated this fraction by acidification and heating the diluted spent solution. According to Gromov and Odincov,[20,21] the quantity of nonprecipitated lignin depended on the treatment conditions. Some low molecular weight phenolic compounds (syringaldehyde, syringic acid, vanillin, vanillic acid, stilbenes, and syringaresinol) were also detected in the hydrotropic lignins by GC during analysis of the extractives, although their total quantity was <1%.

Interestingly, water-soluble lignin degradation products were also found in spent liquors from other autocatalyzed and moderately acidic treatments, such as in hydrolysates after hot water treatment of eucalyptus[22] and sugar maple,[23] and in a spent solution after ethanol−water treatment (Alcell process) of a mixture of hardwoods.[24] In the last studies, the amount of nonprecipitated lignin varied from 20 to 40% of the original lignin in wood.

**Chemical and Elemental Composition of Lignins.** The purity of lignins was analyzed indirectly and expressed through the contents of non-lignin substances. Such substances could originate, for example, from the raw material and the hydrotropic reagent. The former includes wood constituents such as extractives, carbohydrates, and proteins. The latter consists of the hydrotropic salt itself and contaminants present in the salt.

The contents of extractives in the lignins were determined to be 0.50 and 0.44% for R and M lignins, respectively. The detected extractives were in a free form, meaning that they were not strongly bound to lignin. Therefore, they could be analyzed by silylation and GC, that is, a procedure which does not include any destructive steps, such as hydrolysis. The free

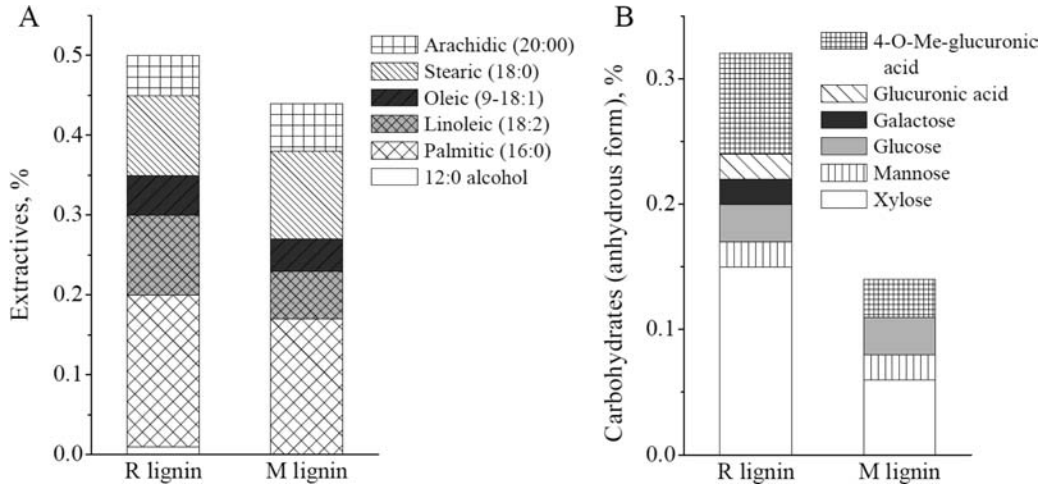

**Figure 2.** (A) Extractives and (B) carbohydrates (as anhydrous units) in the hydrotropic lignins.

extractable matter of the lignins consisted exclusively of fatty acid with palmitic acid being the most abundant (Figure 2A). The only exception was a very small amount of 12-carbon alcohol found in the reference lignin.

The lignins had a very small amount of residual carbohydrates (Figure 2B) owing to extensive hydrolytic reactions, which took place during the treatment. The reactions were catalyzed by the organic acids liberated from wood, mainly acetic and formic.[2] In the case of the modified treatment, destruction of hemicelluloses was additionally intensified by formic acid added to the hydrotropic solution. Therefore, M lignin contained less residual carbohydrates than the reference sample, 0.14 versus 0.32%, respectively. In contrast to the extractives, the residual carbohydrates are covalently bound to lignin and form so-called lignin−carbohydrate complexes. This was also a reason why the carbohydrates were not removed completely during the hydrotropic treatment and lignin recovery. As expected, xylose was the main contaminating sugar, because it was present in the birch wood in a large quantity, around 20%.[5] In the lignins, residual xylose is present in its polymeric form, xylan.

Both lignins exhibited elemental composition typical of technical lignins, for example, kraft and EtOH/$H_2O$ lignins from the literature.[25] Technical lignins usually have a higher content of carbon and lower contents of oxygen and hydrogen than the original lignin in wood (milled wood lignins in the literature[25]). Nitrogen in both samples presumably originated from a small amount of proteins from the wood. Assuming a conversion factor of 6.25,[26] this content of nitrogen corresponded to approximately 1.4% of proteins in the samples. The proteins are most likely strongly bound to the lignins as has been shown by other studies.[26,27]

Both lignins contained sulfur, which indicates that the samples were possibly contaminated with the hydrotropic salt. In that case the salt must be strongly associated with the lignins, because it could not be removed during the washing step. Alternatively, the sulfur might originate from impurities present in the hydrotropic reagent. One such compound, 2,2′,5,5′-tetramethyldiphenylsulfone, or its isomers, was found during the analysis of extractives by GC. The same substance was also detected in the salt and lignins by pyrolysis-GC-MS. Tetramethyldiphenylsulfone is probably a byproduct of manufacturing sodium xylenesulfonate, and it is most likely insoluble in water. The water solubility for different tetramethyldiphenylsulfone isomers varies from 0.026 to 0.037 mmol/L (predicted using Advanced Chemistry Development (ACD/Laboratories) software V11.02). Therefore, it survived the washing step and remained in the lignins. This compound may contribute 0.09 and 0.08%-units to the total sulfur content in R and M lignins, correspondingly. Interestingly, lignin from the modified treatment had a higher content of sulfur. However, the sulfur level in both lignins was substantially lower than in commercially produced kraft lignins (1.0−3.0%) and lignosulfonates (3.5−8.0%).[28]

**H/G/S Ratio by Pyrolysis-GC-MS.** The mass ratios of the *p*-hydroxyphenyl, guaiacyl, and syringyl units were found to be 1:25:74 for R and 2:26:71 for M lignins. The corresponding ratio for the original birch wood lignin was 3:26:71. Hence, the results show that the relative content of the units in the lignins was almost the same as in birch wood lignin; therefore, it can be concluded that the ratio did not change over the course of the hydrotropic treatments. Also, both hydrotropic lignins were comparable with each other, which means that the addition of hydrogen peroxide and formic acid did not affect the unit ratio of lignins. Both lignins can be regarded as SG lignins according to Faix's classification[29] with a high content of S units. It should be noted that small amounts of low molecular weight phenols detected in the lignins by GC (analysis of extractives) were predominantly derived from the S units (syringaresinol, syringaldehyde, and syringic acid).

Another observation made from the results of pyrolysis-GC-MS was related to the formation of catechol units during hydrotropic treatments. Several types of catechols were detected in the pyrograms of the hydrotropic lignins, namely, catechol, 3-methylcatechol, 4-methylcatechol, and 3-methoxycatechol. The pyrogram of birch wood meal did not have such units. Most likely, these structures were formed by demethylation of methoxyl groups of G and S units. The ratios of the sum of H, G, and S units and catechol units were 94:6 and 93:7 for the R and M lignins, respectively.

**FTIR.** Lignin is a complex material and has many bonds and functional groups in its structure. This is reflected in its IR spectrum, which shows many bands, most of which overlap with each other, especially in the fingerprint area. However, IR studies can provide some basic information about lignin purity and its structure and can be further complemented with more sophisticated methods of analysis. FTIR spectra of hydrotropic

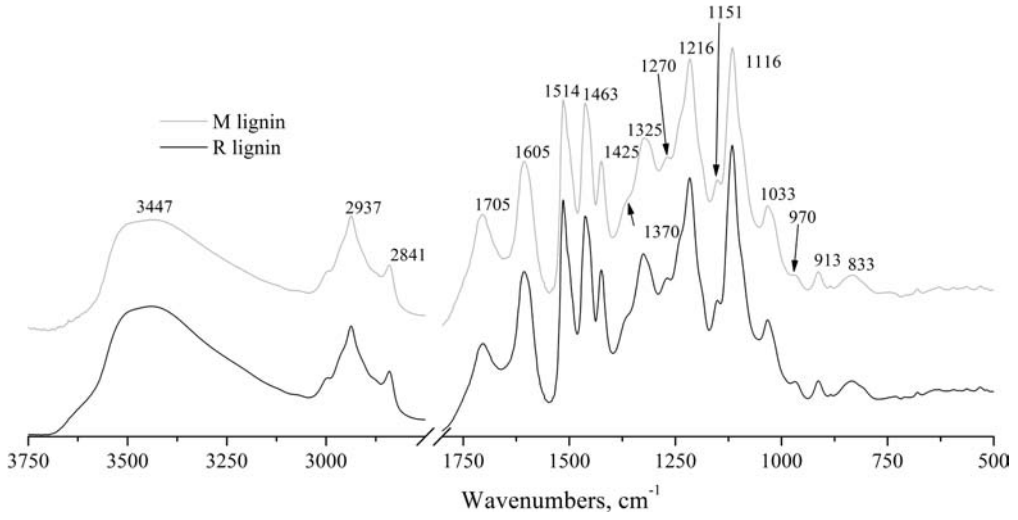

**Figure 3.** FTIR spectra of the hydrotropic lignins.

lignins are shown in Figure 3. The bands were assigned according to the data found in the literature (Table 1).[29,30]

**Table 1. Band Assignment in FTIR**

| wavenumber, $cm^{-1}$ | band assignment |
|---|---|
| 3447 | O—H stretch in aliphatic and phenolic −OH |
| 2937, 2841 | C—H stretch in methyl and methylene groups |
| 1705 | C═O stretching in unconjugated ketones and carboxyl groups; aryl and *α,β* unsaturated esters |
| 1605 | aromatic skeletal vibration (S > G) + C═O stretch |
| 1514 | aromatic skeletal vibrations (G > S) |
| 1463 | C—H asymmetric deformations in methyl and methylene groups |
| 1425 | aromatic skeletal vibrations |
| 1370 | aliphatic C—H symmetric deformation in methyl (not methoxyl) + O—H deformation in phenols |
| 1325 | S ring breathing + G ring substituted in position 5 |
| 1270 | G ring breathing and C—O stretching |
| 1216 | C—O stretching in phenols and ethers |
| 1116 | aromatic C—H in-plane deformations (S units) |
| 1033 | aromatic C—H in-plane deformations in G units + C—O deformations in primary alcohols |
| 970 | C—H out-of-plane deformation of trans-double bond (conjugated with an aromatic ring, *α,β*-double bond) |
| 913 | aromatic C—H out-of-plane deformation (only in GS lignin type) |
| 833 | aromatic C—H out-of-plane deformation (only in GS and H lignin types) |

The spectra showed bands typical of hardwood lignin. A relatively high peak at 1325 $cm^{-1}$ and a strong band at 1116 $cm^{-1}$ are characteristic for an IR spectrum of hardwood lignins.[29,30] In the case of softwood lignin, the former is usually very small, and the latter appears at 1140 $cm^{-1}$. Such shifts have been explained by Faix,[29] who found that the band at 1140 $cm^{-1}$ is shifted toward lower wavenumbers as the content of S units in lignin increases. Bands at 833 and 913 $cm^{-1}$ are also specific to hardwood lignins, and they are absent in spectra of softwood lignins.[29,30] The spectra of both hydrotropic lignins were almost identical, implying that the lignins have similar structures. Compared to other lignins,[31] the spectra look very similar to the spectrum of Alcell lignin. This could suggest that the structures of the hydrotropic and Alcell lignins are close to each other.

A weak band at 970 $cm^{-1}$ is attributed to the *α,β*-double bond. A small amount of low molecular weight stilbenes was found in the lignins in the GC (analysis of extractives). Such compounds are not present in birch wood in either extractives or lignin. In addition, FTIR spectra of milled wood lignins (MWL) do not show absorbance at this wavenumber.[29] Therefore, it can be concluded that such structures were formed during the treatments. A possible route of formation of stilbenes in moderately acidic conditions is described elsewhere.[32] The sequence involves homolysis of a *β-O*-4′ linkage and formation of a *β*-1′ structure, which in acidic media is converted to stilbenes.

**Characterization of Lignins with $^{1}H-^{13}C$ HSQC NMR.** 2D NMR spectrometry was used to estimate the main linkages in the lignins. The spectra are shown in Figure 4, and the main lignin linkages and structures are depicted in Figure 5. The results of the 2D NMR studies are shown in Table 2. Both lignins still contained *β-O*-4′ linkages (structure A), and this type of linkage was the predominant type of bond; *β*-5′ (structure B) and *β-β*′ (structure C) linkages were present in hydrotropic lignins in lower quantities (Table 2). Generally, *β-O*-4′ is the main type of bond in native lignins, and the contents of *β*-5′ and *β-β*′ linkages are much lower. In native birch wood lignin *β-O*-4′ accounts for about 40 per 100 units, and the amounts of *β*-5′ and *β-β*′ are 2−5 and 7−10 per 100 units, respectively.[33−35] Hence, it is clearly seen for *β-O*-4′ and *β-β*′ linkages that their contents decreased during the hydrotropic process. On the other hand, it seems that the amount of *β*-5′ bonds was not affected significantly by the hydrotropic treatments.

Such changes in the structure of the lignins are consequences of the chemical reactions that took place during the hydrotropic treatments. The pH of the process was around 3.5 (pH values of spent solutions from the modified and reference treatments were 3.3 and 3.5, respectively) and, therefore, the type of reactions that happened with the lignin during the treatment are probably those that take place during pulping under moderately acidic conditions and autocatalyzed processes, such as hydrothermal or ethanol−water treatment. It is suggested that the main reaction in such conditions is homolytic cleavage of a *β-O*-4′ bond through quinone methide intermediate

dx.doi.org/10.1021/jf5037728 | J. Agric. Food Chem. 2014, 62, 10759−10767

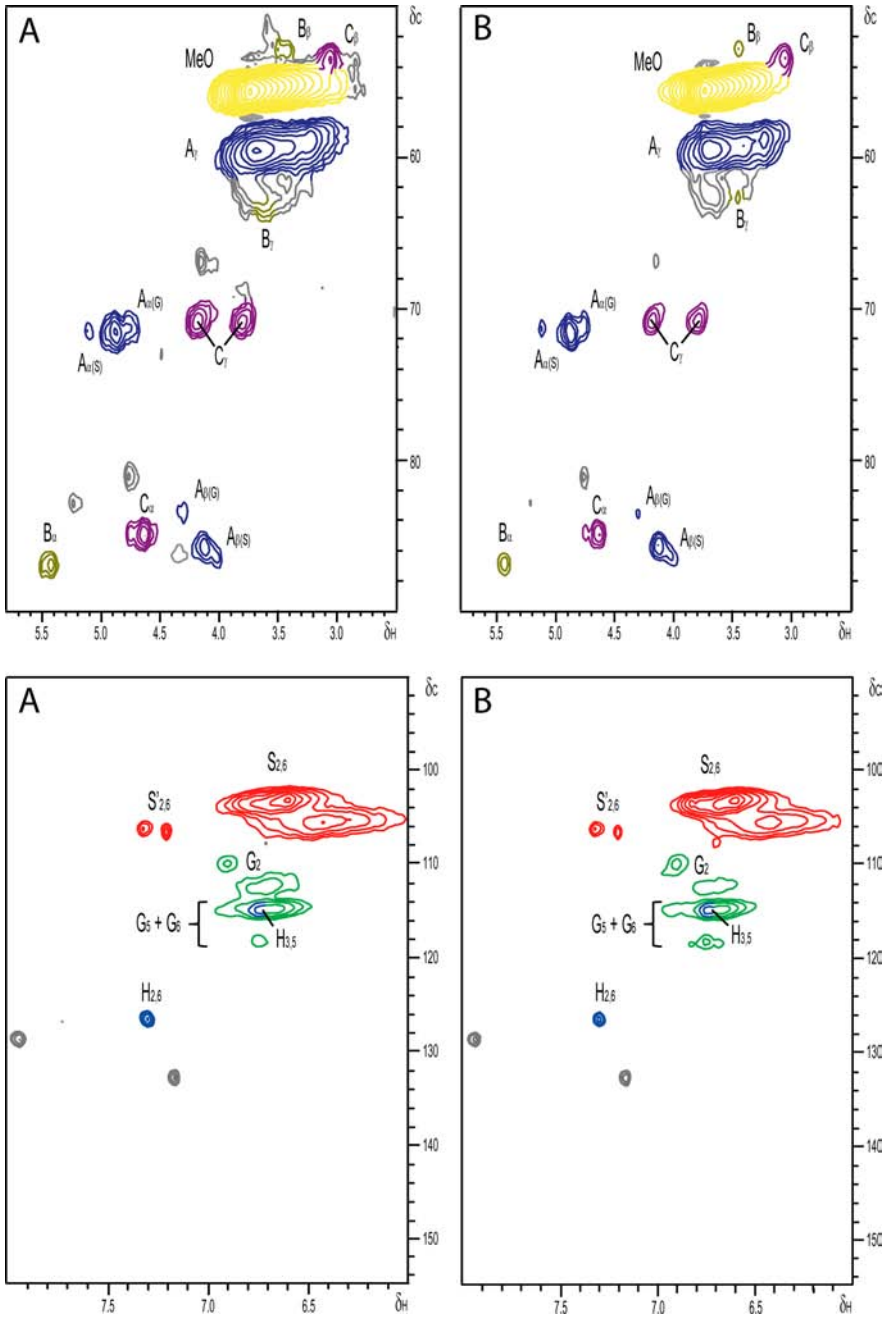

**Figure 4.** HSQC spectra of hydrotropic lignins: (A) R and (B) M. The assigned lignin structures are shown in Figure 5.

followed by radical coupling and radical exchange reactions.[22,32,36] The former path leads to the formation of *β*-1′, *β*-*β*′, and *β*-5′ structures.[32] *β*-1′ and *β*-5′ can be converted to stilbenes (as was discussed under FTIR) with the loss of a C*γ*–OH group as formaldehyde.[32,37] Besides these reactions, lignin also undergoes counterproductive condensation reactions. In the case of the modified process, additional various reactions could take place due to added hydrogen peroxide.[5]

The ratio of the units (H/G/S) calculated from the NMR data differs from the values obtained by pyrolysis-GC-MS, especially the results for the reference lignin (Table 2). However, the results of NMR can be considered more accurate than those of pyrolysis-GC-MS. According to the NMR, both lignins showed difference in the ratio of the units.

Both lignins were quite similar in the amount of bonds. The only difference was the amount of *β*-*O*-4′ linkage. With respect to this, the M lignin seems to be more degraded than the reference one. The reason for this is more severe conditions during the modified treatment due to a higher acidity and the presence of an oxidant. This fact can be also supported by the lower yield of cellulosic pulp obtained with the modified process and lower content of residual lignin in the pulp. In addition, it has been shown previously[5] that the pulp from the modified process has lower viscosity and a smaller amount of residual hemicelluloses in comparison with the reference one, which also indicates the severity of the modified treatment.

**$^{31}$P NMR.** The data from other analyses were extended by quantitative $^{31}$P NMR spectrometry. Before $^{31}$P NMR measurements, the sample is derivatized with 2-chloro-4,4,5,5-

**Table 2. Content of the Main Linkages in the Hydrotropic Lignins, Lignin Units, and Their Ratio Determined by $^1H-^{13}C$ HSQC NMR**

| | linkages, per 100 units | | | units, % | | | | |
|---|---|---|---|---|---|---|---|---|
| lignin | *β-O*-4′ (A) | *β*-5′ (B) | *β*-*β*′ (C) | H, % | G, % | S, % | S′, % | S/G |
| R | 15.0 | 3.3 | 3.2 | 1 | 19 | 78 | 2 | 4.2 |
| M | 11.8 | 3.2 | 3.0 | 2 | 22 | 73 | 3 | 3.4 |

tetramethyl-1,3,2-dioxaphospholane, which reacts with OH moieties of functional groups. Therefore, this technique is used for estimation of aromatic and aliphatic hydroxyl and carboxyl groups in lignin samples.

The amount of functional groups calculated from the $^{31}P$ NMR is summarized in Table 3. Both lignins had a relatively high content of phenolic hydroxyls attached to 5-substituted units. The signal of these units consisted of two poorly resolved signals of S phenolic units and G phenolic units substituted at the fifth position (condensed structures).[38] Therefore, it is quite likely that such a high amount of 5-substituted phenolic hydroxyls was affected by a high content of S units in the lignins.

**Table 3. Some Characteristics of the Hydrotropic and Two Hardwood Technical Lignins**

| | lignins | | | |
|---|---|---|---|---|
| | hydrotropic | | | |
| | R | M | Alcell[a] | HW soda[a] |
| carbohydrates, % | 0.32 | 0.14 | 0.30 | 8.04 |
| sulfur, % | 0.16 | 0.39 | | |
| aliphatic OH, mmol/g | 1.38 | 1.13 | 1.08 | 1.34 |
| 5-substituted (condensed + S) phenolic OH, mmol/g | 2.43 | 2.39 | 1.81 | 1.62 |
| G−OH, mmol/g | 0.64 | 0.60 | 0.70 | 0.51 |
| H−OH, mmol/g | 0.15 | 0.17 | 0.20 | 0.34 |
| total phenolic, mmol/g | 3.22 | 3.16 | 2.71 | 2.47 |
| COOH, mmol/g | 0.30 | 0.32 | 0.30 | 1.06 |
| $M_w$, g/mol | 5306 | 5910 | 3470 | 4570 |
| $M_n$, g/mol | 1035 | 1143 | 850 | 1105 |
| polydispersity | 5.1 | 5.2 | 4.1 | 4.0 |

[a]Data for Alcell and HW soda are from the literature.[19]

The contents of phenolic and aliphatic hydroxyl groups in birch (*Betula pendula*) MWL determined by $^{31}P$ NMR are 1.2 and 5.4 mmol/g, respectively.[39] By comparison of these numbers with the contents of aliphatic and phenolic hydroxyl groups of the hydrotropic lignins, it is clearly seen that the content of phenolic hydroxyl groups in the lignins increased after the treatment, whereas the amount of aliphatic hydroxyls decreased (Table 3). Both the increase of phenolic hydroxyl groups and the decrease of aliphatic OH are consequences of the reactions discussed above. Aliphatic hydroxyls could also be converted into carboxyl groups as a result of oxidation reactions.[36] The amounts of carboxyl groups were 0.30 and 0.32 mmol/g for R and M lignins (Table 3). The contributions of the extractives to the total content of carboxyl groups were not significant and were 6.0 and 4.9% in the case of R and M lignins, respectively.

Generally, the lignins did not differ from each other in the amount of functional groups, except the contents of aliphatic hydroxyl groups. Again, as was discussed previously, the reason for this was the different composition of the hydrotropic solutions employed in the treatments.

**SEC.** The molecular weights of lignins determined by alkaline SEC are shown in Table 3. The values do not differ considerably; however, the M lignin has higher $M_w$ than the reference one. Because the M lignin underwent greater changes due to the severity of the process, the difference between the molecular weights can be explained by the higher degree of condensation in the case of lignin obtained according to a modified process.

**Comparison with Other Technical Lignins.** Table 3 displays some characteristics of two commercial hardwood technical lignins and the hydrotropic lignins. The data are presented only for hardwoods, because lignins from nonwood and softwood raw materials are different by nature. The lignin obtained from the alkaline process has a higher content of carboxyl groups in comparison to the lignins isolated in acidic conditions. This can be explained by the higher oxidation rate of phenolic units by air in alkaline media in comparison to an acidic one.[40] A similar trend as with the carboxylic groups can be observed for carbohydrates. Lower contents of carbohydrates of Alcell and hydrotropic lignins can be attributed to the extensive hydrolytic processes taking place in the acidic media, as was discussed earlier in this paper.

Among the listed lignins, hydrotropic lignins are expected to be closer to Alcell lignin due to the similarity of the nature of the processes. Indeed, the contents of carbohydrates and carboxyl groups are quite similar (Table 3). In addition, the FTIR spectra of thhate hydrotropic lignins were similar to the spectrum of the Alcell lignin. However, due to the difference in the wood species and treatment agents as well as the process conditions (temperature, duration, liquor to solid ratio, etc.), the lignins also showed differences. For example, the Alcell lignin has a lower molecular weight and a lower content of phenolic hydroxyl groups than the hydrotropic lignins (Table 3) Also, the Alcell lignin is sulfur-free, and the hydrotropic lignins contain small amounts of sulfur, which, however, might be due to contamination in the hydrotropic agent.

In conclusion, the present study showed that 67% of the original birch wood lignin could be recovered by conventional

and modified hydrotropic treatments. The structure of lignins was altered during the hydrotropic treatments; the content of phenolic hydroxyl groups increased and that of aliphatic hydroxyls decreased. The lignin from the modified treatment underwent more considerable changes than the reference one, although generally both lignins were quite similar to each other. Also, the lignins showed some similarities with technical organosolv Alcell lignin. Both hydrotropic lignins have very little non-lignin contaminants and potentially present valuable raw materials for further chemical and thermal conversion or for making shaped biobased materials.

related to whether *A. confusa* is suited to produce sugars for bioenergy application is limited, and this hinders the effective utilization of this species. Therefore, the objective of this study was to evaluate the potential of the extractive-free *A. confusa* heartwood for producing fermentable sugars based on two acid-based pretreatments: dilute acid (DA) and sulfite pretreatment (SP). The changes of the chemical characteristics in the cell wall of this species during these pretreatments were evaluated. Original *A. confusa* heartwood with high extractive content was also investigated for comparison.

## MATERIALS AND METHODS

**Wood Materials.** Shavings of a 40-year-old *A. confusa* heartwood were soaked in ethanol at ambient temperature for 3 weeks to remove valuable extracts. The yield of this ethanolic extract was 8.2%.[4] After air-dried at ambient temperature, these shavings were ground to 40−60 mesh wood meals. The wood meals were further extracted with toluene/ethanol (2:1, v/v) and ethanol in a Soxhlet apparatus for 48 h. The extractive yield of this further extraction was 1.1%. A total of 9.3% extractives were obtained from all of the extraction processes. The extractive-free wood meals were further dried over $P_2O_5$ under vacuum for later experiments.

**Pretreatments.** All pretreatments were performed in a cylindrical stainless reactor (25 mL) with a dry-heating system. The solid/liquid ratio (w/v) for all pretreatments was 1:10. For dilute acid pretreatments, 1 g of wood meals was reacted with 0.1% (w/w) $H_2SO_4$ at 150 or 170 °C for 10 or 20 min (150C10M, 150C20M, 170C10M, and 170C20M; Table 1). For sulfite pretreatments, 1 g of wood meals was reacted with 4 or 8% (w/w) $NaHSO_3$ and 1 or 2% (w/w) $H_2SO_4$ at 180 °C for 30 min (4B1A, 4B2A, 8B1A, and 8B2A; Table 1). The initial pH values of the SP liquors were between pH 2.1 and 2.6. After individual pretreatment, the sample was filtered by a sintered glass filter to separate the solid residues [pretreatment residues (PRs)] and pretreatment hydrolysates (PHs). An additional double-distilled water ($ddH_2O$) rinse (50 mL) of the PRs to remove residual pretreatment chemicals and inhibitors was also filtered, collected, and combined into PHs. An aliquot of the pretreatment hydrolysates was used for determination of the neutral sugar contents and other components.

**Table 1. Lists of Different Pretreatment Conditions Used**

| | | condition | |
|---|---|---|---|
| pretreatment | sample | temperature (°C) | time (min) |
| dilute acid[a] | 150C10M | 150 | 10 |
| | 150C20M | 150 | 20 |
| | 170C10M | 170 | 10 |
| | 170C20M | 170 | 20 |
| | | $NaHSO_3$ charge (wt % of wood) | $H_2SO_4$ charge (wt % of wood) |
| sulfite[b] | 4B1A | 4 | 1 |
| | 4B2A | 4 | 2 |
| | 8B1A | 8 | 1 |
| | 8B2A | 8 | 2 |

[a] $H_2SO_4$ (0.1%, w/w). [b] At 180 °C and 30 min.

**Enzymatic Saccharification.** The PRs were further vibration-milled (Wig-L-Bug) for 2.5 min, and the milled solid residues (0.5 g) were subjected to enzymatic saccharification. Enzymatic saccharification was carried out at 1% (w/v) consistency with the enzyme loading of 10.4 filter paper units (FPU)/g of substrate at pH 4.5 (sodium acetate buffer) and 45 °C for 72 h. The enzyme (FiberZyme LBL CONC, Dyadic International, Inc.) was a preparation of carbohydrate hydrolases with cellulase and xylanase activities. After the enzymatic saccharification, the mixtures were centrifuged to collect the supernatant. An aliquot of the supernatant [enzymatic hydrolysates (EHs)] was used for determination of the neutral sugar contents.

The overall performance of individual pretreatment was evaluated by the sugar recovery (%).

$$\text{sugar recovery (\%)} = (\text{sugar from PHs} + \text{sugar from EHs}) \times 100/\text{sugar in the original wood}$$

**Analytical Methods.** All analyses were conducted with three replicates, and all calculations were based on the oven-dried weight basis. The lignin content was determined according to the Klason lignin method,[19] combining both the Klason lignin and acid-soluble lignin to be the total lignin content. The extinction coefficient for acid-soluble lignin was 110 L $g^{-1}$ $cm^{-1}$ at 205 nm.[19]

Neutral sugar contents of samples were determined from the acid-soluble fraction of lignin determinations by the alditol−acetate method[20] and quantified by gas chromatography with a flame ionization detector (GC−FID, Agilent 7890A) and a DB-225 GC column. For the sugar contents released from the pretreatment processes (PHs) or enzymatic saccharification (EHs), aliquots of the corresponding hydrolysates were used for determining the sugar contents by the same alditol−acetate method.

Furfural contents in PHs were also determined by GC−FID (Agilent 7890A) with a Supelcowax 10 GC column. An aliquot of the PHs was diluted in acetone and used for determination of the furfural contents according to a GC method.[21]

Lignin monomeric composition was determined by the nitrobenzene oxidation (NBO) using original wood or pretreated residues according to a previous protocol,[22] and 5-iodovanillin was used as the internal standard.[23] The amounts of each lignin degradation product were quantified by GC−FID (Agilent 7890A) equipped with a DB-5 GC

**Table 2. Chemical Composition of *A. confusa* Cell Walls before and after Different Pretreatments[a]**

| | | composition (%)[b] | | | |

column. H-type lignin was calculated from *p*-hydroxybenzaldehyde; G-type lignin was calculated from the sum of vanillin and vanillic acid; and S-type lignin was from the sum of syringaldehyde and syringic acid. No *p*-hydroxybenzoic acid was found in the nitrobenzene oxidation products.

The cellulose crystallinity indexes (CrIs) of different samples were calculated from the X-ray diffractogram (XRD) of the wood meal with the mesh size ranging from 40 to 60 with or without pretreatments. The XRDs were recorded on a Bruker D2 PHASER diffractometer. All scans were collected at 30 kV and 10 mA in the range of $5° < 2\theta < 40°$ using Cu K$\alpha$ radiation ($\lambda$ = 0.1544 nm). A peak fitting software (PeakFit, Systat Software, Inc.) was used to deconvolute the individual peaks, assuming Gaussian function for each peak and a broad peak at around 20.04° assigned to the amorphous component. Peak fittings were continued until the maximum *F* values were achieved. In all cases, the *F* values were greater than 2700, which corresponding to an $r^2 > 0.98$. The CrI was calculated by dividing the diffractogram area because of the crystalline components (sum of peak areas from 002, 021, 101, 10$\bar{1}$, and 040 peaks) by the total area of the original diffractogram.[24]

Properties of different treatment groups were compared all together by multiple mean comparisons [Tukey's honest significant difference (HSD) test; $\alpha = 0.05$] to test the significant differences among groups (SAS 9.3, SAS Institute, Inc., Cary, NC). Correlation analysis of the specific property pair was also performed with the same software using the multivariate function.

## RESULTS AND DISCUSSION

**Cell Wall Chemical Composition before and after Pretreatments.** Table 2 shows changes in the chemical composition before and after pretreatments. A typical *A. confusa* wood contains about 24.7% lignin and 57.1% polysaccharides. The pretreatment yields of the DA pretreatments were between 70.1 and 79.1%. As the reaction temperatures increased, the yields were reduced. The total lignin contents of the DA-pretreated residues slightly increased as the reaction times became longer. The glucan contents of the DA-pretreated residues did not change, except for the 170C20M sample. However, if the glucan contents of the DA-pretreated residues were calculated back to the glucan contents of the original wood, about 13−28% original glucan was actually lost during the DA pretreatment processes. The xylan contents reduced dramatically as the reaction temperatures increased from 150 to 170 °C. The increased glucan and lignin and reduced xylan contents in pretreated residues were also reported from the dilute-acid-pretreated *Populus trichocarpa*[18,25] and mixed hardwood species.[17,26]

The pretreatment yields of the sulfite pretreatments (62.5−64.1%) were lower than those in the DA pretreatments, as displayed in Table 2. The pretreatment yields from different sulfite pretreatments were similar to each other. The lignin contents of the SP-pretreated residues were increased when compared to that of the original wood, except for the 8B1A sample. The glucan contents of the SP-pretreated residues (46.0−56.9%) were much higher when compared to that of the original wood, and these contents were also higher than those of the DA-pretreated residues. If the glucan contents of the SP-pretreated residues were calculated back to the glucan contents of the original wood, about 1−6% original glucan was lost during the sulfite pretreatment processes except for the 8B2A sample. These glucan losses were lower than those in the DA-pretreated processes. The xylan contents of the SP-pretreated residues (1.7−2.7%) were lower than those of the DA-pretreated residues (4.1−16.8%). These results are consistent with the observation from other researchers, who applied SPORL on various hardwood species.[15,17]

Nitrobenzene oxidation was used to profile the lignin composition of *A. confusa* wood before and after pretreatments, as illustrated in Figure 1. The major monomeric components of

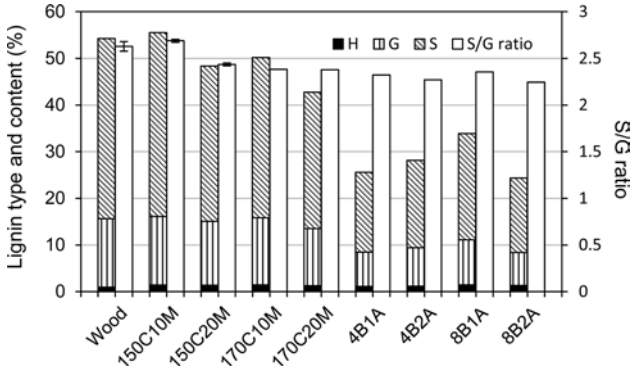

**Figure 1.** Lignin composition of samples before and after different pretreatments. Percentage based on moles of lignin from each sample assuming the molecular weight of one lignin C9 unit to be 210 g/mol. H, *p*-hydroxybenzaldehyde; G, sum of vanillin and vanillic acid; and S, sum of syringaldehyde and syringic acid. Mean ± SE; $n$ = 3. Please refer to Table 1 for the sample name.

*A. confusa* lignin were S- and G-type lignin, and they were about 38.6 and 14.7% based on moles of lignin, respectively. H-type lignin was the minor component and was only about 0.9% (Figure 1). The S/G ratio of *A. confusa* lignin was about 2.6, and the total yield of the nitrobenzene oxidation products was about 54.2%. The total yields of the nitrobenzene oxidation products decreased as the reaction temperatures or times increased during the DA pretreatments, indicating that the noncondensed lignin structures, such as 4-O-alkylated, $\alpha$-O-4, and $\beta$-O-4 lignin structures,[22] were reduced. This suggests that the lignin structures retained in the DA-pretreated residues were more condensed-type than that of the original wood. Recent evidence also revealed that the condensed lignin structures were increased after dilute acid pretreatments in spruce.[16] The DA pretreatments removed more S-type lignin than G-type lignin from the original wood lignin structures as the reaction temperatures or times increased (Figure 1). This caused the S/G ratios of lignin to decrease gradually from 2.7 (150C10M) to 2.4 (170C20M) as the reaction conditions became severe. The H-type lignin was rather stable (~1%) when compared to S- or G-type lignin under these pretreatments. Current results are consistent with the previous reports that $\beta$-O-4 linkages and S/G ratios were reduced during the DA pretreatment on hardwood species and the relative content of H-type lignin was rather unchanged during this process.[18,26]

During the sulfite pretreatments, *A. confusa* lignin was partially sulfonated, and the sulfonated lignin structures were removed by dissolving in the pretreatment liquors. The removals of noncondensed S- and G-type lignin structures in the sulfite pretreatments were more significant when compared to those in the DA pretreatments (Figure 1). The removal of the S-type lignin in the sulfite pretreatments seemed higher than that of the G-type lignin, causing the S/G ratios to reduce to 2.2−2.4 compared to that of the original wood (2.6; Figure 1). The total yields of the nitrobenzene oxidation products from the SP-pretreated samples were reduced in the range from 24% (8B2A) to 34% (8B1A), indicating that the residual lignin in acid bisulfite-pretreated samples was a more condensed type of lignin than that in DA-pretreated samples or modified lignin structures,

which could not be analyzed by the nitrobenzene oxidation. The occurrence of the lignin condensation reaction was reported in acidic sulfite pulping[27] and the SPORL-pretreated spruce,[16] suggesting that a similar condensation reaction might occur in the SP-pretreated *A. confusa* and, hence, increase the condensed lignin structures.

The CrI of original wood without any pretreatment was estimated to be 59.1% (Figure 2). DA pretreatments increased

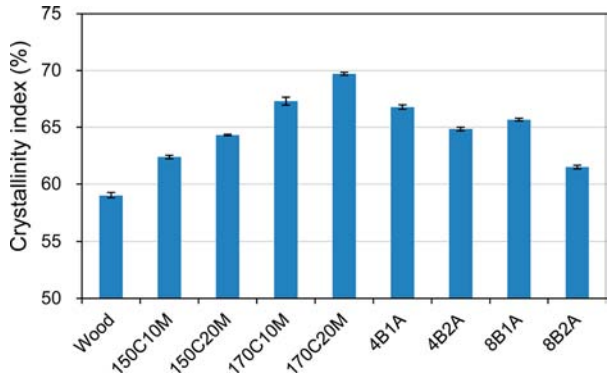

**Figure 2.** CrIs of samples before and after different pretreatments. Mean ± SE; $n$ = 3. Please refer to Table 1 for the sample name.

the CrIs of the pretreated residues when compared to that of the original wood. The increases of these CrIs were positively correlated to the reaction temperatures and times, and the highest CrI was 69.7% (170C20M). The sulfite pretreatments also increased the CrIs of the pretreated residues (61.5−66.8%) compared to that of the original wood. The increasing values of CrIs in pretreated residues were consistent with previous reports that dilute acid or acid bisulfite pretreatments usually elevated the crystallinity of lignocellulosics.[28,29] The increase of the biomass CrI was usually attributed to that of the amorphous hemicelluloses and partial lignin, and amorphous regions of native cellulose were removed and disrupted during the pretreatment process; hence, these would relatively increase the crystalline portion of the pretreated residue. However, current results cannot rule out the possibility that the aggregation of cellulose fibrils might occur because of thermally induced crystallization and aggregate growth under hydrothermal conditions.[28] The increments in CrIs of the SP-pretreated residues were reduced as the charges of bisulfite or acid increased. The reduced increments in CrIs of the SP-pretreated residues were likely attributed to the relatively increased amorphous components resulting from the condensed lignin aggregation.

**Composition of Hydrolysates Released from Pretreatments.** The monosugar components of the pretreatment hydrolysates were further analyzed and expressed as polysaccharide forms, as shown in Figure 3. Both DA and sulfite pretreatments hydrolyzed lots of xylan into the hydrolysates (Figure 3). In the DA pretreatments, 3.4% xylan was recovered from the 150C10M PHs and about 9−10% xylan was recovered from other PHs (Figure 3A). In the sulfite pretreatments, about 12−13% xylan was recovered from the 4% bisulfite-charged PHs and only about 6% xylan was recovered from the 8% bisulfite-charged PHs. The furfural contents in the SP hydrolysates were about 3.9−5.4% (Figure 3B), which were higher than those in the DA hydrolysates (∼2.0%; Figure 3A). Studies have shown that xylan, in comparison to other polysaccharides, can easily be hydrolyzed under acidic conditions and release xylose into the pretreatment hydrolysates,[8] and these xyloses might continue to be broken down into furfural and other degradation products.[30] Hence, by considering the mass balance of xylan, the lower xylan contents of 8% SP hydrolysates compared to those of 4% SP hydrolysates indicated that further degradation might occur during the pretreatment processes.

The DA pretreatments broke down about 1.7−3.3% lignin into the pretreatment hydrolysates (Figure 3A). The same extinction coefficient for acid-soluble lignin was assumed and used to calculate the sulfonated acid-soluble lignin in the SP hydrolysates. The acid-soluble lignin contents in the SP hydrolysates were about 4.6−6.9% (Figure 3B), which were higher than those in the DA hydrolysates. This indicated that more lignins were actually removed from the original wood during the sulfite pretreatments when compared to those during the dilute acid pretreatments. The disrupted and sulfonated

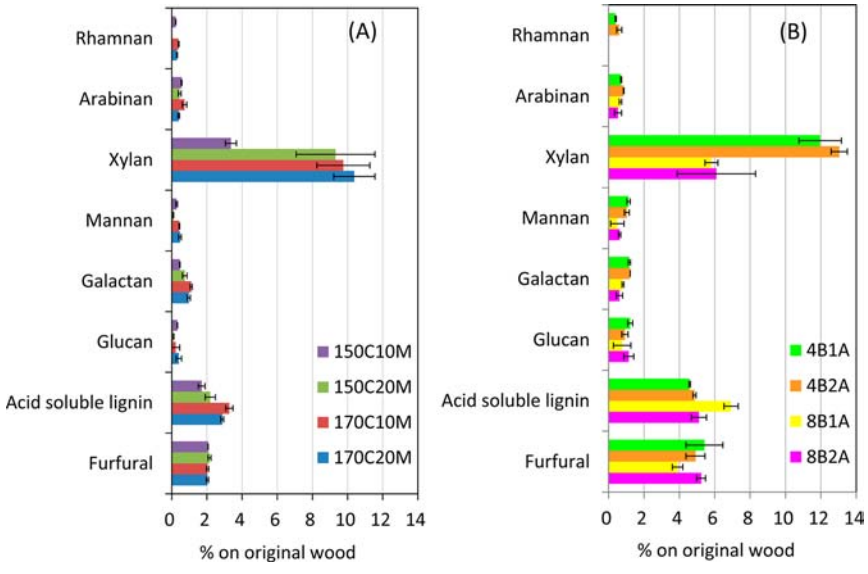

**Figure 3.** Chemical components in different pretreatment hydrolysates: (A) dilute acid pretreatments and (B) sulfite pretreatments. Mean ± SE; $n$ = 3. Please refer to Table 1 for the sample name.

dx.doi.org/10.1021/jf504461c | J. Agric. Food Chem. 2014, 62, 10768−10775

lignin could facilitate cellulose susceptibility to the following enzymatic hydrolysis.[16]

The glucan contents recovered from the pretreatment hydrolysates were not high. It was 0.1−0.4% from the DA hydrolysates (Figure 3A) and 0.8−1.2% from the SP hydrolysates (Figure 3B). Thus, about 12−28% original glucan was degraded to other products during the pretreatments, especially in the DA pretreatments (cf. Table 2 and Figure 3). These degradation products were not measured in the current study. However, previous studies have suggested that fermentation inhibitor compounds, such as 5-hydroxymethylfurfural, 5-methylfurfual, levulinic acid, and formic acid, might come from glucose degradation.[16,30] In spruce, DA pretreatments produced more than twice these inhibitor compounds when compared to those from SPORL pretreatments.[16] These could attribute to the low mass balances of glucan in the DA-pretreated samples (cf. Table 2 and Figure 3).

**Enzymatic Saccharification and Cell Wall Properties.** Without any pretreatment, *A. confusa* wood released about 15% xylose or glucose based on the xylose or glucose contents of the original wood during the enzymatic saccharification (Figure 4).

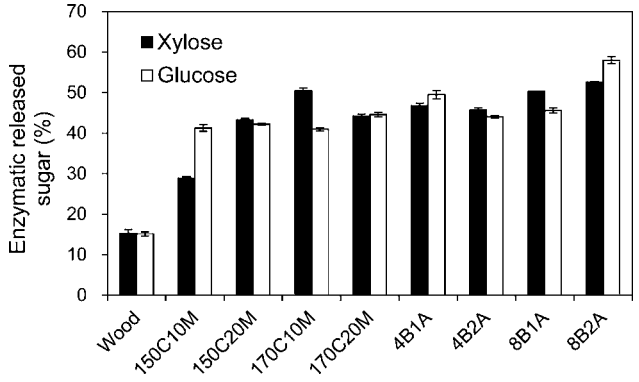

**Figure 4.** Enzymatic released sugar of different samples after 72 h of enzymatic saccharification. Percentage based on xylose or glucose contents in the substrates subjected to enzymatic hydrolysis. Mean ± SE; $n = 3$. Please refer to Table 1 for the sample name.

Both DA and sulfite pretreatments increased the enzymatic saccharification of pretreated residues when compared to that of the original wood without any pretreatment. Because the xylan contents in many of the pretreated residues were rather low (Table 2), the enzymatic saccharification of glucan was more significant than that of xylan in the pretreated residues. A generally higher glucose yield (44.0−58.0%) was obtained from the SP-pretreated residues when compared to that from the DA-pretreated residues (40.9−44.6%; Figure 4). These enzymatic saccharification yields are rather comparable to those obtained in the previous studies, in which various pretreatments, including dilute acid, SPORL, green liquor, autohydrolysis, and ozone pretreatments, were applied on various poplar woods.[17,25]

To further understand the cell wall properties that might have influences on the enzymatic saccharification of glucan, correlation analysis was further performed to profile the relationships (Figure 5). Among the cell wall properties measured in this study, only the xylan content, total yield of nitrobenzene oxidation, and S/G ratio were found to have significant correlations ($p < 0.05$) to the enzymatic saccharification of glucan. Other properties, such as total lignin, glucan content, and CrIs, were tested without significant correlations ($p > 0.13$). Our results indicated that lower xylan contents in the

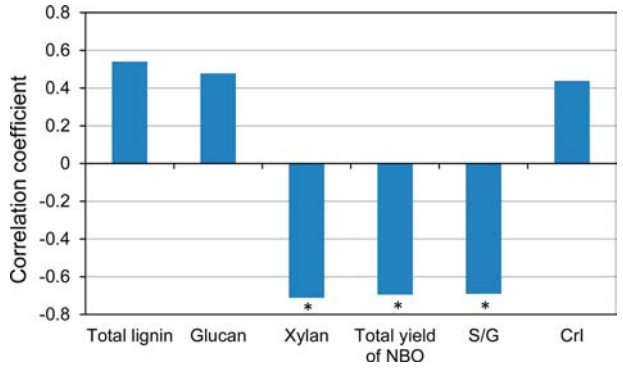

**Figure 5.** Correlation coefficient between enzymatic saccharification of glucan and the cell wall properties. NBO, nitrobenzene oxidation; S/G, S/G ratio; and CrI, crystallinity index. (*) $p < 0.05$.

pretreated residues would increase the enzymatic saccharification of glucan ($r = -0.7122$; Figure 5). Similar results were reported that decreasing the xylan content in the DA-pretreated corn stover[31] and SPORL-pretreated Douglas fir[32] would improve the extent of cellulose digestibility. Xylan is the major hemicellulose of *A. confusa*, and hemicelluloses are spatially associated with cellulose. Removal of hemicelluloses is important to enhance the cellulose digestibility.

The total yield of nitrobenzene oxidation reflects the portion of the noncondensed lignin in the overall lignin structures.[22] The correlation analysis indicated that, if the pretreated residues had less noncondensed lignin (more condensed lignin), the pretreated residues were more enzymatically hydrolyzable ($r = -0.6952$; Figure 5). Similarly, if the lignin S/G ratios of these pretreated residues were lower, the pretreated residues were more enzymatically hydrolyzable ($r = -0.6908$; Figure 5). The influence of lignin composition on cell wall digestibility still remains uncertain, and the results can be very different using various biomass and pretreatment techniques.[33−37] In the current study, the results can be explained by considering the cellulose accessible surface after the pretreatments. Our results indicated that both DA and sulfite pretreatments could break down the lignin barriers to loosen the ultrastructures of the cell walls and the sulfite pretreatments removed more lignin than the DA processes (Figure 3). The removal of lignin was more on the noncondensed lignin (high S/G ratio moieties), and this action left more condensed lignin (low S/G ratio moieties) retained in the SP-pretreated residues (Figure 1). The S/G ratios of the SP-pretreated residues were lower than those of the DA-pretreated residues (Figure 1), indicating that more severe lignin removal and loosened cell walls might exist in the SP-pretreated residues compared to those in the DA-pretreated residues. A previous study in comparing the cell wall structure changes after DA and SPORL pretreatments has demonstrated that the cellulose accessible surfaces from the SPORL-pretreated pine cell wall were about 3 times more than those from the DA-pretreated samples.[38] The cellulose accessible surface was actually created because of the lignin removal and loosened structures during the pretreatments. More cellulose accessible surfaces in the SP-pretreated residues might be created in comparison to those in the DA-pretreated residues, and hence, the enzymatic saccharification of the SP-pretreated residues (low S/G ratio and more condensed lignin) was increased in comparison to those in the DA-pretreated residues. The sulfonated lignin structures of the SP-pretreated residues might also play a significant role in the enzymatic efficiency and enhance the glucose yields.[12]

**Total Sugar Recovery.** To further evaluate the overall performance of different pretreatments, sugar recovery, combining the sugar contents from both PHs and EHs, was calculated. Without any pretreatment, *A. confusa* wood yielded only about 15% sugar recovery based on xylose, glucose, or total sugar of the original wood (Figure 6). All pretreatments could enhance the sugar recovery (>30%) based on xylose, glucose, or total sugar of the original wood. The recoveries of xylose exceeded 65% for many of the pretreatments in either the DA or sulfite pretreatment. These high xylose recoveries (Figure 6) mainly resulted from the xylose contents in the PHs (cf. Table 2 and Figure 3).

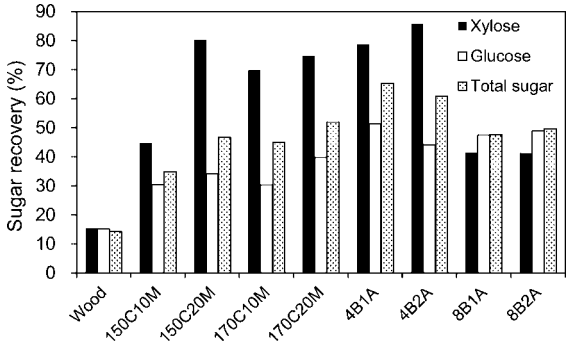

**Figure 6.** Sugar recovery (%) based on xylose, glucose, and total sugar of the original wood after individual pretreatment and enzymatic saccharification. Please refer to Table 1 for the sample name.

All glucose recoveries from different pretreatments were more than 30%, and the highest glucose recovery was from the 4% $NaHSO_3$ and 1% $H_2SO_4$ pretreatment (51.2%; Figure 6). Current glucose recoveries seem lower than the high glucose recovery suggested by the previous report, which showed a near-complete cellulose conversion to glucose in aspen using SPORL pretreatment.[15] About 60−80% original lignin was still remained in the pretreated residues (Table 2), and this residual condensed-type lignin and also the ultrastructures of the pretreated cell walls were still barriers limiting the full accessibility of enzymes during enzymatic saccharification. This indicates that further efforts either chemically or mechanically to increase the accessibility of the hydrolytic enzymes will help to enhance the glucose recoveries of current results. Studies even suggested that post-treatments after the pretreatment process, such as oxygen delignification[39] and mechanical refining,[12,40] would open up the surface areas and pore volumes, which would ultimately improve the enzymatic hydrolysis and finally increase the sugar recovery.

In the DA pretreatments, total sugar recoveries increased when the reaction temperatures and times increased. In the sulfite pretreatments, 4% bisulfite-pretreated samples yielded better total sugar recoveries than 8% bisulfite-pretreated samples. Overall, these total sugar recoveries were comparable to the results of the DA and SPORL pretreatments on various poplar species.[17] In the current study, the best total sugar recoveries from the DA and sulfite pretreatments are 52.0% (170C20M) and 65.3% (4B1A).

**Comparison of Samples with and without Extractives.** A high extractive content (9.3%) was obtained from the *A. confusa* heartwood. The best two pretreatments in the current study, 170C20M and 4B1A, were further chosen to evaluate the influences of extractives on the pretreatment and enzymatic saccharification. Figure 7 shows the sugar recoveries of wood, with and without extractives, after each pretreatment and enzymatic saccharification. Without any pretreatment, the original wood samples performed similarly either with or without extractives, and the total sugar recoveries were 13.0% for wood with extractives and 14.2% for wood without extractives, respectively (Figure 7). For the 170C20M-pretreated sample, the existence of extractives reduced the sugar recovery majorly from the PHs, especially in the recovery of xylose (Figure 7). For the 4B1A-pretreated sample, the existence of extractives reduced the sugar recoveries from both the pretreatment hydrolysates and enzymatic hydrolysates (Figure 7). The combined reductions of total sugar recoveries were 11.7% in the 170C20M-pretreated sample and 17.7% in the 4B1A-pretreated sample, indicating that the existence of extractives would reduce the sugar recoveries from both the DA and sulfite pretreatments.

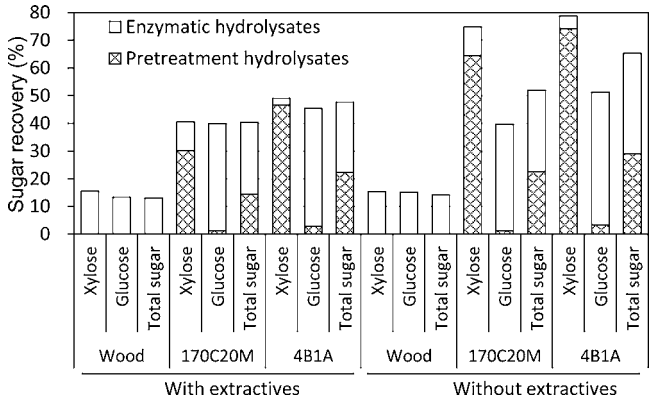

**Figure 7.** Sugar recovery (%) based on xylose, glucose, and total sugars of the original wood with and without extractives after specific pretreatments and enzymatic saccharification. Please refer to Table 1 for the sample name.

The major constituents in the extractives of *A. confusa* heartwood are phenolic compounds, flavonoids, and condensed tannins.[4,41] These compounds are chemically reactive species able to react with other molecules or through condensation reactions under acid treatments or acidic sulfite conditions.[27,42] These side reactions rerouted the pretreatment reactions, which were originally arranged to decrease the recalcitrance of cell walls to facilitate followed enzymatic saccharification. The non-productive adsorption of enzymes onto the condensation adducts from extractives can also be disadvantageous to enzymatic saccharification and, hence, reduce overall sugar recovery efficiency. Therefore, it is worth performing an extraction process in advance to remove the valuable extractives from *A. confusa* heartwood for biomedical purposes, and the resulting extractive-free wood residues will then go for deconstructing the cell walls for bioethanol utilization to maximize the benefits.

In summary, extractive-free *A. confusa* heartwood was subjected to different dilute acid and sulfite pretreatments. Reduced 4-O-alkylated lignin structures, lower S/G ratios, decreased xylan contents, and increased cellulose CrIs were found in all pretreated residues. All pretreated samples showed better sugar recoveries than the untreated wood. Cell wall properties, such as 4-O-alkylated lignin structures, S/G ratios, and xylan contents, of the pretreated residues showed significant correlations with the enzymatic saccharification of glucan. Increased cellulose accessible surfaces in the SP-pretreated samples compared to those in the DA-pretreated samples might enhance the enzymatic saccharification of the SP-pretreated samples. As a result, 4% bisulfite-pretreated samples yielded

higher sugar recovery than the DA-pretreated samples. The best sugar recovery was from the 4% $NaHSO_3$ and 1% $H_2SO_4$ pretreated sample. Current results also revealed that the existence of extractives in *A. confusa* reduced the sugars released from both the pretreatments and enzymatic saccharification.

[a]Calculated as reported by Kyriakidis and Katsiloulis.[26]

solution in methanol and vortexed for 3 min. Then, 200 mL of distilled water and 200 mL of diethyl ether were added. After mixing, the aqueous phase was removed while the etheric phase was repeatedly washed with distilled water (80 mL each time), until neutrality of the discarded water. Then, after filtration on sodium sulfate anhydrous, the ether was removed in a rotary evaporator. The adopted saponification method led to the formation of 98% of MAG, as confirmed by the HPSEC analysis. Obtained MAG were added to each PO (olive, peanut, sunflower, soybean, and palm) to obtain the following MAG/PO proportions: 0.5% (MAG0.5); 1% (MAG1); 2% (MAG2); 3% (MAG3). For each type of oil, as control (C) was used the PO with no added MAG.

**Oven Test.** Five grams of each PO was weighed in 50 mL glass vials and kept for 18 days at 60 °C, which represents the temperature commonly employed in a forced air oven. Fifty vials were prepared for each PO. At 4, 6, 10, 14, and 18 days 10 vials for each PO (two for control and for each MAG/PO proportion) were taken and submitted to analyses.

**Chemical Analyses.** The determinations of the free fatty acids (FFA), peroxide value (PV), and spectrophotometric constants were carried out according to the *Official Journal of the European Communities*.[24]

Fatty acids composition was carried out by gas chromatographic analysis of fatty acid methyl esters, according to the official methods.[24,25] In particular, the oil was treated with 2 N potassium hydroxide solution in methanol and vortexed for 5 min, and then 1 mL of hexane was added. Then, 1 μL of the hexane fraction was injected. The gas chromatographic system was composed of an Agilent model 7890A gas chromatograph (Cernusco, MI, Italy), equipped with a flame ionization detector (FID) and a WCOT fused-silica capillary column, FFAP-CB coating, 0.32 mm i.d. × 25 m length and 0.30 μm film thickness (Chrompack, Middleburg, The Netherlands). The temperature of the split injector was 210 °C, with a splitting ratio of 1:17; the detector temperature was 220 °C. The oven temperature was isothermally at 180 °C. Helium at flow rate of 1 mL $min^{-1}$ was utilized as carrier gas. The identification of each fatty acid was carried out by comparing the retention time with that of the corresponding standard methyl ester purchased from Sigma-Aldrich (St. Louis, MO, USA). RSD was about 5%.

The iodine value (IV) was determined as proposed by Kyriakidis and Katsiloulis,[26] which uses the percentage of fatty acid methyl esters determined from analysis of the fatty acid composition and an equation with coefficients specific for every type of vegetable oil.

The equation proposed is

$$IV = xC_1 + yC_2 + zC_3$$

where $C_1$, $C_2$, and $C_3$ correspond to the sum of the relative percentage concentrations of the unsaturated fatty acids with one, two, and three double bonds respectively, whereas $x$, $y$, and $z$ are the relative coefficients.

TAGP and ox-TAG were determined by means of high-performance size exclusion chromatography (HPSEC) of polar compounds (PCs), previously separated from the oil samples by silica gel column chromatography according to AOAC method 982.27.[27] After elution of the nonpolar components with 150 mL of petroleum ether/diethyl ether (87:13, v/v), the PCs were recovered with 150 mL of diethyl ether. After removal of the diethyl ether, the PCs were recovered in THF and the efficacy of separation was checked by thin layer chromatography as recommended by the same method. The chromatographic system consisted of a PerkinElmer pump, series 200, a 50 μL injector loop, a PL-gel guard column (PerkinElmer, Beaconsfield, UK) of 5 cm length × 7.5 mm i.d., and a series of two PL-gel columns (PerkinElmer) of 7.5 mm i.d. × 30 cm in length each. The columns were packed with highly cross-linked styrene divinylbenzene copolymers with a particle diameter of 5 μm and pore diameters of 500 Å. The detector was a differential refractometer (series 200A, PerkinElmer). The elution solvent used was THF for HPLC at a flow rate of 1.0 mL $min^{-1}$. The identification and quantification of individual peaks was carried out as described in previous papers.[28,29] The precision of the HPSEC method, expressed as RSD% ($n$ = 10), was 1.9% for PCs, 3.2% for TAGP, and 2.3% for ox-TAG.

Three replicates were analyzed per sample for each determination.

**Statistical Analysis.** Analysis of variance (two-way ANOVA) was carried out on the experimental data by using XLStat software (Addinsoft SARL, New York, NY, USA). Two-way ANOVA was performed considering the amount of MAG added to PO (MAG) and the different vegetable oils considered (oil), as well as their first -order interaction, as independent variables; Tukey's HSD test was applied for multiple comparisons.

The surface response regression analysis was carried out by Minitab 16 software (Minitab Inc., State College, PA, USA).

## RESULTS AND DISCUSSION

**Characterization of Raw Materials.** Table 1 reports the fatty acid composition of PO of olive, peanut, sunflower, soybean, and palm oils and of the MAG obtained from the purified soybean oil. The observed values agreed with those of the botanic species they derived from; higher saturated fatty acid levels were detected in palm oil, whereas higher monounsaturated levels were observed in olive, followed by peanut, palm, soybean, and sunflower oils. Linoleic acid was markedly more represented in sunflower, soybean, and peanut oils than in olive and palm oils; soybean oil, finally, showed the highest contents of linolenic acid. The differences in the

[a]PV, peroxide value (mequiv $O_2$ $kg^{-1}$); TAGP, triacylglycerol oligopolymers (g 100 $g^{-1}$); ox-TAG, oxidized triacylglycerols (g 100 $g^{-1}$). [b]Upper case letters are used to compare the samples considering the amount of monoacylglycerols added to purified oil; lower case letters are used to compare the samples considering the combined effect of MAG (%), oilm and MAG × oil interaction: different letters mean significant differences at $p \leq 0.05$.

unsaturation degree were paralleled by the IV, which was higher in sunflower and soybean oils than in the others.

Table 1 shows also that the fatty acid composition of MAG was similar to that of the corresponding soybean purified oil used for their preparation.

POs were constituted by unaltered triacylglycerols (>99.9%) and showed FFA and PV values equal to zero and low values for the spectrophotometric constants (Table 2), similar to those detected in a previous study.[14]

**Oven Test: Oxidation after 10 Days at 60 °C.** Table 3 reports the results of the analyses carried out on each PO and on the same PO with added 0.5, 1, 2, and 3% MAG (MAG0.5, MAG1, MAG2, and MAG3, respectively) after 10 days at 60 °C, as well as the results of statistical analysis (two-way ANOVA followed by Tukey's HSD test for multiple comparisons). The data of oxidation after 10 days were reported as representative of the overall trend during time, to exclude, in the first instance, "time" as a third source of variability, besides MAG amount and type of oil.

The addition of increasing amounts of MAG significantly influenced the oxidative process. In particular, less marked oxidative phenomena were observed when MAG were added to PO derived from olive, palm, peanut, and sunflower, confirming previous results obtained by adding MAG prepared from olive oil to the same olive oil.[21] A different and particular trend, instead, was observed when MAG were added to soybean PO. In this case, all of the analytical indices considered, apart from PV, significantly increased when MAG amounts up to 1% were added, confirming other research,[19,20,22] and decreased at higher MAG doses.

**Oven Test: Surface Response Regression.** In a recent review, Chen and collaborators[30] pointed out the presence of discordant data about MAG behavior toward oxidation. Moreover, the effect of compositional characteristics of MAG (chain length, unsaturation level) have been investigated, but the role of fatty acid composition of the oil to which MAG are added has been scarcely studied, as well as the relationships between the two compositions. We adopted surface response regression analysis to point out the effect of MAG on oxidation in oils having different fatty acid compositions.

Table 4 reports the coefficients of the regressions and the corresponding $p$ values. The use of coded units enables

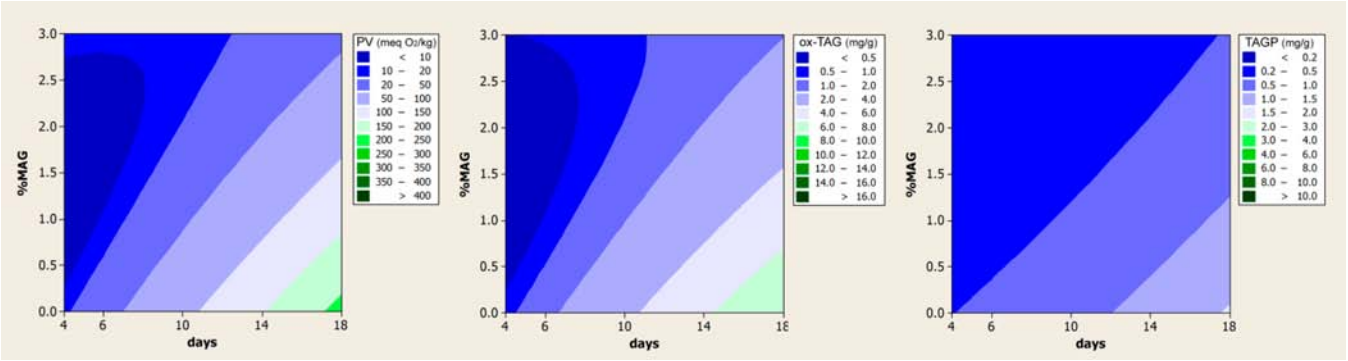

**Figure 4.** Response surface regressions for PV, ox-TAG, and TAGP in palm oil as a function of time (oven test at 60 °C) and amount of added MAG.

evident considering ox-TAG and TAGP, which showed, during the oven test, lower values in MAG3 than in control (PO).

Sunflower PO showed faster oxidation rates than the other oils tested, as evidenced by coefficients of the "time" variable. This result was probably due to higher content of linoleic acid than the other oils. The addition of MAG to sunflower PO induced exclusively antioxidant effect (Figure 2). PV and ox-TAG showed a linear negative correlation with MAG content. TAGP were significantly influenced by the interaction "MAG × time": the antioxidant activity of MAG on TAGP was more evident at longer times.

The addition of MAG to peanut oil had antioxidant effects (Figure 3), as observed in sunflower oil. The influence of MAG on PV increased progressively during time ($p$ value <0.001 for the interaction "MAG × time") and decreased with the increase of MAG amount. The effect observed on ox-TAG, although antioxidant as well, was linear. With regard to TAGP, the MAG amount effect was more evident in the advanced oxidation phases (only the interaction "MAG × time" was significant), confirming the intrinsic nature of these substances that are known to be related to the final steps of oxidative.

Palm oil, characterized by high contents of saturated fatty acids, enabled the observation of a marked antioxidant activity of MAG (Figure 4). The regression coefficients evidenced that the "MAG" variable had a greater contribution than "time". The antioxidant effect did not show a perfectly linear trend and was progressively more evident during time, as evidenced by the significant coefficient of the interaction "MAG × time".

In the case of olive oil (Figure 5) the addition of "MAG" had an impact comparable to that of the "time" variable on the

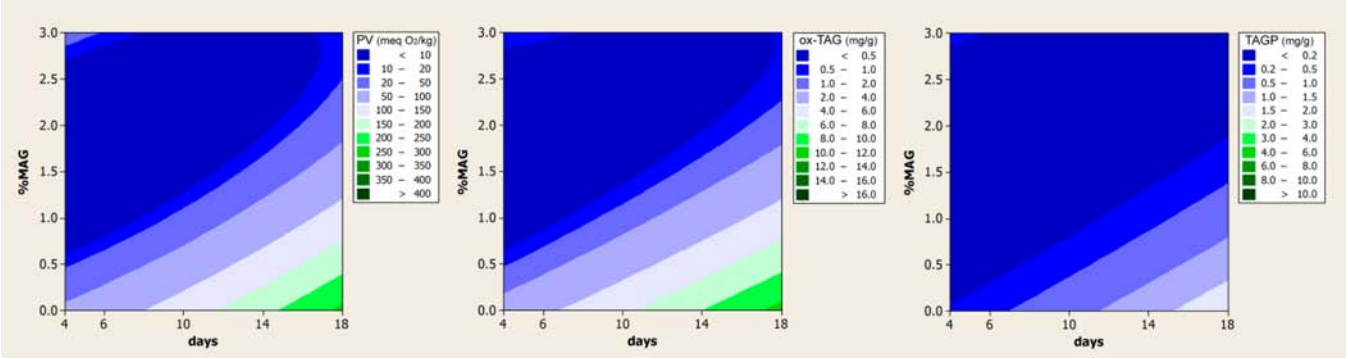

**Figure 5.** Response surface regressions for PV, ox-TAG, and TAGP in olive oil as a function of time (oven test at 60 °C) and amount of added MAG.

variations of the oxidative indices. The intensification of antioxidant activity during time compensated a not perfect linearity observed at the beginning of the forced oxidation in oven.

**Relationships between MAG Activity and Fatty Acid Composition of Oil.** As above-discussed, evident differences were observed in the effects induced by the addition of increasing MAG doses to different types of PO. The antioxidant effect of MAG was significantly higher in oil at low unsaturation level, such as palm and olive oils, with the most positive effects for the latter. Among the most unsaturated oils, peanut and sunflower encountered a linear slowdown of oxidation, slightly less pronounced in sunflower oil, which was the most susceptible to oxidation due to its high content of linoleic acid. A peculiar trend was highlighted for soybean oil, where the antioxidant effect of high amounts of MAG was opposed to a pro-oxidant effect observed up to 1%, coupled to a more limited overall oxidation than in other oils. Mistry and Min[20] observed a pro-oxidant activity of MAG in soybean oil up to 1% and attributed this result to the ability of MAG to situate at the interface oil/air (due to their high polarity) so as to facilitate oxygen solubilization into oil. It is possible that, at higher doses, interface MAG constituted a preferential substrate of oxidation. These phenomena could be more pronounced when differences in fatty acid composition between MAG and triacylglycerols further limit the interactions between oil mass and interface MAG. Hence, the observed results should be interpreted in relation to the fatty acid composition of the MAG used, and it has to be taken into account that we adopted soybean oil as starting oil to prepare MAG; then we obtained highly unsaturated MAG with high content of linolenic (about 5%) and linoleic acid. It remains unclear why olive oil, less unsaturated than palm oil, amplifies the antioxidant behavior of MAG.

protein isolate was compared for its water-binding, emulsification, and gelation properties with egg white and soy protein isolates[11] and was found to have similar or better properties compared to egg white protein,[33] for example, in higher foam stability.[11] With regard to gelation, RuBisCO from alfalfa, tobacco, and spinach were reported to yield strong gels.[6] Libouga et al.[34] determined the critical gelation concentration of RuBisCO (from alfalfa) by heating sealed tubes. Unfortunately, this method yields no information on gelation kinetics. Lamsal et al.[31] performed stress relaxation tests on heat-set soluble leaf protein gels (alfalfa) that were found softer and faster to relax compared to whey protein.

Up to now, the gelation properties of RuBisCO were studied only for limited conditions (concentrations, pH) and experimental setup. No information is available on large deformation, texture properties, or microstructure of heat-induced gels of RuBisCO. For application purposes in food products, information on these properties and comparison with existing (e.g., whey protein, egg white protein) and other plant proteins (e.g., soy, pea, lupine) is essential. Hence, the objective of this study is to obtain insight into the gelation behavior of RuBisCO and the subsequent gel properties with regard to fracture behavior and microstructure. In addition, the heat-induced gelation of RuBisCO is compared to whey protein and egg white protein, which have been studied extensively for their gelation behavior, and to plant proteins such as soy, pea, and lupine. This study aims to show the potential of RuBisCO as a functional ingredient, giving opportunities for the design of new textures at low protein concentration.

## MATERIAL AND METHODS

**Materials.** WPI (BiPRO) was obtained from Davisco (Eden Prairie, MN, USA). Egg white protein was kindly supplied by Bouwhuis Enthoven (Raalte, The Netherlands). Water was purified using a Milli-Q system (Millipore Systems, Molsheim, France). Polyvinylpolypyrrolidone (PVPP), sodium metabisulfite, and Tris-base were obtained from Sigma-Aldrich (St. Louis, MO, USA). Q-Sepharose, Sephadex G75, and Superdex 200 were obtained from GE Healthcare (The Netherlands).

**Extraction RuBisCO.** Fresh spinach was pressed using an Angel juicer (Slowjuice, Naarden, The Netherlands); the juice was collected into a container and mixed with wet PVPP and 0.1% sodium metabisulfite. During collection the juice was stirred and cooled in ice water and stored at 4 °C until further use. To remove the chlorophyll, the collected juice was heated at 50 °C for 30 min while stirring and flushing the headspace with nitrogen. After heating, the juice was cooled to 4−6 °C while stirring in a cold room and centrifuged (15000*g*, 35 min, 6−8 °C). The clear juice was set to pH 8 with solid Tris-base (4 g/L) and 4 M NaOH. The juice was filtered over a 0.45 μm filter before being loaded on a Q-Sepharose fast flow (FF). The clear juice containing the RuBisCO was diluted with Milli-Q water and eluens until conductivity was below 6.5 mS/cm. The resulting solution was loaded on a Q-sepharose FF column (1.4 L, diameter = 10 cm, height = 23 cm) previously equilibrated with 20 mM Tris/HCl, pH 8.0. Immediately after the Q-Sepharose, soluble fractions containing RuBisCO were desalted into 20 mM Tris/HCl, pH 8, using a Sephadex G75 column. The desalted fractions were colorless, treated with a 0.22 μm sterile filter, and stored as a protein concentrate (12.4 mg/mL, 20 mM Tris/HCl, pH 8) at 4 °C until further use. For gelation experiments, this solution was diafiltrated against demineralized water and concentrated to the desired concentration using an Amicon 8200 stirred cell (Merck Millipore, Darmstadt Germany) with a 3K membrane filter. pH was set at pH 7. Yield of RuBisCO from spinach was 10 g/10 kg of spinach.

**Extraction of Plant Proteins.** Pea was extracted from a commercial brand of dry peas (HAK, Almkerk, The Netherlands). The protein content of this source is 22% of proteins. The dried peas were ground to get a flour. Then, the flour was sieved, and only the fraction with size smaller than 180 μm was used for extraction. Lupine was extracted from a lupine flour (*Lupinus angustifolius*, unknown cultivar) product called FRALU CON, from L. I. Frank (Twello, The Netherlands). Soy was extracted from defatted soybean flour (Cargill, Amsterdam, The Netherlands) having a protein content of ∼50 wt %.

For all plant proteins the following steps were performed. Flour was dissolved in Milli-Q water, ratio 1:10. The pH was adjusted to 8, and the mixture was incubated for 1 h at room temperature while stirring. Centrifugation of the suspension was done at 6000*g* for 30 min at 7 °C, and the supernatant was taken for isoelectric precipitation at pH 4.5 (lupine and soy) or pH 4.8 (pea). Incubation was performed for at least 2 h (overnight in the case of soy) at 4 °C. After centrifugation (6000*g* for 30 min at 7 °C), the pellet was washed with cold Milli-Q water and dispersed using an Ultra Rurrax at low speed. For soy, three wash steps (1:3 volume ratio with Milli-Q water) were carried out, whereas for pea and lupine only one wash step (1:10 volume ratio) was done. Centrifugation and collection of the pellet were repeated followed by dispersion of the pellet in 3 volumes of Milli-Q water and adjustment of the pH to 7. Protein solutions were stirred overnight for complete dissolution. A final centrifugation step (10000*g*, 30 min at 10 °C) was performed to get rid of the insoluble material. Sodium azide (0.02%) was added as preservative, and the samples were kept at 4 °C until further use. All protein solutions were set at pH 7.

**Differential Scanning Calorimetry (DSC).** Thermal analysis was performed with a TA Instruments type Q200 modulated differential scanning calorimeter. About 30 mg samples (containing 10% protein) were weighed in MD cups, which were hermetically sealed. The temperature scan in linear mode was performed from 20 to 140 °C with increasing temperature with a rate of 2 °C/min. During this scan the heat flow was measured. Measurements were performed in duplicate, and results are presented as mean values.

**Gelation.** Gelation kinetics were studied as a function of time using a stress-controlled AR2000 rheometer (TA Instruments, Etten-Leur, The Netherlands). A concentric cylinder system with a bob diameter of 14 mm was used. A temperature range was applied in which the temperature increased from 25 to 95 °C with a heating rate of 5 °C $min^{-1}$. It was kept at this temperature for 1 h (strain $10^{-3}$, 6.27 rad $s^{-1}$, frequency 1 Hz) before cooling back to 25 °C. The applied strain was within linear region. $G'$, $G''$, and tan $\delta$ were measured during both steps as a function of time. At the end of the measurement a strain sweep was performed from 0.001 to 1 (25 °C). Samples were covered with a thin layer of paraffin oil to prevent evaporation. Measurements were performed in duplicate, and results are presented as mean values ± standard deviation (SD).

**Texture Analysis.** Samples for large deformation were prepared by heating 10−15% protein solutions (in a skin similar to that of a sausage) in a water bath (95 °C) for 45 min. Heated protein gels were prepared 1 day prior to texture analysis and stored overnight in the refrigerator. Gels were cut into cylindrical pieces (2 cm × 2 cm) using a steel wire. Samples were compressed in a single compression test to 90% of their initial height at a compression speed of 1 mm/s using a Texture Analyzer (TA Instruments) with a flat plate probe (diameter = 75 mm). The compressive stress and strain were determined and recalculated to true Hencky's stress and strain. Young's modulus was calculated from the linear part of the stress over strain curve. Each measurement was performed in triplicate, and results are presented as mean values ± standard deviation (SD).

**Microscopy.** Microstructure was visualized using confocal laser scanning microscopy (CLSM). Protein gels were cut using a wet knife, and protein was colored with a Rhodamine B solution (0.2%). Measurements were performed on a TCS SP2 AOBS Leica Confocal (Leica-microsystems, Mannheim, Germany) mounted on a DM IRE2. Two objectives were used, a 20× objective (HC PL apo CS 20×/0.70 D) and a 63× objective (HCX Pl apo 63×/1.40). An excitation wavelength of 561 nm and an emission wavelength of 571−660 nm were employed. Four pictures were averaged, and a scanning speed of 400 Hz was used.

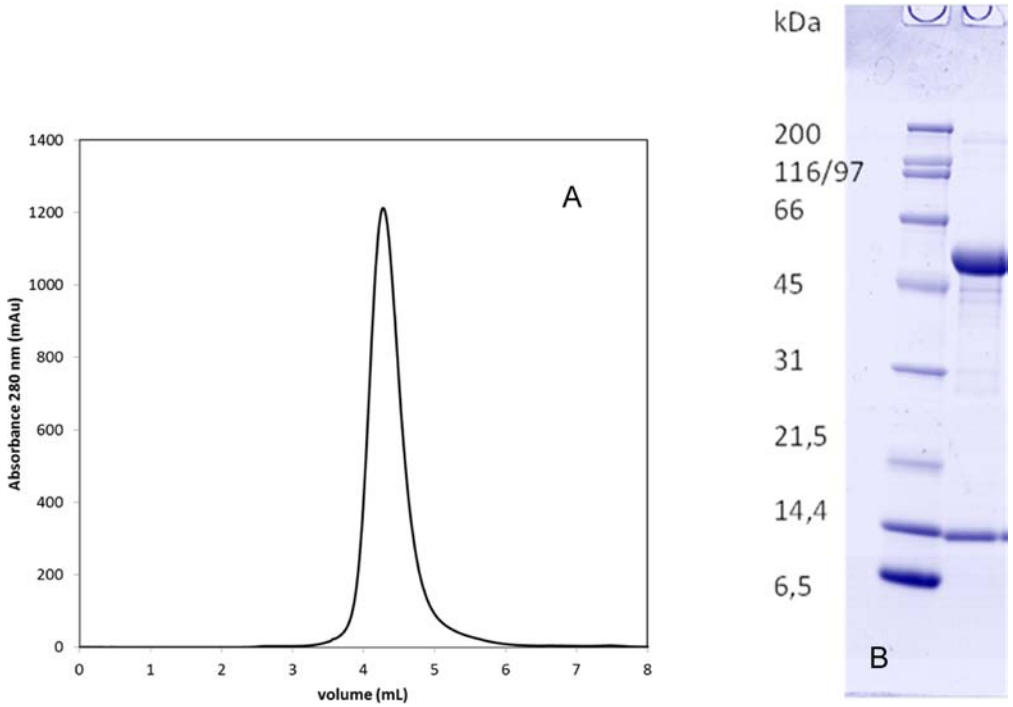

**Figure 1.** Characterization of RuBisCO using (A) size exclusion chromatography and (B) SDS-PAGE, with the left lane being molecular weight markers and the right lane being RuBisCO.

**Protein Interactions.** Solutions of 10% RuBisCO, 10% WPI with 0.2 M NaCl, and 10% egg white protein were heated for 30 min 90 °C in a microwell plate. After heating, the gels were removed from the microwell plate and rolled (roller mixer) in a 15 mL greiner tuber for 24 h with the following solutions: (1) Milli-Q water, (2) Milli-Q + 2% $\beta$-mercaptoethanol, (3) 2 M NaCl, (4) 2 M NaCl + 2% $\beta$-mercaptoethanol, (5) 8 M urea, (6) 8 M urea +2% $\beta$-mercaptoethanol, (7) 2% SDS, or (8) 2% SDS + 2% $\beta$-mercaptoethanol, as previously described by Liu et al.[35] Gels were visually inspected whether they were solubilized or remained intact.

## RESULTS AND DISCUSSION

**Characterization RuBisCO Isolate.** Following the isolation procedure, the purity of the obtained protein isolate was measured with size exclusion chromatography on a Superdex 200 column and gel electrophoresis (see Figure 1). Size exclusion results showed one peak with a narrow distribution indicating a 95% purity of RuBisCO. In addition, the electrophoresis shows two bands at 12.5 and 55 kDa indicating the presence of the small and large subunits of RuBisCO, respectively. Both analyses show that a pure RuBisCO isolate was obtained using the current extraction procedure. UV−vis analysis of the final RuBisCO solution showed no clear sign of any polyphenol absorbance at 340 nm (data not shown). In fact, the ratio between the absorbance at 280 nm and that at 340 nm was >40, indicative of the almost complete absence of polyphenols.

To verify the nativity of the isolated RuBisCO as well as the other plant proteins that were isolated, DSC was performed. Figure 2 shows the thermograms for RuBisCO, isolated plant proteins from soy (SPI), pea (PPI), and lupine (LPI), and, in addition, egg white protein (EWP) and whey protein isolate (WPI). For all proteins clear enthalpic peaks were found indicating the presence of native protein. For RuBisCO the denaturation temperature ($T_d$) was found to be 64.9 °C, which is slightly lower than values found by Libouga et al.[34] and

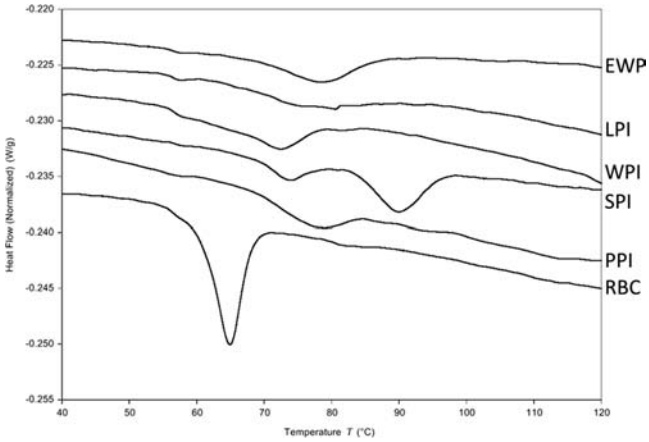

**Figure 2.** DSC thermograms for isolated proteins from (top to bottom) EWP, LPI, WPI, SPI, PPI, and RuBisCO (measured at 10% protein concentration).

Beghin et al.[36] Libouga et al.[34] and Beghin et al.[35] report $T_d$ values of 66.5 and 67.5 °C, respectively, for RuBisCO isolated from alfalfa. The difference is caused by the known higher thermostability of RuBisCO from alfalfa. Compared to WPI, EWP, and especially plant proteins such as SPI, RuBisCO has a relatively low $T_d$. For WPI and EWP, $T_d$ was found to be 72 and 78 °C, similar to the literature.[37,38] For SPI two major peaks were found at ∼73 and ∼90 °C assigned to the main fractions $\beta$-conglycinin and glycinin, respectively, similar to values found by Renkema et al.[39] For pea protein the individual proteins of legumins and vicilins overlap and one endothermic peak was observed with a $T_d$ of 82 °C, which is slightly lower compared to values reported by Shand et al.[40] but similar to those reported by Munialo et al.[41] and Mession et al.[42] For lupine protein also different protein fractions are expected, that is, vicilin ($\beta$-conglutin) and legumin ($\alpha$-conglutin), but the

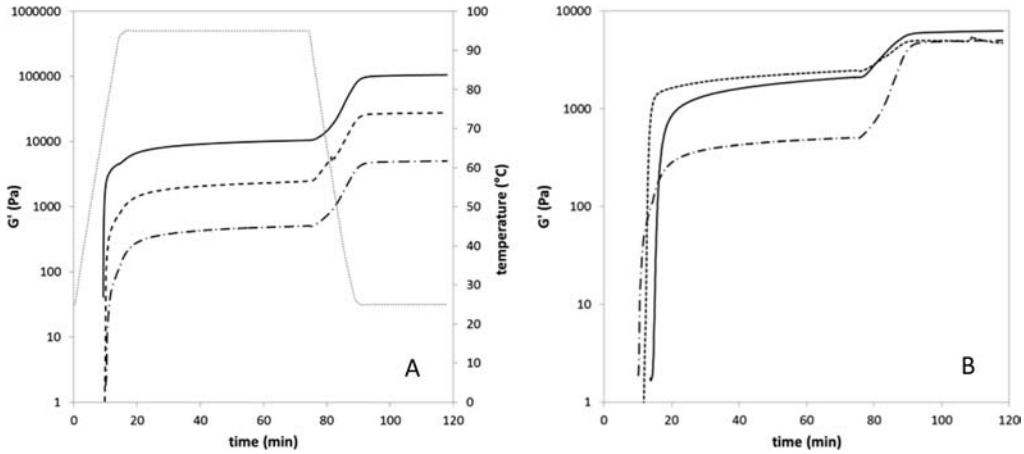

**Figure 3.** Storage modulus $G'$ (Pa) as a function of time during a heating−cooling profile (··· temperature) for (A) (—)10% RuBisCO, (− −) 5% RuBisCO, and (−·−) 2.5% RuBisCO, and (B) (−·−) 2.5% RuBisCO, (—) 10% EWP, and (- - -) 12.5% WPI.

thermogram could not distinguish between these fractions with separate peaks and shows one broad endothermic peak between 66 and 85 °C. Sirtori et al.,[43] however, found two peaks, at 71.5 and 91 °C for the vicilin and legumin, respectively.

**Gelation Properties.** The gelation of RuBisCO was followed by measuring the storage modulus ($G'$) as a function of time during a given heating profile. For 2.5, 5, and 10% protein concentrations, the increase in $G'$ with time is given in Figure 3A. Having a low denaturation temperature, RuBisCO readily gels as shown by the steep increase in $G'$ at short time scale, after which a plateau value is quickly reached. When cooled to room temperature, a further increase in $G'$ is observed, which generally can be appointed to hydrophobic and electrostatic interactions and hydrogen bonds. Already at very low protein concentration (2.5%) RuBisCO was found to form gels with a $G'$ of 5 kPa. With increasing protein concentration $G'$ increases to 104 kPa for 10% RuBisCO, which is extremely high compared to whey protein and egg white protein. Moreover, Figure 3B shows that $G'$ values were obtained in the same order of magnitude for 2.5% RuBisCO, 10% EWP, and 12.5% WPI. The onset in gelation is directly related to the denaturation temperature of the protein as the point at which $G'$ starts to increase (onset gelation time) from RuBisCO to WPI to EWP agrees with $T_d$ of 65, 72, and 78 °C, respectively. The increase in $G'$ during heating, however, is much larger for WPI and EWP than for RuBisCO, whereas during cooling the opposite occurred, in the end leading to similar values for $G'$. Typically, during heating covalent bonds are formed, strengthening the network, whereas during cooling hydrogen bonds and hydrophobic interactions play a role. It can be postulated that for RuBisCO the latter type of interactions are more dominant in determining the final gel strength.

The gelation behavior of RuBisCO was fitted using first-order kinetics

$$G'(t) = G'_{\infty}(1 - e^{-k(t-t_g)}) \quad (1)$$

in which $G'_{\infty}$ is the estimated $G'$ value at infinite time after the heating cycle (at 95 °C), $k$ is a constant, and $t_g$ is the onset gelation time. Table 1 summarizes the findings for $G'_{\infty}$ and $t_g$ for the three different protein concentrations. With increasing protein concentration, $G'_{\infty}$ and $t_g$ increase and decrease, respectively. Similarly, the gelation behaviors of WPI, EWP, SPI, PPI, and LPI were fitted, and the results for $t_g$ and $G'_{\infty}$ are given in Table 2. At a protein concentration of 10%, RuBisCO has the lowest $t_g$ and the highest $G'_{\infty}$ followed by EWP and SPI.

**Table 1. Onset Gelation Time $t_g$, Estimated Infinite $G'_{\infty}$ at 95 °C, and Critical Strain $\gamma_c$ for Different Concentrations of RuBisCO**

| RBC concn (%) | $t_g$ (s) | $G'_{\infty}$ (kPa) | $\gamma_c$ (-) |
|---|---|---|---|
| 2.5 | 630 | 0.5 ± 0.1 | 0.0436 ± 0.004 |
| 5 | 594 | 2.4 ± 0.3 | 0.0397 ± 0.003 |
| 10 | 546 | 10.4 ± 0.2 | 0.0374 ± 0.002 |

**Table 2. Effect of 0.2 M NaCl on Onset Gelation Time $t_g$ and Estimated $G'_{\infty}$ at 95 °C of RuBisCO in Comparison to Other Proteins**

| | 0 M NaCl | | +0.2 M NaCl | |
|---|---|---|---|---|
| protein concn (%) | $t_g$ (s) | $G'_{\infty}$ (kPa) | $t_g$ (s) | $G'_{\infty}$ (kPa) |
| 10% RBC | 546 | 10.4 ± 0.2 | 590 | 6.6 ± 0.4 |
| 10% WPI | no gel | | 726 | 7.7 ± 0.1 |
| 10% EWP | 740 | 4.1 ± 0.2 | 720 | 4.4 ± 0.2 |
| 10% SPI | 790 | 0.40 ± 0.01 | 798 | 0.81 ± 0.04 |
| 15% PPI | no gel | | 438 | 2.8 ± 0.1 |
| 21.5% LPI | 1038 | 0.34 ± 0.03 | 768 | 1.8 ± 0.1 |

Note that WPI does not form a gel at 10% protein concentration, and neither does PPI give a significant value for $G'_{\infty}$ at 95 °C at a concentration of 15%. For the latter, gel formation did occur during cooling. Upon the addition of 0.2 M NaCl, $t_g$ decreased and $G'_{\infty}$ increased for all proteins except for RuBisCO, and now WPI and PPI form a gel as well. The addition of small amounts of salt to globular proteins promotes aggregation due to reduced steric repulsion. Hence, network formation is enhanced and stronger networks are formed. Apparently, the effect of salt on the gelation behavior of RuBisCO is opposite, as $t_g$ increased and $G'$ at infinite time decreased upon addition of 0.2 M NaCl.

During cooling from 95 to 25 °C, $G'$ further increased for all proteins. However, differences in the increase in $G'$ during cooling were observed, and values for $G'$ at 95 and 25 °C are given in Table 3. Two important features can be observed here, that is, a much higher increase in $G'$ during cooling for RuBisCO compared to the other proteins and the higher tan $\delta$ of the same gel when cooled. As postulated before, RuBisCO

**Table 3. Estimated $G'_\infty$ at 95 °C (End of Heating) and 25 °C (End of Cooling) and tan $\delta$ for Proteins Gels Made of RuBisCO (RBC), Whey Protein Isolate (WPI), Egg White Protein (EWP), Soy Protein Isolate (SPI), Pea Protein Isolate (PPI), and Lupine Protein Isolate (LPI)**

forms a network in which different types of interactions play a role, giving it its specific behavior.

After cooling to 25 °C, $G'$ reached a steady state value for all proteins. Plotting this $G'$ value as a function of protein concentration for RuBisCO in comparison to other proteins, it is obvious that the gelation potential of RuBisCO exceeds that of WPI and EWP and by far that of plant proteins such as SPI, LPI, and PPI (see Figure 4). For each protein an increase in $G'$ was found with increasing protein concentration, and the critical gelation concentration for each protein could be estimated from the graph. For RuBisCO the critical gelation concentration ($c_{gel}$) is <2.5%. For RuBisCO from alfalfa, Libouga et al.[34] reported values for $c_{gel}$ of 0.5% at pH 7.5 and 1% at pH 8, well below 2.5% protein. Differences in $c_{gel}$ can be explained by the difference in p$I$ between alfalfa and spinach. For the latter p$I$ values of 5.5, 4.9, or 5.0 were found, whereas for alfalfa p$I$ ~6.[3] At neutral pH, RuBisCO from spinach has a higher net charge compared to alfalfa, leading to enhanced steric repulsion and hence a higher $c_{gel}$. Nevertheless, $c_{gel}$ for RuBisCO is much lower compared to the other proteins given in Figure 4, where the minimum concentration needed to form a gel at pH 7 starts from ~5% (SPI) and the order in which it increases follows SPI < EWP < WPI < PPI < LPI. For SPI the highest concentration that could be measured was 10% as above that concentration the (native) protein solution became too viscous to handle. Critical gelation concentrations for SPI, EWP, and WPI agree with literature values.[44,45]

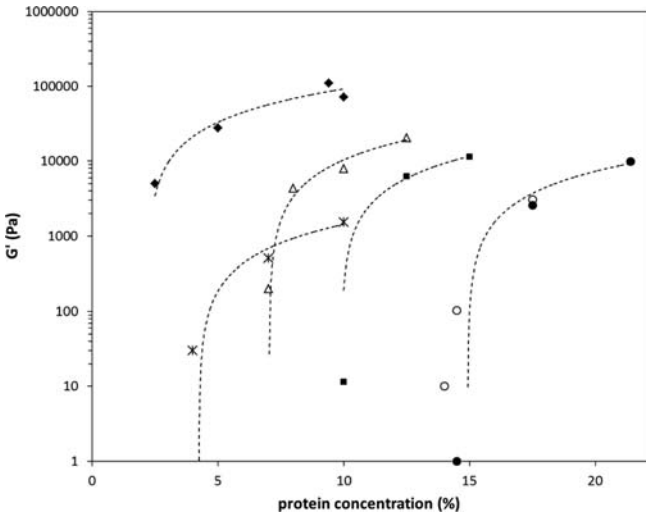

**Figure 4.** Storage modulus $G'$ as a function of protein concentration for (◆) RuBisCO, (■) WPI, (△) EWP, (×) SPI, (●) LPI, and (○) PPI. Dotted lines are to guide the eye.

After a heating and cooling profile had been applied, a strain sweep was performed to study the linear region and breakdown behavior of RuBisCO gels. Figure 5A shows the decrease in $G'$ when the strain increased from 0.001 to 1 for three concentrations of RuBisCO (2.5, 5, and 10%). For all concentrations, it appeared that the linear region for RuBisCO is quite small and, as a result, the critical strain ($\gamma_c$) is low as well. Values for $\gamma_c$ are given in Table 1 and show that with increasing RuBisCO concentration, $\gamma_c$ decreases. In comparison to gels made from WPI and EWP, RuBisCO exhibits a brittle character prone to early breakdown. Figure 5B clearly shows the early breakdown of RuBisCO compared to protein gels made from WPI and EWP and indicates once more that the type of interactions in a RuBisCO gel are of a different, weaker kind. In fact, covalent bonds between protein molecules and aggregates (as commonly found in WPI and EWP gels) tend to be stronger than hydrophobic interactions and hydrogen bonds.

In summary, RuBisCO typically has a very low critical gelling concentration and a low $t_g$, resulting in gels that have a very high $G'$ but also a high tan $\delta$. In addition, early breakdown of RuBisCO gels during the strain sweep was observed. It is postulated that the type of interactions that are formed during aggregation and network formation play a role in RuBisCO's specific behavior. To further investigate this, fracture properties and microstructure were determined. As WPI, EWP, and SPI form self-supporting gels at much lower concentrations than PPI and LPI, the latter two are not further taken into account for comparison with RuBisCO.

**Fracture Properties.** Fracture properties were determined to establish information on (true) fracture stress and (true) fracture strain during compression, as is relevant for textural and sensory properties. Fracture properties of RuBisCO were compared with those of WPI, EWP, and SPI, and true fracture stress ($\sigma_f$) was plotted against true fracture strain ($\varepsilon_f$) for protein gels without and with 0.2 M NaCl (see Figure 6). RuBisCO (10%) has a higher $\sigma_f$ (125 kPa) compared to 10% WPI (no gel), 10% EWP (90 kPa), and 10% SPI (31 kPa) but a similar $\varepsilon_f$ to SPI. The relatively low $\varepsilon_f$ indicates that RuBisCO forms a brittle gel as is commonly observed for SPI.[44] As for 10% WPI no self-supporting gel is formed, a 15% concentration was used for comparison. The higher $\sigma_f$ of 15% WPI compared to that of 10% RuBisCO gels is most probably caused by the higher protein concentration. In addition, WPI (and also EWP) forms more elastic gels. For EWP, WPI, and SPI, the addition of 0.2 M NaCl led to similar or slightly increased values for $\sigma_f$ and lower $\varepsilon_f$. For RuBisCO, however, both $\sigma_f$ and $\varepsilon_f$ decreased drastically when salt was added, similar to the reduction in gel strength observed with small deformation measurements ($G'$ values). In addition, the brittleness of RuBisCO in large deformation is in line with the early breakdown observed for RuBisCO with small deformation experiments.

**Microstructure.** To understand the differences in small and large deformation properties between RuBisCO and other proteins, the microstructure of RuBisCO is probed with CLSM as a function of NaCl concentration for 5 and 10% RuBisCO (see Figure 7) and compared to 10% WPI. Whereas WPI and also EWP and SPI form transparent and hence fine-stranded

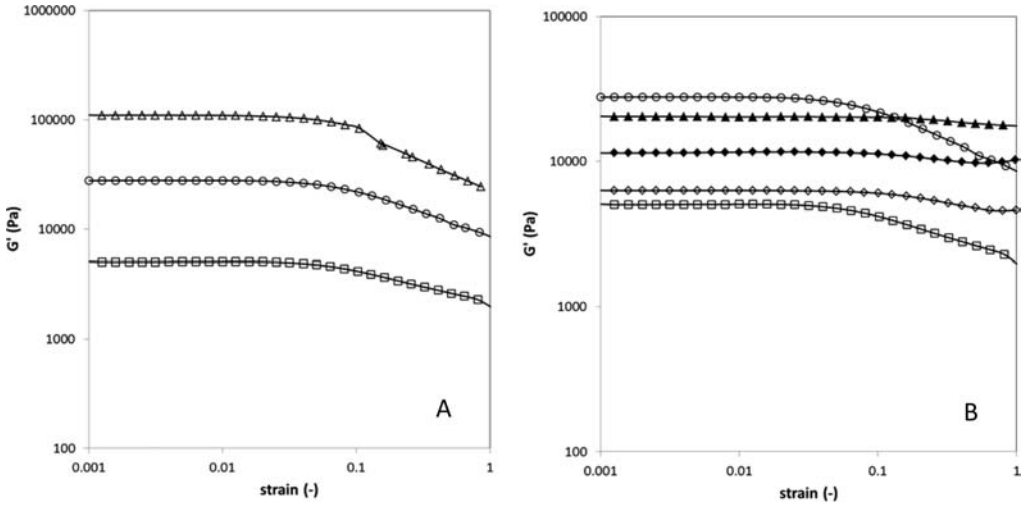

**Figure 5.** (A) Strain sweep for (△) 10% RuBisCO, (○) 5% RuBisCO, (□) 2.5% RuBisCO. (B) Comparison between RuBisCO and (▲) 12.5% EWP, (◇) 12.5% WPI, and (◆) 15% WPI.

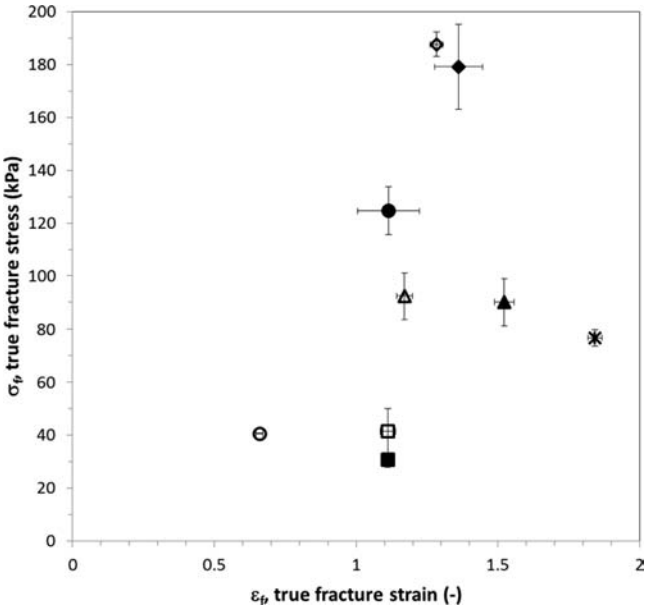

**Figure 6.** Fracture properties in terms of fracture stress (kPa) and fracture strain of various protein gels without salt (solid symbols) and with 0.2 M NaCl (open symbols) for (●) 10% RuBisCO, (◆) 15% WPI, (×) 10% WPI + 0.2 M NaCl, (▲) 10% EWP, and (■) 10% SPI.

gels at neutral pH, RuBisCO formed a white turbid gel. Upon addition of NaCl to WPI and EWP, the transparency of the gels disappeared as a transition occurred from fine-stranded to coarse-stranded gel. This indicates that the aggregation mechanism and how aggregates together build the microstructure of protein network are clearly different for RuBisCO relative to WPI or EWP. Note that the molecular weight for RuBisCO (~550 kDa) is >10 times higher than that for WPI (with $\beta$-lactoglobulin of 18 kDa in monomeric form as most prevalent protein) and EWP (containing predominantly ovalbumin of 44 kDa) and that reported values for hydrodynamic radius, $R_g$, for RuBisCO range from 5 to 7 nm,[7] where ovalbumin and $\beta$-lactoglobulin, the major proteins of EWP and WPI, have values of ~3 and ~2 nm, respectively.[45,46]

With regard to the microstructure as observed with CLSM, the density of the RuBisCO network increased with increasing protein concentration. For 10% protein the addition of 0.2 (B2) and 0.5 M NaCl (B3) does not seem to have a large influence on the network density, although a small increase in coarseness from 0 to 0.2 M NaCl could be observed. For 5% RuBisCO (A1) however, it seems that the network becomes coarser with higher salt concentration (A2 and A3). Addition of 0.2 M NaCl clearly resulted in a coarser network, but upon further increasing NaCl concentration, the coarseness decreased again. By comparing RuBisCO to WPI the following was observed. At 10% WPI (C1) no gel was formed, but from the literature it is known that at 15% WPI a fine-stranded network is formed when no salt is present.[46] The features of such a network cannot be probed with CLSM. With increasing salt concentration (C2), the network becomes more coarse-stranded as charges are screened. When the NaCl concentration is further increased (C3), the coarseness is strongly enhanced. The effect of salt on the microstructure is far more pronounced for WPI than for RuBisCO.

The increase in coarseness with addition of NaCl can be related to the decrease in fracture strain. Fine-stranded gels (without addition of NaCl) tend to be more elastic than coarse-stranded gels (formed when NaCl is added). However, a clear relationship between the microstructure and rheological properties could not be found for RuBisCO. Changes in the type of interactions between RuBisCO molecules as a result of salt addition affect the rheological properties to a greater extent than the microstructure itself. As native RuBisCO is held together by numerous ionic bridges and most of these salt bridges are ruptured during denaturation, dissociation of the subunits occurs and hence a more open structure is created.[34] When salt is added, electrostatic repulsions between the charged groups of the subunits are screened and will drive aggregation. The type of interactions that are formed in the presence of salt may be weaker than when no salt is added.

**Protein−Protein Interactions.** To gain an understanding of the type of interactions that occur between RuBisCO molecules and the relationship with the brittleness of RuBisCO gels, protein−protein interactions were investigated. During aggregation and gelation of globular proteins, different types of interactions play a role. During the heating phase, covalent bonds (e.g., disulfide bridges) can be formed, whereas during the cooling phase, noncovalent interactions such as hydro-

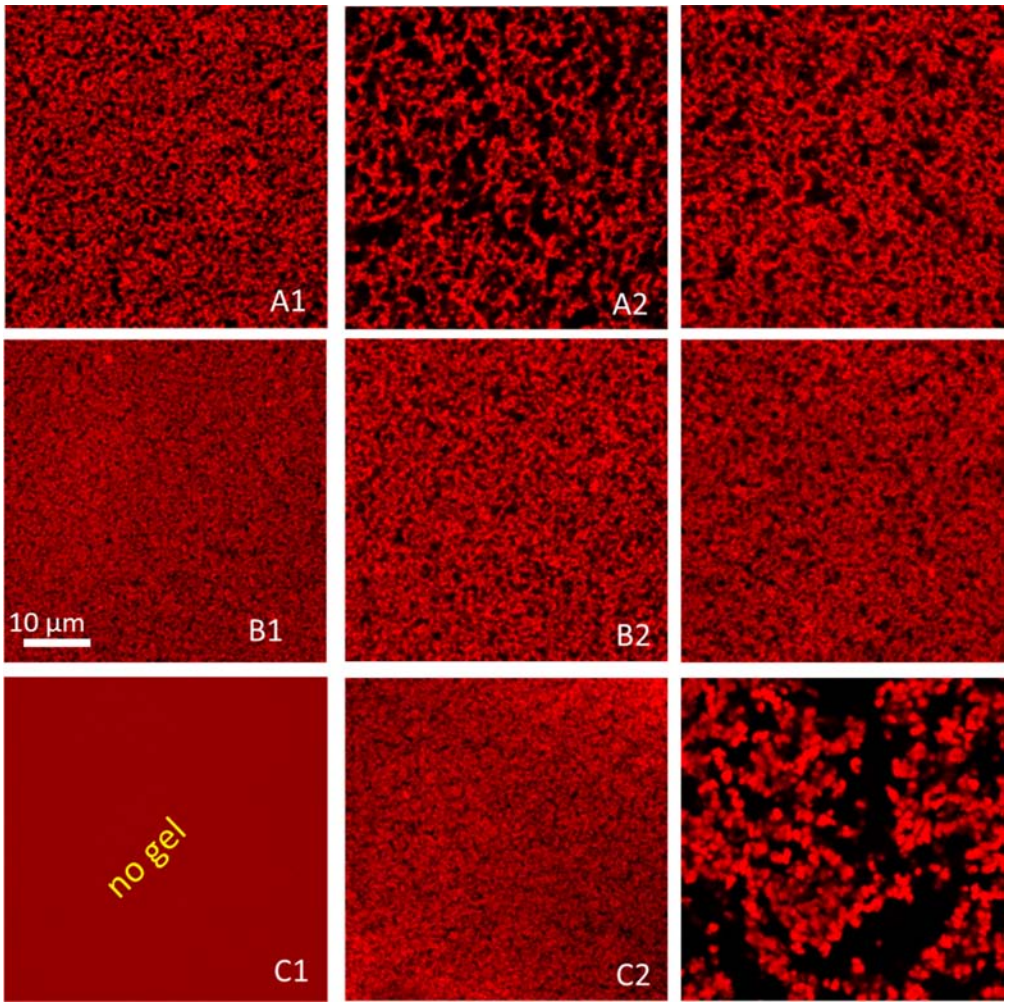

**Figure 7.** Microstructure of RuBisCO gels (A, 5% protein concentration; B, 10% protein concentration) and WPI (C, 10%) as a function of NaCl concentration (1, no salt; 2, 0.2 M; 3, 0.5 M) as measured by CLSM. The scale bar presented in image B1 applies to all images.

phobic interactions and hydrogen bonds come into play. In small deformation rheology a distinction can be made between the increase in $G'$ during the heating phase and the second increase in $G'$ during the cooling phase. From Table 3 it is clear that for RuBisCO the increase in $G'$ during cooling is much higher than for the other proteins, suggesting that noncovalent interactions play a much larger role in strengthening the protein network. To further investigate this, RuBisCO gels were subjected to a series of solvents that each break specific interactions in proteins gels (see Table 4). $\beta$-Mercaptoethanol (ME), NaCl, urea, SDS, and combinations of these solvents were used to distinguish between disulfide bridges, hydrogen bonds, hydrophobic, and electrostatic interactions. Both WPI and EWP gels stayed intact when dissolved in water, ME, 2 M NaCl, or 2 M NaCl+ME. RuBisCO gels, however, changed in size. Upon addition of NaCl, both in the absence and in the presence of ME, the gels shrank, indicating contraction of the protein network due to enhanced hydrophobic interactions. Addition of ME alone resulted in swelling of the RuBisCO gel. As disulfide bridges are present within the large subunits, ME may disrupt these when accessible, leading to a looser and open structure. Urea and SDS are known to disrupt hydrogen bonds and/or hydrophobic interactions. When added to RuBisCO, these gels are partially dissolved, suggesting that hydrogen bonds and hydrophobic interactions play a role in holding the protein network together. The falling apart by urea or SDS is confirmed by Douillard et al.,[7] who reported on dissociation of small subunits from the large ones for spinach RuBisCO already at 3 M urea. As only the small subunits are dissociated, this may explain the partial dissolvement of the gel as opposed to complete dissolvement. Addition of urea or SDS to WPI or EWP led to swelling of the gel. Here, internal hydrogen bonds and hydrophobic interactions are broken, but the presence of disulfide bridges holds the protein network together, acting as a frame with more open pores. For both WPI and EWP the

importance of disulfide bridges in aggregation was frequently studied,[47,48] and hence this confirms the results obtained here. A combination of urea and ME or SDS and ME, targeting all interactions, dissolved all three protein gels. Hence, no differences were observed between RuBisCO, EWP, and WPI.

Using solvents to study the type of interactions resulted in a validation of the hypothesis that hydrophobic interactions and H-bonds play a larger role in RuBisCO gels than in WPI or EWP gels. This explains the higher increase in $G'$ upon cooling (Table 3) and the higher brittleness as these bonds are weaker than the covalent bonds that occur with WPI and EWP.

In conclusion, heat-induced aggregation and network formation of RuBisCO resulted in gels with unique characteristics compared to well-known proteins such as WPI and EWP and plant proteins such as SPI, PPI, and LPI. Having a very low critical gelling concentration and low denaturation temperature, RuBisCO could be applied in a wide range of products that need mild processing conditions. Product categories of interest include meat replacers, either as a bulk ingredient or as a binder, but it could also be applied as a meat improvement agent. The gelation functionality could also be applied in potato starch based products, surimi, or fish cakes. In these applications RuBisCO would be a more sustainable alternative to soy or egg white protein. In general, RuBisCO would be very suitable to partially replace proteins with poorer functional properties to enhance, for example, the gelation behavior. Moreover, the unique set of properties of RuBisCO allows for expansion of the application area, as it forms a strong network at low concentrations (high $G'$, high fracture stress) but upon deformation (oral processing) it has a brittle character (low critical strain, low fracture strain). In relation to fracture properties of food gels made from different types of hydrocolloids or mixtures thereof, the fracture strain of RuBisCO is in the same region as different tofu model systems[44] and of mixtures of whey protein and κ-carrageenan, where κ-carrageenan forms the continuous phase.[49] Selectively mixing RuBisCO with other types of biopolymers would give the opportunity to deliver new textures at low concentrations, similarly to mixtures of soy protein and gelatin.[50] The typical breakdown behavior of RuBisCO can be explained by the dominant role of hydrophobic and electrostatic interactions and H-bonds and by the coarse microstructure, as opposed to disulfide bridges and (more) fine-stranded networks for WPI and EWP. These findings enhance the knowledge currently available on RuBisCO functionality, especially in the area of understanding the mechanical and microstructural properties of RuBisCO gels.

screening of free and/or bound water-soluble manganese fractions from samples with minimal sample preparation.

## MATERIALS AND METHODS

**Reagents and Samples.** A manganese(II) standard solution at a concentration of 1000 $\mu$g mL$^{-1}$ was purchased from Inorganic Ventures (Lakewood, NJ, USA). Suprapure $HNO_3$ (65%, v/v), HCl (30%, v/v), and all other reagents and chemicals used in the fractionation studies were of liquid chromatography (LiChrosolv) or analytical reagent grade and were obtained from Merck (Darmstadt, Germany). The digestive enzymes, pepsin (P7000, from porcine gastric mucosa), pancreatin (P1750, from porcine pancreas), and bile extract (B8631), were obtained from the local suppliers of Sigma-Aldrich (St. Louis, MO, USA) and used for the simulation of in vitro gastric and intestinal digestions. Sodium hydrogen carbonate was a Carlo Erba RPE reagent (Rodano, Milan, Italy) and was used for the preparation of the digestion solutions. Activated carbon (AOX Batch, PPTRE0049, Euroglas, Okehampton, UK) in powder form was used to evaluate the adsorption capabilities of manganese. All of the standards and samples were filtered through Double Rings 103 (12.5 cm filter paper) blue ribbon filter paper, followed by filtration through 0.45 $\mu$m hydrophilic polyvinylidene fluoride (PVDF) syringe filters (Millex-HV, Millipore) prior to analysis. Certified reference materials, NIST 1567a wheat flour (Gaithersburg, MD, USA) and Conostan (S-21-10 $\mu$g g$^{-1}$) oil-based multielement calibration standard (LGC Standards, London, UK), were used for validation purposes. A FAME (fatty acid methyl ester) Mix C4−C24 (Supelco 18919-1AMP, Sigma-Aldrich) standard mixture was used for fatty acid analysis. The water used was of ultrapure grade (18.3 MΩ·cm, Zeener Power I, Human Corp., Seoul, Korea). Highly pure (99.999%) argon and nitrogen gases were purchased from Orsez (Bursa, Turkey). Helium gas (99.999%) was supplied by Linde Gas A.Ş. (Bursa, Turkey).

Among the many varieties of hazelnuts that are cultivated in Turkey, Tombul hazelnuts are known as Giresun or premium quality and are mainly grown in Giresun, Turkey.[9] Thus, Fiskobirlik Efit A.Ş. (hazelnut processing company in Giresun) brand or Giresun quality unshelled and processed (Tombul) hazelnut samples were purchased from markets in Giresun and Bursa.

**Apparatus and Instrumentation.** Total manganese (Mn) analyses were performed after sample digestion using a microwave digestion system (Microwave Labstation MLS 1200 mega, Milestone, Italy). An Elma LC-30H model ultrasonic bath (Singen, Germany) operated at an ultrasonic frequency of 35 kHz and a power of 240 W was used for the sample preparation. A pH meter (Minilab IQ125 Isfet pH tester, IQ Scientific Instruments Inc., Carlsbad, CA, USA) was obtained from PerkinElmer (PerkinElmer SCIEX, Shelton, CT, USA). An unstirred thermostatic water bath (Clifton NE1-22, Nickel Electro Ltd., UK) and an MSE Mistral 2000 centrifuge (MSE Scientific Instruments, UK) were used for the bioaccessibility studies.

A PerkinElmer 200 series high-performance liquid chromatography (HPLC) system consisting of a series 200 quaternary pump, a series 225 autosampler, a series 200 column oven, and a vacuum degasser was used for the chromatographic analyses. The separation and identification of manganese fractions was achieved using a Brownlee DB Aq. C-18 (150 mm × 4.6 mm i.d. and 5 $\mu$m film thickness) analytical column (PerkinElmer SCIEX) equipped with a guard column (40 mm) with the same stationary phase material. The column was maintained at 26 °C, and the elution was performed with filtered and degassed ultrapure water. A methanol/water mixture as a gradient mobile phase was also used to evaluate the separation. The gradient program began with 100:0 (A%/B%, v/v) for 0−1 min, then the following steps were applied: 95:5 (A%/B%, v/v) for 1 min, 97:3 (A%/B%, v/v) for 2 min, and 98:3 (A%/B%, v/v) for 2 min. The elution was performed using a 1.5 mL min$^{-1}$ flow rate, and the injection volume was 30 $\mu$L.

The determination of the total manganese in the samples/fractions and the monitoring of manganese fractions in the extracts were performed by an Elan 9000 ICP-MS (PerkinElmer SCIEX) composed of a PerkinElmer Ryton cross-flow nebulizer, a Scott-type double-pass spray chamber, and a standard glass torch. The sampler and skimmer cones were made of nickel. The operating conditions of the ICP-MS were as follows: RF power, 1000 W; plasma argon flow rate, 17.0 L min$^{-1}$; nebulizer flow rate, 0.85 L min$^{-1}$; sample uptake rate, 1.5 mL min$^{-1}$. The other plasma conditions and acquisition parameters were the same as those reported in our earlier studies.[12] Additionally, total manganese analyses were performed by a Varian (Australia) AA240FS fast sequential atomic absorption spectrometer (AAS) for validation purposes. The optimum parameters for manganese determination were as follows: wavelength, 279.5 nm; HCL current, 10 mA; acetylene flow rate, 2.0 L min$^{-1}$; slit width, 0.2 mm; and flame height, 7 mm. The fatty acid profiles in the hazelnut samples were identified by gas chromatography with flame ionization detection (GC-FID, Shimadzu, Kyoto, Japan) consisting of a DB-WAX analytical column (30 m × 0.25 mm × 0.25 $\mu$m). The injector and detector temperatures were 250 °C. The GC oven was maintained at 210 °C (isothermal). The injection volume was 1 $\mu$L, and the injection mode was split (1:20 ratio). Helium was used as the carrier gas with a flow rate of 1 mL min$^{-1}$.

HPLC was coupled online with ICP-MS through a Rheodyne switching valve apparatus (PerkinElmer SCIEX), which accomplished sample introduction from the outlet of the column to the nebulizer of the ICP-MS instrument via high-purity fluoropolymer tubing (PFA, Poly Fluorinated Alkoxy, 0.019 in. i.d., $^1/_{16}$ in. o.d., and 580 mm length, PerkinElmer SCIEX). The software Chromera version 1.2.254.0 (PerkinElmer SCIEX) was used to assess the online HPLC-ICP-MS chromatograms and data. The $^{55}$Mn isotope was measured on the basis of peak height using three replicates.

**Sample Preparation.** Three packages (90−250 g) of unshelled and processed (peeled, roasted, and ready-to-eat) Giresun-quality hazelnut samples obtained from the same manufacturer were mixed, and a portion of the homogenized sample was ground to a fine powder in a porcelain mortar and then transferred to polyethylene bottles. This preparation procedure described in detail above was separately applied to three different samples of the same quality purchased at different times and markets. Then, the obtained hazelnut samples were coded as samples 1, 2, and 3. The following sample preparation procedures were applied to preweighed samples.

**Major Constituents Analysis.** The moisture contents were determined according to ISO 771:1997.[20] The oil contents of the samples were determined according to TS 765:1969[21] after diethyl ether extraction. Additionally, chloroform/methanol (2:1 v/v) extraction[22] was applied to the samples to compare their lipid contents. The dietary fiber, crude fiber, crude ash, and sugar contents were determined according to AOAC 985.29 1986, ISO 5498:1981, and ISO 5984:2002 standard methods and the Luff Scroll method,[23−26] respectively. Methyl esters of the fatty acids were prepared and analyzed according to methods TS 4504 EN ISO 5509[27] and TS 4664 EN ISO 5508,[28] respectively, with some modifications. Briefly, transesterification was performed with 0.1 g of oil residue remaining from the samples after the application of method TS 765:1969.[21] Isooctane (4 mL) and methanolic KOH (0.8 mL) solutions were used for the transesterification. After vortexing for 30 s at room temperature, the upper isooctane layers of the samples were injected into the GC-FID column.

**Total Manganese Validation Analysis.** To minimize contamination, all of the glassware, polyethylene bottles, polypropylene centrifuge tubes, and pipet tips were soaked in 10% (v/v) nitric acid for at least 48 h and then rinsed several times with ultrapure water before drying in an oven at 40 °C. The hazelnut samples were digested prior to AAS and ICP-MS analyses. The detailed sample preparation procedure based on the DS/EN 14084 method,[29] together with the microwave digestion operating conditions, was reported in our earlier studies.[12] Briefly, 0.5 g of homogenized samples was digested with 6 mL of $HNO_3$ and 1 mL of $H_2O_2$. The microwave digestion operating conditions were as follows: 250 W (2 min), 0 W (2 min), 250 W (6 min), 400 W (5 min), and finally 600 W (5 min). An open-wet digestion method with the same proportion of nitric acid and hydrogen peroxide used in the microwave digestion was also applied. After cooling to room temperature, the samples were transferred to

polypropylene centrifuge tubes and diluted to 25 mL. Three independent replicates were prepared for each of the samples, spiked samples, and reagent blanks. Working solutions of manganese were prepared on a daily basis by appropriate dilution of a single stock solution and used for external calibration. The calibration curve was constructed from eight data points for standard solution concentrations ranging from 0.5 to 80 $\mu$g $L^{-1}$ for ICP-MS analysis and from six data points ranging from 0.1 to 2.0 mg $L^{-1}$ for AAS analysis. Because no hazelnut type certified reference material was available, each of the three hazelnut samples was spiked with aqueous manganese standard solutions at one level (0.1 mg $L^{-1}$) prior to microwave digestion for recovery studies. The calibration methods using aqueous standards and standard addition were compared on the basis of their slopes. Additionally, wheat flour certified reference material (for the defatted hazelnut samples) and the Conostan S-21 oil analysis standard (for the oil fraction of the hazelnut samples) were used to determine the accuracy of the manganese determinations by ICP-MS after the microwave and/or open-wet digestion methods. All microwave-digested samples were analyzed by AAS, followed by ICP-MS. The open-wet digested samples were analyzed only by ICP-MS.

**Fractionation Studies.** Manganese was extracted from 0.1 g of hazelnut sample using 15 mL of various solvents, including water, diethyl ether, *n*-hexane, and methanol. The extractions were performed in closed clear glass vials for 1.5 h at room temperature in an ultrasonic bath. Reagent blanks were also prepared in the same manner. The organic solvents in each fraction were filtered through blue ribbon filter paper and evaporated to dryness under nitrogen gas, and the residue was analyzed by ICP-MS after dissolving in 10 mL of 1% (v/v) $HNO_3$. All of the fractionation studies were performed in triplicate. The final extracts were then analyzed for manganese content by ICP-MS. The fractionation scheme is summarized in Figure 1. Additionally,

**Figure 1.** Fractionation scheme of manganese in hazelnut samples.

the lipids were extracted using a chloroform/methanol (2:1 v/v) extraction. Two grams of the samples was subjected to extraction in an ultrasonic bath for 30 min using 15 mL of the solvent mixture. The samples were filtered through blue ribbon filter paper, and 15 mL of fresh solvent mixture was added to the filtered sample. The entire procedure was applied in triplicate for one sample (hazelnut 1), and the number of independent applications for this sample was five. After this sequential extraction, the samples were dried and the fat content per 100 g was determined on the basis of mass loss. The fractionation approach based on activated carbon adsorption was performed using the method introduced by Kowalewska et al. with some modifications.[30] Briefly, a mixture of 30 mL of ultrapure water, 2.5 mL of methyl isobutyl ketone, and 0.03 g of activated carbon was added to each 0.1 g of sample. After extraction in an ultrasonic bath for 1 h at room temperature, the samples were filtered through blue ribbon filter paper and dried. The manganese contents in the samples were leached with 10 mL of 10% (v/v) nitric acid and determined by ICP-MS after appropriate dilution.

**HPLC-ICP-MS Analysis.** The water-soluble fractions were subjected to online analysis by HPLC-ICP-MS. After fractionation with water, all of the solutions were filtered through 0.45 $\mu$m PVDF filters and stored in clear polypropylene centrifuge tubes at 4 °C until analysis. The calibration standards ranged in concentration from 136 to 595 $\mu$g $L^{-1}$. The retention times of the standards and the samples, together with the peak heights, were compared to screen the manganese levels and the fractions.

**Bioaccessibility Assessments.** The bioaccessible manganese levels were determined after an in vitro enzymatic digestion procedure with appropriate solutions of pepsin and pancreatin. The simulated gastric digestion was initiated by adding 2 mL of freshly prepared pepsin−HCl solution (0.2 g of pepsin in 5 mL of 0.1 M HCl) to 0.03 g of sample. A 15 mL volume of ultrapure water was then added to the samples. The pH values of the solutions were adjusted to 1.9 with 0.1 M HCl. The solutions were incubated in a water bath at 37 °C for 1 h. The enzyme residues were removed by centrifugation at 2135*g* for 5 min, and the manganese contents of the samples determined by ICP-MS were designated the pepsin-digestible amounts. For the simulated intestinal digestion, 2.5 mL of freshly prepared enzyme solution (pancreatin/bile: 0.45 g of bile extract and 0.075 g of pancreatin in 37.5 mL of 0.1 M $NaHCO_3$) was added to 15 mL of the solutions containing 0.03 g of the samples. The pH values of the solutions were adjusted to 6.9 with 0.1 M $NaHCO_3$ or 0.1 M HCl. The solutions were incubated in a water bath at 37 °C for 2 h, and the manganese contents of the samples were determined by ICP-MS after the removal of the enzyme residues. The manganese levels in these solutions were designated the pancreatin-digestible amounts. The simulated gastrointestinal digestion was designated as the pepsin+pancreatin-digestible amount and was prepared by adding 4.5 mL of water to 3 mL of gastric extract. After pH adjustment, 3 mL of the pancreatin/bile solution was added to the samples. The pH values of the solutions were adjusted to 6.9, and the solutions were incubated in a water bath at 37 °C for 2 h.[12,17,31] The gastrointestinal digests were centrifuged at 2135*g* for 5 min. The supernatants were filtered immediately to remove any enzyme residue through PVDF syringe filters prior to being stored at 4 °C and analyzed by ICP-MS. The contents of the digests were analyzed to ensure the inactivity of any remaining enzyme residue. The manganese contents of the enzymatic digestions, together with the total element digestions, were used to calculate the percent bioaccessibility according to the equation

$$\text{bioaccessibility (\%)} = ([Mn^{2+}]_2/[Mn^{2+}]_1) \times 100$$

where $[Mn^{2+}]_2$ and $[Mn^{2+}]_1$ are the total manganese contents determined by ICP-MS after in vitro digestion and microwave-assisted acid digestion, respectively.[17] Additionally, 0.1 g samples were extracted with 15 mL of *n*-octanol to compare with the results obtained from intestinal pancreatic digestion. The extraction was performed in an ultrasonic bath for 1.5 h. Subsequently, a liquid−liquid extraction was performed using 5 mL of 1% (v/v) $HNO_3$ (in

triplicate), and the nitric acid fractions were analyzed by ICP-MS. To evaluate its compatibility, *n*-octanol extraction was applied to the spiked samples (at two levels) for recovery studies.[17]

## RESULTS AND DISCUSSION

**Fractionation Studies.** Manganese fractionation studies are important for establishing the relationship between metal mobility in organisms and nutrition. Additionally, understanding the role of major components of hazelnut is important for predicting manganese-binding food structures, which will provide valuable insights for further bioaccessibility studies. The major food components of hazelnut samples are outlined in Table 1. According to this table, most of the manganese could be present in oil-, protein-, or fiber-bound structures, with the hazelnuts consisting primarily of oil (60%) and protein (18%). The organic solvents selected for fractionation studies should represent these components, and these fractions are important for bioaccessibility assessments. The oil contents were 64.6, 61.2, and 64.7% for samples 1, 2, and 3, respectively. We focused only on the oily matrix for fractionation purposes; the protein contents were discussed within an online method by HPLC-ICP-MS. For fractionation purposes, diethyl ether, *n*-hexane, and methanol extractions were applied to remove the neutral, free, and bound polar lipids,[17,22] respectively. The manganese contents in these fractions ranged from 0.67 to 0.79 mg $kg^{-1}$ in the diethyl ether fractions, from 0.36 to 0.67 mg $kg^{-1}$ in the *n*-hexane fractions, and from 0.15 to 0.42 mg $kg^{-1}$ in the methanol fractions (Table 2). As discussed in the literature, diethyl ether extraction is important for neutral lipids, whereas methanol extraction is important for cell-membrane lipids (phospholipids, glycoproteins, and cholesterol).[22] We can conclude that the manganese content in any lipid fraction will be small compared to the total manganese content, and no substantial differences were observed among them. Thus, manganese should be naturally and mostly bound to other parts of the matrix constituents, the structures of which will help to assess manganese bioaccessibility. The oil contents of the samples achieved by chloroform/methanol extraction were compared with those obtained by standard methods using Soxhlet extraction.[21] The results were comparable, with 64.6 ± 0.7% for the standard method and 61.8 ± 5.6% for the proposed extraction method. The only difference between the two methods was the wide standard deviation in the latter method. This result also shows the similar levels of neutral and total lipids in the hazelnut matrix. Additionally, as reported in the literature, Mn(II) is most likely bound strongly to the carboxylate ends of the fatty acids.[32] To evaluate the fatty acid binding site, fatty acid characterization studies were performed by GC-FID. The results were evaluated according to the chromatographic retention times and peak areas of the corresponding methyl ester standard in the FAME mixture. The fatty acid contents of the three hazelnut samples per 100 g are outlined in Table 3. As observed in this table, the most abundant fatty acids per 100 g in the hazelnut samples, in decreasing order, were oleic, linoleic, palmitic, and stearic acids. The bound manganese levels (methanol fractions) might be associated with the most abundant fatty acid (oleic acid) for the following reasons. First, it is indicated in the literature that the foliar application of $MnCl_2$ to sunflower plants (seed produces oil up to 50% by weight) positively affects the palmitic and oleic acid levels and increases their amounts, whereas it negatively affects the stearic, linoleic, and linolenic acid levels.[33] Palmitic and oleic acids are the saturated and unsaturated fatty acids, respectively. Mn potentially influences the fatty acid profile via promoting acetyl-CoA carboxylase activity, which is important in fatty acid synthesis.[34] From these results, together with the similar oil contents of the seeds and our matrix, oleic and palmitic acids are the most probable manganese complexes among the fatty acids in hazelnuts. Second, it has been reported that $C_{18}$ fatty acids have a tendency to be expelled from water to reduce the total energy and therefore arrange themselves into oligomers or clusters. Fatty acids with straight alkyl chains are known to pack closer together; therefore, it is difficult to strip away the acidic proton in solution. Additionally, trans double bonds are known to pack closer than cis double bonds, subsequently leading to higher $pK_a$ values for trans double bonds.[35] Given this information, the observed $pK_a$ of palmitic acid ($C_{16}$ fatty acid) is expected to be higher than that of oleic acid ($C_{18}$ fatty acid with a cis double bond); therefore, oleic acid may be a preferable manganese binding fatty acid structure. This acid is also the most abundant fatty acid in hazelnuts, as shown in Table 3.

**Table 2. Manganese Levels Released from the Samples Using Fractionation Methods[a]**

| sample | water | diethyl ether | *n*-hexane | methanol |
|---|---|---|---|---|
| 1 | 10.89 ± 2.62 | 0.78 ± 0.15 | 0.36 ± 0.03 | 0.15 ± 0.05 |
| 2 | 13.38 ± 0.02 | 0.79 ± 0.24 | 0.67 ± 0.02 | 0.23 ± 0.01 |
| 3 | 7.33 ± 0.32 | 0.67 ± 0.05 | 0.40 ± 0.02 | 0.42 ± 0.04 |
