**Analysis of Model System Samples and Kinetic Evaluation.** As a specific application to the kinetic study, the proposed method was used to simultaneously detect HAAs and their precursors from lyophilized pork models with different heating times at 195 °C. The kinetic profiles of both the HAAs and their precursors were clearly depicted using the simultaneous method (Figure 4). Without heating (heating time, 0 min), the contents of the precursors were quantified as 34.3 $\mu$g g$^{-1}$ for Phe, 50.98 $\mu$g g$^{-1}$ for Tyr, 41054.26 $\mu$g g$^{-1}$ for creatine, 805.54 $\mu$g g$^{-1}$ for creatinine, and 1651 $\mu$g g$^{-1}$ for Glc using the current kinetic tool—similar to another study,[21] and further demonstrating the precision of our simultaneous method. The amino acid, creatine, and Glc contents sharply decreased within the initial 5 min, especially for creatine, indicating the violence of the reaction process. Then, as the reaction proceeded, the content variation became gentle. The elimination kinetics of creatine appeared to be faster than those of amino acids and Glc, which could be explained by creatine's simultaneous involvement in both creatinine and HAAs formations. The dehydration reaction from creatine to creatinine can be validated by a rapid increase in creatinine at the beginning, which gradually decreases in the subsequent reaction. A continuation of the HAAs formation is observed when the precursors are almost depleted by 20 min, indicating that there may be some other compound or multiple reactions involving in the formation process of HAAs. The kinetic profiles and levels of PhIP at different heating time is good in accordance with a previous study which used the similar lyophilized model,[8] further demonstrating the applicability of our simultaneous method. In the dry model used in this paper, water is removed to ensure the same chemical composition throughout all experiment. Compare with the actual pork model containing water, the PhIP level obtained in our lyophilized pork model are significant higher. For example, no PhIP are detected in wet pressed pork heated at 200 °C for 30 min in a previous study.[21] The author stated that water may play an important role in the PhIP formation, since a markedly higher PhIP level in the dry heated sample was observed. The effect of water or water activity in actual pork can be further demonstrated by the apparent decrease of the PhIP levels after adding the compounds that could enhance the water-holding capacity.[36]

The simultaneous quantitative method proposed in our work was successfully applied to the simultaneous detection of HAAs

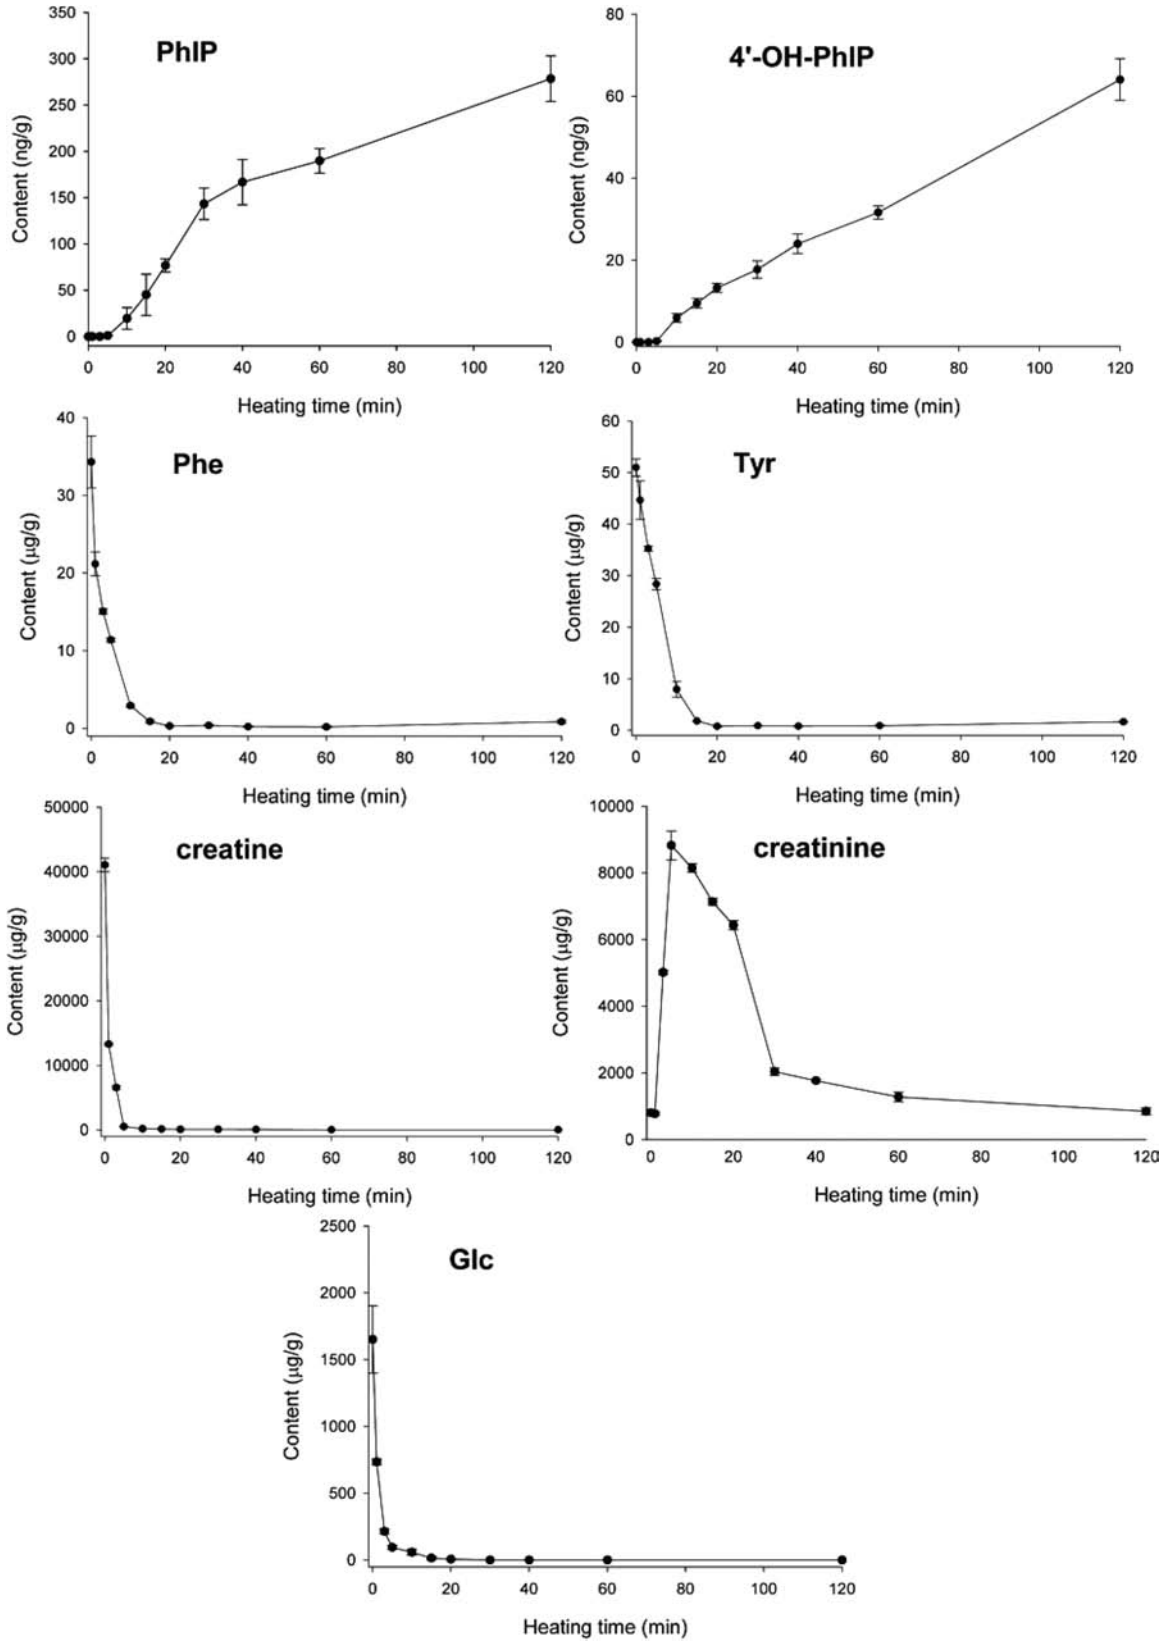

**Figure 5.** Content and kinetic profiles of PhIP, 4′-OH-PhIP, and their precursors (Phe, Tyr, creatine, creatinine, and Glc) in a fresh pork model with different heating time treatments. Each experiment was performed in triplicate repeats ($n$ = 3), and the standard deviation was calculated for the error bar of each point.

and their precursors during the kinetic evaluation. Compared with the separate analysis, the advantage of the proposed method is that it allows the simultaneous detection of all of the target compounds, which could reduce the analysis time and

has not been studied yet. This study hypothesizes that VOO obtained from Picual olives of lower ripening index shows higher stability and lower thermal oxidation than VOO from higher ripening index counterparts when used in repeated frying operations of fresh potatoes. Thus, the aim of the present study was to evaluate the effect of olive ripeness on the thermal oxidation stability during frying of fresh potatoes of VOO obtained from Picual cultivars by quantifying (a) polar compounds, (b) thermal oxidation and hydrolytic compound profiles, (c) polar and nonpolar methyl esters, (d) fatty acid and tocopherol contents and profiles, (e) oxidative stability, and (f) the theoretical number of frying operations at which the three Picual VOOs must be discarded.

## MATERIALS AND METHODS

**Olive Harvesting, Ripening Index, and Oil Elaboration.** Olives of Picual variety were harvested during the 2011/2012 olive season in the Agricultural Experimental Station "La Chimenea", Instituto Madrileño de Investigación y Desarrollo Rural, Agrario y Alimentario (IMIDRA), located in the region of Madrid (Spain).

About 35 kg of olives was hand-picked in perfect sanitary conditions from olives trees at three ripening stages at three weekly intervals from November 19 to December 31. These three ripening stages were selected according to the normal harvesting period for the Picual olive variety. The olive ripening index was determined according to the method described by Uceda and Frias[26] based on the evaluation of the olive skin and pulp colors. Seven maturity states of the fruit (0, bright green skin; 1, green-yellowish skin; 2, green skin with reddish spots; 3, reddish-brown skin; 4, black skin with white flesh; 5, black skin with <50% purple flesh; 6, black skin with ≥50 and >100% purple flesh; and 7, black skin and purple flesh) were used.[22]

Olive oils were extracted using the Abencor system (MC2 Ingenierías y Sistemas, Sevilla, Spain). The oil was decanted, filtered, transferred into 500 mL amber glass bottles, and stored at 4 °C in darkness until analysis. Approximately 4.6 L of VOO was obtained in the first harvesting, 5.0 L in the second, and 6.1 L in the third.

**Fresh Potato Frying.** Domestic deep-fat fryers of 1.1 L stainless steel vessel equipped with a thermostat (SOLAC, Vitoria, Spain) were used for potato frying. A total of six fryers, two per VOO, were used. Spunta variety fresh potatoes (Valencia, Spain) were fried. The proportion of food to frying oil in the repeated frying was kept at 183 g to 1.1 L by replenishment with unused oil every five frying operations to maintain, insofar as possible, a constant food/oil ratio. Oil was heated to 180 °C for about 10 min. Potatoes were sliced to 2 mm thick using a mandolin slicer and introduced into the oil at 180 °C and fried for 8 min. Oil was allowed to cool until 30−35 °C between same-day fryings. The cooling time was approximately 4 h between frying operations. On the basis of previous studies,[27,28] a total of 40 frying operations at the rate of 4 fryings per day were performed with each VOO. The whole procedure was performed in duplicate by using two fryers for each oil. Thirty-five milliliters of oil from each of the two fryers was taken after 5, 10, 15, 20, 25, 30, 35, and 40 frying operations and kept frozen at −20 °C until analysis.

**Fatty Acid Profile.** Analysis of the fatty acid composition of oils was performed by GC after derivatization to fatty acid methyl esters (FAME) with 2 N KOH in methanol.[29] FAME were analyzed by GC using a chromatograph (Agilent Technologies 6850 series II network GC system) equipped with one capillary column Supelco 24111 of 60 m × 0.25 mm i.d. × 0.20 μm (Agilent Technologies). Samples were introduced into the column at 170 °C during 30 min; after this time, the temperature was increased at 5 °C/min to 200 °C and maintained for 12 min. The flow rate of He, used as carrier gas, was 0.6 mL/min. Injector and flame ionization detector temperatures were 230 and 250 °C, respectively.

The absolute amount of each individual FAME was calculated by multiplying the percentage of each FAME by the amount of nonoxidized fatty acid monomers (FAM) giving results equivalent to those obtained using internal standard.[30]

**Polar Compound Assessment.** Total PC contents in the unused oil and used frying oils were determined by gravimetric measurement using silica column chromatography.[23] One gram of sample was separated by column chromatography using 150 mL of hexane/diethyl ether (90:10, v/v) and 150 mL of diethyl ether to elute the nonpolar and polar fractions, respectively.

**Quantitation of Thermal Oxidation and Hydrolytic Compounds.** To obtain further information about changes due to thermal oxidation and hydrolysis during frying, high-performance size exclusion liquid chromatography (HPSEC) analysis of the PC fraction present in the unused and used frying oils was performed following a slight modification of the AOCS method.[23] Briefly, a sample concentration of the previously isolated PC (10−15 mg/mL tetrahydrofuran) was applied in a high-performance liquid chromatograph (HPLC) (Agilent 1100 series, Madrid, Spain) with a 20 μL sample loop. A refractive index detector (Agilent Technologies 1260 infinity, Madrid, Spain) and two 300 mm × 7.5 mm i.d. (5 μm particle size), 0.01 and 0.05 μm, PL gel columns (Agilent, Bellefonte, PA, USA), connected in series, were operated at 40 °C. HPLC grade tetrahydrofuran was used as the mobile phase with a flow of 1 mL/min. Polymers of triglycerides (PTG), dimers of triglycerides (DTG), oxidized triglycerides (OTG), diglycerides (DG), monoglycerides (MG), and free fatty acids (FFA) were quantified in the PC fraction. Hydrolytic compounds (HC) were calculated as the sum of DG, MG, and FFA, whereas thermally oxidized compounds (TC) were calculated as the sum of PTG, DTG, and OTG. Oligomers (OLIG) were calculated as the sum of DTG and PTG.

**Isolation and Quantitation of Altered and Unaltered Fatty Acid Methyl Esters.** Samples of the unused and used frying oils were saponified during 10 min with 0.5 N NaOH in methanol. Methylation was performed according to an AOAC method,[31] using 20% $BF_3$ in methanol, and required 15 min. After methylation, 1 g of sample was separated by column chromatography using 150 mL of hexane/diethyl ether (88:12, v/v) and 150 mL of diethyl ether to elute the nonpolar and polar fractions of methyl esters, respectively.[4,25] Thermal fatty acid dimers (thermal-FAD) and nonoxidized FAM were quantified in the nonpolar fraction, whereas fatty acid polymers (FAP), oxidized fatty acid dimers (oxFAD), and oxidized fatty acid monomers (oxFAM) were quantified in the polar fraction. Aliquot samples of both fractions (10−15 mg/mL tetrahydrofuran) were injected in a HPLC (Agilent 1100 series) with a 20 μL sample loop. The same equipment (refractive index detector and columns) and conditions (temperature and mobile phase flow) as for thermal oxidation and hydrolytic compound quantitations were used.

**Oxidative Stability.** Oxidative stability was analyzed in unused and used frying oils using the Rancimat equipment at 120 °C (Metrohm Ltd., Herisau, Swiss) with a continuous air flow of 20 L/h passing and 2.5 g oil samples. The inflection point of the curve was assigned as the induction time, measured in hours.[32,33]

**Determination of Total Polyphenolic Compounds.** Total phenolic compounds in unused and used frying oils were determined after methanol extraction and subsequent reaction with Folin−Ciocalteu reagent and measured in a Lambda 25 UV−vis spectrophotomer (PerkinElmer, Waltham, MA, USA) at a wavelength of 725 nm.[34]

**Determination of Tocopherols.** The determination of α- and γ-tocopherols present in unused and used frying oils was carried out by HPLC according to IUPAC methods.[35]

**Statistical Analyses.** All determinations were done in duplicate. The Pearson product−moment correlation test was used to find correlations between parameter data. Linear adjustments between the concentration of polar compounds, different thermal oxidation and hydrolytic compounds, various methyl esters compounds, and frying number were assessed. A stepwise multiple regression procedure was used to identify which of the following parameters, total phenolic content, tocopherol content, oleic, linoleic, and linolenic acids, explained better the extent of VOO thermal oxidation during frying. Regression collinearity diagnostics and regression case wise diagnostics were performed to prevent multicollinearity and influential cases. The SPSS 15.0 statistical packet was employed. Comparisons between linear adjustments for the different compounds in the three VOOs were checked by ANCOVA test using SAS 9.2 statistical package. Statistical significance was set at $p < 0.05$.

## RESULTS AND DISCUSSION

**Unused Picual Virgin Olive Oil Characteristics.** Picual olives showed ripening indices of 4.9, 5.3, and 6.0 at the three ripening stages (VOO1, VOO2, and VOO3, respectively), which are normal values for this olive fruit variety.[22]

Initial fatty acid composition of the three VOOs obtained is shown in Table 1. VOO1 showed lower oleic acid and higher palmitic acid than the other two VOOs. Baccouri et al.[36] reported in virgin olive oils extracted from diverse fruits of selected oleasters that "at the beginning of fruit development, palmitic acid content was high, followed by an extreme decrease, then it remained unchanged until the end of fruit development" (sic), suggesting that very green olives are richer in this saturated fatty acid. Ontogenesis of the enzymes participating in the biosynthesis of oleic acid in olives seems to be important in determining the oil fatty acid profile and phenol content.[20] Stearoyl-acyl carrier protein (stearoyl-ACP) is obtained from acetyl-CoA by the action of an enzymatic complex called fatty acid synthase I and III (FAS III/I) followed by FAS II. Stearoyl-ACP is desaturated to oleoyl-ACP (C18:1-ACP) by the stearoyl-ACP Δ9-desaturase, which is highly active in the plastids.[20] As growth proceeds, desaturase transcripts accumulate at higher levels, and the high transcription rate remains up to 28 weeks after flowering. This transcription pattern observed during fruit development parallels well with the synthesis of oleic acid in olives.[37] Thus, Δ9-desaturase converting stearoyl in oleoyl moieties could be less active in less ripened olives.

Unused VOOs presented total PC levels ranging from 1.85 to 2.54 g per 100 g of oil (Table 2). These results suggest the good quality of the oils tested as the PC of fresh oils normally ranges between 0.4 and 6.4 g per 100 g of oil[38] and agree with previous findings of our group in olive oil[28] and extra VOO.[39] Similarly to other quality olive oils[28,39] DG were the major compounds in the polar fraction of the unused oils, whereas PTG and MG were rather low or not detected at all (Tables 2 and 3). Nevertheless, the VOO1 oil exhibited the lowest PC and OTG levels followed by the VOO2 oil. In addition, the TC/HC ratio also increased from VOO1 to VOO3 (Table 3).

As expected, unused VOOs showed low amounts of polar-ME, suggesting that the Picual monovarietal tested oils were

good-quality oils (Table 4). oxFAM where the main compounds followed by far from oxFAD as thermal-FAD and FAP were not detected in the polar-ME of the three unused VOOs tested. These results agree with those reported in previous studies.[40]

The determination of the oxidative stability of VOOs by the Rancimat test is a widely used method, as it is an easy, standardized, and well-controlled method. The oxidative stability, given by the Rancimat method, also decreases with olive fruit ripening, with values of 12.9, 7.6, and 4.0 h in VOO1, VOO2, and VOO3, respectively (Figure 1A). Total tocopherol content exhibited values of 236, 207, and 189 ppm in VOO1, VOO2, and VOO3, respectively (Figure 1B). $\alpha$-Tocopherol was the most abundant isoform of vitamin E in the three VOOs (about 92−93% of the total tocopherol content). Picual VOO1, VOO2, and VOO3 showed average total polyphenol contents of 394, 289, and 78 ppm, respectively (Figure 1C). Differences in the polyphenol content between VOOs were high, suggesting a dramatic effect of ripening in these antioxidant compounds.[20] Gómez-Rico et al.,[21] Baccouri et al.,[36] Beltrán et al.,[41] and Salvador et al.,[42] reported decreases in phenolic compounds and tocopherol content during olive ripening. Yousfi et al.[22] studied the effect of fruit ripening on the quality of the oil extracted and on the amount of phenolic compounds in the Arbequina and Picual varieties and observed that the oil quality was not affected by fruit ripening or by the increase in rainfall of the season. However, Yousfi et al.[22] reported that the changes in oil stability and phenolic compounds strongly differ depending on olive variety and ripeness of the olives from which oils were obtained.

**Oils Changes during Repeated Potato Frying.** *Changes in the Fatty Acid Composition.* As commented, VOO1 presented a higher amount of SFA. The differences in the fatty acid profile of the three tested VOOs have probably determined, at least partially, that VOO1 showed higher stability during frying (Table 1). It is well-known that oils rich in saturated fatty acids are highly thermostable.[1,43] Nonetheless, VOO1 also presents higher amounts of tocopherols and phenolic compounds, contributing to the higher thermal stability of VOO1.

After 40 frying operations, linoleic and linolenic acids markedly decreased (72−74 and 33.3−51.3%, respectively), whereas little difference was observed for oleic acid. These results are in line with general frying bibliography, reflecting that oleic acid decreases relevantly only when reduced linoleic acid content remains in the oil.[3,39,44] Results also confirm that the degradation rate of unsaturated fatty acids is higher than that of monounsaturated and saturated ones.

*Polar Content and Thermal Oxidation and Hydrolytic Changes during 40 Fryings.* As reported in previous studies with olive oils,[3,16,28,39,45] thermal oxidation compounds increased with the number of frying operations, whereas hydrolytic alteration products remained quite stable (Table 2). Casal et al.,[46] frying potatoes with commercial monovarietal extra VOO from the same cultivar region, a refined sunflower oil, and a refined oil and VOO blend, also observed PC increases. These authors reported that PC increased with the number of frying operations in all oils but that extra VOO showed the highest stability, whereas sunflower oil reached the 25% PC cutoff point at least 9 h before the other oils. However, in the present study, after 40 frying operations, the PC and OLIG contents (Table 2) were far from legal limits.[24] Table 2 also shows that after 40 frying operations, a large proportion of the polar fraction (~75%) was constituted by OTG and DTG and to a lesser degree by PTG. Changes in PC and thermal oxidation compounds but not those of most hydrolytic compounds were significantly fitted to linear adjustments (Table 5). These linear adjustments explain >92% ($r^2$ > 0.92) of the data variability of all the thermal oxidation compounds tested.

Previous studies by our group indicate that oil thermal oxidation changes fit linear adjustments when frying was

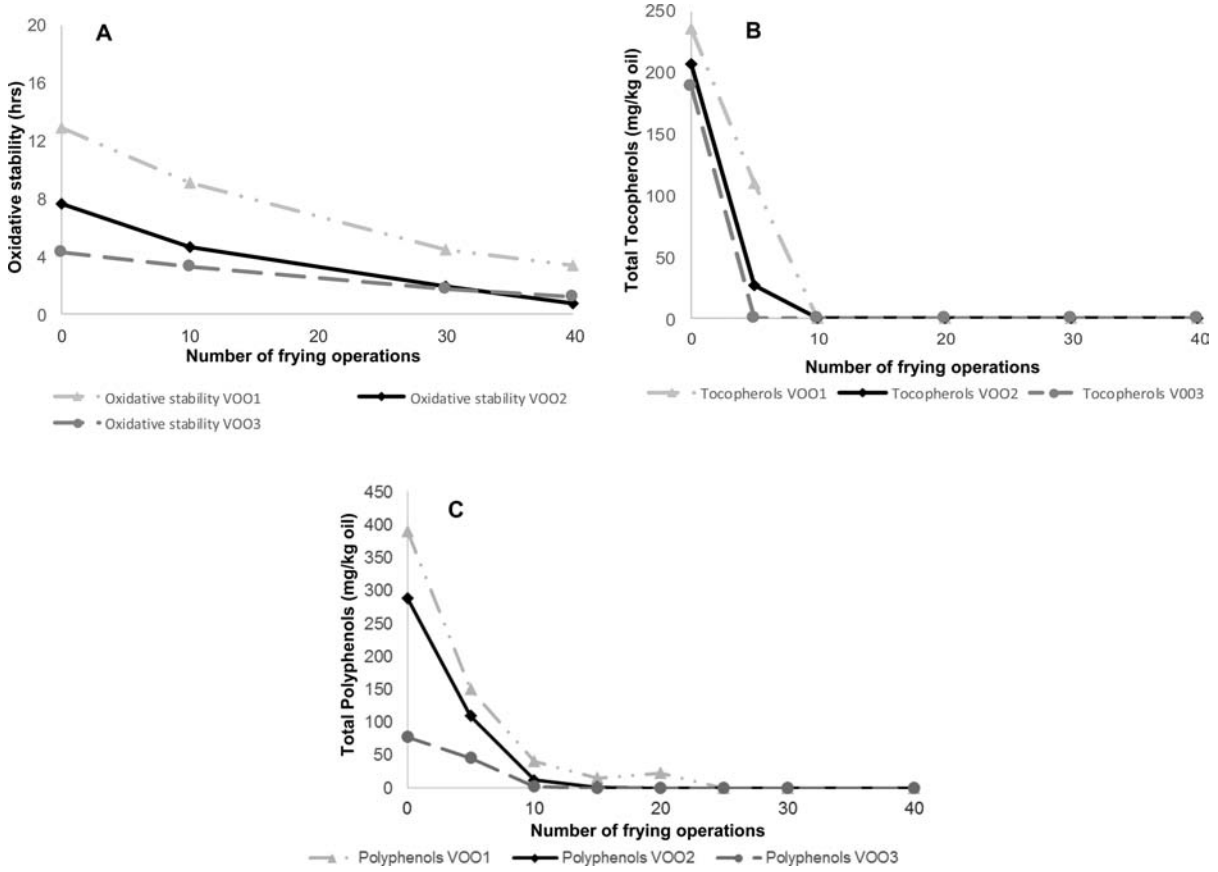

**Figure 1.** Changes in the oxidative stability, total tocopherols, and total polyphenols during 40 discontinuous fryings with virgin olive oils (VOO). (A) Oxidative stability changes (h) in the three Picual VOOs. VOO1, VOO2, and VOO3 correspond to virgin olive oils obtained from Picual olives at different ripening periods; for more details see text. Linear adjustment: $Y$ = intercept (with their values 95% CI) + slope (with their values 95% CI) × $X$, where $Y$ is the oxidative stability and $X$ the number of frying operations: (▲) VOO1, $Y$ = 11.571 (9.900; 13.242) − 0.236 (−0.309; −0.163) × $X$; $r^2$ = 0.839; ($p$ < 0.01); (♦) VOO2, $Y$ = 6.621 (5.567; 7.676) − 0.167 (−0.213; −0.121) × $X$; $r^2$ = 0.867; ($p$ < 0.01); (●) VOO3, $Y$ = 3.941 (3.484; 4.397) − 0.087 (−0.098; −0.058) × $X$; $r^2$ = 0.884; ($p$ < 0.01). Mean values of oxidative stability were significantly different for VOO1 versus VOO3 ($p$ = 0.01) and marginally significant for VOO2 versus VOO3 ($p$ = 0.054) although not significantly different for VOO1 versus VOO2 ($p$ = 0.099). (B) Total tocopherol changes (mg/kg oil) and (C) total polyphenol changes (mg/kg oil) in the three Picual VOOs. VOO1, VOO2, and VOO3 correspond to virgin olive oils obtained from Picual olives at different ripening periods; for more details see text. Nonlinear adjustments were found; thus, comparisons between oils were not performed.

performed with low or null oil turnover but to a power, logarithmic, or quadratic adjustment when frequent turnover was done.[47] The equations presented in Table 5 suggest that during frying of potatoes each frying operation induces increases of 0.307 and 0.317 g/100 g oil of PC and 0.161 and 0.172 mg/100 g oil OLIG in VOO1 and VOO2 oils, respectively, whereas these increases were of 0.412 and 0.222 g/100 g oil of PC and OLIG, respectively, in VOO3 oil. According to OLIG adjustments (Table 5), and in the case of keeping the same experimental frying conditions and trends, the VOO3 oils should be discarded at the 53rd frying, whereas the VOO1 oil should be discarded at the 73rd frying. The increased stability of the oils prepared from olive fruits of minor ripeness index seems to be related to their fatty acid profile and higher (4 and 5 times) polyphenol and higher (14 and 25%) tocopherol contents with respect to their VOO2 and VOO3 oil counterparts.

No linear relationships were found between the frying number and any hydrolytic compounds in any of the Picual VOO tested (data not shown).

*Changes in the Composition of FAME and Formation of Oxidative and Thermal Dimers and Polymers of FAME during 40 Fryings.* Evaluation of specific changes occurring in the fatty acyl chains of triglycerides, by far the most abundant compounds in oils, is an important tool to study in-depth oil degradation.[1] During frying, the formation of dimers (thermal-FAD and oxFAD) and polymers (oxFAD) derived of FAME increases the analysis complexity because of the presence of oxygenated (C−O−C) and nonoxygenated (C−C) bindings between triglyceride fatty acyl groups.[1] Following derivatization, results showed that thermal fatty acid monomers (thermal-FAM) and oxidized oxFAM significantly increased with the number of frying study (Table 4). These increases were fitted to linear adjustments (at least $p$ = 0.05) (Table 6). On the contrary, when the number of frying operations increased, nonoxidized FAM decreased (0.133−0.173 g/100 g oil per frying) (Table 6). After 40 frying operations, VOO3 oil showed less nonoxidized FAM and more oxFAM compared with the other two VOOs (Table 4). Linear adjustments for the different FAME related compounds tended to be higher, although in most cases nonsignificant, in VOO3 oil with respect to VOO1 and VOO2 counterparts. VOO1 showed lower polar-ME increase than VOO3 (0.098 vs 0.140 g/100 g oil increase each frying, $p$ = 0.029) (Table 6). Márquez-Ruiz et al.[25] observed a major increase in the altered fatty acid methyl esters content

[a]VOO1, VOO2, and VOO3 correspond to different harvesting periods; for more details see text. [b]Values (95% CI). [c]$p$, lineal regression adjustment. [d]$p$, significant differences between lineal adjustments. PC, polar compounds; PTG, triglyceride polymers; DTG, triglyceride dimers; OLIG, triglyceride oligomers (PTG plus DTG); OTG, oxidized triglycerides; TC, thermal oxidized compounds (PTG, DTG plus OTG); ns, nonsignificant.

when the oils presented higher PC content in sunflower oil, high-oleic sunflower oil, and palm olein submitted to frying or thermal oxidation. Taking into account the correlation between PC and polar-ME found in the present study [polar-ME = PC × 0.345) + 0.855] it can be calculated that 25% PC corresponds to 9.5% polar-ME. Márquez-Ruiz et al.[25] and Sanchez-Muniz et al.[1] reported that PC values between 21 and 27% corresponded to 8−11% total altered fatty acid values. In the case of discarding oils at this 9.5% cutoff point, the VOO1 oil shelf life could be extended up to the 80th frying in contrast with VOO2 and VOO3 oils, which would be used for only 64 and 55 fryings, respectively. These results clearly indicate the highest stability of the oil obtained from olive fruits of low ripening index.

Pokorný and Dostálová[2] and Romero et al.[47,48] have suggested that slightly higher concentrations of these altered compounds are present in food than in the oil media. These results show the benefits of frying potatoes with the most stable oil as fewer alteration compounds are formed in the oil and absorbed by the food during frying.

*Changes in the Oxidative Stability and Tocopherol and Polyphenol Contents.* The oxidative stability of the three VOOs decreased with the number of frying operations. Andrikopoulos et al.[49] observed while obtaining chip potato that the increase in PC with the number of frying operations in VOO and a commercial vegetable oil was related to a decrease in the oxidative stability of both oils. After 40 fryings, VOO1 appears as the most stable (Figure 1A). However, with respect to its respective basal polyphenol content, VOO2 suffered the highest polyphenol losses followed by VOO1. The oxidative stability of the oils was significantly and negatively correlated ($p < 0.001$) with the contents of PC, OLIG, OTG, and TC and the TC/HC ratio and positively correlated (at least $p < 0.05$) with the TC/OLIG ratio (Table 7). Similarly, the oxidative stability was significantly and negatively correlated (at least $p < 0.01$) with polar-ME and oligomers of methyl esters (oligomers-ME) and positively correlated ($p < 0.001$) with nonpolar-ME (Table 7). The highest stability found for VOO1 with respect to VOO2 and VOO3 was closely related with the loss of tocopherols because approximately 50% of tocopherols remained after five frying operations in VOO1, and only 10% of basal levels remained in VOO2, whereas tocopherols were not detected in VOO3. Nevertheless, tocopherols were exhausted in all tested oils beyond the 10th frying operation (Figure 1B). Frying potatoes with olive oil, Chatzilazarou et al.[3] found a decrease of 41.2% after 10 h of frying, whereas Andrikopoulos et al.[49] described a retention of 50% of tocopherols after only three successive deep-fryings. Márquez-Ruiz et al.[40] suggested that oxidized triglyceride monomers and oligomers significantly increased only when oils were highly depleted in tocopherols.

In the three studied VOOs, the initial total polyphenol content decreased by >50% after six frying operations (Figure 1C). After 10 fryings, the polyphenol contents in VOO1 and VOO2 with respect to their respective basal values were 10 and 5%, respectively, whereas those compounds were not detected in VOO3. These amounts were further reduced as 3.5−5.5% of the initial polyphenol content was found in VOO1 between the 16th and 25th fryings, whereas those compounds were not detected in VOO2 and VOO3 (Figure 1C). Andrikopoulos et al.[49] reported that the major phenols found in virgin olive oils have abruptly diminished (by 50%) after five successive deep-fryings of potatoes. The higher polyphenol content of

[a]VOO1, VOO2, and VOO3 correspond to harvesting period; for more details see text. ∗, $p < 0.05$; ∗∗, $p < 0.01$; ∗∗∗, $p < 0.001$. PC, polar compounds; OLIG, triglyceride polymers plus of triglyceride dimers; OTG, oxidized triglycerides; TC, thermal oxidized compounds (PTG plus DTG plus OTG); DG, diglycerides; MG, monoglycerides; FFA, free fatty acids; HC, hydrolytic compounds (DG plus MG plus FFA); polar-ME, polar methyl esters (fatty acid polymers plus oxidized fatty acid dimers plus oxidized fatty acid monomers); nonpolar-ME, nonpolar methyl esters; total OLIG-ME, total oligomers of methyl esters (fatty acid polymers plus thermal fatty acid dimers plus oxidized fatty acid dimers).

VOO1 throughout repeated fryings is probably due to its initial higher value and to the partial turnover of oil performed after each five fryings to keep the food/oil ratio constant. None of the three VOOs showed polyphenol detectable amounts after the 25th frying.

To identify which parameters explained better the extent of VOO thermal oxidation during frying, the basal contents of total polyphenols, total tocopherols, and oleic, linoleic, and linolenic acids were correlated with the polar content change. Polyphenols ($r = -0.928$; $p = 0.008$) and tocopherols ($r = -0,870$; $p = 0.024$) were negatively and significantly correlated, whereas the other parameters did not show significant relationships. According to the stepwise multiple-regression procedure, a total polyphenol content of unused VOOs explains about 86% ($p = 0.008$) of data variability for the extent of oil thermal oxidation (as polar content change) during 40 fryings in our experimental conditions. Other parameters of the unused VOOs tested were excluded from the stepwise multiple-regression model. This confirms the hypothesis that olive oil phenols play an important antioxidant role during frying.[2,10,49]

In conclusion, Picual olive ripeness affects the VOO composition and stability. Although repeated fryings increased the concentration of all thermal oxidation compounds and decreased the oxidative stability in the three VOOs studied,

oil stability was higher and degradation lower during frying in the VOOs obtained from olives of lower ripeness index. As the potential toxicity of oils used in repeated fryings is ascribed to the amount and profile of alteration compounds, the repeated domestic potato frying with VOO obtained from low ripeness index olives should be recommended to obtain high-quality fried potatoes.

**Figure 1.** Structures of analytes included in the method.

for 2-MCPD esters in edible oils. The scope of these methods has been expanded, as described herein, resulting in the first approach capable of determining exposure to intact 2-MCPD esters in edible oils. The method targets 14 2-MCPD esters (11 2-MCPD diester standards and 3 2-MCPD monoester standards) (see Figure 1) based on palimitic, linolenic, linoleic, oleic and stearic acid. Eleven standards were synthesized to target >90% of the 2-MCPD likely to be found in most commonly consumed edible oils. The method performance has been validated in soybean oil, olive oil, and palm oil matrices at spiked concentrations as low as 100 ng/g (ppb).

## MATERIALS AND METHODS

**Reagents and Materials.** Deuterated internal standards 1,2-dioleoyl-3-chloropropanediol-$d_5$ (3Ol-Old5) (CAS Registry No. 1246933-00-0), 1,2-dilinoleoyl-3-chloropropanediol-$d_5$ (3Li-Lid5), linoleoyl-linolenoyl-3-chloropropanediol-$d_5$ (3Li-Lnd5), palmitoyl-stearoyl-3-chloropropanediol-$d_5$ (3Pa-Std5), 1,2-distearoyl-3-chloropropanediol-$d_5$ (3St-Std5) (CAS Registry No. 1246818-85-8), 1-oleoyl-3-chloropropanediol-$d_5$ (1-Ol3-d5), and 1-palmitoyl-3-chloropropanediol-$d_5$ (1-Pa3-d5) were purchased from Toronto Research Chemicals (Toronto, ON, Canada). Standards 2-chloro-1,3-propanediol (2-MCPD) (CAS Registry No. 497-04-1), 1,3-distearoyl-2-chloropropandiol (2 St-St) (CAS Registry No. 26787-56-4), 1,3-dilinoleoyl-2-chloropropanediol (2Li-Li), 1-linoleoyl-3-linolenoyl-2-chloropropanediol (2Li-Ln), 1-palmitoyl-3-chloropropanediol (1-Pa3) (CAS Registry No. 30557-04-1), 1-linoleoyl-3-chloropropanediol (1-Li3) (CAS Registry No. 74875-98-2), 1-oleoyl-3-chloropropanediol (1-Ol3) (CAS Registry No. 10311-82-7), 2-oleoyl-3-chloropropanediol (2-Ol3) (CAS Registry No. 915297-48-2), 2-palmitoyl-3-chloropropanediol (2-Pa3) (CAS Registry No. 20618-92-2), linoleoyl-linolenoyl-3-chloropropanediol (3Li-Ln), dilinoleoyl-3-chloropropanediol (3Li-Li) (CAS Registry No. 74875-96-0), palmitoyl-linoleoyl-3-chloropropanediol (3Pa-Li) (CAS 1246833-87-3), oleoyl-linoleoyl-3-chloropropanediol (3Ol-Li) (CAS Registry No. 1336935-03-5), dipalmitoyl-3-chloropropanediol (3Pa-Pa) (CAS Registry No. 51930-97-3), palmitoyl-oleoyl-3-chloropropanediol (3Pa-Ol) (CAS Registry No. 1363153-60-9), dioleoyl-3-chloropropanediol (3Ol-Ol) (CAS Registry No. 69161-73-5), stearoyl-linoleoyl-3-chloropropanediol (3St-Li) (CAS Registry No. 1246833-46-4), palmitoyl-stearoyl-3-chloropropanediol (3Pa-St) (CAS Registry No. 1185060-41-6), oleoyl-stearoyl-3-chloropropanediol (3Ol-St) (CAS Registry No. 1336935-05-7), and distearoyl-3-chloropropanediol (3St-St) (CAS Registry No. 72468-92-9) were purchased from Toronto Research Chemicals. Standards for 2-MCPD esters 1-palmitoyl-2-chloropropanediol (1-Pa2) (CAS Registry No. 63326-63-6), 1-linoleoyl-2-chloropropanediol (1-Li2), 1-oleoyl-3-chloropropanediol (1-Ol2), palmitoyl-linoleoyl-2-chloropropanediol (2Pa-Li), oleoyl-linoleoyl-2-chloropropanediol (2Ol-Li), dipalmitoyl-2-chloropropanediol (2Pa-Pa) (CAS Registry No. 169471-41-4), palmitoyl-oleoyl-2-chloropropanediol (2Pa-Ol), dioleoyl-2-chloropropanediol (2Ol-Ol), stearoyl-linoleoyl-2-chloropropanediol (2St-Li), palmitoyl-stearoyl-2-chloropropanediol (2Pa-St), and oleoyl-stearoyl-2-chloropropanediol (2Ol-St) were synthesized according to the procedures described herein,

and their purity was confirmed by $^1$H NMR. *N,N′*-Dicyclohexylcarbodiimide (DCC) (CAS Registry No. 538-75-0), 4-(dimethylamino)-pyridine (DMAP) (CAS Registry No. 1122-58-3), carbon tetrachloride ($CCl_4$) (CAS Registry No. 56-23-5), and silica gel ($SiO_2$) (70−230 mesh, pore size = 40 Å) (CAS Registry No. 112926-00-8) were purchased from Sigma-Aldrich (St. Louis, MO, USA). Liquid chromatographic grade acetonitrile (ACN), isopropanol (IPA), methanol (MeOH), water ($H_2O$), *n*-hexane (hexane), ethyl acetate (EtOAc), methyl *tert*-butyl ether (MTBE), and diethyl ether ($Et_2O$) were from Burdick and Jackson. Formic acid and ammonium formate were of HPLC grade from Sigma-Aldrich. A Visiprep SPE manifold and Branson 2510 ultrasonic cleaner were purchased from Sigma-Aldrich. Silica SPE cartridges (500 mg Si, 3 mL and 1000 mg Si, 6 mL) and $C_{18}$ SPE cartridges (1000 mg $C_{18}$, 6 mL) were purchased from Supelco. Disposable 15 mL glass tubes were purchased from Thermo Fisher Scientific (Pittsburgh, PA, USA). A DB-3 Dri-Block Heater and Sample Concentrator were purchased from Bibby Scientific (Burlington, NJ, USA). Clear glass HPLC vials with preslit PTFE caps were purchased from National Scientific (Rockwood, TN, USA). Soybean oil and extra virgin olive oil were purchased from a local grocery store. Organic palm oil was purchased from Sigma-Aldrich.

**Synthesis of Analytical Standards.** The protocol is based on a published procedure for the synthesis of esters.[22]

*Synthesis of 2-MCPD Monoesters (1-Li2, 1-Ol2, 1-Pa2).* A solution of 2-chloro-1,3-propanediol (1 mmol) and the appropriate fatty acid (0.3 mmol) in $CCl_4$ (5 mL) was stirred at room temperature under nitrogen. A solution of DCC (1.1 mmol) and DMAP (0.3 mmol) in $CCl_4$ (3 mL) was added dropwise with stirring, and the resulting solution was stirred for 5 h. The solution was filtered, the solvent was removed in a rotary evaporator, and the material was purified by column chromatography ($SiO_2$, 20% ethyl acetate in hexane, 1-Li2 $R_f$ = 0.32; 1-Pa2 $R_f$ = 0.33; 1-Ol2 $R_f$ = 0.35). Identity and purity (95+%) were confirmed by LC-MS/MS and $^1$H NMR (400 MHz, $CDCl_3$) (1-Li2 LC-MS *m/z* 390.3 (M + $NH_4$): $^1$H NMR $\delta$ 0.9 (3H, t), 1.3 (14H, m), 1.6 (2H, m), 2.1 (4H, q), 2.4 (2H, t), 2.8 (2H, t), 3.8 (2H, m), 4.1 (1H, m), 4.3 (1H, m), 4.4 (1H, m), 5.3 (4H, m). 1-Pa2 (LC-MS *m/z* 366.2 (M + $NH_4$): $^1$H NMR $\delta$ 0.9 (3H, t), 1.3 (24H, m), 1.6 (2H, p), 2.2 (2H, t), 3.8 (2H, m), 4.1 (1H, m), 4.3 (1H, m), 4.4 (1H, m). 1-Ol2 (LC-MS *m/z* 392.3 (M + $NH_4$): $^1$H NMR $\delta$ 0.9 (3H, t), 1.3 (20H, m), 1.6 (2H, p), 2.0 (4H, m), 2.4 (2H, t), 3.8 (2H, d), 4.1 (1H, p), 4.3 (1H, m), 4.4 (1H, m), $\delta$ 5.3 ppm (2H, m).

*Synthesis of Symmetrical 2-MCPD Diesters (2Pa-Pa, 2Ol-Ol).* A solution of 2-chloro-1,3-propanediol (1 mmol) and the appropriate fatty acid (5 mmol) in $CCl_4$ (5 mL) was stirred at room temperature under nitrogen. A solution of DCC (5 mmol) and DMAP (0.3 mmol) in $CCl_4$ (3 mL) was added dropwise with stirring, and the resulting solution was stirred for 5 h. The solution was filtered, the solvent was removed in a rotary evaporator, and the material was purified by column chromatography ($SiO_2$, 7% ethyl acetate in hexane, 2Pa-Pa $R_f$ = 0.48; 2Ol-Ol $R_f$ = 0.46). Identity and purity (95+%) were confirmed by LC-MS/MS and $^1$H NMR (400 MHz, $CDCl_3$) 2Pa-Pa (LC-MS *m/z* 604.5 (M + $NH_4$): $^1$H NMR $\delta$ 0.9 (6H, t), 1.3 (48H, m), 1.6 (4H, p), 2.2 (4H, t), 4.2 (1H, m), 4.3 (4H, m). 2Ol-Ol (LC-MS *m/z* 656.5 (M + $NH_4$), $^1$H NMR $\delta$ 0.9 (6H, t), 1.3 (40H, m), 1.6 (4H, p), 2.0 (8H, m), 2.4 (4H, t), 4.1 (1H, p), 4.2 (4H, m), 5.3 (4H, m).

*Synthesis of Unsymmetrical 2-MCPD Diesters (2Pa-Li, 2Pa-Ol, 2Pa-St, 2Ol-St, 2Ol-Li, 2 St-Li).* A solution of the appropriate 2-MCPD monoester (0.7 mmol) and the appropriate fatty acid (3.5 mmol) in $CCl_4$ (5 mL) was stirred at room temperature under nitrogen. A solution of DCC (3.5 mmol) and DMAP (0.3 mmol) in $CCl_4$ (3 mL) was added dropwise with stirring, and the resulting solution was stirred for 5 h. The solution was filtered, the solvent was removed in a rotary evaporator, and the material was purified by column chromatography ($SiO_2$, 20% ethyl acetate in hexane, 2Pa-Li, 2Ol-Li, 2 St-Li, 2Ol-St $R_f$ = 0.46; 2Pa-Ol $R_f$ = 0.48; 2Pa-St $R_f$ = 0.50). Identity and purity (95+%) were confirmed by LC-MS/MS and $^1$H NMR (400 MHz, $CDCl_3$) 2Pa-Li (LC-MS *m/z* 628.5 (M + $NH_4$), $^1$H NMR: $\delta$ 0.9 (6H, m), 1.3 (38H, m), 1.6 (4H, m), 2.2 (4H, m), 2.4 (4H, t), 2.8 (2H, t), 4.2 (1H, m), 4.3 (4H, m), 5.3 (4H, m). 2 Pa-Ol (LC-MS *m/z* 630.5 (M + $NH_4$), $^1$H NMR: $\delta$ 0.9 (6H, t), 1.3 (44H, m), 1.6 (4H, p), 2.0 (4H, m), 2.4 (4H, t), 4.1 (1H, p), 4.2 (4H, m), 5.3 (2H, m). 2 Pa-St (LC-MS *m/z* 632.5 (M + $NH_4$), $^1$H NMR: $\delta$ 0.9 (6H, t), 1.3 (52H, m), 1.6 (4H, p), 2.2 (4H, t), 4.2 (1H, m), 4.3 (4H, m). 2Ol-St (LC-MS *m/z* 658.5 (M + $NH_4$), $^1$H NMR: $\delta$ 0.9 (6H, t), 1.3 (48H, m), 1.6 (4H, p), 2.0 (4H, m), 2.4 (4H, t), 4.1 (1H, p), 4.2 (4H, m), 5.3 (2H, m). 2Ol-Li (LC-MS *m/z* 654.5 (M + $NH_4$), $^1$H NMR: $\delta$ 0.9 (6H, m), 1.3 (34H, m), 1.6 (4H, m), 2.2 (8H, m), 2.4 (4H, t), 2.8 (2H, t), 4.2 (1H, m), 4.3 (4H, m), 5.3 (6H, m). 2 St-Li (LC-MS *m/z* 656.5 (M + $NH_4$), $^1$H NMR: $\delta$ 0.9 (6H, m), 1.3 (42H, m), 1.6 (4H, m), 2.2 (4H, m), 2.4 (4H, t), 2.8 (2H, t), 4.2 (1H, m), 4.3 (4H, m), 5.3 (4H, m).

**Standard Solutions.** Individual stock solutions of 500−1000 $\mu$g/mL (ppm) of each standard were prepared by weighing the appropriate amount of each reference standard (corrected for composition and purity) into separate tared 10 mL volumetric flasks (5 mL volumetric flasks for $d_5$ internal standards) and brought to volume with IPA. The spiking solution and the standard stock solution (containing 1-Ol, 1-Pa, 1-Li, 3Li-Ln, 3Li-Li, 3Pa-Li, 3Ol-Li, 3Pa-Ol, 3Ol-Ol, 3Pa-Pa, 3St-Li, 3Ol-St, 3Pa-St, 3St-St, 1-Ol2, 1-Pa2, 1-Li2, 2Li-Ln, 2Li-Li, 2Pa-Li, 2Ol-Li, 2Pa-Ol, 2Ol-Ol, 2Pa-Pa, 2St-Li, 2Ol-St, 2Pa-St, and 2St-St at 10 $\mu$g/mL (ppm)) were prepared by pipetting the appropriate volume of each individual stock solution into separate 25 mL volumetric flasks and brought to volume with IPA. The internal standard spiking solution and the internal standard stock solution (containing 1-Ol3-d5, 3Li-Ln-d5, 3Li-Li-d5, 3Ol-Ol-d5, 3Pa-St-d5, and 3St-St-d5 at 5 $\mu$g/mL (ppm)) were prepared by pipetting the appropriate volume of each individual stock solution into separate 10 mL volumetric flasks. One of the flasks was brought to volume with 20% EtOAc/MTBE, generating the internal standard spiking solution. The other flask was brought to volume with IPA, generating the internal standard stock solution. All individual stock solutions were stored at −20 °C and were stable for at least 1 year. The spiking and standard stock solutions were stored at 4 °C and were stable for at least 4 months.

**Sample Preparation.** The sample preparation used was optimized in previous work at the U.S. Food and Drug Administration.[20,21] A 1 g portion of oil was weighed in a tared 5 mL volumetric flask. A 250 $\mu$L aliquot of internal standard spiking solution and an appropriate volume of spiking solution were added to the flask, and the volume was brought to slightly below the 5 mL mark with 20% EtOAc/MTBE. The flasks were sonicated for 2 min to dissolve the entire sample, after which the solution was brought to the 5 mL mark to generate the sample solution.

For the analysis of 2-MCPD monoesters, a 1000 mg/6 mL $C_{18}$ SPE cartridge was preconditioned with 6 mL of ACN. A 200 $\mu$L portion of the sample solution was added to the cartridge; 14 mL of ACN was added and collected in a 15 mL glass tube. The resulting solution was dried at 70 °C under a stream of nitrogen. A 2 mL portion of 20% EtOAc/hexane was added to the glass tube containing the dried residue from the previous SPE cleanup, sonicated for 15 s, added to a 500 mg/3 mL Si cartridge (preconditioned with 3 mL of 20% EtOAc/hexane), and collected in a 15 mL glass tube. Another 2 mL portion of 20% EtOAc/hexane was added to the glass tube, vortex mixed for 15 s, and added to the Si SPE cartridge; this was repeated two more times, totaling 8 mL. A 1 mL portion of 20% EtOAC/hexane was added directly to the Si SPE cartridge, resulting in a total of 9 mL of elution solvent. The resulting solution was dried at 55 °C under a stream of nitrogen, reconstituted in 1 mL of IPA, vortex mixed for 30 s, and transferred to an HPLC vial for analysis.

For the analysis of 2-MCPD diesters, a 1000 mg/6 mL silica SPE cartridge was preconditioned with 5 mL of MeOH, 5.5 mL of dichloromethane, and two 6 mL portions (12 mL total) of 2% $Et_2O$/hexane. A 100 $\mu$L portion of the sample solution was added to a 15 mL glass tube and dried under a stream of nitrogen. A 2 mL portion of 2% $Et_2O$/hexane was added to the glass tube containing the dried residue from the previous step, sonicated for 15 s, added to the Si SPE cartridge, and collected in a new 15 mL glass tube. Another 2 mL portion of 2% $Et_2O$/hexane was added to the glass tube, vortex mixed for 15 s, and added to the Si SPE cartridge; this was repeated two more times, totaling 8 mL. A 5.5 mL portion of 2% $Et_2O$/hexane was added directly to the Si SPE cartridge, resulting in a total of 13.5 mL of

elution solvent. The solution was dried at 55 °C under a stream of nitrogen. A 2 mL portion of 40% EtOAc/ACN was added to the glass tube containing dried residue from the previous SPE cleanup, sonicated for 15 s, added to a 1000 mg/6 mL $C_{18}$ cartridge (preconditioned with 6 mL of 40% EtOAc/ACN), and collected in a new 15 mL glass tube. Another 2 mL portion of 40% EtOAc/ACN was added to the glass tube, vortex mixed for 15 s, and added to the Si SPE cartridge; this was repeated two more times, totaling 8 mL. A 1 mL portion of 40% EtOAc/ACN was added directly to the $C_{18}$ SPE cartridge, resulting in a total of 9 mL of elution solvent. The solution was dried at 70 °C under a stream of nitrogen, reconstituted in 0.500

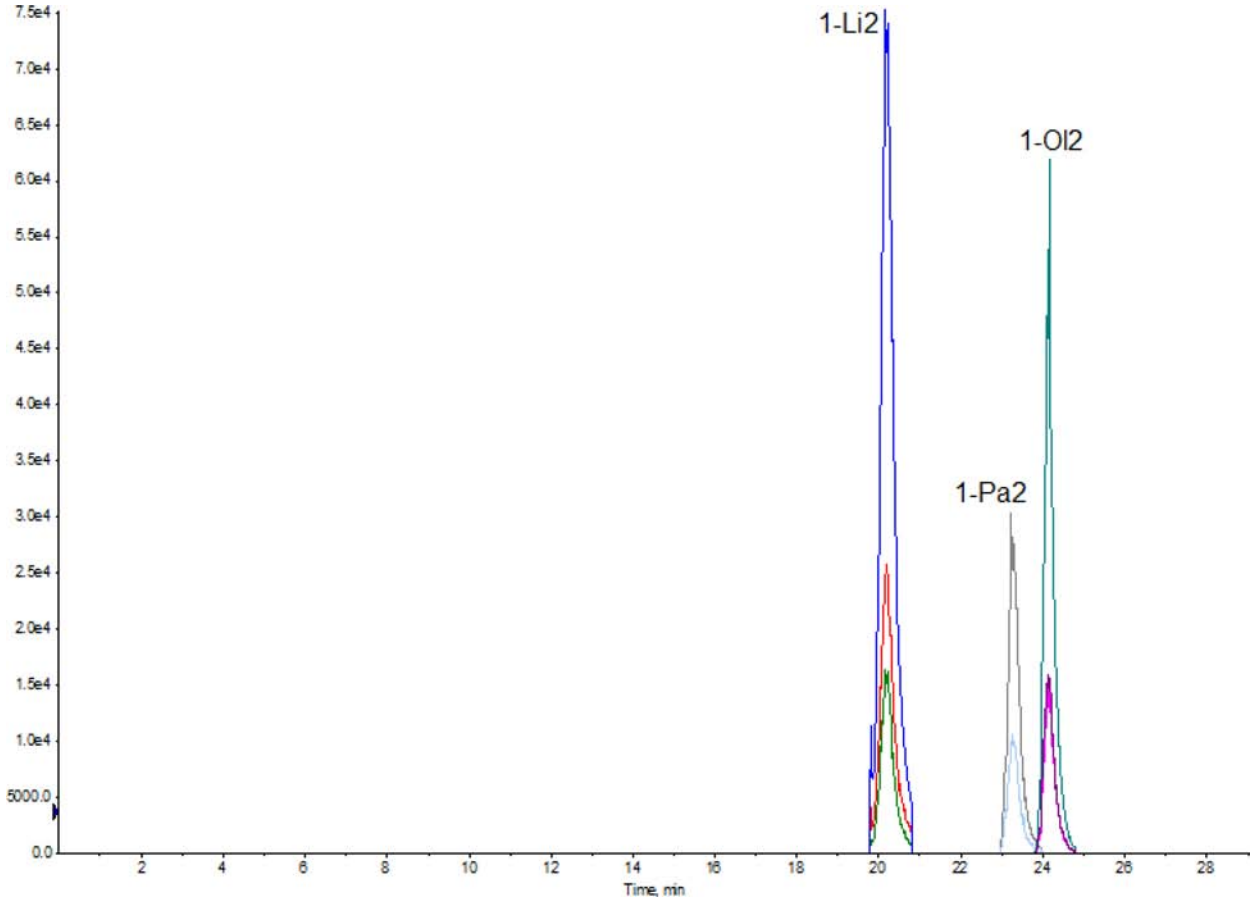

**Figure 2.** LC-MS/MS data for 2-MCPD monoesters.

mL of IPA, vortex mixed for 30 s, and added to an HPLC vial for analysis.

**LC-MS/MS Analysis.** A Prominence UFLC XR liquid chromatography system (Shimadzu, Columbia, MD, USA) with a Pursuit XRs $C_{18}$ column, 2.0 mm × 150 mm with 3.0 $\mu$m particles (Agilent, Santa Clara, CA, USA), was used for the HPLC separation of the 2-MCPD diesters. An initial flow rate of 200 $\mu$L/min of 100% mobile phase A (2 mM ammonium formate/0.05% formic acid in 92:8 MeOH/$H_2O$) was used for the first 2 min (min), stepping to 70% mobile phase A/30% mobile phase B (2 mM ammonium formate/0.05% formic acid in 98:2 IPA/$H_2O$) at 2.1 min, linearly ramped to 50% mobile phase A at 20 min, linearly ramped to 17% mobile phase A at 36 min, stepping to 0% mobile phase A and 250 $\mu$L/min at 36.25 min, holding at 0% mobile phase A until 42.5 min, returning to 100% mobile phase A with the increased flow rate of 250 $\mu$L/min at 42.75 min, holding these conditions until 48.75 min, and returning to initial flow rate of 200 $\mu$L/min at 49 min and stopping the controller. The integrated Valco valve was directed to waste at 0.0 min, to the mass spectrometer at 13.0 min, and to waste at 36.5 min. The injection volume was 5 $\mu$L.

Alternate chromatographic conditions to separate the 2-MCPD monoesters were developed using the same LC system and column described above. An initial flow rate of 200 $\mu$L/min of 100% mobile phase A (2 mM ammonium formate/0.05% formic acid in 75:25 MeOH/$H_2O$) was used for the first 2 min (min), followed by stepping to 70% mobile phase A/30% mobile phase B (2 mM ammonium formate/0.05% formic acid in 98:2 IPA/water) at 2.1 min, holding at 70% mobile phase A until 15 min, linearly ramping to 35% mobile phase A at 30.2 min, stepping to 0% mobile phase A and 250 $\mu$L/min at 30.5 min, holding at 0% mobile phase A until 40.5 min, returning to 100% mobile phase A at 40.75 min, holding at 100% mobile phase A at 250 $\mu$L/min until 46.75 min, returning to the initial flow rate of 200 $\mu$L/min at 47 min, and stopping the controller. The integrated Valco valve was directed to waste at 0.0 min, to the mass spectrometer at 9.0 min, and to waste at 30 min. The injection volume was 5 $\mu$L.

A 5500 QTRAP with an ESI source in positive ion mode with Analyst 1.5.2 software was used to control the LC and the MS (AB Sciex, Foster City, CA, USA). Source parameters such as gas flows, ion spray voltage, and source temperature were optimized for each analyte via T-infusion, combining a 20 $\mu$g/mL standard solution with LC mobile phase, as was collision energy (CE), declustering potential (DP), exit cell potential (CXP), and entrance potential (EP). Q1 and Q3 were set at unit resolution. For the analysis of 2-MCPD diesters, the curtain gas was set at 20 arbitrary units (au), the collisionally activated dissociation (CAD) gas was set at medium, the ion spray voltage was 5500 V, the source temperature was 500 °C, gas 1 pressure was set at 60 au, and gas 2 was 70 au. For the analysis of 2-MCPD monoesters, the curtain gas was set at 20 au, the CAD gas was set at medium, the ion spray voltage was 5500 V, the source temperature was 200 °C, gas 1 pressure was set at 50 au, and gas 2 was 80 au. The individual MS/MS transitions, approximate retention times (RT), internal standards, DP, EP, CE, and CXP for each analyte are shown in Tables 1 and 2 with the quantitation ions listed first, followed by one or two confirmatory ions for each analyte. The precursor ions for the 2-MCPD esters were increased by 0.01 $m/z$ to distinguish them from isomeric 3-MCPD diesters. This does not affect the data on a unit resolution mass spectrometer but is necessary to ensure the results can be processed separately.

Retention times for the target compounds were determined by analyzing a mixed standard under the conditions described above using standard MRM mode (not scheduled MRM). The MS/MS data for all validation samples were collected in scheduled MRM mode with unit resolution in Q1 and Q3, a 5 ms pause between mass ranges, an MRM detection window of 60 s, and a target scan time of 1 s.

**Quantitation.** To calculate recoveries for validation, a nine-point calibration curve with solutions at 1, 2, 5, 10, 25, 50, 125, 250, and 400

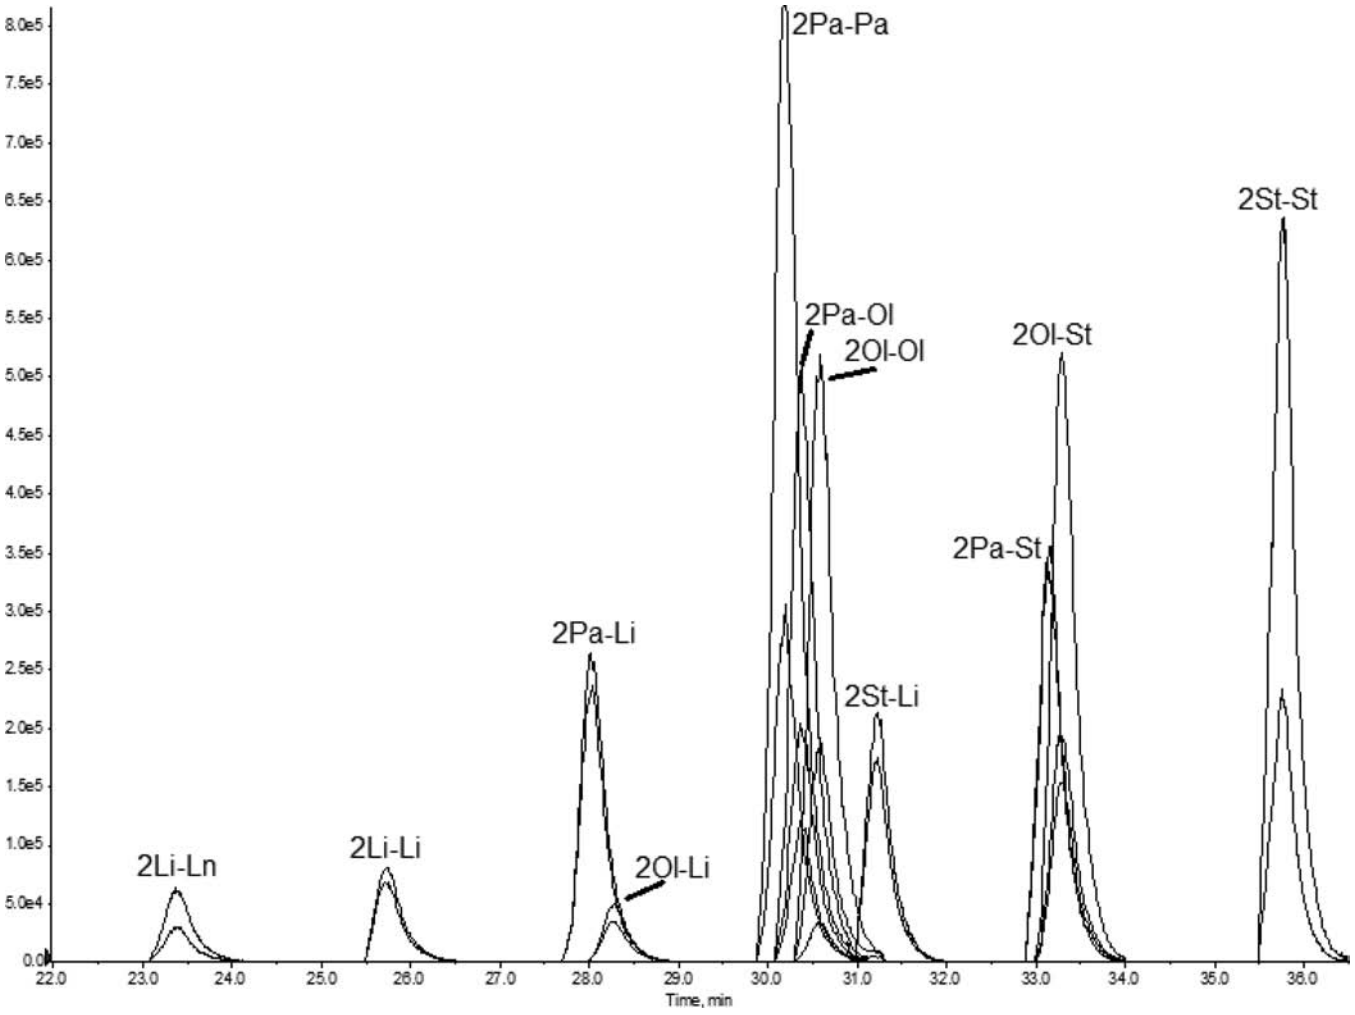

**Figure 3.** LC-MS/MS data for 2-MCPD diesters.

ng/mL (ppb) of each 2-MCPD ester standard (0.05−10.00 μg/g (ppm) on a sample basis), each with 50 ng/mL (ppb) of deuterated internal standard (1.25 μg/g (ppm) on a sample basis), was prepared in IPA and used for quantitation. The calibration curves were generated using the ratio of the MRM chromatographic peak area for each analyte to that of the corresponding internal standard. When appropriate internal standards were not available, analytes were quantified directly by their peak areas. A quadratic calibration curve with $1/X^2$ weighting provided the best fit for the 2-MCPD diesters; a linear fit with $1/X^2$ weighting was the best fit for the monoesters. The $1/X^2$ fit was used to ensure accurate low-end calibration, given the large dynamic range of the curve. All curves had $R^2$ values of ≥0.990.

## RESULTS AND DISCUSSION

**Selection of Standards.** The quality of the occurrence results produced by direct detection of intact 2-MCPD esters is related to the number of standards used in the analysis. Given that only a small number of 2-MCPD esters were commercially available, the standards required for collection of occurrence data in edible oils had to be synthesized. The seven most common fatty acids in edible oils (lauric acid, myristic acid, palmitic acid, linolenic acid, linoleic acid, oleic acid, and stearic acid) can theoretically lead to 28 2-MCPD diesters and 7 2-MCPD monoesters. However, relative 3-MCPD concentrations follow the fatty acid composition of the individual oils, with 2-MCPD ester concentrations likely to show the same trend. As a result, it is possible to target a large percentage of the MCPD esters with a much smaller group of analytical standards. On the basis of theoretical work from Nestlé[23] and later confirmed both by Nestlé's own experimental data[17] and our own occurrence results,[24] a group of nine 2-MCPD diester standards and three 2-MCPD monoester standards ensures >90% of the 2-MCPD will be detected in nearly all commonly consumed edible oils. As only 1 of these 12 standards was commercially available (2Li-Li), the additional fatty acid esters were synthesized to provide adequate detection capability for 2-MCPD in nearly all commonly consumed edible oils (see Figure 1). Representative LC-MS/MS chromatograms for the standards included in the method are shown in Figures 2 and 3. However, due to the absence of standards containing lauric acid and myristic acid, 2-MCPD esters in palm kernel oil and coconut oil will not be accurately accounted for in this method. Although efforts may be made in the future to synthesize additional standards and expand the validation, both oils contain relatively low concentrations of bound 3-MCPD (averages below 0.2 ppm (μg/g))[24] and would likely have low bound 2-MCPD concentrations, as well.

There were no commercially available isotopically labeled 2-MCPD ester standards at the time of analysis. Method development demonstrated that 1-Ol-d5 is a suitable internal standard for all three 2-MCPD monoesters. Average recoveries between 75 and 110% with relative standard deviation (RSD) values <15% demonstrate the success of this approach.

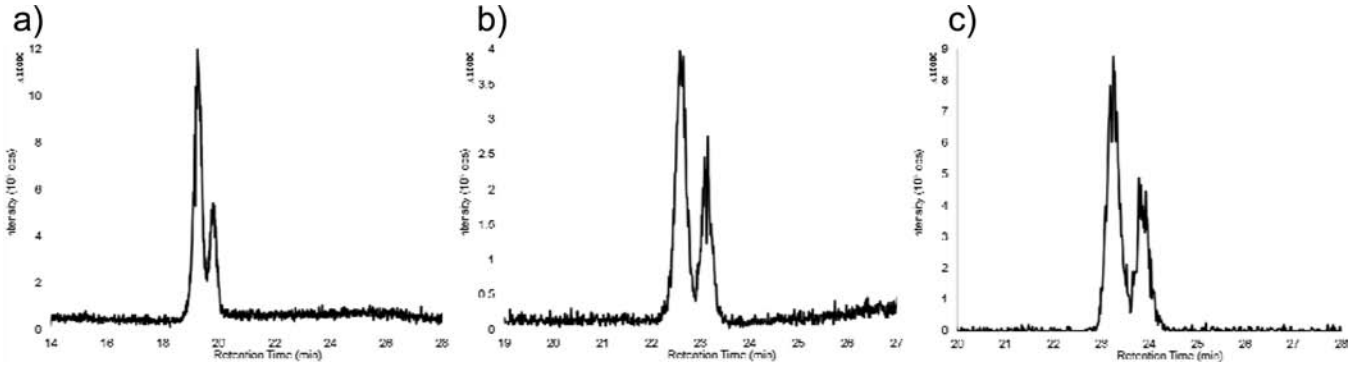

**Figure 4.** LC-MS/MS chromatograms showing the quantitation ion separation of sn-1 3-MCPD monoesters from isomeric 2-MCPD monoesters for (a) 1-Li3 and 1-Li2, (b) 1-Pa3 and 1-Pa2, and (c) 1-Ol3 and 1-Ol2. In all cases, the sn-1 3-MCPD monoester isomer elutes first.

**Method Development.** Standards for 11 of the analytes required for analysis of the most common oils were not commercially available. Because of this, research focused on the synthesis of these compounds, which have not been reported previously. The Steglich esterification was used for the synthesis of the esters[22] with $CCl_4$ as the reaction solvent. This approach leads to precipitation of the dicyclohexylurea reaction by-product, which can be difficult to separate from the desired final products. The reaction was run on a small scale due to the high cost of the 2-MCPD starting material.

The sample preparations for both the 2-MCPD monoesters and 2-MCPD diesters involve two solid-phase extractions. Following the silica cartridge solid-phase extraction, the subsequent $C_{18}$ cleanup for the 2-MCPD diesters does not measurably affect the recoveries of 2-MCPD esters in soybean, palm, or olive oil. The initial silica cleanup removes the majority of the triglycerides, as well as any free fatty acids and partial acylglycerols. The $C_{18}$ preparation is included to remove highly nonpolar material that could negatively affect long-term method and instrument performance. Removal of waxes and other nonpolar matrix components prior to analysis is potentially important in some oils, particularly sunflower oil, as well as in complex foods.

In the analysis of bound 3-MCPD in edible oils, monoesters generally account for a relatively small portion (<15%) of bound 3-MCPD in most oils.[23,24] No direct methods exist for the analysis of 2-MCPD monoesters, so it is unclear if they are actually present in processed oils. The monoesters of 2-MCPD can be separated from isomeric sn-1 3-MCPD monoesters (see Figure 4). However, attempts to chromatographically resolve 2-MCPD monoesters from sn-2 3-MCPD monoesters were not successful. Although they cannot be separated chromatographically, the two isomers have identical MS/MS responses, so it is possible to accurately quantify their combined concentration. However, given the differences in toxicology between 2-MCPD and 3-MCPD, they need to be separated for use in occurrence data. Alternate methods for their separation and individual quantitation are currently being explored. All 2-MCPD diesters were separated chromatographically from isomeric 3-MCPD diesters (see Figure 5).

Due to isomerism in 3-MCPD diesters containing two different fatty acids, the MS/MS fragment produced by the loss of $NH_4Cl$, although not the base peak, was used as the quantitation ion.[21] Unlike 3-MCPD diesters, 2-MCPD diesters with two different fatty acids exist as a single isomer, with the chlorine always occupying the sn-2 position. As a result, fragment ion selection for quantitation is not an issue and the cyclic acyloxonium ion base peak is suitable for quantitation of 2-MCPD diesters. Compared to 3-MCPD diesters, the diesters of 2-MCPD produce a higher relative response for the fatty acid acylium ion, and in several cases (2Li-Ln, 2Pa-Ol, 2St-Li) this ion was selected for quantitation.

**Method Performance.** The goal was to develop a validated method that is suitable for the analysis of a wide variety of edible oils. With this in mind, the method was validated using three different oil matrices to ensure robust performance. Extra virgin olive oil is unprocessed and consists mainly of unsaturated fatty acids, soybean oil is processed and contains primarily unsaturated fatty acids, and palm oil contains a relatively large portion of saturated fatty acids.

To confirm adequate recoveries for bound 2-MCPD in processed oils, each validation sample was spiked with an equivalent amount of the isomeric 3-MCPD ester standard. The presence of the isomeric 3-MCPD ester did not affect 2-MCPD ester isomer recoveries or reproducibilities, ensuring accurate results for the analysis of actual samples that are likely to contain both isomers. To generate validation data, four 1.0 ± 0.01 g portions of olive oil, soybean oil, and palm oil were prepared, in duplicate, and fortified with 0, 10, 100, and 800 $\mu$L of spiking solution, respectively. This produced one blank oil sample, as well as oils containing spiked MCPD ester concentrations of 0.1, 1.0, and 8.0 $\mu$g/g (ppm), respectively. Each fortified sample was spiked with 250 $\mu$L of internal standard spiking solution, generating oils containing 1.25 $\mu$g/g (ppm) of each internal standard. The method recoveries and relative standard deviations (RSD), incorporating labeled internal standards and averaged for three spiking concentrations in the three matrices, are depicted in Table 3. There were 2-MCPD monoesters in the organic palm oil sample blank (ranging from 58 to 263 ng/g (ppb)), along with 2-MCPD diesters in both the organic palm oil blank (ranging from 35 to 585 ng/g (ppb)) and the soybean oil blank (ranging from 31 to 103 ng/g (ppb)), which were subtracted before recoveries were calculated. Several of the analytes (2Pa-Pa, 2Pa-Ol, 2Ol-Li, 1-Li2, 1-Pa2, 1-Ol2) were present in the palm oil sample at higher concentrations than the low spikes, slightly affecting the reproducibility for these compounds.

Actual recoveries for the three 2-MCPD monoesters in olive oil, soybean oil, and palm oil, uncorrected by deuterated internal standards, ranged from 80 to 139% (RSD range, 24–55%), with the highest RSDs (>35%) seen in the 0.1 ppm spikes. As was the case with sn-2 3-MCPD monoester recoveries, 2-MCPD monoesters showed more variability than isomeric sn-1 3-MCPD monoesters. This was expected

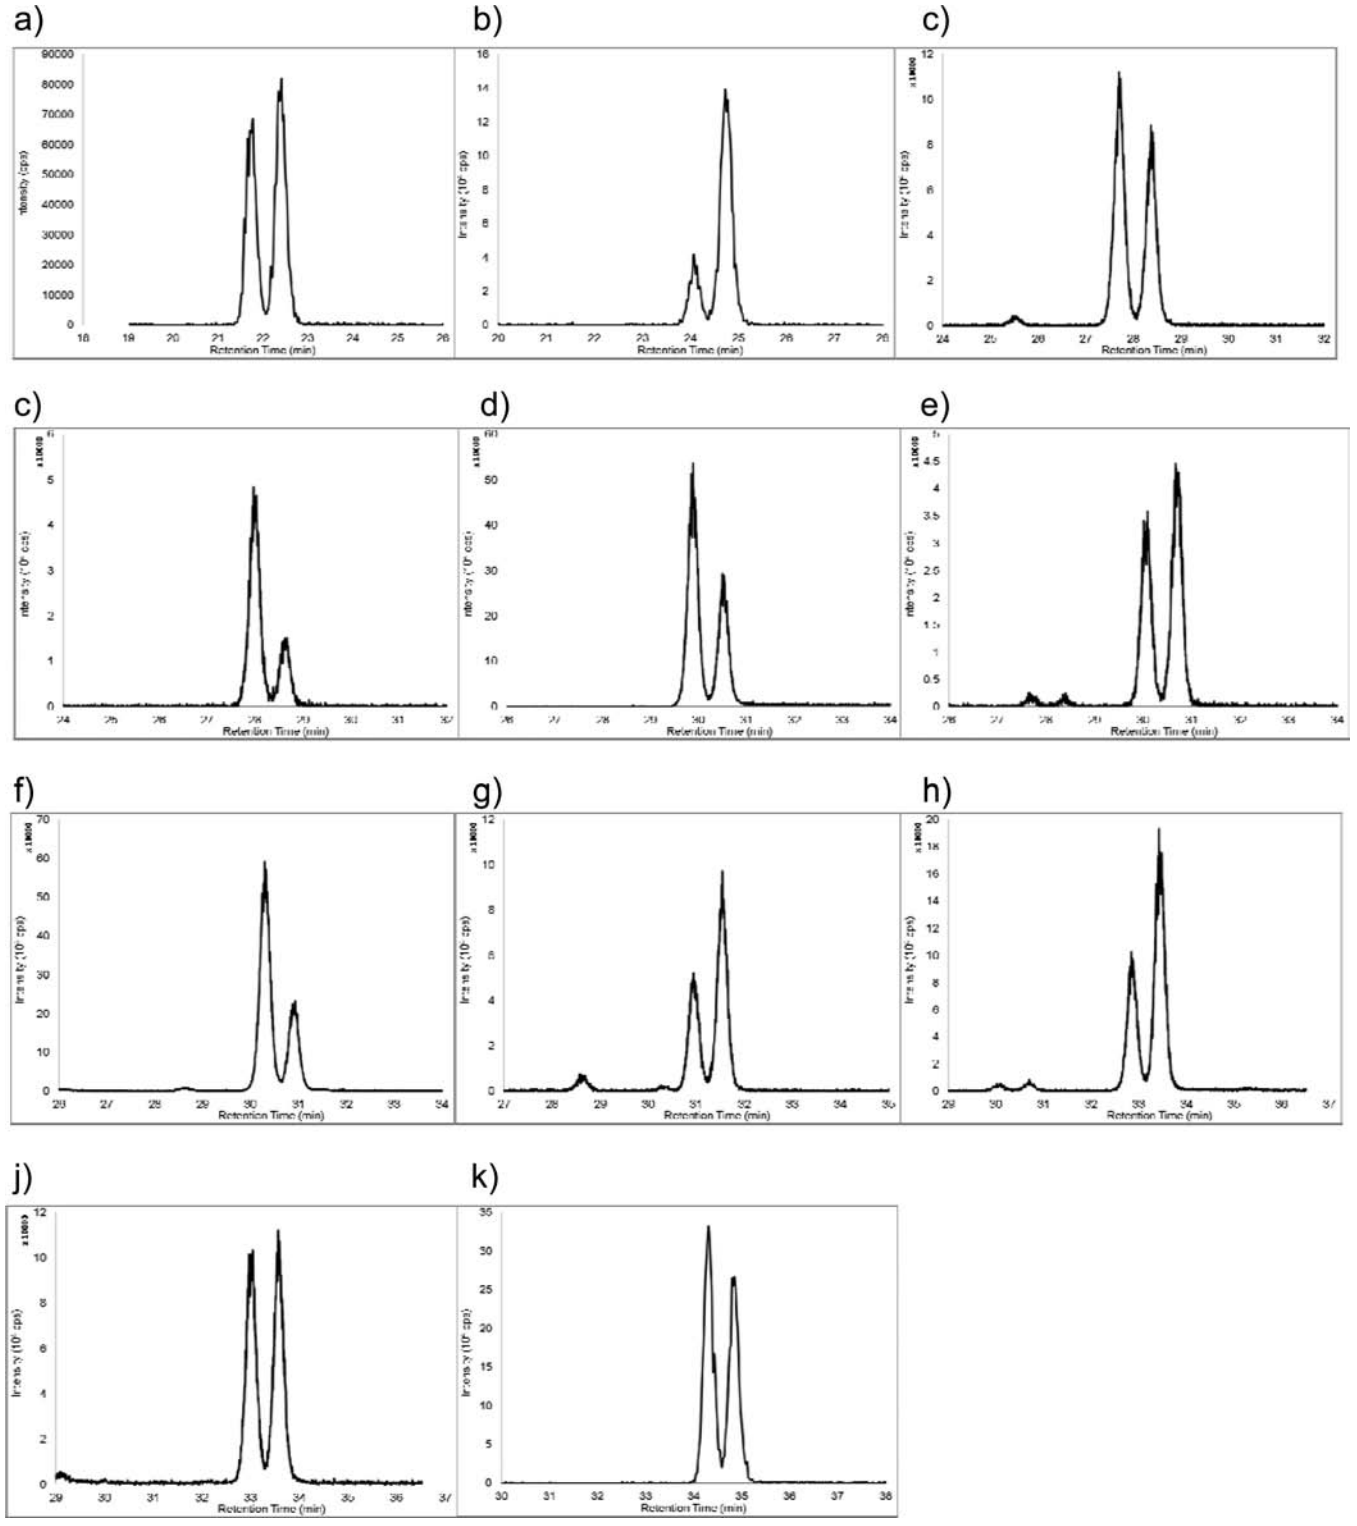

**Figure 5.** LC-MS/MS chromatograms showing the quantitation ion separation of 3-MCPD diesters from isomeric 2-MCPD diesters for (a) 3Li-Ln and 2Li-Ln, (b) 3Li-Li and 2Li-Li, (c) 3Pa-Li and 2Pa-Li, (d) 3Ol-Li and 2Ol-Li, (e) 3Pa-Pa and 2Pa-Pa, (f) 3Pa-Ol and 2Pa-Ol, (g) 3Ol-Ol and 2Ol-Ol, (h) 3St-Li and 2St-Li, (i) 3Pa-St and 2Pa-St, (j) 3Ol-St and 2Ol-St, and (k) 3St-St and 2St-St. In all cases, the 3-MCPD isomer elutes before the 2-MCPD isomer.

due to lower MS/MS responses for the 2-MCPD monoesters and close chromatographic proximity to the larger sn-1 monoester MS/MS peak (see Figure 4). Recoveries for 11 2-MCPD diesters in olive oil, soybean oil, and palm oil without the use of deuterated internal standards ranged from 61 to 104% (RSD range, 5−30%). However, after the incorporation of internal standards, the average recoveries and particularly the reproducibilities for all analytes in the method improved greatly.

The limit of detection (LOD) and limit of quantitation (LOQ) were defined as signal-to-noise (RMS noise) ratios of 3 and 10, respectively, and were determined experimentally by

| LOQ (ng/g, ppb) | 30 | 30 | 20 | 30 | 20 | 20 | 20 | 20 | 20 | 20 | 30 |

analyzing spiked olive oil samples brought through the entire method; the results are shown in Table 4. Olive oil was chosen as the representative oil for limit determination because it consists predominantly of 18-carbon unsaturated fatty acids, as do most other commonly consumed edible oils, including soybean, canola, corn, sesame, sunflower, and peanut, and unlike those oils, unrefined olive oil is readily available commercially to provide a matrix free of incurred 2-MCPD esters. The three 2-MCPD monoesters have LOQs of ≤90 ppb, whereas the maximum LOQ detected among the 11 2-MCPD diesters was 30 ppb. Despite lower LC-MS responses for precursor ions, the LOQs for unsymmetrical 2-MCPD diesters are comparable to the limits in the 3-MCPD isomer. This is because all MS/MS transitions are suitable for accurate quantitation of 2-MCPD diesters.

**Applicability in Sample Analysis.** This is the first method that allows for quantitation of intact 2-MCPD esters in edible oils. It was validated using three different edible oil matrices to ensure reliable method performance and reproducibility. The lack of matrix-matched standards, combined with a straightforward two-step SPE cleanup, allows for rapid analysis of numerous samples in different matrices in a single analytical sequence. This is the first published approach that demonstrates chromatographic separation between sn-1 3-MCPD monoesters and 2-MCPD monoesters. These methods, which simultaneously quantify glycidyl esters and 3-MCPD esters,[20,21] can be used to determine the effectiveness of industrial processing mitigation approaches and in assessing the risk from these contaminants in edible oils.

However, formulation-based drug delivery systems of silymarin in these studies are restricted to either in vitro dissolution studies or optimizing formulations. The major disadvantage of previous reports on the pharmacokinetics of silymarin is that the experimental animals are either restrained or under anesthesia. The stress associated with restraint and conventional blood sampling from conscious rodents affects their physiology, biochemistry, metabolism, and protein expression.[21,22]

In the present investigation, we designed liposome- and ethosome-encapsulated silymarin carriers to evaluate the differences between liposomes and ethosomes on pharmacokinetic profile and tissue distribution in free-moving rats.

Therefore, it is necessary to develop and validate an analysis method to investigate the pharmacokinetics and tissue distribution of liposome- and ethosome-encapsulated silymarin. Silibinin is the major active constituent of silymarin, which is the main target of analysis. A number of analytical methods for determining bioactive components of silymarin extracts in biological fluids and tissues have been reported, including liquid chromatography in combination with ultraviolet (LC-UV), mass spectrometry (MS), and tandem mass spectrometry (MS/MS) in human, dog (beagle and mongrel dog), rat, rabbit, and cat plasma or tissue.[17,18,23−28]

Among these analytical methods, HPLC has been most frequently used for pharmacokinetic studies of silibinin due to its simplicity, sensitivity, and selectivity. The objective of this study to develop and validate a sensitive and rapid LC-MS/MS method to quantify silymarin active compounds (silibinin in rat plasma and organ tissues, including liver, heart, spleen, lung, and kidney) after oral administration of silymarin loaded in liposomes and ethosomes. Furthermore, the pharmacokinetics and organ tissue distribution of silymarin in free form and formulations following oral administration were evaluated and compared.

## MATERIALS AND METHODS

**Chemicals and Reagents.** Cholesterol, heparin, naringin (internal standard, IS) and silymarin were obtained from Sigma−Aldrich Chemical Co. (St. Louis, MO). Hydrogenated soybean phosphatidylcholine (SPC, Phospholipon 80H) was supplied by American Lecithin Co. (Oxford, CT). Distearoylphosphatidylethanolamine−poly(ethylene glycol) with a mean molecular weight of 5000 (DSPE-PEG 5000) was purchased from Nippon Oil (Tokyo, Japan). Cellulose membrane (Cellu-Sep T2, with a molecular weight cutoff of 6000−8000) was obtained from Membrane Filtration Products (Seguin, TX). Acetonitrile, chloroform, ethyl acetate, and sodium chloride were purchased from Merck (Darmstadt, Germany). Milli-Q-grade water (Millipore, Bedford, MA) was used for preparation of solution and mobile phases.

**Preparation of Formulations.** The components of ethosome were similar to liposome, which contained soybean phosphatidylcholine [3.0% (w/v) of final product], cholesterol (0.5%), DSPE-PEG 5000 (0.5%), and triply deionized water with 20% ethanol (liposome only with triply deionized water that did not contain 20% ethanol). Formulations were prepared as follows: soybean phosphatidylcholine [3.0% (w/v) of final product], cholesterol (0.5%), and DSPE-PEG 5000 (0.5%) were dispersed in a chloroform/methanol (2:1) solution (5 mL). The organic solvent was evaporated in a rotary evaporator at 50 °C, and solvent traces were removed by retaining the lipid film under vacuum overnight. The films were hydrated with triply deionized water or triply deionized water with 20% ethanol containing silymarin by use of a probe-type sonicator (VCX600, Sonics and Materials, Newtown, CT) at 35 W for 30 min. The total volumes of the resulting products (liposome- and ethosome-encapsulated silymarin formulations, referred to as LSM and ESM, respectively) were set at 5 mL.

**Formulation Characteristics.** *Determination of Particle Size and ζ Potential.* The mean particle size and polydispersity index (PDI) of formulations were measured by dynamic light scattering (90 Plus, BIC, Holtsville, NY). The ζ potential of formulations was determined on a ζ potential analyzer (90 Plus, BIC, Holtsville, NY).

*Encapsulation of Silymarin in Liposomes and Ethosomes.* Entrapment capacity estimated the amount of LSM and ESM. These formulations were centrifuged at 48000*g* at 4 °C for 30 min in a Beckman Optima MAX ultracentrifuge (Beckman Coulter, Stanwood, WA) to separate the incorporated drug from the free form. The amount of silibinin in the formulation was analyzed by the HPLC-MS/MS system. Entrapment capacities of formulations were calculated as [(total amount of drug − amount of drug detected only in supernatant)/total amount of drug] × 100.[12]

*Morphological Observations by Transmission Electron Microscopy (TEM).* These vesicles were examined by TEM to characterize their microstructure. A drop of a formulation was applied to a 400-mesh carbon-film-covered copper grid to form a thin film specimen, which was stained with 1% phosphotungstic acid. After the stained samples were allowed to air-dry, TEM samples were obtained. Finally, the sample was then examined and photographed by a TEM (JEM-2000EXII, JEOL, Tokyo, Japan).

**Liquid Chromatography−Tandem Mass Spectrometry System and Analytical Method Validation.** *LC-MS/MS System.* An Agilent-1100 HPLC system (Agilent Technologies, Waldbronn, Germany) with an Applied Biosystems/MDS Sciex API 3000 tandem quadrupole mass spectrometer (Framingham, MA) equipped with quaternary pump, injector, vacuum degasser, and autosampler was used. The tandem quadrupole mass spectrometer equipped with electrospray ionization (ESI) turbo ion interface was used with the following parameters: turbo ion spray gas (GAS 2), 6 L/min; nebulizer gas (NEB), 10; curtain gas (CUR), 10; collisionally activated dissociation gas (CAD), 8; ion-spray voltage (IS), −4000 V; and turbo ionspray temperature (TIM), 500 °C. Nitrogen was used in all cases. Negative-ion mode with multiple reaction monitoring (MRM) was used for HPLC-MS/MS analysis. The following precursor → product ion transitions were used: $m/z$ 481.2 → 301.0 for silibinin [declustering potential (DP) −155 V, focusing potential (FP) −380 V, entrance potential (EP) −12 V, collision energy (CE) −22 V, collision cell exit potential (CXP) −12 V] and $m/z$ 579.3 → 271.6 for naringin as an internal standard (IS) (DP −86 V, FP −200 V, EP −11.5 V, CE −49 V, CXP −15 V). A reverse-phase C18 column (50 × 4.6 mm, particle size 5 μm, Phenomenex Luna) was used for HPLC separation. The mobile phase consisted of acetonitrile and 0.1% formic acid (67:33 v/v) at a flow rate of 0.3 mL/min. The sample injection volume was 10 μL.

*Analytical Method Validation.* The stock solution was silibinin and naringin (IS) in 100% acetonitrile (1 mg/mL). A set of standard solutions was prepared by appropriate dilution of the stock solution with mobile phase to make the calibration curve. These solutions were stored at −20 °C before use.

These solutions were further diluted to give a series of working standard solutions and samples for calibration in blank plasma and organ tissues (including liver, heart, spleen, lung, and kidney), prepared by spiking aliquots of the stock solutions into biosamples to obtain final concentrations in the range of 5−1000 ng/mL for plasma and 10−1000 ng/mL for organ tissues (including liver, heart, spleen, lung, and kidney). Samples were processed as described under Sample Preparation.

Pharmacokinetic studies and tissue distribution for bioanalytical assays were based on method validation practices according to FDA guidelines,[29] including tests of selectivity, sensitivity, linearity, precision, accuracy, recovery, and matrix effect.

Selectivity of analytes was determined by confirming the presence or absence of interference as well as the lot-to-lot variation regarding interference in blank plasma and organ tissues.

The limit of quantification (LOQ) is defined as the lowest concentration of the linear range, and the limit of detection (LOD) is

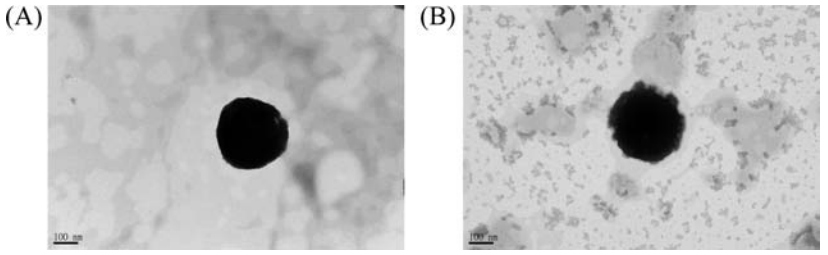

**Figure 1.** TEM micrographs of (A) liposome-encapsulated silymarin formulation (LSM) and (B) ethosome-encapsulated silymarin formulation (ESM). Original magnification 120000×, scale bars 100 nm.

defined as the concentration of analyte that gives a signal-to-noise ratio (S/N) of 3. Calibration curves were constructed by plotting the peak area ratio of silibinin and naringin (IS) versus concentration.

Quantitation of silibinin in plasma and organ samples (including liver, heart, spleen, lung, and kidney) was based on calibration curves, ranging from 5−1000 ng/mL for plasma samples and 10−1000 ng/mL for organ samples. These calibration curves were required to have a correlation coefficient ($r^2$) greater than 0.995.

Precision and accuracy of the analytical method for different biological matrices were assayed by testing the samples in five replicates on the same day (intraday) and on five successive days (interday). Accuracy (bias, as a percentage) was calculated from the nominal concentration ($C_{nom}$) and the mean value of observed concentration ($C_{obs}$) as follows:

$$\text{accuracy (bias)} = [(C_{nom} - C_{obs})/C_{nom}] \times 100$$

Precision (relative standard deviation, RSD, as a percentage) was calculated from the standard deviation and observed concentration as follows:

$$\text{precision (RSD)} = [\text{standard deviation (SD)}/C_{obs}] \times 100$$

Percentage bias (% bias) and percentage RSD (% RSD) for the lowest acceptable reproducibility concentration were defined as being within ±15% (±20% at the low limit of detection).

Matrix effect and recovery of silibinin in various biological samples were assessed at three different concentration levels (25, 250, and 1000 ng/mL). The naringin (IS) concentration was 250 ng/mL in rat plasma and organ tissues. Matrix effect (%) and recovery (%) were calculated by use of the following formulas:

$$\text{matrix effect} = \frac{\text{peak areas for standards spiked after extraction}}{\text{peak areas obtained in neat solution standards}} \times 100$$

$$\text{recovery} = \frac{\text{peak areas for standards spiked before extraction}}{\text{peak areas for standards spiked after extraction}} \times 100$$

**Animal Experiments: Freely Moving Rat Model.** Adult male Sprague-Dawley rats weighing 200 ± 30 g were obtained from the National Yang-Ming University Animal Center, Taipei, Taiwan. The animals were specifically pathogen-free and had free access to food (laboratory rodent diet 5001, PMI Nutrition International LLC, St. Louis, MO) and water. The rats were housed with a 12-h light and 12-h dark cycle. All experimental protocols involving animals were reviewed and approved by the Institutional Animal Care and Use Committee (IACUC number 1020613) of the National Yang-Ming University.

Experimental rats were initially anesthetized by pentobarbital (50 mg/kg, ip), and then polyethylene tubes were implanted in the right jugular and right femoral veins for iv administration. For the oral administration group, only the right jugular was catheterized for blood sampling. The catheter crossed the subcutaneous tissue and was fixed in the dorsal neck region. The patency tubing was maintained by flushing with heparinized normal saline [0.9% NaCl (w/v) solution containing 20 IU/mL heparin sodium salt]. After surgery, the rat was placed in an experimental cage and allowed to recover for 1 day. During the recovery period, the rat was kept warm under a light.

The oral administration group was given silymarin (free form) dissolved in triple-distilled deionized water and present in suspension; for iv administration, silymarin (free form) was completely dissolved in PEG 400 with 15% ethanol.

**Biodistribution.** Blood samples were collected by cardiac puncture at 30 min after silibinin administration (free drug and formulations) and then perfused with normal saline through the left ventricle. The organs (including liver, heart, spleen, lung, and kidney) were collected, weighed, and homogenized. Finally, the biological samples were stored at −20 °C for sample analysis.

**Sample Preparation.** *Plasma Samples.* The real plasma sample (45 μL) was mixed with 5 μL of naringin (IS) and vortexed for 30 s. Next, 1 mL of ethyl acetate was added and the mixture was vortexed for 5 min. The mixture was centrifuged at 16000*g* for 10 min at 4 °C. The supernatant (1 mL) was transferred to an Eppendorf vial and dried at 40 °C in a centrifugation evaporator. The dried sample was reconstituted in 100 μL of mobile phase (acetonitrile/0.1% formic acid = 67:33 v/v) and filtered through a 0.22 μm filter. Finally, the filtrate (10 μL) was applied to the HPLC-MS/MS system for analysis.

*Organ Samples.* After homogenization of the organs with 100% aqueous acetonitrile solution (1:3 w/v), the homogenate was centrifuged at 16000*g* for 10 min at 4 °C and the supernatant was collected and frozen at −20 °C until analysis. To determine silibinin concentration in the organs, sample preparation was similar to that described under Plasma Samples). Additionally, if the concentration of silibinin was over the limit of the linearity range (1000 ng/mL), these analytes were diluted with blank biological samples.

**Pharmacokinetics and Statistics.** All pharmacokinetic analysis was processed by WinNonlin standard edition, version 1.0 (Scientific Consulting Inc., Apex, NC). The Akaike information criterion (AIC) value was used to select the compartment model used for data analysis.

Pharmacokinetic parameters are explained as follows: the area under the concentration−time curve (AUC) is defined as the plot of concentration of drug in blood plasma against time. $t_{1/2,\alpha}$ and $t_{1/2,\beta}$ are the distribution half-life and elimination half-life, respectively. Peak plasma concentration of a drug after administration and time to reach this peak plasma concentration are $C_{max}$ and $T_{max}$, respectively. Clearance (CL), an indicator of drug elimination from the body, is calculated by CL = $D$ (dose)/AUC. Mean residence time (MRT) is the apparent average period drug molecules staying in the body. Bioavailability (%) = $100(AUC_{oral}/D_{oral})/(AUC_{iv}/D_{iv})$.

Pharmacokinetic results are represented as the mean ± standard error of measurement (SEM). Statistical significance was determined by using a one-way analysis of variance (ANOVA), followed by a Schieff post-test (SPSS version 10, SPSS, Chicago, IL) with $p < 0.05$ as the minimal level of significance.

## RESULTS AND DISCUSSION

**Physicochemical Characteristics of Formulations.** These formulations can be prepared successfully by a thin-film dispersion/homogenization method. The physicochemical characteristics of LSM and ESM were investigated by evaluating the formulations' appearance, vesicle size, ζ potential, and drug encapsulation percentage.

In this study, a formulation system containied SPC, DSPE-PEG 5000, and cholesterol, which functioned as the emulsifiers, located at the oil/water interface as a phospholipid membrane surrounding the quercetin-containing core.

TEM images of LSM and ESM are shown in Figure 1. These vesicles were both spherical, and their sizes and $\zeta$ potentials are shown in Table 1. Dynamic light scattering determinted the sizes of LSM and ESM were approximately 272 and 321 nm, respectively. The polydispersity index (PDI) is a measure of the width of the particle size distribution. The values of these formulations were smaller than 0.32, demonstrating highly homogeneous populations of particles for the formulations.[30] $\zeta$ potentials of the LSM and ESM were −27.14 and −36.32 mV, respectively.

**Table 1. Characterization of LSM and ESM by Vesicle Size, $\zeta$ Potential, PDI, and Drug Encapsulation**[a]

| | size (nm) | $\zeta$ potential (mV) | PDI | encapsulation (%) |
|---|---|---|---|---|
| LSM | 272.5 ± 5.11 | −27.14 ± 0.84 | 0.32 ± 0.02 | 60.36 ± 1.78 |
| ESM | 321.1 ± 22.4 | −36.32 ± 4.65 | 0.30 ± 0.01 | 69.13 ± 3.25 |

[a]PDI, polydispersity index; LSM, liposome-encapsulated silymarin formulation; ESM, ethosome-encapsulated silymarin formulation.

From a morphological point of view, the structure of ethosomes is very similar to that of liposomes; however, the results showed that ESM exhibited higher encapsulation efficiency (69.13% ± 3.25%) than LSM (60.36% ± 1.78%). This may be because ethosomes have ethanol, which provides better solubility for lipophilic drugs.[31]

**In Vitro Release.** To examine if silibinin could be readily released from silymarin solution (free form) and formulation groups, in vitro release tests were performed. As shown in Figure 2, release of silibinin from the silymarin solution (free form) was rapid at 24 h; the release kinetics of silibinin from LSM and ESM exhibited slower, more continuous release over 48 h. The drug release percentage of silibinin from the silymarin solution (free form) at the end of the experiment (48 h) showed enhancements of 2.33-fold compared to the formulation groups.

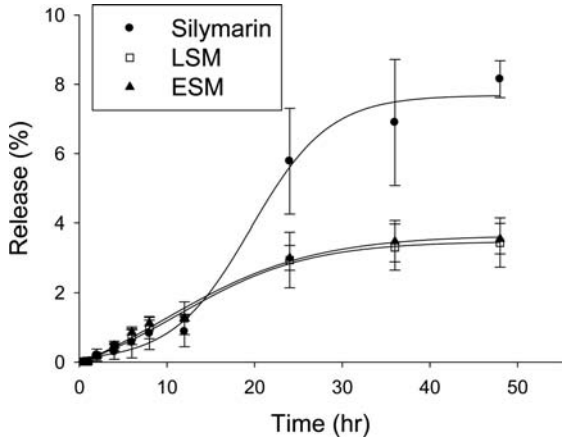

**Figure 2.** In vitro release-time profiles of silibinin from silymarin (free form), LSM, and ESM across a cellulose membrane added to the donor compartment of a Franz diffusion cell (mean ± SD, $n$ = 4).

The sustained release profiles of silymarin from LSM and ESM were consistent with the Higuchi diffusion equation ($r^2$ = 0.97).[32] There were no significant differences between LSM and ESM for in vitro release. LSM and ESM showed suppressed and sustained release of silymarin compared to the control groups.

**LC-MS/MS System and Method Validation.** To develop a sensitive and accurate LC-MS/MS method for the determination of silymarin's major active compound, silibinin, in rat plasma, liver, heart, spleen, lung, and kidney, the triple quadrupole mass spectrometer equipped with an electrospray ionization (ESI) source is currently one of the most useful tools available because of its high sensitivity and selectivity. Therefore, the process of analytical method development and validation could be divided into several parts, including optimization of MS and LC conditions, assessed matrix and recovery of sample preparation, selected calibration range, precision (RSD, %), and accuracy.

In the study, we used an MRM system for qualification analysis, which consisted of selecting the precursor ion (MS 1) and selecting a specific fragment of precursor ion (MS 2); therefore, the analysis method was specific and sensitive. Negative-ion electrospray ionization was used to optimize the HPLC-MS/MS analysis, and the MS/MS conditions of silibinin and naringin (IS) are shown in Table S1 in Supporting Information. The mass transit ion patterns $m/z$ 481.2 → 301.0 and $m/z$ 579.3 → 271.2 were selected to monitor silibinin and naringin (IS), respectively. Mass spectra and chemical structures of silibinin and naringin (IS) are shown in Figure 3.

In this method, the degree of interference was assessed by inspection of the MRM mode. Separation and quantification of silibinin in plasma and organ samples without other endogenous interfering peaks were performed in an optimal mobile phase containing acetonitrile with 0.1% formic acid (67:33 v/v) with a reverse-phase C18 column (50 × 4.6 mm, particle size 5 $\mu$m).

To assess pharmacokinetic and tissue distribution, a suitable assay system for the plasma and different tissue samples should be developed and optimized. In the process optimization, we have examined many methods for sample preparation, including protein precipitation and liquid−liquid extraction. However, we found that background interference appeared in the blank matrix extract after protein precipitation, whether the samples were treated with methanol or acetonitrile. However, background interference did not exist when the samples were treated by liquid−liquid extraction. The results showed that liquid−liquid extraction, using the liquid solvent ethyl acetate, provides the most effective extraction of silibinin from various biological samples.

Panels A−F in Figure S1 (Supporting Information) show the chromatograms of blank plasma, liver, heart, spleen, lung, and kidney, respectively. The chromatograms showed that no significant interfering peaks from the plasma and tissues after liquid−liquid extraction were found at the retention times or the ion channel of silibinin or naringin (IS). Panels G−L in Figure S1 (Supporting Information) shows chromatograms of the plasma and different organ samples containing naringin (IS) and silibinin collected from rats after iv administration of silymarin (100 mg/kg). Retention times of silibinin and naringin (IS) in the chromatograms were 1.4 and 1.9 min, respectively. The analysis time is shorter than previous analysis methods.[16,27]

Analyte matrix effect and recovery were used to assess suitability of the sample preparation method. The matrix effect and recovery percentages were determined at three different

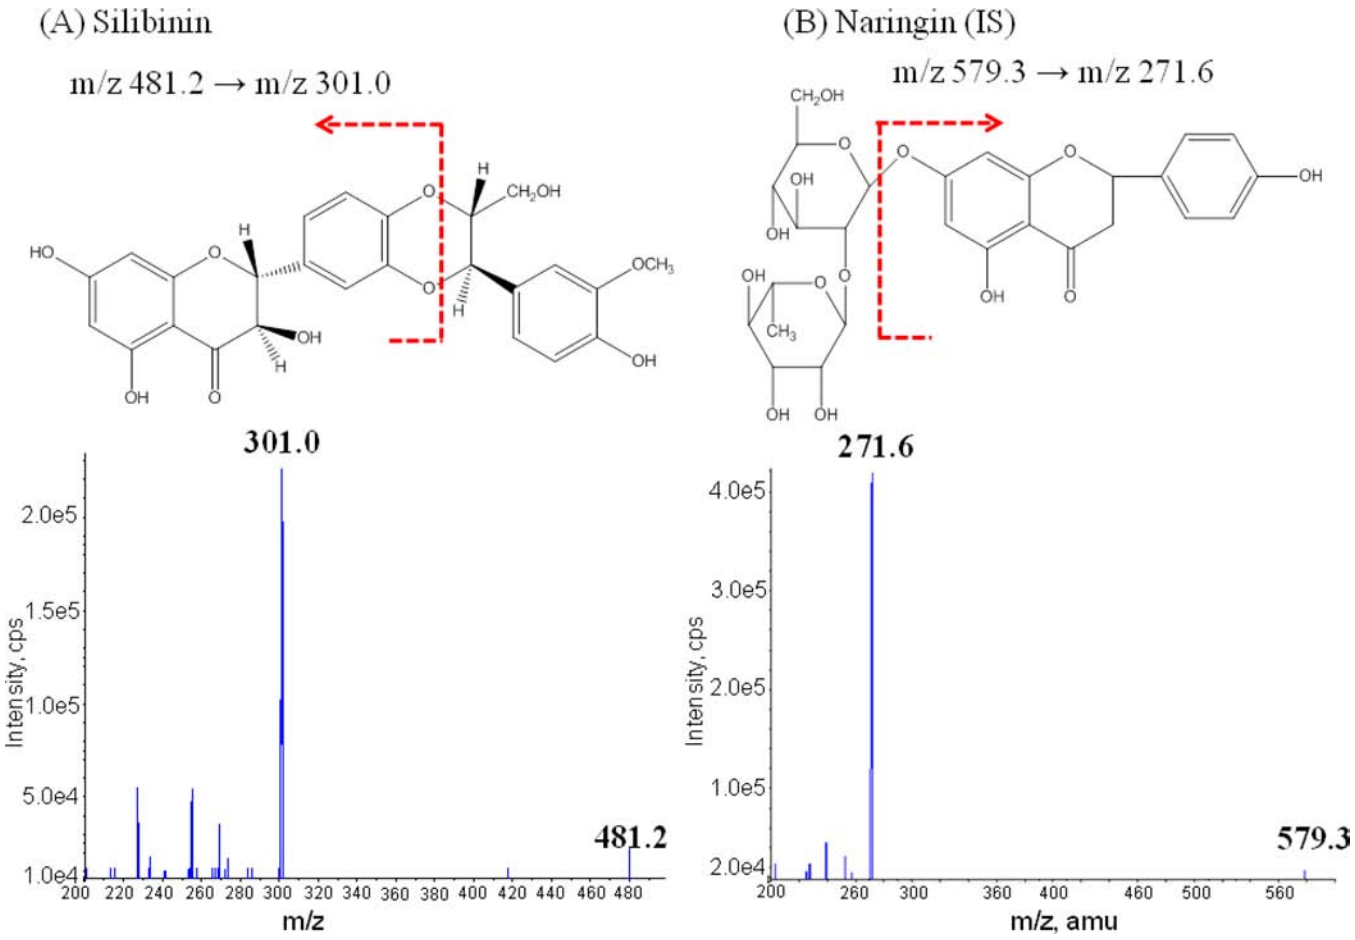

**Figure 3.** Representative product ion mass spectra and chemical structures of (A) silibinin and (B) naringin (IS).

concentrations (low, middle, and high concentrations) for all analytes. The data demonstrated that the mean matrix effect of silibinin in rat plasma and organ samples was 98.26% ± 3.93% and within the range 86.69−100.45%, respectively. No significant matrix effects of silibinin were observed in rat plasma and organ samples, which could be ignored in quantitative analysis (Table S2, Supporting Information). The extraction recovery of silibinin in rat plasma and organ samples was 86.64% ± 3.40% and within the range 88.40−95.57%, which were both considered acceptable (Table S2, Supporting Information).

Average matrix effects and recoveries of naringin (IS) in rat plasma and organ samples are shown in Table S2 (Supporting Information). Because the value of the matrix effect in the organ samples had only a small standard deviation, naringin could be used as a suitable internal standard for the analysis. To evaluate the analytical linearity of the developed method, the peak area ratio of silibinin to naringin (IS) versus concentration was used.

The data demonstrated that the linearity was related to concentration in the range 5−1000 ng/mL for plasma samples and 10−1000 ng/mL for biological samples. The results showed a good correlation coefficient ($r^2 \geq 0.995$) for silibinin over the concentration range from separately prepared analytical runs on different days. The inter- and intraday precision and accuracy values for plasma and organ samples are presented in Tables S3 and S4 (Supporting Information). Precision (RSD, %) and accuracy (bias, %) of plasma ranged from 0.77% to 17.62% and −6.23 to 12.78%, respectively; for organ samples, the percentages ranged from 0.48% to 15.26% and 15.41% to 10.64%, respectively. The LOQ of silibinin was 5 ng/mL in plasma samples and 10 ng/mL in organ sample.

These results showed that the analytical method was sensitive, repeatable, and reliable. The system could be applied to quantification of silibinin in pharmacokinetic studies and tissue distribution.

**Pharmacokinetics and Oral Bioavailability.** Pharmacokinetic and biodistribution assessment of nanoparticles is necessary. Many types of nanoparticles could improve drug distribution profiles, which usually influence drug delivery properties.[33] The morphological structure of ethosomes is similar to that of liposomes, but there have not been any studies about pharmacokinetic differences between them.

To assess the pharmacokinetics and bioavailability of silymarin (free form), LSM, and ESM, each was administered orally (100 mg/kg, po) and intravenously (10 mg/kg, iv) to rats. Rats have also been widely used to test drug efficacy and safety because they are mammals. Their systems could react to medicines, formulations, food products, or cosmetics in a similar manner as human systems; therefore, studying drug efficacy on rats is useful to test if a drug is considered safe enough for human consumption or exposure. Therefore, this animal model is suitable to investigate pharmacokinetics of silymarin loaded in liposomes and ethosomes.

The plasma drug concentration−time profile after intravenous and oral administration of silymarin, LSM, and ESM in

dx.doi.org/10.1021/jf504139g | J. Agric. Food Chem. 2014, 62, 11657−11665

rats is presented in Figures 4 and 5. As seen in Figure 4, there were no differences between silymarin (free form) and

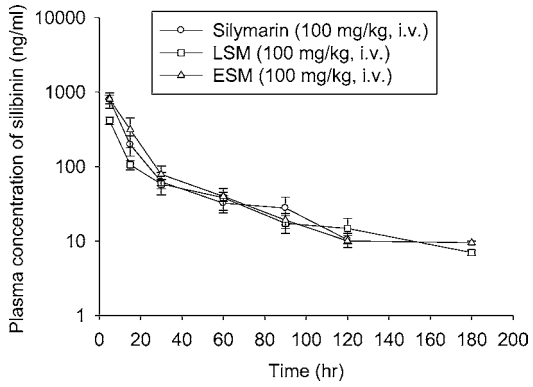

**Figure 4.** Concentration curve of silibinin in rat plasma after iv administration of silymarin (10 mg/kg, iv), LSM (10 mg/kg, iv), and ESM (10 mg/kg, iv); mean ± SEM, $n$ = 5.

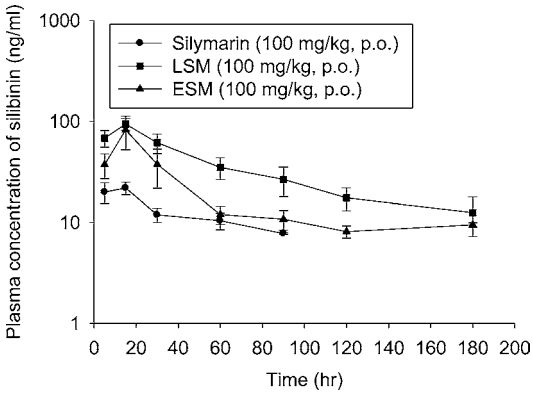

**Figure 5.** Concentration curve of silibinin in rat plasma after oral administration of silymarin (100 mg/kg, po), LSM (100 mg/kg, po), and ESM (100 mg/kg, po); mean ± SEM, $n$ = 5.

silymarin loaded in formulations. However, we found that silibinin could be detected in plasma up to 90 min after oral administration (100 mg/kg, po), while the time was prolonged to 120 min in the group administered LSM and ESM (Figure 5).

Pharmacokinetic parameters were calculated by use of the software program WinNonlin (version 1.1), and the results are summarized in Table 2. The pharmacokinetic models (one- versus two-compartment) were selected according to Akaike's information criterion (AIC),[34] which was calculated by WinNonlin. Smaller AIC values can be observed when the model is more suitable to fit the concentration−time curve.

In this study, the average AIC values from the one-compartment model after silymarin (10 mg/kg, iv), LSM (10 mg/kg, iv), and ESM (10 mg/kg, iv) administration were 56.97, 65.24, and 66.39, respectively. Additionally, the mean AIC values from the two-compartment model after silymarin (10 mg/kg, iv), LSM (10 mg/kg, iv), and ESM (10 mg/kg, iv) administration were 37.56, 52.99, and 57.47, respectively. From these results, the two-compartment model was more suitable than the one-compartment model for intravenous administration in rats (Figure 4 and Table 2).

The two-compartment pharmacokinetic model follows the equation $C_p = Ae^{-\alpha t} + Be^{-\beta t}$, which indicated that there are two different processes in the body, including a distribution phase and an elimination phase, presented as $Ae^{-\alpha t}$ and $Be^{-\beta t}$, respectively. The parameters of the equation, $A$ and $B$, are the concentration ($C$) intercepts for fast and slow disposition phases, respectively, and $\alpha$ and $\beta$ are the disposition rate constants for fast and slow disposition phases, respectively. Analysis of the data after silymarin (10 mg/kg, iv), LSM (10 mg/kg, iv), and ESM (10 mg/kg, iv) administration yielded the pharmacokinetic equations $C = 1.63e^{-0.20t} + 0.12e^{-0.03t}$, $C = 0.82e^{-0.23t} + 0.09e^{-0.03t}$, and $C = 1.49e^{-0.61t} + 0.06e^{-0.02t}$, respectively.

The data showed that the pharmacokinetic parameters for $t_{1/2,\beta}$ (43.1 ± 20.9, 32.54 ± 7.81, and 41.19 ± 6.69 min), CL (1.01 ± 0.34, 1.33 ± 0.16, and 0.78 ± 0.10 L·min$^{-1}$·kg$^{-1}$), and MRT (25.1 ± 9.9, 27.12 ± 5.93, and 23.23 ± 5.33 min) of silymarin, LSM, and ESM were not found to be significantly different between the three groups of each parameter.

Pharmacokinetic parameters for oral administration were calculated by noncompartmental analysis, also called model-independent analysis. The AUC values of silymarin (free form),

**Table 2. Pharmacokinetic Parameters of Silibinin in Rat Plasma**[a]

| | 10 mg/kg, iv | | | 100 mg/kg, po | | |
|---|---|---|---|---|---|---|
| PK parameter | silymarin | LSM | ESM | silymarin | LSM | ESM |

| $T_{max}$ (min) | | | | 10.0 ± 2.9 | 13.0 ± 2.0 | 20.0 ± 10.3 |
| CL (L·min$^{-1}$·kg$^{-1}$) | 1.01 ± 0.34 | 1.33 ± 0.16 | 0.78 ± 0.10 | 130 ± 87 | 9.54 ± 2.10[b] | 32.1 ± 12.2 |
| MRT (min) | 25.1 ± 9.9 | 27.12 ± 5.93 | 23.23 ± 5.33 | 119 ± 45 | 308 ± 153 | 70.2 ± 9.1 |
| AUC (min·$\mu$g·mL$^{-1}$) | 12.9 ± 3.5 | 7.99 ± 0.9 | 14.7 ± 3.2 | 2.04 ± 0.74 | 15.2 ± 6.5[b] | 4.48 ± 1.03 |
| bioavailability (%) | | | | 1.58 | 11.78 | 3.47 |

[a]Data are expressed as mean ± SEM, $n$ = 5. LSM, liposome-encapsulated silymarin formulation; ESM, ethosome-encapsulated silymarin formulation. [b]$P < 0.05$, significantly different from silymarin.

LSM, and ESM were found to be 2.04 ± 0.74, 15.17 ± 6.51, 4.48 ± 1.03 min·μg·mL$^{-1}$, respectively; the results showed that the AUC of LSM was significantly higher than that of silymarin.

$C_{max}$ is often assessed in an effort to show bioequivalence between a known and innovative drug product.[35] Values for LSM and ESM were both significantly higher ($p < 0.05$) than for silymarin, but differences between LSM and ESM were insignificant ($p > 0.05$). The AUC and $C_{max}$ of LSM after oral administration were 7.7- and 5.5-fold higher than for silymarin, respectively. These values for ESM were 2.19- and 4-fold higher than for silymarin, respectively.

The mean $T_{max}$ is the time to maximum concentration of a drug in plasma, which can be used as an indicator of the drug absorption rate. In our study, after oral administration, the $T_{max}$ values for silymarin (free form), LSM, and ESM were not significantly different (approximately 10 min), which was shorter than results reported by Parveen et al.[19] Anesthesia has an influence on the disposition of drugs in animals.[36] Therefore, this discrepancy may be because the previous study used blood samples collected from anesthesized animals, whereas our blood samples were collected from conscious rats.

Additionally, LSM was significantly improved as evidenced by 13.65-fold reduction in CL from silymarin. ESM clearance also decreased by 4.05-fold from silymarin, indicating that these formulations could increase the circulation time of silymarin in rats instead of rapid elimination. Previous in vitro study indicated that silymarin was metabolized by CYP2C8 in the liver.[9] Weingarten et al.[37] supported that liposome could protect the drugs from enzymatic metabolism via oral administration. Our data also observed that LSM and ESM could increase AUC and reduce CL of silibinin after oral administration.

Bioavailability is a term used to indicate the fractional extent to which a dose of drug reaches its site of action or a biological fluid from which the drug has access to its site of action. The formula for calculating bioavailability of a drug administered orally is given as bioavailability (%) = $100(AUC_{oral}/D_{oral})/(AUC_{iv}/D_{iv})$

According to the definition of pharmacokinetics, the bioavailability of iv administration is 100%. However, bioavailability of oral administration usually decreases due to incomplete absorption and first-pass metabolism. In this study, we used the $AUC_{iv}$ value of silymarin (free form) to calculate the bioavailabilities of silymarin (free form), LSM, and ESM. According to the experimental data, the oral bioavailability of silymarin (free form) was 100(2.04/100)/(12.9/10) = 1.58%, that of LSM was 100(15.2/100)/(12.9/10) = 11.78%, and that of ESM was 100(4.48/100)/(12.9/10) = 3.47%. The bioavailability of a substance in the body can be improved by increasing the absorption of the substance in the gastrointestinal tract or by reducing its metabolism in the body.[38]

As discussed above, the higher AUC and shorter CL for LSM and ESM caused their relative bioavailabilities to decrease by 7.45- and 2.2-fold compared to silymarin (free form), respectively. As a result, ethosomes have higher encapsulation efficiency than liposomes. In vitro release tests showed no differences between liposomes and ethosomes, but liposomes have better pharmacokinetic properties than ethosomes when liposomes are encapsulating silymarin.

**Biodistribution Study.** Biodistribution, which could be used to predict the possible mechanisms of action of nanoparticles, was demonstrated to be important for the application of nanoparticles.[39] According to the results from pharmacokinetic profiles, we observed that silibinin was around the intersection between the first and second compartment at 30 min after a single dose of silymarin was administered intravenously (10 mg/kg). Due to the possible high distribution of silibinin in various tissues at 30 min after intravenous administration, we selected this time point for assessing biodistribution of silymarin.

Concentrations of silibinin were determined in rat plasma and various tissues including liver, heart, spleen, lung, and kidney at 30 min after a single dose of silymarin and injectable formulation groups (LSM and ESM) were administered intravenously (10 mg/kg). Biodistribution study results are shown in Figure 6.

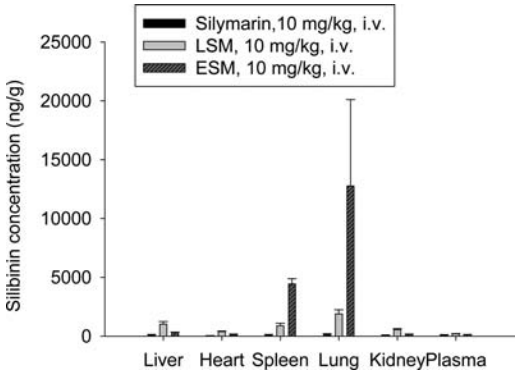

**Figure 6.** Silibinin concentration of rat liver, heart, spleen, lung, kidney, and plasma at 30 min following iv administration of silymarin (free form), LSM, and ESM at 10 mg/kg (mean ± SEM, $n = 6$).

It was shown that the concentrations of silymarin in various organs were lower than for the formulation groups. Distribution patterns of LSM and ESM were in the following order (from high to low): lung > liver > spleen > kidney> heart for LSM and lung > spleen > liver > kidney > heart for ESM. These formulation groups, when administered intravenously, are unable to leave general circulation and rapidly accumulate in mononuclear phagocyte systems (MPS), which are abundant in special tissues and organs such as liver, lung and spleen.[40,41] Therefore, the main organs of distribution in the formation groups were the spleen, lung, and liver instead of kidney.

From the perspective of treatment, silymarin has therapeutic efficacy for liver disease;[42,43] therefore, the level of silymarin accumulation in the liver should be considered. Relatively low levels of silibinin accumulate in the liver following administration of silymarin. The exposures of total silibinin levels in the liver following administration of LSM and ESM were approximately 9- and 3-fold higher than that for silymarin; these results are beneficial for therapy of liver disease. Additionally, according to the data of biodistribution, LSM and ESM appear at low accumulation in the kidney, which may reduce nephrotoxicity.

The tissue distribution patterns of LSM and ESM are similar, except the lung and spleen accumulation of ESM was higher than that of LSM. It is well-known that the biodistribution of vectors could be first affected by their particle size. The sizes of LSM and ESM were not significantly different. Therefore, if distribution differences between LSM and ESM occur, the size factor could be ignored. From a morphological point of view, ethosomes are very similar to liposomes; however, ethosomes

exhibit high encapsulation and soft structure, which may cause the high accumulation of ESM in some tissues.

To our knowledge, this is the first description of biodistribution of ethosomes. The results clarify the difference between ethosomes and liposomes in tissue distribution. ESM had high accumulation in the lung, suggesting that ethosomes have great potential as a lung-targeting drug carrier for the treatment of lung diseases.

In this study, the experiment was divided into four major areas, including development and establishment of analytical methods, formulation of design, pharmacokinetic property studies in awake rats, and biodistribution determination.

The LC-MS/MS method was developed and validated to assess pharmacokinetic profiles and biodistribution of silymarin-loaded liposomes and ethosomes in preclinical study phases. The analysis method is rapid, specific, sensitive, accurate, precise, and linear in the analytical range and has been successfully used in pharmacokinetic and biodistribution studies of silymarin in free-moving rats.

The pharmacokinetic results demonstrated liposome and ethosome could improve the bioavailability of silymarin and that liposomes perform better than ethosomes. Furthermore, LSM and ESM were taken up by the reticuloendothelial system (RES) with good targeting to the liver. Therefore, ethosomes have potential as a therapeutic for lung diseases. Although these results provide preliminary clinical feasibility, more detailed assessments should be required before clinical applications.

propose a process to purify broccoli myrosinase and also a partial characterization of the enzyme.

## MATERIALS AND METHODS

**Plant Material.** Broccoli (*B. oleracea* cv. Avenger) heads (3 days from harvesting) were purchased at the local market (Santiago, Chile) through a single supplier. The vegetables were immediately subjected to protein extraction.

**Protein Extract.** Protein was extracted as previously described.[16] Briefly, samples were pulverized with liquid nitrogen in a mortar until obtaining a homogeneous pulp. After that, 1 mL of buffer was added to 0.25 g of powder. The buffers were 0.1 M acetate at pH 5.0 and 0.1 M phosphate buffer at pH 6.0 and 7.0. The mixture was vortexed and then centrifuged at 15000*g* for 20 min at 4 °C. The supernatant was recovered for analysis.

**Purification.** *Purification Process Design.* In a first stage, the crude broccoli extract was analyzed by sodium dodecyl sulfate−polyacrylamide gel electrophoresis (SDS−PAGE) to visualize the complexity of the sample from which myrosinase was to be purified.[17] The molecular mass of each band was estimated by comparison to full-range rainbow molecular weight markers (12 000−225 000 Da) (GE Healthcare, Uppsala, Sweden). With this information, we performed a database search to characterize the main proteins that must be separated in the purification process. In parallel, the physicochemical properties of Brassicaceae myrosinases were obtained from databases and literature. The database searches were carried out in UniProtKB (http://www.uniprot.org). Finally, considering the characterization of the broccoli protein extract and also the information about purification processes reported for myrosinases from different sources, the purification process was designed.

*Ammonium Sulfate Precipitation.* The protein extract was precipitated with ammonium sulfate at 55% saturation.[17] This saturation percentage was chosen on the basis of literature.[15] The mixture was agitated in a beaker for 10 min in an ice bath and then left at room temperature for 30 min. After that, the suspension was centrifuged at 7000*g* for 30 min, the precipitate was discarded because no activity was detected in it, and the supernatant was used in the subsequent purification steps.

*Dialysis.* The supernatant from ammonium sulfate precipitation (5 mL) was subjected to dialysis against 500 mL of 20 mM Tris−HCl buffer at pH 8.0 plus 0.15 mM NaCl in 0.2 μm dialysis bags [Spectra/Por molecular weight cut-off (MWCO) of 3500]. After 24 h of stirring at room temperature, the sample solution (10.5 mL) was recovered from the dialysis bag.

*Affinity Chromatography.* Chromatographic runs were performed in a BioLogic LP system equipped with a fraction collector and the LP Data View software (Bio-Rad, Hercules, CA). A 1 mL column was packed with concanavalin A resin (GE Healthcare, Uppsala, Sweden). The column was washed and equilibrated (5 column volumes) with 20 mM Tris−HCl at pH 8.0 plus 0.15 mM NaCl (buffer A). The protein extract (5 mL) was loaded into the column and subsequently washed with buffer A (5 column volumes). Elution of myrosinase was obtained with an increasing gradient of methyl-α-D-mannopyranoside (Sigma-Aldrich, Schnelldorf, Germany) formed by mixing buffer A with buffer A added with 0.5 M methyl-α-D-mannopyranoside (buffer B). The elution gradient was 3.33% B/min. The flow rate was constant and equal to 0.5 mL/min. The experiments were conducted at room temperature. All buffers were filtered through 0.22 μm Millipore filters. Absorbance at 280 nm was registered.

**Myrosinase Characterization.** *Native Molecular Mass.* The native molecular mass of broccoli myrosinase was determined by size-exclusion chromatography. A 0.7 × 30 cm Econo-Column (Bio-Rad, Hercules, CA) was packed with 11.5 mL of Sephacryl 200-HR (Sigma-Aldrich, Schnelldorf, Germany). The calibration curve was built using the Gel Filtration Marker Kit for protein molecular weights of 29 000−700 000 Da (Sigma-Aldrich, Schnelldorf, Germany). A total of 1 mL of the purified myrosinase fraction was loaded into the column and eluted with 50 mM Tris−HCl at pH 7.4 plus 0.15 M NaCl at 0.5 mL/min.

*Protein Identification.* Protein spots were excised directly from the SDS−PAGE gels and analyzed by matrix-assisted laser desorption ionization/time-of-flight (MALDI−TOF) at the Central Proteomics Facility of Sir William Dunn Pathology School at Oxford University. Samples were destained using a 25 mM ammonium bicarbonate in 50% acetonitrile/water (Mili-Q-grade) solution. Destained gel pieces were reduced with 10 mM dithiothreitol (DTT) and alkylated with 55 mM iodoacetamide. Reduced and alkylated gel pieces were washed 3 times with solution of 25 mM ammonium bicarbonate in 50% acetonitrile/water and dehydrated with 100% acetonitrile before adding 400 ng of Promega sequencing grade modified trypsin. Samples were left for 1 h at 4 °C to rehydrate. A 25 mM ammonium bicarbonate solution was added to cover the gel pieces, and the samples were incubated at 37 °C overnight. Digestion was stopped with 1 μL of acetic acid, and the supernatant was placed in new low binding microtubes. The gel pieces were covered with 50% acetonitrile/water with 2% formic acid solution and sonicated for 30 min to extract more peptides. The supernatant was added to new microtubes and dried down in a vacuum centrifuge. Samples were resuspended in 10 μL of 0.1% trifluoroacetic acid (TFA) and desalted using Millipore $C_{18}$ ZipTips. Samples were eluted in 3 μL of 0.1% TFA in 50% acetonitrile/water solution, and 0.5 μL of the eluent was spotted onto the MALDI plate and left to air-dry. Dried samples were overlaid with 0.5 μL of MALDI matrix α-cyano-4-hydroxycinnamic acid and left to air-dry. Then, dried samples were analyzed on AB Sciex 4800 MALDI ToF−ToF. The instrument was calibrated using 4700 calibration mixture, and after that, samples were analyzed using mass spectrometry (MS) reflector positive (for MS spectra) and MS/MS 1 kV positive (for MS/MS spectra) methods. The data were searched by GPS explorer software, using Mascot search engine, National Center for Biotechnology Information (NCBI) non-redundant (nr) green plant database (NCBInr 20131208; Sept 30, 2014).

*Effect of pH and Temperature.* The activity of myrosinase was determined at different pH (4.0, 5.0, 6.0, 7.0, and 8.0) and temperature (20, 40, 60, and 70 °C) conditions. We used 0.1 M acetate buffer to achieve pH 4.0 and 5.0 and 0.1 M phosphate buffer to achieve pH 6.0, 7.0, and 8.0. Activity assays were conducted using a thermostatic bath (Stuart, U.K.). All determinations were made in triplicate.

*Kinetic Characterization.* The kinetic behavior of broccoli myrosinase was studied using sinigrin (Sigma-Aldrich, Schnelldorf, Germany) as the substrate at different initial concentrations (0.035, 0.050, 0.075, 0.100, 0.125, and 0.250 mM) at pH 7.0 and 40 °C. The experimental data were adjusted to Michaelis−Menten kinetic models, and the respective parameters were estimated.

**Analytical Determinations.** *Protein Concentration.* The protein concentration was measured by the Bradford method using the Protein Quantification Kit-Rapid (Sigma-Aldrich, Schnelldorf, Germany). Absorbance at 595 nm was registered, and the protein concentration was estimated from a calibration curve made with bovine serum albumin (BSA) as the protein standard.

*Myrosinase Activity.* Enzyme activity was assessed spectrophotometrically through the method described in the literature.[18] A total of 1 mL of substrate buffer (33 mM sodium phosphate buffer at pH 7.4 containing 10 mM sinigrin, 3 mM MgCl, 0.55 mM ATP, 0.72 mM NADP, 3.5 units of hexokinase, and 1.75 units of glucose-6-phosphate dehydrogenase) was preincubated for a sufficient time (3−10 min) at 30 °C. Then, appropriate amounts of the enzyme were added. After mixing, the reaction was monitored at 346 nm. Myrosinase activity was calculated from the absorbance increasing rate, which was due to the formation of NADPH. A total of 1 unit of myrosinase activity was defined as the amount of enzyme that catalyzed the liberation of 1 μmol of glucose/min from sinigrin under the conditions described above. Results were expressed in units per milligram of protein. All chemicals were purchased from Sigma-Aldrich (Schnelldorf, Germany). All determinations were made in triplicate.

*SDS−PAGE.* SDS−PAGE was performed in a mini-chamber (Bio-Rad, Hercules, CA).[17] Each gel (12% acrylamide) had 10 wells, and in each well, 20 μL of protein solution was loaded (14 μg of protein of crude extract and dialysis fraction and 7 μg of the affinity chromatography fraction that contains the pure enzyme). The gels

were run at 120 V for 10 min and after that at 180 V until the advancing front reached the bottom of the gel. After that, the gels were soaked in a solution of 25% methanol and 7.5% acetic acid for 30 min, stained with Coomassie Brilliant Blue R-250 for 12 h (0.1% Coomassie Brilliant Blue R-250, 25% methanol, and 7.5% acetic acid), and destained in a solution of 25% methanol and 7.5% acetic acid. AccuRuler Prestained Protein Ladder (11 000−180 000 Da) (Lamda Biotech, Inc., Ballwin, MO) was used. The protein samples, except for the crude extract, were concentrated by acetone precipitation before SDS−PAGE.[19] Image acquisition was performed with an Image-Scanner II device (GE Healthcare, Uppsala, Sweden). All chemicals were analytical-grade and were purchased from Sigma-Aldrich (Schnelldorf, Germany).

## RESULTS AND DISCUSSION

**Purification.** The analysis of the proteins found in the crude broccoli extract yielded that there are approximately 21 main proteins, detected in the SDS−PAGE (shown in Figure 1), that must be eliminated in the purification process. The molecular weight of the monomers fluctuated between 93 and 19 kDa. According to the literature, among them, there are only two glycoproteins, $\beta$-galactosidase[10] and myrosinase,[2] which should be possible to separate through concanavalin A affinity chromatography. On the other hand, these two proteins differ considerably in their molecular weight. The molecular weight of most Brassicaceae myrosinases is about 62 kDa, while the molecular weight of $\beta$-galactosidase may vary between 52[21] and 130 kDa,[22] and it is usually 93 kDa in Brassicaceae.[20] Besides, myrosinase usually forms homodimers, whereas $\beta$-galactosidase may form dimers or tetramers.[23] As a consequence, a separation technique that exploits size differences would be adequate to purify broccoli myrosinase, such as ammonium sulfate precipitation. Hence, the purification process consisted of ammonium sulfate precipitation followed by concanavalin A affinity chromatography. An intermediate dialysis step was included to eliminate ammonium sulfate excess from the supernatant and also to perform a buffer change.

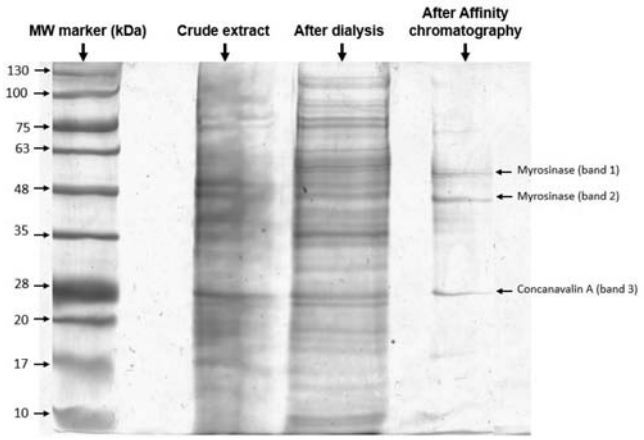

**Figure 1.** Image of SDS−PAGE that shows protein fractions along the purification process: lane 1, molecular weight ladder; lane 2, crude extract; lane 3, fraction after precipitation and dialysis; and lane 4, protein fraction after affinity chromatography.

Figure 1 shows SDS−PAGE that resolved the proteins present in the crude extract (second lane), the sample after ammonium sulfate precipitation and dialysis (third lane), and the active fraction obtained after concanavalin A affinity chromatography (fourth lane). The complexity of the crude protein extract is evident from Figure 1; besides, it is clear that the fraction composition changed after ammonium sulfate precipitation. In the chromatography fraction, three bands were detected, whose identity was elucidated through MS.

Table 1 shows the results from the MS analysis performed on the three bands detected in SDS−PAGE. Bands 1 and 2 were identified as myrosinase from *Brassica napus*, with an acceptable statistical significance (scores higher than 120 and e-values lower than $10 \times 10^{-5}$). These bands differ in their molecular size, in about 5 kDa. This difference can be attributed to different glycosylation states. Band 3 was identified as concanavalin A, which probably was released from the affinity resin.

Figure 2 shows the concanavalin A affinity chromatogram. Two peaks eluted during the elution gradient, the smallest peak at 74% buffer B and the second peak at 95% buffer B, which agrees with the activity curve. The smallest peak showed no myrosinase activity and probably corresponds to one of the myrosinase bands detected in SDS−PAGE. Then, it is likely that this peak corresponds to an inactive isoform of myrosinase.

The purification process proposed here was successful in purifying myrosinase from broccoli extract. Table 2 shows a summary of the purification process. The total myrosinase activity had only a small decrease (12.5%) with respect to the crude extract. Additionally, a high recovery was achieved, with a yield of 88%. Finally, purity increased 1328-fold. These values indicate that the process designed here is very efficient.

This process is simpler than other processes proposed to purify myrosinases from other sources. For example, a four-step process was proposed to purify myrosinase from daikon seedlings, consisting of anion-exchange chromatography, hydrophobic interaction chromatography, size-exclusion chromatography, and a final concanavalin A affinity chromatography.[13] The authors achieved a 49% recovery and a 230-fold purification. Another three-step process was also proposed, concanavalin A affinity chromatography, cation-exchange chromatography, and size-exclusion chromatography, for purifying crambe seed myrosinase.[3] The authors reported a 4% yield and a purification factor of 40-fold. Another three-step process to purify myrosinase from horseradish consisted of ammonium sulfate precipitation, Q-sepharose, and concanavalin A affinity chromatography,[15] resulting in a yield of 20% and a 34-fold purification. A two-step process was developed to separate myrosinase complexes from different Brassicaceae seeds, with a recovery between 18 and 48% and a maximum purification of 573-fold for *Sinapis alba* myrosinase.[2] Then, the process proposed in the present work gave the highest recovery and the highest purification factor compared to the data available in the literature.

**Myrosinase Characterization.** On the basis of the SDS−PAGE, myrosinase subunits have a molecular mass of 50−55 kDa. This value falls within the expected range of 10−110 kDa[1] but differs slightly from the value of 62 kDa reported for myrosinases from *Arabidopsis*, *Wasabia japonica*, *B. napus*, and *B. oleracea* var. Capitata. The number of subunits in the native structure of broccoli myrosinase was determined by size-exclusion chromatography (data not shown). The native molecular mass was equal to 157 kDa, and considering that each subunit weights 50−55 kDa, the native structure of broccoli myrosinase is composed of three subunits.

It is very frequent that myrosinases form complexes with other proteins. These complexes exhibit a high molecular weight (200−600 kDa) and show myrosinase activity.[2] In the

case of broccoli, we can presume that such complexes were not formed. High-molecular-mass proteins or protein complexes are less soluble than small proteins; hence, if broccoli myrosinase forms complexes, they would have precipitated at 55% ammonium sulfate. However, the precipitate showed no myrosinase activity, but the supernatant did. Additionally, when forming complexes, myrosinase would still glycosylated, and therefore, the complexes should have been retained by the concanavalin A affinity column. However, this did not happen, because in SDS−PAGE, only myrosinase and concanavalin A (released from the affinity column) were detected after affinity chromatography. If there were complexes with other proteins, we should have detected different bands corresponding to the proteins bound to myrosinase.

Figure 3 shows myrosinase activity at different pH (Figure 3a) and temperature (Figure 3b) conditions. Myrosinase remained active at acidic pH and showed a decrease in its activity as pH increased, showing a significant loss of activity at pH above 5.0. Myrosinase was active in the temperature range from 20 to 70 °C, agreeing with the literature.[24,25] The optimum temperature at pH 6.0 was around 40 °C. The optimum pH would be below 4.0, differing from the optimum pH reported for other myrosinases. Crambe seed myrosinase has an optimum pH equal to 7.5,[3] and the optimum pH of horseradish myrosinase is 5.7,[15] both using sinigrin as the substrate.

Figure 4 shows myrosinase kinetics on sinigrin. Myrosinase exhibits substrate inhibition, because there is a maximum initial activity at 0.25 mM sinigrin, and at higher sinigrin concentrations, the initial reaction rate decreased drastically. This result agrees with another study[25] about the effect of

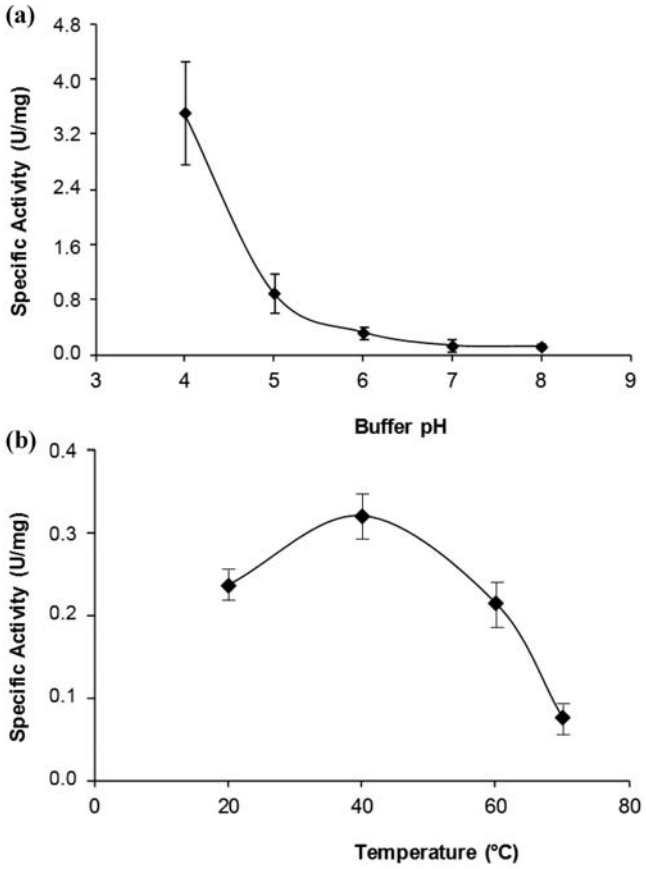

**Figure 3.** Myrosinase stability at different pH and temperature: (a) myrosinase stability between pH 4.0 and 8.0 at 40 °C and (b) myrosinase stability between 20 and 70 °C at pH 6.0.

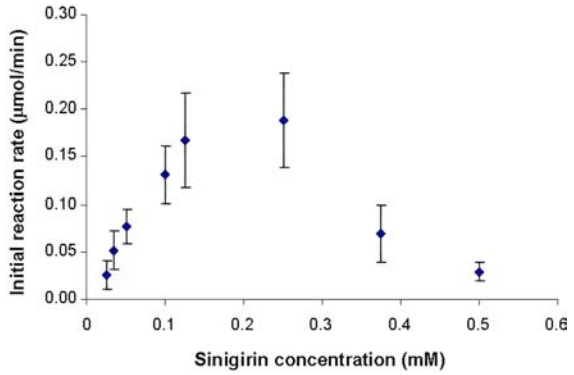

**Figure 4.** Initial reaction rate of myrosinase at different initial sinigrin concentrations.

broccoli blanching on sulforaphane synthesis. The authors suggest that a decrease in myrosinase activity at temperatures above 57 °C may be explained by substrate inhibition, owing to the higher release of glucosinolates from the vegetal matrix. The behavior of broccoli myrosinase differs from that exhibited by horseradish and *Raphanus sativus* myrosinases, which showed no substrate inhibition.[13,15]

The kinetic parameters $V_{mas}$, $K_m$, and $K_I$ were estimated from the Michaelis–Menten model with substrate inhibition (eq 1). Here, $V$ is the initial reaction rate, and $[S]$ is the substrate concentration. The maximum activity predicted by the model occurred at 0.18 mM sinigrin $[S_{max}]$. Myrosinase from *R. sativus* has a $K_m$ value of 2.06 $\mu$mol min$^{-1}$ mg$^{-1}$ and a $V_{max}$ equal to 23 $\mu$M,[13] whereas the kinetic parameters reported for horseradish myrosinase were 0.128 mM and 0.624 $\mu$mol min$^{-1}$, respectively.[15] Despite these authors not considering substrate inhibition, our values are of the same order of magnitude.

$$V = \frac{0.246[S]}{0.086 + [S] + \frac{[S]^2}{0.368}} \quad (1)$$

In summary, broccoli myrosinase was successfully purified by means of a rationally designed process that consists of ammonium sulfate precipitation, followed by concanavalin A affinity chromatography. The process resulted in an 88% recovery and a 1318-fold purification, the highest values reported for the purification of any myrosinase. The subunits of broccoli myrosinase have a molecular weight of 50–55 kDa, and the native structure is composed of three subunits. The maximum myrosinase activity was achieved at pH 4.0 and 40 °C. Broccoli myrosinase is subjected to substrate inhibition, with kinetic parameters that coincide in order of magnitude with those reported for other myrosinases.

using a DNA laddering assay, flow cytometric analysis, and Western blotting. To investigate the global influences within melanoma cells caused by GA induction, two-dimensional gel electrophoresis (2-DE) was used to monitor comprehensive protein expression comparatively from B16F10 melanoma cells with and without GA treatment. Using this method, quantitative analysis of protein expression profiling on a large scale can be achieved by intensity comparison of protein spots stained by silver or Coomassie blue on the gels of control and experimental samples. Differentially displayed proteins can be further hydrolyzed using in-gel digestion, and the protein identities can be identified using tandem mass spectrometry (MS/MS) and database matching. In this study, the regulated proteins from B16F10 melanoma cells under GA stimulation were uncovered, and their relative expressions were validated by Western blotting. The functions of the differentially displayed proteins were further correlated for exploring a more comprehensive mechanism underlying GA-mediated biological action.

## MATERIALS AND METHODS

**Materials.** Protease inhibitor cocktail, Dulbecco's modified Eagle medium (DMEM), and 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) were purchased from Sigma-Aldrich Corp. (St. Louis, MO, USA). Fetal bovine serum (FBS) was from Gibco (Carlsbad, CA, USA). Cell extraction buffer was obtained from BioSource International (Camarillo, CA, USA). The immobilized pH gradient (IPG) strips and sampling buffer were from GE Healthcare (Buckinghamshire, UK). Gallic acid (GA), iodoacetamide (IAA), dimethyl sulfoxide (DMSO), sodium dodecyl sulfate (SDS), trichloroacetic acid (TCA), propidium iodide (PI), RNase A, Triton X-100, cyclosporine A (CyA), and trifluoperazine (TFZ) (mitochondrial permeability transition inhibitors) were obtained from Sigma. Formic acid (FA), acetone, acetonitrile (ACN), ammonium bicarbonate (ABC), and 1,4-dithiothreitol (DTT) were obtained from J. T. Baker (Phillipsburg, NJ, USA). Trypsin used in in-gel digestion was purchased from Promega (Madison, WI, USA). Rabbit anti-mouse TCP1, PRDX-1, Rho-GDI, G-3-P DHase, SOD, aldolase, HSP 60, HSC 71, VDAC-1, ATPase, enolase, and glucokinase antibodies were purchased from ProteinTech Group (Chicago, IL, USA). Antibodies for apoptosis-related proteins such as cleaved caspase-8, cleaved caspase-9, cleaved caspase-3, PARP-1, Bad, AIF, Bax, cytochrome *c*, Mcl-1, Bcl-xL, and Bcl-2 were obtained from Cell Signaling Technology (Danvers, MA, USA). Rabbit anti-mouse $\beta$-actin antibodies (used to recognize $\beta$-actin as the internal control) were obtained from Sigma. Horseradish peroxidase conjugated IgG (goat anti-rabbit) was purchased from Millipore (Bellerica, MA, USA). Chemiluminescent HRP substrate and polyvinylidene difluoride (PVDF) membranes were obtained from Pierce (Rockford, IL, USA). The water used in this study was produced using a Milli-Q (Millipore) water purification system.

**Cell Culture.** The mouse melanoma cell line (B16F10) was obtained from the Food Industry Research and Development Institute (Hsinchu, Taiwan). The cells were cultured in 75 $cm^2$ flasks at approximately $1 \times 10^6$ cells/mL cell density with 90% MEM, 10% FBS, penicillin/streptomycin (100 $\mu$g/mL streptomycin and 100 U/mL penicillin), and 2 mM L-glutamine, and the cells were incubated at 37 °C in 100% humidity, 5% $CO_2$−95% air.

**Viability Assay.** B16F10 cells ($2 \times 10^5$ cells/well) were placed onto 12-well plates and incubated at 37 °C for 24 h prior to be treated with GA at different concentrations (0, 50, 100, 200, and 400 $\mu$M) for various time periods (0, 6, 12, and 24 h). Cell viabilities under different conditions were determined using the MTT assay. A control was carried out using DMSO (0.5%); 0.5% of DMSO did not show any significant impact on cell viability. After incubation, cells were photographed using contrast phase microscope for the observation of morphological changes of B16F10 cells with and without GA stimulation.

**Cell Migration Assay and Wound-Healing Assay.** To validate GA's cytotoxic effect, B16F10 melanoma cells were seeded onto polycarbonate (PC) membranes (8.0 $\mu$m, BD Biosciences, San Jose, CA, USA) in the culture inserts. Then these inserts were transferred into wells with DMEM containing 10% FBS. B16F10 cells with or without GA treatment were incubated for 24 h. After removal of cells on the upper site, migrated cells on the lower site were fixed by 100% methanol and stained using Giemsa (Merck, Darmstadt, Germany). The migrated cells were photographed and counted at 100× magnification under microscope. GA's cytotoxic effect was also examined using the wound-healing assay. B16F10 cells were seeded in 6-well plates to allow the cells to grow to conflux. A pipet tip was used to create an artificial scratch/wound in each well. Detached B16F10 cells were removed by washing with PBS. Images of control and treated samples at different concentrations (0, 100, 200, and 400 $\mu$M of GA) were acquired at 0, 6, 12, and 24 h after the treatments.

**Analysis of DNA Fragmentation by Agarose Gel Electrophoresis.** B16F10 cells ($2 \times 10^5$ cells/well) were incubated in a medium containing GA with various concentrations (0, 100, 200, and 400 $\mu$M) for 24 h. The cells were then washed using cold PBS buffer and kept in a lysis buffer containing 10 mM EDTA, 50 mM Tris-HCl (pH at pH 8.0), 0.5 g/L proteinase K, and 0.25% NP-40 at 50 °C for 2 h. The precipitated DNA was collected using ethanol at 25 °C. The resulting DNA pellets were washed with 70% ice-cold ethanol and then dissolved in TE buffer (0.6 g/mL RNase A and 1 mM EDTA in 10 mM Tris-HCl at pH 8.0), and the DNA mixture was further incubated at 37 °C for 1 h. The DNA separation was performed using horizontal electrophoresis at 200 V on a 1.5% agarose gel using tris/acetic acid/EDTA (TAE) as the running buffer. Finally, the DNA gel was stained with ethidium bromide (EtBr) and visualized under a 2 UV transilluminator (MacroVue UV-20 Hoefer).

**Analysis of Cell Cycle Distribution and Apoptosis.** B16F10 cells were treated with DMSO (0.5%) or with various concentrations (0, 100, 200, and 400 $\mu$M) of GA for 24 h. After treatment, the cells were collected and the reagents were removed by washing with PBS twice. Then the cells were fixed in 70% ethanol overnight. The phase distribution of cell DNA content was determined using PI (Sigma) staining. The cells were precipitated using centrifugation at 700 rpm for 5 min at 4 °C, and the resulting cell pellet was stained with 10 $\mu$g/mL of PI (in PBS buffer containing 10 $\mu$g/mL of RNase A) for 15 min at room temperature in the dark. The apoptotic cells induced by GA were observed using annexin V staining. B16F10 cells at a density of $1 \times 10^6$ cells per 100 mm Petri dish were treated with DMSO (0.5%) or GA at various concentrations (0, 100, 200, and 400 $\mu$M) for 24 h and subsequently labeled with 10 $\mu$g/mL of annexin V−FITC individually. The analysis of cell cycle distribution and apoptosis of GA-treated B16F10 cells were performed using FACScan flow cytometer (Becton-Dickinson, Mansfield, MA, USA) coupled with Cell-Quest software (Becton-Dickinson).

**Protein Extraction and Quantification.** B16F10 cells were treated with solvent vehicle (0.5% DMSO) or indicated concentrations of GA for 24 h, and then the cells were lysed using cell extraction buffer (BioSource International), and protease inhibitor cocktail (Sigma) was added to avoid protein degradation. The protein precipitation from supernatant was carried out using 10% TCA/acetone solution containing 20 mM DTT overnight (−20 °C). The protein pellet was collected, and the supernatant was discarded after centrifugation at 8000 rpm for 30 min at 4 °C. The resulting pellet was dissolved in a rehydration buffer that contained 6 M urea, 2 M thiourea, 0.5% CHAPS, 0.002% bromophenol blue, 20 mM DTT, and 0.5% IPG buffer. The quantification of protein content was performed using a 2-D Quant Kit (GE Healthcare). Here, the calibration curve was established using bovine serum albumin (BSA).

**Two-Dimensional Gel Electrophoresis.** Two-dimensional gel electrophoresis procedure was carried out according to a previous study.[19] The isoelectric focusing (IEF) was performed on GE Healthcare Ettan IPGphor 3 at 20 °C with a current limit of 30 A. Protein mixture was dissolved in a rehydration buffer and applied on

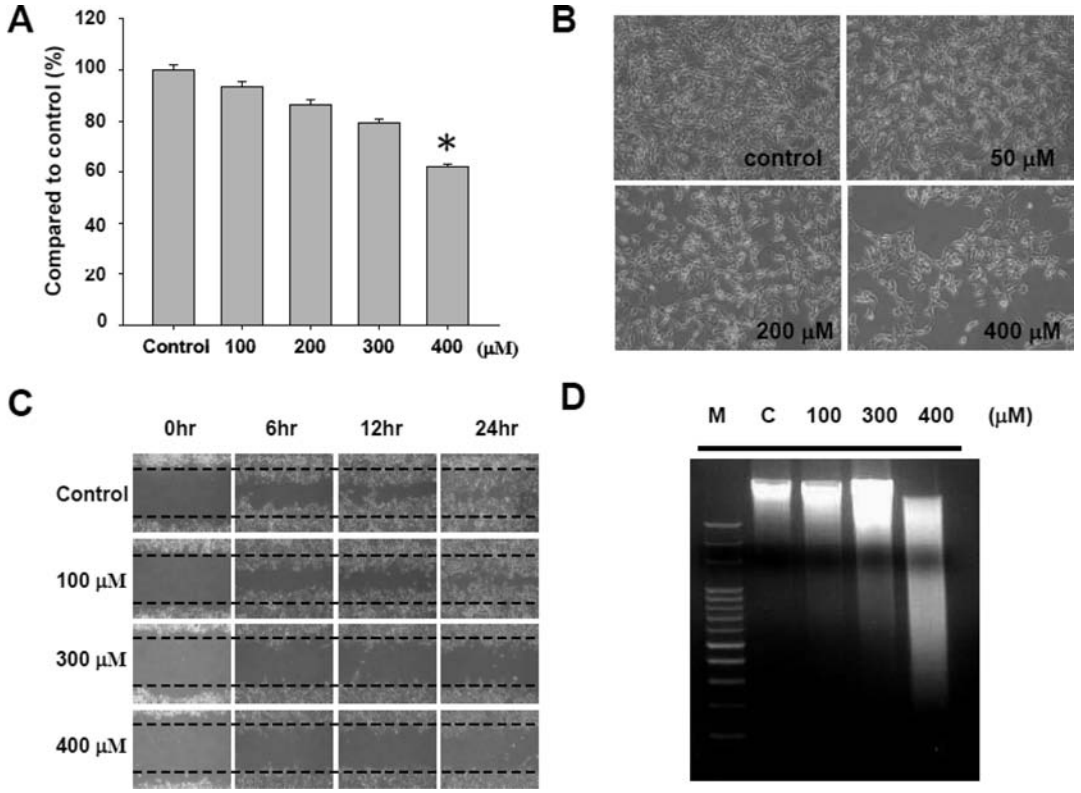

**Figure 1.** Evaluation of cytotoxicity and antimigratory effects of GA at different concentrations on B16F10 cells: (A) MTT assay for B16F10 cells treated with GA at 50−400 $\mu$M for 24 h (data are presented as the mean ± SEM from three independent experiments); (B) population and morphological changes of B16F10 cells treated with GA at different concentrations for 24 h; (C) wound-healing assay at different concentrations and time periods; (D) DNA laddering assay of B16F10 cells treated with GA at different concentrations (M, markers).

an IPG strip. An 11 cm IPG strip (p*I* 3−10) was rehydrated at 30 V for 12 h, and then proteins with different p*I* values were separated and focused using different stages of applied voltages according to the program 200 V (0−2 h), 500 V (2−4 h), 1000 V (4−6 h), 4000 V (6−7 h), 8000 V (7−11 h), until the total voltage (V) × hour (h) reached 39400. The equilibrated strip was placed on the top of a SDS-PAGE gel (12.5%), sealed with 0.5% agarose, and then the gel electrophoresis was performed under SE 600 Ruby (Hoefer, Holliston, MA, USA) at 150 V for 6.5 h. After that, the 2-DE gel was stained by silver, and the resulting silver-stained gel was scanned and analyzed using PDQuest image analysis software (Bio-Rad). 2-DE images were obtained from triplicates for each sample and normalized prior to statistical analysis. Protein spots (the same p*I* and $M_w$) in experimental and control samples showing more than 1.5-fold intensity difference were regarded as statistically significant.

**In-Gel Digestion.** A protein spot of interest was excised, cut into pieces, and immersed in 100 $\mu$L of 25 mM ammonium bicarbonate (ABC) (pH 8.5) containing 50 mM DTT at 37 °C for 1 h. After removal of supernatant, the gel pieces were resuspended in 100 $\mu$L of 100 mM iodoacetamide (IAA) in 25 mM ABC (pH 8.5) and then shaken for 30 min at room temperature in the dark. After removal of supernatant, the gel pieces were soaked in 100 $\mu$L of 50% acetonitrile in 25 mM ABC (pH 8.5) for 30 min, and then the buffer was completely removed by vacuum. The gel pieces were rehydrated and soaked in 100 $\mu$L of 25 mM ABC (pH 8.5) containing 0.1 $\mu$g of trypsin. The trypsin digestion was performed at 37 °C for 16 h. The reaction was quenched using 5 $\mu$L of 5% formic acid, and the resulting peptide mixture was obtained after removal of buffer.

**LC-MS/MS Analysis and Database Search.** The peptide mixture obtained from in-gel digestion was separated by a reversed phase C18 column (PepMap100 C18, 150 mm length, 2.1 mm i.d., 2.6 $\mu$m particle size) on a nano LC (Agilent 1200) system with a gradient from 5 to 70% acetonitrile containing 0.1% formic acid over 90 min at 300 nL/min. The separated peptides were online analyzed using an AB SCIEX QTRAP 5500 Q mass spectrometer (Applied Biosystems, Foster City CA, USA). The LC-MS/MS was performed under a positive survey scan in the range of $m/z$ 100−1000. The raw data were processed into WIFF format with Analyst 1.5.1. The database-assisted protein identification was carried out using Mascot search engine v2.3 (Matrix Science, UK) with the following search parameters: (1) protein database, Swiss-Prot; (2) taxonomy, *Mus musculus* (house mouse); (3) allowed trypsin missed cleavage, 1; (4) precursor and product ion mass tolerance, 2 Da/1 Da; (5) fixed modification, carbamidomethyl (C); (6) variable modifications, oxidation (M); (7) significance threshold, $p < 0.05$. Proteins with scores higher than the threshold were regarded as significant hits.

**Western Blotting Analysis.** GA-treated samples and controls were separated on SDS-PAGE gels, and the separated proteins on gels were transferred to PVDF membranes (Millipore) for 1.5 h at a fixed current of 400 mA under Transphor TE 62 (Hoefer). The membranes were then incubated with mouse antibodies of caspase-3/cleaved caspase-3, caspase-9/cleaved caspase-9, cleaved poly-ADP ribose polymerase (PARP), cytochrome *c*, AIF, Bcl-2, Bcl-xL, Mcl-1, Bax, p-Bad, Bad, TCP1, PRDX-1, Rho-GDI, G-3-P DHase, SOD, aldolase, HSP 60, HSC 71, VDAC-1, ATPase, $\alpha$-enolase, glucokinase, and $\beta$-actin at 4 °C for 2 h or overnight. The membranes were washed three times using PBST (10 mM $NaH_2PO_4$, 130 mM NaCl, 0.05% Tween 20), and then the primary antibodies were recognized and probed with the secondary antibodies (goat anti-rabbit) conjugated with horseradish peroxidase in blocking solution (1:5000) for 1 h. After removal of the excess secondary antibodies and blocking solution, the membranes were washed with PBST three times. The chemiluminescence on the blot was visualized through the redox reaction between horseradish peroxidase and substrate (ECL Western blotting reagent, Pierce).

**Statistical Analysis.** Experiments were done in triplicate or quaduplicate, and data of MTT assay, cell migration assay, and flow cytometric analysis were expressed as the mean ± SE. For the

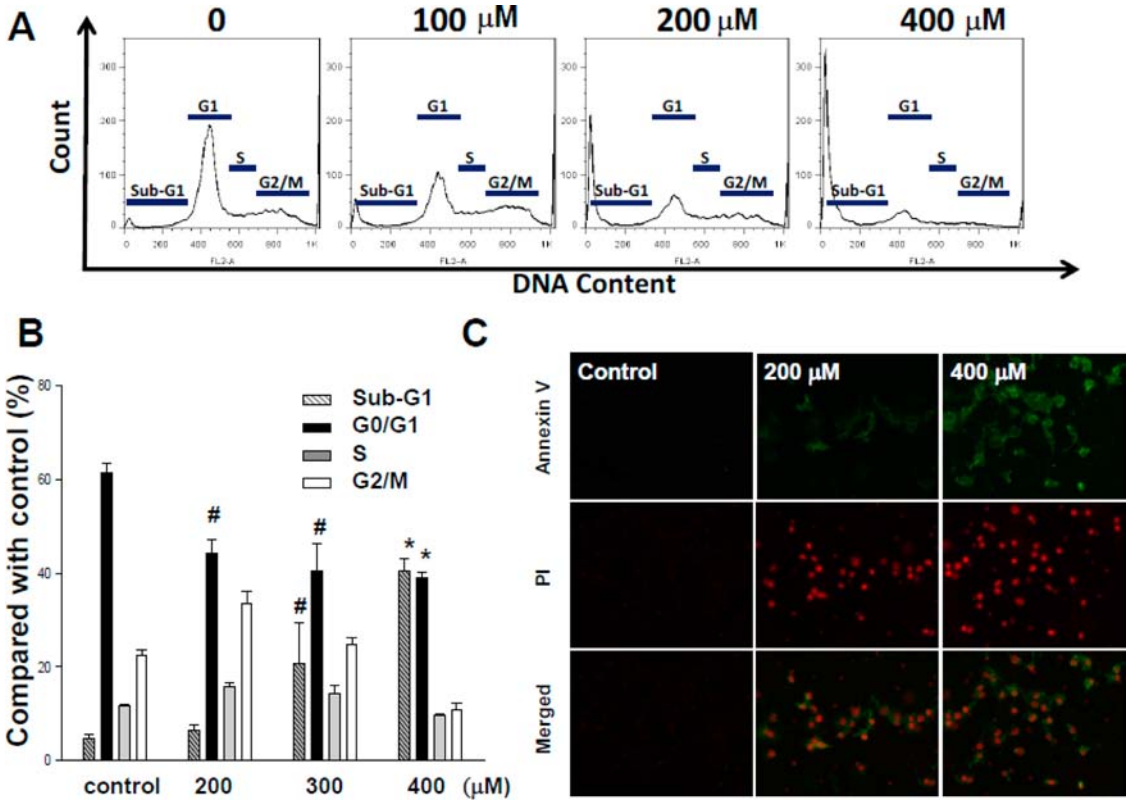

**Figure 2.** Cell cycle distribution and apoptosis: (A) flow cytometric measurement of cell cycle distribution of B16F10 cells treated with GA at different concentrations; (B) quantitative data obtained according to the DNA content measurement in panel A; (C) annexin V-FITC/PI analysis of B16F10 cells treated with GA at different concentrations.

determination of significant differences ($p \leq 0.05$) between experimental groups, one-way ANOVA followed by the Tukey–Kramer test, which was carried out on GraphPad InStat 3 (San Diego, CA, USA), was used in this study.

## RESULTS AND DISCUSSION

**Antitumor Effects of GA on B16F10 Cells.** B16F10 cells were treated with GA of various concentrations (0, 50, 100, 200, 400 $\mu$M) for 24 h. The MTT assay showed that significant cell death occurred (around 40%) when 400 $\mu$M GA was added (Figure 1A). The morphological change and reduced population of GA-treated cells observed by inverted light microscopy also displayed a similar trend (Figure 1B), which indicated that GA at a concentration of 400 $\mu$M can inhibit the proliferation of B16F10 cells. This result was similar to that reported by Locatelli et al.[15] The migratory capability of cells was measured by cell migration and wound-healing assay. After treatment with GA of various concentrations (50, 200, and 400 $\mu$M) in different time periods (6, 12, and 24 h), suppression of B16F10 cell migration was observed, and the migration suppression was also dose-dependent (Figure 1C and Supporting Information Figure S1). To study whether cell death was caused by apoptosis or not, the cells were treated with 0, 100, 200, and 400 $\mu$M GA for 24 h. After incubation, the cellular DNA was extracted and analyzed using agarose gel electrophoresis. As shown in Figure 1D, 400 $\mu$M GA induced the chromatin breakdown and the degraded DNA fragments resulting in ladder-like gel patterns, which indicated that cell death occurred via apoptosis instead of necrosis. According to a previous study, the cytotoxicities of GA and its derivatives toward other cell lines were mainly proposed to be involved in apoptosis-mediated cell death. Some phenomena such as mitochondrial dysfunction, intracellular $Ca^{2+}$ level increase, and DNA fragmentation were associated with this GA-induced apoptosis.[20,21] In fact, the effect of GA and its alkyl esters varies toward different tumor cell lines and results in cell-specific behavior. For example, the apoptotic DNA ladder fragmentation can be observed when mouse B cell lymphoma WEHI 231 cell line is stimulated by GA; however, in the case of GA-treated fibroblast L929 cells, some morphological changes such as cell shrinkage, chromatin condensation, and apoptotic body formation can be simultaneously observed, whereas the DNA fragmentation characteristic does not occur.[20] In this study, GA induced the breakdown of chromatin, resulting in apparent DNA fragmentation in B16F10 cells.

**GA-Induced Apoptosis of B16 Cells.** To investigate the effect of GA on cell cycle, B16F10 cells pretreated with GA at various concentrations (0, 100, 200, and 400 $\mu$M) were analyzed using annexin V–FITC and PI staining on flow cytometry (Becton-Dickinson). Apparently, B16F10 cells at sub-G1 phase were increased dose-dependently, which indicated that the accumulation of small DNA fragments was caused by apoptosis. The percentage of 400 $\mu$M GA-treated B16F10 cells at sub-G1 was enhanced to 41% while the control was only 6% (Figure 2A,B). The GA-induced apoptosis of B16F10 cells was further determined using the flow cytometer based-annexin V staining. Under fluorescent microscopy, the formation of apoptotic bodies indicated that GA concentrations of 200 and 400 $\mu$M dose-dependently increased the percentage of apoptotic cells (Figure 2C). These results all indicated that the cytotoxic effect of GA against B16F10 cells was due to its apparent apoptosis induction. According to the hypothesis

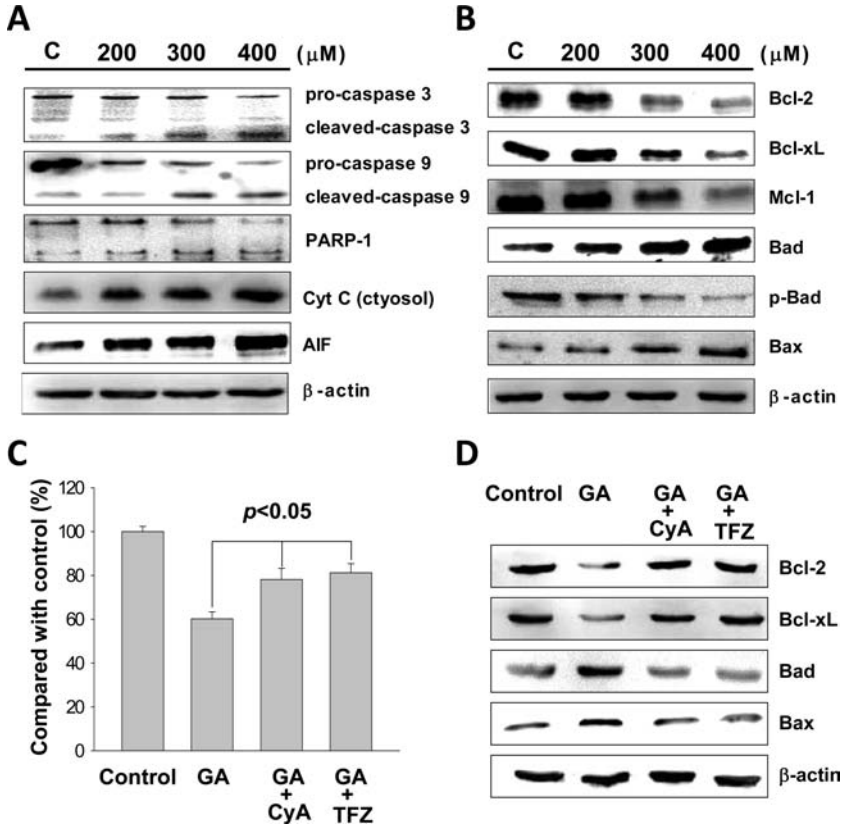

**Figure 3.** Expressions of apoptosis-related proteins in GA-treated B16F10 cells: (A) Western blotting analysis of caspase-3/cleaved caspase-3, caspase-9/cleaved caspase-9, cleaved-poly-ADP ribose polymerase (PARP), cytochrome *c* (cytosolic), and apoptosis-inducing factor (AIF) in B16F10 cells treated with GA at different concentrations; (B) Western blotting analysis of Bcl-2, Bcl-xL, induced myeloid leukemia cell differentiation protein (MCl-1), Bax, p-Bad, and Bad in B16F10 cells treated with GA at different concentrations; (C) cell viabilities (%, compared with the control) of GA (400 $\mu$M)-induced cell apoptosis with and without the mitochondrial permeability transition inhibitors cyclosporine A (CyA) or trifluoperazine (TFZ); (D) expression levels of Bcl2, Bcl-xl, Bax, and Bad proteins in the GA (400 $\mu$M)-induced B16F10 cells with and without mitochondrial permeability transition inhibitors. $\beta$-Actin was used as the internal control.

proposed by Serrano et al., GA can induce apoptosis not only because it can promote the generation of reactive oxygen species (ROS) but also as a consequence of its inhibitory activity toward protein tyrosine kinases (PTKs).[21] In the study of anticancer effects of GA on A549 human lung adenocarcinoma cells, Maurya et al. presented that GA treatment simultaneously decreased mitochondrial membrane potential and increased intracellular ROS, and the caspase activity measurement further showed the activation of caspase-3 but not caspase-8, indicating the involvement of intrinsic cell apoptosis.[10] Ou et al. presented that GA can induce G2/M phase cell cycle arrest in human bladder transitional carcinoma cells through regulating 14-3-3$\beta$ release from activation of Cdc25C and Chk2.[22] In normal human lymphocytes, however, GA shows anti-apoptotic ability via Bcl-2 independent mechanism.[23] Therefore, the detailed mechanism of apoptosis induction by GA in different tumor cells so far is not well-defined.

**Western Blot of Apoptosis Related Proteins.** To determine the mechanism for GA-induced apoptosis, we further analyzed the expression levels of several apoptotic markers including cytosolic cytochrome *c*, caspase-3, caspase-9, cleaved PARP, and apoptosis-inducing factor (AIF) from GA-treated B16F10 cells. Western blot showed dose-dependent down-regulations of pro-caspase-9 and pro-caspase-3. Expression of caspase-3 (17 kDa proteolytic fragments) was elevated when the concentration of GA increased to 200 $\mu$M or higher. Similarly, the increase of cleaved form of caspase-9 was also found at 37 kDa after GA treatment; the enhancement of cytosolic cytochrome *c* released from mitochondria, which activated caspase-dependent cell death, was simultaneously observed. Interestingly, the decrease of PARP-1 (116 kDa) was accompanied by dose-dependent increases of cleaved PARP-1 (89 kDa) and AIF after GA treatment (Figure 3A). This implied that the PARP-1 activation propagated to mitochondria, triggered the AIF translocation from mitochondria to the nucleus, and induced chromatin condensation and DNA fragmentation. The overexpression of AIF in the nucleus suggested that GA-induced apoptosis was also through a caspase-independent apoptosis. Unlike other cancer cell lines in which the GA-induced apoptosis was reported to be occurred solely via a caspase-dependent pathway, GA-induced apoptosis involved in B16F10 cells was simultaneously through caspase-dependent and -independent pathways, which is consistent with the phenomenon occurring in the other melanoma cell, A375.S2.[14] To further verify this conclusion, the expression levels of some mitochondrial cell death effectors such as pro-apoptotic B-cell lymphoma-2 (Bcl-2) family members Bax, Bak, and Bad were simultaneously evaluated with the increase of GA concentration. Meanwhile, the expression of anti-apoptotic Bcl-2, Bcl-xL, Mcl-1, and p-Bad was simultaneously suppressed (Figure 3B). The combined effects promoted the mitochondrial outer membrane permeablization and the release of cytochrome *c* from mitochondria into the cytosol and led to the

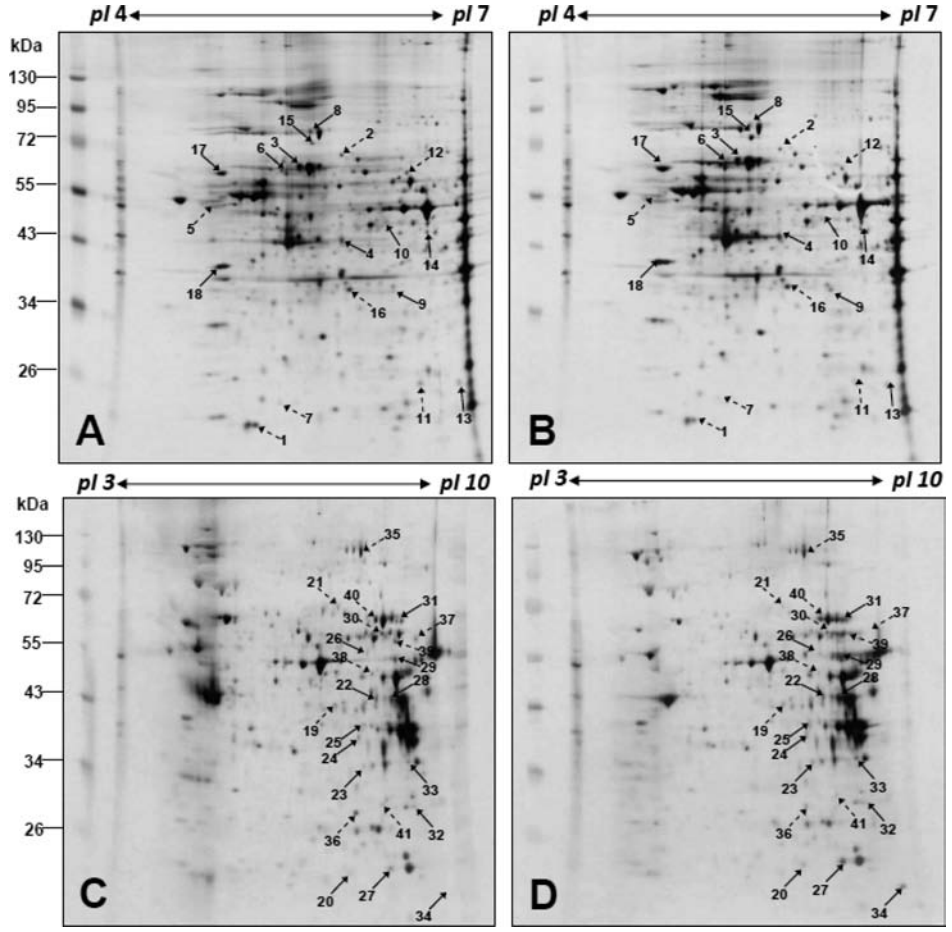

**Figure 4.** 2-DE maps of B16F10 cells treated with 400 $\mu$M GA and the control sample processed in different p*I* ranges: (A) control and (B) treated with 400 $\mu$M GA for 24 h in a range of p*I* 4−7; (C) control and (D) treated samples in p*I* 3−10. Protein spots marked on the maps were considered differentially expressed and identified by LC-MS/MS. The results are representative of three independent runs. Solid arrows denote up-regulated proteins, and dashed ones denote down-regulated proteins.

subsequent activation of caspase-3 and the executioner caspases. The data all indicated that GA induced B16F10 cell apoptosis via a mitochondrial intrinsic pathway. To further confirm that GA-induced cell apoptosis is through a mitochondria-related apoptotic pathway, B16F10 cells were pretreated with either cyclosporine A (CyA) or trifluoperazine (TFZ) (both are mitochondrial permeability transition inhibitors) prior to the GA treatment. The results showed that GA-induced cell apoptosis was significantly decreased when CyA or TFZ was added (Figure 3C). In addition, several mitochondrial-related apoptotic proteins, including Bcl2, Bcl-xl, Bax, and Bad proteins, were estimated by Western blotting, respectively. The expressions of Bcl2 and Bcl-xl were promoted when the cells were pretreated with CyA and TFZ. By contrast, the expression levels of Bax and Bad were decreased in the GA-treated cells when the cells were pretreated with CyA and TFZ (Figure 3D). Taken together, these results suggested that mitochondria dysfunction-mediated apoptotic pathway was involved in GA-induced cell apoptosis. To further uncover the pathway networks associated with this apoptosis, a comprehensive proteome study was used to globally analyze proteins regulated in GA-induced B16F10 cells.

**Proteomic Analysis of B16F10 Cells with GA Stimulation.** Protein spots from samples with and without 400 $\mu$M GA treatment were visualized by silver staining on 2-DE gels, as shown in Figure 4A,B with p*I* 4−7 and Figure 4C,D with p*I* 3−10. The quantitative analysis of protein spots in 2-DE maps between the GA-treated and the control samples was achieved using PDQuest image analysis software (Bio-Rad). Proteins with >1.5-fold spot intensity difference between the experimental and the control samples were defined as differentially expressed proteins. The differentially expressed proteins were hydrolyzed using in-gel trypsin digestion followed by LC-MS/MS analysis. The database-assisted protein identification was achieved using the MASCOT protein identification search engine. A total of 41 differentially expressed proteins were quantified and identified. Using a 1.5-fold intensity difference compared to control as threshold, 25 spots were overexpressed and 16 spots were underexpressed. The identified proteins with their MASCOT scores, identified peptide sequences, calculated $M_w$, p*I*, coverages, and folds of change in expression level (up-regulation or down-regulation) are shown in Table 1. Some up-regulated proteins such as 60 kDa heat shock protein (HSP60), heat shock cognate 71 kDa protein (HSC 71), nucleophosmin (NPM), peroxiredoxin-1 (PRDX-1), succinyl-CoA ligase (SCS-$\beta$G), poly(rC)-binding protein 1 (PCBP1), superoxide dismutase (SOD), voltage-dependent anion-selective channel protein 1 (VDAC-1), and voltage-dependent anion-selective channel protein 2 (VDAC-2) have been reported to be associated with apoptosis.[24−27] Among these up-regulated proteins, HSP60 acts as a chaperone protein to maintain proper folding and assembling of polypeptide chains in

**Table 1. Regulated Proteins Identified Using 2-DE-Based Comparative Proteomics**

| spot no. | protein name (short name) | accession no. | calcd $M_w$/p$I$ | peptides matched | sequence covered (%) | MASCOT score | regulation (-fold change)[a] |

[a]Regulations (-fold changes) of differentially expression proteins are expressed at 24 h of treatment of gallic acid.

mitochondria, and overexpression of HSP60 is regarded as sustaining cellular survival under toxic or stressful conditions;[24] HSC 71 also acts as a chaperone involved in cell proliferation, differentiation, and tumorigenesis. Its increasing level in B16F10 cells after treatment with 400 $\mu$M GA suggested the association with the responses of either apoptosis or cell survival.[25] Similarly, the expressions of some down-regulated proteins such as T-complex protein 1 subunit $\varepsilon$ (TCP-1), vimentin, Rho GDP-dissociation inhibitor 1 (Rho-GDI), peroxiredoxin-6 (PRDX-6), elongation factor 2 (EF-2), and calcyclin-binding protein (CacyBP) are also consistent with those involved in apoptosis reported in the literature.[18,28−31]

The identities and relative expressions of some regulated proteins under GA treatment with various concentrations were further validated by Western blotting (Figure 5). HSP60, HSC 71, VDAC-1, SOD, and PRDX-1 were dose-dependently up-regulated, and their expression levels upon 400 $\mu$M GA treatment were consistent with those measured by 2-DE experiment. Meanwhile, TCP1, Rho-GDI, and ATPase were simultaneously down-regulated, which showed trends similar to those using a proteomics approach. In addition to these regulated proteins, which were regarded as being associated with apoptosis, interestingly, some proteins involved in glycolysis such as $\alpha$-enolase, aldolase, pyruvate kinase, and

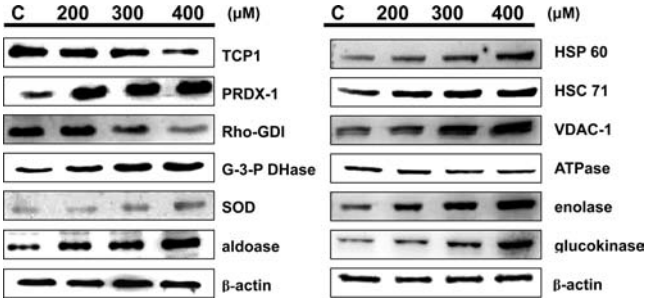

**Figure 5.** Validations of some regulated proteins identified from 2-DE experiment. Western blotting analysis of TCP1, PRDX-1, Rho-GDI, G-3-P DHase, SOD, aldolase, HSP 60, HSC 71, VDAC-1, ATPase, enolase, and glucokinase in B16F10 cells treated with increasing concentrations of GA. $\beta$-Actin was used as the internal control.

GAPDH were simultaneously up-regulated during the GA-induced apoptosis according to 2-DE experiment. The dose-dependent effects of GA on these glycolytic proteins were further confirmed by Western blotting, as shown in Figure 5. The result indicated that enolase, aldolase, pyruvate kinase, and GAPDH were up-regulated dose-dependently in GA-induced B16F10 cells, which implied that GA plays a dual role in both glycolysis and apoptosis. To further validate the activation of glycolysis, the expression of glucokinase, the key glycolysis enzyme, was also examined. The expression of glucokinase was up-regulated accordingly (Figure 5), which further provided evidence for this correlation. As we know, the oxidative phosphorylation of cancer cells is usually suppressed when they are under stressful condition, such as under GA stimulation. The energy supply of cancer cells shifts from oxidative phosphorylation to glycolysis, aiming to produce sufficient ATP, which is known as the Warburg effect.[32] The over-expression of glycolytic proteins in GA-treated B16F10 cells may be due to this effect. Typically, glycolysis and apoptosis are considered as major but independent pathways that are critical for cell survival. Through comparative proteomics, an association between GA-induced apoptosis and metabolic glycolysis in B16F10 melanoma cells was identified and correlated in this study. The interaction between GA-induced apoptosis and metabolic glycolysis may be also explained by the following two reasons: (1) Danial et al. combined the study of proteomics, genetics, and physiology to conclude that BAD and glucokinase reside in a mitochondrial complex that integrates glycolysis and apoptosis,[33] which suggests that GA triggered the intrinsic apoptosis accompanied by glycolysis; (2) GA induces intensive glycolysis and produces a highly reactive metabolite methylglyoxal (MG), which leads to B16F10 cell apoptosis via a mitochondrial intrinsic pathway.[34] However, these two reasons can not fully explain the co-occurrence of GA-induced apoptosis and metabolic glycolysis in B16F10 melanoma cells, so further exploration and validation experiments are required.

In this study, we comprehensively investigated the cytotoxicity on B16F10 melanoma cells caused by gallic acid with a concentration >200 $\mu$M using the MTT assay, wound-healing assay, and cell migration assay. The result of DNA laddering assay and flow cytometry assay further indicated that cell death occurred via apoptosis instead of necrosis. The overexpressions of cleaved forms of caspase-9, caspase-3, and PARP-1 and pro-apoptic Bax and Bad, accompanied by underexpressed anti-apoptotic Bcl-2 and Bcl-XL, indicated that GA induced B16F10 cell apoptosis via a mitochondrial pathway. 2-DE-based comparative proteomics showed that most regulated proteins were associated with apoptosis, consistent with the Western blot data. Notably, the proteomics data also revealed that most proteins involved in glycolysis were simultaneously up-regulated in this GA-induced cell apoptosis. The correlation between glycolysis and apoptosis was further confirmed by Western blot of glucokinase, $\alpha$-enolase, aldolase, and GAPDH.

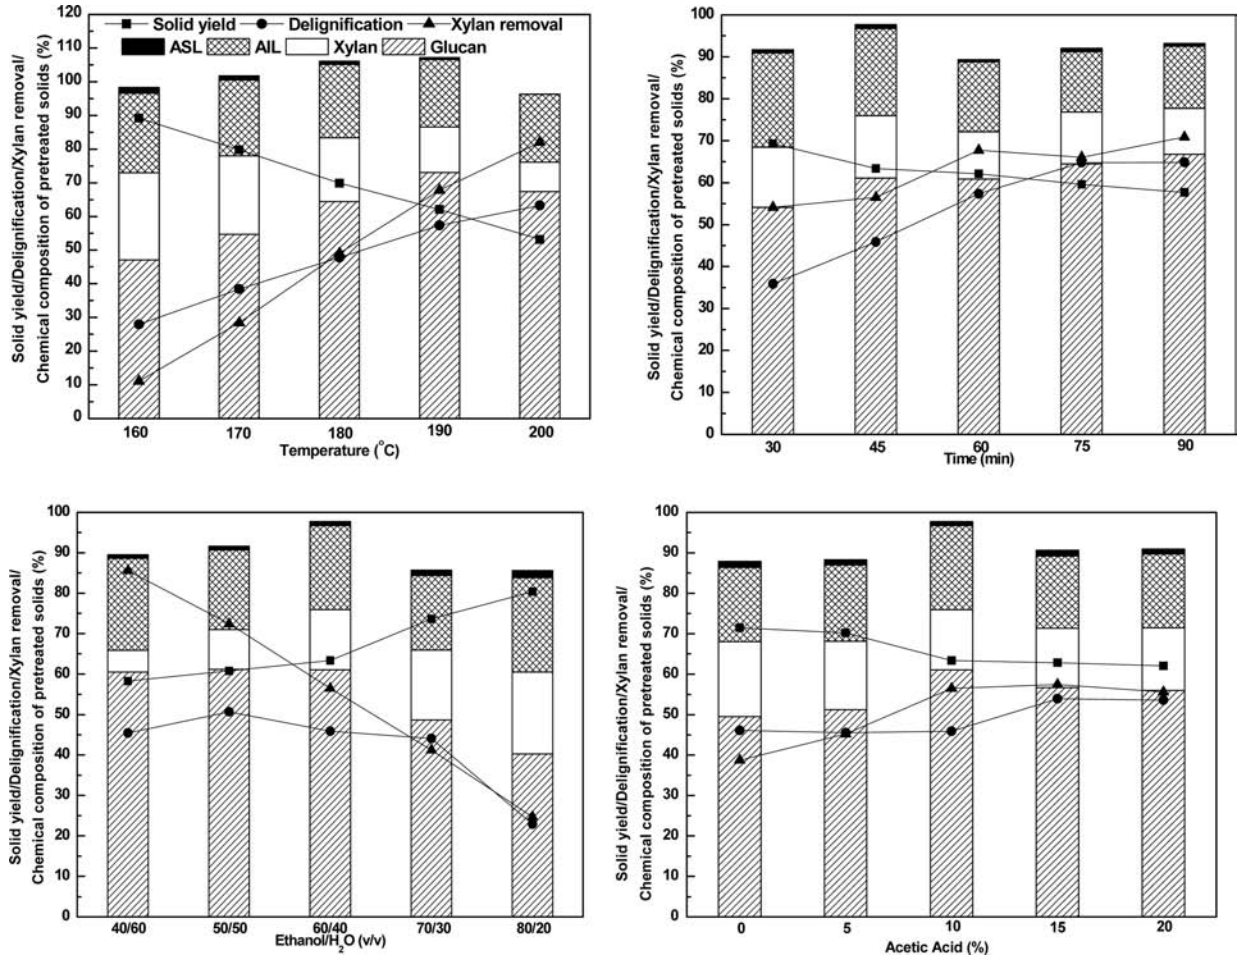

**Figure 1.** Effect of pretreatment conditions on the chemical composition of pretreated solids.

On the basis of the above viewpoint, sugar cane bagasse was subjected to acetic acid organosolv pretreatment for enzymatic saccharification. A parametric study focusing on the temperature, reaction time, ethanol concentration, and acid catalyst dose was performed to determine their influence on compositional changes of pretreated solids and the glucose and xylose yields during the pretreatment process and subsequent enzymatic hydrolysis. Moreover, the parametric effects on the total sugar yields were also investigated. Furthermore, we detected changes in the raw material and pretreated samples (pretreatment conditions of 190 °C, 45 min, 60:40 ethanol/water, and 5 wt % dosage of acetic acid) in crystallinity by X-ray diffraction (XRD) and in the surface structure by scanning electron microscopy (SEM) to provide a relation between delignification, xylan removal, and enzymatic hydrolysis.

## MATERIALS AND METHODS

**Materials.** Sugar cane bagasse obtained in Guangdong, China, was milled to a particle size of <1 mm using a refiner. Then, the milled raw material was air-dried for further use. The chemical composition of the milled sugar cane bagasse (on a dry weight basis) was 39.4 ± 0.7% glucan, 21.6 ± 0.3% xylan, 1.6 ± 0.2% arabinan, 0.4 ± 0.1% galactan, 24.3 ± 0.6% acid-insoluble lignin (AIL), 1.4 ± 0.2% acid-soluble lignin (ASL), and 4.5 ± 0.5% ash.

Ethanol and acetic acid were purchased from Sinopharm Chemical Reagent Co., Ltd. and China Sun Specialty Products Co., Ltd., respectively.

**Organosolv Pretreatment.** A total of 50 g (dry weight) of sugar cane bagasse was treated with aqueous ethanol (40:60−80:20 ethanol/water, v/v) at 1:8 solid/liquid ratio. The pretreatments were carried out in a 1 L high-pressure vessel (Parr Instrument Company, Moline, IL) equipped with a motor-driven electromagnetic stirrer (300 rpm). The reaction mixture were heated at 160−200 °C for 30−90 min in the presence of 0−10 wt % acetic acid based on the weight of raw material. It took 25−35 min to reach the prescribed temperature for the reactor. When the pretreatment was finished, the reactor was immediately cooled to room temperature by cooling water. The pretreated solution were separated by filtration and washed with ethanol/water (60 °C, 60:40, v/v). Then, the washes were combined, and 2 volumes of water were added to precipitate the ethanol organosolv lignin, which could be collected by centrifugation. The pretreated solids were stored in a refrigerator for further enzymatic hydrolysis. The concentration of sugars (glucose and xylose) and inhibitors [hydroxymethylfurfural (HMF) and furfural] in the prehydrolyzate and enzymatic hydrolysis process were analyzed by ion chromatography (IC) and high-pressure liquid chromatography (HPLC), respectively.

**Enzymatic Hydrolysis.** Pretreated sugar cane bagasse samples were immersed in 0.05 mol/L acetic acid sodium acetate buffer (pH 4.8) with 2% (w/w) dry matter and then incubated on a shaker at 150 rpm and 50 °C up to 60 h. The pretreated solids were subjected to enzymatic hydrolysis using the commercial cellulase mixture provided by Genencor (Shanghai, China), with a filter paper activity of 20 filter paper units (FPU)/mL. The cellulases were added at the loading of 20 FPU/g of dry substrate for all hydrolysis experiments. Two drops of acetic ether were added to avoid microorganisms. When the enzymatic hydrolysis reached the setting time, the samples were boiled for 10 min to quench the enzymatic reaction. Then, the enzymatic samples were centrifuged, the supernatants were retained for subsequent sugar analysis, and enzymatic residues were stored for further analysis.

**Table 1. Composition of the Prehydrolyzate after Ethanol-Based Organosolv Pretreatment of Sugar Cane Bagasse under Different Pretreatment Conditions**

| pretreatment condition | | | | composition of prehydrolyzate (g/100 g of raw material) | | | | | | inhibitor (g/L) | |
|---|---|---|---|---|---|---|---|---|---|---|---|
| temperature (°C) | time (min) | ethanol/$H_2O$ (v/v) | acetic acid (%) | glucose | glu-oligo | total glucose | xylose | xyl-oligo | total xylose | HMF | furfural |

**Analytical Techniques.** The chemical composition of sugar cane bagasse and pretreated solids were determined using the standard provided by the National Renewable Energy Laboratory (NREL) in Golden, CO.[21] Because some of the sugars obtained from organosolv pretreatment were oligosaccharides, an acid hydrolysis [4% (w/w) $H_2SO_4$, 121 °C, and 60 min] was performed to obtain monosaccharides for analysis.

All liquid products from the pretreatment process and enzymatic hydrolysis were diluted appropriately with the deionized water and then filtered using a 0.22 $\mu$m filter. The concentration of glucose and xylose were quantitatively analyzed at 30 °C by the IC system (Dionex ICS-3000) with a CarboPac PA20 column. The sugar derivatives (furfural and HMF) were determined using a HPLC system ($C_{18}$ column) at 30 °C based on a diode array detector (DAD). The mobile phase consisted of methanol/water (30:70, v/v) with a flow rate of 1.0 mL/min.[6]

**Crystallinity Measurements.** The crystallinity of native material and pretreated solid (190 °C, 45 min, 60:40 ethanol/$H_2O$, and 5 wt % acetic acid) was determined by XRD using a Bruker D8-ADVANCE (Germany) with Cu Ni radiation ($k$ = 0.154 18 nm). The scattering angle ($2\theta$) was from 5° to 60°. The crystalline index (CrI) was determined on the basis of the formula by Segal et al.[22] as follows:

$$\mathrm{CrI} = \frac{I_{002} - I_{\mathrm{am}}}{I_{002}} \times 100\%$$

in which $I_{002}$ is the scattered intensity at the main peak around 22.5° and $I_{\mathrm{am}}$ is the scattered intensity as a result of the amorphous portion evaluated as the minimum intensity between the main and secondary (the broad peak at 18.0°) peaks.

**SEM Analysis.** SEM of the two samples (raw material and solid pretreated at 190 °C, 45 min, 60:40 ethanol/$H_2O$, and 5 wt % acetic acid) was carried out with a ZEISS EVO18 (Germany) instrument at 10 kV. Each sample was sputter-coated with gold for 180 s prior to the observation. All observations were used at 2000× magnification.

## RESULTS AND DISCUSSION

**Chemical Composition of Sugar Cane Bagasse Pretreated by Different Ethanol Concentrations.** The effect of pretreatment parameters (temperature, reaction time, ethanol concentration, and acetic acid dose) on the solid recoveries and chemical composition of pretreated solids were discussed and presented in Figure 1. Ethanol and acetic acid in the pretreatment process were employed to remove hemicellulose and lignin; thus, the relative content of glucan (cellulose) in pretreated solids was higher than in raw material. Because of the different pretreatment conditions, the solid yields and chemical composition of pretreated biomass differed greatly.[23]

The solid yields decreased with the increment of the pretreatment temperature. When the pretreatment temperature increased from 160 to 200 °C, the solid yields decreased from 89.2 to 53.2%. However, within the same pretreatment parameters, the delignification and xylan removal increased from 27.9 and 11.1% to 63.3 and 82.0%, respectively. The increased delignification and xylan hydrolysis (generation of sugars and inhibitors) made a great contribution to the decreased solid yields. When the reaction time is taken as an example, extension of the reaction time (30−60 min) lead to a decrease of the solid yield (from 69.3 to 62.1%) but increment of the delignification (from 35.9 to 57.4%) and xylan removal (from 54.1 to 67.8%). However, when the reaction time was prolonged from 60 to 90 min, the increment of delignification and xylan removal were not significant. These results suggested that the reaction time seemed not to be a major process parameter for the organosolv pretreatment within a long reaction time (more than 60 min).[15]

As shown in Figure 1, the solid yields increased with the ethanol concentration because of the decreased delignification and xylan hydrolysis. The glucan content of the pretreated solid

decreased from 60.5% (40% ethanol) to 40.2% (80% ethanol). The increased ethanol concentration made a great contribution to the decreased xylan removal, which dropped from 85.6 to 24.7% . This phenomenon could be concluded that a higher concentration of ethanol inhibited xylan hydrolysis, which was in agreement with previous work.[24] As the ethanol concentration increased, more lignin could be soluble in the ethanol.[15] However, the delignification were decreased with the increased ethanol concentration (as shown in Figure 1). This observation suggested that the lower removal of xylan resulted in decreased delignification because of the linkages between lignin and hemicelluloses.

During the organosolv pretreatment process, the hemicellulose hydrolysis could be improved by the addition of the acid catalyst. As a consequence of increasing the acetic acid dose from 0 to 10 wt %, delignification and xylan hydrolysis increased and the solid yield decreased. For acid-soluble lignin (ASL), the composition of pretreated solids was lower than the raw material, suggesting that part of ASL was solubilized by ethanol and/or acetic acid.

**Organosolv Pretreatment.** The influence of reaction parameters on the composition of prehydrolyzate (including monomeric and oligomeric sugars of glucose and xylose) were examined and displayed in Table 1. Xylan was the principal component in hemicellulose, and its monomeric component (xylose) was the major carbohydrate in the prehydrolyzate, as shown in Table 1. When the pretreatment temperature is taken as an example, the xylose yield increased with the temperature, reaching 11.83 g (including 11.27 g of xylo-oligomers) based on 100 g of raw material at 190 °C, representing 48.1% xylose in the raw material. A further increase in the temperature reduced the xylose yield. This was probably due to the degradation of xylose to furfural with a serious pretreatment temperature.[25]

At the same reaction temperature, the reaction time shows a slight influence of the pretreatment at the process conditions tested. However, it may be an important parameter for the production of xylose. During different reaction times, the xylose yield was in the range of 8.42−11.83 g based on 100 g of raw material. When the reaction time reached 45 min, the xylose yield was 11.23 g/100 g of raw material. Although the xylose yield was a little lower than the prehydrolyzate pretreated at 60 min (11.83 g), within the reducing energy consumption during pretreatment, the reaction time of 45 min was regarded as the optimum. The xylose yield with different ethanol concentrations first increased from 8.73 g (40:60 ethanol/water) to 11.38 g (50:50 ethanol/water) and then decreased sharply to 2.97 g (80:20 ethanol/water). These results suggested that the ethanol concentration had significantly impacted the pretreatment and a higher ethanol concentration did not result in the large removal of xylan and high recovery of xylose.[26] The presence of ethanol in the reaction allowed for the performance of the delignification, which was confirmed in Figure 1. With the removal of lignin during the pretreatment, the subsequent enzymatic digestibility could be enhanced because of the removal of the physical barrier preventing enzyme access and nonproductive binding with enzyme,[27] which would be discussed in the following section. In addition, the removal of xylan also played an important role in enzymatic hydrolysis, as shown in the following discussion.

Hemicellulose hydrolysis during the organosolv pretreatment process could be enhanced by acid, thereby improving the subsequent enzymatic cellulose hydrolysis.[15] In this study, acetic acid was regarded as the catalyst and introduced in the pretreatment reaction. It is observed that the acetic acid concentration showed a strong influence on xylose production. As the acetic acid dosage increased from 0 to 10 wt %, the

xylose yield ranged from 6.03 to 11.23 g based on 100 g of raw material. The relative high concentration of acetic acid seemed to favor the production of xylose in the prehydrolyzate.[23] However, more acetic acid lead to the drastic degradation of xylose to furfural, as shown in Table 1.

From Table 1, it could be known that most of the xylose yield was obtained in the form of oligomers. This phenomenon could be concluded that the weak acid (acetic acid) during the pretreatment may enhance acid-catalyzed hydrolysis of hemicellulose to xylo-oligomes but was not strong enough to hydrolyze to xylose monomers. Because of the low content of glucan in hemicellulose and the crystallization structure of cellulose, the glucose yields obtained from organosolv pretreatment were limited. The maximal yield of glucose (0.40 g/100 g of raw material) was obtained at 190 °C, 45 min, 40:60 ethanol/water, and 5 wt % dosage of acetic acid, representing only 0.9% glucose in the raw material. Table 1 also depicted the formation of furfural and HMF during the pretreatment process. The quantities of furfural and HMF were estimated to be below 0.76 and 0.03 g/L, respectively. The very low concentration of furfural and HMF in prehydrolyzate attested to the limited degradation of pentose and hexose, respectively. These results suggested that organosolv pretreatment prevented the degradation of saccharides, which agreed with the former literature.[12]

**Enzymatic Hydrolysis.** Enzymatic hydrolysis of the organolsolv pretreated solid residues were performed using standard literature conditions.[6] The effects of pretreatment factors were analyzed on the basis of the sugar yields during enzymatic hydrolysis, and the results were displayed in Table 2. In comparison to the enzymatic hydrolysis of raw material without pretreatment (4.05 g of glucose and 1.42 g of xylose), the enzymatic hydrolysis of the organosolv pretreated solids showed higher sugar yields after a 60 h hydrolysis time. The result indicated that delignification and hemicellulose removal were beneficial to the subsequent enzymatic hydrolysis of the pretreated solids because lignin and hemicellulose in the raw material as physical barriers could prevent the accessibility of enzyme to cellulose.[19]

From Table 2, it could know that glucose, as the major carbohydrate in enzyme hydrolyzate, differed from each other because of the different pretreatment parameters. When the pretreatment temperature is taken as an example, when it increased from 160 to 190 °C, a rapid growth of the glucose yield could be observed (from 12.87 to 39.52 g/100 g of raw material). As the temperature continued to rise (200 °C), the glucose yield decreased sharply to 32.98 g/100 g of raw material. As the pretreatment time was prolonged from 30 to 45 min at 190 °C, with ethanol/water (60:40, v/v) and 5 wt % dosage of acetic acid, the glucose yield increased from 32.90 to 40.42 g/100 g of raw material. A maximal glucose yield (40.99 g based on 100 g of raw material) could be obtained at 75 min, representing 93.8% of glucose in raw material. For the ethanol concentration, when the ethanol/water ratio increased from 40:60 to 60:40 (v/v), the glucose yield increased gradually (from 38.92 to 40.42 g/100 g of raw material). As the ethanol/water ratio continued to grow, the glucose decreased sharply to 14.46 g based on 100 g of raw material, suggesting that an increase in the ethanol concentration at a certain extent reduced the enzymatic digestibility because of the reduced xylan hydrolysis (shown in Figure 1).[15] A rise in the glucose yield (from 28.25 to 40.42 g/100 g of raw material) upon an increase of the acetic acid dosage from 0 to 5 wt % could be obtained, which could be concluded that acetic acid contributed to the hydrolysis of hemicellulose and the linkages between hemicellulose and lignin breakdown. However, when the acetic acid dose increased to 10 wt %, the glucose yield dropped to 38.30 g based on 100 g of raw material. Moreover, a certain amount of xylose could also be obtained during enzymatic hydrolysis. This phenomenon could be concluded that organosolv pretreatment was beneficial to the recovery of xylose.

As an overview of the efficiency of the pretreatment and subsequent enzymatic hydrolysis, the total sugars recovered from both pretreatment (mainly xylose) and enzymatic hydrolysis (mainly glucose) were also summarized and presented in Table 2. The maximum xylose yield (including xylose monomer and xylo-oligomer) was obtained at 180 °C, 60 min, 60:40 ethanol/water ratio, and 5 wt % dosage of acetic acid, reaching 18.34 g/100 g of raw material, representing 74.6% xylose in the sugar cane bagasse, and 43.1% was obtained from the pretreatment process. The results indicated that amorphous hemicellulose could be easily degraded during pretreatment because of the acidity provided by acetic acid. The highest glucose yield (41.28 g/100 g of raw material) was obtained at 190 °C, 75 min, 60:40 ethanol/water ratio, and 5 wt % dosage of acetic acid, representing 94.4% of glucose in raw material. Among them, 93.8% was obtained during the enzymatic hydrolysis process. This phenomenon suggested that organosolv pretreatment could greatly enhance the efficiency of subsequent enzymatic hydrolysis. To take full use of lignocellulosic biomass, Table 2 also illustrated the combined sugar (xylose and glucose) yields. The largest total sugar yields occurred at 190 °C, 45 min, 60:40 ethanol/water ratio, and 5 wt % dosage of acetic acid, reaching 58.36 g/100 g of raw material (including 40.68 g of glucose and 17.68 g of xylose), representing 85.4% of total sugars in sugar cane bagasse. Although most sugars were obtained during pretreatment and enzymatic hydrolysis processes, there is still some carbohydrates (including 3.30 g of glucan and 9.46 g of xylan based on 100 g of raw material) in the enzymatic residue; how to use the enzymatic residue well is still to be explored.

**Delignification and Xylan Removal.** From Table 2, it could be seen that the enzymatic hydrolysis of pretreated sugar cane bagasse was enhanced greatly. During the ethanol-based organosolv pretreatment, a portion of lignin and hemicellulose was solubilized and the enzymatic hydrolysis of pretreated solids was enhanced greatly, suggesting that the enhanced glucose conversion may have correlation with delignification and xylan removal. TableCurve 3D was used to determine the best fit for glucan conversion, delignification, and xylan removal. A surface representation of these data points was presented in Figure 2, with $R^2 = 1$. As shown in Figure 2, the glucan conversion increased with the increment of delignification and xylan removal to a certain extent. As lignin and/or xylan were extensively removed, the glucan conversion decreased. One possible explanation was that the cellulose structure may be affected by ethanol/water or the extensive delignification and xylan removal.[20] Another explanation may be the degradation of carbohydrates, such as xylan, which formed on the cellulose surface and retarded enzymatic hydrolysis.[28]

**XRD Analysis.** The XRD spectra of untreated and pretreated sugar cane bagasse (190 °C, 45 min, 60:40 ethanol/$H_2O$, and 5 wt % acetic acid) were investigated and depicted in Figure 3. The untreated sugar cane bagasse had a

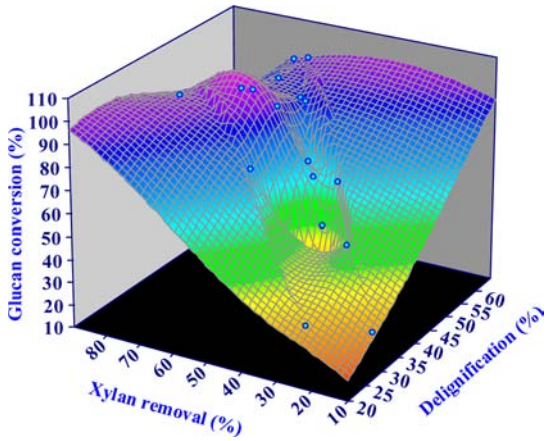

**Figure 2.** Glucan conversion as a function of delignification and xylan removal.

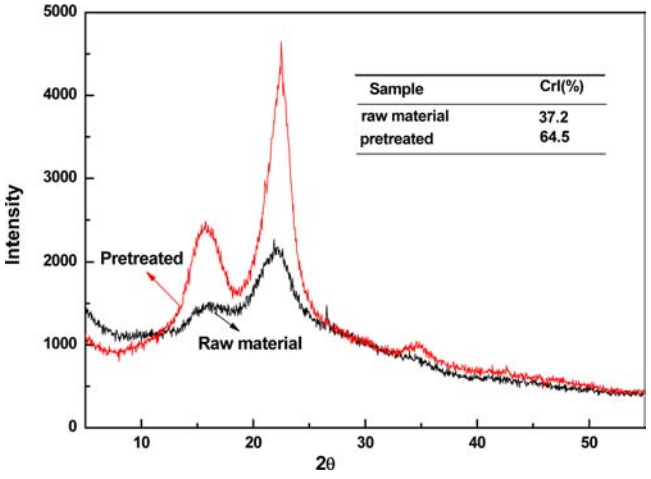

**Figure 3.** XRD patterns and CrI of native material and pretreated solid.

broader peak ($I_{002}$) with a crystallinity degree of 37.2%. The peak ($I_{002}$) became sharper after the pretreatment, and the CrI increased to 64.5%. This phenomenon could be concluded that a large proportion of amorphous lignin and hemicellulose were removed during the pretreatment process; thus, the relative content of crystalline cellulose increased, which was in accordance with previous research.[18,29] However, because of delignification and removal of hemicellulose during the pretreatment process, the intricate structure of native material was destroyed, became less rigid, and made the fibrils more accessible for enzyme. Then, the enzymatic hydrolysis of cellulose in pretreated solids was enhanced greatly, as shown in Figure 2.

**SEM Analysis.** To study the morphologic changes of sugar cane bagasse after ethanol-based organosolv pretreatment, SEM images were carried out. The surface microstructures of sugar cane bagasse before and after pretreatment (190 °C, 45 min, 60:40 ethanol/$H_2O$, and 5% acetic acid) at 2000× magnification are shown in Figure 4. From Figure 4A, it could be seen that the native material exhibited a relatively smooth and rigid surface structure. After ethanol-based organosolv pretreatment, as shown in Figure 4B, the structure became disordered and separated, together with some fragments and a considerable surface roughness, which was probably due to the dissolving of parts of hemicellulose and lignin or the linkages between carbohydrates and lignin breakdown.[30] Because of delignification and removal of hemicellulose, more cellulose fibers were exposed and the enzymatic hydrolysis digestibility could be enhanced (as shown in Table 2 and Figure 2), which is in great agreement with the difference structures apparent in these micrographs.

In conclusion, this study investigated the effect of different pretreatment parameters on the ethanol-based organosolv pretreatment and subsequent enzymatic hydrolysis of sugar cane bagasse. During the pretreatment process, 11.83 g of xylose based on 100 g of raw material could be obtained. After the removal of hemicellulose and lignin, the glucan composition of pretreated solids increased. The maximum glucose yield generated from enzymatic hydrolysis was 40.99 g based on 100 g of raw material, representing 93.8% of glucose in raw material. The highest total sugar yields occurred at 190 °C, 45 min, 60:40 ethanol/water, and 5% dosage of acetic acid, reaching 58.36 g (including 17.68 g of xylose and 40.68 g of glucose) based on 100 g of raw material, representing 85.4% of total sugars in sugar cane bagasse. The enhanced enzymatic hydrolysis was partly due to delignification, xylan removal,

change crystallinity, and exposure of cellulose. The results indicated that ethanol-based organosolv pretreatment with acetic acid can improve the efficiency of subsequent enzymatic hydrolysis; thus, it could be successfully applied to the conversion of sugar cane bagasse to sugars.

**Production of BglW5 by SSF.** *Gongronella* sp. W5 was cultured on potato dextrose agar (PDA) slants at 4 °C. The PDA medium contained 200.0 g potato extract liquid, 20.0 g glucose, 3.0 g $KH_2PO_4$, 1.5 g $MgSO_4{\cdot}7H_2O$, 0.02 g vitamin B1, and 15.0 g agar powder per liter.

To prepare the primary inoculum, an agar plug of 1 $cm^2$ containing actively growing mycelium of *Gongronella* sp. W5 was inoculated into 100 mL basal medium which contained (g/L) 10.0 g glucose, 0.3 g urea, 1.0 g peptone, 1.4 g $(NH_4)_2SO_4$, 2.0 g $KH_2PO_4$, 0.4 g $CaCl_2{\cdot}2H_2O$, 0.3 g $MgSO_4{\cdot}7H_2O$, 50.0 mg $FeSO_4{\cdot}7H_2O$, 16.0 mg $MnSO_4{\cdot}H_2O$, 14.0 mg $ZnSO_4{\cdot}7H_2O$, and 37.0 mg $CoCl_2{\cdot}6H_2O$. The culture was then incubated on a rotary shaker at 28 °C for 48 h.

After incubation, the mycelium was broken into pieces with a homogenizer. Then, 1 mL of the homogenate was inoculated into 4.0 g wheat bran, supplemented with the required volume of mineral salt buffer, which contained (g/L) 0.3 g urea, 0.75 g peptone, 1.4 g $(NH_4)_2SO_4$, 2.0 g $KH_2PO_4$, 0.4 g $CaCl_2{\cdot}2H_2O$, 0.5 g $MgSO_4{\cdot}7H_2O$, 5.0 mg $FeSO_4{\cdot}7H_2O$, 1.6 mg $MnSO_4{\cdot}H_2O$, 1.4 mg $ZnSO_4{\cdot}7H_2O$, and 3.7 mg $CoCl_2{\cdot}6H_2O$.

Fermentation was conducted for 21 days at 28 °C, with the substrate to moisture ratio of 1:1, 1:2, 1:3, and 1:4. At 24 h intervals, 40 mL of Tris-HCl buffer (50 mM, pH 8.5) was added to the fermented wheat bran, and the content was incubated at 25 °C and 200 rpm for 1 h with agitation. The culture suspension was squeezed through sterile absorbent gauze and centrifuged at 12 000 rpm and 4 °C for 30 min. Thus, the cell-free culture supernatant was obtained and assayed for $\beta$-glucosidase activity to study the time course of enzyme production. The enzyme activities were expressed as U/g solid.

**Enzyme Purification.** The cell-free culture broth supernatant was concentrated at 4 °C by ultrafiltration using Minitan Ultrafiltration System with a low-binding regenerated cellulose membrane (Millipore, Bedford, MA., U.S.A.). The supernatant was dialyzed against 20 mM Tris-HCl buffer (pH 7.5). The dialyzed enzyme solution was loaded onto a DEAE Sepharose FF column (10 × 200 mm, Amersham Pharmacia, Uppsala, Sweden) pre-equilibrated with 20 mM Tris-HCl buffer (pH 7.5). The column was washed with 0−0.3 M NaCl linear gradient at 0.8 mL/min. Then, the fractions with high specific activity were pooled and loaded onto a Superdex-75 column pre-equilibrated with 50 mM Tris-HCl buffer (pH 7.5) containing 0.2 M NaCl. The column was eluted with the same buffer at 1 mL/min. The active fractions were pooled and dialyzed against Tris-HCl buffer (50 mM, pH 7.5).

**Molecular Mass and pI Determination.** The apparent molecular mass of the denatured protein was estimated by sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE) with 8% polyacrylamide gel. The molecular mass of the native protein was determined by dynamic light scattering system (Dynapro-99, ProteinSolution Corp.). The isoelectric point (pI) of the purified protein was determined by isoelectric focusing (IEF) in gels of 5% polyacrylamide, with 2% ampholine to obtain a pH range of 4 to 6, and 1 M $H_3PO_4$ and 1 M NaOH in anode and cathode, respectively. After IEF, the pH values were directly measured from the gel to obtain the pI calibration line. Proteins were stained with Coomassie brilliant blue R-250.

**Zymogram Analysis and Protein Deglycosylation.** For zymogram analysis, native-PAGE was separated on 8% polyacrylamide gel and the activity was measured by staining in 50 mM citrate-phosphate buffer (pH 4.5) with the use of 0.1% esculin hydrate (Bio Basic Inc., Canada) and 0.25% ferric ammonium citrate (Bio Basic Inc., Canada).

The enzymatic deglycosylation of BglW5 was performed by incubating the purified enzyme with endoglycosidase H (Endo H, New England BioLabs) following the manufacturer's instructions. After enzymatic treatment, the samples were analyzed by SDS-PAGE. Proteins were stained with Coomassie brilliant blue R-250.

**Enzyme Assays.** The protein concentration was assayed at $A_{595}$ based on the Bradford method with bovine serum albumin as the standard, following the manufacturer's instructions (Sangon Biotech, Co., Ltd., China). $\beta$-Glucosidase activity was assayed using *p*NPG as substrate. The reaction mixture contained 25 $\mu$L of appropriately diluted enzyme, 25 $\mu$L of 10 mM *p*NPG and 450 $\mu$L of 50 mM citrate-phosphate buffer (pH 4.5). After incubation at 70 °C for 10 min, the reaction was stopped by adding ice-cold 0.5 mL of 1 M $Na_2CO_3$, and the enzymatic activity was monitored at 405 nm for the amount of *p*-nitrophenol released. One unit of enzymatic activity (U) was defined as that the amount of enzyme that produced 1 $\mu$mol of *p*-nitrophenol per minute in the reaction mixture under the described assay conditions.

The alternative natural glycoside substrates used for the measurement of $\beta$-glucosidase activity were cellobiose, laminaribiose, sucrose, maltose, lactose, and trehalose. The assay mixture consisted of 25 $\mu$L of appropriately diluted enzyme and 475 $\mu$L of 50 mM citrate−$Na_2HPO_4$ buffer (pH 4.5) containing 5 mM of the specific glycoside substrate. The reaction mixtures were incubated at 70 °C for 30 min, and the amount of glucose released in each mixture was monitored using glucose oxidase/peroxidase reagent according to the manufacturer's instruction (Shanghai Rongsheng Biotech Co., Ltd., China).

**Effects of pH and Temperature on BglW5.** The optimum pH of the purified $\beta$-glucosidase activity was determined at varying pH values ranging from 3.0 to 7.0 by using 50 mM citrate−$Na_2HPO_4$ buffer supplemented with 10 mM *p*NPG or 5 mM cellobiose as substrate. The relative activity was determined. For pH stability assay, the enzyme was preincubated in 50 mM citrate−$Na_2HPO_4$ buffer (pH 3.0 to pH 7.0), or Tris-HCl (pH 7.0 to pH 8.5) buffer at 25 °C for 96 h. The residual activities at different pH levels were determined with 10 mM *p*NPG as substrate. The optimal temperature of BglW5 was measured using *p*NPG or cellobiose as substrate by incubating the reaction mixture for 10 min at varying temperatures ranging from 45 to 85 °C. The enzyme stabilities against temperature were established by incubating the enzyme in 50 mM citrate-phosphate buffer (pH 4.5) under 50 °C, 60 and 70 °C. The residual activities were estimated every hour using 10 mM *p*NPG as substrate.

**Effects of Metal Ions and Chemical Reagents on BglW5 Activity.** The effects of metal ions and chemicals on enzyme activity was measured using *p*NPG as substrate under standard enzyme assay conditions in the presence of $Ca^{2+}$, $Na^+$, $Co^{2+}$, $Mn^{2+}$, $Zn^{2+}$, $Cu^{2+}$, $Fe^{2+}$, $K^+$, $Mg^{2+}$, ethylene diamine tetraacetic acid (EDTA) and sodium dodecyl sulfate (SDS) at concentration of 5 mM and 10 mM, respectively. The relative activity, defined as the activity value relative to the activity of control (without any effector), was also determined using *p*NPG as substrate.

**Determination of Kinetic Parameters.** To determine the kinetic parameters ($K_m$, $V_{max}$, and $K_{cat}/K_m$), appropriate concentration of BglW5 was used under the optimal conditions. The reaction was performed by incubating 0.187 $\mu$g enzyme in 50 mM citrate−$Na_2HPO_4$ (pH 4.5) containing *p*NPG at five concentrations in the range 0.1−1.0 mM, at 70 °C for 10 min. For determination of the kinetic parameters toward cellobiose and laminaribiose, 1.87 $\mu$g purified enzyme was assayed with the substrate at concentrations ranging from 0.1 to 1.0 mM under optimal conditions.

Various concentrations of pure soy isoflavones, daidzin (from 0.1 to 1.0 mM), glycitin (from 0.05 to 1.0 mM), and genistin (from 0.05 to 1.0 mM) were used to determine the kinetic parameters. The reactions were performed in 50 mM citrate-phosphate buffer (pH 5.5) containing 0.4 $\mu$g enzyme at 50 °C for 5 min. The amount of isoflavone aglycones was determined by HPLC assay.

All of the $K_m$ and $V_{max}$ values were calculated by the Lineweaver−Burk equation. The catalytic constant, $K_{cat}$ is equal to $V_{max}$ divided by the total enzyme molar concentration calculated by using the molecular weight of the purified enzyme (105 kDa). The kinetic parameters are given as the mean ± standard deviation of the values calculated from three different experiments ($n$ = 3).

**Effects of Monosaccharides on Bglw5 Activity.** The effects of monosaccharides were evaluated by determining the activities of

BglW5 toward *p*NPG in the presence of glucose (0 mM to 100 mM), xylose (0 to 1.8 M), and fructose (0 to 3.5 M).

The kinetic parameters ($K_m$, $V_{max}$, and $K_{cat}/K_m$) for *p*NPG hydrolysis in the presence of different concentrations of xylose or fructose were estimated under optimal conditions.

**Preparation of Soy Isoflavones Flour Extract.** To evaluate the potential application of BglW5, the commercial soy isoflavone flour (Sinosoy40) was used as substrate for bioconversion. Soy isoflavone flour was produced from soybean cake and contained 10.08% daidzin, 26.85% genistin, 1.6% glycitin, and 3.88% of isoflavone aglycones according to the material data sheet of the manufacturer. According to the method of Rostagno et al., acetonitrile, ethanol, and methanol mixed with certain amount of water are the most used solvents to extract isoflavones.[20] In our study, 50% (v/v) ethanol was used to extract isoflavones from Sinosoy40. Briefly, 1 g of Sinosoy40 flour was dispersed in 5 mL of 50% (v/v) ethanol. The ethanol extract was incubated in an ultrasonic bath at 60 °C for 30 min and then centrifuged at 15 000 rpm for 5 min. The supernatant was stored at 4 °C for further assays.

**Enzymatic Hydrolysis of Soy Isoflavones Flour Extract.** For analysis of hydrolysis products, 0.5 mL reaction mixture was performed at 20 °C, 40 °C, and 60 °C in 50 mM citrate-phosphate buffer (pH 5.5), containing 0.045U β-glucosidase, and 100 μL soybean isoflavone flour extract (containing 1.08 mg daidzin and 0.93 mg genistin). The reaction was stopped by adding 4.5 mL of 50% (v/v) ethanol, and the mixture was centrifuged at 12 000 rpm for 20 min. The supernatant was filtered through a 0.22 μm filter for the quantification of isoflavones by HPLC analysis. Reactions with heat-inactivated (20 min in boiling water bath) enzyme were used as controls.

The productivity (mM/h) was defined as the increase in the concentration of isoflavone aglycones produced in 1 h.[21]

The hydrolysis rate was calculated using the following equation:[22]

$$\text{hydrolysis rate (\%)} = 100 \times (\text{isoflavone glycosides in control samples} - \text{isoflavone glycosides in hydrolyzed samples})/\text{isoflavone glycosides in control samples}$$

**HPLC Analysis of Isoflavones.** Isoflavones were assayed using an Agilent Eclipse Plus C18 column on an HPLC system (Agilent Corp., Palo Alto, CA) equipped with a UV detector set at 254 nm. The column was eluted with a gradient of solvent A (0.1% acetic acid in water) and solvent B (0.1% acetic acid in acetonitrile) at 25 °C. Following injection of 20 μL of the sample, solvent B was gradually increased from 5% to 100% over 60 min. The solvent flow rate was 0.5 mL/min. The peaks of daidzin, glycitin, and genistin, as well as their corresponding isoflavone aglycones, were identified by comparing their elution profile with those of the commercial standards (Sigma Chemical Co., U.S.A.).

## RESULTS AND DISCUSSION

**Production of β-Glucosidase BglW5.** The order of Mucorales consists of genera such as *Mucor*, *Rhizopus*, and *Rhizomucor*, from which some β-glucosidases with excellent features were isolated. Although belonging to the order of Mucorales, Cunninghamellaceae is distinguished from other families. No β-glucosidase-producing fungus has been isolated from this family. Thus, for the first time, β-glucosidase BglW5 was identified from the genus *Gongronella*, family Cunninghamellaceae. Under SSF condition, the maximum activity of 49.9 U/g solid was obtained on ninth day at 28 °C, with the substrate to moisture ratio of 1:2 (Figure S1 in the Supporting Information). Since *Gongronella* sp.W5 was isolated from the soil, its growth and enzyme expression in solid-state is comparable to the natural conditions of the fungus. Thus, under SSF, *Gongronella* sp.W5 is a good producer of β-glucosidase, similar to some known zygomycetous producers from the genera *Gilbertella*, *Mucor*, *Rhizomucor*, and *Rhizopus*, with the β-glucosidase yields of 6 U/g to 426 U/g wheat bran.[9]

Several studies showed that the filamentous fungi from *Gongronella* sp. were good producers of chitosanases.[17,18] Here we reported the isolation of a β-glucosidase from *Gongronella* sp. The chitinolytic and glucanolytic enzyme system may be involved in the metabolism of endogenous or exogenous fungal cell wall polysaccharides to provide the carbon and nitrogen source for fungi.[13] With regard to the distribution of the fungus in soil and its saprotrophic lifestyle, the ability to express glycoside hydrolases may be an adaptation of *Gongronella* sp. to its environment.

**β-Glucosidase Purification.** β-Glucosidase BglW5 was purified from the culture supernatant of *Gongronella* sp.W5 by ultrafiltration, ion exchange and gel filtration chromatography. As shown in Table 1, the enzyme was 5.5-fold purified to a specific activity of 59.0 U/mg with a yield of 2%.

**Table 1. Purification of β-Glucosidase BglW5 from *Gongronella* sp. W5**

| purification steps | total activity (U) | total protein (mg) | specific activity (U/mg) | yield (%) | purification (fold) |
|---|---|---|---|---|---|
| crude extract | 3498 | 321 | 10.8 | 100 | 1 |
| ultrafiltration | 2493 | 185 | 13.5 | 71 | 1.3 |
| DEAE sepharose FF | 600 | 40 | 15.0 | 17 | 1.4 |
| superdex-75 | 83 | 1.4 | 59.0 | 2 | 5.5 |

The purified enzyme exhibited one single band in SDS-PAGE and the apparent molecular weight was approximately 105 kDa (Figure 1A), which is located within the broad range of molecular weights of fungal β-glucosidases (35 kDa to 250 kDa).[22] By dynamic light scattering analysis, the particle size of native BglW5 was assumed to be 4.3 nm with particle dispersion index (PDI) of 13.5%. According to the particle size, the molecular mass of native BglW5 was estimated to be

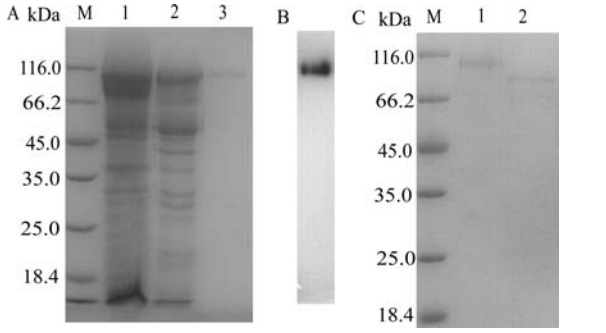

**Figure 1.** SDS-PAGE and native-PAGE analysis of β-glucosidase BglW5. (A) SDS-PAGE analysis of each purification step. M, Protein molecular weight marker (Thermo Fisher Scientific, Inc.); lane 1, crude extract; lane 2, purified BglW5 after DEAE sepharose; lane 3, purified BglW5 after Superdex-75. (B) Native-PAGE analysis of BglW5. BglW5 was stained using 0.1% esculin hydrate and 0.25% ferric ammonium citrate in 50 mM citrate−$Na_2HPO_4$ buffer (pH 4.5). (C) SDS-PAGE analysis of BglW5 hydrolyzed with endoglycosidase H (Endo H). Lane 1, BglW5 without Endo H treatment; lane 2, Endo H treated BglW5. The reduction in molecular mass indicates the presence of the N-glycosylation modification.

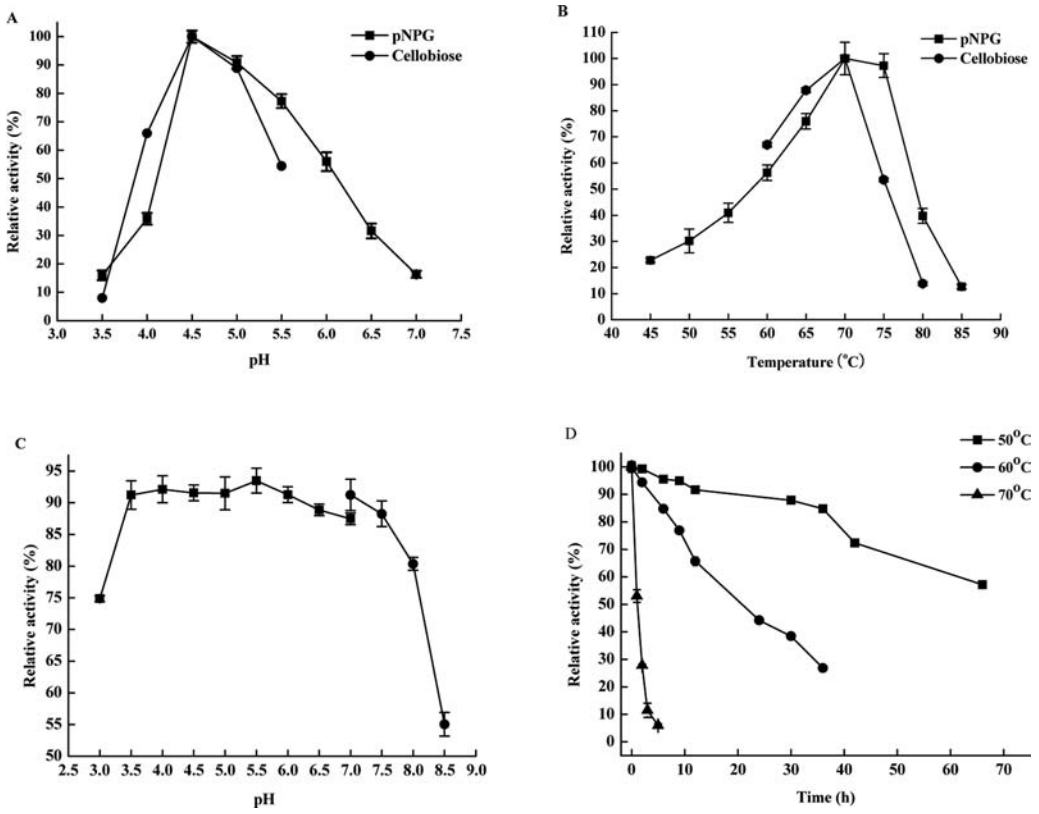

**Figure 2.** Effects of pH and temperature on the activity and stability of $\beta$-glucosidase BglW5. (A) Optimum pH of BglW5. The optimum pH was determined at varying pH levels ranging from 3.0 to 7.0 with *p*NPG or cellobiose as substrate. (B) Optimum temperature of BglW5. The optimal temperature of the enzyme was measured at various temperatures (45 to 85 °C) with *p*NPG or cellobiose as substrate. (C) Effect of pH on enzyme stability. The purified enzyme was preincubated in 50 mM citrate−$Na_2HPO_4$ buffer (pH 3.0−7.0) or Tris-HCl (pH 7.0−8.5) buffer at 25 °C for 96 h, and the remaining activities were measured using *p*NPG as substrate. (D) Effect of temperature on enzyme stability. The purified enzyme was incubated at 50 °C, 60 or 70 °C, and the remaining activity was determined using *p*NPG as substrate. All figures are the average of results from triplicate experiments.

100 kDa, indicating the presence of a monomeric protein. Consistent with this result, native-PAGE showed that the enzyme exhibited activity in the form of monomer (Figure 1B). After treated with Endo H, the molecular weight shifted to 89 kDa, which indicated that the molecular mass was increased about 16 kDa by N-glycosylation (Figure 1C). By IEF analysis, the pI value was estimated to be 4.6.

**Biochemical Properties of BglW5.** The biochemical properties of BglW5 were evaluated. BglW5 exhibited its highest activity at pH 4.5 and 70 °C with *p*NPG or cellobiose as substrates (Figure 2A and B). The enzyme was stable in the pH range from 3.0 to 8.5 at 25 °C for 96 h, maintaining more than 50% of its maximal activity (Figure 2C). Analysis of enzyme activity using *p*NPG as substrate demonstrated that Bglw5 maintained approximately 50% residual activity for 20 h at 60 °C. When incubated at 70 °C, the half-life of BglW5 was 1 h (Figure 2D). The high thermostability of BglW5 is comparable with the enzymes from some thermophilic fungi.[23] Since most applications of $\beta$-glucosidases require higher temperature (50 °C or above),[3,24] BglW5 should have high potential for use as catalysts in industrial bioconversion processes for its thermostability.

The effect of metal ions on BglW5 activity was investigated (Table 2). Significant inactivation was observed by adding $Cu^{2+}$ or $Fe^{2+}$. Interestingly, the activity of BglW5 was stimulated up to 126% in the presence of 10 mM $Mn^{2+}$. BglW5 retained more than 80% of its activity after addition of 10 mM $K^+$, $Zn^{2+}$, $Co^{2+}$, $Mg^{2+}$, $Ca^{2+}$, or $Na^+$, respectively. It is also noted that SDS completely inhibited the activity of BglW5, whereas EDTA only slightly decreased the enzyme activity, implicating that the enzyme is not a metalloprotein.

**Table 2. Effects of Metal Ions and Reagents on Activities of BglW5**[a]

| | relative activity (%) | |
|---|---|---|
| substances | 5 mM | 10 mM |
| $Mn^{2+}$ | 107.62 ± 1.83 | 125.87 ± 3.17 |
| $Na^+$ | 94.53 ± 0.17 | 94.28 ± 2.58 |
| $K^+$ | 93.76 ± 1.10 | 93.43 ± 0.67 |
| $Co^{2+}$ | 90.35 ± 0.51 | 89.62 ± 0.85 |
| $Mg^{2+}$ | 90.75 ± 1.03 | 89.38 ± 1.71 |
| $Zn^{2+}$ | 97.45 ± 1.89 | 89.09 ± 0.50 |
| $Ca^{2+}$ | 93.43 ± 1.72 | 87.92 ± 1.10 |
| $Cu^{2+}$ | 62.17 ± 2.92 | 0 |
| $Fe^{2+}$ | 0 | 0 |
| EDTA | 93.43 ± 0.65 | 85.78 ± 1.06 |
| SDS | 40.21 ± 0.26 | 0 |

[a]Data are expressed as the mean of three experiments ± standard deviation ($n$ = 3).

**Substrate Specificity of BglW5.** Among the saccharides tested, laminaribiose ($\beta$-1,3-linked glucose) and cellobiose ($\beta$-1,4-linked glucose) were the preferred substrates, with similar affinity ($K_m$) values of 1.66 ± 0.02 mM and 1.67 ± 0.03 mM,

respectively (Table 3). However, the higher $K_{cat}/K_m$ of laminaribiose indicated that BglW5 exhibited higher catalytic

**Table 3. Kinetic Parameters of BglW5 Towards Different Substrates**[a]

| substrates | $K_m$ (mM) | $K_{cat}$ ($s^{-1}$) | $K_{cat}/K_m$ ($s^{-1}$ $mmol^{-1}$ L) |
|---|---|---|---|
| *p*NPG | 0.39 ± 0.02 | 19.60 ± 0.98 | 50.26 ± 2.25 |
| cellobiose | 1.67 ± 0.03 | 17.38 ± 0.63 | 10.41 ± 0.20 |
| laminaribiose | 1.66 ± 0.02 | 60.61 ± 0.65 | 36.50 ± 1.66 |
| daidzin | 1.20 ± 0.04 | 328.13 ± 6.90 | 273.52 ± 4.51 |
| glycitin | 0.59 ± 0.02 | 122.50 ± 6.19 | 207.63 ± 10.49 |
| genistin | 1.30 ± 0.03 | 323.75 ± 12.37 | 249.04 ± 9.52 |

[a]The kinetic parameters were determined at the optimal pH and temperature, with the substrate concentrations ranging from 0.05 to 1.0 mM. Data are expressed as the mean of three experiments ± standard deviation ($n$ = 3).

efficiency toward the disaccharide with $\beta$ (1 → 3) linkage than $\beta$ (1 → 4) linkage. In general, $\beta$-glucosidases show stronger activity toward oligosaccharides with $\beta$ (1 → 4) linkages, but several $\beta$-glucosidases, such as the enzymes from *Aspergillus fumigatus*,[23] *Trichoderma koningii*,[23] and *Nasutitermes takasagoensis*,[25] exhibit relatively higher activity toward glucans with $\beta$ (1 → 3) linkages. Such enzymes may be involved not only in cellulose breakdown with cellobiase activity but also in other biological functions with $\beta$-1,3-glucanolytic activity. By using the Carbohydrate Active enzyme (CAZy) annotation analysis of the *Rhizopus oryzae* genome, several candidate protein-encoding ORFs of $\beta$-glucosidase related to exo-1,3-$\beta$-glucanases were identified, which indicated a potential role of $\beta$-glucosidases in the degradation of cell walls of ascomycetes and basidiomycetes, whose cell walls are riched in $\beta$-1,3-glucans.[13] The fact that BglW5 showed high activity toward the disaccharide with $\beta$ (1 → 3) linkage may be an indication that BglW5 is part of the glucanase complex, participating in the degradation of $\beta$-1,3 glucan in the environment to provide carbon and nitrogen source for the fungi.[13] Given that BglW5 exhibited both activities of laminaribiase and cellobiase, its importance in the hydrolysis of biomass is emphasized.[25] Furthermore, BglW5 showed no activity toward sucrose ($\alpha$-D-glucose-(1,2)-$\beta$-D-fructose), maltose ($\alpha$-1,4-linked glucose), and trehalose ($\alpha$-1,1-linked glucose).

Among the pure isoflavones tested, the most preferred substrate for BglW5 was glycitin, following the order glycitin > daidzin > genistin, similar to that of *Pyrococcus furiosus* $\beta$-glucosidase.[21] BglW5 showed the highest catalytic efficiency ($K_{cat}/K_m$) toward daidzin, indicating that daidzin was clearly the preferred substrate among the nonconjugated isoflavone glycosides.

**Effects of Monosaccharides on Enzyme Activity.** In the process of biological degradation of biomass, glucose yields are normally decreased in the presence of other monosaccharides, such as xylose, fructose, mannose, and galactose that are not end products of degradation.[26] Thus, the $\beta$-glucosidases activated by monosaccharides are a group of uncommon yet interesting enzymes,[27] which has the potential to remove a major bottleneck in the industrial application of $\beta$-glucosidases and to broaden their application range.[28] In the present study, BglW5 retained 65% of the maximum activity in the presence of glucose at a concentration up to 30 mM, which is close to the glucose concentration (~27 mM) retained in a simultaneous hydrolysis and fermentation process.[26] Interestingly, at a concentration of 0.5 M, both fructose and xylose significantly stimulated $\beta$-glucosidase activity with a maximal increase of approximately 2.2-fold and 1.6-fold, respectively (Figure 3). However, the activity of BglW5 was gradually inhibited as fructose and xylose concentration is further increased, with IC50 (the concentration of an inhibitor causing 50% activity reduction) of 1.8 M for xylose, and more than 3.5 M for fructose.

Although a few $\beta$-glucosidases with improved activity in the presence of xylose were identified from some thermophilic fungal sources,[29−31] no $\beta$-glucosidase has been reported to be stimulated by both xylose and fructose. To understand the effect of xylose and fructose on BglW5, the kinetic constants of BglW5 were determined in the presence of various concentrations of xylose and fructose (Table 4). The $K_m$ values of BglW5 toward *p*NPG gradually increased at stimulatory concentrations of xylose or fructose, indicating that monosaccharide compete with the substrate to bind to the catalytic site. Nonetheless, the catalytic activity of BglW5 was promoted. The uncommon properties of BglW5 activated by monosaccharides indicated that the monosaccharides may compete with the substrate for the catalytic site, meanwhile bind to some modulator binding site to induce conformational changes, and thus enhance the catalytic activity.[27] At higher monosaccharide

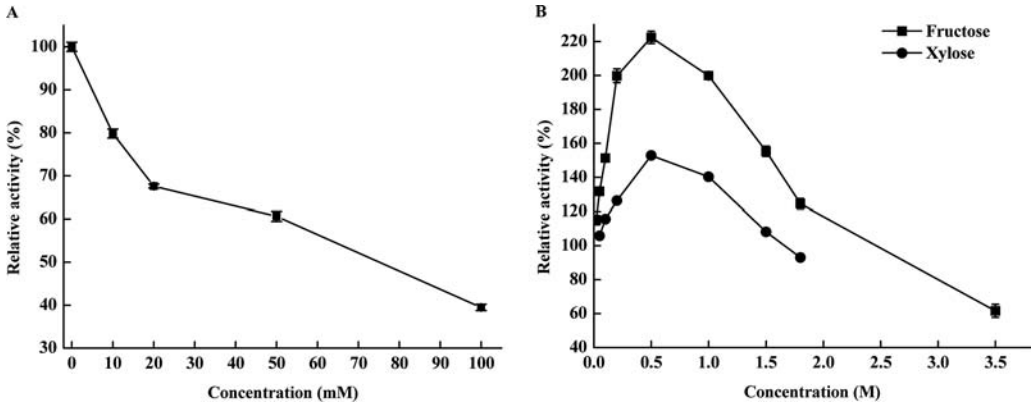

**Figure 3.** Effects of glucose (A), xylose, and fructose (B) on the enzyme activity. Influence of monosaccharide on enzyme activity was measured with *p*NPG as substrate in the presence of glucose, fructose or xylose at the concentrations indicated. All figures are the average of results from triplicate experiments.

**Table 4. Kinetic Parameters of BglW5 for Hydrolysis of *p*NPG in the Presence of Xylose or Fructose[a]**

| | monosaccharide (mol $L^{-1}$) | $K_m$ (mmol $L^{-1}$) | $V_{max}$ (U/mg) | $K_{cat}$ ($s^{-1}$) | $K_{cat}/K_m$ ($s^{-1}$ $mmol^{-1}$ L) |

[a] $\beta$-Glucosidase activity was assayed using 0.187 $\mu$g protein at 70 °C in 50 mM citrate−$Na_2HPO_4$ buffer (pH 4.5), containing fructose or xylose at the concentrations indicated. Data are expressed as the mean of three experiments ± standard deviation ($n$ = 3).

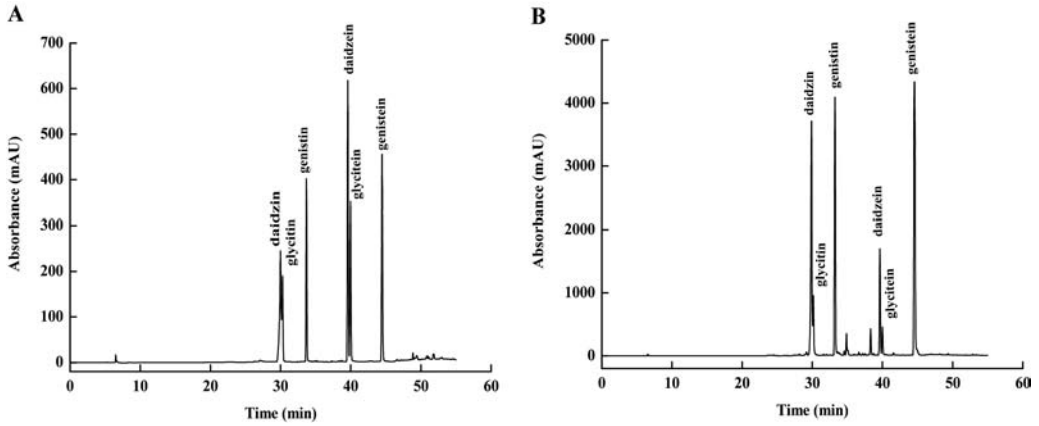

**Figure 4.** HPLC profiles for isoflavone standards and soy isoflavone flour extract. (A) HPLC profiles of daidzin, glycitin, genistin, daidzein, glycitein, and genistein. (B) HPLC profiles of soy isoflavone flour extract. One gram of sample was extracted by 5 mL of 50% (v/v) ethanol at 60 °C during 30 min on the ultrasonic bath.

concentrations, the competition for the catalytic site played a dominant role to decrease the apparent affinity of the enzyme to *p*NPG, which eventually inhibited the enzyme activity.

**Soy Isoflavone Flour Extraction.** Using ultrasound-assisted extraction, a total of 139.39 mg isoflavones was extracted from 1 g soy isoflavone flour, which consisted of 54.10 mg daidzin, 46.44 mg genistin, 13.46 mg glycitin, 15.30 mg daidzein, 2.70 mg glycitein, and 7.39 mg genistein (Figure 4). Daidzin and genistin were the predominant isoflavones in the extract, which occupied 72% of the total amount. Thus, enzymatic hydrolysis toward daidzin and genistin were evaluated in our study.

**Hydrolysis of Soy Isoflavone Flour Extract.** Enzymatic hydrolysis of $\beta$-glucosidases toward isoflavone glycosides is an important application with high commercial value,[3] which has been investigated by direct use of $\beta$-glucosidases from leguminous plants and microorganisms.[32−35] However, in industrial production of isoflavones, low solubility of isoflavones reduces the productivity of isoflavone aglycones.[36] To test the reactivity of BglW5 toward high concentration of isoflavones, the hydrolysis rate and the productivity were measured using isoflavone flour extract as substrate. As shown in Figure 5, BglW5 exhibited maximal hydrolytic activity for daidzin and genistin at 40 and 60 °C after 3 h treatment, with hydrolysis rate more than 96%. By comparison, the hydrolysis rate at 20 °C after 4 h was <50%. Due to its excellent thermostability, BglW5 exhibited effective hydrolysis of isoflavone glycosides at 60 °C within 3 h, with the hydrolysis rates of 96.2% and 96.7%, respectively. Temperature has been

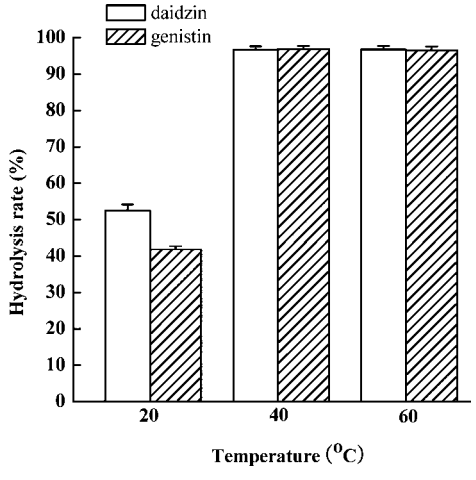

**Figure 5.** Hydrolysis rates of BglW5 toward daidzin and genistin in soy isoflavone flour extract. The reactions were performed in 50 mM citrate−$Na_2HPO_4$ buffer (pH 5.5) containing 0.045 U $\beta$-glucosidase, and isoflavone glucosides (5.20 mM daidzin and 4.30 mM genistin). All figures are the average of results from triplicate experiments.

reported to be a significant factor influencing the extraction of soy isoflavones.[20] Higher extraction efficiencies of isoflavone glycosides were obtained at relatively higher temperatures (e.g., 60∼80 °C).[20,37] Thus, BglW5 offers an advantage for the hydrolysis process of isoflavone glycosides at higher temperature, in which heat treatment of substrates is desirable.

Table 5. Conversion Efficiency of Isoflavone Glycosides to the Aglycone by β-Glucosidases

| substrate | source | daidzin (mM) | daidzein (mM) | genistin (mM) | genistein (mM) | productivity (mM/h) daidzein | productivity (mM/h) genistein | ref |
|---|---|---|---|---|---|---|---|---|
| daidzin | *Sulfolobus solfataricus* | 1.00 | 1.00 | NR | NR | 1.00 | NR | 34 |
| daidzin and genistin | unculturable microbes | 0.50[a] | NR | 0.50[a] | NR | 0.60 | 0.58 | 3 |
| soybean flour extract | *Pyrococcus furiosus* | 0.90 | NR | 1.00 | NR | 0.80 | 1.00 | 21 |
| soybean flour extract | *Aspergillus oryzae* | 2.50 | 1.83 | 1.20 | 0.54 | 0.61 | 0.11 | 35 |

[a]mg/mL. NR, not reported.

As shown in Table 5, BglW5 converted 5.0 mM daidzin and 4.1 mM genistin to aglycones, with the productivities of 1.5 mM/h for daidzein and 1.23 mM/h for genistein, respectively. Although the experimental conditions and the components of isoflavone glycosides extracted were different, BglW5 exhibited higher productivities than *Aspergillus oryzae* β-glucosidase when using high concentration of isoflavones as substrate.[36] These results showed that BglW5 from *Gongronella* sp. can efficiently convert high concentrations of isoflavone glycosides into aglycones.

In summary, a novel β-glucosidase, BglW5 from *Gongronella* sp. was identified, purified, and characterized for the first time. The enzyme exhibited pH-stability and thermostability, and it displayed enhanced activity in the presence of fructose and xylose. Considering its high hydrolysis rate and high productivity on isoflavone glycosides, BglW5 is a promising candidate for enzymatic hydrolysis of soybean isoflavone glycosides.

At the molecular level, OSA substitution positions on anhydroglucosyl units varied for the modified starches by esterification reaction with different physical forms. For chemically modified granular starch, the OSA group was found to preferentially occur on the C-2 and C-3 hydroxyl groups of anhydroglucosyl units, and OSA group distribution was not uniform at the branch level of amylopectin.[23,25] However, OSA substitutions were grafted at C-2, C-3, and C-6 hydroxyl groups as well as the reducing ends of modified maltodextrin.[25]

Although the preparation and physicochemical properties of OSA modified starch have been studied extensively, little work has been reported on the substituted ester group position in OSA modified soluble starch. In this study, OSA starches with low and high degrees of substitution were prepared from sugary maize soluble starch. The substituted starches were hydrolyzed using amyloglucosidase followed by instrumental analysis. The OSA substituent distribution in modified soluble starch was deduced from the comprehensive analyses, which would be helpful in designing a modified starch with tailored functional properties.

## MATERIALS AND METHODS

**Materials.** Sugary-1 maize kernels were purchased from the Chinese Academy of Agricultural Sciences (Beijing, China). Octenylsuccinic anhydride (catalog no. 416487, 97%) and amyloglucosidase from *Rhizopus* sp. (catalog no. A9228, ≥40 units/mg solid) were purchased from Sigma-Aldrich Chemical Co. (St. Louis, MO, USA). All chemicals were of reagent grade and were obtained from Sinopharm Chemical Reagent Co., Ltd. (Shanghai, China).

**Methods.** *Isolating Soluble Starch from Sugary-1 Maize.* The sugary maize soluble starch (SMSS) was isolated from sugary maize in the laboratory following the methods described in a previous study.[5] The sugary-1 maize fresh kernels were dehulled, and endosperm was separated from germ and soaked in 5 times their weight of deionized water at 20 °C overnight. The softened grains were ground in a laboratory blender. The mixture was filtered through 100-mesh sieves and then centrifuged at 10000*g* for 10 min. The supernatant was collected, and the sediment was extracted twice with deionized water. The resulting decantate was heated in a boiling water bath for 30 min to denature the protein. After centrifugation, 1 volume of liquid was measured and 3 volumes of ethanol were added to precipitate the soluble starch. The precipitate was then collected and placed in a fume hood to remove the residual ethanol. The dried solid was ground to form a powder, which was then used for further studies within the next few months.

*Octenylsuccinic Anhydride Modification.* The isolated SMSS was esterification-modified with OSA according to the method of Miao et al.[16] The soluble starch (10 g, dry weight) was suspended in distilled water (30%, w/w) with agitation. OSA (3 or 10% based on the weight of soluble starch) was added to the starch dispersion, whereas the pH was maintained at 8.5 using 3% (w/v) NaOH. After the esterification at 35 °C for 8 h, the pH was adjusted to 6.5 using 2.5 M HCl. The reaction mixture was centrifuged (3000*g*) and washed three times with distilled water and three times with 70% ethanol. The collected material was oven-dried at 40 °C for 24 h and then ground to form a powder (100 mesh) for further analysis. The two types of OSA modified starch samples were named SMSS-OSA-3-0 and SMSS-OSA-10-0, respectively.

*Amyloglucosidase Hydrolysis.* The enzymatic preparation of starch derivatives was carried out by using the method of Huang at al.[10] with some modifications. The soluble starch or OSA starch (OSA-SMSS-3-0 and OSA-SMSS-10-0) dispersion in sodium acetate buffer (50 mM, pH 4.5) was prepared and then heated with agitation in a water bath at 95 °C for 60 min. The temperature of the starch sample was adjusted to 40 °C, and amyloglucosidase (50 U/g dry weight of soluble starch) was added to the each dispersion. Aliquots were withdrawn from each test reaction at 0.5, 1, 2, 3, 5, 10, 20, 30, 60, 120, 240, 360, 600, and 1440 min. The amount of glucose was determined using the Nelson−Somogyi method.[26] Each sample was analyzed in triplicate.

*Determination of the Degree of Substitution.* The DS was measured using the titration method as suggested by He et al.[14] The OSA starch or enzyme-treated OSA starch (0.5 g) was acidified by stirring for 30 min in 3 mL of HCl solution (2.5 M). Ten milliliters of 90% aqueous isopropanol (v/v) was added and stirred for an additional 10 min. The suspension was filtered, and the residue was washed with 90% aqueous isopropanol until no chloride ions were present, as determined by the addition 0.1 M $AgNO_3$; no chloride was present when a white haze of AgCl was no longer observed upon addition. The residue was redispersed in distilled water (30 mL) and heated in a boiling water bath for 30 min. The mixture was titrated with 0.1 M NaOH using phenolphthalein as the end-point indicator. The DS was calculated using the formula

$$\mathrm{DS} = \frac{0.162 \times (A \times M)/W}{1 - [0.210 \times (A \times M)/W]}$$

where $A$ is the titration volume of NaOH, $M$ is the molarity of NaOH, $W$ is the dry weight of sample, and 0.162 and 0.210 are the molecular weight of a glucose unit and an OSA group, respectively. Each sample was analyzed in triplicate.

*Zeta-Potential and Particle Size.* Zeta-potential and particle size analysis was conducted using a Zetasizer Nano ZS (Malvern Instruments Ltd., Malvern, UK) at room temperature. The sample powder (0.01%, w/v) was suspended in distilled water and heated in a boiling water bath for 20 min before measurement. The polystyrene latex nanoparticles were used as a model material; the refractive index and absorption of particle were 1.590 and 0.010, respectively, and data processing was performed using the Nanoapplication program.

*Molecular Weight Distribution Profiles.* The starch sample (10 mg) was added to 5 mL of deionized water and boiled for 15 min to completely dissolve. The dissolved samples were filtered through 5 $\mu$m cellulose acetate filters (Whatman, Maidstone, UK) and injected into a high-performance size exclusion column chromatography system with multiangle laser light scattering detector and a refractive index detector (HPSEC-MALLS-RI) (Wyatt Technology, Santa Barbara, CA, USA). Two series tandem columns (300 × 8 mm, Shodex OH-pak SB-806 and 804, Showa Denko K.K., Japan) with a OH-pak SB-G guard column, a DAWN HELEOS II laser photometer fitted with a He−Ne laser ($\lambda$ = 632.8 nm) with a K-5 flow cell, and a OPTILAB T-rEX Interferometric Refractometer were used. The flow rate was set at 0.5 mL/min with a mobile phase of distilled−deionized water (pH 6.8, 18.2 MΩ cm) containing 0.02% $NaN_3$. A d$n$/d$c$ value of 0.138 was used in the molecular weight calculation, and data processing was performed using ASTRA software (version 5.3.4.14, Wyatt Technology) as described by Miao et al.[5] Weight-average molecular weight ($M_w$, g/mol) and $z$-average radius of gyration ($R_z$, nm) were obtained using the second-order Berry method. The molecular density ($\rho$, g/mol·nm$^3$) was calculated as $M_w/R_z^3$. Each sample was analyzed in triplicate.

*Fourier Transform Infrared Spectroscopy.* The FT-IR spectrum was recorded on a Nicolet Nexus 470 FT-IR spectrometer (Thermo Electron Corp., Waltham, MA, USA) at room temperature. The starch powder was blended with KBr powder at a 1:100 ratio and pressed into tablets before measurement. A region from 400 to 4000 cm$^{-1}$ was used for scanning at 4 cm$^{-1}$ resolution with 32 scans.

*Nuclear Magnetic Resonance.* The $^1$H and $^{13}$C spectra were recorded at 70 °C using a 400 MHz AVANCE III NMR spectrometer (Bruker Co., Billerica, MA, USA) according to the procedure of Gidley.[27] The starch sample (60 mg) was exchanged with deuterium in three rounds of lyophilization with 99.99% deuterium oxide and then dissolved in 0.45 mL of 99.99% deuterium oxide. The parameters of sweep width, center band pulse frequency, npoints, nscans, and probe temperature were respectively set for 20 ppm, 6.175 ppm, 64 K, 64 scans, 333 K, and 240 ppm, 100 ppm, 64 K, 2048 scans, and 333 K for $^1$H and $^{13}$C NMR spectra. Using MestReNova software (version 8.0), chemical shifts ($\delta$) were expressed in parts per million and referenced

internally with acetone and 1,4-dioxane for $^{1}H$ and $^{13}C$ NMR spectra, respectively.

*Confocal Laser Scanning Microscopy (CLSM).* OSA starch sample (0.4 g) was added to 20 mL of deionized water. The pH of the starch dispersion was adjusted to 8.0, and 1% Methylene Blue ($MB^{+}$) solution was added. The mixture was incubated in a shaking water bath at 25 °C for 3 h, and the particles were washed with methanol to remove the excess dye. A TCS SP8 CLSM (Leica, Wetzlar, Germany) was used for the detection of the fluorescence signal from the dye-stained starch particles. The details of the Leica objective lens used were 63 ×plan apo/1.40 oil UV. A laser with a wavelength of 488 nm operating at 30% capacity was used to generate fluorescence. During the image acquisition, each line was scanned four times, and the average was calculated to reduce the noise.

## RESULTS AND DISCUSSION

**Amyloglucosidase Hydrolysis.** As shown in Figure 1, the glucose release from SMSS increased substantially to 182.4 mg/mL in the first 4 h and then incrementally increased to a value of 192.3 mg/mL at 24 h. For enzyme catalytic reaction, enzyme needs first to diffuse toward and bind the substrate and then cleave the glycosidic linkages. Amyloglucosidase is an exoacting enzyme that hydrolyzed both $\alpha$-1,4 and $\alpha$-1,6 glucosidic linkages from the nonreducing ends to yield glucose.[10] Thus, the rate of glucose release was governed by the dendrimer-like structure of soluble starch. On the basis of previous studies,[5−10] the SMSS nanoparticle is believed to have short linear chains densely distributed at the outer surface. At the initial stage of enzyme hydrolysis, effective binding occurred between amyloglucosidase molecules and nonreducing ends. Therefore, only the nonreducing ends at the outer surface of soluble starch were accessible to amyloglucosidase. As enzymatic hydrolysis proceeded, the linear chains were trimmed, resulting in exposure of the $\alpha$-1,6 linkages. According to Pazur and Ando,[28] an $\alpha$-1,4 linkage is hydrolyzed at about 30 times the rate for an $\alpha$-1,6 linkage, which suggested that the presence of $\alpha$-1,6 linkages substantially reduced the hydrolysis rate. Moreover, Butterworth et al.[29] reported that the amylolysis curve for starch with amylase in vitro followed a first-order kinetic equation.

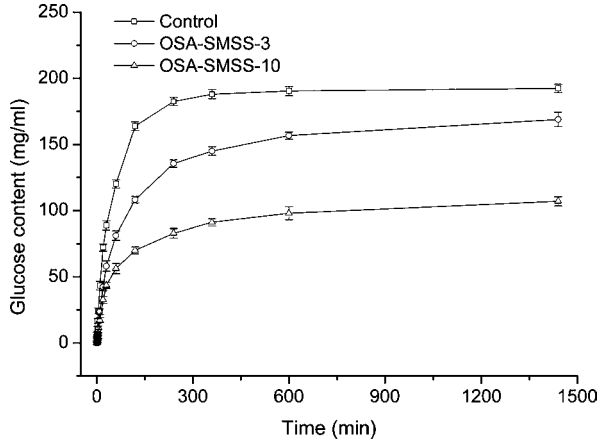

**Figure 1.** Hydrolysis of OSA modified soluble starch by amyloglucosidase over time. Each data point is the mean value of three measurements with error bar of standard deviation.

As depicted in Figure 1, the glucose release profiles between OSA modified starch (OSA-SMSS-3-0, DS 0.019, and OSA-SMSS-10-0, DS 0.0504) and native starch (SMSS) were basically similar; however, the glucose release from OSA modified starch was lower than that from native starch, which was due to OSA modification. According to a review by Sweedman et al.,[12] starch modified with OSA is either more slowly biodegraded or completely resistant to degradation. Viswanathan[30] found that when subjected to multiple enzymes ($\alpha$-amylase, amyloglucosidase, and pullulanase), even small amounts of OSA substitution might cause a considerable decrease in the extent of degradation, indicating that the action of enzyme was inhibited by OSA groups. He et al.[17] also revealed that starch modified by OSA acted like an uncompetitive inhibitor to amyloglucosidase in which the release of enzyme from substrate was delayed due to the physical hindrance or the hydrophobic microenvironment caused by the bulky group of OSA. The enzymatic hydrolysis reaction would stop when amyloglucosidase encounters the OSA groups, which was due to the substitution groups interfering with the binding processing between enzyme and the substrates. Hood and Mercier[31] reported that amyloglucosidase could hydrolyze every glucosidic bond of native starch in an exoenzyme pattern until it reached a modified residue, suggesting that the attachment of enzyme to the substrate was inhibited by the modifying groups on the inner or outer chains near the branch points. Our data revealed that the glucose units released by amyloglucosidase would contain no OSA substituents, whereas the hydrolysis residuals would contain all of the OSA groups. According to the soluble starch model of Huang and Yao,[10] the dispersed molecular density of external

[a]Data expressed as mean ± SD ($n$ = 3). DS, degree of substitution; $M_w$, weight-average molecular weight; $R_z$, $z$-root-mean-square radius of gyration; $\rho$, molecular density. [b]$\rho$ was calculated as $M_w/R_z^3$.

dx.doi.org/10.1021/jf5035064 | J. Agric. Food Chem. 2014, 62, 11696−11705

region (1600 g/mol·nm$^3$) is higher than that of internal regions (950 g/mol·nm$^3$). It is likely that, during the esterification modification of starch, the chemical reagents penetrate more readily into the less dense areas. Therefore, the OSA-SMSS-3-0 (DS 0.019, low OSA modification) contained almost no OSA groups near the nonreducing ends at the outer surface, as opposed to OSA-SMSS-10-0 (DS 0.0504, high OSA modification). On the basis of the above results, five types of dual-modified starches (10 g of OSA starch subjected to amyloglucosidase hydrolysis for 10, 30, 60, or 120 min and then conducted with the same protocol as described SMSS extraction, named OSA-SMSS-3-10, OSA-SMSS-3-30, OSA-SMSS-3-60, and OSA-SMSS-3-120 or OSA-SMSS-10-10, OSA-SMSS-10-30, OSA-SMSS-10-60, and OSA-SMSS-10-120, respectively), were selected to study OSA group distribution in subsequent experiments.

**Degree of Substitution, Zeta-Potential, and Particle Size.** As shown in Table 1, the DS values of modified SMSS using 3 and 10% OSA were 0.0191 and 0.0504, respectively, indicating DS increased with the increased amount of OSA for esterification. In addition, the DS value of amyloglucosidase hydrolyzed OSA starch was increased as the enzyme reaction proceeded, which might be related with OSA substituted position on starch chains as suggested from glucose release profiles.

It is known that the zeta-potential is used to characterize the negative charge at the surface of OSA modified starch. Table 1 shows the zeta-potential of dual-modified starch (OSA modification followed by enzymatic hydrolysis). The zeta-potentials of OSA-SMSS-3-0 (DS 0.0191) and OSA-SMSS-10-0 (DS 0.0504) were −11.1 and −44.4 mV, respectively, which were consistent with previous studies.[12,16] The higher DS was related with a lower zeta-potential, revealing that there were more OSA groups in highly OSA modified starch (OSA-SMSS-10-0). After amyloglucosidase hydrolysis, the zeta-potential of OSA-SMSS (OSA-SMSS-3-0 or OSA-SMSS-10-0) remained at approximately the same value, which indicated that the hydrolysate of OSA starch would contain all of the OSA groups regardless of excessive hydrolysis.

As shown in Figure 2, the particle size distributions of SMSS-OSA have been observed to exhibit ranges from 25 to 400 nm. The average particle size of OSA starch was in the order OSA-SMSS-3-0 (84.9 nm) < OSA-SMSS-10-0 (93.1 nm), which confirmed the higher DS value (high level of OSA esterification) in OSA-SMSS-10-0 obtained using titration method. After amyloglucosidase hydrolysis, the average particle sizes of OSA-SMSS-3-120 and OSA-SMSS-10-120 were 68.0 and 78.3 nm, respectively, revealing that the size decreased as the time increased; however, OSA-SMSS-10 (high OSA modificaition) was more resistant to degradation than OSA-SMSS-3 (low OSA modificaition), which was consistent with the data from glucose release profiles (Figure 1).

**Molecular Weight, Radius of Gyration, and Molecular Density.** As shown by HPSEC-MALLS-RI in Table 1, weight-average molecular weight ($M_w$), $z$-average radius of gyration ($R_z$), and molecular density ($\rho$) of OSA-SMSS-3-0 and OSA-SMSS-10-0 are 2.16 × 10$^7$ g/mol, 32.9 nm, and 605 g/mol·nm$^3$ and 34.8 × 10$^7$ g/mol, 34.8 nm, and 530 g/mol·nm$^3$, respectively. $M_w$ of OSA-SMSS increased accompanied by a rise in substitution of OSA esterification, which was due to the starch chains grafting OSA groups. Similar observations have been reported by Miao et al.[16] and Scheffler et al.[19] During amyloglucosidase hydrolysis, the $M_w$ decreased and reached

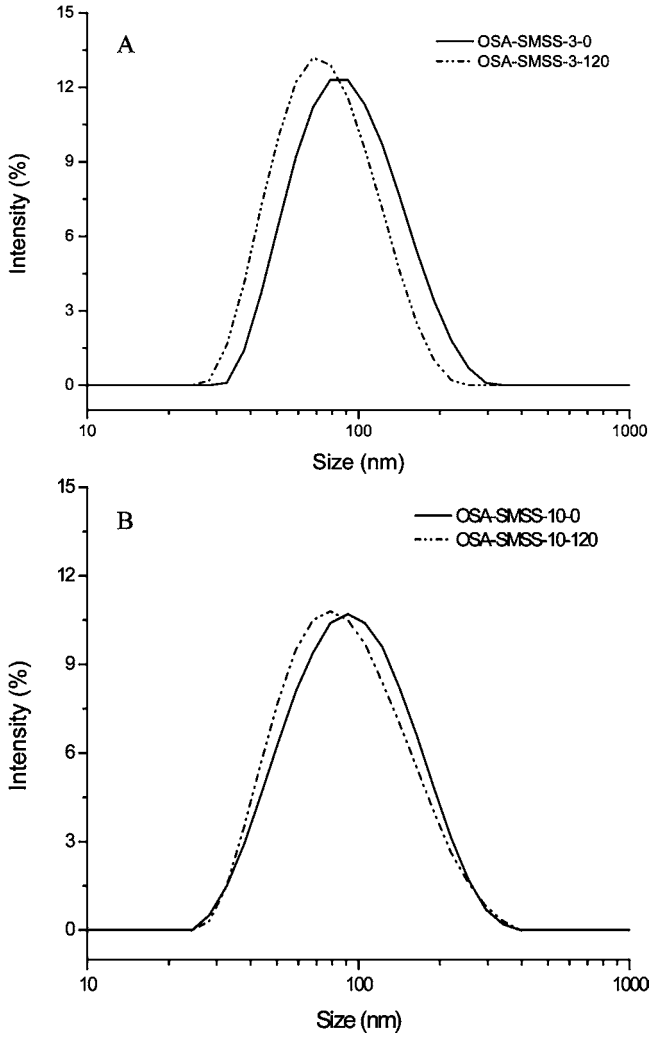

**Figure 2.** Particle size distribution profiles of OSA modified soluble starch after amyloglucosidase hydrolysis: (A) OSA-SMSS-3; (B) OSA-SMSS-10.

1.22 × 10$^7$ and 1.60 × 10$^7$ g/mol after 120 min for OSA-SMSS-3-0 and OSA-SMSS-10-0, respectively.

For OSA modification, the dendritic structure with higher integrity of soluble starch limited the stretching of external chains and restricted the expansion of the particles,[10,16] as evidenced by a slight increase of $R_z$ along with higher DS (Table 1). During the enzyme treatment, the value of $R_z$ for 10 min of hydrolysis dropped off significantly for OSA starch (both OSA-SMSS-3-0 and OSA-SMSS-10-0), indicating that amyloglucosidase hydrolysis primarily reduced the size of soluble starch nanoparticles. After 10 min of hydrolysis, the value of $R_z$ returned to a nearly constant value in each case that was slightly below the native OSA starch, which could be related to a subtle stretching of outer chains caused by an electrostatic repelling force among neighboring negatively charged OSA groups.[16] However, such stretching was limited from causing a substantial change of soluble starch particle size. Moreover, the whole pattern of $R_z$ change was similar to that of $M_w$: $R_z$ decreased much more slowly for 120 min of hydrolysis, reaching 30.1 and 32.9 nm, respectively, which is comparable with the results of particle size analysis (Figure 2).

The $\rho$ value of OSA-SMSS-3-0 was higher than of OSA-SMSS-10-0, which indicated that an increase of DS led to

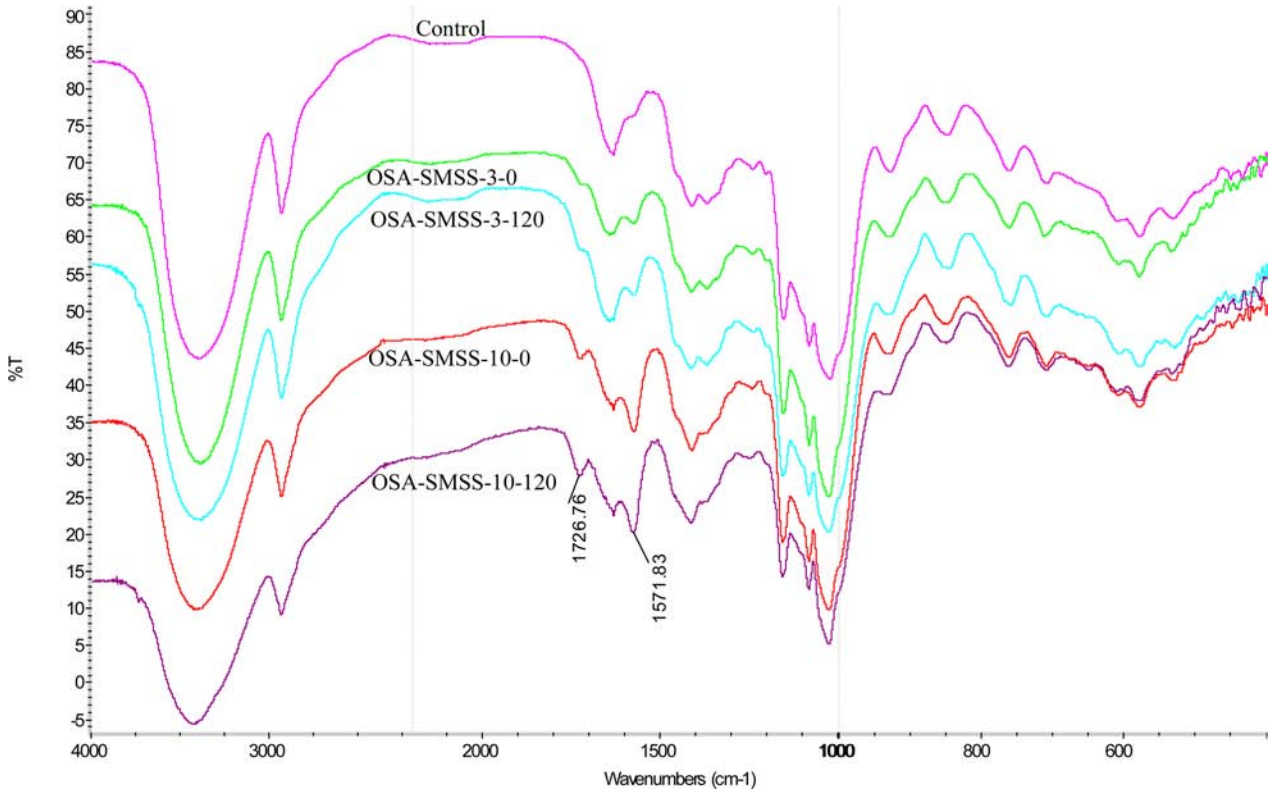

**Figure 3.** FT-IR spectra of OSA modified soluble starch after amyloglucosidase hydrolysis. The vertical lines represented the split of the *X*-axis at 2200 and 1000 $cm^{-1}$.

reduced $\rho$ value. According to some previous studies,[16,19] an increased DS led to reduced density (a low $\rho$ value), which would be caused by electrostatic repulsion among chains grafted with OSA groups. Besides, during amyloglucosidase hydrolysis, $\rho$ remained fairly constant (612 and 558 g/mol·$nm^3$) for the first 10 min and decreased to 446 and 440 g/mol·$nm^3$ after 120 min for OSA-SMSS-3-0 and OSA-SMSS-10-0, respectively. It should be revealed that the change in $M_w$ was due to OSA derivatization, whereas the changes of $R_z$ and $\rho$ were related to the rigid structure of OSA starch, subtle stretching of starch chains grafting OSA groups, and electrostatic repulsion.

**FT-IR Spectroscopy.** The FT-IR spectra of native and OSA starches with different DS (0.0191, 0.0266, 0.0504, 0.0571) are presented in Figure 3. For native starch (control), the FT-IR spectrum contained the following characteristic bands: $\nu$(O−H) 3400 $cm^{-1}$, $\nu$(C−H) 2930 $cm^{-1}$, $\delta$(HOH) 1640 $cm^{-1}$, $\delta$(O−H) 1420 $cm^{-1}$, $\delta$(C−H) 1370 $cm^{-1}$, a complex band $\nu$(C−O) and $\nu$(C−C) 1200−1000 $cm^{-1}$, and $\gamma$(C−H) 1000−700 $cm^{-1}$.[5,32,33] A broad peak appeared around 3400 $cm^{-1}$, indicating the presence of a hydroxyl group (O−H). The characteristic peaks at 2930 and 1640 $cm^{-1}$ were from the C−H stretching vibration and adsorbed water bending vibration, respectively. The spectra also showed C−H deformation at approximately 1410 and 1370 $cm^{-1}$. In the fingerprint region, three characteristic peaks appear between 1000 and 1200 $cm^{-1}$, which have been attributed to C−O bond stretching. The peak around 1020 $cm^{-1}$ also indicated the presence of the $\alpha$-1,6 linkage, the peak near 930 $cm^{-1}$ was assigned to the skeletal mode vibrations of $\alpha$-1,4 linkage, and the peak near 850 $cm^{-1}$ corresponded to C−H and $CH_2$ deformation.

For OSA starches (DS 0.0191, 0.0266, 0.0504, and 0.0571), the FT-IR spectra exhibited an essentially identical major peak, which was similar to that of native starch. By looking into the details, some minor changes are observed in Figure 3. Compared to native starch, two new absorption peaks at 1726.76 and 1571.83 $cm^{-1}$ were shown in OSA modified starch. The characteristic peak occurring at 1726.76 $cm^{-1}$ was C═O stretching vibration of the ester substituent, and the band at 1571.83 $cm^{-1}$ was attributed to an asymmetric stretch of vibration of the carboxyl group.[16,23] The intensity of absorption peaks at 1726.76 and 1571.83 $cm^{-1}$ increased with increasing DS of OSA starch, which was consistent with a previous study by Zhang and co-workers.[34]

**NMR Spectroscopy.** As shown by $^1$H NMR in Figure 4A, all characteristic peaks are assigned as suggested by Bai et al.[20,21,25] The signals at 4.5−5.4 ppm were from anomeric proton; for instance, the small peak at 4.96 ppm was the H-1 at $\alpha$-1,6 branching point, and H-1 at $\alpha$-1,4 internal linkage was characterized at 5.35 ppm. The signals for protons of H-2, H-3, H-4, and H-5 overlapped with each other at 3.19−4.09 ppm, and the peak at 4.37 ppm was assigned to water. The signal at 3.95 ppm was from the internal H-3, and the peak at 3.84 ppm was the overlapping of internal H-3 and H-5, whereas the signal at 3.63 ppm was assigned to the combination of internal H-2 and H-4. Compared to the native starch (control), OSA-SMSS had several additional peaks at 0.8−3.0 ppm and a shoulder at 5.56 ppm, which was from the OSA group. The intensities of signals also increased as DS increased. The peak at 0.8−1.0 ppm was from the methyl protons of the OSA substituent. The signals at 1.0−3.0 ppm were from the methylene and methine protons of the side chain of the OSA group. The signal at 5.56 ppm was from CH═CH of the OSA side chain. Moreover,

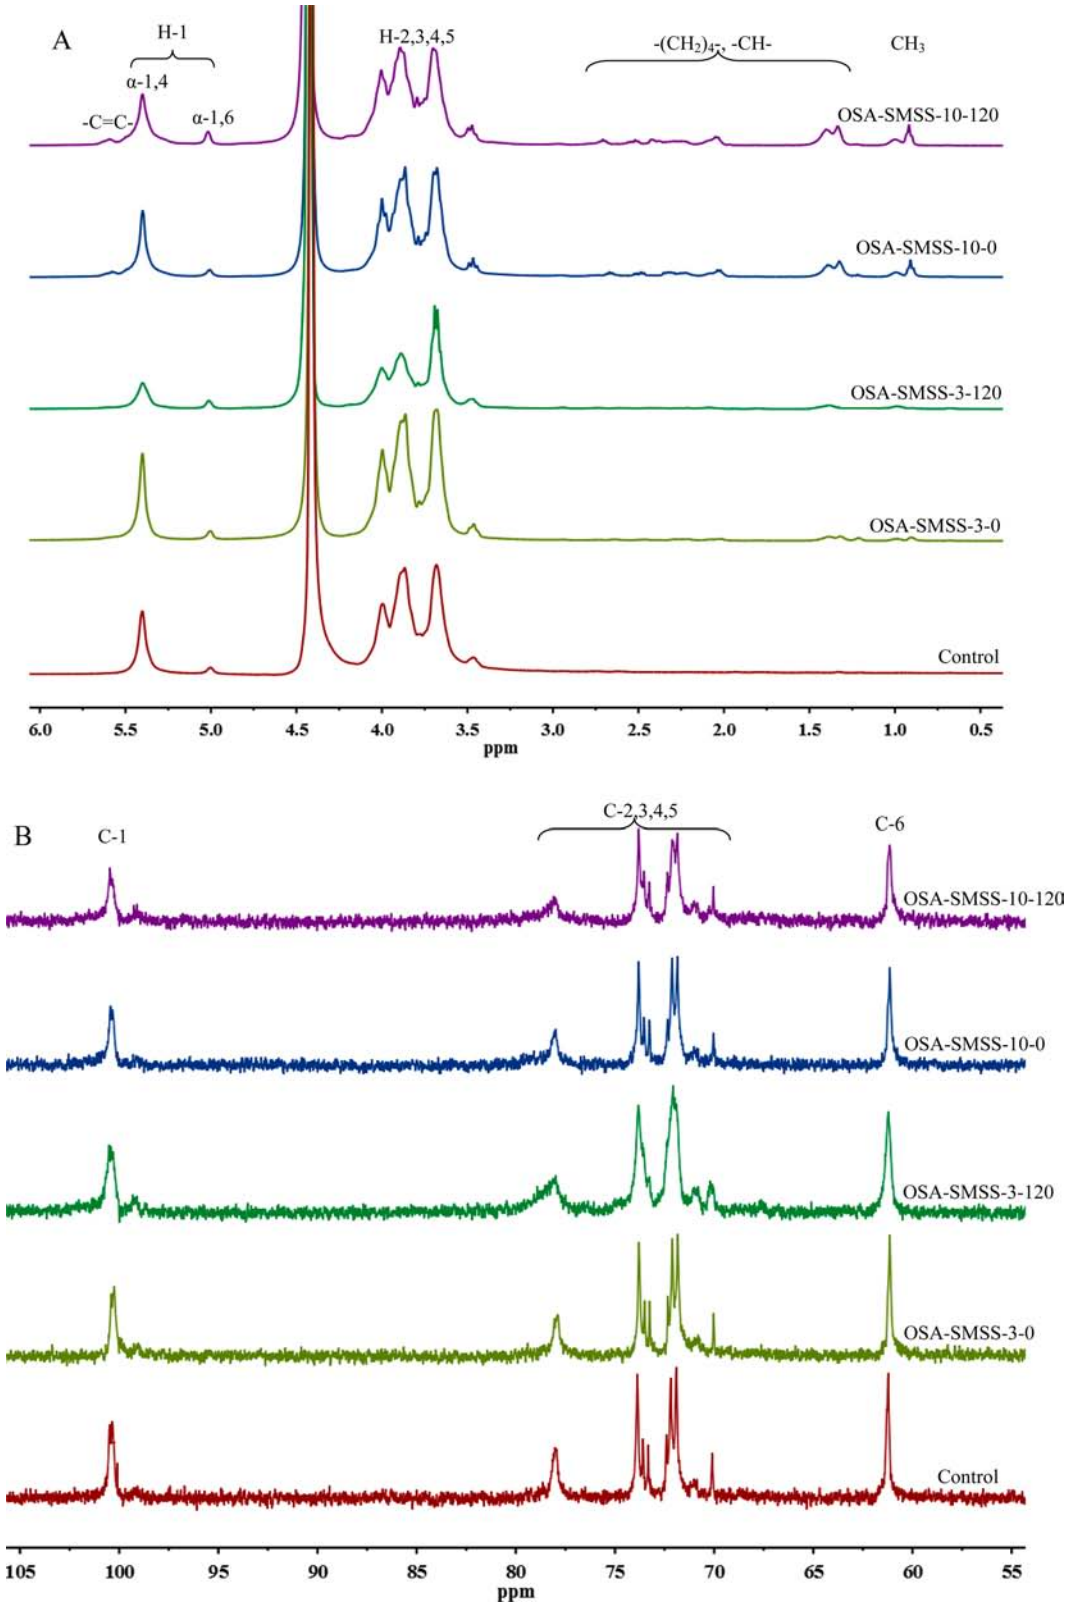

**Figure 4.** $^{1}H$ (A) and $^{13}C$ (B) NMR spectra of OSA modified soluble starch after amyloglucosidase hydrolysis.

peak broadening at 5.35 ppm was observed, which was presumed to be the substitution of OSA at the O-2 position of starch.[20,25]

The percentage of $\alpha$-1,4 and $\alpha$-1,6 linkages was determined using the area ratios of signals at 5.35 and 4.96 ppm. The results show that native SMSS has 6.9% $\alpha$-1,6 linkage, in accordance with several previous papers.[5−9] For OSA starches (DS 0.019, 0.0266, 0.0504, and 0.0571), the concentrations of $\alpha$-1,6 linkage were 13.4, 9.1, 11.7, and 8.2%, respectively. OSA-SMSS-3-0 had a lower ratio of $\alpha$-1,4 to $\alpha$-1,6 linkage than OSA-SMSS-3-10, which might be related to minor hydrolysis of glucosidic linkages at the surface during OSA esterification,[16] Also, the

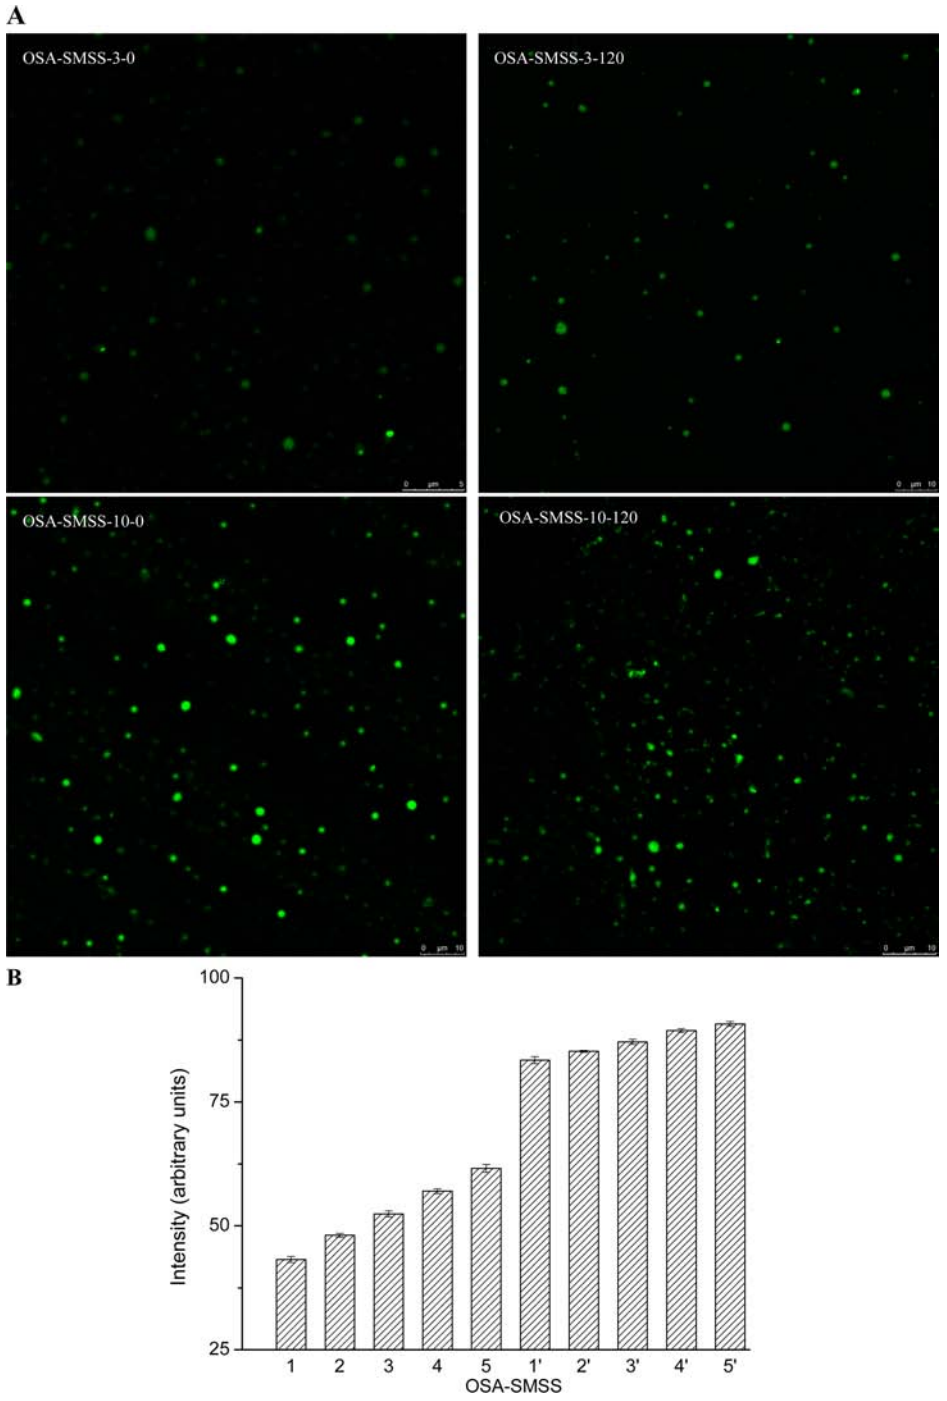

**Figure 5.** CLSM optical sections (A) and fluorescence intensity (B) of OSA modified soluble starch after amyloglucosidase hydrolysis. 1, 2, 3, 4, 5, 1′, 2′, 3′, 4′, 5′ are OSA-SMSS-3-0, OSA-SMSS-3-10, OSA-SMSS-3-30, OSA-SMSS-3-60, OSA-SMSS-3-120, OSA-SMSS-10-0, OSA-SMSS-10-10, OSA-SMSS-10-30, OSA-SMSS-10-60, and OSA-SMSS-10-120, respectively.

percentage of $\alpha$-1,4 linkage increased as DS increased, which was due to relative loss of glucose units resulting from enzyme hydrolysis. After 120 min of enzyme hydrolysis, $\alpha$-1,6 linkages (branching density) reduced 4.3 and 3.5% for OSA-SMSS-3-0 and OSA-SMSS-10-0, respectively, which was comparable with the above results.

As shown by $^{13}$C NMR in Figure 4B, the signal at around 100.47 ppm is from internal anomeric C-1, the multiplets at 70.0−80.0 ppm are from C-2, C-3, C-4, and C-5, and the peak at 61.22 was assigned to C-6. The resonances at 70.20 and 78.10 ppm are assigned to C-4 terminal and internal, whereas the other peaks at 73.80, 72.07, and 71.34 ppm, respectively, are assigned to C-3, C-2, and C-5 of internal $\alpha$-1,4-linked glucosyl units. Compared to SMSS, the C-1 signals of the internal glucosyl units of OSA-SMSS became broader, suggesting that the OS substitution occurred at O-2 and that the O-2 substituent affected the chemical shift of the neighboring C-1.[20] Moreover, additional resonances (shoulder peaks) of C-4 of internal glucosyl units were noted at approximately 78.10 ppm, suggesting that OS groups were substituted at the neighboring O-3 position in OSA-SMSS.[20] As the DS increased to 0.0571, there was no significant difference for the signal at

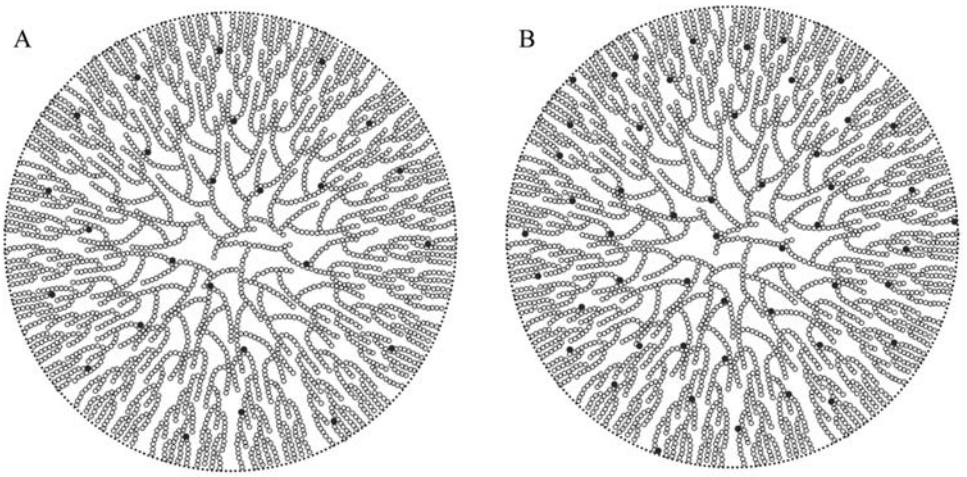

**Figure 6.** Proposed model structure of OSA modified soluble starch: (A) OSA-SMSS-3-0; (B) OSA-SMSS-10-0; (●) OSA group; (○) glucosyl unit.

61.22 ppm, revealing OH at C-6 was not connected with OSA groups.[25]

**CLSM Observation.** According to the transmission electron microscope image in previous studies,[5,6,10] SMSS had a spherical shape with diameters around 30−100 nm, which was comparable with our observations. As shown by CLSM after staining with $MB^+$ dye in Figure 5A, the OSA starches are shown as spherical particles with bright fluorescence. CLSM is used to visualize the internal structures of starch granules to avoid the complicated or invasive sample preparation, such as growth rings, equatorial grooves, channels, cavities, and the distribution of protein, lipid, amylose, or phosphate.[34,35] According to Jayaraj et al.,[36] $MB^+$ is one of the fluorescence dyes that highlight anionic substances, which has been used for specific labeling of $-COO^-$ of OSA substituents. Thus, the OSA group distribution in starch could be clearly revealed. It is observed that OSA groups appeared to be distributed throughout the OSA-SMSS nanoparticles, especially at internal regions of starch sphere. Moreover, OSA starch showed stronger fluorescence intensity as the DS increased (Figure 5B). The higher DS (0.0504, 0.0571) of OSA starch showed stronger fluorescence intensity, indicating that there were more negatively charged groups available to stain with $MB^+$. Zhang et al.[34] reported that OSA starch had only fairly uniform bright fluorescence on the granule surface, which was different from our observation. The cause of the difference might be related to substrate (starch) form during OSA esterification. SMSS is a water-soluble $\alpha$-glucan and well dispersed in the reaction solution, whereas granular starch is in a solid state during reaction. For the starch granule, most OSA droplets could react with the granular surface; only a few penetrate granule channels and arrive at the inner cavity, resulting in higher fluorescence of the granular surface in comparison to the interior under heterogeneous reaction conditions. For soluble starch, the OSA could penetrate the entire SMSS particles and evenly connect at the starch inner chain of internal regions with less density, resulting in a fluorescence sphere. These results reinforced the postulate that more OSA was substituted on the chains near the branch points at less dense areas. After enzyme treatment, there were no changes in the size of OSA starch, suggesting the OSA group was hardly connected at the surface for low OSA modification. Together with the particle size and NMR results, this would suggest fewer glucose units were removed from the OSA-SMSS-10 with higher DS and more $\alpha$-1,4 linkages, indicating that more OSA groups were substituted near the nonreducing end of the starch chains for high OSA modification. The above results revealed that even distribution of OSA groups in the center area of soluble starch particle has been directly observed under CLSM.

**Models of Substitution Distribution in OSA Starch.** The distribution of chemical groups in the granular starch has been revealed to react preferentially in the interior, amorphous domains of amylopectin molecules as well as on the surface,[23,24,34] which revealed that modification reagents penetrate less easily into the crystalline region during chemical derivatization of starch. It is known that the amorphous regions of starch are rich in $\alpha$-1,6 linkages.[31] Thus, the modifying substituents would be expected on the starch molecule near the branch points. Previous works on modified starches have confirmed that substitution reaction takes place preferably at the branched regions of amylopectin and that the linear regions of amylopectin are substituted more heterogeneously than the branched regions.[37−39] Biliaderis[40] reported that waxy maize starch favored a more uniform distribution of the substituent in the starch macromolecules, indicating substitution occurred near the branching points as well as at the nonreducing ends for hydroxypropyl distarch phosphate of waxy starch (DS 0.09). Shogren et al.[23] also found that 72% or less of the branches in an OSA waxy starch molecule (DS 0.11) contained at least one OSA group on the basis of the analysis of the debranched chains, which suggested that some branches were more accessible or reactive toward OSA than others. Recently, Bai et al.[41] investigated the position of OSA groups along the starch chains in the OSA waxy maize starch by enzyme hydrolysis followed by chromatographic analysis. They found that OSA substituents were located on the repeat units near the branching points of amylopectin at a low substitution value (DS 0.018), whereas a high substitution value (DS 0.092) occurred near both the branching points and the nonreducing ends.

In our study, we attempt to envisage the substituted OSA group location in soluble starch on the basis of the above data and the model structures present in Figure 6. The OSA group in modified starch with low DS (0.0191) was postulated to locate near branching points of soluble starch molecules, whereas the OSA starch with DS of 0.0504 had substitution

groups close to nonreducing ends together with near branches. OSA is insoluble in water, and the esterification is a heterogeneous reaction. In the initial stage of OSA esterification, OSA groups were grafted exclusively in the branch part at less dense internal areas of SMSS molecules. Those initial substituted ester groups might cause both electrostatic repelling force and steric hindrance for starch chain stretching, resulting in the outer surface or at least near that surface of SMSS (nonreducing end) being subjected to OSA substitution with increasing DS.

In summary, the substituted OSA group distribution and location in modified sugary maize soluble starch were elucidated by amyloglucosidase hydrolysis and followed by structural analysis of reaction residue. For low OSA modification (DS 0.0191), most substitutions were located near branching points of soluble starch molecules. For high OSA modification (DS 0.0504), substituted ester groups were located near branching points as well as at the nonreducing ends. Further work is underway to obtain the relationship between OSA group distribution and the functionalities and to design a tailor-made OSA starch for some niche applications with high-value-added products.

analysis indicated that there might be more than one copy of *SeFAD2* gene in the sesame genome.[15]

So far, *Sesame indicum* L. is the only large-scale cultivated species in the genus. For improvement of sesame in breeding programs by introgression of useful traits, e.g., resistance to diseases and pests, tolerance to abiotic and biotic stresses, etc., wild relative species of sesame need to be explored. The sesame germplasm collection in the U.S. is maintained by the USDA-ARS, PGRCU, in Griffin, Georgia. Fatty acid composition of the entire USDA collection (1232 accessions) has been evaluated, and significant variability was identified within the collection (Wang et al., unpublished results). From this screening, we selected seven accessions (including two wild species) with significant variation in fatty acid composition, and O/L ratio. These accessions were planted for sequencing the *FAD2* gene coding region and for chemical analysis of the harvested seeds. To our knowledge, we are not aware of any report on association of *FAD2* genotypes with fatty acid profiles in sesame. The objectives of this study were therefore to (1) confirm fatty acid composition and O/L ratio using newly harvested seeds, (2) identify nucleotide diversity in the *FAD2* gene coding region, and (3) identify nucleotide polymorphisms possibly contributing to alter the fatty acid profile and O/L ratio.

## MATERIALS AND METHODS

**Plant Materials and Seed Harvest.** Information on the seven selected sesame accessions is listed in Table 1. Among these, five were from the cultivated form (*S. indicum* L.) and two were from the wild form (*S. radiatum* Schum & Thonn.) based on the passport data (www.ars-grin.gov). One hundred seeds for each accession were acquired from the seed store of USDA-ARS-PGRCU, Griffin, Georgia. Twenty seeds from each accession were planted in large pots (Poly-Tainer-Can, No. 7s, Nursery Supplies Inc., Orange, CA) containing potting soil (Metromix-360, Griffin House and Nursery Inc., Griffin, GA) on April 30, 2012. Two weeks after germination, seedlings were thinned from 20 to 8. During plant growth, water and fertilizer for each pot were controlled. Seeds were harvested on multiple occasions from newly opened capsules. The capsules were collected into a paper bag and dried for 2 weeks at low humidity. After drying, the seeds were removed from the capsules and cleaned for seed morphology observation and chemical analysis.

**Table 1. Information on the Seven Selected Accessions from Seed Quality Analysis**

| PI no. | species | collection site | linoleic acid | O/L ratio |
|---|---|---|---|---|
| 188815 | *S. indicum* L. | Luzon, Philippines | 53.22 | 0.58 |
| 224663 | *S. indicum* L. | Libya | 45.78 | 0.86 |
| 278164 | *S. radiatum* Schum. & Thonn. | Angola | 47.35 | 0.78 |
| 367899 | *S. radiatum* Schum. & Thonn. | Tanzania | 61.79 | 0.34 |
| 490268 | *S. indicum* L. | India | 54.5 | 0.5 |
| 599435 | *S. indicum* L. | Texas, United States | 34.99 | 1.4 |
| 599442 | *S. indicum* L. | Texas, United States | 33.49 | 1.5 |

**Morphological Observation and Chemical Analysis.** Flowering time, leaf shape, plant stature, and seed morphology were observed, measured, and recorded. All samples were measured in triplicate and results averaged for each accession. Fatty acid methyl esters (FAMEs) were prepared from sesame seeds by alkaline transmethylation.[20] Fatty acid composition was determined on an Agilent 7890A GC equipped with a flame ionization detector (FID) following a previously described method.[21] A fatty acid methyl ester (FAME) standard mix was purchased from Sigma. The relative percentage of each fatty acid was calculated from the corresponding peak area. The O/L ratio was determined by % oleic acid/% linoleic acid. Data on fatty acids were recorded by replicates, accessions, and batches (old or new seeds). An analysis of variance was performed on the data, and means were separated using Tukey's multiple comparison procedure (SAS, 2008, Online Doc 9.2. Cary, NC: SAS Institute Inc.). Significant correlations between seed traits were determined using Pearson correlation coefficients.

**Amplification and Sequence of DNA Fragments in the *FAD2* Coding Region.** Genomic DNA was extracted from fresh leaf tissue using an E.Z.N.A. Plant DNA kit from Omega Bio-Tek (Doraville, GA). All DNA samples were dissolved and diluted in 0.1 × TE (1 mM Tris, 0.1 mM EDTA, pH 8.0) to a final concentration 10 ng/$\mu$L for use in PCR. For primer design, the sequence of the *FAD2* gene region was downloaded from GenBank (AY770501). Due to nucleotide divergence between cultivated and wild sesame, some specific primers were designed only for wild species (including some degenerate primers) (Table 2). In total, 33 sets of primers were designed and synthesized by Operon (Qiagen, Germantown, MD, USA, http://www.operon.com). Different PCR conditions were used based on the amplicon size and annealing temperature for DNA fragment amplification.

**Table 2. Primers Designed for Amplification of *FAD2* Coding Region in Cultivated and Wild Species**

| amplified fragment | forward and reverse primers (5′−3′) |
|---|---|
| cultivated 1 | btFAD-5F: TTTTTCGGGTGTTCGTTACC |
| | btFAD-5R: GCCACTGGTAATCGCTGAAT |
| cultivated 2 | btFAD-6F: GCTACCTAGCTTGGCCCATT |
| | btFAD-6R: AGAGCTCCCCTTAGCCAGTC |

| | btFAD-7R: AGAATCCGACCAGCACAGAC |
| wild 1 | SeWCodF1: TTGGGAGGTTTTGATTCAG |
| | SeWCodR1: GAGGCCAACCRAGAGTAAGA |
| wild 2 | SeWCodF2: CCTTGCTTGTGCCCTATTTC |
| | SeWCodR2: CACTAACARAGGAYGCATCTTA |

**Identification of Nucleotide Polymorphisms in the Coding Region and Amino Acid Substitution in the Polypeptides.** After trimming and editing each DNA sequence, gene coding sequences were aligned with a sesame reference sequence (AY770501) using Sequencher (ver. 4.10.1). Following sequence alignment, nucleotide polymorphisms were identified among accessions. From the deduced amino acid sequence, substitutions were identified in the polypeptides.

**Evaluation of Selected Accessions.** An integrated approach including morphological observation, chemical analysis, and DNA sequence analysis was used for evaluation of the selected accessions. A phylogenetic dendrogram was generated from nucleotide polymorphisms in the coding region using the Arlequin 3.01 program.[22] Subsequently, a cladogram was generated from the deduced amino acid sequences along with *Glycine* and *Arachis* sequences using the ClustalW2 (http://www.ebi.ac.uk/Tools/msa/clustalw2) program. The selected accessions clustered into different groups. Misnamed accessions were identified and reclassified.

## RESULTS AND DISCUSSION

**Variation on Plant and Seed Morphology.** There was significant variation in plant and seed morphology among the seven accessions. Variation in plant and seed morphology is shown in Figure 1. All seven accessions were planted on the same day, April 30, 2012. Four accessions flowered 7 weeks after planting, and PI 278164 flowered a week later. PI 490268 flowered in the middle of August, and PI 367899 eventually

**Figure 1.** Plant and seed morphology of the selected sesame accessions. The picture of seed morphology was taken using newly harvested seeds from the plants shown above. The scale bar represents one centimeter.

flowered, but did not produce seeds until the middle of November. This accession was originally collected from Tanzania (Table 1) and may be temperature sensitive (high temperature leading to unsuccessful pollination). PI 224663 produced purple petioles whereas PI 599442 produced curly leaves (Figure 1). By the latter developmental stages, PIs 188815, 367899, and 490268 were taller than 1.2 m with big branches on the main stems. Three accessions (PIs 188815, 367899, and 490268) produced dark, almost black seeds, and the other four accessions produced lighter colored seeds.

**Variation on Fatty Acid Composition.** Significant variation in the fatty acid composition was detected between stored (old) seeds and freshly harvested (new) seeds (Table 3). On average, the freshly harvested seeds contained a higher amount of palmitic acid (C16:0) than the stored seeds (9.22% vs 8.87%), whereas the stored seeds contained higher amounts of stearic (C18:0), arachidic (C20:0), gadoleic (C20:1), and lignoceric (24:0) acids than the freshly harvested seeds (5.73% vs 5.26%; 0.69% vs 0.66%; 0.19% vs 0.16%; and 0.10% vs 0.06%). This variability may be due to environmental conditions. No significant variability in the other five traits was detected between the old and new seeds (Table 3). Since the old seeds were collected from different locations and/or years, comparisons among accessions with the old seeds would not be biologically informative. Only data collected on the new seeds grown under the same conditions in 2012 were used for comparison between accessions, and the data on the old seeds were used simply as reference information.

There was significant variability in oleic acid (23.85% to 42.92%), linoleic acid (41.67% to 58.63%), and O/L ratio (0.41 to 1.03) (Table 3 and Figure S1 in the Supporting Information). Oleic acid had a significantly negative correlation with linoleic acid ($r = -0.99$ at $p < 0.0001$ level). For example, PI 367899 had the highest percentage of linoleic acid (58.63%) and the lowest percentage of oleic acid (23.85%). The ratio of oleic acid and linoleic acid (O/L) can reflect the seed quality and oil properties. Oils with higher oleic acid content generally have a longer shelf life and are healthier for consumption. Among these seven accessions, oil from PI 599442 may have the best quality based on this criterion, containing the lowest percentage of linoleic acid (41.67%) and the highest oleic acid (42.92%).

[a]For each trait, the data in the upper and lower rows were from the old and new seeds, respectively. There is a significant difference if the letters (after values) are different in the same column. [b]PI no. [c]Least significant difference.

**of the *FAD2*, and Phylogenetic Relationship among Accessions.** The sequences in the coding region (1152 bp) of the *SeFAD2* were aligned (Figure S2 in the Supporting Information), and 61 single nucleotide polymorphisms (SNPs) were identified among the seven accessions. The deduced amino acid sequences (383 aa) of *SeFAD2* were aligned (Figure S3 in the Supporting Information), and 12 amino acid substitutions were identified. A phylogenetic dendrogram and cladogram were generated using nucleotide sequences and deduced amino acid sequences, respectively (Figures 2a and 2b). There were no DNA polymorphisms among four accessions (PI 224663, PI 278164, PI 599435, and PI 599442) which were identical to the sesame reference sequence (previously deposited *FAD2* coding sequence, AY770501). These four accessions may belong to the cultivated sesame type (*S. indicum* L., Cluster I). In comparison to these four accessions, PI 188815 had eight SNPs, but only one led to an amino acid substitution (T71A). This accession may still belong to the cultivated type but with significant divergence. Compared to the reference sequence, both PI 367899 and PI 490268 had 46 SNPs resulting in 6 and 8 amino acid substitutions, respectively. These two accessions were closely related and may belong to the wild sesame type (*S. radiatum* Schum. & Thonn., Cluster II). Most SNPs originated between the wild and cultivated sesame. There was an amino acid substitution at 317 from alanine (A) to threonine (T) between the wild and cultivated sesame which was located in the H Box 3 (in the active site of the fatty acid desaturase). This critical substitution may contribute to the altered fatty acid composition between wild and cultivated sesame.

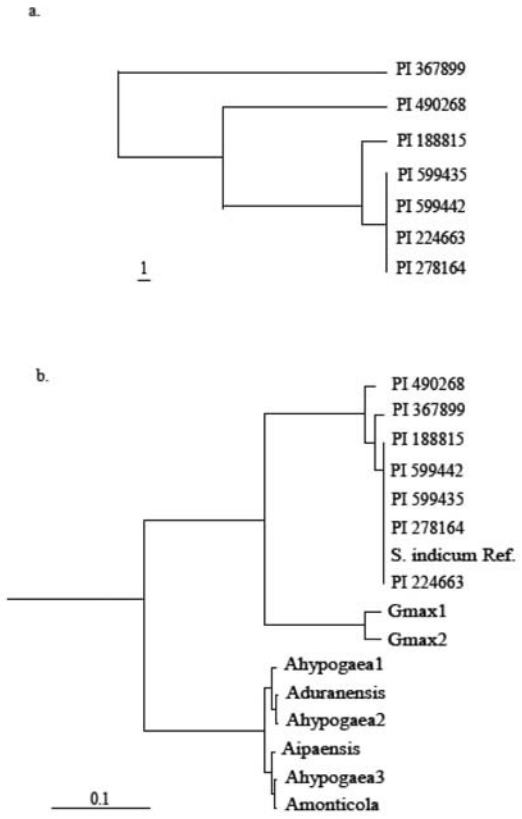

**Figure 2.** Dendrogram and cladogram from cluster analysis using nucleotide and amino acid sequence data, respectively. (a) Dendrogram was generated using nucleotide sequences from seven sesame accessions and (b) cladogram was generated from amino acid sequences from seven sesame accessions plus one sesame reference and two soybean (*Glycine*) and six peanut (*Arachis*) accessions: sesame reference, AAX11454.1; *G. max*1, BAD89862.1; *G. max*2, P48631; *A. hypogaea*1, AAY53559.1; *A. hypogaea*2, AAB84262.1; *A. hypogaea*3, AAK67829.1; *A. duranensis*, AAF82294.1; *A. ipaensis*, AAF82295.1; and *A. monticola*, AAX14399.1. Scale bar represents coefficient similarity.

In general, the results from the dendrogram and the cladogram were consistent; and they suggest that two accessions were misnamed in the GRIN database. PI 278164 does not belong to the wild species (*S. radiatum* Schum. & Thonn.) and should be classified as cultivated sesame (*S. indicum* L.). PI 490268 does not belong to the cultivated sesame and should be classified with the wild species. Our cladogram analysis also indicated that the sesame *FAD2* coding sequence had a higher similarity to the corresponding soybean sequences than to the *Arachis* sequences.

The results from morphological observation, chemical analysis, and *FAD2* gene coding sequence were consistent when freshly harvested seeds were analyzed. PI 278164 and PI 490268 were misnamed in the GRIN database. PI 278164 should be classified with the cultivated form (*S. indicum* L.) instead of the wild form (*S. radiatum* Schum & Thonn.), whereas PI 490268 should be classified as the wild form instead of the cultivated form. Ultimately, more research is still required to determine to which wild form PI 490268 belongs. The wild accessions PI 367899 and PI 490268 flowered and matured later, and they produced seeds with lower amounts of oleic acid (23.85% and 28.44%) but higher amounts of linoleic acid (58.63% and 53.38%) than the cultivated form. Our results demonstrate how an integrated approach including morphological observation, chemical analysis, and genetic analysis can be used to properly characterize and evaluate plant germplasm accessions.

High oleate cultivars have been developed in several major oilseed crops including soybean, canola, sunflower, and peanut;[23] but so far none in sesame. A high oleate sesame line (Ant-33 containing 41.4% oleic acid) was identified by screening 103 Turkey cultivated sesame landraces,[4] but this is much lower than the high oleate soybean containing over 80% oleic acid.[24] This high oleate soybean was developed by crossing two accessions (PI 603452 and PI 283327) which contained spontaneous mutations in *FAD2-1A* and *FAD2-1B*, respectively, and then by selection of the mutant alleles using marker-assisted selection (MAS) in breeding programs. Mutagenesis has been explored in sesame. Closed capsule and determinate growth habit mutants have been successfully identified using $\gamma$-irradiation, but there was limited enhancement of oleic acid only up to 46%.[25] If there are two copies of the *FAD2* gene in the sesame genome, the probability of simultaneously mutating both copies in one individual would be very low. Natural genetic variation in the level of oleic acid may exist in the sesame genome. More sesame germplasm accessions need to be screened for identification of new *FAD2* mutations. Newly identified accessions encompassing different mutant alleles of *FAD2* can be used as breeding materials for further developing high oleate sesame cultivars.

be useful for various applications of high-amylose starches in the food and nonfood industries.

## MATERIALS AND METHODS

**Materials.** Native normal maize starch (S4126) (NS) and high-amylose maize starch (S4180) (HS) were purchased from Sigma-Aldrich.

**Separation of Large-, Medium-, and Small-Sized Fractions.** The native normal and high-amylose maize starches were separated into large-, medium-, and small-sized fractions using five methods (Supporting Information Figures S1−S5). The main procedure of the method is briefly explained below.

**Microsieving.** The starches were separated into different-sized fractions by microsieving according to the method of Kaur et al.[9] with some modifications (Supporting Information Figure S1). Starch suspension (0.2%, w/v) in distilled water was passed sequentially through 10 and 5 $\mu$m sieves. The granules retained on the 10 $\mu$m sieve were collected as the large-sized fraction. The filtrate that passed through the 10 $\mu$m sieve was screened further through the 5 $\mu$m sieve to obtain a filtrate containing the small-sized fraction. The starch retained on the 5 $\mu$m sieve was collected as the medium-sized fraction. The collected starch fractions were centrifuged and washed in distilled water and twice in anhydrous ethanol and then dried at 40 °C for 2 days, ground into powders in a mortar with pestle, and passed through a 100 mesh sieve.

**Extreme Sedimentation.** The starches were separated into different-sized fractions by extreme sedimentation according to the method of Ao and Jane[2] with some modifications (Supporting Information Figure S2). Starch suspension (0.2%, w/v; 150 mL) in distilled water was allowed to settle for 0.5 h in a graduated cylinder (250 mL). The supernatant was decanted to a glass beaker. The starch pellet was made up to 150 mL with distilled water and mixed and then was allowed to settle for 0.5 h to obtain the supernatant and starch precipitate again. The process was repeated 10 times. The starch precipitate was collected as the large-sized fraction. The suspensions were pooled and centrifuged at 5000*g* for 10 min. The resulting precipitate was suspended to 150 mL in the cylinder and allowed to settle for 1 h. The supernatant was decanted to another cylinder and made up to 150 mL with distilled water and was mixed and allowed to settle for 1 h to obtain the supernatant and starch precipitate again. The process was repeated 10 times. The starch in the supernatant was collected as the small-sized fraction. The starch precipitate during the separation of small-sized granules was pooled and collected as the medium-sized fraction. Finally, the starch fractions were washed and dried as described above for microsieving.

**Differential Sedimentation.** The starches were separated into different-sized fractions by differential sedimentation according to the method of Takeda et al.[26] with some modifications (Supporting Information Figure S3). Starch suspension (0.2%, w/v; 150 mL) in distilled water was allowed to settle in 250 mL cylinders for 0.5 and 2 h. The fractions of 0.5 h precipitate, 0.5−2 h precipitate, and 2 h supernatant were collected as large-, medium-, and small-sized granules, respectively. The fractionation was repeated 10 times on each fraction to be refined. Finally, the starch fractions were washed and dried as described above for microsieving.

**Differential Supernatant.** The starches were separated into different-sized fractions by differential supernatant according to the method of Dhital et al.[27] with some modifications (Supporting Information Figure S4). Starch suspension (0.2%, w/v) in distilled water was allowed to settle in a cylinder for 2 and 0.5 h. After the desired time, the top 10 cm of supernatant was pipetted to a beaker. The remaining suspension in the cylinder was then made up to the original volume with distilled water and mixed and then was allowed to settle for collecting supernatant. The pipetting supernatant was repeated 10 times. The starches in the supernatants of 2 and 0.5 h settlement were collected as small- and medium-sized fractions, respectively. The starch precipitate of 0.5 h settlement was collected as large-sized fraction. Finally, the starch fractions were washed and dried as described above for microsieving.

**Glycerol Centrifugation.** The starches were separated into different-sized fractions by glycerol centrifugation according to the method of Peng et al.[28] with some modifications (Supporting Information Figure S5). Starch suspension (2.5%, w/v; 40 mL) in 80% glycerol was centrifuged at 100*g* for 5 min. The supernatant was removed to a beaker. The pellet was suspended with 40 mL of 80% glycerol and centrifuged five times to obtain starch precipitate that constituted the large-sized fraction. The supernatants were pooled and centrifuged at 5000*g* for 10 min. The resulting starch pellet was suspended with 40 mL of 60% glycerol and centrifuged at 100*g* for 5 min. The supernatant was removed to a beaker. The pellet was suspended with 40 mL of 60% glycerol and centrifuged five times to obtain starch precipitate that constituted the medium-sized fraction. The supernatants were pooled and centrifuged at 5000*g* for 10 min. The resulting starch pellet comprised the small-sized fraction. Finally, the starch fractions were washed and dried as described above for microsieving.

**Morphology Observation.** The micromorphology of starch granules was viewed with an Olympus BX53 light microscope according to the method described by Cai et al.[22] For scanning electron microscope (SEM) observation, starch granules were suspended in anhydrous ethanol. Twenty microliters of the starch−ethanol suspension was applied to an aluminum stub using double-sided adhesive tape, and the starch was coated with gold using a sputter coater. Starch samples were observed and photographed using an environmental SEM (ESEM XL-30, Philips, The Netherlands).

**Granule Size Analysis.** Granule size analysis was carried out using a laser diffraction particle size analyzer (Mastersizer 2000, Malvern, UK). The starches were suspended in distilled water and stirred at 2000 rpm. The obscuration in all measurements was >10%. Particle size is defined in terms of the 10th percentile [$d(0.1)$], median [$d(0.5)$], 90th percentile [$d(0.9)$], surface-weighted mean [$D(3,2)$], and volume-weighted mean [$D(4,3)$].

**Apparent Amylose Content (AC) Determination.** Apparent AC was determined using an iodine colorimetric method as described by Man et al.[15]

**Molecular Weight Distribution Analysis.** Starch was deproteinized with protease and sodium bisulfite and debranched with isoamylase according to the methods of Tran et al.[29] and Li et al.[30] The molecular weight distribution of debranched starch was analyzed using a PL-GPC 220 high-temperature chromatograph (Agilent Technologies UK Limited, Shropshire, UK) with three columns (PL110-6100, 6300, 6525) and a differential refractive index detector according to the method of Cai et al.[31]

**Crystal Structure Analysis.** The crystal structure of starch was analyzed on an XRD (D8, Bruker, Germany) spectroscope. The XRD analysis and determination of the relative crystallinity were carried out following the method described by Man et al.[15] Before measurements, all of the specimens were stored in a moist chamber where a saturated solution of NaCl maintained a constant humidity (relative humidity = 75%) for 1 week.

**Short-Range Ordered Structure Analysis.** Short-range ordered structure of starch was analyzed on a Varian 7 000 FTIR spectrometer with a DTGS detector equipped with an ATR single-reflectance cell containing a germanium crystal (45° incidence angle) (PIKE Technologies, USA) as previously described by Man et al.[15] Original spectra were corrected by subtraction of the baseline in the region from 1200 to 800 $cm^{-1}$ before deconvolution was applied using Resolutions Pro. The assumed line shape was Lorentzian with a half-width of 19 $cm^{-1}$ and a resolution enhancement factor of 1.9. Intensity measurements at 1045, 1022, and 995 $cm^{-1}$ were performed on the deconvoluted spectra by recording the height of the absorbance bands from the baseline using Adobe Photoshop 7.0 image software.

**Solid-State $^{13}C$ CP/MAS NMR Analysis.** High-resolution solid-state $^{13}C$ CP/MAS NMR analysis of starch was carried out at $B_0$ = 9.4T on a Bruker AVANCE III 400 WB spectrometer as described previously by Cai et al.[31] Amorphous starch was prepared by gelatinizing native starch following the method of Atichokudomchai et al.[32] The spectrum of amorphous starch was matched to the intensity of native starch at 84 ppm and subtracted to produce the

ordered subspectrum. The quantitative analyses of single-helix, double-helix, and amorphous conformational features within starch were carried out according to the method described by Tan et al.[33]

**SAXS Analysis.** SAXS measurement of starch was performed according to the method of Yuryev et al.[34] with some modifications. Starch was dispersed in an excess of distilled water to form slurries. SAXS measurement was obtained using a Bruker NanoStar SAXS instrument equipped with Vantec 2000 detector and pinhole collimation for point focus geometry. The X-ray source was a copper rotating anode (0.1 mm filament) operating at 50 kV and 30 W, fitted with cross-coupled Göbel mirrors, resulting in Cu K$\alpha$ radiation wavelength of 1.5418 Å. The optics and sample chamber were under vacuum to minimize air scattering. During X-ray exposure, the starch slurries were kept in sealed cells to prevent dehydration. SAXS data sets were analyzed using DIFFRAC$^{plus}$ NanoFit software. Parameters of the SAXS spectrum were determined according to the simple graphical method.[34]

**Statistical Analysis.** The data reported in all tables are mean values and standard deviation. Analysis of variance (ANOVA) by Tukey's test ($p < 0.05$) was evaluated using the SPSS 16.0 Statistical Software Program.

## RESULTS AND DISCUSSION

**Morphology of Large-, Medium-, and Small-Sized Starch Fractions.** Figures S6 and S7 in the Supporting Information show the micromorphologies of native starches and their different-sized fractions. For native normal maize starch, most of the granules were polygonal with large size, and some granules were spherical with small size (Figure S6). For native high-amylose maize starch, some elongated starch granules were also observed except polygonal granules with large size and spherical granules with small size (Figure S7). It is very important to establish the size separation methods that give narrow granule size fractions for investigating the structural properties of different-sized starch granules. In this study, five procedures, including microsieving, extreme sedimentation, differential sedimentation, differential supernatant, and glycerol centrifugation separation, have been used to separate large-, middle-, and small-sized fractions from normal and high-amylose maize starches. Microsieving could not completely separate large-, medium-, and small-sized fractions. Some medium- and small-sized granules were retained in the large-sized fraction. Some large-sized granules passed through the screen and were present with medium- and small-sized granules in the filtrate (Figures S6 and S7). Some literature also reports that microsieving can not give a homogeneous size granule population.[28] Sedimentation in a water column separates different-sized granules on the basis of the difference in sedimentation rates. Different sedimentation procedures have been reported in refs 2, 26, and 27. In this study, extreme sedimentation, differential sedimentation, and differential supernatant separation methods were compared (Figures S6 and S7). The results showed that the extreme sedimentation and differential supernatant separation methods were better than differential sedimentation for giving homogeneous size granules. Because of the low density of water, the difference among sedimentation rates of different-sized granules in water is not large enough to separate the different-sized granules. In addition, it takes a very long time to obtain enough small-sized granules by extreme sedimentation and differential supernatant separation methods. Because glycerol solution has higher density than water, the difference among sedimentation rates of different-sized granules in glycerol is large enough to separate the different-sized granules. Thus, in the present study, the glycerol centrifugations through two glycerol solutions (80 and 60%, v/v) were used to purify large-, medium-, and small-sized granules from native normal and high-amylose maize starches. The granule morphology and sizes were significantly different in different-sized fractions separated by glycerol centrifugation (Figures S6 and S7).

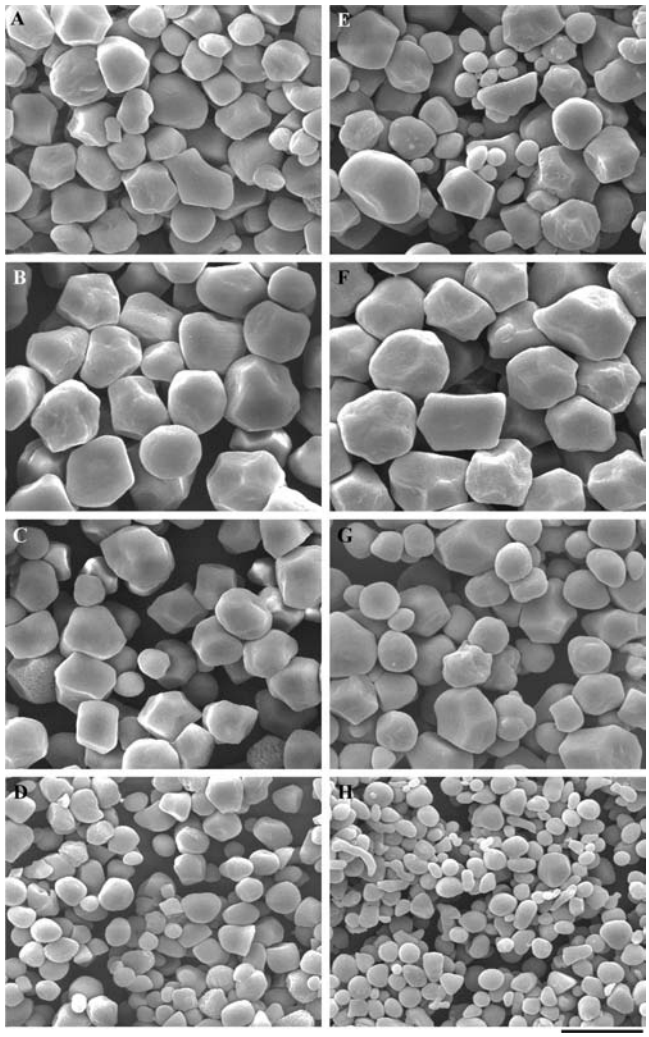

**Figure 1.** SEM photographs of native (A, E) and large- (B, F), medium- (C, G), and small-sized (D, H) fractions of normal (A–D) and high-amylose (E–H) maize starches separated by glycerol centrifugation method. Scale bar = 20 $\mu$m.

SEM was used to complement the light microscope images in an effort to reveal details about the granule surface that could not be distinguished by light microscope (Figure 1). The surfaces of the granules from native and large-, medium-, and small-sized fractions of normal and high-amylose maize starches were smooth. The native starches from normal and high-amylose maizes consisted of mixed populations of large, medium, and small granules. The large and medium granules were mainly polyhedral or irregular in shape, whereas the small granules were mainly spherical or ellipsoidal. In addition, some elongated granules were also observed in the small-sized fraction of high-amylose starch.

**Size of Large-, Medium-, and Small-Sized Starch Fractions.** The laser diffraction instrument for granule size measurement provides derived outputs of a volume distribution, standard mean diameters [$D(3,2)$ and $D(4,3)$], and distribution information [$d(0.1)$, $d(0.5)$, and $d(0.9)$]. The

dx.doi.org/10.1021/jf503865e | J. Agric. Food Chem. 2014, 62, 11711−11721

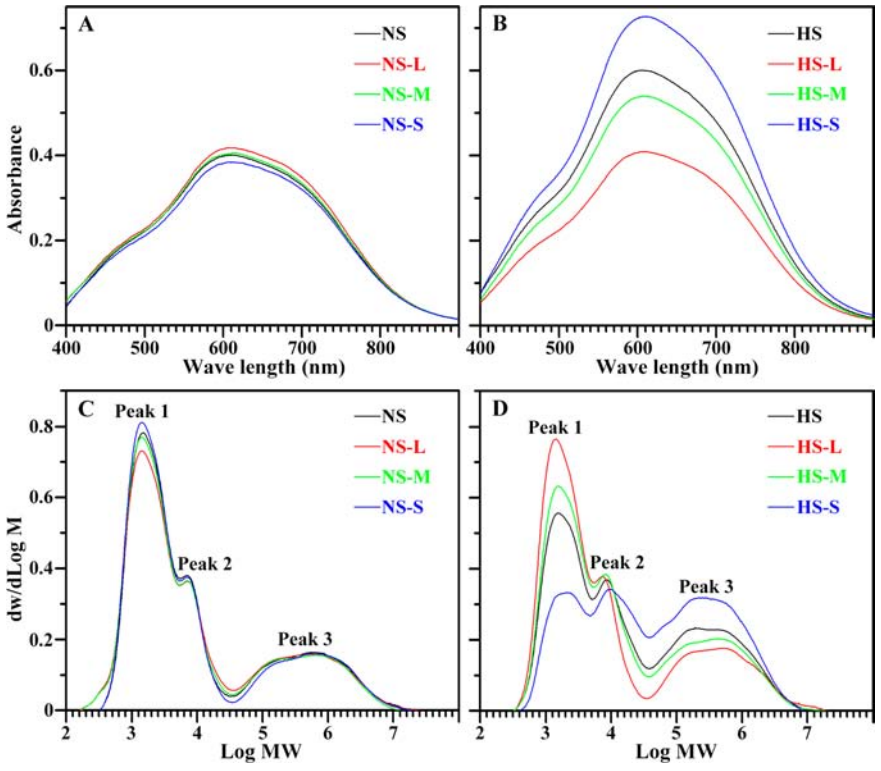

**Figure 2.** Absorbance spectra of starches in the $I_2$/KI solution (A, B) and GPC chromatograms of isoamylase-debranched starches (C, D) from normal (A, C) and high-amylose (B, D) maize starches separated by glycerol centrifugation method. NS, NS-L, NS-M, and NS-S: native and large-, medium-, and small-sized fractions of normal maize starch. HS, HS-L, HS-M, and HS-S: native and large-, medium-, and small-sized fractions of high-amylose maize starch.

volume distributions of different-sized fractions of normal and high-amylose maize starches are presented in Figure S8 in the Supporting Information. Native starches were unimodal distribution and could be separated into large-, medium-, and small-sized fractions. The granule size range of high-amylose maize starch was broader than that of normal maize starch, especially for native starch. An overlap between the fractions could be seen. The results of granule size measurements are listed in Table 1. The $d(0.5)$, $D(3,2)$, and $D(4,3)$ values of large-, medium-, and small-sized fractions were reduced from 17.72 to 13.84 and 8.40 $\mu$m, from 17.11 to 13.16 and 7.79 $\mu$m, and from 18.38 to 14.54 and 9.03 $\mu$m, respectively, for normal maize starch and from 19.75 to 14.36 and 8.15 $\mu$m, from 19.07 to 7.64 and 5.45 $\mu$m, and from 20.48 to 14.41 and 8.52 $\mu$m, respectively, for high-amylose maize starch.

**Apparent AC of Large-, Medium-, and Small-Sized Starch Fractions.** Apparent ACs of native and large-, medium-, and small-sized fractions of normal and high-amylose maize starches were determined using the iodine colorimetric method and are shown in Table 2. The results of five separation methods all showed that the apparent AC slightly decreased with decrease of granule size for normal maize starch, but markedly increased with decrease of granule size for high-amylose starch. For normal unimodal starch, the decrease in AC with decrease of granule size has been previously reported.[6,8−10] However, the significant increase of AC with decrease of granule size was not reported in previous studies. For high-amylose maize starch, it is noteworthy that the large-sized granules had only about 32% apparent AC and the small-sized granules had about 75% apparent AC for differential supernatant and glycerol centrifugation separation methods.

On the basis of the morphologies (Supporting Information Figures S6 and S7), ACs (Table 2), and purified efficiency of different-sized fractions separated by five methods, the separation effectiveness of glycerol centrifugation method was the best among five methods. In this study, structural properties of starches were investigated in the different-sized fractions separated by glycerol centrifugation method.

**Iodine Absorption Spectra of Large-, Medium-, and Small-Sized Starch Fractions.** The absorption spectra of iodine−starch complex are shown in Figure 2A,B. The absorption spectra were similar among native and large-, medium-, and small-sized starch fractions of normal maize (Figure 2A), but significantly different among native and large-, medium-, and small-sized starch fractions of high-amylose maize (Figure 2B). The maximum absorption wavelength was similar among different-sized fractions of normal and high-amylose maize starches. The iodine blue value slightly decreased with decrease of granule size for normal maize starch, but markedly increased with decrease of granule size for high-amylose starch (Table 3).

**Molecular Weight Distribution of Large-, Medium-, and Small-Sized Starch Fractions.** The molecular weight distributions of isoamylase-debranched starches as determined by GPC are shown in Figure 2C,D. A trimodal distribution of low, middle, and high molecular weight peaks, designated peak 1, peak 2, and peak 3, respectively, was observed. Peaks 1 and 2 consist of short (A and short B chains) and long (long B chains) branch-chains of amylopectin, respectively. The area ratio of peak 1 to peak 2 might be used as an index of the extent of branching of amylopectin; the higher the ratio, the higher the branching degree.[35] Peak 3 includes amylose.[36] The GPC

[a]Data are means ± standard deviations, $n = 3$ for iodine blue values and =2 for GPC parameters. Values in the same column with different letters are significantly different ($P < 0.05$). [b]Iodine blue values are the absorbance at 680 nm of starch–iodine complex. [c]GPC parameters of isoamylase-debranched starches. The peak 1/peak 2 ratio is determined according to the area ratio of peak 1 and peak 2.

parameters are summarized in Table 3. The AC determined on the basis of iodine and starch affinity is described as apparent AC, which overestimates AC if there are branched molecules with long side chains that bind iodine.[37] The present results showed that the AC determined by GPC (Table 3) was significantly lower than the apparent AC obtained by iodine colorimetric method (Table 2), which was in agreement with the report of Shi et al.[37] and indicated that the intermediate chain and amylopectin long branch-chain could bind iodine to increase the value of apparent AC. The study of Dhital et al.[6] showed that the molecular weight distributions of fully branched normal maize starch fractions were almost similar, although their apparent ACs were different. In the present study, the small-sized fraction of normal starch also showed significantly lower apparent AC than the large-sized fraction, but the ACs and amylopectin branching degree determined by GPC had no significant difference among different-sized fractions of normal maize starch. The results agreed with the conclusion of Dhital et al.[6] that the lower apparent AC in the smaller normal starch granules was predominantly due to the higher amount of lipids in these granules that might have complexed with amylose and thereby reduced the amount of free amylose available to form a complex with iodine. For high-amylose starch, the AC determined by GPC was markedly lower than the apparent AC, the branching degree of high-amylose starch was also markedly lower than that of normal starch. These results indicated that high-amylose starch contained high levels of intermediate chain and amylopectin long branch-chain. The different-sized fractions of high-amylose starch had a significant increase in the amylopectin long branch-chain and AC and a marked decrease in the amylopectin short branch-chain and branching degree with the decrease of granule size, indicating that the different-sized fractions of high-amylose starch had significantly different molecular structures. However, it is noteworthy that the molecular structure of large-sized fraction of high-amylose starch was similar to that of normal starch.

**XRD Spectra of Large-, Medium-, and Small-Sized Starch Fractions.** Starches can be classified into A-, B-, and C-type crystallinity on the basis of their XRD spectra. C-type starch is a mixture of both A- and B-type polymorphs and can be further classified to $C_A$-type (closer to A-type), C-type, and $C_B$-type (closer to B-type) according to the proportion of A-type and B-type polymorphs.[38] The XRD patterns of native and large-, medium-, and small-sized fractions of normal maize starches are shown in Figure 3A. They all showed strong reflection at about 15° and 23° 2$\theta$, and an unresolved doublet at 17° and 18° 2$\theta$, which resembled the typical A-type XRD pattern of normal cereal starches,[38] indicating that the nature of individual crystallites is similar in all normal maize granules regardless of the granule size. This result was in agreement with previous papers.[2,6]

Native high-amylose maize starch showed strong reflection at about 15°, 17°, and 23° 2$\theta$, a small peak at about 5.6° 2$\theta$, and a shoulder peak at about 18° 2$\theta$ (Figure 3B). The peak at 5.6° 2$\theta$ was characteristic of B-type crystallinity, and the shoulder peak of 18° 2$\theta$ was indicative of the A-type polymorph, which suggested that the starch consisted of A- and B-type polymorphs, with the A-type polymorph being the main component. Therefore, native high-amylose maize starch was $C_A$-type crystallinity. For the large-sized fraction of high-amylose maize starch, the peak at 5.6° 2$\theta$ disappeared, the peaks at 17° and 18° 2$\theta$ became an unresolved doublet, and the

[a]Data are means ± standard deviations, $n = 3$. Values in the same column with different letters are significantly different ($P < 0.05$).

peaks at 15° and 23° 2$\theta$ appeared to sharpen, indicating that the large-sized fraction of high-amylose maize starch was typical A-type crystallinity. The spectrum of the medium-sized fraction of high-amylose maize starch was very similar to that of native high-amylose maize and exhibited a $C_A$-type crystallinity. However, the shoulder peak at 18° 2$\theta$ disappeared and the peak at 23° 2$\theta$ became broad in the small-sized fraction of high-amylose maize starch, exhibiting a typical C-type crystallinity. Most high-amylose starches are B-type crystallinity,[12,14] but some C-type starches have also been reported in high-amylose cereal crops.[20,38] Cheetham and Tao[38] thought that the crystal type of maize starch could be varied from A- to B- via C-type when AC increased; the transition occurred at about 40% AC. In the present study, the AC of native high-amylose maize starch determined by GPC was about 35.6%. The result was in agreement with the report of Cheetham and Tao[38] that maize starch with about 40% AC had C-type crystallinity. C-type starch contains A- and B-type allomorphs. To date, the literature reports that A- and B-type allomorphs are distributed in the same granule. It is never reported that A- and B-type polymorphs are distributed in different granules; that is, C-type starches consist of A-type and B-type granules. In the present study, the results of C-type native starch and A-type large-sized starch from high-amylose maize indicated that C-type starches could contain some A-type granules.

Table 4 shows the relative crystallinities of starches, which were calculated from the XRD patterns. For normal maize starch, the crystallinities did not show significant difference among different-sized fractions. For high-amylose maize starch, the crystallinities significantly decreased with the decrease of granule size. This result was consistent with the findings of Cheetham and Tao[38] that relative crystallinity was negatively correlated with AC.

**ATR-FTIR Spectra of Large-, Medium-, and Small-Sized Starch Fractions.** The ATR-FTIR spectrum of starch is sensitive to the short-range ordered structure, defined as the double-helical order, as opposed to the long-range ordered structure related to the packing of double helices.[39] The variations in spectra among different starches can be interpreted in terms of the short-range ordered structure present in the

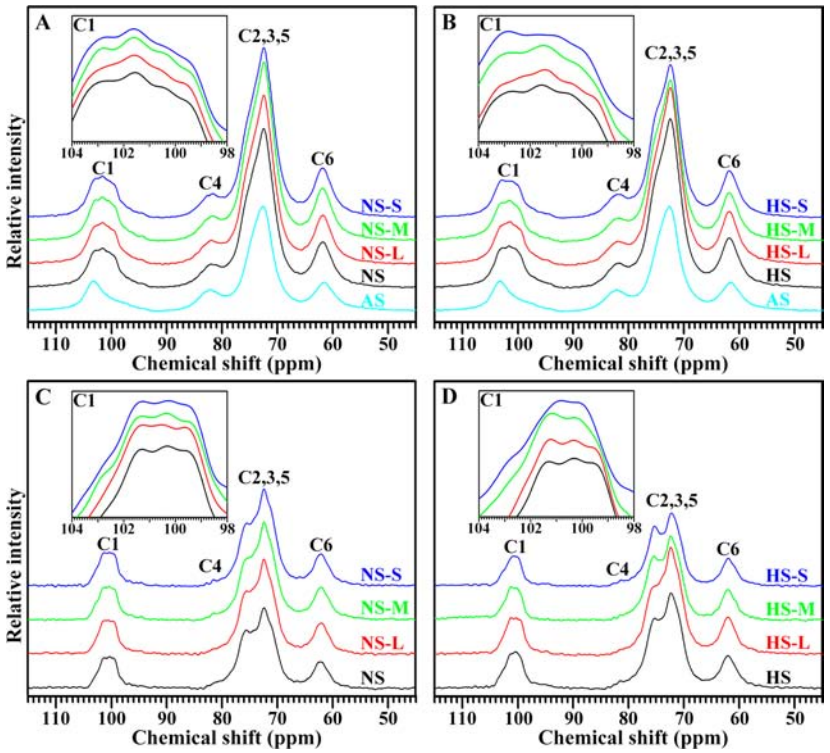

**Figure 4.** $^{13}C$ CP/MAS NMR original spectra (A, B) and ordered subspectra (C, D) of native and large-, medium-, and small-sized fractions of normal (A, C) and high-amylose (B, D) maize starches separated by glycerol centrifugation method. AS: amorphous starch. NS, NS-L, NS-M, and NS-S: native and large-, medium-, and small-sized fractions of normal maize starch. HS, HS-L, HS-M, and HS-S: native and large-, medium-, and small-sized fractions of high-amylose maize starch.

external region of starch granule. The intensity of absorbance at 1045, 1022, and 995 $cm^{-1}$ is sensitive to changes in starch conformation. The bands at 1045 and 1022 $cm^{-1}$ are associated with ordered/crystalline and amorphous regions in starch, respectively. The ratio of absorbance 1045/1022 $cm^{-1}$ is used to quantify the degree of order, and that of 1022/995 $cm^{-1}$ can be used as a measure of the proportion of amorphous to ordered carbohydrate structure in the starch.[39]

The ATR-FTIR spectra of native and large-, medium-, and small-sized fractions of normal and high-amylose maize starches in the 1200−900 $cm^{-1}$ region are shown in Figure 3C,D. The ratios for 1045/1022 and 1022/995 $cm^{-1}$ of starches from normal and high-amylose maizes are shown in Table 4. On the basis of both the spectra and calculated data, the ATR-FTIR characteristics of different-sized fractions of normal maize starch were similar, but high-amylose maize starch had significantly different ATR-FTIR characteristics among different-sized fractions. The ATR-FTIR characteristics of the large-sized fraction of high-amylose maize starch was much closer to those of different-sized fractions of normal maize starch. It is noteworthy that the ratio of 1022/995 $cm^{-1}$ significantly increased with the decrease of granule size for normal maize starch, but markedly decreased for high-amylose maize starch. These results indicated that the different-sized fractions of normal maize starch and large-sized granules of high-amylose maize starch had similar short-range ordered structure, whereas granule size significantly affected the short-range ordered structure of high-amylose maize starch.

**$^{13}C$ CP/MAS NMR Spectra of Large-, Medium-, and Small-Sized Starch Fractions.** The solid-state $^{13}C$ CP/MAS NMR patterns for starches are shown in Figure 4. The resonances at different parts per million were assigned according to data reported in the literature.[32,40] The C1 resonance, which gives information about both the crystalline nature as well as the noncrystalline (but rigid) chains, has been used to examine the structure of different types of starches. The multiplicity of C1 resonance corresponds to the packing type of the starch granule. A-type starch, which has three nonidentical sugar residues, shows a triplet at the C1 region, whereas B-type starch, which has two nonidentical sugar residues, shows a doublet.[32] In general, typical C-type starch has an inconspicuous triplet or doublet at the C1 region. However, $C_A$-type starch shows a triplet at the C1 region and $C_B$-type starch shows a doublet at the C1 region.[40]

The C1 resonances of native and large-, medium-, and small-sized fractions of normal maize starch occurred as triplets at about 99.5, 100.5, and 101.5 ppm (Figure 4A), those of native and large-sized fractions of high-amylose maize starch showed an inconspicuous triplet, and those of medium- and small-sized fractions of high-amylose maize starch showed an inconspicuous doublet (Figure 4B). Panels C and D of Figure 4 show the ordered subspectra of starches. In this analysis, the standard amorphous starch spectrum was subtracted from the test spectrum until there was no residual intensity at 84 ppm (a region of the spectrum with intensity due solely to amorphous conformations).[33] The ordered subspectra were similar to the original spectra, but they had clearer crystalline peaks of C1 resonances than those in the original spectra. The clear triplets were observed in the spectra of different-sized fractions of normal maize starch and native and large-sized fractions of high-amylose maize starch, and the clear doublet was observed in the spectra of medium- and small-sized fractions of high-amylose maize starch. These results, combined with the results from the XRD analysis, further confirmed that the different-

[a]Data are means ± standard deviations, $n = 3$ for the proportions of single-helix, double-helix, and amorphous conformations and = 2 for SAXS parameters. Values in the same column with different letters are significantly different ($P < 0.05$). [b]Relative proportions of single-helix, double-helix, and amorphous conformations are determined by $^{13}C$ CP/MAS NMR. [c]$I_{max}$, peak intensity; $D$, lamellar distance (Bragg spacing).

sized fractions of normal maize starch and the large-sized fraction of high-amylose maize starch were all A-type crystallinity, native and medium-sized fractions of high-amylose maize starch were $C_A$-type crystallinity, and the small-sized fraction was C-type crystallinity.

The ordered subspectra were peak-fitted. A combination (50/50) of Lorentzian and Gaussian profiles gave an acceptable fit (data not shown). The proportions of single-helix, double-helix, and amorphous components are listed in Table 5 and showed similarity among different-sized fractions of normal maize starch but some difference among different-sized fractions of high-amylose maize starch. The amylopectin side chains can form two types of helices in starch granule. Helices that are packed in the short-range order are defined as the double-helical order, and helices that are packed in long-range order are related to the packing of double helices forming crystallinity. The double helices in the short- and long-range distance can both be detected by $^{13}C$ CP/MAS NMR, but only the double helices in the long-range distance can be detected by XRD.[32] Therefore, the double-helix content of starch was generally higher than its relative crystallinity.

**SAXS Spectra of Large-, Medium-, and Small-Sized Starch Fractions.** A comparison of the SAXS patterns of the starches is shown in Figure 5. The well-resolved main scattering peak around scattering vector ($q_0$) of about 0.06 Å$^{-1}$ is thought to arise from the periodic arrangement of alternating crystalline and amorphous lamellae of amylopectin and corresponds to the lamellar repeat distance or Bragg spacing. The location of the peak depends on the size of lamella and may differ among starches from different plants, whereas the peak area or intensity depends mainly on the degree of order in semi-crystalline regions.[41] As shown in Figure 5, all starches were scaled to equal intensity at high $q$ ($q$ = 0.2 Å$^{-1}$) to account for variations in sample concentrations, according to the method of Sanderson et al.[42] The SAXS patterns were at the same relative scale and, therefore, were directly comparable. Native and large-, medium-, and small-sized fractions of normal and high-amylose maize starches all showed the most defined lamellar peak centered at 0.063 Å$^{-1}$, which corresponded to a lamellar repeat distance of 10.0 nm. However, the lamellar peak intensity showed significant difference among these starch fractions, especially for high-amylose maize starch (Table 5). The extremely low lamellar peak intensity of small-sized fraction of high-amylose starch likely indicated a severely disrupted or nonexistent lamellar structure compared to that of large- and medium-sized fractions. Yuryev et al.[34] reported that an increase in AC in wheat starches was accompanied by decreased peak scattering intensity, which resulted from accumulation of amylose tie-chains with increasing AC in the granules. The starch fractions from high-amylose maize showed significantly lower peak intensities with decrease of granule size, which might result from the elevated AC (Tables 2 and 3).

In conclusion, the structural properties of native and large-, medium-, and small-sized fractions of normal and high-amylose maize starches separated by glycerol centrifugation method were investigated to reveal whether structural properties differed among the different-sized fractions of the starches. The results showed that the granule sizes had no significant effect on structural properties of normal starch, but the different-sized fractions of high-amylose maize starch showed markedly different structural properties. The small-sized granules of high-amylose starch had significantly higher AC, amylopectin long branch-chain, and IR ratio of 1045/1022

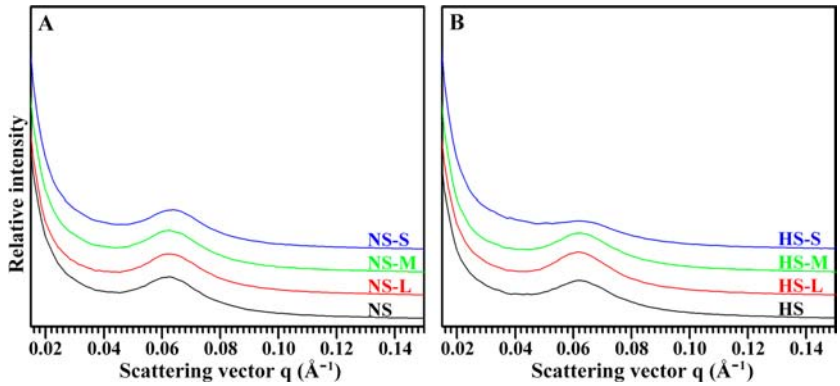

**Figure 5.** SAXS patterns of native and large-, medium-, and small-sized fractions of normal (A) and high-amylose (B) maize starches separated by glycerol centrifugation method. NS, NS-L, NS-M, and NS-S: native and large-, medium-, and small-sized fractions of normal maize starch. cm$^{-1}$, lower amylopectin short branch-chain and branching degree, relative crystallinity, IR ratio of 1022/995 cm$^{-1}$, and peak intensities of lamellar structure than the large-sized granules. The differences in crystal structure among the different-sized fractions indicated that C-type starch might contain A-type starch granules.

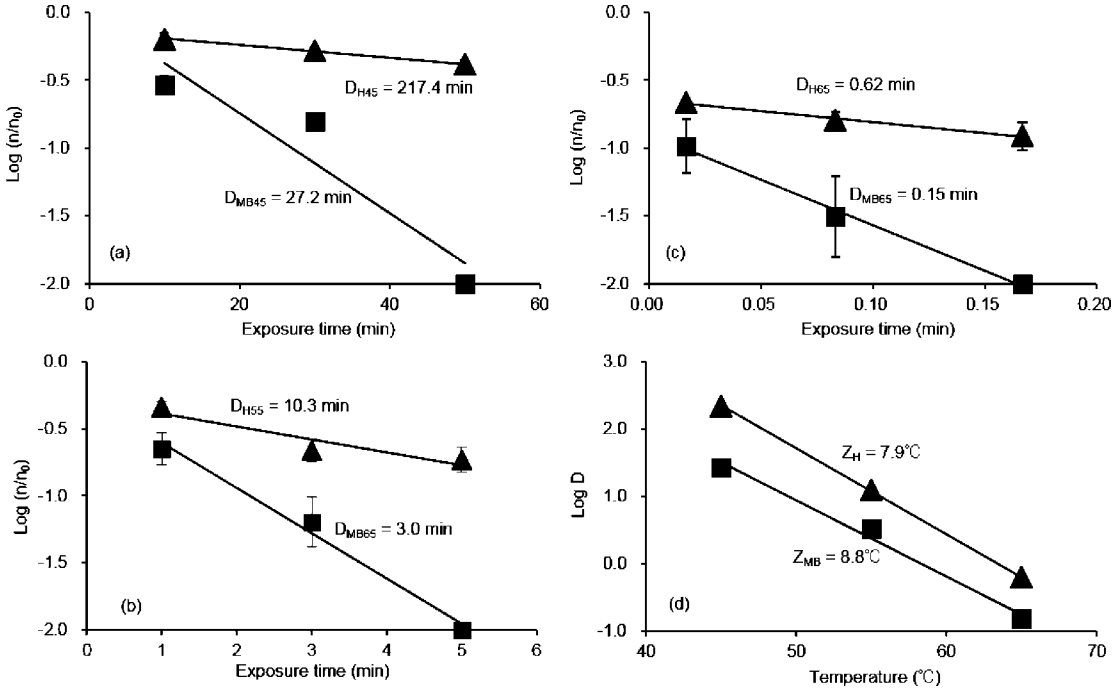

**Figure 1.** Effects of temperature on the heating coil during $\alpha$-glucosidase inactivation by the two-stage MB-$CO_2$ and heat treatments. The two-stage MB-$CO_2$ treatment was performed under the following conditions: the mixing vessel was set to 5 °C and 2 MPa, and the heating coil was set to 45, 55, 65, or 75 °C and 6 MPa. Data are presented as means with standard errors of the results from triplicate experiments.

**Two-Stage MB-$CO_2$ Apparatus and Procedure for Treating the UPS.** The experimental equipment for two-stage MB-$CO_2$ in the present study was used with the modification of the equipment in a previous report.[17] That is, two types of heating coils (5 mm diameter × 5100 mm length, volume 100 mL for 45 and 55 °C, or 4 mm diameter × 2000 mm length, volume 25 mL for 65 and 75 °C) were used.

The two-stage MB-$CO_2$ treatment was performed under the following conditions: temperature and pressure in the mixing vessel were 5 °C and 2 MPa, respectively; temperature, pressure, and exposure time in the heating coil were 45 °C for 10, 30, and 50 min, 55 °C for 1, 3, and 5 min, 65 °C for 1, 5, and 10 s, or 75 °C for 1 s, respectively, under a pressure of 6 MPa; temperature and pressure in the cooling coil were −15 °C and 6 MPa, respectively.

**Heat Treatment.** For comparison, heat treatments were performed only using the heating coil of two-stage MB-$CO_2$ equipment under the same conditions as two-stage MB-$CO_2$ treatment. In addition, to make heat-treated sake (HTS) for sensory evaluation and analysis of the components, a heat treatment was performed at 65 °C for 3 min, which was the same condition as the typical heat treatment of sake.

**Measurement of $\alpha$-Glucosidase Activity.** Residual $\alpha$-glucosidase activity in the sakes was measured using a glucoamylase and $\alpha$-glucosidase assay kit (Kikkoman Co., Noda, Japan). One unit of $\alpha$-glucosidase activity was defined as the amount required to produce 1 $\mu$mol of 4-nitrophenol in 1 min. The residual activity (RA) of $\alpha$-glucosidase was estimated using the following formula.

$$\text{RA}\,(\%) = (\alpha\text{-glucosidase activity after treatment} / \alpha\text{-glucosidase activity before treatment}) \times 100 \quad (1)$$

All experiments were performed in triplicate. Data are presented as means with standard error of the results from triplicate experiments.

**Kinetics Analysis on the Inactivation of $\alpha$-Glucosidase.** The inactivation kinetics of $\alpha$-glucosidase was analyzed using a conventional first-order model as in a previous report.[16]

$$\log(A_t/A_0) = (k/2.303)t \quad (2)$$

$$D = 2.303/k \quad (3)$$

where $A_t$ is the residual enzymatic activity at any time $t$, $A_0$ is the initial enzymatic activity, $k$ is the reaction rate constant ($\text{min}^{-1}$) in a given condition, and the decimal reduction time ($D$ value) is defined as the treatment time required for 90% inactivation of the initial activity at fixed temperature and pressure conditions. $D$ value is calculated using the following equation.[21]

$$\log(D_1/D_2) = (T_2 - T_1)/Z \quad (4)$$

where $Z$ is the temperature increase needed for a 90% reduction in the $D$, and $T_2$ and $T_1$ are the temperatures and pressures that correspond to $D_1$ and $D_2$. The $Z$ value is obtained from the negative slope of the regression line of log $D$ versus $T$.

**Sensory Evaluation.** Sensory evaluation of UPS, HTS, and the sakes treated by two-stage MB-$CO_2$ with a heating coil at 45 °C for 50 min (MB45), 55 °C for 5 min (MB55), 65 °C for 10 s (MB65), and 75 °C for 1 s (MB75) was performed by 10 panelists trained in sensory evaluation (age, 21−61 years; 5 men and 5 women). The panelists evaluated the total aroma and total taste of the sakes on a seven-point scale (3, very good; 2, good; 1, slightly good; 0, normal; −1, slightly bad; −2, bad; and −3, very bad). Data are presented as means with standard errors of the results from 10 panelists.

**Analysis of Organic Acids.** To analyze the organic acid content, 500 $\mu$L of sake filtered through a 0.45 $\mu$m filter was allowed to pass through a Sep-Pak C18 column (Waters Co., Ltd., Milford, MA) and eluted with 2 mL of 5% phosphoric acid solution. The eluate was used for the analysis of organic acids by high pressure liquid chromatography (HPLC, Shimadzu Co., Kyoto, Japan). Measuring conditions of the HPLC were as follows: column, ODS-3 (4.6 mm i.d. × 250 mm, GL Science Inc., Tokyo, Japan); mobile phase, 0.02 mol/L diammonium hydrogen phosphate: methanol at a ratio of 97:3 (pH 2.35); flow rate, 0.5 mL/min; detector, UV detector (SPD-20A, 210 nm); oven temperature, 25 °C. All experiments were performed in triplicate. Data are presented as means with standard errors of the results from triplicate experiments.

**Analysis of Glucose and Isomaltose.** Glucose and isomaltose contents were measured by HPLC (Jasco Co., Hachioji, Japan). Sake diluted 3-fold with distilled water was filtered through a 0.45 $\mu$m filter

and was used as sample. Running conditions for HPLC were as follows: column, Shodex Sugar SC1011 (8 mm i.d. × 300 mm, Showa Denko K. K., Tokyo, Japan); mobile phase, distilled water; flow rate, 1.0 mL/min; detector, RI detector (JASCO RI-930); oven temperature, 80 °C. All experiments were performed in triplicate. Data are presented as means with standard errors of the results from triplicate experiments.

**Analysis of Free Amino Acids.** Sake and 3% sulfosalicylic acid were mixed at a ratio of 1:1, refrigerated overnight, and then filtered through a 0.45 μm filter. Free amino acids in the filtrate were measured by an automated amino acid analyzer (JLC500-500/V2, JEOL Ltd., Akishima, Japan). All experiments were performed in triplicate. Data are presented as means with standard deviation of the results from triplicate experiments.

**Analysis of Volatile Compounds.** Volatile compounds in the sake were measured by gas chromatography mass spectrometry (GC–MS, 6890GC-5973MSD, Agilent Technologies, CA), which was connected to an Entech 7200 (7200 Preconcentrator, Entech Instruments Inc., CA) based on reports by Yoshizaki et al.[22,23] Afterward a 500 mL purpose-built capped glass pot containing 100 mL of sake (diluted to 1/3 with deionized water) and 100 μL of 0.1% methyl hexanoate (Wako Pure Chemical Industries Co. Ltd., Osaka, Japan) as internal standard was heated in a water bath for 15 min at 50 °C. Then, the volatile compounds in the headspace of the glass pots were automatically concentrated by the Entech 7200 and analyzed by GC–MS. Running conditions of GC–MS were as follows: A DB-WAX capillary column (0.25 mm i.d. × 30 m, thickness 0.25 μm; Agilent Technologies, Folsom, CA) was used. The oven temperature was held at 40 °C for 4 min, elevated to 240 °C at 8 °C/min, and then held for 2 min. Helium was used at 30 cm/s as a carrier gas. The interface temperature was 230 °C. Volatile compounds were identified using the NIST mass spectrum database and retention time of authentic compounds, and determined relatively using the internal standard. All experiments were performed in triplicate. Data are presented as means with standard deviation of the results from triplicate experiments.

**Statistical Analyses.** Significant differences were evaluated by the Tukey–Kramer test ($p < 0.01$).

## RESULTS AND DISCUSSION

**Inactivation of α-Glucosidase.** Inactivation of α-glucosidase by two-stage MB-$CO_2$ and heat treatments is shown in Figure 1. α-Glucosidase activity decreased with increasing temperature of the heating coil for both the two-stage MB-$CO_2$ and heat treatments. Complete inactivation of α-glucosidase by two-stage MB-$CO_2$ with a heating coil at 45, 55 and 65 °C was achieved at 50 min, 5 min, and 10 s, respectively. Both two-stage MB-$CO_2$ and heat treatments at 75 °C could completely inactivate α-glucosidase within 1 s of the shortest exposure time. So, the results at 75 °C could not be plotted (data not shown). *D* values for the inactivation of α-glucosidase by two-stage MB-$CO_2$ with a heating coil at 45, 55, and 65 °C were 27.2, 3.0, and 0.15 min, respectively, and the *D* values by the heat treatment were 217.4, 10.3, and 0.62 min, respectively. Therefore, inactivation of α-glucosidase by two-stage MB-$CO_2$ was more effective than that by heat. This result was identical to a previous report that inactivation efficiency of PPO by two-stage MB-$CO_2$ was significantly higher than that by heat.[16] Furthermore, heat resistance of α-glucosidase by two-stage MB-$CO_2$ became lower than that by heat, because *Z* values, which indicated heat resistance, for the two-stage MB-$CO_2$ and heat treatments were 7.9 and 8.8 °C, respectively (Figure 1d). This result was consistent with our report,[16] which showed how the heat resistance of PPO was decreased by two-stage MB-$CO_2$.

**Sensory Evaluation.** Sensory evaluation of UPS, HTS, and sakes in which α-glucosidase was completely inactivated by two-stage MB-$CO_2$ with a heating coil at 45 °C for 50 min (MB45), 55 °C for 5 min (MB55), 65 °C for 10 s (MB65), and 75 °C for 1 s (MB75) is shown in Figure 2. For the evaluation

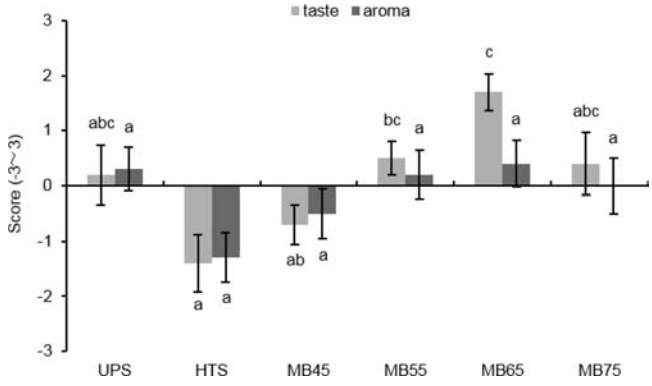

**Figure 2.** Sensory evaluation of unpasteurized, two-stage MB-$CO_2$-treated and heat-treated sakes. Two-stage MB-$CO_2$ treatment was performed under the following conditions: the mixing vessel was set to 5 °C and 2 MPa, and the heating coil was set to 45 °C for 50 min (MB45), 55 °C for 5 min (MB55), 65 °C for 10 s (MB65), or 75 °C for 1 s (MB75), under 6 MPa of pressure. Heat-treated sake (HTS) was produced at 65 °C for 3 min. Data are presented as means with standard errors of the results from triplicate experiments. Different letters indicate significant differences by the Tukey–Kramer method ($p < 0.01$).

of taste, the highest score was observed for MB65, followed in decreasing order by MB55, MB75, UPS, MB45, and HTS. Also, the evaluation of aroma followed the same pattern as those seen for taste, although no significant differences were recognized. Each sake was evaluated by the panelists as follows: strong bitterness and sweetness in UPS; strong bitterness and sourness, and weak sweetness in HTS; strong bitterness and spicy flavor in MB45; overall weakness in MB55; fresh sourness and moderate sweetness in MB65; and strong bitterness and sourness in MB75. Thus, to investigate the differences of taste and flavor in each sake determined by the sensory evaluation, free amino acids, organic acids, sugars, and volatile compounds in the sakes were measured.

**Free Amino Acids.** The main free amino acids in the UPS, HTS, MB45, MB55, MB65, and MB75 are shown in Table 1. The highest total amount of free amino acids in UPS was determined to be in the UPS, followed in decreasing order by HTS, MB75, MB45, MB65, and MB55. A significant amount of the free amino acids in UPS were likely due to decomposition of proteins and peptides by residual enzymes, while most of the free amino acids in MB75 and HTS were probably due to decomposition of proteins and peptides by excess heat. The present results on sensory evaluation and free amino acid contents are consistent with the results reported by Iwano et al. that sensory evaluation index of sake was negatively correlated with free amino acid contents.[24] Glutamic acid, arginine, alanine, and aspartic acid were also reported as taste components in sake.[25] No significant differences were recognized for glutamic acid, arginine, and alanine among all tested sakes, although aspartic acid, which causes sourness,[26,27] was significantly elevated in UPS, HTS, and MB75, thus contributing to the sourness of HTS and MB75 indicated by the sensory evaluation. Furthermore, amino acids that cause bitterness, such as phenylalanine, lysine, leucine, and valine,[28] were significantly higher in the UPS, HTS, and MB75. This

[a]Different letters indicate significant differences in each row. [b]Unit is μmol/mL.

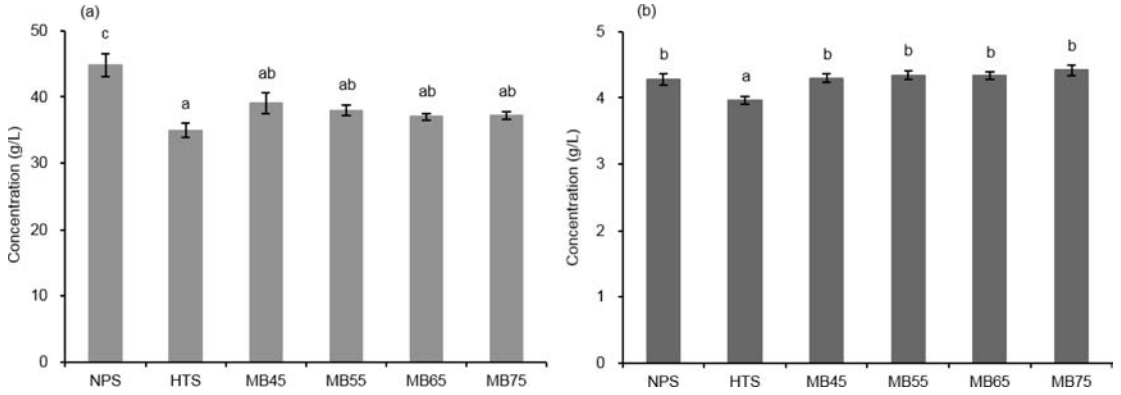

**Figure 3.** Glucose and isomaltose contents in unpasteurized, two-stage MB-$CO_2$-treated and heat-treated sakes. Measured sakes were the same as those used for the sensory evaluation. Data are presented as means with standard errors of the results from triplicate experiments. Different letters indicate significant differences by the Tukey–Kramer method ($p < 0.01$).

may be a cause of the bitterness of UPS, HTS, and MB75 indicated on sensory evaluation.

**Organic Acids.** Organic acids in UPS, HTS, MB45, MB55, MB65, and MB75 are shown in Figure 3. Organic acids in sake are metabolites that are produced by yeast during fermentation.[29] Lactic, succinic, malic, and citric acids contribute largely to the taste of sake.[30] In addition, Iwano et al. reported that succinic, citric, and malic acids had a strong correlation with the sensory evaluation of sake,[31] while pyroglutamic acid showed a weak correlation, and lactic, pyrvic, and acetic acids were not related. The amount of lactic acid, which is a bitter component in sake, was higher in HTS and all two-stage MB-$CO_2$-treated sakes than in UPS, and its levels were the greatest in MB65. Succinic acid, which is a taste component of sake, was significantly increased in MB65. Malic acid, which is a fresh sour component in sake, increased with increasing temperature of the heating coil in two-stage MB-$CO_2$ and was comparable in MB75, UPS, and HTS. Citric acid, which is a sour component in sake, in MB45 and MB55 was significantly lower than that in UPS, HTS, MB65, and MB75. Also, the acetic acid content in UPS, HTS, and MB75 was significantly lower than that in MB45, MB55, and MB65. However, the reason was still in the dark. So, further research is needed to determine the cause of the phenomenon. Acetic acid has been commonly controlled to low concentration, because sake containing acetic acid at high concentration has an acid smell.[32] The fumaric acid content,

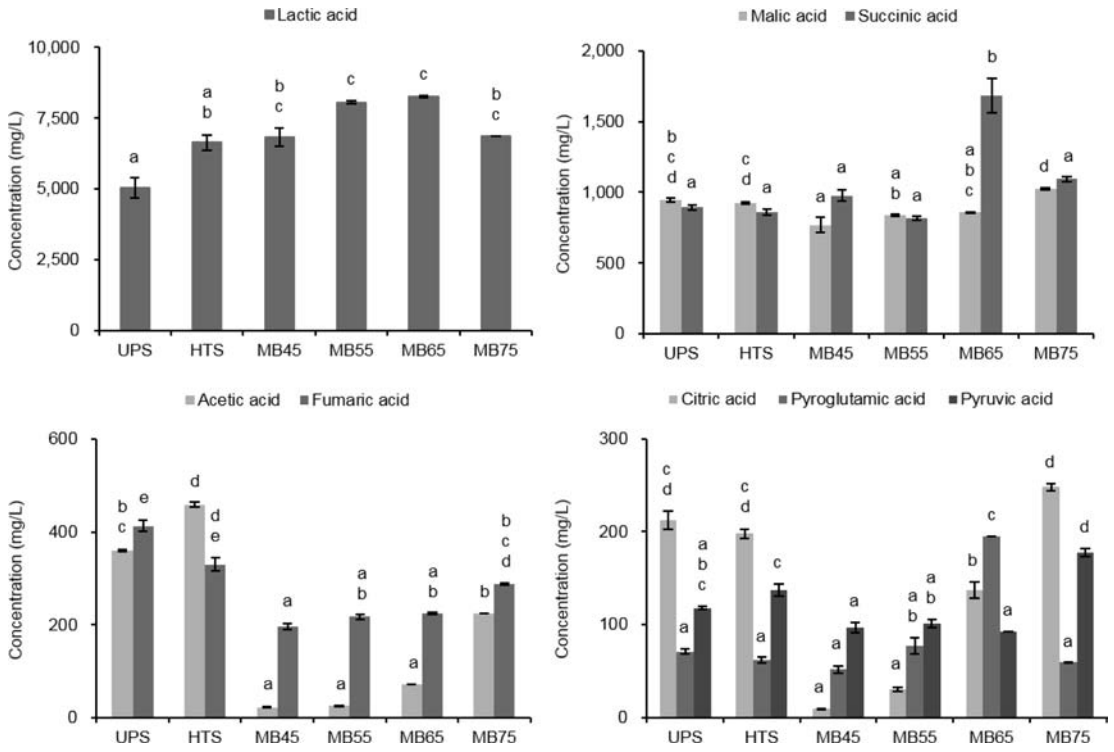

**Figure 4.** Organic acid contents in unpasteurized, two-stage MB-$CO_2$-treated, and heat-treated sakes. Measured sakes were the same as those used for the sensory evaluation. Data are presented as means with standard errors of the results from triplicate experiments. Different letters indicate significant differences by the Tukey–Kramer method ($p < 0.01$).

which is the light sour component in sake,[33] showed a similar pattern as that observed for the malic acid content. Pyroglutamic acid, which is weakly correlated with the sensory evaluation of sake[31] and contributes to umami of food,[34,35] was the highest in the MB65. Therefore, the result was suggested to influence the highest sensory evaluation index of MB65. Also, pyruvic acid, made during early stages of the TCA cycle along with acetic acid,[29,32] was significantly increased in HTS and MB75. It may be related to low sensory evaluation index of HTS and MB75, because pyruvic acid content in sake with high sensory evaluation index is apt to be low.[36] MB65, which was judged to be best by sensory evaluation, had the highest amount of succinic and lactic acids, and contained more malic and citric acids than MB45 and MB55. This suggested that balance of organic acids had a strong influence on the taste of sake. It was reported that malic and succinic acids in sake are decreased, and lactic and acetic acids are increased by heat treatment.[37] In this study, lactic, acetic, and pyruvic acids in HTS were higher than those in UPS and fumaric acid was lower.

**Glucose and Isomaltose.** Glucose and isomaltose in UPS, HTS, MB45, MB55, MB65, and MB75 are shown in Figure 4. The glucose content in HTS and all two-stage MB-$CO_2$-treated sakes was less than that in UPS. Particularly, the content in HTS was the lowest in all sakes. Also, isomaltose content did not differ significantly among UPS and all two-stage MB-$CO_2$-treated sakes, although it was significantly decreased in HTS. High glucose and isomaltose contents in UPS and low glucose and isomaltose contents in HTS contribute to the strong and weak sweetness indicated for UPS and HTS, respectively. The decrease in glucose and isomaltose contents in HTS was probably due to the Maillard reaction, which accelerated with heating time or temperature. However, it was considered that the glucose and isomaltose contents had an insignificant effect on the differences of the sensory evaluation among all the two-stage MB-$CO_2$-treated sakes, since there were no significant differences among these contents in all the two-stage MB-$CO_2$-treated sakes and no correlation between these contents and the sensory evaluation index was shown on the two-stage MB-$CO_2$-treated sake.

**Volatile Compounds.** Volatile compounds in UPS, HTS, MB45, MB55, MB65, and MB75 are shown in Table 2. Total amount of volatile compounds was highest in UPS, followed in decreasing order by MB65, MB55, MB75, MB45, and HTS. Ethyl acetate, 1-propanol, isoamyl acetate, isoamyl alcohol + 2-methyl-1-butanol, and ethyl hexanoate, which are the main compounds of orthonasal aroma in sake,[38] were significantly decreased in MB45, MB75, and HTS, while their levels in MB55 and MB65 were similar to those in UTS. These results are consistent with a previous study that showed that these compounds could be maintained over 80% by using a cooling coil.[17] The decrease of volatile compounds in MB75 and MB45 was considered to be due to high temperature and long exposure time, respectively. It was reported that the extraction efficiency of volatile compounds by supercritical $CO_2$ varies according to the type of compounds, and extraction temperature, pressure and time, respectively.[39−41] Also, changes of amino acids, organic acids, and sugar contents in the two-stage MB-$CO_2$-treated sake may influence flavor release, because volatile compounds were analyzed by concentrating headspace of sake in the study. It was noted that flavor release was changed by adding sucrose and starch into the solution.[42,43] Also, isovaleraldehyde, one of the off-flavors in sake,[44] was significantly decreased by both two-stage MB-$CO_2$ and heat treatments. These results were consistent with the reports by Chen et al., Gasperi et al., and Da Porto et al. that aldehydes in

hami melon and apple juices are significantly decreased by pasteurization by SC-$CO_2$. These factors may be related to the excellent results of MB65 in sensory evaluation.[9−11]

In this study, MB65 was revealed to be extremely good based on sensory evaluations. The reason is that level of free amino acids, which are negatively correlated with sensory evaluation, in MB65 was less than the levels in UPS, HTS, and MB75. Succinic and lactic acid levels were highest in MB65, and malic, citric, and acetic acids were higher than those in MB45 and MB55. However, further research is needed because it is not clear why free amino acid and organic acid contents in sake are changed by two-stage MB-$CO_2$.

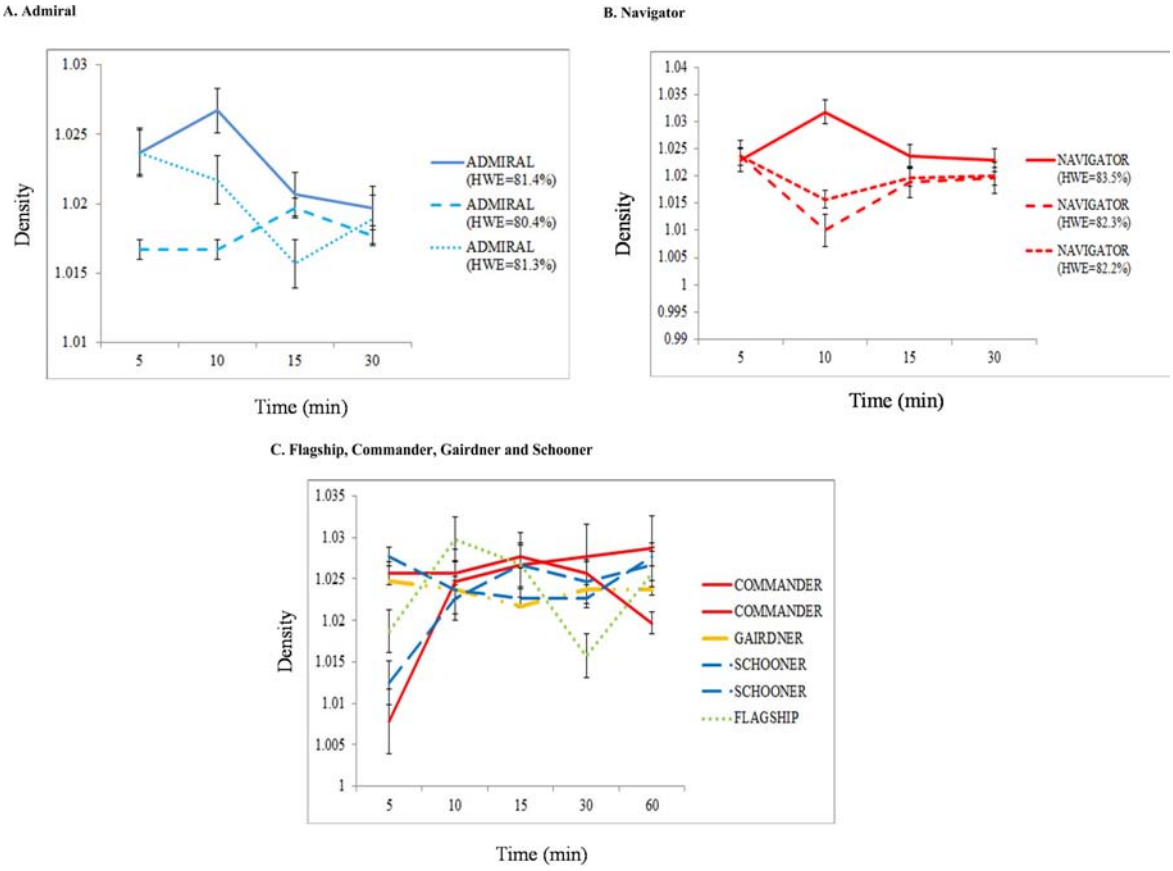

**Figure 1.** Patterns of hydrolysis in different malt varieties having different hot water extract values.

order to ensure the quality and consistency of raw materials and products, as well as allow screening of large quantities of samples.[14−18] Therefore, the combination of multivariate data analysis and IR spectroscopy will be of interest in order to develop high-throughput methods to monitor different steps during malt production or rapid screening of varieties during selection or trade.

The objectives of this study were (a) to compare the time course of hydrolysis of different malting barley varieties and (b) to evaluate the usefulness of mid-infrared (MIR) spectroscopy as high-throughput method to monitor malt hydrolysis.

## MATERIALS AND METHODS

Barley grain (*Hordeum vulgare* L) and corresponding malt samples were sourced from commercial varieties from the Barley Breeding Program (The University of Adelaide, Australia). The commercial barley malt varieties analyzed were Admiral ($n$ = 6), Commander ($n$ = 2), Flagship ($n$ = 2), Gairdner ($n$ = 2), Navigator ($n$ = 6) and Schooner ($n$ = 2), harvested in 2012 at one locality in South Australia (Charlick). Grain samples were malted using a Phoenix automatic micromalting system as reported previously.[19] Hot water extract (HWE) was analyzed using small scale versions of the Analytica-EBC Official methods (European Brewery Convention Analytica-EBC 1998, HWE method 4.5.1).[11,20]

Malt samples (1 ± 0.05 g) were placed in polypropylene tubes (in duplicate), and 10 mL of hot water (65 ± 5 °C) was added to each tube. The tubes were stirred allowing the water to have total contact with the sample and then placed in a water bath (65 ± 5 °C) with continuous agitation. Tubes were taken sequentially at 5, 10, 15, 30, 40, and 60 min and placed immediately in a container with ice to stop any further biochemical reaction. Samples were centrifuged at 2500$g$ for 20 min (Beckman, TJ6, USA). Total soluble solids (°Brix) were measured in the liquid (wort) using a digital portable refractometer (Hanna, HI 96801, Hanna Instruments, Inc. Rhode Island, USA) and converted to density.

The supernatant (wort) samples were scanned using a platinum diamond attenuated total reflectance (ATR) single reflection sampling module cell, mounted in a Bruker Alpha instrument (Bruker Optics GmbH, Ettlingen, Germany). Duplicates of each sample were scanned twice, and the average ATR-mid-infrared (MIR) spectrum of each sample was used for further analysis. The ATR-MIR spectra were recorded on OPUS software version 7.0 provided by Bruker Optics. The spectrum for each sample was obtained by taking the average of 24 scans (resolution of 4 $cm^{-1}$, between 4000 and 375 $cm^{-1}$) with a scanner speed of 7.5 kHz (background of 24 scans). Air was used as reference background spectra. The ATR diamond surface was cleaned with ethanol (95% v/v) before each sample was scanned. The absorption region between 2500 and 2000 $cm^{-1}$ due to carbon dioxide and the ATR diamond cell was discarded prior the calculation.[21,22]

The Unscrambler X software (v. 10.1, CAMO ASA, Norway) was used for preprocessing and chemometric analysis. Principal component analysis (PCA) was performed to determine any relevant and interpretable structure in the data, to detect outlier samples, and to visualize the changes in the MIR spectra related to the time course of the hydrolysis.[23,24] The ATR-MIR spectral data was preprocessed using Savitzky−Golay second derivative (40 smoothing points and second polynomial order) in order to remove and correct for baseline effects.[25] The second derivative is a measure of the change in the slope of the curve ignoring the offset and is very effective in removing both baseline offset and slope from a spectrum.[25]

Classification models were developed separately for each variety and time course of hydrolysis. Discrimination models were developed using partial least-squares discriminant analysis (PLS-DA) (The Unscrambler X, CAMO ASA, Norway).[23,24] Group membership of a new unknown sample was determined by its predicted value using PLS-DA.[23,24] PCA and PLS-DA models were developed by using full cross validation (leave one out) where the number of terms

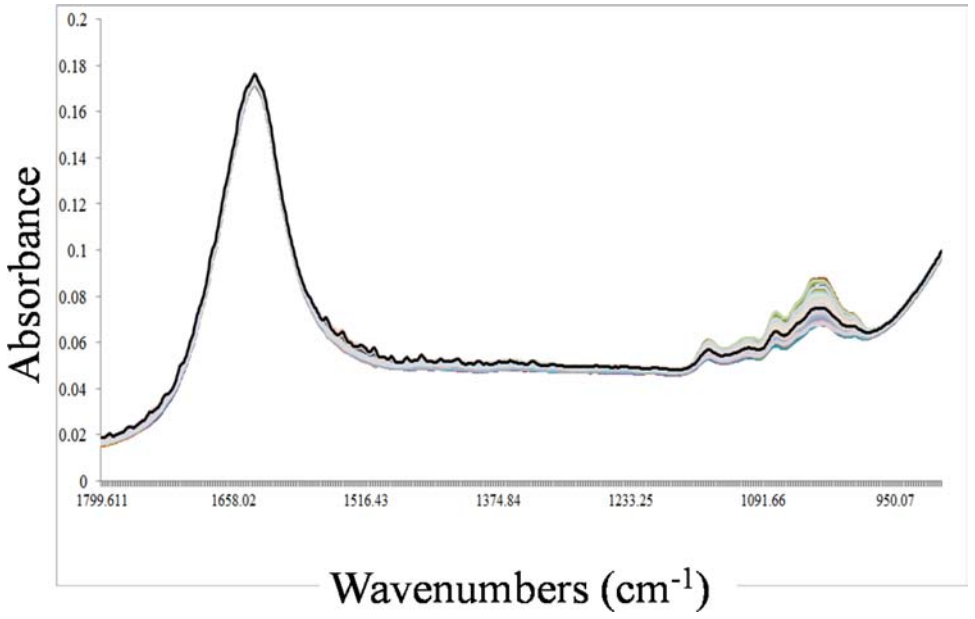

**Figure 2.** Attenuated total reflectance mid-infrared spectra of malt samples sourced from different time points during the malt hydrolysis.

(eigenvectors/loadings) were defined by the prediction residual error sum of squares (PRESS) function in order to avoid overfitting of the models (The Unscrambler, CAMO AS, v. 10.1, Oslo, Norway).

## RESULTS AND DISCUSSION

**Patterns of Hydrolysis: Reference Method.** Figure 1A–C shows the changes in density at different time points during the monitoring of the time course of starch hydrolysis in the different barley malt varieties analyzed. A nonlinear trend in the pattern of hydrolysis was observed between the different malt varieties. However, this pattern was not the same for all malt varieties analyzed. In malt varieties such as Admiral, Commander, and Flagship, an increase in density from 0 to 10 min was observed followed by a steady decrease in density after 15 min, after which time point density tends to increase until 60 min (end point). The opposite trend was observed for malting varieties such as Gairdner, Navigator, and Schooner. Moreover, malt samples from the same variety that have similar HWE (measured using the EBC method) tend to have the same pattern of hydrolysis (Figure 1A,B). At 10 min was observed either a peak or trough in the trend of hydrolysis.

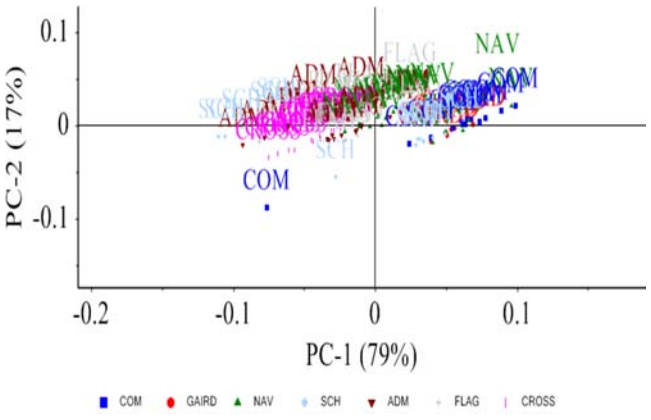

**Figure 3.** Principal component score plot (PC1 vs PC2) of all malt varieties analyzed using attenuated total reflectance mid-infrared spectroscopy.

These differences might be attributed to the different composition in sugars between the barley varieties analyzed. It is well-known that more than 90% of the solids present in wort are related to carbohydrates, where free sugars such as fructose, mannose, glucose, galactose, sucrose, and maltose are the most abundant. Nonstarch water-soluble sugars and cell wall components (e.g., hemicellulose) can also contribute to this.[3,26] Variations in the proportion of free and water-soluble sugars in different varieties of barley grain have been reported by other authors might also explain the observed patterns.[3,26]

It has been reported that HWE extracts from the malt are lower than those for the corresponding polysaccharides from the same grain, indicating that cleavage of some glycosidic bonds has occurred during malting.[3,26] However, all the reported studies on malt extract usually refer to the end point of HWE measured using the EBC method. The results of this study showed that the pattern or trend of starch hydrolysis might be more important than the end value. In particular, the amount of sucrose equivalent or the overall final density that is routinely used to calculate HWE might not explain the observed differences in HWE between barley varieties having high malt extract (HWE > 80%).

The results from this study also suggested that the pool of sugars in the wort tend to have high density such as fructose (1.69 g/cm$^3$) compared with glucose (1.54 g/cm$^3$). The observed differences in density might explain the increases in HWE between the malt varieties analyzed and are in agreement with early reports by other authors.[27−30] These authors reported that during kilning of the malt both glucose and sucrose increased, where the increase in sucrose is particularly well marked, indicating the important role that is played by kilning in altering the characteristics of the grain as well as the action of amylase that naturally becomes more important as malting progresses.[27−30] Some other sugars or oligosaccharides tend also to increase, among these fructosans being the most important.[30]

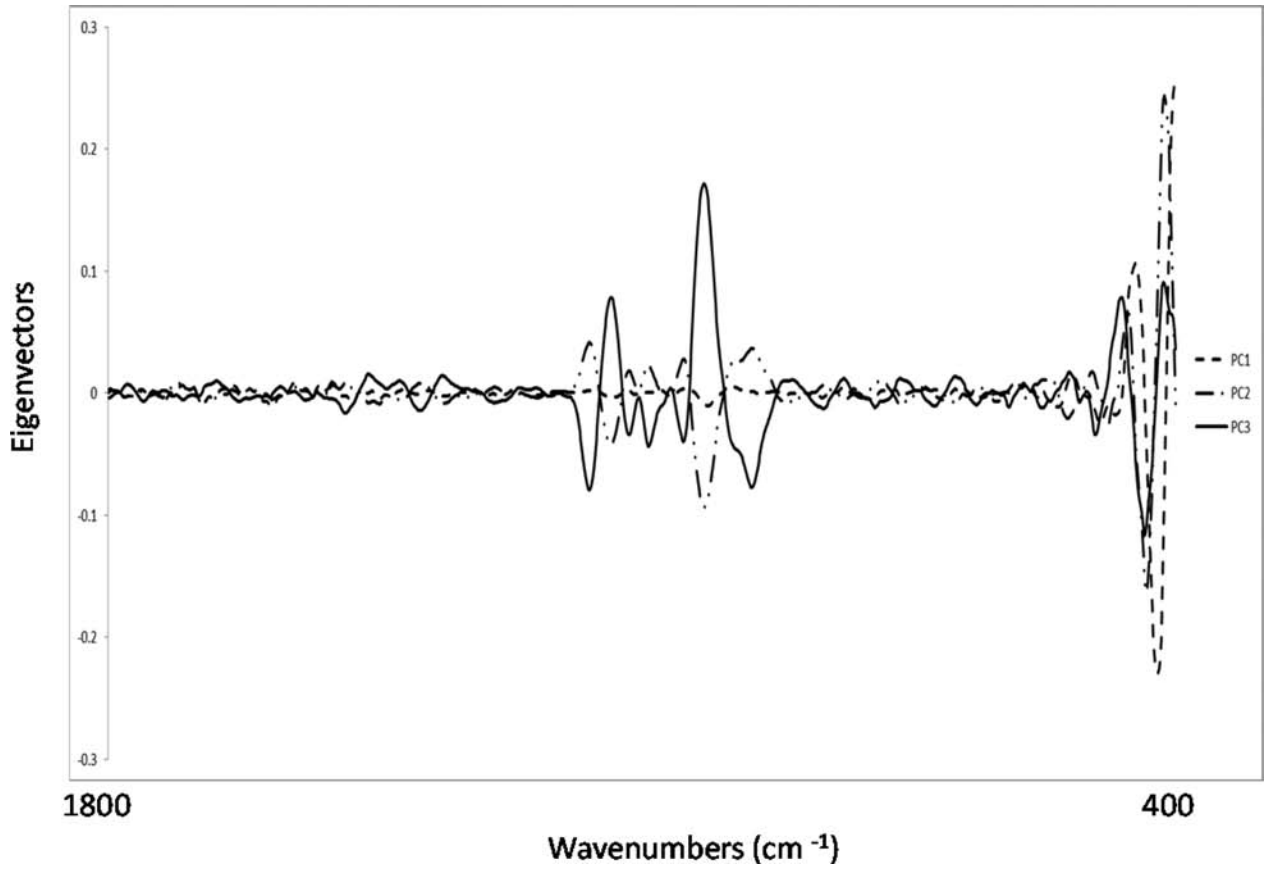

**Figure 4.** Eigenvectors derived from the first three principal component analyses of all malt varieties analyzed using attenuated total reflectance mid-infrared spectroscopy.

It is well-known that the major source of extract in malt wort is starch; however free sugars are also important, sucrose being one of the most abundant. Both mannose and galactose occur combined in malt, but neither is released during mashing. In wort samples, maltose, along with many other compounds, is produced during mashing by the partial hydrolysis of starch. There is some evidence that small amounts of fructans might also occur in malt.[3] These can be regarded as sucrose molecules to which one or more fructose residues have been attached. However, because the levels of fructose do not increase appreciably during mashing, it is likely that the fructans, which are very soluble, are not hydrolyzed, and so they remain with the nonfermentable carbohydrates.[3] Mashing constitutes the enzymatic hydrolysis of starch, resulting in the production of glucose, maltose, and glucose-based oligosaccharides.[31] However, there are other starch based carbohydrates in malted barley, which also contains sucrose.[31] In this context, the activity of the invertase enzyme facilitates the hydrolysis of sucrose to yield both glucose and fructose altering the density of the wort.[31] Therefore, the accumulation of fructose can be similar to the hydrolysis of sucrose, while the accumulation of glucose during mashing can be up to five times greater than the theoretical yield from utilized sucrose alone.[31] This large accumulation of glucose during mashing is most likely due to the combined activity of different enzymes such as invertases, glucoamylases, and $\alpha$-amylase.[31]

**Infrared Analysis: Spectra Interpretation.** In order to further interpret the patterns related to the time course of hydrolysis and the fate of sugars, the ATR-MIR spectra of the wort were recorded and evaluated. Figure 2 shows the ATR-MIR spectra in the fingerprint region of the wort samples analyzed. The spectra were dominated by intense peaks around 1030, 1070, 1160, and 1630 $cm^{-1}$ due to water, sugars, and nitrogen compounds. These peaks might be related to the CH−OH and alkyl frequencies for sugars mainly associated with glucose and fructose, between 1000 and 1200 $cm^{-1}$.[32−38] Most of the variation in the ATR-MIR spectra was observed between 1000 and 1200 $cm^{-1}$ (related to stretching modes of C−C and C−O groups), and it has been mainly related to differences in the release of sugars (measured as density) as a function of the time course of the hydrolysis as reported by other authors.[32−38]

Figure 3 shows the principal component score plot of the time course of hydrolysis using all the malting varieties analyzed using ATR-MIR. The first three principal components explain more than 90% of the variation in the ATR-MIR spectra (PC1 = 79%, PC2 = 17%, and PC3 = 2%). Differences in the patterns of the scores between the malt varieties and within the samples from the same variety as a consequence of the time course of hydrolysis were observed. Figure 4 shows the eigenvectors derived from the score plot of the first three principal components obtained from the analysis of wort samples using ATR-MIR spectra. The analysis of the first three eigenvectors indicated that the MIR regions related to sugars explain most of the observed differences between the malt samples. The highset eigenvectors were observed at 1130 and 1025 $cm^{-1}$ characteristic of sucrose and at 1032 $cm^{-1}$ characteristic of glucose.[32] Characteristic absorption bands of fructose are observed in the range between 1000 and 1100 $cm^{-1}$, while the region between 1056 and 1116 $cm^{-1}$ corresponds to the interference between

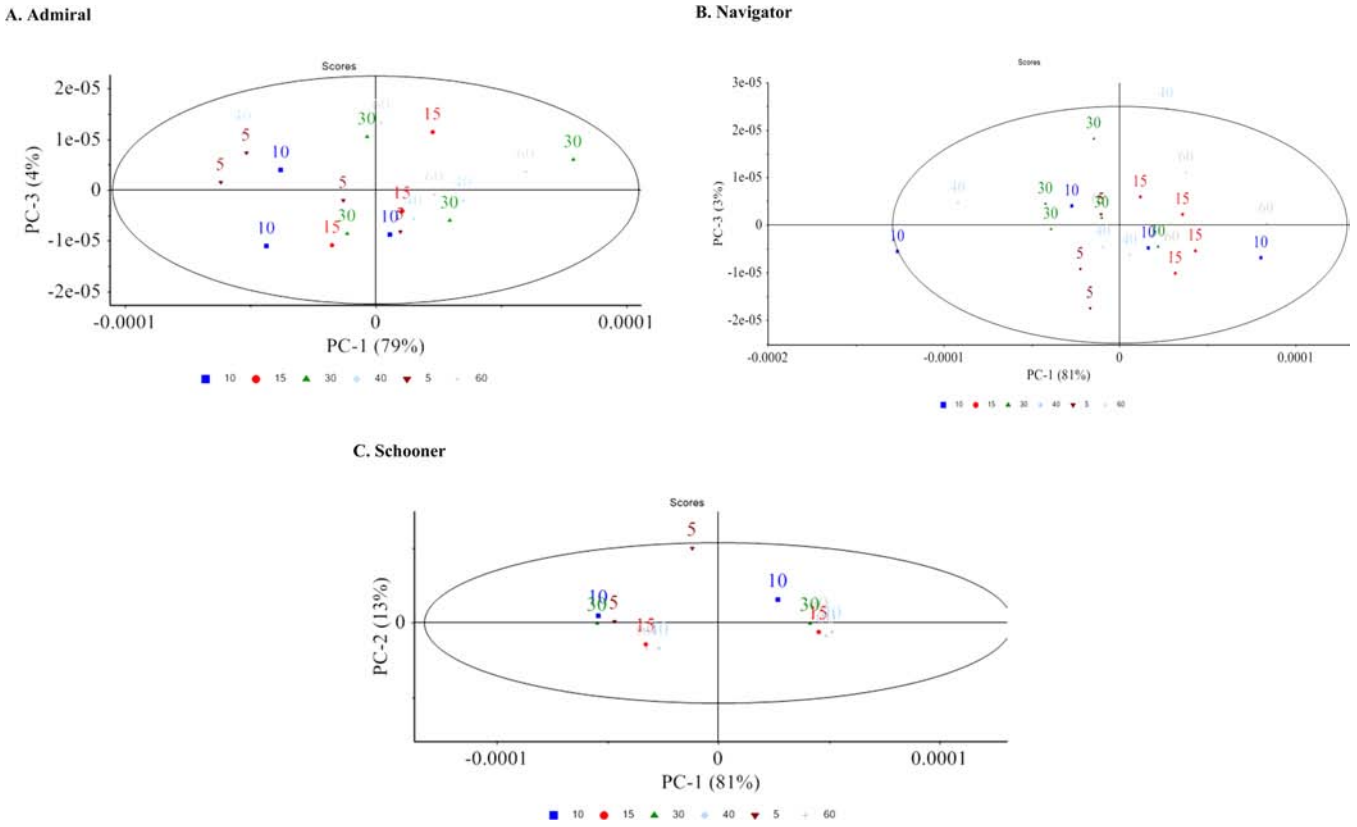

**Figure 5.** Principal component score plot (PC1 vs PC2) of Admiral, Navigator and Schooner malt samples analyzed using attenuated total reflectance mid-infrared spectroscopy labeled by the time course of hydrolysis.

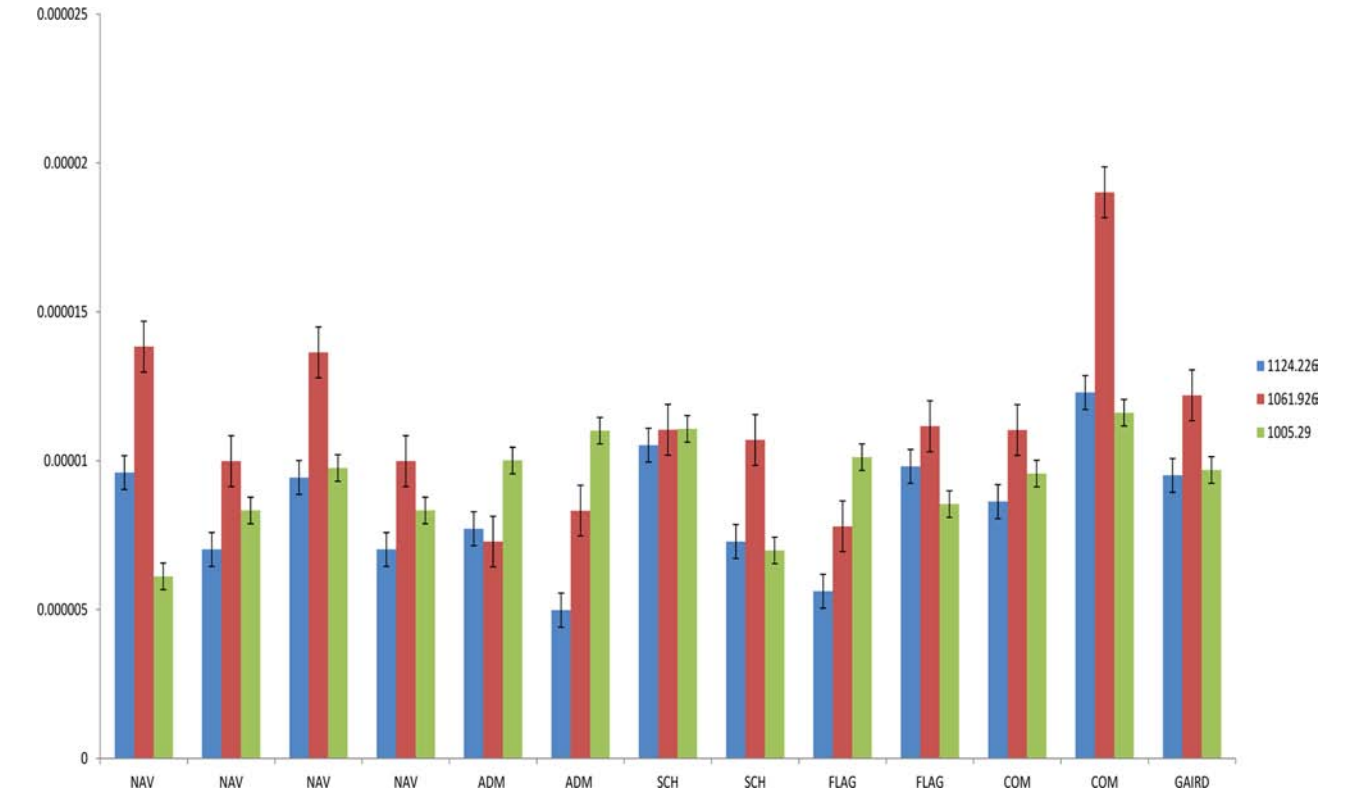

**Figure 6.** Absorbance values at specific frequencies from different barley malt varieties analyzed using attenuated total reflectance mid-infrared spectroscopy.

dx.doi.org/10.1021/jf504116j | J. Agric. Food Chem. 2014, 62, 11730−11736

glucose and fructose as reported by other authors.[32−38] Bands between 900 and 1100 $cm^{-1}$ are assigned to C−O and C−C stretching modes, while those between 1300 and 1100 $cm^{-1}$ are associated with the bending modes of O−C−H, C−C−H, and C−O−H. It has been reported by other authors that the spectra of aqueous solution of glucose show absorbance bands at 917 and 1034 $cm^{-1}$, those of fructose at 1062 and 1151 $cm^{-1}$, and those of sucrose at 926, 1005, 1048, and 1124 $cm^{-1}$,[32−38] while sucrose is characterized by a peak at 1005 $cm^{-1}$ owing to the presence of glycosidic links.[39,40] A major peak at 1034 and 1062 $cm^{-1}$ was observed for glucose and fructose, respectively, while three distinct peaks were obtained for sucrose with the major peak being centered at 1048 $cm^{-1}$. This shift in the frequencies of the major peaks can be explained by the difference in the chemical environment surrounding the atoms concerned with this vibrational band.[41]

**Principal Component Analysis of the Time Course of Hydrolysis in Different Varieties.** In an attempt to gain greater insight into the changes within the different malt varieties analyzed, PCA analysis was carried out for the single varieties separately (Figure 5). Changes in the direction of the scores derived from the MIR spectra were linear from 5 to 15 min, while a change in this trend was observed from 30 to 60 min. Similar changes were observed in the raw and transformed spectra (data not shown). Three main peaks were selected and compared between the varieties, and the relative frequencies for each variety are shown in Figure 6, around 1060 $cm^{-1}$ related to fructose and around 1160 $cm^{-1}$ with the combination of glucose and fructose as reported by other authors.[32−38] It has been observed that malt varieties that tend to yield high HWE present high frequencies in the wavenumber regions associated with high density sugars such as fructose (e.g., Navigator) while malt varieties that tend yield intermediate to high HWE have high frequencies in the region associated with glucose (e.g., Admiral, Flagship).

**Discriminant Analysis.** PLS-DA was used to classify malt samples according to their corresponding variety and time course of hydrolysis. The coefficient of determination ($R^2$) and the standard error of cross validation (SECV) obtained for the prediction of variety and time course of hydrolysis were 0.67 (SECV = 1.01) and 0.38 (SECV = 19.90), respectively. These results suggested that the time course and patterns of hydrolysis are affected by the variety and might be explained by the different composition in sugars as well as other chemical components of the grain.

In this study, the combination of spectroscopy and chemometrics as an analytical tool gave the advantage of rapid monitoring of the changes occurring during malt hydrolysis without the need for quantitative data. These results also suggested that the observed patterns in malt hydrolysis (reference data and PCA scores from the MIR spectra) and the information derived from the eigenvectors indicated that the observed differences in the patterns are mainly associated with variety and not with the time course of the hydrolysis. Although other biochemical components influence the final level of extract including husk thickness, grain size, protein, starch, nonstarch polysaccharides, and enzyme production, as well as the malting process and mashing conditions (pH, temperature, mash time, grist/particle size) only the patterns related to sugars were evaluated in this study.[7]

Compared with traditional laboratory methods, IR provides with new and better insight into complex problems by measuring a great number of chemical compounds at once. These methods are attractive due to their inherent features of versatility, flexibility, effectiveness, and richness of information. Further studies will be carried out in order to validate the proposed methodology with the addition of more samples derived from different harvests, localities and varieties.

technique to pear, it is hypothesized that this method could be applied as pear is a $C_3$ plant and its $^{13}C/^{12}C$ ratio is very similar to that of apple.[14] This technique is limited by its detection limit of approximately 10−15% for $C_4$-based sweeteners (e.g., HFCS) and its inability to detect the addition of beet sugar- or inulin-derived syrups as these are produced from $C_3$ (Jerusalem artichoke and chicory) and Crassulacean acid metabolism (CAM) pathway plants (agave), respectively.[10,15−17] In addition, this technique requires the use of specialized and expensive equipment that limits its routine application.

Another method for the detection of fruit juice adulteration is by oligosaccharide profiling. This technique works by identifying oligosaccharides that are present in the adulterants but are not naturally occurring in the product in question.[18] One of the benefits of this method is that it is a targeted approach; that is, it can be used to not only determine whether a product has been adulterated but also identify which adulterant was used. The two most common techniques used for oligosaccharide profiling are high-performance anion exchange chromatography with pulsed amperometric detection (HPAE-PAD) and capillary gas chromatography with flame ionization detection (CGC-FID). Both HPAE-PAD and CGC-FID methods have been developed and successfully used to detect the debasing of foods rich in carbohydrates such as agave syrup, honey, and maple syrup, as well as in select fruit juices such as apple and grapefruit.[19−23]

To date, no literature reports on the application or development of analytical techniques to detect the debasing of pear juice with less expensive nutritive sweeteners exist. Therefore, the primary goal of this research was to develop an analytical method employing oligosaccharide profiling that would be able to detect the debasing of pear juice at low concentrations (5−10%) with a series of commercially available carbohydrate syrups including HFCS, hydrolyzed inulin syrup (HIS), and total invert sugar (TIS) in a single chromatographic analysis. In addition, a secondary research goal was to expand the developed analytical method to detect select juice-to-juice adulteration (i.e., pear to apple) and to detect juices produced using a total fruit liquefaction process.

## MATERIALS AND METHODS

**Samples.** Thirty-two pure commercial pear juice concentrates (~70 °Brix) representing three production years (2012−2014) and five world production regions (Argentina, Chile, China, New Zealand, United States) were analyzed in this study. Commercial nutritive sweeteners used in this study as debasing agents (i.e., adulterants) included HFCS (HFCS 55 and HFCS 90; CASCO, Canada), HIS (Raffinerie Tirlemontoise S.A., Belgium), and TIS (Lantic Sugar Ltd., Canada).

**Chemicals.** Arbutin, D-fructose, D-glucose, $\beta$-glucosidase (from almond), isomaltose, maltoheptaose, maltohexaose, maltopentaose, maltose, maltotetraose, maltotriose, sodium hydroxide (NaOH) solution (50% w/w), D-sorbitol, D-sucrose, and Sylon TP (TMSI + pyridine, 1:4) were purchased from Sigma-Aldrich Canada Ltd. (Oakville, ON, Canada). Sodium acetate (NaOAc) was obtained from Fisher Scientific (Ottawa, ON, Canada). The water used throughout this study was obtained from a Millipore Milli-Q water system (Millipore Corp., Milford, MA, USA).

**Major Carbohydrate and Polyol Analysis by High-Performance Liquid Chromatography with Refractive Index Detection (HPLC-RI).** Major carbohydrate and polyol analysis was carried out employing an Agilent 1100 series HPLC system with a refractive index detector controlled by ChemStation LC-3D software (Agilent Technologies Canada Inc., Mississauga, ON, Canada). Samples were initially diluted to 12.0 ± 0.1 °Brix (Auto Abbe refractometer; Leica Inc., Buffalo, NY, USA) before being further diluted 1:1 with water. Samples were syringe filtered (nylon, 0.2 $\mu$m pore size; 13 mm diameter; Chromatographic Specialties, Brockville, ON, Canada) prior to analysis. Carbohydrate separation was accomplished on a Capcell-Pak-$NH_2$ column (250 × 4 mm, 5 $\mu$m; Phenomenex, Torrance, CA, USA) in series with a guard column (4 × 3 mm) of the same stationary phase. The mobile phase consisted of acetonitrile/water (75:25, v/v) run isocratically at a flow rate of 1.0 mL/min. The injection volume was 5.0 $\mu$L, and the column and RI detector were maintained at 25 and 35 °C, respectively. Standard curves for fructose, glucose, sorbitol, and sucrose were prepared in water at concentrations ranging from 0.06 to 5.00 g/100.00 mL. Standard curves had $R^2$ values of ≥0.999. All samples and standards were analyzed in triplicate.

**Arbutin Analysis by High-Performance Liquid Chromatography with Photodiode Array Detection (HPLC-PDA).** Samples were initially diluted with water to 12.0 ± 0.1 °Brix before being further diluted 1:1. Arbutin (4-hydroxyphenyl-$\beta$-D-glucopyranoside) content in the pear juice samples was determined employing HPLC with photodiode array (PDA) detection (Agilent Technologies Canada Inc.). Samples were syringe filtered prior to analysis. Arbutin separation from other sample phenolics was carried out employing an ODS-3 (250 × 4.6 mm; 5 $\mu$m $C_{18}$, 100 Å) column (Phenomenex) in series with a guard column (4 × 3 mm) of the same stationary phase. A gradient program employing aqueous 10 mM formic acid (pH 3.5; mobile phase A) and 70% acetonitrile/30% solvent A (v/v; mobile phase B) was used for arbutin separation as follows: initial 100% A for 3.0 min, followed by a linear gradient to 4.0% B at 6.0 min, followed by a linear gradient to 7.0% B at 15.5 min, followed by column washing with 100% B for 10.0 min prior to re-equilibration with 100% A. The flow rate was 0.8 mL/min, and the injection volume was 20.0 $\mu$L. Arbutin detection was afforded by PDA at a wavelength of 280 nm. A standard curve for arbutin prepared in water at concentrations ranging from 5.0 to 110.0 $\mu$g/mL was employed for quantification. Standard curves had $R^2$ values of ≥0.999. All samples and standards were analyzed in triplicate.

**Pure and Intentionally Adulterated Pear Juice Oligosaccharide and Arbutin Analysis by Capillary Gas Chromatography with Flame Ionization Detection (CGC-FID).** Pure pear juice concentrates and debasing agents were individually prepared by dilution with water to 5.5 ± 0.1 °Brix. For pure pear juice samples a 150 $\mu$L aliquot of each sample was freeze-dried (Heto Lab Equipment, Allerod, Denmark) in a 12 × 32 mm glass vial (Chromatographic Specialties) for 1 h. To the resulting dried foam was added 500 $\mu$L of Sylon TP using a gastight glass syringe, and the vials were capped and heated in a block heater (Denville Scientific Inc., Metuchen, NJ, USA) at 70 °C for 1 h with shaking every 10−15 min. Selected pear juice samples were intentionally adulterated with equivalent soluble solid content solutions of HFCS 55 and HFCS 90, HIS, and TIS at levels of 15.0, 10.0, 5.0, and 2.0% (v/v) and prepared as outlined previously. Sample oligosaccharide analysis was carried out using an Agilent 6890 gas chromatograph equipped with an Agilent 6890 series injector autosampler (Agilent Technologies Canada Inc.). Samples were analyzed in the splitless mode using ultrapure hydrogen as the carrier gas at a constant flow rate of 1.5 mL/min. Ultrapure nitrogen was used as the makeup gas at a flow rate of 30.0 mL/min. The injection port temperature was maintained at 250 °C and the detector at 300 °C. Oligosaccharide separation was afforded using an Agilent J&W DB-5 (95% dimethyl−5% diphenyl polysiloxane; 30 m × 0.25 mm, 0.25 $\mu$m film thickness) open tubular fused-silica capillary column (Chromatographic Specialties). The injection volume was 3.0 $\mu$L. Data acquisition and processing were carried out using Agilent ChemStation rev. A.06.03 software (Agilent Technologies Canada Inc.). The following temperature profile was used for oligosaccharide and arbutin analysis: initial temperature of 210 °C for 10.0 min; raised at 0.55 °C/min from 210 to 235 °C; held at 235 °C for 5.0 min; raised at 30 °C/min from 235 to 295 °C; held at 295 °C for 12.0 min. The total run time was 74.45 min. The minimum qualitative detection limit for arbutin was determined as the concentration that would give a peak height equivalent to 3 times the signal-to-noise ratio (s/n).

**Pure and Intentionally Adulterated Pear Juice Oligosaccharide and Arbutin Analysis by High-Performance Anion Exchange Chromatography with Pulsed Amperometric Detection (HPAE-PAD).** Pure pear juice samples and debasing agents were individually prepared by dilution with water to 5.5 ± 0.1 °Brix followed by syringe filtration. Select pear juice samples were intentionally adulterated with equivalent soluble solid content HFCS 55 and HFCS 90, HIS, and TIS solutions at levels of 20.0, 10.0, and 5.0% (v/v). For pear juice intentionally adulterated with HIS, a further dilution (1:3) with water was required. Sample oligosaccharide analysis was carried out on a Dionex Bio LC 4000 gradient HPLC system (Dionex Corp., Sunnyvale, CA, USA) containing a 50.0 $\mu$L sample loop. Carbohydrate separation was performed using two Dionex CarboPac PA1 (Thermo Fisher Scientific) columns (4 × 250 mm) connected in series without a guard column. The flow rate was 0.7 mL/min, and the carbohydrates were detected using a gold electrode employing triple-pulsed amperometry at a sensitivity of 10 K. The electrode was maintained at the following potentials and durations: $E_1$ = 0.05 V, $t_1$ = 120 ms; $E_2$ = 0.80 V, $t_2$ = 120 ms; $E_3$ = −0.60 V, $t_3$ = 420 ms. The gradient mobile phase consisted of 160 mM NaOH (mobile phase A), 160 mM NaOH/1 M NaOAc (mobile phase B), and 1 M NaOH (mobile phase C) with the following linear gradient elution program: initial conditions of 96.0% A and 4.0% B for 15.0 min; gradient to 70.0% A and 30.0% B at 41.0 min; 100% B from 41.1 to 44.0 min; 100% C from 44.1 to 48.0 min. The system was re-equilibrated at the initial conditions for 12.0 min prior to the next injection. Data acquisition and analysis was carried using Chromatography Data Station software (Wei Ma Long Chromatographic Techniques Ltd., Nanning, China).

**Arbutin Identification by Capillary Gas Chromatography−Mass Spectrometry (CG-MS).** Gas chromatographic conditions were as described above for CGC-FID analysis, with the exception of the use of ultrapure helium as the carrier gas. Mass spectrometry was carried out on a VG Analytical 70SE mass analyzer (VG Instruments Canada Inc., St. Laurent, QC, Canada) operated in the electron impact (EI) mode at an ionization energy of 70.0 eV. The source temperature was set at 200.0 °C. Measurements were carried out in full scan mode with scanning from $m/z$ 50.0 to 650.0. A solvent delay of 10.0 min was used. Samples of arbutin and select pure pear juices were prepared as outlined previously for CGC-FID analysis.

**Arbutin Hydrolysis with $\beta$-Glucosidase.** Three pure pear juices representing low (<64.9 $\mu$g/mL; PJ 28), medium (65.0−79.9 $\mu$g/mL; PJ 15), and high (>80.0 $\mu$g/mL; PJ 27) concentrations of arbutin were selected for analysis. These juice concentrates were diluted to 5.5 ± 0.1 °Brix, and approximately 10 U/mL of $\beta$-glucosidase was added to each sample. The solutions were stirred at ambient temperature, and samples were taken after 16 and 24 h. The enzyme reaction was

quenched by placing the samples in boiling water for 5 min. Samples were syringe filtered and analyzed by CGC-FID and HPAE-PAD as outlined previously. Samples of the same juices without enzyme addition were also analyzed as controls.

**Preparation of a Multiply Adulterated Pear Juice Sample with Cellobiose.** A commercial pear juice concentrate (PJ 7) was diluted with water to 5.5 ± 0.1 °Brix; HFCS 55, HIS, and TIS (at the same °Brix) were added at levels of 10.0, 3.0, and 10.0% (v/v), respectively, and cellobiose was added to yield a final concentration of 50.0 ppm. The sample was then freeze-dried, derivatized, and analyzed by CGC-FID as described previously.

## RESULTS AND DISCUSSION

**Major Carbohydrate and Sorbitol Analysis.** The major carbohydrates and polyol in pear juice have been reported to be fructose, glucose, sucrose, and sorbitol, respectively.[7,8] Together, these compounds comprise >95% of the total soluble solids found in pear juice. The major carbohydrate/polyol composition plays an important role in the nutritional and sensory attributes of fruit juices such as pear. In addition, their concentrations and ratios have been used to determine the authenticity of a variety of fruit juices.[20]

The concentrations of fructose, glucose, sucrose, and sorbitol in the 32 commercial pear juice samples used in this study were determined by normal phase HPLC-RI. The mean, range, standard deviation, and fructose/glucose (F/G) ratio results for each of these major pear juice components are reported in Table 1. Comparisons of these values for each of the major carbohydrates were within the literature-reported ranges (adjusted to 12.0 °Brix) of 4.59−8.89% (w/v) for fructose, 0.76−3.90% (w/v) for glucose, and 0.18−3.70% (w/v) for sucrose.[7,8,20,21] The maximum concentration of 3.25% (w/v) observed for sorbitol in this study was greater than that reported in the literature for this compound of 2.96% (w/v).[7]

The observed high content and the wide natural concentration ranges for each of these carbohydrates and sorbitol make pear juice susceptible to adulteration through debasing with commercial sweeteners of lower economic value. Four commercial sweeteners, HFCS 55, HFCS 90, HIS, and TIS, were chosen as potential debasing agents for pear juice on the basis of both their lower economic value and their natural carbohydrate content. The major carbohydrate concentrations and F/G results for each of the commercial sweeteners used as debasing agents in this study are shown in Table 2. On the basis of these values, it is clear that the debasing of commercial pear juices analyzed in this study with any of the analyzed commercial sweeteners on their own or in combination at appreciable (15−30%) levels would not significantly change the major carbohydrate and sorbitol profiles present in the adulterated juices and would also maintain the industry standard final °Brix value (Table 3). As examples, (a) the addition of 30% HIS to a pear juice with average major carbohydrate and sorbitol concentrations (PJ 9) and (b) the additions of 10% TIS, 10% HFCS 90, or 15% TIS + 15% HFCS 90 to PJ 14 would all result in calculated final glucose, fructose, sucrose, and sorbitol concentrations that would fall within the natural ranges (Tables 1 and 3) for these compounds as determined in this study. These results show that the limiting factor in the amount of debasing agent that can be added without resulting in a value below the published minimum is the sorbitol concentration of the starting juice as none of the commonly used commercial sweeteners contain this compound. Therefore, unscrupulous producers may be able to disguise even higher amounts of debasing by the addition of exogenous sorbitol.

It has been suggested that the fructose-to-glucose ratio is a better indicator of pear juice authenticity as it is more constant than absolute concentrations.[8] As such, a fructose-to-glucose ratio of >2.7 with a lower limit of 2.4 has been proposed as the indicator for pear juice authenticity.[7] In this study, 28 of the 32 commercial pear juices showed fructose-to-glucose ratios >2.7; the remaining 4 samples, which had F/G ratios ranging from 2.1 to 2.4, originated from China. Of the four commercial sweeteners analyzed in this study, two (HFCS 90 and HIS) had fructose-to-glucose ratios greater than the lower limit for authentic pear juice of 2.4. As such, pear juice debasing with either of these commercial sweeteners would maintain the major carbohydrate and sorbitol levels within the natural range and would also result in F/G ratios >2.7. The same results would be observed if blends of debasing agents were used such as HIS/TIS, where a 7:1 ratio of these specific samples would result in a calculated F/G ratio of at least 2.7.

It should also be noted that three of the four samples from China (PJ 19, PJ 21, and PJ22) had sorbitol concentrations at the upper end of the natural sorbitol range as determined by this study (Table 1). This indicates that greater amounts of debasing can occur in these samples without their sorbitol concentration dropping below the lower natural sorbitol level. As well, all four of the Chinese pear juices had F/G ratios at or below the lower limit for authentic samples (2.4) due to high glucose concentrations and/or lower than average fructose concentrations (Table 1). This indicates that care must be taken to avoid false positives when the F/G ratio is applied for pear juice authenticity analysis, especially to samples originating from China or to samples of unknown origin.

On the basis of the potential issues previously discussed and the data presented in Table 3, it is clear that the untargeted approach to pear juice adulteration detection based on major carbohydrate and sorbitol concentrations, ranges, and select ratios (i.e., F/G) is not a reliable means for pear juice authenticity analysis and that there is a significant need for a more targeted approach to detect the debasing of this juice with common commercial sweeteners.

A more targeted approach to detecting the adulteration of foods rich in carbohydrates is oligosaccharide fingerprinting.[19−23] This method is based on the formation of oligosaccharides in commercial sweeteners by acid reversion and/or transglycosylation reactions that are unique to each of the identified debasing agents. On this premise, the natural oligosaccharide profiles of the 32 pure commercial pear juice concentrates and the 4 identified debasing agents used in this study were determined by CGC-FID and HPAE-PAD.

**Pear Juice Adulteration with High Fructose Corn Syrup.** High-fructose syrups are produced from a number of different starting materials throughout the world, including a variety of starches isolated from rice, wheat, tapioca, and potato.[24] However, the most common substrate used for the production of high-fructose syrups is corn starch.[24] The commercial production of HFCS from starch normally involves both acid and enzymatic hydrolyses. Starch is first treated with acid (typically hydrochloric acid) to produce a reduced-viscosity syrup with low amounts of reducing sugars (low dextrose equivalent, DE). This syrup is then treated with $\alpha$-amylase (EC 3.2.1.1), glucoamylase (EC 3.2.1.3), and glucose isomerase (xylose isomerase; EC 5.3.1.18).[18] $\alpha$-Amylase and glucoamylase are added first to break down the remaining starch into free glucose molecules forming a monosaccharide-rich syrup. Some of the glucose in this syrup is then isomerized to fructose using glucose isomerase.[24,25] Theoretically, the highest concentration of fructose possible from a typical glucose stream is 47% at equilibrium. However, most processing plants settle for yields around 42% (HFCS 42) due to the amount of enzyme and reaction time needed to produce higher fructose concentrations.[24] To achieve higher concentrations of fructose in the final product, the HFCS 42 syrup is fractionated using a cation exchange resin to separate fructose from glucose and other carbohydrates.[24] The fructose and glucose fractions are then blended in the appropriate proportions to obtain a product with the desired fructose concentration (e.g., HFCS 55 or HFCS 90).

During the production of high-fructose corn syrup a number of oligosaccharides are formed including maltose and isomaltose along with a variety of higher molecular weight glucose polymers.[18] The concentration of these oligosaccharides can be significant. For example, HFCS 42 and HFCS 55 have been reported to contain 5 and 3% oligosaccharides, respectively.[24] This is due to the incomplete hydrolysis of starch, as well as the lack of a debranching enzyme (i.e., isoamylase/pullulanse), which can hydrolyze the $\alpha$-(1→6) glycosidic bonds in starch.[18,25] It is also possible that oligosaccharide formation can occur via the transglycosylation activity of the carbohydrases employed in HFCS production. One method to detect the adulteration of pear juice with HFCS is to look for the presence of these oligosaccharides, which can act as a chemical fingerprint facilitating the identification of this sweetener. A CGC-FID method has been previously developed and successfully used for the detection of HFCS in apple juice at low levels via the detection of isomaltose.[26] However, when the published protocol/temperature program was applied to pear juice, it was found that this method either gave a false positive for HFCS due to the presence of naturally occurring compounds in pure pear juice, which eluted at retention times similar to that of isomaltose, or indicated that isomaltose was a natural constituent of pear juice. To test these hypotheses, a new CGC-FID carbohydrate temperature program was developed that separated the interfering compound(s) that coeluted with $\beta$-isomaltose. This clearly showed that isomaltose was not a natural constituent of pear juice and established that the debasing of pear juice with HFCS could be detected by oligosaccharide fingerprinting employing the developed temperature gradient program. These results are illustrated in Figure 1, where chromatogram A shows the CGC-FID carbohydrate profile of pure pear juice (PJ 7) and chromatogram B shows the same juice intentionally adulterated with 5.0% (v:v) HFCS 55. The ∗ symbol in Figure 1 corresponds to an unknown compound(s) that coelutes with $\alpha$-isomaltose, and the arrow identifies $\beta$-isomaltose with retention times (RT) of 51.6 and 57.5 min, respectively. As supported by the lack of both $\alpha$- and $\beta$-isomaltose peaks, isomaltose was not found in any of the analyzed pure pear juice samples at a detection limit of 6.5 ppm; therefore, its presence in pear juice would be indicative of adulteration with HFCS or a glucose/maltose syrup. Maltose is also formed during the production of HFCS and is a potential fingerprint compound for adulteration detection. However, under the temperature program conditions employed in this study maltose eluted in a region of the chromatogram where pear juice is naturally rich in compounds that interfered with its detection. The detection limit for HFCS 90 in pear juice by CGC-FID was determined to be 2.0% (v/v) on the basis of $\beta$-isomaltose detector response and the 3 times the signal-to-noise ratio detection limit used throughout this study. The concentration of isomaltose in HFCS 55 is >1.5 times that found in HFCS 90,[23] resulting in a lower detection limit (1.0%) for this commercial sweetener. The third sweetener in this class, HFCS 42, was not analyzed in this study due to the fact that its fructose to glucose ratio of approximately 0.7 is considerably lower than that observed in this study for pure pear juices at ≥2.1 and the other commercial sweeteners used in this research. In addition, HFCS 42 has been shown to contain higher concentrations of oligosaccharides such as isomaltose than either HFCS 90 or HFCS 55[24,27] making its undeclared addition to pear juice even easier to detect by the developed CGC-FID method.

The detection of intentionally added HFCS to pear juice by HPAE-PAD posed a significant challenge due to the high monosaccharide content of these samples, which obscured not only the isomaltose peak (RT = 8.5 min) but also that of maltose (RT = 15.2 min). However, the excellent resolving

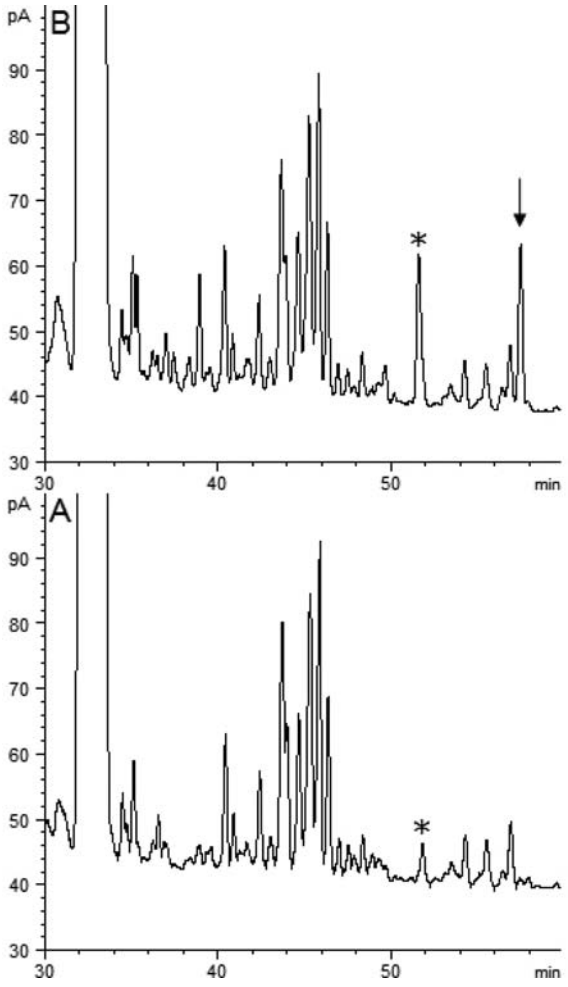

**Figure 1.** CGC-FID chromatograms from 30.0 to 60.0 min of (A) pure pear juice (PJ 7) and the same juice adulterated with (B) 5.0% (v/v) HFCS 55. The compound marked with ∗ corresponds to a naturally occurring oligosaccharide that coelutes with $\alpha$-isomaltose, and the arrow indicates $\beta$-isomaltose.

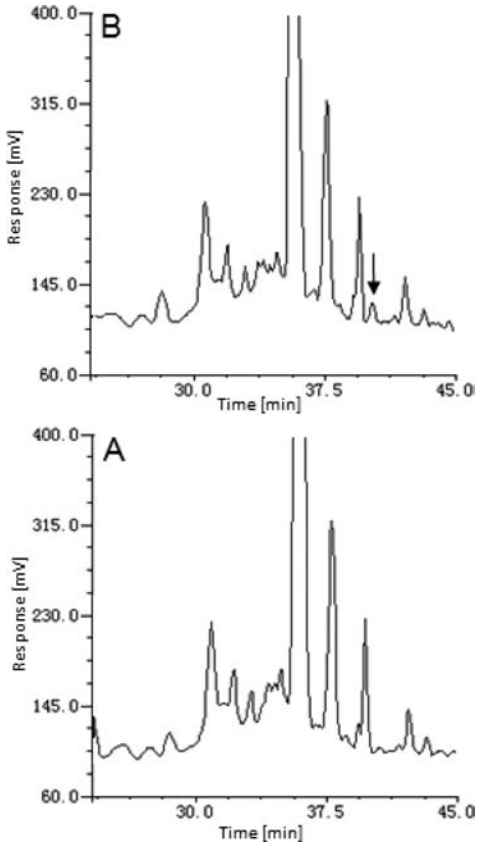

**Figure 2.** HPAE-PAD chromatograms from 22.0 to 45.0 min of (A) pure pear juice (PJ 23) at 5.5 °Brix and (B) the same pear juice intentionally adulterated with 10.0% (v/v) HFCS 55 at 5.5 °Brix. The fingerprint oligosaccharide tentatively identified as maltohexaose is indicated by an arrow.

power and low detection limits of high molecular weight glucose polymers by HPAE-PAD could readily detect the adulteration of pear juice with HFCS. These results are shown in Figure 2, where chromatogram A is of pure pear juice (PJ 23) and chromatogram B is the same pear juice intentionally adulterated with 10.0% (v/v) HFCS 55. We employed the peak eluting at approximately 40.2 min for adulteration detection on the basis of its relative intensity. This peak was tentatively identified as maltohexaose (DP 6) on the basis of retention time comparison to glucose polymer standards (DP 2−7; maltose to maltoheptaose) analyzed under the same conditions. Under the experimental conditions used in this study the detection limit for HFCS 55 by HPAE-PAD was determined to be 3.0% (v/v). Due to the fractionation and blending involved in the production of HFCS 90, the concentration of the DP6 marker is approximately 40−50% lower than in HFCS 55, resulting in a higher detection limit of 5.0% (v/v).

**Pear Juice Adulteration with Total Invert Sugar.** Invert sugar is produced from the treatment of beet or cane sucrose with either acid (typically hydrochloric acid) or invertase (EC 3.2.1.26), which hydrolyzes the glycosidic bond so as to yield equimolar amounts of glucose and fructose.[27] In industry, invert sugar is mainly produced using acid hydrolysis. Invert sugar can be produced to different degrees of inversion by controlling the time and temperature conditions used in its production.[28] Total invert sugar is produced when this reaction is allowed to proceed until only small amounts of sucrose remain (∼5−8%), resulting in a syrup containing a high concentrations of glucose and fructose in a 1:1 ratio.[25] During the production of invert sugar, oligosaccharides may be formed via a process known as reversion.[29] Three of these oligosaccharides have been previously identified as *O*-$\alpha$-D-glucopyranosyl-(1→3)-D-fructose, *O*-$\beta$-D-fructofuranosyl-(2→6)-D-glucose, and *O*-$\alpha$-D-glucopyranosyl-$\beta$-D-glucopyranoside.[28]

Total invert sugar was selected as a potential adulterant in pear juice due to its low level of sucrose as compared to medium invert sugar, which has a glucose to fructose to sucrose ratio of 1:1:2.[25] This means that the addition of medium invert sugar to pear juice should be detectable by a noticeable change in the glucose/fructose/sucrose ratios of the juice. The debasing of pear juice with TIS was readily detected employing the developed CGC-FID method and is illustrated in Figure 3, where chromatogram A shows the CGC-FID carbohydrate profile of pure pear juice (PJ 7) and chromatogram B shows the same juice intentionally adulterated with 10.0% (v/v) TIS. The fingerprint oligosaccharides for TIS detection have retention times of approximately 41.9 and 49.7 min, respectively. The peak eluting at 49.7 min was tentatively identified as IS2 (*O*-$\beta$-D-fructofuranosyl-(2→6)-D-glucose) on the basis of literature results,[3,28] whereas the peak at 41.9 min is currently unidentified. The detection limit for TIS addition to pear

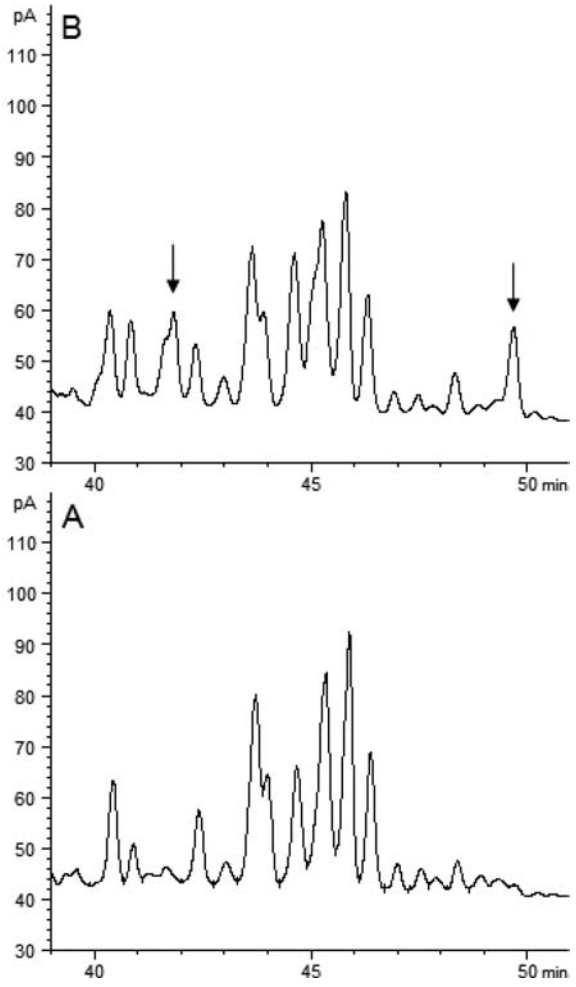

**Figure 3.** CGC-FID chromatograms from 39.0 to 51.0 min of (A) pure pear juice (PJ 7) and (B) the same pear juice intentionally adulterated with 10.0% (v/v) TIS. The fingerprint oligosaccharides tentatively identified as IS2 (*O*-$\beta$-D-fructofuranosyl-(2→6)-D-glucose) and an unknown compound are indicated by arrows.

juice by the developed CGC-FID method was found to be 3.0% (v/v).

Pear juice samples intentionally adulterated with TIS were also analyzed by the developed HPAE-PAD method. Unfortunately, the presence of naturally occurring oligosaccharides and the high concentration of monosaccharides in pure pear juice samples precluded the use of this technique to detect pear juice adulterated with TIS.

**Pear Juice Adulteration with Hydrolyzed Inulin Syrup.** Inulin is a naturally occurring polysaccharide found in plants and some bacterial and fungal species.[30] It is a mostly linear polysaccharide of varying chain length composed of fructose units glycosidically linked by $\beta$-(2→1)-D-fructosyl-fructose units terminated by D-glucose linked via an $\alpha$-(2→1) bond as in sucrose.[31,32] HIS is produced by the controlled enzymatic or acid (typically hydrochloric) hydrolysis of inulin. This results in the production of a syrup that is rich in fructose with minor amounts of glucose present.[33] It has been reported that the hydrolysis of inulin can result in the formation of a variety of different oligosaccharides, which consist either solely of fructose units (inulo-oligosaccharides) or of fructose units linked with a terminal glucose unit (fructo-oligosaccharides).[32]

CGC-FID oligosaccharide profiling of HIS shows the presence of two fingerprint oligosaccharides with retention times of approximately 21.5 and 34.9 min, respectively. When HIS is added to pear juice, the peak at 34.9 min was masked by the naturally occurring oligosaccharides; however, the peak at 21.5 min eluted in a region devoid of interfering compounds. These results are illustrated in Figure 4, where chromatogram A

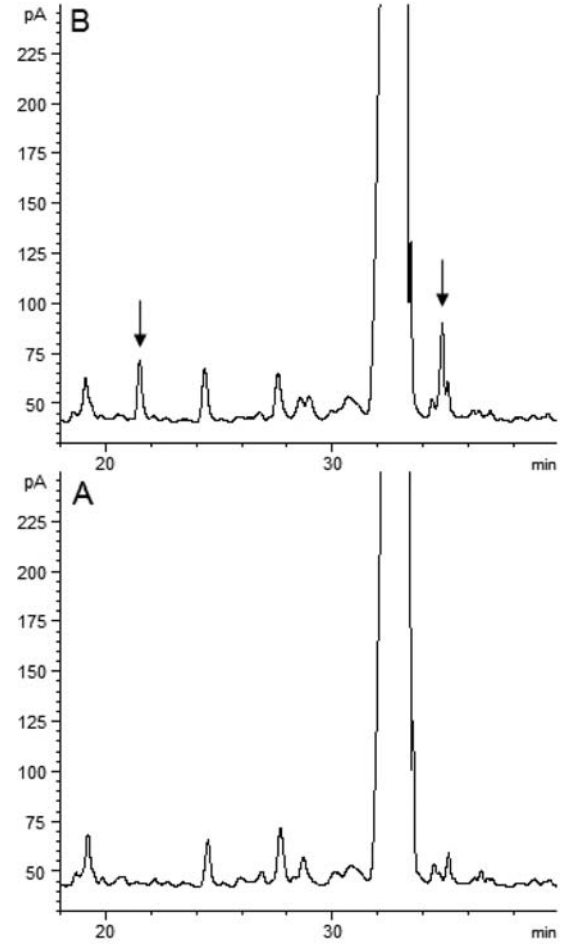

**Figure 4.** CGC-FID chromatograms from 18.0 to 40.0 min of (A) pure pear juice (PJ 7) and (B) the same pear juice intentionally adulterated with 2.0% (v/v) HIS. The fingerprint oligosaccharides tentatively identified as $\alpha$- and $\beta$-inulobiose are indicated by arrows.

shows the CGC-FID carbohydrate profile of pure pear juice (PJ 7) and chromatogram B shows the same juice intentionally adulterated with 2.0% (v/v) HIS. This fingerprint oligosaccharide for HIS is postulated to be a carbohydrate composed of two fructose moieties (i.e., disaccharide) based on inulin structure and hydrolysis and its elution time, which occurs in the typical range for disaccharides.[34] This oligosaccharide has been tentatively identified as inulobiose (*O*-$\beta$-D-fructofuranosyl-(2→1)-D-fructose), a disaccharide commonly reported to be formed during the hydrolysis of inulin, on the basis of both literature results and HPAE-PAD analysis of standards (unpublished results). Supporting evidence for this identification is based on the inulin source used in this study, which was chicory root, which has been reported to contain low amounts of branching (1−2%) when compared to other sources (e.g., bacterial; branching >15%).[33] The detection limit for HIS

addition to pear juice by the developed CGC-FID method was found to be 0.5% (v/v).

Pear juice samples intentionally adulterated with HIS were also analyzed by the developed HPAE-PAD method. A fingerprint oligosaccharide with a retention time of ∼17.5 min was readily identified when HIS was intentionally added to pure pear juice. The application of this method to a pure pear juice (PJ 23; chromatogram A) and the same pear juice intentionally adulterated with 5.0 and 10.0% (v/v) HIS (chromatograms B and C) is shown in Figure 5. The detection limit for HIS addition to pear juice by the developed HPAE-PAD method was found to be 2.0% (v/v).

**Detection of Juice-to-Juice Adulteration by Arbutin Analysis.** The developed chromatographic techniques were examined for their potential to detect types of adulteration besides debasing with less expensive commercial sweeteners. One common method of fruit juice adulteration is the addition of a juice of lesser value to one of higher value. This type of adulteration is referred to as juice-to-juice debasing. Due to the fact that apple and pear juices share similarities in properties such as major carbohydrate and polyol profiles, juice-to-juice adulteration between these two can be a significant problem as it is difficult to detect using traditional methods such as the matrix approach.[7] Arbutin (4-hydroxyphenyl-$\beta$-D-glucopyranoside) has been previously identified as a natural constituent of pear juice that is not found in apple juice.[7] It was found that arbutin could be detected by both of the developed chromatographic methods (i.e., CGC-FID and HPAE-PAD). The presence of arbutin was confirmed in all 32 pure pear juice concentrates by both CGC-FID and HPAE-PAD with retention times of 27.6 and 37.8 min, respectively.

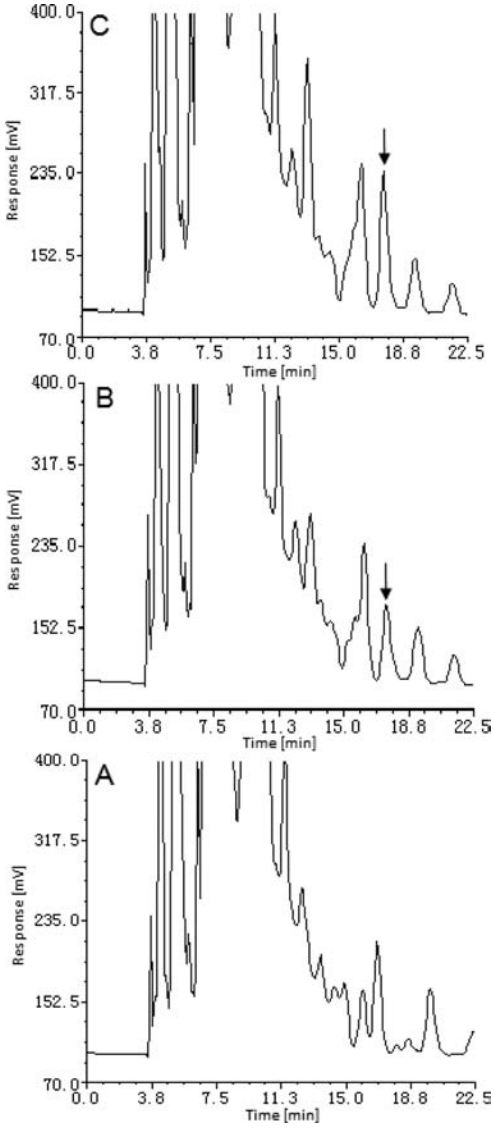

**Figure 5.** HPAE-PAD chromatograms from 0.0 to 22.5 min of (A) pure pear juice (PJ 23) and the same pear juice intentionally adulterated with (B) 5.0% and (C) 10.0% (v/v) HIS. The fingerprint oligosaccharide tentatively identified as inulobiose is indicated by an arrow.

GC-MS was carried out to confirm that the peak observed by CGC-FID corresponded to arbutin and not another compound with a similar retention time. The mass spectra of the silylated arbutin standard and the peak with the matching retention time in pear juice showed good agreement. The spectrum was also matched against those found in the National Institute of Standards and Technology (NIST) Mass Spectral Library as well as with literature data.[35,36] Figure 6 shows the mass spectra of silylated arbutin as found under these conditions. As can be seen, no fragments greater than a mass-to-charge ($m/z$) ratio of 450 were observed even though silylated arbutin has a molecular weight of 632 g/mol. This indicates that the molecular ion readily fragments under the conditions used in this study. Currently, there is only one literature report in which the identities of any of the observed fragments are suggested.[35] However, the authors do not give detailed structures of the proposed fragments and fail to identify a major fragment ($m/z$ 254). As well, the fragment at $m/z$ 217 is clearly misidentified as the proposed structure has an $m/z$ value of only 130. Therefore, more work in this area is needed. A number of the fragments were tentatively identified in this study and are shown in Figure 7.

Loss of the hydroquinone portion of arbutin as a neutral species results in the formation of the fragment at $m/z$ 450 with further fragmentation by loss of trimethylsilyl (TMS) groups and by ring cleavage. This type of behavior has been previously reported for TMS-derivatized glucose during analysis by CG-MS.[37] As well, a structure for the fragment observed at $m/z$ 254 has been suggested. The fragments at $m/z$ 147 (TMS-O-DMS) and $m/z$ 73 (TMS) have been previously identified and are characteristic of trimethylsilylated compounds.[35,37]

A second method was also applied to confirm the presence of arbutin in the pear juice samples. In this method $\beta$-glucosidase (EC 3.2.1.21) was added to select pear juice samples, which resulted in the hydrolysis of arbutin to free D-glucose and hydroquinone. As expected, this hydrolysis resulted in a disappearance of the arbutin peak as observed by both CGC-FID and HPAE-PAD. The use of $\beta$-glucosidase for arbutin identification is beneficial as it is simple to carry out and allows confirmation of the presence of arbutin by both CGC-FID and HPAE-PAD without the use of a mass spectrometer.

The concentration of arbutin in the pure samples was analyzed by HPLC-PDA to determine how effective this compound would be for adulteration detection. The average arbutin content of the 32 samples was found to be 86.7 ± 49.6 $\mu$g/mL with a range of 50.6−286.9 $\mu$g/mL (Table 1). The experimental average was found to be higher than the average arbutin content reported for a similar set of samples of 75.5 $\mu$g/mL (after adjustment to 12.0 °Brix).[7] This is likely due to the

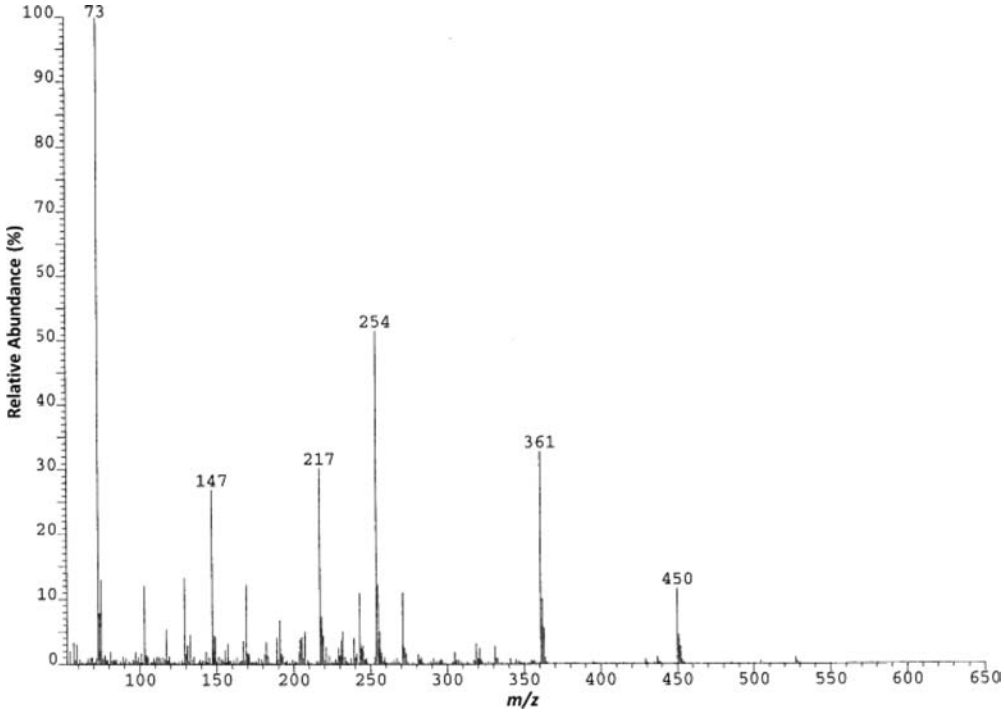

**Figure 6.** CG-MS spectra of silylated arbutin in pear juice.

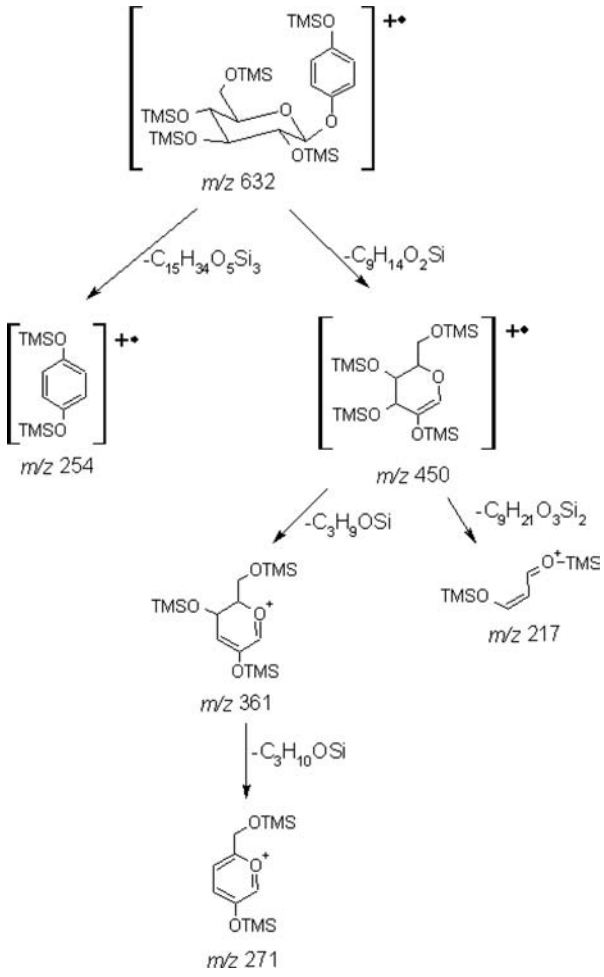

**Figure 7.** Proposed fragments of silylated arbutin under CG-MS condtions. TMS, $-Si(CH_3)_3$.

presence of six samples with arbutin contents >100.0 μg/mL in the present study. Of these six samples, four were obtained from China and two from New Zealand. The arbutin content in all of the remaining 26 pear juice samples was <85.0 μg/mL.

A literature range for pear arbutin content has been reported as 42.3−157.7 μg/mL, which is in agreement with the arbutin values obtained in this study with the exception of PJ 20 and PJ 22, which had concentrations of 223.7 and 286.9 μg/mL, respectively.[7] On the basis of the pear juice sample in this study with the lowest concentration of arbutin and a detection level of 3 times the signal-to-noise ratio, the addition of pear juice to apple juice can be detected at levels down to 3.0% (v/v). This detection limit would be even lower if a pear juice rich in arbutin was used to adulterate a sample. As well, it may be possible to lower this detection limit even further by the application of CG-MS for arbutin detection due to the increased sensitivity of this method.

Arbutin also shows the potential of acting as an indicator for pear juice authenticity. The absence of arbutin in a product claiming to contain pear would be a good indication that pear juice is not actually present in the product. As well, if a sample claiming to be a pure pear juice contains arbutin in concentrations considerably lower than those reported for authentic pear juice, it is likely that the sample is not pure and that further authenticity analysis needs to be undertaken.

**Detection of Total Liquefaction by Cellobiose Detection.** The production of pear and apple juice is aided by the use of enzymes, such as pectinases and amylases, which aid in cell wall breakdown, improving juice extraction and filtration.[38] Total liquefaction involves the addition of cellulases and excess pectinases to the fruit mash to achieve a more complete breakdown of the cell walls, resulting in an increase in the total soluble solids of the final juice.[39] This process is illegal in both North America and the European Union as there are no regulatory guidelines in place for cellulase use in fruit juice production and because little is known about the nutritional

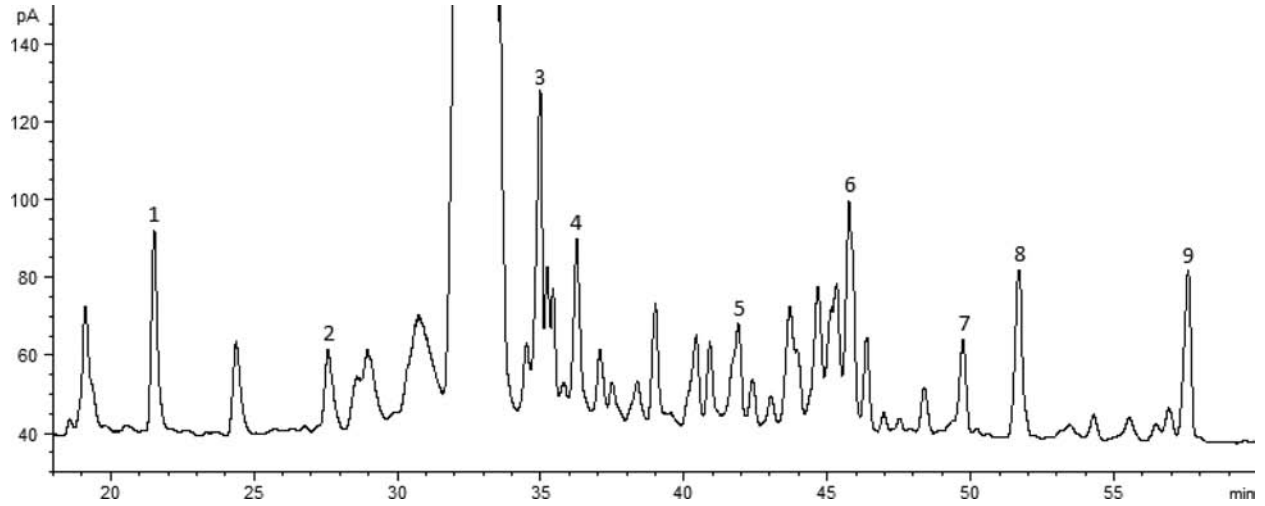

**Figure 8.** CGC-FID chromatogram of pear juice (PJ 7) to which HFCS 55, HIS, TIS, and cellobiose have been added. Identified peaks are as follows: 1, $\alpha$-inulobiose (HIS marker); 2, arbutin (pear marker); 3, $\beta$-inulobiose (HIS marker); 4, $\alpha$-cellobiose (liquefaction marker); 5, unidentified TIS marker; 6, $\beta$-cellobiose; 7, *O*-$\beta$-D-fructofuranosyl-(2→6)-D-glucose (TIS marker); 8, $\alpha$-isomaltose; 9, $\beta$-isomaltose (HFCS marker).

aspects of the liquefaction juice.[39,40] It should also be noted that total liquefaction leads to a lower quality juice with an increased propensity to browning and haze formation.[39] The undeclared substitution or blending of a premium juice with a juice of lower quality produced by liquefaction constitutes adulteration and would be considered illegal. Consequently, it is important to be able to distinguish between juices produced by these different methods.

Cellobiose, a disaccharide composed of two glucose units linked via a $\beta$-(1→4) glycosidic bond, is formed by the breakdown of cellulose found in the cell wall of fruits when cellulases are used for juice production. In one study, cellobiose was not found in apple juices produced using normal enzymatic treatments (premium juice), but was detected in three of four juices produced by total liquefaction at concentrations ranging from 16.6 to 55.4 ppm.[41] The presence of cellobiose, in combination with excess galacturonic acid, is considered to be indicative of pomace liquefaction by the fruit juice industry.[41] Currently, no official limits exist on the concentration of cellobiose in pear and apple juices.[41]

The developed CGC-FID method was shown to be able to effectively separate and detect cellobiose in pear juice. As it is a reducing carbohydrate, cellobiose has two chromatographic peaks at 36.2 and 45.8 min, corresponding to $\alpha$- and $\beta$-cellobiose, respectively. Whereas $\beta$-cellobiose overlaps with naturally occurring pear compounds, $\alpha$-cellobiose is free of such interferences. When analyzed by HPAE-PAD, the high monosaccharide content of pear juice obscured the cellobiose peak (RT = 10.4 min), precluding the use of this method for total liquefaction detection.

Cellobiose was not detected by CGC-FID in any of the 32 pure pear juice concentrates analyzed in this study at a detection limit of 8.0 ppm in the 12.0 °Brix juice by the developed analytical method, clearly indicating that these juices were not produced by total liquefaction.

In summary, these results show that the addition of less expensive nutritive sweeteners, namely, HFCS, HIS, and TIS, can be readily detected in pear juice by the application of the developed CGC-FID method at levels of 0.5−3.0% (v/v). In addition, HPAE-PAD profiling can also be used to confirm the presence of HFCS and HIS in pear juice. CGC-FID fingerprinting also affords the detection of pear to apple (and potentially apple to pear) juice debasing and process adulteration all within a single chromatographic analysis. Figure 8 shows the CGC-FID chromatogram of pear juice to which the studied pear juice adulterants (HFCS, HIS/ and TIS) and cellobiose have been added. The ability to detect each of these adulterants at low concentrations, arbutin (to confirm the presence or absence of pear), and cellobiose (indicator of liquefaction processing) in a single chromatographic run is beneficial as it is both a robust and accurate method and reduces sample preparation and analysis time. In addition, the use of the developed method not only allows an adulterated sample to be identified but also provides information on the adulterant used. It is envisaged that this method will result in a decrease in food fraud so as to maintain consumer confidence in the food industry.

transesterification and esterification reactions.[17] Moreover, Lewis acid has also been proven to be active for the esterification reaction.[18]

Thus far, numerous studies concerning the synthesis of phytosterol esters have been reported. However, the related research on the synthesis of ergosterol esters is still rare in the literature, except for a recent report concerning the synthesis of ergosteryl oleate,[10] in which the highest conversion (72.4%) was obtained using Lipozyme TL IM as the biocatalyst. The present study was aimed at the efficient synthesis of ergosterol ester by esterification using lauric acid as an acyl donor in the presence of a Lewis acid or an acid−surfactant-combined catalyst in a solvent-free system. The synthesized product was separated by silica gel column chromatography, and its chemical structure was characterized by Fourier transform infrared spectroscopy (FTIR), mass spectroscopy (MS), and nuclear magnetic resonance (NMR). The influence of different catalysts, catalyst dose, substrate molar ratio, reaction temperature, and reaction time was also considered. Furthermore, the solubility of ergosterol and its laurate in vegetable oil was studied and compared.

## MATERIALS AND METHODS

**Materials.** Ergosterol (purity of >95%) was provided by Sigma-Aldrich Co., Ltd. (Shanghai, China). Methanol and *n*-hexane used for high-performance liquid chromatography (HPLC) analysis were of spectral grade and provided from Tedia Company, Inc. (Shanghai, China). Petroleum ether (60−90 °C), ethyl acetate, formic acid, *n*-hexane, ethanol, hydrochloric acid (HCl), sodium dodecyl sulfate (SDS), stannous chloride ($SnCl_2$), cuprous chloride (CuCl), and other common reagents used were of analytical grade and purchased from Sinopharm Chemical Reagent Co., Ltd. (Shanghai, China). Silica gel (100−200 mesh) was obtained from Qingdao Haiyang Chemical Co., Ltd. (Qingdao, China).

**Preparation of the Catalyst.** In this study, SDS, SDS + HCl, $SnCl_2$, and CuCl were selected as the potential catalyst. Among these catalysts, SDS + HCl was prepared according to a previous report with minor modification.[11] Briefly, 0.3 g of SDS was weighed and put into a mortar in a fume hood, and 0.2 mL of HCl was added to the mortar. The mixture was ground for 10 min and stood for 20 min in a fume hood to remove the excess HCl by evaporation. The catalyst SDS + HCl was finally obtained. This catalyst was newly prepared every time prior to use. The other catalysts were directly used as catalyst for the esterification.

**Esterification Reaction.** The esterification reaction for ergosterol laurate synthesis was performed on a 20 mL special reaction tube. First, the reaction tube was placed and fixed in a digital oil bath heating device equipped with a magnetic stirring apparatus, and a magnetic stirrer was added. Then, the mixture of lauric acid (1.0−4.0 g) and catalyst (0.02−0.08 g) were added to the reaction tube and, subsequently, heated to the desired temperature under a constant nitrogen flow. A total of 2.0 g of ergosterol was added to the reaction system until lauric acid and catalyst melted completely, starting the reaction and lasting for some time (0.5−4.0 h). Over the time course of the reaction, a portion of the sample was periodically taken out for thin-layer chromatography (TLC) and HPLC analyses. At the end of the reaction, nitrogen flow was stopped until all samples were removed.

**TLC Analysis and Product Purification.** The sample (0.05 g) removed periodically from the reaction system was dissolved in 10 mL of *n*-hexane/ethanol (1:1, v/v) and then used for TLC analysis. A small quantity of sample solution (10 μL) was evenly pointed on a activated TLC plate. Development was then carried out using petroleum ether (60−90 °C)/ethyl acetate (9:1, v/v) as the developing agent, and the TLC plate was located by iodine vapor staining for 20 min. $R_f$ values of different substrates and products were as follows: 0.05−0.09 (lauric acid), 0.16−0.21 (ergosterol), and 0.85−0.91 (ergosterol laurate).

The sample (1.0 g) at the end of the reaction was dissolved in 20 mL of petroleum ether (60−90 °C)/ethyl acetate (9:1, v/v) and then applied to a silica gel column (12 × 1000 mm), eluted with petroleum ether (60−90 °C)/ethyl acetate (9:1, v/v) at the flow rate of 0.8 mL/min. The eluent was collected, and the purity of the product was preliminarily detected by TLC analysis and further analyzed by HPLC. The fractions only containing ergosterol laurate were collected by rotary evaporation under vacuum.

**FTIR Analysis.** The above purified ergosterol laurate was dried under vacuum and then characterized by FTIR analysis. FTIR measurement was performed on a FTIR spectrophotometer (Thermo Nicolet IS50 FT-IR, Waltham, MA) using an attenuated total reflectance method with the spectral scanning scope for 600−4000 $cm^{-1}$, number of scans of 32, and resolution of 4 $cm^{-1}$.

**MS Analysis.** The mass spectrum was obtained by liquid chromatography ion trap mass spectrometry (Thermo LXQ, Waltham, MA) with positive-ion atmospheric pressure chemical ionization (APCI) mode. The MS operating parameters were as follows: vaporizer temperature, 350 °C; sheath gas flow rate, 25 arb; auxiliary gas flow rate, 5 arb; discharge current, 4.0 μA; capillary temperature, 275 °C; capillary voltage, 30 V; tube lens, 120 V; and mass scan range, 100−800 amu.

**NMR Analysis.** The chemical structure of the purified product was further identified by NMR. In detail, $^1H$ and $^{13}C$ NMR and distortionless enhancement by polarization transfer 135 (DEPT 135) spectra of the product were recorded using $CDCl_3$ as the solvent with a Bruker NMR spectrometer (Avance II 400 MHz, Switzerland). The $^1H$ NMR spectrum was acquired using the following settings: temperature, 294.5 K; frequency, 400.13 MHz; acquisition time, 4 s; and number of scans, 16. $^{13}C$ NMR and DEPT 135 spectra were acquired using the same settings as follows: temperature, 295.2 K; frequency, 100.61 MHz; acquisition time, 1.4 s; and number of scans, 549.

**HPLC Analysis.** The reaction sample (0.05 g) periodically removed from the reaction tube was diluted in 20 mL of absolute ethyl alcohol/*n*-hexane (1:1, v/v). The sample (10 μL) was analyzed by Agilent 1100 HPLC using a symmetry-$C_{18}$ column (5 μm, 4.6 × 150 mm, Waters, Milford, MA) controlled at 35 °C. The sample was eluted with methanol/*n*-hexane (9:1, v/v) as the mobile phase at the flow rate of 1.0 mL/min. The eluate was monitored with a Schambeck ZAM 4000 evaporative light scattering detector (ELSD) at 60 °C and nitrogen as the carrier gas at a pressure of 0.5 bar. The purified ergosterol laurate and ergosterol were used as standards, and the corresponding calibration curves were prepared for quantitative analysis. The conversion and selectivity were defined as follows:

$$\text{conversion of ergosterol (\%)} = (\text{EB} - \text{EE})/\text{EB} \times 100$$

$$\text{selectivity of ergosterol laurate (\%)} = \text{ELE}/(\text{EB} - \text{EE}) \times 100$$

where EB is the molar amount of ergosterol at the beginning of the reaction, EE is the molar amount of ergosterol at the end of the reaction, and ELE is the molar amount of ergosterol laurate at the end of the reaction.

**Determination of the Oil Solubility of Ergosterol and Its Laurate.** The solubility of ergosterol and ergosterol laurate in vegetable oil was investigated as follows: 0.2 g of ergosterol or 0.5 g of ergosterol laurate was added to a 100 mL flask, successively. The flask was heated with a oil bath equipped with a magnetic stirring apparatus to 30 °C. Subsequently, the soybean oil was added dropwise until the sample was completely dissolved. Thereafter, the flask stood for 6 h with the help of magnetic stirring. The oil volume were promptly adjusted and recorded on the basis of the dissolution. The oil solubility can be calculated by the amount of sunflower oil to be added and expressed as grams per 100 mL at 30 °C.

## RESULTS AND DISCUSSION

**Product Analysis.** The product was quantified by HPLC. After the purification procedure, the purity of the product was also determined by HPLC. The purified product was characterized by FTIR, MS, and NMR analyses.

*HPLC Analysis.* The conversion of ergosterol to ergosterol laurate was determined by HPLC. ELSD was a kind of universal detector and selected for this study because of lauric acid without ultraviolet (UV) absorption. The peaks of ergosterol and lauric acid were characterized on the basis of their retention times with reference to standards. Lauric acid was first eluted with the retention time of 3.4 min, and then ergosterol was eluted with the retention time of 5.8 min. From the HPLC chromatogram of the reaction mixtures, a new peak at 22.4 min was observed and corresponded to the product ergosterol laurate. Apparently, the products can be clearly distinguished from the reaction substrates.

*FTIR Analysis.* The FTIR spectral data of lauric acid and the potential functional groups were displayed in Figure 1a.

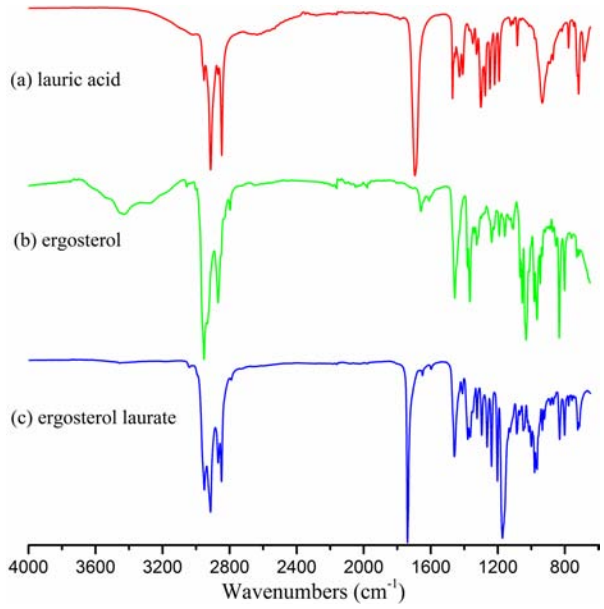

**Figure 1.** FTIR spectra of (a) lauric acid, (b) ergosterol, and (c) ergosterol laurate.

Obviously, the broad peak between 2450 and 3300 $cm^{-1}$ was the characteristic absorption signal of −OH in −COOH, and the strong peak at 1694 $cm^{-1}$ was the characteristic absorption signal of C═O in −COOH, suggesting the presence of a free carboxyl group. The peak at 2953 $cm^{-1}$ was the asymmetrical stretching vibration of C−H in the $CH_3$ group. The peaks at 2913 and 2847 $cm^{-1}$ were the asymmetrical and symmetrical stretching vibrations of C−H in the $CH_2$ group, respectively. The peak at 1471 $cm^{-1}$ was the bending vibration of C−H in the $CH_2$ group. The band at 718 $cm^{-1}$ indicated the presence of four or more $CH_2$ groups in the carbon chain.

The FTIR spectral data of ergosterol and the potential functional groups were displayed in Figure 1b. The broad and weak peak at 3430 $cm^{-1}$ corresponded to the stretching vibration of the hydroxyl group. The weak peak at 3056 $cm^{-1}$ was the signal of C−H in −C═C−H. The peaks at 2953 and 2869 $cm^{-1}$ were the asymmetrical and symmetrical stretching vibrations of C−H in the $CH_3$ group, respectively. The peak at 1366 $cm^{-1}$ was the bending vibration of C−H in the $CH_3$ group. The peaks at 2932 and 1456 $cm^{-1}$ were the asymmetrical and bending stretching vibrations of C−H in the $CH_2$ group, respectively. The medium peak at 1658 $cm^{-1}$ was the vibration signal of C═C. The strong peak at 1031 $cm^{-1}$ corresponded to the vibration of C−O.

The FTIR spectral data of the product and the potential functional groups were displayed in Figure 1c. The weak peak at 3040 $cm^{-1}$ was the signal of C−H in −C═C−H. The peaks at 2952 and 2869 $cm^{-1}$ were the asymmetrical and symmetrical stretching vibration of C−H in the $CH_3$ group, respectively. The peak at 1380 $cm^{-1}$ was the bending vibration of C−H in the $CH_3$ group. The peaks at 2915 and 1460 $cm^{-1}$ were the asymmetrical and bending stretching vibrations of C−H in the $CH_2$ group, respectively. The weak peak at 1651 $cm^{-1}$ was the vibration signal of C═C. The strong peaks at 1740 and 1173 $cm^{-1}$ were the characteristic absorption signals of C═O and C−O in the ester group, respectively. In comparison to the FTIR spectrum of lauric acid, the characteristic absorption signal of the carbonyl group in the product moved to a higher wavenumber, indicating that presence of the ester group. The band at 724 $cm^{-1}$ implied the presence of four or more $CH_2$ groups in the carbon chain.

The absorption signal of the free carboxyl group was observed in lauric acid but not in the product. The characteristic signal of the free hydroxyl group was observed in ergosterol. Nevertheless, the appearance of the ester group and the disappearance of the free hydroxyl group in the product suggesting that the new product may be ergosterol laurate.

**MS Analysis.** A direct sample infusion APCI−MS with positive-ion mode was used to identify the product. A major advantage of this approach was no need of separating the targeted compound from other compounds prior to analysis. The positive APCI−MS spectrum of the purified product was displayed in Figure 2. Theoretically, the relative molecular weight for ergosterol laurate was 578. In Figure 2, the protonated molecular ion $[M + H]^+$ at $m/z$ 579 was observed, indicating that the product was ergosterol laurate. Similarly, the molecular ion $[M + H]^+$ at $m/z$ 661 for oleyl ergosterol was observed in a previous report of the analysis of ergosterol esters isolated from the fruiting bodies of *Mycena chlorinella* using positive APCI−MS.[19] The base peak at $m/z$ 379 [M + H − lauric acid]$^+$ indicated the loss of lauric acid, providing strong evidence for the presence of ergosterol laurate. A similar result was also observed in a previous study, in which dehydrated molecular ions ($[M + H - H_2O]^+$) at $m/z$ 379 were found in ergosterol with strong intensity using positive APCI−MS.[20,21]

**NMR Analysis.** Following the purification procedure, the purified product showed only a single peak in the HPLC chromatograms, indicating that the purity of the product was very high (>98%). The microstructure of the product was further analyzed by $^1H$ and $^{13}C$ NMR and DEPT 135 spectroscopy (Figure 3). The $^1H$ and $^{13}C$ chemical shifts for the product were assigned by the interpretation of their $^1H$ and $^{13}C$ NMR and DEPT 135 spectra and further comparison to those of ergosterol in the literature.[21]

As displayed in Figure 3a, the $^1H$ NMR spectrum was complex, owing to the overlapping of the absorption signal of methylene and/or methylidyne between 1.2 and 2.1 ppm. The resonances below 1.1 ppm were mainly ascribable to methyl units, and those above 2.1 ppm were due to methylidyne units. The 3-H signal at 4.7 ppm in the product had a downfield shift of 1.0 ppm in comparison to that of ergosterol (3.7 ppm),[21]

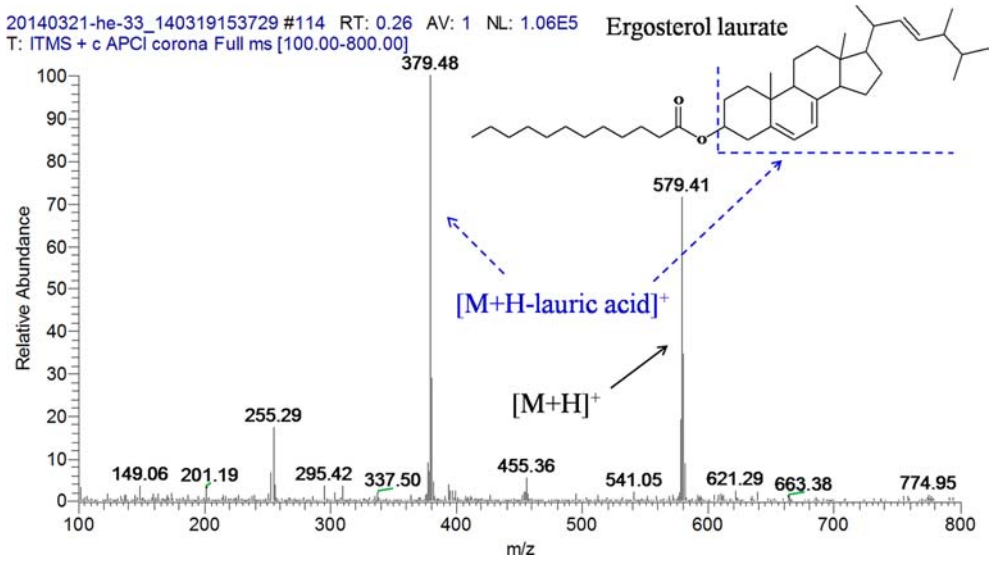

**Figure 2.** MS spectrum of ergosterol laurate.

indicating the presence of an ester bond in the ergosteryl moiety. The signals at 5.2 ppm were attributed to 22-H and 23-H. Furthermore, The resonances at 5.38 or 5.56 ppm were owing to 6-H or 7-H.

DEPT was a very useful method for determining the presence of primary, secondary, and tertiary carbon atoms. The DEPT experiment distinguished between CH, $CH_2$, and $CH_3$ groups by variation of the selection angle parameter. In DEPT 135, all $CH_2$ signals faced downward (negative), CH or $CH_3$ signals faced upward (positive), and quaternary carbon did not appear.

The $^{13}C$ NMR spectrum in Figure 3b illustrated the distribution of all carbon atoms in the product, while the DEPT 135 spectrum in Figure 3c only contained primary, secondary, and tertiary carbon atoms. Obviously, the peaks at 37.11, 37.11, 138.64, 141.47, and 173.33 ppm appearing in the $^{13}C$ NMR spectrum but disappearing in the DEPT 135 spectrum were ascribed to 10-, 13-, 5-, 8-, and 1′-quaternary carbon atoms, in agreement with proposed chemical structure for ergosterol laurate. In Figure 3c, the downward peaks between 21.0 and 39.1 ppm were mainly attributed to secondary carbon atoms. The resonances below 21.0 ppm were mainly ascribed to primary carbon atoms, and those above 39.1 ppm were mainly due to tertiary carbon atoms. By comparison, the number of primary, secondary, tertiary, and quaternary carbon atoms was in close agreement with the proposed chemical structure for ergosterol laurate. Furthermore, the 3-carbon atom signal at 72.5 ppm in the product exhibited a downfield shift of 2.0 ppm in comparison to that of ergosterol (70.5 ppm),[21] indicating the presence of an ester bond on the 3-carbon atom of the ergosteryl moiety. These NMR results together with FTIR and MS results proved that ergosterol laurate was successfully synthesized.

**Determination of Reaction Parameters.** For this esterification reaction, the main product was ergosterol laurate produced by direct esterfication of ergosterol with lauric acid, while there were also some unknown side products generated during the reaction. It has been reported that ergosterol was a rather unstable molecule and could be easily oxidized and photoxidized.[22] Meng et al. considered that the high temperature may be in favor of the dehydration of sterols to dienes.[15,23] In addition, ergosterol in mushrooms has also been found to be converted into vitamin $D_2$ by UV irradiation or sunlight exposure.[24] In this study, the side reaction was partially inhibited under constant nitrogen flow. Therefore, the conversion of ergosterol and the selectivity of the desired product (ergosterol laurate) were synchronously considered. The yield of the desired product (ergosterol laurate) was directly correlated to the selectivity. Under the same conversion, the higher the selectivity, the higher the yield of ergosterol laurate. On the contrary, the lower the selectivity, the higher the yield of side products.

*Selection of the Catalyst.* The effect of different catalysts on the conversion of ergosterol and the selectivity of ergosterol laurate was investigated, and the result is shown in Figure 4. These catalysts were used for the synthesis of ergosterol ester on the basis of the previous reports concerning the synthesis of phytostanyl esters.[11,15] Furthermore, CuCl was also selected to explore the catalytic efficiency for ergosterol ester synthesis because of its potential catalytic activity.[25]

As shown in Figure 4, the catalysts displayed different catalytic activities for the esterification of ergosterol with lauric acid. Among these catalysts, although $SnCl_2$ and CuCl showed excellent selectivity, lower conversion was observed when using $SnCl_2$ or CuCl as the catalyst. In a previous study, SDS + HCl has been found to be effective for the synthesis of phytostanyl esters in a solvent-free system.[11] In this study, the effect of SDS, HCl, or SDS + HCl on the conversion and selectivity was considered and compared for the synthesis of ergosterol ester. Almost no formation of the desired product occurred using HCl alone as the catalyst (data not shown), which was ascribed to be the rapid evaporation of hydrochloride at a high temperature. SDS had a comparable effect to SDS + HCl in the selectivity for this esterification, while the latter was better in the conversion. Therefore, SDS + HCl was used on the basis of the conversion and selectivity for the following experiments.

*Effect of the Reaction Temperature.* The influence of the reaction temperature on the conversion of ergosterol and the selectivity of ergosterol laurate was evaluated varying the reaction temperature from 80 to 120 °C. As shown in Figure 5, the conversion of ergosterol gradually improved as the temperature increased from 80 to 120 °C and then slightly

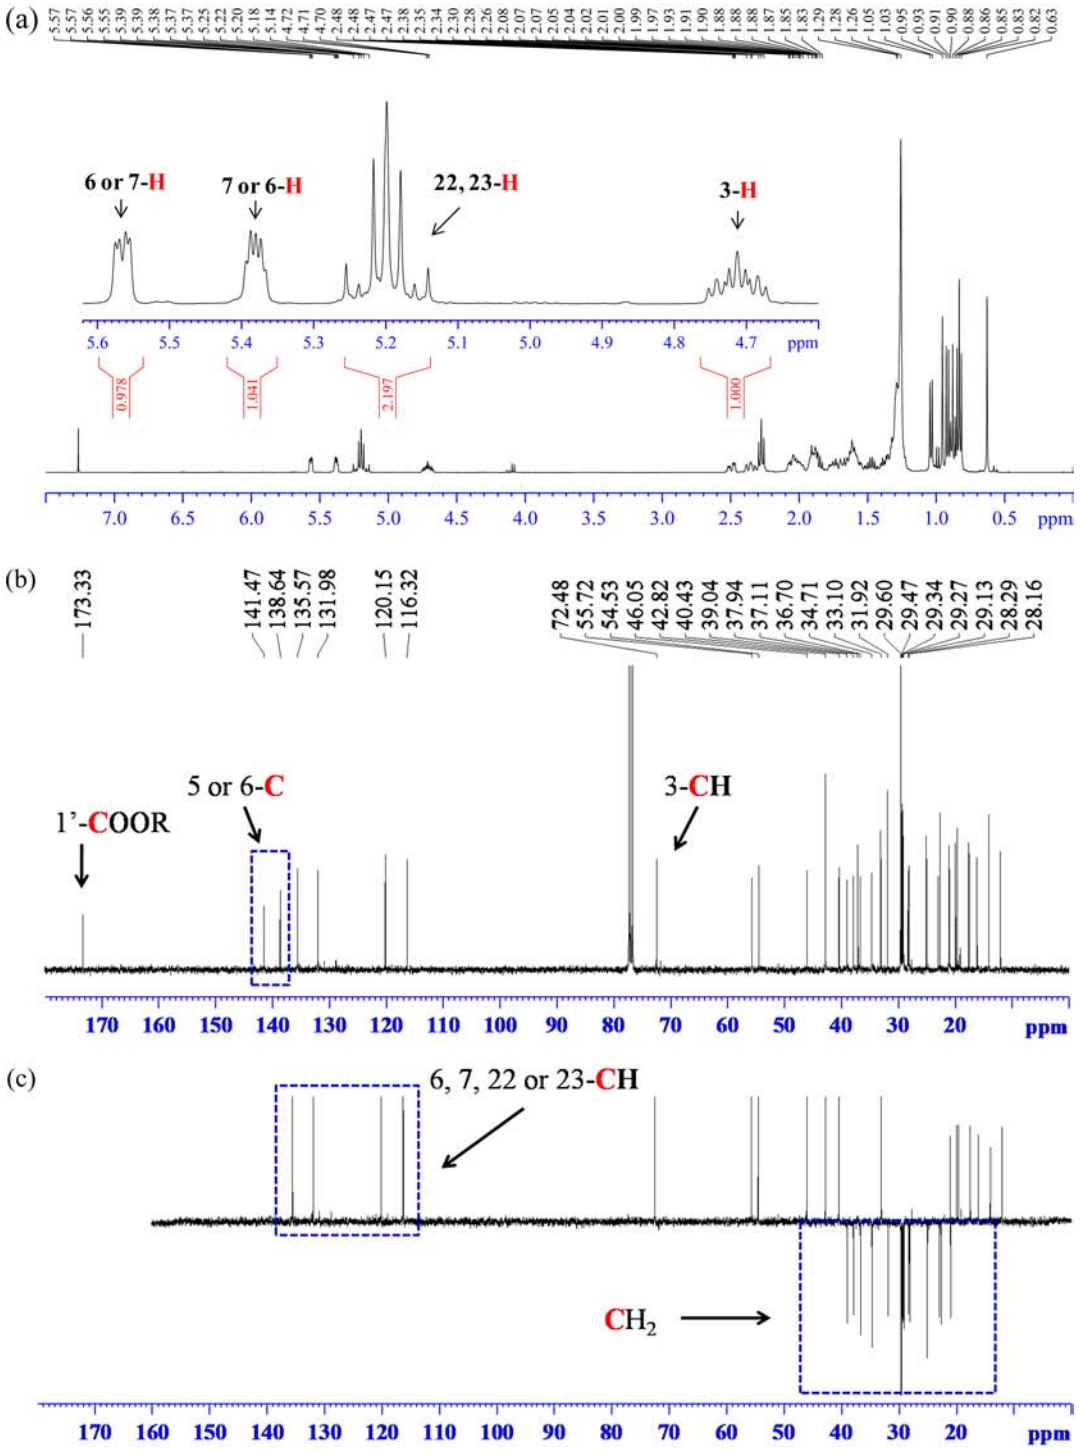

**Figure 3.** (a) $^{1}$H and (b) $^{13}$C NMR and (c) DEPT 135 spectra of ergosterol laurate.

decreased with a further increase of the reaction temperature from 120 to 140 °C. Moreover, the selectivity of ergosterol laurate varied slightly with the increase of the reaction temperature from 80 to 120 °C and then decreased when the temperature surpassed 120 °C. Although there was a high selectivity, the conversion of ergosterol was below 40% at 80 °C. The conversion was significantly improved at 140 °C, while the selectivity of ergosterol laurate was markedly decreased. In general, the esterification reaction would be enhanced as the substrates gradually melted and fully mixed with the gradual increase of the reaction temperature. Nevertheless, side reactions, such as oxidation, dehydration, and degradation, may also be accelerated as the reaction temperature increased, thus resulting in the lower selectivity.

*Effect of the Catalyst Dose.* The influence of the catalyst load on the conversion of ergosterol and the selectivity of ergosterol laurate was considered varying the amount of SDS + HCl from 1 to 5% (w/w), and the results were displayed in Figure 6. Although some ergosterol was consumed and the conversion below 8% was observed in the absence of SDS + HCl, almost no ergosterol laurate was formed at 120 °C (data not shown). As shown in Figure 6, the conversion of ergosterol

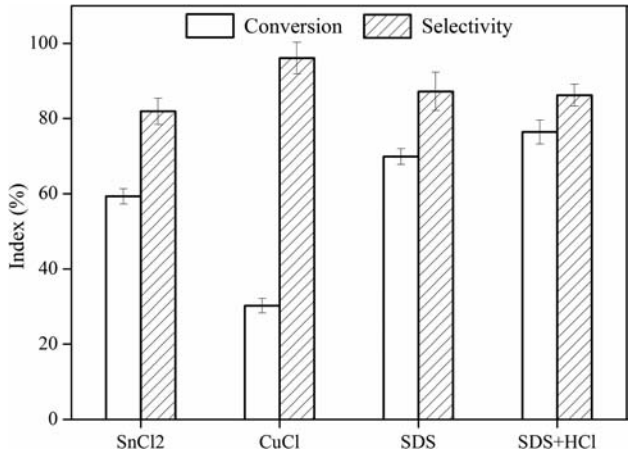

**Figure 4.** Effect of different catalysts on the conversion of ergosterol and the selectivity of ergosterol laurate (2:1 molar ratio of lauric acid/ergosterol, 100 °C, catalyst dose of 4%, and 2 h).

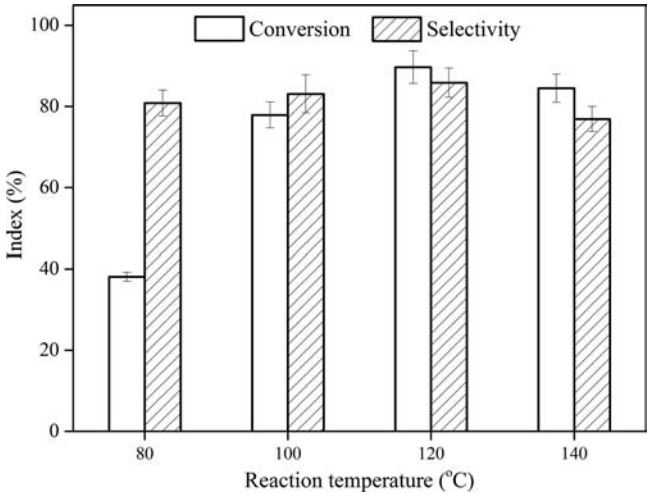

**Figure 5.** Effect of the reaction temperature on the conversion of ergosterol and the selectivity of ergosterol laurate (SDS + HCl as the catalyst, 2:1 molar ratio of lauric acid/ergosterol, catalyst dose of 4%, and 2 h).

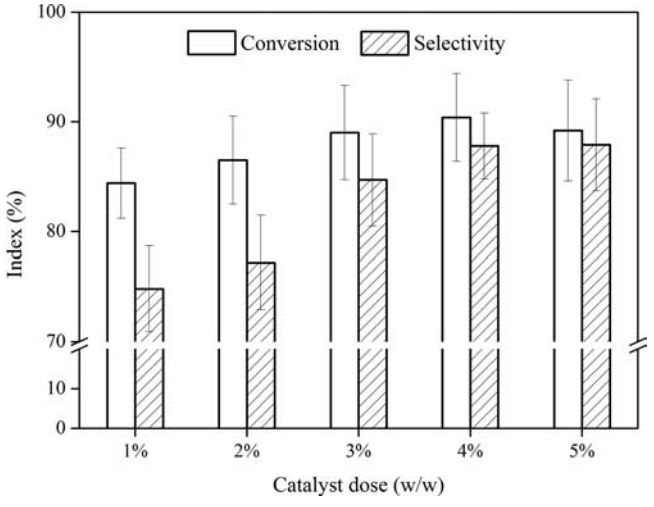

**Figure 6.** Effect of the catalyst dose on the conversion of ergosterol and the selectivity of ergosterol laurate (SDS + HCl as the catalyst, 2:1 molar ratio of lauric acid/ergosterol, 120 °C, and 2 h).

significantly promoted with the addition of 1% SDS + HCl and then gradually increased with a further increase of SDS + HCl and the highest conversion of ergosterol was achieved with 4% SDS + HCl. Meanwhile, the selectivity of ergosterol laurate also improved with the rise of SDS + HCl and then remained steady when the catalyst dose exceeded 4%. At a low catalyst dose, low conversion of ergosterol was still observed, while no ergosterol laurate was formed, which should be the occurrence of a side reaction under a high temperature. With the increase of the catalyst dose, the esterification of ergosterol with lauric acid was gradually activated and the conversion and selectivity also synchronously increased. However, the conversion and selectivity slightly varied with a further rise in the catalyst dose from 4 to 5%, indicating that 4% SDS + HCl was enough to make the substrate fully esterified.

*Effect of the Substrate Molar Ratio.* The influence of the molar ratio of lauric acid/ergosterol on the conversion of ergosterol and the selectivity of ergosterol laurate was evaluated using a molar ratio of lauric acid/ergosterol from 1:1 to 4:1 (Figure 7). In general, equimolar lauric acid and ergosterol

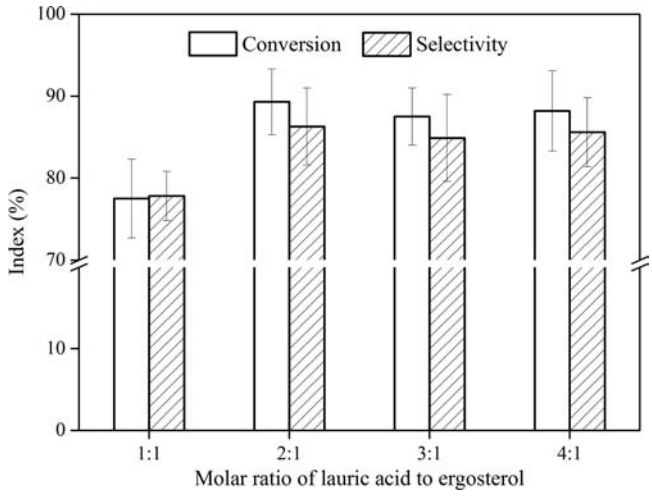

**Figure 7.** Effect of the molar ratio of lauric acid/ergosterol on the conversion of ergosterol and the selectivity of ergosterol laurate (SDS + HCl as the catalyst, 120 °C, catalyst dose of 4%, and 2 h).

should be ideal for direct esterification in view of the economic perspective and further purification. However, such a ratio was not favorable for the desirable product synthesis, and the conversion was below 80%. The conversion were improved with the rise of the molar ratio of lauric acid/ergosterol from 1:1 to 2:1, which was ascribed to a chemical equilibrium shift toward esterification. However, the conversion of ergosterol slightly varied with a further increase of lauric acid/ergosterol from 2:1 to 4:1, indicating that excessive lauric acid could not promote the conversion when the molar ratio exceeded 2:1. Low selectivity of ergosterol laurate was observed at a 1:1 molar ratio of lauric acid/ergosterol, and the selectivity was enhanced with the increase of the molar amount of lauric acid. For this reaction system, both the esterification reaction and side reaction were carried out at the same time, while the selectivity of ergosterol laurate was improved as the esterification shifted with the increase of the molar amount of lauric acid. Therefore, a 2:1 molar ratio of lauric acid/ergosterol was considered to be optimal.

*Effect of the Reaction Time.* The effect of the reaction time on the conversion of ergosterol and the selectivity of ergosterol

laurate was investigated under the above parameters, and the results are shown in Figure 8. In this experiment, all parameters

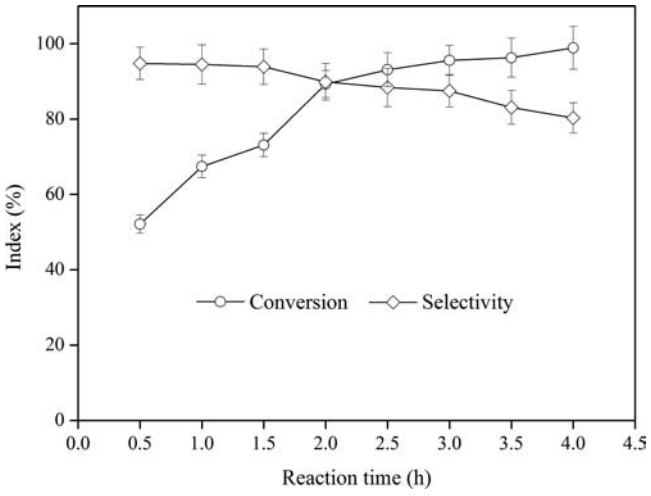

**Figure 8.** Effect of the reaction time on the conversion of ergosterol and the selectivity of ergosterol laurate (SDS + HCl as the catalyst, 2:1 molar ratio of lauric acid/ergosterol, catalyst dose of 4%, and 120 °C).

used have been selected by the above works. Obviously, the conversion of ergosterol rapidly increased with the extension of the reaction time, and the conversion reached 89% at 2 h. Furthermore, the highest selectivity was observed at 0.5 h and then slightly decreased with the rise of the reaction time. The conversion tended to gradually increase as the reaction time further extended from 2 to 4 h, indicating that the esterification of ergosterol with lauric acid had nearly reached equilibrium at 2 h. However, the selectivity of ergosterol laurate still decreased with a further increase of the reaction time from 2 to 4 h, suggesting that a small quantity of ergosterol and its laurate may be converted into side products. Therefore, the conversion and selectivity should be excellent when the esterification of ergosterol with lauric acid was performed for 2 h.

**Comparison of Solubility.** The solubility of ergosterol in vegetable oil was below 0.9 g/100 mL, while the solubility of ergosterol laurate could reach above 5.7 g/100 mL under the same conditions, indicating that the coupling of ergosterol and lauric acid by direct esterification can significantly improve the solubility of ergosterol in oil, thus greatly facilitating the incorporation into a variety of oil-based systems.

In recent years, ergosterol and its derivatives have attracted much attention for a variety of health benefits, while the latter showed excellent advantage in solubility. In the present study, ergosterol laurate was successfully and efficiently synthesized for the first time by direct esterification using SDS + HCl as the catalyst in a solvent-free system. Nevertheless, the side reaction should be prohibited further by exploring some moderate routes. Although the desired product (ergosterol laurate) was purified and characterized, its properties and application still need to be studied.

dioxide in fumigated tomatoes and cantaloupe. An additional objective was to investigate the effect of laboratory illumination on the formation of chloroxyanion byproducts such as chlorate and perchlorate during chlorine dioxide fumigation.

## MATERIALS AND METHODS

**Radiolabel.** Stock $Na^{36}ClO_2$, having a radiochemical purity of 90.5% and a specific activity of 14,000 dpm/$\mu$g was generated from $Na^{36}ClO_3$ as described by Hakk et al.[12] The 9.5% radiochemical impurity present in the stock $Na^{36}ClO_2$ solution was $Na^{36}Cl$ as determined by ion chromatography with radiochemical detection. Radioactive chlorine dioxide ($^{36}ClO_2$) was generated by the mineral acid catalyzed oxidation of $Na^{36}ClO_2$ (aq). For the tomato studies, 315 $\mu$L of stock $Na^{36}ClO_2$ was combined with 36 $\mu$L of sodium chlorite technical solution (318 mg/mL by iodometric titration; ICA TriNova), to a specific activity of 389 dpm/$\mu$g, and 49 $\mu$L of water in a Tyvek sachet (2.6 × 13 cm). Acidification of the chlorite solution with 1.8 M HCl (250 $\mu$L) initiated the release of $^{36}ClO_2$. The specific activity of the $^{36}ClO_2$ gas was 521 dpm/$\mu$g.

For the cantaloupe studies, sequential volumes of 4.925 mL of water; 1.390 mL of stock $Na^{36}ClO_2$, corrected for radiochemical purity; 0.628 mL of sodium chlorite technical solution; and 4.340 mL of 1.8 M HCl were added to a Tyvek sachet (19 × 5 cm, L × W) to initiate $^{36}ClO_2$ release. The specific activity of the $^{36}ClO_2$ gas was 134 dpm/$\mu$g.

**Tomato Studies.** *Tomato Fumigation.* Three separate $^{36}ClO_2$-fumigation experiments (trials A, B, and C) were conducted. In each experiment, approximately 100 g of tomato was exposed to approximately 5 mg of $^{36}ClO_2$ gas during a 2 h fumigation period. Fumigations occurred within a 5.5 L (11 × 22 × 23.5 cm; W × L × D) sealable glass tank (Figure 1). During experiments A and B, no effort was made to protect the fumigation tank from light, but for trial C the fumigation tank and lid were each protected from laboratory illumination by an aluminum foil wrap. Fumigation tanks were placed onto a magnetic stirring plate, and tomatoes were placed onto a slotted glass pedestal within each tank. A stir bar was also placed in the glass chamber and was allowed to rotate during fumigation to facilitate mixing of gases. Reactions were initiated, and the reaction chamber was sealed with a glass plate previously lined with vacuum grease. Glass lids were equipped with butyl-stoppered (20 mm; Kimble Chase; Vineland, NJ) entry and exit holes through which gases could be purged. Exposure periods were 2 h each. Experimental protocols varied slightly between experiments A, B, and C, and these variations are shown in Table 1.

**Recovery of Chamber Gas Radioactivity.** At the end of each fumigation experiment unreacted gas was either released into the fume hood (trial A) or trapped into 2 L of 0.1 N sodium thiosulfate after air was pumped (0.6 to 1.0 h) through the exposure chamber (trials B and C). To this end, entry and exit septa of the chamber lids were pierced with 11-gauge needles connected to Tygon tubing; gas pumped through the fumigation chambers was passed through coarse micro gas dispersion tubes (Chemglass Life Sciences, Vineland, NJ) housed within the thiosulfate.

*Recovery of Tomato Radioactivity.* Tomatoes were removed from the reaction vessel using tongs and placed into a 250 mL beaker containing about 200 mL of water. Tomatoes were rinsed for about 1 min, after which the tomato was removed and the rinsewater placed into a 250 mL volumetric flask; the beaker was rinsed, and the rinsewater was added to the volumetric flask. The volumetric flask was diluted to the mark and mixed, and radiochlorine in 1−2 mL aliquots was quantified by liquid scintillation counting (LSC).

*Recovery of Chamber Residual Radioactivity.* Stir bars and glass pedestals were placed in 250 mL beakers and rinsed with water, which was placed into volumetric flasks (0.5−1 L). Radioactive residues were recovered from the reaction chamber by rinsing sequentially with water. Rinses were transferred to the volumetric flask; the volumetric was diluted to the mark and mixed by inversion. Radioactivity in 1 to 2 mL aliquots was determined by LSC.

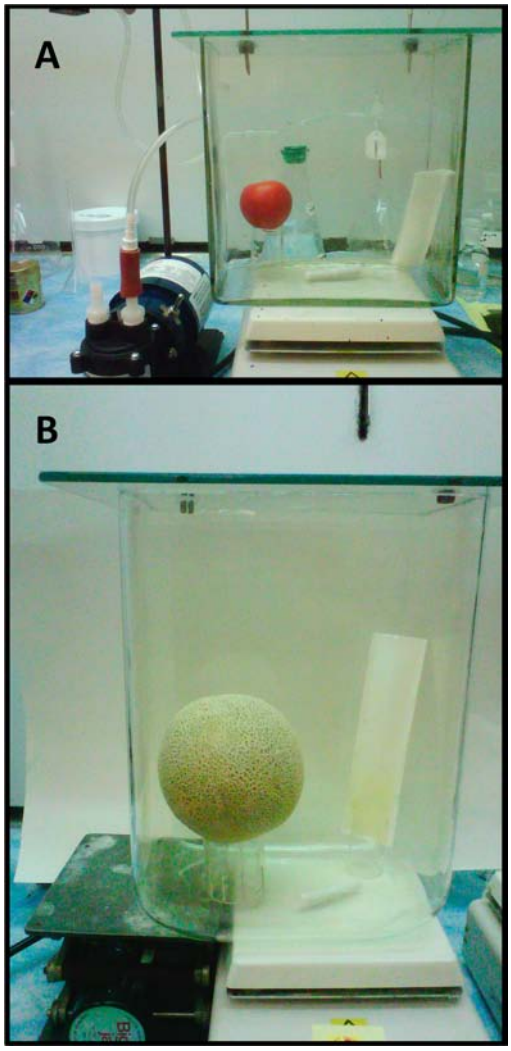

**Figure 1.** Experimental chambers for tomato (panel A) and cantaloupe (panel B) fumigations with $^{36}$Cl-chlorine dioxide. Panel A shows a tomato experiment at the initiation of the venting process. Panel B shows a cantaloupe experiment during fumigation; $^{36}$Cl-chlorine dioxide gas can be clearly seen as the greenish tint in the fumigation chamber. For each fumigation experiment, a slotted glass pedestal was used to support tomatoes or cantaloupe, a stir bar was used to provide gas circulation, and a Tyvek sachet contained the $^{36}ClO_2$ generating system. Glass lids were sealed with vacuum grease, and two butyl septa (embedded in the lids) served as portals through which air was pumped into sodium thiosulfate traps at the termination of the experiment. No effort was made to prevent laboratory illumination of either of the fumigations shown.

Radioactivity remaining within gas generation sachets was recovered after sequential rinsing with water and transfer of the rinse fractions into a 1 L volumetric as described for the tank rinse. Sachet radioactivity not removed by the water rinse was quantified after cutting each sachet into 1 cm strips and counting each strip directly in liquid scintillation fluid by LSC.

*Recovery of Tomato Radioactivity.* Rinsed tomatoes were weighed and homogenized whole (trial A), or the stem scar area was removed (trials B and C) and then the tomato was weighed and homogenized. The stem scar area was removed with a razor so that it contained minimal to no tomato skin or flesh. Aliquots (0.25 g) of puree were placed into glass LSC vials, digested overnight with 6 mL of Carbosorb E (PerkinElmer Life Sci.; Waltham, MA), and counted after the addition of 12 mL of Permaflour E (PerkinElmer Life Sci.; Waltham, MA) using LSC to obtain total radioactive residues (TRR). Stem scar

**Table 1. Experimental Differences between Tomato Fumigation Trials A, B, and C**

| | variable | | |
|---|---|---|---|
| trial | gas purge[a] | stem scar collection[b] | illumination[c] |
| A | no | no | yes |
| B | yes | yes | yes |
| C | yes | yes | no |

[a]Unreacted chlorine dioxide gas was either purged and trapped from the reaction vessel or vented into the fume hood. [b]The stem scar was either left on the tomato during postexposure processing or removed and processed separately. [c]The reaction chamber was unprotected from light for the 2 h reaction period, or it was covered with aluminum foil during the fumigation period and protected from illumination.

areas were added to a known amount of water and (or) crushed ice and were homogenized in a 25 mL stainless steel Waring blender cup. Radioactivity in scar puree was then quantified by LSC as described for tomato puree.

*Preparation of Tomato Serum and Pellet Fractions.* Aliquots of tomato puree were fractionated into liquid serum and solid pellet fractions by centrifugation at 30600*g* for 20 min. Aliquots (0.5 mL) of the serum fraction were counted directly in 15 mL of Ultima Gold LSC fluid; TRR in pellet aliquots (0.25 g) was quantified by LSC after overnight treatment in 6 mL of Carbosorb E followed by dilution in 12 mL of Permafluor LSC fluid.

*Speciation of Radioactive Residues in Tomato Rinse, in Serum Fractions, and in Tank Rinse Fractions.* The strategy for identification and quantification of radioactive metabolites was to fortify aliquots of tomato serum or water rinse samples with nonradioactive chlorite, chloride, and chlorate (21 to 23 $\mu$g; for use as chromatographic markers) and to inject the fortified aliquots onto the ion chromatograph. Each metabolite fraction was collected into a LSC vial as it eluted from the detector, and radioactivity in each fraction was determined by LSC. This strategy is essentially the same as described by Smith et al.[13] for the analysis of radioactive chlorate metabolites in beef tissues. Chlorite, chloride, and chlorate were separated using a Dionex AS11-HC (Thermo-Fisher) column; for perchlorate analysis, a Dionex AS16-HC column was used (see conditions below). Guard columns were not used. For trial C, quantification of perchlorate in the tomato rinse fraction was accomplished using ion chromatography with conductivity detection (described below); conductivity detection was more sensitive than radiochemical determination and could be used because the rinse fraction was free of interferences.

*Digestion of Tomato Pellets and Characterization of Radioactivity.* Radioactivity associated with the pellet fraction formed during the centrifugation of the tomato puree was released by digestion of pellet aliquots (1 g) in 1 M NaOH (50 °C for 72 h). Subsequent to digestion, slurries were recentrifuged at 50000*g* and the supernatant was assayed to determine recovery of radioactivity. Aliquots of digesta supernatant were treated with 0.3 M silver nitrate to precipitate silver $^{36}$Cl-chloride, as were aliquots of blank sodium hydroxide matrix, and sodium $^{36}$Cl-chloride and sodium $^{36}$Cl-chlorate fortified saline samples (controls). The amount of radioactivity remaining in supernatant aliquots was determined by LSC.

*LSC Techniques.* Background radiochlorine and limits of quantification were determined for individual matrices (i.e., tank rinse, tomato puree, tomato serum, tomato pellet, etc.) as described by Smith et al.[14] Individual aliquots of sample within a matrix set were counted for 10 to 20 min each. Radiochlorine was quantified using a Packard 1900 CA (Meriden, CT) liquid scintillation counter calibrated using a sealed radiochlorine standard (Analytics Inc., Atlanta, GA) prepared in Ultima Gold LSC fluid. Quench was corrected using the tSIE (transformed spectral index of the external standard; Packard) option. Net dpm of a sample was determined by subtracting the mean background dpm of a sample set from the gross dpm of a test sample.

*Ion Chromatography.* Chromatography was conducted using a Waters model 600 pump and controller having PEEK pump heads and tubing. For $^{36}$Cl-chlorite, $^{36}$Cl-chloride, and $^{36}$Cl-chlorate analyses, 10 mM NaOH was isocratically pumped at 1 mL/min through a Dionex AS11-HC, 4 × 250 mm, column. A conductivity detector (Dionex CD-25; 0.1 V, 100 mA, range, 3000) with external water suppression (Dionex ASRS 300; 4 mm) was used to monitor the elution of sample components. $^{36}$Cl-Perchlorate was separated using the same chromatograph equipped with a Dionex AS16-HC, 4 × 250 mm column with an isocratic mobile phase of 50 mM NaOH flowing at 1 mL/min. All samples were introduced through a Rheodyne 9725i Teflon injector equipped with a 1 mL injection loop. For each analysis, the detector signal was captured on paper using a Waters model 746 data module.

For some analyses of water rinses, perchlorate analysis was conducted using a Thermo-Fisher ICS-2100 ion chromatograph using the framework outlined in EPA method 314.0.[15] Briefly, sodium perchlorate standards (4, 10, 25, 100, 200, and 400 $\mu$g/L) were prepared in nanopure water. The limit of quantitation (LOQ) was equivalent to the lowest standard (4 $\mu$g/L) with the limit of detection (LOD) at 2 $\mu$g/L. Tomato rinse sample aliquots (1 mL) were injected onto the column, and perchlorate was separated from interferences on a Dionex AS16-HC column protected by an AG16-HC guard column (both 4 mm). An isocratic mobile phase of 50 mM KOH with a flow rate of 1.5 mL/min was generated using a Thermo-Fisher eluent generator. Perchlorate was measured using suppressed conductivity detection in-line with external water ASRS suppression (186 mA).

*Fate of Sodium $^{36}$Cl-Chlorite Injected into Tomatoes.* Fifty individual grape tomatoes (average wt 6.6 g) were each washed with water, blotted dry, weighed, and injected with 50 $\mu$L of sodium $Na^{36}ClO_2$ (862 $\mu$g; 90.5% radiochemical purity; 99 dpm/$\mu$g of sodium chlorite; radiochemical impurity was $Na^{36}Cl$). The injected tomatoes were collectively transferred into a Cuisinart blender and homogenized as described above for fumigated tomatoes. Likewise, total radioactive residues and the composition of residues in injected-tomato serum was determined as described for fumigated tomatoes.

**Cantaloupe Studies.** *Cantaloupe Fumigation.* Two experiments were conducted; for each trial, a single 18-count (851.6 g, trial A; 850.0 g, trial B) cantaloupe was supplied by SunFed Produce, Nogales, AZ; or Frontera Produce, Honduras. Test $^{36}ClO_2$ was generated in a Tyvek sachet as described for tomatoes. After acid addition, the glass exposure chamber (23.2 × 17.1 × 32.3 cm; L × W × D; 12.9 L) was sealed as rapidly as possible. The glass lid used for sealing the chamber was equipped with two 1 cm ports which were each sealed with 2 cm butyl septa. Cantaloupes were treated for 2 h with $^{36}ClO_2$ gas to meet a target exposure of 100 mg of $^{36}ClO_2$ per kg of cantaloupe (Figure 1). Mixing of gases within the exposure chamber was accomplished with magnetic stirring. No attempt to protect either cantaloupe experiment from laboratory light was made. Average light intensity in the laboratory that the experiments were conducted in is 900 ± 17 lx.

*Recovery of Chamber Radioactivity.* Chamber gases were collected as described for tomatoes except that a 1 N sodium thiosulfate trapping solution was used. Exposure chambers were purged for 1 (trial A) or 1.5 (trial B) h each. Radioactive residues were recovered from glass surfaces of the reaction chamber and Tyvek sachets as described for tomatoes.

*Recovery of Cantaloupe Radioactivity.* Cantaloupe were not rinsed after fumigation. Each cantaloupe was bisected with a single stroke of a stainless steel blade, and the seed bed was carefully removed and weighed. Edible cantaloupe flesh was separated from the rind with careful attention directed toward not contaminating the edible flesh with dry or liquid material from the inedible rind. The edible cantaloupe flesh was placed into a clean container and weighed; the rind portion was sliced into manageable pieces and weighed. Seed bed, edible flesh, and rind fractions were homogenized (Cuisinart CB-500) separately, and the resulting purees were analyzed for TRR content by LSC as described for the tomatoes.

*Preparation of Edible Flesh and Inedible Rind Serum and Pellet Fractions.* Aliquots (50 mL) of edible flesh or inedible rind puree were fractionated into liquid (serum) and solid (pellet) fractions by centrifugation at 30600*g* for 20 min. The serum and pellet fractions were separated, and quintuplicate aliquots (0.5 to 1.0 mL) of the sera fractions were counted directly in 15 mL of Ultima Gold

**Table 2. Distribution of Radioactivity after the Fumigation of Test Tomatoes with $^{36}ClO_2$ Gas**

[a]Expressed as a percentage of the starting radioactivity. [b]Total starting radioactivity was 2.27 $\mu$Ci. [c]NA, the stem area was not removed in tomato trial A. [d]NM, not measured. [e]Nonsachet activity is the sum of total tomato activity, gas purge activity, and equipment rinse activity. [f]NC, not calculated because gas was not collected after the termination of the experiment.

(PerkinElmer; Waltham, MA) LSC fluid. Total radioactive residues in quintuplicate pellet aliquots (0.25 g for edible flesh, 0.05 g for inedible rind) were quantified by LSC after overnight treatment in 6 mL of Carbosorb E followed by dilution in 9 mL of Permafluor LSC fluid. Use of greater than 0.05 g of inedible rind pellet caused sample quench due to the intensity of color.

An untreated control cantaloupe was also fractioned into inedible rind, seed bed, and edible flesh fractions. In addition, control serum and pellet fractions were prepared from cantaloupe rind and edible flesh as described for treated melons. Sample aliquots from fractions of the control cantaloupe were used as blanks for determination of background radioactivity during the analysis of treated cantaloupe.

*Speciation of Radioactive Residues.* Radioactive residues in edible flesh, inedible rind sera, and tank rinse fractions were identified as described for tomatoes. Edible flesh serum from cantaloupe trial B, which contained TRR just above the detection limits, was thawed, and quintuplicate 1.25 mL aliquots of serum were fortified with 0.5 mL of 0.85% aqueous NaCl. Additional quintuplicate 1.25 mL aliquots of edible flesh serum were diluted with 0.5 mL of 0.3 M $AgNO_3$. Both sets of samples were centrifuged (15000*g* for 20 min), and 1.25 mL aliquots of each vial were transferred to glass LSC vials for determination of soluble radioactive residues in 15 mL of UltimaGold LSC fluid. For the saline treated serum, soluble radioactive residues would represent the TRR; for the $AgNO_3$ treated serum, the soluble residues would represent any residue present as $^{36}$Cl-chlorite, $^{36}$Cl-chlorate, and (or) $^{36}$Cl-perchlorate.

*Factors Impacting the Formation of Chloroxyanion Byproducts during $ClO_2$ Fumigation.* A 2 × 2 × 2 factorial experiment was designed to investigate the major variables that might impact chlorate and perchlorate formation from chlorine dioxide gas in glass reaction chambers. Main factors were reagent matrix (liquid or dry), chlorine dioxide gas concentration (1.6 or 7.8 mg per 0.95 L), and the presence or absence of light. The complete experiment was replicated on each of four consecutive days for a total "*n*" of four observations for each treatment combination. Reactions were conducted in clear glass quart jars (0.95 L) in the absence of vegetable matter. Jars containing treatments protected from light were entirely covered with aluminum foil, whereas jars containing treatments exposed to light were left uncovered. The levels of chlorine dioxide gas (1.6 and 7.8 mg; nominal concentrations of 600 and 3000 ppmv) were selected to bracket the mass of chlorine dioxide used in radiolabeled experiments (5.5 mg) with tomatoes.

Experiments were conducted in a laboratory illuminated by indirect sunlight, electronically ballasted F28T8 fluorescent laboratory lights (28 W), and F40T12 magnetically ballasted fluorescent laboratory hood lights. With the laboratory and hood lights illuminated, the light intensity was 900 ± 17 lx (mean ± std dev; 54 observations on 6 separate days). With laboratory and hood lights on, overcast or sunny days did not significantly influence in-hood light intensity ($P$ = 0.10).

Dry media chlorine dioxide generation employed FruitGard granules (ICA TriNova; Atlanta, GA). In the dry media experiments equal amounts of FruitGard chlorite impregnate and ICA dry acid activator impregnate were combined in Tyvek sachets or in glass beakers. The media were mixed by hand agitation to commence chlorine dioxide generation. Dry matrix reagents were sequentially and separately weighed (0.21 and 1.05 g of impregnate and activator, respectively, for the 1.6 and 7.8 mg $ClO_2$ treatments). Upon the addition of matrix part B, the contents of each sachet were mixed by hand agitation. Sachets were immediately placed in labeled, transparent 0.95 L canning jars and sealed with a canning jar lid and ring. The time at which each reaction was started was recorded.

Liquid reagents were added to Tyvek sachets in the sequence for 1.6 and 7.8 mg treatments respectively: nanopure water (96 or 529 $\mu$L) and technical grade sodium chlorite (10 or 52 $\mu$L; 318 mg/mL; ICA-TriNova; Atlanta, GA) followed by 1.8 M HCl (66 or 363 $\mu$L). After the addition of HCl, sachets were mixed by hand agitation and immediately placed into labeled, transparent 0.95 L canning jars and jars sealed. The start time was then recorded.

Reactions were allowed to proceed for 2 h, after which each container was unsealed and vented into the fume hood. Sachets were removed and each jar was rinsed sequentially by vigorously shaking four 50 mL aliquots of nanopure water within the sealed jars. Water rinses were transferred to labeled 250 mL volumetric flasks, the flasks were diluted to volume, and each flask was mixed by inverting a

minimum of 10 times. Aliquots of each sample were placed in labeled containers and were frozen until analysis by ion chromatography.

Perchlorate analyses were conducted using a Thermo-Fisher ICS-2100 ion chromatograph using the framework outlined in EPA method 314.0.[15] Sample aliquots (1 mL) were injected onto a Dionex AS16-HC column (4 × 250 mm) protected by an AG16-HC guard column (4 × 50 mm). An isocratic mobile phase of 50 mM KOH, produced using a Thermo-Fisher eluent generator, with a flow rate of 1.5 mL/min was used to elute perchlorate from the column. Perchlorate was measured using suppressed conductivity detection in-line with external water (ASRS 300) suppression (186 mA). Sodium perchlorate standards (4, 10, 25, 100, 200, and 400 μg/L), prepared in nanopure water, were injected in replicate 1 mL aliquots onto the ion chromatograph. Peak areas were regressed against perchlorate concentration using Chromeleon CHM-2 software (Thermo-Fisher). The LOQ was equivalent to the lowest standard (4 μg/L). The LOD of 0.001 μg/L was determined empirically by injecting replicate 1 mL aliquots of 0.5, 1, and 4 μg/L sodium perchlorate standards.

Chlorate analyses were also conducted using a Thermo-Fisher ICS-2100 ion chromatograph. Standards consisting of 5, 25, 100, 500, 1000, and 5000 μg/L of sodium chlorate were prepared in nanopure water. Chlorate was separated from interferences on a 4 × 250 mm Dionex AC19HC column protected by a 4 × 50 mm AS19HC guard column with an isocratic mobile phase of 20 mM KOH. Mobile phase was prepared using a Thermo Fisher eluent generator. Ions were detected using a DS6 conductivity detector with external water suppression (ASRS 300; 50 mA). Sodium chlorate standards were run at the beginning and end of each sample set. Blank samples were also concurrently run with each analysis. For the chlorate analysis, the LOQ was 5 μg/L; the LOD of 1 μg/L was determined empirically.

*Statistics.* SigmaPlot 12.0 (Systat Software, Inc.; San Jose, CA) was used to determine differences in treatment (dry or liquid reagent; chlorine dioxide concentration; or illuminated or dark fumigation) means for perchlorate and chlorate. Main effects of media and chlorine dioxide concentration on chlorate and perchlorate formation were determined using two-way analysis of variance (ANOVA) after passing tests of normality and equal variance. The effect of light was not included in the analyses because of the low to nondetectable levels of chlorate and perchlorate in samples protected from light. Chlorate residues were log-transformed prior to statistical analyses in order to meet the equal variance assumption. The Holm−Sidak method was used to determine differences in treatment means after the 2-way ANOVA *F* statistic indicated significant main effects. *F* statistics of less than 0.05 were considered to be significant.

## RESULTS AND DISCUSSION

**Fate of $^{36}$Cl-Chlorine Dioxide in a Tomato Fumigation System.** Table 2 shows the distribution of radioactivity in tomato fumigation systems after 2 h fumigations with $^{36}ClO_2$. Across trials approximately 12% of the system radioactivity was present on the tomato itself; 2 to 13% was rinsed from the fumigation tank and its associated parts (stir bar, glass pedestal); 15 to 19% was purged from the tank and trapped into sodium thiosulfate; and 44 to 49% was associated with the reaction sachet itself. Total recovery of radioactivity was 80 to 84%. Potential losses of radiochlorine include losses realized immediately after the acid activation of the reaction while the sachet was positioned in the reaction chamber and while sealing the chamber. Additional losses could have occurred during chamber evacuation by chlorine dioxide absorption or condensation on the Tygon tubing that transported gases from the reaction chamber to the thiosulfate trap or during the fumigation period by leakage from the tank. Of the total system radioactivity, approximately 55.9% was converted to $^{36}Cl$-$ClO_2$ (total starting radioactivity less activity remaining in the sachet); thus, of the total chlorine dioxide formed, approximately 22% was associated with the tomato itself.

Of note with regard to the gross disposition of the radioactivity was the apparently smaller amount of radioactivity that was rinsed from the tank wall, lid, pedestal, and stir rod in trial C (1.6%) compared to tank rinses of trials A and B (11 and 13%, respectively). Gases in trial C were protected from light, compared to trials A and B. Because the dark-phase radioactive experiment was not replicated, it would be unwise to make too many inferences from a single observation.

Tomato radioactive residues were the collective residues present in the tomato rinsewater, in the tomato puree, and in the stem scar region (for trials B and C). For trial A, 11.9% of the total starting activity was associated with the tomato after a 2 h exposure period, with 13.7 and 11.0% of the starting radioactivity associated with the tomatoes of trials B and C, respectively. While the surface area of the tomato was small relative to the surface area of the tank and its components, $^{36}ClO_2$ deposition was disproportionately associated with tomatoes. That is, approximately 56% of the total starting radioactivity was converted to $^{36}ClO_2$, with 20−25% of the $^{36}ClO_2$ radioactivity associated with the tomato. The disproportional deposition of radioactivity onto the tomato is not surprising given the water solubility of chlorine dioxide and the expected availability of reducing agents in a tomato matrix. The attraction of chlorine dioxide to the tomato itself also provides context for its efficacy at killing pathogens[16−18] and rot organisms[9,19] on vegetable surfaces.

Between 1.1 and 2.2% of the total system radioactivity was rinsed from the surface of tomatoes after the 2 h exposure. When expressed as the total activity present on the tomato, the rinse contained 10 (trial C) to 16% (trials A and B) of the tomato TRR. Data from trials B and C clearly show that the stem scar region of the tomato preferentially accumulated radioactive residues. For example, the stem scar from trial B contained 28.5% of the total activity associated with the tomato even though the scar region was only 0.64 g; for trial C, the scar area contained 20% of the total tomato activity, while comprising only 0.24 g of the total tomato mass. Given the low mass and the high concentration of TRR, one would expect that chlorine dioxide would have high efficacy at the moist, porous area of the fruit, those regions in which pathogens and rot organisms might have the highest probability of colonizing.

Figure 2 shows example chromatograms of sodium chlorite, sodium chloride, and sodium chlorate standards in water and a representative chromatogram of tomato rinsewater assayed for radiochlorine content by ion chromatography with subsequent trapping of radioactive fractions. Using the AS11-HC column chlorite, chloride, and chlorate were well resolved. The large peaks shown in Figure 2 are a reflection of the fact that each aliquot of tomato rinse chromatographed was fortified with unlabeled standards to assist in accurate trapping. Across trials, radioactive sodium chlorite was typically not present in rinse fractions; in contrast, the sodium chloride and chlorate fractions contained detectable radioactivity across trials. Total recovery of radioactivity was low (generally less than 70%) when sample aliquots were analyzed on the AS11-HC column so sample aliquots were also analyzed using an AS16-HC column which allowed perchlorate elution. Using the AS16-HC column, perchlorate was well resolved from chlorite, chloride, and chlorate, which coeluted (Figure 3).

Table 3 shows the composition of radioactive residues in tomato fractions of trials A, B, and C. Tomato rinse fractions did not contain detectable sodium chlorite in trials A and B, but did contain detectable (0.01 μg/g of tomato) $^{36}$Cl-chlorite in

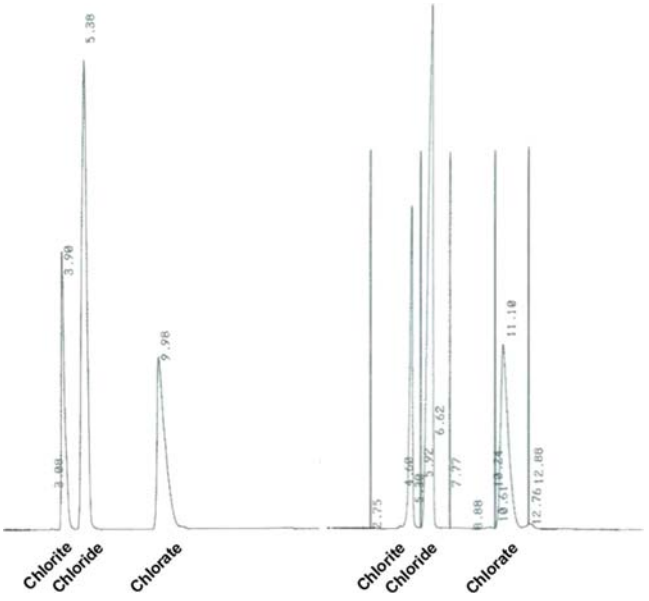

**Figure 2.** Ion chromatographic separation of unlabeled chlorite, chloride, and chlorate standards in water (10 $\mu$L; left panel), and an aliquot (1000 $\mu$L) of tomato rinse fortified with the standard mix (right panel). Vertical lines in the chromatogram of the tomato rinse fraction represent the regions collected directly into LSC vials for determining radioactive residues. Radioactivity was never present in the chlorite fraction of the tomato rinse, but it was significantly above background for the chloride and chlorate fractions in the tomato rinse aliquot. Differences in retention times of standards in the two injections are a function of the differing injection volumes at a constant flow rate (1 mL/min).

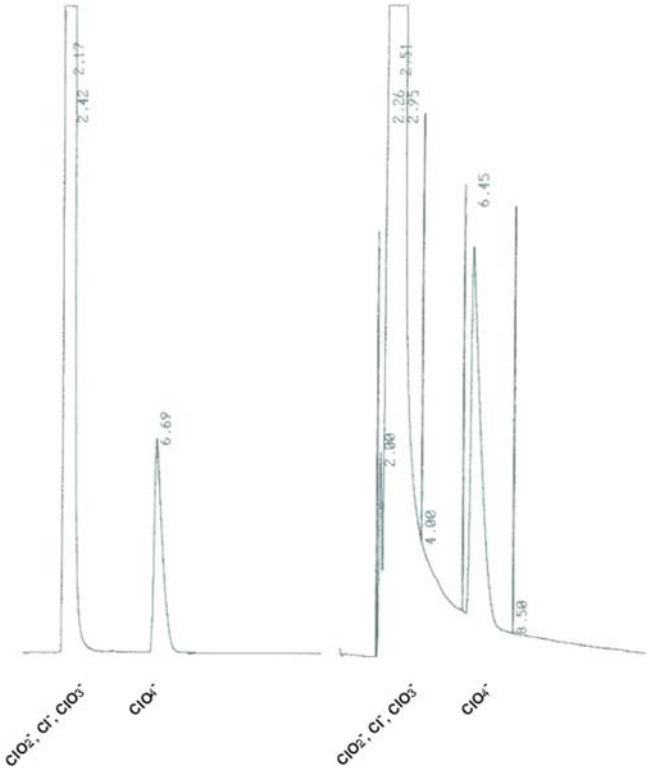

**Figure 3.** Ion chromatographic separation of unlabeled chlorite, chloride, chlorate, and perchlorate standards (left panel) and an aliquot of tomato serum containing incurred residue (right panel) and fortified with the standard mix. Radioactivity present as chlorite, chloride, and chlorate was not resolved on the AS16-HC column and was trapped together; perchlorate was trapped as a single peak, well resolved from chlorite, chloride, and chlorate. Vertical lines in the chromatogram of the tomato rinse fraction represent the regions collected directly into LSC vials for determining radioactive residues.

one of three sample aliquots measured from trial C. Sodium chlorate was the major residue rinsed from tomatoes of trials A and B (56.5 to 67.5% of total residue) but represented 10% of the total residue in trial C, which was run under dark conditions. Similarly, when reactions were run under laboratory illumination (trials A and B), $^{36}$Cl-perchlorate represented significant quantities of radioactivity in the tomato rinse (8.2 to 17.7% of rinse activity), but under conditions protected from light, no detectable $^{36}$Cl-perchlorate was present (trial C; LOQ of 4 ng/mL using ion chromatography). Radioactive chloride ion present on tomato surfaces was greatly influenced by illumination during the experiment, with trial A and B tomato rinses containing 14.8 to 35.2% chloride and trial C (dark) TRR being composed of 89.1% $^{36}$Cl-chloride. Thus, the major factor affecting the composition of residues rinsed from the surface of tomatoes was whether fumigations were exposed to laboratory light.

Of the total radioactive residues present in tomato puree, 53.9 $\pm$ 1.6 of the activity partitioned into the serum, while 46.1% partitioned into the pulp. Tomato serum, prepared from tomato puree, contained no detectable sodium chlorite (Table 3). Radioactive chloride ion represented 80 to 87% of the serum radioactivity in illuminated fumigations (trials A and B) and 93% of the serum radioactivity in the darkened fumigation (trial C). In illuminated fumigations, chlorate represented 13 to 19% of the serum activity, with the proportion dropping to 5% of the total activity for trial C serum (dark). Perchlorate was not consistently detected in sera of tomatoes, regardless of trial (LOQ 0.07 to 0.17 $\mu$g/g).

Stem scar radioactivity, measured in trials B and C, was composed primarily of sodium chloride (86 to 90% of total) and chlorate (9 to 13% of scar radiochlorine); perchlorate residues comprised about 1% of the total stem scar radiochlorine. It should be recalled, however, that the stem area of the tomato, while representing less than 1% of the tomato weight, contained 20 to 25% of the total radioactivity rinsed from, or deposited onto, the tomatoes.

Pellet radioactivity could not be measured directly via ion chromatography, so pellet aliquots were digested in NaOH and then reacted with an excess of silver nitrate to precipitate the $^{36}$Cl-chloride ion. It was assumed that radioactivity not precipitated by silver nitrate had the same chemical composition as stem scar. For trials A and B, 91 to 100% of the radioactivity released by NaOH digestion was precipitated by silver nitrate, indicating that the released radiochlorine was $^{36}$Cl-chloride ion. For trial C, 100% of the radioactivity was released by NaOH digestion, but only 97% of this radiochlorine was precipitated as $^{36}$Cl-chloride ion.

From a qualitative perspective, residues rinsed from the surface of the glass reaction chamber were similar to residues rinsed from tomato surfaces, with laboratory illumination being the major influence on the composition of residues. Oxidized products of chlorine dioxide present in tank rinsewater from trial A represented a major amount of residue (95.3% of tank rinse residue), but for trial C (dark) the major residue was chloride (78.1% of tank rinse activity) with only 13.9% of the radioactivity being present as chlorate or perchlorate. The presence of light greatly influences the propensity of radioactive

[a]Concentration in fraction; calculated by dividing the mass of residue by the fraction wt. (μg ÷ g = μg/g). [b]Limit of quantitation; based on the background radioactivity that was determined with each sample set and also based on the sample aliquot size used. [c]Based on the ion chromatographic separation of $^{36}$Cl-chlorite, $^{36}$Cl-chloride, $^{36}$Cl-chlorate, and $^{36}$Cl-perchlorate with determination of radioactivity in trapped fractions by liquid scintillation counting. [d]Radioactivity was detected and quantified in only 1 of 3 replicates. Thus, the calculated concentration is less than the limit of quantification. [e]Sodium chloride derived from $^{36}ClO_2$ gas; residues do not account for endogenous sodium chloride. [f]NDR, no detectable residue; perchlorate concentration in trial C rinsewater was also determined using ion chromatography having an LOQ of 4 ng/L. [g]Analyte was detected in one of three replicates, thus the calculated concentration is less than the LOQ. [h]Analyte was detected in two of three replicates. [i]98.6% of the pellet radioactivity was released by digestion in NaOH; of the released radioactivity, 100% was precipitated with silver nitrate. [j]97.3% of the pellet radioactivity was released by digestion in NaOH; of this, 91% was precipitated with silver nitrate (indicating chloride ions); it was assumed that the remaining 9% of the radioactivity was chlorate and perchlorate in the same proportion as in the stem scar. [k]100% of the pellet radioactivity was released by digestion in NaOH; of this, 97.3% was precipitated with silver nitrate (indicating chloride ions); it was assumed that the remaining 2.7% of the radioactivity was chlorate and perchlorate in the same proportion as in the stem scar.

residue to be deposited on the tank surface (Table 1), with light exposed chamber rinses containing 10.1 to 12.5% of the total starting activity; only 0.6% of the starting radioactivity in the chamber protected from light was deposited on the tank surface.

**Fate of Sodium $^{36}$Cl-Chlorite Injected into Tomatoes.** We hypothesized that instability of sodium chlorite in weak acids[20] would make it virtually impossible for chlorite residues to survive the acidity of tomatoes during processing. This hypothesis was tested by directly injecting sodium $^{36}$Cl-chlorite into tomatoes and subsequently following the chemical fate of the radiolabel. The exposure level selected (131 μg/g of tomato) was chosen to greatly exaggerate concentrations of chlorite in an anticipated commercial fumigation, even if 100% of a chlorine dioxide fumigation were to be converted to chlorite residue.

Radioactive residues injected into tomatoes distributed primarily to the serum fraction (87.3%) after centrifugation with only 13.7% of the activity distributing to the tomato solids. Radioactivity associated with chloride ion represented 98.3% the serum activity, with chlorate ion composing the complement. No chlorite ion was detected, indicating that 100% of the starting chlorite had been consumed. The qualitative (formation of chloride and chlorate) results are consistent with the aqueous degradation of sodium chlorite in the presence of organic acids.[21]

**Fate of $^{36}$Cl-Chlorine Dioxide in a Cantaloupe Fumigation System.** *Disposition of Radioactive Residues.* Table 4 shows the distribution of radioactivity expressed as total dpm in each fraction and as the percentages of the total starting radioactivity for cantaloupe trials A and B. Table 4 also shows the initial cantaloupe weights, the weights of the edible flesh, seed bed, and inedible rind fractions, and the total recovery of weight for each melon. The total recovery of radioactivity was comparable between cantaloupe trials A (89.4%) and B (88.3%). Unrecovered radioactivity (10.6 and 11.7% of the total for trials A and B, respectively) likely resulted from two factors. First, some $^{36}ClO_2$ was almost certainly lost to the atmosphere between sachet activation, positioning in the exposure tank, and sealing the tank. Additionally, $^{36}ClO_2$ may have been lost because of incomplete gas purging at the end of the treatment period or leakage during fumigation.

The total amount of released $^{36}ClO_2$ was calculated as the difference between the total starting activity and the radioactivity recovered in, and on, the reaction sachet. Therefore, about 63% of the starting activity was associated with the

[a]Concentration in fraction; calculated by dividing the mass of residue by the fraction wt. (μg ÷ g = μg/g). [b]Limit of quantitation; based on the background radioactivity that was determined with each sample set and also based on the sample aliquot size used. [c]Based on the ion chromatographic separation of $^{36}Cl$-chlorite, $^{36}Cl$-chloride, $^{36}Cl$-chlorate, and $^{36}Cl$-perchlorate with determination of radioactivity in trapped fractions by liquid scintillation counting. [d]TRR, total radioactive residue. [e]NDR, no detectable residue. [f]LOQ for total radioactive residues assumes all residue is present as sodium chlorate equivalents. [g]Sodium chloride derived from $^{36}ClO_2$ gas; residues do not account for endogenous sodium chloride.

formation of $^{36}ClO_2$ gas in trials A and B. The specific activity of $^{36}ClO_2$ for each trial was 135 dpm/μg; therefore 104 and 103 mg of $^{36}ClO_2$ were produced in trials A and B, respectively. The cantaloupe weights used for trials A and B were 851.6 and 850.0 g, respectively, corresponding to $ClO_2$ exposures of 123 and 122 mg/kg of cantaloupe. Because *maximal* commercial exposures to chlorine dioxide are expected to be 100 mg of chlorine dioxide per kg of cantaloupe, data presented in this study represent residue levels commensurate with 120% over exposure relative to expected.

Cantaloupes retained 32.5 and 37.4% of the total radioactive charge in trials A and B (Table 4), respectively, representing 51.5 and 60.0% of the total $^{36}ClO_2$ produced from each reaction. Of the TRR present on the cantaloupe, greater than 99.97% of the cantaloupe radiochlorine was associated with the rind, regardless of trial (Table 4). Radioactive residues present

[a]Data are means ± standard deviations of four observations unless indicated by a footnote. NDR signifies no detectable residue. Statistical inferences of chlorate residues generated under lighted conditions were generated using log-transformed data (to meet the equal variance assumption). [b]Nominal concentrations of 600 and 3000 ppmv for the 1.6 and 7.8 mg reactions, respectively. [c]LOQ, 4 μg/L; LOD, 1 μg/L. Data are expressed on a sodium perchlorate equivalent basis. [d]Three of four replicates had no detectable residue; a single replicate had residues >LOD but less than the LOQ. [e]LOQ, 5 μg/L; LOD, 1 μg/L. Data are expressed on a sodium chlorate equivalent basis. [f]Single observation; remaining replicates had NDR. [g]All replicates had chlorate residues less than the LOQ, but greater than the LOD.

in the edible flesh portion of the cantaloupe were below the LOQ of the radiochemical assay (0.240 to 0.360 μg/g of sodium chlorite equivalents). Total radioactive residues present in seed beds represented 0.03% of the total radioactivity produced as $^{36}ClO_2$. Activity removed from the surfaces of the exposure tank, glass pedestal, and stir bar accounted for 1.7% of the total radioactivity in trial A and 2.9% in trial B. Gas purged from the exposure tank represented 18.2% of the initial activity for trial A and 10.5% for trial B. The sachet and its contents contained 37.0 and 37.6% of initial activity respectively for A and B.

Radioactive residues were not detected in edible cantaloupe flesh, indicating that chlorine dioxide gas does not penetrate the rind and acts at the cantaloupe surface. In the inedible rind fraction, radioactivity was nearly equally distributed between the rind serum (57.4 and 45.2% of rind radioactivity in trials A and B, respectively) and pellet fractions (42.6 and 54.8% of rind radioactivity in trials A and B, respectively) even though the serum fraction was the greatest by weight. Because the serum fractions represented 64 to 80% of the total rind fraction, relative concentrations of radioactivity were greater in the rind pellet fractions than in the rind serum fractions.

*Speciation of Radioactive Residues.* Table 5 summarizes residues of $^{36}$Cl-chlorite, $^{36}$Cl-chloride, $^{36}$Cl-chlorate, and $^{36}$Cl-perchlorate measured in fractions containing sufficient radioactive residues for speciation: rind serum and tank rinse fractions for both trials A and B. No sodium $^{36}$Cl-chlorite was detected in inedible rind serum or tank rinse, whereas sodium $^{36}$Cl-chloride was the predominant $^{36}ClO_2$-derived residue on cantaloupe rind comprising 86 to 87% of the rind radioactivity. The only other non-chloride residue on cantaloupe rind of trial A was sodium $^{36}$Cl-chlorate representing about 13% of the rind TRR with sodium $^{36}$Cl-perchlorate being nondetectable in rind serum of trial A, but representing 0.7% of the rind radioactivity in trial B (1.2 μg/g). In the tank rinse fraction, sodium $^{36}$Cl-chlorate and sodium $^{36}$Cl-perchlorate were the predominant radioactive residues, with sodium chlorate representing 56 to 80% of the total residue, and sodium perchlorate representing 14 to 33% of the total residue with sodium chloride a minor radioactive residue, representing 6 to 11% of the TRR. No effort to protect the cantaloupe exposures from light was made. Subsequent experiments with nonlabeled chlorine dioxide have demonstrated that chlorate and perchlorate formation during fumigation of cantaloupe can be essentially eliminated by protecting the reaction from light.

It is notable that the percentage compositions of radioactive residues on the cantaloupe rind and tank rinse fractions were not very similar. On the rind, sodium chloride was, by far, the major chlorine dioxide degradation product, representing between 86 and 87% of the radioactivity, with chlorate representing essentially the balance of activity. Such results are consistent with chlorine dioxide reductive processes and aqueous disproportionation reactions.[21,22] In contrast, glass surfaces contained mainly chlorate (55 to 80% of total glass rinse residue) and perchlorate (14 to 33% of total glass rinse residue), with lesser quantities of sodium chloride (6 to 11% of rinse radioactivity). The formation of mainly perchlorate and chlorate on glass surfaces is consistent with light catalyzed gas-phase reactions.[23,24] The formation of perchlorate from chlorine dioxide gas generated under a number of conditions is light dependent.[25,26]

As stated earlier, puree of edible flesh had no detectable residues in either trial A or B with LOD/Qs below 0.5 μg/g for sodium chlorite, sodium chlorate, and sodium perchlorate. Because it was reasoned that radioactive residues might concentrate in either the solid or liquid portions of the edible flesh, the puree was centrifuged to form liquid (serum) and pellet fractions. When serum was assayed, radioactive residues were detected in trial B cantaloupe edible flesh serum, but not in serum from trial A. Because a 1 g sample size was used to assay serum from trial B, a lower detection limit (<0.12 μg/g for each of sodium chlorite, sodium chlorate, and sodium perchlorate) was obtained. Precipitation of radioactive residues present in trial B serum with silver nitrate caused a 90% loss of activity from the serum, indicating that at least 90% of the edible flesh serum was sodium $^{36}$Cl-chloride. Assuming that the remaining 10% of the radioactive residue in edible flesh serum of trial B was either sodium $^{36}$Cl-chlorate or sodium $^{36}$Cl-perchlorate, then the concentration of radioactivity, expressed as sodium chlorate or sodium perchlorate equivalents, in serum would be 0.017 or 0.019 ng/g, respectively.

*Factors Impacting the Formation of Chlorate and Perchlorate Byproducts from Chlorine Dioxide Fumigation.* This experiment was conducted with a balanced factorial design

with level of chlorine dioxide, laboratory illumination, and reagent matrix (dry vs liquid) as main factors. Table 6 summarizes results of the experiment in which chlorate and perchlorate recovered in reaction jar rinsewater are expressed as $\mu$g/L of the sodium salt equivalents.

Data presented in Table 6 clearly demonstrate that light had a major impact on the formation of both perchlorate and chlorate from chlorine dioxide. Under dark conditions, insufficient perchlorate was formed to exceed the assay LOQ of 4 $\mu$g/L. Of the 16 samples excluded from light, perchlorate was formed in only two samples at levels that surpassed the assay LOD of 1 $\mu$g/L. In contrast, the reaction chambers exposed to light had mean perchlorate concentrations ranging from 438 to 4,334 $\mu$g/L, depending upon the amount of chlorine dioxide produced. In a similar manner, light catalyzed the formation of chlorate (means of 998 to 17,947 $\mu$g/L) on vessel walls; but under dark conditions, chlorate residues were either not detectable (LOD of 1 $\mu$g/L) or low, with a maximum concentration of 11 $\mu$g/L (Table 6). Statistical comparisons between means from dark and light exposed vessels were not possible because the darkened vessels contained insufficient chlorate and perchlorate for the calculation of treatment means (Table 6).

For the treatments exposed to light, however, significant ($P < 0.001$) main effects for both chlorine dioxide concentration and the reaction matrix were noted (Table 3). For perchlorate, a highly significant ($P < 0.001$) interaction between the target chlorine dioxide concentration and reaction matrix was observed, so no simple relationship existed. For chlorate, main effects of chlorine dioxide concentration ($P < 0.01$) and reaction matrix ($P = 0.02$) were significant, with the high chlorine dioxide concentration and liquid reaction matrix consistently producing greater quantities of chlorate than the low chlorine dioxide target concentration and the dry matrix.

The literature suggests that both light[23,24] and gas concentration[27] affect chlorine dioxide stability. Our data are also consistent with the notion that chlorine dioxide decomposition is catalyzed by light and (or) high gas concentrations. Spinks and Porter[23] reported the formation of perchlorate by gaseous chlorine dioxide decomposition, and the formation of perchlorate was dependent upon the presence of water vapor. Crawford and Dewitt[24] suggested that water vapor reacts with unstable chloroxy intermediates to form acid gases of chlorate and perchlorate. They also reported a wall to vessel volume relationship in the rate of reaction intermediate termination; presumably vessel walls act as terminal points for unstable radicals created during gas decomposition. Such data might explain the relatively high degree of deposition of $^{36}$Cl-chorate and $^{36}$Cl-perchlorate on vessel walls in which light exposure was not controlled, even with the presence of chlorine dioxide sinks (tomatoes or cantaloupe).

In the absence of light, but in the presence of water vapor, the terminal (i.e., stable) decomposition products of chlorine dioxide gas would be chlorate and chloride, consistent with the aqueous decomposition of chlorine dioxide.[22,28] Our data (Table 6), however, strongly suggest that, even in the presence of water vapor (i.e., liquid matrix), light must be present to catalyze the formation of chlorate (and also perchlorate). Thus, the mechanism for the formation of both perchlorate and chlorate is through the light catalyzed formation of unstable[25] intermediates such as chlorine perchlorate ($Cl_2O_4$).[26]

Collectively, the experiments reported herein clearly indicate the potential for chlorine dioxide fumigation of vegetables and melons from a residue chemistry perspective. Studies using radiolabel, for example, indicate that edible flesh of cantaloupe contains no chlorine dioxide related residue whatsoever. Additionally, for either tomato or cantaloupe, the major residue associated with vegetable matter is the chloride ion. Nevertheless, radiolabeled studies also show the potential for both chlorate and perchlorate formation during $ClO_2$ fumigation, especially if the fumigation is not protected from light. Further work is being conducted to determine fumigation conditions under which the formation of chlorate and perchlorate on vegetable matter may be minimized or prevented entirely. These studies will provide data supporting or refuting the concept that chlorine dioxide fumigation of produce can be accomplished without the formation of undesirable residual chloroxyanions.

processing of preproproteins,[20] and the 7S globulin from certain plant species also undergoes N-glycosylation.[22] The 7S (Jug r 2) and 11S (Jug r 4) globulin allergens of walnut appear to follow similar patterns of posttranslational modification, but the specific processing mechanisms for this plant are poorly characterized, and the presence of N-linked glycans on Jug r 2 has yet to be demonstrated.[11,13]

Despite their early entrance into the study of plant proteins and their importance for food allergy, relatively few characterization studies have been conducted on walnut proteins, particularly regarding the natural form of the protein occurring in the nut. The objective of this study was to purify and characterize the natural 2S albumin allergen from English walnut. During the course of the study, however, an additional low molecular weight protein species was encountered with its own potential allergenic activity. Electrophoresis and mass spectrometry were employed to characterize these low molecular weight proteins, and their allergenic activity was assessed with a panel of walnut-allergic subjects' sera.

## MATERIALS AND METHODS

**Walnut-Allergic Subject Samples.** A panel of either serum or plasma was assembled from individuals with positive walnut-specific IgE (ImmunoCAP; Thermo Scientific, Uppsala, Sweden) and a convincing history of food allergy to walnut (Table 1). The patient panel was identified from clinic populations in either the United Kingdom (Manchester Respiratory and Allergy Biobank; ManRAB) or Spain (Hospital Clínico San Carlos, Madrid or Hospital Clínic, Barcelona). A pool of plasma from nine atopic, non-food-allergic subjects from Manchester was used as a negative control. Written informed consent was obtained from all patients, either specifically for this study (Madrid and Barcelona) or for future research studies following donation (ManRAB). Ethical approvals for the use of sera were obtained from the appropriate committees (National Research Ethics Service, Research Ethics Committee, 10/H1010/7, ManRAB; Comité Ético de Investigación Clínica and Comité de Investigación del Hospital Clínic, 2012/7805, Barcelona; Comité Ético de Investigación Clínica del Hospital Clínico San Carlos de Madrid, C.P.-C.I 12/365-E, Madrid).

**Materials and Walnut Preparation.** English walnuts (*J. regia* cv. Chandler) were purchased from Gold River Orchards (Oakdale, CA, USA) as raw light halves and pieces. The walnuts were ground (under liquid nitrogen, which was subsequently allowed to evaporate), and defatted walnut flour (DWNF) was produced by combining ground walnuts with hexane at a 1:5 (v/v) ratio and stirring for 1 h at room temperature. The lipid fraction was removed, the partially defatted flour was allowed to dry overnight, the dried flour was ground further, and the defatting process was repeated to produce the final DWNF (stored at −80 °C). Unless stated otherwise, all other chemical reagents were obtained from Sigma-Aldrich (Dorset, UK).

**Purification of Low Molecular Weight Walnut Proteins.** Extraction of protein from DWNF was performed with a high-salt buffer (25 mM Tris-HCl, pH 7.5, containing 1.5 M NaCl, 3 mM sodium azide). Following hydration of 3.5% (w/v) poly(vinylpolypyrrolidone) in the buffer, soluble proteins were extracted from DWNF at a 1:50 (w/v) ratio for 1 h at room temperature, with constant stirring and pH adjustment to 7.5 every 30 min. The extract was centrifuged (3600*g*, 30 min, 15 °C), and the supernatant was filtered (Whatman no. 1 filter paper and sequential 0.45 and 0.2 $\mu$m syringe filters). Total soluble protein concentrations of the DWNF extract and selected protein fractions were determined by microwell BCA assay.

The chromatographic portion of the purification consisted of ConA, gel filtration, and anion exchange stages. The high salt concentration in buffers (1.5 M NaCl) was retained for ConA and gel filtration chromatography to maintain protein solubility. The ConA chromatography was conducted with a Pharmacia XK 16 column (GE Healthcare Life Sciences, Little Chalfont, UK), packed with Concanavalin A Sepharose conjugate and connected to a BioCAD Sprint LC system (Applied Biosystems, Life Technologies, Paisley, UK). Following column equilibration and walnut extract loading, unbound (non-glycosylated) proteins were eluted (in the high-salt buffer used for extraction), followed by bound (glycosylated) proteins (in 25 mM Tris-HCl, pH 7.5, containing 0.4 M methyl $\alpha$-D-mannopyranoside, 1.5 M NaCl, and 3 mM sodium azide). The unbound, protein-containing fractions were pooled and concentrated 4-fold using a stirred-cell ultrafiltration apparatus (5 kDa nominal molecular weight limit (NMWL) membrane; Amicon, Millipore, Watford, UK). The concentrated, unbound fraction (UB pool) was subsequently used for gel filtration chromatography. The bound (glycosylated) fractions were not used further in this study, as they primarily contained higher molecular weight proteins (gel electrophoresis, data not shown).

Separation of UB pool proteins by gel filtration was conducted with a HiLoad 16/600 Superdex 200 column (GE Healthcare Life Sciences, calibrated with Bio-Rad (Hercules, CA, USA) Gel Filtration Standard

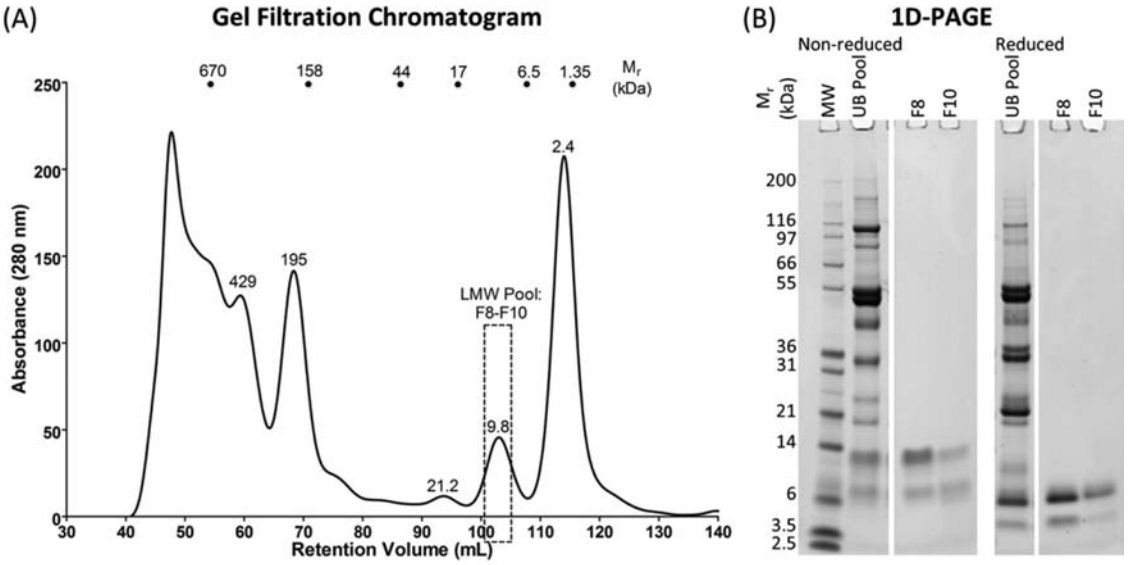

**Figure 1.** Gel filtration and 1D-PAGE analysis of nonglycosylated walnut proteins. (A) The gel filtration chromatogram has the calculated $M_r$ values labeled above each major peak and a dashed box indicating the fractions included in the LMW pool. Points along the top of the chromatogram indicate retention volumes of MW standards. (B) The 1D-PAGE image includes unbound material obtained from ConA chromatography (UB pool, 7.8 $\mu$g of protein loaded) and gel filtration fractions F8 and F10 (loaded in equal volumes) analyzed under nonreducing and reducing conditions. Molecular weight markers (MW) were also loaded (Mark12 unstained standards, Invitrogen; 5 $\mu$L loaded).

and Sigma-Aldrich aprotinin) connected to an ÄKTA FPLC system (Amersham Pharmacia Biotech, GE Healthcare Life Sciences). Following loading, proteins were eluted with the high-salt extraction buffer over 1.2 column volumes. Fractions F8−F10 (retention volume 100.5−105 mL) were combined in equal volumes to give a pooled low molecular weight fraction (LMW pool).

The LMW pooled fraction was dialyzed (3500 Da molecular weight cutoff membrane, against 20 mM Tris-HCl, pH 8.0) and concentrated by ultrafiltration (1 kDa NMWL membrane, Millipore). Anion exchange was conducted with a POROS HQ20 column (4.6 × 100 mm) connected to a BioCAD Sprint LC system. The column was equilibrated in 20 mM Tris-HCl, pH 8.0, running buffer [40% A (50 mM Tris-HCl), 60% B ($H_2O$)]. The LMW pooled fraction was loaded, the column was washed (2.0 column volumes of running buffer, 3.00 mL/min), and proteins were eluted [0−300 mM NaCl linear gradient; 40% A and 60% B to 40% A, 45% B, and 15% C (2.0 M NaCl); 3.00 mL/min]. Fractions were analyzed by gel electrophoresis and mass spectrometry.

**Gel Electrophoresis.** One-dimensional PAGE (1D-PAGE) was conducted with NuPAGE Novex 4−12% Bis-Tris precast gels. Samples were prepared per the manufacturer's instructions, under reducing (50 mM DTT) or nonreducing conditions. Equal volumes of purification fractions (following each chromatographic stage) were loaded, along with Mark12 Unstained Standards, and separated (MES SDS running buffer, 200 V, 35 min). Gels were fixed [50% (v/v) methanol, 10% (v/v) acetic acid; 2 h], stained (SimplyBlue Safe Stain, overnight), and destained (deonized water, 2 h). Gel images were acquired with a Bio-Rad GS-800 scanner. All 1D-PAGE reagents were obtained from Invitrogen (Life Technologies).

**Identification of Protein Bands by MS.** Protein bands were excised from 1D-PAGE gels for in-gel trypsin digestion. Briefly, gel plugs were destained, reduced (10 mM DTT, 30 min at 60 °C), and alkylated (100 mM iodoacetamide, 30 min at room temperature in the dark) and proteins digested with trypsin (Promega Trypsin Gold, Mass Spectrometry grade, 50 ng per plug, 3 h at 37 °C). The digestion was stopped (1% (v/v) formic acid) and peptides were eluted from the gel (50% (v/v) acetonitrile). The peptide solutions were dried in a vacuum centrifuge and resuspended in 0.1% (v/v) formic acid in water for LC-MS/MS analysis.

The tryptic digest samples were analyzed by LC-MS/MS (nanoACQUITY UPLC, Waters Corp., Milford, MA; LTQ Orbitrap XL, Thermo Scientific, Waltman, MA, USA). Peptides were trapped online to a Symmetry C18 trap column (5 $\mu$m, 180 $\mu$m × 20 mm; Waters Corp.), which was subsequently switched to an inline UPLC with a 75 mm × 250 $\mu$m i.d., 1.7 $\mu$m, BEH C18 analytical column (Waters Corp.). Peptides were separated with a gradient of 3−60% (v/v) acetonitrile in water with 0.1% (v/v) formic acid over 25 min at 250 nL $min^{-1}$. A nanospray source was used, and the mass spectrometer was operated in positive ion mode. Precursor ions were measured in the Orbitrap (60000 resolution over the mass range $m/z$ 300−2000). The Orbitrap was operated in data-dependent acquisition mode, and the top five precursor ions (2+ or 3+ charge states) were selected for collision-induced dissociation (CID) fragmentation (dynamic exclusion enabled). Product ions were analyzed in the ion trap (rapid scan rate and normal mass range).

Mascot generic format (mgf) files were generated (Proteome Discoverer software, Thermo Scientific) and searched against the UniProt database (downloaded March 3, 2011; Viridiplantae taxonomy; 592,152 sequences with filter) using a local Mascot server (version 2.2.06, Matrix Science, London, UK). The search parameters were as follows: one missed tryptic cleavage; carbamidomethyl (C) and oxidation (M) as fixed and variable modifications, respectively; peptide mass tolerance of 5 ppm; MS/MS tolerance of 0.6 Da; and Mascot peptide significance threshold of 0.05. The MS proteomics data have been deposited to the ProteomeXchange Consortium (http://proteomecentral.proteomexchange.org) via the PRIDE partner repository[23] (data set identifier PXD000634 and DOI 10.6019/PXD000634).

**Intact Mass Determination by MS.** MALDI-TOF MS was used to analyze the intact masses of the LMW proteins. The LMW pooled fraction (prior to dialysis, concentration, and anion exchange chromatography) was analyzed before and after reduction (DTT added to 5 mM, 10 min at 90 °C) and alkylation (iodoacetamide added to 10 mM, 20 min at room temperature in the dark). Samples were plated onto a polished stainless steel target with a DHB matrix [10 mg of 2,5-dihydroxybenzoic acid in 30% (v/v) acetonitrile, 70% (v/v) water with 0.1% (v/v) TFA] using the dried drop method (0.5 $\mu$L each of matrix and sample). Calibration standards (ProteoMass Peptide & Protein MALDI-MS Calibration Kit; Sigma-Aldrich) were prepared according to the manufacturer's instructions and plated in the same manner. Intact protein spectra were acquired using a Bruker Ultraflex II MALDI-TOF/TOF instrument (Coventry, UK). Positive

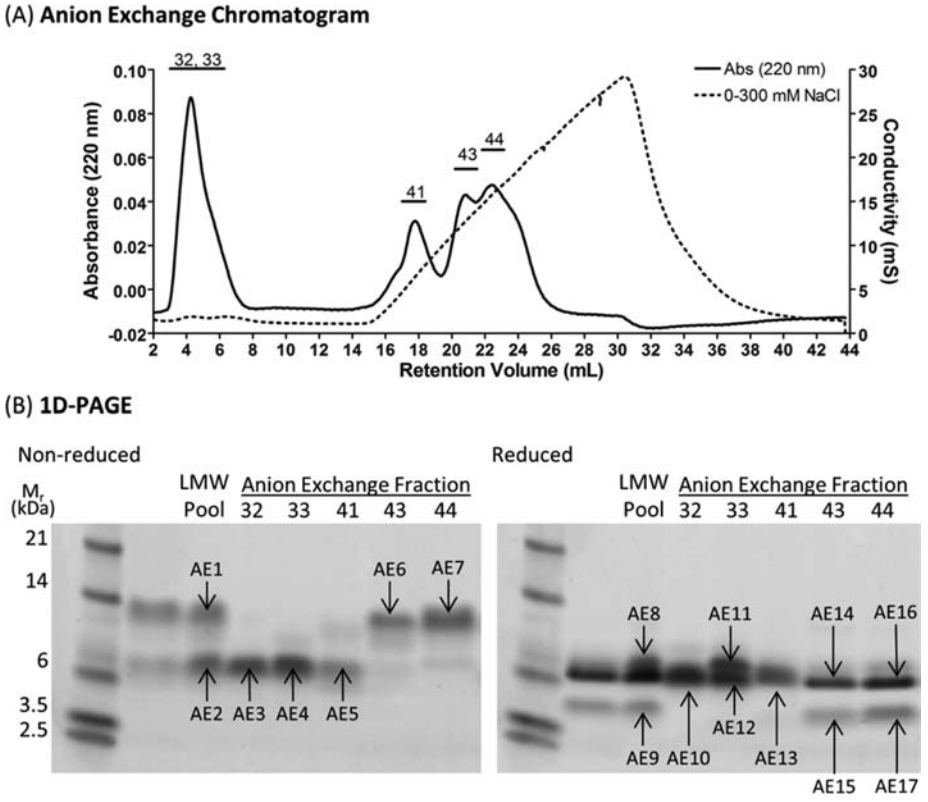

**Figure 2.** Anion exchange separation of LMW pool proteins and 1D-PAGE analysis of resultant fractions. (A) Anion exchange chromatogram shows separation of polypeptides in LMW pool obtained from gel filtration chromatography. (B) The 1D-PAGE of the low molecular weight (LMW) pool (1.8 μg protein) and equal volumes of the anion exchange fractions includes analysis under nonreducing and reducing conditions, with labels indicating bands selected for LC-MS/MS analysis.

ions were analyzed in linear mode, with 200 shots per sample used to produce a summed spectrum.

**IgE Immunoblotting.** Proteins in the LMW pooled fraction (1.0 μg per lane), along with SeeBlue Prestained Standards (Invitrogen), were separated by 1D-PAGE under nonreducing and reducing conditions (described above) and electroblotted onto a polyvinylidene fluoride membrane (0.2 μm, Immobiolon-P$^{SQ}$; Millipore) using a semidry transfer apparatus (Trans-Blot SD Semi-Dry Cell, Bio-Rad). Following protein transfer, membranes were blocked with 0.01 M PBST [0.002 M $NaH_2PO_4$, 0.008 M $Na_2HPO_4$, pH 7.4, containing 0.85% (w/v) NaCl and 0.05% (v/v) Tween 20] containing 5% (w/v) nonfat dry milk (NFDM) for 2 h at room temperature with gentle shaking. Individual serum/plasma samples were diluted 1:10 (v/v) in 0.01 M PBST containing 2.5% (w/v) NFDM. Diluted serum or plasma (0.05 mL/cm$^2$) was applied to the blocked membranes and incubated overnight at room temperature. Bound IgE was detected with a horseradish peroxidase-conjugated mouse anti-human IgE antibody (SouthernBiotech; Birmingham, AL, USA) and a chemiluminescent substrate (Pierce SuperSignal West Dura Extended Duration Substrate, Rockford, IL, USA). Images of chemiluminescence were acquired for 5 min with a CCD camera (FUJIFILM Luminescent Image Analyzer LAS-1000plus, Bedford, UK).

## RESULTS AND DISCUSSION

An extract of defatted walnut flour, prepared using a high-salt buffer, was subjected to ConA affinity chromatography to selectively remove N-glycosylated proteins. Although 2S albumins are classically extracted in water, the addition of salt was found to enhance their extraction from walnut (data not shown).The resulting fraction enriched in nonglycosylated proteins was further separated using gel filtration chromatography. A protein peak with a median relative molecular mass ($M_r$) of 9.8 kDa (LMW Pool, Figure 1A) was retained and analyzed by 1D-PAGE (Figure 1B). This analysis revealed the presence of two protein bands ($M_r$ 11.8 and 6.5 kDa), which after reduction showed a change in mobility, resolving as two bands ($M_r$ 6.0 and 4.2 kDa; Figure 1B).

The polypeptides in the LMW pool were further fractionated using anion exchange chromatography (Figure 2A). 1D-PAGE analysis of fractions from all protein-containing peaks revealed multiple protein band patterns (Figure 2B). The patterns observed with fractions 43 and 44 were analogous to the characteristic bands of other 2S albumins. Specifically, an intact protein of approximately 12 kDa under nonreducing conditions (AE6 and AE7) separated into large (6 kDa; AE14 and AE16) and small (4 kDa; AE15 and AE17) subunits upon reduction. The other fractions (32, 33, and 41) did not exhibit protein band patterns consistent with typical 2S albumin behavior. These fractions all delivered bands of 6−7 kDa on 1D-PAGE, under both nonreducing and reducing conditions (AE3, AE5, and AE10−13). The band patterns from the LMW pool demonstrated the coexistence of these two mobility patterns prior to anion exchange fractionation (AE1, AE2, AE8, and AE9).

In-gel trypsin digestion and LC-MS/MS analysis were used to identify the polypeptides observed with 1D-PAGE (Figure 2B; Table 2). A full listing of peptide spectrum matches is provided in Supporting Information Table S1. As expected, the polypeptides exhibiting typical 2S albumin mobility patterns in the LMW pooled fraction (AE1, AE8, AE9) and in fractions 43 and 44 (AE6, AE7, and AE14−17) were identified as English walnut 2S albumin (UniProt P93198; Figure 2; Table 2). This

**Table 2. LC-MS/MS Identifications of Anion Exchange 1D-PAGE Bands[a]**

| 1D-PAGE band | protein (UniProt accession) | Mascot protein score |
|---|---|---|
| AE1 | 2S albumin (P93198) | 366 |
| AE2 | 7S globulin; pecan (B3STU4/B3STU7) | 239 |
| AE3 | 7S globulin; pecan (B3STU4/B3STU7) | 151 |
| AE4 | 7S globulin; pecan (B3STU4/B3STU7) | 200 |
| AE5 | 7S globulin; walnut (Q9SEW4) | 224 |
| AE6 | 2S albumin (P93198) | 294 |
| AE7 | 2S albumin (P93198) | 349 |
| AE8 | 2S albumin (P93198) | 308 |
| AE9 | 2S albumin (P93198) | 177 |
| AE10 | 7S globulin; pecan (B3STU4/B3STU7) | 116 |
| AE11 | 7S globulin; pecan (B3STU4/B3STU7) | 206 |
| AE12 | 2S albumin (P93198) | 204 |
| AE13 | 7S globulin; pecan (B3STU4/B3STU7) | 226 |
| AE14 | 2S albumin (P93198) | 282 |
| AE15 | 2S albumin (P93198) | 213 |
| AE16 | 2S albumin (P93198) | 339 |
| AE17 | 2S albumin (P93198) | 186 |

[a]The top-ranked protein match (and UniProt accession number) for each band labeled in Figure 2B is given in the table, along with the corresponding Mascot protein score.

walnut 2S albumin was also identified as the top-ranking protein in band AE12, indicating the presence of the protein or a protein fragment in fraction 33.

The remaining low $M_r$ polypeptides in the second set of ion exchange fractions (32, 33, 42) were identified as the 7S seed storage globulin from pecan (*Carya illinoinensis*, B3STU4/B3STU7) and English walnut (Q9SEW4) (Figure 2; Table 2). This result is inconsistent with the experimentally determined $M_r$ of the mature 7S globulin from walnut (44−48 kDa by SDS-PAGE).[11] Inspection of the peptide spectrum matches from these bands showed that the peptide matches were located exclusively in the N-terminal regions of the pecan and walnut 7S globulin sequences (Figure 3A). However, all peptides were not identified in all 1D-PAGE bands (Figure 3B), indicating differences among the bands or in the compatibility of the various peptides with LC-MS/MS. The localization of peptides in the N-terminal region also explains the higher protein scores for the 7S globulin from pecan, as the walnut sequence currently in the public databases is incomplete in the N-terminal region. The walnut and pecan sequences are very similar throughout the portion of the walnut 7S sequence present in the database (92% identical), and therefore the peptide spectrum matches assigned exclusively to the pecan proteins can be assumed to be homology-based matches to walnut proteins and not indicative of the presence of pecan.

As is the case with many seed storage proteins, the 7S vicilin-like globulins are frequently synthesized as a pre-proprotein, which undergoes posttranslational proteolytic processing to produce the mature protein.[20] In some plant species (e.g., peanut, soy, pumpkin, cocoa, and cotton) evidence indicates that along with the proteolytic removal of the signal peptide, an additional hydrophilic portion of the proprotein N-terminal region is removed during the production of the 7S globulin.[24−31] On the basis of N-terminal sequencing data from the mature walnut 7S globulin (indicating an N-terminus at amino acid 173 of the full sequence), the walnut 7S globulin preproprotein processing appears to be similar to that observed in cocoa and cotton, where a large hydrophilic N-terminal region is removed.[11,24,26] Despite the well-documented presence of posttranslational processing of the 7S preproproteins in various plants, the fates of the hydrophilic N-terminal regions are often unknown, as studies have focused primarily on characterization of the mature 7S proteins.

The peptide matches obtained from the LC-MS/MS analysis spanned the entire length of the N-terminal regions of the pecan and walnut 7S proprotein sequences, but the corresponding theoretical masses (46.3 and 21.8 kDa, respectively) are much larger than the molecular masses estimated for the 1D-PAGE bands (5.8−6.7 kDa), implying that this region has undergone significant proteolysis in the seed. MALDI-TOF MS was undertaken on the LMW pooled fraction (under nonreduced and reduced/alkylated conditions) to characterize the molecular masses of the 7S globulin N-terminal fragments and the 2S albumin (Figure 4). Due to the unfractionated nature of the LMW pool, the resulting spectra were complex. On the basis of the LC-MS/MS identifications from 1D-PAGE, the 2S albumins are responsible for peaks near $m/z$ 12600 in the nonreduced sample and $m/z$ 8400 and 3000−4000 in the reduced/alkylated sample. The 7S globulin N-terminal peptides were responsible for the remaining peaks in the $m/z$ 5500−7500 region of both spectra.

Inspection of the $m/z$ range corresponding to the 7S globulin N-terminal peptides ($m/z$ 5500−7500) revealed a consistent pattern of peaks, which showed an $m/z$ shift of +232 Da between the nonreduced and reduced/alkylated samples (Figure 4, inset; Table 3). A shift of this mass is equivalent to the reduction of two disulfide bonds and alkylation of four cysteine residues (net mass change of +58 Da per cysteine residue). The N-terminal regions of the walnut and pecan 7S proproteins are rich in cysteine residues (containing 12 and 25 residues, respectively), which appear to be arranged in clusters of 4 (Figure 3C).

In addition to providing information about the 7S globulin N-terminal peptides, the MALDI-TOF spectra also revealed characteristics of the 2S albumin from walnut. The main peak corresponding to the intact (nonreduced) protein had a mass of 12617.2 Da (Figure 4). The predominant peaks for the small and large subunits were observed at $[M + H]^+$ 4640.1 and 8440.72 Da, respectively, which corresponds well with the predicted mass following reduction and alkylation of four cysteine bonds of the intact protein. Minor peaks were also observed in the regions associated with the intact 2S albumin ($m/z$ 12373.25) and its subunits ($m/z$ 8571.20, 8457.65, 4768.26, 4395.25, 4229.24, 4073.20, 4002.19, 3828.19, 3591.67, 3552.70, and 3435.28). Other tree nut 2S albumins, such as Brazil nut, have a documented level of heterogeneity, due to both sequence isoforms and posttranslational proteolytic processing.[32] In the case of the 2S albumin from English walnut, however, it is difficult to assign all MALDI-TOF or LC-MS/MS spectra as there is only one sequence isoform present in the protein databases.

The role of the English walnut 2S albumin as an allergen was established previously,[10] and it was given the allergen designation Jug r 1. The importance of the 7S N-terminal peptides as allergens in walnut is less well-understood. IgE immunoblotting of the LMW pooled fraction revealed that 3/

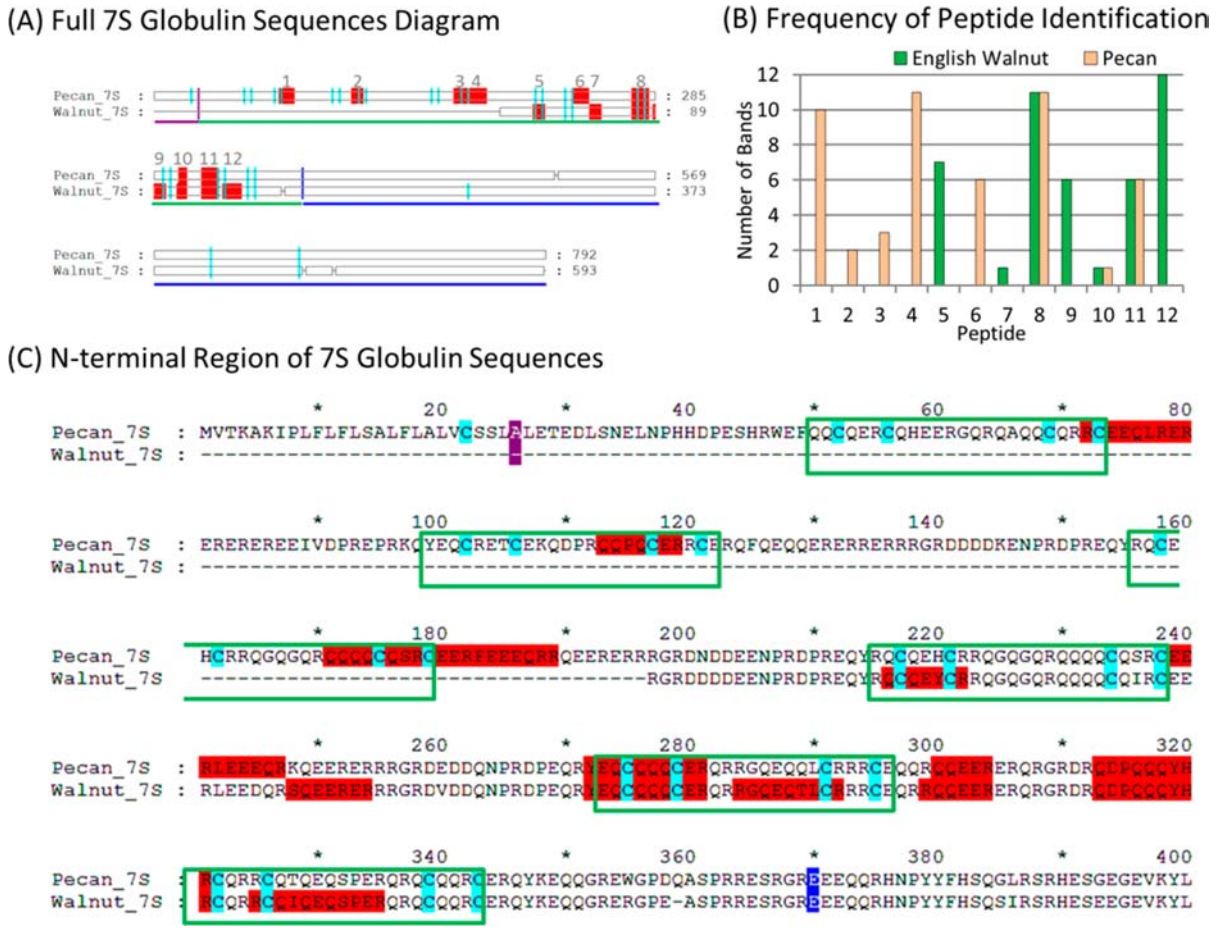

**Figure 3.** Peptide spectrum matches from anion exchange 1D-PAGE bands: (A) aligned, full-length English walnut and pecan 7S globlulin sequences (Q9SEW4 and B3STU4, respectively) are represented as white bars, labeled with red compiled sequence coverage, cyan cysteine residues, purple predicted signal peptide, green N-terminal region, and blue mature 7S globulin protein.[11] (B) The frequency of peptide occurrence is indicated as the number of 1D-PAGE bands in which each peptide (as numbered in panel A) was identified. (C) N-terminal regions of aligned English walnut and 7S globulin sequences are shown with red compiled peptide spectrum matches from all anion exchange LC-MS/MS analysis, purple predicted end of signal peptide, blue N-terminus of mature peptide,[11] and green conserved four-cysteine motifs (C-X-X-X-C-X$_{10-12}$-C-X-X-X-C) labeled.

11 (27%) sera from walnut-sensitized individuals demonstrated IgE binding to the 7S N-terminal peptides, whereas 5/11 (45%) showed IgE binding to the 2S albumin (Figure 5).

The proportion of sera reacting to the 2S albumin was less than the 75% reported by Teuber et al., but the differences could be due to a number of factors, including differences in patient geographical distribution.[10] Interestingly, in the current study, the IgE binding activity seems to be greatly decreased (to levels below the detection limit of the system utilized) when the proteins are analyzed under reducing conditions, which could indicate the presence of conformational epitopes. During the purification of nonspecific lipid transfer protein from English walnut, Pastorello et al. also isolated two peptides originating from the N-terminal region of the 7S vicilin-like globulin, which could be similar to the ones obtained in the present study based on N-terminal sequencing data.[12] In their study population, 10/46 (22%) patient sera showed IgE reactivity to at least one of the 7S globulin fragments, indicating similar levels of reactivity in the two populations.

The polypeptides from the N-terminal region of the English walnut 7S globulin proprotein described in this study are not an isolated occurrence. Similar cysteine-rich peptide fragments have been observed in macadamia nuts. Marcus et al. reported the presence of a series of antimicrobial peptides originating from the N-terminal region of the macadamia nut 7S globulin proprotein.[33] All of the peptides contained the following four-cysteine motif: C-X-X-X-C-X$_{10-12}$-C-X-X-X-C. Both the walnut and pecan 7S globulin sequences contain the same motif repeated three and six times, respectively, throughout the N-terminal region (Figure 3C), and this type of four-cysteine motif is consistent with the mass shifts observed in the MALDI-TOF spectra. The cumulative evidence in the current study indicates that the walnut 7S N-terminal fractions contain a heterogeneous mixture of peptides centered around these types of four-cysteine motifs. The presence of these motifs provides valuable information about the structure and possible biological function of these peptides.

In addition to their documented presence in some tree nut species, similar peptides have been described in other plant species.[34−36] The homologous peptide BWI-2b from buckwheat (*Fagopyrum esculentum*) functions as a trypsin inhibitor and exhibited IgE reactivity in 4/12 buckwheat-allergic subject sera.[34] In addition, the major buckwheat allergen, Fag e 3, also has homology with the 7S globulin proprotein N-terminal region.[35] Another homologous peptide from buckwheat, BWI-2c, was recently sequenced and described as having potent trypsin inhibition functionality and an $\alpha$-helical hairpin structure, stabilized by disulfide bonds of the four-cysteine

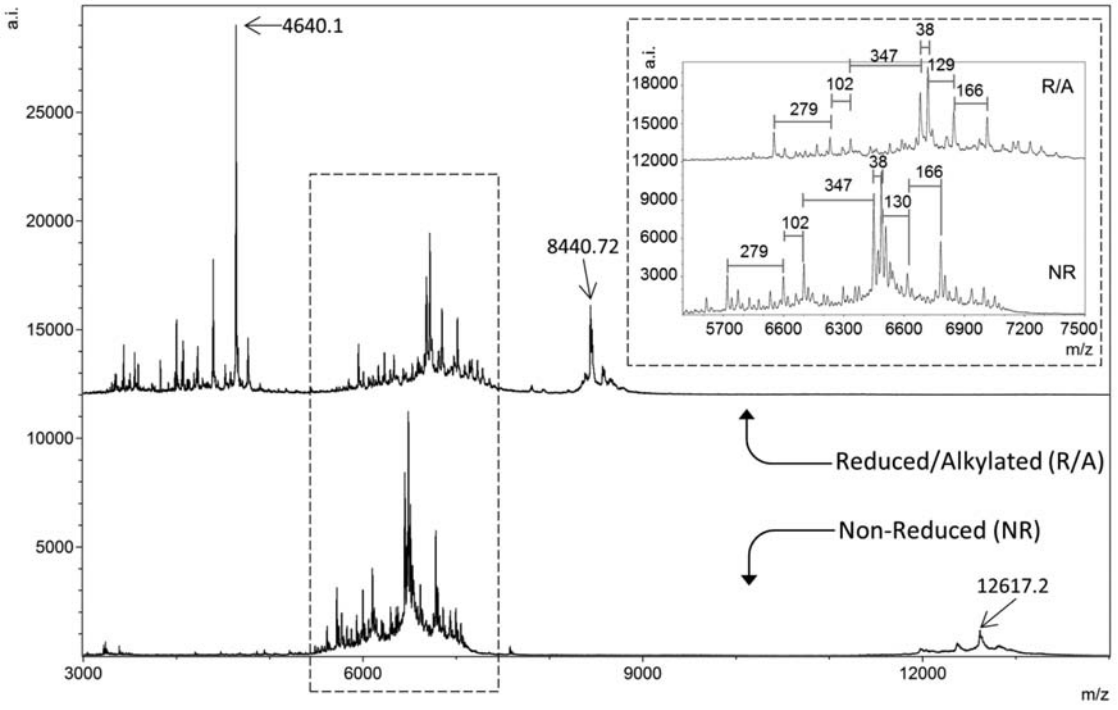

**Figure 4.** MALDI-TOF analysis of walnut LMW pool. Averaged spectra of the LMW gel filtration pool under nonreduced (NR) or reduced and alkylated (R/A) conditions are shown above, with average intensity (a.i.) displayed on the *y*-axis. Labels on inset spectra indicate conserved $m/z$ differences between peaks.

**Table 3. Mass Shifts of 7S Globulin N-Terminal Peptide MALDI-TOF Peaks Following Reduction and Alkylation**[a]

| NR mean $m/z$ | R/A mean $m/z$ | Δ $m/z$ (R/A-NR) |
|---|---|---|
| 5720.2395 | 5952.9377 | 232.6981 |
| 5999.1986 | 6231.6017 | 232.4032 |

| 6448.7647 | 6681.1299 | 232.3652 |
| 6486.8504 | 6718.6630 | 231.8126 |
| 6616.5919 | 6848.1240 | 231.5321 |
| 6782.3607 | 7014.4832 | 232.1224 |

[a]Values shown indicate calculations of the $m/z$ shift of the conserved pattern of peaks illustrated in Figure 4 (inset), under nonreduced (NR) and reduced and alkylated (R/A) conditions.

motif.[36] Finally, cotton (*Gossypium hirsutum*) also has a 7S globulin gene encoding for a hydrophilic N-terminal region (containing three repetitions of the four-cysteine motif), and an isolated heterogeneous population of peptides from this region demonstrated antifungal properties.[37] The independent description of similar N-terminal peptides derived from 7S globulin proprotein sequences in seeds from several different plant species implies that this type of peptide is produced consistently in a variety of plants. Due to the lack of complete plant genomes and proteomes, however, it is difficult to assess the full range of affected plant species.

Purification and analysis of the LMW, nonglycosylated fraction of walnut revealed the presence of two main polypeptide species: the 2S albumin and a mixture of

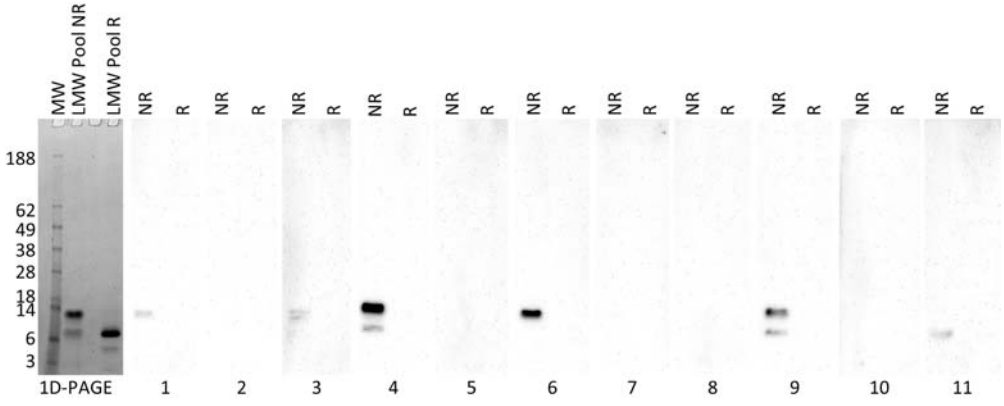

**Figure 5.** IgE reactivity to low molecular weight walnut proteins. Each IgE immunoblot includes the LMW pool (1.0 μg of protein) under nonreducing (NR) and reducing conditions (R), run in the same manner as on the 1D-PAGE gel replicate. Molecular weight markers (MW, SeeBlue prestained standards, 2 μL) were also run for each gel and blot. The numerical labels (1−11) below each immunoblot correspond to the individual serum samples from the walnut-allergic subjects described in Table 1.

polypeptides derived from the N-terminal region of the 7S seed storage globulin proprotein. N-terminal peptides derived from 7S globulin proprotein sequences and containing a conserved four-cysteine motif have been observed in a variety of plants, including walnuts, macadamia nuts, buckwheat, pumpkin, and cotton,[12,24,27,33−37] and gene sequences suggest they may be produced in a number of other plants such as cocoa.[26] In cotton and pumpkin, there is quite convincing evidence that multiple protein products with separate functionalities are produced from the single proprotein sequence typically designated a 7S globulin.[24,27,37] In cases when the peptides have been characterized, they seem to function primarily as a defense mechanism, with antimicrobial or trypsin inhibition activity.[33,34,36,37]

Additionally, these four-cysteine motif containing peptides can be potential allergens, as illustrated by the IgE reactivity observed in walnut- or buckwheat-allergic subjects using immunoblot, ELISA, or RAST analysis.[12,34,35] These data suggest that the N-terminal fragments could represent a subset of the 7S seed storage globulin allergens, which should be considered alongside other low molecular weight allergens such as 2S albumin and LTPs. However, as IgE reactivity alone is not fully indicative of biological activity, further in vivo or in vitro experiments (e.g., histamine release assays) should be conducted to confirm the clinical significance of the N-terminal peptides containing the four-cysteine motif. The implications for these peptides as potential allergens extend particularly to diagnostic and detection methods that aim to characterize allergens at the molecular level.

Component-resolved diagnosis using recombinant allergens, for example, could provide misleading or incomplete information if the N-terminal region of the 7S globulin proprotein is not analyzed separately from the mature protein, as these represent two independent allergenic components. In addition, the development of mass spectrometry-based methods for the detection of allergens in foods must properly assign peptide targets to particular proteins of interest and should recognize the independent nature of the 7S globulin proprotein N-terminal region. This study also shows that the 2S albumin from walnut exhibits a substantial amount of heterogeneity, which is not reflected in protein sequence databases. Without in-depth knowledge of protein isoforms and posttranslational processing, these types of heterogeneity make full characterization of native walnut proteins by mass spectrometry more challenging. As is the case with many plant foods, the genetic characterization of these species lags behind that of many animal and bacterial species. The continued expansion of genomic and proteomic data from plant foods is key to increasing our understanding of plant food allergens and will enhance our ability to use advanced techniques for characterization and quantitation of allergens in foods.

[a]*Leaf spray protocol:* plants with four leaves, covering 1 $dm^2$, were sprayed twice on each leaf. Volume of one spray was 0.14 mL. Therefore, treatments for 1 plant (1 $dm^2$) required 1.12 mL of solution, containing 300 $\mu$g of sulcotrione or 1 $\mu$L of Mikado and/or 900 $\mu$g grape marc for application rates called A1. Treatments A2 and A3 used 2 and 3 times A1 rates, respectively, for each product. For comparison, the application rate of sulcotrione used in fields is reported. *Leaf infiltration protocol:* usually, 50 $\mu$L of liquid (products in ultrapure water) was infiltrated until solutions spread across leaf area of 1 $cm^2$. C1 treatments used 268 $\mu$g/mL sulcotrione solution, either active ingredient or trademark Mikado, and 9 $\mu$g/mL grape marc, either alone or in mixtures. C2 and C3 treatments used 2 and 3 times C1 application rates, respectively, for each product. For comparison, the application rate of sulcotrione used in fields is reported.

commercial product Mikado. The aim of the work was to evaluate consequences of treatments by sulcotrione and trademark Mikado on plant cell physiology and the ability of grape marc to control plant response to determine if such treatments can modify pesticide effects on stress metabolism.

## MATERIALS AND METHODS

**Plant Material and Chemicals.** Sulcotrione, 2-(2-chloro-4-(methylsulfonyl) benzoyl)-1,3-cyclohexanedione ($M_m$ 328.77; dissociation constant, $pK_a$, 3.13; boiling point, 574.5 °C at 760 mmHg; Riedel de Haën, Pestanal, Saint-Quentin Fallavier, France), and commercial product as a concentrated suspension of sulcotrione at 300 g/L (liquid Mikado; Bayer CropScience) were used. Water was purified through a sterile Millipore Milli-Q system (Millipore $\alpha$Q; resistivity, 18 M·cm, DOC, <0.1 mg/L).

The experimental model of *V. faba* var. Aguadulce, is a cultivar with a high sensitivity to pollutants.[5,30] *V. faba* was also used to study responses of oxidative stress markers[31] and other antitoxic plant defenses, such as phytochelatins,[32] to environmental pollutants. Seeds of *V. faba* were surface sterilized with 10% sodium hypochloride, rinsed several times with distilled water, and placed on moistened paper at 25 °C for 4−5 days, allowing them to germinate, then put in pots filled with commercial substrate (40% black, 30% brown, and 30% blond peat moss, pH 6.1) and transfer to greenhouse (22 ± 5 °C; photoperiod, 16 h light/8 h dark). Grape marc (powder Acys; 60% polyphenols containing 25% anthocyanins) was a product from Grap'Sud (30360 Cruviers-Lascours).[21]

**Plant Treatments.** Herbicides, grape marc, and mixtures were applied as aqueous solutions on leaf tissue either as aerosol spray or by infiltration.

*Foliar Spray Treatments.* Spray treatment (1.12 mL per plant) on foliage was made onto the upper face of four leaves (two sprays per leaf). Plants were thus treated as in fields, that is, sulcotrione 300 g/ha or Mikado, 1 L/ha, a trademark that contains sulcotrione (300 g/L). Plants were thus treated using 0.3 mg/$dm^2$ (A1) sulcotrione active ingredient (ai) or sulcotrione in commercial product (i.e., 1 $\mu$L of Mikado). Treatments with grape marc contained 0.9 mg/$dm^2$ grape product for A1 treatments. The mixture of grape marc and sulcotrione then had a ratio 3:1 (w/w), respectively. To use similar ratios of sulcotrione and grape marc for treatments, the mixture made of grape marc and Mikado was 0.9 mg/1 $\mu$L (w/v), respectively. A2 and A3 application rates were 2 and 3 times the A1 rate, respectively, for every product. All products and mixtures were solubilized in 6 mL of sterile ultrapure water before being sprayed. Control leaf samples were sprayed with 1.12 mL of ultrapure water alone.

*Leaf Infiltrations.* These were carried out on leaf blades using plastic syringes. For infiltration treatments, 50 $\mu$L of solutions was usually infiltrated into a leaf area of 1 $cm^2$. Three replicates were performed on different plants. Table 1 describes experimental conditions compared to sulcotrione pesticide used in fields. For transcript analysis by leaf infiltrations, C1 treatments used sulcotrione active ingredient, Mikado (300 mg/mL), and grape marc (0.9 mg/mL), either alone or in mixtures. C2 and C3 treatments were used 2 and 3 times the C1 application rate for each product, respectively. Negative controls were obtained with sterile ultrapure water infiltrated leaves. Plant responses were observed after 2 or 4 days as indicated for treatments.

**Analysis of Membrane Lipoperoxides.** Fresh bean roots were ground in a buffer solution consisting of 0.5% thiobarbituric acid (TBA) and 20% trichloroacetic acid (TCA) (w/v = 1:10) with sterile Fontainebleau sand. The ground material was heated in a water bath at 95 °C for 30 min. During incubation, TBA and aldehyde compounds were bound. The reaction was stopped by immediate cooling in an ice bath. After centrifugation at 10000*g* for 10 min, the supernatant was recovered for a colorimetric assay of lipoperoxides. Their concentrations were determined according to the method of Heath and Packer.[33] The lipid peroxidation products that react with TBA mainly are malondialdehyde, MDA, and endoperoxides.[34] Absorbance of the TBA−MDA complex was measured by spectrophotometer at 532 nm

**Table 2. Primer Sequences for Gene Probes**

and corrected by reading at 600 nm. MDA concentration was calculated using a molar extinction coefficient ($\varepsilon$ = 155 mm/cm).

**Cell Death Assays.** Cell death in leaf tissue was monitored by Evans Blue staining[35] as previously described.[21] Each assay was performed with 10 leaf disks (1 cm in diameter) punched out from each infiltrated area of the same leaf; triplicates were obtained from three different plants. Leaf disks were incubated for 30 min in 0.25% Evans Blue (Sigma, France) at room temperature on a shaker, extensively rinsed to remove excess dye, and ground in a tissue grind tube with 1 mL of 1% SDS solution. Treated leaf extracts were then centrifuged for 20 min at 20000*g*, and supernatants were diluted 8-fold with distilled water. Dye absorbencies were measured with a spectrophotometer at 600 nm and referred to the absorbance versus leaf disk weight, for either sprayed or infiltrated plants. Cell death was measured with plants treated by spray, either with different concentrations of products (A1−A3), pesticide, and grape marc for 4 days, or using the highest rates of products (A3) but for two periods, 2 and 4 days.

**RNA Isolation and Quantification.** Leaf tissues (200 mg) were ground in liquid nitrogen, and RNA extractions were performed using 1 mL of Trireagent solution (Euromedex, France) according to the manufacturer's instructions. Total RNA was cleaned up with 0.5 U DNase I solution (Euromedex, France), containing 20 U RNase inhibitor (Euromedex, France). RNA integrity was analyzed on 1% agarose gel by observation of rRNA spots. RNA concentrations were measured by absorbance at 260 nm. Reverse transcription was performed using total RNA and Euroscript Reverse Transcriptase (Eurogentec, France) according to the manufacturer's instructions. Quantitative assessment of mRNA levels was performed using an iCycler iQv3 (Bio-Rad). PCR reactions were prepared with qPCR kit Mastermix for SYBR green (Eurogentec, France) according to the manufacturer's protocol. The cDNA concentration used threshold cycle values (CT) between 15 and 30 cycles. Amplification specificity was checked by melting-curve analysis[22] and involved 42 cycles (melting, 95 °C; hybridization, 56 °C; elongation, 30 s for each step). PCR efficiencies were calculated for each gene according to Pfaffl.[36] Accumulations of gene transcripts were calculated using reference transcript and actin gene and set relative to control plants (water infiltration). Primer sequences of the studied gene are shown in Table 2.

**Statistical Analysis.** All experiments were done in triplicates. Bars represent the mean of three values ± standard error (SE). Student's test was used to compare the means for determination of significant differences between treated samples and control. The data are written as the mean ± SE. Values were determined to be significant when $p \leq 0.05$.

## RESULTS

**Cell Death Analyses.** Effects of treatments on plants exposed to the herbicide are illustrated in Figure 1. Sulcotrione or Mikado sprayed on leaves displayed a significant depletion of leaf surfaces (Figure 1A) and a higher MDA content in roots (Figure 1B) than control after 2 days of treatment. Treatment by grape marc alone did not show a significant effect. A significant increase was observed in MDA of plant treated by the mixtures sulcotrione or Mikado and grape marc. Such peroxidation could be a result of oxidative degradation of lipids due to a significant change in the cellular redox status in plants generated by herbicide as previously reported.[37] This observation indicated that herbicide spray led to plant membrane modification.

Sulcotrione pesticides, active ingredient and trademark (Mikado), induced higher cell death rate than observed in control leaves. Cell death was also enhanced with trademark product treatments (Figure 2A). Cell death was increased when grape marc was added either to sulcotrione (ai) or to commercial product (Figure 2A). Cell death was shown to be concentration-dependent (Figure 2A). It was triggered by grape marc or pesticides (sulcotrione or Mikado) treatments, but at high rates of pesticides. Mixtures then induced a great cell death, which seems to be related to an addition of product toxicity for sulcotrione but that still was enhanced with Mikado (Figure 2A).

Cell death evolutions were similar for plants treated either with grape marc or sulcotrione (Figure 2B). Addition of grape marc to sulcotrione enhanced cell death (Figure 2B). Mikado treatment displayed quicker cell death than grape marc treatment alone, but a mixture of both products still accelerated cell death, suggesting a synergy effect (Figure 2B).

**Gene Expressions.** Accumulations of intracellular ROS belong to cell death markers. Study of gene expression involved in oxidative burst metabolism clarified effects of plant treatments. Plants were treated by leaf infiltration with

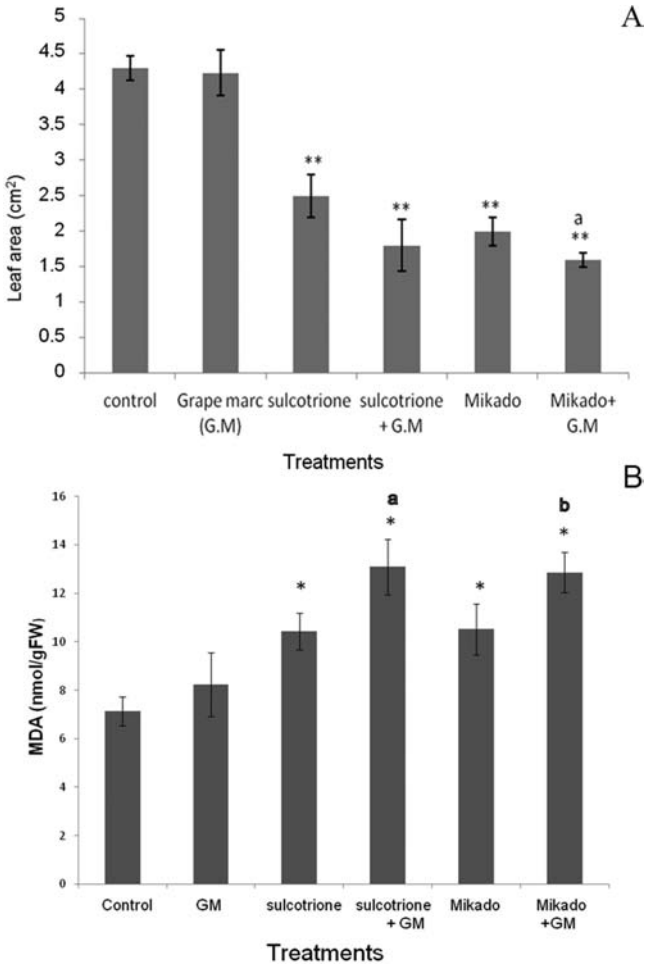

**Figure 1.** Physiological changes of plant, 2 days after treatments, by spray at application rate A3 for each product, as described in Table 1: (A) surfaces of treated *V. faba* leaves; (B) malondialdehyde content in *V. faba* roots. Control leaves were sprayed with ultrapure water. Each independent experiment was performed in triplicates. Bars represent mean values ± SE. Stars are significant differences between treatment samples and control, and a and b letters are significant differences between mixture treatments and corresponding herbicide alone ($p < 0.05$).

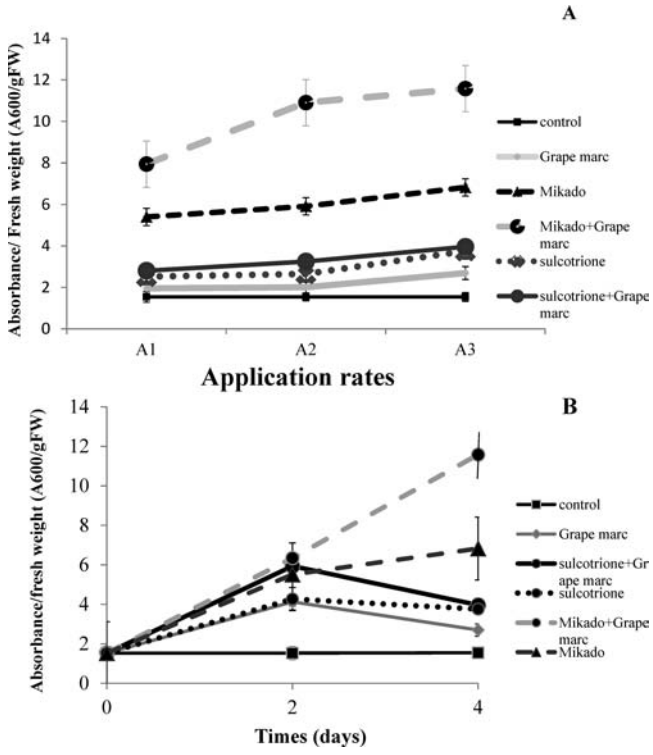

**Figure 2.** Cell death analysis. (A) Cell death induced after 4 days of treatments of *V. faba* leaves by spray. Treatments were done with sulcotrione, Mikado, grape marc, and a mixture of components, compared with *V. faba* control leaves. Application rates for plant treatment (A1) were 0.3 mg/dm$^2$ sulcotrione (ai) or in commercial product (i.e., 1 $\mu$L of Mikado). Grape marc was used at a rate 0.9 mg/dm$^2$ for A1. Mixture of grape marc and sulcotrione was used at a ratio 3:1 (w/w), respectively. Mixture made of grape marc and Mikado had a ratio 0.9:1 (w/v), respectively, to obtain a similar ratio for sulcotrione quantities. A2 and A3 were 2 and 3 times A1 rates for each product, respectively. Control samples were sprayed out with ultrapure water. Dye absorbance was measured at 600 nm. (B) Cell death induced by different spray treatment in leaves. Beans were treated by the highest product concentrations (A3). Absorbencies were measured after 2 and 4 days of treatments.

application rates called C1 for sulcotrione or Mikado (13.4 $\mu$g of active ingredient) and grape marc (40 $\mu$g per infiltration). Mixtures of grape marc and sulcotrione products were used at a ratio 3:1 (w/w), respectively. C2 and C3 are 2 and 3 times C1 rates, respectively, for sulcotrione products or grape marc quantities.

Sulcotrione treatments showed an increase of plastid copper−zinc superoxide dismutase (Cu/Zn-SOD CH) transcripts in leaves of *V. faba*, which was dose-dependent (Figure 3A). Other treatments, grape marc or Mikado (Figures 3A and 4A), displayed increases of transcripts for high concentrations. Addition of grape marc to herbicide enhanced sulcotrione effect (Figure 3A), but lowered induction by Mikado (Figure 4A).

Sulcotrione or Mikado treatments showed increases of cytosol copper−zinc superoxide dismutase (Cu/Zn-SOD CY) transcripts in leaves of *V. faba*, which displayed a dose−response relationship (Figures 3B and 4B). These treatments enhanced ascorbate peroxidase transcript accumulation in *V. faba* leaves mainly for the first rate C1, with a slight decrease for other application rates (Figures 3C and 4C). They also showed increases of catalase, ubiquitin, and hsp 70 transcript accumulations in leaves of *V. faba* that were dose-dependent (Figures 3 and 4D−F, respectively).

Grape marc treatments displayed an increase of cytosol copper−zinc superoxide dismutase (Cu/Zn-SOD CY) transcripts; addition of grape marc to herbicide enhanced effects of sulcotrione and Mikado for all rates (Figures 3B and 4B). In contrast, grape marc treatments displayed ascorbate peroxidase transcript increases that are dose-dependent (Figures 3C and 4C); addition of grape marc to herbicide did not markedly change effects of sulcotrione and Mikado (Figures 3C and 4C). Grape marc treatments displayed an increase of catalase transcript accumulation from the lowest rate C1 (Figures 3D and 4D); addition of grape marc to herbicide enhanced effects of sulcotrione and Mikado, at least for C1and C2 application rates; in contrast, the C3 rate lowered Mikado induction, whereas the effect of sulcotrione still was enhanced (Figures 3D and 4D). Addition of grape marc to herbicide also enhanced ubiquitin and hsp 70 transcript accumulations by sulcotrione and Mikado for every rate (Figures 3E,F and 4E,F, respectively).

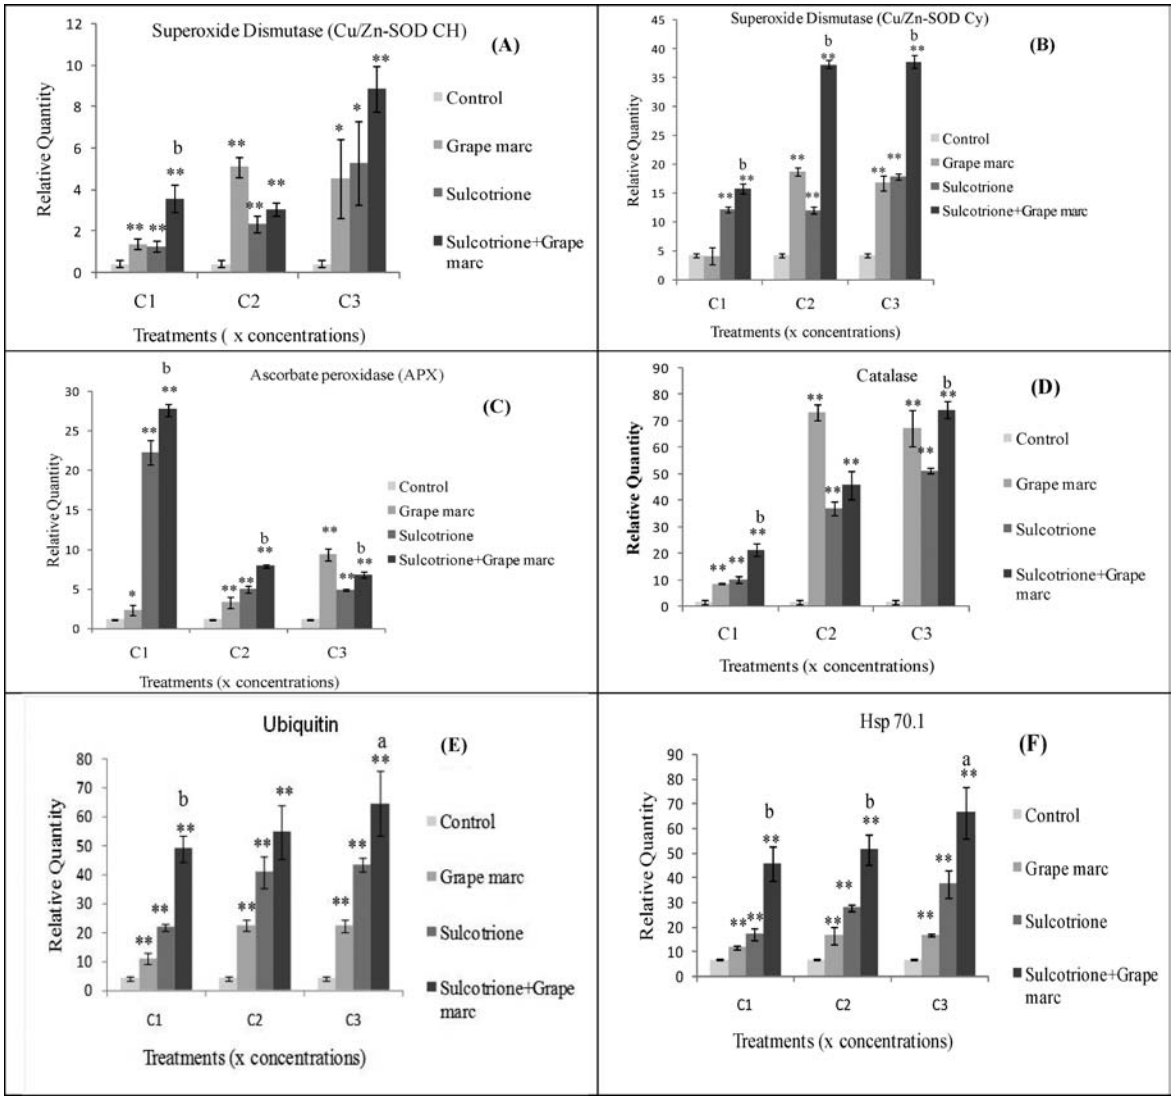

**Figure 3.** Transcript accumulation in *V. faba* leaves after infiltration treatments with sulcotrione, grape marc, and mixture of both components: (A) chloroplast copper−zinc superoxide (Cu/Zn-SOD CH) dismutase; (B) cytosolic copper−zinc superoxide dismutase (Cu/Zn-SOD CY); (C) ascorbate peroxidase (APX); (D) catalase; (E) ubiquitinl; (F) heat shock protein hsp 70.1. Values of treated leaves, with both sulcotrione or Mikado and grape marc, that have letters "a" or "b" are statistically different from values of treated leaves by sulcotrione or Mikado alone, at 5 or 1% significance level, respectively, according to Student's *t* test. Values with one or two stars are statistically different from control at 5 and 1% significance level, respectively. C2 and C3 treatments used 2 and 3 times, respectively, C1 rates for each product as described in Table 1.

## DISCUSSION

We have shown that herbicide can trigger oxidative stress resulting in disruption of cell metabolism, in experimental conditions that did not display leaf bleaching. Sulcotrione, as active ingredient or in a formulated product, Mikado, induced accumulation of MDA; it was suggested that pure sulcotrione or Mikado may induce cell membrane destruction, as was previously reported.[38] Lipid peroxidation has been suggested as one of the mechanisms involved in toxicity induced by pesticides.[39] Treatments of *V. faba* leaves with herbicides sulcotrione or Mikado displayed cell death increases that changed according to active ingredient concentrations and were enhanced using trademark Mikado. Grape marc also displayed slight bean cell death in a dose-dependent manner. Addition of grape marc either to sulcotrione or Mikado enhanced cell death, with higher increases using Mikado than with active ingredient alone. A potentiating effect between grape marc action and adjuvant elements of Mikado was then suggested.

Commercial product Mikado showed greater cell toxicity than active product sulcotrione. This was previously shown with mesotrione and Callisto or glyphosate and Roundup using growth inhibition criteria in several toxicity test organisms.[28,29] Mikado was shown to be toxic for *Pseudokirchneriella subcapitata* growth, whereas its toxicity was quite reduced for *Chlorella vulgaris*.[2] Pesticide action thus may strongly enhance ecotoxicological effects of other chemicals at high mixture concentrations, thereby showing potential synergy. Adjuvant added to herbicide formulations could enhance cell toxicity, as was potentially the case for methanol in Viper.[40] In contrast, it was previously shown that absorption of sulcotrione in maize was not significantly enhanced by adjuvant contained in commercial Mikado.[41] Moreover, most of the absorbed sulcotrione remained in the treated leaf and <14% was translocated to other organs; the presence of adjuvant in Mikado did not significantly modify the translocation of sulcotrione.[41]

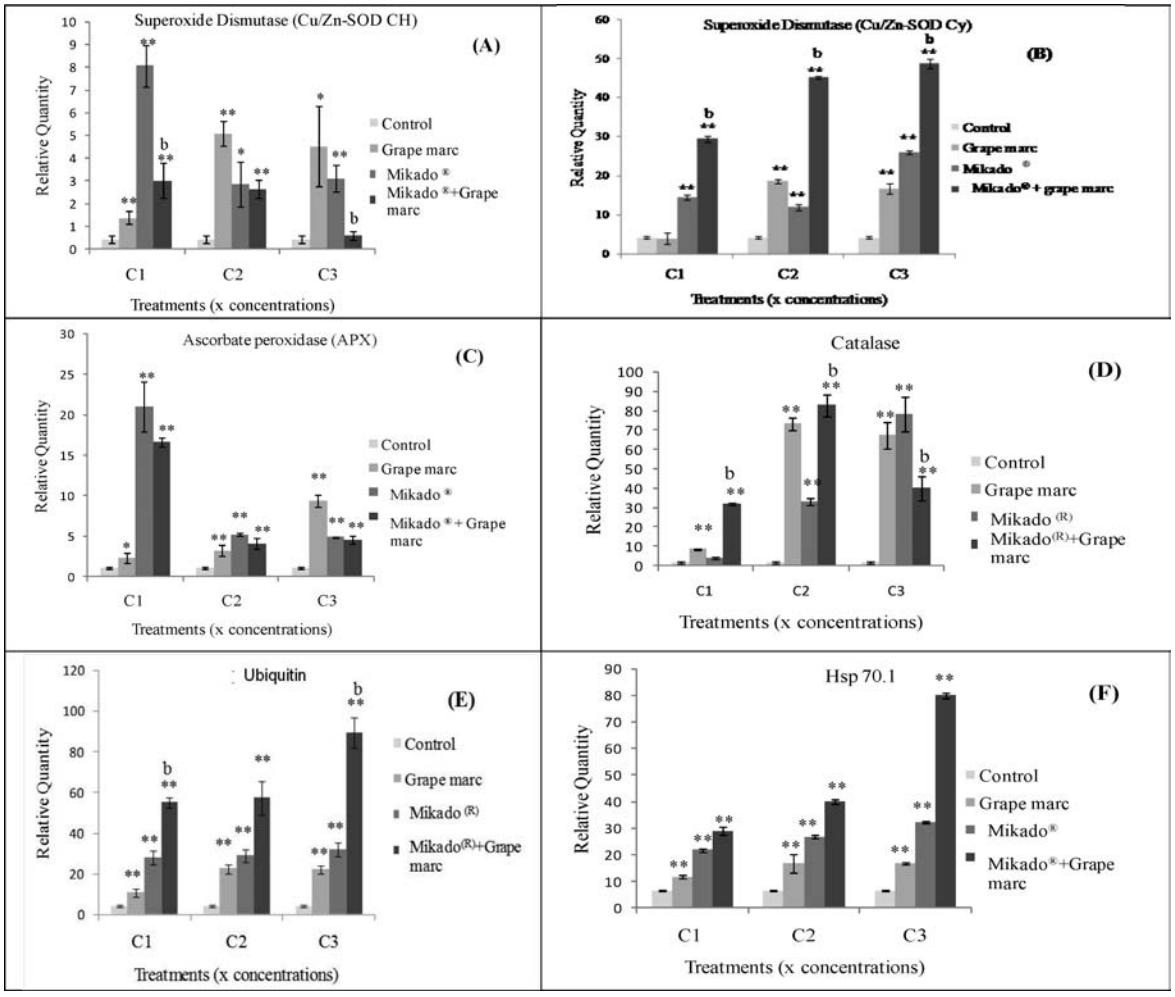

**Figure 4.** Transcript accumulation in *V. faba* leaves after infiltration treatments with Mikado, grape marc, and mixture of both components: (A) chloroplast copper−zinc superoxide (Cu/Zn-SOD CH) dismutase; (B) cytosolic copper−zinc superoxide dismutase (Cu/Zn-SOD CY); (C) ascorbate peroxidase (APX); (D) catalase; (E) ubiquitin; (F) heat shock protein hsp 70.1. Treatment values with letters "a" or "b" are statistically different from pesticide treatment at 5 or 1% significance level, respectively, and those with one or two stars are statistically different from control at 5 and 1% significance level, respectively, according to Student's *t* test. C2 and C3 treatments used 2 and 3 times, respectively, C1 rates for each product as described in Table 1.

Earlier, it was observed that formulation surprisingly increased the rate of sulcotrione phototransformation.[12] Synergistic joint effects on survival of daphnids for fungicide/insecticide and fungicide/herbicide mixtures[42] and for mixtures composed with only herbicides were found.[2,43] It was often explained that the effect of one chemical could be synergized by the presence of others, usually regulated by changes of detoxifying/biotransformation processes.[42] Recently, we have shown that sulcotrione and photoproducts increase chromosomal abnormality frequencies, but photodegraded sulcotrione cocktail has shown a greater toxicity than the parent molecule.[11]

Polyphenols can directly influence different points of apoptotic process and/or expression of regulatory proteins.[44] Mosse et al.[45] have shown that winery wastewater delayed germination and inhibited vegetative growth of several plants. We have studied and shown variations of oxidative stress in bean leaves exposed to pesticides and grape marc, measuring transcript accumulations of stress gene markers, such as superoxide dismutases, catalase, ascorbate peroxidase, ubiquitin, and hsp 70, as previously described.[46−50] Agati et al.[51] recently proposed a model in which chloroplast-located flavonoids scavenge generated ROS, thus avoiding programmed cell death. They suggested that flavonoids in conjunction with peroxidases and ascorbic acid constitute a secondary antioxidant system. In contrast, we showed that the addition of grape marc to herbicide products, sulcotrione or Mikado, had various effects according to herbicide composition (active ingredient alone or commercial product). Marker genes are differently expressed. Mixtures of grape marc and herbicide enhanced transcript accumulation for ubiquitin, hsp 70, and cytosolic SOD genes. Mixtures of grape marc and sulcotrione or Mikado gave different results at the highest rates for chloroplast SOD and catalase transcript accumulations. Grape marc mixtures markedly did not change effects of sulcotrione and Mikado for ascorbate peroxidase transcript accumulation. Depletion of catalase activity was previously reported in fishes exposed to endosulfan (ES) and was attributed to flux of superoxide radicals.[52,53]

Chromosome breakage, misrepaired DNA lesions, or chromosome unsegregation can be induced by oxidative stress[54,55] and could explain a genotoxic effect of sulcotrione previously described.[5] Other herbicide and pesticide chemicals such as insecticides may induce oxidative stress leading to

generation of free radicals and alterations in antioxidative or free radical scavenging enzyme systems.[56−59] It was indicated that enzymes associated with antioxidative defense mechanisms are altered under the influence of pesticides.[59] Moreover, oxidative stress and DNA damage have been proposed as mechanisms linking pesticide exposure to health effects such as cancer and neurological diseases.[60]

Proteins that are involved in cell stress metabolism, such as hsp 70 and ubiquitin, showed transcript increase following treatments by either sulcotrione or Mikado on *V. faba* leaves. Grape marc treatments alone displayed an increased accumulation of the same transcripts. In our conditions, mixtures of grape marc and herbicide enhanced effects of sulcotrione or Mikado for each concentration.

Earlier, it has been shown that intracellular ROS accumulation was attenuated by pretreatment with procyanidin B2.[61] In addition to antioxidative capacity, polyphenols may exert a protective effect by selective inhibition or stimulation of key protein into cell signaling cascades. Flavanols are also potent antioxidants in lipid systems, where they reduce oxidative modifications of membranes by restricting access of oxidants to the bilayer and propagation of lipid oxidation in hydrophobic membrane matrix.[62] In different experimental conditions, changes in catalase (CAT) and superoxide dismutase (SOD) gene expressions were observed after chronic consumption of wine phenolics by men.[63]

In conclusion, transcript accumulations of described genes were shown to be enhanced after treatments of leaves at three different product concentrations of sulcotrione or Mikado, grape marc, and mixtures. Genes that are involved in oxidative species induction (cytoplasmic and plastid SODs),[64] that encode antioxidative enzymes (catalase and ascorbate peroxidase, APX)[65] or which are involved in cellular defense (hsp 70 and ubiquitin)[66−69] were up-regulated after leaf treatments by pesticides and grape marc. Finally, cell death was increased after treatments but with high rates for pesticide cocktails supplemented with grape marc, especially for Mikado (Figure 5). Expression of these genes was also involved in the regulation of different cellular signalization pathways either triggering (SOD) or inhibiting various signal ways (Figure 5). Using suspension-cultured cells of tobacco, grape marc was shown to elicit early perception events and, then activating defense-related genes, ultimately leading to cell death.[70]Pesticide, sulcotrione or Mikado, and grape marc, alone, can induce target plant cell death. Signal transduction may involve ROS as shown in plant stressed conditions.[64,71] A mixture of pesticide and grape marc suggests a potentiating effect of grape marc by adjuvant elements of Mikado. Sulcotrione and mesotrione are herbicides related to a natural $\beta$-triketone, leptospermone from *Leptospermum scoparium*, that specifically inhibits the enzyme HPPD. Plant $\beta$-triketones also possess an array of biological activities such as antimicrobial activities and may protect plants from biotic stresses.[72] Leptospermone has shown toxicity against mite development, a nonherbicide target.[73]

Sulcotrione doses used for gene expression studies were similar for spray treatments or 3 to 4 times higher for infiltration treatments than the sulcotrione amount used in agriculture, as shown in Table 1. Herbicides and grape marc can trigger oxidative stress, resulting in disruption of cellular metabolism. We provide evidence that mixtures (herbicide and grape marc) induced specific gene expression for stress-associated proteins. Addition of grape marc to herbicide products, sulcotrione or Mikado, had different effects according to herbicide composition (active product or commercial product) and, meanwhile, genes are shown to be differently expressed. Therefore, adjuvant can modify the biological features of sulcotrione. Moreover, grape marc can enhance the biological effects of sulcotrione and Mikado but with different gene expression features.

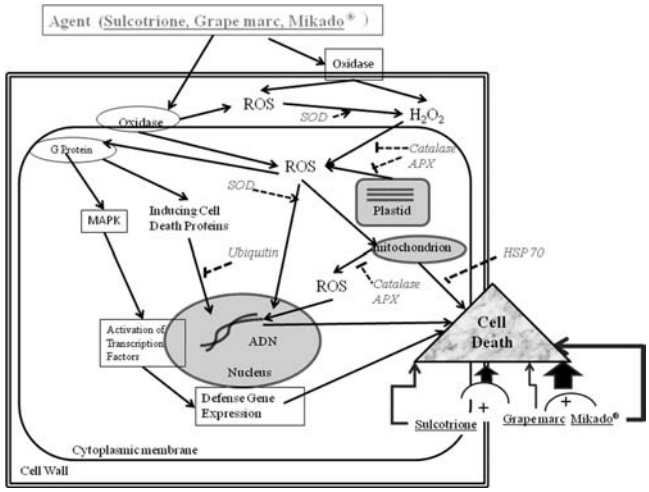

**Figure 5.** Putative interactions of products, such as herbicide (sulcotrione or Mikado) or grape marc, with cellular signalization pathways that can trigger cell defenses or death. Gene expressions are shown activating (arrow) or inhibiting (dash lines) signalization pathways. Gene markers are involved in accumulation of oxidative species (cytoplasmic and plastid superoxide dismutases, SOD, catalase, and ascorbate peroxidase, APX) or in cell defense (hsp 70 and ubiquitin). Cell death is shown to be increased after treatments using high application rates when pesticide cocktails with grape marc were used, especially associated with Mikado, as displayed by arrow thickness.

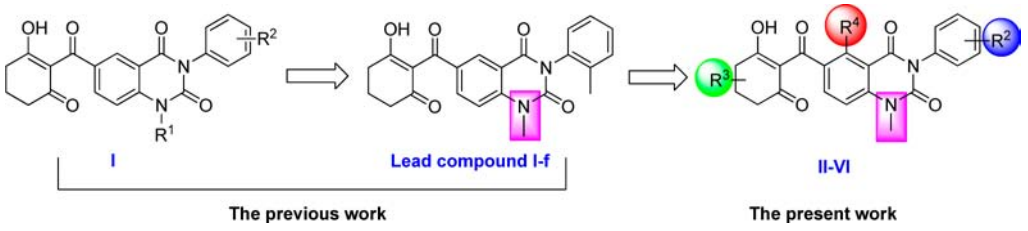

**Figure 1.** Design of title compounds (**II**−**VI**).

containing quinazoline-2,4-dione derivatives possessing a methyl group at the N-1 position of the quinazoline-2,4-dione ring (Figure 1). The biological test indicated that most newly synthesized compounds showed excellent herbicidal activity against broadleaf and monocotyledonous weeds at the dosages of 37.5−150 g of ai/ha. Notably, some compounds showed significantly improved crop selectivity compared to mesotrione. Herein, we have revealed the detailed synthesis, herbicidal activity, and structure−activity relationship (SAR) of compounds **II**−**VI** as potent herbicide candidates.

## MATERIALS AND METHODS

The experimental details and analytical data for all of the intermediates and compounds **II**−**VI** are shown in the Supporting Information.

**X-ray Diffraction.** Compound **IV-d** was recrystallized from a mixture of chloroform and *n*-hexane to afford a suitable single crystal. Light brown crystals of **IV-d** (0.12 × 0.10 × 0.10 mm) were mounted on a quartz fiber with protection oil. Cell dimensions and intensities were measured at 296 K on a Bruker SMART APEX DUO area detector diffractometer with graphite monochromated Mo K$\alpha$ radiation ($\lambda$ = 0.710 73 Å), with $\theta_{max}$ = 25.49, 16 744 measured reflections, and 4817 independent reflections ($R_{int}$ = 0.0253). The data sets were integrated and reduced using SAINT Plus Programme.[16]

Data were corrected for Lorentz and polarization effects and absorption ($T_{max}$ = 0.9613, and $T_{min}$ = 0.9538). The structure was solved by a direct method using SHELXS97 and refined with SHELXL970.[17] Full-matrix least-squares refinement based on $F^2$ using the weight of $1/[\sigma^2(F_0^2) + (0.1322P)^2 + 0.6124P]$ gave final values of $R_1$ = 0.0628, $\omega R_2$ = 0.2008, and GOF($F$) = 1.116 for 403 variables, 403 parameters, and 4817 contributing reflections. Maximum shift/error = 0.002, and maximum/minimum residual electron density = 0.679/−0.506 e Å$^{-3}$. Hydrogen atoms were observed and placed at their ideal positions with a fixed value of their isotropic displacement parameter.

Crystallographic data for compound **IV-d** has been deposited with the Cambridge Crystallographic Data Centre as a supplementary publication with the deposition number 977355. These data can be obtained free of charge from http://www.ccdc.cam.ac.uk/.

[a]Abbreviations: EC, *Echinochloa crus-galli*; SF, *Setaria faberii*; DS, *Digitaria sanguinalis*; AR, *Amaranthus retroflexu*; EP, *Eclipta prostrata*; AJ, *Abutilon juncea*.

*prostrata* (EP), and *Abutilon juncea* (AJ) were evaluated according to the above-mentioned procedure;[18−20] the commercially available triketone herbicide mesotrione was selected as a positive control. All test compounds were formulated as 100 g/L emulsified concentrates using *N*,*N*-dimethylformamide (DMF) as the solvent and Tween-80 as the emulsification reagent. The concentrates were diluted with water to the required concentration and applied to pot-grown plants in a greenhouse. Clay soil was used with pH 6.5, 1.6% organic matter, 37.3% clay particles, and cation-exchange capacity (CEC) of 12.1 mol/kg. The rate of application (g of ai/ha) was calculated by the total amount of active ingredient in the formulation divided by the surface area of the pot. Plastic pots with a diameter of 9 cm were filled with soil to a depth of 8 cm. Approximately 20 seeds of selected weeds were sown in soil at the depth of 1−3 cm and grown at the temperature of 15−30 °C in a greenhouse. Atmospheric relative humidity was 50%. The diluted formulation solutions were applied as a postemergence treatment. Broadleaf weeds were treated at the 2-leaf stage, and monocotyledon weeds were treated at the 1-leaf stage. The postemergence application rate was 150 g of ai/ha. Untreated seedlings were used as the control group, and the solvent (DMF + Tween-80)-treated seedlings were used as the solvent control group. Herbicidal activity was evaluated visually after 15 days from post-treatment. The results of herbicidal activities are shown in Tables 1−4, with three replicates per treatment.

**Crop Selectivity.** The conventional rice, soybean, cotton, wheat, rape, and maize were planted separately in pots (diameter = 12 cm) containing selected soil and grown in a greenhouse at 20−25 °C.[21] After the (crop) plants had reached the 4-leaf stage, new herbicides were applied (spraying) at the dosage of 150 g of ai/ha. The visual injury and growth rate of the individual plants were observed at regular intervals. After 15 days, the final results of crop safety were determined (Table 5), using three replicates per treatment.

**Plasmid Construction, Protein Expression and Extraction, HPPD Purification, Activity Assays, and Kinetic Inhibition Studies.** *Arabidopsis thaliana* HPPD (*At*HPPD) was constructed by polymerase chain reaction (PCR) using cDNA of HPPD in pMD19-T Simple (Hangzhou BIOSCI Biotechnology Company) as the template. The primers, used here were 5′-CATGCCATGGGCCAC-CAAAACGCCGC-3′ (*Nco*I) and 5′-CGCGGATCCT-CAGTGGTGGTGGTGGTGGTGTCCCACTAACTGTTT-3′ (*Bam*HI). PCR conditions were 35 cycles at 94 °C for 30 s, 55 °C for 30 s, and 68 °C for 1.5 min. The amplion was introduced into the expression vector pET-15b and subsequently transformed into *Escherichia coli* BL21(DE3). The DNA sequences of the positive clones were confirmed by DNA sequencing with Shanghai SANGON Company.

Recombinant *At*HPPD was overexpressed in *E. coli* BL21(DE3) cells with pET-15b-HPPD plasmid. Recombinant HGD from human was overexpressed in *E. coli* BL21(DE3) cells with pET-28a-HGD plasmid. The cells were grown at 37 °C in Luria−Bertani broth supplemented with 50 μg/mL kanamycin (pET-28a plasmid) or 100 μg/mL antimycin (pET-15b plasmid) according to the previous publication.[22] Expression of the *At*HPPD plasmid was incubated at 37 °C for 12 h. HGD was induced by 0.5 mM isopropyl-β-D-thiogalactopyranoside (IPTG) when bacterial growth reached $A_{600}$ of 0.6, and then the cells were incubated for another 40 h at 15 °C. After harvesting by centrifugation (5000*g* for 30 min), the pellet was resuspended in buffer [20 mM *N*-2-hydroxyethylpiperazine-*N*′-2-ethanesulfonic acid (HEPES) and 20 mM NaCl at pH 7.0] and washed twice, followed by sonication using a cell disruptor. A crude cell-free supernatant was obtained by centrifugation at 20000*g* for 30 min. The over-expression and the relative molecular weight of recombinant *At*HPPD were validated by both sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE) stained with Coomassie Brilliant Blue-R250 and Simple Western analysis using Simon instrumentation (ProteinSimple, CA)

**Table 6. Binding Free Energies (kcal/mol) of Compounds II-k and VI-c**

| compound | $\Delta E_{ELE}$ | $\Delta E_{VDW}$ | $\Delta E_{GAS}$ | $\Delta G_{SOL}$ | $\Delta E_{MM}$ | $-T\Delta S$ | $\Delta G_{cal}{}^{a}$ | $\Delta G_{exp}{}^{b}$ |

*At*HPPD was purified in two chromatographic steps. The crude cell-free supernatant was loaded onto a nickel–nitrilotriacetic acid (Ni–NTA) column (Qiagen, Canada), equilibrated with 20 mM HEPES at pH 7.0. Then, HPPD was eluted with 20 mM HEPES at pH 7.0, 150 mM NaCl, and 250 mM imidazole. The fractions containing HPPD were concentrated, and the buffer was exchanged for 20 mM HEPES at pH 7.0 by ultrafiltration in Ultrafree filter devices (Millipore, MA). For further purification of the recombinant HPPD, anion-exchange chromatography was carried out on Q resin (Amersham-Pharmacia Biotech, Germany) in 20 mM HEPES at pH 7.0. Elution of the recombinant HPPD was carried out in a linear gradient from 0 to 250 mM NaCl. Again, the HPPD-containing fractions were collected, and the buffer was exchanged to 20 mM HEPES at pH 7.0 by ultrafiltration.

Our coupled enzyme assays for the *in vitro* activity and inhibition of HPPD were measured by a modification of methods previously reported in the literature.[23] Assays were performed in 96-well plates at 30 °C using an ultraviolet/visible plate reader to monitor the formation of maleylacetoacetate at 318 nm ($\varepsilon_{330}$ = 13 500 $M^{-1}$ $cm^{-1}$). The reaction mixture in a total assay volume of 200 $\mu$L contained appropriate amounts of HPPA, 100 $\mu$M $FeSO_4$, 2 mM sodium ascorbate, 20 mM HEPES buffer (pH 7.0), HPPD, and HGD. Before assays were conducted, all reaction components were pre-equilibrated at 30 °C for at least 10 min. The amount of HGD activity was predetermined to be in a large excess of the HPPD activity to ensure that the reaction was tightly coupled (the $K_m$ of HGD for HGA was 25 $\mu$M). Each experiment was repeated at least 3 times, and the values were averaged. HPPD inhibitors were dissolved in dimethyl sulfoxide (DMSO) for stock solution and diluted to various concentrations with reaction buffer just before use. The inhibition constant ($K_i$), the indication of the potency of an inhibitor, was obtained from the Dixon plot of plotting $1/v$ against the concentration of the inhibitor at certain concentrations of substrate. Bovine serum albumin is usually added up to 0.5% of the total reaction volume for coating of the target enzyme during the incubation. In our assay, no obvious effect from bovine serum albumin on the activity of the compounds has been found, which indicated that the new compounds selectively inhibited the target enzyme but did not interact with bovine serum albumin.

**Computational Methods.** The crystal structure of *At*HPPD was taken from the Protein Data Bank (PDB ID 1TFZ). Compounds were constructed and optimized using SYBYL 7.0 (Tripos, Inc.), and Gasteiger–Huckel charges were calculated for them. Docking calculations were performed on the two molecules using AutoDock4.0.[24] The protein and ligand structures were prepared with AutoDock Tools. A total of 256 runs were launched for each molecule. Each docked structure was scored by the built-in scoring function and clustered by 0.8 Å of root-mean-square deviation (RMSD) criterions. The best binding modes were determined by docking scores and also the comparison to available complex crystal structure of HPPD and commercial inhibitors (*Streptomyces avermitilis* HPPD complexed with inhibitor NTBC). Standard Amber ff99 force field parameters were assigned to protein, and general AMBER force field (gaff) was assigned to ligands. The partial atomic charges of ligands were calculated using the AM1-BCC method, and the system was solvated in an octahedral box of TIP3P water with the crystallographic water molecules kept. The edge of the box was at least 8 Å from the solute, and appropriate counterions were added to the system to preserve neutrality. In each step, energy minimization was first performed using the steepest descent algorithm for 1000 steps and then the conjugated gradient algorithm for another 2000 steps.

The MD simulation was performed under periodic boundary conditions using the Sander module of the AMBER9 program.[25] The stable MD trajectory was used to perform the binding free energy ($\Delta G_{bind}$) calculation using a modified MM/PBSA method (Table 6). A total of 100 snapshots were taken from the last 500 ps trajectory with an interval of 5 ps to analyze the binding energy, and at the same time,

the counterions and water molecules (water related to the crucial hydrogen bond was not included) were stripped.

## RESULTS AND DISCUSSION

**Chemistry.** Dependent upon the substituent at $R^4$, compounds **II**–**VI** were synthesized by two different synthetic routes. When the substituent at $R^4$ is H, the detailed synthetic routes of compounds **II**–**V** are outlined in Scheme 1. When $R^4$ is methyl, the detailed synthetic routes of title compounds **VI** are outlined in Scheme 2. As seen in Scheme 1, the target compounds **II**–**V** can be prepared in 10-step synthetic routes using 5-methyl-2-nitrobenzoic acid as the starting material. After oxidation, esterification, and reduction reactions, the key intermediate dimethyl 4-aminoisophthalate (**4**) was obtained in a yield of 83%. According to the reported methods,[26,27] the key intermediate **4** reacted with various (un)substituted phenyl isocyanates in pyridine to afford quinazoline-2,4-dione intermediates **5a**–**5x** in good yields. Then, the intermediates **5a**–**5x** reacted with $CH_3I$ to afford the corresponding intermediates **6a**–**6x** in yields of 81–99%. It was found that the intermediates **6a**–**6x** were very unstable in strong base solution, such as aqueous concentrated NaOH and KOH solution, because of the decomposition of the quinazoline-2,4-dione rings of **6a**–**6x** caused by base. However, to our delight, the quinazoline-2,4-dione rings of intermediates **6a**–**6x** were very stable in acid solution. Finally, using mixed acids (HOAc and $H_2SO_4$) as the hydrolysis reagents, the hydrolysis of intermediates **6a**–**6x** could smoothly proceed with yields of 78–98%. Subsequently, intermediates **7a**–**7y** reacted with $SOCl_2$ in tetrahydrofuran (THF) to obtain the corresponding acid chlorides that were very unstable. Thus, the acid chlorides were used directly in the next step without further isolation. After the reaction of the acid chlorides with substituted-1,3-cyclohexanediones, the key enol esters (**8a**–**8x**, **9a** and **9b**, **10a**–**10v**, and **11**) were generated. Finally, using acetone cyanohydrin as the Fries rearrangement catalyst, the target compounds **II**–**V** were obtained in yields of 64–94%.

Similarly, the title compounds **VI** can be prepared, in an 8-step synthetic route using 2-amino-6-methylbenzoic acid as the starting material, after an iodination reaction with ICl in acetic acid; the key intermediate 6-amino-3-iodo-2-methylbenzoic acid (**13**) was obtained in a yield of 73%. Intermediates **14a**–**14d** and **15a**–**15d** were obtained using the same methods as the preparation of intermediates **6a**–**6x**. Then, compounds **15a**–**15d** reacted with 2 equiv of CuCN in DMF, and the intermediates **16a**–**16d** were obtained in yields of 69–85%. Because the quinazoline-2,4-dione rings of intermediates **16a**–**16d** were also very sensitive to strong base, the reaction could not be proceeded in aqueous base solution. Using mixed acids ($H_2SO_4$ and HOAc) as the reactant, the hydrolysis of the cyano group in the intermediates **16a**–**16d** proceeded smoothly. Using the same method as the synthesis of previously enol

dx.doi.org/10.1021/jf5048089 | J. Agric. Food Chem. 2014, 62, 11786–11796

esters, the intermediates **18a−18d** could be prepared from intermediates **17a−17d** in yields of 62−80%. Subsequent Fries rearrangement reaction using acetone cyanohydrin as the catalyst afforded compounds **VI** in yields of 71−78%.

The structures of all of the synthetic triketone-containing compounds were confirmed by $^{1}H$ and $^{13}C$ nuclear magnetic resonance (NMR) and high-resolution mass spectrometry (HRMS) spectral data. In addition, the crystal structure of compound **IV-d** was further determined by X-ray diffraction analysis (Figure 2).

**Herbicidal Activity and SAR.** The postemergence herbicidal activities of all of the target compounds were evaluated against monocotyledon weeds (*E. crus-galli*, *S. faberii*, and *D. sanguinalis*) and broadleaf weeds (*A. retroflexus*, *E. prostrata*, and *A. juncea*) in the greenhouse environment. Mesotrione was used as the positive control, and the results are shown in Tables 1−4. As anticipated, the treated weeds developed unique bleaching symptoms, as typical HPPD herbicides. The herbicidal activity evaluation indicated that most of the synthetic compounds showed between "good" to "excellent" herbicidal activity against the test weeds. Among them, compounds **III-b** and **VI-a−VI-d** showed an even broader spectrum of weed control than mesotrione, because of their superior control efficacy against the monocotyledon weeds to mesotrione. To summarize systematically the SAR of triketone-containing quinazoline-2,4-diones, some of our previously synthesized compounds were also added to the results depicted in Table 1.[15]

Previously, we have found that compound **I-f** was worth considering for further optimization; therefore, a series of substituents with diversity were introduced at the N-1 position of the quinazoline-2,4-dione ring. As shown in Table 1, compound **I-h** with an ethyl group at $R^1$ displayed almost equipotent herbicidal activity as compound **I-f**. However, compound **I-i** with *n*-Pr at $R^1$ displayed reduced herbicidal activity compared to compound **I-h**. It seems that too small or sterically bulky substituents at $R^1$ are detrimental to the activity of target compounds; for example, compounds **I-g** ($R^1$ = H), **I-k** ($R^1$ = *n*-Bu), and **I-m** ($R^1$ = $CH_2C_6H_5$) are almost inactive against six tested weeds. A possible reason for the poor herbicidal activity of these compounds may be due to their uneasily access into the weeds or rapid degradation in the weeds. However, when we placed an electron-withdrawing (**I-n**, F) or electron-donating (**I-o**, $OCH_3$) group on the benzyl group of **I-m**, the herbicidal activity usually displayed enhanced effects (**I-n** and **I-o** > **I-m**). Therefore, the SAR at this position can be summarized as follows: $CH_3$ and $CH_2CH_3$ > *n*-Pr > $CH_2C{\equiv}CH$ > $CH_2$−2-F−$C_6H_4$, $CH_2$−3-$OCH_3$−$C_6H_4$, iBu, *n*-Bu, H, and $CH_2C_6H_5$.

On the basis of the above SAR results, we kept the methyl group at $R^1$ and synthesized a series of novel compounds with different $R^2$ substitutions to explore further their herbicidal activity (Scheme 1). A variety of substituents were introduced at $R^2$, including electron-withdrawing (F, Br, $OCF_3$, $CF_3$, and $NO_2$), electron-donating ($OCH_3$), sterically small (H), or bulky (2-iPr and 2.6-di-iPr) groups, to evaluate the substituent effect of the substituent at this position on herbicidal activity. As depicted in Tables 1 and 2, when a single group was introduced at $R^2$, in most cases, compounds with substituents at the *ortho* positions would have increased activity and broader spectrum weed control than those with equivalent substitutions on *para* and *meta* positions. For example, the above rule is applied to the chloro-substituted analogues (**I-c** > **I-a** and **I-b**), the methyl-substituted analogues (**I-f** > **I-e** and **I-d**), the methoxyl-substituted analogues (**II-h** > **II-i** and **II-j**), and the trifluoromethyl-substituted analogues (**II-k** > **II-m** and **II-l**). Notably, compounds with multiple substitutions on the phenyl ring showed a decreased herbicidal activity (**II-s−II-x**), even through some of them with substituents at the *ortho* positions. It was also found that compounds with *ortho* substitiutions of electron-donating groups (**I-f**, $CH_3$; **II-h**, $OCH_3$) displayed improved herbicidal activity compared to that of the compounds with electron-withdrawing groups (**I-c**, Cl; **II-b**, F; **II-e**, Br; **II-k**, $CF_3$; and **II-n**, $OCF_3$). The similar structure−activity trends could also be observed for the compounds with substituents at the *para* positions, although there may be a few exceptions.

The SAR results suggested that substituents in the *ortho* positions of compounds can usually improve their herbicidal activity. Inspired by this, we then synthesized compounds **II-q−II-s** with different sizes of substituents on *ortho* positions to examine the steric effects on herbicidal activity. As shown in Table 2, the steric factors had a significant impact on herbicidal activity. Compounds **II-q** ($R^2$ = 2-$C_2H_5$) and **II-r** ($R^2$ = 2-iPr) showed over 80% control in six deferent weed tests at the rate of 150 g of ai/ha. However, compound **II-s** ($R^2$ = 2,6-di-iPr) with more sterically bulky substituents in its *ortho* positions displayed decreased effects and was almost inactive toward *S. faberii* and *A. juncea*. A possible explanation for compound **II-s** with lower activity is that the large subsitutuents would prevent making bonds with plant HPPD.[28]

To examine the effect of $R^3$ substitution on herbicidal activity, we then synthesized another set of compounds (**III−V**). As in Table 3, compounds **III-a** and **III-b**, with a methyl on the 5 position of the 1,3-cyclohexanedione ring, displayed an increased herbicidal effect compared to their non-substituted analogues **II-g** and **II-v**, respectively. Furthermore, compound **III-b** exhibited over 85% control in six deferent weed tests, even at a rate as low as 37.5 g of ai/ha, demonstrating broader spectrum of weed control than mesotrione. However, when another methyl group was also introduced to the 5 position, the herbicidal activity (**IV-g** and **IV-s**) was impaired in most cases. Because of our curiosity, two methyl groups were introduced at 6 positions, with compound **V** displaying an improved herbicidal activity compared to its parent compound **II-t**. One possible reason for this phenomenon is that introducing two methyl groups on 6 posotions would block the metabolism of weeds *in vivo*.[7]

We found that most of the commercial HPPD herbicides have substituents in the *ortho* positions of their benzoyl groups.[7,8,10] It is assumed that placing a substitutent in the *ortho* position would be favorable for increasing their herbicidal activity. In addition, introducing a methyl group in the *ortho* position has been reported, to be able to enhance the herbicidal activity.[9,13] Owning to the structure feature of the triketone-containing quinazoline-2,4-dione motif, we intended to introduce a methyl group in the 5 position of the quinazoline-2,4-dione ring (*ortho* position). To understand whether placing a methyl group in the 5 position is beneficial for herbicidal activity or not, four representative compounds **I-f**, **II-h**, **II-k**, and **II-u** with a promising and broad spectrum of weed control were selected for further optimization. The synthetic methods for these methyl-substituted analogues (**VI-a−VI-d**) are outlined in Scheme 2, the herbicidal activity results are shown in Table 4. Surprisingly, compounds **VI-a−VI-d**, with a methyl group in the *ortho* positions, showed significantly

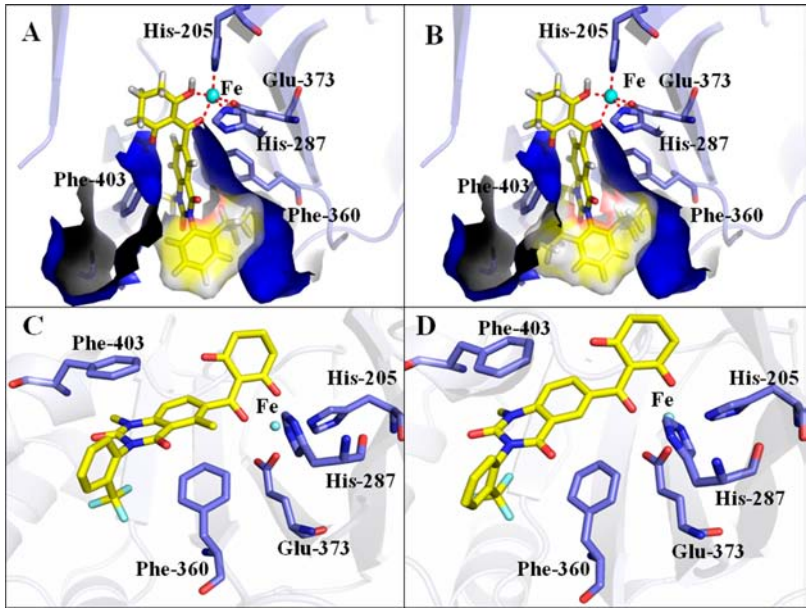

**Figure 3.** Simulated binding models of four representative compounds (A) **II-r**, (B) **II-s**, (C) **II-k**, and (D) **VI-c** in the active site of *At*HPPD, with panels A and B shown as translucent surfaces and panels C and D shown as directly binding models. Fe(II) is depicted as the aquamarine sphere; the structures of inhibitors are indicated in yellow sticks; and the key residues surrounding the active site are displayed in light blue.

improved herbicidal activity compared to their corresponding parent compounds **I-f**, **II-h**, **II-k**, and **II-u**, respectively. All four methyl-substituted analogues displayed strong inhibition (>85%) and broad spectrum for weed control, even at a dosage as low as 37.5 g of ai/ha. Especially, compound **VI-a** displayed almost 100% inhibition in both tests against monocotyledon and dicotyledon weeds, with its herbicidal potency against dicotyledon weeds (*A. retroflexus*, *E. prostrata*, and *A. juncea*) being almost equipotent to mesotrione and its potency against monocotyledon weeds (*E. crus-galli*, *S. faberii*, and *D. sanguinalis*) being superior to mesotrione.

**Crop Selectivity.** Crop selectivity is one of the vital concerns in pesticide discovery. Some representative compounds (**II-h**, **II-k**, **II-u**, **III-b**, and **VI-a**−**VI-d**) were chosen for crop selectivity evaluation. The results are listed in Table 5. It is very interesting that compound **III-b** was safe for three crops of cotton, maize, and wheat after postemergence application at a rate of 150 g of ai/ha, whereas mesotrione was not selective for cotton (70% injury) and wheat (40% injury) at the concentration of 150 g of ai/ha. This result indicated that there is a great potential for **III-b** to be used in cotton, maize, and wheat fields to control weeds. Furthermore, **II-u** was safe for maize and wheat, suggesting that **II-u** has potential to develop as a effective herbicide for controlling weeds in maize and wheat fields. In addition, **II-h** was safe for rape at the rate of 150 g of ai/ha, whereas mesotrione displayed 100% injury effect against it at the same conditions, indicating that **II-h** might has potential to develop as a new herbicide in a rape field. Moreover, **II-k** was safe for maize at the rate of 150 g of ai/ha, which indicated that **II-k** can be developed as a herbicide for maize field. Although compounds **VI-a**−**VI-d** displayed excellent herbicidal activity, they were not safe for the six selected crops. A possible explanation of compounds **VI-a**−**VI-d** to improve their herbicidal activity while decreasing crop selectivity is that the methyl group at $R^4$ would block metabolism of plants at this site.[13]

**HPPD Inhibition and SAR.** For further understanding, the structural basis for these compounds as HPPD inhibitors and the $K_i$ values of compounds **II**−**VI** against *At*HPPD are shown in Tables 2−4. Mesotrione was used as the positive control. Notably, most of newly synthesized herbicides displayed a strong *At*HPPD inhibitory activity, and some of them showed even better potency than mesotrione. Compound **VI-d** ($K_i$ = 9 nM) displayed the highest HPPD inhibitory activity, showing slightly more potency than mesotrione ($K_i$ = 13 nM). Furthermore, compounds **VI-c** ($K_i$ = 10 nM), **II-o** ($K_i$ = 12 nM), and **II-v** ($K_i$ = 13 nM) also showed excellent inhibitory activity, which are comparable to mesotrione.

On the basis of the *in vitro* activity of those compounds, some SARs can be drawn. As shown in Table 2, when the right side of the benzene ring is single-substituted, compounds with *para* substitutions generally have improved activity compared to those with the same substituents in *meta* and *ortho* positions. With regard to the multi-substituted analogues, the positions of substituents can also affect the HPPD inhibitory activity. Compounds with substituents at 2,4 and 3,5 positions would have enhanced activity compared to those at 2,6 positions (**II-v** and **II-x** > **II-t**). It seemed that the electronic factors did not significantly affect the activity; for example, compounds with either *para* substitutions of strongly electron-donating (**II-j**, $OCH_3$) groups or electron-withdrawing (**II-p**, $NO_2$) groups showed almost equal activity (**II-j** = **II-p**). In addition, the steric factors of substituents also have a significant impact on the inhibitory activity. Compounds with sterically bulky groups on the *ortho* position were found detrimental to activity (**II-r** > **II-s**). This was consistent with the herbicide inhibition activity. To understand the structural basis, we investigated the binding modes of the new compounds using compounds **II-r** and **II-s** as two representatives. As shown in panels A and B of Figure 3, the two compounds can form a bidentate association with the active site ferrous ion via its 5′ and 7′ oxygens and the quinazoline-2,4-dione ring can form $\pi-\pi$ stacking interaction with the conserved Phe360 and Phe403. In addition, the 2-isopropyl-substituted benzene ring on the quinazoline-2,4-dione moiety of compound **II-r** embedded deep into the hydrophobic cavity and occupied a major part of this pocket.

dx.doi.org/10.1021/jf5048089 | *J. Agric. Food Chem.* 2014, 62, 11786−11796

However, the 2,6-diisopropyl-substituted benzene ring of compound **II-s** occupied beyond the hydrophobic pocket, showing a strong steric repulsion effect.

It is worth mentioning that, when a methyl group was introduced to the 5 position of the quinazoline-2,4-dione ring, the inhibition of compounds **VI-a**−**VI-d** against *At*HPPD has improved significantly compared to their parent compounds **I-f**, **II-h**, **II-k**, and **II-u**, respectively (Table 4). To investigate why the methyl group at the $R^4$ position significantly improved the activity of the target compounds, compounds **II-k** and **VI-c** were chosen as the representative inhibitors for computational modeling. The energy component analysis showed that the difference mainly came from the electrostatic interaction, solvation, and entropy effects (Table 5). Compound **II-k** had an electrostatic interaction of −128.75 kcal/mol and a solvation penalty of 115.98 kcal/mol, which result in an enthalpy change of −46.33 kcal/mol. Compound **VI-c** had a lower electrostatic interaction of −138.94 kcal/mol and a higher solvation penalty of 124.09 kcal/mol, which result in a similar enthalpy change of −46.82 kcal/mol. However, a higher entropy penalty of **VI-c** (37.72 kcal/mol compared to 34.42 kcal/mol for **II-k**) resulted in a lower binding affinity (−9.16 kcal/mol compared to −11.91 kcal/mol for **II-k**), which demonstrated that the introduction of the methyl group at the 5 position of the quinazoline-2,4-dione ring can help reduce the entropy penalty and be advantageous for activity improvement.

In summary, a series of novel triketone-containing quinazoline-2,4-diones were designed and subsequently optimized on the basis of a systemic SAR study, leading to the discovery of several novel HPPD inhibitors with the excellent *in vitro* inhibitory potency and greenhouse herbicidal activity. Specifically, compounds **II-h**, **II-k**, **II-u**, **III-b**, and **VI-a**−**VI-d** were found with a potential of displaying a broader spectrum of weed control than mesotrione. More importantly, compound **III-b** was very safe for three crops of cotton, maize, and wheat at the rate of 150 g of ai/ha, showing great applicability in the field. Furthermore, at the dosage of 150 g of ai/ha, compound **II-h** was safe for rape, compound **II-k** was safe for maize, and compound **II-u** was safe for maize and wheat. The promising results suggested that the triketone-containing quinazoline-2,4-dione motif is well worth further optimization. Further structural optimizations and field trials of compounds **II-h**, **II-k**, **II-u**, and **III-b** are still ongoing.

strategies prefer an aqueous purification process, where neither the glycosides are modified nor organic solvents are included in the purification.[9] Alternatively, some strategies focus on the isolation of specific constituents, such as rebaudioside A (Ra).[10] Moreover, enzymatic transglycosylation of stevioside and its congeners has been used by some manufacturers to improve the sweetness and reduce the undesirable bitter aftertaste of these compounds. Often, cyclodextrin glycosyltransferases (CGTases) have been used for this purpose. CGTases transfer glycosyl residues from donor substrates, such as cyclodextrins[11] or starch, to the $C_{13}$ and/or $C_{19}$ sugar residues of the natural compounds, yielding a complex mixture of transglycosylated products.[12,13]

Ultrahigh-performance liquid chromatography (UHPLC) is the method of choice for compositional analysis of steviol glycosides in extracts. Different kinds of detectors have been used for identification and quantification: UV,[14,15] pulsed amperometric detection[16] (PAD), charged aerosol detector (CAD),[17] and mass spectrometry (MS).[18,19]

The aim of this study was to determine the chemical composition of the major and minor steviol glycosides by ultrahigh performance liquid chromatography−electrospray ionization−mass spectrometry (UHPLC-ESI-MS) of four commercial *Stevia* products. In addition, the sensory properties of the latter were evaluated by a trained panel to assess the impact of the different manufacturing processes and resulting chemical composition on the sensory quality of the extracts.

## MATERIALS AND METHODS

**Chemicals and Materials.** Stevioside (Sv), rubososide (Ru), steviolbioside (Sb), rebaudioside A (Ra), rebaudioside B (Rb), rebaudioside C (Rc), rebaudioside D (Rd), rebaudioside F (Rf), and dulcoside A (DuA) were purchased from ChromaDex (Irvine, CA, USA); their purity was >97%. UHPLC-MS grade water and acetonitrile (ACN) were purchased from Biosolve BV (Valkenswaard, The Netherlands).

The following materials were used: sucrose (Merck, Darmstadt, Germany), commercial *Stevia* (Daily, Santiago, Chile), caffeine (Sigma-Aldrich, Germany), iron sulfate (Merck), D-sorbitol 98% (Sigma-Aldrich), sucralose (Sugafor, Santiago, Chile), glycyrrhizic acid ammonium salt from *Glycyrrhiza uralensis* root (Sigma-Aldrich), and unsalted rice cookies (Jumbo, Santiago, Chile).

***Stevia* Samples.** Purified *S. rebaudiana* extracts obtained by different process technologies, that is, membrane purification (MP), enzymatic modification (EM), and two samples from ethanol crystallization (EC1 and EC2), were provided by Prodalysa (Concón, Chile), AccoBio (Jiangsu, China), GLG Life Tech Corp. (Vancouver, Canada), and Cargill Truvia (Minneapolis, MN, USA), respectively.

**UHPLC-DAD-ESI-MS$^n$ Analysis.** Samples were analyzed in a Thermo Accela UHPLC system (Thermo Scientific, San Jose, CA, USA) equipped with a pump and autosampler using an Acquity UPLC HSS C18 column (Waters; 150 mm × 2.1 mm i.d.; particle size = 1.8 $\mu$m) at 20 °C. The eluents used were water/acetic acid (100:0.1, v/v) (eluent A) and ACN/acetic acid/dichloromethane (100:0.1:0.1, v/v/v) (eluent B). The elution program was as follows: 0−1 min, 25% B (v/v); 1−16 min, linear gradient of 25−50% B (v/v); 16−22 min, linear gradient of 50−100% B (v/v); 22−28 min, linear gradient of 100−25% B (v/v). The flow rate was 300 $\mu$L/min. MS$^n$ analysis was performed on a Thermo Scientific LTQ VELOS, using electrospray ionization (ESI) and detection in negative mode, with a source voltage of 3.5 kV and an ion transfer tube temperature of 350 °C. The instrument was tuned manually to optimize the ionization process and sensitivity using rebaudioside A. Control of the instrument and data processing were carried out using Xcalibur 2.07 (Thermo Scientific). Identification of compounds was based on the molecular mass of the parent ion and MS$^n$ spectral data. The most abundant ion of MS$^2$ was used for MS$^3$.

To visualize the minor compounds, the analyses were carried out with a divert valve (DV), by which the main peaks (Ra and Sv) could be removed from the chromatograms. The injection volumes were 1 and 5 $\mu$L for analysis without or with DV, respectively. Quantification of Ru, Sb, Rb, Rc, Rd, Rf, and DuA was conducted in SRM mode. Due to their coelution and overlapping fragments in MS$^2$, Ra and Sv were quantified in single ion monitoring (SIR) mode, as the rest of the minor compounds, using the corresponding $[M - H]^-$ ion.

**Calibration Curves.** The standard compounds were accurately weighed and dissolved in MeOH/$H_2O$ (50:50 v/v) to obtain stock solutions with a final concentration of ∼0.1 mg/mL. Dilutions were prepared in MeOH/$H_2O$ (50:50 v/v) in the range of 0.005−1 $\mu$g/mL for Ru, Sb, Rb, Rc, Rd, Rf, and DuA and in the range of 0.1−10 $\mu$g/mL for Sv and Ra. Three independent determinations were conducted for each concentration. Calibration curves were calculated by linear regression of double-logarithmic plots of the area of the selected ions versus the concentration of the respective steviol glycoside standard. These calibration curves were employed to calculate the amount of major and minor steviol glycosides present in the original samples. The obtained linearity coefficients were >0.998 (see Table S1 in the Supporting Information). For some steviol glycosides, no commercial standards were available. Thus, Rd was used for the quantification of minor steviol glycosides and transglycosylated products containing the Glc$\beta$1−2(Glc$\beta$1−3)Glc$\beta$1- chain; and Rc was used for the quantification of compounds containing the Rha$\alpha$1−2(Glc$\beta$1−3)Glc$\beta$1- chain.

**Sensory Analysis.** The sensory attributes 'sweetness', 'bitterness', 'licorice', and 'metallic' of the four commercial samples of *Stevia* (MP, EM, EC1 and EC2) were assessed by a trained panel that was previously recruited by the Centro de Aromas y Sabores following ISO norms.[20] All panelists ($n$ = 13) had previous experience in sensory analysis of other products. The panel received a specific training to assess the sensory properties of the *Stevia* extracts and employed a category-specific scale of 100 mm (product specific) for the sensory assessment.[21] Sensory data were acquired with the software Compusense Five release 5.4 (Guelph, Canada) and analyzed (ANOVA, means, SD) with Senstools (version 3.0.11, OP&P Product Research, Utrecht, The Netherlands).

**Selection and Training of the Panelists.** The selection procedure consisted of two phases. First, 33 female candidates 45 ± 5 years of age were asked to rank seven randomly presented sucrose solutions (2, 3, 5, 7, 9, 11, and 13% w/v sucrose) in order of increasing sweetness. In the second phase, the panelists had to position samples of sorbitol (86200 mg/L), sucralose (78.6 mg/L), and commercial *Stevia* (276 mg/L) within the correctly ordered sucrose solutions. These samples were designed to match the sweetness of a 5% w/v sucrose solution, as proposed elsewhere.[22,23] All of the sessions were performed in standardized sensory booths. Among the candidates, 13 panelists that performed correctly both tests were selected for further training.

The selected panelists completed five introductory training sessions of 2 h each during a 2 month period. First, they were introduced to the main sensory attributes describing sweeteners (sweetness, bitterness, licorice, and metallic taste). For this purpose, five solutions were shown to the panelists to familiarize them with the attributes: sucrose (sweetness), commercial *Stevia* (sweetness), caffeine (bitterness), glycyrrhizic acid ammonium salt (licorice), and iron sulfate (metallic taste).

In a second phase, a product-specific scale was developed to reflect the typical bitterness, licorice, metallic, and sweet tastes of the solutions that were assessed later by the panelists. The intensity range of each attribute was assessed on a scale from 0 to 100 mm. For each attribute, a reference stimulus was provided, which was anchored with an intensity in the middle of the scale at 50 mm. A series of 5% w/v sucrose solutions with increasing concentrations of tastants were presented to estimate the concentration of the reference stimulus, such as its perceived intensity, was similar to the intensity of each attribute present in the four *Stevia* samples. The reference stimuli for each

sensory attribute, with their respective concentrations, were as follows: caffeine for bitterness (0, 65, 110, 155, 210, and 250 mg/L), glycyrrhizic acid ammonium salt for licorice (100, 300, 500, 700, 900, and 1000 mg/L), and iron sulfate for metallic (0, 8, 10, 12, and 14 mg/L). The panelists had to position an aqueous 300 mg/L *Stevia* solution in each of the rankings of standards. For this purpose, the MP extract was randomly selected among the *Stevia* samples.

For determination of the concentration of the reference, the arithmetic mean of the positions selected for each attribute was calculated, and the resulting proportion was assigned to the respective concentration of the standard. The resulting concentrations of the reference stimuli in a 5% w/v sucrose solution anchored at 50 mm of the line scale were 114 mg/L of caffeine for bitterness, 280 mg/L of glycyrrhizic acid ammonium salt for licorice, and 11 mg/L of iron sulfate for metallic. Then, subjects were further trained employing these solutions as reference stimuli.

**Training of the Subjects of the Category Specific Scale.** The training of the panelists on the sensory space of the *Stevia* samples was carried out employing the Feedback Calibration Method (FCM) from Compusense Five software. FCM allows the training time of the panel to be reduced significantly by giving instant feedback on the attribute intensity after performing the assessment of a specific attribute.[24] An introductory session was used to present the 100 mm line scale. The training consisted of dedicated training sessions for each attribute. At least three training sessions were conducted for each attribute separately.

Training sessions in which all attributes were evaluated for one sample composed of mixtures of the reference stimuli were assessed with FCM. In at least six sessions, the levels below and above the anchor of each attribute were evaluated by the panelists. The following concentrations, in a 5% w/v sucrose solution, were evaluated in the training sessions: for bitterness, 75, 85, 95, 114, 150, and 200 mg/L caffeine; for licorice, 140, 210, 280, 420, 490, and 560 mg/L glycyrrhizic acid; for metallic, 8, 9, 11, 13, and 15 mg/L iron sulfate. The maximum concentration represented the highest intensity on the line scale (100 mm), and a blank represented the lowest intensity on the line scale (0 mm). Additionally, a mixture of these standards was prepared to train the panelists in the assessment of all the attributes simultaneously. In the final step of the training, the panel worked on sessions of consensus, where the panelists calibrated themselves with the mean values achieved by the group after evaluating the different *Stevia* samples. The training aimed to allow the panelists to differentiate small differences between the *Stevia* samples, as well as a correct use of the scale. The training sessions were carried out until the standard deviation from the mean of the intensity of each attribute (SD) assessed by the 13 subjects was <20 scale units.[21]

**Sensory Evaluation Procedure.** The four *Stevia* samples, chemically characterized by UHPLC ESI MS, were evaluated in aqueous solution by the trained panel. *Stevia* samples were dissolved in purified water at a concentration close to the sweetness of a 5% w/v sucrose solution, previously estimated by the panel leader and experienced professionals of the field. The following concentrations were used for the sensory evaluation of the *Stevia* samples by the trained subjects: 300 mg/L for MP, 700 mg/L for EM, 250 mg/L for EC1 and 220 mg/L for EC2. All samples were prepared freshly the day the sensory assessment was performed. The reference stimuli for each attribute in solutions of 5% w/v of sucrose were presented prior to the evaluation.

The trained panelists ($n$ = 13) performed a descriptive analysis[25] of the four *Stevia* samples in duplicate, evaluating the attributes sweetness, bitterness, licorice, and metallic. For mouth cleansing between samples, assessors had to use unsalted rice cookies and filtered water. The minimum resting time between samples was set at 3 min to minimize carry-over effects between samples.[4] Samples were presented in a volume of 20 mL in plastic cups with three-digit random numbers in a balanced manner. Panelists drank the sample, swirled it in the mouth for 7 s before swallowing, and then assessed the intensity of each attribute on the category scale presented in the screen of the computer.

**Statistical Data Analysis.** The means and standard deviations were calculated using the software Senstools. A repeated-measures ANOVA was used with samples as factor and judges to test for the significance of differences. A LSD post hoc comparison was performed. A significance level of $p < 0.05$ was chosen.

## RESULTS AND DISCUSSION

**Liquid Chromatography of *Stevia* Extracts Obtained by Different Manufacturing Processes.** Figure 2 illustrates

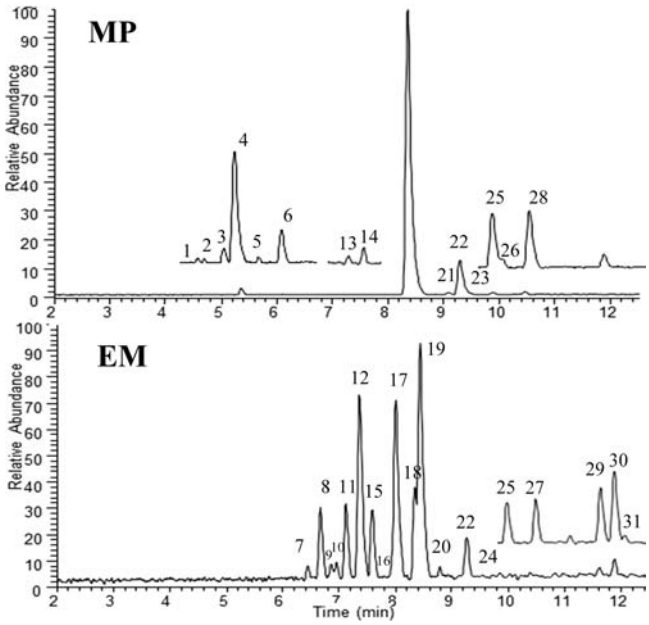

**Figure 2.** Chromatograms (MS-SIR) of *Stevia* extract from Chile (MP, membrane purified) and from China (EM, enzymatically modified). Zooms (100×) of regions with lower intensity signals have been added as insets.

the full MS chromatograms of the MP and EM samples, with a complete separation of 31 compounds, except rebaudioside A (**18**) and stevioside (**19**). The steviol glycosides Rd, Ra, Sv, Rf, Rc, DuA, Ru, Rb, and Sb (Table 1, peaks 4, 18, 19, 21, 22, 23, 28, 29, and 30, respectively) were identified on the basis of coelution with their authentic standards, as well as on their fragmentation pattern upon mass spectrometry. All steviol glycosides showed a consecutive loss of sugar moieties in $MS^2$ fragmentation of the $[M - H]^-$ parent ion (Table 1).

The MP extract is used here to illustrate a typical chromatogram of a purified *Stevia* extract. This chromatogram is similar to that of both EC extracts (not shown), with the main peak corresponding to the sum of Ra (**18**) and Sv (**19**). On the contrary, the chromatogram of the EM sample is very different, with several major peaks eluting earlier than Sv and Ra.

**Identification of Minor Natural Steviol Glycosides.** The various compounds were identified on the basis of the $m/z$ of their $[M - H]^-$ ions, their respective fragmentation patterns, and the literature. Compound **3** with $[M - H]^-$ of $m/z$ 1273 has one deoxyhexose and five hexose moieties attached. In $MS^2$, this parent ion yielded $m/z$ 803 (Table 1), indicating the loss of two hexoses and one deoxyhexose. As $MS^2$ of the commercial standards always showed cleavage of the ester-linked $O-R_1$ bond, prior to the ether-linked $O-R_2$ bond, the $R_1$ side chain might consist of one deoxyhexose and two hexoses moieties, whereas $R_2$ consists of three hexoses. Compound **3** was

[a]Most abundant ions are shown in bold, in $MS^1$ it corresponds to $[M-H]^-$ ion), structures of previously described steviol glycosides confirmed with commercial standards (*) and the others represents the hypothetical distribution of sugar moieties in identified compounds without available commercial standards, see Figure 1. In enzymatic transglycosylation products, the additional glucosyl residues attached to the natural steviol glycoside are underlined. Glc, glucoside; Rha, rhamnoside; Xyl, xyloside; hex, hexoside; deohex, deoxyhexoside.

annotated as rebaudioside N (Rn). Compound **6** with $[M-H]^-$ of $m/z$ 1289 gave the fragment ion of $m/z$ 803 in $MS^2$ (Table 1), indicating the loss of three hexoses from $R_1$. Therefore, **6** was annotated as rebaudioside M (Rm), containing two trihexosyl side chains. Compound **25** with $[M-H]^-$ of $m/z$ 803 is an isomer of Sv, comprising three hexose moieties. The main fragment ion in $MS^2$ was $m/z$ 641 (Table 1), indicating the loss of one hexose, most likely $R_1$. A loss of 324 Da in $MS^3$ represents the dihexosyl moiety of $R_2$. Compound **25** is suggested to be rebaudioside G (Rg). Sv and Rg have the same fragmentation pattern, but they might differ in the type of glycosidic linkage or kind of hexose. Compounds **3**, **6**, and **25** have been previously described.[5] Compounds **1**, **14**, and **26** were annotated as I, II, and III, respectively, similar to steviol glycosides. Compound **I** was described before as compound 6,[27] **II** as compound 1[19] and **III** as compound 2.[26]

Compound **1** with $[M-H]^-$ of $m/z$ 981 had four hexose moieties attached to the kaurene skeleton with a mass of 332 Da (previously described by Ohtani et al.[28]). In $MS^2$, the parent ion yielded $m/z$ 819 (Figure 1), indicating the loss of one hexose, most likely ester-linked to $C_{19}$. The observed ion $m/z$ 465 in $MS^3$ would indicate the loss of two hexoses and $-CH_2OH$ from skeleton 2 (Figure 1). Therefore, peak 1 might be the same degradation product of rebaudioside A, previously described by Chaturvedula et al.[27] Compound **14**, with $[M-H]^-$ of $m/z$ 965, is an isomer of Ra. The $m/z$ 803, the second most abundant fragment ion in $MS^2$, points to the loss of one hexose at the $C_{19}$ and three hexoses moieties at $C_{13}$ (Table 1), similar to Ra, but with different interglycosidic bonds. Therefore, we suggest that **14** is the same as II, as previously reported.[19] Compound **26**, with $[M-H]^-$ of $m/z$ 949, has three hexoses and deoxyhexose moieties attached, confirmed with the observed loss of 146, 162, and 324 Da (Table 1). Compound **26** is the same compound previously reported by Chaturvedula and Prakash.[26]

**Identification of Transglycosylated Products.** The manufacturer of the EM product declared the use of enzymes in the production process. Stevioside and rebaudioside A are the most abundant compounds in *Stevia* leaves. However, a low bitterness threshold for stevioside has been reported recently,[4] which affects their sensory quality.[29] Enzymatic modification of the structure of this compound reduced, at least in part, its residual bitterness.[30] At industrial level, the enzymatic modification of stevioside is widely employed. On the contrary, industrial transglycosylation of rebaudioside A is not feasible.[30]

Therefore, and considering the resulting fragmentation patterns of the EM sample, the identified compounds in this sample probably correspond to transglycosylation products of Sv and Sb (or Ru). Their structural identification must be confirmed, however, by isolating these compounds by semipreparative HPLC and further NMR characterization. Similar fragmentation patterns of a group of these transglycosylated compounds have been reported for natural steviol glycosides obtained from *Stevia* leaves.[5] However, the concentrations of these natural compounds are lower than the concentrations obtained by transglycosylation.

Eleven peaks were proposed to be transglycosylated products in the EM sample. All of these compounds share the same principal structure (steviol), although they show differences in the number (mono-, tri-, tetra-, penta-, and hexasaccharides) and type of sugar moieties (glucose and/or rhamnose) at positions $C_{13}$ and $C_{19}$. We hypothesize that these compounds are transglycosylation products of Sv, Sb, and Rc, resulting from the action of CGTase, because of their earlier elution (higher polarity) and higher masses than the latter. Several authors[13,31] have described the modification of stevioside with CGTases in the presence of soluble starch or cyclodextrins, resulting in a mixture of products with extra mono, di, tri, or larger $\alpha$-glucosyl chains attached at the $C_{19}$- and/or $C_{13}$-glucosyl unit.[11,13,31] The proposed structures are indicated in Table 1.

Compounds **8**, **11**, and **15** eluted at 6.7, 7.1, and 7.6 min, respectively, with the same quasi molecular ion peaks $[M - H]^-$ at $m/z$ 1127 (Figure 3). The tandem mass spectrometric fragmentation patterns of these three compounds were different from each other (Table 1), suggesting that they were isomers with different numbers of glucosyl moieties attached to the $C_{19}$- or $C_{13}$-glucosyl unit of Sv. The molecular weight of Sv is 804 Da, so the above three isomers were assumed to be diglucosylated products, consisting of stevioside with two hexoses attached (stevioside-$(glucosyl)_2$).

Compound **8** had a deprotonated molecular ion at $m/z$ 1127; the fragmentation of this ion yielded a main ion at $m/z$ 965 in $MS^2$ (Table 1), indicating the loss of a hexose attached at $C_{19}$. Therefore, the two hexoses added by CGTase transglycosylation are attached to the $C_{13}$–O-glucosyl unit (Table 1). This structure was also proposed as rebaudioside L,[5] a compound naturally present in *Stevia* leaf, but not in such a high concentration as that found in the EM sample (Table 2). Compound **11**, with a $[M - H]^-$ of $m/z$ 1127, gave a fragment ion of $m/z$ 803 in the $MS^2$ (Table 1), indicating the loss of two hexoses attached at $C_{19}$- and another hexose attached at $C_{19}$-glucosyl (Table 1). Compound **15** showed a product ion at $m/z$ 641 in $MS^2$ (Table 1), indicating the loss of three hexoses attached at $C_{19}$ (Table 1). It is worth noting that compound **16** represents another isomer of $m/z$ 1127, with a fragmentation pattern similar to that of compound **11**. Compound **16**, found in the MP sample, was assumed to be rebaudioside I (Ri), a natural steviol glycoside. It is different from compound **11**, a transglycosylation product, and it has a different retention time in the EM sample (Table 1). Although both compounds have similar fragmentation patterns and the same distributions of sugar moieties (Table 1), they might be different compounds because one of them was found in MP (sample without enzymatic treatment) and the other in the transglycosylation product (EM). Other examples of isomers identified as natural and transglycosylated steviol glycosides that are present in different products are, for instance, compounds **17**, **18**, and **24** with $[M - H]^-$ of $m/z$ 965 and compounds **19**, **25**, and **27**

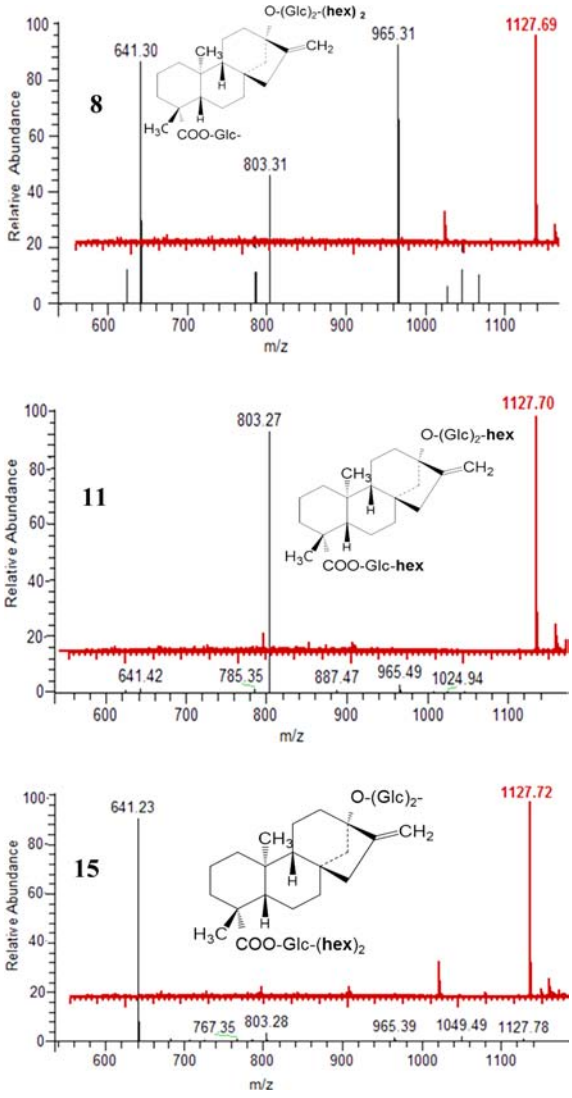

**Figure 3.** Tandem mass spectra ($MS^1$ (in red) and $MS^2$) of the transglycosylated compounds **8**, **11**, and **15**.

with $[M - H]^-$ of $m/z$ 803[5,32] (Table 1). These molecules were annotated in essentially the same way as those with $m/z$ 1127. Furthermore, the natural compounds **18** and **19** were confirmed with their respective commercial standard. The different type of interglycosidic linkage between natural and transglycosylated molecules leads to different elution behavior, on the basis of which these molecules could be distinguished. By this analysis, we demonstrated that the EM sample was obtained by transglycosylation. Of the 24 peaks present in EM, 11 are suggested to be transglycosylation products (Table 1).

**Quantitative Analysis of Steviol Glycosides.** In all commercial *Stevia* extracts, except EM, Ra was the most abundant compound, with a concentration >60 mg/100 mg of extract. Interestingly, MP contained a wide variety of minor steviol glycosides, up to 24 mg/100 mg (Table 2), resulting from the aqueous extraction and membrane purification processes employed for this sample. The slightly higher than 100% total sweetener content obtained for the three samples might result from inaccuracies of the quantification method.

**Descriptive Sensory Analysis of the Commercial *Stevia* Extracts.** The results of the sensory evaluation of MP, EM, EC1, and EC2 samples are presented in Table 3. The

[a]The standard deviation ($n$ = 3) is given in parentheses. [b]Taste threshold ($\mu$M). [c]nd, not detected.

**Table 3. Intensity of Sensory Attributes of *Stevia* Extracts Determined by a Trained Panel ($n$ = 13 in Duplicate)[a]**

| attribute | MP | EM | EC1 | EC2 |
|---|---|---|---|---|
| sweetness | 49.2 ± 7.3a | 49.5 ± 5.0a | 48.3 ± 5.2a | 48.0 ± 2.4a |
| bitterness | 59.1 ± 12.6c | 53.3 ± 11.1bc | 49.7 ± 15.2ab | 44.3 ± 16.4a |
| licorice | 68.3 ± 12.8c | 58.9 ± 12.3b | 51.2 ± 17.9ab | 48.6 ± 16.2a |
| metallic | 53.0 ± 12.0a | 49.1 ± 7.9a | 47.9 ± 8.1a | 45.3 ± 12.6a |

[a]A category specific line scale 0−100 mm was employed for the sensory evaluation. Means and standard deviations are shown (mean ± SD). The same letter indicates that means of intensity are not significantly different between samples at $p < 0.05$ confidence level.

means of intensity, together with the standard deviations, are reported. An ANOVA was performed on all attributes. The intensity of the attributes bitterness [$F(3,36) = 4.19$, $p = 0.01$] and licorice [$F(3,36) = 8.17$, $p = 0.00$] differed significantly between samples. On the contrary, the intensity of the attribute metallic did not differ significantly between samples [$F(3,36) = 2.39$, $p = 0.09$]. Sweetness was not significantly different between samples [$F(3,36) = 0.32$, $p = 0.814$]. All *Stevia* samples were perceived as iso-sweet and compared in sweetness with the reference stimulus (5% w/v sucrose solution anchored at 50 mm of the scale), matching the level of sweetness. The evaluation of the 5% w/v sucrose reference yielded 49.8 ± 0.3 in the attribute sweetness, 4.4 ± 7.7 in bitterness, 1.8 ± 2.9 in licorice, and 3.6 ± 8.9 in metallic.

In the case of MP, the presence of natural minor glycosides, and eventually the remaining impurities that were not

analytically identified in this study, might be responsible for the significantly higher licorice and bitterness intensities. It is worth mentioning that the MP sample has the highest concentration of rebaudioside D, a steviol glycoside containing the highest amount of $\beta$-glycosyl moieties, recently characterized by its high sweetness intensity and low bitterness intensity.[4] However, the amount of rebaudioside D was below its threshold concentration (Table 2) and, therefore, its contribution to the whole sweetness of the sample might be limited. The additive impact of the different constituents, however, should be considered in further research. MP sample also has the highest amount of rebaudioside C, but still below the threshold for bitterness; again, an additive effect among the different rebaudiosides could contribute to the higher perceived bitterness level and should be considered. EC1 and EC2 samples showed no significant differences for any of the attributes, demonstrating that the intensities of the off-flavor are equally intense when compared under iso-sweet conditions, despite their different contents in rebaudioside A and stevioside (Table 2). This difference in composition, however, has a cost impact that is worth considering for industrial applications. All samples do not significantly differ in metallic taste.

The impact of the fraction in the EM sample that remained compositionally unknown (ca. 35% w/w) on the sensory properties could not be assessed. On the other hand, in the EM sample, the concentration of Ra and Sv represents only 9% w/w of the total composition; instead, transglycosylated constituents (Table 2) accounting for almost 47% w/w are accountable for the remaining sweetness.[11]

In conclusion, this study shows that the MP sample contains a wide range of natural steviol glycosides. However, when compared at iso-sweet conditions, this *Stevia* product shows the strongest intensities of the off-taste attributes bitterness, licorice, and metallic compared to *Stevia* samples obtained by other processing techniques. Furthermore, extracts resulting from similar, solvent-extracted, purification processing but with different composition (EC1 and EC2) present similar sensory properties, although the extracts vary considerably in chemical composition. Finally, considering that *Stevia* leaves are particularly rich in Sv, a compound with high bitterness off-taste, our results show that the enzymatic modification occurring in the EM sample is an effective alternative to reduce off-tastes; the similar levels in all attributes of EM and EC1 support this conjecture.

The UHPLC-MS$^n$ method proposed here should allow identifying major and minor steviol glycosides in a single run and could be applied as a routine quality control method for natural and transglycosylated commercial extracts of *Stevia*.

and some sulfur containing compounds like dimethyl disulfide and dimethyl trisulfide.[17]

Different from previous literature reports on goat's milk, this study aimed to characterize not the entire volatile fraction of the milk or some specific odorants, but the most potent aroma compounds by use of GC/O and AEDA. In detail, the odor profile of raw milks from winter and summer season of different farms were compared with each other, also including a human sensory evaluation by means of aroma profile analysis (APA). Since the composition of milk fat is known to be an important contributor to milks' odor profiles, also the fatty acid composition of the raw goat milk was investigated. Furthermore, changes in goat milks' odor profiles as a result of heat-treatment were investigated. In a comparative approach, pasteurized, UHT-treated, and sterilized goat milk were studied by means of analytical and descriptive profiling.

## MATERIALS AND METHODS

**Chemicals.** *Fatty Acid Analysis.* The following chemicals with the stated purities were used (supplier in parentheses): ascorbic acid 95% p.a., 1-butanol 95%, formic acid 85%, sodium dihydrogen phosphate-dihydrate 95% p.a., tridecanoic acid 99% (Fluka, Steinheim, Germany), Celite 545, potassium hydroxide 98.5% p.a. (Sigma-Aldrich, St. Louis, MO), fatty acids calibration kit (Büchi, Essen, Germany).

*GC/O Analysis.* Dichloromethane p.a. was used as the organic solvent and extracting agent (Th. Geyer GmbH and Co. KG, Renningen, Germany). Anhydrous sodium sulfate was purchased from CHEMSOLUTE (Th. Geyer GmbH and Co. KG, Renningen, Germany). For unequivocal identification, the following reference compounds were used in stated purities: 4-hydroxy-3-methoxybenzaldehyde (vanillin) 99% (ABCR, Karlsruhe, Germany), 2-aminoacetophenone 98%, 1-benzopyran-2-one (coumarin) 99%, δ-decalactone 98%, γ-decalactone 98%, decanoic acid 98%, dimethyl trisulfide 98%, dodecanoic acid 98%, 4-ethyloctanoic acid 98%, 2-furaldehyde (furfural) 99%, hexanoic acid 99.5%, 3-hydroxy-4,5-dimethyl-2(5*H*)-furanone (sotolone) 97%, 3-hydroxy-2-methyl-4-pyrone (maltol) 99%, 2-methoxyphenol (guaiacol) 98%, 2 methylbutanoic acid 98%, 3-methylbutanoic acid 99%, 3-methylindole (skatol) 98%, 4-methyloctanoic acid 98%, 3-methylphenol (*m*-cresol) 99%, 3-methylthiopropanal (methional), (*E*,*E*)-nona-2,4-dienal 85%, (*E*,*Z*)-nona-2,6-dienal 95%, γ-nonalactone 98%, δ-nonalactone 98%, nonanoic acid 97%, (*E*)-non-2-enal 97%, octanal 99%, octanoic acid 98%, (*E*)-oct-2-enal 94%, oct-1-en-3-one 50%, phenylacetic acid 99%, phenylethan-2-ol 99%, γ-undecalactone 98% (Aldrich, Steinheim, Germany), 2-acetyl-1-pyrroline 90%, γ-(*Z*)-6-dodecenolactone, *trans*-4,5-epoxy-(*E*)-dec-2-enal 90% (aromaLAB AG, Freising, Germany), γ-octalactone (EGA Chemie, Steinheim, Germany), 1*H*-benzo[*b*]pyrrole (indole) 98.5%, butan-2,3-dione (diacetyl) 99%, butanoic acid 99.5%, (*E*,*E*)-deca-2,4-dienal 85%, dimethyl disulfide 98%, 4-hydroxy-2,5-dimethyl-3(2*H*)-furanone (furaneol) 99%, pentanoic acid 99% (Fluka, Steinheim, Germany), 3-ethylphenol 98% (Riedel-de-Haen, Seelze, Germany), δ-dodecalactone 98%, γ-dodecalactone 97%, 3-propylphenol 99%, (*E*)-undec-2-enal 90% (SAFC, Hamburg, Germany).

**Goat Milk.** Two types of raw milk (winter season, summer season) as well as three types of heat-treated goat milk (pasteurized, UHT-treated, sterilized) were analyzed in a comparative approach. In the case of raw milk, the milks were obtained from two different farms during two periods: winter season ("W", from 15 February to 21 March) and summer season ("S", from 19 July to 10 August). Farm 1 (W1, S1) had a flock size of 120 goats of the breed "Bunte Deutsche Edelziege"; farm 2 had a flock size of 85 goats of the same breed. According to the farmer's statements, both herds were fed on a mixture of home-grown pasture and grains (trefoil-grass, mixture of oat, barley, pea, triticale), given as straw/dried fodder and hay (conserved feed). Farm 2 additionally fed rapeseed meal, sugar beet slices, and carrots. At the beginning of the lactation period, both herds were additionally fed on concentrated feed, including rapeseed meal and sugar beet slices. Both farms fed their herds according to their good practice, and no specific feeding protocol was established in terms of this study to stay as close as possible to a conventional goat milk aroma and fatty acid composition.

Sterilized goat milk was produced by sterilizing raw milk at 121 °C and a pressure of 2 bar for 15 min in a laboratory autoclave (Fedegari Autoklavi Spa, Albuzzano, Italy). Pasteurized and UHT-treated goat milk were purchased from local supermarkets: Leeb Vital Bio-goat milk, pasteurized (Leeb Biomilch GmbH, Schlierbach, Austria), and Andechser Bio-goat milk, UHT-teated (Andechser Molkerei Scheitz GmbH, Andechs, Germany).

**Preparation of Milk Samples and Fatty Acid Analysis.** Sample preparation and gas chromatographic determination of the total fat content and fatty acid profiles were performed according to the DGF standard method C-III 19 (99).[18] By means of this DGF method, both free fatty acids and fatty acids bound in mono-, di-, and triglycerides, phospholipids, and sterols can be detected.

**Isolation of Volatile Organic Compounds (VOCs).** Solvent assisted flavor evaporation (SAFE)[19] was applied for the isolation of volatiles from fresh goat milk samples and heated goat milks. At room temperature (21 ± 1 °C), 25.0 ± 0.1 mL of goat milk was combined with freshly distilled dichloromethane at a ratio of 2:1 (milk/solvent). The mixture was stirred and distilled, and the organic phase of the distillate was separated, dried, and concentrated as it was reported before by Siefarth et al.[20]

**Characterization and Identification of Goat Milk Odorants.** *Characterization.* Concentrated distillates were characterized by applying them to a high resolution gas chromatography/olfactometry system (HRGC/O, type Trace GC Ultra, Thermo Fisher Scientific, Schwerte, Germany). Application was performed by use of the cold-on-column technique (at 40 °C) using the same GC capillaries and settings as described in an earlier study.[20] Two panelists screened the distillate for odor-active volatiles. Screening was performed by sniffing the effluent after gas chromatographic separation at the sniffing port and simultaneously describing the perceived odor impressions (GC/O). Additionally, AEDA was performed on all goat milk samples to screen for the most potent odorants. In detail, an FD series was sniffed via HRGC-O by diluting the concentrated distillates (FD factor $2^n$, concentrate, FD $2^0$ = FD 1) stepwise with dichloromethane (1:1, v/v). Two microliters of each dilution was analyzed on a DB-FFAP capillary.

*Identification.* Odorants were identified based on the following criteria: odor quality, RIs on two stationary phases, and mass spectra. Linear RIs of the compounds were calculated as described by Van Den Dool and Kratz.[21] Identification was performed using a two-dimensional gas chromatographic system (2D-HRGC-MS/O), of which the setup and GC conditions were described in an earlier study.[20] Mass spectra in the electron impact mode (MS/EI) or chemical ionization mode (MS/CI) were acquired ($m/z$ range 35−249 and 60−299, respectively). In the case of EI mode, mass spectra were generated at ionization energy of 70 eV; in CI mode, methanol was used as the reagent gas at a flow of 2.5 mL $min^{-1}$.

**Aroma Profile Analysis (APA).** Sensory analyses were performed in a sensory room at 21 ± 1 °C. Goat milk samples (20 mL) were filled into sensory glass beakers (140 mL, J. Weck GmbH u. Co. KG, Wehr, Germany) and closed with a lid. Trained panelists ($n$ = 11−16, male/female, age 23−45) with normal olfactory and gustatory function participated in the APA sessions. They exhibited no known illness at the time of examination. Prior to this study, the assessors were recruited in weekly training sessions for the recognition of about 200 selected odor-active compounds according to their odor qualities by means of an in-house developed flavor language. A preliminary sensory session was performed to evaluate and collect orthonasal (o) and retronasal (r) odor attributes of the different goat milks. Attributes that were detected by more than 50% of the panelists were selected for subsequent sensory evaluations. Panelists were asked to score the perceived intensities (o, r) of the selected attributes on a seven-point-scale from not perceivable (0) to weak (1), medium (2) and intensely perceivable (3), in increments of 0.5. The results for each odor attribute and goat milk sample were averaged and plotted in spider-web diagrams.

**Table 1. Main Fatty Acid Composition of Raw Goat Milk from Winter (W) and Summer (S) Seasons and Different Farms (1,2)[a]**

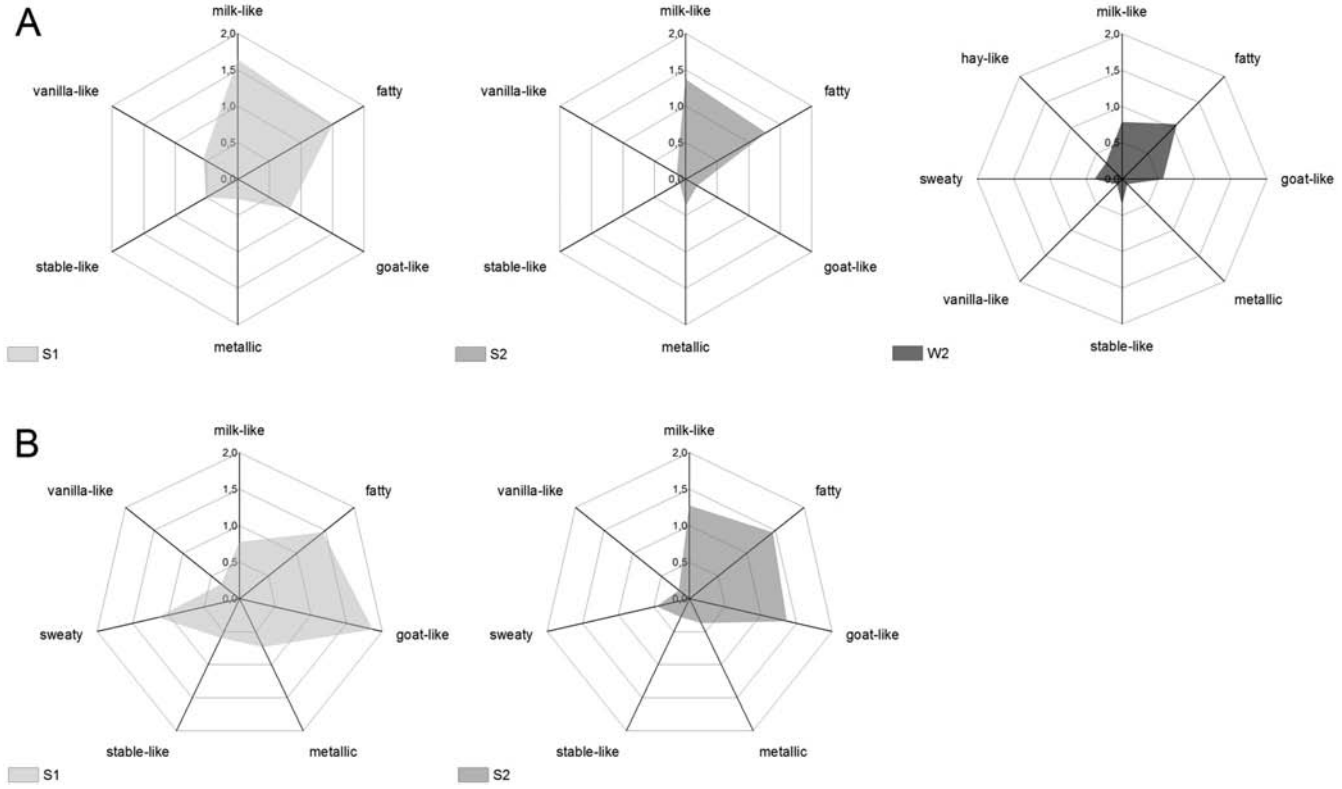

**Figure 1.** Orthonasal (A) and retronasal (B) odor profiles of goat milk: raw milk profiles from summer (S) and winter (W) season.

**Statistical Analysis.** For statistical analyses, Student's *t* test (Welch-test) or Mann–Whitney U-test was performed using OriginPro 9.1 (OriginLab Co., Northampton, MA). The level of statistical significance was set at 5%.

## RESULTS

**Fatty Acids Composition of Raw Milks.** The fatty acid composition of goat's milk was investigated in a comparative approach of winter versus summer milk and thus during different lactation stages (Table 1). Overall, the fatty acid percentage composition of summer and winter milk was quite similar to each other as the statistical comparison of $W_{mean}$ and $S_{mean}$ shows. Thus, average seasonal effects on fatty acid composition of goat's milk were found to be low. Significances were only detected in a few cases ($C_{6:0}$, $C_{14:0}$, $C_{16:0}$, $C_{18:0}$, $p < 0.05$).

Generally, winter milk contained a higher percentage of total MUFAs (monounsaturated fatty acids) while summer milk contained a higher percentage of total SFAs (saturated fatty acids). PUFA (polyunsaturated fatty acid) contents were quite similar between summer and winter milks. However, differences in fatty acid composition were more significant by direct comparison of (a) winter/summer milks from the same farm (W1/S1, W2/S2, seasonal effect) or (b) winter/summer milks from the same season but different farms/herds (W1/W2, S1/S2, farm-specific effect) (Table 1). In detail, most variations were detected in case of the fatty acids $C_{10:0}$, $C_{14:0}$, $C_{16:0}$, $C_{18:0}$, $C_{16:1}$, $C_{18:1}$, $C_{18:3}$, $p < 0.01$. Thus, farmer's seasonal changes in the goat's diet (types of pasture, grains) as well as farm-specific differences between two farms/herds of the same breed (e.g., due to feeding or animal-specific differences) showed an effect on percentage fatty acid composition.

**Sensory Characterization of the Raw Goat Milks by Means of APA.** Orthonasal (o) and retronasal (r) odor profiles of the raw goat milk samples were described by the following eight attributes: milk-like, fatty, goat-like, metallic, stable-like, vanilla-like, sweaty, and hay-like (Figure 1). Those attributes were detected by more than 50% of the trained panelists in one or more of the different raw milks.

Orthonasally, the strongest odor attributes were milk-like and fatty (weak to medium intense; mean values 1.3) followed by weak perception of the attribute *goat-like* (mean value 0.5). All other attributes were just slightly perceivable with mean values below 0.5.

Retronasally, goat-like and fatty were the strongest perceived odor attributes (medium intense; mean values 1.6 and 1.5). The attributes milk-like, sweaty, and metallic were evaluated with weak intensities (mean values 1.0, 0.8, and 0.6), and stable/vanilla-like odors were just slightly perceived (mean values <0.5).

When S1 and S2 (o, r), and thus milks from the same season but two different farms, were compared, odor profiles were evaluated for farm-specific effects. Orthonasally, the summer raw milks were ranked similar with respect to the attributes milk-like, fatty, and metallic (Figure 1). S1 was rated slightly more stable-like and vanilla-like and considerably more goat-like (>0.5 units). Retronasally, odor differences became more clear with respect to the attribute goat-like (mean intensities $_{S1,S2}$: 1.9 and 1.4), but also *sweaty* was perceived more intense in S1 (mean intensities $_{S1,S2}$: 1.1 and 0.5) and *milk-like* in S2 (mean intensities S1 and S2, 0.8 and 1.3). Metallic and stable-like were ranked slightly higher in S1. Thus, the raw milk odor profiles of one season were found to vary from one farm to another.

**Table 2. Characterization and Identification of Potent Odorants (FD ≥ 8) in Raw Goat Milk from Summer and Winter Season Using Gas Chromatography/Olfactometry (GC/O)**

| | | | RI on | | FD-factor[d] in raw goat milk | | | |

[a]The compound was identified by comparison with the respective reference substance on the basis of the following criteria: retention indices (RI) on two stationary phases given in the table (DB-FFAP, DB-5), mass spectra obtained by MS/EI or MS/CI, and odor qualities perceived at the sniffing

dx.doi.org/10.1021/jf5040724 | J. Agric. Food Chem. 2014, 62, 11805−11817

**Table 2. continued**

port(s). [b]MS signals were too weak for an unequivocal interpretation. The compound was identified based on the remaining criteria given in footnote *a*. [c]Odor quality as perceived at the sniffing port. [d]Only compounds that were detected with FD values >8 are displayed. [e]Not determined.

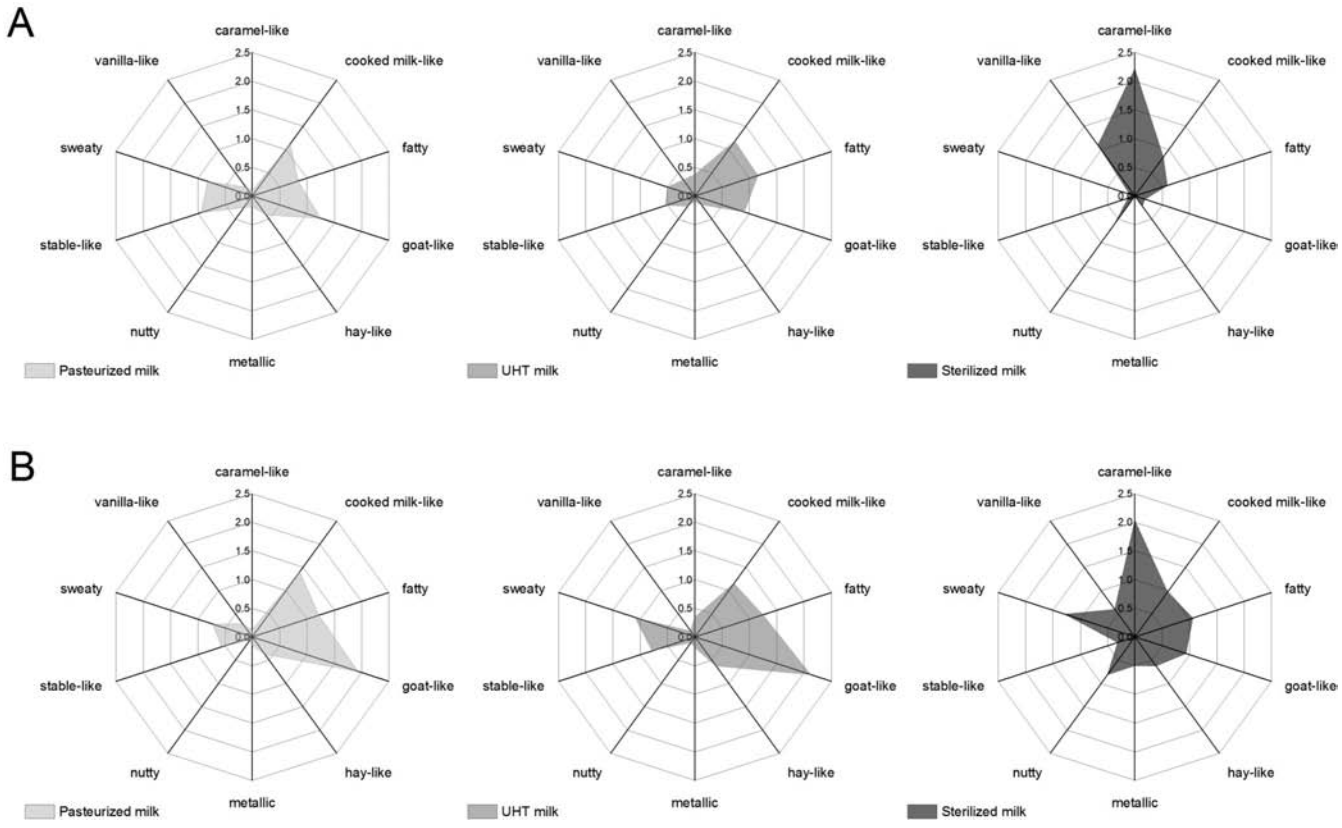

**Figure 2.** Orthonasal (A) and retronasal (B) odor profiles of goat milk: heated milk profiles after pasteurization, UHT-treatment, and sterilization.

Seasonal effects were detected by comparison of the odor profiles (o) of winter and summer raw milks of the same farm. Again, differences in the odor profiles became obvious (here W2, S2) (Figure 1): while S2 had higher rankings for the attribute milk-like (mean intensities S2 and W2, 1.4 and 0.8), W2 was rated more intense with respect to goat-like (mean intensities S2 and W2, 0.2 and 0.6). Metallic and fatty were evaluated slightly higher in S2 and stable-like slightly more intense in W2. The odor attributes sweaty (o) and hay-like (o) were only described for winter raw milk (here: W2), even if ratings were below 0.5.

Hence, besides farm-specific variations in odor profiles of goat milks from different farms (e.g., due to animal-specific or feeding differences), also seasonal variations were detected. These findings correspond with the observations made when studying the fatty acid composition (section Fatty Acids Composition of Raw Milks).

Overall, the only odor attributes ranked with weak to medium intensity ($1.0 < x < 2.0$) were milk-like (o, r), fatty (o, r), goat-like (r), and sweaty (r). No attribute was ranked with intensities above 2.0 (Figure 1), indicating that the overall odor intensity of the raw milks was low. In fact, it needs to be mentioned that the panelists reported that some of the raw milks, like S2, were orthonasally very close to the familiarized plain flavor of cow milk; this is also mirrored by the high ranking of milk-like and fatty odors.

**Characterization of Goat Milks' Odorant Composition.** Raw goat milks were characterized by GC/O, followed by AEDA to reveal the most potent odor-active compounds. Identification was performed by comparing their odor qualities, RIs, and mass spectra (MS-EI; MS-CI) with respective reference compounds.

A total of 54 odor-active volatile compounds were detected with FD factors between 8 and 2048 (Table 2). Especially fatty, sweaty/cheesy, goaty/musty, fecal/stable-like, leather-like/medicinal, and green odor attributes were often recorded descriptors of the odor characters of the volatiles. Additionally, peach-like, coconut-like, fruity, and flowery odor impressions occurred regularly as odor descriptions; these attributes were specifically related to higher FD factors.

A total of 37 compounds were identified unequivocally, as well as five compounds tentatively (without mass spectrum but based on their retention indices and olfactory properties). Compounds with very high intensities (FD $\geq$ 512) in all raw milks were identified as 4-etC8, 3-methylindole (skatol), and one unknown compound with a canola-like, metallic, and green odor character (RI 2715). Generally, a range of (branched-chain) saturated acids and lactones was identified, as well as alkenals and alkadienals (Table 2).

Interestingly, six compounds were associated with goat-like odor characteristics accompanied by the attributes stable-like, fecal, or leather-like. Identification revealed that besides 4-etC8, various saturated acids were among them, namely, nonanoic acid, decanoic acid, dodecanoic acid, and 1*H*-benzo[*b*]pyrrole (indole).

**Table 3. Characterization and Identification of Potent Odorants (FD ≥8) in Heated Goat Milk by Comparison of Pasteurized, UHT-Treated and Sterilized Goat Milk, Using Gas Chromatography/Olfactometry (GC/O)**

| | | | RI on | | FD-factor[d] in heated goat milk | | | |
|---|---|---|---|---|---|---|---|---|
| no. | odorant[a] | odor quality[c] | DB-FFAP | DB-5 | pasteurized | UHT-treated | sterilized | earlier identified in dairy products[e] |
| 1 | butan-2,3-dione (diacetyl) | buttery | 991−998 | | 8 | 32 | 256 | 1,4,5,9,10 |
| 2 | dimethyl disulfide[b] | sweaty, fatty | 1139−1145 | 759−761 | 256 | 128 | 32 | 7,10 |

[a]The compound was identified by comparison with the respective reference substance on the basis of the following criteria: retention index (RI) on two stationary phases given in the table (DB-FFAP, DB-5), mass spectra obtained by MS/EI or MS/CI, and odor quality as well as odor intensity perceived at the sniffing port. [b]MS signals were too weak for an unequivocal interpretation. The compound was identified based on the remaining criteria given in footnote *a*. [c]Odor quality as perceived at the sniffing port. [d]Only compounds that were detected with FD values >8 are displayed. [e]Earlier identified in 1,[3] 2[2] (goat cheese), 3[4−6] (goat milk), 4,[33] 5[51] (cow milk powder), 6,[4,5] 7,[17] 8,[16] 9,[15] 10[14] (heated cow milk), 11[47] (conjugates in cow milk), 12[52] (cow's milk cheese), 13[46] (ruminant milks). [f]Not determined.

AEDA revealed only slight differences with respect to seasonal (W1/S1, W2/S2) or farm-specific (W1/W2, S1/S2) effects (Table 2). For most odorants, the variation was no more than 1 FD factor.

**Sensory Characterization of Goat Milk after Different Heat Treatments.** Odor profiles (o, r) of the heated goat milk samples were described by the trained sensory panel, and 10 attributes were selected for APA: caramel-like, cooked milk-like, fatty, goat-like, hay-like, metallic, nutty, stable-like, sweaty, and vanilla-like (Figure 2). Generally, the odor profiles of pasteurized and UHT-treated milks were more similar to each other than sterilized milk, as the orthonasal and retronasal spider web diagrams demonstrate.

Highest ratings (mean values ≥2.0) were given to goat-like (r) in case of pasteurized/UHT-treated goat milk and caramel-like (o, r) in case of sterilized milk. With mean values ≥1.0, dominant attributes (o/r) of pasteurized and UHT-treated goat milk were also cooked milk-like, fatty, stable-like, and sweaty. Sterilized milk was additionally characterized by vanilla-like odors (o), as well as cooked milk-like, fatty, goat-like, and sweaty odors (r) with weak to medium intensities (mean values ≥1.0).

Overall, increasing rankings with thermal treatment were found for the attributes caramel-like, vanilla-like, and nutty, whereas for the following attributes intensity ratings decreased: cooked milk-like, goat-like, and stable-like (Figure 2). The odor impressions metallic and sweaty were orthonasally (slightly) stronger perceived in pasteurized milk and UHT samples, while retronasally they were stronger in sterilized milk.

**Heat-Induced Changes in Goat Milks' Odorant Composition.** Heated goat milks (pasteurized, UHT-treated and sterilized) were also characterized by GC/O and AEDA for the main odor-active volatiles. Overall, 66 compounds were detected with FD factors in the range of 8 and 2048 (Table 3). Besides fatty, sweaty/cheesy, goaty/musty, fecal/stable-like, leather-like/medicinal, and green odor attributes that were typical odor characters in raw milk (section Characterization of Goat Milks' Odorant Composition), also roasty, caramel-like, popcorn-like, cinnamon-like, and creamy odors were detected. Again, also peach-like, coconut-like, fruity, and flowery odor impressions were among those descriptors that were recorded with higher FD factors.

A total of 45 compounds were identified unequivocally, as well as 6 compounds tentatively (without mass spectrum but based on their retention indices and olfactory properties). Compounds with very high intensities (FD > 512) were identified as 3-methylthiopropanal (methional), pentanoic acid, 4-hydroxy-2,5-dimethyl-3(2*H*)-furanone (furaneol), γ-decalactone, δ-decalactone, 4-etC8, γ-(*Z*)-6-dodecenolactone, skatol, and phenylacetic acid. In all heated milks, 4-etC8, skatol, and phenylacetic acid were the most potent odor-active compounds. Furaneol was only detected in sterilized milk samples, but in a very high intensity (FD 8192) (Table 3). Among all flavor compounds that were only detected in the heated milk samples with FD ≥ 8, the following compounds could be identified: octanal, 2-acetyl-1-pyrroline, dimethyl trisulfide, 2-furaldehyde (furfural), (*Z*)-non-2-enal, (*E*)-undec-2-enal, 2-methoxyphenol (guaiacol), 3-hydroxy-2-methyl-4-pyrone (maltol), and furaneol.

Comparing the results of Table 3 with data on the main odorants in raw milk (Table 2), odor intensities were found to increase for a range of substances with heat treatment. While 14 odor-active volatiles with FD factors ≥128 were detected in raw milk samples, 22 compounds were detected with at least the same intensity in heated milk samples. Among the heated milk samples, sterilized goat milk showed highest odor intensities with 18 compounds of FD ≥ 128 (pasteurized and UHT, 11 and 12 compounds). Overall, the following compounds showed increasing FD factors with increasing thermal treatment: diacetyl, dimethyl trisulfide, methional, pentanoic acid, maltol, furaneol, δ-nonalactone, 4-meC8, γ-decalactone, δ-decalactone, 4-etC8, and phenylacetic acid (Table 3).

## DISCUSSION

**Fatty Acid Composition of Raw Milk.** Generally, the fatty acid composition of goat's milk shows a higher proportion of medium-chain fatty acids, like $C_{6:0}$ (caproic), $C_{8:0}$ (caprylic), and $C_{10:0}$ (capric), compared with cow's milk (8% vs up to 16% of total fatty acids).[22] In our study, fatty acid percentage composition was quite comparable to literature reports, with exception of $C_{6:0}$, which was detected in very low amounts (section Fatty Acids Composition of Raw Milks).[23,24] Alonso et al.[23] reported values for caprylic acid of 2.7% ± 0.1% by investigating milk from five different goat herds that were collected from November to May and 10.0% ± 0.3% for capric acid. Our results in Table 1 show the same characteristics (caprylic acid 3.1% ± 0.1%, capric acid 9.9% ± 0.3%) with just slight, not significant differences between summer and winter milk. According to Alonso et al.[23] and Park et al.,[25] the following five fatty acids (FA) make up the largest part (>75% of total FA) in goat milk: $C_{10:0}$, $C_{14:0}$, $C_{16:0}$, $C_{18:0}$, and $C_{18:1}$. This observation is in agreement with the results from Table 1, where those fatty acids account for 80.2% of total FA in the winter milk (3.1 g total FA/100 g goat milk) and 80.9% of total FA in the summer milk (2.4 g total FA/100 g goat milk).

A marker of authenticity for caprine milk and cheeses is the ratio of $C_{12:0}/C_{10:0}$. In literature, values from 0.46% ± 0.04% to 0.50% ± 0.04% were reported.[23,26] In accordance, a $C_{12:0}/C_{10:0}$ ratio of 0.44% ± 0.03% and 0.45% ± 0.03% was found in case of winter and summer milk, respectively. In the case of cow milk or sheep milk, this ratio is higher.[26]

Regarding seasonal effects, fatty acid analysis in section Fatty Acids Composition of Raw Milks revealed a very similar average percentage composition of summer and winter milk. Winter milk was found to contain a higher percentage of total MUFA while summer milk contained a higher percentage of total SFA. For milks in general, higher levels of SFA are reported during winter season while higher levels of PUFA are stated during summer season. Lock and Garnsworthy[27] described monthly changes of individual fatty acids in cow milk and reported high SFA levels from October to December and high PUFA levels from May to October with maximum values in October (SFA) and July (PUFA), respectively. In our study, PUFA contents were found to be quite similar between summer and winter milks; this observation might be explained by the fact that the diets of both herds were based on home-grown conserved forage all year round (cf. section Goat Milk). At the beginning of lactation, the goats were also fed on concentrate that included high values of rapeseed meal. The latter fact might be responsible for an increased percentage of MUFA in winter milks. Similar observations were reported by Butler et al.,[28] investigating SFA, MUFA, and PUFA composition of cow's milk fat of organic low-input production systems: high SFA levels in August, high MUFA levels in March, and no major differences in PUFA levels comparing March and August.

By direct comparison of winter/summer milks from the same farm (W1/S1, W2/S2; seasonal effect) and season (W1/W2, S1/S2;: farm-specific effect), differences in fatty acid composition were more significant ($C_{10:0}$, $C_{14:0}$, $C_{16:0}$, $C_{18:0}$, $C_{16:1}$, $C_{18:1}$, and $C_{18:3}$). However, the breed and general type of feeding was the same (breed "Bunte Deutsche Edelziege") or similar to each other (mainly conserved pasture and grains). Thus, the farmer's seasonal changes in their home-grown feed as well as individual differences of the animals or fed forage from one farm to the other (e.g., of rapeseed meal, sugar beet slices, and carrots) showed an effect on fatty acid composition. Similar findings on changes in percentage fatty acid composition due to seasonal changes in a goat herd feed were reported by Eknaes et al..[24] Bakke et al.[29] additionally reported differences in milk quality between individuals of the same breed, indicating that milk from different farms will show some variation, for example, in fatty acids profile.

**Characterization of Goat Milk Odor and Odorant Composition.** Descriptive profiling of raw goats' milk revealed milk-like, fatty, and goat-like odor attributes with weak to medium intensity (o, r), among some weak perception of metallic, stable-like, vanilla-like, sweaty, and hay-like odors (section Sensory Characterization of the Raw Goat Milks by Means of APA).

Characterization and identification of the odorant composition by HRGC/O, AEDA, and 2D-HRGC-MS/O (section Characterization of Goat Milks' Odorant Composition) pointed out >50 aroma compounds belonging to various substance classes (e.g., lactones, (branched-chain) saturated acids, alkenals, and alkadienals). Generally, a number of the identified compounds were described in literature before in the context of goat cheese, cow milk, or respective dairy products. However, only 16 of the 42 identified odorants were reported before in raw goat's milk since generally, literature lacks information on that topic (cf. Table 3). Furthermore, to the best of our knowledge, nine odorants were described for the very first time in a goat milk originating product: dimethyl disulfide, (*E*)-oct-2-enal, (*Z*)-non-4-enal, *trans*-4,5-epoxy-(*E*)-dec-2-enal, γ-nonalactone, δ-nonalactone, 3-propylphenol, γ-undecalactone, and γ-(*Z*)-6-dodecenolactone. Details are given in Table 3 and are further discussed in section Heat-Induced Changes in Goat Milk Odor and Odorant Composition.

Some of the raw milk odor-active substances were described with a goaty character, among them 4-etC8, as well as some saturated acids: nonanoic, decanoic, and dodecanoic acid. In literature, $C_{6:0}$ (caproic), $C_{8:0}$ (caprylic), and $C_{10:0}$ (capric) acids were described to be very dominant fatty acids in goat milk (cf. section Fatty Acid Composition of Raw Milk) and, additionally, defined to be partly responsible for the typical "goaty" odor of the milk.[1,2] In agreement with our results, Le Quere et al.[2] also described nonanoic acid and 4-etC8 as odor-active volatiles with a goat-like or goat cheese-like odor.

Generally, the characteristic goat-like or muttony flavor of goat milk (fat) is reported to depend on a wide range of monomethyl-branched and monoethyl-branched compounds, mainly with substitution on $C_4$.[30] Especially, 4-etC8 was found to be the main responsible odorant for the characteristic goat-like aroma in goat milk products, which is, other than 4-meC8, not present in cow's milk.[31−33] However, 4-meC8 lacks the typical goat-like odor note but has, according to literature, a

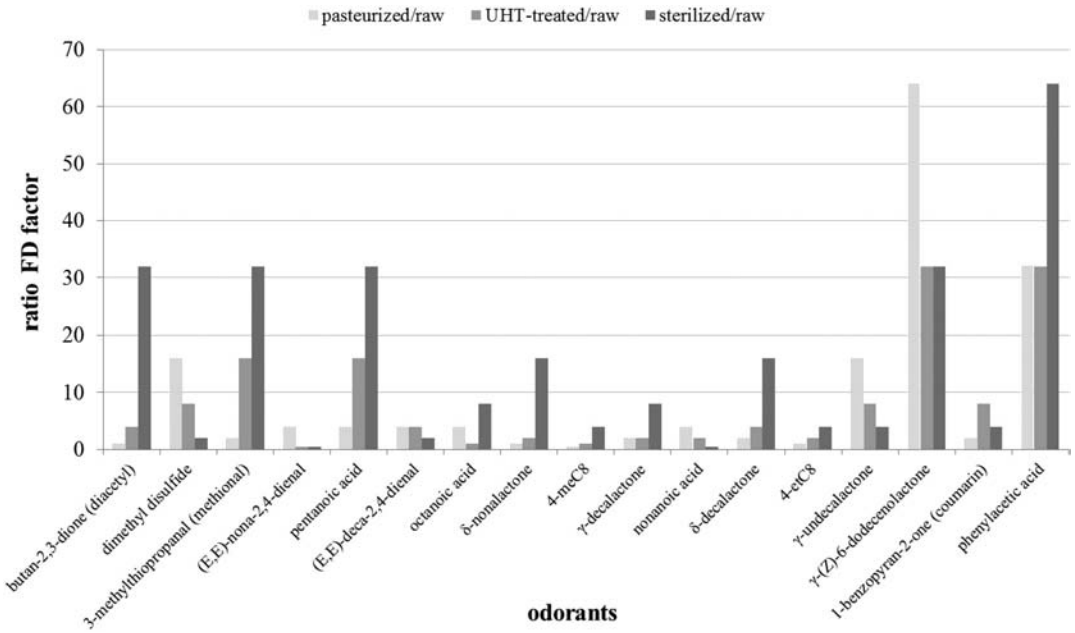

**Figure 3.** Ratio of flavor dilution (FD) factors: $FD_{heated\ milk}/FD_{raw\ milk}$ of selected odorants with $\Delta FD \geq 4$. Raw milk's highest detected FD factor was chosen for calculation. Compounds that were only detected in heated goat milks with FD values ≥8 (e.g., maltol, furaneol) are not displayed.

characteristic muttony smell, which we described as musty, urine-like, and stable-like.[34] In our study, 4-etC8 and skatol were found to be the most potent odorants in goats' raw milk, besides one unknown compound smelling canola-like, metallic, and green with RI 2715. With regard to these very intense odorants, no differences between the diverse types of raw milk were found (Table 2). Overall, only some slight seasonal or farm-specific alterations were observed, mostly within the range of ±1 FD factor.

However, in sensory sessions some differences in the odor profiles of the different raw milks were observed that were confirmed by fatty acid variations in the different raw milks. For example, winter milk was orthonasally found to smell slightly sweaty and hay-like, attributes that were not detectable or were only retronasally detected in summer milk. Indeed, dimethyl disulfide and an unknown compound with a sweaty, goat-like smell (no. 35) were detected in W2 milk in highest FD factors. However, some other compounds with sweaty odor impression were more strongly perceived in summer milks (butanoic acid, 2-/3-methylbutanoic acid, pentanoic acid). Specific hay-like odors were not detected in the course of GC/O screening. Nonetheless, some unsaturated aldehydes and acids were found with comparatively high FD factors in winter milks (e.g., (*E*)-oct-2-enal, (*E*)-non-2-enal), which were described in literature in the context of hay-like (off-) flavors.[35] The sensorial evaluation of summer milk S1 revealed sweaty, goat-like, stable-like, and metallic impressions to be more intense compared with S2. Indeed, a number of odor compounds were found with slightly higher FD factors in S1 (S1 and S2, 11 vs 6 compounds with ≥ FD 128) even if they could not be assigned specifically to one or more of the named attributes (Table 2). The intensities of single odorants in winter milks of different farms were even more similar to each other (W1 and W2, 5 vs 7 compounds with ≥ FD 128). Thus, APA revealed differences between the different raw milks, but FD values were primarily in the range of ±1 FD factor. Accordingly, future quantitative determinations would be required to objectify the differences obtained by our olfactory screening approach; these might then better visualize even minor quantitative variations between the milk samples. Such an observation of minor concentration differences but different substances or substance classes acting additively or synergistically and having a significant influence on the overall flavor of foods or beverages has already been reported in the context of other studies.[20,36,37] Especially odorants with very low odor thresholds, like alkenals, alkadienals, or branched-chain fatty acids, were described to greatly affect the overall flavor profile when concentration ratios slightly change.[20] Due to their comparable odor properties, such substances can also act as a whole in terms of aroma effects.

Overall, coupling of GC/O, AEDA, and 2D-HRGC-MS/O revealed a complete description of the slightly varying odorant composition of unheated goat milk that was obtained directly from two different farms during two seasons. Such detailed information on the odorant composition has, to the best of our knowledge, not been reported in literature before. A complete change of the odor profile between winter and summer milk, as reported by Fedele et al.,[11] was not confirmed by our study.

**Heat-Induced Changes in Goat Milk Odor and Odorant Composition.** Odor profiles of heated milks were also investigated in a comparative approach (pasteurized vs UHT-treated vs sterilized). Caramel-like, vanilla-like, and nutty attributes were found to increase as the heat treatment increased, whereas cooked milk-like, goat-like, and stable-like aroma notes were less perceivable. However, sterilized milks showed not only the highest FD factors in case of, for example, furaneol, maltol, or various lactones, but also of 4-etC8 (goat-like) and some stable-like compounds (4-meC8, skatol), as well as sweaty/sulfurous compounds (pentanoic acid, dimethyl trisulfide). Still, obviously a sensory dominance of the heating-related aroma notes results in the overall profile that might be related to additive or synergistic effects of the increased odorants such as maltol and furaneol, and the lactones; such phenomenon can be often observed in foods but would need to be further substantiated by quantification and aroma reconstitution experiments as done in other cases.[36,38]

In our study, furaneol was only detected in sterilized milk samples but with very high intensity (FD 8192), while 4-etC8, skatol, and phenylacetic acid were dominant odorants in all heated milks. 4-etC8 and skatol were also found among the most potent odor compounds in goats' raw milk. However, skatol was generally more intensely perceived in raw milk (~FD 2048) and 4-etC8 in UHT and sterilized milk (up to FD 4096). While skatol, as well as indol, are typically found in milk, especially from pasture-fed animals, presumably formed due to the degradation of tryptophan,[39,40] the formation of 4-etC8 is attributed to the activity of specific lipases and the specific composition of caprine milk fat.[32] Phenylacetic acid was detected in much lower intensities (FD ≤ 128) in raw milk. Its formation is assumed to derive from Strecker degradation of phenylalanine and oxidation processes.[40,41] A general overview of odorants with increased odor intensities in heated milk compared with raw goat milk is given in Figure 3.

Besides furaneol, some other compounds were only detected in heated goat milks (FD ≥ 8): octanal, 2-acetyl-1-pyrroline, dimethyl trisulfide, furfural, (*Z*)-non-2-enal, (*E*)-undec-2-enal, guaiacol, and maltol. Furaneol, as well as furfural and maltol are typically formed due to thermally induced decomposition of lactose (caramelization) or amino-carbonyl reactions in the course of the Maillard reaction.[42,43] Other thermally generated compounds identified in heated goat milk are vanillin, diacetyl, 2-acetyl-1-pyrroline, and 2-acetyl-2-thiazoline.[41] The latter substance was detected with FD < 8 in heated goat milk and thus was identified but not listed in Table 3. Other dominant odor compounds in the heated milk were methional, γ-decalactone, δ-decalactone, and γ-(*Z*)-6-dodecenolactone. Interestingly, goat milk lacks the amino acid cysteine compared with human and cow milk, which is balanced by a higher methionine content, presumably affecting flavor formation.[44] Indeed, methional is a typical product from Strecker degradation of methionine, as well as dimethyl disulfide or dimethyl trisulfide.[45] Lactones as well as saturated and unsaturated aldehydes are known from fatty acid oxidation, primarily as secondary oxidation products.[20] However, $C_{8:0}$, $C_{10:0}$, and $C_{12:0}$ δ-lactones were also reported in the context of a heat induced formation.[41] Besides δ-decalactone and δ-dodecalactone, we also identified δ-octalactone in heated goat milks, but in lower intensities than for the other substances shown in Table 3 (FD <8).

Moreover, 3-methylphenol (*m*-cresol) was detected in raw and heated goat's milk as well as 3-ethyphenol and 3-propylphenol, all showing leather-like, medicinal odor descriptions. Skjevdal[8] cited a Norwegian report on *o*- and *m*-cresols where both compounds were identified in whey cheese from goat's milk but not from cow's milk origin. According to Kilic and Lindsay,[46] the presence of 3-ethylphenols might contribute to the strong, animal-like flavor of goat milk. To the best of our knowledge, 3-propylphenol was not reported in goat milk products before. However, it was identified as a conjugated compound in cow's milk.[47] 1-Benzopyran-2-one (coumarin) was found in raw milks and with increasing FD values in heated goat milks (Figure 3). To our knowledge, this compound was not identified in goat milk or other ruminant milks before. However, the biosynthesis of coumarin in *Melilotus albus*, a legume used for forage, has been reported in previous studies, as well as the observation that the legume's sweet flavor is transferred into cow's milk.[48,49] Thus, a forage-based origin of coumarin can be assumed.

Apart from that, some odorants showed highest intensities in pasteurized milk samples but decreased with temperature and time of heat treatment: dimethyl disulfide, guaiacol, and γ-undecalactone (Figure 3). Those compounds were not detected or were detected with just low intensity, in the raw milk samples. Other odorants, like butanoic acid, (*E*,*E*)-nona-2,4-dienal, hexanoic acid, nonanoic acid, and an unknown compound with high FD factor (RI > 2900) were detected with high intensities in raw milk samples but decreased from pasteurized to UHT-treated and sterilized milk samples. Oxidations (e.g., fatty acid oxidation) and other thermally induced reactions might have been responsible for chemical rearrangements or degradation processes of those odorants. Thereby, it needs to be kept in mind that many odorants that are formed in the course of thermal and oxidative processes are labile themselves so that they can undergo further degradation if thermal or oxidative stress is continued.[50]

Overall, the main odorants in goat's milk were found to show high analogies to the most potent odorants reported in cow's UHT milk: a variety of lactones and acids, besides some sweet, sulfurous, and roasty compounds like methional (cooked potato-like), furaneol (caramel-like), 2-acetyl-1-pyrroline, 2-acetyl-2-thiazoline, furfural (roasty, popcorn-like), dimethyl disulfide, and dimethyl trisulfide (sweaty, cabbage-like).[15−17] However, since literature lacks information not only on raw goat milk odorants but also on detailed odorant investigations in heated goat milk, seven potent odorants were reported in our study for the first time in heated goat's milk (in addition to the large amount of odorants that were described in section Characterization of Goat Milks' Odorant Composition in raw goat's milk already, but were also reported in our study for the first time, these are dimethyl trisulfide, furfural, (*Z*)-non-2-enal, (*E*)-undec-2-enal, guaiacol, maltol, and furaneol.

Overall, the aim of this study was to characterize and identify the most potent odorants in goat's milk before and after heat treatment. More than 50 odor-active VOCs were described and up to 45 of them were unequivocally identified in the different milks. Of these substances, a total of 16 compounds are reported here for the first time for raw and heated goat's milk that were not described in any goat milk product before. Hence, comprehensive information on goat's milk aroma quality and aroma changes during the year and with thermal treatment is provided in this study, information that has not been as comprehensively reported before. Thus, our findings will close a gap in literature on important quality aspects of goat milk, which is increasingly consumed beside goat cheese worldwide, not least because new markets recently sprang up, like the use of goat milk in infant formulas.

volatiles and chemical reactions responsible for the aroma changes after sunlight exposure.

## MATERIALS AND METHODS

**Standards and Reagents.** A standard series of $C_8$−$C_{20}$ and $C_{10}$−$C_{40}$ alkanes used for retention index (RI) determination were obtained from Sigma-Aldrich Co. Ltd. (St. Louis, MO, USA). Internal standards of ethyl 2-methylbutyrate and ethyl benzoate were also purchased from Sigma-Aldrich Co. Ltd. HPLC grade *n*-hexane was purchased from the Oceanpak Chemical Co. (Gothenburg, Sweden). Volatile standards, including α-pinene, sabinene, β-pinene, and D-limonene, etc. (listed in Table 2), were purchased from Sigma-Aldrich Co. Ltd., Alfa Aesar Co. Ltd. (Heysham, Lancashire, U.K.), Ormah Chemical Inc. Tic Co. (TIC, Hadimkoy, Istanbul), and Penta Manufacturing Co. (PMC, Livingston, NJ, USA). Other chemicals were obtained from Sinopharm Chemical Reagent Co. Ltd. (Shanghai, China).

**Preparation of the Essential Oils Exposed to Sunlight, Oxygen, and Heat.** GuanXi pummelo, a native pummelo species in southeastern China, was harvested by Fujian GuoNong Agricultural Development Co. (PingHe county, Fujian province, China) in October 2013. The fresh flavedo with oil sacs was mechanically pressed to squeeze the oil into a tube containing icy brine water. Then, the oil−water mixture was centrifuged at 13500*g* for 5 min to collect the oil, subsequently dehydrated with $Na_2SO_4$, and immediately stored at −20 °C in a freezer. To differentiate the effects of sunlight, heat, and oxygen on the aroma changes of the EO, the EO was pipetted into small glass tubes with screw caps and respectively treated by the following procedure.

(1) The fresh EO (sample 1) was stored at −20 °C until sensory evaluation and GC-MS analysis. This sample was used as a control for chemical comparison.

(2) For the sunlight-exposed EO under $N_2$ protection (sample 2) the EO was saturateded with pure nitrogen and then exposed under sunlight (i.e., sun) for 72 h at ambient temperature (30 °C) and stored at −20 °C until analysis. This sample was used to test the effect of sunlight (and/or UV) without oxygen on the volatile changes.

(3) To obtain the EO exposed to both sunlight and oxygen (sample 3), the EO was saturated with air and then exposed to sunlight for 72 h simultaneously with the second group. This sample was used to test the combined effect of sunlight and oxygen on the volatile changes.

(4) To obtain the oxygen-exposed EO in darkness (sample 4), the glass tube that contained the EO was filled with air and covered with an aluminum film to avoid exposure to sunlight for 72 h simultaneously with the second group. This sample was used to test the effect of oxygen without sunlight (or UV) on the volatile changes.

(5) Sample 5, the EO heated in darkness under $N_2$ protection, was obtained in a glass tube that contained the EO covered with an aluminum film and filled with nitrogen, followed by incubation at 40 °C in a water bath for 72 h. This sample was used to test the effect of temperature without sunlight and oxygen on the volatile changes.

**Sensory Evaluation of EO Samples after Different Treatments.** An aliquot of 100 μL of the pummelo EO was diluted with 900 μL of ethanol. Thereafter, 10 μL of the dilution was pipetted onto a fragrance test strip and then dried in the open air for 120 s, immediately followed by the sensory evaluation at room temperature under clean air conditions.

The sensory evaluation was conducted by 18 trained panelists, including 8 women and 7 men in a range of 20−30 years old, and another 3 trained panelists including 1 woman and 2 men aged in a range of 30−40 years old. The sensory evaluation adopted a 10-point scale according to the relevant references (refs 14, 19, and 20) and ISO 8589, in which 0 indicates an unperceived attribute intensity and 9 indicates a very strong attribute intensity. Before the sensory evaluation, the panelists were instructed to be familiar with the odor of standards and, as necessary, during the session. The panelists were asked to rate the EOs in a random order for sweet, minty, herbaceous, lemon, floral, and oily notes and gave a score within 0−9. Among these notes, herbaceous and lemon aromas contributed to the fresh odor; sweet and floral aromas contributed to the ripened odor (reduced freshness), whereas oily aroma was an off-flavor like machinery oil or resinous.[21] Mean values were calculated after corrections of effects of session and removal of outliers. An interval gap of 20 s was kept, which was sufficient between individual odor assessments.

**GC-MS Analysis of the Volatiles of Different EO Samples.** Each EO sample (1 μL) was diluted at two degrees. The 5000 times dilution was used for the analysis of the most abundant volatiles, that is, D-limonene and β-myrcene, whereas the 100 times dilution was used for the analysis of the volatiles other than D-limonene and β-myrcene by a gas chromatograph coupled with a mass spectrometer (GC-MS, Shimadzu, QP 2010 plus). Helium was used as the carrier gas, and the column flow rate was 3 mL/min. The injector temperature was set at 250 °C, and the split ratio was 1:5. The oven temperature for the Rtx-5MS column was initially programmed from 50 °C for 3 min, then increased to 220 °C at the rate of 5 °C/min, and held at this temperature for 3 min. The oven temperature for another column (i.e., Rtx-wax) was initially programmed from 30 °C for 3 min, then increased to 200 °C at the rate of 2 °C/min, and held at this temperature for 3 min. The temperatures of the ion source and the interface were set at 250 and 250 °C, respectively. The MS spectrum was operated in a positive electron ionization (EI) mode at 70 eV, and the MS spectra were recorded within a $m/z$ range from 29 to 500 amu.

Two columns, that is, an Rtx-5MS column (60 m × 0.32 mm × 0.25 μm, Restek Corp., Bellefonte, PA, USA) and an Rtx-wax column (60 m × 0.32 mm × 0.25 μm, Restek Corp.), were used to separate and identify the volatiles with a cross-check and comparison of the Kovats retention indices (RI). Most of the volatiles were identified by matching their MS spectra and RI values on both columns to those of standards. Some other volatiles that currently lack standards were temporarily identified by matching their MS spectra to those in the Mass Spectral Library (NIST08, NIST08s, FFNSC1.3) and their RI values to those from relevant references or the database book (Table 2). The volatile with a matching standard was quantified according to their respective calibration curves using the internal standard method. The concentrations of other volatiles were estimated using the calibration curve of the internal reference of ethyl benzoate.

**Analysis of the Odor of the Volatiles and Calculation of the Odor Activity Values.** Single standards, that is, α-pinene, sabinene, β-myrcene, D-limonene, *cis*- and *trans*-limonene oxides mixture (ratio = 1.6:1), *cis*- and *trans*-linalool oxides mixture (ratio = 1:1), neral and geranial mixture (ratio = 0.7:1), octanal, linalool, nonanal, decanal, carvone, geranyl acetate, nootkatone, and α-terpineol, were tested through sensory evaluation by three panelists. Each standard (0.5−50 μL) was properly diluted in propylene glycol and adjusted to a 10 mL volume, followed by sniffing their odors. Afterward, OAVs were calculated by dividing the concentrations of the aroma active compounds with their respective odor threshold values in water obtained from the corresponding literature.[20,22,23]

**Verifying the Contributions of Volatiles to the Changed Aroma.** The omission test was used to investigate the contributions of some aroma-impact volatiles to the change of the aroma profile. A formulated flavoring model sample (FMS) that represented the aroma of the fresh EO (FMS 0) was prepared with the following authentic standard chemicals (ASCs), including β-myrcene (220,000 μg/mL), octanal (500 μg/mL), D-limonene (500,000 μg/mL), linalool (2700 μg/mL), decanal (1000 μg/mL), neral and geranial mixture (17,000 μg/mL, ratio = 0.7:1), dodecanal (350 μg/mL), and nootkatone (1000 μg/mL), according to their concentrations in the fresh EO. Other series of artificial model samples were respectively composed by either adding or removing some volatiles from the model sample (FMS 0) according to the OAVs of the EOs that had been treated with sunlight exposure, oxygen exposure, and heat. In detail, (1) FMS 1 was composed by adding 3000 μg/mL of *cis*- and *trans*-linalool oxides mixture (ratio = 1:1), 10,000 μg/mL of *cis*- and *trans*-limonene oxides mixture (ratio = 1.6:1) into the model sample of the fresh EO (FMS 0) that had pre-excluded 13,000 μg/mL of neral and geranial mixture to simulate the aroma of the sunlight-exposed EO; (2) FMS 2 was formulated by adding 200 μg/mL of *cis*- and *trans*-linalool oxides mixture and 200 μg/mL of *cis*- and *trans*-limonene oxides mixture into

**Table 1. Sensory Evaluation and Average PCA Scores of the Essential Oils[a]**

| | sensory evaluation scores | | | | | | | PCA scores[b] | |

[a]Different letters (a−d) in the same column indicate the data ahead have statistical differences ($p < 0.05$). In the column "EO samples", "sunlight, $N_2$" indicates the EO that was exposed under sunlight but was free from oxygen, "sunlight, $O_2$" indicates the EO exposed in both sunlight and oxygen, "dark $O_2$" indicates the EO that was exposed in oxygen but covered with an aluminum film under sunlight, "40 °C, dark, $N_2$" indicates the EO that underwent heating but was free from sunlight and oxygen. The panelists were trained to be familiar with the odors using the standard series. In short, the odors of limonene oxides and carvone were used to train panelists to score sweet and minty, respectively. A neral and geranial mixture was used as the herbaceous note, a nootkatone and D-limonene mixture was used as the lemon note, a geraniol and $\beta$-myrcene mixture was used as the floral note, and a linalool oxides and $\alpha$-terpineol mixture was used as the oily note. [b]PCA scores were the average scores of PC1 and PC2.

FMS 0, which was used to simulate the oxygen-exposed EO; (3) FMS 3 was prepared by adding 700 $\mu$g/mL of *cis*- and *trans*-limonene oxides mixture into FMS 0 to simulate the heated EO. Besides, other experiments to test the impacts of aroma constituents in EOs included (4) FMS 4 was composed by adding 3000 $\mu$g/mL of *cis*- and *trans*-linalool oxides mixture into FMS 0; (5) FMS 5 was composed by adding 400 $\mu$g/mL of $\alpha$-terpineol into FMS 0; (6) FMS 6 was prepared by removing 14,000 $\mu$g/mL of neral and geranial mixture from FMS 0; and (7) FMS 7 was modified by subtracting 400 $\mu$g/mL nootkatone from FMS 0. Then, the artificially reconstituted samples (FMS 0−7) were analyzed by the sensory evaluation, which was subsequently compared via principal component analysis (PCA).

**Comparison of the Effects of UV and Daylight Lamp Irradiation on the EOs.** The UV-exposed EOs with or without nitrogen gas protection were exposed under irradiation of two UV modulator tubes (FL20SE×2 sunlamps with peak emission at 305 nm; Toshiba Medical Supply, Tokyo, Japan) for 96 h at 30 °C. The electronic power was 40 W, and the distance between the light and the samples was 30 cm. Meanwhile, the same EOs with or without nitrogen gas protection were exposed under a daylight modulator tube (FL40T8DY, Toshiba Medical Supply) for 96 h at 30 °C. The electronic power was 40 W, and the distance between the light and samples was 30 cm. After the treatments, the EOs were subjected to the sensory evaluation and GC-MS analysis.

**Verifying the Chemical Reactions Induced by UV Irradiation.** The single standards, for example, D-limonene and $\beta$-myrcene, were saturated with nitrogen and exposed under irradiation of a UV modulator tube for 96 h at 30 °C, followed by GC-MS analysis to track the chemical changes using the Rtx-5MS column. The oven temperature was initially programmed from 50 °C for 3 min, then increased to 220 °C at the rate of 15 °C/min, and held at this temperature for 3 min.

**Statistical Analysis.** The data from sensory evaluation was analyzed by reliability and validity analysis using SPSS-IBM 19.0 software. The mean values were calculated after a correction for session, panelist effects, and removal of outliers (five of the data). PCA was conducted using the method of biplot visualization (SPSS-IBM 19.0 software), which was used to show relationships between the flavor attributes. The PCA was under varimax orthogonal rotation.

The significant statistical analyses were conducted according to previous methods[13,24] (SPSS-IBM 19.0 software, Microsoft Excel 2013). Cluster analysis was used to classify the volatiles and OAVs through the cosine correlation metric (SPSS-IBM 19.0 software).

## RESULT AND DISCUSSION

**Investigation of the Aroma Changes by Sensory Evaluation.** Sensory evaluation is a commonly used technique to evaluate the human perception of aroma attributes of many flavoring products. For example, it has been used to characterize the aromatic profiles of EOs.[17] By this method

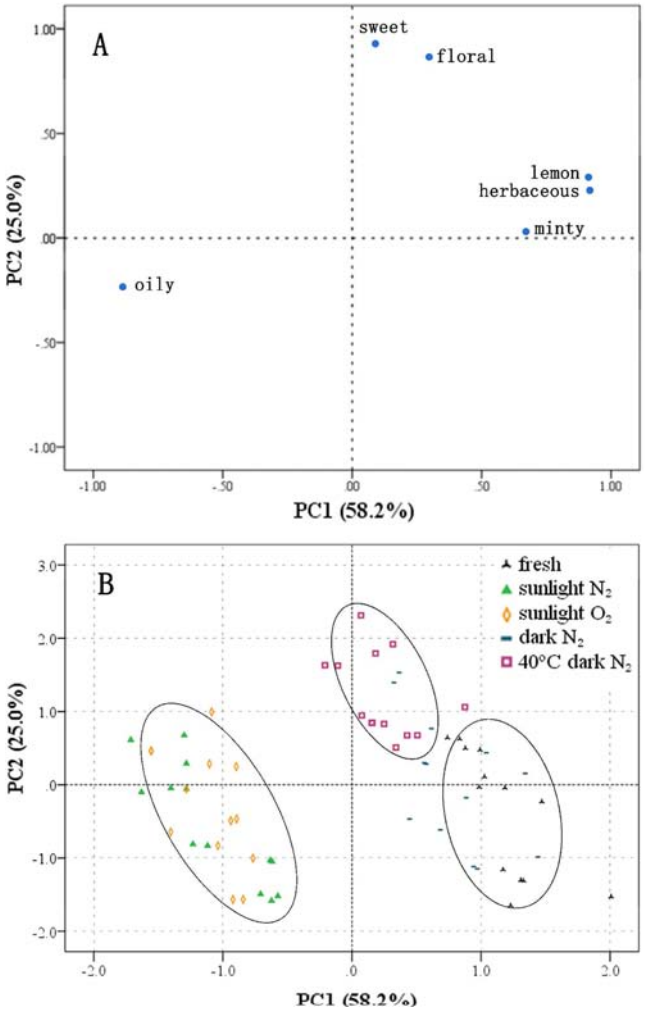

**Figure 1.** PCA scatter plot of the note of the EOs (A) and scatter diagram (B).

and/or in combination with other instrumental methods, the citrus EO was found to be able to maintain its natural aroma when stored at −20 °C.[16,17] In this study, the fresh pummelo EO (sample 1) showed a strong natural fresh flavor, whereas the sunlight-exposed EOs, no matter whether they were protected by $N_2$ (sample 2) or exposed under $O_2$ (sample 3), showed strong off-flavors and a soapy odor. By contrast, the oxygen-exposed EO in darkness (sample 4) possessed a

[a]RT represents the retention time. [b]RI was obtained by GC-MS analysis using an Rtx-5MS column. [c]RI was reported in the literature or NIST Chemistry Web Book (http://webbook.nist.gov/chemistry), which was using a column similar to Rtx-5MS (the column stationary phase is 5% diphenyl and 95% dimethyl polysiloxane, equivalent to United States Pharmacopoeia G27). [d]RI was obtained by GC-MS analysis using an Rtx-wax column. [e]RI was reported in the literature or NIST Chemistry Web Book (http://webbook.nist.gov/chemistry) using a column similar to Rtx-wax (the column stationary phases is polyethylene glycol, equivalent to United States Pharmacopoeia G16). [f]Std indicates the identification has been confirmed by matching a standard; the number following R is the corresponding reference showing the RI values (R8 represents the reference of Njoroge et al. (2005); R9 is Lanphi et al. (2009); R12 is Liu et al. (2012); R14 is Cheong et al. (2012); R26 is Nguyen et al. (2009); R32 is Espina et al. (2011); R33 is Deterre et al. (2012); R34 is Alkateb et al. (2014); R35 is Lan et al. (2006); R36 is Cejudo et al. (2013). The authentic standard chemicals (ASCs) were obtained from Sigma-Aldrich Co. Ltd. (St. Louis, MO, USA); Alfa Aesar Co. Ltd. (Heysham, Lancashire, UK); Ormah Chemical Inc. Tic. Ltd. (TIC, Turkey); and Penta Manufacturing Co. Ltd. (PMC, Livingston, NJ, USA). [g]All of the equations of the calibration curves of ASCs were calculated in the SIM mode. $Y$ is the ratio of the peak area of the ASC to that of the internal standard (IS), and $x$ is the ratio of the concentration of the ASC to that of the IS. [h]CF represents correction factors using this formula: CF = (As/Ms)/(Ar/Mr). As represents the corresponding quantitative ion (SIM mode) area of the IS; Ar represents the corresponding quantitative ion (SIM mode) area of the ASC, Ms represents the concentration of IS, Mr represents the concentration of the ASC (QI of 2-methylbutyrate was 57, QI of ethyl benzoate was 105). [i]R is the Recovery rate, which is measured by adding the standards into either a fresh EO (if the volatile was detected in the fresh EO) or a sunlight-exposed EO (if the volatile was not detected in the fresh EO). The fresh EO and the sunlight-exposed EO show similar recoveries for all of the standards.

[a]0 means the concentration was <50 μg/mL or not detected. All of the identified chemicals were previously reported in citrus volatiles. Rows with different letters (a–d) indicate significant statistical differences ($p < 0.05$).

reduced fresh odor, whereas the heated EO (sample 5) displayed a reduced freshness and a ripened odor (Table 1). In more detail, the fresh EO (sample 1) had the highest scores for herbaceous and lemon notes, simultaneously with the lowest oily note; the sunlight-exposed EOs (samples 2 and 3) presented the strongest oily note and the weakest herbaceous

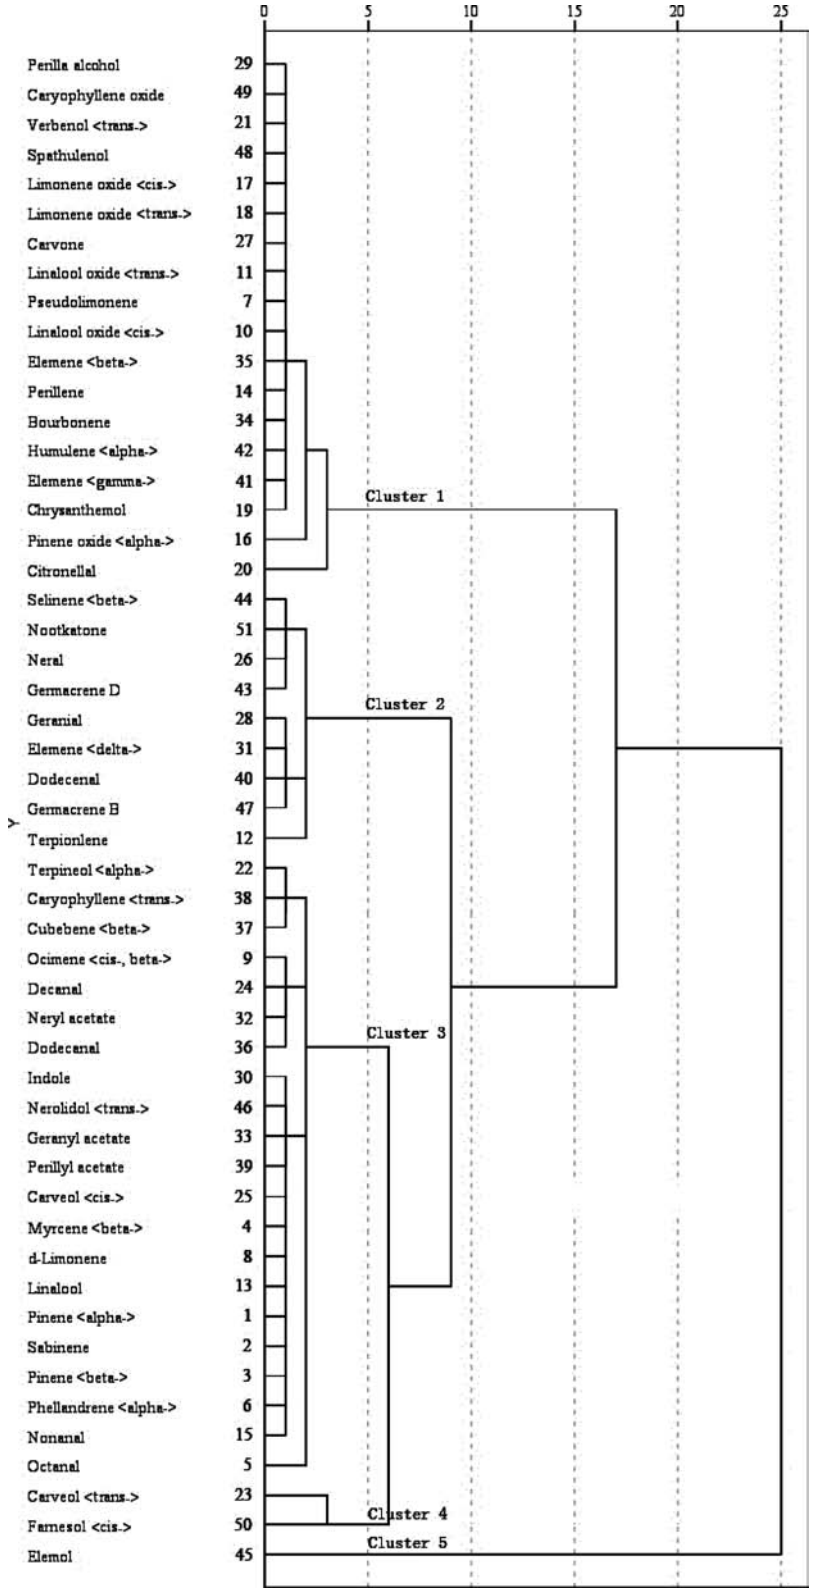

**Figure 2.** Cluster analysis of the volatiles based on their concentration changes after different treatments. The numbers (0−25) above the top line of the figure represent the relative distance using cosine correlation metric method. Cluster 1 represents the volatiles that were not detected or had very low concentrations in fresh EO but increased to a remarkable concentration in the sunlight-exposed EOs. Cluster 2 represents the volatiles that had decreased concentrations after the sunlight exposure. Cluster 3 represents the volatiles that had no significant changes in their concentrations after all of the treatments. Cluster 4 represents the volatiles that did not exist in the fresh EO but appeared in other EOs at low concentrations. Cluster 5 represents the volatiles existing only in heated EO.

[a]Thresholds in water were provided by Du et al. (2011), Guadagni (1963), and Ruth (1986). [b]Odor characteristics were evaluated by standards coupled with the corresponding references in the reference list: 12 is Liu et al. (2012); 26 is Nguyen et al. (2009); 29 is Chisholm et al. (2003); 30 is Perez et al. (2008); 33 is Deterre et al. (2012); and 38 is Lin et al. (2002).

and lemon notes; the oxygen-exposed EO (sample 4) gave light lemon and green notes; and the heated EO (sample 5) attained the highest score for its sweet and floral notes among all of the EOs (Table 1). These results were consistent with a previous study that the herbaceous and lemon aroma resulted in the fresh odor, the sweet and floral aroma was related to the ripened and reduced fresh odor, and the oily odor was a contributor to the off-flavor.[21]

The characteristic aromas were further identified, compared, and illustrated via PCA, which is commonly used to extract interpretable and statistically reliable information from data sets. As a result, two PCs that contributed >83% of the total variances of flavor contributors were extracted to express the main variables affecting the sensory characteristics, among which PC1 mainly represented the herbaceous, lemon, and oily notes, which accounted for 58.2% of the total variance among EO flavors, and PC2 mainly represented the sweet and floral notes, which accounted for 25.0% of total variance (Figure 1A).

The PCA scores showed that the heated EO (sample 5) possessed a higher PC2 score and a lower PC1 score than those of the fresh EO (sample 1) (Table 1; Figure 1B). This result was attributed to the thermal treatment that slightly increased the scores of sweet and floral notes while decreasing the scores of lemon and herbaceous notes (Table 1), which was consistent with previous studies that high temperature reduced the freshness odor of EOs.[14,25] The oxygen-exposed EO (sample 4) showed a slightly lower PC1 score than the fresh EO (Table 1; Figure 1B). This result could be attributed to the slight increase in the scores of sweet and oily notes and the decrease of lemon note (Table 1), which was consistent with a previous study that oxygen was an important factor affecting the aroma of an EO.[26] As shown in Figure 1, the sunlight-exposed EOs (samples 2 and 3) possessed very similar aromatic profiles, which obviously differentiated them from other EOs (Table 1; Figure 1B). This result was in agreement with the increase of the score of an oily note (from 0.2 to 8.3 and 8.2) and a decrease in the scores of the lemon (from 8.2 to 1.5 and 1.6) and decreased herbaceous notes (from 7.4 to 1.6 and 1.5). Both the sensory evaluation (Table 1) and PCA (Table 1; Figure 1) clearly indicated the flavor profiles of the sunlight-exposed EOs were dramatically different from those of the fresh EO, the oxygen-exposed EO, and the heated EO. In this context, sunlight is a key factor for the generation of an oily note and the decrease of herbaceous and lemon notes, whereas oxygen exposure and heating were the causes for the decline in fresh odor and increase in ripened odor.

**Investigation of the Volatile Changes by GC-MS Analysis.** It has been reported that many volatiles are subjected to degradation and oxidation during extraction and storage.[25,27] For instance, monoterpenes could transform to monoterpene alcohols and monoterpene oxide.[28,29] Previous studies have demonstrated that heat and oxygen were the major factors affecting the volatile compositions of citrus EOs.[17,26,30] However, the chemical basis of the sunlight-induced changes in aroma is still unclear. Although the effect of sunlight on milk flavors has been confirmed,[31] its effect on citrus EO has not

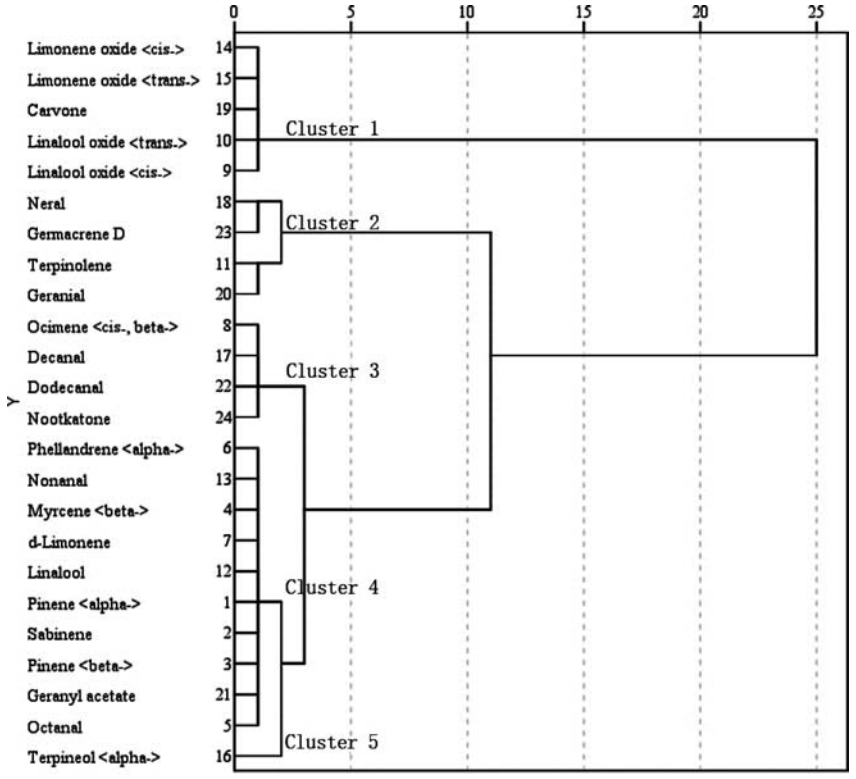

**Figure 3.** Cluster analysis of volatiles based on their changes in OAVs after different treatments. The numbers (0–25) above the top line of the figure represent the relative distance using cosine correlation metric method. Cluster 1 represents the volatiles that had 0 OAV in the fresh EO but increased to show remarkable OAVs in the sunlight-exposed and heated EOs. Clusters 2 and 3 represent the volatiles that had decreased OAVs in the sunlight-exposed EOs. Cluster 4 represents the volatiles that had no significant changes in their OAVs, and cluster 5 represents the volatiles that had increased OAVs in the sunlight-exposed EOs.

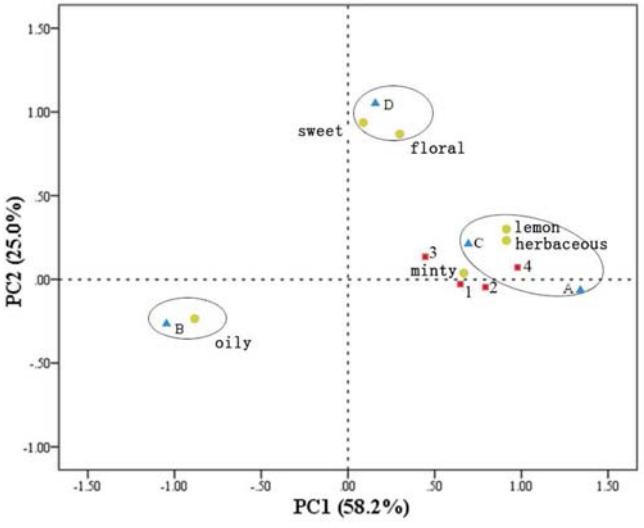

**Figure 4.** CA analysis of the aromas of the samples in the omission test. PC1 mainly represents the fresh odor, and PC2 mainly represents the ripened odor. "A" is the model sample of the fresh EO, "B" is the model sample of the sunlight-exposed EO, "C" is the model sample of the oxygen-exposed EO, and "D" is the model of the heated EO. "1" is the linalool oxides-added sample, "2" is $\alpha$-terpineol-added sample, "3" is neral and geranial mixture decreased sample, and "4" is nootkatone decreased sample.

been reported by other researchers. To explore the more accurate quantitative changes of the volatile constituents after sunlight exposure, oxygen exposure, and heating, the EO samples were subjected to GC-MS analysis.

A total of 51 compounds were detected in the EOs (Table 2), among which 41 volatiles were identifief on the basis of matching their MS and RI with those of standards (Table 2); another 10 volatiles were identified according to the comparison with the MS library and matching the RI with those from previous citrus fruit references.[8,9,12,14,26,32−36] Most of these volatiles have been found in other citrus fruits. Furthermore, the concentrations of the volatiles were quantified by using the calibration curves of the standards obtained in the selective ion monitoring (SIM) mode (Table 2), and the accuracy is shown using the recovery method (Table 2). Other volatiles were quantified through the calibration curve of the internal reference ethyl benzoate (Table 2). The result showed that all of the EOs had similar volatile components consisting of D-limonene and $\beta$-myrcene, germacrene D, geranial, neral, *cis*-$\beta$-ocimene, $\beta$-pinene, linalool, sabinene, and $\alpha$-pinene (Table 3), which are also the major constituents of other citrus EOs.[17]

The cluster analysis showed five clusters of volatiles according to their concentration changes after the treatments of sunlight exposure, oxygen exposure, or heating (Figure 2). Cluster 1 included perilla alcohol, caryophyllene oxide, *trans*-verbenol, spathulenol, *cis*-limonene oxide, *trans*-limonene oxide, carvone, *cis*-linalool oxide, *trans*-linalool oxide, pseudolimonene, $\beta$-elemene, perillene, bourbonene, $\alpha$-humulene, $\gamma$-elemene, chrysanthemol, $\alpha$-pinene oxide, and citronellal. These volatiles had much higher concentrations in the sunlight-exposed EOs (samples 2 and 3) than in other EOs ($p < 0.05$). Among these volatiles, pseudolimonene, perillene, perilla alcohol, *trans*-

[a]Cluster 1 represents the volatiles that had no significant changes in their concentrations, cluster 2 represents the volatiles that had increased concentrations and OAVs in the UV-exposed EO, cluster 3 represents the volatiles that had decreased concentrations and OAVs after UV exposure, cluster 4 represents the volatiles that had increased concentrations and OAVs in both the daylight-exposed and UV-exposed EOs.

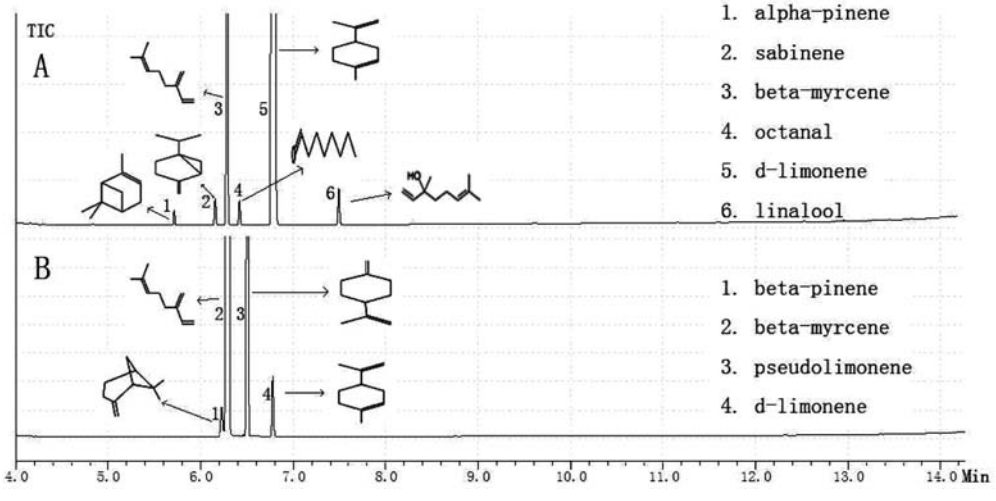

**Figure 5.** Transforming products of D-limonene (A) and $\beta$-myrcene (B) after UV exposure.

verbenol, carvone, bourbonene, $\gamma$-elemene, $\alpha$-humulene, spathulenol, and caryophyllene oxide were detected only in the sunlight-exposed EOs (samples 2 and 3). The volatiles in cluster 2, including $\beta$-selinene, nootkatone, neral, germacrene D, geranial, $\delta$-elemene, dodecenal, germacrene B, and terpinolene, showed significantly lower ($p < 0.05$) concen-

dx.doi.org/10.1021/jf504294g | J. Agric. Food Chem. 2014, 62, 11818−11830

trations after sunlight exposure (samples 2 and 3). Most volatiles in cluster 3 (i.e., α-terpineol, *trans*-caryophyllene, β-cubebene, *cis*-β-ocimene, decanal, neryl acetate, dodecanal, indole, *trans*-nerolidol, geranyl acetate, perillyl acetate, *cis*-carveol, β-myrcene, D-limonene, linalool, α-pinene, sabinene, β-pinene, α-phellandrene, nonanal, and octanal) had no significant statistical differences ($p < 0.05$) in their concentrations in all of the EOs. This result indicated that the volatiles in cluster 3 were relatively stable under the treatments by sunlight, oxygen, and heating, which was consistent with other studies showing most of these volatiles were relatively stable.[16,30] Cluster 4 had two compounds, including *trans*-carveol and *cis*-farnesol. These volatiles did not exist in the fresh EO but could be detected in the sunlight-exposed and heated EOs. Cluster 5 had only one volatile elemol that was generated in the heated EO, which might be transformed from elemene.[16] By comparing the volatile concentrations through cluster analysis, it was obvious that both oxygen and heating had significant influence on the volatile compositions, but sunlight was a more important factor responsible for the changes of volatile chemicals when exposed under sunlight and oxygen at room temperature. Moreover, the sunlight-exposed EOs (samples 2 and 3) presented volatiles (in clusters 1 and 2) entirely different from those of the oxygen-exposed and heated EOs, which indicated sunlight exposure could cause chemical changes different from those induced by oxygen exposure and heating.

**Investigation of the Volatiles Responsible for the Aroma Change by the Analysis of Odor Activity Values.** The aromas that had been reported to be the main aromatic volatiles in citrus fruits and exhibited remarkable changes in concentration after the above-mentioned treatments were analyzed by sensory evaluation,[12,26,30,33,37,38] which confirmed that *cis*- and *trans*-limonene oxides showed typical notes of sweet and floral notes; neral, geranial, and nootkatone had typical herbaceous and lemon notes, whereas α-terpineol, *cis*- and *trans*-linalool oxides displayed a strong oily note (Table 4). Furthermore, the OAVs of these volatiles in the EOs were estimated on the basis of their odor thresholds according to previous studies.[20,22,23] β-Myrcene, decanal, D-limonene, linalool, and octanal had OAVs in ranges of 211,042−223,577, 48,100−83,950, 41,453−42,150, 32,475−36,038, and 13,033−21,867 (Table 4), respectively. These chemicals contributed to the majority of the total OAVs of the EOs, which was consistent with previous studies that D-limonene, β-myrcene, linalool, octanal, citronellal, nonanal, linalool oxide, and nootkatone were the major contributors to the aroma of citrus oils.[12,17,33]

Studies have shown that an overall aromatic profile could be significantly changed by some changes of volatiles in small concentrations but with very low odor thresholds.[17,39] For instance, many oxygenated compounds have been recognized with high OAVs that may have significant impacts on overall flavors.[9,12] To explore the potent volatiles responsible for the aroma changes, the EOs were further compared by the OAVs of their inherent volatiles by cluster analysis, which showed the existence of five principal clusters according to the OAV changes (Table 4 and Figure 3). Cluster 1 represented the volatiles that did not exist in the fresh EO (sample 1) but had been generated with significantly high OAVs in the sunlight-exposed EOs (samples 2 and 3) and heated EOs (sample 5), which contributed to the oily and ripened notes. Clusters 2 and 3 represented the volatiles that presented herbaceous and lemon notes and had decreased OAVs in the sunlight-exposed EOs (samples 2 and 3). Cluster 4 represented the volatiles that had no significant changes in their OAVs among all of the EOs. Cluster 5 represented the volatiles that had increased OAVs of the sunlight-exposed EOs and contributed to the oily note.

In cluster 1, *cis*- and *trans*-limonene oxides that were reported having sweet and floral notes[29] had much higher OAVs in the heated (sample 5) and the sunlight-exposed EOs (samples 2 and 3) than in the fresh EO (sample 1), which was consistent with the reduced freshness of the heated and sunlight-exposed EOs (Table 1). Other volatiles in cluster 1, such as *cis*- and *trans*-linalool oxides that were reported to have the woody and linalool-like odor of *mangshanyegan*,[12] showed much higher OAVs in the sunlight-exposed EOs (samples 2 and 3) than their counterparts in other EOs, providing a reasonable explanation for the strong oily off-flavor of the sunlight-exposed EOs (Table 1). In cluster 2, neral and geranial, which had been reported having herbaceous and lemon notes of kumquat[14] and orange juice,[30] exhibited much lower OAVs in the sunlight-exposed EOs (samples 2 and 3), which was in agreement with the result from the sensory evaluation of the sunlight-exposed EO, which had a decrease in its lemon and herbaceous odor (Table 1). The volatiles (i.e., *cis*-β-ocimene, decanal, dodecanal, nootkatone) in cluster 3 had much lower OAVs in sunlight-exposed EOs. Among these volatiles, nootkatone was identified to possess a strong odor of fresh pummelo aroma and considered as the most important aroma of grapefruit oil.[40] The decreased OAVs of neral, geranial, and nootkatone seemed to provide a reasonable explanation for the less green notes of the sunlight-exposed EOs (samples 2 and 3). The volatiles in cluster 4, that is, α-pinene, sabinene, β-pinene, β-myrcene, D-limonene, linalool, α-phellandrene, nonanal, geranyl acetate, and octanal, showed constant OAVs in all of the EOs (Table 4; Figure 3), which indicated these compounds had little influence on the aroma changes of the EO. In cluster 5, α-terpineol, which was reported to have a strong oily off-flavor,[41] showed much higher OAVs in the sunlight-exposed EOs than that in other EOs, which gave the sunlight-exposed EOs (samples 2 and 3) a more oily note.

The comparison of the OAVs of the volatiles and the cluster analysis suggested that *cis*- and *trans*-linalool oxides, *cis*- and *trans*-limonene oxides, neral, geranial, nootkatone, and α-terpineol were the volatiles that had significantly affected the aroma changes of the sunlight-exposed EOs. Furthermore, *cis*- and *trans*-limonene oxides were also the volatiles responsible for the aroma changes of the heated EO.

**Verifying the Contributions of the Aroma-Impact Volatiles to the Aroma Changes by Omission Test.** The formulated sample model (i.e., FMS 0) possessed a typical fresh odor like the fresh EO. In comparison, FMS 1 possessed a typical oily off-flavor and reduced herbaceous and lemon notes like that in the sunlight-exposed EO; FMS 2 had a reduced freshness like that in the oxygen-exposed EO; FMS 3 showed a reduced freshness and sweet and floral notes like that in the heated EO. In addition, the linalool oxides-added sample (FMS 4) was found to have a slight oily off-flavor by sensory evaluation; the α-terpineol-increased sample (FMS 5) and the nootkatone-decreased sample (FMS 7) did not show obvious differences in comparison to the model sample of fresh EO (FMS 0); the neral and geranial mixture-excluded sample (FMS 6) released the reduced herbaceous and lemon notes (Figure 4). The above results from the reconstituted flavor models (from FMS 0 to 7) confirmed that increasing the contents of

*cis*- and *trans*-linalool oxides and *cis*- and *trans*-limonene oxides could result in the generation of the strong oily off-flavor, whereas increasing the concentrations of *cis*- and *trans*-limonene oxides gave strong sweet and floral notes, resulting in the suppression of the citrus freshness note. Lack of citral (i.e., neral and geranial) was considered to cause the decreased herbaceous and lemon notes. Surprisingly, nootkatone and $\alpha$-terpineol exhibited little effect on the flavor profiles of the formulated aroma models due to their negligible OAVs in comparison to those of the main OAV contributors such as linalool oxides and limonene oxides (Table 4). Nevertheless, all other results supported that the linalool oxides, limonene oxides, and citral (i.e., neral and geranial) were the main volatiles responsible for the aroma changes during sunlight exposure.

**Illustration of UV for the Sunlight-Induced Aroma Deterioration.** UV is the short wavelength light of sunlight; therefore, it has a higher energy than its counterparts in daylight beams. UV can cause the oxidation and degradation of some chemicals, resulting in the generation of free radicals.[25] Previous studies have shown that some volatiles, for example, terpinolene, germacrene D, neral, and geranial, were susceptible to degradation under UV irradiation.[15,26] For instance, Iwanami et al.[15] found the lemon EO had a dusty flavor after UV irradiation. To investigate whether the short-wavelength light is the cause for the sunlight-induced deterioration of the aromas, the pummelo EOs were exposed under a UV light and a daylight lamp, respectively, followed by monitoring of the changes of their aromatic profiles and volatile constituents. As a result, the UV-exposed EO exhibited a strong oily note and decreased lemon and herbaceous notes, whereas the EO exposed under the daylight lamp showed little change from its original aroma. Moreover, the UV-exposed EO had significant increases in the concentrations and OAVs of *cis*- and *trans*-linalool oxides and significant decreases in the contents and OAVs of neral, geranial, and nootkatone (Table 5). Besides, another parallel experiment using the single chemical standards, that is, $\beta$-myrcene and D-limonene, that account for the majority of the pummelo EO, was conducted to expose the chemicals under UV irradiation, respectively. It was found that D-limonene was turned into $\alpha$-pinene, sabinene, $\beta$-myrcene, octanal, and linalool, whereas $\beta$-myrcene was transformed to $\beta$-pinene, pseudolimonene, and D-limonene (Figure 5). These transformation trends were consistent with the concentration changes of these chemicals in the sunlight-exposed EOs (Table 3) and the UV-irradiated EO (Table 5). These results validated that the UV irradiation-initiated degradation and transformation was the main reason for the sunlight-induced deterioration of the EO.

In summary, sunlight exposure could cause remarkable aroma deterioration of pummelo EO. The sunlight-exposed EO had a strong oily and off-flavor odor and a reduced fresh aroma, which was significantly different from that of the oxygen-exposed and heated EOs. The strong oily and off-flavor notes were attributed to the generation of high concentrations of linalool oxides and limonene oxides. The reduced freshness was related to the decrease of neral and geranial. Moreover, the aroma deterioration of pummelo EO induced by sunlight was confirmed to be caused by the degradation and transformation of some aroma-impact volatiles, such as $\beta$-myrcene and D-limonene, initiated by the UV wavelength.

This information might be valuable for industries involved in the production and storage of aromatic products from citrus fruit.

MCs in aquatic environments may be transferred to farmland through agricultural irrigation using toxin-contaminated water and fertilization using harvested toxic cyanobacterial paste.[14] In order to reduce the water contamination, thousands of tons of cyanobacterial blooms have been mechanically salvaged from the eutrophicated water in the past decade in China. Some cyanobacterial blooms from this collection were discharged as organic fertilizers directly onto the farmlands near the waters. Following transfer of the cyanobacterial blooms and the toxin-contaminated water to farmlands, a considerable quantity of toxins is released to farmlands. High levels of MCs, ranging from 2.1 to 6.6 ng/g and 1.4 to 21.3 ng/g, were detected in the cropland soil near Taihu Lake and Dianchi Lake in China, respectively.[15,16]

Previous studies have shown that the morphological characteristics and the productivity of crop plants were affected when exposed to microcystins.[17,18] Furthermore, the exposure of edible crops to microcystins would cause human health risks, as terrestrial crops can take up and accumulate these compounds in the roots, stems, and leaves.[19−21] MCs accumulation in crops (such as vegetables) irrigated with toxin-contaminated water or fertilized with toxic cyanobacterial blooms could introduce MCs to the human food chain and consequently pose a hazard health risk to humans. Recent studies have reported that the consumption of vegetables (for example, salad lettuce) is another important exposure route of MCs to humans, in addition to aquatic products and drinking water exposure.[20,22,23]

The increasing awareness of the human health hazard and occurrence of cyanobacterial toxins in plants highlights the need for highly sensitive and selective analytical methods to examine MCs in plants. The methods commonly used to examine MCs can be categorized as those used for screening and quantitation. The former consisted of enzyme-linked immunosorbent assays (ELISA) and protein phosphatase inhibition assays (PPIA), which detect MCs in samples with high sensitivity. However, they cannot discriminate among MC analogues. The latter methods utilized high performance liquid chromatography (HPLC) combined with ultraviolet (UV) or mass spectrometric detection. Compared to ELISA and PPIA, the recently developed reverse-phase HPLC method can separate toxins and identify each microcystin variant. HPLC with a UV detector has been used for the identification and quantitation of microcystins through the characteristic UV spectra absorption of conjugated Adda diene, trypotophan, or tyrosine at 238, 223, or 232 nm, respectively.[24] However, identifying the target MCs based on chromatographic retention time alone is prone to false positives due to the complicated sample matrices and the similar UV spectra among MCs, which can also interfere with quantitation. Furthermore, the sensitivity of HPLC-DAD is not sufficient to detect trace amounts of MCs in plants.

HPLC coupled with mass spectrometry is an effective and powerful technology to detect the trace organic toxins in complex matrices, as it can provide the necessary sensitivity and selectivity. The feasibility of HPLC−MS/MS used to identify and quantitate trace amounts of microcystins in water and aquatic products, such as fish, shrimps, clams, and crabs, has been described in previous reports.[25−28] However, to our knowledge, simultaneous assays of trace amounts of microcystin variants in vegetable matrices using HPLC−MS/MS have not been reported. In previous studies, the detection of MCs in vegetables was performed using ELISA or HPLC-UV methods, which analyzed total MCs and did not distinguish among MC variants.[17,18]

This study was performed to establish a reliable, sensitive, and convenient method for the determination of MC variants in vegetables. The microcystins selected in our study were the toxins detected most frequently in previous environmental analyses, which included MC-LR, MC-RR, and MC-YR.

Overall, a sensitive and selective method was established for the simultaneous analysis of microcystin variants in various vegetable matrices using solid-phase extraction and HPLC-MS/MS in positive-ionization mode. This method comprised sample treatment procedures and methodologies, was validated with accuracy, precision, and matrix effect, and was applied to assay the MCs in real vegetables with acceptable results.

## MATERIALS AND METHODS

**Reagents.** The microcystin standards were bought from Taiwan Algal Science (Taoyuan, Taiwan) and Enzo Biochem (NewYork, NY), respectively, with purities >95%. Single and mixture microcystin standard stock solutions were prepared in methanol and stored in a refrigerator. Matrix-matched standard solutions were generated by adding serially diluted standard mixture to the microcystin-free (blank) vegetables (lettuce, water spinach, cabbage, choi sum, carrot, turnip, potato, pumpkin, cucumber, and eggplant). The microcystin-free vegetables detected without the target micocystins were purchased from an organic vegetable production base, which was irrigated with clean water and fertilized without the paste of cyanobacterial bloom. All the standard solutions were stored in a refrigerator and used within 3 months.

HPLC-grade acetonitrile and methanol were purchased from Fisher Co. (Fair Lawn, NJ). The solid-phase extraction (SPE) system with 24-port vacuum manifolds was bought from Sigma-Aldrich (St. Louis, MO). The Sep-pak $C_{18}$ cartridges and Oasis HLB were obtained from Waters Corporation (Milford, MA). The cartridge was pretreated with 3 mL of methanol and 6 mL of ultrapure water sequentially before sample extraction. Trifluoroacetic acid (TFA) (≥99%) was purchased from Aladdin Reagent Company (Shanghai, China). All other reagents were analytical grade. Ultrapure water used throughout the entire analytical process was obtained from a Unique-R20 system (Research Scientific Instruments Corporation, Xiamen, China).

**Instrument and Apparatus.** The Applied Biosystems API 4000Q-Trap triple-quadrupole mass spectrometer (Applied Biosystems, FosterCity, Canada) equipped with an electrospray ionization (ESI) source was used in this study. The liquid chromatography system was an Agilent 1100 system equipped with a G1379A degasser, G1311A binary pump, G1313A autosampler and G1316A column oven (Agilent Technologies, Palo Alto, CA). HPLC separation was performed using a 150 mm × 2.1 mm i.d., 5 $\mu$m, Eclipse Plus $C_{18}$ column (Agilent Technologies, PaloAlto, CA).

**Recommended Procedure.** The tested vegetable samples (lettuce, water spinach, cabbage, choi sum, carrot, turnip, potato, pumpkin, cucumber and eggplant), with moisture content of 80.9−95.4%, were collected and immediately transported to the laboratory under the cool conditions, then the fresh vegetables were lyophilized and ground to powder (0.45 mm). Two g (accurate to 0.01 g) of the lyophilized powder of vegetable sample was extracted using 10 mL of acidified methanol aqueous solution (methanol/water/TFA, 80/19.9/0.1 or 80/19/1, v/v/v) by 20 min of vortexing

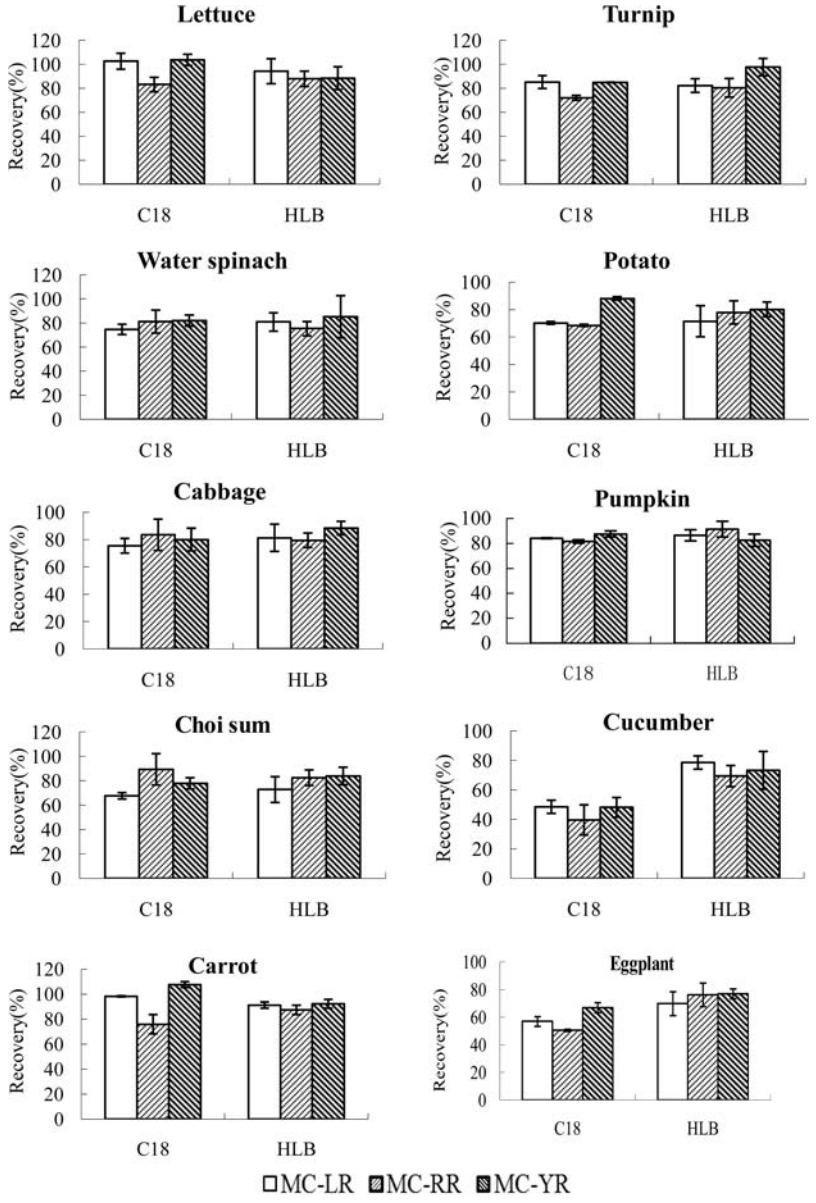

**Figure 2.** Effect of sorbents ($C_{18}$ and HLB) on the recovery of microcystins in different vegetables ($n$ = 5).

extraction and 10 min of ultrasonic extraction, followed by centrifugation at 10000 rpm and 10 °C for 10 min. The supernatant was collected and the vegetable residue was extracted again with 10 mL of acidified aqueous methanol. The supernatants were combined and concentrated to ~2 mL using a rotary evaporator below 40 °C under reduced pressure. The obtained extract was introduced into the $C_{18}$ (HLB cartridge was used for cucumber and eggplant sample) cartridge (500 mg/6 mL) for solid-phase extraction cleanup. The effluent was collected and reintroduced into a $C_{18}$ (or HLB) cartridge for re-extraction. Then the cartridge was rinsed with 5 mL of ultrapure water and vacuum-dried. It was then eluted with 5 mL of acidified aqueous methanol (methanol/water/TFA, 80/19.9/0.1, v/v/v) and the resulting eluate was filtered through a 0.22 $\mu$m filter and concentrated to 1 mL using a nitrogen stream for LC-MS/MS detection. Quantitation was performed using matrix-matched standard calibrations.

Microcystin-free vegetables were used as blanks for validation experiments and matrix-matched standard calibrations. Fortification of the vegetable samples for recovery studies was carried out by delivering 0.4 mL of mixed microcystin standard solutions at 0.1, 1, and 5 $\mu$g/mL in methanol to 2 g of lyophilized vegetable samples to obtain 20, 200, and 1000 $\mu$g/kg dw fortification levels (roughly equivalent to 1, 10, and 50 $\mu$g/kg fresh weight fortification levels, respectively). The fortified samples were left for 12 h at room temperature prior to the sample extraction procedure.

**Chromatographic and Mass Spectrometric Conditions.** *HPLC Operating Conditions.* The mobile phase consisted of acetonitrile (solvent A) and water containing 0.2% (v/v) formic acid (solvent B), the flow rate was 0.3 mL/min. The optimal gradient program started with 20% acetonitrile at the time of injection and increased linearly to 80% acetonitrile over 2 min, which was kept for 4.5 min, and then brought back to 20% acetonitrile over 0.1 min and held for 9.4 min until the next injection. The column oven temperature was maintained at 35 °C. The sample injection volume was 5 $\mu$L. All the three microcystins were eluted within 6.0 min.

dx.doi.org/10.1021/jf5033075 | J. Agric. Food Chem. 2014, 62, 11831−11839

*MS Operating Conditions.* The ESI source in positive multiple-reaction-monitoring (MRM) mode was used for the identification and quantitation of the three microcystin variants. The monitoring parameters were optimized as follows: ion source spray voltage (IS), 5500 V; atomization temperature (TEM), 450 °C; atomization gas pressure (GAS1), 55 psi (nitrogen); heated auxiliary gas (GAS2), 50 psi (nitrogen); air curtain gas pressure (CUR), 25 psi (nitrogen); collision flow ratio (CAD), high.

**Data Analysis.** Microcystin concentrations from LC-MS/MS analysis were determined using Analyst software(version 1.4, Applied Biosystems). The data were exported to Microsoft Excel 2003 (Microsoft Co., Redmond, WA, USA) to calculate the average and to perform statistical (ANOVA) analysis.

## RESULTS AND DISCUSSION

**Optimization of Sample Pretreatment.** Ten vegetables—lettuce, water spinach, cabbage, choi sum, carrot, turnip, potato, pumpkin, cucumber, and eggplant—were selected for the study to represent tropical and subtropical vegetables commonly consumed in China. Ten vegetables were chosen to examine the matrix effects of each vegetable on the determination of MCs in vegetables because the matrix components in the samples can affect the analyte signals. It is believed that the same species of vegetables should have similar matrix effects. Thus, lettuce, water spinach, cabbage, and choi sum could represent green leafy vegetables with high content of chlorophyll.[29] Carrot, turnip, and potato were the representatives of root vegetables, while pumpkin, cucumber, and eggplant represent fruit vegetables.

Microcystin variants in vegetable samples were usually present at trace or even ultratrace amounts, and the vegetable matrix effect may interfere with the HPLC separation and reduce the sensitivity of the mass spectrometry detector; therefore, analyte enrichment and sample cleanup were required prior to HPLC-MS/MS analysis. During the sample treatment process, lyophilization was used to dehydrate the vegetables and concentrate microcystins, with less loss of analyte under vacuum and cool conditions. Furthermore, the volumes of reagents used for sample extraction decreased by 80% compared to the fresh vegetable samples, which could also reduce the time required for the extract to pass through the cartridge.

Previous studies suggested that an acidified aqueous methanol solvent was suitable for the extraction of both hydrophilic and hydrophobic microcystins.[30] Therefore, the extraction efficiencies of solvents at several methanol−water ratios (60%, 80%, and 100% methanol) and acidities (1%, 0.1%, and 0.01% TFA, v/v) were evaluated.

Extraction with 80% methanol provided recoveries higher than 67.6% in all vegetable samples for the three target MCs, while extraction with 60% and 100% methanol yielded low recoveries of 42.6% and 45.3% for MC-LR, 48.1% and 48.8% for MC-RR, and 44.4% and 45.5% for MC-YR in the vegetable samples, respectively. In most of the selected vegetable matrices, the highest extraction efficiencies for the three microcystins were obtained by addition of 0.1% TFA (v/v) in aqueous methanol (19.9/80, v/v) solution, while the highest extraction efficiencies of MC-LR in potato and choi sum, of MC-RR in cucumber and pumpkin, and of MC-YR in water spinach and cabbage were obtained by addition of 1% TFA (v/v) in aqueous methanol.

In the sample cleanup and preconcentration step, two commonly used sorbents, Oasis Sep-Pak $C_{18}$ and HLB cartridges, which could simultaneously retain nonpolar to moderately polar toxins from complicated matrices,[31] were tested in various vegetable matrices to optimize extraction and concentration efficiency. As shown in Figure 2, both recovery and RSD were satisfied when Sep-Pak $C_{18}$ or Oasis HLB was used in lettuce, water spinach, cabbage, choi sum, carrot, turnip, potato, and pumpkin samples. However, the $C_{18}$ cartridge was selected as a sorbent for the above-mentioned eight species of vegetable because it was relatively cheap compared with the HLB cartridge. Nevertheless, microcystin recoveries were very poor (less than 60%) when the $C_{18}$ cartridge was used for cucumber and eggplant samples, suggesting that interfering impurities in the matrices were not completely eliminated. Otherwise, when HLB was used in these matrices, both recoveries (>70%) and RSD were acceptable in terms of removing pigments from cucumber and eggplant (Figure 2). Therefore, $C_{18}$ (500 mg/6 mL) was used to clean up lettuce, water spinach, cabbage, choi sum, carrot, turnip, potato, and pumpkin samples, while HLB (500 mg/6 mL) was chosen to purify cucumber and eggplant in the study.

In the elution step, the retained microcystins should be completely eluted using as little volume of eluent as possible. Microcystins are relatively polar molecules with hydrophobic regions, such as the Adda residue or hydrophobic substituents of amino acids. Some investigations found that the efficiency of eluting solvents depended on various factors, such as the water content of the sample and eluent polarity.[32,33] Thus, various aqueous/methanol ratios from 10% to 100% methanol were tested for elution of the adsorbed microcystins from the cartridges. When the solutions (5 mL) contained less than 50% methanol, they could not remove the target microcystins. The pure methanol resulted in more efficient elution of MC-LR and MC-YR, but the yield of MC-RR, a strong polar, was not sufficient. However, the desired elution yields of the three microcystin variants were obtained when using 80% methanol. Therefore, 5 mL of 80% methanol aqueous solution was optimal to elute the tested microcystin variants from the cartridges.

**Liquid Chromatography.** The reverse-phase HPLC system with a $C_{18}$ stationary phase and an acetonitrile in the water mobile phase is a typical method of separating microcystin variants.[34] Two Agilent Eclipse Plus $C_{18}$ columns, both 150 mm × 2.1 mm i.d., but with different particle sizes of 5 and 3.5 $\mu$m were compared for separation of the target microcystins. A better reproducibility and sensitivity of the three target microcystins was observed when separated with the 5 $\mu$m particle size column compared to the 3.5 $\mu$m particle size column. Thus, the Agilent Eclipse Plus $C_{18}$ column with 5 $\mu$m particle size was selected.

The mobile phase, which consists of acetonitrile gradients in the presence of organic acid, such as formic acid, is capable of separating microcystin variants with greater chromatographic efficiency than the neutral mobile phase because the acid could improve the protonation of carboxylic acid groups in the toxins and decrease the interactions between basic groups of the microcystin molecule and the silanol groups coated on the particle surface in the column.[35] The effects of the formic acid addition ratio in the mobile phase on the MCs defect sensitivity were evaluated. It can be found that a mobile phase containing 0.2% formic acid provided the highest sensitivity. Under this

condition, the liquid chromatography elution order was MC-RR, MC-YR, and MC-LR.

**Mass Spectrometry.** Individual standard solutions of each microcystin were infused into the ESI source to create an ion transition under the positive-ionization mode. In the full-scan mass spectrum, the protonated molecules ($[M + H]^+$) of $m/z$ 996.1 and 1046 were produced by MC-LR and MC-YR, respectively, and the double-charged protonated molecular ion $[M + 2H]^{2+}$ of $m/z$ 520 was produced by MC-RR, which contains two basic Arg residues in the molecule. The protonated molecule was selected as a precursor ion and was subjected to fragmentation. The fragment ions of $m/z$ 135 and 213 were the major product ions for the three target microcystins and used as the quantitative and qualitative ions, respectively. The product ion mass spectra of MC-LR, MC-RR, and MC-YR are shown n Figure 3. The fragment ion of $m/z$ 135 was identified as the $[\text{phenyl-CH}_2\text{–CH(OCH}_3)]^+$ ion formed by cleavage of the Adda residue between C-8 and C-9, and $m/z$ 213 was $[\text{Glu-Mdha+H}]^+$ formed by the cleavage of the $\alpha$-linked glutamic acid (D-Glu) and *N*-methyldehydroalanine (Mdha) residue.[36] Two major ion pairs for each analyte and the optimal MS/MS parameters for each ion pair are described in Table 1.

**Method Validation.** *Matrix Effects.* The matrix effect (ME), which impacts the quantitation greatly, depends on various factors, including the instrument, the type and amount of matrix, the treatment procedure, and the properties of the analyte.[37,38] The matrix effect in vegetable matrices was studied by comparing the slopes of the calibration curves of standards in methanol and sample matrices. The following expression was used to quantitate signal suppression or enhancement for each microcystin:

$$ME = 100 \times \left(\frac{slope_m}{slope_s} - 1\right)\%$$

The $\text{slope}_m$ and $\text{slope}_s$ represent the slopes of the matrix-matched and solvent-only (matrix-free) calibration curves, respectively. The matrix effect was considered mild when it ranged from −20% to −10% or from +10% to +20%, medium when it ranged from −50% to −20% or from +20% to +50%, and strong when it was below −50% or above +50%. If it ranged from −10% to +10%, the effect could be ignored. These results reveal the suppressive effects of vegetable components on the tested microcystins in the range of −63% to −2%. The matrix effects of three tested microcystins in lettuce (−13 to −5%) and carrot (−10 to −2%) could almost be ignored, but those in water spinach, choi sum, turnip, cucumber, and eggplant matrices showed medium suppression (−50 to −20%). A strong signal-suppressive effect was detected in potato and pumpkin for MC-RR and in cabbage and pumpkin for MC-YR. Generally, matrix effects originated from insufficient elimination of sample endogenous materials such as pigments and fatty acids. The coexistence of the impurities would affect the ionization efficiency and weaken the response of the analytes. Therefore, in order to get more accurate results, the matrix-matched calibration curves should be used for quantitation due to the existence of matrix effects.

*Linearity and Limit of Quantitation (LOQ).* The linearity and LOQ were obtained using the peak areas of the product ions acquired from the MS/MS mode. The matrix-matched calibration curves were constructed using least-squares linear regression analysis of the matrices (lettuce, water spinach, cabbage, choi sum, carrot, turnip, potato, pumpkin, cucumber, and eggplant) spiked with MC-LR, MC-RR, and MC-YR at 5–2500 ng/mL. The correlation coefficients ($R^2$) were higher than 0.9876 in all cases, and the limit of detection (LOD) was below 7.5 μg/kg, while the LOQ was 1.6–10.0 μg/kg (dw), 6.3–25.0 μg/kg (dw), and 5.6–25.0 μg/kg (dw) for MC-LR, MC-RR, and MC-YR in different vegetable matrices, respectively. Regarding specificity, no responses were detected in the

procedure blank or vegetable sample blank, suggesting the high specificity of MS-MS detection.

*Accuracy and Precision.* The recovery analysis was performed to evaluate the performance of the proposed method by analyzing 10 species of vegetable samples spiked with 20, 200, or 1000 $\mu$g/kg of MC-LR, MC-RR, and MC-YR. The precision of the method was expressed using the intraday and interday relative standard deviation (RSD). The intraday RSD was measured by comparing the standard deviation of the recovery rates of the spiked samples analyzed in the same day. The intraday RSD was determined by analyzing the spiked samples for three distinct days. Table 2 showed the detailed recovery and repeatability data for the microcystins in various vegetable matrices. The recoveries of the microcystins were in the range of 61.3−117.3% ($n$ = 5), and the RSD of the intraday ($n$ = 5) and interday ($n$ = 15) ranged from 0.2−17.9% and 1.6−18.3%, respectively. The MRM chromatograms of the blank and the positive lettuce sample are shown in Figure 4, and this indicates that the proposed method can maintain blanks below a critical threshold.

**Method Application.** To demonstrate its functionality, the proposed method was applied to determine the field vegetable samples collected from the farmlands irrigated with Dianchi Lake water. Dianchi Lake is China's sixth largest fresh water lake, fed by several rivers and located at 1700 m above sea level in Yungui Plateau in southwest China. This lake is used to irrigate millions of hectares of grains and vegetables in a lush agricultural region in Yunnan Province, and it was formerly one of China's most important freshwater fisheries. With the rapid economic development over the past 30 years, the lake has been subjected to serious eutrophication, which has caused frequent outbreaks of cyanobacteria blooms during years.[39−41]

A total of 28 vegetable samples (8 lettuce samples, 3 water spinach samples, 12 cabbage samples and 5 choi sum samples) with moisture content ranging from 91.4% (water spinach) to 95.4% (lettuce) were collected in the winter of 2013 from

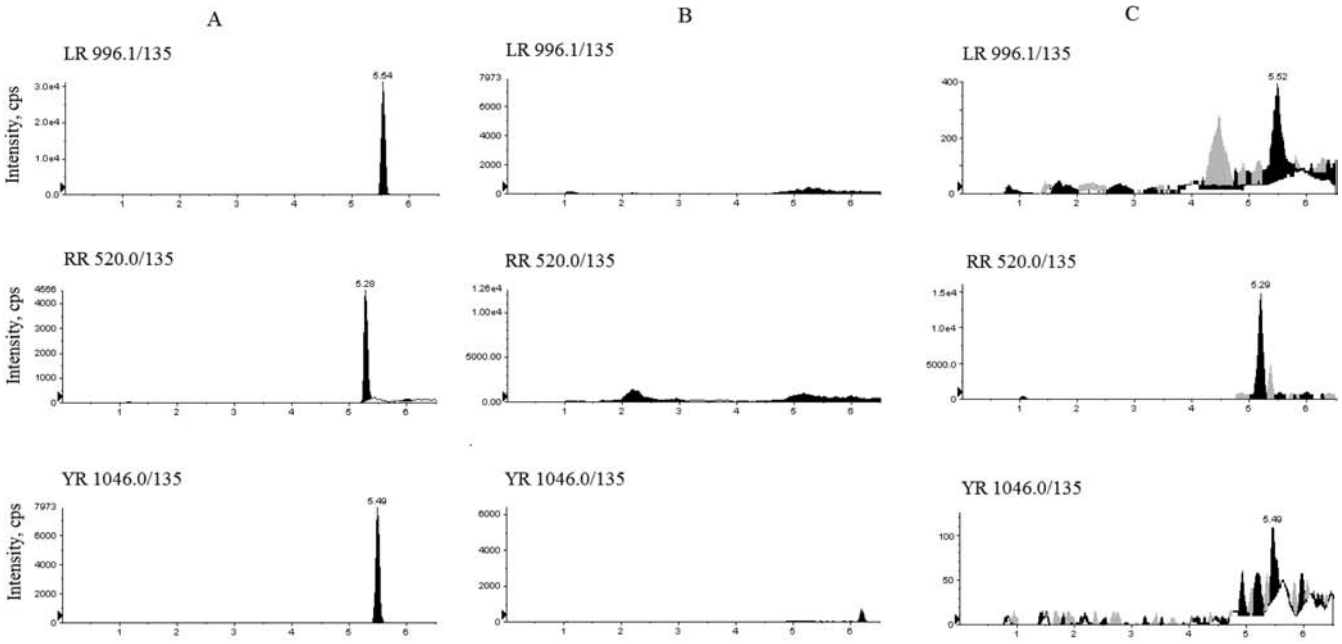

**Figure 4.** MRM chromatograms of (A) standard solution; (B) lettuce matrix; and (C) positive lettuce sample by HPLC-MS/MS.

**Table 3. Concentrations of the Three Microcystin Variants in Vegetables**

| MC | Vegetable | Moisture content (%) | Sample no. | Positive sample no. | Range (dw[a]/fw[b]) (μg/kg) | Average (dw) ± SD (μg/kg) |
|---|---|---|---|---|---|---|
| MC-LR | Lettuce | 95.4 | 8 | 0 | ND[c]/ND | |
| | Water spinach | 91.4 | 3 | 1 | 23.7/2.0 | |
| | Cabbage | 94.9 | 12 | 0 | ND/ND | |

[a]dry weight. [b]fresh weight. [c]not detected.

farmlands along the lake shore, which were irrigated with the lake water. Three quality controls (QCs) at 20, 200, and 1000 μg/kg were included for each vegetable sample in the analysis sequence.

The concentrations of MCs in the analyzed samples are listed in Table 3. The detected frequencies of the target microcystins were 3.6%, 89.3%, and 7.1% for MC-LR, MC-RR, and MC-YR, respectively, in the Dianchi Lake vegetable samples. The most frequently detected microcystin in the vegetable samples was MC-RR, which was consistent with the results reported previously in Dianchi Lake water.[22] All the tested vegetable samples, with the exception of two cabbage samples and a choi sum sample, contained MC-RR at 36.4−2352.2 μg/kg (dw). The vegetable samples with high MC-RR concentrations, exceeding 1000 μg/kg, were cultivated in a greenhouse. One water spinach sample and one lettuce sample contained MC-LR and MC-YR with 23.7 and 22.8 μg/kg, respectively. Similar concentrations were found in various vegetables cultivated around Taihu Lake (the third largest freshwater lake in China) using an ELISA screening method (∑MCs concentration: 30−360 μg/kg).[14]

In summary, a sensitive, selective, and reliable method based on HPLC-MS/MS was developed through stepwise optimization for the individual analysis of three microcystins in common vegetables. This method requires less than 6 min to perform each sample analysis. Using a simple solid-phase extraction procedure consuming only 2 g of lyophilized vegetable samples for cleanup and analyte enrichment, the method can be used to simultaneously determine trace microcystin variants (MC-LR, MC-RR, and MC-YR) in various vegetables at μg/kg levels. The optimized method was applied to analysis of vegetables collected from farmlands irrigated with cyanobacterial bloom water. The results indicated that vegetables were contaminated with microcystins, of which MC-RR exhibited the highest concentration, 2352.2 μg/kg. More research is clearly needed to

evaluate the human health risk exposed to microcystins via edible terrestrial plants such as vegetables in the future.

recently become an emerging method for protein quantification.[18−20] If the power of the speciation and quantification of mass spectrometry technology can be used for the analysis of mammalian gelatins, it will definitely be of great interest to the food industry.

Currently, most of the quantitative proteomics approaches by mass spectrometry use the isotopic labels as the reference for either relative or absolute quantification.[21] The incorporation of stable isotopes into peptides results in a fixed mass shift with no effect on the chemical properties of the peptides (i.e., peptide LC elution time or ionization efficiency). Therefore, the relative abundances of the labeled peptides from different samples can be accurately quantified using LC-MS.[22−24] Isotopes can be introduced by many methods including metabolic labeling,[25,26] chemical labeling through derivatization,[27,28] and enzymatic labeling.[29,30] Among these methods, as a powerful labeling strategy for quantitative proteomics application, enzymatic $^{18}O$ labeling shows many advantages including high labeling specificity, relatively lower price, and compatibility with almost any source of protein.[31,32] Serine proteases such as trypsin, chymotrypsin, Lys-C, and Glu-C can catalyze C-terminal carboxyl group oxygen exchange for $^{18}O$ labeling; nevertheless, different enzymes target various amino acid C-termini.[24,33] It was reported that trypsin, Glu-C, or Lys-C could incorporate two $^{18}O$ atoms into the C-terminus of the resulting peptide, whereas chymotrypsin and Asp-N introduced only one $^{18}O$ atom.[34,35] Trypsin-catalyzed $^{18}O$ labeling is particularly popular because it is simple, cost-effective, and able to specifically label all peptides that end with Arg or Lys residue on the peptide C-terminus.[24] Combined with mass spectrometry, trypsin-catalyzed $^{18}O$ labeling has been used to quantify many proteins in the biochemistry and medicine fields including human plasma proteins[36] and plasma membrane proteins.[37]

The purpose of this study was to establish a method by combining trypsin-catalyzed $^{18}O$ labeling and high-resolution mass spectrometry to quantify the bovine or porcine gelatins. At the first step, we identified characteristic marker peptides for the gelatins with or without $^{18}O$ labeling. High-energy C-trap dissociation (HCD) was selected to determine the sequence and identify the modification owing to its capability to detect the low mass fragments, which are often not detectable due to the low mass cutoff in ion trap collision-induced dissociation (CID). We then mixed the gelatin peptides with different ratios of $^{16}O$−$^{18}O$ to check whether the method was suitable to quantify the gelatins. Our results clearly demonstrated that trypsin-catalyzed $^{18}O$ labeling combined with mass spectrometric analysis was an accurate approach for the quantification of bovine and porcine gelatins.

## MATERIALS AND METHODS

**Materials.** Bovine gelatin (G9382), porcine gelatin (G2500), and Lys-C were purchased from Sigma Chemical Co. (St. Louis, MO, USA). $H_2{}^{18}O$ (97%) was obtained from Cambridge Isotope Laboratories, Inc. (Andover, MA, USA). Water ($H_2{}^{16}O$) was purified with a Milli-Q apparatus (Millipore, Schwalbach, Germany). Trypsin was purchased from Promega Corp. (Madison, WI, USA). All other reagents used were of analytical grade.

**Sample Digestion.** The bovine or porcine gelatin was dissolved in the digestion buffer composed of 20 mM, pH 8.0, Tris-HCl, 50 mM NaCl, and 50 mM $CaCl_2$. One hundred microliters of the gelatin solution (1 mg/mL) was mixed with 100 μL of the digestion solution in a 500 μL centrifuge tube. ProteaseMax Surfactant (Promega Corp.) was added into the mixed solution at the concentration of 0.01% (w/v). Fifteen microliters of 100 mM DTT was added to the tube, and the whole sample was incubated at 95 °C for 5 min and then cooled in an ice bath. Thirty microliters of the alkylation buffer (100 mM iodoacetamide) was added to the tube and incubated in the dark at room temperature for 20 min. Twenty microliters of 0.05 μg/μL Lys-C was added to hydrolyze the gelatin sample at 37 °C for 4 h. Twenty micorliters of 0.1 μg/μL trypsin was added to further hydrolyze the gelatin at 37 °C overnight.

**$^{18}O$-Labeling for Sample.** Fifty microliters of 0.1 μg/μL trypsin was added to the tube and mixed uniformly. The solution was split into two aliquots and freeze-dried. Eighty microliters of acetonitrile was added to every aliquot, and then the sample was dried by vacuum centrifugation at room temperature. Ten microliters of acetonitrile and 40 μL of $H_2{}^{18}O$ were added to one aliquot, whereas 10 μL of acetonitrile and 40 μL of $H_2{}^{16}O$ were added to another aliquot. The samples were incubated at 30 °C for overnight. After labeling, trypsin was inactivated by cysteine alkylation to minimize the back-exchange of $^{18}O$ to $^{16}O$. The inactivation of trypsin was done according to the protocol reported by Staes et al.[38] with slight modifications. Ten microliters of 50 mM tris(2-carboxyethyl)phosphine (TCEP) was dried in a centrifugation tube, and 15 μL of 100 mM iodoacetamide was dried in another tube in the dark. The labeled sample was transferred to the tube containing TCEP and incubated at 37 °C for 1 h. The solution was then transferred to the tube containing iodoacetamide and incubated at 37 °C for 90 min in the dark. The $^{16}O$ labeling sample was also prepared by the trypsin inactivation step. After the above steps, the samples were stored at −80 °C for further use.

**Liquid Chromatography and Mass Spectrometry Analysis.** A Shimadzu HPLC (Shimadzu, Kyoto, Japan), with two LC-10AD pumps, was used to generate a gradient with a 50 μL/min flow rate. Solvent A was 5% acetonitrile in $H_2O$ and 0.1% formic acid (FA), whereas solvent B consisted of 95% acetonitrile in $H_2O$ and 0.1% FA. For analysis of proteolytic peptides, 3 μg of digested gelatin sample was injected onto a 2.0 mm i.d. × 100 mm C18 column (Phenomenex Inc., Torrance, CA, USA). After desalting for 5 min with 2% B, the peptides were eluted at 50 μL/min with a 2−20% gradient for 40 min and 20−95% gradient for 2 min. The effluent was infused into a LTQ-Orbitrap Velos mass spectrometer (Thermo Fisher Scientific, Waltham, MA, USA) for MS/MS analysis to identify the characteristic peptides of the gelatins. The signals detected in the precursor ion scanning were further submitted to a HCD fragmentation to detect those fragment ions including low $m/z$ range. The normalized collision energy was set to 35% for HCD. Dynamic exclusion was enabled with exclusion duration of 90 s.

**Database Search.** Thermo proteome discoverer (ver. 1.4.0.288) was used to generate the mgf file from mass spectrometric data, and then Mascot Daemon (ver. 2.4.0, Matrix Science, Boston, MA, USA) was used to perform the searches against the in-house database including bovine and porcine collagen sequences, which were acquired from the uniprot database and a published patent.[39] Carbamidomethyl (C) was set as a fixed modification, and oxidations on P and K were set as variable modifications. Additional search settings included a maximum of five missed cleavages, peptide tolerance of ±25 ppm, and MS/MS tolerance of ±0.5 Da. The peptides with a Mascot ion score >40 were considered to be positive identification or extensive similarity ($p < 0.05$).[40] The targeted peptides are those characteristic peptides unique to either bovine or porcine gelatin.[16]

**$^{18}O/^{16}O$ Ratio Calculation.** The ratio of the abundance of the $^{18}O$-labeled peptide to the $^{16}O$-labeled peptide can be calculated from the heights of the monoisotopic peaks. Corrected for $^{13}C$ contributions and single $^{18}O$ incorporation, the calculated formula is

$$\frac{^{18}O}{^{16}O} = \frac{I_4 - \frac{M_4}{M_0}I_0 - \frac{M_2}{M_0}\left(I_2 - \frac{M_2}{M_0}I_0\right) + I_2 - \frac{M_2}{M_0}I_0}{I_0} \quad (1)$$

where $I_0$, $I_2$, and $I_4$ represent the observed relative intensities of the monoisotopic peak for the peptides without $^{18}O$ label, the peak with masses 2 Da higher, and the peak with 4 Da higher masses, respectively. $M_0$, $M_2$, and $M_4$ represent the theoretical relative intensities of the monoisotopic peak for the peptides, the peak with masses 2 Da higher, and the peak with 4 Da higher masses, respectively. In this work, the

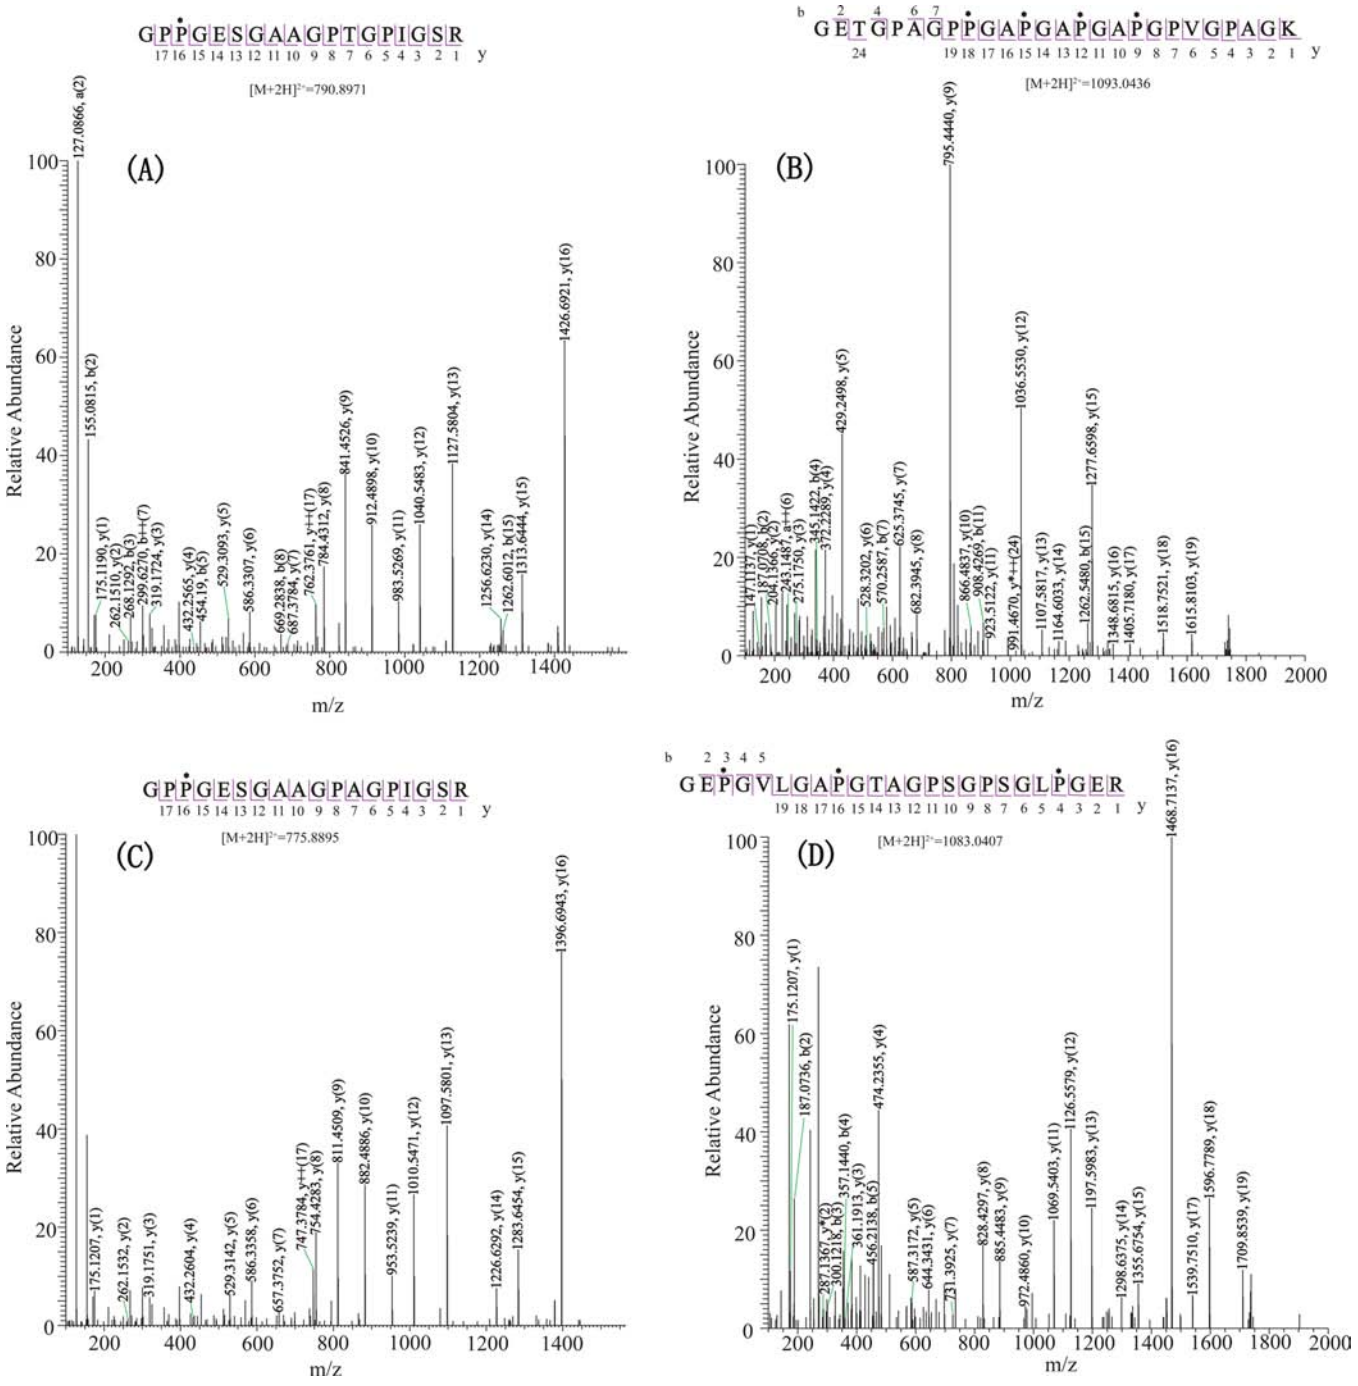

**Figure 1.** Sequence identification and hydroxylation determination by tandem mass spectrometry for marker peptides: (A) peptide from bovine gelatin at $m/z$ 790.8971$^{2+}$; (B) peptide from bovine gelatin at $m/z$ 1093.0436$^{2+}$; (C) peptide from porcine gelatin at $m/z$ 775.8895$^{2+}$; (D) peptide from porcine gelatin at $m/z$ 1083.0407$^{2+}$. The sequence of each peptide is shown on top of the peptide. The hydroxylated prolines are indicated by the asterisk. The b and y ions are indicated by the numbers and lines.

values of $M_4/M_0$ and $M_2/M_0$ are replaced by $2 \times 10^{-12}M_r^{3.2684}$ and $3 \times 10^{-7}M_r^{1.9241}$ ($M_r$ is the molecular weight of the peptide) according to the procedure of Johnson and Muddiman.[41] For bovine and porcine gelatins, 10 characteristic peaks were chosen to obtain the average $^{18}O/^{16}O$ ratio for minimum error.

## RESULTS AND DISCUSSION

**Gelatin Modification Identification.** Collagen contains a range of post-translational modifications that are essential for triple-helix assembly and stability, intermolecular cross-linking, and strength of fibrils and tissue function.[42] For instance, collagen includes abundant hydroxyproline (Hyp) resulting from the post-translational hydroxylation of some proline residues.[43] From the partial hydrolysis of the collagen, the gelatin also has a number of Hyp residues. Therefore, prior to the quantification of bovine or porcine gelatins, it is necessary to identify the modification sites by accurate mass and tandem mass spectrometry.

With the optimized hydrolysis of the gelatin followed by high-performance liquid chromatography−LTQ/Orbitrap high-resolution mass spectrometry, we accurately identified many modified sites of bovine and porcine gelatins. Figure 1 shows

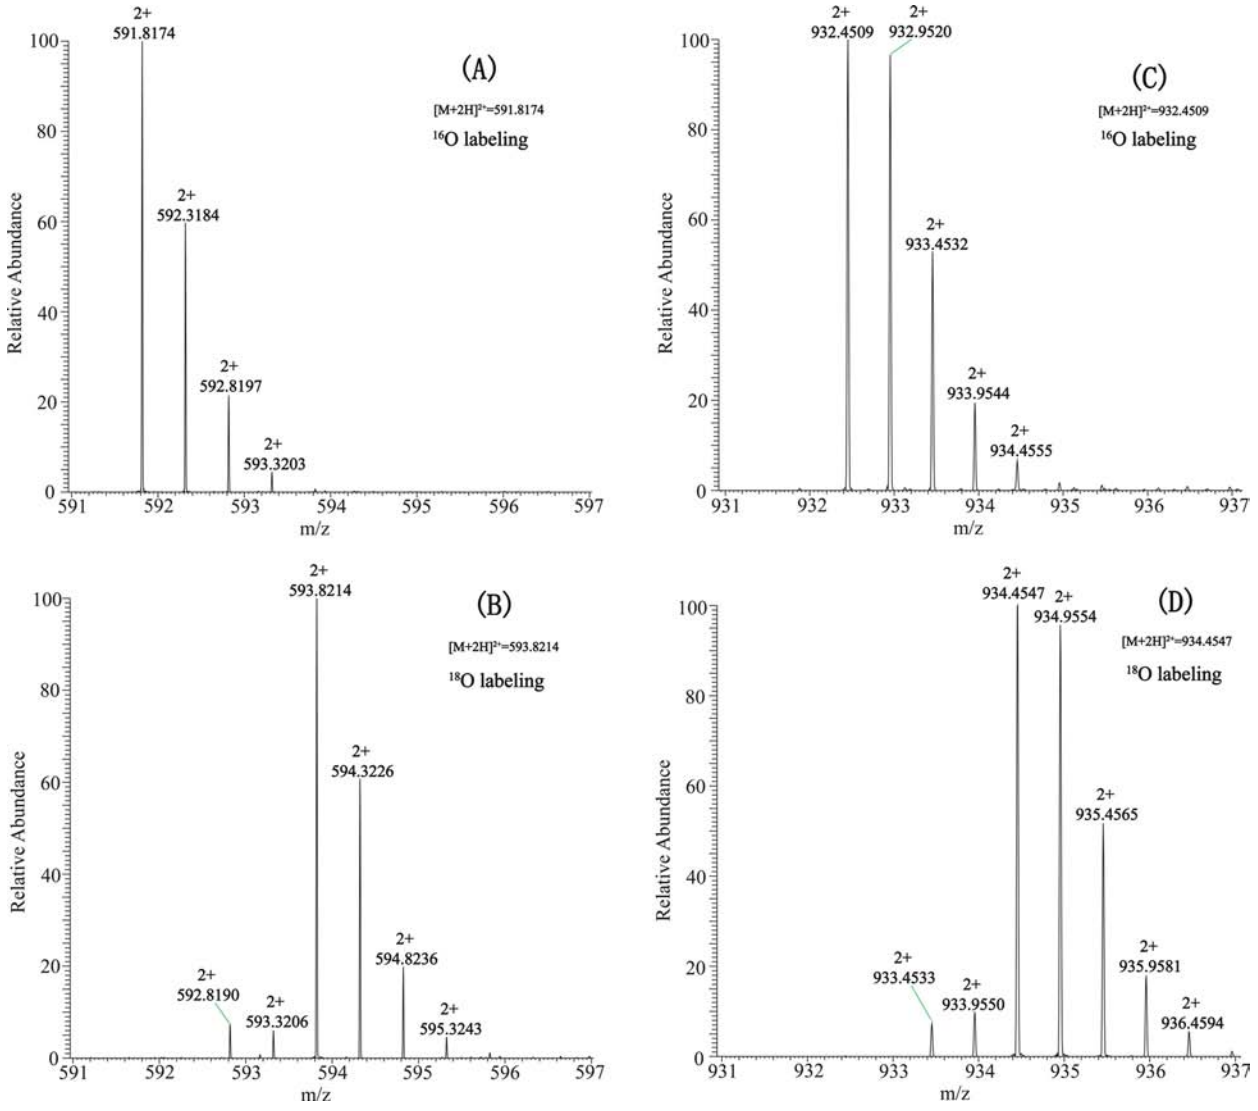

**Figure 2.** Comparison of the mass spectra of bovine gelatin peptides after $^{16}O$ and $^{18}O$ labeling: (A, B) peptide $^{465}$EGPVGL*PGIDGR$^{476}$ after $^{16}O$ and $^{18}O$ labeling, respectively; (C, D) peptide $^{451}$GEPG*PTGIQGP*PGPAGEEGK$^{470}$ after $^{16}O$ and $^{18}O$ labeling, respectively.

the determination of hydroxylated proline sites for four peptides from the bovine or porcine gelatin. From Figure 1A, the mass of the peptide (1579.7796) with $m/z$ 790.8971$^{2+}$ matched well with that of the Pro oxidation form (1579.7591) with the sequence $^{592}$GP*PGESGAAGPTGPIGSR$^{609}$ (the asterisk indicates that Pro594 was hydroxylated) from the $\alpha_2$ chain of the bovine gelatin. Moreover, the HCD MS/MS of the peptide generated a series of b and y ions (y1−y17 in Figure 1A), unambiguously confirming the sequence of the peptide. The location of the hydroxylation (Pro594) was obtained by the mass difference between the y15 and y16 ions, which is the corresponding mass of Hyp. From Figure 1B, Pro1047, Pro1050, Pro1053, and Pro1056 were identified as the hydroxylated proline sites in the sequence of $^{1039}$GETGPAGP*PGA*PGA*PGA*PGPVGPAGK$^{1064}$ with $m/z$ of 1093.0436$^{2+}$ from the $\alpha_1$ chain of the bovine gelatin. The series of b and y ions ensured the positive identification of the peptide sequence (b2, b4, b6, b7, y1−y19, and y24) and Hyp location (y8, y9, y11, y12, y14, y15, y17, and y18). Similarly, on the basis of the y15 and y16 ions in Figure 1C, Pro594 was identified to be the Hyp in the peptide $^{592}$GP*PGESGAAGPAGPIGSR$^{609}$ with $m/z$ 775.8895$^{2+}$ from the $\alpha_2$ chain of the porcine gelatin. On the basis of the b2, b3, y15, y16, y3, and y4 ions in Figure 1D, Pro624, Pro630, and Pro642 were identified to be three hydroxylated proline sites in the peptide with the sequence of $^{622}$GE*PGVLGA*PGTAGPSGPSGL*PGER$^{645}$ with $m/z$ 1083.0407$^{2+}$ from the $\alpha_2$ chain of the porcine gelatin.

**$^{18}$O-Labeling Identification.** To use the $^{18}O$ labeling to quantify the bovine or porcine gelatin, it is important to ensure all of the characteristic peptides from the targeted gelatin are labeled at their maximum. Figure 2 shows the mass spectra of two characteristic $^{16}O$ labeling peptides from bovine gelatin and their corresponding peptides labeled by $^{18}O$, respectively. During the $^{18}O$ labeling processing for the gelatin peptides, two $^{18}O$ atoms are exchanged by trypsin into the $\alpha$-carboxyl group of peptides C-terminally ending with a lysine or arginine residue because tryptic peptides interact with trypsin by forming covalent intermediates with repeated binding/hydrolyses cycles in the $H_2{}^{18}O$.[44] As a result, the $m/z$ of the peptides will increase by 4 Da when the $^{18}O$ labeling is complete. As shown in Figure 2A, the monoisotopic peak at $m/z$ of 591.8174$^{2+}$ was found from $^{16}O$ labeling peptides after bovine gelatin digestion. The MS and MS/MS confirmed that this peptide was from $\alpha_2$ chain of the bovine gelatin with the sequence of $^{465}$EGPVGL*PGIDGR$^{476}$. Among the two proline

dx.doi.org/10.1021/jf503876a | J. Agric. Food Chem. 2014, 62, 11840−11853

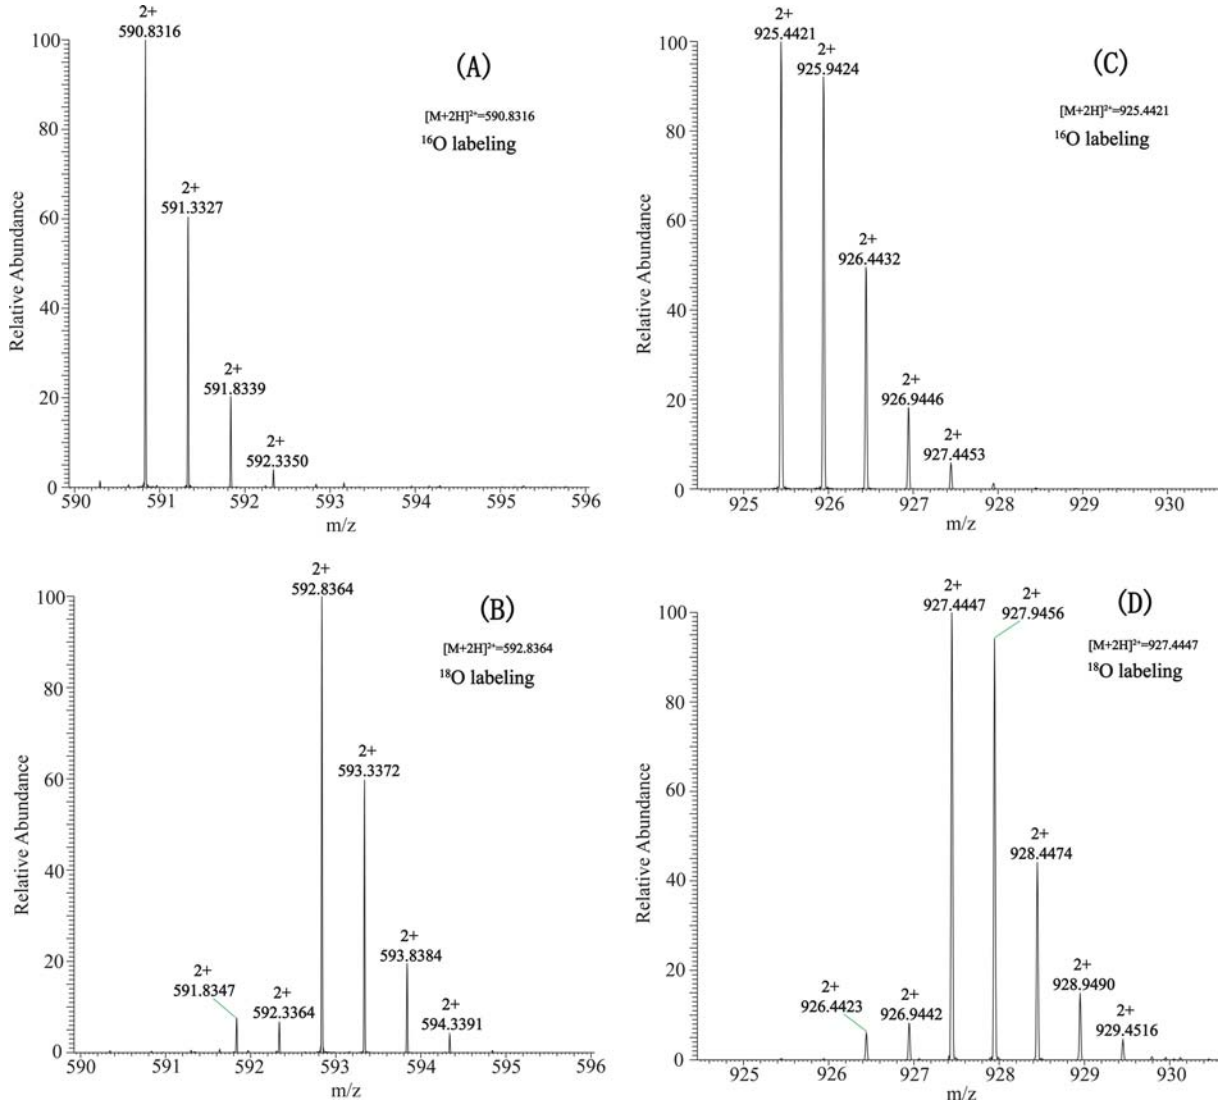

**Figure 3.** Comparison of the mass spectra of porcine gelatin peptides after $^{16}O$ and $^{18}O$ labeling: (A, B) peptide $^{1068}$TGQPGAVGPAGIR$^{1080}$ after $^{16}O$ and $^{18}O$ labeling, respectively; (C, D) peptide $^{451}$GEPG*PTGVQGP*PGPAGEEGK$^{470}$ after $^{16}O$ and $^{18}O$ labeling, respectively.

residues contained in this sequence, only proline 471 was oxidized. After $^{18}O$ labeling, the monoisotopic peak of this peptide shifted to $m/z$ of 593.8214$^{2+}$ (Figure 2B). The mass shift of 4.0080 Da was well matched to the theoretical shift of 4.0085 Da for $^{18}O$ labeling with only 0.4 ppm difference. Figure 2C shows another example of the mass shift of a bovine peptide after $^{16}O$ labeling. The peak with $m/z$ 932.4509$^{2+}$ represents the peptide $^{451}$GEPG*PTGIQGP*PGPAGEEGK$^{470}$ with two oxidized proline. As shown in Figure 2D, the $^{18}O$ labeling resulted in the disappearance of this peak and the appearance of a new peak at $m/z$ 934.4547$^{2+}$. Again, the mass shift of 4.0076 Da was well matched to the theoretical shift of 4.0085 Da for $^{18}O$ labeling. Similarly, $^{18}O$ labeling for porcine samples is given in Figure 3. The peaks with $m/z$ 590.8316$^{2+}$ and 925.4421$^{2+}$ found in the $^{16}O$ labeling porcine gelatin sample represent the peptides $^{1068}$TGQPGAVGPAGIR$^{1080}$ and $^{451}$GEPG*PTGVQGP*P GPAGEEGK$^{470}$, respectively. The $^{18}O$ labeling shifted these two peptides to the expected $m/z$ of 592.8364$^{2+}$ and 927.4447$^{2+}$, with mass changes of 4.0096 and 4.0052 Da, respectively. The exact mass shift of 4 Da by $^{18}O$ labeling indicates that two $^{18}O$ atoms have been incorporated into these peptides. Table 3 lists 10 characteristic peptides for both bovine and porcine gelatin samples. All of these peptides reached their optimal $^{18}O$ labeling as indicated by complete $^{16}O$ to $^{18}O$ exchange (disappearance of $^{16}O$ in concert with the appearance of $^{18}O$ peptide).

It should be noted, however, because the labeling reagent ($H_2{}^{18}O$) is not 100% pure, there will be a small fraction of $^{16}O$ incorporated into one or two C-terminal carboxyl groups of the $^{18}O$-labeling peptides.[24] In this work, the purity of $H_2{}^{18}O$ was 97%, resulting in the peaks with one $^{16}O$ atom being detected with very low intensities in the $^{18}O$-labeled peptides (Figures 2 and 3). In addition, the $^{18}O$ back-exchange can readily happen and affect the accuracy of this quantitative method. In this work, TCEP reduction followed by cysteine alkylation was performed to disrupt the three-dimensional structure of trypsin and thus minimize the $^{18}O$ back-exchange.[43] As shown in Figures 2 and 3, the minimal $^{16}O$ incorporation indicated the samples were well labeled by $H_2{}^{18}O$.

To ensure the 4 Da shifted peptides resulted from the $^{18}O$ labeling, we further verified these peptides by tandem mass spectrometry. Figure 4 shows the MS/MS spectra of the peptides carrying $^{18}O$ or $^{16}O$ labels from the digested bovine or porcine gelatin. The accurate mass of the peptide as well as the complete sequencing by HCD with consecutive y ions (y1−y11,

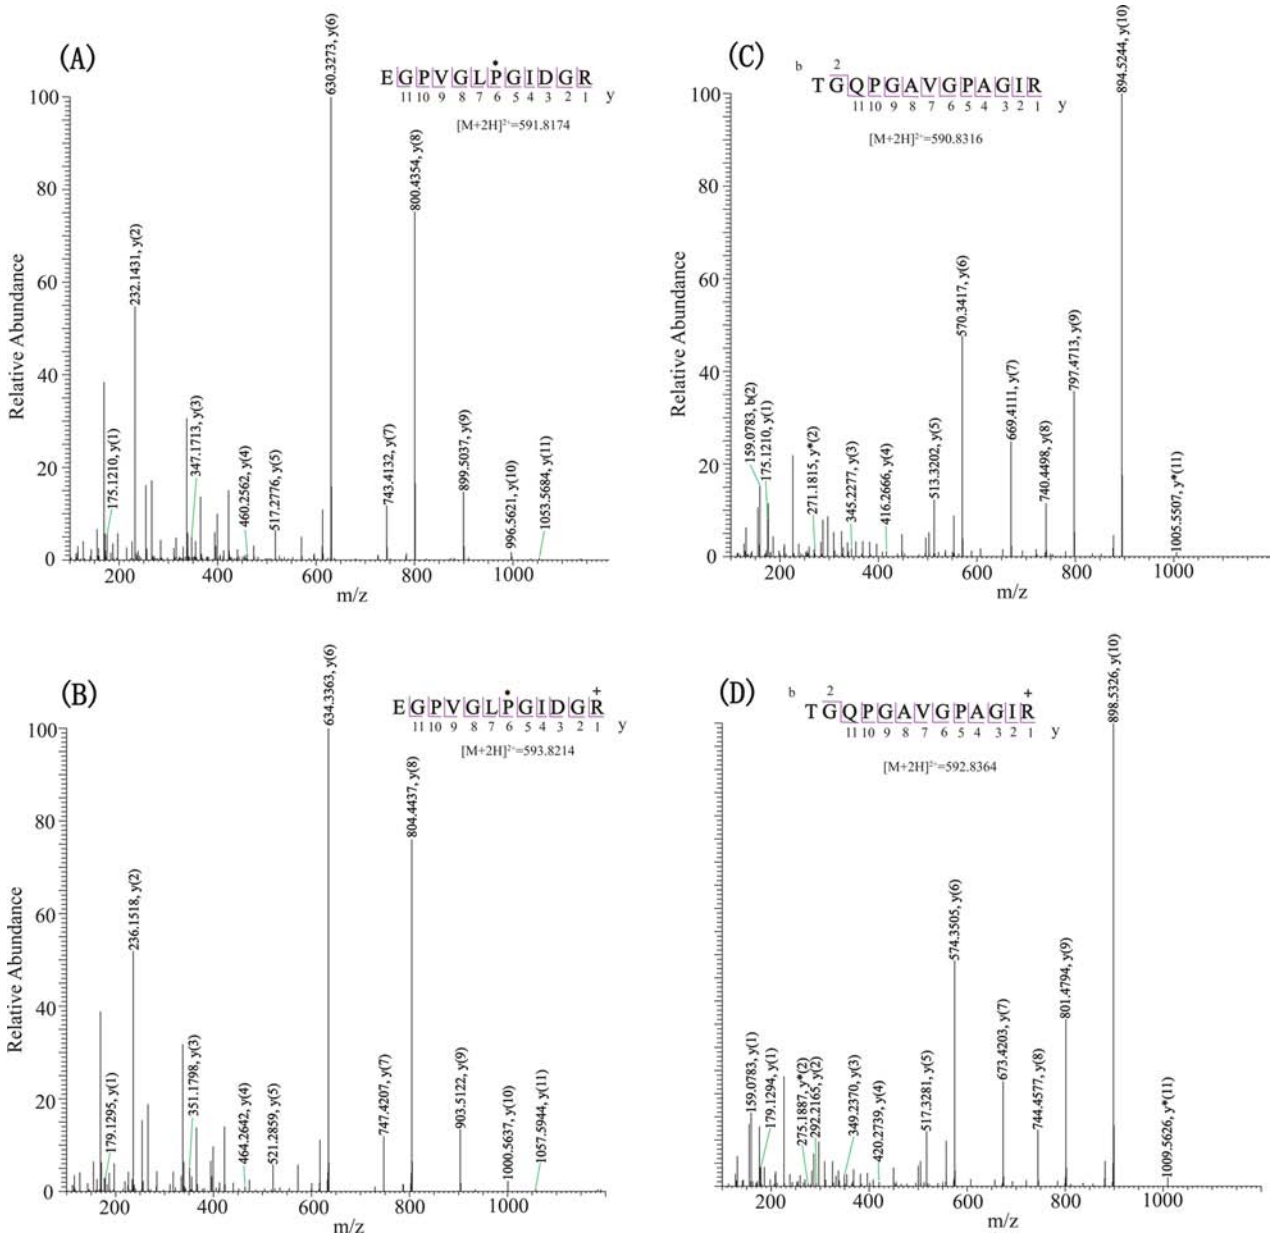

**Figure 4.** Sequence identification and localization of $^{18}O$ labeling by comparing MS/MS spectra of marker peptides labeled by $^{16}O$ and $^{18}O$: (A) peptide from bovine gelatin with $^{16}O$ labeling at $m/z$ 591.8174$^{2+}$; (B) peptide from bovine gelatin with $^{18}O$ labeling at $m/z$ 593.8214$^{2+}$; (C) peptide from porcine gelatin with $^{16}O$ labeling at $m/z$ 590.8316$^{2+}$; (D) peptide from porcine gelatin with $^{18}O$ labeling at $m/z$ 592.8364$^{2+}$. The sequence of each peptide is shown on top of the peptide. The $^{18}O$-labeled arginine is marked by the plus sign. The identified hydroxylated prolines are marked by the asterisk. The b and y ions are indicated by the numbers and lines.

unambiguously confirmed the sequence of the peptide and proline oxidation at positive of 471 ($^{465}$EGPVGL*PGIDGR$^{476}$). The mass of the $^{18}O$-labeled peptide at $m/z$ 593.8214$^{2+}$ matched well with that of the Pro oxidation and $^{18}O$ labeling (1185.6127). Two $^{18}O$ atoms were confirmed to attach to the terminal residue, Arg476, as suggested by the 4 Da mass increase of y1 ions. This is further confirmed by all y ions exhibiting a mass increase of 4 Da. The mass spectrometric results determined that the sequence was $^{465}$EGPVGL*PGIDG$^{+}$R$^{476}$ ($^{18}O$ labeling is indicated by the plus sign) from the $\alpha_2$ chain of the bovine gelatin. Similarly, accurate mass and tandem mass spectrometry of the peak with $m/z$ 590.8316$^{2+}$ determined the sequence of this peptide was $^{1068}$TGQPGAVGPAGIR$^{1080}$ in the $\alpha_2$ chain of the porcine gelatin, without any modification. After $^{18}O$ labeling, the peak moved to $m/z$ 592.8364$^{2+}$ with a mass increase of 4 Da, and this mass increase was found to be in the C-terminal amino acid residue of Arg1080.

Isotopic peaks annotated A, A+2, and A+4 are typically used in $^{18}O/^{16}O$ quantification.[41] A is the monoisotopic peak, representing the light sample. The A+2 peak is a composite of signals arising from (1) single $^{18}O$ labeled sample and (2) the third peak of the naturally occurring isotopes (e.g., $^{13}C$, $^{34}S$) of the light sample. The A+4 peak is also a composite containing three variables: (1) double $^{18}O$ labeled sample, (2) the third peak of the naturally occurring isotopes of the single $^{18}O$ labeled sample, and (3) the fifth peak of the naturally occurring isotopes of the light sample. Because of these three variables in A+4 peak, eq 1 is necessary to eliminate the interference from these isotopic

[a]The marker peptides and their sequence numbers, based on the sequence alignment results, were obtained from Zhang et al. *P indicates the hydroxylated proline. The modification site, $m/z$ value, and match condition are only shown in the detected unique peptides in this work. [b]$m/z$ within the same row as "—" denotes the theoretical monoisotopic peak in charge state of 2+ without any modification. [c]—, theoretical unique peptides that were not detected in this work.

contributions. Theoretically, peptides being doubly, triply, or quadruply charged can all be used for the quantitative purpose. However, because triply and quadruply charged ions are usually longer peptides, the isotopic interference from light sample via its naturally occurring A+4 isotopic peak will be much higher than that of shorter peptides that are doubly charged. For example, for the peptide $^{1068}$TGQPGAVGPAGIR$^{1080}$ with $m/z$ 590.8316$^{2+}$, the contribution from the light sample via its naturally occurring A+4 isotopic peak is only 1.12%, whereas it is drastically increased to 19.31% for the longer peptide $^{544}$GEQG*PAGPPGFQGLPG*PAGTAGEVGK*PGER$^{573}$ with $m/z$ 940.8010$^{3+}$. Therefore, to minimize this effect, we chose doubly charged shorter peptides for the following quantitative analysis.

The sequence homologies for $\alpha_1$ and $\alpha_2$ chains from bovine and porcine gelatins were 95.9 and 95.3%, respectively. A little less than 5% of the sequence divergence between two types of gelatin can generate many characteristic tryptic peptides.[16] Tables 1 and 2 list the theoretical characteristic peptides for bovine and porcine gelatins. In this work, with the combined digestion by Lys-C and trypsin and high-performance liquid

[a]The marker peptides and their sequence numbers based on the sequence alignment results were obtained from Zhang et al. *P and *K indicate the hydroxylated proline and lysine, respectively. The modification site, $m/z$ value and match condition were only shown in the detected unique peptides in this work. [b]The $m/z$ within the same row as "—" denotes the theoretical monoisotopic peak in charge state of 2+ without any modification. [c]—, theoretical unique peptides that were not detected in this work.

chromatography-LTQ/Orbitrap high-resolution mass spectrometry, the sequence coverages for $\alpha_1$ and $\alpha_2$ chains from bovine gelatin were 62 and 70%, respectively. The sequence coverages for $\alpha_1$ and $\alpha_2$ chains from porcine gelatin were 64 and 73%, respectively. In total, we detected 18 distinctive peptides from bovine gelatin (591.8174$^{2+}$, 596.8522$^{2+}$, 634.3497$^{2+}$, 714.3776$^{2+}$, 722.3748$^{2+}$, 746.8590$^{2+}$, 780.9210$^{2+}$, 790.8971$^{2+}$, 816.9313$^{2+}$, 824.9285$^{2+}$, 923.4631$^{2+}$, 932.4509$^{2+}$, 1068.0354$^{2+}$, 1076.0321$^{2+}$, 1077.0491$^{2+}$, 1085.0461$^{2+}$, 1093.0436$^{2+}$, and 1131.0834$^{2+}$) and 18 peptides from the porcine gelatin (590.8316$^{2+}$, 629.3225$^{2+}$, 739.8483$^{2+}$, 775.8895$^{2+}$, 824.4170$^{2+}$, 925.4421$^{2+}$, 929.4823$^{2+}$, 1014.5465$^{2+}$, 1061.0131$^{2+}$, 1078.0370$^{2+}$, 1083.0407$^{2+}$, 1103.0501$^{2+}$, 1183.0894$^{2+}$, 1200.6263$^{2+}$, 1234.1156$^{2+}$, 1283.1388$^{2+}$, 1308.6522$^{2+}$, and 1410.6967$^{2+}$), respectively. As shown in Tables 1 and 2, all detected peaks of the characteristic peptides from bovine and porcine gelatins matched well with the theoretical values below 15 ppm. Moreover, the $^{18}$O labeling forms of all above unique peptides were also positively confirmed with less than 15 ppm using accurate mass and tandem mass spectrometry. From the above unique peaks, we selected the 10 strongest peaks for further quantification of the bovine or porcine gelatin. The corresponding sequences of the 10 peptides are shown in Table 3.

**$^{18}$O/$^{16}$O Ratio Determination.** To validate the $^{18}$O labeling method for quantification of gelatins, we prepared gelatin digests with four different mixing ratios of $^{18}$O and $^{16}$O, those being 20:1,

[a] *P indicates the hydroxylated proline.

dx.doi.org/10.1021/jf503876a | J. Agric. Food Chem. 2014, 62, 11840−11853

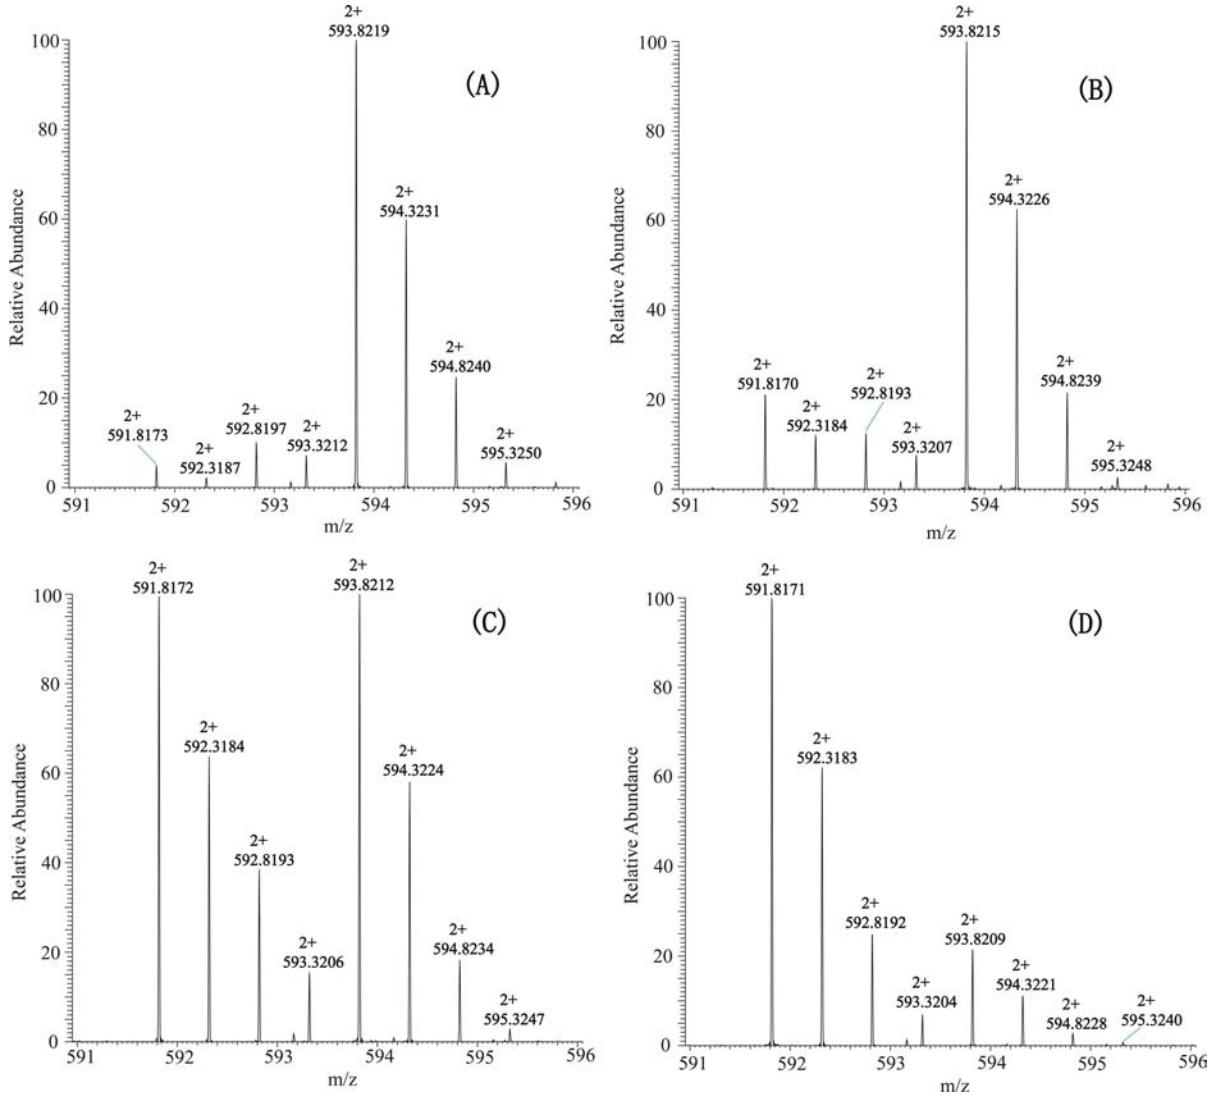

**Figure 5.** Mass spectra of the peptide $^{465}$EGPVGL*PGIDGR$^{476}$ from bovine gelatin with various $^{18}O/^{16}O$ mixing ratios: (A) 20:1; (B) 5:1; (C) 1:1; (D) 1:5.

5:1, 1:1, and 1:5, respectively. The deviation of the measured values from the mixing values for the characteristic peaks will allow us to evaluate the accuracy of this method. For each type of gelatin, 10 characteristic peptides with strongest signal were used for quantification by averaging the measured $^{18}O/^{16}O$ ratios. For example, Figure 5 shows the mass spectra at various mixing ratios of the $^{16}O$ labeling peptide at $m/z$ 591.8174$^{2+}$ and corresponding $^{18}O$-labeled peptide at $m/z$ 593.8219$^{2+}$ from bovine gelatin sample. The S/N ratios of these two peaks were high, and the $^{18}O/^{16}O$ ratios of these two peaks were visually very close to the mixing ratios. Similarly, for the porcine gelatin sample as shown in Figure 6, the mass spectra of the peptide with $m/z$ 590.8316$^{2+}$ exhibited relative intensities very close to their mixing ratios.

Table 3 lists the sequences and mixing ratios of 10 characteristic peptides from bovine and porcine gelatins, respectively. The samples with mixing $^{18}O/^{16}O$ ratios of 20:1, 5:1, 1:1, and 1:5 from the bovine gelatin were measured to be 20.41 ± 0.84, 4.93 ± 0.07, 1.00 ± 0.02, and 0.19 ± 0.02, respectively. For porcine gelatin, the ratios of the peptides for $^{18}O/^{16}O$ mixing ratio at 20:1, 5:1, 1:1, and 1:5 were measured to be 20.59 ± 0.56, 4.97 ± 0.11, 0.99 ± 0.04, and 0.20 ± 0.02, respectively. The experimental values were very close to the mixing value with small standard deviation, suggesting this mass spectrometry-based method is very accurate.

**Specificity of the Quantitative Method.** $^{16}O$- and $^{18}O$-labeled peaks for all characteristic peptides from bovine and porcine gelatins were unambiguously identified by accurate mass and tandem mass spectrometry. As demonstrated in Figures 5 and 6, all characteristic peptides showed the coelution of the $^{16}O$- and $^{18}O$-labeled forms. The retention time for each unique peptide in the chromatography remained consistent in the samples with various mixing ratios of $^{18}O$ to $^{16}O$ (data not shown). Moreover, 10 characteristic peptides for each type of gelatin all showed easily recognizable peaks without strong impurity peak interference in the mass spectra. The $^{16}O$- and $^{18}O$-labeled peaks could be clearly distinguished in LTQ/Orbitrap high-resolution mass spectrometry. All of these indicate that the specificity of this method for gelatin quantification is excellent.

**Sensitivity of the Quantitative Method.** In this work, a HPLC equipped with a microcolumn was used for the separation of the digested mixture of gelatin. When 3 μg/mL digested gelatin mixture was loaded, the signal-to-noise level for all characteristic peptides of bovine or porcine gelatin was much

dx.doi.org/10.1021/jf503876a | J. Agric. Food Chem. 2014, 62, 11840−11853

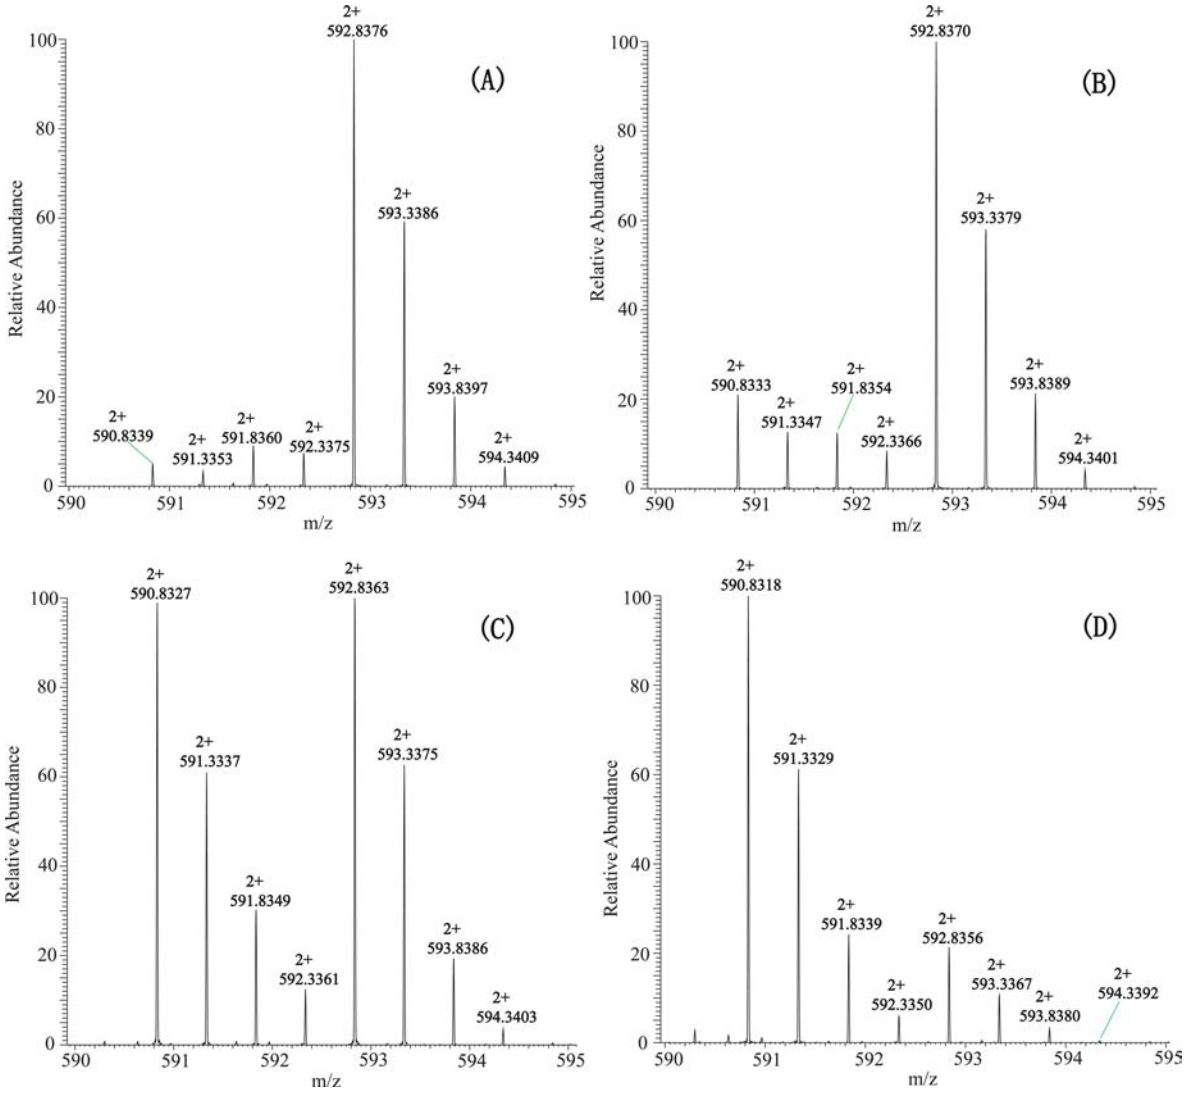

**Figure 6.** Mass spectra of the peptide $^{1068}$TGQPGAVGPAGIR$^{1080}$ from porcine gelatin with various $^{18}O/^{16}O$ mixing ratios: (A) 20:1; (B) 5:1; (C) 1:1; (D) 1:5.

larger than 10, providing a reliable identification and quantification for $^{16}O$- and $^{18}O$-labeled peptides. In a separate experiment, we were able to detect the characteristic peptides of bovine gelatin at a concentration of 0.11 $\mu$g/mL when a UPLC equipped with a nanocolumn (the nanoACQUITY UPLC system) was utilized (Supporting Information Supplemental Figure 1).

**Dynamic Range of the Quantitative Method.** To access the dynamic range of relative quantification, we plotted the $^{18}O/^{16}O$ ratios of peak height ($y$) against the concentration ratios of all 10 peptides. For example, Figure 7A shows two of the plots represented by bovine peptide $^{592}$GP*PGESGAAGPTG-PIGSR$^{609}$ with $m/z$ 790.8971$^{2+}$ and porcine peptide $^{451}$GEPG*PTGVQGP*PGPAGEEGK$^{470}$ with $m/z$ 925.4421$^{2+}$, respectively. Both peptides exhibited a linear response in relative $^{18}O/^{16}O$ concentration ratios from 0.2 to 20 with correlation coefficients ($R^2$) of 0.9995 and 0.9993, respectively. To evaluate the overall dynamic range for the gelatin quantification, $^{18}O/^{16}O$ ratios of all 10 peptides were averaged and plotted against concentration ratios of these peptides (Figure 7B). The results indicated the quantification method by $^{18}O$ labeling and high-resolution mass spectrometry had the excellent linear relationship in relative $^{18}O/^{16}O$ concentration ratios from 0.2 to 20 with $R^2$ of 0.9997 and 0.9995 for bovine gelatin and porcine gelatin, respectively. The dynamic range of relative quantification based on $^{18}O/^{16}O$ labeling can be defined as the ranges of $^{18}O/^{16}O$ concentration ratios that show linear response on isotopic peak area/height ratios.[45] Fenselau and Yao[46] summarized previous work on the quantification method by $^{18}O$ labeling and mass spectrometry and concluded that the dynamic range was limited to about 1:20, which is consistent with our results. It should be noted that the typical quantification method by $^{18}O$ labeling and mass spectrometry employs direct comparison of the peak area or height of the $^{18}O$-labeled and unlabeled peptide pair. A recent quantification method developed by Kim et al.[45] suggests that selected reaction monitoring (SRM) could potentially improve the dynamic range of this type of quantification method.

**Reproducibility of the Quantitative Method.** The reproducibility of the method was evaluated by analyzing the relative standard deviation (RSD) from triplicate. As shown in Table 4, the peptides with $m/z$ values of 790.8971$^{2+}$ and 925.4421$^{2+}$ were used to represent the characteristic peaks from the bovine and porcine gelatins, respectively. The average values of three replicates were very close to the real mixing $^{18}O/^{16}O$

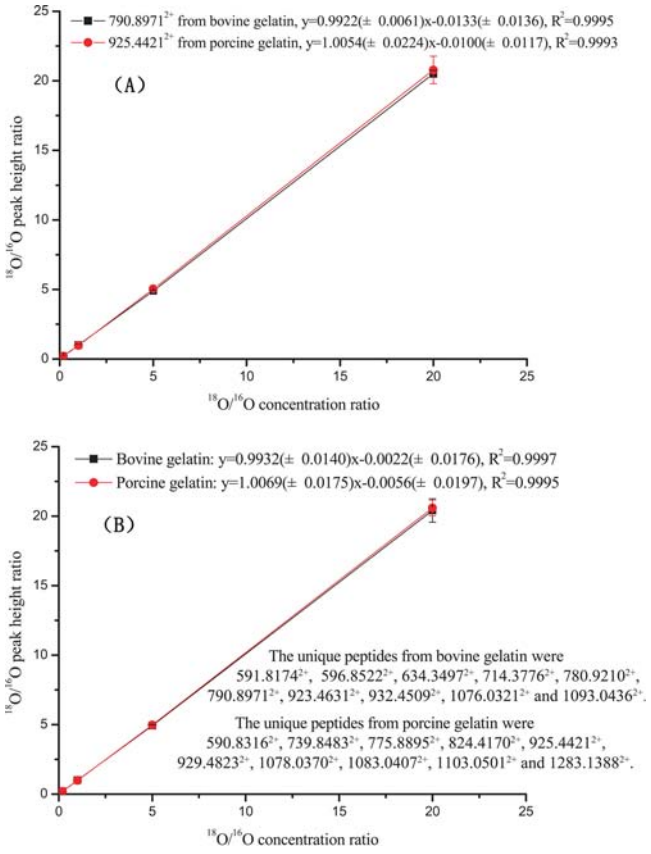

**Figure 7.** Calibration curves of bovine and porcine gelatins: (A) calibration curves of the peptides with $m/z$ 790.8971$^{2+}$ ($^{592}$GP*PGESGAAGPTGPIGSR$^{609}$) and 925.4421$^{2+}$ ($^{451}$GEPG*PTGVQGP*PGPAGEEGK$^{470}$) from bovine and porcine gelatins, respectively; (B) calibration curves by averaging 10 characteristic peptides from bovine and porcine gelatins, respectively.

ratios of 20:1, 5:1, 1:1, and 1:5. All RSD values of below 7.11% were obtained for the peptides from both bovine and porcine gelatins, indicating excellent reproducibility of the gelatin quantification method by $^{18}$O labeling and high-resolution mass spectrometry. The reproducibility is visualized in Supplemental Figure 2, represented by the mass spectra of the peptide 925.4421$^{2+}$ from porcine gelatin at the mixing ratios of 20:1, 5;1, 1:1, and 1:5. At all $^{18}O/^{16}O$ ratios, the mass spectra from three replicates showed peak height ratios close to their mixing ratios.

Gelatin quantification by oxygen-18 labeling utilizes isotopically labeled peptides as internal standards. The $^{18}O/^{16}O$ peptide pairs share the same elution time and ionization efficiency. The interference of the matrix, if there is any, will be equally executed on both $^{18}$O and $^{16}$O peptides. Therefore, the reproducibility of the quantification results should be minimally affected by matrix for the real gelatin sample. To evaluate the reproducibility of this quantification method for the real sample, we performed wide selected ion monitoring (SIM) experiments on gelatin films prepared by mixing bovine and porcine gelatins with glycerol and sorbitol. Five SIM scans with a wide mass window of 200 Da covering the mass range from 500 to 1500 Da were acquired with high resolution and mass accuracy by LTQ-Orbitrap. This method allows us to perform protein/peptide quantification and evaluate whether there are any changes when matrix is present. As shown in Supplemental Figure 3, the extracted ion peak area for the bovine peptide $^{592}$GP*PGESGAAGPTGPIGSR$^{609}$ with $m/z$ 790.8971$^{2+}$ was consistent for three replicates with an RSD value of 7.94%, indicating excellent reproducibility for the samples in the matrix. Similarly, the extracted ion peak area for the peptide from porcine gelatin with $m/z$ 925.4421$^{2+}$ showed excellent reproducibility with an RSD value of 3.81%.

Our results proved that the trypsin-catalyzed $^{18}$O labeling can serve as an excellent internal standard. When combined with high-resolution mass spectrometry, it can be a highly accurate and sensitive method for quantification of the bovine or porcine gelatin. It is important to note that high-resolution mass spectrometry is crucial for this type of analysis. After $^{18}$O labeling, the peptide pair labeled by $^{18}$O and $^{16}$O differ only by 4 Da (4.0085 Da for high resolution) in mass. Under electrospray ionization (ESI), peptides are typically detected as multiple charged ions including doubly, triply, or quadruply charged ions. The differences between the peptide pair are thus only 2, 1.33, and 1 Da in $m/z$, respectively, for these charges. Use of high-resolution mass spectrometers is always considered to be necessary for such close mass difference as it can be difficult with low-resolution mass spectrometers such as ion traps to differentiate the peak pair. An LTQ Orbitrap Velos mass spectrometer can routinely provide mass resolution of 100,000, which can sufficiently separate the peptide pair even at higher charge state. In addition, because proline hydroxylation commonly occurs on bovine or porcine collagen, it is always suggested to use a high-resolution mass spectrometer, which can offer a much easier determination of the sequence modified by hydroxylation.[47] For example, a pair of marker peptides from bovine and porcine gelatins contains very similar sequences of $^{520}$GAGPDGNNGAQGPPGLQGVQGGK$^{542}$ and $^{520}$GAGPDGNNGAQGPPGPQG VQGGK$^{542}$, respectively. If Pro$^{535}$ is hydroxylated, the two sequences will be essentially the same for low-resolution mass spectrometers as the mass difference between Leu and Hyp (0.036 Da) is too small to be differentiated. However, this mass difference can be accurately distinguished when high resolution is applied. In this case, a resolution of 56000 or a mass accuracy of 17 ppm will be able to make a distinction between these two peptides. The LTQ Orbitrap mass spectrometer used in this work constantly provides resolution and mass accuracy better than 60000 and 15 ppm, respectively, and therefore is suitable for this type of analysis.

**Table 4. Reproducibility of the Method**

| | | | average ratio of $^{18}$O to $^{16}$O | | | | | | | |
|---|---|---|---|---|---|---|---|---|---|---|
| gelatin source | selected characteristic sequence[a] | $m/z$ | 20:1 | RSD[b] (%) | 5:1 | RSD (%) | 1:1 | RSD (%) | 1:5 | RSD (%) |
| bovine skin | $^{592}$GP*PGESGAAGPTGPIGSR$^{609}$ | 790.8971$^{2+}$ | 20.50 | 1.20 | 4.91 | 0.62 | 1.00 | 5.40 | 0.19 | 7.11 |
| porcine skin | $^{451}$GEPG*PTGVQGP*PGPAGEEGK$^{470}$ | 925.4421$^{2+}$ | 20.78 | 4.76 | 5.03 | 3.03 | 0.97 | 3.08 | 0.19 | 5.25 |

[a]*P indicates the hydroxylated proline. [b]RSD (%) represents relative standard deviation. The RSD value was obtained by data analysis from three replicates.

Using trypsin-catalyzed $^{18}O$ labeling coupled with high-resolution mass spectrometry, we are able to accurately determine the ratios of the marker peptides ranging from 20:1 to 1:5 ($^{18}O$ vs $^{16}O$). The peptide pair with an $^{18}O/^{16}O$ mixing ratio of 1:20 was also tested; the computed ratio of $^{18}O/^{16}O$ mixture from eq 1 deviated a lot from the mixing ratio. As the contribution of the naturally occurring A+4 isotopic peak from $^{16}O$-labeled peptide and naturally occurring A+2 from single-$^{18}O$-labeled peptide are required to be taken out, any variation of the signal will deposit error in the computation. At an $^{18}O/^{16}O$ mixing ratio of 1:20, $^{18}O$-labeled peptide is only 5%, which is similar or even smaller than the naturally occurring A+4 isotopic peak from $^{16}O$-labeled peptide. When subjected to calculation by eq 1, the resulting error will be intolerant to the signal variation. In contrast, when the mixing ratio is higher than 1:5, the results are mostly accepted because at 20% relative intensity, the signal variation is more forgivable. Among all of the results of various ratios for $^{18}O/^{16}O$ mixtures, the 1:1 mixing ratio showed the most veracity with $1.00 \pm 0.02$ and $0.99 \pm 0.04$ for the bovine and porcine gelatin quantification, respectively. Therefore, the most accurate measurement can be obtained by mixing the equivalent of $^{18}O$- and $^{16}O$-labeled samples.

It is anticipated that this quantification method can be applied to any other type of gelatin under the conditions that the gelatin can be purified and measured accurately so $^{18}O$-labeled internal standard can be prepared. Because this method compares the relative intensities of the marker peptides, matrix effects should not be a problem as long as these marker peptides can be detected by mass spectrometry. The divergent sequence can generate unique marker peptides for each type of gelatin, and this quantification can be extended to mixtures of gelatins. Under this circumstance, an $^{18}O$-labeled internal standard for each gelatin is required. As a simple and accurate way, trypsin-catalyzed $^{18}O$ labeling is also a promising method to quantify other proteins in the food industry.

conducted using high-performance liquid chromatography (HPLC), carried out with a Sunniest-C18 column (150 × 4.6 mm, 5 μm; ChromaNik, Osaka, Japan). Analytes were dissolved in a methanol ($CH_3OH$) gradient solvent system (5 min hold at 15%, 5−50 min, linear gradient of 15−40%, and 50−160 min, linear gradient of 40−80%) in 0.1% trifluoroacetic acid in water. The flow rate was 1.0 mL/min, and analytes were detected at 275 nm. All analyses by HPLC were carried out at the Institute for Bee Products & Health Science, Yamada Bee Company, Inc.

**Shaving and Depilation of Mice.** Female C57BL/6N mice were purchased from Japan SLC (Shizuoka, Japan) and were maintained under conventional conditions at 22−25 °C. At 8 weeks of age, when the back skin was at the telogen stage, mice were anesthetized by intraperitoneal administration of sodium pentobarbital and were then shaved or depilated.

For the gentle anagen induction experiments, the back skin of mice ($n$ = 10), under anesthesia, was shaved with an electric shaver, and ethanol-extracted propolis, diluted 10-fold in 99.5% ethanol, was topically applied to the shaved skin at 100 μL/d for 3 weeks. Control mice ($n$ = 10) were similarly shaved, and 99.5% ethanol was used in place of diluted propolis. The treated skin regions of all 20 mice were excised and fixed in 4% formaldehyde in phosphate buffered saline (PBS).

For the forced anagen induction experiments, the back hair of anesthetized mice was shortened with an electric shaver, and then club hairs were removed from the back skin using depilatory wax. Eight days after depilation, 10% ethanol-extracted propolis was topically applied to the dorsal skin at 100 μL/d for 3 d ($n$ = 6). Control mice ($n$ = 5) were depilated and then treated with ethanol only. The treated skin regions were excised and fixed in 4% formaldehyde in PBS.

All experimental procedures in this study were approved by the Animal Resource Committee of Hokkaido University (approval number: #09-0125) and were conducted in accordance with Hokkaido University guidelines for the care and use of laboratory animals.

**Identification of Anagen Induction in Shaved Mice.** In shaved mice, the hair cycle progresses from the caudal end toward the cranial end of the back skin, and melanin granules are produced in the hair bulb during middle and late anagen.[16,27] Therefore, we visually identified middle anagen induction based on the degree of melanization of the caudal regions of the back skin in shaved mice.

**Antibodies.** The following antibodies were used as primary antibodies for immunofluorescence staining: mouse antibodies against pan-keratin (Sigma-Aldrich, St. Louis, MO, U.S.A.), cytokeratin 10 (CK10; Progen, Heidelberg, Germany), cytokeratin 14 (CK14; Sigma-Aldrich), cytokeratin 15 (CK15; Thermo Scientific, Fremont, CA, U.S.A.), and 5-bromo-2′-deoxyuridine (BrdU; BioLegend, San Diego, CA, U.S.A.). Similarly, rabbit antibodies against perilipin (Cell Signaling Technology, Danvers, MA, U.S.A.), laminin (LSL, Tokyo, Japan), and zonula occludens-1 (ZO-1; Life Technologies, Gaithersburg, MD, U.S.A.), a rat antibody against Ki-67 (DakoCytomation, Glostrup, Denmark), and a goat antibody against versican (R&D Systems, Minneapolis, MN, U.S.A.) were also used as primary antibodies.

The following antibodies were purchased from Cell Signaling Technology and were used as secondary antibodies: Alexa Fluor 488-conjugated goat anti-rabbit, Alexa Fluor 488-conjugated and Alexa Fluor 546-conjugated goat anti-mouse, Alexa Fluor 488-conjugated donkey anti-mouse, Alexa Fluor 546-conjugated donkey anti-goat, and Alexa Fluor 488-conjugated and Alexa Fluor 546-conjugated goat anti-rat antibodies.

**Immunofluorescence Staining.** After fixation (as described above), surgically excised regions of skin were embedded in paraffin and sliced into 5 μm sections. The sections were deparaffinized and rehydrated. After they were heated in a microwave oven in antigen retrieval buffer consisting of 10 mM Tris-HCl (pH 9.0) and 0.5 mM ethylene glycol tetraacetic acid (Sigma-Aldrich), the sections were incubated in blocking solution (5% bovine serum albumin in PBS) to preclude nonspecific interactions. The sections were then incubated overnight at 4 °C in various primary antibodies diluted in blocking solution. After the sections were washed with PBS containing 0.05% Tween 20, they were exposed to secondary antibodies diluted in blocking solution for 1 h at room temperature. Controls for autofluorescence and the unspecific binding of the secondary antibody were treated in the same manner, but without primary antibodies. Images of the stained sections were obtained using a confocal laser-scanning microscope (TCS SP5; Leica, Mannheim, Germany).

**Measurement of Matrix Cell Migration Distance.** In middle and late anagen, hair matrix keratinocytes actively proliferate and then migrate toward the upper part of the HFs, leading to hair shaft elongation.[19] Therefore, to evaluate hair growth activity, proliferating matrix keratinocytes were labeled by intraperitoneal injection of BrdU into mice (1 mg/mouse in 100 μL of PBS, Sigma-Aldrich). Mice were sacrificed 24 h after injection, and skin samples were excised and fixed (as described above). The migration distance between the bottom of the hair bulb and the furthermost BrdU-positive cells in the hair shaft was measured in 19 sagittally sectioned HFs from 6 propolis-treated and 5 vehicle-treated (control) mice.

**Skin Organ Culture.** Organ culture was performed using depilated, middle anagen stage back skin to investigate the influence of propolis on the proliferation of hair matrix keratinocytes. The back skin was harvested from mice 5 d after depilation and washed with RPMI-1640 medium containing penicillin and streptomycin. Each skin sample was placed on a cell culture insert with a pore size of 0.2 μm and was then cultured for 3 d in RPMI-1640 containing 10 μg/mL insulin, 10 ng/mL hydrocortisone, and either a low concentration (0.005%) of propolis ($n$ = 6), a high concentration (0.05%) of propolis ($n$ = 6), or ethanol as vehicle ($n$ = 6). After 3 d in culture, skin samples were fixed in 4% formaldehyde in PBS, and paraffin sections were prepared.

To measure the proliferation rate of hair matrix keratinocytes, paraffin sections were assayed by immunofluorescence with anti-Ki-67 antibodies and stained with 4′,6-diamidino-2-phenylindole (DAPI). The Ki-67-positive cells were counted, and the percentages of proliferating cells were calculated by dividing this count by the total number of DAPI-stained matrix cells.

**Keratinocyte Isolation and Culture.** Keratinocytes were isolated from the back skin of neonatal C57BL/6N mice 1 d after birth, as follows. Excised regions of back skin were immersed in 0.1% collagenase type III (Worthington Biochemical, Freehold, NJ, U.S.A.), and the epidermis and dermis were separated with fine forceps. Keratinocytes in the separated epidermis were collected by washing with keratinocyte growth medium (CELLnTEC Advanced Cell Systems, Bern, Switzerland), and the cell suspension was passed through a 40 μm cell strainer (BD Biosciences, San Jose, CA, U.S.A.). The cell suspension was then centrifuged at 500$g$ for 5 min, and the epidermal keratinocytes obtained were seeded in 96-well plates at $1 \times 10^3$ cells/well and cultured for 1 d. The medium was then replaced with new medium that lacked growth factors but contained either propolis or vehicle (ethanol). After 2 d of culture, the proliferation activity of these keratinocytes was evaluated using a WST-8 Cell Counting Kit (Dojindo, Osaka, Japan).

**Statistical Analysis.** Statistical analysis was performed using the Analyze-It add-in (Analyze-it Software, Ltd., Leeds, United Kingdom) for Microsoft Excel (Microsoft Corporation, Redmond, WA, U.S.A.). In the case of in vitro experiments, differences between propolis and vehicle groups were analyzed using the unpaired Student's $t$-test. Differences were considered significant at a $p$-value of <0.05 and very significant at a $p$-value of <0.005. These $p$-values are indicated herein by * and **, respectively.

## RESULTS

To confirm the concentrations of specific propolis components, the propolis ethanol extract was analyzed by HPLC (Table 1). The propolis extract contained physiologically active substances responsible for keratinocyte differentiation and reepithelialization, such as caffeic acid and chlorogenic acid.[12,15] Likewise, artepillin C, baccharin, $p$-coumaric acid, drupanin, and kaempferide, which suppress tumor cell growth,[28−30] were abundant in the propolis extract. Propolis also contained a small

**Table 1. Concentrations of Specific Components of Ethanol-Extracted Propolis**

| compd | concn (% w/v) |
|---|---|
| artepillin C | 8.1 ± 0.110 |
| baccharin | 1.5 ± 0.026 |
| caffeic acid | 0.13 ± 0.001 |
| chlorogenic acid | 0.074 ± 0.001 |
| *p*-coumaric acid | 1.2 ± 0.019 |
| drupanin | 1.7 ± 0.027 |
| kaempferide | 1.4 ± 0.024 |
| kaempferol | 0.13 ± 0.001 |

quantity of kaempferol, which promotes apoptosis in human bladder and ovarian cancer cells.[9,10]

**Propolis Facilitates Normal Hair Growth in the Shaved-Mouse Model.** The influence of the propolis extract on hair growth was investigated using two types of in vivo mouse models. In the shaved-mouse model (also known as the gentle anagen induction model), the middle anagen stage was identified by the degree of melanization of the caudal back skin. In those mice that were treated with topical application of propolis, it was induced around 10 d after the mice were shaved, versus around 18 d after shaving in the mice that were treated with topical application of ethanol (vehicle) (Figure 1A). There was a significant difference in the timing of induction of middle anagen between propolis-treated and vehicle-treated mice (Figure 1B). Additionally, 21 d after treatment, 33.3% (5 out of 15) of the propolis-treated mice, compared with only 14.3% (2 out of 14) of the vehicle-treated mice, had hair covering over half of the back skin area.

The histology of the HFs induced into late anagen by propolis treatment was compared with that of the late-anagen HFs in vehicle-treated skin. Hematoxylin and eosin (H&E) staining did not reveal any detectable morphological differences between HFs in propolis-treated and vehicle-treated mice (Figure 2A). The pan-keratin-positive ORS structures were invaginated normally into the perilipin-positive subcutaneous fat layer in both propolis-treated and vehicle-treated skin (Figure 2B). Likewise, in both propolis-treated and vehicle-treated HFs, most of the hair matrix keratinocytes in the hair bulb were Ki-67 positive (Figure 2C). Versican, a dermal papilla-specific proteoglycan,[31] was observed by immunofluorescence in both propolis-treated and vehicle-treated skin, and no obvious differences in versican expression were noted between the two (Figure 2D). CK15 is an intermediate filament protein that is expressed in stem cells in the bulge region and in precursor cells in the ORS and in the epidermal basal layer.[32] In the propolis-treated skin, CK15-positive cells were distributed in the bulge and in the ORS, as well as in the basal layer in the epidermis, similarly to those in vehicle-treated skin (Figure 2E).

**Propolis Facilitates Hair Shaft Elongation in the Depilated-Mouse Model.** The effects of propolis on hair growth in the forced anagen induction model were investigated using depilated mice. Depilation synchronized the hair cycles, such that there were no temporal differences between individuals or spatial differences between caudal and cranial regions of the back skin, regardless of whether the mice were treated with propolis or with vehicle (Figure 3A). HFs were observed to be in late anagen in mice that were depilated and then, 8 d later, treated with either propolis or vehicle for 3 d. Most of the matrix keratinocytes in the hair bulb were Ki-67 positive, and there were no detectable differences between propolis-treated and vehicle-treated HFs (Figure 3B). In contrast, cells that had been labeled with BrdU in the hair matrix 24 h prior were found to have migrated more distally along the hair shaft in the propolis-treated HFs than in the vehicle-treated HFs (Figure 3B). Thus, the migration distance of BrdU-labeled cells significantly increased with propolis treatment (Figure 3C).

**Propolis Facilitates Keratinocyte Proliferation in Vivo and in Vitro.** The effects of propolis on the epidermis were also examined. H&E staining showed the stratified squamous structure of the epidermis in both propolis-treated and vehicle-treated skin, 3 d after initiation of treatment and 11 d after depilation (Figure 4A). Propolis-treated epidermis was somewhat thickened compared with vehicle-treated epidermis. Ki-67-positive cells were detected in the basal layer of the epidermis in both propolis-treated and vehicle-treated skin (Figure 4B); however, the ratio of Ki-67-positive cells to total

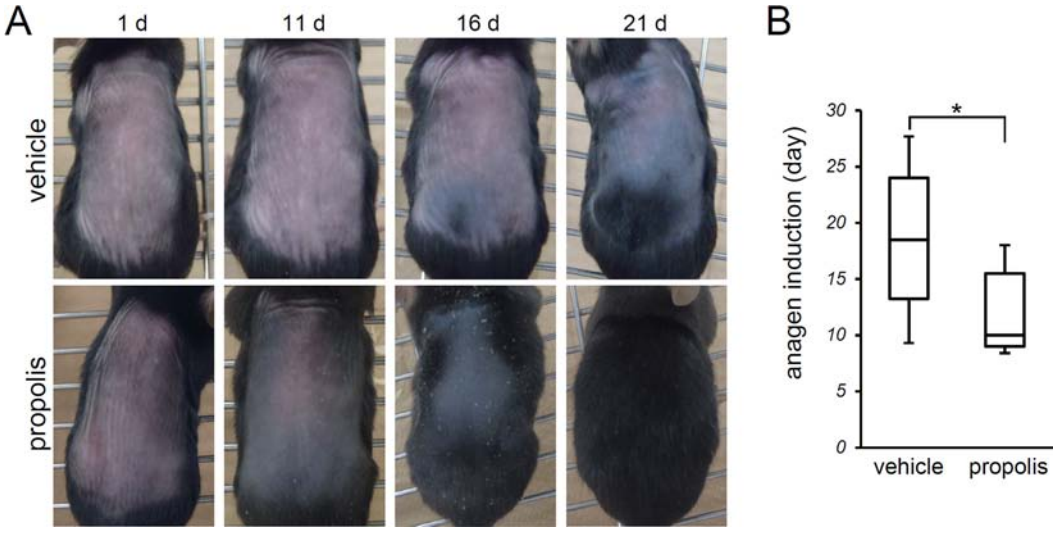

**Figure 1.** Stimulatory effect of propolis on anagen induction in the shaved-mouse model. (B) Box plots displaying the day of anagen induction, identified based on the degree of melanization of the caudal region of the back skin. *$p < 0.05$.

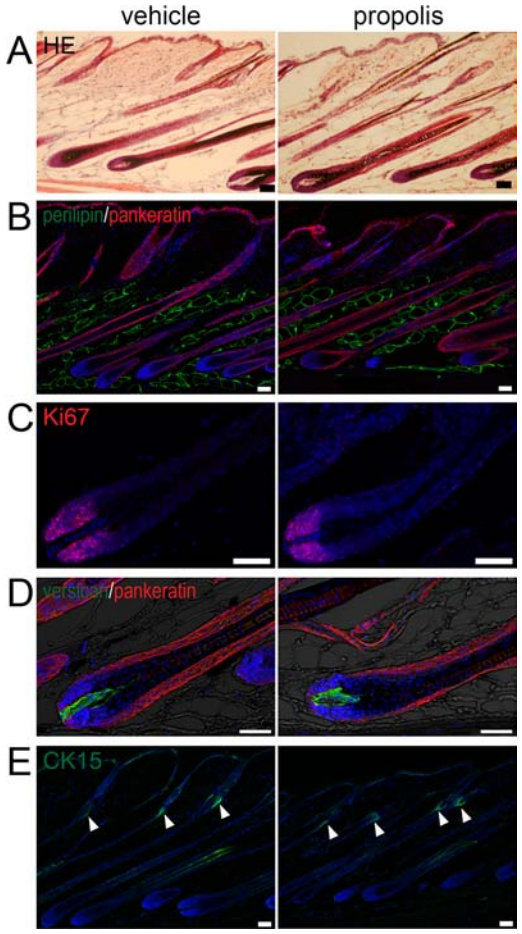

**Figure 2.** Histological assessment of hair follicles induced into anagen stage by propolis in the shaved-mouse model. Images show (A) hematoxylin and eosin (H&E) staining and (B–E) immunofluorescence detection of pan-keratin (red; B, D), perilipin (green; B), Ki-67 (red; C), versican (green; D), and CK15 (green; E) in mouse back skin treated with propolis (left) or vehicle (right) at late anagen stage. Arrowheads indicate the hair stem cells in the bulge region. Nuclei were stained with 4′,6-diamidino-2-phenylindole (DAPI; blue). Bars = 50 $\mu$m.

epidermal cells significantly increased in propolis-treated epidermis (Figure 4C). CK14 and CK10 are specific markers of undifferentiated keratinocytes in the basal layer and of differentiated keratinocytes in the suprabasal layer, respectively.[33] In propolis-treated skin, CK14-positive and CK10-positive keratinocytes lined the basal and suprabasal layers of the epidermis, respectively, similarly to those in vehicle-treated skin (Figure 4D). A continuous basal membrane was observed as a laminin-positive line beneath the basal layer in propolis-treated skin, similar to that observed in the vehicle-treated skin. ZO-1 is a membrane-associated component of both the tight junctions and adherens junctions found at sites of cell–cell contact.[34] In both propolis-treated and vehicle-treated skin, ZO-1 was localized between keratinocytes, except in the fully keratinized cornified layer, as expected in normal skin.

The influence of propolis on the proliferation of hair matrix keratinocytes was examined by organotypic culture of depilated back skin. Some of the matrix keratinocytes in the hair bulb were Ki-67 positive under both vehicle and propolis treatments (Figure 5A). Approximately 45%–48% of matrix keratinocytes were Ki-67 positive in vehicle-treated skin and in skin treated with 0.005% propolis (Figure 5B). However, after treatment with 0.05% propolis, the number of Ki-67-positive hair matrix keratinocytes significantly increased, compared with vehicle treatment.

The influence of propolis on the proliferation of epidermal keratinocytes was examined by culturing isolated epidermal keratinocytes. Isolated keratinocytes exhibited a cobblestone-like shape (Figure 6A), which is the typical shape of epidermal keratinocytes. The proliferation activity of these cells significantly increased when they were treated with 0.05% propolis, compared with vehicle treatment, although lower concentrations of propolis did not influence proliferation (Figure 6B).

## DISCUSSION

During anagen, the hair shaft is produced by active proliferation of hair matrix keratinocytes in the hair bulb. Active proliferation and differentiation of hair epithelial cells is also required to develop hair follicle structures during the telogen–anagen transition. In this study, propolis facilitated anagen induction and activated the proliferation of matrix keratinocytes and the growth of the hair shaft. Propolis is a traditional medicine used for accelerating skin regeneration in wounds, and its components have various stimulatory and regulatory roles in epithelial cell proliferation and differentiation.[14,21,22,35] In particular, chlorogenic acid and caffeic acid facilitate keratinocyte proliferation and differentiation, respectively.[12,15] The Brazilian propolis ethanol extract used in this study contained both chlorogenic acid (0.7 mg/mL) and caffeic acid (1.3 mg/mL). Therefore, it is possible that propolis stimulated hair growth in shaved and depilated mice via the effects of its components on hair keratinocyte proliferation and differentiation.

We confirmed that propolis could influence the morphologically normal development of HFs. HFs stimulated by propolis treatment were normally invaginated into the subcutaneous fat layer and formed well-developed hair bulb structures with hair matrix cells that could actively proliferate. Hair stem cells in the bulge region and progenitor cells in the epidermal basal layer exhibited similar distribution patterns in propolis-treated skin and vehicle-treated skin. The size and shape of hair shafts were not noticeably different in vehicle-treated versus propolis-treated HFs. Versican, which is a marker protein for functional dermal papilla cells,[36] was also distributed normally in propolis-treated HFs. These results indicate that propolis facilitates normal hair growth.

The influence of propolis on the epidermis was also assessed. The normal multilayer structure of the epidermis consists of a CK14-positive basal layer, a CK10-positive suprabasal layer, and a denucleated squamous cell layer.[33] A similar multilayer structure was observed in the epidermis of propolis-treated mice, and tight cell–cell contacts and a continuous basal membrane were observed by ZO-1 and laminin immunofluorescence, respectively, with no detectable differences between vehicle-treated and propolis-treated skin. In contrast, the number of Ki-67-positive proliferating keratinocytes increased in the epidermis with the topical application of propolis. The stimulatory effects of propolis on epidermal keratinocytes were confirmed in assays utilizing cultured isolated keratinocytes. Thus, propolis appears to stimulate the proliferation of epidermal keratinocytes, which stratify into the normal multilayer structure of the epidermis. These results are

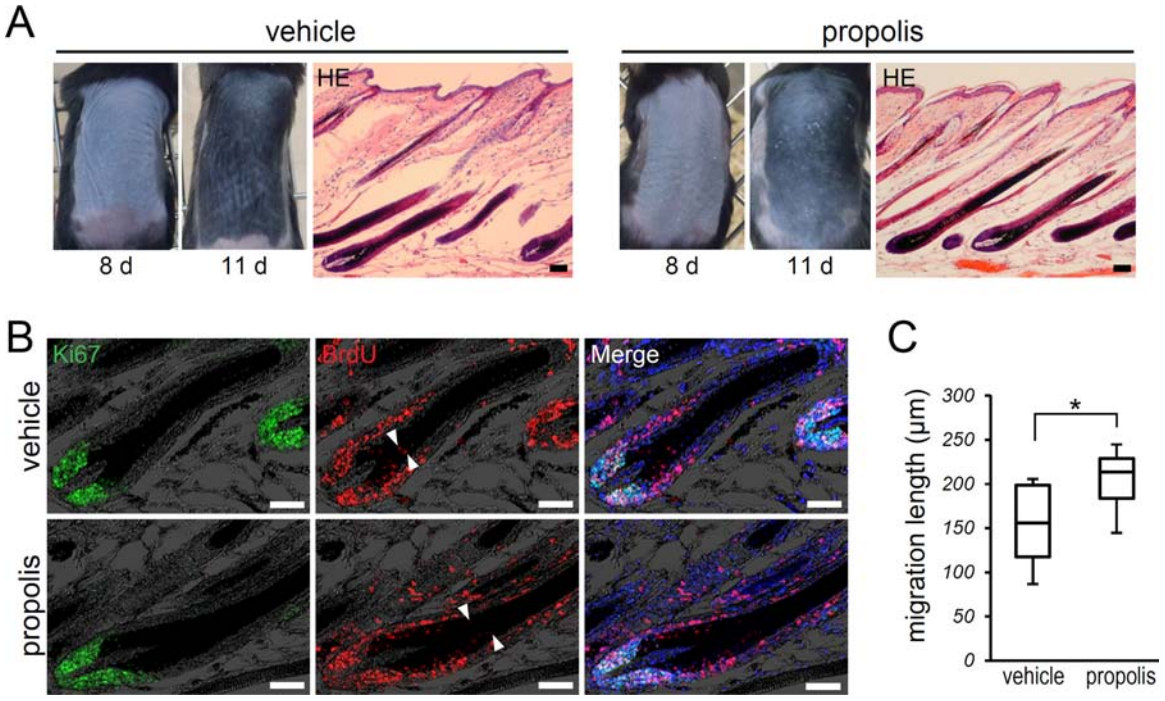

**Figure 3.** Representative images of mice after topical applications of propolis or vehicle to the depilated back skin. (A) Melanization of the back skin and elongation of hair shafts occurred after 8 and 11 d in mice, respectively, following depilation. H&E staining of the back skin 11 d after depilation revealed that hair follicles were at anagen stage following 3 d of propolis or vehicle treatment. (B) Images show immunofluorescence detection of Ki-67 (green) and 5-bromo-2′-deoxyuridine (BrdU; red); rightmost pictures are merged images. Nuclei were stained with DAPI (blue). Over 24 h, BrdU-positive cells migrated out of the hair matrix region and along the hair shaft (arrowheads). (C) Propolis increased the extent of migration, as indicated by a graph of distances traveled by BrdU-labeled cells from the bottom of the hair matrix region. Bars = 50 $\mu$m. *$p$ < 0.05.

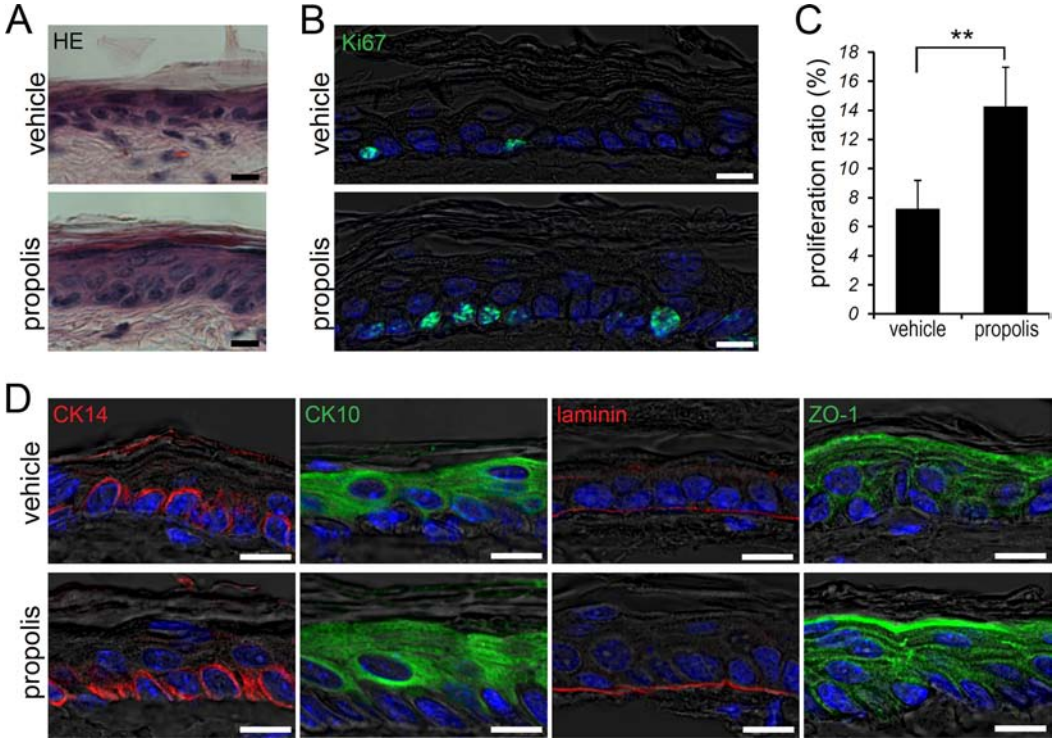

**Figure 4.** Images show (A) H&E staining and (B, D) immunofluorescence detection of Ki-67 (green; B), CK14 (red; D), CK10 (green; D), laminin (red; D), and ZO-1 (green; D) in the skin of mice after topical application of propolis (top half) or vehicle (bottom half) to depilated back skin. Nuclei were stained with DAPI (blue). Bars = 10 $\mu$m. (C) Propolis increased keratinocyte proliferation, as indicated by a graph of the ratio of Ki-67-positive, proliferating cells to total epidermal cells. **$p$ < 0.005.

supported by previously published research that investigated the relationships between propolis and epithelial cells.[14,21,22,35]

Several substances, such as finasteride and minoxidil, have been reported to facilitate hair growth via distinct pathways. Finasteride blocks the hair loss that occurs in androgenetic alopecia by inhibiting steroid 5$\alpha$-reductase, which catalyzes the conversion of testosterone into dihydrotestosterone.[37] Minoxidil extends anagen by activating $\beta$-catenin signaling and the opening of ATP-sensitive potassium channels in dermal papilla cells.[38,39] Conversely, neither finasteride nor minoxidil stimulates keratinocyte proliferation, although minoxidil does slow the senescence of keratinocytes.[40] Thus, propolis utilizes a different pathway from finasteride and minoxidil in promoting hair growth. Therefore, propolis and either minoxidil or finasteride, if applied in combination, would be expected to promote hair growth synergistically.

In this study, we demonstrated the effects of propolis on hair growth through its effects on keratinocyte proliferation. However, the components in propolis that are responsible for the induction of keratinocyte proliferation remain unclear; it is also not known whether propolis has multiple components that contribute to hair growth. Propolis contains several components, such as coumaric acid, artepillin C, and CAPE. Artepillin C acts as a ligand for peroxisome proliferator-activated receptor gamma (PPAR$\gamma$) and enhances adipocyte differentiation, while also inhibiting the macrophage inflammatory response.[41,42] CAPE is a specific inhibitor of nuclear factor kappa B (NF-$\kappa$B) and demonstrates anti-inflammatory and antioxidant effects in several kinds of cells through inhibition of NF-$\kappa$B signaling.[43−46] *p*-Coumaric acid inhibits human tyrosinase activity and melanin synthesis in human epidermal melanocytes.[47,48] PPAR$\gamma$, NF-$\kappa$B, and tyrosinase all take part in biological processes related to hair growth.[49−51] Further investigation is required to elucidate which of these or other components of propolis stimulate hair growth and to determine how to best apply propolis, or its active components, in a clinical setting.

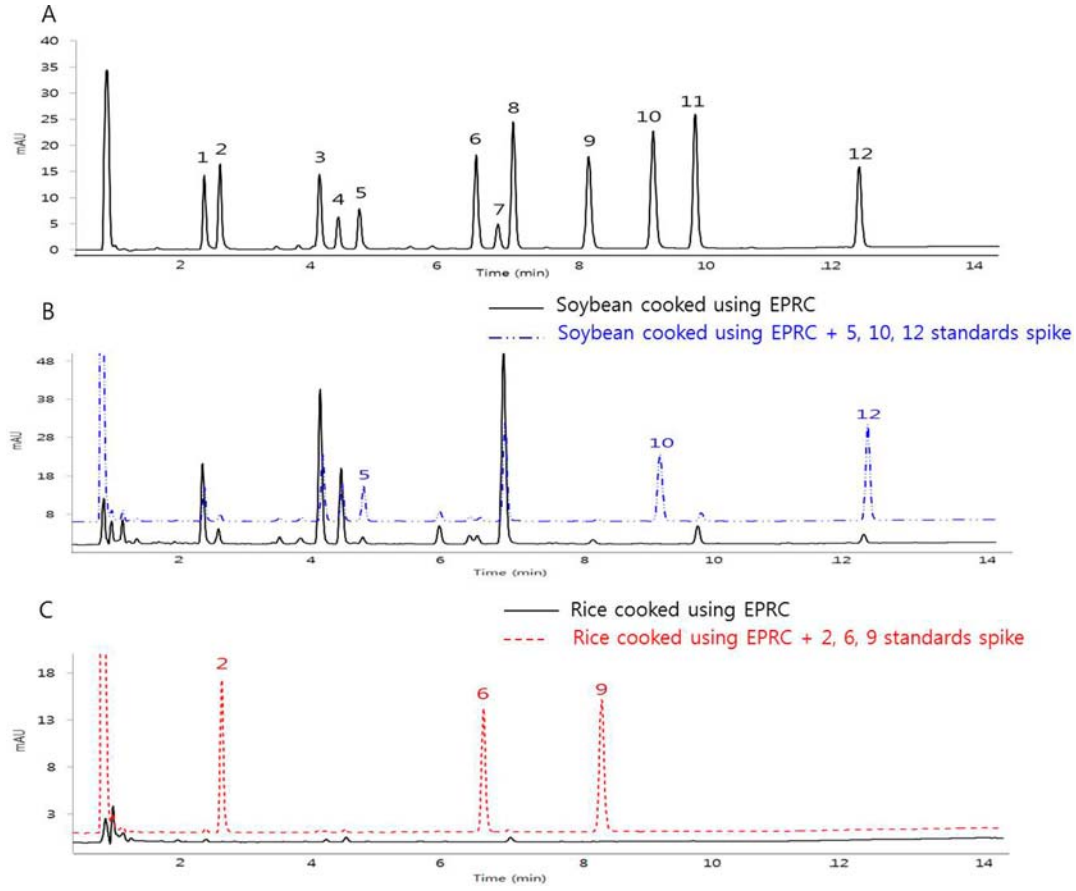

**Figure 1.** (A) Representative UPLC chromatograms of 12 isoflavone STDs and the isoflavones in cooked soybeans and rice. (B) Comparison of chromatograms of the soybeans cooked using an EPRC (black solid line) and the same soybean aliquot spiked with isoflavone STDs 5, 10, and 12 (blue dotted line). (C) Comparison of chromatograms of the rice cooked using the EPRC (black solid line) and the same rice aliquot spiked with isoflavone STDs 2, 6, and 9 (red dotted line). Isoflavone STDs: 1, Din; 2, Glin; 3, Gin; 4, MD; 5, MGl; 6, AD; 7, MG; 8, AGl; 9, Dein; 10, Glein; 11, AG; and 12, Gein.

of soybeans and soy foods.[8,15,21−24] However, to the best of our knowledge, few studies have examined the effects of a combination cooking method involving heat and pressure treatment on isoflavone composition and content of soybean−rice mixtures cooked using rice cookers. Therefore, the present study investigated the effects of heat and pressure processing on the composition and content of 12 isoflavones in soybeans during soybean−rice mixture cooking using an ERC and an EPRC. The present study also examined the transfer of these 12 isoflavones between soybeans and rice after ERC and EPRC cooking of a soybean−rice mixture. The results of the present study describe the effects of cooking on the composition and content of isoflavones in soybeans and provide basic information for the development of functional foods using soybeans in the food industry.

## MATERIALS AND METHODS

**Chemicals.** All solvents used for isoflavone extraction and analysis were of high-performance liquid chromatography grade. All solvents and reagents were obtained from Fischer Scientific Korea, Ltd. (Seoul, Korea), Merck (Darmstadt, Germany), J.T.Baker (Phillipsburg, NJ), or Daejung Chemical & Materials Co., Ltd. (Gyeonggi-Do, Korea). A total of 12 isoflavone standards (STDs) were purchased from Wako Pure Chemical Industries, Ltd. (Osaka, Japan).

**Rice and Soybean Materials.** The soybean cultivar "Chung-ja" (black-coated soybean seed) was cultivated, harvested, and obtained from the Rural Development Administration in 2012. In general, "Chung-ja" is classified as the type of soybean cooked with rice in Korea.[25] The rice cultivar "Choochung" was purchased from a local market in Seoul, Korea, to be cooked with the soybeans. This rice grain had a moisture content of approximately 14% and was stored at room temperature until it was cooked with the soybeans.

**Soybean−Rice Mixture Cooking.** Two rice cookers were used in the present study: an ERC (LJ-MG0402) and an EPRC (LJP-SA063E), both from Lihom (Seoul, Korea). During the soybean−rice mixture cooking, the ERC was operated at a cooking temperature of ∼100 °C and a cooking pressure of ∼14.7 psi, whereas the EPRC was operated at a cooking temperature of 120−130 °C and a cooking pressure of 25−30 psi. For soybean−rice mixture cooking, 40 and 300 g of soybeans and rice, respectively, were weighed and combined. Tap water (400 mL) was added, and the soybeans and rice were soaked together in water for 30 min at room temperature. Thereafter, the soybeans and rice were cooked using the ERC and EPRC ($n$ = 3). Then, the soybeans and rice were separated and lyophilized at −45 °C for 3 days and pulverized for isoflavone analysis.

**Isoflavone Extraction.** Isoflavones from the soybean and rice samples were extracted using acidic extraction.[7] Pulverized samples (2 g each; $n$ = 3) were added to 10 mL of acetonitrile and 2 mL of 0.1 N hydrochloric acid and then extracted for 2 h at room temperature on a shaker at 200 rpm (Green-Sseriker, Vision Scientific Co., Ltd., Gyeonggi-Do, Korea). The crude extract was filtered through No. 42 Whatman filter paper (125 mm diameter, Maidstone, U.K.), and the filtrate was evaporated at a temperature lower than 32 °C with a vacuum evaporator (EYELA, SB-1200, Tokyo Rikakikai Co., Ltd., Gyeonggi-Do, Korea). The dried samples were reconstituted with

[a]Dein, daidzein; Gein, genistein; Glein, glycitein; Din, daidzin; Gin, genistin; Glin, glycitin; AD, acetyldaidzin; AG, acetylgenistin; AGl, acetylglycitin; MD, malonyldaidzin; MG, malonylgenistin; and MGl, malonylglycitin. [b]The calibration curve was composed of 4−8 different concentrations for each standard solution. [c]The LOD and LOQ were calculated as follows: LOD = 3SD/$S$ and LOQ = 10SD/$S$, where SD is the standard deviation of the $y$ intercept in the calibration curve and $S$ is the slope of each calibration curve.[26]

10 mL of 80% methanol and then filtered through a 0.2 $\mu$m nylon membrane syringe filter (Sun Sri, Rockwood, TN).

**Isoflavone Analysis with Ultraperformance Liquid Chromatography (UPLC).** Isoflavones were analyzed with an Agilent UPLC system coupled with a diode array detector (1290 infinity binary pump, Agilent, Seoul, Korea). A reverse-phase column (Agilent Zorbax Eclipse $C_{18}$, 100 × 2.1 mm internal diameter, 1.8 $\mu$m) was used to separate the 12 isoflavones. The ultraviolet and reference wavelengths were set at 254 and 360 nm, respectively. The mobile phase consisted of 0.1% glacial acetic acid in water (solvent A) and 0.1% glacial acetic acid in acetonitrile (solvent B). The gradient conditions of the mobile phases were slightly modified as previously described[7] and optimized for isoflavone analysis using UPLC as follows: initial, 85% A/15% B; 10 min, 75% A/25% B; 13 min, 65% A/35% B; 16 min, 65% A/35% B; and 20 min, 85% A/15% B. The stop time was set at 20 min, and the post time (equilibrium time) was set at 5 min. The injection volume was 1 $\mu$L, and the flow rate was 0.5 mL min$^{-1}$. The isoflavones were identified by comparing the retention times of the authentic STDs and the peaks in the sample aliquots. Furthermore, each isoflavone STD was added to the sample aliquots (sample aliquot + isoflavone STD) to confirm the correct peak assignment in the sample aliquots; we could then properly assign the isoflavone peaks in the samples (Figure 1). The limit of detection (LOD) and limit of quantification (LOQ) were calculated using the calibration curve as follows: LOD = 3SD/$S$ and LOQ = 10SD/$S$, where SD is the standard deviation of the $y$ intercept of the calibration curve, and $S$ is the slope of the calibration curve.[26] The LOD and LOQ of the 12 isoflavones were 0.01−0.23 and 0.02−0.78 $\mu$g mL$^{-1}$, respectively (Table 1).

**Statistical Analysis.** Statistical analysis was performed using the general linear model procedure of the SAS software (SAS Institute, Inc., Cary, NC). The results were analyzed using a variance analysis. Additionally, Fisher's least significant difference test at the 0.05 probability level ($LSD_{0.05}$) was used to determine differences among the means of the samples.

## RESULTS

**Composition and Content of Isoflavones in Soybeans and Rice before Cooking.** The composition and content of the 12 isoflavones in soybeans and rice before cooking are shown in Table 2. The total isoflavone content in the soybeans was 562.9 ± 21.2 $\mu$g g$^{-1}$. Among the four isoflavone groups, malonylglucosides (sum of malonyldaidzin, malonylgenistin, and malonylglycitin) were the most abundant (83.5 ± 3.1%) in the soybeans before cooking. Glucosides (12.8 ± 0.5%), acetylglucosides (2.8 ± 0.1%), and aglucon (0.9 ± 0.1%) were the next most abundant isoflavone groups, and the differences in abundance were statistically significant ($p < 0.05$). The total daidzein (sum of daidzein, daidzin, acetyldaidzin, and malonyldaidzin), total genistein, and total glycitein in the soybeans before cooking were 69.4 ± 3.1, 220.9 ± 7.8, and 12.1 ± 0.6 $\mu$g g$^{-1}$ (aglucon equivalents), respectively ($p < 0.05$; Table 3). Among the 12 isoflavones, malonylgenistin was the major isoflavone type (359.1 ± 12.6 $\mu$g g$^{-1}$), accounting for approximately 64% of the total isoflavone content in the soybeans before cooking. Acetylglycitin and glycitein were not detected or found in only trace levels (indicating levels below the limit of detection, <LOD). In addition, isoflavones were not found in the rice before cooking (Table 2 and Figure 2).

**Changes in Isoflavone Composition and Content in the Soybean−Rice Mixture after ERC Cooking.** In comparison to that before cooking, the total isoflavone content in soybeans cooked using the ERC decreased by approximately 10% (before cooking, 562.9 $\mu$g g$^{-1}$; after cooking, 504.4 ± 2.9 $\mu$g g$^{-1}$). Malonylglucosides and glucosides constituted approximately 68 and 26%, respectively, of the total isoflavone content in the soybeans cooked using the ERC. In comparison to that before cooking, the malonylglucoside content in the soybeans decreased by ∼16% and the glucoside content increased by ∼13% after ERC cooking. Therefore, some of the malonylglucosides in the soybeans were converted to the glucosides during ERC cooking (Table 2). In comparison to the isoflavones (total daidzein, total genistein, and total glycitein) in the soybeans before cooking, the total genistein and total glycitein in the soybeans cooked using the ERC decreased by ∼11 and ∼7%, respectively ($p < 0.05$). The total daidzein content increased by ∼3% in the ERC-cooked soybeans; however, the difference was not statistically significant (see Table 3). Among the 12 isoflavones, malonylgenistin was the major isoflavone (52.3 ± 0.3%) in the soybeans cooked using the ERC and glycitin and acetylglycitin were detected at trace levels (<LOD) or not detected. Furthermore, the genistin content increased by approximately 82% (before cooking, 42.6 $\mu$g g$^{-1}$; after cooking, 77.4 $\mu$g g$^{-1}$) in the soybeans after ERC cooking (Table 2).

After soybean−rice mixture cooking using the ERC, the total isoflavone content in the rice was 14.0 ± 0.1 $\mu$g g$^{-1}$ (dry basis of ERC-cooked rice), which equaled approximately 85 $\mu$g g$^{-1}$ (dry basis of ERC-cooked soybeans), approximately 15% of the total isoflavones in the soybeans before cooking. Malonylglucosides were the major isoflavones (∼90%) in the rice cooked

[a]Aglucon equivalents were calculated as follows: total daidzein = [daidzein + (0.611 × daidzin) + (0.555 × acetyldaidzin) + (0.506 × malonyldaidzin)], total genistein = [genistein + (0.625 × genistin) (0.570 × acetylgenistin) + (0.521 × malonylgenistin)], total glycitein = [glycitein + (0.637 × glycitin) + (0.582 × acetylglycitin) + (0.534 × malonylglycitin)]. The constant used for aglucon equivalent calculation was from a normalization of the molecular weight of individual algulcon and glucoside isoflavones. [b]Isoflavone contents were expressed as micrograms per 1 g of lyophilized/pulverized soybean (aglucon equivalents, $\mu$g g$^{-1}$, on a dry basis of the soybean). [c]Isoflavone contents were expressed as micrograms per 1 g of lyophilized/pulverized rice (aglucon equivalents, $\mu$g g$^{-1}$, on a dry basis of the rice). [d]ND = not detected.

using the ERC. Furthermore, aglucons and acetylglucosides were not found or found below LOD in rice cooked using the ERC (Table 2 and Figure 2).

**Changes in Isoflavone Composition and Content in the Soybean−Rice Mixture after EPRC Cooking.** In comparison to that before cooking, the total isoflavone content in the EPRC-cooked soybeans decreased by ∼10%. Malonylglucosides and glucosides comprised approximately 48 and 40%, respectively, of the total isoflavones in the soybeans cooked using the EPRC (Table 2). In particular, the genistin (before cooking, 42.6 $\mu$g g$^{-1}$; after cooking, 120.2 $\mu$g g$^{-1}$) and daidzin (before cooking, 22.3 $\mu$g g$^{-1}$; after cooking, 65.8 $\mu$g g$^{-1}$) contents in the EPRC-cooked soybeans increased ∼3-fold compared to those in the soybeans before cooking because of the conversion of malonylglucosides to glucosides (Table 2 and Figure 2). Furthermore, in comparison to that before cooking, the acetylglucoside content in the soybeans cooked using the EPRC increased by >3-fold (Table 2). In comparison to that before cooking, the total genistein and total glycitein contents in the EPRC-cooked soybeans decreased by 2−12%, whereas the total daidzein content increased by ∼17% in the soybeans cooked using the EPRC ($p < 0.05$; Table 3). Malonylgenistin and genistin comprised 37 and 24%, respectively, of the total isoflavone content in the soybeans cooked using the EPRC and were the most abundant isoflavones. Acetylglycitin and glycitein were also found at trace levels (<LOD) or not detected in soybeans cooked using the EPRC (Table 2).

After soybean−rice cooking using the EPRC, the total isoflavone content in the rice was 12.7 ± 0.3 $\mu$g g$^{-1}$ (dry basis of EPRC-cooked rice), which equaled approximately 78 $\mu$g g$^{-1}$ (dry basis of EPRC-cooked soybean), approximately 14% of the total isoflavones in the soybeans before cooking. Among the isoflavones in the rice cooked using the EPRC, 85% were malonylglucosides; aglucons and acetylglucosides were found at trace levels (<LOD; Table 2) or not detected.

## DISCUSSION

In many countries, soybeans are usually consumed as soy curd, soy paste, soy sauces, soy milk, soy bread, and other soy products. Among the various functional substances in soybeans and soy foods, isoflavones in particular have attracted attention as nutraceutical compounds, owing to constituents, such as phytoestrogens, which have health benefits.[27,28] To increase the nutritive value of rice, particularly essential amino acid content,[5] the practice of cereal−legume complementation is widely followed in Korea. Both ERCs and EPRCs are generally used for soybean−rice mixture cooking. The difference in these cooking methods is that EPRCs use a relatively higher pressure than ERCs. Therefore, the soybean−rice mixture cooking time is usually accelerated when cooking with EPRCs, resulting in a greater degree of gelatination because of the higher boiling point of water, which can be attributed to the higher pressure during cooking.[29,30]

The composition and content of isoflavones in soybeans and soy foods are influenced by various processing conditions, such as soaking, heating, acid hydrolysis, deforming, and pressure treatment.[7,20,31,32] During soybean and soy food processing, isoflavones are usually generated by converting malonylglucosides to acetylglucosides, glucosides, and aglucon through chemical reactions, such as decarboxylation or ester hydrolysis.[33,34] Previous studies have shown that heat treatment affects the conversion of malonylglucosides to acetylglucosides and glucosides,[35] whereas microbial fermentation affects the conversion of glucoside isoflavones to aglucon.[7] In particular, the conversion of malonylglucosides to other types of isoflavones is most likely and rapid during heating.[35] Furthermore, in comparison to dry heat treatment, moist heat treatment converts a higher number of malonylglucosides to glucosides but only limited amounts of malonylglucosides to acetylglucosides.[17,36,37] The order of isoflavone stability under heat treatment conditions (above 160 °C) is daidzin > genistin > glycitin.[33]

In the present study, the total isoflavone content in the cooked soybeans and rice relative to that in the soybeans before cooking was ∼90 and 14−15%, respectively, after both ERC and EPRC cooking, which indicates that most isoflavones in soybeans were preserved during soybean−rice mixture cooking. However, the composition of isoflavones in soybeans cooked using the ERC and EPRC was significantly different from that in soybeans before cooking ($p < 0.05$). Furthermore, the malonylglucoside content in soybeans cooked using the EPRC showed an additional ∼20% decrease relative to that in soybeans cooked using the ERC, whereas the glucoside content in soybeans cooked using the EPRC showed a further increase of ∼15% relative to that in soybeans cooked using the ERC (Table 2 and Figure 2). In the present study, malonylgenistin was highly susceptible to isoflavone conversion under the cooking conditions. These results were partially similar to those of a prior study showing that the malonylglucoside content is significantly decreased relative to glucoside and aglucon contents in yellow and black soybeans under boiling and steaming processing conditions.[21] The reduced conversion of malonylglucoside to aglucon in the present study may have resulted from differences in cooking conditions (e.g., cooking temperature and cooking period). Furthermore, the other previous study[33] showed that the aglucon content also increases during heating

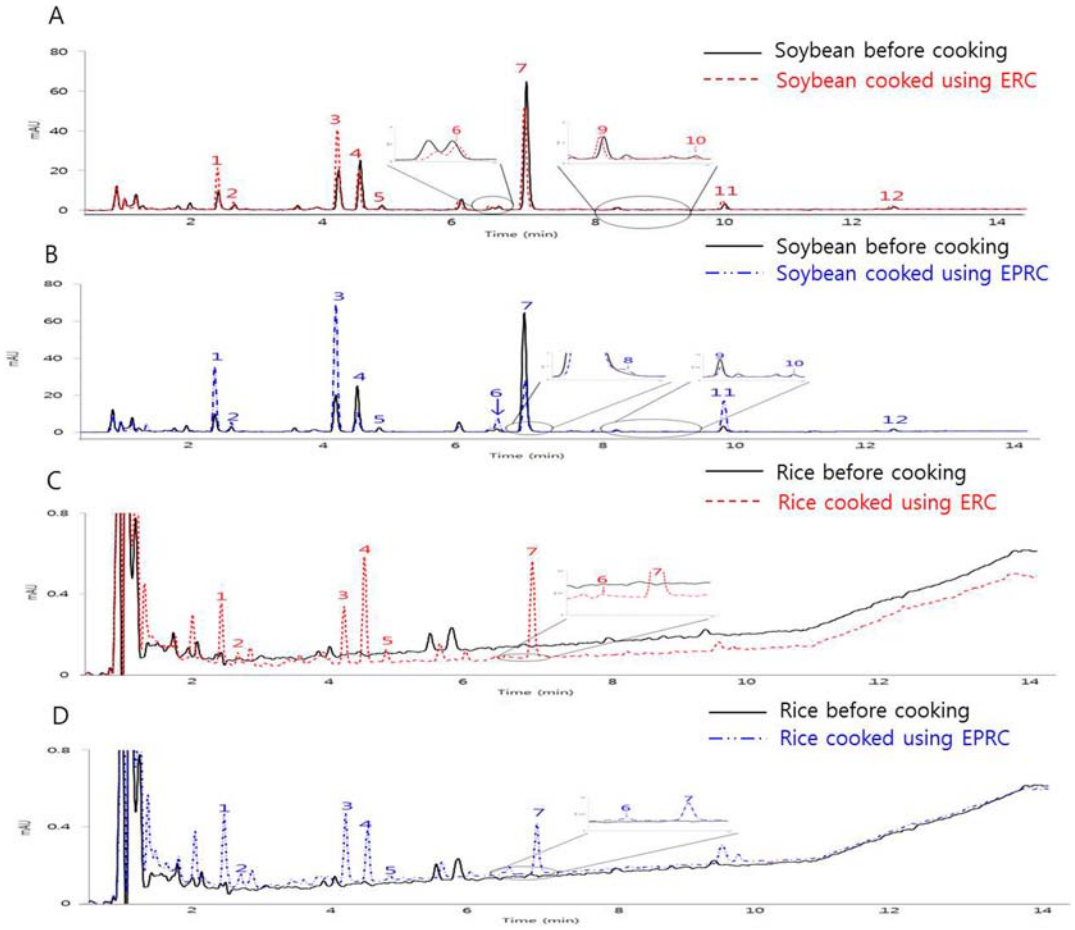

**Figure 2.** Representative UPLC chromatograms of isoflavones in soybeans and rice cooked using an ERC and an EPRC. (A) Comparison of the soybeans before and after soybean−rice mixture cooking using the ERC. (B) Comparison of the soybeans before and after soybean−rice mixture cooking using the EPRC. (C) Comparison of the rice before and after soybean−rice mixture cooking using the ERC. (D) Comparison of the rice before and after soybean−rice mixture cooking using the EPRC. Isoflavone STDs: 1, Din; 2, Glin; 3, Gin; 4, MD; 5, MGl; 6, AD; 7, MG; 8, AGl; 9, Dein; 10, Glein; 11, AG; and 12, Gein.

at temperatures above 135 °C. In the present study, soybeans prepared using the EPRC were cooked under conditions with a higher boiling point of water (120−130 °C) compared to that used to cook soybeans with the ERC; however, the aglucon content in the soybeans did not change significantly during the soybean−rice mixture cooking (Table 2). The combination of adiabatic heating and pressure treatment has been shown to affect isoflavone conversion in soy milk significantly, especially the conversion of malonylglucosides to glucosides. The aglucon content in soy milk also remains constant under adiabatic heating and pressure treatments.[20] These results may explain why isoflavone conversion, especially that of malonylglucosides, in soybeans cooked using the EPRC was decreased to a greater extent than that in soybeans cooked using the ERC in the present study.

Isoflavone composition is generally changed by various processes, but the total isoflavone content does not change if sample mass loss does not occur.[7] In the present study, no mass loss occurred during soybean−rice mixture cooking using the ERC or the EPRC, and 14−15% of the total isoflavone content in the soybeans before cooking was transferred to the rice through ERC and EPRC cooking. However, soybean−rice mixture cooking using the EPRC slightly increased the total daidzein content of the cooked soybeans but decreased the total genistein and glycitein contents. The increase in total daidzein in EPRC-cooked soybeans was caused by the greater increase of acetyldaidzin and daidzin in the EPRC-cooked soybeans compared to those in the soybeans before cooking. However, although no sample loss occurred during the soybean−rice cooking, it remains unclear why the total daidzein content in the EPRC-cooked soybeans was slightly higher than that in the soybeans before cooking.

In conclusion, the composition of isoflavones in soybeans was significantly changed by heat treatment, pressure treatment, or both during soybean−rice cooking. In particular, the combination of heat and pressure treatments had a greater effect on isoflavone composition compared to the effect of heat treatment alone ($p < 0.05$) but did not affect the total isoflavone content. In comparison to that in the soybeans before cooking, a total isoflavone content of 90% was found in the soybeans cooked using the ERC and EPRC; the rest of the isoflavones were transferred to the rice during soybean−rice mixture cooking. Malonylglucosides, especially malonylgenistin, were the isoflavone types most susceptible to conversion, and they were normally converted to glucosides rather than acetylglucosides or aglucons during ERC and EPRC cooking of the soybean−rice mixture. The results of the present study describe the alteration of isoflavone composition and content in a soybean−rice mixture after ERC and EPRC cooking and may provide insight into the use of functional substances, such as isoflavones, in soybeans or soy foods.

analytical techniques.[13] van Platerink et al.[14] developed a sensitive method to detect peptides in human plasma samples with detection limits from 0.01 to 0.001 ng/mL. Although the research on the absorption of antihypertensive peptides has revealed that certain short peptides, di- and tripeptides such as VY and IPP, can reach bloodstream undegraded after oral administration, either in fasted or fed states, very low absorption extents were reported.[15−17] To the best of our knowledge, kinetic studies with longer peptides than tripeptides from dietary sources have not been reported.

Because the information regarding the kinetic profile is needed to establish a scientific basis for efficacy in the use of any food supplement, the objective of this study was to investigate the oral bioavailability and the kinetic behavior of the antihypertensive peptide HLPLP after its administration to rats, determining HLPLP plasma concentrations using a sensitive and specific analytical method. In addition, this technique allowed us to monitor the plasma concentrations of two derived peptide fragments, LPLP [β-casein fragment f(135−138)] and HLPL [β-casein fragment f(134−137)].

## MATERIALS AND METHODS

**Chemicals.** The peptides HLPLP, β-casein f(134−138), HLPL, β-casein f(134−137), HLP, β-casein f(134−136), LPLP, β-casein f(135−138), LPL, β-casein f(135−137), PLP, and β-casein f(136−138) were used in this study. These peptides were prepared in-house following the solid-phase synthesis method with fluorenyl-methoxy-carbonyl (FMOC), using a 431A peptide synthesizer (Applied Biosystems Inc. Überlingen, Germany). Their purities, verified by reversed phase high performance liquid chromatography−ultraviolet−mass spectrometry (RP-HPLC-UV-MS) as previously described,[18] were 98.0%, 97.68%, 96.20%, 93.43%, and 99.36%, respectively. Peptide PLP, with a purity of 92.94%, was purchased from SynPeptide CO, LDT (Shanghai, China). All other chemicals were of the highest quality grade and obtained from commercial sources.

**Animals and Experimental Design.** The study was undertaken in accordance with the ethics requirements and authorized by the official ethical committee of University Complutense of Madrid. Adult male Wistar rats (Charles River Inc., Margate, Kent, UK) each weighing 220−230 g at 9 weeks of age were used. The animals were individually housed in polycarbonate cages with sawdust bedding and maintained in environmentally controlled rooms (22 ± 2 °C and 50 ± 10% relative humidity) with a 12 h light/dark cycle (light from 08.00 to 20.00 h). Food (A04 rodent diet, Panlab SL, Barcelona, Spain) and water were available ad libitum. The rats were divided into two groups, one group of 60 animals (group 1) received the synthetic peptide HLPLP intravenously and the other group of 84 animals (group 2) orally. Group 2 rats were deprived of food for 12 h before the single oral administration of 40 mg/kg body weight, but they had ad libitum access to water. The peptide was dissolved in distilled water (10 mg/mL) and was administered by oral gavage in a volume of 1 mL peptide solution/rat of 250 g of body weight. Group 1 rats were given a single iv injection of 4 mg/kg body weight into the lateral tail vein (in this case a peptide solution of 4 mg/mL was prepared, and 0.25 mL peptide solution/rat of 250 g of body weight was injected). The iv 4 mg/kg and oral 40 mg/kg doses of peptide HLPLP were selected on the basis of preliminary experiments where both doses and routes of administration did not show any adverse effects, abnormal clinical signs, behavioral changes, body weight changes, or change in food and water consumption in the animals treated (data not shown). The oral HLPLP dose was higher than the iv dose due to the low absolute oral bioavailability described for other food-derived peptides in pigs, approximately 0.1%.[17] The administered oral dose is higher than that reported to cause a significant decrease in the systolic blood pressure in spontaneously hypertensive rats (SHR).[10] Five additional animals were used as control to collect blank blood samples and to prepare calibration curves from plasma control fortified with the synthetic peptides HLPLP, LPLP, and HLPL.

Animals in groups 1 and 2 were killed by cervical dislocation (six animals at each time) and then exsanguination at 0, 1.5, 2, 3, 5, 8, 10, 15, 20, and 30 min after iv and at 0, 3, 5, 10, 15, 20, 30, 40, 45, 50, 55, 60, 65, and 70 min after oral administration of peptide HLPLP, respectively. Time points were selected based on preliminary experiments, and the limit of quantification (LOQ) of the analytical method was taken into account. Blood samples (1 mL) were withdrawn from the jugular vein and collected in heparinized tubes. Plasma was separated by centrifugation and stored frozen at −80 °C until analyzed. Blood samples at times greater than 70 or 30 min after oral or iv HLPLP doses, respectively, were not collected, because preliminary experiments (data not shown) showed that at these times no levels of the synthetic peptides HLPLP, LPLP, and HLPL were detected.

**Analysis of Plasma Samples.** *Plasma Sample Preparation.* Plasma samples from rats were prepared by adding 40 μL of an aqueous solution of 10% of trifluoroacetic acid (TFA) to 1 mL of plasma and homogenized in a vortex, and the mixture was heated at 99 °C for 2 min to precipitate proteins, as previously described.[14] Then the samples were centrifuged (MiniSpin, Eppendorf, Hamburg, Germany) at 8500*g* for 30 min. The supernatant was purified using mixed mode cation exchange cartridges (Bond Elut Plexa PCX, 60 mg, 1 mL, Agilent, Santa Clara, CA). Cartridges were preconditioned with 1500 μL of methanol and 2500 μL of Milli-Q water (Millipore, Bedford, MA). The plasma sample, previously mixed (1:3 v/v) with an aqueous solution containing 2% orthophosphoric acid, was loaded. The cleaning step consisted of the addition of 1500 μL of 2% formic acid in Milli-Q water and 2500 μL of a mixture composed of 50% methanol and 50% acetonitrile (v/v). The elution step was carried out by adding 1 mL of ammonia at 5% (35% purity) in methanol:acetonitrile (50:50, v/v). The elution volume was afterward totally dried by vacuum centrifugation (SpeedVac SC 200 Savant, Irving, TX). For the injection, the dried samples were reconstituted with 50 μL of 0.1% formic acid.

To prepare the standard curves, the synthetic peptides HLPLP, LPLP, and HLPL were diluted in Milli-Q water to final concentrations that ranged from 0.08 to 300 ng/mL, corresponding to 0.13 to 521 nmol/L, 0.18 to 682.9 nmol/L, and 0.17 to 625.9 nmol/L, respectively, in rat control plasma. Immediately after addition of the peptide solution to the plasma, they were treated as described previously for the preparation of plasma samples from rat assays. The calibration curves were injected on the same day as the rat samples.

*Peptide Analysis by UPLC-Q-TOF.* The analyses of samples were performed on an Acquity ultrahigh performance liquid chromatography (UPLC) instrument from Waters (Milford, MA), coupled to a Microtof-QII (Bruker Daltonik, Bremen, Germany). The LC-MS system was controlled by HyStar 3.2 software (Bruker). The column employed for the analyses was an Acquity UPLC BEH 130 $C_{18}$ of 2.1 mm × 100 mm (Waters), with a particle size of 1.7 μm. The analyses were run at 30 °C, the flow rate was 0.2 mL/min, and the injection volume was 25 μL. A linear gradient was set from 0 to 45% of solvent B (acetonitrile/formic acid 0.1%) and 55% of solvent A (water/formic acid 0.1%) in 16 min. The nebulizer pressure was set at 3 bar, the temperature of the source at 180 °C, and the capillary voltage at 4.5 kV. MS full-scan acquisitions were first performed during UPLC runs, using a 50−1200 mass-to-charge ratio ($m/z$) range. The method developed was pseudoselected reaction monitoring (SRM) in which the parent ion with $m/z$ 576.343 was selected for fragmentation. The peptide HLPLP was identified by its retention time and also by its fragmentation profile. The identification of the possible derived peptide fragments, i.e., LPLP and HLPL, HLP, LPL, and PLP, was performed using the retention time and the extraction of the characteristic molecular ions $m/z$ 439.284, 479.290, 366.206, 342.231, and 326.200, respectively. The Q-TOF analyzer was calibrated on a daily basis in MS mode, using the $m/z$ ratios of adduct ions arising from sodium formate as reference.

**Data Analysis.** The mean plasma concentration versus time after iv and oral administration was sequentially fitted to one-, two-, and

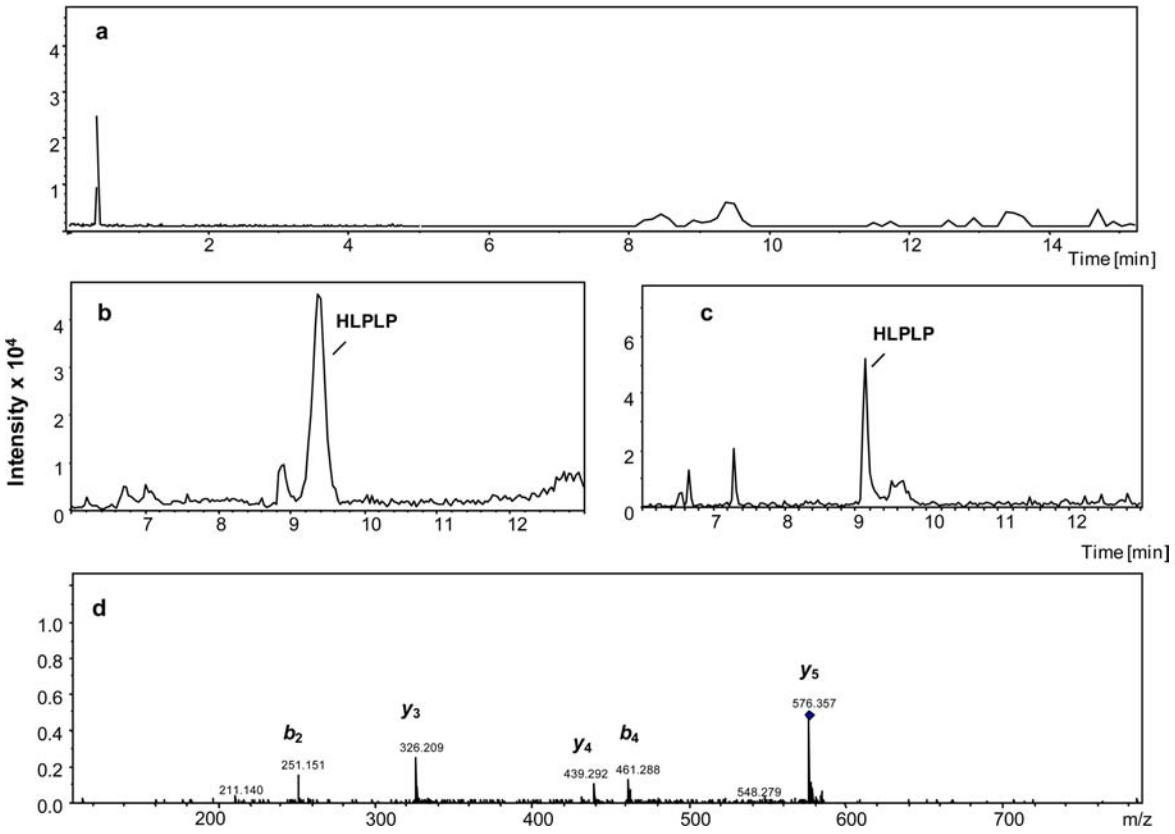

**Figure 1.** (a) Extracted ion chromatogram (EIC) of HLPLP ($m/z$ 576.343; $t_R$ 9.4), LPLP ($m/z$ 439.284; $t_R$ 10.5), and HLPL ($m/z$ 479.290; $t_R$ 8.4) in blank plasma. EIC of the peptide HLPLP ($m/z$: 576.343; $t_R$ 9.4 min) (b) at 15 after oral administration and (c) at 20 min after intravenous administration. (d) Fragmentation pattern of HLPLP at 15 min after oral administration.

multiple-compartment models, using the computer program WinNonlin (Version 6.3; Pharsight Corporation, Mountain View, CA). The model was determined for best fit on the basis of a smaller value for the Akaike's Information Criterion (AIC).[19] The two-compartment model was the best fit for the two animal groups. This model was used to establish pharmacokinetic characteristics. Mean plasma concentration curves of peptide HLPLP after a single iv and oral administration and those of the peptides LPLP and HLPL (metabolites in plasma) after a single iv administration of HLPLP were fitted to the following exponential equations:

$$C = A_1 \times e^{-\alpha t} + A_2 \times e^{-\beta t} \text{ (iv)}$$

$$C = A_1 \times e^{-\alpha t} + A_2 \times e^{-\beta t} - A_3 \times e^{-K_a t} \text{ (oral)}$$

where $C$ is the plasma concentration of the compound, $A_1$, $A_2$, and $A_3$ are mathematical coefficients (i.e., $A_1$ and $A_2$ are the plasma concentrations extrapolated to time zero of the first and second elimination phases of the compound and $A_3$ for the absorption phase), $\alpha$ is the hybrid rate constant for the distribution phase, $\beta$ is the hybrid rate constant for the elimination terminal phase (i.e., $\alpha$ and $\beta$ are the slopes of the first and second elimination phases of the compound disposition), and $t$ is the time. Absorption half-life ($T_{1/2a}$), half-life of $\alpha$ phase ($T_{1/2\alpha}$), the half-life of $\beta$ phase ($T_{1/2\beta}$), distribution rate constants for transfer of the compound from the central to the peripheral compartment ($K_{12}$) and from the peripheral to the central compartment ($K_{21}$), and the elimination rate constant ($K_{10}$) were calculated using standard equations as described.[20,21] After iv and oral administration, the area under the concentration−time curves (AUC) was calculated as follows:

$$\text{AUC} = (A_1/\alpha) + (A_2/\beta)$$

or

$$\text{AUC} = (A_1/\alpha) + (A_2/\beta) - (A_3/K_a)$$

where bioavailability ($F$) is $(\text{dose}_{iv} \times \text{AUC}_{oral})/(\text{dose}_{oral} \times \text{AUC}_{iv})$.

Total plasma clearance (CL) was calculated, using the following formula:

$$\text{CL} = [\text{dose (mg/kg)}]/\text{AUC}$$

or

$$\text{CL} = [\text{dose (mg/kg)}](F)/\text{AUC}$$

Mean residence time (MRT) (only for HLPLP iv administration) was calculated as follows:

$$\text{MRT} = [(A_1/\alpha^2) + (A_2/\beta^2) \times (1/\text{AUC})]$$

Volume of distribution in the central compartment ($V_1$) (only for HLPLP iv administration) was determined as follows:

$$V_1 = [\text{dose (mg/kg)}]/A_1 + A_2$$

Apparent volume of distribution in the second compartment ($V_2$) (only for HLPLP iv administration) was determined as follows:

$$V_2 = (V_1) \times (K_{12}/K_{21})$$

Volume of distribution at steady state ($V_{ss}$) (only for HLPLP iv administration) was determined as follows:

$$V_{ss} = \text{MRT} \times \text{CL}$$

Maximum drug plasma concentration ($C_{max}$) after oral administration and the time at which $C_{max}$ was achieved ($T_{max}$) was determined directly from the concentration versus time curve.

## RESULTS

**Quantitative Determination of Peptides by UPLC-Q-TOF.** In preliminary experiments, the quantification of the HLPLP peptide was attempted with a sample preparation protocol consisting of the addition of 10% TFA to 1 mL of plasma followed by heating at 99 °C for 2 min to precipitate the proteins and further centrifugation. However, this protocol did not allow determining plasma peptide concentrations below 12.5 ng/mL. Therefore, peptide purification and concentration was investigated by using different solid-phase extraction (SPE) cartridges, such as reversed phase $C_{18}$ cartridges, mixed-mode cation, anion, and weak cation exchangers, and several solvent mixtures for the elution step. The best recovery values were obtained with a cation exchanger with mixed sorbent characteristics suitable for polar and nonpolar bases. The elution solvent selected was ammonia at 5% (35% purity) in methanol:acetonitrile (50:50, v/v).

The calibration curves provided linear results for HLPLP concentration values from 0.13 to 521 nmol/L in plasma ($R^2$ = 0.99). Figure 1a shows the extracted ion chromatogram of a blank plasma sample indicating the masses of the pentapeptide HLPLP and both tetrapeptides, HLPL and LPLP, where no interferences with endogenous compounds are expected. The extracted ion chromatogram of the pentapeptide after oral and iv administration and its fragmentation pattern are shown in Figure 1b, 1c, and 1d, respectively. One of the most intense fragment ions was observed at $m/z$ 326.207, corresponding to $y$-type ion $y_3$. Other major fragment ions were detected at $m/z$ 251.149 and 461.290, corresponding to $b$-type ions $b_2$ and $b_4$, respectively. These fragments ($y_3$, $b_2$, and $b_4$) resulted from the cleavage at N-terminal proline, which often generates highly intense $b$- and $y$-type fragment ions.[22] The recovery was calculated as the ratio between the concentration determined in a blank plasma sample spiked with HLPLP and further subjected to SPE purification and the concentration determined in a spiked sample after SPE purification. This was performed in triplicate using two concentrations of the peptide. The recovery values ranged from 96.9% to 98.7%. The reproducibility was estimated by the analyses of five spiked plasma extracts purified by SPE on three different days separated by 10 days, and repeatability by performing these determinations in consecutive analyses. Relative standard deviations (RSD) of the peak areas were 6% and 5% for reproducibility and repeatability, respectively. These values reflect the high performance achieved in the present study in terms of accuracy and precision. The limit of detection (LOD) was estimated to be 0.03 nmol/L, equivalent to 0.02 ng/mL, and was calculated as the concentration of peptide that gave a signal equal to 3 times the standard deviation of the blank. The LOQ was estimated at 0.17 nmol/L, equivalent to 0.10 ng/mL, by using 10 times the standard deviation of blank signal. With respect to the peptides LPLP and HLPL, the calibration curves provided linear results from 0.18 to 682.9 nmol/L ($R^2$ = 0.98) and 0.17 to 625.9 nmol/L ($R^2$ = 0.99), respectively. The LOD values for LPLP and HLPL were estimated at 1.13 ng/mL (0.50 nmol/L) and 0.11 ng/mL (0.22 nmol/L), respectively. The LOQ values for these peptides resulted in 1.67 ng/mL (3.71 nmol/L) and 0.36 ng/mL (0.75 nmol/L), respectively.

**Pharmacokinetics of Peptide HLPLP and Its Biotransformed Peptides LPLP and HLPL.** In the plasma samples collected at time 0, i.e., before HLPLP iv and oral administration, peptides HLPLP, HLPL, and LPLP were not detected. The two peptide fragments ($m/z$ 479.290, 439.284) corresponding to HLPL and LPLP respectively, were found in plasma from 1.5 min until 30 min after iv administration of HLPLP. However, after oral administration, peptide fragments were detected between 5 and 60 min although they could not be quantified at all time points. Figure 2 shows the extracted

ion chromatogram of the derived peptides, LPLP and HLPL, at different times after oral and iv administration, and their corresponding fragmentation patterns.

Mean plasma concentrations of peptide HLPLP and its biotransformed peptides LPLP and HLPL after single HLPLP iv administration and mean plasma concentrations of peptide HLPLP after single oral administration are shown in Figure 3.

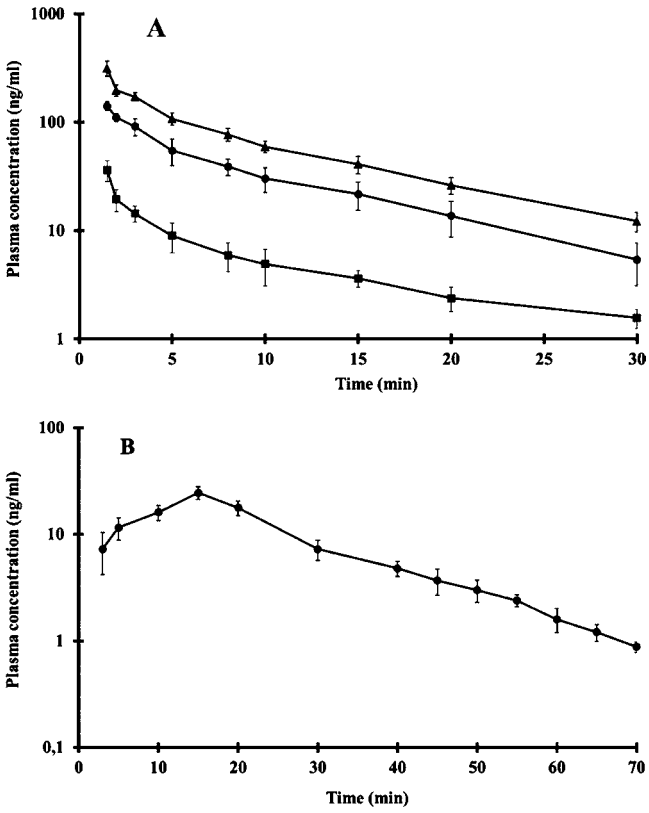

**Figure 3.** (A) Mean plasma concentrations of the peptides HLPLP (●), LPLP (▲), and HLPL (■) after single HLPLP intravenous dose of 4 mg/kg of body weight. (B) Mean plasma concentrations of the peptide HLPLP (●) after single oral dose of 40 mg/kg of body weight. Data represent mean ± SD values for six rats (i.e., six rats/time) (one-way ANOVA). Symbols without bars indicate that SD is within the symbols.

**Table 1. Kinetic Parameters for Peptide HLPLP and Its Biotransformed Peptides LPLP and HLPL after a Single HLPLP iv Dose of 4 mg/kg Body Weight in Rats**

| parameters[a] | HLPLP | LPLP | HLPL |
|---|---|---|---|
| $A_1$ (ng/mL) | 189 | 537 | 91.8 |
| $A_2$ (ng/mL) | 75.7 | 141 | 9.60 |
| $\alpha$ (1/min) | 0.64 | 0.77 | 0.90 |
| $\beta$ (1/min) | 0.09 | 0.08 | 0.06 |
| $T_{1/2\alpha}$ (min) | 1.08 | 0.90 | 0.77 |
| $T_{1/2\beta}$ (min) | 7.95 | 8.38 | 10.9 |
| $V_1$ (L/kg) | 15.1 | – | – |
| $V_2$ (L/kg) | 15.7 | – | – |
| $V_{ss}$ (L/kg) | 30.8 | – | – |
| $K_{12}$ (1/min) | 0.25 | 0.35 | 0.42 |
| $K_{21}$ (1/min) | 0.24 | 0.23 | 0.14 |
| $K_{10}$ (1/min) | 0.23 | 0.28 | 0.40 |
| AUC ($\mu$g min/L) | 1163 | 2404 | 253 |
| MRT (min) | 8.95 | 8.97 | 9.87 |
| CL (L/min/kg) | 3.41 | – | – |

[a]Kinetic parameters were calculated from the mean plasma concentration−time curves.

**Table 2. Kinetic Parameters for Peptide HLPLP after Oral Administration in Rats**

| parameters[a] | oral dose (40 mg/kg body weight) |
|---|---|
| $B_1$ (ng/mL) | 242 |
| $B_2$ (ng/mL) | 56.9 |
| $B_3$ (ng/mL) | 299 |
| $\alpha$ (1/min) | 0.29 |
| $\beta$ (1/min) | 0.06 |
| $K_a$ (1/min) | 0.25 |
| $T_{1/2\alpha}$ (min) | 2.38 |
| $T_{1/2\beta}$ (min) | 11.7 |
| $T_{1/2a}$ (min) | 2.79 |
| AUC ($\mu$g min/L) | 603 |
| $F$ (%) | 5.18 |
| CL (L/min/kg) | 3.41 |
| $C_{max}$ (ng/mL) | 20.1 |
| $T_{max}$ (min) | 11.8 |

[a]Kinetic parameters were calculated from the mean plasma concentration−time curve.

Analysis of plasma concentration-versus-time curves indicated a biphasic decrease after iv and oral administration. Good fit of the observed data for a two-compartment open model was obtained. The values of the kinetic parameters of HLPLP and its derived peptides LPLP and HLPL after iv administration of HLPLP are presented in Table 1. Values of the relevant kinetic variables that described absorption and disposition kinetics of HLPLP after oral administration are presented in Table 2.

## ■ DISCUSSION

The limited information available on the absorption of antihypertensive peptides derived from food proteins makes it difficult to interpret the functional properties of these bioactive peptides and to make an efficacy assessment as a new food supplement. These topics are commonly under debate for most functional ingredients.

Efficacy and safety assessment of many substances are normally extrapolated from animal data to humans. Laboratory animals, particularly rodents, are widely used for these evaluations. When several factors such as differences in species sensitivity are considered, kinetic variables are of major importance and should be taken into account in extrapolation of laboratory data to humans, because changes in various kinetic parameters are either easily determined experimentally or can be predicted with a reasonable accuracy. It is apparent that the principles of pharmacokinetics are indispensable in the overall assessment of human health risk.

Kinetic characteristics combined with dynamic patterns should be considered in the efficacy evaluation of peptide HLPLP. Preclinical pharmacokinetic information in experimental animals, such as the rat, is essential in designing further pharmacokinetic studies in humans which should be applied to the safe and effective use of this bioactive peptide.[23]

To the best of our knowledge, the present paper is the first report of plasma disposition of HLPLP peptide in rats using a selective analytical method to evaluate its pharmacokinetic profile. The LC-MS determination of the peptide was carefully optimized by selecting the parameters and analysis mode

providing the highest signal-to-noise ratio. The validation parameters used show that the method is reliable and sensitive and allow an adequate characterization of the disposition of peptide HLPLP in rat plasma. In addition, this analytical method also allowed the identification and the quantification of two derived fragments, LPLP and HLPL, from the hydrolysis of HLPLP by the action of plasma peptidases. However, the presence of shorter fragments derived from the action of plasma peptidases on HLPLP cannot be excluded. The inherent limitations of the mass spectrometry techniques to identify small peptides and the complexity of the matrix may have impaired detection of shorter fragments.

This study reports the kinetics of the peptide HLPLP after a single iv (4 mg/kg body weight) and oral (40 mg/kg body weight) administration in rats. Plasma disposition of HLPLP after iv and oral administration in rats as well as the appearance of the peptide fragments, LPLP and HLPL, after iv administration of HLPLP were best described by use of a two-compartment open model. Disappearance of the peptide from plasma was characterized by an initial rapid distribution phase followed by a rapid elimination phase. van der Pijl et al.[17] reported in pigs that elimination from plasma of the proline-rich tripeptides IPP, VPP, and LPP followed a two-compartment decay process only for 18 of the 30 observations. Therefore, it was concluded that the pharmacokinetic behavior of these peptides in pigs can be described with both one- and two-compartment models, although values for AIC for fitted peptide plasma concentrations after iv administration were lower using a two-compartment model.[17]

In the present study, after iv administration of HLPLP at 4 mg/kg, the distribution phase was rapid ($T_{1/2\alpha}$ = 1.08 min) and with a high value of $V_{ss}$ (30.79 L/kg) which suggests that the peptide HLPLP is distributed into extravascular tissues. The elimination half-life ($T_{1/2\beta}$) calculated after iv administration was 7.95 min, much longer than that reported in pigs for peptides IPP, LPP or VPP (range $T_{1/2el}$ = 2.5−3.1 min)[17] The $T_{1/2\beta}$ of peptide HLPLP increased from 7.95 min after iv to 11.7 min after oral administration. This may indicate that the plasma disposition of HLPLP after oral administration could be conditioned by the absorption process.

Peptide HLPLP was extensively biotransformed to peptides LPLP and HLPL in rats and, after iv administration, represented 206% and 21.8% of the HLPLP plasma concentrations, respectively, as calculated by the ratio between the AUC for LPLP or HLPL and AUC for HLPLP. This suggests that these biotransformed peptides might contribute to the physiological activity of the peptide. In this respect, further experiments aiming at the evaluation of the activity of these derived peptides are already in progress.

When orally administered, HLPLP was rapidly absorbed through the gastrointestinal tract in rats, as reflected in a $T_{1/2a}$ of 2.79 min. This $T_{1/2a}$ is comparable to that previously obtained in pigs for the tripeptides IPP, LPP, and VPP, where after a single oral dose of 4 mg/kg body weight, the absorption half-life ranged from 2.0 to 4.6 min.[17] The absorption rate of the peptide HLPLP was low with a $C_{max}$ of 20.1 ng/mL at 11.8 min ($T_{max}$) after an oral dose of 40 mg/kg body weight. However, it has to be highlighted that, as shown after iv administration, HLPLP is rapidly hydrolyzed by plasma peptidases into smaller fragments but were not considered in the calculation of absorption rate. In addition, it is hypothesized that other smaller fragments, tri- and dipeptides, might be released by the action of the peptidases, and due to the rapid degradation of the peptide, the effective absorption is underestimated. Nevertheless, the oral bioavailability found for HLPLP (5.18%) in rats was higher than that estimated for peptides IPP, LPP, and VPP in pigs, for which approximately 0.059−0.077% of the dose was absorbed.[17] Probably, the low bioavailability of HLPLP observed in the present study could be due to first-pass effect (metabolism in gastrointestinal tract or liver before reaching systemic circulation).[24,25] However, the absolute bioavailability of 5.18% after oral administration of the peptide HLPLP, which is not high for a small organic molecule, is valuable data for a peptide, given that they are subjected to extensive metabolism by peptidases before, during, and after the absorption process. The bioavailability of a chemical compound is a prime consideration in formulation approaches, especially when attempting to increase bioavailability through physico-chemical and technical manipulations in regard to the dosage form. Further studies in this concern should be conducted.

In summary, the present study indicates that when orally given, peptide HLPLP is absorbed and distributed throughout the body by the bloodstream. The kinetic characteristics of peptide HLPLP identified in this study warrant further research on possible new ways of supplementation in food to increase its absorption and time of exposure. The present pharmacokinetic information in rats can play an important role designing future kinetic studies in humans for assessing HLPLP dose−response relationship. In addition, this work reports an accurate analytical method for the determination of HLPLP, which also allowed the identification and quantification of some derived peptide fragments. Although the pentapeptide reaches the bloodstream, its rapid degradation in plasma affects the estimation of the kinetic parameters. This study raises, as well, the question about the final active form of dietary compounds, and specifically of dietary peptides, in the organism.

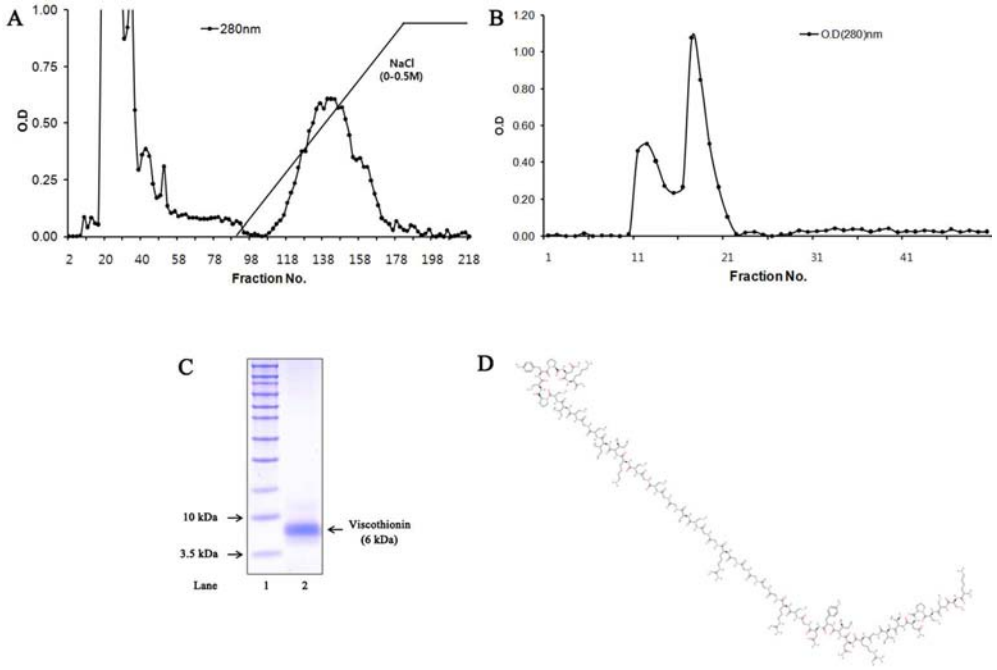

**Figure 1.** Isolation of viscothionin from Korean mistletoe: (A) activity-guided chromatography fractionation of viscothionin from Korean mistletoe using a CM Sepharose FF cation exchange column; (B) chromatographic isolation of viscothionin from the CM Sepharose−NaCl elution fraction using a Sephadex G-50 gel filtration column; (C) SDS-PAGE pattern of purified viscothionin obtained from mistletoe extracts (lanes: 1, molecular weight marker; 2, purified viscothionin (9 kDa cutoff)).

activity and, if so, what the underlying mechanisms of this activity are.

Thus, in the present study, we extracted and identified viscothionin from Korean mistletoe and investigated its effects on AMPK-mediated lipid metabolism as it relates to NAFLD using in vitro and in vivo models.

## MATERIALS AND METHODS

**Preparation of Korean Mistletoe.** Korean mistletoe, growing on oak trees, was collected in February 2013 in the Kangwon province of South Korea. Mistletoe plants were washed twice with distilled water before removal of the excess water by drying in the shade for 2 days, after which the plants were freeze-dried. Mistletoe leaves and branches were ground in a homogenizer (Hanil, Seoul, South Korea) and strained through a sieve with a mesh size of 500 $\mu$m. The resultant mistletoe powder was stored at −80 °C until use.

**Isolation of Viscothionin from Korean Mistletoe.** Isolation of viscothionin from mistletoe was performed as described previously with slight modification.[18] Briefly, 50 g of powdered mistletoe was mixed with 750 mL of 2% acetic acid and stirred overnight at 4 °C. The homogenate was centrifuged at 6000 rpm for 30 min, and the resulting supernatant was lyophilized. The dried matter was then dialyzed using membrane tubing (molecular weight cutoff 3.5 kDa) against 25 mM sodium acetate buffer (pH 4.8) at 4 °C. The dialysate was loaded on a CM Sepharose Fast Flow cation exchange column (20 × 4.6 cm) and washed with the same acetate buffer. Retained compounds were then eluted with a NaCl gradient (0−0.5 M), and 15 mL fractions were collected using a DC-1200 fraction collector (Eyela, Sunnyvale, CA, USA). The eluted fractions were monitored by determining their absorbance at 280 nm (Figure 1A), and the appropriate fractions were pooled for eventual lyophilization. Specifically, the pooled fractions were first dialyzed against distilled water using the same membrane tubing as described above. Next, the NaCl-free dialysate was relyophilized, dissolved in 1.5 mL of distilled water, and passed through a Sephadex G-50 gel filtration column (70 × 1.4 cm). Among the collected fractions, the fractions in the second peak, which showed cytotoxic activity (Figure 1B), were pooled and concentrated by centrifugation using a centrifugal filtration unit with a molecular weight cutoff of 9 kDa (Thermo Scientific, Rockford, IL, USA). The preparation of isolated viscothionin resulted in a single polypeptide band, approximately 6 kDa in size, as determined by SDS-PAGE analysis (Figure 1C).

**Polyacrylamide Gel Electrophoresis and Immunoblotting.** Polyacrylamide gel electrophoresis of isolated viscothionin was carried out using precast 12% NuPAGE Bis-Tris gels (Invitrogen, San Diego, CA, USA) at 100 V for 1 h in NuPAGE 2-(*N*-morpholino)-ethanesulfonic acid (MES) sodium dodecyl sulfate running buffer (Invitrogen) according to the manufacturer's instructions. A SeeBlue Plus2 prestained standard protein marker (Invitrogen) was used to determine the apparent molecular masses of the extracted and concentrated mistletoe proteins. Gels were stained with Coomassie Brilliant Blue R-250 for visualization.

**Chemicals.** DMSO, oleic acid (OA), and compound C were purchased from Sigma (St. Louis, MO, USA). Primary antibodies for AMPK, phosphorylated AMPK (pAMPK), ACC, phosphorylated ACC (pACC), and $\beta$-actin were purchased from Cell Signaling (Beverly, MA, USA). Secondary antibodies (horseradish peroxidase-conjugated anti-rabbit, anti-goat, and anti-mouse IgG antibodies) were obtained from Millipore (Temecula, CA, USA). Cell culture medium and other in vitro ingredients were purchased from Hyclone (Logan, UT, USA).

**Cell Culture.** HepG2 cells (American Type Culture Collection, Manassas, VA, USA) were cultured at 37 °C under a humidified atmosphere supplemented with 5% $CO_2$. Cells were routinely subcultured twice per week and maintained in Dulbecco's modified Eagle's medium (DMEM) supplemented with 10% fetal bovine serum (FBS), 100 U/mL penicillin, 100 $\mu$g/mL streptomycin, and 5.5 mM D-glucose. Upon reaching 70% confluence, medium on HUVEC cells was replaced with serum-free DMEM overnight, and cells were used as described previously.[19]

**Cell Viability Assay.** Cell survival was determined using a 3-(4,5-dimethylthiazoldimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) assay kit from Sigma. HepG2 cells were seeded in 48-well plates at a density of $2.0 \times 10^4$ cells per well, incubated for 48 h, and treated with various concentrations (0.5−10 $\mu$M) of viscothionin for

24 h. After the incubation period, 20 μL of the kit solution was added to each well. Plates were then incubated for 3 h at 37 °C in 5% $CO_2$. The resultant formazan crystals were subsequently dissolved in MTT solubilization solution, and the absorbance of each well at 540 nm was determined using a PowerWave2 multiplate reader spectrophotometer (Bio-Tek Instruments, Winooski, VT, USA).

**Lipid Accumulation Analysis.** Lipid accumulation was analyzed using an Oil Red O staining kit according to the manufacturer's suggested protocol (Lifeline Cell Technology, Carlsbad, CA, USA). Oil Red O-stained cells were imaged with an Observer A1 microscope (Carl Zeiss, Jena, Germany) at 100× magnification. After image acquisition, accumulated intracellular Oil Red O dye was eluted with isopropanol and quantified by determining its optical absorbance at 540 nm using a PowerWave2 multiplate reader spectrophotometer (Bio-Tek Instruments).

**Animals and in Vivo Experimental Design.** Forty male C57BL/6J mice, approximately 6 weeks of age, were purchased from Dae-han Biolink (Daejeon, South Korea). All mice were verified to be free of murine viruses, bacteria, and parasites and were maintained in microisolator cages under pathogen-free conditions on a 12 h light/dark schedule for 1 week. Mice were randomly divided into two groups and fed either a normal diet ($n$ = 8) or a high-fat diet (HFD, $n$ = 32) containing 45% of its calories from fat. HFD mice were fed for 8 weeks to induce obesity. After 8 weeks, mice receiving the normal diet were orally administered 0.1 mL of saline daily, whereas HFD-fed mice were randomly divided into four subgroups. Each subgroup was orally administered either 0.1 mL of saline ($n$ = 8), 1 mg/kg viscothionin in 0.1 mL of saline ($n$ = 8), 10 mg/kg viscothionin in 0.1 mL of saline ($n$ = 8), or 10 mg/kg simvastatin in 0.1 mL of saline daily for 4 weeks. Treatments were maintained while the mice were fed a HFD from weeks 0 to 4. All mice had free access to food and water. Body weight for each mouse was measured 1 and 4 weeks after beginning the treatments. At the end of the experimental period, food was withheld for 12 h and the mice were anesthetized with ether. Subsequently, cardiac punctures were performed, and the mice were perfused with cold physiological saline. The livers were then harvested, weighed, photographed, and processed. Livers were processed for histology, real-time RT-PCR, immunoblotting, and other analyses; samples were stored at −80 °C until needed for analysis. All animals were cared for in accordance with the Chonbuk National University institutional guidelines for the care and use of experimental animals.

**Histopathology.** Trimmed liver tissues were fixed in 10% normal buffered formalin for 24 h. All of the fixed samples were embedded in paraffin and cut into 4−5 μm sections. The resulting sections were deparaffinized with xylene, rehydrated with a graded alcohol series, and stained with hematoxylin and eosin (H&E). Tissue histopathology was then evaluated using a conventional light microscope (magnification 200×; Carl Zeiss). H&E-stained sample sections were imaged, and the areas of the stained regions, in pixels, were quantified using the Image Pro analysis program.

**Measurement of Intracellular Triglyceride Contents.** Intracellular triglyceride contents were measured using a commercial triglyceride assay kit (BioAssay Systems, Hayward, CA, USA) according to the manufacturer's instructions. Briefly, HepG2 cells were pretreated with viscothionin at various concentrations (0, 1, or 5 μM) for 1 h before treatment with 10 mM OA in conditioned medium for 48 h. Additionally, cells were pretreated either with or without compound C (20 μM) or viscothionin (5 μM) for 1 h and then treated with OA for 48 h. After treatment, cells were washed twice with phosphate-buffered saline (PBS) prior to the addition of 75 μL of homogenizing solution (154 mM KCl, 1 mM EDTA, 50 mM Tris, pH 7.4) to lyse the cells. The resultant cell lysate was centrifuged at 3000$g$ for 5 min at 4 °C to remove cellular lipids. The supernatants were then assayed for triglyceride and protein contents. Triglyceride contents were normalized to protein concentrations, which were determined from a standard BSA curve. Results were expressed as milligrams of triglyceride per milligram of cellular protein. To evaluate the triglyceride contents in liver tissues, the tissues were homogenized in 1 mL of PBS, and the protein concentrations of the resultant lysates were determined. Homogenates were extracted with 5 mL of a chloroform/methanol mixture, vortexed vigorously, allowed to separate into two phases, and centrifuged at 2500 rpm for 15 min at 4 °C. The total hepatic triglyceride concentrations were normalized to the respective protein concentrations and are presented as milligrams of lipid per gram of tissue protein.

**Immunoblotting.** Total proteins from HepG2 cell lysates and liver tissue lysates were subjected to sodium dodecyl sulfate−polyacrylamide gel electrophoresis using 12−15% gels. Proteins were then electrophoretically transferred to polyvinylidene difluoride membranes (Bio-Rad Laboratories, Hercules, CA, USA). Membranes were blocked in 5% skim milk in PBS and then incubated with primary antibodies, which were diluted 1:500 in 1% skim milk in PBS overnight at 4 °C. Membranes were then incubated with peroxidase-conjugated goat anti-rabbit IgG antibodies (1:5000; Millipore, Bedford, MA, USA) for 1 h. Immunoreactive bands were visualized with SuperSignal West Dura Extended Duration Substrate (Thermo Scientific, San Jose, CA, USA) and analyzed using a chemiImager analyzer system (Alpha Innotech, San Leandro, CA, USA).

**RNA Preparation and Real-Time RT-PCR.** Total RNA was isolated from cells and precipitated with Ribo EX (Geneall, Daejeon, South Korea) according to the manufacturer's instructions. mRNA was reverse transcribed to cDNA using a Maxime RT PreMix kit (Intron, Seongnam, South Korea) according to the manufacturer's instructions. For real-time RT-PCR, cDNA was amplified using a Mastercycler Gradient 5331 thermal cycler (Eppendorf, Germany). Real-time PCR runs were monitored by measuring the fluorescence signal after each cycle with an ABI Step One Plus Sequence Detection System (Applied Biosystems, Singapore). Specific primers for each gene were designed using Primer Express software (Applied Biosystems). The following sense and antisense primers were used for real-time RT-PCR quantification in HepG2 cells (forward and reverse): 5′-GGAGCCATGGATTGCACTTT-3′ and 5′-TCAAATAGGCCAGGGAAGTCA-3′ for SREBP-1; 5′-CGTCCTCTTCCCCGCCACT-3′ and 5′-GCACCACATCCTCAAACACCACA-3′ for FAS; and 5′-TCTCCTCTGACTTCAACAGCGAC-3′ and 5′-CCCTGTTGCTGTAGCCAAATTC-3′ for glyceraldehyde-3-phosphate dehydrogenase (GAPDH), which was used as a housekeeping gene. The following sense and antisense primers were used in real-time RT-PCR for quantification in liver tissue (forward and reverse): 5′-GCAGCCACCATCTAGCCTG-3′ and 5′-CAGCAGTGAGTCTGCCTTGAT-3′ for SREBP-1; 5′-CCTGGATAGCATTCCGAACCT-3′ and 5′-AGCACATCTCGAAGGCTACACA-3′ for FAS; and 5′-GCATGGCCTTCCGTGTTC-3′ and 5′-GATGTCATCATACTTGGCAGGTTT-3′ for GAPDH, which was used as a housekeeping gene. All experiments were performed at least three times.

**Statistical Analysis.** Results are presented as the mean ± standard error. Data were analyzed using Student's $t$ test (for two groups), one-way ANOVA, and Tukey's test (for more than two groups). $P$ values <0.05 were considered statistically significant. All analyses were performed using the Statistical Package for Social Sciences, version 13.0, for Windows (SPSS, Inc., Chicago, IL, USA).

## RESULTS

**Cell Viability in HepG2 Cells Treated with Viscothionin.** Figure 1D shows the structure of viscothionin. Before proceeding with the main experiment, we evaluated the effect of viscothionin on HepG2 cell viability using an MTT assay. We found that viscothionin was not significantly cytotoxic at concentrations <10 μM (Figure 2). Thus, viscothionin concentrations ≤5 μM, which were found to be nontoxic in HepG2 cells, were used in subsequent experiments.

**Viscothionin Increases Phosphorylation of the AMPK/ACC Signaling Pathway.** AMPK plays a critical role in the regulation of lipogenesis in the liver. To examine whether AMPK is activated by viscothionin, the phosphorylation status of AMPK was analyzed by immunoblotting cellular extracts after various treatments. As shown in Figure 3A, viscothionin treatment increased the levels of phosphorylated AMPK and

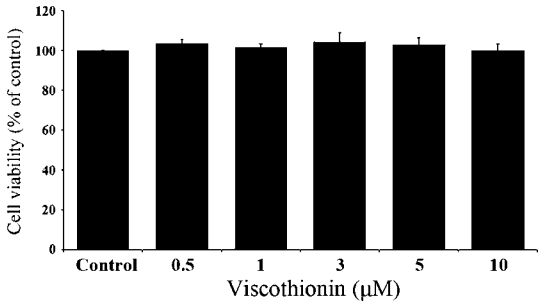

**Figure 2.** Viability of HepG2 cells treated with viscothionin. HepG2 cells were treated with various concentrations of viscothionin (0.5−10 $\mu$M) for 24 h and analyzed by MTT assay.

ACC compared with untreated controls. Importantly, this effect was dose-dependent, although 10 $\mu$M viscothionin did not stimulate AMPK or ACC phosphorylation to the same extent as 5 $\mu$M viscothionin. We hypothesized that this apparent discrepancy could be explained by different kinetics of phosphorylation associated with the two doses. Specifically, we confirmed that phosphorylation occurs more rapidly and transiently with high doses of viscothionin compared with low doses of viscothionin (data not shown), which likely explains the apparent inconsistency of the dose-dependent results. A number of previous studies have established that OA-treated HepG2 cells are an appropriate in vitro model of NAFLD.[20−22] On the basis of these studies, we used OA (10 mM) to induce lipid accumulation in HepG2 cells. As shown in Figure 3B, the levels of phosphorylated AMPK and ACC were decreased by treatment with 10 mM OA, whereas treatment with viscothionin counteracted the OA-induced reduction of phosphorylated AMPK and ACC in a dose-dependent manner. These results indicated that viscothionin was able to activate the AMPK signaling pathway. To determine whether viscothionin acts via AMPK, HepG2 cells were pretreated for 1 h with compound C, a selective AMPK inhibitor. The levels of phosphorylated AMPK and ACC in cells treated with compound C alone were significantly decreased compared with those in control cells. As predicted, pretreatment with compound C counteracted the viscothionin-induced increase in levels of phosphorylated AMPK and ACC in the OA-treated group (Figure 3C). Taken together, these results suggest that viscothionin counteracts the effect of OA on HepG2 cells by activating AMPK.

**Viscothionin Attenuates OA-Induced Lipid Accumulation in HepG2 Cells via Activation of the AMPK Signaling Pathway.** To verify the inhibitory effect of viscothionin on OA-induced lipid accumulation, HepG2 cells were treated with the indicated concentrations of viscothionin in the presence of OA for 48 h. As shown in Figure 4A, lipid accumulation was visualized with Oil Red O, which stains lipid droplets red in HepG2 cells. Quantification of intracellular lipids revealed that viscothionin treatment significantly attenuated OA-induced lipid accumulation in a dose-dependent manner. Moreover, treatment with compound C significantly reduced the effect of viscothionin in OA-treated cells. Consistent with previous results, cellular triglyceride levels (Figure 4B) and the expression of lipogenic genes such as SREBP-1 (Figure 4C) and FAS (Figure 4D) were reduced in viscothionin-treated HepG2 cells compared with OA-treated HepG2 cells. Moreover, compound C reduced the effects of viscothionin on cellular triglyceride concentration as well as on the expression of SREBP-1 and FAS in OA-treated HepG2 cells. These results are consistent with those presented in Figure 4A and suggest that viscothionin antagonizes OA-induced hepatic lipid accumulation via activation of the AMPK signaling pathway.

**Viscothionin Treatment Improves Some Symptoms of NAFLD.** To validate our in vitro results in vivo, we utilized the HFD-induced obese mouse model of NAFLD. Initial histopathological examinations indicated that viscothionin was not cytotoxic to any of the organs examined, including the liver, kidney, and spleen in normal mice (data not shown). As shown

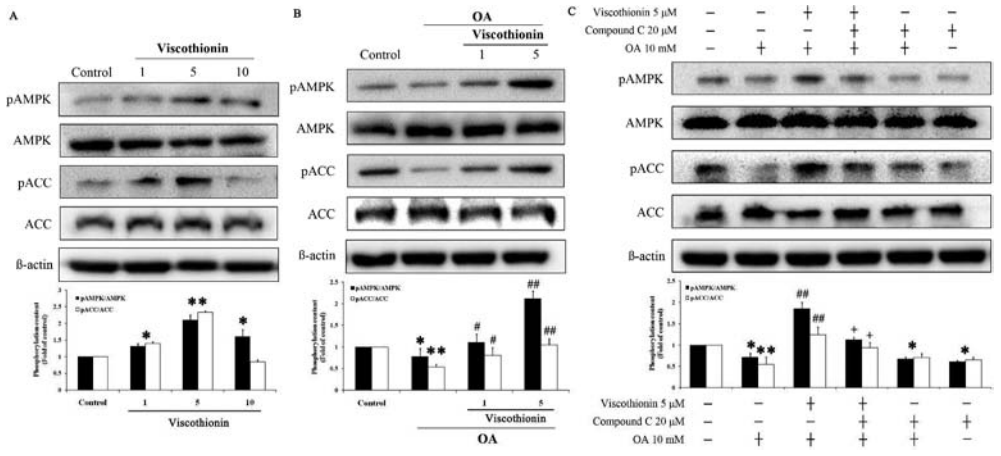

**Figure 3.** Effects of viscothionin on the levels of phosphorylated AMPK and ACC in HepG2 cells. Immunoblotting analysis was used to determine the levels of phosphorylated AMPK and ACC. (A) HepG2 cells were treated with viscothionin (1, 5, or 10 $\mu$M) for 1 h. (B) HepG2 cells were pretreated with the indicated concentrations of viscothionin (1 or 5 $\mu$M) for 1 h and then incubated with 10 mM OA for 1 h. (C) HepG2 cells were treated with compound C (20 $\mu$M) for 1 h and then incubated with or without 5 $\mu$M viscothionin for an additional 1 h. Cells were then incubated with OA for 1 h. The intensities of the control bands were set to 100%, and the relative intensities of all other bands were calculated. Protein levels were normalized to the levels of total AMPK or ACC as appropriate. Immunoblots were analyzed by densitometry; data are presented as relative intensity units. Data are presented as the mean ± SEM ($n$ = 3). (*) $p < 0.05$ compared with the control; (**) $p < 0.01$ compared with the control; (#) $p < 0.05$ compared with the OA-alone group; (##) $p < 0.01$ compared with the OA-alone group; (+) $p < 0.05$ compared with the viscothionin + OA group.

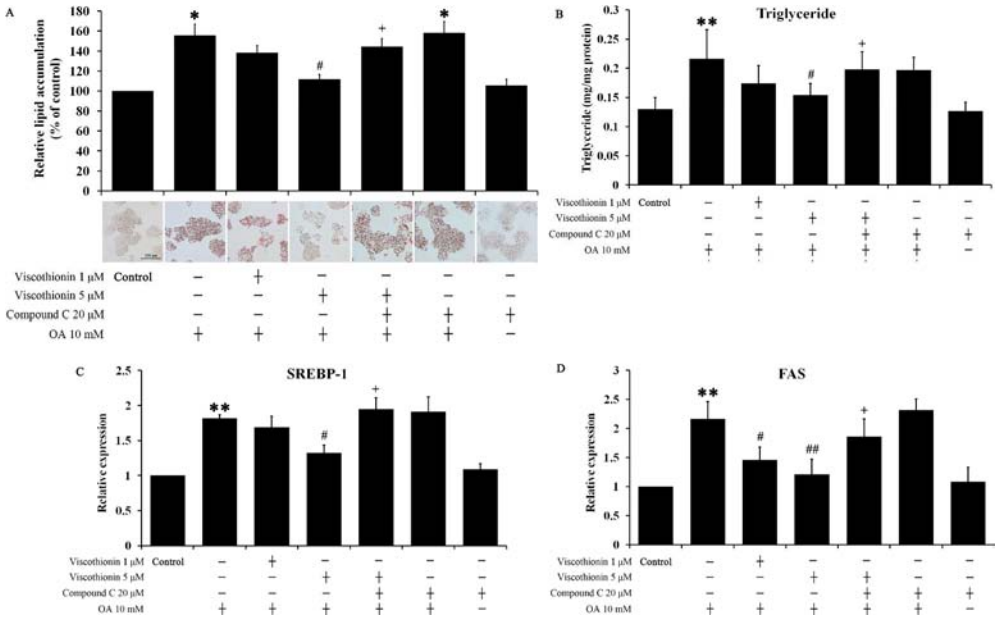

**Figure 4.** Viscothionin-mediated effects on AMPK activation, lipid accumulation, and expression of lipogenic genes in OA-treated HepG2 cells. HepG2 cells were treated with the AMPK inhibitor compound C (20 $\mu$M) for 1 h. Cells were then incubated with or without 5 $\mu$M viscothionin for an additional 1 h followed by OA for 24 h. (A) Intracellular lipid droplets in HepG2 cells were stained with Oil Red O and observed at 200× magnification. Lipid droplets were quantified by measuring the resultant absorbance at 540 nm. (B) Intracellular triglyceride contents were measured. The expression levels of the lipogenic genes SREBP-1 (C) and FAS (D) were examined by real-time RT-PCR. Data are presented as the mean ± SEM ($n$ = 3). (*) $p < 0.05$ compared with the control; (**) $p < 0.01$ compared with the controlL (#) $p < 0.05$ compared with the OA-alone group; (##) $p < 0.01$ compared with the OA-alone group; (+) $p < 0.05$ compared with the 5 $\mu$M viscothionin + OA group.

in Figure 5A,B, significant differences in the average body and liver weights of the experimental groups were observed at the end of the study. To investigate the effects of viscothionin in the liver, HFD-induced obese mice (1 week of treatment) were used at 14 weeks. Specifically, these mice were administered either viscothionin or simvastatin orally until reaching 17 weeks (4 weeks of treatment). Viscothionin treatment decreased the average body weight (10 mg/kg, 28.5 ± 1.1) and liver weight (10 mg/kg, 2.62 ± 0.22) in HFD-induced obese mice compared with the saline control group. These measurements were similar to those of mice treated with 10 mg/kg simvastatin, a commercially available antiobesity agent. Moreover, notable morphological changes were observed in the gross appearances of the livers from each experimental group. Compared with those of the control group, livers from the saline-only group were significantly enlarged and had a pale appearance. These apparent abnormalities of the liver, reminiscent of those found in NAFLD, were improved in a dose-dependent manner by viscothionin (Figure 5C). Accordingly, histological evaluation with H&E staining revealed significant differences among the groups (Figure 5C). Specifically, liver sections in the saline-only group exhibited typical ballooning signs of degeneration, whereas these histological changes in the liver, which were digitized from section images, were almost completely prevented by treatment with viscothionin in a dose-dependent manner. These results suggested that viscothionin improved the pathogenesis of NAFLD in HFD-induced obese mice. Additionally, several factors involved in lipid metabolism were analyzed in hepatic tissue. The levels of triglycerides in the livers of the saline-only group were significantly elevated compared to those in the normal control group (Figure 5D). Furthermore, viscothionin treatment (10 mg/kg) led to a marked decrease in the levels of liver triglycerides (about 0.5-fold) compared with the saline-only group. The liver mRNA expression of several factors involved in lipid metabolism, namely SREBP-1 and FAS, were also examined (Figure 5E,F). The expression levels of SREBP-1 and FAS in the saline-only group were increased 6.8- and 17.3-fold, respectively, compared with those of the normal control group. On the other hand, viscothionin treatment (10 mg/kg) resulted in 0.6- and 0.87-fold lower levels of SREBP-1 and FAS, respectively, compared with the saline-only group. Taken together, these results indicated that viscothionin exerts effects similar to those of simvastatin, a known antiobesity agent, against HFD-induced NAFLD.

**Viscothionin-Mediated Effects on AMPK Activation in NAFLD.** To extend our in vitro results and confirm whether the hypolipidemic effects of viscothionin were mediated by AMPK, we examined the levels of phosphorylated AMPK in liver tissues. Viscothionin treatment increased the levels of ACC and AMPK phosphorylation in a dose-dependent manner in the livers of the experimental groups compared with the livers in the saline-only group (Figure 6). These data suggested that viscothionin also exerts hypolipidemic effects against NAFLD via AMPK activation in vivo. Additionally, we confirmed that viscothionin and simvastatin exert similar effects on AMPK phosphorylation. Thus, we concluded that viscothionin exerts effects against NAFLD similar to those of simvastatin.

## DISCUSSION

NAFLD is globally recognized as a hepatic sign of lipid metabolic syndrome and is rising as one of the most general causes of chronic liver disease.[23] NAFLD stimulates progression of various liver diseases such as simple hepatic steatosis to steatohepatitis, advanced fibrosis, and cirrhosis.[24] Although the pathogenic mechanisms by which steatosis advances to early and advanced stages of NAFLD have not yet been clearly identified, the "two-hit" hypothesis[25] is now generally accepted.

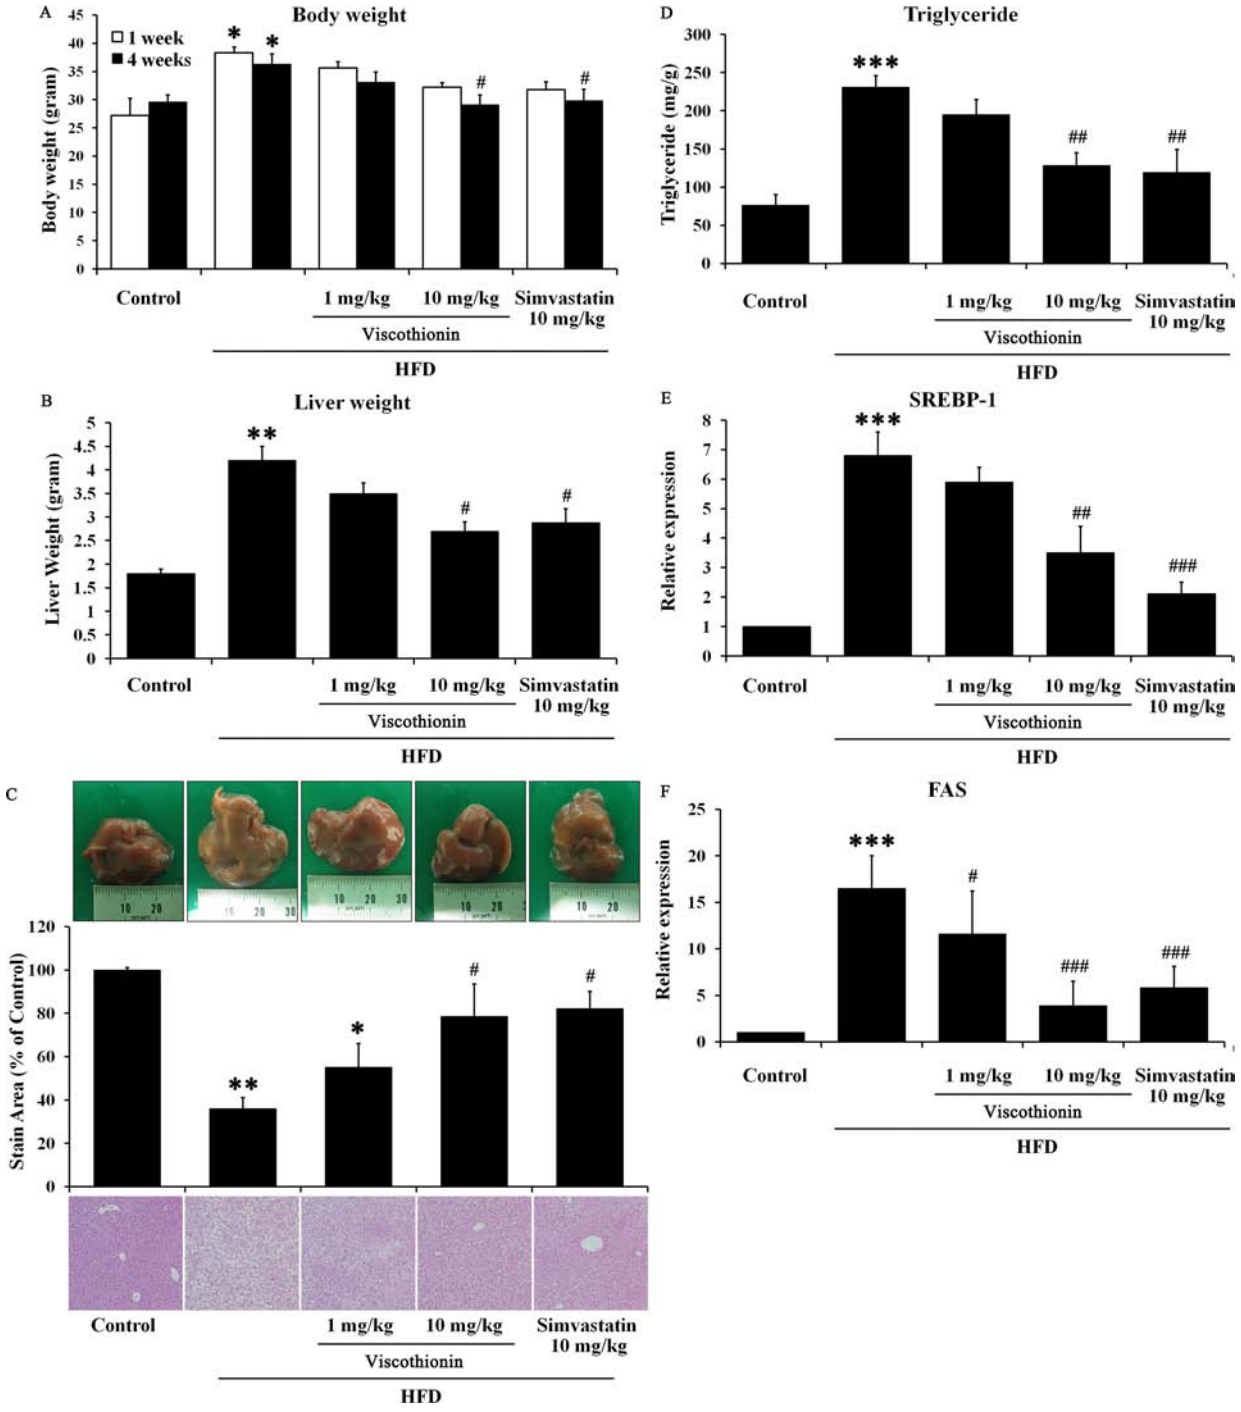

**Figure 5.** Effects of viscothionin on a mouse model of NAFLD. (A) Body weights were determined at 14 weeks (1 week of treatment) and 17 weeks (4 weeks of treatment). (B) Liver weights for all experimental mice were determined at 17 weeks. Panel C shows gross appearances and histological analyses of liver sections from each experimental group. Liver sections were obtained at 17 weeks. H&E staining (magnification 200×) was quantified by determining the stained area, in pixels, in each image using the Image Pro analysis program. (D) Hepatic concentrations of triglycerides were measured in all experimental groups. The expression levels of SREBP-1 (E) and FAS (F) in livers were determined by real-time RT-PCR. Data are presented as the mean ± SEM ($n$ = 8). (*) $p < 0.05$ compared with the control; (**) $p < 0.01$ compared with the control; (***) $p < 0.001$ compared with the control; (#) $p < 0.05$ compared with the saline-only group; (##) $p < 0.01$ compared with the saline-only group; (###) $p < 0.001$ compared with the saline-only group.

Hepatic lipid accumulation, which was thought to be an initial developmental factor, represents the "first-hit" in this progression and can therefore be an early indication of NAFLD. Thus, reducing hepatic lipid accumulation is thought to be an important strategy for preventing and treating NAFLD.

In the present study, we examined whether viscothionin, a compound isolated from Korean mistletoe, could improve NAFLD in both in vitro and in vivo models. Moreover, we explored the possible mechanisms of action of viscothionin, in particular the role of AMPK. Mistletoe is a semiparasitic plant that grows on many different kinds of deciduous trees all over

dx.doi.org/10.1021/jf503535s | J. Agric. Food Chem. 2014, 62, 11876−11883

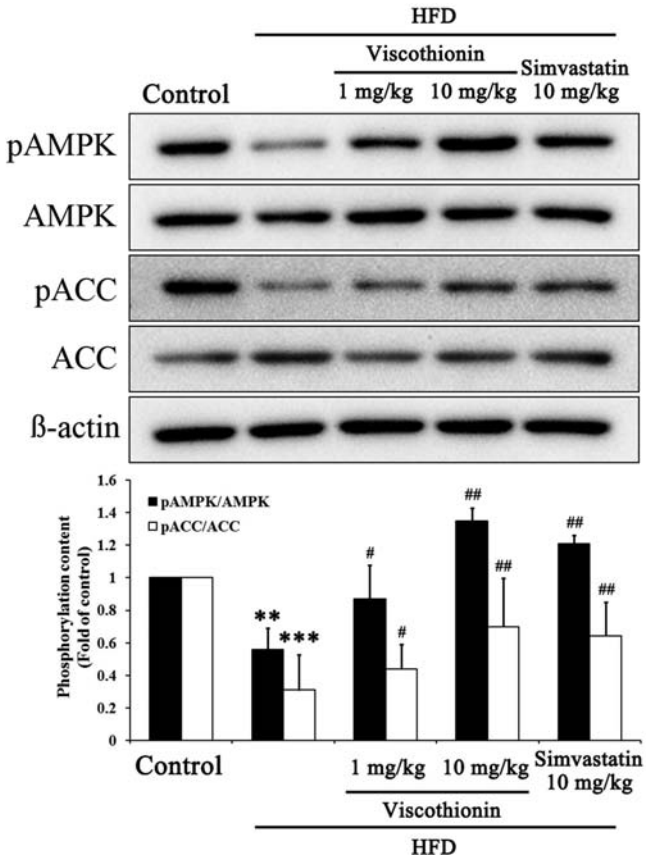

**Figure 6.** Effects of viscothionin on AMPK activation in an animal model of NAFLD. Levels of pAMPK, AMPK, pACC, ACC, and $\beta$-actin in liver lysates were determined by immunoblot analysis. The intensities of the control bands were set to 100%, and the relative intensities of all other bands were calculated. Protein levels were normalized to that of total AMPK or ACC as appropriate. Immunoblots were analyzed by densitometry. Data are presented as relative intensity units as the mean ± SEM ($n$ = 8). (**) $p < 0.01$ compared with the control; (***) $p < 0.001$ compared with the control; (#) $p < 0.05$ compared with the saline-only group; (##) $p < 0.01$ compared with the saline-only group.

the world. Importantly, mistletoe has been investigated as an alternative treatment for many diseases including cancer, hypertension, cardiac vascular disease, epilepsy, arthritis, menopausal symptoms, and rheumatism.[13−16] Likewise, several recent studies have demonstrated that Korean mistletoe has potential anticancer[16] and antiobesity effects.[17] On the basis of these findings, we purified potential candidate molecules from Korean mistletoe and confirmed that viscothionin is the active component involved in lipid metabolism. Moreover, we investigated the effect of viscothionin on the liver, which is the organ most vulnerable to excessive lipid accumulation.

AMPK is a heterotrimeric protein consisting of one catalytic subunit ($\alpha$) and two noncatalytic subunits ($\beta$ and $\gamma$). Phosphorylation of AMPK on threonine 172 (Thr172) of the $\alpha$-subunit changes the cellular energy ratio and leads to AMPK activation. The activity of ACC, an enzyme that converts acetyl-CoA into malonyl-CoA and thus provides substrates for fatty acid synthesis,[27] can be regulated by AMPK-mediated phosphorylation,[26] and phosphorylation of ACC potently reduces lipogenesis, because the carboxylase activity of ACC is suppressed.[26] These studies suggest that AMPK signaling pathways are potential targets for the treatment of metabolic disorders such as insulin resistance and NAFLD.[27] Thus, we examined the relationship between AMPK activation and viscothionin. As expected, viscothionin increased the levels of phosphorylated AMPK and ACC in a dose-dependent manner (Figure 3A). Viscothionin also increased the levels of phosphorylated AMPK and ACC, even in the presence of OA, which normally reduces the levels of phosphorylated AMPK and ACC (Figure 3B). Moreover, compound C, a known inhibitor of AMPK, significantly reduced the effects of viscothionin on the phosphorylation of AMPK and ACC (Figure 3C). These results indicated that viscothionin acts via the AMPK signaling pathway. We also confirmed the presence of lipid accumulation in our model of NAFLD. As shown in Figure 4, OA-induced lipid accumulation was attenuated by 5 $\mu$M viscothionin. Additionally, we also observed reduced SREBP-1 gene expression and down-regulation of its target adipogenic gene, FAS, in viscothionin-treated HepG2 cells (Figure 4C,D). SREBP-1 is an important transcription factor that stimulates several adipogenic enzymes related in liver fatty acid synthesis[28] and also regulates the expression of ACC. AMPK activation has been shown to directly inhibit ACC activity and to also indirectly inhibit FAS expression via suppression of SREBP-1.[29] Consistent with our immunoblotting data, compound C significantly attenuated the effects of viscothionin on SREBP-1 and FAS gene expression in OA-treated HepG2 cells. Together, these findings indicated that viscothionin exerts its lipid-reducing effects via the AMPK signaling pathway.

We confirmed the effects of viscothionin in an in vivo model of NAFLD. As expected, viscothionin treatment resulted in notably improved liver histology in mice with obesity-induced NAFLD. Moreover, the average body weight of the viscothionin-treated group (10 mg/kg) was lower than that of the saline-treated group (Figure 5A). Weight, gross abnormalities, and ballooning degeneration in the liver are considered to be early indicators of NAFLD.[23] Consistent with these observations and our results to this point, we found that viscothionin treatment resulted in reduced liver weight, improvements in gross abnormalities, and reduced ballooning degeneration of the liver in mice with NAFLD compared with mice with NAFLD treated with saline alone (Figure 5B,C). As expected, viscothionin treatment also reduced the level of hepatic triglycerides (Figure 5D), high levels of which are a marker of lipid metabolism in NAFLD.[30] Promotion of triglyceride synthesis has been proposed to excessively provoke other deleterious reactions such as lipid peroxidation.[31] Moreover, the expression levels of SREBP-1 and FAS in the liver were also reduced in the viscothionin-treated group. Viscothionin also significantly increased the levels of phosphorylated AMPK and ACC compared with the saline-only group in a dose-dependent manner, which was consistent with our in vitro data. On the basis of these results, we concluded that viscothionin exerts its anti-NAFLD actions via activation of AMPK.

In conclusion, this study demonstrated that viscothionin isolated from Korean mistletoe decreases hepatic lipid accumulation. The beneficial effect of viscothionin was shown to involve AMPK-mediated regulation of fatty acid metabolism and was confirmed in both in vitro and in vivo models of NAFLD. Thus, viscothionin appears to exert notable hepatic protective and therapeutic properties against NAFLD, and we obtained insight into the underlying molecular mechanisms regarding the effects of viscothionin. Taken together, our

findings indicate that viscothionin is a novel potential therapeutic agent for the treatment of NAFLD.

Table 1. Sequences of the Primers Used for PCR[a]

| gene | forward (5′−3′) | reverse (5′−3′) |
|---|---|---|
| LDL receptor | CAGCTCTGTGTGAACCTGGA | TTCTTCAGGTTCGGGATCAG |
| CYP7A1 | CACCATTCCTGCAACCTTTT | GTACCGGCAGGTCATTCAGT |
| GLUT-4 | GACATTTGGCGGAGCCTAAC | TAACTCCAGCAGGGTGACACAG |
| PPAR-$\alpha$ | GGTCATACTCGCAGGAAA | AGCAAATTATAGCAGCCAC |
| PPAR-$\gamma$ | TCAGGGCTGCCAGTTTCG | GCTTTTGGCATACTCTGTGATCTC |
| $\beta$-actin | TGTTGTCCCTGTATGCCTCT | TAATGTCACGCACGATTTCC |

[a]LDL receptor, low-density lipoprotein receptor; CYP7A1, cholesterol 7$\alpha$-hydroxylase; GLUT-4, glucose transporter-4; PPAR-$\alpha$, peroxisome proliferator-activated receptor-$\alpha$; and PPAR-$\gamma$, peroxisome proliferator-activated receptor-$\gamma$.

[certificate number SCXK (Su) 2011-0003, Changzhou, China]. All animals were housed under the conditions of 23 ± 1 °C and 12/12 h of light/dark cycle with *ad libitum* food and water for 1 week before commencement of the animal experiment. All animals used in this study were cared for in accordance with the Guidelines for the Care and Use of Laboratory Animals published by the U.S. National Institutes of Health (NIH Publication 85-23, 1996), and all experimental procedures were approved by the Nanchang University Medical College Animal Care Review Committee.

**Experimental Design.** After acclimation, 10 rats were fed a standard normal chow diet and the others were fed with a high-fat diet. The high-fat diet consists of 66.5% (w/w) normal chow diet, 10% lard, 20% sucrose, 2.5% cholesterol, and 1% sodium cholate.[14] After 8 weeks of dietary manipulation, rats fed a high-fat diet were fasted for 12 h and injected with STZ (Sigma Chemical Co., St. Louis, MO) at the dose of 30 mg/kg of body weight into the tail vein to induce type 2 diabetes. Rats fed on a standard normal chow diet received an equivalent volume of vehicle. Hyperglycemia was confirmed by the levels of fasting blood glucose (FBG) higher than 11.1 mmol/L at day 7 after STZ injection.

A total of 40 type 2 diabetic rats were randomly divided into four groups ($n$ = 10 in each group) as follows: untreated diabetes mellitus (DM), DM treated with $10^9$ CFU/mL *L. plantarum* NCU116 (NCU), DM treated with fermented carrot juice with *L. plantarum* NCU116 (FCJ, $10^9$ CFU/mL), and DM treated with non-fermented carrot juice (NFCJ). A total of 10 rats fed on a standard normal chow diet served as a non-diabetes mellitus group (NDM) and received the same volume of saline. All treatments were conducted with 10 mL/kg of body weight by oral administration once daily over a 5 week period.

**Measurement of Metabolites in Carrot Juices.** $\beta$-Carotene,[17] short-chain fatty acid (SCFA),[18] and other organic acids (citric acid, malic acid, and lactic acid)[19] in the carrot juices were measured as described in previous reports. Amino acids in the juices were determined by an amino acid analyzer (L-8900, Hitachi, Japan).

**Measurements of Blood Glucose, Lipids, and Hormones.** At the end of the 5 week experimental period, blood glucose levels in the rats were determined following food deprivation for 12 h by Accu-Chek Performa (Roche Diagnostics, Mannheim, Germany). Then, the rats were humanly anesthetized with chloral hydrate via peritoneal injection. Blood samples were obtained by cardiac puncture and centrifuged at 1000*g* for 10 min, and the serum was recovered for further analyses. Samples of liver, pancreas, kidney, skeletal muscle, and feces in colon were quickly removed and stored at −80 °C until use. Levels of serum lipids, including total cholesterol (TC), high-density lipoprotein cholesterol (HDL-C), low-density lipoprotein cholesterol (LDL-C), and triacylglycerols (TG), as well as hormones, including serum insulin, leptin, and glucagon, were measured by a radioimmunoassay method, as described previously.[13] Contents of glucagon-like peptide (GLP)-1 and peptide tyrosine-tyrosine (PYY) were determined by enzyme-linked immunosorbent assay (ELISA) kits (Xinyu Biotech Co., Shanghai, China).

**Determination of Serum Oxidative Stress and Kidney Function.** Activities of superoxide dismutase (SOD), glutathione peroxidase (GSH-Px), and catalase (CAT) and levels of malondialdehyde (MDA), total antioxidant capacity (T-AOC), uric acid, creatinine, and urea nitrogen were determined using commercial kits (Jiancheng Bioengineering, Nanjing, China) according to the instructions of the manufacturer.

**Determination of SCFA in Colonic Feces.** SCFA of colonic feces were measured as described in a previous report.[18]

**Histopathological Examination.** The pancreas and kidney samples were collected from the animals under anaesthetized conditions, and a portion of the samples was fixed in 10% buffered formalin, dehydrated through graded alcohol, and embedded in paraffin wax. Sections with 5 $\mu$m thickness were mounted on slides. The samples were stained with hematoxylin and eosin after deparaffinization. The stained slides were mounted in neutral balsam and covered with coverslips. Histopathological changes were observed with a Nikon Ti series inverted microscope equipped with bright-field high-quality objectives. Images were acquired by a digital camera (Nikon Digital Sight DS-Fi1c) and image acquisition software.

**Reverse Transcription Quantitative Polymerase Chain Reaction (RT-qPCR) Analyses of Gene Expression.** Total RNA was extracted from the liver and skeletal muscle, and cDNA was obtained by reverse transcription using the RevertAid First Strand cDNA Synthesis Kit (Thermo Scientific, Vilnius, Lithuania) according to the instructions of the manufacturer. The PCR reactions were performed by a 7900HT fast real-time PCR system (Applied Biosystems, Foster City, CA) using SYBR Premix Ex Taq (Takara, Kusatsu, Japan). Data analysis was carried out using the $2^{-\Delta\Delta C_T}$ method. The housekeeping gene, $\beta$-actin, was used for normalization. The sequences of the primers (Invitrogen China, Ltd., Beijing, China) used for RT-qPCR are shown in Table 1.

**Statistical Analysis.** Results were expressed as the mean ± standard error of mean (SEM), and the data were analyzed by SPSS 17.0 software (SPSS, Inc., Chicago, IL). One-way analysis of variance (ANOVA) with Duncan's multiple range test was used to compare the differences among various groups. A value of $p < 0.05$ was considered to be statistically significant.

## RESULTS

**Metabolite Composition in Carrot Juices.** The metabolite concentrations in NFCJ and FCJ are shown in Table 2. In

Table 2. Metabolite Composition in Carrot Juices[a]

| parameter | NFCJ | FCJ |
|---|---|---|
| acetic acid (mmol/L) | 8.99 ± 0.41 | 18.58 ± 0.66 |
| propionic acid (mmol/L) | 0.31 ± 0.02 | 0.47 ± 0.03 |
| butyric acid (mmol/L) | ND | 0.25 ± 0.02 |
| SCFA (mmol/L) | 9.30 ± 0.42 | 19.29 ± 0.67 |
| citric acid (mmol/L) | 1.28 ± 0.02 | 1.46 ± 0.01 |
| malic acid (mmol/L) | 26.11 ± 0.08 | 12.54 ± 0.06 |

[a]NDM, non-diabetes mellitus + saline; DM, diabetes mellitus + saline; NCU, DM + $10^9$ CFU/mL *L. plantarum* NCU116; FCJ, DM + fermented carrot juice with *L. plantarum* NCU116; and NFCJ, DM + non-fermented carrot juice. Data are expressed as the mean ± SEM ($n$ = 10). Values within a row with different letters are significantly different ($p < 0.05$).

comparison to the NFCJ, with the fermentation of *L. plantarum* NCU116, FCJ showed more concentrations of acetic acid, propionic acid, total SCFA (=acetic acid + propionic acid + butyric acid), citric acid, lactic acid, and amino acids. In addition, the butyric acid in NFCJ was not detected, but the FCJ contained about 0.25 mmol/L of the acid. However, the concentrations of malic acid and β-carotene in FCJ decreased in comparison to that of NFCJ.

**Blood Glucose.** As expected, the level of fasting blood glucose (FGB) in the DM group (26.72 mmol/L) was markedly higher than that in the NDM group (4.55 mmol/L). Interestingly, the FGB levels in NCU and FCJ groups (19.37 and 17.19 mmol/L, respectively) were significantly lower than that of the DM group ($p < 0.05$). The animals that received NFCJ (23.34 mmol/L) also showed a significant decrease in the blood glucose level compared to the DM group.

**Hormones.** The levels of serum insulin, glucagon, and leptin in the DM group were significantly higher than those in the NDM group ($p < 0.05$). Supplementation of NCU and FCJ reduced their levels close to the NDM group, especially glucagon and leptin levels in the FCJ group. The levels of the three hormones in the NFCJ group were not significantly different from the DM group. Meanwhile, levels of GLP-1 and PYY in the DM group were abatement compared to the NDM group, and the levels of these two parameters in NCU and FCJ groups were obviously increased ($p < 0.05$; Table 3).

**Serum Lipids.** As shown in Table 3, TC, TG, and LDL-C levels in DM group were all notably increased in comparison to the NDM group. Interestingly, the levels of these three parameters in NCU and FCJ groups declined significantly ($p < 0.05$). The HDL-C contents in the four diabetic groups were all significantly lower than that in the NDM group (1.00 mmol/L), but there were no significant differences between the four groups (0.74−0.85 mmol/L; Table 3).

**Oxidative Stress.** As shown in Table 4, the activities of SOD (156.94 units/mL), GSH-Px (289.28 units/mL), and CAT (98.65 units/mL) and level of T-AOC (6.67 unit/mL) in the DM group were significantly lower than those in the NDM group ($p < 0.05$). The treatment of FCJ significantly increased the levels of these parameters (200.35, 361.72, 150.32, and 13.35 units/mL, respectively). MDA contents in NCU and FCJ groups decreased to lower levels compared to that in the NFCJ group.

**Kidney Function.** A high-fat diet and STZ-induced diabetes were found to raise the levels of urea nitrogen, creatinine, and uric acid. Interestingly, the treatment of NCU and FCJ led to a significant reduction in the levels of these parameters. These results suggested that supplementation of NCU and FCJ improved kidney function in diabetes (Table 4).

**SCFA Composition in Feces.** As shown in Figure 1, the DM group contained significantly lower concentrations of acetic acid (120.54 μmol/g), propionic acid (49.15 μmol/g), butyric acid (16.44 μmol/g), and total SCFA (186.13 μmol/g) in feces compared to the NDM group ($p < 0.05$). These acids in feces of the NCU-, FCJ-, and NFCJ-treated groups were higher than those in the DM group, especially the NCU and FCJ groups ($p < 0.05$).

**Histopathology of the Pancreas and Kidney.** Histological analysis of the pancreas showed that pancreatic cells of the NDM group had normal proportions of islets of Langerhans. Acinar cells, which stained strongly, were arranged in lobules with prominent nuclei and surrounding healthy islet

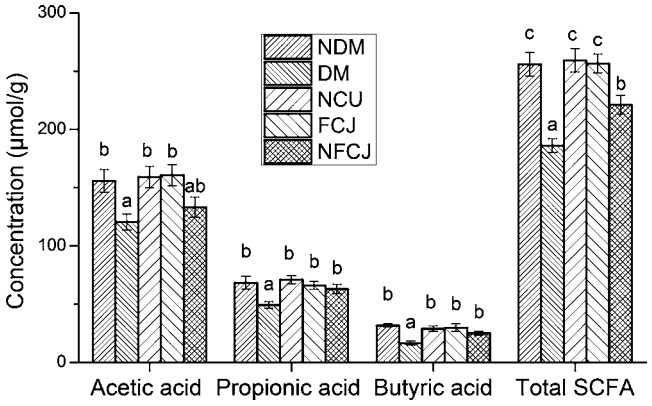

**Figure 1.** Changes in SCFA in feces of five groups of rats: non-diabetes mellitus (NDM), untreated diabetes mellitus (DM), DM plus *L. plantarum* NCU116 (NCU), DM plus fermented carrot juice with *L. plantarum* NCU116 (FCJ), and DM plus non-fermented carrot juice (NFCJ). Data are expressed as the mean ± SEM ($n$ = 10). Values with different letters are significantly different ($p$ < 0.05).

cells. A marked decrease in pancreatic $\beta$-cell size and number of Langerhans was found in the DM group compared to that in the NDM group, and the DM group also showed degeneration and atrophy of the islets. DM rats treated with NCU and FCJ showed an improvement of cell damage, as shown by partial restoration of islet cells, increase in the number of islets, and decrease in $\beta$-cell necrosis and vacuolization, respectively (Figure 2A).

Similarly, in comparison to the NDM group, diabetic rats exhibited a prominent feature of glomerular injury, with evidence of both diffuse and nodular glomerulosclerosis. In addition, tubulointerstitial pathology was present in these diabetic rats. This pathological appearance was reversed by NCU and its fermented carrot juice treatments. This reduction was greater with FCJ than with NCU. However, the NFCJ group had no notable change compared to the DM group (Figure 2B).

**mRNA Expression of Lipid and Glucose Metabolism.** As shown in Figure 3, diabetes downregulated the expression of LDL receptor, GLUT4, and PPAR-$\alpha$, and the supplementation of *L. plantarum* NCU116 increased the expression of these

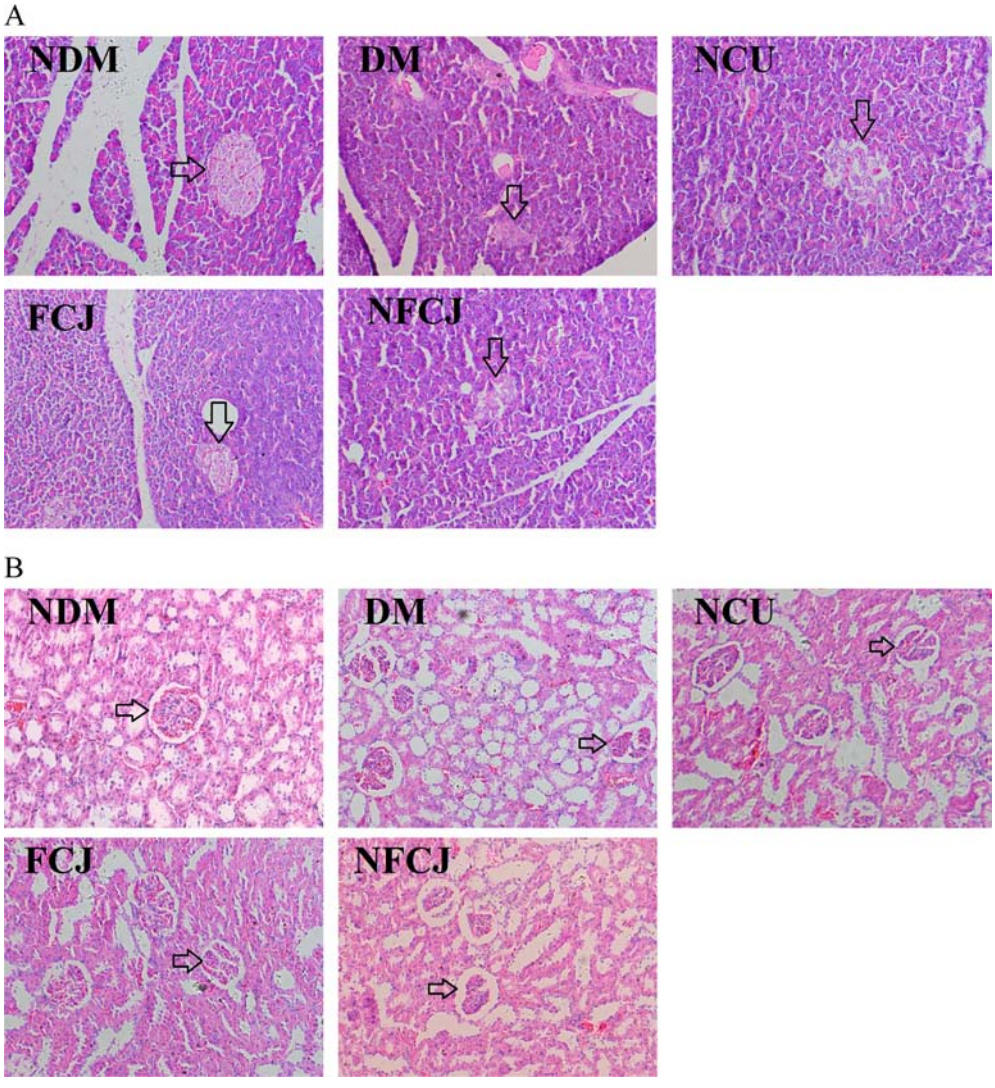

**Figure 2.** Effect of NCU and FCJ treatments on histology (100×) of the pancreas and kidney in five groups of rats: non-diabetes mellitus (NDM), untreated diabetes mellitus (DM), DM plus *L. plantarum* NCU116 (NCU), DM plus fermented carrot juice with *L. plantarum* NCU116 (FCJ), and DM plus non-fermented carrot juice (NFCJ). A, pancreas; B, kidney, with hematoxylin and eosin staining.

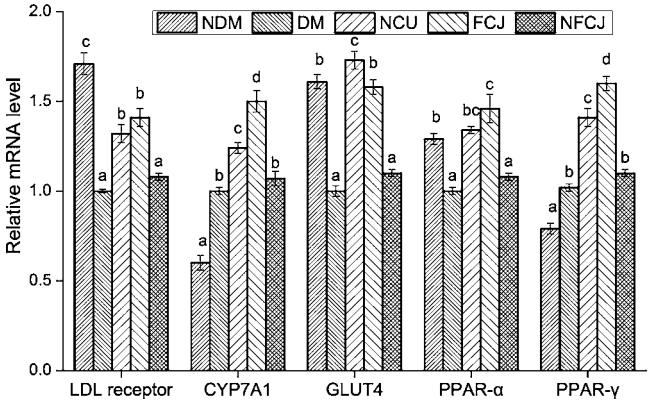

**Figure 3.** Effect of NCU and FCJ treatments on mRNA levels of low-density lipoprotein (LDL) receptor, cholesterol 7$\alpha$-hydroxylase (CYP7A1), glucose transporter-4 (GLUT-4), peroxisome proliferator-activated receptor-$\alpha$ (PPAR-$\alpha$), and peroxisome proliferator-activated receptor-$\gamma$ (PPAR-$\gamma$) in five groups of rats: non-diabetes mellitus (NDM), untreated diabetes mellitus (DM), DM plus *L. plantarum* NCU116 (NCU), DM plus fermented carrot juice with *L. plantarum* NCU116 (FCJ), and DM plus non-fermented carrot juice (NFCJ). The graph represents the mRNA levels relative to $\beta$-actin. Data are expressed as the mean ± SEM ($n$ = 10). Values with different letters are significantly different ($p < 0.05$).

genes after the 5 week experimental period. Simultaneously, the expression of CYP7A1 and PPAR-$\gamma$ in diabetic rats was raised, and higher expression levels of these two genes were found in the NCU and FCJ groups.

## DISCUSSION

T2DM, which has a higher incidence (90−95%) than T1DM, previously referred to as non-insulin-dependent diabetes or adult onset diabetes, encompasses individuals who have insulin resistance and usually have relative (rather than absolute) insulin deficiency.[2] A high-fat diet and low-dose STZ used in the study resulted in destruction of pancreatic $\beta$-cells, an increased blood glucose level (hyperglycemia), and induced oxidative stress. The T2DM experimental rat model mimics closely metabolic characteristics of human T2DM.[20]

The T2DM model used in this study apparently showed the basic phenotypes of hyperglycemia and insulin resistance (Table 3). Evidence from our study clearly demonstrated that supplementation of NCU and FCJ significantly attenuated hyperglycemia and insulin resistance.

Organic acids, the main products of probiotic fermentation, contribute toward an appropriate colonic pH and protect against pathological changes in the colonic mucosa.[21] In this study, it must be noted that the concentrations of SCFA in fermented carrot juice (FCJ) supplemented with *L. plantarum* NCU116 were significantly increased compared to those of non-fermented carrot juice (NFCJ). Interestingly, the butyric acid was not detected in non-fermented carrot juice (NFCJ), which means *L. plantarum* NCU116 could ferment the dietary fiber in the carrot juice to produce certain kinds of SCFA, such as butyric acid. Thus, in this study, we focused on the function of SCFA to the diabetic rats.

Because *L. plantarum* NCU116 had the property of promotion of SCFA production *in vitro*, we determined the SCFA concentrations *in vivo* of rat colonic feces. Studies showed that 90−95% of the SCFA present in the colon is constituted by acetic acid, propionic acid, and butyric acid. Ingestion of a high-fat diet reduced the SCFA concentration, and fermentable dietary fibers increased SCFA in the colon.[22,23] In these high-fat diet (fed) and low-dose STZ-induced diabetic rats, the fecal SCFA was obviously decreased in comparison to that of the NDM group. The NCU and FCJ groups showed a higher levels of SCFA than the DM and NFCJ groups (Figure 1). SCFA has several physiological properties that might suppress diabetes by different pathways; SCFA is probably a key component in the growth of lactobacilli and bifidobacteria and in lowering intestinal pH, all of which are expected to have beneficial effects on diabetes.[24] The main beneficial activities of SCFA were identified in the decrease of levels of glucose in serum, insulin resistance, inflammation, and increase in protective PYY and GLP-1 secretion.[22]

Propionate has been shown to decrease glucose production in rat hepatocytes.[25] In this experiment, the results suggested that the consumption of *L. plantarum* NCU116 and carrot juice led to an increase of propionic acid for preventing hyperglycemia, but a more pronounced effect was found when carrot juice was fermented with *L. plantarum* NCU116. The hypoglycemic effect of the FCJ observed in this study could be related to the synergistic effects of both $\beta$-carotene in carrot, gut microbiota, and the production of SCFA.[26] In addition, hormones, such as insulin, glucagon, and leptin, play an important role in diabetes. Previous studies have suggested that leptin secretion is affected by insulin and that rats with metabolic syndrome exhibit high plasma levels of leptin.[27] It has been reported that supplementation of *L. plantarum* NCU116 significantly decreased the oral glucose tolerance and insulin resistance in hyperlipidaemic rats, indicating that the probiotic fermented carrot juice could regulate the production of insulin and glucagon by pancreatic cells.[13] These results suggested that the decrease in insulin, glucagon, and leptin levels may have resulted from the improvement of insulin sensitivity by the oral supplementation of *L. plantarum* NCU116. Changes in the microbiota and, consequently, in SCFA composition have been hypothesized to be associated with the development of insulin resistance and diabetes.[22] Alterations to the composition and metabolic capacity of gut microbiota in metabolic syndrome influence metabolic processes in peripheral organs, the release of hormones from the gut (such as GLP-1 and PYY; Table 3), and the synthesis, storage, or metabolism of lipids in the adipose tissue, liver, and muscle.[28] Studies performed in G-protein-coupled receptor 41 (GPR41)-deficient mice suggested that the activation of GPR41 by SCFA is responsible for the release of the gut hormones PYY. The peptide has been shown to decrease the intestinal transit time, which indicates that it promotes the absorption of nutrients, mostly glucose.[29] It has been reported that propionic and butyric acids were shown to reduce low-grade inflammation and induce hormone release. In addition, SCFA have been linked to increased GLP-1 secretion in both animal and human models. GLP-1 is an incretin hormone that participates in glucose homeostasis, mainly by lowering the plasma glucose concentration and preserving pancreatic $\beta$-cell function.[22] The gastrointestinal hormones have antidiabetic effects primarily by stimulating glucose-dependent insulin release and promoting glucose homeostasis.[7,30]

Dyslipidemia is the common character in T2DM and is the primary cause of cardiovascular diseases in patients with diabetes.[6] In the STZ-induced diabetic rat model, it has been shown that TC, TG, and LDL-C levels increased and the HDL-C level decreased and that the supplementation with soymilk

fermented with *Lactobacillus rhamnosus* CRL981 could ameliorate lipid profiles compared to the unfermented soymilk.[16] It is well-known that high levels of serum TC and LDL-C can increase the risk of cardiovascular events. Decreasing TC and LDL-C levels in serum is effective for reducing the risk of atherosclerosis. A previous study showed that *L. plantarum* NCU116 significantly decreased the levels of serum TC, TG, and LDL-C and increased the HDL-C level in a hyperlipidaemic rat model.[13] Butyrate-producing intestinal bacteria seem to play an important role in blood glucose regulation and lipid metabolism, as shown by fecal transplantation studies.[22] In the present study, the administration of FCJ showed the best ability of regulating TC, TG, and LDL-C compared to the other treatments, and it might relate to the increase of butyric acid production in the colonic content by the gut microbiota (Table 3).

Oxidative stress is considered to play an important role in the pathogenesis of type 2 diabetes. The increased risk of dyslipidemia and hyperglycemia damage the antioxidant system of tissues.[31] Diabetes is associated with the increase of oxidative stress, which is essentially an imbalance of free radicals and antioxidant defenses.[32] Oxidative stress can impair the living cell membrane, and this may be the reason for the injury to the islets of Langerhans and glomeruli of kidney. It has been shown that STZ-induced diabetes in rats caused an abnormal decrease of SOD, GSH-Px, and CAT activities and T-AOC level, resulting in the accumulation of reactive oxygen species (ROS), such as hydrogen peroxide and superoxide radicals.[33] MDA, as an end product and marker of the lipid peroxidation process, is toxic to DNA and protein. In this study, the administration of NCU and FCJ caused as a significant increase in activities of SOD, GSH-Px, and CAT and level of T-AOC. This may be due to the biologically active $\beta$-carotene present in the fermented carrot juice with *L. plantarum* NCU116 bioconversion, because non-fermented carrot juice did not show the same level of increase (Table 4).

Hyperglycemia and dyslipidemia in diabetes are related to the increased production of free radicals. Consequently, oxidative damages and pancreas and kidney injuries leading to failure and dysfunctions were observed. Interestingly, after NCU and FCJ supplementation, reduction of pancreas and kidney injuries was found in the histopathology study (Figure 2). NCU and FCJ could enhance pancreatic activity in regenerating $\beta$-cells by reducing $\beta$-cell necrosis and vacuolization.[34] To our knowledge, rare studies have shown the effect of fermented carrot juice administration on histology, except for a few studies showing the effect of $\beta$-carotene supplementation on the incidence of type 2 diabetes.[35]

A long period of hyperglycemia can induce damage to blood vessels that can affect the functionality of some organs, such as the pancreas, liver, and kidney. Consequently, oxidative damages and kidney tissue damage leading to failure and dysfunctions were observed. The disability of the kidney in the diabetic rats to filter properly leads to the accumulation of waste and toxic substances, such as uric acid, creatinine, and urea nitrogen in the blood.[36] STZ-induced diabetic rats showed an increase of uric acid, creatinine, and urea nitrogen, and the supplementation with soymilk fermented with *L. rhamnosus* CRL981 did not have any effect in diabetic rats.[16] Morphologically, the findings of this study revealed the efficiency of NCU and FCJ in protecting the kidney of diabetic rats, which was evidenced by the lower rates observed for kidney dysfunction indices (Table 4 and Figure 2).

The gut microbiota not only affect the metabolic syndrome by SCFA production but also influence the expression of host genes and control fatty acid absorption, oxidation, and storage.[29] A previous study showed that oral administration of *L. plantarum* NCU116 could regulate LDL receptor and CYP7A1 to alleviate the high-fat diet induced hyperlipidaemic symptom in rats. The increased expression of these genes in liver may be the mechanism by which *L. plantarum* NCU116 reduces TC and LDL-C in serum.[13] In this study, mRNA expression levels of LDL receptor and CYP7A1 in NCU and FCJ groups were significantly increased, which may result in the decrease of the serum LDL-C level. GLUT-4 is the insulin-regulated glucose transporter found primarily in adipose tissues and skeletal muscle, which is responsible for insulin-stimulated glucose transport into the cell. Conditional depletion of GLUT4 in certain organs caused a roughly equivalent incidence of diabetes in animals.[37] We found that GLUT4 mRNA expression was increased in the skeletal muscle of NCU and FCJ groups compared to the untreated DM group. With more than 80% insulin-stimulated glucose disposal in the skeletal muscle, the increased GLUT4 mRNA expression by supplementation of NCU and FCJ could enhance glucose uptake in diabetic rats.[38] It has been known that PPARs play a key role in inflammation and glucose homeostasis. PPAR-$\alpha$ may relate to the improvement insulin sensitivity, and PPAR-$\gamma$ is a therapeutic drug target for metabolic syndrome.[39,40] Our results suggested that NCU and FCJ could regulate glucose homeostasis and insulin sensitivity in the diabetic rats via regulating the expression of these genes (Figure 3). The possible mechanism involved in antidiabetic effects of *L. plantarum* NCU116 and its fermented carrot juice on a high-fat diet (fed) and low-dose STZ-induced type 2 diabetic rat model is provided in Figure 4.

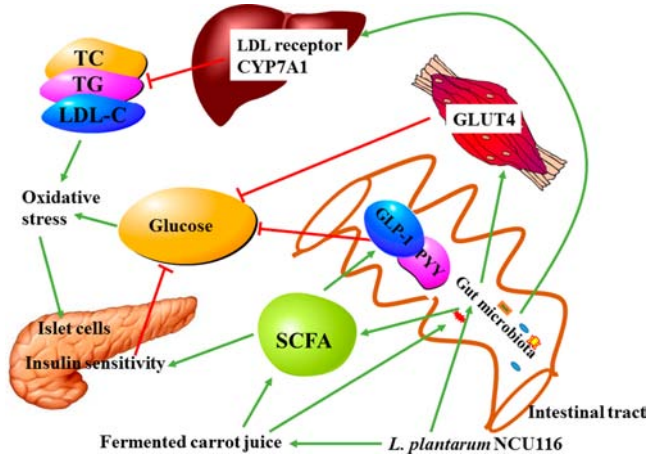

**Figure 4.** Possible mechanism involved in antidiabetic effects of *L. plantarum* NCU116 and its fermented carrot juice on a high-fat diet (fed) and low-dose STZ-induced type 2 diabetic rat model. Red arrows represent inhibition, and green arrows represent promotion.

In conclusion, this study demonstrated that the antidiabetic effect of NCU and FCJ on a high-fat diet (fed) and low-dose STZ-induced type 2 diabetic rat model. *L. plantarum* NCU116 was found to increase SCFA in the fermented carrot juice (FCJ); meanwhile, NCU and FCJ increased SCFA in the colonic feces of diabetic rats. The results have shown that NCU and FCJ had the potential abilities to regulate levels of blood glucose and its related hormones (insulin, glucagon, GLP-1,

and PYY) and ameliorated diabetes induced damage of the pancreas and kidney. In addition, NCU and FCJ also decreased serum lipids and oxidative stress and regulated the expression levels of lipid and glucose metabolism. The possible mechanism of the paper was that NCU and FCJ changed the gut microbiota and, consequently, SCFA composition, which were associated with the development of diabetes. Thus, these results indicated that *L. plantarum* NCU116 and the probiotic fermented carrot juice have potential for the treatment of diabetes.

Table 1. Carotenoid and Theoretical Retinol Feed Concentrations (nmol/g feed)[A] Prepared for Laying Hens using a Combination of Different maize Genotypes and Fortificants

| | treatment[B] | | | |
|---|---|---|---|---|
| carotenoid | orange | tangerine | yellow | white |
| lutein | 6.2 ± 0.32[b] | 4.40 ± 0.48[b] | 24.8 ± 5.83[a] | 4.0 ± 0.89[b] |
| zeaxanthin | 3.42 ± 0.57[a] | 0.72 ± 0.09[c] | 2.14 ± 0.73[b] | 0.68 ± 0.27[c] |
| β-cryptoxanthin | 5.64 ± 0.39[a] | 4.85 ± 0.75[a] | 0.79 ± 0.03[b] | 0.13 ± 0.06[c] |
| α-carotene | 0.24 ± 0.11[a] | 0.13 ± 0.03[bc] | 0.20 ± 0.05[ab] | 0.06 ± 0.03[c] |
| 9-*cis*-β-carotene | 0.93 ± 0.13[a] | 0.20 ± 0.07[b] | 0.23 ± 0.02[b] | 0.10 ± 0.01[c] |
| all-*trans*-β-carotene | 3.37 ± 0.20[a] | 0.87 ± 0.29[b] | 0.60 ± 0.03[c] | 0.27 ± 0.03[d] |
| 13-*cis*-β-carotene | 1.03 ± 0.30[a] | 0.22 ± 0.07[b] | 0.33 ± 0.04[b] | 0.15 ± 0.06[b] |
| theoretical retinol | 16.3 ± 1.36[a] | 8.69 ± 1.71[b] | 3.24 ± 0.26[c] | 1.07 ± 0.33[c] |

[A]Concentrations are mean ± SD; $n$ = 27 for white maize; $n$ = 21 for other treatment feeds. All carotenoid and theoretical retinol differed by treatment using one-way ANOVA (All $P < 0.0001$). Lowercase superscript letters in a row designate differences between feeds (tested with LSMEANS at $P < 0.05$). [B]Treatment groups are designated by color regarding maize and/or fortification. Orange = high β-cryptoxanthin biofortified maize, tangerine = white maize + tangerine-peel fortificant, yellow = yellow maize + lutein fortificant, white = white maize only.

The source of β-cryptoxanthin may impact the bioavailability of β-cryptoxanthin in hens for egg yolk deposition. The objective of this study was to comprehensively compare the source of β-cryptoxanthin in hens' feed, that is, orange maize or tangerine peel, and the impact on egg yolk color, skin color, carotenoid concentrations, and VA status of the laying hens compared with the industry-recommended lutein standard.

## MATERIALS AND METHODS

**Maize, Feed Preparation, and Analysis.** Four different maize feeds were prepared. The high β-cryptoxanthin (orange) maize genotype was conventionally bred and obtained from the International Maize and Wheat Improvement Center/HarvestPlus maize provitamin A biofortification project and was grown in Mexico at Agua Fria, Puebla (20°32′N, 97°28′ W; 110 m above sea level). Ears were harvested and dried, and grain was stored at −20 °C before shipping to University of Wisconsin-Madison. The kernels were stored at −24 °C for the duration of the study. Kernels were ground to a fine powder before hen feed preparation using a C&N Hammermill No. 8 (Christy-Norris Ltd., Ipswich, U.K.). Feed composition was identical to Liu et al. with the only source of VA through the orange and yellow maize[25] or tangerine peel. Tangerine peel was freeze-dried for 48 h, finely ground, and stored at −80 °C until preparation of the tangerine-fortified white maize feed. The white maize was sourced locally (DeLong Co., Inc., Clinton, WI) and approximately 40 g ground freeze-dried tangerine peel was added per 1 kg feed, which was based on the β-cryptoxanthin concentration of the orange maize feed (5.64 ± 0.39 nmol/g feed). Concentrations were based on saponified β-cryptoxanthin because 75 to 94% of β-cryptoxanthin is esterified in tangerine peel,[27] but only 1−5% of xanthophylls are esterified in maize.[28,29] Lutein ORO GLO-20 (graciously donated by Kemin Industries, Inc., Des Moines, IA) was added to the yellow maize (DeLong Co., Inc., Clinton, WI) at 0.05%, according to industry recommendations.[30]

Feeds were mixed and analyzed weekly, and stored at −20 °C to prevent carotenoid degradation. Carotenoid composition of maize and feeds (Table 1) was determined using an adapted saponification method.[10,29] This ensured that the carotenyl esters present in the tangerine peel were hydrolyzed to the free form,[31] which was subsequently quantified in the tissues. After preheating 0.6 g maize feed suspended in 6 mL ethanol at 85 °C for 5 min, saponification was done with addition of 500 μL 80:20 potassium hydroxide/water (w/v) for 10 additional min. Water (3 mL) was added to aid phase separation during hexane extraction (3 × 3 mL hexane). The hexane extracts were dried, reconstituted in 500 μL 50:50 methanol/dichloroethane, and 50 μL aliquots were analyzed by HPLC using a YMC C30 column (4.6 × 250 mm).[4] A 40 min multistep, binary gradient [A: 92:8 methanol/water (10 mM ammonium acetate); B: methyl tertiary butyl ether] was run at 2 mL/min (Supporting Information Table S1). Extraction efficiencies ranged from 90 ± 7 to 95 ± 3% for the different maize feeds.

**Hens.** All animal procedures were approved by the College of Agricultural and Life Sciences Animal Care and Use Committee, University of Wisconsin-Madison. Single Comb White Leghorns ($n$ = 32), 28 wk into their laying cycle, were individually housed in metal battery cages under a 16-h light/8-h dark cycle. The hens were checked daily to ensure adequate supply of ad libitum feed and water and to monitor health status. Hens were given approximately 110 g feed/d, but total feed intake was not measured. Hens were killed by $CO_2$ fixation on intervention d 50. Hens were weighed before blood, liver, and breast skin were harvested.

**Experimental Design.** Laying hens were fed a white-maize feed for a 10-d depletion period. For the next 40 d, hens were divided into 4 treatments based on maize genotype and fortificant ($n$ = 8/treatment): high β-cryptoxanthin biofortified orange maize (orange), tangerine-fortified white maize (tangerine), lutein-fortified yellow maize (yellow), and white maize only (white) as a negative control. Eggs were collected every day and subjected to colorization every other day. Upon breaking the shell, yolks were separated from the whites and color was analyzed using a portable Konica Minolta colorimeter (Chroma Meter CR-300, Konica Minolta Sensing Americas, Inc., Ramsey, NJ) using the complementary color model. Color space (often referred to as L*a*b*) was used for assessment of changes in yolk color over the course of the study ($n$ = 6−8/treatment and collection time). The L-scale represents lightness, with a value of 0−100 (L = 0 indicates darkest, L = 100 lightest). The a-scale represents redness on a scale from −60 (green), to +60 (red). The b-scale represents yellowness on a scale from −60 (blue) to +60 (yellow). After color analysis, yolks were transferred into black conical tubes and stored at −80 °C.

**Analysis of Egg Yolk.** Egg yolk samples from every 4 d were prepared for carotenoid and retinol equivalent composition analysis using an adaptation from a previously published method.[22] Yolk (0.3 g) was mixed with 1 mL deionized water using a vortex, followed by 3 mL ethanol (0.1% butylated hydroxytoluene as antioxidant). Potassium hydroxide/water (500 μL, 50:50, w/v) was added and the mixture was saponified for 30 min at 60 °C. One mL cold deionized water was added to quench the reaction and 200 μL C-23-*apo*-carotenol was added as internal standard. The mixture was extracted with 4 mL 9:1 hexane/ethyl acetate (v/v) and then twice more with 3 mL. The organic layers were pooled, dried under nitrogen, and reconstituted in 200 μL 75:25 methanol/dichloroethane (v/v); 4 μL was injected onto a Waters Ultra Performance Liquid Chromatograph (UPLC) equipped with an ACQUITY HSS C18 1.8 μm, 2.1 × 150 mm column at 35 °C (Milford, MA). Solvent A was 90:10 water/isopropanol (10 mM ammonium acetate) and solvent B was 80:20 acetonitrile/isopropanol at 0.45 mL/min with a total runtime of 25 min. The gradient started with 30% solvent A and 70% solvent B switching to 5% A and 95% B from 0 to 10 min, with a change to 1% A

and 99% B at 12 min and holding until reverse conditions from 21.5 to 25 min. Retention times are noted in Supporting Information Table S1.

All-*trans*-$\beta$-carotene (537 g/mol; Sigma-Aldrich, St. Louis, MO), $\beta$-cryptoxanthin (553 g/mol; CaroteNature, GmbH, Lupsingen, Switzerland), lutein (569 g/mol; GNC, Inc., Pittsburgh, PA), and zeaxanthin (569 g/mol; GNC, Inc., Pittsburgh, PA) were quantified using HPLC-purified standards. Provitamin A equivalents were the sum of $\beta$-cryptoxanthin, $\alpha$-carotene, and twice the $\beta$-carotene due to the theoretical yield of retinol from the chemical structures.

**Analysis of Chicken Livers, Serum, and Skin.** Livers were prepared and analyzed for carotenoids, retinol, and retinyl esters using an adaptation of published methods.[32] Serum was prepared and analyzed for carotenoids and retinol and retinyl esters using previously published methods.[10] Retinol and retinyl esters were quantified at 325 nm and carotenoids were quantified at 450 nm. Chicken skin was colorized with the colorimeter.[25] Skin (1 g) was ground with 4−5 g sodium sulfate, 150 $\mu$L $\beta$-*apo*-8′-carotenal was added as internal standard, and the mixture was extracted with 25 mL dichloromethane. A 5 mL aliquot was dried under nitrogen, suspended in 750 $\mu$L ethanol (0.1% butylated hydroxytoluene), and saponified with 300 $\mu$L potassium hydroxide/water (50:50, w/v) for 15 min at 45 °C. After saponification, 1 mL deionized water was added to quench the reaction and the mixture was extracted 3 times with 2 mL hexanes. Organic layers were pooled and dried under nitrogen, reconstituted in 150 $\mu$L methanol/dichloroethane (50:50, v/v); 75 $\mu$L was injected onto a Waters Resolve $C_{30}$ 5 $\mu$m, 3.9 × 300 mm reversed-phase column (Waters, Milford, MA) equipped with a guard column. The HPLC system consisted of a 1525 binary pump, a 717 autosampler, and a 996 photodiode array detector (Waters). Solvents and run-time were similar to published methods[32] (Supporting Information Table S1).

**Statistical Analysis.** Values are means ± SD. Data were analyzed using Statistical Analysis System software (SAS version 9.2, SAS Institute, Cary, NC). A repeated measures two-way ANOVA with mixed effects was used with PROC MIXED for egg color analysis and carotenoid and retinol concentrations of saponified egg yolk. The overall differences in color were evaluated using eq 1:[33]

$$\Delta E = \sqrt{(\Delta L)^2 + (\Delta a)^2 + (\Delta b)^2} \quad (1)$$

The influence of treatment on liver VA stores and serum retinol concentrations were evaluated using one-way ANOVA for the hens. LSMEANS was used to determine differences between treatments. Main treatment effects for feed type and time, and the interaction of treatment by time were considered significant at $P \leq 0.05$.

## RESULTS

**Carotenoid Concentration of Feeds.** By design, orange and tangerine feeds did not differ in total $\beta$-cryptoxanthin concentration determined after saponification, although they presumably did differ in percentage of free versus esterified $\beta$-cryptoxanthin. The theoretical value of provitamin A equivalents were different due to the endogenous $\beta$-carotene in the orange maize (Table 1). Much lower amounts of provitamin A equivalents were present in the yellow and white maize feeds (Table 1). The yellow feed had four times more lutein than the orange feed. Zeaxanthin was similar in orange and yellow feeds, and it was more than four times higher than that of the tangerine and white feeds.

**Egg and Hen Weight.** Egg weights (53.4 ± 2.80 g) among treatment groups across all time periods did not differ (Supporting Information Figure S1). However, egg weight increased over time as the hens aged ($P < 0.0001$). A paired $t$ test comparing eggs at d 10 (end of washout period) and d 50 (end of treatment phase) found a significant increase in egg weight (5.07 ± 3.31 g) from hens in all treatment groups ($P < 0.0001$). A treatment by time interaction occurred ($P = 0.02$) where egg weight increase in the tangerine group (3.1 ± 3.3 g) was less than the other treatment groups (5.2 ± 3.2 g). Egg production differed among treatment groups ($P < 0.01$), but was almost 1 egg/d. Egg percent production (eggs/d on treatment × 100) were 93.0 ± 5.3%, 90.8 ± 7.2%, 97.2 ± 2.4%, and 99.0 ± 3.6% for hens fed the orange, tangerine, yellow, and white treatments, respectively, where yellow and white groups produced more eggs than orange and tangerine groups. One hen in the white group was euthanized early due to a prolapsed follicle. Hen weight at kill (1.40 ± 0.11 kg) did not differ among treatment groups.

**Color Assessment of Egg Yolk.** The L-scales for the yolks were different among treatments, time, and an interaction existed ($P < 0.0001$ for all; Supporting Information Figure S2). Although the L-scale remained relatively flat over time, yolks from all hens were significantly lighter on d 10 at the end of the washout period with VA-depleted white maize than d 0 at the beginning of the study ($P < 0.0001$). Similar to the L-scale, the a-scale responded to treatment, time, and an interaction existed ($P < 0.0001$) (Supporting Information Figure S3). The yolks from orange and yellow groups had similar a-scale values throughout the treatment phase of the study and were significantly higher than the tangerine and white groups' yolks ($P < 0.0001$). Similar to the other scales, the b-scale differed by treatment, time, and an interaction between the two existed ($P < 0.0001$; Supporting Information Figure S4). After the initial washout period, the b-scale remained relatively flat. Total color differences (Table 2) were significant by treatment group ($P = 0.006$), as well as overall between treatment groups ($P < 0.011$). The orange and yellow groups' yolks had similar values as did the tangerine and white groups' yolks.

**Egg Yolk Carotenoid and Retinol Concentrations.** Carotenoid concentrations in yolks from the orange group, but not other treatment groups, increased until d 24 and then stabilized ($P < 0.0001$) (Table 3). $\beta$-Cryptoxanthin concentrations were significantly different among treatment groups, increased with time, and a treatment by time interaction occurred (all $P < 0.0001$). $\beta$-Cryptoxanthin concentration was highest in yolks from chickens fed orange maize, followed by tangerine, yellow, and white groups. $\beta$-Cryptoxanthin increased following the wash-out period in the orange, tangerine, and yellow treatments, but little change occurred in the white control (Table 3). In eggs from hens fed orange maize, $\beta$-cryptoxanthin concentration increased >2 times between d 16 and 24 and plateaued throughout the remainder of the study. As expected, lutein concentration was significantly higher in eggs from chickens fed yellow maize than that of any other group, but also increased with time across all groups and a treatment by time interaction occurred (all $P < 0.0001$). Yolks from the yellow group were the only yolks to reach lutein concentrations similar to the beginning of the washout period. Zeaxanthin was significantly higher in yolks from the orange group throughout the treatment period but decreased with time across all groups and a treatment by time interaction occurred (all $P < 0.0001$). Thus, after the washout period, yolk lutein was high from yellow maize but generally abundant from all feeds, while yolk zeaxanthin was particularly high from orange and yellow feeds. Yolk $\beta$-cryptoxanthin had moderate increases according to feed but remained less than lutein or zeaxanthin concentrations. Treatment alone did not impact yolk retinol concentration, but time had a significant effect, and an interaction between treatment and time occurred (both $P <$

| yellow vs white | 10.2 |

[A]All L*a*b* scale measurements can be found in Supporting Information Figures S2−4. [B]Values are means ± SD; $n$ = 8/treatment group. [C]Treatment groups: orange = high $\beta$-cryptoxanthin maize, tangerine = white maize + tangerine peel fortificant, yellow = yellow maize + lutein fortificant, white = white maize only. [D]The treatment effect within a group is significant ($P$ = 0.006); means with lowercase superscript letters are significantly different using LSMEANS at $P$ < 0.05. [E]$\Delta E$ is a measure of change in L-, a-, and b-scales from the beginning (d 10) to end (d 50) of the experimental feeding period (see eq 1). [F]Means of each group on d 50 of the experiment were compared between groups for $\Delta E$; $P \leq 0.011$.

0.0001). Egg yolk retinol concentrations were lower on d 50 than d 0 (Table 4).

**Chicken Liver and Serum Retinol and Carotenoid Concentrations.** Hen liver weights (37.0 ± 6.4 g) did not differ among treatment groups. Liver VA concentration and total liver VA reserves, which includes both retinol and retinyl esters, were significantly different among treatment groups (Figure 1A, B; $P$ < 0.0001, $P$ = 0.0004, respectively), and total retinol decreased in the order of orange ≥ tangerine = yellow = white groups. Treatment also affected liver carotenoid concentrations (Figure 2A). $\beta$-Cryptoxanthin, zeaxanthin, and $\beta$-carotene concentrations of free carotenoids and total carotenoid liver reserves were highest in chickens from the orange group (Figure 2A, B, all $P$ < 0.0001). Lutein concentration and total liver lutein reserves were highest in the yellow group. However, zeaxanthin was consistently the most abundant carotenoid in liver, except for in the tangerine group where $\beta$-cryptoxanthin was similar to zeaxanthin (Figures 2A, B). $\alpha$-Carotene was not detected in the chicken liver.

Hen serum retinol concentrations differed among treatment groups ($P$ < 0.0001) and were highest in the tangerine group (Figure 1C). Serum retinol concentrations did not follow the same pattern as the retinol concentrations in the liver. All hens had serum retinol concentrations ≥1.0 $\mu$mol/L. Hen serum $\beta$-cryptoxanthin and zeaxanthin concentrations were highest in the orange group ($P$ < 0.0001). Serum lutein was highest in the yellow group ($P$ < 0.0001) (Figure 2C). While serum lutein, zeaxanthin, and $\beta$-cryptoxanthin concentrations reflected those in the liver, $\beta$-carotene was not detectable in any group. In contrast, liver $\beta$-carotene concentrations were detectable and highest in the orange group compared with other groups.

**Chicken Skin Colorization and Carotenoids.** No differences were observed among the skin from any of the feeding groups for the L-, a-, and b-color scales. Lutein and zeaxanthin were highest in the yellow group's skin, but no significant differences existed (Table 5, $P$ = 0.09, $P$ = 0.38, respectively). Skin $\beta$-cryptoxanthin concentration was low compared with lutein and zeaxanthin but was significantly higher in the orange group than other groups (Table 5, $P$ = 0.002).

## DISCUSSION

This study evaluated the impact of $\beta$-cryptoxanthin from biofortified orange maize or tangerine peel powder on egg yolk color and VA status of laying hens fed for 40 d. The orange feed resulted in deeper orange yolk, which was visible to the naked eye, significantly higher concentrations of $\beta$-cryptoxanthin (∼2 times higher) and zeaxanthin (∼4 times higher), and differentiated color from the tangerine group on all color scales, even though both feeds contained similar concentrations of $\beta$-cryptoxanthin. Eggs from hens that were fed orange maize became significantly darker on the L-scale, redder on the a-scale, and more yellow on the b-scale. Total color difference was small between white and tangerine and between orange and yellow, which was expected because they were similar on each color-scale measurement.

Hens consuming the orange maize had the highest liver VA stores, which were 1.5 times higher than the tangerine group and 2.6 times higher than the yellow group. Tangerine peel was chosen as a fortificant because it is considered a waste product in juice production and therefore could be repurposed in chicken feed manufacturing. Considering the difference in theoretical retinol equivalents between the orange maize and tangerine peel feeds, it is likely that the $\beta$-cryptoxanthin from the tangerine peel was serving as a major source of VA for the hen itself, because other provitamin A carotenoids were absent in the tangerine peel feed. Follow-up studies should equalize maize feeds for provitamin A equivalents to determine if $\beta$-cryptoxanthin is less bioavailable from the tangerine peel matrix compared with orange maize, and to investigate different levels of tangerine fortificant to maximize the $\beta$-cryptoxanthin response in the egg yolk in addition to meeting the hen's VA needs. In addition, the degree of fatty acid esterification of the $\beta$-cryptoxanthin in the tangerine peel should be determined to investigate whether this has any effect on bioavailability in the chicken.[31]

In addition to this study, two prior studies fed biofortified maize feeds to laying hens that resulted in enhanced $\beta$-cryptoxanthin of the yolks.[25,26] The $\beta$-cryptoxanthin concentration in egg yolks from this study, on d 28, were twice that (8.66 ± 0.53 nmol/g) of a previous study (4.20 nmol/g), yet similar $\beta$-cryptoxanthin concentrations were fed (4.71 nmol/g and 5.64 nmol/g, respectively).[25] Furthermore, a recent study in which biofortified $\beta$-cryptoxanthin maize was fed to laying hens for 140 d with a concentration of 9.8 nmol/g, found a

[A]Retinol is defined as free retinol and retinyl esters hydrolyzed during saponification in egg yolk. [B]Values are mean ± SD; $n$ = 6−8/time and feed group. [C]Using two-way ANOVA, time and an interaction between treatment and time were significant (both $P < 0.0001$); feed alone was not significant. Using LSMEANS, unlike lowercase superscript letters represent significant differences by time ($P < 0.05$).

mean egg yolk β-cryptoxanthin concentration of 10.1 nmol/g after freeze-drying.[26] Raw egg yolk is approximately 50% water;[34] therefore, the prior two study values are similar. Interaction between zeaxanthin and β-cryptoxanthin for uptake into the egg yolk may contribute to these discrepancies. However, yolk concentration of β-cryptoxanthin did mirror theoretical provitamin A intake in this study. β-Carotene in the orange maize likely met the VA requirements of the hens, which allowed for more β-cryptoxanthin to be deposited into the egg yolk than utilized for VA needs.

Unlike the prior studies, this study also evaluated the VA statuses of the hens, which were impacted by the level of β-

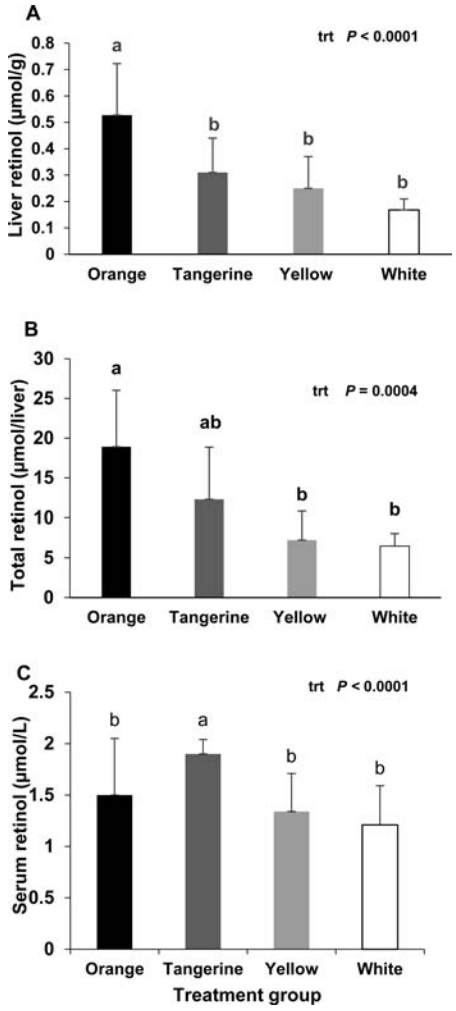

**Figure 1.** Liver VA concentrations and reserves, which includes retinol and retinyl esters, in hens ($n$ = 7 white maize, $n$ = 8 all other treatment groups) fed either orange, tangerine-fortified white, lutein-fortified yellow, or white maize feeds. Means were analyzed using PROC MIXED and LSMEANS was used to make comparisons between groups. Bars with unlike lowercase letters are different at $P < 0.05$. (A) Liver VA concentrations were significantly different among treatment groups ($P < 0.0001$). (B) Total liver VA reserves were significantly different among treatment groups ($P = 0.0004$). (C) Serum retinol concentrations were higher in the tangerine-fortified white maize group and did not reflect the relationship of liver VA concentrations.

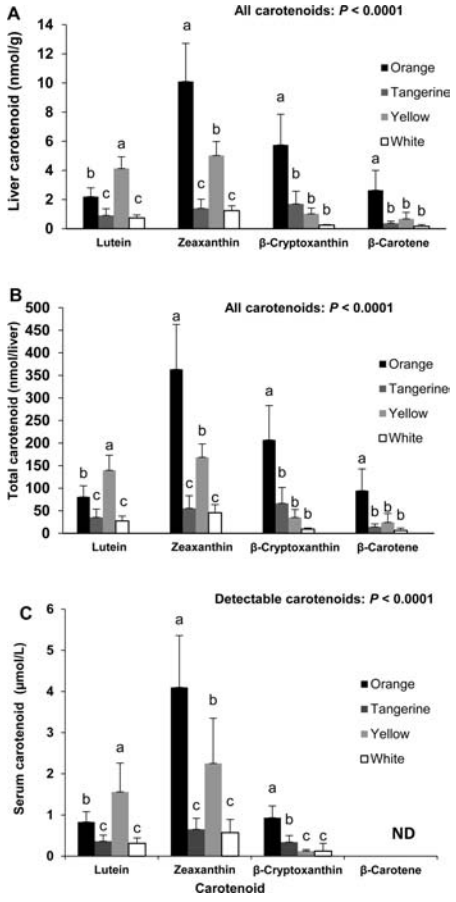

**Figure 2.** Liver and serum carotenoid concentrations and reserves in hens ($n$ = 7 white maize, $n$ = 8 all other treatment groups) fed either orange, tangerine-fortified white, lutein-fortified yellow, or white maize feeds. Means were analyzed using PROC MIXED and LSMEANS was used to make comparisons between groups. Bars with unlike lowercase letters are different at $P < 0.05$. (A) Liver carotenoid concentrations were significantly different among treatment groups for lutein, zeaxanthin, $\beta$-cryptoxanthin, and $\beta$-carotene. (B) Total liver carotenoid reserves differed among treatment groups for lutein, zeaxanthin, $\beta$-cryptoxanthin, and $\beta$-carotene. (C) Serum carotenoid concentrations were significantly different among treatment groups for lutein, zeaxanthin, and $\beta$-cryptoxanthin. ND, not detected.

cryptoxanthin and other provitamin A carotenoids. Currently, there is no carotenoid requirement for poultry, although dietary carotenoids contribute to plumage, beak, skin, and egg yolk color.[15] Consequences of VA deficiency in laying hens are decreased egg production and yolk VA concentration, and lesions in the upper respiratory tract (esophagus) and ovarian follicle.[35] The National Research Council's VA requirement for mature Leghorn laying hens is 300 IU VA/d (90 $\mu$g/d).[36] According to international standards and theoretical VA concentrations in the feeds, all hens except those on the white maize feed met 300 IU/day. Assuming they ate ~100 g feed/day, hens fed orange maize theoretically consumed 1555 IU/d, the tangerine group consumed 828 IU/d, the yellow group consumed 309 IU/d, and the white group consumed 102 IU/d. Although they were theoretically consuming one-third the VA requirement, hens fed the white maize had adequate liver reserves [0.17 $\mu$mol/g liver compared with 0.1 $\mu$mol/g liver[37]] after 50 d treatment. Retinol concentration in the eggs was not impacted by the level of provitamin A equivalents in the feed during this short-term study, which indicates highly regulated deposition of VA into the yolk. Hens fed orange maize had higher liver VA concentrations and total reserves than other groups. Using biofortified orange maize or tangerine fortificant could eliminate the need for addition of preformed retinyl palmitate to feed. According to serum retinol and liver VA concentrations, hens on all treatments were VA-adequate meeting the cutoffs of 0.7 $\mu$mol retinol/L serum and 0.1 $\mu$mol VA/g liver, respectively.

The orange feed was higher in $\beta$-carotene than other groups. Hens are efficient at cleaving $\beta$-carotene to retinol, most likely contributing to the increased VA concentration and reserves in hen liver; however, liver $\beta$-carotene concentrations were significantly higher in hens fed orange maize, indicating that some absorption of intact $\beta$-carotene did occur in this study. Hens fed the orange maize also had higher liver $\beta$-cryptoxanthin concentrations than other groups, reflective of $\beta$-cryptoxanthin concentrations in the feed. Lutein and

[A]Values are means ± SD; $n = 7$ white maize, $n = 8$ all other treatment groups. One-way ANOVA was used to determine differences among treatment groups for each carotenoid. Using LSMEANS, different lowercase superscript letters in a row designate differences ($P < 0.05$).

zeaxanthin accumulation in liver reflected feed intake, similar to results found when feeding high lutein and zeaxanthin feeds to Leghorn chicks.[38] Lutein concentration was highest in the yellow group's livers. Zeaxanthin was highest in the orange group and greater than the β-cryptoxanthin concentration. Furthermore, the ratio of liver β-cryptoxanthin to lutein (2.6) was higher than the ratio in the orange feed (0.9), which may indicate a bias against accumulation of lutein in the chicken liver. Differences among animal models in carotenoid metabolism are interesting. A common model used for provitamin A carotenoid metabolism is Mongolian gerbils, but they have the limitation of only absorbing and storing very small amounts of lutein and zeaxanthin.[39,40] Chickens appear to be a better model for studying xanthophyll carotenoid bioavailability. Similar to gerbils, serum concentrations of β-carotene were not detectable, which may be because chickens have higher HDL than LDL.[41] β-Carotene is predominantly carried by LDL, whereas lutein and zeaxanthin are carried by HDL.[42]

Chicken skin color is strongly associated with dietary concentration of carotenoids,[43] but there were no color differences among treatment groups in this study using L*a*b* scales. β-Cryptoxanthin was present in small amounts in chicken skin and was significantly higher in chickens fed orange maize. Even though the lutein concentration in the yellow group was extremely high, lutein concentrations did not differ in the skin. However, the hens used in this study were young and early in their laying cycle. Hens in peak egg production withdraw xanthophyll carotenoids from skin and deposit them in egg yolk. Increased deposition of xanthophyll carotenoids into skin is probably best studied in non-egg-laying chickens.

In order to be effective, biofortified foods must be accepted by targeted populations. Consumers have documented egg yolk preferences. Consumers in Germany, Belgium, Netherlands, and Spain prefer an orange-colored yolk, whereas those in Ireland and Sweden prefer a lighter yolk.[43] Dietary sources of β-cryptoxanthin are few and most humans obtain it from orange citrus fruits. Although β-cryptoxanthin concentration varies by fruit source, a mean value for orange juice is ∼200 μg/100 mL.[44] Thus, two biofortifed egg yolks (e.g., 30 g yolk with 5 μg β-cryptoxanthin/g) could provide about 75% of that amount or provide more than a medium fresh orange, which contains ∼60 mL juice.

The consumption of white staple foods by both humans and livestock in developing countries provides no VA. Many countries prefer nutrient-poor white maize to meet their daily calorie needs.[45] The introduction of provitamin A biofortified crops, such as orange maize, has the potential to raise xanthophyll intakes in humans and animals.[4,10−14] Due to the xanthophyll profile of maize, it should be especially targeted, because it is the primary ingredient in many livestock feeds, such as chickens, swine, and cattle. By substituting biofortified orange maize, which has enhanced β-cryptoxanthin, lutein, and zeaxanthin, for white or yellow maize in chicken feed, the need for VA or lutein-fortified feeds could be diverted lowering the cost for hen husbandry and improving the nutritional profile of eggs for human consumption.

The introduction of biofortified maize as a human food and an animal feed in developed and developing countries could have economic and health considerations for all. Eggs are a target for provitamin A carotenoid biofortification through feeding orange maize to laying hens, which could further eggs' status as a functional food with enhanced nutrition.[46] Furthermore, lutein and zeaxanthin, which are also enhanced in many genotypes of biofortified maize, may contribute to decreased risk of macular degeneration.[47] Thus, future studies should determine the impact of the complete carotenoid profile of the biofortified egg on human health.

ArO•

**Figure 1.** Molecular structures of α-, β-, γ-, and δ-tocopherols (Tocs) and α-, β-, γ-, and δ-tocotrienols (Toc-3s), γ-oryzanol, and aroxyl radical (ArO•).

brans prepared from many kinds of rice were found to contain different concentrations of α-, β-, γ-, δ-Tocs and -Toc-3s. However, to the best of our knowledge, a detailed kinetic study of the free radical scavenging activity of rice brans has not been carried out.

In the present study, measurements of the rate constants ($k_s^{Extract}$ ($f$) and $k_s^{Extract}$ ($t_{1/2}$)) and the relative ARAC values were performed for seven kinds of rice bran extracts 1−7 (Table 1), which were prepared from Japanese and Korean rice varieties, in ethanol, to evaluate the free radical scavenging activity of rice brans, and to demonstrate that the ARAC method is applicable to not only pure α-, β-, γ-, δ-TocHs, but also general food extracts. Measurement of the rate constants ($k_s^{\gamma\text{-Ory}}$ ($f$) and $k_s^{\gamma\text{-Ory}}$ ($t_{1/2}$)) for γ-Ory was also performed, as rice brans generally include high concentrations of γ-Ory.[14,18,19,22]

In addition, the concentrations (in mg/100 g) of α-, β-, γ-, δ-Tocs and -Toc-3s included in extracts 1−7 were determined using HPLC-MS/MS.[24] The concentration of γ-Ory was determined from the UV−vis absorption spectra of rice bran extracts 1−7.[14] Furthermore, comparison of the $k_s^{Extract}$ ($f$) values observed for the above extracts 1−7 with the sum of the product $\{\sum k_s^{AOH\text{-}i}$ ($f$) [AOH-$i$]/$10^5\}$ of the $k_s^{AOH\text{-}i}$ ($f$) values obtained for each AOH-$i$ and the concentration ([AOH-$i$]/$10^5$) of AOH-i included in the extracts was performed, in order to ascertain the validity of the ARAC assay method developed.[17]

## MATERIALS AND METHODS

**Materials.** α-, β-, γ-, δ-Tocs, and -Toc-3s were kindly supplied by Eisai Co. Ltd. (Tokyo, Japan). γ-Ory extracted from rice germ is commercially available (Wako Chemicals, Japan). The ArO• radical was prepared by following the method of Rieker et al.[25]

**Preparation of Rice Bran Extracts 1−7.** Seven kinds of crude rice bran samples 1−7 (Nipponbare (1), Wataribune (2), Koshihikari (3), Oiran (4), Moritawase (5), γ-rich Koshihikari (6), Milyang-23 (7); Table 1) were prepared from domestic Japanese (or Korean) dehulled rice using a Toyo-Tester grain-polishing machine (Toyo Rice Corporation, Tokyo, Japan).[15] γ-Rich Koshihikari (extract 6), which includes high concentrations of γ-Toc and -Toc-3 (Table 2), is a mutant of Koshihikari (extract 3). The weight of each sample was approximately 10% of the dehulled rice.

Measurements of the amounts of Tocs and Toc-3s and total γ-oryzanol in the rice bran were performed by Chen and Bergman[14] and Sookwong et al.,[15] using 2-propanol as an extraction solvent. In the present work, 2-propanol was similarly used to prepare the seven rice bran extracts 1−7.

Specifically, freshly prepared rice bran powder (40.2 g) of Nipponbare (1) was ground in a mortar using a pestle and subsequently freeze-dried for 6 h. To 38.3 g of dried powder, 150 mL of 2-propanol was added, and extraction was performed for 10 min at 20 °C using a magnetic stirrer. The extraction was repeated 3 times. Approximately 400 mL of the extracted 2-propanol solution was evaporated using a rotary evaporator. The resultant oil was then dried for 2 h using a vacuum pump to eliminate the remaining 2-propanol and water. Finally, 7.75 g of rice bran extract 1 was obtained. Repeating the extraction by 2-propanol from dried powder resulted in a notable decrease in the weight of the extract, so that the final quantity of the extract obtained by the third extraction was only 8% of that of the first extraction.

Rice bran extracts 2−7 were prepared similarly from ∼40 g of rice brans 2−7. An approximately 5% weight loss was observed by freeze-drying rice brans 2−7 for 6 h. The weight ratios of rice bran extracts 1−7 to freeze-dried rice bran powders 1−7 were 0.200, 0.243, 0.191, 0.123, 0.196, 0.178, and 0.189, respectively, all of which were similar to each other with the exception of Oiran (4). Taken together, these results suggest that the method of preparation of rice bran extracts 1−7 via 2-propanol extraction is reasonable.

Measurements of the ArO•-radical scavenging rates ($k_s^{Extract}$($f$) and $k_s^{Extract}$($t_{1/2}$)) and the concentrations of 4 Tocs and 4 Toc-3s included in extracts 1−7 were performed using the extracts prepared as described above.

**HPLC-MS/MS Measurement of the Concentrations of α-, β-, γ-, δ-Tocopherols and -Tocotrienols Included in Rice Bran Extracts 1−7.** Concentrations of α-, β-, γ-, δ-Tocs and -Toc-3s included in rice bran extracts 1−7 were determined by using a HPLC-MS/MS technique.

Approximately 10 mg of rice bran extracts whose weight was correctly measured was dissolved in 3.00 mL of $n$-hexane. This solution (50.0 μL) was further diluted with $n$-hexane to yield a final volume of 250 μL. Next, a portion (20.0 μL) of the prepared solution was subjected to

[a]mg/100 g shows the contents (mg) of 4 Tocs and 4 Toc-3s and $\gamma$-Ory included in 100 g of rice bran extracts 1−7. [b]Values are expressed as mean ± SD ($n$ = 3).

HPLC-MS/MS measurement.[15,24] Separation was performed at 40 °C using a silica column (ZORBAX Rx-SIL, 4.6 × 250 mm; Agilent, Palo Alto, CA). A mixture of hexane/1,4-dioxane/2-propanol (100:4:0.5) was used as the mobile phase at a flow rate of 1.0 mL/min. Tocs and Toc-3s were detected in atmospheric pressure chemical ionization mode (APCI). MS/MS parameters were optimized with Tocs and Toc-3s standards in APCI mode (positive). Tocs and Toc-3s were detected using multiple reaction monitoring (MRM) as follows: $\alpha$-Toc, $m/z$ 431.3 > $m/z$ 165.1; $\beta$-Toc, $m/z$ 417.3 > $m/z$ 151.3; $\gamma$-Toc, $m/z$ 417.3 > $m/z$ 151.0; $\delta$-Toc, $m/z$ 403.3 > $m/z$137.0; $\alpha$-Toc-3, $m/z$ 425.3 > $m/z$ 165.1; $\beta$-Toc-3, $m/z$ 411.3 > $m/z$ 151.1; $\gamma$-Toc-3, $m/z$ 411.3 > $m/z$ 151.2; $\delta$-Toc-3, $m/z$ 397.2 > $m/z$ 137.0. Typical MRM chromatograms of standard vitamin E homologues (A) and a rice bran extract (B) are shown in Figure S1A and B, respectively (Supporting Information). Tocs and Toc-3s concentrations in the rice bran extracts were calculated using calibration curves of standard Tocs and Toc-3s. The concentration was determined three times for each sample, and the average values are summarized in Table 2.

**UV−Vis Absorption Measurement of the Concentration of $\gamma$-Oryzanol Included in Rice Bran Extracts 1−7.** As reported previously,[14,19] $\gamma$-Ory extracted from rice germ oil contains 10 kinds of phytosterols. However, measurement of the concentration of each phytosterol included in rice bran extracts 1−7 was not performed in the present work, because the ArO•-scavenging rate of $\gamma$-Ory is two to 3 orders of magnitude smaller than those of $\alpha$-, $\beta$-, $\gamma$-, and $\delta$-Tocs and -Toc-3s, as will be discussed later. In the present work, the total concentration of $\gamma$-Ory included in rice bran extracts 1−7 was determined in ethanol from the UV−vis absorption spectrum, following the method performed by Chen and Bergman.[14] The values obtained are listed in Table 2, together with those for $\alpha$-, $\beta$-, $\gamma$-, and $\delta$-Toc and -Toc-3.

**Measurements.** Measurement of the second-order rate constants ($k_s^{AOH}(f)$ and $k_s^{AOH}(t_{1/2})$) and ARAC values for the reaction of ArO• with AOH (reaction 1) was performed using a Unisoku single-mixing stopped-flow spectrophotometer (Model RSP-1000), by mixing equal volumes of ethanol solutions of ArO• and AOH under nitrogen atmosphere.[17,26−28] The reaction was monitored with either single wavelength detection (Figure 2B) or a photodiode array detector (Figure 2A) attached to the stopped-flow spectrophotometer. All measurements were performed at 25.0 ± 0.5 °C. Experimental errors in the rate constants ($k_s^{AOH}(f)$ and $k_s^{AOH}(t_{1/2})$) were estimated to be about 7% in ethanol solution. Details of the measurements were described previously.[17,26−28]

## RESULTS AND DISCUSSION

**Rates of the Aroxyl-Radical-Scavenging ($k_s$) of Rice Bran Extracts 1−7 and $\gamma$-Oryzanol in Ethanol Solution.** UV−vis absorption spectra of rice bran extracts 1−7 and $\gamma$-Ory were measured in ethanol. The spectra observed for Koshihikari (3) and $\gamma$-Ory are shown in Figure 3A and B, respectively. The spectrum of Koshihikari (3) shows an absorption maximum ($\lambda_{max}$) at 328 nm and a shoulder ($\lambda_{shoulder}$) at ∼300 nm. Similar spectra were observed for extracts 1, 2, and 4−7. The absorption at 328 nm is attributable to $\gamma$-Ory ($\lambda_{max}$ = 328 nm ($\varepsilon_{max}$ = 35.6 L g$^{-1}$cm$^{-1}$) and $\lambda_{shoulder}$ ∼ 300 nm).[14,19] Weak broad absorption in the region between 380−500 nm (Figure 3A) is due to several carotenoids included in rice brans, as previously reported.[19] $\alpha$-, $\beta$-, $\gamma$-, $\delta$-Tocs and -Toc-3s show absorption maxima, $\lambda_{max}$, between 292−298 nm in ethanol, as previously reported.[29] The absorption bands of these Tocs and Toc-3s are thought to overlap with that of $\gamma$-Ory, because the $\varepsilon_{max}$ values (7.24−9.00 L g$^{-1}$cm$^{-1}$) of Tocs and Toc-3s are several times smaller than that of $\gamma$-Ory ($\varepsilon_{max}$ = 35.6 L g$^{-1}$cm$^{-1}$), and the concentrations of Tocs and Toc-3s are lower than that of $\gamma$-Ory (Table 2), as will be discussed later.[29]

The rate constant ($k_s^{Extract}$) for the reaction of the ArO• radical with rice bran extracts 1−7 was determined in ethanol at 25.0 °C (reaction 1). By reacting Oiran 4 with ArO• radical, the absorbance at 376 and 580 nm of the ArO• decreases, and the absorbance at 428 nm of Toc• and Toc-3• radicals, which will be mainly due to $\alpha$-Tocs• and $\alpha$-Toc-3•, increases, as shown in Figure 2A.[27,28] The decay rate ($k_{obsd}(f)$) of the ArO• radical was measured by following the decrease in absorbance at 580 nm (Figure 2B), because the absorption at 376 nm overlaps with that of Oiran 4 (specifically that of $\gamma$-Ory, as described above[19]). The pseudo-first-order rate constants ($k_{obsd}(f)$) at 580 nm were

dx.doi.org/10.1021/jf503996z | J. Agric. Food Chem. 2014, 62, 11901−11909

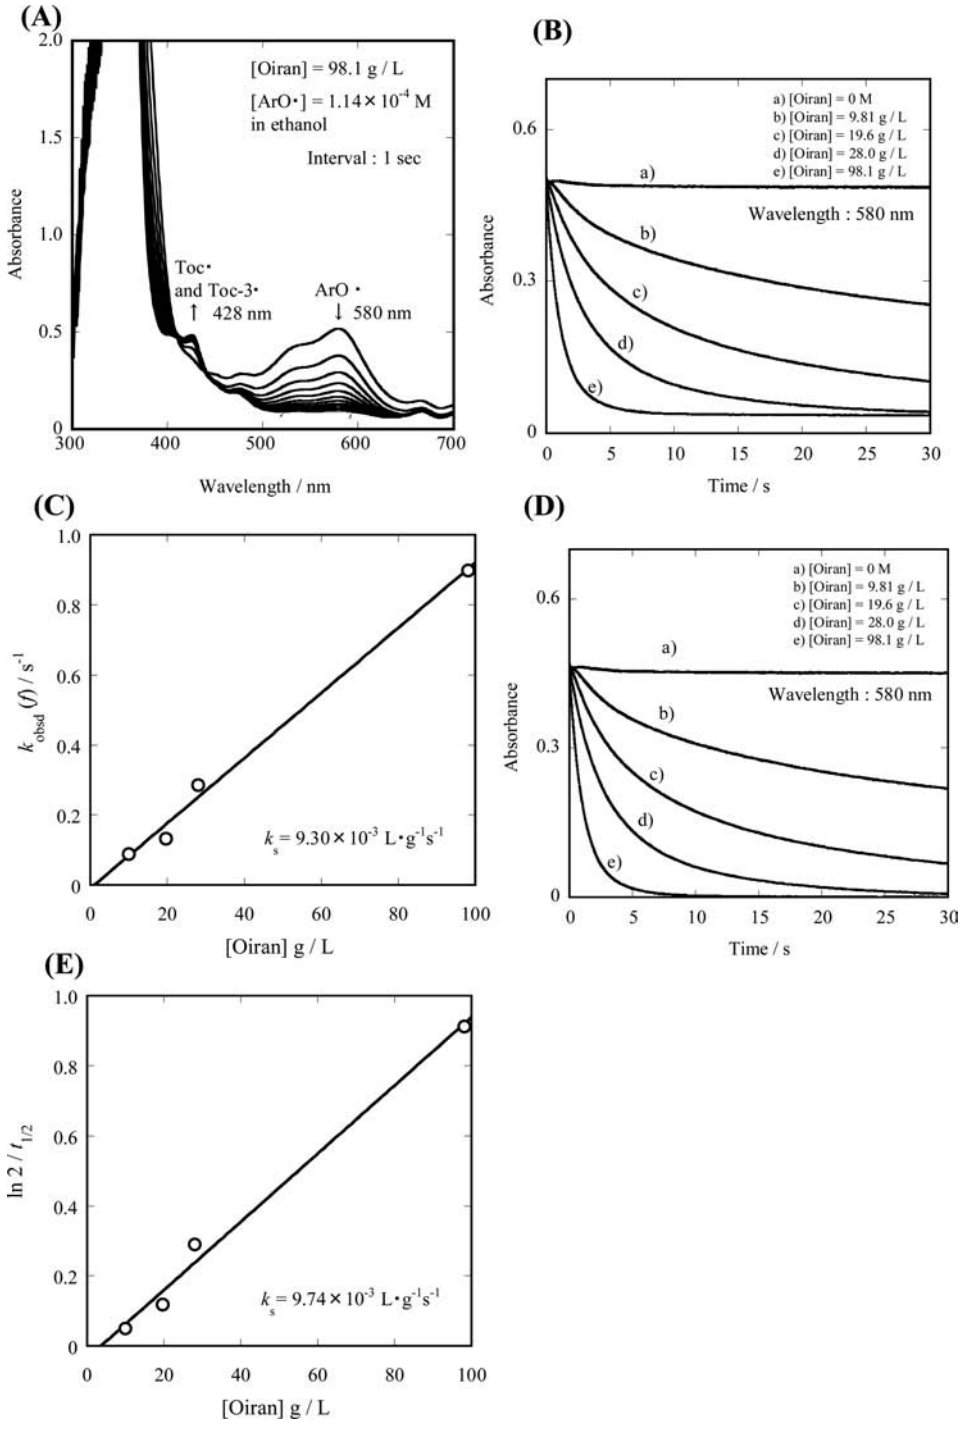

**Figure 2.** (A) Change in electronic absorption spectra of ArO• and Toc• (and Toc-3•) radicals during the reaction of ArO• with Oiran (4) in ethanol solution at 25.0 °C. The initial concentrations are [ArO•] = $1.14 \times 10^{-4}$ M and [Oiran] = 98.1 g/L. The spectra were recorded at 1 s intervals. The arrow indicates a decrease (ArO•) and increase (Toc• and Toc-3•) in absorbance with time. (B) Time dependences of the absorbance of the ArO• radical (at 580 nm) in solution containing five different concentrations of extract 4 at 25.0 °C. (C) Pseudo-first-order rate constant ($k_{obsd}$ ($f$)) versus [Oiran] plot. (D) Baseline correction. (E) ln $2/t_{1/2}$ versus [Oiran] plot.

linearly dependent on the concentration of the extract ([Extract]), and thus the rate equation is expressed as

$$-\mathrm{d}[\mathrm{ArO}\bullet]/\mathrm{d}t = k_{obsd}(f)\,[\mathrm{ArO}\bullet] = k_s^{\mathrm{Extract}}(f)\,[\mathrm{Extract}]\,[\mathrm{ArO}\bullet] \quad (2)$$

where $k_s$ ($f$) is the second-order rate constant for the oxidation of the extract by the ArO• radical. The rate constants ($k_s(f)$) were obtained by plotting $k_{obsd}(f)$ against [Extract], as shown in Figure 2C. Units of g/L were used for the concentrations of rice bran extracts 1−7. The $k_s(f)$ value obtained for Oiran (4) is $9.30 \times 10^{-3}$ L $g^{-1}s^{-1}$ (Table 1).

Equation 3 is easily obtained by substituting the relation for the first-order reaction ($k_{obsd}(f) = \ln 2/t_{1/2}$) into eq 2:

$$\ln 2/t_{1/2} = k_s^{\mathrm{Extract}}(t_{1/2})\,[\mathrm{Extract}] \quad (3)$$

dx.doi.org/10.1021/jf503996z | J. Agric. Food Chem. 2014, 62, 11901−11909

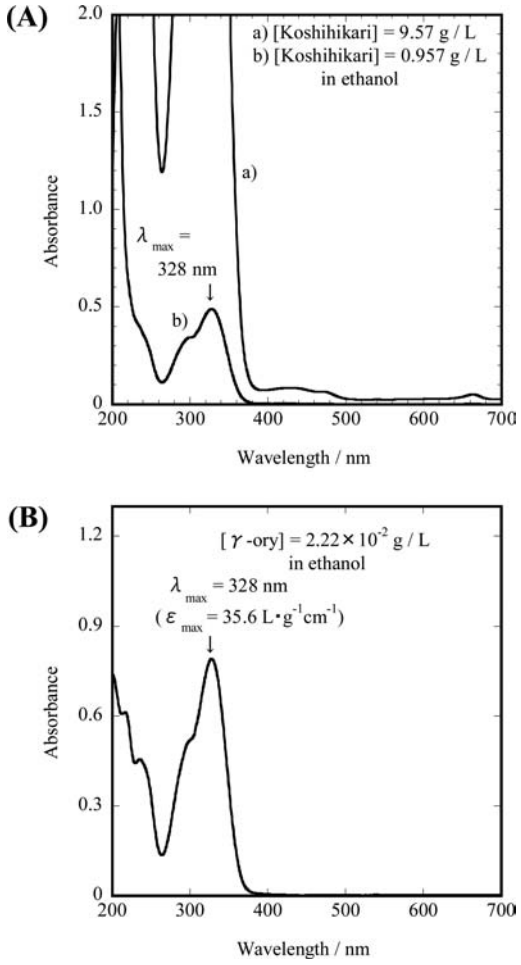

**Figure 3.** UV−vis absorption spectra of (A) Koshihikari (extract 3) and (B) γ-oryzanol in ethanol.

where $t_{1/2}$ is the half-life of ArO● in the presence of extract. To obtain the correct $t_{1/2}$ value in eq 3, baseline correction was performed for the decay curve of ArO● in Figure 2B. The results obtained are shown in Figure 2D. Equation 3 indicates that the $k_s^{Extract}$ ($t_{1/2}$) value can be obtained from a plot of ln $2/t_{1/2}$ versus [Extract]. An example for Oiran (4) is shown in Figure 2E. The value of $k_s^{Oiran}(t_{1/2})$ (= $9.74 \times 10^{-3}$ L $g^{-1}s^{-1}$) obtained for Oiran (4) was in good agreement with that of $k_s^{Oiran}(f)$ (= $9.30 \times 10^{-3}$ L $g^{-1}s^{-1}$), as listed in Table 1.

Similar measurements were performed for the reaction of ArO● with extracts 1−3, 5−7, and γ-Ory in ethanol solution. The result obtained for γ-Ory is shown in Figure 4. The $k_s^{Extract}(f)$ and $k_s^{Extract}(t_{1/2})$ values obtained for extracts 1−7 are summarized in Table 1, together with those of γ-Ory and α-Toc. Both $k_s^{Extract}(f)$ and $k_s^{Extract}(t_{1/2})$ increase in the following order:

$$\text{Milyang-23 (7)} \leq \gamma\text{-rich Koshihikari (6)} < \text{Moritawase (5)} \sim \text{Oiran (4)} < \text{Wataribune (3)} \sim \text{Koshihikari (2)} < \text{Nipponbare (1)} < \gamma\text{-oryzanol} < \alpha\text{-Toc} \quad (4)$$

Nipponbare (1) exhibits a $k_s^{Extract}(f)$ value 1.5 times larger than that of Milyang-23 (7). The $k_s^{\gamma\text{-Ory}}(f)$ value of γ-Ory is 2.1 times larger than that of Nipponbare (1). However, the value is 450 times smaller than that of α-Toc. The $k_s^{Extract}(f)$ values obtained for extracts 1−7 are shown as a bar graph in Figure 5A.

**Development of an Aroxyl Radical Absorption Capacity (ARAC) Assay Method for Food Extracts.** As

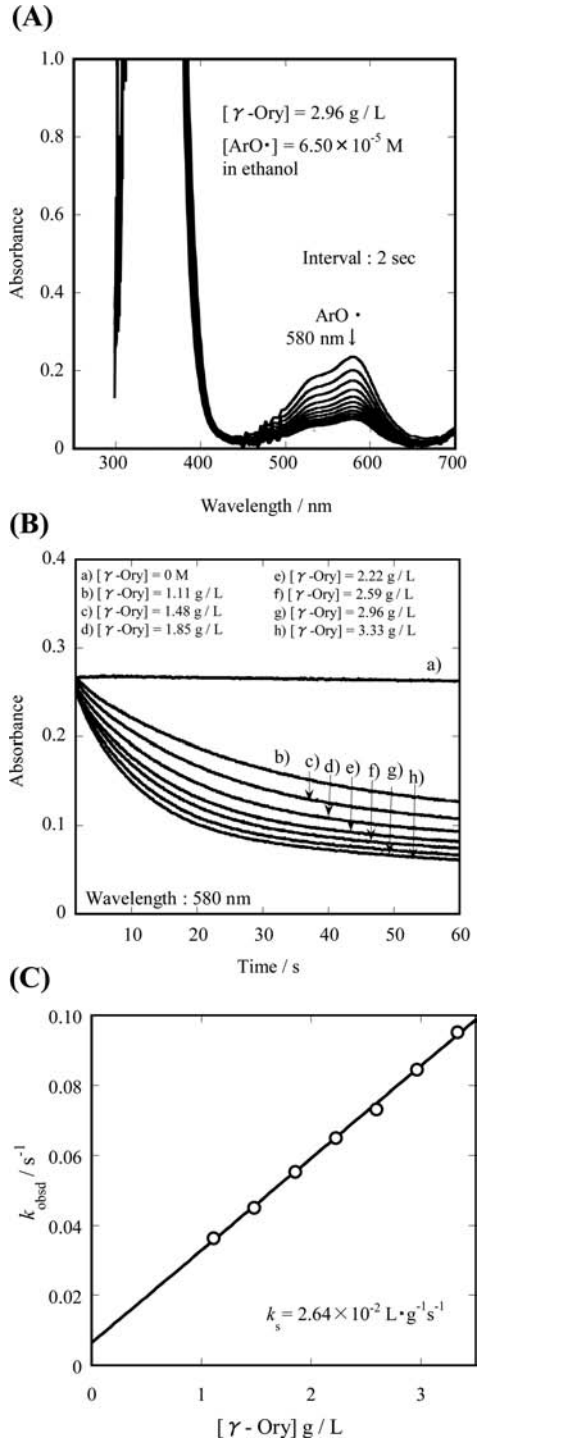

**Figure 4.** (A) Change in electronic absorption spectrum of the ArO● radical during the reaction of ArO● with γ-Ory in ethanol at 25.0 °C. [ArO●] = $6.50 \times 10^{-5}$ M and [γ-Ory] = 2.96 g/L. (B) Time dependences of the absorbance of the ArO● radical (at 580 nm) in ethanol containing eight different concentrations of γ-Ory at 25.0 °C. (C) Pseudo-first-order rate constant ($k_{obsd}(f)$) versus [γ-Ory] plot.

proposed previously,[17] relative ARAC ($f$) and ARAC ($t_{1/2}$) values for AOH were defined according to eqs 5 and 6:

$$\text{relative ARAC } (f) \text{ value (based on molar concentration unit (M = mol/L))} = k_s^{AOH}(f)\ (M^{-1}\,s^{-1}) / k_s^{\alpha\text{-Toc}}(f)\ (M^{-1}\,s^{-1}) \quad (5)$$

dx.doi.org/10.1021/jf503996z | J. Agric. Food Chem. 2014, 62, 11901−11909

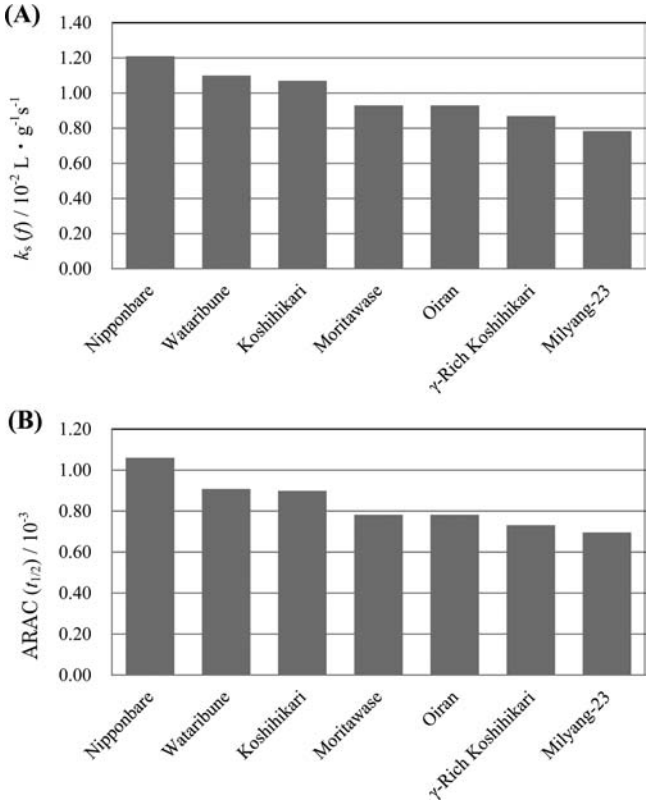

**Figure 5.** Comparison of (A) the $k_s(f)$ values and (B) the relative ARAC ($t_{1/2}$) values for seven kinds of rice bran extracts 1−7 in ethanol.

$$\text{relative ARAC } (t_{1/2}) \text{ value} = k_s^{\text{AOH}}(t_{1/2})\ (\text{M}^{-1}\,\text{s}^{-1}) / k_s^{\alpha\text{-Toc}}(t_{1/2})\ (\text{M}^{-1}\,\text{s}^{-1}) = (t_{1/2}{}^{\alpha\text{-Toc}}/t_{1/2}{}^{\text{AOH}}) \times ([\alpha\text{-Toc}]/[\text{AOH}]) \quad (6)$$

Equation 5 indicates that the ARAC ($f$) value corresponds to the ratio ($k_s^{\text{AOH}}(f)/k_s^{\alpha\text{-Toc}}(f)$) of the scavenging rate of ArO• ($k_s^{\text{AOH}}(f)$) by AOH to that ($k_s^{\alpha\text{-Toc}}(f)$) by $\alpha$-Toc. $\alpha$-Toc was used as a standard compound of ARAC assay.

By substituting the relation eq 3 into the second line of eq 6, we can obtain the third line of eq 6. According to eq 6, ARAC ($t_{1/2}$) value may be determined by the measurement of the half-life of the ArO• radical ($t_{1/2}{}^{\text{AOH}}$) and the concentration of AOH ([AOH]) without analysis of the decay rate of ArO•.

In the ARAC assay method, $\alpha$-Toc was used as a standard compound for the following reasons: (i) $\alpha$-Toc is a representative phenolic antioxidant, (ii) $\alpha$-Toc shows the same order of $k_s$ value as those for the other phenolic antioxidants (such as tocopherol homologues (4 Tocs and 4 Toc-3s), catechins, and ubiquinol-10),[17,26−28,30] (iii) $\alpha$-Toc and the above phenolic antioxidants often coexist in general foods[31−33] and biological systems (such as plasma[34] and mitochondria[35]), and function as free radical scavengers at a similar reaction field. Furthermore, $\alpha$-Toc was used as a standard compound in the singlet oxygen absorption capacity (SOAC) assay method, which was recently developed to evaluate the singlet oxygen quenching activity of many natural AOHs and food extracts.[36−38]

Units of g/L were used for the concentrations of rice bran extracts 1−7, while units of L $g^{-1}$ $s^{-1}$ were used for $k_s^{\text{Extract}}(f)$ and $k_s^{\text{Extract}}(t_{1/2})$ values. The ARAC values for extracts 1−7 were also calculated using g/L as the unit of concentration for AOH in eqs 5 and 6. The relative ARAC ($f$) (and ARAC ($t_{1/2}$)) values obtained for extracts 1−7 are shown as a bar graph in Figure 5B.

As summarized in Table 1, the $k_s^{\text{Extract}}(f)$ and $k_s^{\text{Extract}}(t_{1/2})$ values and the relative ARAC ($f$) and ARAC ($t_{1/2}$) values obtained for rice bran extracts 1−7 and $\gamma$-Ory are in good agreement with each other, suggesting that the ARAC assay method developed is applicable to the estimation of the free radical scavenging activity of food extracts. Measurement of ARAC values for many kinds of food extracts, including vegetable and fruit extracts and edible oils, will be necessary to verify the applicability of the ARAC assay method to food extracts, as performed for the SOAC assay method.[29,36−38]

**Contents of Eight Vitamin E Homologues and $\gamma$-Oryzanol in Rice Bran Extracts 1−7.** To compare the $k_s^{\text{Extract}}(f)$ value observed for rice bran extracts 1−7 with the value of $k_s^{\text{Extract}}(f)$ calculated using the rate constants ($k_s^{\text{AOH-i}}(f)$) and the concentrations ([AOH-i]) of each AOH included in extracts 1−7, measurements of the concentrations of 4 Tocs and 4 Toc-3s and $\gamma$-Ory were performed.

The concentrations (in mg/100 g) of 4 Tocs and 4 Toc-3s included in extracts 1−7 were measured using HPLC-MS/MS, as described in Materials and Methods. The results obtained are listed in Table 2. The concentrations of $\alpha$-, $\beta$-, $\gamma$-, $\delta$-Tocs, and -Toc-3s obtained for extracts 1−7 are in reasonable agreement with previously reported values.[15] High concentrations of Toc-3s are included in rice bran extracts 1−7, as listed in Table 2. Nipponbare (1) and Oiran (4) contain high total concentrations of $\alpha$-Toc and $\alpha$-Toc-3. Specifically, high concentrations of $\gamma$-Toc and $\gamma$-Toc-3 were included in $\gamma$-rich Koshihikari (6) and Milyang-23 (7).

On the other hand, the total concentration of $\gamma$-Ory included in extracts 1−7 was determined from the UV−vis absorption spectrum. As reported previously,[14,19] $\gamma$-Ory extracted from rice germ oil contains 10 kinds of phytosterols. Three of these, namely, cycloartenyl ferulate, 24-methylenecycloartanyl ferulate, and campesteryl ferulate, were major components of $\gamma$-Ory. In the present work, commercially available $\gamma$-Ory extracted from rice germ oil was used as a standard. The $\varepsilon_{\text{max}}$ value (35.6 L $g^{-1}cm^{-1}$) of $\gamma$-Ory at 328 nm in ethanol was determined from the UV−vis absorption spectrum of $\gamma$-Ory (see Figure 3B). Using this $\varepsilon_{\text{max}}$ value, the concentration (in mg/100 g) of $\gamma$-Ory included in extracts 1−7 was tentatively estimated. The values obtained are listed in Table 2, together with those for $\alpha$-, $\beta$-, $\gamma$-, and $\delta$-Toc, and -Toc-3. The concentration of $\gamma$-Ory in extracts 1−7 were similar (between 1400−1970 mg/100 g), and about 1 order of magnitude larger than those of total Tocs and Toc-3s (112−152 mg/100 g), as listed in Table 2.

**Comparison of Observed and Calculated ArO•-Scavenging Activities for Rice Bran Extracts 1−7.** It is well-known that various AOHs coexist not only in foods and plants, but also in human tissues. The $k_s^{\text{Extract}}(f)$ (L $g^{-1}s^{-1}$) values for rice bran extracts 1−7 were determined from a plot of $k_{\text{obsd}}(f)$ versus [Extract (g/L)] using eq 7.

$$k_{\text{obsd}}(f) = k_s^{\text{Extract}}(f)\ [\text{Extract}] \quad (7)$$

$$k_{\text{obsd}}(f) = \{\Sigma k_s^{\text{AOH-}i}(f)[\text{AOH-}i]/10^5\}\ [\text{Extract}] \quad (8)$$

As listed in Table 2, 4 Tocs and 4 Toc-3s and $\gamma$-Ory (abbreviated as AOH-i) are included in extracts 1−7. Polyphenols are also included in rice bran.[21,23] However, the concentrations of these polyphenols are not reported. Furthermore, carotenoids are included in rice bran extracts, as shown in Figure 3A.[21] However, as the free radical scavenging activity of

Table 3. Comparison between Observed and Calculated ArO• Scavenging Rates ($k_s^{Koshihikari}$ (Obsd.) and $\Sigma k_s^{AOH\text{-}i}(f) \times ([AOH\text{-}i]/10^5)$ (Calcd.)) for Koshihikari (3) in Ethanol Solution

carotenoids is generally low, the contribution of carotenoids to the ArO•-scavenging rate is thought to be small and negligible.

Recently, measurements of the ArO•-scavenging rate constants ($k_s^{AOH}(f)$) of AOHs ($\alpha$-, $\beta$-, $\gamma$-, $\delta$-Tocs and -Toc-3s) were performed in ethanol solution.[30] $k_s^{AOH}(f)$ values of $\alpha$-, $\beta$-, $\gamma$-, $\delta$-Toc-3s were in good agreement with those of the corresponding $\alpha$-, $\beta$-, $\gamma$-, $\delta$-Tocs. The $k_s^{AOH}(f)$ values reported are listed in Table 3. The $k_s^{AOH}(f)$ value for $\gamma$-Ory was measured in the present work.

Consequently, the $k_s^{Extract}(f)$ values for extracts 1−7 were calculated using eq 8, that is, $\{\Sigma k_s^{AOH\text{-}i}(f)\,[AOH\text{-}i]/10^5\}$, where the $k_s^{AOH\text{-}i}(f)$ (L $g^{-1}s^{-1}$) values are the rate constants for 4 Tocs, 4 Toc-3s, and $\gamma$-Ory in ethanol (see Tables 3 and 4). [AOH-$i$] is the concentration (in mg/100 g) of Tocs, Toc-3s, and $\gamma$-Ory included in extracts 1−7 (see Table 2). As an example, the result of the detailed analysis performed for Koshihikari (3) is listed in Table 3. Good agreement between the observed $k_s^{Koshihikari}(f)$ value (= $1.07 \times 10^{-2}$ L $g^{-1}s^{-1}$) and calculated $\{\Sigma k_s^{AOH\text{-}i}(f)\,[AOH\text{-}i]/10^5\}$ value (= $1.13 \times 10^{-2}$ L $g^{-1}s^{-1}$) observed for Koshihikari (3). The contribution of $\gamma$-Ory to the total $k_s^{Koshihikari}(f)$ value is small and about 3.3% of the total rate. A similar result was obtained for Nipponbare (1) (see Table 4). These results indicate that the total ArO•-scavenging activity of Nipponbare (1) and Koshihikari (3) may be explained by only considering the contribution of 8 kinds of vitamin E homologues and $\gamma$-Ory included in Nipponbare (1) and Koshihikari (3). The contribution of the other AOHs is negligible. Furthermore, this result suggests that the interactions between 8 vitamin E homologues and among vitamin E homologues and many molecules included in rice bran extracts are weak and negligible in solution.

On the other hand, as listed in Table 4, $k_s^{Extract}(f)$ (Obsd.) values for extracts 2 and 4−7 are 14−27% smaller than the corresponding ($k_s^{Extract}(f)$ (Calcd.)) values calculated using only the concentrations of 4 Tocs, 4 Toc-3s, and $\gamma$-Ory. We may expect that the $k_s^{Extract}(f)$ (Obsd.) values for extracts 1−7 are similar to or larger than those ($k_s^{Extract}(f)$ (Calcd.)) calculated, because the other AOHs, such as polyphenols included in extracts 1−7, may also contribute to the $k_s^{Extract}(f)$ (Obsd.) values.[26]

In a previous study, measurements of the ArO•-scavenging rate constants ($k_s^{AOH}(f)$) of AOHs ($\alpha$-Toc, ubiquinol-10 ($UQ_{10}H_2$) and sodium ascorbate ($Na^+AsH^-$)) were performed in 2-propanol/water (5/1, v/v) solution.[28] $k_s^{AOH}(f)$ values were measured not only for each AOH but also for the mixtures of two AOHs ((i) $\alpha$-Toc and $UQ_{10}H_2$ and (ii) $\alpha$-Toc and $Na^+AsH^-$). A notable synergistic effect, namely, that the $k_s^{AOH}(f)$ values increase 1.6, 2.5, and 6.8 times for $\alpha$-Toc, $UQ_{10}H_2$, and $Na^+AsH^-$, respectively, was observed for the solutions containing two kinds of AOHs.

Furthermore, measurements of the ArO•-scavenging rate constants ($k_s^{AOH}(f)$) of AOHs ($\alpha$-, $\beta$-, $\gamma$-, $\delta$-Tocs) were recently performed in ethanol solution, not only for each AOH but also for the mixtures of two AOHs ((i) $\alpha$-Toc and $\beta$-Toc, (ii) $\alpha$-Toc and $\gamma$-Toc, and (iii) $\alpha$-Toc and $\delta$-Toc).[30] A considerable synergistic effect, namely, that the $k_s^{AOH}(f)$ value increases 12%, was observed for the solutions containing $\alpha$-Toc and $\gamma$-Toc. On the other hand, a canceling effect, namely that the $k_s^{AOH}(f)$ value decreases by (i) 7% and (ii) 24%, respectively, was observed for the solutions containing (i) $\alpha$-Toc and $\beta$-Toc and (ii) $\alpha$-Toc and $\delta$-Toc. Similar results were observed for the mixtures of $\alpha$-, $\beta$-, $\gamma$-, $\delta$-Toc-3s.[30]

In rice bran extracts 1−3 and 5, the concentrations of total $\alpha$-Toc and $\alpha$-Toc-3 and of total $\gamma$-Toc and $\gamma$-Toc-3 were higher than those of total $\beta$-Toc and $\beta$-Toc-3 (and total $\delta$-Toc and $\delta$-Toc-3), while the concentrations of total $\alpha$-Toc and $\alpha$-Toc-3

were similar to those of total γ-Toc and γ-Toc-3 (Table 2). Consequently, we may expect a synergistic effect (that is, an increase of the $k_s^{Extract}(f)$ values) for rice bran extracts 1−3 and 5. However, the $k_s^{Extract}(f)$ values observed for extracts 1−3 and 5 were similar to or smaller than the corresponding calculated values. High concentrations of proteins, lipids, and carbohydrates are included in rice bran extracts. The interactions between these compounds and Tocs (and Toc-3s) molecules may affect the ArO•-radical scavenging activity of AOHs. However, the reason is not clear at present. A detailed study will be necessary to clarify the reason why the values of the ratio ($k_s^{Extract}(f)$ (Obsd.)/$k_s^{Extract}(f)$ (Calcd.)) obtained for extracts 1−7 are ≤1 (Table 4).

In recent years, various methods to assess the free radical scavenging activity of natural antioxidants and vegetable and fruit extracts have been proposed.[16] The oxygen radical absorbance capacity (ORAC) assay method is one of the most frequently used methods.[39−42] The ORAC values for extracts of nearly 300 vegetables and fruits have been measured and are listed on the US Department of Agriculture (USDA) Web site (http://www.ars.usda.gov/SP2UserFiles/Place/12354500/Data/ORAC/ORAC07.pdf). However, to our regret, in 2012 the USDA's Nutrient Data Laboratory (NDL) removed the USDA ORAC Database for Selected Foods from the NDL Web site because of mounting evidence that the values indicating antioxidant capacity have no relevance to the effects of specific bioactive compounds, including polyphenols, on human health.[43] Accordingly, several alternative methods have been proposed to assess antioxidant capacity against free radicals.[16,44]

In a previous work, a new assay method that can quantify the aroxyl radical absorption capacity (ARAC) of phenolic AOHs, including α-, β-, γ-, δ-Tocs and five tocopherol derivatives, was proposed.[17] However, the examples of food extracts investigated were limited to a palm oil extract. In the present work, relative ARAC ($f$) and ARAC ($t_{1/2}$) values were measured for seven rice bran extracts 1−7, which include eight kinds of vitamin E homologues (4 Tocs and 4 Toc-3s) and γ-Ory. Results suggest that the ARAC assay method may be applicable not only to general natural AOHs but also to food extracts that include many kinds of AOHs.

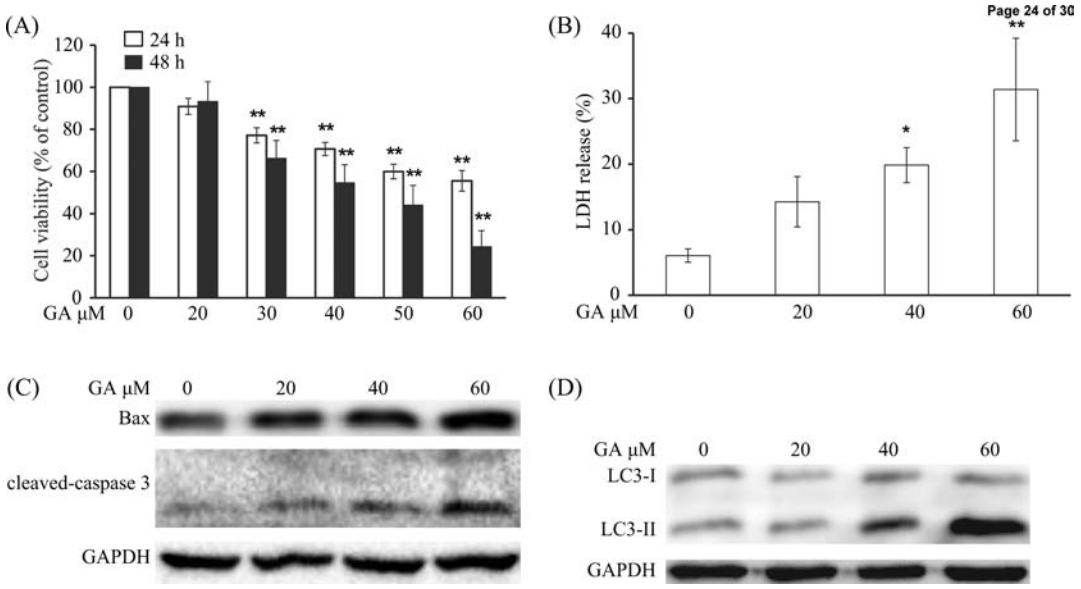

**Figure 1.** GA reduced the cell viability, enhanced LDH release, and increased the expression of Bax, cleaved caspase-3, and LC3-II in HCC cells. (A) Cells were treated with indicated concentrations of GA for 24 or 48 h. The cell viability was evaluated by MTT assay. (*) $P < 0.05$ and (**) $P < 0.01$, compared with 0 $\mu$M GA treatment. (B) Cells were treated with 0, 20, 40, and 60 $\mu$M GA for 24 h, and the LDH assay was performed according to the manufacturer. (*) $P < 0.05$ and (**) $P < 0.01$, compared with 0 $\mu$M GA treatment. (C, D) HepG2 cells were treated with indicated dosages of GA for 24 h. Cell extracts were analyzed for the expression levels of Bax, cleaved caspase-3, and LC3 by Western blot analysis.

dysfunctional cellular components through the actions of lysosomes.[18,19] In the initiation of tumors, autophagy inhibits tumor formation by degradation of damaged organelles or proteins.[20] However, after tumor formation, the tumors can utilize the autophagy as a survival mechanism to ensure growth advantage of cancer cells in a hypoxia, starvation, and acid environment.[21] Herein, we confirmed that GA induced autophagy in HCC cells by activation of extracellular regulated protein kinases (ERK), and inhibition of autophagy or ERK activation, GA-induced proliferative inhibition, and apoptosis were enhanced. Our study suggested that the GA triggered autophagic effect may attenuate the anticancer efficiency of GA or chemotherapeutic drugs loaded with GA-modified TDDS and requires further evaluation.

## MATERIALS AND METHODS

**Reagents.** GA was obtained from National Institutes for Food and Drug Control (Shenzhen, Guangdong, China). Monodansylcadaverine (MDC), chloroquine (CQ), bafilomycin A1 (BAF), and dimethyl sulfoxide (DMSO) were obtained from Sigma (St. Louis, MO, USA). PD98059 and U0126 were purchased from Beyotime Biotechnology Corp. (Shanghai, China). A Cytotoxicity Detection Kit (lactate dehydrogenase, LDH) was obtained from Roche Diagnostics (Mannheim, Germany). 3-(4,5-Dimethyl-2-thiazolyl)-2,5-diphenyltetrazolium bromide (MTT) was purchased from Molecular Probes (Eugene, OR, USA). Dulbecco's modified Eagle's medium (DMEM) medium, fetal bovine serum (FBS), antibiotics (100 U/mL penicillin and 100 mg/mL streptomycin), and phosphate-buffered saline (PBS) were purchased from Gibco (Carlsbad, CA, USA). Primary antibodies, that is, microtubule-associated protein light-chain 3 (LC3), ERK, p-ERK (Thr202/Tyr204), Bax, cleaved caspase-3, cleaved caspase-9, and GAPDH, and the secondary antibodies were purchased from Cell Signaling Technology Inc. (Beverly, MA, USA).

**Cell Culture.** Hepatocellular carcinoma HepG2 and Hep3B cells were obtained from the American Type Culture Collection (ATCC, Rockville, MD, USA) and cultured in a DMEM supplemented with 10% (v/v) FBS and 1% (v/v) antibiotics (100 U/mL penicillin, 100 $\mu$g/mL streptomycin). Cells were cultured in a 5% $CO_2$ incubator at 37 °C. Exponentially growing cells were used in the experiments.

**MTT Assay.** Cell viability was examined by the MTT assay. Exponentially growing HepG2 cells were seeded onto 96-well plates. Upon reaching approximately 70−80%, cells were incubated with a series of concentrations of the test compounds. Then, cell viability was determined by incubating the cells in a medium containing 1 mg/mL MTT for 4 h before 100 $\mu$L of DMSO was added to solubilize the formazan. The absorbance at 570 nm was measured with a microplate reader (PerkinElmer, 1420 Multilabel Counter Victor3, Wellesley, MA, USA).

**LDH Assay.** HepG2 cells were cultured to 70−80% concentration on 96-well plates and then treated with the indicated concentrations of GA for 24 h. The cellular toxicity was studied by detection of the LDH released into the incubation medium by the cytotoxicity detection kit according to the manufacturer's instructions.

**MDC Staining.** The autofluorescent agent MDC (excitation, 360 nm; emission, 535 nm) was utilized to evaluate the abundance of acidic vesicular organelles (AVOs) in the cells because it can accumulate in AVOs and exhibit fluoresced bright green dots.[22] For qualitative analysis, cells were seeded onto 96-well plates, treated with indicated concentrations of GA for 24 h and stained with 50 $\mu$M MDC in PBS for 30 min. Cells were washed with PBS three times and immediately analyzed using In Cell Analyzer 2000 imaging system (GE Healthcare, Uppsala, Sweden). For qualitative analysis, cells were seeded onto 24-well plates and treated with a series of concentrations of the test compounds. Then, cells were stained with 50 $\mu$M MDC in PBS for 30 min. After washed with PBS three times, the mean fluorescence intensities of the cells were determined with a flow cytometer (Becton Dickinson FACS CantoTM, BD Biosciences, San Jose, USA).

**Transmission Electron Microscopy (TEM) Assay.** After treatment or not with 40 $\mu$M GA for 24 h, the cells were harvested and washed with PBS and then fixed in ice-cold 2.5% glutaraldehyde for 1 h. After being washed with PBS three times for 15 min, cells were postfixed in 1% $OsO_4$ for 1 h and stained with 2% uranyl acetate for 30 min at room temperature. Then cells were dehydrated through a graded series of ethanol (50, 70, and 90%) for 15 min each, ethanol (100%) for 20 min, and 100% acetone for 20 min, respectively, and embedded in Epon812. Ultrathin sections (120 nm) were obtained before staining with 2% uranyl acetate for 20 min and lead citrate for 5 min and then examined using a TECNAI 10 transmission electron

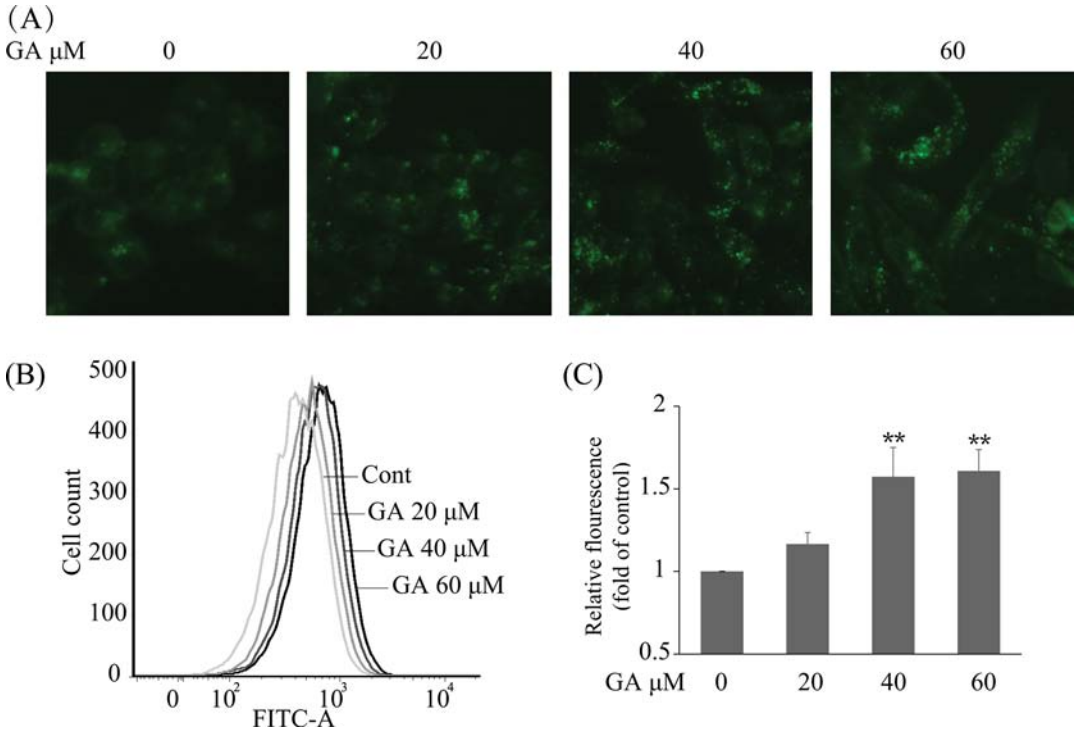

**Figure 2.** GA -triggered autophagy in HepG2 cells by MDC staining. (A) HepG2 cells were treated with GA at indicated concentrations for 24 h. The cells were collected, washed with PBS, and incubated with 50 $\mu$M MDC probe for 30 min. AVOs (bright green dots) in HepG2 cells were imaged with a fluorescent microscope. (B) The treated cells were stained with 50 $\mu$M MDC probe for 30 min, collected, washed, and resuspended. The intracellular fluorescence was quantified using flow cytometry. (C) Statistical result of three independent tests of (B). Data represent the mean ± SD, and one-way ANOVA was performed to evaluate the significance of different treatment. (∗) $P < 0.05$ and (∗∗) $P < 0.01$, compared with 0 $\mu$M GA treatment.

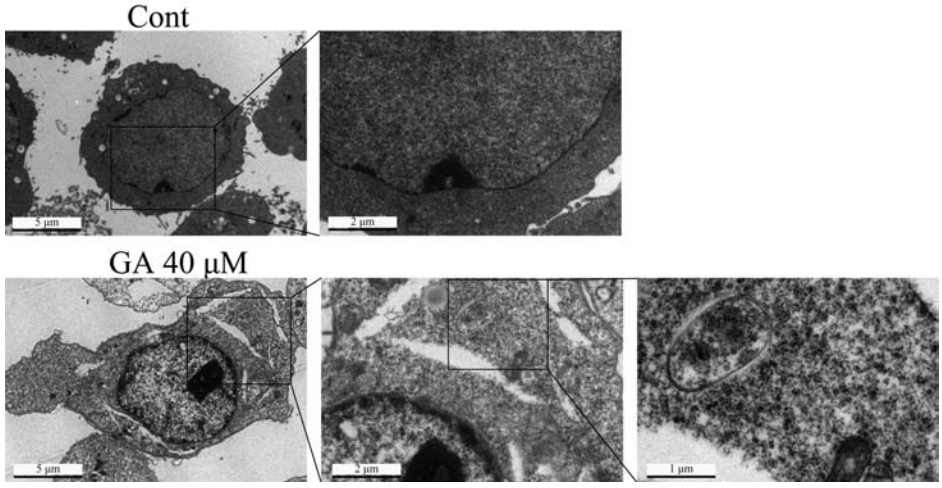

**Figure 3.** GA-triggered autophagy in HepG2 cells by TEM observation. HepG2 cells were treated with 40 $\mu$M GA or vehicle control for 24 h. Cells were collected, fixed, and observed under a TEM.

microscope (Phillips, Eindhoven, The Netherlands) at high voltage of 80 kV.

**Western Blot Analysis.** Proteins were extracted with a radioimmunoprecipitation lysis buffer containing 1% phenylmethanesulfonyl fluoride and 1% protease inhibitor cocktail for 25 min. The protein concentrations were measured with a BCA Protein Assay Kit (Pierce, Rockford, IL, USA). Equal amounts of proteins were separated using sodium dodecyl sulfate–polyacrylamide gel electrophoresis and transferred to a polyvinylidene fluoride membrane, which was blocked in 5% nonfat dried milk for 1 h. The membranes were probed with specific primary antibodies against LC3, p-ERK (Thr202/Tyr204), ERK, Bax, cleaved caspase-3, cleaved caspase-9, and GAPDH followed by incubation with the corresponding secondary antibodies. The specific protein bands were detected with an ECL advanced Western blot analysis detection kit (BD Biosciences, Bedford, MA, USA).

**Statistical Analysis.** The mean ± standard deviation (SD) was determined for each group. Statistical analysis was performed with one-way analysis of variance (ANOVA) and Tukey's test. Differences were considered statistically significant for (∗) $P < 0.05$ and (∗∗) $P < 0.01$.

## RESULTS

**GA Reduced the Cell Viability, Enhanced LDH Release, and Increased the Expression of Bax, Cleaved Caspase-3, and LC3-II in HCC Cells.** First, the MTT assay was used to evaluate the cell viability. As shown in Figure 1A, the cell viability of HepG2 cells was concentration- and time-dependently reduced after GA treatment. After treatment with 40 $\mu$M GA for 24 and 48 h, 71 and 55% HepG2 cells survived, respectively. We also found that GA increased LDH release into the medium in a concentration-dependent manner (Figure 1B), indicating that necrosis has occurred.[23] The apoptosis-related proteins, such as Bax and cleaved caspase-3, were also obviously enhanced after GA treatment (Figure 1C), which was similar to a previous study.[11] Besides, the expression of LC3-II, which correlates with the number of autophagosomes,[24] was concentration-dependently up-regulated after GA treatment (Figure 1D).

**GA Triggered Autophagy in HCC Cells.** To further confirm GA-triggered autophagy in HepG2 cells, multiple approaches were used. As AVOs are a hallmark of autophagy,[25] we initially evaluated the generation of AVOs by autofluorescent agent MDC, which accumulates in AVOs and fluoresces bright green dots.[22,26] The formation of AVOs in HepG2 cells was enhanced after treatment with various concentrations of GA for 24 h as evidenced by obvious green dot formation, whereas the control cells exhibited faint fluorescence only (Figure 2A). The GA-mediated AVO accumulation was also quantified using flow cytometry; GA concentration-dependently increased fluorescence intensity in HepG2 cells after 24 h of treatment. The 40 $\mu$M GA-treated cells exhibited an approximately 1.57-fold increase in fluorescence intensity compared with that of the control group (Figure 2B,C), which was consistent with morphological observations, suggesting that GA truly induces AVO production in HepG2 cells. Another traditional and classical method for autophagy observation is transmission electron microscopy (TEM) analysis.[27] Herein, the TEM experiment was performed to confirm the formation of AVOs after GA treatment in HepG2 cells. As shown in Figure 3, more AVOs were developed in the GA-treated group than in the control group. To further study GA-induced autophagic flux in HepG2 cells, two autophagy inhibitors, that is, chloroquine (CQ) and bafilomycin A1 (BAF), which cause accumulation of LC3-II protein by blocking the fusion between autophagosome and lysosome or suppressing the acidification of the lysosome,[27] were used. After pretreatment with CQ (10 $\mu$M) or BAF (100 nM), the GA-induced up-regulation of LC3-II was more prominent than in nontreated cells (Figure 4B), indicating that GA induces autophagic flux in HepG2 cells. GA-triggered autophagy was also confirmed in HCC Hep3B cells as evidenced by GA concentration-dependently increased expression of LC3-II (Supporting Information Supplemental Figure 1). Taken together, these data collectively indicate that GA triggers autophagy in HCC cells.

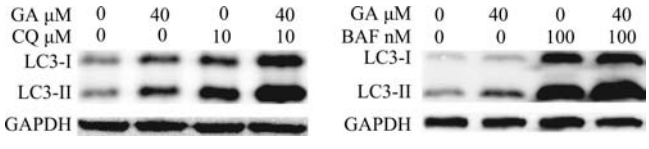

**Figure 4.** GA-triggered autophagic flux in HepG2 cells by Western blot analysis. HepG2 cells were incubated in 40 $\mu$M GA for 24 h with or without pretreatment of CQ (10 $\mu$M, 1 h) or BAF (100 nM, 1 h). Cell extracts were analyzed for LC3 expression levels using Western blot analysis.

**GA-Triggered Protective Autophagy in HCC Cells.** Natural compound-induced autophagy may be either pro-survival or pro-death in cancer therapy.[28,29] Herein, to clarify the effect of GA-induced autophagy in HCC cells, we evaluated the GA-mediated cell survival and apoptosis in cells pretreated with the autophagy inhibitors CQ (10 $\mu$M, 1 h) or BAF (100 nM, 1 h). MTT results indicated that survival rates of GA-treated HepG2 cells were decreased from 69.79 to 46.09 or 22.13% via pretreatment with CQ or BAF, respectively (Figure 5A). Western blot analysis indicated that pretreatment with CQ or BAF obviously enhanced the protein levels of cleaved caspase-3 and cleaved caspase-9 in HepG2 cells (Figure 5B). Besides, the cell viability of Hep3B cells was decreased from 63.47% (GA only) to 52.85% (GA + CQ) or 53.47% (GA + BAF), respectively (Supplemental Figure 2). Taken together, these data suggest that GA triggers a protective autophagy in HCC cells.

**GA-Triggered Autophagy by Activation of ERK in HepG2 Cells.** To further determine the molecular mechanism of GA-triggered autophagy induction in HepG2 cells, we evaluated the activation status of ERK signaling, a critical pathway of autophagy induction.[30,31] Phosphorylated ERK (p-ERK) and total ERK were assayed after cells had been treated with different concentrations of GA. As shown in Figure 6A, expression of p-ERK was concentration-dependently increased after treatment with GA for 24 h, indicating that GA activated ERK in HepG2 cells. In addition, we examined whether the activated ERK was critical for GA-triggered autophagy. Cells were pretreated with the MEK inhibitor (U0126 or PD98059), the p-ERK, as well as the GA-induced expression of LC3-II was decreased (Figure 6B,C). Furthermore, the GA-induced AVO formation was also decreased after pretreatment with PD98059 (Figure 6D).

**Inhibition of ERK Enhanced GA-Induced Cell Death and Apoptosis.** We further studied the effects of the ERK pathway in GA-induced cell death and apoptosis. As shown in Figure 7A, the cell viability of HepG2 was 69.79% after treatment with GA alone, whereas it decreased to 54.78% after combined treatment with PD98059 and GA. Furthermore, the expression of cleaved caspase-3 was more obvious in the PD98059 + GA group compared with the GA alone group (Figure 7B).

## DISCUSSION

Targeted drug treatment is a novel promising strategy for HCC, which specifically delivers chemotherapeutic drugs to HCC and results in increased local concentrations and reduced side effects.[32] GA is an excellent ligand for HCC-targeting due to the abundant binding sites on the cellular membrane of liver cells.[14] Besides, GA exhibits potential anti-HCC effects by inhibition of proliferation and induction of apoptosis and cell cycle arrest.[11] Herein, we demonstrated that GA induced cell viability reduction, LDH release, and up-regulation of Bax and cleaved caspase-3, indicating that necrosis and apoptosis may contribute to GA-induced cell death. We also found, for the first time, that GA triggered the autophagic response in HCC cells as evidenced by obvious up-regulation of AVO formation by MDC staining and TEM detection, and by elevation of LC3-II protein expression by Western blot analysis and that

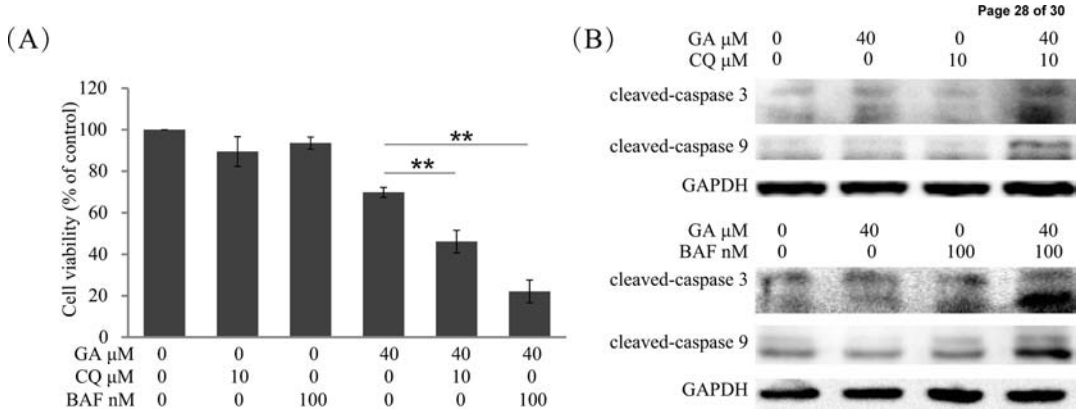

**Figure 5.** Inhibition of autophagy enhanced GA-induced cell death and apoptosis in HepG2 cells. (A) HepG2 cells were treated with indicated concentrations of GA for 24 h with or without pretreatment of CQ (10 $\mu$M, 1 h) or BAF (100 nM, 1 h). Cell viability was evaluated by MTT assay. (*) $P < 0.05$ and (**) $P < 0.01$. (B) HepG2 cells were treated with 40 $\mu$M GA for 24 h with or without pretreatment of CQ (10 $\mu$M, 1 h) or BAF (100 nM, 1 h). Cell extracts were analyzed for the levels of cleaved caspase-3 and cleaved caspase-9 by Western blot analysis.

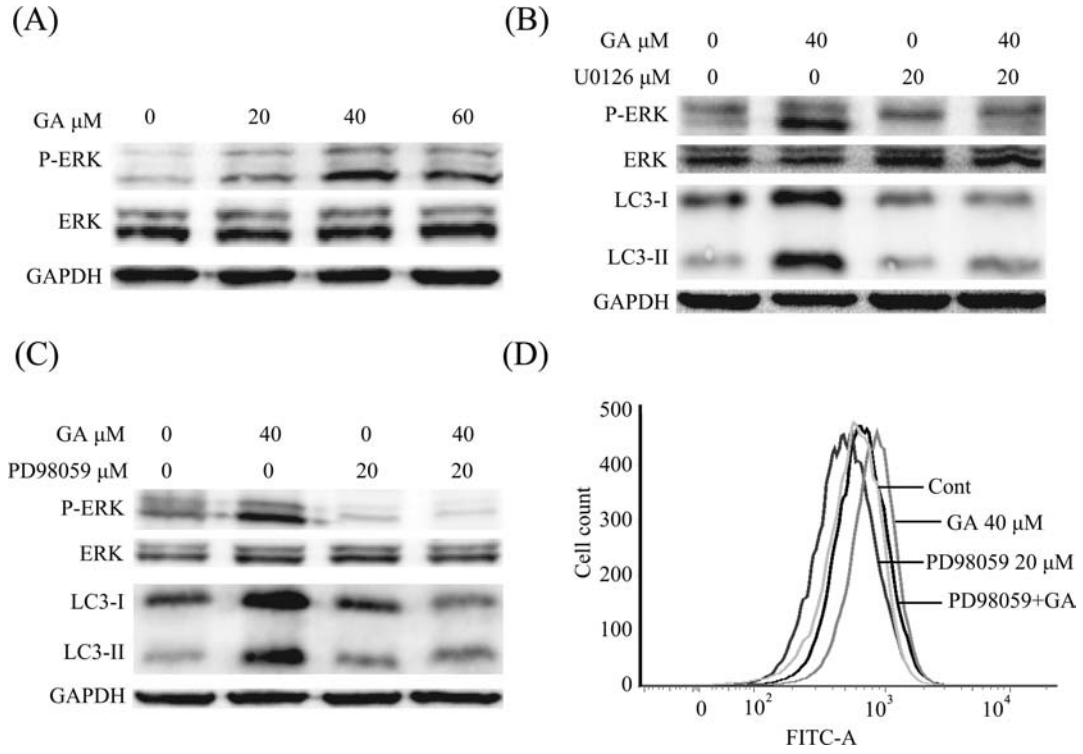

**Figure 6.** GA-triggered autophagy in HepG2 cells by activation of ERK pathway. (A) HepG2 cells were incubated with the indicated concentrations of GA for 24 h. Cell extracts were analyzed for phosphorylated ERK (Thr202/Tyr204), total ERK, and LC3 expression by Western blot analysis. (B, C) HepG2 cells were incubated with 40 $\mu$M GA for 24 h with or without pretreatment of U0126 (20 $\mu$M, 1 h) or PD98059 (20 $\mu$M, 1 h). Cell extracts were analyzed for phosphorylated ERK (Thr202/Tyr204), total ERK, and LC3-II expression by Western blot analysis. (D) Treated cells were stained with 50 $\mu$M MDC probe for 30 min, collected, washed, and resuspended. The intracellular fluorescence was quantified using flow cytometry.

cotreatment of GA and CQ or BAF caused an up-regulation of LC3-II protein expression.

The effects of autophagy, pro-survival or pro-death, are controversial in cancer.[33] In the progress of cancer cells, autophagy can be activated by hypoxia, starvation, and acid environment and act as a survival mechanism to protect cancer cells from those adverse environments.[21] However, excessive autophagy may result in cancer cell death.[34] The functions of autophagy induced by diverse compounds are also distinguishing.[35] For example, resveratrol and quercetin can induce a pro-survival autophagy in esophageal squamous carcinoma cells and gastric cancer cells, respectively,[28,36] whereas silibinin induces a pro-death autophagy in fibrosarcoma cells.[29] In the present study, we have demonstrated that GA triggered a protective autophagy in HCC HepG2 and Hep3B cells, as evidenced by the enhanced proliferative inhibition and/or apoptosis after blocking autophagy, which may be a mechanism for attenuating its anticancer effects or GA-modified TDDS loaded chemotherapeutic drugs. Besides, it has been reported that some nanoparticles can also induce protective autophagy in cancer cells.[37] These may partially explain why the GA-modified liposome nanoparticles loaded with docetaxel (0.7 $\mu$g/mL

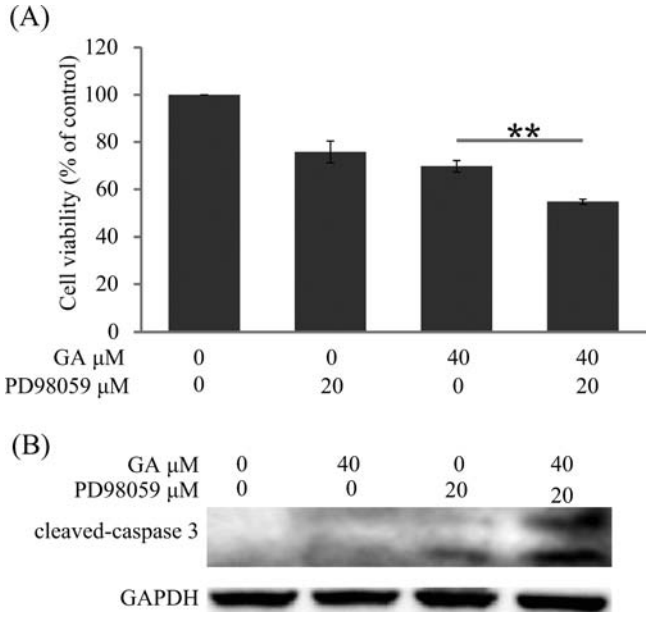

**Figure 7.** Inhibition of ERK enhanced GA-induced cell death and apoptosis. (A) HepG2 cells were treated with 40 $\mu$M GA for 24 h with or without pretreatment of PD98059 (20 $\mu$M, 1 h). The cell viability was evaluated by MTT assay. (*) $P < 0.05$ and (**) $P < 0.01$. (B) HepG2 cells were incubated with 40 $\mu$M GA for 24 h with or without pretreatment of PD98059 (20 $\mu$M, 1 h). Cell extracts were analyzed for cleaved caspase-3 expression by Western blot analysis.

docetaxel) presented fewer antiproliferative effects compared with docetaxel alone[17] and why GA-modified sulfated chitosan nanoparticles loaded with doxorubicin (0.0039, 0.0156, and 0.0625 $\mu$g/mL of doxorubicin) showed fewer antiproliferative effects compared with doxorubicin alone in HepG2 cells.[38] Thus, the autophagic effects might be a mechanism attenuating anticancer effects. In terms of cancer treatment by GA-modified TDDS, combination of an autophagy inhibitor might be a valuable strategy for TDDS-based HCC therapy.

Recently, accumulating studies have indicated the activation of ERK results in autophagic induction.[39] The present study showed that ERK was activated after GA treatment. ERK activity was remarkably inhibited by pretreatment with MEK inhibitor (U0126 or PD98059), and the autophagic protein marker LC3-II and the formation of AVOs were decreased accordingly, indicating that GA, at least partially, induced autophagy in HepG2 cells by activation of ERK. It is notable that inhibition of ERK activity by U0126 or PD98059 and the GA-induced protein expression of LC3-II and AVO formation were still slightly observed, compared with control group (Figure 6B−D), indicating other pathways might also participate in GA-induced autophagy, for example, the Akt/mammalian target of rapamycin pathway, which is one of the most important regulatory pathways for autophagy.[40] Moreover, as the Raf-MEK-ERK pathway (Raf activates MEK, which then activates ERK) is a classical signaling in cells,[39] how GA activates ERK warrants further study.

In summary, GA triggered a protective autophagy in HCC cells via activation of ERK, which might attenuate the anticancer effects of GA or GA-modified nanoparticle-loaded chemotherapeutics. The combined treatment with autophagy inhibitor and GA-modified nanoparticle-loaded anticancer drugs might be a promising strategy for HCC therapy.

Seven strains of *Paecilomyces gunnii* were selected for rescreening (Figure 1). The strains were cultured with the same medium and

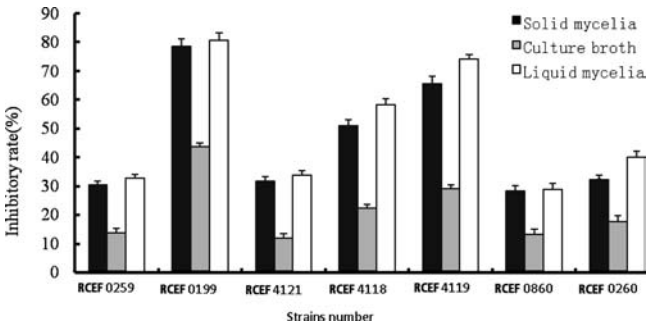

**Figure 1.** Inhibition rates of mycelia extracts and fermentation broth extracts from different strains against diphenolase of tyrosinase.

condition as that of the 50 fungal isolates or cultured in liquid medium (40 g/L glucose, 10 g/L yeast extract, and 10 g/L peptone) under shaking at 130 rpm and 25 °C for 10 days. The mycelia of the liquid cultures were separated from fermentation media. All of the mycelia were freeze-dried and then pulverized to save for use. The fermentation broths were condensed to $^1/_4$ of their original volume under reduced pressure and then freeze-dried.

The freeze-dried samples were sonicated in methanol by a solid/liquid ratio of 1 g/30 mL at 25 °C for 30 min and then statically extracted at 4 °C for 6 h. After centrifugation, the supernatants of the extracts were concentrated under reduced pressure and lyophilized to give the crude methanol extracts.

**Tyrosinase Inhibition Assay.** Extracts and isolated compounds (initial concentration of 5.0 mg/mL) were first dissolved in dimethyl sulfoxide (DMSO) and then diluted to different concentrations using DMSO. L-DOPA and tyrosinase were dissolved in 50 mmol/L phosphate buffer (pH 6.8). A total of 150 μL of substrate solution (1.0 mmol/L) and 10 μL of sample solution were added to 96 well microtiter plates and incubated at 30 °C for 5 min, and then 40 μL of tyrosinase solution (100 μg/mL) was quickly added and immediately mixed. After thorough mixing by vortex, initial absorbance at 475 nm was measured.

The enzyme activity was obtained by calculation of the slope of the time line through tracking and measuring the optical density ($OD_{475}$) at a wavelength of 475 nm. The molar extinction coefficient of the product at 475 nm was calculated as 3700 mol $L^{-1}$ $cm^{-1}$, and the relative inhibition rate was calculated as follows:

$$\text{relative inhibition rate } (\%) = (1 - \Delta A_m/\Delta A_c) \times 100\%$$

where $\Delta A_m$ is the enzyme activity of the sample and $\Delta A_c$ is the enzyme activity of the control (sample was replaced by an equal volume of solvent). Triplicate experiments were performed, and half inhibition concentration ($IC_{50}$) of the extract on tyrosinase was determined for each compound. The inhibition type was assayed by the Lineweaver−Burk plot, and the inhibition constant was determined by the second plot of the apparent $K_m/V_m$ or $1/V_m$ versus the concentration of the inhibitor.

**HPLC−PAD−HRMS Analysis.** A total of 10 μL of methanol solution of the sample (1.0 mg/mL) was injected into the analytical column. The flow rate was 0.8 mL/min. The column was eluted with a water/methanol (both contain 0.05% formic ammonium) gradient from 90:10 to 55:45 for 10 min, from 55:45 to 40:60 for a further 15 min, from 40:60 to 0:100 (%) for another 5 min, and pure methanol for the final 15 min. The eluates were monitored with a PAD at full length scan from 200 to 600 nm and a HRMS detector under negative and positive modes. Drying gas of the ESI ion source was 12 L/min at 325 °C. The nebulizer pressure was 35 psig. The capillary voltage was 3500 V for negative mode and 4000 V for positive mode. The fragmentor voltage was 175 V for negative mode and 215 V for positive mode. The scan range was 50−1200 amu.

**HPLC−MS−Bioactivity Combined Analysis.** A total of 10 μL of methanol solution of the sample (3.0 mg/mL) was injected into the analytical column and eluted with the above conditions. A total of 20% of the eluates was monitored with the MS detector through a distribution valve. The other 80% of the eluates was automatically collected every 5 min. The injection was repeated 9 times. Every three collections of the same time were combined as one sample and condensed to dry with the centrifugal concentrator. The dried eluates were dissolved with 15 μL of DMSO, and 10 μL of the solutions were transferred to 96 well microtiter plates for tyrosinase inhibitory activity detection.

**Selection of the Two-Phase Solvent System for HSCCC.** The two-phase solvent system was selected according to the partition coefficient ($K$) of each target component. The concentration of the target component in the upper phase ($C_A$) and lower phase ($C_B$) was analyzed by HPLC−MS. $K = C_A/C_B$.

According to the fact that the target components are methanol-soluble and possibly have moderate polarity, we selected a two-phase solvent system (*n*-hexane/ethyl acetate/methanol/water), which was suitable for the separation of compounds with medium polarity.[13] To obtain a better separation effect by HSCCC, a partition coefficient ($K$) between 0.5 and 2 is highly needed and the retention rate of the stationary phase has to be kept more than 50%.[14] On the basis of the selected basic solvent system and HSCCC separation pretests, we created a series of solvent systems (Table 1), and system 5 with 72% retention rate of the stationary phase was selected as the optimal solvent system for target compound preperation.

**HSCCC Separation.** The sample solution was prepared by dissolving the crude sample in a solvent mixture consisting of equal volumes of both upper and lower phases (4 mL for each phase). In each separation, the coiled column of HSCCC was first entirely filled with the upper phase as the stationary phase at a flow rate of 9.99 mL/min. Then, the lower phase (mobile phase) was pumped into the column at a flow rate of 2.0 mL/min, while the apparatus was run at a speed of 850 rpm. After the mobile phase front emerged and hydrodynamic equilibrium was established in the column, the sample solution (8 mL) containing 100 mg of crude extract was injected. All through the experiment, the separation temperature was controlled at 25 °C. The effluent of the column was monitored at 254 nm and automatically collected in a 10 mL test tube per 2 min.

**Structural Identification and Statistical Analysis.** The structural identification of each HSCCC peak fraction was carried out by the analysis of HPLC−PAD−ESI−HRMS, $^1$H and $^{13}$C NMR data, and two-dimensional (2D) NMR. Student's paired $t$ test for comparison of means was performed with the obtained data.

**Table 1. Distribution Coefficient ($K$) of the Target Compounds in Different Solvent Systems**

| | | $K$ | | |
|---|---|---|---|---|
| | *n*-hexane/ethyl acetate/ methanol/acetic acid/water | compound **1** | compound **2** | compound **3** |
| 1 | 5:5:5:0:5 | 0.45 | 0.18 | 0.14 |
| 2 | 2:5:2:0:5 | 7.35 | 2.25 | 1.80 |
| 3 | 2.5:5:2.5:0:5 | 1.55 | 0.90 | 0.68 |
| 4 | 2.5:5:2.5:0.15:5 | 5.32 | 1.45 | 0.91 |
| 5 | 3.5:5:3.5:0.15:5 | 1.56 | 0.86 | 0.53 |

## RESULTS AND DISCUSSION

**Preliminary Screening of Tyrosinase Inhibitory Activity of Fungal Extracts.** Screening was conducted on the methanol extracts of solid-cultured mycelia of the selected 50 strains by testing their inhibition rates against tyrosinase diphenolase in Table S1 of the Supporting Information. An obvious difference was found in the tyrosinase inhibition activity among different species and strains of the same species. Among the measured strains, *P. gunnii* showed relative higher inhibitory activity; therefore, further rescreening experiment was carried out on multiple strains of *P. gunnii*.

**Rescreening of Seven Strains of *P. gunnii*.** To better understand the tyrosinase inhibitory activities of the active strains of *P. gunnii*, the methanol extracts of the solid-cultured mycelia, liquid-cultured mycelia, and broth were tested (Figure 1 and Table S2 of the Supporting Information). The inhibitory activities of the liquid-cultured mycelia were significantly ($p < 0.05$) higher than that of the others, and the differences between mycelia and broth were very significant ($p < 0.01$; see Table S2 of the Supporting Information), indicating that the active ingredients mainly exist in the mycelia. Of all of the tested samples, the methanol extract of the liquid-cultured mycelia of the strain RCEF0199 showed the highest activity; therefore, it was selected for further bioassays and follow-up searching for the active compounds.

**$IC_{50}$ of the Extract on Tyrosinase.** With L-DOPA as a substrate, inhibitory rates of different concentrations of the methanol extract of the strain RCEF0199 on tyrosinase were measured. The amount of product formation is proportional to the reaction time, and the response slope of the line is the enzyme activity. The effect curve was obtained through plotting the concentrations versus enzyme activities. The results showed that the enzyme activity decreased with an increased concentration of the extract, and the $IC_{50}$ of the extract on tyrosinase was calculated as 48 $\mu$g/mL (see Figure S1A of the Supporting Information).

**Tyrosinase Inhibitory Mechanism of the Extract.** The inhibition mechanism on the enzyme by the methanol extract for oxidation of L-DOPA was investigated. In the experiment, the concentration of the substrate L-DOPA was constant while changing the concentration of the extract and the enzyme. The

results are shown in Figure S1B of the Supporting Information. A group of straight lines through the origin was obtained for the extract, and the slop of the line decreased with the increased concentration of the sample, which indicated that the inhibitory effect of the extract on tyrosinase was a reversible process. Therefore, the extract was a reversible inhibitor of tyrosinase.

**Competitive Inhibitory Type of the Extract on Tyrosinase.** The effects on the enzyme activity of different concentrations of the extract were measured by changing the concentration of the substrate (L-DOPA) while maintaining the amount of the enzyme. Using the Lineweaver−Burk double-reciprocal plot method, a set of straight lines intersecting the $y$ linear axis was obtained, as shown in Figure S1C of the Supporting Information, indicating that the methanol extract was a competitive inhibitor on the tyrosinase. The Michaelis constant ($K_m$) increased with the ascended concentration of the extract. The affinity of the enzyme with the substrate was reduced with the increase of the concentration of the extract. The extract impeded the binding of the enzyme and substrate and led to a lower catalytic activity. The Michaelis constant ($K_m$) was calculated as 1.02 mM without adding extract in the reaction system. The maximum reaction velocity ($V_{max}$) was 186.44 units/min based on the linear slope and $K_m$ values. The equilibrium constant ($K_I$) for the extract binding to the free enzyme was obtained from the secondary plot of the line slope versus the concentration of the extract (see Figure S1D of the Supporting Information). The value of $K_I$ was 555.56 $\mu$g/mL.

**Bioactive Fractions of the Extract.** Combined analysis of HPLC−MS and tyrosinase inhibitory activities shows that the HPLC fraction collected from 10 to 15 min has the strongest bioactivity (Figure 2B). The HPLC chromatogram shows that the main bioactive fraction contains three components, where the purities of the target compounds **1**, **2**, and **3** were 23.9, 6.6, and 15.7%, respectively, based on the HPLC peak area percentage (Figure 2A). The three compounds will be used as targets for HSCCC separation.

**HSCCC Preparation for the Target Compounds.** The target components were isolated by the optimal solvent system as compounds **3**, **2**, and **1** with retention times at 70, 110, and 210 min, respectively (see Figure S2 of the Supporting Information). The collected fractions were analyzed by HPLC, and fractions with the same component were combined. After solvent evaporation under vacuum at 50 °C, compound **1** (20.4 mg), compound **2** (5.2 mg), and compound **3** (12.5 mg) were obtained with the purities of 96.8, 95.8, and 95.0%, respectively, based on HPLC analysis (panels 1A−3A of Figure 3).

**Structural Identification.** Full wavelength scan of active ingredient absorption spectra are shown in panels 1A−3A of Figure 3. Identification of peak fractions was performed with ESI−HRMS (panels 1B−3C of Figure 3), $^{1}H$ and $^{13}C$ NMR, and 2D NMR (see Figure S3 of the Supporting Information). The $^{1}H$ and $^{13}C$ NMR data are given in Table 2.

Compound **1**, peak 1 in Figure 2A, is a yellow powder. The ultraviolet (UV) spectrum (panel 1A of Figure 3) shows the existence of a long conjugated system. UV (MeOH) $\lambda_{max}$ (log $\varepsilon$): 218 (5.0), 256 (sh, 2.6), and 380 (2.0). ESI−HRMS ($m/z$) showed the pseudo-molecular peak at 289.07083 (M + H, calcd. 289.07066) in positive mode and 287.05662 (M − H, calcd. 287.05611) in negative mode (panels 1B and 1C of Figure 3). Thus, its molecular formula was calculated as $C_{15}H_{12}O_6$, which suggested that it has a carbon skeleton with 10 degrees of unsaturation. The $^{1}H$ and $^{13}C$ NMR (Table 2) spectra of compound **1** indicated the presence of one naphthalene ring system, which has 10 aromatic carbons, including 1 methine carbon ($\delta_H$ 6.82, $\delta_C$ 117.23) and 9 quaternary carbons ($\delta_C$ 111.6, 144.9, 162.2, 105.4, 170.0, 131.07, 173.0, and 103.3), as well as 1 methoxy group ($\delta_H$ 4.00, $\delta_C$ 56.7), 1 methyl group ($\delta_H$ 2.74, $\delta_C$ 25.8), and 1 conjugated carbonyl system ($\delta_{CO}$ 172.3, $\delta_C$ 97.3 and 166.8). The above NMR and HRMS data suggested that it has a very high degree of unsaturation, consistent with a tricyclic phenalenone framework. A literature search showed that it is very similar to the known phenalenone compound myeloconone A2 (Figure 4), which was found from the lichen *Myeloconis erumpens*,[15] except that compound **1** has a hydroxyl group instead of a methoxyl group at position C-8.

Further evidence for the structure of compound **1** was provided by heteronuclear multiple-bond correlation (HMBC) long-range C−H connectivities, as illustrated in Figure 4. The

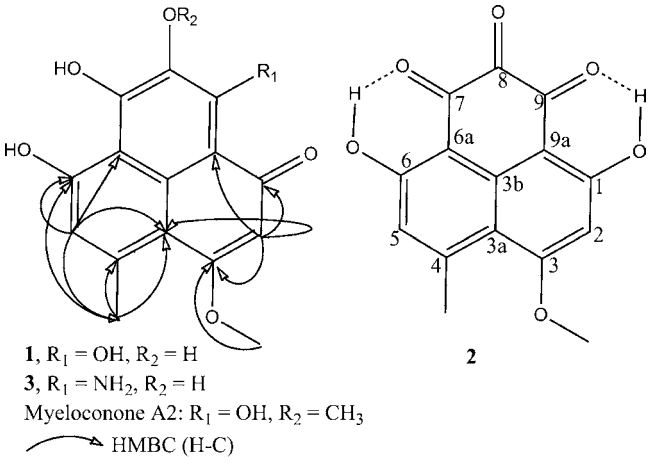

**Figure 4.** Chemical structures of phenanelones from methanol extracts of liquid-cultivated mycelia of *P. gunnii* and HMBC correlations (arrows with arrowhead) around the protons in the structure: H-5, $CH_3$, H-2, and $OCH_3$ of compound **1**.

aromatic proton singlet at $\delta_H$ 6.82 (H-5) yielded three strong C−H long-range correlations, assigned as $^3J_{CH}$ couplings, to quaternary carbon atoms at $\delta_C$ 111.6 (C-3a) and 105.4 (C-6a) and the methyl carbon atom at $\delta_C$ 25.8. In addition, a weak connectivity to an oxysubstituted carbon atom ($\delta$ 162.9) was assigned as a $^2J_{CH}$ correlation to C-6. Similarly, three strong correlations involving the methyl protons at $\delta_H$ 2.74 can be found at $\delta_C$ 111.6 (C-3a), 117.3 (C-5), and 144.9 (C-4), and a weak correlation at $\delta_C$ 166.8 (C-3) also existed. The strong correlations involving $\delta_H$ 6.51 (H-2) are at $\delta_C$ 103.3 (C-9a), 111.6 (C-3a), 166.8 (C-3), and 172.3 (C-1), with a weak correlation at $\delta_C$ 144.9 (C-4). The strong correlation involving the methoxy group $\delta_H$ 4.00 ($OCH_3$-3) is at $\delta_C$ 166.8 (C-3), which confirmed that the methoxy group is at position C-3. Besides, a weak correlation of $OCH_3$-3/C-2 ($\delta_C$ 97.4) was also found. Thus, the $^1$H and $^{13}$C NMR spectra of compound **1** were consistent with a highly oxygenated phenalenone and very similar to those of the known phenalenone myeloconone A2. Finally, in combination with the above HRMS and NMR information, compound **1** can be deduced as 6,7,8,9-tetrahydroxy-3-methoxy-4-methyl-1*H*-phenalen-1-one and named as paecilomycone A (Figure 4).[15,16]

Compound **2**, peak 2 in Figure 2A, is an orange powder. The UV spectrum (panel 2A of Figure 3) shows the existence of a long conjugated system. UV (MeOH) $\lambda_{max}$ (log $\varepsilon$): 220 (2.6), 255 (2.7), and 332 (1.5). ESI−HRMS ($m/z$) showed the pseudo-molecular peak at 287.05498 (M + H, calcd. 287.05501) in positive mode and 285.04035 (M − H, calcd. 285.04046) in negative mode (panels 2B and 2C of Figure 3). Thus, its molecular formula was calculated as $C_{15}H_{10}O_6$. The $^1$H NMR spectra of compound **2** showed similarity to those of compound **1** (Table 2). However, its molecular formula has one more oxygen atom while short of two hydrogen atoms, which suggests 1 more degree of unsaturaton in the structure. Thus, it should be a more oxygenated phenalenone-type compound compared to compound **1**. In the $^1$H NMR experiment, two lower field single peaks were found at $\delta_H$ 12.85 and 13.53, which are two typically strongly hydrogen-bonded hydroxyl groups ascribed to the positions OH-1 and OH-6 (Figure 4). In comparison of the above-mentioned HRMS and NMR data to those of compound **1**, its structure was decided as 4,9-dihydroxy-6-methoxy-7-methyl-1*H*-phenalene-1,2,3-trione, as shown in Figure 4, and named as paecilomycone B.

Compound **3**, peak 3 in Figure 2A, is an olive powder. The UV spectrum (panel 3A of Figure 3) shows the existence of a long conjugated system. UV (MeOH) $\lambda_{max}$ (log $\varepsilon$): 208 (2.2), 260 (sh, 1.3), and 380 (1.3). ESI−HRMS ($m/z$) showed the pseudo-molecular peak at 288.08624 (M + H, calcd. 288.08665) in positive mode and 286.07217 (M − H, calcd. 286.07210) in negative mode (panels 3B and 3C of Figure 3). Thus, its molecular formula was decided as $C_{15}H_{13}NO_5$. The $^1$H and $^{13}$C NMR (Table 2) spectra of compound **3** indicated the presence of one naphthalene ring system, which has 10 aromatic carbons, including 1 methine carbon ($\delta_H$ 6.67, $\delta_C$ 117.2) and 9 quaternary carbons ($\delta_C$ 110.7, 144.8, 165.0, 106.5, 169.9, 131.0, 174.0, and 102.3), as well as 1 methoxy group ($\delta_H$ 3.96, $\delta_C$ 56.4), 1 methyl group ($\delta_H$ 2.75, $\delta_C$ 25.8), and 1 conjugated carbonyl system ($\delta_{CO}$ 174.3, $\delta_C$ 96.3 and 166.6). The above NMR data are very similar to those of compound **1**. In comparison of its HRMS and NMR data to those of compound **1**, one $NH_2$ group ($\delta_H$ 8.95, br s, 2H) substituted one OH group in the structure of compound **3**, which was assigned to $NH_2$-9 because the $NH_2$ group is hydrogen-bonded with the carbonyl group of C-1, which led to the lower field signal ($\delta_H$ 8.95). In combination with the above HRMS and NMR information, compound **1** can be deduced as 9-amino-6,7,8-trihydroxy-3-methoxy-4-methyl-1*H*-phenalen-1-one and named as paecilomycone C (Figure 4).[15,16] For further confirmation of the presence of a $NH_2$ group in the deduced structure, compound **3** was tried with the ninhydrin reaction and showed a positive purple reaction in the TLC plate (see Figure S6 of the Supporting Information).[17]

**Inhibition Capacity of Paecilomycones A−C on Tyrosinase.** According to the above assay method, initial solutions of paecilomycones were diltuted to 3−9 fold and the inhibitory rates at each dilution were measured. $IC_{50}$ of the three new phenalenones paecilomycones A−C were 0.11, 0.17, and 0.14 mM, respectively (Table 3), which are almost as strong as that of kojic acid (0.10 mM) and stronger than that of arbutin (0.20 mM). Both kojic acid and arbutin are well-known tyrosinase inhibitors, which are usually used as the positive control of the tyrosinase inhibitor and commercially used in whitening cosmetics and food to prevent browning.[18]

**Table 3. $IC_{50}$ of Compounds 1−3 on Tyrosinase**

| compound | $IC_{50}$ (mM) ± SD |
|---|---|
| paecilomycone A (**1**) | 0.11 ± 0.010 |
| paecilomycone B (**2**) | 0.17 ± 0.009 |
| paecilomycone C (**3**) | 0.14 ± 0.004 |
| kojic acid | 0.10 ± 0.003 |
| arbutin | 0.20 ± 0.005 |

The three new phenalenones are the main tyrosinase inhibitors in the methanol extract of *P. gunnii*. The competitive inhibitory mechanism of the extract means that the three new compounds combine with tyrosinase in a manner that competes for the same binding site on the enzyme as the substrate L-DOPA or L-tyrosine. The three phenalenones are natural polyphenols with several phenolic hydroxyl groups in their structure. The tyrosinase inhibition test showed that the number of hydroxyl groups plays an important role in its activity: paecilomycone A has four hydroxyl groups with the highest activity ($IC_{50}$ = 0.11 mM); paecilomycone B has one

hydroxyl group with the lowest activity ($IC_{50}$ = 0.17 mM); and paecilomycone C has three hydroxyl groups with mid-activity ($IC_{50}$ = 0.14 mM) (Figure 4).

Phenalenone originated from very restricted natural resources, including Fungi Imperfecti.[19] *P. gunnii* is one species of Fungi Imperfecti, which suggested that its presence of related phenalenones is reasonable and it should share a similar biosynthetic pathway to produce the phenalenones through folding of a linear $C_{14}$-polyketide.[19] Phenalenones were reported to have antibacterial, antitumor, anti-HIV activity through inhibition of HIV-1 integrase, and antiprotozoal activities.[19−21] Recently, two phenalenone compounds were found to exhibit considerable effects against the malaria parasite, one of which maintained the same level of activity in a chloroquine-resistant strain, which is the first report of the antimalarial activity of this type of scaffold compound.[22] The structure of the newly isolated compound paecilomycone A is very similar to the anti-HIV target funalenone (anti-HIV, $IC_{50}$ = 1.7 $\mu$M),[20] while there is a $NH_2$ group at C-9 of paecilomycone C instead of the normal OH group, which could be a hint that the two new compounds could be potential effective anti-HIV compounds and highly valuable for continuing studies.

Entomogenous fungi are a treasury for searching for bioactive compounds, and many interesting results have been found from them.[23−30] However, few tyrosinase inhibitors were reported from these species. This study revealed that tyrosinase inhibitors truly existed in the secondary metabolites of entomopathogenic fungi. Tyrosinase is one of the main enzymes involved in immunity and defense response of insects;[9−11,31] therefore, tyrosinase inhibitors from metabolites of entomopathogenic fungi, such as paecilomycones A−C, must play an important role in virulence of the fungus and can possibly be used as virulence factors for high-virulent strain screening and used in novel pesticide production. Most of the currently used pesticides kill insects by targeting their nervous system and have a neurotoxic effect in mammals as well;[9,32] however, tyrosinase inhibitors targeting the immune and defensive systems of insects may have wider application prospects. Additionaly, similar to some popularly used tyrosinases in the food industry and cosmetics, paecilomycones A−C also have the possibility to be used in these areas.

[a]MF = molecular formula. [b]MW = molecular weight.

is the most efficient tool for controlling fire ant colonies in large areas, even in phorid fly released areas. In the last several decades, numerous attempts have been made to develop efficient baits. A toxicant (the active ingredient usually less than 1.0%), an attractant, such as soybean oil, and an inert carrier, such as corn cob grits, were used to formulate bait for fire ant control.[16,17] A recently developed fire ant bait consisting of dried distillers grains with solubles as a carrier was found to be water-resistant and compatible with a number of pyrethroid insecticides.[18] Communication in social insects is based primarily on the use of pheromones, and many of these pheromones have attractive properties. The highly evolved fire ant uses a complex of pheromones, such as trail pheromone, alarm pheromone, and queen-produced recognition pheromone, for colony communications.[9] The incorporation of these ant pheromones with attractive properties could enhance the attractiveness and harvest of bait because the efficacy of bait largely depends upon ant foraging activity.[19] For instance, alarm pheromonal components from leaf-cutting ants (*Atta* spp.) have previously been proven to substantially increase the attractiveness and harvest of the bait.[20,21] The potential of alarm pheromones in fire ant control is that they elevate workers to a heightened state of alertness and movement, resulting in quicker location of a bait particle than otherwise possible.[22]

Previous studies have shown that pheromone homologues and analogues could elicit biological activity in insects comparable to the natural compounds[23−26] and may have a high potentiality as alternative material in integrated pest management strategies.[27] Thus, the present study aimed to examine both electroantennogram (EAG) and behavioral responses of *S. invicta* workers to the commercially available 2-ethyl-3,6(5)-dimethyl pyrazine (mixture of the 3,5- and 3,6-dimethyl isomers, herein referred to as pheromone isomers) and related alkylpyrazine analogues. Because an alarm response is a rapid reaction and, therefore, requires compounds of low molecular weight (between 100 and 200 with 5−10 carbons) with high volatility, we selected 13 alkylpyrazine analogues

whose molecular weights range from 94 to 164. For both EAG and behavioral bioassays, a series of dilutions were made to test both EAG and behavioral dose−responses of fire ant workers from various colonies to pheromone isomers and the selected analogues. The pyrazine analogues that proved to be very active in both EAG and behavioral bioassays would potentially be used as bait enhancers for the control of the fire ants in the invaded regions.

## MATERIALS AND METHODS

**Insects.** Eight mature colonies of *S. invicta* were collected on the campus of South China Agricultural University (Guangzhou, Guangdong, China). All colonies were considered polygyne because of the presence of multiple queens during collection. Colonies were reared with soil under laboratory conditions and provided daily with purified water, 10% honey solution, and larvae of *Tenebrio molitor* L. Tests were carried out within 1 month of ant collection.

**Reagents and Test Chemicals.** Acetonitrile ($CH_3CN$) was of high-performance liquid chromatography (HPLC) grade and was used without further purification. Water was purified with a model 7155 Barnstead Nanopure system (Thermo Scientific, Marietta, OH) and subsequently filtered through a 0.45 $\mu$m membrane. The alarm pheromone component, 2-ethyl-3,6-dimethylpyrazine (**1a**), was commercially available as a mixture with the 2-ethyl-3,5-dimethylpyrazine (**1b**) isomer (Sigma-Aldrich, St. Louis, MO). The mixture consisted of about 45% of compound **1a** and 55% of compound **1b** [gas chromatography (GC) analysis]. A total of 13 structurally related alkylpyrazine analogues were purchased from Sigma-Aldrich or Acros Organics (Geel, Belgium). The chemical structures of these compounds are shown in Table 1. Each compound was diluted with HPLC-grade *n*-hexane to make a 100 $\mu g/\mu L$ solution. Further serial 10-time dilutions were made to give solutions with different concentrations ranging from 0.01 ng/$\mu$L to 10 $\mu g/\mu L$ for EAG and behavioral tests. The solutions were kept in a freezer at −20 °C until use.

**HPLC Analysis.** HPLC separation of compound **1** was performed on an Agilent HP 1260 instrument (Agilent Technologies, Palo Alto, CA), using a stainless-steel, 250 × 4.6 mm inner diameter, 5 $\mu$m, HC C-18 column (Agilent Technologies, Middelburg, Netherlands). A solution of compound **1** at 10 $\mu g/\mu L$ was prepared with $CH_3CN$ for both analytical separation and semi-preparation. All chromatographic experiments were performed in the isocratic mode. $CH_3CN$/water was selected as the mobile phase, followed by a previously reported liquid chromatography−mass spectrometry (LC−MS) analysis.[28] Various percentages (20−50%) of $CH_3CN$ were tested to optimize the separation efficiency of the mobile phase. The flow rate was 0.2 mL/min, and the detection wavelength was ultraviolet (UV) 278 nm. The injection volume was 1 $\mu$L in analytical separations. On the basis of nuclear magnetic resonance (NMR) spectroscopic data obtained by LC−NMR, 2-ethyl-3,5-dimethylpyrazine (**1b**) was found to be eluted first, followed by 2-ethyl-3,6-dimethylpyrazine (**1a**).[28] In semi-preparative separation, a 5 $\mu$L sample loop was used. Each peak fraction was manually collected according to the elution profile. After 2 weeks of semi-preparative separation, the collected fractions were combined (**1a**, 150 mL; **1b**, 180 mL) and subjected to sequential liquid−liquid partitions to remove $CH_3CN$ and water. The pooled fractions were first partitioned with hexane (50 mL × 3), and then the resultant hexane layer was acidified with 20 mL of 0.1 N HCl. After removal of the hexane layer, the acid layer was neutralized to pH 10 with 15 mL of 0.2 N NaOH and subsequently partitioned with hexane (20 mL × 3). The resultant hexane layers were combined and dried over anhydrous $Na_2SO_4$. The hexane extract was finally concentrated to 2 mL under a mild stream of nitrogen and subjected to HPLC quantitation.

To quantitate pyrazine **1a** or **1b** in the hexane extract, 2,3-diethylpyrazine (**9**) was used as an external standard. A stock solution of standard compound **9** (10 $\mu g/\mu L$) was prepared and then diluted to a series of concentrations ranging from 0.25 to 8 $\mu g/\mu L$. All dilutions were transferred to the HPLC autosampler, and 1 $\mu$L of each dilution was used for HPLC analysis under the same conditions as above at a flow rate of 1 mL/min. A standard curve was calculated by linear regression analysis. The concentration of pyrazine in the 2 mL hexane extract was calculated against the standard curve. The hexane extracts of compounds **1a** and **1b** were thereafter diluted to 1 $\mu g/\mu L$ for EAG study and to 10 ng/$\mu$L for behavioral study. A mixture of an equal volume of both compound **1a** and **1b** solutions at the same concentration was bioassayed to determine the synergistic effect.

**EAG Experiment.** The EAG sensitivity of *S. invicta* workers was determined by conventional EAG methods.[29,30] Briefly, the reference glass electrode was connected to the neck of an isolated head of a major worker, and the recording electrode was connected to the antennal tip. The analogue signal was detected through a PRG-3 probe, amplified with a data acquisition controller IDAC-2, and analyzed with software EAG 2000 (all from Syntech, Kirchzarten, Germany). A 10 $\mu$L aliquot of each test compound (in hexane) was applied to a piece of filter paper (4 × 40 mm, Whatman no. 1). After solvent evaporation, the odor-impregnated filter paper strip was placed in a glass Pasteur pipet. Fresh stimulus pipets were prepared before each set of experiments. Hexane was used as the solvent control. Stimuli were delivered as 0.2 s puffs at a humidified flow rate of 1000 mL/min generated by an air stimulus controller CS-55 (Syntech, Kirchzarten, Germany).

A test series of the pyrazines of the same dose (0.1, 1, 10, 100, or 1000 $\mu$g) was applied to a single antennal preparation, and the presentation order of these compounds was randomized. A blank stimulus (solvent control) was presented before and after the 14 test compounds. EAG recordings were obtained from eight antennal preparations for each dose. For analyses, EAG response to the solvent control (average of two recordings per antennal preparation, less than 0.20 mV) was deducted from the EAG amplitudes elicited by the test compounds. The corrected EAG data were analyzed for each dose using one-way analysis of variance (ANOVA) to establish significant differences among the treatments (test compounds). Means across all 14 compounds for certain doses were compared by the Tukey−Kramer honestly significant difference (HSD) comparison test ($p < 0.05$).[31]

**Behavioral Bioassay.** Behavioral bioassays were conducted as described by Vander Meer et al.,[9] with slight modification. At least 2 h prior to a bioassay, 0.1 g of workers (approximately 100−150) from each colony were added to a plastic cup (9 cm tall × 14 cm inner diameter) with the inside wall coated with Fluon to prevent escape. A 1 $cm^3$ sugar-agar block (10% sugar water + 1% agar after boiling and chilling) was placed on the bottom of the cup to allow feeding. Water was provided by filling a 1.5 mL microcentrifuge tube with distilled water and threading a cotton string through a hole in the cap of the tube. A filter paper strip (1 × 3 cm) folded into a triangle was put in an empty space in the bottom of the cup. The experiment was not started until the worker ants had settled into a quiescent group. A total of 10 $\mu$L of sample solution was loaded onto the filter paper strip with a micropipet in a gentle movement that would not generate a response. The alarm response of ant workers was observed and recorded. The response to a test compound was evaluated on the number of workers that were running out of the quiescent group during the recording time. After each test, the filter paper strip was replaced with a new strip for the next test. All ant bioassay units (i.e., cups) were tested with the control (10 $\mu$L of hexane), and all of the samples were at the same dose. Bioassay units were evaluated in sequence, but the samples presented to the ants were randomized. In this way, workers of a test unit that were alarmed had enough time (more than 30 min) to recover prior to the next test. Ants from a colony were considered as one replicate. A test series of the alkylpyrazines of the same dose (0.1, 1, 10, 100, or 1000 ng) was replicated 8 times. Bioassay data were determined to be normally distributed and then analyzed using one-way ANOVA, followed by the Tukey−Kramer HSD comparison test ($p < 0.05$), to establish significant differences among the treatments.[31]

For correlation analysis, behavioral response to the solvent control was deducted from that elicited by the test compounds. It appears that all compounds elicited dose-dependent responses in both EAG experiment and behavioral bioassay. A pilot analysis indicated that the

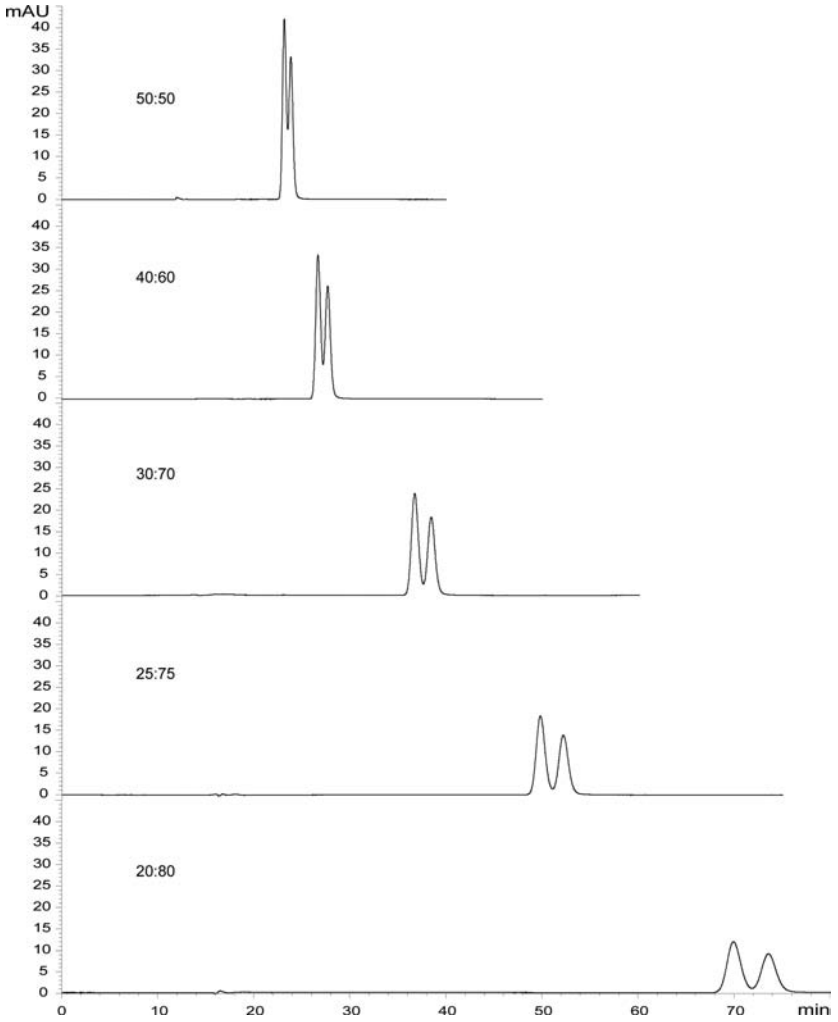

**Figure 1.** Separation of fire ant alarm pheromone isomers in $CH_3CN$/water mobile phases of various compositions (as indicated in the figure) on an Agilent HC C-18 column.

EAG data at five doses correspond well to the behavioral data from the low to high doses. Therefore, the correlation between the corrected EAG data and the corrected behavior data was analyzed using the PROC CORR procedure of SAS statistical software.[31]

**Bait Attraction Bioassay.** Three alkylpyrazines with relatively high activity in both EAG and behavior bioassays were selected for further food bait tests. The potential for using these alarm pheromone compounds to enhance the attractiveness of food bait was examined for *S. invicta* workers. A total of 0.5 g of ant workers was transferred into a plastic basin (55 cm diameter at the bottom) with the inside wall coated with Fluon to prevent escape. A moisturized cotton wad in a Petri dish cover ($d$ = 6 cm) for provision of water was placed at the center of the basin. Holes were made at the side wall of the Petri dish cover for ant movement. Ants were attracted to the water source and left for a 2 h period of acclimatization to settle into a quiescent group. During this period, three aluminum foil disks (5 cm diameter) were mounted on the bottom of the basin. Foil disks were positioned 20 cm away from the center of the basin and at an equal distance from each other. On the foil disk was then placed a filter paper disk (4 cm diameter). Prior to the start of evaluation, a block of ham sausage (0.1 g) used as food bait was placed onto the filter paper disk. A total of 10 $\mu$L of hexane was loaded onto both filter paper disk and food block with a micropipet in a gentle movement. For the other two food blocks, 10 $\mu$L of sample solution was loaded onto either the filter paper disk or the food block. The number of ants on a filter paper disk was counted at 2, 5, 15, 30, and 45 min after impregnation of the sample solution (or hexane control) onto a filter paper disk or food block. After each test, ants were discarded and the basin was cleaned with soap water and air-dried for the next test. Each sample solution was repeated 8 times. Two doses (10 and 100 ng) of each compound were tested. Mean numbers of ants for the same compound−dose combination on different filter paper disks were compared using the Tukey−Kramer HSD comparison test ($p < 0.05$).[31]

## RESULTS AND DISCUSSION

As expected, separation of 2-ethyl-3,6-dimethylpyrazine (**1a**) and 2-ethyl-3,5-dimethylpyrazine (**1b**) in the commercial product was accomplished on a reverse-phase C-18 column using $CH_3CN$/water mobile phase. Figure 1 illustrates elution profiles of compound **1** at a flow rate of 0.2 mL/min with variable ratios of $CH_3CN$/water mobile phase. The injection results in two chromatographic peaks, which correspond to the two regio-isomers. The percentage of $CH_3CN$ in the mobile phase had a significant influence on separation efficiency. The separation efficiency increases with the decrease of the $CH_3CN$/water ratio. However, when the $CH_3CN$/water ratio decreases, chromatographic retention time increases significantly. At a ratio of 20:80 (v/v), the two regio-isomers, compounds **1a** and **1b**, are nearly baseline-separated. Because general preparative separations are time-consuming and tedious, we used a ratio of 25:75 (v/v) for scaling-up the preparation of pure isomers at the semi-preparative level. The

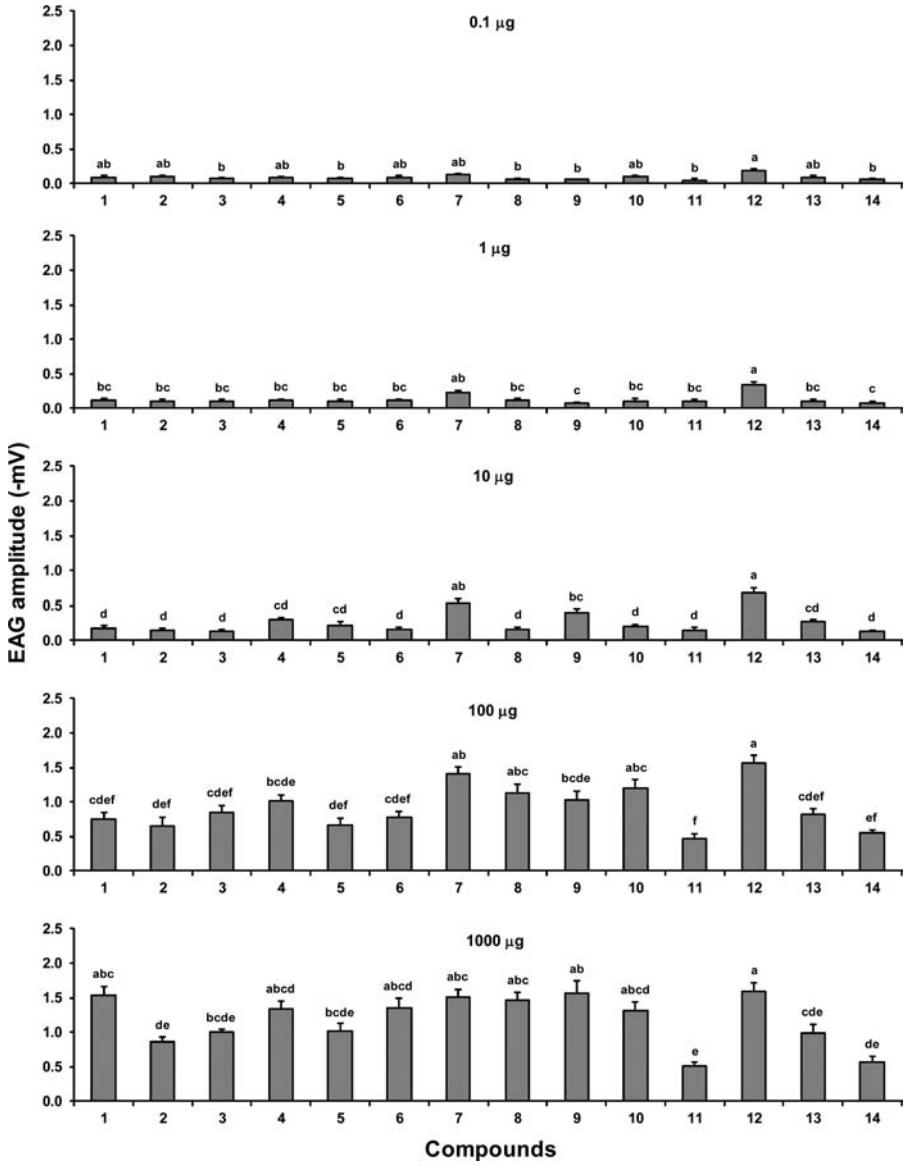

**Figure 2.** EAG response [−mV ± standard error (SE)] of *S. invicta* workers to 14 alkylpyrazines. Means for the same dose having no letter in common are significantly different ($p < 0.05$; Tukey HSD test).

two peaks derived from preparative compounds **1b** and **1a**, respectively, were observed at 49.6 and 51.7 min at 278 nm. The external standard method was used to obtain the regression equation, $A = 608.6090C + 2.7015$, where $A$ is the peak area and $C$ is the concentration of the standard compound ($\mu g/\mu L$). The standard compound showed excellent linearity ($r^2 = 0.999\,98$; $p < 0.001$) in selected concentration ranges. With the obtained calibration curve, the concentrations of 2 mL preparative compound **1a** and **1b** solutions were determined to be 2.14 and 3.02 $\mu g/\mu L$, respectively.

All tested compounds elicited dose-dependent responses from the antennae of *S. invicta* workers (Figure 2). Significant differences were recorded in the EAG response of ant workers to the various compounds at all tested doses. Statistical analyses (ANOVA) of the corrected EAG data revealed that both the chemical structures and doses of alkylpyrazines influenced electrophysiological responses. Antennal responses to pheromone isomers (**1**) varied between 0.09 and 1.53 mV across all doses. In comparison to compound **1**, EAG responses to 7 compounds of 13 tested analogues were similar or relatively higher at both the lowest and highest doses. At moderate doses (1, 10, and 100 $\mu g$), responses to compounds **7** and **12** were significantly higher than that to compound **1**, except for response to compound **7** at a dose of 1 $\mu g$. Among the 14 tested alkylpyrazines, compound **12** elicited the highest responses at every dose tested.

All alkylpyrazines elicited apparent alarm behavioral responses of *S. invicta* workers. When exposed to odors of pyrazine analogues, workers were observed to leave the quiescent group rapidly toward the source of odors. The alarm bioassay results for all tested compounds are shown in Figure 3. Among the 14 tested alkylpyrazines, three compounds, **1**, **7**, and **12**, elicited significant alarm responses at every dose tested. Furthermore, the responses to these three compounds increased in a dose-dependent manner. In contrast, the remaining 10 compounds failed to elicit significant behavioral response at low doses. In comparison to compound **1**, behavioral responses to the two active alkylpyrazines, compounds **7** and **12**, were not significantly different at all tested doses, except that the response to compound **12** was

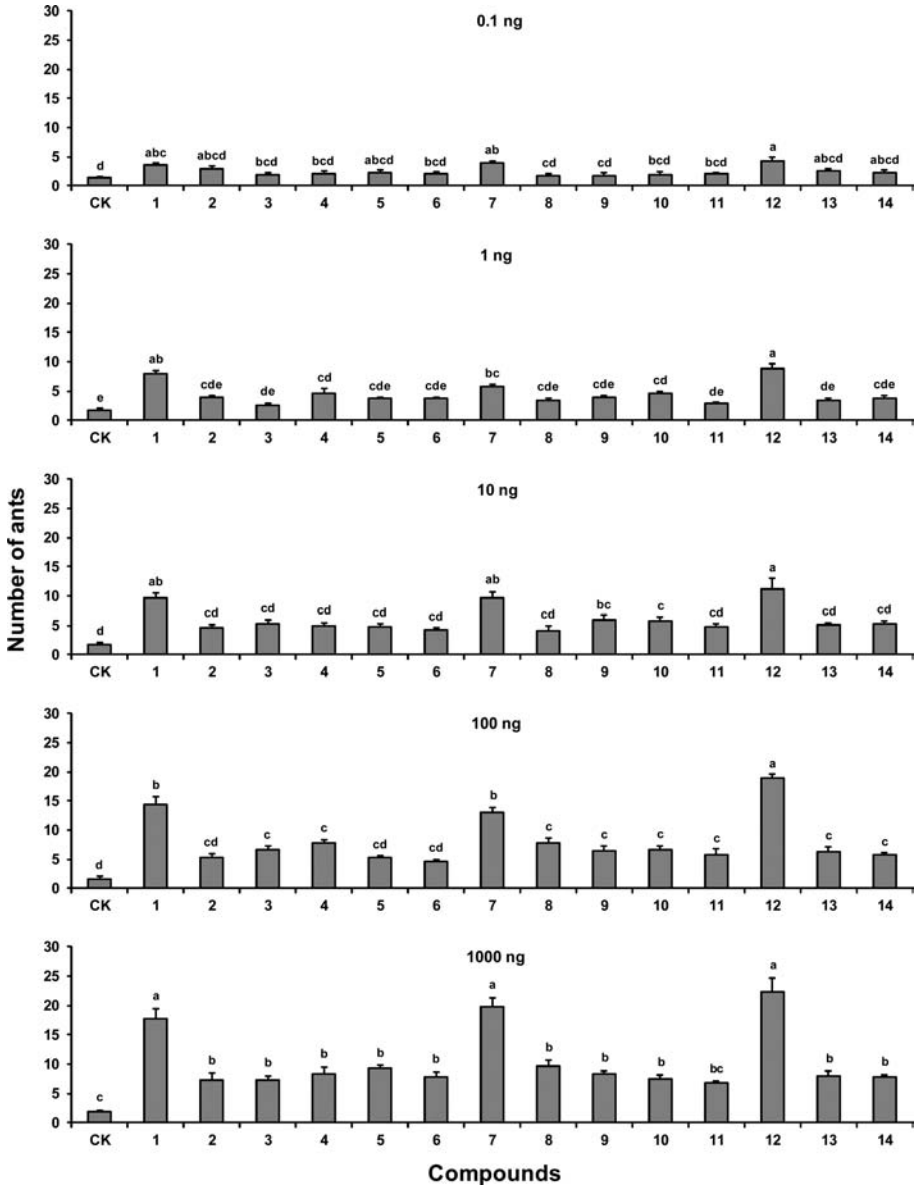

**Figure 3.** Alarm response of *S. invicta* workers to 14 alkylpyrazines. Means for the same dose having no letter in common are significantly different ($p < 0.05$; Tukey HSD test).

significantly higher than that to compound **1** at a dose of 100 ng. Generally, the alarm responses induced by the remaining 10 alkylpyrazine analogues were significantly less than that induced by compound **1** at all doses but the lowest dose (0.1 ng).

A good correlation between the EAG and behavioral responses was obtained for all 14 alkylpyrazines ($y = 6.3857x + 1.3999$; $r^2 = 0.5963$; $p < 0.0001$). This suggests that these alkylpyrazine analogues target the same olfactory neurons on the antennae of fire ant workers.

When pure isomers were tested at a dose of 10 $\mu$g, compound **1a** elicited significantly greater EAG response than compound **1b** (Table 2). A mixture of both isomers (1:1) at the same dose elicited intermediate EAG response, suggesting that there exists an addition effect between the two isomers. Furthermore, the EAG response to compound **1a** in the second EAG experiment was comparable to responses to compounds **7** and **12** in the first EAG experiment. The data from the behavioral bioassay with pure isomers of compound **1** at a dose of 100 ng showed that the number of workers responding to odors was significantly more than the number of workers responding to hexane (Table 3). Compound **1a** elicited a significantly higher alarm response than compound **1b**, and the activity of the mixture of both isomers (1:1) was similar to that of compound **1b**.

identification of fire ant alarm pheromone component, 2-ethyl-3,6-dimethyl pyrazine (**1a**).[9] Compound **1a** was found to be significantly more active than 2-ethyl-3,5-dimethyl pyrazine (**1b**) in both EAG and behavior bioassays. This is in agreement with previous reports demonstrating that compound **1b** was less active than compound **1a** in the alarm response experiment with fire ant workers and in the trail following experiment with the Mediterranean ant *Pheidole pullidulu*.[9,32] Interestingly, 2,3-diethyl-5-methylpyrazine (**12**) elicited significantly higher EAG responses compared to pheromone isomers **1** for doses of 1, 10, and 100 μg. In the EAG experiment, we puffed 100 μg of compound **1** to serve as a standard before the tests of all samples. This stimulation may have significant influence on the EAG responsiveness of the isolated head preparation to the same compound **1**, especially at low doses, in the following tests. EAG responsiveness of the isolated head preparation to the same stimulus has proven to decrease rapidly, falling below 50% of initial EAG responses after 20 min.[33] It seems likely that compound **1** elicits the same level of EAG response of fresh antennal preparation that has not been tested to standard (100 μg of compound **1**) as the two active pyrazine analogues **7** and **12**. This interpretation is supported by the fact that EAG response to compound **1a** is similar to EAG responses to compounds **7** and **12** at a dose of 10 μg. At a dose of 100 ng, the alarm response to compound **12** was significantly greater than that to compounds **1** and **7** but was similar to the alarm response to compound **1a**, indicating that compound **12** is equally active as the fire ant alarm pheromone component (**1a**). Di- and trialkyl-substituted pyrazines are known components of alarm/trail pheromones of ant species, including *Linepithema humilis* (Mayr), *Eutetramorium mocquerysi* Emery, and *Wasmannia auropunctata* (Roger).[34−36] It is possible that compound **12** is an unidentified component of the alarm pheromone of *S. invicta* or the observed response to compound

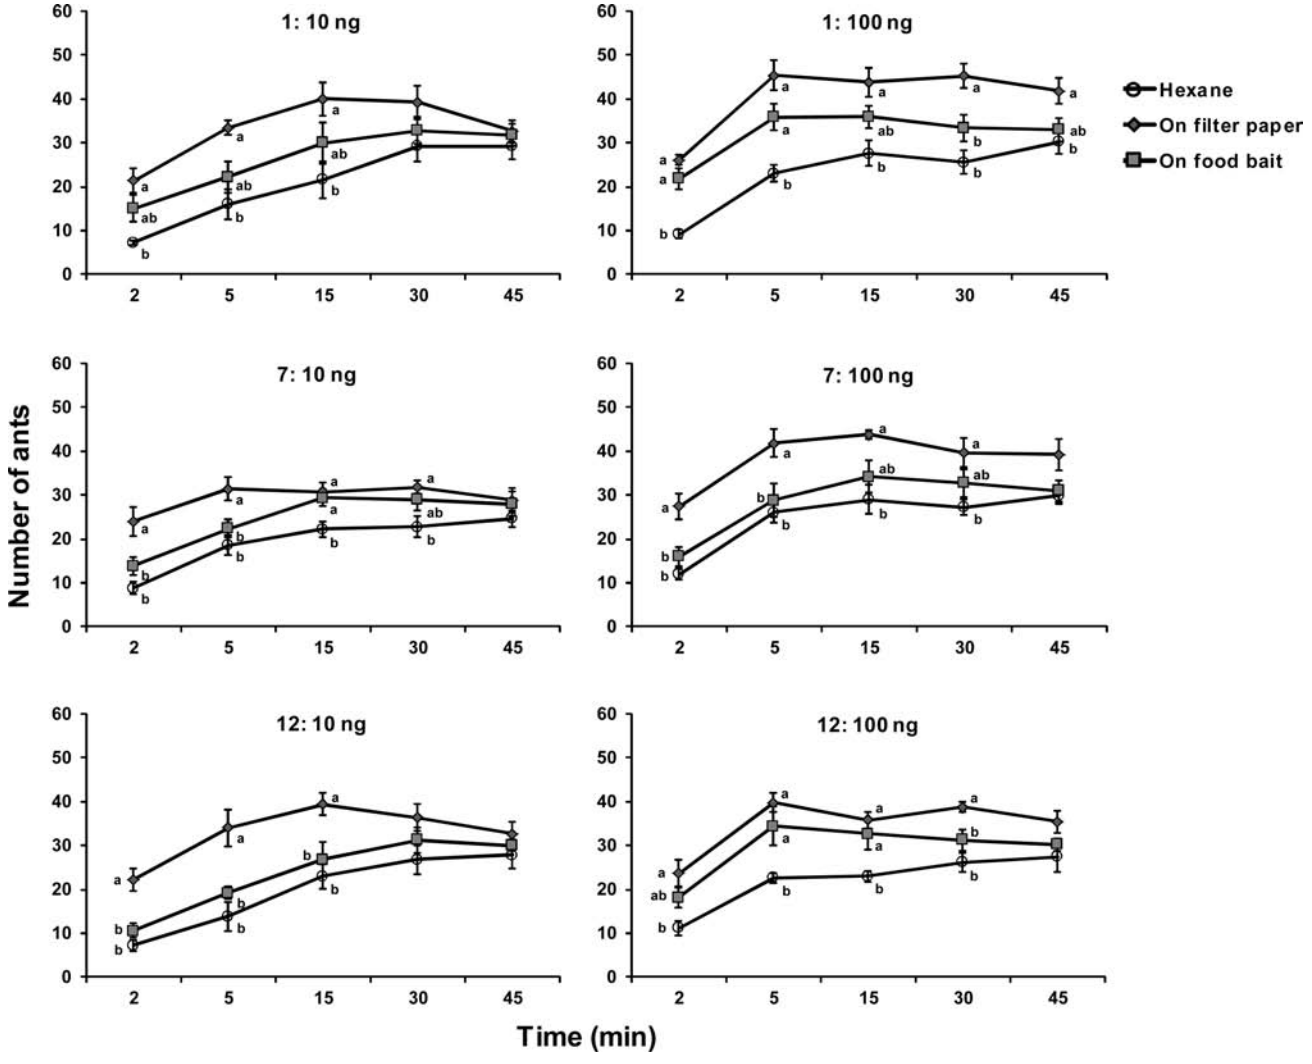

**Figure 4.** Responses of *S. invicta* workers in bait attraction bioassay to the three most active alkylpyrazines at two doses (10 and 100 ng). Means for the same time period having no letter in common are significantly different ($p < 0.05$; Tukey HSD test).

**12** may simply be due to their structural similarity to the alarm pheromone component **1a**.

For methyl-substituted pyrazines, only trimethyl-substituted pyrazine was EAG- and behaviorally active. In contrast, mono-, di-, and tetramethyl-substituted pyrazines turned out to be behaviorally much less active or even inactive, regardless of the position of the methyl substituents. In general, disubstituted pyrazines, for instance, 2-ethyl-3-methylpyrazine (**8**), 2,3-diethylpyrazine (**9**), 2-methyl-3-propylpyrazine (**10**), 2-isobutyl-3-methylpyrazine (**13**), attracted significantly more workers than hexane control but elicited significantly lower response than pheromone isomers **1**. The 6 substitution on the pyrazine ring of 2-ethylpyrazine appears to be important because 3-methyl- and 3-ethyl-2-ethylpyrazines (**8** and **9**) were much less behaviorally active than compound **1**. Thus, the number of substituents (methyl and ethyl) and the position of substituents in alkylpyrazines exerted a strong influence on the behavioral response. Substitution with propyl, isobutyl, or *sec*-butyl groups would result in a significant decrease of response. In contrast to the behavioral data, a relatively smaller influence of the chemical structure on the responsiveness was detected by the electrophysiological experiments with the EAG technique. All compounds tested, including the behaviorally inactive compounds, elicited dose-dependent physiological responses from the antennae of ant workers.

Three alkylpyrazines, **1**, **7**, and **12**, with both significant EAG and behavior responses were selected for bait discovery bioassays. Immediately after loading samples, ant workers were observed to run toward the odor sources, showing an alarm response. At the beginning of the test, workers ran around the food bait without feeding, then climbed up, and bit the bait intensely. After a few seconds, the workers turned back to their "nest" to recruit nestmates. About 4 min later, a large number of workers ran onto the food bait and started feeding. Workers near the sample-treated food bait appeared more agitated than those in the hexane control and fed on the food bait in a more aggressive manner. The number of workers around food bait increased rapidly over time (Figure 4), and reached the highest level in 45 min for the hexane control and in 15 min for both alkylpyrazine treatments. In general, the sample loaded onto filter paper disk attracted significantly more workers than the sample loaded on food bait and hexane control in 2 and 5 min periods, possibly because of the quick evaporation of the test compound on filter paper disk. In most cases, the number of workers in treatment of the sample loaded onto food bait were not significantly greater than that in the hexane control in a 15 min period. At the end of observation, generally no significant difference was observed in the number of workers among the three treatments of a pyrazine compound and among the six compound × dose combinations ($p > 0.05$). These results suggest that the three selected alkylpyrazines could significantly enhance bait attractiveness to *S. invicta* workers.

Eusocial insects are generally attracted to emission sources of alarm pheromones and exhibit a collective response to these chemical releasers. Alarm pheromones can also frequently function as recruitment stimuli that recruit large numbers of aggressive individuals to a pheromonal point source with incredible rapidity.[37,38] In this study, we observed this characteristic behavior in fire ants. Because excited ant workers would move rapidly to emission sources of alarm pheromones, we used the number of workers on the food bait to evaluate the activity of the three selected alkylpyrazines, **1**, **7**, and **12**, for food bait tests. These samples stimulated the same behaviors when incorporated in food baits. The sample loaded onto filter paper disk attracted more workers than loaded onto bait directly in the first 5 min period presumably because of faster recruitment of the sample evaporated in the air from the filter paper disk. Relatively more workers were attracted to bait incorporated with sample in the first 5 min period than to bait incorporated with hexane, but the difference was statistically significant only for compounds **1** and **12** at the high dose. The attraction to food bait by the sample-treated filter paper disk has potential applications. Alkylpyrazines can be used to improve harvest of toxic bait as proven by the alarm pheromone of leaf-cutting ants (*Atta* spp.), 4-methyl-3-heptanone, to significantly increase the attractiveness of enhanced bait sachets and the discovery of nearby unenhanced sachets in the field.[20] Future work will test the influence of alkylpyrazines on bait transportation and substantial control of the imported fire ants.

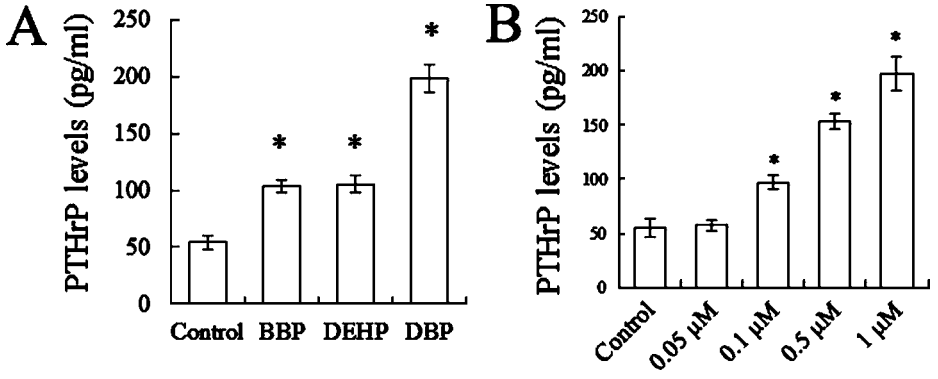

**Figure 1.** Phthalate esters increased PTHrP expression in breast cancer. (A) The effects of BBP, DBP, and DEHP on PTHrP levels in MDA-MB-231 cells. (B) DBP increased PTHrP expression in a dose-dependent manner. MDA-MB-231 cells treated with butylbenzyl phthalate (BBP), di-2-ethylhexyl phthalate (DEHP), and dibutyl phthalate (DBP) at the same concentration of 1 $\mu$M or various concentrations of DBP for 6 h. After washing and a 24-h culture, the condition media of phthalate esters-treated MDA-MB-231 cells (BBP-, DEHP-, and DBP-MDA-MB-231-CM) were harvested, and the PTHrP expression levels in these conditioned media were then assessed. The expression of PTHrP was assessed by ELISA. Each value is the mean ± SD of three independent experiments. * indicates significant difference between the control and test groups ($p < 0.05$).

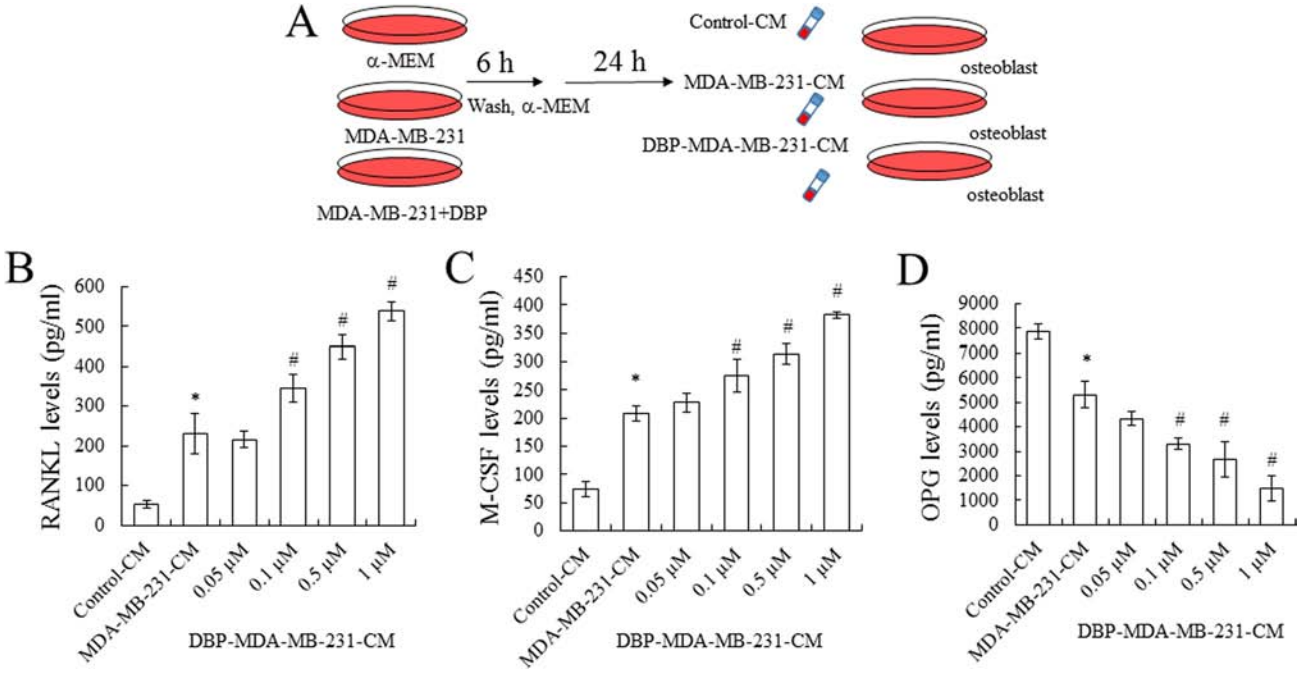

**Figure 2.** DBP reinforced the stimulatory effect of breast cancer in osteoblasts. (A) Flowchart showing production of control-MDA-MB-231-CM and DBP-MDA-MB-231-CM. DBP enhanced the stimulatory effect of MDA-MB-231 cells on the expression of (B) RANKL and (C) M-CSF in osteoblasts. (D) DBP potentiated the inhibitory effect of breast cancer on OPG expression in osteoblasts. MDA-MB-231 cells treated with or without DBP (0.05−1 $\mu$M) at for 6 h. After washing and a 24 h culture, the condition medium of nontreated or DBP-treated MDA-MB-231 cells (MDA-MB-231-CM and DBP-MB-231-CM) were harvested and stored at −80 °C. Osteoblasts were treated with various CMs for 24 h. The levels of M-CSF, RANKL or OPG in the supernatants of osteoblasts were assessed by ELISA. Each value is the mean ± SD of three independent experiments. * indicates significant difference with control-CM treatment, # indicates significant difference with MDA-MB-231-CM treatment, $p < 0.05$.

IL-8 were assessed and quantified using the DuoSet ELISA (enzyme-linked immuno-sorbent assay) (R&D Systems). Parathyroid hormone-related protein (PTHrP) levels were also determined by an ELISA kit (Abnova Corporation, Taipei, Taiwan).

**Analysis of Cell Viability.** MDA-MB-231 cells ($1 \times 10^5$ /well), osteoblasts ($0.5 \times 10^5$ /well), or CD14+monocytes ($1 \times 10^6$ /well) were seeded in a 96 well plate. Cells were treated with phthalates or various condition media for 24 h (BBP, DEHP, and DBP for MDA-MB-231 cells; control-MDA-MB-231-CM and DBP-MDA-MB-231-CM for osteoblasts and CD14 monocytes). The cell viability of MDA-MB-231 or CD14+ monoctytes was assessed using Premixed WST-1 Cell Proliferation Reagent (Clontech Laboratories Inc., Mountain View, CA, U.S.A.).

**Isolation of CD14$^+$ Monocytes and Differentiation of Osteoclasts.** Monocytes were purified from peripheral blood mononuclear cells (PBMCs) obtained from healthy consenting donors. Mononuclear cells were isolated from blood by Ficoll-Hypaque gradient (GE Healthcare Bio-Sciences, Little Chalfont, U.K.). CD14$^+$ monocytes were purified using CD14$^+$ monoclonal antibody-conjugated magnetic beads (MACS MicroBeads, Miltenyi Biotec), according to the manufacturer's protocol. Osteoclasts were generated by culturing CD14$^+$ monocytes in culture medium containing control 20% vehicle control-CM or DBP-MDA-MB-231-CM presented in 100 ng/mL M-CSF and 50 ng/mL RANKL (R&D Systems, Minneapolis, MN) for 14−21 days. The medium was replaced with fresh medium containing M-CSF and RANKL every 5 days. Osteoclast formation was measured by quan-

dx.doi.org/10.1021/jf5042905 | J. Agric. Food Chem. 2014, 62, 11933−11940

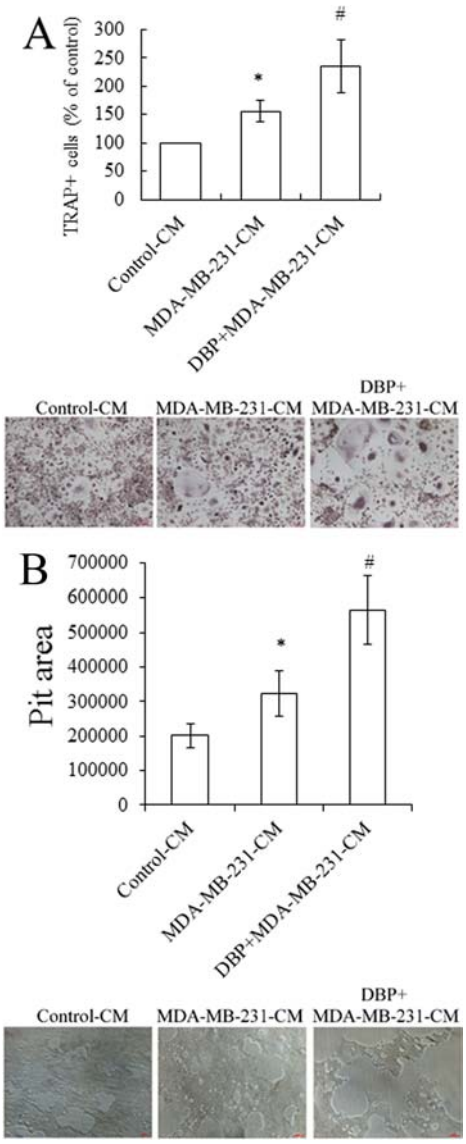

**Figure 3.** DBP reinforced the stimulatory effect of breast cancer in osteoclastogenesis and bone resorption. (A) DBP increased the effect of MDA-MB-231 cell on osteoclast differentiation and (B) their bone resorption activities. Osteoclastogenesis was determined by TRAP staining (osteoclast/nuclei > 3, TRAP positive). CD14+ monocytes were treated with MDA-MB-231-CM and DBP-MB-231-CM (20%) and cultured with M-CSF and RANKL for 14−21 days. Media were replaced every 5 days. Osteoclasts were stained by TRAP. Multinucleated (3+ nuclei) TRAP-positive cells are defined as osteoclasts. The pit area was determined by AlphaEase FC Software. Each value is the mean ± SD of three independent experiments. * indicates significant difference with control-CM treatment, # indicates significant difference with MDA-MB-231-CM treatment, $p < 0.05$.

tifying cells positively stained by TRAP (Sigma-Aldrich, St. Louis, MO, U.S.A.). Osteoclasts were deemed TRAP-positive by light microscopy that revealed staining of multinuclear (>3 nuclei) cells. The TRAP-positive cells and the number of nuclei per TRAP-positive cell in each well were counted. Osteoclasts' bone resorption activity was assessed by a 48-well plate bone resorption assay (Cosmo Bio Co., Ltd., Tokyo, Japan), under the same culture conditions as described above.

The Institutional Review Board (IRB) of Kaohsiung Medical University Hospital approved the study protocol and all of the participants provided written informed consent in accordance with the Declaration of Helsinki (IRB No.: KMUH-IRB-990174 and KMUH-IRB-20120362).

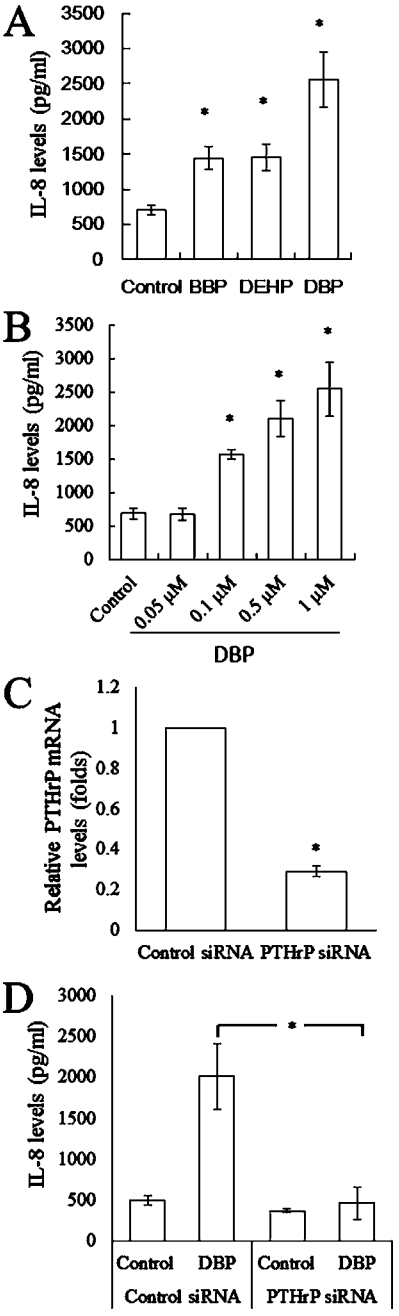

**Figure 4.** Phthalate esters increased the expression of IL-8 by increasing PTHrP in breast cancer. (A) The effect of BBP, DBP and DEHP on IL-8 levels in MDA-MB-231. (B) DBP increased IL-8 expression in a dose-dependent manner. (C) The efficiency of PTHrP siRNA transfection. (D) Inhibition of PTHrP decreased the up-regulation of IL-8 by DBP in MDA-MB-231 cells. MDA-MB-231 cells were transfected with either control siRNA or PTHrP siRNA (10 nM). After 24 h post-transfection, the knockdown efficacy was determined by qRT-PCR. MDA-MB-231 or siRNA transfected MDA-MB-231 cells treated with BBP, DBP or DEHP (1 $\mu$M) or various concentrations of DBP for 24 h. The PTHrP expression levels in these conditioned media were determined by ELISA. Each value is the mean ± SD of three independent experiments. *$p < 0.05$, or significant difference between the control and test groups.

**Real-Time Polymerase Chain Reaction (qRT-PCR).** The TRIzol reagent (Invitrogen, Carlsbad, CA, U.S.A.) was used for RNA isolation, while cDNA was prepared using an oligo-(dT) primer and reverse transcriptase (Takara, Shiga, Japan) following standard protocols. The

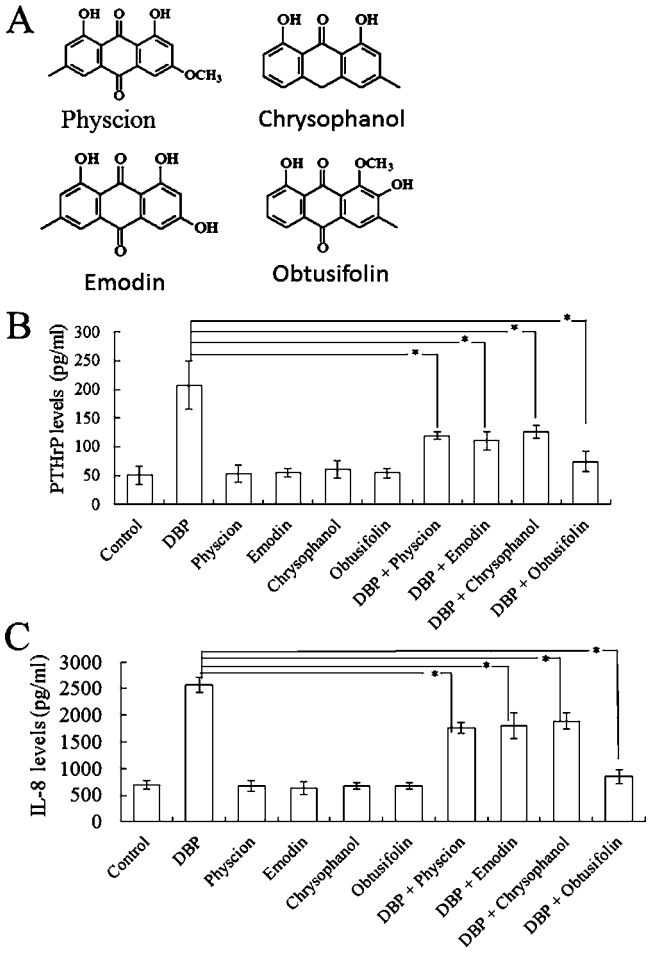

**Figure 5.** Active constituents of *Cassia tora* seeds decreased the effect of DBP on PTHrP and IL-8 expression. (A) Chemical structures of physcion, emodin, chrysophanol, and obtusifolin. The active components of *Cassia tora* L. seeds decreased the up-regulation of DBP on (B) PTHrP and (C) IL-8. MDA-MB-231 cells were pretreated with physcion, emodin, chrysophanol, and obtusifolin for 1 h, then incubated with DBP (1 $\mu$M) for another 6 h for PTHrP, or 24 h for IL-8 analysis. After washing and a 24 h culture, the culture media were collected and PTHrP levels were assessed using ELISA kit. Each value is the mean ± SD of three independent experiments. *$p$ < 0.05, or significant difference between the control and test groups.

qRT-PCR was performed using SYBR Green on the ABI 7500 Real-Time PCR System (Applied Biosystems, Foster City, CA, U.S.A.). Each PCR reaction mixture contained 200 nM of each primer, 10 $\mu$L of 2× SYBR Green PCR Master Mix (Applied Biosystems), and 5 $\mu$L of cDNA and RNase-free water for a total volume of 20 $\mu$L. The qRT-PCR was conducted with a denaturation step at 95 °C for 10 min, then for 40 cycles at 95 °C for 15 s, and 60 °C for 1 min. All PCRs were performed in triplicate and normalized to internal control glyceraldehyde-3-phosphate dehydrogenase (GAPDH) mRNA. The relative expression level was presented using the $2^{-\Delta\Delta CT}$ method.

**PTHrP Knockdown.** MDA-MB-231 cells were transfected with 20 nM nontarget or PTHrP siRNAs pool (Dharmacon, Lafayette, CO, U.S.A.) by DharmFECT 4 reagents, according to the manufacturer's instructions. After 24 h transfection, the medium was changed to whole medium and the cells treated with DBP. PTHrP changes were measured by qRT-PCR.

**Statistical Analysis.** Data were expressed as means ± standard errors. Statistical comparisons of the results were made using analysis of variance (ANOVA). Significant differences ($p$ < 0.05) between the means of the test groups were analyzed by Student's $t$ test.

## RESULTS

**Phthalate Esters Induced PTHrP Secretion in Human Breast Adenocarcinoma Cells.** To investigate the biological significance of the phthalate esters on PTHrP regulation in breast cancer cells, MDA-MB-231 cells were treated with butylbenzyl phthalate (BBP), di-2-ethylhexyl phthalate (DEHP), and dibutyl phthalate (DBP) at the same concentration of 1 $\mu$M for 6 h. After washing and culturing for 24 h, the condition medium of phthalate esters-treated MDA-MB-231 cells (BBP-, DEHP-, and DBP-MDA-MB-231-CM) were harvested, and the PTHrP expression levels of these conditioned media were then assessed. BBP, DEHP, and DBP increased the production of PTHrP in MDA-MB-231 cancer cells (Figure 1A). The effect of DBP on the induction of PTHrP expression was greater than that of BBP or DEHP. Because DBP had the strongest effect in increasing PTHrP secretion of MDA-MB-231, DBP was selected as the model to investigate the mechanism of phthalate esters in breast cancer bone metastasis. Consequently, treatment with different concentrations of DBP revealed that DBP increased the production of PTHrP in MDA-MB-231 cells in a dose-dependent manner after 6 h of stimulation followed by a 24 h culture (Figure 1B). To eliminate the possibility of PTHrP enhancement due to altered cell viability, we assessed the effect of phthalate esters on cell viability of MDA-MB-231 cells. The data shows that phthalate esters did not affect the viability of MDA-MB-231cells, suggesting that phthalate esters increased the expression of PHTrP (data not shown).

**Conditioned Medium of DBP-treated MDA-MB-231 Increased M-CSF and RANKL Expression, and Decreased OPG Expression in Osteoblasts.** PTHrP regulation enhanced osteoclastogenesis by changing the ratio of osteoclastogenesis activator (RANKL and M-CSF)/inhibitor (osteoprotegrin (OPG)) produced by osteoblasts.[23,24] To determine the effects of DBP on breast cancer in the secretion of RANKL, M-CSF, and OPG in osteoblasts, MDA-MB-231 cells were treated with 0.1% DMSO or DBP for 6 h. After removing DBP by washing, the cells were cultured with fresh medium before the medium was collected (defined as control-MDA-MB-231-CM and DBP-MDA-MB-231-CM). The CMs were added to human osteoblasts to assess the effect of DBP on breast cancer-osteoblast interaction (Figure 2A). Control-MDA-MB-231-CM increased M-CSF and RANKL expressions in osteoblasts, and this stimulatory effect was further enhanced when MDA-MB-231 cells were pretreated with DBP (Figure 2B and C). In contrast, MDA-MB-231 decreased the expression of OPG in osteoblasts (Figure 2D). To eliminate the likelihood of M-CSF, RANKL, and OPG changes resulting from different cell counts, we assessed the effect of control-MDA-MB-231-CM and DBP-MDA-MB-231-CM on the cell viability of osteoblasts. The data shows that neither control-MDA-MB-231-CM nor DBP-MDA-MB-231-CM affected the cell viability of osteoblasts, suggesting that DBP-MDA-MB-231-CM enhanced the M-CSF/RANKL and decreased OPG expression on osteoblasts (data not shown). This effect of breast cancer on osteoblasts worsened when breast cancer cells were exposed to DBP.

**Phthalate Esters Increased Breast Cancer Cell-Mediated Osteoclastogenesis and Bone Resorption.** The effect of DBP on breast-cancer-mediated osteoclastogenesis was assessed. MDA-MB-231-CM increased osteoclastogenesis, and this effect was reinforced when MDA-MB-231 cells were pretreated with DBP (Figure 3A). Similarly, MDA-MB-231-CM enhanced osteoclast bone resorption activity, and this

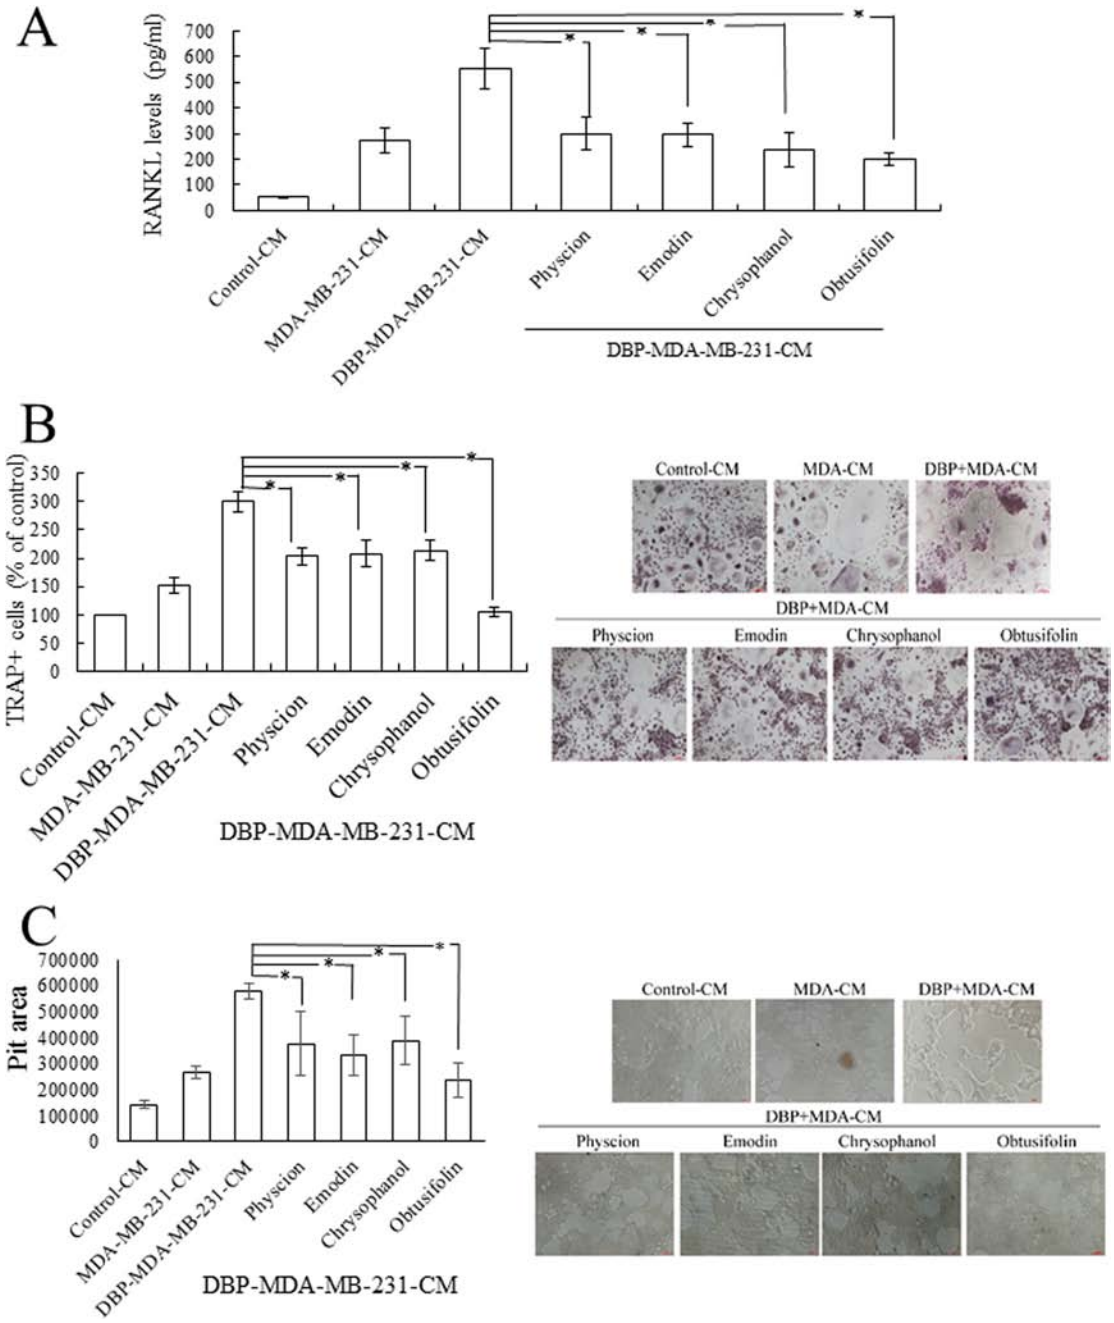

**Figure 6.** Active constituents of *Cassia tora* L. seeds decreased the effects of DBP on breast cancer bone metastasis events. *Cassia tora* L. seeds' compounds decreased the synergetic effects of DBP on (A) the RANKL expression of osteoblasts, (B) osteoclastogenesis, and (C) bone resorption. RANKL levels were measured by ELISA kit. For part A, MDA-MB-231 cells were pretreated with physcion, emodin, chrysophanol, and obtusifolin for 1 h, then incubated with DBP (1 $\mu$M) for another 6 h. After washing and a 24 h culture, the culture media were collected, then added to osteoblasts for a 24 h culture, The levels of RANKL in the supernatants of osteoblasts was assessed by ELISA. For parts B and C, MDA-MB-231 cells were pretreated with physcion, emodin, chrysophanol, and obtusifolin for 1 h, then incubated with DBP (1 $\mu$M) for another 6 h. After washing and a 24 h culture, the culture medium (20%) was collected, then added to CD14+ monocytes presenting in M-CSF and RANKL for a 14−21 days. The osteoclastogenesis and bone resorption was conducted as described above. Each value is the mean ± SD of three independent experiments. *$p$ < 0.05, or significant difference between the control and test groups.

stimulatory effect of breast cancer was further intensified by DBP pretreatment (Figure 3B). However, the cell viability of monocytes was not affected by MDA-MB-231-CM or DBP-MDA-MB-231-CM (data not shown).

**PTHrP/IL-8 Autocrine Loop Was Involved in the Stimulation of DBP on Breast-Cancer-Mediated Osteoclastogenesis.** Since PTHrP has been reported to increase cancer cell expression of IL-8,[25] this study assessed whether phthalate esters increased the inductive effect of MDA-MB-231 on osteoclastogenesis by targeting the PTHrP/IL-8 loop. The level of IL-8 was higher in BBP-, DEHP-, and DBP-treated MDA-MB-231 than in the control group (Figure 4A). In inducing PTHrP expression, the effect of DBP on IL-8 secretion was greater than that of BBP or DEHP in MDA-MB-231. DBP increased IL-8 expression in MDA-MB-231 in a dose-dependent manner (Figure 4B). To confirm the role of PTHrP on the

up-regulation of IL-8 induced by DBP, MDA-MB-231 cells were transfected with PTHrP siRNA. Transfection of MDA-MB-231 cells with PTHrP siRNA decreased PTHrP mRNA expression in MDA-MB-213 cells by 74.5% (Figure 4C). Silencing prevented the up-regulation of DBP on the expression of IL-8 in MDA-MB-231 cells (Figure 4D).

**Obtusifolin Suppressed Phthalate Esters-Mediated Bone Resorption.** This study assessed the effects of physcion, emodin, chrysophanol, and obtusifolin on DBP-induced breast cancer bone metastasis (Figure 5A). DBP induced PTHrP and IL-8 secretion in human breast adenocarcinoma cells, whereas physcion, emodin, chrysophanol, and obtusifolin treatment decreased PTHrP and IL-8 secretion (Figure 5B and C). Of these compounds, obtusifolin completely reversed PTHrP and IL-8 secretion of breast cancer cells upon exposure to DBP. Similarly, the CM of DBP-treated MDA-MB-231 mediated RANKL up-regulation in osteoblasts. Osteoclastogenesis and bone resorption were totally abrogated by obtusifolin treatment, whereas they were only partially reversed by treatment with physcion, emodin, or chrysophanol alone (Figure 6).

## DISCUSSION

Bone metastasis is a disturbing development in patient care because cancer's spread to the bone increases morbidity and mortality rates.[6,26,27] Previous studies indicate that exposure to phthalate esters is associated with increased risk of breast cancer.[11−14] Furthermore, Hsieh et al. have indicated that phthalate esters increase the proliferation and invasiveness of breast cancer cells.[15,16] This study is the first to demonstrate that phthalate increases the stimulatory effect of breast cancer on osteoclastogenesis and osteoclast bone resorption activity directly via PTHrP/IL8 and by interfering in the osteoblast-osteoclast interaction.

Parathyroid hormone-related protein (PTHrP), a potent activator of osteoclastic bone resorption, is an important pathologic factor for hypercalcemia among cancer patients.[28−30] PTHrP stimulates osteoclastogenesis by increasing receptor activator of NF-κB ligand (RANKL) expression and by reducing osteoprotegerin (OPG) expression in osteoblasts. However, it does not act directly on osteoclast precursors.[31,32] RANKL binds with the RANK receptor in osteoclast precursors and induces the formation of mature osteoclasts in the presence of macrophage colony stimulating factor (M-CSF).[33,34] Since OPG is a soluble decoy receptor for RANKL, with the ability to decrease osteoclastogenesis,[35] a relative increase of RANKL/OPG ratio by cancer-derived PTHrP results in osteoclastic bone resorption.[36] This study shows that phthalate esters, BBP, DEHP, and DBP, cause an up-regulation of PTHrP in breast cancer. Consistent with PTHrP enhancement, DBP reinforces the interference of breast cancer on osteoblasts, including increased M-CSF and RANKL, and decreased OPG. These results suggest that phthalate esters may worsen bone metastasis in breast cancer.

Many studies report that breast cancer expresses high levels of IL-8, which enhances both osteoclastogenesis and bone resorption.[37−39] PTHrP has been reported to increase osteoclastogenesis by increasing the expression of osteoclast stimulatory factors such as IL-8.[36] The present study reveals that phthalate esters increase IL-8 expression in breast cancer cells. Inhibition of PTHrP by siRNA transfection prevents phthalate-mediated up-regulation on IL-8 secretion, suggesting that PTHrP is the major mediator involved in the stimulatory effect of phthalate esters on IL-8 production. Moreover, DBP enhances the stimulatory effect of breast cancer on osteoclastogenesis and their bone resorption activity. Thus, the regulation of IL-8 expression by phthalate esters through PTHrP is a key point that contributes to phthalate esters-induced osteoclastogenesis and bone resorption.

Current treatments for bone metastases have limited efficacy and are merely palliative. Side effects such as renal toxicity and osteo-necrosis of the jaw are considered clinically significant, potentially painful, and debilitating enough to decrease the quality of life of breast cancer patients.[40] Since eliminating all phthalate exposure may be impossible because phthalate esters are widely used in modern life, it is therefore important that strategies be developed for the prevention of bone metastasis in breast cancer. The data here shows that the components of Jue-ming-zi, including physcion, emodin, chrysophanol, and obtusifolin, exhibit effects that decrease PTHrP expression in MDA-MB-231 cells. These agents also simultaneously decrease IL-8 expression, resulting in the inhibition of MDA-MB-231-mediated osteoclastogenesis and bone resorption.

Moreover, these agents also decrease the stimulatory effect of breast cancer on the expression of RANKL in osteoblasts. Among these active constituents of seeds from *Cassia tora* L., obtusifolin has the most significant effect on the prevention of breast cancer-mediated osteolytic events, suggesting that Jue-ming-zi or obtusifolin may be potential agents to prevent the exacerbating of breast cancer related bone metastasis by phthalate esters.

In conclusion, the present study is the first to investigate the interaction of breast cancer cells, osteoblasts, and osteoclasts after exposure to phthalate esters. These esters, BBP-, DEHP-, and DBP, cause human breast cancer cell line MDA-MB-231 to secrete PTHrP and IL-8, which mediate RANKL up-regulation and OPG down-regulation in osteoblasts, thereby inducing osteoclastogenesis and bone resorption. This is the first investigation that provides evidence that obtusifolin, a major bioactive compound present in the seeds of *Cassia tora* L., has great potential in preventing phthalate esters-associated breast cancer bone metastasis. This is also the first investigation to provide evidence that the seeds of *Cassia tora* L. have great potential as a novel antibreast cancer bone metastasis agent.

MALDI matrix 2,5-dihydroxybenzoic acid (DHB), peptide calibration standard II, and protein calibration standard II were from Bruker (Billerica, MA). $C_4$ ziptips were from EMD Millipore (Darmstadt, Germany). Other reagents, including HPLC grade acetonitrile (ACN), trifluoroacetic acid (TFA), and ammonium bicarbonate (AMBIC) were from Fisher Scientific (Waltham, MA). Water was purified on a Milli-Q Advantage A10 system (EMD Millipore). Dithiothreitol was from Acros Organics (New Jersey) and iodoacetamide was from BioRad (Hercules, CA). For gene cloning, an RNeasy Plant Mini Kit (Qiagen, Venlo, Limburg), a SMARTer RACE cDNA Amplification kit, and an Advantage 2 PCR kit from Clontech (Mountain View, CA), a pGEM-T vector (Promega), and *Escherichia coli* strain JM109 were used.

**Molecular Mass Measurement.** Purified WPTP was dissolved in 0.1% TFA, mixed 1:1 with a MALDI matrix solution (20 g/L DHB in 50% ACN, 0.1% TFA), spotted onto a polished steel target plate (Bruker), and allowed to air-dry. The molecular mass was measured with an Ultraflex III MALDI-TOF/TOF mass spectrometer (Bruker) in linear positive mode. In 200 shot increments, 1500 laser shots were accumulated. The matrix suppression cutoff, using gating, was at 9500 $m/z$. Pulsed ion extraction (PIE) delay was set to 150 ns. Instrument voltages were at 25 kV (ion source 1 [IS1]), 23.1 kV (IS2), and 6.5 kV (lens). The WPTP molecular mass value was calibrated using the protein mix II calibration standard (Bruker). Spectrum processing, consisting of peak detection (centroid algorithm, peak width 1000 $m/z$) and smoothing (Savitzky−Golay algorithm, 1 cycle at 20 $m/z$), was performed in Flex Analysis 3.4 (Bruker).

**Top-Down Sequencing.** Top-down sequencing (TDS) of native WPTP was performed after solid-phase reduction of its disulfide bonds. BSA was used as the control and the molecular mass calibrator. For solid-phase disulfide bond reduction, a $C_4$ ziptip was wetted with 50% ACN in 250 mM AMBIC solution several times. The protein sample (25 pmol in 15 $\mu$L of 100 mM AMBIC) was loaded on the tip equilibrated with 100 mM AMBIC by slowly repipetting at least 10 times. Then, 50 mM dithiothreitol (200 $\mu$L) was introduced to the tip by aspirating and dispensing the solution for 2 min at 60 °C. The ziptip was then incubated in that solution for 30 min at 60 °C. The tip was washed three times with 0.1% TFA. The protein was eluted with 5 $\mu$L of a MALDI matrix solution (40 g/L DHB in 70% ACN, 0.1% TFA), and 0.25 $\mu$L was spotted directly on the target plate and allowed to air-dry.

TDS spectra were acquired with an Ultraflex III MALDI-TOF/TOF mass spectrometer in reflector positive mode. In 200 shot increments, 19 000 laser shots were accumulated. The matrix suppression cutoff, using deflection, was at 900 $m/z$. PIE delay was set to 40 ns. Instrument voltages were at 25 kV (IS1), 21.4 kV (IS2), 9.7 kV (lens), 26.3 kV (reflector 1), and 13.8 kV (reflector 2). Spectrum processing, consisting of peak detection (SNAP algorithm, peak width 0.75 $m/z$), baseline subtraction (TopHat algorithm), and smoothing (Savitzky−Golay algorithm, 5 cycles at 1.5 $m/z$), as well as peak annotation was carried out in Flex Analysis 3.4. Peaks were assigned with a mass tolerance of 300 ppm. Interpretation of the ions comprising the near C-terminus was aided by the characteristic $m/z$ difference of 15 ($\Delta$ $m/z$) between y- and z+2-ion series. Additional annotation was performed with BioTools (Bruker) and Sequence Editor (Bruker).

**Bottom-Up Sequencing.** WPTP (10 $\mu$g, 1 $\mu$g/$\mu$L in 25 mM AMBIC) was reduced with 50 mM dithiothreitol (20 $\mu$L) for 30 min at 60 °C, alkylated with 100 mM iodoacetamide (25 $\mu$L) for 45 min at room temperature in the dark. The alkylation reaction was quenched by addition of 1 $\mu$L of 143 mM dithiothreitol. Reduced and alkylated WPTP was diluted with water and then digested in solution with 0.5 $\mu$g of trypsin (50 $\mu$L) at 37 °C for 12 h. Peptides were dried via SpeedVac and resuspended in 5% ACN in 0.1% TFA. The peptide solution was mixed 1:1 with a MALDI matrix solution (20 g/L DHB in 50% ACN, 0.1% TFA) and then spotted on a target plate.

Mass spectra of the peptides were acquired with an Ultraflex III MALDI-TOF/TOF mass spectrometer in reflector positive mode. In 200 shot increments, 600 shots were accumulated. The matrix suppression cutoff, using deflection, was at 850 $m/z$. PIE delay was set to 0 ns. Instrument voltages were at 25 kV (IS1), 21.45 kV (IS2), 9.5 kV (lens), 26.3 kV (reflector 1), and 13.8 kV (reflector 2). External calibration was performed using peptide mix II calibration standard (Bruker). Spectrum processing, consisting of peak detection (SNAP algorithm, peak width 0.75 $m/z$) and smoothing (Savitzky−Golay algorithm, 1 cycle at 0.2 $m/z$), was performed in Flex Analysis 3.4.

Several peaks in the mass spectrum were selected for fragmentation in LIFT mode.[17] Several thousand laser shots were accumulated in 200 shot increments. PIE delay was set to 0 ns. Instrument voltages were at 8 kV (IS1), 7.2 kV (IS2), 3.6 kV (lens), 29.5 kV (reflector 1), and 13.85 kV (reflector 2). Spectrum processing, consisting of peak detection (SNAP algorithm, peak width 0.75 $m/z$) and smoothing (Savitzky−Golay algorithm, 4 cycles at 0.15 $m/z$) as well as peak annotation, was carried out in Flex Analysis 3.4. Additional annotation was performed with BioTools and Sequence Editor with a mass tolerance of 0.3 $m/z$ for peptides and 1 $m/z$ for glycopeptides. Fragmentation spectra were interpreted and used for primer design in the gene cloning experiment.

**Cloning and Sequencing of the cDNA.** Total RNA was isolated from 0.1 g of *T. fortunei* leaves using an RNeasy Plant Mini Kit (Qiagen). The first-strand cDNA was synthesized from the isolated RNA using a SMARTer RACE cDNA Amplification kit (Clontech). The WPTP gene was cloned in two steps. In the first step, the forward degenerate primers (5′-GAYCTNCARATHGGNTT-3′ and 5′-GAYTTRCAR-ATHGGNTT-3′) targeted the previously determined amino acid sequence of the N-terminus of WPTP (DLQGIFY).[15] The reverse primer, UPM, was provided with the same kit. PCR amplification was performed using an Advantage 2 PCR kit (Clontech). The PCR protocol consisted of an initial denaturation step at 94 °C (2 min), which was followed by 5 cycles of denaturation at 94 °C (30 s), annealing at 60 °C (30 s), and extension at 68 °C (1 min); then 5 cycles of denaturation at 94 °C (30 s), annealing at 55 °C (30 s), and extension at 68 °C (1 min); then followed by 25 cycles of denaturation at 94 °C (30 s), annealing at 50 °C (30 s), and extension at 68 °C (1 min); and then a final extension for 3 min at 68 °C. The resulting 1200 bp product was used as a template in the second step. The forward primer (5′-ATGCAYTTYCAYGAYTGYTT-3′) was designed from the amino acid sequence MHFHDCF, obtained by tandem mass spectrometry analysis of WPTP tryptic peptides in this study. The PCR protocol was the same as above except that the annealing temperatures were 65 °C, 62 °C, and 60 °C, respectively. The PCR product was cloned into a pGEM-T vector and transformed into *E. coli* strain JM109. Positive transformants were screened by PCR. Plasmids were extracted from positive clones and confirmed by sequencing. For 5′-RACE, the reverse primer, 5′-GGACCTGGTAGGTGATGTTGCCG-3′, was designed from the DNA sequence obtained in the previous step. The forward primer, UPM, was from the same kit. The PCR protocol was the same as above except that the annealing temperatures were 65 °C, 62 °C, and 58 °C, respectively. The PCR product was cloned, transformed, screened, and sequenced as before. The complete cDNA sequence of WPTP was obtained by combining the 5′- and 3′-cDNA sequences which were overlapping with each other. Analysis of the data was conducted with the software Mega5.[18] These data can be accessed at NCBI accession: KM504969.

## RESULTS AND DISCUSSION

**Determination of the Molecular Mass of WPTP.** The MALDI-TOF mass spectrum of WPTP indicated the presence of a single glycoprotein with considerable heterogeneity (Figure 1A). An expanded view of the +2 charged peak revealed that it was composed of many partially resolved peaks, probably corresponding to WPTP glycoforms, i.e., differentially glycosylated WPTP (Figure 1B). A similar view of the +1 charged peak also showed multiple, partially resolved peaks.

The obtained data allowed for calculation of the MW of WPTP which ranged from 41 to 45 kDa (Figure 1C). These values are a little lower than the value previously reported for WPTP (50 kDa), which was measured using SDS-PAGE.[15] Due to decreased binding of SDS to glycans relative to the polypeptide backbone, the migration of a glycoprotein during SDS-PAGE is altered relative to what is expected for a similarly sized nonglycosylated protein.[19] Therefore, the previous measurement

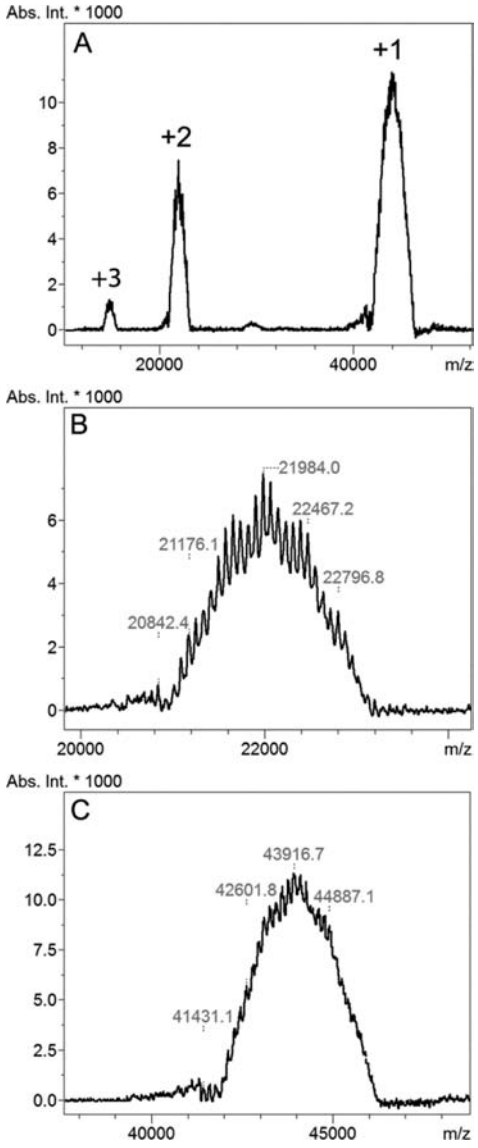

**Figure 1.** MALDI-TOF MS of WPTP to determine the molecular mass: (A) +1, +2, and +3 charged peaks and an expanded view of the (B) +2 charged and (C) +1 charged peak.

was likely an overestimation. Similarly, the first report of RPTP's MW, as measured by SDS-PAGE, was 51 kDa[20] and the MW as measured by mass spectrometry was 44 596 Da.[14]

**Top-Down Sequencing.** It is well-known that drawbacks of MALDI-TDS are the requirement of a high purity of analyte, low sensitivity, and lack of fragmentation in the presence of disulfide bonds.[21] The isolated WPTP used in this study was high purity.[15] WPTP was immobilized onto a C4 ziptip by hydrophobic interactions, and its disulfide bonds were then reduced. This provided a quick and effective way to reduce WPTP's disulfide bonds, remove contaminating salts, and concentrate the reduced protein in one simple step.

MALDI-TDS results in ladder fragmentation of the intact protein, leaving glycans attached to the modified Asn residues.[22] Partial amino acid sequence near the N-terminus of WPTP was gained through interpretation of the c-ion series in the MALDI-TDS spectrum (Figure 2A, MHFHD). The y- and $z$+2-ions were interpreted as a continuous 30-amino acid residue sequence (Figure 2A, DN*LTAWVAKFAQAIVKMGQIQVLTGTQ-GEI). A protein BLAST search of the NCBInr database (blast.ncbi.nlm.nih.gov) predicted that this sequence originated from a protein in the peroxidase superfamily. The top hit was RPTP (PDB: 3HDL; $E$ value: $6 \times 10^{-16}$). The y ions at $m/z$ 5290.1 and 6575.7 (N*) (and the corresponding $z$+2-ions) had a mass difference corresponding to a glycosylated Asn, Asn-$GlcNAc_2Man_3FucXyl$ (exact $\Delta$ $m/z$ 1284.5 and accurate $\Delta$ $m/z$ 1285.6). This glycan is the predominant glycan found on HRP,[23] soybean peroxidase (SBP),[24] RPTP,[14] and other plant peroxidases. A scheme of the glycan is depicted in Figure 2B according to the conventions of the Consortium for Functional Glycomics. All assigned peaks had a mass error within 200 ppm and the root-mean-square error (RMSError) was 65.32 ppm.

**Bottom-Up Sequencing.** Additional amino acid sequence information was gained through a more traditional "bottom-up" approach. For this, WPTP was digested with trypsin, and the resulting tryptic peptides were subjected to MALDI-TOF MS (Figure 3A). Tandem mass spectrometry was performed to obtain the amino acid sequence of the tryptic peptides of WPTP (Figure 3B–F). Among these, fragments of the parent ion at $m/z$ 1264.6 could be unambiguously interpreted as $M^{[ox]}$HFHDCFVR (Figure 3D). Furthermore, this sequence overlapped with an amino acid sequence ladder from the MALDI-TDS experiment. Thus, this amino acid sequence was used for primer design for cDNA cloning and sequencing of WPTP.

Fragments of the parent ion at $m/z$ 2890.3 displayed a characteristic spectrum of a glycopeptide (Figure 3F). Man and GlcNAc oxonium ions were observed at $m/z$ 162.7 and 203.7, respectively. We also observed cross-ring fragmentation of the innermost GlcNAc ($^{0,2}$X). Additionally, the glycan moiety fragmented into a series of y-ions corresponding to mass shifts indicative of the glycan $GlcNAc_2Man_3XylFuc$ (Figure 2C).

**cDNA Sequencing.** The gene for WPTP was cloned and sequenced from mRNA isolated from the leaves of *T. fortunei*. The gene consisted of 5′- and 3′- untranslated regions, which included a poly-A tail, and 1032 bp encoding a polypeptide of 344 amino acids (Figure 4). There was an N-terminal signal peptide upstream of the previously sequenced N-terminus of mature WPTP, which targets class III peroxidases to the secretory pathway.[25] Some peroxidases additionally bear a C-terminal signal peptide for vacuolar targeting.[25] Insights into in vivo processing of the C-terminus of WPTP were obtained by combining information from the MALDI-TDS spectrum of intact WPTP and its cDNA sequence. In a MALDI-TDS spectrum, the ion with the lowest $m/z$ value in each ion series corresponds to the mass of the N-terminus (for c-ions) or the C-terminus (for y- and z-type ions). Therefore, the y 11-ion corresponded to the mass of RTN*CSVVNSAS (Figure 2A; exact $m/z$ 2307.9 and accurate $m/z$ 2307.8), where the mass shift for $Asn^{298}$ (N*) in the WPTP sequence corresponded to $GlcNAc_2Man_3FucXyl$. Thus, the vacuolar targeting signal for WPTP was LGDIVMASGHLTEVATS (Figure 4, gray italics).

Using the same logic for the N-terminus, the c 38-ion at $m/z$ 6098.4 (Figure 2A) corresponded to the sequence DLQIG-FYN#QSCPSAESLVQQAVAAAFAN*NSGIAPGLIR (Figure 4), where the mass difference of 2178.3 relative to the expected peptide mass (3920.1 Da) could be accounted for by adding a glycan to $Asn^{8}$ (N#) and one to $Asn^{28}$ with the potential sequences $GlcNAc_2Man_2FucXyl$ ($\Delta$ $m/z$ 1008.4) and $GlcNAc_2Man_3FucXyl$ ($\Delta$ $m/z$ 1170.4), giving an overall mass error of 65.6 ppm (exact $m/z$ 6098.7 and accurate $m/z$ 6098.4).

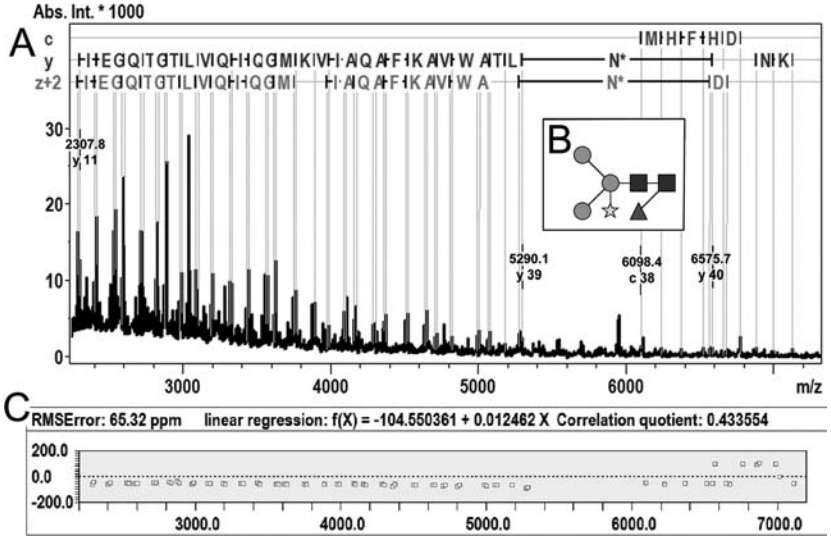

**Figure 2.** MALDI-top-down sequencing of WPTP to determine the amino acid sequence near the protein termini. The amino acid sequence was interpreted from c-, y-, and z+2-ion series. (A) Δ $m/z$ between y 39 at $m/z$ 5290.1 and y 40 at 6575.7 corresponded to Asn modified with the glycan $GlcNAc_2Man_3XylFuc$ (N*). (B) A cartoon structure of the glycan $GlcNAc_2Man_3XylFuc$. (C) A plot showing the mass error (ppm) for each matched ion. (■) *N*-Acetylglucosamine (GlcNAc); (●) mannose (Man); (▲) fucose (Fuc); (★) xylose (Xyl).

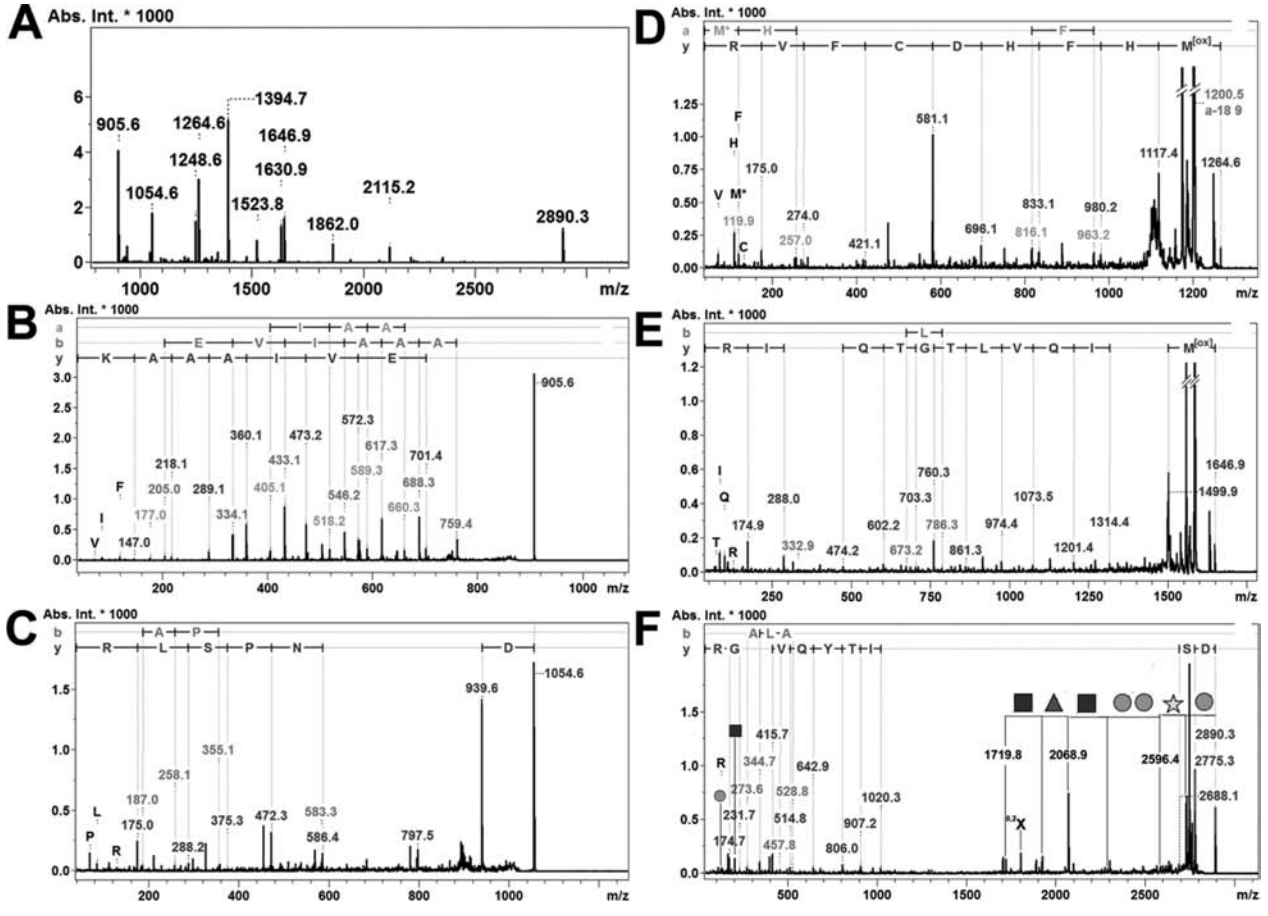

**Figure 3.** MALDI-TOF/TOF MS/MS of WPTP tryptic peptides for primer design: (A) mass spectrum WPTP tryptic peptides and fragmentation spectra of the parent ion at $m/z$ (B) 905.6, (C) 1054.6, (D) 1264.6, (E) 1646.9, and (F) 2980.3. ($M^{[ox]}$) oxidized methionine; (■) *N*-acetylglucosamine (GlcNAc); (●) mannose (Man); (▲) fucose (Fuc); (☆) xylose (Xyl).

**Structure Overview.** Mature WPTP was composed of a single polypeptide, 306 amino acid residues in length, with an average mass of 32 172 Da. The cDNA sequence showed that there were 13 potential glycosylation sites, identified by the sequence Asn-Xxx-Ser/Thr, where Xxx is any amino acid except Pro. The MW, as measured by MALDI-TOF MS (Figure 1), ranged from 41−45 kDa. Considering this and the polypeptide mass, WPTP has 21−29% glycans. This level of complexity made

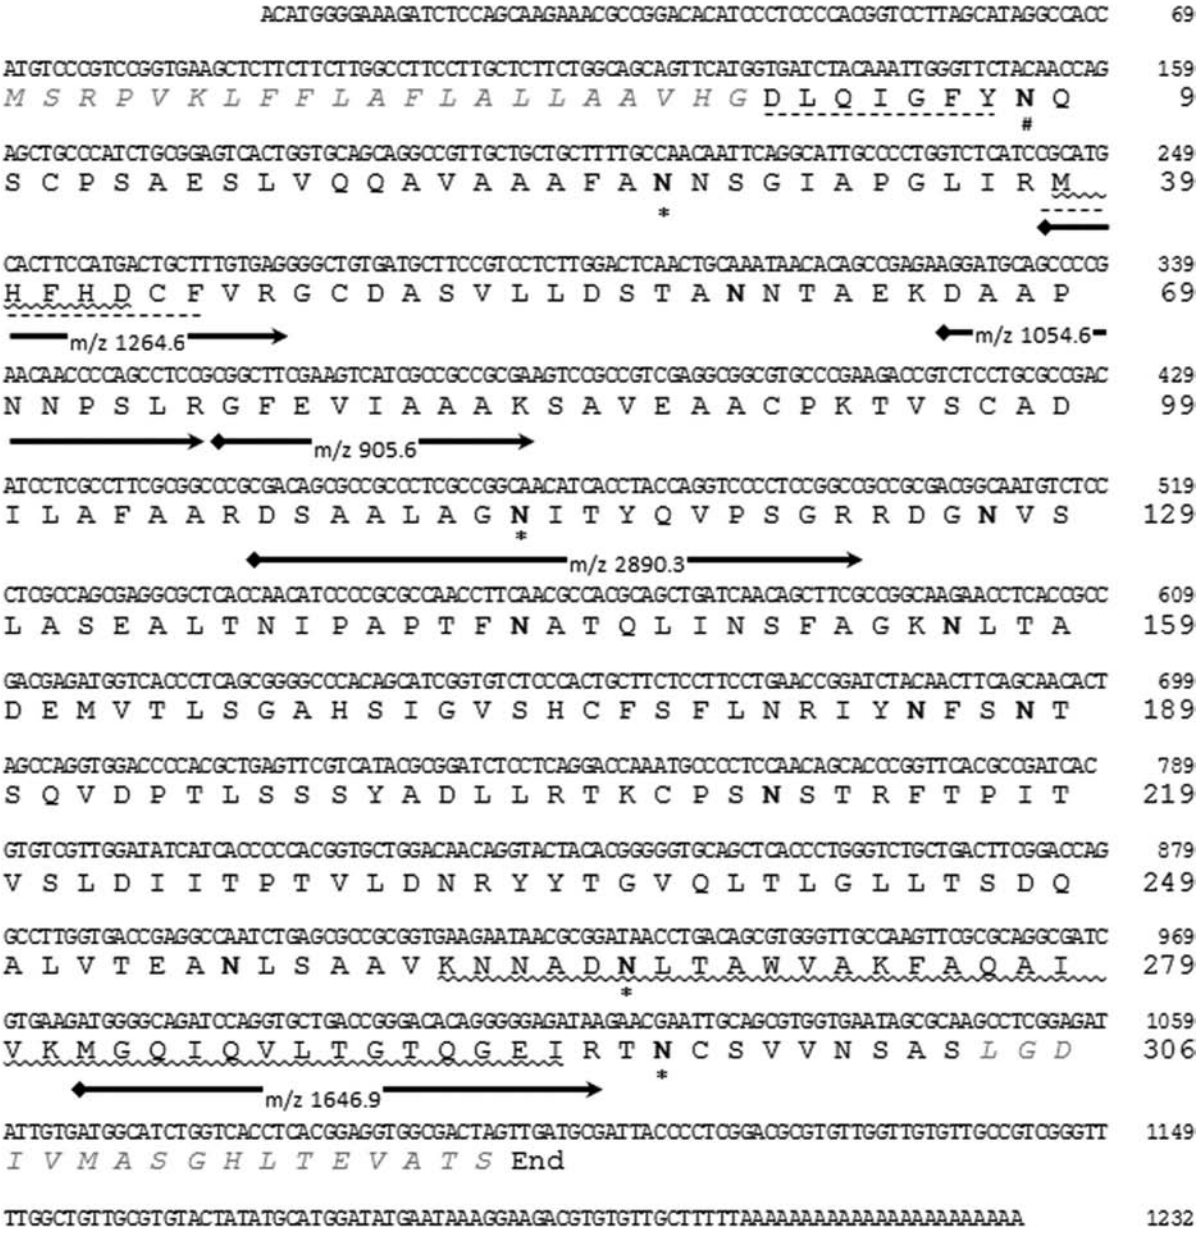

**Figure 4.** cDNA sequencing of WPTP to determine the complete amino acid sequence. Nucleotide and amino acid residue numbers are on the right. (gray italicized) N- and C-terminal signal peptides; amino acid sequence (----) used for primer design, (zig-zag) covered by MALDI-TDS, and (→) determined by MALDI-TOF/TOF MS/MS; (**N**) potential glycosylation site; (#) $GlcNAc_2Man_2FucXyl$; (*) $GlcNAc_2Man_3FucXyl$.

it difficult to assign a specific glycoform structure to each peak in that spectrum. Positions 8, 28, 114, 267, and 298 were glycosylated. A more detailed study of WPTP's glycosylation profile is underway.

Class III peroxidases share a common 3D structure despite a low sequence identity.[2,16,26] For example, RPTP and HRP were only 36% identical, but their C$\alpha$ backbone structures were closely related, having an overall root mean squared deviation of 1.07 Å.[14] A structurally guided alignment revealed that WPTP and RPTP were 88% identical in primary structure and likely were very similar in secondary and tertiary structures (Figure 5).

Structural integrity of plant peroxidases is maintained largely by an extensive hydrogen bonding network that extends above and below the heme-containing active site to distal and proximal $Ca^{2+}$.[32] Additionally, four invariant disulfide bridges tie the protein together. These eight cysteine residues were present in WPTP (Figure 5, c). Importantly, the disulfide bridge between $Cys^{44}$ and $Cys^{49}$ stabilizes the BC loop, which comprises the majority of the distal $Ca^{2+}$ binding residues (Figure 5, +). Distal $Ca^{2+}$ was critical for maintaining the proper tertiary structure of the active site.[33] The disulfide bridge between $Cys^{176}$ and $Cys^{208}$ stabilizes the region between helices F and H, which is important for substrate binding and contains residues necessary for binding proximal $Ca^{2+}$. The additional 4.5 $Ca^{2+}$ found in the WPTP structure were difficult to account for because only one other peroxidase, anionic peanut peroxidase,[34] had elevated $Ca^{2+}$ content and its 3D structure was still not available.

**Features of Potential Importance to Substrate Specificity.** The new WPTP structure information presented in this study allowed for exploration of features of potential importance in palm tree peroxidases. One striking functional difference is substrate reactivity differences between WPTP, RPTP, and HRP (Table 1). Ferulic acid was the better substrate for RPTP and HRP.[20] Moreover, the difference in reactivity

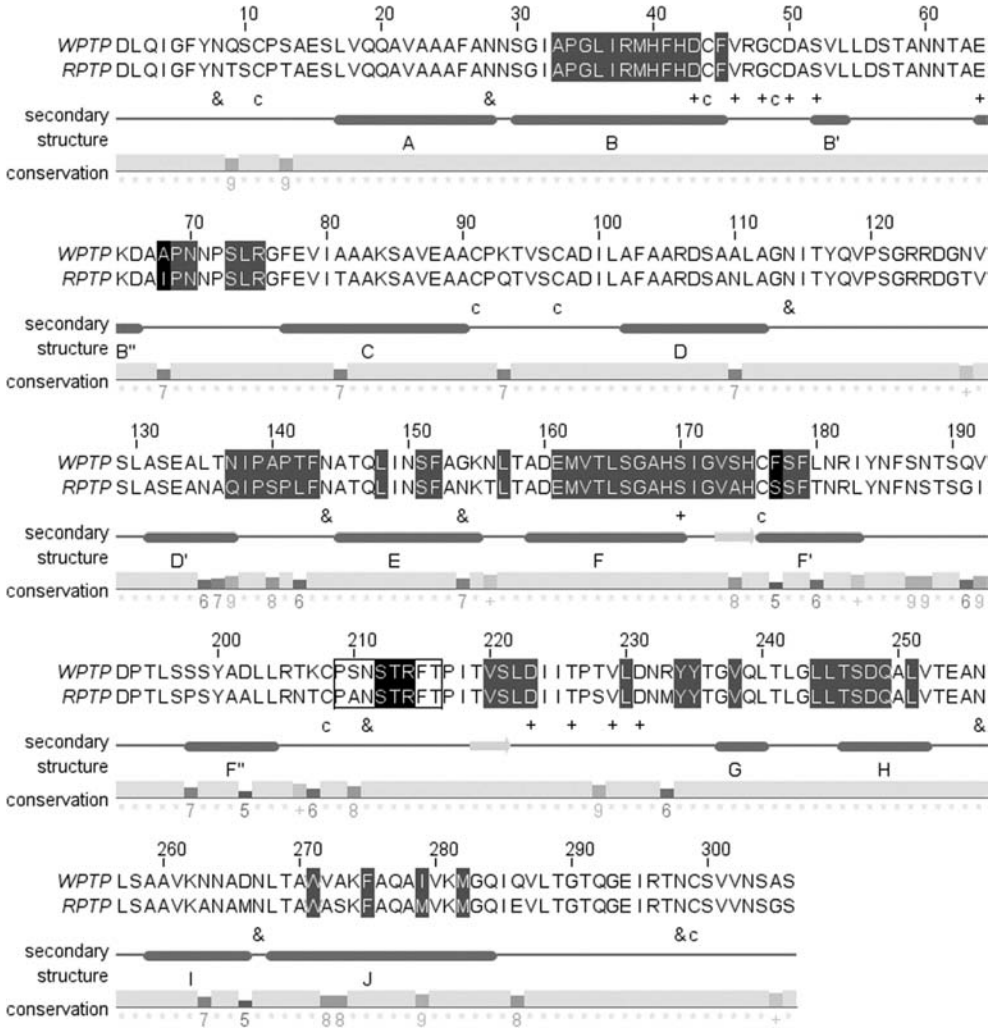

**Figure 5.** Alignment of WPTP and RPTP (PDB: 3HDL) according to the method of Armougom et al.[27] to determine features related to substrate specificity. Determination of (highlighted in gray) residues less than 12 Å from heme iron and (highlighted in black) less than 4.6 Å from MES with Swiss-PdbViewer 4.1.0[28] and (box) residues with significant structural deviation between RPTP and HRP (PDB: 1ATJ) with a protein structure alignment tool.[29] (&) Occupied glycosylation site;[14] (c) cysteine; (+) $Ca^{2+}$ binding. Secondary structure: (dark gray) helices; (light gray) sheets. Helices labeled according to Watanabe et al.[14] and conservation according to Livingston and Barton.[30] The figure was drawn in JalView.[31]

**Table 1. Substrate Reactivity As Measured by $k_{app}$ ($M^{-1}$ $s^{-1}$)**

| | WPTP[a] | RPTP[b] | HRP[b] |
|---|---|---|---|
| ferulic acid | $3.0 \times 10^6$ | $6.3 \times 10^7$ | $1.3 \times 10^7$ |
| ABTS[c] | $6.0 \times 10^7$ | $5.0 \times 10^7$ | $4.0 \times 10^6$ |

[a]The data for WPTP are from ref 15. [b]The data for RPTP and HRP are from ref 20. [c]2,2′-Azinobis(3-ethylbenzothiazoline-6-sulfonic acid).

between ferulic acid and ABTS was not too different for those two peroxidases, i.e., there was a 1.26-fold difference for RPTP and 3.25-fold difference for HRP.[20] The better substrate for WPTP was ABTS, and ferulic acid had 20-fold lower reactivity.[15] Investigation of the 3D structure of RPTP, using Swiss-PdbViewer 4.1.0,[28] revealed amino acid residues and features of known and putative importance to substrate binding (Table 2).

Amino acids involved in substrate binding should be within 12 Å of the heme iron, as indicated by NMR studies of HRP–substrate complexes.[38] There were 64 residues within this distance in RPTP (Figure 5, highlighted in gray) and 5 of those differed between WPTP and RPTP. Of those 5, the lowest conservation was at position 142. Interactions between residue 142 and conserved Phe[143] resulted in topological features thought to affect interactions with substrates.[2,39] Residue 142 was hydrophobic in HRP, RPTP, and WPTP, except that it was large in HRP (Phe) and RPTP (Leu) but small in WPTP (Thr). This difference could be a major factor causing the large deficit in WPTP's reactivity toward ferulic acid. The absence of a 3D structure complex between peroxidase and ABTS prevented speculation about features responsible WPTP's superior catalysis of that large substrate.

The RPTP crystal structure contained a potential inhibitor, an MES molecule.[14] Residues within van der Waals radius (4.6 Å) of MES may affect substrate reactivity. Nine residues (Ile[68], Ser[140], Pro[141], Leu[142], Ser[177], Ser[178], Ser[212], Thr[213], and Arg[214]) were within that region. Five of the nine residues did not overlap with the residues that were 12 Å from the heme iron (Figure 5, highlighted in black). The position with the lowest conservation between between RPTP and WPTP was at position 177 and WPTP was at position 177. In WPTP, it was large, hydrophobic, and aromatic Phe, whereas in RPTP, it was small and polar Ser. Moreover, this MES binding site was in the most structurally divergent region between HRP and RPTP (Figure 5, box). In

**Table 2. Residues of Known and Potential Importance for Protein−Substrate Interactions**

| position[a] | WPTP | RPTP | predicted effect | evidence |
|---|---|---|---|---|
| Distance within 12 Å of Heme Iron | | | | |
| 38 | R | R | critical | two H-bonds to ferulic acid (FA) (HRP);[35] $Arg^{38}$ to Leu 10−100 times slower substrate oxidation (HRP)[36] |
| 69 | P | P | minor | putative hydrophobic interaction between FA and anionic *Arabidopsis thaliana* peroxidase (ATP A2)[37] |
| 138 | I | I | minor | putative hydrophobic interaction with FA (ATP A2)[37] |
| 139 | P | P | major | H-bond to active site $H_2O$ which is H-bonded to FA (HRP)[35] |
| 140 | A | S | minor | Ala: tiny[b] and hydrophobic vs Ser: small[c] and polar; hydrophobic interaction with FA (HRP: $Ala^{140}$);[35] H-bond to MES[d] (RPTP)[14] |
| 142 | T | L | major | Thr: small[c] and hydrophobic vs Leu: large, hydrophobic, and aliphatic; hydrophobic interaction with FA (HRP)[35] |
| Distance within 4.6 Å of MES[d] | | | | |
| 68 | A | I | minor | Ile: large, hydrophobic, and aliphatic vs Ala: tiny[b] and hydrophobic; hydrophobic interaction with FA (HRP: $Gly^{68}$)[35] |
| 177 | F | S | major | Phe: large, hydrophobic, and aromatic vs Ser: small[c] and polar |
| 212−214 | STR | STR | major | structurally distinct region (HRP vs RPTP) and H-bond with MES[d] (RPTP: $Arg^{214}$)[14] |

[a]Position in the amino acid sequence (Figure 5). [b]Less than 35 $Å^3$. [c]Less than 60 $Å^3$. [d]2-(*N*-Morpholino)ethanesulfonic acid.

HRP, this loop region was pointing away from the active site, whereas in RPTP, it was pointing toward it. This difference in topology brought $Arg^{214}$ into hydrogen bonding distance with MES.[14] Further investigation into this distinct region is warranted.

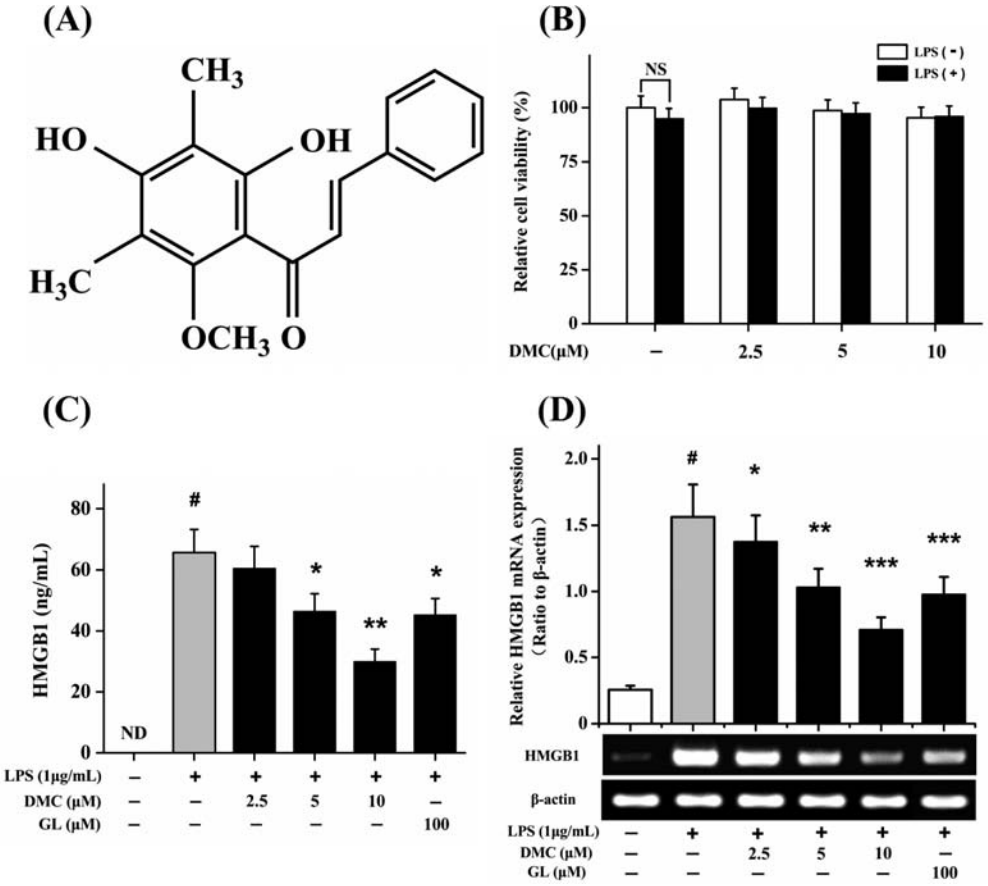

**Figure 1.** 2′,4′-Dihydroxy-6′-methoxy-3′,5′-dimethylchalcone (DMC) inhibits high-mobility group box 1 (HMGB1) secretion and transcription in lipopolysaccharide (LPS)-stimulated Kupffer cells. Kupffer cells were pretreated with or without the indicated concentrations of DMC or glycyrrhizin (GL) (100 $\mu$M) for 2 h before LPS (1 $\mu$g/mL) treatment for 24 h. Panel A shows the chemical structure of DMC. (B) CCK-8 assay data showed the concentrations of DMC in Kupffer cells. The data are expressed as percentage of surviving cells. (C) DMC dose-dependently decreased the LPS-stimulated HMGB1 secretion from Kupffer cells. Levels of HMGB1 were measured by ELISA. (D) RT-PCR was used to evaluate mRNA levels of HMGB1. $\beta$-Actin was used as a loading control. The bar graph showing semiquantitative densitometric analysis summarizes the fold change of HMGB1 expression in each group. Each value represents the mean ± SD of triplicate experiments. (#) $P < 0.001$ as compared with control group; (*) $P < 0.05$, (**) $P < 0.01$, and (***) $P < 0.001$ as compared with LPS-stimulated group only; NS, nonsignificant; ND, not detectable.

C (PKC), phospho-PKC, phospho-PKC$\alpha$, phospho-PKC$\beta$I, phospho-PKC$\beta$II, phospho-PKC$\gamma$, phosphoserine, $\beta$-actin, and histone H3.1 were obtained from Cell Signaling Technology (Danvers, MA, USA). Mouse anti-HMGB1 monoclonal antibody (mAb) and fluorescein-5-isothiocyanate (FITC) labeled anti-mouse immunoglobulin G (IgG) were purchased from Invitrogen (Carlsbad, CA, USA). Cell Counting Kit 8 (CCK-8) assay kit was purchased from Jiancheng Institute (NJ, China). HMGB1, tumor necrosis factor-alpha (TNF-$\alpha$), interleukin-1 beta (IL-1$\beta$), and interleukin-6 (IL-6) were respectively determined by using a double-antibody sandwich enzyme-linked immunosorbent assay (ELISA) kit from Jiancheng Institute. Alkaline phosphatase (AP) labeled anti-mouse IgG was purchased from Cell Signaling Technology.

**Primary Cell Isolation and Culture.** Kupffer cells were isolated from rat as described.[43] First, fresh cells were cultured in Roswell Park Memorial Institute 1640 (RPMI-1640) containing 2 mM glutamine, heat-inactivated fetal bovine serum (FBS, 10%), streptomycin, and penicillin. They were maintained in an incubator at 37 °C with an atmosphere of humidified 5% $CO_2$. Second, after 15 min of culture, nonadherent cells were removed and adherent cells were collected. Finally, Kupffer cell purity was >90% as evaluated by CD68 staining. The ability of phagocytosis with Kupffer cells was also examined.

**Cell Viability Assay and Stimulation.** The viability of the Kupffer cells was determined by the CCK-8 Counting Kit following the manufacturer's instructions. The cells were plated onto 96- and 6-well culture dishes. Cells cultured for 12 h were washed and replaced with fresh medium (RPMI-1640 medium containing 0.25% heat-inactivated FBS) with DMC (2.5, 5, and 10 $\mu$M) for 2 h before LPS (1 $\mu$g/mL) treatment for 24 h. Cell-free supernatants, protein, and RNA extracts were stored at −80 °C. Cells cultured in media alone acted as a negative control. Pretreatment with GL (100 $\mu$M) acted as the positive control in all tests.

**Measurement of Cytokines.** The cytokines including HMGB1, TNF-$\alpha$, IL-1$\beta$, and IL-6 were respectively evaluated by ELISA kits according to the manufacturer's instructions. NO assay was measured by Griess reagent.[44]

**Semiquantitative Reverse Transcription Polymerase Chain Reaction (RT-PCR).** Cell's total RNA extraction and cDNA synthesis were examined following the manufacturer's instructions (RT-PCR kit, Roche, Germany). The RT-PCR primer sequences for analysis of HMGB1, IL-6, IL-1$\beta$, inducible nitric oxide synthase (iNOS), TNF-$\alpha$, and $\beta$-actin expression were as follows: HMGB1, 5′-ATGGGCAAAGGAGATCCTAA-3′ and 5′-CTCTGTAGGCAGGAATATCC-3′; IL-6, 5′-GGATACCACCCACAACAGAC-3′ and 5′-TTGCCGAGTAGACCTCATAG-3′; IL-1$\beta$, 5′-TCATTGTGGCTGTGGAGAAG-3′ and 5′-CTATGTCCCGACCATTGCTG-3′; iNOS, 5′-GCATCCCAAGTACGAGTGGT-3′ and 5′-GAAGGCGTAGCTGAACAAGG-3′; TNF-$\alpha$, 5′-GTAGCCCACGTCGTAGCAAA-3′ and 5′-CCCTTCTCCAGCTGGAAGAC-3′; $\beta$-actin, 5′-TGCTGTCCCTGTATGCCTCT-3′ and 5′-TGATGTCACGCACGATTTCC-3′. The PCR products were resolved by electrophoresis and analyzed by staining ethidium bromide with ultraviolet light illumination. The band

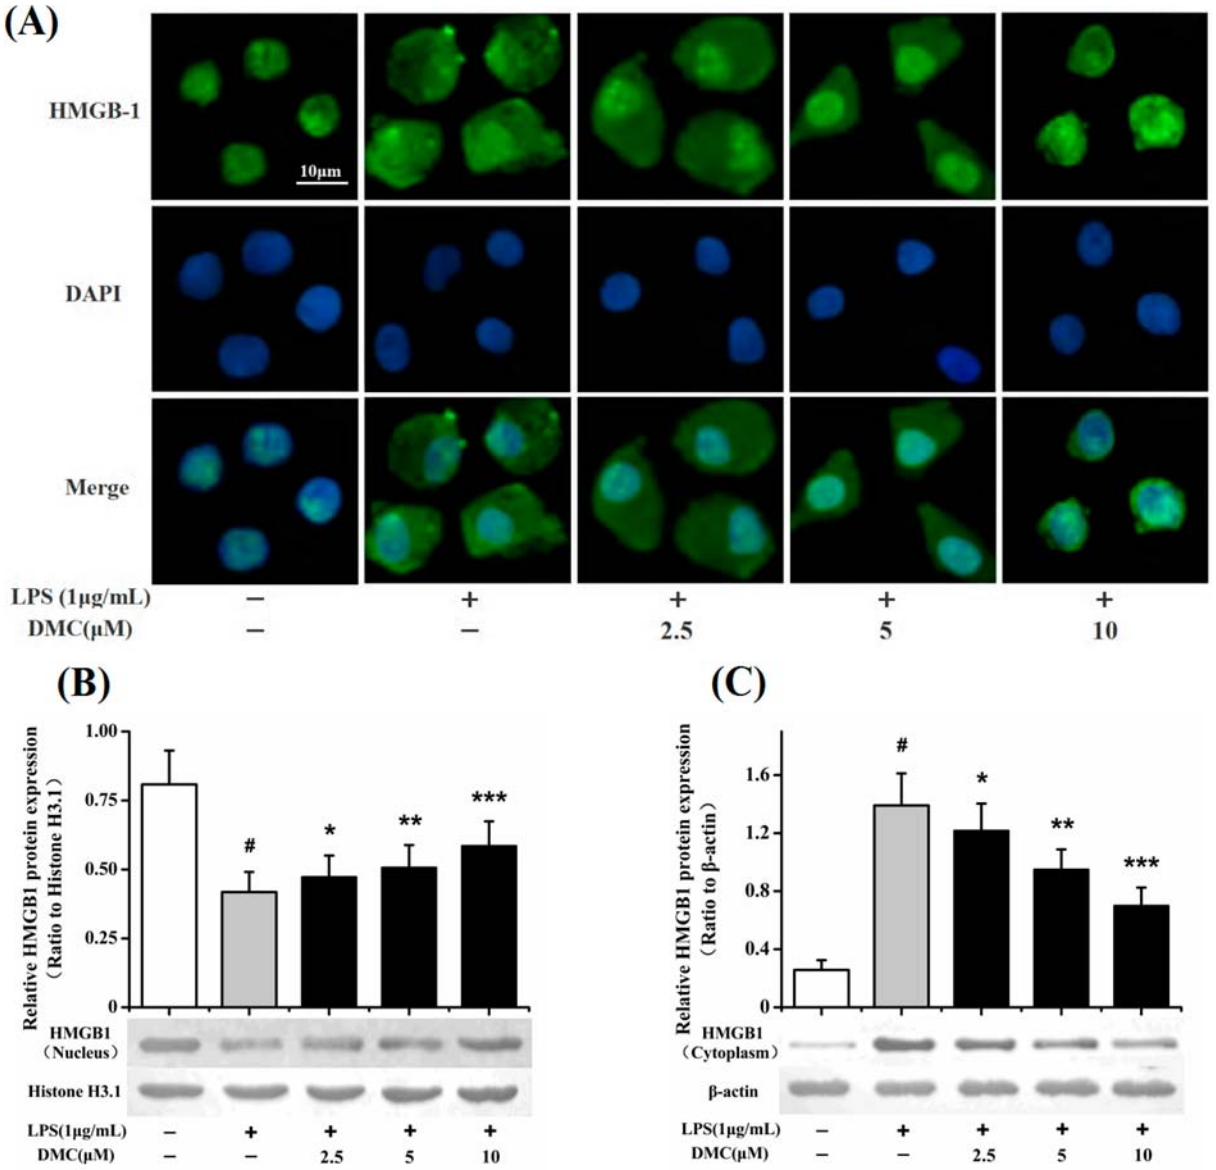

**Figure 2.** Inhibitory effect of DMC on nucleocytoplasmic translocation of HMGB1. Kupffer cells were pretreated with or without the indicated concentrations of DMC for 2 h before LPS (1 $\mu$g/mL) treatment for 24 h. HMGB1 nucleocytoplasmic translocation assay was measured by laser scanning confocal microscopy. Cell fractionation was evaluated by Western blotting. (A) HMGB1 was mostly distributed in the nuclear region of unstimulated group (first column). HMGB1 was localized in both nuclear and cytoplasmic regions of LPS-stimulated Kupffer cells (second column). The indicated concentrations of DMC treatment greatly inhibited LPS elicited intracellular HMGB1 movement (third to fifth columns). Nucleus (blue, DAPI staining), HMGB1 (green). Bar = 10 $\mu$m. The cytoplasmic and nuclear protein was extracted separately, and the level of HMGB1 was detected by Western blotting. (B) Nuclear HMGB1 protein, normalized by histone H3.1 protein. (C) Cytoplasmic HMGB1 protein, normalized by $\beta$-Actin protein. The bar graph showing semiquantitative densitometric analysis summarizes the fold change of HMGB1 expression in each group. Each value represents the mean ± SD of triplicate experiments. (#) $P < 0.001$ as compared with control group; (*) $P < 0.05$, (**) $P < 0.01$, and (***) $P < 0.001$ as compared with LPS-stimulated group only.

intensities were measured with a densitometer, and the results were normalized with $\beta$-actin.

**Immunofluorescence.** Kupffer cells were cultured in monolayers on glass coverslips. Cells were pretreated with the indicated concentrations of DMC for 2 h before LPS (1 $\mu$g/mL) treatment. The samples were fixed for 30 min with 4% formaldehyde. Cells were permeabilized for 15 min with 0.3% Triton X-100 and then blocked for 1 h with 2% bovine serum albumin. The samples were probed with anti-HMGB1. FITC-labeled IgG was used as secondary antibody. Finally, samples were stained for 15 min with DAPI. Fluorescence were analyzed by laser scanning confocal microscopy (Olympus Inc., Center Valley, PA, USA).

**Western Blot Analysis.** The samples were lysed with lysis buffer on ice for 30 min. For collection of nuclear and cytosolic proteins, protein extracts were respectively enriched according to the manufacturer's instructions (Cytoplasmic and Nuclear Extraction Kit, Roche, Germany). Protein samples were quantified by using an Enhanced BCA Protein Assay Kit (Beyotime, Jiangsu, China). The proteins were separated by SDS-PAGE and electroblotted to PVDF membranes (Millipore, Bedford, MA). Membranes were blocked with 5% nonfat milk and probed with primary antibodies (diluted at 1:1000) for HMGB1, PI3K, p-PI3K, PDK1, p-PDK1, p-PKC, p-PKC$\alpha$, p-PKC$\beta$I, p-PKC$\beta$II, p-PKC$\gamma$, $\beta$-actin, and histone H3.1 at 4 °C overnight. After three washings with PBS (0.1% Tween 20), the membranes were incubated with AP-labeled secondary antibody. Finally, membranes were stained for 10 min with BCIP/NBT. The relative band intensity was analyzed by a software Quantity

dx.doi.org/10.1021/jf504527r | J. Agric. Food Chem. 2014, 62, 11949−11956

One v4.62 (Bio-Rad, Inc., Berkeley, CA, USA) to quantify the protein levels.

**Co-immunoprecipitation.** Kupffer cells were pretreated with the indicated concentrations of DMC for 2 h before LPS treatment for 60 min. The nuclear extracts were harvested as described above. Nuclear extract (500 $\mu$g) was incubated with antiphosphoserine and anti-PKC onto protein G-Sepharose beads at 4 °C overnight. After three washings with lysis buffer and PBS, the precipitated complexes were solubilized by boiling in SDS buffer. Western blotting was performed using anti-HMGB1 antibody.

**Molecular Docking Calculations.** The crystal structures of the HMGB1 (entry 2GZK[45]) and the B box (entry 1hmf[46]) were from the RCSB Protein Data Bank. The three-dimensional structure of DMC was downloaded from the National Centre for Biotechnology Information PubChem. The interaction between B box and DMC was evaluated by AutoDock 4.2 (Scripps Research Institute, La Jolla, CA, USA). The interaction analysis was carried out by using Pymol 0.99 (DeLano Scientific LLC, Portland, OR, USA) and Ligplus v1.4.5 (EMBL-EBI, Cambridge, UK).

**Statistical Analysis.** Data were performed by using one-way ANOVA followed by Duncan's test. The results were expressed as the mean ± SD. Statistical difference of $P < 0.05$ was considered significant.

## RESULTS

**DMC Inhibits HMGB1 Secretion from Activated Liver Macrophage.** In our previous study, we have demonstrated that DMC had a potential hepatoprotective effect through preventing acute liver injury in mice.[20] In this work, to exclude cells' necrotic release of HMGB1, cytotoxic concentrations of DMC with LPS were evaluated by CCK-8 assay. As shown in Figure 1B, the indicated concentrations of DMC did not show cytotoxic effect, demonstrating that the release of HMGB1 was mostly from the active pathway. As shown in Figure 1C, LPS alone significantly ($P < 0.001$) stimulated HMGB1 release. DMC could dose-dependently reduce LPS-stimulated HMGB1 release. Pretreatment with DMC (5 $\mu$M) could be comparable to positive control group treated with GL (100 $\mu$M). The maximum inhibition was achieved at the DMC concentration of 10 $\mu$M ($P < 0.01$). In addition, treatment with DMC significantly ($P < 0.05$) inhibited the expression of HMGB1 mRNA (Figure 1D), the results were consistent with the changes of HMGB1 levels in the supernatant. These results demonstrated that the potential hepatoprotective effect of DMC might be related to the inhibition of HMGB1 release.

**DMC Inhibits LPS-Stimulated HMGB1 Release through Blocking Its Nucleocytoplasmic Translocation.** During normal conditions, HMGB1 was mainly distributed in the nuclear. LPS could visibly trigger the nucleocytoplasmic translocation of HMGB1 (Figure 2A). DMC could markedly inhibit HMGB1 nucleocytoplasmic translocation. Pretreatment of DMC (10 $\mu$M) almost completely blocked HMGB1 cytoplasmic translocation. To further investigate the above observations, cytoplasmic and nuclear fractions were respectively isolated and immunoblotted with mAb specific for HMGB1. The results of Western blot assay showed the ratio of nuclear (Figure 2B) to cytoplasm (Figure 2C) for HMGB1 protein expression levels. Pretreatment with DMC could not only significantly ($P < 0.05$) accumulate HMGB1 in cell nuclei but also markedly ($P < 0.05$) decrease HMGB1 in the cytoplasm. These data indicated that DMC could suppress HMGB1 nucleocytoplasmic translocation.

**DMC Modulates LPS-Elevated PI3K-PDK1-PKC$\alpha$ Signaling.** As shown in Figure 3A, LPS stimulation evoked obvious phosphorylation of PI3K ($P < 0.001$). Pretreatment

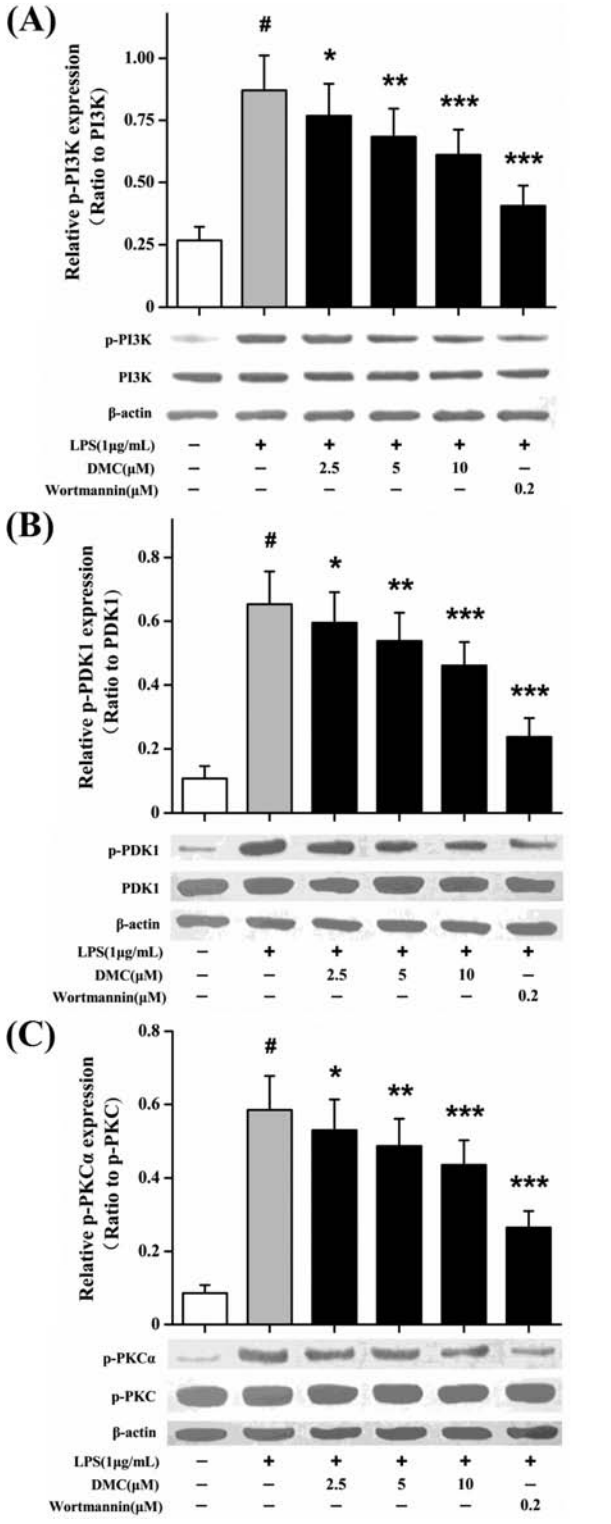

**Figure 3.** Effects of DMC on activation of the PI3K-PDK1-PKC$\alpha$ pathway in LPS-stimulated Kupffer cells. Kupffer cells were pretreated with or without the indicated concentrations of DMC for 2 h before LPS (1 $\mu$g/mL) treatment for 60 min. Phospho-PI3K (A), PDK1 (B), and PKC$\alpha$ (C) levels were measured by Western blotting. PI3K inhibitor wortmannin was used as a control. The bar graph showing semiquantitative densitometric analysis summarizes the fold change of total PI3K, PDK1, and p-PKC expression in each group. Each value represents the mean ± SD of triplicate experiments. (#) $P < 0.001$ as compared with control group; (*) $P < 0.05$, (**) $P < 0.01$, and (***) $P < 0.001$ as compared with the LPS-stimulated group only.

with DMC decreased dose-dependently the LPS-stimulated PI3K phosphorylation. Maximum inhibition was achieved at the DMC concentration of 10 $\mu$M ($P < 0.001$). To further explore the effect of DMC on PI3K-related pathway, we investigated the influence of DMC on PDK1 phosphorylation. Consistently, PDK1 phosphorylation was significantly ($P < 0.05$) inhibited by DMC in LPS-stimulated cells in a dose-dependent manner, and maximum inhibition was achieved at the DMC concentration of 10 $\mu$M ($P < 0.001$) (Figure 3B). It was interesting to note that DMC could dose-dependently reduce the LPS-stimulated phosphorylation of PKC$\alpha$ ($P < 0.001$) (Figure 3C), but not of p-PKC$\beta$I, p-PKC$\beta$II, and p-PKC$\gamma$ (data not shown). These results demonstrated that DMC could modulate the PI3K-PDK1-PKC$\alpha$ signaling pathway, and PKC$\alpha$ played a role in this pathway but had no apparent effect on all conventional PKC (cPKCs: $\alpha$, $\beta$, and $\gamma$).

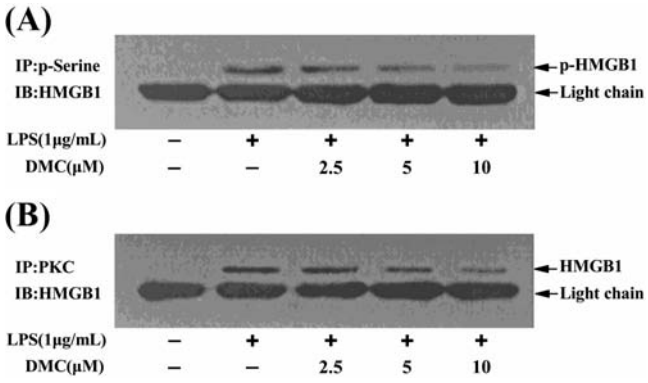

**Figure 4.** Inhibition of HMGB1 phosphorylation by DMC. Kupffer cells were pretreated with or without the indicated concentrations of DMC for 2 h before LPS (1 $\mu$g/mL) treatment for 60 min. The nuclear extracts were harvested. (A) HMGB1 phosphorylation was measured in LPS-stimulated Kupffer cells through immunoprecipitation-linked immunoblotting. Nuclear extracts were immunoprecipitated with antiphosphoserine antibody and then immunoblotted with anti-HMGB1 antibody. (B) The interaction between HMGB1 and PKC was measured in LPS-stimulated Kupffer cells through immunoprecipitation-linked immunoblotting. Nuclear extracts were immunoprecipitated with anti-PKC antibody, then immunoblotted with anti-HMGB1 antibody.

**DMC Blocks HMGB1 Nucleocytoplasmic Translocation through Suppressing HMGB1 Phosphorylation.** Several papers have suggested that HMGB1 phosphorylation and acetylation play a critical role in its nucleocytoplasmic translocation. During LPS stimulation, HMGB1 phosphorylation and acetylation localize to serine and lysine residues, respectively.[47] Therefore, we further investigated how DMC inhibited HMGB1 secretion. As shown in Figure 4A, various concentrations of DMC treatment markedly suppressed the phosphorylation of HMGB1, but not the acetylation (data not shown). Pretreatment of DMC (10 $\mu$M) almost completely blocked HMGB1 phosphorylation. Furthermore, DMC (10 $\mu$M) markedly inhibited the interaction between PKC and HMGB1 (Figure 4B). These results suggested that DMC directly suppressed HMGB1 phosphorylation through hampering the interaction between PKC and HMGB1.

**Modeling of DMC Interaction with B Box of HMGB1.** The detailed interaction between DMC and HMGB1 was analyzed by molecular modeling tools. Interestingly, the molecular modeling results revealed that the binding site was only localized to the B box of HMGB1. Specifically, this binding site localized to the L-shape fold (Figure 5A), which exhibited van der Waals with the hydrophobic side chains of Ala88, Pro89, Pro92, Pro93, Ala95, Phe96, and Phe97 (Figure 5B). Furthermore, DMC formed four hydrogen bonds with Lys90,

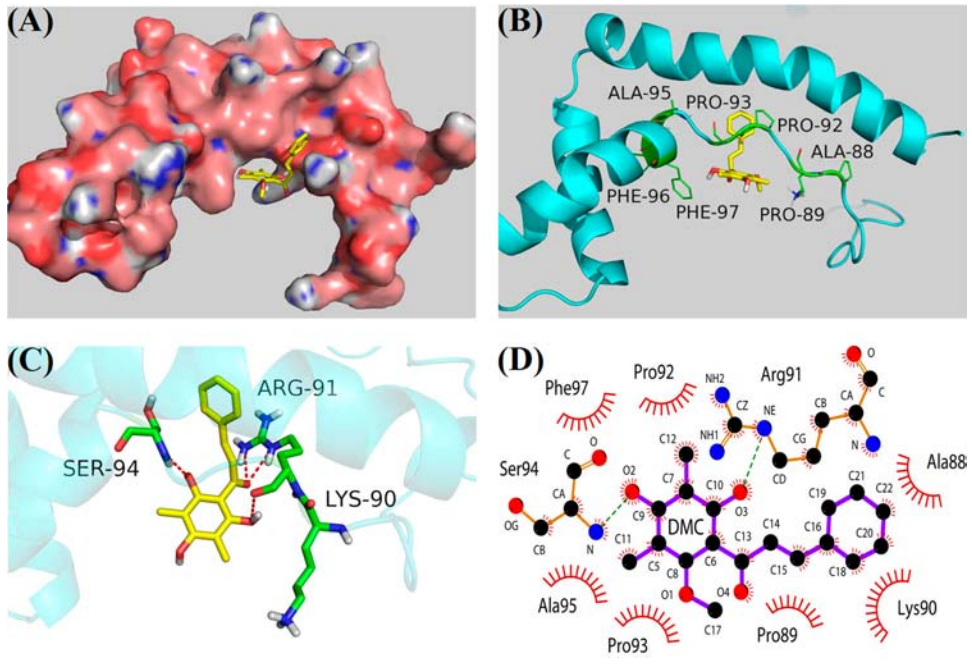

**Figure 5.** Predicted binding modes of DMC in the active site of the B box. (A) DMC was accommodated at the L-shape fold. (B) DMC exhibited favorable van der Waals with the hydrophobic side chains of Ala88, Pro89, Pro92, Pro93, Ala95, Phe96, and Phe97 (green). (C) DMC formed hydrogen bonds with Lys90, Arg91, and Ser94, respectively. The hydrogen bonds are depicted using a red dashed line. Panel D shows the hydrophobic interactions and hydrogen bonds for DMC binding with B box. The residues and DMC involved in hydrophobic interactions are highlighted using spoked arcs and spokes, respectively. The hydrogen bonds are depicted using a green dashed line.

dx.doi.org/10.1021/jf504527r | J. Agric. Food Chem. 2014, 62, 11949−11956

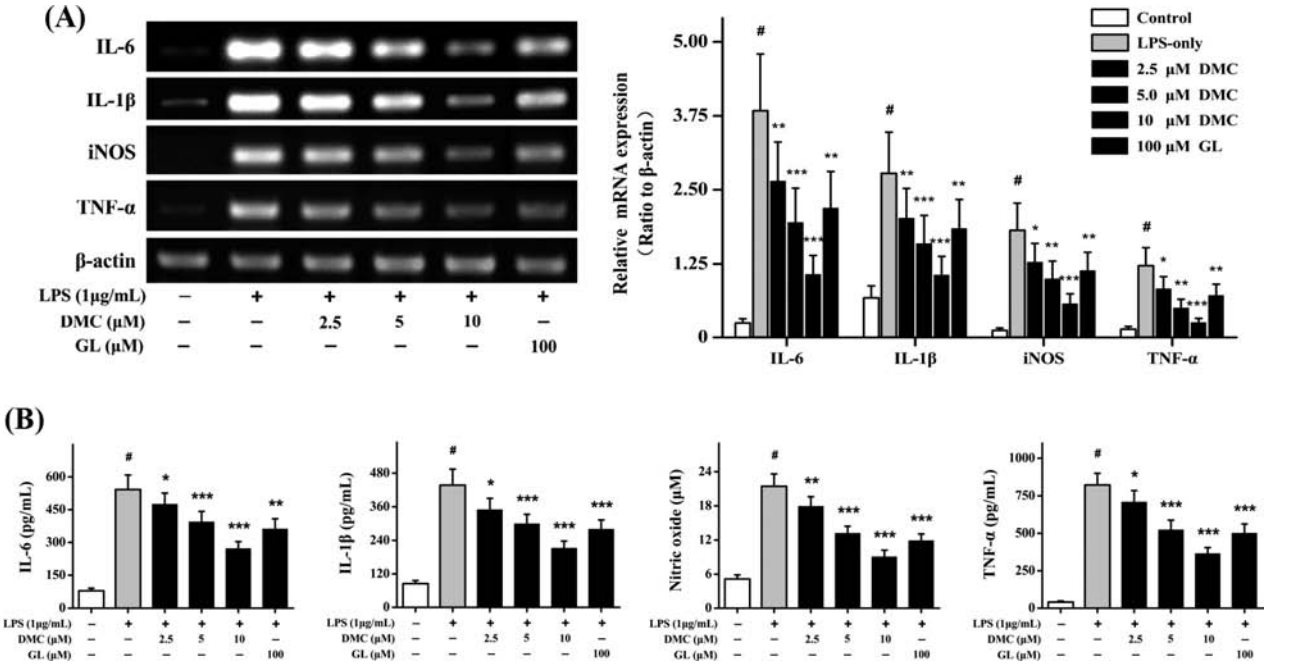

**Figure 6.** Effects of DMC on the expression of HMGB1-dependent inflammatory cytokines in LPS-stimulated Kupffer cells. (A) Representative blots show the effects of DMC with or without LPS treatment on mRNA expression levels of pro-inflammatory IL-6, IL-1$\beta$, iNOS, and TNF-$\alpha$. Similar treatment with GL (100 $\mu$M) was taken as positive control. $\beta$-Actin was used as a loading control. The bar graph showing semiquantitative densitometric analysis summarizes the fold changed of IL-6, IL-1$\beta$, iNOS, and TNF-$\alpha$ expression in each group. (B) DMC dose-dependently decreased the LPS-stimulated IL-6, IL-1$\beta$, NO, and TNF-$\alpha$ release from Kupffer cells. Levels of IL-6, IL-1$\beta$, and TNF-$\alpha$ were measured by ELISA. NO assay was measured by Griess reagent. Each value represents the mean ± SD of triplicate experiments. (#) $P < 0.001$ as compared with control group; (*) $P < 0.05$, (**) $P < 0.01$, and (***) $P < 0.001$ as compared with the LPS-stimulated group only.

Arg91, and Ser94, respectively (Figure 5C). The binding cavity was mainly formed by hydrophobic residues Ala88, Pro89, Lys90, Pro92, Pro93, Ala95, and Phe97 (Figure 5D). From the molecular modeling study, it could be speculated that DMC possessed the direct binding force to the B box of HMGB1.

**DMC Inhibits HMGB1-Dependent Inflammatory Molecule Expression.** The expression of mRNA was measured by RT-PCR. As shown in Figure 6A, LPS stimulation significantly ($P < 0.001$) up-regulated the mRNA expression of iNOS, IL-6, TNF-$\alpha$, and IL-1$\beta$ compared with the negative control group. Various concentrations of DMC treatment significantly ($P < 0.05$) reduced their expression in a dose-dependent manner. Pretreatment with DMC (5 $\mu$M) was found to be comparable to the positive group treated with GL (100 $\mu$M). Maximum inhibition was achieved at the DMC concentration of 10 $\mu$M ($P < 0.001$). Furthermore, DMC significantly decreased the levels of NO, IL-6, TNF-$\alpha$, and IL-1$\beta$ (Figure 6B), and the trends were consistent with the changes of mRNA expression. These data demonstrated that DMC could suppress HMGB1-dependent inflammatory molecule expression.

## DISCUSSION

In our previous study, we have demonstrated that DMC had a potential hepatoprotective effect through preventing acute liver injury in mice and the amelioration of inflammatory cells infiltration in the liver.[20] However, the anti-inflammatory activity of DMC and the underlying molecular mechanisms were still unclear. Thus, we further explored the direct correlation between HMGB1 and DMC and found that DMC suppressed both HMGB1 secretion and its pro-inflammatory activity.

The development of hepatic diseases is usually accompanied by inflammation. Upon inflammatory stimuli, HMGB1 would be rapidly and actively released by Kupffer cells (the resident macrophages of the liver) in response to pro-inflammatory cytokines.[11−14] During hepatic inflammation, activated HMGB1 promoted nucleocytoplasmic translocation. DMC could suppress both HMGB1 molecule expression and its nucleocytoplasmic translocation, suggesting that DMC might act as an inhibitor of HMGB1 secretion.

The underlying molecular mechanisms of how DMC down-regulated the expression of HMGB1 are still unknown. Some papers have suggested that secretion of HMGB1 was associated with the PI3K-PDK1-cPKC signal pathway.[48,49] The results showed that the phosphorylation of PI3K and PDK1 was significantly blocked by DMC. Interestingly, DMC dose-dependently blocked the phosphorylation of PKC$\alpha$, but not of p-PKC$\beta$I, p-PKC$\beta$II, and p-PKC$\gamma$ (data not shown). Therefore, it is possible that DMC could modulate the PI3K-PDK1-PKC$\alpha$ signaling pathway.

It has been reported that the important phosphorylation binding sites on HMGB1 localize to serine residues. In addition, PKC has been reported to be involved in HMGB1 phosphorylation.[47−49] DMC could directly suppress HMGB1 phosphorylation through hampering the interaction between PKC and HMGB1. Furthermore, some researchers have reported that the first 20 amino acid residues of B box are considered a potential pro-inflammatory agent.[15,16] According to molecular modeling results, it is possible that DMC has direct binding force to the B box of HMGB1. The direct binding between DMC and HMGB1 might map to a 10 residue fragment of the full-length protein (HMGB1 residues 88−97), reflecting the important role in blocking HMGB1 pro-inflammatory

activity. It is suggested that DMC could serve as a promising HMGB1 inhibitor.

HMGB1 not only is regarded as an inflammatory mediator but also mediates gene transcription.[11,12] Emerging evidence had suggested that HMGB1 might be an inflammatory inducer or booster in the progression of inflammation.[13,14] The late mediators (such as HMGB1) may promote the expression of early pro-inflammatory cytokines including iNOS, IL-6, TNF-$\alpha$, IL-1$\beta$, and so on.[50] DMC could decrease the production of NO, IL-6, TNF-$\alpha$, and IL-1$\beta$. Therefore, DMC exerts preventive effects on hepatitis through decreasing the production of pro-inflammatory factors.

In conclusion, the present study demonstrates that DMC is a promising HMGB1 inhibitor that exhibits a duplicate role in inhibiting both HMGB1 secretion and its pro-inflammatory activity, mostly related to (1) DMC markedly inhibiting the nucleocytoplasmic translocation and secretion of HMGB1, (2) DMC modulating the PI3K-PDK1-PKC$\alpha$ signaling pathway, (3) DMC hampering the interaction between PKC and HMGB1, (4) DMC possessing direct binding force to the B box of HMGB1, and (5) DMC suppressing HMGB1-dependent inflammatory molecule expression.

extracts enriched in phenolic antioxidants have also been broadly examined. It was reported, for instance, that *Curcuma longa* extract, besides acting as antioxidant, significantly increased anti-inflammatory cytokine IL-4 production and reduced A$\beta$ and tau levels in A$\beta$-overexpressing mice.[13] *Ginkgo biloba* extracts showed significant neuroprotective effects in murine models and improved cognitive function in AD patients.[14] Aqueous garlic extracts showed antiamyloidogenic properties inhibiting A$\beta$ fibril formation and also defibrillating A$\beta$ preformed fibrils.[15] In recent times, we have demonstrated the ability of a phenol-rich extracts from *Laurus nobilis* leaves to promote a dose-dependent regression of the formation of A$\beta$ oligomers in neuronal SH-SY5Y and SK-N-BE(2)C cell lines, pretreated in the previous 24 h with the A$\beta$(25−35) neurotoxic fragment, expounding a promising neuroprotective effect.[16]

In this context, the neuroprotective capability of an alcoholic extract from *Pistacia lentiscus* leaves (P*l*-M) was of interest. *Pistacia lentiscus* L., commonly known as mastic tree or lentisk, is an aromatic bush indigenous to Italy and other Mediterranean and Middle East countries. The plant, belonging to the Anacardiaceae family, is a dioecious species with red flowers and fruits, whose resin (Chios mastic gum), rich in terpene molecules, found extensive use in folk medicine for their antibacterial, antiasthmatic, hepatoprotective, sedative, anti-inflammatory, and antitumor activities.[17] *Pistacia lentiscus* essential oil was showed to exert beneficial effect in cerebral hyperfusion/reperfusion for preventing early neuroinflammatory events. The chemical composition of alcoholic *Pistacia lentiscus* leaf extracts was also investigated.[18,19] In particular, a comprehensive characterization of a methanol extract from *P. lentiscus* leaves, collected in Algeria, was recently reported:[20] As geographical and climatic conditions have remarkable influence in the plant phenol production, the LC-ESI-MS/MS analysis of a polyphenol leaf extract (P*l*-M) from *P. lentiscus* plants collected in Southern Italy was carried out. To this purpose, leaves were previously deprived of their apolar constituents through maceration in $CHCl_3$. In order to hypothesize the setting up of an antioxidant preparation with important effects in counteracting invalidating neurodegenerations as Alzheimer's disease, P*l*-M antioxidant and antiamyloidogenic effectiveness was evaluated.

## MATERIALS AND METHODS

**Reagents and Chemicals.** All of the solvents and reagents used for assessing antioxidant screening were purchased from Sigma-Aldrich Chemie (Buchs, Switzerland) except ABTS [2,2′-azinobis(3-ethylbenzothiazolin-6-sulfonic acid)], which was from Roche Diagnostics (Roche Diagnostics, Mannheim, Germany). Cell culture media and reagents for cytotoxicity testing were purchased from Invitrogen (Paisley, U.K.), MTT [3-(4,5-dimethyl-2-thiazolyl)-2,5-diphenyl-2H-tetrazolium bromide], SRB (sulforhodamine B), INT [(2-(4-iodophenyl)-3-(4-nitrophenyl)-5-phenyl-2H-tetrazolium chloride)], A$\beta$ 25−35 fragment, phenazine methosulfate, and lactic acid were from Sigma-Aldrich Chemie.

**Plant Collection and Fractionation.** Leaves from *Pistacia lentiscus* L. collected in May 2011 in Caserta (Italy) were identified by Dr. Assunta Esposito of the Second University of Naples. A voucher specimen has been deposited at the Herbarium of the Department of Environmental, Biological, and Pharmaceutical Sciences and Technologies of the Second University of Naples. These were dried in a thermo-ventilated oven at 40 °C for 7 days, powdered in a mill and extracted by sonication (Dr. Hielscher UP 200S) for 1 h, using $CHCl_3$ as extracting solvent. Then, the samples were centrifuged at 2044*g* for 10 min in a Beckman GS-15R centrifuge (Beckman Coulter, Milano, Italy) fitted with rotor S4180. The deterpenated and dried plant material underwent four sonication cycles (each sonication cycle was 40 min) using MeOH as extracting solvent. The supernatant was dried under vacuum to yield a crude extract (24.4 g, P*l*-M).

**RP-HPLC-ESI-MS/MS Analyses.** The chromatographic analyses were carried out using an HPLC Agilent 1200 system (Agilent Technologies Inc., Palo Alto, CA, U.S.A.), provided of binary pump, *microvacuum* degasser, and autosampler. The chromatographic separation was carried using the reverse phase column (Luna $C_{18}$, 5.0 $\mu$m, 250 × 4.6 mm id, Phenomenex) and as a mobile phase a mixture of A ($H_2O/CH_3COOH$, 975:25) and B (MeOH). The following gradient was applied: a linear gradient from 5% to 40% of B in 10 min, a linear gradient from 40% to 51% of B in 20 min, a linear gradient from 51% to 68% of B in 4 min, a linear gradient from 68% to 95% of B in 3 min, a linear gradient from 95% to 100% of B in 4 min, an isocratic elution for 5 min at 100% of B and a last linear gradient from 100% to 5% of B in 5 min. The flow was set at 0.4 mL/min. The P*l*-M injection volume (1.0 mg/mL) was of 10 $\mu$L. The LC system was coupled to the mass spectrometer API QTRAP 2000 (Applied Biosystem). The ESI mass spectra were recorded in negative mode. The HPLC eluates *full scan* MS mass spectra were acquired in the mass range 50−1000 *m*/*z* in *electrospray* mode with negative ions $[M-H]^-$. In order to obtain more structural information, MS/MS experiments (mass range: 20-value *m*/*z* of the parental ion) were performed.

**Assessment of the Antiradical Capacity.** Three methods were used to assess the ability of the extract of being *chain breaker*, which means free radicals' inactivating. MeOH extract, previously dissolved in DMSO as stock solutions of 125.0 mg/mL, was evaluated at different concentration levels (DMSO final concentration was equal to 0.1% (v/v)). Tests were carried out performing three replicate measurements for three samples ($n$ = 3) of the extract (in total, 3 × 3 measurements). Recorded activities were compared to a blank. Results are the mean ± SD values. Student *t*-test was applied in order to determine statistical significance (significance level was set at $P < 0.05$).[21,22]

**Determination of 2,2-Diphenyl-1-picrylhydrazyl (DPPH) Radical Scavenging Capacity.** In order to estimate the DPPH$^\bullet$ (2,2-diphenyl-1-picrylhydrazyl) scavenging capability, *P. lentiscus* leaf extract (2.5, 5.0, 10.0, 25.0, 50.0, and 100.0 $\mu$g/mL, final concentration levels) was dissolved in a DPPH$^\bullet$ methanol solution ($9.4 \times 10^{-5}$ M; 1.0 mL) at room temperature. After 10 min, when the reaction has gone to completion, the absorption at 515 nm was measured by a Shimadzu UV-1700 spectrophotometer in reference to a blank. The results were expressed in terms of the percentage decrease of the initial DPPH$^\bullet$ radical absorption by the test samples.

**Determination of ABTS$^{\bullet+}$ Scavenging Capacity.** The determination of ABTS$^{\bullet+}$ ([2,2′-azinobis(3-ethylbenzothiazolin-6-sulfonic acid)] radical cation) solution scavenging capacity was estimated as previously reported. ABTS radical cation was generated by reacting ABTS (7.0 mM) and $K_2S_2O_8$ (2.45 mM). The mixture was allowed to stand in the dark at room temperature for 12h. Thus, the ABTS$^{\bullet+}$ solution was diluted with PBS (pH 7.4) in order to reach an absorbance of 0.70 at 734 nm. P*l*-M extract (2.5, 5.0, 10.0, 25.0, 50.0, and 100.0 $\mu$g/mL, final concentration levels) was dissolved in 1.0 mL of diluted ABTS$^{\bullet+}$ solution. After 6 min of incubation, the absorption at 734 nm was measured by a Shimadzu UV-1700 spectrophotometer in reference to a blank. The results were expressed in terms of the percentage decrease of the initial ABTS$^{\bullet+}$ absorption by the test samples.

**Determination of Oxygen Radical Absorbance Capacity (ORAC).** The ORAC assay was performed as follows: P*l*-M extract (20 $\mu$L; 1.0, 2.5, and 5.0 $\mu$g/mL, final concentration levels) and fluorescein (FL, 120.0 $\mu$L; 70 nM, final concentration) were preincubated for 15 min at 37 °C in 75 mM phosphate buffer (pH 7.4). Then 2,2′-azobis(2-amidinopropane)-dihydrochloride (AAPH) solution (60.0 $\mu$L; 12 mM, final concentration) was rapidly added. In parallel with the test samples, a blank (FL + AAPH) and solutions of the reference antioxidant Trolox (1−8 $\mu$M, final concentration levels) were properly prepared in PBS. The fluorescence decay ($\lambda_{ex}$ = 485 nm, $\lambda_{em}$ = 525 nm) was recorded every minute for 120 min using a Tecan

**Table 1. Main Constituents of the Alcoholic Extract from *Pistacia lentiscus* L. Leaves Detected by LC-ESI-MS/MS in Negative Ionization Mode**

SpectraFluor fluorescence and absorbance reader. Antioxidant curves (fluorescence vs time) were normalized to the curve of the blank. From the normalized curves, the area under the fluorescence decay curve (AUC) was calculated. Linear regression equations between net AUC ($AUC_{antioxidant}-AUC_{blank}$) and antioxidant concentration were calculated for all the samples. The antioxidant activity (ORAC value) was calculated by using the Trolox calibration curve. The ORAC values were expressed as Trolox equivalents ($\mu$M).

**Cytotoxicity Assessment.** Cytotoxicity assays that use different parameters associated with cell death and proliferation were performed. P*l*-M extract was prepared as a stock solutions of 125.0 mg/mL in DMSO and further diluted in cell culture medium to appropriate final dose levels (DMSO final concentration was equal to 0.1% (v/v)). Tests were carried out performing 12 replicate ($n$ = 12) measurements for three samples of each extract (in total: 12 × 3 measurements). Recorded activities were compared to an untreated blank arranged in parallel to the samples. Results are the mean ± SD values. Student $t$-test was applied in order to verify statistical significance (significance level was set at $P < 0.05$).[21,22]

**Cell Cultures.** Rat C6 glioma cell line and human SH-SY5Y neuroblastoma cells were purchased from ATCC (American Type Culture Collection); SK-N-BE(2)-C human bone marrow neuroblastoma cells were purchased from ICLC (Interlab Cell Line Collection) at Istituto Nazionale per la Ricerca sul Cancro, Genoa (Italy). Rat C6 and SH-SY5Y cell lines were grown in DMEM high glucose medium while SK-N-BE(2)-C cell line in RPMI 1640. All the culture media were supplemented with 10% fetal bovine serum, 50.0 U/mL penicillin, and 100.0 $\mu$g/mL streptomycin. The cells were cultured at 37 °C in a humidified atmosphere containing 5% $CO_2$. The cell count, for each assay, was carried out using Countess Automated Cell Counter (Invitrogen).

**MTT Cell Viability Test.** The MTT is a colorimetric assay which values the activity of the mitochondrial dehydrogenase to reduce the tetrazolium ring of 3-(4,5-dimethyl-2-thiazolyl)-2,5-diphenyl-2H-tetrazolium bromide (MTT), yellow colored, generating a chromogenic compound, which is formazan. C6, SH-SY5Y, and SK-N-BE(2)-C cell lines were seeded in 96-multiwell plates at a density of $1.0 \times 10^4$ cells/well. After 24 h of incubation, cells were treated with P*l*-M at five dose levels (2.5, 10.0, 25.0, 50.0, and 100.0 $\mu$g/mL). At 24, 48, and 72 h of incubation, cells were treated with 150 $\mu$L of MTT (0.50 mg/mL), dissolved in the culture medium, for 1 h at 37 °C in a 5% $CO_2$ humidified atmosphere. The MTT solution was then removed and 100 $\mu$L of DMSO were added to dissolve the formazan originated. Finally, the absorbance at 570 nm of each well was determined using a Tecan Spectra Fluor fluorescence and absorbance reader. The results were expressed as percentage of mitochondrial redox activity of the cells treated with the extracts compared to the untreated control.

**SRB Cell Viability Test.** C6, SH-SY5Y, and SK-N-BE(2)-C cell lines were seeded in 96-multiwell plates at a density of $1.0 \times 10^4$ cells/well. After 24 h of incubation, cells were treated with P*l*-M at five dose

levels (2.5, 10.0, 25.0, 50.0, and 100.0 μg/mL). At 24, 48, and 72 h of incubation, cells were fixed with ice-cold TCA (10% w/v, 40 μL) for 1 h at 4 °C. The plates were washed five times in distilled water and allowed to dry. Then, 50 μL of sulforhodamine B (SBR, 0.4% w/v in 1% aqueous *acetic acid*) solution was added to each well of the dried 96-well plates and incubated at room temperature for 30 min. In order to remove unbound dye, the plates were quickly washed with 1% aqueous acetic acid and dried subsequently. The bound SRB was solubilized by adding 100 μL of 10 mM unbuffered Tris Base (pH 10.5) to each well and shaking for 5 min on a shaker platform. Finally, the absorbance at 570 nm of each well was measured using a Tecan SpectraFluor fluorescence and absorbance reader.

**Lactate Dehydrogenase (LDH) Leakage Assay.** The lactate dehydrogenase (LDH) leakage assay is a colorimetric assay for the quantification of cell death and cell lysis based on the measurement of LDH released into the supernatant from the cytosol of damaged cells. The oxidation reaction (LDH oxidizes lactate to pyruvate and converts $NAD^+$ to NADH) catalyzed by this enzyme produces NADH that is reacted in vitro with a tatrazolium salt 2-(4-iodophenyl)-3-(4-nitrophenyl)-5-phenyltetrazolium chloride (INT), yellow colored to generate a formazan salt purple/red colored; this coloration can be measured using a spectrophotometer. C6, SH-SY5Y, and SK-N-BE(2)-C cell lines were seeded in 24-multiwell plates at a density of $4.0 \times 10^4$ cells/well. Twenty-four hours after seeding, the cells were treated P*l*-M extract (100.0 μg/mL). After the exposure times of 24 h, 48 h, and 72 h, the supernatant (100 μL) was treated with 100 μL of the reaction mixture (0.7 mM INT; 54.0 mM lactic acid; 0.3 mM phenazine methosulfate; 0.8 mM $NAD^+$ in 0.2 M Tris-HCl pH 8.0) in a 96-wells plate. The reaction was carried out for 45 min in the dark under gentle stirring at 37 °C and stopped by addition of 1 M HCl (50 μL). The absorbance was red at 492 nm by a Tecan SpectraFluor fluorescence and absorbance reader. Data obtained were expressed in reference to a blank prepared using a Triton X-100 (1%) solution. The increase in the amount of formazan detected in culture supernatant reflects the membrane integrity and directly correlates to the increase in the number of lysed cells. Hence, cell vitality is inversely proportional to the LDH released.

**Determination of Cytoprotective Effect in Oxidized Cell Systems.** SK-N-BE(2)-C cell line was seeded in 96-multiwell plates at a density of $1.0 \times 10^4$ cells/well. After 24 h of incubation, cells were cotreated with P*l*-M extract (25.0, 50.0, and 100.0 μg/mL, final concentration levels) and $H_2O_2$ (400 μM) or A$\beta$(25−35) peptide domain (100 μM) for 24 h. After the treatment period, cell viability inhibition (CV) was assessed by MTT assay.[16]

## RESULTS AND DISCUSSION

The diverse array of bioactive nutrients present in plant natural products plays a pivotal role in prevention and cure of various neurodegenerative diseases, such as Alzheimer's disease (AD). Accumulated evidence suggests that naturally occurring phytocompounds, such as polyphenolic antioxidants may potentially hinder neurodegeneration, and improve memory and cognitive function.[23]

In order to investigate the neuroprotective potential of Mediterranean medicinal plants, *Pistacia lentiscus* was of interest. Leaf plant drug was analyzed for its antioxidant and cytoprotective effectiveness, whereas its chemical composition was characterized by means of a LC-MS/MS approach.

**LC-MS/MS Metabolic Profiling of the Alcoholic Extract from *Pistacia lentiscus* L. Leaves.** LC-ESI-MS/MS techniques allowed us to obtain qualitative information about the biochemical constitution of P*l*-M extract. Forty-six main secondary metabolites were tentatively identified by means of LC-MS/MS data (Table 1). Among them ten compounds (**6**, **11**, **17**−**19**, **27**, **31**, **36**, **40**, **41**) were tentatively characterized for the first time in *Pistacia lentiscus* leaves.

Compound **1** was identified on the basis of its mass spectrum, as shikimic acid.[24] A $[M\text{-}H]^-$ pseudomolecular ion at $m/z$ 173 and the corresponding dimeric deprotonated ion $[2M\text{-}H]^-$ a $m/z$ 347 were detectable. The selection of the $[M\text{-}H]^-$ precursor ion and the subsequent dissociation ($MS^2$ experiment) generated a fragment ion at $m/z$ 155, due to the loss of a water molecule, probably including the hydroxyl function at C-5. A second fragment ion at $m/z$ 111 was putatively attributed to the ion $[M\text{-}H\text{-}CO_2\text{-}H_2O]^-$.

Compound **2** was characterized as quinic acid on the basis of its fragmentation pattern. In fact, the collision activated decomposition of the deprotonated molecule at $m/z$ 191, beside the ion at $m/z$ 173 (- $H_2O$), led to the formation of the fragment ion at $m/z$ 127, corresponding to the loss of CO and of two water molecules.[25] Metabolites **12**−**14** and **16** are quinic acid derivatives, and in particular they were identified as galloyl-quinic acid isomers, showing a deprotonated pseudomolecular ion at $m/z$ 343, which in turn generated product ions at $m/z$ 191 and 169, following the neutral loss of a quinic acid residue and a gallic acid moiety, respectively. The discrimination between the four isomers was performed on the basis of their relative retention times and according to the data previously reported.[26] The P*l*-M extract also contained four peaks characterized by a pseudomolecular deprotonated ion at $m/z$ 495 (compounds **20**-**23**). The fragmentation of the $[M\text{−}H]^-$ ion at $m/z$ 495 provided the fragments at $m/z$ 343 ($[M\text{-}H\text{-}152]^-$) and $m/z$ 191 ($[M\text{-}H\text{-}304]^-$) corresponding to the loss of one and two galloyl moieties, respectively. The fragment at $m/z$ 169 was attributed to gallic acid anion. On the basis of these experimental evidence they were identified as isomers of digalloyl quinic acid, recently identified in *P. lentiscus* leaves.[20]

Metabolites **3**−**5**, **7**, **8** exibited the same pseudomolecolar deprotonated ion at $m/z$ 331. On the basis of the data arising from $MS^2$ experiments, compared with those present in literature,[27] the compounds were tentatively identified as hexoside isomers of gallic acid. In fact, the collision activated decomposition of the precursor ions at $m/z$ 331 led to the formation of product ions consistent with this hypothesis, namely the fragment ions at $m/z$ 271 ($[M\text{-}H\text{-}60]^-$), 241 ($[M\text{-}H\text{-}90]^-$), and 211 ($[M\text{-}H\text{-}120]^-$), due to the cross-ring fragmentation of the hexose moiety. Furthermore, the product ion at $m/z$ 169 ($[M\text{-}H\text{-}C_6H_{10}O_5]^-$) could be due to the neutral loss of the hexose residue, and could consequently be ascribed to the deprotonated gallic acid, which in turn lost a 44 Da moiety (likely $CO_2$) to give the ion at $m/z$ 125.

Compound **6** exhibited a pseudomolecular deprotonated ion at $m/z$ 609. The $MS^2$ spectrum showed characteristic fragment ions that allowed us to identify the molecule as the proanthocyanidin prodelphinidin B-4, a dimer of gallocatechin and epigallocathechin.[28] In fact, beside the ion at $m/z$ 305, due to the loss of one monomer ($[M\text{-}H\text{-}304]^-$), the ions at $m/z$ 441 and 423 could be formed following a retro Diels−Alder fragmentation mechanism involving the C ring (cleavage of O1−C2 and C3−C4 bonds) and subsequent water loss.

Metabolite **9**, characterized by a $[M\text{-}H]^-$ pseudomolecular ion at $m/z$ 315, was tentatively identified as gentisic acid hexoside.[20] The product ions deriving from MS/MS experiments were detected at $m/z$ 255, 225, 195, corresponding to cross-ring cleavage of the sugar moiety (−60, −90, and −120 Da, respectively), and at $m/z$ 153, attributable to the deprotonated gentisic acid. The deprotonated compound **36** differed from **9** for 30 mass units, having a $[M\text{-}H]^-$ pseudomolecular ion at $m/z$ 285. Its fragmentation pattern

showed product ions at $m/z$ 225, 203, 153 and 108, consistent with the presence of a pentose instead of hexose. For this reason, it was putatively identified as gentisic acid pentoside.

Compound **15** was characterized by a deprotonated pseudomolecular ion at $m/z$ 289, attributable at least in principle to catechin or epicatechin. The relative intensity of the characteristic fragment ions detected in the fragmentation pattern of this molecule (ions at $m/z$ 245, 203, 179), even if compared with literature,[29] was insufficient to discriminate between the two epimers.

Similarly the metabolite **10** was putatively identified as the flavonol (epi)gallocatechin. Indeed, the mass spectrum showed the peak of the $[M\text{-}H]^-$ ion at $m/z$ 305 and characteristic fragments at $m/z$ 261, 219, 179, and 125. The presence of the fragment at $m/z$ 125 was identifiable in the intact flavonoid A ring.[30] The metabolite **11**, on the basis of data provided by mass spectrometry experiments, was putatively identified as (epi)catechin gallate. The fragmentation of the $[M\text{-}H]^-$ ion at $m/z$ 441 generated two major fragments at $m/z$ 331 and 169. The formation of the former fragment could be due to the loss of the only catechol B ring and introduction of a new unsaturation between carbons C2−C3 of the C ring. The fragment at $m/z$ 169 consisted of gallic acid anion.

The $[M-H]^-$ ion for the metabolite **18** at $m/z$ 457 yielded main fragment ions at $m/z$ 331, 305, and 169. The product ion at $m/z$ 331 was due to the neutral loss of intact B-ring, whereas the ion at $m/z$ 305 consisted of deprotonated epigallocatechin or gallocatechin, formed by the loss of the galloyl moiety (−152 Da). Finally, the ion at $m/z$ 169 corresponded to the gallic acid anion.[31] The abundance of this latter, respect to that at $m/z$ 305, allowed us to unequivocally identify this compound as gallocatechin gallate.[29]

Compound **17** was identified as *p*-coumaroylhexose on the basis of its $MS^2$ spectrum compared with literature.[32] In fact, the deprotonated molecular ion at $m/z$ 325, once fragmented, yielded product ions at $m/z$ 163, likely corresponding to deprotonated *p*-coumaric acid formed after the loss of the hexose residue as 162 Da, and $m/z$ 145 and 119 due to the subsequent loss of a water molecule and $CO_2$, respectively.

The compound **24**, with the $[M\text{-}H]^-$ pseudomolecular ion at $m/z$ 647, was identified as trigalloylquinic acid (e.g., pistafolin A).[33] The fragments at $m/z$ 343 and 495 were reported as successive losses of two molecules of gallic acid.

The fragmentation pattern of the metabolite **25** was in agreement with the presence of glabrol, a molecule that reduces the absorption of cholesterol and modulates the expression of genes involved in lipid metabolism and recently was found in *P. lentiscus* leaves.[20] The pseudomolecular ion at $m/z$ 391 gave rise to the fragments at $m/z$ 331 and 161. The latter, corresponding to a residue of 2-(3-methylbut-2-enyl)phenol, could be formed after the loss of a benzo-$\gamma$-pyrane core that brought an isoprenic chain in C-8.

Metabolite **27** showed a deprotonated pseudomolecular ion at $m/z$ 335 and a characteristic fragment ion at $m/z$ 183, which allowed us to identify it as methyl digallate on the basis of literature data.[27]

It has previously reported that the Anacardiaceae family is characterized by the occurrence of both gallic acid and myricetin derivatives.[34] Our data confirmed these evidence. In fact, beside the gallic acid derivatives discussed above, the alcoholic extract of *P. lentiscus* under study also contained myricetin glycosides (compounds **28**−**30**, **32**). In particular, metabolite **28** was identified as the flavonol myricetin *O*-rutinoside ($[M-H]^-$ at $m/z$ 625). The presence of fragments at $m/z$ 479 and 316 in $MS^2$ spectrum was attributable to the loss of a deoxyhexose moiety $[M-H-146]^-$ and to the aglycone radical myricetin, respectively. The formation of this latter was probably due to the homolytic cleavage of the glycosidic bond. Compounds **29** and **30** were tentatively identified as myricetin *O*-hexoside isomers ($[M-H]^-$ at $m/z$ 479). Also in this case, the formation of the aglycone radical $[Aglicone-H]^{-\bullet}$ was observed. The metabolite **32** was putatively identified as myricetin *O*-deoxyhexoside. In fact, the homolytic cleavage of the $[M-H]^-$ ion at $m/z$ 463 generated the aglycone radical and a glycanic radical (−147 Da) of deoxyhexose nature. Other three myricetin derivatives (**38**, **39**, **42**) were found to be present in P*l*-M extract, characterized by the presence of a galloyl moiety as evidenced by neutral losses of 152 Da, beside a deoxyhexoside residue. They were tentatively identified as myricetin *O*-galloyl-deoxyhexoside isomers.

On the basis of their fragmentation pattern metabolites **34**, **35**, **37**, **43** were identified as quercetin glycosides, which differed for the sugar residue (rutinose, hexose, deoxyhexose). The product ions at 301 and 300 likely corresponded to deprotonated quercetin and quercetin radical, respectively. The two hexoside isomers (**35** and **37**) differed mainly for the relative abundance of these ions, whose ratio suggested the glycosylation position at the C-3 for compound **37**, and C-7 or C-4′ for compound **35**.[35,36] Compounds **40** and **41** were putatively identified as quercetin *O*-galloylpentoside isomers. In fact, following the collision induced dissociation of the deprotonated molecules at $m/z$ 585, the ions at $m/z$ 301 were generated, likely due to the loss of a pentose sugar and a galloyl moiety (132 + 152 Da). Metabolite **44** was characterized as quercitrin gallate, according to MS/MS evidence. In fact, it showed a molecular deprotonated ion at $m/z$ 599, which yielded fragment ions at $m/z$ 447, due to the loss of the galloyl moiety, and $m/z$ 301, likely the deprotonated quercetin arising from the further loss of a deoxyhexoside residue. This compound was recently reported as a component of *P. lentiscus* leaves.[20]

Compounds **19** and **26** were putatively ascribed to glycosylated dihydroflavonols. In particular the $MS^2$ spectrum of metabolite **19**, sharing a $[M\text{-}H]^-$ pseudomolecular ion at $m/z$ 481, showed the product ion at $m/z$ 319 after the loss of a hexose residue (162 Da), likely corresponding to dihydromyricen (ampelopsin), whereas deprotonated compound **26** at $m/z$ 465, once fragmented, gave rise to the ion at $m/z$ 303, likely dihydroquercetin (taxifolin). According to these experimental data, compounds **19** and **26** were tentatively characterized as ampelopsin *O*-hexoside and taxifolin *O*-hexoside, respectively.

Metabolite **31** was putatively identified as a hexoside of the flavanone eriodictyol ($[M-H]^-$ a $m/z$ 449). The fragment ion at $m/z$ 287 ($[M\text{-}H\text{-}C_6H_{10}O_5]^-$) suggested the presence of the flavonone for loss of a six carbon atoms glycidic moiety.[37]

Compounds **33** and **45** were tentatively identified as hexosides of the flavonoid kaempferol and/or luteolin. In fact, they showed the same $[M\text{-}H]^-$ molecular ion at $m/z$ 447, and the same product ion at $m/z$ 285, formed after the loss of a hexose residue (−162 Da). Unfortunately mass spectrometric data did not allow us to discriminate between the two aglycone isomers. For the same reason metabolite **46** was putatively identified as kaempferol-3-*O*-deoxyhexoside or luteolin-3-*O*-deoxyhexoside. The $MS^2$ spectrum of the deprotonated molecular ion at $m/z$ 431 provided a base peak at $m/z$ 285,

which allowed us to hypothesize the presence of kaempferol/luteolin as aglycone, and a deoxyhexosyl glyconic moiety (−146 Da).

**Antioxidant and Cytoprotective Capabilities of Pl-M Extract.** The antiradical properties of Pl-M extract were evaluated through three methods, useful to define the capability of the investigated plant complex to act as a source of secondary antioxidants (*chain breaker*), which are chemical species able to inactivate dangerous free radicals transferring them an hydrogen atom and/or a single electron (Figure 1).

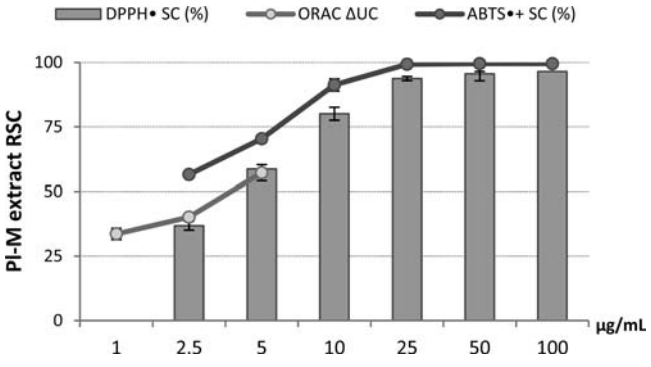

**Figure 1.** Radical scavenging capacity (RSC, %) of *P. lentiscus* investigated extract toward DPPH radical, $ABTS^{+}$ radical, and $ROO^{\bullet}$ radicals. These latter are reported as the mean of ΔAUC values from ORAC assay. Values, reported as percentage vs a blank, are the mean ± SD of measurements carried out on 3 samples ($n$ = 3) analyzed three times.

The extract showed an efficacious reducing power the target radical species $ABTS^{\bullet+}$ and $DPPH^{\bullet}$. In fact, 0.6 µg/mL Pl-M dose level was able to reduce $ABTS^{\bullet+}$ by 50%, whereas a dose equal to 2.9 µg/mL was required to scavenge the same percentage of DPPH radical. The scavenging effectiveness appeared to be strongly dependent on the dose tested. In particular, it was observed that the complete conversion of the radical cation ABTS in its reduced form was realized when the probe was exposed to an extract dose equal to 25.0 µg/mL. The massive antiradical activity was confirmed by ORAC data. The high sensitivity of the ORAC method required, in order to obtain useful information, the use of extract doses lower than those adopted in the colorimetric tests (1.0, 2.5, and 5.0 µg/mL). The values of ΔAUC (area under the curve) shown in Figure 1 and ORAC values, reported as equivalents of Trolox, a water-soluble analogue of vitamin E commonly used as a standard positive, highlighted the antiradical effectiveness of the extract capable to exercise at a dose of 1.0 µg/mL an activity comparable to that exerted by 3.1 µg/mL of Trolox.

The evaluation of the cytotoxic effects of the extract through MTT and SRB assays that it exerted only an mild cell viability inhibition (Figure 2A, B). In particular, it was observed that the extract influenced in a time dependent manner the proliferation of murine cell line, whereas both the human neuroblastoma cell lines showed a similar cytotoxic behavior at all the three exposure times. SK-N-BE(2)-C cell line appeared to be less sensitive to the addition of toxic. In fact, an inhibition of cell viability of approximately 10% was detected when SK-N-BE(2)-C cells were treated with the extract highest tested dose (100 µg/mL). Data obtained emphasize that Pl-M complex did not adversely influence the growth and proliferation of tested cell lines opening a favorable scenario for an its likely therapeutic application.

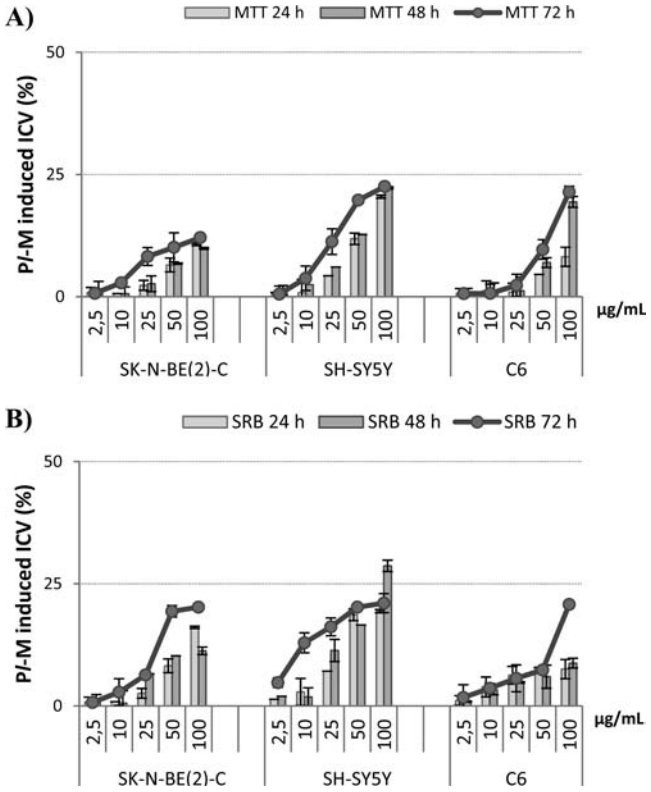

**Figure 2.** Pl-M cell viability inhibition (CVI, %) toward SK-N-BE(2)-C, SH-SY5Y, and C6 cell lines at 24, 48, and 72 h exposure times by means of (A) MTT test results, (B) SRB test results. Values, reported as percentage vs an untreated control, are the mean ± SD of measurements carried out on 3 samples ($n$ = 3) analyzed 12 times.

In order to further explore the Pl-M toxic effects, lactate dehydrogenase (LDH) release was also investigated. The test (Figure 3) was performed toward the three cell lines using the single dose of 100.0 µg/mL. Detected data allowed us to state that the extract did not affect LDH release.

The evaluation of the plant extract effect on $H_2O_2$-induced oxidative stress in SK-N-BE(2)-C cells was tested. Co-treatment with 25.0, and 50.0 µg/mL Pl-M extract showed viability values slightly lower than those elicited by $H_2O_2$-treated group (Figure 4A). Only the cells treated with Pl-M

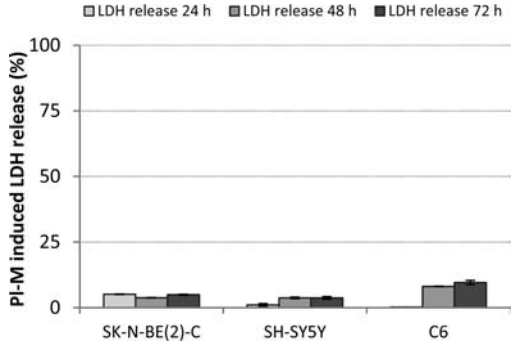

**Figure 3.** Pl-M induced LDH release (±SD) vs SK-N-BE(2)-C, SH-SY5Y, and C6 cell lines. The evaluation of LDH release was carried out treating cells with 100.0 µg/mL extract dose at 24, 48, and 72 h exposure times. Values, reported as percentage vs an untreated control, are the mean ± SD of measurements carried out on 3 samples ($n$ = 3) analyzed 12 times.

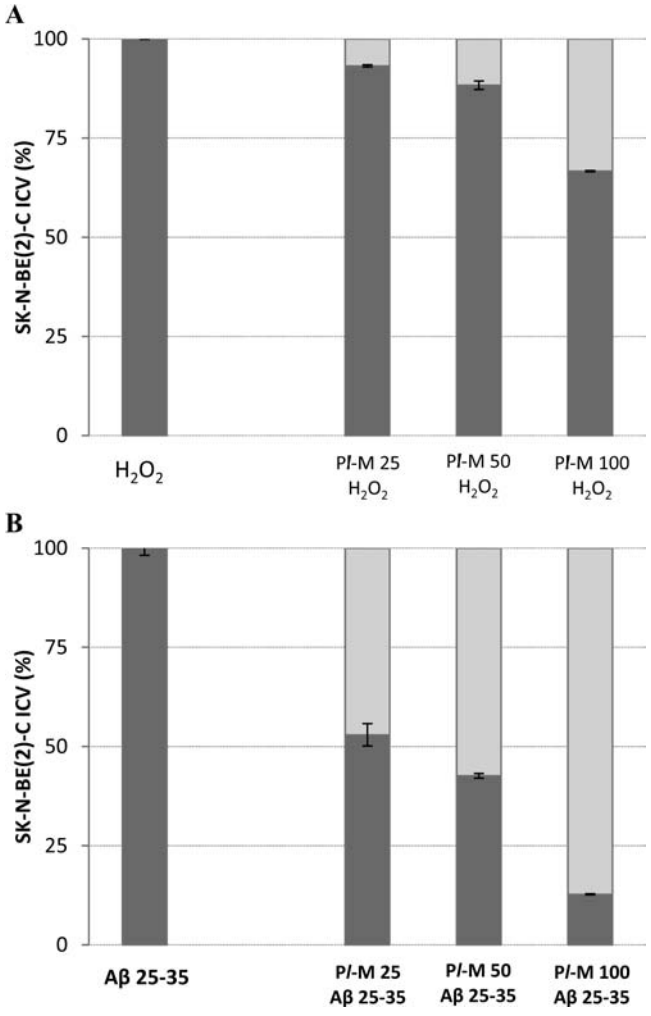

**Figure 4.** Cell viability inhibition (CVI, %) toward SK-N-BE(2)-C cell line cotreated with P*l*-M extract and (A) $H_2O_2$ (400 $\mu$M) or (B) A$\beta$(25−35) fragment (100 $\mu$M) at 24 h exposure time by means of MTT test results. Values, reported as percentage vs. an untreated control, are the mean ± SD of measurements carried out on 3 samples ($n$ = 3) analyzed 12 times.

100.0 $\mu$g/mL dose level presented a high and significant value of cell viability compared to $H_2O_2$-treated group. In order to determine the possible beneficial effect of the extract against the phenomena of oxidative stress induced by amyloid plaques in Alzheimer's dementia, its antioxidant capacity in a system utilizing the functional domain of the $\beta$-amyloid peptide, A$\beta$(25−35), as oxidizing agent, was tested. As the cellular reduction of MTT represents a specific indicator of the initial events underlying the mechanism of $\beta$-amyloid peptide toxicity,[38,39] MTT test was first carried out exposing the three cell lines at increasing concentrations of A$\beta$(25−35) fragment (12.5, 25.0, 50.0, and 100.0 $\mu$M). A$\beta$(25−35) fragment was found to induce cytotoxicity in SK-N-BE-(2)-C cell line. The results of the MTT test carried out after exposure of SK-N-BE-(2)-C cell line to A$\beta$ 25−35 increasing concentrations (12.5, 25.0, 50.0, and 100.0 $\mu$M) allowed us to identify the domain concentration to which it induced the highest cell viability inhibition. The effects of cotreatment of the cell line for 24 h with A$\beta$ 25−35 100.0 $\mu$M and increasing extract dose levels (25.0, 50.0, and 100.0 $\mu$g/mL) were assessed through MTT test (Figure 4B). P*l*-M extract was able to reduce by nearly 50%, the A$\beta$ 25−35-induced toxicity at the lowest dose level tested. A marked neuroprotective effect was observed when P*l*-M 100.0 $\mu$g/mL dose level was screened. In fact, the results underlined the high antioxidant capacity of this P*l*-M dose level able to counteract almost completely the cytotoxic action of the oxidant.

There is ample scientific and empirical evidence supporting the use of plant-derived antioxidants for the control of neurodegenerative disorders. Antioxidants may have neuroprotective (preventing apoptosis) and neuroregenerative roles, by reducing or reversing cellular damage and by slowing progression of neuronal cell loss.

Dementia pathologies such as Alzheimer's disease (AD) are reaching epidemic proportions, yet they are not successfully managed by effective symptomatic treatments.[40] Since two of the currently licensed drugs for AD are based on natural products (galantamine and rivastigmine), different plants are now being investigated as a potential source of new therapy for AD.[41,42] Furthermore, different studies have revealed that natural polyphenols can reduce A$\beta$ neurotoxicity[43,44] possibly via an antioxidative mechanism and inhibition of A$\beta$ oligomerization.[45] The A$\beta$ lowering properties of these substance could be mainly mediated via their effect on NF-$\kappa$B signaling which in turn could affect the regulation of BACE-1 expression.

A significant inverse association between phenolics intake and dementia risk, was found.[46] In neuronal cell cultures, it was observed that EGCG was able to regulate the proteolytic processing of APP (amyloid precursor protein) and to reduce A$\beta$ generation.[47] The molecular mechanism involved in the neuroprotection effect of EGCG could also due to its ability to decrease the expression of pro-apoptotic genes.[48] Upon their antioxidant properties, phenol compounds as chlorogenic acid, gallic acid, and quinic acid, together with various flavonoids, were reported to be potential inhibitors of acetylcholinesterase. Thus, the use of these substances could be used to counteract the AD deficiency in acetylcholine production.[49] Furthermore, previous bioavailability studies allow us to encourage the use of *Pistacia lentiscus* leaf alcoholic extract as an alternative source for the preparation of functional food enriched in flavan-3-ols and galloyl esters. Indeed, although absorption, distribution, metabolism, and excretion (ADME) studies highlighted that polyphenols bioavailability varies widely from one compound to another, as it is influenced by their chemical structure and molecular weight,[50] positive data are available on molecules identified in Pl-M extract. An acute feeding study, through HPLC-$MS^3$ analysis of plasma and urine samples of healthy human subjects fed with green tea products, showed that (−)-epigallocatechin-3-*O*-gallate and (−)-epicatechin-3-*O*-gallate appeared unmetabolized in plasma.[51] The passage of ECG and EGCG through the wall of the small intestine into the circulatory system without metabolism could be a consequence of the presence of the 3-*O*-galloyl moiety interfering with phase II metabolism. Gallic acid per se is readily absorbed with a reported urinary excretion of 37% of intake, and so, the gallate ester might exhibit improved absorption.[52] The absence of detectable amounts of EGCG in urine was hypothesized to be due to the kidney inability to remove it from the bloodstream.[53] Preclinical studies speculated that EGCG may be removed from the bloodstream in the liver and returned to the small intestine in the bile.[54] The level of EGCG found in the major organs was found to be ∼1/10 that found in the serum. Most interestingly, this includes the brain, suggesting that EGCG passes through

the blood-brain barrier.[55] In this latter context, little and controversial information deals with the interaction of polyphenols or their circulating metabolites with the blood brain barrier (BBB). The layer of brain endothelial cells is sealed by complex tight junctions that possess few pinocytotic vesicles but express a number of specific uptake and efflux transport systems and metabolic enzymes. Together, these properties enable the BBB to restrict the passage of most small polar molecules and macromolecules from the cerebrovascular circulation to the brain, to exert tight control over trans-endothelial molecular traffic and to contribute to regulation of brain extracellular fluid composition. Youdim and co-workers[56] investigated the potential BBB permeability of flavonoids and their physiologically relevant metabolites using the ECV304/C6 coculture BBB model. Aglycones, due to their lipophilicity, were found to cross BBB by passive transcellular diffusion. Moreover, some evidence suggested that polyphenol constituents from *Pistacia lentiscus* leaves could be able to cross BBB. Epigallocatechin gallate (EGCG), for instance, was reported to enter the brain after a gastric administration of [$^3$H]EGCG,[57] whereas gallic acid was found to pass through BBB and protect or improve neuronal function in critical brain regions involving cognition after cerebral damage by ischemia.[58] $^{14}$C-labeled grape polyphenols was also demonstrated to reach the brain following oral administration.[59] Importantly, in in vitro and in situ models of the blood brain barrier, it was demonstrated that quercetin was able to enter different regions of the brain as a substrate of P-glicoproteins, a BBB efflux transporter.[60] Studies have indicated that the accumulation of flavonoids in the brain is not dependent on the brain region. Vauzour and co-workers,[61] reviewing the neuroprotective potential of flavonoids, stated that these molecules traverse BBB and are able to localize in the brain, suggesting that they are candidates for direct neuroprotective and neuromodulatory actions. Indeed, although the uptake and distribution of dietary polyphenols within the brain are well documented, the question of the dose reaching the target tissues remains uncertain. Data from studies using exsanguinated and perfused animals or applying the recently published mathematical correction model suggest that polyphenols usually localize in the brain at levels below 1 nmol/g tissue.[62]

In conclusion, a host of products from plant species and derivatives have neuroprotectant effects in vitro and in vivo. Reported data are in accordance with the preparation of a polyphenol-rich alcoholic extract of *Pistacia lentiscus* (Pl-M) with strong antiradical and antioxidant activity. The extract, which was highly cytocompatible in neuronal and glial tested cell lines, at concentrations up to 100 $\mu$g/mL, showed protective effect against hydrogen peroxide-induced oxidative stress and marked antiamyloidogenic activity in neuronal cells. The positive and promising effects, probably the result of an appropriate mixture of ingredients, allow us to hypothesize that the enrichment of a food matrix with polyphenol bioactives from a broadly available and renewable source, as *Pistacia lentiscus* leaves, could represent a valuable method to counteract Alzheimer's disease onset.

In the present study, LC-MS analyses were performed to unravel the chemical complexity of this potential botanical dietary supplements, which represents, likely green tea and wine, an active and rich source of gallic acid esters and glycosides. The massive presence of some of these compounds, e.g. galloyl and digalloyl quinic acids, poorly available in human diet, addresses Pl-M extract bioavailability and preclinical studies, able to define its active doses and to assess *Pistacia lentiscus* polyphenol extract safety and efficacy as nutraceutical in an AD mouse model and aged mice.

including the limit of polyphenol bioconversion and absorption as compared to in vivo studies which are less stable in human gut due to environmental conditions and diversity of microbes.[19] To our knowledge, there is no information regarding the nature or biological properties of naturally occurring phenolic lipids that could result from natural lipid−phenolic interactions in olive oil. The specific objectives of this research were the following: (i) to investigate the occurrence of natural lipid−phenolic interactions in virgin olive oil via evaluation of the total content of free and lipid-bound phenolic compounds and identification of individual lipid phenolic compounds in virgin olive oil; and (ii) test the biological properties of free and bound phenolic compounds in terms of antioxidant activity, α-amylase and ACE inhibitory activities, and antitumorigenic activity.

## MATERIALS AND METHODS

**Plant Materials.** Nepali olive sample was obtained from Rahoub Valley (Irbid, Jordan). Samples were harvested in the winter of 2010 at proper harvesting stages according to the International Olive Oil Council method (IOOC).[20] Olives were subjected to milling at commercial industrial two-phase olive oil (Irbid, Jordan) to obtain the virgin olive oil. Olive oil samples were filled in plastic containers of 10 L. The virgin olive oil was graded into upper and lower layers of 10 L containers after storage of three months to remove sediments and then stored at −18 °C prior to analysis.

**Phenolic Compounds Extraction.** *Free Phenolic Compounds Extraction.* Free phenolic compounds were extracted according to the method described by Alu'datt et al.[21] with modifications. A 15 mL sample of two layers from virgin olive oil was extracted with 25 mL of methanol at 30 °C for 1 h in a shaking water bath. The supernatant oil samples were filtered using Whatman 3 filter paper, and the resulting extract was designated as free phenolic extract at 30 °C (FP-30 °C). The supernatant that remained after methanol extraction at 30 °C was subjected to methanol extraction with 25 mL at 60 °C for 1 h in a shaking water bath. After filtration with Whatman 3 filter paper, the extract was designated as free phenolic extract at 60 °C (FP-60 °C). The FP-30 °C and FP-60 °C extracts were stored at −18 °C for further analysis.

*Bound Phenolic Compounds Extraction.* Bound phenolic compounds were extracted according to the method described by Alu'datt et al.[21] with modifications. The residue remaining after extraction of free phenolic compounds at 30 and 60 °C as described above was hydrolyzed with dilute alkaline solution (25 mL, pH 12.0, 0.1 M NaOH) for 24 h at 30 °C in a shaking water bath, and then the alkaline solution was freeze-dried (LFD-5508 freeze-dryer, Korea). The liberated bound phenolic compounds from alkaline hydrolysis were subjected to methanol extraction (25 mL) at 30 °C for 1 h. The supernatant was filtered using filter papers (Whatman 3), and the resulting extract was designated as bound phenolic at 30 °C (BP-30 °C). Following extraction with 25 mL of methanol at 60 °C for 1 h, the extract that was generated was designated as bound phenolic at 60 °C (BP-60 °C). All extracts were stored at −18 °C for further analysis.

*Total Phenolic Compounds Content.* Determination of the total phenol content in each phenolic extract was conducted by using the Folin−Ciocalteu method as previously described by Hoff and Singleton.[22] Standard curves of gallic acid were prepared using a stock solution of 5 mg/mL. A 100 μL portion of the extract containing phenolic compounds was added to 8.4 mL of distilled water. A 0.5 mL portion of the Folin−Ciocalteu solution was added and mixed well in the test tube after 4 min, which was followed by addition of 1.0 mL of 5% sodium carbonate and vortex-mixed for several seconds. The absorbance was measured 1 h later at 725 nm using UV−vis spectrophotometry (UV 1800, Biotech Engineering Management Co., Ltd., U.K.). The total phenolic content was expressed as mg/L gallic acid equivalents (mg GAE/L).

*Determination of Antioxidant Activity.* Antioxidant activity of phenolic extract was determined according to the method of Alu'datt et al.[21] with modifications. A 5 mg portion of β-carotene was dissolved in 50 mL of chloroform. The β-carotene/linoleic acid stock solution was prepared by mixing 3 mL of β-carotene solution with 50 μL of linoleic acid and 400 mg of Tween 20. The chloroform was evaporated under nitrogen gas followed by addition of 100 mL distilled water, and the resulting emulsion was shaken for 2 min. A 100 μL portion of the bound phenolic methanolic extract (BP-30 °C or BP-60 °C) was mixed with 3 mL of the emulsion. The absorbance was measured at time 0 and after incubation for 1 h at 50 °C at 470 nm. A 100 μL portion of solvent was used in the blank control sample. The percent antioxidant activity (AA%) was calculated as amount of β-carotene bleaching in sample to control according to the following equation:

$$AA\% = 100*((DRc - DRs)/DRc)$$

Here, AA% is the percent antioxidant activity. DRc is the degradation rate of the blank control sample [DRc = (ln(A/B)/60)]. DRs is the degradation rate of the sample DRs = (ln(A/B)/60). A is the absorbance at t = 0, and B is the absorbance at t = 60 min.

*Measurement Inhibitory activity for α-Amylase Enzyme.* The activity of α-amylase was evaluated according to the method described by McCue et al.[23] with modifications. Porcine pancreatic α-amylase (10080, Sigma Chemical Co.) was prepared by mixing 0.030 g of the enzyme in 100 mL of distilled water. A potato starch solution of 0.5% (w/v) was prepared by dissolving 0.125 g of starch in 25 mL of phosphate buffer (pH 6.9; 65 °C/20 min). A colorimetric reagent was prepared by mixing well 19.8 g of sodium hydroxide with 10.6 g of 3,5-dinitrosalicyclic acid solution (DNS) in 1.416 L of distilled water and then adding this to a mixture of 3.06 g of sodium potassium tartarate, 7.6 g of phenol, and 8.3 g of sodium metabisulfite, and mixing by shaking for 15 min. A 100 μL portion of phenolic extract (BP-30 °C or BP-60 °C), 500 μL of phosphate buffer (pH 7.0), and 500 μL of α-amylase solution were incubated at 25 °C for 10 min. The control sample consisted of 100 μL of solvent. After the preincubation, 500 μL of potato starch solution was added, and the mixture was incubated in a 25 °C water bath for 10 min. The reaction stopped by adding 1 mL of DNS. The mixture was then incubated in a boiling water bath for 5 min and then cooled to room temperature. The total volume of reaction mixture was diluted to 10 mL by adding distilled water. To determine the amount of liberated maltose the absorbance was measured at 540 nm via a spectrophotometer (Spectrophotometer-UV 1800, Biotech Engineering Management Co., Ltd., U.K.). The percent α-amylase inhibition was expressed as amount of liberated maltose in sample to control and calculated according to the followin equation:

$$\alpha\text{-amylase inhibition } \% = 100[(Ac - As)/Ac]$$

Here, Ac is the absorbance of the control sample at 540 nm, and As is sample absorbance.

*Determination Inhibitory Activity of Angiotensin 1-Converting Enzyme (ACE).* ACE inhibition was measured according to the method described by Cushman and Cheung[24] with modifications. A 0.3% (w/v) solution of hippuryl-L-histidyl-L-leucine (HHL) solution was dissolved in 50 mM 4-(2-hydroxyethyl)-1-piperazineethanesulfonic acid (HEPES) HCl buffer with 300 mM sodium chloride (pH 8.3 at 37 °C). The ACE enzyme solution was prepared by mixing of 0.33 U in 1 mL of distilled water. An aliquot of 200 μL of HHL was mixed with 100 μL of either the BP-30 °C or BP-60 °C phenolic extract. An aliquot of 50 μL of ACE solution was added, and the mixture was incubated at 37 °C for 15 min. The reaction was stopped by adding 0.25 mL of HCl, and then 2 mL of ethyl acetate was added to extract the liberated hippuric acid. A 1 mL portion of the ethyl acetate layer was separated by centrifugation (3000 rpm/3 min) and evaporated by using boiling water bath for 15 min, and then 3 mL of distilled water was added. The amount of liberated hippuric acid was quantified by measuring the absorbance at 228 nm (UV 1800, Biotech Engineering Management Co., Ltd., U.K.). A blank was prepared by adding of 200 μL of HHL and 50 μL of ACE in 100 μL of distilled water. The amount of hippuric acid liberated in the control samples was defined as 100% ACE activity. The ACE inhibition was expressed as the amount of liberated hippuric acid in the sample to the control and calculated using the following equation:

$$\text{ACE inhibition \%} = [(A228\ \text{blank} - A228\ \text{sample})/A228\ \text{blank})100]$$

Here, $A$ is the absorbance.

**Measurement of Anti-Tumorigenic Activity Using Human Colorectal Cancer Cells.** *Cell Culture.* Two different human colorectal cancer cells (CRC1 and CRC5) were supplied by Dr. Rick Throm, University of Newcastle, Australia. The cell lines were cultured as monolayer and attached in Dulbecco's modified essential medium (DMEM) supplemented with 10% fetal calf serum (FCS) (Lonza, Verviers, Belgium), 1% penicillin-streptomycin (5000 U penicillin/mL and 5000 U streptomycin/mL) (Lonza, Verviers, Belgium), and amphotericin B (250 μg/mL) (Lonza, Verviers, Belgium). Cells were incubated in a humidified atmosphere containing 5% $CO_2$, at 37 °C in $CO_2$ incubator (Shell Lab).

*Cell Viability Assay.* The four types of phenolic extracts derived from the virgin olive oil layer characterized by having the highest phenolic content were chosen for studying the antitumorigenic effects of phenolics in olive oil. The cytotoxic effect of different concentrations of phenolic extracts (10−200 μL) was determined by using 3-(4,5-dimethylthiazo-l-2-yl)-2,5-diphenyltetrazolium bromide (MTT) assay according to the method described by Wu et al.[25] Cells were seeded at 5000 cells/well onto flat-bottomed 96-well culture plates, and allowed to grow for 24 h before treatment. Cells were incubated with five different concentrations of phenolic extracts (0, 10, 50, 100, and 200 μL; 0.0, 1.4, 7.1, 14.2, and 28.4 μg for FP-30 °C; 0.0, 0.7, 3.5, 7.0, and 14.0 μg for FP-60 °C; 0.0, 0.6, 3.0, 6.0, and 12.0 μg for BP-30 °C; and 0.0, 0.68, 3.4, 6.8, and 13.6 μg for BP-60 °C). After 48 h of incubation, cells were incubated with 10 μL of MTT for 4 h from Vybrant MTT assay cell proliferation assay kit (Molecular Probes, Eugene, OR) according to manufacturer's instruction. After MTT incubation, the supernatant was aspirated, and the insoluble formozan product was dissolved with dimethyl sulfoxide (80 μL DMSO). Cell proliferation was measured by measuring absorbance using a microplate reader (model 3550, Bio-Rad Laboratories, CA) at 540 nm.

*Identification and Quantification of Individual Phenolic Compounds by Using Liquid Chromatography-Electrospray Ionization Tandem Mass Spectrometry (LC/ESI-MS/MS).* A 10 mL portion of free and bound phenolic extracts that were characterized with the highest phenolic content was evaporated under a stream of nitrogen and then dissolved in 1 mL of methanol and stored at −18 °C until further analysis. Standard curves were prepared by using a stock standard solution prepared by dissolving 5 mg of each phenolic standard in 50 mL of methanol. Virgin olive extracts were analyzed by LC-MS/MS according to the method described by Obied et al.[26] The analysis of phenolic compounds was carried out using Agilent 1100 chromatography system (Agilent 1100, Agilent Technologies, Wilmington, DE) equipped with a diode array UV detector. The samples were injected into a Thermo $C_{18}$ reversed phase column (pore size 5 μm, 250 mm × 4.6 mm i.d., Thermo Fisher Scientific, San Jose, CA).

The analysis was carried out by a gradient solvent system using aqueous formic acid (1%) as solvent A, and methanol/acetonitrile/formic acid mixture (89.5/9.5/1 v/v/v) as solvent B. A seven-step linear gradient elution for total run time of 65 min was carried out using the solvent gradient as follows: 0−10 min 90−70% solvent A and 10−30% solvent B, 10−15 min isocratic, 15−25 min 60% solvent A and 40% solvent B, 25−40 min 50% solvent A and 50% solvent B, 40−50 min to 100% solvent B, 50−55 min 90% solvent A and 10% solvent B and 55−65 min isocratic. An injection volume of 15 μL at constant flow of 0.75 mL/min was used for each analysis. The entire flow from the HPLC was directed into the tandem mass spectrometer. Triple-quadrupole mass spectrometer (API 3200; MDS Sciex, Concord, ON, Canada) was used. The mass spectral data was acquired on negative ion mode, capillary voltage 4000 V, ion source atmospheric pressure chemical ionization (APCI), a cone voltage 70 V, collision energy 10 eV, drying temperature 350 °C, drying gas $N_2$ with 4.0 L/min flow rate, nebulizer gas helium with 40 psi flow rate, software used for data processing was Analyst software version 3.5.1. Diode array UV detector was used to scan between 200 and 400 nm to evaluate contents of individual phenolic compounds. A maximum absorbance of 280 nm was selected to determine the contents of individual phenolic compounds. The eluted compounds of samples and standards were detected at 280 nm. Mixture of external standards (*p*-hydroxybenzoic acid, gallic acid, caffeic acid, ferulic acid, vanillic acid, tyrosol, hydroxytyrosol, *p*-coumaric acid, syringic acid, apigenin, hesperidin, luteolin, quercetin, rutin, sinapic acid, and oleuropein) was used to quantify the contents of individual phenolic compounds.

*Analysis of the Fatty Acids by Gas Chromatography (GC).* Fatty acid analysis was carried out according to the method described by Ereifej et al.[27] with modifications. Fatty acid profiles of virgin olive oil before and after removal of free and bound phenolic compounds were analyzed by GC-MS (Varian 450-GC/Varian 320-MS). Fatty acid methyl esters of virgin olive were prepared as follows: 0.1 g of olive oil was dissolved in 2 mL of heptane and mixed with a 0.2 mL solution of 2 M methanolic potassium hydroxide and then shaken vigorously for 30 s. The upper layer of the solution containing fatty acid methyl esters was separated, and 15 μL was injected in a split/split injector. An Agilent HP-INNOwax column (30 m × 0.25 mm i.d., 0.25 μm film thickness) was employed. The oven temperature program was as follows: column temperature was programmed from 50 °C (kept for 4 min) to 200 °C at 25 °C/min, 2 min at 200 °C, from 200 to 240 °C at 4 °C/min, 18 min at 240 °C. A constant helium carrier gas flow rate of 0.8 mL/min was used. A standard of fatty acid methyl esters was used to identify the content of fatty acids and was expressed as percent of total content of fatty acids.

*HPLC Separation of Acylglycerols.* Acylglycerols for virgin olive oil before and after removal of free and bound phenolic compounds were analyzed by HPLC. Olive oil samples were dissolved in tetrahydrofuran (THF). HPLC separation was carried out by Agilent 1100 series instrument (Wilmington, DE) equipped with UV−vis diode-array detection operated at 215 nm using a Zorbax SB-$C_{18}$ reverse phase column (pore size 5 μm, 250 mm × 4.6 mm i.d., Restek Co., Bellefonte, PA) operated at 60 °C. Elution was carried out at flow rate of 0.8 mL/min, with an injection sample volume of 10 μL. The elution of the injected sample was carried out by a gradient solvent system using distilled water as solvent A, and acetonitrile/methyl tetra-butyl ether mixture (9:1, v/v) as solvent B. Linear gradient started from 87% solvent B, and increased to 100% solvent B over 25 min. The initial conditions were then re-established over 4 min. The fractionation of individual peaks obtained from HPLC analysis of glycerols for virgin olive oil before and after removal of free and bound phenolic compounds involved elution from the column and collection of the fractions that were pooled and freeze-dried (LFD-5508 freeze-dryer, Korea). A 4 mL portion of distilled water were added to each fraction, which was divided into two parts and then freeze-dried. The first part was extracted with methanol, while the second part was hydrolyzed with dilute alkaline solution (2 mL, pH 12.0, 0.1 M NaOH) for 24 h at 30 °C water bath followed by freeze-drying and then extracted with methanol. All fractionated samples were stored at −18 °C for further analysis.

*Statistical Analysis.* Statistical analysis was performed by applying the General Linear Model (GLM) of the SAS software package (Version 9.1 SAS 2002 Institute Inc., NC). The least significant difference (LSD) multiple-range test was used for means separation using an $\alpha$ level of 0.05.

## RESULTS AND DISCUSSION

**Free and Bound Phenolic Distribution.** Table 1 shows the content of extracted free and bound phenolic compounds from the lower layer A and upper layer B. The total phenolic content of olive oil from the combined fractions was 567.83 mg/L for layer A and 506.64 mg/L for layer B. The total content of extracted free phenolics in virgin olive oil ranged from 330.8 to 353.53 mg/L while the total content of extracted bound phenolics ranged from 175.84 to 214.3 mg/L. The above results are comparable with the upper range phenolic concentrations noted in previous studies, which found that the total content of phenolic compounds in virgin olive oil ranged

from 0.04 to 900 mg/kg.[28,29] The variations in phenolic content are likely related to varieties of cultivar, extraction method, storage, and package conditions.[8] In terms of individual fractions, the highest content of phenolic compounds in layers A and B was observed in the FP-30 °C extract with values of 237.37 and 232.2 mg/L, respectively. The lowest phenolic values were observed in the BP-30 °C extract with values of 100.74 and 86.09 mg/L for layers A and B, respectively. The above findings are in agreement with Alu'datt et al.[21] who found that the majority of free phenolics were extracted from olive cake in first step cycle.

Figure 1 illustrates the percent content of phenolic compounds of the FP-30 °C, FP-60 °C, BP-30 °C, and BP-60 °C extracts. The highest percent phenolic content was observed for the FP-30 °C extract, which had 41.80% and 45.86% for layers A and B, respectively. On the other hand, total phenolics in the FP-60 °C extract represented only 20.64% and 19.44%, respectively. These latter results were consistent with the finding of Alu'datt et al.[21] who found that a majority of phenolic compounds were extracted in the first three cycles of extraction from olive cake. The percent extraction of free phenolic compounds by heat treatment at 60 °C was lower than the percent phenolics obtained from the extraction carried out at 30 °C (Figure 1). The percent phenolic content of BP-30 °C in layers A and B was 17.74% and 16.99%, respectively. Similarly, the percent content of BP-60 °C in layers A and B was 20.00% and 17.71%, respectively. These results are in agreement with values obtained by Alu'datt et al.[21] who found that the percent content of bound phenolic

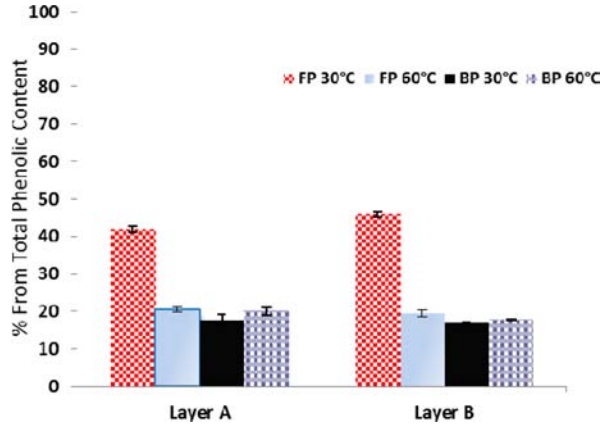

**Figure 1.** Distribution of free and bound phenolic compounds (percent of total phenolic content) at 30 and 60 °C.

compounds in olive cake ranged between 10% and 25%. In contrast, Alu'datt et al.[17] have reported that the percent content of bound phenolic compounds from olive meal represented less than 10% of total phenolic content. These results suggest that the phenolic compounds are present in free and bound forms in virgin olive oil.

**Antioxidant Activity of Free and Bound Phenolics Extracts.** Table 1 demonstrates the antioxidant activity of free and bound phenolic extracts of virgin olive oil. The antioxidant activities were the highest (55.0−58.1%) in layers B and A of FP-30 °C. The antioxidant activity of BP-30 °C in layer B was higher (45.1) as compared to antioxidant activities with layer B from FP-60 °C (39.3). The lowest antioxidant activities were found in BP-60 °C for both layers B and A with values in the range 5.7−6.7%. The above results indicate that the antioxidant activities of extracted free or bound phenolic compounds extracted at 30 °C are higher than those observed with the phenolics extracted at 60 °C. These latter results are inconsistent with previous findings showing a negative relationship between temperature of extraction and antioxidant activity.[30] The above ranges of antioxidant activities are similar to the 13.2−40.2% antioxidant activities reported by Gorinstein et al.[31] in Spanish olive oils. Conversely, Baiano et al.[16] found that the antioxidant activities of Italian virgin olive oils ranged between 70.67% and 87.83%. A weak positive linear correlation (0.571) was observed between total phenolic content and antioxidant activity (Table 2) which is in agreement with previous work showing that phenolic content was positively correlated with the antioxidant activity of olive oil.[16]

**Inhibitory Activity of α-Amylase of Free and Bound Phenolics Extracts.** Table 1 shows the α-amylase inhibitory activity of free and bound phenolic extracts from virgin olive oil. The maximum inhibitory activities of α-amylase were observed for layers A and B with the BP-30 °C extract with a range of values between 33.20% and 37.67%. The lowest inhibitory activities of α-amylase for the two layers were seen with the FP-60 °C extract with a range of values of 21.49−27.99%. The bound phenolic extracts of virgin olive oil generally had a better α-amylase inhibitory activity than the free phenolic extracts. Also, the free or bound phenolic extracts at 30 °C had higher inhibitory activity of α-amylase than free or bound phenolic extracts at 60 °C. Variations in inhibitory activities of α-amylase by the phenolic extracts may be due to differences in type, quantity, and polarity of phenolic compounds in extracts. These results are in agreement with the findings by Loizzo et al.[32] who

Table 2. Correlation Coefficients ($r$) between Phenolic Content, $\alpha$-Amylase Inhibitory Activity, Anticancer Activity (CRC1 and CRC5), Antioxidant Activity, and ACE Inhibitory Activity of Phenolic Extracts from Virgin Olive Oil

| | antioxidant activity | ACE inhibitory activity | $\alpha$-amylase inhibitory activity | anticancer (CRC1) | anticancer (CRC5) |
|---|---|---|---|---|---|
| content | 0.571 | 0.209 | 0.080 | 0.206 | −0.830 |
| antioxidant activity | | 0.117 | 0.241 | 0.115 | −0.495 |
| ace inhibitory activity | | | 0.943 | −0.911 | −0.720 |
| $\alpha$-amylase inhibitory activity | | | | −0.882 | −0.585 |

reported that the phenolic extracts of virgin olive oil inhibit $\alpha$-amylase activity. Several studies have reported the affinity of phenolic compounds to inhibit amylases and ACE enzymes.[30]

**Inhibitory Activity of Angiotensin 1-Converting Enzyme (ACE) of Free and Bound Phenolic Extracts.** Table 1 shows the inhibitory activities of free and bound phenolic extracts from olive oil on ACE enzyme inhibition. All free and bound phenolic extracts of olive oil had relatively good ACE inhibitory activity against enzyme apart from the free phenolic extract at 60 °C. Shahidi and Naczk[30] have reported that the ACE inhibitory activity of phenolic compounds depends upon the polarity and solubility of phenolic compounds. The highest inhibitory activity of ACE was observed with the bound phenolic extract in layer A at 30 °C with value of 37.57% whereas the lowest inhibitory activity (17.51%) was found in the free phenolic extract at 60 °C. Similarly, the highest ACE inhibitory activity in layer B was observed in bound phenolic extract at 30 °C with value of 29.39%, and the lowest inhibitory activity was found in free phenolic extract at 60 °C with value of 11.60%. Similar ACE inhibitory activities of phenolic extracts of extra virgin have been previously reported by Loizzo et al.[32] On the other hand, a high correlation was observed between ACE inhibitory activity and $\alpha$-amylase inhibitory activity (0.943).

**Proliferation Inhibition Activity of Free and Bound Phenolic Extracts.** The antiproliferative activity of extracted free and bound phenolic compounds from virgin olive oil against colorectal cancer cells is shown in Table 3. For the colorectal cancer cell line CRC 1, the lowest IC50 value was found with bound phenolic extract at 60 °C, which was significantly ($p < 0.05$) lower than both free phenolic extracts. For the CRC 5 colorectal cancer cell line, the lowest value of IC50 was found with the free phenolic extract at 60 °C that was significantly ($p < 0.05$) different from the IC50 of the free phenolic extract at 30 °C. The above results suggest that both free and bound phenolics can exert antiproliferative effects against CRC1 and CRC5 cells. These findings are consistent with previous observations that oleuropein and hydroxytyrosol can have antiproliferative effects against colon cancer cell lines (HT-29 and SW620).[33,34] Likewise, Fini et al.[35] have reported that extracted phenolics from virgin olive oil inhibited proliferation of RKO and HCT116 colorectal cancer cells lines. Results showed that the temperature does not have an effect on the anticancer properties.

Table 3. IC50 Values ($\mu$L/mL) of MTT Cytotoxicity Assay against Colorectal Cancer Cell Lines of Free Phenolic Compounds (FP) at 30 and 60 °C and Bound (BP) Phenolic Compounds at 30 and 60 °C from Virgin Olive Oil[a]

| | IC 50 ($\mu$L/mL) | | |
|---|---|---|---|
| type of extract | CRC1 | CRC5 | SE |
| FP-30 °C | 93.05a A | 140.37a A | 16.3 |
| FP-60 °C | 96.55a A | 86.52b A | 4.99 |
| BP-30 °C | 84.22ab A | 109.47ab A | 7.38 |
| BP-60 °C | 57.06b A | 100.61ab A | 8.96 |
| SE | 7.13 | 12.74 | |

[a]Means are average of two replicates. Column values with the same small letters and row values with same capital letters were not significantly different ($p < 0.05$). SE: standard error.

In contrast, CRC1 anticancer activity showed a strong negative correlation with ACE inhibitory and $\alpha$-amylase inhibitory activities with values of −0.911 and −0.882, respectively. The CRC5 anticancer activity had a weak negative correlation with antioxidant (−0.495) and $\alpha$-amylase inhibitory (−0.585) activities. The CRC5 antitumorigenic activity had a strong negative correlation with phenolic content (−0.830) and ACE inhibitory activity (−0.720).

**LC-MS/MS Analysis of Individual Free and Bound Phenolic Compounds.** Table 4 shows the phenolic profile identified by LC-MS/MS in the free and bound phenolic extracts of virgin olive oil. The LC-MS/MS profile of FP-30 °C extract showed the presence of gallic acid, *p*-hydroxybenzoic acid, vanillic acid, tyrosol, hydroxytyrosol, hesperidin, and quercetin that were not present in FP-60 °C extract. The major predominant individual phenolic compounds in FP-30 °C extract were luteolin, apigenin, and hydroxytyrosol with values of 49.02%, 32.33%, and 8.02% of total phenolic content, respectively, whereas the major predominant individual phenolic compounds in FP-60 °C extract were apigenin, luteolin, and sinapic acid with values of 45.84%, 25.04%, and 23.65% of total phenolic content, respectively. The above results are consistent with previous findings that gallic, *p*-hydroxybenzoic, vanillic, *p*-coumaric, and sinapic acids are the major phenolic acids found in virgin olive oil.[12] Reboredo-Rodríguez et al.[36] reported that the contents of apigenin, vanillic acid, and *p*-coumaric in extra virgin olive oil were present in minor amounts. Regueiro et al.[37] reported that the liquid chromatography-linear trap quadrupole (LC-LTQ-Orbitrap) analysis had an extensive identification of the phenolic compounds in walnuts. The LC-MS/MS profile of BP-30 °C was similar to the profile of BP-60 °C except for the presence of hesperidin in BP-30 °C extract and *p*-coumaric acid in BP-60 °C extract. The major predominant individual phenolic compounds in BP-30 °C extract were apigenin, luteolin, and quercetin with values of 44.39%, 25.04%, and 10.32% of total phenolic content, respectively, whereas the major predominant individual phenolic compounds in BP-60 °C extract were apigenin, luteolin, and rutin with values of 34.00%, 33.86%, and 25.18% of total phenolic content, respectively. The above results thus indicate the presence of flavonoids (apigenin, luteolin, and rutin) in detectable amounts as both free and bound phenolic compounds, which agrees with previous work showing that apigenin and lutolein are the major flavonoids compounds identified in virgin olive oil.[15] The presence of hesperidin, rutin, and quercetin in olives has been previously reported by Alu'datt et al.[17] On the other hand, Tuck and

Hayball[11] reported that the major phenolic compounds in virgin olive oil are oleuropein, hydroxytyrosol, and tyrosol. The variation in profile of phenolic compounds for olive oil may be due to many factors including degree of olive maturity,[13] and filtration of virgin olive oil during extraction and processing.[14] Storage appears to be a major factor as tyrosol and hydroxytyrosol were found at low concentrations after storage of olive oil for more than six months.[16] Reboredo-Rodríguez et al.[38] reported that the contents of individual phenolic compounds were 19.3−66.8 mg/kg for hydroxytyrosol and tyrosol, 3.3−8.4 mg/kg for apigenin and luteolin, 2.9−5.8 mg/kg for pinoresinol, and trace contents for vanillic acid and *p*-coumaric acid.

**Effect of Removal of Free and Bound Phenolics on Fatty Acids Content.** Table 5 shows the fatty acid composition (g/100 g olive oil) for virgin olive oil before and after removal of free and bound phenolic compounds. The major predominant fatty acids in virgin olive oil in either the presence or absence of phenolic compounds were oleic acid (83.026−83.859%), palmitic acid (7.502−8.008%), and linoleic acid (5.837−6.190%) whereas myristic, palmitoleic, arachidic, eicosenoic, and behenic acids were found in minor amounts. Olive oil after removal of free and bound phenolic compounds showed a significant decrease in oleic acid (C18:1) content while concentrations of palmitoleic, stearic, linoleic, and linolenic acids were increased. The decrease in oleic acid content after removal of free and bound phenolics is likely due to conjugation of oleic acid with phenolic compounds in mono- and diacylglycerols. The alkaline hydrolysis may have released the conjugated complex of oleic acid with phenolic compounds into the extracts. The increased levels of palmitoleic, stearic, linoleic, and linolenic acids may be the result of the breakage of bound phenolic compounds with free fatty acids by alkaline hydrolysis leading to the release of free fatty acids following the methanolic extraction of phenolics. The above findings are suggestive that phenolic compounds can be bound to either oleic acid in mono- and diacyglycerols or to palmitoleic, stearic, linoleic, and linolenic acids as free fatty acids.

Table 5. Fatty Acid Composition (g/100 g Virgin Olive Oil) of Virgin Olive Oil, Virgin Olive Oil after Removal of Free Phenolic Compounds, Virgin Olive Oil after Removal of Free and Bound Phenolics[a]

| fatty acid | formula | olive oil (g/100 g) | olive oil after removal of free phenolics (g/100 g) | olive oil after removal of free and bound phenolics (g/100 g) | SE |

**Effect of Removal of Free and Bound Phenolic Compounds on RP-HPLC Analysis of Acylglycerols.** The RP-HPLC chromatogram of virgin olive acylglycerols before removal of phenolic compounds showed the presence of four major fractions (F1, F2, F3, and F4) (Figure 2a). The chromatogram for olive oil before removal of phenolic compounds was similar to the profile of olive oil after removal of free phenolic compounds except the presence of F1, which was subdivided to three major peaks F1a, F1b, and F1c (Figure 2b). This latter result suggests that the removal of phenolic compounds in F1 may have affected the polarity of acylglycerols. The RP-HPLC chromatogram for olive oil after removal of free and bound phenolic compounds was similar to the chromatogram for olive oil before removal of those phenolics except that fraction F4 was subdivided into three major peaks after hydrolysis, which suggests that alkaline hydrolysis may have led to partial hydrolysis of acylglycerols in fraction F4. Reboredo-Rodríguez et al.[38] and Reboredo-Rodríguez et al.[39] reported that the predominant fatty acids in olive oil were oleic and linoleic acid.

**LC-MS/MS Analysis of Extracted Phenolic Compounds from Fractionated Acylglycerols via RP-HPLC.** Table 6 shows the percent content of free and bound phenolic

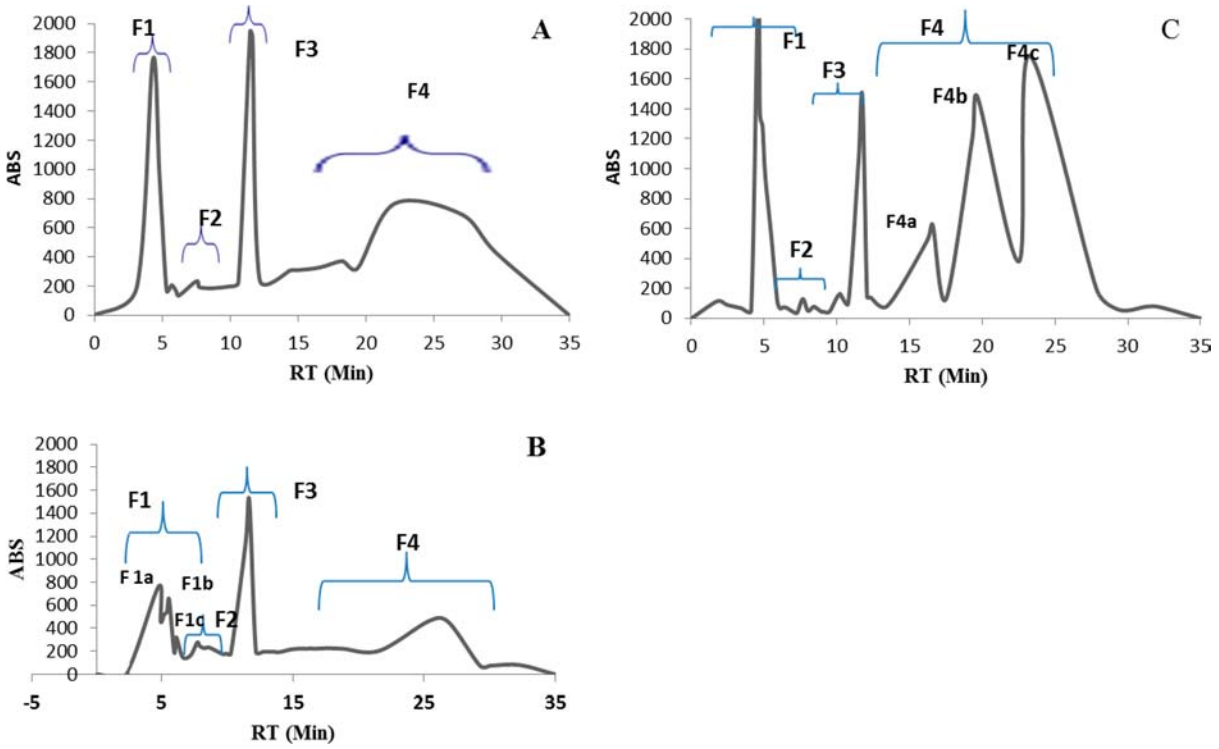

**Figure 2.** RP-HPLC separation for acylgycerols before and after removal of free and bound phenolic compounds from virgin olive oil: (A) olive oil before removal of phenolic compounds, (B) olive oil after removal of free phenolic compounds, (C) olive oil after removal of free and bound phenolic compounds.

[a]Percent of total phenolic content. ND: not detected.

compounds in RP-HPLC fractionated acylglycerols from olive oil before and after removal of the phenolic compounds. The presence of *p*-hydroxybenzoic acid and tyrosol was detected in both the free and acylglycerol-bound form. After removal of the free phenolic compounds, fraction number 1 showed the presence of *p*-hydroxybenzoic acid and tyrosol in the bound form, which were not detected before alkaline hydrolysis. After removal of free and bound phenolic compounds, *p*-hydroxybenzoic acid and tyrosol were not detected. This suggests that *p*-hydroxybenzoic acid and tyrosol were bound to the glycerol fraction. Phenolic compounds were not detected in the other RP-HPLC fractionated glycerols from olive oil either before or after removal of free and bound phenolic compounds. The above study is the first to demonstrate natural lipid and phenolic interactions in virgin olive oil although Alu'datt et al.[40] have previously suggested the presence of lipid−protein−phenolic interaction in oilseeds such as soybean and flaxseed. It appears that phenolic−lipid interaction in virgin olive oil can occur via two pathways that include either interaction of tyrosol with palmitoleic, stearic, linoleic, or linolenic acids in the free form or via interaction of *p*-hydroxybenzoic acid and oleic acid in conjugated form that is located in mono- and diacylglycerols.

Free and bound phenolic extracts from virgin olive oil showed antioxidant action, $\alpha$-amylase, and ACE inhibitory activities as well as antiproliferative effects in two colorectal cancer cell lines. Free phenolic extracts at 30 °C had superior antioxidant activities as compared to bound phenolic extracts whereas bound phenolic extracts at 30 °C had greater $\alpha$-amylase and ACE inhibitory activities than the free phenolic extracts. The major predominant phenolic compounds in free and bound phenolic extracts from virgin olive oil were apigenin, luteolin, and rutin. The presence of natural lipid−phenolic

interactions was indicated via the presence of *p*-hydroxybenzoic acid and tyrosol in the acylglycerol fractions of virgin olive oil. The biological effects demonstrated with the lipid-bound phenolics in the present work require in vivo verification since there is extensive biotransformation of polyphenols by gut microbiota to secondary metabolites. The present findings, however, present the possibility that naturally occurring lipid bound phenolics might affect the bioaccessibility and bioavailability of the phenolic compounds. The present study indicates natural phenolic lipid interactions are present in virgin olive oil that may generate biologically active natural phenolic lipids for use in pharmaceutical and nutraceutical applications.

carried out at 25 ± 2 °C and a relative humidity of 70 ± 10%. The photoperiod inside the rearing room was set to 16/8 h light/dark.

**Collection of Volatiles.** The three replicates of each experimental case were simultaneously collected by SPME using three Supelco SPME holders equipped with polydimethylsiloxane/divinylbenzene fibers (PDMS/DVB; 100 μm film thickness; Supelco Inc., Bellefonte, PA, USA). SPME fibers were conditioned before volatile sampling in a GC injector at 250 °C for 10 min with a He flow rate of 20 mL/min.

Each set of 10 olives was placed inside 50 mL round-bottom flasks with a screw-top connecting adapter. Sampling was static, and each SPME needle was inserted through the septum; then, the fibers were exposed to each sample headspace for 20 h at 25 ± 1 °C. After this period, fibers were removed and inserted into the GC injection port to desorb volatiles.

**Chromatographic and Spectroscopic Analysis.** SPME fibers were thermally desorbed into the GC injection port for 1 min. The injector temperature was set at 250 °C, and it was operated in splitless mode. The extracted volatiles were analyzed by gas chromatography coupled with mass spectrometry (GC-MS) using a Clarus 600 GC-MS from PerkinElmer Inc. (Wellesley, MA, USA), equipped with a ZB-5MS fused silica capillary column (30 m × 0.25 mm i.d. × 0.25 μm; Phenomenex Inc., Torrance, CA, USA). The oven was held at 40 °C for 2 min and then programmed at 5 °C/min to 180 °C and, when reached, raised to 280 °C at 10 °C/min and maintained at 280 °C for 1 min. Helium was used as the carrier gas with a flow of 1 mL/min. The detection was performed in EI mode (ionization energy, 70 eV; source temperature, 180 °C). The spectrum acquisition was performed in scanning mode (mass range $m/z$ 35−500). Chromatograms and spectra were recorded by means of GC-MS Turbomass software version 5.4 (PerkinElmer Inc.). Compounds were identified by comparing their retention indices and mass spectra with those of pure standards and high probability matches (>80%) according to the NIST MS Search routine (NIST Mass Spectral Search Program for the NIST\EPA\NIH mass Spectral Library, version 2.0, build 4/2005).

To confirm the presence of α-copaene and unequivocally identify each isomer, additional olive samples and both α-copaene enantiomer standards were analyzed by chiral GC-FID with a Clarus 500 GC (PerkinElmer Inc.), equipped with an InertCap CHIRAMIX capillary column (30 m × 0.25 mm i.d. × 0.25 μm; GL Sciences Inc.) supplied by Teknokroma Analítica SA (Barcelona, Spain). In this case, the oven was held at 60 °C for 1 min, then programmed at 1 °C/min to 180 °C, and maintained at this temperature for 10 min.

**Chemicals.** All reagents and solvents (reagent grade) were purchased from Sigma-Aldrich (Madrid, Spain) and employed without additional purification unless stated. (+)-α-Copaene (>95% purity by GC) and (−)-α-copaene (>97% purity by GC) were isolated from angelica seed oil (Sigma-Aldrich) or copaiba balsam oil (Sigma-Aldrich) respectively, according to the procedure described by Jacobson et al.[10]

**Oviposition Preference Bioassay.** Twenty mated 8−10-day-old *B. oleae* females were introduced in 30 × 25 × 25 cm PMMA cages and held there for 24 h for acclimation before olive fruits were offered for oviposition test. The flies had free access to food and water at any time.

Green olive fruits used in the experiments were freshly collected from *O. europaea* cv. Serrana and had an equivalent ripening grade (green colored and firm flesh) and size (19−21 mm length). The fruits were gently wiped with a cellulose towel and carefully examined for punctures after 24 h from the collection to ensure that they were uninfested before the assay. A set of 10 olive fruits was placed in a polystyrene 100 × 15 mm Petri dish plate; then, 50 μL of the test solution was dropwise added to each fruit, allowing the solvent to evaporate for 3 min. The test solutions consisted of 1 mg/mL enantiopure α-copaene standard solutions in pentane. Control olive fruits were treated with 50 μL of pentane each.

All treated pairs of olive sets consisting of one α-copaene-added set and one control set were simultaneously offered to the mated females by introducing them inside the assay cage for 240 min. Then, the plates were taken from the cage and allowed to stand for 24 h before examination and recording the number of punctures present in the fruits of each set.

Each experiment was repeated six times in different cages with flies that were not previously used for other bioassays. In each replicate of the assay, the relative position of test substances and control was randomized.

**Statistical Analysis.** Oviposition preference was evaluated by analysis of the ratio of damaged fruits on each set of olives from the offered pair. Ratio of attacked olives (RAO) was calculated by dividing the number of punctured fruits by the total number of fruits for each set. All of the calculated values were transformed to arcsine square root values to normalize the error distribution prior to the analysis of variance (ANOVA). The means were compared and separated by the Tukey−Kramer HSD test at $P = 0.05$. All statistical analyses were conducted using SPSS Statistics version 19 from IBM Corp. (Armonk, NY, USA).

## RESULTS AND DISCUSSION

The first approach for the present study was undertaken by means of a regression analysis between infestation degree and the relative areas of GC-MS peaks obtained from SPME sampling of a set of eight olive cultivars taken from the collection of varieties maintained at CIRGO (Universidad de Córdoba, ceiA3). The sesquiterpene fraction represented ca. 1% of the olive volatile profile for the analyzed samples, but a strong direct correlation was found only between the relative ratio of α-copaene (ranging from approximately 0.015 to 0.15% of the total chromatograms, KI 1381 in a ZB-5MS column) in the volatile fraction of the different samples and their respective percentage of infested olive fruits (Figure 1).

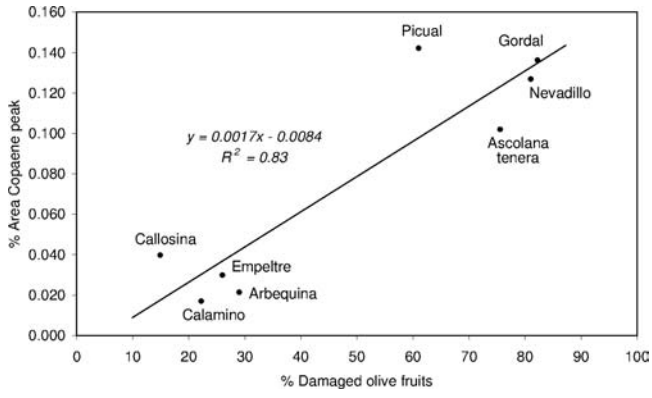

**Figure 1.** Scatter plot of data from different olive varieties according to the percentage of infested fruits and relative α-copaene amount in their volatile profiles. A regression model of these data was obtained by means of least-squares method and provided the depicted line.

This preliminary result encouraged us to carry out a two-year study to determine the changes in the relative amount of α-copaene released from uninfested fruit for a single variety (cv. Serrana) according to their phenological stage as they developed in the tree. This variety is included in the Regulation of Protected Designation of Origin (POD) for Valencian Olive Oil, and it is one of the most cultivated on the east coast of Spain, the latter being the main reason for our selection of this cultivar as it allowed us total availability to collect fresh samples when required.[11] These SPME-GC-MS analyses indicated that α-copaene is not detected until pit hardening is evident (Figure 2); then, the amount of this sesquiterpene rapidly increases to a maximum while the green fruit grows. The subsequent fast decrease of the α-copaene amount is related to fruit ripening,

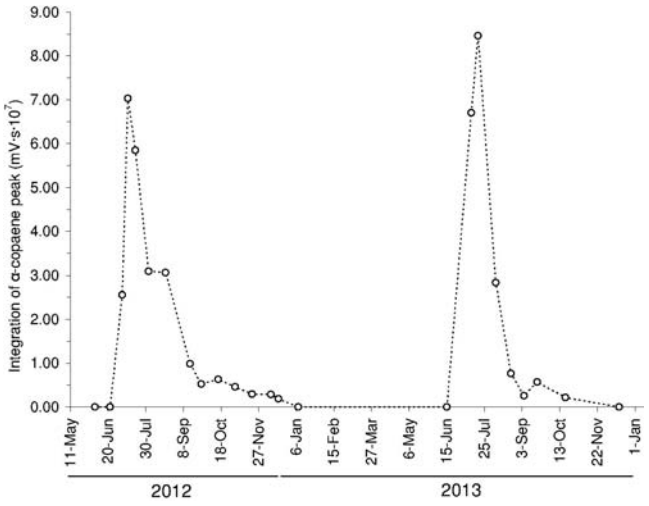

**Figure 2.** Variation of the relative amount of $\alpha$-copaene in the volatile fraction of *Olea europaea* L. cv. Serrana fruits collected at different dates during two years.

and this compound is no longer detected as fruit starts to soften and become darker (Figure 2). These results are in agreement with the decrease of $\alpha$-copaene content in olive oils obtained from fruits at different ripening states found by Vichi et al.[12] On the other hand, it is known that, within a variety, unripe green olives are preferred to ripe red or purple olives, reinforcing the hypothesis that $\alpha$-copaene could play an important role in fruit susceptibility to *B. oleae* attack.[7,13]

Males of many tephritid species are strongly attracted to the odors of particular synthetic or natural compounds.[14] Specifically, angelica seed and root oils from *Angelica archangelica* L. were found to be attractants for the Mediterranean fruit fly (*Ceratitis capitata* Wiedemann).[15] The potent activity of these oils was further attributed to the compound (+)-$\alpha$-copaene, the levorotatory isomer being much less attractive.[10,16] Although $\alpha$-copaene had been widely described as an olive oil volatile, no analysis of its enantiomeric identity has been addressed to date. Given the importance of the compound stereochemistry for the biological activity, the isomeric identity of this compound was assessed in the present study for both Serrana and Picual variety samples, showing a similar ratio of 70:30 for dextro and levo isomers, respectively, by means of chiral GC-FID analysis (according to retention indices of the respective enantiopure standards in a InertCap CHIRAMIX column, KI 1374 and KI 1382 for (+)- and (−)-$\alpha$-copaene, respectively). Although $\alpha$-copaene had been widely described as an olive oil volatile, to our knowledge, no analysis of its enantiomeric identity has been addressed to date.[17−19] In the present study, the isomeric identity of this compound was assessed for both Serrana and Picual variety samples, showing a similar ratio of 70:30 for dextro and levo isomers, respectively, by means of chiral GC-FID analysis according to retention times of the respective enantiopure standards.

To establish the activity of the isomers, an oviposition preference test was carried out for each enantiomer of $\alpha$-copaene from enantiopure standards that were isolated from essential oils and for the racemic mixture prepared from them. The results from these experiments revealed that the addition of (+)-$\alpha$-copaene to olive fruits increases significantly the ratio of attacked olives (Figure 3). On the other hand, the addition of the same amount of (−)-$\alpha$-copaene to olive fruits produced

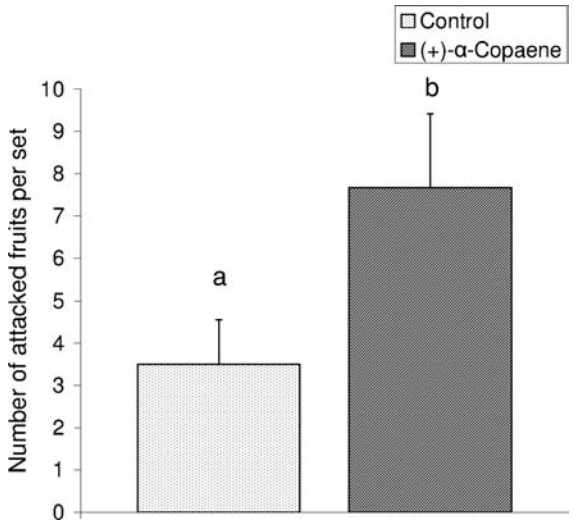

**Figure 3.** Mean (± SD, $N = 6$) number of attacked olive fruits per set in oviposition preference competitive bioassay between olives with added (+)-$\alpha$-copaene and control fruits. Results of ANOVA test performed over arcsine-square root transformed values of RAO: $F_{1,10} = 42.26$, $P < 0.001$. Bars with the same letters are not significantly different by means of Tukey−Kramer HSD test at $P = 0.05$.

no significant differences in this parameter when compared to control (Figure 4). Finally, no synergistic or detrimental effects of the levorotatory isomer on the activity of (+)-$\alpha$-copaene were observed when a racemic mixture was assessed (Figure 5).

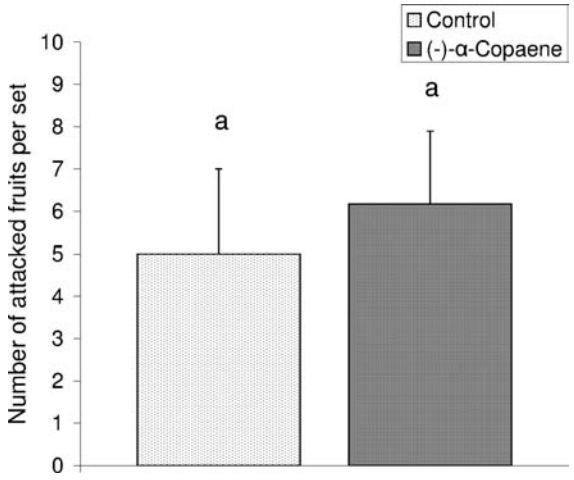

**Figure 4.** Mean (± SD, $N = 6$) number of attacked olive fruits per set in oviposition preference competitive bioassay between olives with added (−)-$\alpha$-copaene and control fruits. Results of ANOVA test performed over arcsine-square root transformed values of RAO: $F_{1,10} = 4.07$, $P = 0.08$. Bars with the same letters are not significantly different by means of Tukey−Kramer HSD test at $P = 0.05$.

The results of the present work showed that (+)-$\alpha$-copaene is clearly contributing to an increase in the susceptibility of olive fruits to attack by *B. oleae* females. Nevertheless, as suggested in previous studies carried out by other authors, it is likely that a combination of several factors is affecting the ovipositional preference for this insect−plant system.[20,21] This is the first study on the effect of the olive-occurring volatile compound $\alpha$-copaene on the behavior of *B. oleae*, contributing to a better understanding of the chemical ecology between this

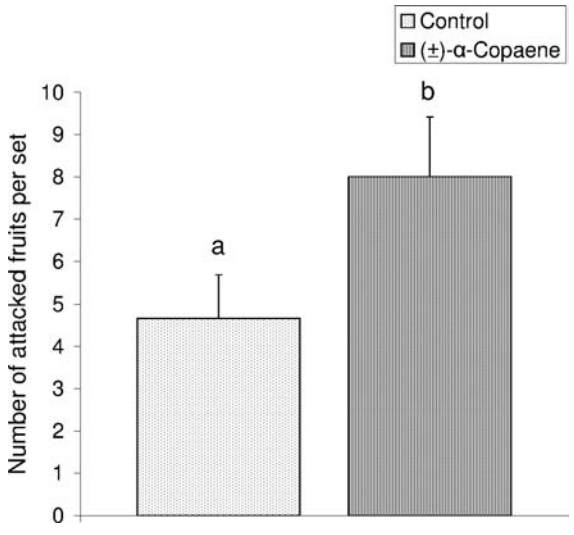

**Figure 5.** Mean (± SD, $N = 6$) number of attacked olive fruits per set in oviposition preference competitive bioassay between olives with added (±)-α-copaene and control fruits. Results of ANOVA test performed over arcsine-square root transformed values of RAO: $F_{1,10} = 91.62$, $P < 0.001$. Bars with the same letters are not significantly different by means of Tukey–Kramer HSD test at $P = 0.05$.

pest and its host, which may result in the development of new control strategies.

Further, to develop high viscous base stocks, the unsaturation in branched mono- and polyol esters was modified to the acylated derivatives. The base stocks with the above modifications are novel and are reported for the first time.

## MATERIALS AND METHODS

**Materials.** Sal fat was procured from M/s. Paras Vanaspathi, Raipur, India. Hydrogen peroxide, formic acid, sulfuric acid, acetic acid, 4 N hydrobromic acid, iodine monochloride (ICl), potassium hydroxide, hydrochloric acid, *n*-butanol, pyridine, chloroform, acetic anhydride, 2-ethylhexanol (2-EtH), NPG, TMP, *p*-tolunesulfonic acid (p-TSA), 4-(dimethylamino)pyridine (DMAP), xylene, aluminum oxide active basic, sodium hydroxide (NaOH), methanol, urea, and sodium sulfate were procured from M/s SD. Fine chemicals Pvt. Ltd., (Mumbai, India). Propionic, butyric, and hexanoic anhydrides were procured from Sigma-Aldrich (St. Louis, MO, U.S.A.). Hexane, methanol, and ethyl acetate were purchased from Industrial Solvents and Chemicals Pvt. Ltd. (Mumbai, India). All the solvents and reagents were of analytical grade and used directly without purification.

**Methods.** *Spectral Analysis.* Infrared (IR) spectra were obtained on a 1600 FT-IR PerkinElmer Spectrometer (Norwalk, CT) with a liquid film between NaCl cells. Proton nuclear magnetic resonance ($^1$H NMR) spectra were recorded in $CDCl_3$ on Avance 300 MHz spectrometer. Chemical shifts relative to TMS as internal standard are given as $\delta$ values in ppm. Carbon nuclear magnetic resonance ($^{13}$C NMR) spectra were recorded in $CDCl_3$ on a Varian (75 MHz) spectrometer.

*Thermogravimetric Analysis (TGA).* TGA studies were carried out in nonisothermal mode in a Mettler Toledo TGA instrument to get the decomposition pattern of the base stocks. About 5 mg of the sample was taken in an aluminum crucible and heated slowly up to 600 °C at a rate of 10 °C/min under nitrogen atmosphere. The TGA degradation onset temperature was obtained by extrapolating the horizontal baseline and intercept of this line with tangent to the downward portion of the weight curve was taken as onset temperature.

*Physico-Chemical Analyses.* The lubricant properties namely, acid value, hydroxyl value, density, specific gravity, kinematic viscosity, viscosity index, pour point, flash point, copper corrosion, TGA degradation onset temperature, oxidative stability, weld load, and wear of the lubricant base stocks were also determined using standard AOCS and ASTM methods. All the analyses were carried out in duplicates and the results are the average of the two values.

**Procedure for Enrichment of Unsaturation in Sal Fatty Acids.** Sal fatty acid methyl esters (SFAME) 100 g were taken in methanol (1000 mL, 1:10 w/v ratio of SFAME) and urea (200 g, 1:2 w/w ratio of SFAME) was added. The contents were stirred mechanically under reflux until urea was completely dissolved. The contents were cooled to room temperature and stored at 0−5 °C for 12 h. The material was then filtered to remove urea complex and concentrated. The filtrate was extracted with hexane, washed with diluted HCl to remove traces of urea followed by water until it was acid free.[22] The hexane extract was concentrated on rotary evaporator to obtain oleic acid rich SFAME (51 g, 51% yield). The fatty acid composition of enriched SFAME (72.6%, by GC) is shown in Table 1.

The enriched sal fame was hydrolyzed to get oleic acid rich sal fatty acids (ORSFA). ORSFA was further reacted with branched monoalcohol (2-ethylhexanol) and polyols (NPG, TMP) in the presence of a p-TSA and xylene medium at 135−140 °C to obtain corresponding oleic acid rich branched mono and polyol esters (ORS2-EtHE, ORSNPGE, ORSTMPE).[17]

**Table 1. Fatty Acid Composition (wt %) of Oleic Acid Rich Sal Fat**

| | fatty acid composition (wt %) | | | | |
|---|---|---|---|---|---|
| sample name | 16:0 | 18:0 | 18:1 | 18:2 | 20:0 |
| oleic acid rich sal FAME | 9.5 | 15.8 | 67.7 | 4.9 | 2.1 |

**Hydroxylation of Oleic Acid Rich Sal 2-Ethylhexyl Esters.** In a typical experiment, ORS2-EtHE (300 g, 0.764 mol), formic acid (85%) (43.35 mL, 1.14 mol), and concentrated sulfuric acid (3.37 mL, 2% weight of formic acid and hydrogen peroxide) were stirred under mechanical stirring at 5−10 °C. Hydrogen peroxide solution, 30% concentration (234.23 mL, 2.29 mol), which was pre-equilibrated at the same temperature was added slowly to the contents through addition funnel for a period of 2 h. This precaution was taken to prevent over heating of the system due to the exothermic nature of epoxidation. After addition of the $H_2O_2$ the temperature was slowly raised to 60 °C. After 3 h, the temperature of the reaction was raised to 90 °C and stirred for 24 h. The course of the reaction was monitored by withdrawing aliquots of the reaction mixture at various time intervals and analyzed for oxirane value. After complete conversion, the reaction mixture was cooled, extracted with ethyl acetate, and washed with water until it was acid free. The final product was analyzed for acid value, oxirane value, iodine value, and hydroxyl value. The structure of hydroxylated ORS2-EtHE was characterized by IR, $^1$H NMR, and $^{13}$C NMR.

A similar procedure was followed for the preparation of hydroxy ORSNPGE (HydORSNPGE) and hydroxy ORSTMPE (HydORSTMPE) taking ORSNPGE (0.477 mol), formic acid (46.1 mL, 1.19 mol), sulfuric acid (3.5 mL), and hydrogen peroxide solution, 30% concentration (2.38 mol); ORSTMPE (0.325 mol), formic acid (37.78 mL, 0.97 mol), sulfuric acid (3.26 mL), and hydrogen peroxide solution, 30% concentration (2.28 mol) respectively. The hydroxylated polyol esters were analyzed for acid, oxirane, iodine, and hydroxyl values. The structures of the compounds were characterized by IR, $^1$H NMR, and $^{13}$C NMR.

**HydORS2-EtHE.** IR (neat, cm$^{-1}$): 3448 (—OH), 2925 (C—H), 1736 (—C═O), 1168 (C—(C═O)—O); $^1$H NMR ($CDCl_3$, $\delta$ ppm): 0.89 (t, C$\underline{H}_3$—CH$_2$—), 1.19−1.41 (m, (—C$\underline{H}_2$—)$_n$), 1.46−1.51 (m, —CH(OH)—C$\underline{H}_2$—), 1.54−1.72 (m, —CH$_2$—C$\underline{H}_2$—CH$_2$—C═O), 2.31 (t, —CO—C$\underline{H}_2$—CH$_2$—), 3.36−3.45 (m, —C$\underline{H}$—OH), 3.98 (d, —CH—C$\underline{H}_2$—O—CO—CH$_2$—); $^{13}$C NMR ($CDCl_3$, $\delta$ ppm): 10.96, 14.02, 14.08, 22.64, 22.95, 23.76, 24.94, 25.03, 25.56, 25.64, 28.89−29.67, 30.38, 31.89, 34.36, 34.43, 38.70, 66.63, 74.49, 174.09.

**HydORSNPGE.** IR (neat, cm$^{-1}$): 3460 (—OH), 2928 (C—H), 1740 (—C═O), 1162 (C—(C═O)—O); $^1$H NMR ($CDCl_3$, $\delta$ ppm): 0.88 (t, C$\underline{H}_3$-CH$_2$—), 0.96 (s, C$\underline{H}_3$—C—C$\underline{H}_3$), 1.14−1.39 (m, (—C$\underline{H}_2$—)$_n$), 1.40−1.53 (m, —CH(OH)—C$\underline{H}_2$—), 1.54−1.7 (m, —CH$_2$—C$\underline{H}_2$—CH$_2$—C═O), 2.31 (t, —CO-—C$\underline{H}_2$—CH$_2$—), 3.36−3.45 (m, —C$\underline{H}$—OH), 3.87 (s, —C—C$\underline{H}_2$—O—CO—CH$_2$—); $^{13}$C NMR ($CDCl_3$, $\delta$ ppm): 14.08, 21.7, 22.63, 23.83, 24.93, 25.51, 25.63, 28.98−29.88, 31.83, 33.54, 34.21, 34.56, 68.95, 74.39, 74.45, 173.77.

**HydORSTMPE.** IR (neat, cm$^{-1}$): 3461 (—OH), 2924 (C—H), 1742 (—C═O), 1160 (C—(C═O)—O). $^1$H NMR ($CDCl_3$, $\delta$ ppm): 0.88 (t, C$\underline{H}_3$—CH$_2$—), 1.21−1.38 (m, (—C$\underline{H}_2$—)$_n$), 1.44−1.53 (m, —CH(OH)—C$\underline{H}_2$—, —C—C$\underline{H}_2$—CH$_3$), 1.54−1.67 (m, —CH$_2$—C$\underline{H}_2$—CH$_2$—C═O), 2.30 (t, —CO—C$\underline{H}_2$—CH$_2$—), 3.36−3.43 (m, —C$\underline{H}$—OH), 4.01 (s, —C—C$\underline{H}_2$—O—CO—CH$_2$—); $^{13}$C NMR ($CDCl_3$, $\delta$ ppm): 7.30, 14.08, 22.6, 22.9, 23.8, 24.87, 25.65, 28.9−29.6, 31.83, 33.54, 34.12, 40.5, 42.7, 63.62, 74.4, 173.5.

**Propionylation of HydORS2-EtHE.** HydORS2-EtHE (300 g, 0.716 mol), propionic anhydride (2.148 mol), DMAP (0.3 g, 0.1% DMAP based on weight of HydORS2-EtHE), and xylene (150 mL) were taken in a three-necked round-bottom flask and stirred at 135−140 °C for 8 h. The progress of the reaction was monitored by TLC using hexane/ethyl acetate (80:20 v/v) and IR. The crude product was distilled at 140 °C and 5 mm Hg to remove excess propionic anhydride and xylene. The residue was extracted into ethyl acetate, washed with water, passed over anhydrous sodium sulfate, and concentrated using a rotary evaporator and dried under reduced pressure to obtain acylated product. The product was further purified to remove traces of propionic acid by passage through a basic alumina column to obtain propionylated ORS2-EtHE (PrORS2-EtHE) with an acid value of <0.2. The product was analyzed for hydroxyl value. The

structure of the product was confirmed by IR, $^1$H NMR, and $^{13}$C NMR spectral studies.

Similar procedure was followed for the butanoylation and hexanoylation of HydORS2-EtHE (HydORS2-EtHE) and alkanoylation of HydORSNPGE and HydORSTMPE, by taking HydORSNPGE (300 g, 0.439 mol) and alkanoic anhydride (2.198 mol); HydORSTMPE (300 g, 0.439 mol) and alkanoic anhydride (2.097 mol), respectively. The products were analyzed for acid and hydroxyl values. The structures of all the alkanoylated esters were confirmed by IR, $^1$H NMR, and $^{13}$C NMR spectral studies.

**Propionylated Esters of Oleic Acid Rich Sal 2-Ethylhexyl Esters (PrORS2-EtHE).** IR (neat, cm$^{-1}$): 2928 (C—H), 1739 (—C═O), 1182 (C—(C═O)—O); $^1$H NMR ($CDCl_3$, $\delta$ ppm): 0.85–0.92 (m, C$\underline{H}_3$—CH$_2$—), 1.15 (t, C$\underline{H}_3$—CH$_2$–C═O), 1.20–1.39 (m, (—C$\underline{H}_2$—)$_n$), 1.47–1.53 (m, —C$\underline{H}_2$—CH—CO), 1.53–1.65 (—C$\underline{H}_2$—CH$_2$—C═O), 2.26–2.40 (m, —CH$_2$—C$\underline{H}_2$—C═O), 3.94–4.02 (m, —CH—C$\underline{H}_2$—O—CO—), 4.98–5.03 (m, O═C—O—C$\underline{H}$—); $^{13}$C NMR ($CDCl_3$, $\delta$ ppm): 9.25, 10.94, 13.99, 22.63, 22.93, 23.71, 24.90, 25.05, 27.61, 28.86–29.65, 30.34, 30.66, 31.77, 31.86, 34.33, 34.39, 38.66, 66.56, 73.57, 173.97, 174.09.

**Butanoylated Esters of Oleic Acid Rich Sal 2-Ethylhexyl Esters (BuORS2-EtHE).** IR (neat, cm$^{-1}$): 2929 (C—H), 1736 (—C═O), 1178 (C—(C═O)—O);$^1$H NMR ($CDCl_3$, $\delta$ ppm): 0.86–0.91 (m, C$\underline{H}_3$—CH$_2$—), 0.95 (t, C$\underline{H}_3$—(CH$_2$)$_2$—C═O), 1.19–1.39 (m, (—C$\underline{H}_2$—)$_n$), 1.47–1.53 (m, —C$\underline{H}_2$—CH—CO), 1.53–1.71 (—C$\underline{H}_2$—CH$_2$—C═O), 2.26–2.33 (m, —CH$_2$—C$\underline{H}_2$—C═O), 3.94–4.02 (m, —CH—C$\underline{H}_2$—O—CO—), 4.98–5.03 (m, O═C—O—C$\underline{H}$—); $^{13}$C NMR ($CDCl_3$, $\delta$ ppm): 10.96, 13.66, 14.00, 18.52, 22.61, 22.94, 23.76, 24.94, 25.03, 25.08, 28.89–29.66, 30.38, 30.73, 31.79, 31.89, 34.35, 34.42, 36.25, 38.71, 66.60, 73.48, 173.15, 174.00.

**Hexanoylated Esters of Oleic Acid Rich Sal 2-Ethylhexyl Esters (HeORS2-EtHE).** IR (neat, cm$^{-1}$): 2927 (C—H), 1735 (—C═O), 1171 (C—(C═O)—O); $^1$H NMR ($CDCl_3$, $\delta$ ppm): 0.85–0.92 (m, C$\underline{H}_3$—CH$_2$—), 1.20–1.39 (m, (—C$\underline{H}_2$—)$_n$), 1.46–1.52 (m, —C$\underline{H}_2$—CH—CO), 1.53–1.67 (—C$\underline{H}_2$—CH$_2$—C═O), 2.26–2.34 (m, —CH$_2$—C$\underline{H}_2$—C═O), 3.94–4.01 (m, —CH—C$\underline{H}_2$—O—CO—), 4.98–5.03 (m, O═C—O—C$\underline{H}$—); $^{13}$C NMR ($CDCl_3$, $\delta$ ppm): 10.94, 13.85, 13.99, 22.28, 22.63, 22.92, 23.71, 24.70, 24.90, 24.99, 25.07, 28.86–29.65, 30.34, 30.72, 31.27, 31.77, 31.86, 34.30, 38.66, 66.56, 73.43, 173.33, 173.97.

**Propionylated Esters of Oleic Acid Rich Sal NPG Esters (PrORSNPGE).** IR (neat, cm$^{-1}$): 2927 (C—H), 1740 (—C═O), 1177 (C—(C═O)—O); $^1$H NMR ($CDCl_3$, $\delta$ ppm): 0.88 (t, C$\underline{H}_3$—CH$_2$—), 0.96 (s, C$\underline{H}_3$—C—C$\underline{H}_3$), 1.15 (t, C$\underline{H}_3$—CH$_2$—C═O), 1.2–1.35 (m, (—C$\underline{H}_2$—)$_n$), 1.44–1.53 (m, —C$\underline{H}_2$—CH—CO), 1.54–1.67 (m, —C$\underline{H}_2$—CH$_2$—C═O), 2.27–2.40 (m, —CH$_2$—C$\underline{H}_2$—C═O), 3.88 (s, —C—C$\underline{H}_2$—O—CO—CH$_2$—), 4.98–5.03 (m, O═C—O—C$\underline{H}$—); $^{13}$C NMR ($CDCl_3$, $\delta$ ppm): 9.28, 14.08, 21.7, 22.63, 23.74, 24.85, 24.93, 25.05, 27.61, 29.03–29.88, 30.66, 31.77, 31.83, 32.9, 34.18, 34.56, 68.95, 73.61, 173.65, 173.97.

**Butanoylated Esters of Oleic Acid Rich Sal NPG Esters (BuORSNPGE).** IR (neat, cm$^{-1}$): 2926 (C–H), 1736 (—C═O), 1175 (C—(C═O)—O); $^1$H NMR ($CDCl_3$, $\delta$ ppm): 0.88 (t, C$\underline{H}_3$—CH$_2$—), 0.91–1.01 (m, C$\underline{H}_3$—C—C$\underline{H}_3$, C$\underline{H}_3$—(CH$_2$)$_2$—C═O), 1.19–1.36 (m, (—C$\underline{H}_2$—)$_n$), 1.45–1.54 (m, —C$\underline{H}_2$—CH—CO), 1.55–1.73 (m, —C$\underline{H}_2$—CH$_2$—C═O), 2.3 (t, —CH$_2$—C$\underline{H}_2$—C═O), 3.87 (s, —C—C$\underline{H}_2$—O—CO—CH$_2$—), 4.97–5.05 (m, O═C—O—C$\underline{H}$—); $^{13}$C NMR ($CDCl_3$, $\delta$ ppm): 7.3, 13.87, 14.07, 22.3, 22.6, 22.86, 24.73, 24.87, 25.1, 28.99–29.64, 30.72, 31.27, 31.77, 34.09, 34.30, 40.5, 63.56, 73.42, 173.32.

**Hexanoylated Esters of Oleic Acid Rich Sal NPG Esters (HeORSNPGE).** IR (neat, cm$^{-1}$): 2927 (C—H), 1740 (—C═O), 1170 (C—(C═O)—O); $^1$H NMR ($CDCl_3$, $\delta$ ppm): 0.86–0.91 (m, C$\underline{H}_3$—CH$_2$—, —CO—(CH$_2$)$_4$—C$\underline{H}_3$), 0.96 (s, C$\underline{H}_3$—C—C$\underline{H}_3$), 1.20–1.36 (m, (—C$\underline{H}_2$—)$_n$), 1.46–1.53 (m, —C$\underline{H}_2$—CH—CO), 1.54–1.66 (m, —C$\underline{H}_2$—CH$_2$—C═O), 2.26–2.35 (m, —CH$_2$—C$\underline{H}_2$—C═O), 3.87 (s, —C—C$\underline{H}_2$—O—CO—CH$_2$—), 4.97–5.03 (m, O═C—O—C$\underline{H}$—); $^{13}$C NMR ($CDCl_3$, $\delta$ ppm): 13.88, 14.08, 21.72, 22.3, 22.65, 23.75, 24.73, 24.96, 25.1, 26.04, 26.14, 29.06–29.9, 30.74, 31.3, 31.78, 31.89, 32.93, 34.2, 34.27, 34.33, 34.46, 34.61, 38.53, 42.8, 68.96, 73.46, 73.72, 173.32, 173.61, 173.71.

**Propionylated Esters of Oleic Acid Rich Sal TMP Esters (PrORSTMPE).** IR (neat, cm$^{-1}$): 2926 (C—H), 1741 (—C═O), 1180 (C—(C═O)—O); $^1$H NMR ($CDCl_3$, $\delta$ ppm): 0.88 (t, C$\underline{H}_3$—CH$_2$—), 1.15 (t, C$\underline{H}_3$—CH$_2$—C═O), 1.2–1.36 (m, (—C$\underline{H}_2$—)$_n$), 1.42–1.54 (m, —C$\underline{H}_2$—CH—CO), 1.55–1.66 (—C$\underline{H}_2$—CH$_2$—C═O), 2.24–2.42 (m, —CH$_2$—C$\underline{H}_2$—C═O), 4.0 (s, —C—C$\underline{H}_2$—O—CO—CH$_2$—), 4.96–5.05 (m, O═C—O—C$\underline{H}$—); $^{13}$C NMR ($CDCl_3$, $\delta$ ppm): 7.3, 9.25, 14.05, 22.63, 22.86, 23.74, 24.84. 25.05, 27.6, 28.88–29.64, 30.66, 31.83, 34.12, 40.49, 63.56, 73.61, 173.38, 173.97.

**Butanoylated Esters of Oleic Acid Rich Sal TMP Esters (BuORSTMPE).** IR (neat, cm$^{-1}$): 2926 (C—H), 1740 (—C═O), 1177 (C—(C═O)—O); $^1$H NMR ($CDCl_3$, $\delta$ ppm): 0.88 (t, C$\underline{H}_3$—CH$_2$—), 0.95 (t, —CO—(CH$_2$)$_2$—C$\underline{H}_3$), 1.2–1.34 (m, (—C$\underline{H}_2$—)$_n$), 1.44–1.53 (m, —C$\underline{H}_2$—H—CO), 1.53–1.71 (—C$\underline{H}_2$—CH$_2$—C═O), 2.25–2.34 (m, —CH$_2$—C$\underline{H}_2$—C═O), 2.38 (t, —CH$_2$—C$\underline{H}_2$—C═O), 4.01 (s, —C—C$\underline{H}_2$—O—CO—CH$_2$—), 4.97–5.03 (m, O═C—O—C$\underline{H}$—); $^{13}$C NMR ($CDCl_3$, $\delta$ ppm): 7.3, 13.64, 14.05, 18.5, 22.63, 22.89, 23.739, 24.87, 25.07, 29.20, 29.64, 30.72, 31.83, 34.12, 36.22, 40.50, 63.57, 73.46, 173.13, 173.42.

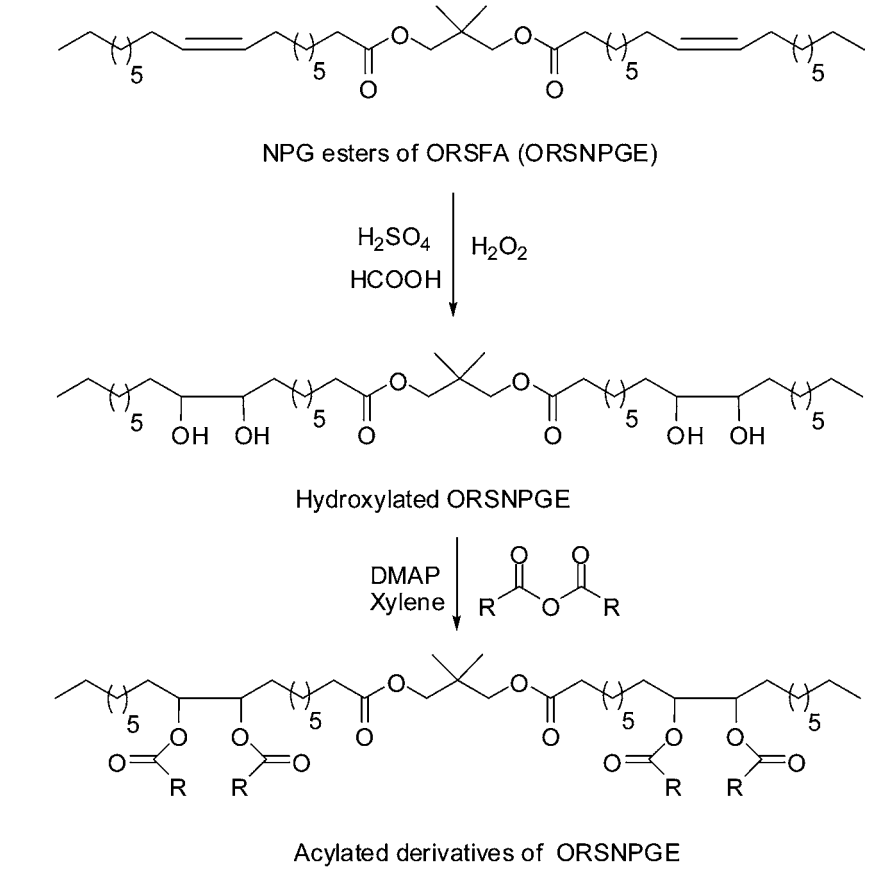
**Hexanoylated Esters of Oleic Acid Rich Sal TMP Esters (HeORSTMPE).** IR (neat, cm$^{-1}$): 2927 (C—H), 1740 (—C═O), 1168 (C—(C═O)—O); $^1$H NMR ($CDCl_3$, $\delta$ ppm): 0.83–0.95 (m, C$\underline{H}_3$—CH$_2$—, —CO—(CH$_2$)$_4$—C$\underline{H}_3$), 1.21–1.37 (m, (—C$\underline{H}_2$—)$_n$), 1.43–1.53 (m, —C$\underline{H}_2$—CH—CO), 1.55–1.69 (m, —C$\underline{H}_2$—CH$_2$—C═O), 2.24–2.41 (m, —CH$_2$—C$\underline{H}_2$—C═O), 4.01 (s, —C—C$\underline{H}_2$—O—CO—CH$_2$—), 4.95–5.06 (m, O═C—O—C$\underline{H}$—); $^{13}$C NMR ($CDCl_3$, $\delta$ ppm): 7.3, 13.87, 14.08, 22.28, 22.6, 22.86, 24.78, 25.1, 29.03–29.67, 30.72, 31.27, 31.82, 34.24, 40.49, 63.56, 73.43, 173.33.

## RESULTS AND DISCUSSION

Sal fat (containing 56.5% saturated fatty acids) based polyol esters synthesized in our earlier study[17] showed viscosities ranging between ISO viscosity grades 10 to 68 suitable for high temperature applications. However, the base stocks were found to exhibit high pour points.[17] With this background, an attempt was made to further chemically modify sal fat to generate high viscosity base stocks which are in more demand for high temperature industrial applications such as gear oil applications (involving BS 150 lubricant base stocks), forging lubricants and metal working fluids. As these base-stocks require very high viscosities and low pour points, sal fatty acids were chemically modified employing a four step process. Initially, oleic acid rich sal fatty acid esters were prepared employing urea complexation method and then hydrolyzed to get oleic acid rich sal fatty acids. These fatty acids were esterified with branched mono- and polyols such as 2-EtH, NPG, and TMP to prepare esters in 95.5 to 93% yields.

The branched mono- and polyol esters were hydroxylated using one pot synthesis of epoxidation followed by hydroxylation using Prilezhaev dihydroxylation method.[23] The hydroxylated products were analyzed for oxirane value, hydroxyl value, and iodine value and characterized using spectral techniques. The products with low oxirane < 0.1, iodine ≤ 1.5, and high hydroxyl values of 168–119, indicated complete hydroxylation of branched mono- and polyol esters. The presence of prominent —OH stretching band (~3450) as observed in IR spectra along with disappearance of ═C—H and epoxy stretching bands supported the complete hydroxylation. The presence of a multiplet at ~1.40–1.53 ppm related to —CH(OH)—C$\underline{H}_2$— and multiplet at ~3.36–3.45 ppm related to —C$\underline{H}$—OH in $^1$H NMR and also characteristic

**Scheme 1. Synthesis of Acylated Neopentyl Glycol Esters of Oleic Acid Rich Sal Fatty Acids**



peaks at ~74.5 ppm related to $C_9$ and $C_{10}$ hydroxyl carbons in $^{13}C$ NMR further confirmed complete hydroxylation.

Further, the hydroxylated branched mono- and polyol esters were acylated by using propionic anhydride, butyric anhydride, and hexanoic anhydrides in the presence of DMAP and xylene medium at 135−140 °C, as branching helps in reducing the pour points and improving oxidation stability.[24] The progress of the reaction was monitored by TLC using hexane/ethyl acetate (80:20 v/v) and IR spectra. The lower hydroxyl value (≤3.1) indicated the completion of acylation. A total of nine products were prepared and thoroughly characterized using spectral data (IR, $^1H$ NMR, and $^{13}C$ NMR). The scheme involved in the preparation of the above esters is shown by taking NPG esters of ORSFA acylation as a representative in Scheme 1.

In IR spectra, the noticeable disappearance of −O−H stretching band in the region of (~3450) $cm^{-1}$ and appearance of prominent intensity of carbonyl functionality at ~1740 $cm^{-1}$ were also observed; this is due to increasing the ester functionality in the products confirming complete acylation.

In $^1H$ NMR spectra, the presence of triplet at 1.15 ppm related to methyl protons of the propanoyl side chain, multiplet at 4.98−5.03 ppm related to acylated $C_9$ and $C_{10}$ protons and also increase in area of peak at 2.2−2.4 ppm, related to methylene protons $\alpha$ to the corbonyl group of the acyl side chain, indicated the complete propanoylation of branched mono- and polyol esters. In butanoylation the presence of new peak, triplet at 0.95 ppm related to methyl protons of the butanoyl side chain and multiplet at 4.98−5.03 ppm related to acylated $C_9$ and $C_{10}$ protons and also increase in area of peak at around 2.2−2.3 ppm, related to methylene protons $\alpha$ to the corbonyl group of the acyl side chain, confirmed the butanoylation of branched mono- and polyol esters. The presence of multiplets at around 0.83−0.95 ppm, 4.98−5.03 ppm related to acylated $C_9$ and $C_{10}$ protons and also increasing the area of peak at 2.26−2.4 ppm due to methylene protons $\alpha$ to the carbonyl group of the acyl side chain confirmed the complete hexanoylation of branched mono- and polyol esters. The dissappearance of multiplet at 3.36−3.45 ppm related to −C<u>H</u>−OH further supported the acylation.

In $^{13}C$ NMR spectra, the peaks at around 9.25 ppm related to propanoyl side chain methyl carbon, 73.6 ppm of $C_9$ and $C_{10}$ carbons of propanoylated esters and 173.97 ppm confirmed the propanoylation. The peaks at around 13.7 ppm related to butanoyl side chain methyl carbon, $C_9$ and $C_{10}$ carbons of butanoylated esters 73.4 and 173.4 ppm indicates the butanoylation. The presence of peaks at 13.88 ppm related to hexanoyl side chain methyl carbon, 73.4 ppm of $C_9$ and $C_{10}$ carbons of hexanoylated esters and 173.4 ppm confirmed the hexanoylation of branched mono- and polyol esters.

All the nine base-stocks were characterized for lubricant properties such as density, specific gravity, kinematic viscosity, viscosity index, pour point, flash point, thermogravimetric analysis (TGA), rotating pressurized vessel oxidation test

(RPVOT), weld load, and wear (Tables 2, 3 and 4) using standard test methods.

**Kinematic Viscosity.** Viscosity of lubricant is the resistance to flow and is directly related to the film formation. It was observed that in case of acylated TMP esters of oleic acid rich sal fatty acids the viscosities ranged between 427 to 468 cSt at 40 °C which could be due to larger number of acyl groups.[18] A lubricant oil with high viscosity flows very slowly and is good to

form stable film between two moving surfaces.[25] The base-stocks in this viscosity range lie within the viscosity of BS 150 mineral oil and those required for high temperature applications such as forging lubricants and metal working fluids. With the shift in polyol from TMP to NPG, the viscosities of the corresponding acylated NPG esters (268.81 to 318.84 cSt) showed a decrease by about 150−200 units. This could be due to the smaller number of acyl groups and difference in molecular size compared to TMP esters. Similar observations were found in case of rubber based polyol esters.[16] These viscosities are related to ISO VG 320 and well suited for the industrial applications such as SAE gear oil No. 80W-140, bearing lubricants and positive displacement blowers, forging lubricants and metal working fluids. On further acylation of 2-ethylhexyl esters, the viscosities drastically fell by several folds ranging from 20.94 to 23.44 cSt, related to ISO VG 22 viscosity grade base stocks. These low viscosity grade base stocks are in more demand today in several industrial applications.[9]

Among the nine acylated TMP, NPG, and 2-EtH esters, the viscosities and densities were found to decrease as the alkyl chain increased from propyl to butyl, butyl to hexanoylated polyol esters. The degree of attenuation in viscosity of acylated lubricant basestocks was observed with increased substituent group chain length. This could be the effect of branching in the chain, which tends to introduce sphericity in the molecule, causing attenuation in the viscosity.[8] Similar observations were found in viscosities of acylated derivatives of milkweed oil,[8] branched polysaccharides,[26] branched synthetic polymers[27,28] and oligomerized estolides of oleic acid.[29]

**Viscosity Index (VI).** VI describes the change of viscosity with change in temperature. A high VI indicates there is little change over a wide temperature range. The acylated polyol esters exhibited high viscosity indices ranging from 138 to 157 in acylated TMP esters, 142−150 in acylated NPG esters and 137−150 in the acylated 2-ethylhexyl esters indicating their multirange applications.[15,30] Even though the VI increased with the molecular weight of the acyl group, it slightly decreased with branching. A similar trend was reported by Yao et al.[31] for ricinoleic acid−based acylated products. The VI values of the reported acylated derivatives are comparable to those of synthetic oils and superior to those of mineral oils.[8,9,32,33] Based on viscosity index, sal oleic acid rich acylated polyol esters belong to group II and group III, category of base fluids as per API classification. The viscosity indices are also well within the specifications required for BS 150 mineral oil base stocks, forging, and metal working fluid applications.

**Pour Point.** Pour point indicates the low temperature fluidity of lubricants. Vegetable oils have a tendency to form macrocrystalline structures at low temperature through uniform stacking of the "bend" triacylglycerol backbone. Such macro-crystals restrict the easy flow of the system due to loss of kinetic energy of individual molecules during self-stacking. The property can be improved by increasing the unsaturation and modification at the unsaturation and also at −COOH. Presence of a polyol and branched mono alcohol attached to the fatty acid does not allow the molecules to come closer due to steric interactions, preventing easy stacking of the individual molecules resulting in better fluidity of the total mixture. Among the nine base stocks, acylated TMP esters of oleic acid rich sal fatty acids exhibited high pour points (3 to 9 °C) compared to the corresponding acylated NPG (−3 to 3 °C) and acylated 2-EtH esters of oleic acid rich sal fatty acids (−3 to −6 °C). It was observed that the pour points of the base stocks under study are much lower compared to corresponding sal fatty acid based branched mono and polyol esters.[17] This could be due to effective disruption of molecular packing in the former with high degree of branching due to acylated groups compared to the later. The pour points of TMP esters are higher compared to that of BS 150 mineral oil base stocks, which can be further reduced by using appropriate pour point depressants and diluents.[14] The pour point decreased with branching as seen in the corresponding acylated 2-ethylhexyl esters of oleic acid rich sal fatty acids (−6 to −3 °C). Similar observation was reported for acylated jatropha alkyl esters[9] and acylated soy bean oil derivatives.[13] The base stocks with low pour points are useful for machine tool and hydraulic systems applications.[34]

**Flash Point.** Flash point is useful in determining a biolubricant volatility, fire resistance, and transportation and storage temperature requirements. The flash point should be high to allow the safe operation and minimum volatilization at the maximum operating temperature. The flash point values of all the 9 acylated branched mono- and polyol esters as observed in the range 238−375 °C are useful for multirange applications. Among all the acylated derivatives acylated TMP esters exhibited high flash points (333−375 °C) followed by acylated NPG esters (300−329 °C) and acylated 2-EtH esters (238−252 °C). The high flash point of the acylated TMP esters is due to the high molecular weight and side chain branching. The flash point specification for hydraulic oils as per IS: 3098 is 150 °C. All the acylated derivatives with flash point of ≥165 °C lie well within the range of hydraulic oils.[35] The lubricant base stocks with high flash point ≥300 °C are suitable for the applications that are in more demand, such as gear oil lubricants and aviation jet engine lubricants.[36]

**TGA.** The thermal stability of a fluid is its ability to resist decomposition on exposure to high temperatures. It establishes the ultimate high-temperature limit for a tribological system fluid that will ensure continual unimpaired service. The most significant change in fluid properties caused by thermal decomposition of organic molecules is an increase in vapor pressure caused by the shearing of molecules into smaller, more volatile fragments. Ester functionality is more prone to thermolysis and removal of $\beta$-hydrogen in the triglyceride by reacting with a polyol and branched alcohols improves the thermal stability.[37]

Among the nine base stocks prepared, the acylated TMP esters exhibited very high thermal stabilities as observed by their TGA onset temperatures, 376−385 followed by NPG esters, 347−357. The stability of the branched mono esters was found to decrease drastically due to disturbance in crystalline packing.[37] However, the values were found higher compared to the undecenoic acid−based polyol esters and other vegetable oil based polyol esters.[15,39] The high thermal stabilities of the acylated TMP and NPG esters are suitable as substitutes to BS 150 mineral oil base stocks and for high temperature applications such as forging and metal working fluid applications.

**Rotating Pressurized Vessel Oxidation Test (RPVOT).** Oxidation stability is another important property which determines the degree of resistance of the lubricant to oxidation. In general, the ester group is oxidatively stable and increases the stability of the adjacent carbon atoms.[38,39] Removal of the $\beta$-hydrogen in the triglyceride by reacting with a polyol and branched alcohols improves the oxidation stability. In general, TMP esters are more stable compared to

NPG and branched esters.[37] However, in the present study, it was observed an increase in unsaturation by urea adduct complexation, followed by reaction with polyols and branched alcohols, which on further acylation increased the oxidation stabilities of all the base stocks. The oxidation stabilities of all the base stocks were higher or comparable to other vegetable oil-based synthetic esters.[9,15,16,33] All the nine base stocks with good oxidation stabilities can be well exploited as mineral oil base stock substitutes in a variety of lubricant formulations.

**Extreme Pressure Test (Weld Load).** Weld load is another important property of lubricant base stocks, which determines the load-carrying capacity of the lubricants. The weld load capacity of the acylated ORSTMP esters is found to be more (180−190 kg), followed by acylated ORSNPG esters (155−170 kg) and acylated ORS2-EtHE (130−140 kg). All the 9 acylated base stocks were is found to possess high load carrying capacity compared to other reported polyols.[16,17]

**Wear.** This property indicates the antiwear properties of the lubricant between two sliding surfaces preventing the surfaces from the dimensional loss of one solid, with or without any actual decoupling and loss of material. In case of polyol esters, the effect of nature of the polyol involved has hardly any effect on the property.[40] Similar observation was seen in the TMP and NPG acylated products understudy. However, all the acylated polyol and branched mono-esters exhibited good antiwear properties suitable for high pressure and high temperature applications such as the forging and metal working fluid applications.

In conclusion, Sal fat was chemically modified to develop acylated branched mono and polyol esters of oleic acid rich sal fatty acids with a wide range of properties matching with BS 150 mineral oil base stocks in case of TMP acylated products, forging and metal working fluid applications in case of NPG acylated products. The modification resulted in low viscous 2-EtH acylated products suitable for metal working and hydraulic fluid applications. The thermal and oxidative stabilities of the base stocks have been improved with the above modification and found comparable to synthetic esters. Overall, all the base stocks with stringent properties are promising candidates to replace most of the mineral oil base stocks in a variety of industrial applications either as such or after formulations.

volatiles do not have an important defensive function against this bacterial pathogen.[16] The overexpression of *TomloxD* gene in transgenic tomato plants resulted in a marked increase in the LOX activity and jasmonic acid (JA) accumulation, which indicted that TomloxD may use ALA as a substrate to produce (13*S*)-hydroperoxyoctadecatrienoic acid (13-HPOT), and 13-HPOT was further metabolized to synthesize JA.[15] In comparison to non-transformed tomato plants, the transgenic plants overexpressing TomloxD were more tolerant to *Cladosporium fulvum* and high-temperature stress.[15] The overexpression of TomLoxD also leads to elevated wound-induced JA biosynthesis and increased expression of wound-responsive genes, thereby enhanced resistance to insect herbivory attack and necrotrophic pathogen infection.[17] Therefore, TomloxD is involved in endogenous JA synthesis and tolerance to biotic and abiotic stress.[16,17]

Both ALA and LA in tomato are EFAs for humans. To improve the nutrition value of the tomato fruits, increasing the content of ALA or LA is advantageous. We produced some transgenic tomato plants silencing five LOX family genes. Transgenic tomato plants with greatly reduced TomloxA, TomloxB, TomloxC, TomloxD, and TomloxE were identified by quantitative real-time polymerase chain reaction (PCR) and LOX activity assays. Significant improvement in the contents of ALA or LA in tomato fruit was achieved.

## MATERIALS AND METHODS

**Experimental Materials and Growth Conditions.** All experiments were performed using a near-isogenic line of diploid tomato (*Solanum lycopersicum* cv. Ailsa Craig) plants. The inbred tomato was cultivated in soil. After 20 days of growth, seedlings were collected, frozen in liquid nitrogen, and used to extract RNA.

**Cloning of the Fragments of *TomloxA*, *TomloxC*, and *TomloxD* Genes.** Total RNA was isolated from the seedlings using the Trizol reagent (Gibco-BRL, Grand Island, NY). Reverse transcription (RT) was conducted with 500 ng of total RNA using the SuperScript III RNase H Reverse Transcriptase kit (Invitrogen, Carlsbad, CA) and 10 mM anchored olig(dT)$_{18}$ primer according to the instructions of the manufacturer.

On the basis of the TomloxA, TomloxC, and TomloxD cDNA sequences (GenBank accession numbers U09026, U37839, and U37840, respectively), the primers TomA-f, TomA-r, TomC-f, TomC-r, TomD-f, and TomD-r were designed. The appropriate restriction sites were added at the 5′ end of primers (Table 1). The fragments of *TomloxA*, *TomloxC*, and *TomloxD* genes were amplified from cDNA by PCR using PrimeSTAR HS DNA Polymerase (Takara, Dalian, China) with primers TomA-f and TomA-r, TomC-f and TomC-r, and TomD-f and TomD-r, respectively. The PCR products were cloned into pMD18-T vector (Invitrogen, Carlsbad, CA) and sequenced to obtain vectors TomloxA-T, TomloxC-T, and TomloxD-T, respectively.

**Construction of RNA Interference (RNAi) Vector TomloxACDi-pBIN19 and Plant Transformation.** RNAi expression vector TomloxACDi-pBIN19 was constructed as follows: (1) *TomloxC* gene fragment from the plasmid TomloxC-T (cut by *Bam*HI and *Sal*I) was cloned into the plasmid TomloxA-T in the sense orientation at *Bgl*II and *Sal*I restriction sites of the plasmid TomloxA-T and obtained TomloxAC-T vector. (2) *TomloxD* gene fragment from the plasmid TomloxD-T (digested with *Xho* I and *Sal*I) was cloned into the plasmid TomloxAC-T in the sense orientation at *Sal*I restriction sites of the plasmid TomloxAC-T and obtained TomloxACD-T vector. (3) ACD fragment from the plasmid TomloxACD-T (cut by *Bam*HI and *Sal*I) was linked into the pDHG 5.2 plasmid at *Bam*HI and *Sal*I restriction sites in the antisense orientation and obtained plasmid pDHG5.2-rTomloxACD. (4) The ACD fragment from the plasmid TomloxACD-T (digested by *Kpn*I and *Bam*HI) was linked into the plasmid pDHG5.2-rTomloxACD at *Kpn*I and *Bam*HI restriction sites in the sense orientation and was called pDHG5.2-fTomloxACD-rTomloxACD vector. (5) The double-stranded (ds) RNA expression unit from the plasmid pDHG5.2-fTomloxACD-rTomloxACD vector, including the cauliflower mosaic virus (CaMV) 35S promoter, *TomloxACD* fragment in sense orientation, *GFP* gene fragment, *TomloxACD* fragment in antisense orientation, and 35S terminator, was subcloned into the plant binary vector pBIN 19 (Takara, Dalian, China) with *Eco*RI to yield RNAi vector TomloxACDi-pBIN19 for Tomlox family genes silencing (Figure 1). The construct was confirmed by PCR, restriction digest analysis, and sequencing of the *TomloxACD* fragment.

The binary vector TomloxACDi-pBIN19 was used to transform tomato cotyledon explants. After the construct was transferred into *Agrobacterium tumefaciens* LBA4404 by the freeze−thaw method,[18] transformation was carried out according to the *Agrobacterium*-

**Figure 1.** Construct of RNAi vector TomloxACDi-pBIN19 for Tomlox family gene silencing. The fragments of *TomloxA*, *TomloxC*, and *TomloxD* genes in the sense and antisense orientations were linked with a GFP gene fragment and as a transcriptional unit for hairpin RNA expression, which was controlled by the CaMV 35S promoter and terminated by the 35S terminator.

mediated co-cultivation method.[19] Transgenic plants that rooted on kanamycin were transferred to compost and grown.[11]

**Confirmation and Phenotype Analysis of Positive Transgenic Plants.** The genomic DNA of transgenic and wild-type plants was isolated using Plant Genomic DNA Extraction kit (VOK-Bio, Beijing, China) according to the instructions of the manufacturer and used as templates. The forward primer *NPTII f* and reverse primer *NPTII r* were designed according to the *NPTII* gene sequence (Table 1). The positive transgenic plants were validated by PCR analysis. The phenotype of transgenic tomato plants was investigated.

**Real-Time RT-PCR Analysis of Transgenic Tomato Plants.** Total RNA was isolated from the leaf tissues of transgenic and wild-type tomato plants using Trizol reagent and subsequently treated with DNase I. The RNAs were reverse-transcribed as described above. The specific primers of real-time RT-PCR analysis are listed in Table 1. The real-time RT-PCR analysis of *TomloxA*, *TomloxB*, *TomloxC*, *TomloxD*, and *TomloxE* genes was carried out using the quantitative SYBR Green PCR kit (Tianwei, China) as described by He et al.[20] Real-time RT-PCR was performed using the CFX96 real-time system (C1000 thermal cycler, Bio-Rad, Hercules, CA). The gene expression was normalized to the *LeEF-1* gene from the tomato plant.[21]

**LOX Activity Assays.** LOX activity from leaf tissues was determined spectrophotometrically. The extraction of tomato LOXs and LOX activity assay were performed using the methods as described by Hu et al.[12] Proteins were measured by the Bradford method.[22] A total of 1 unit of activity was defined as the quantity of enzyme catalyzing an increase in absorbance of 0.01 at 234 nm/min under assay conditions.

**Quantification of Endogenous ALA and LA in Tomato Fruits.** Frozen samples of ripe fruits (8−10 days after breaker stage) were homogenized with a polytron apparatus, and 5 g of the homogenate was digested with 10 mL of HCl for 1 h at 70−80 °C. The mixture was cooled and extracted twice, each time being shaken for 2 min with 10 mL of ethanol, 10 mL of aether, and 25 mL of petroleum ether, followed by 10−20 min of quiescence. The supernatant liquid was transferred to another beaker and evaporated under reduced pressure. After saponification with 1 mL of 2 M NaOH−methanol for 15−20 min at 65 °C, the sample was methyl-esterified with 1 mL of 2 M HCl−methanol for 5 min at 65 °C. The resultant fatty acid methyl esters were recovered by adding 2 mL of saturated NaCl solution and 1 mL of hexane, vortexing, and centrifugation at 1000 rpm for 5 min to give the upper hexane layer.

Fatty acid analysis was performed by the application of 100 μL aliquots to a gas chromatograph (LC-2010, Shimadzu, Japan) equipped with a TC-70 capillary column (30 cm × 0.25 mm, GL Sciences, Japan) under a temperature program of 180−220 °C at a rate of 4 °C/min. ALA and LA were calculated on the basis of the area of each peak, and the amount was obtained by comparison to the ALA and LA standards, respectively.

**Statistical Analysis.** All experiments were repeated 3 times for two biological replicates. The data are means of six independent experiments ± standard deviation (SD). Student's *t* test was used for statistical analysis to compare the data. A *p* value of <0.05 was considered to indicate a statistically significant difference.

## RESULTS

**Generation, Confirmation, and Phenotype Analysis of Transgenic Plants.** To silence LOX family genes, RNAi expression vector TomloxACDi-pBIN19 was constructed. The plasmid TomloxACDi-pBIN19 was introduced to *A. tumefaciens* LBA4404 and transformed into *S. lycopersicum* cv. Ailsa Craig plants by the *Agrobacterium*-mediated co-cultivation method. The transgenic plants were selected with kanamycin. The regenerated seedlings were acclimated for 2 weeks in zippy pot soil in a greenhouse, then transferred to soil, and cultured under field conditions. The transgenic lines were obtained and further verified by PCR. Because the *NPTII* gene is closely adjacent to the target gene in the plasmid TomloxACDi-pBIN19 and not present in the wild-type tomato genome, the positive transgenic plants should have a specific 493 bp amplified product, which did not appear in wild-type tomato plants (Figure 2). The transgenic tomato lines were used for further analysis.

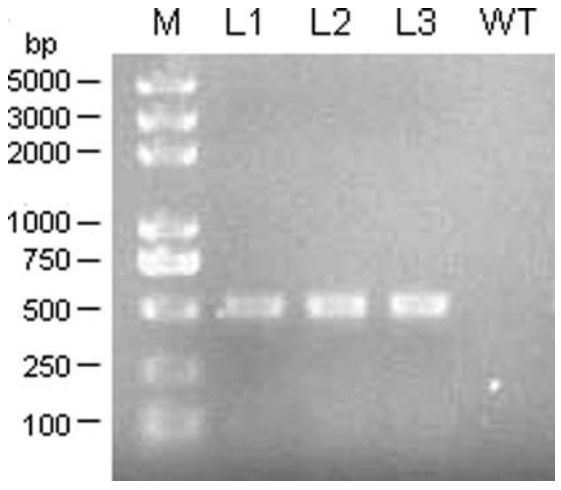

**Figure 2.** PCR analysis of transgenic tomato plants. M, DNA marker; L1, L2, and L3, independent transgenic lines; WT, wild-type tomato.

To examine the effect of silencing LOX family genes, the growth, development, and phenotype of the positive transgenic plants were analyzed. In comparison to wild-type tomato, the plant architectures, flowers, and fruits of transgenic tomato appeared normal. There was no detectable phenotypic difference between transgenic plants and wild-type tomato plants.

**Silence of LOX Family Genes in Transgenic Plants.** Real-time RT-PCR was used to investigate the expression of LOX family genes in transgenic tomato plants. The results showed that the expression of *TomloxA*, *TomloxB*, and *TomloxE* in transgenic tomato plants was drastically repressed. The expression of their transcript in transgenic lines 1, 2, and 3 was only approximately 0.05−5.79% of the wild-type tomato plants. The expression of *TomloxC* and *TomloxD* in transgenic plants was also seriously suppressed. There was no *TomloxC* expression in transgenic line 1, and the expression level of the *TomloxC* mRNA in transgenic lines 2 and 3 was 17.56 and 32.56% of the wild-type plants, respectively. The expression level of *TomloxD* mRNA in transgenic lines 1, 2, and 3 was only 2.45, 0.35, and 9.53% of the wild-type tomato, respectively (Figure 3).

**Repression of LOX Family Genes Decreased LOX Activity.** LOX activity of crude extracts from the transgenic and wild-type tomato plants was detected. The transgenic tomato always had lower LOX activities than the wild-type tomato (Figure 4). Among three transgenic lines, the LOX

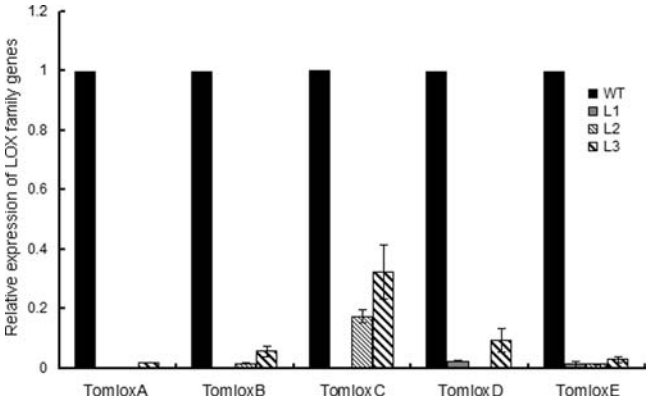

**Figure 3.** Expression of LOX family genes analyzed by real-time RT-PCR. WT, wild-type tomato; L1, L2, and L3, independent transgenic lines.

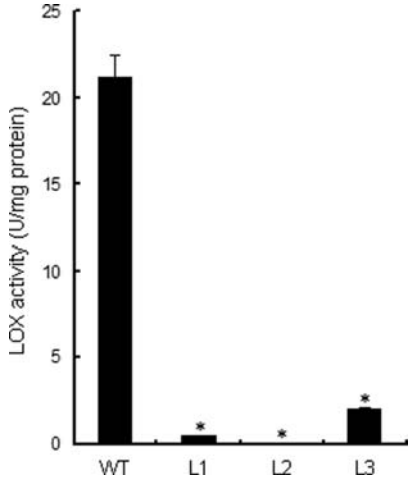

**Figure 4.** LOX activity in transgene tomato. WT, wild-type tomato; L1, L2, and L3, independent transgenic lines. (*) $p < 0.05$ versus wild-type tomato.

activities of lines 1, 2, and 3 were only 2.46, 0.35, and 9.53% of the wild-type plants, respectively (Figure 4). The result suggested that the repression of LOX family genes reduced LOX activity.

**Fruits of Transgenic Tomato Had Higher Endogenous ALA and LA.** Gas chromatographic analysis was used to determine the contents of endogenous ALA and LA in tomato fruits. The results showed that the contents of the endogenous ALA and LA in tomato fruits varied in the different transgenic lines. In comparison to the wild-type tomato, the transgenic tomato had higher accumulations of the endogenous ALA and LA in their fruits, which were 1.65−3.99 and 2.91−4.98 times that of the wild-type plants, respectively.

The highest levels of the endogenous ALA and LA were in the fruits of line 2, which contained 388.42 μg of ALA and 443.36 μg of LA per gram of tomato fruit (Table 2). The findings suggested the repression of LOX family genes resulted in a striking increase in the levels of endogenous ALA and LA in tomato fruits.

## DISCUSSION

The major objectives of genetic engineering of crops aim at improving tolerance toward various biotic and abiotic stresses, increasing output and enhancing nutritional value. Biotechnology techniques involving plant tissue culture and recombinant DNA technologies are powerful tools that can complement conventional breeding. In the case of tomato, genetic transformation via *Agrobacterium* is certainly an important tool to modify tomato growth,[23] nutritional quality,[24] facilitate genetic improvement against several diseases caused by phytopathogenic fungi, bacteria, and viruses,[25,26] and enhance resistance to abiotic stresses, such as high salinity, metal ions, hyperosmotic, heat, chilling stress, and ultraviolet radiation.[24,27,28]

**Table 2. Contents of ALA and LA in Tomato Fruits[a]**

| plant line | ALA (μg/g of fruit) | LA (μg/g of fruit) |
|---|---|---|
| wild type | 97.28 ± 27.89 | 88.99 ± 24.08 |
| line 1 | 160.70 ± 17.77 | 266.20 ± 55.86 |
| line 2 | 388.42 ± 63.22 | 443.36 ± 31.08 |
| line 3 | 223.99 ± 47.69 | 258.90 ± 47.89 |

[a]The data are means of six independent experiments ± SD.

In our present study, we constructed an RNAi expression vector using *TomloxC* fragment, *TomloxD* fragment, and partial *TomloxA* sequence that is highly identical with *TomloxB* and *TomloxE* to silence LOX family genes in tomato plants and investigated the expression levels of LOX family genes, LOX activity, and the contents of ALA and LA. In comparison to wild-type tomato, the expression of the LOX family genes *TomloxA*, *TomloxB*, *TomloxC*, *TomloxD*, and *TomloxE* was drastically repressed in transgenic tomato lines and the total LOX activity in transgenic tomato was lower. The contents of endogenous ALA and LA in transgenic tomato fruits were higher than that in the wild-type tomato fruits. LOXs can catalyze the dioxygenation of ALA and LA. In the transgenic lines, silencing LOX family genes resulted in the reduction of LOX activities, which led to a marked decrease in using ALA and LA substrates. Therefore, ALA and LA accumulated and transferred to fruit, and ALA and LA contents in fruit increase. The total LOX activities varied depending upon the transgenic lines and were relatively well-correlated with ALA and LA contents. Among three transgenic lines, line 2 had the lowest LOX activity and the highest contents of endogenous ALA and LA in their fruits, whereas lines 1 and 3 had higher LOX activity and less endogenous ALA and LA compared to line 2. The findings suggested that the lower the LOX activity, the higher the contents of endogenous ALA and LA (Figure 4 and Table 2).

The antisense suppression of TomloxA, TomloxB, and TomloxE in tomato fruits caused no significant changes in the contents of $C_6$ flavor volatile aldehydes and alcohols in tomato fruits compared to wild-type controls.[11,13] Taking into account that the majority of the hydroperoxides (HPOs) formed by LOX activity in tomato are the 9 isomers and that TomloxA, TomloxB, and TomloxE have high expression levels in wild-type tomato fruits, it is most likely that the majority of the HPOs formed by TomloxA, TomloxB, and TomloxE in tomato are the 9-HPOs.[11,29−32] Our previous work showed that TomloxC is a chloroplast-targeted lipoxygenase isoform that can use both ALA and LA as substrates and produce 13-hydroperoxy products, which appear to be specifically used as the precursors of volatile $C_6$ short-chain flavor compounds and metabolized further by the action of the 13-HPLs to give rise to hexanal, hexenal, and the corresponding alcohols.[11] The TomloxD protein also has a chloroplast target signal. Our previous investigation suggested that TomloxD can produce

13-HPOs, which is metabolized further to synthesize JA.[15] Therefore, it is the silencing of LOX family genes in tomato plants that leads to reduction of the LOX activity, in turn, causing the enhanced accumulation of ALA and LA in transgenic tomato fruits.

LOXs have been associated with some processes in a number of developmental stages and environmental stresses.[33,34] LOXs and the products of the LOX pathway were involved in a series of biological events, which include seed germination, tuber development, sex determination, nodule development, fruit ripening, plant senescence, and cell death.[11,34−40] Another important role of plant LOXs is an involvement in defense responses to wounding, heat, microbial pathogens, nematode infection, insect attack, and herbivore attack.[15,38,41−44] Therefore, inhibiting LOX activity is closely associated with plant development and defense mechanisms. Although there was no detectable phenotypic difference between transgenic and wild-type tomato plants, the suppression of *TomloxC* and *TomloxD* lead to the decrease of aroma volatile and JA in transgenic plants. JA regulates plant developmental plasticity and is the key regulators of plant defense mechanisms against pathogens, insects, and adaptation to abiotic stress.[45] Therefore, the transgenic tomatoes could potentially be a developmental defect and more venerable to biotic and abiotic stress factors, which are the potential ecological disadvantages of these transgenic plants. To overcome disadvantages of the transgenic tomato plants, further research is to construct a RNAi vector of LOX family genes using a fruit-specific promoter and transform wild-type tomato to obtain transgenic tomato plants, in which LOX family genes will be silenced only in tomato fruits.

In summary, the expressions of TomloxA, TomloxB, TomloxC, TomloxD, and TomloxE are greatly reduced by genetic transformation of RNAi constructs, which leads to the decrease of LOX activity and the increase of the contents of ALA and LA in transgenic tomato fruits. The research has the potential in engineering cropping plants that improve nutritional quality.

We have previously developed a construct-specific method for detection and quantitation of Embrapa 5.1 GM common bean, named OLA assay.[14,15] However, it is necessary to develop an event-specific assay in order to distinguish authorized and unauthorized GM events containing the same inserted DNA. OLA assay was unable to differentiate between Embrapa 2.3 and Embrapa 5.1 events. The present work reports the development of an event-specific method for detection and quantitation of Embrapa 5.1 GM common bean. In the present work, we designed a primer pair and a hydrolysis probe targeting a junction sequence between the common bean genomic DNA and the inserted DNA of Embrapa 5.1 GM common bean. This event-specific DNA assay, named FGM assay, was the first assay successfully developed for specific real-time PCR quantitation of Embrapa 5.1 event.

## MATERIALS AND METHODS

**Plant Material.** Two Embrapa 5.1 GM common bean lines, namely GM Pérola and GM Pontal, derived from the cultivars Pérola and Pontal, respectively, were used as positive controls. Non-GM Pérola, non-GM Pontal, 44 different *Phaseolus vulgaris* L. non-GM varieties, cowpea (*Vigna unguiculata* L.), lima bean (*Phaseolus lunatus*), and sword bean (*Canavalia gladiata*) were used as negative controls. The GM common bean Embrapa 2.3, a noncommercial event that contains the same construct of Embrapa 5.1, was used as the main negative control. Seeds of these samples were provided by Embrapa Arroz e Feijão (Santo Antônio de Goiás, GO, Brazil). Non-GM soybean and pea grains were purchased from local markets in Florianópolis, SC, Brazil. Certified reference materials (CRM) from RR soybean (5%, BF410), MON810 (5%, BF413f), Bt11 (4.89%, BF412f) and Bt176 (5%, BF411f) were purchased from IRMM (Institute for Reference Material and Measurements, Geel, Belgium).

Leaf material was obtained as follows: Two seeds of each sample were placed on moistened germination paper and germinated in a growth chamber at 25 °C without light for 2 days. Afterward, seeds were transferred to seedling pots containing soil and cultivated in a controlled environment growth chamber, adjusted to 12 h photoperiod, photosynthetic active radiation of 150 $\mu mol \cdot m^{-2} \cdot s^{-1}$, at 25 °C, watered daily. After 11 days, leaves were collected and stored at −80 °C. Powder seed material was obtained as follows: Embrapa 5.1 GM common bean seeds were cryo-ground in an analytical mill (IKA model A11 basic), followed by manual crushing with mortar and pestle in the presence of liquid nitrogen.

**DNA Extraction.** Genomic DNA was extracted from frozen leaf material by two protocols: cetyltrimethylammonium bromide (CTAB) and DNeasy plant minikit (Qiagen).[16] Genomic DNA was extracted from seed material by use of DNeasy plant minikit (Qiagen). DNA was extracted at least twice for each sample. DNA concentration was estimated from measurements at 260 and 280 nm on a Thermo Scientific NanoDrop 2000 spectrophotometer (Wilmington, DE).

**Primers and Probe Design.** Primers and probe were designed on the basis of the Embrapa 5.1 GM common bean DNA sequence that was provided by EMBRAPA (Figure S1, Supporting Information). Primer Express 3.0 software (Applied Biosystems) was used for designing the primers and the probe in the border junction sequence of common bean DNA and inserted DNA (Table 1).

**Table 1. Primers and FGM Probe Sequences Designed for Event-Specific qPCR of Embrapa 5.1 GM Common Bean[a]**

| oligonucleotide | sequence 5′−3′ |
|---|---|
| BeanF primer | CTGATTCAATCGACGCCTTACTT |
| VectorR primer | CGCGGTATTATCCCGTATTGAC |
| FGM probe | VIC-TTAATAAATAAGTGGATCTCTTGCC-MGB |

[a]Amplicon size is 77 bp.

**Chemicals.** DNA extraction performed with DNeasy plant minikit used all reagents provided by Qiagen (Valencia, CA): buffer AP1, RNase A, buffer P3, QIAshredder spin column, buffer AW1, DNeasy mini spin column, buffer AW2, and buffer AE. Ethanol, chloroform, and sodium chloride were purchased from Synth (São Paulo, Brazil); 2-propanol was purchased from Vetec (Rio de Janeiro, Brazil), proteinase K was from Promega (Madison, WI), and CTAB was from USB (Cleveland, OH). qPCR reagents (2× SYBR Green master mix and 2× TaqMan universal PCR master mix) were purchased from Applied Biosystems (Foster City, CA). The primer pair, named BeanF/VectorR, was synthesized by IDT (Coralville, IA) and the TaqMan probe, named FGM, was synthesized by Life Technologies (Foster City, CA).

**Real-Time PCR Conditions.** Quantitative real-time polymerase chain reaction (qPCR) was performed in ABI PRISM 7500 detection system (Applied Biosystems, Foster City, CA). The amplification reactions were carried out in a final volume of 25 $\mu$L containing 12.5 $\mu$L of 2× SYBR Green master mix or 2× TaqMan universal PCR master mix, primer pair, probe, water, and 50 ng of template DNA. All reactions were carried out in duplicate under the following cycling conditions: 2 min at 50 °C; 10 min at 95 °C; 40 cycles of 15 s at 94 °C and 1 min at 60 °C. All real-time PCR runs were evaluated separately by using the automatic software settings for each run. Tested and optimized primer pair and probe concentrations are presented in Table 2.

**Table 2. Primers and FGM Probe Concentrations Used for Event-Specific qPCR of Embrapa 5.1 GM Common Bean**

| | SYBR Green | TaqMan |
|---|---|---|
| Tested Concentrations (nmol/L) | | |
| BeanF/VectorR primers | 100, 200, 300, 400, 500 | 300 |
| FGM probe | | 150, 250 |
| Optimized Concentrations (nmol/L) | | |
| BeanF/VectorR primers | 300 | 300 |
| FGM probe | | 250 |

**Specificity of Primer Pair and Probe.** The specificity of SYBR Green assay was assessed by use of DNA extracted from soybean, pea, non-GM common beans Pérola and Pontal, GM common bean Embrapa 2.3, and two GM common beans Embrapa 5.1 (GM Pérola and GM Pontal). Primer specificity was evaluated under the PCR conditions described in the previous section.

In order to evaluate the specificity of FGM assay, negative samples were tested, including 46 *P. vulgaris* varieties (including non-GM Pérola and Pontal), one *P. lunatus*, one *V. unguiculata*, one *C. gladiata*, and Embrapa 2.3 GM. Primers and probe concentrations were respectively 300 and 250 nM.

**Construction of Standard Curves.** Genomic DNA isolated from leaves of Embrapa 5.1 GM common bean was used for serial dilution in water, to final concentrations from $10^5$ to $10^0$ DNA copies, or in DNA solution of non-GM common bean, to final concentrations of $10^2$ and $10^1$ DNA copies. The number of genome copies was calculated from the equation $m = n(660)(1/6.023 \times 10^{23})$, incorporating the 1C value of 637 Mbp for *P. vulgaris* L., the molecular weight of DNA (660 Da/bp), and Avogadro's constant. Therefore, the estimated number of genome copies in standard curves ranged from $10^5$ to $10^0$ copies of haploid genome, corresponding to mass quantities of 69.8 to $(6.98 \times 10^{-4})$ ng of DNA that were used as template in PCR. Amplification efficiency values were calculated from the equation $E = (10^{-1/S} - 1) \times 100$, where $E$ is the efficiency (percent) and $s$ is the slope obtained from the standard curve.

**qPCR Assay Repeatability.** Repeatability of the TaqMan FGM assay for DNA samples extracted with DNeasy plant minikit was evaluated by two approaches. In the first approach, DNA samples extracted from Embrapa 5.1 GM Pérola and Embrapa 5.1 GM Pontal were analyzed in three PCR runs, on different days, in duplicate. The second approach was performed with three DNA extracts from

Embrapa 5.1 GM Pérola. The PCR runs were performed in 4 days, by use of the three DNA extracts, in duplicate.

Repeatability of the TaqMan assay for samples extracted with CTAB was performed with one DNA sample extracted from Embrapa 5.1 GM Pérola and one DNA sample extracted from Embrapa 5.1 GM Pontal in four qPCR runs, in duplicate.

## RESULTS

**qPCR Parameters for SYBR Green Assay.** In order to test the specificity of the primers, SYBR Green assays were performed at four primer concentrations: 400, 300, 200, and 100 nM with negative and positive control samples. Low variation in Cq values of positive samples (GM Pérola and GM Pontal) was observed for primer concentrations of 400, 300, and 200 nM (Table S1, Supporting Information). For primer concentration of 100 nM, quantitation cycle (Cq) values of the positive samples were higher than Cq values at other primer concentrations.

Regarding the negative controls (pea, GM and non-GM soybean, GM maize, non-GM Pérola, non-GM Pontal, and Embrapa 2.3), amplification signals with late Cq were verified for GM and non-GM soybean, GM maize, and non-GM common bean Pontal samples at primer concentration of 400 nM and for non-GM common bean Pérola, GM and non-GM soybean, and GM maize at primer concentration of 200 nM. For 300 nM primer concentration, no amplification signals were observed for the large majority of negative controls. In this case, only five positive signals were observed out of 25 with late Cq (Cq > 34.9) (Table S1, Supporting Information).

Standard curves were obtained at five primer concentrations (500, 400, 300, 200, and 100 nM) with DNA samples extracted with DNeasy plant minikit from Embrapa 5.1 GM Pérola and GM Pontal. Efficiency values ranged from 95% to 110% for GM Pérola and from 94% to 112% for GM Pontal (Table 3). Primer concentrations of 300 and 200 nM showed suitable efficiency values, and they were selected to obtain standard curves for GM Pérola and GM Pontal samples extracted by the CTAB method. For GM Pérola the amplification efficiency values were 107% and 104%, respectively, and for GM Pontal the efficiencies were 104% and 110%, respectively (Table 3). For primer concentrations of 200 and 300 nM, amplification efficiency values presented standard deviation of 4.55 and 2.52, respectively, for the samples extracted with both DNA extraction methods. Given the amplification efficiency values and the results obtained in the specificity tests, the primer concentration of 300 nM was selected to be used in further experiments.

**Table 3. qPCR Efficiency Values and $R^2$ of SYBR Green Assay[a]**

| | Embrapa 5.1 Pérola | | Embrapa 5.1 Pontal | |
|---|---|---|---|---|
| [primer] (nmol/L) | efficiency (%) | $R^2$ | efficiency (%) | $R^2$ |
| DNA from DNeasy Plant Minikit | | | | |
| 500 | 95 | 0.987 | 103 | 0.999 |
| 400 | 106 | 1.000 | 94 | 0.998 |
| 300 | 110 | 0.997 | 110 | 1.000 |
| 200 | 104 | 0.999 | 100 | 1.000 |
| 100 | 106 | 0.993 | 112 | 0.988 |
| DNA from CTAB Method | | | | |
| 300 | 107 | 1.000 | 104 | 0.993 |
| 200 | 104 | 0.999 | 110 | 0.991 |

[a]Template DNA came from Embrapa 5.1 GM Pérola and Embrapa 5.1 GM Pontal common bean varieties, extracted by DNeasy plant minikit or CTAB method..

**qPCR Parameters for TaqMan Assay of Leaf DNA.** Standard curves were obtained for 250 and 150 nM FGM probe concentrations, 300 nM BeanF/VectorR primer pair, and GM Pérola and GM Pontal samples extracted from leaf material with DNeasy plant minikit. Curves for 250 nM FGM probe showed efficiency values close to 100%, and this concentration was selected to be used in further experiments (Figure 1).

The specificity of FGM probe was assessed under optimized conditions of primers and probe concentrations. For *P. vulgaris* varieties, only 35 out of 158 reactions (22%) presented a positive signal. For Embrapa 2.3 GM event, only six out of 26 reactions (23%) present a positive signal (Table 4). All positive results presented a late Cq, higher than 37.

**Repeatability of TaqMan Assay.** The repeatability assay was performed in four PCR runs with three GM Pérola DNA extracts (Table 5). Each DNA extract resulted in a standard curve obtained from a 10-fold serial dilution. The efficiency values ranged from 85% to 101%. A mean standard curve was generated by use of all data obtained from this experiment ($n$ = 24). The mean efficiency value was 95% and the correlation coefficient was 0.998 (Figure 2).

Repeatability of the TaqMan assay was also assessed for one DNA extract of Embrapa 5.1 GM Pérola and one DNA extract of Embrapa 5.1 GM Pontal, in 3 days. Efficiency values ranged from 90% to 103% for GM Pérola and from 94% to 98% for GM Pontal (Figure S2, Supporting Information).

DNA samples extracted by the CTAB method were also used to verify the repeatability of the TaqMan assay. Efficiency values for GM Pérola and GM Pontal were 89% and 86%, respectively. Both curves presented a correlation coefficient of 0.97 (Figure 3).

**Limit of Detection of qPCR Assay.** The limit of detection (LOD) for FGM assay was determined through the repeatability test: four qPCR runs for three DNA extracts (A, B, and C), in duplicate. The limit of detection also was assessed with DNA from Embrapa 5.1 diluted with non-GM common bean DNA and compared with results obtained in the construct-specific OLA assay (Table 6).

Embrapa 5.1 DNA extracted with DNeasy plant minikit and diluted in water was detected in 24 out of 24 reactions (100%) to $10^1$ DNA copy number. Positive reactions were observed in 14 out of 24 (58%) for $10^0$ DNA copy number. For samples extracted with CTAB, Embrapa 5.1 DNA diluted in water was detected in 16 out of 16 reactions (100%) for $10^2$ DNA copy number. A positive signal was observed in 12 out of 16 reactions (75%) for $10^1$ DNA copy number.

Embrapa 5.1 DNA diluted in non-GM common bean was detected in all 12 reactions (100%) evaluated up to the dilution of $10^2$ for FGM assay and in 11 out of 12 reactions (92%) for OLA assay. OLA assay showed positive signal in 21 out 24 reactions (87.5%) for $10^1$ DNA copies while FGM probe showed 22 out of 24 reactions (92%) for $10^1$ DNA copies (Table 6).

**qPCR Parameters for TaqMan Assay of Seed DNA.** Standard curves were also obtained for four DNA extracts from bean material. DNA was extracted from powder seeds by use of DNeasy plant minikit. Standard curve with 250 nM FGM probe and 300 nM primers showed mean efficiency value of 100% (Figure 4).

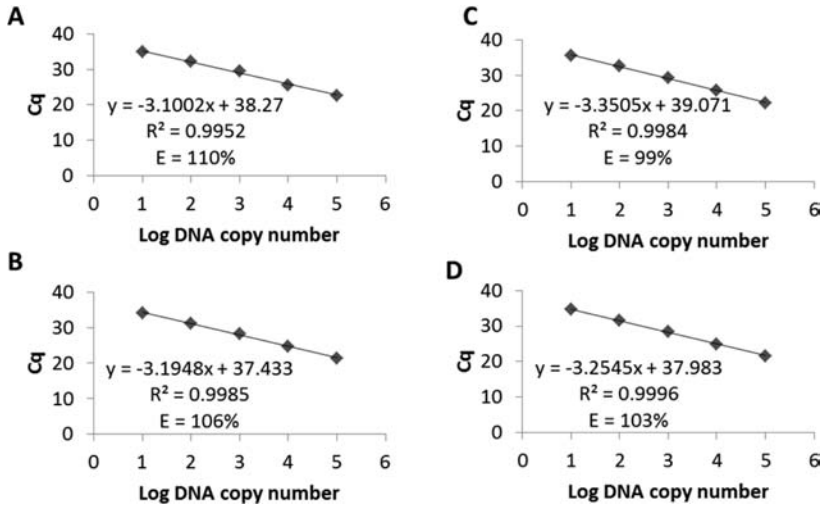

**Figure 1.** TaqMan FGM assay stardard curves for two FGM probe concentrations (250 and 150 nM) and template DNA extracted by use of DNeasy plant minikit from leaves of two GM common beans. (A) Embrapa 5.1 GM Pérola DNA and 150 nM FGM probe ($n$ = 4); (B) Embrapa 5.1 GM Pérola DNA and 250 nM FGM probe ($n$ = 4); (C) Embrapa 5.1 GM Pontal DNA and 150 nM FGM probe ($n$ = 2); (D) Embrapa 5.1 GM Pontal DNA and 250 nM FGM probe ($n$ = 2). Assays were performed with 300 nM BeanF/VectorR primer pair.

**Table 4. Specificity Test for TaqMan FGM Assay with Optimized Primers and Probe Concentrations**

| DNA sample[a] | positive/total | mean Cq | SD |
|---|---|---|---|
| Embrapa 5.1 GM Pérola | 4/4 | 21.20 | 0.21 |
| Embrapa 5.1 GM Pontal | 4/4 | 21.81 | 0.20 |

[a]DNA from Embrapa 5.1 GM Pérola was extracted from leaves by use of DNeasy plant minikit.

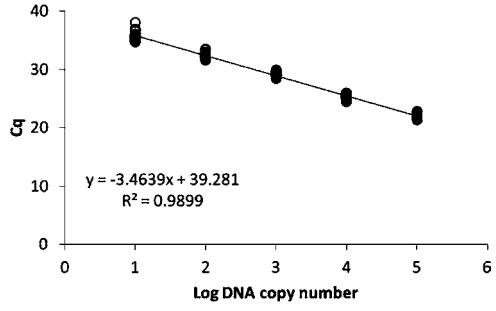

**Figure 2.** TaqMan FGM assay stardard curves performed in four qPCR runs on different days with three DNA extracts from leaves of Embrapa 5.1 GM Pérola in duplicate ($n$ = 24). Samples were extracted by use of DNeasy plant minikit.

**Comparison between OLA and FGM Assays.** In order to compare the efficiency values of FGM and OLA assays, serial dilutions were prepared for DNA from Embrapa 5.1 GM Pérola, Embrapa 5.1 GM Pontal, and Embrapa 2.3 GM event samples and tested for both assays. The results showed that for OLA assay the efficiency values ranged from 90% to 97%, while for FGM assay the efficiency values were 95% and 113% (Table 7). As expected, the FGM assay did not present positive amplification signals for DNA extracted from Embrapa 2.3 common bean event.

## DISCUSSION

Event-specific methods present the highest specificity in order to differentiate GMO events.[17] Two GM common bean events obtained with the same construct (Embrapa 2.3 and Embrapa 5.1) showed high resistance to bean golden mosaic virus,[2,18] but only Embrapa 5.1 GM common bean event was submitted for approval and approved for commercialization in Brazil.

In order to develop an event-specific assay for Embrapa 5.1, common bean DNA was extracted from leaf tissue to be used as certified reference material. Seed powder for GMO analysis presented some limitations, such as limited quantitation range, inconvenient preparation procedures, and difficulty in obtaining homogeneous candidate samples.[19] Furthermore, the genetic

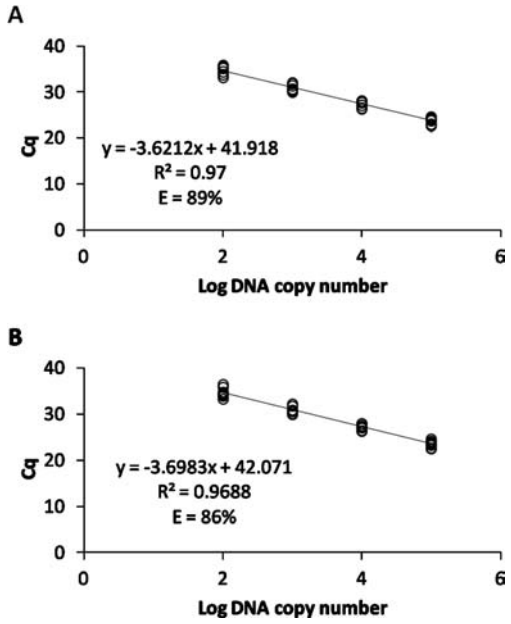

**Figure 3.** TaqMan FGM assay stardard curves performed in four qPCR runs on different days. Curves were generated for two DNA extracts from leaves: (A) Embrapa 5.1 GM Pérola ($n$ = 8) and (B) Embrapa 5.1 GM Pontal ($n$ = 8). Samples were extracted by the CTAB method.

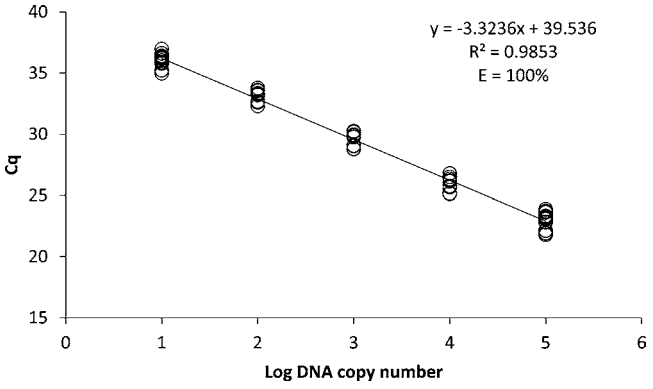

**Figure 4.** TaqMan FGM assay stardard curves performed in two qPCR runs on different days with four DNA extracts from seeds of Embrapa 5.1 GM Pérola in duplicate ($n$ = 12). Samples were extracted by use of DNeasy plant minikit.

purity of a powder produced from GM seeds is difficult to check.[9]

The specificity of the developed primers was assessed by SYBR Green assay. The results showed that Cq values were similar for Embrapa 5.1 DNA samples at 200, 300, and 400 nM primers. However, the 300 nM concentration detected the target with no cross-reaction with non-GM common bean. Efficiency values obtained in the SYBR Green assay, with five primer concentrations and samples extracted with DNeasy plant minikit or CTAB method, are in accordance with the European Network of Genetically Modified Organism Laboratory (ENGL).[20] According to this guideline, the efficiency values of standard curves must range from 90% to 110%, and the correlation coefficient ($R^2$) must be higher than 0.98. One efficiency value was out of this range (112%) and all correlation coefficients were higher than 0.98.

**Table 7. Comparison of Amplification Efficiency Values and $R^2$ for Two GM Events, Embrapa 2.3 and Embrapa 5.1[a]**

| | OLA assay | | FGM assay | |
|---|---|---|---|---|
| DNA sample | efficiency (%) | $R^2$ | efficiency (%) | $R^2$ |
| Embrapa 2.3 common bean | 95[b] | 1.000 | | |
| Embrapa 5.1 Pérola | 90[b] | 0.980 | 113[c] | 0.998 |
| Embrapa 5.1 Pontal | 97[c] | 0.924 | 95[c] | 0.993 |

[a]qPCR was performed in TaqMan OLA (construct-specific) assay and FGM (event-specific assay for Embrapa 5.1). [b]Limit of detection at $10^0$. [c]Limit of detection at $10^1$.

Because of its high specificity, a TaqMan probe was developed. FGM probe uses the minor-groove-binding (MGB) technology that allows the design of shorter probes with higher melting temperatures[21] and with high specificity of the hybridization.[22] When FGM probe was tested with nontarget samples, positive signals in 42 out of 192 samples (22%) were observed. The samples that showed a positive signal presented a late Cq (Cq > 37) for 50 ng of DNA, equivalent to $10^{4.85}$ DNA copies. The Cq value of positive samples (GM Pérola and GM Pontal) with the same DNA quantity (50 ng) is approximately 21. The observed ΔCq of 16

**Table 6. Cq Values Generated by qPCR TaqMan OLA (Construct-Specific) and FGM (Event-Specific) Assays for Mixed DNA Samples**

| samples | GM Pérola + Pérola[a] | GM Pérola + Pontal[a] | GM Pontal + Pérola[a] | GM Pontal + Pontal[a] |
|---|---|---|---|---|

[a]Template DNA was mixed DNA: Embrapa 5.1 GM Pérola ($10^2$ or $10^1$ DNA copies) in the presence of background DNA of non-GM common bean (Pérola and Pontal) varieties (10 ng or 14 327 copies)

is sufficient to propose that these amplifications of few negative samples were unspecific.

Standard curves for quantitation of Embrapa 5.1 GM common bean by the FGM probe were prepared from serial dilutions of GM Pérola and GM Pontal leaf material. For GM Pérola, 14 out 15 (93%) efficiency values were between 90% and 110%, in accordance with ENGL. For GM Pontal, the efficiency values were between 94% and 98%. All curves presented $R^2$ higher than 0.99. A mean standard curve was generated by the repeatability assay, using DNA samples of GM Pérola, presenting an efficiency of 95% and an $R^2$ of 0.99. Dinon et al.[14] reported an efficiency of 89% for the standard curve generated with OLA probe. By comparison of these results, FGM probe seems to be more suitable for detection and quantitation of Embrapa 5.1 GM common bean, as the efficiency of the assay was closer to 100% and mainly for being event-specific.

The LOD is defined as the lowest amount of DNA that can be reliably detected. According to ENGL,[20] qPCR methods should detect the presence of the analyte at least 95% of the time. For FGM assay, the LOD was 10 DNA copies based on the haploid genome of common bean for DNA extracted with DNeasy plant minikit diluted in water. The Cq value of 10 DNA copies (corresponding to 6.98 pg) is approximately 35.66. For Embrapa 5.1 DNA extracted by the CTAB method, FGM assay showed a LOD of 100 DNA copies. Wang et al.[10] reported a LOD of 100 copies for an event-specific qPCR assay of GM rice Kefeng-8. For a qPCR assay of GM rice Kefeng-6, Guertler et al.[11] reported a LOD of 5 copies. We observed that amplification occurred later for DNA samples extracted by the CTAB method since the Cq of these samples was approximately 24 for $10^5$ DNA copies, while the samples extracted with DNeasy plant mini kit presented a Cq of 22. The DNA extraction method can influence the quantitation because of its effectiveness in removing substances that can interfere in the PCR.[23] In order to verify applicability of the FGM assay for seed samples, standard curves for DNA extracted from powder seeds were obtained and efficiency value of 100% was obtained. DNA extraction methods applied to one matrix may not be suitable for other matrices. In this case, DNA extraction method (DNeasy plant minikit) was suitable for both leaf and seed materials.

When Embrapa 5.1 DNA was diluted in non-GM common bean DNA solution, the LOD of FGM assay was $10^2$ DNA copies, with a mean Cq of 32.5. Positive reactions were still observed in 22 out of 24 reactions (92%) for $10^1$ DNA copy numbers, with a mean Cq of 35.8, showing that amplification was not highly influenced by the presence of a background DNA. Andersen et al.[21] reported that the presence of large amounts of background DNA did not promote a severe effect in the results of DNA amplification. When OLA assay (construct-specific) and FGM assay for DNA samples diluted in non-GM common bean were compared, the methods presented the same LOD and the Cq values were very similar.

FGM and OLA assays were compared for serial dilutions of Embrapa 5.1 GM Pérola, Embrapa 5.1 GM Pontal, and Embrapa 2.3 GM event. For OLA probe the efficiency values were 90%, 97%, and 95%, respectively. For FGM probe the efficiency value for GM Pérola was 113% and for GM Pontal was 95%. DNA from Embrapa 2.3 was not detected in any of the points of the standard curves. Therefore, the FGM probe was suitable to differentiate authorized from nonauthorized GM common bean events.

Recent reports have been published about development of GM event-specific qPCR assays for several new GMOs. Guertler et al.[11] developed an assay for detection of Kefeng-6 GM rice. Event-specific assays were developed for specific detection of a GM herbicide-tolerant soybean, A2704-12 event,[24] of GM Chinese cabbage[25] and GM flax.[12] Other authors also reported the development of event-specific assays.[12,13,26−28]

The method developed in the present work is reliable for detection and quantitation of Embrapa 5.1 GM common bean. Even when it is considered that some negative samples presented a positive signal, the Cq values were higher than the Cq value of the LOD, considered to be 100 DNA copies in the presence of background DNA. Both qPCR chemistries used in this work are suitable for quantitation of GM common bean Embrapa 5.1. A new endogenous reference gene assay, named LEC assay, was developed for quantitation of common bean DNA in food.[29] The FGM assay developed here, together with the LEC assay, can be useful for surveys of compliance with GMO-labeling legislation by regulatory authorities in Brazil and in other countries.[30] Moreover, this new event-specific assay is an important tool in GMO analysis because it allows specific quantitation of an authorized GM event.

2-picrylhydrazyl (DPPH•) and to distinguish the kinetic behavior of different antioxidants, quantifying the type of antioxidants and determining the molar ratio of antioxidant to DPPH•. Oszmianski et al.[13] also proved that EPR spectroscopy appeared to be a much better method than UV−visible spectrophotometry, the first methodology reflecting more accurately the content in procyanidins. Moreover, EPR detection is not affected either by the turbidity of samples or by the presence of colored samples, thus avoiding the necessity for corrections for background absorbance.[13]

With the present work we aimed at studying more in depth the behavior of hydrophilic extracts from lettuce related to a different phenolic composition. In fact, from preliminary analyses, the hydrophilic extract showed to be more interesting than the lipophilic one having an antioxidant capacity many fold higher (data not shown). To better discriminate the antioxidant capacity of phenolics, we focused our study on differently colored lettuces [green (G); green/red (G/R); and red (R)] with the aim of identifying the antioxidant kinetic behavior of the different antioxidant-rich cultivars.[15] The three cultivars of lettuce have been characterized for the profile and concentrations of phenols, including conjugated forms, which until now have been less studied.[8] Even if several authors have tried to correlate the antioxidant capacity of food with a specific antioxidant compound,[11,16] this is the first approach in lettuce that aimed at correlating the kinetic behavior of hydrophilic extracts from different pigmented cultivars with their relative antioxidant composition. This study could contribute to fully characterize plant antioxidants, adding useful information about the different importance of each hydrophilic antioxidant in the human diet.

## MATERIALS AND METHODS

**Chemicals and Reagents.** All solvents were of highest purity and were purchased from Sigma-Aldrich (Milan, Italy). Water was of Milli-Q grade. All solvents and water were accurately degassed before use in the analyses. The standards luteolin-7-*O*-glucoside, rutin, apigenin-7-*O*-glucoside, quercetin, quercitrin, luteolin, kaempferol, quercetin-3-*O*-glucuronide, cyanidin, and cyanidin-3-*O*-glucoside were purchased from Extrasynthèse (Genay, France). The standards gallic, protocatechuic, *p*-hydroxybenzoic, chlorogenic, vanillic, caffeic, syringic, *p*-coumaric, ferulic, and chicoric acids as well as free stable DPPH• and 2,2′-azinobis(3-ethylbenzothiazoline-6-sulfonic acid) (ABTS) were purchased from Sigma (Milan, Italy).

**Plant Material and Growing Conditions.** Seeds of three commercially available cultivars of lettuce, a green-leaf cultivar (Blonde of Paris Batavia, G), a green/red-leaf cultivar (Marvel of Four Seasons, G/R), and a red-leaf cultivar (Oak Leaf, R) (Clemente Viven, Vitoria-Gasteiz, Spain) were planted in plastic pots (13 cm side × 15 cm high) containing a mixture of perlite/vermiculite (3:1, v/v). Seven days after sowing (DAS), the most uniformly sized lettuce plants were selected, leaving one plant per pot. Seedlings were grown in a controlled growth chamber maintained at 24/20 °C (day/night) with a relative humidity of 60/80% (day/night); seedlings were watered with Hoagland's solution[17] every 2 days. Photosynthetic active radiation was 400 μmol photons $m^{-2}$ $s^{-1}$ with a photoperiod of 14 h. To minimize the effects of intrachamber environmental gradients, plants were randomly repositioned within the chamber each week. At the end of the experiment (46 DAS) the antioxidant capacity and the concentration of the different antioxidant compounds were measured in the fully expanded external leaves chosen at random.

**Sample Extracts.** Fresh leaves (0.5 g) were pulverized with liquid nitrogen by a tissue homogenizator (MM301, Fisher Bioblock Scientific, France). Extraction was performed in the dark with 70% methanol containing 1% HCl using a mortar. Homogenization was completed with sonication for 30 min. After centrifugation at 4 °C at 12100*g* for 15 min, supernatants were filtered by Sartorius (Goettingen, Germany) filters (Minisart 0.45 μm) to remove any suspended material.

**Quantification of Antioxidant Capacity by EPR Analysis.** The antioxidant capacity was measured using DPPH• quenching. DPPH• is a commercially available free radical compound that is soluble and stable in ethanol. All operations were performed in the dark to avoid photochemical effects on DPPH• as well as on leaf extracts. EPR spectra were recorded with a Varian E112 (X-band) spectrometer equipped as previously reported[2] at the conditions specified in Sgherri et al.[14] Computer-based simulations of EPR spectra were performed using the Winsim program.[18] All data analyses were performed using the CurveExpert software (version 1.34). The incubation mixture contained DPPH• at a final concentration of 400 μM in ethanol. This concentration was chosen by preliminary experiments because it was much in excess to the initial concentration of antioxidants in the sample, thus allowing all of the antioxidants to react with the radical.[12] In these conditions the reactions with DPPH• were completed after several hours. To determine the decay of the radical before measuring antioxidant capacity, decay kinetics of DPPH• without the extract were recorded. The amplitude of the central line of DPPH• spectra was taken for registration of kinetics, which started soon after the addition of the sample to the radical solution. In this way, the scan time was 1 min, and many experimental points could be monitored. Both rate constant and number of DPPH• molecules reduced by extracts in the tube were obtained by fitting of the kinetic curves. Antioxidant capacity was the result of the number of DPPH• molecules reduced by 1 g of plant material and of the EPR decay rate constants ($M^{-1}$ $s^{-1}$).

The following equation, 1, which is a special form of the pseudo-first-order kinetic model previously applied to the determination of antioxidant capacity of lipid extracts of basil[14] as well as of oil fractions,[12] was employed in the analyses of the experimental kinetic data:

$$A = A_S \exp(-k_S' t) + A_I \exp(-k_I' t) + A_F \exp(-k_F' t) + A_R \quad (1)$$

$A$ is DPPH• molar concentration at time $t$, $A_S$, $A_I$, and $A_F$ are the initial DPPH• molar concentrations that can be reduced by the slow, intermediate, and fast fractions, respectively, and $A_R$ is the remaining DPPH• concentration in the medium because of the antioxidant depletion.

$k_S$, $k_I$, and $k_F$ represent the rate constants of the slow, intermediate, and fast fractions, respectively, and were calculated as follows:

$$k_S = k_S'/[\mathrm{DPPH}]_{t0}$$

$$k_I = k_I'/[\mathrm{DPPH}]_{t0} \text{ and}$$

$$k_F = k_F'/[\mathrm{DPPH}]_{t0}$$

Equation 1 is the solution of more than one differential equation of second order assuming that the initial molar concentration of DPPH• ($[\mathrm{DPPH}]_{t0}$) is greater than the molar concentration of antioxidants in the reactions.[12]

**Quantification of Antioxidant Capacity by Spectrophotometric Analysis.** The radical cation 2,2′-azinobis(3-ethylbenzothiazoline-6-sulfonic acid) ($ABTS^{•+}$) was generated as described by Pellegrini et al.[19] The radical solution was diluted in ethanol to obtain an absorbance at 734 nm of 0.7 ± 0.05. After addition of the extract, the decrease in absorbance was monitored and compared to that of the trolox standard. Antioxidant capacity was expressed in terms of trolox equivalent antioxidant capacity (TEAC) per gram dry weight (DW) of plant material.

**Determination of Total Phenols.** Determination of total phenolic compounds was performed on methanolic extracts following the method reported by Nguyen and Niemeyer[20] based on the reaction between phenols with Folin−Ciocalteu reagent. Calculations were performed using a calibration curve prepared with gallic acid as standard.

**Determination of Total Anthocyanins.** Approximately 0.01 g of lettuce fresh weight was homogenized in liquid nitrogen and extracted

with 3 M HCl/$H_2O$/MeOH (1:3:16 v/v/v) using a tissue homogenizer. The extracts were centrifuged at 16100*g* for 5 min, and anthocyanin levels were estimated (as cyanidin-3-glycoside equivalents) using a molar extinction coefficient of 33000 $M^{-1}$ $cm^{-1}$.[21] Absorbance of anthocyanins at 524 nm was corrected by subtracting the interference due to pheophytin as $A_{524} - 0.24A_{653}$.[22]

**Analysis of Flavonoids.** Qualitative and quantitative analyses were performed by RP-HPLC. Twenty microliters of extract was injected into a Waters model 515 HPLC system fitted with a 4.6 mm × 250 mm Prodigy ODS column (Phenomenex, Bologna, Italy). Detection was at 360 nm, using a Waters 2487 dual $\lambda$ UV−visible detector. Mobile phase A contained water acidified with formic acid (pH 2.7), and mobile phase B contained methanol. A linear gradient of 10−90% mobile phase B was run for 26 min at 1 mL $min^{-1}$. The identity of the free flavonoids was confirmed by cochromatography with authentic standards. Quantification was performed using standard curves in the range of 10−500 ng of a standard mixture containing luteolin-7-*O*-glucoside, rutin, apigenin-7-*O*-glucoside, quercitrin, quercetin-3-glucuronide, quercetin, luteolin, and kaempferol. Chromatogram analysis was performed by the software Millennium 32 (Waters). Hydrolyzable flavonoids were detected after hydrolysis of methanolic extracts at 85 °C for 30 min with 4 N HCl containing 0.1% (w/v) ascorbic acid.

Detection of cyanidin and cyanidin-3-*O*-glucoside was performed in the dark similarly to that of flavonoids with the exception of absorbance, which was changed to 520 nm. The quantification of anthocyanins was obtained after cochromatography with cyanidin and cyanidin-3-*O*-glucoside in the range 0.1−0.5 $\mu$g.

**Analysis of Phenolic Acids.** Qualitative and quantitative analyses were performed by RP-HPLC as previously reported in Sgherri et al.[23] The identity of the free phenolic acids was confirmed by cochromatography with authentic standards, and quantification was performed using a standard curve in the range 0.1−0.5 $\mu$g of standard mixtures containing gallic, protocatechuic, *p*-hydroxybenzoic, chlorogenic, vanillic, caffeic, syringic, *p*-coumaric, ferulic, and chicoric acids. Chromatogram analysis was performed as previously reported for flavonoid determination.

Detection of conjugated phenolic acid was performed after alkaline hydrolysis of methanolic extracts. Samples were added of 4 N NaOH (1:1, v/v) containing 1% ascorbic acid and 10 mM ethylenediaminetetraacetic acid (EDTA) to prevent the degradation of phenolic acids during alkaline hydrolysis. After incubation for 1 h in the dark under a continuous flux of nitrogen, samples were acidified using 12 N HCl to achieve a pH value of about 2. The resulting mixtures were extracted three times with 1 mL of ethyl acetate. The organic phases were collected after centrifugation at 3000*g* for 5 min and evaporated to dryness at 35 °C in a rotary evaporator. Immediately before analysis, the residue was redissolved in 50% (v/v) acetonitrile and then passed through a Sartorius (Goettingen, Germany) filter (Minisart 0.45 $\mu$m) to remove any suspended material.

**Statistical Analysis.** The results are the means from three replicates of three independent experiments ($n$ = 9). All data are reported as mean values ± SE. The significance of differences among mean values was determined by one-way ANOVA. Comparisons among means were performed using Duncan's multiple-range test. Means in tables and figures accompanied by different letters are significantly different at $p \leq 0.05$. When necessary, an arc sin or angular transformation was applied before statistical analysis was performed.

## RESULTS

The EPR spectrum of DPPH•, previously reported by Sgherri et al.,[2,14] is characterized by five lines that are narrow enough, compared to the spectrum acquisition time, to be used for registration of kinetics with many points close. DPPH• shows a well-resolved quintet EPR spectrum with $a_{N1}$ = 0.927 mT and $a_{N2}$ = 0.846 mT at $g$ = 2.0036, and its unimolecular decay constant was 2.06 × $10^{-6}$ $s^{-1}$.[14,24] The model of scavenging stable DPPH• is a widely used method to evaluate antioxidant capacity, and the radical reactions involved during its scavenging by an antioxidant are well detailed in Espín et al.[12] Decay kinetics of DPPH• following the addition of the hydrophilic extracts from lettuce leaves (G, G/R, and R) are shown in Figure 1. The decay kinetics of DPPH• in the presence of the hydrophilic extract were due to the contribution of two or three pseudo-first-order kinetics, depending on the cultivar: two for G and R and three for G/R. This is related to the presence of different antioxidants or groups of antioxidants that differ in their velocity to scavenge the radical with the rate constants ($k$) to be considered as a measure of the speed of DPPH• disappearance.[12] G cultivar was characterized by an intermediate and a slow rate constant and R by a fast and an intermediate rate constant, whereas G/R was characterized by a fast, an intermediate, and a slow rate constant (Table 1). These $k$ values, which characterize the decay kinetics of DPPH•, are indicative of the presence of antioxidants in the hydrophilic extract distinguishable for a fast, intermediate, and slow action. For this reason, we can calculate (by EPR kinetics) a fast, an intermediate, and a slow antioxidant capacity of the hydrophilic extract. Each antioxidant capacity, detected by EPR, is expressed as the ability to reduce DPPH• molecules by 1 g of lettuce leaves (Table 1). Substantial increases in the fast antioxidant capacity of the hydrophilic extract were observed in G/R compared to G (not detectable) and in R compared to G/R. A significant increase in the slow antioxidant capacity of the hydrophilic extract was also observed in G/R compared to G, whereas R lettuce did not show any slow antioxidant capacity. Although G and G/R showed similar intermediate antioxidant capacities, in R lettuce intermediate antioxidant capacity was about 5 times higher than in G and G/R (Table 1).

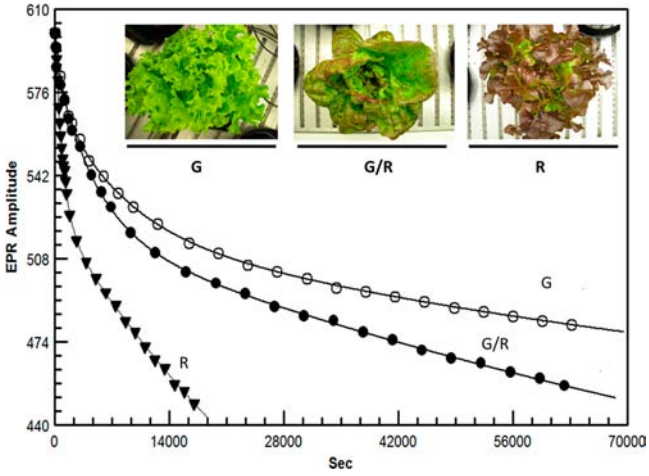

**Figure 1.** EPR decay kinetics of 400 $\mu$M 1,1-diphenyl-2-picrylhydrazyl (DPPH•) after the addition of hydrophilic extracts from green (G), green/red (G/R), and red (R) lettuces.

Data obtained by the discoloration of $ABTS^{\bullet+}$ (Figure 2A) confirmed what is reported in Table 1, namely, that antioxidant capacity of hydrophilic extracts increased with the increase in red pigmentation. In particular, the enhancement in antioxidant capacity was about 120% in G/R and 400% in R, compared to G lettuce. The enrichment in total phenols (Figure 2B) and total anthocyanins (Figure 2C) followed a similar trend. In fact, compared to G lettuce, the contents of total phenols and total anthocyanins increased by 3- and 5-fold in G/R and by 4- and 12-fold in R, respectively.

**Table 1. Decay Rate Constants and Number of Antioxidants Obtained from EPR Decay Kinetics of DPPH after the Addition of Hydrophilic Extract from Green (G), Green/Red (G/R), and Red (R) Lettuces[a]**

| | decay rate constant ($M^{-1}$ $s^{-1}$) | | | no. of antioxidants (no. DPPH• reduced × $10^{19}$/g) | | |
|---|---|---|---|---|---|---|
| | $k_F$ | $k_I$ | $k_S$ | FRA | IRA | SRA |
| G | nd | 0.51 ± 0.04 | 0.017 ± 0.003 | nd | 2.34 ± 0.07 | 3.85 ± 0.09 |
| G/R | 2.75 ± 0.09 | 0.32 ± 0.03 | 0.023 ± 0.005 | 1.43 ± 0.08 | 2.71 ± 0.05 | 4.62 ± 0.05 |
| R | 2.55 ± 0.06 | 0.41 ± 0.02 | nd | 3.70 ± 0.07 | 14.58 ± 0.09 | nd |

[a] $k_F$, fast rate constant; $k_I$, intermediate rate constant; $k_S$, slow rate constant; nd, not detectable. FRA, fast-rate antioxidants; IRA, intermediate-rate antioxidants; SRA, slow-rate antioxidants.

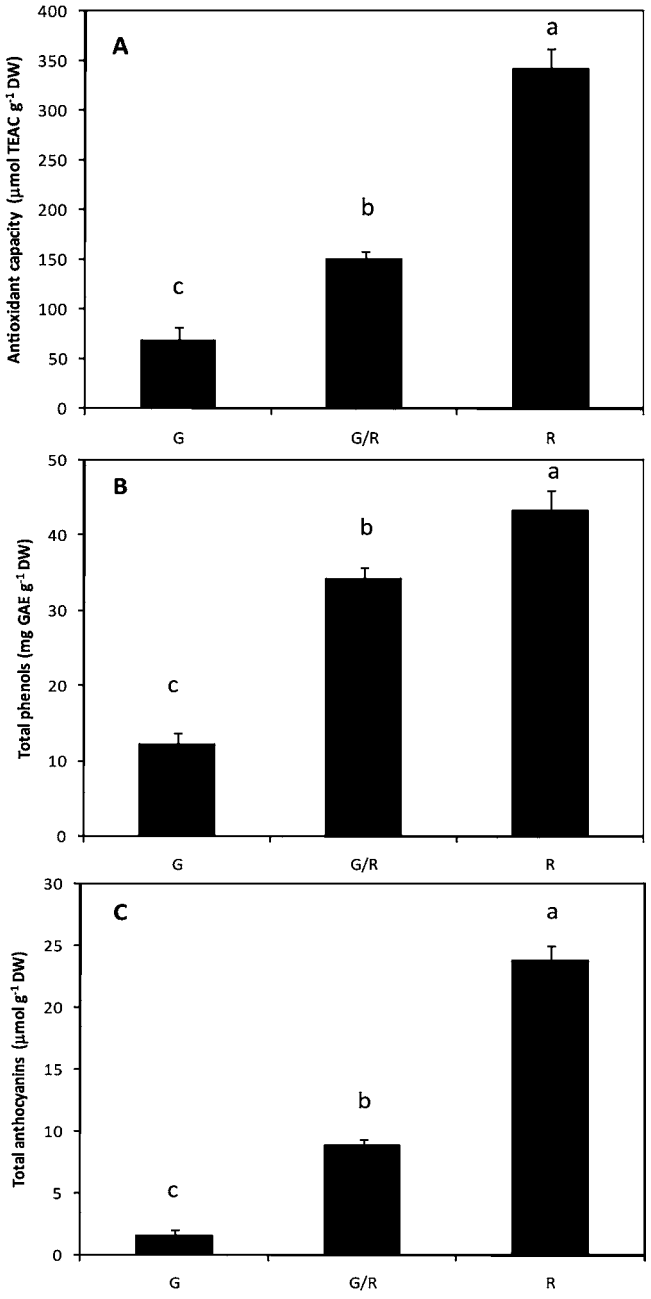

**Figure 2.** Antioxidant capacity determined by discoloration of 2,2′-azinobis(3-ethylbenzothiazoline-6-sulfonic acid) (A), total phenols (B), and total anthocyanins in leaves of green (G), green/red (G/R), and red cultivars (R) of lettuce. All data are reported as mean values ± SE. Means accompanied by different letters are significantly different at $p < 0.05$. TEAC, trolox equivalent antioxidant capacity; GAE, gallic acid equivalent.

Among phenols, Tables 2 and 3 showed that both flavonoids (in free and conjugated form) and phenolic acids (in free and conjugated form) were significantly affected by cultivar type, increasing their total amounts as a function of red pigmentation. In G the main free flavonoids were represented by quercetin and kaempferol, in G/R by kaempferol and quercetin-3-*O*-glucuronide, whereas in R by quercetin, quercetin-3-*O*-glucuronide, and luteolin-7-*O*-glucoside (Table 2). In each lettuce cultivar the most abundant conjugated flavonoid was quercetin, with an average contribution between 56 and 80%. Other hydrolyzable flavonoids identified in lettuce were luteolin and kaempferol (Table 2). In comparison with G, the G/R cultivar showed about double values of total free and hydrolyzable flavonoids. With regard to free flavonoids, this was due to a general increase in all flavonoids, with the exception of quercetin, which remained constant. The increase in the total amount of conjugated flavonoids was instead ascribable to a 2-fold increment of quercetin and kaempferol. R lettuce showed values 15- and 5-fold higher than G lettuce for total free and hydrolyzable flavonoids, respectively. In the R cultivar, each flavonoid took part in the increase in free flavonoids, whereas, similarly to what happened for G/R, only quercetin and kaempferol were responsible for the increase in hydrolyzable flavonoids, luteolin remaining almost constant (Table 2).

For all cultivars the composition in free phenolic acids was characterized by the prevalence of chlorogenic acid, contributing for 63−73% to the total (Table 3). Noteworthy was also the presence of ferulic and chicoric acids. After alkaline hydrolysis, the most representative phenolic acid became caffeic acid, contributing 70−80% to the total amounts of conjugated phenolic acids (Table 3). In comparison with G, higher contents in free phenolic acids showed by G/R and R were mainly related to the increases in chlorogenic, *p*-coumaric, and chicoric acids, whereas those of conjugated phenolic acids were prevalently ascribable to gallic, caffeic, *p*-coumaric, and chicoric acids (Table 3).

With regard to anthocyanins, we detected both cyanidin and cyanidin-3-*O*-glucoside, with cyanidin being prevalent (Figure 3). In G none of these compounds was observed, whereas in R lettuce values for cyanidin and cyanidin-3-*O*-glucoside were 22- and 12-fold higher than in G/R, respectively.

## DISCUSSION

Although in our previous studies DPPH• was employed to analyze the antioxidant behavior of lipid extracts,[2,14,24] the use of DPPH• in an ethanol mixture makes it suitable also for the determination of the antioxidant power of hydrophilic extracts (Figure 1; Table 1). Moreover, because without extract DPPH• shows a decay constant many times lower than that of Fremy's salt,[24] it is more suitable for monitoring long-lasting decay kinetics.

**Table 2. Changes in the Composition (Percent of the Total) and in the Total Amount (Micrograms per Gram Dry Weight) of Free and Conjugated Flavonoids in Different Cultivars of Lettuce[a]**

| | G cultivar | | G/R cultivar | | R cultivar | |

[a]All data are reported as mean values ± SE. For each compound, in free or conjugated form, means accompanied by different letters are significantly different at $p \leq 0.05$ among cultivars. G, green; G/R, green/red; R, red.

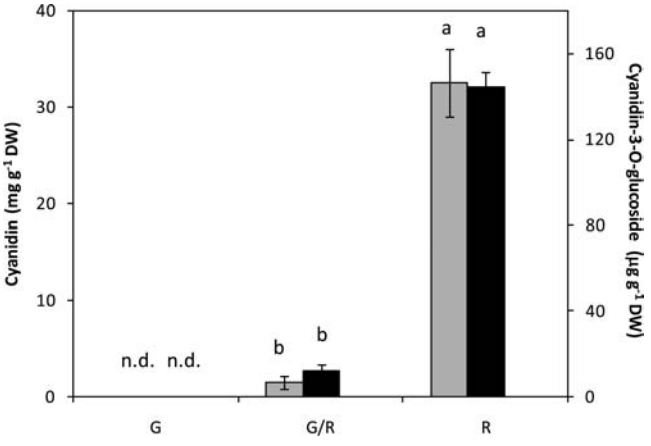

**Figure 3.** Contents of cyanidin (mg $g^{-1}$ DW, left axis; grey) and cyanidin 3-*O*-glucoside ($\mu$g $g^{-1}$ DW, right axis; black) in leaves of green (G), green/red (G/R), and red cultivars (R) of lettuce. All data are reported as mean values ± SE. Means accompanied by different letters are significantly different at $p < 0.05$.

The idea that a different pigmentation of plants is related to a different antioxidant capacity of their extracts is not new,[9,10,15] but the possibility to monitor and simulate EPR decay kinetics of DPPH•, as previously done for lipophilic extracts,[14] may add information about the kinetic behavior of the different antioxidants present in lettuce. Applying this methodology[14] to hydrophilic extracts, we could distinguish among slow-, intermediate-, and fast-rate antioxidants (Figure 1; Table 1). For the moment, we cannot attribute the kinetic behavior to a specific antioxidant, but only state that G/R contains antioxidants belonging to both G and R lettuce (SRA, IRA, FRA) and that G possesses the slowest antioxidants, whereas R the fastest ones (Table 1). The next step will be the identification of a specific kinetic behavior for each hydrophilic antioxidant (mostly representative for lettuce composition) by the study of the decay kinetics of authentic standards, which is currently underway in our laboratory and which was, in part, already performed for lipophilic antioxidants.[24]

Our results suggest that the different decay rates (Table 1) were related to the presence or absence of some antioxidants (Tables 2 and 3; Figure 3). Noteworthy is the relationship between the presence of cyanidin and cyanidin-3-*O*-glucoside and the fastest antioxidant behavior of R and R/G compared to G, which does not contain those antioxidants. Thus, as red pigmentation increased (see inset of Figure 1), the hydrophilic antioxidant capacity was higher (Figure 2A). This result from EPR analysis was further confirmed by spectrophotometric determinations (Figures 1 and 2; Table 1).

In the red lettuces (R and G/R) the higher antioxidant capacity, compared to G, could be also related to the presence of higher amounts of phenols (Figure 2B; Tables 2 and 3). In fact, the lettuce cultivars analyzed showed a positive correlation between the presence of phenols and the antioxidant potential (Figures 1−3; Tables 1−3). However, it is known that not all phenols have an antioxidant capacity,[25] making difficult the

understanding of the relative contribution of the different antioxidant compounds to the higher antioxidant capacity of R lettuce.

Because phenols represent the most important hydrophilic antioxidants in lettuce,[10,26] they are likely the most responsible for its antioxidant capacity. Chlorogenic and chicoric acids being the most representative free phenolic acids for all cultivars (Table 3), it was expected that after basic hydrolysis caffeic acid prevailed in all samples, reaching about 70−80% of the total (Table 3). In fact, chlorogenic acid is the ester of caffeic and quinic acid, whereas chicoric acid results from the esterification of caffeic with tartaric acid. The fact that other authors[10,11] found different values of phenolic acids in lettuce might be attributed to the different growing conditions, as environment affects significantly the phenolic composition.[10] Another source of variation might be represented by the extraction method and, in particular, by the solvent used in the extraction.[27]

Among the variety of phenolic compounds, phenolic acids have attracted considerable interest in the past few years due to their many potential health benefits.[7] The antioxidant nature of phenolic acids and their esters is related to the number of hydroxylations and methoxylations on their aromatic rings.[25] The increase, among others, in chlorogenic acid from G to R could account for the enhancement in antioxidant capacity because Zlotek et al.[11] found that the DPPH$^{\bullet}$ scavenging ability of lettuce was significantly and positively correlated with the presence of chlorogenic acid.

In lettuce the most commonly found flavones and flavonols, having dihydroxylations in the 3′- and 4′-positions of the B ring, were represented by quercetin, quercetin-3-*O*-glucuronide, rutin, luteolin, and luteolin-7-*O*-glucoside (Table 2). Less commonly present were instead those with the lone B-ring hydroxyl group in the 4′-position, that is, kaempferol and apigenin-7-*O*-glucoside (Table 2). It is known that aglycones such as quercetin, luteolin, and kaempferol are more potent antioxidants than their corresponding glycosides.[28] Furthermore, according to Rice-Evans et al.[5] the antioxidant capacity of flavonoids is related to the number and positions of hydroxyl groups, and Soobrattee et al.[4] found that quercetin (3,5,7,3′,4′-OH) has a higher TEAC value than luteolin (5,7,3′,4′-OH) and kaempferol (3,5,7,4′-OH). Thus, also the increase in flavonoids as well as in their glycoside forms (Table 2) could account for the enhancement in the antioxidant capacity of R lettuce compared to G and G/R.

From the results of the present study and the finding of Zlotek et al.[11] that the DPPH$^{\bullet}$ scavenging ability of lettuce is significantly and positively correlated with the presence of quercetin, we could hypothesize that this flavonoid might be one of the antioxidants responsible for the intermediate-decay activity. In fact, G/R and G contained similar concentrations of quercetin, showing the same levels of intermediate-rate antioxidants (Table 1), whereas in R, where quercetin approached a value 20-fold higher (Table 2), the concentration of intermediate-rate antioxidants was much higher (Table 1).

In the R cultivar cyanidin mostly contributed to the amount of total phenols, different from its glucosidic form cyanidin-3-*O*-glucoside (Figures 2 and 3). Anthocyanins are particularly important food bioactive compounds having a double interest: one technological (sensorial characteristics of food products) and the other one related to their health properties.[29] Because glycosylation of anthocyanidins in the 3-position diminishes the antioxidant capacity of its aglycone,[25] cyanidin should contribute mainly to the antioxidant capacity recorded in R lettuce (Figure 1; Table 1).

About 70% (in R) and 90% (in G and G/R) of the phenolic acids detected in lettuce were in the bound form (Table 3). The same pattern was detected for flavonoids (Table 2). Reasons for conjugation of phenolic compounds are related to their potential toxicity and their sequestration in the plant vacuoles.[30] Because it was previously demonstrated that the antioxidant capacity of a free phenolic acid mixture was higher than that of a mixture of bound phenolics,[31] we can assume that the higher antioxidant capacity of R lettuce, compared to G and G/R, could be also related to the decreased presence of the conjugated forms on the total (Tables 2 and 3). However, these results are in contrast with those reported for some barley varieties by Maillard and Berset,[32] who attributed a higher antioxidant capacity to bound phenolic acids. Moreover, it has been demonstrated that also flavonol glycosides can be absorbed as intact molecules.[33] Thus, it is advisible to give attention to the identification and quantification of both free and conjugated forms.

In conclusion, as long as lettuce had higher red pigmentation, the hydrophilic antioxidant capacity increased together with the contents in free and conjugated phenolic acids, free and conjugated flavonoids, and anthocyanins. The study of EPR decay kinetics allowed the identification of slow-, intermediate-, and fast-rate antioxidants in the three different lettuce cultivars. At present, we cannot attribute a kinetic behavior to a specific antioxidant, but we can suggest that the flavonoid quercetin accounted for the majority of the intermediate-rate antioxidants, whereas anthocyanins accounted for the majority of the fast-rate antioxidants.

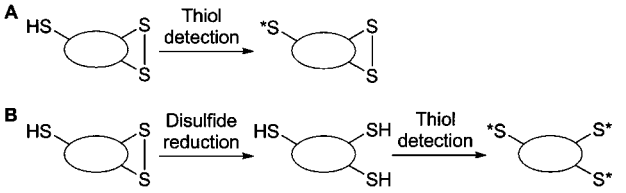

**Figure 1.** Approach for detection of (A) free thiols and (B) total thiols. Thiols destined for detection are denoted S* (modified with permission from ref 15. Copyright 2009 Elsevier).

maximum absorbance at 412 nm in the pH range from 6 to 9.5.[14,15] An alternative to DTNB is 4,4′-dithiodipyridine (4-DPS), which reacts in a similar way with thiol groups, forming 4-thiopyridone (4-TP) that absorbs at 324 nm. The small size of this detection reagent makes it easier to reach poorly accessible thiols within the protein core. 4-TP also has a higher extinction coefficient than NTB, suggesting that 4-DPS is a more sensitive thiol detection agent than DTNB.[16] Furthermore, 4-TP is stable in lower pH ranges (pH 3−7), making thiol detection possible at low pH as in common reversed-phase high-performance liquid chromatography (HPLC) conditions.[17] Ruan et al.[18] found 4-DPS to be less affected by pH and denaturants compared to DTNB and, thus, found 4-DPS more suitable and reliable for thiol detection in soy protein. The measurement of disulfide bonds is based on the reduction of disulfides, followed by detection of the newly reduced thiols (Figure 1B). The amount of disulfides can then be calculated by subtracting the amount of free thiols from total thiols. To reduce disulfide bonds during SDS−PAGE, dithiothreitol (DTT) is often used. This reagent is less suitable for disulfide quantification because of its slow reaction rate and the cross-reactivity with thiol detection agents.[15,17] Liu et al.[19] have quantified disulfide bonds in myofibrillar proteins based on a method described by Damodaran.[20] In this procedure, disulfides are cleaved by adding an excess of sodium sulfite. However, oxidative sulfitolysis of disulfide bonds is slow and rarely quantitative in the absence of catalysts.[15,21] An alternative reducing agent is sodium borohydride (BH), a highly reactive and strong reductant, whose main advantage is that its excess can be removed by acidification.[15,22]

The aim of the present study was to investigate the extent of reversible and irreversible thiol oxidation in ground beef during storage. A sensitive and reliable method for the quantification of protein disulfides in meat was established on the basis of disulfide reduction with sodium borohydride and thiol detection with 4-DPS. The method was subsequently used for quantification of reversible and irreversible thiol oxidation in ground beef during storage in high-oxygen modified atmosphere packaging (HiOx MAP) and compared to SDS−PAGE-based methodology.

## MATERIALS AND METHODS

**Chemicals.** All chemicals were of analytical grade or the highest available purity. Citric acid was purchased from Carl Roth GmbH (Karlsruhe, Germany). Disodium hydrogen phosphate was purchased from Panreac Química, S.A.U. (Castellar del Vallès, Barcelona, Spain). Trisodium citrate dihydrate, sodium dodecyl sulfate (SDS), hydrochloric acid, tris(hydroxymethyl)-aminomethane (Tris), 1-octanol, sodium hydroxide, and bovine serum albumin (BSA) were obtained from Merck (Darmstadt, Germany). Guanidine hydrochloride (GuHCl), L-cysteine, and sodium borohydride were purchased from Sigma-Aldrich Co. (St. Louis, MO). 4-DPS and oxidized glutathione (GSSG) were obtained from Acros Organics (Geel, Belgium). NuPAGE Novex 3−8% Tris−acetate gels, lithium dodecyl sulfate (LDS) sample buffer, SDS Tris−acetate running buffer, and Molecular Probes SYPRO Ruby Protein Gel Stain were purchased from Invitrogen (Carlsbad, CA). Precision Plus Protein Standard All Blue was obtained from Bio-Rad Laboratories, Inc. (Hercules, CA). DTT was purchased from Applichem GmbH (Darmstad, Germany). Water was prepared using a Millipore Mill-Q purification system (Millipore Corp., Bedford, MA).

**Sampling of HiOx MAP Ground Meat.** Two independent storage trials (trials 1 and 2) were performed for sampling of HiOx MAP ground beef. For trial 1, ground beef stored in HiOx MAP was obtained from a local Danish supermarket. The meat had been packed under modified atmosphere (high oxygen) the day before and consisted of nine packages of 400 g each. Three packages (replicates A, B, and C) were opened, and the meat was vacuum-packed in portions of 50 g and stored at −80 °C until analysis (day 0). The remaining six packages were stored in darkness at 4 °C until day 4 or 9, at which point another three replicates (A, B, and C) were collected, vacuum-packed, and frozen to −80 °C.

For trial 2, similar sampling was performed for freshly ground beef obtained from a local Belgian butcher, ground 3 days after slaughter of the animal. The meat was packed under modified atmosphere (70% $O_2$ and 30% $CO_2$) into 15 packages of 450 g each and stored at 4 °C until sampling day. On days 0, 3, 6, 9, and 12, three packages (replicates A, B, and C) were opened, vacuum-packed in portions of 75 g, and stored at −80 °C until analysis.

**Influence of pH and Denaturant on the Molar Extinction Coefficients of 4-TP.** A total of 24 buffers were prepared, by varying the buffering capacity, the pH value, and the presence of a denaturant. Six buffers with a low buffering capacity were prepared by mixing 0.1 M citric acid and 0.2 M $Na_2HPO_4$ to pH values of 2.5, 3.5, 4.5, 5.5, 6.5, and 7.5. Likewise, six high-capacity buffers were prepared by mixing 1 M citric acid and 1 M trisodium citrate dihydrate to the aforementioned pH values. SDS buffers were prepared by adding 5% (w/v) SDS to the low-capacity buffers. The same was performed for guanidine hydrochloride by adding 6 M GuHCl to the high-capacity buffers. Concentrations of L-cysteine ranging from 2.5 to 500 μM were prepared in all buffers. Thiol detection with 4-DPS was performed on the basis of the study by Riener et al.,[16] by diluting 500 μL of L-cysteine solution with 2 mL of the corresponding buffer and adding 500 μL of 4-DPS solution (4 mM 4-DPS in 12 mM HCl). The absorbances were measured at 324 nm against water before the addition of 4-DPS ($A_{pre}$) and after exactly 30 min of reaction with 4-DPS in the dark at room temperature ($A_{post}$). The absorbance corresponding to the thiol concentration was calculated by subtracting $A_{pre}$ and $A_{blank}$ (2.5 mL of buffer + 500 μL of 4-DPS solution) from $A_{post}$. Molar extinction coefficients ($\varepsilon$) were calculated from the slope of the standard curves according to the Lambert−Beer law ($A$ is the absorbance, and $l$ is the path length).

$$A = \varepsilon l c \quad (1)$$

**Optimization of Disulfide Reduction.** The efficiency of the disulfide reduction was tested by the reduction of known concentrations (25−200 μM) of commercially available GSSG. The expectation was to find thiol concentrations in the form of reduced glutathione (GSH) double the aforementioned molarities (50−400 μM). GSSG was dissolved in 6 M GuHCl in 100 μM Tris buffer (pH 8.0), because this was the buffer system that was chosen to solubilize the meat proteins. The method was developed on the basis of disulfide reduction according to Hansen et al.[17] The reduction was performed by adding 100 μL of 30% (w/v) alkaline borohydride to 3 mL of sample. After incubation at 50 °C, the excess of borohydride was removed with 6 M hydrochloride (final concentration of 1.8 M) at room temperature. Different conditions and parameters were tested by varying the solvent for sodium borohydride (1, 2, and 4 M NaOH), the incubation time for the reduction with borohydride (15, 30, 60, and 150 min), and the hydrolysis time of the residual borohydride (2, 10, 20, 30, 40, 45, 60, 90, 150, 165, and 180 min).

**Quantification of Free and Total Thiols in MAP Ground Beef Using 4-DPS.** The vacuum-packed meat was thawed in water at room

temperature for 30 min before homogenizing 1.0 g of meat in 25 mL of 6 M GuHCl in 100 mM Tris buffer (pH 8.0) using an Ultra Turrax. The homogenates were centrifuged (for 20 min at 5311*g* and 4 °C), and supernatants were filtered (qualitative filter paper, particle retention of 11 μm). Samples were kept on ice at all times. The protein concentration of the filtrates was determined spectrophotometrically at 280 nm using a five-point standard curve prepared from BSA. Disulfide reduction was performed according to the optimized procedure, as described in the previous section. Hence, an aliquot of 3 mL of filtrate was subjected to disulfide reduction by adding 50 μL of 1-octanol (as an anti-foaming agent) and 100 μL of freshly prepared 30% (w/v) sodium borohydride in 1 M NaOH. After incubation at 50 °C for 30 min, an aliquot of 1.35 mL of 6 M HCl was added, followed by stirring for 10 min.

Free and total thiols were determined with 4-DPS in the non-reduced and reduced filtrates, respectively. An aliquot of 500 μL of filtrate was mixed with 2 mL of 6 M GuHCl in 1 M citric acid buffer (pH 4.5) and 500 μL of 4-DPS solution (4 mM 4-DPS in 12 mM HCl). The absorbance was measured at 324 nm against 6 M GuHCl in 1 M citric acid buffer (pH 4.5) before the addition of 4-DPS ($A_{pre}$) and after exactly 30 min of reaction with 4-DPS in the dark at room temperature ($A_{post}$). A mixture of 2.5 mL of 6 M GuHCl in 1 M citric acid buffer (pH 4.5) and 500 μL of 4-DPS solution was prepared as a blank sample ($A_{blank}$). The absorbance corresponding to the thiol concentration was calculated by subtracting $A_{pre}$ and $A_{blank}$ from $A_{post}$. The thiol concentration was calculated on the basis of a five-point standard curve ranging from 2.5 to 500 μM L-cysteine in 6 M GuHCl in 1 M citric acid buffer (pH 4.5). The thiol content was expressed as nanomoles of thiol per milligram of protein. Because treatment of disulfide bonds with sodium borohydride yields two thiol groups,[23] the disulfide content was calculated as half of the difference between total and free thiols.

**SDS–PAGE Analysis.** The meat from trial 1 was subjected to SDS–PAGE analysis. The meat was thawed at room temperature for 30 min before an aliquot of 1.0 g of meat was homogenized in 25 mL of 5% (w/v) SDS dissolved in 100 mM Tris buffer at pH 8.0 using an Ultra Turrax. The homogenates were placed in a water bath at 80 °C for 30 min, followed by centrifugation for 20 min at 950*g*. The supernatant was filtered (particle retention of 5–13 μm), and the protein concentration was determined spectrophotometrically at 280 nm using a standard curve prepared from BSA. The homogenates were analyzed by gel electrophoresis using NuPAGE Novex 3–8% Tris–acetate gels according to the instructions of the manufacturer (Invitrogen, Carlsbad, CA). Reduced samples were prepared by mixing 1.6 μL of diluted sample (2.0 mg of protein/mL) and 14.4 μL of loading solution, which was prepared from 60 μL of LDS sample buffer, 24 μL of 1.0 M DTT, and 132 μL of Milli-Q water. The non-reduced samples were prepared by mixing 1.6 μL of diluted sample (2.0 mg of protein/mL) and 14.4 μL of loading solution, which was prepared from 60 μL of LDS sample buffer and 156 μL of Milli-Q water. Aliquots of 10 μL of reduced or non-reduced samples as well as 3 μL of Precision Plus Protein Standard All Blue marker were loaded to the wells of the gels. Electrophoresis was run for 90 min at 150 V in cassettes containing ice-cold SDS Tris–acetate running buffer. After electrophoresis, the gels were fixed overnight in fixation solution (50% ethanol and 7% acetic acid) at room temperature on a rocking table. Following staining overnight by the fluorescence SYPRO Ruby Protein Gel Stain, the gels were photographed by a charge-coupled device (CCD) camera (Raytest, Camilla II, Straubenhardt, Germany). The protein concentration of the bands were estimated by the pixel intensity as determined by the freeware GelAnalyzer by Dr. Istvan Lazar, www.gelanalyzer.com. Band intensities were quantified from the volume of the pixel intensity when analyzing the gels with GelAnalyzer. To correct for total protein content of each sample, the pixel intensities of cross-linked myosin heavy chain (CL-MHC) and myosin heavy chain (MHC) were divided by the total pixel volume of all bands in each lane of the gel to obtain the relative intensity of CL-MHC and MHC for each sample. The degree of cross-linking was calculated on the basis of gels containing both reduced and non-reduced samples and was considered equal to the ratio of the relative intensity of CL-MHC in the non-reduced samples to the relative intensity of MHC in the reduced samples at day 0 ($CL\text{-}MHC_{non\text{-}red}/MHC_{red,\ day\ 0}$, %).

**Statistical Analysis.** Statistical analysis was performed using SAS 9.3 package (SAS Institute, Inc., Cary, NC). Recovery percentages were analyzed using a linear model with the concentration as fixed effect. Free and total thiols were analyzed using a linear model with the storage time (days), treatment (with or without reduction), and their interaction as fixed effects. Disulfides and degrees of cross-linking were analyzed using a linear model with the storage time as fixed effect. The correlation between the 4-DPS assay and SDS–PAGE was assessed using Pearson correlation. Effects were considered significant at $p < 0.05$.

## RESULTS AND DISCUSSION

**Influence of pH and Denaturant on the Molar Extinction Coefficients of 4-TP.** To determine the optimal pH for thiol detection with 4-DPS, two types of buffer solutions with a low and high buffering capacity were prepared that ranged from pH 2.5 to 7.5. It is strictly necessary to include protein denaturants in the buffer during analysis of thiols in meat to prevent precipitation of some of the cross-linked protein. In the absence of protein denaturants, such precipitants would not be included in the assay, resulting in erroneous quantifications. The effect of denaturants was therefore tested by adding 5% SDS and 6 M GuHCl to the low- and high-capacity buffers, respectively. Molar extinction coefficients were calculated from the slope of a L-cysteine standard curve, which was subjected to the 4-DPS assay at all pH and denaturant conditions.

According to Riener et al.,[16] the molar extinction coefficient of 4-TP is 21 400 $M^{-1}$ $cm^{-1}$ at pH 7.0. As shown in Figure 2,

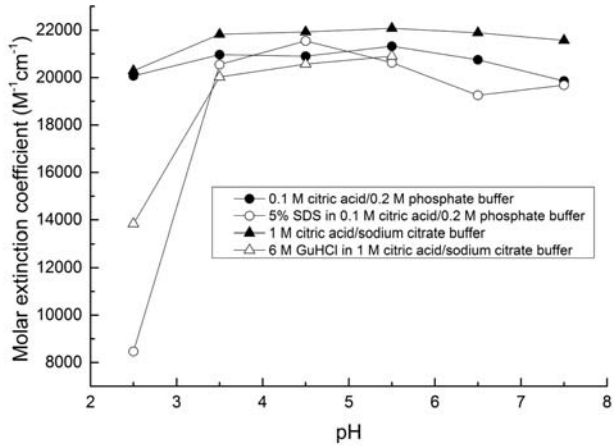

**Figure 2.** Molar extinction coefficients of 4-DPS as a function of pH.

the molar extinction coefficients in all low- and high-capacity buffers without denaturants stay close to this value. However, adding denaturants to the buffers clearly narrows the pH range in which the molar extinction coefficients are stable. This is in agreement with the findings by Hansen and Winther,[15] who found that the presence of denaturants decreased the alkylation rate of NTB by *N*-ethylmaleimide. The lowest 4-TP absorptions were measured at pH 2.5 with buffers added 5% SDS and 6 M GuHCl ($\varepsilon$ = 8500 and 13 800 $M^{-1}$ $cm^{-1}$, respectively). The amount of GuHCl was not soluble at pH 6.5 and 7.5; thus, Figure 2 shows no results for these conditions.

Overall, optimal molar extinction coefficients were found in buffers containing denaturants ranging from pH 3.5 to 5.5. Two

factors were considered to select the optimal working buffer. First, the pH value in the samples was very low after acidification in the reduction step. Therefore, a high-capacity buffer was needed to ensure correct pH adjustment. Second, a strong denaturant is crucial to ensure good solubility of meat proteins. We therefore chose to use 6 M GuHCl in 1 M citric acid buffer at pH 4.5 as a working buffer for determining the free and total thiols in meat using 4-DPS.

**Optimization of Disulfide Reduction.** It was necessary to optimize the disulfide reduction in the buffer systems chosen for the meat samples, and this was established by determination of recovery percentages for the reduction of GSSG based on incubation at 50 °C with alkaline borohydride, followed by removal of residual borohydride by acidification. The reduction procedure was tested by combining different sodium hydroxide concentrations with varying times of incubation and hydrolysis, as described above. For each combination, a known concentration of GSSG in 6 M GuHCl in 100 mM Tris buffer (pH 8.0) and a blank (6 M GuHCl in 100 mM Tris buffer at pH 8.0) were subjected to the reduction assay. Twice as much GSH as GSSG in molar concentrations was expected; thus, the recovery percentages were calculated according to eq 2.

$$\text{recovery percentage (\%)} = \frac{\text{thiols quantified}}{\text{thiols expected}} \times 100 \quad (2)$$

It is well-known that sodium borohydride rapidly decomposes at neutral or acidic pH.[24] Therefore, solutions of 30% (w/v) borohydride in 1, 2, and 4 M NaOH were freshly prepared for the reduction of GSSG. After mixing 3 mL of sample with 100 μL of BH dissolved in 1, 2, and 4 M NaOH, the pH was approximately 8.6, 11.0, and 12.0, respectively. Although Patsoukis and Georgiou[25] highlighted that a high alkaline environment (pH 12.0 rather than pH 8.0) is needed for optimal disulfide reduction by borohydride, we found similar recovery percentages with the 1 M NaOH treatment as with 2 and 4 M NaOH (data not shown). The lack of correlation between our results and those reported by Patsoukis and Georgiou[25] may be due to the use of different buffers and derivatization agents.

After the addition of BH, the mixtures were incubated at 50 °C as recommended by Patsoukis and Georgiou.[25] The optimal incubation time for effective reduction depends upon the concentration and reactivity of BH and the accessibility of the protein disulfides. Incubation must take long enough to let BH reach and reduce all disulfides. Prolonged incubation, however, might promote reoxidation of the newly formed thiols.[22] Furthermore, $NaBH_4$ can decompose over time, even at alkaline pH.[22,26] For the current method development, oxidized glutathione was incubated with BH during 15, 30, 60, and 150 min and optimal recovery percentages were found with 30 min of incubation (data not shown).

Subsequent to incubation, the residual BH was removed by acidification with 6 M HCl, bringing the final concentration of HCl in the mixture to 1.8 M. Acidification of $NaBH_4$ completely discharges the reactive hydride, yielding hydrogen gas ($H_2$)[15,27] and causing the protein solution to foam. This foaming was avoided by adding a small amount of 1-octanol.[15] During the method optimization, the acidified solutions were left to stir on a magnetic stirrer at room temperature for various time periods, ranging from 2 min to 3 h. The best recovery percentages were found when stirring for 10 min after the addition of HCl and subsequently readjusting the pH with 6 M GuHCl in 1 M citric acid buffer (pH 4.5) for the 4-DPS assay (data not shown). Although the low pH of the BH−HCl mixture is likely to protect the reduced thiols from reoxidation,[15] oxygen inclusion because of prolonged and vigorous stirring may induce further oxidation after the reducing agent has been deactivated.[22]

The method for disulfide reduction was adjusted on the basis of all of the above-mentioned considerations. Optimal recovery percentages in the range from 25 to 200 μM GSSG were obtained when carrying out the reduction as follows: 50 μL of 1-octanol and 100 μL of freshly prepared 30% (w/v) sodium borohydride in 1 M NaOH were added to 3 mL of sample. The mixture was incubated at 50 °C for 30 min with occasional stirring. After incubation, the excess of borohydride was removed by adding 1.35 mL of 6 M HCl, followed by stirring for 10 min. This procedure was applied for the reduction of various concentrations of GSSG. The quantified thiols and recovery percentages are presented in Table 1.

**Table 1. Recovery of GSH after Reduction of GSSG in 6 M GuHCl and 100 mM Tris Buffer (pH 8.0), with 30% (w/v) Sodium Borohydride in 1 M NaOH at 50 °C for 30 min, Followed by Acidification with 6 M HCl (Final Concentration of 1.8 M) and Stirring for 10 min[a]**

| GSSG (μM) | thiols expected (μM) | thiols quantified (μM) | recovery (%) |
|---|---|---|---|
| 0 (blank) | 0 | 3.8 ± 1.6 | |
| 25 | 50 | 42.9 ± 3.6 | 85.8 ± 7.1 |
| 50 | 100 | 82.7 ± 4.7 | 82.7 ± 4.7 |
| 75 | 150 | 129.1 ± 2.6 | 86.1 ± 1.7 |
| 100 | 200 | 175.3 ± 1.2 | 87.7 ± 0.6 |
| 125 | 250 | 211.5 ± 8.6 | 84.6 ± 3.4 |
| 150 | 300 | 262.7 ± 5.6 | 87.6 ± 1.9 |
| 175 | 350 | 304.7 ± 6.5 | 87.1 ± 1.9 |
| 200 | 400 | 350.1 ± 8.1 | 87.5 ± 2.0 |

[a]Recovery percentages are expressed as the ratio quantified to expected thiols (described in eq 2).

No significant differences between recovery percentages were found among the GSSG concentrations ($p = 0.642$), indicating that the reduction procedure is precise for concentrations ranging from 25 to 200 μM disulfides and resulted in an approximate recovery of 86%. According to AOAC International, the expected recovery is from 80−90 to 107−110% in the concentration range of the quantified thiols used in the present study; therefore, the observed accuracy is acceptable.[28]

**Quantification of Disulfides in MAP Ground Beef with 4-DPS.** MAP ground beef obtained from trials 1 and 2 were subjected to thiol and disulfide quantification by the 4-DPS assay at various storage times. Caution should be made when comparing the meat from trials 1 and 2 for several reasons: (1) the batches of meat were not obtained from the same animal; (2) ground beef often comes from different muscles; thus, any observed difference in thiol or disulfide concentrations between the two trials could be ascribed to differences in the types of muscles used in each batch of meat; and (3) there are differences in time between slaughter and packaging and the exact gas composition (unknown for trial 1).

The significant decrease in free thiols in the meat from trial 1 as well as trial 2 (Tables 2 and 3, respectively) shows that thiol oxidation (ca. 30 and 33% loss of thiols, respectively) took place during storage, which is in agreement with previous studies.[3,29] After reduction of the proteins from the beef

**Table 2. Thiol and Disulfide Quantification with 4-DPS in Ground Beef from Trial 1, Stored under High-Oxygen Atmosphere at 4 °C for up to 9 Days[a]**

| storage time | free thiols (nmol/mg of protein) | total thiols (nmol/mg of protein) | disulfides (nmol/mg of protein) |
|---|---|---|---|
| day 0 | 37.6 ± 0.5 a | 51.7 ± 0.8 a | 7.0 ± 0.6 a |
| day 4 | 30.0 ± 1.1 b | 49.2 ± 1.5 a | 9.6 ± 1.1 b |
| day 9 | 26.5 ± 1.7 c | 49.4 ± 1.4 a | 11.5 ± 1.4 c |

[a]Results are shown as the mean ± standard deviation (SD) of three independent replicates. Different letters (a–c) within a column denote statistical differences among storage times ($p < 0.05$).

**Table 3. Thiol and Disulfide Quantification with 4-DPS in Ground Beef from Trial 2, Stored under High-Oxygen Atmosphere at 4 °C during 12 Days[a]**

| storage time | free thiols (nmol/mg of protein) | total thiols (nmol/mg of protein) | disulfides (nmol/mg of protein) |
|---|---|---|---|
| day 0 | 58.3 ± 1.6 a | 61.8 ± 0.2 a | 1.8 ± 0.9 a |
| day 3 | 44.4 ± 1.2 b | 55.1 ± 1.2 b | 5.3 ± 1.1 b |

[a]Results are shown as the mean ± SD of three independent replicates. Different letters (a–c) within a column denote statistical differences among storage times ($p < 0.05$).

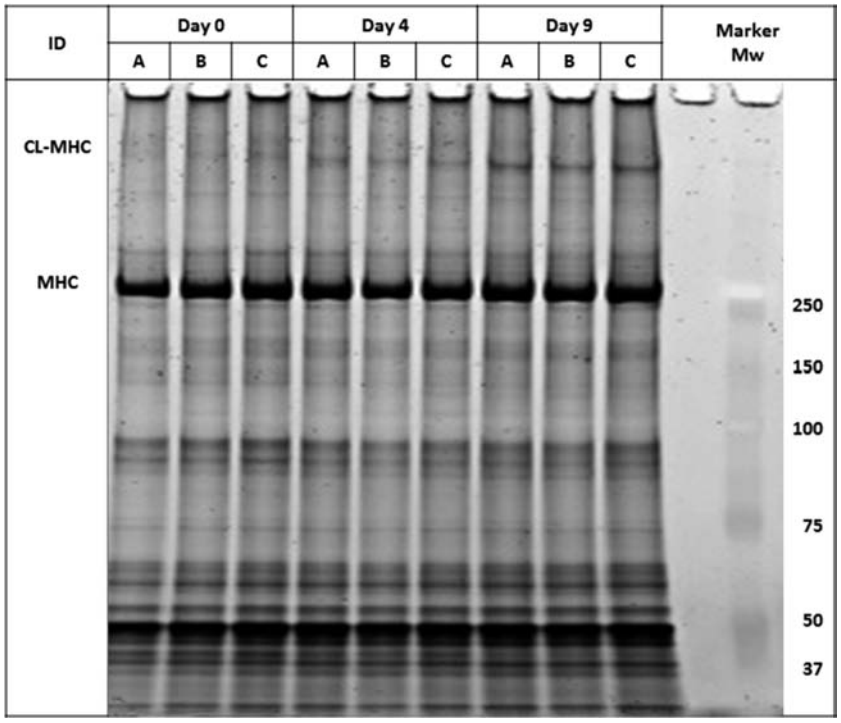

**Figure 3.** SDS–PAGE gel of non-reduced ground beef from trial 1 stored under high-oxygen atmosphere at 4 °C for 9 days. The gel shows all samples in triplicate (A–C). CL-MHC, cross-linked myosin heavy chain; MHC, myosin heavy chain.

samples from trial 1 with borohydride, the amount of total thiols was significantly higher than the amount of free thiols at all sampling days, indicating the formation of disulfides. No significant changes in total thiol levels were found during the 9 days of storage (Table 2). This suggests that all thiols lost during 9 days of storage could be fully reduced by borohydride and were, hence, lost because of reversible thiol oxidation (most likely disulfide formation).

When subjecting the beef from trial 2 to borohydride reduction, no significant difference was found between the free and total thiol level on day 0, indicating that the initial level of oxidation in this meat was minimal. After 3 days of storage, the concentration of free thiols was significantly lower than at day 0 (Table 3) ($p < 0.001$), confirming thiol oxidation during storage. Reduction of the beef proteins resulted in a significantly higher concentration of total thiols than free thiols at day 3 ($p < 0.001$), proving the formation of disulfides. However, the concentration of total thiols significantly decreased from day 0 to day 3 ($p < 0.001$), showing that irreversible thiol oxidation had taken place concomitantly to the disulfide formation. Although the amount of total thiols stayed constant between days 3 and 12, there was a significant decrease of free thiols between days 3 and 12, indicating that predominantly protein disulfides were formed in this storage period. With subtraction of the free thiol concentration on day 0 with the free thiol concentration on day 12, a loss in free

thiols of 19 nmol/mg of protein was obtained. Similarly, the loss in total thiols over 12 days of storage was only 10 nmol/mg of protein, which means that, over the full duration of storage, about half of the thiols was lost because of irreversible oxidation and the other half was lost because of reversible oxidation. The consequence of thiol oxidation in meat has previously been ascribed mainly to disulfide formation;[3,29] however, thiol oxidation is very complex, and numerous oxidation products may be formed, such as sulfenic acid, sulfinic acid, sulfonic acid, and thiosulfinates.[10] The present study shows that other thiol oxidation products than disulfides may be formed in meat during storage. While the formation of sulfonic acid is irreversible, sulfenic acid is extremely reactive and may react further to create compounds, such as disulfides or sulfonic acid. Because of the efficient reducing capacity of BH, it is likely that sulfenic acids are also reduced to thiols by this reducing agent; thus, it is unknown whether a part of the quantified total thiols is in fact derived from the reduction of sulfenic acid, thus overestimating the amount of disulfides. However, the approach based on BH and 4-DPS has previously been used for the quantification of the thiol−disulfide redox status in cells without considering a potential sulfenic acid formation.[30] The formation of sulfenic acids in living cells has been shown to be rather widespread in some cases,[31] but it has never been determined in meat samples during storage.

**Comparison between SDS−PAGE and 4-DPS for the Quantification of Disulfides in MAP Ground Beef.** The quantification of thiols and disulfides in the ground beef from trial 1 with 4-DPS was compared to the conventional cross-linking analysis by SDS−PAGE. MHC has previously been found to be the meat protein that is most susceptible to oxidation, and SDS−PAGE analysis has been widely used to study disulfide cross-link formation in meat and meat products.[3,8,13,29] The non-reduced samples showed an increase of the CL-MHC band intensity on the SDS gel as the storage time increased (Figure 3), whereas no CL-MHC was seen in the reduced samples (data not shown).

The degrees of disulfide formation in the ground beef according to the 4-DPS assay and SDS−PAGE are compared in Table 4. With both methods, a significant increase of disulfides was found in the ground beef during 9 days of storage under high-oxygen atmosphere ($p < 0.001$ and $p = 0.005$ for 4-DPS and SDS−PAGE, respectively). A Pearson correlation of 0.913 was found between the two methods, but the concentration of disulfides found by the 4-DPS assay was considerably higher than that by SDS−PAGE. This can be explained by the fact that two proteins may be cross-linked by several disulfide bridges; consequently, cleaving these disulfide bridges leads to more than two newly formed thiol groups. From the three-dimensional protein structure of MHC, it can be seen that several cysteine residues are transversely positioned in the tail of MHC; thus, it is likely that several intermolecular disulfides are formed between two MHC molecules. Furthermore, thiols may be lost to disulfide formation intramolecularly in MHC, without causing a cross-link between two proteins, that is, without generating the CL-MHC band that appears in the SDS−PAGE gel. Additionally, it is worth noting that severely CL-MHC polymers are probably too large to enter the SDS gel,[12] leading to an underestimation of CL-MHC. This is a problem that is actually one of the many drawbacks with the gel electrophoresis methods. Finally, even though MHC has been found to be the meat protein that is most prone to thiol oxidation,[32] disulfide formation in other meat proteins may also contribute to the values obtained with the 4-DPS assay, and as mentioned above, the potential presence of sulfenic acid may contribute to an overestimation of disulfides by the 4-DPS assay. In conclusion, SDS−PAGE analysis provides information about intermolecular disulfide formation in MHC for moderately oxidized samples, while the 4-DPS assay provides a more accurate and quantitative assessment of protein thiols and intra- and intermolecular disulfides and, thus, offers a good tool to investigate the thiol−disulfide reactions in meat and potentially also in meat products.

In the present study, we have shown that both reversible and irreversible thiol oxidation takes place in meat during storage. Disulfide formation is often the consequence of thiol oxidation, as observed by a thiol loss, but our results clearly show that disulfide formation in meat during storage is not the only consequence of thiol oxidation. This is an important observation in relation to the further development of strategies to avoid or repair thiol oxidation.

**Table 4. Degrees of Cross-Linking in Ground Beef Obtained from Trial 1 during 9 Days of Storage under High-Oxygen Atmosphere at 4 °C, Measured with 4-DPS and SDS−PAGE[a]**

| | 4-DPS assay | SDS−PAGE |
|---|---|---|
| storage time | disulfides/total thiols$_{day\ 0}$ (%) | CL-MHC$_{non\text{-}red}$/MHC$_{red,\ day\ 0}$ (%) |
| day 0 | 13.6 ± 0.4 a | 3.1 ± 1.6 a |
| day 4 | 18.6 ± 0.9 b | 6.9 ± 1.0 b |
| day 9 | 22.2 ± 0.3 c | 8.5 ± 1.2 b |

[a]Degrees of cross-linking are expressed as the level of cross-linking (disulfides and CL-MHC for 4-DPS and SDS−PAGE, respectively) divided by the reference level of reduced protein on day 0 (total thiols and MHC$_{red}$ for 4-DPS and SDS−PAGE, respectively). Results are shown as the mean ± SD of three independent replicates. CL-MHC, cross-linked myosin heavy chain; MHC, myosin heavy chain. Different letters (a−c) within a column denote statistical differences among storage times ($p < 0.05$).

collected, and only green leaf was collected in other time points. Leaf samples of lingonberry (*V. vitis-idaea* L.) were collected in the forest of the Paattinen area, Turku, Finland (latitude, 60° 36′ 15″ N; longitude, 22° 22′ 33″ E) at intervals of approximately 10 days from the end of June to mid-September 2013. Both locations consisted of a moraine-type soil. The location in Paattinen was facing east/southeast, and the location in Kohmo was flat. Information on the weather conditions in the Turku area during the growth period can be found in Supplemenatary Table 1 in the Supporting Information. At each time point, samples were picked from five different blocks within the same area. After this, the samples were pooled together into a representative sample and mixed well before being frozen at −18 °C until analysis.

**Reference Compounds and Reagents.** Hyperoside (quercetin-3-*O*-galactoside), isoquercitrin (quercetin-3-*O*-glucoside), kaempferol-3-*O*-glucoside, rutin (quercetin-3-*O*-rutinoside), cyanidin-3-*O*-glucoside chloride, cyanidin-3-*O*-galactoside chloride, and cyanidin-3-*O*-arabinoside chloride were purchased from Extrasynthese (Genay, France). Quercetin-3-*O*-glucuronide, kaempferol-3-*O*-glucuronide, quercetin-3-*O*-rhamnoside, epicatechin, catechin, and chlorogenic acid (5-*O*-caffeoylquinic acid) were purchased from Sigma-Aldrich Co. (St. Louis, MO, USA), methanol (HPLC grade) and formic acid from J. T. Baker (Deventer, The Netherlands), and acetone (HPLC grade) and acetonitrile (HPLC grade) from VWR International Oy (Espoo, Finland).

Deuterium oxide ($D_2O$) was from VWR Internatinal BVBA (Leuven, Belgium). Acetone-$d_6$ and 3-(trimethylsilyl) propionic-2,2,3,3-$d_4$ acid sodium salt (TSP) were from Sigma-Aldrich Co.

**Sample Preparation for HPLC Analysis of Phenolic Compounds.** A sample of 10 g of frozen bilberry leaves or lingonberry leaves was milled to a fine powder with the aid of liquid nitrogen. About 1.5 g of leaf powder was extracted with 20 mL of 70% aqueous acetone in an ultrasonicator bath for 15 min, followed by centrifugation (4420*g*) for 5 min. The supernatant was collected. After centrifugation, the residue was extracted twice, and the supernatants of three extractions were combined and evaporated until dry with a vacuum rotary evaporator at 35 °C. The extract was redissolved in 5 mL of methanol and filtered through a 0.45 μm filter before analysis. Two parallel extracts were prepared for each leaf sample, and the extracts were analyzed twice.

**Sample Preparation for GC-FID Analysis of Fatty Acids.** Total lipids in the bilberry and lingonberry leaves were extracted using a modified method of Folch et al.[20] A sample of 100 mg of leaf powder (prepared in the same way as above) was taken, and 0.40 mg of triheptadecanoin (1,2,3-triheptadecanoylglycerol) dissolved in chloroform were added as an internal standard. The mixture was extracted with 5 mL of chloroform/methanol (2;1, v/v) in a sonicator bath for 30 min. The extract was washed with 1 mL of 0.88% KCl and centrifuged. The organic phase was transferred to a tube with a screw cap. After that, the solvent was evaporated under $N_2$ flow. The methylation of the total fatty acids was carried out by adding of 1 mL of 10% $BF_3$ in methanol to the extracts and incubating at 80 °C for 60 min. After that, 1 mL of water was added to the solution, and fatty acid methyl esters (FAMEs) were extracted with 1 mL of hexane. Two parallel samples were prepared for each time point, and each sample was analyzed twice.

**Measurement of Dry Mass.** The dry mass was determined gravimetrically by heating the samples in an oven at 105 °C until they reached a constant weight.

**Sample Preparation for NMR Analysis.** The leaf samples were lyophilized and ground, and 50 mg of leaf powder was extracted with 800 μL of solvent consisting of deuterated acetone/$D_2O$/TSP (95:5:0.05, v/v/w). The extraction lasted for 1 h in a shaker, followed by centrifugation for 5 min (1650*g*). The supernatant was collected and was either analyzed immediately or stored at −80 °C until analysis.

**Qualitative Analysis with HPLC-DAD-ESI-MS/MS.** HPLC-DAD-ESI-MS/MS analysis was performed using a Waters Acquity Ultra Performance LC system in combination with a Waters 2996 DAD and a Waters Quattro Premier mass spectrometer (Waters Corp., Milford, MA, USA) equipped with an electrospray interface. A Phenomenex Aeris peptide XB-C18 (3.6 μm, 150 × 4.60 mm, Torrance, CA, USA) column was used, and the temperature of the column oven was 25 °C. A binary solvent system was employed consisting of formic acid/water (0.1:99.9, v/v) as solvent A and formic acid/acetonitrile (0.1:99.9, v/v) as solvent B. The gradient program was as follows: 0 min with 15% solvent B, 0−15 min with 15−20% B, 15−20 min with 20−25% B, 20−25 min with 25% B, 25−30 min with 25−60% B, 30−35 min with 60−15% B, and 35−40 min with 15% B. The flow rate of the mobile phase was 0.5 mL/min, and the injection volume was 5 μL. UV chromatograms were recorded at four different wavelengths (280 nm for all phenolic compounds, 320 nm for phenolic acids, 360 nm for flavonol glycosides, and 520 nm for anthocyanins) with a DAD.

The mass spectrometer was operated in both positive and negative modes. The capillary voltage was set to 3.5 kV, the cone voltage to 22 V, and the extractor voltage to 3 V. The source temperature was 150 °C and the desolvation temperature, 300 °C. Mass spectra were obtained by scanning ions between $m/z$ 100 and 1000. For tandem MS, the collision energy was set at 25 eV. The HPLC-ESI-MS system was operated using MassLynx 4.1 software.

Phenolic compounds were identified by comparing the retention times, UV spectra, and mass spectra of the analytes with those of the reference compounds and on the basis of previous reports of these compounds in the literature. Both the methanol solution of reference compounds and the sample spiked with reference compounds were analyzed to confirm the retention times.

**LC-DAD-ESI-TOF-MS Analysis.** The exact masses of the identified compounds were achieved using a micrOTOF-Q mass spectrometer (Bruker Daltonics, Bremen, Germany) connected to an Agilent HPLC 1200 series (Agilent Technologies, Waldbronn, Germany) via an ESI interface. The chromatographic conditions were the same as described above. The HPLC system was controlled by Hystar software (Bruker BioSpin, Rheinstetten, Germany). The eluent flow was split before introduction into the ion source. The mass spectrometer was operated in both positive and negative ion modes. The capillary voltage was set to 4000 V (negative ion mode) or 4500 V (positive ion mode) and the end plate offset to −500 V. Nebulizer gas ($N_2$) pressure was 1.6 bar. The flow rate of the drying gas ($N_2$) was 12.0 L/min and the drying gas temperature, 200 °C. Mass spectra were obtained by scanning ions between $m/z$ 100 and 2000. The internal mass spectrum calibration was achieved with 5 mM sodium formate injected at the end of each LC-MS experiment, and the calibration was performed using HPC mode. The spectrometer was controlled by Compass micrOTOF control software, and the data were processed by Compass DataAnalysis software (both Bruker Daltonics, Bremen, Germany).

**Quantitative HPLC-DAD Analysis.** The HPLC-DAD system used for quantitative analysis consisted of a DGU-20A5 vacuum degasser, two LC-30AD pumps, an SIL 30AC automatic injector, a CTO-20AC column oven, an SPD-M20A VP photodiode array detector (DAD), and a CBM-20A system controller (Shimadzu, Kyoto, Japan). The system was operated using Labsolution Workstation software (Shimadzu). For the analysis of flavonol glycosides and phenolic acids, the HPLC columns, gradient program, temperature of the column oven, flow rate and injection volume were the same as described for the HPLC-DAD-ESI-MS/MS analysis. The peaks were recorded at 360 nm. For the analysis of anthocyanins in the extracts of red bilberry leaves, a binary solvent system was used consisting of formic acid/water (5:95, v/v) as solvent A and acetonitrile as solvent B, and the gradient program was as follows: 0−15 min with 10% solvent B, 15−25 min with 10−20% B, 25−30 min with 20% B, 30−35 min with 20−25% B, 35−40 min with 25−60% B, 40−45 min with 60−10% B, and 45−50 min with 10% B. The peaks were recorded at 520 nm.

Quantitative analysis of flavonol glycosides, phenolic acids, and anthocyanins in the extracts was carried out using an external standard method. The calibration curves were constructed by HPLC-DAD analysis of standard solutions of hyperoside, isoquercitrin, kaempferol-3-*O*-glucoside, quercetin-3-*O*-glucuronide, kaempferol-3-*O*-glucuronide, rutin, chlorogenic acid (5-*O*-caffeoyl quinic acid), cyanidin-3-*O*-glucoside chloride, cyanidin-3-*O*-galactoside chloride, and cyanidin-3-*O*-arabinoside in the concentration range of 0.01−0.15 mg/mL. The standard solutions of anthocyanins were prepared by dissolving the standards in methanol/HCl (99:1). The other standards were dissolved in pure methanol. The calibration curve of every compound was constructed using five different concentrations and by plotting the peak

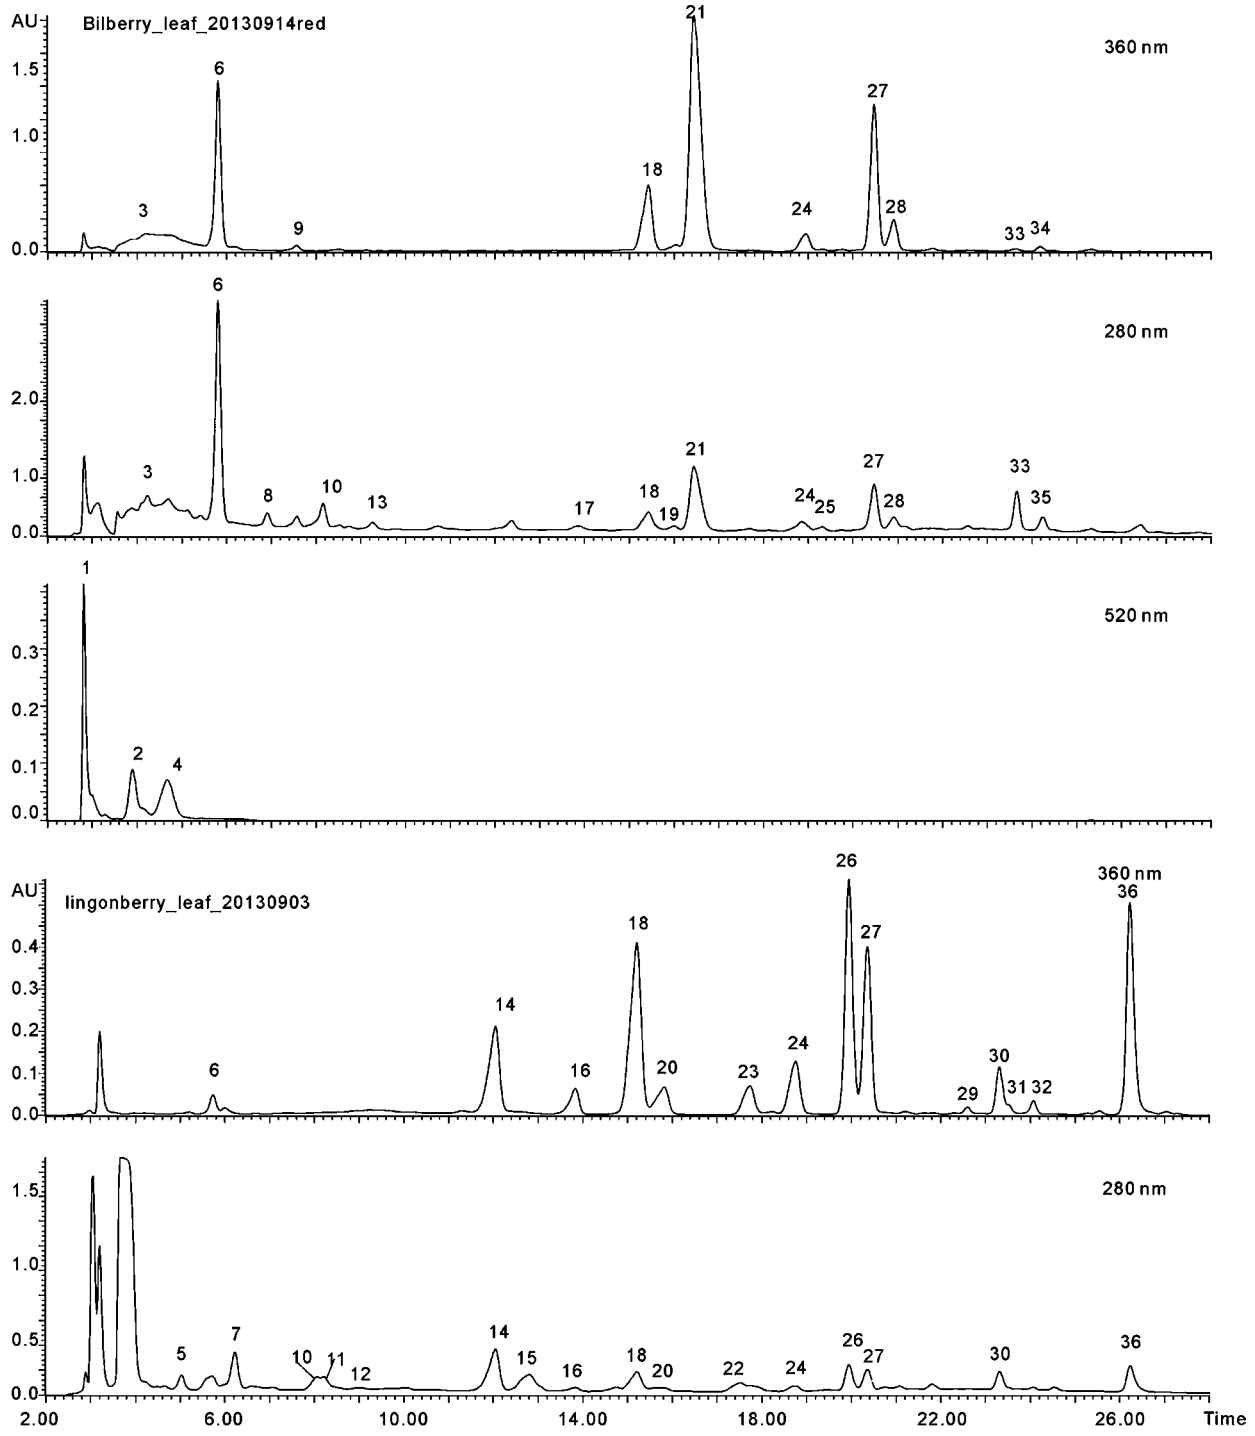

**Figure 1.** HPLC-UV chromatograms of extracts of bilberry leaves (red leaves picked on September 13, 2013) at 360, 280, and 520 nm and of lingonberry leaves (picked on September 3, 2013) at 360 and 280 nm. The numbering and identification of peaks are according to Table 1.

areas against the concentrations. The quantification of quercetin-pentosides and quercetin-3-*O*-(4″-3-hydroxy-3-methylglutaryl)-rhamnoside was carried out using the calibration curve of hyperoside, and the quantification of caffeoyl-hexose-hydroxyphenol and caffeoylquinic acid isomers was performed using the calibration curves of chlorogenic acid (5-*O*-caffeoylquinic acid).

**GC-FID Analysis.** The methyl esters of fatty acids were analyzed using a Shimadzu GC-2010 equipped with an AOC-20i autoinjector and a flame ionization detector. The column used was a DB-23 (60 m × 0.25 mm i.d × 0.25 $\mu$m $d_f$, Agilent Technologies, J. W. Scientific, Santa Clara, CA, USA). A sample of 0.5 $\mu$L was injected into a split/splitless injector (in splitless model). The flow rate of the carrier gas helium was 1.35 mL/min. The temperature of the injector was 270 °C and that of the detector, 280 °C. The column temperature was programmed as 1 min at 130 °C, raised to 170 °C at a rate of 4.5 °C/min, then raised to 220 °C at a rate of 10 °C/min, held at 220 °C for 14.5 min, raised to the final temperature of 230 °C at a rate of 60 °C/min, and held at 230 °C for 3 min.

The fatty acids were identified by comparing the retention times with those of the FAME mix standards Supelco 37 (Supelco, St. Louis, MO, USA) and 68D (Nu-Check-Prep, Elysian, MN, USA).

**NMR Data Acquisition.** NMR analyses were performed on a Bruker Avance 500 spectrometer operated at 500.13 MHz and equipped with a BBI-5 mm-Zgrad-ATM probe.

**Table 1. Phenolics Determined by HPLC-DAD and HPLC-ESI-MS in the Aqueous Acetone Extracts from Leaves of Bilberry and Lingonberry**

| compound[a] | $t_R$[b] (min) | $\lambda_{max}$ (nm) | $[M+H]^+$ ($m/z$) | other ions (positive) | $[M-H]^-$ ($m/z$) | other ions (negative) | $[M-H]^-$[c] ($m/z$) | identification[d] | source |
|---|---|---|---|---|---|---|---|---|---|

[a]Compound numbers are according to peak labels in Figure 1. [b]Retention time according to HPLC-DAD chromatograms. [c]High-resolution mass spectra were obtained using LC-DAD-ESI-TOF-MS. [d]Compounds with * were identified with reference compounds, with **, with NMR; the others were identified on the basis of UV and mass spectra. [e]HMG, 3-hydroxy-3-methylglutaryl.

*1D $^1$H NMR.* $^1$H NMR spectra were acquired for all samples with 180 scans at 25 °C using an 1D pulse sequence with water suppression by presaturation (Bruker's pulse program zgpr) with a relaxation delay of 5 s. Free induction decays (FIDs) were collected with 64K data points, an acquisition time of 3.28 s, and a spectral width of 10000.0 Hz. Fourier transformation was applied to the FID.

*2D NMR.* Standard 2D NMR experiments DQF-COSY (cosygpmfqf), TOCSY (mlevgpph) with a mixing time of 300 ms, $CH_2$-edited HSQC (hsqcedetgpsisp.2), and HMBC (hmbcgplpndqf) with couplings of 5.0 and 10.0 Hz were performed for selected lingonberry leaf and bilberry leaf samples.

*Data Preprocessing.* All of the $^1$H NMR spectra were manually calibrated and corrected for phase and baseline using TopSpin 3.2 NMR

**Figure 2.** Chemical structures of chorogenic acid (5-*O*-caffeoylquinic acid), arbutin, and 2-*O*-caffeoylarbutin and their chemical shifts in crude bilberry/lingonberry leaf extracts in aqueous acetone-$d_6$.

software. Chemical shifts were referenced (internally) to TSP ($\delta$ 0.0). Preprocessed $^1$H NMR spectra were integrated to consecutive 0.005 ppm wide buckets using Amix software. Spectra of eight sampling points of bilberry leaves and six sampling points of lingonberry leaves were used for metabolomic comparison. The spectra of the rest of the samples (one sampling point of bilberry leaf and three sampling points of lingonberry leaves) were not included due to shifting of the signals caused by the residue of acetone used for washing the NMR tubes. The spectrum of red bilberry leaf was also excluded due to its highly exceptional profile.

**Analysis of Pearson Correlation Coefficient and Hierarchial Clustering.** Pearson correlation (Pearson product moment correlation) was applied in Excel to the spectral integrals generated by Amix to find correlations between the changes in concentrations of different metabolites. Specific integrals were chosen in turn as reference signals. R software (v. 3.0.1) with plotrix library was used to create graphical presentations of correlations between metabolites.[21,22]

The same integrated spectral areas were used to create a hierarchial clustering analysis visualized by dendrogram tree using SIMCA-P+ software package (version 12.0, Umetrics AB, Umeå, Sweden).

## RESULTS AND DISCUSSION

**Identification of Phenolics and Fatty Acids in Leaves of Bilberry and Lingonberry by Chromatographic Methods and NMR.** Figure 1 presents exemplary HPLC-DAD chromatograms of extracts of bilberry and lingonberry leaves. Thirty-seven phenolic compounds were identified/tentatively identified from the extracts (Table 1). Twenty-one phenolic compounds were detected from the extracts of the red bilberry leaves, 18 phenolics from the green bilberry leaves, and 25 phenolics from lingonberry leaves. 2D NMR analyses were used to support the identification based on HPLC and MS analyses.

Some of the compounds listed in Table 1 have been reported previously.[13,23,24] Quercetin-acetylglucoside (compound **29**), B-type procyanidin dimer-hexoside (compound **17**), 2-*O*-caffeoyl-6-*O*-acetylarbutin (compound **31**), caffeoyl-glucoside derivative (compound **25**), and *p*-coumaroyl-glucoside derivatives (compound **33** and **35**) are identified for the first time.

*Anthocyanins.* Compounds **1**, **2**, and **4** had UV spectra typical for anthocyanins with absorption maxima around 520 nm. By comparing their retention times and mass spectra with those of reference compounds, these compounds were identified as cyanidin-3-*O*-galactoside, cyanidin-3-*O*-glucoside, and cyanidin-3-*O*-arabinoside, respectively. These anthocyanins were found in the extracts of red bilberry leaves, but not in those of green leaves.

*Phenolic Acids and Arbutin Derivatives.* Derivatives of phenolic acids were identified on the basis of their UV spectra with typical absorption maxima around 280 and 320 nm.

Compound **6** was identified as chlorogenic acid (5-*O*-caffeoylquinic acid) by comparing its UV and mass spectra as well as retention time with those of the reference compound, and the identification was confirmed by the NMR data. The position of the caffeoyl group was concluded on the basis of the coupling constants of H3 and H5, where the first one showed only small couplings (equatorial) and the latter also large ones (axial) based on the total width of the signals. Thus, the correct structure could be identified even though exact values of coupling constants cannot be detected because of other overlapping signals from other compounds. Compounds **3** and **9** had very similar UV and mass spectra with compound **6**. The ion at $m/z$ 163 in the mass spectra in the positive mode derived from the caffeoyl unit and the ion at $m/z$ 191 in the negative mode from quinic acid. The $[M + H]^+$ at $m/z$ 355 indicated that they were isomers of chlorogenic acid. Chemical shifts and couplings of 5-*O*-caffeoylquinic acid obtained by NMR are presented in Figure 2.

The most dominant compound in lingonberry crude extract was identified as $\beta$-*p*-arbutin on the basis of the 2D NMR spectra

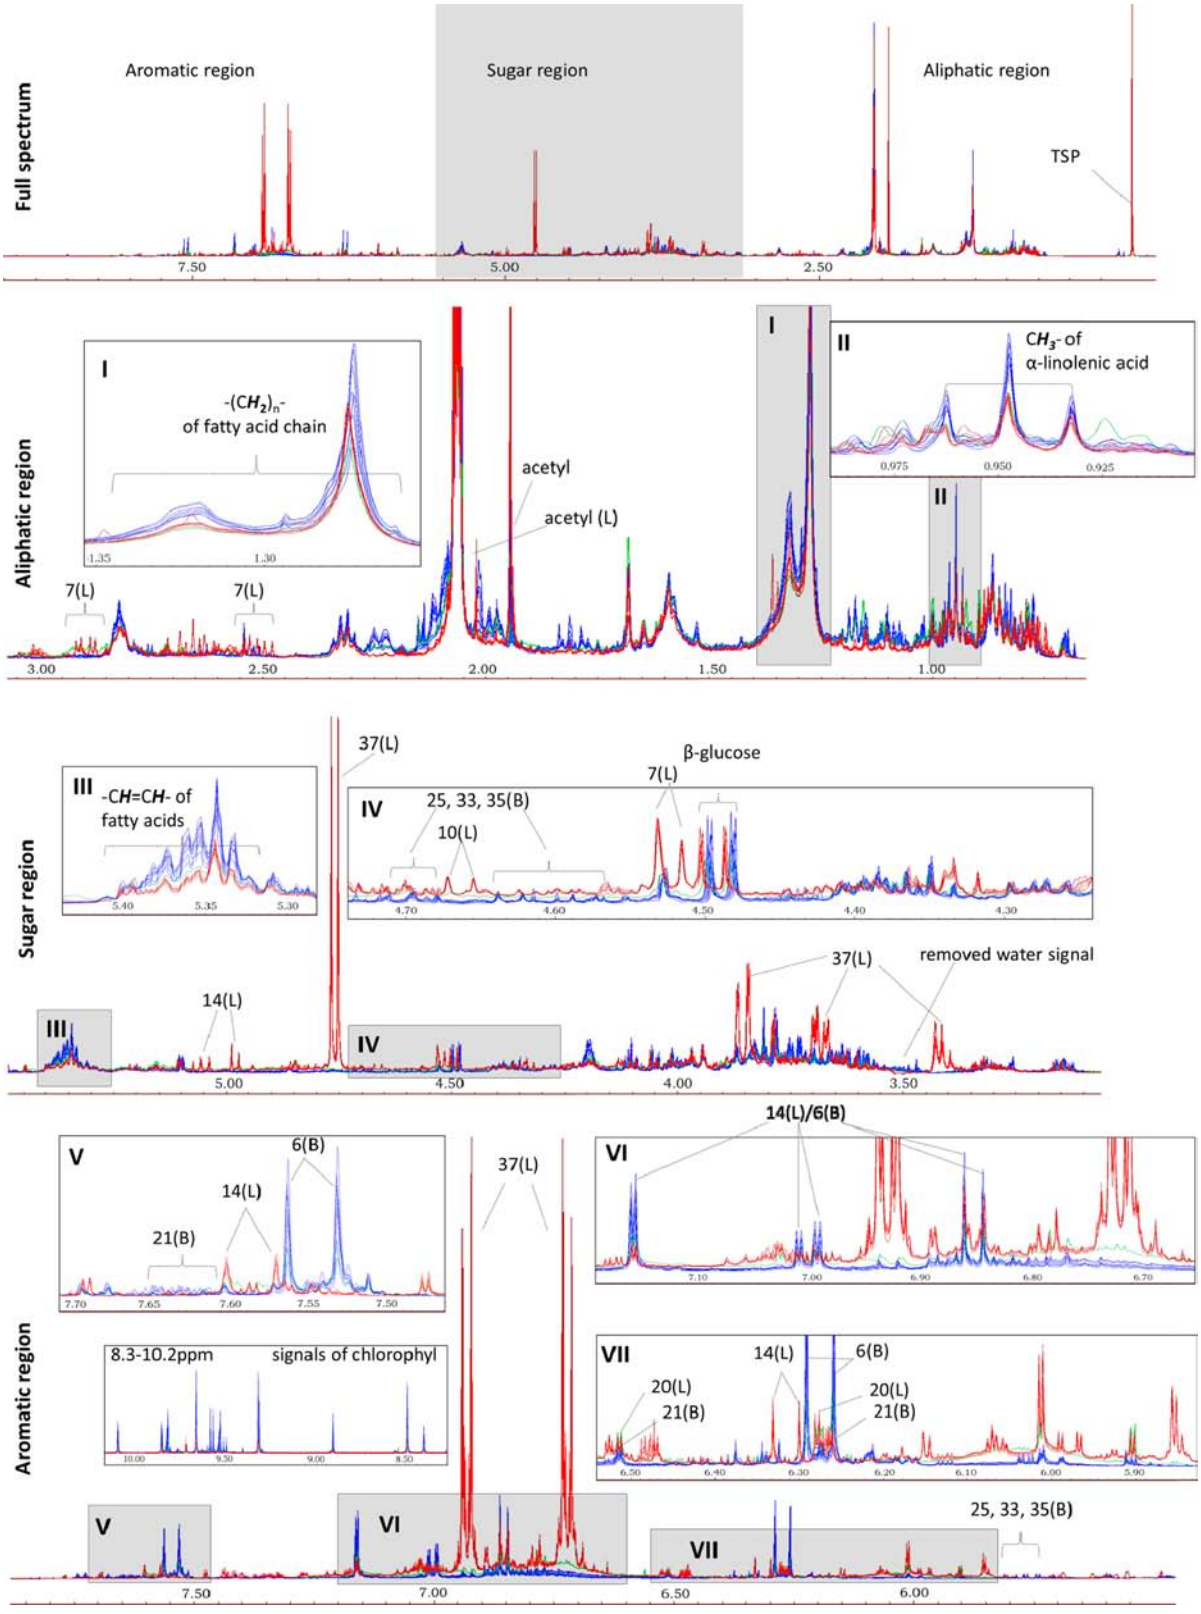

**Figure 3.** [1]H NMR spectra of crude extracts of green bilberry (blue), red bilberry (green), and lingonberry (red) leaves collected during the growing season. Spectra of lingonberry leaves are almost uniformly overlapping with each other, whereas more variation in spectral fingerprints can be found between bilberry leaves of different collection points. (L) refers to the compounds detected from lingonberry leaf samples, and (B) refers to bilberry leaves. Some of the compounds can be found in both plants (no letter attached). Compounds presented in the figure: chlorogenic acid (**6**), catechin (**7**), epicatechin (**10**), 2-*O*-caffeoyl arbutin (**14**), quercetin-3-*O*-glucoside (**20**), quercetin-3-*O*-glucuronide (**21**), *p*-coumaroyl and caffeoyl-glucoside derivatives (**25**, **33**, **35**), and *β*-*p*-arbutin (**37**).

dx.doi.org/10.1021/jf503521m | *J. Agric. Food Chem.* 2014, 62, 12015−12026

(Figure 2). The resonances originated from this compound were easily perceived due to their exceptionally high intensities. Two doublets ($J$ = 8.9 Hz) at the aromatic region ($\delta$ 6.72 of H2, H6; and $\delta$ 6.93 of H3, H5) indicated the presence of para-substituted aromatic ring structure. HMBC correlations from H2 and H6 to carbon at $\delta$ 155.3 indicated the presence of a hydroxyl group attached to the 4-carbon, and HMBC correlations from H3, H5, and H1′ to carbon at $\delta$ 153.8 linked the phenol group to a sugar moiety. Resonances from the sugar moiety are disrupted by the removal of the solvent signal at $\delta$ 3.50. However, by the selective 1D TOCSY experiment it was possible to specify all of the protons belonging to the same spin system as the anomeric doublet signal at $\delta$ 4.76 (Figure 2). The arbutin had maximum absorption at about 280 nm in the UV spectrum. However, the peak of arbutin in the HPLC chromatograms under 280 nm overlapped with the peaks of other compounds forming the huge peak from 3.5 to 4.1 min (Figure 1). This made it impossible to extract clear UV and mass spectra.

Compound **14** was a prevalent phenolic acid in the extracts of lingonberry. The ions at $m/z$ 435 and 457 represented $[M + H]^+$ and $[M + Na]^+$ ($[M + 23]^+$), respectively. The ion at $m/z$ 163 in the mass spectrum in the positive mode indicated the existence of a caffeoyl unit. The mass spectrum was identical to that of caffeoyl-hexose-hydroxyphenol previously reported.[23] 2-*O*-Caffeoylarbutin was reported to be the most abundant caffeoyl-hexose-hydroxyphenol isomer in lingonberry leaves.[23] In our 2D NMR analyses, correlations over the glycosidic bonds between the 1″-position of $\beta$-glucose and hydroxyphenol as well as the 2″-position of glucose and the caffeoyl vinyl group were detected, supporting the previous identification (Figure 2).

Compound **31** was identified as 2-*O*-caffeoyl-6-*O*-acetylarbutin on the basis of the UV and mass spectra and literature. An acetyl moiety was also detected in the $^1$H NMR spectra of lingonberry leaf extracts. Via HMBC a very weak coupling from the 6″ proton of a glucose moiety of the caffeoyl arbutin to carbonyl carbon of acetyl could be detected, supporting the identification (Supplementary Figure 1). However, the integration of the acetyl moiety revealed the concentration to be only one-sixth of the corresponding anomeric glucose doublet ($\delta$ 4.98), indicating that most of the caffeoyl arbutin remains without acetylation (compound **14**). Similar types of compounds with a hydroxyphenyl moiety have previously been identified from *Vaccinium dunalianum*, which is an evergreen perennial shrub distributed in China, Myanmar, and Vietnam.[25] Tea made from the leaves of this plant has been traditionally used as folk medicine to treat articular rheumatism, similarly to lingonberry leaves. Arbutin has been postulated to play an important role in the bioactivity of leaves in these two plants.[14,25] However, a potent mutagenic activity of hydroquinone and its analogues such as arbutin has also been reported.[26] The deleterious properties of the analogues are probably due to the cleavage of hydroquinone via deglycolysation.[26] On the contrary, in the study of Takebayashi et al., hydroquinone as well as arbutin showed strong antioxidant activity assessed by several methods,[27] yet the hydroquinone in higher concentrations exhibited cytotoxicity when the protective effects against oxidative stress in fibroblasts were studied in vitro, whereas arbutin retained its protective properties.

Compound **25** was detected in the extracts of bilberry leaves and identified as a caffeoyl derivative. Ions at $m/z$ 163 in the mass spectrum derived from the caffeoyl unit. The difference of 162 amu between the $[M + H]^+$ at $m/z$ 429 and a fragment at $m/z$ 267 indicated a hexose unit esterified to the caffeoyl. The mass spectrum also showed an unknown fragment (114 amu) likely linked to the caffeoyl unit. Compounds **33** and **35** were isomers with similar structures with compound **25**, but the caffeoyl unit being replaced by *p*-coumaroyl. A closer inspection of 2D NMR spectra established a cis orientation of a vinyl group in these hydroxycinnamic acid derivatives and a $\beta$-glucose to be the potential hexose unit based on the variation of the proton signals between different samples. In the 2D COSY experiment the signal of H2 protons of this sugar resonated at $\delta$ 4.67−4.89, which refers to a linkage of electronegative group to the 2-carbon. The cis conformation is supported by Kort et al., who demonstrated a shortening of the coupling constant from 15.9 Hz (trans) to 12.8 Hz (cis) as a result of photoisomerization in *p*-coumaric acid (Figure 3).[28]

*Flavanols and Procyanidins.* Flavanols and procyanidins commonly have clear absorption maxima at around 230 and 280 nm. Compounds **7** and **10** were identified as catechin and epicatechin, respectively, on the basis of their UV and mass spectra as well as confirmation with reference compounds. Signals of the C-ring of catechin and epicatechin were also detected by NMR measurements (Figure 3). Signals of A and B rings overlapped with others signals on the aromatic region, but HMBC couplings could be detected for catechin (Supplementary Figure 2).

Compounds **5**, **8**, **11**−**13**, **15**, **17**, **19**, and **22** were identified as procyanidins on the basis of their UV spectra. Compounds **5**, **8**, and **19** showed mass spectra typical for B-type procyanidin dimers.[29,30] In negative mode, the mass spectra of compounds **15** and **22** had $[M - H]^-$ ions at $m/z$ 575 and fragment ions at $m/z$ 289. These two compounds were identified as A-type procyanidins because the $m/z$ values of the $[M - H]^-$ ions were lower than those of the corresponding B-type procyanidin dimers by 2 amu. Compound **13** had $[M + H]^+$ at $m/z$ 867 and $[M + Na]^+$ at $m/z$ 889 in the mass spectrum and are assigned as a B-type procyanidin trimer. Compounds **11** and **12** had $[M + H]^+$ at $m/z$ 865 and were identified as A/B-type procyanidin trimers. The $m/z$ value of the $[M + H]^+$ ion of compound **17** was 162 amu higher than those of B-type procyanidin dimers, suggesting the presence of a hexose or a caffeoyl group linked to the procyanidin dimer.[30] The exact mass ($m/z$ 739.1660 for $[M - H]^-$) obtained using high-resolution mass spectrometry suggested it is a caffeoyl procyanidin dimer.

*Flavonol Glycosides.* Flavonol glycosides were among the major phenolics in the extracts from bilberry leaves and lingonberry leaves. All of the flavonol glycosides detected in bilberry and lingonberry leaves had quercetin or kaempferol as the aglycons. Compounds **16**, **18**, **20**, **21**, and **27** were identified as rutin (quercetin-3-*O*-rutinoside), hyperoside (quercetin-3-*O*-galactoside), isoquercitrin (quercetin-3-*O*-glucoside), quercetin-3-*O*-glucuronide, and quercetin-3-*O*-rhamnoside, respectively, with the aid of reference compounds. On the basis of the mass spectra, compounds **23**, **24**, and **26** were identified as quercetin-pentosides, and by comparing the order of the elution with references, these compounds were likely quercetin-3-*O*-xyloside, quercetin-3-*O*-arabinoside, and quercetin-3-*O*-arabinofuranoside, respectively.[13,23] Compound **29** was indentified as quercetin-acetylglucoside on the basis of the mass spectrum. The ions at $m/z$ 303 in the mass spectra indicated that compound **30** was a derivative of quercetin, and compound **36** was quercetin-3-*O*-(4″-3-hydroxy-3-methylglutaryl)-rhamnoside.[13,23]

Compound **28** was confirmed as kaempferol-3-*O*-glucuronide with reference compound. Compounds **32** and **34** were

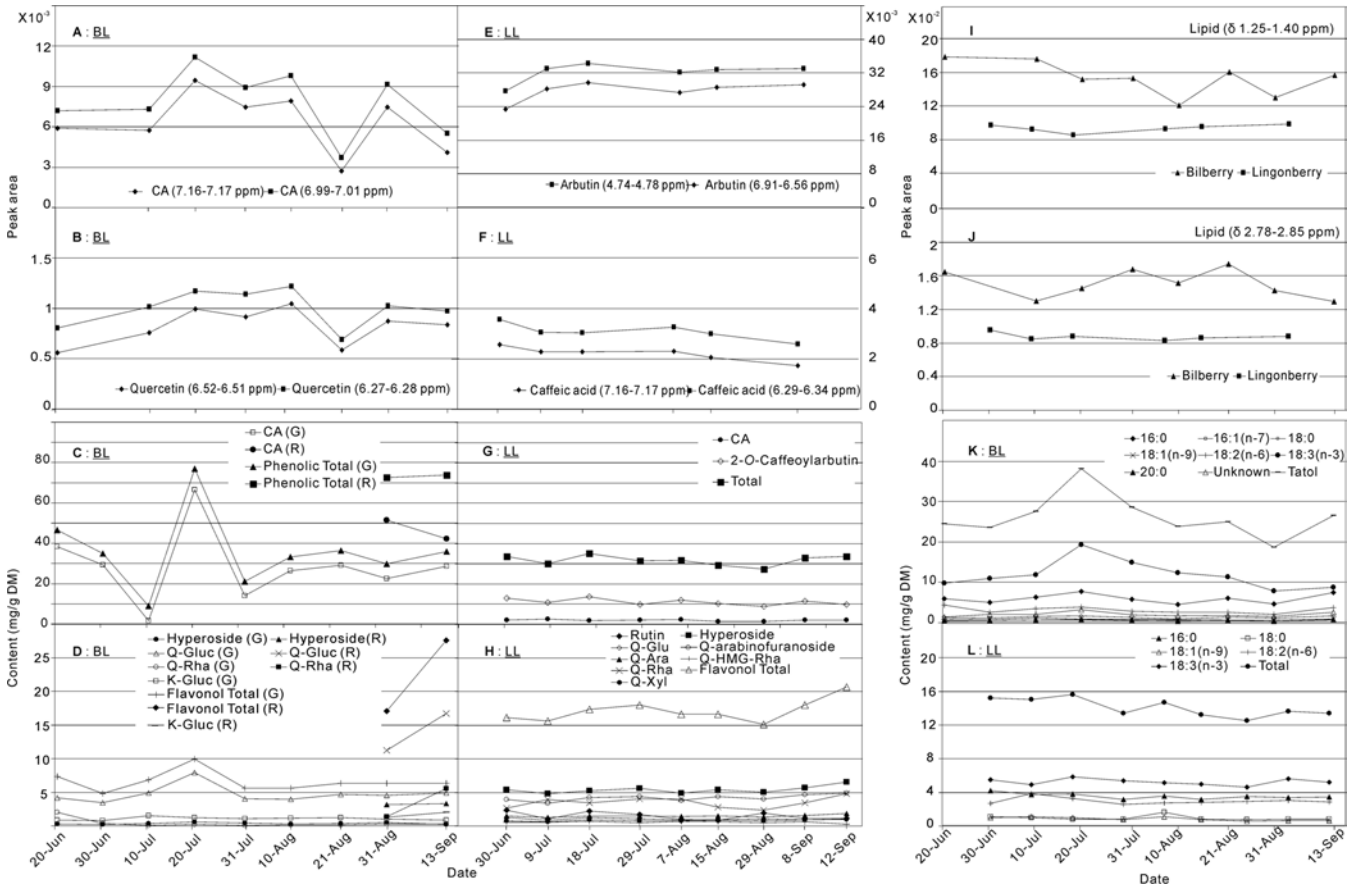

**Figure 4.** Changes in the content of phenolic compounds in bilberry leaves (A–D) and lingonberry leaves (E–H) and the content of lipids in bilberry and lingonberry leaves (I–L) during the growing season in 2013. Panels A, B, E, F, I, and J are based on the results of NMR analyses; panels C, D, G, and H are based on the results of HPLC-DAD analyses; panels K and L are based on the results of GC-FID analyses. BL, bilberry leaves; LL, lingonberry leaves; CA, chlorogenic acid; Q, quercetin; K, kaempferol; Gluc, glucuronide; Glu, glucoside; Rha, rhamnoside; Xyl, xyloside; Ara, arabinoside; HMG, 3-hydroxy-3-methylglutaryl; G, green leaves; R, red leaves.

identified as kaempferol-pentoside and kaempferol-rhamnoside, respectively.

*Fatty Acids.* $\alpha$-Linolenic acid (18:3n-3), palmitic acid (16:0), stearic acid (18:0), oleic acid (18:1n-9), linoleic acid (18:2n-6), and arachidic acid (20:0) were the major fatty acids in both lingonberry and bilberry leaves. Also, some minor fatty acids were found. An unknown fatty acid peak with retention time of 15.1 min was detected in the chromatograms of only bilberry leaves, but not in those of lingonberry leaves (Supplementary Figure 3).

**Metabolomic Changes during the Growing Season.** An untargeted approach was exploited to reveal the overall similarities and differences between bilberry and lingonberry samples and to investigate the changes occurring during the growing season. Targeted approaches were applied for more accurate quantification of specific metabolites.

*Untargeted Metabolomics.* The untargeted metabolomic analysis of metabolite fingerprints obtained by $^1$H NMR revealed differing compositional profiles of the crude extracts of bilberry and lingonberry leaves (Figure 3). The most notable differences occurred in the major phenolic compounds and lipids. In general, the aromatic region of the spectra of lingonberry leaf encompassed more intensive signals than the corresponding spectra of bilberry leaf. However, the fingerprints of red bilberry leaf extracts deviated from green bilberry leaves, especially by the broad signals in the aromatic region, as found in the lingonberry leaves. The intensities of several signals in bilberry spectra varied considerably among the collection points, whereas the signals of lingonberry extracts remained at relatively constant level regardless of the time of collection (see insets I–VII in Figure 3). These differences between different types of leaves were also indicated by statistical analysis (Supplymentary Figure 4). In dendrograms based on hierarchical clustering analysis of the samples analyzed by untargeted $^1$H NMR, two clearly separated groups were created, dividing the samples of lingonberry and bilberry into different branches. In addition, the red leaf of bilberry creates its own branch, being more similar to green bilberry leaves than lingonberry leaves. It is also indicated on the basis of the hierarchical clustering analysis that the differences in the metabolite composition between bilberry leaves are more notable than those between the lingonberry leaves at different collection times (Supplymentary Figure 4).

The major phenolic compounds as well as a few minor compounds could be addressed from the $^1$H NMR fingerprints obtained by untargeted approach (Figure 3). In the bilberry leaf extracts, chlorogenic acid (5-*O*-caffeoylquinic acid) was the most abundant phenolic compound in all of the collection points, whereas it remained as a minor one in the lingonberry leaf extracts. Arbutin or its derivates were not detected in the extracts from bilberry leaves, but they were the most prevalent compounds in all the lingonberry leaf extracts.

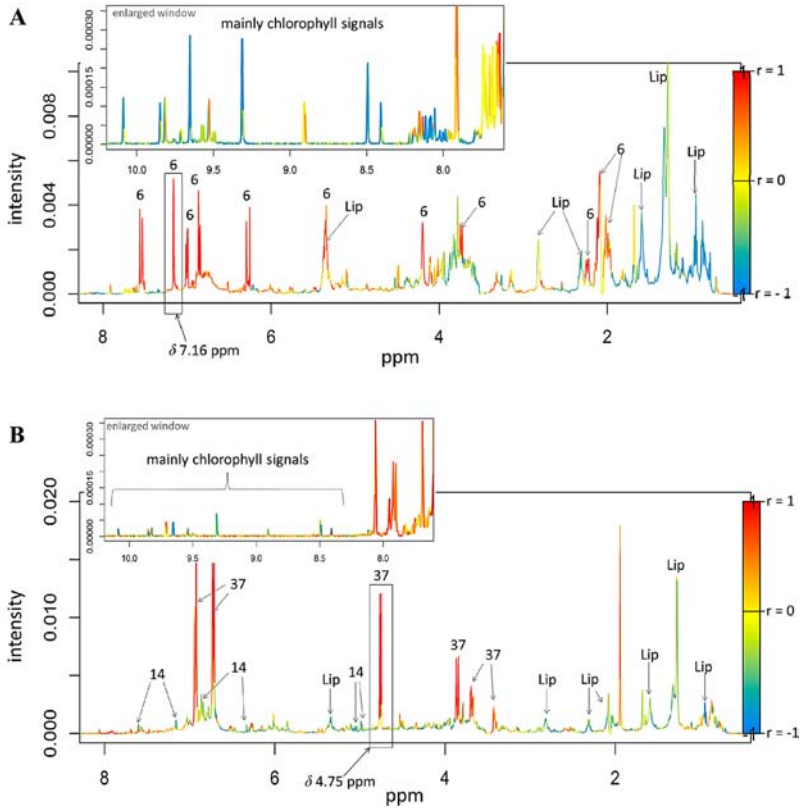

**Figure 5.** $^1$H NMR spectrum of leaf crude extract is colored according to Pearson correlation coefficients: (A) correlation between the changes of other bilberry leaf metabolites with chlorogenic acid signal at $\delta$ 7.16 during the growing season; (B) correlation between the changes of other lingonberry leaf metabolites with arbutin signal at $\delta$ 4.75 during the growing season. Correlation coefficients ($r$) of 0.5−1.0 (red) and 0.3−0.5 (orange) indicate strong and moderate positive correlations, respectively, and −0.5−1.0 (blue) and −0.3−0.5 (green) indicate strong and moderate negative correlations, respectively, between the metabolites. Compounds allocated in the figure: chlorogenic acid (**6**), 2-*O*-caffeoyl arbutin (**14**), *β*-*p*-arbutin (**37**), and lipid signals (Lip).

On the basis of $^1$H NMR spectra, the overall lipid content appeared to be higher in the crude extracts of bilberry leaves (Figure 3, insets I−III). Also, the changes in lipid content during the growth period were apparent in the bilberry samples, whereas lingonberry leaves showed less variation. Furthermore, the content of n-3 fatty acids was found to be slightly higher in bilberry leaves than in lingonberry leaves on the basis of the integrals of methyl groups of n-3 fatty acids ($\delta$ 0.95).

*Changes in Lipids Profiles of Bilberry and Lingonberry Leaves.* The integrated lipid areas of $^1$H NMR spectra resulted in different changing patterns in the lipids of leaf samples during the season, especially in the case of bilberry leaf extracts (Figure 4I,J, targeted NMR). The integrals of the signal $\delta$ 2.78−2.85, consisting of the resonances of =CH—C$\underline{H}_2$—CH= protons, showed a different changing trend from those of the integrals of $\delta$ 1.25−1.40 [−(C$\underline{H}_2$)$_n$−] and $\delta$ 2.29−2.36 (−OCO—C$\underline{H}_2$−), and the latter two showed a similar trend with each other (Figure 4I,J). This may reflect the compositional changes in the fatty acid profile.

Targeted analysis by GC-FID supported the results from untargeted analysis (Figure 4K,L). However, $^1$H NMR measures the amount of protons in the fatty acid chain, whereas peak integral in GC chromatogram indicates the number on fatty acid molecules, which might explain some of the differences between these two methods. By choosing very specific proton types, such as $\alpha$- or $\beta$-protons ($\delta$ 2.29...2.36 and 1.54...1.63, respectively) from the carbonyl group, for integration, the number of protons should linearly correlate with the number on fatty acid molecules.

Analyses by GC showed generally higher content and wider deviation of fatty acids in bilberry extracts than in lingonberry extracts. The content of fatty acids in extracts of bilberry leaves ranged from 19 to 38 mg/g DM (dry mass) during the growing season (Figure 4K). The highest contents were found in the samples picked on July 20 (Figure 4K). $\alpha$-Linolenic acid was the most abundant fatty acid, accounting for almost half of the total in all of the samples (Figure 4K). No major difference was noted in the content of fatty acids between the green leaves and red leaves picked on the same day.

The levels of fatty acids in lingonberry leaves were 13−16 mg/g DM during the season (Figure 4L). $\alpha$-Linolenic acid was the most abundant fatty acid in extracts of all the samples except the one collected on August 7. The contents of palmitic acid and linoleic acid were found similarly quite close (Figure 4L).

*Changes in Phenolic Profile in Bilberry and Lingonberry Leaves.* The changing trends constructed using selected signals of phenolic compounds based on NMR integrals are shown in Figure 4A,B. Changing trends of 10 major phenolic compounds (chlorogenic acid and its two isomers, hyperoside, quercetin-3-*O*-glucuronide, quercetin-rhamnoside, kaemperol-3-*O*-glucouronide, cyanidin-3-*O*-galatoside, cyanidin-3-*O*-glucosdie, and cyanidin-3-*O*-arabinoside) in the extracts from leaves studied by the HPLC-DAD method are shown in Figure 4C,D. Targeted analyses by HPLC-DAD showed results largely consistent with the findings obtained by NMR approach.

The total phenolics in green bilberry leaves ranged from 9 to 77 mg/g DM. The contents in red bilberry leaves were 73 mg/g

DM on August 31 and 74 mg/g DM on September 13, respectively. Chlorogenic acid accounted for a vast majority of the total content of phenolic compounds in bilberry leaves (Figure 4C).

The content of chlorogenic acid varied dramatically during the whole growing season from 2 to 66 mg/g DM in bilberry leaves (Figure 4C). The highest levels were found in the red leaves (51 and 42 mg/g) and the green leaf samples picked on July 20 (66 mg/g DM). The red leaves contained a higher amount of chlorogenic acid than the green ones picked on the same day. With minor deviations in the samples picked on July 10 and August 21, the changing pattern during the growth period shown by NMR spectral integrals was similar to the trend acquired by targeted HPLC method (Figure 4A,C).

Flavonol glycosides were the second most abundant group of phenolic compounds in the bilberry leaves. The total content ranged from 5 to 10 mg/g DM in green leaves and from 17 to 28 mg/g DM in red leaves (Figure 4D). Quercetin-3-*O*-glucuronide was the major flavonol glycoside in all of the samples. In the green leaves, the content of flavonol glycoside increased from the end of June and reached its highest level in the middle of July and then decreased. The changing pattern in phenolic profile obtained by HPLC and NMR results were analogous in the case of total flavonol content and quercetin-3-*O*-glucuronide (Figure 4B,D). The contents of flavonol glycosides in the red leaves were notably higher than the levels found in the green leaves.

Anthocyanins were found only in the extracts of the red bilberry at a level close to 3 mg/g DM.

The correlation between flavonoid biosynthesis in bilberry leaves and solar radiation has been investigated before. An increasing expression of the genes related to the biosynthesis of flavonoids has been detected in leaves growing under high radiation.[31] Red leaves are often found in bilberry shrubs in sunny locations. This might explain why the red bilberry leaves contained higher amounts of phenolics than the green leaves.

In the extracts of lingonberry leaf, 10 phenolic compounds, including chlorogenic acid (5-*O*-caffeoylquinic acid), 2-*O*-caffeoylarbutin, rutin, hyperoside, quercetin-3-*O*-glucoside, 3 isomers of quercetin-pentoside, quercetin-3-*O*-rhamnoside, and quercetin-3-*O*-(4″-3-hydroxy-3-methylglutaryl)-rhamnoside, were quantified using HPLC-DAD. During the growing season, the levels of contents of total phenolics and individual compounds did not vary remarkably in lingonberry leaves (Figure 4G,H).

2-*O*-Caffeoylarbutin was the most abundant polyphenol in all of the lingonberry samples quantified by HPLC-DAD, and its content ranged from 9 to 14 mg/g DM (Figure 4G).

On the basis of $^1$H NMR, arbutin was the most abundant phenolic compound in lingonberry leaf. It was not quantified with HPLC-DAD because of overlapping peaks of other compounds. On the basis of integrated areas in $^1$H NMR spectra, the content of arbutin was roughly 6−10-fold higher than the level of 2-*O*-caffeoylarbutin. The contents of two metabolites profiles correlated negatively in the samples collected at different time points (Figure 5).

Hyperoside, quercetin-3-*O*-arabinoside, and quercetin-3-*O*-rhamnoside were the major flavonol glycosides (5−7 mg/g DM) in the extract from lingonberry leaves, whereas quercetin-3-*O*-glucuronide (3−17 mg/g DM) was the major flavonol glycoside in bilberry leaves (Figure 4H). The total contents of flavonol glycosides in the extracts of lingonberry leaves (15−20 mg/g DM) were higher than those of green bilberry leaves (5−10 mg/g DM) but lower than the level found in the red bilberry leaves (17−28 mg/g DM).

In plants, the biosynthesis of phenolic compounds are influenced by a matrix of potentially overlapping regulatory signals, including developmental signals, such as during lignification of new growth or the production of anthocyanins during fruit and flower development, and environmental signals for protection against abiotic and biotic stresses.[32] Temperature, radiation, and other weather conditiond will also affect the accumulation of phenolic compounds in the plant tissues.[32] The weather information for the Turku region during the study period is presented in Supplementaty Table 1. During the period from early June to late July, the average temperature and hours of sunshine were higher than the periods before and after, which may have contributed to the variation in the content of phenolic compounds. A common phenomenon seems to be that the leaves contain less phenolics during the development period of berry/fruit than the other time, as in the cases of leaves of black currant and hawthorn.[33,34] The content of phenolic compounds in bilberry leaves followed this pattern very well. The ripening time of lingonberry (after mid August) occurs much later than that of the bilberry (early to mid July). This could explain the relatively stable content of the phenolics found in our study.

*Correlation between the Trends in Compositional Changes.* By comparing the integrals acquired by $^1$H NMR and spectral bucketing, some correlations were found between the metabolomic changes occurring between the collection points. In the fingerprints of bilberry leaf extracts, a negative correlation was found between the signals of chlorogenic acid and lipids (Figure 5A). A strong negative correlation was found between the signals in the aliphatic region and those of chlorogenic acid. The protons resonating on the aliphatic region close to 1 ppm commonly originate from methyl groups of fatty acid but also from short-chain hydroxyl fatty acid or amino acids. Moreover, in bilberry leaf fingerprints a strong negative correlation was revealed between the signals of chlorogenic acid and signals originating from chlorophyll structure.

On the basis of the $^1$H NMR fingerprints of lingonberry leaves a moderate negative correlation occurred between the changes of arbutin and lipids, and a strong negative correlation was observed between arbutin and caffeoylarbutin (Figure 5B).

In higher plants, acetyl-CoA carboxylase (ACCase) and fatty acid synthase (FAS) are the key enzymes for the biosynthesis of fatty acids. The cytosolic homomeric ACCase generates a malonyl-CoA pool for elongation of fatty acids and biosynthesis of secondary metabolites such as flavonoids and other phenolic compounds.[35] Therefore, there is competition for carbon sources between the biosynthesis of lipids and phenolic compounds. This competition may explain the negative correlation between the contents of these two groups of metabolites. For example, inhibition of lipid metabolism enhanced the accumulation of anthocyanins in rape (*Brassica napus* L.) leaves.[36]

Bilberry and lingonberry leaves collected during the growing season were studied by both targeted and untargeted approaches. Although bilberry and lingonberry belong to the same genus, *Vaccinium*, the compositional profiles of phenolic compounds and lipids in the leaves of the two species were very different. The contents of different metabolites varied remarkably in bilberry leaves, whereas in lingonberry leaves the metabolites maintained quite constant levels during the growing season. The different methods were complementary and could support each other in characterization of metabolomic profiles of the leaves during the growth season. The chromatographic−mass spectrometric

methods can give accurate detailed information on specific group of compounds, whereas NMR analysis gave a broader view of the overall profiles. The consistency between the key results obtained by targeted and nontargeted analyses suggests nontargeted NMR metabolomic analysis is an efficient tool for fast screening of various leaf materials.

Both lingonberry leaf and bilberry leaf are potential raw materials of health food and food ingredients. Phenolic compounds are the major bioactive components in these materials. Our results suggest that the collection time of bilberry should be carefully selected to achieve the highest concentration of phenolic compounds in the leaves. The content of phenolic compounds in lingonberry leaf seems to be rather constant during the season. It is important to note that samples collected from several years should be analyzed to reach a general conclusion on the optimal collection time for the leaves.

carried out 15, 30, and 45 days after planting. Each pot was fertilized with a solution containing calcium nitrate (1.12 g), magnesium sulfate (0.50 g), potassium nitrate (0.36 g), monobasic potassium phosphate (0.30 g), iron chelate (0.07 g), and manganese sulfate (0.01 g). After 45 days, the plants were randomly subjected to different levels of water stress: 65, 35, 24, and 12% SM, by suppressing irrigation for a period of 7, 16, 21, and 26 days, respectively. For the same amount of time as for each treatment, a control was carried out (irrigation every 3 days, at 85% SM). Treatments and controls included 6 replicates, producing a total of 48 experimental units (pots).

Plant response to drought stress was determined by the increase in shoot length ($n$ = 12) as well as longitudinal growth and leaf expansion ($n$ = 24), which were evaluated by measuring the length of the leaf from the base to the apex (longitudinal growth) and at the broadest part (transverse growth). All of these parameters were measured at day 45 and after 7, 16, 21, and 26 days without water added.

**Harvest and Infusion Preparation.** Immediately after each drought treatment, after 7, 16, 21, and 26 days without water added, midlife leaves were collected from each experimental unit, dried at 45 °C for 24 h using a convection oven (Fisher Scientific, 650D, Waltham, MA), and milled in an herb grinder (Krups GX4100, Mexico) to a particle size of 0.7−1.0 mm. Infusions were prepared by adding 1 g of ground material to 100 mL of freshly boiled distilled water; the mixture was allowed to stand for 10 min and was then filtered using a 0.5 mm pore size filter. These conditions simulate the recommended preparation of commercial infusions.

**Total Phenolic and Flavonoid Contents.** The total phenolic compound content of the peppermint infusions was determined according to the Folin−Ciocalteu colorimetric method.[8] Briefly, 40 μL of the infusion diluted in 480 μL of water was mixture with 450 μL of a 1 M Folin−Ciocalteu reagent and 1250 μL of a sodium carbonate solution (5%, w/v). The tubes were left at room temperature for 120 min, and the absorbances were measured at 765 nm. Results are expressed as milligrams of gallic acid (GA) equivalents per milliliter of infusion (mg of GAE/mL).

The flavonoid content was determined according to the method described by Liu et al.[9] Briefly, 0.25 mL of each infusion were diluted with 1.25 mL of water and mixed with 75 μL of 5% $NaNO_2$. After 6 min, 150 μL of a 10% $AlCl_3{\cdot}6H_2O$ solution and 500 μL of 1 M NaOH were added, and the reaction was adjusted to 2.5 mL with distilled water. The absorbances were measured at 510 nm, and the results are expressed as milligrams of (+)-catechin equivalents per milliliter of infusion (mg of CAE/mL).

**Identification and Quantification of Phenolic Compounds.** For the identification of phenolic compounds by high-performance liquid chromatography with photodiode array detection and mass-spectrometric detection (HPLC/DAD−MSD) analysis, the extract was lyophilized and suspended in methanol at a concentration of 10 mg/mL. Separation and identification was carried out using an Agilent 1200 HPLC−DAD system connected to a SL quadrupole mass spectrometer Agilent 1100 equipped with an electrospray interface. The samples were injected into a reversed-phase column [Zorbax octadecylsilane (ODS-$C_{18}$), 15 × 4.6 mm] operated at room temperature. A total of 10 μL of sample was injected, and the compounds were eluted at 1 mL/min using a linear gradient system consisting of two solvents: (A) 2:98 (v/v) acetic acid/water and (B) (2:30:68, v/v/v) acetic acid/acetonitrile/water. The ratios of mobile phases were 90% A and 10% B at $t$ = 0 min and 0% A and 100% B at $t$ = 30 min. The absorbance was set at $\lambda_{max}$ of 260, 280, and 320 nm. The mass spectrometer was operated in the negative ion mode, under the following conditions: capillary voltage, 4000 V; nebulizer pressure, 40 psi; drying gas flow rate, 10 L/min; gas temperature, 300 °C; skimmer voltage, 50 V; octapolerf, 150 V; and fragmentor voltage, 130 V. Liquid chromatography−mass spectrometry (LC−MS) accurate mass spectra were recorded across the range of $m/z$ 50−1000. Quantification was carried out using phenolic acid and flavonoid standards (caffeic, coumaric, sinapic, and rosmarinic acids, eriocitrin, naringenin, rutin, vanillin, luteolin, quercetin, and hesperidin).

**Identification of Low-Molecular-Weight Metabolites.** A sample solution (10 mg/mL) was prepared in methanol with lyophilized infusions, which was concentrated with a nitrogen gas stream. Then, 50 μL of derivatizing agent, *N*,*O*-bis(trimethylsilyl)-trifluoroacetamide (BSTFA) + 1% trimethylchlorosilane (TMCS), was added and stirred for 2 min at room temperature. Finally, 1 μL was injected into an Agilent GC series 7890A (Wilmington, DE) coupled to an Agilent single quadrupole MS detector (Agilent 5975C), with electron energy set at 70 eV and mass range at $m/z$ 50−700. A HP-5MS capillary column (30 m × 0.25 mm inner diameter × 0.25 μm) was used. The injector temperature was set at 250 °C in splitless mode. The initial oven temperature was 100 °C, held for 1 min, and raised to 220 °C at 6 °C $min^{-1}$, which was held for 1.23 min, then raised to 290 °C at 10 °C $min^{-1}$, then raised to 310 °C at 40 °C/min, and held for 7.5 min. The flow rate of the carrier gas (helium) was maintained at 1 mL $min^{-1}$. Gas chromatography−mass spectrometry (GC−MS) control and data processing were performed using Chem-Station (Agilent Technologies) software.

**Free Radical Scavenging Assays.** The capacity of peppermint infusions to bleaching diphenylpicrylhydrazyl (DPPH) radical was determinate by the method described by Brand-Williams et al.[10] Aliquots of peppermint infusions were made to a total volume of 1 mL using methanol. A freshly prepared DPPH solution (98 μg/mL) was added, stirred, and left to stand at room temperature for 30 min in the dark. The inhibition capacity was determined by the decrease in absorbance at 517 nm.

The 2,2′-azinobis(3-ethyl-benzthiazoline-6-sulfonic acid) (ABTS) radical scavenning assay was carried out as described by Re et al.[11] $ABTS^{\bullet+}$ was obtained by reacting 7 mM ABTS stock solution with 2.45 mM potassium persulfate, and the mixture was left to stand in the dark at room temperature for 12−16 h before use. The $ABTS^{\bullet+}$ solution was diluted with 5 mM phosphate-buffered saline (pH 7.4) to an absorbance at 730 nm of 0.70. After the addition of 10 μL of aliquots of sample to 1 mL of diluted $ABTS^{\bullet+}$ solution, the absorbance was measured at 7 min.

Furthermore, nitric oxide radical scavenging capacity was measured as described by Marcocci and Parker,[12] with some modifications. Sodium nitroprusside (SNP, 5 mM) in phosphate-buffered saline was added to the sample at different concentrations to make up a volume of 3 mL and incubated at room temperature (27 °C) for 90 min. This incubated solution (1.5 mL) was added to 1.5 mL of Greiss reagent. The inhibition of nitrite formation was determined by the decrease in absorbance at 546 nm.

All of these results were expressed as the half-maximal inhibitory concentration ($IC_{50}$) and compared to a (+)-catechin standard.

***In Vitro* Digestive Enzyme Inhibition Assays.** The α-amylase activity was determined according to the methodology proposed by Kandra et al.[13] Thus, 50 μL of the peppermint infusions and 50 μL of α-amylase from *Bacillus subtilis* (50 units/mg) were pre-incubated for 20 min in a water bath at 37 °C. The substrate was starch (1%) prepared in phosphate buffer at pH 7.0 with 38 mmol/L NaCl. After the addition of 100 μL of the substrate, the mixture was incubated for 2 h. The product (glucose) was quantified by the glucose oxidase−peroxidase method with a commercial kit (Spinreact) and measured at 540 nm.

For determination of α-glucosidase inhibition, we used the method described by Apostolidis et al.,[14] with some modifications, using 5 mmol/L *p*-nitrophenyl-α-D-glucopyranoside as the substrate in a 0.1 mol/L citrate−phosphate buffer at pH 7. In the assay, 50 μL of the infusion and 100 μL of enzyme (10 units/mg) were incubated in a water bath at 37 °C for 30 min after the addition of 50 μL of the substrate. The reaction was interrupted adding 1.000 μL of 0.05 mol/L NaOH, and the product was read in a spectrophotometer at 410 nm.

Pancreatic lipase inhibition was measured according to the method described by McDougall et al.[15] The mixture of 100 μL of porcine pancreatic lipase, 50 μL of the infusion, and 50 μL of 4 mmol/L *p*-nitrophenyl laurate in 0.05 mmol/L Tris−HCl buffer at pH 8.0 containing 0.5% Triton X-100 was incubated for 30 min. The reaction was stopped, transferring the tubes to an ice bath and adding 1.000 μL of 0.05 mmol/L Tris−HCl buffer at pH 8.0. *p*-Nitrophenol, a product of the lipase action on *p*-nitrophenyl palmitate, was read in a spectrophotometer at 410 nm.

**Table 1. Changes in Fresh and Dry Weight of Leaves and Growth of Shoots and Leaves of Peppermint (*M. piperita*) Grown at Different Levels of SM[a]**

| | leaf growth (cm) | | | | |
|---|---|---|---|---|---|
| soil water content | leaf width | leaf length | shoot growth (cm) | fresh weight (mg leaf$^{-1}$) | dry weight (mg leaf$^{-1}$) |

[a]Results are the average of three independent determinations ± SE. Different letters indicate significant statistical differences between drought treatments ($p < 0.05$; Tukey's test). [b]Significant statistical differences between controls (plant growth of 85% SM over the same number of days of the respective treatment) and their respective treatment ($p < 0.05$; Dunnett's test).

The results of these determinations were expressed as a percentage of inhibition exhibited by a concentration of 10 mg/mL peppermint infusion.

**Statistical Analysis.** All results were expressed as the mean ± standard error (SE). Data were analyzed by one-way analysis of variation (ANOVA), and differences among treatments were determined by a comparison of means using Tukey's test or Dunnett's test when was compared to a control. The level of statistical significance was considered at $p < 0.05$. Pearson correlation was performed to verify the association between measurements ($p < 0.01$).

## RESULTS AND DISCUSSION

**Evaluation of Growth Parameters.** Table 1 shows the effect of drought stress on the growth parameters of the plants. The plants grown at 35, 24, and 12% SM decreased in leaf width (20, 15, and 21%), leaf length (11, 16, and 17%), and shoot length (14, 15, and 14%) compared to the control plants, while the 65% SM treatment did not produce significant effects on growth parameters compared to the control. A similar trend was observed in the fresh weight of leaves (11, 23, and 20% for 35, 24, and 12% SM, respectively). However, the dry weight was less affected by drought treatments, resulting in decreases of approximately 5, 7, and 7% for 35, 24, and 12% SM, as compared to their respective controls. These effects were similar to those reported by Moeini et al.,[16] who observed 2-, 6-, and 4-fold decreases in plant height, leaf area, and fresh yield, respectively, in basil (*Ocimum basilicum*) plants cultivated under constant water stress (at 60% of field capacity) for 6 weeks.

The reduced growth of the aerial part of the plant is widely described as a consequence of water stress and depends upon the severity and duration of the stress period. The decrease in growth is mainly due to a loss of cell turgor (a physical process). Under normal conditions, water enters the cells because of a difference in potential, which is more negative inside, the cell swells, and the plasma membrane exerts turgor pressure against the cell wall. In drought conditions, the water potential is lower outside than inside the cell; therefore, the water tends to leave the cell, and this also causes the closure of stomata. In these situations, turgor pressure disappears and the plasma membrane detaches from the cell wall in some sections. The main consequence of this loss of turgor is the absence of cell growth and a reduction in plant biomass production.[17,18] This may explain the decrease of fresh and dry weight observed in drought treatments. However, it is important to mention that the dry weight of leaves was not significantly affected in the treated plants, which may be of industrial importance, because peppermint infusions are prepared from dry material.

**Quantification of Total and Individual Phenolic Compounds.** The total polyphenol and flavonoid contents as well as the phenolic profile of infusions of peppermint leaves cultivated under water stress are shown in Figure 1 and Table 2, respectively. Infusions prepared from peppermint grown at 35, 24, and 12% SM showed an increase of 32, 60, and 12% in total

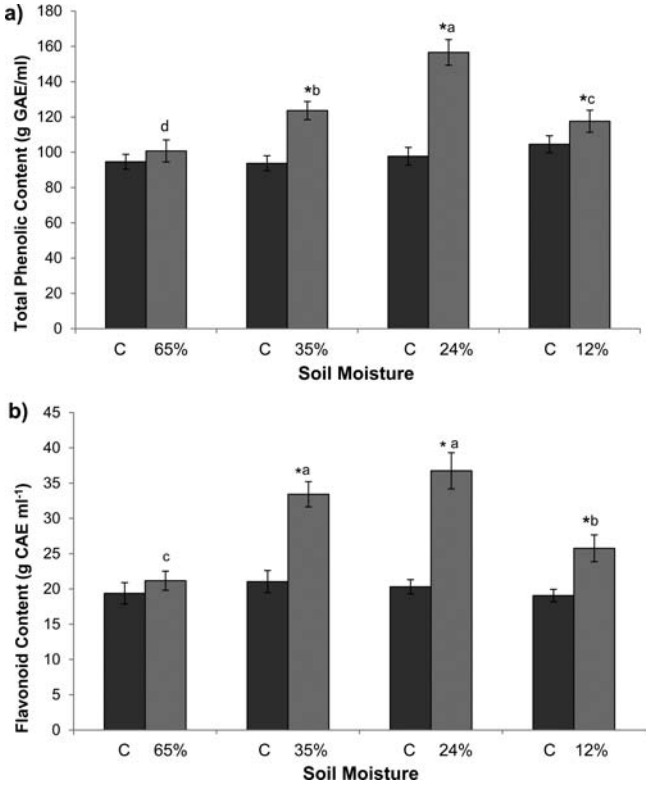

**Figure 1.** (a) Total phenolic and (b) flavonoid contents in infusions prepared from peppermint (*M. piperita*) leaves grown at different levels of SM. Results are expressed as milligrams of (a) gallic acid or (b) catechin equivalents per milliliter of peppermint infusion and are the average of three independent determinations ± SE. (*) Significant statistical differences between controls (black bars, plant growth at 85% SM over the same number of days as the respective treatment in gray bars) and treatments ($p < 0.05$; Dunnett's test). Different letters indicate significant statistical differences between treatments ($p < 0.05$; Tukey's test).

[a]Results are expressed as a percentage of the total area. [b]LDL = lower than the detection limit.

phenolic content and 71, 80, and 31% in total flavonoid content, respectively. However, the 65% SM treatment produced no significant effect on total phenolic and flavonoid contents. An increase of 10 and 71% in total phenolic content after 4 and 8 days of water stress in different tea (*Camellia sinensis*) cultivars has been reported, as compared to control

plants, along with a decrease of about 75% in these compounds when the stress period was prolonged for 12 days.[19]

Plants exposed to drought present increased levels of abscicic acid (ABA) in leaves, shoots, and roots, which induces several responses in the plant, including the accelerated production of ROS in chloroplasts, mitochondria, and peroxisomes, which stimulates antioxidant enzyme activity and the synthesis of phenolic compounds. This mechanism is used in plants as an adaptation strategy to overcome oxidative stress.[7]

The phenolic profile of the different controls used for each treatment was determined, and no significant differences were found; hence, only the control corresponding to the 24% SM treatment is shown in Table 2 and in the following results.

The main phenolic compounds identified in the peppermint infusions were phenolic acids and flavonoids. Most of these compounds were increased in infusions obtained from stressed plants, and this effect was greater in the 35 and 24% SM treatments. Among the compounds that were increased by drought treatment were rosmarinic acid (1.5-fold at 35% SM) and hesperidin (2-fold at 24% SM), which are the most abundant in this plant and have been related to the beneficial health effects of peppermint infusions.[1] Furthermore, coumaric acid, luteolin, quercetin, naringenin, and vanillin were found in infusions of stressed leaves but not in controls. In a previous study, we treated peppermint plants with different concentrations of elicitors [salicylic acid (SA) or hydrogen peroxide] and found similar results, increasing the hesperidin and rosmarinic acid in leaves, among other phenolic compounds, and we also found some compounds, such as naringinin, in SA-treated plants but not in controls; these compounds are different in comparison to those found in this study, which suggests that different types of abiotic stress induce different pathways involved in phenolic compound synthesis.[20]

**Identification of Low-Molecular-Weight Compounds.** Table 3 shows the identification of low-molecular-weight polar compounds, such as amino acids, carbohydrates, organic acids, fatty acids, and alcohols, obtained by GC−MSD analysis. Drought stress led to important changes in the metabolite profile of infusions compared to the control. For instance, most of the amino acids identified in the control, such as Ser, Thr, Phe, and Asn, among others, were not detected in infusions prepared from stressed plants. Similar results were previously reported in tobacco (*Nicotiana tabacum* L.) leaves after 4 days of water deprivation, where decreases of approximately 40−70% were observed in the concentrations of some amino acids, such as Asp, Glu, Ser, and Gly, as well as a decrease in $NO_3^-$. The low level of transpiration and turgor pressure because of water deficit leads to a decrease in root absorption of $NO_3^-$ and transport of $NO_3^-$ to the leaves, decreasing amino acid synthesis. This effect could explain the changes in the amino acid profile found in peppermint infusions made from stressed leaves, because some amino acids were not detected in plants grown under severe drought stress conditions.[21]

However, in several studies, the opposite effect has been shown for some amino acids, such as proline. Ghorbanli et al.[22] found that severe drought stress ($^1/_3$ field capacity) on tomato cultivars growing under greenhouse conditions for 9 weeks resulted in a 6-fold increase of the amount of proline in the leaves. It has been shown that increased proline in drought-stressed plants may be an adaptation to stress conditions, because this amino acid has a scavenger function and acts as a supply of osmolytes and energy for the growth and survival of cells, thereby helping the plant to tolerate water stress.[23] In this study, we found this amino acid in all water stress treatments; however, it is necessary to perform a quantitative study of proline to demonstrate the aforementioned effect.

Despite the fact that amino acids are not the main bioactive compound in peppermint infusions and that these beverages are not consumed for nutritional purposes, these results showed that drought stress affected amino acid biosynthesis in the leaves. Carbohydrates, such as arabinose and D-glucose, were identified in the peppermint infusions; however, these compounds were found in all infusions evaluated, both control and treated. In addition, a similar trend was found for the majority of organic and fatty acids, in which no differences were found between the profiles of control and stressed plants. However, some of these compounds, such as citric and oleic acids, were only identified in infusions made from stressed plants. These compounds are primary metabolites and can be found in large amounts in all plants; in a manner similar to that of phenolic compounds, some organic and fatty acids may also play a protective role against various oxidative diseases because of their antioxidant properties,[24] as is the case of citric acid because it has the ability to act as a singlet oxygen quencher and scavenger of $OH^\bullet$ radicals.[25] Moreover, these compounds are key components of some mechanisms used by plants for the management of nutrient deficiencies, plant−microbe interactions, and water stress, operating at the root−soil interface.[26]

Pantothenic, linoleic, and $\alpha$-linolenic acids were found only in infusions made from control plants, suggesting that drought conditions decrease the amount of these compounds in leaves. Gigon et al.[27] reported approximately 3-fold decreases of the total lipid content in *Arabidopsis thaliana* subjected to drought for 14 days. Similar results were found by Benhassaine-Kesri et al.,[28] who reported decreases in linoleic and linolenic acid contents in rape leaves (*Brassica napus*) growing under water stress conditions for 6 days. Several plant species respond to environmental stresses by altering their membrane lipid composition.[27] Indeed, membranes are primary targets of degradative processes induced by drought stress, and it has been shown that, under water stress, a decrease in the membrane lipid content is correlated with an inhibition of lipid biosynthesis and a stimulation of lipolytic and peroxidative activities, decreasing the lipid content of plant. However, the response may be different depending upon the class of lipid studied.[27−29]

**Evaluation of Antioxidant Capacity.** Antioxidant capacity is related to the presence of compounds with the ability to counteract the formation of free radicals by different mechanisms.[30] Table 4 shows the antioxidant capacity of peppermint infusions as determined by DPPH, ABTS, and

**Table 4. Capacity of Infusions Prepared from Peppermint (*M. piperita*) Leaves Grown at Different Levels of SM, for Inhibition of $ABTS^+$, $DPPH^\bullet$, and $NO^\bullet$ Radicals[a]**

| treatment | $IC_{50}$ $DPPH^\bullet$ | $IC_{50}$ $ABTS^+$ | $IC_{50}$ $NO^\bullet$ |
|---|---|---|---|
| control | 61.2 ± 1.4 a | 16.5 ± 0.4 a | 48.5 ± 0.9 a |

| 12% | 53.4 ± 1.3 b | 15.2 ± 0.3 a | 51.2 ± 1.8 a |

[a]Results are expressed as $\mu$g/mL and reflect averages of triplicate assays ± SE. Different letters indicate significant statistical differences for each treatment ($p < 0.05$; Tukey's test).

nitric oxide scavenging assays, expressed as $IC_{50}$ values. ABTS and DPPH are the main assays used for the evaluation of the ability of compounds to donate electrons or hydrogen atoms, respectively.[30] We found that infusions made from control and stressed peppermint leaves reached a maximum inhibition percentage of approximately 92 and 94% for DDPH and ABTS, respectively (data not shown). However, the infusions obtained from peppermint subjected to water stress exhibited an important decrease in $IC_{50}$ values, as compared to the control in both assays. SM of 35 and 24% had the greatest antioxidant activity, because $IC_{50}$ values were reduced by 33 and 25% for ABTS and 60 and 47% for DPPH, respectively, as compared to the control infusion. These effects could be attributed to the increase of some phenolic compounds, such as coumaric acid, luteolin, rutin, rosmarinic acid, naringenin, and caffeic acid, in drought-stressed plants, because we found high correlation coefficients between these compound concentrations and the DPPH ($r$ = 0.67−0.98) and ABTS ($r$ = 0.80−0.98) scavenging capacities.

On the other hand, we measure the ability of infusions to compete with oxygen to scavenge nitric oxide, which was generated from SNP. Results showed that infusions from all treatments exhibited a maximum inhibition of approximately 82%, while (+)-catechin reached a maximum of 91% (data not shown). Infusions obtained from stressed peppermint showed decreased $IC_{50}$ values by approximately 31 and 37% for the 24 and 35% SM treatments, respectively, as compared to the control. Furthermore, we found a high correlation coefficient between the sinapic acid concentration and NO scavenging activity ($r$ = 0.98). These results suggest that all infusions are likely to have a nitric oxide scavenging activity, which was monitored indirectly by the nitrite production. Nitrite is the final product of the reaction of nitric oxide with oxygen through reactive intermediates, such as $NO_2$ and $N_2O_3$. Therefore, the inhibitory effect of peppermint infusions on nitrite production could be attributed to not only their NO scavenging activity but also their reaction with other nitrogen oxides.[12,31]

**Inhibition of Digestive Enzymes.** It has been demonstrated that peppermint infusions reduce the blood concentration of glucose and triglycerides; therefore, the evaluation of *in vitro* digestive enzyme inhibition represents a preliminary approach to the biological potential of peppermint infusions. Pancreatic α-amylase hydrolyzes starch to oligosaccharides, which are then hydrolyzed to glucose by intestinal α-glucosidase. Pancreatic lipase hydrolyzes triglycerides to free fatty acids and is responsible for the hydrolysis of 50−70% of total dietary fats.[32,33] Therefore, the inhibition of these digestive enzymes could reduce glucose and lipid absorption. It has been reported that some polyphenols may inhibit digestive enzymes involved in the breakdown of lipids and starches, leading to positive effects on obesity and blood glucose control.[15,32] Therefore, we evaluated the capacity of the infusions for inhibition of α-amylase, α-glucosidase, and pancreatic lipase activity.

Table 5 shows that infusions obtained with 35, 24, and 12% SM presented 4-, 24-, and 14-fold increases in α-amylase inhibition, as compared to the control; however, the maximum percentage of inhibition achieved was only 12% (with the 24% SM treatment), suggesting that peppermint infusions are not highly able to inhibit this enzyme. This inhibition was obtained with the concentration used to prepare this kind of beverage (10 mg/mL); however, the peppermint infusions presented a dose-dependent inhibitory capacity, and the maximum α-amylase inhibition (45%) was achieved with 60−80 mg/mL (data not shown). McCue and Shetty[34] reported that pure rosmarinic acid exhibits an inhibitory activity over pancreatic α-amylase in a concentration-dependent manner, and these authors suggested that phenolic synergies in plant extracts may contribute to additional amylase inhibitory activity. Nevertheless, this is not in agreement with our results because we found a low correlation coefficient between the rosmarinic acid concentration and inhibition values to this enzyme ($r$ = 0.19). However, high correlation coefficients were found between hesperidin ($r$ = 0.95), quercetin ($r$ = 0.77), and sinapic acid ($r$ = 0.76) and the amylase inhibition. On the other hand, peppermint infusions (10 mg/mL) inhibited about 7−8% of the activity of α-glucosidase, finding the highest correlation with vainillin and luteolin ($r$ = 0.86 and 0.82, respectively); however, no significant changes were found in infusions made from stressed leaves, as compared to the control. The maximum inhibitory capacity (24%) was reached at 50−65 mg/mL (data not shown). It has been reported that some phenolic compounds, such as quercetin, rutin, and chlorogenic acid, present in *Gynuramedica* leaf extracts have the capacity to inhibit α-glucosidase activity *in vitro*; however, we found low correlation coefficients between inhibition of this enzyme and rutin and quercetin concentrations ($r$ = 0.54 and 0.60, respectively), which suggest that these inhibitions could be related to synergic effects between different compounds in plants.[35]

**Table 5. Inhibition of Digestive Enzyme Activity by Infusions Prepared from Peppermint (*M. piperita*) Leaves (10 mg $mL^{-1}$) Grown at Different Levels of SM[a]**

[a]Results are expressed as a percentage of enzyme inhibition and reflect averages of triplicate assays ± SE. Different letters indicate significant statistical differences for each treatment ($p$ < 0.05; Tukey's test).

Control infusions inhibited approximately 45% of the pancreatic lipase activity, while infusions made from plants stressed with 24 and 12% SM showed inhibitions of 53.5 and 55.1%, respectively. However, the 65 and 35% SM treatments produced no significant changes, as compared to the control. It has been previously reported that hesperidin has the ability to inhibit pancreatic lipase activity *in vitro*, and this effect is associated with its chemical structure, specifically with the 7 position of rutinose on the C ring of the flavonoid structure.[36] Furthermore, the highest correlation coefficient between phenolic compounds and lipase inhibition capacity was found for hesperidin ($r$ = 0.68).

The results of this study suggest that water deficit has an important effect on the synthesis of phenolic compounds in the peppermint plant, which is reflected in an increased *in vitro* antioxidant capacity and inhibition of digestive enzyme activity of the resulting infusions. However, drought stress negatively affected metabolites, such as amino acids and unsaturated fatty acids; therefore, further research is required to determine the biological significance of this effect in the peppermint plant and infusions.

α-amylase resistant, water-soluble oligosaccharides from maltodextrins (partially hydrolyzed starches). These enzymes cleave off the nonreducing glucose moiety and then reattach the glucose moiety to an α-glucan chain via an (α1 → 6)-, (α1 → 2)- or (α1 → 3)-glycosidic linkage, predominantly resulting in chain elongation, though branches are also formed.

A new development in this field are 4,6-α-glucanotransferase enzymes, which have been shown to convert (1 → 4)-α-D-gluco-oligosaccharides into linear α-glucans with consecutive (α1 → 6)-glycosidic bonds build onto (1 → 4)-α-D-gluco-oligosaccharides.[23−25] These enzymes cleave off the nonreducing glucose moiety of a (1 → 4)-α-D-gluco-oligosaccharide and attach this glucose moiety to the nonreducing end of another (α1 → 4)-glucan chain via an (α1 → 6) linkage without forming branches. This catalytic cycle is repeated several times, yielding α-glucans with consecutive (α1 → 6) linkages.

Here, we report the production of a novel type of dietary fiber from starch using the 4,6-α-glucanotransferase enzyme GTFB of *Lactobacillus reuteri* 121.

## MATERIALS AND METHODS

**GTFB Expression and Purification.** GTFB was produced in *Escherichia coli* BL21(DE3) carrying the plasmids pRSF-GTFB and pBAD22-GroELS. Plasmid vector pRSF-GTFB was constructed by cloning the *gtfB* gene of pET15b-GTFB[23] into the *Nco*I/*Eco*RV sites of pRSFduet (Novagen/EMD Chemicals Inc., Darmstadt, Germany). The encoded GTFB protein carries a C-terminal $(His)_6$-tag. *E. coli* was cultured at 30 °C in Luria Broth medium supplemented with ampicillin (100 mg $L^{-1}$) and kanamycin (25 mg $L^{-1}$). Expression of GTFB and GroELS was induced at an $OD_{600}$ of 0.4−0.5 by the addition of isopropyl β-D-1-thiogalactopyranoside (0.5 mM) and L-arabinose (0.02% w/v), respectively, and the incubation was continued for 8 h. Coexpression with the GroELS chaperones increases the yield of GTFB (data not shown). Cells were harvested by centrifugation, washed with buffer A (20 mM Tris/HCl pH 8.0, 250 mM NaCl, 1 mM $CaCl_2$) and stored at −20 °C. Following resuspension in buffer A supplemented with Triton X100 (0.25% v/v) and β-mercaptoethanol (5 mM), the cells were broken by sonication and the supernatant was obtained by centrifugation (10,000*g*; for 30 min). GTFB was purified by His-tag affinity column chromatography using buffer A and eluted with imidazole (200 mM). Purity was checked on sodium dodecyl sulfate-polyacrylamide gel electrophoresis (GTFB is ∼170 kDa) and the protein concentration was measured with Bradford reagent (Bio-Rad, Hercules, CA) and bovine serum albumin as standard.

**Starches, Maltodextrins, and Other Carbohydrates.** The native starches, maltodextrins and amylose V were provided by AVEBE (Veendam, The Netherlands) (Table 1). Maltoheptaose, glycogen type IX (bovine liver), glycogen type VIII (Crepidula), dextran with an average molecular weight of 6,000, and cellulose were from Sigma-Aldrich (St. Louis, MO). Vivinal GOS (galacto-oligosaccharides) was from Friesland-Campina Domo (Beilen, The Netherlands) and FOS Orafti P95 (fructo-oligosaccharides) was from BENEO-Orafti (Oreye, Belgium). Debranched Eliane 100 (waxy potato), Eliane MD6 and Etenia 457 (4-α-glucanotransferase-treated potato starch), also provided by AVEBE, were made using the debranching enzyme Promozyme D2 Pullulanase (Novozymes, Bagsvaerd, Denmark). Briefly, 10% (w/w) starch/maltodextrin was incubated with 5 mg of pullulanase per g of starch/maltodextrin at pH 4.7 and 60 °C for 1 day. Isoamylase (*Pseudomonas* sp.; Megazyme, Wicklow, Ireland) debranched Etenia 457 and glycogen type IX were made by dissolving 0.5 g in 20 mL of sodium acetate buffer (25 mM, pH 4.0) supplemented with 0.02% (w/v) sodium azide. Fifty units of isoamylase were added and the mixture was incubated at 37 °C for 68 h. The reactions were terminated by heating to 90 °C for 5 min.

**Table 1. Evaluation of Various Starches and Maltodextrins As Substrates in IMMP Synthesis[a]**

| substrate | amylose content (apparent) | average DP[f] | % (α1→6) in IMMP | % (α1→6) in IMMP using debranched substrate |

[a]The substrates were incubated with *Lactobacillus reuteri* 121 GTFB enzyme, and the percentages of (α1 → 6)-glycosidic linkages in the obtained products were determined by $^1$H NMR spectroscopy. [b]Maltodextrins manufactured from potato starch. [c]Maltodextrins manufactured from corn starch. [d]Maltodextrins manufactured from waxy potato starch. [e]n/a, not applicable. [f]Values as reported in ref 40. [g]Values as reported in ref 41. [h]Values as reported in ref 42. [i]Degree of polymerization. [j]Isoamylase debranched. [k]Pullulanase debranched. [l]The debranching and GTFB reactions were carried out simultaneously.

**Substrate Evaluation.** A series of starches and maltodextrins were incubated with GTFB at a concentration of 0.5% (w/v) in sodium acetate buffer (10 mM, pH 5.0) supplemented with $CaCl_2$ (1 mM) and sodium azide (0.02% w/v) at 37 °C. Native starches were pregelatinized by autoclaving (15 min, 120 °C), amylose V was dissolved in sodium hydroxide (1 M) and neutralized by hydrochloric acid, and maltodextrins were solubilized by heating to 90 °C in buffer. Incubations of the α-glucan solutions, cooled to 37 °C, were started by the addition of 0.5 mg of GTFB per gram of substrate. The progress of the reactions was followed by analyzing samples at different time intervals ($^1$H NMR analysis). The GTFB

reactions were stopped by heating the samples to 95 °C for 10 min. All reactions were performed at least in duplicate.

**IMMP Production on Gram Scale.** Seven different isomalto/malto-polysaccharide (IMMP) products were produced on multigram scale from the potato starch maltodextrins Paselli MD6, MD10, and SA2, from the waxy potato starch maltodextrin Eliane MD6 (2×), potato starch, and waxy potato starch. Production with the latter two was performed in the presence of a debranching enzyme. The substrate concentrations ranged from 2.5 to 5% (w/w). The other reaction parameters were as above.

**Simultaneous Starch Debranching and GTFB Conversion.** Starch debranching during GTFB conversion was performed by adding isoamylase (5 units per g of starch) or pullulanase (5 mg per g of starch) to the GTFB incubation mixtures under the above-described GTFB reaction conditions.

**α-Amylase Treatment of GTFB Products.** GTFB products (25 mg) were dissolved in 625 μL sodium acetate buffer (34 mM) and incubated with porcine pancreas type I-A α-amylase (Sigma Aldrich) at pH 7 and 37 °C for 24 h.

**Isolation of Individual α-Glucan Structures.** Ten milligrams of the reaction mixture product derived of Paselli MD10 by GTFB treatment, and 10 mg of the same product incubated with excess pig pancreatic α-amylase, were fractionated by size-exclusion chromatography on a Bio-Gel P-2 column (100 × 0.9 cm) (Bio-Rad) using ammonium bicarbonate (10 mM) as eluent at a rate of ∼10 mL $h^{-1}$. Selected fractions were lyophilized, dissolved in water, and further fractionated by high-pH anion-exchange chromatography (HPAEC) on a Carbo-Pac PA-1 column (250 × 9 mm) (Thermo Scientific Dionex, Amsterdam, The Netherlands), assembled in a Dionex DX500 workstation equipped with an ED40 pulsed amperometric detector, using a linear gradient of 30 to 600 mM sodium acetate in 100 mM sodium hydroxide (4 mL $min^{-1}$); see text for specific elution programs. Eluting fractions were collected manually and neutralized directly with 4 M acetic acid. The fractions were desalted using 150 mg CarboGraph SPE columns (Grace, Breda, The Netherlands) and analyzed by matrix-assisted laser-desorption ionization time-of-flight mass spectrometry (MALDI-TOF-MS) and nuclear magnetic resonance (NMR) spectroscopy.

**NMR Spectroscopy.** One-dimensional NMR spectra were recorded on a Varian Inova 500 spectrometer (NMR Center, University of Groningen) and one- and two-dimensional NMR spectra on a Bruker DRX-500 spectrometer (NMR Spectroscopy, Bijvoet Center, Utrecht University) at probe temperatures of 300 K. Prior to analysis, samples were exchanged twice in $D_2O$ (99.9 atom % D, Cambridge Isotope Laboratories, Inc., Andover, MA) with intermediate lyophilization, and then dissolved in 0.6 mL of $D_2O$. Suppression of the HOD signal was achieved by applying a WEFT (Bruker) or WET1D (Varian) pulse sequence for one-dimensional experiments and by a presaturation of 1 s during the relaxation delay in two-dimensional experiments. The two-dimensional TOCSY (total correlation spectroscopy) spectra were recorded using an MLEV-17 mixing sequence with spin-lock times of 20−200 ms. The two-dimensional ROESY (rotating frame Overhauser enhancement spectroscopy) spectra were recorded using standard Bruker XWINNMR software with a mixing time of 200 ms. The carrier frequency was set at the downfield edge of the spectrum to minimize TOCSY transfer during spin-locking. Natural abundance two-dimensional $^1H-^{13}C$ HSQC (heteronuclear single quantum coherence) experiments ($^1H$ frequency 500.0821 MHz, $^{13}C$ frequency 125.7552 MHz) were recorded without decoupling during acquisition of the $^1H$ FID. Resolution enhancement of the spectra was performed by a Lorentzian-to-Gaussian transformation for one-dimensional spectra or by multiplication with a squared-bell function phase shifted by $\pi/(2.3)$ for two-dimensional spectra, and when necessary, a fifth order polynomial baseline correction was performed. Chemical shifts ($\delta$) are expressed in ppm by reference to internal acetone ($\delta$ 2.225 for $^1H$ and $\delta$ 31.08 for $^{13}C$). Carbohydrate structures were determined using the previously developed $^1H$ NMR structural-reporter-group concept of α-D-glucans.[25,26]

**MALDI-TOF-MS.** MALDI-TOF-MS experiments were performed on an Axima mass spectrometer (Shimadzu Kratos Inc., Manchester, UK) equipped with a nitrogen laser (337 nm, 3 ns pulse width). Positive-ion mode spectra were recorded using the reflector mode at a resolution of 5000 fwhm and delayed extraction (450 ns). The accelerating voltage was 19 kV with a grid voltage of 75.2%; the mirror voltage ratio was 1.12, and the acquisition mass range was 200−7000 Da. Samples (1 μL) were mixed in 1:1 ratio with a solution of 10 mg $mL^{-1}$ 2,5-dihydroxybenzoic acid in 1:1 acetonitrile/$H_2O$.

**Dietary Fiber.** Dietary fiber measurements were performed according to an all-in-one measurement,[27] with slight modifications, which is based on the Englyst,[16] McClearly[28] and AOAC 2001.03 procedures. One gram of sample in 5 mL water was homogenized for 5 min (150 rpm). Subsequently, 10 mL of 7.5 g $L^{-1}$ pepsin (P7000, Sigma-Aldrich) in 0.05 M HCl, supplemented with 0.25% saturated benzoic acid, was added, and samples were incubated for 30 min at 37 °C (150 rpm). After raising the pH to 6.0 with 0.7 mL of 0.75 M NaOH and 4 mL of 0.4 M sodium maleate buffer (pH 6.0), 20 mL of 0.4 M sodium maleate buffer (pH 6.0), supplemented with 4 mM $CaCl_2$, 0.02% sodium azide, 0.27% (w/v) pancreatic α-amylase (P7545, Sigma-Aldrich) and 0.18% (v/v) amyloglucosidase (3.26 U $mL^{-1}$; Megazyme), was added. The samples were incubated at 37 °C (150 rpm) for 16 h. After incubation, the pH was adjusted to pH 4.3 with 2 M acetic acid. High-molecular-weight dietary fiber (HMWDF) was precipitated with 180 mL of preheated 95% ethanol of 60 °C. After 16 h at room temperature, the samples were sieved through a tarred and dried crucible containing 1 g of Celite filter, and washed twice with 15 mL of 76% ethanol, once with 95% ethanol, and once with acetone. The samples were dried overnight at 103 °C and weighed, resulting in the weight of the "residue". This fraction was subsequently used to determine ash content by heating at 550 °C for 5 h or protein content using Kjeldahl analysis. The amount of low-molecular-weight dietary fiber (LMWDF) was determined according to the AOAC 2001.03 procedure. In short, the filtrate containing the LMWDF was evaporated to near dryness, mixed with 10 mL of aqueous ethylene glycol (10.2 mg $mL^{-1}$) and water was added up to 50 mL. This sample was loaded on a column containing 25 g of Amberlite IRA-67 (anion-exchange resin) and 25 g of Amberlite 200 ($H^+$ form). After elution of the column with 250 mL of water at a flow rate of 0.8 mL per min, the collected eluate was evaporated to near dryness, and the sample was analyzed quantitatively using high-performance liquid chromatography (TSK-GEL G2500PWXL; Tosoh Corp, Tokyo, Japan). The total dietary fiber fraction (TDF) of a sample is the residue weight, minus protein and ash fraction, plus the LMWDF fraction, which was subsequently expressed as a w/w percentage of the original sample. Control samples were

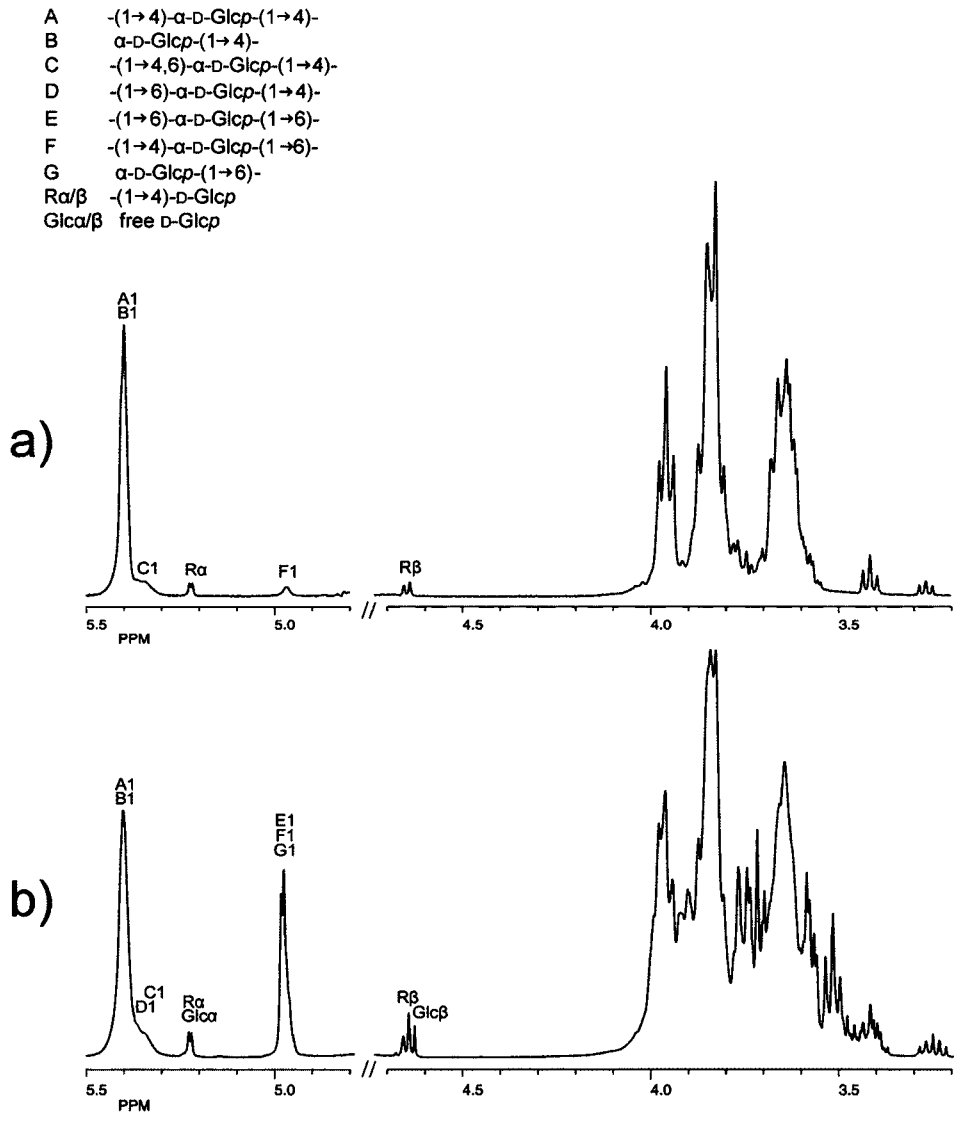

**Figure 1.** $^{1}$H NMR spectra ($D_2O$, 300 K) of (a) the Paselli MD10 maltodextrin substrate (average DP = 12) and (b) the IMMP product derived of Paselli MD10 maltodextrin upon GTFB treatment.

analyzed to compensate for any contribution of reagents and or enzymes used in the procedure.

**Enzymatic Digestion Using Brush Border Enzymes.** Fifty milligrams of rat intestinal acetone powder (Sigma-Aldrich), containing the rat brush border enzymes, was dissolved in 1.5 mL of 0.9% NaCl. Following sonication on ice and centrifugation (10,000*g*; 30 min), the supernatant was used as brush border preparation in the digestion assays. Serial dilutions of various oligosaccharides were prepared in sodium maleate (100 mM; pH 6.0). Incubations were performed in sealed 96-well plates containing 30 $\mu$L oligosaccharide solution and 20 $\mu$L of enzyme mixture at 37 °C. Progress of the digestion was followed in time by taking samples, heat inactivation (10 min; 100 °C), and measuring the amount of glucose released with a glucose assay kit (GAGO-20, Sigma-Aldrich).

**In Vitro Fecal Fermentation.** Culture media for in vitro fecal fermentations were prepared according to Kabel et al.,[29] with minor modifications. Solutions S1 and S3 were adapted to maintain a stable pH during the fermentation. Fermentation substrates were dissolved in S1 (1.05 g $L^{-1}$ $KH_2PO_4$, 1.05 g $L^{-1}$ $K_2HPO_4$ and 4.7 g $L^{-1}$ $Na_2CO_3$) and the pH was adjusted to 6.8. S2 is 6.7 g $L^{-1}$ bacto yeast nitrogen base (Difco, Detroit, MI) dissolved in water. S3 is a 40% (v/v) solution of 0.2 g $L^{-1}$ $MgSO_4$, 0.2 g $L^{-1}$ $CaCl_2$, 1 g $L^{-1}$ $K_2HPO_4$, 1 g $L^{-1}$ $KH_2PO_4$, and 2 g $L^{-1}$ NaCl, supplemented with 5% (w/v) casein enzymatic hydrolysate (N-Z Amine A, Sigma-Aldrich) and 0.5% (w/v) sodium thioglycolate. The pH of S2 and S3 were adjusted to 6−7 with 1 M NaOH. The three solutions S1, S2, and S3 were combined in a ratio of (v/v) 17:1:2 in serum flasks, which were filled at 50% and closed by a butyl rubber stopper. Filter-sterilized S2 was added only after the flasks had been autoclaved (15 min, 121 °C).

Anaerobic conditions were created by exchanging the air with nitrogen. Fecal samples were obtained from a healthy human volunteer in sterile plastic cups and were processed shortly after defecation to avoid aerobic conditions. Samples were processed as described by Kabel et al.[29]

A 10% (w/v) fecal slurry was prepared by adding ∼10 g of each fecal sample to 90 mL of inoculation solution, composed of 1 g $L^{-1}$ Bacto Peptone, 8 g $L^{-1}$ NaCl, and 0.5 g $L^{-1}$ L-cysteine-HCl at pH 6.9. The fecal slurry was mixed, and after an

equilibration time of 30 min, the slurry was diluted to 0.5% (w/v) with phosphate buffered saline solution (pH 6.8), of which 10 mL was added anaerobically to 40 mL culture media in serum flasks using a syringe adapted with a needle. The flasks were incubated at 37 °C. Samples were removed between 0 and 72 h for optical density measurements at 600 nm.

**Short Chain Fatty Acids.** Short chain fatty acids (SCFA) were measured by HPLC using an organic acids column (Column IOA-1000; Alltech) equipped with a refractive index detector. The column was hold at 60 °C and run with 5 mM sulfuric acid at a flow rate of 0.5 mL $min^{-1}$. Fermentation samples taken after 0, 3, 6, 14, 48, and 72 h were analyzed.

## RESULTS AND DISCUSSION

**Maltodextrins Are Substrates for the GTFB Enzyme.** Recently, we reported the synthesis of isomalto/malto-oligosaccharides from short (DP4-DP7) (1 → 4)-α-D-gluco-oligosaccharides using GTFB and two homologous enzymes.[23−25] Here we call the products isomalto/malto-**poly**saccharides (IMMPs), because this better reflects the molecular sizes of the molecules obtained with the larger substrate molecules used in this study. So, IMMPs are α-glucans with one or more (α1 → 4)-linked glucose monomers at its reducing end and one or more glucose units linked via (α1 → 6)-glycosidic bonds at its nonreducing end. They are synthesized via the stepwise addition of single glucose moieties, via (α1 → 6)-glycosidic bonds, onto the nonreducing end of an α-glucan chain.[25] Since α-amylases cannot hydrolyze (α1 → 6) linkages, IMMPs, or more precisely the IMMP fragments rich in (α1 → 6) linkages will not be digested in the upper part of the gastrointestinal tract, and may also escape digestion in the small intestine and then enter the large intestine, where they will be fermented. IMMPs can therefore be regarded as a novel type of dietary fiber and as such they are potentially valuable food ingredients. However, for IMMPs to be of commercial interest it is crucial to produce them from affordable and readily available materials, instead of the expensive monodisperse DP4 to DP7 (1 → 4)-α-D-gluco-oligosaccharides used in the original reports.[23−25] Therefore, it was explored whether GTFB can convert maltodextrins, that is, partially hydrolyzed starches, into IMMPs. Reaction progress was monitored by taking samples over time, followed by enzyme inactivation and subsequent $^1$H NMR analysis. The strong increase observed in the percentage of (α1 → 6)-glycosidic bonds (Table 1) demonstrates that maltodextrins are excellent substrates for GTFB. As a typical example, the $^1$H NMR spectrum of the IMMP product derived from Paselli MD10 maltodextrin (average DP = 12) with GTFB is presented in Figure 1. Figure 1a shows clearly the spectrum of a maltodextrin. The H-1 signal at δ 5.40 reflects high amounts of -(1 → 4)-α-D-Glc*p*-(1 → 4)- internal fragments (residue **A**) combined with α-D-Glc*p*-(1 → 4)-terminal units (residue **B**). The low percentage of branching is indicated by the broad H-1 resonance at δ ∼5.35, derived from -(1 → 4,6)-α-D-Glc*p*-(1 → 4)- branching fragments (residue **C**), combined with the low-intensity H-1 signal at δ 4.97 for -(1 → 4)-α-D-Glc*p*-(1 → 6)- internal fragments (residue **F**). Furthermore, the low-molecular mass of the maltodextrin is evident from the visible H-1α and H-1β signals at δ 5.223 and δ 4.650, respectively, of the -(1 → 4)-D-Glc*p* reducing end unit (residue **R**). Going to the spectrum in Figure 1b, recorded after GTFB treatment, besides the H-1 signals of the residues **A**, **B**, **C**, **F**, **Rα**, and **Rβ**, some new signals are detected. Especially, the H-1 signal at δ 4.97 (residue **F**) has strongly increased, now also belonging to -(1 → 6)-α-D-Glc*p*-(1 → 6)- internal fragments (residue **E**) combined with α-D-Glc*p*-(1 → 6)-terminal units (residue **G**). Furthermore, the broad signal at δ ∼5.35 (residue **C**) has somewhat increased, due to the presence of minor amounts of -(1 → 6)-α-D-Glc*p*-(1 → 4)- internal fragments (residue **D**). The signals present at δ 4.637 (α-D-Glc*p* H-1) and δ 5.223 (β-D-Glc*p* H-1) indicate the formation of a small amount of free glucose (**Glc**). The latter demonstrates that GTFB has a low hydrolytic activity on maltodextrin, as also observed with monodisperse DP4−7 maltooligosaccharide substrates.[25] Note that the products generated of the lowest average DP maltodextrins (i.e., average DP < 5) possessed somewhat less (α1 → 6) linkages (Table 1). This indicates that short chain oligosaccharides are relatively poor glucose donors, which is in agreement with our previous study showing that (1 → 4)-α-D-gluco-oligosaccharides shorter than maltotetraose are very slow glucose donor substrates of the enzyme.[23] Important to note here is that the IMMPs are more soluble in water than the substrates used, as based on visual observation. In conclusion, it can be stated that GTFB effectively converts maltodextrins into water-soluble IMMPs.

**High Amylose Starches Are Preferred Substrates of GTFB.** In the above section, it was shown that maltodextrins are good starting materials for modification with the GTFB enzyme. This raised the question whether starches themselves might be good starting materials. Because starches are not readily soluble in water, making the starch inaccessible to enzymatic modification, the starches were first gelatinized (i.e., solubilized). This was done at a low concentration of 5 g $L^{-1}$ to slow down the process of retrogradation, that is, aligning of (α1 → 4)-glucan chains in a solution enabling hydrogen bond formation which results in a kind of crystalline structure, which basically makes the (α1 → 4)-glucan chains inaccessible for enzymatic modification; note that the process of retrogradation is used to make type 3 resistant starch. $^1$H NMR analysis of the reaction products revealed that GTFB also utilizes native (gelatinized) starches as substrate (Table 1). Importantly, the percentage of (α1 → 6)-glycosidic linkages in the IMMP products obtained is strongly dependent on the type of starch. There are two important factors. First, the amylose content of the starch is positively correlated with the percentage of (α1 → 6)-glycosidic bonds in the IMMP product produced (Figure 2A). Second, the degree of branching (i.e., (α1 → 4,6)-glycosidic bonds) of the starch is negatively correlated with the percentage of (α1 → 6) linkages in the IMMP product (Figure 2B). Indeed, the highly branched α-glucan glycogen, with 7−10% branching, is not a substrate of GTFB, as incubation with GTFB did not significantly increase the percentage of (α1 → 6) linkages (data not shown). The negative correlation with the degree of branching is explained by the exoacting nature of GTFB which forces the enzyme to stop when it reaches a branch point in the glucose donor substrate. Thus, the fraction of glucose moieties available for transfer by GTFB will be lower in more branched substrates. Linear (1 → 4)-α-D-poly/oligosaccharides thus are the best substrates for producing IMMPs with a high percentage of (α1 → 6)-glycosidic bonds. Indeed, the virtually linear substrate amylose V delivered an IMMP product with 91% of (α1 → 6) linkages (Table 1, see Supporting Information Figure S1 for the $^1$H NMR spectrum). This high percentage of (α1 → 6) linkages reached with amylose V demonstrates that once the first elongation step occurs the product becomes a better acceptor substrate. Otherwise all available α-glucan chains would be rapidly

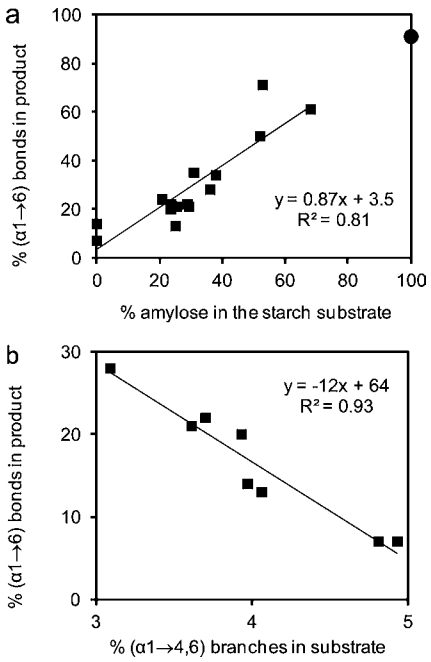

**Figure 2.** Preference of the GTFB enzyme for high amylose starches in the synthesis of IMMPs. (a) Plot of the percentage of ($\alpha$1 → 6) linkages in the IMMP products versus the percentage of apparent amylose in 16 starch substrates (see Table 1). The IMMP derived of amylose V is also indicated (filled circle), but is excluded from the linear regression. (b) Plot of the percentage of ($\alpha$1 → 6) linkages in the IMMP products versus the degree of ($\alpha$1 → 4,6) branching of eight starch substrates (see Table S1 of the Supporting Information).

capped with an ($\alpha$1 → 6)-linked glucose unit, which cannot be cleaved by GTFB at a measurable rate, which would effectively prohibit the further synthesis of IMMPs as there are no longer glucose donor substrates available. Note here that Amylose V is a slightly degraded amylose, as a result of the extraction procedure used to isolate it from regular potato starch. There are thus some shorter ($\alpha$1 → 4)-glucan chains that may serve as initial acceptor substrates. Starting with relative short acceptor substrates, instead of longer ($\alpha$1 → 4)-glucan chains, also ensures that less of the potential glucose donor substrates become inaccessible as donor substrate for GTFB due to the formation of the first ($\alpha$1 → 6) linkage at the nonreducing end of a long ($\alpha$1 → 4)-glucan chain. Overall, it is clear that native (gelatinized) starches are good substrates of GTFB and that high amylose starches can be converted into IMMPs with up to 70% ($\alpha$1 → 6) linkages (Table 1).

**Debranched Starches Are Efficient Substrates of GTFB.** Because high amylose starches are the preferred substrates of GTFB, it may be rationalized that debranched starches will deliver IMMPs with a higher percentage of ($\alpha$1 → 6) linkages compared to their native starches. However, this required confirmation as debranched amylopectin is composed of relatively low DP $\alpha$-glucan chains compared to native amylose chains. The experiment indeed demonstrated that all debranched $\alpha$-glucans evaluated are substrates of GTFB, producing IMMP products with over 60% of ($\alpha$1 → 6) linkages (Table 1). Even glycogen, which itself is not converted into IMMP by GTFB, becomes a substrate upon debranching. Since glycogens have about 7−10% branching, these results as such demonstrate that relative short chains with an average DP of around 10 are long enough to be converted into IMMPs with over 60% of ($\alpha$1 → 6) linkages. The higher percentage of ($\alpha$1 → 6) linkages obtained with isoamylase-debranched Etenia (4-$\alpha$-glucanotransferase-treated potato starch) compared to pullulanase-debranched Etenia, is in agreement with the typical incomplete hydrolysis of branches obtained with pullulanase.

In an industrial setting, it would be advantageous to perform the debranching and GTFB reactions simultaneously in a single reactor. Such one pot reactions are, in addition, also expected to slow down the retrogradation of the linear ($\alpha$1 → 4)-glucan chains resulting from debranching, as the in situ formed ($\alpha$1 → 4)-glucans can be directly utilized by GTFB. Since both GTFB and debranching enzymes (isoamylase as well as pullulanase) require slightly acidic conditions the tandem reaction is expected to work well. As proof of concept experiment, potato starch and waxy potato starch were converted into IMMP with GTFB under standard reaction conditions in the presence of pullulanase or isoamylase, respectively. This yielded products with 92 and 83% ($\alpha$1 → 6)-glycosidic bonds, which is much higher than without the debranching enzyme treatment (Table 1). Thus, incubations with debranching enzyme plus GTFB yield IMMPs with a high percentage of ($\alpha$1 → 6) linkages from starches with a regular amylose content or even waxy starches and glycogen.

**Molecular Structures of the IMMP Products.** To further explore the structural characteristics of the IMMP products, the IMMP generated of maltodextrin Paselli MD10 (average DP = 12) (Figure 1) was separated using Bio-Gel P-2 size-exclusion chromatography, yielding six fractions, denoted **F1**−**F6** (data not shown). MALDI-TOF-MS analysis showed that fraction **F1** contained polymeric material of DP > 30, **F2** mainly DP13−30, **F3** mainly DP10-DP17, **F4** mainly DP8-DP11, **F5** mainly DP5-DP7 and **F6** mainly DP3-DP5. Subsequent $^1$H NMR analysis, comparing the peak areas of the ($\alpha$1 → 4)- and ($\alpha$1 → 6)-related H-1 signals, demonstrated that the fractions consisting of DP8-DP30 $\alpha$-glucans (**F2**−**F3**−**F4**) have slightly more ($\alpha$1 → 6) than ($\alpha$1 → 4) linkages, whereas the shorter (**F5**−**F6**) and larger (**F1**) molecules have more ($\alpha$1 → 4) than ($\alpha$1 → 6) linkages (Figure 3). The fractions **F3** and **F6** were further
