**ABSTRACT:** Glucagon-like peptide-1 (GLP-1) and peptide YY (PYY) are hormones important for satiation and are involved in the process called "ileal brake". The aim of this study was to investigate the GLP-1- and PYY-stimulating efficacy of rebaudioside A, casein, and sucrose. This was studied using tissue segments collected from various regions of the pig small intestine. GLP-1 release was strongest from the distal ileum. There, control release was 0.06 ± 0.01 (GLP-1) and 0.07 ± 0.01 (PYY) pmol/cm$^2$ of tissue. Rebaudioside A (2.5, 12.5, and 25 mM) stimulated GLP-1 release (0.14 ± 0.02, 0.16 ± 0.02, and 0.13 ± 0.02 pmol/cm$^2$ of tissue, $p < 0.001$) and PYY release (0.19 ± 0.02, 0.42 ± 0.06, and 0.27 ± 0.03 pmol/cm$^2$ of tissue, $p < 0.001$). Sucrose stimulated GLP-1 release (0.08 ± 0.01 pmol/cm$^2$ of tissue, $p < 0.05$) only at 10 mM. Casein (0.5%, 1%, and 2.5%, w/v) stimulated GLP-1 release (0.15 ± 0.03, 0.13 ± 0.02, and 0.14 ± 0.01 pmol/cm$^2$ of tissue, $p < 0.001$) and PYY release (0.13 ± 0.02, 0.20 ± 0.03, and 0.27 ± 0.03 pmol/cm$^2$ of tissue, $p < 0.01$). These findings may help in developing dietary approaches for weight management.

**KEYWORDS:** *rebaudioside A, GLP-1, PYY, ex vivo intestinal porcine model*

## INTRODUCTION

The presence of nutrients and other molecules in the small intestine stimulates the release of satiety hormones, such as cholecystokinin (CCK), glucagon-like peptide-1 (GLP-1), and peptide YY (PYY).[1,2] The release of these hormones results in decreased gastric emptying and activation of the so-called intestinal brake. This poorly explored mechanism refers to a physiological feedback mechanism that is triggered by nutrients at a specific location in the intestine, resulting in reduced appetite and food intake.[3,4] Lipids have been widely researched and are known to activate this ileal brake mechanism, resulting in the release of satiety hormones and reduced food intake.[5−8] However, whether other macronutrients such as carbohydrates and proteins could also activate the ileal brake mechanism is still unknown.[4] Knowledge of the satiety-hormone-inducing properties of macronutrients is relevant to better understanding the intestinal response to ingested food and may contribute to the development of products with satiating properties.

The efficacies of noncaloric sweeteners to induce the release of satiety hormones are also partly unknown. However, a study by Anton et al. showed that preloads containing the sweetener stevia reduced daily caloric intake by 301 kcal and reduced postprandial glucose and insulin levels compared to preloads containing sucrose.[9] Such a reduced caloric intake as well as glucose and insulin responses may be caused by reduced caloric content of the preload but may also be caused by other mechanisms such as GLP-1 release. The glycoside rebaudioside A is one of the most abundant sweet compounds extracted from the leaves of *Stevia rebaudiana* Bertoni. Rebaudioside A is reported to be the most potent sweetener among the steviol glycosides,[10] with a relative sweetness 200−400 times greater than that of sucrose.[11] Rebaudioside A is increasingly used in food products as a natural noncaloric sweetener. It has been approved in the United States since 2008[12] and by the European Union since 2010.[13]

It is unknown if ileal delivery of macronutrients other than lipids and sweeteners could also stimulate the release of satiety hormones and consequently activate the ileal brake. Stimulation of GLP-1 and PYY release from isolated ileal tissue has been demonstrated for lipids including unsaturated fatty acids. This was shown using a recently described ex vivo porcine intestinal model.[14] For other macronutrients such as sucrose and casein, such studies have not been performed yet, although their efficacy to induce gut hormone release has been shown in cell cultures.[15−17] The pig was chosen as a model because the gastrointestinal tract of the pig shows a high degree of macroscopic and microscopic resemblance to that of humans.[18−20] The present study primarily focused on the GLP-1- and PYY-inducing efficacy of casein, sucrose, and the noncaloric sweetener rebaudioside A at various locations of the small intestine. We hypothesize that rebaudioside A, the protein casein, and the carbohydrate sucrose are effective stimulators of GLP-1 and PYY release from various locations of the small intestine and thus may be effective activators of the ileal brake in vivo.

## MATERIALS AND METHODS

**Chemicals.** Casein protein (food grade, sodium caseinate purity >82%, batch number 158156) was obtained from Dutch Protein Services BV, Tiel, The Netherlands. Rebaudioside A (Figure 1, food

grade, purity >97%, batch number 20110301, ChemSpider ID 5294031) was obtained from SteviJa Natuurlijk BV, Drachten, The Netherlands. Sucrose (food grade, purity >99.9%) was supplied by Suiker Unie, Oud Gastel, The Netherlands. Safflower oil (food grade, composed of 3−8% C16:0, 2−5% C18:0, 9−15% C18:1, and 75−85% C18:2) was provided by De Wit Specialty Oils, De Waal, The Netherlands. Xantham gum and guar gum were supplied by GF Supplies, Amsterdam, The Netherlands. Chemicals to make the Krebs−Ringer bicarbonate (KRB) buffer (D-glucose (1.8 g/L), magnesium chloride (0.0468 g/L), potassium chloride (0.34 g/L), sodium chloride (7.0 g/L), sodium phosphate dibasic (0.1 g/L), sodium phosphate monobasic (0.18 g/L), HEPES (5579 g/L)) were obtained from Sigma, Zwijndrecht, The Netherlands. The pH of the KRB buffer was adjusted to pH 7.4.

**Collection of Porcine Intestinal Tissues.** Intestinal tissues were obtained from 10 healthy male pigs (*Sus scrofa domesticus*). The pigs were considered healthy after evaluation by a veterinarian. The protocol for this study was approved by the Animal Ethics Committee Utrecht (Ethics Committee Permit Number 2012.I.09.096, Utrecht, The Netherlands). The pigs had a mean (±SEM) body mass of 141 ± 2 kg and mean (±SEM) age of 6 ± 0.1 months. They were housed in groups and were fed ad libitum with the standard pig diet (vitaal P 003103, de Heus, Ede, The Netherlands) and had free access to water. Within 10 min after the pigs were sacrificed, the intestines were excised, and segments of different anatomical regions were stored in ice-cold oxygenated (95% $O_2$, 5% $CO_2$) KRB buffer. Jejunum (4.5 m proximal to the ileocecal junction) and proximal, middle, and distal ileum (0.5 m of intestine sampled from 1.5, 1, and 0.5 m proximal to the ileocecal junction, respectively) were collected for the experiments. Tissues were transported to the laboratory and immediately used for ex vivo experiments. The time between excision and start of the experiments was approximately 30 min.

**Nutrient Exposure of Intestinal Tissue and Viability Tests.** Incubations with casein (0.5, 1, and 2.5%, w/v), rebaudioside A (2.5, 12.5, and 25 mM), sucrose (2.5, 5, and 10 mM), and safflower oil (3.35%, w/v) were performed with porcine intestinal tissue as described previously[14] with some minor adaptations. In brief, upon arrival at the laboratory, the intestine was rinsed with KRB buffer and cut open in a longitudinal direction. The outer muscle layers were carefully stripped off with the basolateral side upward. The mucosal tissue was placed on gauze (pores 250 μm, Sefar Nitex 03-250/50, Sefar, Heiden, Switzerland) with the apical side upward, and circles of tissue with a diameter of 11.8 mm (about 1.0 $cm^2$) were punched out using a biopsy punch. The intestinal segments were randomized, per region, in a beaker glass, transferred to a 24-well plate which was filled with 500 μL of ice-cold KRB buffer/well, and kept on ice until the start of the experiment. Thereafter, the tissues were brought to room temperature within 30 min, followed by a preincubation step at 37 °C for 1 h in a humidified incubator (5% (v/v) $CO_2$). To study the release of GLP-1 and PYY, incubations were initiated by replacing the KRB buffer solution with 500 μL of prewarmed (37 °C) KRB without D-glucose containing the test compounds. KRB buffer without D-glucose was used as a control since D-glucose might induce gastrointestinal hormone release. Then the tissue was put in a humidified incubator for 1 h at 37 °C and 5% (v/v) $CO_2$. After incubation, the solutions were collected, mixed with 100 μM phenylmethanesulfonyl floride (PMSF) (Sigma-Aldrich, Zwijndrecht, The Netherlands) to inactivate dipeptidyl peptidase IV, aliquoted, and stored at 4 °C for further analysis of lactate dehydrogenase (LDH) or stored at −80 °C for further analysis of GLP-1 and PYY.

Tissue viability was checked by measuring the leakage of intracellular LDH in supernatant. LDH, a stable cytosolic enzyme, was analyzed using an LDH kit (Sigma-Aldrich). LDH activity in the supernatant was expressed as a percentage of the total LDH activity present in control tissue collected before incubation. Total tissue levels of LDH were determined per region in 1.0 $cm^2$ tissue samples, which were homogenized in ice-cold KRB buffer with a Potter−Elvehjem-type Teflon pestle tissue grinder (Braun, Melsungen, Germany) for 5 min at 200 rounds/min. Samples were only included for further analysis when LDH leakage did not exceed 10% of the total LDH tissue content.[14,21] No samples had to be excluded applying this criterion.

**Analysis of Satiety Hormones GLP-1 and PYY.** GLP-1 active levels were analyzed using commercially available enzyme-linked immunosorbent assay (ELISA) kits obtained from Millipore (Billerica, MA) and used according to the manufacturer's instructions using a BioTek Synergy HT fluorescence microplate reader (BioTek Instru-

[a]Key: a, $p < 0.05$; b, $p < 0.01$; c, $p < 0.001$. $p$ values are based on comparison to the control (ANOVA + Tukey correction). The incubations were performed in triplicate ($n = 6$ for jejunum and $n = 10$ for proximal, middle, and distal ileum).

dx.doi.org/10.1021/jf501105w | J. Agric. Food Chem. 2014, 62, 8365−8370

ments Inc., Winooski, VT). Since the GLP-1 hormone gene sequence is highly preserved, this kit could be applied for analyzing porcine GLP-1. The range of this assay is approximately 2−100 pM. The interassay coefficient of variation is 11%, and the intraassay variation is 6%. When necessary, samples were diluted in assay buffer from the kit to be in this range.

PYY release was measured from the distal ileum only, since PYY is known to be colocalized with GLP-1.[22] PYY concentrations were measured using a PYY ELISA kit for total PYY (Bachem, Penisula Laboratories, San Carlos, CA) according to the manufacturer's instructions using a BioTek Synergy HT microplate reader (BioTek Instruments Inc.). This kit measures porcine PYY, which is identical to human PYY.[23] The range of this assay is approximately 0.32−5 ng/mL (4.6−1150 pM). The interassay coefficient of variation for this assay is 6%, and the intraassay coefficient of variation is 3%. The lower detection limit of this kit was 20 pg/mL (4.6 pM). It was not necessary to dilute samples for this assay.

**Statistical Analysis.** Statistical analysis was performed using the SAS statistical software package (SAS version 9; SAS Institute, Cary, NC). Both variables GLP-1 and PYY were compared with a mixed analysis of variance (ANOVA) model. GLP-1 and PYY were both log transformed to meet the requirements for ANOVA. The ANOVA model included the fixed factors dose solution (control, sucrose (2.5, 5, and 10 mM), casein (0.5%, 1%, and 2.5%, w/v), rebaudioside A (2.5, 12, and 25 mM), and safflower oil (3.35%, w/v)), intestinal location (jejunum and proximal middle, and distal ileum), and number of incubations per condition (incubations were performed in triplicate). The factor pig, which specifies the individual pig, was added to the model as a random factor. The Tukey post hoc test was used to correct for multiple comparisons. Data are presented as the mean ± SEM and considered significant at $p < 0.05$.

## RESULTS

**Effects of Rebaudioside A and Other Compounds/Mixtures on GLP-1 Release.** Table 1 shows the GLP-1 concentrations in the medium following incubation with the test compounds or mixtures using tissues taken from different locations. In all parts of the small intestine investigated, rebaudioside A caused a significant release of GLP-1 already at the lowest concentration tested (2.5 mM) ($p < 0.01$), except for the jejunum where the release was significant at a concentration of 12.5 mM ($p < 0.05$). The highest relative increase of GLP-1 after incubation with rebaudioside A was seen in the distal ileum ($p < 0.001$). The release at 25 mM was not higher than that at 12.5 mM. As also shown in Table 1, safflower oil (3.35%, w/v) significantly increased GLP-1 release from the proximal ileum ($p < 0.05$) and even more from the distal ileum ($p < 0.001$). Safflower oil did not increase GLP-1 release from the middle ileum and only marginally increased it from the jejunum. At the concentrations tested sucrose did not stimulate GLP-1 release from jejunal and middle ileal tissue. The only significant stimulation was seen in tissues from the distal ileum at a sucrose concentration of 10 mM ($p < 0.05$).

Casein, at 1% and 2.5% (w/v), increased GLP-1 release ($p < 0.001$) from tissues collected from the jejunum, whereas 0.5% (w/v) casein did not. Both 0.5% and 2.5% (w/v) casein stimulated GLP-1 release from the proximal ileum ($p < 0.001$). A concentration of 1% (w/v) casein stimulated GLP-1 release from the proximal ileum ($p < 0.010$), but exposure to 0.5% and 2.5% (w/v) casein caused a higher GLP-1 release. None of the casein concentrations, 0.5%, 1%, and 2.5% (w/v), stimulated GLP-1 release from the middle ileum. All three casein concentrations stimulated GLP-1 release from the distal ileum ($p < 0.001$). Similar to that by rebaudioside A, the most pronounced stimulation of GLP-1 by casein was observed in the distal ileum.

**Regional Differences in GLP-1 Release.** Exposing intestinal tissue to the control did not result in regional differences in control GLP-1 release. However, after exposure to the nutrients, regional differences were observed. For GLP-1 both an overall incubation and location effect ($p < 0.001$) and an interaction effect between incubation and location ($p < 0.05$) were found. Overall GLP-1 release from all ileal locations (distal, middle, and proximal ileum) was higher than GLP-1 release from the jejunal locations ($p < 0.001$). Furthermore, GLP-1 release from the distal ileum was higher than GLP-1 release from the middle ileum ($p < 0.001$). Hormone release from the middle and proximal ileum did not differ, nor did release from the proximal and distal ileum ($p < 0.08$).

**Effects of Compounds and Mixtures on PYY Release.** The compounds and mixtures stimulating GLP-1 release were also tested for their PYY-releasing capacity from the distal ileum (Table 2). Safflower oil was found to stimulate PYY release, whereas sucrose at the concentrations tested did not. Casein stimulated PYY release from the distal ileum at all three concentrations tested. Release after exposure to 1% (w/v) casein was higher than that after exposure to 0.5% (w/v) casein ($p < 0.05$). Rebaudioside A stimulated PYY release from the distal ileum ($p < 0.001$). The effect at 12.5 mM rebaudioside A was higher than that at 2.5 mM ($p < 0.05$).

**Table 2. PYY Concentrations Released from Distal Ileum Intestinal Tissue Segments after Exposure to Various Compounds[a]**

| solution | concn | PYY concn released (pmol/cm$^2$ tissue) |
|---|---|---|
| control | | 0.07 ± 0.01 |
| safflower oil | 3.35% | 0.17 ± 0.01 c |
| sucrose | 2.5 mM | 0.14 ± 0.03 |
| | 5 mM | 0.12 ± 0.02 |
| | 10 mM | 0.08 ± 0.01 |
| casein (%) | 0.5% | 0.13 ± 0.02 b |
| | 1% | 0.20 ± 0.03 c |
| | 2.5% | 0.27 ± 0.03 c |
| rebaudioside A | 2.5 mM | 0.19 ± 0.02 c |
| | 12.5 mM | 0.42 ± 0.06 c |
| | 25 mM | 0.27 ± 0.03 c |

[a]Key: a, $p < 0.05$; b, $p < 0.01$; c, $p < 0.001$. $p$ values are based on comparison to the control (ANOVA + Tukey correction). The incubations were performed in triplicate ($n = 10$).

## DISCUSSION

Our study confirmed our hypothesis that rebaudioside A and casein induce GLP-1 and PYY release from porcine intestinal tissue segments. Remarkably, rebaudioside A was found to stimulate GLP-1 release from all ileal and jejunal regions investigated, whereas sucrose (10 mM) only caused GLP-1 release from the distal ileum. Rebaudioside was effective in stimulating hormone release from more locations of the small intestine than casein. Therefore, taking into account that the model and the tested concentrations make a direct comparison difficult, our results suggest that rebaudioside A and the protein casein are candidate substances that may activate the ileal brake in vivo via the release of GLP-1 and PYY.

Some sweeteners including sucralose were found not to affect satiety hormone release in vivo.[24,25] For stevia, Anton et al. demonstrated satiation-inducing properties which may be due to increased satiety hormone release. However, since satiety

hormones were not measured in that study, this association cannot be made from these findings. To our knowledge, no reports have shown the satiety-hormone-inducing capacity of the noncaloric sweetener rebaudioside A as was done in our study.

Nutrients such as casein and sucrose could stimulate satiety hormone release following interaction with G-protein-coupled receptors and some solute carrier transporters located on enteroendocrine cells in the intestinal epithelium.[26] A potential mechanism by which rebaudioside A could stimulate GLP-1 and PYY release is via the sweet taste receptor. Recently, it was found that rebaudioside A has affinity for the sweet taste receptor TAS1R2/TASR3.[10] This receptor is involved in glucose-dependent release of GLP-1 and PYY in vivo.[27] Furthermore, TAS1R2/TASR3 is present on brush cells and enteroendocrine cells.[28] However, mechanisms other than via the taste receptors by which rebaudioside A and casein could induce satiety hormone release cannot be excluded and should be further studied.

Already more than 100 compounds have been identified in *S. rebaudiana*. However, the steviol glycosides stevioside and rebaudioside A have been found to be the most abundant. Steviol glycosides are metabolized into steviol upon their arrival in the colon and are absorbed thereafter.[29] Incubation of the murine enteroendocrine STC-1 cells with stevia preparations resulted in higher GLP-1 and CCK release compared to incubation with sucrose,[17] which is in line with our findings. The same study also demonstrated GLP-1 and CCK release after incubation with sucralose. However, only relatively high concentrations of sucralose (150 and 300 mM) and sucrose (600 mM) were able to stimulate GLP-1 and CCK release from STC-1 cells. In our study 2.5 mM rebaudioside A resulted in higher GLP-1 release compared to 2.5 mM sucrose ($0.14 \pm 0.02$ vs $0.06 \pm 0.01$, $p < 0.001$, distal ileum). Concentrations of sucrose and rebaudioside A in this study were in the same range (0−25 mM). Further in vitro studies should explore the dose−effect relationships of these compounds.

Safflower oil was used as a positive control in our study. Safflower oil (3.35%) was found to activate the ileal brake in vivo and to increase satiety and gastrointestinal hormone concentrations.[5,7] As expected, safflower oil effectively stimulated GLP-1 release from the ileum mainly from the distal part whereas no such stimulation occurred from the middle ileum. This difference may relate to the enteroendocrine cell distribution. Enteroendocrine L-cells are most abundant in the distal part of the small intestine[30] corresponding to the intestinal tissue content of GLP-1.[14] The protein casein increases satiety in vivo,[31] and in vitro it stimulates GLP-1 release from enteroendocrine murine STC-1 and human NCI-H716 cells.[15,16,32] In our study casein induced GLP-1 and PYY release, which confirms these previous findings and suggests that casein is a candidate to induce the ileal brake in vivo.

Apart from the differences in efficacy of various nutrients to stimulate GLP-1 and PYY, some other questions remain. An important question is to what extent the effects on satiety hormone release found in our model can be reproduced in in vivo models and specifically in humans. Another relevant question is whether the capacity to induce satiety hormone release will lead to satiation in vivo. In one study by Veldhorst et al., it was shown that breakfast with a higher casein content (25% vs 10%) increased visual analogue scale (VAS) scores in fullness and satiety whereas subsequent energy intake was not reduced and GLP-1 plasma concentrations did not differ per condition.[33] Food intake is regulated by a whole cascade of responses which have to be taken into account if studying satiation in vivo. Therefore, knowledge of the satiety-hormone-releasing capacity of macronutrients and noncaloric sweeteners could be useful to understand this so-called "satiety cascade".[34]

The current in vivo data are based on lipid infusions mainly. Those data could be extended into infusion studies using rebaudioside A and casein since the results from this study suggest that the satiety-hormone-releasing effect of sweeteners and proteins might be at least as effective as that of fat. These human interventions will then further substantiate the relevance of this ex vivo intestinal model.

One could question whether the concentrations of the selected compounds are relevant in view of those reached in the gut after dietary intake. Nutrient concentrations in the small intestine depend on the rate of gastric emptying of a meal, the rate of absorption, and (or) digestion of the nutrients the meal contained.[35−37] Data on actual concentrations of the selected products are very scarce. There is only one animal study showing that luminal glucose concentrations after a meal vary between 0.2 and 48 mM depending on the postprandial time and the small intestinal region.[38] Although the data are limited, one could estimate intestinal concentrations on the following assumptions: 1 cup of coffee or tea (200 mL) with 0.3 g of rebaudioside A (based on an acceptable daily intake (ADI) of 0.4 mg/kg of body mass/day), or 1 cube of sugar (1 g), in a total volume of 300 mL (100 mL of gastric juice is added in the stomach).[17] These assumptions would yield an estimate of approximately 10 mM sucrose and 1 mM rebaudioside A for the small intestine. The estimate for casein is based on the assumption that one glass of milk is consumed (total volume including gastric juice 300 mL) with a casein concentration of 80% of the total milk protein content, which is approximately 35 g/L. This means that a concentration of approximately 3% may initially be reached in the small intestine. Although these values are estimates only, they suggest that the concentrations used in this study may be relevant from a dietary perspective.

The hormone-secreting capacity of nutrients and other compounds is often studied in vitro using enteroendocrine cell lines including murine STC-1,[15,39−41] GLUTag cells,[42] and the human NCI-H716 cell line.[43] The advantage of the current ex vivo model compared to cell lines is that this model consists of all different cell types present in the gut. Another model to study the GLP-1- and PYY-inducing capacity of nutrients is the Ussing chamber technology using animal or human biopsies.[44] It is, however, challenging to obtain human biopsies, especially from the ileum, which makes the ex vivo intestinal porcine segment system a valuable alternative. However, there are still some technical limitations such as tissue viability and intrasubject variation. In this study tissue viability was evaluated by LDH leakage as before,[14] and LDH leakage did not exceed 10%. Also, hormone release in the control condition was low. Both conditions indicate a good tissue viability. However, we cannot exclude that hormone release may be due to aspecific processes such as cell lysis. Also, a high number of replicates were needed because of a high intrasubject variation. This variation may be caused by the relatively low number of enteroendocrine cells (reported to account for only 1% of the epithelial cell population in the small intestine), and these cells may be unevenly distributed.[2,28]

In conclusion, the present study showed that rebaudioside A and casein, but not sucrose, induced satiety hormone release at various locations of the small intestine using an ex vivo model.

These findings may contribute to the development of dietary approaches improving weight management and glucose control. However, in vivo studies are necessary to confirm the potential satiety-inducing properties of rebaudioside A and casein in vivo.

**ABSTRACT:** The current study aimed to demonstrate the effects of pterostilbene in rats fed an obesogenic diet. For this purpose, pterostilbene was administered at doses of 15 mg/kg body weight/day (PT15 group) or 30 mg/kg body weight/day (PT30 group) for 6 weeks. Pterostilbene reduced adipose tissue mass −15.1% (PT15) and −22.9% (PT30). In this tissue, it decreased malic enzyme (−39.4 and −49.5% for PT15 and PT30 groups, respectively) and fatty acid synthase (−45 and −53.4% for PT15 and PT30) activities. Acetyl-CoA carboxylase activity was reduced and AMPK activity was increased only in the PT30 group. In the liver, pterostilbene (PT30) reduced malic enzyme (−29.5%) and glucose-6-P dehydrogenase (−43.2%) activities and increased carnitine palmitoyltransferase-1a (37.5%) and acyl-coenzyme A oxidase (42.5%) activities. This increased oxidative capacity was not associated with increased mitochondriogenesis. Among biochemical serum parameters, only insulin was modified by pterostilbene (−31.6%) in the PT15 group. The amounts of pterostilbene in serum and tissues from rats in the PT30 group were in not all cases 2-fold greater than those found in the PT15 group. In conclusion, pterostilbene shows antiobesity properties due, at least in part, to reduced lipogenesis in adipose tissue and increased fatty acid oxidation in liver.

**KEYWORDS:** *adipose tissue, bioavailability, fatty acid oxidation, lipogenesis, pterostilbene*

## INTRODUCTION

Obesity and overweight are major public health concerns that are spreading throughout the world, afflicting not only adults but also many children and adolescents. Moreover, obesity is associated with several chronic diseases, such as diabetes, strokes, and hypertension.[1] Considerable efforts are being made to identify naturally occurring molecules that are active and safe when administered orally and can be employed for obesity management, using a broad range of in vivo and in vitro methodologies.[2]

Phenolic compounds make up one of the groups of molecules that have been most frequently studied in recent years. In this context, resveratrol has been reported to decrease triacylglycerols in cultured adipocytes[3−5] and to reduce adipose tissue in various animal models, such as mice,[6] rats,[7] and primates.[8] However, resveratrol has a very low bioavailability as a consequence of its rapid metabolism in the gut and liver.[9] This poor bioavailability is highly dependent on its free hydroxyl groups, making it susceptible to glucuronidation and sulfation.[10] Due to this fact, the scientific community is looking for other resveratrol-related molecules showing higher bioavailability. In this context, pterostilbene, a dimethyl ether derivative of resveratrol that is less metabolized than resveratrol, is a good candidate.[11]

Pterostilbene is a phenolic compound biologically classified as a phytoalexin, which is part of a plant's defense system and is synthesized in response to pathogen infection, as well as to excessive ultraviolet exposure. Pterostilbene is known to have diverse benefits in the prevention and treatment of several diseases, including cancer,[12] dyslipidemia,[13] diabetes,[14] and cardiovascular and cognitive function degeneration.[15] However, the potential effects of pterostilbene on body fat accumulation have not been studied yet.

In this scenario, the aim of the present study was to determine the effect of pterostilbene on body fat in rats fed an obesogenic diet. The analysis of several mechanisms of action underlying this effect was also assessed.

## MATERIALS AND METHODS

**Chemicals.** 3T3-L1 preadipocytes were supplied by American Type Culture Collection (Manassas, VA, USA). Pterostilbene (purity > 98%) and resveratrol (purity > 98%) were obtained from Bertin Pharma (Montigny le Bretonneux, France). Dulbecco's modified Eagle medium (DMEM) was purchased from Life Technologies (Grand Island, NY, USA). Infinity Triglycerides reagent for triacylglyceride content and BCA reagent for protein determination were obtained from Thermo Scientific (Rockford, IL, USA). Antibodies for phosphorylated acetyl-CoA carboxylase (ACC1) (Ser 79), ACC1, phosphorylated-adenosine monophosphate-activated protein kinase (AMPK) (Thr 172), and AMPK were purchased form Cell Signaling Technology (Beverly, MA, USA). Trizol for RNA isolation was acquired from Invitrogen (Carlsbad, CA, USA). Primers for gene

expression were purchased from Integrated DNA Technologies, Inc. (Leuven, Belgium).

For pterostilbene analysis, $\beta$-glucuronidase (from *Escherichia coli*, Type IX-A) and sulfatase (from abalone entrails, Type VIII) were acquired from Sigma-Aldrich (St. Louis, MO, USA), and bis-[trimethylsilyl]-trifluoroacetamide/dimethylformamide (BSTFA/DMF, 1:1), the derivation reagent, was obtained from Pierce Biotechnology, Inc. (Rockford, IL, USA).

All other reagents and chemicals were of the highest purity grade available and from Sigma-Aldrich.

**Cell Culture.** 3T3-L1 preadipocytes were cultured in DMEM containing 10% fetal bovine serum (FBS). Two days after confluence (day 0), the cells were stimulated to differentiate with DMEM containing 10% FBS, 10 $\mu$g/mL insulin, 0.5 mM isobutylmethylxanthine (IBMX), and 1 $\mu$M dexamethasone for 2 days. On day 2, the differentiation medium was replaced by FBS/DMEM (10%) medium containing 10 $\mu$g/mL insulin and from day 4 onward by FBS/DMEM (10%) medium containing 0.2 $\mu$g/mL insulin. This medium was changed every 2 days until cells were harvested. All media contained 1% penicillin/streptomycin (10000 U/mL), and the media for differentiation and maturation contained 1% (v/v) biotin and panthothenic acid. Cells were maintained at 37 °C in a humidified 5% $CO_2$ atmosphere.

For the adipocyte treatment, cells grown in 6-well plates were incubated with pterostilbene or resveratrol at 1 $\mu$M (diluted in 95% ethanol) for 24 h on day 12 after differentiation. By that day, >90% of cells were mature adipocytes with visible lipid droplets. This cell treatment was carried out in triplicate.

**Adipocyte, Adipose Tissue, and Liver Triacylglycerol Content.** For triacylglycerol extraction, cells were washed extensively with phosphate-buffered saline (PBS) and incubated three times with 800 $\mu$L of hexane/isopropanol (2:1). The total volume was then evaporated under nitrogen, and the pellet was resuspended in 200 $\mu$L of Triton X-100 in 1% distilled water. Afterward, triacylglycerols were solubilized by a sonicator, and the content was measured using Infinity Triglycerides reagent. For protein determination, cells were lysed in 0.3 N NaOH and 0.1% SDS. Protein measurements were performed using the BCA reagent.

Adipose tissue and liver total lipids were extracted following the method described by Folch et al.[16] The lipid extract was dissolved in isopropanol and triacylglycerol content, was measured using a commercial kit (BioSystems, Barcelona, Spain).

**Cytotoxicity Assay.** Cell viability was assessed in cells treated for 24 h with 1 $\mu$M pterostilbene or resveratrol by the neutral red assay (TOX4 kit, Sigma-Aldrich, St. Louis, MO, USA).

**Animals, Diets, and Experimental Design.** The experiment was conducted with 27 male Wistar rats (6 weeks old) with an initial body weight of 180 ± 2 g purchased from Harlan Ibérica (Barcelona, Spain) and took place in accordance with the University of the Basque Country's guide for the care and use of laboratory animals (reference protocol approval CUEID CEBA/30/2010). The rats were individually housed in polycarbonate metabolic cages (Techniplast Gazzada, Guguggiate, Italy) and placed in an air-conditioned room (22 ± 2 °C) with a 12 h light−dark cycle. After a 6 day adaptation period, rats were randomly divided into three experimental groups of nine animals each and fed a commercial obesogenic diet, high in sucrose (20.0%) and fat (22.5%) (Harlan Ibérica, TD.06415). Pterostilbene (purity = 99.9%) was synthesized according to a published procedure.[15] This polyphenol was added to the diet in amounts that assured doses of 15 mg/kg body weight/day (PT15 group) or 30 mg/kg body weight/day (PT30 group). All animals had free access to food and water. Food intake and body weight were measured daily.

At the end of the experimental period (6 weeks), animals were sacrificed, after an overnight fasting, under anesthesia (chloral hydrate) by cardiac exsanguination. White adipose tissue from different anatomical locations (perirenal, epididymal, mesenteric, and subcutaneous) and liver were dissected and weighed. Serum was obtained from blood samples after centrifugation (1000*g* for 10 min at 4 °C). All samples were stored at −80 °C until analysis.

**Serum Parameters.** Serum insulin, triacylglycerols, and nonesterified fatty acids (NEFAs), as well as aspartate aminotransferase (AST/GOT) and alanine aminotransferase (ALT/GPT) activities, were measured using a commercial kits (BioSystems, Barcelona, Spain; EZRMI-13K, Linco, St. Charles, MO, USA; Roche Diagnostics GmbH, Mannheim, Germany; and Spinreact, Barcelona, Spain, respectively). An ELISA kit was used for interleukin 6 (IL6) determination (Quantikine ELISA, R&D Systems, Abingdon, UK).

**Enzyme Activities in White Adipose Tissue and Liver.** For lipogenic enzyme analysis, samples of subcutaneous adipose tissue (1 g) or liver (0.5 g) were homogenized in 5 mL of buffer (pH 7.6) containing 150 mM KCl, 1 mM $MgCl_2$, 10 mM *N*-acetylcysteine, and 0.5 mM dithiothreitol. After centrifugation at 100000*g* for 40 min at 4 °C, the supernatant fraction was used for quantitation of enzyme activities. Fatty acid synthase (FAS), glucose-6-phosphate dehydrogenase (G6PDH), malic enzyme (ME), and lipoprotein lipase (LPL) activities were measured as previously described.[17] Enzyme activities were expressed either as nanomoles of NADPH consumed (FAS) or as nanomoles of NADPH produced (G6PDH and ME) per minute per milligram of protein. Protein was assessed using the Bradford method.[18]

Carnitine palmitoyltransferase-1a (CPT-1a) and acyl-coenzyme A oxidase (ACO) activities in liver were assessed in the mitochondrial/peroxisomal fraction as previously described.[16] CPT-1a activity was expressed as nanomoles of CoA formed per minute per milligram of protein and ACO activity as nanomoles of NADH formed per minute per milligram of protein.

**Extraction and Analysis of RNA and Quantification by Reverse Transcription Polymerase Chain Reaction (Real-Time RT-PCR).** RNA samples were extracted from cells by using Trizol, according to the manufacturer's instructions. The integrity of the RNA extracted from all samples was verified and quantified using an RNA 6000 Nano Assay (Thermo Scientific, Wilmington, DE, USA). RNA samples were then treated with DNase I kit (Applied Biosystems, Foster City, CA, USA) to remove any contamination with genomic DNA.

One microgram of total RNA in a total reaction volume of 20 $\mu$L was reverse transcribed using the iScript cDNA Archive Kit (Applied

[a]Values are means ± SEM ($n = 9$). Values in the same row with different letters are significantly different at $P < 0.05$ as determined by Newman–Keuls test. PT, pterostilbene; NS, not significant; PR, perirenal; MS, mesenteric; E, epididymal.

Biosystems Inc., Foster City, CA, USA) according to the manufacturer's protocols. Reactions were incubated initially at 25 °C for 10 min and subsequently at 37 °C for 120 min and at 85 °C for 5 min.

Relative mRNA levels were quantified using real-time PCR with an iCycler MyiQ Real Time PCR Detection System (Bio-Rad, Hercules, CA, USA). β-Actin mRNA levels were similarly measured and served as the reference gene. The PCR reagent mixture consisted of 1 μL of each cDNA (10 pmol/μL). Specific primers were synthesized commercially, and the sequences and PCR conditions are shown in Table 1.

**Western Blot Analysis.** For acetyl-CoA carboxylase (ACC) and adenosine monophosphate-activated protein kinase (AMPK) activity determinations, the amounts of total ACC and phosphorylated ACC or those of total AMPK and phosphorylated AMPK were measured.

Tissue extracts were obtained by homogenizing 100 mg of subcutaneous adipose tissue or liver in a PBS buffer (pH 7.4) and centrifuged (40*g*, 10 min, 4 °C). For ACC activity determination, 15 μg of tissue extracts in the case of subcutaneous adipose tissue or 60 μg in the case of liver was separated by electrophoresis in a SDS–polyacrylamide gel and transferred to PVDF membranes (Millipore, Bedford, MA, USA). For AMPK activity determination, 25 μg of subcutaneous adipose tissue extracts was used for eletrophoretic separation and transfer to PVDF membranes. Then, the membranes of the two assays were blocked with casein PBS–Tween buffer for 2 h.

The membranes were incubated overnight at 4 °C with ACC antibody (1:1000) or AMPK antibody (1:2000), respectively. Antibodies were visualized by using a chemiluminescent substrate (Thermo Scientific). The intensity of the bands was determined by densitometric analysis and quantified by a ChemiDoc MP imaging system (Bio-Rad). After antibody stripping, the membranes were blocked and then incubated with a phosphorylated ACC antibody (1:1000) or with a phosphorylated AMPK antibody (1:2000) and measured again.

**Analysis of Pterostilbene in Serum and Tissues.** Serum pterostilbene extraction was performed according to the procedure published by Kotani et al.,[19] with modifications. Serum from −80 °C storage was thawed on ice. Fifteen microliters of β-glucuronidase (from *E. coli*, Type IX-A; 250 U/15 mL sodium phosphate buffer, 0.1 M, pH 6.8) and 15 μL of sulfatase (from Abalone Entrails, Type VIII; 20 U/15 mL sodium phosphate buffer, 0.1 M, pH 6.8) were added to 50 μL of serum and then vortex-mixed. This mixture was incubated for 20 h at 37 °C while shaking at 750 rpm using an Eppendorf Thermomixer R (Eppendorf North America, Hauppauge, NY, USA), cooled to room temperature, and then partitioned with ethyl acetate (75 μL × 3). The ethyl acetate layers were combined and dried under nitrogen. The dried sample was derivatized with 40 μL of *N,O*-bis[trimethylsilyl]trifluoroacetamide/dimethylformamide (BSTFA/DMF, 1:1), heated at 70 °C for 40 min, and used for the analysis of pterostilbene by gas chromatography–mass spectrometry (GC-MS).

Pterostilbene in liver was extracted following a published procedure,[20] with minor modifications. One hundred milligrams of fresh tissues was homogenized in 1 mL of saline solution (0.9% NaCl in $H_2O$). Enzyme solution (300 μL; 793.67 U/mL sulfatase and 666.66 U/mL β-glucuronidase in sodium acetate buffer, pH 5), was added to the homogenates, vortex-mixed, and incubated at 37 °C for 16 h while shaking at 750 rpm. Then, 100 μL of 0.1 N HCl was added to this mixture and then partitioned with ethyl acetate (800 μL × 2). The ethyl acetate layers were combined and then dried under nitrogen. The dried sample was derivatized with BSTFA/DMF under the same conditions used for the analysis of pterostilbene in serum.

For the analysis of pterostilbene in adipose tissues, 100 mg of lyophilized tissue was homogenized in 300 μL of sodium acetate buffer and then sonicated for 30 min. Enzyme solution (300 μL; 793.67 U/mL sulfatase and 1333.33 U/mL β-glucuronidase in sodium acetate buffer, pH 5) was added to the homogenate, vortex-mixed, and incubated at 37 °C, with shaking at 750 rpm, for 16 h. After incubation, 500 μL of ice-cold acetonitrile were added, vortexed for 1 min, and then centrifuged (648.7*g*, Savant SpeedVac Concentrator; ThermoFisher Scientific, Waltham, MA, USA) for 20 min. The clear supernatant was collected and treated again with 500 μL of ice-cold acetonitrile, vortexed, and then centrifuged for 20 min. The supernatant was then dried under a stream of nitrogen and derivatized with BSTFA/DMF using the same conditions as in the analysis of pterostilbene in serum.

GC-MS analysis of pterostilbene in serum and tissues was performed using a J&W DB-5 capillary column (0.25 mm internal diameter, 0.25 μm film thickness, 30 m length; Agilent Technologies, Foster City, CA, USA) on a JEOL GCMate II Instrument (JEOL USA Inc., Peabody, MA, USA). For the serum samples, the GC temperature program was as follows: initial, 180 °C; held at this temperature for 1 min; increased to 264 °C at a 12 °C/min rate; held at this temperature for 4 min; increased to 300 °C at a rate of 30 °C/min; and held at this temperature for 0.5 min. The retention time of pterostilbene was 9.7 min. For the tissue samples, the GC temperature program was as follows: initial, 180 °C; held at this temperature for 1 min; increased to 263 °C at a 14 °C/min rate; held at this temperature for 5 min; increased to 300 °C at a rate of 35 °C/min; and held at this temperature for 0.5 min. The retention time of pterostilbene was 8.6 min. The carrier gas was ultrahigh-purity helium, at a 1 mL/min flow rate. The injection port, GC-MS interface, and ionization chamber were at 250, 230, and 230 °C, respectively. The volume of injection was 1 μL, splitless injection. The mass spectrum was acquired in positive, electron impact (70 eV), low-resolution, selected ion

monitoring mode using masses $m/z$ 328, 313, and 296. Quantitation was performed from a calibration curve of a standard sample of pterostilbene.

**Statistical Analysis.** Results are presented as means ± standard error of the means. Statistical analysis was performed using SPSS 17.0 (SPSS Inc., Chicago, IL, USA). All of the parameters are normally distributed according to the Shapiro--Wilks test. Thus, data from the in vivo experiment were analyzed by using one-way ANOVA followed by a Newman−Keuls post hoc test with the exception of pterostilbene amounts in serum and tissues, which were analyzed by using Student's $t$ test. Also in the in vitro experiment Student's $t$ test was used to compare treated cells with each dose of pterostilbene or resveratrol with control cells and also to compare both polyphenols at every dose. Statistical significance was set at the $P < 0.05$ level.

## RESULTS

**Final Body Weight, Food Intake, Body Weight Gain, White Adipose Tissue Weights, Fat Mass, Liver Weight, Liver Triacylglycerol Content, and Serum Parameters.** No statistical differences in food intake, body weight gain, and final body weight were found among experimental groups. Nevertheless, pterostilbene significantly reduced total adipose tissue mass (−15.1% in PT15 group and −22.9% in PT30 group) ($P < 0.05$). With regard to specific anatomical locations, whereas only the subcutaneous depot was significantly affected in the PT15 group, in the PT30 group perirenal, mesenteric, and subcutaneous locations were reduced ($P < 0.05$) (Table 2). This reduction was mirrored in fat mass data (expressed as percentage of body weight): 10.4 ± 1.6 in the control group, 7.80 ± 0.6 in the PT15 group, and 7.07 ± 0.4 in the PT30 group ($P < 0.05$).

As far as liver is concerned, no significant differences in organ weight or triacylglycerol content were observed among experimental groups (Table 2).

Serum parameters are shown in Table 3. Due to the fact that lipogenesis is controlled by insulin, we also measured serum concentrations of this hormone. No differences were found between the control rats and the rats treated with 30 mg/kg/day pterostilbene. By contrast, the rats treated with 15 mg/kg/day pterostilbene showed significantly reduced serum concentrations of this hormone ($P < 0.05$). No significant changes were observed in triacylglycerols and NEFAs.

AST and ALT activities were measured to assess potential liver damage induced by pterostilbene, and no significant changes were found among the experimental groups. Finally, serum concentrations of IL6, a marker of inflammation, remained unchanged (Table 3).

**Enzyme Activities in Adipose Tissue and Liver.** Table 4 shows that the activities of ME and FAS were significantly reduced in subcutaneous adipose tissue from rats of the PT15 and PT30 groups ($P < 0.01$). G6PDH and HR-LPL remained unchanged.

Phosphorylation of ACC leads to its inactivation. Thus, the phosphorylated-ACC/total ACC protein ratio is an index of ACC activity. This index was significantly increased by pterostilbene in rats from the PT30 group ($P < 0.05$), meaning that this enzyme was significantly inhibited (Figure 1A).

By contrast, the greater the phosphorylation rate of AMPK, the greater the activation of this enzyme. In the present study, only the higher dose of pterostilbene (30 mg/kg/day) increased the phosphorylatedAMPK/total AMPK protein

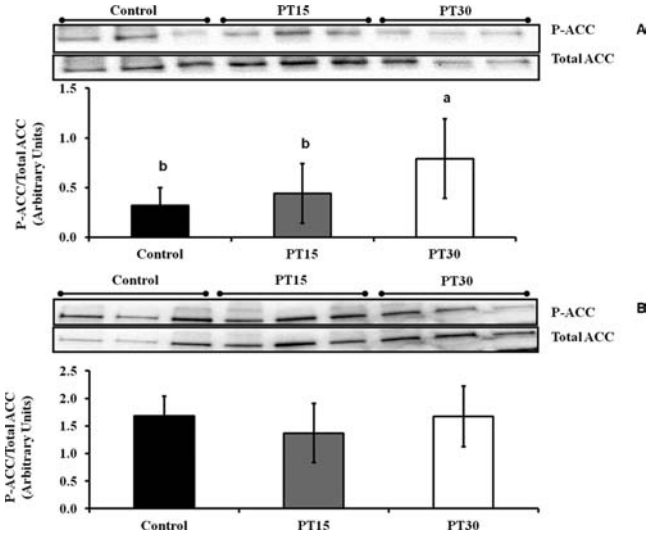

**Figure 1.** Phosphorylated-ACC/total ACC ratio in adipose tissue (A) or liver (B) of rats from the experimental groups. Values are means ± SEM for nine animals per group. Bars not sharing a common letter are significantly different ($P < 0.05$).

ratio ($P < 0.05$). This result means that AMPK was significantly activated in the PT30 group (Figure 2).

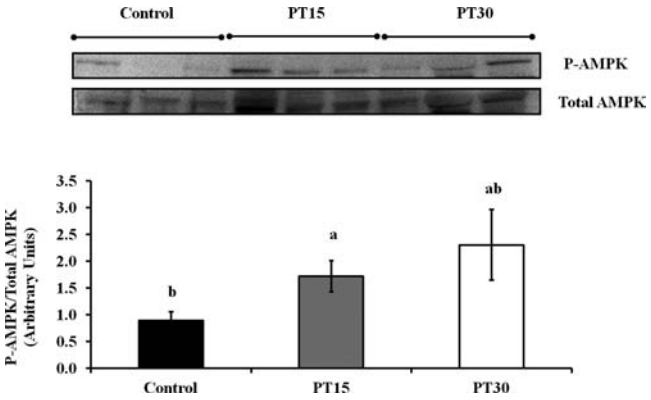

**Figure 2.** Phosphorylated AMPK/total AMPK ratio in adipose tissue of rats from the experimental groups. Values are means ± SEM for nine animals per group. Bars not sharing a common letter are significantly different ($P < 0.05$).

In liver, the activities of enzymes that provide NADPH for lipogenesis (ME and G6PDH) were decreased in rats from the PT30 group, but not in rats from the PT15 group ($P < 0.05$) (Table 4). By contrast, the activities of the rate-limiting lipogenic enzymes (FAS and ACC) were not modified (Table 4; Figure 1B).

As far as the activities of enzymes involved in fatty acid oxidation (CPT-1a and ACO) are concerned, both were significantly increased in the PT30 group ($P < 0.05$ and $P < 0.01$, respectively) (Table 4).

**Gene Expressions in Adipose Tissue and Liver.** In adipose tissue gene expressions of fatty acid synthase (FAS), adipose triglyceride lipase (ATGL), hormone sensitive lipase (HSL), and IL6 were measured. None of these genes showed significant changes after pterostilbene treatment (Table 5). Similarly, hepatic gene expressions of CPT-1a, cluster of differentiation 36 (CD36), mitochondrial transcription factor (TFAM), and cytochrome *c* oxidase subunit II (COX-II) remained unchanged (Table 5).

**Table 5. Gene Expression (Arbitrary Units) in Adipose Tissue and Liver of Rats Fed the Experimental Diets for 6 Weeks[a]**

| | control | PT15 | PT30 | ANOVA |
|---|---|---|---|---|
| adipose tissue | | | | |
| FAS | 1.00 ± 0.22 | 0.52 ± 0.22 | 1.30 ± 0.35 | NS |
| ATGL | 1.00 ± 0.13 | 1.34 ± 0.37 | 1.61 ± 0.42 | NS |
| HSL | 1.00 ± 0.28 | 1.03 ± 0.33 | 1.74 ± 0.41 | NS |

| COX-II | 1.00 ± 0.68 | 1.22 ± 0.68 | 0.50 ± 0.23 | NS |

[a]FAS, fatty acid synthase; ATGL, adipose triglyceride lipase; HSL, hormone sensitive lipase; IL6, interleukin 6; CPT, carnitine palmitoyltransferase; CD36, cluster of differentiation 36; TFAM, mitochondrial transcription factor; COX-II, cytochrome *c* oxidase subunit II.

**Serum and Tissue Levels of Pterostilbene.** Pterostilbene was detected in the serum and in all of the tissues analyzed. The accumulation of this polyphenol was greater in the liver than in adipose tissue. Rats from the PT30 group received a dose of pterostilbene 2-fold higher than rats from the PT15 group, but the amounts of this molecule found in serum and tissues in rats from the PT30 group were not in all cases 2-fold greater than those found in rats from the PT15 group (Table 6).

**Table 6. Serum and Tissue Levels of Pterostilbene in Rats Fed Pterostilbene-Supplemented Diets for 6 Weeks[a]**

| | PT15 | PT30 |
|---|---|---|
| serum (ng/mL) | 384 ± 19.3 | 788 ± 100.6*** |
| liver (ng/100 mg FW) | 30.8 ± 4.8 | 70.6 ± 4.3*** |
| epididymal (ng/100 mg FW) | 1.09 ± 0.2 | 3.07 ± 0.4*** |
| subcutaneous (ng/100 mg FW) | 2.05 ± 0.5 | 3.54 ± 0.3* |

[a]Values are means ± SEM. Pterostilbene amounts in serum and tissues were analyzed by using Student's *t* test: *, $P < 0.05$; ***, $P < 0.001$. PT, pterostilbene; FW, fresh weight.

**Cell Viability and Triacylglycerol Content in Mature 3T3-L1 Adipocytes.** 3T3-L1 mature cells exposed to 1 μM pterostilbene and resveratrol for 24 h showed no loss of viability. Figure 3 shows the results obtained by the neutral red test after 24 h.

Pterostilbene, as well as resveratrol, showed a delipidating effect in 3T3-L1 mature adipocytes at 1 μM (Figure 4).

## DISCUSSION

As described in the Introduction, resveratrol, a polyphenol that has recently been reported to reduce body fat, shows a very low bioavailability. Consequently, interest in other resveratrol-related molecules that share the beneficial properties of resveratrol but show higher bioavailability is growing. In this context, the potential antiobesity properties of pterostilbene, a resveratrol dimethyl ether derivative, were analyzed in the present study.

It is known that the substitution of a hydroxy with a methoxy group in polyphenols increases their transport into cells, as well

dx.doi.org/10.1021/jf501318b | J. Agric. Food Chem. 2014, 62, 8371−8378

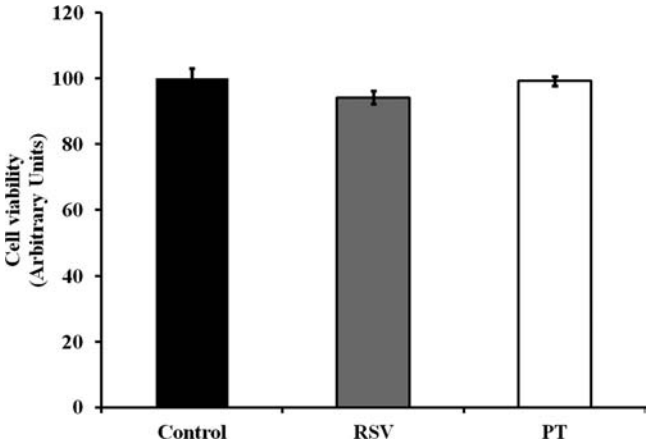

**Figure 3.** Cell viability in 3T3-L1 mature adipocytes treated for 24 h with resveratrol or pterostilbene at 1 $\mu$M. Values are means ± SEM. Comparisons between each treatment and the control were analyzed by Student's *t* test. RSV, resveratrol; PT, pterostilbene.

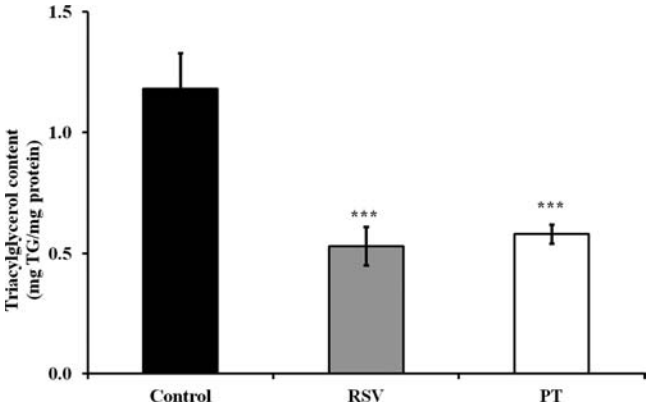

**Figure 4.** Triacylglycerol content in 3T3-L1 mature adipocytes treated for 24 h with resveratrol or pterostilbene at 1 $\mu$M. Values are means ± SEM. Comparisons between each treatment and the control were analyzed by Student's *t* test. Asterisks represent differences between pterostilbene- or resveratrol-treated cells and control cells: (***) $P < 0.001$. RSV, resveratrol; PT, pterostilbene.

as their bioavailability.[21] Pterostilbene is not as quickly glucuronidated and sulfated as resveratrol. The influence of the number and position of the hydroxy/methoxy groups in the stilbene-based molecular structure has not been extensively studied.[22,23] Thus, this issue needs further investigation. With regard to the antiobesity properties of pterostilbene, as far as we are aware few studies have been performed so far.[24]

In the present study, data concerning serum concentrations and tissue amounts of pterostilbene obtained in rats fed an obesogenic diet and treated with 15 or 30 mg pterostilbene/kg/day allowed us to confirm that this compound showed greater bioavailability than resveratrol. Resveratrol serum concentrations, after oral doses similar to those used in the present study, are in the nanomolar range (10−60 nM).[25−27] In good accordance with the literature,[10] we observed that pterostilbene serum concentrations were definitely higher. In the case of tissues, the greater bioavailability of pterostilbene as compared to that of resveratrol is even more evident. Whereas in the present study the amounts of pterostilbene found in liver and adipose tissue were in the range of nanomoles per gram after an overnight fasting, resveratrol, as the parent compound, was not found in a previous study from our laboratory carried out by using the same experimental conditions.[28]

To assess the antiobesity properties of pterostilbene, we analyzed its effect on body fat accumulation in the rats fed the obesogenic diet. This phenolic compound significantly reduced body fat accumulation. The antiobesity effect of the higher dose was greater than that of the lower dose (22.9 vs 15.1% decrease in total adipose tissue mass), but significant differences between these two groups were not found. As far as specific anatomical locations are concerned, whereas the lower dose mainly affected the subcutaneous depot, the higher dose reduced both subcutaneous and internal (mesenteric and perirenal) depots.

This reduction in fat accumulation was not due to a decrease in food intake. Thus, to find potential mechanisms underlying the body fat decrease, the effects of pterostilbene treatment on several metabolic pathways related to triacylglycerol metabolism were assessed. For this purpose, we chose subcutaneous adipose tissue because it showed the greatest reduction.

The activity of the enzymes involved in de novo lipogenesis was significantly reduced, meaning that the attenuation of this metabolic pathway was involved in the body fat lowering effect of pterostilbene. By contrast, the uptake of triacylglycerols from circulating lipoproteins, as well the lipolytic capacity, did not seem to be modified, because significant changes were not observed either in the activity of HR-LPL or in the gene expression of ATGL and HSL.

It has been reported that pterostilbene suppresses lipogenesis in human prostate cancer cells by activating AMPK.[29] To elucidate whether this mechanism also takes place in vivo in adipose tissue, AMPK activity was measured and seen to be increased by the higher dose of pterostilbene. This can justify the decreased ACC activity in the PT30 group, because it has been demonstrated that AMPK inhibits ACC activity by phosphorylation.[30] As far as FAS is concerned, we observed increased activity without changes in its gene expression, suggesting that this pterostilbene-mediated regulation took place at a post-transcriptional level.

It is well-known that insulin regulates the activity of lipogenic enzymes.[31] In the present study, the lack of a clear parallelism between changes in serum insulin concentrations and changes in lipogenic enzyme activities induced by pterostilbene suggests that the effects of pterostilbene do not seem to be mediated by this hormone.

The lack of change in serum insulin concentration in the PT30 group can be surprising. Nevertheless, this situation sometimes takes place with polyphenols. In a previous study performed by our group in obese Zucker rats treated with resveratrol at doses of 15 and 45 mg/kg/day, we observed that this polyphenol significantly increased hepatic CPT-1a activity and reduced serum transaminase concentrations when administered at 15 mg/kg body weight/day, but not at 45 mg/kg body weight/day.[32] Cho et al.[33] fed C57BL/J mice a diet supplemented with 0.02 or 0.005% resveratrol. They found that plasma total cholesterol was reduced by only the lower concentration. Moreover, the reductions induced in hepatic cholesterol and triacylglycerol contents by the lower concentration of resveratrol were significantly greater than those induced by the higher concentration. It seems that pterostilbene is showing the same pattern of response as its related compound, resveratrol.

Pterostilbene has been demonstrated to reduce several inflammatory markers, such as IL6 in 3T3-L1 adipocytes after induction of inflammation by TNF$\alpha$.[34] In the present study, no

changes either in adipose tissue gene expression or in serum concentrations of IL6 were observed. This lack of effect can be due to the fact that the increase in body fat induced by obesogenic feeding was not big enough to induce inflammation. In fact, serum concentration of this interleukin was no greater than that of lean rats fed a standard chow diet (data not shown).

The accumulation of fat in adipose tissue depends on lipid metabolism not only in this tissue but also in other tissues and organs such as the liver. Although pterostilbene, at a dose of 30 mg/kg/day, significantly reduced the activity of hepatic ME and G6PDH, two enzymes involved in the production of NADPH, the activity of hepatic FAS and ACC, two rate-limiting enzymes,[33] was not significantly modified. Therefore, the contribution to the antiobesity effects of pterostilbene of a reduced hepatic triacylglycerol synthesis, and thus of a reduced amount of triacylglycerols in plasma from the liver and available for adipose tissue uptake, may be disregarded.

To analyze the effects of pterostilbene on liver fatty acid oxidation, the activities of two rate-limiting oxidative enzymes, CPT-1a and ACO, were measured. Only the higher dose of pterostilbene significantly increased the activity of both enzymes. It is well-known that an increase in fatty acid oxidation is an underlying mechanism of action for the antiobesity effect of several molecules, such as resveratrol. Under these metabolic conditions fatty acids are channeled toward oxidative routes instead of toward storage routes.[35,36] The present results suggest that at 15 mg/kg/day the antiobesity effect of pterostilbene results from the direct action on adipose tissue and that an additional contribution of hepatic lipid metabolism takes place when pterostilbene doses increase. This could explain why the antiobesity effect of 30 mg/kg/day, although not significant, was greater than that of the lowest dose. The increased activity of CPT-1a seems not to be associated with increased mitochondria density because no changes were induced in the expression of TFAM, a mitochondriogenesis marker, and COX-II a mitochondrion-encoded protein embedded in the lipid bilayer of the inner mitochondrial membrane. When liver triacylglycerol content was measured, no differences were found among experimental groups. This suggests that apparently the increase in fatty acid oxidation was not sufficient to reduce liver fat accumulation. Although surprising, this fact has also been found in other studies.[37−39] To find a potential contribution of increased liver fatty acid uptake from serum to this situation, gene expression of CD36 was measured but no significant changes were observed.

If we compare the present results with those obtained in the study from our laboratory, carried out with resveratrol and previously mentioned,[35] we observe that pterostilbene was more efficient than resveratrol at a dose of 15 mg/kg/day. At 30 mg/kg/day both stilbenes showed similar responses. This can be justified, at least in part, by the higher bioavailability of pterostilbene. Nevertheless, a potential involvement of a higher activity of pterostilbene, due to its specific chemical structure (two additional methoxy groups as compared to resveratrol's structure) could not be discarded. The exclusive influence of a differential activity cannot be elucidated in an in vivo study, and as a consequence, an in vitro study was conducted.

The results obtained show that at a dose of 1 $\mu$M, pterostilbene and resveratrol showed similar delipidating effects, suggesting that the substitution of two hydroxyl groups by two methoxy groups did not modify the activity of pterostilbene. The reduction in triacylglycerol content induced by both phenolic compounds was not due to reduced cell viability.

In summary, pterostilbene shows antiobesity properties. Reduced lipogenesis in adipose tissue and increased fatty acid oxidation in liver contribute to this effect. In the range of the doses studied, a dose−response effect was not observed.

**ABSTRACT:** Food-grade organogels are semisolid systems with immobilized liquid edible oil in a three-dimensional network of self-assembled gelators, and they are supposed to have a broad range of potential applications in food industries. In this work, an edible organogel with tea polyphenols was developed, which possesses a highly effective antioxidative function. To enhance the dispersibility of the tea polyphenols in the oil phase, a solid lipid−surfactant−tea polyphenols complex (organogel complex) was first prepared according to a novel method. Then, a food-grade organogel was prepared by mixing this organogel complex with fresh peanut oil. Compared with adding free tea polyphenols, the organogel complex could be more homogeneously distributed in the prepared organogel system, especially under heating condition. Furthermore, the organogel loading of tea polyphenols performed a 2.5-fold higher antioxidation compared with other chemically synthesized antioxidants (butylated hydroxytoluene and propyl gallate) by evaluating the peroxide value of the fresh peanut oil based organogel in accelerated oxidation conditions.

**KEYWORDS:** *organogel, tea polyphenols, antioxidation*

## INTRODUCTION

Oxidative deterioration of foods remains a very difficult and real problem while we attempt to maintain minimum quality standards. One of the principal causes of food quality deterioration is lipid peroxidation.[1,2] The oxidation of lipids is a free radical driven, chain reaction process, which can cause many deleterious changes including loss of nutritional values and formation of toxic compounds.[3,4] Most of these toxic compounds are known to damage DNA or cause cancers[5] and as a key phenomenon in chronic diseases.[6,7] At present, the principal method to minimize oxidative deterioration in lipid-containing foods and edible oils is the application of antioxidants. Antioxidants terminate the lipid peroxidation chain reactions by removing free radical intermediates and inhibit other oxidation reactions.[8] Synthetic antioxidants, such as butylated hydroxyanisole (BHA), butylated hydroxytoluene (BHT), and propyl gallate (PG), are widely used in the food and cosmetics industries[9,10] due to their high efficiency and relatively low costs. However, the safety of synthetic antioxidants with regard to human consumption has long been questioned.[11−14] In response, natural antioxidants are identified and used as safer and alternative sources of antioxidants in the prevention of oxidative deterioration of foods.[15,16]

Tea polyphenols, which include a wide range of chemical compounds, such as flavonoids, tannins, and catechins, possess outstanding antioxidative properties.[16,17] The main mechanisms for inhibition of oxidative reactions by tea polyphenols include scavenging reactive oxygen species, chelating redox-active transition metal ions, and inhibition of "pro-oxidant" enzymes.[18] However, tea polyphenols are severely restricted to direct use in foods with high lipid content, due to their low solubility in oil phase.

Organogel-based delivery systems for functional ingredients are relatively new in food science and drug delivery.[19−21] Organogels are semisolid systems containing liquid oil trapped within a three-dimensional networked structure, which is formed by the self-assembly of a relatively low concentration of organogelator molecules.[19,22] This structured network appears to be based on the orientational ordering of the hydrocarbon chains,[23] which can facilitate an improved dispersibility of aliphatic functional compounds in the oil phase.[24] Meanwhile, the structure also influences the oxidative stability of the oil entrapped in the system.[25] In recent years, these semisolid products have gained much importance in the food and nutraceutical industries due to applications including the restriction of oil mobility and their ability to control the rate of nutraceutical release.[19,26]

In this paper, we describe the development of an edible oil organogel laden with tea polyphenols, which has a thermal reversibility. To enhance the dispersibility of the tea polyphenols in the oil phase, a solid lipid−surfactant−tea polyphenols complex (organogel complex) was prepared using a novel method.

The resultant organogel displayed highly effective antioxidative properties. A novel method to produce the organogel complex formed of stearic acid, surfactant, and tea polyphenols was developed. The food-grade organogel was prepared by mixing this complex with fresh peanut oil. Microscopy, Fourier transform infrared (FTIR), and X-ray diffraction (XRD) were used to characterize the structure of the organogel complex. Furthermore, the antioxidative properties of the organogel

containing tea polyphenols was also tested and analyzed and were compared with those of stearic acid based organogels with free tea polyphenols and chemically synthesized antioxidants.

## EXPERIMENTAL PROCEDURES

**Materials and Methods.** Tea polyphenols were obtained from Jiangsu Dehe Biotechnology Co., Ltd., China. The composition of these tea polyphenols was determined by using UPLC-MS (XEVO-G2QTOF, Waters, USA). The result is shown in Table 1. Stearic acid (98%, w/w) was purchased from Aladdin Co. (Shanghai, China). Sucrose erucate (ER290) was obtained from Mitsubishi-Kagaku Foods Corp. (Tokyo, Japan). HPLC-grade water was from Alfa Aesar (Lawrence, KS, USA). Glacial acetic acid, isooctane, potassium iodide, sodium thiosulfate, and starch were of analytical reagent grade.

**Table 1. Composition of the Tea Polyphenols (PLC-MS)**

| peak | retention time (min) | $[M - H]^-$ ($m/z$) | compound | area | % |
|---|---|---|---|---|---|
| 1 | 3.29 | 305 | gallocatechin (GC) | 2106 | 2.25 |
| 2 | 3.52 | 305 | epigallocatechin (EGC) | 7113 | 7.62 |
| 3 | 3.72 | 289 | catechin (C) | 4563 | 4.88 |
| 4 | 3.94 | 457 | epigallocatechin-3-gallate (EGCG) | 49175 | 52.65 |
| 5 | 3.99 | 457 | gallocatechin-3-gallate (GCG) | | |
| 6 | 4.22 | 471 | epigallocatechin-3-(3″-*O*-methyl)gallate (EGCmetG) | 3651 | 3.91 |
| 7 | 4.33 | 441 | epicatechin-3-gallate (ECG) | 26787 | 28.68 |

We chose peanut oil as the sample oil to prepare the organogel. Peanut oil possesses a well-balanced fatty acid profile and has been credited with cardioprotective and anti-inflammatory properties.[27] Fresh peanut oil was squeezed out using a small edible oil press (6YL-95A, SRS, China). During the process, the peanuts were mildly toasted to remove the internal water and then pressed to obtain fresh peanut oil.

**Procedure for Preparation of a Stearic Acid−Surfactant−Tea Polyphenols Complex (Organogel Complex).** One hundred milligrams of tea polyphenols dissolved in 2 mL of water was used as aqueous phase. Stearic acid (10 g) containing sucrose erucate ER290 (5%w/w) was placed in an 80 °C water bath and stirred at 500 rpm until a homogeneous clear solution was obtained. Then the aqueous phase and the oil phase were homogenized (HENC homogenizer, Shanghai, China) at 26000 rpm for 2 min to form a stable W/O emulsion. The aqueous and oil phases were homogenized at 80 °C to ensure that the oil phase remained in a liquid state during the homogenization process. The resulting emulsion was frozen rapidly in liquid nitrogen and subsequently lyophilized (FD-1C-50, Beijing, China). The control organogel complex was prepared in the same way only without tea polyphenols in aqueous phase.

**Determination of Critical Gelation Concentration (CGC) and Gel−Sol Transition Temperature.** Gelation was considered successful when the gels failed to flow under gravity on inversion of the vials.[28,29] The CGC is the lowest concentration of gelator (the organogel complex) that induces gelation of edible oil.[30] When determining the CGC, various amounts of the organogel complex were added to peanut oil, following which the mixture was carefully heated to 80 °C and stirred at 500 rpm and subsequently allowed to cool at room temperature under static conditions for 3 h before it was inverted. The lowest concentration of added organogel complex that induced gelation determined the CGC. Meanwhile, the homogeneity of tea polyphenols in the organogel could be visually inspected.

Gel (nonflow)−sol (flow) transition was determined using the inverting tube method. The inverting tube method used in our study was similar to the one used by Motulsky, Behare, and co-workers.[31,32] The organogels with tea polyphenols complex (5, 10, 20, or 30%) were heated in a temperature-controlled water bath as the temperature was varied from 20 to 80 °C at an increment of 2 °C. The samples were equilibrated for 5 min at the previous temperature for 5 min before the temperature increment was made. Sol−gel phase transition temperature ($T_{SG}$) and gel−sol phase transition temperature ($T_{GS}$) are defined as the midpoint of the temperature range above which gelation changes.[33] Sol−gel phase transition temperature was measured by cooling the sample stepwise to 20 °C, following the same procedure.

**Preparation of Different Organogel Samples.** Generally, the organogels with tea polyphenols complex (5, 10, 20, or 30%) were prepared to add organogel complex (1, 2, 4, or 6 g) in 20 g of peanut oil. Then, all of the samples were heated at 80 °C and stirred at 500 rpm to obtain the homogeneous solutions. The samples were cooled to room temperature and crystallized under static conditions. The control organogel was obtained in the same manner with the control organogel complex.

Organogel complex (0.04 g) and stearic acid (0.06 g) were added into 20 g of peanut oil and stirred at 500 rpm to obtain the homogeneous solution. The solution was cooled to room temperature and crystallized under static conditions. Then the organogel with tea polyphenols complex (2%) was prepared.

The organogels with free tea polyphenols, BHT, or PG (0.02%) were prepared by adding free tea polyphenols, BHT, or PG (0.004 g) into 20 g of peanut oil, respectively. The concentrations of BHT, PG, and free tea polyphenols were 0.02% (w/w) in peanut oil, which were the same as the content of tea polyphenols in the organogel containing 5% organogel complex. Then, all of the samples were heated at 80 °C and stirred at 500 rpm. The samples were cooled to room temperature and crystallized under static conditions.

**Characterizations of the Organogel Complex and Organogel Containing Tea Polyphenols.** *Microscopic Analysis.* A compound optical microscope (Olympus, Japan) was used for analyzing the microstructure of the organogels. Attempts were made to understand the mechanism of formation of the organogels through the variation of the proportions of organogel complex in the organogels.

*FTIR Spectra Analysis.* FTIR spectra were investigated to detect the functional groups of compounds through a TENSOR 27 FTIR spectrometer (Bruker, Germany). Stearic acid and representative complexes were prepared for scanning in the range from 4000 to 500 $cm^{-1}$ to examine the interactions among the components of the organogel complex.

*X-ray Diffractometry.* XRD analyses of the samples were carried out with an XRD-600 (Shimadzu, Japan). Samples were scanned in the range from 5° to 95°/2$\theta$, and the scanning rate was 2°/min. Measurements were operated at a voltage of 40 kV, 40 mA.

**Accelerated Oxidation Conditions and Determination of the Peroxide Value (PV).** A range of organogel samples with various antioxidant substances were placed in open transparent glass beakers. The range of organogel samples was prepared by the way of organogel preparation and contained different compositions (see details in Table 3). The range of samples contained various controls and was designed to investigate the effectiveness of tea polyphenols as an antioxidant in an organogel. To artificially induce an accelerated oxidation of the lipids, all samples were marked and stored in an oven at 90 °C for 84 h. During this process of oxidation, the PVs of samples were determined every 12 h.

The PV was evaluated following the NP-904 (1987) method. This method consists of a reaction carried out in darkness of a mixture of oil and isooctane/acetic acid 2:3 (v/v) with a saturated potassium iodide solution. Autoxidation causes the formation of peroxides, which in turn causes the release of iodine. The free iodine formed is then titrated with a sodium thiosulfate solution. The peroxide value was expressed as milliequivalents of active oxygen per kilogram of oil (mequiv/kg). The experiment was conducted in triplicate, and at least three determinations were performed for each sample.

## RESULTS AND DISCUSSION

**Preparation and Characterization of Organogel Complex.** In recent years, there has been a great deal of interest in studying gelling of edible oils with fatty acid derivatives.[34−36] However, saturated fatty alcohols showed lower efficiencies compared to saturated fatty acids of the same length in their ability to form oleogels with various oils.[34] Furthermore, the melting point of stearic acid is lower than that of (*R*)-12-hydroxystearic acid. The solubility of stearic acid in edible oil is higher than that of (*R*)-12-hydroxystearic acid. Thus, stearic acid was chosen as the organogelator to form an organogel complex in this work.

The addition of tea polyphenols to stearic acid resulted in a stable homogeneous emulsion when the tea polyphenols were added up to a concentration of 5% (w/w). At any concentration in excess of 5% (w/w) tea polyphenols, a precipitate would occur. Unless otherwise indicated, all experiments were carried out with a tea polyphenols loading of 1% (w/w).

To assess the molecular interactions due to the presence of tea polyphenols, we undertook FTIR spectroscopy, which included samples of pure stearic acid, control organogel complex (without tea polyphenols), and an organogel complex (with tea polyphenols). We observed that the spectra of the three samples were similar except the different intensity of the broad peaks in the range from 3700 to 3300 $cm^{-1}$ corresponding to O−H stretching (Figure 1). The intensity

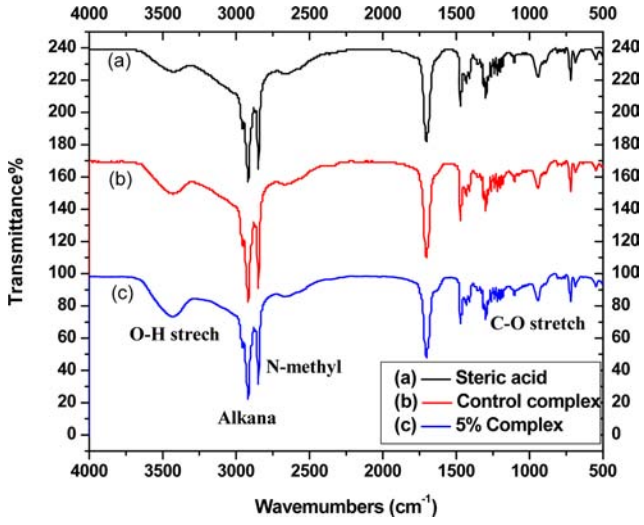

**Figure 1.** FTIR analyses of (a) pure stearic acid, (b) control organogel complex (no tea polyphenols), and (c) organogel complex with 1% (w/w) tea polyphenols.

of the peak corresponding to the O−H stretching vibration increased in the organogel complex containing 1% (w/w) tea polyphenols. This may have been due to the presence of a phenolic hydroxyl group in the tea polyphenol molecules. The characteristic functional groups stretches indicate the presence of alkane (3001 and 2934 $cm^{-1}$), *N*-methyl (2867 $cm^{-1}$), and C−O stretch (1156 $cm^{-1}$) in the samples.[37] There was no significant difference in the rest of the spectra, which indicates that the chemical functionality of the components within the organogel complex was conserved.

To further investigate the molecular arrangements of the structure forming those crystals within the organogel complex, XRD measurements were employed. A control organogel complex and organogel complexes containing 1 and 2% (w/w) tea polyphenols were taken as representative samples. The organogel complexes containing tea polyphenols displayed the same angle diffraction peaks compared to the control organogel complex (Figure 2). These peaks were the result of the

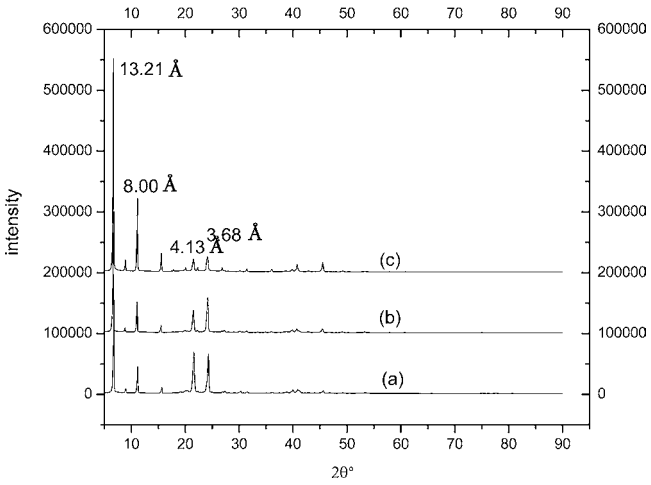

**Figure 2.** X-ray diffraction patterns of (a) control organogel complex, (b) organogel complex containing 1% (w/w) of tea polyphenols, and (c) organogel complex containing 2% (w/w) of tea polyphenols.

scattering associated with stearic acid and showed an elevated crystallinity with sharp peaks. A layer thickness of 13.21 Å can be observed in all of these samples. The results indicated that the crystals were well developed in this direction and cause clear diffraction intensity. All of these samples showed short spacings around 4.13 and 3.68 Å, which are characteristic for an orthorhombic packing, and were similar to the $\beta'$ packing of triacylglycerols.[38] As the concentration of tea polyphenols increased, a peak at 11° with higher intensity could be observed; on the contrary, the short spacings around 4.13 and 3.68 Å showed a weaker intensity (Figure 2), indicating that the corresponding crystals were much thinner in the direction of the unit cell. These results indicate that an increase in tea polyphenols affects the crystal structure and the texturing properties of the organogel complex.

**Preparation and Characterizations of Peanut Oil Based Organogels with Tea Polyphenols.** The dissolution of the organogel complex in peanut oil at 80 °C resulted in the formation of a homogeneous solution. When the temperature was reduced, a change in the solubility parameter of the organogel complex resulted in the crystallization of the stearic acid molecules in the oil continuous phase and formed self-assembled structures. Depending on the concentration of the organogel complex in peanut oil, the solution either remained cloudy and liquid or formed a semisolid-like structure. Through the inverse experiments, the CGC of the organogel was found to be 5% (w/w) (Figure 3); hence, further analyses of the organogels were performed using gels having complex concentration ≥5% (w/w).

The gel−sol and sol−gel transition temperatures were determined by using the inverting tube method. It is an important parameter for gel stability and shelf life.[39] $T_{GS}$ and $T_{SG}$ were very close, because of the same concentration of organogel complex (shown in Table 2). The temperature at which transition occurred increased with organogel complex

**Figure 3.** CGC of organogel loading of tea polyphenols: S-1, organogel containing 4% (w/w) organogel complex; S-2, organogel containing 5% (w/w) organogel complex.

**Table 2. Results of Sol−Gel Phase and Gel−Sol Transition**

| organogel sample | $T_{SG}$[a] (°C) | $T_{GS}$[b] (°C) |
|---|---|---|
| organogel (5% complex)[c] | 48.0 | 51.0 |
| organogel (10% complex)[d] | 50.0 | 53.0 |
| organogel (20% complex)[e] | 54.0 | 57.0 |
| organogel (30% complex)[f] | 57.0 | 60.0 |

[a]Sol−gel phase transition temperature ($T_{SG}$). [b]Gel−sol phase transition temperature ($T_{GS}$). [c]Organogel contains 5% tea polyphenols organogel complex. [d]Organogel contains 10% tea polyphenols organogel complex. [e]Organogel contains 20% tea polyphenols organogel complex. [f]Organogel contains 30% tea polyphenols organogel complex.

concentration. Transitions were fully reversible, and the organogel had a thermal reversibility. The phenomenon of transition temperature was similar to reported results.[38,39]

Microstructure analysis showed the presence of needle-shaped crystals of stearic acid in peanut oil when 5% (w/w) organogel complex concentration was used (Figure 4A). As the concentration of organogel complex was increased, these clusters aggregated to form fiber-like structures (Figure 4B,C). The density of these fiber-like structures increased with the increase of the organogel complex concentration, and these fiber-like structures were found to form a networked skeleton, which helped in the immobilization of the peanut oil. To study the effect of incorporation of tea polyphenols on the crystallinity of the peanut oil based organogel, XRD measurements was also employed to test the representative samples (Figure 5). As the concentration of organogel complex increased from 20 to 30% (w/w), the organogels showed a higher crystallinity, which can be observed from the larger peaks in Figure 5. The larger peaks are indicative of a greater presence of stearic acid in the peanut oil, causing a more pronounced crystallinity in the organogels, and the broader peaks that can be evidenced in Figure 5 correspond to the peanut oil in the organogel.

**Determination of the Antioxidation of the Organogel Loading of Tea Polyphenols.** To test the effectiveness of the presence of tea polyphenols as antioxidants in the organogel, the generation of peroxides was monitored by a modified oven test at 90 °C for up to 84 h. Compared with the peanut oil (blank), the addition of stearic acid alone to peanut oil (control) did not reduce the kinetics of peroxide formation at the early stages of the oven test (Figure 6), but it did reduce the formation of peroxides by about 14% over 84 h, which seems to indicate that the structural characteristics of the organogel systems influence the oxidative reaction.[23] The addition of 5% organogel complex to fresh peanut oil (5% complex) caused a 60% reduction in the formation of peroxides (Figure 6). These

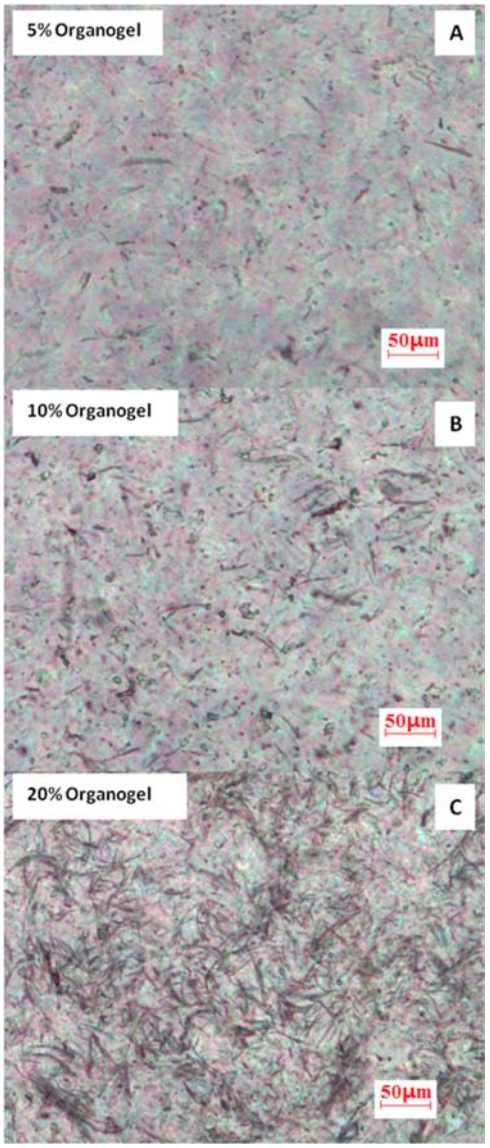

**Figure 4.** Micrographs of organogels. 5% organogel, organogel containing 5% (w/w) organogel complex; 10% organogel, organogel containing 10% (w/w) organogel complex; 20% organogel, organogel containing 20% (w/w) organogel complex.

results indicate that the organogel loading of tea polyphenols performs an obvious antioxidative effect.

To compare the function of different antioxidants, and according to the existing food additive regulations published by the U.S. Food and Drug Administration, BHA and PG can be used individually or in combination at a maximum accumulative level of 0.02%. Stearic acid based organogel samples containing 0.02% (w/w) of BHT, PG, and free tea polyphenols were also prepared (Table 3), and their ability to delay the onset of oxidative rancidity was determined (Figure 7). It is clear that the organogel (2% complex) has a much greater antioxidative effect than organogel with free tea polyphenols (0.02% free TPs), and both of them have the same weight of tea polyphenols, which indicates the organogel complex could improve the dispersibility of tea polyphenols in the oil phase. The addition of either BHT or PG at 0.02% in a stearic acid based organogel only slightly improves the antioxidative effect of organogel (Figures 6 and 7). The addition of 0.02% free tea

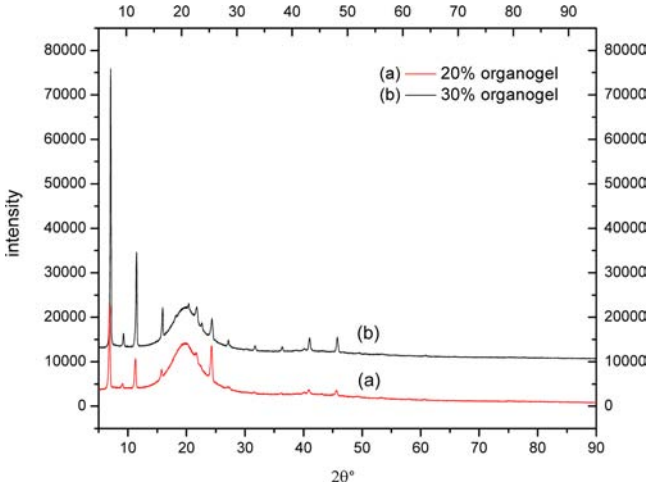

**Figure 5.** X-ray diffraction patterns of organogels. 20% organogel, organogel containing 20% (w/w) organogel complex; 30% organogel, organogel containing 30% (w/w) organogel complex.

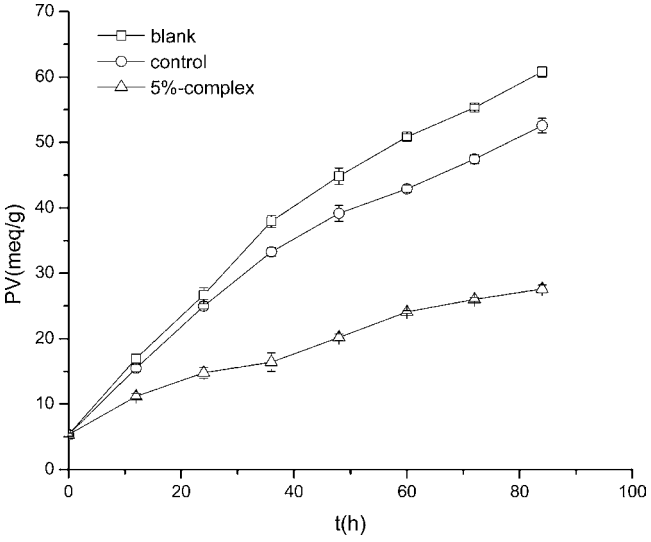

**Figure 6.** Influence of tea polyphenols on delaying the onset of rancidity as measured by changes in peroxide value of organogels as a function of storage time at 90 °C. The "blank" (□) contains pure peanut oil; the "control" (○) contains 5% stearic acid and no tea polyphenols in peanut oil; and "5% complex" organogel (△) contains no stearic acid and 5% organogel complex in peanut oil.

**Table 3. Composition of the Organogel Samples Used for Antioxidation Analysis**

| organogel sample code | fresh peanut oil (g) | stearic acid (%) | antioxidant |
|---|---|---|---|
| blank | 20 | 0 | |
| control | 20 | 0 | control organogel complex (1000 mg) |
| 5% complex | 20 | 0 | organogel complex[a] (1000 mg) |
| 2% complex | 20 | 3 | organogel complex[a] (400 mg) |
| 0.02% free TPs[b] | 20 | 5 | free tea polyphenols (4 mg) |
| 0.02% BHT | 20 | 5 | BHT (4 mg) |
| 0.02% PG | 20 | 5 | PG (4 mg) |

[a]Organogel complex contains 1% tea polyphenols. [b]Tea polyphenols.

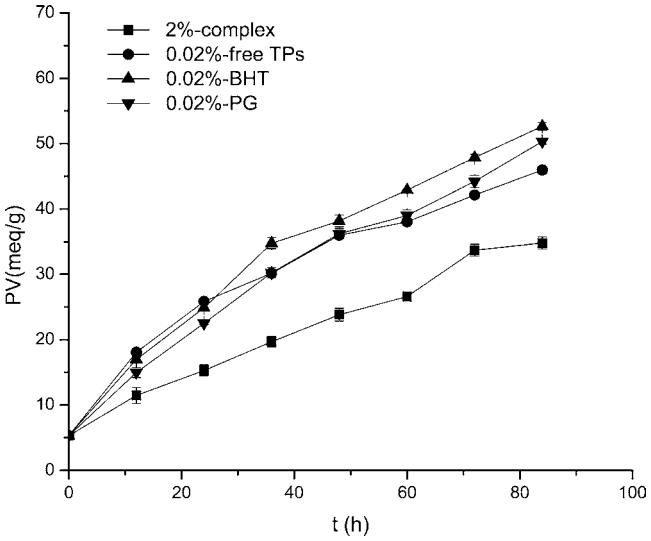

**Figure 7.** Influence of a range of antioxidants on delaying the onset of rancidity as measured by changes in peroxide value of organogels as a function of storage time at 90 °C. The "2% complex" organogel (■) contains 2% organogel complex plus 3% stearic acid in peanut oil; "0.02% free TPs" organogel (●) contains 5% stearic acid plus 0.02% tea polyphenols in peanut oil; "0.02% BHT" organogel (▲) contains 5% stearic acid plus 0.02% BHT in peanut oil; and "0.02% PG" organogel (▼) contains 5% stearic acid plus 0.02% PG in peanut oil.

polyphenols in a stearic acid based organogel yielded a slight improvement in antioxidative ability compared to either BHT or PG (Figure 7). In general, after the oven test for 84 h, the organogel 2% complex, which contained 0.02% tea polyphenols, reduced the formation of peroxides by about 45%, and the stearic acid based organogels, 0.02% TPs, 0.02% PG, and 0.02% BHT, separately caused 27, 18, and 15% reductions in the formation of peroxides. The organogel loading of tea polyphenols performed a 2.5-fold higher antioxidation compared with other chemically synthesized antioxidants (BHT, PG) by evaluating the peroxide value of the fresh peanut oil based organogel in the oven test.

In summary, a novel method was developed to prepare an organogel loaded with tea polyphenols, which significantly improved the dispersibility of tea polyphenols in the organogel system. Furthermore, the organogel loading of a stearic acid−tea polyphenols complex greatly enhanced the ability to delay the onset of oxidative rancidity. More importantly, the method developed here allows the addition of water-soluble, natural active ingredients into lipid-rich foods such as fried foods, cocoa butter, and cream products to improve the shelf life of the food.

# *Camelina sativa* Defatted Seed Meal Contains Both Alkyl Sulfinyl Glucosinolates and Quercetin That Synergize Bioactivity

Nilanjan Das,[†] Mark A. Berhow,[‡] Donato Angelino,[†] and Elizabeth H. Jeffery*[,†]

[†]Department of Food Science and Human Nutrition, University of Illinois at Urbana−Champaign, 905 S. Goodwin Avenue, Urbana, Illinois 61801, United States

[‡]Agricultural Research Service, United States Department of Agriculture, Peoria, Illinois 61604, United States

**ABSTRACT:** *Camelina sativa* L. Crantz is under development as a novel oilseed crop, yet bioefficacy of camelina phytochemicals is unknown. Defatted camelina seed meal contains two major aliphatic glucosinolates (GSLs), glucoarabin (9-(methylsulfinyl)nonylglucosinolate; GSL 9) and glucocamelinin (10-(methylsulfinyl)decylglucosinolate; GSL 10), with traces of a third, 11(methylsulfinyl)undecylglucosinolate and several flavonoids, mostly quercetin glycosides. In Hepa1c1c7 cells, hydrolyzed GSLs (hGSLs) 9 and 10 upregulated the phase II detoxification enzyme quinone reductase (NQO1), with no effect on cytochrome P450 (CYP) 1A1 activity. Isobologram graphs revealed synergy of NQO1 induction for a combination of hGSL 9 and quercetin. These findings suggest that defatted camelina seed meal should be evaluated for anticancer activity, similar to broccoli and other Brassicaceae family members. Interestingly, synergy of NQO1 induction was also seen for physiologically relevant doses of sulforaphane (SF) and quercetin, two key bioactives present in broccoli. This suggests that SF within broccoli may be more potent than purified SF.

**KEYWORDS:** *camelina, glucosinolate, quercetin, NQO1, synergy, sulforaphane*

## INTRODUCTION

There is significant interest in developing novel oilseed crops in both the United States and Canada. *Camelina sativa* L. Crantz, a flowering plant belonging to the Brassicaceae family and commonly known as gold-of-pleasure or false flax, is native to Northern Europe and Central Asia, has been cultivated as an oilseed crop. Although, camelina was introduced more recently into North America, radiocarbon dating of archaeobotanical samples identifies its presence from 720 to 520 cal B.C.[1] Because of its high polyunsaturated C18-fatty acid content, less weather dependency, consistent yields, low requirements for tillage and weed control, and relatively cheap production cost, interest in camelina is growing rapidly for use as an oil crop, source of biodiesel production, and renewable feedstock.[2] Camelina oil consists of about 45% polyunsaturated fatty acids, 35% monounsaturated fatty acids, 10% saturated fatty acids, and up to 10% free fatty acids, tocopherols, sterols, other terpenes, and volatiles. High levels of omega-3 fatty acids and antioxidants such as tocopherols have been the focus of potential health benefits of camelina to date.[3,4] Defatted camelina seed consists of approximately 10% residual oils, 45% protein, up to 15% insoluble fiber, up to 10% soluble carbohydrates, 5% minerals, approximately 0.2% nucleic acids, and 14% or more of a mixture of phytochemical components consisting mostly of glucosinolates (GSLs) and flavonoids.[5] Camelina accumulates significant levels of two aliphatic GSL in its seeds: glucoarabin (9-(methylsulfinyl)nonylglucosinolate; GSL 9) and glucocamelinin (10-(methylsulfinyl)decyl-glucosinolate; GSL 10), with a trace amount of a third, 11(methylsulfinyl)undecylglucosinolate (GSL 11).[6] Moreover, mature camelina seed contains several flavonoids, the most plentiful of which is the flavonol quercetin.[7]

GSLs occur as secondary metabolites, mainly in the Brassicaceae. They act as natural pesticides, preventing herbivory.[8,9] Myrosinase, a thiohydrolase present in GSL-containing plants, can cleave glucose from GSL in the presence of water to form an unstable intermediate that rapidly rearranges to a thiocyanate, isothiocyanate, or nitrile; these serve to defend the plant.[10] Importantly, when ingested by mammals, isothiocyanates exhibit chemoprotective activity against the initiation of tumors, inducing detoxification enzymes, inhibiting enzyme activation, modifying steroid hormone metabolism, and generally improving the host-defense system.[11]

The bioactivity of the isothiocyanate sulforaphane (SF) from broccoli has been studied in detail.[12] Although SF and other hydrolysis products may have multiple sites of action, upregulation of the phase II detoxification enzyme NAD(P)-H:quinone oxidoreductase 1 (NQO1), is often used as a biomarker of beneficial bioactivity.[13] In addition to NQO1, aliphatic GSL hydrolysis products are typically associated with upregulation of antioxidant, anti-inflammatory, and anticancer effects. In contrast, aromatic and indolyl GSLs exert mixed effects, often including upregulation of cytochrome P450 (CYP) 1A1 as well as phase II enzymes, such as NQO1. Possibly associated with CYP1A1 induction, the aromatic and indolyl GSLs have been reported to promote some cancers, even though they protect against others.[14] In contrast, aliphatic GSL hydrolysis products have been found to act as inhibitors of CYP activation of carcinogens.[15]

Much research is ongoing to establish camelina as a biofuel crop, yet little is known about the potential bioefficacy of camelina GSLs and flavonoids. Preparative and countercurrent chromatography has been used to purify GSLs and flavonoids from camelina seed extract.[16] The GSLs in camelina are methyl sulfinyl aliphatics, similar to glucoraphanin the parent GSL to SF, suggesting that they may provide health benefits similar to those of SF. However, they are far larger molecules than the bioactive compounds found in common cruciferous vegetables: 9−11 carbons in length, rather than 3−5. For this reason, we decided to evaluate induction of phase I and phase II detoxification enzymes CYP1A1 and NQO1, as biomarkers of potential bioactivity. Because camelina seed extract also contains the bioactive flavonoid quercetin in several glycosidic forms including rutin, we chose to evaluate the impact of GSL 9, GSL 10, quercetin, and rutin individually, in combination, and as the defatted seed meal extract. We did not evaluate GSL 11, as it is present in negligible amounts (<2 mg/g of seed meal). We also evaluated interactive induction of NQO1 activity between major camelina GSLs and the flavonoid quercetin, comparing this to SF and quercetin, to determine if these were additive, synergistic, or antagonistic in their effect on NQO1 induction. A synergy of action has been reported previously for SF and quercetin in the inhibition of self-renewal of pancreatic cancer stem cells.[17] Our aim was to determine if defatted camelina seed meal might be a health promoting byproduct of biofuel production.

## MATERIALS AND METHODS

**Chemicals.** SF was purchased from LKT Laboratories (St. Paul, MN, USA). Glucose-6-phosphate dehydrogenase was obtained from Roche diagnostics (Indianapolis, IN, USA). Fetal bovine serum (FBS) was purchased from Atlanta Biologicals (Flowery Branch, GA, USA). All other chemicals including myrosinase from *Sinapis alba*, quercetin, and rutin were of the highest grade available and purchased from Sigma (St. Louis, MO, USA).

**Analytical Sample Preparation and Purification of Bioactive Compounds from Camelina Sseeds.** Camelina seeds were harvested according to the method described previously.[16] Camelina GSLs were purified from methanol extracts of defatted meal, using flash chromatography, followed by semipreparative reverse-phase HPLC,[16] or according to the modified counter-current chromatography method described by Toribio et al.[18] Purification of GSLs (GSL 9 > 95%; GSL 10 > 97%), confirmed by NMR addition analysis using acetone as a comparison standard, has been reported in detail elsewhere.[16]

**Cell Culture and Treatments.** Hepa1c1c7 mouse hepatoma cells ($10^4$ cells/mL) were purchased from the American Type Culture Collection (ATCC; Manassas, VA, USA). Cells were cultured in $\alpha$-MEM, enriched with 10% heated and charcoal-inactivated FBS, supplemented with 2.2 g/L $NaHCO_3$, penicillin (100 U/mL), and streptomycin (100 $\mu$g/mL), and maintained at 37 °C in 95% air and 5% $CO_2$. After 24 h incubation, SF (dissolved in DMSO at 0.1% final concentration), GSL 9 or GSL 10 (dissolved in cell culture medium), quercetin (dissolved in DMSO at 0.1% final concentration), and rutin (dissolved in water) were added to the culture medium alone or in combination according to the experimental design and incubated for 24 h. Myrosinase (20 mU/mL) was added to media containing camelina GSLs immediately before adding the media to cultured cells, since early studies showed that, without hydrolysis, GSLs were without effect. Medium treated with GSL 9 and GSL10 plus myrosinase formed the expected isothiocyanate hydrolysis products, confirmed by GC/MS.[16]

**MTT Cytotoxicity Assay.** Any adverse effects of SF or hydrolyzed GSLs (hGSLs) 9 or 10 on cell growth were determined using a standard MTT assay. Hepa1c1c7 cells were placed in 96-well culture plates ($10^4$ cells/well) in complete medium and incubated at 37 °C. After 24 h, the medium was replaced with treatment media containing camelina GSLs plus myrosinase (20 mU/mL) and incubated for another 24 h. Cytotoxicity of the hGSLs and SF was then evaluated using the MTT assay,[19] and results were quantified using a $\mu$Quant microplate reader (Bio-Tek Instruments, Winooski, VT, USA) at 595 nm. Data are reported as percent cell survival relative to respective controls.

**NQO1 Inductive Activity.** The NQO1 inducing activity of different samples was estimated as previously described.[20] Hepa1c1c7 cells, grown in $\alpha$-MEM and enriched with 10% FBS, were seeded in a 96-well plate at a density of $10^4$ cells/well and maintained at 37 °C in 95% ambient air and 5% $CO_2$. After 24 h, cells were exposed to fresh media containing SF, hGSL 9, hGSL 10, quercetin, or rutin for a further 24 h, alone or in combination. Concentrations used for the treatments with hGSL 9, hGSL 10, quercetin, and rutin were 1.25, 2.5, and 5 $\mu$M. In a second study, cells were treated with 2.5 mg seed extract/mL and with the individual components, at the concentration present in 2.5 mg seed extract/mL: 0.86 $\mu$M hGSL 9, 2.2 $\mu$M hGSL 10, together with 1.46 $\mu$M quercetin and 0.48 $\mu$M rutin. Treated cells were rinsed with phosphate buffer at pH 7.4, lysed with 50 $\mu$L 0.8% digitonin in 2 mM EDTA, incubated, and agitated for 10 min. A 200 $\mu$L aliquot of reaction mix was added to the lysed cells. Readings were made at five time points, 50 s apart, using a $\mu$Quant microplate reader at 610 nm. Immediately after completion of the readings, 50 $\mu$L of 0.3 mM dicumarol in 25 mM Tris−Cl buffer was added to each well, and the plate was read again (five time points, 50 s apart) to determine nonspecific MTT reduction. Total protein content was measured by the BioRad assay (Bio-Rad, Hercules, CA, USA) following manufacturer's instruction. Activity was expressed as NQO1 specific activity (nmol MTT reduced/min/mg protein). For each study, incubations were carried out in triplicate; studies were repeated three times.

**Measurement of CYP1A1 Catalytic Activity.** Hepa1c1c7 cells were seeded on 96-well plates at a density of $10^4$ cells/well in $\alpha$-MEM supplemented with 10% FBS and stabilized for 24 h. Cells were then treated for 24 h with 1.25, 2.5, and 5 $\mu$M GSLs 9 or 10 plus myrosinase (20 mU/mL) alone, in combination, and in the presence or absence of the CYP1A1 inducing agent $\beta$-naphthoflavone (5 $\mu$M). The catalytic activity of 7-ethoxyresorufin-*O*-deethylase (EROD) was measured as described elsewhere.[21] Briefly, monolayers were washed with PBS and then treated with 100 $\mu$L of serum free medium/well, containing 8 mM 7-ethoxyresorufin and 10 mM dicumarol (to inhibit cytosolic NQO1) followed by 150 $\mu$L Tris−MeOH (15% methanol in 50 mM Tris−Cl buffer). Fluorescence was measured at 530 nm excitation and 590 nm emission, using a FLx800 universal microplate reader. Specific activity was expressed as picomoles of resorufin formed per minute per milligram of protein, comparing the resorufin formed to the standard curve of known concentrations of resorufin.

**Synergy Study Using Major Camelina GSLs and Flavonoids.** To evaluate synergy between camelina bioactives, we developed an isobologram[22] using concentrations of GSL 9 and quercetin, individually or together, that doubled NQO1 activity in Hepa1c1c7 cells after 24 h incubation, compared to activity in untreated cells. We compared this to synergy between SF and quercetin, major bioactives present in broccoli, under similar conditions.

**Statistical Analysis.** One way analysis of variance (ANOVA) was used to identify differences among treatment groups. Between individual groups, statistical significance was assessed using Student's *t*-test with a *p* value of less than 0.05 indicating a significant difference between data sets.

## RESULTS

**Impact of Defatted Camelina Seed Extract and Its Individual Bioactive Components on Cellular Survival.** We tested the cytotoxicity of hGSL 9, hGSL 10, quercetin, and rutin for three doses 1.25, 2.5, and 5 $\mu$M as well as the existing concentration ratios in the seed extract (2.5 mg/mL) (Figure 1A). We also tested the cytotoxicity of the seed extract itself at three doses, 0.5, 1.25, and 2.5 mg/mL (Figure 1B). Neither the

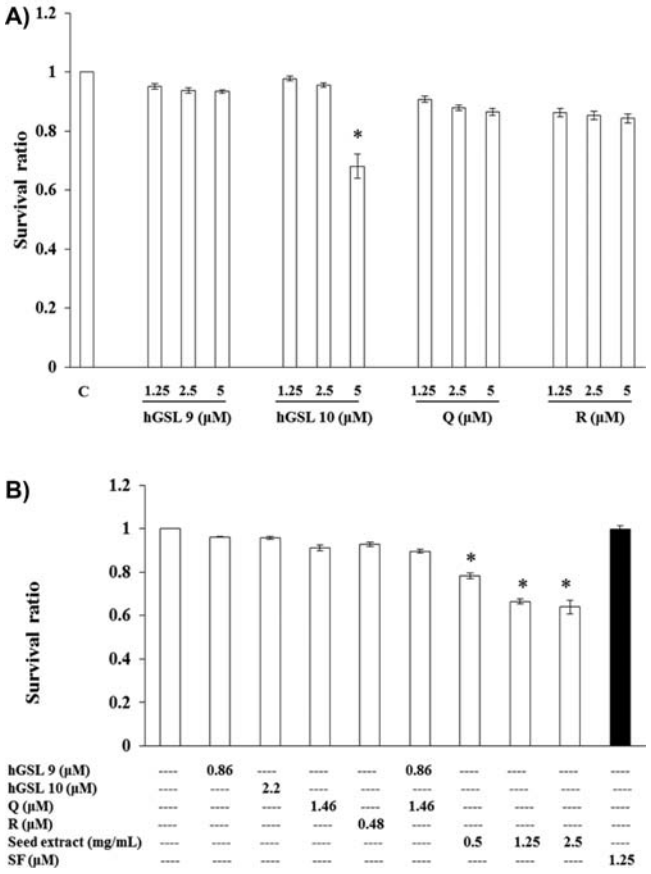

**Figure 1.** Cytotoxicity of camelina seed extract and of individual bioactives from camelina. (A) Individual cytotoxicity dose–response of hydrolyzed GSLs 9 (hGSL 9) and 10 (hGSL 10), quercetin (Q), and rutin (R). (B) Cytotoxicity of the camelina extract and of the components present in 2.5 mg extract/mL. Survival of treated cells was compared to the survival of the untreated control, which was set to 1. Values are mean ± SD; $n = 3$. *Different from control ($p < 0.05$, using Student's $t$ test).

hGSLs nor the flavonoids from the camelina seed extract exhibited cytotoxicity at the concentrations used to determine bioactivity. However, the highest concentration of hGSL 10 (5 $\mu$M) and all the doses of the seed extract showed some cytotoxicity.

**Induction of NQO1.** We found dose-dependent NQO1 induction with hGSL 9, hGSL 10, quercetin, and rutin, four major bioactives of defatted camelina seed meal (Figure 2). Treatment with 1.25, 2.5, and 5 $\mu$M hGSL 9 showed 2.6-, 3.2-, and 3.6-fold induction of NQO1 activity, respectively. Similar inducing activity was seen for hGSL 10, which showed 1.98-, 2.7-, and 3.3-fold induction, respectively. Quercetin also showed a similar range of activity, 1.7-, 2.7-, and 3-fold induction, respectively, as did rutin, with 1.4-, 2.25-, and 2.8-fold induction, respectively (Figure 2). Used as a positive control, SF (1.25 $\mu$M) showed 3.5-fold induction over control (Figure 2). In the study of NQO1 induction by the two GSL at the concentrations present in 2.5 mg/mL camelina seed meal extract (0.86 $\mu$M GSL 9 and 2.2 $\mu$M GSL 10), we found that induction was 1.42-fold and 2.1-fold by hGSLs 9 and 10, respectively. When used in combination at these low concentrations, these two GSLs caused 3.6-fold NQO1 induction, not different from the expected, theoretical value of 3.52 from addition of the individual values (Figure 3). All four major bioactives of camelina seed (GSL 9, GSL 10, quercetin, and rutin) caused NQO1 induction alone and in combination (Figure 4). The combination treatment of bioactives, reflecting that found in 2.5 mg defatted seed extract/mL medium (0.86 $\mu$M GSL 9 and 2.2 $\mu$M GSL 10, together with 1.46 $\mu$M quercetin and 0.48 $\mu$M rutin) caused 4.8-fold induction of NQO1, not significantly different from the 5.1-fold induction caused by the 2.5 mg extract/mL (Figure 4).

Interestingly, combination of only hGSL 9 and quercetin at these concentrations caused a far greater than additive, 4-fold induction of NQO1 (Figure 5). No other combination of camelina seed bioactives showed greater than the expected value from the theoretical addition of data from the individual treatments. Rather, combination of hGSL 10 and quercetin

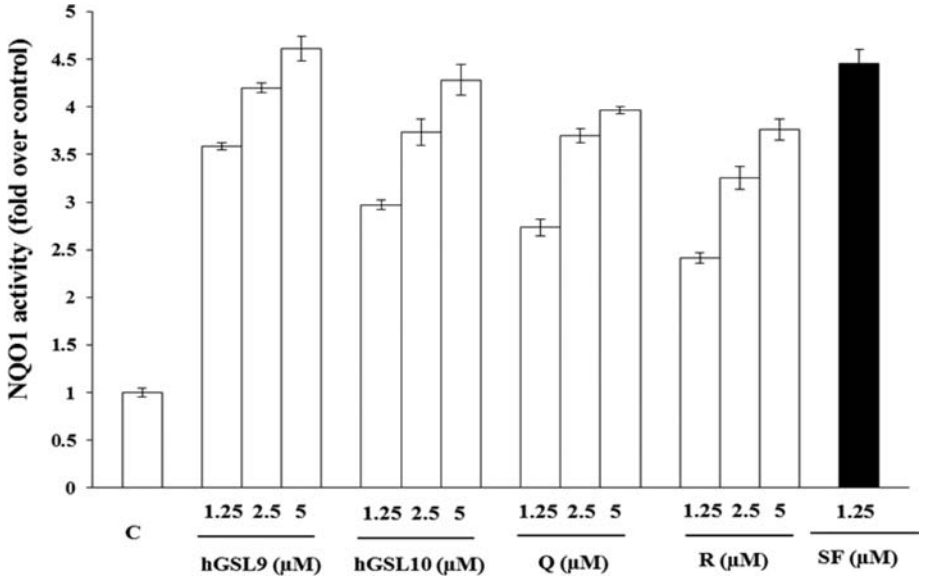

**Figure 2.** Induction of NQO1 activity by hydrolyzed GSLs 9 (hGSL 9) and 10 (hGSL 10), quercetin (Q), and rutin (R). Sulforaphane (SF) was used as a positive control. Myrosinase (20 mU/mL) was added to the medium for GSL hydrolysis. Relative NQO1 activity was calculated in relation to the untreated control, which was set to 1. Values are mean ± SD; $n = 3$ ($p < 0.05$).

dx.doi.org/10.1021/jf501742h | J. Agric. Food Chem. 2014, 62, 8385–8391

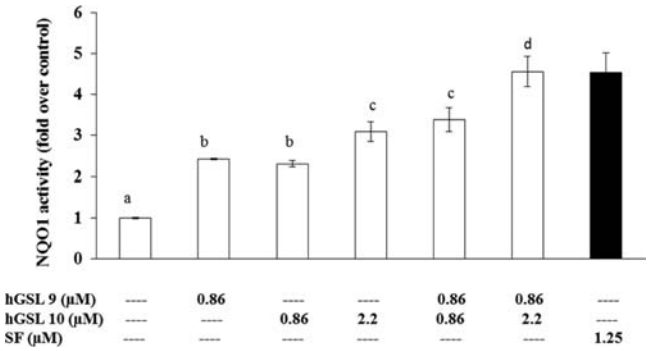

**Figure 3.** NQO1 activity of hydrolyzed GSLs 9 (hGSL 9) and 10 (hGSL 10) alone and in combination. Sulforaphane (SF) was used as a positive control. Relative NQO1 activity was calculated in relation to the untreated control, which was set to 1. Values are mean ± SD; $n$ = 3. Values with different superscripts are different ($p < 0.05$).

caused a small but nonsignificant loss of activity compared to theoretical addition of their individual activities.

**Synergistic Action of hGSL9 and Quercetin and Its Similarity to That of SF and Quercetin from Broccoli.** To evaluate in more detail the interactive activity between GSL 9 and quercetin, we developed an isobologram. First, a five-point concentration range was used to determine the dose needed to double NQO1 activity with GSL 9 or quercetin individually (data not shown). We found that individually, 0.48 μM hGSL 9 and 2.07 μM quercetin were necessary to double NQO1 activity in 24 h. By using different concentrations of hGSL9 ($^1/_{10}$, $^2/_{10}$, and $^3/_{10}$ of 0.48 μM hGSL 9, the concentration needed to double the NQO1 activity), a range of quercetin concentrations was evaluated at each of the GSL 9 doses, to determine the concentration of quercetin needed to enhance the GSL 9 effect sufficiently to double NQO1 activity. Synergy was apparent only at the $^3/_{10}$ and $^2/_{10}$ concentrations of GSL 9, whereas antagonism appeared at the $^1/_{10}$ concentration of hGSL 9 (Figure 6A). Because we had used SF as a positive control and because quercetin is present in broccoli, we evaluated synergy between SF and quercetin (Figure 6B), developing a similar isobologram. We found that 0.38 μM SF was required to double NQO1 activity. Then, we set the concentration combinations as we did for hGSL 9 and quercetin and found synergy with all three combinations evaluated, but again, we found the greatest synergy at lower quercetin concentrations.

**CYP1A1 Activity.** Although we evaluated CYP1A1 inducing activity of all four camelina bioactives under study, none of these compounds caused induction of CYP1A1 alone or in combination (Figure 7A). Further, we determined if any of these compounds were able to inhibit β-naphthoflavone-mediated induction of CYP1A1 activity, since β-naphthoflavone is a potent CYP1A1 inducer. However, we did not find any inhibitory action by camelina bioactives against β-naphthoflavone-mediated induction of CYP1A1 activity (Figure 7B).

## DISCUSSION

To our knowledge, this is the first article to evaluate the impact of camelina seed bioactives on detoxification enzymes, as a measure of bioactivity. We chose to evaluate defatted camelina seed meal as a potential bioactive food, not only because it is a byproduct of camelina fuel oil production but because it contains both GSLs and flavonoids, well-known for their health benefits. The content of GSLs can vary over a range of approximately 10−25 μmol/g defatted seed meal, due to variation in the growing environment, in the genotype, and in processing losses.[23] This is similar to the 20−75 μmol/g freeze-dried brassica vegetables and thus considerably greater than the GSL content of fresh brassica vegetables.[24] The dried methanol extract that we used for these studies contained ∼250 μmol GSL/g extract, about a 10-fold increase in concentration over the defatted seed meal. A dried ethanol extract, appropriate for human consumption, could be expected to be similar. The flavonoids in the extract are mainly quercetin glycosides, almost entirely in the form of rutin (quercetin rutinoside) or more complex glycosides of rutin.[23] Rutin is only partly absorbed whole, and no free quercetin was evident in the extract. However, we used the aglycone quercetin in these studies, since this is the form that is considered the active form within cells.

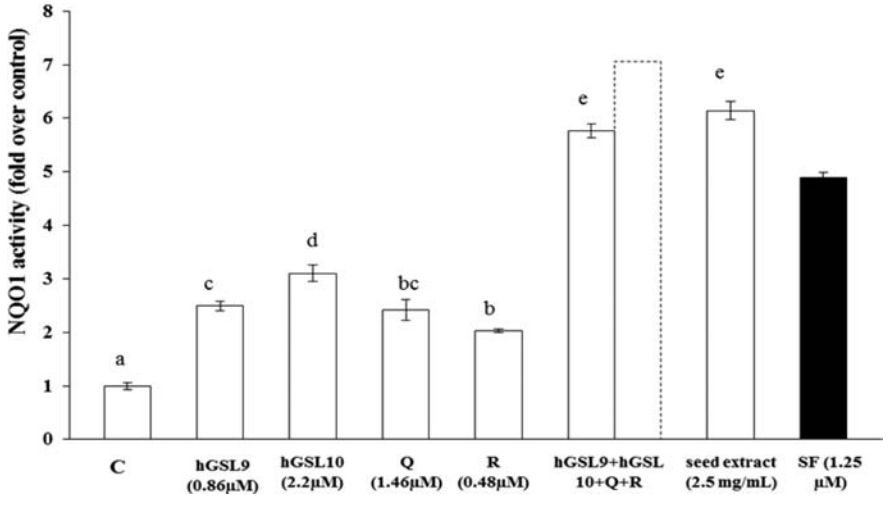

**Figure 4.** NQO1 activity of camelina seed extract and major components. Cells were treated with the four bioactives individually or combined, at the concentrations found in 2.5 mg extract/mL, and compared to the activity of whole extract, 2.5 mg/mL. Hydrolysed GSLs 9 (hGSL 9) and 10 (hGSL 10), quercetin (Q), rutin (R), and sulforaphane (SF). Relative NQO1 activity was calculated in relation to the control, which was set to 1. Values are mean ± SD; $n$ = 3. Values with different superscripts are different ($p < 0.05$). Dashed bars show the theoretical value, calculated by addition of values derived from individual agents.

dx.doi.org/10.1021/jf501742h | J. Agric. Food Chem. 2014, 62, 8385−8391

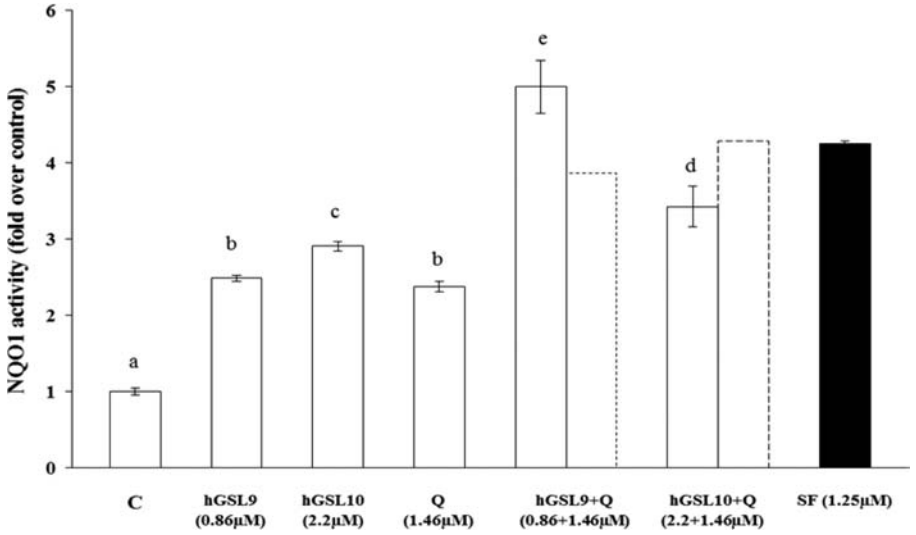

**Figure 5.** Interactive NQO1 activity between glucosinolates and quercetin. Relative NQO1 activity was calculated in relation to the untreated control, which was set to 1. Hydrolysed GSLs 9 (hGSL 9) and 10 (hGSL 10), quercetin (Q), and sulforaphane (SF).Values are mean ± SD of three experiments performed in triplicate. Values with different superscripts are different ($p < 0.05$). Dashed bars show the theoretical value, calculated by addition of values derived from individual agents.

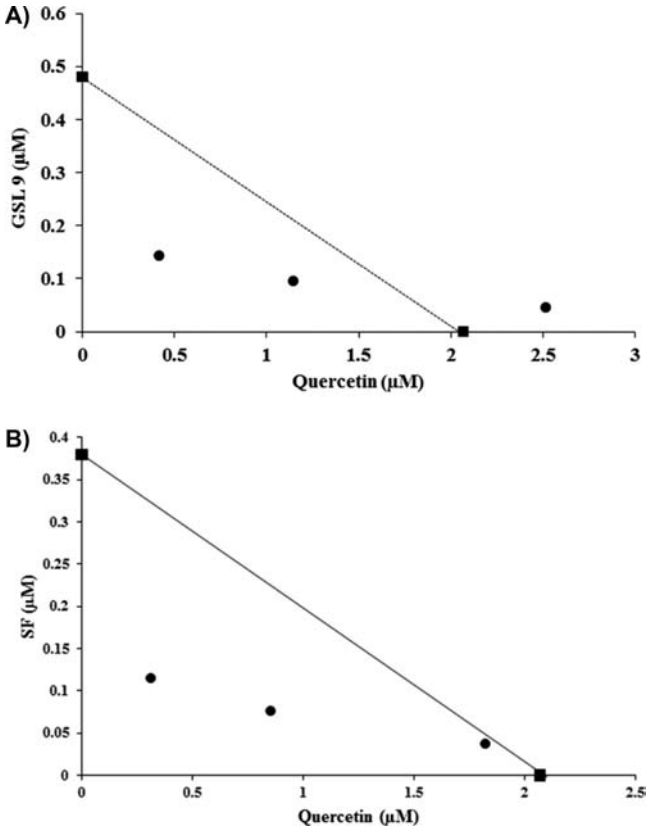

**Figure 6.** Isobolographic representation of interactive NQO1 inducing activity between different concentration combinations of (A) hGSL 9 and quercetin, (B) sulforaphane (SF) and quercetin. The squares are the concentrations of each individual bioactive necessary to double NQO1 activity in 24 h; the line joining them described the theoretical concentrations necessary to double NQO1 activity if activities are additive. The circles show concentrations found to double NQO1 activity when both compounds were present at the concentrations shown. For details on isobologram construction, see the Materials and Methods section.

Most quercetin glycosides are hydrolyzed in the gut, either by lactase phlorizin hydrolase, an enzyme of the brush border, or $\beta$-glucosidases present intracellularly.[25] The free quercetin is then conjugated within the cell, mainly to glucouronide or sulfate conjugates, and thought to be released at the surface of cells by a $\beta$-glucuronidase before it enters the cell in the free form to exert its activity.[26] We therefore chose to evaluate bioactivity of rutin and free quercetin, over a range representing that present in camelina seed meal.

Initially, we evaluated possible cytotoxicity of the four major bioactive components, GSL 9, GSL 10, quercetin, and rutin. At the concentrations tested, only hGSL 10 exhibited any toxicity, causing an approximately 30% loss of cell count at 24 h at the largest dose tested, 5 $\mu$M (Figure 1). The complete extract, at the dose containing this level of hGSL 10 (2.5 mg extract/mL culture medium) caused a similar loss in viability. However, lower doses also caused some losses, suggesting that, whereas hGSL 10 was a major cause of toxicity, it was not solely responsible for this loss of viability.

Following hydrolysis of the two GSLs, all four of the camelina bioactives under study caused a dose-dependent induction of NQO1, in the concentration range 1.25−5 $\mu$M, Figure 2. The two GSLs each induced NQO1 activity in a similar dose range to SF, and this was additive when they were both present, Figure 3.

When cells were treated with a mixture of all four bioactives, the effect on NQO1 induction was similar to that of the whole extract, Figure 4. In an effort to identify the major bioactives responsible for this combinatorial effect, we examined the interaction between hGSL 9 and free quercetin and found that together these gave a significantly greater than additive effect, although this was possibly countered by hGSL 10 and quercetin together causing less induction than expected, Figure 3. Focusing on the effect of hGSL 9 and quercetin, we decided to develop an isobologram, to determine if there was any synergy in the NQO1 inducing activity shown by their combination. The isobologram showed synergy, particularly strongly at the 20% and 30% of maximal GSL 9 doses. Although there are several ways to assess synergy, an advantage

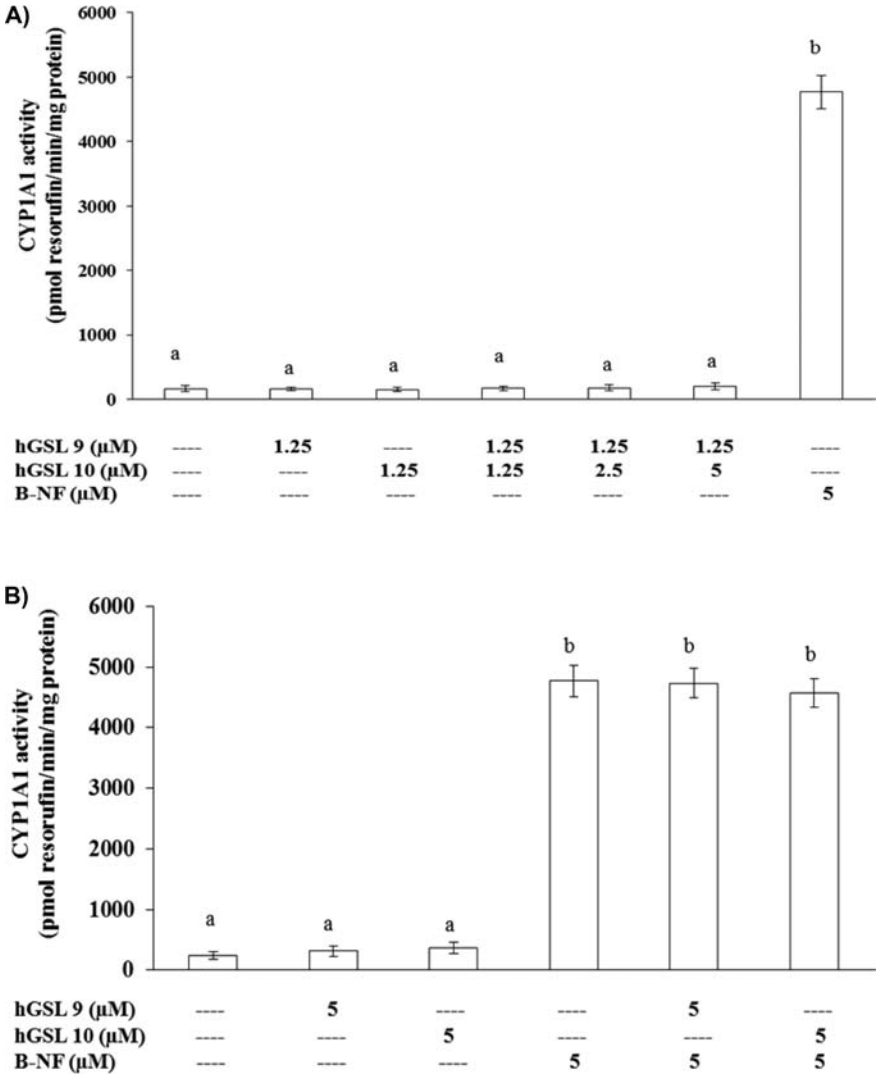

**Figure 7.** Influence of hGSL 9 and hGSL 10 on ethoxyresorufin-*O*-deethylase (CYP1A1) activity. (A) Cells were treated with GSLs or $\beta$-naphthoflavone ($\beta$-NF, 5 $\mu$M) as positive control. (B) Cells were treated with hGSLs and $\beta$-NF, to evaluate the potential of GSLs to inhibit $\beta$-NF-mediated CYP1A1 induction. Values are mean ± SD of three experiments performed in triplicate. Values with different superscripts are different ($p < 0.05$).

in using isobologram construction is that it is independent of the mode of action and thus applies under many conditions. An isobole is an "iso-effect" curve, in which a combination of constituents is represented on a graph, the axes of which are the dose axes of the individual agents.[22] A line is then drawn joining the individual concentrations that cause a chosen, specific effect; here, we chose doubling of NQO1 at 24h. If the two compounds do not cause an interactive effect (synergy or antagonism) when used in combination, then resulting dose combinations required to cause doubling will fall on the line joining the points. If there is a synergy, that is, the effect of the combination is greater than expected from their individual dose−response curves, the doses of the combination needed to produce the same effect will be less than for the sum of the individual components, and the curve will appear concave. The opposite applies for antagonism, in which the dose of the combination is greater than expected, and will produce a convex isobole. We found that, when hGSL 9 was provided at a very low dose (only 10% of that needed to provide doubling), the quercetin required was greater than that required individually to double induction, showing an antagonism or interference. Whereas we did not evaluate the mechanism further, one explanation would be that, when quercetin is at very high doses, it is competitive with hGSL 9.

In all our experiments, we used SF as a positive control for comparison, as it is known to have potent NQO1 inducing ability. We therefore did the same synergy evaluation for SF with quercetin, developing a second isobologram, Figure 6B. Just as we found that quercetin synergizes the upregulation of NQO1 by hGSL 9, we also saw synergy between quercetin and SF. This is particularly interesting, given that broccoli is a good source of quercetin as well as SF. We interpret this to mean that whole broccoli may exert a stronger potency than can be explained based on purified SF of the same concentration. The impact of quercetin on bioefficacy of broccoli is worthy of further study.

Because indolyl, but not aliphatic, GSLs have been reported to upregulate CYP1A1, we had hypothesized that camelina GSLs would not increase CYP1A1 activity. None of the camelina bioactives tested induced CYP1A1 or inhibited $\beta$-naphthoflavone-mediated induction of CYP1A1 activity. Compounds upregulating phase II detoxification enzymes

such as NQO1 but not the phase I CYP1A1 enzyme have been termed monfunctional. Monofunctional inducers are considered to have greater health promoting activity than bifunctional inducers that upregulate both phase I and phase II enzymes. This is based on the finding that some precarcinogens are activated by CYP1A1.[15] In this regard, camelina has even greater potential to be viewed as a food with positive health benefits. In summary, we found the *C. sativa* seed meal contains bioactivity stemming from two alkyl sulfinyl GSLs and quercetin. We also found that the major bioactive from broccoli, SF, exhibits a synergistic upregulation of NQO1 with quercetin, a flavonoid that is naturally present in broccoli.

**ABSTRACT:** Microbial transformations of intrinsic substrates offer immense potential for generating new bioactive compounds in fermented food products. The aim of this work was to characterize the secondary metabolites in soy sauce, one of the oldest fermented condiments. Ethyl acetate extract (EAE) of soy sauce was separated using flash column chromatography, crystallized, and analyzed by nuclear magnetic resonance (NMR), single-crystal X-ray diffraction (SC-XRD), and mass spectroscopy. Dihydrocanadensolide (DHC), an antiulcer agent, was identified in a food for the first time. The natural stereostructure of DHC, which remained controversial for several decades, was determined as (3*S*,3a*S*,6*R*,6a*R*)-6-butyl-3-methyltetrahydrofuro[3,4-*b*]furan-2,4-dione using SC-XRD analysis. Kojic acid (KA) and vanillic acid (VA) were also identified from EAE as bioactive metabolic products of fungi and yeasts. Moreover, a new polymorphic form of KA was determined by SC-XRD.

**KEYWORDS:** *bioactive metabolites, soy sauce, dihydrocanadensolide (DHC), kojic acid, polymorphism, single-crystal X-ray diffraction (SC-XRD), NMR, GC-MS*

## INTRODUCTION

Fermented foods have fascinated humans since antiquity. Over the past few decades, extensive research has been done on the secondary metabolites in fermented foods and their potential health-promoting benefits. In fermented dairy foods, besides the notable B vitamins (over)produced by lactic acid bacteria (LAB), the essential biogenic peptides generated by LAB also drew attention because of their antihypertensive, antimicrobial, and immunomodulatory properties.[1−3] *Monascus* species-fermented "red mold rice" contains bioactive metabolites, such as monacolins, monascin, and monascopyridines; this red mold rice is a popular functional food regarded in East Asia as conferring antioxidant, cancer chemopreventive, hypolipidemic, hypotensive, and hypoglycemic benefits.[4,5] Kojic acid (KA), first isolated from cultures of *Aspergillus oryzae* in steamed rice, is widely used now as an antibrowning food additive and a skin-lightening agent in the cosmetics industry.[6] Discovery of the beneficial activities of secondary metabolites produced by microorganisms has resulted in renewed interest and exploration of fermentation processes.

Soy sauce, one of the world's oldest fermented soy products, is documented for being effective in suppressing inflammation and clearing toxins according to ancient Chinese literature.[7,8] Since the 1990s, there have been increasing studies on the chemopreventive, antioxidant, and antimicrobial activities of soy sauce.[9] Many aroma compounds in soy sauce, such as Furaneol, homofuraneol, norfuraneol, 4-ethylphenol, 4-ethylguaiacol, and 2-phenylethanol, exhibit antioxidant functions. These compounds were identified as byproducts of a salt-tolerant yeast *Zygosaccharomyces rouxii*.[10−13] The newly found phase II enzyme inducers in soy sauce, flazin and perlolyrin, are metabolic products of *Pediococcus halophilus*, and they are candidates for further evaluation as cancer preventive agents.[14,15] Owing to the complexity of the raw materials and the fact that mixed microbes collectively contribute to the whole fermentation process, soy sauce could be a rich reservoir of a diversity of food-derived microbial products that remain to be identified.[16]

In the present study, we report the isolation and identification of bioactive microbial metabolites in traditional fermented soy sauce based on solvent extraction, column chromatography, nuclear magnetic resonance (NMR), gas chromatography−mass spectrometry (GC-MS), and single-crystal X-ray diffraction (SC-XRD) analyses.

## MATERIALS AND METHODS

**Materials.** KA, vanillic acid (VA), formic acid, ethyl acetate, hexane, and acetone were purchased from Sigma-Aldrich Chemical Co. (St. Louis, MO, USA). Silica gel for column chromatography

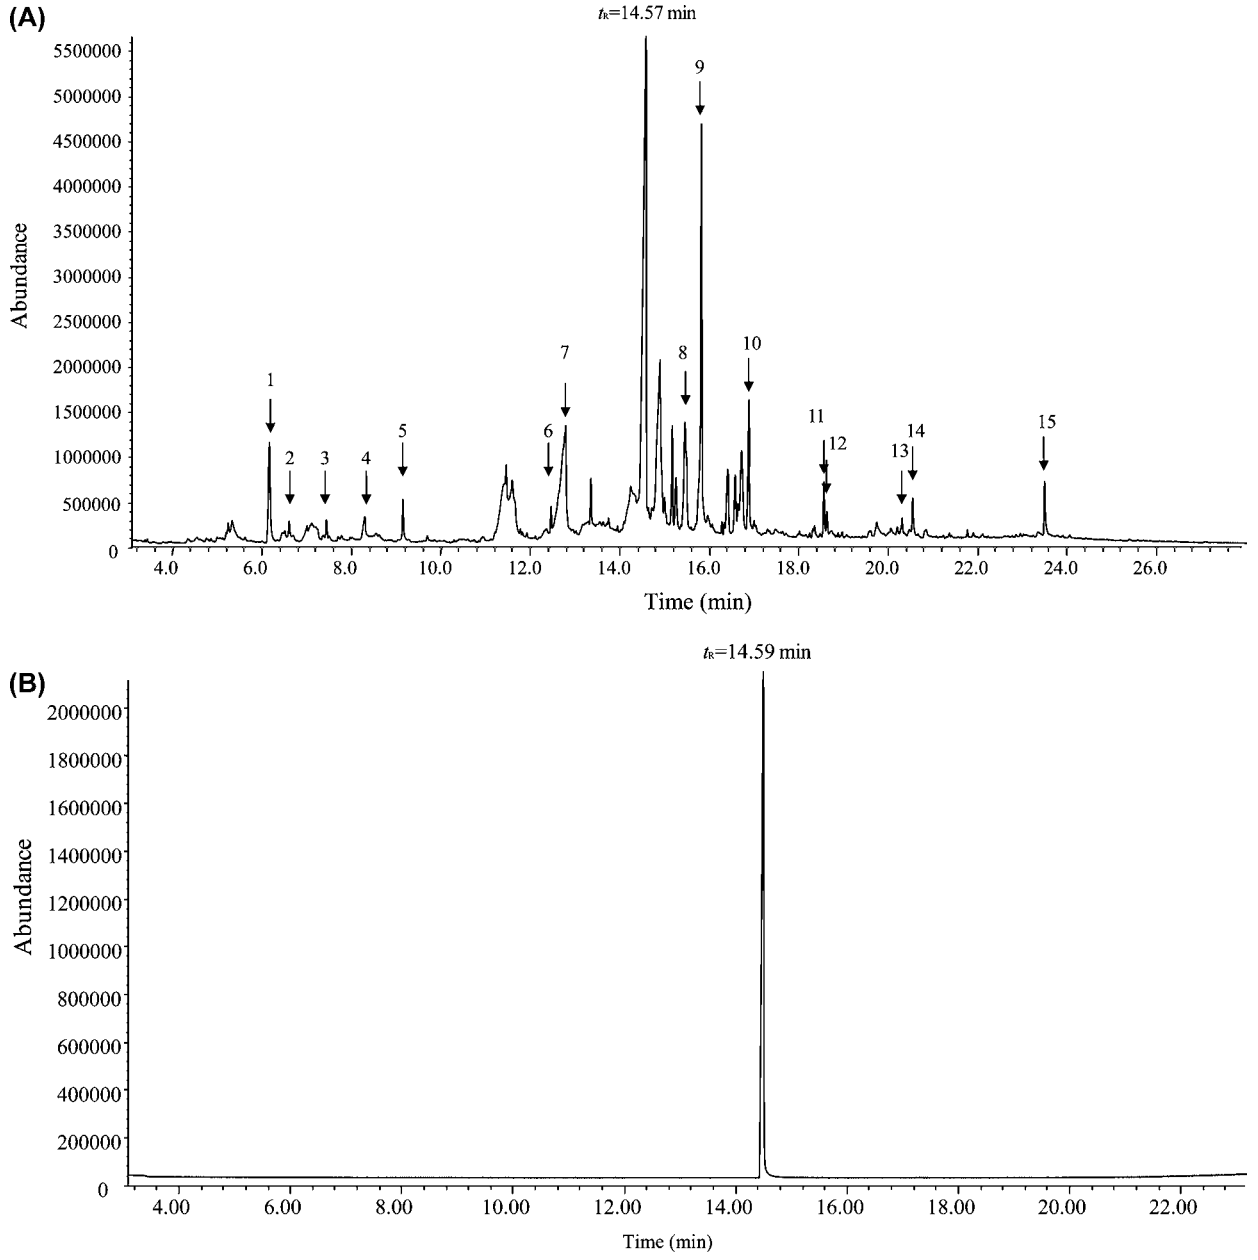

**Figure 1.** GC-MS total ion chromatograms of ethyl acetate extract of raw soy sauce (A) and dihydrocanadensolide (B). Peaks in (A): 1, maltol; 2, pyranone; 3, methylmaltol; 4, benzeneacetic acid; 5, 2-methoxy-4-vinylphenol; 6, 4-hydroxybenzoic acid; 7, vanillic acid; 8, syringic acid; 9, phthalic acid, isobutyl octyl ester; 10, palmitic acid; 11, oleic acid; 12, stearic acid; 13, oleylamide; 14, cyclo(phe-pro); 15, erucylamide.

(230−400 mesh, 60 Å) and thin-layer chromatography (TLC) glass plates (precoated with silica gel 60 $F_{254}$) were purchased from Merck (Darmstadt, Germany).

Soy sauce produced by the traditional high-salt dilute-state fermentation method was obtained from a local manufacturer (Guangdong, China). The fermentation process was conducted as follows: Raw whole soybeans were thoroughly cooked by steam at 125 °C for 15 min and mixed with wheat flour. Spore suspensions (*Aspergillus oryzae*) were inoculated (0.05%, w/w) into the mixtures of soybean and flour, and the medium was kept at 35−40 °C, relative humidity 70−90% for 2−3 days (*koji* process). After turning yellowish-green, the molded materials were mixed with NaCl solution (16−18%, w/v) to make wet mash (*moromi*). Finally, raw soy sauce was obtained by collecting liquid dripping from the wet mash after 3 months of fermentation. Raw soy sauce was batch-pasteurized at 80 °C for 30 min before analysis.

**Flash Column Chromatography.** One and a half liters of pasteurized soy sauce was extracted with ethyl acetate (1:1, v/v) three times by continuous shaking in a separatory funnel for 10 min each. The combined ethyl acetate phases were dried over anhydrous $Na_2SO_4$ and concentrated using a rotary evaporator under vacuum (Buchi rotavapor RII, Buchi Labortechnik AG, Flawil, Switzerland) to yield ∼3 g of solids from the ethyl acetate extract (EAE).

Two grams of EAE solids was redissolved in minimum volume of ethyl acetate and mixed with 10 g of silica gel. Then the mixture was dried in a vacuum desiccator at room temperature (∼25 °C) for 4 h. The extract-laden silica gel was then loaded onto a normal phase silica gel flash column (4.5 cm i.d. × 12.2 cm). The column was eluted successively with a gradient of hexane/acetone (9:1, 8:2, ..., 2:8, 1:9; 500 mL for each step). Portions (120 mL) of eluate collected were subject to solvent evaporation, and a small sample (∼10 μL) of each portion was applied to a 20 cm × 10 cm precoated TLC plate (silica gel 60 A $F_{254}$). Spots were detected by ultraviolet illumination (254

dx.doi.org/10.1021/jf502159m | J. Agric. Food Chem. 2014, 62, 8392−8401

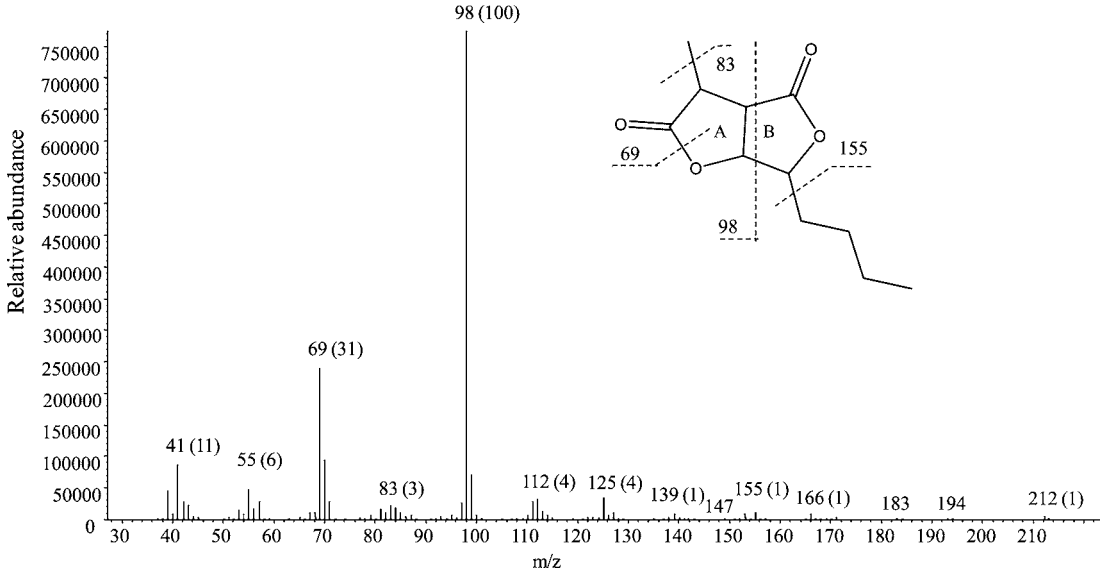

**Figure 2.** Mass spectra (EI/MS) fragmentation and cleavage sites of dihydrocanadensolide.

and 365 nm) and iodine vapors. The consecutive portions of eluate showing single spots with the same $R_f$ on TLC developed by the same developing solvents (mixtures of hexane and ethyl acetate) were combined into fractions and concentrated. Fraction 1 comprised material migrating to an $R_f$ of 0.26 on a TLC plate developed with hexane/ethyl acetate/formic acid (80:20:1, v/v/v). This fraction was concentrated under vacuum to ~2 mL and sealed in vials held at room temperature (~25 °C) to allow slow crystallization. The resulting colorless rectangular prismatic crystals (~40 mg) were washed carefully with methanol and recrystallized with ethyl acetate for further analysis. Fraction 2 was recovered as material migrating to an $R_f$ of 0.52 on TLC plates that were developed by hexane/ethyl acetate/formic acid (60:40:1, v/v/v). Upon evaporation of desorbing solvent, 15 mg of white powder was recovered. Fraction 3 was composed of material migrating to an $R_f$ of 0.37 on TLC plates developed by hexane/ethyl acetate/formic acid = 70:30:1 (v/v/v). The recovered material afforded colorless needle-shaped crystals (~18 mg) after slow solvent evaporation in sealed vials.

**Gas Chromatographic Analyses.** GC-MS analyses of EAE and dihydrocanadensolide (DHC) were performed on a 6890N gas chromatograph (Agilent Technologies, Palo Alto, CA, USA) with a mass spectrometer (MS 5975, Agilent Technologies). Helium was used as a carrier gas with a flow rate of 1 mL/min. Diluted EAE (0.2 $\mu$L) was injected into a splitless injector (270 °C). An HP-5MS (5% phenyl methyl siloxane) capillary GC column (30 m length, 0.25 mm i.d., 0.25 $\mu$m film thickness, Agilent Technologies) was used. The GC oven temperature was held at 80 °C for 3 min, then increased to 280 °C at 10 °C/min, and finally held for 5 min at 280 °C. The mass selective detector was operated in positive electron ionization (EI) mode (70 eV) with a mass scan range from $m/z$ 33 to 450. The database NIST.05 was used to determine compound structures. Quantitative GC analysis was carried out using an Agilent 5890 II instrument with a flame ionization detector (FID). The capillary column and temperature program were the same as those of the GC-MS analysis.

**Nuclear Magnetic Resonance (NMR) Analysis.** $^1$H NMR, $^{13}$C NMR, and gradient correlation spectroscopy (gCOSY) NMR spectra were recorded with a Bruker AVANCE spectrometer (Bruker DRX400, Bruker Biospin Co., Karlsruhe, Germany) using solvent signals as an internal standard. Chemical shifts ($\delta$) and coupling constants ($J$) are expressed in parts per million (ppm) and hertz (Hz), respectively. MestReNova V5.3 was used to visualize and process NMR data (Mestrelab, Escondido, CA, USA). Signal multiplicities were described as follows: s (singlet), d (doublet), dd (doublet of doublets), ddd (doublet of doublets of doublets), dt (doublet of triplets), dq (doublet of quartets), t (triplet), m (multiplet), and b (broad).

**Single-Crystal X-Ray Crystallography (SC-XRD) Analysis.** Well-shaped single crystals of fractions 1 and 3 were selected for the X-ray diffraction experiment. The crystals were mounted on glass fibers and positioned on the goniometer head. SC-XRD data of both fractions were collected on an R-axis Spider diffractometer (Rigaku, Japan) at 293(2) K using monochromatic Mo K$\alpha$ radiation ($\lambda$ = 0.71073 Å) at the Analytical and Testing Center of South China University of Technology. The programs SHELXS-97 and SHELXL-97 were used for structure determination and refinement. All H atoms were placed at calculated positions. Before the last cycle of refinement, all H atoms were fixed and were allowed to ride on their parent atoms.

## RESULTS AND DISCUSSION

**GC-MS Analysis of EAE.** Previous studies of GC-MS analysis of volatile compounds in soy sauce were usually conducted on polar GC capillary columns, such as DB-FFAP/HP-FFAP,[17,18] DB-WAX,[19] and HP-Innowax.[20] In this study, a nonpolar HP-5MS column was adopted, in the hope of searching for a different polarity category of metabolites in soy sauce. A total ion chromatogram of volatile compounds in EAE of soy sauce separated by the HP-5MS column was obtained (Figure 1A). Among the tentatively identified compounds, maltol, VA, and syringic acid were reported to possess antioxidant activities, nitric oxide scavenging effects, and cytoprotective ability in the prevention of diabetic neuropathy complications.[21−24] Other principal peaks included oleic acid, palmitic acid, and stearic acid, which were likely derived from soybean lipids.[25] However, no match was found for the mass spectrum of the major peak (retention time = 14.57 min) in the commercial mass spectra libraries or online mass spectra database. For structure identification, this unknown compound was isolated from EAE by silica gel column chromatography.

**Identification of DHC in Soy Sauce and Its Absolute Configuration.** Eluates of silica gel chromatography were pooled according to their TLC patterns. Fraction 1 formed colorless crystals after slow solvent evaporation. After washing and recrystallizing, the crystal emanated a strong characteristic odor of soy sauce. In GC-MS TIC spectra, the peak retention time and mass spectrum of this compound (Figure 1B) were consistent with those of the major peak in Figure1A. The

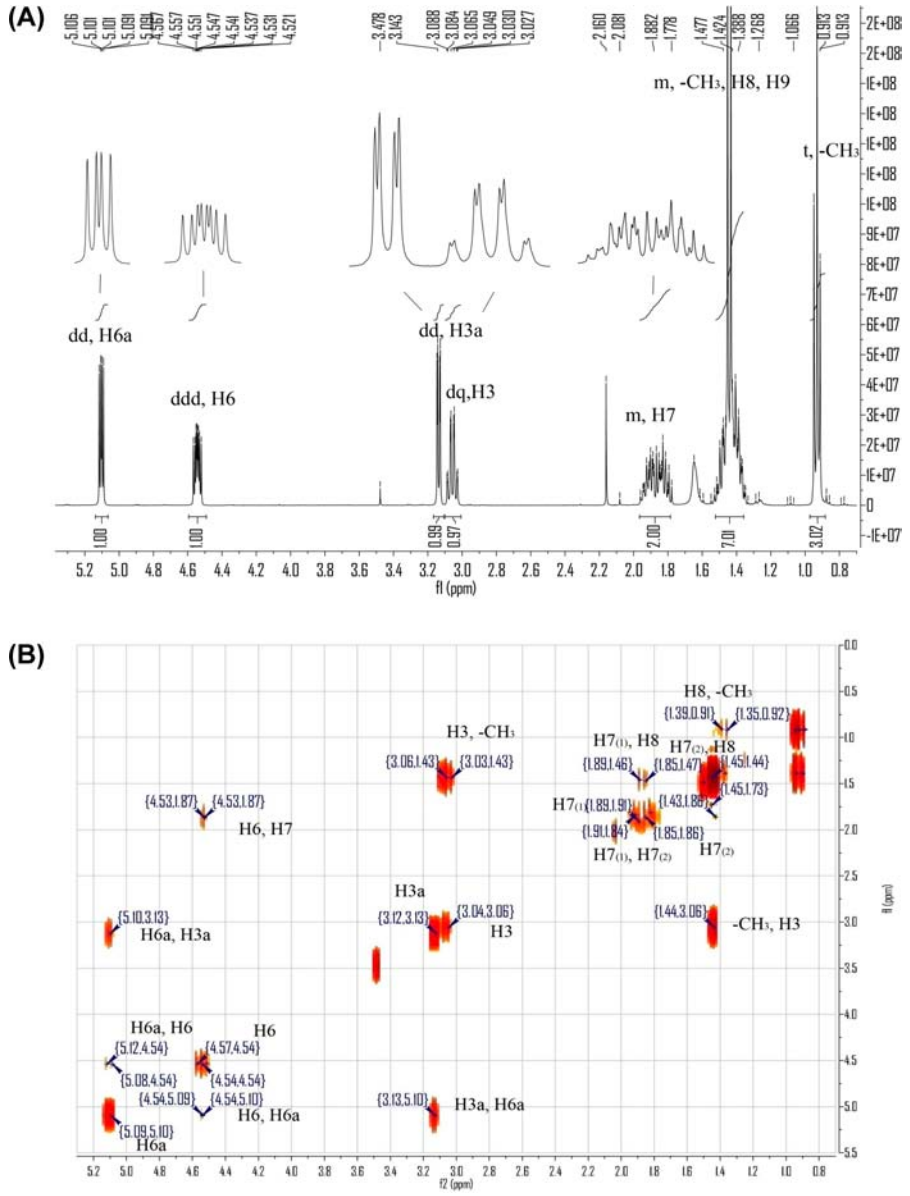

**Figure 3.** (A)$^{1}$H NMR spectrum of DHC in $CDCl_3$; (B) gCOSY spectrum of DHC in $CDCl_3$ For the convenience of interpretation, atomic numbers of C, H, and O were designated as shown in Figure 4.

molecular weight of the compound was $m/z$ 212 according to the EI mass spectrum (EI/MS) (Figure 2).

Confirmation of the structure and assignment of this compound were conducted from detailed analyses of the $^{13}$C NMR spectra, $^{1}$H NMR spectra (Figure 3A), gCOSY (Figure 3B), and EI/MS (Figure 2). First, the chemical shifts observed by $^{13}$C NMR analysis (in $CDCl_3$) were $\delta$ 13.98, 17.31, 22.59, 27.68, 28.72, 38.57, 49.22, 78.49, 82.61, 174.83, and 176.90. The chemical shifts in high field permitted the assignments of two R−COO−R′ groups. From the $^{1}$H NMR spectra, no signal was evident in the range of $\delta$ 6−14 ppm, indicating no carboxylic acid, benzene ring, or double bond present in the molecule. The integration of two peaks at $\delta$ 4.4−5.2 in $^{1}$H NMR were both 1, suggesting two $\alpha$ hydrogen within two −COO−CH− fragments. The $^{13}$C NMR signals at $\delta$ 78.49 and 82.61 imply two carbons are connected to oxygen atoms. Therefore, the two ester groups appeared to be confirmed. Second, the four chiral centers (C3, C3a, C6, and C6a in Figure 4A) in the *cis*-fused dilactonic ester structures could explain the characteristic splitting patterns in the $^{1}$H NMR spectra. The signals of protons on C3a and C6a were dd because they were affected not only by each other ($J$ = 6 Hz) but also by H3 and H6, respectively ($J$ = 1.4 and 4 Hz). For H3, the quartet intensity 1:3:3:1 ($J$ = 8 Hz) suggested that a methyl group was connected to C3, and the pattern of quartet peaks splitting to doublets occurred owing to the influence of H3a at the adjacent stereocenter ($J$ = 1.4 Hz). It is not surprising that H6 showed a similar pattern of ddd ($J$ = 8, 6, 4 Hz), which was also observed by Sharma.[26] Attention should be paid to the interpretation of the ddd effect of H6, evoked by vicinal coupling from H6a, and individual diastereotopic protons H7$_{(1)}$ and H7$_{(2)}$. This could be easily confused with a doublet of triplets, which was the case interpreted by Birch and led to stereostructure III in Table 1.[27] Third, an *n*-butyl residue on C6 could be deduced from the downfield $^{1}$H NMR spectra. The chiral center C6 may cause the restricted rotation of diastereotopic protons on C7, resulting in geminal coupling of these two protons. Similar geminal coupling effects were also recorded by Isaka in the

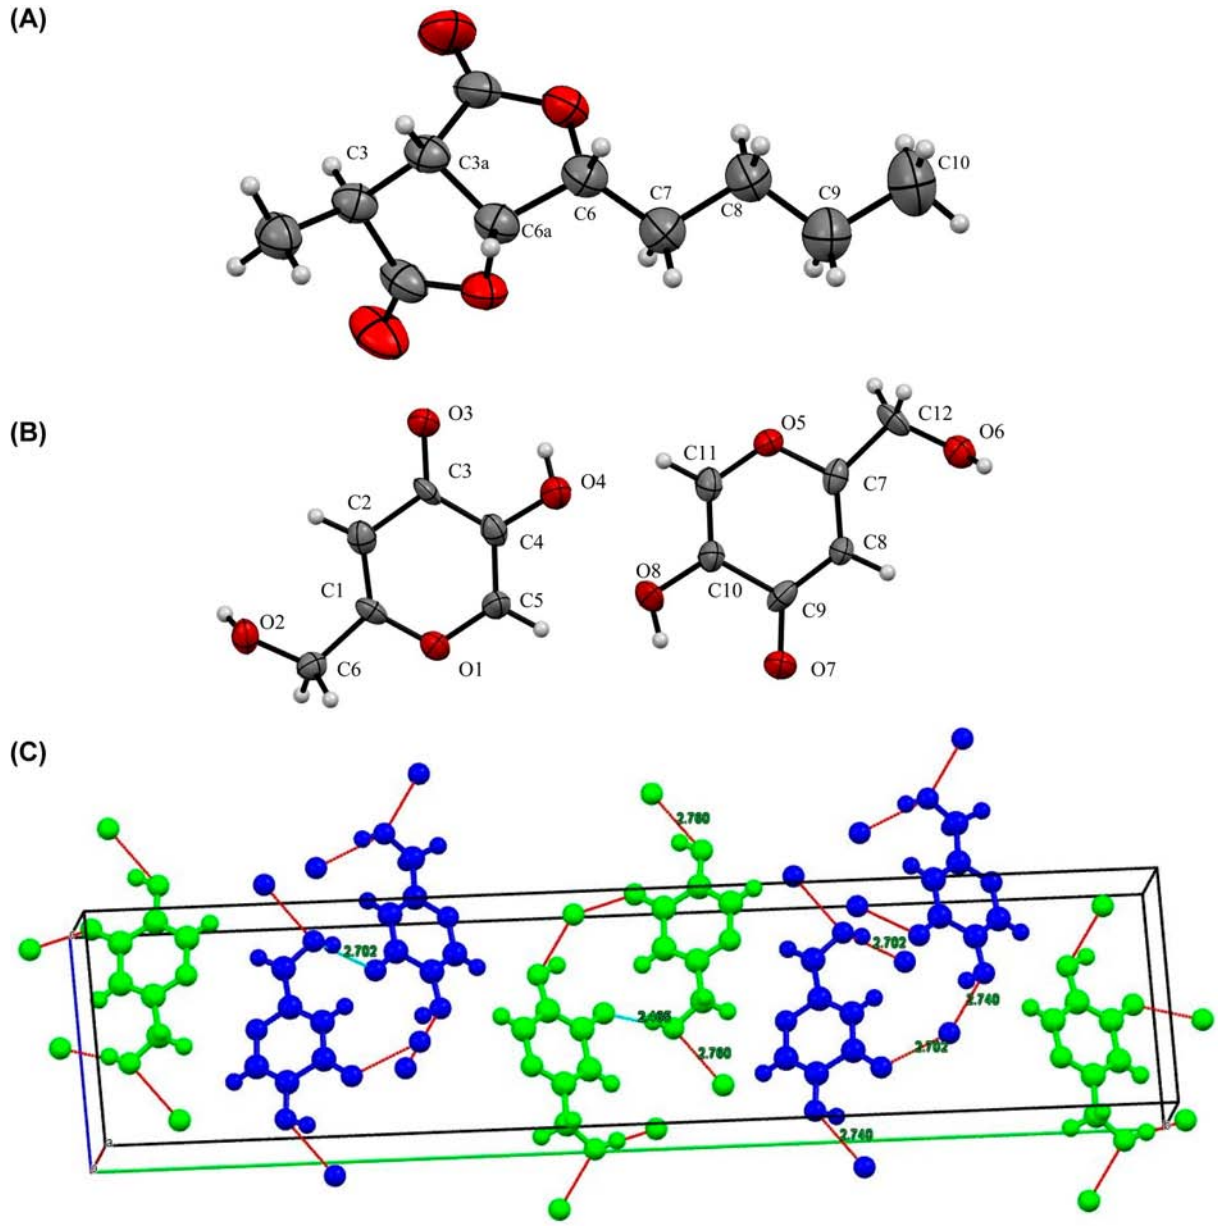

**Figure 4.** (A) Oak Ridge thermal ellipsoid plot (ORTEP) diagram for crystal structures of DHC; (B) ORTEP of KA; (C) packing diagram of KA. Molecules of equivalent symmetry are shown in the same color. Lengths of O−H···O hydrogen bond: 2.465, 2.702, 2.740, and 2.760 Å.

identification of a furofurandione.[28] Also considering the influence from H8, splitting patterns of H7 appeared to be more complex than a triplet of doublets (1.7−2.0 ppm in Figure 3A), consistent with locating the *n*-butyl group on C6 ($-CH_3$). These effects were confirmed by gCOSY spectra, which reflect the interactions between the coupling protons H3a−H6a, H6−H6a, H6−H7, H3−$CH_3$, $H7_{(1)}$−H8, $H7_{(2)}$−H8, and $H7_{(1)}$−$H7_{(2)}$ (Figure 3B). In addition, analysis of EI/MS spectra is consistent with the speculated structure of DHC (Figure 2). The parent peak indicated that *m*/*z* of the molecule was 212. The base peak at *m*/*z* 98 probably results from loss of the *n*-butyl connected B ring. The appearance of the second major molecular ion peak at *m*/*z* 69 can be ascribed to fragmentation by ring opening of ring A. The differences of 13, 15, 16, 18, and 29 among other minor ions were postulated to arise from the loss of the groups −CH, $-CH_3$, −O, $H_2O$ (or CO), and −CH−O, respectively (Figure 2). Although mass fragments of DHC were previously reported by Birch,[27] the detailed EI/MS spectra provided here have the advantage of indicating the relative abundance of fragments.

Because of the complexity brought about by the four chiral centers, there has been debate about the natural configuration of DHC since its discovery (Table 1). When McCorkindale first isolated DHC from synthetic medium of *Penicillum canadense*, the structure was suggested as **III**.[29] In the same year, Birch identified DHC, also as III, from *Aspergillus indicus*.[27] However, in their studies, the absence of NMR data of protons H7 precluded a discussion of the possibility of stereoconfiguration reflected by long-range couplings from H6a, if **III** was the correct assignment of structure. More recently, Yoshikoshi reported the protons on the B ring had been interpreted as *trans*-positioned by McCorkindale, and corrected the structure **III** to **II** by evidence obtained from stereoselective synthesis of (+)-canadensolide from hex-1-

yne.[30,31] However, this correction still mistakenly adopted the structure of a synthetic epimer as the natural configuration. After comparing samples from both McCorkindale and Yoshikoshi, Anderson and Fraser-Reid suggested a dehydro-**I** as the natural structure of canadensolide in 1978.[32] In 1975, Aldridge[32] patented a formula containing fermented DHC as a gastric and duodenal ulcer-healing agent and acknowledged **II** as the structure corrected by Yoshikoshi.[30,31] Over the past two decades, chemical synthesis of DHC in its natural configuration has been gaining increasing attention. Although extensive studies have been done by exploring the synthetic processes for **I**, **II**, and the epimers **III** and **IV**, the natural configuration of DHC has not been conclusively established.[26,30,33−37]

Molecular chirality is essential to activities of biologically/pharmacologically active compounds, as many drug components exhibit significant differences in their pharmacologic activities compared with their enantiomers.[39] Therefore, knowledge of the absolute configuration of chemicals that are potential therapeutic agents is extremely important. By far, the most powerful structural method for determination of the absolute configuration of molecules is single-crystal X-ray crystallography.[40] Because the anomalous dispersion effect of heavy atoms can be measured very accurately, the absolute stereostructure obtained by SC-XRD is clear and unambiguous.[41] The critical issue for SC-XRD is obtaining a single crystal with suitable size.[42] In this study, single crystals weighing up to 15 mg of DHC were obtained for SC-XRD analysis for the first time. Information on crystallographic data collection and structure refinement is summarized in Table 2. The

absolute configuration of DHC isolated from soy sauce was identified as (3*S*,3a*S*,6*R*,6a*R*)-6-butyl-3-methyltetrahydrofuro-[3,4-*b*]furan-2,4-dione (**I** in Table 1). A search of the Cambridge Structural Database and online databases showed no match with crystallographic data reported here for DHC. Detailed chemical bond lengths and bond angles of DHC can be found in the CIF format data deposited with the Cambridge Crystallographic Data Centre (CCDC) under reference no. 982491.

Previous studies on bioactivities of DHC were mostly focused on the antiulcer activities on gastric or duodenal ulcers. Animal experiments revealed that DHC produced by fermentation method showed better healing properties in gastric ulceration induced by betamethasone and fenclozic acid, compared to the commonly used drug carbenoxolone. In addition, DHC significantly reduced duodenal ulceration in rats induced by acetic acid, whereas carbenoxolone did not show this property.[38,43]

The reported fermentation method for producing DHC involved 10 days of agar fermentation and 33 days of submerged fermentation, which was similar to the *koji* (solid) and *moromi* (liquid) fermentation process of soy sauce, respectively.[38] DHC was discovered in the metabolites of *Penicillium canadense* and *Aspergillus indicus*.[29] *Penicillium* and *Aspergillus* species were also found in soy sauce. *A. oryzae* and *A. sojae* are two important starter fungi for soy sauce fermentation.[44,45] In our study, ∼40 mg of DHC crystals was obtained in 2 g of EAE (i.e., ∼40 mg/L soy sauce). Considering the loss during extraction, isolation, and crystallization processes, the concentration of DHC in soy sauce should be

dx.doi.org/10.1021/jf502159m | J. Agric. Food Chem. 2014, 62, 8392−8401

higher than this value. Quantification of DHC in the ether extract of raw soy sauce was performed by GC-FID under the same conditions as GC-MS described under Materials and Methods, using purified DHC (>99% judged by GC-MS) as an external standard. The results showed that the concentration of DHC in raw soy sauce was approximately 83 mg/L.

Although chemically diverse, all secondary metabolites are produced via a few common biosynthetic pathways.[46] Studies with [2-$^{14}$C]acetic acid suggested that DHC might arise from the condensation of two chains, octanoic acid and pyruvic acid (or oxaloacetic acid with subsequent decarboxylation).[27] Oxaloacetic acid is an intermediate in the citric acid cycle, a major metabolic pathway of primary metabolism found in living systems. On the basis of these facts, it is likely that DHC is derived from the citric acid cycle of fungi. Ma et al. reported that a nucleophile-promoted, biscyclization of keto acids could spontaneously happen, suggesting this mechanism might be involved in the biosynthesis of natural bicyclic lactones.[47] Similar biosynthetic routes have been defined for canadensolide, indicating that this compound was mainly formed by condensation of $\alpha$-methylene of a fatty acid and the carbonyl group of oxalacetic acid.[48] 1-$^{14}$C- and 2-$^{13}$C-labeling during the evolution of another bislactone, avenaciolide, gave more evidence for this biosynthetic pathway.[48]

**Identification of VA.** Identification of fraction 2 was conducted by GC-MS and $^1$H NMR. The EI/MS profile of fraction 2 matched that of VA in the NIST 0.05 database. Its retention time ($t_R$ of 12.78 min, Figure 1A) on an HP-5MS column, as well as $^1$H NMR profile [$\delta$ 7.59 (1H, dd, $J$ = 8.0 Hz, 2.0 Hz, H4), 7.56 (1H, d, $J$ = 2.0 Hz, H6), 6.92 (1H, d, $J$ = 8.0 Hz, H3), 3.90 (3H, s, $-OCH_3$), 400 MHz, acetone-$d_4$)] corresponded with that of the authentic compound. VA is a flavoring compound in soy sauce.[49] It might be derived directly from soybeans, which contain VA as a major phenolic acid.[50] Another phenolic compound, ferulic acid in soybeans, can be converted to VA through the metabolism of *Aspergillus niger*,[51] *Debaryomyces hansenii*,[52] and *Pseudomonas putida*.[53] Moreover, *Zygosaccharomyces rouxii*, a salt-tolerant yeast commonly found in soy sauce, is capable of producing VA as a metabolite.[54]

The concentration of VA in soy sauce recovered in this study was ~15 mg/L, which was within the range of 1.9−294 mg/L reported by others.[49,55,56] Considering the dry contents in soy sauce (25−58 g/100 mL),[57] the concentration of VA relative to total solids of soy sauce was comparable to that in the root of the medicinal plant *Angelica sinensis* (or Dang Gui), which contains the highest known amount of VA among all plants (6.1−94.4 mg/kg).[58,59] Hence, soy sauce may be a rich source for VA.

VA has been reported to exhibit potential antiulcer activity in ulcerative colitis.[60] It reduced the severity of the clinical signs of dextran sulfate sodium-induced colitis in mice, including weight loss and shortening of colon length, and the disease activity index. A hepatoprotective effect of VA was also reported.[61] VA significantly decreased the transaminase activity and suppressed the disorganization of the hepatic sinusoids in concanavalin A-treated mice. VA was capable of reducing plasma interleukin-6 in both ulcerative colitis-healing and hepatoprotective effects. Moreover, VA has been associated with antihypertensive and antioxidant activities demonstrated in rats.[62] VA restored systolic and diastolic blood pressure to normal levels, preserved the plasma nitric oxide metabolites concentration, and reduced plasma lipid peroxidation products and cellular defensing enzymes. The potential of inhibiting carcinogenesis[63] and preventing the secondary complications of diabetes[64] by VA have also gained increasing attention.

**Identification of KA.** Fraction 3 was separated by normal phase column chromatography and obtained as colorless needle-like crystals. $^1$H NMR spectra ($\delta$ 4.35 (2H, s, H6), 6.47 (1H, s, H2), 8.16 (1H, s, H5), 5.75 (1H, b, −O(2)H), 9.13 (1H, b, −O(4)H), 400 MHz, DMSO-$d_6$) and data obtained from an authentic compound confirmed this compound as 5-hydroxy-2-hydroxymethyl-4-pyrone (KA).[65] As the physical appearance of KA crystal obtained in this study was different from that described in the literature (0.1 × 0.15 × 0.15 mm, KA obtained from *Aspergillus tamaril* strain),[66] a further analysis oby SC-XRD was carried out to gain more insight into the crystal polymorphs, because SC-XRD was considered to outweigh other methodologies on providing detailed and undisputable crystal packing information.[67] A crystal of KA (1 × 0.8 × 3 mm) was mounted on a glass fiber and positioned on the goniometer head for SC-XRD analysis. Our results showed different unit cell dimensions from reports in the literature,[66] mainly in the observation that $Z$ = 8 molecules instead of 4 molecules (Table 1; Figure 4B,C). Another report showed that a crystal of KA (0.48 × 0.5 × 0.08 mm) obtained from the strain of *Aspergillus oryzae* WP-D-1 had the formula $(C_6H_6O_4)_2$.[68] The crystal packing of KA in our study was more complex than those previously reported. Whereas all KA molecules were connected by hydrogen bonding with three other molecules instead of two, they were aligned along the *b*-axis facing mainly two directions (Figure 4C). More specifically, the planes of KA were tilted ~23.4°, ~26.7°, ~153.3°, and ~156.6° off the *bc* plane and approximately normal to the *ab* plane. The difference in packing motif provides evidence for the polymorphism of KA, and our report added an additional polymorphic variety.

Because of its superior activities of antioxidant and inhibition of tyrosinase, KA has been used as an antibrowning food additive and a skin-lightening agent in the cosmetics industry.[6] Other health beneficial effects such as antimelasma and antineoplastic activities have also been reported.[69,70] Literature on the presence of kojic acid in soy sauce is the subject of debate. Nakadai claimed that KA was not detected in commercial soy sauce.[71] Shinshi studied 84 commercially used koji-mold strains for their capabilities of producing KA. Most of them generate <2 mg/mL KA under fermentation conditions for soy sauce, whereas some strains produced up to 24 mg/mL.[72] Decomposition of KA during soy sauce liquid fermentation was observed to be nearly 100% at the end of 140 days.[73] In our study, ~18 mg of KA was recovered from 2 g of EAE after extraction and isolation, so the concentration of KA was likely to be >18 mg/L in the original sample.

Kojic acid is produced by numerous *Aspergillus* species. Carbon sources for KA fermentation include reducing sugars, sugar acids, and sugar alcohols. The chain length of these compounds could be 2−7 carbons or 12 or 18 carbons. Polysaccharides can also serve as a carbon source for KA.[74] Although the studies on the biosynthesis of KA started six decades ago, the pathway remains speculative.[6] One important theory suggesting that KA can be synthesized from glucose via direct conversion was supported by isotope-traced D-glucose experiments.[75] Typically, oxidation of glucose to 3-ketoglucose by glucose 3-dehydrogenases was suggested as the initial step, followed by dehydration at the 4- and 5-positions of 3-ketoglucose to form KA. For carbon sources with fewer than six carbon atoms, it was difficult to determine the exact route,

because the presence of a $C_6$ precursor has not been definitely identified, and $^{14}C$ positions in the KA product were more extensively redistributed than direct conversion, by evidence obtained with [2-$^{14}$C]-dihydroxyacetone and [1-$^{14}$C]-D-ribose.[6,76]

Fermentation is the major production technology for soy sauce by far. Typically, the fermentation process consists of two stages, namely, *koji* (aerobic growth of the starter fungi on soy- and wheat-based materials for a few days) and *moromi* (anaerobic incubation of molded materials in salt solutions for months).[77] Depending on the temperature and the ratio of solid to brine solution, the producing methods are mainly categorized into high-salt dilute-state (HSDS) and low-salt solid-state (LSSS) fermentation. HSDS fermentation is widely adopted among Asian countries, although there are differences in raw materials (whole soybean, defatted soy flake, roast wheat, flour, and wheat bran), starter fungal species, and fermentation time for *moromi* (3−9 months). On the other hand, LSSS fermentation requires less time for both *koji* (1 day) and *moromi* (3 weeks) processes, a smaller volume of *moromi* brine solution (half that of HSDS), and a higher *moromi* temperature (40−45 °C).[78] It has been known that the amounts and compositions of amino acids and the aroma compounds in soy sauce can be regulated by controlling the fermentation conditions.[78,79] Similarly, it can be inferred that bioactive compounds can also be modulated. Considering the possible biosynthesis routes of KA, this compound may arise from heterocyclic compounds derived from the primary intermediates in the citric acid cycle of fungal metabolism during fermentation. The primary intermediates, particularly oxalacetic acid in the citric acid cycle, can be converted to secondary intermediates, which may be responsible for the formation of DHC in soy sauce. Secondary metabolites are usually not produced during the phase of rapid growth (trophophase); instead, they are synthesized during the subsequent production state (idiophase), especially when microbial growth is limited by the exhaustion of one key nutrient.[80] Therefore, the production of microbial secondary metabolites could be enhanced by (1) allowing sufficient microbial growth and exhaustive utilization of certain culturing ingredients in the *koji* process, followed by (2) proceeding to the *moromi* stage at which the brine solution could further inhibit the rapid growth of the microbes. This was supported by reports that solid fermentation followed by liquid fermentation resulted in a higher yield of KA, compared to adopting liquid fermentation alone.[6,81,82] The relatively short time (1 day) of *koji* and high temperature of *moromi* processes of the LSSS method are designed to achieve highest protease activities, which may compromise the adequate conditions for microbial trophophase growth and idiophase metabolite production, compared to HSDS fermentation. In addition, VA in soy sauce is generated from various sources, including the soy materials and enzymatic modification of ferulic acid by fungi, yeasts, or bacteria. Utilization of soy materials with high VA and/or ferulic acid contents may be beneficial for elevating the levels of VA in soy sauce. Until now, the key fermentation conditions that affect microbial survival status, metabolic pathways, and microbe-culturing material interaction are still largely unknown. Further studies need to be done on the effects of various fermentation factors on the contents of bioactive compounds in soy sauce.

The findings of the present study illustrate the isolation and structural determination of three bioactive microbial secondary metabolites, namely, DHC, VA, and KA. To our knowledge, this study is the first to offer SC-XRD data of DHC and identify DHC in a food. This is an advance over earlier attempts to resolve the long-lasting debate on natural configuration of DHC. In addition, polymorphism of KA was discovered by SC-XRD analysis. The polymorphic variety observed in this study had the crystal packing of eight molecules in a unit cell, and each molecule was connected with three other molecules via hydrogen bonding. These data, as well as the detailed information on EI fragmentation in EI/MS spectra of DHC, can extend our knowledge of the structural identification of similar microbial metabolites in a wide range of fungus-fermented foods. On the basis of the results from this study, future works can be done on the quantification of these bioactive compounds in various fermented foods, improvement of fermentation processes to enrich these metabolites, and development of new food products bearing potential ulcer protection activities.

# Comparison of Food Antioxidants and Iron Chelators in Two Cellular Free Radical Assays: Strong Protection by Luteolin

Tim Hofer,*[,†] Trond Ø. Jørgensen,[‡] and Ragnar L. Olsen[#]

[†]Department of Chemicals and Radiation, Division of Environmental Medicine, The Norwegian Institute of Public Health, N-0403 Oslo, Norway

[‡]MabCent-SFI and [#]Norwegian College of Fishery Science, University of Tromsø, N-9037 Tromsø, Norway

**ABSTRACT:** Liver (HepG2) cells were incubated with 21 edible flavonoids, carotenoids, polyunsaturated fatty acid (PUFA) chromones, and metal chelators for 1 h, washed in PBS, and challenged in the cellular antioxidant activity (CAA) and the cellular lipid peroxidation antioxidant activity (CLPAA) assays. These microplate format assays assess the compounds' ability to protect against cytosolic peroxyl radicals (CAA) and induced membrane lipid peroxidation (CLPAA), respectively. Incubation encompassing a broad compound concentration range determined half-maximal inhibitory concentrations ($IC_{50}$) by using sigmoidal curve fits. Overall, considering both assays, luteolin offered the greatest protection. The carotenoid astaxanthin offered only modest protection, whereas $\beta$-carotene was ineffective. Subtle structural differences between flavonoids were found to have amplified effects on protective abilities, and mechanisms of flavonoid antioxidant action are discussed. Membrane-permeable iron chelators (deferasirox and SIH) offered strong protective effects in CLPAA, but not in CAA, suggesting that CLPAA is dependent on membrane-associated free iron ions.

**KEYWORDS:** *catechin, curcumin, hydroxytyrosol, resveratrol, acetylsalicylic acid (ASA)*

## INTRODUCTION

Several human diseases and conditions involve free radicals and/or metal dyshomeostasis.[1−3] Iron levels rise in multiple tissues during disease states and aging,[1,4] increasing the likelihood of oxidative damages from reactive oxygen species (ROS; $O_2^{\bullet-}$, $H_2O_2$, ROOH, HOCl, etc.) during events such as inflammation and ischemia. ROS can induce lipid peroxidation,[5,6] a process generating other toxic reactive species, for example, aldehydes. Antioxidant mechanisms are commonly related to free radical scavenging and metal chelating. Low-molecular-weight antioxidants and metal chelators have received increased interest both as protectors from disease onset and as therapeutics.[7,8] A regular intake of fruits and vegetables containing antioxidants can counteract undesired health conditions, but it is not clear which dietary compounds are the most beneficial in terms of antioxidant effects. These effects are best evaluated in living cells and organisms. Antioxidants need to be constantly replenished because they are eventually oxidized (some are recycled, e.g., vitamin E and certain flavonoids)[9] or are metabolized and excreted.[10,11] Intake of flavonoid-rich foods (dark chocolate, red wine, green tea, etc.) have shown promising effects in humans, and flavonoids can scavenge radicals, chelate catalytic metal ions, and pass cellular membranes.[6,12,13] Clinically administered iron chelators treat iron overload conditions, but will cause iron deprivation and other toxicities in normal subjects.

Numerous papers describe the effects of antioxidants in chemical assays, but few demonstrate effects in living cells, which requires cell membrane passage and compound stability. Compound testing in cell cultures can provide valuable insights into which compounds are likely to have an impact in higher organisms. We recently established the cellular lipid peroxidation antioxidant activity (CLPAA) assay in the microplate format.[14,15] Another commonly used free radical assay is the cellular antioxidant activity (CAA) assay.[16−18] Both assays are described below. Loosely chelated iron from the labile iron pool (LIP) can redox cycle ($Fe^{3+} \leftrightarrow Fe^{2+}$) and mediate biomolecular oxidation reactions by ROS (Fenton chemistry) as well as accelerate lipid peroxidation reactions; however, the role of iron in the CLPAA and CAA assays has been less clear. The objective of this study was to test different classes of edible (low toxicity) hydrophilic and lipophilic antioxidants and investigate the role of LIP in the CAA and CLPAA assays using metabolically active human hepatocarcinoma cells (HepG2). The compounds studied are all much in focus as antioxidants and often studied using chemical antioxidant assays.

## MATERIALS AND METHODS

**Chemicals.** All chemicals used were of the highest quality, and purity is indicated when relevant. The compounds tested for bioactivities are shown in Figure 1. Acetylsalicylic acid (ASA; Sigma A7356; 99.8%), apigenin (Fluka 10798; 95.4%), L-ascorbic acid (Sigma A5960; 99.3%), astaxanthin (Sigma A9335; synthetic; 95.6%), $\beta$-carotene (Fluka 22040; 98.0%), cumene hydroperoxide (cumOOH; Aldrich 513296, 88% (*cautionary note: handle concentrated cumOOH inside a hood as vapors are toxic*)), deferoxamine mesylate (DFOM; Sigma D9533; 95.0%), 2′,7′-dichlorofluorescin diacetate (DCFH-DA; Fluka 35847), resveratrol (Sigma R5010; 99.0%), and quercetin (Sigma Q0125; >99.9%) were purchased from Sigma-Aldrich Corp., St. Louis, MO, USA. 2,2′-Azobis(2-amidinopropane (abbreviated ABAP or AAPH; 82235), (+)-catechin (70940; >99.9%), epigallocatechin gallate (EGCG, 70935; >99.9%), 3,4-dihydroxyphenylethanol (hydroxytyrosol; 70604; 98.0%), and luteolin (10004161; 99.0%) were purchased from Cayman Europe,

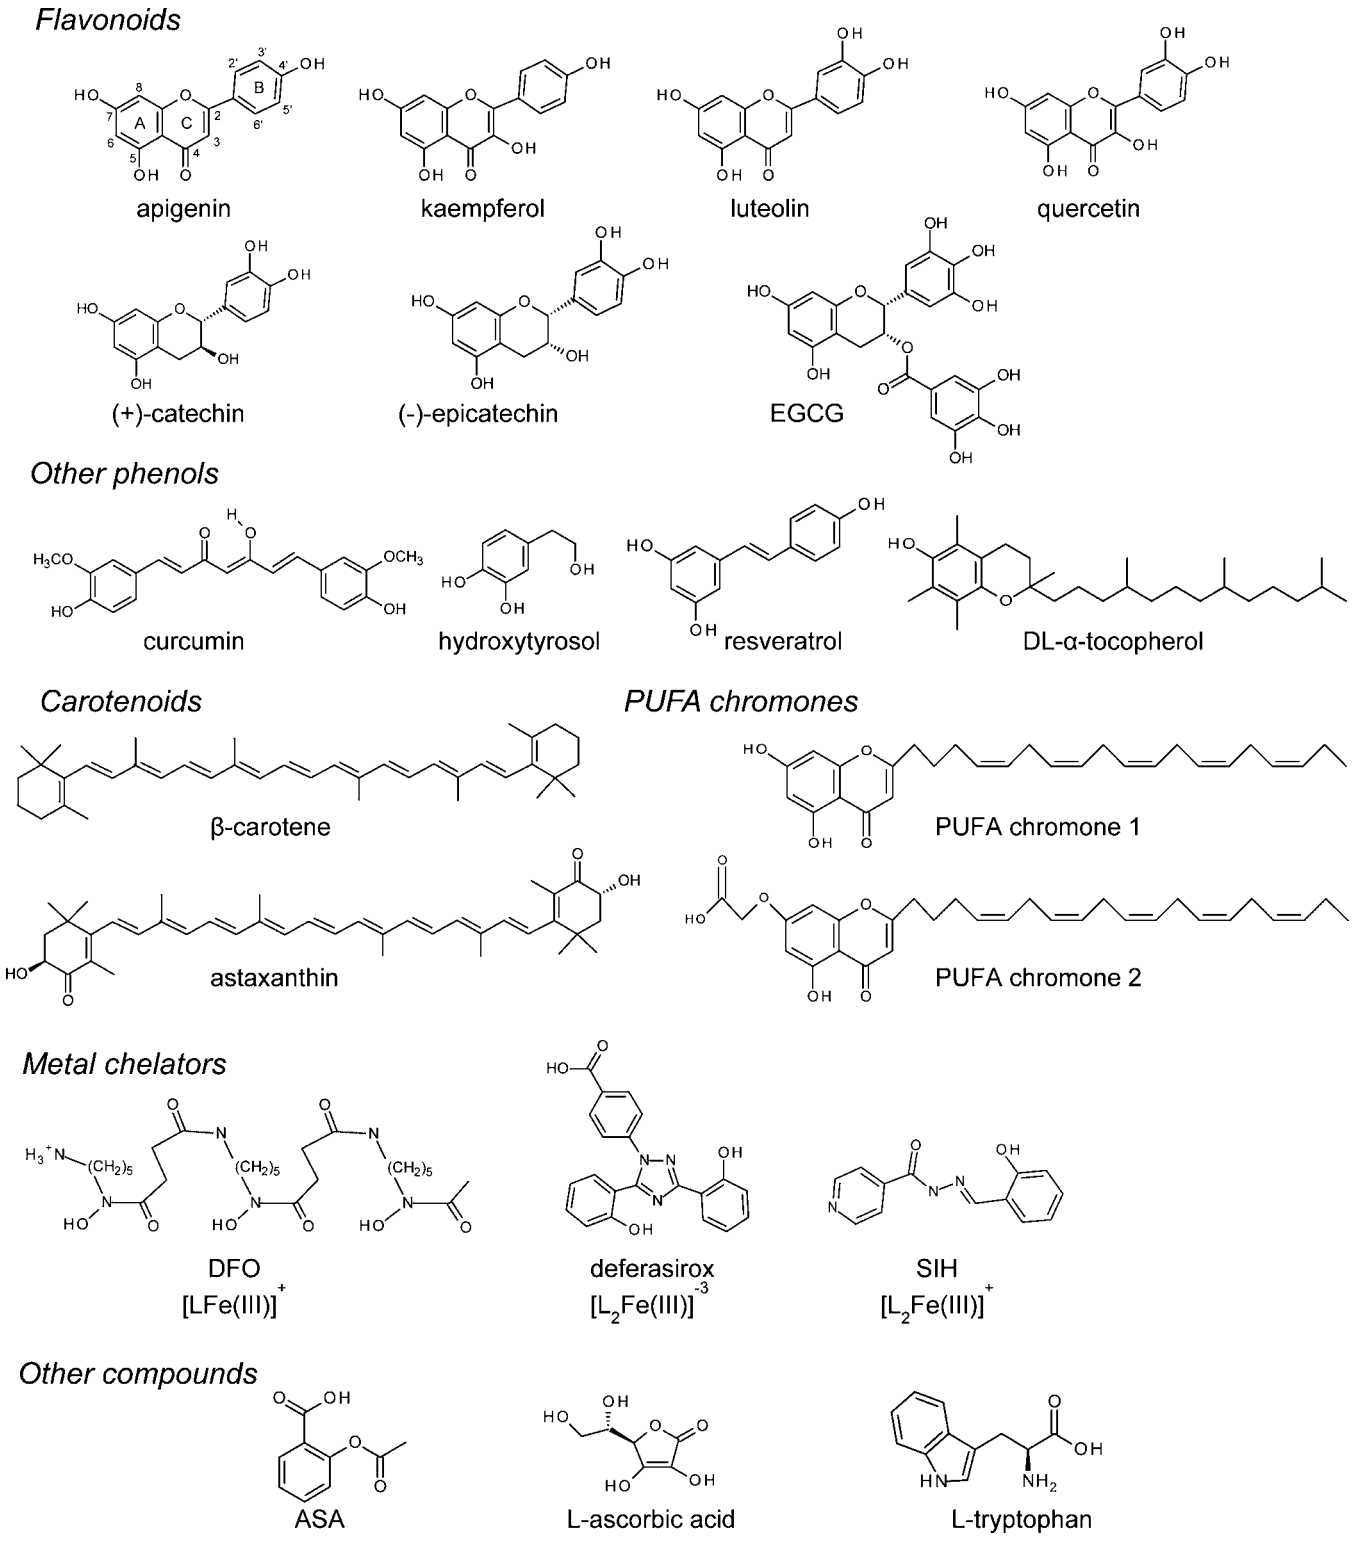

**Figure 1.** Categories and chemical structures of compounds tested. Numbering of the basic flavonoid structure is illustrated for apigenin. Apigenin and luteolin are flavones; kaempferol and quercetin are flavon-3-ols; and (+)-catechin, (−)-epicatechin, and EGCG are flavan-3-ols. Resveratrol is a stilbenoid, and DL-$\alpha$-tocopherol is a lipophilic methylated phenol (a member of the vitamin E family). For metal chelators the number of ligands in the resulting major Fe(III) complex and the net charge at pH 7.4 are indicated. DFOM dissolves as DFO (charge +1) at pH 7.4 and forms a ferrioxamine−$Fe^{3+}$ hexadentate ligand 1:1 complex with net charge +1. Deferasirox chelates $Fe^{3+}$ as a tridentate ligand 2:1 complex with net charge −3.[44] Also, SIH chelates $Fe^{3+}$ as a tridentate ligand 2:1 complex but with net charge +1.[43] Acetylsalicylic acid (ASA), the active ingredient in aspirin, is a small synthetic prodrug of salicylic acid, a phenol. L-Ascorbic acid (vitamin C) is a hydrophilic acidic sugar present as the ascorbate anion ($AscH^-$) at pH 7.4. L-Tryptophan is an amino acid containing an indole group.

Tallinn, Estonia. (−)-Epicatechin (A3894; >99.9%) and kaempferol (A3288; 98.9%) were from AppliChem GmbH, and L-tryptophan (108374; 99.5%) was from Merck Chemicals, both located in Darmstadt, Germany. DL-$\alpha$-Tocopherol (A17039; synthetic; 98.8%)

dx.doi.org/10.1021/jf5022779 | J. Agric. Food Chem. 2014, 62, 8402−8410

was from Alfa Aesar, Ward Hill, MA, USA. Curcumin was from Alexis Biochemicals (350-028; 99.0%) purchased through Enzo Life Sciences Inc., Farmingdale, NY, USA. 4,4-Difluoro-5-(4-phenyl-1,3-butadienyl)-4-bora-3a,4a-diaza-*s*-indacene-3-undecanoic acid ($C_{11}$-BODIPY, D3861) was from Invitrogen, Eugene, OR, USA. Deferasirox (ICL670; 99.9%) was kindly provided by Novartis Pharma AG, Basel, Switzerland, and salicylaldehyde isonicotinoyl hydrazone (SIH; 99.0%) by Dr. Katherine J. Franz, Duke University, Durham, NC, USA. PUFA chromone 1 (*all*-(*Z*)-5,7-dihydroxy-2-(4*Z*,7*Z*,10*Z*,13*Z*,16*Z*-nonadecapentaenyl) and PUFA chromone 2 (2-((5-hydroxy-2-((4*Z*,7*Z*,10*Z*,13*Z*,16*Z*)-nonadeca-4,7,10,13,16-pentaen-1-yl)-4-oxo-4*H*-chromen-7-yl)oxy)acetic acid) were synthesized as described[19] and donated by Dr. Trond V. Hansen, Oslo University, Norway. PUFA chromone 2 has a carboxylic acid group ether-linked to the chromone moiety, making it more hydrophilic than PUFA chromone 1 (see Figure 1). Screening a small synthetic library of natural compounds identified PUFA chromone 1 and PUFA chromone 2 as powerful antioxidants, particularly in CLPAA, but also in CAA.[19]

Compounds to be tested were weighed out in rubber-sealed cryo vials and dissolved in appropriate media using a vortex or, when necessary, an ultrasonicator combined with heating (60 °C) for the shortest possible time (minutes). Ascorbic acid, EGCG, (−)-epicatechin, DFOM, and L-tryptophan were dissolved in aqueous cell culture media (without fetal bovine serum, FBS). Quercetin was dissolved in 1 M NaOH. Catechin, hydroxytyrosol, kaempferol, luteolin, and resveratrol were dissolved in ethanol. Apigenin, astaxanthin, $\beta$-carotene, the chromones, curcumin, deferasirox, and SIH were dissolved in DMSO. Three stocks were prepared for each compound, which thereafter were stored at −80 °C. On assay days, two stocks containing different compounds were thawed and serially diluted 1:1 using cell culture media. Tested previously using HepG2 cells, short-term (1−2 h) incubations with up to 2% v/v dimethyl sulfoxide (DMSO) or ethanol did not significantly alter reaction rates or induce cell necrosis in any of the assays.[15] For compounds dissolved in ethanol, cells were maximally exposed to 2% v/v ethanol at the highest compound concentration investigated, and the ethanol concentration was negligible at lower compound concentrations. Lipophilic compounds dissolved in DMSO, however, were diluted in culture media maintaining a minimum 5% v/v DMSO so as not to stick to plastics and were eventually diluted 1:5 (20 + 80 $\mu$L) into each well, giving a final DMSO concentration of 1% v/v DMSO on cells also in control wells. DL-$\alpha$-Tocopherol, a highly sticky viscous liquid, was diluted in 100% DMSO but also incubated on cells at 1% v/v DMSO (final dilution 1 + 99 $\mu$L) along with controls. Aliquots of DCFH-DA (20 mM in ethanol), ABAP (200 mM in water), and $C_{11}$-BODIPY (6 mM in DMSO) were kept at −80 °C and thawed immediately prior to use.

**Cell Culture.** Human hepatocellular carcinoma (HepG2) cells were purchased from the American Type Culture Collection (Manassas, VA, USA) and routinely cultivated as monolayers in minimum essential medium Earle's (MEM Earle's; F0325 from Biochrom AG, Berlin, Germany) supplemented with gentamycin (10 $\mu$g/mL), L-alanyl-L-glutamine (2 mM), nonessential amino acids (1%), sodium pyruvate (1 mM), and 10% FBS in 175 $cm^2$ flasks in a humidified 5% $CO_2$ atmosphere at 37 °C. After washing cells with phosphate-buffered saline (PBS, $Mg^{2+}$- and $Ca^{2+}$-free), cells were detached using trypsinization and resuspended in cell culture medium. The cell concentration was determined by using Bürker chamber counting, and 80000 cells (in 100 $\mu$L) were seeded into wells (0.32 $cm^2$ cell growth surface area) of black microplates with transparent bottoms (product 3603) obtained from Corning Inc. Life Sciences, Tewksbury, MA, USA. Cells were allowed to settle at room temperature to minimize plate edge effects[20] before incubation at 37 °C. After 24 h, experiments were conducted when microplate wells had ∼50% monolayer cell confluence. Positive and negative controls were included on each microplate. $IC_{50}$ values are influenced by the cell density and other experimental conditions; hence, maintaining constant conditions is necessary for reproducible results. Background levels of antioxidants (vitamin E, selenium) in cultured cells are commonly low and dependent on culture media additives.

**CLPAA Assay.** To measure effects of antioxidants on cellular lipid membrane peroxidation, we recently established the cellular lipid peroxidation antioxidant activity (CLPAA) assay in microplate format,[14,15] where after cellular uptake of the lipophilic oxidation sensitive probe $C_{11}$-BODIPY (fluorescent red) and subsequent antioxidant uptake, lipid peroxidation is induced by adding cumene hydroperoxide (cumOOH; lipophilic), capable of generating oxidizing (and initiating lipid membrane peroxidation) hydroxyl radicals ($HO^{\bullet}$) in the presence of redox-cycling metals such as ferrous iron ($Fe^{2+}$).

$$\text{cumOOH} + Fe^{2+} \rightarrow \text{cumO}^{-} + HO^{\bullet} + Fe^{3+} \quad (1)$$

$$R - H + HO^{\bullet} \rightarrow R^{\bullet} + H_2O \quad (2)$$

$$R^{\bullet} + O_2 \rightarrow ROO^{\bullet} \quad (3)$$

$$ROO^{\bullet} + RH \rightarrow ROOH + R^{\bullet} \text{ and so on} \quad (4)$$

Free radical attack of $C_{11}$-BODIPY generates two similar fluorescent green products (both having lost a phenyl moiety), correlative to the degree of lipid peroxidation that has taken place.[21,22]

$$C_{11}\text{-BODIPY(red)} \ (+\text{oxidation}) \rightarrow C_{11}\text{-BODIPY oxidation products (green)} \quad (5)$$

Usage of the $C_{11}$-BODIPY probe provides an indirect measure of lipid peroxidation. The process generates reactive secondary oxidation products such as malondialdehyde (MDA) and 4-hydroxynonenal (4-HNE) that are more challenging to measure. HepG2 cells grown in serum-supplemented media sustain a non-ferritin-bound redox-active labile iron pool (LIP) (in isolated primary hepatocytes it is about 5−10 $\mu$M),[23,24] so the addition of extra $Fe^{3+}$ was found not to be necessary.[14]

After cells had been washed in PBS, 100 $\mu$L of cell culture medium (without FBS) containing 5 $\mu$M $C_{11}$-BODIPY was added (at 5 $\mu$M, $C_{11}$-BODIPY is not toxic to cells)[25] to the microplate and placed inside a 37 °C water-saturated 5% $CO_2$ chamber for 30 min. After medium withdrawal, 100 $\mu$L of cell culture medium (without FBS) containing diluted antioxidant was added before the microplate was placed back into the 5% $CO_2$ incubator at 37 °C. After 60 min, the cells were washed in PBS and 100 $\mu$L of clear Hanks' salt solution supplemented with 50 $\mu$M cumOOH was added. The microplate was immediately placed inside a Wallac VICTOR3 1420 multilabel counter (PerkinElmer, Waltham, MA, USA) preheated at 37 °C and set on bottom reading mode. The green (485/14 and 520/10 nm filters; CW-lamp setting: 20000)[14] fluorescence was monitored over 60 min. The rate (slope) of fluorescently green $C_{11}$-BODIPY oxidation product increase (obtained from linear regressions of slopes over 0−40 min using the inbuilt plate reader software Workout 2.0 from Dazdaq Solutions Ltd.) is related to the rate of cellular membrane lipid peroxidation.[14] As diluted peroxides are unstable, a 0.1 M cumOOH stock was prepared immediately prior to use on a daily basis.

**CAA Assay.** The CAA assay was used as described[16] with minor modifications.[15] CAA is based on simultaneous cellular uptake of antioxidants and the ROS-sensitive nonfluorescent probe 2′,7′-dichlorofluorescin diacetate (DCFH-DA), which is hydrolyzed into cytosolically trapped DCFH that upon oxidation by peroxyl radicals forms 2′,7′-dichlorofluorescein (DCF; fluorescent green), which is monitored.[15,16] The formation of peroxyl radicals from thermal decomposition of the azo compound ABAP is illustrated by the equations below:

$$-R—N{=}N—R-(+\text{heat}) \rightarrow 2\,-R^{\bullet} + N_2 \quad (6)$$

$$-R^{\bullet} + O_2 \rightarrow -ROO^{\bullet} \quad (7)$$

After cells had been washed in PBS, 100 $\mu$L of cell culture medium (without FBS) containing diluted antioxidants and DCFH-DA (25 $\mu$M) was added and the microplate placed inside a 37 °C water-saturated 5% $CO_2$ chamber. After 60 min of preincubation, the cells were washed in PBS, and 100 $\mu$L of clear Hanks' salt solution supplemented with glucose (L2035 from Biochrom) containing ABAP (600 $\mu$M) was added before starting ($t$ = 0 min) to monitor green fluorescence (485/14 nm excitation and 520/10 nm emission filters; CW lamp setting: 15000 stabilized

energy, 0.1 sec) inside a Wallac VICTOR3 1420 multilabel counter set at bottom reading mode. Control wells having no oxidant and a known potent antioxidant were included in all plates. The microplate was placed upon a specially designed alumina block in direct contact with all wells intended to provide uniform heating inside a water-saturated 5% $CO_2$ chamber held at 37 °C. Finally, the green fluorescence was monitored again ($t$ = 60 min). CAA data for each well were baseline corrected by subtracting the starting value from final value by using the inbuilt plate reader software Workout 2.0. This corrects for the antioxidant's own light absorption as well as probe background fluorescence and ensures evaluation of only experimentally generated DCF.

**Curve Fitting.** Log transformation of data and curve fitting was performed using Prism 5.0 (GraphPad Software, San Diego, CA, USA) by employing the four-parameter logistic equation (also called the Hill slope model) that yields half-maximal inhibitory concentrations ($IC_{50}$, a measure of the effectiveness of a compound) and Hill slopes (examples are shown in Figure 2). A strong concentration dependence was seen for potent antioxidants in the micromolar−millimolar range (−6 to −3 on a log scale, see Figure 2). In cases when full protection could not be achieved, approximate $IC_{50}$ values were obtained by extrapolating the curve to the lower plateau.

## RESULTS AND DISCUSSION

In this study, cells were preincubated with the compound of interest for 1 h prior to washing and thereafter exposed to a radical inducer. This preincubation should allow sufficient time for cell membrane passage of most compounds and antioxidant defense establishment prior to adding the inducer, which may otherwise pass cellular membranes more quickly than the antioxidant investigated. Preincubation also ensures that protective effects occur within cells, and are not due to antioxidants reacting with the radical inducer outside cells. Nevertheless, some compounds (e.g., DFO, being taken up by endocytosis)[26] may require longer incubations for effective cellular uptake, and rapidly membrane passing compounds could, to some extent, also leak from the cells and pass back into the medium. The HepG2 cell line was chosen due to its human origin, preservation of cellular functions,[27,28] metabolic activity,[28−30] ease of cultivation, and frequent use for similar tests.[16,31] However, HepG2 cells have been reported to express low basal levels of phase I cytochrome P450 metabolizing enzymes and may (for certain compounds) be less responsive than, for example, the HepaRG cell line[30,32] and human primary liver cells, in particular.[32,33] Human primary liver cells, however, can show profound interindividual differences[30] and are today unrealistically expensive for a study requiring large numbers of cells such as this one. Cellular uptake and eventual time-dependent compound metabolite formation may differ between cell types, and LIP levels may be influenced by the culturing conditions. These factors should be considered when results from different studies are compared. Testing two compounds simultaneously over broad concentration ranges for each microplate and then performing dose−response curve fitting by using the four-parameter logistic equation worked fine for both assays; see representative examples in Figure 2. The obtained $IC_{50}$ values (given in both mg/L and $\mu$M units) are shown in Table 1 (CLPAA) and Table 2 (CAA), respectively. These results can be useful for selecting candidate compounds for testing in higher organisms and also provide insight into how the CLPAA and CAA assays function similarly and differ from one another. No obvious correlations between size ($M_w$) or lipophilicity (XLogP3; a calculated octanol−water partition coefficient) with antioxidant effect ($IC_{50}$) among the tested compounds were found in either assay.

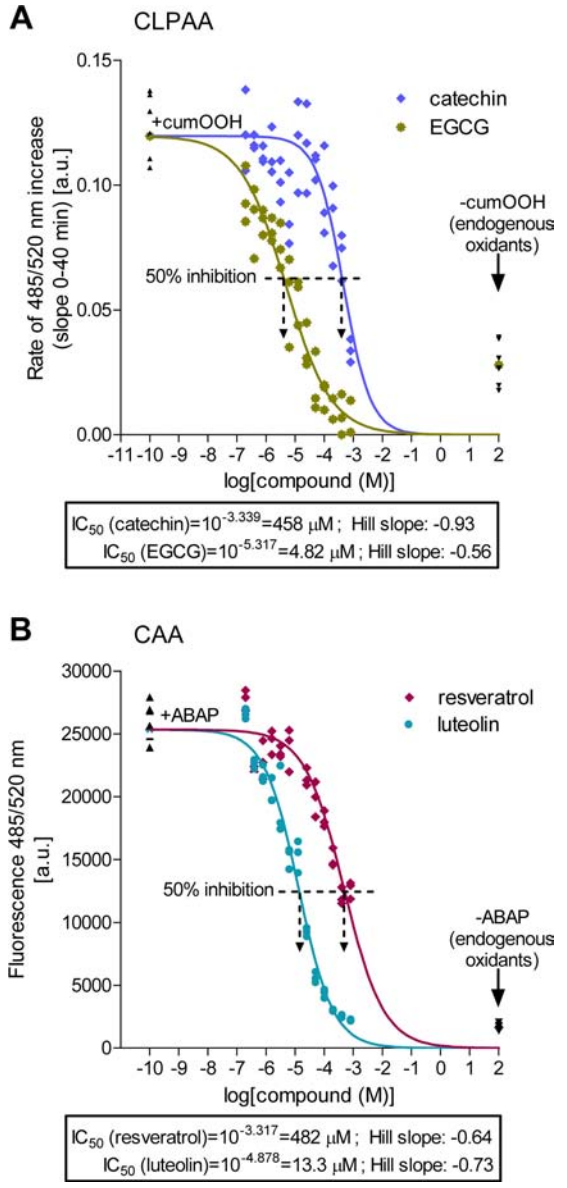

**Figure 2.** Dose−response testing compounds in the CLPAA and CAA assays. Representative examples are shown comparing two compounds in parallel over the range 0.2−800 $\mu$M using HepG2 cells. See Tables 1 and 2 for all obtained $IC_{50}$ values. (A) Parallel dose−response testing of catechin and EGCG in the CLPAA assay. For this particular run, catechin and EGCG produced $IC_{50}$ values of 458 and 4.82 $\mu$M, respectively. (B) Parallel dose−response testing of luteolin and resveratrol in the CAA assay. For this particular run, luteolin and resveratrol gave $IC_{50}$ values of 13.3 and 482 $\mu$M, respectively. Experiments were performed in a 96-well microplate, and each concentration was tested in triplicate ($N$ = 6 for each control (+added oxidant (▲); no added oxidant (▼)) selectively placed at concentrations distant from the tested range of antioxidants). For $IC_{50}$ value calculations a "theoretical zero level" is used as the lower plateau ($y$ value constrained to 0, reflecting a "perfect antioxidant") for extrapolation of dose−response curves. The top plateau is constrained to the mean of the +added oxidant (▲) value, a measure of both added and endogenous oxidants. a.u., arbitrary units.

**Flavonoids.** With the exception of apigenin, which displayed no activity in either assay and also not at realistically obtainable concentrations in vivo (protection was noticeable first at several mM), most flavonoids were effective antioxidants in both assays.

[a]Data are shown as averages (mean ± SD) from three separate experiments where separate preparations were tested on separate days. The PUFA chromenone data have been published,[19] but are included for comparison. [b]Lipophilicity data were obtained from NCBI Pubchem. [c]For hydroxytyrosol and the PUFA chromones, only one preparation was available, which was tested on three different days. [d]Clog$P^a$ value from ref 19. [e]Kaempferol gave a biphasic effect curve with CLPAA, and only the protective range (up to 100 $\mu$M) was used for curve-fits. High kaempferol concentrations (≥200 $\mu$M) offered no protection and increased probe oxidation. MEME = minimum essential medium Earle's.

| SIH | 241.3 | 1.9 | $Fe^{3+}$ chelator, permeable | >550[e] | >4000 | | MEME + 1% DMSO |

[a]Data are shown as averages (mean ± SD) from three separate experiments where separate preparations were tested on separate days. The PUFA chromenone data have been published,[19] but are included for comparison. [b]Lipophilicity data were obtained from NCBI Pubchem. [c]For the PUFA chromones and hydroxytyrosol only one preparation was available, which was tested on three separate days. [d]Clog$P^a$ value from ref 19. [e]SIH provided no protection and even increased the fluorescence over that of the positive control at ≥200 $\mu$M.

Interestingly, luteolin, which displayed the highest antioxidant activity of all compounds tested considering both assays (see Tables 1 and 2), differs structurally from apigenin by just one extra hydroxyl group on the B-ring (Figure 1); both are flavones and have similar molecular weight and lipophilicity (Tables 1 and 2). Thus, luteolin's dual ortho-positioned 3′,4′-dihydroxy substituents (catechol-type) on its extruding aromatic B-ring appear to have provided the extra edge. Luteolin was found to have a half-peak oxidation potential (Ep/2) of +180 mV, whereas apigenin could not be oxidized up to the maximum tested 1 V.[12]

Still, both apigenin and luteolin display iron chelating abilities,[12] although not nearly as strong as the metal chelators tested in this study ($pFe^{3+}$ values of deferasirox, DFO, and SIH are 22.5, 26.6, and 50, respectively;[34] $pFe^{3+}$ values for most compounds investigated in this study could not be found but are considerably lower). Thus, it seems that a potent flavonoid lipid peroxidation inhibitory activity requires a combination of metal chelating ability and low oxidation potential. The large difference between apigenin and luteolin in redox potential likely explains how the two compounds differed in performances in the CAA assay as well. Luteolin exhibits a high degree of electrochemical reversibility that is substantially higher than that of quercetin, for example, which is an even better electron donor (Ep/2 = +30 mV)[12] that also can redox cycle its 3′,4′-dihydroxy substituents on its B-ring in a $2e^- -2H^+$ step,[9] implying that the C-ring structure affects the compound's electrochemical properties. Higher concentrations of luteolin stained the cells yellow. Both flavanols, kaempferol and quercetin, displayed protective effects in both assays. However, kaempferol produced a biphasic effect in CLPAA (an increased dose−response protection was observed up to around 200 μM, but at higher concentrations, the protective effect disappeared), so only the protective range (low concentration) was used for curve fits. The reason for the biphasic effect curve in CLPAA is unclear; however, concentrations >200 μM are not biologically realistic in any case. Kaempferol (Ep/2 = +120 mV)[12] has a single hydroxyl group on the B-ring as apigenin, but differs in that it is substituted with an oxidizable hydroxyl group at C-3 on its C-ring, which allows it to also oxidize as a conjugated system in a $2e^- -2H^+$ step (its B- and C-ring −OH substituents → =O).[35] The electrochemical reversibility of luteolin and kaempferol could potentially be a disadvantage[12] as redox cycling could produce ROS (as in the case of redox cycling quinones),[36] but only unrealistically high (≥200 μM) kaempferol (not luteolin) concentrations had a pro-oxidant effect in this study (in the CLPAA assay only). The large flavonoid EGCG offered protection in both assays. EGCG is relatively lipophilic and has two 3′,4′,5′-trihydroxy (pyrogallol-type) phenolic rings that are also easily oxidized.[9] (+)-Catechin and (−)-epicatechin (isomers) offered similar protection in both assays. The reason why (+)-catechin and (−)-epicatechin offered much less protection in comparison to luteolin (all three have ortho-positioned 3′,4′-dihydroxy substituents on the B-ring, and catechin's Ep/2 of +160 mV[12] is nearly the same as that of luteolin) and EGCG is unclear but may be due to the catechins' different C-ring structure, which likely influences the compound's reversibility or their lower lipophilicity. Possibly their metal chelatability or a cellular metabolic effect (HepG2 cells are metabolically active) may have affected the outcome. Several flavonoids were found to reach and protect the nuclei in HepG2 cells with maximum incorporation after 30 min, and quercetin and luteolin were found to be effective in suppressing ABAP-induced 8-oxodG formation in DNA.[31]

**Other Phenols.** It has been suggested that in particular the *o*-diphenolic substitution gives high antioxidant ability, as opposed to *m*-diphenolic or single hydroxyl substitution.[8] This observation in addition to the obtained results for the flavonoids is further supported by the performance of hydroxytyrosol. Hydroxytyrosol is a small but major olive oil *o*-diphenolic derived from hydrolysis of oleuropein,[8] which offered protection in both assays. DL-α-Tocopherol displayed antioxidant activity in cellular membranes (CLPAA), but not in the aqueous cytosol (CAA). It was previously observed that the oxidation of $C_{11}$-BODIPY in rat-1 fibroblast was prevented by preincubation of the cells with a mixture of α- and γ-tocopherol.[21] Curcumin and resveratrol offered protection in both assays, and at higher curcumin concentrations (≥100 μM) necrotic (cell detachment, etc.) effects were visually observed, reflecting cytotoxicity on the HepG2 cells; however, toxicity in cancer cells (i.e., HepG2) may be considered beneficial.

**Carotenoids.** Carotenoids are highly lipophilic and partition into cellular membranes. Carotenoids contain multiple carbon−carbon double bonds that absorb UV light[2] and can react with singlet oxygen ($^1O_2$) produced from UV light-induced photosensitization reactions;[37] however, $^1O_2$ is of relatively low physiological importance. Carotenoids may also react with peroxyl radicals[38] and are oxidized during lipid peroxidation reactions but seem incapable of stalling this process, becoming degraded themselves.[39] In humans, carotenoids are well absorbed, contrary to many experimental animals, but it has been suggested that their antioxidant role in humans is not very strong.[40] In this study, astaxanthin and β-carotene stained the cells intensely red and orange, respectively, reflecting high cellular uptake. However, astaxanthin's low and β-carotene's absent effects in CLPAA suggest poor stalling of lipid peroxidation. The suggestion that astaxanthin would be a "super vitamin E"[41] could not be supported. It should, however, be noted that oxidative damage indicative probes such as $C_{11}$-BODIPY and DCFH could potentially oxidize more easily than biomolecules such as proteins or certain lipid constituents, and cellular membranes consist of a whole range of different lipids. For example, in a cell-free system measuring oxidation of 1-stearoyl-2-arachidonyl-*sn*-glycero-3-phosphocholine (SAPC), $C_{11}$-BODIPY was more sensitive to oxidative damage than the SAPC lipid.[42]

**PUFA Chromones.** The PUFA chromones tested are novel unexplored compounds that may offer promising activities in vivo. However, further toxicokinetic and toxicity testing is required. The more lipophilic PUFA chromone 1 resulted in a somewhat stronger response than PUFA chromone 2 (the PUFA chromone results were recently published[19] but are included for comparison as the testing conditions were identical).

**Metal Chelators.** The protective effects offered by the lipophilic cell membrane permeable $Fe^{3+}$ chelators SIH[43] and deferasirox[44] in CLPAA (Table 1) suggest that this assay involves membrane-associated Fe ions that catalyze membrane peroxidation reactions upon cumOOH addition and eventually cause $C_{11}$-BODIPY oxidation with the formation of measurable green fluorescent $C_{11}$-BODIPY products. Thus, the CLPAA assay should be suitable for screening new Fe chelators. The low, or lacking, protective effect by deferasirox and SIH in CAA (Table 2), however, demonstrates that ABAP-induced oxidation of intracellular DCFH is largely independent of labile Fe ions. In CAA, SIH was the only compound that at higher (≥200 μM) concentrations increased the fluorescence compared to the positive control in a dose−response manner. Noticeably, deferasirox offered a relatively limited protection in CAA compared to its strong protection in CLPAA. The hydrophilic membrane impermeable $Fe^{3+}$ chelator DFO offered no protection at reasonable concentrations in either assay (noticeable effects appeared first at mM concentrations; $IC_{50}$ was 1.7 mM in CAA and even higher in CLPAA). DFO is mainly taken up intracellularly into lysosomes by endocytosis (a slow process)[26] and requires subcutaneous infusion for optimal effect in patients. Whereas deferasirox and DFO are clinically used, SIH is not, presumably due to lower stability in vivo.

**Other Compounds.** ASA has anti-inflammatory and antiplatelet (inactivates cyclooxygenase enzymes COX-1 and -2) physiological effects but is also a free radical scavenger,

dx.doi.org/10.1021/jf5022779 | J. Agric. Food Chem. 2014, 62, 8402−8410

particularly against free hydroxyl radicals ($^{\bullet}OH$).[3,45] Here, however, ASA offered no protection in either assay, indicating that free $^{\bullet}OH$ has no major role in the CLPAA and CAA assays. Thus, the initiating CLPAA assay reactions 1 and 2 above appear to be "caged" events (no freely diffusing $^{\bullet}OH$).[46] L-Ascorbic acid (vitamin C) offered protection in the CAA assay, but not in the CLPAA assay. Passive plasma membrane passage of ascorbate ($AscH^-$) is expected to be very low due to low lipophilicity and charge, but active ascorbate import is mediated in most cell types (also hepatocytes) by sodium vitamin C transporters SVCT1 and SVTC2.[47] The amino acid L-tryptophan (contains an indole group) offered no protection in either assay and was merely included as a negative control.

**Comparisons between CLPAA and CAA and Mechanistic Assay Insights.** The two biologically relevant assays measure different parameters. CLPAA measures lipid peroxidation inhibition, and CAA measures intracellular peroxyl radical scavenging; hence, these are very complementing assays.[14−16] For CLPAA, we previously concluded that the rate of green fluorescence appearance ($C_{11}$-BODIPY decomposition products) was more sensitive than the disappearance of red fluorescence ($C_{11}$-BODIPY)[14] and that the background fluorescence from the plastic microplate interfered in the red light range.[14] As CLPAA is based on analyzing the slope of green BODIPY product formation, it is not affected by individual absorption from tested compounds. With CAA, however, light-absorbing effects by the compound can be an issue for particularly strong light (excitation and/or emitted light) absorbing compounds such as carotenoids by producing a false effect (increased effect at increased compound concentration). This can be checked and possibly normalized for by using a blank control with only the addition of test compound to cell-free medium containing a known concentration of the fluorescent probe. Moreover, the CAA assay is also more sensitive toward plate heating effects than CLPAA, and the variation among positive control values in CAA also increases (more than for CLPAA) with incubation time. Random placement of samples in the microplate can circumvent edge and corner effects (outer wells generally warm up more rapidly).

Overall, our results together with those by others[48,49] suggest that peroxides (cumOOH, $H_2O_2$, etc.) depend upon catalytic transition metal ions to oxidize organic compounds, whereas both production of azo compound (e.g., ABAP) oxidizing peroxyl radicals ($ROO^{\bullet}$ as in the CAA assay) and their oxidation of organic compounds can take place independent of transition metals. Thus, the choice of oxidant in an assay relates to which antioxidant characteristics are being assessed.

**Implications.** This study encourages further in vivo studies with administration of the better performing compounds (Tables 1 and 2), and an increased intake of foods rich in these compounds could be beneficial for our health. Luteolin, the most promising compound in this study, is present in multiple plants to various degrees; for example, high luteolin contents are present in peanut shells (here extractable luteolin exists in the studied aglycone form)[50] and in certain edible herbs such as peppermint and sage,[51] where luteolin mainly exists chemically attached to sugars (i.e., rutinose or glucose), bonds that hydrolyze during gastrointestinal passage.[10,52] Interestingly, chrysanthemum flower tea extract is rich in luteolin constituents and has been used in folk medicine for centuries.[52]

# α-Amylase Inhibitory Triterpene from *Abrus precatorius* Leaves

Ryuta Yonemoto, Miyuki Shimada, Maria D. P. T. Gunawan-Puteri, Eisuke Kato, and Jun Kawabata*

Division of Applied Bioscience, Graduate School of Agriculture, Hokkaido University, Sapporo, Hokkaido 060-8589, Japan

**ABSTRACT:** In the screening experiments for porcine pancreatic α-amylase inhibitors in 18 plants obtained from Indonesia, a potent inhibitory activity was detected in the extract of leaves of *Abrus precatorius*. The enzyme assay-guided fractionation of the extract led to the isolation of a triterpene ketone, lupenone (**1**), as a potent α-amylase inhibitor, together with 24-methylenecycloartenone (**2**) and luteolin (**3**). The mode of inhibition of compound **1** against porcine pancreatic α-amylase was a mixed inhibition. This is the first report that describes the potent α-amylase inhibitory activity of the low-polar triterpene ketone similar to compound **1**. A comparison of the activities of the isolate and related compounds indicated the importance of C-3 ketone and the lupane skeleton in the α-amylase inhibitory activity.

**KEYWORDS:** *Abrus precatorius, α-amylase inhibitor, triterpene ketone*

## INTRODUCTION

Diabetes mellitus is a typical chronic disease related to both obesity and aging and has thus become a serious global health problem.[1] One of the therapeutic approaches for preventing diabetes is the suppression of intestinal digestion and absorption of dietary carbohydrates through the inhibition of carbohydrate-hydrolyzing enzymes, α-amylase and α-glucosidase, in the digestive organs.[2] In this context, several research efforts have screened for effective α-amylase and α-glucosidase inhibitors from natural sources to develop a physiological functional food or lead compounds for the use of antidiabetic medicines.[3,4]

In the course of our continuing search for rat intestinal α-glucosidase inhibitory principles from plants, we have isolated and identified several active compounds from a variety of plants.[5−9] However, the search for α-amylase inhibitors from natural sources have led to relatively scarce results.[10−12] It is well-known that α-amylase recognizes a consecutive glucose chain as a substrate using its subsite.[13] In fact, acarbose, a typical α-amylase inhibitor, has a strong affinity for the enzyme because of its pseudo-tetrasaccharide structure.[14] This is partly the reason for the limited number of cases involved with the identification of small-molecule α-amylase inhibitors from natural sources. Most of these are polyphenols with low enzyme specificity.[15−19] Recently, a triterpene glycoside has been isolated as a specific inhibitor by high-throughput screening,[20] and more surprisingly, a simple low-polar ketone, chalcone, has been found to possess considerable α-amylase inhibitory activity.[21] The molecular docking study revealed that the low-polar small molecule could interact with hydrophobic amino acid residues near the active site of the enzyme. From these results, we have thus focused on searching for non-polyphenolic low-polar α-amylase inhibitors from plant origin.

In this paper, we present the results of a study on α-amylase inhibition and identification of active principles from the plant extract of indigenous plants obtained from Indonesia that show a potent inhibitory activity. In the screening experiments for porcine pancreatic α-amylase (PPA) inhibitors in 18 plants obtained from Indonesia, the potent α-amylase inhibitory activity was found in a tannin-free low-polar extract of the leaves of *Abrus precatorius*. *A. precatorius* (Fabaceae) is a perennial climber found in tropical and subtropical regions. It is famous for its beans, which contain a proteinaceous toxin.[22,23] In addition, several other biological activities have been reported,[24−26] although there have been no reports on α-amylase and α-glucosidase inhibitory activities of this plant.

## MATERIALS AND METHODS

**Materials.** A total of 18 Indonesian plants, including *A. precatorius* leaves, were purchased from Merapi Farma Traditional Herbs Distributor, Yogyakarta, Indonesia, in January 2007. PPA (A3176) was obtained from Sigma-Aldrich Co. (Tokyo, Japan). All chemicals used in the present study were of reagent grade and were purchased from Wako Pure Chem. Co. (Osaka, Japan), unless otherwise stated.

**General Procedure.** Nuclear magnetic resonance (NMR) spectra were recorded on Bruker AMX500 ($^1$H, 500 MHz; $^{13}$C, 125 MHz) and Jeol EX-270 ($^1$H, 270 MHz) instruments. Chemical shifts were determined relative to a reference signal of tetramethylsilane in chloroform-*d* ($\delta_H$, 0.00 ppm; $\delta_C$, 0.0 ppm) or a residual solvent signal of methanol-$d_4$ ($\delta_H$, 3.30 ppm). Field desorption mass spectra (FD-MS) were determined by a Jeol T100GCV instrument.

**PPA Inhibitory Activity Determination.** The PPA inhibitory activity was determined using the method described by Ali et al.,[27] with a slight modification. PPA was dissolved in sodium phosphate buffer (20 mM, pH 6.9) containing 6.7 mM NaCl to give a concentration of 0.5 unit/mL solution. Potato starch (0.01 g/mL) in the same buffer was used as a substrate solution. A coloring reagent [3,5-dinitrosalicylic acid (DNS)] was prepared by mixing a 4.8 M 3,5-dinitrosalicylic acid solution (20 mL) and a solution of (+)-sodium potassium tartrate tetrahydrate (12 g) in 0.4 M NaOH (40 mL). A sample solution (100 μL) in 50% dimethyl sulfoxide (DMSO) and the PPA solution (150 μL) were mixed in a microtube (1.5 mL). The tube was stoppered and preincubated at 37 °C for 15 min. The starch solution (250 μL) was then added, and the mixture was incubated at 37 °C for 15 min. To terminate the reaction, the tube was dipped in boiling water for 1 min. After cooling, the contents of the microtube were directly passed through a small ODS (Cosmosil 75$C_{18}$-OPN, Nacalai Tesque Co., Kyoto, Japan) column (3 mL) to remove any

sample constituents that may interfere with the following color reaction. The reaction mixture (100 μL) was then mixed with DNS reagent (50 μL) in a microtube, stoppered, and heated in boiling water for 15 min. The ice-cooled mixture was diluted with water (450 μL); the solution (200 μL) was transferred to a 96-well microplate; and the optical density was determined at a wavelength of 540 nm. The control experiment was performed using 50% DMSO in place of the sample solution. Blank experiments for the sample and control were performed using the sodium phosphate buffer in place of the enzyme solution, and each blank value was subtracted from the sample and the control values, respectively. The inhibitory activity (%) was calculated as $[1 - OD_{540}\ (\text{sample})/OD_{540}\ (\text{control})] \times 100$.

**Screening Experiment.** The screening experiments for PPA inhibition were performed with extracts of 18 plant species. Each dried plant was extracted with 50% aqueous methanol. The extracts were evaporated and partitioned with chloroform/methanol/water (4:1:5). The organic phase was washed with 1% saline to give a tannin-free extract,[28] which was then evaporated, redissolved in 50% aqueous DMSO, and subjected as the test sample to the assay for PPA inhibitory activity at the final concentration of the extractable constituents obtained from 0.3 g of plant material in 1 mL of solution.

**Isolation of Lupenone (1), 24-Methylenecycloartenone (2), and Luteolin (3) from *A. precatorius* Leaves.** Dried leaves (40 g) of *A. precatorius* were extracted with 50% aqueous MeOH. The extract was concentrated and partitioned with chloroform/methanol/water (4:1:5). The organic phase was washed with 1% saline and evaporated to give a tannin-free chloroform-soluble part (1.5 g). This fraction was charged onto a silica gel column and eluted successively with hexane/ethyl acetate (9:1, F1), hexane/ethyl acetate (3:1, F2), hexane/ethyl acetate (1:1) containing 0.1% formic acid (F3), ethyl acetate containing 0.1% formic acid (F4), and methanol containing 0.1% formic acid (F5). The PPA inhibitory activity was observed in F1, F4, and F5.

The less polar F1 (114 mg) was further fractionated by silica gel column chromatography with a hexane/ethyl acetate gradient. The PPA inhibitory activity was eluted mainly in a hexane/ethyl acetate (30:1) eluate (F1-2, 78 mg). F1-2 was further purified by silica gel preparative thin-layer chromatography (TLC) (11:1 hexane/ethyl acetate) to give an active band (F1-2-2, $R_f$ = 0.50, 11 mg). F1-2-2 was finally purified by preparative high-performance liquid chromatography (HPLC) [column, Inertsil ODS-3, 4.6 × 250 mm, GL-Science Co., Tokyo, Japan; mobile phase, MeOH; flow rate, 1.0 mL/min; and detection, ultraviolet (UV) at 210 nm]. Two major peaks were collected and identified as lupenone (**1**, $t_R$ = 21.0 min, 0.7 mg) and 24-methylenecycloartenone (**2**, $t_R$ = 16.0 min, 0.3 mg).

The more polar active fraction (F4, 200 mg) of the first silica gel column was rechromatographed by a silica gel column (hexane/ethyl acetate/methanol). The most polar fraction (F4-4, 110 mg) eluted by hexane/ethyl acetate (1:5) and methanol showed PPA inhibitory activity. The final polar fraction (F5, 480 mg) of the first column was expected to contain the similar active constituents to F4-4, and thus, F4-4 and F5 were merged (F45) and subjected to further fractionation. F45 was chromatographed on a silica gel column with a chloroform/methanol gradient. The PPA inhibitory activity was eluted in a chloroform/methanol (10:1 and 7:1) eluate (F45-5, 75 mg). F45-5 gave a single peak ($t_R$ = 41.3 min) by HPLC analysis [column, Inertsil ODS-3, 4.6 × 250 mm; mobile phase, 10−100% MeOH in water containing 0.1% formic acid (0−60 min); flow rate, 1.0 mL/min; and detection, UV at 254 nm] and was identified as luteolin by comparison to an authentic sample.

*Luteolin (**3**).* FD-MS *m/z*: 286 ([M]$^+$). $^1$H NMR (270 MHz, methanol-$d_4$) δ: 6.20 (1H, d, *J* = 2.1 Hz), 6.43 (1H, d, *J* = 2.1 Hz), 6.54 (1H, s), 6.90 (1H, d, *J* = 8.7 Hz), 7.38 (2H, m).

## RESULTS AND DISCUSSION

In the screening experiment, tannin-free extracts from 2 of 18 Indonesian plants, namely, *A. precatorius* leaves (73%) and *Baeckea frutescens* bark (58%), showed >50% PPA inhibitory activity (Table 1). On the basis of this result, we chose extracts of *A. precatorius* for identifying active principles.

**Table 1. PPA Inhibitory Activity of Tannin-Free Extracts of Indonesian Plants**

| plant | part | inhibitory activity (%)[a] |
|---|---|---|
| *Abrus precatorius* | leaf | 73 |
| *Carica papaya* | leaf | 33 |
| *Gynura procumbens* | aerial part | 6 |
| *Menta arvensis* | leaf | 15 |
| *Ruella napifera* | leaf | 15 |
| *Sida rhombifolia* | aerial part | 12 |
| *Tribulus terrestris* | aerial part | 0 |
| *Caesalpinia sappan* | bark | 0 |
| *Ruellia tuberosa* | fruit | 23 |
| *Helicteres isora* | leaf | 4 |
| *Sonchus arvensis* | fruit | 5 |
| *Cryptocarya massoy* | bark | 0 |
| *Piper nigrum* | seed | 18 |
| *Bruceal javanica* | seed | 2 |
| *Alyxia stellata* | bark | 39 |
| *Baeckea frutescens* | bark | 58 |
| *Murraya paniculata* | aerial part | 22 |
| *Borreria hispida* | leaf | 21 |

[a]The concentration was adjusted to the extractable constituents obtained from 0.3 g of plant material in 1 mL of solution.

The tannin-free organic phase of *A. precatorius* leaves was chromatographed on a silica gel column, and PPA inhibitory activity was observed in two discrete fractions. The less polar active fraction was further chromatographed on a silica gel column followed by silica gel preparative TLC and reverse-phase HPLC to afford two major peaks in the final active fraction. These two constituents were identified as lupenone (**1**)[29] and 24-methylenecycloartenone (**2**)[30] by comparison of their analytical data to those reported in the references and an authentic specimen of lupenone. The more polar active fraction of the first column was also chromatographed on silica gel, and the resultant active eluate showed a single peak in the reverse-phase HPLC analysis. The active constituent of the final fraction was identified as luteolin (**3**) by comparison to an authentic specimen (Figure 1).

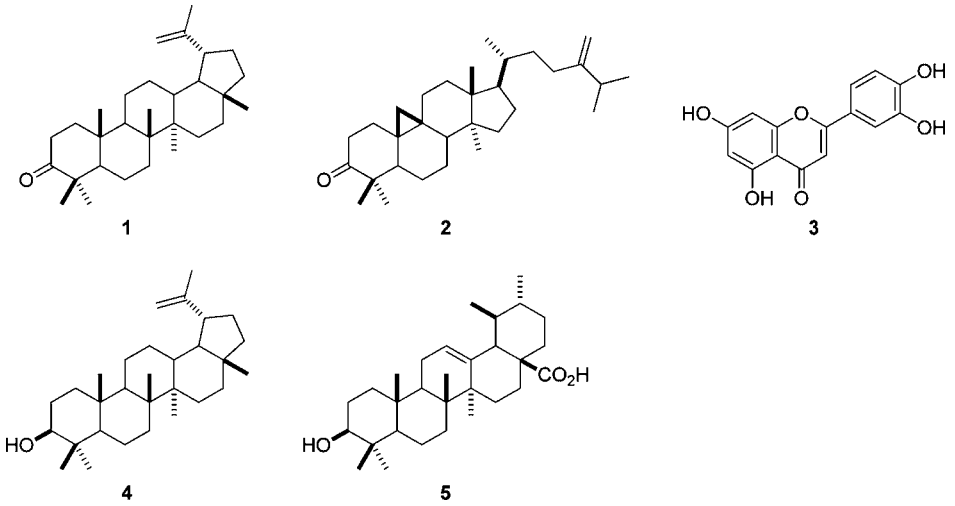

**Figure 1.** Structures of compounds **1**–**5**.

The PPA inhibitory assay of the isolates showed a potent activity of compound **1** ($IC_{50}$ = 31 $\mu$M) and a weaker activity of compound **3** ($IC_{50}$ = 3.1 mM) (Table 2). The activity was not observed in compound **2** (0%) at 0.6 mM, although a further experiment using a higher concentration could not be performed because of the limited sample amount. The potent inhibitory activity of compound **1** against PPA has not ever been reported, whereas compound **3** has been known as a moderate PPA inhibitor.[15,19] The inhibition mode of compound **1** was determined to be mixed-inhibition-type by the double-reciprocal plot experiment (Figure 2).

**Table 2. PPA Inhibitory Activity of Isolated and Related Compounds**

| | inhibitory activity (%) | |
|---|---|---|
| | 50 $\mu$M | 100 $\mu$M |
| **1** | 84 | 87 |
| **2** | *a* | 0[b] |
| **3** | *a* | *a* and *c* |
| **4** | 8 | 16 |
| **5** | 32 | 45 |

[a]Not tested. [b]0% at 0.6 mM. [c]$IC_{50}$ = 3.1 mM.

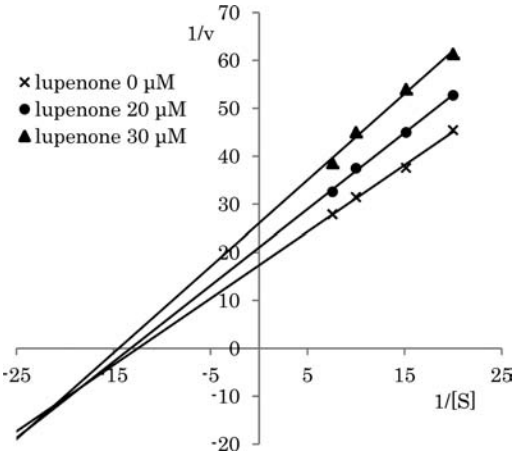

**Figure 2.** Double-reciprocal plot (Lineweaver–Burk) for the $\alpha$-amylase inhibition by lupenone (**1**).

It is interesting that a low-polar triterpene, such as compound **1**, showed significant PPA inhibition, because only few studies have investigated the PPA inhibitory activity of triterpenes. Ali et al. reported triterpenic inhibitors, ursolic acid, oreanolic acid, and lupeol, from a Malaysian plant, *Phyllanthus amarus*, and ursolic acid showed the highest activity among the isolates.[27] The structural similarity of those triterpenes and compound **1** prompted us to perform brief activity comparison experiments. The PPA inhibitory assay of commercially available lupenone (**1**), lupeol (**4**), and ursolic acid (**5**) (Figure 1) at a concentration of 50 $\mu$M showed the strongest activity of compound **1** (84%), followed by compound **5** (32%), and the lowest activity of compound **4** (8%) (Table 2). These results together with the low inhibitory activity of compound **2** show that both the lupane skeleton and a ketone at C-3 would be essential for exerting a potent PPA inhibition. To the best of our knowledge, this is the first finding of the potent PPA inhibitory activity of lupenone, although some other biological activities,[29,31] including $\alpha$-glucosidase inhibition,[32] have been reported for compound **1**. There are a few examples of non-polyphenolic low-polar small-molecular inhibition against PPA. It should be interesting to determine how efficiently a low-polar molecule, such as compound **1**, could associate with the PPA enzyme.

In conclusion, the enzyme assay-guided fractionation of the extract from the dried leaves of *A. precatorius* led to the isolation of a triterpene ketone, lupenone (**1**), as a potent PPA inhibitor, together with lower active luteolin (**3**). The relatively higher activity of compound **1** and the larger amount of compound **3** present in *A. precatorius* leaves suggest that both compounds contribute to the inhibitory activity of this plant. *A. precatorius* may have a potential for the treatment of diabetes, although *in vivo* experiments are warranted.

**ABSTRACT:** Capsaicinoids exist in chili peppers, whereas capsinoids are present in some sweet peppers. The present study investigated the effects of capsaicinoids and capsinoids on plasma lipids, relaxation of the aorta, atherosclerotic plaque development, and fecal sterol excretion in hamsters fed a high-cholesterol diet. Five groups of male hamsters were given the control diet or one of the four experimental diets containing 1.3 mmol of capsaicinoids (NL), 2.6 mmol of capsaicinoids (NH), 1.3 mmol of capsinoids (OL), or 2.6 mmol of capsinoids (OH), respectively. Results showed capsaicinoids but not capsinoids could decrease plasma total cholesterol (TC), reduce the formation of atherosclerotic plaque, and relax the aortic artery. This was accompanied by a 28−175% increase in fecal excretion of acidic sterols in hamsters fed the diets containing capsaicinoids. Similarly, capsaicinoids but not capsinoids could decrease the pad weights of epididymal and prerenal adipose tissues. It was concluded that capsaicinoids but not capsinoids could favorably modulate plasma lipids and possess beneficial vascular activity.

**KEYWORDS:** *aorta, capsaicinoids, capsinoids, cholesterol, atherosclerosis, pepper*

## INTRODUCTION

Capsaicinoids refer to a group of well-known pungent compounds found in the fruits of chili pepper plant *Capsicum*, whereas capsinoids are the nonpungent analogues of capsaicinoids isolated in the fruits of sweet pepper *Capsicum* CH-19.[1,2] Capsaicinoids consists of mainly two isomers, namely, capsaicin and dihydrocapsaicin, whereas capsinoids also have two major isomers, capsiate and dihydrocapsiate (Figure 1). The structural difference is that capsaicinoids are fatty acid amides linked with vanillylamine, whereas capsinoids are fatty acid esters linked with vanillyl alcohol.

Health benefits associated with the consumption of capsaicinoids have been well reported. It has been shown that capsaicinoids can promote weight reduction by enhancing fat oxidation and increasing adrenergic activity and energy expenditure.[3] Research has also demonstrated that capsaicinoids have some beneficial effect on the human cardiovascular system, possess some antitumor activity, and also decrease plasma lipids.[4−8] Like capsaicinoids, capsinoids are also able to reduce body fat by increasing thermogenesis[9] and possess some antitumor activity.[4]

Capsaicinoids are beneficial for people who love spicy foods, whereas capsinoids may be an alternative for people who cannot tolerate spicy foods. In view of the structural similarity between capsaicinoids and capsinoids, the present study was the first to examine if capsaicinoids and capsinoids were both able to reduce plasma cholesterol concentration and formation of atherosclerosis plaque. We also sought to ascertain whether capsaicinoids and capsinoids could improve endothelial function and possess beneficial vascular activity. The major findings were that only capsaicinoids but not capsinoids could reduce the plasma cholesterol concentration and possessed vasorelaxation activity.

## MATERIALS AND METHODS

**Capsinoid Synthesis.** Capsinoids are not commercially available in large quantities. We therefore had to use capsaicinoids as starting materials to synthesize their corresponding capsinoids. Capsaicinoids containing 51.3% capsaicin and 46.2% dihydrocapsaicin were purchased from Henan Bis-Biotech Co. Ltd. (Henan, China). Vanillyl alcohol was purchased from Sigma-Aldrich Chemical Co. (St. Louis, MO, USA). Lipase enzyme (Lipozyme 435) was purchased from Guangzhou Minagyao Trading Co. Ltd. (Guangzhou, China). To obtain a capsinoid mixture of 51.3% capsiate and 46.2% dihydrocapsiate, the mixture of acyl donors was prepared with capsaicinoids according to the method described by Kobata et al.[10] and Dong et al.[11] In brief, 3 g of capsaicinoids was dissolved in 1 L of 4 N HCl in 67% methanol and was refluxed for 48 h. Then *n*-hexane was added to the solution to extract the acyl donors (Figure 1). Capsinoids were synthesized by adding 10 g of Lipozyme 435 into a solution of acetone (1 L) containing vanillyl alcohol (7.7 g) and acyl donors (14.2 g). After being incubated in a shaker at 25 °C for 48 h, the reaction mixture was filtered to remove the enzymes, and the solvent was evaporated in a rotary evaporator. The crude capsinoids were loaded onto a silica column and eluted using a solvent mixture of hexane and ethyl acetate (6:1, v/v), producing 4 g of capsinoids. Structures of synthesized capsinoids were confirmed using NMR (Supporting Information Supplementary Figures 1 and 2). HPLC analysis found that capsinoids consisted of 52.4% capsiate and 44.9% dihydrocapsiate

with such a ratio being similar to that in sweet pepper (Supporting Information Supplementary Figure 3).

**Diet.** Five diets were prepared by modifying the formulation as we previously described.[12] The control diet was prepared by mixing all powdered ingredients (g/kg): corn starch, 507; casein, 241; lard, 50; sucrose, 119; mineral mix, 40, vitamin mix, 20; geltatin, 20; DL-methionine, 1; cholesterol, 2 (Table 1). The four experimental diets were similarly prepared by mixing the control diet with 1.3 mmol of capsaicinoids (NL), 2.6 mmol of capsaicinoids (NH), 1.3 mmol of capsinoids (OL), or 2.6 mmol of capsinoids (OH), respectively. Such amounts of capsaicinoids and capsinoids added into diets were equivalent to a daily dose of 7−14 mg/kg body weight, which could be achieved by humans who love chili hot foods.[13] All five diets contained 0.2% cholesterol by weight and had 68.2, 26.4, and 5.4% energy from carbohydrate, protein, and fat, respectively.

**Hamsters.** We chose hamsters as model because cholesterol metabolism in hamsters is close to that in humans.[14] The experiments were approved and conducted in accordance with the guidelines set by the Animal Experimental Ethics Committee, The Chinese University of Hong Kong. Golden hamsters ($n$ = 50, body weight = 116 ± 6 g) were divided into five groups and fed the control or one of the four experimental diets as described above for 6 weeks. All hamsters were given fresh diet daily and housed in an animal room at 23 °C with a 12/12 h light/dark cycle. The hamsters were allowed free access to food and water. Blood sample was taken from the retro-orbital sinus under light anesthesia using a mixture of ketamine, xylazine, and saline (4:1:5; v/v/v) after overnight fasting at weeks 0, 3, and 6. At the end of experiment, all hamsters were killed under carbon dioxide anesthesia; the abdomen was opened with blood being sampled from the aorta into a syringe. The fecal output from each hamster was collected and pooled at weeks 1 and 6, then freeze-dried, ground, and saved for neutral and acidic sterol analyses.

**Plasma Lipids.** Plasma total cholesterol (TC), high-density lipoprotein cholesterol (HDL-C), and triacylglycerols (TG) were measured using their respective commercial enzymatic kits from Infinity (Waltham, MA, USA) and Stanbio Laboratories (Boerne, TX, USA), respectively. Non-HDL cholesterol (non-HDL-C) was calculated by deducting HDL-C from the TC.

**Atherosclerotic Plaque.** The aorta was used to assess atherosclerosis as we previously described.[12] In brief, the thoracic aorta was cut open vertically followed by staining in a 10 mL ethanol solution containing 0.5 g of Sudan III for 3 h. Afterward, Sudan III was washed with distilled water three times and scanned with a table scanner. The area of atherosclerotic plaque was measured with the aid of a computer image analysis program (Sigma Scan Pro 5.0, SPSS, Inc., Chicago, IL, USA).[12]

**Hepatic Cholesterol.** Total cholesterol in the liver was quantified as previously described.[15] Total liver cholesterol was extracted using a mixture of chloroform/methanol (2:1, v/v). 5$\alpha$-Cholestane as an internal standard was added during the extraction. Other lipids were saponified and removed. The nonsaponified fraction containing cholesterol was saved, and free cholesterol was converted to its TMS-ether derivative by a commercial TMS reagent (Sigma, Hong Kong). Analysis of the cholesterol TMS-ether derivative was performed in an SAC-5 column in a Shimadzu GC-14B GLC equipped with a flame ionization detector. Hepatic cholesterol was calculated according to the amount of internal standard 5$\alpha$-cholestane added.

**Fecal Neutral and Acidic Sterols.** The total fecal output was collected and saved for the measurement of total fecal neutral and acidic sterols as previously described.[15] In brief, total fecal sterols were extracted with 5$\alpha$-cholestane being added as an internal standard for quantification of fecal neutral sterols, whereas hyodeoxycholic acid was added as an internal standard for the quantification of total acidic sterols. First, the fecal samples were saponified, the total neutral sterols were extracted into cyclohexane, and the neutral sterols were converted into their TMS derivatives. Second, total fecal acidic sterols in the aqueous phase after cyclohexane extraction were also extracted

and similarly converted into their TMS derivatives. Individual neutral and acidic sterol TMS derivatives were then subjected to GC analysis on an SAC-5 column in a Shimadzu GC-14B GLC equipped with a flame ionization detector.

**Endothelium-Dependent Relaxation in Rat Mesenteric Artery.** To assess the effect of capsaicinoids and capsinoids on the functionality of the artery, endothelium-dependent relaxation was measured in rat mesenteric artery as previously described.[16] In brief, rats were sacrificed by $CO_2$ suffocation. Superior mesenteric arteries were dissected out and placed in ice-cold Krebs solution (mmol/L): 119 NaCl, 4.7 KCl, 2.5 $CaCl_2$, 1 $MgCl_2$, 25 $NaHCO_3$, 1.2 $KH_2PO_4$, and 11 D-glucose. Arteries were cleaned of adhering tissue and cut into ring segments of 2 mm in length. Rings were suspended in a myograph (Danish Myo Technology, Aarhus, Denmark) for recording of changes in isometric tension. After a 60 min equilibration period, each ring was first contracted by 60 mmol/L KCl and then washed in Krebs solution three times. Phenylephrine at 1 μmol/L was used to induce steady contraction of the ring and the effect of capsaicinoids or capsinoids was then determined.

**Culture of Human Umbilical Cord Vein Endothelial Cells (HUVECs).** HUVECs (CC-3317, Clonetics, Lonza, Walkersville, MD, USA) were grown in endothelial cell growth medium (Clonetics) supplemented with bovine brain extract and 1% penicillin and streptomycin. Cells were grown in 75 $cm^2$ flasks and maintained at 37 °C in a 95% humidified air/5% $CO_2$ atmosphere. Medium was changed every 2 days. Confluent cells were passaged by trypsinization (0.25% trypsin with 2.5 mmol/L EDTA in PBS). Experiments were performed on cells at passage 4−8 when 80−90% confluency was achieved.

**Measurement of Intracellular $Ca^{2+}$ Concentration by Fluorescence Microscopy.** HUVECs were treated at 37 °C for 60 min with 10 μmol/L calcium indicator fluo-4 AM (Molecular Probes,

Eugene, OR, USA) in normal physiological saline solution containing (mmol/L) 140 NaCl, 5 KCl, 1 $CaCl_2$, 1 $MgCl_2$, 10 glucose, and 5 HEPES (pH ~7.4). Fluorescent images were obtained under a fluorescence microscope (Olympus, Tokyo, Japan) (excitation, 495 nm; emission filter, 505−525 nm) every 5 s continuously. Changes in intracellular $Ca^{2+}$ concentration triggered by the addition of capsaicinoids or capsinoids was expressed as $F_1/F_0$ ratio, where $F_1$ is the fluorescence intensity at a specific time point and $F_0$ is the signal measured at the starting point of image recording.

**Statistical Analysis.** Data are expressed as the mean ± SD ($n$ = 10 for the experiment on hamsters and $n$ = 4 for the experiment on aortic relaxation). One-way analysis of variance followed by using Fisher's LSD method was used to statistically evaluate differences in plasma lipids, aortic functions, and atherosclerotic plaque among the five groups.

## RESULTS

**Food Intake and Body and Organ Weights.** No differences in food intake, body weight, and relative weights of heart, kidney, and testis were seen among the five groups (Table 2). However, the relative weights of epididymal and perirenal fat pats were smaller in NL and NH groups fed the diets containing capsaicinoids compared with those in the control hamsters ($P < 0.05$). However, no significant difference was seen among the control, OL, and OH hamsters.

**Plasma TC, HDL-C, Non-HDL-C, and TG.** The five groups of hamsters had similar concentrations of plasma TC, HDL-C, non-HDL-C, and TG at week 0 (Table 3). When the experiment reached the end of weeks 3 and 6, NH groups had plasma TC, non-HDL-C, and TG concentrations significantly lower than the control hamsters. It was clear that capsaicinoids decreased plasma cholesterol in a dose-dependent manner ($P < 0.05$). However, two capsinoids groups, OL and OL, had no effect on plasma TC, non-HDL-C, and HDL (Table 3).

**Liver Cholesterol and Atherosclerotic Plaque.** Two capsaicinoids groups, NL and NH, significantly decreased hepatic cholesterol concentrations in a dose-dependent manner compared with the control hamsters, whereas two capsinoids groups, OL and OH, had no effect on hepatic cholesterol concentration (Table 3). A similar trend in atherosclerotic plaque was seen. Hamsters fed NL and NH diets had less atherosclerotic plaque, whereas those fed OL and OH groups had levels of atherosclerotic plaque similar to those of the control hamsters (Table 3).

**Fecal Neutral and Acidic Sterols.** In the colon, cholesterol is subjected to microbial bioconversion, producing series of cholesterol microbial metabolites with coprostanol and dihydrocholesterol being the major products. To simplify the presentation, only data on fecal samples collected from week 6 are reported. As shown in Table 4, capsaicinoids had a trend of increasing the excretion of fecal cholesterol and coprostanol; however, the effect was statistically insignificant. Capsinoids had no effect on total excretion of fecal neutral sterols. With regard to fecal acidic sterol excretion, it was evident that capsaicinoids but not capsinoids increased their excretion.

**Endothelium-Dependent Relaxation.** In phenylephrine-contracted superior mesenteric arteries, capsaicinoids beneficially induced relaxation in a dose-dependent manner. By contrast, capsinoids were without any beneficial effect (Figure 2A).

**$Ca^{2+}$ Influx.** Acute exposure to capsaicinoids stimulated an increase of intracellular $Ca^{2+}$ level in HUVECs in a concentration-dependent manner (Figure 2B), whereas capsinoids led to little rise of intracellular $Ca^{2+}$ (Figure 2C).

## DISCUSSION

Capsaicinoids are present in large quantity in most chili peppers and can induce strong pungent sensations, whereas capsinoids are not pungent and are present in only a small amount in sweet pepper CH-19.[1] It has been estimated that the consumption of chili pepper by humans who like hot spicy foods could reach 2.5−20 g/person/day, equivalent to 0.5−4 mg capsaicinoids/kg body weight/day provided that capsaicinoids in chili pepper are 1% by weight.[17] In contrast, no data are available for us to assess the intake of capsinoids in humans. Structurally, capsaicinoids and capsinoids are similar except that the former are the amides of vanillylamine with fatty acids, whereas the latter are the esters of vanillyl alcohol with fatty acids (Figure 1). For individuals who like spicy foods, capsaicinoids provide a pleasurable sensation upon ingestion. In addition to the use for releasing pain, capsaicinoids also act as an antioxidant and increase the oxidation of body fat, thus being used as a target for obesity management.[18,19] However, the burning and pungent sensation may prevent their wide application, particularly for people who dislike or cannot tolerate spicy foods. In this regard, capsinoids could be an alternative if they had bioactivity similar to that of capsaicinoids because they are nonpungent. In fact, capsinoids have been

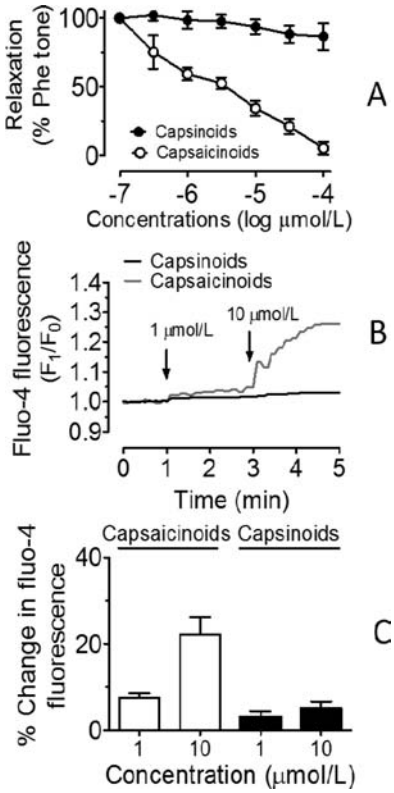

**Figure 2.** Effect of capsaicinoids and capsinoids on the relaxation of rat mesenteri artery and intracellular $Ca^{2+}$ concentration in human umbilical cord endothelial cells (HUVECs). (A) Capsaicinoids but not capsinoids caused vasodilatation on phenylephrine (1 $\mu$mol/L)-contracted mesenteric arteries. (B) Representative tracing and (C) summarized data show that capsaicinoids stimulated $Ca^{2+}$ entry in HUVECs in a concentration-dependent manner, whereas capsinoids had little effect. Data are expressed as the mean ± SEM; $n$ = 4.

similarly proposed to be a dietary supplement in weight management, as they are equally effective in increasing the energy expenditure by increasing fatty acid oxidation in vivo.[20] The present results demonstrated that capsaicinoids could reduce the size of both epididymal and prerenal fat pads, which were the two visible adipose tissues in rodents (Table 2). However, the effects of dietary capsinoids on two fat pads were found to be insignificant. This discrepancy with previous studies was probably because the duration of the present study was only 6 weeks, which might be not long enough for capsinoids to exert any antiobesity effect in hamsters.

The present study was the first time to compare the effect of capsaisinoids on plasma TC with that of capsinoids. Results clearly demonstrated that capsaicinoids but not capsinoids were able to decrease plasma TC in hamsters fed a 0.2% cholesterol diet (Table 3). Reduction in plasma TC caused by dietary capsaicinoids was accompanied by a decrease in both liver cholesterol and atherosclerotic plaque. The result regarding the effect of capsaicinoids on plasma TC was in agreement with that of Liang et al.[13] In another study, it was found that 0.015% capsaicinoids in the diet could reduce serum TC by 23% in Sprague–Dawley rats fed a 30% fat diet.[7] In the present hamster model fed a diet containing 5% lard and 0.2% cholesterol, we found that reduction in plasma TC could reach 16%.

To explain why capsaicinoids but not capsinoids could decrease plasma TC, we quantified the excretion of fecal total sterols. It was clear that both capsaicinoids and capsinoids had no significant effect on the excretion of fecal neutral sterols. However, only capsaicinoids but not capsinoids could increase the excretion of fecal bile acids (Table 4). To be specific, it was found that dietary capsaicinoids at 1.3 and 2.6 mmol in the diet could increase the excretion of fecal bile acids by 28 and 175%, respectively. The present result was in agreement with that of Zhang et al., who found that the gavage of capsaicinoids at 10 mg/kg body weight could increase the excretion of fecal bile acids by 13% in rats given a 2% cholesterol diet.[21] In contrast, no significant effect of capsinoids on the excretion of fecal bile acids was seen. Because excess cholesterol in mammals is usually disposed of via bile fluid duct or by conversion to bile acids, the increase in bile acid excretion is likely the primary mechanism underlying the plasma TC-reducing activity of capsaicinoids.

Capsaicinoids have been shown to decrease atherosclerotic plaque and possess some beneficial effect on aortic function.[13,21] To ascertain if capsinoids also had similar activity, we studied the vasodilatory effect of both capsaicinoids and capsinoids in the mesenteric arteries from rats. It was clear that only capsaicinoids but not capsinoids beneficially induced the relaxation of mesenteric arteries. Moreover, acute treatment of capsaicinoids triggered a favorable increase of intracellular $Ca^{2+}$ concentration in endothelial cells, which in turn promotes nitric oxide formation and causes endothelium-dependent relaxation. It has been shown that the favorable effect of capsaicinoids on the aorta is at least in part mediated by their inhibition on either activity or expression of cylco-oxygenase 2 (COX-2).[13] Up-regulation of COX-2 is associated with endothelial dysfunction, atherosclerotic plaque, and inflammation.[22]

In summary, capsaicinoids and capsinoids are naturally present in chili or sweet peppers; however, their biological properties differ in many ways. Under the present physiological conditions, capsaicinoids were able to favorably modulate plasma lipoprotein profile and possess beneficial vascular activity, whereas analogue capsinoids had no such properties. It was therefore concluded that nonpungent capsinoids could not be used as an alternative of pungent capsaicinoids in relation to their favorable modification of plasma lipids and cardiovascular benefit.

# Chemical and Thermal Characterization of Potato Peel Waste and Its Fermentation Residue as Potential Resources for Biofuel and Bioproducts Production

Shaobo Liang[†] and Armando G. McDonald*[,†,‡]

[†]Environmental Science Program, University of Idaho, Moscow, Idaho 83844-3006, United States

[‡]Department of Forest, Rangeland and Fire Science, University of Idaho, Moscow, Idaho 83844-1132, United States

**ABSTRACT:** The growing demand for renewable fuels has driven the interest in the utilization of alternative waste materials such as potato peel waste (PPW) which contains fermentable carbohydrate. Fermentation of PPW using a mixed microbial consortium yielded about 60% unreacted PPW fermentation residue (PPW-FR). The PPW and PPW-FR were characterized by a combination of Fourier transform infrared (FTIR) and nuclear magnetic resonance (NMR) spectroscopies, gas chromatography−mass spectrometry (GC-MS), and thermogravimetric analysis (TGA) to quantify changes after fermentation. Fermentation of PPW resulted in fermentation of starch and concentrating lignin plus suberin and lipids in PPW-FR. TGA analysis showed that decomposition peaks differed for PPW (423 °C) and PPW-FR (457 °C). Pyrolysis-GC/MS showed an increase in phenolic and long chain fatty acid compounds with a concomitant decrease in carbohydrate derived compounds in the PPW after fermentation. Both the PPW and PPW-FR have shown potential based on properties to be converted into crude biofuel via thermochemical processes.

**KEYWORDS:** *potato peel waste, fermentation residue, chemical analysis, thermo gravimetric analysis*

## INTRODUCTION

Potatoes are the world's fourth largest crop behind corn, rice, and wheat and have experienced a steady growth over the last two decades as a stable food crop and a major source of starch.[1] According to data from the National Potato Council,[2] United States (U.S.) ranks fifth of potato producing countries with a production over 21.7 billion kg in 2011. A typical potato processing plant can generate 6−10% potato peel waste (PPW) from the peeling process,[3] and other defect removal, trimming, and cutting processes can generate an additional 15% waste. This combined waste stream can pose a significant waste management effort, and therefore, knowing this waste's composition will facilitate its utilization into bioproducts.

The composition of steam PPW was determined by Camire et al.[4] and shown to contain starch (25%), nonstarch polysaccharide (30%), acid insoluble and acid soluble lignin (20%), protein (18%), lipids (1%), and ash (6%). The lipid fraction was shown to comprise long chain fatty acids, triglycerides, alcohols, sterols, sterol esters, and phenolics.[5] Suberin, a rubbery polyester material composed of polyaromatic and polyaliphatic domains, has been found in the cell walls of potatoes.[6] Lignin, a three-dimensional polymer made up of phenylpropane units, has also been detected in the plant cell wall.[7]

PPW has been utilized in a variety of applications and traditionally has been used for local animal feed.[4,8−12] Suberin and lignin fractions have been pressure extracted from PPW to obtain value added antioxidants and bioactive chemicals.[8,9] While fermentation of PPW starch has been employed to generate alcohols and organic acids. Arapoglou et al.[10] converted PPW by sequential enzymatic hydrolysis and fermentation using *Saccharomyces cereviciae* to yield ethanol. Lactic acid has also been produced from PPW using pure cultures of *Lactobacillus* var. or *Rhizupus* var.[11,12] Recently, PPW has been directly converted to primarily lactic acid, a useful chemical building block for the production of polylactic acid, using undefined mixed microbial culture fermentation.[13,14] The advantage of using a mixed microbial system is that the fermenters do not require expensive pure cultures or sterilized conditions to operate, and the microbial community self-regulated to predominately lactic acid producing bacteria.[13] However, a significant amount of unreacted solid PPW fermentation residue (PPW-FR) was obtained in the process.[10,13,14] This PPW-FR waste will also need to be managed and forms the basis of this characterization study to maximize its utilization. Another popular option for waste management of PPW is by anaerobic digestion (AD) to produce $CH_4$ and electricity.[15] However, AD systems require large digesters based on the slow methanogenic bacterial conversion of biomass to $CH_4$ and unpleasant odor (namely, $H_2S$) generation.[15] Work by Kang and Min[16] has used PPW as a novel substrate for making biobased flexible films for packaging applications with good barrier properties.

Currently, food crops such as corn and soybean are the two predominant biomass resources widely used for liquid bioethanol and biodiesel production worldwide.[17] However, the controversy between food and fuel also promoted the utilization of other noneligible biomass materials, such as agricultural and forestry residues,[18] animal manure,[15] algae,[19]

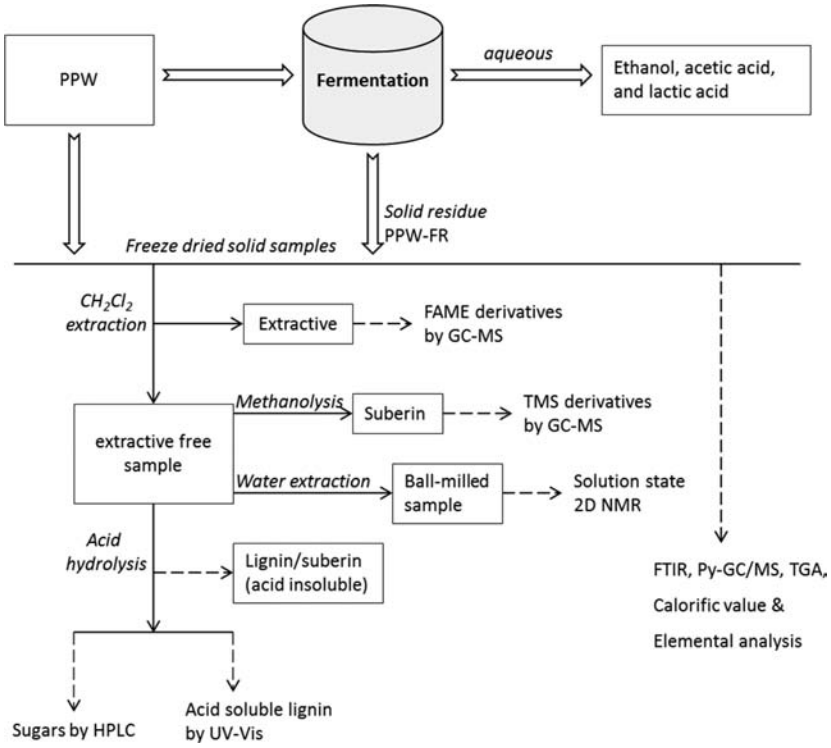

**Figure 1.** Schematic diagram of PPW and PPW-FR sample generation and analytical procedures.

and food processing wastes.[20] PPW and more recently PPW-FR are promising carbon rich waste resources for producing value added biofuels and bioproducts. Onal et al.[21] used steam pyrolysis of PPW (at 500 °C) to generate >25% bio-oil and contained significant amounts of aliphatics that could be used in transportation fuels. Biochar from pyrolyzed PPW, another coproduct, was shown to remove heavy metals from aqueous solutions.[22] These approaches to utilize PPW will minimize waste streams, reduce the carbon footprint, mitigate greenhouse gases, and generate a range of bioproducts.

The aim of this study is to characterize the chemical and thermal properties of PPW and PPW-FR, an uncharacterized bioresource, in order to target possible thermochemical processes, such as pyrolysis, for conversions of these wastes into biofuel and bioproducts. A combination of characterization techniques was employed, and the results of this study can be used in future work to evaluate the pyrolysis based biofuel and bioproduct production from PPW and PPW-FR.

## MATERIALS AND METHODS

**Sample Preparation.** The PPW (*Russet Burbank*) sample was collected from a potato processing plant (J.R. Simplot Company, Nampa, ID) over a 2 h period in May 2012, and the sample was mixed thoroughly and stored frozen for fermentation studies using a consistent feed stock and a portion freeze-dried for subsequent analysis. Hybrid poplar (*Populus deltoides* × *Populus tremuloides*) sample was obtained from Greenwood Resources (Portland, OR) and Wiley milled to <0.5 mm particle size.

The fermentation process primarily produced lactic acid and to a lesser extent ethanol, and acetic acid from PPW was described by Liang.[13,14] A 1 L glass bottle with an air-lock was used as a reactor, operated in sequencing batch mode with moderate mixing speed and at 35 °C. The fermenter was inoculated with 5% mixed microbial cultures (sewage sludge from Moscow Wastewater Treatment Plant, Idaho) only at the first day running. Gelatinized PPW (boiled for 30 min and cooled down) was fed daily with the same amount of mixed slurry that was drawn off and using a retention time of 2 days and solid loading of 40 g $L^{-1}$ was kept constant. Sampling was conducted after 4 weeks running to obtain a steady state, and the PPW-FR was collected over a 3−4 week period, then recovered by centrifugation, and freeze-dried for subsequent analyses. A detailed characterization flow process is shown in Figure 1. All of the results in this study were calculated on a dry weight basis biomass and measured in triplicate.

**Compositional and Calorific Analyses.** Freeze-dried samples (4−5 g) were Soxhlet extracted with $CH_2Cl_2$ (150 mL) for 16 h according to ASTM D 1108-96[23] and the extractives (lipids) were determined gravimetrically. The lignin and suberin complex was divided into acid insoluble and acid soluble fractions, and the analyses were performed on extractive free samples according to ASTM D 1106-96[24] and Schoening and Johansson,[25] respectively. Carbohydrate analysis was performed on the 2-stage acid-hydrolyzates according to ASTM E 1758-01.[26] More specifically, the dried sample (200 mg) was incubated in 72% $H_2SO_4$ (2 mL) for 1 h at 30 °C, then diluted into 4% $H_2SO_4$, and subjected to secondary hydrolysis in an autoclave (117 KPa and 121 °C) for 30 min. The hydrolyzate was filtered to obtain acid insoluble (Klason lignin + suberin) residue content gravimetrically. The hydrolysis filtrate was made up to 250 mL and an aliquot portion taken to determine acid soluble lignin (+ suberin complex) fraction content at 205 nm using an absorption coefficient of 110 L $g^{-1}$ $cm^{-1}$ (Beckman DU640 spectrometer). An aliquot portion of the hydrolyzate (5 mL) was transferred to a centrifuge tube to which internal standard (inositol, 1 mL, 0.5 mg $mL^{-1}$) and $PbCO_3$ (0.16 g) were added, mixed well, centrifuged, and the supernatant (4 mL) deionized (column of Amberlite IR-120 $H^+$ (0.5 mL) and Amberlite IRA35 $OH^-$ (0.5 mL) resins) and filtered (0.45 $\mu$m) into HPLC vials. Monosaccharides were the quantified by HPLC using two RPM columns in series (7.8 mm × 30 cm, Phenomenex) at 85 °C equipped with a differential refractive index detector (Waters Associates model 2414) on elution with 0.5 mL $min^{-1}$ water. Starch content was estimated by an enzymatic hydrolysis assay according to AACC method 76-11[27] using glucoamylase (Sigma-Aldrich) and the sugars analyzed by HPLC. More specifically, the sample (0.50 g) was dissolved in water (25 mL) and heated to 135 °C for 1 h, cooled, acetate buffer (pH 4.8, 2.5 mL) and glucoamylase (5 mL, 150 IU)

dx.doi.org/10.1021/jf5019406 | J. Agric. Food Chem. 2014, 62, 8421−8429

added to the solution, incubated at 55 °C for 2 h, and analyzed by HPLC.

The ash content was determined by furnacing samples at 600 °C according to ASTM D 1102-84.[28] The C, H, and N content was determined using a CE-440 elemental analyzer (EAI Exeter Analytical), and O content was calculated by the difference. The calorific values for pressed dried pellet samples (5.5 mm × 6.3 mm Ø) were determined by bomb calorimetry (Model 1261, Parr Instruments) according to ASTM D 5865-04.[29]

**GC-MS Analysis of $CH_2Cl_2$ Extractives and Suberin.** The $CH_2Cl_2$ extract (5.0 mg) was weighed into a 5 mL reacti-vial to which 2 mL of $CH_3OH/H_2SO_4/CHCl_3$ (1.7:0.3:2.0 v/v/v) was added, and the mixture was heated for 90 min at 90 °C to form fatty acid methyl ester (FAME) derivatives.[30] $CHCl_3$ contained 1-napthalaneacetic acid as an internal standard (50 $\mu$g mL$^{-1}$). To the cooled mixture, water (1 mL) was added, vigorously shaken, centrifuged, the $CHCl_3$ layer removed, dried through anhydrous sodium sulfate, and transferred to a GC vial. The prepared FAME derivatives were analyzed by GC-$MS_{EI}$ (FOCUS-ISQ, ThermoScientific); temperature profile, 40 °C (1 min) to 320 °C at 5 °C min$^{-1}$ with injector temperature of 320 °C, mass transfer line temperature of 325 °C, and ion source temperature of 240 °C; GC capillary column, RTx-5MS (30 m, 0.25 mm Ø, 0.25 $\mu$m film thickness, Restek). The eluted compounds were identified with authentic standards (C12, C14, C16, and C18) and by spectral matching with the National Institute of Standards and Technology (NIST) 2008 mass spectral library. The abundance of each compound was referenced against the area of internal standard.

Suberin analysis was performed on samples by $NaOCH_3$-catalyzed methanolysis and subsequent GC-MS analysis.[6] The $CH_2Cl_2$ extractive free sample (500 mg) was refluxed in freshly prepared 12 mmol L$^{-1}$ $NaOCH_3$ in dry $CH_3OH$ (50 mL) for 3 h. The reaction mixture was filtered (glass fiber paper) and the residue washed with $CH_3OH$ (25 mL) and $CHCl_3$ (25 mL). The filtrate (1 mL) in a GC vial was concentrated to dryness to which $CH_2Cl_2$ (containing anthracene as internal standard (50 $\mu$g mL$^{-1}$, 1 mL)), *N,O*-bis (trimethylsilyl)-trifluoro-acetamide containing 1% trimethylchlorosilane (50 $\mu$L), and pyridine (50 $\mu$L) were added and then heated to 70 °C for 30 min. Suberin derived trimethylsilyl (TMS) derivatives were analyzed by GC-$MS_{EI}$ (Focus-ISQ, ThermoScientific)); temperature profile, 40 °C (1 min) to 300 °C (20 min) at 5 °C min$^{-1}$ with an injector temperature of 320 °C, mass transfer line temperature of 300 °C, and ion source temperature of 240 °C; GC capillary column, RTx-5MS (30 m, 0.25 mm Ø, 0.25 $\mu$m film thickness, Restek). The eluted compounds were identified with authentic standards, literature, and by spectral matching with the NIST 2008 mass spectral library, and the abundance of each compound was referenced against the area of internal standard.

**Spectroscopy.** FTIR spectroscopic analysis was performed using an Avatar 370 spectrophotometer (Thermo Nicolet) with an attenuated total reflection (ATR) probe (ZnSe crystal). The spectra were ATR and baseline corrected using Omnic v7.0 software.

$^{13}C-^{1}H$ HSQC NMR spectroscopy was performed on a 500 MHz Bruker AVANCE 500 spectrometer. $CH_2Cl_2$ extractive free samples (10 g) were extracted with water overnight and the solid residue freeze-dried and ball-milled in a porcelain jar (0.5 L) for 14 d. The ball-milled samples (40 mg) were dissolved in dimethyl sulfoxide (DMSO)-$d_6$ (1 mL) with the aid of sonication and analyzed according to Kim et al.[31]

**Thermogravimetric Analysis.** TGA was performed on samples (4−6 mg) using a TGA-7 (PerkinElmer) instrument using a temperature program of 30 to 900 °C at a heating rate of 5, 10, 20, 30, 40 K min$^{-1}$ under $N_2$ (30 mL min$^{-1}$). TGA and differential thermogravimetry (DTG) data were analyzed using Pyris v8 software. Activation energy ($E$) and pre-exponential factor ($A$) were calculated according to ASTM E 1641-07.[32] The decomposition kinetics was assumed to be first-order to determine $E$ and $A$ by the following equations:

$$E = -\left(\frac{R}{b}\right) \times \frac{\Delta(\log \beta)}{\Delta(1/T)} \quad (1)$$

$$A = -\left(\frac{\beta'}{E_r}\right) \times R \times \ln(1-\alpha) \times 10^a \quad (2)$$

where, $R$ is the gas constant, 8.314 J mol$^{-1}$ K$^{-1}$, $b$ is the approximate derivative given by ASTM E 1641 numerical integration constants, $\beta$ is the heating rate at K min$^{-1}$, $\beta'$ is the heating rate nearest the midpoint of the experimental heating rates at K min$^{-1}$, $T$ is the temperature (K) at constant conversion, $E_r$ is the refined value of Arrhenius $E$, $\alpha$ is the conversion value of decomposition, and $a$ is the approximation integral taken from ASTM E 1641 of numerical integration constants.

**Py-GC/MS Analysis.** Samples (<0.1 mg) were injected into a quartz capillary tube and pyrolyzed at 500 °C in an inert atmosphere (He, 0.125 MPa) using a Pyrojector II unit (SGE Analytical Science) coupled to a GC-$MS_{EI}$ (FOCUS-ISQ, ThermoScientific) instrument. The compounds were separated on a RTx-5ms (30 m × 0.25 mm Ø, 0.25 $\mu$m film thickness, Restek) capillary column with a temperature program of 50 to 250 °C (10 min) at 5 °C min$^{-1}$ with an injector temperature of 255 °C, a mass transfer line temperature of 255 °C, and an ion source temperature of 240 °C. The eluted compounds were identified with the NIST 2008 library matching and by their mass spectra, and the relative abundance of each derived compound was calculated using $CO_2$ as internal standard.[30,33]

**Statistical Analysis.** Statistical analyses of obtained data were conducted by SAS 9.3 (SAS Inc., Cary, NC, USA) under analysis of variance (ANOVA) at an $\alpha$ level of 0.05 to determine significant differences between the measured properties.

## RESULTS AND DISCUSSION

**Chemical, Elemental, and Calorific Value Analyses.** Chemical, elemental, and calorific value analyses were performed to obtain base chemical properties of the PPW and PPW-FR materials and establish what classes of components have been removed by fermentation. PPW and PPW-FR compositions, elemental contents, and calorific values are given in Table 1, which were significantly different. The PPW contained approximately 17% starch and 22% nonstarch polysaccharides. It was observed that most of the starch was consumed and converted to ethanol, acetic acid, and lactic acid during fermentation leaving 2% residual starch and 20% nonstarch polysaccharides in the PPW-FR.[13,14] Lignin and

[a]The nonstarch glucan, galactan, mannan, xylan, and arabinan are listed as anhydro-sugar units present in nonstarch polysaccharides.

dx.doi.org/10.1021/jf5019406 | J. Agric. Food Chem. 2014, 62, 8421−8429

suberin complex content increased during fermentation from 22% to 37% with a concomitant removal of carbohydrate. The extractives (lipids and secondary metabolites) comprise fats, waxes, long-chain fatty acids, and alcohols, accounting for 2 and 8%, respectively, in PPW and PPW-FR. After fermentation, extractives accumulated in PPW-FR, which is in accordance with the distiller dried grains from ethanol fermentation.[34]

A decrease of ash content from 11% to 7% was observed and could be attributable to solubilization. Elemental composition analysis showed a significant difference between the PPW-FR and PPW. The C and H content increased, while the O content decreased after fermentation due to the removal of carbohydrates. The C (48%) and H (6.4%) contents in the PPW-FR were similar to hardwood biomass (48−52% C; 4.5−6.5% H) but higher than herbaceous biomass (wheat straw (43% C; 5.0% H) and corn stover (44% C; 5.6% H)).[35] A 10% increase in calorific value was observed after biomass fermentation (19.2 MJ $kg^{-1}$), and this is consistent with the higher C/H ratio obtained by other researchers on fermentation residues (19−21 MJ $kg^{-1}$)[36] and comparable to that of some hardwoods (13.5−19.4 MJ $kg^{1-}$).[35] These findings suggest that the PPW-FR could be a promising biomass resource for biofuel production.

**Compositional Analysis of Extractives and Suberin.** Lipids are an important class of compounds because they are used in biodiesel production and therefore were characterized to determine composition. The $CH_2Cl_2$ extracts were converted to their FAME derivatives and semiquantitatively analyzed by GC/MS, in which total 17 compounds ranging from C12 (lauric acid) to C30 (melissic acid) were identified (Table 2 and Figure 2). The total biomass lipid content increased from 7.5 to 14.3 mg $g^{-1}$ after fermentation. Linoleic (C18:2, 39%), palmitic (C16:0, 18%), and linolenic (C18:3, 16%) acids were the main components in PPW and were in agreement with the results from Dobson et al.[5] The levels of linoleic, palmitic, and linolenic acids increased, respectively, by 29.7%, 70.8, and 84.3% upon fermentation. Other minor (<10%) fatty acids were also found: lauric (C12:0), myristic (C14:0), pentadecanoic (C15:0), heptadecenoic (C17:0), stearic (C18:0), eicosanoic (C20:0), heneicosanoic (C21:0), docosanoic (C22:0), tricosanoic (C23:0), tetracosanoic (C24:0), hexacosanoic (C26:0) acids, montanic acid (C28:0), nonacosylic acid (C29:0), and melissic acid (C30:0). Dobson et al.[5] quantified lipids, as FAMEs, in two potato species from C14 to C24 and also detected odd numbered (C15:0, C17:0, C21:0, and C23:0) fatty acids. The total 17 fatty acids increased by 90% after fermentation, and the increasing lipids could be produced by microorganisms during fermentation.[37]

We determined the abundances of the lignin and suberin complex in the previous section at 22 and 37%, respectively, for PPW and PPW-FR. Suberin is regarded as a major constituent of potato cell walls,[6] and a further semiquantitative analysis to obtain a better content value and composition was necessary. Figure 3 shows the composition of suberin, which mainly comprised glycerol, alkanoic acids, $\alpha,\omega$-diacids, and $\omega$-hydroxyacids, as well as minor amounts of alkan-1-ols, hydroxycinnamic acids, and amino acids. Similar suberin constituents were also identified by other researchers.[38,39] Glycerol was the most abundant component in suberin at 48%, a cross-linker of the aliphatic and aromatic domains, and content is consistent with the literature.[40] Estimated suberin content was shown to increase in PPW after fermentation from 58 to 166 mg $g^{-1}$ as starch levels decreased.

**Table 2. FAME Derivatives of PPW and PPW-FR Extracts**

| no. | compound | retention time (min) | $M^+$ ($m/z$) | PPW (mg/g) | PPW-FR (mg/g) |
|---|---|---|---|---|---|
| 1 | lauric acid (C12:0) | 22.59 | 214 | 0.00 | 0.01 |
| 2 | myristic acid (C14:0) | 27.07 | 242 | 0.02 | 0.03 |
| 3 | pentadecanoic acid (C15:0) | 29.15 | 256 | 0.02 | 0.02 |
| 4 | palmitic acid (C16:0) | 31.13 | 270 | 1.37 | 2.34 |
| 5 | heptadecenoic acid (C17:0) | 33.04 | 284 | 0.01 | 0.02 |
| 6 | linoleic acid (C18:2) | 34.31 | 294 | 2.93 | 3.80 |
| 7 | linolenic acid (C18:3) | 34.43 | 296 | 1.21 | 2.23 |
| 8 | stearic acid (C18:0) | 34.86 | 298 | 0.25 | 0.38 |
| 9 | eicosanoic acid (C20:0) | 38.27 | 326 | 0.06 | 0.10 |
| 10 | heneicosanoic acid (C21:0) | 39.89 | 340 | 0.02 | 0.03 |
| 11 | docosanoic acid (C22:0) | 41.42 | 354 | 0.09 | 0.14 |
| 12 | tricosanoic acid (C23:0) | 42.91 | 368 | 0.01 | 0.02 |
| 13 | tetracosanoic acid (C24:0) | 44.34 | 282 | 0.20 | 0.28 |
| 14 | hexacosanoic acid (C26:0) | 47.07 | 410 | 0.28 | 0.58 |
| 15 | montanic acid (C28:0) | 49.61 | 438 | 0.67 | 2.61 |
| 16 | nonacosylic acid (C29:0) | 50.82 | 452 | 0.14 | 0.60 |
| 17 | melissic acid (C30:0) | 51.99 | 466 | 0.26 | 1.15 |
| | total | | | 7.54 | 14.33 |

**Spectroscopic Analysis.** FTIR spectroscopy was further used to analyze chemical functional group changes of PPW and PPW-FR, and their spectra are shown in Figure 4. The main characteristics were attributed to the presence of cellulose/starch, hemicellulose, lignin−suberin complex, and protein. A strong hydrogen bonded O−H stretching band[18] at 3329 $cm^{-1}$ and C−H ($CH_3$, $CH_2$) stretching vibration bands at 2974, 2915, and 2849 $cm^{-1}$ were observed for PPW, whereas similar characteristic bands appeared at 3339, 2917, and 2850 $cm^{-1}$, respectively, for PPW-FR. Absorption ester bands for fatty acid, hydroxy fatty acid, and diacids in lipids and suberin polymers[38] were detected at 1735 $cm^{-1}$ (C═O) and 1238 $cm^{-1}$ (−C-O-C) in PPW-FR. However, these bands were detected, at low intensity, in PPW at 1733 and 1255 $cm^{-1}$ and were reflective of lower lipid and suberin contents. These results are in agreement with the compositional analysis mentioned above. A distinct amide I C═O stretching band,[41] for protein, was detected at 1609 $cm^{-1}$ in PPW, whereas the band was shifted to 1628 $cm^{-1}$ in PPW-FR. Other functional groups associated with proteins were observed and overlapped with carbohydrate and lignin bands at 3640−3040 $cm^{-1}$ for N−H stretching and 1600−1500 $cm^{-1}$ for amide II C−N stretching and N−H bonding absorptions.[42]

In general, the absorption bands from 1600 to 1400 $cm^{-1}$ derived from C═C vibration of the aromatic ring were assigned to lignin.[43] Three distinct bands at 1515, 1452, and 1418 $cm^{-1}$ were detected in PPW-FR, while only two bands at 1514 and 1408 $cm^{-1}$ and a shoulder around 1450 $cm^{-1}$were detected in PPW. A clear absorption band at 1370 $cm^{-1}$

pyranose sugar rings (carbohydrates) in both PPW and PPW-FR samples.

2D-NMR spectroscopy was employed to nondestructively analyze PPW and PPW-FR by fully solubilizing the samples in DMSO following the approach by Kim et al.[31] and Lu and Ralph,[45] which were developed for woody biomass. This approach was out to trial to assess its suitability to characterize PPW. Figure 5 shows the 2D HSQC $^{13}C-^{1}H$ correlation spectra of ball-milled hybrid poplar, PPW, and PPW-FR samples. Most of the $^{1}H-^{13}C$ correlations in the $\delta_C/\delta_H$ 50–120/2.5–5.5 ppm region belong to polysaccharides, and the $\delta_C/\delta_H$ 100–150/6–8 ppm region is contributed by aromatic components. Hybrid poplar as a model lignocellulosic substrate exhibited significant cellulose, hemicellulose, and lignin signals, where the anomeric C/H correlation of cellulose and xylan appear at $\delta_C/\delta_H$ 103/4.4 ppm for (1 → 4)-$\beta$-D-Glc*p*, 104/4.2 ppm for (1 → 6)-$\beta$-D-Glc*p*, and 102/4.3 ppm for (1 → 4)-$\beta$-D-Xyl*p*. Correlations of lignin appear at $\delta_C/\delta_H$ 104/6.7 ppm for $C_2-H_2$ and $C_6-H_6$ in syringyl units, 111/7.0, 115/6.7, and 119/6.8 ppm for $C_2-H_2$, $C_5-H_5$, and $C_6-H_6$ in the guaiacyl

unit, respectively. Other clusters of C/H correlations for polysaccharides and lignin were also observed, and the results are in accordance with Lu and Ralph.[45] In this research, nonderivatized solution state 2D NMR was first introduced to analyze potato peel samples (Figure 5), and the NMR spectra of PPW and PPW-FR samples were quite different from those of hybrid poplar. The clusters of $^1H-^{13}C$ correlations were associated with polysaccharides, suberin, and lignin. The methyl signal appears at $\delta_C/\delta_H$ 21/2.1 ppm for the acetyl group in polysaccharides,[31] aliphatic methylenic groups ($-CH_2-$) appear at $\delta_C/\delta_H$ 29/1.4 ppm for suberin components,[39] C6 appears at $\delta_C/\delta_H$ 61/3.8 ppm for $C_6-H_6$ in cellulose and $C_\gamma$-$H_\gamma$ in $\beta$-O-4 substructures, C5 and C4 appear at $\delta_C/\delta_H$ 73−74/3.6−3.8 ppm for $C_5-H_5$ and $C_4-H_4$ correlations in cellulose, and anomeric C1 appears at $\delta_C/\delta_H$ 100/4.9−5.3 ppm for anomeric C/H of (1 → 4)-$\alpha$-D-Glc*p* and (1 → 6)-$\alpha$-D-Glc*p* in

dx.doi.org/10.1021/jf5019406 | J. Agric. Food Chem. 2014, 62, 8421−8429

starch[31,45,46] and were present in both PPW and PPW-FR. Signals attributable to lignin at $\delta_C/\delta_H$ 56/3.6−3.9 ppm (methoxyl group) and $\delta_C/\delta_H$ 115/6.5−6.8 ppm ($C_5$−$H_5$ correlation for guaiacyl) were observed only in the PPW-FR, which are in agreement with FTIR and Py-GC/MS data. Unfortunately, due to the poor spectral dispersion in the NMR spectra of PPW and PPW-FR limited chemical information was obtained. This may be due to the complex nature of PPW samples (containing protein, suberin, and lipids) as compared to that of hybrid poplar. Therefore, this approach to analyze PPW directly by NMR was not successful and may require further optimization.

**TGA/DTG Analysis.** TGA analysis was performed to examine the thermal degradation behavior of PPW and PPW-FR, which will provide useful information on the pyrolysis of these materials, such as pyrolysis temperature and decomposition kinetics. Figure 6 shows the TGA and DTG thermograms for PPW and PPW-FR samples. Thermal degradation of biomass can be classified into four regions: (i) dewatering at 50−130 °C; (ii) evaporation of volatile compounds due to degradation 130−220 °C; (iii) thermolysis/pyrolysis of polymers (depolymerization) at 220−460 °C; and (iv) char formation at >460 °C.[47,48] Thermal decomposition of the following main constituents occurs at 280−350 °C for starch; 315−400 °C for cellulose; and 220−315 °C for hemicelluloses; and starts at 250 °C for lignin and 290 °C for suberin. Two distinct peaks were observed from the DTG thermograms at 279 and 423 °C for PPW and 285 and 457 °C for PPW-FR, respectively. In addition, less char/ash was seen in the PPW-FR than PPW, which is in accordance with ash content determination. The $E$ before 70% $\alpha$ of samples at 5% conversion intervals were calculated based on ASTM methods. Generally, the $E$ values for PPW and PPW-FR were similar, where decreased trends were observed in both samples after 45% conversion. However, slightly lower values were found in PPW-FR than PPW after $\alpha$ reached 45%. The average $E$ and $A$ values were, respectively, 214 kJ mol$^{-1}$ and $9.18 \times 10^{24}$ for PPW and 209 kJ mol$^{-1}$ and $1.65 \times 10^{22}$ for PPW-FR. Similar values of $E$ and $A$ for the wheat straw sample were observed at 260 kJ mol$^{-1}$ and $2.00 \times 10^{22}$.[47] The lower $E$ in PPW-FR indicates that less energy is required for thermal decomposition and suitable for pyrolysis.[49]

**Py-GC/MS Analysis.** Py-GC/MS was used as a tool to rapidly analyze biomass samples and assess potential pyrolysis bio-oil chemical products. Py-GC/MS products of PPW and PPW-FR at 500 °C are listed in Table 3. A total of 51 pyrolysis products were identified with the main product being $CO_2$ followed by acetic acid (14% for PPW and 7.0% for PPW-FR), acetic anhydride (7.9% and 5.1%), hexadecenoic acid (5.5% and 5.5%), and phenol (5.3% and 5.7%). A range of phenolic compounds, including guaiacyl and syringyl derivatives, were observed totaling at 26.7% in PPW and 35% in PPW-FR. Long chain fatty acids and alkane were derived from lipid and suberin decomposition,[30,50] and the relative percentage increased from 22% into 28% after fermentation. The carbohydrate derived compounds decreased from 45% into 31% from PPW during fermentation. Nitrogen containing compounds (such as pyrrole, methylpyrrole, acetamide, and indolizine) derived from protein were also identified with similar relative percentages in both PPW and PPW-FR samples, which is in agreement with the C, H, and N analyses.

In this study, we have performed a comprehensive chemical and thermal characterization of PPW and PPW-FR to obtain information to improve the utilization of this resource for the production of bioproducts, via thermochemical conversion. A significant increase of lignin/suberin, C/H contents, and calorific value was observed in PPW-FR as a result of fermentation, which will provide higher levels of phenolics and long chain hydrocarbon products after thermochemical conversion. Thermal characterization by TGA and Py-GC/MS analyses indicated that PPW-FR required less energy and lower temperature for thermal conversion processes, such as pyrolysis, and more high value chemical compounds (phenolics and long chain fatty acids, alcohols, and hydrocarbons) can be recovered and upgraded catalytically to transportation fuels. The composition (high in lipids, suberin, and lignin) and thermal properties of PPW-FR, and to a lesser extent PPW, make it a promising renewable biomass for biofuel and bioproducts production. Future work will explore the thermochemical conversion of PPW and PPW-FR in an Auger reactor to produce a crude bio-oil, fractionation of the bio-oil into aqueous and nonaqueous fractions, and their characterization as biofuels.

**ABSTRACT:** The effects of lignosulfonate (SXSL) and long-chain fatty alcohols (LFAs) on the rheology and enzymatic hydrolysis of high-solid corncob slurries were investigated. The application of 2.5% (w/w) SXSL increased the substrate enzymatic digestibility (SED) of high-solid corncob slurries at 72 h from 31.7 to 54.0%, but meanwhile it increased the slurry's yield stress and complex viscosity to make the slurry difficult to stir and pump. The smallest molecular weight (MW) SXSL fraction had the strongest enhancement on SED. The SXSL fraction with large MW had a negative effect on rheology. *n*-Octanol (C8) and *n*-decanol (C10) improved the rheological properties of high-solid slurry and are strong enough to counteract the negative effect of SXSL. Furthermore, C8 and C10 clearly enhanced the enzymatic hydrolysis of high-solid corncob slurries with and without SXSL. A mechanism was proposed to explain the observed negative effect of SXSL and the positive effect of LFAs on the rheological properties.

**KEYWORDS:** *lignosulfonate, long-chain fatty alcohols, high-solid enzymatic hydrolysis, rheology, corncob slurry*

## INTRODUCTION

Enzymatic hydrolysis of lignocellulosic biomass has been recognized as a main method to depolymerize the lignocellulose into fermentable sugars for conversion to biofuels and other chemicals.[1,2] However, it still needs technological improvements to make the products of lignocellulose economically competitive.[3] The consumption of lignocellulose feedstock and enzymes and the energy inputs for pretreatment and distillation are the important factors that cause the high cost of lignocellulosic ethanol.[3,4] Economic analyses suggested that the ethanol concentration in fermentation broth should be above 4% (w/w) to make the subsequent distillation economical.[4] Therefore, enzymatic hydrolysis should be conducted at high-solid loadings to increase the concentration of sugar and ethanol and decrease the cost of distillation processes.[5,6]

However, high-solid slurries have difficulties in mixing and pumping for lack of water.[7,8] Improving the rheological properties of high-solid lignocellulosic slurry can result in economic benefits because of (1) decreased utility costs associated with pumping and mixing of slurries, (2) decreased capital costs associated with increased pump and reactor lifetimes, and (3) decreased capital costs associated with smaller reaction vessels.[9] Therefore, several chemical additives were studied for their ability to modify the rheology of lignocellulosic biomass, including polymers, proteins, and nonionic, anionic, and cationic surfactants.[10] Although anionic surfactants, such as sodium dodecyl benzenesulfonate and sodium dodecyl sulfonate, were very effective at reducing the yield stress, their presence was very detrimental to the enzymatic hydrolysis of high-solid cellulosic slurries.[10]

Meanwhile, the enzymatic hydrolysis efficiency of lignocellulosic substrate at high-solid loading is always lower than that at low-solid loading.[11] Increasing the enzymatic hydrolysis efficiency of lignocellulose at high-solid loading can reduce the consumption of substrate and enzymes to decrease the production cost. Therefore, a low-cost additive with strong improvement on the rheology properties and enzymatic hydrolysis efficiency of high-solid lignocellulosic slurry is urgently required to lower the cost of lignocellulosic ethanol.

In previous studies, we have reported that lignosulfonate (SXSL), as an anionic polymeric surfactant from pulping waste liquor of the papermaking industry, has the potential to increase the enzymatic hydrolysis efficiency of low-solid lignocellulose through reducing the nonproductive binding of cellulose and improving the cellulase adsorption on cellulose.[12−14] However, the effect of SXSL on enzymatic hydrolysis efficiency of high-solid lignocellulose has not been discovered. Especially, the adsorption of SXSL on lignin could increase the hydrophilicity and negative charge of lignocellulose substrate.[12] The former would increase the slurry viscosity; the latter would decrease it. Therefore, the effect of SXSL on the rheology properties of high-solid lignocellulose slurry should be explored for its application.

On the other hand, long-chain fatty alcohols (LFAs) could improve the physicochemical properties of calcium lignosulfonate solution, such as dynamic and equilibrium surface tension

and apparent viscosity.[15,16] It has been found that LFAs could improve the enzymatic hydrolysis of lignocellulose and the rheology properties.[14] Synergistic effects between SXSL and LFAs on the improvement of enzymatic hydrolysis and the rheology properties of high-solid lignocellulosic slurries could be expected.

In China, >20 million tons of corncobs are generated annually.[17] Corncob is an important feedstock for xylose and xylitol production due to its high xylan content. The xylan fraction of corncob can easily be hydrolyzed into xylose by diluted acids.[18] The cellulose and lignin fractions remain in the solid residue. Currently, approximately half a million tons of corncob residues are produced annually,[17] which are usually burned to get heat energy. Because the upstream diluted acid hydrolysis has greatly removed its hemicellulose fraction and destroyed its lignocellulose cell wall structure and its cellulose content is >60%,[17,19] it is a cheap raw material for ethanol and biorefinery and needs no pretreatment.

This study is focused on the effects of SXSL and LFAs on the enzymatic hydrolysis and rheology of high-solid corncob residue slurry. The objectives are (1) to investigate the synergistic effects between SXSL and LFAs on enzymatic hydrolysis and rheology and (2) to discover the effect of SXSL molecular weight on enzymatic hydrolysis and rheology.

## MATERIALS AND METHODS

**Substrates.** Brown corncob residue particles were provided by Shengquan Corp. Ltd. (Jinan, Shandong province, China). Prior to enzymatic hydrolysis, the corncob residues were treated at 121 °C for 1 h by autoclave and then washed by deionized water. The washed corncob residues were directly used for enzymatic liquefaction and hydrolysis without sieving. The chemical composition of the washed corncob residues was analyzed and is given in Table 1.

**Table 1. Chemical Composition of Washed Lignocellulosic Substrates**

| | main carbohydrates (%) | | lignin (%) | | |
|---|---|---|---|---|---|
| substrate | glucan | xylan | acid-soluble lignin | acid-insoluble lignin | ash (%) |
| washed corncob residue | 74.40 | 0.08 | 0.72 | 18.84 | 1.18 |

**Additives.** Lignosulfonate was produced from sulfite pulping of poplar wood by Shixian Papermaking Corp. Ltd. (Yanbian, Jilin province, China). SXSL was separated into four fractions by an ultrafiltration apparatus (Wuxi Membrane Science and Technology Corp., China). The fractions with molecular weight (MW) ranges of >50000 (SL1), 10000−50000 (SL2), 2500−10000 (SL3), and <2500 (SL4) were used. Table 2 shows the properties of all MW fractions used in this study. Long-chain fatty alcohols (*n*-octanol and *n*-decanol, AR) were purchased from Tianjin Kemiou Chemical Reagent Co., Ltd.

**Enzymes.** Commercial cellulase enzyme Cellic CTec2 (abbreviated CTec2) derived from the fungus *Trichoderma reesei* (*Hypocrea jecorina*) was generously provided by Novozymes North America (Franklinton, NC, USA). The cellulase activity was 150 filter paper units (FPU)/mL as determined according to a literature method,[20] and its protein concentration was 73.6 mg/mL by using the Bradford method.[21]

**High-Solid Enzymatic Hydrolysis.** Enzymatic hydrolysis of corncob residues was conducted at 13% (w/w) solid loading with acetate buffer (50 mM) in a shaker (DDHZ-300, Jiangsu Taicang equipment factory, China) at 50 °C and 200 rpm. The dosage of SXSL and LAFs by weight was on an oven-dry substrate basis. The pH of the slurries was adjusted to 4.8. The CTec2 loading was 3 FPU/g glucan. Aliquots of 1 mL were taken at 72 h for glucose analysis after centrifugation at 10000 rpm for 10 min. Glucose in enzymatic hydrolysates was measured with a commercial SBA-40E biosensor by a $H_2O_2$ electrode sensor (Institute of Biology of the Shandong Academy of Sciences, China). Control experiments without substrates were also carried out for comparison. Substrate enzymatic digestibility (SED), defined as the percentage of substrate glucan enzymatically hydrolyzed to glucose, was used to represent the enzymatic hydrolysis efficiency. Each data point is the average of two analyses. The experimental error in enzymatic hydrolysis was <2.5% based on replicate runs. Error bars are shown in the figures.

**Rheometry.** High-solid lignocellulosic slurries were prepared with sieved corncob (40 mesh) and acetate buffer (50 mM, pH 4.8) without cellulase, and their rheological properties were investigated at 25 °C by a Haake Mars-III rotational rheometer (Thermo Scientific, Germany) with vane-in-cup geometry. The average particle diameter was 118.4 ± 6.4 μm measured by using an MS2000 laser diffraction particle size analyzer (Malvern Instruments, Malvern, UK). The cup diameter was 26 mm, and the vane diameter was 22 mm, resulting in a gap width of 1 mm.

## RESULTS AND DISCUSSION

**Effect of Lignosulfonate on Enzymatic Hydrolysis Efficiency and Rheology of High-Solid Corncob Slurries.** Lignocellulosic residues from corncob by acidolysis to convert xylan into furfural were enzymatically hydrolyzed with SXSL dosage on dry substrate ranging from 0.25 to 5.0% at a high-solid dry content of 13% (Figure 1). The enzymatic hydrolysis was conducted at a CTec2 loading of 3 FPU/g glucan and 50 °C in acetate buffer of pH 4.8. The addition of 2.5 and 5.0% SXSL increased the SED of corncob residues at 72 h from 31.7 to 54.0 and 67.7%. This result was consistent with the enhancement of lignosulfonate on the enzymatic hydrolysis of softwood and hardwood substrates in our previous studies at a low-solid dry content of 2%.[12,13] This indicated that lignosulfonate could be used to improve the enzymatic hydrolysis efficiency of high-solid lignocellulosic slurries. The enhancement on enzymatic hydrolysis of high-solid lignocellulosic substrate increases with the dosage of SXSL.

Lignosulfonate is an amphiphilic polymer with hydrophobic phenylpropanoid backbone linked to the hydrophilic sulfonate group. It was proved that lignosulfonate would bind to solid

**Table 2. Properties of the Four Lignosulfonate Fractions Used**

| sample label | MW (Da) | weight percentage | sulfonic acid group (mmol/g) | lignosulfonate content (%) | glucose content (%) | conductivity[a] (ms/cm) |
|---|---|---|---|---|---|---|
| SXSL | 9900 | 100 | 2.11 ± 0.04 | 49.60 | 3.63 | 1.66 |
| SL1 | 19900 | 42 | 1.67 ± 0.01 | 100 | 0 | 0.13 |
| SL2 | 6000 | 22 | 1.98 ± 0.02 | 86.03 | 0 | 0.47 |
| SL3 | 4300 | 18 | 2.44 ± 0.07 | 63.11 | 0.32 | 1.23 |
| SL4 | 2360 | 18 | 2.96 ± 0.05 | 16.23 | 9.85 | 6.77 |

[a]Conductivity was measured in lignosulfonate aqueous solution for which the concentration was the same with the high-solid corncob slurries.

dx.doi.org/10.1021/jf502534s | J. Agric. Food Chem. 2014, 62, 8430−8436

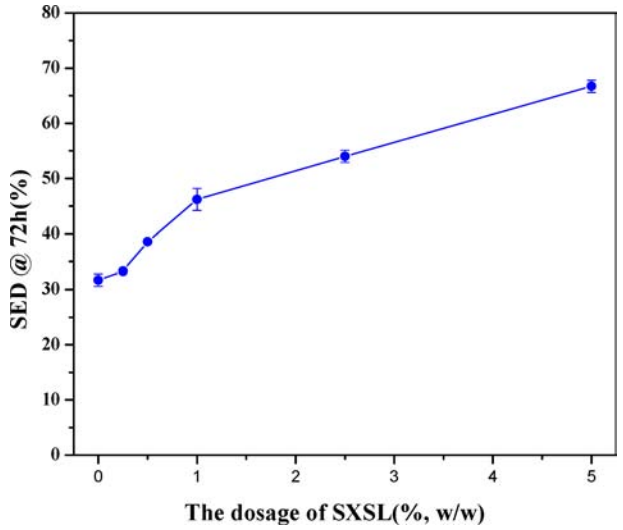

**Figure 1.** Effects of dosage of lignosulfonate on SED of high-solid corncob slurries at 72 h.

lignin in substrate by hydrophobic interaction to reduced nonproductive cellulase binding to lignin to improve the enzymatic hydrolysis in previous studies.[13,18,22] Lignosulfonate is more hydrophilic than lignin in substrate because of its higher sulfonic acid group content. The application of lignosulfonate may increase the hydrophilicity of substrate by covering the surface of lignin in substrate and modifying the viscosity and rheology of corncob slurries.

Transient flow rheometer experiment is a reliable measurement of the yield stress for high-solid lignocellulosic slurries.[10] The stress−strain measurements of Figure 2a were taken at a shear rate of 0.01 $s^{-1}$, as low as that in other studies.[10] Considering the inhomogeneity of high-solid slurries, these experiments were carried out in duplicate to ensure the repeatability. As shown in Figure 2a, the shear stress initially increases linearly with the vane displacement as the slurries are elastically deformed. The shear stress reaches a peak when plastic deformation dominates and then declines as the slurries are plastically deformed. The peak shear stress in these measurements is an indication of the characteristic yield stress of the slurry. The yield stress of the control slurries ranged from 72.3 to 82.7 Pa, averaging 77.5 Pa. The application of 2.5% SXSL nearly doubled the yield stress, increasing to about 140 Pa. Results of the oscillatory frequency sweeps are shown in Figure 2b. The complex viscosity is an essential parameter to characterize the rheological properties of a viscoelastic slurry, which does not vary with oscillatory stresses in the linear viscoelastic region. Slurries with a low value of complex viscosity are relatively "soft" and more easily deformed, whereas slurries with a high value of complex viscosity tend to be considered "hard" and deformation is more difficult.[10] As shown in Figure 2b, the addition of SXSL generally provided a small increase in the complex viscosity of the high-solid corncob slurries.

Although SXSL improved the enzymatic hydrolysis of high-solid corncob slurry, it increased the slurry's viscosity, which would produce a higher mixing and pumping power to increase the cost. Therefore, it needs to develop a way to decrease the viscosity of high-solid corncob slurries with application of SXSL.

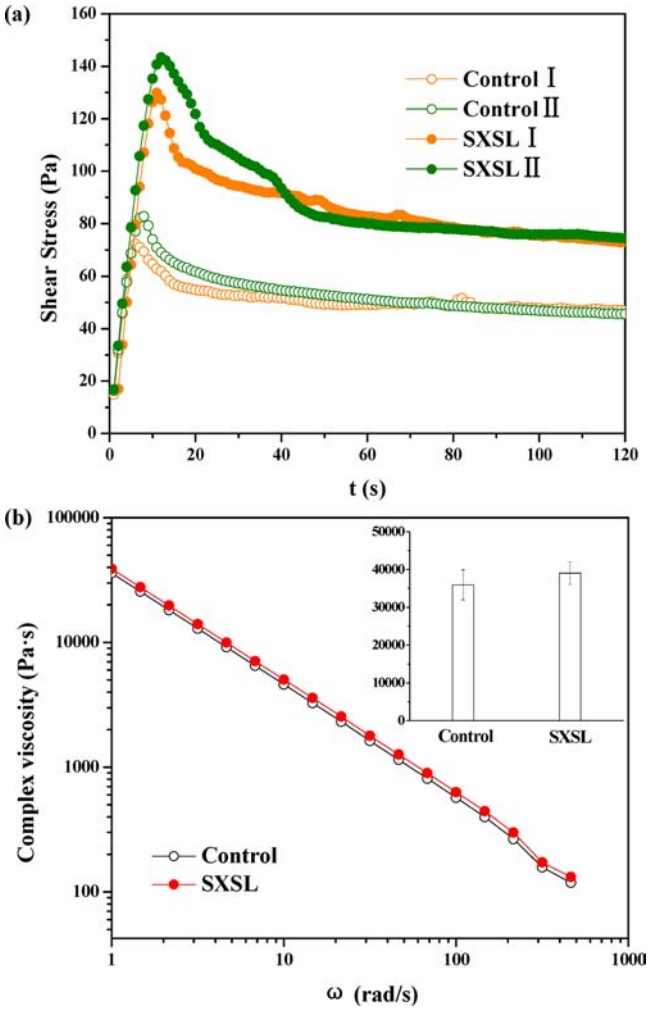

**Figure 2.** Effects of SXSL on the rheology of high-solid corncob slurries: (a) typical transient flow curves of control slurries and those with added 2.5% (w/w) SXSL (multiple flow curves are shown for each condition to show the reproducibility of the method); (b) typical oscillatory frequency sweep recorded from control suspensions and those with added 2.5% (w/w) SXSL using 10 Pa stress; (inset) complex viscosity on a linear scale with $\omega$ at 1 rad/s.

**Effect of LFAs on the Rheological Properties with SXSL.** LFAs derived from plant oils or fats by hydrolysis and catalytic hydrogenation[23] have been observed to enhance the enzymatic hydrolysis of crystalline cellulose and improve the rheological properties of high-solid lignocellulosic slurry in our previous studies.[14] LFAs were applied to improve the rheological properties of high-solid corncob slurries with the addition of SXSL. The effect of LFAs on the yield stresses and complex viscosity of the corncob slurries at dry content of 13% are shown in Figures 3 and 4. The application of 2.5% (w/w) C8 and C10 clearly reduced the shear stress at a shear rate of 0.01 $s^{-1}$ (Figure 3a), and the yield stress decreased from 136.7 to 86.7 and 58.7 Pa, as shown in Figure 3b. Meanwhile, C8 and C10 reduced the complex viscosity at the rotating speed range from 1 to 100 rad/s (Figure 4a). The complex viscosity at 1 rad/s decreased from 39060 to 21850 and 14770 Pa·s (Figure 4b), and the yield stress and complex viscosity of the high-solid corncob slurry with 2.5% SXSL and 2.5% C10 was lower than those without SXSL and C10. The results indicated that LFAs could improve the rheological properties of high-solid corncob

dx.doi.org/10.1021/jf502534s | J. Agric. Food Chem. 2014, 62, 8430−8436

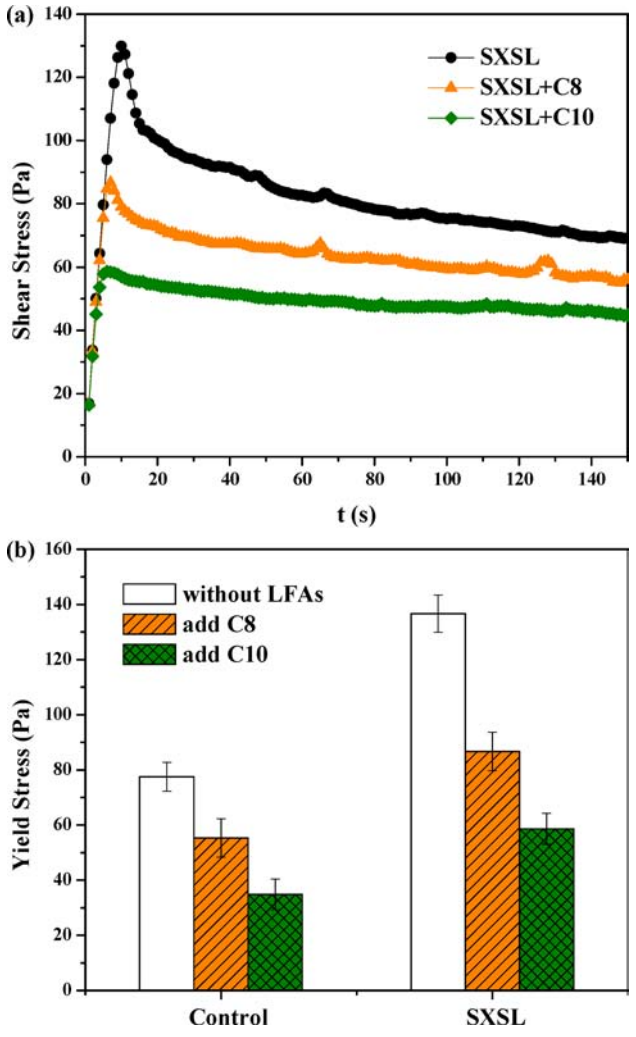

**Figure 3.** Effects of LFAs on the yield stress of high-solid corncob slurries at additives' concentration of 2.5% (w/w): (a) typical transient flow curves; (b) yield stresses of high-solid corncob slurries.

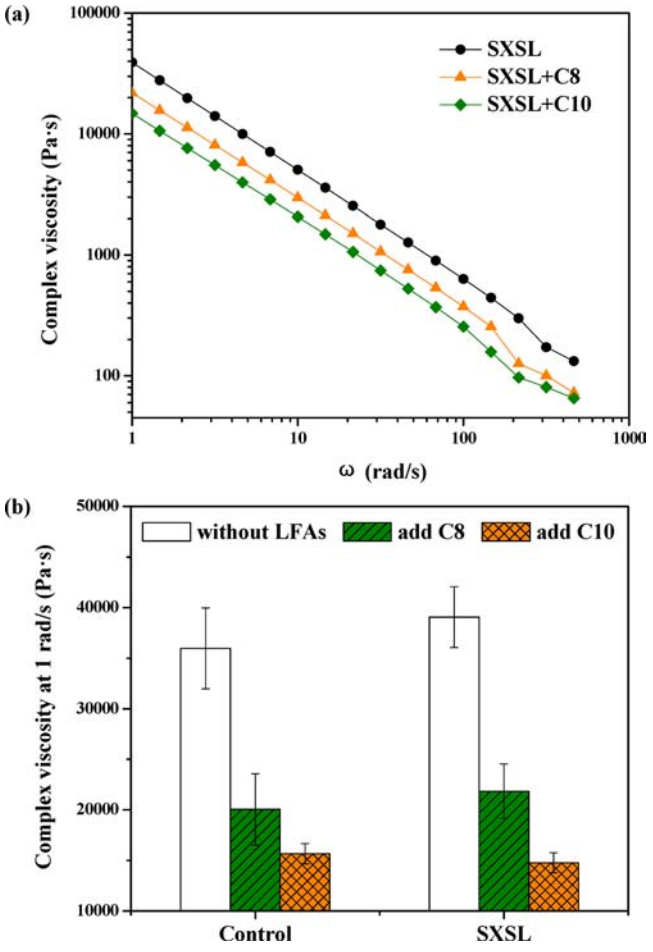

**Figure 4.** Effects of LFAs on the complex viscosity of high-solid corncob slurries at additives' concentration of 2.5% (w/w): (a) oscillatory frequency sweep; (b) complex viscosity of high-solid slurries on a linear scale with $\omega$ at 1 rad/s.

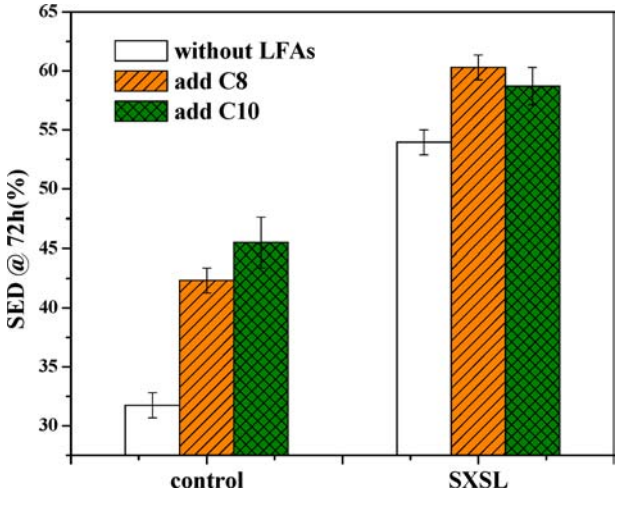

**Figure 5.** Effects of C8 and C10 on SED of high-solid corncob slurries at 72 h.

slurry with and without the application of lignosulfonate. The improvement of LFAs increases with the carbon chain length, and 2.5% C10 is enough to counteract the negative effect of 2.5% lignosulfonate on high-solid corncob slurry.

**Effect of LFAs on the SED of High-Solid Corncob Residues with SXSL.** The effects of C8 and C10 on the SED of high-solid corncob slurries at 72 h are shown in Figure 5. In the absence of SXSL, 2.5% C8 and C10 increased the SED at 72 h from 31.7 to 42.3 and 45.5%, respectively. This observed enhancement agrees with our previous study.[14] In the presence of 2.5% SXSL, 2.5% C8 and C10 increased the SED at 72 h from 54.0 to 60.3 and 58.7%, respectively. These results indicated that LFAs could improve the enzymatic hydrolysis of high-solid corncob slurry with and without lignosulfonate.

**Lignosulfonate MW Effects on the Enzymatic Hydrolysis and Rheology of High-Solid Corncob Slurries.** Four SXSL fractions prepared by ultrafiltration were applied to compare the enzymatic hydrolysis efficiency and rheological properties of high-solid corncob slurry at the same loading of 2.5% with and without LFAs. The SXSL fraction concentrations were corrected by UV measurement. As shown in Figure 6, in the absence of LFAs, all SXSL fractions enhanced the enzymatic hydrolysis of high-solid corncob, in agreement with the observed enhancement of woody substrate at dry content of 2% in our previous study.[13] The order of enhancement at 72 h is SL4 > SL3 ≈ SL2 > SL1. The small MW fraction SL4 doubled the SED of corncob slurries at 13% from 31.7 to 63.5%. In the presence of SXSL fractions, the application of C8

dx.doi.org/10.1021/jf502534s | J. Agric. Food Chem. 2014, 62, 8430−8436

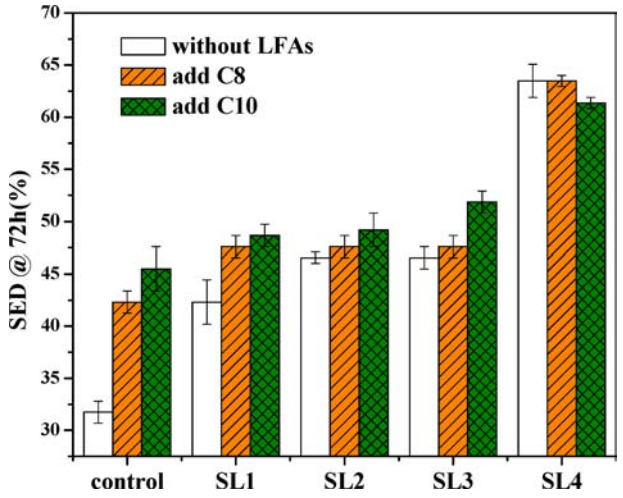

**Figure 6.** Effects of MW of lignosulfonate on SED of high-solid corncob slurries at 72 h.

and C10 improved the enzymatic hydrolysis of corncob slurries with large MW fractions of SL1, SL2, and SL3 and had negligible effect on that with small MW fraction SL4 containing much sugars and inorganic salts. The mechanism of lignosulfonate enhancement on enzymatic hydrolysis mainly includes the effect on cellulase nonproductive adsorption on lignin[12,24] and the effect on enzymatic hydrolysis of pure cellulose.[25] It has been found that lignosulfonate could efficiently reduce the cellulase nonproductive adsorption on lignin in lignocellulosic substrate by increasing the lignin surface hydrophilicity and by electrostatic repulsion between lignosulfonate adsorbed on lignin and cellulase.[12,26] SXSL fraction with higher MW had a stronger blocking effect on cellulase nonproductive adsorption on lignin due to its larger adsorption on lignin. On the other hand, the concept of "lignosulfonate-cellulase aggregate stabilized and enhanced cellulase binding to cellulose" has been proposed to explain the lignosulfonate enhancement on enzymatic hydrolysis of pure cellulose in our previous study.[25] SXSL fraction with lower MW had stronger enhancement on pure cellulose by increasing the cellulase adsorption at a buffer pH of 4.8 and with a relatively low dosage. In the high-solid corncob slurry, the SXSL fraction effect on the cellulase adsorption on cellulose may be the dominant factor of enhancement on enzymatic hydrolysis. Therefore, SXSL fraction with lower MW had stronger enhancement on the enzymatic hydrolysis of corncob. LFAs have been found to improve the lignosulfonate adsorption on $TiO_2$ particles.[15] LFAs could improve the enzymatic hydrolysis of high-solid corncob slurry with SXSL by increasing the SXSL fraction adsorption on cellulase to stabilize cellulase binding on cellulose. SL4, the smallest MW fraction, is highly sulfonated with high negative charges. The highly negatively charged SL4–cellulase aggregates would produce sufficiently strong electrostatic repulsion between the aggregates on cellulose to limit the cellulase adsorption on cellulose, even if LFAs could improve the formation of SL4–cellulase aggregates. Therefore, LFAs have negligible enhancement on the enzymatic hydrolysis of high-solid corncob with 2.5% SL4.

In addition, four SXSL fractions were applied to investigate the effect of lignosulfonate MW on the rheological properties of high-solid corncob slurry at the same loading of 2.5%. As shown in Figure 7, the largest MW faction SL1 increased the yield stress and complex viscosity of high-solid corncob slurry. SL2

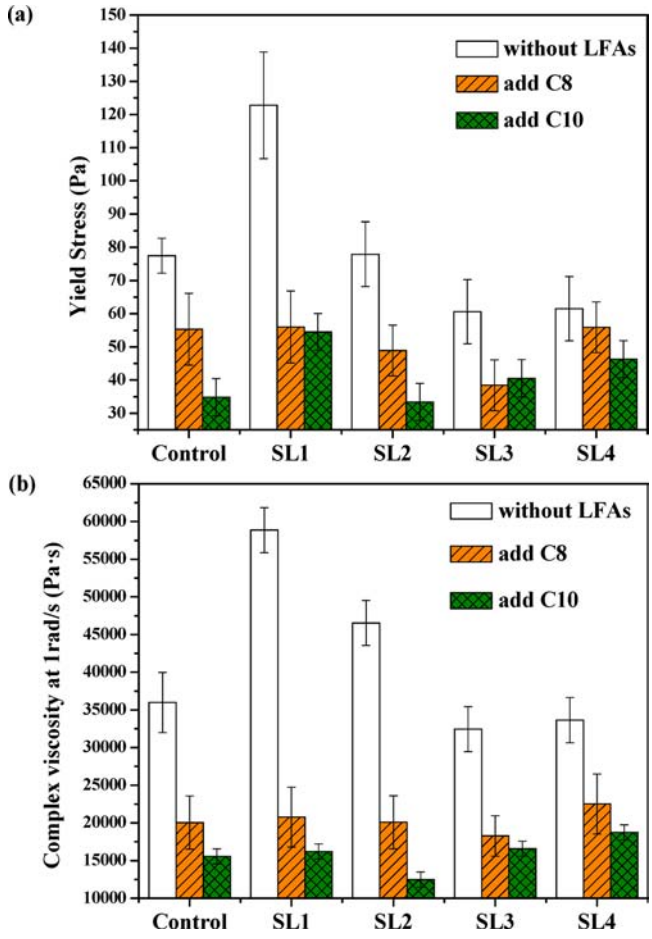

**Figure 7.** Effects of MW of lignosulfonate on rheology of high-solid corncob slurries: (a) changes in yield stresses measured via transient flow experiments; (b) changes in complex viscosity measured by typical frequency sweep on a linear scale with $\omega$ at 1 rad/s.

had negligible effect on the yield stress, but increased the complex viscosity. The small MW fractions of SL3 and SL4 slightly reduced the shear stress and yield stress. After the addition of LFAs, the yield stress and complex viscosity at 1 rad/s of the corncob slurry with SXSL fractions clearly decreased and was lower than that without the application of lignosulfonate and LFAs (control run). LFAs strongly improved the rheology of high-solid slurry with SL1 loaded and made it similar to other fractions. Furthermore, C10 has a stronger reduction in the yield stress and complex viscosity than C8.

**Mechanism Understanding of Lignosulfonate and LFAs on Rheology of Lignocellulosic Substrate.** The negative effect of SXSL on the rheological properties of corncob slurries could be explained using a cartoon shown in Figure 8. In the absence of lignosulfonate, lignocellulose would absorb water through hydrogen bonding between hydroxyl groups in cellulose or hemicellulose and water molecules. A hydration layer would form on the surface of cellulose and hemicellulose parts in lignocellulosic substrate. Because lignin is more hydrophobic than cellulose and hemicellulose, it is difficult to form a hydration layer on the lignin surface in lignocellulose. After adding lignosulfonate, lignosulfonate can be adsorbed on the surface of lignin by $\pi-\pi$ interactions between aromatic rings in lignin and lignosulfonate[27] and hydrophobic interactions.[12] The hydrophilic part (e.g., sulfonic

dx.doi.org/10.1021/jf502534s | J. Agric. Food Chem. 2014, 62, 8430–8436

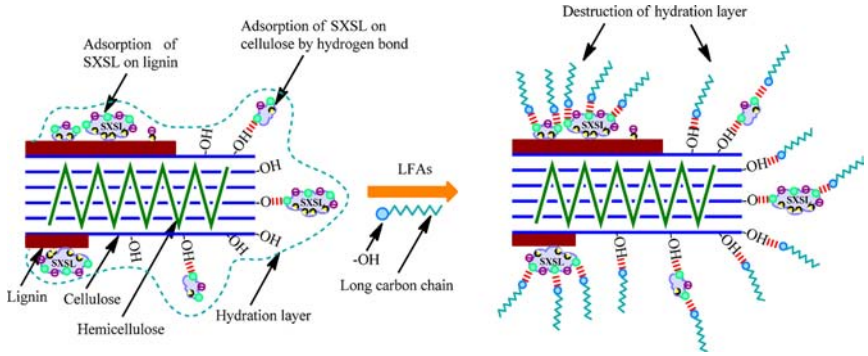

**Figure 8.** Schematic diagram of the effect of lignosulfonate and LFAs on the rheological properties of high-solid lignocellulosic slurries.

acid group, hydroxyl group, carboxyl group) of lignosulfonate would face toward water and make the lignin surface hydrophilic. Thus, the lignosulfonate on lignin surface would adsorb water in the slurry and form a hydration layer. As a result of the reduction of free water in the slurry, the rheological properties would become poor, such as the observed increment of yield stress and complex viscosity. On the other hand, lignosulfonate can be adsorbed on the cellulose surface to disrupt the network of high-solid lignocellulose slurry formed among the lignocellulose particles by hydrogen bonds, which made lignocellulose particles negatively charged and dispersive to improve the rheology. However, the yield stress measured at a very low shear rate of 0.01 $s^{-1}$, which is too slow to disrupt the lignocellulose network in slurry, increased significantly due to the reduction of free water with the application of lignosulfonate. Because the adsorption amount of lignosulfonate fraction on lignin increases with its MW,[12] more SL1 and free water would be adsorbed on lignin to result in a more negative effect on the rheological properties. Complex viscosity measured at a high rotating speed of 1 rad/s, equivalent to 1100 times that in yield stress measurement, was affected not only by the reduction of free water but also by the dispersion improvement. As a balanced result, there is a small increase in the complex viscosity after the addition of lignosulfonate.

LFAs are composed of a long alkyl chain and a hydroxyl group. LFAs would bind to the hydroxyl group on cellulose, hemicellulose, lignin, and lignosulfonate on lignin through hydrogen bonding. The alkyl chain in LFAs would make the lignocellulose surface more hydrophobic and destroy the hydration layers around cellulose and lignosulfonate, freeing water molecules and improving the rheological properties of high-solid lignocellulosic slurry.

Lignosulfonate enhanced the enzymatic hydrolysis of high-solid corncob slurry, and the enhancement increased with the decrease of the MW. Lignosulfonate with high MW and low sulfonation degree increased the slurry's yield stress and complex viscosity to make it difficult to stir and pump. LFAs including C8 and C10 could clearly decrease the yield stress and complex viscosity with and without lignosulfonate and be strong enough to counteract the negative effect of lignosulfonate. Both the negative effect of lignosulfonate and the positive effect of LFAs on rheology may be attributed to the hydrophobicity change of lignocellulose particles. Furthermore, LFAs would improve the enzymatic hydrolysis of high-solid corncob slurry with and without lignosulfonate, but further investigation is needed to better understand the synergistic effect mechanism between LFAs and lignosulfonate on the enhanced enzymatic hydrolysis of lignocellulose.

**ABSTRACT:** This study was performed to evaluate and compare the effects of different pre-treatments of whole grape berries (freezing with dry ice or in a cold room, steam blanching with different exposure times, and microwave heating with different exposure times and microwave power density) on total content of some phenolic compounds and the composition of individual anthocyanins released into the pulp during the treatment and those extracted during the maceration step. Two red winegrape varieties with different proportions of di- and trisubstituted anthocyanins were used (Nebbiolo and Barbera, respectively). Pulp-extracted anthocyanins were more significantly influenced by the pre-treatment. The results highlighted that freezing with dry ice, followed by freezing in a cold room and steam blanching for 5 min, have a great potential from an industrial point of view. They facilitated the extraction of anthocyanins in the must prior to maceration, when compared with the control samples, increasing their total content (+37.8−83.6%), and modifying the anthocyanin profile through the enrichment in the most stable compounds (+2.8−6.6% malvidin derivatives) to the detriment of others more prone to oxidation (−0.8−11.0% cyanidin derivatives). In Nebbiolo winegrapes, an improved extraction of low- and high-molecular weight flavanols into the pulp was also observed (+60.4−73.4%). Significant relationships between the phenolic composition of treated berries and the corresponding skin mechanical properties were also studied, but they were variety dependent. Discriminant analysis permitted a correct classification of the samples according to the variety and pre-treatment.

**KEYWORDS:** *grape pre-treatments, anthocyanins, flavanols, extraction, skin mechanical properties, dry ice, microwave*

## INTRODUCTION

The biosynthesis of grape anthocyanins depends on several factors, including maturity, climate, seasonal variations, soil, variety and viticultural practices.[1−3] Nevertheless, the grapevine genome determines the characteristic anthocyanin profile of each variety. In fact, the anthocyanin fingerprinting enables the chemotaxonomic differentiation of red winegrape varieties.[4−7]

The degradation of the cell-wall polysaccharide structures during grape ripening is a fundamental step to increase the release of anthocyanins from grape skins during winemaking, and the chemical composition of berry skin cell walls at harvest is important for the anthocyanin extractability.[8−10] On the other hand, the mechanical properties of berry skin also influence the anthocyanin extraction from the grape skin into the must/wine. Therefore, the anthocyanin extraction can be successfully predicted by instrumental texture analysis. In particular, the berry skin break force can be considered the best mechanical parameter to estimate anthocyanin extraction kinetics with adequate reliability.[11]

However, these colored compounds are only partially extracted during fermentation/maceration. In the initial phase of maceration, 3′-hydroxylated anthocyanins are preferentially extracted from winegrape varieties with hard skins and may be easily oxidized by the enzymes present in the juice.[12] Once released, anthocyanin compounds suffer chemical reactions (oxidation, hydrolysis, cycloaddition, condensation, and polymerization), may be adsorbed by the yeasts, and also fixed again onto the solid parts of the grapes. This affects the color stability and taste of the must/wine. Particularly, the formation of flavanol−anthocyanin complexes promotes the color stability and contributes favorably to the sensory characteristics by decreasing the astringency perception.[13,14] Therefore, the extraction of flavanols is also of great relevance for the color of the final product.

Alternative techniques to traditional maceration have been used to promote the diffusion of phenolic compounds from the berry skin and their solubilization in the must. The rate and extent of the extraction of anthocyanins and proanthocyanidins are influenced by the enological technique applied.[15] In particular, the use of pectolytic enzymes, maceration temperature and time, and ethanol content affect the cell and membrane permeability in grape berries.[16−21]

Grape freezing and heat treatment prior to crushing do not constitute maceration techniques themselves but are possible pre-treatments aiming at the preparation of the grapes to

ACS Publications © 2014 American Chemical Society

encourage release of phenolic compounds from the skins. Grape freezing causes the berry cells to burst, breaking the cell membranes and thus releasing preferentially water-soluble compounds into the must.[22] Consequently, the anthocyanin extraction from the skins is enhanced.[18,23−25] The thermal treatment of grape berries also damages the hypodermal cell membranes, favoring preferential anthocyanin release into the must.[22] Nevertheless, some authors reported that the heat can cause partial thermal degradation of anthocyanins[26] and adverse effects on the sensory attributes of the final product.[27]

The use of microwave heating as an alternative to conventional grape blanching and drying has been recently reported in the literature.[27−29] Moreover, the advantages of microwave-assisted extraction of anthocyanins in alcoholic and/or acidic medium from grape skins have been investigated.[30,31] Microwave energy has a high penetration power, which allows rapid heating throughout the sample while reducing both the exposure time and the impact of temperature on thermolabile compounds and sensory characteristics.[32] Lin and Brewer[33] also demonstrated that microwaves enable an efficient heat transfer with little or without water, which reduces nutrient losses compared with the traditional method. In fact, microwave hydrodiffusion permits the rapid juice extraction by internal heating of the water present inside the grape until its boiling point because of the expansion of the cells and consequent cell-wall rupture.[34] The same principle could be applied to the release of the cell constituents into the surrounding juice enhancing the extraction efficiency. In this sense, many attempts were carried out to produce a grape juice enriched in polyphenols.[35]

The new enological trends aim at implementing the production of high-quality red wines and colored juices from the exploitation of the intrinsic chromatic characteristics of the grapes and their preservation in the final product. Therefore, the aim of this work was to evaluate and compare the impact of different treatments on winegrapes prior to crushing, such as grape freezing, steam blanching, and microwave heating, on the skin mechanical properties and the extraction of anthocyanins from red winegrapes. Many experimental conditions influencing the anthocyanin release from berry skins were investigated. In particular, the study was carried out on *Vitis vinifera* L. cv. Nebbiolo and Barbera to assess the effect in grape berries with a high proportion of di- and tri-substituted anthocyanins, respectively, because of the different trends of these compounds to be lost during winemaking. Given the relevance for color, the extraction of low- and high-molecular weight flavanols from the skin was also evaluated. These are important and well-known Italian varieties, giving grapes used for the production of renowned red wines that are commercialized worldwide.

## MATERIALS AND METHODS

**Grape Samples.** Twenty whole bunches of red grape cultivars *Vitis vinifera* L. cv. Nebbiolo and Barbera were harvested at technological maturity (24.0°Brix, 8.41 g/L tartaric acid and 24.3°Brix, 6.66 g/L tartaric acid, respectively) from as many vines in commercial vineyards located in the same growing zone (Piedmont, Cuneo province, northwest Italy) in 2012. Once in the laboratory, for each variety, a subsample of approximately 1.5 kg of grapes (1000−1200 berries) was randomly selected by picking berries with attached pedicels, cut in the proximity of the receptacle, from different positions in the cluster (shoulders, middle and bottom). The presence of the pedicel prevents grape must losses. For each subsample, the berries were sorted according to their density by flotation using different saline solutions (from 100 to 190 g/L sodium chloride corresponding to densities comprising between 1069 and 1125 kg/m$^3$) and following the protocol described by Rolle et al.[2] This densimetric sorting allows obtaining more homogeneous samples and minimizing the possible ripening effect among berries. The comparative study was carried out on the berries belonging to the most representative class with a density of 1107 kg/m$^3$ and a relative weight of 60% w/w. The sorted berries were washed with water and visually inspected; those with damaged skins were discarded. For each variety studied, seven sets of 30 sorted berries (three replicates of 10 berries)[36] were randomly selected to apply the different pre-treatments, and another one of 30 sorted berries was used as control sample (untreated grapes, CS).

**Grape Pre-treatments.** Three grape pre-treatments were studied at different experimental conditions: steam blanching, freezing, and microwave heating. Each replicate of sorted berries was weighed by means of a technical balance (Gibertini E1700, Modena, Italy). Therefore, three replicates of each experiment were performed for a total of seven experiments. The grape berries were treated using the following methods.

*Steam Blanching.* The berries were treated with the vapor released during water heating at 100 °C for 1 min (HS1) or 5 min (HS5). Subsequently, the grapes were quickly cooled at 4 °C in a refrigerator down to ambient temperature (20 ± 1 °C).

*Freezing.* The berries were frozen using two different cooling methods: direct freezing in a freezer at −18 °C for 2 days (DF), or by adding 3 mm thick dry ice pellets in the same amount as the berries weight (DI) as proposed by Busse-Valverde et al.[15] for crushed grapes. Then, the grapes were defrosted at ambient temperature.

*Microwave Heating.* Microwave treatments were conducted by using a 2450 MHz microwave oven with maximum delivered power of 1000 W (Panasonic NE 1037). The berries were arranged in a single layer on the rotating glass plate and placed in the center of the oven. The treatments were performed at two different microwave power densities and exposure times using 1 W/g for 30 s (MW1D30), 1 W/g for 60 s (MW1D60), or 2 W/g for 60 s (MW2D60), thereby preventing grape must losses during the treatment.[34] The grapes were quickly cooled at 4 °C in a refrigerator down to ambient temperature.

Pulp and surface temperatures of grape berries were measured immediately after heating pre-treatments (HS1, HS5, MW1D30, MW1D60, MW2D60) employing two different techniques. Pulp temperature was measured inserting a T-type thermocouple (0.6 mm diameter and 10 mm long junction) in the center of two berries. A DeltaOHM HD32.8.16 thermocouple datalogger recoded data. Surface temperature was evaluated adopting the infrared (IR) thermography technique. IR images were acquired by an Avio TVS-500 camera and analyzed with the Goramtec Thermography Studio (GTS 4.8) software. Emissivity parameter was assessed heating a sample of ten grape berries at 30, 40, 50, and 60 °C in a thermostatic chamber and acquiring, for each condition, an IR image once the thermal equilibrium was achieved. The cooling time of the berries was evaluated considering the pulp temperature for each heating pre-treatment. In particular, the temperature was monitored during the entire cooling process, and the cooling time was assumed as the time required to the three thermocouples to achieve the temperature of 20 ± 0.5 °C. The same technique was followed to assess the thawing time for DF and DI pre-treatments and the freezing time for DI pre-treatment. In this last case, the pulp temperature of grape berries was measured until they achieved the same temperature of dry ice.

**Instrumental Texture Analysis.** A Universal Testing Machine (UTM) TA.XTplus texture analyzer (Stable Micro Systems, Godalming, Surrey, UK), equipped with an HDP/90 platform and a 5 kg load cell, was used for grape texture analysis. The berry skin hardness was assessed by a puncture test using an SMS P/2N needle probe (Stable Micro Systems), a test speed of 1 mm/s and a penetration depth of 3 mm.[37] Each berry (untreated or treated) was individually punctured in the lateral face, and two parameters were measured: skin break force (N, as $F_{sk}$) and skin break energy (mJ, as $W_{sk}$). The first variable corresponds to the skin resistance to the needle probe penetration, and the second variable is represented by the area under the force−time curve, which is limited between 0 and $F_{sk}$.[37] The use of

a needle probe allows separate estimation of this skin mechanical characteristic, minimizing the possible interferences caused by the pulp firmness on the results. All data acquisitions were made at 500 points per second, and the skin mechanical properties were calculated from force−distance curves using the Texture Exponent software package (Stable Micro Systems).

**Chemical Analysis.** Solvents of HPLC-gradient grade and all other chemicals of analytical-reagent grade were purchased from Sigma (Milan, Italy). The solutions were prepared in deionized water produced by a Purelab Classic system (Elga Labwater, Marlow, UK). Anthocyanin standards (delphinidin-3-*O*-glucoside chloride, malvidin-3-*O*-glucoside chloride, petunidin chloride, peonidin-3-*O*-glucoside chloride, and cyanidin-3-*O*-glucoside chloride), (+)-catechin, and cyanidin chloride were supplied from Extrasynthèse (Genay, France).

*Technological Ripeness Parameters.* Soluble solids concentration (°Brix) was measured using an Atago 0−32 Brix temperature compensating refractometer (Atago Corporation, Tokyo, Japan), and titratable acidity (g/L tartaric acid) was estimated using the OIV method.[38]

*Extraction and Determination of Phenolic Compounds.* Once the berries have been punctured, the berry skins were manually removed from the pulp using a laboratory spatula. The pulp was introduced into a tube containing 100 mg sodium metabisulfite, weighed, and subsequently diluted (9:1, m/m) with 5 mol/L sulfuric acid.[39] Afterward, the pulp was homogenized at 9500 rpm for 30 s with an Ultraturrax T10 high-speed homogenizer (IKA Labortechnik, Staufen, Germany) and centrifuged in a PK 131 centrifuge (ALC International, MI, Italy) for 15 min at 3000*g* at 20 °C. In the resulting solution, pulp phenolic compounds were determined in untreated berries and compared to those extracted during the grape pre-treatment. The skins were weighed and quickly immersed into 25 mL of a hydroalcoholic buffer at pH 3.2 containing 5 g/L tartaric acid, 100 mg/L sodium metabisulfite and 12% v/v ethanol. After remaining 48 h at 25 °C, the solution was used for determining extracted skin phenolic compounds during the maceration step.[40] In these conditions, an extraction time of 48 h was sufficient to achieve a plateau for all compounds investigated.[11,40] The residual berry skins were quickly immersed into 25 mL of a new hydroalcoholic buffer containing 600 mg/L sodium metabisulfite. Afterward, the skins were homogenized at 8000 rpm for 1 min with an Ultraturrax T25 high-speed homogenizer (IKA Labortechnik, Staufen, Germany) and centrifuged for 15 min at 3000*g* at 20 °C. The supernatant was then used for determining non-extracted skin phenolic compounds.[40] Total contents of anthocyanins (expressed as mg malvidin-3-*O*-glucoside chloride/kg grape, as TA), proanthocyanidins (expressed as mg cyanidin chloride/kg grape, as PRO) and flavanols reactive to vanillin (expressed as mg (+)-catechin/kg grape, as FRV) were determined by spectrophotometric methods[39,41] using an UV-1800 spectrophotometer (Shimazdu Corporation, Kyoto, Japan).

The determination of the anthocyanin profile was performed after the berry skin or pulp extract had been submitted to reversed-phase solid-phase extraction using a 1 g SEP-PAK $C_{18}$ cartridge (Waters Corporation, Milford, MA, USA) with methanol as the eluent.[42] The HPLC-DAD system and chromatographic conditions were those used in a previous work.[42] A LiChroCART analytical column (25 cm × 0.4 cm i.d.) purchased from Merck (Darmstadt, Germany), which was packed with LiChrospher 100 RP-18 (5 $\mu$m) particles supplied by Alltech (Deerfield, IL, U.S.A.), and a Spectra Focus diode array detector (DAD, Spectra Physics Analytical, Inc.) operating at 520 nm were used. The mobile phases were: A = formic acid/water (10:90, v/v); B = formic acid/methanol/water (10:50:40, v/v), working at a flow-rate of 1 mL/min. The identification of the free forms of anthocyanins was achieved by comparing their retention times with those of pure standards. The acylated forms of anthocyanins were identified by matching the DAD spectrum and retention time of each chromatographic peak, and by comparing these data with those available in the literature.[7] Individual anthocyanins were expressed in percentages. All of the analyses were performed in duplicate and then averaged.

**Statistical Analysis.** Statistical analyses were carried out using the SPSS Statistics software package version 19.0 (IBM Corporation, Armonk, NY, U.S.A.).

## RESULTS AND DISCUSSION

As a consequence of minimizing the ripening effect by densimetric sorting of berries, all the berries belonging to the same density class of 1107 kg/m$^3$ have similar soluble solids concentration of 24.2 ± 0.2 and 24.2 ± 0.1°Brix for Barbera and Nebbiolo winegrapes, respectively, and titratable acidity value of 8.74 ± 0.11 and 6.81 ± 0.03 g/L tartaric acid, respectively.

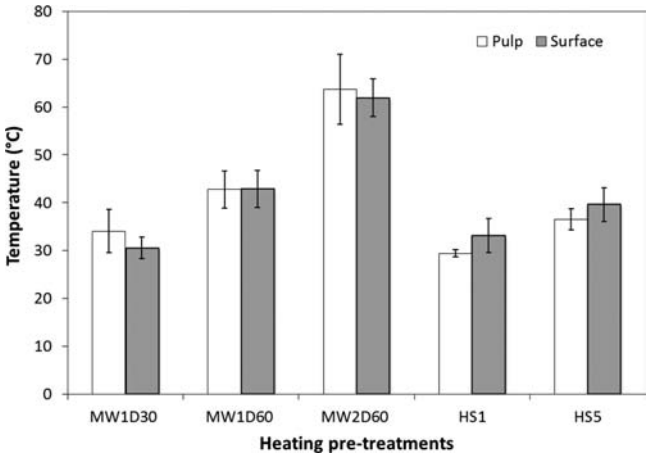

**Figure 1.** Pulp and surface temperatures of grape berries measured immediately after heating pre-treatments. MW1D30 = microwave heating at 1 W/g for 30 s, MW1D60 = microwave heating at 1 W/g for 60 s, MW2D60 = microwave heating at 2 W/g for 60 s, HS1 = steam blanching at 100 °C for 1 min, HS5 = steam blanching at 100 °C for 5 min.

**Grape Pre-treatments.** Figure 1 shows pulp and surface temperatures of grape berries measured immediately after heating pre-treatments by steam and microwave energy (HS1, HS5, MW1D30, MW1D60, and MW2D60). The temperatures achieved increased with longer heating times and/or higher microwave power density. The cooling time of the berries to achieve the temperature of 20 ± 0.5 °C was 8, 16, 21, 26, and 30 min, respectively. The freezing time for the DI pre-treatment (−77 °C) was 38 min, whereas the thawing time for the DF and DI pre-treatments was 85 and 220 min, respectively.

**Total Anthocyanins and Flavanols.** Total content of phenolic compounds released from the skin to the pulp during the grape pre-treatment, extracted skin phenolic compounds during the maceration step and non-extracted skin phenolic compounds for the two red winegrape varieties studied is shown in Table 1. As regards total skin anthocyanins (sum of pulp, extracted skin, and non-extracted skin anthocyanins) of Barbera grapes, the concentration obtained (753 ± 52 mg/kg) was lower than that reported for berries with higher contents of reducing sugars.[41] This agreed with the significant increase (16−31%) in the concentration of total anthocyanins (TA) in Barbera grapes with increasing the sugars content between 235 and 269 g/L for most of the production zones evaluated.[41] The concentration of total skin anthocyanins in Nebbiolo grapes (440 ± 29 mg/kg), although low, was usual for this variety as shown in other works performed on berries containing a similar content of reducing sugars or belonging to the same density

class.[2,42] In addition to the ripening effect, the influence of the growing location on the content of TA has been observed for both Barbera and Nebbiolo varieties in several studies.[41,42]

For Nebbiolo untreated berries, the average anthocyanin extraction yield was 80.5% (100-non-extracted skin anthocyanins, expressed as percentage), this value being lower than that published (91.1−94.2%) for different harvest dates and berry densities.[2] However, the average percentage obtained of non-extracted skin anthocyanins (19.5%, Table 1) agreed with that reported (19.9%) for Nebbiolo berries with hard skins.[11] For Barbera grapes, no study has been previously carried out on the extraction yield of anthocyanins from the skin into the pulp or a wine-like solution, and only the cellular maturity index (EA%) was determined in some works.[41]

The sum of pulp, extracted skin, and non-extracted skin contents of proanthocyanidins (PRO) and flavanols reactive to vanillin (FRV) (602 ± 116 and 200 ± 39 mg/kg for Barbera grapes, and 2700 ± 288 and 1104 ± 98 mg/kg for Nebbiolo grapes, respectively) was in the range published for total contents in the skin of the same varieties,[2,41] with the exception of FRV in Barbera grapes for which the values obtained in the present work were higher. The influence of the growing location on the content of FRV in the skin was very evident.[41] For Nebbiolo untreated berries, the average extraction yields of PRO and FRV were 75.0 and 78.9% (100-non-extracted skin compounds, expressed as percentage), respectively; these values agreed with those reported for different harvest dates and berry densities.[2]

TA contents in the pulp lower than 18 and 13 mg/kg for Barbera and Nebbiolo untreated berries, respectively, could be due in part to the inevitable manipulation of the sample during the step of removing the skin from the pulp. Only direct freezing of berries in a freezer (DF) and by adding dry ice (DI) facilitated the releasing of skin anthocyanins to the pulp for both Barbera and Nebbiolo winegrapes, as well as the pre-treatment of the berries by steam blanching for 5 min (HS5) for Nebbiolo. For the Barbera variety, the highest content of pulp TA was obtained when the pre-treatment with dry ice was used (67.7 mg/kg). For the Nebbiolo variety, the highest contents were associated with the pre-treatment by steam blanching for 5 min (74.8 mg/kg), but they were not significantly different from the ones corresponding to the pre-treatment with dry ice (60.9 mg/kg). For each variety, there were no significant differences in the content of extracted skin TA among treated and untreated berries. Therefore, in Barbera winegrapes, the percentage of non-extracted anthocyanins was significantly lower for the DI pre-treatment than for untreated berries (CS) or those treated with heat (HS or MW). On the other hand, non-extracted TA were significantly lower for the HS5 pre-treatment in Nebbiolo winegrapes although they did not differ from TA remaining in the skin after freezing (DF and DI).

As occurred for TA in Nebbiolo winegrapes, the DF, DI, and HS5 pre-treatments facilitated the releasing of PRO and FRV from the skin to the pulp. The lowest percentages of non-extracted skin PRO and FRV corresponded to the HS5 pre-treatment, although they did not differ significantly from PRO and FRV remaining in the skin after freezing (DF and DI) or shorter steam blanching (HS1). In Barbera winegrapes, significant differences were only found in the percentages of non-extracted skin PRO and FRV. In this case, the percentage of non-extracted skin PRO was significantly lower for freezing pre-treatments (DF and DI), as well as that of FRV for the DF

[a]TA = total anthocyanins, PRO = proanthocyanidins, FRV = flavanols reactive to vanillin. [b]Sign: *,**,*** and ns indicate significance at $p <$ 0.05, 0.01, 0.001 and not significant, respectively ($n$ = 21). [c]$F_{sk}$ = skin break force, [d]$W_{sk}$ = skin break energy.

pre-treatment, than for CS berries. Therefore, the improved extraction of anthocyanins and flavanols from the skin could favor the long-term color stability through the formation of pigmented polymers.[13,14] Furthermore, an increase in the proportion of PRO (high-molecular weight flavanols) released from the skin usually leads to a softening effect on the mouthfeel because of the lower astringency perception.[15]

Other studies revealed that the wines obtained using different low-temperature pre-fermentative treatments (grape freezing in a freezer, must freezing with dry ice, and cold maceration) show higher concentrations of TA at the end of fermentative maceration than the control wine.[15,18,19,43] Particularly, freezing may provide better results in winegrape varieties characterized by skins having a more rigid structure.[18] The use of dry ice also facilitated the extraction of high-molecular weight PRO from skins by degrading the structures.[15] Freezing with dry ice facilitates the extraction of phenolic compounds probably due to a quick thermal shock that induces the formation of ice crystals within the berry skin. The increased volume of the intracellular liquids causes the breakage of the cell walls and membranes. An additional advantage of dry ice is the protective effect against oxidation of extracted anthocyanins before fermentation, as it sublimates to gaseous carbon dioxide displacing completely the oxygen present in the medium and inhibits the activity of polyphenoloxidase enzymes.[15,22,25] The carbon dioxide saturation maintains the inhibitory effect even when temperature reaches normal fermentation values.[18] However, other works reported that the effectiveness of these treatments depends on the grape ripeness, the berry size, and the composition of the skin cell walls.[20,23,44]

In the scientific literature, dry ice is usually added to the must after grapes crushing, whereas the uncrushed grapes are directly frozen in a freezer. The comparative studies carried out on the use of these two pre-fermentative cold treatments provide contradictory results. Gil-Muñoz et al.[18] pointed out that must freezing with dry ice leads to higher contents of TA at the end of alcoholic fermentation. However, Heredia et al.[25] justified lower anthocyanin contents on the basis of a local effect on the skin just in the mass being directly in contact with dry ice. When pre-fermentative cold maceration of the must with the solid parts (crushed grapes) was carried out, higher extraction of TA was achieved with the addition of dry ice instead of keeping the sample in the freezer.[20] In the present study, the two pre-treatments (DF and DI) were applied to uncrushed berries, and the release and solubilization of anthocyanins into the pulp for Barbera and Nebbiolo winegrapes were also more favored using the DI pre-treatment as compared with the DF pre-treatment.

According to the results obtained for steam blanching of whole berries, TA, PRO, and FRV released into the pulp during the pre-treatment seem to increase with increasing heating time for the Nebbiolo variety. In some works, higher concentrations of anthocyanins in wines were obtained by heating partially dejuiced grapes at 90−95 °C for 1 min,[45] by mash thermal

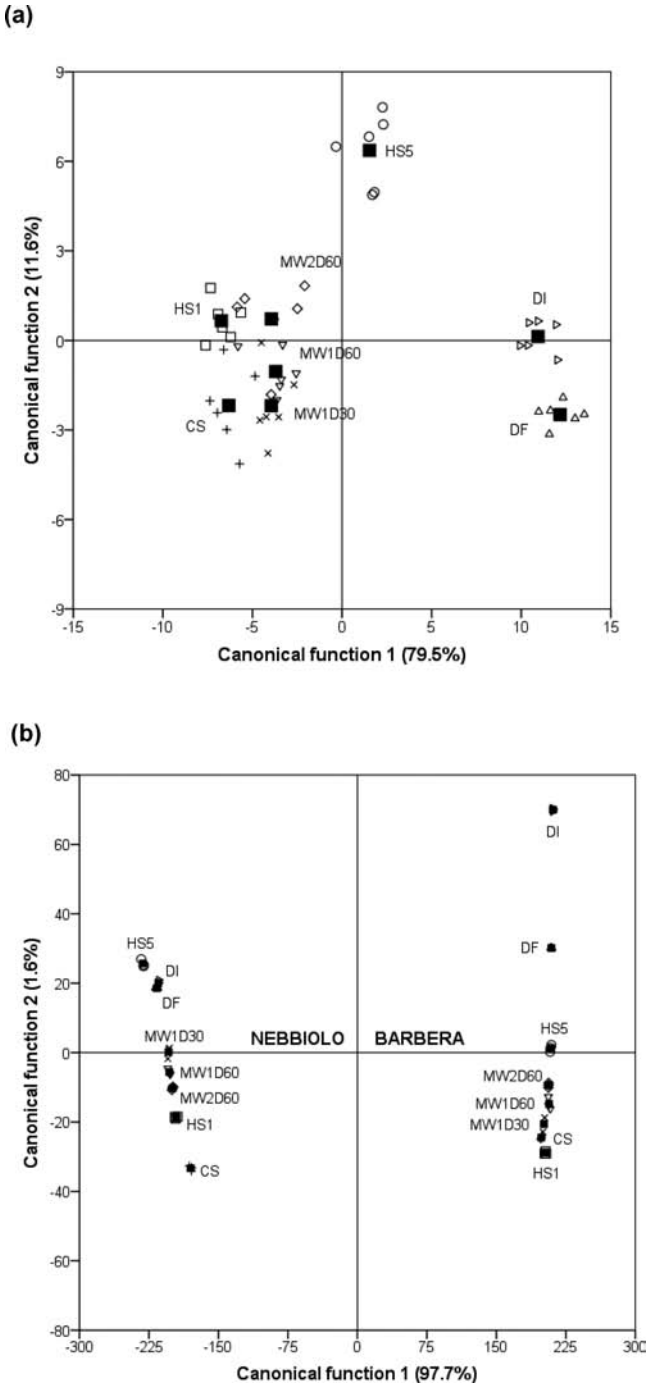

**Figure 2.** Projection of winegrape berries untreated and submitted to the different pre-treatments studied in the plane defined by the two first canonical functions considering Barbera and Nebbiolo varieties simultaneously (a) and separately (b). HS1 = steam blanching at 100 °C for 1 min, HS5 = steam blanching at 100 °C for 5 min, DF = direct freezing in a freezer at −18 °C for 2 days, DI = freezing by adding dry ice, MW1D30 = microwave heating at 1 W/g for 30 s, MW1D60 = microwave heating at 1 W/g for 60 s, MW2D60 = microwave heating at 2 W/g for 60 s, CS = control.

treatment at 50 °C for 15 min[46] or by mash pre-fermentative heating up to 65 °C and cooling down for 24 h (30 °C)[47] than using the untreated grapes. On the contrary, other researchers reported lower content of TA but higher one of total flavanols in the wine obtained by mash pre-fermentative heating at 65 °C for 8 h than in the control wine.[16] Therefore, temperature and time of heating seem to be important factors. Although the degradation of monomeric anthocyanins occurs more rapidly with increasing temperature, shorter treatment time at higher temperatures might be ideal for enhancing the extraction of thermally labile compounds.[26] Mild blanching of the berries can inactivate polyphenoloxidase enzymes, protecting anthocyanins against enzymatic degradation.[48] On the other hand, the water content is the most common absorbing phase for microwave energy and, therefore, plays a key role during the microwave treatment of grapes. In the present work, significant differences were not found in the content of pulp TA for microwave-treated berries (MW) in relation to untreated berries (CS). According to the results obtained, the anthocyanin degradation was not observed using the thermal pre-treatments of whole berries with steam or microwave energy, probably due to the short treatment times and/or low microwave power densities.[49]

**Anthocyanin Profile.** The qualitative composition of skin anthocyanins released into the pulp before and after the grape pre-treatment, extracted skin anthocyanins during the maceration step, and non-extracted skin anthocyanins for Barbera and Nebbiolo winegrapes are shown in Tables 2 and 3, respectively. For Barbera untreated grapes, malvidin derivatives were the predominant anthocyanin compounds (about 62%), and the richness in trisubstituted anthocyanin forms ranged from 77% to 92% (Table 2). However, the anthocyanin profile was slightly different as a function of the extraction easiness of anthocyanins (Table 2). In particular, peonidin derivatives were the second most abundant pulp anthocyanins (11%), whereas petunidin derivatives were for extracted and non-extracted skin anthocyanins (13% and 20%, respectively). Furthermore, simple glucoside (free or unacylated) forms accounted for around 75% of extracted and non-extracted skin anthocyanins, but they achieved 92% of pulp anthocyanins mainly at the expense of acetylated forms. Although the general profile of extracted and non-extracted skin anthocyanins in Barbera untreated winegrapes was similar, non-extracted skin anthocyanins showed slightly lower percentages of malvidin derivatives, which resulted in higher abundance of the other trisubstituted anthocyanins. Despite some small differences attributable to the growing zone and seasonal variability,[6] the anthocyanin profile of Barbera untreated grapes was similar to the extractable anthocyanin profile previously reported in other works,[5,36,41] particularly for extracted and non-extracted skin anthocyanins. The works published to date did not consider pulp anthocyanins during the manipulation step of the berry skin.

Regarding the Nebbiolo variety, Table 3 shows that untreated winegrapes were rich in disubstituted anthocyanin forms with percentages ranging from 63% to 81%. The major anthocyanin compounds were peonidin derivatives (about 45%). Malvidin derivatives were also abundant extracted and non-extracted skin anthocyanins (about 23%), although lower than peonidin forms. However, cyanidin derivatives (35%) predominated over malvidin derivatives (13%) in pulp anthocyanins. This constitutes an important enological aspect because of the high percentage of disubstituted anthocyanin forms easily extracted in the pulp (77−81%). As occurred in Barbera untreated grapes, simple glucoside forms accounted for 97% of pulp anthocyanins, whereas they only reached percentages comprising between 84% and 88% of extracted and non-extracted skin anthocyanins. The qualitative composition of extracted and non-extracted skin anthocyanins for Nebbiolo untreated grapes was quite similar and agreed, with

some small differences, with the extractable anthocyanin profile previously reported in the scientific literature.[2,5,42,50]

When the profile of extracted skin anthocyanins was compared with that of pulp anthocyanins in untreated and treated berries, greater percentages of delphinidin, petunidin and malvidin derivatives were usually observed in the former for both Barbera and Nebbiolo varieties, whereas the percentages of cyanidin and peonidin forms were lower. The diffusion of disubstituted anthocyanins is faster than the one corresponding to trisubstituted anthocyanins,[12] which justifies the higher relative abundance of the first compounds in the pulp, but the percentage of trisubstituted anthocyanins increases during the first days of maceration.[12] On the other hand, the proportion of unacylated forms in extracted skin anthocyanins was lower in favor of higher proportions of acetylated and cinnamoylated glucosides. Acylated anthocyanins are very important because they participate in intramolecular copigmentation processes, protecting the flavylium cation.[18] In the present work, some exceptions were found to this general behavior, particularly in malvidin and peonidin derivatives for Barbera and Nebbiolo winegrapes, respectively. Therefore, for a given variety the different pre-treatments studied on whole berries may influence the anthocyanin profile of the final product, favoring preferential releasing of a certain anthocyanin form from the skin into the must. This fact is of great importance because the reactivity of the different anthocyanins depends on their structure. Particularly, 3′-hydroxylated molecules (delphinidin, cyanidin, and petunidin) are more prone to oxidation and thermolabile,[51,52] and therefore the juices/wines with higher proportions of these molecules are more sensitive to color degradation. In fact, anthocyanins without ortho-hydroxylated groups can interact with flavanols and ethanal, leading to a stable red pigmentation. In varieties characterized by an important presence of disubstituted anthocyanins, such as Nebbiolo, a remarkable loss of these anthocyanin compounds has been also noticed during winemaking.[53] The next step was to evaluate the effect of each grape pre-treatment studied on the profile of pulp, extracted skin and non-extracted skin anthocyanin compounds for Barbera and Nebbiolo berries.

The different pre-treatments of the berries caused changes of different magnitude in the anthocyanin profile of Barbera grapes if compared with untreated berries (Table 2). Most of significant differences were found in pulp anthocyanins. Freezing with dry ice (DI) was the grape pre-treatment that affected more significantly the profile of pulp anthocyanins. Although the proportions of trisubstituted anthocyanins like delphinidin and petunidin forms experienced a significant decrease, total trisubstituted anthocyanins were more abundant in the berries treated with dry ice because of a significant decrease in the percentage of cyanidin derivatives and the largest increase in the percentage of malvidin derivatives (+6.4%). This effect of the DI pre-treatment on the profile of pulp anthocyanins agreed with the observed in wines made from winegrapes rich in trisubstituted anthocyanins.[54] The DI pre-treatment also induced the greatest decrease in the relative abundance of simple glucoside anthocyanins in favor of the more significant increase in acetylated glucosides (+2.3%). The influence of freezing of the berries in a freezer (DF) on the profile of pulp anthocyanins was similar to the one corresponding to the DI pre-treatment but to a much lesser extent. Microwave heating at 2 W/g for 60 s (MW2D60) also promoted a marked increase in the percentage of total trisubstituted anthocyanins as a consequence of the lowest percentages of cyanidin and peonidin derivatives released from the skin into the pulp during the berries pre-treatment

(decreasing −3.0% and −1.7%, respectively). The MW2D60 pre-treatment and steam blanching for 5 min (HS5) caused an important increase in the percentage of malvidin derivatives. In the case of the HS5 pre-treatment, the lowest percentages of other trisubstituted anthocyanins like delphinidin and petunidin derivatives were obtained (decreasing −2.8% and −1.9%, respectively). Microwave heating at 1 W/g for 60 s (MW1D60) was the grape pre-treatment giving the highest proportion of disubstituted anthocyanins and the greatest decrease in the percentage of malvidin derivatives in the pulp (−1.9%). Microwave heating using any experimental condition investigated permitted a significant increase in the proportion of acetylated glucoside anthocyanins at the expense of simple glucoside forms.

The effect of the different pre-treatments applied to the berries on the anthocyanin profile of Nebbiolo winegrapes is shown in Table 3. As already mentioned for the Barbera variety, most of significant differences among untreated and treated berries were found in pulp anthocyanins. The most influential grape pre-treatments were DI, DF and HS5. The DI pre-treatment caused the largest increase in the percentage of malvidin compounds (+6.6%) and the greatest decrease in the proportion of cyanidin derivative pulp anthocyanins (−11.0%). Although this last treatment also favored the significant increase in the percentage of peonidin derivatives, total trisubstituted anthocyanins were more abundant in the berries treated with dry ice. Furthermore, the more significant increase in the proportion of acetylated glucoside pulp anthocyanins at the expense of free glucosides corresponded to the DI pre-treatment. On the other hand, the greatest increase in the percentage of peonidin derivatives (+6.3%) was associated with the DF pre-treatment, but it was balanced with a significant reduction in the proportion of cyanidin derivatives and an important increase in the percentage of malvidin forms of pulp anthocyanins. This fact implied that the relative abundance of total trisubstituted anthocyanins was not significantly different among freezing pre-treatments (DF and DI). The percentage of these compounds also agreed with that obtained in the pulp after the HS5 pre-treatment of the berries, as a consequence of the highest increase found in the proportions of delphinidin and petunidin derivatives (+1.2% and +0.8%, respectively) together with a significant reduction in the percentage of cyanidin derivatives and an important increase in malvidin forms in relation to untreated berries. However, the percentage of peonidin derivatives increased significantly. Furthermore, the lowest proportion of free glucoside pulp anthocyanins (decreasing −0.9%), in favor of acetylated glucosides, corresponded to the HS5 pre-treatment. The anthocyanin

dx.doi.org/10.1021/jf502656d | J. Agric. Food Chem. 2014, 62, 8437−8451

profile of the berries steam blanched for 1 min (HS1) or microwave heated (MW) was not significantly different from the one corresponding to untreated berries.

For each variety, only a few significant differences were found in the profile of extracted and non-extracted skin anthocyanins among untreated and treated berries. Because the grape pre-treatment can cause changes in the skin tissues that facilitate the extraction of anthocyanins during the maceration step, the profile of extracted skin anthocyanins for Barbera winegrapes showed some significant changes affecting mainly petunidin derivatives (+2.1%) when the DI pre-treatment was applied (Table 2). For the Nebbiolo variety (Table 3), the only significant difference was the lowest percentage of simple glucosides (−1.7%) when the berries were submitted to the HS5 pre-treatment in favor of cinnamoylated glucosides. Regarding the qualitative composition of anthocyanins that remain in the skin after maceration, the most important changes were observed for Nebbiolo berries where the greatest decrease in the percentages of delphinidin derivatives and simple glucosides (about −1.4% and −2.3%, respectively), in favor of cinnamoylated glucosides, was obtained after the DI and HS5 pre-treatment.

Regarding general trends, some aspects are particularly relevant. Freezing of whole berries (DF and DI) improved the extraction of malvidin derivatives from the skin into the pulp for both Barbera and Nebbiolo winegrapes, which agreed with the increased extraction of malvidin-3-glucoside into the wine using different pre-fermentative cold maceration treatments of crushed berries.[23,54] Since malvidin derivatives are the most stable forms of anthocyanins (particularly acylated forms), their higher diffusion into the pulp may contribute favorably to the color stability of the resulting juice/wine. When acylation was considered, higher percentages of acylated glucosides were observed in pulp anthocyanins after the DI pre-treatment of Barbera and Nebbiolo winegrapes than after the DF pre-treatment. Heredia et al.[25] have also found lower abundance of monoglucosides during cryomaceration with dry ice when compared with refrigeration of the berries in a freezer.

According to the results obtained, the effect of heating time and/or microwave power density depended on the variety. Microwave power density affected mainly the anthocyanin profile of Barbera winegrapes, whereas the effect of treatment time was particularly important for the Nebbiolo variety using steam as heating source. Other work showed that, after alcoholic fermentation, the wine obtained by pre-fermentative mash heating at 65 °C for 8 h contains less malvidin-3-glucoside and more delphinidin-3-glucoside and petunidin-3-glucoside than the control wine, even though malvidin-3-glucoside is the most abundant monomeric anthocyanin in Okuzgozu grapes.[16] These results disagreed with those obtained in the present work. The variety and the experimental conditions of heating may be very influential factors on the anthocyanin profile of the resulting juices/wines and, therefore, on their color stability.

**Instrumental Texture Analysis.** The skin mechanical properties of Barbera and Nebbiolo winegrapes before and after the different pre-treatments studied are shown in Table 4. The values obtained in untreated berries are comprised in the usual range for these varieties, particularly from Piedmont growing zone.[41,42,50] The magnitude of the effect of the different freezing and heating pre-treatments on the instrumental texture parameters defining the skin hardness ($F_{sk}$ and $W_{sk}$) depended on the variety. For Barbera winegrapes, freezing with dry ice (DI) reduced significantly the skin break energy ($W_{sk}$), achieving the lowest values in relation to berries untreated and treated with any other methodology studied. No significant difference was found in the skin break force ($F_{sk}$) among untreated and treated berries for the Barbera variety. For Nebbiolo winegrapes, the hardest skins were found after the thermal pre-treatment of the berries by steam blanching for 5 min (HS5), with values of $F_{sk}$ and $W_{sk}$ being significantly higher than those corresponding to untreated and differently treated berries. A possible explanation could be the caramelization of sugars closer to the skin, which occurs at high temperatures. The DI pre-treatment also promoted a significant increase in the values of $W_{sk}$ in relation to untreated berries.

Instrumental texture parameters of the skin have been proposed as anthocyanin extractability markers.[11] However, the relationships between the skin mechanical properties and the anthocyanin extraction yield are variety dependent. The chemical composition of grape skin cell walls may determine the mechanical resistance of the berry skin to the anthocyanin release.[8] In Nebbiolo grapes, higher values of $F_{sk}$ facilitated more complete anthocyanin release from the skin.[11] In the present work, significant correlations (correlation factor $R > 0.5$, $p < 0.05$) were found for each variety between the value of $W_{sk}$ in treated whole berries and the corresponding content of TA ($n = 21$, 7 treatments × 3 replicates of 10 berries). Thus, the amount of pulp TA and the percentage of non-extracted skin TA were better correlated with the value of $W_{sk}$ for Nebbiolo ($R = 0.736$, $p < 0.001$ and $R = -0.721$, $p < 0.001$, respectively) than for Barbera winegrapes ($R = -0.553$, $p < 0.01$ and $R = 0.615$, $p < 0.01$, respectively), as shown in Table 5. Furthermore, the relationships were inverse for the two varieties. The results obtained agreed with those reported by Rolle et al.[11] for the Nebbiolo variety, the higher the skin hardness the higher the extracted anthocyanins. Because higher skin hardness probably involves greater cell wall fragility, the higher the $W_{sk}$ values the higher the amounts of pulp flavanols (PRO and FRV) ($R = 0.640$, $p < 0.01$ and $R = 0.681$, $p < 0.001$, respectively) for Nebbiolo winegrapes, and therefore the lower the percentages of non-extracted skin flavanols ( $R = -0.751$, $p < 0.001$ and $-0.755$, $p < 0.001$, respectively). As occurred for TA in Barbera winegrapes, the content of PRO (high-molecular weight flavanols) released into the pulp was negatively correlated with the value of $W_{sk}$ ($R = -0.576$, $p < 0.01$), whereas no significant correlation was found for FRV (low-molecular weight flavanols).

The berry skin hardness also affected the individual anthocyanin composition of the hydroalcoholic extracts for Nebbiolo skins.[11] Only in the early phases of the anthocyanin diffusion, harder skins (more fragile) exhibited significantly higher percentages of extracted petunidin-3-glucoside (+0.8%), cyanidin-3-glucoside (+3.6%), and peonidin-3-glucoside (+6.0%) derivatives at the expense of malvidin-3-glucosides (−9.6%). After macerating for 10 min, no significant differences were found in the extracted anthocyanin profile of skins with different hardness. Since the values obtained of $F_{sk}$ in the present work for Nebbiolo winegrapes correspond to hard skins, higher proportions of peonidin derivatives in pulp anthocyanins (+1.6−6.3%) are justified for treated berries if compared with untreated berries. On the other hand, a higher number of significant relationships between the berry skin mechanical properties and the anthocyanin profile were associated with pulp anthocyanins (Table 5), probably due to the fact that they were more quickly released from the skin.

Considering only the most significant correlations (Table 5, $R > 0.675$, $p < 0.001$), in Nebbiolo treated winegrapes, the percentages of delphinidin and petunidin glucosides increased with increasing values of $F_{sk}$ and $W_{sk}$, whereas those of cyanidin decreased with increasing $W_{sk}$, for pulp anthocyanins. However, the most important variation in pulp anthocyanins with $W_{sk}$ corresponded to the percentages of cyanidin and malvidin glucosides. Harder skins of Nebbiolo treated berries provided lower relative abundance of cyanidin glucosides (sensitive to oxidation reactions) and higher percentage of malvidin glucosides (highly stable). Furthermore, the proportion of unacylated glucosides decreased significantly, and the relative amount of cinnamoylated forms increased with rising values of $W_{sk}$ for extracted skin anthocyanins in Nebbiolo treated berries. In Barbera treated winegrapes, the significant correlations were less numerous and weaker than in Nebbiolo ones (Table 5, $R < 0.670$, $p > 0.001$) with general inverse trends for the two varieties.

**Multivariate Analysis.** Discriminant analysis based on the contents of TA, PRO and FRV, and the composition of individual anthocyanins released into the pulp, extracted during maceration and remaining in the skin (as defined in the Materials and Methods section), and the skin mechanical properties for treated and untreated Barbera and Nebbiolo winegrapes (Tables 1−4) showed a very clear classification of the berries according to the pre-treatment (Figure 2a). A perfect clustering of scores of the samples for each pre-treatment was observed. The two first canonical functions accounted for 91.0% of total variance in the original data. Function 1 explained 79.5% of the variability and was mainly related to the percentages of cyanidin and peonidin derivatives of pulp anthocyanins, particularly unacylated forms. The highest positive values of function 1 corresponded to the berries frozen (DF and DI pre-treatments). Function 2 accounted for 11.6% of the cumulative variance and was mainly associated with the relative abundance of pulp petunidin derivatives, extracted skin cyanidin and peonidin derivatives, and non-extracted skin cyanidin derivatives, as well as the content of extracted skin TA and PRO, the thermal pre-treatment HS5 corresponding to the highest positive values. The standardized coefficients of canonical functions are shown in Table 6. Although the differentiation of berries untreated and treated by other thermal pre-treatments was not so clear, 95.8% of the samples were correctly classified. When discriminant analysis was carried out separately on Barbera and Nebbiolo winegrapes (Figure 2b), a perfect clustering of scores of the samples for each variety and pre-treatment was observed. The two first canonical functions accounted for 99.2% of total variance in the original data. Function 1 explained 97.7% of the variability and was mainly related to the content of pulp PRO, extracted skin TA and PRO and non-extracted skin TA. The highest positive and negative values of function 1 were associated with Barbera and Nebbiolo winegrapes, respectively. Therefore, function 1 permitted a good differentiation of the samples according to the variety. Function 2 accounted for 1.6% of the cumulative variance and was mainly associated with the percentage of cyanidin derivatives of extracted skin anthocyanins and the relative abundance of petunidin derivatives of non-extracted skin anthocyanins, particularly unacylated and acetylated forms. The highest positive values of function 2 corresponded to freezing pre-treatments (DF and DI) and the thermal pre-treatment HS5, whereas the highest negative values were associated with untreated berries (CS) and the thermal pre-treatment HS1. The standardized coefficients of the seven first canonical functions are shown in Table 7. In this case, 100% of the samples were correctly classified. Therefore, function 2 facilitated the differentiation of untreated berries and those submitted to the different pre-treatments studied.

In conclusion, different pre-treatments of whole berries (freezing with dry ice, freezing in a freezer and steam blanching for 5 min) enhanced mainly the releasing of anthocyanins from the skin into the pulp. Nevertheless, the magnitude of the effect depended on the grape pre-treatment, experimental conditions used, anthocyanin compound and variety. The varietal effect may be related to the changes occurring in the skin tissue during the pre-treatment, which affected the facility to break the cell-walls and to release anthocyanins. In fact, the significance and strength of the correlations between the berry skin mechanical properties and the phenolic composition of treated berries depended strongly on the variety studied. Freezing with dry ice can be considered a promising treatment for industrial processing of uncrushed grape berries, not only because of increased total content of pulp extracted anthocyanins but also the modified anthocyanin profile in favor of more stable compounds. It is particularly important for winegrape varieties with a high proportion of disubstituted anthocyanins, such as Nebbiolo. For this variety, the use of dry ice also facilitated the release of low and high molecular weight flavanols from the skin into the pulp, which may lead to more colored juices/wines with lower astringency perception. In future works, the practical application of the most advantageous pre-treatments will be thoroughly evaluated by means of chemical, chromatic and sensory quality of the juices and/or wines obtained. Particularly, the production of grape juices rich in anthocyanins could be of great interest for offering a product with higher nutritional value, better chromatic characteristics and improved acceptance by consumers.

# Isoflavones of the Soybean Components and the Effect of Germination Time in the Cotyledons and Embryonic Axis

Alécio Quinhone Júnior[†] and Elza Iouko Ida*[,†]

[†]Departamento de Ciência e Tecnologia de Alimentos, Programa de Pós Graduação em Ciência de Alimentos, Universidade Estadual de Londrina, Londrina, Paraná 86057-970, Brazil

**ABSTRACT:** The aim of this study was to evaluate the content of different forms of isoflavones of BRS 284 soybean components and the effect of germination time in the cotyledons, radicle, and hypocotyl. Seeds were germinated until 168 h at 35 °C and collected each 24 h. The isoflavone content was determined by ultraperformance liquid chromatography, and the data were subjected to regression analysis. In cotyledons, germination time had a quadratic effect on daidzin and genistin contents and a linear effect on malonyldaidzin and malonylgenistin contents. In radicles, germination time had a quadratic effect on daidzin, glycitin, malonylgenistin, and malonylglycitin contents in addition to a linear effect on malonyldaidzin content. In hypocotyls, germination time showed a cubic effect on daidzin and genistin contents, a quadratic effect on malonyldaidzin, malonylgenistin, and malonylglycitin contents, and a linear effect on genistein content; glycitin, daidzein and glycitein were detected in a few germination times.

**KEYWORDS:** *soybean sprouts, hypocotyl, aglycone, radicle, seedling*

## INTRODUCTION

Soybean (*Glycine max* (L.) Merrill) and its derivatives have received more attention in recent years due to their potential beneficial effects on human health, such as protective effects against bone loss in postmenopausal women,[1] prevention of cardiovascular diseases,[2] relief of menopausal symptoms,[3] and protective effects against breast cancer[4] and prostate cancer.[5]

The main soy isoflavones are divided into aglycones (daidzein, genistein, and glycitein), $\beta$-glucosides (daidzin, genistin, and glycitin), malonylglucosides (6″-*O*-malonyldaidzin, 6″-*O*-malonylgenistin, and 6″-*O*-malonylglycitin), and acetylglucosides (6″-*O*-acetyldaidzin, 6″-*O*-acetylgenistin, and 6″-*O*-acetylglycitin).[6] During seed development of soybean, aglycones are synthesized by the phenylpropanoid metabolic pathway and stored in vacuoles as $\beta$-glucosides and malonylglucosides.[7,8] However, aglycones and acetylglucosides are absent or in low concentrations.[9,10]

Isoflavone contents in soybean seeds display a broad range of variation because their synthesis and accumulation are affected by multiple environmental and genetic factors.[11,12] Isoflavones may vary between soybean components. Total isoflavone content in the embryonic axis can be 5.0−25.0-fold higher than that in the cotyledons, whereas the seed coat is substantially free of isoflavones.[8,13,14]

During the course of soybean domestication, China gradually transformed soybean seeds in various forms of foods that are versatile, tasty, and digestible, such as tofu, sauce, paste, extract, and soybean sprouts.[15] Soybean sprouts, which are produced after 6−7 days of germination, are an important vegetable source, are rich in nutrients, are available all year, and have been consumed for thousands of years in countries, such as Korea, China, and Japan.[16] However, interest in healthy and functional foods has increased the demand for soybean sprouts in the West.[17]

Soybean germination can be used as a processing method to improve the sensorial quality[6] and nutritional value[10,18] of soybean seeds because it reduces the amount of undesirable substances, such as phytic acid,[19,20] oligosaccharides,[17,21] and trypsin inhibitors, in addition to lipoxygenase activity.[10] Germination can also promote a significant increase of vitamins,[22] phytosterols, tocopherols,[23] isoflavones,[24,25] and isoflavone aglycones.[10,14,17,23] In addition, the germination process is simple and inexpensive, and soybean sprouts have been investigated for several decades due to the high content and quality of protein and essential amino acids.[6]

The germination time may exert distinct effects depending on the soybean sprout components or isoflavone forms. In soybean cotyledons germinated for 72 h, the content of $\beta$-glucosides does not vary significantly, but the malonylglucoside content increases throughout the germination time. In radicles, however, a decrease in malonylglucoside and $\beta$-glucosides content occurs.[13] In contrast, in cotyledons and hypocotyls germinated for 120 h, a decrease in malonylglucoside and $\beta$-glucoside contents in addition to an increase in aglycone content have been reported.[14] However, the biotransformation of the various forms of isoflavones in soy components as a function of germination time has not been fully explored, and a few existing studies did not follow the entire process of germination considering the different forms of isoflavones in the various components of the germinated soybeans.

The objective of this study was to evaluate the content of different forms of isoflavones of BRS 284 soybean components and the effect of germination time up to 168 h on the content of these isoflavones in cotyledons and the embryonic axis.

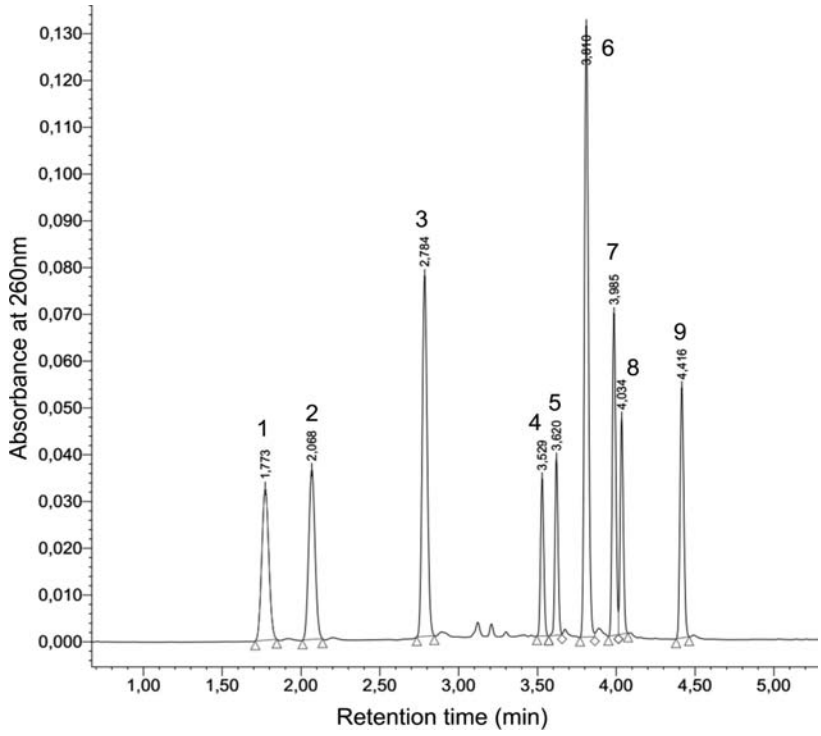

**Figure 2.** Typical UPLC chromatogram of isoflavones in a standard solution.

## MATERIALS AND METHODS

**Materials and Reagents.** Soybean seeds of the BRS 284 cultivar, a conventional cultivar, grown during the 2011/2012 season were provided by a specialist company in the region and were used for this study. According to the Empresa Brasileira de Pesquisa Agropecuária,[26] this cultivar is used for industrial processing, and it has an average size of 14.6 g per 100 seeds and contains 38.7% protein and 20.4% lipids; because of these characteristics, BRS 284 was used for this study. All reagents used were of analytical grade and from different sources. Acetylglucosides and malonylglucosides were obtained from Wako Pure Chemical Industries, Ltd. (Osaka, Japan), and the $\beta$-glucosides and aglycones were obtained from Sigma–Aldrich Co. (St. Louis, MO, USA) and were used as isoflavone standards. All standard solutions were filtered through a 0.22 $\mu$m syringe filter (Millex-GV, Millipore, Billerica, MA, USA) prior to injection into the ultraperformance liquid chromatography (UPLC) instrument.

**Experimental Design of the Germination Process.** Soybean seeds were previously selected to eliminate damaged seeds, stained seeds, or any foreign material. Fifty soybean seeds were placed on two pieces of germination paper (37.5 cm × 28.2 cm; Germitest) previously wetted with distilled water and supported by a perforated plate. The seeds were then covered with another piece of paper of which the bottom edge was folded, and the papers were curled longitudinally to form rolls.

To evaluate the effect of soybean germination time on the different forms of isoflavones in cotyledons and the embryonic axis, a randomized complete block design with three replications was used. For each block and germination time, 15 paper rolls were used. Germination was performed in a germination chamber (model Mangelsdorf, J. Prolab - São José dos Pinhais, PR, BR) with natural light at 35 °C (±1 °C) and relative humidity of 100% for 24, 48, 72, 96, 120, 144, and 168 h, as described by Yoshiara et al.[27] The effect of germination time on the isoflavone content in radicles and hypocotyls was considered only after 48 h of germination when it was possible to observe these components and separate them manually. Germinated seeds were collected at each germination time, and the cotyledons, hypocotyls, and radicles (Figure 1) were separated manually and in sufficient quantity for analysis. Epicotyls and seed coats of germinated seeds were discarded. Thereafter, the components were identified, freeze-dried, ground (model A-11, Ika), placed in polyethylene bags, and stored at −22 °C for analysis. The components of ungerminated seeds were used for comparison.

**Analytical Procedures.** Moisture content of the lyophilized samples was determined in a drying oven at 105 °C. The percentage of each structural part of the soybean seed was determined in triplicate using 100 g of seeds. Cotyledons, the embryonic axis, and seed coats were manually separated and weighed. The content of the different forms of isoflavones was also analyzed in these components.

Prior to quantification of isoflavones, the lyophilized and milled samples were defatted with hexane at 1:10 (w/v) for 1 h at room temperature by continuous and rotary agitation followed by vacuum filtration. The isoflavone extraction was performed in triplicate with 0.1 g of defatted sample with 2 mL of extraction solution containing ultrapure water, acetone, and ethanol (1:1:1, v/v/v) as described by Yoshiara et al.[28] The quantification of all isoflavones forms was performed simultaneously, in triplicate, using a UPLC system as described by Handa et al.[29] The different forms of isoflavones and the sum of all forms of isoflavones were expressed as micromoles of the form

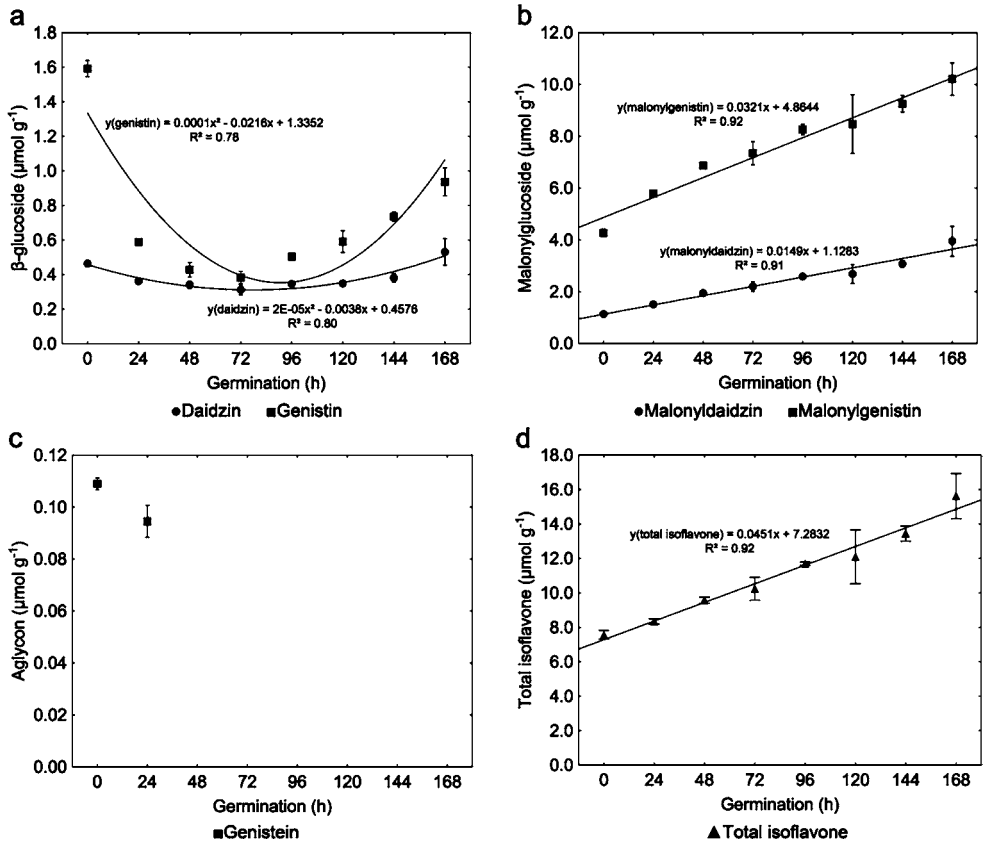

Figure 3. (a) $\beta$-glucoside, (b) malonylglucoside, (c) aglycone, and (d) total isoflavone contents in cotyledons of germinated BRS 284 soybeans.

of isoflavone per gram of sample on a dry and defatted basis. A typical UPLC chromatogram of isoflavones in the standard is show in Figure 2.

**Experimental Design and Statistical Analysis.** The results of the content of different forms of isoflavones in soybean seeds and their components were subjected to analysis of variance (ANOVA), and the means were compared by Tukey's test ($p < 0.05$). Regression analyses between germination time and content of different forms of isoflavones were also performed using all the experimental data with Statistica 10.0 software (StatSoft Inc., Tulsa, OK, USA).

## RESULTS AND DISCUSSION

**Content of Different Forms of Isoflavones in Soybean Seed Components.** The BRS 284 soybean seeds were composed of 89.9% cotyledons, 2.4% embryonic axis, and 7.7% seed coat. These results were similar to those reported by Yuan et al.[14] However, Ribeiro et al.[13] reported that BRS 213 soybeans have 86.8% cotyledons, 3.2% embryonic axis, and 10.0% seed coat. According to Phommalth et al.,[25] the proportion of soybean components depends on its size, so smaller seed sizes result in a greater percentage being the embryonic axis.

BRS 284 soybeans (Table 1) had 8.757 ± 0.566 $\mu$mol of total isoflavones per gram of soybean on a dry basis. The isoflavone content of soybean seeds can vary according to biotic and abiotic factors, such as cultivar, harvest year,[30,31] sowing date, growing location,[9] pathogen load in soybean growing season,[32] and elicitors.[33]

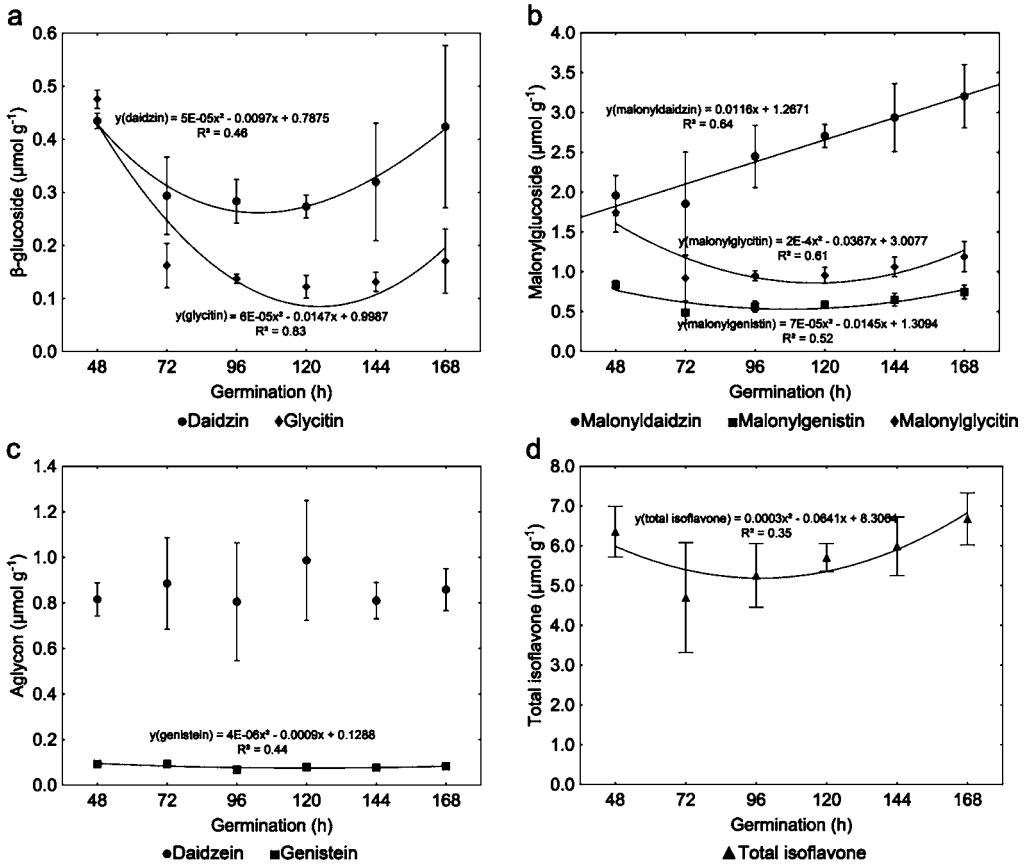

**Figure 4.** (a) $\beta$-glucoside, (b) malonylglucoside, (c) aglycone, and (d) total isoflavone contents in radicles of germinated BRS 284 soybeans.

The concentration of the various forms of isoflavones in BRS 284 soybean (Table 1) varied according to its components ($p < 0.05$). The total isoflavone content in the embryonic axis was 7.1-fold higher than that in cotyledons. These results were similar to those described by Yuan et al.[14] However, Silva et al.[34] reported that the total isoflavone content in the embryonic axis is 6.5–15.5-fold higher than in cotyledons. In addition, Berger et al.[31] observed that the total isoflavone content in cotyledons is dependent on environmental conditions and that the embryonic axis genotype has greater influence.

Isoflavone forms have not been found in seed coats of BRS 284 soybeans as observed.[8,34] Thus, considering the percentage of each component in the soybean, 84.2% and 15.8% of the total isoflavones are present in cotyledons and the embryonic axis, respectively. Similar results have been observed by Tsukamoto et al.[9] However, 51.8% and 48.2% of total isoflavone content is located in cotyledons and the embryonic axis, respectively, in BRS 213 soybeans.[13] These differences in the concentration and distribution of isoflavones among soybean components may be attributed to differences in cultivars, growing conditions,[30,31] seed size,[35] and other factors.

In BRS 284 soybeans, cotyledons and the embryonic axis showed similar proportions of $\beta$-glucosides, malonylglucosides, and aglycones isoflavones (Table 1). In relation to total isoflavones, the seeds, cotyledons, and embryonic axis showed 26.0%, 27.2%, and 29.4% $\beta$-glucosides, 72.9%, 71.4%, and 70.0% malonylglucosides, and 1.2%, 1.4%, and 0.6% aglycones, respectively. In soybean, the daidzein, genistein, and glycitein isoflavones are synthesized via the phenylpropanoid pathway and are stored in the vacuole as malonylglucosides and $\beta$-glucosides.[7,8]

**Effect of Soybean Germination Time on Different Forms of Isoflavones in Cotyledons.** Regression analysis of the effect of germination time on daidzin ($R^2 = 0.80$, $p < 0.01$) and genistin ($R^2 = 0.78$, $p < 0.01$) contents in germinated soybean cotyledons indicated that the quadratic model showed a good fit to the experimental data (Figure 3a). However, glycitin was not detected in germinated cotyledons.

In cotyledons germinated up to 72 h, the daidzin and genistin contents decreased by 1.5- and 4.2-fold followed by an increase of 1.7- and 2.5-fold between 72 and 168 h, respectively. This initial decrease in daidzin and genistin contents may be associated with the translocation of these isoflavones from cotyledons to radicles.[7] The daidzin content in cotyledons germinated for 168 h was similar to ungerminated cotyledons, but the concentration of genistin was reduced by 1.7-fold (Figure 3a). In soybean cotyledons, the amount of $\beta$-glucosides decreases until 120 h of germination.[14] However, Ribeiro et al.[13] described that the germination time of 72 h of BRS 213 soybean cotyledons does not influence the profile of the genistin and daidzin isoflavones. The nondetection of glycitin in soybean cotyledons throughout the germination process has also been observed by Kudou et al.[8] in ungerminated soybean cotyledons and by Ribeiro et al.[13] in ungerminated soybean cotyledons and soybean cotyledons germinated for 72 h.

Regression analysis of the effect of germination time on malonyldaidzin ($R^2 = 0.91$, $p < 0.01$) and malonylgenistin ($R^2 = 0.92$, $p < 0.01$) contents in germinated soybean cotyledons indicated that the linear model showed a good fit to the experimental data (Figure 3b). However, malonylglycitin was not detected in germinated cotyledons. Between 0 and 168 h of germination, the malonyldaidzin and malonylgenistin contents

dx.doi.org/10.1021/jf502927m | J. Agric. Food Chem. 2014, 62, 8452–8459

increased by 3.5- and 2.4-fold, respectively. According to Ribeiro et al.,[13] the malonyldaidzin and malonylgenistin contents in BRS 213 soybean cotyledons germinated for 72 h are 3.3- and 2.6-fold higher than those in ungerminated cotyledons, respectively. It is noteworthy that the soybean cotyledons germinated for 168 h had 25.3% malonyldaidzin and 65.3% malonylgenistin in relation to the total isoflavone content. The malonylglycitin isoflavone was not detected in ungerminated soybean cotyledons and soybean cotyledons germinated up to 168 h. Similar results of malonyl isoflavones have been reported by Ribeiro et al.[13]

It was not possible to perform regression analysis on the aglycone content for germinated soybean cotyledons, since genistein was only detected in ungerminated cotyledons and cotyledons germinated for 24 h without differing in 0 and 24 h of germination ($p > 0.05$) presenting an average of 0.102 ± 0.010 $\mu$mol g$^{-1}$ of cotyledons (Figure 3c). Additionally, daidzein and glycitein were not detected in the cotyledons during the entire germination process. According to Ribeiro et al.,[13] genistein is the only isoflavone aglycone present in BRS 213 soybean cotyledons that are either ungerminated or germinated for 6 h. However, in cotyledons of 17 soybeans germinated for 120 h with and without light, three types of aglycones are detected with daidzein showing higher concentrations than genistein and glycitein.[24] According to Wang and Murphy,[30] these differences may be associated with the cultivar, crop year, and location of soybean cultivation.

Regression analysis of the effect of germination time on total isoflavone content ($R^2 = 0.92$, $p < 0.01$) in germinated soybean cotyledons indicated that the linear model showed a good fit to the experimental data (Figure 3b) with an increase of 1.4- and 2.1-fold in total isoflavone content after 72 and 168 h of germination, respectively. Similar results have been reported by Phommalth et al.,[25] who described that total isoflavone contents in cotyledons of Aga3 and Pungsannamulkong soybeans germinated for 168 h at 20 °C are 1.5- and 1.7-fold higher than in ungerminated cotyledons, respectively. However, Ribeiro et al.[13] observed an increase of 2.4-fold in total isoflavone content from BRS 213 soybean cotyledons germinated for 72 h. During germination, the increase in the concentration of total isoflavones can be attributed to activity and/or synthesis of novel enzymes[36] that are responsible for the isoflavone biosynthesis and metabolism as well as the degradation of proteins, lipids, or carbohydrates that can promote a reduction in seed dry matter[17,37] and contribute to an increase in the relative concentration of total isoflavones.

**Effect of Soybean Germination Time on Different Forms of Isoflavones in Radicles.** The effect of germination time on the isoflavone content in radicles was considered only after 48 h of germination when it was possible to observe the radicles and manually separate them from the other components of the embryonic axis.

Regression analysis of the effect of germination time on daidzin ($R^2 = 0.46$, $p = 0.01$) and glycitin ($R^2 = 0.83$, $p < 0.01$) contents in germinated soybean radicles indicated that the quadratic model fitted to the experimental data (Figure 4a). However, genistin was not detected in germinated radicles. The concentration of daidzin from germinated soybean radicles showed a decrease of 1.6-fold until 120 h with a new increase of 1.5-fold up to 168 h of germination, but the glycitin content showed a marked reduction of 2.9-fold between 48 and 72 h of germination and then remained constant averaging 0.145 ± 0.021 $\mu$mol g$^{-1}$ between 72 and 168 h. When compared to the embryonic axis of ungerminated seeds, it was observed that the daidzin and glycitin contents decreased by 17.2- and 51.2-fold after 72 h of germination, respectively. However, Ribeiro et al.[13] reported that the concentration of the daidzin and glycitin isoflavones in BRS 213 soybean radicles germinated for 72 h decrease by 6.7- and 10.9-fold, respectively. The decrease in daidzin and genistin in the early stages of germination may be associated with an intense metabolic activity of seeds and conversion of these isoflavones into aglycones and subsequent exudation by the root system.[7]

Genistin was not detected in radicles of germinated seeds, which has also been observed by Ribeiro et al.[13] in radicles of BRS 213 soybeans germinated up to 72 h. However, Kim et al.[38] reported that the genistin content ranges from 0.074 to 0.437 $\mu$mol g$^{-1}$ radicles in three soybean cultivars germinated for 168 h. However, the genistin content in radicles of 17 soybean cultivars germinated for 120 h in the presence of light ranges from 0.377 to 5.480 $\mu$mol g$^{-1}$ radicle.[24]

Regression analysis of the effect of germination time on malonyldaidzin ($R^2 = 0.64$, $p < 0.01$) content in germinated soybean radicles indicated that the linear model fit to the experimental data and that the quadratic model fit to the experimental data of malonylgenistin ($R^2 = 0.52$, $p < 0.01$) and malonylglycitin ($R^2 = 0.61$, $p < 0.01$) contents (Figure 4b). The malonyldaidzin content increased by 1.6-fold between 48 and 168 h of germination. However, the malonylgenistin and malonylglycitin contents decreased between 48 and 72 h with a less pronounced increase after 72 h of germination (Figure 4b). When compared to the embryonic axis of ungerminated seeds, the malonyldaidzin, malonylgenistin, and malonylglycitin contents in radicles germinated for 72 h decreased by 6.9-, 13.1-, and 20.2-fold, respectively. Ribeiro et al.[13] also observed a reduction in malonylglucoside content in BRS 213 soybean radicles germinated for 72 h with light. According to Graham,[7] the conjugates of daidzein and genistein in addition to several unidentified aromatic metabolites are selectively excreted into root and seed exudates, and the analysis of seed exudates suggests that this is a continuous but saturable event.

Regression analysis of the effect of germination time on daidzein content in soybean radicles germinated indicated that the linear, quadratic, or cubic models did not fit the experimental data ($p > 0.05$). However, the quadratic model showed a low fit to the experimental data for the genistein concentration ($R^2 = 0.44$, $p = 0.01$). These results indicated that there was little influence of germination time on the concentration of these two aglycones between 48 and 168 h. Thus, it was verified that the mean concentration of genistein and daidzein between 48 and 168 h of germination was 0.860 ± 0.069 and 0.082 ± 0.010 $\mu$mol g$^{-1}$ radicle, respectively. Glycitein was not detected in radicles throughout the entire germination time. However, radicles of 17 soybean varieties germinated for 120 h with and without light have 2.9% glycitein relative to total isoflavone content.[24] In relation to total isoflavone content, the percentage of aglycone in germinated soybean radicles was 14.1%. The highest percentage of isoflavone aglycones in radicles compared to cotyledons and hypocotyls can be attributed to the highest activity of the $\beta$-glucosidase enzyme in radicles[39] with subsequent hydrolysis and release of aglycones that participate in interactions between plants and symbiotic microorganisms as well as act as a defense agent against infection by pathogens.[40] The daidzein and genistein isoflavones are the major components in soybean root extracts responsible for inducing *nod* genes in *Bradyrhizobium japonicum*, which are responsible for the formation of nitrogen-fixing root nodules.[41]

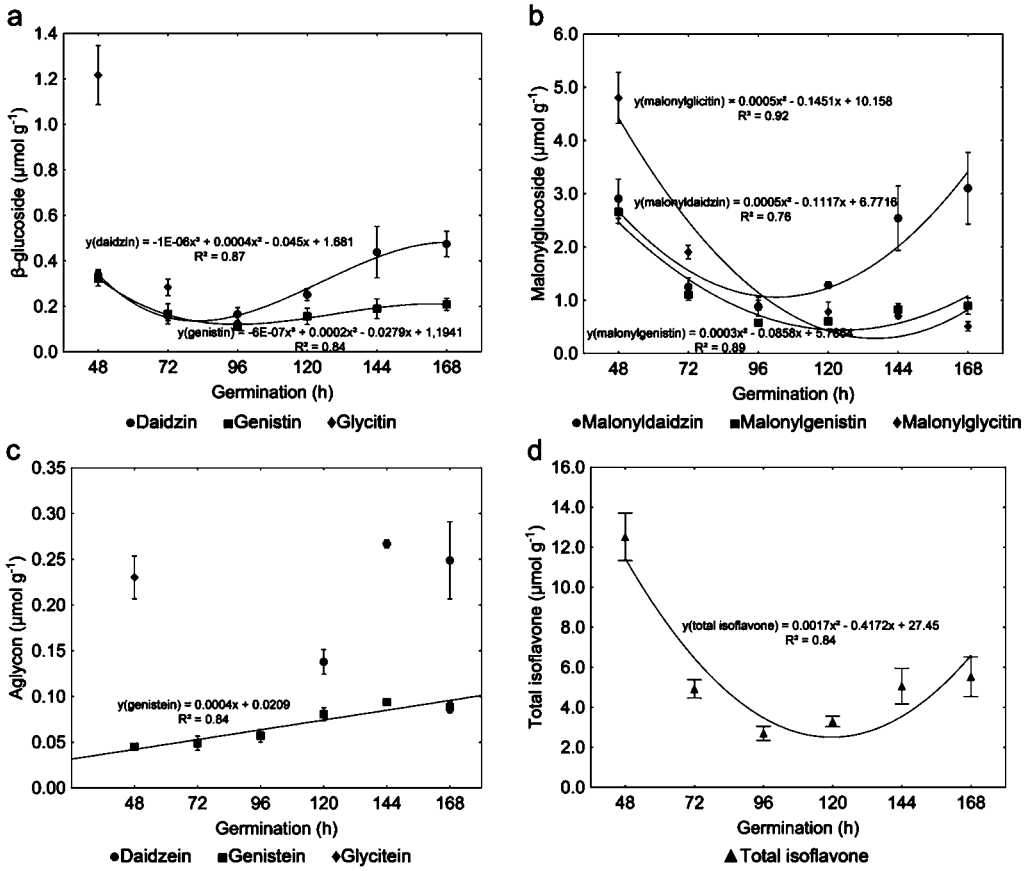

**Figure 5.** (a) $\beta$-glucoside, (b) malonylglucoside, (c) aglycone, and (d) total isoflavone contents in hypocotyls of germinated BRS 284 soybeans.

Regression analysis of the effect of germination time on total isoflavone content ($R^2 = 0.35$, $p = 0.04$) in germinated soybean radicles indicated that the quadratic model showed a low fit to the experimental data (Figure 4d), thereby indicating that the germination time between 48 and 168 h had a low effect on the total isoflavone content. Thus, in this interval of germination, the average total isoflavone content was 5.778 ± 0.125 $\mu$mol g$^{-1}$ radicle. The low change observed for isoflavone content in radicles may be due to high variability in the experimental data, which is intrinsic to the experiment because germination is a biological phenomenon in which several factors in addition to time can influence the isoflavone content.

In the embryonic axis of ungerminated soybean seeds, the total isoflavone content was 53.844 ± 3.863 $\mu$mol g$^{-1}$ sample. Thus, after 168 h of germination, the total isoflavone content decreased by 9.3-fold. A decrease of 6.3-fold was observed by Ribeiro et al.[13] in BRS 213 soybean radicles germinated for 72 h. This decline may be associated with exudation of isoflavones to the external environment or metabolism of isoflavones in other constituents.[7]

**Effect of Soybean Germination Time on Different Forms of Isoflavone in Hypocotyls.** The effect of germination time on the isoflavone content in hypocotyls was considered only after 48 h of germination when it was possible to observe the hypocotyls and to manually separate them from the other components of the embryonic axis.

Regression analysis of the effect of germination time on daidzin ($R^2 = 0.87$, $p < 0.01$) and genistin ($R^2 = 0.84$, $p < 0.01$) contents in germinated soybean hypocotyls indicated that the cubic model fit to the experimental data (Figure 5a). Thus, the daidzin and genistin contents in soybean hypocotyls decreased by 2.1- and 2.9-fold between 72 and 96 h of germination, respectively, followed by an increase of 2.8- and 1.7-fold, respectively, up to 144 h with a little tendency to change between 144 and 168 h. The glycitin isoflavone was detected at 48 h with a reduction of 4.3-fold at 72 h. After this germination time, glycitin was not detected, thus excluding regression analysis for glycitin. However, the glycitin content ranges from 0.100 to 0.776 $\mu$mol g$^{-1}$ hypocotyl in 17 soybean cultivars germinated for 120 h with light.[24] When compared to the embryonic axis of ungerminated seeds, the daidzin, genistin, and glycitin contents decreased by 15.0-, 7.6-, and 6.8-fold, respectively, after 48 h of germination. Graham[7] reported a higher concentration of daidzein and genistein conjugates in hypocotyl hooks and reported that the contents of these isoflavones undergo a programmed and dramatic decrease between 48 and 96 h of germination. Additionally, Graham found an inverse correlation between the concentration of isoflavone conjugates and expansion of the hypocotyl hook.

Regression analysis of the effect of germination time on malonyldaidzin ($R^2 = 0.76$, $p < 0.01$), malonylgenistin ($R^2 = 0.89$, $p < 0.01$), and malonylglycitin ($R^2 = 0.92$, $p < 0.01$) contents in germinated soybean hypocotyls indicated that the quadratic model showed a good fit to the experimental data (Figure 5b). The malonyldaidzin content decreased by 3.3-fold up to 96 h of germination and returned to the initial concentration after 168 h of germination. However, the malonylgenistin and malonylglycitin contents decreased by 4.6- and 5.3-fold, respectively, up to 96 h of germination with little change between 96 and 168 h. When compared to the embryonic axis of ungerminated seeds, the malonyldaidzin content decreased by 22.0- and 4.1-fold at 96 and 168 h, respectively, and the malonylgenistin and malonylglycitin contents were decreased by 7.2- and 36.7-fold

dx.doi.org/10.1021/jf502927m | J. Agric. Food Chem. 2014, 62, 8452−8459

after 168 h of germination. These results showed similar tendencies to those observed by Yuan et al.,[14] who found a reduction of 9.0-, 25.6-, and 125.0-fold for the malonyldaidzin, malonylgenistin, and malonylglycitin contents in soybean hypocotyls germinated for 120 h in the presence of light.

Regression analysis of the effect of germination time on genistein ($R^2$ = 0.84, $p < 0.01$) content in germinated soybean hypocotyls indicated that the linear model showed a good fit to the experimental data (Figure 5c). The genistein content increased by 2.0-fold between 48 and 168 h of germination. Similar trends were observed by Yuan et al.,[14] who reported an increase of 9.7-fold for the genistein content in soybean hypocotyls germinated for 72 h followed by a decrease of 1.4-fold between 72 and 120 h of germination. In hypocotyls, daidzein was detected only after 120 h, and glycitein was detected only after 48 h of germination. Therefore, no regression analysis was performed for these components. In hypocotyls, the daidzein content doubled between 120 and 144 h and remained constant up to 168 h with an average of 0.258 ± 0.013 $\mu$mol g$^{-1}$ hypocotyl. In hypocotyls of 17 soybean cultivars germinated for 120 h, the daidzein content ranges between 0.231 and 1.019 $\mu$mol g$^{-1}$ hypocotyl.[24] The daidzein content in soybean hypocotyls germinated for 120 h increases by 5.1-fold compared to nongerminated hypocotyls.[14] The glycitein content after 48 h of germination was 0.230 ± 0.023 $\mu$mol g$^{-1}$ hypocotyl. However, in hypocotyls of 17 soybean cultivars germinated for 120 h with and without light, the glycitein concentrations range from 0.067 to 0.814 $\mu$mol g$^{-1}$.[24]

Regression analysis of the effect of germination time on total isoflavone content ($R^2$ = 0.84, $p < 0.01$) in germinated soybean hypocotyls indicated that the quadratic model showed a low fit to the experimental data (Figure 5d). The total isoflavone content decreased by 4.6-fold between 48 and 96 h of germination followed by a 2.0-fold increase between 96 and 168 h. Comparing the embryonic axis of ungerminated soybeans with soybean hypocotyls germinated for 168 h, the total isoflavone content decreased by 9.8-fold (Table 1). Similar results have been observed in the Aga3 and Pungsannamulkong cultivars germinated for 168 h.[25]

In conclusion, soybean BRS 284 showed 89.9% cotyledons, 2.4% embryonic axis, and 7.7% seed coat, and 84.2% and 15.8% of total isoflavones are present in cotyledons and the embryonic axis, respectively; however, the total isoflavone content in the embryonic axis was 7.1-fold higher than that in cotyledons. The germination time exerted different effects depending on the components of germinated soybeans and the different forms of isoflavones. In cotyledons germinated up to 168 h, the total isoflavone content increased 2.1-fold in relation to ungerminated cotyledons, and aglycones were not detected. In radicles, germination time exerted low influence on the daidzein and genistein content, while the malonyldaidzin increased 1.6-fold between 48 and 168 h, and in hypocotyl, the genistein content increased by 2.0-fold between 48 and 168 h of germination. Therefore, in this study, it was concluded that, in the germination process by 168 h, the total isoflavones showed higher concentration in the cotyledons and aglycones were detected only in the hypocotyl and radicle.

In the present study, the effects of germination time were modeled, and it was possible to monitor the whole process of germination in relation to the content of different forms of isoflavones and different components of soybeans germinated. Our results imply that, to obtain soybean sprouts for human consumption with higher levels of total isoflavones, it is necessary to carry germination until 168 h and not eliminate the cotyledons. In addition, if the main purpose is the intake of aglycones isoflavones, the consumption of radicle and hypocotyls may be sufficient as cotyledons germinated for 168 h does not contain these forms of isoflavones.

**ABSTRACT:** AbnZ1, with optimal pH of 6.0 and optimal temperature of 40 °C, is a cold-adapted endo-1,5-α-L-arabinanase encoded by the gene *abnZ1* from *Paenibacillus polymyxa* Z6. The specific activity of AbnZ1 remained 54.1% of maximum at 5 °C. To apply AbnZ1 in acidic conditions, three basic hsitidine (His) residues, $His^{48}$, $His^{218}$, and $His^{297}$, around the catalytic domain were selected as mutation sites, which were replaced with Asp, Glu, Arg, and Lys, respectively, to yield 12 mutants, H48D/E/R/K, H218D/E/R/K, and H297D/E/R/K. The optimum pH of mutant H218D shifted toward the acidic direction by 0.5 unit, and the relative activity was enhanced from 20.4 to 55.7% at pH 5.0. Furthermore, the specific activity of H218D in optimal conditions was 82.6 U/mg versus that of wild type, 73.4 U/mg, and the $K_m$ decreased from 11.9 to 7.1 mg/mL. This work provided an arabinanase candidate for juice clarification and pectin extraction.

**KEYWORDS:** *arabinanase, cold-adapted, site-directed mutagenesis, molecular modeling, pH stability*

## INTRODUCTION

Arabinans, mainly composed of α-L-arabinofuranosyl residues, are generally arranged in α-1,5-linked chains with various numbers of residues substituted with other α-L-arabinofuranosides at the O2 and/or O3 position.[1] In the plant primary cell wall, arabinans are concentrated on rhamnogalacturonan I regions of pectin and act as a vital neutral sugar side chain of pectin, which connects pectin to cellulose.[1,2]

Enzymes that can release arabinoses are found in various bacteria and fungi. These enzymes involved in degradation of arabinan can be mainly divided into three types by their action mode and substrate specificity:[3] (1) Endo-1,5-α-L-arabinanases (endo-ABNs, EC 3.2.1.99) cleave internal linkages of arabinan backbone, producing arabino-oligosaccharides. (2) Exo-α-L-arabinanases cleave arabinan backbone from terminal arabinose, yielding arabinoses. (3) The last is α-L-arabinofuranosidases (AFs, EC 3.2.1.55), exotype enzyme, which hydrolyze terminal nonreducing residues from arabinose-containing polysaccharides and are active on 4-nitrophenyl-α-L-arabinofuranoside.[4] AFs remove arabinan side chain, allowing ABNs to cleave the glycosidic bonds of the arabinan backbone.

The arabinan is soluble in water, whereas debranched arabinan produced by AFs is insoluble in cold water. Therefore, in fruit and vegetable juice processing, if AFs in the enzyme preparations cause haze formation due to the precipitation of polymeric debranched arabinans, endoarabinanases can be applied to prevent haze formation by degrading polymeric debranched arabinan.[5,6] In addition, as arabinan was one of the major components in plant cell wall, endoarabinanase could be used with AFs together in the juice industry for improving the yield of juice because they can promote the degradation of the pectin in fruits and vegetables. Endoarabinanases from several microorganisms have been characterized, but most of them were mesophilic and thermophilic. Their optimal temperatures are 50 °C for *Aspergillus niger*,[7] 60 °C for *Bacillus subtilis* and *Penicillium chrysogenum*,[8,9] 70 °C for *Bacillus thermodentrificans*, and 73 °C for *Thermotoga petrophila*.[10,11] Compared with the mesophilic and thermophilic endoarabinanases, cold-active endoarabinanases should be more attractive in the juice industry as colder conditions hamper spoilage and avoid changes in nutritional properties.[12] However, only a few cold-active endoarabinanases have been reported, such as Abnc from *Penicillium chrysogenum* 31B, which was mostly active at 30−40 °C and remained 55% of maximal activity at 10 °C.[6]

Besides, endoarabinanases have potential application in the enzymatic extraction of pectin. As a vital member of protopectinases, endoarabinanases can promote the solubilization of protopectin through cleaving the link between protopectin and cellulose.[13,14] However, the raw material used for industrial pectin extraction, such as pomace from fruit juice processing, is usually at lower pH than the optimal pH for most natural endoarabinanases. Large-scale pH adjustments will significantly increase costs for pH modifier and treatment of wastewater with high ionic strength, and the same problem happened in the application of endoarabinanases in juice clarification because of the acidity of juices. Such issues can be resolved by modification of the enzyme molecule through site-directed mutagenesis based on rational design to

improve the protein stability and catalytic efficiency under acidic conditions.

In this study, we cloned and characterized a novel endoarabinanase from *Paenibacillus polymyxa* Z6 with excellent cold-adapted properties such as remaining at 54.1% of maximum activity at 5 °C. Following site-directed mutagenesis based on rational design, 12 mutants were generated, among which the replacement of His with Asp in the position 218 produced an apparent positive mutant with a shift of pH optima from pH 6.0 to pH 5.5 and higher pH stability in lower pH.

## MATERIALS AND METHODS

**Chemicals and Reagents.** Sugar beet linear $\alpha$-1,5-L-arabinan, sugar beet red debranched arabinan, sugar beet arabinan, wheat flour arabinoxylan (medium viscosity), larch arabinogalactan, arabinose, arabinobiose, arabinotriose, and arabinotetraose were obtained from Megazyme International Ireland Co., Ltd. (Wicklow, Ireland). Xylan from beechwood and 4-nitrophenyl-$\alpha$-L-arabinofuranoside were purchased from Sigma-Aldrich Co., Ltd. (St. Louis, MO, USA). Gum arabic and soluble starch were obtained from Shanghai Hushi Co., Ltd. (Shanghai, China). Genomic DNA extraction kits, plasmid extraction kits, gel extraction kits, and Ni-Sepharose resin were purchased from Tiangen Biotech Co., Ltd. (Beijing, China). Kod plus mutagenesis kit was from Toyobo Biotech Co., Ltd. (Shanghai, China). All other molecular cloning reagents were from Takara Biotechnology Co., Ltd. (Dalian, China).

**Strain, Media, and Plasmids.** The *P. polymyxa* Z6 used in this study was screened from a planting soil sample collected from an apple orchard in Xi'an, Shanxi province, China. The *P. polymyxa* Z6 was deposited in the China Center for Type Culture Collection (CCTCC AB 2014036). *Escherichia coli* DH5$\alpha$, *E. coli* BL21 (DE3), and the plasmid pET21a (+) were used for cloning and expression of the gene *abnZ1*. Transformants were grown in LB medium (1% peptone, 1% NaCl, and 0.5% yeast extract) with 100 $\mu$g/mL ampicillin.

**Cloning, Expression, and Purification of AbnZ1.** The coding sequence of *abn*Z1 was amplified by PCR with the forward primer abn-f11 and the reverse primer abn-r11 by using genomic DNA of *P. polymyxa* Z6 as the template (Table 1). The products of PCR reaction were cloned in the plasmid pET21a (+) containing a C-terminal His-tag for purification of AbnZ1.

The recombinant plasmid was transformed into *E. coli* BL21 (DE3) and grown on solid LB medium containing 100 $\mu$g/mL ampicillin. Then the positive recombinant *E. coli* was cultivated in 50 mL of liquid LB medium at 37 °C with 100 $\mu$g/mL ampicillin until the $OD_{600}$ reached 0.6. After that, 0.2 mM IPTG was added to the medium to induce enzyme expression, and the culture continued to grow at 20 °C for 20 h.

The target protein was purified by using Ni-Sepharose through elution with imidazole in a linear gradient from 10 to 250 mM. Phosphate buffer (pH 7.0, 100 mM) was used in the Ni-Sepharose column. The concentrated active fractions were stored in 100 mM phosphate buffer (pH 7.0) containing 10% glycerol at −20 °C.

**Site-Directed Mutagenesis.** The mutants were obtained by using the KOD-plus-Mutagenesis Kit (Toyobo, Shanghai, China) to amplify the recombinant plasmid pET21a (+)-*abnZ1*. The primers used for the site-directed mutagenesis are listed in Table 1. The mutants of the recombinant plasmid was transformed into *E. coli* BL21 (DE3) and grown on solid LB medium containing 100 $\mu$g/mL ampicillin. The clones grown on the ampicillin-resisted plates were transferred to liquid LB medium containing 100 $\mu$g/mL ampicillin and selected for DNA sequencing. Then, the positive clones were stored in 15% glycerol at −20 °C and used for further research.

**Determination of Protein Content, Molecular Mass, and Association Form.** The protein content was determined using the Bradford reagent with bovine albumin as standard. A 5800 MALDI-TOF/TOF (AB SCIEX, USA) was used to detect the association form and the molecular weight of AbnZ1. A solution of CCA was prepared by dissolving 10 mg of matrix in 1 mL of water solvent containing 0.1% TFA and 50% ACN. The protein solution (1.0 g/L) was placed on a MALDI plate and evaporated at room temperature. Following this, 1 $\mu$L of different matrix solutions was used to overlay the protein sample spots, and the resulting droplets were left for crystallization by air-drying. Mass spectrometric measurements were performed using a 5800 MALDI-TOF-TOF instrument. An accelerating voltage of 20 kV was used. Mass spectra were recorded in the linear mode.

**Enzyme Activity Assay.** The arabinanase activity was determined by measuring the amount of reducing sugar released in a reaction mixture containing 200 $\mu$L of 0.25% arabinan in 100 mM buffer and 50

dx.doi.org/10.1021/jf501328n | J. Agric. Food Chem. 2014, 62, 8460−8469

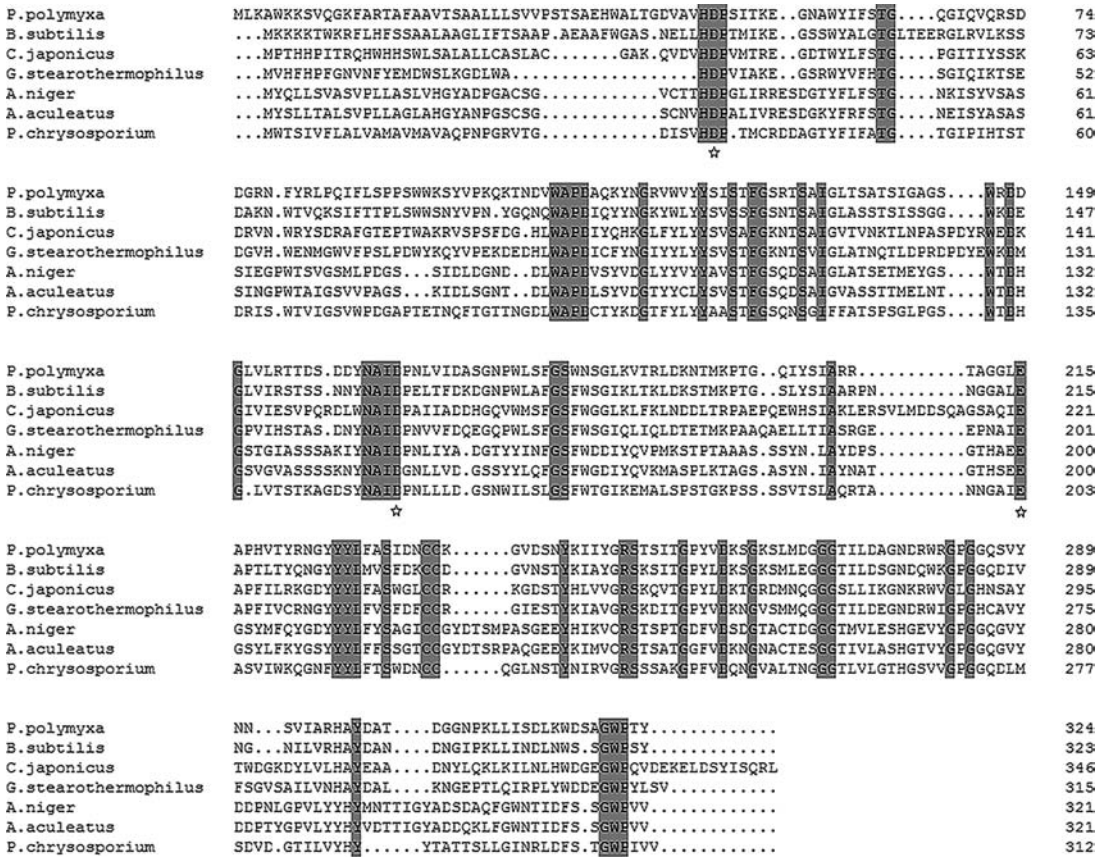

**Figure 1.** Multiple sequence alignment of AbnZ1 with some GH43 endoarabinanases. AbnZ1 was compared with endo-1,5-$\alpha$-L-arabinanase from *B. subtilis* 168T+ (AAV87172), *C. japonicus* (CAA71485), *G. stearothermophilus* (B3EYM8), *A. niger* (P42256), *A. aculeatus* (Q9HFS9), and *P. chrysosporium* (AFN42888). The catalytic residues are marked with asterisks. Residues that are identical in all sequences are shaded in gray.

$\mu$L of enzyme samples. Reducing sugars were measured by using the 3,5-dinitrosalicylic acid (DNS) method.[5] One unit of enzyme activity was defined as 1 $\mu$mol of reducing sugar as arabinose produced per minute.

**Determination of pH and Temperature Optima and Stability.** The optimal pH was measured at 37 °C for 30 min from pH 4.0 to 9.0 by using sodium acetate buffer (pH 4.0−6.0), sodium phosphate buffer (pH 6.0−8.0), and Tris-HCl buffer (pH 8.0−9.0). The optimal temperature was measured at temperatures ranging from 5 to 70 °C in 100 mM sodium acetate buffer (pH 6.0) for 30 min. For pH stability, the enzyme was incubated in buffers ranging from pH 5.0 to 7.0 at 20 °C for various periods. For temperature stability, the enzyme was incubated in 100 mM sodium acetate buffer (pH 6.0) at temperatures ranging from 20 to 50 °C for various phases. Then, the residual enzyme activity was measured at an optimal pH and temperature for 30 min. Substrate was 0.25% (w/v) debranched arabinan.

**Substrate Specificity and Degradation Pattern of AbnZ1.** The substrate specificity was determined by measuring the enzyme activity with sugar beet linear 1,5-$\alpha$-L-arabinan, sugar beet red debranched arabinan, sugar beet arabinan, 4-nitrophenyl-$\alpha$-L-arabinofuranoside, xylan from beechwood, wheat flour arabinoxylan, larch arabinogalactan, gum arabic, and starch soluble at the optimal pH and temperature for 5 min.

For the degradation pattern, high-performance anion exchange chromatography (HPAEC) was used to determine hydrolysis products. The hydrolysis products of 1% sugar beet linear 1,5-$\alpha$-arabinan were analyzed with HPAEC using an Agilent 1100 series system (Agilent, Santa Clara, CA, USA) with a 300 × 6.5 mm Sugarpak1 column (Waters, Milford, MA, USA) maintained at 80 °C using double-distilled deionized and degassed water as mobile phase at a flow rate of 0.5 mL/min. The effluent was monitored with a differential refractive index detector.

**Determination of Kinetic Parameters.** The kinetic parameters were determined through the Lineweaver−Burk plot method at the optimal pH and temperature by using the linear 1,5-$\alpha$-L-arabinan at concentrations ranging from 0.1 to 1% (w/v) for 5 min.[15]

**Sequence Analysis.** Multiple nucleotide sequence alignment of gene *abnZ1* was calculated and presented by using the DNAMAN program. The signal peptide was predicted by the SignalP program. The molecular weight and p*I* were predicted by using the Compute pI/Mw tool on the ExPASy Bioformatics Resources Portal (http://web.expasy.org/compute_pi/).

**3-D Structure Model Analysis of Wild-Type and Mutants.** A theoretical structure of AbnZ1 with residues 47−324 was built by automated protein structure homology modeling from the Swiss Model server (http://swissmodel.expasy.org/) with the crystal structure of endo-1,5-$\alpha$-L-arabinanase (1UV4) from *B. subtilis* 168+ as template. The estimated absolute model quality (QMEAN *Z*-score) of modeling structure was 0.22,[16] and the sequence identity between template and target was 60.2%.[17−19] The 3-D model and structure alignment between AbnZ1 and BsArb43B (2x8f) from *B. subtilis* were conducted and shown by the software PyMOL. Amino acid mutations were inserted into the structure using the mutation tool Swiss-Viewer followed by energy minimization.

**Nucleotide Sequence Accession Number.** The nucleotide sequence data of the wild-type gene *abnZ1* reported in this study were submitted to Genbank under accession no. KF481913.

## RESULTS

**Sequence Analysis of *P. polymyxa* AbnZ1.** The gene *abn*Z1 had an open reading frame of 972 bp encoding 324 amino acids. The molecular weight and p*I* of AbnZ1 were

predicted as 35 477 Da and 9.18, respectively. AbnZ1 was classified as a member of the glycoside hydrolase family 43 (GH43) according to its primary protein sequence and displayed 99% identity to the product of the *abnA* gene from *P. polymyxa* M1. Moreover, the amino acid sequence of AbnZ1 displayed 55, 39, 51, 33, 33, and 37% identity with the sequences of endo-1,5-α-L-arabinanase from *B. subtilis* 168T+, *Cellvibrio japonicus*, *Geobacillus stearothermophilus*, *A. niger*, *A. aculeatus*, and *Phanerochaete chrysosporium* (Figure 1).

The active sites of endoarabinanases consisted of three key amino acids, Asp, Asp, and Glu, which were conserved in glycoside hydrolase (GH) family 43.[20] Such amino acid residues are $Asp^{49}$, $Asp^{165}$, and $Glu^{215}$, conserved in the mature AbnZ1 according to the result of multiple sequence alignment (Figure 1).

**Expression in *E. coli* and Purification of Recombinant AbnZ1.** We cloned and expressed the gene *abn*Z1 in pET21a (+) with a $His_6$-tag at the C-terminus. Parts of the recombinant AbnZ1 overexpressed in *E. coli* BL21 (DE3) were soluble and active (Figure 2a). The enzyme was purified by using a Ni-

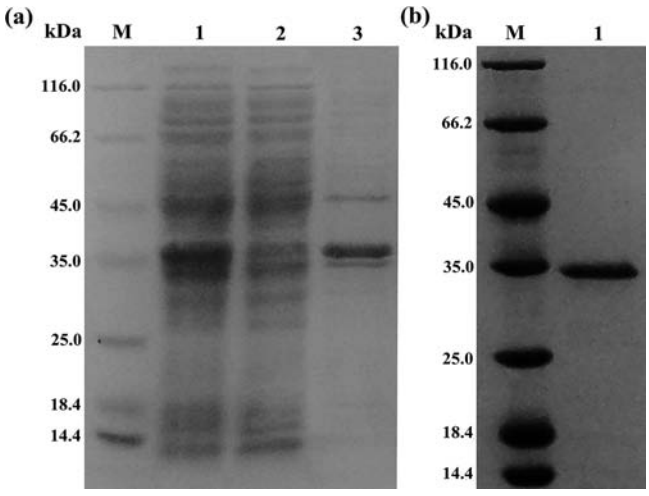

**Figure 2.** Expression and purification of AbnZ1: (a) analysis of the protein expression (lanes: 1, crude cell lysate after cold osmotic shock; 2, soluble fraction of the crude cell lysate after cold osmotic shock; 3, insoluble fraction of the crude cell lysate after cold osmotic shock); (b) recombinant AbnZ1 purified by Ni-Sepharose column. The proteins were separated by 12.5% SDS-PAGE gels.

Sepharose column. The specific activity measured under pH 6.0 and 40 °C was 73.4 U/mg. The purified AbnZ1 is shown in Figure 2b, which indicated that the molecular weight of the recombinant protein after purification was about 35 kDa, in good accordance with the predicted molecular weight (Figure 2b). The result of further MALDI-TOF/TOF testing (Figure 3) showed that the monomeric molecular weight of AbnZ1 was about 32.6 kDa, whereas that of the dimer was 65.2 kDa, and there was no distinct peak of its trimer formation to be determined, which indicated that the association form of AbnZ1 is dimer.

**Biochemical Properties of Purified AbnZ1.** The optimal reaction temperature of purified AbnZ1 ranged from 30 to 40 °C (Figure 4a). The specific activity of AbnZ1 was kept about 54.1% of maximal activity at 5 °C (Figure 4a), which was rare in reported arabinanases. AbnZ1 could maintain most of the initial activity after incubation at 20 °C for 4 h while losing most activity when incubated at 50 °C for 30 min (Figure 4b).

AbnZ1 reached the highest activity at pH 6.0 and 40 °C in 100 mM sodium acetate buffer and achieved about 20.4 and 83.6% of the maximal activity at pH 5.0 and 7.0, respectively (Figure 4c). AbnZ1 was stable at pH 7.0 compared with 55.5 and 5.78% of maximal activity remaining after 30 min of incubation at pH 6.0 and 5.0 respectively (Figure 4d).

The substrate specificity of recombinant AbnZ1 was measured on linear α-1,5-L-arabinan, red debranched arabinan, sugar beet arabinan, 4-nitrophenyl-α-L-arabinofuranoside, xylan from beechwood, wheat flour arabinoxylan, larch arabinogalactan, gum arabic, and soluble starch. AbnZ1 was found to be active toward only linear arabinan, red debranched arabinan, and sugar beet arabinan with specific activities of 73.4, 44.0, and 9.3 U/mg, respectively, but showed no activity toward the rest of the substrates.

Linear α-1,5-L-arabinan was selected as substrate for product analysis.[21] HPAEC mutagenesis, forming six mutan analysis (Figure 5) showed arabinobiose and arabinotriose were the major final products of the hydrolysis by the recombinant AbnZ1, which supported that AbnZ1 is an endoarabinanase.

Kinetic parameters toward the optimal substrate linear α-1,5-L-arabinan were measured at 40 °C and pH 6.0 for 5 min by the Lineweaver−Burk plot method. The $K_m$ and $V_{max}$ toward linear arabinan were 11.6 mg/mL and 117.7 μmol $min^{-1}$ $mg^{-1}$, respectively. Kinetic parameters of AbnZ1 toward linear arabinan are listed in Table 2.

**Theoretical Three-Dimensional Model and Site-Directed Mutagenesis of AbnZ1.** A 3-D model was constructed by the Swiss model with the structure of endoarabinanase Ara43a (1UV4) as template to determine the mutation site of AbnZ1 for improving acidic-adapted ability of AbnZ1. As shown in Figure 6a, AbnZ1 displayed a characteristic β-propeller fold structure, containing five β-sheets called blades arranged around a pseudo axis. An α-helix was located after blade I, which exists commonly in endoarabinanases.[22] The catalytic domain of AbnZ1 comprised three key active sites $Asp^{49}$, $Asp^{165}$, and $Glu^{215}$, which were conserved in all members of GH families 32, 43, 62, and 68.[20]

The function of three key active sites from the arabinanase BsArb43B has been identified.[22] On the basis of the results of multiple sequence alignment (Figure 1) and structure alignment between AbnZ1 and BsArb43B (Figure 6b), $Asp^{49}$ in AbnZ1 was deduced to serve as a general base catalyst, deprotonating the nucleophilic water molecule that attacks the bond, whereas $Glu^{215}$ served as a general acid catalyst protonating the glycosidic oxygen.[23] Putative roles of $Asp^{165}$ include acting as a $pK_a$ modulator and maintaining the correct alignment of the general acid residue relative to the substrate.[24]

Given the similar catalytic mechanism among the glycoside hydrolases and the importance of the electrostatic interactions around the active sites, three basic histidine (His) residues around the catalytic domain of AbnZ1 were selected as mutation sites (Figure 6a) according to the 3-D model of AbnZ1, which were $His^{48}$, $His^{218}$, and $His^{297}$. They were further replaced respectively with acidic amino acid residues, aspartate and glutamate, and alkaline amino acid residues, arginine and lysine, via site-directed mutagenesis, forming 12 mutants H48D/E/R/K, H218D/E/R/K, and H297D/E/R/K.

The mutants H48D/E/R/K, H297D/E/R/K, and H218R/K lost their activity (data not shown). Mutant H218E was active, but it did not change the enzymatic property obviously under acidic condition compared with the wild type. Fortunately, the optimal pH of H218D shifted toward the acidic direction.

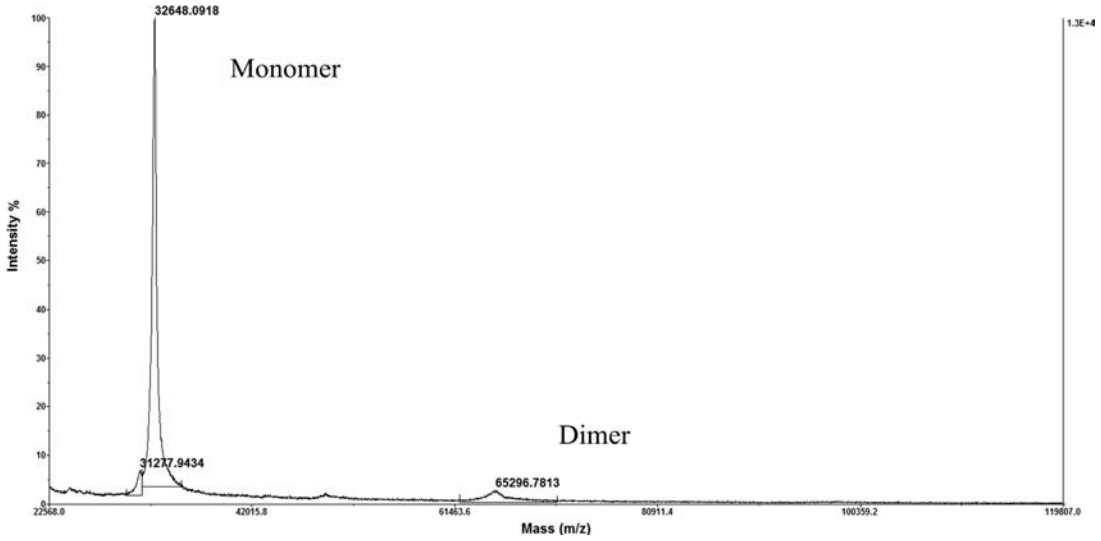

**Figure 3.** MALDI-TOF/TOF showing the association form and molecular weight of AbnZ1.

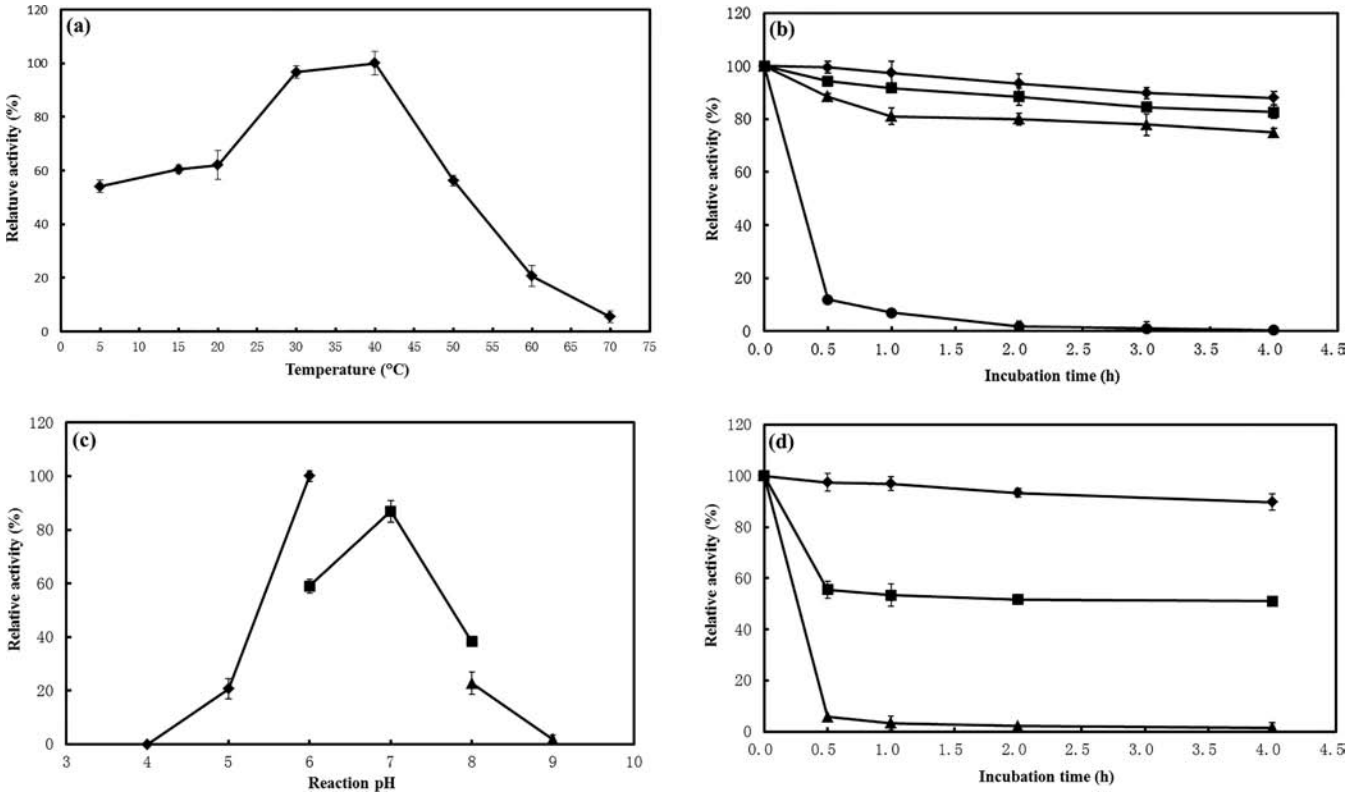

**Figure 4.** (a) Effect of temperature on enzyme activity. Reactions were conducted for 30 min in 100 mM, pH 6.0, sodium acetate buffer. (b) Effect of temperature on enzyme stability. The enzyme was incubated at temperatures ranging from 20 to 50 °C in 100 mM, pH 6.0, sodium acetate buffer for a period of time, and residual activity was assayed at optimal temperature and pH by using the DNS method. Solid rhombuses, squares, triangles, and circles represent AbnZ1 at 20, 30, 40, and 50 °C, respectively. (c) Effect of pH on enzyme activity. Activity was measured at 40 °C for 30 min at the indicated pH values in 100 mM of each buffer: sodium acetate (pH 4.0−6.0, solid rhombuses), sodium phosphate (pH 6.0−8.0, solid squares), and Tris-HCl (pH 8.0−9.0, solid triangles). (d) Effect of pH on enzyme stability. The enzyme was incubated at 20 °C in pH 5.0−7.0 100 mM buffers for a period of time. After that, residual activity was assayed at optimal temperature and pH by using the DNS method. Solid rhombuses, squares, and triangles represent AbnZ1 at pH 7.0 sodium phosphate, pH 6.0 sodium acetate, and pH 5.0 sodium acetate. In all panels, the highest activity was taken as 100%. Reaction substrate was 0.25% red debranched arabinan.

**Biochemical Characterization of Mutant Enzyme H218D.** There were no obvious differences in recombinant protein concentration between the wild-type AbnZ1 and the mutant H218D according to the graph of SDS-PAGE (Figure 7a), which implied the substitution of His residue did not affect the expression of recombinant protein. A single band in Figure 7b indicated H218D was successfully purified. The specific activity of H218D was 82.6 U/mg under pH 6.0 and 40 °C. The optimal pH of H218D is 5.5, and the specific activity of H218D in pH 5.0 was 55.7% of the highest activity compared

[a]Specific activity was measured by purified recombinant AbnZ1 with linear arabinan at 40 °C, pH 6.0. The data of AbnZ1 shown are the averages and standard deviations of three independent experiments.

with that of the wild AbnZ1, 20.4% (Figure 8a). Meanwhile, the stability of H218D at pH 6.0 was slightly higher than that of the wild AbnZ1 (Figure 8b). Sixty percent of the initial activity was retained after H218D had been incubated in pH 6.0 at 20 °C for 4 h, whereas that for wild-type was 50%. Besides, the mutation did not bring about change in the reaction temperature between the H218D and the wild AbnZ1 (Figure 8c).

The $V_{max}$ and $K_m$ of H218D were changed to 171.3 μmol $min^{-1}$ $mg^{-1}$ and 7.1 mg/mL, and $K_{cat}$ was improved about 45% versus that of the wild AbnZ1. Kinetic parameters of H218D and the wild AbnZ1 toward linear arabinan are listed in Table 2, which showed that H218D was given higher catalytic efficiency.

## DISCUSSION

Unlike AFs have been grouped into GH families 3, 10, 43, 51, 54, and 62 on the basis of their amino acid sequences; all known endoarabinanases are in GH family 43.[9] Among the reported arabinanases, cold-adapted arabinanases were scarce but valuable in the food industry. We cloned and characterized a novel cold-adapted endo-1,5-α-L-arabinanase gene *abnZ1* from *P. polymyxa* Z6 in this study.

Most reported endoarabinanases were mesophilic and thermophilic. Compared with most reported endoarabinanases, the optimal reaction temperature of purified AbnZ1 ranged from 30 to 40 °C and was lower. Furthermore, the specific activity of AbnZ1 was about 54.1% of maximal activity at 5 °C, which was rare in reported arabinanases. Only a few cold-active endoarabinanases have been reported, such as Abnc from *Penicillium chrysogenum* 31B, which was mostly active at 30−40

dx.doi.org/10.1021/jf501328n | J. Agric. Food Chem. 2014, 62, 8460−8469

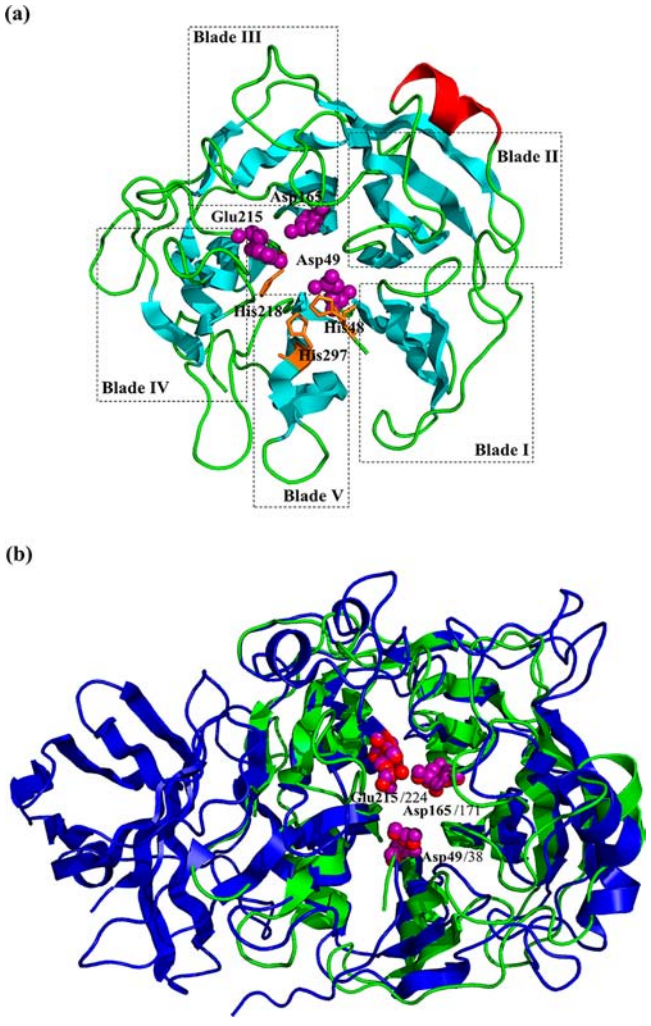

**Figure 6.** (a) 3-D model structure of wild-type AbnZ1 created by Swiss model and processed by PyMol. AbnZ1 contains a five-blade $\beta$-propeller, which is a characteristic structure in GH43. Blade I to blade V is marked with a dotted box. The $\alpha$-helices and $\beta$-sheets are shown in red and cyan, respectively. Loops and other secondary structure are shown in green. The catalytic residues Asp[49], Asp[165], and Glu[215] are shown in purple balls. The positions of the point mutation are shown in orange sticks. (b) Structure alignment with endoarabinanase BsAra43B from *B. subtilis* (2x8f). The 3-D model structure was created by PyMol. AbnZ1 is shown in green and BsArb43B in blue. The catalytic residues of AbnZ1 are shown in purple balls and printed in bold. The catalytic residues of BsArb43B are shown in red balls.

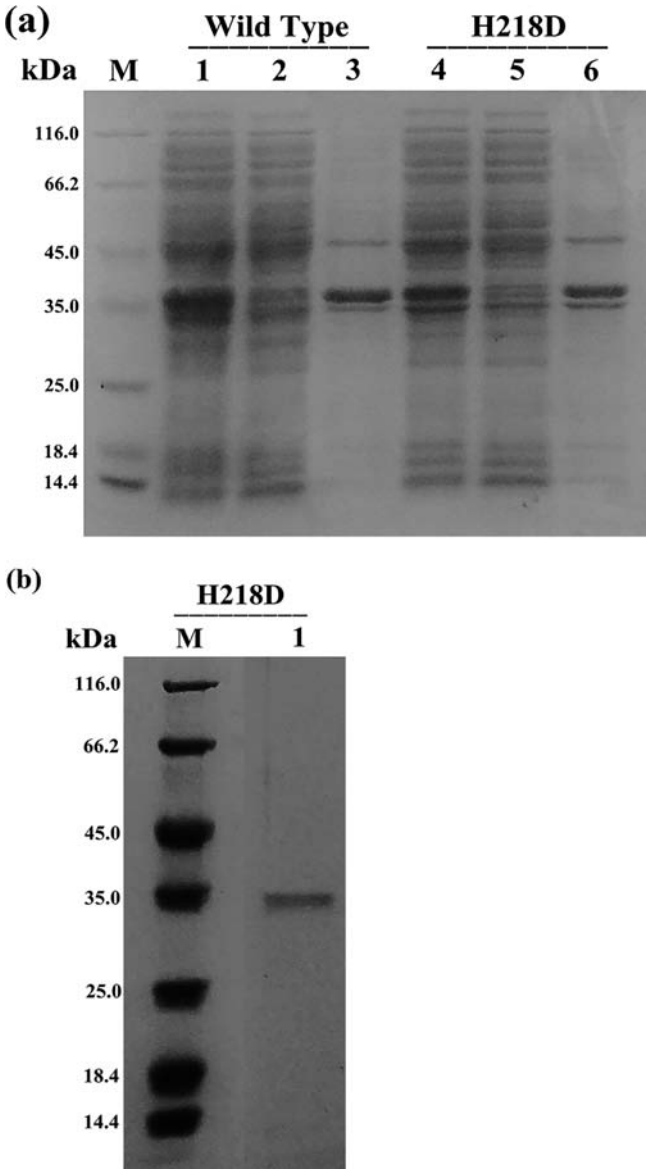

**Figure 7.** Expression of purification of the mutant H218D: (a) analysis of protein expression (lanes: 1 and 4, crude cell lysate after cold osmotic shock; 2 and 5, soluble fraction of the crude cell lysate after cold osmotic shock; 3 and 6, insoluble fraction of the crude cell lysate after cold osmotic shock); (b) recombinant H218D purified by Ni-Sepharose column. The proteins were separated by 12.5% SDS-PAGE gels.

°C and retained 55% of maximal activity at 10 °C,[6] indicating AbnZ1 performed better than Abnc under the low temperature. In addition, AbnZ1 had a higher specific activity, 73.4 U/mg, when compared with Abnc, the specific activity of which was 6.5 U/mg.[6] Thus, AbnZ1 was an excellent cold-adapted enzyme and would have potential application in some food processing under lower temperature.

The HPAEC result supported that AbnZ1 was an endoarabinanase. Generally, in the case of exoacting enzymes, only monomers or dimers accumulate throughout the enzyme reaction, whereas in the case of endoacting enzymes, bigger oligomers, such as arabinotriose and arabinotetraose, formed even in the initial stage of hydrolysis (Figure 5). Besides, the ability of hydrolyzing red debranched arabinan also indicated that AbnZ1 acts in an endo manner, because dye molecules attached to nonreducing terminal arabinose of arabinan prevent the exoarabinanases from releasing arabinose from the nonreducing end.[3]

The optimal pH of reported endoarabinanases is mostly at ≥6.0, such as 6.0−7.0 for AbnS1 from *P. chrysogenum*,[9] 6.0 for an endoarabinanase from *Bacillus licheniformis*,[25] 6.5 for that from *Caldicellulorsiruptor saccharolyticus*, 7.0 for Abn2 from *B. subtilis*,[3,26] and 6.0 for the present AbnZ1. AbnZ1 also showed rapidly decreased specific activity under acidic environment, which would limit its application for either enzymatic extraction of pectin or juice clarification, the pH of the raw material usually being about 4.0−4.5. Considering the situation of pectin extraction from fruit pomace, as the pH modifier (alkali) was used, the advantages of enzymatic extraction of pectin would be lost compared with the present industrial acidolysis method.

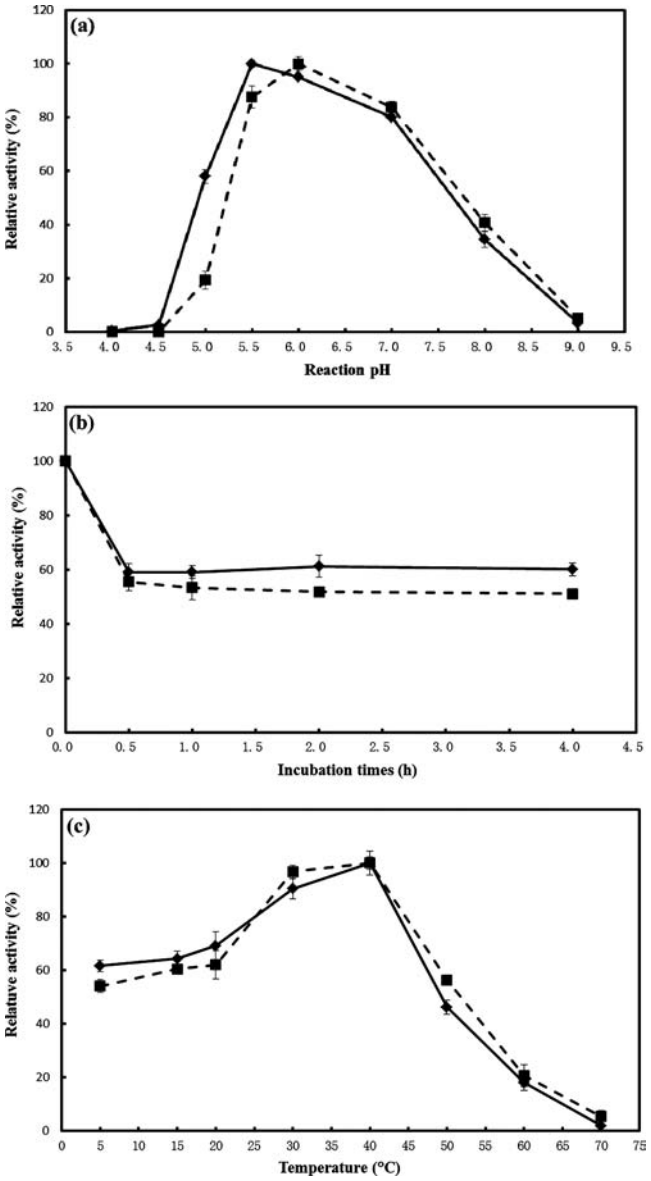

**Figure 8.** (a) Effects of mutation on the reaction pH. Activity was measured at 40 °C for 30 min at the indicated pH values in 100 mM of each buffer: sodium acetate (pH 4.0–6.0). (b) Effects of mutation on the pH stability at pH 6.0. The enzyme was incubated at 20 °C in pH 6.0, 100 mM, buffer for a period of time. After that, residual activity was assayed at optimal temperature and pH by using the DNS method. (c) Effects of mutation on the reaction temperature. Reactions were conducted for 30 min in 100 mM, pH 6.0, sodium acetate buffer. In all panels, full lines and dotted lines represented mutant H218D and wild-type AbnZ1, respectively. The highest activity was taken as 100%. The 0.25% red debranched arabinan was used as reaction substrate.

Therefore, modification of the AbnZ1 molecule aimed at acidic reaction condition is necessary. A directed evolution method (also called irrational design, such as error PCR and DNA shuffling) is a common way to change the property of an enzyme. However, directed evolution needs a lot of experimental work, which costs a lot of time and labor. More recently, rational design based on the catalytic mechanism and protein structure is booming. Some research has succeeded in improving protein efficiency under acidic conditions of some glycoside hydrolases though rational design, such as amylase.[27] However, there are no analogous reports about arabinanases so far.

Glycoside hydrolases hydrolyze the glycosidic bonds requiring two critical residues, a proton donor and a nucleophilic catalytic base, via general acid catalysis. Two major mechanisms, retaining mechanism and inverting mechanism, were involved in glycosidic bond hydrolysis.[23] Within GH family 43, the enzymes work in an inversion manner, in which protonation of the glycosidic oxygen and aglycone departure are accompanied by a concomitant attack of a water molecule that is activated by the base residue. Accordingly, $Asp^{49}$ worked as a nucleophilic catalytic base and $Glu^{215}$ worked as a proton donor on the basis of the 3-D structure of AbnZ1 (Figure 6b).

The specific activity of mutant enzyme was influenced by the distance between the mutant group and the catalytic site. The distance between $His^{48}$ and $Asp^{49}$ was 5.41 Å, and the distance between $His^{297}$ and $Asp^{49}$ was only 3.74 Å, which indicated that these two mutation sites were adjacent to $Asp^{49}$, one of the active sites (Figure 9a). When $His^{48}$ and $His^{297}$ were replaced by Asp/Glu or Arg/Lys, the active site $Asp^{49}$ might be not correctly deprotonated and then the general base catalyst $Asp^{49}$ could not deprotonate the nucleophilic water molecule, which caused the complete activity loss of H48D/E/R/K and H297D/E/R/K.

The decreased $K_m$ and improved $K_{cat}$ of H218D toward linear arabinan indicated the affinity between the enzyme and substrate as well as the catalytic efficiency was enhanced. The changed kinetic parameters of AbnZ1 after substitution of $His^{218}$ by Asp displayed that position 218 was important for the catalytic efficiency of arabinanase at an acidic reaction condition. On the one hand, it was previously reported that $Asp^{49}$ must be deprotonated in the first step of hydrolysis reaction of glycosidic bonds, whereas the general acid $Glu^{215}$ must be protonated at the same time according to the proposed GH catalytic mechanism.[27,28] After mutation, the acidic amino acid $Asp^{218}$ near the hydrogen donor $Glu^{215}$ (Figure 9a) could bear a negative charge and would stabilize the protonated form of $Glu^{215}$ according to Liu et al.[29] This change in structure caused the increment of catalytic efficiency under acidic condition and the shift of pH optima. On the other hand, the residue $His^{218}$ locating around the catalytic domain had a bigger side chain than Asp; thus, the steric hindrance might be reduced after the substitution of His by Asp, which resulted in the reduced steric hindrance and easier substrate attack of the catalytic domain and, subsequently, the decreased $K_m$. These two factors might cause the change of kinetic parameters and improve the catalytic efficiency of endoarabinanase.

As for the stability of enzyme, the hydrogen bonding network around the catalytic domain played critical roles. After the substitution of His with Asp at position 218, four new hydrogen bonds formed and one hydrogen bond disappeared, and the number of hydrogen bonds around the mutation site was increased from 8 to 11 (Figure 9b,c). Thus, the stability of endoarabinanase at pH 6.0 after the mutation might be enhanced by the three newly formed hydrogen bonds according to Yang et al.[27]

In this study, we found a novel cold-adapted endo-$\alpha$-1,5-L-arabinanase, AbnZ1, which would be especially attractive in both juice clarification under low processing temperature, to hamper spoilage and avoid changes in nutritional properties, and enzymatic extraction of pectin. The substitution of the basic residue by an acidic residue around the catalytic domain

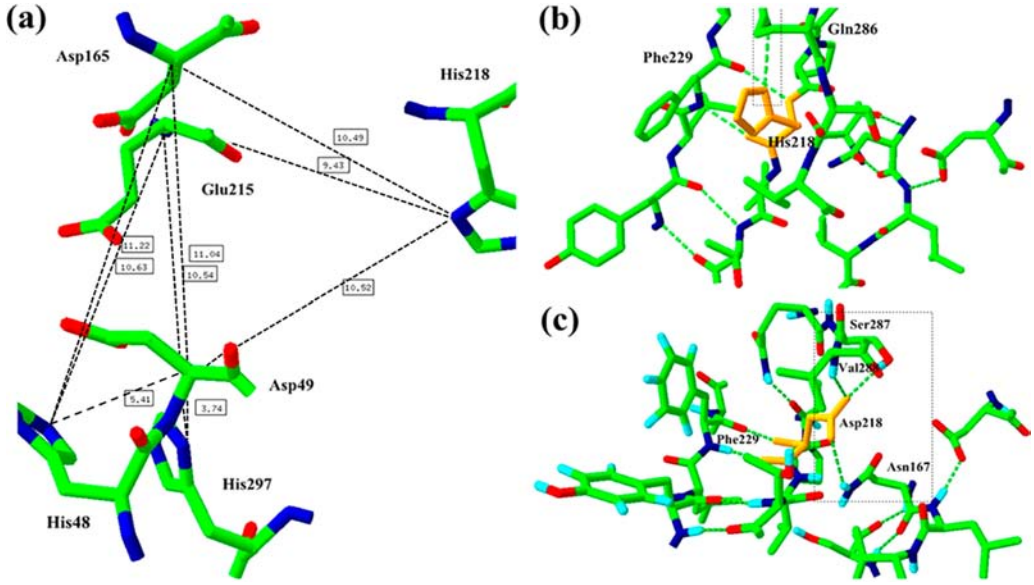

**Figure 9.** (a) Distances from the respective catalytic residues to $His^{48}$, $His^{218}$, and $His^{297}$ in AbnZ1, respectively. (b, c) Local hydrogen bonding network (amino acids within 6 Å around the mutation site; b, wild-type AbnZ1; c, mutant H218D). The oxygen atoms, nitrogen atoms, and hydrogen atoms are shown in red, blue, and cyan, respectively. Change in the number of hydrogen bonds is marked with a dotted box. The positions of the point mutation are shown in orange.

was performed for modification of the enzyme molecule to overcome the unsteady enzyme activity under the acidic condition. On the basis of this study, our next work will focus on two aspects to enhance the catalytic efficiency of endoarabinanases under acidic condition, including more basic amino acids around the catalytic domain chosen as mutation sites, such as arginine (Arg) and lysine (Lys). The distance between mutation sites and key active sites will also be considered as an important factor for the choice of mutation sites. After that, we hope that AbnZ1 will have greater prospects for application in the food industry.

# Identification of Bitter Modulating Maillard-Catechin Reaction Products

Liyun Zhang,[†] Youlin Xia,[‡] and Devin G. Peterson*[,†]

[†]Department of Food Science and Nutrition, University of Minnesota, 1334 Eckles Avenue, St. Paul, Minnesota 55108, United States
[‡]MNMR Center, University of Minnesota, St. Paul, Minnesota 55455, United States

**ABSTRACT:** The influence of thermally induced reaction products of a known dietary bitter compound, catechin, on bitterness perception was investigated. Catechin was reacted in low-moisture simple Maillard models (200 °C for 15 min) consisting of glycine and a reducing sugar (D-glucose, D-xylose, or D-galactose). Based on liquid chromatrography−mass spectrometry (LC-MS) isotopic labeling techniques, eight reaction products were identified and subsequently structurally elucidated by tandem LC-MS/MS and two-dimensional NMR analysis; six were report to be flavan-3-ol−spiro-C-glycosides reaction products. One of the spiro products was reported to significantly suppress the perceived bitterness intensity of a caffeine solution. Additionally, this specific spiro product was further identified in cocoa and reported to increase in concentration during bean roasting.

**KEYWORDS:** *Maillard reaction, bitter modulation, catechin, roasting*

## INTRODUCTION

Bitter taste is one of the basic gustatory taste sensations that can cause consumer dislike in foods and beverages.[1] Common approaches for decreasing the bitterness of commercial foods often involve the addition of sugar or salt.[2] However, with the increasing demand for healthier but tasty foods, the discovery of novel ingredients that are able to modulate bitterness is desirable. Consequently, the discovery of compounds with bitter modulator activity is of commercial interest to improve the palatability of food with bitter attributes, particular for reduced sugar and salt formulations.

Screening and identifying bitter modulating compounds is an analytically challenging task.[3] Recently, a series of flavan-3-ol−*C*-glycosides isolated from cocoa were suggested to suppress the bitter intensity of cocoa beverages.[4] Additionally, $\beta$-D-glucopyranosides were reported to activate one of the human bitter receptors (T2Rs) with high specificity and stereoselectivity, based on the conformation at the C1 position of the pyranose moiety.[5] Therefore, slight changes of the compound structure (e.g., the pyranose moiety attached to a flavonoid) have been reported to influence the taste profile or even modulate the bitter perception.[3]

Natural product taste compounds are known to be chemically modified by food reactions during food manufacture; however, how common food reactions could modulate these taste attributes is not well understood. Previously our group has reported that dietary bitter compounds, the flavan-3-ols, were chemically modified by reactive carbonyl species (i.e., dicarbonyls) generated by food reactions, such as Maillard pathways.[6,7] The main goal of the current study was thus to investigate if the modification of known dietary bitter compounds, such as the flavanols, generated new chemical species that modulated the perception of bitterness intensity. These results were further extrapolated to cocoa beans to investigate if related phenolic-Maillard adducts existed.

## MATERIALS AND METHODS

**Chemicals.** D-Glucose, D-xylose, D-galactose, glycine, (+)-catechin hydrate (≥98%), high-purity quartz sand, formic acid, and methanol-$d_4$ (99.8% enrichment) were obtained from Sigma-Aldrich Co. (St. Louis, MO, USA). High-performance liquid chromatography (HPLC) grade acetonitrile and methanol were obtained from Fisher Scientific (Fair Lawn, NJ, USA). Distilled deionized water was further purified through a Barnstead Nanopure Diamond water purification system (Thermo Scientific, Dubuque, IA, USA). $^{13}C_6$-Glucose, $^{13}C_6$-galactose, and $^{13}C_1$-xylose were obtained from Cambridge Isotope Laboratories, Inc. (Andover, MA, USA).

**Low-Moisture Maillard Reaction Model with Catechin.** Reactions were conducted according to those of Jiang et al.[8] Briefly, the reaction apparatus consisted of a round-bottom flask (500 mL) attached with a Vigreux column and a glass stirrer fitted with a Teflon blade (Ace Glass, Vineland, NJ, USA). The reaction vessel was heated by oil bath and connected to a rheostat (PowerStat, The Superior Electric Co., Bristol, CT, USA) for temperature control. The reactants (reported in Table 1) were mixed with 15 g of quartz sand (previously cleaned and dried) and 1.5 g of water. The reactant mixture was mixed at 40−60 rpm in the round-bottom flask for 2−3 min. The apparatus was then placed in an oil bath maintained at 200 °C, and the reaction was conducted for 15 min, then immediately removed from the oil bath, and prepared for further analysis.

**Sample Preparation for Model Reactions.** Extraction was performed with methanol (3 × 30 mL), the isolate was filtered, and the filtrate was separated by means of ultrafiltration equipped with 1 kDa MW cutoff membrane (8200 Series stirred cell, EMD Millipore, Billerca, MA, USA). The permeate fraction was concentrated until precipitate appeared under vacuum (Buchi Rotavapor, model R110, New Castle, DE, USA; 0.1 atm; water bath was maintained at 30 °C) and subsequently filtered through a 0.2 $\mu$m Nylon tip filter (Sigma-Aldrich Co.) and analyzed by liquid chromatography−mass spectrometry (LC-MS).

*LC-MS-TOF Isotopomeric and Accurate Mass Analysis.* Maillard-phenolic reaction products were characterized by identifying isotopomers as previously reported (Table 1,[6]). Analysis was conducted with a Waters 2D UPLC Acquity iClass coupled with a Xevo G2 QTof system (Waters, Milford, MA, USA). Accurate mass acquisition of the ion of interest was performed by chromatography injection using dual electroscpray ion source. Reserpine (100 mg/L) was used as the lockspray injecting at 10 μL/min. Injections of 2 μL each of the extracts were injected on ACQUITY UPLC BEH C18 1.7 μm column (2.1 mm × 50 mm; Waters) maintained at a temperature of 25 °C. The mobile phase was maintained at a flow rate of 0.3 mL/min using a binary solvent system of 0.1% formic acid in water (A) and methanol (B). The elution gradient started at 10% B, linearly increased to 90% B (1−6.35 min), held at 100% B (6.35−8.35 min), and then held at 10% B (8.35−10 min). Mass spectrometric ionization conditions were as follows: desolvation temperature of 400 °C; source temperature of 110 °C; capillary voltage of 1.1 kV. For samples analyzed in both positive and negative sensitivity scan mode, the scan range was 50−1000 Da.

**Prep-LC.** Target analytes were purified using a LC system that consisted of a binary pumping system (LC-10 ADvp), a degasser (DGU-14A), an autosampler (SIL-10vp), a variable-wavelength UV−vis detector at 254 and 280 nm (Shimadzu, SPD-10A), a fraction collector (Shimadzu, FRC-10A), and a RP-C18 column (150 mm × 21.2 mm, Pursuit 5, Varian, USA). The HPLC condition was as follows: the injection volume was 1.5 mL, the column temperature was 25 °C, binary mobile system A was 0.1% formic acid aqueous solution, pH 3.0 and B was 100% acetonitrile, column and flow rate was 10 mL/min. The gradient was started with 5% B (0−10 min), then increased to 50% B (10−40 min), then held at 100% B (40−50 min), and then decreased to 5% B (50−70 min). The total run time was 70 min. The effluent was collected with a fraction collector. Compounds **1** and **2**, generated from model A, were collected at 19.5 and 20.5 min, respectively; compounds **3**, **4**, and **5** obtained from model B were collected at 20.3, 21.0, 22.0 min, respectively; compounds **6**, **7**, and **8** were collected at 20.4, 21.4, and 21.9 min, respectively (refer to Figure 1 for compound structures). Second dimension off-line liquid chromatography was conducted for further purification until at least 95% purity was achieved based on $^1$H NMR. The binary mobile phase for the second dimension was as follows: mobile phase A was water with pH = 7; mobile phase B was methanol. The second dimension gradient was started with 5% B (0−5 min), then increased to 20% B (5−10 min), then slowly increased to 30% B (10−40 min), then further increased to 100% B (41−50 min), and then decreased to 5% B (50−60 min). About 0.5−1 mg of the Maillard-catechin adducts was collected as dry mass for each model reaction (models A−C, Table 1).

**Circular Dichroism Spectrum.** For circular dichroism (CD) spectrum, methanolic solutions of the samples were analyzed by means of a Jasco Model CD-1595 circular dichroism chiral detector (Easton, MD, USA; 0.190 ± 0.30° for D- and L-camphorsulfonic acid as references).

**Nuclear Magnetic Resonance Spectrum.** $^1$H, correlation spectroscopy (COSY), heteronuclear multiple quantum coherence (HMQC), heteronuclear multiple bond correlation (HMBC), $^{13}$C, and nuclear Overhauser enhancement spectroscopy (NOESY) nuclear magnetic resonance (NMR) measurements were performed on a Bruker 700 MHz spectrometer with TXI cryoprobe and a Bruker 850 MHz spectrometer with TCI cryoprobe. Data were processed and analyzed with Topspin 3.1 and MestRenova 8.1. Methanol-$d_4$ was used as the NMR solvent. The solvent residual peak of methanol-$d_4$ at $\delta$ 4.78 was set as the internal reference. NOESY correlations were verified within reasonable range (<4 Å) using ChemBio 3D software.

**Sensory Analysis.** *Subjects and Training.* A panel of eight judges (ages 23−45, 3 males and 5 females) from the Department of Food Science and Nutrition, St. Paul, MN, evaluated the bitterness of the test solutions. Prior to analysis, all panelists participated in 12 training sessions of approximately 1 h in duration over a period of 4 weeks. Panelists were initially trained on a 10-point scale with four references provided (0.03, 0.04, 0.08, and 0.15% (w/w) of caffeine in water), corresponding to bitterness intensity ratings of 2, 3.5, 5, and 10, respectively. Inconsistencies in the ratings were addressed with panelists as part of the training.

*Evaluation.* The test samples (Figure 1) were evaluated for bitterness modulation activity. Two separate sample evaluations were conducted. In the first session, all eight test compounds were evaluated followed by a second session consisting of two select compounds (numbers **2** and **7**, Figure 1). For all evaluation sessions, the samples were evaluated in duplicate. Three reference levels were provided (0.03, 0.04, and 0.08% (w/w) of caffeine in water), corresponding to bitterness intensity ratings of 2, 3.5, and 5, respectively. All samples were prepared the morning of the evaluation. During the first session, each test compound (1.9 mg) was added to 32 mL of 0.04% caffeine solution. The ratio of test compound to caffeine was 1:7 (w/w), which was based on the quantification of these two analytes in roasted cocoa (Figure 3).

For the second evaluation session the concentrations of compounds **2** and **7** were doubled to 3.8 mg of each test compound in the 32 mL of 0.04% caffeine solution (ratio of 2:7 (w/w)). Solutions were stirred for 10 min, and then 2 mL of each solution was dispensed in sample cups labeled with three-digit codes. Panelists used a PTFE dropper to dispense 2 mL of solution on the center of their tongue. Water and unsalted crackers were used as palate cleansers.

*Data Analysis.* Ratings were averaged and the differences among treatments were evaluated by analysis of variance (ANOVA) followed by Tukey's HSD pairwise comparison. All analyses were performed with Statistix Software (version 9). Significance was established at $p < 0.05$.

**Sample Preparation of Cocoa Samples.** Samples of 15 g amounts of unroasted or roasted beans (135 °C for 15 min) were ground for 2 min then extracted with a mixture (2:1, v/v; 3 × 100 mL) of ethanol and water for 2 h at room temperature with stirring. The ethanol/water extract was added with methylparaben (100 ppm) as internal standard. Then it was concentrated until precipitate appeared under vacuum (Buchi rotavapor, model R110, New Castle, DE, USA; 0.1 atm; water bath was maintained at 30 °C) and then filtered through a 0.2 μm Nylon tip filter (Sigma-Aldrich Co.) and analyzed by LC-MS.

**LC-MS Identification of Compounds 2 and 7 in Cocoa.** Cocoa isolates were analyzed on a Waters ACQUITY UPLC system interfaced with a Quattro Premier XE mass spectrometer (Waters). Two microliters were injected on to an ACQUITY UPLC BEH C18 1.7 μm column (2.1 mm × 50 mm; Waters) at 25 °C. The mobile phase was maintained at a flow rate of 0.3 mL/min using a binary solvent system of 0.1% formic acid in water (A) and methanol (B). The elution gradient started at 10% B, linearly increased to 90% B (1−6.35 min), held at 100% B (6.35−8.35 min), and then held at 10% B (8.35−10 min). The Quattro Premier XE mass spectrometer was equipped with an electrospray ionization probe, and the operational parameters were positive ion mode, with a source temperature of 110 °C, desolvation temperature of 350 °C, and capillary voltage of 3.0 kV. Data were collected in multiple-reaction monitoring (MRM) mode. The ion transitions for the compounds were optimized according to the ion intensity of the product ion through full scan MS/MS. The MRM method was optimized by direct infusion of authentic compounds. The MS acquisition was collected as follows: compound **2**, $m/z$ 435 → 283 and 435 → 417, cone 35 V, collision 15 V; compound **7**, $m/z$ 435 → 247 and 435 → 123, cone 30 V, collision 20 V.

**LC-MS Quantification of Compound 2 and Caffeine in Cocoa.** Analysis was conducted by LC-MS in MRM mode. The ion transitions for the compounds were as follows: compound **2**, $m/z$ 435 → 283 and 435 → 417, cone 30 V, collision 15 V; caffeine, $m/z$ 195 → 138 and 195 → 110, cone 30 V, collision 20 V. The dwell time was 0.5 s for the analytes; the interscan delay was 0.1 s, and interchannel delay was 0.005 s. All samples were analyzed in duplicate. Quantification was conducted by internal standard (methylparaben, 0.3 M) and external five-point calibration curve of compound **2** and caffeine at $10^{-2}$−$10^2$ mM that showed good linearity with regression coefficient ranging from 0.97 to 0.99.

**Spectral Data of Compounds 1−8 (Figure 1).** *Compound **1**, (2R,2′R,3S,3′S,4S,5R)-2′-(3,4-Dihydroxyphenyl)-5-(hydroxymethyl)-2′,3′,4,4′,5,9′-hexahydro-3H-spiro[furan-2,8′-furo[2,3-h]chromene]-3,3′,4,5′-tetraol.* CD (MeOH): 280 (−0.12). MS-TOF: *m/z* 433.1123 ([M − H]$^-$, 3 ppm). $^1$H NMR (700 MHz, $CD_3OD$): $\delta$ 2.46 [dd, 1H, *J* = 16.1, 7 Hz, H−C(4b)], 2.69 [dd, 1H, *J* = 16.1, 4.9 Hz, H−C(4a)], 2.82 [d, 1H, *J* = 16.8 Hz, H−C(1″b)], 3.30 [d, 1H, *J* = 16.8 Hz, H−C(1″a)], 3.55 [dd, 1H, *J* = 11.9, 3.5 Hz, H−C(6″b)], 3.65 [dd, 1H, *J* = 11.9, 3.5 Hz, H−C(6″a)], 3.87 [dd, 1H, *J* = 5.6, 3.5 Hz, H−C(4″)], 3.94 [m, 1H, H−C(3)], 3.95 [m, 1H, H−C(5″)], 4.02 [d, 1H, *J* = 3.5 Hz, H−C(3″)], 4.61 [d, 1H, *J* = 7 Hz, H−C(2)], 5.87 [s, 1H, H−C(6)], 6.65 [dd, 1H, *J* = 7.7, 2.1 Hz, H−C(6′)], 6.70 [d, 1H, *J* = 7.7 Hz, H−C(5′)], 6.73 [d, 1H, *J* = 2.1 Hz, H−C(2′)]. $^{13}$C NMR (175 MHz, $CD_3OD$): $\delta$ 28.1 [C-4], 33.6 [C-1″], 62.9 [C-6″], 68.6 [C-3], 78.9 [C-4″], 82.5 [C-3″], 82.6 [C-2], 85.6 [C-5″], 91.2 [C-6], 101.6 [C-10], 103.3 [C-8], 114.9 [C-2′], 116.2 [C-5′], 119.7 [C-6′], 121.1 [C-2″], 132.2 [C-1′], 146.2 [C-3′, C-4′], 152.1[C-9], 156.9 [C-5], 158.8 [C-7].

## RESULTS AND DISCUSSION

In order to investigate the influence of thermal reactions on the modulation of bitterness in food, catechin, a known dietary bitter compound, was reacted in simple Maillard reaction model systems consisting of a simple sugar (glucose, galactose, or xylose) and glycine (Table 1, Models A−C). It was expected

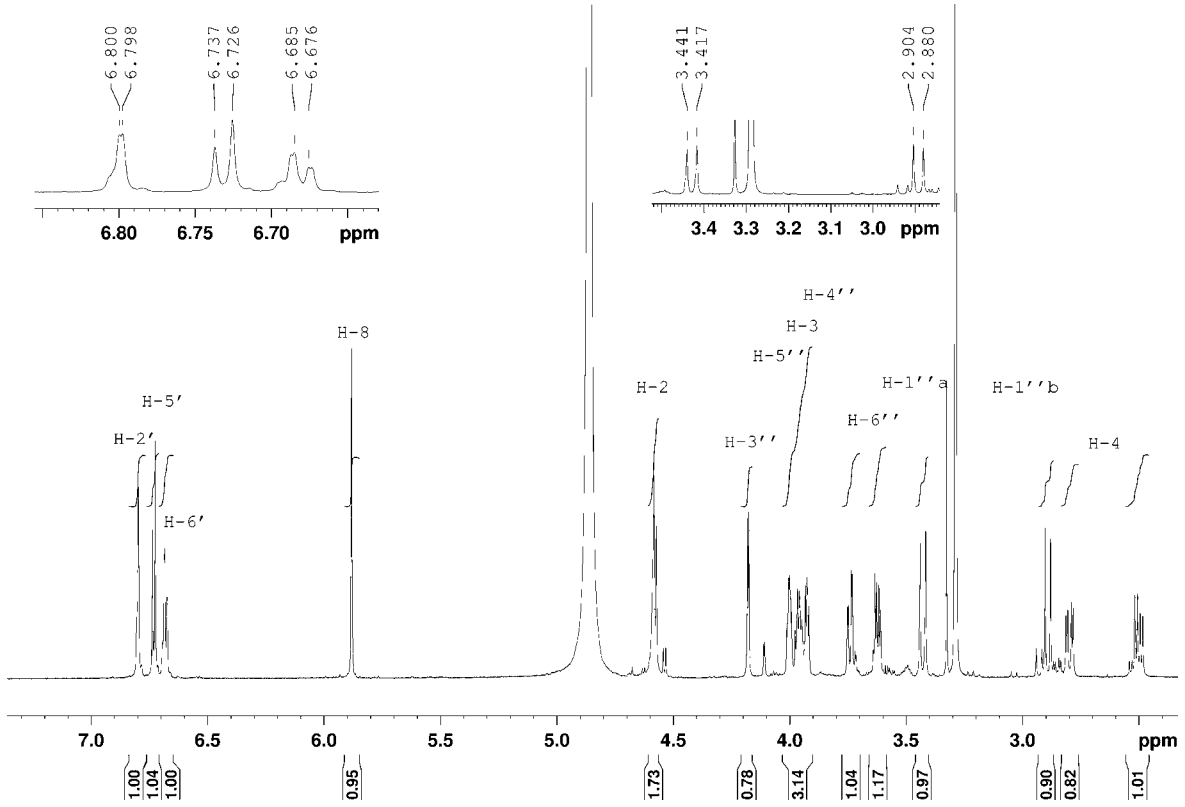

**Figure 2.** $^{1}$H spectrum of compound **2**.

[a] $^{1}$H NMR experiment was conducted on a 700 MHz cryoprobe. Samples were dissolved in $CD_3OD$. [b] The identified structure is matched with ref 10.

the unique stereocenters of the two hexose sugars would be transferred to catechin-Maillard reaction products, providing the ability to investigate structure−activity relationships on bitter perception. Additionally, the pentose sugar (xylose) was selected similarly to provide additional reaction products. Utilization of simple Maillard model systems provided the

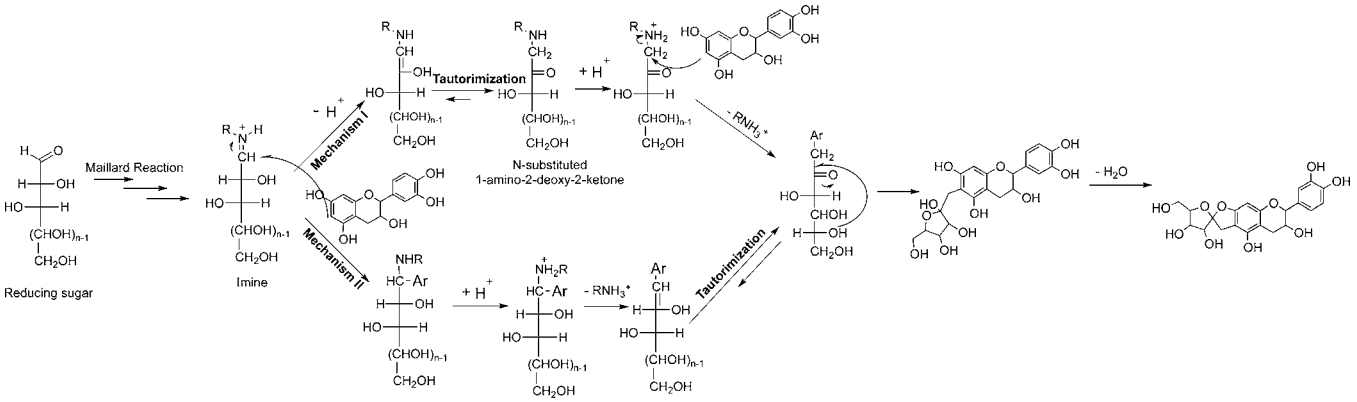
**Scheme 1. Proposed Mechanism for Generating the spiro-*C*-Glycosides**



ability to enrich one of the reactants (in this example the simple sugar) with $^{13}$C-labeling for the identification of phenolic-Maillard reaction products (Table 1, Models D−F) as we as we have previously reported.[6]

**Identification of Catechin−*C*-spiro-Glycoside Adducts.** Adducts were identified by LC-MS isotopomeric analysis of Models D−F, with the same unlabeled parent ion reported in Models A−C, respectively, at the same retention time. Isotopomeric analysis of models D−F indicated an intact sugar moiety was incorporated in the selected products. No reaction products were also detected in models H (glucose and glycine) and I (catechin only). Similarly reaction products were not identified in model G (glucose and catechin), indicating the importance of the amino acid for product generation. Overall, eight main reaction products were identified and isolated for structural determination.

Two reaction products (compound **1** and compound **2**, Figure 1) were isolated from model A (catechin, glucose, and glycine). The carbons from the sugar moiety are noted as 1″ to 6″ while the carbons from catechin are marked as 2 to 9 and 1′ to 6′. For compound **1**, the majority of the $^{1}$H spectra of (+)-catechin (data not shown) were easily deduced. A pair of doublets at 3.30 and 2.82 with *J*-coupling of 16.8 Hz indicated a pair of geminal hydrogens is incorporated and connected directly to the A ring of catechin, which is unique compared with other flavan-3-ol−*C*-glycosides that have been reported.[4] According to NMR HMBC spectrum, the sugar moiety was connected through C-8. In considering the distinctive carbon chemical shifts, the 7-hydroxyl loses one molecule of water with the C-2″ acetal group forming a spiro [4,4] structure. The structure of the sugar moiety is supported by ref 9. NOESY spectrum shows spatial correlation between H-1″ and H-6″ and correlation between H-1″ and H-4″. In consideration of the stereochemistry of the starting material as well, the stereochemistry of compound **1** is indicated in Figure 1.

Compound **2**, based on the $^{1}$H spectrum (Figure 2), again shows a pair of geminal hydrogens connecting between catechin and the sugar moiety; compound **2** is distinctive in its HMBC correlations compared with the assignment of compound **1**. The presence of $^{3}J_{\text{H1″-C7}}$ and $^{3}J_{\text{H1″-C5}}$ indicate that the sugar moiety is connected to the C-6 of catechin as shown in Table 2. Spatial correlation is shown in Figure 1 according to NOESY correlations.[10] It is found that the volume ratio of H3″−H4″ cross-peak and H1″a−H1″b (1.8 Å) cross-peak is 0.0053, which shows H3″ and H4″ have a very weak NOESY correlation; thus H3″ and H4″ are not planar.

For model B (catechin, xylose, and glycine, Table 1) compounds **3**, **4**, and **5** (Figure 1) were isolated. According to the molecular mass (MW = 422), compound **3** is different from other analytes isolated in model B (MW = 404), which indicates one less dehydration step occurred. Moreover, no methylene moiety is found in connection with the A ring of catechin which renders compound **3** structurally different from others. The $^{13}$C chemical shift (82−68 ppm) indicates no acetal group was incorporated. Additionally, a pyran ring formed for the distinctive chemical shift of C-3″ and C-4″(<78 ppm). The *J*-coupling constants of H1″−H2″, H2″−H3″, H3″−H4″, and H4″−H5″b are 9−10 Hz while H4″−H5″a is 5 Hz, indicating all of the hydrogens of the sugar moiety are axial hydrogens except H5″a is equatorial.[11] The structure of xyloside moiety is further supported by ref 12.

For compounds **4** and **5**, HMBC spectrum shows xyloside is connected to catechin C-8 for compound **4** while the xyloside of compound **5** is attached to the C-6 of catechin. A typical furan carbohydrate carbon chemical shift is observed for compound **4** and compound **5**. H-1″ has NOESY correlation with H-3″ in compound **4** and compound **5** supported by refs 13−15.

For model C (catechin, galactose, and glycine) compounds **6**, **7**, and **8** (Figure 1) were isolated. For compound **6**, COSY and HMBC spectra followed the same trend as that of compound **2**. However, the chemical shifts of the sugar moiety at the 3″, 4″, and 5″ and the coupling constants are unique compared with compound **2**; hence, the stereochemistry of the sugar moiety of compound **6** is different from compound **2**. NOESY shows H1″−H6″ and H3″−H4″ correlations of similar strengths, indicating that the stereochemistry of compound **6** at the 4″ position is different from that at compound **2**. For compound **6**, H-3″ is much closer to H-4″ compared with that in compound **2** since the volume ratio of NOESY correlations H3″−H4″ and H1″a−H1″b is 0.88, much higher than that for compound *2*. Therefore, compound *6* was reported as a diastereomer of compound *2*.

The HMBC spectrum of compound **7** shows H-1″ has correlations with C-7 and C-9; thus the reaction happens on the C-7 and the C-8 of catechin. Moreover, HMBC correlations confirm that there are correlations between H6″−C2″ corresponding to a pyran ring spiro-fused with a furan ring. Additionally, the carbon chemical shifts of the sugar moiety belong to a [4,5] ring instead of a [4,4] ring structure. H1″−H3″ NOESY correlation indicates the stereochemistry as shown in Figure 2.[16,17]

dx.doi.org/10.1021/jf502040e | J. Agric. Food Chem. 2014, 62, 8470−8477

For compound **8**, it is a C-8 substituted *C*-glycoside adduct. The 6″ hydroxyl group loses one molecule of water to form the acetal with C-1″ as confirmed by HMBC correlation (C1″−H6″). As illustrated above, the stereochemistry of compound **8** is discussed by both NOESY and *J*-coupling constants.[18,19]

**Plausible Mechanisms for the Spirocyclic Catechin-Maillard Products Generation.** To gain insights into how the catechin−*C*-spiro-glycosides were generated in these simple model Maillard reaction systems, two mechanisms are proposed. In mechanism I (see Scheme 1), the Maillard-derived imine rearranges to the keto form of the N-substituted 1-amino-2-deoxy-2-ketone, which is then protonated and trapped by catechin at the $\alpha$ to the carbonyl group.[20,21] The 5-hydroxyl group of the sugar moiety then attacks the carbonyl to form an acetal. According to LC-MS, one molecule of water is lost; hence, the spirocyclic glycoside catechin is formed. For mechanism II, catechin traps the cation of the imine, then undergoes elimination followed with tautomerization to afford the same catechin-Maillard intermediate, and then dehydrated and ring-closed to generate the spiro-*C*-glycosides product.

**Taste-Modifying Activity of Maillard-Catechin Products.** The eight isolated Maillard-catechin compounds (Figure 1) were screened for bitter modulation activity in a caffeine solution (see Table 3). Caffeine was selected because it is a highly ubiquitous dietary bitter compound and has been previously used to screen for bitter masking compounds.[22] Additionally, caffeine is also a major bitter compound found in cocoa.[23] To provide perhaps a more food-relevant dosage, both compounds **2** and **7** were screened in cocoa beans. Only compound **2** was identified in cocoa and was subsequently quantified in addition to caffeine. The concentration of compound **2** is reported in Figure 3, for both unroasted and roasted cocoa. The concentration of compound **2** in roasted cocoa is approximately three times higher in comparison to unroasted cocoa, suggesting it was not only a natural product of microbial provenance in cocoa beans but also generated through roasting (thermal treatment) as well. Similar compound structures (*C*-spiro-glycoside flavonoids) such as compound **2** have been previously reported as fungal products with anti-inflammation activities.[24,25] Comparing the concentration of compound **2** (0.15 mg/g) to the concentration of caffeine (1.03 mg/g) in roasted cocoa, a concentration ratio of 7:1 (caffeine:test compound) was determined. At the same concentration level (caffeine:test compound = 7:1, w/w) trends in the bitterness enhancement or suppression were observed among the different compound structures, albeit there were no significant differences in bitter ratings between caffeine base and caffeine with test compounds added. Unfortunately, dose−response analysis was beyond the scope of this project due to the limited quantities of the reaction products available. However, based on the noted suppression of the average bitterness rating for both compounds **2** (generated from glucose, glycine, and catechin) and **7** (generated from galactose, glycine, and catechin), these compounds were further selected for evaluation at a higher dosage level. Subsequently, compound **2** was added at a double dosage level (caffeine:test compound = 7:2, w/w) to further investigate potential modulation activity (see Table 4); compound **7** was also included for comparison. In the cocoa sample, an isomer of compound **2** consisting of epicatechin (as apposed to catechin) was also predicted by MS/MS fragmentation analysis and reported to be at a similar concentration (data not shown). This suggested epicatechin reaction product was not isolated from cocoa, nor was the taste activity tested. Given that compound **2** was a natural (fungal) product in the raw beans and also generated by thermal processing as well as other similar reaction products could be generated, the assessment of compound **2** at 2-fold the concentration reported in the beans used in the current study (Figure 3) was predicted to be within normal natural product variation. At this higher dosage level compound **2** was reported to significantly decrease the bitterness perception of the caffeine solution or compound **2**

**Table 3. Mean Bitterness Intensity Ratings of 0.04% Caffeine Solution with and without Maillard-Catechin (MC) Compounds at a 7:1 Mass Ratio**

| samples (7:1, w/w)[a] | bitterness ratings[b] | SD |
|---|---|---|
| caffeine: MC 5 | 3.95a | 0.95 |
| caffeine: MC 6 | 3.77a | 0.73 |
| caffeine: MC 1 | 3.60a | 0.99 |
| caffeine: MC 3 | 3.51a | 0.68 |
| caffeine: MC 4 | 3.45a | 0.82 |
| caffeine: MC 8 | 3.40a | 1.46 |
| caffeine | 3.31a | 0.71 |
| caffeine: MC 7 | 3.06a | 0.79 |
| caffeine: MC 2 | 3.05a | 1.08 |

[a]Derived from quantitation of MC 2 and caffeine in roasted cocoa (Figure 3). [b]Bitterness ratings are based on 10-point rating scale; a rating of 2, 3.5, and 5 corresponded to 0.03%, 0.04%, and 0.08% caffeine solution, respectively. Mean ratings with letters in common do not differ significantly (5% significance level).

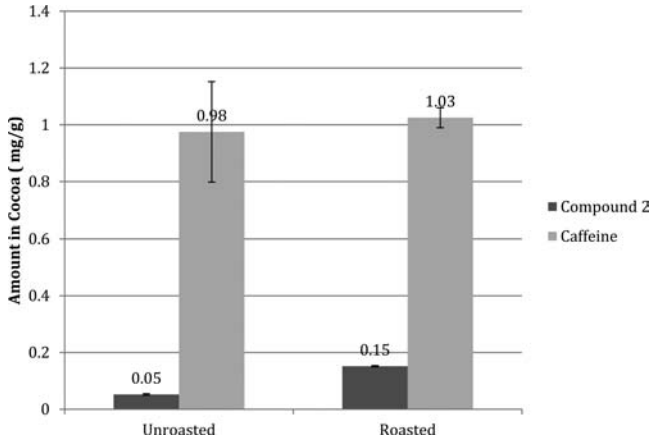


**Figure 3.** Mean concentrations of compound **2** and caffeine in roasted and unroasted cocoa. (Error bars represent standard deviation from duplicate extraction.)

**Table 4. Mean Bitterness Intensity Ratings of 0.04% Caffeine Solutions with and without Maillard-Catechin (MC) Compounds 2 and 7 at a Scaled-up 7:2 Mass Ratio**

| test samples (7:2, w/w) | bitterness rating[a] | SD |
|---|---|---|
| caffeine | 3.50a | 0.46 |
| caffeine: MC 7 | 3.19ab | 0.85 |
| caffeine: MC 2 | 2.75b | 0.66 |

[a]Bitterness ratings are based on 10-point rating scale; a rating of 2, 3.5, and 5 corresponded to 0.03%, 0.04%, and 0.08% caffeine solution, respectively. Mean ratings with letters in common do not differ significantly (5% significance level).

functioned as a bitter blocker (Table 4). This finding suggested the bitterness attributes of cocoa beans and related products could be influenced not just by bitter compounds but also by compounds that modulate this taste attribute.

In summary, the chemical modification of a dietary bitter compound by common thermally induced food reactions was reported to modulate this taste attribute. The role of reaction products of taste compounds on the flavor properties of foodstuffs is not well understood and provides a novel basis to develop food processing strategies for flavor optimization by suppressing or enhancing specific taste attributes of interest.

Supporting Information

**ABSTRACT:** Medium-chain fatty acids (MCFAs) and ethyl esters are considered to contribute to some organoleptic properties, such as fatty odor and bitterness in Japanese sake. However, the relationships between these compounds and the organoleptic properties of sake remain unclear. Here, we quantified MCFAs and ethyl hexanoate in *ginjo* sake using gas chromatography with a flame ionization detector (GC-FID). The hexanoic acid concentration strongly correlated with fatty odor ($p < 0.0001$). The octanoic acid/hexanoic acid ratio correlated with butanoic acid concentration, which is likely correlated with inharmonious bitter taste. Multiple comparison analysis revealed that the ethyl hexanoate level was negatively correlated with bitterness. We then identified other chemical compounds correlating with fatty odor and bitterness using comprehensive two-dimensional GC coupled with time-of-flight mass spectrometry. By performing correlation analysis between certain compounds and sensory values following statistical selection for chemical compounds, we identified several candidate compounds correlating with fatty odor and bitterness in sake.

**KEYWORDS:** *medium-chain fatty acid (MCFA), ethyl hexanoate, Japanese sake, alcoholic beverage, gas chromatography with a flame ionization detector (GC-FID), comprehensive two-dimensional gas chromatography coupled with time-of-flight mass spectrometry (GC × GC−TOFMS)*

## INTRODUCTION

Medium-chain fatty acid (MCFA) ethyl esters in premium Japanese sake (*ginjo* sake) provide a pleasant, fruity apple-like flavor. This flavor is an essential trait for *ginjo* sake, and MCFA ethyl esters are considered to play an important role in flavor quality. On the other hand, MCFAs such as hexanoic acid and octanoic acid, precursors to ethyl esters, are recognized as a rancid or unpleasant fatty odor in reconstituted sake.[1] In sake fermentation, although the mechanism of MCFA ethyl ester formation during sake fermentation is poorly understood, it is considered that they are chemically generated (without enzymes) or by biosynthesis through enzymes in sake yeast, *Saccharomyces cerevisiae*.[2] Cerulenin-resistant sake yeast is generally used in modern *ginjo* sake brewing. This yeast harbors a point mutation at base 3748 of the fatty acid synthase 2 gene, encoding the alpha subunit of the fatty acid synthesis enzyme complex.[3,4] In this type of sake yeast, MCFAs, which are intermediates in the biosynthesis of long-chain fatty acids, accumulate to high concentrations. In turn, MCFAs combine during fermentation to form ethyl alcohol and generate MCFA ethyl esters.[3,5,6] Therefore, it is increasingly important to quantify MCFA concentrations during the brewing process and to develop techniques that control the production of these compounds during *ginjo* sake fermentation.

In our previous work, we developed a simple method for simultaneously quantifying MCFAs and ethyl hexanoate in sake using gas chromatography with a flame ionization detector (GC-FID). Based on these quantification data, we proposed a concept regarding the efficiency of ethyl ester production in sake.[7] In addition, this low-cost method is less labor intensive than other data analysis methods, and it is therefore suitable for processing large sample numbers. In contrast, this method is not suitable for analyzing target chemicals that are present in less than sub-ppm concentrations or for nontarget analyses.

In recent developments of analytical instruments and data processing techniques, the comprehensive two-dimensional gas chromatography (GC × GC) coupled with high-speed data acquisition using time-of-flight mass spectrometry (GC × GC−TOFMS) has emerged as a powerful analytical method that can be used to reveal large numbers of metabolites in complex samples. In combination with a statistical approach that combines multidimensional data, including first and second retention times, mass spectra, and variance of replicates, the compositional differences between samples can be effectively determined.[8,9] Many studies of relationships between brewing conditions, organoleptic properties, and metabolites have been published in the context of winemaking[10−15] and beer brewing.[16,17] However, whereas comprehensive metabolomics studies on sake were performed by Sakamoto et al.[18] using GC−MS, and by Sugimoto et al.[19,20] using capillary electro-

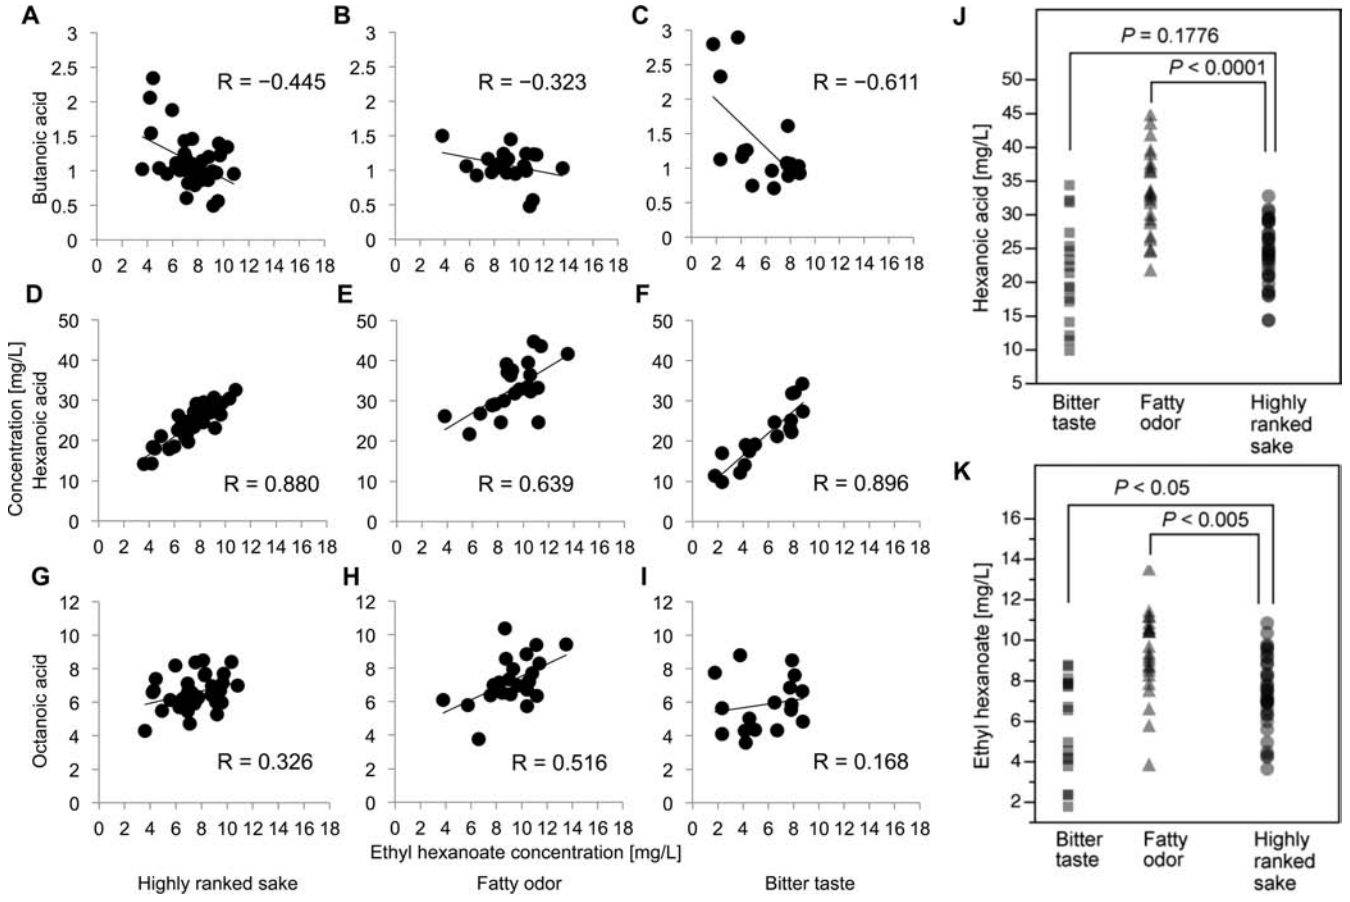

**Figure 1.** Correlation between ethyl hexanoate and MCFAs in Japanese sake. Indicated chemical compounds (ethyl hexanoate, butanoic acid, hexanoic acid, and octanoic acid) in sake were quantified using GC-FID. Graphs (A), (D), and (G) show results from the highly ranked sake (control). Graphs (B), (E), and (H) show results from fatty odor sake, and graphs (C), (F), and (I) show results from inharmonious bitter taste sake. Panels (J) and (K) show the statistically significant differences in hexanoic acid and ethyl hexanoate concentrations between highly ranked sake and fatty odor sake. Statistically significant differences were identified using the Dunnett's post hoc test. Typical data from three independent analytical procedures are shown.

phoresis TOFMS (CE−TOFMS), no metabolomics studies of sake report data from GC × GC−TOFMS analyses.

In this study, we determined MCFA and ethyl hexanoate concentrations in *ginjo* sake using GC-FID, and investigated correlations between MCFA and ethyl hexanoate with fatty odor and inharmonious bitter taste. Subsequent analysis of MCFAs and ethyl hexanoate in the sake mash *moromi* demonstrated that MCFA composition appeared to associate with ethyl hexanoate generation. We finally used GC × GC−TOFMS to analyze and identify other chemical compounds that correlate with fatty odor and inharmonious bitter taste in sake.

## MATERIALS AND METHODS

**Materials.** Premium Japanese sake samples were selected from entries in the National New Sake Awards competition held by the National Research Institute of Brewing (NRIB) in Japan during 2009, 2010, and 2011. Other samples were obtained by brewing at the NRIB using 40 kg of polished rice (Japanese cultivar: *Yamadanishiki*) and a cerulenin-resistant sake yeast strain (Kyokai No. 1801). Sake mash (*moromi*) was sampled in the morning dairy on days 2−39. *Moromi* samples were paper-filtered, and liquid fractions were used for chemical analysis. Samples were dispensed and preserved at −30 °C until use.

All chemicals were purchased from Wako Pure Chemical Industries Ltd. (Osaka, Japan). HP-FFAP capillary columns were purchased from Agilent Technologies (Palo, Alto, CA, USA), and DB-1 and BPX-50 capillary columns were purchased from Agilent Technologies and SGE Analytical Science Japan Inc. (Yokohama, Japan), respectively.

**Sensory Evaluation.** Sensory evaluations were performed by 15 well-trained panelists, as described in Japanese governmental reports.[21−23] To semiquantify sensory properties, the presence or absence of fatty odor and inharmonious bitter taste was determined on the basis of "check-all-that-apply (CATA)" assessments.[24,25] Sake samples in which fatty odor or inharmonious bitter taste were identified by more than four panelists were defined as fatty odor or inharmonious bitter taste sake, respectively.

**Sample Pretreatment for GC-FID Analysis.** Analysis of chemical components using GC-FID was performed according to a previously described Method[7] with some modifications. Briefly, 400-$\mu$L aliquots of sake samples were mixed with 2-propanol (1.2 mL). After centrifugation (17,000*g* for 5 min at room temperature), the supernatant was separated from the precipitate. An equal volume of 100% (v/v) 2-propanol was then added to the supernatant, diluting the sample. To estimate injection and detection efficiencies, an internal standard comprising 500 mg/L 1-pentanol (for ethyl hexanoate) and 200 mg/L heptanoic acid (for butanoic acid, hexanoic acid, and octanoic acid) in 17.0% ethanol was added to the diluted samples at a ratio of 9:1 (sample:internal standard).

**Quantification of MCFAs and Ethyl Hexanoate Using GC-FID.** A GC-FID (GC-17A-FID version 1; Shimadzu, Kyoto, Japan) coupled with an AOC-20i autosampler (Shimadzu, Kyoto, Japan) was used as previously described.[7] Splitless injections were performed for all samples with injection volumes of 1.2 $\mu$L. Two HP-FFAP columns

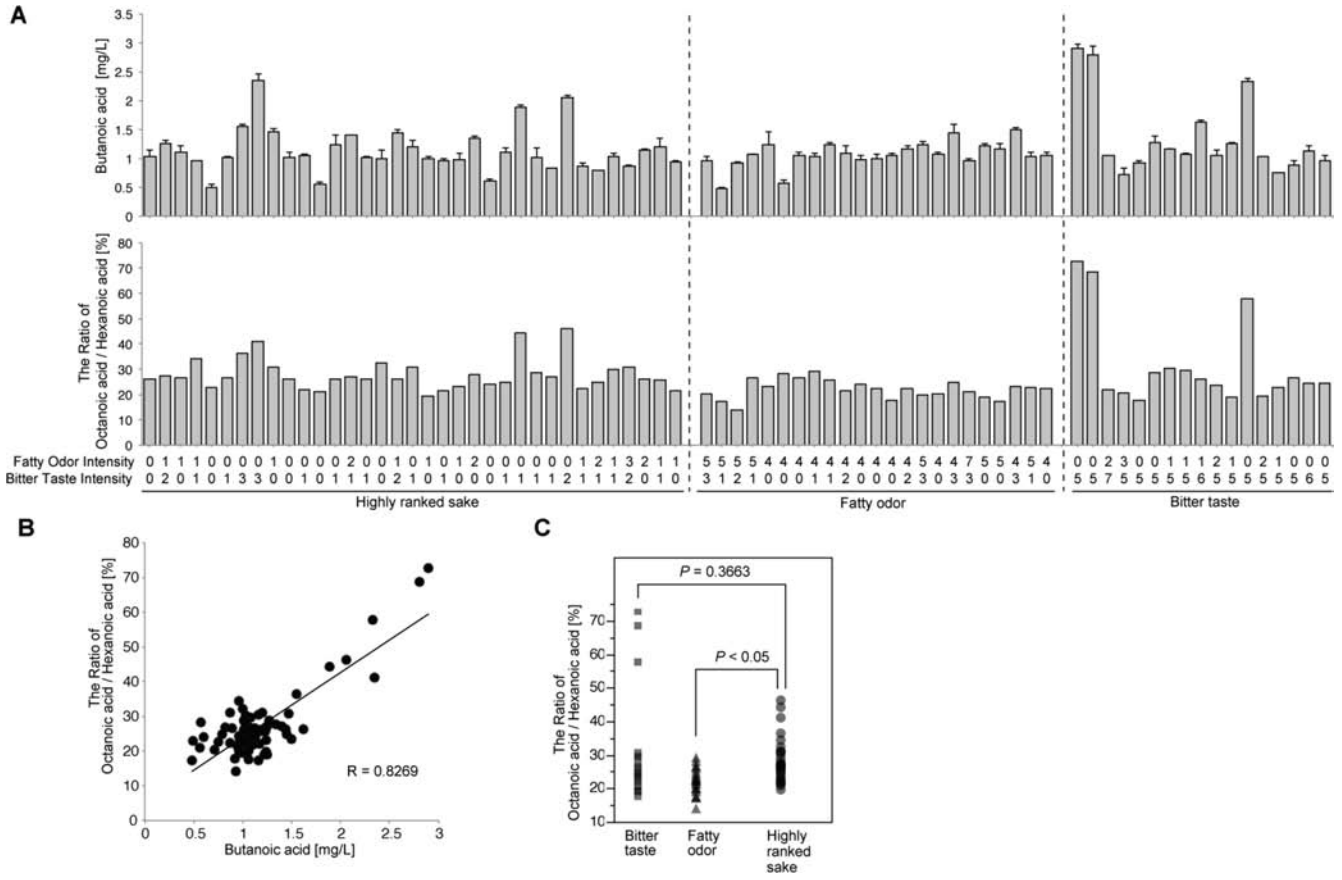

**Figure 2.** Positive correlation of butanoic acid concentrations and the octanoic acid/hexanoic acid (OA/HA) ratios in Japanese sake. Indicated chemical compounds (butanoic acid, hexanoic acid, and octanoic acid) were quantified using GC-FID. (A) *Upper panel*, The butanoic acid concentrations in sake are grouped according to the characteristics (highly ranked sake, fatty odor, and inharmonious bitter taste sake). Groupings are based on the numbers of sensory evaluation panelists who identified fatty odor or inharmonious bitter taste (shown below the graph). *Lower panel*, corresponding OA/HA ratios in sake. (B) Correlation between the OA/HA ratio and butanoic acid concentrations in all sake. (C) No statistically significant differences in OA/HA ratios between highly ranked and inharmonious bitter taste sake were identified using the Dunnett's post hoc test. Error bars indicate the variance between two technical replicates. Typical data from three independent analytical processes are shown.

(30 m × 0.32 mm i.d., 0.25-$\mu$m film thickness) were connected in tandem using a universal press-tight column connector (Restek, Bellefonte, PA, USA). The oven was initially set at 50 °C (for 3 min), and the temperature was increased from 50 to 235 °C at 7 °C/min, and was then maintained at 235 °C for 15 min. The temperature was subsequently increased from 235 to 240 °C at 30 °C/min and was maintained at 240 °C for 5 min. Peak areas on the chromatograms were quantified using GC-solution software version 2 (Shimadzu).

**Analysis of General Components of *moromi* and Sake.** The general components of the *moromi* during fermentation and those of sake were analyzed by the standard method established by the National Tax Administration Agency of Japan. In this analysis, ethanol content was determined using GC with an Rtx-624 column (Restek).

**Analysis of Choline-Containing Phospholipids.** The amount of choline-containing phospholipids in sake samples was determined using a colorimetric enzyme assay for detecting serum lipids with minor modification (Phospholipid C kit 433-36201, Wako Pure Chemicals, Osaka, Japan). Briefly, 10 $\mu$L of sake, filtered sake mash (*moromi*), or standards were mixed with 1.5 mL of assay reagent, incubated for 5 min at 37 °C, and the absorbance was measured at 600 nm.

**Sample Pretreatment for GC × GC−TOFMS Analysis.** The following manipulations were performed below 15 °C. Eleven sake samples (15 mL each), which were entries into the 2011 NRIB National New Sake Awards competition, were diluted with equal volumes of water and were passed through a 1-cc Oasis HLB cartridge containing 30 mg of sorbent (Waters, Milford, MA, USA) under slightly negative pressure (approximately from −0.002 to −0.005 MPa) using a GL-SPE vacuum manifold system (GL Science, Tokyo, Japan). After washing with 200 $\mu$L of water, the chemical components were eluted with 400 $\mu$L of organic solvent (2-propanol:methanol = 4:1), and 37.5-fold condensed elutes were tightly packed in glass vials and stored at 4 °C until further analysis.

**GC × GC−TOFMS Analysis.** The GC × GC system comprised an Agilent 7890N instrument equipped with an auto sampler 7683B series injector (Agilent). The nonpolar DB-1 (30 m × 0.25 mm i.d., 0.25-$\mu$m film thickness) was used as a primary separation column, and the BPX-50 (1.5 m × 0.1 mm i.d., 0.1-$\mu$m film thickness), which enables medium polarity separation, was used as a secondary column. A LECO Pegasus 4D TOFMS (LECO, St. Joseph, MI, USA) was connected in series with the GC × GC separation system. During modulation, cold pulses were generated using dry nitrogen gas cooled by liquid nitrogen, and heated dry air was used for hot pulses. Injector, transfer line, and ion source temperatures were set at 250 °C. The oven temperature program for the primary column began at 40 °C (for 5 min) and increased to 310 °C at 7 °C/min, and then the temperature was maintained at 310 °C for 1 min. The oven temperature program for the secondary column began at 55 °C (for 5 min) and increased to 325 °C at 7 °C/min, and then the temperature was maintained at 325 °C for 2 min. The modulator offset was +10 °C relative to the primary oven, and the modulation period was 5 s. Ultra-high-purity helium (>99.9999%) was used as a carrier gas with a constant flow rate of 1.5 mL/min. The injection volume was 1.0 $\mu$L.

Mass spectrometry parameters included electron ionization at 70 eV with a detector voltage of −1750 V, a mass range between 29 and 500

dx.doi.org/10.1021/jf502071d | J. Agric. Food Chem. 2014, 62, 8478−8485

Da, and an acquisition rate of 200 spectra/s. Data are presented as nominal mass.

Analyses were performed 4 times per sample, and the first data set obtained for each sample was discarded to avoid contamination by carryover compounds from the previous analysis. Data from the subsequent three analyses were then processed.

**Data Processing and Semiquantification.** Deconvolution of GC × GC−TOFMS spectra was conducted using ChromaTOF software ver. 4.50, which was optimized for the LECO Pegasus 4D TOFMS instrument. Chromatograms were processed with a baseline offset of 0.5, automatic peak smoothing, peak find with a minimum signal-to-noise ratio (S/N) of 30, a first dimension peak width of 15 s, and a second dimension peak width of 0.1 s. Compound mass spectral data were compared against the Wiley09 database library to calculate "similarity" and "reverse" parameters. Analytical conditions and parameters are summarized in Supporting Information Table 1.

**Statistical Analyses.** Descriptive statistical, multiple variance, and principal component analyses were conducted using JMP software version 10.0.2 (SAS Institute Inc., Cary, NC, USA).

## RESULTS AND DISCUSSION

**Quantification of MCFAs and Ethyl Hexanoate in Sake Using GC-FID.** Premium Japanese sake "*ginjo* sake" is known for its fruity flavor. However, little is known of the flavor-generating mechanisms in sake. In particular, sensory evaluations of sake sometimes identify problematic fatty odor and inharmonious bitter taste, although the relevant chemical compounds remain uncharacterized. To address this issue, we initially selected three types of sake, which were entries into the NRIB National New Sake Awards Competition from 2009 to 2011, for use as samples. Highly ranked sake samples were used as controls, and sake samples with fatty odor or inharmonious bitter taste were examined. The numbers of highly ranked sake were 9 (2009), 13 (2010), and 13 (2011). The numbers of sake with fatty odor were 5 (2009), 12 (2010), and 6 (2011), and the numbers of sake with inharmonious bitter taste were 4 (2009), 8 (2010), and 5 (2011).

After selection of sake samples, we quantified the concentrations of butanoic acid, hexanoic acid, octanoic acid, and ethyl hexanoate in sake using GC-FID. Figure 1 shows correlations between ethyl hexanoate and MCFAs. As expected, higher ethyl hexanoate and MCFAs concentrations were found in sake samples (Figure 1) than in commercial sake products that were previously determined.[7] Using multiple comparison analysis, we found that ethyl hexanoate and hexanoic acid were present in significantly higher quantities in fatty odor sake than in the highly ranked sake (Figure 1J and K). The average hexanoic acid concentration in highly ranked sake was 24.2 mg/L, whereas that in fatty odor sake was 9.9 mg/L higher (34.1 mg/L). In contrast, the average octanoic acid concentration differed by only 0.7 mg/L. Yamane et al. previously showed that the addition of 8 mg/L hexanoic acid to sake resulted in increased perceptions of unpleasant fatty-related odors,[1] which is consistent with our results. Furthermore, we performed verification tests by adding 20 mg/L hexanoic acid to three sake samples containing 14.2−19.6 mg/L hexanoic acid, resulting in increased perception of fatty odor ($p < 0.01$ by $\chi^2$ test). As shown in Figure 1D−F, ethyl hexanoate was positively correlated with hexanoic acid, as previously described.[26] A stronger positive correlation between ethyl hexanoate and hexanoic acid ($R = 0.88$) was observed in highly ranked sake (Figure 1D). As expected, the addition of 6 mg/L ethyl hexanoate to sake did not increase any perception of fatty odor, but unexpectedly rather decreased perception of fatty odor ($p < 0.01$ by $\chi^2$ test). These results suggested that increased hexanoic acid but not ethyl hexanoate concentration is a primary contributor to fatty odor in sake.

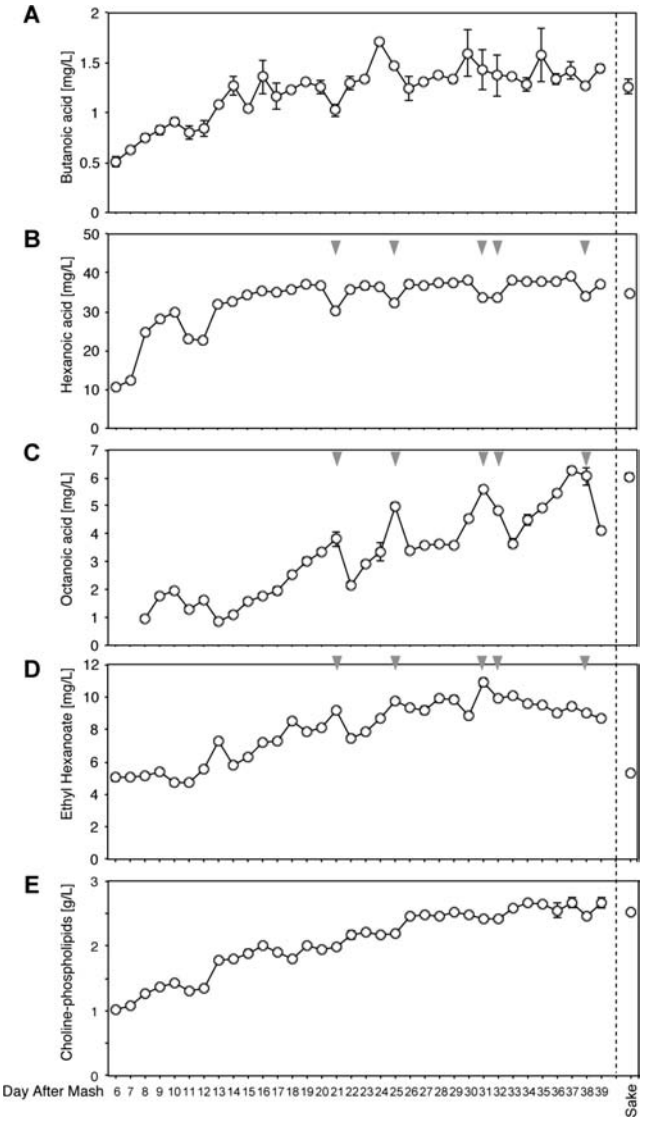

**Figure 3.** Variable patterns of MCFA and ethyl hexanoate concentrations in sake mash. Japanese sake was brewed on a semi-industrial scale, and chemical compounds concentrations were determined in samples taken during the fermentation period, and in samples of the final product (separated by dotted lines). (A) Butanoic acid, (B) hexanoic acid, (C) octanoic acid, (D) ethyl hexanoate, (E) choline-phospholipids concentrations in *moromi* samples and in final product; the *x*-axis shows the number of days after starting the mash. Gray arrowheads indicate days on which uncharacteristic patterns of hexanoic acid, octanoic acid, and ethyl hexanoate concentrations were observed. Errors bar indicate the variance between two technical replicates. Typical data from three independent analytical processes are shown.

No significant differences in hexanoic acid levels were found between highly ranked and inharmonious bitter taste sake. However, ethyl hexanoate levels were relatively lower in inharmonious bitter taste sake (Figure 1J and K), suggesting that ethyl hexanoate negatively correlated with inharmonious bitter taste.

Unexpectedly, ethyl hexanoate levels were found to negatively correlate with butanoic acid (Figure 1A−C). Butanoic acid concentration varied considerably even brewed

dx.doi.org/10.1021/jf502071d | J. Agric. Food Chem. 2014, 62, 8478−8485

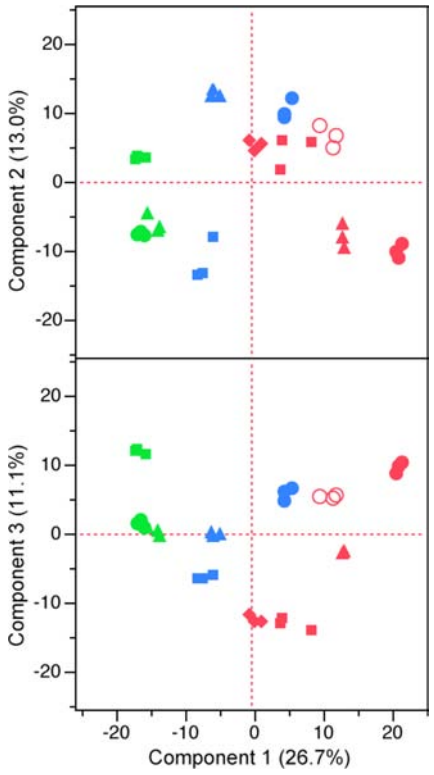

**Figure 4.** Principal component analysis (PCA) of Japanese sake. After selecting compounds using Fisher ratio criteria, PCA was performed for 11 sake samples in triplicate. Highly ranked sake ($n$ = 5) is shown in red, fatty odor sake ($n$ = 3) is shown in green, and inharmonious bitter taste sake ($n$ = 3) is shown in blue.

using the same fermentation materials and under the same conditions, including rice species, yeast strain, and *shubo* (seed mash) type. However, butanoic acid concentration tended to be slightly higher in sake samples, brewed using rice species, *Omachi*.

**Positive Correlation between Butanoic Acid and the Octanoic Acid/Hexanoic Acid Ratio.** Because we were interested in our findings showing that MCFAs did not uniformly vary between sample groups (Figure 1), the molecular ratios of chemical compounds were analyzed. Figure 2A shows the butanoic acid concentrations and the octanoic acid/hexanoic acid (OA/HA) ratios. Some sake samples with high butanoic acid concentrations also had high OA/HA ratios (Figure 2A), which were likely to be correlated with inharmonious bitter taste. As shown in Figure 2B, butanoic acid concentration correlated with the OA/HA ratios. Although inharmonious bitter taste was not significantly correlated with butanoic acid or the OA/HA ratios (Figure 2C), some inharmonious bitter taste sake samples contained higher butanoic acid concentrations, or higher OA/HA ratios (Figure 2A and B).

**Variable Patterns of MCFA and Ethyl Hexanoate Concentrations in Sake Mash.** To determine when MCFAs and ethyl hexanoate were generated during the sake brewing process, we brewed *ginjo* sake. In the sake brewing process, *moromi* stirring was minimized to promote the discharge of $CO_2$ gas during fermentation. The final ethanol concentration in the sake product was 16.2%. Parts A–C of Figure 3 show changes in butanoic acid, hexanoic acid, and octanoic acid concentrations, respectively, over time in *moromi*. Hexanoic acid concentrations reached a maximum level during the early-to-middle stage of the fermentation period (Figure

3B). In contrast, octanoic acid concentrations increased with ethyl alcohol production (data not shown) and reached a maximum at a later stage of the fermentation period (Figure 3C). These differences may reflect differences in hydrophobicity. Figure 3D shows the ethyl hexanoate concentration in *moromi*, which reached a maximum during the middle stage, and was markedly decreased in the final product. This phenomenon has long been observed in the sake industry and was expected because ethyl hexanoate is thought to exist in the yeast cells, although details of its localization are unknown. Interestingly and unexpectedly, we observed several points: the lower hexanoic acid concentrations, but higher concentrations of octanoic acid and ethyl hexanoate (Figure 3B−D). These changes in concentrations were probably attributable to the minimal *moromi* stirring before sampling. In previous reports, yeast ethyl ester biosynthesis 1 (Eeb1) and ethanol hexanoyl transferase 1 (Eht1) catalyzed the esterification of hexanoic acid (hexanoyl-coenzyme A) and ethanol, producing ethyl hexanoate.[2] Saerens et al. also showed that the *EEB1* gene was particularly considered to be robustly upregulated in the presence of octanoic acid.[27] Thus, the variable concentration of hexanoic acid, octanoic acid, and ethyl hexanoate in *moromi* may reflect the expression of genes such as *EEB1 and EHT1*. The butanoic acid concentrations in *moromi* did not change significantly over time (Figure 3A) and were not associated with the OA/HA ratio, indicating that butanoic acid concentration does not always correlate with OA/HA ratio.

Choline-containing phospholipids in *moromi* were positively correlated with hexanoic acid (Figure 3E). Although we did not identify predominating choline-containing phospholipid species and fatty acids in cerulenin-resistant yeast, the concentration of choline-containing phospholipids in *moromi* was positively correlated with hexanoic acid, but not with octanoic acid.

In conclusion, MCFA and ethyl hexanoate concentrations did not uniformly increase in *moromi*. This pattern has not been previously observed in the sake fermentation process. In yeast cells, MCFAs are primarily generated in the cytosol by the traditional fatty acid synthase complex. However, MCFAs such as octanoic acid, which is involved in the formation of $\alpha$-lipoic acid, are also generated in the mitochondria.[28,29] Hence, cytosolic MCFA composition may differ from that generated in the mitochondria. In the present study, sake fermentation was performed under completely anaerobic conditions, indicating that sake yeast does not require the tricarboxylic acid cycle to produce energy in mitochondria. However, the mechanisms behind MCFA generation and accumulation in sake yeast during the brewing process remain unknown, and further targeted cell biology studies are required.

**Comprehensive Analysis of Compounds Using GC × GC−TOFMS.** We showed that fatty odor and inharmonious bitter taste in sake correlate with MCFA contents, indicating that yeast metabolism may change during sake brewing. Thus, the present comparisons of sake metabolites other than MCFA in these three types of Japanese sake (highly ranked sake, fatty odor sake, and inharmonious bitter taste sake) are critical for understanding the factors that contribute to certain organoleptic properties. Hence, a comprehensive analysis of volatile compounds in these three types of sake was performed using a GC × GC−TOFMS system.

In these experiments, 11 sake samples, including 5 highly ranked sake samples, 3 fatty odor sake samples, and 3 inharmonious bitter taste sake samples, were selected from entries into the NRIB National New Sake Awards competition held in 2011. Sake samples were analyzed in triplicate using GC × GC−TOFMS equipped with a LECO Pegasus 4D system, giving a total of 33 sets of two-dimensional total ion chromatogram (TIC) data. Analytical conditions are summarized in Supporting Information Table 1. Typical TIC data for each type of sake are shown in Supporting Information Figure 1A−C, and corresponding intensity data are shown in Supporting Information Figure 1D−F. Supporting Information Figure 1 shows similar patterns of most peaks from the three different types of sake, although some differences are indicated. Subsequently, after performing peak deconvolution using ChromaTOF software, an automatic data mining program was applied, and detected peaks were aligned using the statistical-compare function of ChromaTOF software.

**Correlations of Chemical Compounds with Fatty Odor and Inharmonious Bitter Tastes.** GC × GC−TOFMS analyses showed >3,000 peaks. For convenience, peaks with poor reproducibility were denoted as "unknown", and peaks with good reproducibility (with similarities of >600) were denoted as "analytes". Specific compound names were assigned to peaks with similarities >650. A total of 1,182 analytes were thus identified, and specific chemical compounds were inferred for 1,110 of these. Using the area values of these compounds, we performed a Fisher ratio calculation using ANOVA to identify significant differences between samples. Consequently, 568 peaks remained after Fisher ratio selection with $F$ values of >5.0. Principal component analysis (PCA) was performed using semiquantification data from the 568 peaks as parameters. The results of PCA show clear separation of fatty odor sake from highly ranked sake and inharmonious bitter taste sake (Figure 4). Highly ranked sake may not have been clearly separated from inharmonious bitter taste sake because nonvolatile compounds contributed more to the bitter taste than volatile compounds. Although the replicates were repeatable, the five highly ranked sake samples were not tightly clustered (Figure 4). Nonetheless, fatty odor sake was clearly distinguished by component 1, indicating that numerous chemical compounds in sake contribute to its characteristics. Hence, loading plot analysis after PCA was not used to estimate correlations of chemical compounds with class separation. Instead, we correlated certain compounds with semiquantitative sensory

data (numbers of notations for fatty odor and inharmonious bitter taste) using a relational analysis method.

Compounds that correlated with fatty odor and inharmonious bitter taste are listed in Tables 1 and 2, respectively. Several compounds, such as long-chain alkanes, some MCFA-related compounds, and some indole-related compounds, were positively correlated with fatty odor (Table 1). Alkanes in yeast can be generated intracellularly by the decarboxylation of fatty acids.[30] MCFAs and fatty acids with longer carbon chains may be converted to more volatile alkanes in decarboxylation reactions and may enhance fatty odor. MCFAs are toxic to microorganisms.[31−33] Hence, for protection against exposure to MCFAs, yeast may express proteins that esterify or export MCFAs.[34,35] Fungi similarly express enzymes that decarboxylate MCFAs such as *E,E*-2,4-dihexenoic acid (common name, sorbic acid).[36] Thus, the presence of alkanes in sake may reflect microbe-assisted decarboxylation reactions. Accordingly, MCFA-related compounds were correlated with fatty odor (Table 1), and this finding corresponded with the results shown in Figure 1. Although hexanoic acid was not identified in fatty odor sake, the derivative lactone (2H-pyran-2-one, tetrahydro-6-methyl-) was present (Table 1), despite the strong correlation between hexanoic acid concentrations and fatty odor. Some failures in peak picking were caused by peak saturation of some high concentration compounds such as hexanoic acid, and they may have lowered the Fisher ratio value to <5.0 in this experiment. Semiquantitative analysis of decanoic acid using GC-FID showed that decanoic acid positively correlated with both octanoic acid and hexanoic acid with correlation coefficients of $R = 0.59$ and $R = 0.33$, respectively (data not shown). For further information on MCFA-related compounds and alkanes, targeted analysis for these compounds is required.

Furan and ketone compounds were positively correlated with inharmonious bitter taste (Table 2). Furan is a well-known thermally generated compound that imparts food a bitter taste. Moreover, among ketones, 2-en ketone was particularly correlated with inharmonious bitter taste. However, neither direct nor indirect mechanisms have been described for the relationship between inharmonious bitter taste and these compounds.

Because GC analysis detects only volatile compounds, nonvolatile compounds were not identified. Thus, the GC analysis of derivatized compounds, and analysis using alternative instruments such as liquid chromatography and CE, may be required to investigate the roles of nonvolatile compounds in sensory qualities.

In conclusions, we quantified MCFAs and ethyl hexanoate in premium Japanese *ginjo* sake using GC-FID. These experiments showed a strong correlation between hexanoic acid and fatty odor, and a possible correlation between butanoic acid and the OA/HA ratio, and inharmonious bitter taste. The variable MCFA content in *moromi* apparently correlates with ethyl hexanoate concentrations, and can be linked to the expression of yeast genes. Furthermore, the chemical compounds found in fatty odor and inharmonious bitter taste sake were investigated using comprehensive GC × GC−TOFMS analysis. These experiments revealed direct correlations of MCFA derivatives and long-chain alkanes, and fatty odor. Taken together, MCFAs, MCFA derivatives, and long-chain alkanes could contribute to unpleasant fatty odor in sake. The present data indicate relationships between volatile compounds and the organoleptic properties of sake and provide fundamental knowledge for future research into the production of alcoholic beverages.

## ACKNOWLEDGMENTS

This work involved the study of *ginjo* sake samples, which were supplied by entrants into the NRIB National New Sake Awards competition. We greatly appreciate all the participating breweries, particularly those that entered in the competition in 2011. We wish to thank Ms. Fumie Kabashima (LECO Corporation Japan) and Ms. Hiromi Kohno for scientific help.

**ABSTRACT:** Corn starch has become a common adjunct for beer brewing in Chinese breweries. However, with increasing ratio of corn starch, problems like poor wort filtration performance arise, which will decrease production capacity of breweries. To solve this problem, factors affecting wort filtration were evaluated, such as the size of corn starch particle, special yellow floats formed during liquefaction of corn starch, and residual substance after liquefaction. The effects of different enzyme preparations including $\beta$-amylase and $\beta$-glucanase on filtration rate were also evaluated. The results indicate that the emerging yellow floats do not severely block filtration, while the fine and uniform-shape corn starch particle and its incompletely hydrolyzed residue after liquefaction are responsible for filtration blocking. Application of $\beta$-amylase preparation increased the filtration rate of liquefied corn starch. This study is useful for our insight into the filtration blocking problem arising in the process of high-adjunct-ratio beer brewing and also provides a feasible solution using enzyme preparations.

**KEYWORDS:** *beer brewing, corn starch, high-adjunct-ratio brewing, filtration blocking, wort filtration*

## INTRODUCTION

As an important industrial raw material, corn starch is applied widely in various bioprocesses, such as production of syrup, lactic acid,[1−3] itaconic acid,[4] and ethanol.[5−7] It is also often used as adjunct in the brewing industry.[8−10] Corn starch has been used as an adjunct for beer brewing since 1970s and is proved to have no negative influence on wort quality and beer flavor except slightly thin flavor.[11]

In the beer brewing industry, starch-rich materials are often used as adjuncts, for example, corn starch, rice, wheat, and barley.[10,12] Corn starch and rice are the most widely used due to their low-cost and abundant resources in China. The beer made from corn starch as adjunct is characterized by light color, white foam, light flavor, and pure taste,[12] which exactly meet the tastes of Chinese consumers. Besides, corn starch has a higher degree of fermentability than other adjuncts. With the application of high-gravity brewing technology,[13] high-adjunct-ratio beer brewing technology is adopted widely in some Chinese breweries.

However, severe problems like sluggish wort filtration using frame filter often occur when corn starch is used with a high proportion such as 50%, which significantly decreases production capacity of brewery. In contrast, this filtration problem does not occur when rice flour is used as adjunct. There are multiple factors that may cause slower lautering including incompletely degraded cell wall fragments (e.g., hemicelluloses and pentosans) causing high wort viscosity and incompletely hydrolyzed small starch granules resulting in longer lautering time.[14] Particle size distribution of fines in mash is also the predominant factor affecting wort filtration performance.[15,16]

These factors causing slower lautering all originate from malt and have been studied widely. Some combinational enzyme preparations such as $\beta$-glucanase, xylanase, and glucoamylase have been developed to solve these problems of filtration blocking. However, few investigations have been done with respect to the adjunct in the process of high-adjunct-ratio brewing. As practical experience, the high proportion of corn starch caused severe extension of lautering time, while combinational application of corn starch and rice flour does not. To evaluate factors causing slower lautering and origin from pure adjunct of corn starch, we focused on comparative analysis of corn starch, rice flour, and their liquefied mash using scanning electron microscopy and particle size distribution in this study. The components in incompletely hydrolyzed residue of liquefied corn starch were also analyzed, and the effects of some amylolytic enzymes on filtration rate were evaluated.

## MATERIALS AND METHODS

**Brewing Materials and Enzyme Preparations.** Corn starch was purchased from COCFO Biochemical Energy Co., Ltd. (Jilin Province, China). Rice was milled in a Buhler Miag disk mill (DLEUW 22050, Buhler Miag) using a fine grind and sieved through 80 mesh to obtain rice flour. The Canada Harrington barley was malted in Dalian malting (Liaoning Province, China). Malt was milled with a disk mill set at 0.2 mm disk distance.

Thermostable $\alpha$-amylase preparation and $\beta$-glucanase preparation were provided by Novozymes. Liquid $\beta$-amylase preparation was purchased from a local enzyme plant, Boli Biological Products Co., Ltd. (Jiangsu Province, China). The usage amount of enzyme preparation was according to the manufacturer's instructions. The specifications of all enzyme preparations used in this study are shown in Table 1.

**Assay of the Content of Total Starch, Total Nitrogen, and Fat.** Total starch content was analyzed by the dinitrosalicylic acid (DNS) method.[17] Samples (0.1 g) were hydrolyzed in 10 mL of 6 mol/L HCl at 100 °C for 30 min, and the concentration of glucose in the hydrolysate was determined by the DNS method. The obtained hydrolysate was adjusted with 6 mol/L NaOH to neutral pH using phenolphthalein as an indicator and then was filtered with a filter paper. The filtrate was diluted

by 10-fold with deionized water for further analysis. One milliliter of the diluted hydrolysate was added to 1 mL of DNS solution (6.3‰ w/v) and 1 mL of water. The mixture was boiled for 5 min and then cooled in water for 2 min. 22 mL of deionized water was added, and the mixture was used to measure the absorbance at 540 nm. The absorbance was used to calculate the concentration of reducing sugar according to a standard curve of glucose solution (0−0.6 mg/mL). The total starch content was calculated as the concentration of reducing sugar × 0.9.

Total nitrogen content was determined using a Kjeldahl 8400 Analyzer Unit (Foss).[18] Protein content was estimated as 6.25 times total nitrogen content.

Fat content was analyzed by Soxhlet extraction method using diethyl ether. Samples (3.0 g) were weighed in an extraction thimble and placed in the extraction tube, which was connected to a condenser above and a flask below. Diethyl ether was added to 1/2 to 3/5 of the volume of the flask. Extraction was carried out by diethyl ether reflux at 55 °C for 6−8 h. After extraction, diethyl ether was subjected to evaporation at the rotary evaporator and the flask was dried at 105 °C for 90 min until constant weight (weight difference was within 0.0002 g). The fat content was calculated according to the increased weight of the flask.

**The Procedures of Gelatinization, Liquefaction, and Mashing in the High-Adjunct-Ratio Brewing Process.** In the high-adjunct-ratio brewing process used in this study, a high ratio of material to water (1:2.5) was used during gelatinization and liquefaction of the adjunct. 50 g of the adjunct was mixed with 125 mL of preheated water (55 °C) in the mashing cup of Agreement Saccharification Instrument (BGT-8A, Bioer) and stirred immediately. The mixture was heated to 75 °C and incubated for 10 min and then heated to 95 °C and incubated for 30 min. The thermostable $\alpha$-amylase preparation (0.6 mg/g corn starch) was added at the beginning of gelatinization at 55 °C. The evaporated water was readded into the cup according to its weight.

The mashing procedure was as follows: 30 min at 48 °C, 40 min at 63 °C, 20 min at 72 °C and before mashing off at 78 °C. The heating rate for temperature ramp up was 1 °C per min. 50 g of malt barley was milled and mashed with a water-to-malt ratio of 3.5:1 in the mashing bath (BGT-8A, Bioer). After the step of 30 min at 48 °C, the mash was mixed with the above liquefied adjunct and was heated to 63 °C.

**Analysis of Scanning Electron Microscopy (SEM).** The samples for SEM analysis were prepared as follows: corn starch and milled rice were directly used as the samples; yellow floats and the incompletely degraded residue in liquefied corn starch were collected on a filter paper as the samples. All of the collected samples were fixed with glutaraldehyde, then washed with 35% (v/v) alcohol solution before dehydration, and dried at the critical temperature. Samples were then mounted on a SEM stub with silver plate and spatter-coated with platinum by ion coater, and they were observed under a constant accelerating voltage of 5.0 kV using a scanning electron microscope (FEI Quanta 200, Holland).

**Particle Size Analysis.** Particle size was measured in a Microtrac SDC laser-diffraction analyzer (Microtrac Inc., USA) using the flow-through, 300 mL reservoir. Starch granules and starch slurries were added into the reservoir until the concentration value reach between 12% and 17%. Settings were optimized for the refractive index of starch in water, and particle size was recorded as volume average diameter automatically by transferring light scattering signals to electrical signals.

**Evaluation of Filtration Rate.** The liquefied solution of adjunct and the mash were filtered through a filter paper and the filtrate was collected by a graduated cylinder. The volume of filtrate was recorded every 10 min in the first 60 min and then every 20 min for another 60 min. The filtration rate was evaluated by the collected total volume of filtrate. Another evaluation method of filtration rate is dependent upon the filtration time. This method was carried out as follows: the first 100 mL of filtrate was collected and refiltrated, and the time for 150 mL of filtrate was recorded and used to evaluate the filtration rate. Each experiment of filtration was carried out in triplicates.

## RESULTS

**The Differences in Component and Dimension between Corn Starch and Rice Flour.** Both corn starch and rice flour are commonly used as adjunct in the brewing process. However, corn starch often causes a serious extension of lautering time, while rice flour does not. The differences in component and dimension were compared. Protein content in rice flour was more than that in corn starch (Table 2). Corn starch granules were polygonal granules with several edges and a uniform shape (Figure 1A). The size of the granule in diameter was from about 5 to 25 $\mu$m with an average volume diameter of 14 $\mu$m (Figure 1C). In contrast, the dimension of rice flour granules was irregular (Figure 1B), from about several microns to hundreds of microns in diameter, and its average volume diameter was 173 $\mu$m (Figure 1C).

**Table 2. Components of Corn Starch and Rice Flour (w/w)[a]**

| content (%) | corn starch | rice flour |
|---|---|---|
| starch | 94.6 ± 2.1 | 86.7 ± 1.8 |
| protein | 0.34 ± 0.1 | 8.3 ± 0.1 |
| fat | 0.57 ± 0.2 | 0.7 ± 0.1 |

[a]Date are means ± standard deviation of three replicates.

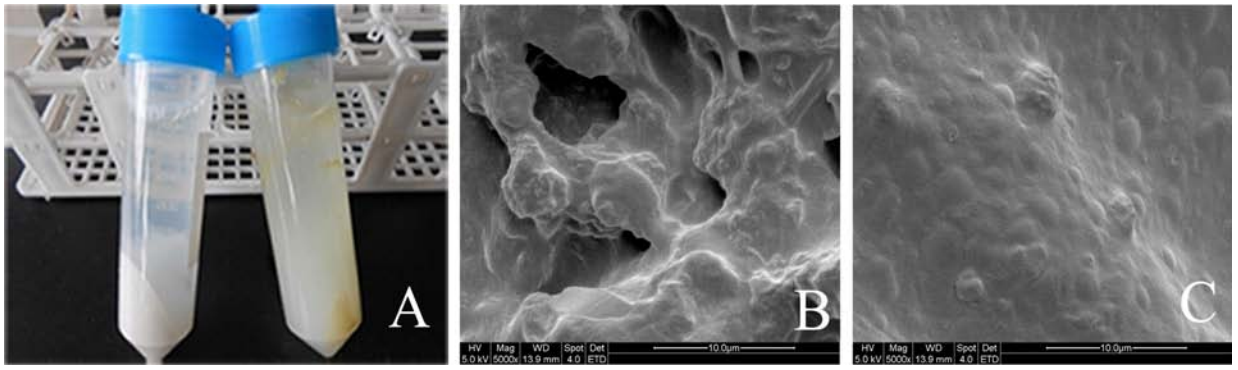

**Figure 2.** Special yellow floats formed during liquefaction of corn starch. (A) The comparison of liquefied solution between rice flour (right) and corn starch (left). (B) SEM image (5000×) of the yellow floats from liquefied corn starch. (C) SEM image (5000×) of the bottom precipitate from liquefied corn starch.

**Analysis of Yellow Floats in Liquefied Corn Starch.** The differences in liquefied adjuncts between corn starch and rice flour mainly included yellow floats and residual insoluble particle. After liquefaction using the thermostable $\alpha$-amylase, liquefied corn starch was a uniform, highly viscous, and colloidal solution, while liquefied rice flour was not viscous and contained many visible granules. Especially, during liquefaction of corn starch, some yellow substances floated on the surface of thick mash, which were intuitively thought as a main potential factor of filtration blocking.

After centrifugation at 8,000 rpm for 10 min, there was a distinct difference between liquefied corn starch and liquefied rice flour (Figure 2A). The upper layer of liquefied rice flour was clean and did not contain any floats, so the upper liquid layer was clean and transparent and the bottom layer was sedimentation. Unlike rice flour, some yellow floats appeared in the upper layer of liquefied corn starch, moreover, the boundary between the middle liquid layer and the bottom sedimentation layer was obscure due to many suspended particles, which may contain very small and incompletely degraded corn starch particles.

The factors that affected the formation of yellow floats during liquefaction of corn starch were also evaluated. The results indicated that the high ratio of corn starch to water, liquefaction time, boiling process, and boiling time significantly promoted formation of yellow floats (data not shown). The more the ratio of corn starch to water increased and the longer the liquefaction time and boiling time, the more corn floats formed. Especially, the boiling process produced quite a lot of yellow floats arising on the surface of liquefied corn starch.

To analyze the dimensions and components of yellow floats, these floats were collected, dried, and then analyzed by SEM analysis and chemical analysis methods. As SEM photographs showed (Figure 2B,C), yellow floats had a relatively loose structure compared with the bottom sedimentation in liquefied corn starch. Overall compositions of corn floats formed under different conditions were similar, which contained polysaccharides (70 ± 5%), ether-soluble substances (13 ± 1%), proteins (5 ± 1%), and other unknown components (12%). The density of yellow floats was lower than that of liquefied corn starch since it floats on the surface, which can also be explained by its loose structure and relatively high fat content over the raw material of corn starch. However, its density was still larger than that of water. Yield of yellow floats was around 0.8 g (dry weight)/100 g of corn starch, and yield of the sedimentation was 1.52 g (dry weight)/100 g of corn starch. Components in sedimentation consisted of polysaccharides (61.4 ± 0.6%), proteins (0.5 ± 0.04%), and fat (2 ± 0.2%). Therefore, the main components in both yellow floats and sedimentation were incompletely degraded corn starch, which might be the main reason for filtration blocking.

**Evaluation of Factors of Filtration Blocking in Liquefied Corn Starch.** Since corn starch can block filtration while rice flour does not, the retention substances on a filter paper from the two-type liquefied adjuncts were compared by SEM imaging. As shown in Figure 3A, the filtration rate of liquefied corn starch was significantly slower than that of rice flour. The SEM photos showed that filter medium formed from liquefied rice flour was porous and loose (Figure 3D), which did not cause the problem of filtration blocking. In contrast, filter medium formed from liquefied corn starch was very dense (Figure 3C), which could seriously block filtration. The dense filter medium of corn starch should result from the mixture of yellow floats and sedimentation, therefore, its main component should be the incompletely degraded starch particle.

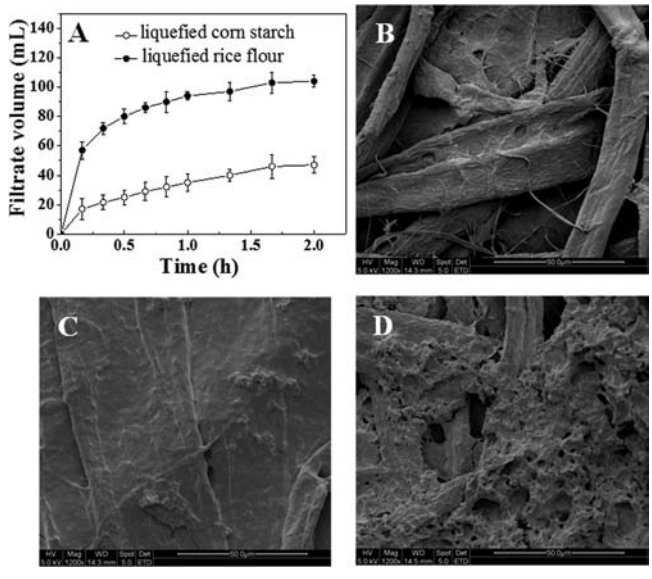

**Figure 3.** Comparison of filtration rate of liquefied adjunct and SEM analysis of the filter medium (1200×). (A) The filtration rate of liquefied corn starch and liquefied rice flour within 2 h. In consideration of increased fat content in yellow floats that may influence filtration, the effects of yellow floats on filtration rate were compared with those of liquid corn oil. As shown in Figure 4, when 5% (w/w) of corn oil was added into liquefied

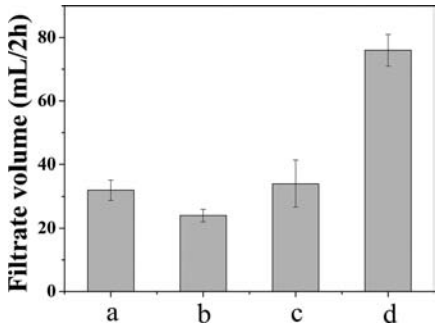

**Figure 4.** Effects of corn floats, corn oil and $\beta$-amylase on filtration rate of liquefied corn starch. (a) Liquefied corn starch. (b) Liquefied corn starch with addition of 5% (w/w) corn oil. (c) Liquefied corn starch with removal of yellow floats. (d) Liquefied corn starch with addition of 100 U/g of $\beta$-amylase.

corn starch, the filtration rate did not change significantly, which indicated that the corn oil should not be the main reason for filtration blocking. When the yellow float was removed from the surface of liquefied corn starch, the filtration rate also did not change significantly (Figure 4). When 100 U/g of $\beta$-amylase was added to further degrade the liquefied corn starch for 1 h, the filtration rate was increased by 2-fold (Figure 4). These results indicated that the main reason for filtration blocking of corn starch was the incompletely degraded starch particle.

**Evaluation of Factors of Filtration Blocking in Mash.** As for the mash that mixed liquefied adjunct with malt, the problem of filtration blocking was similar to that of pure adjunct (Figure 5A). The filtration rate of mash mixed with rice flour was rapid and almost a constant, while that of mash mixed with corn starch was slower and gradually reduced. The filter medium formed after mash filtration was different. The medium mixed with rice flour was more loose and stable, which maintained filtration rate as a constant. In contrast, filter media mixed with corn starch are viscous and layered, where fine particles gradually accumulated in the upper layer of filter media. The layer of fine particles was very thin but greatly weakened filter layer permeability and thus significantly reduced filtration rate.

As permeability of filter medium was greatly dependent on decomposition of cell-wall components from malt such as $\beta$-glucan and xylan and the corn starch particles, effects of $\beta$-amylase and Ultraflo Max (combinational enzyme preparation of $\beta$-glucanase and xylanase) were added into mash respectively, to further degrade the corn starch particles and cell-wall components of malt. The result showed that the filtration rate of mash was increased significantly when the amount of enzyme preparations was increased (Figure 5B,C). Therefore, amylolytic enzyme preparations and cell wall degrading enzymes should be a potential solution for improving high corn starch ratio wort filtration performance.

## DISCUSSION

A rapid mash filtration rate is necessary for high productivity of brewery, so some enzyme preparations have been widely applied to degrade the component causing filtration blocking in the brewing industry like $\beta$-glucanase and xylanase. However, when new material and brewing technology were used in recent years in China like high corn starch ratio beer brewing, new factors blocking mash filtration arose. The emerging problem of filtration blocking cannot be solved very well only by the available brewing enzyme preparations. This study was carried out to evaluate these emerging factors in the process of high corn starch ratio beer brewing and provide new solutions of enzyme preparation for brewery. The results indicate that the emerging factors of filtration blocking should be the incompletely degraded and fine corn starch particles. These residual corn starch particles could not be degraded well by the thermostable $\alpha$-amylase under the condition of high ratio of corn starch to water (1:2.5) even if its dosage was increased by 10 times (data not shown), but could be further degraded by some mesophilic amylolytic enzymes like $\beta$-amylase. However, its industrial application should be further optimized in consideration of the cost of enzyme preparations. Since malts contain intrinsic mesophilic $\beta$-amylase and $\alpha$-amylase, their activity might be not enough for degradation of corn starch during the mashing process when a high adjunct ratio (up to 50%) was used.

Unlike rice flour, corn starch causes obvious extension of lautering time. Besides, the mixture of corn starch and rice flour can reduce the lautering time significantly. According to comparative analysis of the two adjuncts, the distinct filtration performance caused by corn starch and rice flour should mainly result from their different particle character. Corn starch granules were small and uniform in shape, which formed dense and

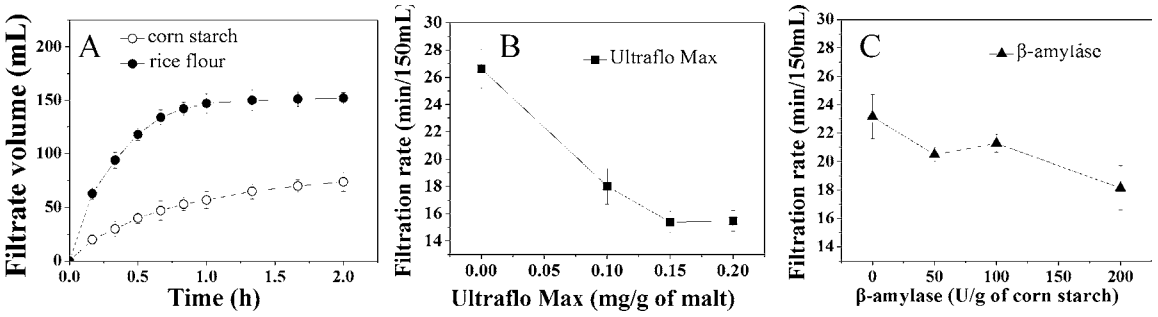

**Figure 5.** Evaluation of enzyme preparations on filtration rate of the mash mixed with high-ratio adjunct (corn starch and rice flour). (A) The filtration rates of mash mixed with different adjuncts (malt:adjunt = 1:1 (w/w)). The filtration rate was evaluated by the total volume of filtrate. (B, C) The effect of different amount of enzyme preparations on filtration rate of mash mixed 50% corn starch (B, Ultraflo Max; C, $\beta$-amylase). Mash mixed corn starch was filtered through a filter paper. The first 100 mL of filtrate was collected and refiltrated, and the filtration time for 150 mL of filtrate was used to evaluate the filtration rate.

dx.doi.org/10.1021/jf5023109 | J. Agric. Food Chem. 2014, 62, 8486−8490

viscous filter media, while rice flour granules were large and irregular, which formed loose and stable filter media. Besides, corn starch particles were easily suspended in wort and could not uniformly deposit with malt husk and formed a thin and dense layer of filter medium on the upper part of the filter medium, which greatly reduced the filtration rate of mash. Therefore, as an adjunct, rice flour can help to form a stable skeleton structure in filter media to maintain a constant filtration rate, while corn starch blocks the filtration pore and forms a dense layer on the surface of filter media to gradually reduce the filtration rate.

The other feature of corn starch that distinguished it from rice flour was the formation of yellow floats. At the later stage of liquefaction of corn starch with high ratio of material to water (1:2.5), some yellow substances floated on the surface and were called yellow floats. They were intuitively thought of as main factors blocking filtration by most breweries' technicians. According to the component analysis, the yellow floats contained a large proportion of polysaccharides and little fat and proteins. Compared with components in the material of corn starch, both the fat content and protein content in corn floats slightly increased, but their amount was still very small. The formation of corn floats was promoted by a high ratio of material to water and elongation of liquefaction time and boiling time. According to these results, we speculate the formation mechanism of yellow floats as follows: high ratio of material to water causes high density of solution; extension of liquefaction time and boiling time caused more water evaporation, resulting in an increased liquid density; some fine corn starch particles interact with pigment, protein, and a small amount of fat to form an aggregation with a low density and loose structure, which floats on the surface. Therefore, the main component in yellow floats is corn starch particles; although they float on the surface, yellow floats are not the factors blocking filtration.

In conclusion, for the filtration process of high corn starch ratio wort, the major factor blocking filtration is the incompletely degraded and fine corn starch particles. Filtration rate mainly depends on the degradation of these small particles. Additional $\beta$-amylase preparation could effectively increase filtration rate. Ultraflo Max that can degrade the known blocking factors like $\beta$-glucan and xylan also performed well. Therefore, the results in this study are useful for our insight into solving the filtration problem causing by high-ratio corn starch, and a combined enzyme preparation including mesophilic amylolytic enzyme and glucanase is proposed.

**ABSTRACT:** Three different varieties of *Opuntia ficus-indica* (R, red; Y, yellow; RY, red-yellow) have been considered in this study. Attention was focused on differential tristimulus colorimetry and on the analysis of individual betalains (HPLC-DAD-ESI-ToF-MS) and phenolic content, scarcely previously reported in these kinds of samples. The importance of this research stems from the elucidation of the parts and varieties of cactus pear more optimal for use as natural colorants and sources of phenolics and betalains. Thus, the RY pulp was appropriate to obtain colorants with high color intensity ($C^*_{ab}$ = 66.5), whereas the whole Y fruit and R pulp reached powerful and stable yellow and red colors, respectively ($C^*_{ab}/h_{ab}$, 57.1/84.7 and 61.1°/81.8°). This choice was also based on the visually appreciable differences ($\Delta E^*_{ab} > 5$) among samples, mainly quantitative ($\%\Delta^2L$, $\%\Delta^2C$). In addition, seeds of all *Opuntia* varieties showed significantly ($p < 0.05$) similar phenolic content (around 23.3 mg/g) and color characteristics.

**KEYWORDS:** *Opuntia ficus-indica, differential tristimulus colorimetry, betalains, phenolics, HPLC-DAD-ESI-ToF-MS*

## INTRODUCTION

In the past few years, consumers have become more conscious of the importance of healthy and natural food both in the manufacture or in consumption. One part of this reality is the use of natural products as colorants. In this way, there is a large extent of natural colorants, extracted from different natural raw materials, rich in compounds such as anthocyanins, carotenoids, and chlorophylls. Apart from those, there is a group of chemical compounds that it is still poorly investigated, betalains.

Betalains are water-soluble compounds present in a restricted number of families of the plant order Caryophyllales and of the genus *Amanita* of the Basidiomycetes.[1] Numerous advantageous on consuming betalain-rich food have been reported, such as antioxidant activity, antiviral, anti-inflammatory, and anticarcinogenic effects.[2,3] Betalains are structured in two chemical families (betacyanins and betaxanthin). The common moiety of both chemical families corresponds to betalamic acid, and the nature of the additional residue determines the pigment classification as betacyanin (hydroxycinnamic acid derivatives or sugars) or betaxanthin (amines or amino acids),[4] with maximum absorptions around 540 and 480 nm, respectively.[2,5]

There are manifold species and varieties used as natural food colorants. In that way, although the most studied and widely distributed source of betalains is the red beet (*Beta vulgaris* L.),[6−8] betalains have been also studied in other raw materials. Some examples are the Swiss chard vegetable,[9] flowers (*Gomphrena globosa* L. and *Bougainvillea* sp.),[10] and fruits such as pitaya[11] and cactus pear (*Opuntia* sp.).[12−16]

*Opuntia ficus-indica* is a type of cactus that provides edible prickly pears. This kind of cactus is widely cultivated in the world due to its adaptability to difficult growing conditions (arid and semiarid zones).[17] Recently, the study of cactus pear has become more and more prominent because of its high content of betalains and other phenolic compounds. In fact, those compounds have been previously studied on this matter in different edible and nonedible parts of prickly pears such as pulps,[14] skins,[16] and seeds.[18,19] These research studies have been focused on the general chemical characterization,[12,20] the total content of both phenolic and betalains,[21−23] and the antioxidant activity determination.[24] However, only a few studies have been developed about individual betalains in that raw material.[13,14,25] Moreover, although this fruit has a potential enterprise projection as natural colorant, hitherto, scarce advanced colorimetric studies have been developed.[12,21,26] Therefore, there are still many aspects to be elucidated about the repercussion on the color of *O. ficus-indica* when it is added as safe colorant.

Therefore, the aim of this research was to carry out an extensive chemical and colorimetric characterization of *O. ficus-indica* [L.] Mill cultivated in Algeria. Different parts of three cactus pear varieties were taken into account, which have not been previously considered in conjunction. Our interest was focused on the study of the phenolic content and individual betalain profile and also on colorimetric characteristics by applying differential tristimulus colorimetry, scarcely reported in the literature. Therefore, the objective is not only the chemical characterization of different parts of prickly pears but

its practical application as a natural colorant by deepening the study of differential colorimetry and betalain profile.

## MATERIALS AND METHODS

**Chemicals and Solvents.** Methanol of analytical or HPLC grade was purchased from J. T. Baker (Baker Mallinckrodt, Mexico), and formic acid and Folin−Ciocalteu reagent were supplied by Sigma-Aldrich (St. Louis, MO, USA). HPLC grade water was obtained by a Milli-Q plus water purification system (Millipore Corp., Bedford, MA, USA). Sodium ascorbate and L-ascorbic acid were from Panreac (Barcelona, Spain). Betanin was supplied by Cymit Quimica S.L. (Barcelona, Spain).

**Samples.** Three different cultivars of prickly pear fruits (*O. ficus-indica* [L.] Mill.) with diverse physical qualities have been selected for this study. Those cactus pear varieties were typically cultivated in the area of Bousselam (Setif, Algeria). Fully ripe cactus pears were collected in August from different points of the plant and in various parts of the parcel. Samples were selected on the basis of their color (both pulp and skin) and the shape and presence of cladode spines (R, red, ovoid and cladode spineless; Y, yellow, elongate with cladode spines; RY, red-yellow, ovoid with cladode spines). Fruits were harvested at a desirable maturity and in good sanitary conditions (R, Y, and RY: pH, 6.14, 5.86 and 5.95; titratable acidity, 0.10, 0.11, and 0.09; °Brix, 12.83, 11.55, and 14.22, respectively).

Fruits were carefully washed and manually peeled. The seeds were removed from the pulp and washed with distilled water. Three different parts of each variety was studied, corresponding to the edible part of the fruit: seeds, pulp, and whole fruit (seeds + pulp). They were separately lyophilized (Christ, Alpha 1-4 LD plus, Germany), ground with a crusher (IKA A 11B, Germany), and passed through a 500 μm sieve.

**Preparation of Extracts.** Lyophilized samples (1 g) were added to 3 mL of methanol/water (50:50) containing 50 mM sodium ascorbate (for avoiding possible oxidations). Subsequently, samples were stirred at 225 rpm for 10 min in darkness. Afterward, samples were centrifuged at 12000*g* at 10 °C for 5 min, separating supernatants from the plant tissue. To achieve the complete discoloration of the plant material, the residues was rinsed once more with the extraction solution and finally with 100% methanol. The extracts were then concentrated in a vacuum (30 °C) until around 3 mL to remove methanol, adding purified water until a total of 4 mL. The mean pH values of the resulting extracts were similar among varieties, as follows: seeds, 5.83; pulp, 6.20; and whole fruit, 6.04. All experiments were carried out in triplicate.

**Colorimetric Measurements.** A Hewlett-Packard UV−vis HP8452 spectrophotometer (Palo Alto, CA, USA) was used to carry out color measurements. The whole visible spectrum (380−770 nm) was recorded at constant intervals ($\Delta\lambda$ = 2 nm) using 2 mm path length glass cells and distilled water as reference. The CIELAB parameters ($L^*$, $a^*$, $b^*$, $C^*_{ab}$, and $h_{ab}$) were determined by using the original software CromaLab[27] following the Commission Internationale de L'Eclariage's recommendations,[28] the CIE 1976 10° Standard Observer and the Standard Illuminant D65. Euclidean distances between two points in the three-dimensional space define by $L^*$, $a^*$, and $b^*$ were used for calculating color differences ($\Delta E^*_{ab}$ of CIELAB): $\Delta E^*_{ab} = [(\Delta L^*)^2 + (\Delta a^*)^2 + (\Delta b^*)^2]^{1/2}$. Moreover, the relative contribution of the three color attributes with respect to $\Delta^2 E^*_{ab}$ that constitutes the total CIELAB color difference was also calculated, expressed as percentage of the quadratic increases of lightness, chroma, and hue.[29]

**Total Phenolic (TP) Content.** TP content was determined using a modification of the Folin−Ciocalteu method.[30] Absorbance was measured at 765 nm, and the results were expressed as milligrams of gallic acid per liter (mg GAE/L). Subsequently, total phenolic content was expressed as milligrams per gram of dry weight (DW). To eliminate the contribution of ascorbic acid to the measurement of absorbance in the Folin−Ciocalteu assay, a correction factor was calculated,[31] quantifying also the ascorbic acid present in each sample.[32] Subsequently, the impact of ascorbic acid in terms of milligrams of GAE per liter was deduced from the spectrophotometrically determined total polyphenol values.

**HPLC-DAD-ESI-ToF-MS Analysis of Betalains.** HPLC separation, identification, and semiquantification of betalains were performed in an Agilent 1200 chromatographic system equipped with a quaternary pump, an UV−vis diode array detector, an automatic injector, and ChemStation software (Palo Alto, CA, USA). Prior to direct injection, the samples were filtered through a 0.45 μm nylon filter (E0034, Análisis Vínicos, Spain). All analyses were made in triplicate.

The betalains' identification was carried out following the method proposed by Castellanos-Santiago and Yahia,[14] using 1% formic acid in water (v/v, eluent A) and methanol (eluent B). Betalains were separated in a Zorbax C18 column (250 × 4.6 mm, 5 μm particle size) maintained at 25 °C, at a flow rate of 1 mL/min. The injection of the volume for all extracts was 20 μL. Betalain compounds were separated starting with 100% A, followed by a linear gradient from 0 to 10% B in 20 min, then a linear gradient from 10 to 30% B in 10 min, and from 30 to 100% B in 5 min. To re-establish the initial conditions, a linear gradient from 100% B to 100% A was used during 5 min. UV−vis spectra were recorded from 200 to 800 nm with a bandwidth of 1.0 nm. Betacyanins and betaxanthins were monitored at 535 and 482 nm, respectively. The identification of each chromatographic peak was tentatively assigned by their visible spectral characteristics in comparison with standard and retention times according to the method proposed by Castellanos-Santiago and Yahia.[14] Semi-

quantification was done on the basis of the mean areas of individual betalains.

The identity of individual betalains was confirmed by mass spectrometry. The separation was performed in a Dionex Ultimate 3000RS U-HPLC (Thermo Fisher Scientific, Waltham, MA, USA), using the column and mobile phase above indicated but with a postcolumn split of 0.4 mL/min. The mass spectra was obtained using a microToF-QII high-resolution time-of-flight mass spectrometer (UHR-ToF) with Q-ToF geometry (Bruker Daltonics, Bremen, Germany) equipped with an electrospray ionization (ESI) source. The instrument was operated in positive ion mode using a scan range from $m/z$ 50 to 1200. Nitrogen was used as the dry gas at a flow rate of 8 mL/min with nebulizing (1.2 bar), and the nebulized temperature was set at 200 °C. Mass spectra were acquired in MS full scan mode, and data were used to perform multiple target screening using Target Analysis 1.2 software (Bruker Daltonics). Instrument control was performed using Bruker Daltonics HyStar 3.2. The accurate mass data of the molecular ions were processed through the software Data Analysis (Bruker Daltonics). The accepted accuracy threshold for confirmation of elemental compositions has been established at 5 ppm.

**Statistical Analysis.** Statistical analysis was carried out by using Statistica version 8.0 software.[33] Univariate analyses of variance (Tukey test and ANOVA) and correlation analysis were applied to discriminate among the means of chemical data by "variety" and by "part of the fruit" factors.

## RESULTS AND DISCUSSION

**Colorimetric Characteristics.** The color was objectively calculated by tristimulus colorimetry, and the values of $L^*$, $C^*_{ab}$, and $h_{ab}$ of each sample are shown in Table 1. The color points represented in the ($a^*b^*$) color diagram as well as the lightness of the sample extracts appear in Figure 1.

The different locations of the diverse parts of *Opuntia* varieties could permit the objective establishment of the chromatic characteristics of the fruits. As can be seen, two different groups are formed: seeds (S), on the one hand, and pulp (P) and whole fruit (W), on the other hand. Regardless of the "variety", P and W were located in the first quadrant (positive values of $a^*$ and $b^*$) of the ($a^*$–$b^*$) plane, whereas S was situated between the first and second quadrants (positive values of $b^*$). It can be noted that, although seed extracts showed intense yellowish tonalities (values of hue close to 90°), their chromatic intensity was very low (values of $C^*_{ab}$ between 4 and 8) (Table 1). However, P and W had a very intense orange-yellow color (values of $C^*_{ab}$ and $h_{ab}$ around 60° and 82°, respectively) (Table 1). Pulp extracts of the different varieties were clearly separated in the space according to both $b^*$ and $a^*$ parameters, whereas the whole fruits were discriminated only on the basis of $b^*$ (Figure 1). Moreover, a separation "by variety" of these samples was observed (Figure 1). Thus, the red-yellow (RY) variety showed the highest values of $b^*$, whereas $a^*$ is the predominant parameter in the red (R) variety. With regard to the lightness, seeds and pulp (especially RP) were noted to occupy opposite positions, keeping the whole fruit extracts in an intermediate stage.

Among "variety" and "part of the fruit" factors, it was largely the latter the most influenced color (Table 1). When ANOVA was applied to the set of data to draw attention to the possible significant differences according to "variety" and "part of the fruit" ($n$ = 27 and $n$ = 9, respectively; data not shown), only the latter factor showed significance. For a better understanding, a comparison by pairs using the Tukey test was applied (Table 1). Thus, when the "part of the fruit" factor was considered, the

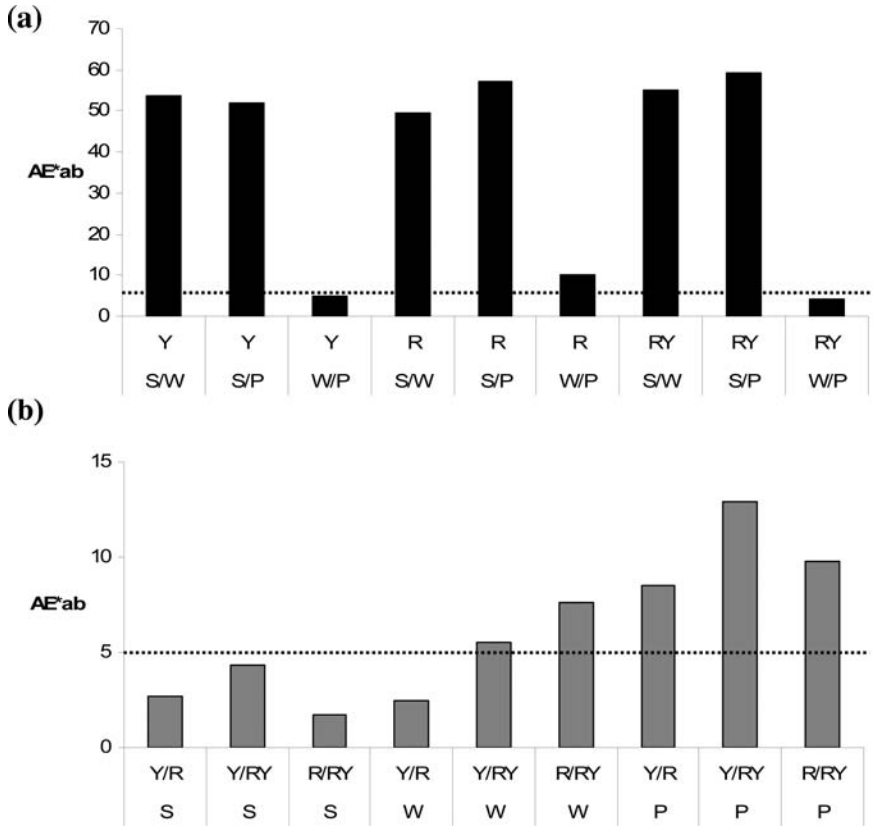

**Figure 2.** Color variation ($\Delta E^*_{ab}$) by pairs in relation to the part of the fruit (a) and variety (b) factors. S, seeds; P, pulp; W, whole fruit; R, red variety; Y, yellow variety; RY, red-yellow variety. Dotted line represents the value of $\Delta E^*_{ab}$ appreciable to the human eye.

major significant variations on CIELAB parameters were assigned to the R variety. Clearly, as could be expected, S significantly differed from P and W for all *Opuntia* varieties in all colorimetric parameters. Moreover, due to the absence of significance ($p > 0.05$) in $C^*_{ab}$ and $h_{ab}$ between P and W extracts in Y and RY varieties, both pulp and whole fruit for both varieties could lend the same color to foods and they could be used indistinctly as natural yellow colorants. However, the values of chroma in P extracts of R variety were significantly higher when compared with W, with a considerably strong red tonality. Seeds could contribute to those differences between W and P because of their low values of chroma, producing an attenuation of the color intensity of W (Table 1). Therefore, it is more suitable to use the pulp of R variety to confer a more powerful red color.

With regard to the "variety" factor, P was considered the most influential part of the fruit to discriminate among varieties, above all regarding chroma and hue. Thus, if pulp extract was considered to be used as natural colorant, the Y variety would confer the significantly highest yellow tonalities.[34] On the contrary, if the whole fruit extract was taken into account, the RY variety should be employed, due to its noticeably higher chromatic intensity. It was also remarkable that the colorimetric characteristics were not significantly affected by "variety" when S extracts were taken into account.

From an industrial point of view, it is easier and economically advantageous to avoid the time-consuming manipulation that some technological procedures require, such as the separation of the seeds from the pulp. Therefore, the whole Y fruit and the pulp of R varieties are optimal for use as yellow and red colorants, respectively, whereas the whole RY fruit could be useful as an additive to confer vivid colors.

**Differential Colorimetry.** In an attempt to evaluate the colorimetric differences among "varieties" and "parts of the fruit", the mean color difference ($\Delta E^*_{ab}$) among samples was calculated (Figure 2). Taking into account that $\Delta E^*_{ab}$ of up to 5 CIELAB units indicates "big color differences" appreciable to the human eye,[35,36] it was confirmed that visually perceptible color differences were observed among the different parts of the fruit of each variety (Figure 2a). On the one hand, the significant variations among S/P and S/W for all varieties previously commented were also appreciable to human eyes. This fact is predictable because they greatly differ from the phenolic profile and, consequently, from the color.[34] When the role of each color attribute with respect to $\Delta^2 E^*_{ab}$ was calculated ($\%\Delta^2 L$, $\%\Delta^2 C$, $\%\Delta^2 H$), results evidenced that these differences were mainly quantitative, with major values of quadratic variations of chroma ($\%\Delta^2 C > 90$) and practically negligible values of lightness and hue. In addition, also noticeable and quantitative color differences were seen for W and P in R variety, lightness being mainly responsible ($\%\Delta^2 L > 65$). The negligible quadratic percentages of hue demonstrated that this parameter did not contribute to the establishment of significant differences of color.

On the other hand, when a comparison among varieties was carried out (Figure 2b), it was observed that several significant differences in the pulps were mainly due to chroma ($\%\Delta^2 C \sim 65$ and 87 when Y/R and Y/RY, respectively, were compared). However, it was lightness that was mainly responsible for the discrepancy between R/RY varieties ($\%\Delta^2 L = 68$). In the case of the whole fruit, only quantitative variations contributed to

the color differences among RY/Y and R/RY (%$\Delta^2C$ > 95). The contribution of quadratic variations of lightness was negligible. No appreciable color differences among varieties were found in seeds.

**Polyphenolic Content.** The values of phenolic compounds of the different parts of cactus pears are shown in Table 1. The ANOVA test applied to the whole set of data revealed that no significant differences were assigned either by "part of the fruit" or by "variety" (data not shown). However, as was performed with CIELAB parameters, the Tukey test was applied to elucidate possible significant variations by pairs. It is highlighted that the "part of the fruit" factor showed significance for all three varieties (Table 1). In the case of the Y variety, as expected, the phenolic content of W was the most predominant, followed by P and S. Khatabi et al.[34] also reported an abundant amount of polyphenols in the whole fruit and pulp of Moroccan prickly pears. Furthermore, according to the "variety" factor, Y variety (both P and S) had the significantly lowest phenolic content in comparison with the rest of the varieties. Similar results were also obtained by Khatabi et al.[34] when comparing pulps of yellow and red varieties of prickly pears. Furthermore, seeds were attributed minor values of total polyphenols, but, even so, prickly pear seeds could be considered as an important natural source of polyphenols with direct application in the food or health industry.[18,19] No variance in the polyphenolic content among varieties was found, contrarily to that observed by Morales et al.[22] in seeds of diverse species of *Opuntia*.

**Betalain Identification.** In this research, several types of betalains have been identified by HPLC coupled with electrospray mass spectrometry. The identities of betalains were achieved on the basis of the retention times, spectra, and $m/z$ values. Figure 3 shows the chromatographic pattern and peak assignment of the two families of betalains (betacyanins and betaxanthin), monitored at 535 and 482 nm, respectively. As well, the EIC chromatogram and MS positive mode of the major compounds belonged to each kind of betalains (betanin and indicaxanthin, respectively) were included. These compounds are summarized in Table 2, which shows the retention times, UV−vis data, and mass spectra of each betalain identified of *O. ficus-indica* by HPLC-DAD-ESI-ToF-MS. Concretely, the whole fruit of the red-yellow variety has been selected as representative because of its higher values of areas. Individual betalains were identified in both pulp and whole fruit. However, seeds lacked betalains.

A great number of betaxanthins have been identified in this study. Among them, the presence of indicaxanthin, well-described in cactus pears, has been confirmed (peak 4, molecular ion at 309.1102 $m/z$ units, and a daughter ion at $m/z$ 263.1018) (Table 2; Figure 3). Moreover, the identification of several additional betaxanthins is highlighted, the structures of which involved amino acids such as aminobutyric acid (peak 3, $m/z$ 297.1106 and 253.1227), valine (peak 5, $m/z$ 311.1275 and 137.0628), isovaline (peak 6, $m/z$ 311.1195 and 137.0654), isoleucine (peak 7, $m/z$ 325.1408 and 219.1094), and leucine (peak 8, $m/z$ 325.1369 and 209.0844) (Table 2). Other betalains have been tentatively identified on the basis of UV−vis spectra and the retention times of the chromatographic method used:[14] muscaarin (peak 1, 476 nm), vulgaxanthin (peak 2, 472 nm), and phenylalanine (peak 9, 468 nm). In addition, three betacyanin compounds have been correctly assigned: the well-known betanin (peak 10, $m/z$ 551.1554), its isomer isobetanin (peak 11, $m/z$ 551.1485), and a minor one, poorly described, called gomphrenin (peak 12, $m/z$ 551.1987). The different attachment of the glucose moiety (C-6 and C-5) caused the different elution times between gomphrenin and betanin, respectively.[14] All betacyanins produced a fragment near $m/z$ 389.1243 units corresponding to the protonate aglycones ($[\text{betanidin} + H]^+$ or $[\text{isobetanidin} + H]^+$) (loss of a fragment of $m/z$ 162 units corresponding to the glucose molecule).

**Semiquantification of Betalain.** Two different wavelengths have been monitored to carry out the semiquantification of betalains, 535 nm for betacyanins and 482 nm for betaxanthins. It is noteworthy that, although both betacyanins and betaxanthins were present in all cactus pear varieties, the mean areas of betaxanthins were, by far, considerably higher in comparison with that of betacyanins (Table 3). Among them, indicaxanthin was the major betaxanthin compound in *O. ficus-indica*, with an average

percentage of area around 90%. Similar results were reported in the pulps of different Mexican and Moroccan prickly pear cultivars.[14,34] Muscaarin took second place, with 2% of the total mean area of betalains, followed by the aminobutyric acid moiety betaxanthin (around 1%). With regard to betacyanins, betanin was the dominate compound in *O. ficus-indica*, but represents only 2% of the total area of betalains.[12] The rest of the identified betaxanthins and betacyanins were found in an area percentage below 1%.

When ANOVA was applied to the set of data, and similarly to that described for the color of extracts, the "part of the fruit" was largely the most influential factor of significant variance in virtually all betalain compounds (data not shown). In fact, all individual betalains were highly ($p < 0.05$) correlated with chromatic characteristics (positive for $L^*$ and $h_{ab}$, and negative for $C^*_{ab}$). Concretely, $C^*_{ab}$ and $h_{ab}$ were the chromatic parameters more correlated with betalains (Pearson correlation coefficients: $C^*_{ab}$, 0.8500; $h_{ab}$, −0.7000; $L^*$, −0.5500), so the chromatic intensity and the tonality of the samples were directly related with the content of betalains. The "variety" factor, however, practically did not affect this kind of compound. To test the diversity among pairs of samples, statistical main differences (Tukey test) on the main areas of betalain compounds were scrutinized (Table 4). As can be seen, the major considerable differences on betacyanins among W and P were ascribed to the Y variety, with remarkable areas in the whole fruit. With regard to betaxanthins, pulps of R and RY varieties had main areas in plenty in comparison with that observed in the whole fruit. These results were in concordance with the phenolic content previously commented. In fact, individual betalains and phenolic content were positively and highly correlated ($p < 0.05$), with Pearson correlation coefficients >0.7000 in the majority of individual betalains. Moreover, although Y was the variety with most differences on individual betaxanthins ($p < 0.05$), muscaarin, aminobutyric acid, and valine moiety compounds were the betalains with significance in all three prickly pears.

With regard to the "variety" factor, when the whole fruit was considered, RY significantly held the first position of total area of individual betacyanins and betaxanthins, whereas Y and R were at the tail end ($p < 0.05$) (Table 3). However, different behaviors followed the pulp extracts, with significantly lower values of Y variety and without variance among R and RY varieties. That pattern was in concordance with the aforementioned content of total polyphenols. In short, the Y variety showed the significantly lowest areas of betalains, the pulp of the RY variety being the one that adopted the greater values.

In summary, it might be concluded that *O. ficus-indica* could be an important choice for use as a natural colorant and source of phenolic and betalain compounds. The choice of the best part of cactus pears with that objective has been directed not only toward the highest values of polyphenols and betalains but also to the best color properties. Thus, the whole grain of yellow cactus pear could be more suitable as yellow colorant, whereas it could be more appropriate to use the pulp of the red variety to obtain a more reddish colorant. Finally, also the pulp of red-yellow prickly pear is optimal as a complement due to its high colorant intensity. Moreover, regardless of the variety, *Opuntia* seeds could be used as an important source of polyphenols. In addition, the possibility of the presence of essential amino acids in the structure of betaxanthins makes possible the use of *O. ficus-indica* as an important essential dietary colorant or as a diet fortification with essential amino acids. This study could be a great step forward in the food, cosmetics, and drug industries, among others.

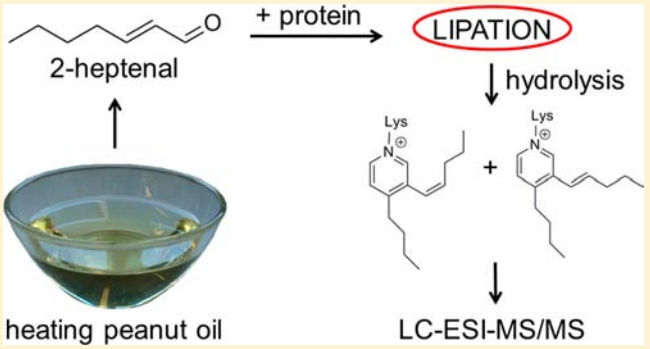
# Studies on the Reaction of *trans*-2-Heptenal with Peanut Proteins

Martin Globisch, Marco Schindler, Jana Kreßler, and Thomas Henle*

Institute of Food Chemistry, Technische Universität Dresden, D-01062 Dresden, Germany

**ABSTRACT:** Hexanal, 2-heptenal, and nonanal were identified as relevant reaction products formed in the course of the lipid peroxidation of heated peanut oil. For the identification of potential amino acid side chain adducts, kinetic studies between $N^{\alpha}$-benzoylglycyl-L-lysine as a model for protein-bound lysine and *trans*-2-heptenal were performed, showing a strong decrease of the lysine-derivative whereupon the loss of *trans*-2-heptenal was moderate. Following acid hydrolysis of the incubation mixture of $N^{\alpha}$-acetyl-L-lysine and *trans*-2-heptenal, two UV-active major lipation products were observed, isolated and identified as isomeric pyridinium-derivatives, namely (*Z*)- and (*E*)-1-(5-amino-5-carboxypentyl)-4-butyl-3-(pent-1-en-1-yl)pyridin-1-ium (*cis*- and *trans*-BPP-lysine). After heating of a native peanut protein extract with *trans*-2-heptenal, both derivatives were quantitated by LC-ESI-MS/MS after acid hydrolysis and the modification of lysine was measured by amino acid analysis. At low, "food-relevant", concentrations of *trans*-2-heptenal, up to 80% of the lysine modification could be explained by the formation of *cis*- and *trans*-BPP-lysine, showing that these two lipation derivatives represent good markers for a protein modification by the lipid peroxidation product *trans*-2-heptenal.



**KEYWORDS:** *peanuts, lipid peroxidation, 2-heptenal, lipation, pyridinium derivatives, BPP-lysine, carbonyl-protein-reaction*

## INTRODUCTION

Peanuts are a common food and serve as ingredients for many foods, being a rich source of protein (25%) and fat (48%).[1] In the U.S. and Europe, peanuts are commonly consumed roasted, whereas in Asian countries peanuts are mostly consumed boiled or fried.[2,3] Heat-induced protein modifications occurring during food processing can influence the allergenic potential of peanuts. Findings concerning a relationship between heating of peanuts and their allergenic potential are currently contradictory. On the one hand, no difference in the immunoreactivity between proteins isolated from raw and commercially roasted peanuts was observed[4] and even a reduction of the allergenic potential of Ara h 1 was measured following boiling of the isolated protein.[5] On the other hand, extracts from roasted peanuts exhibited at 90-fold higher binding to serum IgE of allergic patients when compared to the raw extracts.[6] Additionally, Ara h 1 and Ara h 3 modified with advanced glycation endproducts (AGEs) were found to interact with the receptor for AGEs (RAGE), and thus may be involved in allergic sensitization.[7] After heating of Ara h 1 at low moisture in the presence or absence of glucose, the degranulation capacity of basophils was increased, whereas for Ara h 2 the degranulation capacity was decreased.[8] These results show that heating in the presence or absence of reactive carbonyls can have different effects, depending on the protein structure. Among the reactions that can occur during the roasting process, besides glycation, the lipid peroxidation is of particular importance. Recently, it could be shown that up to 30−40% of lysine was modified as a result of peanut roasting.[9] However, only about one tenth of the totally observed lysine modification could be explained by the formation of the Maillard reaction products $N^{\epsilon}$-fructosyllysine, pyrraline and $N^{\epsilon}$-carboxymethyllysine. Taking into account the relatively high content of fat in peanuts and the fact that about 85% of the fatty acids are unsaturated,[10] it is highly likely that lipid peroxidation occurs in the course of the peanut roasting process. Actually, a large variety of secondary lipid peroxidation products have been detected by analyzing peanut oils obtained from raw and roasted peanuts,[11] ranging for monocarbonyl compounds from 8 to 26 μmol per 100 g oil, respectively.[12] Well known secondary products are α,β-unsaturated aldehydes like 4-hydroxyalkenals and 2-alkenals.[13,14] Due to their high reactivity, these electrophiles readily form covalent adducts, for example with nucleophilic amino acid side chains of proteins.[15] Having two electrophilic centers, 2-alkenals initially can form Michael- and Schiff base-adducts which can undergo further reactions. In model mixtures consisting of *trans*-2-hexenal and $N^{\alpha}$-acetylglycyllysine methyl ester, several pyridinium derivatives resulting from the reaction of alkenals with one amino group and arising cross-links were detected, but no information about formation of corresponding compounds at proteins under conditions relevant for food processing were given.[16] Under physiological conditions, *trans*-2-nonenal was found to

modify human and bovine serum albumin, resulting mainly in a modification of lysine residues and the formation of two *cis*–*trans*-isomeric pyridinium derivatives.[17] After acid hydrolysis, both derivatives could be quantitated in model proteins as well as in oxidatively modified LDL (*ox*LDL) and mice kidneys after exposure of the animals to ferric nitrilotriacetate.[17]

Regarding reactions in food, very little information is available concerning modification of proteins by lipid peroxidation products. Using ELISA, protein adducts in beef and rice seeds were detected, which resulted from reactions with 4-hydroxynonenal-, malondialdehyde- and alkenals with 6 to 9 C atoms.[18] In 22 fresh food products ε-*N*-pyrrolylnorleucine, representing a reaction product of 4,5-epoxy-2-alkenals and the ε-amino group of lysine,[19] was quantified by capillary electrophoresis after alkaline hydrolysis.[20] The concentration ranged from 0.24 to 6.36 μmol/g of food and the amount in peanuts was 2.89 μmol/g. The authors concluded that ε-*N*-pyrrolylnorleucine is a normal component of fresh food products.

The aim of this study, therefore, was to identify newly formed lipation products in food proteins and to develop an LC-ESI-MS/MS method for direct quantification. To identify potential precursors for amino acid side chain modifications arising during the peanut roasting process, peanut oil was heated under roasting conditions and volatile secondary products were semiquantitated by GC-MS. In kinetic studies, the reaction behavior of *trans*-2-heptenal and the lysine derivative $N^{\alpha}$-benzoylglycyl-L-lysine was studied by HPLC. For identification of relevant reaction products with the ε-amino group of lysine, $N^{\alpha}$-acetyl-L-lysine was incubated with *trans*-2-heptenal and reaction products were identified by LC-ESI-MS/MS. After isolation of two isomeric pyridinium derivatives arising from *trans*-2-heptenal and the ε-amino group of lysine, both derivatives were quantitated for the first time in peanut proteins by LC-ESI-MS/MS. Additionally, modification of lysine was measured by amino acid analysis.

## MATERIALS AND METHODS

**Materials.** Heptanal, pepsin (EC 3.4.23.1), Pronase E (EC 3.4.24.4), and hydrochloric acid (37%) were obtained from Merck (Darmstadt, Germany). Leucine aminopeptidase (EC 3.4.11.1), prolidase (EC 3.4.13.9), dialysis tubing cellulose membrane (MWCO 14 kDa), *trans*-2-heptenal (≥95%), hexanal, 2-hexenal, octanal, *p*-xylene, 1,3-diethylbenzene, tetradeuteromethanol, and petroleum ether (boiling point 40–60 °C) were obtained from Sigma-Aldrich (Taufkirchen, Germany). $N^{\alpha}$-acetyl-L-lysine, $N^{\alpha}$-benzoylglycyl-L-lysine, and *N*-benzoylglycyl-L-phenylalanine were obtained from Bachem (Bubendorf, Switzerland). Nonanal, methanol, dichloromethane, heptafluorobutyric acid, and cyclohexanol were obtained from VWR (Darmstadt, Germany). Acetonitrile was obtained from Fischer Scientific (Schwerte, Germany). Sodium bicarbonate, monosodium phosphate, and disodium phosphate were obtained from Grüssing (Filsum, Germany). Tris(hydroxymethyl)aminomethan was obtained from Serva (Heidelberg, Germany). Thymol was obtained from Carl Roth (Karlsruhe, Germany). All chemicals were of highest purity unless otherwise indicated. For all experiments, ultrapure water was used prepared by an ELGA LabWater Purelab Plus water system (Celle, Germany). For LC-ESI-MS/MS-measurements, double-distilled water, prepared in the presence of potassium permanganate, was used. Refined peanut oil was obtained from a local market.

**GC-MS (EI) Analysis of Volatile Compounds Formed during Heating of Peanut Oil.** After adding 75 μL of an internal standard solution containing *p*-xylene and 1,3-diethylbenzene in dichloromethane (6 mM each) to 50 g of peanut oil, the sample was heated in a three-neck flask while stirring for 20 min at 170 °C using a gentle airstream to transfer the volatile compounds in the head space into a gas washing bottle filled with 100 mL dichloromethane. After evaporation of the dichloromethane to a volume of 5 mL using a rotary evaporator at atmospheric pressure at 46 °C, an aliquot was used for GC-MS (EI) analysis. This was performed using an Agilent 7890A System, consisting of an 7683 Series injector with a sample tray, a 5975C MS detector working in EI mode, a HP-5MS capillary column (30.0 m × 0.25 mm ID, 0.25 μm film thickness), all from Agilent (Böblingen, Germany), and a Zebron Z-guard column (deactivated, 5.0 m × 0.25 mm ID, Phenomenex, Germany). Helium was used as carrier gas with a constant flow of 1 mL/min. The injector temperature was set to 250 °C and 1 μL sample was injected by using the pulsed splitless mode. The auxiliary temperature was set to 250 °C, ion source and quadrupole to 230 and 150 °C, respectively. The initial oven temperature was set to 40 °C and held for 9 min, then raised at 3 °C/min to 61 °C and held for 3 min, then raised at 3 °C/min to 76 °C, at 6 °C/min to 90 °C, at 20 °C/min to 110 °C and held for 1 min and finally raised at 30 °C/min to 300 °C. The post run time was set to 3 min at 300 °C. The mass spectrometer was working in electron impact mode at 70 eV in the SCAN mode (mass range: $m/z$ 30.0–300.0). Identification of the analytes was performed by comparing retention times and mass spectra to corresponding standard samples. Semiquantitation of the volatile compounds was performed by evaluating the peak areas of the analytes related to the peak areas of the internal standards. Depending on their boiling points, hexanal, 2-hexenal, and heptanal were evaluated related to *p*-xylene whereas 2-heptenal, octanal, and nonanal were evaluated related to 1,3-diethylbenzene. Identification of compounds was obtained by reference compounds.

**Kinetic Studies on the Incubation of *trans*-2-Heptenal with $N^{\alpha}$-Benzoylglycyl-L-lysine.** $N^{\alpha}$-benzoylglycyl-L-lysine and *trans*-2-heptenal, 4 mM each in methanol, were incubated for 24 h at 37 °C under nitrogen atmosphere. Every 2 h an aliquot of 400 μL was taken and mixed with 1200 μL of water to stop further reactions. Samples were filtered (0.45 μm) and *trans*-2-heptenal and $N^{\alpha}$-benzoylglycyl-L-lysine quantitated using a Knauer HPLC system (Berlin, Germany), which consisted of a degasser, a solvent organizer K-1500, a WellChrom pump K-1001, a dynamic mixing chamber K-5001, an automatic injector Basic Marathon, a column oven and a diode array detector WellChrom K-2700. Samples of 20 μL were separated using an Eurospher 100–5 C18 column (250 × 4.6 mm$^2$) from Knauer (Berlin, Germany) at 30 °C at a flow rate of 0.9 mL/min and a detection wavelength of 227 nm. A gradient was used with solvent A (water) and B (acetonitrile), each containing 13 mM heptafluorobutyric acid. Gradient was as follows: Increased from 10% B to 70% B within 30 min, to 90% B within 5 min, held at 90% B for 10 min, decreased within 2 min to 10% B and held at 10% B for 10 min. For external calibration, *trans*-2-heptenal and $N^{\alpha}$-benzoylglycyl-L-lysine were used.

**Nuclear Magnetic Resonance spectroscopy (NMR).** $^{1}$H NMR was recorded on a Bruker Avance 600 instrument (Rheinstetten, Germany) at 600,16 MHz. $^{13}$C NMR was recorded on a Bruker DRX 500 instrument at 150,9 MHz. Tetradeuteromethanol (MeOH-d4) was used as solvent. All chemical shifts are given in parts per million (ppm) relative to the solvent signal serving as internal standard. The following 2D-NMR experiments were performed additionally: COSY (correlation spectroscopy), NOESY (nuclear overhauser enhancement spectroscopy), HSQC (heteronuclear single quantum coherence), and HMBC (heteronuclear multiple bond correlation).

**Elemental Analysis.** Elemental analysis was performed using an EuroEA3000 (Eurovector, Milan, Italy) to quantitate the product content in the purified standards. *Cis*- and *trans*-BPP-lysine were isolated as salts of heptafluorobutyric acid, so the molecular ratio of cationic pyridinium derivative and heptafluorobutyric acid in the isolated products was not known. Therefore, the analyzed percentage of nitrogen was compared to the calculated nitrogen percentage. The pure amount of cationic pyridinium derivative in the product without counterion is expressed in percent by weight.

**Acid and Enzymatic Hydrolysis.** For acid hydrolysis of proteins, a ratio of 3 mg protein per 1.0 mL 6 M hydrochloric acid was used. Samples were hydrolyzed under nitrogen for 23 h at 110 °C. For enzymatic hydrolysis,[21] 3.0 mg of protein were dissolved in 1.0 mL of

0.02 M hydrochloric acid (HCl) containing a crystal of thymol and incubated with 1 FIP-U of pepsin for 24 h at 37 °C. After adding 0.25 mL of 2 M TRIS-HCl buffer (pH 8.2) and 400 PU of Pronase E, samples were incubated for 24 h at 37 °C. Following addition of 0.3 U of leucine aminopeptidase and 2 U of prolidase, samples were incubated for another 24 h at 37 °C and finally lyophilized.

**Amino Acid Analysis.** Amino acid analyses were performed using a SYKAM S4300 amino acid analyzer (Fürstenfeldbruck, Germany) after acid hydrolysis for the acid-stable amino acids valine, histidine, lysine, and arginine and enzymatic hydrolysis for the acid-labile amino acid cysteine. Amino acids were separated by cationic ion exchange chromatography, derivatized by ninhydrin, and detected using a wavelength of 570 nm.[22] Valine was taken as internal standard and amino acids were expressed as valine equivalents.

**Incubation of *trans*-2-Heptenal with $N^{\alpha}$-Acetyl-L-lysine.** For identification of major amino acid side chain reaction products between *trans*-2-heptenal and $N^{\alpha}$-acetyl-L-lysine, 10 mM *trans*-2-heptenal and 10 mM $N^{\alpha}$-acetyl-L-lysine were heated for 4 h at 75 °C in 5 mL methanol in a 10 mL round-bottom flask under reflux. 1.0 mL was taken for direct HPLC-DAD-ESI-MS/MS analysis and 3.0 mL were evaporated under a gentle stream of nitrogen. After hydrolysis with 3 mL of 6 M hydrochloric acid for 23 h at 110 °C under nitrogen, 1.0 mL of the sample was dried at 37 °C in vacuo by using a SpeedVac vacuum concentrator (Thermo Fisher Scientific, Waltham, U.S.A.), redissolved in 2.0 mL methanol and analyzed by LC-DAD-ESI-MS/MS.

**Preparation of Modified Peanut Proteins.** Previously shelled and skinned raw peanuts were crushed and defatted by Soxhleth extraction using petroleum ether for 6 h at 78 °C. For protein extraction, 21 mL 0.1 M sodium bicarbonate (pH 10.4) were added to 3.0 g defatted peanut meal.[23] Samples were homogenized using an ultraturrax at 11.200 rpm for 2 min and proteins extracted for 1 h at 6 °C while stirring constantly. After centrifugation at 8643*g* for 15 min at 4 °C, the supernatant was collected and the residue was extracted analogously. Following dialysis (14 kDa MWCO) against deionized water for 48 h at 6 °C, the samples were lyophilized. Protein content was analyzed by the Kjeldahl method using the factor 5.3 for oilseeds.[24] Amino acid composition was analyzed by amino acid analysis. Amino acid contents of cysteine, histidine, lysine, and arginine were 3.83 ± 0.79, 19.27 ± 0.06, 32.58 ± 1.39, and 70.58 ± 3.22 mmol/100 g protein, respectively. Approximately 100 mg of peanut proteins were dissolved in 0.1 M phosphate buffer (pH 7.4) and *trans*-2-heptenal was added in 1.0 mL methanol in following molar ratios related to the sum of relevant reactive amino acids histidine, lysine, and arginine: 0.1:1, 0.2:1, 0.5:1, 1:1, 5:1, and 10:1. Finally, the samples were made up to 25 mL with phosphate buffer (pH 7.4). Additionally, a blank sample consisting of peanut proteins without *trans*-2-heptenal was prepared. The incubation was carried out under a nitrogen atmosphere for 24 h at 37 °C while stirring. After dialysis (14 kDa MWCO) against deionized water for 24 h at 6 °C, the samples were lyophilized and protein contents were analyzed by the Kjeldahl method. For analysis of the amino acid modification rate (lysine, histidine, and arginine), the samples were hydrolyzed by hydrochloric acid and subjected to amino acid analysis. For cysteine analysis, samples were hydrolyzed enzymatically. For analysis of BPP-lysine, 12 mg of samples were hydrolyzed by 4 mL 6 M hydrochloric acid for 23 h at 110 °C. 1.0 mL of samples were dried in vacuo using a SpeedVac vacuum concentrator (Thermo Fisher Scientific, Waltham, U.S.A.) at 37 °C, redissolved in 0.25 mL deionized water, 0.2 mL methanol and 0.05 mL of internal standard *N*-benzoylglycyl-L-phenylalanine in methanol:water (50:50, v/v) with a final concentration of 1 μg/mL. After filtration (0.45 μm), samples were subjected to HPLC-ESI-MS/MS analysis.

**Isolation of (*Z*)-1-(5-Amino-5-carboxypentyl)-4-butyl-3-(pent-1-en-1-yl)pyridin-1-ium (*cis*-BPP-lysine) and (*E*)-1-(5-Amino-5-carboxypentyl)-4-butyl-3-(pent-1-en-1-yl)pyridin-1-ium (*trans*-BPP-lysine).** In a 500 mL round-bottom flask 376.5 mg (2.0 mmol) $N^{\alpha}$-acetyl-L-lysine and 827.0 μL (6.0 mmol) *trans*-2-heptenal were heated for 4 h at 75 °C in 200 mL methanol under reflux. After evaporation of methanol in vacuo at 40 °C, 150 mL 6 M hydrochloric acid were added and heated for 23 h at 110 °C. Afterward, the hydrochloric acid was removed using a water-jet vacuum pump at 40 °C. *cis*- and *trans*-BPP-lysine were purified using a semipreparative HPLC system. The system consisted of a Smartline solvent manager 5000, a Smartline pump 1000, and a Smartline UV-detector 2500 (all from Knauer, Berlin, Germany). Two mg of the unpurified reaction mixture were dissolved in 1.0 mL of methanol and separated after filtration (0.45 μm) using an Eurospher 100−10 C18 column (250 × 16 $mm^2$; Knauer, Berlin, Germany) at 23 °C room temperature, a flow rate of 3 mL/min and a detection wavelength of 227 nm. A gradient was used with solvent A (water) and B (acetonitrile), each containing 13 mM heptafluorobutyric acid. The gradient program started with 25% solvent B for 5 min, increased to 50% B within 20 min, followed by isocratic elution with 50% B for 31 min, a flow reduction to 0.7 mL/min from 35 to 55 min, increased to 95% B within 2 min at a flow rate of 3 mL/min, isocratic elution with 95% B for 5 min, decreased to 25% B within 2 min, isocratic elution with 25% B for 15 min. *cis*- and *trans*-BPP-lysine eluted between 37 and 41 min and 41 and 51 min, respectively. Multiple separations were performed, relevant fractions containing the two compounds combined and finally the solvent was evaporated in vacuo at 40 °C. To increase purity, both compounds were purified for a second time prior to HPLC-ESI-MS/MS and one- and two-dimensional NMR analysis. For *cis*-BPP-lysine, results were as follows: ESI-MS (positive mode), $[M]^+$ $m/z$ 333.3; $^1$H NMR (600 MHz, MeOH-d4): $\delta$ 0.98 (t, 3H, $J$ = 7.5 Hz, H-16), 1.04 (t, 3H, $J$ = 7.5 Hz, H-20), 1.51 (m, 2H, H-19), 1.57 (m, 2H, H-15), 1.72 (m, 2H, H-18), 1.60−1.69 (m, 2H, H-8A,B), 2.03−2.10 (m, 2H, H-9A,B), 2.13 (m, 2H, H-7), 2.19 (q, 2H, $J$ = 7.5 Hz, H-14), 2.96 (t, 2H, $J$ = 7.9 Hz, H-17), 4.05 (t, 1H, $J$ = 6.4 Hz, H-10), 4.67 (t, 2H, $J$ = 7.5 Hz, H-6), 6.24 (dt, 1H, $J$ = 7.5 Hz, $J$ = 11.3 Hz, H-13), 6.60 (d, 1H, $J$ = 11.3 Hz, H-12), 8.02 (d, 1H, $J$ = 6.4 Hz, H-5), 8.75 (s, 1H, H-3), 8.81 (d, 1H, $J$ = 6.4 Hz, H-4). Purity of cation based on elemental analysis: 42.9%. For *trans*-BPP-lysine, results were as follows: ESI-MS (positive mode), $[M]^+$ $m/z$ 333.3; $^1$H NMR (600 MHz, MeOH-d4): $\delta$ 1.06 (t, 3H, $J$ = 7.5 Hz, H-20), 1.08 (t, 3H, $J$ = 7.5 Hz, H-16), 1.53 (m, 2H, H-19), 1.60−1.71 (m, 2H, H-8A,B) 1.66 (m, 2H, H-15), 1.72 (m, 2H, H-18), 2.04−2.09 (m, 2H, H-9A,B), 2.15 (m, 2H, H-7), 2.41 (q, 2H, $J$ = 7.2 Hz, H-14), 3.02 (t, 2H, $J$ = 7.9 Hz, H-17), 4.07 (t, 1H, $J$ = 6.4 Hz, H-10), 4.65 (t, 2H, $J$ = 7.5 Hz, H-6), 6.62 (dt, 1H, $J$ = 6.8 Hz, $J$ = 15.8 Hz, H-13), 6.76 (d, 1H, $J$ = 15.8 Hz, H-12), 7.93 (d, 1H, $J$ = 6.4 Hz, H-5), 8.71 (d, 1H, $J$ = 6.4 H, H-4), 9.04 (s, 1H, H-3). Purity of cation based on elemental analysis: 35.7%.

**HPLC-DAD-ESI-MS/MS Analysis.** For identification of major reaction products between *trans*-2-heptenal and $N^{\alpha}$-acetyl-L-lysine, for characterization of isolated BPP-standards and for quantitation of *cis*- and *trans*-BPP-lysine in modified peanut proteins, HPLC-DAD-ESI-MS/MS analysis were performed. The HPLC system consisted of a degasser, a pump, an autosampler and a diode array detector, all from Agilent Technologies 1200 Series (Böblingen, Germany). For MS/MS-measurements, a Triple Quad LC/MS 6410 from Agilent Technologies was used. For identification of major reaction products between *trans*-2-heptenal and $N^{\alpha}$-acetyl-L-lysine, 5 μL of samples were separated using an Eurospher 100−5 C18 column (250 × 3.0 $mm^2$; Knauer, Berlin, Germany) at 30 °C, a flow rate of 0.38 mL/min and a detection wavelength of 227 nm. A gradient was used with solvent A (water) and B (acetonitrile), each containing 2 mM heptafluorobutyric acid and 11 mM acetic acid. The gradient increased from 5% B to 70% B within 50 min, to 90% B within 15 min, held at 90% B for 20 min, followed by a decrease within 3 min to 5% B and isocratic elution at 5% B for 10 min. At first full scan analyses and then product ion scans were performed. Full scan analyses were performed from 5.1 to 78.0 min in positive mode, scan ranges were from $m/z$ 70 to 1000, scan time 500 ms, fragmentor voltage was set to 135 V, gas temperature to 300 °C, gas flow to 11 mL/min and nebulizer pressure to 15 psi. Product ion scans were performed for the hydrolyzed sample from 25 to 45 min with precursor ion $m/z$ 333.3, using the same conditions as described above. Product ion scan ranges were from $m/z$ 60 to 500 with a scan time of 200 ms, a fragmentor voltage of 135 V and a collision voltage of 25 V for *cis*- and 20 V for *trans*-BPP-lysine,

respectively. For quantitation of BPP-lysine in modified peanut proteins 1 to 10 μL of samples were separated using a Zorbax SB-C18 column (50 × 2.1 mm) from Agilent Technologies (Böblingen, Germany) at 30 °C and a flow rate of 0.25 mL/min. A gradient was used with solvent A (water) and B (acetonitrile), each containing 2 mM heptafluorobutyric acid and 11 mM acetic acid. Gradient was as follows: 2% B was held for 5 min, increased to 51% B within 17 min, to 90% B within 2 min, held at 90% B for 6 min, decreased to 2% B within 1 min and held at 2% B for 6 min. Measurements were performed using the multi reaction monitoring (MRM) mode in positive mode, gas temperature was set to 300 °C, gas flow to 11 mL/min and nebulizer pressure to 15 psi. Internal standard *N*-benzoylglycyl-L-phenylalanine was analyzed from 18 to 20.1 min with a mass transition from *m*/*z* 327.1 to 166.1 for quantitation using fragmentor and collision voltages of 80 and 4 V, respectively and a dwell time of 300 ms. Mass transition from *m*/*z* 327.1 to 105.1 was used for qualification using fragmentor and collision voltages of 80 and 32 V, respectively and a dwell time of 300 ms. *cis*-BPP-lysine was analyzed from 20.1 to 21.0 min with a mass transition from *m*/*z* 333.3 to 204.2 for quantitation using fragmentor and collision voltages of 133 and 21 V, respectively, and a dwell time of 100 ms. Mass transition from *m*/*z* 333.3 to 84.2 was used for qualification using fragmentor and collision voltages of 133 and 33 V, respectively, and a dwell time of 100 ms. *trans*-BPP-lysine was analyzed from 21.0 to 23.5 min with a mass transition from *m*/*z* 333.3 to 204.2 for quantitation using fragmentor and collision voltages of 134 and 21 V, respectively, and a dwell time of 100 ms. Mass transition from *m*/*z* 333.3 to 84.2 was used for qualification using fragmentor and collision voltages of 134 and 30 V, respectively and a dwell time of 100 ms. Quantification was realized using authentic *cis*-and *trans*-BPP-lysine in a native peanut protein hydrolyzate matrix calibration after addition of internal standard *N*-benzoylglycyl-L-phenylalanine with a final concentration of 1 μg/mL.

**Statistical Treatment.** Results are expressed as mean values ± standard deviations of two separate measurements.

## RESULTS AND DISCUSSION

**Identification of Volatile Secondary Lipid Peroxidation Products of Heated Peanut Oil.** To identify potential precursors for amino acid side chain modifications formed in the course of lipid peroxidation during roasting of peanuts, refined peanut oil was heated under roasting conditions for 20 min at 170 °C. Figure 1 shows selected volatile carbonyl compounds in the headspace analyzed by GC-MS (EI). Identification was achieved by comparing retention times and mass spectra to corresponding reference material. Compounds were semiquantitated by evaluating the peak areas of the analytes related to the peak areas of the internal standards *p*-xylene and 1,3-diethylbenzene. Hexanal, 2-heptenal, and nonanal are the most important secondary products of lipid peroxidation. Hexanal and 2-heptenal are mainly formed by the autoxidation of linoleic acid and nonanal is mainly formed from oleic acid.[14] Being a rich source of unsaturated fatty acids, peanut oil consists of about 55% oleic acid and 22% linolenic acid.[1] Considering the high reactivity of the 2-alkenals,[15−17] it is likely that in the presence of peanut proteins, these compounds can easily react with nucleophilic amino acid side chains for example the ε-amino group of lysine.

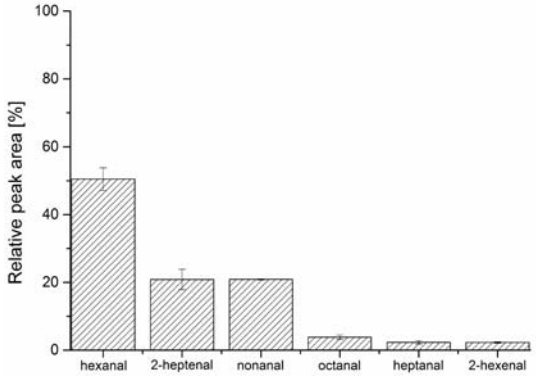

**Figure 1.** Semiquantitated amounts of selected volatile lipid peroxidation products of peanut oil heated under roasting conditions for 20 min at 170 °C.

**Kinetic Studies on the Reaction of *trans*-2-Heptenal and $N^{\alpha}$-Benzoylglycyl-L-lysine.** Focusing on 2-heptenal, kinetic studies were performed to get an insight into the reaction behavior with the ε-amino-group of lysine using $N^{\alpha}$-benzoylglycyl-L-lysine as a model for protein bound lysine. *trans*-2-Heptenal and $N^{\alpha}$-benzoylglycyl-L-lysine were incubated in equimolar amounts under mild reaction conditions at 37 °C for 24 h in methanol. Analogously, blank samples consisting only of *trans*-2-heptenal or $N^{\alpha}$-benzoylglycyl-L-lysine, respectively, were incubated. Figure 2 shows that the amounts of

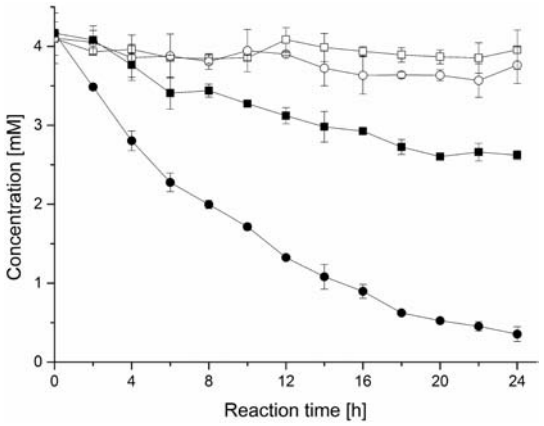

**Figure 2.** Kinetic studies on the reaction of equimolar amounts of *trans*-2-heptenal and $N^{\alpha}$-benzoylglycyl-L-lysine at 37 °C for 24 h in methanol. Open squares, blank samples of $N^{\alpha}$-benzoylglycyl-L-lysine; open circles, blank samples of *trans*-2-heptenal; filled squares, $N^{\alpha}$-benzoylglycyl-L-lysine in equimolar reaction mixture; filled circles, *trans*-2-heptenal in equimolar reaction mixture.

*trans*-2-heptenal and $N^{\alpha}$-benzoylglycyl-L-lysine in the blank samples were stable over the reaction time, whereas both the amounts of *trans*-2-heptenal and $N^{\alpha}$-benzoylglycyl-L-lysine in the equimolar reaction mixture were decreasing. The observation that *trans*-2-heptenal decreased more than 2-fold faster than $N^{\alpha}$-benzoylglycyl-L-lysine may indicate *trans*-2-heptenal was decomposed or polymerized in the presence of the ε-amino-group of lysine. A proposed reaction pathway for polymerization initially starts with the formation of Schiff base adducts which polymerize by aldol condensation resulting in polymers from which the amino compound even may cleave.[25,26] Another possibility is that he majority of the newly formed adducts arised by the reaction of two or more molecules of *trans*-2-heptenal and one molecule $N^{\alpha}$-benzoylglycyl-L-lysine. Possible reaction products are pyridinium derivatives as previously described for other 2-alkenales and the ε-amino-group of lysine (see the Introduction).[16,17,27]

**Identification of Major Reaction Products of *trans*-2-Heptenal and $N^{\alpha}$-Acetyl-L-lysine.** For the identification of major reaction products of *trans*-2-heptenal and the ε-amino-group of lysine, *trans*-2-heptenal and $N^{\alpha}$-acetyl-L-lysine were

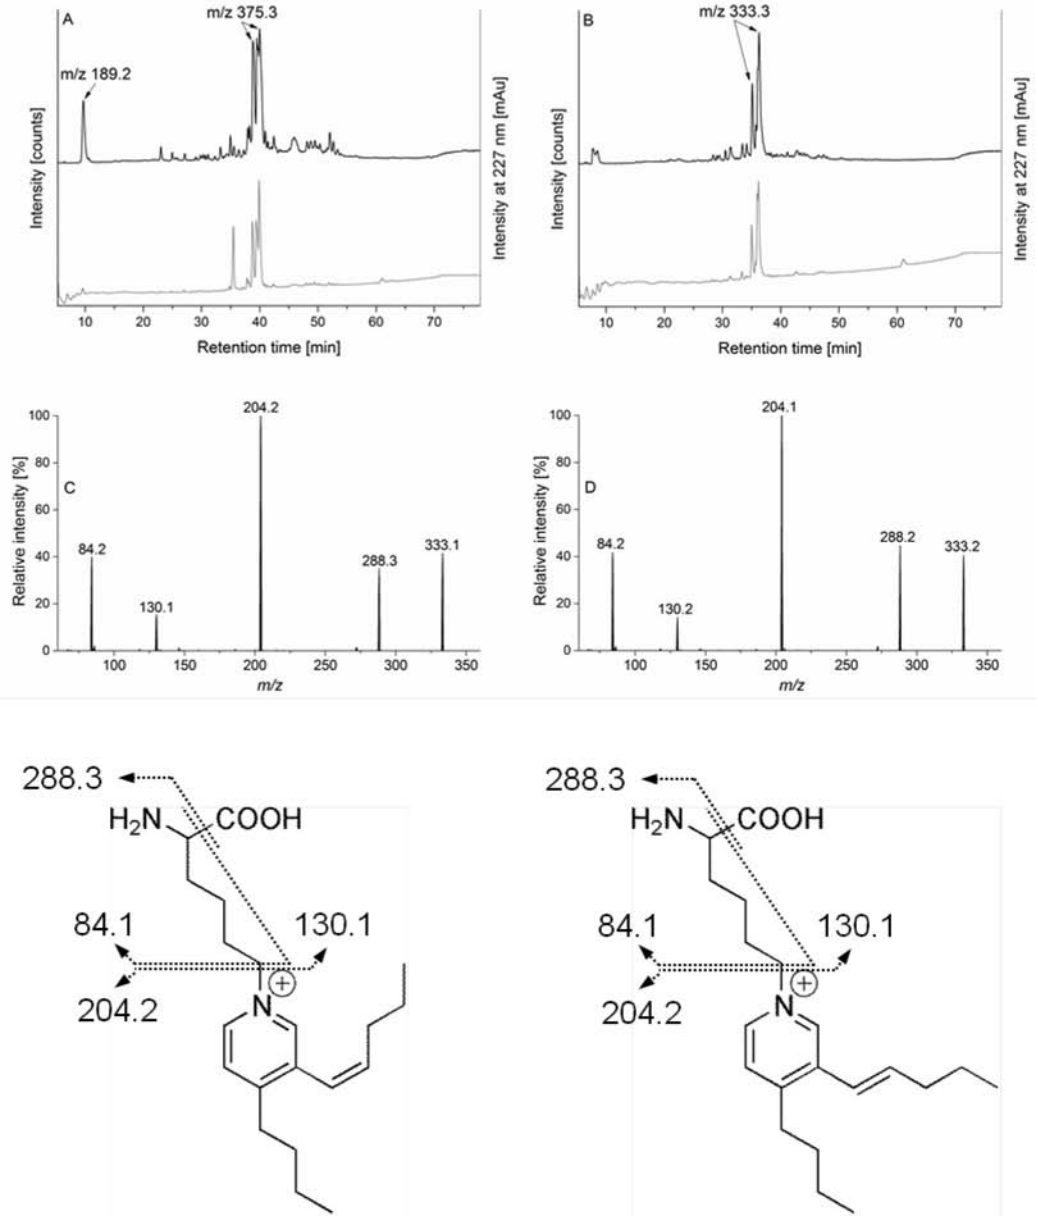

**Figure 3.** Identification of *cis*- and *trans*-BPP-lysine by HPLC-DAD-ESI-MS/MS after incubation of $N^{\alpha}$-acetyl-L-lysine with *trans*-2-heptenal in equimolar amounts in methanol for 4 h at 75 °C. (A, B) HPLC-ESI-MS-scan-chromatograms and HPLC-UV-chromatograms (gray) at 227 nm before and after acid hydrolysis, respectively. Arrows indicate peaks resulting from $N^{\alpha}$-acetyl-L-lysine ($m/z$ 189.2) and the two pyridinium derivatives ($m/z$ 375.3 and $m/z$ 333.3). (C, D) product ion patterns after fragmentation of the hydrolyzed pyridinium derivatives with $m/z$ 333.3 (first and second peak) and individual ions resulting from *cis*- and *trans*-pyridinium derivatives with $m/z$ 333.3, respectively.

incubated in equimolar amounts in methanol for 4 h at 75 °C. Newly formed products were analyzed before and after acid hydrolysis by HPLC-DAD-ESI-MS/MS. Figure 3A shows that under these conditions, two UV-active main products with monoisotopic masses of $m/z$ 375.3 were detectable. These masses are indicative for pyridinium derivatives resulting from one molecule $N^{\alpha}$-acetyl-L-lysine, two molecules of *trans*-2-heptenal, the loss of two water molecules and an oxidation step. As previously described, *cis*- and *trans*-derivatives may be formed, being the cis-derivative of the compound eluting earlier in the chromatogram.[16,17] Even when the reaction partners were incubated in equimolar ratio, some amounts of $N^{\alpha}$-acetyl-L-lysine ($M+H^+$ peak at $m/z$ 189.2) were remaining. This fits with the previous results of the kinetic studies, underlining that the formed adducts consist of more than one molecule of *trans*-2-heptenal. After acid hydrolysis, two UV-active main adducts with $m/z$ 333.3 were detectable, showing that the deacetylation (mass difference, −42) was successful (Figure 3B). The stability of pyridinium derivatives against acid hydrolysis was analogously described for lysine-2-nonenal-pyridinium derivatives.[17] To ensure these findings, product ion scans of the two hydrolyzed adducts were performed. Figure 3C,D indicates that both substances lead to the same product ions. The fragmentation patterns show typical lysine fragments with $m/z$ 84.2 and $m/z$ 130.1 as well as a decarboxylation step with $m/z$ 288.3. The ions with $m/z$ 204.2 result from a fragmentation between the $\delta$-carbon of lysine and the $\epsilon$-nitrogen being incorporated in the pyridinium structure and therefore are strong hints for the existence of pyridinium derivatives. Due to the fact that both structures gave the same fragmentation

dx.doi.org/10.1021/jf502501f | J. Agric. Food Chem. 2014, 62, 8500−8507

patterns, the presence of the *cis*- and *trans*-pyridinium derivatives can be assumed. The formation of the cis-derivative with *trans*-2-heptenal as reactant may be due to an isomerization of the *trans*-2-heptenal in the presence of the ε-amino-group of lysine.[17] On the basis of the UV-chromatograms before and after acid hydrolysis, it can be seen that the trans-derivative is the major product. This may be due to its thermodynamically preferred structure or due to the fact that the isomerization only leads to lower amounts of the cis-derivative. This is confirmed by a recent literature report, in which *cis*- and *trans*-nonenal-pyridinium derivatives were quantitated in mice kidneys in comparable amounts after exposing the animals to ferric nitrilotriacetate.[14] It is, therefore, likely that in real food samples, the *cis*- and *trans*-2-heptenal derivatives of lysine will also appear in equimolar amounts.

For the isolation and unequivocal structure elucidation of the formed reaction products, $N^{\alpha}$-acetyl-L-lysine was incubated with a 3-fold excess of *trans*-2-heptenal to induce the formation of the pyridinium derivatives. After acid hydrolysis, the products were separated and isolated by semipreparative HPLC with UV-detection, using an RP-18 column. Identification was realized by LC-ESI-MS/MS measurements and one and two-dimensional NMR spectroscopy. Following collision-induced fragmentation, both substances showed the same identical fragmentation patterns as previously described. Figure 4 shows

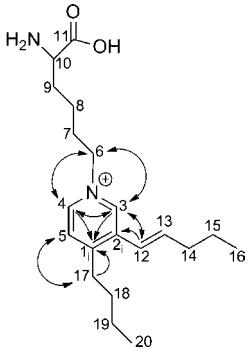

**Figure 4.** Structure of *trans*-BPP-lysine showing the observed relevant heteronuclear multiple bond correlations (HMBC).

exemplarily the structure of (*E*)-1-(5-amino-5-carboxypentyl)-4-butyl-3-(pent-1-en-1-yl)pyridin-1-ium (*trans*-BPP-lysine) and relevant heteronuclear multiple bond correlations (HMBC). The couplings in the HMBC spectrum of (Z)-1-(5-amino-5-carboxypentyl)-4-butyl-3-(pent-1-en-1-yl)pyridin-1-ium (*cis*-BPP-lysine) were analogous. Differentiation of *cis*- and *trans*-BPP-lysine was possible on the basis of the $^1$H vinyl proton (H-12 and H-13) coupling constants $J$ = 11.3 Hz for the cis-derivative and $J$ = 15.8 Hz for the trans-derivative and by means of 2D $^1$H/$^1$H NOESY experiments. Strong NOEs were observed between proton 3 and protons 14, 15, and 16 (weak) being indicative for the *cis*-product. Additionally, no NOE was observed between protons 3 and 13 and only a weak NOE was observed between protons 12 and 14. In contrast, no NOEs were observed between proton 3 and protons 14, 15, 16 by analyzing the trans-product, whereas strong NOEs between protons 3 and 13 and protons 12 and 14 were observed. To the best of our knowledge, this is the first profound structural characterization of these two lysine derivatives. Analogously to the reaction of the ε-amino-group of lysine with *trans*-2-hexenal,[16] an exemplarily proposed reaction mechanism for the formation of *trans*-BPP-lysine following the reaction of *trans*-2-heptenal with the ε-amino-group of lysine is given in Figure 5. In the first step, *trans*-2-heptenal probably reacts with the ε-amino-group of lysine, resulting in a Schiff's base adduct, followed by a Michael addition of a second molecule of *trans*-2-heptenal, cyclization, and oxidation reaction to the final pyridinium derivative.

**Quantitation of BPP-Lysine Derivatives in Modified Peanut Proteins.** To investigate whether the pyridinium derivatives can be formed in food proteins as well, extracted proteins of native peanuts were incubated with *trans*-2-heptenal under mild physiological conditions at 37 °C for 24 h in phosphate buffer (pH 7.4) as previously described for other 2-alkenals.[17,28,29]

Incubations were performed in different molar ratios between *trans*-2-heptenal and the sum of relevant reactive amino acids histidine, lysine and arginine. The amounts of these amino acids in the native peanut protein extract were 19.27 ± 0.06, 32.58 ± 1.39 and 70.58 ± 3.22 mmol/100 g protein, respectively. Cysteine was not regarded as a relevant amino acid because of its low amount in peanut proteins (3.83 ± 0.79 mmol/100 g protein) and its ability to form disulfide bonds. After acid hydrolysis, both BPP-lysine derivatives were quantitated by LC-ESI-MS/MS (MRM mode). Figure 6 shows a representative LC-ESI-MS/MS-chromatogram ($m/z$ 333.3 > 204.2) of the hydrolyzed peanut proteins modified in the 0.1:1 ratio. It can be seen that the separation of the cis- and trans-derivatives can be achieved using an RP-18 column and addition of heptafluorobutyric acid to the regular ion pair reagent acetic acid. The quantitated amounts of both derivatives are shown in Figure 7. These results show clearly that a modification of peanut proteins by *trans*-2-heptenal is possible and that the amounts of formed BPP-lysine derivatives depend on the amount of *trans*-2-heptenal within the incubation samples. In the blank sample, consisting of peanut proteins treated in the same way but without *trans*-2-heptenal,

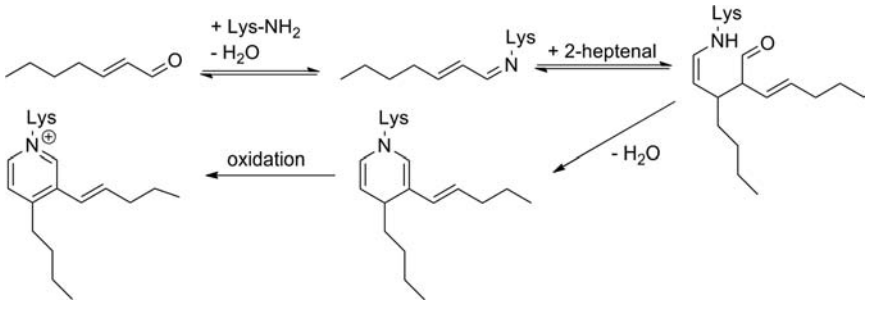

**Figure 5.** Proposed formation pathway for the formation of *trans*-BPP-lysine.

dx.doi.org/10.1021/jf502501f | J. Agric. Food Chem. 2014, 62, 8500−8507

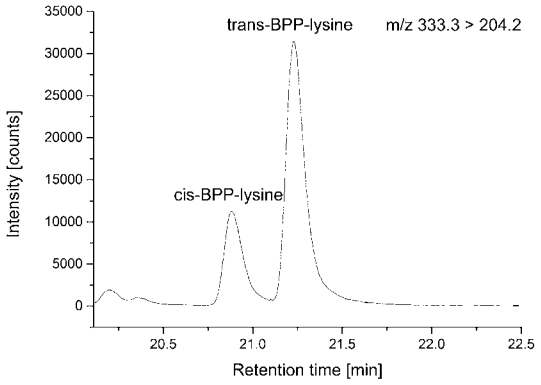

**Figure 6.** Representative LC-ESI-MS/MS-chromatogram (MRM mode, transition $m/z$ 333.3 > 204.2) of the acid hydrolyzate of the peanut protein extract modified by *trans*-2-heptenal in the ratio 0.1 to 1 related to the sum of the potentially reactive amino acids histidine, lysine and arginine.

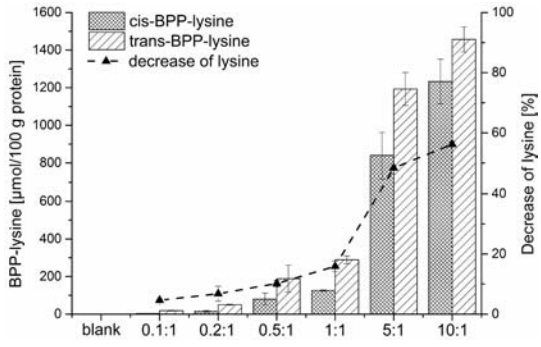

**Figure 7.** Quantitated amounts of *cis*- and *trans*-BPP-lysine in modified peanut protein extracts by LC-ESI-MS/MS and decrease of lysine analyzed by amino acid analysis.

no derivatives could be measured. As previously discussed, the *trans*-derivative is the major product formed. Additionally, a direct relationship between the formation of the BPP-lysine derivatives and the decrease in lysine can be seen (Figure 8). In the slightly modified samples, up to 80% of the decrease in lysine can be explained by the formed BPP-lysine derivatives. At higher levels of *trans*-2-heptenal further reactions will become relevant. Having two electrophilic centers, possible reactions might be the formation of Michael- and Schiff's base-adducts. These can lead for example to lysine cross-links by involving

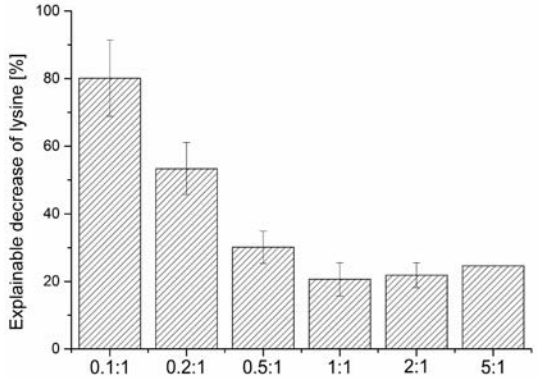

**Figure 8.** Explainable decreases of lysine due to the formation of *cis*- and *trans*-BPP-lysine.

only one molecule of *trans*-2-heptenal. Further cross-linking may occur due to a Michael addition of a pyridinium derivative to a Schiff base-adduct.[16] Taking into account that the amounts of 2-heptenal formed in the course of lipid peroxidation as a result of peanut roasting will be probably lower than the amounts of *trans*-2-heptenal added to the peanut protein extract samples, it can be shown that especially in the presence of small amounts of *trans*-2-heptenal, nearly the whole lysine modification can be explained by the formation of the BPP-lysine derivatives. So it is possible to cover most of the adducts formed by the reaction of the $\varepsilon$-amino group of lysine and 2-heptenal by measuring the two BPP-lysine derivatives.

In conclusion, we were able to show that *trans*-2-heptenal, a well-known secondary product formed in the course of the autoxidation of linoleic acid,[14] is one of the most important volatile carbonyl compounds formed during heating peanut oil under roasting conditions and is able to modify the $\varepsilon$-amino group of lysine, leading to the formation of two isomeric pyridinium derivatives. Considering the whole peanut, it is likely that the volatile compounds formed in the course of the lipid peroxidation during the roasting process are able to react with the amino acid side chains of peanut proteins. Hence, these two derivatives represent good markers for a protein modification by 2-heptenal. Taking into account that other 2-alkenals, like 2-hexenal, 2-octenal, or 2-nonenal, are able to form analogous adducts[16,17,27] and that "mixed" derivatives consisting for example of one molecule each of lysine, 2-hexenal, and 2-heptenal, respectively, are possible, a large variety of adducts can be expected. Furthermore, other secondary products of the lipid peroxidation like alkanals, 2,4-alkadienals or 4-hydroxyalkenals are also able to form adducts with amino acid side chains.[13,30,31] Due to the broad spectrum of possible precursors, we conclude that in food, especially as a result of roasting lipid-rich peanuts, a complex spectrum of adducts between amino acid side chains and secondary products of lipid peroxidation can be formed accounting for the large modification rate of lysine. Analogous to glycation reactions between reducing carbohydrates and amino compounds (also referred to a Maillard reaction or nonenzymatic glycosylation), the complex reactions involving carbonyl compounds from lipid peroxidation and amino acids could be called "lipation". Due to the formation of these post-translationally formed lipation products, the binding ability of immunoglobulines E against peanut proteins may be altered. This could have an influence on the allergenic potential of roasted peanuts. Further studies are needed to investigate whether lipation products are formed in roasted peanuts as well and whether these modifications have an influence on the allergenic potential of roasted peanuts.

Supporting Information

**ABSTRACT:** *Octopus vulgaris*, *Octopus maya*, and *Eledone cirrhosa* from distinct marine environments [Northeast Atlantic (NEA), Northwest Atlantic (NWA), Eastern Central Atlantic, Western Central Atlantic (WCA), Pacific Ocean, and Mediterranean Sea] were characterized regarding their lipid and vitamin E composition. These species are those commercially more relevant worldwide. Significant interspecies and interorigin differences were observed. Unsaturated fatty acids account for more than 65% of total fatty acids, mostly $\omega$-3 PUFA due to docosahexaenoic (18.4−29.3%) and eicosapentanoic acid (11.4−23.9%) contributions. The highest $\omega$-3 PUFA amounts and $\omega$-3/$\omega$-6 ratios were quantified in the heaviest specimens, *O. vulgaris* from NWA, with high market price, and simultaneously in the lowest graded samples, *E. cirrhosa* from NEA, of reduced dimensions. Although having the highest cholesterol contents, *E. cirrhosa* from NEA and *O. maya* from WCA have also higher protective fatty acid indexes. Chemometric discrimination allowed clustering the selected species and several origins based on lipid and vitamin E profiles.

**KEYWORDS:** *octopus, fatty acids, cholesterol, vitamin E, nutritional assessment, chemometric discrimination*

## INTRODUCTION

Cephalopods are part of the traditional diet of Japan, Korea, Argentina, Taiwan, and China, and of coastal communities of southern Europe, such as Spain, Portugal, Morocco, Mauritania, Greece, and Italy. Unfortunately, octopus catches have been declining through time mainly due to stock overexploitation in some areas.[1] Still, cephalopods comprise, in general, a major food resource for human consumption with catches of 3.77 million tonnes in 2010 and representing always high values in terms of auction transaction of the wholesale market registered for marine species.[1,2] In terms of world trade and landing, *Octopus vulgaris* (common octopus), *Eledone cirrhosa* (curled octopus), and *Octopus maya* (Mexican four-eyed octopus) represent the most important octopus species available to consumers being those selected for this study. The two former species are the most abundant species from their taxonomical genus.[3] Based on FAO information, the world geographical distribution of the three species is presented in Figure 1. As it can be seen, *O. vulgaris* have a wide distribution, being found in the Atlantic, Indian, and Pacific Oceans (PO) as well as in the Mediterranean Sea (MS). The endemic species *O. maya* is specifically found in the Yucatan peninsula, in the Gulf of Mexico. On the other hand, *E. cirrhosa* is distributed in the Northeast Atlantic Ocean (NEA) and in the MS.[3]

Seafood is known to be very important in human nutrition regarding the prevention of health disorders due to the presence of polyunsaturated fatty acids in their lipid composition [including the essential linoleic (C18:2) and alpha-linolenic (C18:3) acids, as well as docosahexaenoic (DHA; C22:6$\omega$-3) and eicosapentanoic acids (EPA; C20:5$\omega$-3)][4] and octopus species are no exception. Thus, some nutritional parameters such as total fat, fatty acids, cholesterol, and fat soluble vitamins are nowadays taken into account in order to maintain a good nutritional balance, since they are positively or negatively associated with health problems. To the best of our knowledge, *O. vulgaris* from MS[5−9] and NEA[10−13] have been analyzed for their fatty acids, but there is a lack of information on this subject concerning other geographical provenance, as well as regarding the other most relevant species, *E. cirrhosa*[14] and *O. maya*.[15] Also, data are very limited regarding the levels of cholesterol and vitamin E in these species and their different origins, being inexistent for *O. maya*. Furthermore, several studies[16−18] reported that cephalopods are highly sensitive to the environmental changes during all stages of the cephalopod's life, being able to respond to these changes actively (for example, migrating to areas with more propitious environmental conditions for feeding or spawning) or passively (using optimum environmental conditions to reach certain life stages at different growth rates between different generations).[17]

Thus, the aim of the present work was to characterize the total fat, fatty acids, cholesterol, and vitamin E concentrations in the arms of the three aforementioned species of octopus from distinct marine environments [NEA, Northwest Atlantic Ocean (NWA), Eastern Central Atlantic Ocean (ECA), Western Central Atlantic Ocean (WCA), PO, and MS]. The selected species are representative of the current octopus

generally consumed worldwide, being those commercially available in Portugal. The interspecies and interorigin composition variability and the associated benefit−risk balance of consumption of these species were evaluated. Also, the suitability of using fatty acids, cholesterol, and vitamin E concentrations as chemical descriptors to differentiate the octopus species and oceanic provenance was assessed.

## MATERIAL AND METHODS

**Reagents.** For cholesterol, vitamin E, fatty acids, and total fat analysis, propan-2-ol, cyclohexane, and HPLC grade *n*-hexane were purchased from Merck (Darmstadt, Germany), while 1,4-dioxane was from Sigma-Aldrich (Steinheim, Germany). Methanol and potassium hydroxide were acquired from Panreac (Spain). Boron trifluoride in methanol (14%), butylated hydroxytoluene (BHT), and ascorbic acid were obtained from Sigma-Aldrich. The internal standard for fatty acids quantification, triundecanoin, was also from Sigma-Aldrich (Steinheim, Germany), while the internal standard for vitamin E quantification, tocol, was obtained from Matreya (USA). Alfa-tocopherol and cholesterol standards were from Sigma-Aldrich (Steinheim, Germany), and the fatty acids methyl esters (FAMEs) standard was from Supelco (Bellefonte, PA). All other chemicals were of analytical grade from diverse suppliers.

**Sample Collection.** Octopus ($n$ = 69) from the different geographical origins available to Portuguese consumers was purchased frozen randomly from the markets in the NW region of Portugal during spring 2012. The species collected were *O. vulgaris* from NWA ($n$ = 8), NEA ($n$ = 8), ECA ($n$ = 8), WCA ($n$ = 8), PO ($n$ = 8), and MS ($n$ = 5); *O. maya* from ECA ($n$ = 8) and WCA ($n$ = 8); and *E. cirrhosa* from NEA ($n$ = 8). The origin was established based on the label information, as well as the date of capture (from 11 October to 9 December 2011). Sample collection, biometric characterization, and preparation were performed in accordance with the EPA Guide No. 823-B-00-07, DL No. 187/2005,[19] and CE Regulation No. 333/2007.[20] Specimens were carefully identified and manually eviscerated. Only the edible tissues were preserved. Homogenization was performed mechanically with a blender until a smooth paste was obtained. For each sample, three independent subsamples were defined. Samples were preserved at −18 °C, and subportions were freeze-dried (Telstar Cryodos-80, Terrassa, Barcelona) for fatty acid, cholesterol, and vitamin E quantification.

Moisture was evaluated using 10 g of sample according to the Portuguese Standard NP 2282-1991 and the official AOAC method.[21]

**Fatty Acids, Cholesterol, and Vitamin E Analysis.** For total fat content, approximately 1 g (accurately weighed) of the homogenized sample was extracted with 30.0 mL of acetone:ether petroleum (1:2, v/v) by microwave-assisted extraction, according to Ramalhosa et al.[22]

Extraction and analysis of fatty acids, cholesterol, and vitamin E were performed according to a validated study, conducted by Cruz and co-workers.[23] Briefly, an accurate freeze-dried sample portion (300 mg) was extracted with a ternary mixture of propan-2-ol, cyclohexane, and 0.9% (m/v) KCl, in the presence of the internal standards (tocol and triundecanoate), plus antioxidants (ascorbic acid and BHT). One-third of the organic extract was directly used for vitamin E analysis by HPLC, after being taken to dryness under a gentle nitrogen stream and reconstituted in *n*-hexane. The remaining extract was hydrolyzed with KOH (0.5 mol/L in methanol) at 100 °C (10 min) and further methylated with $BF_3$ (30 min at 100 °C) to convert the acyl-*sn*-glycerols and free fatty acids in the samples to volatile methyl esters (FAMEs). The lipids were extracted with *n*-hexane, and the solution was used initially for cholesterol quantification by HPLC, and thereafter for fatty acids analysis by GC-FID.

**HPLC Conditions for Vitamin E and Cholesterol Analysis.** The liquid chromatograph consisted of a Jasco integrated system (Japan) equipped with an LC-NetII/ADC data unit, a refrigerated autosampler (AS-2057 Plus), a PU-980 Intelligent Pump, and a multiwavelength DAD (MD-910, recorded at 210 nm), connected in series to a FD (FP-2020 Plus; $\lambda_{exc}$ = 290 nm and $\lambda_{em}$ = 330 nm; gain 10). The chromatographic separation was achieved on a Supelcosil LC-SI column (75 × 3.0 mm, 3 μm; Supelco, Bellefonte, PA) operating at constant room temperature (23 °C). A mixture of *n*-hexane and 1,4-dioxane (97.5:2.5, v/v) was used as eluent at a flow rate of 0.8 mL/min. Data were analyzed with the ChromNAV Control Center—JASCO Chromatography Data Station (Japan). The compounds were identified by chromatographic comparisons with authentic standards, by coelution, and by their UV spectra. Vitamin E was evaluated by the internal standard method based on the fluorescence data. Cholesterol was quantified at 210 nm, with calibration based on external standard solutions.

**Gas Chromatographic Conditions for Fatty Acids Analysis.** Gas chromatography was performed on a Chrompack CP 9001 chromatograph (Chrompack, Middelburg, The Netherlands) equipped with a split−splitless injector, a flame-ionization detector, and a Chrompack CP-9050 autosampler. The temperatures of the injector and detector were 250 and 270 °C, respectively. Separation was achieved on a 50 m × 0.25 mm i.d. CP-Sil 88 column (0.19 μm film; Chrompack-Varian), using a temperature program from 140 to 220 °C. Helium was used as the carrier gas at an internal pressure of 120 kPa. Fatty acid identification (from C14:0 to C22:6ω-3) was accomplished by comparing the relative retention times of FAMEs of commercially available fatty acids methyl esters (Supelco 37-FAME mix, Supelco, USA). Total fatty acids content was estimated on the basis of the total fatty acid methyl ester area counts in comparison with the undecanoic methyl ester by converting the FAMEs to their respective fatty acid equivalents using the appropriate conversion factors. Individual fatty acids were initially quantified on a g/100 g fatty acids basis and then converted to mg/100 g wet weight (ww) using the fatty acid internal standard (C11:0) and moisture content. Saturated fatty acids (SFA) include 12:0, 14:0, 15:0, 16:0, 17:0, 18:0, 20:0, and 22:0; monounsatured fatty acids (MUFA) include 16:1 isomers (ω-7 plus ω-9), 18:1 (ω-7 and ω-9), 20:1ω-9, 22:1ω-9, and 24:1ω-9; while polyunsaturated fatty acids (PUFA) include several omega-6 (18:2ω-6, 20:2ω-6, 20:3ω-6, 20:4ω-6, and 22:4ω-6) and omega-3 (18:3ω-3, 20:5ω-3, 22:2ω-6, 22:5ω-3, and 22:6ω-3) fatty acids.

**Nutritional Assessment.** The most relevant nutritional lipid quality indexes such as total ω-3/ω-6 ratio, PUFA/SFA, DHA + EPA sum, atherogenicity index (AI), thrombogenicity index (TI), and hypocholesterolemic:hypercholesterolemic ratio (HH) were estimated.[24] AI, TI, and HH indexes were calculated using eqs 1, 2, and 3, respectively:

dx.doi.org/10.1021/jf502502b | J. Agric. Food Chem. 2014, 62, 8508−8517

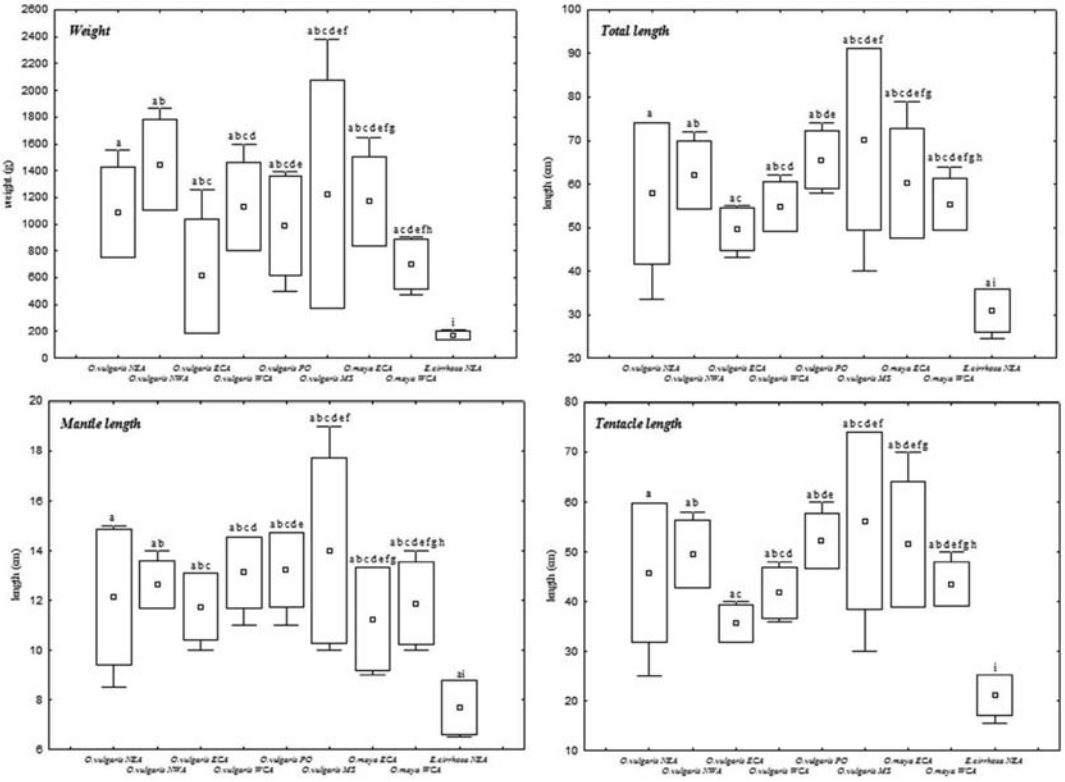

**Figure 2.** Biometric parameters (□, mean; rectangles, mean ± standard deviation; bars above and below rectangles, range) of the characterized octopus species ($n$ = 69). Each letter (a–i) corresponds to a species and inherent origin (a, *O. vulgaris* from Northeast Atlantic Ocean (NEA); b, *O. vulgaris* from Northwest Atlantic Ocean (NWA); c, *O. vulgaris* from Eastern Central Atlantic Ocean (ECA); d, *O. vulgaris* from Western Central Atlantic Ocean (WCA); e, *O. vulgaris* from Pacific Ocean (PO); f, *O. vulgaris* from Mediterranean Sea (MS); g, *O. maya* from ECA; h, *O. maya* from WCA; i, *E. cirrhosa* from NEA). The same letters in a box plot indicate that the given means are not statistically different ($p > 0.05$).

$$\mathrm{AI} = \frac{\mathrm{C12{:}0} + 4 \times \mathrm{C14{:}0} + \mathrm{C16{:}0}}{\sum \mathrm{MUFA} + \sum \omega\text{-}3 + \sum \omega\text{-}6} \quad (1)$$

$$\mathrm{TI} = \frac{\mathrm{C14{:}0} + \mathrm{C16{:}0} + \mathrm{C18{:}0}}{0.5\sum \mathrm{MUFA} + 0.5\sum \omega\text{-}6 + 3\sum \omega\text{-}3} \quad (2)$$

$$\mathrm{HH} = (\mathrm{C18{:}1}\omega\text{-}9 + \mathrm{C18{:}2}\omega\text{-}6 + \mathrm{C20{:}4}\omega\text{-}6 + \mathrm{C18{:}3}\omega\text{-}3 + \mathrm{C20{:}5}\omega\text{-}3 + \mathrm{C22{:}5}\omega\text{-}3 + \mathrm{C22{:}6}\omega\text{-}3)/(\mathrm{C14{:}0} + \mathrm{C16{:}0}) \quad (3)$$

**Statistical Analysis.** Statistical analysis was performed using the SPSS (IBM SPSS Statistics 20) and Statistica software (v. 7, StatSoft Inc., USA). Data were expressed as mean ± standard deviation and range and were grouped according to species and origins. Mean values were compared through the nonparametric Mann–Whitney $U$ test, since normal distribution was not observed by Shapiro–Wilk's test. Statistical significance was defined as $p \leq 0.05$. Principal components analysis (PCA) was applied, after variable standardization to mean zero and unit variance to assess which variables may be used as chemical descriptors among the three species or origins.

## RESULTS AND DISCUSSION

**Biometric Data.** The collected biometric data is presented in Figure 2. Generally, *E. cirrhosa* may be clearly distinguished from the other species due to its statistically significantly reduced dimensions, which explain its lower market price. On average, the heavier specimens were from *O. vulgaris* from NWA (1443 ± 336 g) while the biggest (14.0 ± 3.7 cm for mantle, 56.3 ± 17.9 cm for tentacle, and 70.3 ± 21.0 cm for total length) were from MS *O. vulgaris* species. Generally, the commercialized individuals of each species and origin were highly heterogeneous in length and weight, particularly *O. vulgaris* from the MS, which hindered the identification of biometric differences between the several tested species and geographical origins. Still, this high variability is in accordance with other documented results and may be related to biological factors.[7,10,12,13,25,26]

**Fatty Acids Composition.** In opposition to the biometric data, the fatty acids composition (as relative percentage of total fatty acids) was highly homogeneous in terms of fatty acids classes among the samples analyzed. PUFA is the more abundant class, followed by SFA and MUFA. Total PUFA ranged from 51.9% (*O. maya* from ECA) to 59.0% (*O. vulgaris* from NWA), followed by SFA from 25.6% (*E. cirrhosa* from NEA) to 31.1% (*O. maya* from ECA) and MUFA from 11.6% (*O. vulgaris* from WCA and MS) to 14.1% (*O. vulgaris* from NEA). Unsaturated fatty acids (PUFA + MUFA) account for more than 65% of total fatty acids.

The majority of the published studies in octopus composition concern *O. vulgaris* caught in MS. The attained results for this species are in accordance with Estefanell et al.,[5,6] Ozogul et al.,[7] and Passi et al.[8] while much higher SFA contents were reported by Karakoltsidis et al.[9] (41%). In particular, some authors have determined the fatty acid profiles of *O. vulgaris* captured in NEA. The reported values are similar to ours with only slight variations: SFA 31.9–34.6%, MUFA 9.2–11.6%, PUFA 55.7%;[10] SFA 27.3–33.2%, MUFA 9.6–10.4%, PUFA 54.8–59.2%;[12] SFA 34.2–40.8%, MUFA 4.5–7.9%, PUFA 47.6–56.4%;[11] SFA 25.9%, MUFA 15.5%, PUFA 58.6%.[13] The results reached for *O. vulgaris* from PO and *E. cirrhosa* are also

dx.doi.org/10.1021/jf502502b | J. Agric. Food Chem. 2014, 62, 8508–8517

in agreement with those scarce previously published (Turner et al.[27] for *O. vulgaris* from PO; Rosa et al.[14] for *E. cirrhosa*).

To the best of our knowledge, no information exists in the literature about fatty acids composition of *O. vulgaris* from NWA, ECA, and WCA, as well as wild *O. maya*. Studies concerning reared octopus were not used for comparison purposes since marine specimens created in captivity show differences from the wild ones because feeding habits are different.[28] In recent years, chemical and nutritional compositions of cephalopods have been extensively studied for aquaculture and industrial production purposes. Benthic species like *O. vulgaris* and *O. maya* are examples with high potential for aquaculture due to the worldwide high consumption demand and to their physiological, behavioral, and environmental characteristics.[28]

Regarding the fatty acids composition on an edible basis (mg/100 g ww) only the ones with more quantitative/nutritional importance are detailed in Table 1. There were wide variation and significant differences ($p < 0.05$) among the fatty acid profiles of the different species and origins in terms of total and individual compounds. Overall, *E. cirrhosa* stands out for its statistically significantly greater concentrations of the three main classes of fatty acids (SFA, MUFA, and PUFA) followed by *O. maya* from WCA. The MUFA and PUFA levels of *O. maya* from WCA were only similar to those from *O. vulgaris* from NWA. Within the different oceanic regions of *O. vulgaris*, the maximum total fatty acids mean (including the higher average value per fatty acid class) was observed in specimens from NWA. In contrast, the poorest species in fatty acids content was the most expensive and consumed worldwide species, *O. vulgaris* from MS. Still, its PUFA and SFA levels were similar to those from the same species from NEA and ECA, as well as to those of *O. maya* from ECA.

Concerning total PUFA averages, more than 56% (*O. maya* from WCA) up to 89% (*O. vulgaris* from NWA) are $\omega$-3 fatty acids, ranging respectively from 83 ± 27 to 341 ± 60 mg/100 g on a fresh basis. Marine organisms living in cold waters have usually a higher percentage of $\omega$-3 fatty acids composition,[29] which is consistent with this benthic species. The compounds that contributed most for total PUFA proportions in the fatty acids were, by descending order, docosahexaenoic acid (DHA; C22:6$\omega$-3) with 18.4% for *O. maya* from ECA (47 ± 18 mg/100 g ww) to 29.3% for *E. cirrhosa* from NEA (195 ± 31 mg/100 g ww), followed by eicosapentanoic acid (EPA; C20:5$\omega$-3) ranging 11.4% for *O. maya* WCA (31 ± 11 mg/100 g ww) to 23.9% (94 ± 11 mg/100 g ww) for *O. vulgaris* NWA, and arachidonic acid (ARA; C20:4$\omega$-6) with 4.6% for *O. vulgaris* NWA (19 ± 2 mg/100 g ww) to 19.4% for *O. maya* WCA (86 ± 10 mg/100 g ww). This pattern of variation is slightly different for *O. vulgaris* from WCA and PO, as well as for *O. maya* from ECA due to the higher contribution of ARA than EPA. In absolute amounts, as consumed, the lowest DHA (27 mg/100 g ww) and EPA (15 mg/100 g ww) contents were detected in *O. maya* from ECA while the highest were determined in *E. cirrhosa* from NEA, with 252 and 171 mg/100 g ww, respectively. Interestingly, the same *O. maya* but from WCA was the third group with higher DHA amounts (82 ± 11 mg/100 g), just after *O.vulgaris* from NWA. DHA and EPA are important in marine species since they are components in membrane cells where they maintain structural functions and their extremely low freezing temperatures are consistent with the demands of a life in cold seas. Taking a deeper look into the $\omega$-6 PUFA concentrations, it can be also observed that *O. maya* from WCA exhibits the highest levels (1.6−3.9 times higher) of $\omega$-6 PUFA mainly due to the contributions of ARA and C22:4$\omega$-6 and supported by the higher lipids content.

MUFA content ranged from 23.0 mg/100 g ww (*O. vulgaris* from MS and *O. maya* from ECA) to 126 mg/100 g ww (for *E. cirrhosa* from NEA). Oleic acid (C18:1; here reported as the sum of $\omega$-7 and $\omega$-9 isomers) was the most abundant within the monounsaturated class representing 31% (*O. vulgaris* from PO) to 46% (*O. vulgaris* from NWA) of the total MUFA mean amounts. Considering all species and origins, the strongest significant differences in C18:1 concentrations were detected between *E. cirrhosa* and the others ($p < 0.01$), as well as among *O. vulgaris* NWA and all the species apart from *O. maya* from WCA. Within the studied *O. vulgaris* sources, individuals from the NWA location presented the major statistical differences.

SFA values varied from 51 mg/100 g ww (*O. maya* from ECA) to 219 mg/100 g ww (*E. cirrhosa* from NEA). Statistical differences were found between *E. cirrhosa* and the other species ($p < 0.01$), as well as among *O. maya* WCA and all the remaining ones ($p < 0.01$). Palmitic acid (C16:0) followed by stearic acid (C18:0) were the compounds that contributed most for the total SFA mean. C16:0 corresponded to 13.9% (*O. maya* WCA) to 17.7% (*O. vulgaris* NWA) while C18:0 represented 5.4% (*E. cirrhosa* NEA) to 10.4% (*O. maya* ECA). The same statistical differences as those for the SFA class were found between species for C16:0 and C18:0.

Among all the factors influencing cephalopod fatty acid composition, diet is the most important and what affects most.[30] Several reports about cultured octopus have shown that fatty acid profile is significantly affected by the prey composition.[28,31−33] The availability of certain preys and the feeding habits of the species are connected, to some extent, with the geographical region. Octopus lipid composition is also largely influenced by water temperature (which depends on location and season), such that in colder water they store more fat.[15,34] Other influencing factors are oogenesis, spermatogenesis, and starvation of females during brooding.[7,9,11,12]

**Vitamin E.** The high prevalence of unsaturated fatty acids requires effective measures to protect them from oxidation. In nature, vitamin E levels are usually allied with high concentrations of unsaturated fatty acids.[35,36] The oxidation of a methyl group in PUFA gives formation to a free radical by a hydrogen atom removal becoming reactive and goes under chain reaction. Vitamin E that is incorporated in biological membranes acts as chain-breaking antioxidant. The phenol group of vitamin E compounds donates a hydrogen atom to the peroxyl radical, forming a tocopherol radical and a lipid hydroperoxide. The tocopherol radical can then link to another peroxyl radical forming inactive molecular products.[35]

Vitamin E embraces several lipophilic tocochromanols with antioxidant properties, but in the octopus samples analyzed only $\alpha$-tocopherol was detected and quantified. As expected, higher amounts of vitamin E were quantified in the samples with higher PUFA amounts (Figure 3 and Table 1). Detectable concentrations of vitamin E varied from 0.29 (for *O. vulgaris* from WCA) to 2.5 mg/100 g ww (for *O. vulgaris* from NWA). The results varied about a factor of 10 showing high intervariability between species and origins. The mean vitamin E content of *O. vulgaris* from NWA (1.60 ± 0.5 mg/100 g ww), *E. cirrhosa* from NEA (1.25 ± 0.46 mg/100 g ww), and *O. vulgaris* from PO (1.00 ± 0.45 mg/100 g ww) may be clearly distinguished from the other species by their highest contents. No statistical differences were verified between the mean of *E.*

**Table 1. Moisture (%) and Total and Fatty Acids Composition (Mean ± Standard Deviation and Range; mg/100 g wet weight) in the Arms of Octopus from Different Origins[a]**

[a]Each letter (a–i) corresponds to a species and inherent origin (a, *O. vulgaris* from Northeast Atlantic Ocean (NEA); b, *O. vulgaris* from Northwest Atlantic Ocean (NWA); c, *O. vulgaris* from Eastern Central Atlantic Ocean (ECA); d, *O. vulgaris* from Western Central Atlantic Ocean (WCA); e, *O. vulgaris* from Pacific Ocean (PO); f, *O. vulgaris* from Mediterranean Sea (MS); g, *O. maya* from ECA; h, *O. maya* from WCA; i, *E. cirrhosa* from NEA). The same letters in a row indicate that the given means are not statistically different ($p > 0.05$). [b]SFA = saturated fatty acids. [c]MUFA = monounsaturated fatty acids. [d]PUFA = polyunsaturated fatty acids. [e]AI = atherogenic índex. [f]TI = thrombogenic index. [g]HH = hypocholesterolaemic/hypercholesterolaemic ratio.

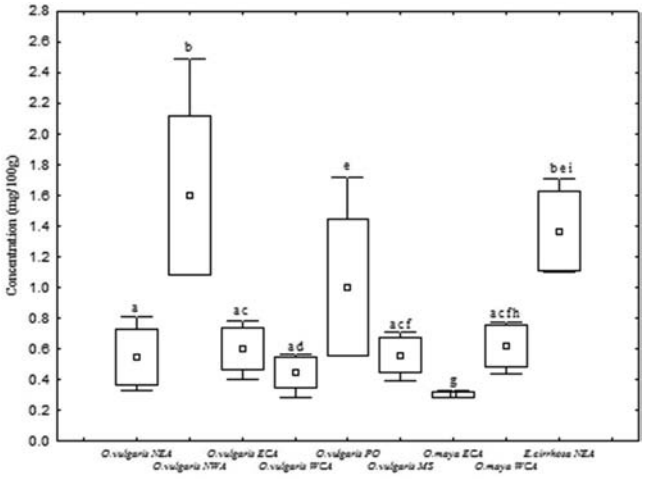

**Figure 3.** Vitamin E concentrations (□, mean; rectangles, mean ± standard deviation; bars above and below rectangles, range; mg/100 g wet weight) in the edible tissues of the characterized octopus species. Each letter (a–i) corresponds to a species and inherent origin (a, *O. vulgaris* from Northeast Atlantic Ocean (NEA); b, *O. vulgaris* from Northwest Atlantic Ocean (NWA); c, *O. vulgaris* from Eastern Central Atlantic Ocean (ECA); d, *O. vulgaris* from Western Central Atlantic Ocean (WCA); e, *O. vulgaris* from Pacific Ocean (PO); f, *O. vulgaris* from Mediterranean Sea (MS); g, *O. maya* from ECA; h, *O. maya* from WCA; i, *E. cirrhosa* from NEA). The same letters in a box plot indicate that the given means are not statistically different ($p > 0.05$).

*cirrhosa* and those of *O. vulgaris* from NWA and from PO. In contrast, *O. maya* ECA was the octopus with the lowest vitamin E content, being simultaneously among the ones with lower PUFA content. Statistical differences were found between *O. maya* ECA and all the other species ($p = 0.01$).

Data concerning vitamin E levels in octopus species are quite scarce and were not found for *O. vulgaris* from NWA, ECA, WCA, and PO, as well as for *O. maya* and *E. cirrhosa*. The attained concentrations for *O. vulgaris* from MS and NEA are in agreement with those previously reported by Passi et al.[8] (0.74 mg/100 g ww for *O. vulgaris* from MS), Nunes et al.[37] (0.73 mg/100 g ww for *O. vulgaris* from NEA), and Dias et al.[38] (0.78 mg/100 g ww for *O. vulgaris* consumed in Portugal with no indication of the geographical provenance). Villanueva and co-workers[36] characterized the vitamin E contents in the early life stages of *O. vulgaris* laboratory hatchlings and wild juveniles (9.2–14.2 g ww) from MS. They reported a much higher value (9.1 mg/100 g ww) possibly because vitamin E content seems to be higher in the early stages of cephalopods compared to adult stages and due to the fact that vitamin E was analyzed in whole octopus instead of in edible parts. It is known that digestive gland and gonads have higher contents of lipids than muscle parts.[10,14]

**Cholesterol.** Cephalopod consumption is usually associated with elevated cholesterol ingestion. Cholesterol plays an important role in cephalopods, with structural functions in cell membranes, and acts as a precursor of steroid hormones.[14] In opposition, and humans having the inherent ability to synthesize cholesterol, dietary cholesterol has been positively associated with low density lipoprotein (LDL) cholesterol and deleterious health outcomes. Therefore, in order to support adequately the data obtained from the nutritional point of view, the intra- and interspecific variability of the cholesterol concentrations in octopus edible tissues was also analyzed (Figure 4). Cholesterol mean content ranged from 85 ± 14

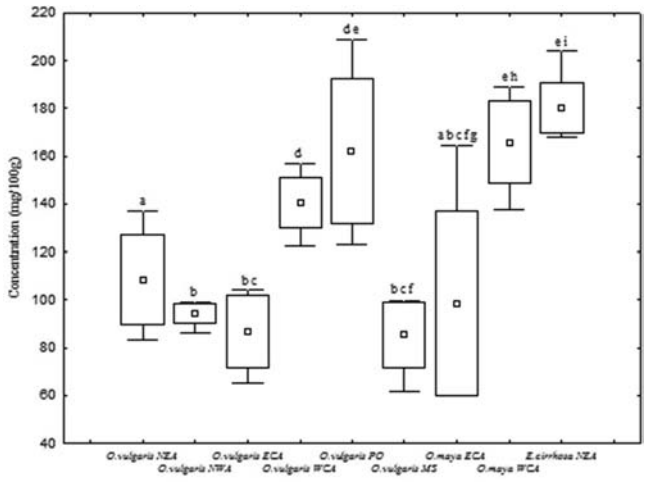

**Figure 4.** Cholesterol concentrations (□, mean; rectangles, mean ± standard deviation; bars above and below rectangles, range; mg/100 g wet weight) in the edible tissues of the characterized octopus species. Each letter (a−i) corresponds to a species and inherent origin (a, *O. vulgaris* from Northeast Atlantic Ocean (NEA); b, *O. vulgaris* from Northwest Atlantic Ocean (NWA); c, *O. vulgaris* from Eastern Central Atlantic Ocean (ECA); d, *O. vulgaris* from Western Central Atlantic Ocean (WCA); e, *O. vulgaris* from Pacific Ocean (PO); f, *O. vulgaris* from Mediterranean Sea (MS); g, *O. maya* from ECA; h, *O. maya* from WCA; i, *E. cirrhosa* from NEA). The same letters in a box plot indicate that the given means are not statistically different ($p > 0.05$).

mg/100 g ww for *O. vulgaris* from MS to 180 ± 11 mg/100 g ww for *E. cirrhosa* (Figure 4). This variability is highly interesting from the nutritional point of view indicating that one cannot classify all species and origins on the same basis regarding this parameter. Edible tissues of *O. vulgaris* from WCA (141 ± 11 mg/100 g ww) and from PO (162 ± 30 mg/100 g ww), *O. maya* from WCA (166 ± 17 mg/100 g ww), and *E. cirrhosa* from NEA exhibited significantly higher mean levels of cholesterol than the other species. Although some authors have concluded that cholesterol is not correlated with fat content (Oehlenschläger, 2006),[38] as confirmed in the present study, these species have all superior SFA and ω-6 PUFA amounts. In humans, some studies indicate that SFA as C16:0 and myristic acid (C14:0) raise blood cholesterol by decreasing LDL receptors that are responsible for cholesterol regulation.[4] *O. maya* from WCA and *E. cirrhosa* from NEA only exhibited similarity with *O. vulgaris* from PO ($p = 0.76$ and $p = 0.16$, respectively). The highest intravariability was observed for *O. maya* from ECA (65−164 mg/100 g ww), but the mean content (99 ± 39 mg/100 g ww) was not statistically different from those of *O. vulgaris* from NEA (109 ± 19 mg/100 g ww), from NWA (94 ± 4 mg/100 g ww), from ECA (87 ± 15 mg/100 g ww), and from MS (85 ± 14 mg/100 g ww).

There is limited information about cholesterol levels in octopus species. Data was found for only *E. cirrhosa*[14,25] and *O. vulgaris* from NEA[37,39] and from MS,[9,26,40,41] ranging from 64 mg/100 g ww[37] to 158 mg/100 g ww;[40]. Morillo-Velarde et al.[41] reported lower values in the muscle of *O. vulgaris* caught in the MS (31.6−62.2 mg/100 g ww) which may be explained by the fact that the individuals were analyzed after artificial feeding or absence of it (induced starvation of 4 days). Octopus natural preys are bivalves and crustaceans like shrimp, crab, and lobster,[3] all containing elevated cholesterol amounts. However, the food habits of octopuses are not completely known especially in the paralarva stage. According to Rosa et al.,[10] other factors, besides dietary, such as the demand during oogenesis and spermatogenesis, may affect the cholesterol content in cephalopods.

**Nutritional Assessment.** Although no specific data concerning octopus per capita consumption were found, cephalopod species are highly appreciated, particularly in Mediterranean and Asian countries. According to FAO,[1] in 2010 the average cephalopod intake varied widely worldwide, being 3.4 kg per capita per year in Portugal and reaching 6.5 kg per capita per year in Korea, of which octopuses represent an important part. Nowadays, there is clear evidence that the type of fat is more important in diminishing metabolic and cardiovascular disease risk than the total quantity of fat in the diet.[4] In addition, marine lipids are generally regarded as healthy, due to their high amounts of long chain PUFA, particularly EPA and DHA. Thus, to assess the potential health outcomes from the consumption of the characterized octopus species, the most important nutritional quality indexes were analyzed. Regarding the fatty acid composition, all the selected species had a favorable ω-3/ω-6 ratio, from 1.7 ± 0.5 to 9.2 ± 1.2 for *O. vulgaris* from WCA and NWA, respectively, 1.3 ± 0.2 to 2.2 ± 1.3 for *O. maya* from WCA and ECA, respectively; and 5.9 ± 0.7 for *E. cirrhosa* from NEA, confirming the importance of these species for ingestion of ω-3 PUFAs. The geographical provenance of *O. vulgaris* showed a marked influence on this ratio. A portion of 78 g (*E. cirrhosa* from NEA) to 321 g (*O. maya* from ECA) provides 250 mg of DHA + EPA, the daily recommended intake.[42] DHA and EPA are described as hypotriacylglycerolemic, antiarrhythmic, antiatherogenic, antithrombotic, and anti-inflammatory, being considered as protective agents against coronary heart diseases.[43] Also, the attained PUFA/SFA ratios are significantly higher (1.7 for *O. maya* from ECA to 2.2 for *E. cirrhosa* from NEA) than the recommended minimum of 0.45.[44]

The atherogenic and thrombogenic indexes, AI and TI, estimated on the basis of the fatty acid composition, are indicative of potential cardiovascular disease risk factors and therefore must be kept low. The fatty acid influence on cholesterol synthesis is also frequently estimated by the hypocholesterolemic/hypercholesterolemic (HH) index (Table 1). The AI attained mean (0.24 ± 0.03 (*O. maya* from WCA) to 0.31 ± 0.03 (*O. vulgaris* from ECA)) and TI from 0.14 ± 0.01 (*E. cirrhosa* from NEA) to 0.23 ± 0.06 (*O. maya* from ECA) can be considered favorable for the consumption of all species due to the cardioprotective effect of their MUFA and PUFA concentrations. Concerning the obtained HH index (3.3 ± 0.2 for *O. vulgaris* from ECA and NEA to 4.0 ± 0.6 for *O. maya* from WCA) high values are desired from a nutritional standpoint[24] since it estimates effects of specific fatty acids on cholesterol metabolism. *E. cirrhosa* from NEA and *O. maya* from WCA presented simultaneously the highest cholesterol amounts and the more protective HH indexes. Therefore, despite the elevated cholesterol amount in some species and origins, the octopus HH is protective from the nutritional point of view, balancing the potential health effects derived from cholesterol ingestion. These results constitute an added value for food consumption choices since these species are marketed at lower prices when compared with *O. vulgaris*.

Still, to exceed the guideline target of less than 300 mg/day established by the American Heart Association,[45] a portion of 20 to 25% of the whole collected specimens should be consumed corresponding to the entire individual for *E. cirrhosa*.

dx.doi.org/10.1021/jf502502b | J. Agric. Food Chem. 2014, 62, 8508−8517

The potential negative effects of dietary cholesterol are relatively small compared to those of SFA.[4] The SFA levels in octopus species are considerably lower than those of meat products (about 40%). Both SFA and cholesterol are unavoidable in omnivorous diets, and attempts to reduce intake completely would require significant changes to dietary patterns and introduce undesirable effects, such as inadequate intakes of micronutrients and protein.[4]

The reached AI, TI, and HH compare favorably in terms of nutritional evaluation with those determined for other cephalopods, such as squids[46] and common cuttlefish,[47] as well as for other worldwide consumed marine species (hake, silver and black scabbardfish, ray, angler, blackbelly rosefish, and megrim).[48,49]

Although existing at low concentrations in the studied species, vitamin E protects unsaturated fatty acids from peroxidation, preventing the formation of free radicals and subsequent health disorders.[35,50] The ingestion of a portion of 100 g of octopus will contribute to 2.0 (*O. maya* from ECA) to 10.7% (*O. vulgaris* from NWA) of the recommended dietary allowance (RDA) established for adult males and females (15 mg/day) by the Food and Nutrition Board of Institute of Medicine.[51]

**Principal Components Analysis.** PCA was applied as a pattern recognition technique to identify chemical descriptors for the selected species (Figure 5) or origins (Figure 1S, Supporting Information). PCA allowed explaining 93.8% of total data variance by using two principal components based on seven individual fatty acids (C18:1, C16:0, C22:6$\omega$-3, C22:5$\omega$-3, C20:5$\omega$-3, C22:4$\omega$-6, and C20:4$\omega$-6).

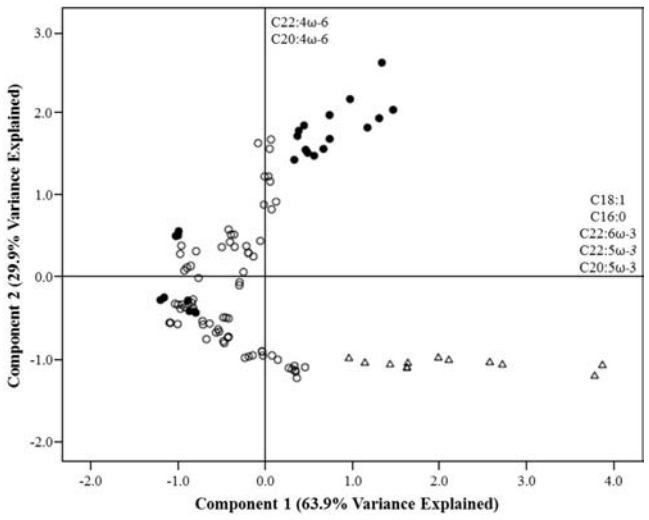

**Figure 5.** Principal components analysis of the characterized octopus species (○, *O. vulgaris*; ●, *O. maya*; and △, *E. cirrhosa*) based on concentrations of selected individual fatty acids (C18:1, C16:0, C22:6$\omega$-3, C22:5$\omega$-3, C20:5$\omega$-3, C22:4$\omega$-6, and C20:4$\omega$-6).

In Figure 5, three distinct octopus groups are represented corresponding to *O. vulgaris*, *O. maya*, and *E. cirrhosa* clusters. The first principal component factor (PC1), which comprises 63.9% of the total variance, is able to separate the three groups, being *O. maya* and *E. cirrhosa*, in general, located in the positive region, while *O. vulgaris* is positioned in the negative region. Still, some *O. maya* samples revealed greater similarities to those of *O. vulgaris*. All these may be justified by the fact that *O. maya* and *E. cirrhosa* samples, in general, reported higher figures for C18:1 (PC1 loading = 0.956), C16:0 (PC1 loading = 0.953), C22:6$\omega$-3 (PC1 loading = 0.933), C22:5$\omega$-3 (PC1 loading = 0.895), and C20:5$\omega$-3 (PC1 loading = 0.843) than *O. vulgaris* samples. The second component factor (PC2), which justifies 29.9% of the total variance observed, was able to separate at least *O. maya* from *E. cirrhosa*, which may be explain by the higher C22:4$\omega$-6 (PC2 loading = 0.937) and C20:4$\omega$-6 (PC2 loading = 0.910) content of the former. PCA was also tested to infer the oceanic origin of octopus species. Four main clusters corresponding to NEA, WCA, NWA, and PO/ECA/MS can be distinguished based on both components. NEA samples are characterized by lower C22:4$\omega$-6 and C20:4$\omega$-6 amounts than WCA samples. On the other hand, both of these oceans showed higher C18:1, C16:0, C22:6$\omega$-3, C22:5$\omega$-3, and C20:5$\omega$-3 contents than all the remaining ones. The observed results match the statistical differences observed in the fatty acids composition. Despite the difficulty of defining a biochemical profile representative of a specific species and oceanic area based on a limited number of individuals, the attained differentiation may be useful for authenticity control. It can be particularly relevant for mislabeling detection since *O. vulgaris* is usually highly rated on the market when compared with *O. maya* and *E. cirrhosa*. Prato and Biandolino[52] and Torrinha et al.[46] also applied successfully chemometric discrimination to cluster several marine organisms based on the most important fatty acids.

# Thermally Induced Oxidative Decarboxylation of Copper Complexes of Amino Acids and Formation of Strecker Aldehyde

Ossanna Nashalian and Varoujan A. Yaylayan*

Department of Food Science and Agricultural Chemistry, McGill University, 21111 Lakeshore, Sainte Anne de Bellevue, Quebec H9X 3V9, Canada

**ABSTRACT:** In the Maillard reaction, independent degradations of amino acids play an important role in the generation of amino-acid-specific products, such as Strecker aldehydes or their Schiff bases. Such oxidative decarboxylation reactions are expected to be enhanced in the presence of metals. Preliminary studies performed through heating of alanine and various metal salts (Cu, Fe, Zn, and Ca) under pyrolytic conditions indicated that copper(II) and iron(III) because of their high oxidation potentials were the only metals able to induce oxidative decarboxylation of amino acids and formation of Strecker aldehyde or its derivatives as detected by gas chromatography/mass spectrometry. Furthermore, studies performed with synthetic alanine and glycine copper complexes indicated that they constituted the critical intermediates undergoing free-radical oxidative degradation, followed by the loss of carbon dioxide and the generation of Strecker aldehydes, which were detected either as stable Schiff base adducts or incorporated in moieties, such as pyrazine or pyridine derivatives.

**KEYWORDS:** *Strecker aldehydes, metal salts, amino acid metal complexes, oxidative decarboxylation of amino acids*

## INTRODUCTION

Metal salts, such as copper sulfate, are commonly found or added to foods for a variety of reasons. The corresponding metal complexes formed during processing with amino acids and sugars (Figure 1) or other Maillard reaction products[1] may alter their chemical reactivity during thermal treatment, generating or enhancing specific reaction products, such as those of oxidation or decomposition. Understanding how these independent complexes thermally degrade provides important insight into their fundamental behavior in the context of the Maillard reaction. Over the past few decades, the role of metal salts and their potential to affect the Maillard reaction has been studied by several researchers.[1−4] Considerable efforts have been expended to study the catalytic role of metal salts in promoting oxidation pathways and affecting the rates of the reaction in aqueous systems. Moreover, recently, it has been demonstrated that metal ions can accelerate the formation of specific Maillard reaction products, such as advanced glycosylation end product (AGE)-modified peptides.[5] On the other hand, the use of cations and their salts were explored in mitigation strategies in lowering or preventing the formation of certain Maillard reaction products, such as acrylamide, in both model systems involving asparagine and sugars and food models.[6,7] Although the exact mechanism of how metal ions can affect the Maillard reaction is still not clear, it has been proposed that metals increase the rate of the reaction because of their ability to oxidize Amadori compounds, accelerating the formation of melanoidins.[3] High-molecular-weight reductones have also been reported to form complexes with metal ions through polynuclear ligands.[1,3] Their ability to complex with amino acids, change the structural configurations of proteins, catalyze redox reactions, and act as Lewis acid catalysts by forming metal coordination complexes with sugars has also been reported.[8] Amino acids could be considered as prime targets for metal complex formation, and although the role of such complexes in the Maillard reaction has not been studied, enhancements in the Strecker aldehyde formation were reported in the presence of copper ions by Hofmann and Schieberle.[9] Furthermore, copper was found to catalyze the oxidative decarboxylation of a synthetic amino dioic acid in aqueous solution, converting it into an amino monocarboxylic acid.[10] Recently, Yablokov et al.[11] reported the kinetics of thermal degradation of copper complexes of several amino acids at 230 °C, indicating an oxidative degradation mechanism of the complex initiated with the formation of carboxylamine free radical, followed by the loss of carbon dioxide and the generation of alkylamine radicals and its recombination products. Furthermore, the rate constants for the thermal degradation reactions of various amino acid copper complexes were highly dependent upon the nature and bulkiness of their side chains, and rates of degradation of such amino acid complexes decreased in the following order: Ser > Phe > Leu > Ile > Val > Gly > Ala.

The objective of this study was to explore the thermal degradation of synthetic copper complexes of various amino acids, particularly alanine and glycine, and their degradations in the presence of various metal salts {iron(II) or iron(III) chlorides, zinc chloride, calcium chloride [two generally recognized as safe (GRAS) metal chloride salts], and copper(I) and (II) chlorides}. The chloride salts of metals were selected because of their ability to form more volatile chlorinated reaction products.[12] In this study, we explore the role of metal salts and amino acid metal complexes in the decomposition reactions of amino acids.

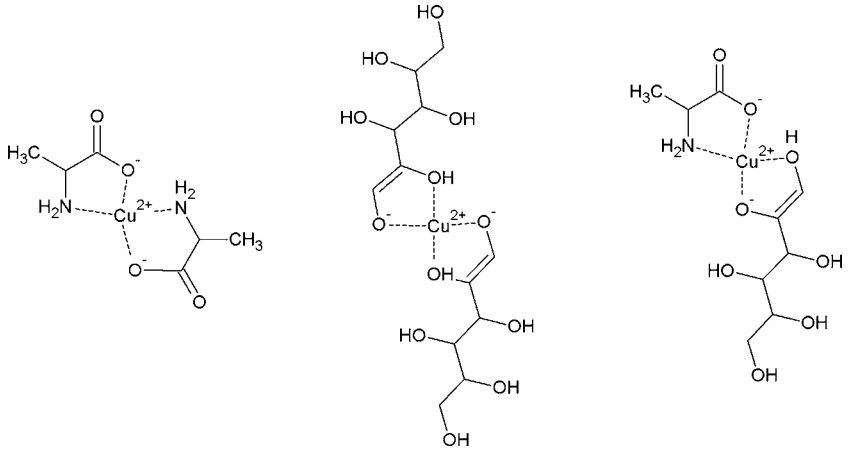

**Figure 1.** Possible complexes of copper with glucose and alanine.

## MATERIALS AND METHODS

**Materials and Reagents.** L-Alanine (99%), L-methionine (99%), L-leucine (99%), L-glycine (98%), copper(II) chloride ($CuCl_2$) (99.9%), copper(I) chloride (CuCl) (97%), calcium chloride ($CaCl_2$), zinc chloride ($ZnCl_2$) (98%), chloral hydrate (98%), 2-methylpyridine (98%), potassium hydroxide, D-glucose, and acetaldehyde (99.5%) were purchased from Sigma-Aldrich Chemical Co. (Oakville, Ontario, Canada). [$^{13}$C-1]Alanine (98%), [$^{13}$C-2]alanine (98%), [$^{13}$C-3]alanine (98%), [$^{15}$N]alanine, and [$^{13}$C-1, $^{13}$C-2]glycine (98%) were purchased from Cambridge Isotope Laboratories (Andover, MI).

**Preparation of Model Systems.** Model systems comprising of amino acids alone, amino acids with metal salts (in a 2:1 relative molar ratio), or synthetic amino acid metal complexes (see Table 1) were homogenized and mixed using a microscale porcelain mortar and pestle. After thorough homogenization, approximately 0.5 mg of the individual reactants or their mixtures were weighed into a quartz tube (0.3 mm thickness), plugged at both ends with glass wool (Supelco, Bellefonte, PA), inserted inside the coil probe, and pyrolyzed at 250 °C for 20 s under a helium atmosphere, as described below. All samples were analyzed in duplicate.

**Table 1. Composition of the Reactants in the Model Systems**

| amino acid[a] | metal salt | synthetic metal complex |
|---|---|---|
| alanine | $CuCl_2$/CuCl | $(Gly)_2Cu$ |
| glycine | $FeCl_2$/$FeCl_3$ | $(Ala)_2Cu$ |
| leucine | $ZnCl_2$ | (Gly)Cu(Ala) |
| methionine | $CaCl_2$ | |

[a]All of the listed amino acids were studied in the presence and absence of metal ions. The amino acids alanine and glycine were studied with all of the metal salts listed in the table and as synthetic metal complexes. Leucine and methionine were studied only with $CuCl_2$.

**Synthesis of Amino Acid–Metal Adducts.** Alanine–copper and glycine–copper complexes or mixed complexes were prepared by dissolving alanine (0.89 g), glycine (0.75 g), [$^{13}$C-1, $^{13}$C-2]glycine, or an equimolar mixture of alanine and glycine at room temperature in methanol (10 mL) in the presence of KOH (0.05 g) and stirred until all completely dissolved, followed by the addition of 0.5 mol of $CuCl_2$. The dark blue (with $CuCl_2$) precipitates were filtered, washed with methanol, and dried.

**Pyrolysis–Gas Chromatography/Mass Spectrometry (Py–GC/MS).** A Varian CP-3800 gas chromatograph coupled to a Saturn 2000 ion-trap detector interfaced to a CDS Pyroprobe 2000 unit through a valved interface (CDS 1500) was used for Py–GC/MS analysis of model systems shown in Table 1. The samples were packed in the quartz tube inserted inside the coil probe and pyrolyzed at 250 °C for 20 s under a helium atmosphere.

The separation was performed using a fused silica DB-5MS column (50 m length × 0.2 mm inner diameter × 33 μm film thickness). The GC method used for the analysis of the volatiles was as follows: The GC column flow rate was regulated by an electronic flow controller (EFC) and set at a pressure pulse of 55 psi for the first 3 min, then decreased to 32 psi at the rate of 300 psi/min, and finally, increased to 70 psi at a rate of 1.23 psi/min for the rest of the run. The GC oven temperature was set at −5 °C for first 5 min using $CO_2$ as the cryogenic cooling source and then increased to 50 °C at a rate of 50 °C/min. Then, the oven temperature was again increased to 270 °C at a rate of 8 °C/min and kept at 270 °C for 5 min. The samples were detected using an ion-trap mass spectrometer. The MS transfer-line temperature was set at 250 °C; the manifold temperature was set at 50 °C; and the ion-trap temperature was set at 175 °C. The ionization voltage of 70 eV was used, and electron multiplier voltage (EMV) was set at 2000 V. The generated data was analyzed using the AMDIS_32, version 2.69, computer software, and peak identification will be performed using the National Institute of Standards and Technology (NIST), version 2.0, mass spectral research program.

**Liquid Chromatography–Mass Spectrometry (LC–MS) Analysis of the Amino Acid–Copper Synthetic Adducts.** The dry samples were dissolved in deionized water (Millipore, Billerica, MA) to a concentration of 1 mL/mg. The sample was then diluted 10-fold in 10% methanol prior to analysis by LC–MS. The LC–electrospray ionization (ESI)–MS analysis comprised of a Dionex Ultimate 3000 RS liquid chromatograph (Dionex, Germering, Germany) coupled to a Bruker Maxis Impact quadruple-time-of-flight mass spectrometer (Bruker Daltonics, Bremen, Germany) in positive mode. A total of 1 μL of the sample was injected directly into LC–MS. The electrospray interphase settings were the following: nebulizer pressure, 0.6 bar; drying gas, 8 L/min; temperature, 180 °C; and capillary voltage, 4500 V. The scan range was from $m/z$ 100 to 1000. The data were analyzed using Bruker Compass DataAnalysis software, version 4.1.

**Structural Identification.** Specific reaction products (listed in Table 2) were identified by comparison of their retention times and mass spectra to commercial or *in-situ*-generated standards in addition to NIST library matches and stable isotope labeling data (Table 2). Elemental composition of selected metal complexes was based on their accurate mass determination by ESI–QqTOF analysis [alanine–copper complex at $m/z$ 261.9985 [M + Na] (calculated for $C_6H_{12}CuN_2NaO_4$ with an error of −1.4 ppm and glycine copper complex at $m/z$ 233.9665 [M + Na] (calculated for $C_4H_8N_2O_4CuNa$ with an error of 5.443 ppm].

## RESULTS AND DISCUSSION

Under the Maillard reaction conditions, independent degradation reactions of amino acids play an important role in the generation of amino-acid-specific products that result from thermal decarboxylation or oxidative decarboxylation (Figure

**Table 2. Decomposition Products Observed in the Alanine−Copper Complex and Alanine $CuCl_2$ Mixtures**

| model system | structure | retention time[a] (min) | isotope incorporation |
|---|---|---|---|
| Alanine-$CuCl_2$ |  chloral hydrate | 10.2 (10.2) | 1 x C-2<br>1 x C-3<br>0 x N |
| Alanine-$CuCl_2$<br>Alanine-CuCl |  2-ethylideneamino propanoic acid[b] | 13.2 (13.2) | 1 x C-1<br>2 x C-2<br>2 x C-3<br>1 x N |
| Alanine-$CuCl_2$ |  2-methylpyridine | 12.2 (12.2) | 3 x C-2<br>3 x C-3<br>1 x N |
| Alanine-$CuCl_2$ |  3,6-dimethyl piperazine-2,5-dione | 25.9 (25.9) | 2 x C-2<br>2 x C-3<br>2 x N |

[a]Values in parentheses represent those of the commercial or synthesized standards. [b]The *in situ* preparation of 2-ethylideneamino propanoic acid comprised 0.5 mg of alanine and 1 $\mu$L of acetaldehyde mixed and pyrolyzed under standard pyrolytic conditions.

2), leading to the formation of amines[13] and Strecker aldehydes captured as imines by the amino acid or its corresponding

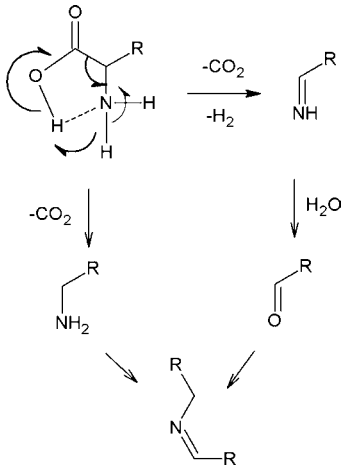

**Figure 2.** Proposed mechanism of thermally induced oxidative autodecarboxylation of amino acids.

amine.[14,15] Such oxidative decarboxylation reactions are expected to be enhanced in the presence of oxidizing species, such as copper,[10] and contribute to the pool of aroma-active aldehydes. On the other hand, oxidative decomposition of sugars leads to the formation of $\alpha$-dicarbonyl compounds, such as glucosone and deoxyglucosone, that can trigger the Strecker reaction of amino acids, producing even more Strecker aldehydes along with 2-aminocarbonyl compounds, the precursors of pyrazines. Currently, the relative contribution of the two pathways of generating Strecker aldehydes is not known in food products. Because of the importance of these aldehydes, enhancement of the pathways generating them could be a critical factor in flavor production and control. Because of the oxidative capacity of some metal salts, such as copper salts, it was predicted that, in their presence, the oxidative decarboxylation reactions could be encouraged. To understand metal−amino acid interactions and their influence on the production of specific reaction products, such as Strecker aldehydes, model systems containing amino acids were studied in the presence and absence of metal ions as both their free salts or synthesized amino acid−copper complexes (see Table 1). The purpose of the latter was to eliminate the effect of counterions, such as chlorides, and assess its importance as an intermediate.

Unlike other amino acids with longer side chains, such as leucine and methionine,[15] alanine when pyrolyzed in the absence of metal salts did not generate any significant amount of degradation products that could be observed under the experimental conditions. However, when the synthetic copper salt ($Ala_2Cu$) of alanine was pyrolyzed, a single major peak was observed that was characterized, resulting from the Schiff base formation between the intact alanine and its Strecker aldehyde (see Table 2). The same peak was also observed in the various copper and iron(III) salt/alanine mixtures along with other products. On the other hand, leucine and methionine in the absence of metal salts generated under pyrolytic conditions Schiff bases of Strecker aldehydes with their corresponding decarboxylated amino acids[15] (see Figure 2). Similarly, the formation of these Schiff bases was increased in the presence of copper salts. These observations clearly indicated that, although some amino acids can undergo thermally induced oxidative decarboxylation on their own and generate Strecker aldehydes, however, in the presence of copper or iron(III) salts, this ability is greatly facilitated or even accelerated by the formation of copper complexes.

dx.doi.org/10.1021/jf502751n | J. Agric. Food Chem. 2014, 62, 8518−8523

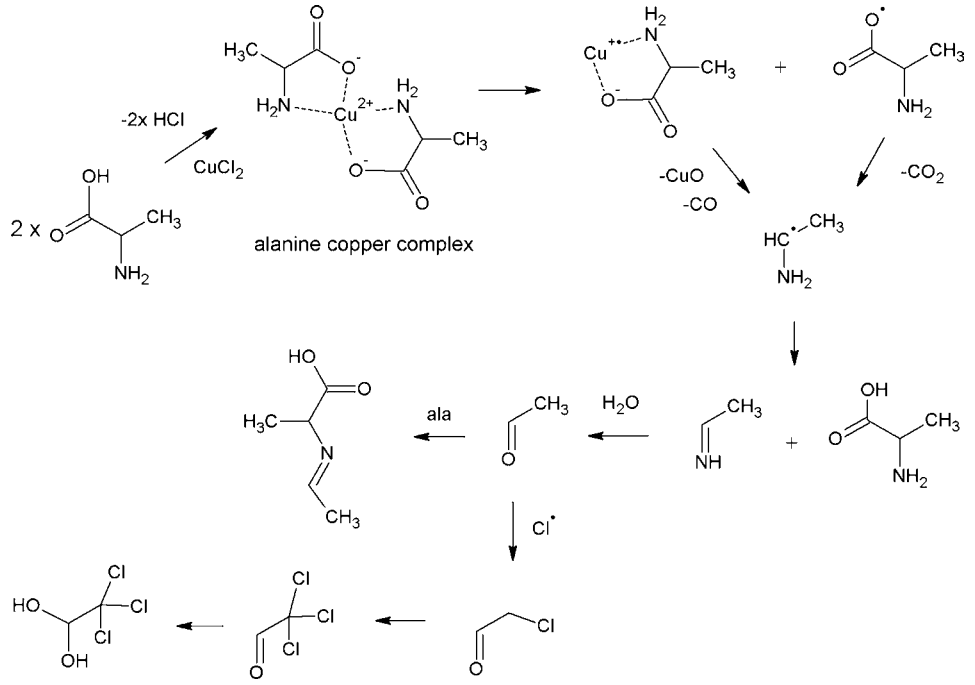

**Figure 3.** Proposed mechanism of copper-assisted thermal decarboxylation of alanine and acetaldehyde formation.

To confirm the generality of this observation, another amino acid glycine was chosen that behaves similar to alanine and does not undergo oxidative decarboxylation on its own. However, when glycine was pyrolyzed in the presence of copper salts or as its copper complex, it generated various Strecker aldehyde derivatives, such as pyrazines,[16] that were verified through NIST library searches and isotope-labeling studies using synthetic [$^{13}$C-1, $^{13}$C-2]glycine−copper complex, which generated pyrazine and two of its derivatives methyl- and 2,6-dimethyl pyrazines, incorporating four, five, and six glycine atoms, respectively. This label incorporation pattern was consistent with those reported by Guerra and Yaylayan.[16] Pyrazine and alkyl-substituted pyrazines can be formed through dimerization of azomethine ylides, which, in turn, can be formed from the Schiff base adducts of glycine and formaldehyde, the Strecker aldehyde of glycine. The same complex also generated 4-hydroxybutanal, the aldol product of two acetaldehyde molecules. Guerra and Yaylayan[16] also demonstrated that acetaldehyde can be generated from glycine and formaldehyde through a chain elongation reaction.

Although other metals, such as calcium and zinc, can also complex with amino acids, however, when copper or iron(III) chloride was replaced with calcium or zinc chlorides in the reaction mixtures, they did not promote Strecker aldehyde formation. This observation underlines the significance of the nature and reactivity of the metal ions in these complexes, considering that copper in its oxidation sate +2 and iron in its oxidation state +3 are known to have higher redox potentials compared to the other metals studied. The high redox potential enhances the electron affinity of copper, which, in turn, affects its reactivity and how easily it can accept and donate electrons.[17] In addition, the Lewis acid character of the metal ions also influences the stability of the complexes by forming metal−amino acid bonds with differing bond strengths depending upon the metal type, which, in turn, would affect their thermal dissociation capacity. On the other hand, when alanine was replaced with other amino acids, such as leucine and methionine, in the $CuCl_2$ reaction mixtures, similar enhancements in their corresponding Strecker aldehyde concentrations were observed relative to the model systems lacking $CuCl_2$ salts. Interestingly, when the mixed glycine/alanine copper complex (AlaCuGly) was analyzed, a significant enhancement in the formation of pyrroles, pyridines, and pyrazines relative to single amino acid complexes was observed. Furthermore, ethylamine and acetic acid were observed in iron(III) chloride/alanine model systems, in addition to the Schiff base adducts of Strecker aldehyde, indicating the ability of the iron to oxidize acetaldehyde and generate nitrogen-centered free radicals.

**Proposed Mechanism of Copper-Assisted Oxidative Decarboxylation of Alanine and Acetaldehyde Formation.** The analysis of the metal salt−alanine reaction products indicated that the influence of the metal ions on the thermal degradation profile of alanine was highly dependent upon the type of metal ion. Among the metal chloride salts investigated, CuCl, $CuCl_2$, and $FeCl_3$ were found to be the only salts that induced significant changes to the thermal degradation profile of alanine that could be observed under the experimental conditions, causing the generation of new products (see Table 2). The results pointed to the role of copper to be stoichiometric rather than catalytic, as supported by the generated products and their formation mechanism (see Figure 3). $CuCl_2$ can form stable complexes with 2 mol of alanine with the release of HCl, as shown in Figure 3, and the resulting complex can undergo thermal decomposition through an intramolecular redox reaction to generate a copper-centered radical cation and a carboxylamine radical.[11,18] Both products can be converted into the ethylamine radical, the former through the loss of CuO and CO and the latter through the thermal decarboxylation mechanism. A subsequent disproportionation reaction between the carboxylamine radical and ethylamine radical generates free alanine and ethanimine molecules. The hydrolysis of imine can lead to the formation of the Strecker aldehyde, which can immediately form a Schiff

dx.doi.org/10.1021/jf502751n | J. Agric. Food Chem. 2014, 62, 8518−8523

base adduct with the released free alanine, as shown in Figure 3. This identified adduct, which confirms the formation of both acetaldehyde and alanine, as predicted in the proposed mechanism, was the main product observed when the synthetic copper complex of alanine was pyrolyzed. The identity of this adduct was verified through comparison of its retention time to that of pyrolytically generated standard from alanine and acetaldehyde and through isotope-labeling experiments with [$^{13}$C-1]alanine, [$^{13}$C-2]alanine, [$^{13}$C-3]alanine, and [$^{15}$N]-alanine (see Table 2), in addition to its mass spectral fragmentation pattern, which was consistent with the proposed structure (see Figure 4). Further evidence for the release of free

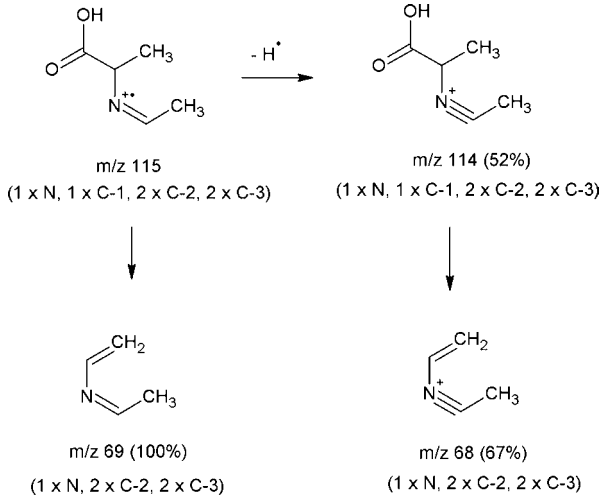

**Figure 4.** Mass spectral fragmentation patterns of 2-ethylidineamino propionic acid (values in parentheses represent the observed alanine atom incorporations).

alanine was the detection of 3,6-dimethyl piperazine-2,5-dione, as shown in Table 2. The same diketopiperazine was also observed in the alanine copper complexes analyzed at 270 °C by Yablokov et al.[11] On the other hand, the model systems containing chloride salts, such as $CuCl_2$, that can release HCl provided additional evidence for the formation of acetaldehyde because of the ability of HCl to chlorinate acetaldehyde and form chloral hydrate (Figure 3). The structure of chloral hydrate was confirmed by comparison of its mass spectrum and retention time to a commercially available standard (Table 2). Additionally, the labeling studies confirmed that chloral hydrate contains $^{13}$C-2 and $^{13}$C-3 atoms of alanine, while the number of chlorine atom incorporation was confirmed through its natural isotope abundance pattern. In addition to chloral hydrate, several chlorinated and non-chlorinated methylpyridines were also detected in $CuCl_2$–alanine model systems. Isotope-labeling studies have indicated that 2-methylpyridine incorporated three $^{13}$C-2, three $^{13}$C-3 atoms, and one nitrogen atom from alanine, implying an aldol-type condensation involving acetaldehyde and ethanimine, followed by cyclization (Figure 5). The mass spectra and retention time of 2-methylpyridine were further confirmed using a commercially available standard.

Copper(II) and iron(III) were found to be the most reactive metals that are able to complex with amino acids, promote their oxidative decarboxylation in a thermally induced free-radical pathway, and enhance the formation of important Strecker aldehydes. This ability was demonstrated when the amino acid was replaced with the alanine copper complex in a Maillard model system consisting of glucose and alanine. In this reaction system, the total intensity of ethyl-substituted pyrazines that incorporated $^{13}$C-2 atoms of alanine was increased by 10-fold compared to the total intensity of corresponding ethyl-substituted pyrazines in the glucose alanine model system, indicating enhanced production of the Strecker aldehyde acetaldehyde and its subsequent reaction with dihydropyrazines to generate various ethyl-substituted derivatives. With the absence of any toxicological evidence to prohibit their use as flavor-potentiating additives, these amino acid–metal complexes might provide a cost-effective way to enhance the flavor of heated foods. This pathway of generating Strecker aldehydes through thermal degradation of easily available metal–amino acid complexes in the absence of sugar-derived $\alpha$-dicarbonyl compounds can be considered a convenient strategy to introduce such aroma-active volatiles in foods lacking carbohydrates or a sugar source.

# Isotope-Labeling Studies on the Formation Pathway of Acrolein during Heat Processing of Oils

Alice Ewert,[†] Michael Granvogl,[‡] and Peter Schieberle*[,†,‡]

[†]Deutsche Forschungsanstalt für Lebensmittelchemie and

[‡]Lehrstuhl für Lebensmittelchemie, Technische Universität München, Lise-Meitner-Straße 34, D-85354 Freising, Germany

**ABSTRACT:** Acrolein (2-propenal) is classified as a foodborne toxicant and was shown to be present in significant amounts in heated edible oils. Up to now, its formation was mainly suggested to be from the glycerol part of triacylglycerides, although a clear influence of the unsaturation of the fatty acid moiety was also obvious in previous studies. To unequivocally clarify the role of the glycerol and the fatty acid parts in acrolein formation, two series of labeled triacylglycerides were synthesized: [$^{13}C_3$]-triacylglycerides of stearic, oleic, linoleic, and linolenic acid and [$^{13}C_{54}$]-triacylglycerides with labeled stearic, oleic, and linoleic acid, but with unlabeled glycerol. Heating of each of the seven intermediates singly in silicon oil and measurement of the formed amounts of labeled and unlabeled acrolein clearly proved the fatty acid backbone as the key precursor structure. Enzymatically synthesized pure linoleic acid and linolenic acid hydroperoxides were shown to be the key intermediates in acrolein formation, thus allowing the discussion of a radical-induced reaction pathway leading to the formation of the aldehyde. Surprisingly, although several oils contained high amounts of acrolein after heating, deep-fried foods themselves, such as donuts or French fries, were low in the aldehyde.

**KEYWORDS:** *Acrolein, foodborne toxicant, frying, fatty acid hydroperoxides, labeling studies*

## INTRODUCTION

Acrolein (2-propenal) is a highly reactive aldehyde commonly formed by incomplete combustion of organic material. Thus, the aldehyde has been found in cigarette smoke, fireplaces, incense, candles, and fuels.[1−4] Furthermore, acrolein has been detected in the exhaust of kitchens and thermally processed cooking oils[5−10] as well as in biological samples.[11,12]

Acrolein has been classified by the U.S. Environmental Protection Agency (EPA) as a pulmonary toxicant and is among the air toxicants posing the greatest health risk.[13−18] Its toxicity is related to a reaction with, for example, the sulfhydryl group of cysteine in proteins and glutathione, leading to interferences in the intermediary cell metabolism and to modified proteins by introducing inter- and intramolecular cross-links.[8,19,20] Furthermore, administration of acrolein to rats decreased lung and liver levels of glutathione, ascorbic acid, and $\alpha$-tocopherol.[21] In addition, acrolein has been reported to induce the generation of oxygen radicals[22,23] and has been associated with several illnesses, such as atherosclerosis,[24] Alzheimer's disease,[25] and cancer.[26,27]

Despite extensive toxicological studies, data on the formation pathway of acrolein from food constituents are scarcely available in the literature. Presently, two published major hypotheses can be found: acrolein may be generated by either partial hydrolysis of triacylglycerides, followed by dehydration of liberated glycerol to acrolein,[28,29] or, in particular, a degradation of the unsaturated fatty acid backbone.[7,30] Fujisaki et al.[26] showed that the amount of acrolein in processed oil was well correlated with the experimental oxygen concentration (2−20%) in the air, and Bastos and Pereira[31] observed a clear increase of acrolein during oil processing in the presence of metal ions, suggesting that hydroperoxide formation is involved.

Umano and Shibamoto[7] assumed the necessity of free fatty acids for acrolein formation, and acrolein generation was suggested from linolenic acid via its 13-hydroperoxide as key intermediate.[10] Esterbauer et al.[32] proposed that acrolein originates from the center of the fatty acid chain involving $\beta$-cleavage of the 9-hydroperoxide. However, this formation mechanism needs $\omega$-3 or $\omega$-6 fatty acids, respectively, as precursors, but it remains unclear how acrolein can also be generated from, for example, oleic acid. The ability of free fatty acids as well as their esters to generate acrolein was also observed by Tamura et al.[33] as well as by Pan et al.[34]

Recently, it was shown by our group that the amount of acrolein generated during heat processing of different edible fats and oils was well correlated with the content of unsaturated fatty acids in the oil sample.[6] However, the reaction pathway leading to acrolein from triacylglycerides is still unclear. Thus, the objectives of this study were, first, to identify the most efficient precursor structures using several $^{13}C$-labeled triacylglycerides as well as unlabeled fatty acid hydroperoxides in a model system with silicon oil, and, second, to quantitate acrolein in different types of fried foods and to correlate the amounts with the concentrations present in the frying oil.

## MATERIALS AND METHODS

*CAUTION:* Acrolein, as well as [$^{13}C_3$]-acrolein, is classified as toxic and may cause cancer. Be careful when handling these chemicals.

**Food Samples.** Vegetable oils, potato chips, precooked French fries, and donuts were purchased in local supermarkets.

**Chemicals.** [$^{13}C_3$]-Acrolein was obtained from Isotec Stable Isotopes (St. Louis, MO), and acrolein and dicyclohexyl carbodiimide were from Fluka (Steinheim, Germany). Glycerol, stearic acid, oleic acid, $\alpha$-linoleic acid, $\alpha$-linolenic acid, [$^{13}C_3$]-glycerol, [$^{13}C_{18}$]-stearic acid, [$^{13}C_{18}$]-oleic acid, [$^{13}C_{18}$]-linoleic acid, 4-(dimethylamino)-pyridine, soybean lipoxygenase type I, and xylenol orange were obtained from Sigma-Aldrich (Taufkirchen, Germany). L-Ascorbic acid, D,L-*all-rac*-$\alpha$-tocopherol, silicon oil, sulfuric acid (96%), and ferrous ammonium sulfate hexahydrate were from VWR International (Darmstadt, Germany). Silica gel (230−400 mesh, grade 60) and LiChroprep Diol (40−63 $\mu$m) were from Merck (Darmstadt). Argon, oxygen, and liquid nitrogen were obtained from Linde (Munich, Germany). All other reagents were of analytical grade.

**Synthesis of $^{13}$C-Labeled Triacylglycerides.** The glycerides were prepared according to a general procedure published previously.[35] Either unlabeled glycerol (0.15 mmol) was reacted with each of the carbon-13 labeled fatty acids (0.5 mmol), or [$^{13}C_3$]-glycerol was reacted with each of the unlabeled fatty acids dissolved in dichloromethane (2.5 mL) under an argon atmosphere. The solution was stirred and cooled to 0 °C while dicyclohexyl carbodiimide (0.75 mmol) and 4-(dimethylamino)pyridine (0.05 mmol) were added within 5 min. The reaction mixture was stirred for 3 h at room temperature, and the dicyclohexyl urea formed was removed by filtration. After extraction with hydrochloric acid (0.5 mol/L; total volume = 40 mL) and an aqueous saturated sodium bicarbonate solution (total volume = 40 mL), the organic phase was dried over anhydrous sodium sulfate and concentrated to a final volume of ∼1 mL using a rotary evaporator. The crude product obtained was purified by column chromatography (220 mm × 22 mm i.d.) on silica gel (230−400 mesh, grade 60). Elution was performed with dichloromethane/*n*-pentane (8:2; v/v). Structures of the seven target compounds were confirmed by LC-MS in positive atmospheric pressure chemical ionization (APCI$^+$) mode as well as by $^1$H and $^{13}$C NMR spectroscopy ([$^{13}C_3$]-labeled compounds). Yields of synthesized $^{13}$C-labeled triacylglycerides were determined by LC-MS (APCI$^+$) and calculated from external five-point calibration curves using defined triacylglyceride solutions. Reference solutions were prepared in dichloromethane from a stock solution (5 mg/mL) in the concentration range between 10 and 200 $\mu$g/mL.

**Analytical Data of the Synthesized Triacylglycerides.** *[$^{13}C_3$]-Glyceryl tristearate:* MS-APCI$^+$, *m/z* (%) 611.3 (100), 551.3 (30), 648.9 (15), 895.4 ([M + H]$^+$; 10).

$^1$H NMR (400 MHz; $CDCl_3$; 298 K): $\delta$ 0.90 (t, 7.0 Hz, H-C18′/H-C18″), 1.21−1.39 (m, H-C4′−H-C17′/H-C4″−H-C17″), 1.55−1.70 (m, H-C3′/H-C3″), 2.33 (t, 7.6 Hz, H-C2′), 2.34 (t, 7.5 Hz, H-C2″), 4.17 (dm, 145.6 Hz, $H_a$-C1), 4.23 (dm, 148.3 Hz, $H_b$-C1), 5.29 (dm, 149.2 Hz, H-C2). **Preparation of Hydroperoxides.** Fatty acid hydroperoxides were prepared as previously described.[36] Either linoleic acid or linolenic acid (200 mg each) was treated with soybean lipoxygenase type I (4 mg) for 60 min under an atmosphere of pure oxygen at room temperature. Separation of the hydroperoxides from the residual fatty acids was performed by means of preparative flash-column chromatography using a LiChroprep Diol stationary phase and *n*-hexane/2-propanol/methanol/water (900:50:2:1; v/v/v/v) as the mobile phase. Due to the high regio- and stereospecifity of LOX I (94−97% of 13-hydroperoxy-(*Z*,*E*)-9,11-octadienoic acid), no further separation of the isomers was needed.[37] The 13-hydroperoxides were identified by LC-MS (APCI$^+$). Quantitation of the fatty acid hydroperoxides was performed photometrically.[38]

*13-Hydroperoxy-(Z,E)-9,11-octadecadienoic acid:* MS-APCI$^+$, *m/z* (%) 279.9 (100), 294.9 (50), 207.0 (40), 313.0 ([M + H]$^+$; 35), 608.2 (30), 625.3 (25), 592.2 (20), 349.1 (20).

*13-Hydroperoxy-(Z,E,Z)-9,11,15-octadecatrienoic acid:* MS-APCI$^+$, *m/z* (%) 311.1 ([M + H]$^+$; 100), 277.8 (60), 293.1 (60), 603.5 (40), 587.6 (20), 621.4 (10).

**Heating of Oils.** Rapeseed oil (100 g) or a commercial frying fat (100 g) was mixed either with D,L-*all-rac*-$\alpha$-tocopherol (100 mg) or with L-ascorbic acid (100 mg; finely powdered, forming a suspension), respectively, before heat treatment. For comparison, rapeseed oil or the frying fat was analyzed without antioxidants. All samples were heated at 180 °C for 4 h.

**Degradation of Labeled Triacylglycerides or Monohydroperoxides.** Silicon oil (5 mL) was mixed singly either with each of the isotopically labeled triacylglycerides or with the hydroperoxides as well as with the respective free fatty acids (20 mg each). A control experiment was performed by heating silicon oil without any additives to prove the absence of signals and background interferences within the mass traces of acrolein (*m/z* 57 in chemical ionization (CI) mode) or [$^{13}C_3$]-acrolein (*m/z* 60), respectively. Samples were heated at 140 °C for 4 h under continuous stirring in closed glass vessels in a thermocontrolled metal block.

**Preparation of Food and Frying.** *Donuts.* Yeast (42 g) was suspended in warm water, and wheat flour (500 g), whole milk (150 mL), sugar (50 g), eggs (100 g), and water (25 mL) were added to obtain a homogeneous dough, which was divided into pieces of about 50 g and stored at 30 °C for 2 h before frying.

*Different foods (potato chips, precooked French fries, and donuts)* were fried at 180 °C either in rapeseed oil, in safflower oil, or in a commercial frying fat: potato chips (peeled, 1.5 mm of cross section) for 2 min, French fries for 3.5 min, and donuts for 6 min. To provide similar reaction conditions, the first five batches of the respective fried foods were discarded, and only the sixth batch was used for analysis. The frying process (100 g of each food) was carried out in a DF320 Kenwood deep-fryer (Heusenstamm, Germany) containing 2.3 L of oil, which was preheated for 10 min prior to frying.

**Quantitation of Acrolein.** *Model System with Antioxidants, Free Fatty Acids, and Hydroperoxides.* Immediately after cooling to room temperature, the internal standard [$^{13}C_3$]-acrolein (dissolved in dichloromethane; 1−214 $\mu$g, depending on the amounts determined in preliminary experiments) was added to an aliquot of each sample (5 g). The sample was vortexed (1 min) and ultrasonified (5 min), and aliquots (1 g) were weighed into gastight headspace vials (20 mL), which were immediately capped and stirred for 20 min at room temperature prior to headspace GC-MS measurement (CI mode) as recently described.[6]

*Model System with Labeled Triacylglycerides.* Quantitation was performed by preparing acrolein standards in dichloromethane from a stock solution (1.372 mg/mL) in the concentration range from 1 to

500 μg acrolein/mL containing a fixed amount of internal standard (10 μg/mL). Calibration curves were newly prepared prior to each measurement and showed good-quality fit ($r^2 > 0.993$).

For acrolein quantitation in foods, the material was frozen in liquid nitrogen and ground with a laboratory mill. Aliquots (5 g) were weighed into gastight headspace vials (100 mL) containing silicon oil (30 mL). After addition of [$^{13}C_3$]-acrolein (100 ng), the vials were immediately capped, and the suspensions were stirred for 20 min at 30 °C prior to headspace GC-MS measurement (CI mode) as recently described.[6]

**High-Performance Liquid Chromatography–Mass Spectrometry (HPLC-MS).** Mass spectrometry was performed by means of an LCQ ion trap mass spectrometer connected to an SCM 1000 high-performance liquid chromatography system (both Finnigan MAT, Bremen, Germany) equipped with a 150 mm × 2.0 mm i.d., 4 μm Synergi Polar RP 80 Å column kept at 30 °C and connected to a 4 mm × 2.0 mm i.d. polar RP precolumn (both Phenomenex, Aschaffenburg, Germany). Elution was done isocratically using a mixture of *n*-hexane/2-propanol/methanol/water (900:50:2:1; v/v/v/v). Flow rate was set at 0.8 mL/min, and injection volume was 50 μL. Analytes were detected in full scan using APCI$^+$ mode. The sheath and auxiliary gas nitrogen nebulized the effluent with flows of 80 and 20 arb, respectively. Further parameters were the following: discharge current, 5 μA; vaporizer temperature, 400 °C; heated capillary temperature, 200 °C; capillary voltage, 4 V; and tube lens offset, 30 V. The ion trap operated at a helium pressure of $1.3 \times 10^{-4}$ kPa.

**Nuclear Magnetic Resonance (NMR) Spectroscopy.** $^1$H and $^{13}$C NMR spectra were recorded using a 400 MHz DRX spectrometer (Bruker, Rheinstetten, Germany). Sample was dissolved in deuterated chloroform ($CDCl_3$; 0.7 mL), and chemical shifts ($^1$H NMR) were determined using either tetramethylsilane (0.03%) as the internal standard or the carbon signal of $CDCl_3$ at 77.0 ppm ($^{13}$C NMR), respectively.

## RESULTS AND DISCUSSION

**Model Studies.** *Effect of Antioxidants on Acrolein Formation.* To check if a radical mechanism is involved in acrolein generation, in a first series of experiments, the antioxidant α-tocopherol or L-ascorbic acid was singly added to rapeseed oil as well as to a commercial frying fat before heating. The oils were selected on the basis of their different fatty acid compositions: the frying fat consisted of >50% of saturated fatty acids, whereas rapeseed oil mainly consisted of unsaturated fatty acids. Compared to the samples heated without antioxidant addition (expt 3) (Table 1), in the presence of both antioxidants, acrolein formation was strongly reduced during heating, although to a lesser extent in the frying fat (expts 1 and 2) (Table 1). In the presence of α-tocopherol, which was the more effective antioxidant, acrolein concentration in rapeseed oil was reduced to ∼15% compared to the oil heated without the antioxidant. The results supported data on wok-cooking[19] indicating that acrolein emissions were reduced when the antioxidant BHA was added to the cooking oil. The more effective reduction of acrolein found for α-tocopherol in comparison to L-ascorbic acid might be explained by the better solubility of α-tocopherol in the fatty matrix. On the basis of these results, it can be assumed that acrolein generation in oils involves a radical-induced degradation of the triacylglycerides.

**Table 1. Amounts of Acrolein Formed by Heating of Rapeseed Oil and a Common Frying Fat at 180 °C for 4 h in the Presence or Absence of Antioxidants**

| | | concn (mg/kg)[a] in | |
|---|---|---|---|
| expt | additive | rapeseed oil | frying fat |
| 1 | α-tocopherol[b] | 9.8 (7.6–12.1) | 19.6 (17.8–21.4) |
| 2 | ascorbic acid[b] | 16.9 (15.8–17.1) | 35.4 (33.4–37.6) |
| 3 | without[c] | 67.5 (63.2–69.7) | 51.8 (48.9–53.1) |

*Stable Isotope Labeling Studies with Triacylglycerides.* To get further insight into the formation pathway of acrolein from triacylglycerides, experiments using isotopically labeled precursors were undertaken. Recently, it was shown that acrolein formation from oils containing linoleic or linolenic acid is significantly higher than from oils mainly consisting of saturated or monounsaturated fatty acids.[6] However, up to now, no systematic investigations on the formation pathway of acrolein were reported in the literature.

Thus, two kinds of labeled triacylglycerides were synthesized: in one group of four triacylglycerides only the glycerol backbone was carbon-13 labeled, and in the other group of three labeled triacylglycerides the entire fatty acid moiety of either stearic, oleic, and linoleic acid was labeled, whereas glycerol was left unlabeled. All compounds were characterized by LC-MS analysis in APCI$^+$ mode and by NMR spectroscopy ([$^{13}C_3$]-labeled compounds). As an example, the mass spectrum of [$^{13}C_3$]-tristearate (Figure 2) and the respective $^{13}$C NMR spectrum (Figure 3) are shown.

In the next step, the four triacylglycerides labeled in the glycerol backbone were individually heated at 140 °C for 4 h in silicon oil, and the formation of acrolein was measured. In a control experiment, the oil did not show any mass traces at *m/z* 57 (acrolein) or *m/z* 60 ([$^{13}C_3$]-acrolein) when heated for 4 h.

When [$^{13}C_3$]-trioleate was heated (expt 2) (Table 2), the amount of unlabeled acrolein was higher by a factor of >8 compared to the carbon-13 labeled acrolein, clearly indicating the fatty acid moiety as the main precursor structure. The labeled acrolein formed from [$^{13}C_3$]-trilinoleate and [$^{13}C_3$]-trilinolenate (expts 3 and 4) (Table 2) was also as low as found for [$^{13}C_3$]-trioleate, but the amounts of unlabeled acrolein increased with the number of double bonds in the fatty acid moiety, amounting to 6240 μmol/mol from the linolenic acid residues. By contrast, from the saturated [$^{13}C_3$]-tristearate no acrolein was formed (expt. 1) (Table 2). Altogether, these results proved that the acrolein originates from the fatty acid

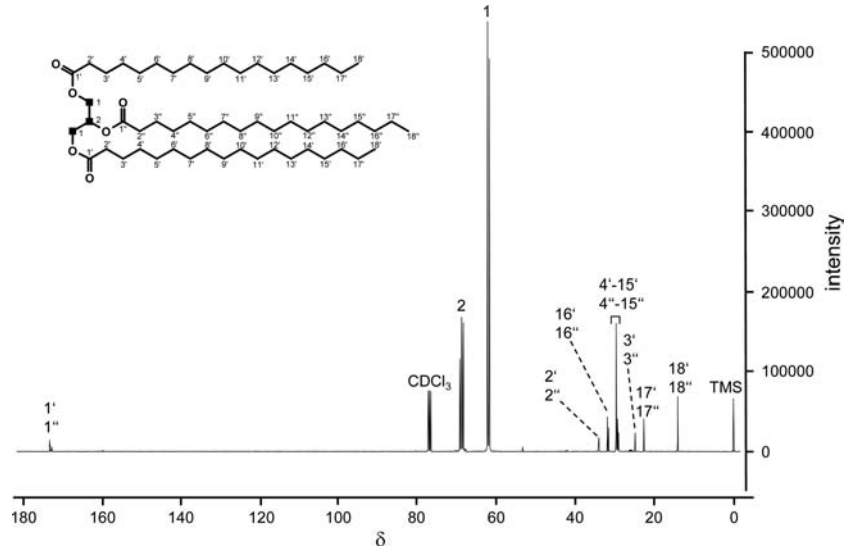

**Figure 3.** $^{13}C$ NMR spectrum of [$^{13}C_3$]-glyceryl tristearate. (■) $^{13}C$-labeling.

**Table 2. Amounts of Unlabeled Acrolein and [$^{13}C$]-Acrolein Formed by Heating of Triacylglycerides Labeled either in the Glycerol Backbone ([$^{13}C_3$]-Compounds) or in the Fatty Acid Moieties ([$^{13}C_{54}$]-Compounds) at 140 °C for 4 h**

| | | concn[a] (μmol/mol precursor) | |
|---|---|---|---|
| expt | precursor | [$^{13}C_3$]-acrolein | acrolein |
| 1 | [$^{13}C_3$]-tristearate | nd[b] | nd |
| 2 | [$^{13}C_3$]-trioleate | 30 (10−40) | 260 (240−280) |
| 3 | [$^{13}C_3$]-trilinoleate | 30 (20−40) | 710 (680−740) |
| 4 | [$^{13}C_3$]-trilinolenate | 40 (30−60) | 6240 (5980−6310) |
| 5 | [$^{13}C_{54}$]-tristearate | nd | nd |
| 6 | [$^{13}C_{54}$]-trioleate | 240 (220−260) | 20 (10−40) |
| 7 | [$^{13}C_{54}$]-trilinoleate | 780 (760−810) | 20 (10−30) |

[a]Mean values of three independent heat processings. Concentration ranges in parentheses. [b]Not detected (limit of detection = 0.25 μmol).

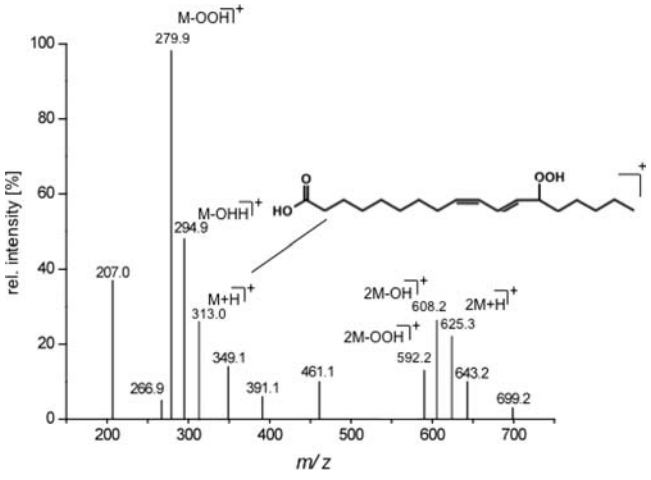

**Figure 4.** Mass spectrum (APCI$^+$) of 13-hydroperoxy-(*E*,*Z*)-9,11-octadecadienoic acid.

moiety of triacylglycerides containing at least one double bond. Further experiments with the triglycerides containing the labeled fatty acid moieties corroborated this finding. From these precursor triacylglycerides, higher amounts of [$^{13}C_3$]-acrolein were formed as compared to unlabeled acrolein, with trilinoleate being more effective than trioleate (expts 6 and 7) (Table 2). Again, the labeled tristearate did not form acrolein, which leads to the suggestion that at least one double bond in the fatty acid moiety is needed to initiate the formation of acrolein from the fatty acid moiety or the glycerol backbone. Thus, these results are additional proof that the fatty acid moiety plays the major role in acrolein formation. For the first time, the high precursor potential of unsaturated fatty acid moieties compared to the glycerol backbone, which was considered as a main acrolein precursor until now,[28] was proven. Hence, this model system is well in line with former findings that linseed oil containing high amounts of linolenic acid showed the highest precursor potential.[6]

**Table 3. Amounts of Acrolein Formed either from Free Linoleic Acid and Free Linolenic Acid or from 13-Hydroperoxy-(*Z*,*E*)-9,11-octadecadienoic Acid (13-HPOD) and 13-Hydroperoxy-(*Z*,*E*,*Z*)-9,11,15-octadecatrienoic Acid (13-HPOT) during Heating at 140 °C for 4 h**

| expt | precursor | concn[a] (μmol/mol precursor) |

*Stable Isotope Labeling Studies with Fatty Acid Hydroperoxides.* To get more information about the transient reaction steps of acrolein formation from fatty acids, the precursor potential of fatty acid hydroperoxides was studied. The high regio- and stereospecifity of soybean lipoxygenase type I was used to synthesize the 13-hydroperoxides of linoleic as well as of linolenic acid. The mass spectrum of the 13-hydroperoxide from linolenic acid showed high fragmentation (APCI$^+$) (Figure 4), which was advantageous for the identification of the target molecule.

Single-model experiments with defined amounts of either free linoleic acid or linolenic acid as well as the respective 13-hydroperoxides were performed in silicon oil at 140 °C for 4 h. Also, the free linoleic acid and the free linolenic acid generated acrolein, with linolenic acid being the better precursor (expts 1

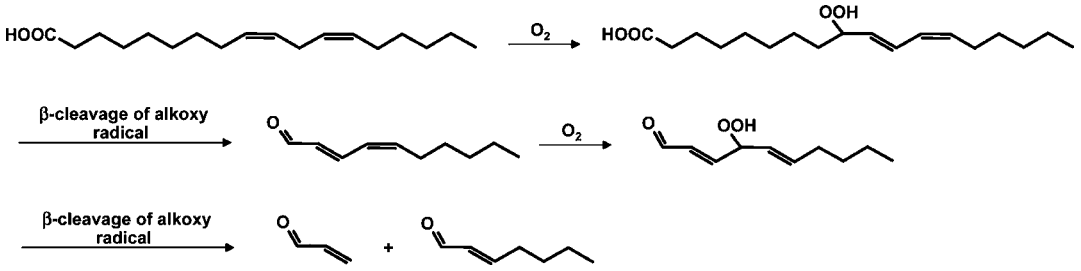

**Figure 5.** Reaction pathway leading to acrolein via 9-hydroperoxy-(*E*,*Z*)-10,12-octadecadienoic acid (following the idea of ref 32).

**Table 4. Influence of the Type of Fat Used in the Frying Process of Several Foods on Acrolein Formation**

| | acrolein concn[a] (μg/kg) in food after frying using | | | |
|---|---|---|---|---|
| sample | safflower oil | rapeseed oil | frying fat | commercial samples[b] |
| potato chips | 17.0 (15.3−17.9) | 23.3 (22.0−24.9) | 16.3 (15.1−17.1) | 18.3 (16.9−19.7) |
| French fries | 18.1 (15.5−19.8) | 14.8 (12.6−17.1) | 19.9 (17.4−22.5) | 18.5 (16.4−19.8) |
| donuts | 14.4 (11.3−15.5) | 15.0 (14.1−15.9) | 14.1 (11.7−16.3) | 16.9 (15.3−18.0) |

[a]Mean values from three independent frying processes. Concentration ranges in parentheses. LoD = 3 μg/kg, LoQ = 9 μg/kg according to ref 39. [b]For comparison.

and 2) (Table 3). Heating of the respective hydroperoxides led to higher amounts of acrolein with the 13-linolenic acid hydroperoxide generating higher amounts (expts 3 and 4) (Table 3). Thus, these results suggest that the formation of hydroperoxides is an important step in acrolein formation, leading to the introduction of the oxygen moiety.

In the literature, it was proposed that acrolein may originate from the unsaturated part of the aliphatic chain, that is, by *β*-cleavage of 9-hydroperoxides resulting in the respective aldehyde and an alkyl fragment. By Hock fragmentation, the released carbonyls lead to two aldehyde fragments (Figure 5). Contrary to the suggested mechanism via linolenic acid 13-hydroperoxide,[10] this pathway may also explain acrolein generation from the monounsaturated oleic acid. To the best of our knowledge, these results are the first proof for acrolein generation from fatty acid hydroperoxides.

**Identification and Quantitation of Acrolein in Fried Foods.** In the next experiments, it was clarified whether a high concentration of acrolein in the frying oil must consequently result in high amounts in the fried food. Thus, French fries, donuts, and potato chips were fried either in oils high in unsaturated fatty acids, such as safflower oil and rapeseed oil, or in a commercial frying fat. As previously shown,[6] rapeseed oil in particular generated the highest amounts of acrolein simply by heating without foods. Acrolein quantitation in the self-prepared as well as in the commercial samples revealed comparable amounts of acrolein, nearly independently from the type of frying oil used (Table 4). Acrolein concentrations in fried potato chips ranged from 16.3 μg/kg prepared with a common frying fat to 23.3 μg/kg using rapeseed oil, and the analysis of commercial potato chips revealed an acrolein concentration of 18.3 μg/kg. The average acrolein content in French fries ranged from 14.8 μg/kg prepared in rapeseed oil to 19.9 μg/kg in frying fat. Analysis of fried donuts showed slightly lower acrolein concentrations compared to the other food samples with 14.1 μg/kg in donuts fried in frying fat, 15.0 μg/kg in donuts prepared in rapeseed oil, and 16.9 μg/kg in donuts from a local bakery (Table 4).

Compared to the acrolein amounts measured in heated fats and oils from previous studies (46.8 mg/kg of safflower oil, 55.8 mg/kg of frying fat, 157 mg/kg of rapeseed oil; heating conditions, 180 °C/24 h),[6] the fried food itself does not seem to be a significant source of free acrolein in the human diet.

In conclusion, the formation pathways of the toxicologically relevant acrolein were proven on the basis of labeling experiments. A formation pathway from the carbon backbone of unsaturated fatty acids, in particular, linolenic acid via the 13-hydroperoxide, seems very likely, whereas the glycerol backbone does not play a key role. Surprisingly, however, acrolein was low in different types of foods, although the investigated oils and fat were high in acrolein. This result suggests that acrolein might be bound to, for example, macromolecular structures in foods, thus no longer existing in the free state. Experiments to study this assumption are currently underway due to the fact that Watzek et al.[40] were able to show that the amounts of acrolein-related mercapturic acids excreted in urine after potato crisp intake were much higher than calculated from the previously analyzed amounts of free acrolein in the crisps.

[§]Institute of Pharmacy and Food Chemistry, University of Würzburg, Am Hubland, 97074 Würzburg, Germany

**ABSTRACT:** This study describes the approach of $^1$H NMR profiling for the authentication of organically produced tomatoes (*Solanum lycopersicum*). Overall, 361 tomato samples of two different cultivars and four different producers were regularly analyzed during a 7 month period. The results of principal component analysis showed a significant trend for the separation between organically and conventionally produced tomatoes ($p < 0.001$ using the $t$ test). Linear discriminant analysis demonstrated good discrimination between the growing regimens, and external validation showed 100% correctly classified tomato samples. Further validation studies, however, also disclosed unexpected differences between individual producers, which interfere with the aim of predicting the cultivation method, yet the results indicate significant differences between $^1$H NMR spectra of organically and conventionally grown tomatoes.

**KEYWORDS:** *$^1$H NMR, multivariate data analysis, tomato, Solanum lycopersicum, organic, conventional*

## INTRODUCTION

The demand for organically produced food has been increasing considerably; it almost tripled between 2002 and 2011, when its market share reached a worth of U.S. $62.8 billion.[1] Because consumers are prepared to purchase organic food at higher prices, the risk for conventional produce fraudulently labeled as "organic" has also been increasing. To prevent and detect counterfeit, there is a strong need for analytical methods that allow the verification of organic cultivation. This study examines the differentiation between organically and conventionally grown tomatoes (*Solanum lycopersicum*), which are widely consumed in Europe,[2] by means of multivariate data analysis of $^1$H NMR spectra.

Within the European Union, the requirements for organic farming are stated in Council Regulation (EC) 834/2007 and Commission Regulation (EC) 889/2008. With respect to the ban of the use of synthetic pesticides and synthetic mineral fertilizer for organic farming, there are a variety of starting points for analytical differentiation.

Organically produced food is often associated with statements about a better nutritional value due to allegedly increased contents of bioactive compounds and lower levels of pesticides and contaminants. Higher contents of polyphenolic compounds and higher antioxidant capacity were analyzed for tomatoes,[3] tomato ketchup,[4] and tomato juice.[5] However, the amounts of bioactive compounds are influenced by variations due to crop year, origin,[6,7] amount of fertilizer and soil nitrate,[8] stage of maturity,[9,10] and ripening type.[11] Thus, differences in organic and conventional tomatoes were occasionally inconsistent within different varieties or crop years,[12,13] and individual results are hardly comparable due to different conditions in cultivation.[14] Pesticide screening of organic food is meaningful to detect the illegitimate usage of synthetic pesticides, yet residue findings can also be the result of contaminations from nearby conventional farms or anthropogenic inherited waste. Furthermore, conventional farming is not necessarily combined with the use of pesticides for plant protection, which, especially in greenhouse cultivation, can also be performed by means of beneficial insects.

Other studies show that nitrogen fertilization affects the composition of amino acids in vegetables,[15] whereas these results are likewise affected by variety[16] and degree of ripeness.[17,18] Furthermore, variations in the pattern of mineral concentrations in organically and conventionally grown tomatoes have been described,[19] which may be attributed to the metabolism of arbuscular mycorrhizal fungi in organic soils.[20]

Up to now, the most reliable analytical method for authentication is presented by the composition of the nitrogen isotope: the nitrogen isotope composition of the fertilizer predefines the nitrogen isotope composition of the grown crop.[21−23] As the nitrogen of synthetic mineral fertilizer originates from atmospheric nitrogen with a $\delta^{15}$N value around 0‰ ($\delta^{15}$N is expressed as the relative difference from atmospheric nitrogen as standard), improper usage of conventional fertilizers can be identified by lower $\delta^{15}$N values than common values for organic farming.[21] However, there exists an overlap between the $\delta^{15}$N values of organically and conventionally grown crops[24] that suggests the development of further analytical methods for the verification of the growing regime.

As recently described by Esslinger et al.,[25] the application of spectroscopic data combined with multivariate data analysis to verify food authenticity is becoming increasingly important. Using these profiling techniques is especially reasonable in the area of food products, where attributes of authenticity represent unique quality parameters and legitimate higher prices, as is the case for organic food. Previous examples of use cover authenticity control in terms of analyzing botanical[26] or geographical origin[27,28] and adulteration[29] of honey, geographical origin[30−33]

and adulteration[34] of olive oil, botanical[35] or geographical origin[36−40] and quality[41] of wine and authenticity control of fruit juice.[42] Both the multitude of recent applications and their output of results show the importance of $^1$H NMR profiling in terms of authenticity analysis.

Previous NMR measurements of tomatoes and tomato products focused on carotenoid composition,[43] degree of ripeness,[44,45] quantitative NMR,[4] magnetic resonance imaging (MRI) measurements,[46] or diverse 2D NMR experiments.[47] Here, the suitability of $^1$H NMR profiling for the purpose of differentiation between organic and conventional tomatoes is discussed. Our key aim is the development of a sufficient method for an authentication of organic tomatoes against the background of food surveillance and consumer protection, independent from nutritional perspectives.

Because no set definition for organic or conventional farming exists, there is ample scope for a variety of cultivation methods. For example, numerous fertilizers may be used and fruits can be grown in greenhouses as well as on open land. It is accordingly unfeasible to create an experimental design that fulfills the possible growing conditions in all facets. In this study, attention was turned on greenhouse cultivation, and authentic tomatoes were grown conventionally with mineral substrate and mineral fertilizers as well as organically with soil and organic fertilizers. An essential difference of these cultivation methods may be represented by different nitrogen availabilities. This cultivation experiment certainly does not reflect the wide range of actually existing ways of farming, but rather demonstrates a proper starting point to verify the basic suitability of $^1$H NMR profiling for a differentiation between organically and conventionally grown tomatoes.

## MATERIALS AND METHODS

**Sample Collection.** *Cultivation Experiment (CE).* The tomato cultivars Mecano and Tastery were grown in two different greenhouses at the Bavarian State Research Institute of Viticulture and Horticulture, both organically and conventionally (LWG, Bamberg, Germany; tomato samples are referred to as "CE organic" and "CE conv" in the following text). Thereby, conventional growing conditions were carried out as hydroponic culture using perlite substrate and mineral fertilizer, whereas organic growing conditions were carried out using soil and clover-grass silage, vinasse, Patentkali, sheep's wool, and winter rye (previous culture for green manure) as organic fertilizer. Except for conventionally grown tomatoes of the cultivar Mecano (planted in both January and March), all plants were grown in March. For each cultivar and farming method at least three parcels of tomato plants (each consisting of 10 plants) were grown: for organic cultivation of Mecano, 4 parcels, and for Tastery, 4 parcels; for conventional cultivation of Mecano, 7 parcels (thereof 3 parcels with tomatoes planted in January and 4 parcels planted in March), and for Tastery, 5 parcels. Harvesting was performed at regular intervals of 2 weeks between weeks 21 and 45 (13 harvest times), and sampling was done by picking tomatoes systematically from different plants in the greenhouse. Tomatoes from each parcel were analyzed individually and, in addition, tomatoes from equal parcel of the same cultivation method and cultivar were pooled to one mixed sample for analysis. At this, altogether 325 CE samples were analyzed, with 52 samples from tomatoes planted in January and 273 samples from tomatoes planted in March.

*Trading Firms (TF).* Additionally, three trading firms (referred to as "TF organic", "TF conv 1", and "TF conv 2" in the following text) cultivated the same cultivars (Mecano and Tastery). Conventional growing conditions were again carried out as hydroponic culture using perlite substrate and mineral fertilizer, and organic growing conditions were carried out using soil and hair meal and compost as organic fertilizer. Fruits were harvested from May to October once a month, so that in total 36 tomato samples were analyzed (3 producers × 2 cultivars × 6 months).

*Validation Data Set Comprising CE and TF Tomato Samples.* To test the suitability of statistical models, an external validation data set was created by systematically excluding both CE and TF tomato samples from calibration (validation of LDA1): overall, 81 tomato samples, organically grown at CE (harvested at weeks 23, 31 and 39), conventionally grown at CE (harvested at weeks 27, 35, and 43; excluding tomatoes planted in January), and organically grown at TF (harvested at weeks 21, 29, and 37) as well as conventionally grown at TF (harvested at weeks 24, 32 and 40), were used for validation purposes.

*Additional Tomato Samples for Validation.* In addition, several other fruits were analyzed and used for validation (validation of LDA2):

The cultivar Tica was grown under the same conditions as organically grown CE tomatoes. Fruits from six different parcels were harvested individually and as a pooled sample of these parcels at week 30 and another pooled sample of these parcels at week 35, resulting in overall eight tomato samples.

Furthermore, cultivars Mecano and Tastery, grown at the CE (planted in March), were harvested as ripening (red-turning) tomatoes at week 35. Overall, 4 tomato samples were measured, one for each cultivar and type of farming.

From another producer (school for horticulture in Fürth, Germany), the cultivar Mecano was grown conventionally in a greenhouse using mineral fertilizer and different substrates: cocos-plate, wood-perlite mixture, and perlite. Fruits were harvested at weeks 30 and 31, with one tomato sample for each substrate, yielding six tomato samples.

**Chemicals.** For 1 M NaOH and 1 M HCl, NaOH pellets were purchased from VWR (Leuven, Belgium) and HCl (37%) from Sigma-Aldrich (St. Louis, MO, USA). $TSPd_4$ (3-(trimethylsilyl)propionic acid-$d_4$ sodium salt, 98 atom % D), $D_2O$ (99.9 atom % D), EDTA (ethylenediaminetetraacetic acid), and $NaN_3$ were purchased from Merck (Darmstadt, Germany).

**Sample Preparation.** At least 250 g of tomato was pureed and subsequently stored at −18 °C. After thawing, the samples were centrifuged for 5 min at 3528*g*, and the residual liquid tomato phase was used for subsequent $^1$H NMR measurement. For this purpose, 900 $\mu$L of liquid tomato phase was mixed with 100 $\mu$L of TSPd4 solution (containing 7 mM TSPd4, 10 mM EDTA, and 2 mM $NaN_3$ in $D_2O$), and the pH value of all samples was adjusted to pH 4.00 ± 0.03 using 1 M NaOH or 1 M HCl. Finally, 600 $\mu$L of the pH-adjusted solutions was filled into 5 mm NMR tubes (PP-507, purchased from Rototec-Spintec, Griesheim, Germany) for NMR measurement.

**$^1$H NMR Measurement.** Hardware and software equipment used for NMR measurement was completely purchased from Bruker (Bruker BioSpin, Rheinstetten, Germany) comprising a Bruker Avance 400 spectrometer with a 5 mm SEI probe with *Z*-gradient coils, an automatic sample changer (B-ACS-60), a BCU 05 temperature unit, and TopSpin 3.0 software.

All tomato samples were measured at 301.8 ± 0.1 K, without rotation and using 4 dummy scans prior to 128 scans. Acquisition parameters have been set as follows: size of fid = 64K, spectral width = 20.5524 ppm, receiver gain = 16, acquisition time = 3.98 s, relaxation delay = 10 s, FID resolution = 0.25 Hz. Data acquisition was achieved using an experiment with a NOESY presaturation pulse sequence (Bruker 1D noesygppr1d) with water suppression via irradiation of the water frequency during the recycle and mixing time delays. The spectra were automatically phased, baseline-corrected, and calibrated to the TSP signal at 0.0 ppm.

**Multivariate Statistical Analysis.** Data reduction was achieved by transforming NMR spectra into buckets (bundling spectral regions to one rectangular bucket, whereas the value of a bucket represents the signal intensity of the respective spectral region). Two different types of buckets (given in Table 1) were generated with Amix 3.9.12 software (Bruker Biospin GmbH).

Subsequent multivariate data analysis was done on the assumption of normally distributed data. Principal component analysis (PCA) was performed with Unscrambler X version 10.0.1 (Camo Software AS, Oslo, Norway) with buckets of $^1$H NMR spectra scaled to unit variance. Linear discriminant analysis (LDA) of buckets was carried out with SPSS statistics 21 (IBM Corp., Armonk, NY, USA) using equal a priori probabilities for all groups and stepwise selection procedure

**Table 1. Description of the Bucketing Process and the Application of Buckets for Multivariate Data Analysis**

| | bucketing 1 | bucketing 2 |
|---|---|---|
| spectral region | 0.00−10.00 ppm | 2.86−8.67 ppm |
| exclusions | 4.85−4.67 ppm | 7.91−6.67 ppm |
| | 3.70−3.60 ppm | 6.12−5.39 ppm |
| | 1.22−1.14 ppm | 5.02−4.49 ppm |
| | | 3.15−2.98 ppm |
| reason for exclusions | elimination of residual water and ethanol signals (NMR tubes were reused and washed with ethanol) | elimination of irrelevant signals for a differentiation between organic and conventional tomato samples |
| bucket width | 0.200 ppm | 0.007 ppm |
| application | PCA, LDA1 | LDA2 |

(chosen method, minimization of Wilks' lambda; selection criterion, $F$ probabilities of 0.050 for inclusion and 0.100 for exclusion for LDA1 and 0.005 for inclusion and 0.010 for exclusion for LDA2). $t$ tests were performed using OriginPro 9G software (OriginLab Corp., Northampton, MA, USA).

## RESULTS AND DISCUSSION

**$^1$H NMR Measurement and Optimization of Sample Preparation.** On average, tomatoes contain 94% water and the remaining 6% of dry matter consists of 55% sugar (mainly glucose and fructose), 20% alcohol-soluble constituents (proteins, cellulose, pectin, and polysaccharides), 12% organic acids (mainly citric acid), 8% inorganic substances (minerals), and 5% of other substances, such as amino acids.[48] Hence, $^1$H NMR spectra of tomatoes are dominated by signals of sugar and citric acid, whereas an enlarged view also reveals diverse amino acids and other minor components (Figure 1 and Table 2). Thereby, the signals obtained are in good agreement with those reported previously.[49]

As several citrate species exist in fast exchange with each other (protonated or ionic, complexed with $Ca^{2+}$ and $Mg^{2+}$), the observed citrate signal represents an average of the signals from those species.[50] Additionally, broadened lines can arise from paramagnetic substances that lead to enlarged values of line width by shortening T2 relaxation times.[51,52] To achieve high resolution and optimized line widths, small amounts of EDTA were added to each sample, because EDTA enables signal sharpening via serving as chelating agent. With regard to the $^1$H NMR spectra of tomato samples, especially the line width of citric acid was clearly reduced by the addition of EDTA, whereas no major effects on chemical shifts could be detected.

For the best possible conditions for multivariate data analysis, highest reproducibility has to be achieved. Therefore, all samples were pH adjusted (pH 4.00 ± 0.03) to minimize variation in chemical shifts due to protonation or deprotonation processes. As the chemical shift of citric acid is highly influenced by deviations from the requested pH value, it was used as a quality marker for adequate pH adjustment to define control limits for tolerable chemical shift deviations (deviations up to ±3.5 Hz from the left signal top of the citric acid duplet at 2.881 ppm were accepted).

**Principal Component Analysis.** To get an overview of the given data, PCA was performed with $^1$H NMR spectra of tomatoes from both cultivars and types of farming (309 tomato samples are included in the evaluation, 273 from CE, excluding fruits planted in January, and 36 from TF).

The scatter plot of PC1 versus PC4 (Figure 2) shows the separation of the two cultivars Mecano (circles) and Tastery (triangles) along PC1. With the aim of recognizing the effect of different cultivars, two very dissimilar cultivars were analyzed (Tastery is small fruited with an average weight of 20 g/fruit, and Mecano is normally fruited with an average weight of 100 g/fruit) and, thus, differentiation according to their cultivar is quite

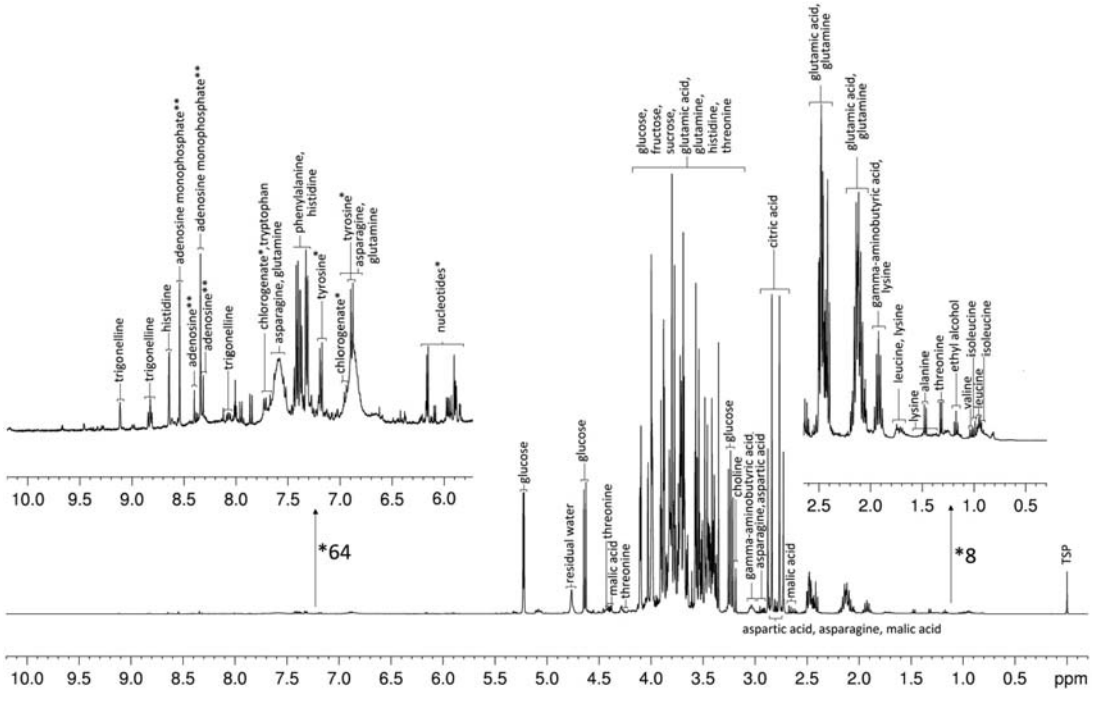

**Figure 1.** $^1$H NMR spectrum of the aqueous phase of a tomato sample with an enlarged view on the spectral range from 0.5 to 2.6 ppm (*8) and from 5.8 to 10.0 ppm (*64), measured with a 400 MHz spectrometer. Signal assignments are based on reference spectra and the literature (*Mounet et al.;[45] and **Le Gall et al.[53]).

understandable. In addition, a separation of the organically and conventionally grown groups is apparent for each cultivar, notably along PC4: both Mecano and Tastery show higher values of PC4 for the conventional than for the organic group. Given the existing overlap of organic and conventional tomato samples, values of PC4 are not capable of a reliable classification of organic fruits. Nevertheless, the findings confirm the approach that $^1$H NMR spectra show significant differences between the cultivation methods ($p < 0.001$ using $t$ test of PC4 values).

Comparability of all other impact parameters has to be ensured to reason that differences between organic and conventional tomato samples can be attributed to the kind of growing regimen. As immoderate heating of greenhouses is contradictory to the concepts of environmental acceptability for organic cultivation,

dx.doi.org/10.1021/jf502113r | J. Agric. Food Chem. 2014, 62, 8530−8540

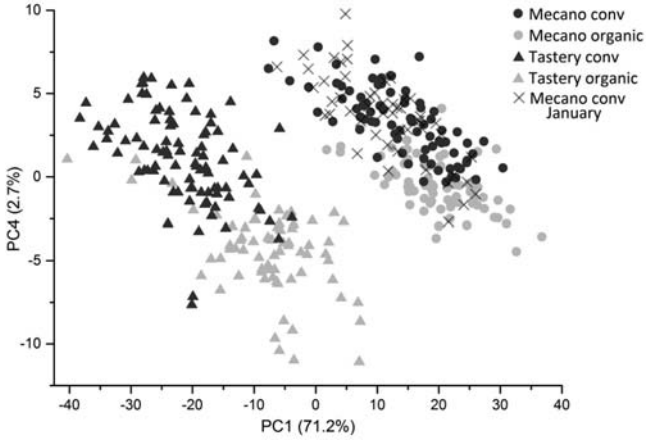

**Figure 2.** Scatter plot of PC1 versus PC4: triangles, Tastery; circles, Mecano; dark gray data points, conventional tomatoes; light gray data points, organic tomatoes. The group of Mecano conventionally planted in January is projected into the PCA plot and marked by crosses.

the planting is commonly performed later than in case of conventional farming using intensively heated greenhouses. To determine whether potential differences in organic and conventional tomatoes are irrespective of the planting date, Mecano cultivar was planted conventionally in both January and March, and $^1$H NMR spectra were subsequently checked for differences. When the group of Mecano cultivar planted in January was projected into the previously mentioned PCA model, no data separation from the group of conventionally grown Mecano cultivar planted in March is recognizable (Figure 2). Hence, the planting date evidently did not affect the composition of tomato ingredients.

Next, PCA was performed with each cultivar individually with overall 148 NMR spectra for Mecano cultivar (130 for CE planted in March and 18 for TF) and 161 NMR spectra for Tastery cultivar (143 for CE and 18 for TF). PCA scatter plots show a significant separation ($p < 0.001$ using $t$ test) between the groups of organically and conventionally grown tomatoes for both cultivars, observed along PC3 for Mecano and along PC1 for Tastery (Figure 3). Because PC3 explains only 4.6% of the data variance for the PCA of Mecano in comparison to PC1 with 55.8% explained variance for the PCA of Tastery, variations of $^1$H NMR spectra according to the type of farming seem to have a higher impact on the total variance in $^1$H NMR spectra for Tastery than for Mecano.

**Linear Discriminant Analysis.** Just as PCA, LDA forms linear combinations of variables to best explain the given data. The main difference between PCA and LDA is the fact that LDA is a supervised method. At first, each sample is assigned to a group subject to the sample's properties. Second, discriminant variables are examined by weighing the sample's variables, so that the differentiation between the predefined groups is maximized and differences of samples within one group are minimized. Once a discriminant analysis has been carried out, the resulting model can serve for an assignment of unknown samples to one of the predefined groups.

At first, LDA was performed with the two groups of organically or conventionally produced tomatoes (LDA1; altogether 309 NMR spectra were used for examination, 273 for CE, with tomatoes planted in March, and 36 for TF). As can be seen in Figure 4, the groups are successfully separated without any region of overlap. Moreover, the unwanted differentiation of the cultivars Mecano and Tastery does not occur because variables for cultivar separation are consciously weighted low in the computation of LDA.

The major disadvantage of supervised multivariate data analysis techniques such as LDA is the risk for building overfitted models. A possibly biased focus on model samples can hamper the application of group prediction for other samples. Hence, representative model samples are a key prerequisite for capable LDA models. In this context, validation of LDA1 was performed to evaluate the suitability for a prediction of the group membership.

The data set was separated into a calibration data set and a validation data set in two different ways. First, the calibration data set was created by systematically excluding both tomato samples

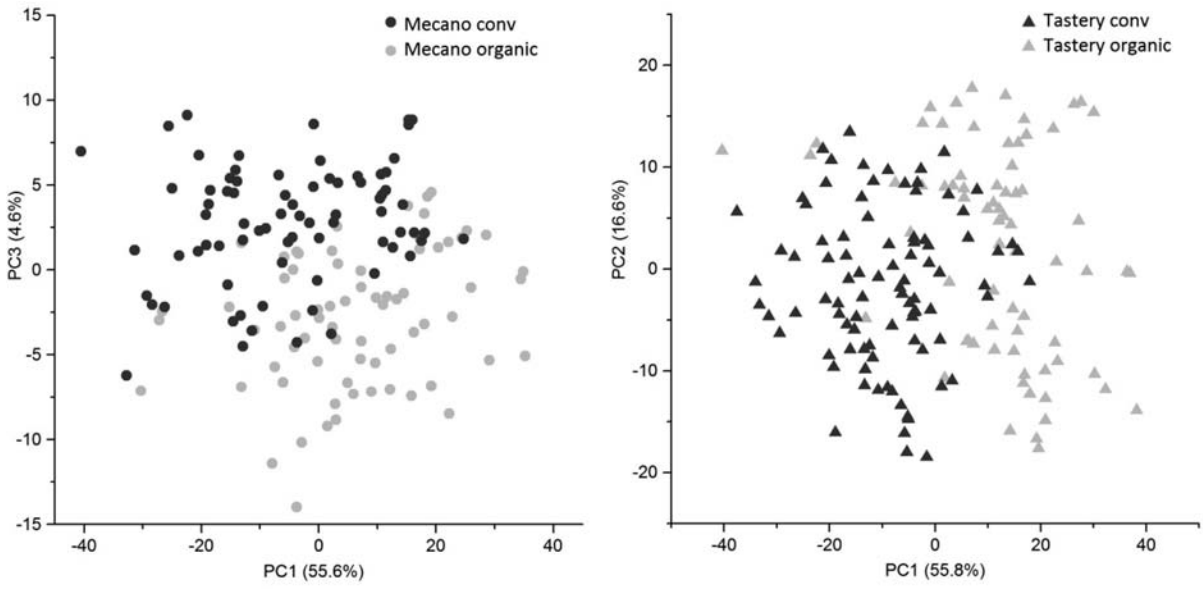

**Figure 3.** Scatter plots of PC1 versus PC3 of PCA for Mecano samples (circles; left side) and PC1 versus PC2 for Tastery samples (triangles; right side): dark gray data points, conventional tomatoes; light gray data points, organic tomatoes.

dx.doi.org/10.1021/jf502113r | J. Agric. Food Chem. 2014, 62, 8530−8540

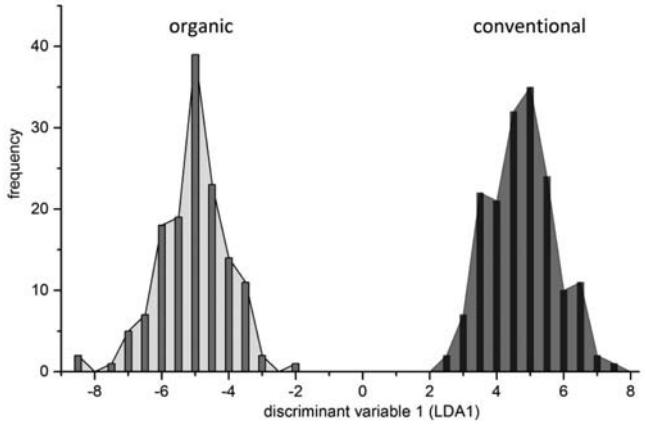

**Figure 4.** Frequency histogram of the values of discriminant variable 1 obtained by LDA1: dark gray, conventional tomato samples; light gray, organic tomato samples.

from CE and TF for validation. Overall, 81 tomato samples formed the validation data set, which is 26.21% of all 309 tomato samples (see Materials and Methods). In this case, validation showed excellent results with 100% correctly predicted group identities. Second, fruits from CE were used as calibration data set and fruits from TF as validation data set. Thus, merely 72.2% of group identities were predicted correctly.

When the calibration model is based only on fruits grown at CE, it is rather differentiating between the two specific CE greenhouses than between organic and conventional tomatoes in general, which makes it inapplicable for a group prediction of tomatoes from TF. In this context, the promising validation results (when both CE and TF tomato samples are included in the calibration data set) need to be questioned critically in terms of a basic suitability for an authentication of organic tomatoes from other producers. However, this validation illustrates the potential for differentiation if representative cultivation conditions are taken into consideration for LDA.

At this point the question arises whether it is possible to build a sufficient database of $^{1}$H NMR spectra from authentic tomatoes that fulfills the requirement to reflect the actually given variety of variable organically and conventionally grown tomatoes. Given the limitation of the present data set, this question cannot be answered yet, but the results so far suggest an extension of the experimental design with additional tomato varieties, producers, and farming conditions.

Moreover, it is reasonable to further examine the unwanted differences between greenhouses of the same growing regimen. For this, another LDA (LDA2) was performed with CE and TF tomato samples from each greenhouse classified with a single group, resulting in overall five groups (CE organic, CE conv, TF conv 1, TF conv 2, TF organic). Best separation results were achieved when a selection of spectral regions was used instead of the whole range from 0 to 10 ppm (Table 1). The selection was based on spectral regions with apparent differences between NMR spectra of organically and conventionally grown tomatoes, defined by a visual comparison when overlaying spectra with different colors according to organic and conventional cultivation. This rather represents a preselection, because another stepwise selection (using critical $F$ values) is performed when buckets are undergoing LDA.

The results of LDA2 can be seen at Figure 5. As the two groups of conventional TF tomato samples are hardly separated, it can be assumed that no relevant differences exist between them, yet all other groups are separated well. The unwanted differentiation between CE groups (circles) and TF groups (triangles and squares) appears along discriminant variable 2, showing higher values for CE groups than for TF groups. Besides, the key information on LDA2 is the separation achieved by discriminant variable 1: the conventional groups show higher values of discriminant variable 1 than the organic groups (Figure 5). Thus, the type of farming obviously represents a latent factor herein, and it was tested if LDA2 enables a prediction of the growing regimen based on the value of discriminant variable 1.

For this purpose, first validation steps with additional tomato samples were performed. Basically, two cases of wrong

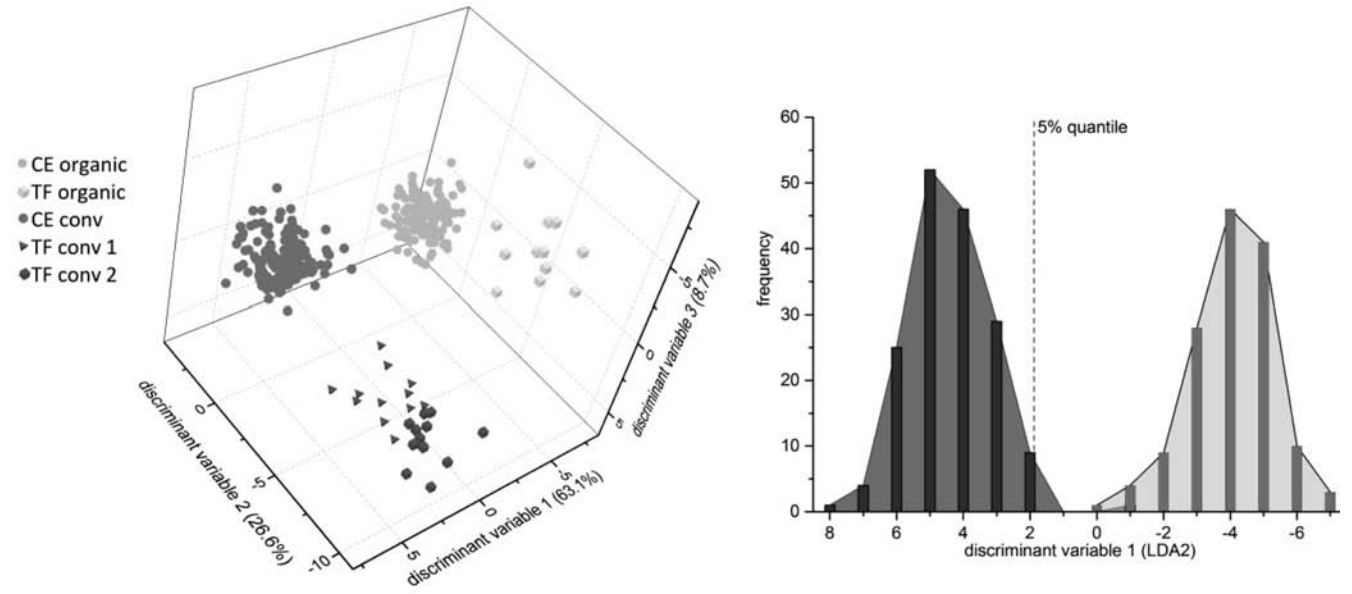

**Figure 5.** 3D scatter plot of discriminant variables 1, 2, and 3, with sphere symbols for CE samples, tetrahedral symbols for TF organic and TF conv 1, and cube symbols for TF conv 2: dark gray data points, conventional tomaotes; light gray data points, organic tomatoes (left side). Frequency histogram of the values of discriminant variable 1 obtained by LDA2: dark gray, conventional samples; light gray, organic samples (the auxiliary line shows the 5% quantile of the values of discriminant variable 1 for conventional tomato samples; right side).

**Table 3. Results for the Prediction of the Growing Regimen Based on the Value of Discriminant Variable 1 (Obtained by LDA2) for Several Additional Tomato Samples (See Materials and Methods)**

| sample type and no. of samples ($n$) | | dv1 (LDA2) | growing regimen | prediction |
|---|---|---|---|---|
| (i) tomatoes of cultivar Tica organically grown at CE ($n$ = 8) | Tica | −1.56 | organic | organic |
| | Tica | −3.85 | organic | organic |
| | Tica | −2.73 | organic | organic |
| | Tica | −5.19 | organic | organic |
| | Tica | −1.79 | organic | organic |
| | Tica | −5.84 | organic | organic |
| | Tica | −5.10 | organic | organic |
| | Tica | −3.76 | organic | organic |
| (ii) tomatoes (cultivar Mecano) of another producer (Fürth, Germany) organically grown using different substrates, ($n$ = 6) | wood-perlite | 1.51 | conventional | organic |
| | wood-perlite | 4.19 | conventional | conventional |
| | cocos | 2.93 | conventional | conventional |
| | cocos | 5.38 | conventional | conventional |
| | perlite | 2.87 | conventional | conventional |
| | perlite | 3.68 | conventional | conventional |
| (iii) unripe (red-turning) tomatoes (cultivars Mecano and Tastery) organically/conventionally grown at CE ($n$ = 4) | Mecano | −3.20 | organic | organic |
| | Tastery | −4.04 | organic | organic |
| | Mecano | 2.41 | conventional | conventional |
| | Tastery | 4.83 | conventional | conventional |

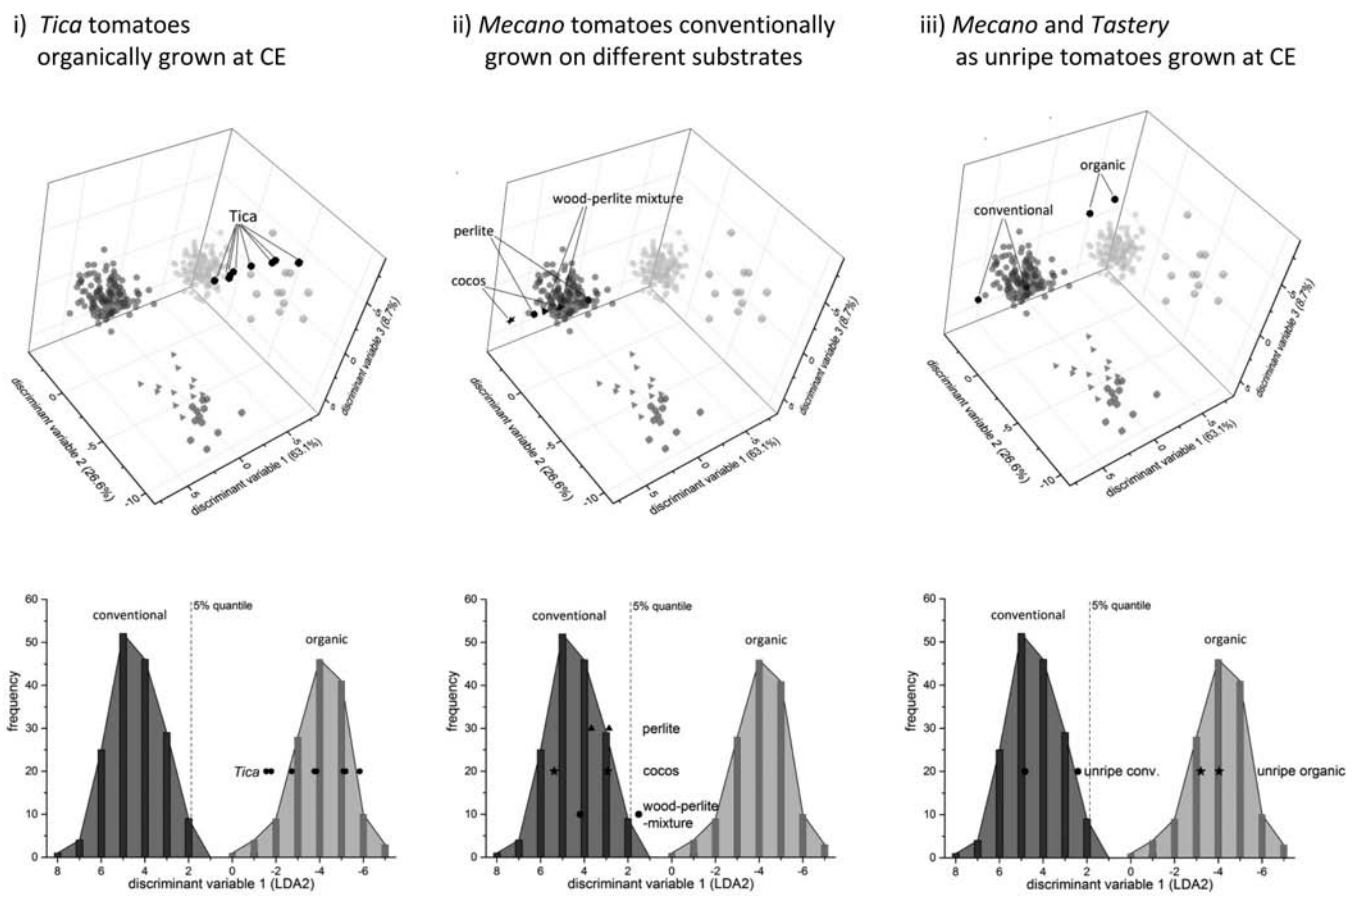

**Figure 6.** Projection of the prediction results for (i) Tica samples (left), (ii) Mecano samples conventionally grown on different substrates (middle), and (iii) unripe CE samples of Mecano and Tastery (right) into the 3D scatter plot of LDA2 (top; see Figure 5) and into the frequency histogram of the values of discriminant variable 1 obtained by LDA2 (bottom; see Figure 5).

predictions can occur: an organic fruit is falsely determined as conventional or a conventional fruit is falsely determined as organic. With the aim of preventing unjust allegations against reliable organic producers, the risk for conventionally grown tomatoes being falsely assigned as organic is rather accepted than the risk for organically grown tomatoes being falsely identified as

dx.doi.org/10.1021/jf502113r | J. Agric. Food Chem. 2014, 62, 8530−8540

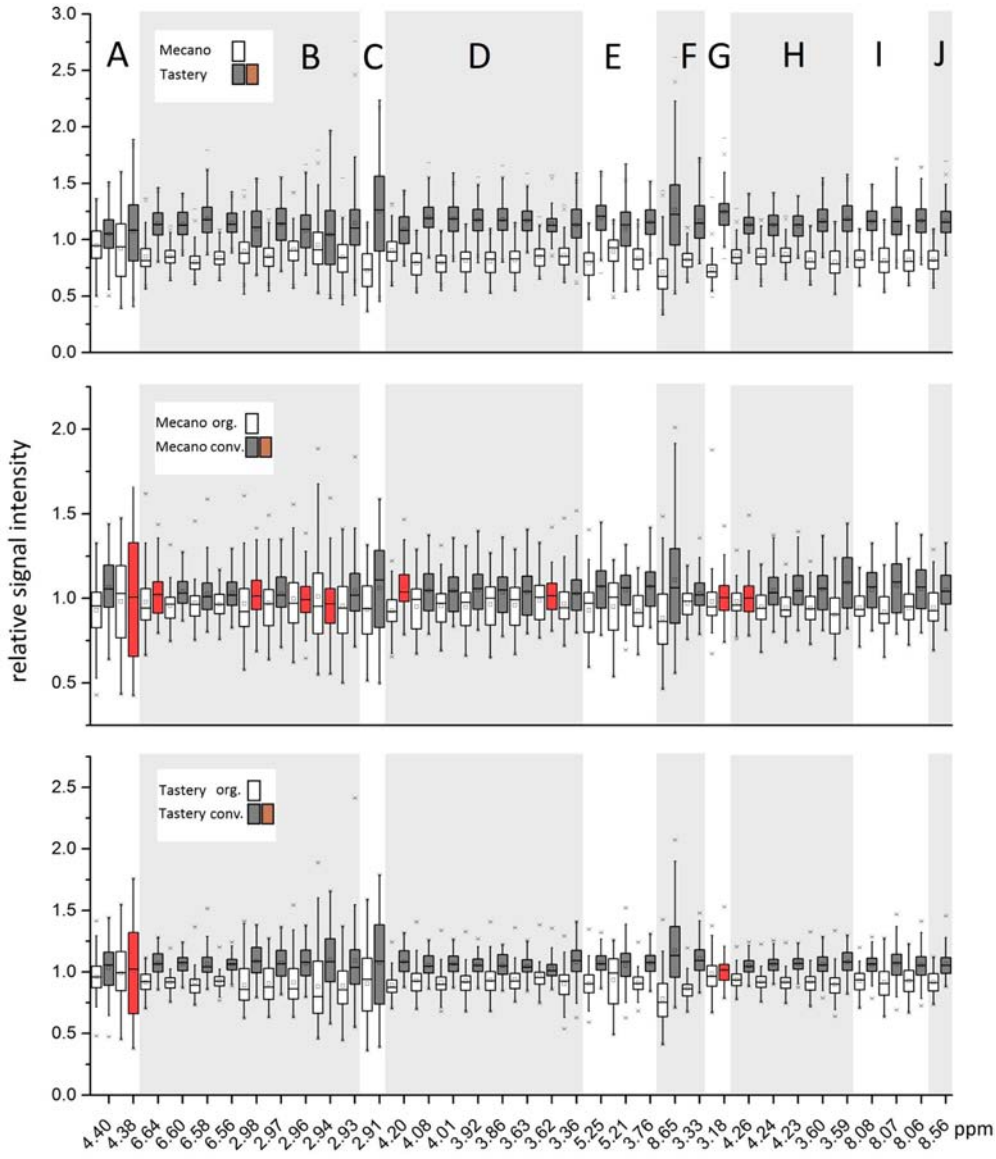

**Figure 7.** Box plot of relative bucket intensities for the cultivars Mecano and Tastery (top) and organically and conventionally grown tomatoes for Mecano (middle) and Tastery (bottom). Each box is determined by the 25th and 75th percentiles and each whisker by the 5th and 95th percentiles. Values higher than 75th percentile +1.5*interquartile range and lower than 25th percentile −1.5*interquartile range are marked by a cross as outliers. Significantly different bucket intensities are colored white/gray, and nonsignificantly different bucket intensities are colored white/red.

conventional. Hence, the decision rule for an assignment was built on the consideration that no more than 5% of conventional tomato samples are accepted to be falsely predicted as organically grown fruits. The value of discriminant variable 1 within LDA2 served as predictive indicator for the validation data set: values lower than the 5% quantile for discriminant variable 1 of conventional tomato samples (discriminant variable < 1.88) were assigned to organic farming and higher values to conventional farming (Figure 5).

In this way prediction was applied for several additional fruits that vary in cultivar, type of substrate for conventional farming, and degree of ripeness (see Materials and Methods). Results are displayed in Table 3 and Figure 6.

The results for the cultivar Tica are very promising, especially when considering that this cultivar was not taken into account within the LDA2 model. Because the cultivar Tica is close to Mecano, it can be assumed that once a cultivar type is part of the model, adequate prediction for similar cultivars can be performed. The results for additional tomato samples grown on different substrates are also satisfying: although no further tomato samples of this specific producer are part of the LDA2 model, correct predictions were achieved for five of six tomato samples, and the falsely predicted one has a value very close to the decision limit of the 5% quantile. Hence, the sort of substrate did not interfere with a prediction of conventional farming. The prediction for unripe fruits of Mecano and Tastery cultivar was right for all samples and, consequently, the degree of ripeness did not hamper an assignment of the cultivation method.

**Designation of Substances That Are Relevant for Differentiation.** In view of the differentiation between organically and conventionally grown tomatoes based on $^{1}$H NMR spectra, it is especially interesting to detect spectral regions and the corresponding substances that are responsible for data separation.

Given the promising validation results for an assignment of the growing regimen based on discriminant value 1 of LDA2, the

dx.doi.org/10.1021/jf502113r | J. Agric. Food Chem. 2014, 62, 8530−8540

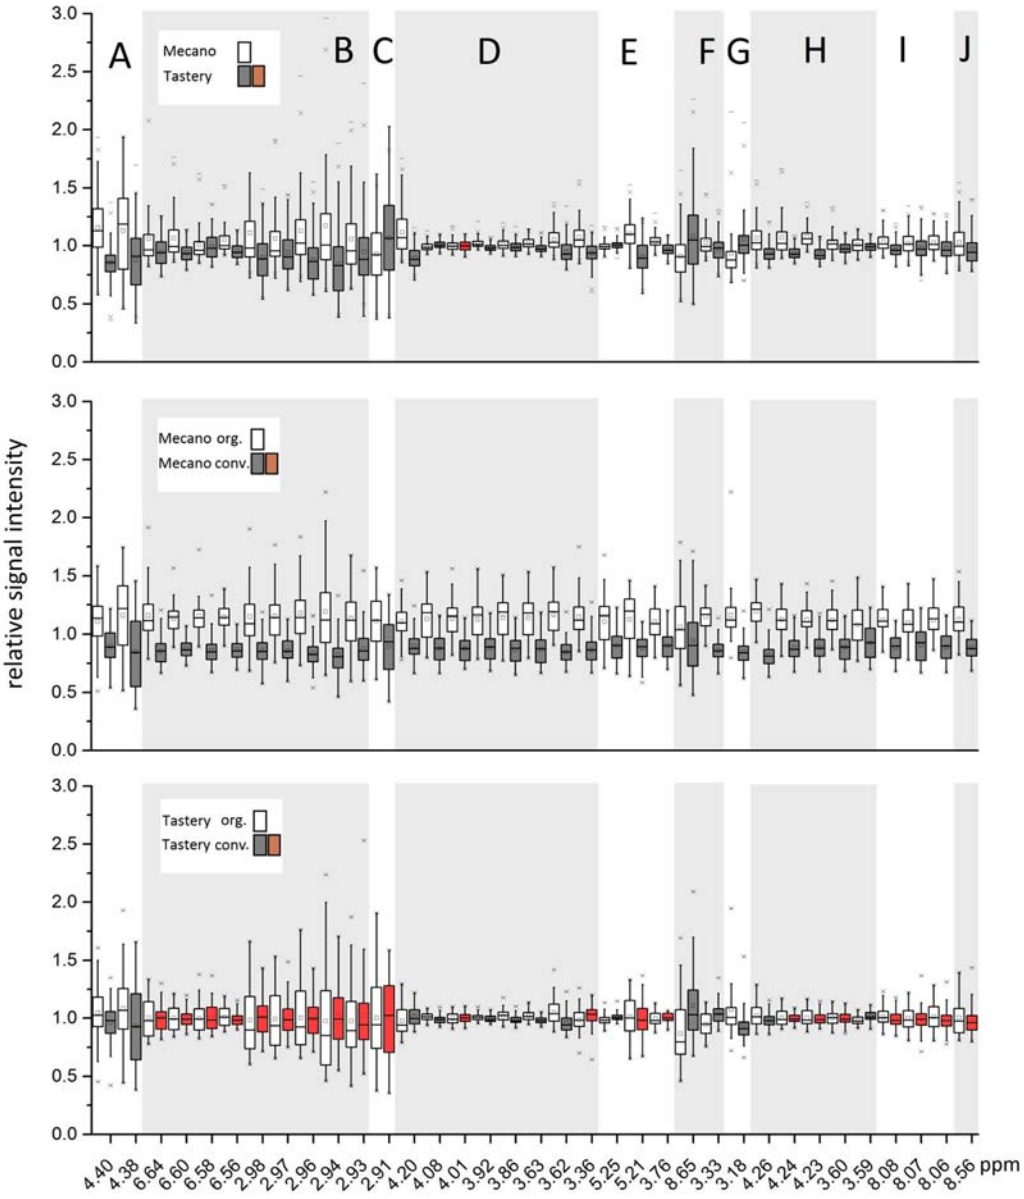

**Figure 8.** Box plot of relative bucket intensities, scaled to total signal intensities of the respective NMR spectra, for the cultivars Mecano and Tastery (top) and organically and conventionally grown tomatoes for Mecano (middle) and Tastery (bottom). Each box is determined by the 25th and 75th percentiles, and each whisker by the 5th and 95th percentiles. Values higher than 75th percentile +1.5*interquartile range and lower than 25th percentile −1.5*interquartile range are marked by a cross as outliers. Significantly different bucket intensities are colored white/gray, and nonsignificantly different bucket intensities are colored white/red.

overall 66 buckets used for its calculation were analyzed in more detail. Thirty-five buckets could be assigned to the reference signals of malic acid (A), asparagine (B), aspartic acid (C), fructose (D), glucose (E), histidine (F), choline (G), threonine (H), trigonelline (I), and adenosine monophosphate (J; assignment according to the literature[53]). These buckets were checked for significant differences between the cultivars Mecano and Tastery as well as for differences between organically and conventionally grown tomatoes between each cultivar.

Figures 7 and 8 show a comparison of the relative bucket intensities within cultivars and growing regimens in a box-plot diagram, whereby nonsignificantly different bucket intensities are highlighted white/red ($t$ test: $p > 0.05$) and significantly different bucket intensities are colored white/gray ($t$ test: $p < 0.05$). Figure 7 illustrates that the bucket intensities are mainly influenced by the tomato cultivar and consistently higher for the group of Tastery than for the group of Mecano. Additionally, within both cultivars, the signal intensities show on average higher values for conventionally grown than for organically grown tomatoes. In this connection, the differences are more distinct for Tastery than for Mecano.

Because the bucket intensities are continuously increased for the respective conventional group, this may be attributed to increased dry matter levels in conventionally grown fruits[2] instead of compositional differences. To reduce the influence of dry matter, the bucket intensities were referred to the total signal intensity of the spectra and again compared within cultivars and cultivation methods (Figure 8; the total intensity was defined as signal intensity from 0 to 10 ppm minus the regions of water and ethanol signals from 4.85−4.67, 3.70−3.60 and 1.22−1.14 ppm).

This scaling procedure massively changes the image of bucket intensities: the separation of Mecano and Tastery as well as the separation of the organic and conventional group for Tastery deteriorated, whereas the separation of organic and conventional Mecano tomato samples improved. Moreover, higher signal intensities are averaged for the organic group compared to the conventional group, opposed to previous results for unscaled buckets.

However, individual buckets show irregular distributions, although they are actually assigned to the same substance. For example, the bucket at 4.40 ppm shows significant differences between organically and conventionally grown tomatoes for Mecano cultivar, whereas the bucket at 4.38 ppm is non-significantly different for these growing regimens (Figure 7), despite both buckets being attributed to malic acid (A). This is presumably due to an overlap with signals from other ingredients that are not assigned yet. Thus, the present results are first estimations, and at this point classical quantitative methods are needed to confirm these results.

# Impact of Cationic Surfactant on the Self-Assembly of Sodium Caseinate

Marko Vinceković,*[,†] Marija Ćurlin,[‡] and Darija Jurašin*[,§]

[†]Department of Chemistry, Faculty of Agriculture, and [‡]Department of Histology and Embryology, School of Medicine, University of Zagreb, Zagreb, Croatia

[§]Division of Physical Chemistry, Ruđer Bošković Institute, Zagreb, Croatia

**ABSTRACT:** The impact of a cationic surfactant, dodecylammonium chloride (DDACl), on the self-assembly of sodium caseinate (SC) has been investigated by light scattering, zeta potential, and rheological measurements as well as by microscopy (transmission electron and confocal laser scanning microscopy). In SC dilute solutions concentration-dependent self-assembly proceeds through the formation of spherical associates and their aggregation into elongated structures composed of connected spheres. DDACl interacts with SC via its hydrophilic and hydrophobic groups, inducing changes in SC self-assembled structures. These changes strongly depend on the surfactant aggregation states (monomeric or micellar) as well as concentration ratio of both components, leading to the formation of soluble and insoluble complexes of nano- to microdimensions. DDACl monomers interact with SC self-assembled entities in a different way compared to their micelles. Surfactant monomers form soluble complexes (similar to surfactant mixed micelles) at lower SC concentration but insoluble gelatinous complexes at higher SC concentration. At surfactant micellar concentration soluble complexes with casein chains wrapped around surfactant micelles are formed. This study suggests that the use of proper cationic surfactant concentration will allow modification and control of structural changes of SC self-assembled entities.

**KEYWORDS:** *casein, cationic surfactant, self-assembling, complexation*

## INTRODUCTION

Biopolymers and surfactants are often used simultaneously in the food, pharmaceutical, and cosmetics industries, production of agrochemicals, etc. Understanding their interactions at the molecular level is therefore of great importance in tailoring the final properties of manufactured products. Intensive research on intermolecular interactions between biopolymers (proteins or polysaccharides) and low molecular weight surfactants has provided many new insights into the processes and mechanisms of interactions; however, there is no universal theory describing their complex interactions.[1−3] Understanding the behavior of mixtures containing amphiphilic molecules, such as proteins and low molecular weight surfactants, is not straightforward because these species self-assemble in bulk solution and at interfaces by different mechanisms, leading to competitive association and adsorption processes.[2] Although much is known about the interactions between surfactants and proteins, knowledge of their molecular structure/reactivity relationship in relationship to their functionality in complex systems is still rather limited, and empirical approaches continue to be required in tackling the problem of improvement and optimization of processing conditions.

Depending on aqueous conditions (pH, ionic strength, temperature) and features of the molecular structures of both proteins and surfactants as well as on their concentration and molar ratio, the overall character of their interactions may be significantly different. Addition of small-molecule surfactants to protein solutions modifies the protein functional properties both at the interfaces and in bulk. It was found that hydrophobic and electrostatic interactions as well as hydrogen bonding are the main factors governing protein and surfactant complexation, resulting in specific surface properties of complexes and conformational changes of proteins.[3] This is of special concern in controlled release application, such as plant protection. There are increasing concerns about the level of plant protection active agents found in soil and plant materials causing environmental and health problems. In line with global efforts toward sustainable agriculture, encapsulation with biopolymer matrices has been recognized as an effective method for controlled release of an active agent used for plant protection.[4] The development of systems for controlled release strongly depends on adequate physicochemical properties of biopolymers and on economically sustainable production. Milk proteins are widely available, inexpensive, and generally recognized as safe raw materials with many structural properties and functionalities that make them highly suitable natural vehicles for bioactives.[5] The presence of anionic phosphoserine and other anionic amino acid residues makes caseins available for cation binding, which is important for the delivery of bioactive cations (copper, iron, etc.) to plants in acceptable form. The main objective of the present work was to explore the possibility of guiding the self-assembly of sodium caseinate (SC) with the model cationic surfactant dodecylammonium chloride (DDACl) and consequently to enhance the suitability of SC self-assembled structures for loading bioactive cations.

Most of the studies dealing with the impact of surfactants on the supramolecular organization of the main milk proteins,

caseins, have been conducted with anionic or nonionic surfactants.[3,6] Data on the interaction with cationic surfactants are relatively scarce.[7−10] One of the interesting features of the mixture of oppositely charged amphiphilic molecules is that the self-assembled structures and the charge of their electrical double layer can be manipulated by simple variation of concentrations and molar ratio of components.

Sodium caseinate is the sodium salt of the main milk proteins, caseins. Caseins are relatively small, amphiphilic, randomly or flexibly structured molecules composed of four main proteins: $\alpha_{s1}$-, $\alpha_{s2}$-, $\beta$-, and $\kappa$-caseins. They are proteins characterized by an open structure and a high degree of hydration. In none of their native states do they adopt random coil conformation, but they contain significant amounts of defined secondary structure with few tertiary folds, but do not, for various reasons, fold into compact globular proteins.[11] Casein monomers as complex amphiphilic copolymers exhibit differences in self-association due to the different hydrophobic and hydrophilic regions along the protein chain; $\beta$- and $\kappa$-caseins self-assemble as surfactants, whereas $\alpha_s$-caseins associate in a series of consecutive steps to form open aggregates, which can be rigid worm-like structures.[12] Besides expressed self-association, casein molecules also interact with each other, forming associated structures with the $\kappa$-casein mainly located on the surface and other caseins mainly located in the interior of self-assembled entities.[13−16] The microenvironment, such as pH, ionic strength, concentration, temperature, and surfactant, can significantly alter the self-assembled structures of casein molecules.[12,17,18]

All literature data dealing with casein and oppositely charged surfactant interactions rely on the experiments performed at various surfactant concentrations and constant casein concentration. On the contrary, our data rely on experiments performed at a constant concentration of cationic surfactant and various SC concentrations to show how surfactant aggregation state (monomer or micellar) affects SC self-assembly. The major novelty of our research is the comprehensive focus on the overall changes in the mechanism of SC self-assembly induced by the addition of constant concentration, both monomer and micellar, of model cationic surfactant. We hope that the results obtained will provide better insight into the nature of interactions between caseins and an oppositely charged surfactant, providing an opportunity to control the formation of SC self-assembled structures.

## EXPERIMENTAL PROCEDURES

**Materials and Sample Preparation.** Commercial food-grade SC containing protein with sodium ≤3% and calcium ∼0.1% (Sigma-Aldrich, USA) was used throughout without purification and was dried in a vacuum before weighing. Preparation and purification of DDACl were described earlier.[19] Stock solutions were prepared by dissolving dried SC or DDACl in deionized water, treated in an ultrasonic bath, filtered through a 0.45 $\mu$m filter (Millipore Corp.), and left to stand overnight.

Numerous literature data relating to casein self-assembly have generally been obtained at adjusted pH and ionic strength. On the contrary, we prepared samples with various SC concentrations in the presence or absence of constant DDACl concentrations (monomer (0.001 mol dm$^{-3}$) or micellar (0.03 mol dm$^{-3}$)) with no pH adjustment or salt added. Samples were left to equilibrate for 24 h in a water bath at 298 K. All samples contained 0.01 wt % $NaN_3$ as a bacteriostatic agent.

**Methods.** *Electrical Conductivity and Surface Tension Measurements.* Electrical conductivity ($\kappa$) measurements were performed in a temperature-controlled double-walled glass container with a circulation of water using a conductivity meter (Metrohm, Herisau, Switzerland). The $\kappa$ was measured to within 0.01 $\mu$S. The surface tension ($\gamma$) was determined using the Du Noüy ring method (interfacial tensiometer K100, Krűss, Hamburg, Germany). The $\gamma$ was measured to within 0.001 mN m$^{-1}$. These values then were corrected by using the tables of Huh and Mason. The surface tension of water was measured regularly to provide values for the pure solvent and to check that the technique was being properly carried out. All measurements were performed at 298 K.

*Light Scattering and Zeta Potential Measurements.* Light scattering and electrophoretic measurements were performed using Zetasizer Nano ZS (Malvern Instruments, Malvern, UK). The size of particles ($d$) was determined by means of a dynamic light scattering (DLS) technique using a photon correlator spectrophotometer equipped with a 532 nm "green" laser. DLS measurements were performed at a backscatter angle of 173° to reduce the extent of multiple scattering as well as the effects of dust. Numerous static and DLS studies in SC solutions have shown that variation in their chemical composition resulting from the preparation procedure and methods of sample preparation (centrifugation, filtration, etc.) as well as the experimental conditions led to differences in the reported light scattering data.[20−24] Casein self-assembled entities are polydisperse in size, including in some cases the coexistence of several populations as well as a residual lipid material that could not be completely removed upon sample purification. In a polydisperse sample, the scattering intensity of large particles dominates that of smaller ones and the meaning of the average hydrodynamic size is not straightforward; that is, the intensity-weighted size distribution given by DLS overestimates larger aggregates. To distinguish the contribution of SC from that of large particles, DLS data have been analyzed by relying on the volume and number size distributions. The data processing was done by the Zetasizer software 6.32 (Malvern Instruments). The mean diameters derived from volume and number size distributions were always based on six or more measurements with a relative standard deviation of ±20%.

The zeta potential ($\zeta$) of particles was calculated from the measured electrophoretic mobility by means of the Henry equation using the Smoluchowski approximation ($f$(Ka) = 1.5). Results are reported as an average value of five measurements with a relative standard deviation of ±10%. Samples were prepared by dilution of stock solutions in triple-distilled water, which was previously filtered through a 0.45 $\mu$m Millipore filter.

All measurements were performed at 298 K.

*Rheological Measurements.* Rheological measurements were employed to obtained the flow behavior and viscosity data. Measurements were performed with a stress-controlled rheometer with a double-gap Couette cell (MC1, Paar Physica, Graz, Austria). Flow curves were determined by recording the steady shear rate ($\gamma$) for a series of imposed shear stress ($\sigma$). All flow curves revealed that SC solutions behaved as Newtonian fluids. The plots of shear stress versus shear rate gave straight lines, from which viscosity ($\eta$) was derived with the linear regression coefficient close to unity for all plots. All measurements were run in triplicate and performed at 298 K.

*Microscopic Observations.* Microscopic phases were identified by transmission electron microscopy (TEM 902A, Zeiss, Thornwood, NY, USA) and confocal laser scanning microscopy (CLSM; TCP SP2, Wetzlar, Germany). The transmission electron microscope (TEM) was operated in bright field mode at an acceleration voltage of 80 kV. Images were recorded with a Canon Power Shot S50 camera attached to the microscope. Samples for TEM were were negatively stained with uranyl acetate (2 wt %). A drop of the sample solution was placed on a carbon-coated mesh copper grid. The sample was allowed to dry for 5 min, and then any excess solution was removed by filter paper; dried sample was stained and allowed to dry. All sample preparations for microscopic observation were performed at room temperature.

Samples for CLSM were stained with Rhodamine B (RhB). RhB (0.05 wt %) was dispersed in the SC solution prior to its mixing with DDACl.

*pH Measurements.* pH measurements were performed using a combined electrode connected to an ion meter (Metrohm).

## RESULTS AND DISCUSSION

**Self-Assembly in SC Dilute Solutions.** Sodium caseinate is a heterogeneous mixture of phosphorus-containing proteins containing many ionizable groups on the side chains of their amino acids as well as their amino and carboxyl termini. Depending on solution conditions, functional groups of the side chains belonging to amino acids combined into the protein polypeptide chain can be either protonated or deprotonated.[25−27] The polar regions of the caseins are dominated by phosphoseryl residues and thus carry a net negative charge above the pH called the isoelectric point (p*I*). The average p*I* of caseins is around 4.6 at 293 K;[28] at p*I* casein is electrically neutral due to the presence of an equal amount of oppositely charged ionizable groups. The increase of the net negative charge beyond the p*I* arises from the deprotonation of carboxyl groups, loss of positive charge on the histidines and lysines, and increased negative charge on the phosphoseryl residues.[29]

Figure 1a shows variation of pH with SC concentration. It is evident that at very low concentrations SC aqueous solutions are basic, showing rapid pH decrease with increasing concentration up to the critical concentration, denoted *c**. The pH decrease with increasing SC concentration indicates a release of hydrogen ions into solution. As the SC concentration increased beyond the *c**, the pH continued to decrease to a smaller extent, approaching the pH of milk. The self-buffering power of proteins is diminished in dilute solutions,[30] and it seems that small amount of ions commonly present in a commercial sample overcome the SC self-buffering capacity. This effect is compensated at higher SC concentration.

Like other amphiphilic molecules, caseins self-assemble in aqueous solutions, thus inducing changes in the behavior of physicochemical properties (such as conductivity, surface tension, light scattering, etc.). Figure 1b shows the plots of specific conductivity and surface tension against SC concentration. The intersection point between two linear parts of the $\kappa$-*c*(SC) curve (denoted *c**) indicates a change in the conductivity behavior of the species present, that is, a change in the SC self-assembled structures.

The considerable exposure of hydrophobic amino acid residues caused by the open structure of casein molecules underlies the ability of SC to adsorb readily at the air/water interface, thus decreasing the surface tension. It can be seen in the inset that the decrease in surface tension starts immediately at a very low SC concentration. The break point between the steeply descending and fairly constant branch of the $\gamma$-*c*(SC) curve indicates the monolayer formation at the air/water interface and corresponds to the *c** obtained by pH and specific conductivity measurements. Constant surface tension beyond the *c** indicated that the air/liquid interface is occupied with surface active casein molecules. Compared to a conventional surfactant, SC lowers the surface tension of water to a smaller extent. Our results are in good agreement with literature data; maximum lowering of surface tension is consistent with the equilibrium surface tension obtained for sodium caseinate dissolved in water with 0.1 mol dm$^{-3}$ NaCl.[31]

The origin of an abrupt change in measured physicochemical properties of SC solutions was systematically examined by light scattering, zeta potential, and rheological measurements. Literature data based on light scattering measurements revealed polydispersity as a characteristic property of SC solutions. Commonly, a bimodal size distribution with the variable relationship between peak areas (PA) depending on the origin

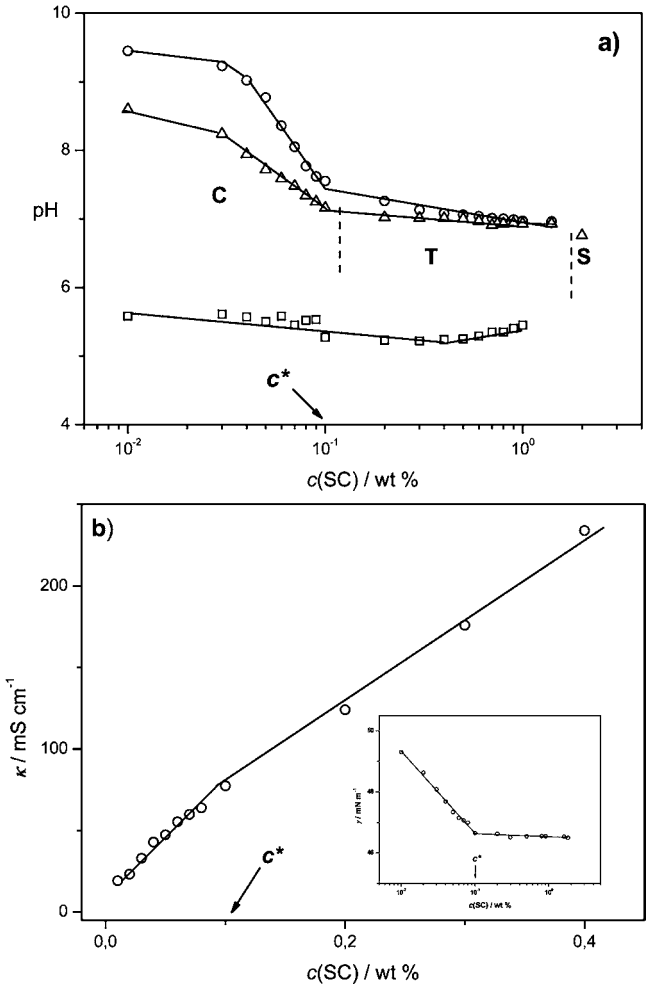

**Figure 1.** (a) Variation of pH with SC concentration (*c*(SC)) for samples without (○) and with constant DDACl concentration (*c*(DDACl) = 0.001 mol dm$^{-3}$ (△) and 0.03 mol dm$^{-3}$ (□)). of SC sample and the experimental conditions was obtained.[15,23,32,33] To avoid overestimation arising from the scattering intensity of large particles (especially of a small weight fraction of complexes containing fat that cannot be removed completely by sample purification),[15] we have analyzed DLS data relying on the comparison between volume and number size distributions. Volume and number size distributions were used to estimate the relative amounts of multiple size peaks and are not considered absolute.

A typical example of volume size distributions for SC samples below the *c** presented in Figure 2a shows the existence of two particle populations. A population of smaller particles with the *d* value of 25 nm at the peak maximum (PA = 57%; *d* varies in the range from 16 to 50 nm) along with a population of larger particles with the *d* value of 191 nm at the peak maximum (PA = 43%; *d* varies in the range from 70 to 712 nm) were observed. The number size distribution (Figure 2b) revealed the presence of 99.7% of smaller particles and a negligible

amount of larger particles. Complementary information obtained by TEM observation (Figure 2c) confirmed the coexistence of prevailing small spherical particles and their aggregates with the size consistent with those obtained by DLS measurements.

On the contrary, volume size distributions of samples beyond the $c^*$ generally indicated the existence of one population of particles with a broad size distribution. A typical example presented in Figure 2d shows volume size distribution ($d$ varies in the range from 69 to 710 nm) with the value of 216 nm at the peak maximum. The number size distribution (Figure 2e) revealed that particles having smaller size are dominant. It is not possible to discern the structure of formed particles from DLS data; however, evidence from electron microscopy revealed the presence of more or less elongated and flexible aggregates composed of small spheres with a diameter close to that of the individual spherical particles below the $c^*$ (Figure 2f).

To distinguish the contribution of prevailing SC self-assembled entities, DLS data are presented in Figure 3a as the change of the peak maximum volume sizes of dominant particles with $c$(SC). Two separate concentration regions can be recognized, below and above the $c^*$. The first region is dominated by the presence of spherical associates with the size very close to the formerly reported size of SC in the presence of electrolyte[23,32,33] as well as to the value reported for the size of native casein micelle building blocks, called submicelles.[34]

Like other proteins, casein molecules carry charges according to their amino acid sequence and the aqueous pH in which they are dissolved. Generally, when pH >4.6, caseins have a net negative charge and when pH <4.6, caseins have a net positive charge. It can be clearly seen in Figure 3b that spherical associates are negatively charged. Owing to the relatively high negative $\zeta$-potential value, they are relatively stable, showing only a slight change in size up to $c^*$. An abrupt increase in the peak maximum volume size and the absolute value of the average zeta potential decrease at the $c^*$ indicated the onset of aggregation, that is, formation of elongated aggregates (Figure 2f). The size of elongated aggregates is consistent with the size of the dominant population detected in sodium caseinate aqueous solutions under similar experimental conditions[33] as

dx.doi.org/10.1021/jf5016472 | J. Agric. Food Chem. 2014, 62, 8543−8554

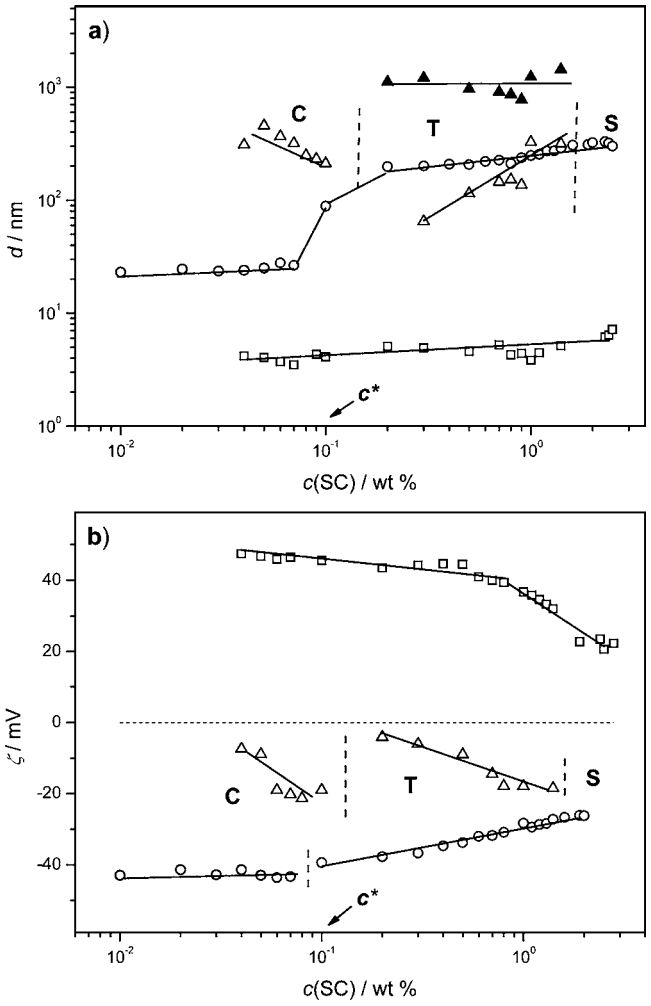

**Figure 3.** (a) Variation of the peak maximum volume size ($d$) and (b) the average zeta potential ($\zeta$) with SC concentration ($c$(SC)) for samples without (○) and with constant DDACl concentration; $c$(DDACl) = 0.001 mol dm$^{-3}$ (△ and ▲ denote the peak volume size of population with smaller and larger particles (a), and △ denotes the average zeta potential ($\zeta$) (b)), and $c$(DDACl) = 0.03 mol dm$^{-3}$ (□). All SC samples were dispersed in water without addition of salt or pH adjustment. Critical SC concentration ($c$*) is denoted by an arrow. Temperature is 298 K.

well as with the size of native casein micelles containing calcium phosphate.[27,35−37] With the increase in SC concentration, the size of elongated aggregates as well as the absolute value of the average zeta potential increased due to the partial charge neutralization caused by the interactions between oppositely charged functional groups of casein molecules.

The change in SC self-assembly behavior around $c$* was also confirmed by rheological measurement. Over the range of concentrations investigated, viscosity did not depend on the shear rate, that is, at least up to $\dot{\gamma} = 10^3$ s$^{-1}$. This finding is in reasonable agreement with literature data for SC suspension at concentrations below $c$ < 7 wt %.[38] Figure 4 shows the concentration dependence on the specific viscosity. The specific viscosity slightly increased up to $c$* due to an insignificant change in size and charge of the spherical associates. An abrupt increase in the specific viscosity beyond the $c$* can be attributed to the onset of aggregation. Results are consistent with literature data (continuous shear rheology and TEM micrographs),[14] which also attributed the viscosity enhancement to aggregation into weakly branched rod-like aggregates.

Viewing individual casein molecules as amphiphilic block copolymers, the formation of small spherical associates can be explained via a balance of attractive hydrophobic interactions and electrostatic repulsion.[12,14] The high proline content in caseins causes a particular bending of the protein chain and inhibits the formation of ordered structures; that is, they have a relatively random, open structure. Without an ordered structure there is considerable exposure of hydrophobic residues, which promotes self-association in water and adsorption at interfaces at very low concentrations. Increase in SC concentration followed by a pH decrease and $\zeta$-potential decrease promotes aggregation beyond the $c$*. Aggregation of SC spherical associates into elongated structures may be ascribed to decreased electrostatic repulsions forcing them to interact more frequently with each other. Like other proteins, casein contains a large number of ionizable groups (acidic and basic residues) to which protons can be attached. Depending on solution conditions they can be either protonated or depronated, giving to the molecule a complex electric charge distribution.[30,39] In dilute solutions and low ionic strength this fluctuating charge may significantly contribute to the intermolecular interactions, thus causing aggregation.

Comparison of supramolecular organization between native casein and SC self-assembled entities revealed differences, sponge-like micelles of the former and soft fragile aggregates of the latter.[15,32,40] The difference in their structures arises from the fact that native casein micelles are, besides hydrophobic and steric interactions, additionally stabilized by specific interactions of colloidal calcium phosphate with casein chains.[41,42] Native casein micelles are similar to surfactant micelles only in the sense that a hydrophilic part resides at the surface and that they

dx.doi.org/10.1021/jf5016472 | J. Agric. Food Chem. 2014, 62, 8543−8554

are spherical. In comparison with surfactant micelles having a homogeneous hydrophobic core, the interior of casein micelles containing submicelles is heterogeneous, porous, and hydrated.[16] The minor amount of calcium arising from the commercial SC sample could not play an important role in aggregation at $c^*$; the hydrophobic interaction and hydrogen bond and electrostatic actions are the main factors governing their formation.[18]

**Self-Assembling of SC in DDACl Solutions.** Interactions between proteins and surfactants have many similarities to interactions between surfactants and polyelectrolytes.[1] Proteins may be considered as amphoteric polyelectrolytes with some hydrophobic groups or as amphiphilic polymers with variable charge density. Interactions between a polyelectrolyte and an oppositely charged surfactant are characterized by the fact that the complexation takes place in a highly cooperative manner. Strong complexation between oppositely charged species is primarily of electrostatic origin, although hydrophobic interactions also enhance the binding of surfactants to polyelectrolyte chains. Surfactants could interact with protein self-assembled entities via their hydrophilic and hydrophobic groups, inducing changes in their organization. These changes strongly depend both on the surfactant and protein structure and on their concentrations.[6]

Earlier, we denoted the self-assembled entities in SC dilute aqueous solutions as small spherical associates below and elongated aggregates beyond the $c^*$. On the other hand, DDACl, as a conventional cationic surfactant, self-assembles in aqueous solutions beyond the cmc (0.015 mol dm$^{-3}$); in dilute aqueous solutions DDACl is present in the form of monomers and beyond the cmc as micelles and monomers. DDACl is a salt of the weak base dodecylamine (DDA) and hydrolyzes in aqueous solutions. In acidic and neutral pH range, DDACl solutions contain only dodecylammonium ions ($C_{12}-NH_3^+$). As the pH increased beyond pH 8, the concentration of $C_{12}-NH_3^+$ drastically decreased as a result of hydrolysis into dodecylamine ($C_{12}-NH_2$), and around pH 9 phase separation of DDA occurred.[43] The increasing concentration of DDA drastically changes important surfactant parameters such as solubility, Krafft point, and cmc.[44]

Having in mind the self-assembly of both SC and DDACl, we have studied the influence of DDACl monomers and micelles on the SC spherical associates and elongated aggregates. Addition of DDACl to SC solutions resulted in pH decrease due to the release of protons from the carboxylic groups of casein molecules (Figure 1a) as was similarly observed upon complexation with positively charged lactoferrin.[45] To avoid hydrolysis of DDACl, all experiments were performed only with samples at pH <8.

*Cross Section with DDACl Monomers.* Samples at the cross section with the constant DDACl monomer and increasing SC concentration range from clear (C) to turbid (T) and to the sedimentation region (S), showing a clear difference in comparison with single SC samples, which were clear and appeared slightly turbid only when approaching 2 wt % of SC. The most turbid milky samples were observed around 0.2 wt % of SC (Figure 5). The difference in the sample appearance with and without DDACl may be primarily attributed to the interactions of surfactant monomers with spherical associates at lower and elongated aggregates at higher SC concentrations.

Interactions between SC spherical associates and DDACl monomers resulted in their complexation. Complexes are significantly larger in size (Figure 3a) and less net negatively charged (Figure 3b) than SC spherical associates. Volume size distributions of samples below the $c^*$ generally indicated the existence of one population of particles. A typical example in Figure 6a shows a broad volume size distribution with the value of 310 nm at the peak maximum ($d$ varies in the range from 100 to 700 nm). Complementary information obtained by TEM observation (Figure 6b) revealed the coexistence of individual spherical particles with size around 4−5 times higher than that of SC spherical associates. With the increase in SC concentration, the size of complexes continuously decreased and the absolute value of zeta potential increased. Zeta potential measurement is a way of evaluating the electrostatic interactions between SC and DDACl. At a constant monomer concentration level and increasing $c$(SC), the continuous increase in the absolute zeta potential value can be explained by the increasing SC/DDACl molar ratio in complexes. Continuous increase in zeta potential indicates an increase in net negative charge, thus enhancing electrostatic repulsion and diminishing the size of complexes.

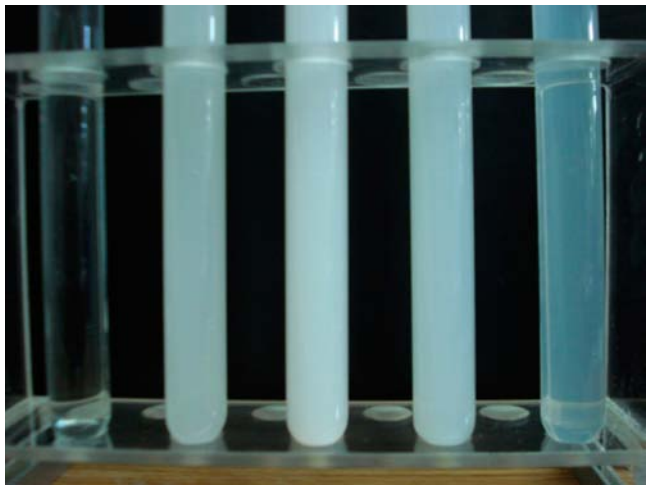

**Figure 5.** Photographs of samples from the turbid region containing, from left to right, increasing concentrationd of SC and constant $c$(DDACl) = 0.001 mol dm$^{-3}$. From left to right, SC concentrations are 0.10, 0.15, 0.20, 0.50, and 0.70 wt %. Note maximum turbidity of the central sample.

Beyond the $c^*$, DDACl monomers interact with SC elongated aggregates. Immediately beyond the $c^*$, DLS measurements (Figure 6c) detected the appearance of one population with large micrometer-sized complexes, which are slightly negatively charged (Figure 3b), indicating almost matching charges. The abrupt decrease in the absolute value of the average zeta potential can be explained by charge neutralization upon complexation and the appearance of larger complexes, which is an additional factor determining the electrophoretic mobility from which zeta potential is derived.[46] Microphotographs from the milky region show that the largest complexes are visible under CSLM as red spots (Figure 6d). It can be seen that fluorescence was regularly distributed in the photograph, indicating the complexes were spread all over the sample. Further increase in $c$(SC) was followed by the appearance of additional particle population. A typical example of volume size distribution is presented in Figure 6e. The population of smaller particles with the value of 145 nm at the peak maximum (PA = 7%; $d$ varies in the range from 79 to 255 nm) coexists along with population of larger particles with the value of 728 nm at the peak maximum (PA = 93%; $d$ varies in

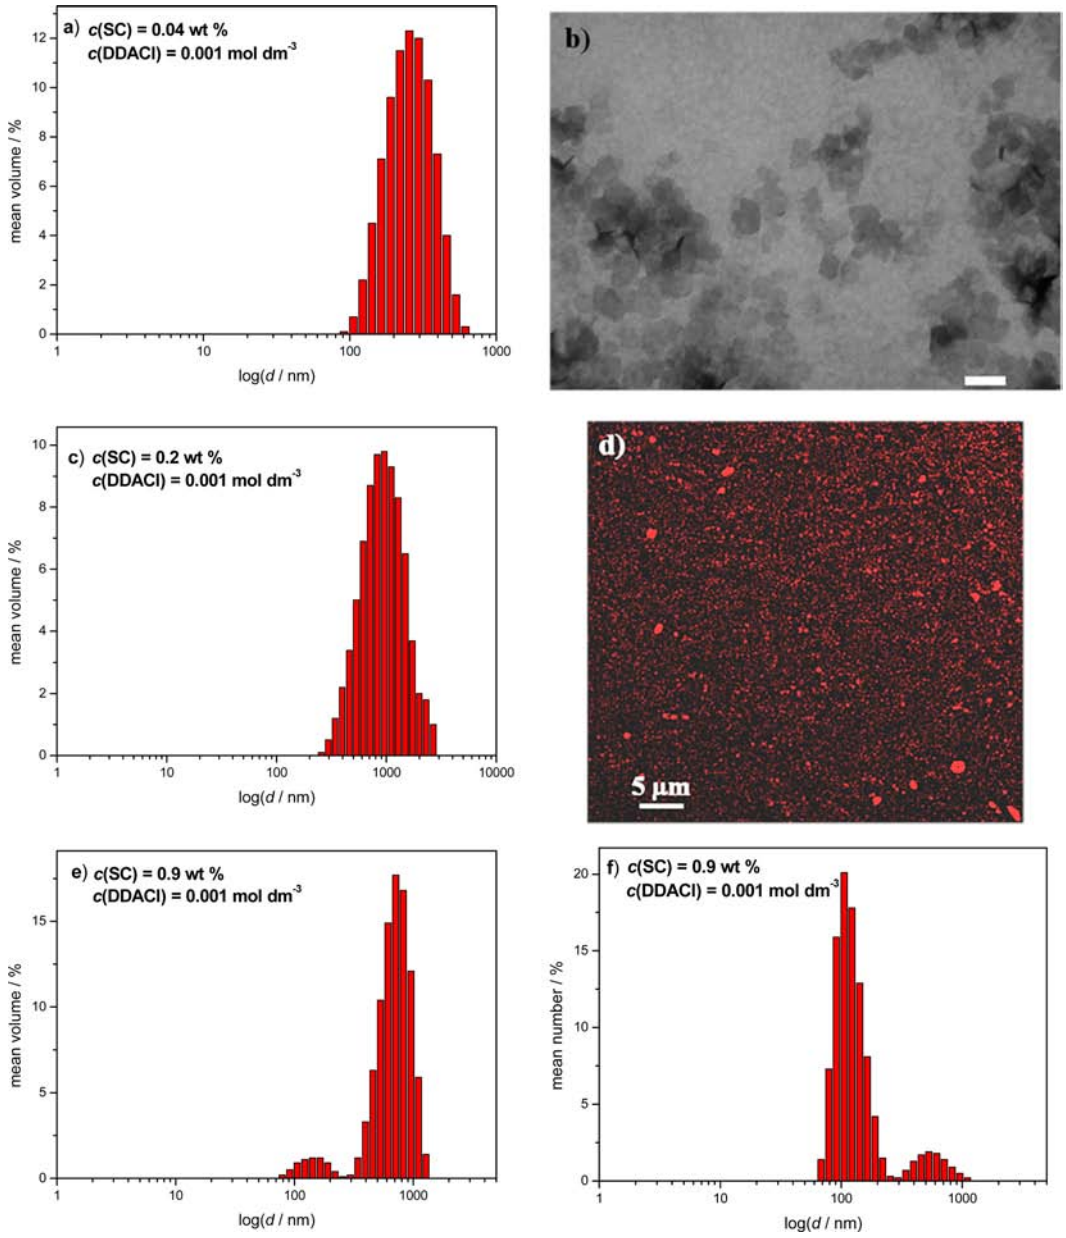

**Figure 6.** Size distribution by volume (a, c, e) and number (f) of DDACl/SC complexes prepared at denoted SC concentration ($c$(SC)) and constant DDACl concentration ($c$(DDACl) = 0.001 mol dm$^{-3}$). All SC samples were dispersed in water without addition of salt or pH adjustment. Corresponding images taken with transmission electron microscope ((b), bar = 100 nm) and confocal laser scanning microscope (CLSM) (d) are displayed at right. Sample for visualization with CLSM was stained with Rhodamine B.

the range from 295 to 1300 nm). Corresponding number size distribution (Figure 6f) revealed the presence of a small amount of larger particles. The absolute value of the average zeta potential continuously increased with increasing $c$(SC). It seems that only close to the $c^*$ is there enough DDACl for complete complexation with SC elongated aggregates. Number size analysis indicated that the fraction of larger particles continuously decreased from 1 at $c$(SC) = 0.2 wt % to 0.1 at $c$(SC) = 1 wt % concomitantly with the increasing fraction of smaller particles. Somewhat lower average size of smaller particles than the size of SC elongated aggregates without DDACl indicates their fragile structure. The observed decrease in size could be also attributed to the change of particle shape from spherical to elongated structures.

Plots of shear stress versus shear rate of samples with DDACl monomers suggested Newtonian behavior of all investigated samples. Higher specific viscosity (Figure 4) than that of single SC solutions is a consequence of complex formation, as observed in mixtures of polyelectrolytes and monomers of oppositely charged surfactants.[47,48] DDACl interacts with SC through electrostatic and hydrophobic interactions, leading to a strengthened association between casein chains and thus to increased specific viscosity in comparison with a single SC solution. Decrease of the specific viscosity up to the $c^*$ is consistent with the decreasing size and increasing charge of complexes (Figure 3). An abrupt increase in the specific viscosity beyond the $c^*$ is related to the appearance of micrometer-sized complexes. Further increase in $c$(SC) drastically decreases the fraction of larger complexes from ~1

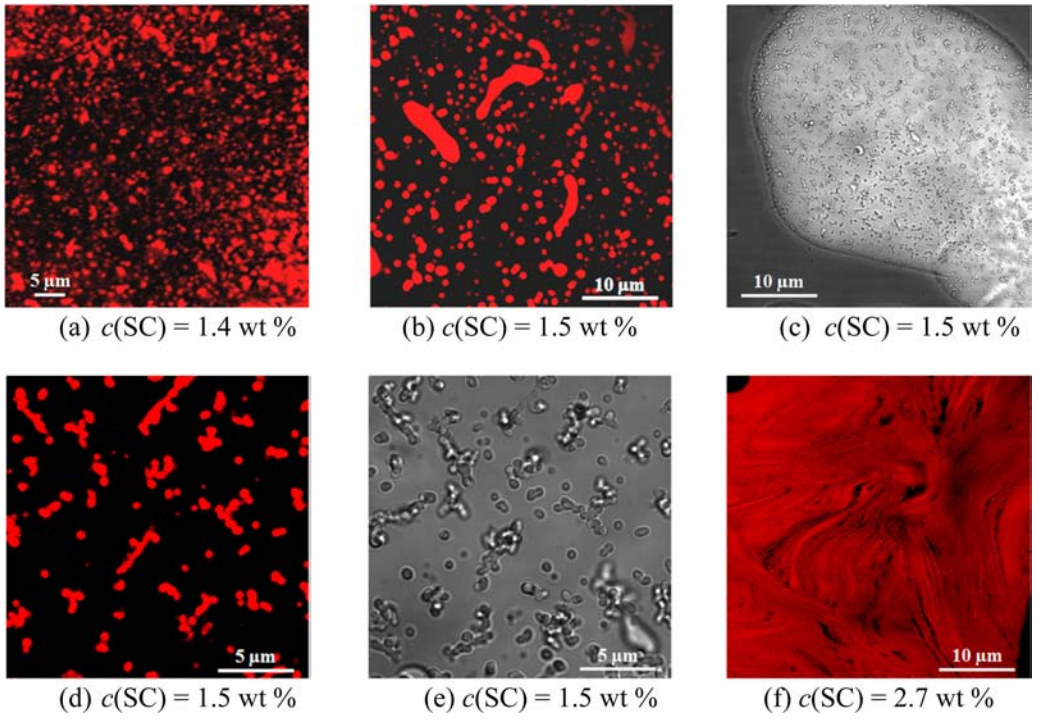

**Figure 7.** Images taken with confocal laser scanning microscope (CLSM) of samples in fluorescence (a, b, d, f) and reflection (c, e) modes, taken at denoted SC ($c$(SC)) and constant monomer DDACl concentration ($c$(DDACl) = 0.001 mol dm$^{-3}$). Samples for visualization with CLSM were stained with Rhodamine B. Bars are indicated.

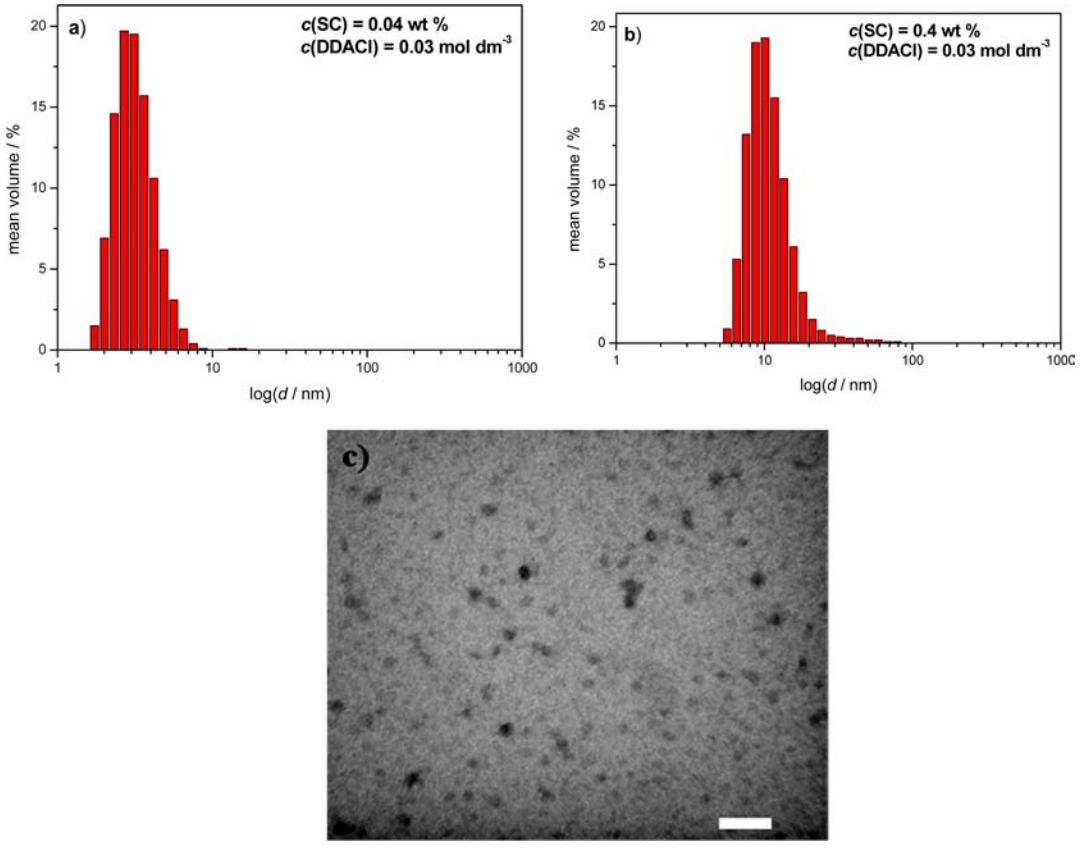

**Figure 8.** Size distribution by volume (a, b) of DDACl/SC complexes prepared at denoted SC concentration ($c$(SC)) and constant DDACl concentration ($c$(DDACl) = 0.03 mol dm$^{-3}$). (c) Transmission electron microscope image of the sample which corresponding volume distribution is shown on the right ($c$(SC) = 0.4 wt %); bar = 100 nm.

dx.doi.org/10.1021/jf5016472 | J. Agric. Food Chem. 2014, 62, 8543−8554

to 0.1 and, consequently, approaching the gelatinous sediment region, specific viscosity increases more slowly than the specific viscosity of single SC solutions.

Light scattering, electrophoretic, and rheological measurements were not performed beyond 1.4 wt % $c$(SC) because due to the presence of a gelatinous phase they could not provide correct information. Labeling with RhB allowed us to see the structure of larger SC/DDACl complexes, which appear red in the micrographs. At the beginning of the sedimentation region, sample microphotographs show a large number of aggregates (Figure 7a), which at slightly higher SC concentration coexist with the fragments of gelatinous phase (Figure 7b). Gel-like fragments formed at this relatively low SC concentration undergo sedimentation under their own weight without forming a continuous gel phase through the medium. Figure 7c clearly shows the coexistence of gelatinous sediment and embedded bulk phase containing spherical complexes; most of them joined into worm-like structures. The sedimented gel-like phase appeared homogeneously red. The enlarged part of Figure 7c shows some spherical complexes are joined into beaded chains (Figure 7d,e). An unstable and very viscous gelatinous phase evolved into a more compact structure at higher SC concentration. The CLSM microphotograph of an insoluble complex (Figure 7f) exhibited the appearance of flexible layers; however, preliminary X-ray analysis has not indicated any ordering. It seems that the SC complex with DDACl retained the tendency of casein micelles to self-aggregate into elongated structures.[8,14] Sedimentation of caseins with net negative charge on binding of a cationic surfactant is a common phenomenon, the behavior analogous to that of mixtures of polyelectrolytes and oppositely charged surfactants.[19,48]

*Cross Section with DDACl Micelles.* At the cross section with micellar DDACl the pH is shifted to the slightly acidic region, showing a slight decrease up to the $c^*$ and a small increase when approaching higher SC concentration (Figure 1). All samples were clear, indicating the formation of soluble complexes. Volume size distributions revealed the presence of particles with the size close to or slightly higher than DDACl micelles ($d_{DDACl} \sim 3.2$ nm[17]). Typical examples of volume size distribution for samples below and beyond the $c^*$ are presented in panels a and b, respectively, of Figure 8. Figure 8a presents the population of small particles with the value of 4.1 nm at the peak maximum ($d$ varies in the range from 1.8 to 7.4 nm). A negligible amount of larger particles (PA = 0.3%) with $d$ varied in the range from 12 to 18 nm was not detected in the number size analysis. From low to the highest SC concentrations the value of the peak maximum volume size distribution was shifted to ∼10 nm (Figure 3a) concomitant with broadening of volume size distribution and increasing fraction of larger particles. Figure 8b presents typical volume size distribution beyond the $c^*$; $d$ varies in the range from 5.9 to 79 nm. Complementary information obtained by TEM observation (Figure 8c) revealed the presence of individual globular particles with the size in accordance with DLS data.

All complexes are positively charged (Figure 3b), indicating strong electrostatic interactions between SC and DDACl. The absolute zeta potential value continuously decreases from 50 mV at 0.04 wt % to 23 mV at 2.8 wt % of SC. This high net charge decrease is followed by a relatively small variation in size. Obtained results suggested that the DDACl micellar concentration induces disintegration of both spherical associates and elongated aggregates. Decrease in the zeta potential value and a slight increase in complex size indicate that casein chains with negatively charged sites bind to the positively charged surfactant head groups located at the micelle/solution interface and wrap around DDACl micelles. It seems that due to very high excess of DDACl compared to SC, only a part of DDACl micelles may be wrapped by casein chains.

Plots of shear stress versus shear rate of samples with DDACl micellar concentration suggested Newtonian behavior of all investigated samples. It can be seen in Figure 4 that at lower SC concentration specific viscosity is higher than that of single SC solutions, although lower than that of DDACl micellar solution (0.463)[49] due to mixed complex formation. Differences in the specific viscosity between samples with and without DDACl disappear around 0.5 wt % SC, and after that, become slightly lower than the viscosity of single SC solutions.

In summary, the presented results give evidence of the concentration-dependent SC self-assembly in dilute aqueous solutions and of changes induced by a cationic surfactant addition. Self-assembly in single SC solutions proceeds in several steps, leading to the formation of spherical associates below and elongated aggregates beyond the $c^*$, showing strong structural difference in comparison with native casein, which, due to the presence of colloidal calcium phosphate, self-assemble into casein micelles.

Surfactants can interact with protein self-assembled entities via their hydrophilic and hydrophobic groups, leading to complexation. The three most commonly encountered models for protein and ionic surfactant complexes are (i) the pearl necklace model,[50] (ii) the rod-like prolate ellipsoidal model,[51] and (iii) the flexible capped helical model.[52] Some literature data concerning the influence of cationic surfactants on casein self-assembly suggested the pearl necklace model to describe the structure of cationic surfactant−casein complexes.[7−9] Both the results obtained with constant casein concentration at levels, at which caseins are present as random coil chains[7] or as micelles,[8,9] and those obtained with increasing concentration of cationic surfactants were described by a mechanism adopted for a polyelectrolyte chain and oppositely charged surfactant; electrostatic binding of cationic head groups to the negatively charged amino acid sites on casein chains at lower concentration; aggregation of micelle-like aggregates at casein chains at critical concentration; insoluble complex precipitation due to negative casein charge neutralization; redissolution of insoluble complexes in the excess of cationic surfactant; and formation of positively charged casein/surfactant complexes and cationic surfactant free micelles.

In this work, we have investigated the impact of constant DDACl concentration on SC self-assembled structures that evolved with increasing concentration from spherical associates to elongated aggregates. Both SC spherical associates and elongated aggregates have hydrophobic domains in their interior, where the hydrophobic part of DDACl monomers can be solubilized and accordingly the formation of complexes with varying stoichiometry may be regarded similar to a mixed micelle of two oppositely charged surfactants.[1] Bearing a net negative charge, SC associates will interact with the positively charged surfactant head groups predominantly via electrostatic attraction. Electrostatic attractions between the positively charged surfactant headgroup and negatively charged SC associates promote hydrophobic interactions.

Hydrophobic segments of casein molecules have some hydrophilic and polar amino acid residues in the sequence. These residues modify the packing behavior in the interior of

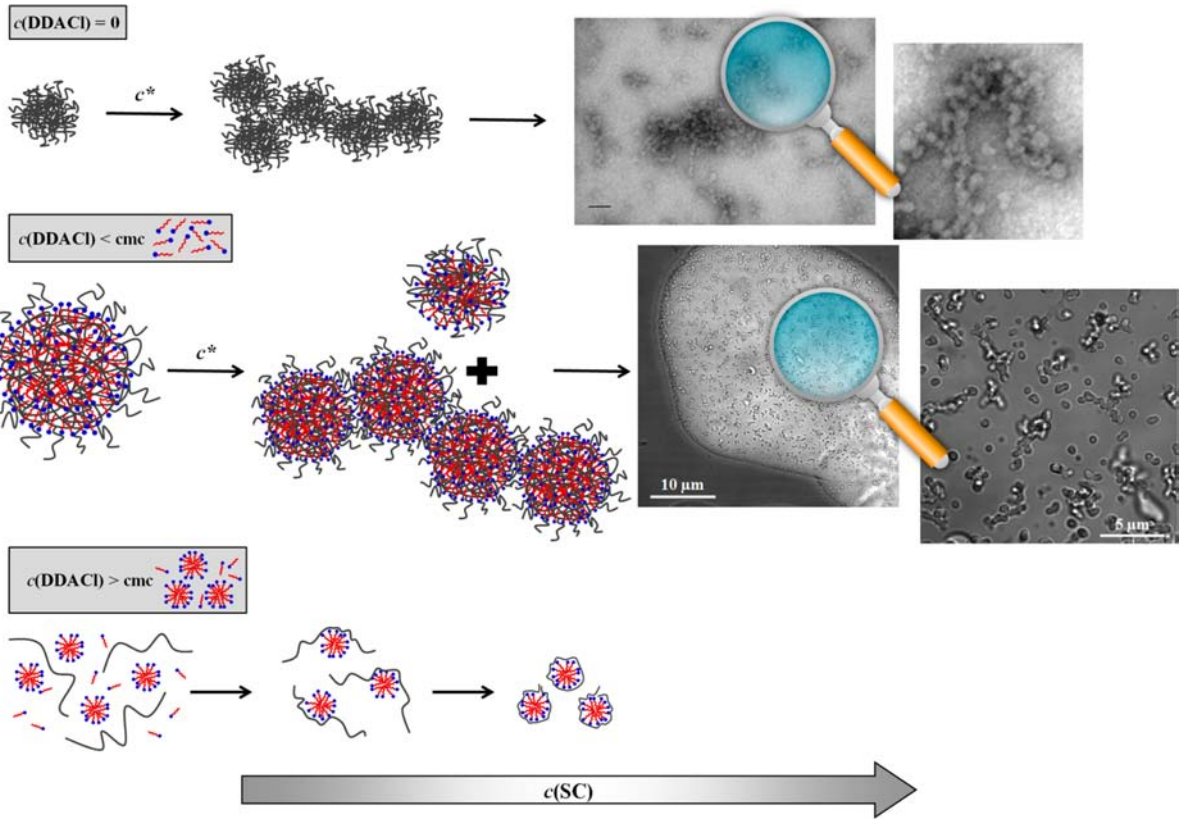

**Figure 9.** Schematic presentation describing interactions of DDACl monomers ($c$(DDACl) < cmc) and monomers and micelles ($c$(DDACl) > cmc) with SC spherical associates and elongated aggregates. Black color represents casein chains, red color represents DDACl hydrophobic tails, and blue color represents surfactant head groups. CLSM image taken from the sedimentation region clearly shows the coexistence of spherical and wormlike aggregates and gelatinous sediment (bars are denoted). TEM image, bar = 100 nm.

casein associates and make it less compact compared to a surfactant micelle.[15,21,40] The relatively open structure of SC associates allows a relatively easy transfer of DDACl hydrocarbon chains into the interior. It seems that despite the decreasing fraction of larger complexes, the increasing number of smaller particles at higher SC concentration forced them to interact more frequently with each other, leading to sedimentation of the gelatinous phase. At the beginning of the sedimentation region, CLSM microphotographs show spherical complexes connected like pearls, indicating that complexes retained the tendency of SC spherical associates to aggregate into elongated structures.[8]

The observed impact of DDACl micellar concentration may be attributed to the influence of the high ionic strength; thus, SC chains may reach only their limited size comparable with the size of DDACl micelles. Another possible scenario of DDACl effects at micellar concentration might involve the influence of both DDACl monomers and micelles. In the micellar region, surfactant micelles and monomers are in equilibrium, and it is generally accepted that the surfactant monomer concentration is equal to the critical micelle concentration, remaining constant at higher concentrations. Owing to the very high monomer concentration (~0.015 mol $dm^{-3}$),[19] one may suppose two steps of interactions, the first step comprising disintegration of SC self-assembled entities into single casein chains due to the incorporation of a large amount of DDACl monomers, and the second step comprising the binding of casein negatively charged sites to the positively charged surfactant head groups located at the micelle/solution interface; casein chains are wrapped around DDACl micelles. It seems that fast disintegration of casein associates into single chains was immediately followed by electrostatic interactions with surfactant micelles. Acting as a multivalent electrolyte, casein chains induce very strong electrostatic binding concomitant with the release of counterions from both the surfactant and casein chains.[53] This scenario is similar to the effect of surfactants on the denaturation of globular proteins. It was shown that depending on surfactant concentration, the unfolding pathway during globular protein denaturation involves several steps and formation of intermediates/complexes; the initial monomer concentration shows a propensity to stimulate protein aggregation, whereas micellar surfactant concentration exhibits strong dispersive abilities.[54]

We did not detect particles with a size corresponding to the size of SC small associates. The small size of complexes may be ascribed to increased ionic strength as well as to the high excess of surfactant micelles wrapped by casein chains without cross-linking.

DDACl monomer antinomian effects leading to the formation of mixed complexes at lower or DDACl micelles wrapped with SC chain at higher concentration may be explained by the influence of the SC/DDACl molar ratio. Owing to their flexible and dynamic nature, casein molecules associate into a loose hierarchical structure of substructures having a hydrophobic interior and a hydrophilic surface with some hydrophobic patches.[12] Addition of a lower monomer concentration results in monomer incorporation and formation of mixed complexes similar to mixed micelles. Both possible

dx.doi.org/10.1021/jf5016472 | J. Agric. Food Chem. 2014, 62, 8543−8554

scenarios, the effect of the high ionic strength or incorporation of a high excess of monomers inside loose SC structures, in the micellar region result in SC chains wrapped around DDACl micelles.

Considering all of the results described, two mechanisms are supposed to describe the complexation of caseins at a constant level of DDACl concentration, one with surfactant monomers and the other with monomers and micelles (Figure 9). In the absence of DDACl, SC exists in several aggregation states, spherical associates below and elongated aggregates beyond the $c^*$. For simplicity, casein associates are shown as spherical aggregates with a hairy layer.

A better understanding of the mechanisms of interactions between SC and oppositely charged surfactants may provide an opportunity to modify and control structural changes of their complexes useful for the production of new materials and may also find a potential in encapsulation and controlled release of bioactive compounds (plant protection agents, drugs, nutraceuticals, etc.).

**ABSTRACT:** Weed infestation has been known to cause considerable reductions in crop yields, thereby hindering sustainable agriculture. Many plants in genus *Euphorbia* affect neighboring plants and other organisms by releasing chemicals into the environment. In view of the serious threat of weeds to agriculture, the allelochemicals of *Euphorbia himalayensis* and their allelopathic effects were investigated. The extract of root exudates from rhizosphere soil exhibited allelopathic activities against crops (wheat, rape, and lettuce) and grasses (*Poa annua*, *Festuca rubra*, and red clover). Bioassay-guided fractionation and isolation from the root extract of *E. himalayensis* led to the characterization of two ellagic acid derivatives and a jatrophane diterpene, which observably showed phytotoxic activities against lettuce, *Festuca arundinacea*, and *F. rubra*. They were further confirmed by ultra-performance liquid chromatography−tandem mass spectrometry to have concentrations of 3.6, 3.8, and 8.99 nmol/g in the rhizospere soil, respectively. Bioassay indicated that the combination of the allelochemicals could be selective plant growth regulator in agriculture.

**KEYWORDS:** *Euphorbia himalayensis, root exudates, ellagic acid derivatives, esulone A, allelopathy*

## INTRODUCTION

Weeds pose an important biological constraint to crop productivity. Many weeds release allelochemicals to interfere with the germination and growth of crops growing around them.[1] It has long been suspected that an allelopathic mechanism should play an important role in the interference of weed with the crop plants.

The genus *Euphorbia* is one of the largest and most widely distributed in the spurge family (Euphorbiaceae), in which most species are found in temperate regions. The plants of the genus are herbs, shrubs, and cactus-like, growing in nearly all climate types, and are often characterized by the presence of a milky latex.[2] Many plants in the genus, such as leafy spurge, are reported to affect adjacent plants through allelochemicals released into the environment.[3,4] A yield reduction of 4−85% has been reported in field crops with different *Euphorbia* species and distinct occurrence densities. The plants in this genus decrease herbage production by 10−100% in pasture and rangelands.[5] *Euphorbia* species have herbicidal and insecticidal properties, but there is a need to establish their commercial utility potential as environmentally friendly plant protection measures.

*Euphorbia himalayensis* Boiss. commonly grows in non-irrigated farmlands and infests cultivated fields in the Tibetan Plateau. The plant is also toxic to livestock and poses a serious threat to crop and livestock production. In light of the ecological benefits of *E. himalayensis* in farmland, the investigation of chemical constituents with phytotoxic activities was processed. Using a bioassay-directed approach, three active compounds were isolated and elucidated, which were responsible for obvious phytotoxic activities. Furthermore, these allelochemicals were identified from the rhizosphere soil by high-performance liquid chromatography (HPLC) and ultraperformance liquid chromatography−mass spectrometry (UPLC−MS). To the best of our knowledge, this is the first report of this plant on the phytochemical investigation and allelopathic activities. These results would be useful to explore how *E. himalayensis* becomes a successful competitor against other plants in nature. In this study, a rapid and highly sensitive method was developed with the use of ultraperformance liquid chromatography−tandem mass spectrometry (UPLC−MS/MS) to determine the levels of allelochemicals in the rhizospere soil.

## MATERIALS AND METHODS

**General Experimental Instruments and Procedures.** Electron ionization−mass spectrometry (EI−MS) was recorded on a VG ZABHS instrument (VG, East Sussex, U.K.), and electrospray ionization (ESI) ion-trap data were recorded on an Esquire 6000 instrument (Bruker Daltonics, Billerica, MA). $^{1}H$ and $^{13}C$ nuclear magnetic resonance (NMR) spectra with tetramethylsilane (TMS) as the internal standard were measured on a Varian Mercury-400BB instrument (Bruker, Karlsruhe, Germany) operating at 400 and 100 MHz, respectively. Silica gel (200−300 mesh) (Qingdao Haiyang Chemical Co., Ltd., Qingdao, China), Sephadex LH-20 (25−100 mm) (Pharmacia Fine Chemical Co., Ltd., Berlin, Germany), and silica gel 60 RP18 (230−400 mesh) (Merck, Whitehouse Station, NJ) were used in column chromatography (CC). Thin-layer chromatography (TLC) was performed on precoated silica

gel 60 $F_{254}$ plates (Qingdao Haiyang Chemical Co., Ltd., Qingdao, China), and spots on the plates were observed under ultraviolet (UV) light of 254 nm and visualized by spraying with 5% $H_2SO_4$ in EtOH (v/v), followed by heating.

The HPLC analysis was performed on a HP1200 system (Agilent, Santa Clara, CA) with a diode array (G1315D) and the GraceSmart RP18 C18 column (2.5 cm × 4.6 mm, 5 μm) (Grace Corporation, Columbia, MD). Liquid chromatography (LC)-grade methanol and acetonitrile were purchased from Tedia Company, Inc. (Anhui Fulltime Co., Ltd., Hefei, China) and filtered through a 0.45 μm membrane filter before HPLC analysis. Ultrapure water was purified by a water purification system (Shanghai Laikie Instrument Co., Ltd., Shanghai, China) and filtered through a 0.45 μm membrane filter before use.

**Plant Material.** Roots of *E. himalayensis* were collected among the mountains (91° 51′ E, 29° 46′ N) in Maizhokunggar county, Tibet province, China, in August of 2012 and identified by Prof. Huanyang Qi from Lanzhou Institute of Chemical Physics, Chinese Academy of Sciences (CAS). The plant mainly grew in the side of farmland as the dominant species. The *Euphorbia* specimens collected in the study were healthy and in the fruit period. The voucher specimen (Eh001) was deposited in Lanzhou Institute of Chemical Physics, CAS. The seeds of wheat, rape, red clover, lettuce, *Poa annua*, *Festuca arundinacea*, and *Festuca rubra* were bought from the seed market in Lanzhou. Wheat and rape were the main crops in Tibet, and the other plants were associated plants of *E. himalayensis*.

**Sample Preparation Procedures of Root Exudates.** The plants of *E. himalayensis* were carefully uprooted. The roots with soil were taken in tubes and fiercely shaken off rhizosphere soil. The rhizosphere soil of *E. himalayensis* (8.58 kg, $1.80 \times 10^{-2}$ $m^3$) was extracted ultrasonically with methanol 3 times (30 min each). The filtrate was concentrated in vacuum to near dryness on a rotary evaporator, yielding the root exudates (2.66 g). Then, 70 mg of the extract was dissolved in 8.75 mL of 80% methanol to prepare a solution that was filtered through a Millipore filter (0.45 μm) prior to HPLC analysis and bioassay.

**Biology Assays.** Inhibitory activities on the growth of crops and other plants were evaluated using the plate-culture method.[6] The seeds of the tested plants were soaked in 0.1% mercuric chloride (w/v) for 7 min, washed by distilled sterile water 5 times, and germinated on filter paper with a photoperiod condition of 16/8 h day/night at 22 °C. After 3 days, the lettuce seedlings were transferred to 12-well plates (VWR Scientific, Inc., Shanghai, China) supplemented with $^1/_2$ MS liquid medium, and then the extracts, root exudates, and chemicals isolated were diluted with dimethyl sulfoxide (DMSO) and added to each of the treated pores. The extracts and root exudates were prepared in the final concentrations of 200 and 100 μg/mL, and compounds **1**−**3** were prepared for 200, 100, and 50 μg/mL. Four replicates were performed per treatment. Then, the plants were incubated in a constant temperature humidity chamber at 22 °C for 3 days, under 16 h light/8 h dark photoperiod conditions. The fresh weights and root length were measured at the end of the experiment. Inhibitory ratios (%) of root lengths were determined by the formula: [(control root length − plant length treated)/control root length] × 100. The inhibitory ratios (%) of fresh weights were also calculated by reference to the control. Control bioassays only contained the same amount of DMSO. Significant differences were evaluated by analysis of variation (ANOVA) ($p < 0.05$). Similar procedures were taken to evaluate the phytotoxic activities against other plants. The 2-day-old seedlings of wheat were monitored for 2 days. The 3-day-old seedlings of red clover and rape were monitored for 3 days. The 14-day-old seedlings of *P. annua*, *F. arundinacea*, and *F. rubra* were monitored for 7 days.

**Bioactivity-Driven Isolation of Phytotoxins.** Air-dried roots of *E. himalayensis* (472 g) were smashed and extracted with EtOH at room temperature, and then the solution was concentrated under reduced pressure to obtain the root extract (28 g). The root extract was submitted to silica gel CC (18 × 145 cm) with petroleum ether/$Me_2CO$ [1:0 (3 L), 50:1 (3 L), 20:1 (4 L), 10:1 (5 L), 5:1 (8 L), 2:1 (5 L), and 0:1 (2.3 L)], to give fractions A−G by means of TLC analysis. The fractions E and F showed significant inhibitory activities in the bioassays against lettuce seedlings. Fraction E was separated by CC on silica gel CC (2 × 75 cm), eluted with a gradient of petroleum ether/$Me_2CO$ [10:1 (1.5 L), 5:1 (0.8 L), 2:1 (0.6 L), and 0:1 (0.32 L)], and then repeated silica gel CC to produce compound **3** (9 mg). Fraction F was chromatographed on silica gel CC (2 × 75 cm), eluting with a $CHCl_3/CH_3OH$ gradient [20:1 (0.5 L), 5:1 (1 L), 2:1 (1.6 L), and 0:1 (0.4 L)], then was passed through a Sephadex LH-20 column (1.1 × 60 cm, 30 g) (1:1 $CHCl_3/CH_3OH$), and repeated silica gel CC to produce compound **1** (16 mg) and compound **2** (6 mg).

**HPLC Analysis.** HPLC analysis was measured on an Agilent apparatus equipped with a diode array detector (DAD) and a reverse-phase C18 column with 5 μm particle sizes. UV spectra were recorded at 200−400 nm, and the compounds were monitored at 254 and 275 nm. The mobile phase was composed of (A) 0.1% aqueous acetic acid and (B) methanol/acetonitrile (1:2, v/v) for analysis of compounds **1** and **2** and programmed as follows: 0−5 min, 15% B; 5−10 min, from 15 to 40% B; 10−20 min, from 40 to 55% B; 20−35 min, from 55 to 70% B; and 35−42 min, 70% B. The flow rate was 0.6 mL/min with an injection volume of 20 μL at the temperature of 30 °C. To analyze compound **3** in the root exudates, the other mobile phase was composed of (A) 0.1% aqueous acetic acid and (B) methanol. The gradient schedule was as follows: 0−5 min, 40% B; 5−10 min, from 40 to 55% B; 10−20 min, from 55 to 60% B; 20−25 min, 60% B; 25−40 min, from 60 to 70% B; 40−45 min, from 70 to 90% B; and 45−50 min, from 90 to 100% B. The method for analysis of compounds **1**−**3** in the extract of roots at the concentration of 0.1 mg/mL was the same as that with the compounds **1** and **2**.

The analytical HPLC methods described above were validated by compounds **1** and **3**. Mean recovery rates (accuracy) were >98% with a relative standard deviation of <5% and were decided by adding a certain amount of standards into the extract of soil samples. Precision of the intraday assay was determined using six continuous injections during the same day, while that of the interday assay was measured in 3 consecutive days. All relative standard deviation (RSD) values of peak area were found to be <5%.

**Identification and Quantitation of Allelochemicals in the Rhizosphere Soil.** Identifications of the phenolic compounds in the

rhizosphere soil of *E. himalayensis* were completed by comparing the retention times and UV spectra to the standards of compounds **1**−**3**. The standard curves were performed using the linear regression method, and peak areas at 275 nm were plotted versus concentrations. The regression equations of compounds **1**−**3** were $y = 17619x + 59.108$ ($r^2 = 0.9999$), $y = 16519x + 39.108$ ($r^2 = 0.9979$), and $y = 869.86x - 1925.8$ ($r^2 = 0.9964$) in the concentration range of 0.001−0.2 mg/mL, respectively. Limit of detection (LOD) was defined as the concentration for which the signal-to-noise ratio was 3, and limit of quantitation (LOQ) was defined as the concentration for which the signal-to-noise ratio was 10. The LOD was calculated to be 0.03 μg/mL, and the LOQ was 0.1 μg/mL for compounds **1**−**3**. Compounds **1**−**3** were also verified to exist in the soils by the internal standard method.[6] The same soil sample used in the HPLC analysis was further analyzed by UPLC−MS/MS.

**UPLC−MS/MS Equipment and Conditions.** UPLC was measured on a Waters Acquity Ultra Performance LC system (Waters Corp., Milford, MA), which was equipped with a binary solvent delivery pump, a column oven, a photodiode array detector, and an auto-sampler and coupled to a TQD mass spectrometer (Waters Corp., Milford, MA) with an ESI source. The analytes were separated on a BEH C18 column with 1.7 μm particle sizes (50 mm length and 2.1 mm inner diameter) (Waters Corp., Milford, MA) at the temperature of 30 °C. Chromatographic separation was performed through a 6 min gradient delivery of a mixture of (A) methanol and (B) 0.1% aqueous acetic acid, at a flow rate of 0.3 mL/min. The gradient schedule was as follows: 0−1 min, 30% A; 1−2 min, 30−45% A; 2−4 min, 45−50% A; 4−5 min, 50−80% A; and 5−6 min, 80% A. The system was re-equilibrated with 30% A for 2 min before the next sample run. The absorption spectra of the compounds were recorded in the range of 190−400 nm. The injection volume was 2 μL.

MS/MS detection was performed on a Waters Micromass Quattro Premier triple quadrupole mass spectrometer with an ESI source at the negative mode. The cone gas flow was set at 50 L/h; desolvation gas flow was 600 L/h; and capillary voltage was operated at 3.0 kV. The source and desolvation temperatures were 110 and 350 °C, respectively. The argon gas collision energy was set with the cone voltage at 35 V.

## RESULTS AND DISCUSSION

**Allelopathic Effects of the Root Exudates of *E. himalayensis* on Crops and Grasses.** Wheat and rape are common crops in the Tibetan Plateau. The bioassay showed that the extract of the root exudates from rhizosphere soil of *E. himalayensis* had significant allelopathic effects on crops (wheat, rape, and lettuce) and grasses (*F. rubra*, *P. annua*, and red clover) (Figures 1 and 2), indicating that the plant exudes sufficient quantities of allelochemicals to influence other neighboring plants. Interestingly, it was found that the extract of the root exudates showed an inhibitory effect at a concentration of 100 μg/mL but promoted the growth and development of wheat seedlings when the tested concentration was increased to 200 μg/mL (Figure 1), indicating that the allelochemicals and their combination could be explored as a selective plant growth regulator for weed control and a friendly promoter for the growth of wheat in the agricultural ecosystem.

**Allelopathic Metabolites Isolated from Roots of *E. himalayensis*.** The isolations of allelopathic compounds from roots of *E. himalayensis* were achieved by a bioactivity-guided fractionation approach. Three compounds including 4-*O*-[*β*-D-xylopyranosyl]-3,3′-di-*O*-methylellagic acid (**1**),[7] 3,3′-di-*O*-methylellagic acid (**2**),[7] and esulone A (**3**)[8] were isolated from the active fractions of the root extracts and characterized by spectroscopic methods (Figure 3).

Compound **1** was obtained as a white amorphous powder. The $^1$H and $^{13}$C NMR with [distortionless enhancement by

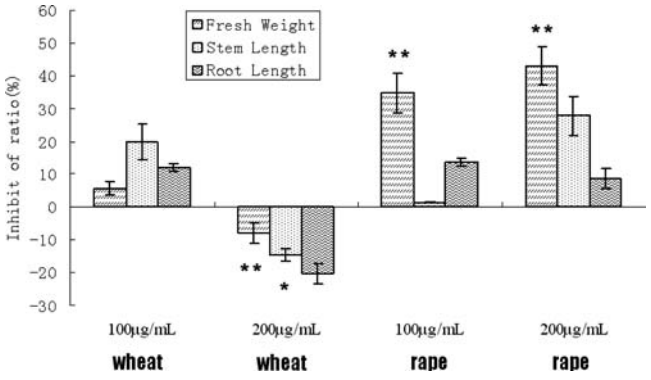

**Figure 1.** Phytotoxic effects of root exudates of *E. himalayensis* against wheat and rape at the concentrations of 100 and 200 μg/mL, respectively. Values are presented as a percentage of the mean compared to the control. Means significantly lower than the DMSO controls are indicated with one asterisk (∗) (Dunnett's one-sided *t* test; $p < 0.05$) or two asterisks (∗∗) ($p < 0.01$). Error bars are one standard error of the mean. $N = 4$.

polarization transfer (DEPT)] spectra of compound **1** displayed signals of 2 methoxyls, 1 methylenes, 6 methines, and 12 quaternary carbon atoms (including 2 carbonyl and 10 aromatic carbon atoms). In particular, six proton signals at $\delta_H$ 5.16 (d, 1H, $J = 7.6$ Hz) and 3.21−3.87 (m, 5H) in the $^1$H NMR together with five carbon atoms at $\delta_C$ 101.7, 72.9, 76.0, 69.1, and 65.7 in the $^{13}$C NMR enabled us to establish the skeleton of ellagic acid as well as xylopyranosyl group connection. The structure of compound **1** was finally established as 4-*O*-[*β*-D-xylopyranosyl]-3,3′-di-*O*-methylellagic acid by comparison to the reported data.[7]

The $^1$H and $^{13}$C NMR spectra of compound **2** were similar to those of compound **1**, except lacking the signals of the xylopyranosyl group. By comparison to the literature values,[7]

the structure of compound **2** was identified as 3,3′-di-*O*-methylellagic acid.

Compound **3** was found to possess a molecular formula of $C_{38}H_{42}O_{12}$ requiring 18 degrees of unsaturation, which was evidenced by ESI–MS at $m/z$ 689.25 $[M - H]^-$ and $^{13}C$ NMR. Four characteristic methyl groups at $\delta_H$ 1.31 (s, 3H, H-16), 1.34 (s, 3H, H-18), 1.26 (s, 3H, H-19), and 1.41 (d, 3H, $J$ = 6.0 Hz, H-20) and $\delta_C$ 25.1 (C-16), 23.0 (C-18), 20.0 (C-19), and 23.5 (C-20) and one exocyclic double bond at $\delta_H$ 5.75 (brs, 1H, H-17a) and 6.12 (brs, 1H, H-17b) and $\delta_C$ 136.8 (C-6) and 124.0 (C-17) suggested that compound **3** was a jatrophane diterpene. The structure of compound **3** was determined to be esulone A, which had been reported in literature isolated from the plant belonging to the same genus *Euphorbia*.[8]

**Allelopathic Activities of the Purified Metabolites.** Compounds **1**–**3** isolated and purified from the roots of *E. himalayensis* were evaluated by the bioassays of the allelopathic activities against seedlings of lettuce, *F. arundinacea*, and *F. rubra*. Results indicated that the growth of the tested lettuce seedlings were inhibited by all three compounds to different degrees, with compounds **1**–**3** showing obvious inhibitory effects (Figure 4). The allelopathic effects of three compounds showed dose-dependent alterations. Compound **3** had an inhibitory activity against weeds *F. arundinacea* and *F. rubra* (Figure 5), while the other compounds only exhibited very slight activities. In addition, the inhibitory activity of compound **3** against *F. arundinacea* was stronger than that against *F. rubra*, especially at low concentrations. It was found that compound **3** did not kill the other plants but mainly inhibited the growth of their roots. These results may be induced by the compound through mediating the polar auxin transport or inhibiting the synthesis of auxin, which should be

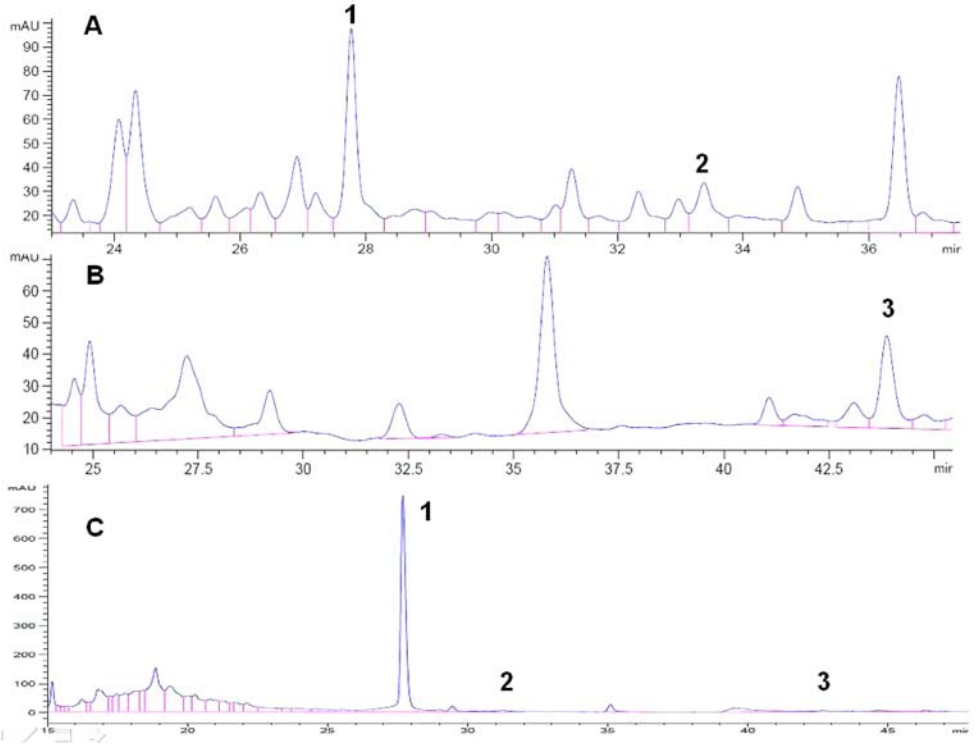

**Figure 6.** HPLC analysis of the rhizosphere soil and root of *E. himalayensis*. (A and B) Compounds **1**, **2**, and **3** were shown in the HPLC chromatogram of the rhizosphere soil at 275 nm and had the following LC retention times of 27.77, 33.38, and 43.87 min, respectively. (C) Compounds **1**, **2**, and **3** were shown in the HPLC chromatogram of the root at 275 nm and had the following LC retention times of 27.77, 33.38, and 41.13 min, respectively.

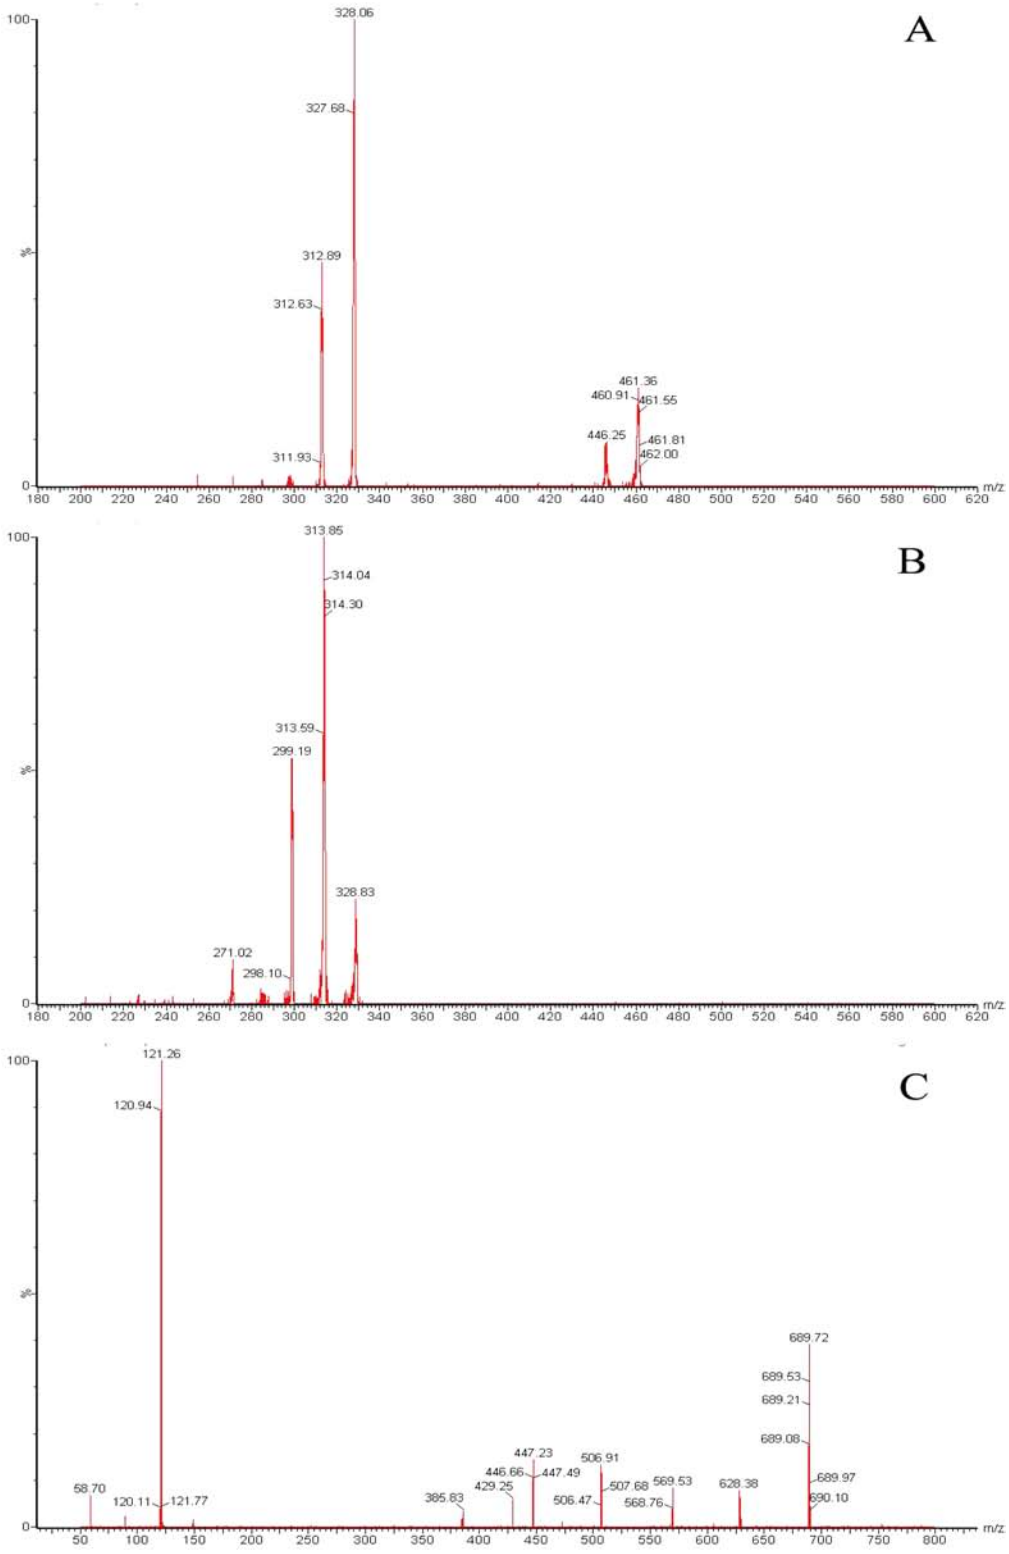

**Figure 7.** (A–C) Tandem mass spectra of compounds **1**–**3**, respectively.

demonstrated by further studies. Thus, the identification of these compounds could lead to the discovery of new, natural herbicides, which can be more environmentally friendly and potentially have new modes of action when compared to the currently used synthetic herbicides.

**Identification and Quantitation of Allelochemicals in the Rhizosphere Soil.** To achieve identification of the allelochemicals released from the plant into soil during its growth, HPLC was used to confirm the existence of the allelochemicals in the rhizosphere soil (Figure 6). The chromatogram was measured at 275 nm, at which most of the compounds had absorbance. Compounds **1**–**3** were identified as allelochemicals in the rhizosphere soil and confirmed by the internal standard method.[6] In comparison to the chromatogram of the soil, the

dx.doi.org/10.1021/jf502020v | J. Agric. Food Chem. 2014, 62, 8555–8561

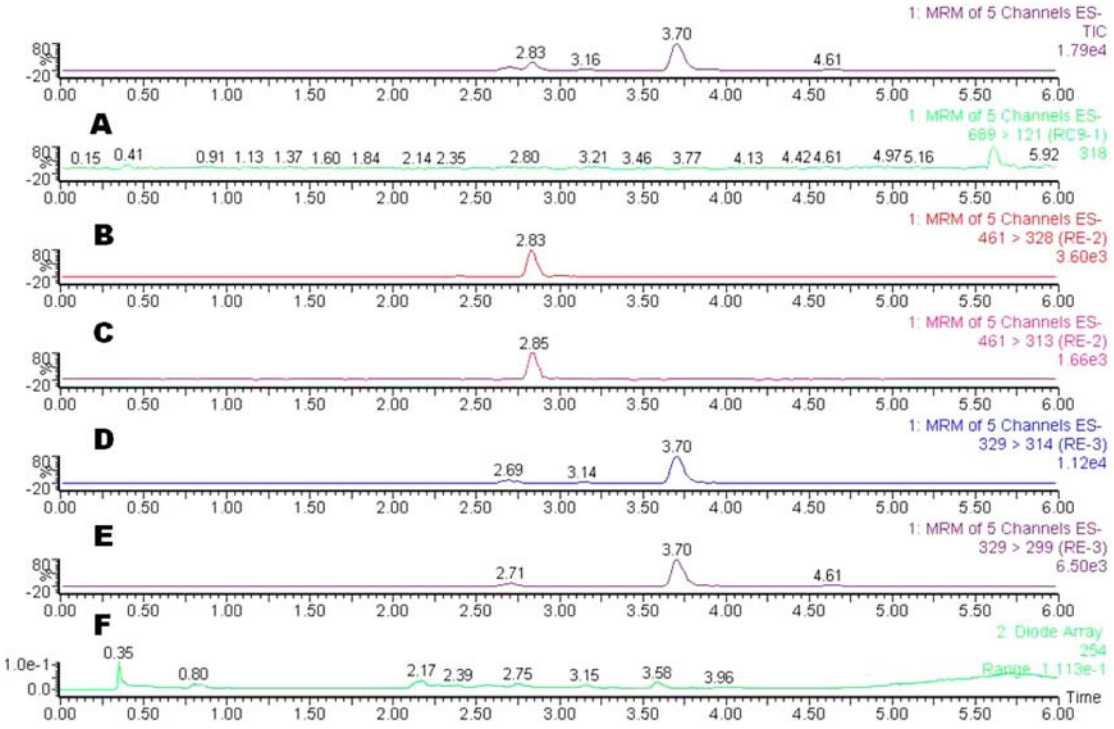

**Figure 8.** UPLC analysis of the root exudates of *E. himalayensis*. Compounds **1**, **2**, and **3** are shown in the UPLC chromatogram and had the following LC retention times of 2.85, 3.70, and 5.62 min, respectively: (A) compound **3** (689 > 121), (B) compound **1** (461 > 328), (C) compound **1** (461 > 313), (D) compound **2** (329 > 314), (E) compound **2** (329 > 299), and (F) UPLC chromatogram with a photodiode array detector at 254 nm.

peaks of compounds **1**−**3** were enhanced obviously after the injection of the standards into soil samples and no new peaks appeared.

The allelochemicals in the soil matrix were further identified by means of mass spectra, because they were the key to research of allelopathic effects. UPLC−MS/MS and HPLC−DAD were successfully used in this study to determine the existence of the allelochemicals in the rhizosphere soil of *E. himalayensis*. Accurate MS and MS/MS data confirmed the composition of each of the daughter ions. Fragmentation of the protonated molecular ion of compound **1** ($[M - H]^-$ $m/z$ 461) in negative-ion ESI mode produces a number of daughter ions, notably $m/z$ 446 (loss of $CH_3$), $m/z$ 328 (loss of $C_4H_6O_5$), and $m/z$ 313 (loss of xylopyranosyl) (Figure 7). Although compounds **1** and **2** have the same nucleus, the protonated molecular ion $[M - H]^-$ $m/z$ 329 of compound **2** produces corresponding daughter ions of $m/z$ 314 (loss of $CH_3$) and $m/z$ 299 (loss of two $CH_3$). The most dominant daughter ion observed at $m/z$ 121 was chosen as the transition ($m/z$ 689 → 121) for verification of compound **3** using a multiple reaction monitoring (MRM) program on UPLC−MS/MS. The detection of three compounds in the UPLC−MS/MS chromatogram of the rhizosphere soil is shown in Figure 8.

The standard curves were obtained by use of the linear regression method, and peak areas at 275 nm were plotted to calculate concentrations; thus, the concentrations of compounds **1**, **2**, and **3** in the soil were determined as 3.6, 3.8, and 8.99 nmol/g of soil, respectively.

It is well-known that plants usually synthesize secondary metabolites used to adapt to the environment and enable their survival and well-being. The compounds of ellagic acid type, which belonged to compounds **1** and **2**, were reported to exhibited varied activities, such as inhibitors of auxin transport.[9] Allelochemicals **1** and **2** possessed the same skeleton and maybe mutual reverse in nature. The replacement of the xylose group at the C-4 position would improve the water solubility and enlarge the application range of compound **2**, although the activity of compound **2** was slightly weaker than that of compound **1**. Compound **3** belongs to jatrophane diterpenes usually isolated from Euphorbiaceae plants and exhibits cytotoxic, antitumor, insect deterrent, and antimicrobial activities *in vitro*.[10] The phytotoxic compounds isolated from roots were also present in the root exudates, suggesting that they were allelochemicals of *E. himalayensis*. These two types of compounds might be leached into the soil and accumulated in the rhizosphere, resulting in a competitive superiority for *E. himalayensis* with its neighboring plants in the natural plant ecosystem.

It is also interesting to note that compounds **1**−**3** have been reported to present in roots of leafy spurge, an invasive species in the same genus.[7,11] Of particular interest is the observation that compounds **1** and **2** were also found in the root exudates of leafy spurge. It is known that the skeletal structures of secondary metabolites from the same genera are usually the same or similar.[12]

*E. himalayensis*, a toxic weed to livestock and humans in the Tibetan Plateau, exhibits allelopathic effects on crops, but the phytotoxic activities of the purified metabolites have not been reported thus far. In this study, compounds **1**−**3** isolated from the root extract of *E. himalayensis* showed observably phytotoxic activities. These compounds were also determined as allelochemicals of the plant released into the soil environment. The bioassay showed that the extract of the root exudates from the rhizosphere soil of *E. himalayensis* had significant allelopathic effects on crops and grasses. Our findings suggest that *E. himalayensis* is able to exert an effect on other plants through the release of allelochemicals. Production of these

dx.doi.org/10.1021/jf502020v | J. Agric. Food Chem. 2014, 62, 8555−8561

chemicals can increase the fitness of *E. himalayensis* and provide the plant a superiority to become a successful competitor in the natural plant ecosystem. The bioassay results showed that the extract of the root exudates had an inhibitory effect at a lower concentration but promoted the growth of wheat seedlings once the test concentration was increased to 200 μg/mL, suggesting that the combination of the allelochemicals could be explored as a plant growth inhibitor for weed control and promoter for the growth and development of Gramineae crops, such as wheat in agriculture.

Supporting Information

**ABSTRACT:** Nonfermented soaking of barley feedstuff has been established as an in vitro procedure prior to the feeding of pigs as it can increase protein digestibility. In the current study, two feed cultivars of barley (Finlissa and Zephyr) were soaked in vitro either nonbuffered or buffered at pH 3.6 and 4.3. Solubilized and degraded proteins evaluated by biuret, SDS-PAGE, and differential proteomics revealed that pH 4.3 had the greatest impact on both solubilization and degradation. In order to boost proteolysis, the recombinant barley endoprotease B2 (rec-HvEP-B2) was included after 8 h using the pH 4.3 regime. Proteolysis evaluated by SDS-PAGE and differential proteomics confirmed a powerful effect of adding rec-HvEP-B2 to the soaked barley, regardless of the genotype. Our study addresses the use of rec-HvEP-B2 as an effective feed enzyme protease. HvEP-B2 has the potential to increase the digestibility of protein in the pig, either supplied as recombinant additive or as possible new selection criterion in barley breeding.

**KEYWORDS:** *pH, barley, Hordeum vulgare L., soaking, protein, cysteine endoprotease B2, rec-HvEP-B2*

## INTRODUCTION

Inefficient nitrogen utilization in intensive animal production results in environmental pollution problems. When barley (*Hordeum vulgare* L.) is used as dry porcine feedstuff, the apparent total tract digestibility of protein is ∼73%.[1] This may be the result of relative low retention times in the stomach and ileum (5 h in total[2]) and limited accessibility of the digestive proteases to the nutrients. When cereals are soaked or fermented prior to feeding of the pig, an increased apparent ileal digestibility of protein is reported,[3] indicating a "predigestion" of the cereal protein. In vitro methods, estimating the ileal digestibility of feed protein, assume that soluble and proteolyzed peptides with molecular sizes smaller than 5 kDa is digested and absorbed in vivo.[4−6] However, soaking of barley in liquid feed preparations may activate barley proteases to degrade water-insoluble hordeins to a degree that fulfills the digestibility criteria. During germination of the barley grain, cysteine endoproteases degrade and solubilize storage proteins,[7,8] which are further proteolyzed into amino acids[9,10] and transported to the growing embryo.[11,12] The cysteine endoproteases have acidic pH optima and are active during the first 7 days of the germination when the pH becomes acidic in the storage vacuole.[13,14] Acidification also takes place when ground cereals are soaked or fermented for liquid feed, creating optimal conditions for endoprotease activity. Unfortunately, acidification under these conditions can take up to 24 h.[15−17] This period of time is not realistic in the case of nonfermented liquid feed, which is preferred for fast feed preparation. Acidifying and buffering pH in the range of the pH optima of endogenous proteases may speed up the proteolysis and thereby shorten the time of degradation and soaking. Moreover, the addition of additional protease activity may improve the protein digestibility and shorten the soaking time even further. A promising protease is the *H. vulgare* cysteine endoprotase B2 (HvEP-B2), which has been produced recombinantly and proved to be effective for hydrolyzing barley hordein storage proteins in vitro.[18,19] Recombinant HvEP-B2 (rec-HvEP-B2) degrades hordeins at pH 4.5 and may be a new candidate for improving protein digestibility in soaked barley.[18]

The present study was conducted to investigate if it is possible to increase the proteolytic degradation of the barley storage proteins during soaking. This was attempted by the means of pH buffering and addition of rec-HvEP-B2.

## MATERIALS AND METHODS

**Materials.** Two winter barley feed cultivars, Finlissa and Zephyr were used in this study. Two cultivars were selected to increase the statistical strength of the study. Finlissa and Zephyr were provided by Sejet Plant Breeding and were selected from multiplication fields in 2010.[20] Grains (100 g) of each cultivar were grinded using a hammer mill with a 0.5 mm sieve. The total amount of nitrogen in the grain was determined using a modified Kjeldahl method.[21] The protein content was calculated by use of a protein-to-nitrogen conversion factor of 5.45, which is specific for barley.[22]

**Soaking of Barley and Buffering pH.** Samples of Finlissa and Zephyr were weighed out in repetitions of three for six time points: 0, 4, 8, 12, 24, and 48 h. Samples of 1.5 g ground barley were weighed out in 10 mL screw cap tubes and mixed with water or buffer in a 1:2.75 (w/w) ratio.[23] Three conditions were tested: (1) nonbuffered, where the dry samples were mixed with water in the ratio mentioned

above; (2) pH 4.3, where 100 mM acetic acid pH 4.3 was used; and (3) pH 3.6, obtained by soaking the sample with 100 mM lactic acid pH 3.6 buffer. The pH increased 0.2 units during the initial mixing of buffer and barley flour, resulting in samples with pH 4.5 and 3.8, respectively, for conditions 2 and 3. The samples were soaked at 20 °C under shaking conditions (250 rpm) and subsequently at the chosen time points, centrifuged at 4200*g*, 4 °C for 20 min after incubation. The amount of water-soluble proteins in the supernatant was measured using a modified biuret method[24] and were correlated with the total amount of protein in the cultivars. The proteins in the soluble fraction and the pellet were analyzed by SDS-PAGE (NuPAGE 4−12%, Life Technologies, U.S.A.) and stained by Coomassie (Brilliant Blue R-250) for monitoring the level of proteolysis.

**Addition of Rec-HvEP-B2.** Before the addition of rec-HvEP-B2 (produced recombinantly in *Pichia pastoris*[18]), it was activated by adding 4 mM cysteine (final concentration in the soaking) to reduce the nucleophilic cysteine in the active site. It was tested if the addition of 4 mM cysteine itself in the soaking mixture would affect the proteolysis. SDS-PAGE analysis on the pellet fraction revealed no changes after addition of 4 mM cysteine (not shown). The soluble fraction was analyzed by label-free differential LC-MS analysis, but in this case, no significant changes were observed (Table 4 in Supporting Information). Next, the addition of 4 mM cysteine along with rec-HvEP-B2 was tested. The amount of rec-HvEP-B2 protease to add was determined by initial titration experiments where increasing amounts of soaked barley ground seeds were added to a fixed amount of rec-HvEP-B2. In detail, 500 mg of 0.5 mm ground Finlissa and Zephyr were soaked at 20 °C in 5 mL of 100 mM acetic acid pH 4.3 containing 4 mM cysteine for 1 h and thereafter centrifuged at 4000*g* for 10 min. Different volumes of extracts were mixed with 0.04 U of activated rec-HvEP-B2, and the activity was measured with an 0.1 mM of endoprotease specific chromogenic substrate, (*Z*)-Phe-Arg-*p*NA-HCl (Z-F-R-pNA, Bachem) as described by Rosenkilde et. al 2013.[18] In this study, one rec-HvEP-B2 unit equals 1 μmol per min of *p*-nitroaniline liberated at 42 °C. Increasing amounts of barley extracts caused a decreasing rec-HvEP-B2 activity, compared to the positive control (0.04 U activated rec-HvEP-B2 without barley extracts). This indicated a clear inhibitory effect of rec-HvEP-B2 by barley.

The amount of rec-HvEP-B2 exceeding the inhibitory effect was calculated to be 6 and 6.7 U of rec-HvEP-B2 for 1 g of Finlissa and Zephyr, respectively. Hence, 9 U per g barley was chosen as the amount of rec-HvEP-B2 calculated in excess for breaking the endogenous inhibitory activity of barley extracts. Prior to the addition, the cultivars were soaked at 20 °C in 2.5 mL of 100 mM acetic acid, pH 4.5, for 8 h, which allowed the endogenous proteases to hydrolyze endogenous substrates.

After 8 h of soaking, 2.25 U of rec-HvEP-B2 was added to 250 mg of fine ground barley cultivars (Finlissa and Zephyr). The samples were then incubated for additional 4 h. After centrifugation at 4200*g* for 20 min, the soluble fraction and the pellet sample were mixed 1:3 with 3× SDS sample buffer, boiled for 10 min, and analyzed by SDS-PAGE for monitoring the level of proteolysis, compared to untreated controls. The proteins in the pellet were extracted with 1:2.75 (w/w) ratio 8 M urea, shaken for 30 min at RT, and centrifuged for 3 min at 20.000*g*. The supernatant of the 8 M extracted pellet was mixed 1:3 with the 3× SDS sample buffer and directly loaded for SDS-PAGE.

**Electro-Elution of Proteins.** Soluble fractions after 12 h soaking for each condition (water, pH 4.3, and pH 3.6) were separated using a Gelfree 8100 apparatus (Expedeon, U.S.A.). Electro-elution was performed after 60, 75, and 90 min of a total of 3 h run of a 12% polyacrylamide cartridge, using settings described by the manufacturer.[25] At the different time points, withdrawals were sampled for proteomic analysis and for SDS-PAGE for visualizing the size of the proteins/peptides obtained (Figure 3A,B).

**Statistical Analysis.** For each treatment, three replicates were measured. Soluble proteins determined by biuret were statistically evaluated by the MIXED procedure of SAS version 9.3 (SAS Institute Inc., 2011). Comparison of the inhibition curves (Figure 4) was performed using the Student's *t*-test. The differential proteomics were evaluated by one-way ANOVA obtained from Progenesis LC-MS software. Effects were considered significant when $P \leq 0.05$. The results presented are least-mean square means (LS means). Standard error of mean is given as a measure for variance.

**Sample Preparation for Proteomic Analysis.** Soluble proteins (200 μL) were denatured, and disulfide bonds were reduced with 200 μL of 8 M urea, 10 μL of 1 M DTT, 50 μL of 1 M ABC (ammonium bicarbonate buffer pH 8.0) buffer at 37 °C for 30 min. Pellet proteins were solubilized as described above, and 200 μL of the 8 M urea solubilized proteins were treated with 5 μL of 1 M DTT, 25 μL of 1 M ABC buffer at 37 °C for 30 min. Cysteine alkylation was performed adding 30 μL and 15 μL of 0.5 M iodoacetamide in 100 mM $NH_4HCO_3$, respectively, for the soluble and pellet proteins. This mixture was incubated for 45 min at RT in the dark. After that, the alkylated proteins were desalted by $C_4$ silica spin chromatography (VYDAC 214TP) by lowering the pH with 20 μL of 100% formic acid (FA) and loading the samples onto a spin column containing 20 mg of the $C_4$ resin. The spin column was centrifuged at 2000*g* for 1 min and the pass through was discarded. Bound proteins were washed three times by 0.1% FA solution and spun at 2000*g* for 1 min. The alkylated proteins were eluted in two batches with 50 μL each of 80% acetonitrile (ACN) containing 0.1% FA.

The alkylated proteins were lyophylized using a speedyvac (Concentrator 5201, Eppendorf). The protein pellet was resuspended in 50 μL 0.1 M ABC buffer containing 0.1% Rapigest surfactant (Waters, Milford, U.S.A.), and either 1 μg of proteomics grade trypsin or chymotrypsin (Pierce, Thermoscientific, U.S.A.). The digestion was performed at 37 °C for 2 h and then stopped by adding 5 μL of 5% FA. Peptide desalting was performed by Supel-Tips C18 Micropipette Tips (Sigma-Aldrich, Supelco) according to the manufacturer specifications. The desalted peptides were lyophilized and dissolved in 0.1% FA containing 3% ACN. The amount of peptides per sample was evaluated by 280 nm Abs using a Nanodrop 1000 (Thermoscientific, U.S.A.).

Per sample, 500 ng of desalted peptides were analyzed in triplicate onto an Xbridge BEH130 C18 5 μm desalting/trap column with a BEH300 C18 1.7 μm nanoUPLC analytical capillary column (100 μm x 100 mm) on an Acquity nanoUPLC-LC system interfaced with a nano source to a Q-TOF Premiere MS (Waters, Milford, MA, U.S.A.). The entire length of the LC run was 90 min, starting with a gradient of ACN/0.1 FA (0 to 40%) from 0 to 70 min followed by 90% ACN wash. Data acquisition was performed in V positive mode. MS and MS/MS data was recorded in DDA mode (MS scan every 1 s, MS/MS every 1 s with selection of 4−8 ions and real time mass exclusion) and MSe mode by the software Masslynx version 4.1 (Waters). $MS^E$ runs were analyzed by the Protein Lynx Global Server 2.5 software and ExpressionE using a lock mass standard of 556.2771 $m/z$ for leucine-enkephaline (Leu-Enk), 60 ppm error tolerance for MS data and 30 ppm error for MSe data. Search parameters included HvEP-B2 main cleavage specificity "/Q-\P", where/indicate the cleavage site and −the amino group of the P1 site; also "\P" indicate no cutting if Q was followed by a proline. Furthermore, a semi trypsin or chymotrypsin, cleavage was selected, with one missed cleavage and no specificity from one end of the peptide as other cleavage options. The fixed modification was the carbamidomethyl cysteine (ΔMass +57.02), and many other variable modifications: deamination NQ (+.98), oxidation MHW (15.99), carbamilation N-term (+43.01), Dehydration DSTY, C-term (−18.01), Hydroxylation DKNPRY (+15.99), Pyrrolidinone P (−30.01), Pyroglutamic P (13.98), Pyro-glu from Q (−17.03) and Pyro-glu from E (−18.01).

**Differential Proteomics.** A differential approach involving the shot gun proteomics of the soluble and insoluble (pellet) fraction was performed with both the ExpressionE software ver. 2.5 (Waters) and the Progenesis LC-MS ver. 4.1 (Nonlinear Dynamics, U.K.). The different samples were compared according to their exact mass versus retention time ratio after normalization with 50 fmol of enolase 1 (swissprot P00924, ENO1, *Saccharomyces cerevisiae*) standard tryptic digest (MASSprep Enolase, Waters). Peptides were identified using the mass search engines PLGS 2.5 and PEAKS 6.0.

**Differential Proteomic Analysis of the pH Effect.** Up or down regulation of proteolysis of soluble proteins is indicated by the fold

changes (log of the expression ratio value). Proteins remaining in the soluble fractions of the three conditions were treated with trypsin, and the $MS^E$ search was carried out only for trypsin cleavages. Hence, the fold changes reported here represent the effective amount of intact proteins in the different conditions not proteolyzed by barley endogenous proteases (Tables 1 and 2). The highest mean for the presence of a detected protein at a given condition represents the effective solubilization or proteolysis.

## RESULTS

**Effect of pH, Time, and Cultivar.** The amount of soluble protein increased during the soaking, depending on time, genotype, and acidic buffering (Figure 1). For Finlissa, comparable increases in soluble protein for the three soaking conditions were observed until 8 h (Figure 1). After 12 h, the pH 4.3 condition diverged from the two others by solubilizing

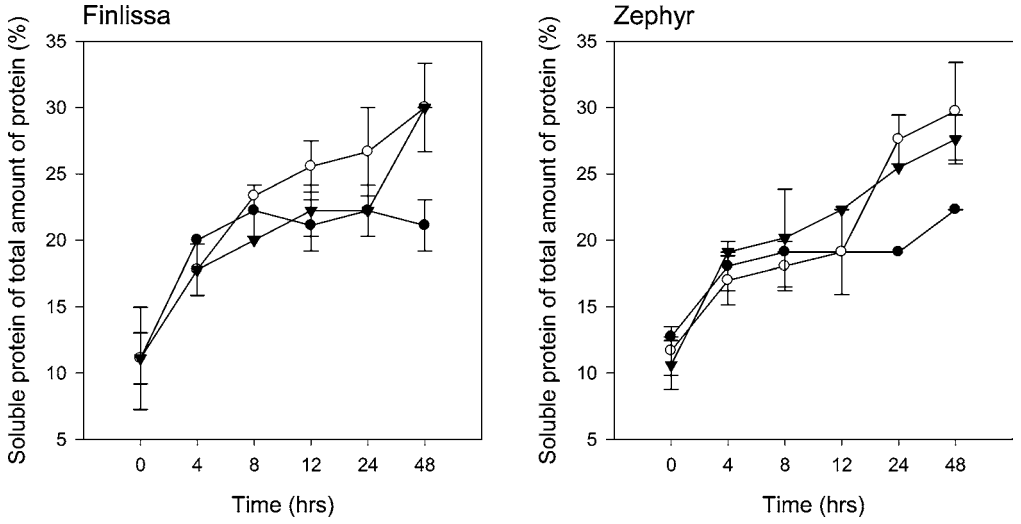

**Figure 1.** Effect of pH on the solubilization of barley protein during 48h of soaking. (●) Nonbuffered soaking. (▼) 100 mM acetic acid pH 3.6. (○) 100 mM lactic acid pH 4.3. Number of replicates was three. Standard deviations are shown as error bars for each data point.

significantly more of the total grain protein (26% vs ∼22%). For the buffered conditions, the difference was equalized after 48 h of soaking where in both cases ∼30% of the total protein was solubilized. This is ∼9% units more than for the nonbuffered condition ($P < 0.0001$).

For Zephyr, no difference was observed between the three conditions up to 8 h (Figure 1). Significant differences were first apparent after 24 h. Both buffered conditions diverged from the nonbuffered condition by solubilizing 25−28% of the total grain protein. This is 6−9% more than for the nonbuffered condition ($P < 0.0001$). After 48 h of soaking, the amount of soluble proteins at pH 3.6 and 4.3 increased to 28 and 30%, respectively.

**Protein Degradation Monitored by SDS-PAGE.** SDS-PAGE on soluble proteins at the different time points revealed that hydrolysis reached a maximal level after 12 h of soaking (data not shown). Compared to the nonbuffered sample, a significant higher degradation was seen in the buffered samples. Predominant bands (i.e., at ∼60 kDa) almost disappeared at condition pH 4.3 (Figure 2). The degradation was also affected at pH 3.6 for both cultivars (lane 3 and 6). Hence, for both cultivars, the highest degree of proteolysis was found at the pH 4.3 condition. SDS-PAGE analysis on the pellet proteins revealed no visible degradation (not shown).

**Differential Proteomic Analysis of the pH Effect.** In order to further elucidate the extent of proteolysis after 12 h of soaking, a label-free LC-MS-based differential proteomics analysis was performed. The point of interest was the small molecular weight (proteolyzed) peptides, which are highly relevant from a feed perspective. For both genotypes, the lowest proteolysis values of the identified peptides were found in the nonbuffered conditions (highest mean in $H_2O$) compared to the buffered conditions (Table 1 and 2). This indicated a pH-dependent proteolysis by endogenous proteases. The largest max fold change occurred between the nonbuffered (water soaking) and the pH 4.3 buffered condition (Table 1 and 2). A Progenesis LC-MS analysis performed on the same samples, covering both genotypes, showed a more profound proteolysis for Finlissa at pH 4.3 than for Zephyr (Table 1 in Supporting Information). This revealed a possible interaction between pH and genotype. However, the LC separation of the peptides using a total shotgun proteomic

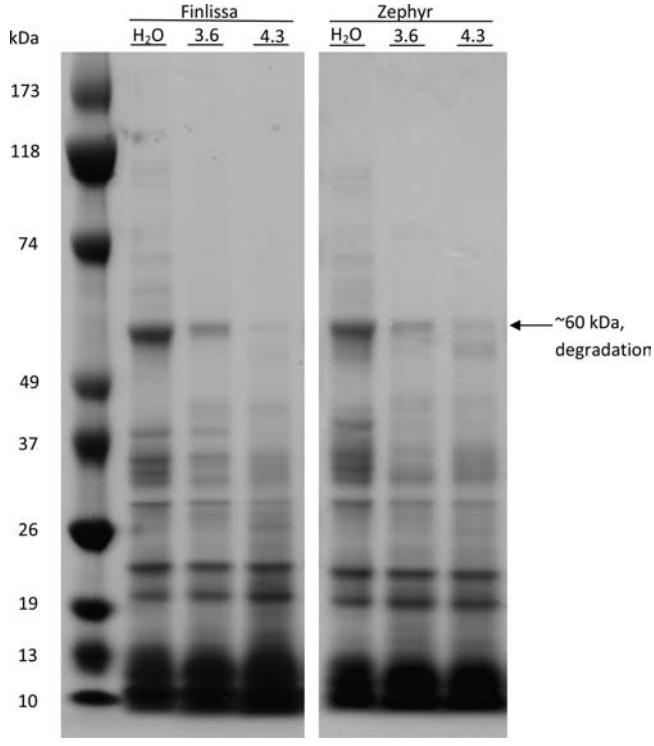

**Figure 2.** Effect of pH on the degradation of soluble proteins after 12 h of soaking. Coomassie staining of water-extractable proteins/peptides visualized in a 4−12% SDS-PAGE gel.

analysis can lead to a so-called ion-suppression effect, resulting in underestimating the quantity and quality of the peptides. This is in particular relevant for small proteolyzed peptides and can in theory cause a biasing of the results. To alleviate a potential ion suppression effect, low molecular weight peptides were isolated prior to proteomic analysis, using a Gelfree 8100 electro-elution after 60, 75, and 90 min run (Figure 3A,B). After 60 min, electro-elution only gave a limited number of hits in the subsequent Progenesis LC-MS analysis, and these samples were therefore excluded from further analysis. After 75 and 90 min, low molecular weight peptides were efficiently eluted, accompanied for 90 min by a significant amount of

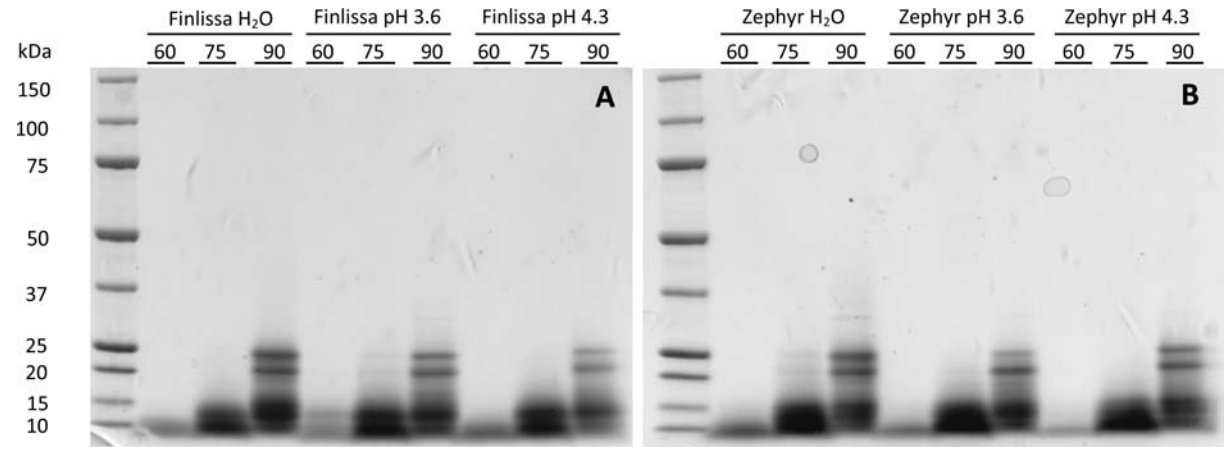

**Figure 3.** SDS-PAGE of Gelfree 8100 electro-eluted proteins after 30, 75, and 90 min of gel electrophoresis. (A) Finlissa; (B) Zephyr. Soaked for 12 h.

larger peptides. A pair-wise comparison at the different conditions as well as phenotypes revealed no obvious differences between the three conditions and the genotypes. Based on Progenesis LC-MS analysis, soaking at pH 4.3 showed a higher degree of proteolysis than soaking at pH 3.6, which again showed greater proteolysis than the nonbuffered soaking (water) condition (Tables 2 and 3 in Supporting Information). However, analysis of the pellet fraction proteins by SDS-PAGE showed no proteolysis of the hordein storage proteins as a result of the soaking (data not shown). It was therefore decided to add rec-HvEP-B2 to the soaking process.

**Addition of Rec-HvEP-B2.** Initial studies using SDS-PAGE with fixed amounts of rec-HvEP- B2 in soaked ground barley (1−2 U/g barley) showed very little or no effect on the proteolysis of soluble and insoluble proteins (data not shown). Moreover, no protease activity was seen when rec-HvEP-B2 was mixed with barley extracts and the chromogenic substrate Z-F-R-pNA. This indicated a potential inhibition by endogenous barley protease inhibitors. By mixing different volumes of barley extracts with a fixed amount of rec-HvEP-B2 endoprotease (0.04 U) and chromogenic substrate (Z-F-R-pNA), protease inhibition curves could be plotted ($P$ = 0.006) (Figure 4). For the chromogenic substrate, the effect of barley endogenous inhibitors was competitive. A barley extract corresponding to 12 $\mu$g material caused 50% of inhibition ($K_i$) on the amount of rec-HvEP-B2 activity used (0.04 U, Figure 4). From these ratios, it can be calculated that 6 and 6.7 U of enzyme per g Zephyr and Finlissa, respectively, is needed to get a 100% noncompetitive activity of rec-HvEP-B2.

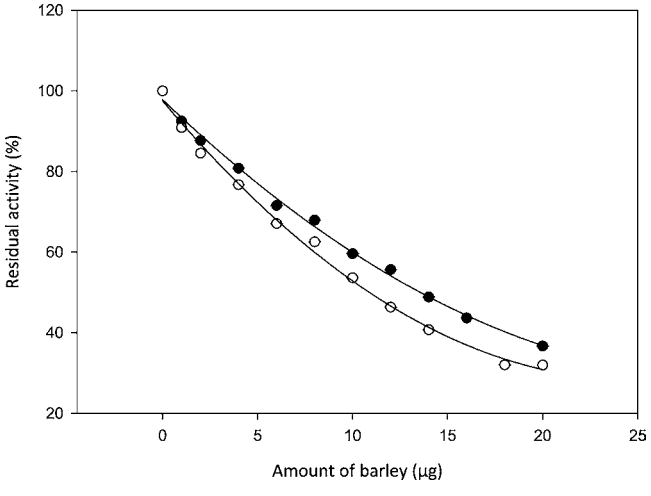

**Figure 4.** Titration of the activity of 0.04 U rec-HvEP-B2 with different volumes of barley extracts. (●) Finlissa and (○) Zephyr.

In order to further study the proteolysis by rec-HvEP-B2 in the soaking process, an experiment was carried out where the amounts of Finlissa and Zephyr were scaled down. The protease was introduced after 8 h of soaking at pH 4.3, allowing the preformed endogenous proteases to initiate the hydrolysis of endogenous substrates. Rec-HvEP-B2 was then allowed to hydrolyze the proteins for an additional 4 h. After the 12 h of total soaking, a substantial proteolysis of the water-insoluble proteins (pellets) was observed in samples incubated including rec-HvEP-B2 (Figure 5). Moreover, the addition of rec-HvEP-B2 caused a substantial hydrolytic effect on the proteins in the soluble fraction (Lanes 4 and 5 in Figure 6). Because the 4−12% polyacrylamide gels used in the initial studies does not effectively retain proteins with a molecular size smaller than 5 kDa, label-free LC-MS was used to quantify and assess qualitatively the extent of the proteolysis.

**Differential Proteomics after Addition of Rec-HvEP-B2.** As evaluated by SDS-PAGE, clear effects of the added protease (visible as decreasing band size, intensities, and smearing) were seen for both water-soluble and insoluble proteins (Figures 5 and 6). Differential proteomics was performed in order to further elucidate the proteolytic effect and to reveal potential genotypic effects. Proteolytic fragments of the typical water-insoluble hordeins D, B2, and B3 were found among the water-soluble proteins after addition of rec-HvEP-B2 (Table 3). The substrate specificity of HvEP-B2 produced in *E. coli* has previously been studied,[34] and according to this, short time incubation (10−30 min) gives mainly hydrolytic cleavages after glutamine residues. Longer and extended incubation time results in increased nonspecific cleavage leading to end products of di or tri peptides. In the present proteomic analysis, the soluble and insoluble proteins/peptides were further treated with trypsin which cleaves immediately after arginine or lysine residues. In the current study, the ratio of tryptic cleaved peptide versus both tryptic from one side and HvEP-B2 from the other was used as evaluation parameter in the Progenesis LC-MS software. The hordeins were detected with the "lowest mean", indicating that

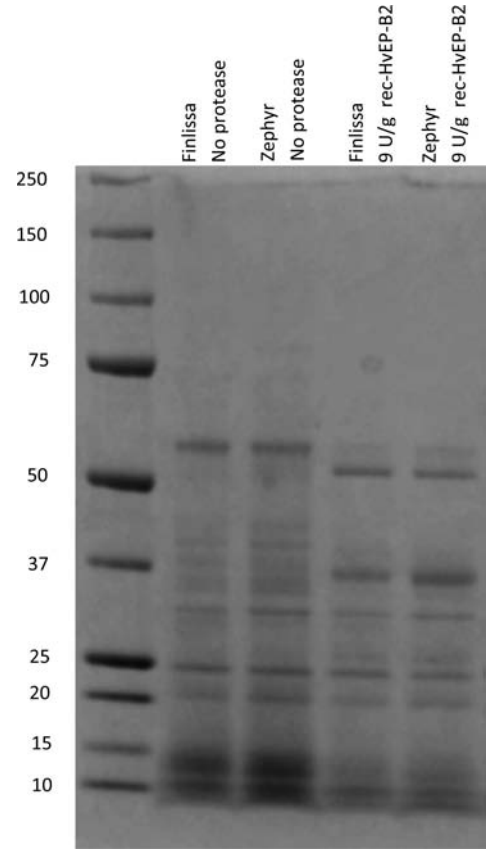

**Figure 6.** Proteolysis of water-soluble proteins analyzed by SDS-PAGE.

these proteins were effectively proteolyzed by rec-HvEP-B2 (Table 3). Proteins not affected by the rec-HvEP-B2 are included as highest mean conditions, meaning that most of the peptides detected were full tryptic peptides (Table 3). Examples on solubilized proteins that stayed intact after addition of rec-HvEP-B2 are heat shock protein 70 (HSP70), the protease inhibitor I4 (serpin), and the endochitinase. Effective rec-HvEP-B2 proteolysis is observed when D and B3 hordein fragments are found in the water-soluble phase. Rec-HvEP-B2 was more effective in hydrolyzing D hordein when rec-HvEP-B2 was added to Finlissa than to Zephyr. In contrast, better proteolysis of B3 hordein was observed when rec-HvEP-B2 added to Zephyr than to Finlissa. Among the insoluble proteins, the following substrates were good substrates: B1, B3, D, Gamma-1,-2, −3 hordeins, hordoindoline b, alpha glucosidase, alpha amylase inhibitor, peroxidase, PDI and thaumatin (Table 4). A genotypic effect was also observed here. Finlissa was better than Zephyr in the hydrolysis of all the hordein isoforms except for the B3 hordein (Table 4 and Figure 5, lane 4, band between 37 and 50 kDa, identified as B3-hordein by LC-MS). Zephyr was also effective in the hydrolysis of the hordeins except for the gamma-2 hordein (Table 4 and Figure 5, band slightly smaller than 37 kDa).

## DISCUSSION

The present study has investigated the possibility of increasing the proteolytic solubilization and degradation of proteins in soaked barley. This can potentially increase the digestibility of proteins in pig feed and speed up the preparation of nonfermented liquid feed. To increase the hydrolytic activity in the barley, pH was buffered in the range of the optima of plant endogenous acidic protease (pH 3.5 to 4.5).[14] Moreover, to further increase proteolysis, a recombinant barley cysteine endoprotease B2 was added under pH 4.3 buffered conditions. Preformed proteases in barley seeds are thought to act primarily on reserve proteins during early germination. This is not directly comparable with the soaking process for cereal-based feed. However, potentially, preformed enzymes could get activated during soaking and initiate the degradation of abundant grain proteins such as hordeins, 7S and 11S globulins. However, hydrolysis by preformed protease such as phytepsin and carboxypeptidase II[26] constitutes only a limited contribution to the concerted hydrolysis of storage proteins. The activities by preformed proteases is accompagnied by a substantial de novo synthesis of proteases during germination. A main de novo synthesized specific proteolytic activity in germination barley derives from the cysteine endoproteases. Moreover, in addition to regulation of proteolytic potential by temporal and spatial synthesis patterns, endogenous protease activity is also regulated via endogenous polypeptide inhibitors.[27,28] For the cysteine endoproteases, the protein is synthesized as an inactive pro-enzyme, including a pro-domain, which is cleaved and thereby activated upon exposure to low pH and reducing agents.[26] Thus, besides optimizing the proteolysis by lowering the pH, low pH may also have a mediating effect by activating preformed proteases.

**Effect of Buffering pH.** Lowering the pH in the soaking had a clear effect on protein solubilization in soaked barley (Figures 1 and 2). This may be due to optimized conditions for endogenous acidic barley endoproteases.[7] Endoproteases from barley are most active between pH 3.5 and pH 4.5,[29] a similar pH range that occurs after ∼24 h of soaking.[15−17] The significant interaction between time and pH shows that most of

[a]These results are related to Finlissa (1) and Zephyr (2) peptides obtained after 4 h of proteolysis with rec-HvEP-B2 and hence further cleaved by Trypsin and analyzed by Progenesis LC-MS. Trypsin plus unspecific cut was searched for the related peptides.

the proteins and peptides are solubilized after 24 to 48 h of soaking when pH is lowered. This is consistent with previous characterization of the barley proteolytic activity[8,30] and in agreement with a general cultivar and time-dependent solubilization (Christensen, unpublished). Cultivar variations regarding enzymatic activity or target proteins have so far not been reported but may nevertheless be at least part of the reason for the observed genotypic variations. Differential proteomics including the electro-elution of the small molecular mass peptides confirmed that proteolysis at pH 4.3 was more effective than at pH 3.6 and in water, respectively (Tables 1 and 2, and Tables 1, 2, and 3 in Supporting Information). However, no degradation of the hordeins, which accounts for more than 50% of total grain proteins, was observed. The missing hordein degradation could be due to lack of activation of preformed cysteine endoproteases, low abundance, a tight regulation by pH, an unsuitable redox potential,[31,32] or by endogenous inhibitory polypeptides (i.e., cystatins). In order to uncover a potential redox effect, soaking was carried out at pH 4.3, plus or minus the addition of cysteine. However, no visible effects of

cysteine addition alone were observed in the insoluble and soluble proteins (data not shown). This indicates that the cysteine proteases are not main contributors to the degradation seen during the pH-induced degradations.

**Effect of Barley Inhibitors and Addition of Rec-HvEP-B2.** The hypothesis of this section was that cysteine endoproteases constitutes a limiting factor for protein degradation during soaking. However, initial studies including 0.04−1.0 U of rec-HvEP-B2 to 1.5 g of soaked barley (pH 4.3) showed no activity toward Z-F-R-pNA included in the sample. The lack of activity was hypothesized to be mediated by endogenous protease inhibitors.[33] In order to estimate the level of protease inhibition in the grain flour, a fixed amount of rec-HvEP-B2 and increasing amounts of extracts from the two cultivars were added. By these means, it was possible to unravel the amount of enzyme needed to exceed the inhibitory effect. Moreover, it showed that the inhibition curves for the two cultivars were not identical, indicating cultivar-dependent differences in the content of inhibitors.

In order to reveal an effect of the recombinant protease, a high level of rec-HvEP-B2 (9 U/g barley flour) was added. Following the addition, a comprehensive proteolysis of the hordeins in the pellets of the two genotypes could be observed. This is supported by previous studies reporting an efficient hydrolysis of the hordeins by HvEP-B2.[18]

Based on criteria for estimating ileal digestibility of protein, it seems likely that buffering at low pH during soaking plus addition of rec-HvEP-B2, in amounts exceeding the endogenous inhibitor, increases the digestibility of barley proteins. Internal inhibitor levels of the cultivars needs to be taken into account when strategies for improving digestibility are designed. Here, optimized conditions including rec-HvEP-B2 above inhibitor level (here 9 U/g barley), pH 4.3 and 4 mM cysteine, led to a substantial increased hydrolysis including mobilization of peptides from the insoluble pellet fraction to the soluble fraction. D and B3 hordein were highly proteolyzed after the addition of rec-HvEP-B2. A genotype effect was visible in the proteolysis of the hordeins in the insoluble pellet fraction. Thus, Finlissa was better than Zephyr for hydrolyzing all hordein isoforms except for hordein B3.

In conclusion, by using the best pH condition, pH 4.3, and after 4 h of partial proteolysis with a titrated amount of rec-HvEP-B2, for two barley feed genotypes, quantitative and qualitative differential proteolytic action revealed that rec-HvEP-B2 caused highly improved hydrolysis of soluble and insoluble barley storage proteins. For analysis purposes, it was necessary to stop the reaction after 4 h. Otherwise, the hydrolysis could have led to di- or tripeptides that are difficult to assign to the protein of origin by proteomic analysis. Therefore, the hydrolysis pattern of the current study cannot be considered as complete. However, on the basis of the current data, we propose that rec-HvEP-B2 constitutes a promising feed additive for mobilizing the insoluble proteins in liquid feed. In addition to this, it may also represent a new selection criterion in plant breeding as well as a candidate enzyme for genetic modifications of barley cultivars.

# Synthesis and Fungistatic Activity of Bicyclic Lactones and Lactams against *Botrytis cinerea*, *Penicillium citrinum*, and *Aspergillus glaucus*

Paulina Walczak, Jakub Pannek, Filip Boratyński, Agata Janik-Polanowicz, and Teresa Olejniczak*

Department of Chemistry, Wrocław University of Environmental and Life Sciences, Norwida 25, 50-375 Wrocław, Poland

Supporting Information

**ABSTRACT:** Six analogues of natural *trans*-4-butyl-*cis*-3-oxabicyclo[4.3.0]nonan-2-one (**3**) and three derivatives, **11**, **12**, and **13**, of Vince lactam (**10**) were synthesized and tested as fungistatic agents against *Botrytis cinerea* AM235, *Penicillium citrinum* AM354, and six strains of *Aspergillus*. Moreover, bioresolution carried out by means of whole cell microorganisms and commercially available enzymes afforded opposite enantiomerically enriched (−) and (+) isomers of Vince lactam (**10**), respectively. The effect of compound structures and stereogenic centers on biological activity has been discussed. The highest fungistatic activity was observed for four lactones: **3**, **4**, **7**, and **8** ($IC_{50}$ = 104.6−115.2 μg/mL) toward *B. cinerea* AM235. *cis*-5,6-Epoxy-2-aza[2.2.1]heptan-3-one (**13**) indicated significant fungistatic activity ($IC_{50}$ = 107.1 μg/mL) against *Aspergillus glaucus* AM211. *trans*-4-Butyl-*cis*-3-oxabicyclo[4.3.0]nonan-2-one (**3**) and *trans*-4-butyl-*cis*-3-oxabicyclo[4.3.0]non-7-en-2-one (**7**) exhibited high fungistatic activity ($IC_{50}$ = 143.2 and 110.2 μg/mL, respectively) against *P. citrinum* AM354 as well.

**KEYWORDS:** *lactones, Vince lactam, $IC_{50}$, Botrytis cinerea, Penicillium thomi*

## INTRODUCTION

It has been assessed that pathogenic fungi, mainly filamentous ones, are the cause of at least 20% of losses in the food industry and crop production,[1] and also they are responsible for mycotoxin contamination of foods.[2,3] Filamentous fungi pose a serious health hazard for people with low immunoresistance, causing dermatomycosis and pulmonary mycosis during hospital treatment. Additionally, they are often the cause of allergies.[4−6]

Nowadays, there is growing interest in new compounds that inhibit growth of filamentous fungi.[7−9] The most attractive are the ones of low toxicity and high biodegradability or the ones of high selectivity of action, not affecting the growth of saprophytic fungi.

Such compounds may include natural lactones biosynthesized by plants. Plants have evolved many secondary metabolites involved in their defense against phytopathogens.[10−13] Compounds with a lactone moiety display a wide spectrum of biological activities, such as fungistatic, bacteriostatic, and cytostatic ones.[14−16] They are often found among insect pheromones.[17] Additionally, several lactones are present in vegetables, fruits, and food products, being responsible for their aromas (mainly fruity ones) and taste (sweet, coconut, or spicy).[18]

In this regard we have developed interest in bicyclic lactones produced by plants of the family Apiaceae Lindl. (*Ligusticum officinale* (loveroot, old English lovage), *Ligusticum chuanxiong*, *L. wallichii* (Chinese lovage), *Angelica sinensis* (Chinese angelica), *Apium graveolens* (celeriac), and *Petroselinum crispum* (parsley)). Some of them are described in the literature.[19−23] There is a need to perform a systematic study on the relationship between structure and biological activity of these compounds. For this purpose we have synthesized natural lactone, its derivatives, and lactam analogues.

In this paper we have obtained bicyclic lactones, compounds of selective growth inhibition activities toward filamentous fungi of the genera *Aspergillus*,[24,25] *Penicillium*,[26,27] and *Botrytis*,[28−30] and we analyzed them with respect to the structure−activity relationship, including the effect of a stereogenic center. The fact that (+)- and (−)-enantiomers may have different biological activities is the background of the modern approach to understanding the mechanisms of action of biologically active compounds.[31]

The biocatalytic potential of microorganisms and their enzymes is used in the production of many valuable chemical compounds.[32] Microbial systems are very profitable due to the short time in which they can double their biomass. Additionally, the methods of genetic manipulations of microorganisms are well-known and established.[33] Therefore, biotransformations using microorganisms and isolated enzymes have enormous potential in the production of pharmaceuticals and compounds useful in agriculture.

## MATERIALS AND METHODS

**Analytical Methods.** Composition of extraction mixtures after biotransformations, syntheses, and purity of products were determined on the basis of complementary information received from gas chromatography (GC) and thin layer chromatography (TLC). TLC analyses were carried out on glass plates covered with silica gel (silica gel 60 $F_{254}$ (Merck)) and developed in eluting systems containing hexane/acetone or methylene chloride/methanol. The same eluents were applied for separation of the products by column chromatography (silica gel 60, 230−400 mesh).

GC analyses were performed with an Agilent 6890N GC instrument, equipped with a flame ionization detector (FID) and

capillary columns Carbowax (30 m, 0.53 mm, film = 0.88 μm) and HP-1 (25 m, 0.32 mm, film = 0.25 μm), using $H_2$ as carrier gas at 2 mL/min of flow. Enantiomeric excesses of the products were determined on chiral columns: Cyclosil-B (30 m × 0.25 mm × 0.25 μm). Specific optical rotations were measured with an Autopol IV automatic polarimeter (Rudolph), equipped with a thermostatic system.

The structures of compounds were determined by means of spectral analysis: $^1$H NMR, $^{13}$C NMR, IR. and GC-MS. NMR spectra were recorded with a Bruker Avance DRX-500 spectrometer in $CDCl_3$ solutions. IR spectra were measured with a Mattson FTIR-300 Thermo Nicolet spectrometer. Molecular weights of products were established on the basis of GC-MS spectra (ionization energy = 70 eV), recorded with a Varian Chrompack GC/MS CP-3800 Saturn 2000 instrument.

**Chemicals.** The chemicals used for the syntheses were purchased from Sigma-Aldrich and Fluka. Potato dextrose agar (PDA) for fungistatic tests was purchased from BTL in Poland. Didecyldimethylammonium chloride (DDAC; 50% solution in propan-2-ol/water 2:3) was purchased from Merck. The substrate for biotransformation and fungistatic tests, racemic 2-azabicyclo[2.2.1]hept-5-en-3-one (**10**), was purchased from Sigma-Aldrich.

**Enzymes.** The following hydrolases were used for bioresolution of racemic lactam **10**: isolated esterase immobilized on Eupergit C from hog liver and esterase from *Rhizomucor miehei* recombinant from *Aspergillus oryzae* were purchased from Fluka, and lipases from *Aspergillus niger* (Amano), *Burkholderia cepacia*, *Candida antarctica* (lipase B immobilized on Innobead 150, recombinant from *Aspergillus oryzae*), *Mucor javanicus*, *Mucor miehei*, *Penicillium camemberti*, *Rhizopus oryzae*, and Lipozymer from *Mucor miehei* were purchased from Sigma-Aldrich.

**Microorganisms.** In our study, in both biotransformation processes and fungistatic activity tests, the microorganisms from the collection of the Institute of Botany of Medical University of Wrocław were used.

The following microorganisms were used: *Aspergillus candidus* AM386, *Aspergillus glaucus* AM211, *Aspergillus nidulans* AM243 *Aspergillus ochraceus* AM456, *Aspergillus* sp. AM31, *Aspergillus wenthi* AM 413, *Botrytis cinerea* AM235, *Candida viswanathi* AM120, *Fusarium culmorum* AM282, *Fusarium oxysporum* AM13, *Inonotus radiatus* AM70, *Laetiporus sulphurens* AM514, *Penicillium camemberti* AM83, *Penicillium citrinum* AM354, *Penicillium notatum* AM904, *Penicillium thomi* AM91, *Pezicula cinnamomea* AM53, *Poria placenta* AM38, *Prosthemium* sp. AM52, *Rhodotorula marina* AM77, *Rhodotorula rubra* AM4, *Sclerophoma pythiophila* AM55, *Sparassis crispa* AM535, *Stemphylium botryosum* AM279, *Yarrowia lipolytica* AM77.

**Synthesis of Lactones 2−4 and 6−8.** *cis-3-Oxabicyclo[4.3.0]-nonan-2-one* (**2**) *and cis-3-Oxabicyclo[4.3.0]non-7-en-2-one* (**6**) were prepared in good yields according to the literature procedures[34] and confirmed by GC-EIMS: 141 (M + 1) for lactone **2**; 139 (M + 1) for lactone **6**.

*trans-4-Butyl-cis-3-oxabicyclo[4.3.0]nonan-2-one* (**3**) was obtained in a three-step synthesis: To 0.48 g (0.02 mol) of magnesium activated with iodine was added anhydrous diethyl ether (50 mL), and the mixture was stirred, followed by the slow addition of freshly distillated *n*-butyl bromide (2.88 g; 0.021 mol). The reaction was continued until all magnesium reacted, and then the reaction mixture was heated under reflux for 1 h. After the mixture had cooled to room temperature, anhydrous cadmium chloride (1.65 g; 0.009 mol) was added, and the reaction mixture was heated under reflux for 1 h. After the mixture had cooled to room temperature, a diethyl ether solution of *cis*-1,2,3,6-tetrahydrophthalic anhydride (**1**) (1.39 g; 0.009 mol) was added dropwise at room temperature and heated under reflux for 6 h. The reaction mixture was poured into 10% HCl and extracted with diethyl ether (5 × 50 mL). The extract was dried over $MgSO_4$, and then solvent was evaporated off.

*Reduction.* Crude product was diluted with 50 mL of methanol and reduced by $NaBH_4$ (0.342 g; 0.009 mol) with 200 μL of 0.1 M NaOH. The reaction mixture was stirred overnight at room temperature, and then methanol was evaporated off.

*Lactonization.* Crude product of reduction was diluted with a solution of 50 mL of THF/$H_2O$ (2:1 v/v), and then 70% $HClO_4$ was dropped until the pH of the reaction mixture was acidic. The reaction mixture was heated under reflux for 3 h. THF was evaporated, and the product was extracted with diethyl ether (5 × 50 mL). The extract was dried over $MgSO_4$, then solvent was evaporated off, and finally crude product was purified by column chromatography using hexane/acetone (3:1) as eluent to give lactone 0.76 g (43% yield after three-step synthesis and purification).

The physical and spectral data of lactone **3** are a follows: mp 104 °C; $^1$H NMR (500 MHz, $CDCl_3$) $\delta$ 0.90 (t, 3, $J$ = 7.1 Hz, $CH_3$-13), 1.07−1.10 (m, 2, $CH_2$-12), 1.29−1.36 (m, 2, $CH_2$-9), 1.37−1.65 (m, 8, $CH_2$-6, $CH_2$-7, $CH_2$-8, $CH_2$-11), 1.70−1.72 (m, 1, one of $CH_2$-10), 2.15−2.18 (m, 1, one of $CH_2$-10), 2.29−2.31 (m, 1, CH-5), 2.69−2.72 (m, 1, CH-1), 4.20−4.24 (m, 1, CH-4); $^{13}$C NMR (151 MHz) $\delta$ 13.91 ($CH_3$-13), 22.48 ($CH_2$-12, $CH_2$-11), 22.55 ($CH_2$-7), 22.88 ($CH_2$-10), 23.58 ($CH_2$-8, $CH_2$-6), 27.96 ($CH_2$-9), 38.95 (CH-5), 42.08 (CH-1), 82.03 (C-4), 178.10 (C-2); IR (NaCl, $cm^{-1}$) 3019 (s), 2400 (m), 2253 (m), 1765 (s); GC-EIMS 197 (M + 1).

*trans-4-Butyl-cis-3-oxabicyclo[4.3.0]non-7-en-2-one* (**7**) was obtained by using the same procedure as for *trans*-4-butyl-*cis*-3-oxabicyclo[4.3.0]-nonan-2-one (**3**) from *cis*-4-cyclohexene-1,2-dicarboxylic anhydride (**5**) (1.37 g; 0.009 mol). Lactone **7** was obtained with 45% (0.79 g) yield. The physical and spectral data of lactone 7 are as follows: oil; $^1$H NMR (500 MHz, $CDCl_3$) $\delta$ 0.85 (t, 3, $J$ = 7.1 Hz, $CH_3$-13), 1.28−1.39 (m, 3, one of $CH_2$-11, $CH_2$-12), 1.45−1.50 (m, 1, one of $CH_2$-11), 1.50−1.54 (m, 2, one of $CH_2$-11, one of $CH_2$-10), 1.68−1.74 (m, 1, one of $CH_2$-10), 1.77−1.82 (m, 1, one of $CH_2$-6), 1.94−1.97 (m, 1, one of $CH_2$-6), 2.30−2.32 (m, 1, one of $CH_2$-9), 2.38−2.41 (m, 1, one of $CH_2$-9), 2.49−2.51 (m, 1, CH-5), 2.78−2.81 (m, 1, CH-1), 4.29−4.32 (m, 1, CH-4), 5.63−5.65 (m, 2, CH-7, CH-8); $^{13}$C NMR (151 MHz) $\delta$ 13.92 ($CH_3$-13), 19.63 ($CH_2$-12), 21.98 ($CH_2$-6), 22.56 ($CH_2$-9), 28.00 (CH-1), 28.91 ($CH_2$-11), 35.32 ($CH_2$-10), 39.95 (CH-5), 82.61 (CH-4), 124.35 (CH-7), 125.22 (CH-8), 178.65 (C-2); IR (NaCl, $cm^{-1}$) 3019 (s), 2400 (m), 1767 (s), 1521 (m); GC-EIMS 195 (M + 1).

*4,4-Dibutyl-cis-3-oxabicyclo[4.3.0]nonan-2-one* (**4**). To a stirred solution of 1.24 g (0.05 mol) of magnesium (activated with iodine) in anhydrous diethyl ether (80 mL) was slowly added *n*-butyl bromide (6.85 g; 0.05 mol). The reaction was continued until all of the magnesium was reacted, and then *cis*-1,2,3,6-tetrahydrophthalic anhydride (**1**) (2.62 g; 0.017 mol) was added dropwise at room temperature. After 12 h, the reaction mixture was poured into 10% HCl and extracted with diethyl ether (5 × 60 mL). The extract was dried over $MgSO_4$, the solvent was evaporated off, and the crude product was purified by column chromatography using hexane/acetone (3:1) as eluent to give 3.31 g of lactone **4** (yield = 77%). The physical and spectral data of lactone **4** are as follows: mp 43−45 °C; $^1$H NMR (500 MHz, $CDCl_3$) $\delta$ 0.87−0.91 (m, 6, $CH_3$-13, $CH_3$-13′), 1.02−1.14 (m, 4, $CH_2$-12, $CH_2$-12′), 1.19−1.34 (m, 8, $CH_2$-7, $CH_2$-8, $CH_2$-11, $CH_2$-11′), 1.49−1.51 (m, 4, $CH_2$-6, $CH_2$-9), 1.70−1.75 (m, 3, $CH_2$-10′, one of $CH_2$-10), 2.11−2.18 (m, 2, CH-5, one of $CH_2$-10), 2.94−2.97 (m, 1, CH-1); $^{13}$C NMR (151 MHz) $\delta$ 14.01 ($CH_3$-13, $CH_3$-13′), 22.79 ($CH_2$-12), 22.95 ($CH_2$-12′), 23.14 ($CH_2$-11′), 23.17 ($CH_2$-11), 31.04 ($CH_2$-7), 24.65 ($CH_2$-10′), 25.85 ($CH_2$-10), 26.16 ($CH_2$-8), 31.41 ($CH_2$-6), 34.04 ($CH_2$-9), 39.79 (CH-5), 41.74 (CH-1), 88.79 (C-4), 177.90 (C-2); IR (NaCl, $cm^{-1}$) 3019 (s), 2400 (m), 1765 (s); GC-EIMS 253 (M + 1).

*4,4-Dibutyl-cis-3-oxabicyclo[4.3.0]non-7-en-2-one* (**8**) was obtained by using the same procedure as for 4,4-dibutyl-*cis*-3-oxabicyclo[4.3.0]-nonan-2-one (**4**) from *cis*-4-cyclohexene-1,2-dicarboxylic anhydride (**5**) (2.59 g; 0.017 mol). Lactone **8** was obtained with 75% (3.19 g) yield. The physical and spectral data of lactone **8** are as follows: oil; $^1$H NMR (500 MHz, $CDCl_3$) $\delta$ 0.87−0.91 (m, 6, $CH_3$-13, $CH_3$-13′), 1.22−1.34 (m, 8, $CH_2$-11, $CH_2$-12, $CH_2$-11′, $CH_2$-12′), 1.52−1.59 (m, 2, one of $CH_2$-10, one of $CH_2$-10′), 1.68−1.74 (m, 2, one of $CH_2$-10, one of $CH_2$-10′), 1.71−1.73 (m, 1, one of $CH_2$-6), 2.03−2.08 (m, 1, one of $CH_2$-6), 2.26−2.28 (m, 1, one of $CH_2$-9), 2.33−2.39 (m, 1, one of $CH_2$-9), 2.42−2.46 (m, 1, CH-5), 3.00−3.04 (m, 1, CH-1), 5.73−5.76 (m, 2, CH-7, CH-8); $^{13}$C NMR (151 MHz) $\delta$ 13.95 ($CH_3$-13′),

13.97 ($CH_3$-13), 21.83 ($CH_2$-12), 23.68 ($CH_2$-12′), 23.16 ($CH_2$-11), 23.17 ($CH_2$-11′), 25.86 ($CH_2$-9), 26.07 (CH-6), 32.42 ($CH_2$-10), 35.67 (CH-10′), 38.22 (CH-1), 39.67 (CH-5), 89.72 (C-4), 125.70 (CH-7), 126.01 (CH-8), 178.97 (C-2); IR (NaCl, $cm^{-1}$) 3019 (s), 2400 (m), 1757 (s), 1522 (m), 1425 (m); GC-EIMS 251 (M + 1).

**Synthesis of Lactams 9 and 11−13.** *cis-3-Azabicyclo[4.3.0]non-7-en-2-one (**9**).* Synthesis of lactam **9** was performed using a high-pressure autoclave Berghof HR equipped with a Teflon liner. To the solution of *cis*-3-oxabicyclo[4.3.0]nonan-2-one (**6**) (1.518 g, 0.011 mol) in 2.0 mL of DMF placed in the Teflon liner was added 60 mL of 25% ammonia. The Teflon liner was put in a tightly closed autoclave. The reaction mixture was stirred with heating at 160 °C for 15 h (pressure increases to 21 bar). Product was extracted with diethyl ether (5 × 50 mL). The extract was dried over $MgSO_4$, and the solvent was evaporated off. Crude product was purified by column chromatography methylene chloride/methanol (97:3). Lactam **9** was obtained with 65% (0.98 g) yield. The physical and spectral data of lactone **9** are as follows: mp 63−66 °C; $^1$H NMR (500 MHz, $CDCl_3$) $\delta$ 1.80−1.85 (m, 1, one of $CH_2$-6), 2.11−2.17 (m, 1, one of $CH_2$-9), 2.23−2.26 (m, 1, one of $CH_2$-6), 2.38−2.41 (m, 1, CH-1), 2.48−2.50 (m, 2, one of $CH_2$-9, CH-5), 2.94−2.95 (m, 1, one of $CH_2$-4), 3.41−3.44 (m, 1, one of $CH_2$-4), 5.66−5.72 (m, 2, CH-7, CH-8), 6.14 (s, 1, NH); $^{13}$C NMR (151 MHz) $\delta$ 21.82 ($CH_2$-6), 25.91 ($CH_2$-9), 31.71 (CH-5), 38.71 (CH-1), 47.65 ($CH_2$-4), 125.46 (CH-7), 126.07 (CH-8), 180.13 (C-2); IR (NaCl, $cm^{-1}$) 3154 (s), 2253 (s), 1695 (s); GC-EIMS 138 (M + 1).

*2-Butyric-2-azabicyclo[2.2.1]hept-5-en-3-one (**11**).* To 2-azabicyclo[2.2.1]hept-5-en-3-one (**10**) (0.3 g, 2.47 × $10^{-3}$ mol) was added anhydrous THF (5 mL), followed by the addition of NaH (8.3 × $10^{-3}$ mol). Then, butyric acid chloride at room temperature was added dropwise (5.64 × $10^{-3}$ mol). The reaction was continued until all of the substrate was reacted (checked by TLC, 48 h). The reaction mixture was filtered and purified by column chromatography using methylene chloride/methanol (98:2.5) as eluent to give 0.24 g of pure product **11** and 0.07 g of contaminated product **11** (yield = 63%, $R_f$ = 0.27). The physical and spectral data of lactone **11** are as follows: oil; $^1$H NMR (500 MHz, $CDCl_3$) $\delta$ 0.92 (t, 3, $J$ = 7.4 Hz, $CH_3$-11), 1.56−1.69 (m, 2, $CH_2$-10), 2.17 (dt, 1, $J$ = 8.6, 1.7 Hz, one of $CH_2$-7), 2.27 (dt, 1, $J$ = 8.6, 1.7 Hz, one of $CH_2$-7), 2.67−2.74 (m, 2, $CH_2$-9), 3.40−3.41 (m, 1, CH-4), 5.26−5.27 (m, 1, CH-1), 6.62−6.64 (m, 1, CH-5), 6.87−6.88 (m, 1, CH-6); $^{13}$C NMR (151 MHz) $\delta$ 13.69 ($CH_3$-11), 17.81 ($CH_2$-10), 37.80 ($CH_2$-9), 54.69 ($CH_2$-7), 54.77 (CH-1), 60.24 (CH-4), 138.10 (CH-5), 140.50 (CH-6), 173.02 (C-8), 177.53 (C-3); IR (NaCl, $cm^{-1}$) 3019 (s), 2400 (m), 1700 (m), 1521 (m); GC-EIMS 180 (M + 1).

*2-Butyl-2-azabicyclo[2.2.1]hept-5-en-3-one (**12**).* To 2-azabicyclo[2.2.1]-hept-5-en-3-one (**10**) (0.3 g, 2.47 × $10^{-3}$ mol) was added anhydrous THF (5 mL), followed by the addition of NaH (8.3 × $10^{-3}$ mol). Then, butyl bromide at room temperature was added dropwise (4.96 × $10^{-3}$ mol). The reaction was continued until all of the substrate was reacted (checked by TLC, 48 h). The reaction mixture was filtered and purified by column chromatography using methylene chloride/methanol (98:2.5) as eluent to give 0.15 g of pure product **12** and 0.097 g of contaminated product **12** (yield = 54.4%; $R_f$ = 0.33). The physical and spectral data of lactone **12** are as follows: oil; $^1$H NMR (500 MHz, $CDCl_3$) $\delta$ 0.90 (t, 3, $J$ = 7.4 Hz, $CH_3$-11), 1.22−1.27 (m, 4, $CH_2$-9, $CH_2$-10), 2.11 (dt, 1, $J$ = 7.5, 1.7 Hz, one of $CH_2$-7), 2.28 (dt, 1, $J$ = 5.8, 1.7 Hz, one of $CH_2$-7), 2.84−2.88 (m, 1, one of $CH_2$-8), 3.09−3.14 (m, 1, one of $CH_2$-8), 3.30−3.31 (m, 1, CH-4), 4.14−4.15 (m, 1, CH-1), 6.62 (dt, 1, $J$ = 7.3, 5.6 Hz, CH-5), 6.69 (dt, 1, $J$ = 7.3, 4.8 Hz, CH-6); $^{13}$C NMR (151 MHz) $\delta$ 13.81 ($CH_3$-11), 20.09 ($CH_2$-10), 29.92 ($CH_2$-9), 43.43 ($CH_2$-8), 54.00 ($CH_2$-7), 59.10 (CH-4), 63.14 (CH-1), 138.16 (CH-5), 139.66 (CH-6), 180.52 (C-3); IR (NaCl, $cm^{-1}$) 3019 (s), 2400 (m), 1695 (m), 1518 (m); GC-EIMS 165 (M + 1).

*cis-5,6-Epoxy-2-azabicyclo[2.2.1]heptan-3-one (**13**).* To 2-azabicyclo[2.2.1]hept-5-en-3-one **10** (0.3 g, 2.47 × $10^{-3}$ mol) was added methylene chloride (15 mL), followed by the addition of *m*-CPBA (4.14 × $10^{-3}$ mol). The reaction was continued until all of the substrate was reacted (checked by TLC, 24 h). The reaction mixture was purified by column chromatography using methylene chloride/methanol (98:2.5) as eluent to give 0.265 g (yield = 77.3%; $R_f$ = 0.29). The physical and spectral data of lactone **13** are as follows: mp 95−100 °C; $^1$H NMR (500 MHz, $CDCl_3$) $\delta$ 1.62−1.64 (m, 1, one of $CH_2$-7), 1.80−1.82 (m, 1, one of $CH_2$-7), 2.84−2.90 (m, 1, CH-4), 3.56−3.58 (m, 1, CH-5), 3.64−3.69 (m, 1, CH-6), 3.87−3.90 (m, 1, CH-1), 6.24−6.26 (s, 1, NH); $^{13}$C NMR (151 MHz) $\delta$ 31.12 ($CH_2$-7), 46.88 (CH-4), 51.46 (CH-1), 55.61 (CH-5), 55.63 (CH-6), 180.43 (C-3); IR (NaCl, $cm^{-1}$) 3019 (s), 2400 (m), 1720 (s), 1518 (m), 1422 (m); GC-EIMS 126 (M + 1).

**Bioresolution of (±)-2-Azabicyclo[2.2.1]hept-5-en-3-one ((±)-10).** *Microbial Transformations of (±)-2-Azabicyclo[2.2.1]hept-5-en-3-one ((±)-**10**).* (a) Screening Scale Biotransformation. Microorganisms were cultivated in Erlenmeyer flasks (300 mL) containing 75 mL of the cultivation medium S (a solution of peptone 1% and glucose 3%) or C (an aqueous solution of $NaNO_3$ 0.3%, $KH_2PO_4$ 0.1%, KCl 0.05%, $MgSO_4·7H_2O$ 0.005%, $FeSO_4·7H_2O$ 0.001 g, and saccharose 3%). After 3−5 days of growth, 0.02 g of substrate (±)-**10** in 0.5 mL of acetone was added to the shaken cultivation mixture. The transformation was continued for 24, 72, 120, and 144 h. The products were extracted with diethyl ether or chloroform and analyzed using TLC and GC techniques. Enantiomeric excesses were determined by GC using chiral column Cyclosil-B (30 m × 0.25 mm × 0.25 $\mu$m with temperature program 80 °C (1 min), 130 °C (1 °C/min), and 250 °C (40 °C/min). For selected microorganisms optimization of biotransformation conditions was performed with regard to increased enantioselectivity and efficiency of a biocatalyst.

(b) Preparative Scale Biotransformation in Bench-Bioreactor. Bench-scale batch runs were carried out in 7 L vessels of the bioreactor (Brunswick, USA) in the selected conditions established on the basis of screening experiments. Growth of *P. thomi* AM91 was performed with the following parameters under control: medium volume (3 L), aeration rate (1 v/m), stirring speed (200−300 rpm), temperature (26 °C), pH. After 4 days of growth on mineral medium ($NaNO_3$ 0.3%, $KH_2PO_4$ 0.1%, KCl 0.05%, $MgSO_4·7H_2O$ 0.005%, $FeSO_4·7H_2O$ 0.001 g, and saccharose 3%) (pH 4.2), 30 g of peptone was added (pH 8.3). After 4 h, 1.0 g of (±)-**10** in 2 mL of acetone was added. The biotransformation was followed by GC with chiral column, once the substrate (±)-**10** was not detectable; the reaction mixture was overnight extracted in the same manner as in the screening procedure. The crude product was purified by column chromatography (methylene chloride/methanol, 97:3). The yield of the biotransformation calculated only for lactam **10** was 70% and the enantiomeric excess, 93% (GC, chiral column); $[\alpha]_{589}^{20}$ = −565° (*c* 2.0, $CHCl_3$) ($[\alpha]_{589}^{20}$ = −525.9° (*c* 1.0, $CH_3OH$)).[35] The physical and spectral data of lactone **10** are as follows: mp 55 °C; $^1$H NMR (500 MHz, $CDCl_3$) $\delta$ 2.19−2.20 (m, 1, one of $CH_2$-7), 2.37 (dt, 1, $J$ = 6.0, 1.7 Hz, one of $CH_2$-7), 3.19−3.23 (m, 1, CH-4), 4.31−4.35 (m, 1, CH-1), 5.85 (s, 1, NH), 6.64 (dt, 1, $J$ = 7.4, 5.0 Hz, CH-5), 6.76 (dd, 1, $J$ = 7.4, 5.0 Hz, CH-6); $^{13}$C NMR (151 MHz) $\delta$ 53.21 ($CH_2$-7), 59.32 (CH-1), 60.29 (CH-4), 138.18 (CH-5), 141.12 (CH-6), 185.34 (C-3); IR (NaCl, $cm^{-1}$) 3019 (s), 2400 (m), 1709 (s), 1521 (m); GC-EIMS 110 (M + 1).

*Biotransformations of (±)-2-Azabicyclo[2.2.1]hept-5-en-3-one ((±)-**10**) with the Use of Isolated Enzymes.* (a) Screening Scale Biotransformation. Substrate (±)-**10** (5 mg) was added to enzyme (the amount equal to 20 enzyme units of activity), dissolved in 0.5 mL of the phosphate buffer of pH 7.2. The reaction was stirred at room temperature. At the end of the process the reaction mixture was filtered through Celite, and the biotransformation products were extracted with diethyl ether. The enantiomeric excess of substrate **10** was determined by means of GC with application of chiral columns.

(b) Preparative Scale Biotransformation. Substrate (±)-**10** (0.2 g) was added to enzyme (the amount equal to 800 enzyme units of activity of Lipase B from *Candida antarctica* immobilized on Innobead 150, recombinant from *Aspergillus oryzea*), dissolved in 40 mL of the phosphate buffer of pH 7.2. The reaction was stirred at room temperature. At the end of the process the reaction mixture was filtered through Celite, and the biotransformation products were extracted with diethyl ether. The enantiomeric excess of substrate **10**

was determined by means of GC with application of chiral columns. The crude product was purified by column chromatography (methylene chloride/methanol, 97:3). The yield of the biotransformation was calculated only for lactam **10** and reached 74% with enantiomeric excess of (+)-**10**, ee = 99% (GC, chiral column); $[\alpha]_{589}^{20}$ = +565° (*c* 2.0, $CHCl_3$) ($[\alpha]_{589}^{20}$ = +555.9° (*c* 0.5, $CH_3OH$)).[35]

**Antifungal Assays.** All compounds dissolved in DMSO were mixed with sterilized PDA (0.01 mL of DMSO for 1 mL of agar) to achieve concentrations of 50, 100, 150, 200, 250, or 300 μg/mL, and the solution was poured into 6 cm Petri dishes. After inoculation by mycelium of a fungus, the tested dishes were incubated at 27 °C and 60−80% of relative humidity. The growth of mycelium was continued until the diameter of the growth zone in control sample dishes (nutrient with DMSO, without compound added) reached 4.5−5.0 cm. Then, the growth zone in experimental dishes was measured. All of the compounds were tested tripled at a concentration of 200 μg/mL as well as at three more concentrations, which were chosen individually. Fungistatic activity, expressed in $IC_{50}$ (the half-maximal inhibitory concentration) values for each tested compound, was determined on the basis of four measured values, as a percent of growth inhibition. $IC_{50}$ values were calculated according to the formula: $(1 - D_a/D_b) \times 100\%$, where $D_a$ is the diameter of the growth zone in the experimental dish (cm) and $D_b$ is the diameter of the growth zone in the control dish (cm). DDAC was used as reference compound. Statistical analysis was done using ANOVA ($p = 0.05$), and the means were compared by calculating the least significant difference (LSD, Tukey).

## RESULTS AND DISCUSSION

On the one hand, the aim of our research was the synthesis of *trans*-4-butyl-*cis*-3-oxabicyclo[4.3.0]nonan-2-one (**3**), one of the possible diastereoisomers of naturally occurring lactones. On the other hand, we planned to obtain a number of its derivatives from two groups of compounds: bicyclic lactones and bicyclic lactams. Our goal was to compare the fungistatic activities of natural lactone **3** and both groups of synthesized derivatives with those of lactone and lactam moiety. Moreover, we conducted enantioselective hydrolysis of lactam (±)-**10** by applying whole cells of fungi and isolated enzymes as well. The resulting compounds, including enantiomerically enriched isomers of lactam **10**, were tested for fungicidal activity against selected strains of filamentous fungi of the *Botrytis*, *Penicillium*, and *Aspergillus* genera.

**Synthesis of Bicyclic Lactones 2−4 and 6−8.** Taking into consideration the structure of natural lactone **3** (Figure 1), the effects of substituents at carbon atom C-4 and the C7−C8 double bond on fungistatic activity were investigated. Therefore, starting from two commercially available anhydrides, *cis*-1,2,3,6-tetrahydrophthalic anhydride (**1**) and *cis*-4-cyclohexene-1,2-dicarboxylic anhydride (**5**), the corresponding lactones without substituents ((±)-**2**, (±)-**6**), with *n*-butyl substituent ((±)-**3**, (±)-**7**), with two *n*-butyl substituents ((±)-**4**, (±)-**8**) at carbon atom C-4 were synthesized (Scheme 1). The influence of the double bond on the biological activity was also examined by comparing the results obtained from lactones (±)-**6**, (±)-**7**, and (±)-**8** possessing a C7−C8 double bond with their saturated derivatives (±)-**2**, (±)-**3**, and (±)-**4**.

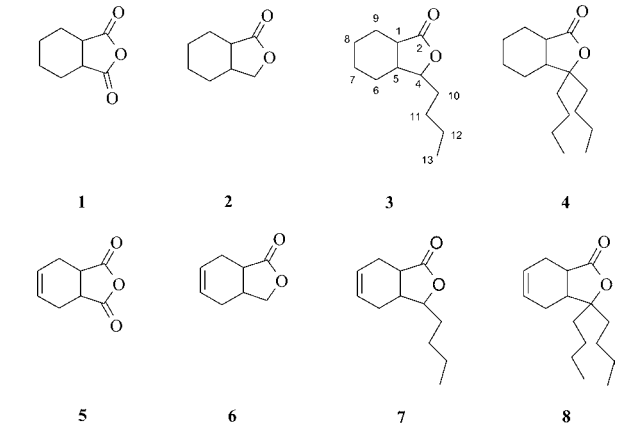

**Figure 1.** Structures of anhydrides (**1**, **5**) and bicyclic lactones (**2**−**4**, **6**−**8**) examined for fungistatic tests.

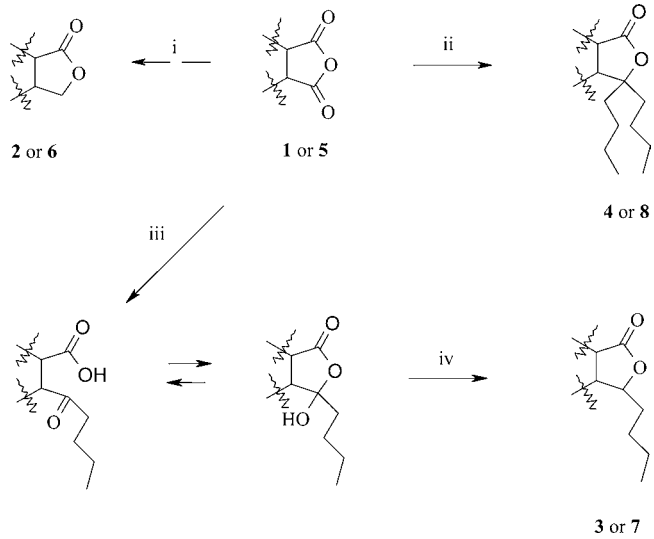
**Scheme 1**[a]



[a]i, $LiAlH_4$ $Et_2O$; ii, *n*-$C_4H_9MgBr$ (3 equiv), $Et_2O$ or THF; iii, (1) $Cd(n\text{-}C_4H_9)_2$, $Et_2O$ or THF, (2) HCl; iv, (1) $NaBH_4$, MeOH, (2) $THF/H_2O/HClO_4$, reflux.

Lactones (±)-3-oxabicyclo[4.3.0]nonan-2-one ((±)-**2**) and (±)-3-oxabicyclo[4.3.0]non-7-en-2-one ((±)-**6**) were obtained with high yield in reduction of the respective anhydrides **1** and **5** with lithium aluminum hydride in anhydrous diethyl ether. Signals in the $^1H$ NMR spectrum from two protons at carbon atom C-4 from lactone **2** were observed at 3.92 ppm (d, 1, $J$ = 8.8 Hz, one of $CH_2$-4) and 4.16 ppm (dd, 1, $J$ = 8.8, 5.0 Hz, one of $CH_2$-4); and from lactone **6** at 4.00 ppm (dd, 1, $J$ = 8.8, 2.0 Hz, one of $CH_2$-4) and 4.30 ppm (dd, 1, $J$ = 8.8, 5.1 Hz, 1H, one of $CH_2$-4).

(±)-*trans*-4-Butyl-*cis*-3-oxabicyclo[4.3.0]nonan-2-one ((±)-**3**), of the structure of the natural lactone,[19−23] was obtained in a three-step synthesis carried out without purification of intermediate products. In the first step the anhydride **1** reacted with a cadmium−organic compound[36,37] obtained from the reaction of *n*-butylmagnesium bromide with cadmium chloride. The reaction product isolated from acidic condition was a mixture of ketoacid and its cyclic form. The purification process of mixtures of ketoacid and the product of its cyclization was inefficient. Therefore, after evaporation of solvents, reduction with $NaBH_4$ in methanol and subsequent product cyclization in a mixture of $THF/H_2O/HClO_4$ was performed. Finally, the purification of reaction mixture on column chromatography afforded only one diastereoisomer, (±)-*trans*-**3**. The structure of the expected lactone (±)-*trans*-**3** was confirmed by the presence of a multiplet at 4.20−4.24 ppm from one proton at C-4 in the $^1H$ NMR spectrum. Lactone (±)-*trans*-4-butyl-*cis*-3-oxabicyclo[4.3.0]non-7-en-2-one

dx.doi.org/10.1021/jf502148h | J. Agric. Food Chem. 2014, 62, 8571−8578

((±)-**7**) was prepared from the respective anhydride **5** in the same procedure. The signal from proton at carbon atom C-4 was observed as a multiplet at 4.29−4.32 ppm.

The other two lactones, (±)-4,4-dibutyl-*cis*-3-oxabicyclo-[4.3.0]nonan-2-one ((±)-**4**) and (±)-4,4-dibutyl-*cis*-3-oxabicyclo[4.3.0]non-7-en-2-one ((±)-**8**), were obtained with good yields in Grignard reactions of 3 equiv of *n*-butylmagnesium bromide with 1 equiv of the corresponding anhydrides **1** and **5** (Scheme 1).

**Synthesis of Bicyclic Lactams 9−13.** Our studies concerned also bicyclic lactams, the second group of lactone **3** derivatives. We were interested in how the substitution of oxygen to nitrogen will influence the biological activity in the pair of lactone (±)-*cis*-3-oxabicyclo[4.3.0]non-7-en-2-one (**6**) and lactam (±)-*cis*-3-azabicyclo[4.3.0]non-7-en-2-one (**9**). The spectrum range of lactams applied in our research was increased by Vince lactam (2-azabicyclo[2.2.1]hept-5-en-3-one (**10**),[29−41] which we added to our studies (Figure 2). Both bicyclic lactams **9** and **10** have a double bond and γ-lactam moiety as well; however, they differ in the ring structure.

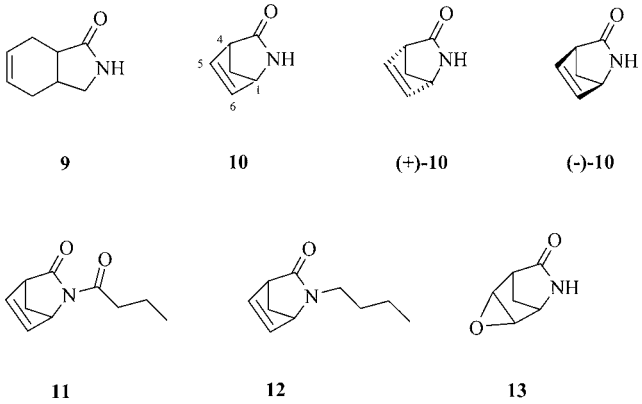


**Figure 2.** Structures of bicyclic lactams examined for fungistatic tests.

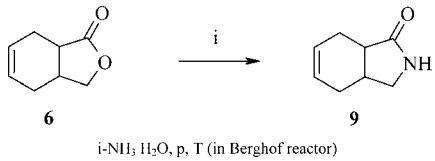
The obtained lactone (±)-**6** was used as the substrate for synthesis of lactam (±)-**9** conducted in a high-pressure autoclave (Berghof) using aqueous ammonia at high temperature and pressure as well (Scheme 2).

**Scheme 2**[a]



[a] i, $NH_3$ $H_2O$, p, T (in Berghof reactor).

Lactam (±)-**10**, with a structure similar to that of lactone **3** counterpart, was achieved by acylation of the nitrogen atom with butyric acid chloride, affording (±)-2-butyric-2-azabicyclo[2.2.1]hept-5-en-3-one ((±)-**11**) (Scheme 3). On the other hand, alkylation of lactam (±)-**10** with butyl bromide gave (±)-2-butyl-2-azabicyclo[2.2.1]hept-5-en-3-one ((±)-**12**) (Scheme 3). It was also worth checking the influence of the epoxy group on biological activity. Therefore, lactone (±)-**10** was oxidized to (±)-*cis*-5,6-epoxy-2-azabicyclo[2.2.1]heptan-3-one ((±)-**13**).

**Scheme 3**[a]

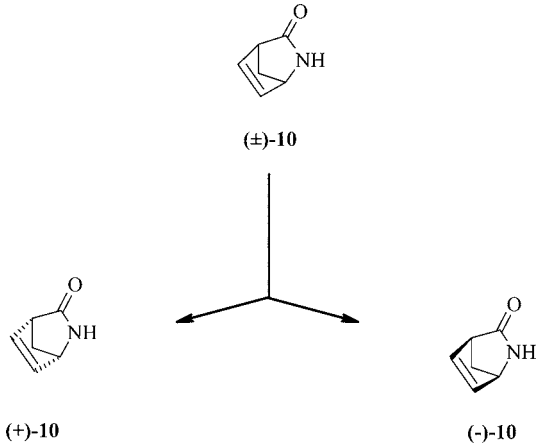
**Bioresolution of (±)-2-Azabicyclo[2.2.1]hept-5-en-3-one ((±)-10).** Resolution of the racemic mixture of lactam (±)-**10** involved screening of nine commercially available enzymes (Scheme 4; Table 1). All enzymes (entries 1−9, Table 1)

**Scheme 4**



hydrolyzed more quickly enantiomer (−)-(1*R*,4*S*)-**10**, leaving in a reaction mixture unreacted optically active (+)-(1*S*,4*R*)-2-azabicyclo[2.2.1]hept-5-en-3-one ((+)-**10**) isomer. All enzymatic transformations were carried out in phosphate buffer solution. The best result was obtained after 7 days of biotranformation with *Candida antarctica* lipase B (recombinant in *Aspergillus oryzea*). The (−)-enantiomer of **10** was hydrolyzed preferentially, whereas the opposite isomer, (+)-**10** (ee = 99%), was extracted from the reaction mixture. The scale-up methodology (up to 200 mg of the substrate) was easily increased.

In parallel to enzymatic reactions, the lactam (±)-**10** was subjected to a microbial transformations with the following 18 strains: *Aspergillus ochraceus* AM456, *Candida viswanathi* AM120, *Fusarium culmorum* AM282, *Fusarium oxysporum* AM13, *Inonotus radiatus* AM70, *Laetiporus sulphurens* AM514, *Penicillium camemberti* AM83, *Penicillium notatum* AM904, *Penicillium thomi* AM91, *Pezicula cinnamomea* AM53, *Poria placenta* AM38, *Prosthemium* sp. AM52, *Rhodotorula marina* AM77, *Rhodotorula rubra* AM4, *Sclerophoma pythiophila* AM55,

*Sparassis crispa* AM535, *Stemphylium botryosum* AM279, and *Yarrowia lipolytica* AM77.

Only strains of the *Penicillium* genus and *C. viswanathi* AM120 possess enzymes capable of the enantioselective hydrolysis of the γ-lactam ring. It needs to be emphasize that selected strains were not previously described as biocatalysts useful in racemic resolution of (±)-**10**. In our opinion the aforementioned strains are a valuable source of lactam hydrolases, and in this regard they can be considered for further investigation.

It should be noted that lipase isolated from *P. camemberti* catalyzed hydrolysis of the opposite enantiomer of (±)-**10** than whole cell culture of *P. camemberti* AM83. We assume that other enzymes from a broad range of lipases were involved in biotransformation.

In preparative biotransformation of (±)-**10** *P. thomi* AM91 was applied. This strain enantioselectively hydrolyzed (+)-**10** isomer, leaving enantiomerically enriched (−)-**10** isomer (ee = 93%) (structures given in Figure 2). During condition optimization of the biotransformation, it was noted that the enzymes involved in amide bond hydrolization were biosynthesized in the presence of peptone growth medium or in a similar source of nitrogen. In contrast, in the mineral medium supplemented with $NaNO_3$, hydrolysis did not occur. Therefore, in the preparative biotransformation, *P. thomi* AM91 initially grew on a mineral medium until peptone induction. After 4 days, 1% of peptone was added, and the pH of the medium increased to 8.3. After another 4 h, 1 g of (±)-**10** was added. Finally, (−)-**10** isomer with an enantiomeric excess of 93% was formed after 2 days of biotransformation.

**Fungistatic Activity.** The fungistatic activity of racemic mixtures of lactones **2**−**4** and **6**−**8** (Figure 1), lactams **9**−**13**, and enantiomerically enriched (+)-**10** and (−)-**10** isomers (Figure 2) against three phytopathogenic strains (*P. citrinum* AM354, *B. cinerea* AM235, *A. glaucus* AM211) was estimated. Screening tests were conducted at a concentration of 200 μg/mL. Then, $IC_{50}$ in the range from 0 to 350 for each connection was determined. Compounds of $IC_{50}$ above 350 were considered as not active, and the $IC_{50}$ value was not specified.

Among the studied compounds, six of them ((±)-**3**, (±)-**4**, (±)-**7**, (±)-**8**, (±)-**9**, (±)-**10**) indicated high activity with $IC_{50}$ from 104.6 to 130.0 μg/mL (entries 2, 3, and 5−8, Table 2) against *B. cinerea* AM235, the pathogen of grapes. Promising high fungistatic activity of lactones **3** ($IC_{50}$ = 143.2 μg/mL) and **7** ($IC_{50}$ = 110.2 μg/mL) against *P. citrinum* AM354, in contrast to low fungistatic activity against *A. glaucus* AM211 (epoxylactam **13** $IC_{50}$ = 107.2 μg/mL), was observed. Our interests focused on combating fungi of the *Aspergillus* genus; therefore, we examined the activity of racemic lactones **2**−**4** and **6**−**8** and lactams **9** and **10** against the other five strains belonging to species of *Aspergillus*. Figure 3 shows the percentage of mycelium growth inhibition at a concentration of 200 μg/mL.

**Table 2. Half-Maximal Inhibitory Concentration ($IC_{50}$) for Compounds 2−4 and 6−13 against *Aspergillus glaucus* AM211, *Botrytis cinerea* AM235, and *Penicillium citrinum* AM354[a]**

| entry | compound no. | *A. glaucus* AM211 (μg/mL) | *B. cinerea* AM235 (μg/mL) | *P. citrinum* AM354 (μg/mL) |
|---|---|---|---|---|
| 1 | **2** | 142.9 | >350 | >350 |
| 2 | **3** | 246.3 | 104.6 | 143.2 |
| 3 | **4** | 238.6 | 115.2 | >350 |
| 4 | **6** | >350 | >350 | >350 |
| 5 | **7** | >350 | 107.7 | 110.2 |
| 6 | **8** | >350 | 103.3 | >350 |
| 7 | **9** | 250.0 | 127.4 | 220.0 |
| 8 | **10** | 262.6 | 130.4 | 219.0 |
| 9 | (+)-**10** | 245.0 | 125.3 | 220.6 |
| 10 | (−)-**10** | 282.4 | 147.5 | 256.2 |
| 11 | **11** | 203.8 | >350 | >350 |
| 12 | **12** | 226.9 | >350 | >350 |

| 14 | DDAC | 57.1 | 30.4 | 41.3 |

[a]Statistical analysis was done using ANOVA ($p$ = 0.05), and the means were compared by calculating the least significant difference (LSD, Tukey). $IC_{50}$ was calculated on the basis of standard curve with standard deviation ±1.745−2.050.

**Fungistatic Acticity of Bicyclic Lactones 2−4 and 6−8.** The tests were performed with six racemic bicyclic lactones **2**−**4** and **6**−**8** (Scheme 1) of the structure allowing determination of the effect of substituents on carbon atom C-4 and the influence of the C7−C8 double bond on fungistatic activity

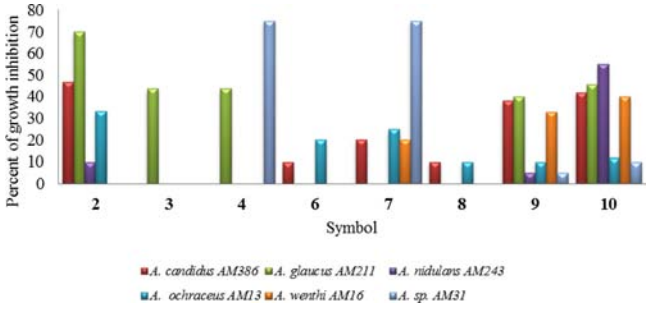

**Figure 3.** Percentage of growth inhibition of *Aspergillus* genus mycelium at a concentration of 200 μg/mL for lactones **2**−**4** and **6**−**8** and lactams **9** and **10**. Statistical analysis was done using ANOVA ($p$ = 0.05), and the means were compared by calculating the least significant difference (LSD, Tukey). $IC_{50}$ was calculated on the basis of standard curve with standard deviation ±1.745−2.050.

dx.doi.org/10.1021/jf502148h | J. Agric. Food Chem. 2014, 62, 8571−8578

against *A. glaucus* AM211, *B. cinerea* AM235, and *P. citrinum* AM354.

**Effect of Substituents on Carbon Atom C-4 on Fungistatic Activity.** Lactones (±)-**2** and (±)-**6**, without a substituent at carbon atom C-4, exhibited low fungistatic activity against tested strains (Table 2). Introducing one or two butyl groups caused a significant increase in fungistatic activity against *B. cinerea* AM 235 for (±)-**3** ($IC_{50}$ = 104.6 μg/mL (entry 2, Table 2)), (±)-7 ($IC_{50}$ = 107.7 μg/mL (entry 5, Table 2)), (±)-**4** ($IC_{50}$ = 115.2 μg/mL (entry 3, Table 2)), and (±)-**8** ($IC_{50}$ = 103.3 μg/mL (entry 6, Table 2)), respectively.

Otherwise, the aforementioned lactones affected the growth of *P. citrinum* AM354. Lactones with only one butyl group at C-4 were active: lactone (±)-**3** with the structure of natural lactone ($IC_{50}$ = 143.2 μg/mL (entry 2, Table 2)) and its analogue (±)-7 with the double bond at position C-7 ($IC_{50}$ = 110.2 μg/mL (entry 5, Table 2)).

**Effect of the C7−C8 Double Bond on Fungistatic Activity.** The presence of the C7−C8 double bond in the racemic lactones **6**−**8** indicated negligible or no effect on fungistatic activity against *P. citrinum* AM354 and *B. cinerea* AM235. In contrast, significant differences exist while for the inhibition of the growth of mycelium of *A. glaucus* AM211. Saturated racemic lactones **2**−**4** ($IC_{50}$ between 142.2 and 246.3 μg/mL, entries 1−3, Table 2) were more active than their analogues **6**−**8** ($IC_{50}$ > 350 μg/mL, entries 4−6, Table 2) with a double bond.

**Fungistatic Activity of Bicyclic Lactams 9−13.** *Effect of Heteroatom in the Five-Membered Ring on Fungistatic Activity.* By comparing the fungistatic activities against *B. cinerea* AM235 of lactone (±)-**6** and its analogue, lactam (±)-**9** (entries 4 and 7, Table 2), a significant increase in activity (from $IC_{50}$ > 350 μg/mL for lactone **6** to $IC_{50}$ = 127.4 μg/mL for lactam **9**) was observed.

*Effect of Ring Structure on Fungistatic Activity.* Both bicyclic lactams (±)-**9** and (±)-**10** possessed a γ-lactam ring and a double bond; however, they differed in the space structure (Scheme 3). These compounds inhibited the growth of all tested fungi to a comparable extent (entries 7 and 8, Table 2); therefore, we assumed that the γ-lactam ring and the nitrogen proton N−H significantly affect the biological activity.

*Effect of Substituents on the Nitrogen Atom of γ-Lactams on Fungistatic Activity.* The fungistatic activity of substituted lactams (±)-**11** and (±)-**12**, especially against *B. cinerea* AM235 and *P. citrinum* AM354, considerably decreased in comparison to that of unsubstituted lactam (±)-**10** from $IC_{50}$ = 130.0 μg/mL and 219.0 μg/mL (entry 8, Table 2) to $IC_{50}$ > 350 μg/mL (entries 11 and 12, Table 2).

*Effect of Double-Bond Oxidation on Fungistatic Activity.* Lactam (±)-**13**, the epoxy derivative of lactam (±)-**10**, was active ($IC_{50}$ = 107.1 μg/mL) against *A. glaucus* AM211 (entry 13, Table 2), but did not inhibit the growth of the other two strains tested.

*Effect of the Stereogenic Center on Fungistatic Activity.* Isomer (+)-(1*S*,4*R*)-**10** (ee = 91%) (entry 9, Table 2) inhibited more strongly the mycelium growth of all three strains (*A. glaucus* AM211, *B. cinerea* AM235, *P. citrinum* AM354), with an average of 15−20%, than its mirror image, (−)-(1*R*,4*S*)-**10** (ee = 93%) (entry 10, Table 2). Moreover, the (+)-**10** isomer was more active than the racemic mixture of 2-azabicyclo[2.2.1]hept-5-en-3-one ((±)-**10**).

**Fungistatic Activity against the *Aspergillus* Genus.** In general, synthesized lactones **2**−**4** and **6**−**8** and lactams **9** and **10** indicated low activity against *A. candidus* AM386, *A. nidulans* AM243, and *A. ochraceus* AM456 (Figure 3). Only compounds without an *n*-butyl substituent, (±)-3-oxabicyclo[4.3.0]nonan-2-one ((±)-**2**), (±)-3-azabicyclo[4.3.0]non-7-en-2-one ((±)-**9**), and (±)-2-aza-bicyclo[2.2.1]hept-5-en-3-one ((±)-**10**), inhibited more strongly the growth of mycelium of tested *Aspergillus* genus. Moreover, the growth of *A. glaucus* AM211 was inhibited by lactone (±)-**2**. Lactone (±)-4,4-dibutyl-3-oxabicyclo[4.3.0]nonan-2-one ((±)-**4**) and its analogue with a double bond ((±)-7) inhibited more strongly the growth of *Aspergillus* sp. AM31.

Analogues of natural *trans*-4-butyl-*cis*-3-oxabicyclo[4.3.0]-nonan-2-one (**3**) with a double bond at C-7 (**7**) or an additional butyl group at C-4 (lactones **4** and **8**) indicated the highest fungistatic activity ($IC_{50}$ = 104.6−115.2 μg/mL) toward *B. cinerea* AM235. However, only *trans*-4-butyl-*cis*-3-oxabicyclo-[4.3.0]nonan-2-one (**3**) and *trans*-4-butyl-*cis*-3-oxabicyclo-[4.3.0]non-7-en-2-one (**7**) exhibited high fungistatic activity ($IC_{50}$ = 143.2 and 110.2 μg/mL, respectively) against *P. citrinum* AM354, whereas lactones **3**, **4**, and **6**−**8** slightly inhibited the growth of mycelium of *A. glaucus* AM211.

The effect of a heteroatom in the five-membered ring on fungistatic activity was checked by comparing *cis*-3-oxabicyclo-[4.3.0]non-7-en-2-one (**6**) and its analogue, lactam *cis*-3-azabicyclo[4.3.0]non-7-en-2-one ((±)-**9**). A significant increase in activity (from $IC_{50}$ > 350 μg/mL for lactone **6** to $IC_{50}$ = 127.4 μg/mL for lactam **9**) against *B. cinerea* AM235 was observed. Also, (+)- and (−)-enantiomers of Vince lactam (**10**) and its three derivatives **11**−**13** were tested as fungistatic agents against *B. cinerea* AM235, *P. citrinum* AM354, and *A. gluacus* AM211. Isomer (+)-(1*S*,4*R*)-**10** with an average of 15−20% strongly inhibited mycelium growth of all tested strains.

The fungistatic activity of substituted nitrogen atom γ-lactams (±)-**11** and (±)-**12** considerably decreased in comparison to that of unsubstituted lactam (±)-**10** against *B. cinerea* AM235 and *P. citrinum* AM354. In contrast, oxidation of the double bond of lactam (±)-**10** increased the activity of epoxy derivative (**13**) ($IC_{50}$ = 107.1 μg/mL) against *A. glaucus*. As we indicated low activity of tested compounds against *A. glaucus* AM211, we have checked other *Aspergillus* genus species. Only compounds without an *n*-butyl substituent ((±)-3-oxabicyclo[4.3.0]nonan-2-one ((±)-**2**), (±)-3-azabicyclo[4.3.0]non-7-en-2-one ((±)-**9**), and (±)-2-aza-bicyclo[2.2.1]hept-5-en-3-one ((±)-**10**)) strongly inhibited growth of mycelium of tested *Aspergillus* genus species. Lactone (±)-4,4-dibutyl-3-oxabicyclo[4.3.0]nonan-2-one ((±)-**4**) and its analogue with a double bond ((±)-**8**) strongly inhibited growth of *Aspergillus* sp. AM31.

**ABSTRACT:** Herbicides, which are ubiquitously present in soil and food, have been proven to cause human health hazard effects, hence development of new herbicide-active compounds is recommended. In this paper, nine 2,4-bis(cycloalkyl)-6-chloro-*s*-triazines were considered as herbicide candidates and their pharmacokinetics and toxicity were reviewed on the basis of in silico descriptors. Both, pharmacokinetic and toxicity predictors were presented as functions of their lipophilicity, quantified with retention constants that were obtained by liquid chromatography. None of the candidates investigated has functional groups for genotoxicity hazards and endocrine disruptions; they have acceptable toxicity and favorable pharmacokinetic properties based on computer-aided analyses. Two candidates have been selected as lead compounds for further research.

**KEYWORDS:** *herbicide candidates, triazines, in silico, pharmacokinetics, toxicity*

## INTRODUCTION

*s*-Triazines are compounds with pharmaceutical, chemosterilant and industrial importance. They are widely used as herbicides in agriculture and industry, and some of the compounds also have fungicidal properties.[1] Several of the most widely used herbicides (the class of 2-chloro-*s*-triazines) have been proven to induce the human aromatase enzyme (which converts androgens to estrogens) in vitro at relatively low concentrations. During critical developmental periods, aromatase induction may contribute to estrogen-mediated toxicities and inappropriate sexual differentiation.[2,3]

Hence, development of new *s*-triazine derivatives that have herbicide activity but fewer side effects is justified. It can be very informative to apply the main postulates of a drug designing process in an herbicide candidate screening process and to determine both compounds that have preferable pharmacokinetic and biological properties and to alert for those compounds with highly undesirable behavior in the human body in order to avoid late-stage attrition.[4] The implementation of appropriate management strategies requires that adequate information be developed regarding the types, physical and chemical properties, and toxicity of these compounds. The biological activity of a compound depends, among other factors, on its ability to reach the intended site of action.[5−7]

The physicochemical properties of a drug or pesticide have an important impact on its pharmacokinetic and metabolic fate in the body. Measurement and prediction of physicochemical characteristics are crucial in the development process of in silico models that allow early estimation on absorption, distribution, metabolism, and excretion (ADME) and toxicity data (together called ADMET data). Today, simple multiple linear regression and modern multivariate analysis techniques are now being applied to the analysis of ADME data and present the most applied quantitative structure−activity (or property) relationship [QSA(P)R] strategies.[8]

One of the most commonly referred descriptors in QSA(P)R analyzes is lipophilicity of a substance. It is usually quantified as the logarithm of the water−octanol partition coefficient for partitioning of the agent between the two immiscible solvent phases and expressed as log *P*. Partition coefficient, *P*, quantified as log *P*, can be precisely computed by using atomic or fragment-addition approaches or experimentally determined by a traditional shake-flask method or by application of chromatographic methods. In addition, the presence of more than one species (ionizable and molecular) in solutions with different pH values results in an apparent partition coefficient or distribution coefficient *D*, expressed as log *D*.[9]

The chromatographic methods are a useful alternative for lipophilicity quantification of drug or pesticide candidates. Net of bonds and interactions of the molecule with nonpolar stationary and polar mobile phase are very similar to the partitioning between the phospholipids bilayer and body fluids, which influences pharmacokinetic properties.[10,11] Thin-layer chromatography (TLC) allows the possibility of simultaneous analysis of several analytes, it is simple and economical, and it equalizes the differences that arise from the application of various organic solvent−water mixtures because extrapolated values to 0% of the organic solvents are applied; so it has still been an attractive method for lipophilicity quantification.[12] In

this paper some *s*-triazines are overviewed as herbicides candidates, their pharmacokinetic and toxicity descriptors are discussed and presented as a function of lipophilicity described as retention constants.

## MATERIALS AND METHODS

A new series of nine *s*-triazine derivatives (Table 1) has been studied for their retention behavior on reversed-phase thin layer chromatography (RP-TLC), and the obtained retention constants $R_M^0$, which reflect their lipophilicity, have been correlated to pharmacokinetic and toxicological descriptors obtained with acd/i-lab-2.0 software package. RP-TLC was performed on silica gel C18 (Macherey-Nagel) with five different volume fractions ($\varphi$) of acetone in water−acetone mobile phase. Solutions for chromatographic investigations were prepared by dissolving in chloroform and were spotted on the plates with micropipette. Approximately 0.2 $\mu$L of each freshly prepared solution was spotted on the plates. Ascending technique has been used for chromatographic development. Dried plates after development were examined at 254 nm. $R_f$ values were calculated as an average out of three measurements.

## RESULTS AND DISCUSSION

The retention behavior of *s*-triazines was investigated by changing the amount of organic modifier in the mobile phase and has been already previously reported.[13−16] The $R_M$ value for each compound was calculated as

$$R_M = \log\left(\frac{1}{R_f} - 1\right) \quad (1)$$

Relationships between retention values, $R_M$, of the compound and the volume fraction, $\varphi$, of organic modifier in the mobile phase were, as expected, linear and are expressed by the well-known equation:

$$R_M = R_M^0 + b\varphi \quad (2)$$

where $R_M^0$ (intercepts) are the extrapolated values corresponding to $\varphi$ = 0% and $b$ are the slopes of the linear plot. Regression equations derived for individual compounds are characterized by different slopes, which means that changes in mobile-phase composition have different effects on the $R_M$ values and that the slopes, $b$, correlate with the eluent strength of organic modifier. Linear relationships between the intercept, $R_M^0$, and the volume fraction of the organic modifier were characterized by high correlation coefficients (Table 2).

[a] $p < 0.0001$.

In partition chromatography there is usually a linear correlation between $R_M^0$ and slope $b$. If linearity is observed, the compounds form a congeneric class.[17] Linear relationship between intercept $R_M^0$ and slope $b$ is given as

$$R_M^0 = -1.754 - 1.181b$$

where adj $r^2$ = 0.949, $F$ = 148.628, and $p < 0.0001$.

Sum effect of intermolecular interactions between analyte, stationary phase, and mobile phase define the chromatographic behavior of a molecule. Hydrophobic interactions dominantly guide the retention process of agents in reversed-phase liquid chromatography, hence good correlations (linear or parabolic) between the retention factor, $R_M^0$ and the standard lipophilicity parameter, log $P$, can be expected.[18]

Linear correlation was obtained between retention constants determined in RP TLC and log $P$ (ClogP and ACDlogP calculated by different software packages; Table 3) and more importantly with log $D$ (Table 3), which is consistent with literature data[19] in which a linear relationship between the retention constant log $k_w$ determined in HPLC and different log $P$ values has been described. Since the relationship between slopes $b$ and intercepts $R_M^0$ of the RP TLC equations has excellent statistical quality, the slopes can be considered alternative to intercepts for lipophilicity parameters. The slopes $b$ of RP TLC equations were correlated with log $P$ and log $D$ from calculation chemistry. It is evident that the slopes $b$ of TLC equation (eq 2) may be applied for lipophilicity expression (Table 4) of the compounds investigated with similar reliability like the intercepts, which well agrees with a report by Valko.[20]

Both retention constants $R_M^0$ and $b$ also vary with the size of the molecules quantified as molecular weight (MW)—that is, the number of C atoms (nC) in the substituent rings—since other physicochemical properties of the analytes do not alter with the change of their structure. Namely, the polarity of the molecules, described as total polar surface area (TPSA), number of hydrogen-bond donors (NHBD) and acceptors (NHBA), and elasticity of the molecules, quantified as number

of rotatable bonds (NRB), are constant for the analytes observed in this paper (Table 3), so the factors that influence the retention behavior of molecules are their lipophilicity and molecular size (Figure 1).

Pharmacokinetic predictors, calculated by use of computation program i-lab 2.0, are presented in Table 5.

High oral bioavailability is an important factor for the development of bioactive molecules as therapeutic agents but is undesirable for any xenobiotic that can be ingested. The rate and extent of intestinal absorption are mainly dependent on (i) dissolution rate of the drug (xenobiotics) in gastrointestinal fluids and (ii) rate of transport across the intestinal membrane. In light of present knowledge, it is probable that the predominant process of absorption for most conventional drugs (and xenobiotics) is passive diffusion. Varying types of approaches are used to predict the rate of passive intestinal absorption of drug candidates (or xenobiotics).[21]

Models applied in the early discovery phase typically allow rapid screens of a large number of compounds. The highest throughput can be obtained with computational quantitative structure−property relationship (QSPR) models.[22] Models developed to predict passive intestinal absorption can be evaluated by employing them to predict the intestinal absorption of a set of passively absorbed compounds with known values of the percentage of dose absorbed (abs%) in humans or constant of absorption $k_a$, defined as the ratio of natural logarithm of 2 and the half-time of compound absorption ($t_{a1/2}$): $k_a = \ln 2/(t_{a1/2})$. Compared with predicted abs%, predicted $k_a$ is more informative in the drug discovery process because the rate of absorption among completely absorbed drugs can vary.[9]

Properties of molecules such as bioavailability or membrane permeability have often been connected to simple molecular descriptors such as log $P$, MW, or counts of hydrogen-bond acceptors and donors in a molecule.[23−25] Lipinski et al.[26] have used these molecular properties to formulate the "rule of five". The rule states that most molecules with good membrane permeability have ClogP ≤ 5, molecular weight ≤ 500, number of hydrogen-bond acceptors ≤ 10, and number of hydrogen-bond donors ≤ 5. Investigated *s*-triazines have molecular weight under 500, two hydrogen-bond donors, five hydrogen-bond acceptors, and four rotatable bonds (Table 3). However, only three compounds have ClogP under 5, for which good oral absorption can be assumed. Compounds with more than 6 C atoms in substituent rings have ClogP over 5 and violate one rule; hence, for these compounds low membrane permeability can be expected, due to very low solubility (Table 3), and consequently very poor absorption. Nevertheless, absorption constants for compounds investigated are predicted to be low (0.048−0.06 $\text{min}^{-1}$, Table 5); that is, they have short half-times of absorption (11−15 min), which practically guarantee unomitted permeation through enterocytes. However, very low solubility for over 6C-in-rings-compounds should not be neglected for herbicide candidates.

The absorption constant defines the rate of transport through membrane and it is completely associated with lipophilicity quantifiers $R_M^0$ and $b$:

$$k_a = 0.066 - 0.004R_M^0$$

where adj $r^2 = 0.983$, $F = 466.892$, and $p < 0.0001$, and

$$k_a = 0.072 + 0.004b$$

where adj $r^2 = 0.902$, $F = 74.658$, and $p < 0.0001$, although only compounds with 3, 4, 5, and eventually 6 carbons in the rings should be considered for further pharmacokinetic profiling on the basis of violation of Lipinski's rule for the rest of the compounds. This good and fast absorption for compounds can be expected for these four molecules, so their further action in the human body will be the key in the selection process of herbicide candidates with the least side effects. The change of pharmacokinetic behavior of all considered compounds, however, is very informative, and all compounds will be considered.

The concentration of drug (or xenobiotic) in the plasma or tissues depends on the amount of xenobiotic systemically absorbed and the volume in which the xenobiotic is distributed. The apparent volume of distribution in the body, $V_d$, is the most important pharmacokinetic parameter that determines the extent of drug or any other xenobiotic distribution. It is simply a proportionality constant that relates the amount of xenobiotic in the body and/or compartments of the body (peripheral compartments) to its plasma (central compartment) concen-

tration. $V_d$ is assumed to be constant for a xenobiotic that follows a one-compartment pharmacokinetic model and is calculated as the dose taken divided by the plasma concentration of the compound at time zero ($C_0$):[27,28] $V_d$ = dose/$C_0$.

Since accumulation of xenobiotic in fat tissue causes major problems and for many xenobiotics is the main health concern, $V_d$ of newly synthesized compounds that may have frequent use in everyday life is an important subject. These homologous series of investigated compounds have moderate predicted $V_d$ values (range 1.8−7.1 L/kg) (Table 5), indicating that no serious accumulation of compound in fat tissue occurs. $V_d$ can be larger for very hydrophobic compounds, which accumulate in the fat tissue. Lipophilicity of analytes has a leading role in the distribution process (as in absorption process) of investigated triazines. Figure 2 shows the change of $V_d$ with lipophilicity of the triazines investigated. The most important observation is that compounds which should have good oral absorption (**1**−**4**) are the least lipophilic compounds and are presumed to have the smallest $V_d$, which is highly preferable.

In the drug development process, it is desirable to recognize those drug candidates which are potential high binders for plasma proteins in early virtual screening procedures. Drug bound to plasma proteins is not active i.e. —that is, it is not able to cross membranes, pass the central compartment, and diffuse into the interstitial space—hence it cannot permeate to the site of action nor bind to receptors.[29] Although drugs require low binding values for xenobiotics, it is preferable to have a small free compound concentration in plasma in order to prevent possible side effects and remain nonpharmacologically active in the human body. From Table 5 it can be observed that compounds investigated are expected to have

dx.doi.org/10.1021/jf502405k | J. Agric. Food Chem. 2014, 62, 8579−8585

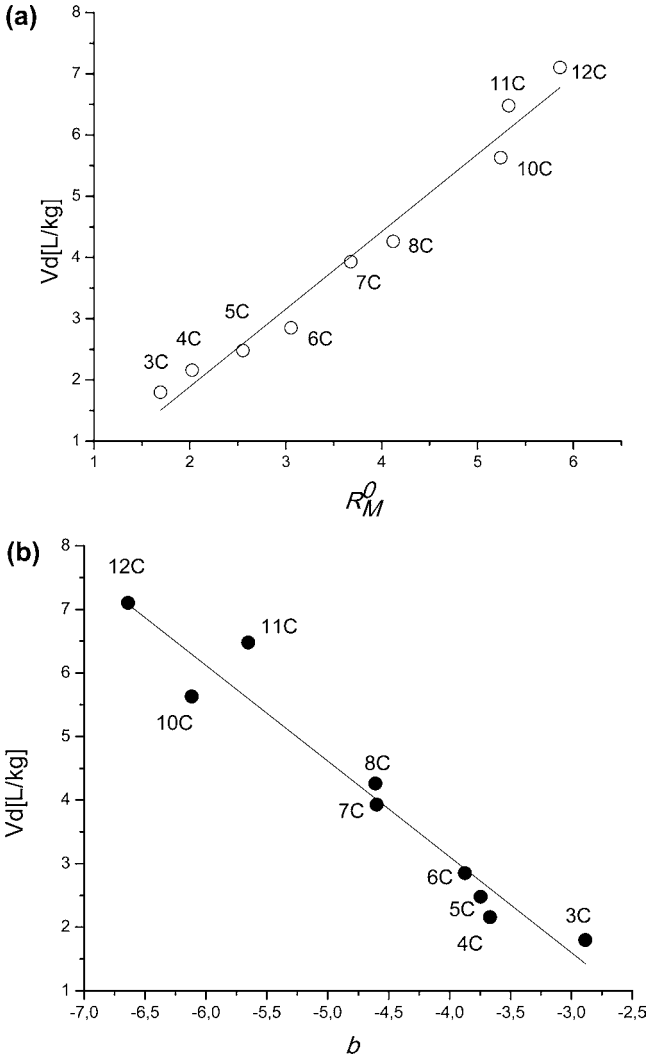

**Figure 2.** In silico estimated volume of distribution, $V_d$, presented as linear function of (a) lipophilicity of the analytes, quantified as $R_M{}^0$ and given as $V_d = -0.642 + 1.266R_M{}^0$ [adj $r^2 = 0.970$, $F = 262.309$, $p = 8.324 \times 10^{-7}$], and (b) slopes $b$, presented as $V_d = -2.914 - 1.506b$ [adj $r^2 = 0.936$, $F = 118.626$, $p = 1.215 \times 10^{-5}$].

very low free concentration (only 8% or less) in plasma, which guarantees small or no pharmacological effectiveness in the human body. It is widely accepted that protein binding and especially binding of drugs and other xenobiotics to serum albumin is generally nonspecific and strongly influenced by hydrophobic interactions within small congeneric series of compounds. However, lipophilicity seems not to be the dominant chemical property for albumin binding affinity when structurally different drugs or xenobiotics are compared.[30]

Since we are dealing with structurally similar compounds, the examination of dependence between PPB and lipophilicity is strongly recommended. Statistically high square function was determined between lipophilicity and PPB. As the number of C atoms in the ring increases, both lipophilicity and affinity for albumins elevate until the highest level (over 99% bound for human plasma albumins) is achieved for compounds that have 10 or more C atoms in rings:

$$\text{PPB} = 83.572 + 5.727R_M{}^0 - 0.512(R_M{}^0)^2$$

where adj $r^2 = 0.941$, $F = 64.256$, and $p < 0.0001$, and

$$\text{PPB} = 72.027 - 8.719b - 0.686b^2$$

where adj $r^2 = 0.807$, $F = 17.718$, and $p < 0.005$. It should be emphasized that high affinity for plasma proteins and very small free plasma concentration is characteristic for these sets of compounds, including those that are expected to absorb easily and in great percentage.

The blood–brain barrier is the formidable obstacle that restricts the brain entry of most hydrophilic compounds. Permeation of drugs through the blood–brain barrier is usually described as a logarithmic value. For many neurological drugs, a positive value for log BBB that tends to reach 1 is preferable, while for most xenobiotics, a negative value for log BBB or values close to zero indicate that those compounds are unable to gain access to the brain or lack sufficient concentration for an appropriate time; hence neurotoxicity should be diminished.[31,32]

The novel set of compounds observed in this paper, as demonstrated in Table 5, have log BBB values that vary from −0.17 up to 0.77. It can be assumed that compounds with only 3 and 4 C atoms or those with more than 10 C atoms in the rings are expected to have very low log BBB. Nevertheless, compounds with 5–8 C atoms in rings have moderate log BBB, and for them poor penetration in the brain can be predicted. These assumptions agree with Clark's[33] rule of thumb, on which basis all compounds violate at least one of the following rules:

- Rule 1: The sum of nitrogen and oxygen (N + O) atoms in a molecule should be five or fewer to facilitate brain permeation.
- Rule 2: ClogP − (N + O) > 0 is recommended.
- Rule 3: Polar surface area (PSA) of the compound should be below 90 Å$^2$ (60–70 Å$^2$).
- Rule 4: If molecular weight (MW) is below 450, then the molecule has a high chance of entering the brain.
- Rule 5: If log $D$ value is in the range 1–3, then log BBB is likely to be positive.

These compounds do have polar surface area around 60 Å$^2$ and molecular weight around 450 and less, as well as a sum of nitrogen and oxygen atoms 5 or fewer. However, all compounds violate rule 1 or rule 5. Compounds with 5 or fewer C atoms in the substituent rings do not obey the rule ClogP − (N + O) > 0, while rule 5, log $D$ = 1–3, is broken by compounds with 5 or more C atoms in rings. For potential herbicides that can be absorbed in the human body, low permeation in the brain is desirable as it is predicted. The most important is the small brain permeability by compounds with 3C, 4C and 5C atoms in the substituent rings, which have the best features for herbicide candidates.

The generally accepted physicochemical models of BBB permeability have recognized as their primary determinants for passive transport the analyte's lipophilicity and polarity.[34] Having in mind the constant polarity of the compounds (Table 3), log BBB should be associated only with the lipophilicity of the analytes. For this set of compounds, parabolic correlation with high statistical quality has been established between log BBB and lipophilicity of the solutes:

$$\log \text{BBB} - 1.981 + 1.384R_M{}^0 - 0.182(R_M{}^0)^2$$

where adj $r^2 = 0.864$, $F = 26.350$, and $p < 0.005$, and

$$\log \text{BBB} = -4.634 - 2.157b - 0.220b^2$$

dx.doi.org/10.1021/jf502405k | J. Agric. Food Chem. 2014, 62, 8579–8585

where adj $r^2$ = 0.802, $F$ = 15.151, $p < 0.01$, and compound **8** is excluded.

The increment of C atom number in the rings leads to elevation of the molecular weight and lipophilicty of the molecules which at first facilitates permeability into the brain. Further elevation of lipophilicity diminishes their permeation, probably due to low solubility and dissociation in water body fluids.

The critical point in drug development programs, which is recognized by the pharmaceutical industry and safety assessment regulatory authorities, is the early identification of serious toxicological issues in order to prevent significant investment of time and resources for new drugs in late stages of clinical development.[35] For new herbicide candidates, low animal and human toxicity is one of the most important issues. On the basis of in silico calculations, predicted acute toxicity of the compounds investigated (Table 6) compared to data for

toxicity of atrazine,[36,37] simazine,[38−42] propazine,[43−47] and terbuthylazine[48,49] indicates slight to moderate toxicity to humans and other animals for the compounds investigated; that is, they have acceptable toxic properties.

In addition, not only do predicted oral absorption and distribution of compounds investigated depend on their lipophilicity, but values of toxicity predictors are also changed in accordance with lipophilicity alternation. There is a linear increment of both intravenous and intraperitoneal toxicity in mouse (i.e., decrement of $LD_{50}$ dosages predicted on the basis of structure) with the elevation of lipophilicity of the analytes experimentally quantified as retention constants $R_M{}^0$ and $b$:

$$LD_{50}\ (\text{ip mouse}) = 315.490 - 33.959R_M{}^0$$

where adj $r^2$ = 0.825, $F$ = 38.646, and $p < 0.0005$;

$$LD_{50}\ (\text{iv mouse}) = 90.866 - 14.747R_M{}^0$$

where adj $r^2$ = 0.811, $F$ = 35.259, and $p < 0.001$;

$$LD_{50}\ (\text{ip mouse}) = 376.480 + 40.400b$$

where adj $r^2$ = 0.796, $F$ = 32.123, and $p < 0.001$; and

$$LD_{50}\ (\text{iv mouse}) = 118.021 + 17.688b$$

where adj $r^2$ = 0.797, $F$ = 32.441, and $p < 0.001$.

Finally, investigated compounds were tested in silico as possible causes of human endocrine system disorders and genotoxic hazards. Namely, several members of the class of 2-chloro-*s*-triazine herbicides (atrazine, simazine, and propazine) induce the human aromatase enzyme (which converts androgens to estrogens) in vitro at relatively low concentrations. A logical concern would be that exposure of wildlife and humans to triazine herbicides, which are produced and used in large quantities and are ubiquitous environmental contaminants, may similarly contribute to estrogen-mediated toxicities and inappropriate sexual differentiation.[50,51] Investigated derivatives of *s*-triazine, according to in silico analyses, do not have functional groups for genotoxicity hazards and endocrine disruptions.

On the basis of the obtained results, it can be concluded that for further herbicide candidates, compounds **1** and **2** with 3C and 4C atoms in the substituent rings can be reviewed.

Supporting Information

**ABSTRACT:** A UV Fenton-like digestion method was developed first time for a complete digestion of milk samples by using 1.6 g $L^{-1}$ $Fe_3O_4$ magnetic nanoparticles, 0.2% (v/v) nitric acid, and 6% (w/w) $H_2O_2$. During the digestion, the liberated As-, Sb-, and Bi-containing species were preconcentrated onto the surface of $Fe_3O_4$ magnetic nanoparticles, which were conveniently separated with a hand-held magnet and subsequently dissolved in hydrochloric acid prior to hydride generation atomic fluorescence spectrometric detection. Owing to the integration of UV Fenton-like digestion, solid phase extraction, and magnetic separation into a single step, the developed method significantly simplifies sample preparation steps and reduces chemical consumption and hazardous waste. Limits of detection of 0.0015, 0.0022, and 0.0025 $\mu$g $L^{-1}$ were obtained for As, Sb, and Bi, respectively, using a 50 mL milk sample. The method was applied to the determination of these elements in a Certified Reference Material and milk samples.

**KEYWORDS:** *$Fe_3O_4$ MNPs, Fenton reaction, sample pretreatment, hydride generation, solid phase extraction*

## INTRODUCTION

Generally, the accurate and precise determination of toxic or essential elements in food samples involves a sample pretreatment step (e.g., digestion, separation, and concentration) and a signal acquisition step. The performance of the latter has been significantly improved in recent years; however, the sample pretreatment techniques have changed little. Unfortunately, sample pretreatment not only seriously affects the accuracy and reproducibility of final results but also generates wastes which are toxic and have adverse effects on the environment. Consequently, there is a growing interest in developing green sample pretreatment procedures that produce less hazardous wastes to the environment.[1−4] For the determination of trace metals in solid or organic matrix food samples by atomic spectrometry, samples need to be digested into homogeneous aqueous solutions prior to their analyses. Typically, digestion is carried out by either open-vessel or closed-vessel techniques with relative large amounts of concentrated acids (e.g., HCl, $HNO_3$, $H_2SO_4$) at high temperature conditions.[5−10] Major drawbacks of open-vessel digestion techniques include the potential analyte loss and generation of toxic acid mist through volatilization. Closed-vessel digestion techniques, especially microwave assisted-digestion, can reduce digestion time, minimize analyte loss, and alleviate toxic wastes. However, the concentrated mineral acids in the digested solutions are not favorable to the subsequent measurements, thus, a tedious and time-consuming procedure of separation and concentration is needed, such as extraction and evaporation.

UV photo-oxidation is considered as a green alternative for the digestion of organic matrix sample.[11] Compared to the conventional acid digestion, only small amounts of reagents are required. Thus, the potential pollution is significantly minimized, which benefits the operator and the environment. In general, a few hours are needed for a complete digestion of samples in typical UV digestion (UVD).[11] As a result, microwave assistance[12−14] was frequently applied in this system to improve the digestion efficiency. The Fenton reaction may be considered as one of the most efficient and advanced oxidation techniques because of its long historical association with degradation of organic compounds and other pollutants.[15−17] Similar to UVD, the active species (for example, $^{\bullet}OH$) are produced by the reduction of $H_2O_2$ with Fe(II) or other transition metal ions at a suitable pH range. As a result, Fenton reaction has been frequently combined with UVD to significantly improve the degradation efficiencies of pollutants and reduce the degradation time.[18,19] Although homogeneous Fenton reaction using Fe(II) or other transition metal ions is of high efficiency, it remains several disadvantages including narrow working pH range (2.5−3.5) and the accumulation of large excess of unrecyclable transition metals containing sludge to environment.[20] To overcome these drawbacks, the development of heterogeneous Fenton reaction such as using solid iron oxides is gaining popularity as an alternative to homogeneous Fenton reaction.[21,22] Unfortunately, additional energies are required due to their weak catalytic activity of bulk materials.[23]

Despite its 120-year history, Fenton reaction technique has been continuously improved over the last of a few decades. Recently, an intriguing oxidase-mimic property of $Fe_3O_4$ magnetic nanoparticles (MNPs) which can convert $H_2O_2$ into $^{\bullet}OH$ radicals to efficiently break down organic substances, was discovered by Yan et al.[24] Other nanomaterials have also attracted attention on their use for the degradation of various organic compounds.[25−29] Despite an increased interest in the Fenton reaction over the past 50 years, applications in sample pretreatment have remained limited. Recently, Shelor et al.[30] reported an interesting study on the use of homogeneous Fenton reaction for the digestion of milk prior to the determination of iodine by isotope dilution inductively coupled plasma mass spectrometry (ID ICP-MS), but the whole digestion had to be held in an oven overnight at 60 °C. On the basis of previous studies,[24−30] it is suggested that the performance of UV Fenton digestion (FD) may be significantly improved by the oxidase activity of $Fe_3O_4$ MNPs. However, no such attempt has emerged.

In general, the accurate determination of trace elements in many environmental and biological samples is a challenge even when complete digestion of sample can be realized, because of their very low contents. Thus, numerous preconcentration protocols have been developed to improve the detection limits.[31−33] Among those, solid phase extraction (SPE) using $Fe_3O_4$ MNPs has been proven to be a simple, organic solvent free and environmentally benign technique for the preconcentration of analytes, wherein analytes can be conveniently separated from matrix by using a permanent hand-held magnet.[34−36] In this study, a novel UV Fenton-like digestion (FLD) method using $Fe_3O_4$ MNPs and UV-FD under simple and mild conditions was developed for the determination of trace metals in food samples. The determination of As, Sb, and Bi in milk was selected to evaluate the proposed methodology since these elements are very toxic to humans and animals.[35,36] To the best of our knowledge, this is the first study utilizing $Fe_3O_4$ MNPs as an effective catalyst and adsorbent to accomplish complete digestion of milk, and to integrate UV-FLD, SPE and magnetic separation into a single step. The separated $Fe_3O_4$ MNPs were dissolved in hydrochloric acid prior to hydride generation (HG) AFS detection. The proposed method not only significantly alleviates the disadvantages of conventional acid digestion but also provides unique advantages of excellent digestion efficiency, high sample throughput, green analytical chemistry, and the elimination of tedious separation steps during SPE.

## MATERIALS AND METHODS

**Chemicals.** All reagents used were analytical grade or better. 18.2 MΩ-cm deionized water (DIW) produced by a water purification system (Chengdu Ultrapure Technology Co., LTD, China) was used to prepare solutions throughout the study. Standard solutions were prepared daily by diluting stock solutions (1000 mg $L^{-1}$) of As(III), Sb(III), and Bi(III) that were purchased from National Research Center of China (NRCC, Beijing, China). Thiourea was purchased from Kelong Chemical Reagents Co. (Chengdu, China) and used for prereduction of high oxidation state of As, Sb, and Bi prior to hydride generation. $H_2O_2$ (30%, w/w), HCl, $HNO_3$, KOH, $KBH_4$, $FeCl_2$, $FeCl_3$, $FeSO_4$, and $NH_3{\cdot}H_2O$ were also purchased from Kelong Chemical Reagents Co. $KBH_4$ solution was prepared daily by dissolving a proper amount of solid reagent in 0.5% (w/v) KOH. High-purity argon (Ar) and nitrogen ($N_2$) were obtained from Qiaoyuan Gas Co. (Chengdu, China).

A commercial milk sample (HX) spiked at 20 μg $L^{-1}$ of Sb(III) and 10 μg $L^{-1}$ of As(III) and Bi(III) was used to investigate the optimum experimental conditions. A Certified Reference Material (CRM, milk powder, GBW10017-GSB-8) from Beijing Century Oak Biotechnology Co., Ltd. and four commercial milk products (HX, YL, GM, and MN) bought at the local market were analyzed to evaluate the accuracy of the proposed method.

**Instrumentation.** A homemade UV digestion device consisting of a 15 W low pressure UV mercury lamp (Philips Co., Holland), a cylindrical glass container, a black rubber stopper, and six quartz digestion tubes (11 cm length × 8 mm i.d. × 10 mm o.d.; about 7 mL internal volume) or four bigger quartz digestion tubes (11 cm length × 28 mm × 30 mm o.d.; about 60 mL internal volume) was used to digest milk samples. The lamp and the quartz tubes were tightly bound together and further fastened through the holes made on the stopper, and then jam-packed and housed in the container over which a flow of Ar was passed to eliminate oxygen to avoid ozone generation. The container was wrapped with aluminum foil to reflect UV radiation from the lamp, enhancing digestion efficiency, and protecting the operator.

A commercial double-channel HG nondispersive atomic fluorescence spectrometer (AFS, Model AFS-2202, Beijing Haiguang Instrument Co., Beijing, China) was used for all measurements. This instrument as described in details in previous works[37,38] was equipped with coded high intensity hollow cathode lamps (HCL) of As, Sb, and Bi, a quartz argon−hydrogen flame atomizer and a hydride generator consisting of a four-channel peristaltic pump and a quartz gas liquid separator (GLS). An Agilent 7700x inductively coupled plasma mass spectrometer (ICP-MS) (Aglient Technologies, U.S.A.) was also used to evaluate the proposed method. An inductively coupled plasma optical emission spectrometer (ICP-OES) (ARCOS FHS12, SPECTRO Analytical Instruments GmbH, Germany) was used to determine the concentration of $Fe^{2+}/Fe^{3+}$ leached from $Fe_3O_4$ MNPs. Typical operating conditions for AFS and ICP-MS are summarized in Table S1 (see Section 1 of the Supporting Information, SI).

The size and surface morphology of $Fe_3O_4$ MNPs were characterized by scanning electron microscopy (SEM, JSM-7500F, JEOL, Japan). Wide-angle (10−70°, 40 kV/35 mA) powder X-ray diffraction (XRD) measurements were carried out using a X'Pert Pro X-ray diffractometer (Philips, Holland) with Cu K$\alpha$ radiation ($K$ = 1.5406 Å).

**Preparation and Characterization of $Fe_3O_4$ MNPs.** $Fe_3O_4$ MNPs were prepared following a previous coprecipitation method[39] (See section 2 of the SI). The representative SEM images of the prepared $Fe_3O_4$ MNPs were reported in our previous study,[39] and showed that these MNPs are spherical and homogeneous. The crystalline structure and the purity of the prepared MNPs were further characterized by powder X-ray diffraction. The positions and relative intensities of diffraction peaks agree well with the standard pattern of $Fe_3O_4$ indexed from the JCPDS 75-1609 card.

**$Fe_3O_4$ MNPs Accelerated UV Fenton-like Digestion.** Digestion of milk samples using the proposed method was performed for five samples and one blank simultaneously. One milliliter of each tested milk sample was transferred to individual quartz digestion tube, and then 8.0 mg of $Fe_3O_4$ MNPs with diameter of 30 nm, 1.0 mL of 30% (w/w) $H_2O_2$ and 2.0 mL of DIW were added. The contents in each tube were mixed on a vortex mixer (XH-B, Jiangsu Kangjian Medical Apparatus Co., Ltd., China). The mixture was acidified with 10 μL of $HNO_3$ and subsequently diluted to 5 mL with DIW. The digestion tubes were capped loosely and inserted into the UVD device, and allowed to expose to UV irradiation for 60 min. After the UV irradiation, $Fe_3O_4$ MNPs were deposited onto the bottom of the digestion tube with the aid of a permanent hand-held magnet. The supernatant was discarded, and the residual MNPs were directly dissolved in 0.3 mL of HCl and diluted to 5 mL solution with thiourea solution prior to analysis by HG-AFS.

In order to demonstrate the feasibility of both digestion and solid phase extraction, 10 mL of milk and proportional amounts of MNPs, $H_2O_2$ and $HNO_3$ were added into a 60 mL quartz digestion tube and operated using the above-described procedure except that the residual

MNPs were dissolved and diluted to 2.5 mL solution with thiourea prior to analysis.

**Microwave Assisted Digestion.** In order to evaluate the accuracy of the proposed method, a microwave assisted digestion method was employed to digest milk samples prior to their determination by ICP-MS. Briefly, each 5 mL of the tested milk samples, 10 mL of concentrate nitric acid and 5 mL of 30% (m/v) hydrogen peroxide were added into precleaned Teflon vessels. Sample blanks were processed along with the samples. The vessels were closed, fastened, and then placed in a microwave oven (Master 40, Shanghai Sineo Microwave Chemistry Technology Co., China) for microwave-assisted digestion. The digestion program was performed as follows: 5 min at 130 °C and 2200 W; 10 min at 150 °C and 2200 W; and 15 min at 180 °C and 2200 W. After cooling, the caps were removed and the digests were transferred to precleaned 50 mL volume Teflon tubes. The digests were then diluted to 50 mL with DIW prior to analysis by ICP-MS.

**Analytical Procedure and Data Analysis.** Quantification of As, Sb, and Bi was accomplished by flow injection HG-AFS, which is similar to our previous works.[37,38] Briefly, 2 mL of tested solution was initially directed to the sample loop through a six-port valve by a peristaltic pump. The valve was activated to pass the carrier solution (3% (v/v) HCl solution) to flush the digested solution to mix with 2% (m/v) $KBH_4$ solution containing 0.5% (m/v) KOH for the generation of As, Sb, and Bi hydrides. Finally, the sample was flushed into a GLS by the carrier solution and Ar carrier gas, wherein the resultant hydrides were separated from liquid phase and then introduced into the AFS for detection. Peak area signal of the atomic fluorescence intensity was recorded.

For comparison purpose, samples were also digested using a conventional microwave oven and analyzed by ICP-MS. Statistical analysis of *t* test was applied to the results obtained using the proposed method in the Certified Reference Material in order to validate the method.

## RESULTS AND DISCUSSION

**Experiment Design and Possible Reaction Mechanism.** An initial attempt was made to integrate conventional UVD and FD for the digestion of milk sample aiming to achieve high sample throughput, minimize chemical consumption, and analyte loss, and alleviate interference on the subsequent hydride generation. Unfortunately, complete digestion of a milk sample was not possible under conditions of 5 mL mixture containing 1 mL of milk, 100 $\mu$L of 0.1 M $Fe^{2+}$, 1 mL of 30% (w/w) $H_2O_2$, and 20 $\mu$L of $HNO_3$ even with a long digestion time of 6 h. Since $Fe_3O_4$ MNPs can catalytically generate $^{\bullet}OH$ radicals from $H_2O_2$ for a rapid degradation of complex organic substances, 20 mg of $Fe_3O_4$ MNP with diameter of 80 nm was thus added into 5 mL mixture containing 1 mL of milk, 1 mL of 30% (w/w) $H_2O_2$ and 20 $\mu$L of $HNO_3$. This mixture was subsequently exposed to UV irradiation. The milk solution turned clear and transparent within 90 min.

To investigate the possible mechanism of the above reaction, free iron ion concentration in the leaching solution was determined by ICP-AES. $Fe_3O_4$ MNPs with diameter of 30 nm were incubated under typical experimental conditions of 0.2% (v/v) $HNO_3$ and 6% (w/w) $H_2O_2$ for 60 min, and then removed by a hand-held magnet. The iron content of the leaching solution was found to be 0.45 mM, which agrees well with the amount required in the conventional Fenton reaction.[15,16,33] A comparison study to evaluate the digestion efficiencies induced by the leaching solution of $Fe_3O_4$ MNPs, 0.45 mM $FeSO_4$, or 10 mg of $Fe_3O_4$ with diameter of 30 nm, was performed by using each 5 mL mixture containing 1 mL milk sample, 6% (w/w) $H_2O_2$ and 0.2% (v/v) $HNO_3$. As shown in Figure 1, the milk sample was still opaque in the case of using either the leaching solution (Figure 1A) or 0.45 mM $FeSO_4$ (Figure 1B) even with the digestion time longer than 120 min, whereas it became clear and transparent within 60 min with use of $Fe_3O_4$ MNPs (Figure 1C). This observation indicates that the digestion activity provided by the MNPs is not only generated from the iron ions leaching into solution, but also attributed to the MNPs. The role of UV irradiation in the digestion was investigated by comparing the digestion efficiencies that carried out with and without UV irradiation, respectively. In the absence of UV, the tested milk samples could not be completely digested within 8 h with use of 30 nm of $Fe_3O_4$ MNPs as catalyst, confirming that the generation efficiency of hydroxyl radical was improved in the presence of UV irradiation.

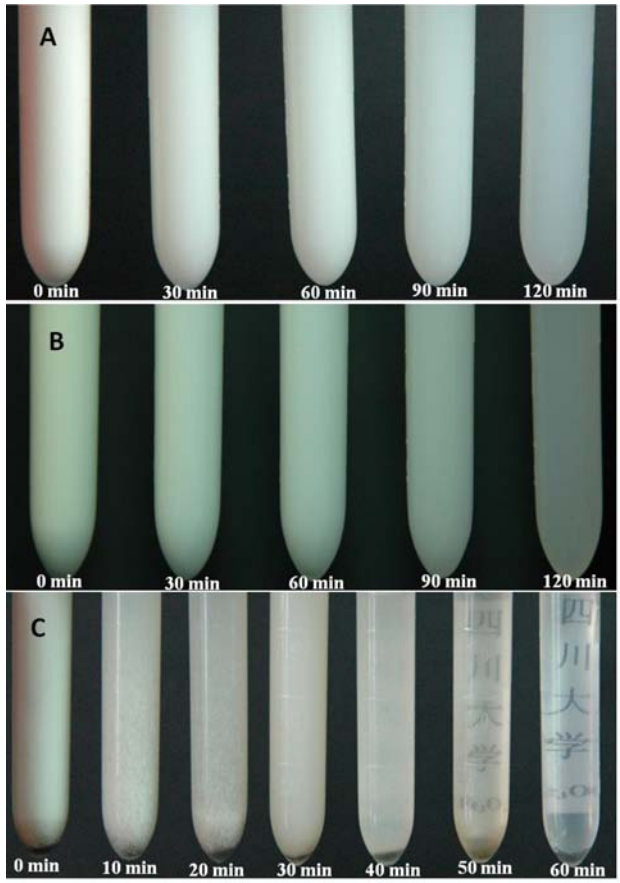

**Figure 1.** UV digestion of 5 mL mixture containing 1 mL milk sample, 6% $H_2O_2$ and 0.2% (v/v) $HNO_3$ using different catalyst. (A) the leaching solution of $Fe_3O_4$ MNPs; (B) 0.45 mM $FeSO_4$ solution; and (C) 10 mg of $Fe_3O_4$ with diameter of 30 nm.

According to the previous studies by Yan,[24] Xu,[25] Luo,[26] and Ai,[39] and their colleagues, this rapid digestion may be mainly attributed to the iron species of $\equiv Fe^{2+}$/ $\equiv Fe^{3+}$, rather than just the free $Fe^{2+}$ ions leached from the MNPs as previously presumed in the conventional Fenton reaction, where $\equiv Fe^{2+}$ and $\equiv Fe^{3+}$ represent Fe(II) and Fe(III) sites on the MNPs surface, respectively. On the basis of the observations from previous studies[24−26,39] and the above study, the reaction mechanism may consist of a dominant digestion and a subsidiary digestion, which have occurred on the surface of MNPs and in the leaching solution, respectively. Figure 1A,B shows that the mixture can be digested to some extent in the

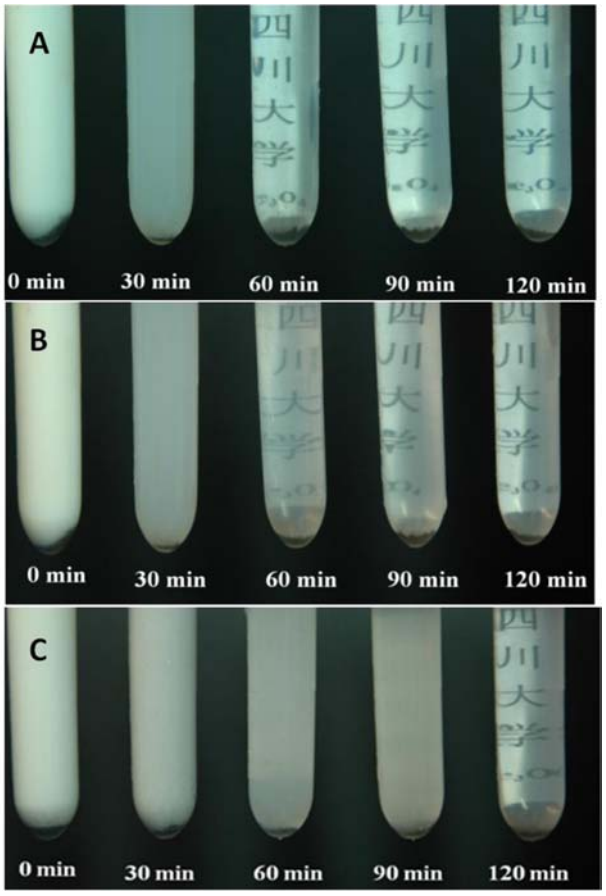

**Figure 2.** Effect of the diameter of $Fe_3O_4$ MNPs on the UV Fenton-like digestion: (A) 30 nm; (B) 80 nm, and (C) 120 nm. Experimental condition: 5 mL of mixture containing 1 mL of spiked milk, 10 mg $Fe_3O_4$ MNPs, 9% (w/w) $H_2O_2$, and 0.3% (v/v) $HNO_3$.

cases using leaching solution or 0.45 mM $FeSO_4$ solution. This supports the generally accepted mechanism of conventional FD[18,19,30] that part of organic compounds (OC) in milk were degraded by free hydroxyl radicals ($^{\bullet}OH_{free}$ and $^{\bullet}OOH_{free}$) produced from free Fe ions. The dominant digestion of the sample has occurred on the surface of MNPs because the milk sample can only be completely digested in the presence of $Fe_3O_4$ MNPs (Figure 1C). $\equiv Fe^{2+}$ react with $H_2O_2$ to generate surface-bound hydroxyl radicals ($^{\bullet}OH_{ads}$) and $\equiv Fe^{3+}$. Then the original $\equiv Fe^{3+}$ together with the generated $\equiv Fe^{3+}$ interact with $H_2O_2$ or $^{\bullet}OOH$ to produce more $\equiv Fe^{2+}$, which further improve the generation of $^{\bullet}OH_{ads}$. Moreover, the $^{\bullet}OH_{ads}$ can react with $H_2O_2$ to produce $^{\bullet}OOH_{ads}$. Finally, the OC of milk were adsorbed onto the surface of MNPs and then efficiently decomposed to $CO_2$ and $H_2O$ by $^{\bullet}OH_{ads}/^{\bullet}OOH_{ads}$ on the surface of MNPs.

**Experimental Conditions for MNP Based Digestion.** In order to investigate the effect of diameter of MNPs on the milk digestion and to gain further insight into the role played by the MNPs in the proposed method. $Fe_3O_4$ MNPs with diameter of 30, 80, and 120 nm were tested to digest the milk mixture under the same experimental conditions, as shown in Figure 2. Interestingly, catalytic activity of $Fe_3O_4$ MNPs was clearly decreased with increasing of its particle diameter, and the milk solution can be completely digested within 60 min using MNPs with 30 nm diameters, while a much longer time was required in the case of MNPs with 80 or 120 nm diameters. This much more efficient digestion may be attributed to the fact that smaller MNPs provide higher adsorption capability and more $\equiv Fe^{2+}/\equiv Fe^{3+}$ because of its greater surface-to-volume ratio. $Fe_3O_4$ MNPs with a diameter of 30 nm were thus chosen in all subsequent experiments.

As previously reported, the catalytic activity of $Fe_3O_4$ MNPs is also strongly dependent on the concentrations of $Fe_3O_4$ MNPs and $H_2O_2$ as well as acidity and reaction temperature. Thus, further investigations of these parameters are necessary. The effect of the concentration of MNPs on response is summarized in Figure 3A. The results show that the responses of As, Sb, and Bi increased in a range from 0.4 to 1.6 g $L^{-1}$ $Fe_3O_4$ MNPs, and followed by a plateau at higher concentrations. This is probably due to inefficient digestion at lower concentrations of $Fe_3O_4$ MNPs. A concentration of 1.6 g $L^{-1}$ $Fe_3O_4$ MNPs was chosen for the subsequent experiments. The effects of concentrations of $H_2O_2$ and $HNO_3$ on the digestion efficiencies of milk samples are presented in Figure 3B,C, respectively. The AFS responses increased as $H_2O_2$ concentration increased from 0 to 3% (w/w) and reached a plateau at higher concentrations. Consequently, the concentration of 6% (w/w) $H_2O_2$ was selected for all subsequent experiments in a consideration of achieving efficient digestion and the minimization of $H_2O_2$ consumption. The responses for As(III), Sb(III), and Bi(III) increased as $HNO_3$ concentration increased from 0 to 0.2% (v/v), remained relatively stable in the range of 0.2−0.5% (v/v), and then decreased at higher concentrations. Low acidity results in low catalytic activity of the $Fe_3O_4$ MNPs and insufficient digestion of milk, while high acidity leads to dissolution of MNPs and thus decreases its catalytic activity. Consequently, a concentration of 0.2% (v/v) of $HNO_3$ was chosen for further studies, which is much lower than that needed in the conventional acid digestion and benefits the reduction of chemical consumption and subsequent hydride generation.

The digestion time is usually reduced by increasing the digestion temperature during UVD.[12] To gain insight into the effect of temperature on digestion, a mercury thermometer was inserted into the quartz digestion tube to measure the temperature. The temperature was found to increase to about 65 °C after 20 min of UV irradiation and remained relatively stable at longer irradiation times. Therefore, the effect of temperature on the digestion time was investigated by putting the UVD device in a water bath to conveniently control the digestion temperature at 30, 40, 60, 70, and 90 °C, respectively. The results show that the digestion time was reduced with increased temperature from 30 to 70 °C. However, dark brown floccules were formed and the mixture could not be completely digested at 90 °C. This phenomenon may be resulted from the fact that the proteins in milk solution were denaturized and deposited onto the bottom of digestion tube at this temperature. Fortunately, on the basis of the above results, the optimal digestion temperature can be achieved with use of UV lamp only, and thus no additional heating source is required, which significantly simplified the operational process and experimental setup.

The effect of digestion time on response was investigated under the previously optimized conditions of 6% (w/w) $H_2O_2$, 0.2% (v/v) of $HNO_3$, and 1.6 g $L^{-1}$ of 30 nm $Fe_3O_4$ MNPs. The effect of digestion time on response is summarized in Figure 3D. It is evident that maximum responses can be achieved with a 40 min digestion or longer. Sixty min of

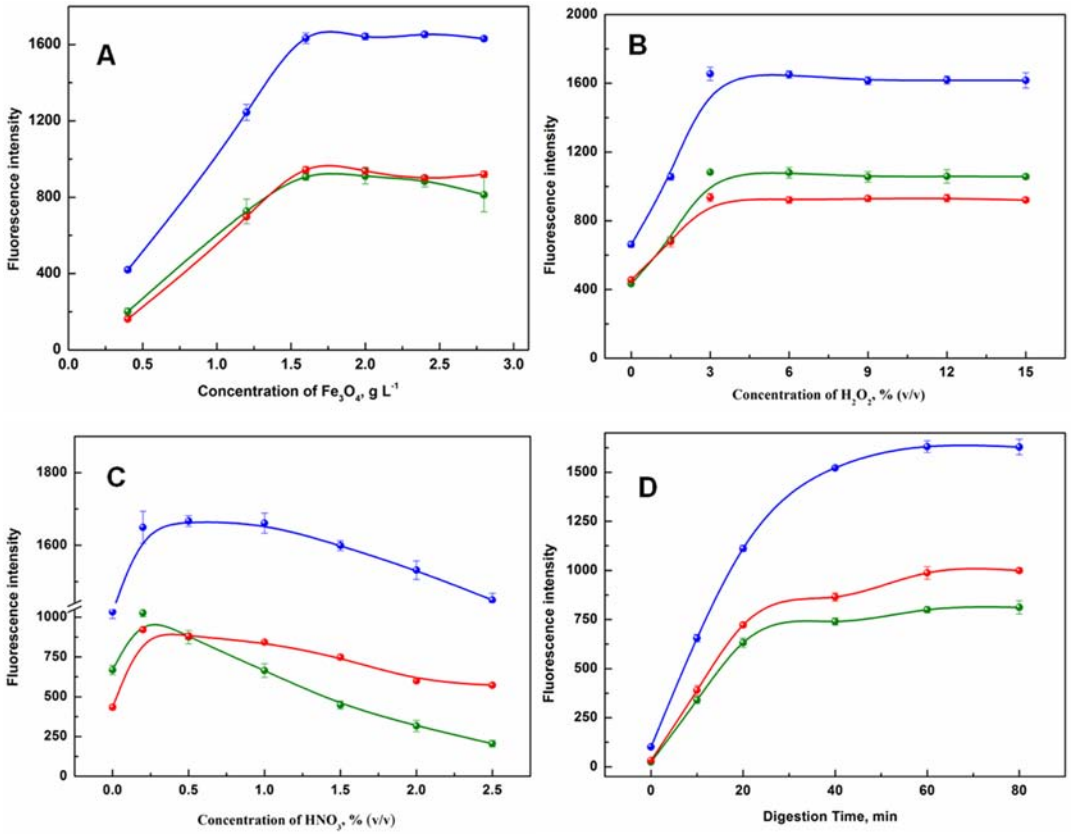

**Figure 3.** Effects of experimental conditions on the $Fe_3O_4$ MNPs accelerated, and UV-induced Fenton-like digestion (blue, As; red, Sb; green, Bi). (A) effect of the concentration of $Fe_3O_4$; (B) effect of the concentration of $H_2O_2$; (C) effect of the concentration of $HNO_3$; and (D) effect of the digestion time. Error bars indicate standard error of the mean ($n$ = 5).

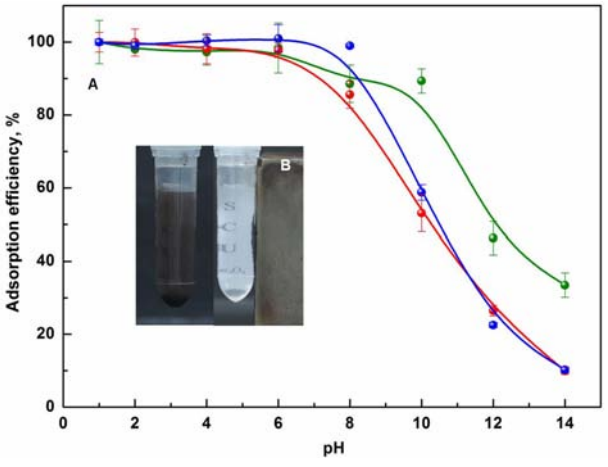

**Figure 4.** (A) Effect of pH of sample solution on the adsorption efficiencies of As(III), Sb(III), and Bi (III) (blue, As; red, Sb; green, Bi; $n$ = 5, error bars indicate standard error of the mean); and (B) visual demonstration of the feasibility of magnetic separation of the prepared $Fe_3O_4$ MNPs.

digestion time was thus chosen for all subsequent experiments to ensure a complete digestion.

**Experimental Conditions for $Fe_3O_4$ MNPs Based Solid Phase Extraction.** In order to improve limits of detection of the proposed method, $Fe_3O_4$ MNPs were used not only as a catalyst to improve digestion, but also as an adsorbent to preconcentrate analytes. SPE efficiency for metals is normally dependent on the pH of the sample solution and the adsorption time. Therefore, 50 mL mixture containing 10 mL spiked milk was used to investigate effects of these parameters on the adsorption efficiencies of As(III), Sb(III), and Bi(III). The adsorption efficiency was estimated from a comparison of the relative concentrations of analytes in the tested solution and in its supernatant after SPE. In order to avoid the dissolution of MNPs, the effect of pH on the adsorption efficiencies of analyte ions was studied in a range of pH 1.0−14.0. The adsorption efficiency was estimated from a comparison of the relative concentrations of analytes in the tested standard solution and in its supernatant after the adsorption by $Fe_3O_4$ MNPs. As shown in Figure 4A, all these tested analytes can be efficiently adsorbed in the pH range of 1.0−6.0, which agree well with those reported earlier.[40,41] This optimum pH range is particularly beneficial, since tedious pH adjustment is eliminated prior to analysis because the pH value of the digested sample solution is about 2, within this optimum pH range.

**Table 1. Figures of Merit**

| | without preconcentration | preconcentration |

[a]Mean and standard deviation ($n$ = 3). [b]Detected by ICP-MS after microwave assisted digestion. [c]mg kg$^{-1}$. [d]Certified value.

The adsorption time counted after the digestion procedure, and its effect on adsorption efficiencies of As(III), Sb(III), and Bi(III) was investigated. The results show that adsorption equilibriums were obtained within a short time of less than 1 min. This remarkably fast adsorption actually can be attributed to the fact that the adsorption must be synchronized with the digestion. Therefore, no additional adsorption time was needed for subsequent experiments, and the sample throughput is increased.

The adsorption capacities of the prepared $Fe_3O_4$ MNPs for As(III), Sb(III), and Bi(III) were also evaluated via spiking various amounts of these analytes into 5 mL milk sample solutions and with each 8 mg $Fe_3O_4$ MNPs added. Saturation of the adsorption capacities of $Fe_3O_4$ was found to be 10, 5, and 8 mg g$^{-1}$ for As(III), Sb(III), and Bi(III), respectively, which can meet the requirement of routine analysis. Magnetic separation is simpler, faster, and more convenient than centrifuge separation. In order to visually demonstrate the feasibility of magnetic separation of the prepared $Fe_3O_4$ MNPs, the magnetic separation of 8 mg of $Fe_3O_4$ after complete digestion and adsorption of analytes ions in 5 mL sample solution is shown in Figure 4B. This fast magnetic separation arising from the strong magnetic response of the prepared $Fe_3O_4$ MNPs significantly simplified the separation procedure, eliminated organic solvent and reduced overall analysis time.

**Optimization of the HG-AFS Determination.** As a sample introduction technique, HG provides unmatched sensitivity and analyte−matrix separation, elemental specificity, and high sample introduction efficiency for atomic spectrometry, and is enjoying increasing interest for inorganic trace analysis. Previous study[42] found that HG efficiencies of As, Sb, and Bi were affected by many factors, especially $KBH_4$ concentration, concentration of prereducing reagent and the reaction medium. Therefore, these factors were carefully investigated, as shown in Figure S1 (see section 3 of the SI). Six percent (v/v) HCl, 2% (m/v) $KBH_4$, 1.0% (m/v) thiourea, and 10 min of prereduction time were finally chosen for better responses.

Since Fe MNPs were dissolved together with analytes and then directly reacted with $KBH_4$ for the generation of their hydrides, the effects of $Fe^{2+}/Fe^{3+}$ concentration on the HG efficiencies of 10 $\mu$g L$^{-1}$of As, Sb and Bi were thus investigated. No significant interferences was observed using the proposed method, even at a concentration of $Fe^{2+}/Fe^{3+}$ as high as 2 g L$^{-1}$.

**Analytical Performance.** A series of 5 mL mixture containing 1 mL milk and various concentrations of As(III), Sb(III), and Bi(III) were analyzed to establish the calibration curves under optimal experimental conditions, as shown in Figure S2A (see Section 4 of the SI). The linear coefficient for each curve is higher than 0.999. The limits of detection (LODs) defined as the analyte concentration equivalent to three times of the standard deviation of 11 measurements of a blank solution, were 0.027, 0.038, and 0.040 $\mu$g L$^{-1}$ for As, Sb, and Bi, respectively. Precisions of replicate measurements, expressed as relative standard deviations (RSDs, $n$ = 9), are better than 6% at 5 $\mu$g L$^{-1}$ analytes concentrations. In order to evaluate the improvement of sensitivity and LODs by $Fe_3O_4$ based SPE, a series of 50 mL of mixture containing 10 mL milk and various concentrations of As(III), Sb(III), and Bi(III) were used. After digestion, the MNPs were dissolved and diluted to a final 2.5 mL prior to analysis. The obtained calibration curves were described in Figure S2B (see section 4 of the SI). LODs of 0.0015, 0.0022, and 0.0025 $\mu$g L$^{-1}$ were obtained for As, Sb, and Bi, respectively, providing 18-, 17-, and 16-fold improvements over those obtained from this method without preconcentration. The analytical figures of merit achieved are summarized in Table 1.

**Preliminary Analytical Application.** Four milk samples obtained from a local market were analyzed to check the accuracy of the proposed method. Analytical results are summarized in Table 2 using external standard calibration. It was necessary to spike all the original milk samples with 10 $\mu$g L$^{-1}$ As, 20 $\mu$g L$^{-1}$ Sb and 10 $\mu$g L$^{-1}$ Bi because their endogenous concentrations were not detectable by the proposed method. Good spike recoveries of arsenic (103−106%) for these samples were achieved, and the analytical results are in good agreement with those obtained by use of microwave assisted digestion and ICP-MS detection, confirming the accuracy of the proposed methodology for routine elemental analysis of milk. Slightly lower recoveries for Sb and Bi maybe due to sample matrix effects, and their recoveries could be increased to 92−101% when a longer digestion time (80 min) was used. The accuracy of the proposed technique was further demonstrated by the determination of As in a Certified Reference Material (milk powder, GBW10017-GSB-8), as shown in Table 2. The $t$ test showed that the analytical results obtained by the proposed method were not significantly different from the certified value for As at the confidence level of 95%.

In summary, a unique and green method combining heterogeneous UV Fenton-like digestion, solid phase extraction, and magnetic separation was developed for the determination of trace toxic elements in milk. This method not only overcomes disadvantages associated with conventional acid digestion and UV digestion, but also provides several unique advantages including: simpler operation, greener analytical chemistry, higher sample throughput, cost-effectiveness, and reduction of chemical consumption. In addition, a tedious and time-consuming separation procedure was simplified in the proposed method because of the simple and convenient magnetic separation.

# Water Distribution in Tofu and Application of $T_2$ Relaxation Measurements in Determination of Tofu's Water-Holding Capacity

Teng Li, Xin Rui, Wei Li, Xiaohong Chen, Mei Jiang, and Mingsheng Dong*

College of Food Science and Technology, Nanjing Agricultural University, Nanjing, Jiangsu 210095, People's Republic of China

**ABSTRACT:** Low-field nuclear magnetic resonance (LF-NMR) was introduced for the elucidation of tofu in the present study. After multiexponential analysis of relaxation decays, three water fractions centered at about 1.5−2.6, 24−114, and 132−305 ms were detected and identified as $T_{2b}$, $T_{21}$, and $T_{22}$, respectively. Principal component analysis (PCA) of the data revealed that sample aggregation was dependent on solubility of coagulants and contained anions. Stepwise centrifugation and microwave drying were employed as dehydration methods. Significant correlations were observed between $T_{21}$ and $T_{22}$ relaxation times and water-holding capacity (WHC) in both dehydration processes, which implied LF-NMR measurements could be an efficient method for determination and prediction of tofu's water-holding capacity. Ten linear equations that could be applied in prediction of WHC for tofu were reported. LF-NMR was suggested to be a powerful tool for the study of tofu.

**KEYWORDS:** *tofu, low-field nuclear magnetic resonance, water-holding capacity*

## INTRODUCTION

Tofu or soybean curd is a gel-like food made by adding different coagulants to soymilk.[1] In order to optimize production technologies and expand understanding of the coagulant's effects on tofu formation, various physical and chemical properties of tofu have been studied.[2−4] The ability of tofu to retain water in its matrix, also known as the water-holding capacity (WHC), is of paramount importance as it relates to tofu's yield and sensory attributes. However, due to limited analytical techniques, WHC of tofu has generally been studied in isolation.

In recent years, many instruments have been applied to the study of tofu. Electrical impedance spectroscopy was introduced for the study of tofu's coagulation process by Li et al.[5] Hsieh et al.[6] studied proteomic profiling of the coagulation of soymilk proteins induced by magnesium chloride using two-dimensional polyacrylamide gel electrophoresis. Other technologies, such as scanning electronic microscopy (SEM) and sodium dodecyl sulfate−polyacrylamide gel electrophoresis (SDS−PAGE) have been utilized in the characterization of tofu-making.[7−9] However, the measurement of tofu's WHC is still limited to centrifugation, which is a sample-consuming and destructive method.

Low-field nuclear magnetic resonance (LF-NMR) technologies have been widely applied in food study. Due to the contribution of Bertram et al.,[10,11] LF-NMR measurements have been widely applied in the evaluation of WHC of pork. Besides, the applications of LF-NMR have been successfully expanded to the effects of cooking and different freezing storage conditions on the quality of various meats.[12−15] The relaxation behaviors of different water fractions in water−casein system and milk have been studied in depth by Mariette and co-workers.[16−19] It has been demonstrated that LF-NMR measurement is a highly sensitive method to study changes of water mobility and corresponding water populations during the cooking process of potatoes.[20,21] Bosman and co-workers[22−24] reported that LF-NMR could be used as a powerful tool to evaluate various properties of different types of bread. Although the self-diffusion coefficient of water in $CaCl_2$-induced tofu was reported by Young et al.,[25] the number of water fractions and their spatial locations in different types of tofu are still unknown. Besides, due to the intimate connection between water distribution and microstructure, LF-NMR is assumed to build a bridge between water-related properties to structure-related properties of tofu. Therefore, in the present study, LF-NMR was introduced into the study of water distribution in different types of tofu. Centrifugation and microwave drying were performed to achieve a series of different WHC gradients for each type of tofu. The potential use of LF-NMR for determination and prediction of tofu's WHC were exploited.

## 2. MATERIALS AND METHODS

**Materials.** The coagulants of calcium sulfate (CS), magnesium sulfate (MS), calcium chloride (CC), magnesium chloride (MC), and glucono-$\delta$-lactone (GDL) were obtained from a local food ingredient supplier. All the chemicals were analytical-grade. Commercial soybeans from northeast China were kindly provided by Key Laboratory of Biology and Genetic Improvement of Soybean, Ministry of Agriculture, P. R. China (Nanjing, P. R. China).

**Preparation of Soymilk.** Soybeans were rinsed and soaked in deionized water in a ratio of 1:3 (w/w) for 12 h at 20 °C. Once hydrated, soybeans were rinsed once more and placed into a household soymilk maker BL-747 (Deer Co., Ltd., Guangdong, China) and ground with deionized water in ratios of 1:10 and 1:5 (w/w), respectively, for salt-induced tofu and GDL tofu. After the soymilk maker cycle was completed, okara (soymilk insoluble fiber) was removed by filtering the soymilk through a strainer and passing twice through double layers of cheesecloth. The soymilk was then stored at 4 °C until further use.

**Preparation of Salt-Induced Tofu.** Soymilk was heated to the boiling point, maintained for 3 min with stirring, and cooled to 90 °C. Dispersions of four divalent salt coagulants were prepared at concentration of 3% (w/w) in hot deionized water (90 °C). The prepared coagulant dispersions were added into the soymilk immediately to achieve a final coagulant concentration of 15 mM. As coagulants were added into soymilk, the mixtures were continuously stirred with a stainless steel spoon for 10 s. Then the soymilk was decanted into a water bath for heat preservation at 90 °C for 20 min for better coagulation of soybean proteins. After that, the mixtures were transferred to a wooden mold and pressed in order to obtain tofu curd and exclude the whey. In order to avoid the influences of different pressing pressures on water distribution of salt-induced tofu, all salt-induced tofu was pressed at 0.01 kg/cm$^2$ for 30 min. After pressing, tofu was stored in airtight containers at 4 °C before analysis.

**Preparation of Glucono-$\delta$-lactone Tofu.** For GDL tofu, soymilk was heated to the boiling point, maintained for 3 min with stirring, and cooled to 80 °C, and then 2% (w/w) GDL solution was added to achieve a final concentration of 0.4% (w/w). The mixtures were incubated in a water bath at 80 °C for 30 min. The coagulation of GDL tofu could form automatically without external pressures. The final tofu curd was stored in airtight containers at 4 °C before analysis.

**Vacuum Freeze-Drying Pretreatment of Tofu Samples.** Vacuum freeze-drying (VFD) was employed to pretreat the tofu samples used for evaluation of influence of fat on $T_2$ measurements. The samples were prefrozen at −18 °C for 24 h and then decanted to a Labconco freezone 12 L console freeze-dry system (Labconco Co., Ltd., Kansas City, MO) with temperature of −50 °C for 30 h.

**Centrifugation Treatments of Tofu Curds.** Thirty grams of cylindrical samples were obtained from the central portion of three tofu curds (CS, MC, and GDL) with a stainless cylindrical cutter and placed into a CT15RT centrifugal filter system (Techcomp Co., Ltd., Shanghai, China). Stepwise centrifugation was performed at 420*g*, 650*g*, 1660*g*, 2600*g*, 3740*g*, 5000*g*, 6640*g*, 8400*g*, 10380*g*, 12560*g*, and 14940*g* for 15 min at 20 °C (for GDL and CS tofu). The centrifugation of MC tofu only reached 8400*g* since no significant change of WHC was observed at higher centrifugation force. The weight of released water was subsequently measured. Water-holding capacity was expressed as the ratio of sample weight after centrifugation to initial weight:

$$\text{WHC}\ (\%) = \frac{(A - B)}{A} \times 100 \tag{1}$$

where $B$ is the weight (grams) of water lost from the tofu sample during centrifugation and $A$ is the initial weight (grams) of the sample. Each measurement was performed in triplicate.

**Microwave Treatments of Tofu Curds.** Microwave treatments were employed to provide another way to generate a series of different WHC gradients of tofu. Samples of CS and MC tofu were cut into cuboids of 1.5 cm thick, 15 cm long, and 1.5 cm wide and placed in an EM-309Eb1 microwave oven (Sanyo Co., Ltd., Osaka, Japan). Samples were heated for 30, 45, 60, 75, 90, 105, 120, 135, 150, or 165 s at 600 W. Three replicate tests were carried out for each heating time. WHC was calculated according to eq 1.

**Low-Field Nuclear Magnetic Resonance Measurements.** Low-field nuclear magnetic resonance measurements (LF-NMR) were performed on a 22.4 MHz NMR Analyzer PQ001 (Niumag Co., Ltd., Shanghai, China). After storage at 4 °C for 1 h, the tofu samples were thermostated to 32 °C in a water bath for 20 min. Approximately 2 g of different tofu samples were taken from the middle of tofu curd and placed into 15 mm NMR glass tubes. Then the tubes were inserted in the NMR probe. $T_2$ relaxation times were measured by use of a Carr−Purcell−Meiboom−Gill sequence. The $T_2$ measurements were performed with a $\tau$-value of 150 $\mu$s (time between 90° and 180° pulse). Data from 3000 echoes were acquired as 16 scan repetitions. The repetition time between two successive scans was 3 s. The relaxation measurements were performed at 32 °C.

MultiExp Inv Analysis software (Niumag Co., Ltd., Shanghai, China) was employed for data analysis. This software performs distributed exponential curve fitting. In the time domain, spin−spin relaxation data is presumed to be a sum of exponentials:

$$R_{\text{mag}}(t) = \sum_{j=1}^{n} p_{2j} \exp\left(\frac{-t}{T_{2j}}\right) + e(t) \tag{2}$$

where $R_{\text{mag}}$ is the residual magnetization as a function of acquisition time $t$; $P_{2j}$ and $T_{2j}$ are the transverse relaxation amplitude and time, respectively, of the $j$th component; and $e$ is residual error. MultiExp Inv Analysis software performed multiexponential fitting analysis on the relaxation data according to a modified inversion method of Xiao et al.[26] Plots of relaxation amplitude versus relaxation time were obtained. The relaxation time $T_{2i}$ and its corresponding water population (signal area ratio) $M_{2i}$ were recorded.

**Statistical Analysis.** Principal component analysis (PCA) was performed with the software Simca-P+ (Umetrics AB). PCA was achieved on $T_2$ relaxation data to identify cluster patterns. Statistical analyses were performed with SPSS version 18.0. Linear regression analysis was performed with Origin 8.1. Adjust determination coefficients (adj-$R^2$) were used to evaluate the fitting degree and are defined as

$$\text{adj-}R^2 = 1 - \frac{(n - 1)(1 - R^2)}{n - m} \tag{3}$$

where $R^2$ is the original determination coefficient and $n$ and $m$ are the number of samples and variables, respectively. The significance levels are defined as (*) $p < 0.05$ and (**) $p < 0.01$.

## RESULTS AND DISCUSSION

**LF-NMR Analysis of Different Tofu Curds.** Since oil can be detected by LF-NMR,[25,27] the influence of oil on tofu's $T_2$ measurements should be evaluated before further studies are performed. Although soybean is rich in oil, the final oil content in tofu curd is very limited. Previous data showed that the oil content of final tofu matrix ranged from 1.4% to 2.2% when similar proportion of soybean and water was used.[7] In order to evaluate the influence of constant oil content on tofu's $T_2$ measurements, tofu samples were pretreated by vacuum freeze-drying (VFD) and then measured by LF-NMR. Figure 1 shows the multiexponential fitting relaxation curves of three types of tofu before and after VFD treatments. After pretreatment by VFD, samples presented two weak peaks. The component centered at about 86−100 ms was likely to be the signal of oil in tofu, which accounted for less than 1% compared to that of samples without VFD treatment. Therefore, the influence of oil in tofu on its $T_2$ relaxation measurements is negligible.

A representative LF-NMR $T_2$ measurement distribution of five types of tofu curds (without dehydration treatment) after multiexponential fitting is presented in Figure 2. All five types of tofu samples showed three peaks, and these peaks were identified as $T_{2b}$, $T_{21}$, and $T_{22}$ according to previous assignments.[10,11] The number of fractions was similar to the number detected in meat but lower than that of potato and other plant tissues.[10,11,20,27] $T_{2b}$ was a minor fraction with a relaxation time between 1.5 and 2.6 ms and accounted for only 1−2.5% of total signal. The mean value of $T_{2b}$ relaxation time was about 2 ms regardless of the type of tofu (data not shown). $T_{21}$ was regarded as the major fraction (about 90% of total signal) with a relaxation time of 24−114 ms, while $T_{22}$ was the slowest fraction with a relaxation time of 114−305 ms.

LF-NMR results after multiexponential fitting are shown in Table 1. $T_{21}$ values descended in the following order: GDL > CS > MS > MC > CC. Pronounced differences in $T_{21}$ relaxation times were observed between GDL tofu and salt-induced tofu, which might be explained by their different coagulation

mechanisms and final microstructures. The formation of salt-induced tofu is usually considered to be driven by salt-bridge effects between soybean proteins and coagulants.[28] Due to the pH reducing effect, mechanism of GDL tofu's formation is generally regarded as a special form of acid-induced coagulation.[29] Noh et al.[7] reported a globular stacked (or honeycomb) microstructure of salt-induced tofu which proteins were integrated into clumps. Bin et al.[30] found a well-connected network microstructure of GDL tofu. $T_{21}$ water fraction of GDL tofu, which accounted for 98% of total signal, was higher than the other samples, while salt-induced tofu samples shared similar $T_{21}$ water populations of approximately 90%; nevertheless, $T_{21}$ water fraction was the dominant population in all types of tofu. $T_{22}$ relaxation times of different tofu samples presented the same tendency as $T_{21}$ relaxation times but with inverse population order among different samples. GDL tofu showed the lowest value of $T_{22}$ water population of 1.73%, while salt-induced tofu shared similar values of about 7%.

Interpretation of $T_2$ transverse relaxation of heterogeneous systems has been extensively discussed. On the basis of the diffusive and chemical exchange model of heterogeneous system established by Hills et al.,[31−33] different water fractions in many biological tissues have been identified. Three water fractions detected in meat are generally regarded as $T_{2b}$ (water bound to proteins), $T_{21}$ (water trapped within the myofibrils), and $T_{22}$ (water outside the cell).[10,11] In the case of plant tissues, the component with the slowest relaxation time (550−650 ms) is ascribed to vacuolar water, while the second (200−250 ms) and third components (50−60 ms) are assigned to cytoplasmic and extracellular water, respectively. The component with the shortest relaxation time, about 5−10 ms, is considered to be water associated with the cell wall.[27] As suggested by Hills et al.,[31] proton relaxation measurements reflect the state of biopolymers and morphology rather than the state of water. Due to the existence of membrane systems, the microstructures of food matrixes mentioned above are different from that of tofu. Tofu is formed by aggregation of soybean protein and lacks a membrane system. However, cheese, a membrane-free milk protein matrix induced by rennet, is much more similar to tofu compared to biological tissues. Therefore, the studies of different water fractions in cheese may be pertinent to the present study. Water distribution in milk protein mixtures has been widely studied.[34,35] In general, transverse water proton relaxation in heterogeneous systems like cheese and tofu is influenced by the network structure of food matrix because water is influenced by its surroundings. The distance between water and the surrounding protein network is the key factor giving rise to the different relaxation times of three water fractions in tofu. Gianferri et al.[34] reported four fractions in mozzarella cheese. Except for the fraction derived from fat droplets, the other three fractions were considered to be water fractions located in different spatial areas of cheese's microstructure. The slowest fraction with a relaxation time of 488 ms was ascribed to water free of the influence of protein surface. The intermediate fraction was considered to be water molecules entrapped in meshes of gel. The fastest fraction, with a relaxation time centered at about 7.2 ms, was attributed to water molecules trapped within casein junction zones.[34] Although the microstructures of salt-induced tofu and GDL tofu are different, they still show some similarities. Thus, both salt-induced tofu and GDL tofu are characterized by the presence of big pores and small meshes in the microstructure.[2,7,30] Based on the identification of different water

fractions in cheese and the microstructure of tofu, the following assignments to the three fractions in tofu's microstructure are proposed. The slowest fraction $T_{22}$ is ascribed to water molecules remote from the protein network whose motion can be little affected by the protein network. In conjunction with the microstructure of tofu, the big pores and gaps in tofu's three-dimensional network may provide space for $T_{22}$ water fraction. The intermediate component $T_{21}$ can be ascribed to water molecules near to the surface of protein network and is influenced by the interaction between protein network and water molecules. Due to the Brownian movement of water molecules, $T_{21}$ water fraction diffuses from the bulk to protein interface and its $T_2$ value is controlled by diffusive exchange. Small meshes in tofu's microstructure and gaps in the space of protein's tertiary and quaternary structures may provide space for the $T_{21}$ water fraction. The fastest fraction $T_{2b}$, with a relaxation time about 2 ms, can be assigned to the water molecules tightly associated with protein and can be regarded as an integral part of the protein structure. Its transverse relaxation time is essentially dominated by a fast chemical exchange with exchangeable protons of hydrophilic groups, such as hydroxyl, carboxyl, and sulfydryl, resulting in a short $T_2$ relaxation time. According to previous research,[10] the influence of $T_{2b}$ fraction on physical characteristics and WHC is minor, and it will therefore not be further discussed in this paper. On the basis of assignments of different water fractions in tofu matrix, we established a simplified model of tofu's microstructure (Figure 3). Pores and meshes with different sizes exist in tofu's three-dimensional network, leading to a heterogeneous microenvironment and multiple-exponential relaxation behavior of water in it.

The effects of divalent salts on the coagulation process of soymilk have been intensively studied, but no convincing conclusion has been obtained yet.[28,36] Both cation and anion seem to affect the coagulation process as well as the physical properties of final matrix.[37] Parameters such as viscosity[38] and turbidity[39] have been introduced for coagulation studies of tofu. Although differences were observed between GDL tofu and salt-induced tofu, the differences among four types of salt-induced tofu were not intuitively revealed. In order to obtain an overview of variation in the multivariate LF-NMR relaxation data of salt-induced tofu, PCA analysis was performed. As shown in Figure 4, PC1 explained 63.58% of the variation in the data and discriminated clearly according to the different divalent salts of tofu. PC2, explaining 19.55% of the variation in the data, was considered to be largely due to the variation between replicates. A clear separation of CS tofu from other samples in PC1 was observed and might be explained by low water solubility of CS. The amount of cations and anions available for reactions in CS–soymilk mixtures were lower than the other three salt–soymilk mixtures due to the low water solubility of CS, which might lead to different coagulation speeds, microstructures, and final water distribution. It is noteworthy that the separation of MS tofu and chloride salt-induced tofu in PC1 seemed to be determined by type of anion. Previous studies have demonstrated that anions affect the coagulation speed and textural properties of tofu,[38,39] which is in accordance with our results.

**Relationship between WHC and LF-NMR.** Water-holding capacity defines the capacity of tofu to retain water in its microstructure and is an important parameter. Centrifugation is a process that removes water through physical pressure without any chemical reaction between water and macromolecules. Due to a similar principle, stepwise centrifugation can simulate different pressures under which salt-induced tofu is made. CS, MC, and GDL tofu was stepwise centrifuged (Table 2). Both $T_{21}$ and $T_{22}$ relaxation times of all three tofu samples decreased with increases in centrifugation force. Similar findings were observed in a study of centrifugation

[a]Results are presented as the mean ± standard deviation. Lowercase letters (a–j) in the same column mean significant differences ($P < 0.05$).

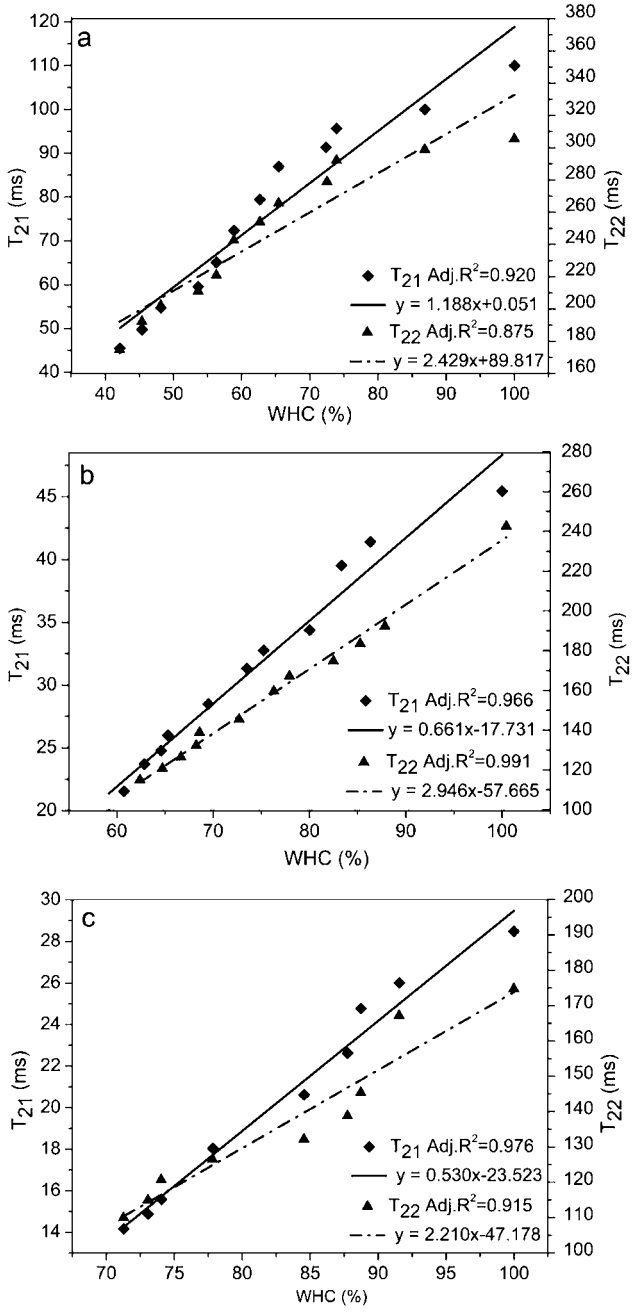

**Figure 5.** Linear regression equations to explain the linear relationships between WHC and $T_{2i}$ relaxation times during the process of centrifugation. (a) GDL tofu ($n$ = 12); (b) CS tofu ($n$ = 12); (c) MC tofu ($n$ = 9).

of pork.[10,11] As the centrifugation force increased, tofu formed a more compact microstructure, which shortened the distance of water molecule diffusion from the bulk to protein network interface, resulting in less mobility of water and lower values of $T_{21}$ and $T_{22}$ relaxation times.

Due to potential correlations between $T_{21}$ and $T_{22}$ relaxation times and WHC of tofu, Pearson correlation analysis was carried out, and the results are shown in Table 3. In the case of centrifugation, $T_{21}$ relaxation times presented significant correlations with WHC. This was in agreement with the results derived from continuous distribution analysis of pork reported by Bertram et al.[10] However, in the present study, the correlations between $T_{22}$ relaxation times and WHC were

also significant. Besides, Bertram et al.[10] revealed that $T_{2i}$ populations presented closer relationships with WHC compared with $T_{2i}$ relaxation times in the determination of WHC in pork, while $T_{2i}$ populations of three types of tofu were almost unchanged during the centrifugation process (data not shown) and the correlations were insignificant. We deduce that the dissimilar changes of $T_2$ parameters between tofu and pork meat during centrifugation processes can be ascribed to their different microstructures. $T_{21}$ and $T_{22}$ water fractions of meat exist in different compartments of muscular tissues. Cell membranes are considered to act as physical barriers for the different water fractions, giving rise to their different contribution to centrifugation water loss and significant correlations between $T_{2i}$ populations and WHC. Compared with meat, the water transfer in tofu during centrifugation can be faster and unhindered because, unlike a membrane system, water in tofu is present in a system regardless of obstacles. Water transfer in tofu during centrifugation is most likely a dynamic process. Due to shrinkage of tofu matrix, both $T_{21}$ and $T_{22}$ water fractions could be expelled outside without the obstacles of cellular tissues during centrifugation.

According to previous studies, linear relationships existed between $T_{2i}$ relaxation times and WHC of different food matrixes.[11,15] In order to analyze the quantitative relationships between $T_{2i}$ relaxation times and WHC, mean values of $T_{21}$ and $T_{22}$ relaxation times and WHC were used to establish simple linear equations. Six equations were obtained from linear regression (Figure 5). High adj-$R^2$ values (0.875−0.991) indicated high fitting degrees of prediction equations. Accordingly, LF-NMR could be an effective method to monitor and predict the WHC of tofu during centrifugation.

Microwave drying was introduced as another method of dehydration. Unlike centrifugation, microwave drying achieved dehydration by heating the tofu matrix integrally. Moreover, microwave induced a high temperature condition which might cause some chemical and physical changes of soybean proteins. GDL tofu was not included because severe destruction of texture occurred during microwave drying. Table 4 shows the LF-NMR results of microwave drying of tofu made with CS and MC. $T_{21}$ and $T_{22}$ relaxation times decreased along with the microwaving, which was similar to the centrifugation results. With increasing drying time, $T_{21}$ populations decreased while $T_{22}$ populations increased, which might indicate the density of water in tofu's matrix changed due to potential changes of tofu microstructure during microwave drying. It is noteworthy that the relaxation time of the major water fraction decreased to below 10 ms, which was generally regarded as the boundary relaxation time between $T_{2b}$ and $T_{21}$. In centrifugation, limits of $T_{21}$ relaxation time (above 10 ms) and WHC seem to exist when centrifugation force reached a threshold. Like MC tofu, when centrifugation reached 8400$g$, no significant changes of WHC and $T_{2i}$ relaxation times were observed at centrifugation forces exceeding this level. However, even though the water loss was much more than that of centrifugation, the $T_{21}$ relaxation time and WHC had not reached their limits during microwave drying. In microwave drying, both the microstructure and chemical properties of protein network might extensively alter due to the high temperature induced by microwave. Thus, different mechanisms of these two dehydration methods are considered to be the reason for the dissimilar changes of $T_2$ parameters and WHC. Although the relaxation time of the major water component was below 10 ms, this portion was still likely to be responsible for further water loss from 46% to 41% (CS tofu) and from 53% to 44% (MC tofu). As mentioned before, $T_{2b}$ water could hardly contribute to water loss of food matrix. Besides, the $T_2$

relaxation time of the major component was still significantly slower than tofu's $T_{2b}$ (0.80−2.6 ms). So it seems to be reasonable that the major portion of water was assigned as $T_{21}$ water fraction.

It is noteworthy that when drying time exceeded 60 s (165 s for CS tofu), a new fraction, of which the relaxation time was 72−37 ms, was observed and identified as $T_{21n}$ (Figure 6). The population of $T_{21n}$ increased from 1% to 14% (for MC tofu) along with prolonged drying time. A previous study demonstrated that microwave treatment could transform soybean protein dispersions to a gel-like curd.[40] Consequently the formation of this new fraction may be explained by further changes of tofu's microstructure driven by microwave drying. During the microwave drying process, some proteins experienced thermal denaturation and formed special microstructures, which could retain the water molecules expelled from inner spaces. This portion of water might become the source of $T_{21n}$ water.

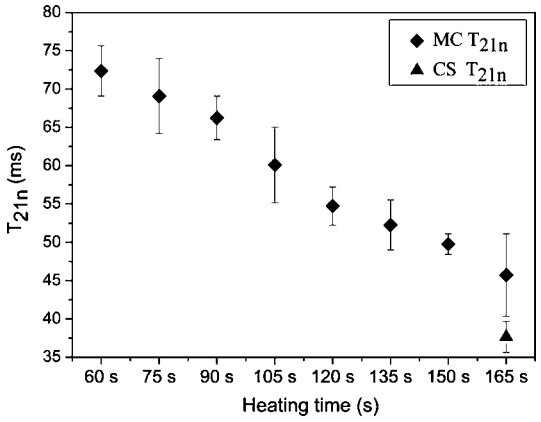

**Figure 6.** Relaxation time of new water component $T_{21n}$ in MC and CS tofu samples.

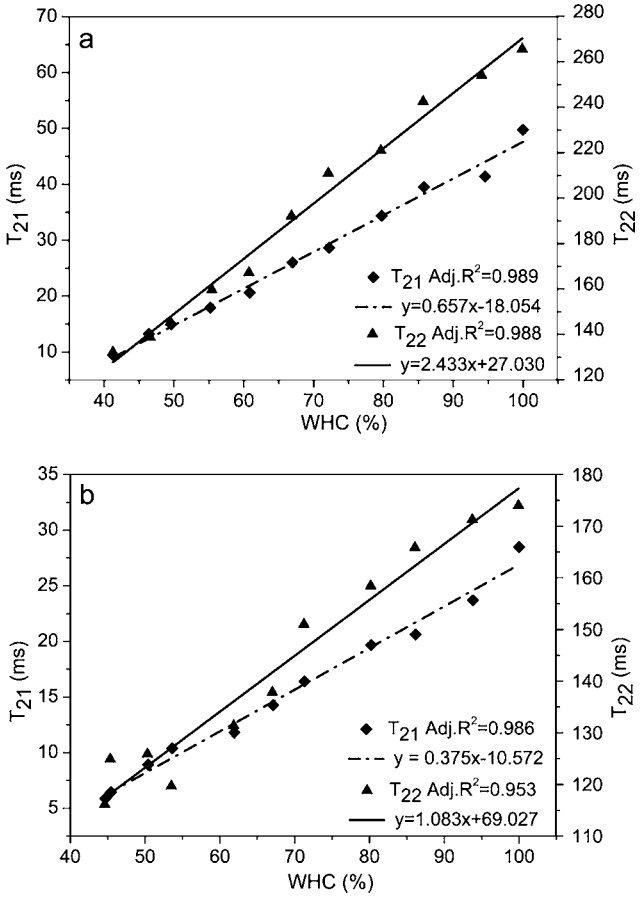

**Figure 7.** Linear regression equations to explain the linear relationships between WHC and $T_{2i}$ relaxation times during the process of microwave drying. (a) CS ($n$ = 11); (b) MC tofu ($n$ = 11).

Pearson's correlations between $T_2$ data and WHC are shown in Table 3. Significant correlations between $T_{2i}$ relaxation times and WHC were observed in the case of centrifugation. Although the mechanism of decrease of $T_{2i}$ relaxation times may be complex due to overlying effects in microwave drying, it still seems to be feasible to make a prediction of tofu's WHC by its $T_{2i}$ relaxation times because of the significant correlations between them. Therefore, linear regression analysis was performed on mean values of $T_{2i}$ relaxation times and WHC (Figure 7). Four equations with adj-$R^2$ ranging from 0.953 to 0.989 were obtained to explain the correlations between $T_{2i}$ relaxation times and WHC.

In conclusion, we consider that the $T_{21}$ and $T_{22}$ relaxation times can be good parameters in monitoring tofu's WHC during microwave dehydration.

Supporting Information

**ABSTRACT:** Nine strains of the fungus *Phomopsis* spp. were isolated from a vineyard showing decline from the disease esca. Strains were screened for their ability to produce secondary metabolites showing chemical diversity. The culture extracts of each strain were analyzed by liquid chromatography−ultraviolet−diode array detection−mass spectrometry. Three strains were selected for the isolation and characterization of eight of the major metabolites. Structures were elucidated by spectroscopic analyses including two-dimensional NMR and mass spectrometry and by comparison to literature data. Among the isolated metabolites were the known phomopsolide B (**1**), sydowinin A (**6**), sydowinol (**7**), cytosporone B (**8**), and four new furanones named phomopsolidones A−D (**2**−**5**). The fungal strains were identified as *Phomopsis* sp., *Phomopsis viticola* Sacc and, *Phomopsis viticola* complex. Biological assays on *Vitis vinifera* leaves and callus tissue, antibacterial, and insecticidal activities were evaluated. The results revealed variability regarding secondary metabolites with species of *Phomopsis* sp. associated with grapevine, raising the question of cultivar-driven strain selection and phytotoxins biosynthesis in grapevine plants.

**KEYWORDS:** *Phomopsis sp., Phomopsis viticola, phytotoxins, grapevine, esca*

## INTRODUCTION

Esca, one of the grapevines trunk disease, causes decline and premature dieback of vineyards and has become a growing threat to grapevines worldwide.[1] The disease is most damaging when wet weather occurs early in the season. The disease does not spread rapidly but builds up progressively in a vineyard over a number of years, leading to a general decline in vigor and yield of the vines.[2] The foliar symptoms are characterized by interveinal chlorosis that later develops into large necrotic areas in summer.[2] More than a 158 fungal species have been reported from the necrotic wood of adult plants showing esca symptoms,[3−5] mainly *Phaeomoniella chlamydospora*, *Phaeoacremonium aleophilum*, *Fomitiporia mediterranea*, *Eutypa lata*, *Cadophora* sp., *Botryosphaeria* sp., and *Phomopsis* sp. fungal species have been reported to have medium to high incidence. *Phomopsis viticola* is a fungus responsible for the phomopsis cane blight and leaf spot disease[6] of grapevine and is more often reported together with the Botryosphaeriacea from esca symptomatic plants.[5] In grapevine trunk disease, pathogens are isolated from both symptomatic and asymptomatic plants, and it remains unclear whether fungi act successively and/or in combination and whether wood-inhabiting microflora influences the decay process.[5] The endophytic genus *Phomopsis* sp. comprises plant pathogens often associated with disease of agricultural crops and is known to be a rich source of bioactive secondary metabolites with diverse structures,[7] but to our knowledge, there have been no reports of secondary metabolites isolated from the grapevine pathogen *P. viticola* Sacc. Since the fungus cannot be detected in leaves of infected grapevine trunk diseased plants, it was hypothesized that foliar symptoms are caused by toxic compounds produced by the fungi in wood tissue that are either translocated to the leaves or induce chain reactions leading to the symptoms on the leaves. A comprehensive review highlighting the metabolites biosynthesized by some of the fungi inhabiting the wood of grapevine has been published.[8]

In an ongoing effort to identify phytotoxic metabolites from pathogenic fungi of grapevine trunk disease,[9−11] we investigated several strains of *Phomopsis* isolated from *V. vinifera* Merlot, Cabernet sauvignon, and Cabernet franc showing or not esca symptoms. We report here the isolation and structural elucidation of eight metabolites isolated from three different strains of *Phomopsis* sp. Their phytotoxicity was assessed on grapevine leaves and callus tissue as well as their antimicrobial and larvicidal activities. Finally, a correlation between cultivars susceptibility, strain species, and their capacity to biosynthesize secondary metabolites was attempted.

## MATERIALS AND METHODS

**General Experimental Procedures.** $^{1}H$ and $^{13}C$ NMR spectra were recorded on a Bruker AMX 400 spectrometer (400 MHz)

(Fällenden, Switzerland). Chemical shifts were referenced to TMS. Optical rotations were determined on a PerkinElmer 241 digital polarimeter (Waltham, MA, USA) with a 1 dm cell. IR spectra were obtained on a PerkinElmer 1720 X spectrometer. UV spectra were recorded on a Shimadzu UV-190. High-performance liquid chromatography (HPLC) analysis and purification was carried out on an Agilent 1100 (Palo Alto, CA, USA) coupled to a diode array detector (DAD). Mass spectra were measured on an Agilent 1100 LCMSD Trap using the electrospray ionization (ESI) source in negative or positive ionization mode. High-resolution electrospray ionization mass spectrometry (HRESI MS) was performed on a Bruker FTMS 4.7T BioAPEX II or an Agilent 3100 QTof.

**Plant Materials and Fungal Strain Isolation.** Ten plants of 15 years old of *V. vinifera* cv. Merlot, Cabernet sauvignon, and Cabernet franc were rooted in 2003 for further analysis from a vineyard in Riva San Vitale (Ticino, Switzerland). Half of the plants already exhibited esca foliar symptoms in 2000 and/or 2001. Plants were ripped out and cut in disks as reported.[12]

**Strain Growth and Extraction Method for Strain Screening.** Nine strains of *Phomopsis* sp. (DC110, DC275, DC283, DC180, DC239, DC279, DC281, DC282, and DC301,) were isolated and maintained on potato dextrose agar (PDA) (Difco, Sparks, MD, USA) (Table 2) for chemical analysis. For each strain, 10 replicates were grown from 7 day old native cultures and incubated at 25 °C in the dark. The fungal cultures were extracted separately with ethyl acetate (EtOAc) (3 × 600 mL) and evaporated under reduced pressure to dryness. An aliquot (10 mg/mL) was dissolved in MeOH for LC-DAD-MS analysis, and 20 $\mu$L was examined by reverse-phase chromatography (Nucleosil 100-7, C-18, 250 $\mu$m × 4.6 $\mu$m, 7 $\mu$m, Machery−Nagel, Duren, Germany) on a gradient of methanol and water starting at 40% of methanol for 5 min, increasing to 90% at 30 min and to 100% at 40 min at the flow rate of 1 mL/min.

**Growth Conditions and Extraction Methods.** Four strains were selected for their chemical diversity and identified by the Belgium Coordinated Collections of Microorganisms (BCCM) as *Phomopsis* sp. DC275 isolated from asymptomatic cv. Merlot, *P. viticola* complex DC239 isolated from asymptomatic cv. Cabernet sauvignon and DC281 isolated from symptomatic Cabernet franc, and finally, *P. viticola* (Sacc.) Sacc. DC180 isolated from asymptomatic cv. Cabernet Sauvignon. Three strains (DC275, DC239, and DC180) were selected for high scale culture. Each strain was grown on 40 PDA Petri plates for 21 days at 25 °C in the dark. Cultures were extracted with EtOAc (3 × 3 L) to yield dry residues of 1.68 g for DC275, 1.8 g for DC239, and 1.0 g for DC180. Crude extract of each strain was dissolved in water and extracted with *n*-hexane for defatting.

The remaining defatted material from *Phomopsis* sp. DC275 was further extracted with dichloromethane ($CH_2Cl_2$). This extract showed the highest phytotoxic activity against grape leaves and was further purified by a successive column chromatography (CC) on Si gel 60°A eluted with a gradient solvent of *n*-hexane/$CH_2Cl_2$ (1:1, v/v) to $CH_2Cl_2$/MeOH (1:1, v/v). A final purification by the solvent mixture $CHCl_3$/*i*PrOH (9:1, v/v) afforded three pure compounds **1** (75 mg), **2** (3.2 mg), and **3** (3.6 mg) and a mixture of **4** and **5** (10 mg).

Ethyl acetate extracts from *P. viticola* complex DC239 and *P. viticola* Sacc. DC180 were subjected to Sephadex LH-20 (70 cm × 1.2 cm) CC (GE Healthcare, Piscataway, NJ, USA). The eluent was a mixture of chloroform/methanol (1:1, v/v) for the first extract and methanol for the second one. The final pure compounds from the strain DC239 were obtained by purification with semipreparative HPLC using a gradient of MeOH/$H_2O$ (starting with 70% MeOH and reaching 80% MeOH after 15 min, at the flow rate of 3.5 mL/min on a Nucleosil 100-7 C-18 column, (250 mm × 8 mm i.d., Macherey−Nagel, Düren, Germany). *P. viticola* complex afforded three compounds **6** (7 mg), **7** (1.3 mg), and **8** (2 mg). Finally, using the same HPLC conditions as above, the strain (DC181) afforded **8** (8 mg).

*Sydowinin A (**6**).* Yellowish powder (7 mg). ESI MS (+) *m/z* 323.1 $[M + Na]^+$ calcd for $C_{16}O_6H_{12}Na$; IR (film) $\nu_{max}$ cm$^{-1}$: 3430, 1735, 1720, 1649, 1620, 1600; UV (MeOH) $\lambda_{max}$ nm (log $\varepsilon$): 233 (3.81), 257 (3.78), 291 (2.7), 362 (1.9). $^1$H NMR ($CDCl_3$) $\delta_H$ 4.0 ($CH_3$, s), 4.75 ($CH_2$, s), 6.70 (CH, d, 1.3 Hz), 6.95 (CH, d, 1.3 Hz), 7.33 (CH, dd, 6.9; 2.6 Hz), 7.56 (CH, dd, 6.9; 2.9 Hz), 7.78 (CH, dd, 6.9 Hz), 12.1(OH, s); $^{13}$C NMR ($CDCl_3$) $\delta_C$ 133.8 (C), 122.9 (CH), 135.4 (CH), 119.9 (CH), 156.4 (C), 156.3 (C), 104.5 (CH), 152.5 (C), 108.5 (CH), 162.0 (C), 108.2 (C), 117.8 (C), 180.9 (C), 170.0 (C), 53.6 ($CH_3$), 64.7 ($CH_2$).

*Sydowinol (**7**).* Yellow powder (1.3 mg), HRESI MS (−) *m/z* 315.0532 $[M - H]^-$ (calcd for $C_{16}O_7H_{12}$, 315.0510); IR (film) $\nu_{max}$ cm$^{-1}$: 3430, 1728, 1720, 1656, 1585, 1550; UV (MeOH) $\lambda_{max}$ nm (log $\varepsilon$): 233 (4.30), 257 (4.18), 291 (2.1), 362 (1.9); $^1$H NMR (MeOH-$d_4$) $\delta_H$ 3.96 ($CH_3$, s), 4.67 ($CH_2$, s), 6.73 (CH, d, *J* = 1.1 Hz), 6.97 (d, *J* = 1.1 Hz), 7.37 (d, *J* = 9.1 Hz), 7.51 (d, *J* = 9.1 Hz); $^{13}$C NMR (MeOH-$d_4$), $\delta_C$ 52.23 ($CH_3$), 63.36 ($CH_2$), 104.25 (CH), 107.49 (C), 120.30 (C), 118.06 (C), 125.05 (CH), 130.39 (C), 150.02 (C), 151.37 (C), 153.3 (C), 156.5 (C), 161.65 (C), 169.2 (C), 181.12 (C).

*Cytosporone B (**8**).* Colorless powder (9 mg); HRESI MS (+) $[M + Na]^+$ *m/z* 345.1674 (calcd for $C_{18}H_{27}O_5Na$, 345.1672) . ESI $MS^2$ (−) of *m/z* 321.3 $[M - H]^-$ gave the fragment 275 $[M-C_2H_5OH-H]^-$; IR (film) $\nu_{max}$ cm$^{-1}$: 3234, 1732, 1622, 1456, 1368, 1174 cm$^{-1}$; UV ($CH_3CN$) $\lambda_{max}$ nm (log $\varepsilon$): 219 (4.33), 268 (3.33); $^1$H NMR ($CDCl_3$) $\delta_H$ 6.30 (CH, d, 2.4 Hz), 6.28 (CH, d, 2.4 Hz), 4.22 (2H, t, 7 Hz), 3.85 (2H, s), 2.84 (2H, t, 7), 1.26−1.27−1.28−1.29−1.32 (8H, bm) 1.30 (3H, t, 7 Hz), 0.88 (3H, t, 7 Hz); $^{13}$C NMR ($CDCl_3$) $\delta_C$ 171.9 (C), 42.2 ($CH_2$), 137.0 (C), 103.7 (CH), 160.8 (C), 113.1 (CH), 160.8 (C), 207.1 (C), 117.0 (C), 43.8 ($CH_2$), 25.4 ($CH_2$), 29.5 ($CH_2$), 29.6 ($CH_2$), 32.1 ($CH_2$), 23.0 ($CH_3$), 14.5 ($CH_3$), 62.1 ($CH_2$), 14.6 ($CH_3$).

**Biological Assays.** *Grapevine Leaf Disc Assays.* The compounds were dissolved in 2% aqueous ethanol at concentrations of 500, 250, and 100 μg/mL. Grapevine leaves *V. vinifera* cv. Chasselas were cut into discs of 5 mm of diameter with a cork borer and immersed in 1 mL of the solutions. The phytotoxicity of the crude extracts and the pure compounds was evaluated by measuring the area of necrotic tissues related to the total leaf disc area. Eutypine was used as a positive control and 2% ethanol as a negative control.

*Grapevine Callus Assay.* Phomopsolide B (**1**) was also tested on grapevine callus tissue from *Vitis vinifera* cv. Gamay (kindly supplied by Prof. Roustan, INRA, Toulouse, France). Callus cultures were cultivated on a growth medium according to a method previously described[11] with 12 h daylight for 28 days at 28 °C. Calli were weighed before and after incubation, and percent growth was calculated.

*Antibacterial Assays.* The antibacterial activity was measured by the bioautography method on thin-layer chromatography plates. Different concentrations of test compounds were prepared by the 2-fold serial dilution method described previously.[13]

*Larvicidal Efficiency.* Phomopsolide B (**1**) and phomopsolidones A (**2**) and B (**3**) were screened for larvicidal activities. The assay was performed at the Research Station Agroscope Changins-Wädenswil (Nyon, Switzerland) according to a method previously described.[14] In short, *Lobesia botrana* larvae were reared on an artificial diet of "Manduca - Heliothis Premix" (Stonefly Industries, Bryan, TX, USA) containing the dissolved product. By using a spatula, 1−2 g of the contaminated diet (1 and 10 ppm) was placed into each of 60 small plastic boxes. One newborn larva from rearing was then placed into each box. The larvae were reared under laboratory conditions at 25 °C. After 14 days, a first count of the surviving larvae was made. Rearing was then continued to the adult stage. The development time of the larvae was also assessed.

## RESULTS AND DISCUSSION

We investigated nine strains of *Phomopsis* isolated from grapevine plants showing esca symptoms in Ticino, Switzerland. Ten PDA Petri dishes of each strain were extracted with ethyl acetate and screened for secondary metabolites by HPLC-DAD-MS analyses and for phytotoxic activity on grapevine leaf disc assays. Three strains DC275, DC239, and DC180 were selected for further study according to the chemical differences in the secondary metabolites produced.

The first strain *Phomopsis* sp. DC275, isolated from a Merlot cultivar, afforded five pure compounds, phomopsolide B (**1**) as the major compound and four new furanones (**2**−**5**) given the trivial names phomopsolidones A−D (Figure 1). The HRESI

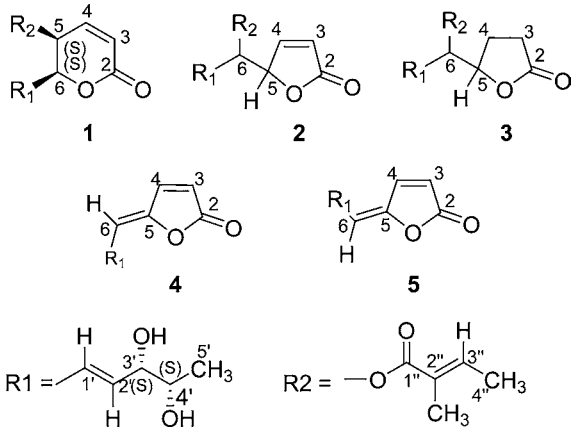

**Figure 1.** Compounds isolated from *Phomopsis* sp. DC275: phomopsolide B (**1**) and phomopsolidones A−D (**2**−**5**).

MS (+) spectrum *m/z* 319.1153 $[M + Na]^+$ of **1** indicated a molecular formula of $C_{15}H_{20}O_6Na$ supported by detailed IR, UV, $^1$H, $^{13}$C, one-dimensional (1D) and two-dimensional (2D) NMR, and MS data. The carbonyl group was also deduced from IR spectra and a signal at $\delta$ 162.5 in the $^{13}$C NMR spectrum. On the basis of COSY and HMBC and optical rotation spectra, compound **1** was identified as phomopsolide B (**1**) previously reported from cultures of *Phomopsis* species.[15−17]

Compound **2** showed the same molecular mass and HRESI MS (+) mass spectrum as **1** *m/z* 319.1153 $[M + Na]^+$ with the same molecular formula $C_{15}H_{20}O_6Na$. The downfield shift of the carbonyl atom signal of C-2, C-4, C-5, and C-6 at $\delta$ 172.4, $\delta$ 152.6, $\delta$ 83.3, and $\delta$ 71.7, respectively, in the $^{13}$C NMR spectrum indicated that the main differences occurred on the unsaturated $\gamma$-lactone moiety. Furthermore, the downfield chemical shift of H-3 ($\delta$ 6.21) and H-4 ($\delta$ 7.45) and the coupling constant (*J* = 1.6, 2.0, and 4.1) between H-3, H-4, and H-5 were characteristic of a 2-furanone ring indicating that group 2-methyl-but-2-enoic acid substituted at C-5 of **1** migrated to C-6 of **2** inducing a shielding of the H-6 chemical shift ($\delta$ 5.64). Thus, compound **2** was isolated for the first time and named phomopsolidone A.

dx.doi.org/10.1021/jf501141g | J. Agric. Food Chem. 2014, 62, 8602−8607

Compound **3** named phomopsolidone B had a molecular mass of 298, HRESI MS (1) *m/z* 321.1309 $[M + Na]^+$ indicating a molecular formula of $C_{15}H_{22}O_6Na$. The $^1H$ and $^{13}C$ NMR spectra of **3**, compared to those of **2**, indicated a hydrogenation of the furanone ring at positions C-3 and C-4 leading to a dihydrofuranone. However, the absolute configurations of **2** and **3** were not elucidated in this study, although the optical rotation spectra were similar to the results reported for the furanones from *Nigrospora sacchari*.[18]

Compounds **4** and **5**, named phomopsolidones C and D, were obtained as a mixture of two isomers. Because of the low amount of compounds available and the lack of activity, no further purification was performed. Nevertheless, HRESI MS and $^1H$ and $^{13}C$ NMR spectra, compared to those of **2**, indicated the presence of the furanone ring with the elimination of the group $R_2$. The presence of two new carbon atoms at $\delta$ 149.1 and $\delta$ 113.5 for compound **4** and $\delta$ 150.9 and $\delta$ 114.5 for compound **5** indicated the formation of an ethylenic bond between C-5 and C-6 with the configuration *Z* and *E*. A long-range coupling constant between H-3 and H-4 and H-6 in compound **5**, characteristic of a W system, indicated an *E* configuration of the double bond between C-5 and C-6. HRESI MS (+) *m/z* 219.0637 $[M + Na]^+$ confirmed the molecular formula $C_{10}H_{12}O_4Na$.

The second strain DC239 afforded three compounds (Figure 2). Compound **6**, a yellow amorphous solid, had a UV

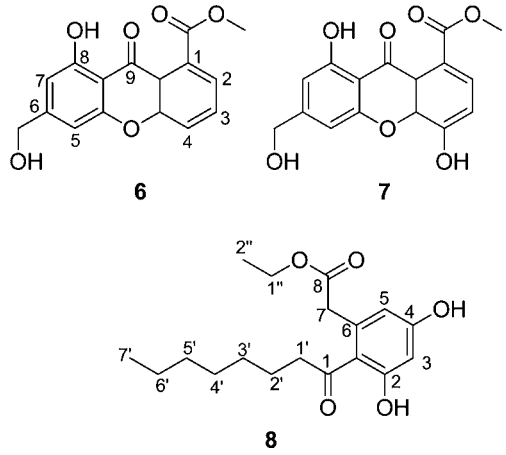

**Figure 2.** Compounds isolated from *P. viticola* complex and Sacc. DC239 and DC180: sydowinin A (**6**), sydowinol (**7**), and cytosporone B (**8**).

spectrum specific for a xanthone, with $\lambda_{max}$ at 233, 257, 291, 301, 362 nm. The molecular formula was deduced from $^1H$ NMR, $^{13}C$ NMR, DEPT, COSY, HMBC, and HMQC data as $C_{16}O_6H_{12}$ according to ESI MS (+) *m/z* 300.09 $[M + H]^+$ and $MS^2$ *m/z* 269.2 corresponded to the loss of a methoxyl group. Thus, compound **6** was identified as sydowinin A previously described from *Aspergillus sydowii*.[19]

The molecular formula $C_{16}O_7H_{12}$ for **7** was deduced from $^1H$ NMR, $^{13}C$ NMR, and DEPT data combined with MS data. The HRESI MS (−) *m/z* 315.0532 $[M - H]^-$ and $MS^2$ *m/z* 285.2 corresponded to the loss of the group methoxyl. 2D NMR data allowed the identification of compound **7** as sydowinol.[19] However, the identification of compounds **6** and **7** was reported only by $^1H$ NMR data; we report, in the Materials and Methods section, the complete spectral characterization by $^{13}C$ NMR.

The third compound **8** isolated from the second strain DC239, also isolated from the third strain *P. viticola* (Sacc.) Sacc. DC180, had a molecular formula of $C_{18}H_{26}O_5$, as deduced from $^1H$, $^{13}C$, and DEPT NMR spectroscopic data and HRESI MS (+) 345.1674 $[M + Na]^+$. The 1D and 2D NMR spectra in comparison with the literature led to the identification of compound **8** as cytosporone B, previously isolated from *Cytospora* sp. and *Diaporthe* sp.[20]

Biological activities for phomopsolide B (**1**) were previously reported for its antiboring/antifeeding activity against the elm bark beetle *Scolytus* sp.[16] and its good antibacterial activity against *Staphylococcus. aureus*.[21] Cytosporone B (**8**) was reported to have broad antifungal activities against *Aspergillus niger*, *Trichoderma* sp., *Fusarium* sp., and *Candida albicans*[22] and antibacterial activity against the methicillin-resistant *S. aureus* (MRSA ) bacterial strain;[23] however, there were no biological activities reported for sydowinin A and sydowinol.

Phytotoxic activity on grapevine leaves of cv. Chasselas was examined for all isolated compounds at the concentrations of 100, 250, and 500 $\mu$g/mL. Eutypine, the major phytotoxin isolated from *E. lata*,[24] was used as positive control at 500 $\mu$g/mL. Leaf necrosis was assessed 24 h after inoculation, and the values obtained are the mean of three replicates. Necrosis started to appears after 6 h at 500 $\mu$g/mL for cytosporone B (**8**) and eutypine. After 12 hours, eutypine, cytosporone B (**8**), and phomopsolide B (**1**) induced full necrosis on the leaf discs, whereas sydowinin A (**6**) and sydowinol (**7**) showed necrosis only on the leaf edges and phomopsolidones A−D did not induce leaf necrosis. The necrosis induced by phomopsolide B (**1**) was a bleaching type in opposition to the brownish ones usually observed, whereas cytosporone B induced a brown necrosis and the green part of the leaf became darker. Phytotoxicity against grapevine callus tissue was performed only with the major compound phomopsolide B (**1**) that induced 100% inhibition of callus growth at 60 $\mu$g/mL.

The antibacterial activity of compounds **1**−**3** was measured by the bioautography method on thin-layer chromatography against *Bacillus subtilis* and *Escherichia coli*. All three compounds showed minimal inhibitory concentration (MIC) at 0.1 ng against *B. subtilis* but did not show activity at 200 ng on *E. coli*.

Compounds **1**−**3**) were subjected to a larvicidal assay on larvae of the grapevine moth *L. botrana*. The trial was carried out at 1 and 10 ppm (mg/kg). The larvicidal activity of the product was calculated in relation to the corresponding control experiment for both the larval surviving rate at 14 days and also for the whole duration of the trial up to moth emergence. For the larvae reared with the contaminated diet, no significant difference in the survival rate was observed. The larval survival rates with 10 ppm at adult emergence reached 91.7% in the control, 65.0% with phomopsolide B (**1**), 90.0% with phomopsolidone A (**2**), and 68.3% with phomopsolidone B (**3**). The development delay at 10 ppm was more significant. The mean development time for the larvae for the control was 28 days, for phomopsolide B (**1**) was 31.41 days, for phomopsolidone A (**2**) was 30.48 days, and for phomopsolidone B (**3**) was 34.41 days.

Phomopsolidones A and B (**2** and **3**) with the furanone moiety displayed weaker phytotoxic and antibacterial activities than phomopsolide B (**1**) with the pyranone moiety; these results are in accordance with the herbicidal activity reported for phomalactone A (pyranone) and its furanone cometabolites isolated from *N. sacchari*.[24]

[a]As: asymptomatic plants; S: plants showing esca symptoms. [b]Strains identified by the Belgium Coordinated Collections of Microorganisms.

Four out of the nine strains studied were identified by the Belgian Coordinated Collections of Microorganisms (BCCM) of the Catholic University of Louvain-la-Neuve. Strain DC180 was identified as the typical type of strain found on *Vitis*, *P. viticola* (Sacc.) Sacc. Strains DC239 and DC281) were described as being very similar, with the dimensions of $\alpha$-conidia slightly bigger than those described for the typical *viticola* strain. The molecular biological analysis and sequencing of the ITS and 28S zones made it possible to note that the two samples have a succession of bases similar to that described by Mostert et al.[1] called *Phomopsis* sp. 2 and taken up in the "*P. viticola* complex". Strain DC275 showed smaller $\alpha$-conidia and shorter $\beta$-conidia than those described for the *viticola* species, but a molecular biological study did not give results allowing further identification of the strain. Thus, the strain could only be identified as being a species belonging to the *Phomopsis* sp.

In order to examine the compounds produced as a function of strain species, the original LC-DAD-MS data of the nine strains were reinvestigated in the light of the identified metabolites (Table 2). The strains could be divided into three groups. The first group included the strain producing phomopsolide, phomopsolidones, and cytosporone B (strains DC110, DC275, DC283, DC279, DC282, and DC301) and correlate with *Phomopsis* sp. The second group included a strain producing cytosporone B (**8**) alone corresponding to *P. viticola* (Sacc.) Sacc (DC180), and finally, the third group producing cytosporone B (**8**) together with sydowinin A (**6**) and sydowinol (**7**) corresponded to *P. viticola* v. complex (strains DC239 and DC281). Three out of the six strains producing the phytotoxic phomopsolide B (**1**) were isolated from asymptomatic cv. Merlot (a less susceptible cultivar). From plants showing esca symptoms,[12] two strains were isolated from Cabernet franc and one from Cabernet sauvignon (both sensitive cultivars); these strains produce compounds **1** and **2** together with cytosporone B (**8**). Strains producing cytosporone B (**8**) and xanthones **6** and **7** were isolated from symptomatic Cabernet franc and asymptomatic cv. Cabernet sauvignon. These results indicate that *Phomopsis* sp. of sensitive cultivars in plants showing esca symptoms produce the phytotoxic compounds phomopsolide B (**1**) and cytosporone B (**8**) raising the question of cultivar-driven strain selection and the stimulation of phytotoxins biosynthesis in grapevine plants. Phomopsolide B (**1**) has been reported from several species of *Phomopsis* from several host plants such as elm willow, quercus, platanus, heliconia, myrica, and liriodendron,[7] indicating that the biosynthesis of this secondary metabolite does not seem to be correlated with the host plant from which the *Phomopsis* isolate was obtained. It is likewise for cytosporone B (**8**) reported from *Phomopsis* sp. isolated from different host plants such as cacao, coffee, and mango.[25,26]

This study revealed that the *Phomopsis* isolates, associated with grapevine showing esca decline, show high variability with regard to secondary metabolites production. The role played by the fungi is not clear, but they may be weak pathogens, saprophytes, or endophytes.[5] The complexity of signaling between microorganisms and plants and between microorganisms themselves in grapevine trunk disease is still poorly understood. Characterization of metabolites biosynthesized by several fungi infecting grapevine wood is crucial not only for the phytotoxic properties but also is essential to better understand the conditions under which the fungi start producing the toxins and modify their lifestyle from endophytic to saprotrophic.

# Functional Analyses on Antioxidant, Anti-inflammatory, and Antiproliferative Effects of Extracts and Compounds from *Ilex latifolia* Thunb., a Chinese Bitter Tea

Ting Hu, Xiao-Wei He, and Jian-Guo Jiang*

College of Food and Bioengineering, South China University of Technology, Guangzhou 510640, China

**ABSTRACT:** *Ilex latifolia* Thunb., widely distributed in China, has been used as a functional food and drunk for a long time. This study was aimed to identify the bioactive constituents with antioxidant, antitumor, and anti-inflammatory properties. *I. latifolia* was extracted with 95% ethanol and then partitioned into four fractions: petroleum ether fraction, ethyl acetate fraction, *n*-butanol fraction, and water fraction. Results showed that the ethyl acetate fraction was found to have significant ferric reducing antioxidant power activity, DPPH radical scavenging activity, and oxygen radical absorbance capacity, cytotoxicity against human cervix carcinoma HeLa cells, and inhibitory effect on NO production in macrophage RAW 264.7 cells. Five compounds were isolated from the ethyl acetate fraction, and they were identified as ethyl caffeate (**1**), ursolic acid (**2**), chlorogenic acid (**3**), 3,4-di-*O*-caffeoylquinic acid methyl ester (**4**), and 3,5-di-*O*-caffeoylquinic acid methyl ester (**5**), the last two of which were isolated for the first time from *I. latifolia*. Compounds **4** and **5** exhibited cytotoxicity actions against tumor cell line. Compound **3** showed the strongest anti-inflammatory activity of all the compounds. The results obtained in this work might contribute to the understanding of biological activities of *I. latifolia* and further investigation on its potential application values for food and drug.

**KEYWORDS:** *I. latifolia, antioxidant, antitumor, anti-inflammatory, ursolic acid, chlorogenic acid, 3,4-di-O-caffeoylquinic acid methyl ester, 3,5-di-O-caffeoylquinic acid methyl ester*

## INTRODUCTION

*Ilex latifolia* Thunb. is a bitter tea of Chinese origin. It has been consumed traditionally as a kind of tea in China and southeastern Asia for a long time. The taste of *I. latifolia* is much more bitter than that of tea made from the leaves of *Camellia sinensis*.[1] The main species are *I. latifolia* and *Ilex cornuta*, which belong to the same genus as Mate (*Ilex paraguariensis*).[2−4] *I. latifolia* has gained attention as a functional tea in the past decade because of its potential health and economic significance. Many beneficial functions of *I. latifolia* such as cardiovascular, antioxidant, antiobesity, antidiabetic, anti-inflammatory, hepatoprotective, and neuroprotective effects have been reported.[5,6]

There is a growing interest in *I. latifolia* about its chemical composition and functions due to its applications in cancer chemotherapy and other various pharmacological effects, particularly antitumor and anti-inflammatory activities.[7,8] *I. latifolia* remains an underutilized natural resource. To develop its health-promoting compounds into new food ingredients or nutraceutical applications, more research is urgently needed for the isolation and identification of the compounds with efficient procedures from *I. latifolia* extracts.

The main purpose of the present study was to isolate the bioactive constituents with antioxidant, antitumor, and anti-inflammatory properties. The crude extract and four fractions (petroleum ether fraction, ethyl acetate fraction, *n*-butanol fraction, and water fraction), which partitioned from a 95% ethanol extract of *I. latifolia*, were measured to compare their activities by the use of ferric reducing antioxidant power assay (FRAP), 2,2-diphenyl-1-picrylhydrazyl (DPPH) radical scavenging assay, oxygen radical absorbance assay (ORAC), cell proliferation assay against human cervix carcinoma HeLa cells, and inhibitory effect on NO production in LPS-induced RAW 264.7 macrophages. The activities of five compounds isolated from the ethyl acetate fraction were also determined.

## MATERIALS AND METHODS

**Plant Material.** *I. latifolia*, derived from Wuzhishan city (Hainan province, China), was purchased from Forest Drugstore Chain Co., Ltd., of Guangzhou, China. Samples were air-dried under shade for 1 week and pulverized to powder. The dried materials were stored in a well-closed container for further use.

**Reagents.** Methanol, HPLC grade water, Folin−Ciocalteu phenol reagent, and sodium carbonate were purchased from chemical reagent factory (Tianjing, China). DPPH, lipopolysaccharide (LPS), 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT), *N*-1-naphthylethylenediamine dihydrochloride, sulfanilamide, 5-fluorouracil, gallic acid, and Trolox were purchased from Sigma Chemical Co. (USA). Human cervix carcinoma HeLa cell line and mouse macrophage RAW 264.7 cell line were obtained from the cell bank of the Chinese Academy of Sciences (CAS, Shanghai, China). Cell culture medium and all other materials required for cell culture were purchased from Life Technologies Corp. (Grand Island, NY, USA). All the other chemicals were of analytical grade.

**Extraction, Isolation, and Purification.** The process of *I. latifolia* extraction and isolation is shown in Figure 1. The dried powder (3 kg) of *I. latifolia* was extracted with 95% ethanol (3 × 10 L) for 3 h at 80 °C. The crude extract was evaporated to dryness under reduced pressure. The extract was suspended in water (1.5 L) first and then partitioned with petroleum ether, ethyl acetate, and *n*-butanol in sequence with the same volume (shaken sharply to mixt, then allowed to stand for 4 h at room temperature and atmosphere pressure every

[a]Data are expressed as means ± standard deviation. Averages followed by different lower case letters in different columns differ significantly by one-way analysis of variance−Duncan's multiple-range test ($p \leq 0.05$). GAE, gallic acid equivalent; TE, Trolox equivalent; DW, dry weight.

time), which yielded a petroleum ether fraction (111.3 g), an ethyl acetate fraction (456.2 g), an *n*-butanol fraction (153.5 g), and a water fraction (177.4 g), respectively (for extraction yields see Table 1). The ethyl acetate fraction was chosen for further isolation becausse of its better activity among the four fractions in the biological activity screening tests.

It was dissolved in chloroform, applied to a silica gel (200−300 mesh) column (7.5 cm × 1.2 m), and eluted with a gradient of chloroform and methanol (100:0, 98:2, 95:5, 90:10, 80:20, 50:50, 0:100, v/v, each 10 L). The eluates were pooled into 28 fractions (100:0, fractions 1−2; 98:2, fractions 3−7; 95:5, fractions 8−12; 90:10, fractions 13−17; 80:20, fractions 18−22; 50:50, fractions 23−27; 0:100, fraction 28) on the basis of thin-layer chromatography (TLC) and high-performance liquid chromatography (HPLC). Fraction 6 (from the 98:2 fraction) was loaded on an ODS column and eluted with a mixture of methanol and water (30, 60, 90, and 100%, v/v, each 2.5 L) to obtain four fractions. The 30% methanol fraction was further purified by Sephadex LH-20 column chromatography, and compound **1** was obtained (300 mg). The 100% fraction appears as a crystal, and compound **2** was obtained (13 g). Fraction 17 was purified by Sephadex LH-20 column chromatography eluted with methanol, and compound **3** was obtained (5 g). Fraction 20 (from 90:10 fraction) was dissolved in chloroform and applied on a second silica gel column (5 cm × 80 cm). The column was eluted with a stepwise mixture of chloroform and methanol (99:1, 98:2, 95:5, 90:10, v/v, each 5 L), and the 98:2 fraction continued to separate followed by semipreparative HPLC using a 48% methanol solution as the mobile phase, to yield compounds **4** (1.2 g) and **5** (900 mg). The yields of extraction of five compounds (based on the initial 3 kg of dried *I. latifolia*) are 0.01, 0.43, 0.17, 0.04, and 0.03%, respectively.

The isolated compounds and 95% EtOH extract were dissolved in methanol (approximately 2 mg/mL) filtered through a 0.45 $\mu$m micropore membrane before use, and 20 $\mu$L was injected into the HPLC instrument for analysis. The relative contents in percentage of each compound in the initial extract were determined and calculated with the area normalization method, which are 0.22, 2.09, 1.07, 0.35, and 0.28%, respectively. The purity of the five compounds was detected by HPLC, and all were >95%.

**Determination of Total Phenolic Content (TPC).** A precisely weighed amount of samples was used for TPC, which were dissolved in methanol solution. The TPC was determined by using Folin−Ciocalteu's reagent method.[9] Briefly, the appropriate sample solution was oxidized with the Folin−Ciocalteu reagent, and sodium carbonate was used to neutralize the reaction. After a 30 min incubation period, absorbance was measured at 765 nm. The concentration was calculated using gallic acid as standard, and the results were expressed as

dx.doi.org/10.1021/jf501670v | J. Agric. Food Chem. 2014, 62, 8608−8615

milligrams of gallic acid equivalents (GAE) per gram of dry weight (DW) and are shown in Table 1.

**Assays for FRAP.** Assays for FRAP were measured by using the method of Benzie and Strain,[10] in which the absorbance at 593 nm was measured. Results were expressed as Trolox equivalents per gram of dry weight (TE/g DW).

**Assays for DPPH Radical Scavenging.** Assays for DPPH radical scavenging were determined by the method of Villaño et al.[11] with some modifications. Briefly, a total of 0.1 mL of sample in ethanol was added to 3.0 mL of DPPH ethanolic solution. Absorbance was measured at 517 nm after 30 min at room temperature in the dark. All measurements were performed in triplicate. The percent DPPH scavenging ability was calculated as DPPH scavenging ability = $(A_{control} - A_{sample}/A_{control}) \times 100$. $IC_{50}$ values calculated denote the concentration of a sample required to decrease the absorbance at 517 nm by 50%. The lower the $IC_{50}$ value, the more powerful the antioxidant capacity.

**Assays for ORAC.** Assays for PRAC were determined according to the method of Dávalos et al.[12] with some modifications. In brief, samples were diluted with $NaH_2PO_4$–$Na_2HPO_4$ solution (75 mM, pH 7.4) and then placed on microplates along with fluorescein solution (39.9 $\mu$M) and AAPH solution (38.25 mM). The plates were incubated in an automated microplate reader at 37 °C and read every minute for 70 min using a fluorescence detector with an excitation wavelength of 485 nm and an emission wavelength at 520 nm. A calibration curve was prepared using Trolox, and the results were expressed as Trolox equivalents per gram of dry weight (TE/g DW).

**Cell Culture.** The cell lines used in this study were human cervix carcinoma HeLa and mouse macrophage RAW 264.7. Cells were maintained and cultured in tissue culture flasks (25 $cm^2$, Corning) containing DMEM (Gibco BRL) supplemented with 10% fetal bovine serum (FBS), 1% penicillin (100 IU/mL), and streptomycin (100 $\mu$g/mL) at 37 °C in a humidified incubator with 5% $CO_2$. The medium was changed every 24–48 h.[13]

Dried samples were first dissolved in DMSO and then were diluted with the culture medium into different concentrations. The final concentration of DMSO in the culture medium was maintained at <0.5% (v/v) to avoid solvent toxicity.

**Antitumor Activity.** The effect of samples on the proliferation of HeLa cell was tested by MTT assay. MTT is captured by cells and reduced intracellularly in a mitochondrion-dependent reaction to yield formazan product. The ability of cells to reduce MTT provides an indication of their intactness and mitochondrial activity that serves as a measure of viability.[14,15] Exponential growth phase HeLa cells were plated into 96-well culture plates ($5 \times 10^4$ cells/mL, 100 $\mu$L/well) and incubated overnight. When the cells were attached to the plates, an equal volume of fresh medium containing different concentrations of samples was added. After 24 h, the supernatant was discarded and cells were washed with PBS two times. Two hundred microliters of fresh medium containing 20 $\mu$L of MTT (0.5 mg/mL) solution was added to each well followed by incubation for 4 h at 37 °C. After this period, the supernatant was removed and 150 $\mu$L of DMSO was added to dissolve formazan crystals. The absorbance was measured at 490 nm after the plates had been shaken for 8 min. 5-Fluorouracil is a kind of natural antitumor drug, and it shows a strong effect in antitumor assays. It was very popularly used as a positive control in antitumor activities. Therefore, 5-fluorouracil was used as a positive control in this work. The percentage of cell proliferation inhibition was calculated using the following formula (eq 1):[16]

$$\text{cell proliferation inhibition (\%)} = \left(1 - \frac{OD_{sample}}{OD_{control}}\right) \times 100\% \quad (1)$$

**Anti-inflammatory Assays.** The anti-inflammatory activities of total crude extraction fraction, ethyl acetate fraction, petroleum ether fraction, water fraction, *n*-butyl alcohol fraction, and isolated compounds were tested with RAW 264.7 macrophages in vitro. First, a cytotoxicity test should be performed by MTT assay to choose the samples for further investigation, which were nontoxic to normal cells. Thereafter, the samples with no toxicity could be done using the anti-inflammatory activity below.

Exponential growth phase RAW 264.7 cells were seeded into 96-well culture plates ($1 \times 10^5$ cells/mL, 100 $\mu$L/well) and incubated overnight. When the cells were attached to the plates, an equal volume of fresh medium containing different concentrations of samples was added. Then cells were stimulated with LPS (final concentration was 1 $\mu$g/mL). After 24 h, the supernatants were collected to measure NO content using the Griess reaction[17] with minor modifications. In brief, 100 $\mu$L of cell supernatants was added with 50 $\mu$L of 0.1% *N*-1-naphthylethylenediamine dihydrochloride in distilled water and 50 $\mu$L of 1% sulfanilamide in 5% $H_3PO_4$. The absorbance was measured at 540 nm after the plates were allowed to stand for 8 min at room temperature. A sodium nitrite standard curve was obtained and used to calculate the nitrite level in samples. NO inhibition rate was calculated using the following formula (eq 2):[18]

$$\text{NO inhibition (\%)} = \frac{OD_{LPS} - OD_{LPS+sample}}{OD_{LPS} - OD_{blank}} \times 100\% \quad (2)$$

**Statistical Analysis.** All of the experiments were carried out in three replications. The data were expressed as the mean ± standard deviation (SD). SPSS statistical analysis software was used to perform analysis of variance (ANOVA). Each group treated was compared with the corresponding controls by means of Student's *F* test and correlation test. Significant difference was checked by Duncan's multiple-range test, and the level was set at $p < 0.05$.

## RESULTS AND DISCUSSION

**Total Phenolic Content and Antioxidant Activity of Extract and Fractions from *I. latifolia*.** The crude extract (95% EtOH) made from *I. latifolia* with 95% ethanol was fractionated through solvent–solvent partitioning to obtain four fractions: petroleum ether fraction (PE), ethyl acetate fraction (EA), *n*-butanol fraction (*n*-BuOH), and water fraction (W). The extraction yields of 95% EtOH, PE, EA, *n*-BuOH, and W on the basis of freeze-dried starting material (3 kg) were 30.4, 3.7, 15.2, 5.1, and 5.9%, respectively (Table 1). The total recovery of the four fractions was 29.9%, and the remaining 0.5% may be lost during the solvent–solvent partition, concentration, and lyophilization.

The Folin–Ciocalteu reagent is used to obtain a crude estimate of the amount of phenolic compounds present in an extract. In the present study, a TPC of 95% EtOH and the four fractions was determined using the Folin–Ciocalteu method. As a result, TPC of the crude extract and four fractions decreased in the following order: EA > *n*-BuOH > 95% EtOH > W > PE, which is shown in Table 1. The TPC of the ethyl acetate fraction was much higher than those of the 95% EtOH and other fractions. It seems that ethyl acetate was the most suitable solvent to concentrate phenolic substances. Moreover, a lower TPC was found in the petroleum ether fraction.

Dietary antioxidants have been shown to prevent the oxidation of biomolecules, which can be regarded as effective scavengers of detrimental free radicals.[24,25] Tea is a good source of dietary antioxidants, such as caffeoylquinic acids and tea polyphenols. The antioxidant properties of tea are primarily owed to the phenolic content, and several epidemiological research studies have shown the chemoprotective properties of polyphenols.[26] In this work, the antioxidant activities of extract and fractions from *I. latifolia* have been evaluated in vitro. The crude extract (95% EtOH) and its four fractions, PE, EA, *n*-BuOH, and W, were evaluated for antioxidant activities using FRAP, DPPH radical scavenging activity, and ORAC, and the results were compared (Table 1). The activities decreased in the order EA > *n*-BuOH > 95% EtOH > W > PE, according to the FRAP and ORAC assays, with the exception of the rank order of *n*-BuOH and 95% EtOH in the DPPH assay.

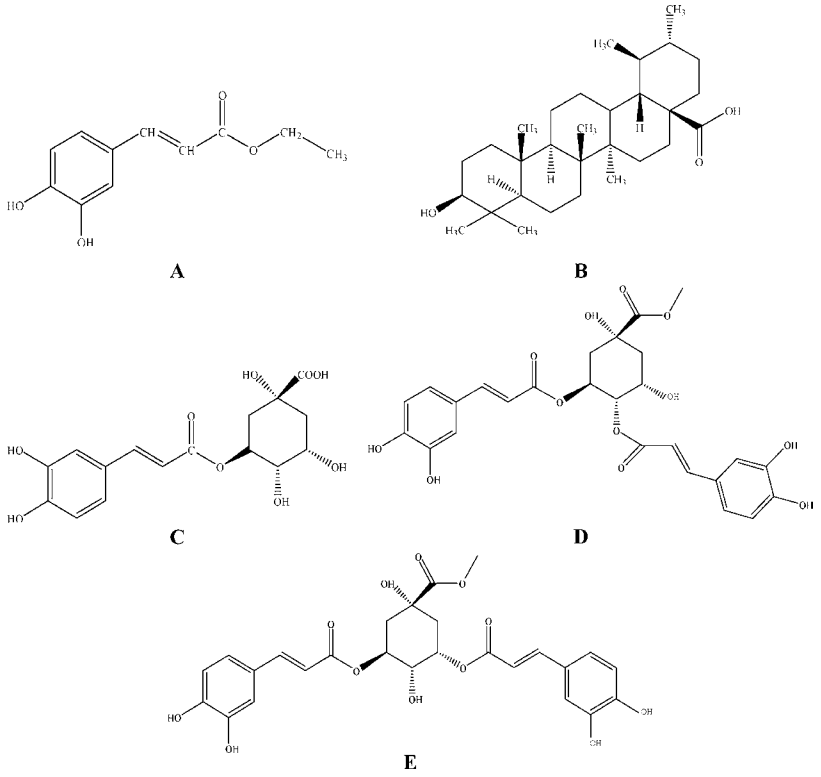

**Figure 2.** Compounds and their chemical structures isolated from *I. latifolia*: (A) ethyl caffeate; (B) ursolic acid; (C) chlorogenic acid; (D) 3,4-di-*O*-caffeoylquinic acid methyl ester; (E) 3,5-di-*O*-caffeoylquinic acid methyl ester.

This trend was similar to that observed for the TPC. The ethyl acetate fraction of *I. latifolia* exhibited a remarkable FRAP value (265.05 ± 1.5 μmol TE/g DW), free radical scavenging activity against DPPH ($IC_{50}$ = 16.3 ± 3.3 μg/mL), and ORAC value (2367 ± 88 μmol TE/g DW). By comparing 95% EtOH and its four fractions, the antioxidant power of 95% EtOH was less than those of EA and *n*-BuOH in the FRAP and ORAC assays, which may result from the active components through condensation effects during the solvent−solvent partitioning progress. The extract of *I. latifolia* was certified to contain a large number of caffeoylquinic acids, which contributed to the antioxidant activity.[27] It is observed that *I. latifolia* is a beneficial herbal drink due to its antioxidant activity.

**Identification of Isolated Compounds.** The structure identification of isolated compounds was performed with MS, $^1$H NMR, and $^{13}$C NMR analyses and comparison with the previously reported spectral data; the chemical structures of five compounds were identified and are shown in Figure 2. Spectroscopic data are described below.

*Compound **1** was obtained as a brown acicular crystal.* The negative ESI-MS showed a quasi-molecular ion at *m*/*z* 206.8 $[M - H]^-$. $^1$H NMR ($CD_3OD$-$d_4$, 400 MHz) δ 7.52 (1H, d, *J* = 15.9 Hz), 6.23 (1H, d, *J* = 15.9 Hz), 7.03 (1H, d, *J* = 1.9 Hz), 6.77 (1H, d, *J* = 8.4 Hz), 6.92 (1H, dd, *J* = 1.9, 8.4 Hz), 4.18 (2H, q, *J* = 6.6 Hz), 1.30 (3H, t, *J* = 6.6 Hz); $^{13}$C NMR ($CD_3OD$-$d_4$, 101 MHz) δ 167.4 (C-1), 114.8 (C-2), 145.5 (C-3), 127.4 (C-4), 115.5 (C-5), 146.2 (C-6), 148.7 (C-7), 116.2 (C-8), 122.3 (C-9), 60.4 (C-1′), 14.5 (C-2′). Compared with the NMR and MS data given in ref 19, compound **1** was identified as ethyl caffeate.

*Compound **2** was obtained as a white prismatic crystal.* The negative ESI-MS showed a quasi-molecular ion at *m*/*z* 455.2 $[M - H]^-$. $^1$H NMR ($CD_3Cl$-$d_4$, 400 MHz) δ 2.10 (1H, d, H-18), 3.13 (1H, t, H-3), 5.26 (1H, t, H-12), 0.80 (3H, d, *J* = 7.6 Hz, H-29), 0.70 (3H, d, *J* = 7.6 Hz, H-30), 1.26, 1.10, 0.89, 0.86, 0.78 (5 × 3H, s); $^{13}$C NMR ($CD_3Cl$-$d_4$, 101 MHz) δ 38.7 (C-1), 27.3 (C-2), 79.1 (C-3), 38.8 (C-4), 55.3 (C-5), 18.4 (C-6), 33.0 (C-7), 39.6 (C-8), 47.7 (C-9), 37.1 (C-10), 23.4 (C-11), 125.9 (C-12), 138.0 (C-13), 42.1 (C-14), 28.2 (C-15), 24.3 (C-16), 47.9 (C-17), 52.8 (C-18), 39.1 (C-19), 38.8 (C-20), 30.7 (C-21), 36.8 (C-22), 28.1 (C-23), 15.6 (C-24), 15.5 (C-25), 17.0 (C-26), 23.6 (C-27), 181.2 (C-28), 17.5 (C-29), 21.4 (C-30). These ESI-MS, $^1$H NMR, and $^{13}$C NMR data were similar to those in a previous paper;[20] therefore, compoud **2** was identified as ursolic acid. It was found to be the major constituent isolated from *I. latifolia*.

*Compound **3** was obtained as a white powder.* The negative ESI-MS showed a quasi-molecular ion at *m*/*z* 352.7 $[M - H]^-$. $^1$H NMR ($CD_3OD$-$d_4$, 400 MHz) δ 2.21 (dd, *J* = 13.6, 3.1 Hz), 2.07 (dd, *J* = 13.6, 4.4 Hz), 4.20 (ddd, *J* = 3.1, 4.4, 3.1 Hz), 3.76 (dd, *J* = 8.5, 3.1 Hz), 5.37 (ddd, *J* = 9.3, 4.8, 8.5 Hz), 2.11 (dd, *J* = 13.6, 9.3 Hz), 2.26 (dd, *J* = 13.6, 4.8 Hz), 7.08 (d, *J* = 2.0 Hz), 6.81 (d, *J* = 8.2 Hz), 6.98 (dd, *J* = 8.2, 2.0 Hz), 7.59 (d, *J* = 15.9 Hz), 6.29 (d, *J* = 15.9 Hz); $^{13}$C NMR ($CD_3OD$-$d_4$, 101 MHz) δ 126.6 (C-1), 114.1 (C-2), 144.2 (C-3), 147.0 (C-4), 116.0 (C-5), 122.6 (C-6), 145.9 (C-7), 115.2 (C-8), 168.9 (C-9), 76.6 (C-10), 38.8 (C-11), 70.6 (C-12), 72.8 (C-13), 71.0 (C-14), 37.3 (C-15), 180.1 (C-16). These data were in good agreement with the reported compound, chlorogenic acid.[21]

*Compound **4** was obtained as a yellow powder.* The negative ESI-MS showed a quasi-molecular ion at *m*/*z* 529 $[M - H]^-$. $^1$H NMR (DMSO-$d_6$, 400 MHz) δ 6.82 (2H, br d, *J* = 8.1 Hz, H-5′,5″), 7.03 (2H, dd, *J* = 8.1, 2.1 Hz, H-6′,6″), 7.07 (2H, d, *J* = 2.1 Hz, H-2′,2″), 7.56 (1H, d, *J* = 15.9 Hz, H-7′), 7.47 (1H, d, *J* = 15.9 Hz, H-7″), 6.32 (1H, d, *J* = 15.9 Hz, H-8′), 6.19 (1H, d, *J* = 15.9 Hz, H-8″), 5.32 (1H, m, H-3), 5.02

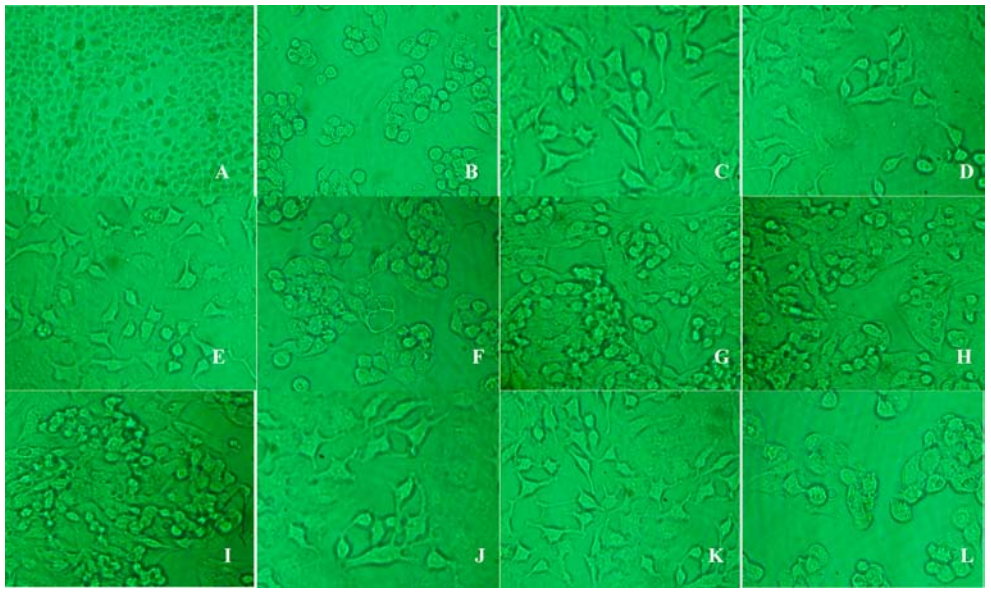

**Figure 3.** Morphological changes in the growth and survival of HeLa cells as examined by phase-contrast microscopy (magnification, 200×): (A) control group or blank group; (B) 95% EtOH (50 $\mu$g/mL); (C) petroleum ether fraction (50 $\mu$g/mL); (D) ethyl acetate fraction (50 $\mu$g/mL); (E) *n*-butanol fraction (50 $\mu$g/mL); (F) water fraction (50 $\mu$g/mL); (G) ethyl caffeate (10 $\mu$M); (H) ursolic acid (10 $\mu$M); (I) chlorogenic acid (10 $\mu$M); (J) 4-CAME (10 $\mu$M); (K) 5-CAME (10 $\mu$M); (L) 5-fluorouracil (10 $\mu$M).

(1H, m, H-4), 4.20 (1H, m, H-5), 3.65 (3H, s, $OCH_3$), 2.27 (2H, m, H-2, 6), 2.00 (2H, m, H-1,7); $^{13}$C NMR (DMSO-$d_6$, 101 MHz) $\delta$ 73.2 (C-1), 37.8 (C-2), 67.9 (C-3), 72.4 (C-4), 65.5 (C-5), 36.8 (C-6), 173.5 (C-7), 125.6 (C-1′), 125.3 (C-1″), 114.5 (C-2′,2″), 145.7 (C-3′), 145.5 (C-3″), 148.7 (C-4′), 148.6 (C-4″), 115.9 (C-5′), 114.9 (C-5″), 121.5 (C-6′), 121.0 (C-6″), 147.6 (C-7′), 147.1 (C-7″), 113.9 (C-8′), 113.4 (C-8″), 166.6 (C-9′), 165.3 (C-9″), 52.1 ($OCH_3$). By comparison of the above data with the literature,[22] compound **4** was identified as 3,4-di-*O*-caffeoylquinic acid methyl ester (4-CAME).

*Compound **5** was obtained as a yellow powder.* The negative ESI-MS showed a quasi-molecular ion at *m*/*z* 529 $[M - H]^-$. $^1$H NMR (DMSO-$d_6$, 400 MHz) $\delta$ 2.09−2.33 (4H, m, H-2,6), 3.71 (3H, s, $OCH_3$), 4.34 (1H, m, H-5), 5.10 (1H, dd, *J* = 8.0, 3.2 Hz, H-4), 5.50 (1H, m, H-3), 6.16 (1H, d, *J* = 16.0 Hz, H-8′), 6.28 (1H, d, *J* = 16.0 Hz, H-8″), 6.74 (2H, d, *J* = 8.0 Hz, H-5′,5″), 6.90 (1H, m, H-6′,6″), 7.00 (1H, d, *J* = 2.0 Hz, H-2′), 7.02 (1H, d, *J* =2.0 Hz, H-2″), 7.49 (1H, d, *J* = 16.0 Hz, H-7′), 7.59 (1H, d, *J* = 16.0 Hz, H-7″); $^{13}$C NMR (DMSO-$d_6$, 101 MHz) $\delta$ 177.5 (C-7), 168.4 (C-9″), 167.9 (C-9′), 149.7 (C-4′,4″), 147.7 (C-7″), 147.6 (C-7′), 146.7 (C-3′,3″), 127.7 (C-1″), 127.5 (C-1′), 123.1 (C-6′,6″), 116.5 (C-5″), 116.4 (C-5′), 115.1 (C-2′,2″), 114.7 (C-8′,8″), 75.8 (C-1), 74.9 (C-4), 69.0 (C-5), 68.6 (C-3), 53.0 ($OCH_3$), 38.5 (C-2), 38.3 (C-6). Compound **5** was identified as 3,5-di-*O*-caffeoylquinic acid methyl ester (5-CAME) according to the literature.[23]

Compounds **4** and **5** were isolated and identified from *I. latifolia* for the first time.

**Evaluation of Cytotoxicity against HeLa Cells.** In this investigation, the 95% EtOH extract, fractions, and isolated compounds **1**−**5** from *I. latifolia* were evaluated for their antiproliferative activities against HeLa human cervix carcinoma cell line using the MTT bioassay. Figure 3 indicates the morphological changes on the growth and survival of HeLa cells as examined by phase-contrast microscopy. The cell proliferation inhibition rates of samples are shown in Figure 4. Among the crude extract and four fractions, 95% EtOH and EA both exhibited the strongest cytotoxicity (Figure 4A). Although the inhibition rate of extract and four fractions was lower than that of 5-fluorouracil, the inhibition rate of 95% EtOH and EA fraction reached nearly 50 and 55%, respectively, at the concentration of 50 $\mu$g/mL. This result showed that the active ingredients on antitumor were concentrated in the EA fraction after 95% EtOH was partitioned into four fractions.

The isolated compounds show significant cytotoxicity against HeLa cell line except chlorogenic acid (Figure 4B). When the concentration was below 4 $\mu$M, all compounds showed very lower inhibition rates as compared to positive control. However, the inhibition rates of 4-CAME and 5-CAME increased significantly at concentrations of 6−10 $\mu$M. The inhibition rate of ursolic acid rose with the increase of concentration and reached about 28% at the maximum concentration. The further increase of concentration resulted in the inhibition rate of chlorogenic acid changing slightly. Ethyl caffeate also exhibited a poor effect at concentrations from 1 to 10 $\mu$M.

4-CAME and 5-CAME are derivatives of caffeoylquinic acid found in several plants. There is little study of the antitumor activity on these two compounds, but the physicochemical property of caffeoylquinic acid was widely reported in the literature. Hu et al.[28] reported that methyl 3,5-dicaffeoylquinate inhibited proliferation in a dose-dependent manner as detected by MTT, trypan blue exclusion, and flow cytometric assays using HT-29 cells. 5-Caffeoylquinic acid was used in preparing antitumor medicine in the form of tablets, capsules, or slow-release tablets or used for inhibiting growth and transfer of tumors. In our study, the two derivatives (4-CAME and 5-CAME) showed significant cytotoxicity against HeLa cell line, which can be potential antitumor drugs in the future.

**Effect of the Extract, Fractions, and Compounds on NO Production in RAW 264.7 Macrophages.** MTT colorimetric assays were carried out to evaluate the toxic effect of compounds on RAW 264.7 macrophage cell line, and the results were shown as relative cell viability referred to control

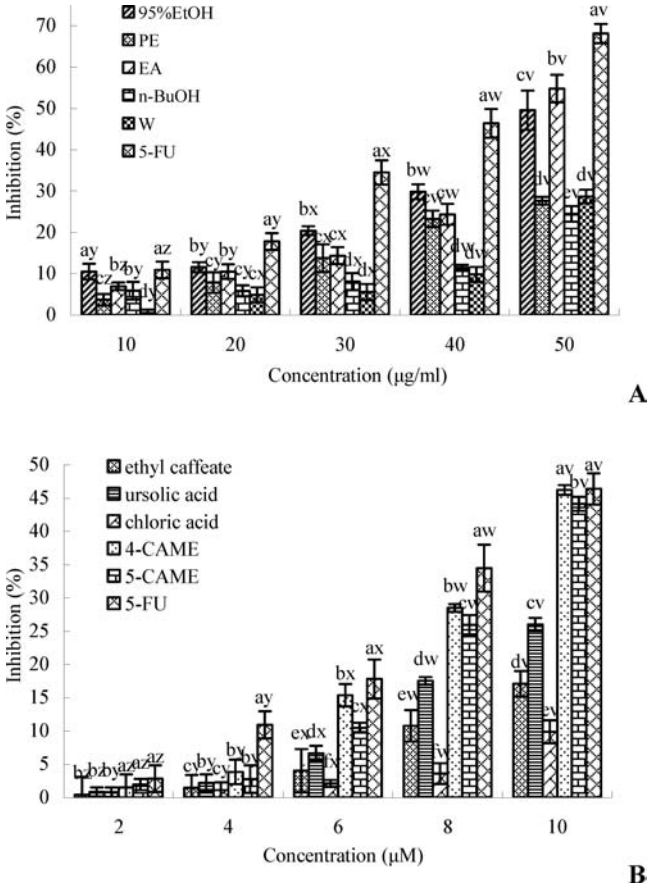

**Figure 4.** Cell proliferation inhibition rates of samples: (A) 95% ethanol extract (95% EtOH), petroleum ether fraction (PE), ethyl acetate fraction (EA), *n*-butanol fraction (*n*-BuOH), and water fraction (W), 5-FU (5-fluorouracil); (B) isolated compounds ethyl caffeate, ursolic acid, chlorogenic acid, 3,4-di-*O*-caffeoylquinic acid methyl ester (4-CAME), 3,5-di-*O*-caffeoylquinic acid methyl ester (5-CAME), 5-FU (5-fluorouracil). Letters a−e refer to significant differences within a fraction and v−z to comparisons across fractions by one-way analysis of variance−Duncan's multiple-range test ($p \leq 0.05$). Results are means ± standard deviation, which were calculated on the basis of data from three trials with three replicates per trial.

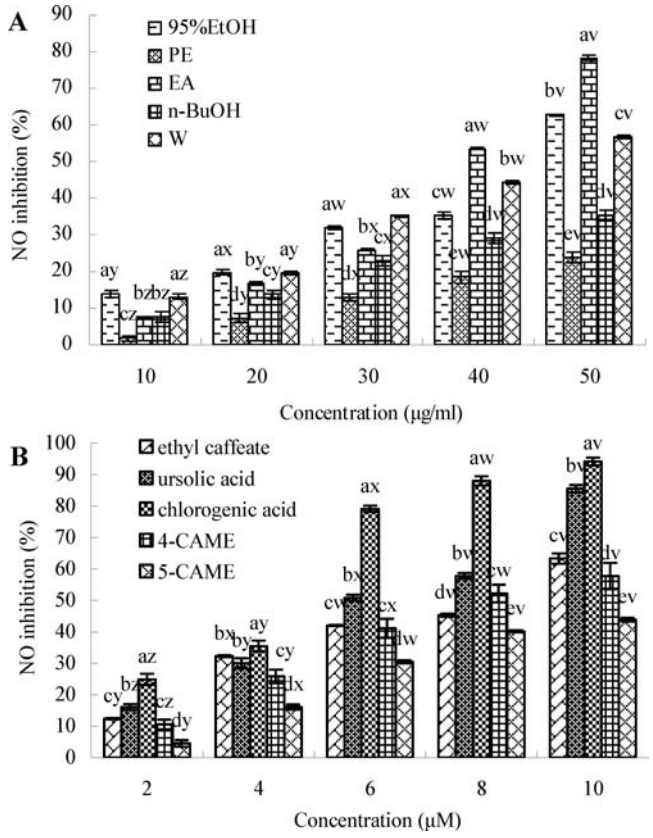

**Figure 5.** Inhibitory effect on NO production of total extract, four fractions, and isolated compounds from *I. latifolia* in LPS-induced RAW 264.7 macrophages: (A) 95% ethanol extract (95% EtOH), petroleum ether fraction (PE), ethyl acetate fraction (EA), *n*-butanol fraction (*n*-BuOH), water fraction (W); (B) isolated compounds ethyl caffeate, ursolic acid, chlorogenic acid, 3,4-di-*O*-caffeoylquinic acid methyl ester (4-CAME), 3,5-di-*O*-caffeoylquinic acid methyl ester (5-CAME). Letters a−e refer to significant differences within a fraction and v−z to comparisons across fractions by one-way analysis of variance−Duncan's multiple-range test ($p \leq 0.05$). Results are means ± standard deviation, which were calculated on the basis of data from three trials with three replicates per trial.

(equal to 100%). Cell viabilities all reached >92% (data not shown). Generally speaking, it could be considered as non-toxicity that the survival rate was >90% when treated with samples.

Current research has demonstrated the participation of reactive oxygen species in systems of inflammation.[29] *I. latifolia* was studied as a potential inhibitor of NO production in inflammatory reactions. Stimulation of LPS-induced RAW 264.7 cell leads to overproduction of NO, and it could be detected and quantified. Figure 5A displays that crude extract and four fractions significantly inhibited NO release and decreased in the order EA (78.16%), 95% EtOH (62.78%), W (56.63%), *n*-BuOH (35.11%), and PE (23.87%) at the concentration of 50 μg/mL. It was clear that EA showed the most active anti-inflammatory effect among the crude extract and all fractions. Many previous literature papers have shown that methanol/ethanol extracts or fractions had good anti-inflammatory activity. Yang et al.[30] reported that the ethyl acetate fraction of the seeds of *Brucea javanica* showed a significant decrease on NO production in LPS-induced RAW 264.7 macrophages. In addition, Pinheiro et al.[31] reported that ethanol extract and hexane and ethyl acetate fractions from *Couroupita guianensis* Aublet leaves exhibited anti-inflammatory activity. In this study, the ethyl acetate fraction showed a better anti-inflammatory ability than that of the 95% ethanol extract.

Inhibitory rates of compounds **1**−**5** on NO production decreased in a turn of chlorogenic acid ($EC_{50}$ = 4.15 μM), ursolic acid ($EC_{50}$ = 6.49 μM), ethyl caffeate ($EC_{50}$ = 7.72 μM), 4-CAME ($EC_{50}$ = 7.81 μM), and 5-CAME ($EC_{50}$ > 10 μM). Among the five isolated compounds, ursolic acid and chlorogenic acid showed strong anti-inflammatory ability on NO production in RAW 264.7 macrophages (Figure 5B). Chlorogenic acid was reported to efficiently inhibit LPS-induced pro-inflammatory responses in hepatic stellate cells, and the anti-inflammatory effect may be due to inhibition of the LPS/ROS/NF-κB signaling pathway.[32]

According to the above results, ursolic acid showed the best radical quenching capacity and a similar ferric reducing capacity as chlorogenic acid, whereas the latter showed the best anti-inflammatory activity and the worst antiproliferative effect. Thus, it can be seen that different compounds often have different biological activities. They may exert a strong effect in a certain activity, but a very weak effect in others. Chlorogenic

dx.doi.org/10.1021/jf501670v | J. Agric. Food Chem. 2014, 62, 8608−8615

acid showed a better antioxidant capacity and anti-inflammatory activity, which may be related to its structure with a lot of hydroxyl groups. However, the mechanism of antioxidant and anti-inflammatory activity in ursolic acid and chlorogenic acid should be further investigated in a future study.

In conclusion, an efficient method for bioassay-guided preparative isolation was used for identifying the antioxidant, antitumor, and anti-inflammatory constituents in *I. latifolia*. Five compounds were isolated and identified. Antioxidant, antitumor, and anti-inflammatory effects of extract, four fractions, and five isolated compounds were evaluated. The ethyl acetate fraction was found to exhibit effective antioxidant, antitumor, and anti-inflammatory activities. In the evaluation of cytotoxicity against tumor cell line, compounds 4-CAME and 5-CAME showed fine activities at high concentrations in comparison to 5-fluorouracil. In addition, chlorogenic acid showed stronger anti-inflammatory activity than the others. These results indicated that after the fractional extraction of 95% EtOH into four fractions, the active ingredients were concentrated into the ethyl acetate fraction. Compounds 4-CAME and 5-CAME are the bioactive chemical compositions isolated from *I. latifolia*, and they were isolated and identified from *I. latifolia* for the first time. The results obtained in this work might contribute to understanding the biological activity and further investigation of *I. latifolia* Thunb. for food and drug application.

# Possible Antioxidant Mechanism of Melanoidins Extract from Shanxi Aged Vinegar in Mitophagy-Dependent and Mitophagy-Independent Pathways

Lei Yang,[†,§] Xuping Wang,[†] and Xiaolan Yang*[,†]

[†]College of Life Science, Shanxi University, Taiyuan 030006, China

[§]College of Life Sciences, Nankai University, Tianjin 300073, China

**ABSTRACT:** Melanoidins are widely reported to have antioxidant activity; however, their mechanism has not been frequently studied. In this study, we found that melanoidins from Shanxi aged vinegar induced mitopahgy, the specific autophagic elimination of mitochondria, as assessed by up-regulation of the autophagy markers LC3-II and Beclin1 as well as degradation of the autophagy substrate p62 and mitochondrial proteins. Melanoidins reduced reactive oxygen species (ROS) in normal human liver cells and mouse livers through a mitophagy-dependent pathway, by the observation that the reducing ROS effect of melanoidins was partially lost when mitophagy was inhibited by chloroquine. Impaired Akt signaling was found in cells treated with melanoidins, which might explain the activation of autophagy induced by melanoidins. These results suggest that in addition to direct free radical scavenging activity, melanoidins decreased ROS levels through mitophagy in which damaged mitochondria, the source of ROS, were degraded.

**KEYWORDS:** *antioxidant, melanoidins, autophagy, mitophagy, oxidative stress, reactive oxygen species, vinegar, mouse livers*

## INTRODUCTION

Interest in the potential health effects of dietary vinegar is increasing worldwide. In China, vinegar has been traditionally produced from cereals for more than 3000 years.[1] Studies have reported antioxidative health effects of fruit vinegar,[2−4] but little is known about cereal vinegar. Shanxi aged vinegar (SAV) is a traditional Chinese cereal vinegar. Its unique fermentation and roasting processing (6 days at 85 °C) lead to the formation of high amounts of melanoidins,[5] which are high molecular weight nitrogenous, brown compounds[6] that contribute to the flavor and color of SAV. The potential health impacts of melanoidins include antioxidant, antimicrobial, anticariogenic, anti-inflammatory, antihypertensive, and antiglycative activities.[7] The in vitro antioxidant activity of melanoidins that has been evaluated includes 1,1-diphenyl-2-picrylhydrazyl (DPPH) radical-scavenging activity, reducing power, and inhibitory effects on hydroxyl radicals.[8] Protection of cells against oxidative damage by melanoidin has been reported for coffee,[9] biscuits,[10] and prunes.[11] However, because of the complexity of cells, the underlying molecular mechanisms of cellular antioxidant activity remain unclear, and a deeper exploration is needed.

Mitochondria are responsible for 90% of cellular energy. In ATP synthesis through mitochondrial oxidative phosphorylation, reactive oxygen species (ROS) are produced by electrons prematurely reacting with $O_2$, especially at respiratory chain complexes I and III.[12] Accumulating evidence demonstrates that ROS are involved in liver injuries including alcohol abuse, hepatitis C virus infection, iron overload, and chronic cholestasis.[13,14] Antioxidants have been proposed as therapies in experimental models and patients with chronic liver injury.[15,16] However, clinical studies have been controversial, with limited or no benefit reported from chronic administration of antioxidants such as vitamin A, vitamin E, or $\beta$-carotene.[17] These antioxidants not effective enough to attenuate oxidative stress-induced disorders or diseases, possibly because of an inability to target mitochondria, the primary source of ROS.[18]

Pharmacological inducers of autophagy have been described as ROS scavengers. For example, resveratrol, a natural polyphenol known to have antioxidative effects since the 1990s,[19] was believed to explain the "French paradox," in which a relatively low incidence of coronary heart disease is seen in a population with a high dietary intake of cholesterol and saturated fats.[20] However, the concentrations of resveratrol in red wine are low and cannot entirely account for this phenomenon.[21] The possible underlying mechanisms might relate to the autophagic activity of resveratrol. Duan et al. found that in addition to ROS clearance, autophagy is involved in resveratrol prevention of oxidative stress in restrained mice,[22] which might explain the antioxidant effect of resveratrol.

In this study, we found that melanoidins from SAV induced mitopahgy, the specific autophagic elimination of mitochondria, which reduced ROS in normal human liver cells and mice livers. The ability of melanoidins to reduce ROS and protect cells was lost when mitophagy was inhibited by chloroquine (CQ). Impaired Akt signaling was found in cells treated with melanoidins, which might explain the activation of autophagy induced by melanoidins. Thus, melanoidins and SAV acted as pro-autophagic compounds and could be beneficial in oxidative damage-related disease.

## MATERIALS AND METHODS

**Chemicals, Cell Lines, and Culture Conditions.** SAV was from local supermarkets. Blue dextran-2000, L-tyrosine, bovine serum albumin, chicken egg albumin, curd protease A, cytochrome *c*, 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT), dimethyl sulfoxide (DMSO), hydrogen peroxide ($H_2O_2$) CQ, 2′,7′-dichlorofluorescein diacetate (DCFH-DA), and bromobenzene (BB) were from Sigma-Aldrich (St. Louis, MO, USA). Immortalized human liver LO2 cells and HepG2 cells were cultured according to the method of Zhang et al.[23] Cells were seeded in 6- or 96-well plates and adapted to the culture substrate for 12−24 h before experiments.

**Melanoidins Isolation and Purification.** Components of SAV were prepared as in Figure 1. Briefly, 2 L of SAV was diluted with 2 L of distilled water. The resulting dispersion was filtered through Whatman filter paper 4 to remove insoluble matter. The filtrate was concentrated under vacuum using an RE-52 rotary evaporator (Yarong Experimental Instrument Co., Ltd., Shanghai, China) and freeze-dried to obtain Shanxi aged vinegar extract (SAVE), which was 21.3% of the SAV. To obtain high molecular weight material (HMW), 100 g of SAVE was dissolved in 2 L of distilled water and fractionated through ultrafiltration membranes (AMFOR, 10 kDa cutoff) with two washings with 2 L of distilled water to reduce contamination in the retentate from low molecular weight material (LMW). The resulting filtrate (MW <10 kDa, LMW, 73.6% of SAVE) and retentate (MW >10 kDa, HMW, 26.4% of SAVE) were frozen and freeze-dried.

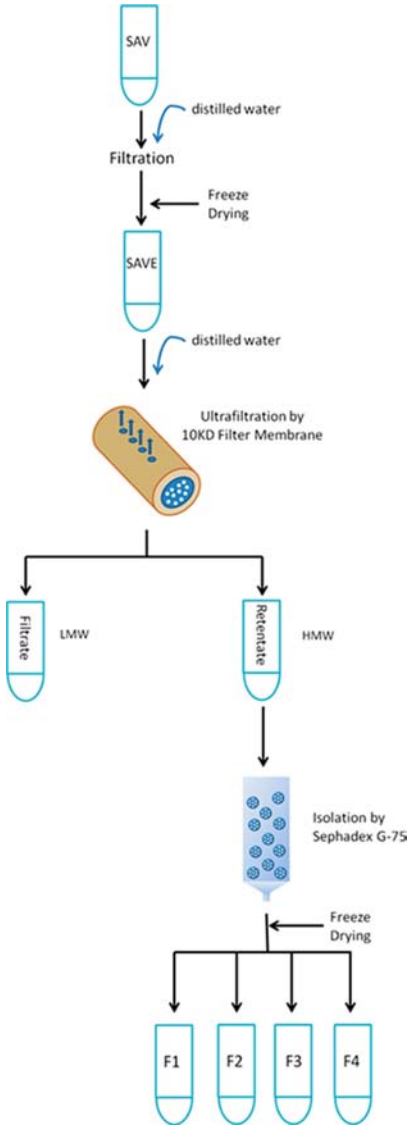

**Figure 1.** Scheme for melanoidin isolation and purification from Shanxi aged vinegar (SAV).

HMW was subjected to a second purification by size exclusion chromatography with a Sephadex G-75 column (60 × 1.6 cm). Freeze-dried HMW was dissolved to 10 mg/mL in distilled water and filtered with 0.45 μm microporous membranes to 2 mL of filtrate for chromatographic separation. The eluent was distilled water at a flow rate of 0.5 mL/min, continuously monitored by absorbance at 280 nm. Collection was 3 mL, and total sugars were determined by using the phenol−sulfuric acid method at 490 nm.[24] A color index was determined by absorbance at 420 nm. Column exclusion ($V_0$) was determined with blue dextran-2000 (20000 kDa) and total volume ($V_t$) was determined with L-tyrosine (181 Da). Fractions 1−4 (F1−F4) (F1, 6.8% of HMW; F2, 82.4% of HMW; F3, 7.2% of HMW; and F4, 3.6% of HMW) were collected, and the molecular weight was calculated by log MW − $V_e$ protein standard curves: lg MW = $-0.0288V_e + 5.9402$, $3r = 0.996$, which was calculated by four protein markers: bovine serum albumin (67 kDa), chicken egg albumin (43 kDa), curd protease A (25 kDa), and cytochrome *c* (12.4 kDa).

**DPPH Radical-Scavenging Activity Assays.** DPPH radical-scavenging activity was determined according to the method of Slusarczyk et al.[25] with slight changes. Test samples were mixed with DPPH radical solution in ethanol (1:2 v/v) and incubated at room temperature in the dark for 30 min, and absorbance was measured at 517 nm. Each test was repeated three times. DPPH radical-scavenging activity was calculated as DPPH radical scavenging (%) = $[A_0 - (A_1 - A_2)]/A_0 \times 100$, where $A_0$ is the absorbance of the DPPH solution, $A_1$ is the absorbance of the mixture of sample and DPPH solution after incubation, and $A_2$ is the absorbance of the sample.

**Total Reducing Power Assays.** Total reducing power was determined as in Zhu et al.[26] with slight changes. A test sample of 0.5 mL was mixed with 2.5 mL of phosphate buffer (0.2 mol/L, pH 6.6) and 2.5 mL of potassium ferricyanide (1%), incubated at 50 °C for 20 min, mixed with 2.5 mL of trichloroacetic acid (10%), blended, and centrifuged at 3000 rpm for 10 min. A 2.5 mL supernatant sample was mixed with 2.5 mL of distilled water and 1 mL of $FeCl_3$ (0.1%) and reacted for 10 min, and absorbance was measured at 700 nm.

**Determination of Cell Viability.** Cell viability was determined by using the MTT assay as previously described.[27] Cells were cultured in 96-well microtiter plates and exposed to $H_2O_2$ or F2 for 24 h. After treatment, 5 mg/mL MTT solution was added and incubated for 4 h at 37 °C. After a washing with PBS, purple-blue formazan was dissolved in 1 mL of DMSO, and absorbance was determined at 550 nm.

**Determination of Cellular ROS Level.** Samples were incubated with 20 μM DCFH-DA for 30 min. Intracellular ROS-mediated oxidation of DCFH-DA to the fluorescent compound DCF was measured.[28] Cells were harvested, and pellets were suspended in 1 mL of PBS and analyzed by flow cytometer (Becton Dickinson, Franklin Lakes, NJ, USA) with excitation of 488 nm and emission of 535.

**Western Blotting.** Cells were washed with ice-cold PBS, harvested, and lysed for 1 h in ice-cold lysis buffer (1% NP40, 0.5% sodium deoxycholate, 0.1% SDS, 1 mM EDTA, 1 mM EGTA, 1 mM $Na_3VO_4$, 20 mM NaF, 0.5 mM DTT, 1 mM PMSF, protease inhibitor cocktail in PBS, pH 7.4). After centrifugation at 4 °C (12000*g*, 10 min), supernatants were collected and solubilized in 6× loading buffer (0.5 M Tris-HCl, pH 6.8, 30% glycerol, 10% SDS, 5% β-mercaptoethanol, 0.012% bromophenol blue). Lysates were separated by 10 or 15% SDS-PAGE and transferred to PVDF membranes (Millipore, Billerica, MA, USA). Proteins were detected with antibodies and HRP-conjugated secondary antibodies. ECL Western Blotting Substrate (Thermo Fisher Scientific) was the HRP substrate. Antibodies were against β-actin (Sigma), beclin1, p62, LC3, tom20, tim23, cytochrome *c* (BD), phosphor-Akt ($Ser^{47}$), pan-Akt, and the C subunit of protein phosphatase 2A (PP2A-C) (Cell Signaling Technology).

**Animals and Treatment.** Hepatotoxicity assays were performed with 48 male Kunming mice from Shanxi Medical University Animal Research Center. Mice were housed in a temperature- and humidity-

dx.doi.org/10.1021/jf501690e | J. Agric. Food Chem. 2014, 62, 8616−8622

controlled room with a 12 h light−dark cycle and free access to a standard pellet diet and water. All animal protocols were approved by the Animal Care Committee of Shanxi University. After 1 week of adaptation, mice were randomly divided into six groups of eight mice per group: control, BB, low-dose SAVE (ig 500 mg/kg SAVE + BB), medium-dose SAVE (ig 1000 mg/kg SAVE + BB), high-dose SAVE (ig 2000 mg/kg SAVE + BB), and CQ+SAVE (ip 60 mg/kg CQ + ig 1000 mg/kg SAVE + BB). Mice were administered compounds or distilled water for 30 days and challenged ig with BB dispersed in 0.2 mL of plant oil at 0.47 mg $kg^{-1}$ body weight, followed by an 18−22 h recovery stage before determination of liver biochemical parameters. All biochemical parameters, thiobarbituric acid reactive substances (TBARS), superoxide dismutase (SOD), and glutathione peroxidase (GSH-Px) were measured as previously reported.[29]

**Statistical Analysis.** All data were expressed as the mean ± standard deviation (SD) and analyzed using SPSS statistical software (SPSS Inc., Chicago, IL, USA). One-way ANOVA with Duncan's test was used for intergroup comparison. $P$ values of <0.05 were considered statistically significant.

## RESULTS

**SAV Contains Melanoidin Complexes.** HMW separated from aqueous extracts of food by ultrafiltration as melanoidins have been explored for biological activity without purification to remove non-melanoidin material.[30,31] In our study, we obtained purified melanoidins and screened for highly antioxidative substances by obtaining HMW (26.4% of SAVE) by ultrafiltration and subjecting HMW to a second purification by size exclusion chromatography. Most HMW was under 80 kDa, and a small part was eluted at the $V_0$ of the column (Figure 2A). The four fractions had molecular weights of F1, >80 kDa; F2, 80−10 kDa; F3, 10−3 kDa; and F4, <3 kDa. F3 and F4 were probably LMW contaminants in the HMW that should not pass though a 10 kDa ultrafiltration membrane. Another possibility is that the LMW material present in the HMW isolated by ultrafiltration can be loosely linked to the HMW by hydrogen bonds or other noncovalent interactions that are released during the size exclusion chromatography method. Melanoidins are defined as brown HMW that are a final product of a Maillard reaction between reducing sugars and compounds with a free amino group.[6] Therefore, an index of total sugar (measured at 490 nm), protein (measured at 280 nm), and brown color (measured at 420 nm) was determined. Results showed that total sugar and protein elution profiles almost perfectly matched the brown color elution profile of F1, F2, and F3, which fit the compositional characteristics of melanoidins. These results demonstrated that we obtained purified melanoidins. F4 appeared to contain free proteins that did not participate in the Maillard reaction.

**In Vitro Antioxidative Activity of SAVE.** We evaluated the in vitro antioxidant activity of SAVE by DPPH radical-scavenging activity assays and total reducing power assays. At 0.05−2.5 mg/mL, SAVE had dose-dependent DPPH radical-scavenging activity with an $IC_{50}$ of 0.49 mg/mL (Figure 2B). SAVE had a dose-dependent total reducing power at 0.5−4.5 mg/mL with an $EC_{50}$ of 4.29 mg/mL (Figure 2C).

**SAVE F2 Is Responsible for Its in Vitro Antioxidative Activity.** To determine if the main antioxidative component in SAVE was melanoidins, we further separated HMW from SAVE. HMW had higher DPPH radical-scavenging activity and total reducing power than LMW and SAVE at the same concentration (Figure 2D,E). To avoid interference from non-melanoidins in the soluble HWM, such as unreacted proteins and carbohydrates, HMW was purified by size exclusion chromatography. Four fractions were collected (F1−F4), and in

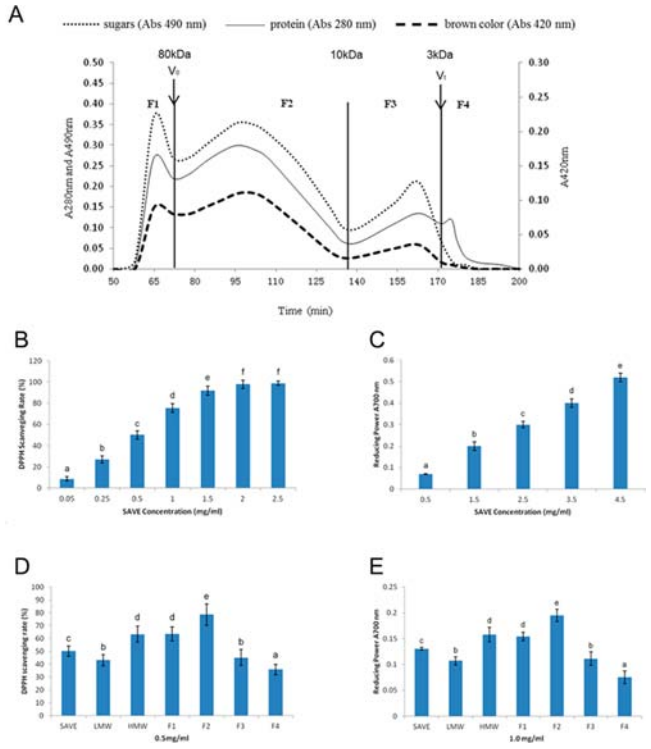

**Figure 2.** Fraction 2 (F2) in Shanxi aged vinegar extracts (SAVE) is responsible for in vitro antioxidative activity. (A) High molecular weight material (HMW) was subjected to a second purification by size exclusion chromatography. Panels B and C show DPPH radical-scavenging activity and total reducing power of SAVE. Panels D and E show DPPH radical-scavenging activity and total reducing power of different SAVE molecular weight fractions. Values are means ± SD, $n$ = 3. Different letters above columns indicate significant differences ($P$ < 0.05).

vitro antioxidative activity showed that F2 had the highest DPPH radical-scavenging activity and total reducing power (Figure 2D,E). The greatest amount of all fractions obtained by size exclusion chromatography was F2 (Figure 2A). These results indicated that F2 had further purified melanoidins responsible for the antioxidative activity of SAVE in vitro. We used F2 to evaluate antioxidative effects in cells.

**F2 Had No Toxicity to Human LO2 Normal Liver Cells.** For food safety and potential clinical use, F2 needed to be tested for toxic effects. Cell survival and redox status were determined for cells treated for 24 h with different concentrations of F2. At 50−1000 μg/mL, F2 did not influence LO2 growth (Figure 3A). Consistent with the MTT results, flow cytometer assays that analyzed the fluorescence intensity of intracellular ROS labeled by DCFH-DA showed that F2 did not influence intracellular basal ROS levels (Figure 3B,C). These results indicated that F2 had no toxicity at the selected concentrations and could safely be studied for potential protective effects.

**F2 Inhibited Cellular ROS Production Induced by $H_2O_2$.** We first established the concentration of $H_2O_2$ needed to increase ROS generation in LO2 cells. Cell survival was tested by an MTT method following treatment with 50−450 μM $H_2O_2$ for 24 h. $H_2O_2$ significantly decreased cell survival to about 60% at 50 μM (Figure 3D), suggesting abundant ROS generation. Cells treated with 250 μg/mL F2 were rescued from 50 and 150 μM $H_2O_2$-induced damage, indicating that F2 attenuated the state of oxidative stress in cells. To quantify the

dx.doi.org/10.1021/jf501690e | J. Agric. Food Chem. 2014, 62, 8616−8622

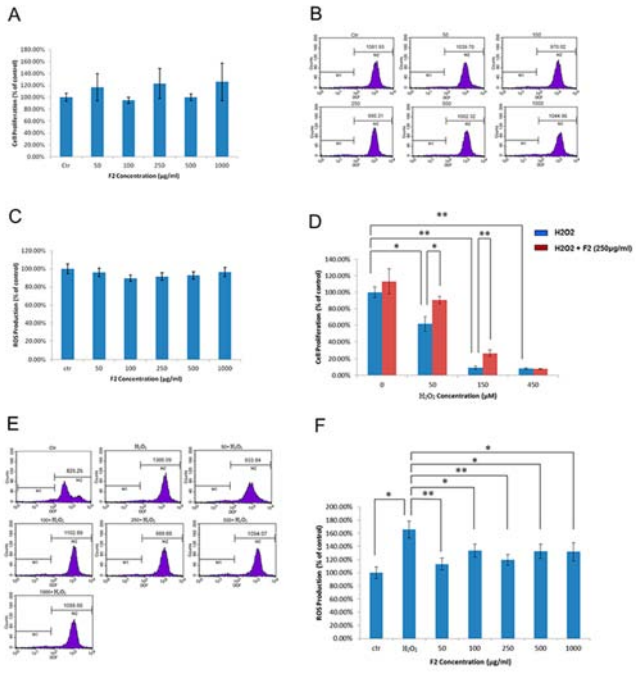

**Figure 3.** F2 attenuated reactive oxygen species (ROS) production in LO2 cells. (A) F2 did not affect cell proliferation measured by MTT test. (B, C) F2 did not affect intracellular basal redox status measured by flow cytometry for fluorescence intensity of intracellular ROS labeled with DCFH-DA. LO2 cells were treated with F2 at 50−1000 $\mu$g/mL for 24 h. (D) Cells treated with 250 $\mu$g/mL F2 rescued 50 and 150 $\mu$M $H_2O_2$ damage. (E, F) F2 non-dose-dependently inhibited cellular ROS production by $H_2O_2$. Values are means ± SD of three experiments. (*) $P < 0.05$; (**) $P < 0.01$.

protective effect of F2, 50 $\mu$M $H_2O_2$ for 24 h was chosen. Compared to the control group, increased ROS generation in the $H_2O_2$-treated group was mitigated by the addition of F2 at different concentrations (Figure 3E,F). The ROS-reducing effect of F2 was not dose-dependent, indicating that in addition to direct free radical-scavenging ability, F2 used another mechanism to attenuate ROS production.

**F2 Triggered Mitophagy in LO2 Cells.** Mitochondria are a major source of ROS, so mitophagy might be a mechanism to eliminate ROS. We hypothesized that the ROS-reducing effect of F2 in cells depended on mitophagy. To estimate the promotion of mitophagy by F2 in LO2 cells, expression of autophagy-related and mitochondrial proteins was determined by Western blots (Figure 4A). F2 at 250 $\mu$g/mL induced autophagy by increasing an endogenous, membrane-associated, phosphatidylethanolamine-conjugated form of LC3 (LC3-II). Beclin1, a mammalian protein that mediates autophagy,[32] was also up-regulated. The autophagy substrate p62, a polyubiquitin-binding protein that is degraded by autophagy and functions as an adaptor protein for selective types of macroautophagy such as mitophagy,[33] was degraded by F2 treatment. To monitor the last step of mitochondrial degradation, three mitochondrial proteins were analyzed to represent mitochondrial mass. The proteins were tom20 (an outer mitochondrial membrane protein), tim23 (an inner mitochondrial membrane protein), and cytochrome *c* (a mitochondrial intermembrane space protein). All three mitochondrial proteins were degraded. Taken together, the results showed that F2 could induce mitophagy.

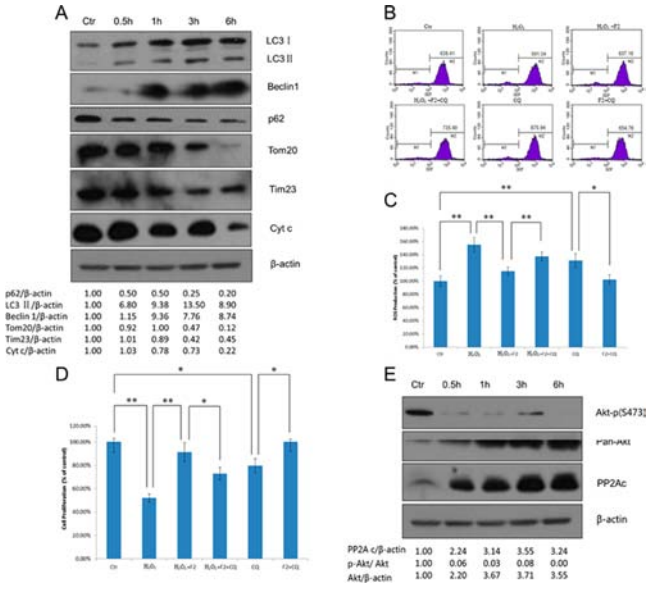

**Figure 4.** Mechanism of F2 antioxidant effect in mitophagy-dependent and mitophagy-independent pathways. (A) At 250 $\mu$g/mL, F2 triggered mitophagy in LO2 cells. (B, C) ROS-reducing effect of F2 was partly prevented by the autophagy inhibitor chloroquine (CQ). (D) MTT results were consistent with flow cytometry: protection by F2 against $H_2O_2$ was inhibited by CQ. (E) F2 activated autophagy through PP2A/Akt signaling. $\beta$-Actin was the loading control. Values are means ± SD of three experiments. (*) $P < 0.05$; (**)$P < 0.01$.

**F2 Used a Different Pathway to Lower ROS Production in Cells.** To determine if mitophagy might be partly involved in the effect of F2 on reducing oxidative stress, we inhibited autophagy by co-incubating cells with the lysosomal inhibitor CQ. Flow cytometry showed that the ROS-reducing effects of F2 were partly prevented by CQ (Figure 4B,C) and cell survival decreased (Figure 4D). We also found that the ROS promotion effect of CQ was blocked by F2, which supported F2 having an ROS-reducing effect that contributed to mitophagy and direct free radical-scavenging activity. These results indicated that F2 had two ways to lower ROS production in cells: (1) mitophagy to degrade damaged mitochondria that are the source of ROS and (2) direct free radical scavenging.

**F2 Activated the PP2A-AKT Signaling Pathway To Induce Autophagy.** Melanoidins impair the Akt signaling pathway,[34] which positively regulates autophagy, suggesting Akt might be the target in an upstream signaling pathway induced by F2. Therefore, we explored changes in the phosphorylation of Akt kinase in LO2 cells. Western blots showed that F2 at 250 $\mu$g/mL markedly reduced Akt phosphorylation at $Ser^{473}$ (Figure 4E), indicating that Akt kinase activity decreased. We also investigated the Akt negative regulator PP2A. After treatment with F2, expression of PP2A-C increased, suggesting that PP2A activity was increased by F2.

**Protective Effect of SAVE on BB-Induced Hepatotoxicity.** To determine if the in vitro biological activities attributed to melanoidins in SAVE were observed in vivo, we tested the antioxidative activity of SAVE in a BB-induced mouse hepatotoxicity model. No differences in body weight or food intake were observed among the six experimental groups (data not shown). Compared with the control group, the BB group showed significantly increased liver TBARS levels and significantly decreased SOD and GSH-Px activities (Table 1),

dx.doi.org/10.1021/jf501690e | J. Agric. Food Chem. 2014, 62, 8616−8622

**Table 1. Protective Effect of SAVE on BB-Induced Hepatotoxicity in Mice[a]**

| group | Ctr | BB | low SAVE | medium SAVE | high SAVE | medium SAVE + CQ |
|---|---|---|---|---|---|---|
| TBARS (nmol/mg protein) | 5.78 ± 0.55 | 9.11 ± 0.98** | 8.51 ± 0.86 | 6.71 ± 0.63## | 5.33 ± 0.59## | 8.09 ± 0.88△ |
| SOD (U/mg protein) | 634.70 ± 47.50 | 427.50 ± 47.30** | 462.60 ± 69.50 | 593.10 ± 66.90## | 680.80 ± 76.20## | 495.85 ± 75.10△ |
| GSH-Px (U/mg protein) | 425.10 ± 33.30 | 328.80 ± 34.20** | 353.30 ± 43.70 | 467.30 ± 35.20## | 488.60 ± 54.70## | 387.53 ± 48.20△ |

[a]Values are means ± SD ($n$ = 8): (**) $P < 0.01$ vs Ctr group; (##) $P < 0.01$ vs BB group; (△) $P < 0.05$ vs medium SAVE group. Ctr, control; BB, bromobenzene; SAVE, Shanxi aged vinegar extracts; CQ, chloroquine; TBARS, thiobarbituric acid reactive substances; SOD, superoxide dismutase; GSH-Px, glutathione peroxidase.

indicating that the construction of a BB-damaged mouse model was successful. Compared with the BB group, groups receiving medium or high doses of SAVE showed significantly decreased liver TBARS levels and significantly increased liver SOD and GSH-Px activities. The medium dose of SAVE was chosen to test whether the antioxidative activity of SAVE was dependent on mitophagy. The hepatic protective effect of SAVE was partially inhibited by CQ, consistent with results obtained with LO2 cells.

## DISCUSSION

In this study, we evaluated the in vitro antioxidative activity of SAVE and SAVE fractions with melanoidins of different molecular weights. DPPH radical-scavenging activity assays and total reducing power assays showed that SAVE had antioxidant activity in vitro and that the HMW fraction had higher antioxidant activity than the LMW fraction. This result was consistent with other studies. Borrelli et al. found that low molecular mass melanoidin fractions from bread and biscuits showed low antioxidant activity.[30] Morales et al. found that high molecular mass fractions (>10 kDa) were more effective as antioxidants than other fractions because of the direct scavenging activity against radicals and a stronger metal-chelating capability.[31] However, larger molecular weight melanoidins do not necessarily have stronger antioxidative ability. Our purification to produce HMW showed that F2 (10−80 kDa) had higher DPPH radical-scavenging activity and total reducing power than F1 (>80 kDa). Although the mechanism remains unclear, this result might be related to differences in the composition of melanoidins in fractions with different molecular weights, with different melanoidin populations exhibiting antioxidative capacities through different mechanisms.[7] We observed that the antioxidative ability of melanoidins of different molecular weights correlated with their polyphenol content (data not shown). Further study of melanoidin structures will improve the understanding of their antioxidant properties.

To evaluate the ROS-reducing effect of F2 in cells, we used $H_2O_2$ to activate mitochondrial oxidative stress. $H_2O_2$, a specific ROS, was sufficient and essential for inducing oxidative stress. $H_2O_2$ interacts with metal ions such as $Fe^{2+}$, forming metal-centered oxygen radicals and hydroxyl radicals ($OH^{\bullet}$) that are highly reactive and oxidatively damage mitochondria.[35] Mitochondria are the major site of ROS production and the major target of their detrimental effects.[36] We found a significantly increased ROS level in $H_2O_2$-treated groups, indicating that mitochondria were damaged and produced excessive ROS. Consistent with these studies, we observed a decrease in cell survival rates in $H_2O_2$-treated groups. Treatment with F2 reduced ROS levels and improved cell survival, indicating that F2 had protective effects on LO2 cells.

Autophagy can be nonselective or selective. Nonselective autophagy is an evolutionarily conserved mechanism in which intracellular proteins or organelles are degraded in lysosomes during nutrient deprivation, providing cells with recycled cellular components and energy from degraded components. Conversely, even under nutrient-rich conditions selective autophagy occurs, which specifically removes protein aggregates and damaged organelles, for example, in mitophagy, which targets permeabilized mitochondria.[37] Autophagy is vital for organisms. Autophagic ability decreases in older organisms,[38] which might lead to age-related diseases such as neurodegeneration and cancer. In this study, we hypothesized that the ROS-reducing effect of F2 depended on autophagic stimulation to remove oxidized mitochondria. We tested this hypothesis using Western blots to check if F2 selectively removed mitochondria. Removal of damaged mitochondria through autophagy requires two steps: (1) activation of general autophagy and (2) priming of mitochondria for selective autophagic recognition. First, we determined if F2 altered the expression autophagy markers in LO2 cells. The conversion of atg8/LC3 (LC3) from the soluble form (LC3-I) to the autophagosome-associated form (LC3-II) implies an increase of autophagosomes within cells.[39] F2 significantly up-regulated LC3-II expression. Beclin 1 (Vps30/Atg6), a mammalian protein that mediates autophagy,[32] was also up-regulated. We also determined the expression of p62/SQSTM1, an adaptor that, through direct interaction with LC3, recruits autophagosomal membranes to the mitochondria.[40] P62 was degraded, indicating that F2 induced mitophagy. Analysis of mitochondrial mass showed degradation of the outer mitochondrial membrane protein tom20. Recent studies suggest that most outer mitochondrial membrane proteins are preferentially degraded by the ubiquitin proteasome system, whereas matrix proteins are degraded through autophagy, although the exact mechanisms and reasons for the different degraded mechanisms are not clear.[41] Hence, we also analyzed proteins from all mitochondrial compartment proteins: outer mitochondrial protein tom20, inner mitochondrial protein tim23, and intermembrane-space protein cytochrome *c*. All three mitochondrial proteins were significantly degraded, demonstrating that F2 induced mitophagy.

Enhancement of mitophagy or autophagy might be a way for cells to reduce oxidative stress. In normal conditions, mitochondria and the cytoplasm have detoxifying enzymes and nonenzymatic antioxidant systems that prevent oxidative damage.[42] However, under stress or pathological conditions, damaged mitochondria produce excess ROS that overcome cellular defenses and oxidatively modify cellular components. Therefore, enhancement of autophagic ability with an autophagy inducer might maintain mitochondrial quality by eliminating damaged mitochondria and preventing oxidative damage. Dutta et al. showed that activation of autophagy by rapamycin protects cardiomyocytes from oxidative stress-induced toxicity.[43] Kurihara et al. demonstrated that mitophagy contributes to mitochondrial quantity and quality control in

yeast by eliminating mitochondria to a basal level and preventing excess ROS production.[44] Han et al. reported that curcumin protects human endothelial cells from oxidative damage via autophagy.[45] Our results also support these findings. We observed that activation of autophagy by F2 protected cells from oxidative stress and decreased cell survival and that CQ treatment blocked this protective effect.

Akt kinase (protein kinase B) is a serine/threonine protein kinase that negatively regulates autophagy.[46] Because melanoidins impair the Akt signaling pathway[34] and down-regulation of phospho-Akt (P-Akt) activates autophagy, we hypothesized that autophagic activity by F2 might be because of Akt kinase inhibition. F2 decreased the Akt protein kinase activity by impaired Akt phosphorylation at serine 473. Akt phosphorylation is determined by a balance between kinases and phosphatases.[47] Therefore, we investigated F2 effects on PP2A and P-Akt. PP2A is in a family of serine/threonine phosphatases that down-regulate Akt phosphorylation. Increasing evidence shows that PP2A is important in autophagy promotion.[48] PP2A contains a highly active core dimer of a catalytic C subunit (PP2A-C) and a structural A subunit (PP2A-A) that recruits one of several regulatory B subunits (PP2A-B) to form a PP2A heterotrimeric complex.[49,50] F2 treatment notably up-regulated PP2A-C expression, indicating that F2 increased PP2A activity. These results indicated that F2 might have activated autophagy through the PP2A/Akt signaling pathway.

Autophagy is protective against liver injury.[51−53] We did not obtain enough F2 for animal tests, so we used SAVE. We imitated pathological hepatic conditions using a BB-induced liver injury model to evaluate the antioxidative activities of SAVE. We previously demonstrated that BB is a strong oxidant that causes hepatic lipid peroxidation.[29] Liver oxidative damage was evaluated by lipid peroxidation production of TBARS and two antioxidant enzymes, SOD and GSH-px. The hepatic protective effect of SAVE was partially inhibited by CQ (Table 1). Similar to our results in LO2 cells, which showed that F2 had mitophagy-dependent pathways to lower ROS production (Figure 4B−D), the in vivo experiment also showed that SAVE had mitophagy-dependent pathways to lower liver oxidative damage, which suggested that F2 might contribute to the protective effect of SAVE in vivo, through mitophagy-dependent pathways. Taken together, these results suggested that F2-mediated autophagy might be important for preventing liver injury in vivo.

We demonstrated that mitophagy was involved in the ability of melanoidins extracted from SAV to protect the liver from oxidative stress in vitro and in vivo. Melanoidins might activate autophagy through the PP2A/Akt signaling pathway. This study provides novel insights into the cellular mechanisms of the antioxidative effect of melanoidins and potential future therapeutic strategies.

Food Science and Human Nutrition Department, Institute of Food and Agricultural Sciences, University of Florida, Gainesville, Florida 32611, United States

**ABSTRACT:** Honeys contain phenolic compounds and α-dicarbonyls with antioxidant and antimicrobial capacities, respectively. The type and concentration of these compounds vary depending on the floral source and geographical location where the honey is produced. Seventeen varietal honeys, including 12 monofloral and 5 multifloral honeys, were sampled from different regions of Florida. The monofloral honeys included those from citrus, tupelo, palmetto, and gallberry. These honeys were evaluated for their antioxidant capacity, total phenolic content, and free radical scavenging capacity and compared with three New Zealand Manuka honeys. Phenolic phytochemicals and α-dicarbonyls were identified and quantified using HPLC-DAD-MS$^n$. Several honey varieties from gallberry, Manuka, and multifloral displayed a total phenolic content >1000 μg GAE/g. A citrus honey had the lowest total phenolic content of 286 μg GAE/g. The oxygen radical absorbance capacity of the honeys ranged from 1.48 to 18.2 μmol TE/g. All honeys contained 3-deoxyglucosone at a higher concentration than methylglyoxal or glyoxal. Manuka honeys had higher concentrations of methylglyoxal than other varieties. Plant hormones 2-*cis*,4-*trans*-abscisic acid and 2-*trans*,4-*trans*-abscisic acid were the most abundant phytochemicals in all honeys. Coumaric acid, rutin, chrysin, pinocembrin, quercetin, luteolin, and kaempferol were also found in samples but at lower concentrations.

**KEYWORDS:** *honey, Manuka, carbonyls, methylglyoxal, phytochemicals*

## INTRODUCTION

Honey is a natural product produced by bees from the nectar of various plants. The composition of honey is known to vary depending on the season, geographical location, and floral source. Honey is mostly composed of fructose and glucose, but it has also been shown to contain phenolic phytochemicals. These compounds are mostly phenolic acid derivatives and flavonoid aglycones, although some flavonoid glycosides have also been identified.[1,2] Flavonoids are ubiquitous in plants, and they possess antioxidant, radical scavenging, antimuntagenic, anti-inflammatory, and anticarcinogenic functions.[3] Phenolic compounds, specifically flavonoids, are known to contribute to the sensory characteristics of honey, such as color, flavor, and taste as well as potential health-promoting properties. The composition of these compounds was proposed as a quicker and easier way than pollen analysis to determine the floral source of honeys.[1,4−8]

Honeys have also been shown to contain α-dicarbonyls including glyoxal, methylglyoxal, and 3-deoxyglucosone. These compounds react with proteins to produce advanced glycation end products (AGEs) through the Maillard reaction.[9,10] Manuka honey from New Zealand and Australia have well-documented antimicrobial properties.[11−13] The high concentration of methylglyoxal in Manuka honeys is considered the major factor contributing to their high antimicrobial capacity.[11,12,14] Manuka honeys are classified and sold according to their methylglyoxal concentration or "Unique Manuka Factor"; the larger the Unique Manuka Factor value, the higher the antimicrobial capacity. In addition to α-dicarbonyls, some phenolic compounds such as kaempferol, quercetin, and myricetin also possess antimicrobial properties.[13,15]

There are several studies on the phenolic composition of honey from Europe, New Zealand, and Asia, but little exists on the phenolic and α-dicarbonyl composition of North American honey.[16−18] The present work aims to identify and quantify the phenolic compounds from various Florida honeys while determining their antioxidant capacities. Furthermore, the identification and quantification of the main α-dicarbonyls in honey were also performed.

## MATERIALS AND METHODS

**Chemicals.** 2,2′-Azobis(2-amidinopropane) (AAPH) was a product of Wako Chemicals Inc. (Bellwood, RI, USA). Trolox (6-hydroxy-2,5,7,8-tetramethylchroman-2-carboxylic acid), 2,2-diphenyl-1-picrylhydrazyl (DPPH), glyoxal (40% aqueous solution), pinocembrin, ellagic acid, luteolin, apigenin, morin, and galangin were purchased from Sigma-Aldrich (St. Louis, MO, USA). The 3-deoxyglucosone standard was a product of Toronto Research Chemicals Inc. (Toronto, Canada). Folin−Ciocalteu reagent, HPLC grade methanol, formic acid, acetic acid, 2-*cis*,4-*trans*-abscisic acid, coumaric acid, chlorogenic acid, syringic acid, naringenin, hesperetin, rutin, quercetin, chrysin, and kaempferol were purchased from Fisher Scientific (Pittsburgh, PA, USA). The $C_{18}$ (3 mL) solid phase extraction cartridges were from Dionex (Sunnyvale, CA, USA). Methylgloxal (40% aqueous solution) was purchased from MP Biomedicals, LLC (Solon, OH, USA).

**Samples.** A total of 20 honey samples, 15 monofloral and 5 multifloral honeys, were collected from Florida apiarists. The monofloral honeys included those from citrus, tupelo, palmetto, gallberry, and Manuka honeys. Their harvesting regions are listed in Table 1. Three Manuka honeys with certified antimicrobial capacity indices of 12+, 15+, and 16+ were purchased from New Zealand. A lower index number corresponds to a lower capacity, whereas a higher number corresponds to stronger antimicrobial capacity based on the Unique Manuka Factor index. The honeys were stored in darkness at 4 °C prior to analysis. On the day of analysis honeys were removed from refrigeration, and samples were run under warmed water to help create a homogeneous liquid sample.

**Table 1. Floral Sources and Harvesting Region of Honeys[a]**

| sample | floral type | region of Florida (FL, USA) and season |
|---|---|---|
| 1a | citrus | central, West Bradenton, FL, spring 2011 |

[a]Due to the year-round blooming of *Leptospermum scoparium*, the harvesting time for commercial Manuka honey was unknown. North region is defined above 29.28° N, the central region from 29.21° to 27.08° N, and the south region below 26.95° N.

**Total Phenolic and Antioxidant Capacity Assay.** Total phenolic content was determined using the Folin−Ciocalteu assay.[19,20] Contents were expressed as microgram gallic acid equivalents per gram of honey (μg GAE/g). The DPPH scavenging activities of honeys were measured according to a published method.[21] DPPH scavenging activities were expressed as micromole Trolox equivalents per gram of honey (μmol TE/g). Oxygen radical absorbance capacity (ORAC) values for each honey were determined using a modified method from Huang et al.[22] Samples (1 g) were diluted with 10 mL of the phosphate buffer solution and then brought to a final dilution of 1:300. No acetone/water extraction solution was used. Antioxidant capacities were expressed as micromole Trolox equivalents per gram of honey (μmol TE/g).

**Color Assay.** The color of honeys was determined using a published method on a SPECTRAmax 190 microplate reader (Molecular Devices, Sunnyvale, CA, USA).[23] Honey was diluted 50% (w/v) with warm water. The solutions were sonicated for 5 min and filtered through 0.45 μm filter units to remove large particles. The absorbance was measured at 450 nm using 720 nm as a reference wavelength to determine the color of honeys. Color was expressed as absorbance units (AU) at the 450 nm wavelength.

**Derivatization and HPLC Analysis of α-Dicarbonyls.** α-Dicarbonyls were analyzed as their corresponding quinoxalines after derivatization with *o*-phenylenediamine following the method from Mavric et al.[12] One milliliter of 15% (w/v) honeys in phosphate buffer (0.5 M, 6.5 pH) was mixed with 0.6 mL of 1% (w/v) *o*-phenylenediamine in phosphate buffer. The honey solutions were kept in darkness at room temperature for at least 12 h for the reaction to complete. After derivatiztion, solutions were filtered through a membrane (0.45 μm), and 20 μL was injected for HPLC analysis.

An Agilent 1200 HPLC system consisting of an autosampler, a binary pump, and a diode array detector (Agilent Technologies, Palo Alto, CA, USA) were interfaced to a HCT ion trap mass spectrometer (Bruker Daltonics, Billerica, MA, USA). A Zorbax SB-C18 column (250 mm × 4.6 mm, 5 μm particle size, Agilent Technologies) was used for the separation. Column temperature was set at 30 °C. The binary mobile phase consisted of (A) methanol/acetic acid (99.85:0.15 v/v) and (B) methanol/acetic acid (99.97:0.03 v/v). The 49 min gradient is described as follows: 0−2 min, 20% B isocratic; 2−22 min, 20−40% B linear; 22−37 min, 40−100% B linear; 37−42 min, 100% B isocratic; 42−49 min, 100−20% B linear, at a flow rate of 0.8 mL/min followed, by 5 min of re-equilibration of the column before the next sample run.[12] The detection wavelength was 312 nm. The estimated limits of detection for glyoxal, methylglyoxal, and deoxyglucosone were 0.083, 0.063, and 0.130 μg/mL, respectively. Electrospray ionization in positive mode was performed using nebulizer, 50 psi; drying gas, 10 L/min; drying temperature, 290 °C; and capillary, 4000 V. The full scan mass spectra of the quinoxalines were recorded in a range of $m/z$ 100−3000. Auto $MS^2$ was conducted with 80% compound stability and 80% trap drive level. Pure compounds of methylglyoxal, glyoxal, and 3-deoxyglucosone were used as external standards to quantify the quinoxalines formed after derivatization. The concentration ranges of external standard for 3-deoxglucosone, glyoxal, and methylglyoxal were 3−520, 0.1−60, and 0.1−250 mg/L, respectively. The α-dicarbonyls were identified on the basis of full scan and product ion mass spectra and UV−vis spectra on a diode array detector and compared to authentic standards.[10,12,24]

**HPLC Analyses of Phenolic Phytochemicals.** The procedure for the extraction of phenolic phytochemicals from honeys was adapted from that of Hadjmohammadi et al.[25] Honey (10 g) was mixed with 40 mL of deionized water. The solution was filtered to remove any solid residue. The SPE C18 cartridges (0.5 g packing) were preconditioned with 6 mL of methanol followed by 3 mL of deionized water. The honey solutions were loaded on the individual cartridges and rinsed with 15 mL of water followed by 3 mL of 10% (v/v) methanol to remove potential sugars. The phenolic fractions were recovered by eluting the cartridge with 6 mL of methanol. The eluent was dried in a SpeedVac concentrator (Thermo scientific ISS110, Waltham, MA, USA) overnight at room temperature. The dried extracts were then dissolved in 500 μL of methanol, sonicated for 10 min, and centrifuged at 17000*g* for 5 min. Twenty microliters of the supernatant was injected for analysis on HPLC.

A Zorbax SB-C18 column (250 mm × 4.6 mm, 5 μm particle size, Agilent Technologies) was used for the separation. The binary mobile phase consisted of (A) water/formic acid (99.5:0.5, v/v) and (B) methanol at a constant flow rate of 0.8 mL. A 60 min gradient was adapted from a published paper.[7,26] The gradient is described as follows: 0−5 min, 5% B isocratic; 5−20 min, 5−30% B linear; 20−32 min, 30−35% B linear; 32−45 min, 35−50% B linear; 45−50 min, 50−80% B linear; 50−60 min, 80−5% B linear, followed by 5 min of re-equilibration of the column before the next injection. The detection wavelengths were set at 290 and 340 nm, because a majority of the phenolics' UV absorption maxima are at these wavelengths.[5,27−29] Electrospray ionization in negative mode was performed using nebulizer, 50 psi; drying gas, 11 L/min; drying temperature, 350 °C; and capillary, 4000 V. The full scan mass spectra of the phytochemicals were recorded from $m/z$ 100 to 1000. Auto $MS^2$ was conducted with 80% compound stability and 50% trap drive level. Galangin, pinocembrin, quercetin, 2-*cis*,4-*trans*-abscisic acid, luteolin, rutin, coumaric acid, chrysin, and kaempferol were used as external standards to quantify flavonoids and phenolic acids that were identified from mass analysis. Phenolic phytochemicals were identified using a combination of full scan and product ion mass spectra, UV−vis spectra on diode array detector with comparison to authentic standards, and comparison with published papers.[3]

[a]Results are the mean ± SD of three determinations on a fresh weight basis. ORAC values are the mean of two determinations. Values in each column are grouped into four quartiles (a > 75th, b = 50th−75th, c = 25th−50th, and d < 25th percentile).

**Statistical Analysis.** Data was expressed as the mean ± standard deviation of three independent observations per each honey sample unless otherwise stated. Total phenolic content, antioxidant capacities, and color of honeys were grouped into four quartiles. The lowest and highest values were in quartiles 1st−25th and 75th−100th, respectively. Pearson correlation for the different comparable assays was determined using SigmaPlot software (version 12, Systat software Inc., Chicago, IL, USA).

## RESULTS AND DISCUSSION

**Total Phenolic Content, Antioxidant Capacity, and Color Analysis of Honeys.** Table 2 shows the total phenolic content, antioxidant capacity, and color analysis results of the 20 honeys analyzed, including the 3 New Zealand Manuka honeys. The total phenolic content in the monofloral and multifloral honeys ranged from 286 to 1080 μg GAE/g on a fresh weight basis. This range of values was in agreement with previously published values of honeys from other regions of the world.[3,17,23,30,31] Manuka honeys had the highest total phenolic content (averaging 961 μg GAE/g) among all of the honeys. This value is similar to those reported in honeydew honeys (1150 μg GAE/g) from Burkina Faso.[31] The highest total phenolic content in the multifloral honeys was 1040 μg GAE/g in sample 6b. This honey was collected from southern Florida during the fall season. There was no apparent correlation between total phenolic content and harvesting time or location for the multifloral honeys. This may be due to the fact that Florida's subtropical climate allows for the same plants to be grown in multiple seasons and multiple areas of the state. A previous study from Cuba and Portugal showed that the highest total phenolic content for honeys produced in these countries was 700 μg GAE/g.[32,33] These contents were comparable to Florida monofloral honeys of tupelo and palmetto, which had average total phenolic contents of 761 and 716 μg GAE/g, respectively. The multifloral varieties had a higher average total phenolic content of 819 μg GAE/g than most of the monofloral varieties examined.

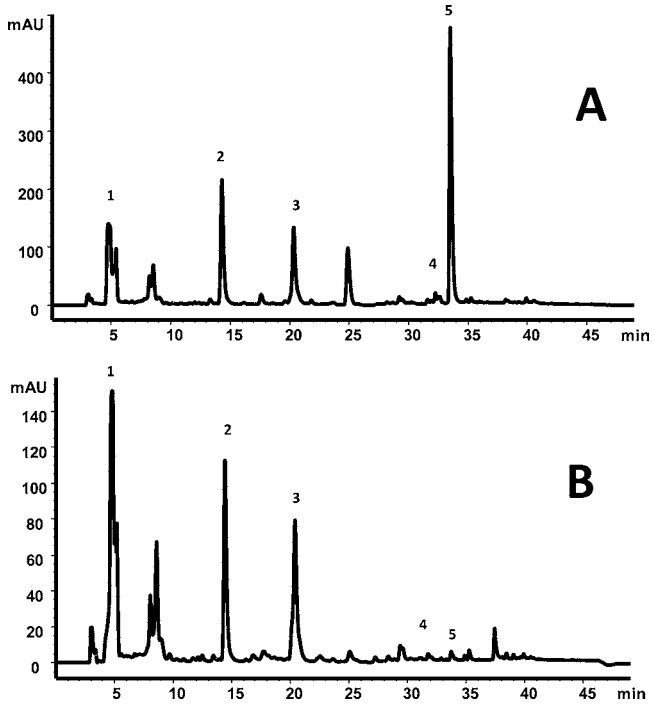

Figure 1. HPLC chromatogram of α-dicarbonyls in Manuka honey 3b (A) and multifloral honey 6 (B) after derivatization. Peaks 1, 2, 3, 4, and 5 are *o*-phenylenediamine, glucosone, 3-deoxyglucosone, glyoxal, and methylglyoxal, respectively.

It has been shown that color can also be an indicator of total phenolic content and honey's antioxidant capacity. Darker honeys often have a higher phenolic content and antioxidant capacity.[17,23] The color of honeys ranged from 77 mAU in a

[a]Results are the mean ± standard deviation of three determinations on a fresh weight basis. Values in each column are grouped into four quartiles (a > 75th, b = 50th–75th, c = 25th–50th, and d < 25th percentile).

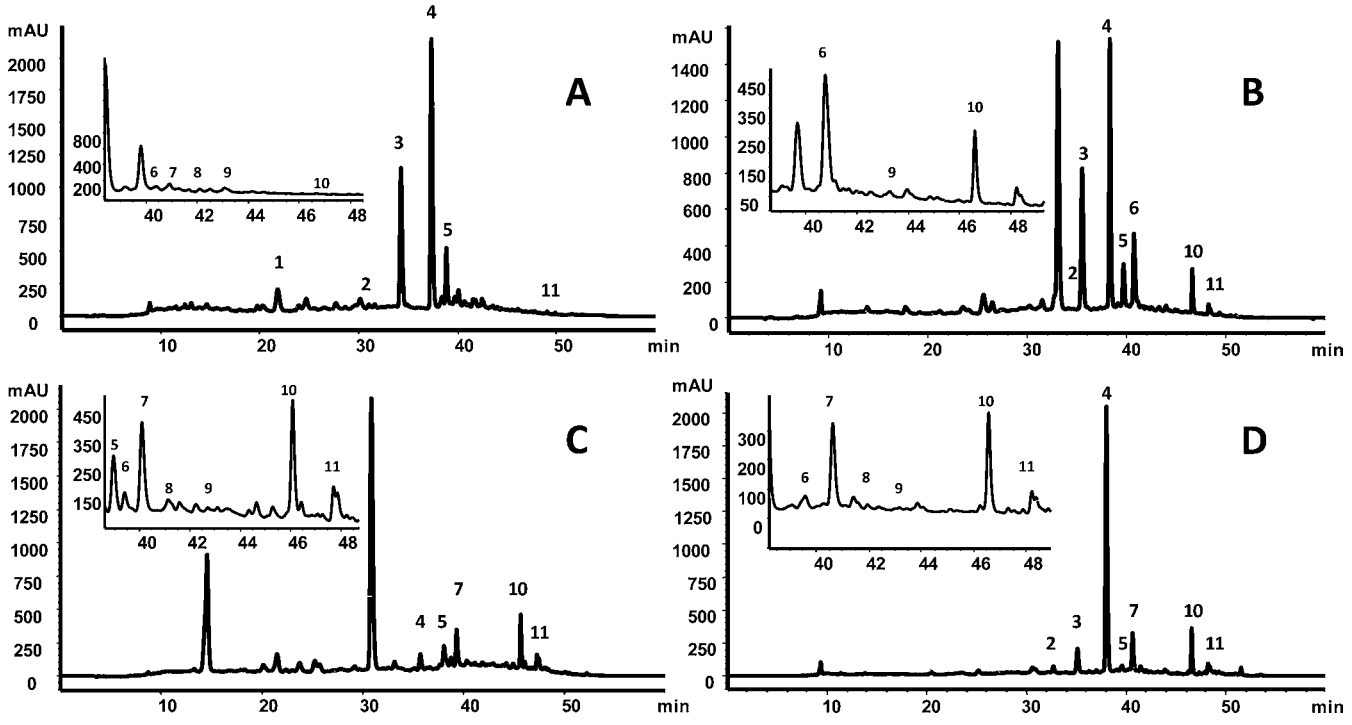

**Figure 2.** HPLC chromatogram of phenolic phytochemicals in palmetto honey 4a (A), palmetto honey 4b (B), Manuka honey 3b (C), and citrus honey 1a (D). Peak number and identification are listed in Table 4.

light colored citrus honey to 480 mAU in a multifloral honey. The range of absorbance is consistent with previously reported values.[23,34] Citrus honeys 1b and 1c had the lowest absorbance and were visually fairer than the other varieties. Two multifloral honeys, 6c and 6d, had the highest absorbances at 480 and 380 mAU, respectively, among all of the honeys analyzed. Citrus honey 1c showed lower values for color, total phenolic content, and antioxidant capacity (Table 2). This observation helps to support the conclusion that color and total phenolic content in honey are directly correlated. The multifloral variety had an average absorbance of 344 mAU, which was higher than the average absorbance of monofloral honeys (212 mAU). The correlation coefficient ($r$) between total phenolic concentration and color was 0.47. This $r$ value is lower than those reported

[a]Nine compounds were identified by comparison with authentic standards. Peaks 5 and 7 were unidentified. [b]2-*trans*,4-*trans*-Abscisic acid was tentatively identified using tandem mass spectra. [c]Chrysin and galangin coeluted in peak 11.

between total phenolics and color in other foods.[23,31] However, the correlation was significant at $p < 0.05$. The color of honeys can be attributed to flavonoids and Maillard reaction products, which can differ according to floral source and age of honey. Researchers have shown that proline content correlates with honey color.[35] Also, vitamins such as ascorbic acid may have an influence on honey's unique color. Carotenoids, minerals, and pollen are other pigment compounds that can be read at 450 nm and may be contributing to the low correlation between total phenolics and color.[36]

The DPPH scavenging activity of honeys ranged from 0.282 to 2.07 μmol TE/g honey. Multifloral honey 6d had the highest free radical scavenging capability among all honeys. The orange blossom honeys 1b and 1c had the lowest free radical scavenging values at 0.282 and 0.384 μmol TE/g honey, respectively. Honeys with paler colors, such as the citrus honeys, had lower absorbance and scavenging capacities compared to other varieties. It has been suggested that darker honeys generally have higher radical scavenging potential.[23] The correlation between total phenolic concentration and DPPH concentration was close to significant with a $p$ value of 0.058. Whereas correlation between total phenolic content and DPPH assay was shown for honeys, lack of correlation was also observed.[37] The DPPH assay measures the presence of compounds able to donate an electron to scavenge the DPPH radical. Phenolic compounds are not the only compounds capable of donating an electron. Islam et al. showed that amino acids and other nonphenolic compounds were also able to scavenge DDPH.[38] Honeys are complex matrices of compounds with different scavenging capabilities; therefore, it is possible that total phenolics and DPPH scavenging do not significantly correlate.

The antioxidant capacity of honeys, expressed as ORAC values, ranged from 1.48 to 18.2 μmol TE/g honey, which are comparable with those reported previously.[23] The ORAC value of multifloral honey 6a was higher than those of all other honeys tested. The multifloral varieties had an average ORAC value of 11 μmol TE/g, which is comparable to that of the gallberry honeys (10 μmol TE/g). The correlation coefficient ($r$) between total phenolic concentration of the honeys and ORAC values was 0.60 with $p < 0.05$. The ORAC assay does not measure antioxidant capacity due to phenolics alone; amino acids and other nucleophiles may also quench the free radicals in this method. The $r$ value between the ORAC and DPPH assays was 0.29. This low $r$ value was likely caused by the differences in the chemistry of these two methods. The ORAC assay is based on a hydrogen atom transfer reaction, whereas the DPPH assay uses an electron transfer mechanism.[39]

**Identification and Quantification of α-Dicarbonyls in Honey.** Carbonyl compounds were detected using UV−vis detection at 312 nm after a derivatization step with *o*-phenylenediamine to form quinoxalines (Figure 1). Peak 1 was excessive *o*-phenylenediamine. Peak 2 was tentatively identified as glucosone according to $[M + H]^+$ 251 and a published study.[24,40,41] Peak 3 produced $m/z$ 235 $[M + H]^+$, which fragmented into $m/z$ 217 and 199. These spectra were consistent with 3-deoxyglucosone.[24,41] Peak 4 was identified as glyoxal by comparing UV−vis and retention time with standard. Peak 5 yielded $m/z$ 145 $[M + H]^+$ and was identified as the quinoxaline formed after the reaction between *o*-phenylenediamine and methylglyoxal.[12,24] The α-dicarbonyl profiles in honeys differed according to floral sources and harvesting locations. For example, Manuka honey (Figure 1A) showed a predominant peak for methylglyoxal, whereas the methylglyoxal concentration in all of the other varieties was much lower (Figure 1B).

Table 3 provides the concentrations of glyoxal, methylglyoxal, and 3-deoxyglucosone in monofloral and multifloral honeys. Glucosone was not quantified in this experiment due to its artificial formation in select buffers and sample matrices. The contents of methylglyoxal in Manuka honeys 3a, 3b, and 3c were 86.9, 483, and 92.1 μg/g, respectively. Methylglyoxal concentration in other honeys ranged from 3.63 to 13.0 μg/g. Methylglyoxal in Manuka was 7−37 times more concentrated than the next highest (gallberry honey, 2c). Other studies have shown methylglyoxal concentrations ranging from undetectable to >1500 μg/g.[11,12,14,18,42] Stephen et al. showed that the longer a Manuka honey was aged, the higher the methylglyoxal concentration became.[18] The high levels of methylglyoxal in the Manuka honeys were not seen in any other foods.[12] A number of researchers suggested that the high levels of methylglyoxal in Manuka honeys are the major contributing factor to high antimicrobial capacity.[12] Glyoxal concentrations ranged from 2.19 to 7.35 μg/g, which is similar to the concentrations reported in honeys collected from other regions of the world.[11,12,15,34] Among three α-dicarbonyls, 3-deoxyglucosone had the highest concentration in all honeys. The higher concentration of 3-deoxyglucosone relative to methylglyoxal and glyoxal in honeys is expected because 3-deoxyglucosone is the initial product of glucose degradation and honey has a high sugar content.[10] Retro-aldolization of 3-deoxyglucosone produces methylglyoxal.[10] Thus, when 3-deoxyglucosone decreases, methylglyoxal should increase. This was not confirmed as a processing study was not performed on honeys to examine this reaction.

**Identification and Quantification of Phenolic Phytochemicals.** Figure 2 depicts the HPLC chromatograms of phenolic phytochemicals in different honeys after samples were purified using solid phase extraction. Chromatograms were recorded at 290, 340, and 520 nm, although only the chromatograms at 290 nm are shown. This is because most phenolic compounds can be detected at this wavelength.[20]

[a]Results are the mean ± standard deviation of three determinations on a fresh weight basis. ND, not detected. 2-*trans*,4-*trans*-abscisic acid was quantified using the 2-*cis*,4-*trans*-abscisic acid as a standard.

dx.doi.org/10.1021/jf501329y | J. Agric. Food Chem. 2014, 62, 8623−8631

Mass spectrometry was operated in the negative mode due to its higher sensitivity toward flavonoids than positive ionization mode.[43] Phenolic compounds in honeys were identified on the basis of mass spectra, UV−vis spectra from diode array detector, and comparison with standards. The retention time, $[M - H]^-$, and production ions of identified phenolic acids and flavonoids are listed in Table 4. Nine compounds were identified in honeys by comparison with authentic standards and using $MS^n$. 2-*trans*,4-*trans*-Abscisic acid was tentatively identified using $MS^n$. Identification of two peaks was inconclusive. Identified compounds included flavones, flavonols, flavanones, isomers of the terpenoid abscisic acid, phenolic acids, and phenolic derivatives. These compounds had all been previously reported in other honey varieties or propolis.[4,5,7,27,44−50]

*Phenolic Acids.* Peak 1 was confirmed to be coumaric acid by comparing retention time and mass spectra with authentic standards.

*Terpenoids.* Peak 4 was identified as 2-*cis*,4-*trans*-abscisic acid by comparison with authentic standard. It produced a $[M - H]^-$ at $m/z$ 263 that further dissociated to form $m/z$ 219 and 153 after loss of $CO_2$ and the side chain, respectively. Peak 3 also produced $m/z$ 263 $[M - H]^-$. This peak had two main fragments, $m/z$ 204 after the loss of both $CO_2$ and $CH_3$, and $m/z$ 219 after the loss of $CO_2$. The peak was tentatively identified as 2-*trans*,4-*trans*-abscisic acid. Both isomers of abscisic acid had been identified in other honey varieties.[5,32,47,49]

*Flavanones.* Peak 10 was identified as pinocembrin by comparison of the retention time and mass spectra with its standard. Peak 10 gave an ion at $m/z$ 255 $[M - H]^-$, which further dissociated into $m/z$ 213 from the loss of $C_2H_2O$ (42 Da) and $m/z$ 151 from the RDA reaction.[46]

*Flavonols.* Multiple flavonols were identified in the honeys. Peak 2 was rutin. It produced $m/z$ 609 $[M - H]^-$, which further dissociated into $m/z$ 301 after the loss of the rutinose group corresponding to the deprotonated quercetin aglycone.[43,51] Peak 6 was confirmed to be quercetin. The maximum absorbance was seen at 340 nm. Its retention time and mass spectrum matched those of an authentic standard. Peak 9 was identified as kaempferol by comparison of the retention time and mass spectra with those of authentic standards. Kaempferol produced an ion at $m/z$ 285 $[M - H]^-$ and two product ions at $m/z$ 267 $[M - H - H_2O]^-$ and $m/z$ 151 from RDA reaction. Peak 11 contained two flavonoids, galangin and chrysin. Galangin produced an ion with $m/z$ 269 $[M - H]^-$, which further dissociated into $m/z$ 197, which was formed from the loss of both a $CO_2$ and a CO (62 Da) group and $m/z$ 227.

*Flavones.* Luteolin (peak 8) and chrysin (peak 11) were identified in honey by comparison of retention times and mass spectra with standards. Chrysin has been previously identified in many different varieties of honeys, and thus its presence would not be beneficial in authenticating a particular variety of honey.[8,52,53] We did not detect flavonoid glycosides in honey samples. There are two possible explanations for the predominance of aglycone in honey. First, flavonoids in the nectar are different from those in the plant. Second, bees have glucosidase enzymes that can hydrolyze flavonoid glycosides.[54]

*Unidentified Peaks.* Peak 5 produced $m/z$ 285 $[M - H]^-$, which further dissociated into $m/z$ 267 and 252. Peak 7 produced $m/z$ 271 $[M - H]^-$, which further dissociated into $m/z$ 253, corresponding to the loss of water. Identification of these two peaks was inconclusive.

The concentrations of the 10 phenolic compounds quantified in the honeys are listed in Table 5. Figure 2 shows the phenolic phytochemical profiles were similar in honeys of the same variety. These profiles in palmetto honey show the phenolic "fingerprints" of honeys and may help to identify the floral source of unknown honeys. It was speculated that the multifloral honeys could be classified according to composition of phenolic phytochemicals. The Manuka honey (sample 3a) in Figure 2C had two large peaks that were unidentifiable from mass data. Honey is a complex mixture that may include other compounds such as pesticides, antibiotics, peptides, amino acids, dicarboxylic acids, and other residues that may not be easily identifiable with the current method.[35,36,55,56]

The concentrations and profiles of phenolics in the multifloral honeys varied according to seasons, locations, and apiarists. There was a higher concentration of abscisic acids in multifloral honey 6 than in all other honeys.

A majority of the phenolic compounds identified and quantified were in small amounts of <1 $\mu$g/g. The plant hormone, abscisic acid, was seen in almost all honeys in two isomeric forms, 2-*cis*,4-*trans*-abscisic acid and 2-*trans*,4-*trans*-abscisic acid. 2-*cis*,4-*trans*-Abscisic acid (peak 4) was the most abundant phytochemical found in most of the honeys. The presence of abscisic acid was not surprising as it is commonly seen in all plants. Abscisic acid has also been documented in other honey varieties.[5,32,47,49]

Honey samples in this study were collected by experienced beekeepers. The floral sources of honey were reported by beekeepers but were not verified by pollen counting. It is often difficult to determine the floral sources of a honey because bees can forage over 32000 acres. We speculated that some of the monofloral honeys may contain honeys from other floral sources. This remains a limitation of this study.

In conclusion, Florida honeys contain antioxidant phenolic phytochemicals and antimicrobial $\alpha$-dicarbonyls. The concentrations and compositions of these compounds varied according to floral source, harvesting season, and location. Floral source appears to be the most significant influence on honey characteristics. Several Florida varietal honeys, such as gallberry and multifloral honeys, had higher antioxidant capacities and concentrations of flavonoids, phenolic acids, and $\alpha$-dicarbonyls. These honeys may have better health-promoting properties and other medicinal benefits.

**ABSTRACT:** The mechanisms by which meat enhances human absorption of non-heme iron remain unknown. Recently, anchovy (*Engraulis japonicus*) muscle protein hydrolysate (AMPH) was found to mediate the formation of nanosized ferric hydrolysis products in vitro. The current paper evaluates the effects of AMPH on the bioavailability and the intestinal speciation of non-heme iron in rats, followed by an investigation of cellular uptake pathways of in vitro-formed AMPH-stabilized nanosized ferric hydrolysis products (ANPs) by polarized human intestinal epithelial (Caco-2) cells. The hemoglobin regeneration efficiencies in anemic rats followed the order ferric citrate (9.79 ± 2.02%) < commercial bare $\alpha$-$Fe_2O_3$ nanoparticles (16.37 ± 6.65%) < mixture of ferric citrate and AMPH (40.33 ± 6.36%) ≈ ferrous sulfate (40.88 ± 7.67%) < ANPs (56.25 ± 11.35%). Percentage contents of intestinal low-molecular-weight iron in the groups of FC+AMPH, $FeSO_4$, and ANPs were significantly lower than the corresponding hemoglobin regeneration efficiencies ($P < 0.05$), providing strong evidence for the involvement of nanosized iron in intestinal iron absorption from FC+AMPH, $FeSO_4$, and ANPs. Calcein-fluorescence measurements of the labile iron pool of polarized Caco-2 cells revealed the involvement of both divalent transporter 1 and endocytosis in apical uptake of ANPs, with endocytosis dominating at acidic extracellular pH. Overall, AMPH enhancement of non-heme iron absorption involves a nanoparticle-mediated mechanism.

**KEYWORDS:** *iron bioavailability, muscle protein, anchovy, rats, Caco-2 cell, nanoparticle*

## INTRODUCTION

After birth, humans have to acquire iron from the diet to support growth and compensate for iron loss; over 2 billion people worldwide suffer from iron deficiency. Although dietary iron can be found in the form of heme or non-heme iron, interventions to reduce iron deficiency usually focus on increasing non-heme iron absorption, which is greatly influenced by various dietary components. Inhibitors of non-heme iron absorption in humans include phytates, oxalates, polyphenols, fibers, calcium, copper, and zinc; ascorbic acid and muscle foods (i.e., meat, poultry, and fish) enhance non-heme iron absorption.[1] The enhancing effect of muscle foods on non-heme iron absorption is usually attributed to certain "meat factors" (e.g., peptides, acidic polysaccharides, and L-$\alpha$-glycerophosphocholine), which may react with non-heme iron in the intestinal lumen, thereby increasing iron solubilization and absorption.[2−4] However, the chemical nature of such soluble non-heme iron has still not been fully elucidated.

One economical meat source that could be used to combat iron deficiency in developing countries is the anchovy, a small marine pelagic fish harvested in huge quantity worldwide, mainly for nonfood uses.[5] Recently, we demonstrated that anchovy (*Engraulis japonicus*) muscle protein hydrolysate (AMPH) could mediate the formation of nanosized ferric hydrolysis products within a pH range similar to that of human digestive lumen;[6] thus, AMPH might enhance non-heme iron absorption in humans via a nanoparticle-mediated mechanism. The current research examined the effects of AMPH on the bioavailability and the intestinal speciation of non-heme iron in rats, followed by an investigation of cellular uptake pathways of in vitro-formed AMPH-stabilized nanosized ferric hydrolysis products (ANPs) in polarized human intestinal epithelial (Caco-2) cells.

## MATERIALS AND METHODS

**Materials.** Japanese anchovies, *E. japonicus* (5−8 cm total length), caught in the Yellow Sea by Allen Ship Service Co. Ltd. (Shandong, China) were frozen immediately at −35 °C on board and transported in a Styrofoam-insulated box to the laboratory refrigerator (−20 °C) within 4 h. Trypsin from bovine pancreas with a declared activity of 250 U/mg was purchased from Sinopharm Chemical Co. Ltd. (Shanghai, China). Nano-$\alpha$-$Fe_2O_3$ powder with declared diameters of 20−30 nm was purchased from Beijing Nachen Co. Ltd. (Beijing, China). Bathophenanthrolinedisulfonic acid (BPDS), deferoxamine mesylate (DFB), ethylenediaminetetraacetic acid (EDTA), nitrilotriacetic acid (NTA), phytic acid sodium salt, diethylenetriaminepentaacetic acid (DTPA), *trans*-1,2-cyclohexanediaminetetraacetic acid (CDTA), sodium selenite, hydrocortisone, and triiodothyronine were obtained from Sigma-Aldrich Co. (St. Louis, MO, USA). Calcein

acetoxymethylester, cell culture mediums, insulin, and epidermal growth factor were purchased from Gibco (Grand Island, NY, USA). All other reagents used in this study were commercially available and of analytical grade.

**Preparation of AMPH and ANPs.** AMPH was obtained as described previously.[7] Briefly, 25% (w/v) homogenates of anchovy meat were hydrolyzed by trypsin with a 25:1 substrate to enzyme ratio (w/w) at 37 °C and pH 8 for 4 h with continuous magnetic stirring, followed by heat inactivation of the enzyme in a boiling water bath for 10 min, and the reaction mixture was then centrifuged at 10000*g* for 20 min. The supernatant was stored at 4 °C for no more than 48 h and filtered through 0.22 μm cellulose acetate filters before use. Total protein concentration in the supernatant was determined according to Lowry's method using bovine serum albumin as the standard protein.[8]

ANPs were prepared according to the procedure described by Wu et al.[6] with slight modification. Briefly, 1 volume of freshly prepared ferric chloride (20 mM) was added dropwise into 10 volumes of magnetically stirred AMPH solution (20 g peptide/L) with the solution pH maintained at 7.0 ± 0.2 using 1 M sodium hydroxide. The obtained sample solution was stored at 4 °C for no more than 24 h and filtered through 0.22 μm cellulose acetate filters before use. For the structural characterization of ANPs, sample solutions were dropped onto carbon-coated copper grids, allowed to air-dry, and then examined in a JEM 1200 EX (JEOL, Tokyo, Japan) electron microscope. Iron content in the sample solution was determined by flame atomic absorption spectroscopy using a Shimadzu AA-6800 spectrometer (Kyoto, Japan).

**Animal Experiments.** All animal handling was conducted according to the principles and guidelines outlined in the National Institutes of Health (NIH) *Guide for the Care and Use of Laboratory Animals* and approved by the Ethical Committee of Animal Care and Use at Ocean University of China (Permit 20001013). Sprague−Dawley rats were obtained from Shandong Lukang Pharmaceutical Group Co., Ltd. (Shandong, China). Pelletized purified AIN-93G-based diets were prepared by TROPHIC Animal Feed High-tech Co., Ltd. (Nantong, China). The Fe-deficient diet contained ∼10 mg/kg iron derived from raw materials. The Fe-sufficient diet contained ∼25 mg/kg iron in the form of ferric citrate (FC) and ∼10 mg/kg iron derived from raw materials. The Fe-repletion diets contained ∼10 mg/kg iron derived from raw materials and ∼20 mg/kg iron in the forms of ferrous sulfate ($FeSO_4$), ANPs, FC, mixture of FC and AMPH (FC +AMPH), and commercial bare $\alpha$-$Fe_2O_3$ nanoparticles (Nano-$\alpha$-$Fe_2O_3$). The iron compounds were incorporated into the diets during preparation of the wet ingredient mixtures. $FeSO_4$, FC, or Nano-$\alpha$-$Fe_2O_3$ equivalent to 20 mg iron was mixed with 1 kg of the other dry ingredients and 200 mL of Milli-Q water to obtain the wet ingredient mixture. To incorporate the solution form of AMPH (18 g peptide/L) and ANPs (1.8 mM iron and 18 g peptide/L), 200 mL of either of them was mixed with 1 kg of the other dry ingredients to make the wet ingredient mixture. After being pelletized, the wet ingredient mixture was dried overnight at 40 °C in a drying oven. Iron contents in the dried pelletized diets were determined by flame atomic absorption spectroscopy using a Shimadzu AA-6800 spectrometer. Rats received Milli-Q water ad libitum throughout the experiments. Body weight was recorded at the beginning and end of each experimental period.

The iron bioavailability was measured in anemic rats using a hemoglobin regeneration bioassay.[9,10] Female Sprague−Dawley rats ($n$ = 12) breastfeeding male pups (16 days old; $n$ = 52) were housed in individual stainless steel cages with four to five pups each and fed a Fe-deficient diet ad libitum for a week. On the weaning day, 52 male rats (23 days old) were transferred into individual stainless steel cages under controlled conditions at temperatures of 22 ± 2 °C and relative humidities of 55 ± 10% with a light/dark cycle of 12/12 h. The just-weaned rats were stratified according to body weight and within each stratum were randomly allocated to two groups: the Fe-depleted group ($n$ = 48) fed a Fe-deficient diet ad libitum and a control group ($n$ = 4) fed a Fe-sufficient diet ad libitum. After a Fe-depletion period of 27 days, 20 μL of fresh rat blood sampled by tail vein incision was diluted with EDTA and subsequently analyzed using a Cell-Dyn 1600 hematology analyzer (Abbott Laboratories, Abbott Park, IL, USA). The mean hemoglobin concentrations of the Fe-depleted group and the control group were 71.1 ± 13.8 and 153.8 ± 13.9 g/L, respectively. Rats in the Fe-depleted group were stratified by the hemoglobin concentrations and randomized into six groups (eight rats each). The rats in each group consumed one of the five Fe-repletion diets containing $FeSO_4$, ANPs, FC, FC+AMPH, or Nano-$\alpha$-$Fe_2O_3$ or the Fe-deficient diet for 13 days (the repletion period) ad libitum. Rats in the control group remained on the Fe-sufficient diet during the repletion period.

Periodically, the daily food intake of each rat was manually recorded. A known and adequate amount of a diet was given to a rat in the feeding container between 9:00 and 10:00 a.m. After 24 h, the diet remaining in the feeding container and at the bottom of the cage was reweighed; calculating the differences showed the rat's daily food intake.

At the end of the repletion period, blood samples were once again taken by tail vein incision. The rats were anesthetized with ether before their livers were taken, rinsed with saline, and stored at −20 °C. Iron concentration in the liver was measured by flame atomic absorption spectroscopy using a Shimadzu AA-6800 spectrometer.

Hemoglobin (Hb) iron pool (mg), assuming a total rat blood volume of 6.7% body weight and an iron content in hemoglobin of 0.335%, was calculated as follows:[10]

$$\text{Hb iron pool (mg)} = \text{body wt (kg)} \times 0.067 \times \text{Hb concn (g/L)} \times 3.35$$

The hemoglobin regeneration efficiency was calculated by using the following equation:

$$\text{Hb regeneration efficiency (\%)} = [\text{final Hb iron pool (mg)} - \text{initial Hb iron pool (mg)}] / \text{total iron consumed (mg)} \times 100$$

The relative biological value was calculated on the basis of the hemoglobin regeneration efficiencies:

$$\text{relative biological value (\%)} = \text{Hb regeneration efficiency of each animal} / \text{av Hb regeneration efficiency of the } FeSO_4 \text{ group} \times 100$$

Iron speciation analysis of rat intestinal contents was carried out as previously described by Kapsokefalou and Miller[11] and Simpson et al.[12] with some modifications. Male Sprague−Dawley rats (53 days old; $n$ = 40) weighing 290−310 g were stratified according to body weight and within each stratum were randomly distributed into five groups (eight rats each). The rats were fed the Fe-deficient diet for a week before they were daytime fasted for 9 h. The fasted rats in each group then consumed one of the five Fe-repletion diets for 30 min ad libitum and were anesthetized with ether 90 min after consumption of the meal. The rats were killed by cervical dislocation before an abdominal midline incision was performed. After the small intestine was removed from the carcass, the content in the proximal one-third segment was flushed with saline into a centrifuge tube and further fractionated into two fractions using Millipore filters (Göttingen, Germany): the 0.22 μm filtrate and the 3 kDa (≈1 nm) filtrate. Iron concentrations in the intestinal content, 0.22 μm filtrate, and 3 kDa filtrate were determined by flame atomic absorption spectroscopy using a Shimadzu AA-6800 spectrometer.

**Cellular Uptake Experiment.** Caco-2 cells were obtained from the Cell Bank of the Chinese Academy of Sciences (Shanghai, China) and seeded at a density of $5 \times 10^4$ cells/cm$^2$ in collagen-treated 24-well plates (BD Biosciences, San Jose, CA, USA). The cells were routinely maintained in high-glucose (4.5 g/L) Dulbecco's modified Eagle medium supplemented with 10% heat-inactivated fetal bovine serum, 25 mM HEPES, 4 mM glutamine, and 1 mM sodium pyruvate at 37 °C in an incubator with a 95% air/5% $CO_2$ atmosphere at constant humidity, and the medium was renewed every 2 days. After reaching confluence (2−3 days postseeding), the cells were maintained in

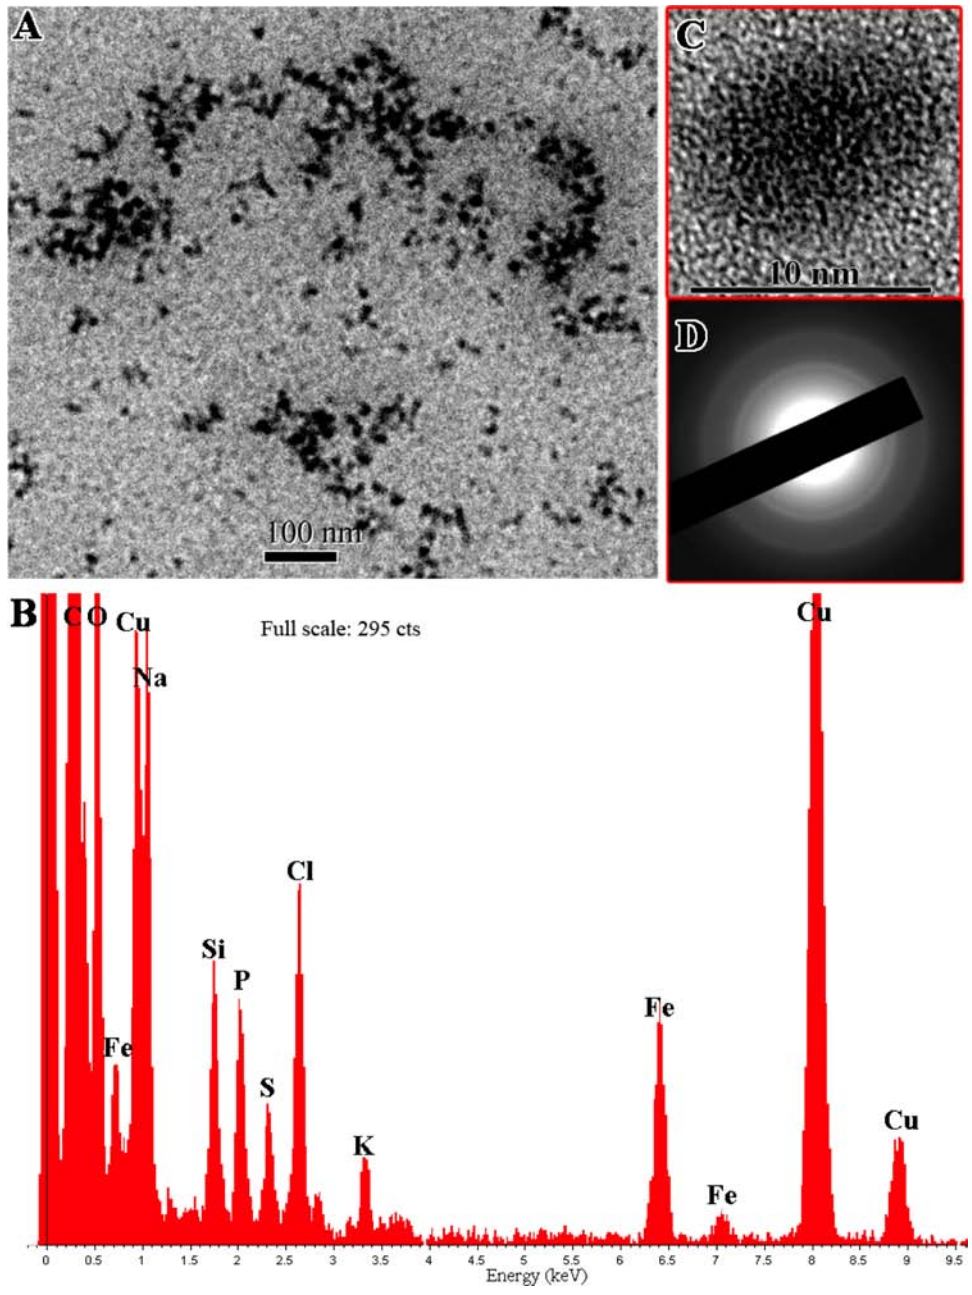

**Figure 1.** Structural characterization of in vitro-formed nanosized ferric hydrolysis products stabilized by anchovy muscle protein hydrolysate (ANPs): (A) transmission electron microscopy images collected from a drop of ANPs; (B) whole area energy dispersive X-ray analysis of one of the particles in panel A showing elemental compositions (peaks for sodium (Na), copper (Cu), potassium (K), silicon (Si), phosphorus (P), sulfur (S), chlorine (Cl), carbon (C), and oxygen (O) are identified); (C) high-resolution transmission electron microscopy; (D) selected area electron diffraction.

complete Dulbecco's modified Eagle medium for another 12 days to differentiate completely and further incubated for 24 h in serum-free minimum essential medium supplemented with 4 mg/L hydrocortisone, 5 mg/L insulin, 5 $\mu$g/L selenium, 34 $\mu$g/L triiodothyronine, and 20 $\mu$g/L epidermal growth factor. Following this, the medium was aspirated, and the cells were stained with 1 $\mu$M calcein acetoxymethylester in Hanks' balanced salt solution (HBSS) for 30 min at 37 °C before being washed three times with HBSS. The cells were then incubated in Tyrode solution (137 mM NaCl, 2.7 mM KCl, 1 mM $MgCl_2$, 1.8 mM $CaCl_2$, 5.5 mM D-glucose) buffered with 20 mM MES (pH 5.5) or MOPS (pH 7.0) containing $FeSO_4$, ANPs, or any of 1:1 ferric chelates of NTA, phytate, EDTA, DTPA, CDTA, and DFB at the concentration equivalent to 20 $\mu$M iron in a Synergy H4 hybrid microplate reader (Bio-Tek, Winooski, VT, USA) at 37 °C for 2.5 h, and calcein fluorescence (485 nm excitation, 530 nm emission) was monitored every 5 min. To trap and detect ferrous iron, 100 $\mu$M BPDS was used, and the absorbance of the ferrous tris(BPDS) complex was measured at 536 nm (molar extinction coefficient, $\varepsilon$ = $1.927 \times 10^4$ L $mol^{-1}$ $cm^{-1}$). Stock solution of $FeSO_4$ (1 mM) was freshly prepared before use. Stock solution of ferric chelates (1:1 molar ratio) of NTA, phytate, EDTA, DTPA, CDTA, and DFB was prepared by mixing equal volumes of chelators (2 mM) and freshly prepared $FeCl_3$ (2 mM).

**Statistical Analysis.** Data are expressed as the mean ± standard deviation (SD). Differences between groups were tested for significance by the least significant difference (LSD) mean comparison using the SPSS software program (SPSS Inc., Chicago, IL, USA). The relationship between variables was determined by the Pearson

correlation test. The probability level <0.05 was considered statistically significant.

## RESULTS AND DISCUSSION

To evaluate the structural properties of ANPs, that is, the products of ferric hydrolysis in the presence of AMPH in vitro at room temperature, we used transmission electron microscopy (TEM), high-resolution transmission electron microscopy (HRTEM), electron diffraction, and energy dispersive X-ray spectroscopy (EDX). TEM imaging (Figure 1A) showed that the average particle size ranged from 10 to 20 nm, and this size was greater than that of pure two-line ferrihydrite (2−4 nm).[13] Whole area EDX analysis (Figure 1B) of one of the particles in Figure 1A revealed three peaks (0.7, 6.4, and 7.1 keV) that corresponded to the L$\alpha$, K$\alpha$, and K$\beta$ lines of iron, respectively, so the particles in the TEM image were iron-containing. In addition, the EDX spectra also showed prominent peaks for copper, sodium, potassium, chloride, sulfur, carbon, oxygen, phosphorus, and silicon. The copper obviously represented the supporting copper grid, and the silicon peak was presumably due to contamination. Spurious silicon peaks have been recognized as a problem in EDX analysis of biological specimens due to silicon contamination from oils or greases during the course of specimen preparation or from the vacuum system of the electron microscope.[14] Any remaining peaks would presumably represent true compositions of AMPH or the specimen support film. The HRTEM image (Figure 1C) revealed no recognizable lattice fringe, suggesting the amorphous property of ANPs. The selected area electron diffraction (Figure 1D) showed a two-ring pattern similar to that of two-line ferrihydrite with the obtained *d*-spacing values (2.90 and 1.97 Å), a little higher than typical corresponding values of the latter (~2.5 and 1.5 Å). ANPs are likely to be a poorly crystalline ferric oxyhydroxide similar to two-line ferrihydrite. It is known that poorly crystalline iron oxides are prone to electron beam damage,[15] so the actual structure of ANPs might vary somewhat in size and crystalline phase from that observed under TEM, HRTEM, and electron diffraction.

Details and results of the hemoglobin regeneration bioassay are shown in Table 1. It is known that body iron is distributed in hemoglobin (65%), iron stores (ferritin and hemosiderin, 30%), myoglobin (3.5%), and other heme proteins (1.5%).[16] Liver iron stores did not show a significant increase in all Fe-repletion groups during the repletion period (Figure 2), so most of the iron absorbed should be used to generate new hemoglobin molecules, amounts of which could be calculated from changes of blood volumes and hemoglobin concentrations. The negative changes of the hemoglobin concentrations in Fe-deficient, FC, and Fe-sufficient groups were the result of a marked increase in blood volume, which is proportional to body weight, during fast growth of the anemic rat. As shown in Table 1, body weights and hemoglobin concentrations varied independently among the groups, so to measure iron bioavailability by hemoglobin regeneration in anemic rats, it is necessary to calculate the hemoglobin regeneration efficiencies from body weight gain, diet intake, diet iron content, and hemoglobin concentration.

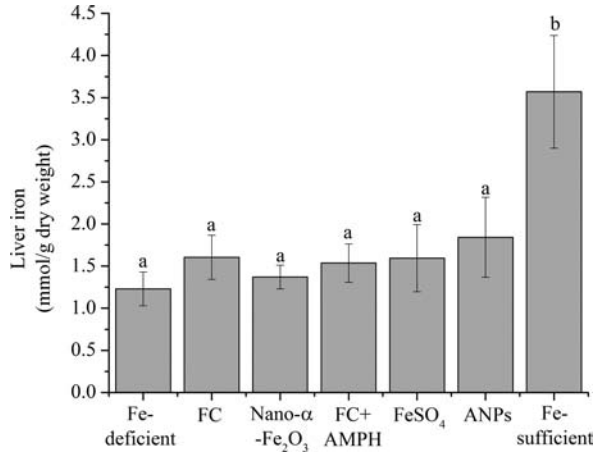

**Figure 2.** Liver iron concentrations at the end of the iron repletion period. Abbreviations: FC, ferric citrate; FC+AMPH, mixture of ferric citrate and anchovy muscle protein hydrolysate; $FeSO_4$, ferrous sulfate; ANPs, in vitro-formed nanosized ferric hydrolysis products stabilized by anchovy muscle protein hydrolysate; Nano-$\alpha$-$Fe_2O_3$, commercial bare $\alpha$-$Fe_2O_3$ nanoparticles. Values are means ± standard deviations of a representative experiment ($n = 4$ for the Fe-sufficient group; $n = 8$ for the other groups). Groups not sharing a common letter are significantly different ($P < 0.05$).

As shown in Table 2, the hemoglobin regeneration efficiency of FC+AMPH was as high as that of $FeSO_4$, a gold standard in iron bioavailability studies, and significantly higher than that of FC alone ($P < 0.05$). Apparently, AMPH effectively enhanced iron absorption from FC. ANPs displayed an even higher hemoglobin regeneration efficiency than FC+AMPH and $FeSO_4$, although not statistically significant ($P = 0.06$ and 0.12, respectively). Because crystallized bare iron oxide nanoparticles feature simple production process and low cost, we examined the bioavailability of iron from Nano-$\alpha$-$Fe_2O_3$, a commercial product with declared size similar to that of ANPs. The hemoglobin regeneration efficiency of Nano-$\alpha$-$Fe_2O_3$ was found to be significantly lower than that of ANPs ($P < 0.05$). Interestingly, the relative biological value of Nano-$\alpha$-$Fe_2O_3$

**Table 2. Hemoglobin Regeneration Efficiencies and Percentage Contents of Intestinal Iron species in different groups**

| group[b] | hemoglobin regeneration efficiency (%) | percentage contents of intestinal iron species[a] | | |
|---|---|---|---|---|
| | | total soluble iron[c] | low-molecular-weight iron[d] | nanosized iron[e] |
| FC | 9.79 ± 2.01a | 43.18 ± 4.49ef | 12.44 ± 3.47ab | 30.74 ± 6.49d |
| Nano-$\alpha$-$Fe_2O_3$ | 16.37 ± 6.65abc | 56.57 ± 11.69fg | 24.35 ± 4.67cd | 32.22 ± 12.24de |
| FC+AMPH | 40.33 ± 6.36ef | 60.74 ± 6.84g | 18.31 ± 4.16bc | 42.43 ± 3.40ef |
| $FeSO_4$ | 40.88 ± 7.67ef | 59.01 ± 9.02g | 19.21 ± 5.26bc | 39.80 ± 8.87def |
| ANPs | 56.25 ± 11.35fg | 61.24 ± 11.01g | 14.47 ± 2.63ab | 46.77 ± 8.89f |

[a]Values are means ± SD of a representative experiment ($n$ = 8). Means in a column without a common letter (a−g) are statistically different, $P$ < 0.05. [b]Abbreviations: FC, ferric citrate; Nano-$\alpha$-$Fe_2O_3$, commercial bare $\alpha$-$Fe_2O_3$ nanoparticles; $FeSO_4$, ferrous sulfate; ANPs, in vitro-formed nanosized ferric hydrolysis products stabilized by anchovy muscle protein hydrolysate; FC+AMPH, mixture of ferric citrate and anchovy muscle protein hydrolysate. [c]Iron in the 0.22 $\mu$m filtrate. [d]Iron in the 3 kDa filtrate. [e]Calculated by subtraction of low-molecular-weight iron from total soluble iron. Abbreviations:

(39.0 ± 15.8%) was also found to be significantly lower than those of previously reported ZnO-, MgO-, CaO-, or $FePO_4$-doped iron oxide nanopowders, namely, $Fe_2O_3$/ZnO/MgO (81.8−100.1%), $Fe_2O_3$/ZnO/CaO (72.4−92.6%), $Fe_2O_3$/ZnO (68.0−87.5%), and $Fe_2O_3$/$FePO_4$ (69.0−87.4%),[9] which might be explained by the higher iron dissolution rates of these latter iron oxide nanostructures in gastric acid due to doping with compounds more soluble in dilute acid than iron oxide.[17]

To elucidate whether nanosized iron involved iron absorption in vivo, we analyzed iron speciation in the luminal content of the proximal one-third segment of the small intestine, where dietary iron is mainly absorbed.[18] Iron in the 3 kDa filtrates was regarded as the truly dissolved iron species or low-molecular-weight (LMW) iron, whereas that in the 0.22 $\mu$m filtrate was supposed as total soluble iron including both LMW iron and nanosized colloidal iron. As shown in Table 2, percentage contents of intestinal LMW iron in the groups of FC+AMPH, $FeSO_4$, and ANPs were significantly lower than the corresponding hemoglobin regeneration efficiencies ($P$ < 0.05), so LMW iron alone was unlikely to account for total iron absorption in these groups. This provided strong evidence for the involvement of nanosized iron in intestinal iron absorption from FC+AMPH, $FeSO_4$, and ANPs.

LMW iron in the intestinal tract might be ferrous iron or ferric chelates. Except for $FeSO_4$, the other four iron compounds in the present study are all in the form of ferric iron. The reducing power of *tert*-butylhydroquinone, the fat-soluble antioxidant added in the AIN-93G diet, might not contribute to the formation of intestinal LMW iron due to its very low solubility in the aqueous phase. Although meat digestion products are capable of reducing non-heme ferric iron to the ferrous form in vitro,[19] AMPH and ANPs did not increase the percentage content of LMW iron (Table 2), which might be explained by the oxidation of protein sulfhydryl groups during the preparation and storage of AMPH and pelletized diets.[20] There are usually considerable amounts of residual phytates in the commercial starch that comprises an important part of the AIN-93G diet,[21] so iron phytate chelates might account for part of the intestinal LMW iron in the present study. It is also possible that some vitamins added in the AIN-93G diet could form LMW ferric complexes in the intestinal lumen.[22]

Ferric hydrolytic polymers could be stabilized at the nanoscale by biomacromolecules (e.g., polysaccharides and peptides) derived from some common food components (e.g., starch, carrageenan, pectin, alginate, casein, whey, and muscle protein) or gastrointestinal secretions (e.g., mucins).[6,23−27] The percentage contents of nanosized iron in the rat proximal small intestinal tracts were calculated by subtraction of LMW iron from total soluble iron (Table 2) and were found to be >30% in all five groups, suggesting that the AIN-93G diet could induce a high basal level of intestinal nanosized iron. This might be attributed to the digestion products of maltodextrin, starch, and casein in the basal formulation of AIN-93G diet or gastrointestinal secretions. Interestingly, the percentage of nanosized iron for the $FeSO_4$ group was also significantly higher than that of its LMW counterpart ($P$ < 0.05), which might be explained by the formation of nanosized iron via rapid in situ oxidation and hydrolysis of ferrous iron bound to soluble macromolecules in the presence of swallowed oxygen in the intestinal tract. Due to their tendency to aggregate and sediment in aqueous solutions, bare iron oxide nanoparticles are difficult to disperse into stable suspensions within the nanoscale range unless very efficient dispersing techniques (e.g., probe ultrasonication) are employed,[28] so it is unsurprising that Nano-$\alpha$-$Fe_2O_3$ induced a significantly lower level of intestinal nanosized iron than ANPs ($P$ < 0.05).

The involvement of intestinal nanosized iron in iron absorption from FC+AMPH, $FeSO_4$, and ANPs raises questions about how gut epithelial cells absorb intraluminal nanosized iron. Usually, exogenous iron enters the cellular labile iron pool before it is stored in ferritin, exported from the cell, or used to synthesize iron proteins.[29] Calcein, a fluorescence probe for the labile iron pool, has been frequently used to monitor cellular iron uptake in real time.[30,31] We thus used calcein-loaded polarized Caco-2 cell monolayers as a gut epithelial model to investigate the intestinal iron absorption from ANPs, a mimetic for intraluminal nanosized iron. As shown in Figure 3, iron uptake from $FeSO_4$ and ANPs at concentrations equivalent to 20 $\mu$M iron was monitored by the quenching of calcein fluorescence, that is, the incorporation of exogenous iron into the cellular labile iron pool, under two pH conditions (5.5 and 7.0) simulating those in the proximal and distal small intestine.[32] BPDS, a strong ferrous chelator, was used to block iron absorption via the divalent metal transporter 1 (DMT1). As expected, cellular iron uptake from $FeSO_4$ was completely blocked by BPDS at pH 5.5 and 7.0 (data for the latter pH are not shown), whereas iron uptake from ANPs was only partially blocked at both pH values, suggesting that both DMT1-dependent and DMT1-independent mechanisms are involved in iron absorption from ANPs.

The two best known DMT1-independent iron uptake mechanisms are by means of heme carrier protein 1 and endocytosis. Heme carrier protein 1 is specific to heme iron uptake,[33] so endocytosis, a very common mechanism for cellular entry of nanoparticles, attracted much attention in

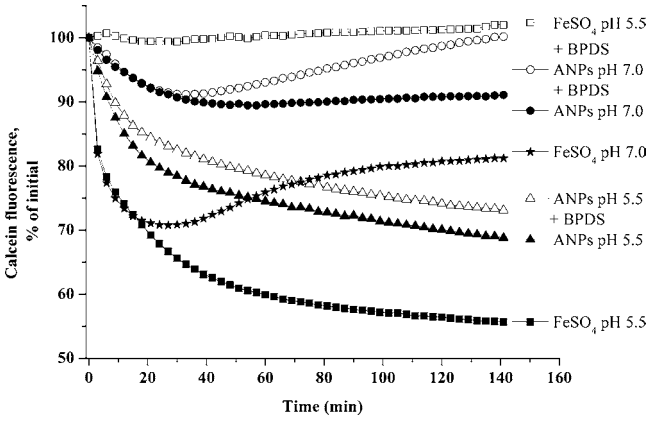

**Figure 3.** Iron uptake by polarized Caco-2 cell monolayers in the presence of 20 $\mu$M iron at extracellular pH values of 5.5 and 7.0. Abbreviations: $FeSO_4$, ferrous sulfate; ANPs, in vitro-formed AMPH-stabilized nanosized ferric hydrolysis products; BPDS, bathophenanthrolinedisulfonic acid. Cellular uptake of exogenous iron into the labile iron pool was measured as the quenching of calcein fluorescence. BPDS is a strong ferrous chelator to block the divalent metal transportor-1 pathway. Data are means of three independent experiments with standard deviations of <1.6.

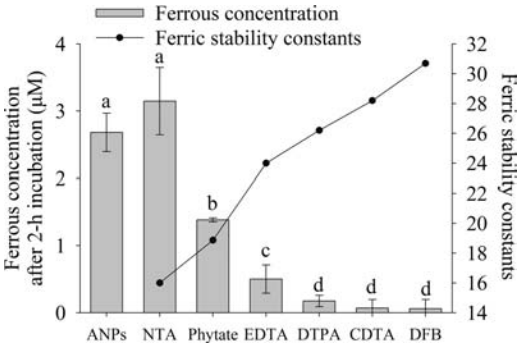

**Figure 4.** Ferrous concentrations after 2 h of incubation of 20 $\mu$M different forms of ferric iron with polarized Caco-2 cell monolayers at an extracellular pH of 5.5. Abbreviations: ANPs, in vitro-formed nanosized ferric hydrolysis products stabilized by anchovy muscle protein hydrolysate; CDTA, *trans*-1,2-cyclohexanediaminetetraacetic acid; DFB, deferoxamine mesylate; DTPA, diethylene triamine pentaacetic acid; EDTA, ethylenediaminetetraacetic acid; NTA, nitrilotriacetic acid. Ferric stability constants were obtained from the literature.[40] Data are presented as means ± standard deviations of three independent experiments. Groups not sharing a common letter are significantly different ($P < 0.05$).

recent studies on intestinal absorption of nanosized iron. Work by Theil and colleagues demonstrated that iron absorption from ferritin (i.e., ferrihydrite-like nanostructures encapsulated by a protein cage) is independent of heme iron and ferrous salts in both female human and rat intestinal segments,[34] and a paper published later by Antileo et al. revealed an endocytic pathway of ferritin in Caco-2 cells using TEM and fluorescence confocal microscopy.[35] The elegant studies of Pereira et al. and Powell et al.,[36,37] utilizing Caco-2 cells and mice, proved that intestinal uptake of luminally hydrolyzed nanosized iron invokes a nanoparticulate endocytic pathway. Thus, endocytosis could be the mechanism for DMT1-independent apical uptake of ANPs.

The calcein fluorescence changes in Figure 3 also showed a more noticeable uptake of iron from ANPs at pH 5.5 in the presence of BPDS than those observed at pH 7.0, suggesting a lower intraluminal pH in the proximal small intestine favors the endocytic uptake of ANPs. Acidic extracellular pH enhancement of endocytosis due to the proton-induced change of cellular membrane properties has been well-documented,[38] so it is not surprising that in the present study an extracellular pH of 5.5 was more favorable for the endocytic uptake of ANPs compared to pH 7.0. The marginal inhibition of iron absorption from ANPs by BPDS at pH 5.5 indicated the dominant role of the endocytic pathway at acidic extracellular pH. Iron uptake from $FeSO_4$ at pH 7.0 without the presence of BPDS was less evident than that at pH 5.5 after about 20 min of incubation, which could be explained by the relatively fast oxidation rate of ferrous iron at pH 7.0.[39]

Ferric iron must be reduced to the ferrous form by duodenal cytochrome *b* in the apical membrane of enterocytes before being absorbed by the DMT1 pathway, so the part played by the DMT1-dependent pathway in apical uptake of ANPs depends on the reducibility of ANPs. As shown in Figure 4, the reducibility of ferric chelates of NTA, phytate, EDTA, DTPA, CDTA, and DFB to polarized Caco-2 cells followed the reversed order of ferric stability constants of the chelators,[40] and ANPs were as reducible as ferric NTA, which is the most reducible of these ferric chelates.

Some previous studies have revealed that reduction rates of ferric chelates by plant roots (*Arachis hypogeae* L.) and yeast (*Saccharomyces cerevisiae*) were inversely related to the ferric stability constants,[41,42] and our data confirmed the previous observations in human intestinal cells. The reducibility of iron oxides is greatly dependent on their crystalline phases (e.g., ferrihydrite, lepidocrocite, maghemite, goethite, and hematite) and surrounding organic substances. Ferrihydrite is the most reducible phase of iron oxides. The phase of intestinal nanosized iron in the present study should be similar to ANPs, a poorly crystalline ferric oxyhydroxide-like two-line ferrihydrite. Iron-binding organic substances such as AMPH in the present study might enhance reduction dissolution of iron oxides via solubilizing ferric iron from the oxide surface or complexation of ferrous iron.[43] The high reducibility of ANPs to polarized Caco-2 cell monolayers could thus be easily understood.

In summary, our data suggest that intestinal nanosized iron involves AMPH enhancement of non-heme iron absorption in rats. Although both DMT1 and endocytosis play parts in the intestinal absorption of luminal nanosized iron, endocytosis dominates at acidic extracellular pH levels.

**ABSTRACT:** Food-derived phytochemicals, many known for their health beneficial effects, often exist in conjugated forms containing sugar moieties such as glucose or rhamnose in foods. The uptake of these compounds requires colonic bacterial cleavage of sugar moieties. However, most studies involved in screening extracts for biological activities do not take this process into account. This study seeks to determine the utility of commercially available hesperidinase to mimic colonic digestion and to test the effects of this treatment on the biological properties of extracts. Using hesperidinase resulted in efficient hydrolysis of *Engelhardia roxburghiana* Wall. extract containing rhamnose conjugates. Enzymatic digestion enhanced the extract's cellular antioxidant ability by 2-fold in HepG2/C3A and the anti-inflammatory effect on lipopolysaccharide-induced interleukin (IL)-1$\beta$ and IL-6 expression in mouse macrophage J774A.1 and human monocyte THP-1 cells. Enzymatic digestion also efficiently processed extracts with mixed rhamnose and glucose conjugates and altered their biological activities. Results of the present study supported the importance of considering enzymatic digestion during the biological activity studies of botanicals.

**KEYWORDS:** *hesperidinase, enzymatic digestion, antioxidant, anti-inflammation, xenobiotic metabolism*

## INTRODUCTION

Research has led to a wealth of evidence supporting the consumption of plant-based foods rich in phytonutrients as being closely linked to lowered risks of various chronic noncommunicable diseases including inflammation, cardiovascular disease, and cancers as well as aging.[1−3] A variety of naturally occurring phenolic compounds have been reported to possess antioxidant and anti-inflammatory properties along with an ability to induce xenobiotic metabolizing enzymes involved in drug and carcinogen removal.[4−6] The most common and largest class of polyphenols is the flavonoids, which are known to be responsible for the color, flavor, and potential beneficial effects of plants.[7] Also, flavonoids are often considered as safe diet-derived health-promoting substances. The C6−C3−C6 backbone is the basic structure of all flavonoids.[8] In nature, flavonoids often exist as conjugated forms[9] that are attached to various sugar moieties, such as rhamnose and glucose.[10] The phenolic ring, the hydroxyl groups, and the double bonds of a flavonoid structure are thought to contribute to its antioxidant capacity, such as free radical neutralization and ROS inhibition, by donating hydrogen atoms.[11] Moreover, oxidative stress, which is caused by the imbalance of oxidants and antioxidants, plays a crucial role in the damage of proteins, lipids, carbohydrates, and DNA.[12] Oxidative stress has been demonstrated as a mediator of chronic inflammation by activating the expression of over 500 genes including growth factors, chemokines, and inflammatory cytokines.[13] Both enzymatic and nonenzymatic antioxidants are involved in the reduction of ROS formation, and they help to prevent, intercept, and repair damage from oxidative stress.[14] Hence, the modulation of oxidative stress and inflammation, as well as the induction of xenobiotic metabolizing enzymes, may be the mechanisms by which phytochemicals, such as flavonoids, can benefit human health.

Flavonoid glycosides are digested, absorbed, and excreted as they traverse through the gastrointestinal (GI) tract in humans.[15] More than 95% of polyphenols are not absorbed in the small bowel or stomach but transit into the colon,[16] where they are degraded by gut microbiota.[17] The degradation process in the colon includes the removal of glycosides from the conjugated phytochemicals. This naturally occurring process in our body causes changes to the chemical structures of flavonoids, thereby increasing their absorption.[18] Approximately 5000 naturally occurring flavonoids have been identified;[7] however, the majority of them possess one or more sugar groups (e.g., glucose, rhamnose, rutinose) while occasionally existing as aglycones.[11] In our previous study with *Engelhardia roxburghiana* Wall. (ER), we isolated and characterized astilbin and engeletin, which are the major constituents in the ER leaf extracts.[19] Our study has demonstrated that *Gynostemma pentaphyllum* (Thunb.) Makino (GP), another purported health-promoting plant, showed complex conjugated flavonoid composition.[20] It appears that the removal of glycosides might be necessary to release the active forms of flavonoids, and the differences in the structures of aglycones and glycosides might lead to significant differences in their polarities, bioavailabilities, biological activities, and

effects on human health.[18] A recent study by a Korean research group has demonstrated that most of the flavonoid glycosides could be efficiently degraded by gastrointestinal enzymes to their aglycone forms.[21]

Microbial enzymes involved in the processing of glycosides have been studied.[22,23] α-L-Rhamnosidase (EC 3.2.1.40) is an enzyme that cleaves the terminal α-L-rhamnose from natural glycosides.[22] This enzyme has been reported to occur in animal tissues, fungi, and bacteria.[22] Flavonoid glycosides, such as quercetin-3-*O*-rhamnoside, could be efficiently catalyzed and hydrolyzed to quercetin by gut microflora, for example, α-rhamnosidase-containing *Bacteroides distasonis*.[22] Other microorganism-derived enzymes, such as hesperidinase, are enzymes with both α-L-rhamnosidase (EC 3.2.1.40) and β-D-glucosidase (3.2.1.21) activities that can remove both rhamnose and glucose. Recently, approximately $10^{12}$ microorganisms/$cm^3$ have been reported to exist in the colon.[23] Thus, these microbial-derived enzymes may account for a significant aspect of flavonoid processing in the colon. Interestingly, in most studies of biological activities of naturally derived extracts, such as antioxidant and anti-inflammatory capacities, colonic processing of glycosides is often not considered.[24−26]

The purpose of this study is to explore the utility of commercially available hesperidinase from *Penicillium* sp. in mimicking colonic digestion of flavonoid glycosides and to test if (1) the treatment with hesperidinase catalyzes the processing of conjugated extracts and (2) the treatment with hesperidinase alters the biological activities of the extracts. In this study, a simplified assay system for the enzymatic digestion was developed using a water extraction from ER. Also, we validated the effects of enzymatic digestion on bioactivities, including antioxidant property, anti-inflammatory effect, and xenobiotic metabolizing capacity. The utility of enzymatic digestion was further evaluated on five complex extracts from leaf and whole-plant samples of diploid and tetraploid GP.[20] Our results indicated that the alteration of biological activities by enzyme treatment and the incorporation of hesperidinase digestion might provide a more realistic assessment of biological functions during in vitro screening of health-promoting properties of plant extracts.

## MATERIALS AND METHODS

**Materials and Reagents.** Human hepatocarcinoma cell HepG2/C3A, mouse macrophage J774A.1, and human leukemic cell THP-1 were purchased from American Type Culture Collection. Hesperidinase from *Penicillium* sp., HPLC grade water, acetic acid, sodium acetate, HEPES, hydrocortisone, penicillin, streptomycin, gentamicin, insulin, and dimethyl sulfoxide were purchased from Sigma-Aldrich (St. Louis, MO, USA). 2′,7′-Dichlorofluorescin diacetate, Williams' medium E without phenol red, RPMI medium with phenol red, and Hanks' balanced salt solution were purchased from Gibco Life Technologies (Grand Island, NY, USA). An ATPlite Luminescence Assay System Kit was from PerkinElmer Life and Analytical Sciences (Boston, MA. USA). DMEM, antibiotic−antimycotic, fetal bovine serum, and TRIzol reagent were purchased from Invitrogen (Carlsbad, CA, USA). 2,2-Azobis(2-amidinopropane) dihydrochloride (ABAP) was obtained from Wako Chemicals USA, Inc. (Richmond, VA, USA). All other chemicals were of analytical reagent grade and used without any further purification.

**Plant Extract Preparations.** Leaves of ER were collected and prepared as described in previous work.[19] All of the dried botanical materials were stored at room temperature in the dark before being used. GP samples including two diploid leaf samples (GP1 and GP2), two tetraploid leaf samples (GP3 and GP4), and one tetraploid whole-plant sample (GP5) were obtained and prepared following the published protocol.[20] To obtain the extracts, 2 g of ground ER leaves was weighed, added to 200 mL of water, and set in an 80 °C water bath for 15 min to simulate the tea-making procedure. Next, samples were filtered and freeze-dried. Five grams of pulverized GP dried leaves was weighed and extracted in pure methanol for 6 h using a Soxhlet apparatus. The sample solutions were filtered through a 0.45 μm membrane filter, and methanol was vaporized using gas nitrogen as described.[20]

**Enzyme Digestion Procedure.** Digestion reaction was performed in a 10 mL total volume containing 400 μg/mL of ER or GP samples and 400 μg/mL hesperidinase in either acetic acid−sodium acetate buffer (10 mM, pH 5.0) or HPLC grade water at 37 °C for 2 h. The enzyme was then inactivated at 80 °C in a water bath for 3 min. Digested samples were filtered by a 0.2 μm membrane filter, freeze-dried, and redissolved in 500 μL of DMSO for subsequent HPLC analysis or cell-based studies.

**Analysis of Astilbin, Engeletin, and Their Enzymatic Metabolites Taxifolin and Dihydrokaempferol in ER by HPLC.** Astilbin and engeletin, as well as their metabolites taxifolin and dihydrokaempferol, were identified using an HPLC-DAD method. ER extract before or after hydrolysis dissolved in DMSO was analyzed using a Shimadzu LC-20AD with an autosampler plus a C18, 250 × 4.6 mm, 5 μm column at 35 °C. The flow rate was kept at 1 mL/min. A binary gradient system was used with mobile phase A consisting of acetonitrile and mobile phase B consisting of 0.1% acetic acid in water. At 0−2 min, the constitution of mobile phase A was increased from 16 to 20% (linearly), then at 2−12 min increased from 20 to 40%, at 12−16 min increased from 40 to 90%, and at 16−19.5 min decreased from 90 to 16%. The wavelength for UV−vis detection was set at 290 nm. All of the flavonoids in ER were identified via comparison to the standards for retention time and UV spectrum, and the amount of flavonoids was compared via the area under the peaks.

Conversion rate was calculated by using the following formula:

$$\text{conversion rate} = \frac{\text{area under the peak of digested}}{\text{area under the peak of undigested}} \times 100\%$$

**Cytotoxicity Test of ER before and after Digestion in HepG2/C3A Cell Line.** Cell viability test was conducted using ATPlite assay[27] according to the manufacturer's protocol (PerkinElmer Life and Analytical Sciences). Briefly, $6 \times 10^4$ cells per well of HepG2 human hepatoma cells were plated into 96-well plates in Williams' medium E at 37 °C with 5% $CO_2$. After 24 h, culture medium was aspirated and 100 μL of control medium and medium containing 62.5, 125, or 250 μM ER before and after hesperidinase digestion was added to different wells. After 24 h of treatment, 100 μL of reconstituted ATPlite solution was added to each well, and luminescence was read using a Victor[3] multiwell plate reader (PerkinElmer) immediately. Experiments were conducted in triplicate.

**Cell-Based Antioxidant Activities.** Cell-based antioxidant assays were performed according to Wolfe's protocol.[28] Briefly, HepG2/C3A, $6 \times 10^4$ cells per well, was seeded in 96-well plates and kept in a 37 °C incubator with 5% $CO_2$. After 24 h, culture medium was removed and replaced with medium containing test extracts/compounds. After 24 h of pretreatment, the medium was removed and the cells were washed with prewarmed HBSS. HepG2/C3A cells were then treated with the extracts and 25 μM DCFHDA for 1 h. Next, 100 μL of 37 °C 600 μM ABAP was added to the cells. Fluorescence was read in 5 min intervals for 1 h with emission at 538 nm and excitation at 485 nm at 37 °C. Cell-based antioxidant activities of samples were expressed as micromoles of quercetin per gram of dried ER leaves.

**Effects of Enzymatic Digestion on Anti-inflammatory Properties of ER in Mouse J774A.1 Macrophages, Human THP-1 Monocytes, Human THP-1 Macrophages, and Xenobiotic Metabolism Activities of ER in Human THP-1 Monocytes.** The effects of enzymatic digestion on inflammatory response were first evaluated in mouse macrophage J774A.1, a cell line widely used for inflammation studies and anti-inflammation investigation.[29] A 2 mL cell suspension of J774A.1 ($7.5 \times 10^4$/mL) was seeded in a 6-well plate overnight in DMEM with 10% FBS and 1% antibiotic−antimycotic and reached 80% confluence at 37 °C with 5% $CO_2$.

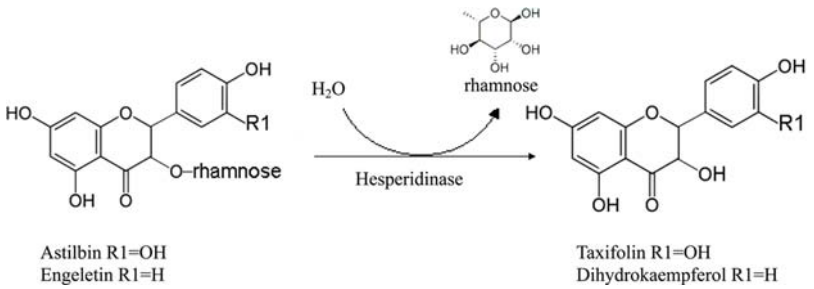

**Figure 1.** Transformation of major components in ER using hesperidinase.

For human THP-1 monocytes, 2 mL of cells ($2.5 \times 10^5$ cells/mL) was plated in 6-well plates in RPMI medium with 10% FBS and 1% antibiotic–antimycotic at 37 °C with 5% $CO_2$.

To prepare differentiated human THP-1 macrophages, 2 mL of human THP-1 monocytes ($5 \times 10^5$ cells/mL) with the differentiating agent PMA (25 ng/mL)[30] was plated in 6-well plates in RPMI medium with 10% FBS and 1% antibiotic–antimycotic at 37 °C with 5% $CO_2$ for 48 h until cells were all localized and attached to the plate. Treatments were initiated after this incubation.

Concentrations of 0, 10, and 25 $\mu$M (calibrated by the average molecular weight of two main components) of ER samples before and after digestion dissolved in DMSO solution were used for anti-inflammatory studies. Treatment was started 24 h after cell plating, and the treatment medium was replaced every 24 h by fresh medium containing the extract. After 48 h of treatment, lipopolysaccharide (LPS) was added at the concentration of 10 ng/mL for 4 h. mRNA isolation, cDNA synthesis, and real-time PCR were conducted according to our previously published protocol.[29,31] TATA-binding protein (Tbp) mRNA was used as housekeeping gene for normalization. TaqMan Assay-On-Demand gene expression assays were obtained from Applied Biosystems: Tbp (Mm00446973_m1; Hs00427620_m1), IL-1$\beta$ (Mm01336189_m1; Hs01555410_m1), IL-6 (Mm00446190_m1; Hs00985639_ml), and CYP1B1 (Hs02382916_s1). The amplification parameters were set as follows for PCR: 50 °C for 2 min, 95 °C for 10 min, and 46 cycles of amplification at 95 °C for 15 s and 60 °C for 1 min.

**Statistical Analysis.** Tests were conducted in triplicate, and data are reported as means ± standard deviation. The significance level of differences in means was analyzed using one-way ANOVA and Tukey's test. Statistics software SPSS for Windows (version rel. 10.0.1, 1999, SPSS Inc., Somers, NY, USA) was used. Statistical significance was defined at $P \leq 0.05$.

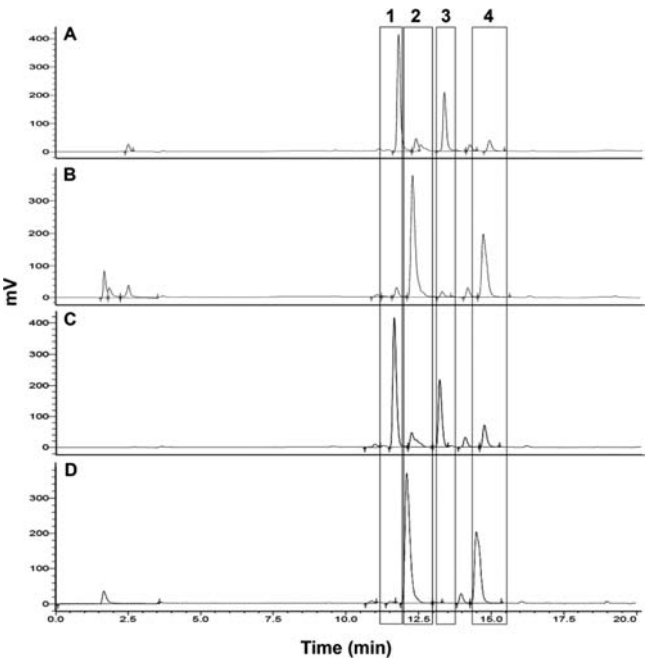

**Figure 2.** HPLC analysis of components of ER water extracts before and after 2 h of enzymatic digestion by hesperidinase from *Penicillium* sp.: (A) ER before digestion in buffer system; (B) ER after digestion in buffer system; (C) ER before enzymatic digestion in water system; (D) ER after enzymatic digestion in water system. Components in ER: (1) astilbin; (2) taxifolin; (3) engeletin; (4) dihydrokaempferol.

## RESULTS

**Effects of Hesperidinase Digestion on ER Extract.** As previously reported, ER extract contains a relatively simple array of two major compounds, astilbin and engeletin (Figure 1).[19] Therefore, we used ER extract to test the utility of hesperidinase treatments. The enzyme activity of hesperidinase was tested in two systems, a sodium acetate (NaAc) buffer system and a water system. The NaAc system was selected to mimic the colonic pH of ~5.0. The water system was chosen for its simplicity, as no additional components in the solvent after removal will affect subsequent bioactivity assays. On the basis of the preliminary optimization trials (data not shown), 400 $\mu$g/mL of ER extract and 400 $\mu$g/mL of hesperidinase were selected for the efficiency of glycosides hydrolysis. Compositions of ER extract in buffer system before and after enzymatic digestion were compared in the HPLC analysis. As illustrated in Figure 2, four major peaks were detected exclusively before and after digestion. Peaks designated 1–4 represent astilbin, taxifolin, engeletin, and dihydrokaempferol (retention times of 11.55, 12.12, 13.08, and 14.51 min), respectively. In NaAc-buffered condition (Figure 2A,B), rhamnosides astilbin and engeletin were efficiently degraded after digestion. Their aglycones, taxifolin and dihydrokaempferol, were the major components observed after hydrolysis (Figure 2B). The results of the water system as shown in Figure 2C,D were identical to those of the buffered system. The 400 $\mu$g/mL extracts with 400 $\mu$g/mL hesperidinase were selected for subsequent experiments.

Both the NaAc-buffered system and water system were further characterized to compare their effects on the efficiency of hesperidinase to catalyze the hydrolysis of naturally occurring flavonoids. For the buffered system, 10 mM sodium acetate was used and the pH was adjusted to 5.0. In the water system, the pH remained at 7.0 during the 2 h of enzymatic digestion. As illustrated in Figure 3, the hydrolysis rates of astilbin and engeletin for buffered and water systems were 92 and 97%, respectively. In the water system, the conversion was comparable to or even slightly higher than that in the buffered system. These results indicated that the $\alpha$-L-rhamnosidase processing ability was not affected by the pH ranging from 5.0 to 7.0 at 37 °C after 2 h of incubation. These results also indicated that the water system might be a simple, convenient

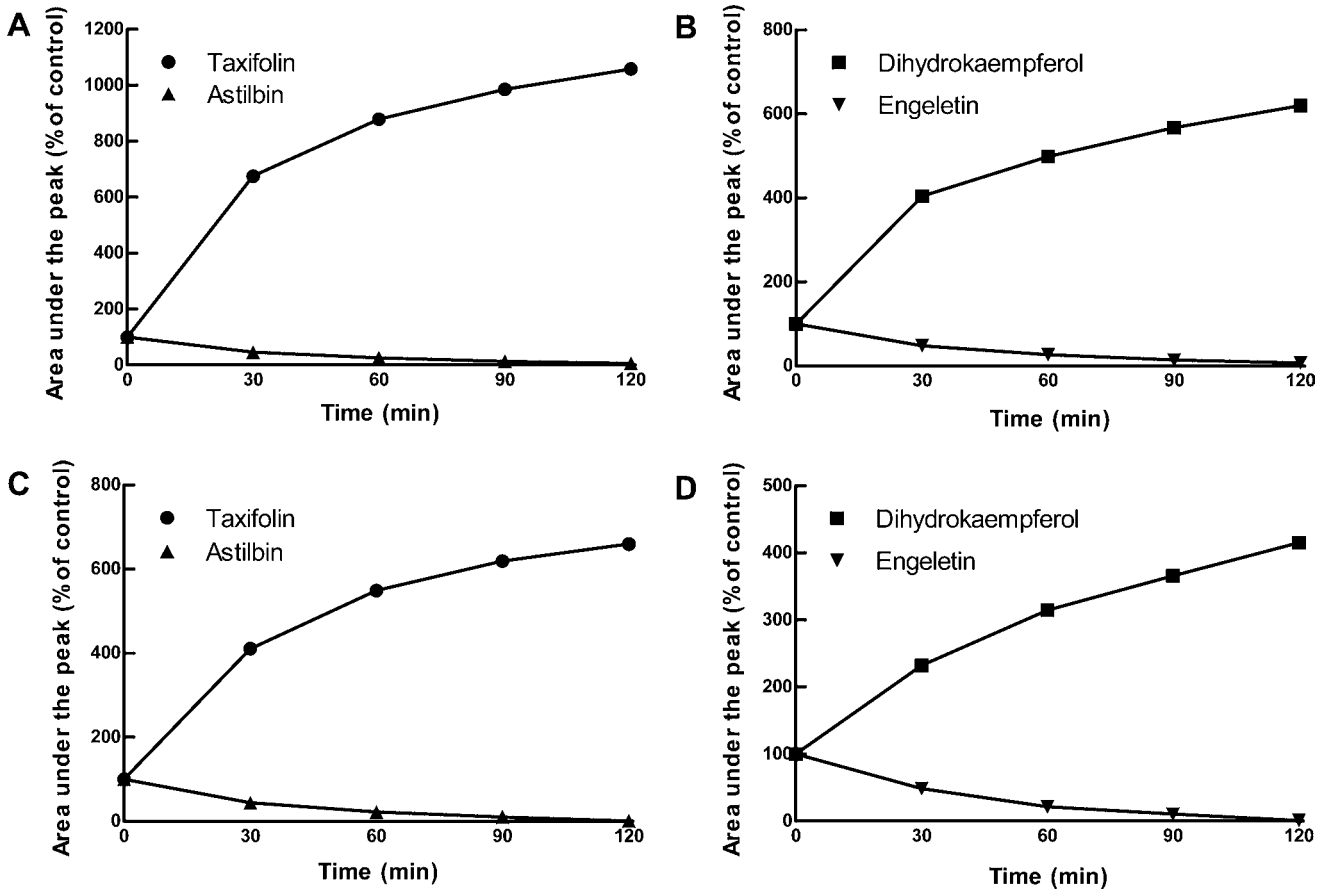

**Figure 3.** Comparison of the conversion rates of astilbin and engeletin to their hydrolyates taxifolin and dihydrokaempferol by hesperidinase treatment of ER extract during 2 h. Conversion rates of glycosides and aglycones were expressed as percent of the control: (A) astilbin and taxifolin in buffer; (B) engeletin and dihydrokaempferol in buffer; (C) astilbin and taxifolin in water; (D) engeletin and dihydrokaempferol in water.

condition for hesperidinase processing of extract in vitro. Therefore, the water assay system was used for the subsequent experiments.

**Analysis of Cytotoxicity and Cellular Antioxidant Activity of ER Water Extracts before and after Enzymatic Digestion in HepG2/C3A Cell Line.** We first examined the effect of ER extracts on cytotoxicity as a global end point. As shown in Figure 4A, concentrations up to 250 $\mu$M were nontoxic to HepG2 cells. Furthermore, digestion did not affect the cytotoxicity of ER extract as no changes in the proliferation index were observed. The effect of digestion on antioxidant properties of extracts using the cellular antioxidant activity assay (CAA) was examined, as flavanoids are known to possess antioxidant properties. A 250 $\mu$M ER water extract was used for CAA on the basis of cytotoxicity data. As illustrated in Figure 4B, after the digestion, the antioxidant activity of the ER extract increased from 14.23 to 24.99 $\mu$mol quercetin equivalents/g dried ER leaves. The enzymatic digestion of ER significantly enhanced its antioxidant capacity by ~2-fold.

**Anti-inflammatory Effects of ER before and after Digestion.** Exposure of monocyte/macrophage to LPS mimics the response of inflammation in vitro by the induction of inflammation-related cytokines such as interleukin-1$\beta$ (IL-1$\beta$), IL-6, and tumor necrosis factor-$\alpha$ (TNF-$\alpha$). Hence, we examined the response of monocyte/macrophage to LPS to assess the effects of enzymatic digestion on inflammation. As shown in Figure 5, the mRNA level of both IL-1$\beta$ and IL-6 in mouse J774A.1 cell line was increased by LPS stimulation.

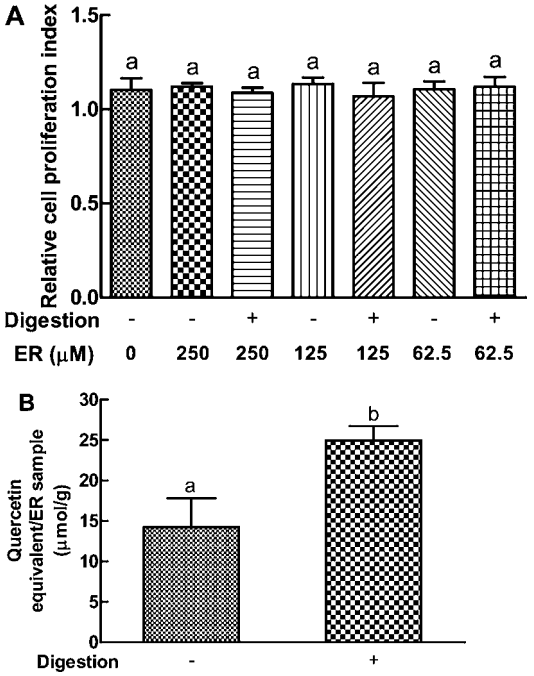

**Figure 4.** (A) Cytotoxicity and (B) cellular antioxidant capacity of ER water extracts before and after digestion in HepG2/C3A cell line. Each column represents the mean ± SD ($n$ = 3). Columns marked by different letters are significantly different from each other ($P \leq 0.05$).

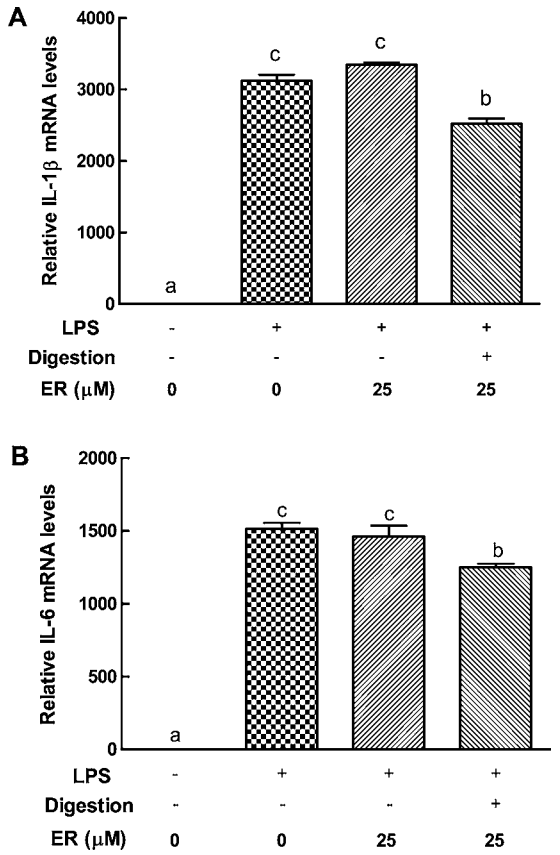

**Figure 5.** Anti-inflammation study of ER before and after digestion in mouse macrophage J774A.1 cell line: (A) IL-1$\beta$ expression; (B) IL-6 expression. Each column represents the mean ± SD ($n$ = 3). Columns marked by different letters are significantly different from each other ($P \leq 0.05$).

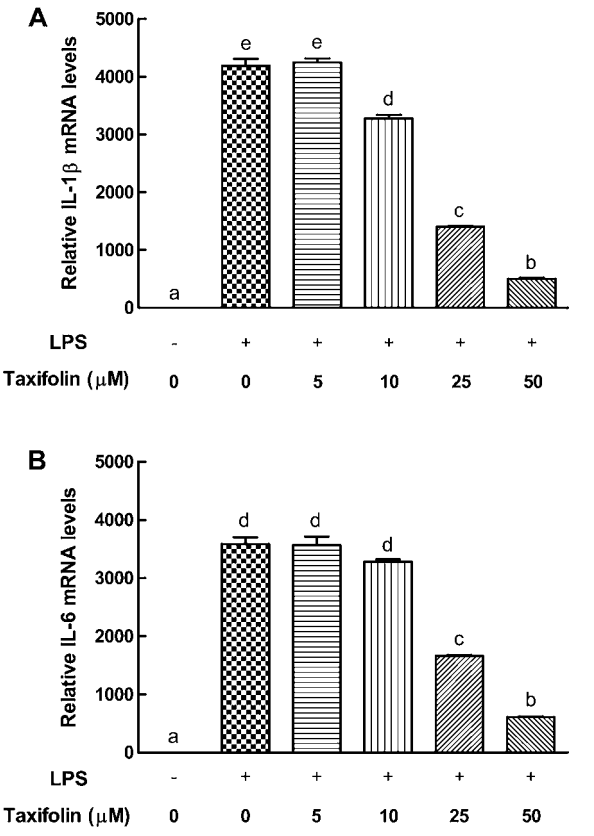

**Figure 6.** Anti-inflammation study of taxifolin in mouse macrophage J774A.1 cell line: (A) IL-1$\beta$ expression; (B) IL-6 expression. Each column represents the mean ± SD ($n$ = 3). Columns marked by different letters are significantly different from each other ($P \leq 0.05$).

Enzymatically digested extract (25 $\mu$M) exhibited significantly higher inhibitory effects on LPS induction of IL-1$\beta$ and IL-6 mRNA than that before digestion. The inhibitions of IL-1$\beta$ and IL-6 mRNA expression by 25 $\mu$M digested ER extract were 24.67 and 14.38%, respectively. As illustrated in Figure 6, elevated taxifolin concentrations resulted in greater IL-1$\beta$ and IL-6 mRNA down-regulation.

The anti-inflammatory effects of ER before and after hesperidinase digestion in human THP-1 monocytes and PMA differentiated THP-1 macrophage were also examined. Phorbol 12-myristate 13-acetate (PMA) was added to THP-1 cells to induce differentiation into adherent macrophage-like cells.[30] Consistent with the results found in mouse macrophage, 25 $\mu$M ER after digestion exhibited significantly higher capacity to inhibit the mRNA level of IL-1$\beta$ and IL-6 (Figure 7). Additionally, significant inhibition of IL-1$\beta$ was also observed in differentiated THP-1 macrophages (Figure 8).

**Enzymatic Digestion Effects on Xenobiotic Activities by ER before and after Digestion in Human THP-1 Monocytes.** Cytochrome P450 1B1 (CYP1B1) is a member of the CYP 1 gene family that metabolizes xenobiotics and carcinogens.[32] As illustrated in Figure 9, digestion led to an induction of CYP1B1 in human THP-1 monocytes. Furthermore, stimulation of THP-1 cells by LPS inhibited CYP1B1 mRNA expression, and treatment with digested ER extract reversed the effects of LPS and increased the mRNA of CYP1B1 to the control level.

**Cellular Antioxidant Activity of Five GP Species before and after Enzymatic Digestion in HepG2/C3A Cell Line.** We further tested our water digestion system in a more complex extract system to see if enzyme digestion may affect biological activities of the extracts. Five extracts from diploid and tetraploid GP leaves and whole plant were used to undergo the same digestion process by hesperidinase. The cellular antioxidant activities were determined. As illustrated in Figure 10, the digestion process altered the biological efficacies of the samples. Digestion increased the antioxidant capacity of GP1 by >2-fold. The antioxidant ability of GP2 was decreased after enzymatic treatment. GP3 and GP4 did not show significant changes of cellular antioxidant properties before and after digestion, whereas GP5 increased the oxidative level after digestion.

## DISCUSSION

Microbial-derived enzymes contribute significantly to flavonoid processing in the colon. This process occurs naturally in the human body, which might cause changes to the bioactivities of flavonoids. Our study focused on mimicking the colonic enzymatic digestion of flavonoid-rich botanicals to reveal their physiological bioactivities using commercially available hesperidinase. The use of enzyme hesperidinase sufficiently cleaved the rhamnose groups from astilbin and engeletin in both buffer and water systems at 37 °C, with hydrolysis rates of 92 and 97%, respectively (Figure 3). High efficiency in the water system is especially attractive because it allows for minimal manipulation and once removed, as in our case by

dx.doi.org/10.1021/jf501963a | J. Agric. Food Chem. 2014, 62, 8640−8647

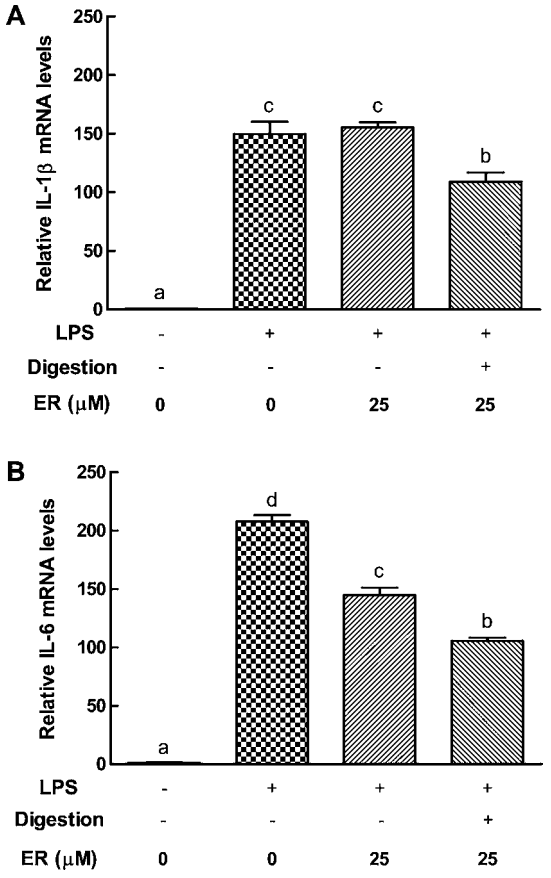

**Figure 7.** Anti-inflammation study of ER before and after digestion in human monocyte THP-1 cell line: (A) IL-1$\beta$ expression; (B) IL-6 expression. lyophilization, should not affect subsequent biological activity. The efficiency of hesperidinase on the digestion of ER (Figure 2) supported the selectivity of the enzyme on removal of $\alpha$-L-rhamnose sugar groups in flavonoids and the use of commercially available hesperidinase from *Penicillium* sp. to simulate the enzymatic digestion of flavonoids in the gut. The composition of ER is comparably simple as it contains only two major components, astilbin and engeletin. However, most of the botanicals might consist of far more complex compositions, and how they could be digested and affect human health will need further investigation. For example, the GP extracts we studied contain 40 different compounds that vary with ploidies and parts of the plant.[19] Some of the identified components are known as quercetin-di(rhamno)hexoside, kaempferol 3-*O*-di-*p*-coumaroylhexoside, kaempferol 3-*O*-di-*p*-coumaroylhexoside, quercetin-rhamnohexoside, rutin, kaempferol-rhamnohexoside, kaempferol-3-*O*-rutinoside, quercetin, and kaempferol.[19] As listed, most phytochemicals in GP are glycosides. Our assay of hesperidinase digestion efficiently processed this complex mixture (Figure 10), suggesting that the hesperidinase was able to remove rhamnose and glucose from glycosides, although further authentication is necessary.

As hypothesized, enzymatic processing altered the biological activity of an extract. The cellular antioxidant activity of the ER water extract was nearly doubled after the digestion process when compared to the undigested extract (Figure 4). The smaller and less polar chemical structures of taxifolin and dihydrokaempferol were likely to result in stronger ROS inhibition after digestion, because it would be easier for these compounds to migrate through cell membranes. Inflammation has been reported to be a critical component associated with the development of chronic diseases including cancer, obesity, heart disease, and others.[33−35] Inhibitory effects on pro-inflammatory cytokines IL-1$\beta$ and IL-6 were elevated in both mouse macrophage J774A.1 cells and human THP-1 monocytes when ER extracts went through digestion (Figures 5, 7, and 8). Additionally, ER extract after digestion also up-regulated the mRNA level of the xenobiotic enzyme CYP1B1 in human THP-1 monocytes, whereas undigested extract did not affect CYP1B1 expression, indicating that digested extract might be more efficient in getting into the cells. The enzymatic digestion process therefore might increase the metabolizing capacity of toxic or carcinogenic compounds. Moreover, the expression of CYP1B1 was found inversely correlated with inflammatory activity. Our results indicated that the removal of rhamnose might be important for the biological efficacies of ER extract. The digestion also accounted for significant changes in the biological efficacies of the GP extracts. The effects varied among the extracts (Figure 10). In some cases, digestion of GP extracts (for example, diploid GP1 and tetraploid GP5; Figure 10) led to significant alteration in antioxidant activity. These results further supported the value of our hesperidinase treatment procedures as the physiologically relevant properties

of an extract may depend on the release of aglycones. It is also indicated that how food is processed in the colon might affect its biological activity. Hence, the consideration of enzyme processing during the screening of extracts is important.

In summary, the current study demonstrated the utility of commercially available hesperidinase from *Penicillium* sp. in simulating colonic processing of phytochemicals in vitro. We determined that a simple water system can be used for enzymatic digestion on the basis of the conversion rate of flavonoid glycosides to their aglycones. More importantly, we showed that digestion can result in the alteration of biological properties of an extract such as anti-inflammation property, antioxidant ability, and xenobiotic metabolizing potential. These results suggest that colonic enzymatic processing during food digestion alters the structure of food components and changes of their biofunctions, which may ultimately lead to different health-promoting effects in human. We recommend incorporating this simple enzymatic digestion step into functional food research studies of the biological efficacies in health promotion and disease prevention of foods.

College of Light Industry and Food Sciences, South China University of Technology, Guangzhou 510640, China

**ABSTRACT:** The intracellular antioxidant activities of diosmetin were evaluated by cellular antioxidant activity (CAA) assay, 2,2-azobis(2-amidinopropane) dihydrochloride (AAPH)-induced erythrocyte hemolysis assay and cupric chloride ($CuCl_2$)-induced plasma oxidation assay. The results showed that diosmetin exhibits strong cellular antioxidant activity ($EC_{50}$ = 7.98 $\mu$mol, CAA value = 58 $\mu$mol QE/100 $\mu$mol). It was also found that diosmetin treatment could effectively attenuate AAPH-induced erythrocyte hemolysis (91.0% inhibition at 100 $\mu$g/mL) and $CuCl_2$-induced plasma oxidation through inhibition of intracellular reactive oxygen species (ROS) generation. Diosmetin could significantly restore AAPH-induced increase of intracelluar antioxidant enzyme (SOD, GPx, and CAT) activities to normal levels, as well as inhibit intracellular malondialdehyde (MDA) formation. Thus, the intracellular antioxidant detoxifying mechanism of diosmetin is associated with both nonenzymatic and enzymatic defense systems.

**KEYWORDS:** *diosmetin, cellular antioxidant activity, oxidative hemolysis, plasma oxidation*

## INTRODUCTION

Diosmetin (3′,5,7-trihydroxy-4′-methoxyflavone) is bioflavonoid found in citrus fruits, spearmint, and legume leaves[1] that has antibacterial activity against *Helicobacter pylori*(1),[2] *Staphylococcus aureus*,[3] and *Bacillus subtilis*.[4] In addition, diosmetin also exhibits antimutagenic, antioxidant, and anti-inflammatory activities.[5,6] Recent evidence had revealed that diosmetin possessed immunoregulating activity; for example, it could modulate macrophage colony-stimulating factor (M-CSF) induced proliferation and reduced the production of transforming growth factor beta 1 (TGF-$\beta$1), interleukin-10 (IL-10), and tumor necrosis factor alpha (TNF-$\alpha$) in mouse macrophages.[7] Other studies in cancer cell lines and animal models indicated that diosmetin had strong cancer chemopreventive and antiproliferative abilities.[8−12] The latest study also demonstrated that diosmetin could significantly enhance adenosine triphosphate (ATP) levels in liver and kidney cells.[13]

One factor underlying the pathology of many diseases, including cancer, diabetes, and coronary artery disease, is an increase in oxidative stress;[14−16] this suggests that the numerous beneficial properties of diosmetin may be related to its antioxidant activity. However, although the extracellular antioxidant activity of diosmetin has been extensively studied, there is little information on its antioxidant properties within cells. This is significant because extracellular assays mostly rely on chemical methods that do not take the metabolism and bioavailability of antioxidants into account. Therefore, tests of diosmetin's intracellular antioxidant activity, which address issues of uptake, distribution, and metabolism, are urgently needed.

The cellular antioxidant activity (CAA) assay is a newly developed approach that quantifies the antioxidant capacity of bioactive compounds in cell cultures.[17] The CAA assay represents a marked improvement over traditional chemical antioxidant activity assays because it simulates cellular biochemical processes, including cellular uptake and metabolism. Therefore, the CAA assay should allow a better understanding of how antioxidants behave under physiological conditions. To date, little information about the evaluation of the antioxidant activity of diosmetin by CAA has been done.

One of the main causes of intracellular oxidation is the presence of reactive oxygen species (ROS); for example, ROS can react with unsaturated fatty acids in phospholipids to form lipid peroxides, leading to damage of the cell membrane. The production and destruction of ROS is normally maintained in a steady-state balance by inherent cellular defense systems, including enzymatic and nonenzymatic antioxidants.[18,19] However, oxidative stress will occur either when there is an excess of ROS or when the intrinsic defenses are damaged. In cell models, oxidative stress can be induced by many reagents, for example, 2,2-azobis(2-amidinopropane) dihydrochloride (AAPH).[20,21] Thus, an AAPH-induced erythrocyte hemolysis assay can visually reveal biologically relevant radical-scavenging ability by measuring ROS and malondialdehyde (MDA) levels, as well as activities of intracellular antioxidant enzyme activities (superoxide dismutase, SOD; glutathione peroxidase, GPx; and catalase, CAT). Up to now, little information about the protective effects of diosmetin on AAPH-induced erythrocyte hemolysis is available.

A variety of studies suggested that cupric chloride ($CuCl_2$) was a pro-oxidant agent, which could cause lipid oxidation.

Although copper (Cu) is an essential component of many enzymes and participates in various physiological processes, Cu releases from proteins can facilitate the formation of hydroxyl radicals and lead to lipid peroxidation.[22] Thus, the $CuCl_2$-induced plasma oxidation assay can be used as a biologically relevant method for evaluating the antioxidant capacity of bioactive compounds. In this research, the $CuCl_2$-induced plasma oxidation assay was first applied to investigate the intracellular antioxidant capacity of diosmetin.

In the present study, the intracellular antioxidant properties of diosmetin were investigated using the CAA, AAPH-induced erythrocyte hemolysis, and copper-induced plasma oxidation assays. The results showed that diosmetin exhibited potent antioxidant activity via both nonenzymatic and enzymatic mechanisms.

## MATERIALS AND METHODS

**Materials.** Diosmetin, AAPH, and 4-(2-hydroxyethyl)-1-piperazineethanesulfonic acid (HEPES) were purchased from Sigma Co. (St. Louis, MO, USA). An MDA kit was purchased from Nanjing Jiancheng Institute of Biotechnology (Jiangsu, China). Kits for the determination of SOD, cellular GPx, CAT, ROS, and bicinchoninic acid (BCA) were purchased from Beyotime Institute of Biotechnology (Shanghai, China). Dulbecco's modified Eagle's medium (DMEM), Hank's balanced salt solution (HBSS), and phosphate-buffered saline (PBS, pH 7.4) were obtained from Gibco Life Technologies (Grand Island, NY, USA). Human hepatocellular carcinoma (HepG2) cells were obtained from the Medical College of Sun Yat-Sen University (Guangzhou, China). Heat-inactivated fetal bovine serum (FBS) was purchased from Sijiqing Co. Ltd. (Hangzhou, China). Ultrapure water was obtained from a Milli-Q water purification system (Millipore, Bedford, MA, USA).

**CAA Assay.** *CAA of Diosmetin.* The intracellular antioxidant capacity of diosmetin was assessed using the CAA assay as described[16] with some modifications. Briefly, HepG2 cells were grown in DMEM with 10% FBS, 100 $\mu$g/mL streptomycin, and 100 units/mL penicillin.[23] During the logarithmic growth phase, cells ($6 \times 10^5$/mL) were seeded into a 96-well microplate (100 $\mu$L/well) and incubated for 24 h in a fully humidified atmosphere in a 5% $CO_2$, 37 °C incubator. The culture medium was then removed, and the cells were washed with 200 $\mu$L of PBS and incubated for an additional 2.5 h with medium that contained diosmetin and 2′,7′-dichlorofluorescein diacetate (DCFH-DA) (final concentration = 25 $\mu$M). The culture medium was then removed, and the cells were washed with 200 $\mu$L of PBS, after which 100 $\mu$L of new medium (HBSS plus 10 mM HEPES) containing 600 $\mu$M AAPH was added to each well. The 96-well microplate was placed in a Fluoroskan Ascent microplate fluorometer (Thermo Electron Corp., Vantaa, Finland), and the fluorescence was monitored every 5 min for 1 h (ex/em, 488/525 nm). Each plate included triplicate blank wells, which contained cells treated without oxidant.

*Quantification of CAA.* The blank and initial fluorescence values were subtracted, and the CAA value of each diosmetin concentration was calculated as the integration of the area below the curve of fluorescence versus time, according to the following equation:[24] CAA (units) = $1 - (\int SA/\int CA)$, where $\int SA$ is the integration of the area under the sample fluorescence versus time curve and $\int CA$ refers to the integration of the area under the control curve. The 50% effective concentration ($EC_{50}$) for diosmetin was determined from the median effect plot of $\log(f_a/f_u)$ versus log(dose), where $f_a$ is the effective fraction of the treatment (CAA units) and $f_u$ is the ineffective fraction (1 − CAA units) of the treatment. The $EC_{50}$ was presented as the mean ± SD and calculated for triplicate data sets. $EC_{50}$ values were expressed as micromoles of quercetin equivalents (QE) per 100 $\mu$mol of diosmetin; the $EC_{50}$ value for quercetin was obtained from four separate experiments.

**Assay for Erythrocyte Hemolysis Mediated by Peroxyl Free Radicals.** The intracellular antioxidant activity of diosmetin was evaluated as the inhibition of erythrocyte hemolysis based on the method described by Cheung et al.[25] with some modifications. Blood samples were collected from normal male adult volunteers under 30 years of age. Erythrocytes were separated from plasma by centrifugation at 1200*g* for 10 min at 4 °C and washed three times with PBS (pH 7.4). An aliquot of 0.2 mL of a 20% erythrocyte suspension in PBS was mixed with 0.2 mL of PBS (absorbance A) or diosmetin (absorbance B) at different concentrations. The mixture was incubated at 37 °C for 20 min with gentle shaking, after which 0.4 mL of 200 mM AAPH was added, and the incubation continued at the same temperature for another 2 h. Finally, the reaction solution was diluted with 8 mL of PBS and centrifuged at 1200*g* for 10 min at 4 °C. The absorbance of the supernatant was measured at 540 nm. To achieve complete hemolysis, 8 mL of ultrapure water was added to the mixture, which was then centrifuged at 1200*g* for 10 min at 4 °C, and the absorbance of the supernatant was determined at 540 nm. The percentage of hemolysis inhibition was calculated as

$$\%\ \text{hemolysis inhibition} = (1 - A/B) \times 100\%$$

where *A* refers to the absorbance A and *B* refers to absorbance B as metioned above.

**Plasma Oxidation Assay.** Plasma samples were obtained from blood by centrifugation at 1200*g* for 10 min at 4 °C and then diluted 40-fold with PBS and stored at 4 °C until use. Then 0.2 mL of plasma was mixed with 0.2 mL of PBS or diosmetin at different concentrations and incubated at 37 °C for 20 min with gentle shaking. Subequently, 0.4 mL of 200 $\mu$M $CuCl_2$ was added as oxidant and the incubation continued for another 2 h. Levels of conjugated dienes were determined every 10 min by measuring absorption at 245 nm.

**Scanning Electron Microscopy (SEM).** Erythrocyte imaging was carried out using a scanning electron microscope (Hitachi TM3000, Hitachi Ltd., Tokyo, Japan). A film consisting of a single layer of red blood cells was made by spreading the treated blood samples onto newly split mica and settled with 2.5% glutaraldehyde, after which the film was placed on the specimen holder and images of blood samples were acquired.

**Determination of Intracellular ROS Level.** A ROS assay kit with DCFH-DA as a fluorescent probe was used to determine the relative levels of intracellular ROS. Treated red blood cells were collected by centrifuging at 1200*g* for 10 min at 4 °C, washed three times with PBS, and then incubated at 37 °C for 20 min in the presence of 10 $\mu$M DCFH-DA. DCFH-DA is transformed to the fluorescent compound 2′,7′-dichlorofluorescin (DCF) within cells. The fluorescence intensity of cells was measured using a Fluoroskan Ascent microplate fluorometer (ex/em, 488/525 nm).

**MDA, GPx, SOD, and CAT Assays.** Red blood cells were collected and washed as described above. Cells were then resuspended in 600 $\mu$L of cold ultrapure water and stored at −80 °C before determination. A BCA protein assay kit and microscale MDA kit were used to monitor the protein and MDA contents, respectively. The Cellular Glutathione Peroxidase Kit, Total Superoxide Dismutase Assay Kit, and Catalase Assay Kit were used to measure the activities of GPx, SOD, and CAT according to the manufacturer's instructions.

**Statistics.** Experiments were carried out in triplicate, and all data are reported as the mean ± standard deviation (SD). The significant differences between the means of parameters were calculated by Duncan's multiple-range test ($p < 0.05$) using SPSS 17.0 software (SPSS, Inc., Chicago, IL, USA).

## RESULTS AND DISCUSSION

**Cellular Antioxidant Activity of Diosmetin.** The intracellular antioxidant activity of diosmetin was evaluated using the CAA assay, which was regarded as a more biologically relevant assay than commonly used chemical antioxidant activity assays.[26] For the CAA assay, the membrane-permeable intracellular probe DCFH-DA was deacetylated to DCFH by cellular esterases in HepG2 cells. DCFH was then trapped within the cells and oxidated by peroxyl radicals generated from

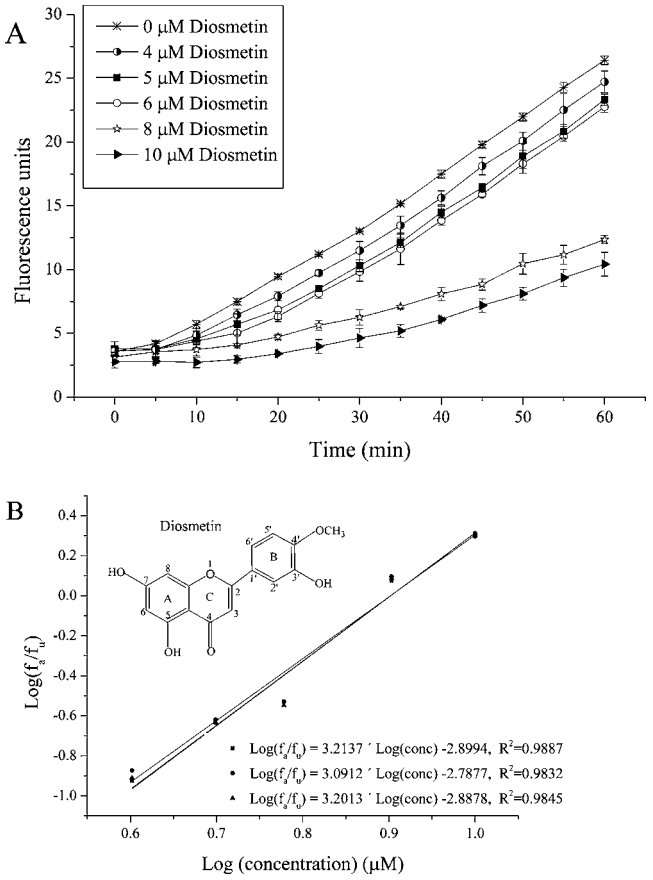

**Figure 1.** Inhibitory effects of diosmetin on peroxyl radical-induced oxidation of DCFH in HepG2 cells (A) and $EC_{50}$ plots for inhibition of peroxyl radical-induced DCFH oxidation by diosmetin (B).

[b]QE, quercetin equivalents.

AAPH to form a fluorescent substance, DCF. The level of fluorescence was proportional to the degree of oxidation. The reduction of cellular fluorescence compared to the control group indicates the antioxidant activity of the tested samples.[27−29]

The kinetics of DCFH oxidation induced by AAPH are shown in Figure 1A. It was found that diosmetin significantly inhibited this oxidation process in a dose-dependent manner as indicated by the obvious decrease of the fluorescence level. The $EC_{50}$ for the inhibitory action of diosmetin on DCFH oxidation was calculated from the median effect curve plotted for each concentration (Figure 1B). On the basis of the fitting curves, the CAA value of diosmetin was determined (Table 1). Quercetin was used as a standard, as it has already been shown previously to have high CAA capacity compared to other

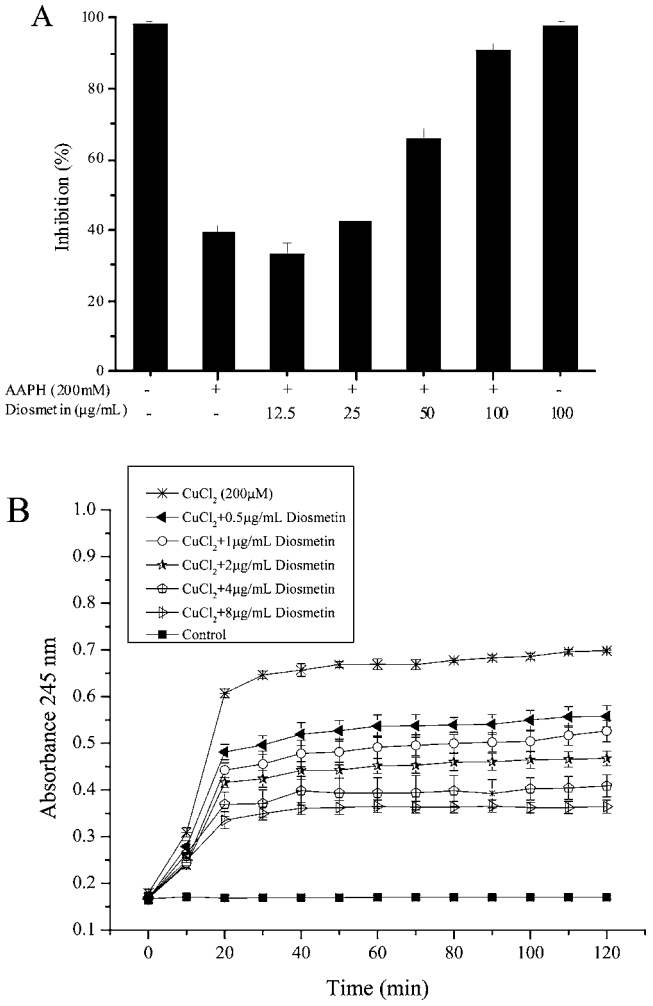

**Figure 2.** Protective effects of diosmetin on AAPH-induced erythrocyte hemolysis assay (A) and $CuCl_2$-induced accumulation of conjugated dienes in plasma (B). Erythrocytes were pretreated with different concentrations (12.5−100 μg/mL) of diosmetin for 25 min prior to AAPH (200 mM) treatment for 2 h; the positive group was treated with 200 mM AAPH only. Plasma was pretreated with different concentrations (0.5−8 μg/mL) of diosmetin for 10 min prior to $CuCl_2$ (200 μM) treatment for 2 h. The positive group was treated with 200 μM $CuCl_2$ only.

known phytochemicals such as kaempferol, myricetin, epigallocatechin gallate (EGCG) and luteolin.[16]

The $EC_{50}$ value of diosmetin was 7.98 ± 0.20 μmol, and the CAA value of diosmetin was 58.0 ± 0.02 μmol QE/100 μmol diosmetin, which is higher than those of EGCG (33.1 ± 1.0 μmol of QE/100 μmol), myricetin (36.8 ± 3.8 μmol of QE/100 μmol), and luteolin (32.3 ± 0.9 μmol of QE/100 μmol), and lower than that of only kaempferol (81.1 ± 2.7 μmol of QE/100 μmol), as reported by Wolfe et al.,[17] indicating that diosmetin had strong cellular antioxidant activity. This high activity probably results from the chemical structure of the diosmetin molecule (Figure 1B). It has three hydroxyl groups, one each attached to C3′, C5, and C7. Of these, the hydroxyl group attached to C3′ has the most positive effect on the free radical scavenging activity of diosmetin.[30] The 2,3-double bond conjugated with a 4-oxo group in the C ring of diosmetin also contributes significant activity against oxidation by $H_2O_2$.[29]

**Attenuation of Erythrocyte Hemolysis and Plasma Oxidation by Diosmetin.** The antioxidant ability of

dx.doi.org/10.1021/jf502359x | J. Agric. Food Chem. 2014, 62, 8648−8654

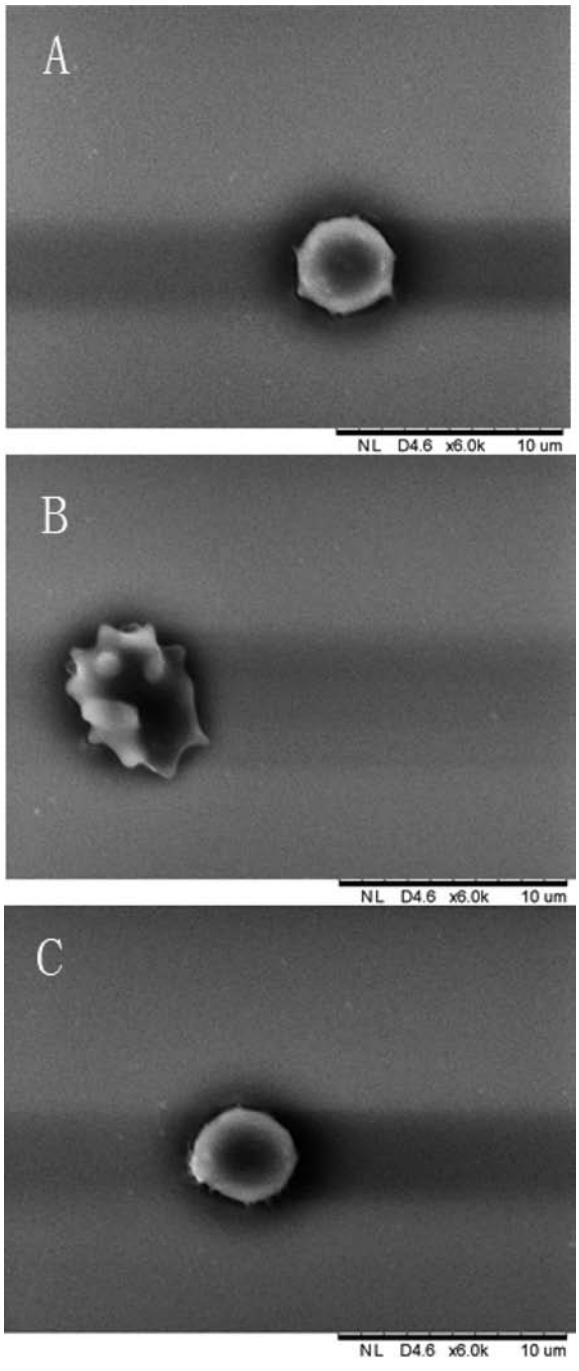

**Figure 3.** SEM micrographs of erythrocyte samples: (A) normal erythrocyte; (B) AAPH-treated erythrocyte; (C) erythrocyte pre-incubated with diosmetin prior to AAPH treatment.

diosmetin was further examined using erythrocyte hemolysis and plasma oxidation assays. In the erythrocyte hemolysis assay, AAPH, which can decompose at 37 °C to generate an alkyl radical, is used as an initiator. In the presence of oxygen, these alkyl radicals will be converted to peroxyl radicals that can cause lipid peroxidation and loss of erythrocyte membrane integrity, which could ultimately lead to hemolysis. Therefore, the rate of inhibition of hemolysis is an indirect way to measure the antioxidant activity of diosmetin. As shown in Figure 2A, erythrocyte hemolysis induced by AAPH was effectively attenuated by diosmetin in a dose-dependent manner: the inhibition rate was enhanced as diosmetin concentration

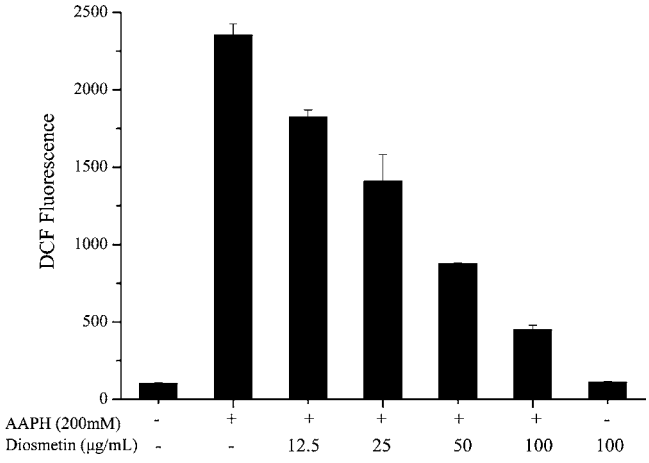

**Figure 4.** Inhibitory activity of diosmetin on AAPH-induced ROS overexpression in human erythrocytes. Erythrocytes were pretreated with different concentrations (12.5−100 μg/mL) of diosmetin for 30 min prior to AAPH (200 mM) treatment for 2 h; the positive group was treated with 200 mM AAPH only.

increased from 0 to 100 μg/mL. At a dose of 100 μg/mL, the inhibition rate of diosmetin on erythrocyte hemolysis was 91.0%, which was comparable to that of vitamin C, a well-known antioxidant with an inhibition rate of 96.9% at 1 mg/mL (data not shown).

Using SEM, we examined the morphological effect of oxidation on the red cell membranes with or without the addition of diosmetin. The normal biconcave discoid shape of erythrocytes can be clearly seen in Figure 3A. After treatment with AAPH, the erythrocyte lost its normal profile and showed a spiny configuration on its surface due to the severe damage of the cell membrane (Figure 3B). However, this damage was dramatically reduced in cells pretreated with 100 μg/mL diosmetin before the addition of AAPH (Figure 3C). This result confirmed the protective effect of diosmetin on AAPH-induced morphological changes in the red cell.

Lipoprotein oxidation in plasma has great pathological significance on atherosclerosis and hyperlipemia. Oxidation of low-density lipoprotein (LDL) is thought to be a great contributing factor to the development of atherosclerosis, whereas oxidation of high-density lipoprotein (HDL) may lead to hypercholesterolemia.[31] In a further test of the antioxidant activity of diosmetin, we used the plasma oxidation assay, where plasma is treated with $CuCl_2$, which can induce the formation of conjugated dienes. As shown in Figure 2B, the concentration of conjugated dienes increases over time. Diene accumulation, a hallmark of lipid peroxidation, was induced when plasma was treated with 200 μM copper(II) ions, as indicated by the high absorbance value at 245 nm. Diosmetin at different concentrations (0.5, 1.0, 2.0, 4.0, and 8.0 μg/mL) could significantly decrease copper-induced diene accumulation, which showed indirect protection of plasma from oxidative damage. Again, dose dependence could be demonstrated.

**Diosmetin Inhibits AAPH-Induced ROS Generation in Erythrocytes.** The antioxidant protection of erythrocytes by diosmetin is considered to be due to its effect on intracellular ROS generation.[32] To further test this, intracellular ROS generation was quantified using DCFH-DA, a fluorescein-labeled dye that can cross the plasma membrane into the cytoplasm, where it is hydrolyzed by nonspecific esterases to nonfluorescent DCFH. In the presence of ROS, DCFH is

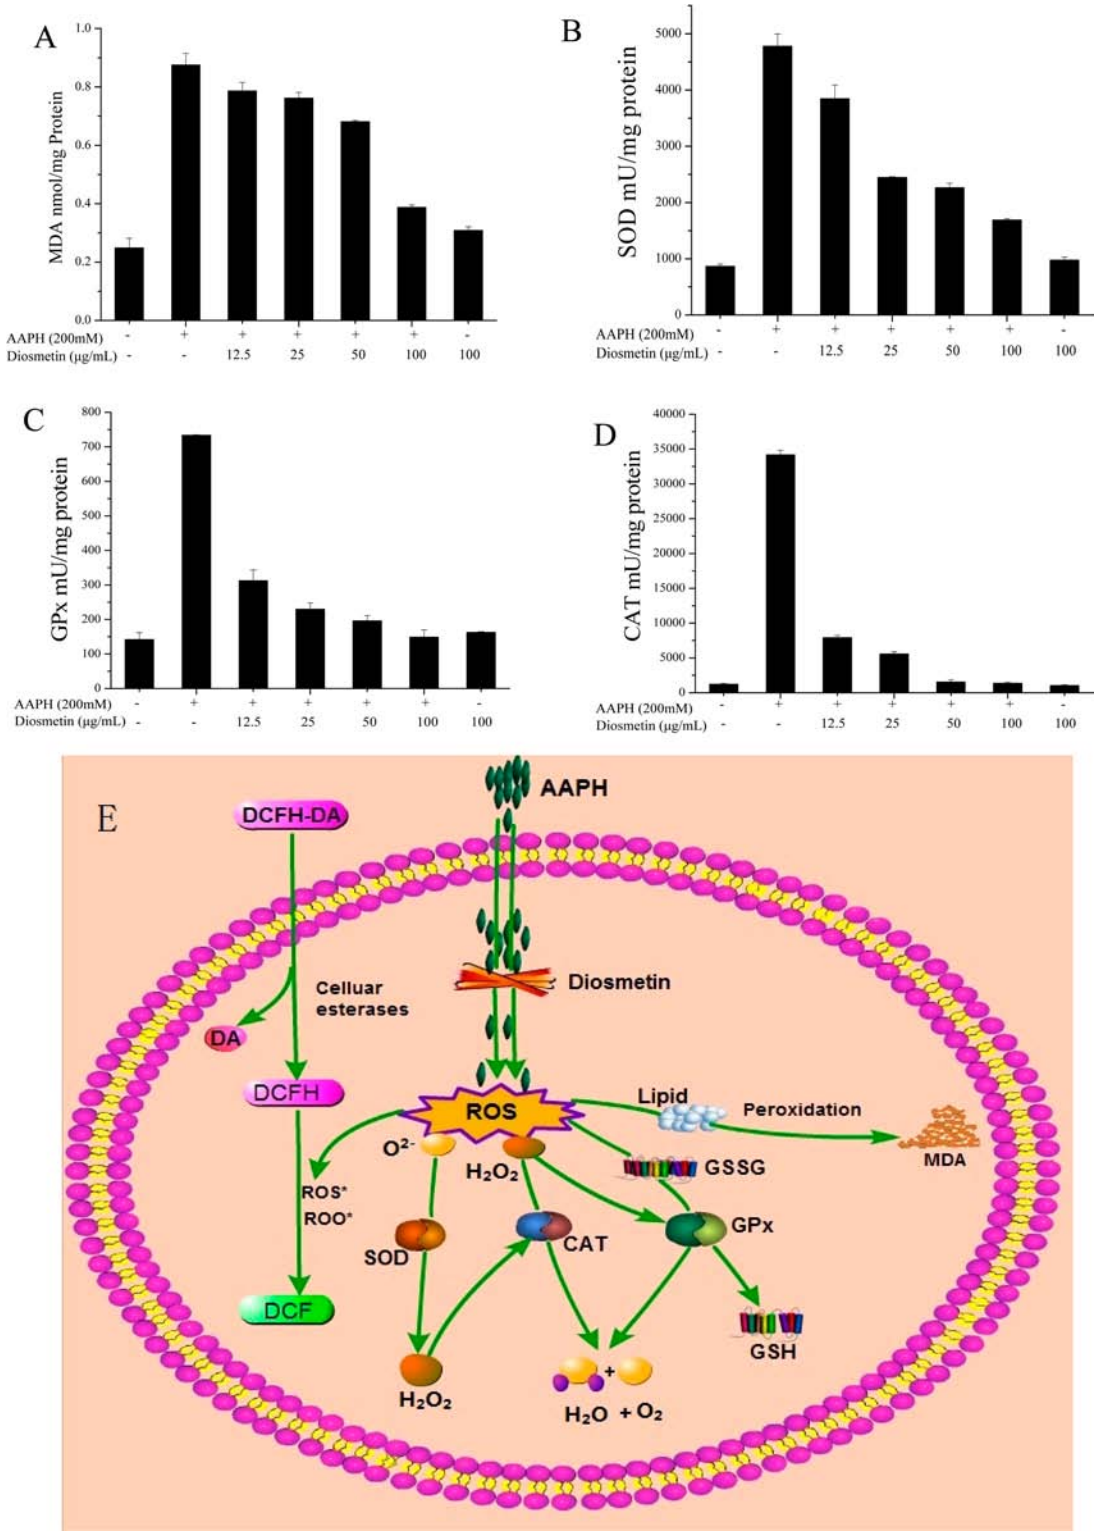

**Figure 5.** Changes in MDA content (A) and enzyme activities of SOD (B), GPx (C), and CAT (D) in erythrocytes. Erythrocytes were pretreated with different concentrations (12.5−100 μg/mL) of diosmetin for 30 min prior to AAPH (200 mM) treatment for 2 h; the positive group was treated with 200 mM AAPH only. (E) Possible intracellular antioxidant detoxifying mechanisms of diosmetin that attenuate AAPH-induced oxidative stress through inhibition of ROS generation.

oxidized to DCF, a highly fluorescent compound. Therefore, inhibition by diosmetin of AAPH-induced ROS generation can be measured by the ability of the diosmetin to prevent the oxidation of DCFH and, as a result, the formation of DCF. As shown in Figure 4, the DCF fluorescence intensity of erythrocytes exposed to AAPH (200 mM) was much higher than that of the control, demonstrating that AAPH treatment produced a large amount of ROS. However, cells pretreated with diosmetin (12.5, 25, 50, and 100 μg/mL) exhibited apparently lower DCF fluorescence intensity in a dose-

dx.doi.org/10.1021/jf502359x | J. Agric. Food Chem. 2014, 62, 8648−8654

dependent manner, indicating that diosmetin inhibited ROS generation. As a control, cells treated with diosmetin without AAPH addition did not show significantly different DCF fluorescence, implying that diosmetin itself did not cause ROS generation in normal erythrocytes. Taken together, these results confirm that diosmetin can reduce intracellular oxidative stress.

**Diosmetin Prevents AAPH-Induced MDA Accumulation and Modulates Intracellular Antioxidant Enzyme (GPx, SOD, and CAT) Activities.** AAPH-induced ROS generation can cause lipid peroxidation and result in the release of MDA. MDA is involved in tumor promotion, cellular metabolism disruption, and cell membrane dysfunction due to its high reactivity. Excess MDA can ultimately lead to disruption of cellular metabolism.[32] As seen in Figure 5A, the MDA level in erythrocytes was significantly increased from 0.25 to 0.87 nmol/mg protein after treatment with 200 mM AAPH for 2 h, indicating the occurrence of lipid peroxidation caused by AAPH-induced oxidative stress. For the cells incubated with different concentrations of diosmetin (12.5, 25, 50, and 100 $\mu$g/mL), the level of MDA in erythrocytes was decreased, especially at the high diosmetin concentration (100 $\mu$g/mL), where the MDA concentration declined almost to that of the control. For cells incubated with diosmetin without AAPH supplementation, the MDA level was comparable to that of the control, showing that diosmetin itself does not induce MDA formation. Thus, lipid peroxidation caused by ROS generation was efficiently inhibited by diosmetin.

Major radical scavenging antioxidant enzymes in the human body include SOD, GPx, and CAT. These enzymes constitute an intracellular defense system, which can coordinate the elimination of free radicals through a series of chain reactions. Changes in the activities of these antioxidant enzymes may be related to the cell's antioxidant response. The intracellular level of these antioxidants is crucial for maintaining a steady state of superoxide radicals and hydrogen peroxide.[33,34] SOD can catalyze the dismutation of the highly reactive superoxide anion $O_2^{\bullet-}$ into $O_2$ and hydrogen peroxide ($H_2O_2$), which is less reactive. CAT converts the $H_2O_2$ generated within cells to $H_2O$ and $O_2$ and prevents the conversion of $H_2O_2$ into more active species, such as hydroxyl radicals ($^{\bullet}OH$), which can ultimately lead to cell death. As for GPx, it catalyzes the reaction of hydroperoxides with glutathione (GSH), thereby protecting cells from oxidative damage. As shown in panels B, C, and D of Figure 5, the activities of SOD, GPx, and CAT in erythrocytes were significantly increased after 200 mM AAPH treatment for 2 h, showing that AAPH treatment activated the enzymatic antioxidant defense systems in erythrocytes.

The cellular antioxidant system depends on quenching of $O_2^{\bullet-}$ by SOD and further protection by CAT to convert $H_2O_2$ to $H_2O$ (Figure 5E). Pretreatment with diosmetin provided effective control of red cell antioxidant defense systems as indicated by the lower GPx (Figure 5B), SOD (Figure 5C), and CAT (Figure 5D) levels. This was particularly the case for high (100 $\mu$g/mL) diosmetin treatment, which maintained enzyme activities at normal levels. Thus, diosmetin can effectively attenuate AAPH-induced oxidative stress in erythrocytes, mainly through the inhibition of ROS generation, as illustrated in Figure 5E.

In conclusion, in a cell-based CAA assay, diosmetin efficiently attenuated AAPH-induced oxidative stress in human erythrocytes. Diosmetin prevented the generation of intracellular ROS, inhibited the formation of MDA, and regulated intracellular antioxidant enzyme (GPx, SOD, and CAT) activities. The particular chemical structure of diosmetin, for example, the hydroxyl group attached to C3′ and the 2,3-double bond conjugated with a 4-oxo group in the C ring, contributes significantly to its antioxidant activity. Diosmetin effectively attenuated AAPH-induced oxidative stress in erythrocytes and plasma by inhibition of intracellular ROS generation. It also significantly decreased copper-induced diene accumulation and protected plasma from oxidative damage. Because oxidative stress is involved in the pathogenesis of a number of chronic diseases including heart disease, cancer, type 2 diabetes, and inflammatory diseases,[35] our results demonstrated that diosmetin could be good candidate for the treatment of diseases in which ROS overproduction is the etiological factor. It can be developed either as functional foods or as complementary medicines.

Supporting Information

**ABSTRACT:** A novel microbial transglutaminase-catalyzed aqueous−organic biphasic reaction system was successfully developed to prepare caseinate derivatives by cross-linking and incorporating nonpolar octyl tails for the first time. SDS-PAGE and $^1$H NMR analysis confirmed that cross-linking and octyl conjugation occurred simultaneously. The octyl substitution degree (SD) was measured by $^1$H NMR and used as an index to determine a suitable reaction condition. It was found that at the condition of 0.125% (w/v) protein concentration and 6 h of reaction time, the modified caseinate had the highest SD of 28.96%. The modified caseinate also had an increased surface hydrophobicity, better emulsifying activity, and improved thermal and salt stabilities. However, its emulsion stability or in vitro enzymatic digestibility was slightly lower than that of the native caseinate.

**KEYWORDS:** *sodium caseinate, octylamine, microbial transglutaminase, biphasic system, functional properties*

## INTRODUCTION

Milk proteins are widely used in the food industry. As a major protein fraction in the milk, casein provides many important functions for processed foods, including film-forming,[1] emulsifying,[2] foaming,[3] and microencapsulating capacities.[4] The further improvement in functional properties through physical, chemical, or enzymatic modification might increase and extend the applicability of casein in different food systems. Among various modifications applied to casein, the interaction between casein and reducing sugars through Maillard reaction has been widely studied and shown to produce marked changes in the functional properties, such as solubility,[5] antioxidant,[6] foam and emulsion stability,[7] and heat stability,[8] as well as micro- and nanoencapsulating properties.[9,10] However, the Maillard reaction of food proteins might generate mutagenic compounds and undesired color, consequently affecting the sensory attributes of the final product or causing safety issues.[11,12] Therefore, the enzymatic approach, which requires milder reaction conditions, allows for easier control of the extent of the reaction, and yields minimal formation of byproduct, is much more preferable.[13]

Transglutaminase (TGase, EC 2.3.2.13) catalyzes an acyl-transferring reaction in which $\varepsilon$-($\gamma$-glutamyl) lysine bonds are formed using the $\gamma$-carboxyamide groups of peptide-bound glutamine residues and the amino groups of lysine side chains.[14,15] Transglutaminase is mainly classified into the microbial transglutaminase (MTGase) derived from *Streptomyces mobaraensis*, and the tissue transglutaminase (TGase), such as guinea pig liver transglutaminase. MTGase has several essential advantages in comparison to TGase, such as lower molecular weight, calcium-independent, and broader suitable pH and temperature ranges.[16] The effect of TGase-induced cross-linking through the formation of $\varepsilon$-($\gamma$-glutamyl) lysine intra- and intermolecular cross-links on the functional properties of various food proteins has been investigated. Treatment of millet protein by TGase was found to improve the heat stability and emulsifying capacity of the protein.[17] The cross-linked soy protein prepared using TGase as the catalyst was able to act as an effective wall-forming agent and increase the storage stability and emulsion-controlled release behavior.[18] Besides cross-linking of natural proteins, many attempts were made to incorporate lysine alternatives into protein, such as lysine analogue $\omega$-amino acids,[16] glucosamine,[19] and oligosaccharide using alkylamine as an alkyl donor.[20] Moreover, Ohtsuka et al. investigated the substrate specificity of TGase for aliphatic primary amines and suggested that four carbon atoms or more are required for an aliphatic primary amine without side chains to be a substrate for TGase.[21] The ability to arbitrarily incorporate various functional groups into the glutamine residues of proteins using TGase would allow for the introduction of nonpolar tails into a protein molecule or cross-links within and between protein molecules. However, the propensity of TGase to interact with a protein substrate is also dependent upon its molecular structure and conformation through altering the accessibility of its glutamine and lysine residues.[22] It has been noted that casein, a flexible random coil protein, is an excellent target protein for TGase.[23]

In fact, the incorporation of nonpolar groups into protein macromolecules may improve their surface activity dramatically.[24] Casein is a block copolymer comprising blocks containing hydrophobic and hydrophilic amino acid residues. Therefore, casein exhibits a strong tendency to self-assemble into casein micelles. Through the chemical reaction of casein

ACS Publications © 2014 American Chemical Society

with fatty acids, casein derivatives exhibited better surface tension, wetting ability, and foaming properties than native casein.[25] Nevertheless, there is little information in the literature on modifying casein with nonpolar groups by using a TGase-induced enzymatic method. This may be because TGase generally catalyzes a reaction in aqueous systems, whereas nonpolar groups have little solubility in water, thus greatly impairing the reaction efficiency. On the other hand, the biphasic reaction system is widely used in peptide synthesis and enzymatic hydrolysis to overcome insolubility of substrates, unfavorable thermodynamic equilibrium, difficult product recovery, and enzyme inhibition by reagents and/or products.[26,27]

Therefore, the present work tried for the first time to use a commercial microbial transglutaminase (MTGase) as a biocatalytic agent, sodium caseinate as the acyl donor, and octylamine as the acyl acceptor in an aqueous−organic biphasic system to modify caseinate and obtain cross-linked and octyl-conjugated caseinate derivatives. The effects of reaction conditions on the substitution degree of octyl groups in the modified caseinates were also investigated using a $^1$H NMR-based analysis. The physicochemical and functional properties of the modified caseinate, including surface hydrophobicity, emulsifying activity and stability, thermal and salt stabilities, and in vitro digestibility, were evaluated and compared to those of the native caseinate.

## MATERIALS AND METHODS

**Chemicals.** Sodium caseinate, octylamine (>99% purity), 8-anilino-1-naphthalenesulfonic acid (ANS, 97% purity), pepsin (≥250 units/mg solid), trypsin (≥10000 BAEE units/mg protein), and trichloroacetic acid (TCA, >99% purity) were purchased from Sigma-Aldrich Chemical Co., Ltd. (St. Louis, MO, USA). Microbial transglutaminase (MTGase) was kindly donated by Jiangsu Yiming Fine Chemical Industry Co., Ltd. (Qinxing, Jiangsu, China) with a declared activity of 100 units/g. The Bradford reagent and standard protein markers used in SDS-PAGE analysis were purchased from Bio-Rad Co. (Richmond, CA, USA). Dialysis membranes (molecular weight cutoff (MWCO) 3500 Da) were purchased from Spectrum Laboratories, Inc. (Rancho Dominguez, CA, USA). All other reagents were of analytical grade and used without further purification. Water purified with a Milli-Q system was used for all experiments.

**Developing a MTGase-Catalyzed Aqueous−Organic Biphasic Reaction Procedure for Structural Modification of Sodium Caseinate.** The modification of sodium caseinate was carried out with sodium caseinate and octylamine as the substrates and MTGase as the catalyst. The reaction mixture containing sodium caseinate in 0.1 M Tris·HCl buffer (pH 7.5) with different concentrations (0.0625, 0.125, 0.25, and 0.5% w/v) and octylamine (feed mass ratio to sodium caseinate of 1:5) in cyclohexane were added into a 250 mL conical flask with a ground-in glass stopper, and the reaction was started by adding MTGase (10 units/g sodium caseinate) to the aqueous phase and carried out in a thermostatic oscillator (SWB25, Thermo Fisher Scientific Inc., Waltham, MA, USA) at 37 °C with continuous vibration at 60 rpm. At different reaction time points (2, 4, 6, 8, and 10 h), the organic phase was removed from the reaction system, and MTGase in the aqueous phase was inactivated immediately by heat treatment at 85 °C for 10 min. The heat-treated aqueous phase was cooled rapidly to ambient temperature and dialyzed against distilled water for 48 h. The prepared samples were then lyophilized and stored at −20 °C for further study. To serve as a control, a cross-linked caseinate was also prepared under the selected conditions in the absence of octylamine. Suitable reaction conditions, including protein concentration and reaction time, were selected on the basis of the maximum substitution degree (SD) value of octyl groups introduced into the modified product and applied to prepare a modified product for further study.

**Determination of Substitution Degree.** SD values were determined by $^1$H NMR using a Bruker AVANCE III 400 MHz NMR spectrometer at 298 K. Octylamine was dissolved in $d_6$-DMSO, and protein samples were dissolved in $D_2O$ at the concentration of 0.5% (w/v), using TMS as an internal reference (0 ppm). $D_2O$ signal was suppressed by the presaturation method.[28] For the $^1$H NMR spectrum of octylamine, the parameters for observation were as follows: number of data points, 64 K; spectral width, 8223.68 Hz; acquisition time, 4.00 s; relaxation delay time, 1.0 s; number of scans, 16. The parameters for the $^1$H NMR spectra of protein samples were as follows: number of data points, 32 K; spectral width, 8012.82 Hz; acquisition time, 2.04 s; relaxation delay time, 5.0 s; number of scans, 256. An exponential line broadening (0.30 Hz), automatic phase correction, and baseline correction (degree of polynomial equal to 5) were applied to each spectrum.

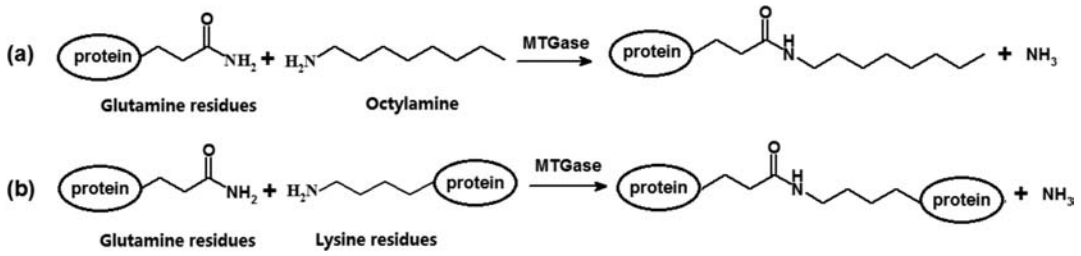
**SDS-PAGE Analysis.** Protein samples were analyzed by SDS-PAGE according to a procedure reported by Jiang et al.,[19] using a 12% separating gel and a 5% stacking gel. The sample solution (0.08% w/v) was prepared in a buffer containing 2% (w/v) sodium dodecyl sulfate (SDS), 5% (v/v) $\beta$-mercaptoethanol, 10% (v/v) glycerol, 0.02% (w/v) bromophenol blue, and 70 mM Tris·HCl (pH 6.8) and heated at 95 °C for 5 min. The samples and a protein ladder were loaded into separated wells (6 μL/well). Following electrophoresis, the gels were stained with Coomassie Brilliant Blue R250 and digitized using an Epson perfection 1270 image scanner (Epson America Inc., Long Beach, CA, USA).

**Determination of Surface Hydrophobicity.** ANS fluorescence assay[29] was carried out to determine the surface hydrophobicity of native caseinate and the modified products. Protein samples (10 mg) were dissolved in 1 mL of 0.1 M phosphate buffer (pH 7.0) and stirred overnight. The sample dispersions were then centrifuged at 20000*g* for 20 min to sediment insoluble proteins. The resultant supernatants were subjected to protein content determination using the Bradford method.[30] Then, the protein solutions were diluted 10, 20, 50, 80, and 100 times to make a series of diluted protein solutions. The ANS (100 μg/mL) was prepared in the same buffer and filtered through a 0.22 μm Acrodisc syringe filter membrance (Pall Co., Newquay, UK). The diluted protein solutions were mixed with the same volume of ANS solution. After 1 h of incubation at 25 °C (HERATHERM Incubator, Thermo Fisher Scientific Inc.), the mixture was observed for its fluorescence intensity (FI) on a TECAN Infinite M200 PRO multilabel plate reader (Tecan Group Ltd., Mannedorf, Switzerland). The excitation and emission wavelengths were 355 and 460 nm, respectively. For each protein sample, a linear regression equation was established for FI versus protein concentration ($R^2$ > 0.99), and the slope ($S_0$) was used as an index for surface hydrophobicity.

**Thermogravimetry/Derivative Thermogravimetry (TG/DTG) Determination.** TG/DTG analysis of protein samples was performed in a Pyris 1 TGA device by PerkinElmer (Santa Clara, CA, USA) in the temperature range from 30 to 600 °C, using platinum crucibles with ∼5 mg of samples, under a dynamic nitrogen atmosphere (20 mL/min) and heating rate of 10 °C/min.

**Determination of Emulsifying Capacity.** The emulsifying capacity of the protein samples was evaluated by assessing the emulsifying activity index (EAI) and emulsion stability index (ESI) using a classic turbidimetric method.[31] To prepare emulsions, 1.0 mL of soybean oil and 3.0 mL of a protein solution (0.2% w/v) in 0.1 M phosphate buffer (pH 7.0) were homogenized with a high-speed homogenizer (VWR VDI 12, Radnor, PA, USA) at 12000 rpm for 1 min. The freshly prepared emulsion (50 μL) was taken from the bottom of the beaker and dispersed into 5 mL of 0.1% (w/v) SDS solution. The absorbance of the solution was measured at 500 nm against a 0.1% (w/v) SDS blank. The prepared emulsion was kept undisturbed for 10 min. Then, 50 μL aliquots were taken from the bottom of the beaker and dispersed into 5 mL of 0.1% (w/v) SDS solution. The absorbance of the sample was measured at 500 nm against 0.1% (w/v) SDS as described above. EAI and ESI of the protein samples were calculated by using eqs 1 and 2, respectively:

**Scheme 1. Proposed MTGase-Catalyzed Acyl-Transferring Reactions**



$$\mathrm{EAI}\left(\frac{\mathrm{m}^2}{\mathrm{g}}\right) = \frac{2 \times 2.303 \times A_{500} \times \text{dilution}}{C \times (1 - \Phi) \times 10^4} \quad (1)$$

$$\mathrm{ESI}\ (\%) = \frac{A_{10}}{A_0} \times 100 \quad (2)$$

In these equations, $A_{500}$ is the absorbance of the sample at 500 nm, $C$ is protein concentration (g/mL) before emulsion, $\Phi$ is the oil volume fraction (v/v) of the emulsion, dilution = 100, and $A_{10}$ and $A_0$ are the absorbance at 500 nm after 10 min and at time zero, respectively.

**Determination of Salt Stability.** The protein samples (50 mg) were dispersed in 10 mL of NaCl solutions with different concentrations (1−5 M) and stirred overnight. The sample dispersions were centrifuged at 20000*g* for 20 min to sediment insoluble proteins. The supernatant was diluted 20 times and assayed for protein content using the Bradford method.[30] Salt stability of protein samples was indirectly assessed using the protein solubility in the salt solution, whereas protein solubility was expressed as the percentage of protein content in the supernatant with respect to the protein content in the dispersion. All assays were performed in triplicates.

**Determination of in Vitro Digestibility.** The in vitro digestibility of the protein samples were examined using one-step and two-step hydrolysis as reported by Zhang et al.[32] with slight modifications. For one-step hydrolysis, 10 mL of protein dispersion of 1% (w/v) at pH 2.0 (by addition of 1 M HCl) was prepared, followed by the addition of 2 mg of pepsin. The hydrolysis was carried out at 37 °C for 2 h and stopped by adding an equal volume of 20% (w/v) TCA. For two-step hydrolysis, the starting dispersion was prepared and treated as above. After incubation at 37 °C for 1 h, the hydrolysis was stopped by heating at 90 °C for 5 min and cooling to 4 °C. Then the dispersion was lyophilized and reconstituted in 10 mL of 0.2 M phosphate buffer (pH 8.0), followed by the addition of 6 mg of trypsin. The incubation was carried out at 37 °C for 1 h, and then the hydrolysis was stopped by adding an equal volume of 20% (w/v) TCA. The suspensions were centrifuged at 10000*g* for 20 min to collect the supernatant. The TCA-soluble nitrogen released into the supernatant was diluted with a 6-fold volume of distilled water and monitored for absorbance at 280 nm. The value obtained was used to reflect in vitro digestibility of the protein sample.

**Statistical Analysis.** Data were reported as the mean ± SD for triplicate determinations. One-way ANOVA and Tukey's test were employed to identify differences in means. Statistics were analyzed using SPSS for Windows (version rel. 10.0.5, 1999, SPSS Inc., Chicago, IL, USA). Statistical significance was declared at $P < 0.05$.

## RESULTS AND DISCUSSION

**Developing a MTGase-Catalyzed Aqueous−Organic Biphasic Reaction Procedure for Structural Modification of Sodium Caseinate.** MTGase has been recognized for its ability to catalyze the cross-linking between the γ-carboxyamide groups and the ε-amino group of lysine residues to form an ε-(γ-glutamyl) lysine isopeptide bond in caseinate molecules.[14] The reactive lysine may be substituted by certain different compounds containing appropriate primary amino groups, giving different derivatives.[21] However, little previous study has tested the possibility of performing the MTGase-catalyzed reaction in a nonaqueous solvent system, which has limited the substrates to polar chemicals with adequate water solubility. In this study, a MTGase-catalyzed aqueous−organic biphasic reaction procedure was developed to modify sodium caseinate with nonpolar octylamine. It was hypothesized that octylamine might compete with the ε-amino group of lysine residues to incorporate into caseinate molecules at the interphase, and the cross-linking and octyl conjugation may occur simultaneously in the modified product (Scheme 1). To test the hypothesis, a reaction was performed with sodium caseinate and octylamine as the substrate and MTGase as the catalyst in a solvent system consisting of Tris·HCl buffer and cyclohexane. SDS-PAGE (Figure 1) and $^1$H NMR analyses (Figure 2) confirmed that the

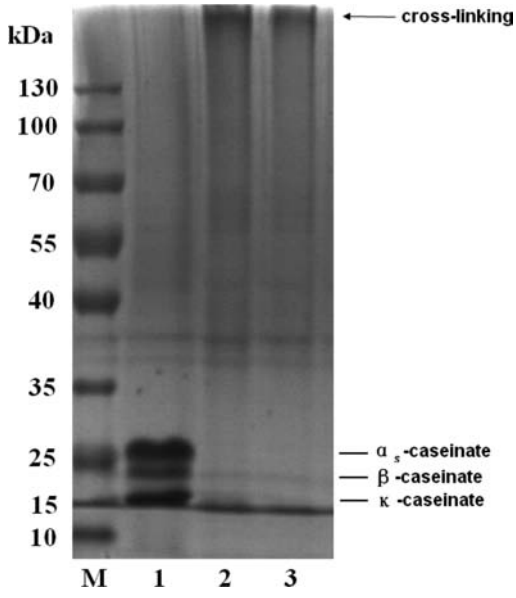


**Figure 1.** SDS-PAGE profiles of protein samples. Lanes: M, standard protein markers; 1, native caseinate; 2, cross-linked caseinate; 3, octyl-conjugated caseinate.

MTGase was able to successfully cross-link and introduce octyl conjugation in the caseinate molecule under the experimental condition. In Figure 1, lane 1 shows major protein components (subunits) of $\alpha_s$-, β-, and κ-caseinates in the native caseinate. In contrast, these bands for most of the subunits in the cross-linked and octyl-conjugated caseinates became less dense. Meanwhile, some new bands at higher molecular weights (>130 kDa) appeared on the top of the separating gel in lanes 2 and 3, evidencing the cross-linking between caseinate molecules, as octyl conjugation might not increase the molecular weight of caseinate to this extent. The $^1$H NMR spectra of octylamine and those for the native, cross-linked, and octyl-conjugated

dx.doi.org/10.1021/jf5024998 | J. Agric. Food Chem. 2014, 62, 8655−8662

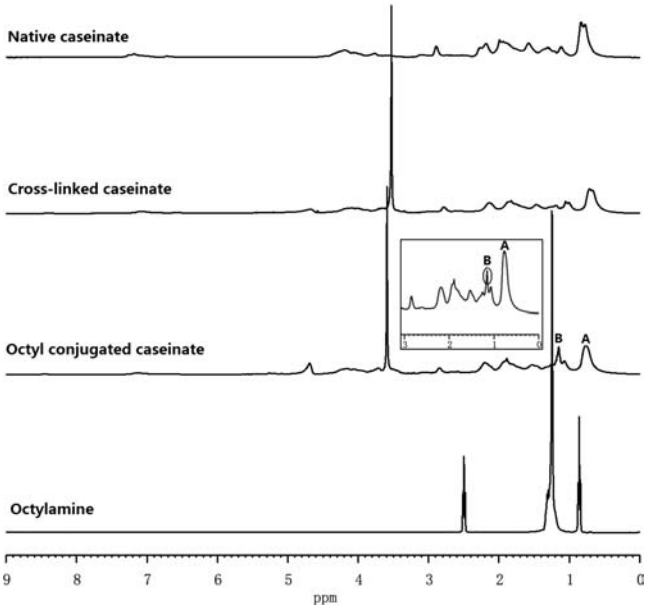

**Figure 2.** $^1$H NMR spectra of 0.5% (w/v) octylamine dissolved in $d_6$-DMSO and protein samples dissolved in $D_2O$. The substitution degree of octyl group in the octyl conjugated caseinate is 28.96%. The sharp peak at 3.7 ppm in the cross-linked and octyl-conjugated caseinate is due to residual Tris buffer.[34]

caseinate are shown in Figure 2. Octylamine showed multiple signals at 0.86, 1.28, and 2.50 ppm, which could be attributed to the protons of its methyl, methylene, and amino groups. Because of the high molecular weights of protein samples, the signals were considerably broader and less well-resolved than that for the smaller molecule octylamine. In the characteristic aliphatic hydrogen resonance region (0−3 ppm), a new peak B at 1.15 ppm (as a circle indicated in the inset) was detected only in the spectrum of the octyl-conjugated caseinate, but not in that of the native or cross-linked caseinate. This new peak originated very probably from the methylene protons of octyl groups covalently linked to the glutamine residues in caseinate, although chemical shifts of methylene protons in small molecules of octylamine (1.28 ppm) and octyl groups of the modified caseinate (1.15 ppm) showed a slight difference. This slight difference might be due to the different chemical environments of methylene protons in the octylamine and the modified protein.

To achieve the desired degree of octyl conjugation, the reaction conditions were examined for their influence on the degree of octyl conjugation, including feed protein concentration (0.0625, 0.125, 0.25, and 0.5% w/v) and reaction time (2, 4, 6, 8, and 10 h). At the protein concentration of 0.0625% (w/v), the obtained octyl-conjugated caseinate showed very poor solubility in water, regardless of the reaction time. This made the measurement of SD value of conjugated octyl groups and further application of the modified products in the food industry less possible. For the protein concentration of 0.125−0.5% (w/v), the modified products showed a good solubility in water.

**Determination of Substitution Degree.** A novel approach was developed in the present study to determine the SD value of conjugated octyl groups in the modified proteins according to the relative intensity between broad peak A (0.04−0.93 ppm) and peak B (1.15 ppm). The broad peak A between 0.04 and 0.93 ppm corresponded to the methyl protons of isoleucine, leucine, and valine residues[33] and octyl groups conjugated to the caseinate, whereas a new peak B at 1.15 ppm was attributed to the methylene protons of octyl groups (Figure 2). The SD of octyl groups conjugated into caseinate could be defined as the moles of conjugated octyl groups in the modified caseinate per mole glutamine units in the caseinate before modification and could be calculated by eqs 3−5:

$$I_{\text{peak A}} = (M_{\text{isoleucine}} \times N_{\text{isoleucine}} + M_{\text{leucine}} \times N_{\text{leucine}} + M_{\text{valine}} \times N_{\text{valine}} + yN_{\text{octylamine-CH}_3}) \times x \quad (3)$$

$$I_{\text{peak B}} = yN_{\text{octylamine-CH}_2} \quad (4)$$

$$\text{SD}\ (\%) = \frac{y}{N_{\text{glutamine}} \times x} \times 100 \quad (5)$$

In these equations, $I_{\text{peak A}}$ and $I_{\text{peak B}}$ are average integral areas of peaks A and B, $x$ is the mole number of the tested octyl conjugated caseinate, $y$ is the mole number of octyl groups in the tested octyl conjugated caseinate, $N_{\text{isoleucine}}$, $N_{\text{leucine}}$, $N_{\text{valine}}$, and $N_{\text{octylamine-CH}_3}$ are the number of protons of methyl signal in isoleucine (6H), leucine (6H), valine (6H), and octylamine (3H), $N_{\text{octylamine-CH}_2}$ is the number of protons of methylene signal in octylamine (14H), and $M_{\text{isoleucine}}$, $M_{\text{leucine}}$, $M_{\text{valine}}$, and $M_{\text{glutamine}}$ are the mole numbers of isoleucine (11.73), leucine (18.39), valine (14.61), and glutamine (18.54) residues per mol caseinate before modification, respectively. These data may be calculated from the amino acid compositions of each subunit of caseinate, which is available in the Supporting Information.

A group of octyl-conjugated caseinates with different SD values were prepared (Table 1). Table 1 shows that the SD of octyl groups increased with the reaction time increasing from 2 to 6 h and then decreased upon further increasing reaction time. At the same reaction time of 6 h, the maximal octyl conjugation was achieved for 0.125% (w/v) of protein concentration. Under this reaction condition, about 28.96% of glutamine units in caseinate were conjugated with octyl groups.

**Table 1. Effect of Protein Concentration and Reaction Time on the Substitution Degree of the Octyl Group in the Octyl-Conjugated Caseinates**

| | substitution degree (%) | | | | |
|---|---|---|---|---|---|
| protein sample | 2 h | 4 h | 6 h | 8 h | 10 h |
| octyl-conjugated caseinate, 0.125% (w/v) | 10.30 | 13.00 | 28.96 | 6.11 | 5.22 |
| octyl-conjugated caseinate, 0.25% (w/v) | 12.44 | 13.66 | 19.49 | 11.75 | 8.28 |
| octyl-conjugated caseinate, 0.50% (w/v) | 6.30 | 11.68 | 16.40 | 11.71 | 9.70 |

**Surface Hydrophobicity.** The surface hydrophobicity index, measured using ANS as a fluorescence probe, is an important parameter indicative of the hydrophobic region in a protein. The surface hydrophobicity index of the native, cross-linked, and octyl-conjugated protein samples is shown in Figure 3. The cross-linking and octyl conjugation increased the surface hydrophobicity index significantly ($P < 0.05$), from 23.92 (native caseinate) to 27.07 (cross-linked caseinate) and 32.66 (octyl-conjugated caseinate). This observation was in good agreement with a previous report that transglutaminase

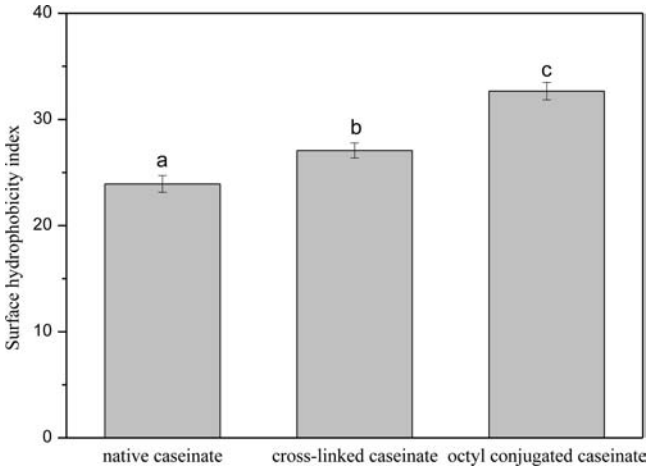

**Figure 3.** Surface hydrophobicity index of native caseinate, cross-linked caseinate, and octyl-conjugated caseinate. Different letters (a–c) above the columns indicate that the data are significantly different ($P < 0.05$). Values are expressed as means ± standard derivatives of triplicate measurements.

treatment increased surface hydrophobicity of sodium caseinate, whey protein isolate, and total milk protein by Hiller and Lorenzen.[35] They suggested that the increase in protein hydrophobicity corresponded to an unfolding of protein structure upon enzymatic treatment and thus an exposure of hydrophobic amino acid residues buried within the tertiary structure of original protein molecules. The conjugation of the octyl group, which is neutral and hydrophobic, could further increase the surface hydrophobicity of the modified caseinate.

**Thermal Stability.** Figure 4 and Table 2 present TGA/DTG curves and characteristic parameters of native, cross-linked, and octyl-conjugated caseinate under a flow of $N_2$ at a heating rate of 10 °C/min. The onset temperatures (temperature at 5% mass loss, $T_{5\%}$) proceeded at a relatively low temperature range (230.83–258.29 °C), at which chemical bonds could not be broken, and it could be attributable to the elimination of water physically retained by caseinate.[36] Comparable with those of native caseinate, the $T_{50\%}$ and $T_{max}$ of the cross-linked caseinate increased 10.99 and 16.84 °C, whereas these indices of the octyl-conjugated caseinate increased 9.05 and 20.23 °C, respectively. These data demonstrated that the thermal stabilities of cross-linked and octyl-conjugated protein samples were better than that of the native caseinate. Similar results were reported for millet protein and whey protein isolate polymerized by transglutaminase.[17,37] According to Flanagan,[38] this is probably due to the formation of intra- and intermolecular association between protein polymers, which delayed a heat-induced unfolding and denaturation of MTGase-treated proteins.

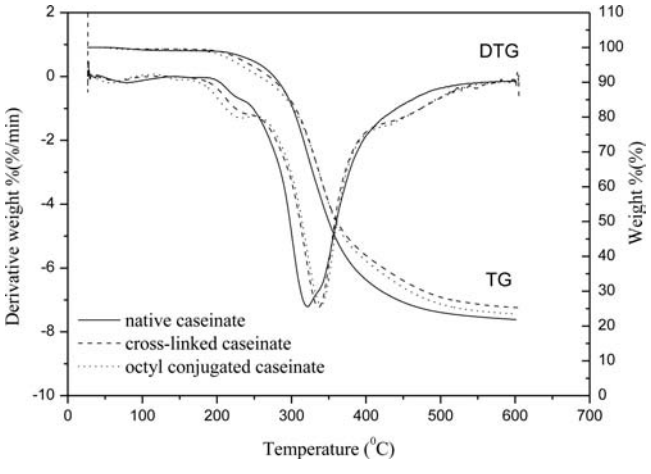

**Figure 4.** TGA/DTG curves of native caseinate, cross-linked caseinate, and octyl-conjugated caseinate under nitrogen atmosphere at a heating rate of 10 °C/min.

**Table 2. Characteristic Parameters for the Native, Cross-Linked, and Octyl-Conjugated Caseinates by TGA/DTG**

| protein sample | $T_{5\%}$ (°C) | $T_{50\%}$ (°C) | $T_{max}$ (°C) | residue weight (wt %) |
|---|---|---|---|---|
| native caseinate | 258.29 | 350.06 | 319.34 | 21.85 |
| cross-linked caseinate | 244.84 | 361.05 | 336.18 | 25.31 |
| octyl-conjugated caseinate | 230.83 | 359.11 | 339.57 | 23.47 |

**Emulsifying Property.** The emulsifying activity and emulsion stability index of the three protein samples were measured and expressed as EAI and ESI (Figure 5). The EAIs were 20.52, 33.50, and 37.38 $m^2/g$ and the ESIs were 7.42, 6.82, and 4.45% for the native, cross-linked, and octyl-conjugated caseinates, respectively. Compared with those of native caseinate, cross-linked and octyl-conjugated caseinate had significantly increased EAIs by 63.25 and 82.16%, and decreased ESIs by 8.08 and 40.02%, respectively. Surface hydrophobicity is positively associated with the ability of protein to act as an emulsifer.[39] In an earlier study, Sen et al.[40] have shown that highly alkylated casein derivatives had a better emulsion activity than the unmodified protein. For most proteins, higher surface hydrophobicity indicates a better emulsifying property as a large portion of hydrophobic residues may anchor to the surface of oil droplets and form a strong film.[41] However, it should be pointed out that increasing protein hydrophobicity may have in many instances adverse effects on emulsifying activity,[31,42] which implies the involvement of other factors in determining emulsion activity of proteins, such as protein solubility and distribution of hydrophobic and hydrophilic residues in the polypeptide

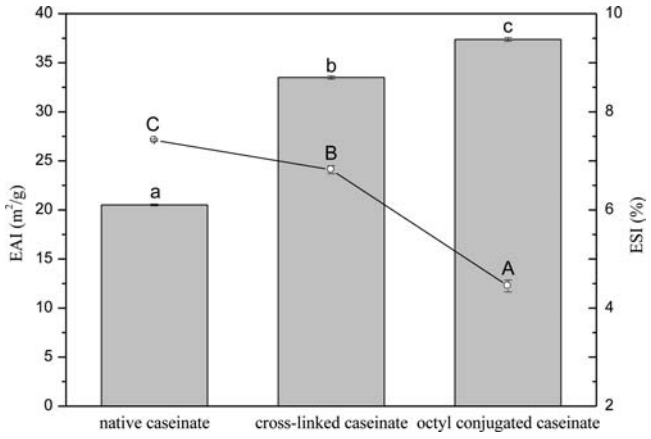

**Figure 5.** Emulsifying activity index (EAI, column) and emulsion stability index (ESI, curve) of native caseinate, cross-linked caseinate, and octyl-conjugated caseinate. Different letters (a–c or A–C) above the columns or curve indicate significant differences ($P < 0.05$), respectively. Values are expressed as means ± standard derivatives of triplicate measurements.

Table 3. Solubility Measurements of Different Protein Samples at Selected NaCl Concentrations

| protein sample | protein solubility[a] (%) | | | | |
|---|---|---|---|---|---|
| | 1 M | 2 M | 3 M | 4 M | 5 M |
| native caseinate | 97.73 b ± 0.46 | 94.67 a ± 2.61 | 92.80 c ± 1.11 | 22.40 a ± 0.72 | ~0 a[b] |
| cross-linked caseinate | 92.27 a ± 1.40 | 90.20 a ± 1.71 | 89.40 b ± 1.64 | 88.53 c ± 1.01 | 4.47 c ± 0.07 |
| octyl-conjugated caseinate | 93.07 a ± 2.27 | 92.80 a ± 1.05 | 86.00 a ± 0.5 | 77.13 b ± 1.21 | 4.32 b ± 0.04 |

[a]Values are expressed as means ± standard derivatives of triplicate measurements. Different lower case letters in the same column indicate significant differences ($P < 0.05$). [b]The absorbance was below the lowest detection limit of the calibration curve, which was established on the basis of the Bradford method.

chains.[43] Moreover, the impaired effect of cross-linking and octyl conjugation on ESIs may be explained by the fact that the huge, extended protein oligomers/polymers facilitate aggregation and coalescence by simultaneously participating in the interface areas of different oil droplets.

**Salt Stability.** Salt stability of protein samples was indirectly assessed using the protein solubility in the NaCl solution. The solubilities of native, cross-linked, and octyl-conjugated caseinates in different concentrations (1−5 M) of NaCl solutions were evaluated by measuring protein solubilities in supernatants after protein dispersions had been centrifuged (Table 3). The native caseinate exhibited high solubilities in 1 M (97.73%), 2 M (94.67%), and 3 M (92.80%) NaCl solutions. Upon cross-linking and octyl conjugation, <8% changes in solubilities were observed for cross-linked and octyl-conjugated caseinate at the above-mentioned NaCl concentration range. However, native caseinate exhibited a sharply reduced solubility (22.40%) in 4 M NaCl concentration, which was significantly lower than those of cross-linked (88.53%) and octyl-conjugated caseinates (77.13%) at the same NaCl concentration. The salt solubility of native caseinate supported the earlier argument that salts at low concentrations normally stabilize proteins and may prevent proteins from initial binding and subsequent conformation changes and aggregation. At a high ionic strength, excessive charge shielding may cause protein aggregation.[44] The improved salt stability of the cross-linked and octyl-conjugated caseinate might be explained by Melander and Horvath's extended cavity theory,[45] which was originally developed by Sinanoglu and Abdulnur.[46] At higher salt concentrations, protein molecules require the surface free energy to greatly exclude salts and create a cavity for themselves. A higher concentraion of salts renders a larger surface tension increment of water; that is, a greater surface free energy is required for proteins, although such surface free energy to create a cavity is reduced, upon protein−protein interactions, which reduces the total surface area. Therefore, the cross-linked and octyl-conjugated caseinates could tolerate higher salt concentration (4 M), due to the formation of intra- and intermolecular protein polymers. When the NaCl concentration increased to 5 M, nearly all of the protein samples aggregated (Table 3).

**In Vitro Digestibility.** Figure 6 shows the absorbance at 280 nm for the supernatants collected during in vitro pepsin or pepsin−trypsin hydrolysis of native, cross-linked, and octyl-conjugated caseinate, reflecting the TCA-soluble peptides released. Under these two hydrolysis conditions, an impaired in vitro digestibility of the cross-linked and octyl-conjugated caseinates were observed as the released amount of the peptides with significantly reduced molecular mass, compared to that of the native caseinate. The results implied that the cross-linking and octyl-conjugated caseinates might sterically shield the peptide bonds against proteolysis, thus decreasing enzymatic digestibility in vitro. The observation agreed with the previous report by Tang et al.[47] that TGase-induced cross-linking of soy protein isolates led to a decrease of its pepsin−trypsin digestibility.

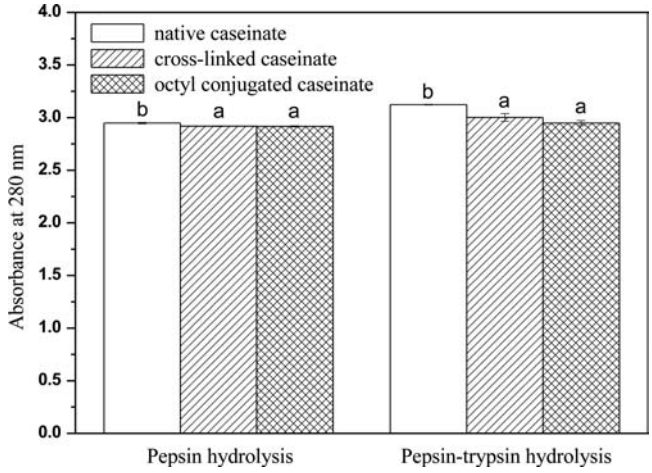

**Figure 6.** In vitro digestibility of protein samples evaluated by pepsin (one-step) or pepsin−trypsin (two-step) hydrolysis, respectively. Different letters (a, b) above the columns indicate significant differences ($P < 0.05$), respectively. Values are expressed as means ± standard derivatives of triplicate measurements.

In conclusion, a novel MTGase-catalyzed procedure was successfully developed to modify sodium caseinate by cross-linking and octylation in an aqueous−organic biphasic solvent system. The substitution degree of conjugated octyl groups was determined using a $^1$H NMR-based analysis for the first time, and this new analysis method could also be applied to other alkylation substitutions. Compared with the native caseinate, the octyl-conjugated caseinate has improved functional properties, such as better emulsifying activity and higher heat and salt stabilities. The reaction may also be applied to modify other food and nonfood proteins.

# Biofunctional Constituent Isolated from *Citrullus colocynthis* Fruits and Structure−Activity Relationships of Its Analogues Show Acaricidal and Insecticidal Efficacy

Ju-Hyun Jeon and Hoi-Seon Lee*

Department of Bioenvironmental Chemistry and Institute of Agricultural Science and Technology, College of Agriculture and Life Sciences, Chonbuk National University, Jeonju 561-756, Republic of Korea

**ABSTRACT:** The acaricidal and insecticidal potential of the active constituent isolated from *Citrullus colocynthis* fruits and its structurally related analogues was evaluated by performing leaf disk, contact toxicity, and fumigant toxicity bioassays against *Tetranychus urticae*, *Sitophilus oryzae*, and *Sitophilus zeamais* adults. The active constituent of *C. colocynthis* fruits was isolated by chromatographic techniques and was identified as 4-methylquinoline on the basis of spectroscopic analyses. To investigate the structure−activity relationships, 4-methylquinoline and its structural analogues were tested against mites and two insect pests. On the basis of the $LC_{50}$ values, 7,8-benzoquinoline was the most effective against *T. urticae*. Quinoline, 8-hydroxyquinoline, 2-methylquinoline, 4-methylquinoline, 6-methylquinoline, 8-methylquinoline, and 7,8-benzoquinoline showed high insecticidal activities against *S. oryzae* and *S. zeamais* regardless of the application method. These results indicate that introduction of a functional group into the quinoline skeleton and changing the position of the group have an important influence on the acaricidal and insecticidal activities. Furthermore, 4-methylquinoline isolated from *C. colocynthis* fruits, along with its structural analogues, could be effective natural pesticides for managing spider mites and stored grain weevils.

**KEYWORDS:** *Citrullus colocynthis, Sitophilus oryzae, Sitophilus zeamais, structure−activity relationship, Tetranychus urticae*

## INTRODUCTION

Both spider mites and weevils are pests of various plants, vegetables, and postharvest grains in a wide range of agricultural environments.[1−3] Populations of these insect pests cause serious economic losses and a decline in the grain quality of agricultural products worldwide.[1,4] The management of these insect pests has principally been carried out using synthetic chemical applications such as contact, fumigant, or spraying treatments with organophosphate and insect-growth regulators.[3,5] Although these substances are useful for controlling insect pests, their repeated use could pose a meaningful risk to human health and cause environmental pollution, as well as unwanted toxicity on nontarget organisms.[3,4,6] For these reasons, various studies have investigated the effects of phytochemicals as useful alternatives to insect pest management agents.

Botanical pesticides have long been used as an alternative source to synthetic chemicals for pest management because plant secondary metabolites show a broad range of insecticidal effects against agricultural, hygienic, and stored product insect pests, such as aphids, mites, mosquitoes, and weevils.[1,3,7,8] Moreover, because plant-derived materials have multiple novel target points of action, the chance of developing a resistant individual is very low.[9] *Citrullus colocynthis*, a member of the Cucurbitaceae family, is a medicinal plant distributed throughout Asia, which has been used in material for traditional medicines for arthritis, diabetes, inflammatory disorders, and stomachache.[10−13] However, the acaricidal and insecticidal activities of the active constituent isolated from *C. colocynthis* fruits and its structurally related analogues against *Tetranychus urticae*, *Sitophilus oryzae*, and *Sitophilus zeamais* adults have not yet been reported. Therefore, the aim of the current study was to investigate the acaricidal and insecticidal properties of *C. colocynthis* fruits against the mites and two insect pests and to determine their structure−activity relationships.

## MATERIALS AND METHODS

**Chemicals and Plant Material.** Quinoline (98%), 2-hydroxyquinoline (98%), 4-hydroxyquinoline (98%), 6-hydroxyquinoline (95%), 8-hydroxyquinoline (99%), 2-methylquinoline (98%), 6-methylquinoline (98%), 8-methylquinoline (97%), and 7,8-benzoquinoline (97%) were purchased from Sigma-Aldrich Chemical Co. (St. Louis, MO, USA) (Figure 1). Abamectin and dichlorvos, which were used as positive control, were obtained from Fluka Chemical Co. (Buchs, Switzerland). All other chemical materials used in the study were of reagent grade and are commercially available. The fruits of *C. colocynthis* were supplied from the International Biological Material Research Center in Daejeon, South Korea. A voucher specimen was authenticated by Prof. Jeongmoon Kim and deposited in the herbarium at the Department of Landscape Architecture, Chonbuk National University.

**Plant Preparation.** *C. colocynthis* fruits were air-dried and ground to a powder. The dried *C. colocynthis* fruits (100 g) were extracted twice with methanol (10 L) in a shaking incubator at 25 ± 2 °C for 36 h and filtered (filter paper No. 2, Toyo Roshi, Tokyo, Japan) under vacuum. The methanol extracts were concentrated and combined under a vacuum at 45 °C to yield a crude extract (12.7%, based on the dry weight of the fruits). The methanol extract (10 g) was sequentially partitioned into hexane (1.93 g), chloroform (2.88 g), ethyl acetate (1.52 g), butanol (1.81 g), and water-soluble (1.56 g) fractions for

subsequent bioassays. The fractions were concentrated using rotary vacuum evaporation and were refrigerated prior to use at 4 °C.

**Isolation and Identification.** To isolate the active compound of the chloroform fraction derived from the methanol extract of *C. colocynthis* fruits, the chloroform fraction was chromatographed on a silica gel column (Merck 70−230 mesh, 12 × 15 cm; Rahway, NJ, USA) and eluted with a gradient of chloroform/ethyl acetate (from 10:0 to 0:10, v/v). The separated fractions were collected and analyzed by thin-layer chromatography (TLC; chloroform/ethyl acetate = 8:1, v/v), and similar fractions based on their TLC pattern were combined to yield subfractions designated CF1−CF5. The active CF4 fraction was chromatographed on a silica gel column and was eluted with chloroform/ethyl acetate (9:1, 8:2, 7:3, and 5:5, v/v). The active CF43 fraction was also chromatographed on a silica gel column and eluted with chloroform/ethyl acetate (7:3, v/v), and the fractions obtained were bioassayed against the target insects. To determine the insecticidal constituent in fraction CF432, further isolation was performed using preparative HPLC (recycling preparative HPLC; Japan Analytical Industry Co., Ltd.). A JAI gel W series column (W 253 500 mm + W 252 500 mm) was used with chloroform (100%) as the mobile phase at a flow rate of 3.5 mL/min. During this step, three subfractions (CF4321−CF4323) were obtained and were then bioassayed. The active CF4322 fraction was subjected to further chromatography using a JAI gel GS series column (GS 310 500 mm + GS 310 300 mm) with chloroform (100%) at a flow rate of 3.0 mL/min. Finally, the potent active principle (CF43221) was isolated to a single peak. The structure of CF43221 was determined by spectroscopic analyses. Electron ionization (EI) mass spectra were obtained on a GSX 400 mass spectrometer (JEOL Ltd., Tokyo, Japan). $^1$H and $^{13}$C NMR spectra were analyzed in $CD_3OD$, using a JNM-ECA600 spectrometer, at 600 and 150 MHz (with tetramethylsilane as an internal standard), respectively, with the chemical shifts expressed in $\delta$ (ppm).

**Mite and Insect Rearing Conditions.** Respective cultures of *T. urticae*, *S. oryzae*, and *S. zeamais* used for the bioassay were obtained from the National Academy of Agricultural Science, Rural Development Administration (Suwon, Korea). *T. urticae* were reared in the laboratory on kidney bean (*Phaseolus vulgaris* L.) seedlings, and *S. oryzae* and *S. zeamais* were reared on rice grains in plastic containers (30 × 30 × 30 cm). They were maintained in the laboratory at 25 ± 1 °C, 65 ± 5% relative humidity (RH), and a 16 h light/8 h dark photoperiod. No mites and insects were exposed to any known acaricides or insecticides during maintenance.

**Bioassay.** The acaricidal and insecticidal activities against the three insect species were evaluated by leaf disk, contact, and fumigant bioassays using *C. colocynthis* extract, the active constituent, and its structural analogues, using the bioassays presented by Akhtar et al.[1] and Jeon et al.[3] The initial concentrations were chosen in a previous screening. Adults of mixed sex were used for each bioassay.

To evaluate the residual toxicity against *T. urticae*, leaf disks (2.5 cm diameter) cut from kidney bean were dipped in solutions (2.0, 1.0, 0.5, 0.1, 0.05, 0.025, 0.010, and 0.005 $\mu$g/mL) of the test materials for 15 s, and the disks were then evaporated for 20 min in a hood. Acetone was utilized as a carrier solvent. Twenty *T. urticae* adults were introduced onto the leaf disk supported by a cotton pad in a Petri dish (60 × 15 mm), which was then covered with a lid.

To evaluate the contact toxicity of the test materials against *S. oryzae* and *S. zeamais* adults, various amounts (2.10, 1.05, 0.52, 0.26, 0.13, 0.06, 0.03, 0.01, 0.005, 0.001, and 0.0005 mg/cm$^2$) of each material were liquefied in ethanol and applied to filter paper (5 cm

diameter) (Whatman Co., Maidstone, UK), with an ethanol-only negative control. Each filter paper was placed in the bottom of a Petri dish (5.5 cm diameter × 1.5 cm) after being dried in a fume hood for 10 min. Groups of 20 insects were separately placed in the Petri dish, and the lid was replaced. To evaluate the fumigant toxicity against *S. oryzae* and *S. zeamais*, filter papers were impregnated with ethanol solutions (100 μL) of different concentrations (1.40, 0.70, 0.35, 0.18, 0.09, 0.05, 0.01, 0.005, 0.001, and 0.0005 mg/cm$^3$) of each test material. Filter paper treated with ethanol (100 μL) was used as a negative control. After drying in a hood for 10 min, each filter paper was placed in the lid of a Petri dish (5.5 cm diameter × 1.5 cm). Twenty adult weevils were then placed in the Petri dish, which was covered with a 60 mesh cloth to avoid direct contact with the samples tested, and the lid was replaced to assess the fumigant action. *T. urticae*, *S. oryzae*, and *S. zeamais* adults placed in treated Petri dishes were kept under the same conditions as for rearing. All treatments were replicated three times, and mortalities were recorded after 48 h of treatment.

**Statistical Analysis.** $LC_{50}$ values were determined and transformed to arcsine square root values for analysis of variance (ANOVA).[14] The effects of each treatment were determined to be significantly different at $P < 0.05$.

## RESULTS AND DISCUSSION

The acaricidal and insecticidal toxicities of the methanol extract and the five fractions (hexane, chloroform, ethyl acetate, butanol, and water-soluble) obtained from *C. colocynthis* fruits are shown in Table 1, from evaluations using the leaf disk, contact toxicity, and fumigant toxicity applications against *T. urticae*, *S. oryzae*, and *S. zeamais*. Significant differences were observed in the acaricidal and insecticidal toxicities against the different insects. Upon examination of the methanol extract of the *C. colocynthis* fruits, a clear dose−response relationship was observed against *S. oryzae* and *S. zeamais*. Moreover, the chloroform and hexane fractions produced strong and weak insecticidal toxicities against *Sitophilus* spp., respectively. However, no activity was observed from the ethyl acetate, butanol, and water-soluble fractions (data not shown). When tested against *T. urticae*, the methanol extract of *C. colocynthis* fruits and its fractions showed a dramatic decrease in the acaricidal toxicity during the leaf disk bioassay. No mortality was observed for the negative controls (solvent only). These results indicate that the acaricidal and insecticidal toxicities of plant-derived materials can have different potencies depending on the species of insect investigated.

Due to the strong insecticidal toxicities observed from the chloroform fraction of the methanol extract of *C. colocynthis* fruits, the active constituent was isolated from this fraction by silica gel column chromatography and preparative HPLC. Structural determination of the isolated constituent was performed by spectroscopic analyses, including EI/MS, $^1$H NMR, $^{13}$C NMR, COSY, DEPT, and HMQC NMR and then by direct comparison with an authentic reference compound. The active compound was characterized as 4-methylquinoline. It was identified on the basis of the following evidence: 4-methylquinoline ($C_{10}H_9N$); EI/MS (70 eV) $m/z$ M$^+$ 143 (100, base peak), 135 (40), 105 (39), 107 (40), 79 (46), 51 (13); $^1$H NMR ($CD_3OD$, 600 MHz) $\delta$ 2.61 (s), 7.26−7.27 (d, $J$ = 6.7 Hz), 7.42−7.43 (t, $J$ = 6.9 Hz), 7.63−7.75 (t, $J$ = 83.1 Hz), 8.00−8.05 (d, $J$ = 35.7 Hz), 8.09−8.11 (d, $J$ = 7.3 Hz), 8.42−8.43 (d, $J$ = 1.6 Hz); $^{13}$C NMR ($CD_3OD$, 150 MHz) $\delta$ 150.6, 148.2, 135.5, 130.0, 128.5, 128.1, 126.5, 124.4, 122.9, 19.6. The spectroscopic data of authentic 4-methylquinoline were found to be similar to those of the previous data.[10,15]

The acaricidal and insecticidal activities of 4-methylquinoline isolated from *C. colocynthis* fruits and structurally related analogues against three insect pests were evaluated using the leaf disk, contact toxicity, and fumigant toxicity bioassays. Acaricidal activities of 4-methylquinoline and its structural analogues against *T. urticae* were examined by the leaf disk method (Figure 2). On the basis of the 48 h mortality rates, the

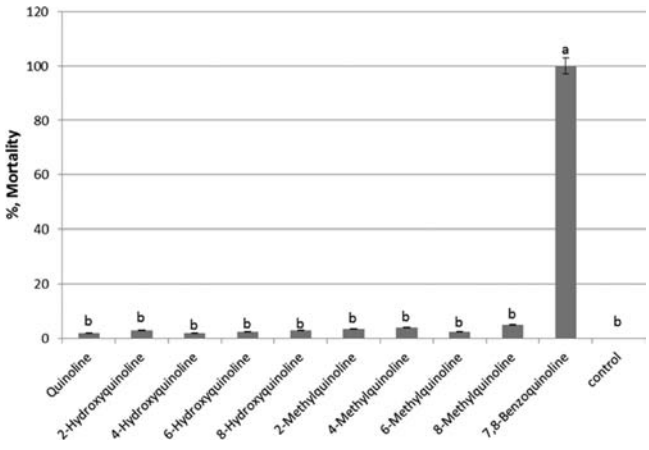

**Figure 2.** Responses of *T. urticae* adults to 4-methylquinoline and its structural analogues, determined by a leaf disk assay at 1.0 mg/mL, at 48 h. Twenty adults per replicate; 3 replicates per treatment; $n$ = 60. Mean values corresponding to each treatment with the same letters are not significantly different ($P$ = 0.05; Scheffe's test).

analogue 7,8-benzoquinoline demonstrated the highest mortality (100% at 1.0 mg/mL). However, other compounds (quinolone, 2-hydroxyquinoline, 4-hydroxyquinoline, 6-hydroxyquinoline, 8-hydroxyquinoline, 2-methylquinoline, 4-methylquinoline, 6-methylquinoline, and 8-methylquinoline) were found to have no acaricidal activity against *T. urticae*. The excellent acaricidal activity of 7,8-benzoquinoline against *T. urticae* was compared with that of a synthetic acaricide (abamectin) (Table 2). On the basis of the $LC_{50}$ values to *T. urticae* calculated from the leaf disk method, 7,8-benzoquinoline (0.017 μg/mL) was determined to be 31.06 times more toxic than abamectin (0.528 μg/mL). These results indicate that 7,8-benzoquinoline was the most effective for control of *T. urticae*, due to the low concentration required to produce strong activity.

The insecticidal activities of 4-methylquinoline and its structural analogues against *S. oryzae* and *S. zeamais* were tested on the basis of their active radicals ($R_1$, $R_2$, $R_3$, and $R_4$) by comparing the $LC_{50}$ values using contact toxicity and a fumigant toxicity bioassay (Tables 3 and 4). From the 48 h $LC_{50}$ values obtained with the contact toxicity bioassay, the most toxic compound against *S. ozryae* was 8-methylquinoline (0.001 mg/cm$^2$), followed by quinoline (0.071 mg/cm$^2$), 7,8-benzoquinoline (0.077 mg/cm$^2$), 2-methylquinoline (0.094 mg/cm$^2$), 4-methylquinoline (0.132 mg/cm$^2$), 8-hydroxyquinoline (0.163 mg/cm$^2$), and 6-methylquinoline (0.166 mg/cm$^2$). 8-Methylquinoline (0.001 mg/cm$^3$) was also the most toxic compound identified from the fumigant toxicity bioassay against *S. oryzae*, followed by 2-methylquinoline (0.034 mg/cm$^3$), 7,8-benzoquinoline (0.045 mg/cm$^3$), quinoline (0.064 mg/cm$^3$), 6-methylquinoline (0.081 mg/cm$^3$), 4-methylquinoline (0.096 mg/cm$^3$), and 8-hydroxyquinoline (0.109 mg/cm$^3$). Among the 4-methylquinoline analogues, 8-methylquinoline (which has a methyl group at the $R_4$ position in the quinoline

skeleton) showed the most toxicity against *Sitophilus* spp. and was approximately 57.0−71.0 times more effective than quinoline (the parent structure). However, whereas the introduction of a hydroxyl group in the $R_1$, $R_2$, and $R_3$ positions of quinoline showed no activities, introduction at the $R_4$ position caused an increase in insecticidal activities. The insecticidal activities of 4-methylquinoline analogues against *S. zeamais* were similar to those against *S. oryzae*. These results demonstrate that introducing various functional groups (hydroxyl, methyl, and arene) into the quinoline structure can change the insecticdal activity of the compound. In addition, the placement of hydroxyl or methyl groups in the $R_4$ position seems to be very important for increasing insecticidal toxicities against *Sitophilus* spp. Furthermore, 7,8-benzoquinoline (which has an arene group in the quinoline's benzene ring) showed higher potential toxicity than the other quinoline analogues against *T. ureticae*. In our earlier study, we reported that the biological activity depends on the presence of various functional groups in the parent structure (benzene, naphthoquinone, anthraquinone, or quinoline).[16−19] Taken together, introducing or changing the position of the functional groups in the quinoline skeleton had potent acaricidal and insecticidal activities against the three insect species. Our study is the first report on the acaricidal and insecticidal activity of the constituent isolated from *C. colocynthis* fruits against *T. urticae*, *S. oryzae*, and *S. zeamais*.

Recent studies have sought to develop newer and safer control agents to replace older pesticides due to toxicity, pest resistance, and environmental damage.[20] Diwan et al.[21] reported that the acute lethal doses of the methanol extract and water-soluble fraction derived from *C. colocynthis* were 200 and 2000 mg/kg, respectively. According to the safety database,[22] the oral $LD_{50}$ values in mammals of 8-hydroxyquinoline (1200 mg/kg), 2-methylquinoline (1230 mg/kg), and 6-methylquinoline (800 mg/kg) indicate low and moderate acute toxicities. Sakthivadivel and Daniel[23] reported larvicidal activity of the petroleum ether extract of *C. colocynthis* against *Culex quinquefasciatus*, *Anopheles stephensi*, and *Aedes aegypti*. Moreover, quinoline analogues have been widely used as components in the food industry and in traditional medicines for many years.[19,24,25] On the basis of our results, 4-methylquinoline isolated from natural sources and its structurally relative analogues would be good replacements for synthetic pesticides. For this reason, further studies should be conducted to evaluate the effects of the 4-methylquinoline analogues on a wide range of insect pests, as well as to develop formulations to increase the potency and stability.

Supporting Information

**ABSTRACT:** Procyanidins, polymeric flavan-3-ols, are known to possess antioxidant, antiatherogenic, and anticarcinogenic properties. In the present study, we investigated the role of almond (*Prunus amygdalus*) skin procyanidins (ASP) in regulating the protein expression of phase II detoxifying and antioxidant enzymes in HepG2 cells and acetaminophen (APAP)-treated hepatotoxic mice. Treatments of ASP significantly induced the expression of phase II enzymes including NAD(P)H:quinone-oxidoreductase 1, catalase, glutathione peroxidase, and superoxide dismutase in the cells and mice. ASP also potently enhanced the expression of nuclear factor-E2-related factor 2 (Nrf2) and antioxidant response element (ARE)-reporter gene activity in vitro. APAP-induced hepatotoxic markers including AST and ALT in mice were inhibited by ASP administration. However, regulation of upstream kinases by ASP was different between in vitro and in vivo models. Collectively, ASP could induce the activation of Nrf2/ARE-mediated phase II detoxifying/antioxidant enzymes but with differential regulation on upstream kinases between in vitro and in vivo.

**KEYWORDS:** *Prunus amygdalus, almond skin, procyanidins, Nrf2, ARE, antioxidant enzymes, MAPKs, cytoprotection, acetaminophen, hepatotoxicity*

## INTRODUCTION

One of the important strategies of chemopreventive phytochemicals against cancer is the activation of cellular defensive mechanisms to block or prevent cells/tissues from exposure to carcinogens including chemical carcinogens and reactive oxygen species (ROS).[1,2] This could be achieved from the induction of the phase II detoxifying and/or antioxidant enzymes such as heme oxygenase-1 (HO-1), NAD(P)H:quinoneoxidoreductase 1 (NQO1), catalase (CAT), superoxide dismutase (SOD), glutathione peroxidase (GPx), and glutathione *S*-transferase (GST). Most of these enzymes are known to contain a specific nucleotide sequence called antioxidant response element (ARE) in their 5′-upstream promoter region and regulated by the nuclear factor-E2-related factor 2 (Nrf2), a member of CNC family of bZIP transcription factor.[3,4] Activation of Nrf2 by stimuli leads to the liberation of Nrf2 from Keap1 (a cytosolic repressor, Kelch-like ECH-associated protein 1) and facilitates Nrf2 translocation to the nucleus, where it heterodimerizes with small Maf proteins and transcriptionally activates ARE-mediated phase II detoxifying and antioxidant genes.[5] Many studies have indicated that the mechanism of signal transduction for the activation of Nrf2 and Nrf2/ARE-driven detoxifying and antioxidant enzymes is related to the activation of the upstream protein kinases including mitogen-activated protein kinases (MAPKs), protein C kinase (PCK), and phosphatidylinositol-3-kinase (PI3K) via phosphorylation.[6,7]

Acetaminophen (APAP) is a well-known and widely used analgesic and antipyretic drug that is regarded safe at therapeutic doses.[8] However, an overdose of APAP can lead to severe liver damage resulting from the formation of the highly reactive intermediate *N*-acetyl-*p*-benzoquinone imine (NAPQI) due to saturation and incompletion of detoxifying metabolism of APAP by glucuronidation and sulfation.[9] The covalent binding of NAPQI to cellular macromolecules can lead to series of molecular events, including protein alkylation, membrane lipid peroxidation, and formation of ROS and reactive nitrogen species (RNS), which are responsible for acute liver failure.[10] These events lead to a decline of intracellular defense system consisting of various antioxidant enzymes, which results in cell death caused by oxidative stress.[11]

Procyanidins are phenolic polymers mainly composed of the monomeric flavan-3-ol units such as (+)-catechin and (−)-epicatechin, and they are found in various fruits, vegetables, nuts, seeds, and grains.[12] Biological activities of procyanidins may depend on their isomerization, monomer bonding type, and degree of polymerization. Recent reports support that the consumption of dietary procyanidins is an

dx.doi.org/10.1021/jf5027247 | J. Agric. Food Chem. 2014, 62, 8668−8678

important strategy to promote health due to their beneficially biological properties, such as prevention of cardiovascular diseases and cancer.[13,14] Procyanidins have also been well-known as a strong anti-inflammatory agent both in vitro and in vivo by modulating nuclear factor κB (NF-κB) and MAPKs pathways.[15,16] Almond skin has been reported to contain abundant phenolic compounds including catechins and the polymer procyanidins with different degrees of polymerization. Existence of catechins, B-type procyanidin dimers, procyanidin trimers, tetramers and A- and B-type oligomers has been determined in almond skins.[17,18] A roasted almond skin has recently been reported to contain a series of procyanidin polymers with up to 11-mer.[19] Although the composition of almond skin procyanidins has been relatively well-characterized, the biological roles of almond skin procyanidins have not been extensively studied. Previous findings on biological properties of almond skin procyanidins have been limited to radical scavenging antioxidant activity, α-amylase inhibition, and metabolic profiles in human.[17−20] However, chemopreventive and cytoprotective roles of almond skin procyanidins (ASP) have been poorly characterized.

In this study, we isolated ASP and evaluated their cytoprotective properties and the underlying mechanism in regulation of Nrf2/ARE pathway in the human hepatoma-HepG2 cell line as well as in the APAP-induced hepatotoxic mouse model.

## MATERIALS AND METHODS

**Reagents.** The skins of almond (*Prunus amygdalus*) resulting from the blanching of almonds were a courtesy gift of Almond Board of California (Modesto, CA). Phloroglucinol and Toyopearl HW-40F were supplied by Sigma Chemical Co (St. Louis, MO). Solvents for column chromatography and HPLC analysis were of HPLC grade and purchased from Fisher Scientific (Springfield, NJ). MTT [3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide], sulforaphane (SFN), DMSO, acetaminophen, and silymarin were purchased from Sigma-Aldrich (St. Louis, MO). The colorimetric aspartate transaminase (AST) and alanine transaminase (ALT) assay kits were supplied by Young-Dong Co. (Seoul, Korea). Anti-Nrf2, anti-NQO1, anti-SOD2, anti-GPx, and horseradish-peroxidase-conjugated antigoat immunoglobulin IgG antibodies were purchased from Santa Cruz Biotechnology Inc. (Santa Cruz, CA). Anti-p-ERK, anti-p-JNK, anti-p-p38, anti-p-Akt, anti-CAT, and horseradish-peroxidase-conjugated antirabbit immunoglobulin IgG were purchased from Cell Signaling Technology (Beverly, MA). U0126 (MEK1/2 inhibitor), SP600125 (JNK inhibitor), SB202190 (p38 inhibitor), and LY294002 (PI3K inhibitor) were purchased from Cell Signaling Technology. All other reagents used in this study were of the highest grade commercially available.

**Preparation of ASP.** ASP was purified from aqueous extracts of almond skins. Briefly, almond skins (100 g) were milled to fine particles and extracted in 70% aqueous acetone for 48 h at room temperature. After the extraction, the solution was filtered twice through Whatman No.1 filter paper, and the acetone was evaporated using a rotary evaporator with vacuum at 35 °C. After removing the lipids by hexane, the aqueous residue was lypophilized to yield a dry powder. The powder sample was dissolved in 50% methanol and loaded onto a size exclusion chromatographic column packed with Toyopearl TSK HW-40-F (Sigma), which was preconditioned by eluting with 50% methanol (three times of column volume). After preconditioning, the loaded sample was washed with 50% methanol to remove monomeric phenolic compounds, and then eluted with 66% acetone to obtain procyanidins isolate. The eluted ASP isolate was further analyzed.

**BuOH-HCl Hydrolysis and Vanillin Assay in Glacial Acetic Acid.** To determine the presence of interflavan units of ASP isolate, a butanol-acid hydrolysis was carried out according to the methods of Guyot et al.[21] and Porter et al.[22] Two and half milliliters of acidic reagent [5% (v/v) concd HCl in BuOH] and 100 μL of iron reagent [2% (w/v) solution of $NH_4Fe(SO_4)_2 12H_2O$ in 2 M HCl] were added to about 5 mg of the procyanidin isolate in a glass screw-capped test tube. The tube was sealed with a screw cap, agitated vigorously, and heated for 40 min at 95 °C. To determine the presence of procyanidin and the degree of polymerization of ASP isolate, the vanillin assay in glacial acetic acid was performed by the method of Butler et al.[23] The isolate was dissolved in a minimum volume of methanol and filled up to 1 mL with glacial acetic acid. The isolate solution was reacted with 5 mL of vanillin reagent consisting of 0.5% vanillin and 4% concd HCl in glacial acetic acid (1:1, v/v) at room temperature for 20 min. The absorbance of the reaction mixture was measured at 510 nm. Catechin was used as a standard.

**Depolymerization of Procyanidins with Phloroglucinol.** Depolymerization of ASP was performed according to the method of Kennedy and Jones[24] with slight modification. ASP (10 mg), phloroglucinol (20 mg), and ascorbic acid (5 mg) were dissolved in 1 mL of 0.1 N HCl in methanol. The mixture was shaken vigorously and reacted at 50 °C for 20 min. After reaction, the solvent was evaporated by a stream of nitrogen gas and dissolved in 500 μL of distilled water. The solution was extracted 5 times with 1 mL of ethyl acetate. The ethyl acetate extracts were combined, and the solvent was removed by nitrogen gas. The residue was dissolved in 500 μL of methanol and analyzed by HPLC-MS.

**HPLC-Mass Spectrometry (MS) Analyses.** HPLC-MS was carried out using a VG Platform II mass spectrometer (Micromass, Beverly, MA) equipped with atmospheric pressure chemical ionization (APCI) probe in the positive ion mode. The HPLC system consisted of a Varian 9012 HPLC equipped with Varian 9050 UV detector and a Supelcosil LC-18 column (250 × 4.6 mm, particle size 5 μm). Detection wavelength was set at 280 nm, and injection volume was 20 μL. The mobile phase included 1% acetic acid (A) and methanol (B) as follows; isocratic: 0% B, 5 min; gradient: 0−15% B, 5−30 min; 15−60% B, 30−65 min; 60−90% B, 65−90 min. The mass was scanned between 50 and 2000 amu. The source temperature was set at 150 °C, and the probe temperature was 450 °C. The cone voltage and the corona discharge were 15 V and 3 kV, respectively. The scan rate and interscan delay were 2 and 0.3 s, respectively.

**Cell Culture and Treatment.** The human hepatoma cell line, HepG2, purchased from American Type Culture Collection (Rockville, MD), was maintained at 37 °C, humidified atmosphere of 5% $CO_2$ in Dulbecco's modified Eagle's medium (DMEM) supplemented with 10% fetal bovine serum (FBS), streptomycin (100 μg/mL), penicillin (100 units/mL), 1% essential amino acids, and 1% glutamax. The culture medium was renewed once after 2 days. HepG2 cells were allowed to grow about 80−90% confluency and then starved overnight with serum-free DMEM medium prior to treatment with either vehicle (DMSO, 0.1%) or various concentrations of ASP for the indicated periods.

**Cell Viability Assay.** The viability of HepG2 cells in medium containing ASP was determined by MTT assay, which is based on the metabolism of mitochondrial succinate dehydrogenase in viable cells. The cells were seeded onto 24-well plates at a density of $5 \times 10^5$ cells/well and incubated at 37 °C, 5% $CO_2$ for 24 h in a complete medium. After starvation, the cells were treated with a series of ASP concentrations for 24 h and followed by incubation with 50 μL of MTT solution (5 mg/mL) at 37 °C for 4 h in dark. A product from MTT metabolism, formazan crystal, was dissolved in DMSO (500 μL/well). The absorbance was read at 570 nm with a microplate reader (BioTek, Winooski, VT). The levels of cell survival were expressed as a percentage of that in 0.1% DMSO-treated control.

**Preparation of Cytosolic and Nuclear Extract.** The cytosolic and nuclear proteins were prepared by using a Nuclear and Cytoplasmic Extraction Reagents kit (Pierce Biotechnology Inc., Rockford, IL) according to the manufacturer's instructions. Protein concentrations were measured by BCA protein assay (Pierce Biotechnology).

**Assay of Reporter Gene Activity.** The HepG2-C8 cell line containing pARE-T1-luciferase reporter gene was previously de-

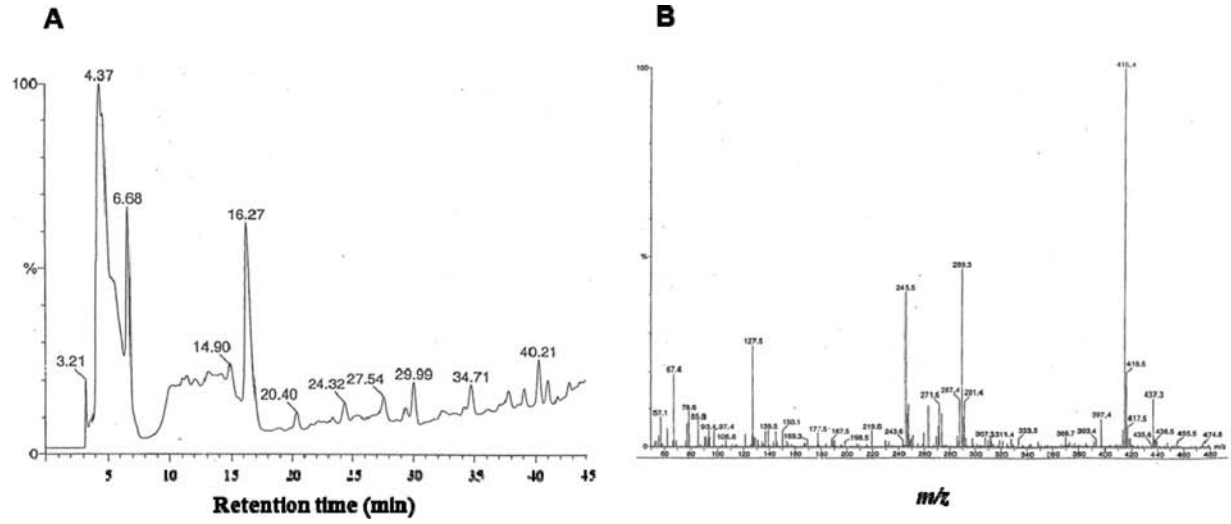

**Figure 1.** HPLC chromatogram of depolymerization products from ASP (A) and APCI-MS spectrum of major peak (peak at 16.27 min) (B).

scribed.[25] ARE-luciferase activity was measured by using luciferase kit (Promega, Madison, WI) following the manufacturer's instruction. Briefly, after treatment with ASP for 12 h, the cells were collected in 1× cell lysis buffer containing 25 mM Tris (pH 7.8 with $H_3PO_4$), 2 mM EDTA, 2 mM DTT, 10% glycerol, 1% triton X-100. After centrifugation, a 10 $\mu$L aliquot of supernatant was assayed for luciferase activity by using GloMax 20/20 luminometer (Promega). Luciferase activity was normalized against total protein concentration, determined by BCA protein assay, and expressed as a fold of induction over that in vehicle-treated control.

**Assay for Antioxidant Enzymes Activity.** For samples from cells, after exposure to ASP for 12 h, the cells were homogenized in ice-cold 50 mM phosphate buffer (pH 7.4) by sonication, followed by centrifugation at 10 000*g* for 20 min to separately obtain supernatant and pellet for further experiments. For samples from mice, liver tissues were collected and homogenized in phosphate buffer (pH 7.0). The protein content was determined using the BCA protein assay (Pierce). CAT activity was determined by the method of Abei[26] following the decrease in absorbance of $H_2O_2$ at 240 nm. One unit of CAT was defined as the amount of enzymes that decomposes 1.0 $\mu$M of $H_2O_2$ in a minute. GPx activity was performed according to the method of Bongdanska et al.[27] A unit of GPx was defined as an amount of enzyme that oxidized 1 nM of NADPH per minute. SOD activity was determined by the method of Oyanagui.[28] The amount of protein required for 50% inhibition in the absorbance at 550 nm was defined as one unit of SOD activity.

**Animals and Experimental Design.** Male Balb/c mice (6 weeks old, 20−25 g) used in the study were obtained from Hyochang Science (Daegu, Korea). The mice were housed in an environmentally controlled room at 25 ± 2 °C, 55−60% humidity, 12 h light/dark cycle and allowed free access to standard laboratory diet and distilled water ad libitum for at least 1 week prior to the experiments. The mice were assigned to six groups ($n$ = 5) and treated as follows: Group1 (control group), animals received only 50% polyglycol as vehicle. Group 2 (ASP group), animals were orally gavaged with 10 mg/kg ASP for three times per week. Group 3 (APAP group), mice were received 50% polyglycol for three times per week and then injected intraperitoneally (ip) with a single dose of APAP (300 mg/kg) in 10 mL/kg saline. Groups 4 and 5 (APAP + ASP group), animals were orally administered with 1 or 10 mg/kg of ASP, per os three times per week and then were exposed to APAP (300 mg/kg, ip) 2 h after the last dose of ASP. Group 6 (APAP + silymarin group), silymarin (50 mg/kg) was administered for three times per week and followed by single dose of APAP (300 mg/kg) once only. Silymarin has been well-known as a natural hepatoprotective agent in treatment of toxic liver diseases and is therefore considered as a positive control in this experiment.[29] Eight hours after APAP administration, the mice were sacrificed to obtain their blood and livers for further biochemical analysis.

**Measurement of Serum ALT and AST Levels in APAP-Treated Mice.** The level of liver damage was determined by detecting the enzymatic activities of plasma ALT and AST. Blood samples from mice were centrifuged at 3000*g* at 4 °C for 10 min, and the ALT and AST activities in serum supernatant were measured using commercially available kits (Youngdong Tech Co., Ltd).

**Western Blot Analysis.** For samples from cells, HepG2 cells were washed with ice-cold PBS (pH 7.4) after treatments, and cells were lysed in 200 $\mu$L of cold cell lysis buffer (20 mM Tris-HCl (pH 7.4), 150 mM NaCl, 1 mM $Na_2EDTA$, 1 mM EGTA, 1% triton, 2.5 mM sodium pyrophosphate, 1 mM $\beta$-glycerophosphate, 1 mM $Na_3VO_4$, 1 $\mu$g/mL leupeptin, 1 mM phenylmethanesulfonyl fluoride) on ice, for 1 h. To analyze protein expression, the proteins (40 $\mu$g) of each sample, normalized by BCA protein assay kit (Pierce), were resolved on SDS-PAGE gels and then transferred onto polyvinylidene fluoride membranes using semidry transfer system (Bio-Rad, Hercules, CA). The membranes were then blocked in PBST (0.1% Tween 20 in phosphate-buffered saline) containing 5% nonfat dried milk for 2 h at 4 °C and followed by incubation with specific primary antibodies overnight at 4 °C. After hybridization with primary antibodies, the membranes were washed with PBST four times, incubated with horseradish-peroxidase-conjugated antirabbit or antigoat immunoglobulin IgG secondary antibodies for 3 h at 4 °C, and washed with PBST four times. Finally, blots were visualized using enhanced chemiluminescence Western blotting reagents (Santa Cruz Biotechnology). For samples from mice, liver tissues were collected and homogenized in cell lysis buffer. Liver tissue homogenates were then centrifuged at 13 000 rpm for 10 min, 4 °C to obtain supernatants. The analytical procedure was the same as that mentioned above.

**Statistical Analysis.** Data were expressed as means ± SD. Statistical comparisons were evaluated using analysis of variance (ANOVA) followed by Tukey's test. $P < 0.05$ was considered as significant.

## RESULTS

**Isolation and Detection of Procyanidins.** Isolation and purification of ASP was carried out by conventional isolation methods as described in the Materials and Methods section. The presence of procyanidins in ASP isolate was determined by hydrolytic reactions such as BuOH-HCl and vanillin assays. The BuOH-HCl hydrolysis reaction of the ASP isolate in the presence of iron(III) salts and heat (95 °C) produced a deep red color (data not shown). Accordingly, these results indicate the presence of interflavan bonds procyanidins in ASP.[21,22] The

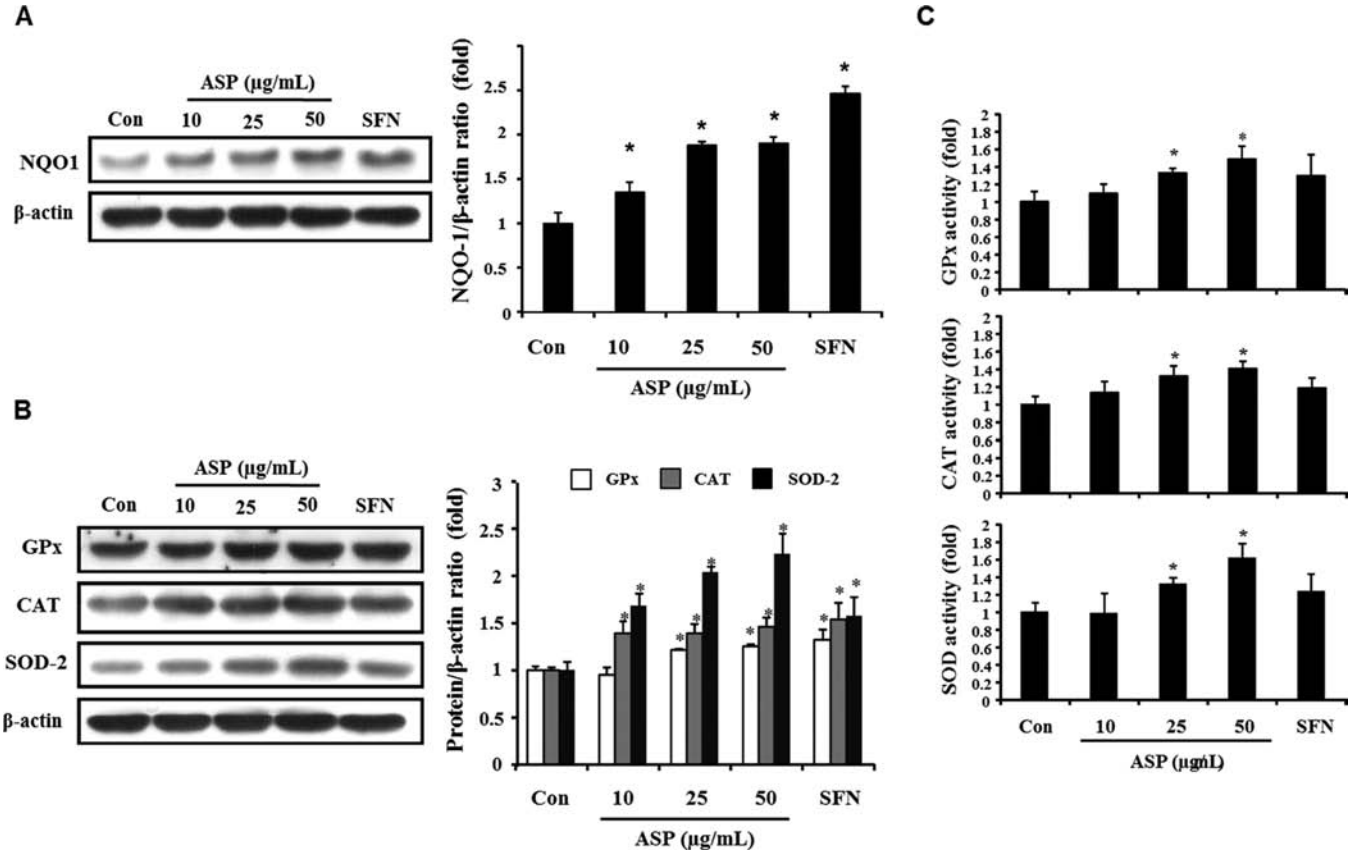

**Figure 2.** Induction of phase II detoxifying and antioxidant enzymes by ASP in HepG2 cells. (A) Protein expression of NQO1. (B) Protein expression of GPx, CAT, and SOD-2. The cells were treated with either vehicle (DMSO 0.1%) or indicated concentrations of ASP for 12 h. Equal amounts of total protein were subjected to Western blotting to analyze the expression of each protein. The results were quantitated by densitometry, and the levels of proteins were normalized with $\beta$-actin. (C) Enzyme activity of GPx, CAT, and Mn-SOD. After treatment with indicated concentration of ASP, the activity of CAT, GPx, and Mn-SOD enzymes was determined, as described in Materials and Method section. Sulforaphane (SFN, 25 $\mu$M) was used as a positive control. Data represent the average ± SD of three independent experiments with the similar results. (*) $p < 0.05$ compared to the vehicle-treated control.

approximate polyphenol content of the ASP isolate by vanillin assay in glacial acetic acid was also carried out. As a result, the ASP isolate showed about 24.1% polyphenol content when catechin, one of major monomeric flavan-3-ol units of procyanidins, was used to standardize this assay. The vanillin assay is a sensitive and simple method to determine flavan-3-ols, dihydrochalcones, and procyanidins. Although the ASP isolate might contain other compounds, the values could be underestimated because the assay has the limitation that only the terminal units of procyanidins react with vanillin in glacial acetic acid. However, this characteristic of the vanillin assay makes it possible to estimate the degree of polymerization. The degree of polymerization can be estimated as the ratio of absorbance of monomer to polymer when measured as the same amount.[23] As a result, the polymerization degree of ASP was found to be 4.2.

**HPLC-MS Analysis of ASP.** The ASP was directly analyzed by HPLC with C18 column, and a broad hump peak at 280 nm was observed (see the Supporting Information Figure S1), which strongly demonstrated the presence of polymeric procyanidins as major constituents in the isolate. Moreover, depolymerization reaction of the ASP isolate with phloroglucinol permitted the evaluation of ASP composition. The interflavan bonds of procyanidins can be cleaved under acidic condition, releasing extension and terminal subunits. The releasing extension subunit intermediates (electrophiles) can be trapped by phloroglucinols (nucleophiles) to produce detectable adducts.[24] The HPLC-MS analysis permitted the determination of cleavage products from the polymeric almond skin procyanidins. The depolymerization of procyanidins yielded several peaks (Figure 1A). However, except for the peaks before 7 min attributed to solvent, ascorbic acid and phloroglucinol, only one major peak at 16.27 min was observed from the HPLC chromatogram. The mass spectrum of the major peak showed $m/z$ = 415 $[M + H]^+$ as base peak, $m/z$ = 437 $[M = Na]^+$, $m/z$ = 289 $[M - H]^+$, $m/z$ = 245 $[289 - CO_2]$, and $m/z$ = 127 [phloroglucinol + $H]^+$ (Figure 1B). Therefore, the major peak was assigned as phloroglucinol adduct resulting from the reaction between phloroglucinol and flavanol extension unit of polymeric procyanidins. These findings suggest that there is only one predominant flavanol as extension subunits in the polymer, which is either (+)-catechin or (−)-epicatechin. A polymeric procyanidin fraction from unripe almond fruit flesh has been shown to contain only procyanidins presenting (−)-epicatechin in their extension units but with both catechin and epicatechin as terminal units (ratio of 3:2).[30] (+)-Catechin (peak at 20.4 min) and (−)-epicatechin (peak at 24.32 min) as terminal subunits were found in the depolymerization reaction mixture by the HPLC-MS analysis. These compounds were identified by the interpretation of their mass spectrum as well as by comparison of their retention time with standard materials and with the

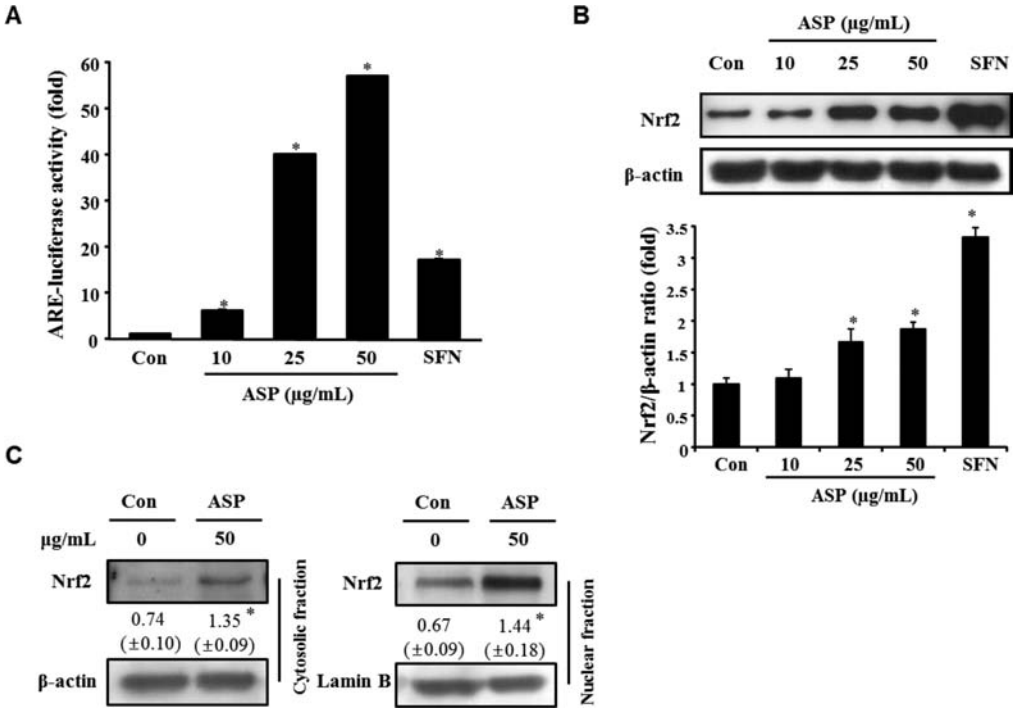

**Figure 3.** Induction of ARE-reporter gene activity and Nrf2 expression by ASP in HepG2-C8/HepG2 cells. (A) ARE-luciferase acidity. HepG2-C8 cells stably transfected with pARE-luciferase reporter gene were treated with either vehicle (DMSO 0.1%) or ASP (10, 25, and 50 $\mu$g/mL) for 12 h. Luciferase activity was normalized with total protein content and expresses as fold induction of vehicle-treated control. (B) Nrf2 expression. HepG2 cells were exposed to either vehicle or indicated concentrations of ASP for 2 h. Equal amounts of total protein were subjected to Western blot analysis using specific antibodies for Nrf2 and $\beta$-actin. (C) Nuclear localization of Nrf2. Cytosolic and nuclear fractions were prepared and analyzed by Western blotting. The results were quantitated by densitometry, and Nrf2 protein levels were normalized with $\beta$-actin (cytosolic fraction) or Lamin B (nuclear fraction). Sulforaphane (SFN, 25 $\mu$M) was used as a positive control. All data represent means ± SD of three independent experiments. (*) $p < 0.05$ compared to the vehicle-treated control.

literature.[24,31] The amount of these terminal subunits was quite small compared to the extension subunits, suggesting that the almond skin polymeric procyanidins might have a very high degree of polymerization. The HPLC-MS analysis also showed compounds with MW 576, $m/z$ = 577 $[M + H]^+$ (peak at 29.99 min). The molecular ion at 577 is two units lower than the (epi)catechin dimer with C−C interflavan bond, indicating that the presence of A-type double interflavan linkage.[30] A- and B-type procyanidins have been found in almond skin with polymerization degrees from dimer to 11-mer.[18,19,30]

**Expression and Activity of Phase II/Antioxidant Enzymes by ASP in HepG2 Cells.** To determine the appropriate concentrations of ASP in HepG2 cells, cell viability was determined after treatments with various concentrations of ASP (0−200 $\mu$g/mL) using the MTT assay. Over 90% of the cells survived after treatments with up to 100 $\mu$g/mL ASP for 24 h and 80% at the dose range 100−200 $\mu$g/mL (see the Supporting Information Figure S2). Based on the cell viability data, doses below 50 $\mu$g/mL of ASP were used for further experiments.

Expression of NQO1, a phase II detoxifying enzyme, in HepG2 cells was examined by Western blotting after exposure of cells to 10, 25, and 50 $\mu$g/mL of ASP for 12 h. As illustrated in Figure 2A, ASP treatment significantly increased the NQO1 protein expression in a dose-dependent manner. The maximal induction of NQO1 (1.8 fold) was obtained at 50 $\mu$g/mL ASP, whereas sulforaphane displayed more potent induction of the protein expression (2.3-fold).

To determine the effects of ASP on the expression of antioxidant enzymes, the protein levels of SOD-2, CAT, and GPx were measured after incubating HepG2 cells with ASP. The expressions of all three antioxidant enzymes were significantly and concentration-dependently upregulated by ASP treatment in the cells (Figure 2B). Especially, the protein expression levels of SOD-2 induced by ASP at the indicated dose range were greater than that induced by SFN (25 $\mu$M). These inductions of antioxidant enzymes by ASP have been found to be correlated with the activity of these enzymes. Correlation coefficients ($R^2$) between protein expressions and enzyme activities of CAT, GPx, and Mn-SOD are 0.66, 0.83, and 0.82, respectively. As displayed in Figure 2C, ASP treatments resulted in the enhancement of the enzymes' activity, although Mn-SOD activity was most potently induced by ASP at 50 $\mu$g/mL.

**Induction of ARE-Reporter Gene Activity and Nuclear Translocation of Nrf2 by ASP in Cells.** To elucidate whether the induction of phase II detoxifying and antioxidant enzymes by ASP was mediated by activation of Nrf2/ARE pathway, the HepG2-C8 cells stably transfected with a pARE-TI-luciferase reporter gene were treated with ASP for 12 h. As illustrated in Figure 3A, the luciferase activity dramatically increased in response to ASP treatments at the indicated doses. The cells exposed to 10, 25, and 50 $\mu$g/mL of ASP displayed the ARE-luciferase activity to 6-, 40-, 55-fold compared to untreated control, respectively. The induction of ARE-luciferase activity by ASP at above 25 $\mu$g/mL was much greater than that induced by SFN (18-fold). Transcription factor Nrf2 is known to play a crucial role in the expression of ARE-mediated phase II detoxifying/antioxidant enzymes such as NQO1, SOD, CAT, and GPx.[32,33] Therefore, we further evaluated whether the

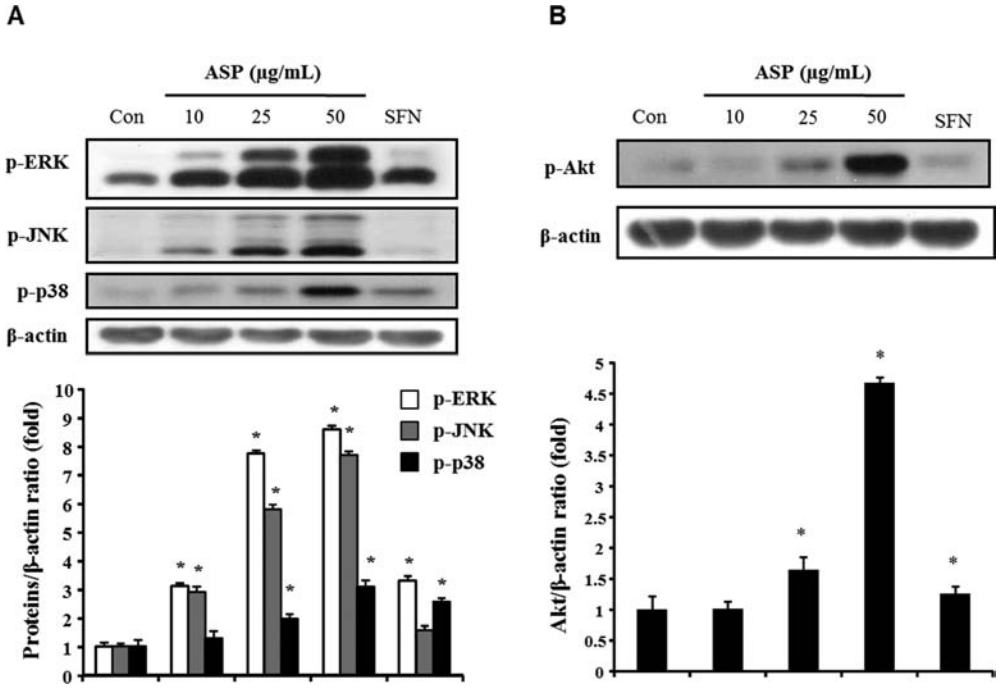

**Figure 4.** Effects of ASP on phosphorylations of MAPKs (A) and Akt (B) in HepG2 cells. The cells incubated in the absence or presence of ASP (10, 25, and 50 $\mu$g/mL) for 1 h were subjected to Western blot analysis using specific antibodies for p-ERK, p-JNK, p-p38, p-Akt, and $\beta$-actin. The intensity of indicated proteins was detected by densitometry and expressed as fold of vehicle-treated control. Sulforaphane (SFN, 25 $\mu$M) was used as a positive control. Each data represents the means ± SD of three independent experiments. (*) $p < 0.05$ compared to the vehicle-treated control.

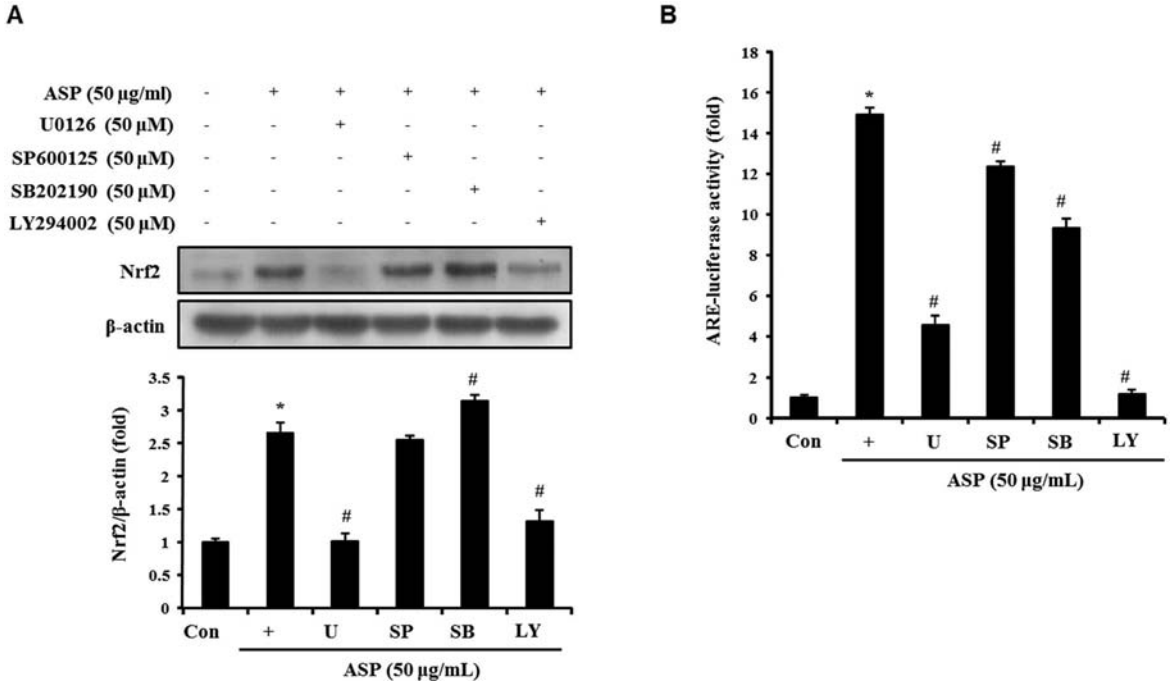

**Figure 5.** Effect of MAPK inhibitors on ASP-induced Nrf2 expression (A) and ARE-luciferase activity (B) in HepG2/HepG2-C8 cells. Cells were pretreated with or without U0126 (MEK1/2 inhibitor), SP600125 (JNK inhibitor), SB202190 (p38 inhibitor), and LY294002 (PI3K inhibitor) for 1 h and then incubated in the absence or presence of ASP (50 $\mu$g/mL) for another 1 h (A) or 12 h (B). The Nrf2 expression was determined by Western blotting, and ARE-luciferase activity was evaluated as described in the Materials and Methods section. The intensity of indicated proteins was detected by densitometry and expressed as fold of vehicle-treated control. Each data represents the means ± SD of three independent experiments. (*) $p < 0.05$ compared to the vehicle-treated control. (#)$p < 0.05$ indicates difference from the ASP alone group.

enhanced expressions of ARE-mediated phase II enzymes by ASP were associated with the induction of Nrf2. As expected, the ASP-treated HepG2 cells exhibited an increased expression of Nrf2 protein in a dose-dependent manner (Figure 3B). Moreover, ASP treatment resulted in the translocation of Nrf2 protein from cytosol to the nucleus (Figure 3C). These data strongly suggest that the induction of phase II detoxifying/antioxidant enzymes by ASP may be mediated by the enhanced

expression and nuclear translocation of Nrf2 in cooperation with ARE.

**Phosphorylations of Upstream Protein Kinases by ASP in Cells.** In order to elucidate whether ASP participates in the Nrf2/ARE-related upstream signaling pathways, we examined the phosphorylations of three MAPK subfamilies including ERK, JNK, and p38 as well as PI3K/Akt. As shown in Figure 4, ASP dramatically and dose-dependently stimulated the phosphorylation levels of all three MAPKs as well as Akt. The phosphorylation levels of ERK, JNK, p38, and Akt by ASP at the highest concentration of 50 $\mu$g/mL reached approximately 8.6-, 7.6-, 3.1-, and 4.6-fold, respectively, compared to that by vehicle-treated control. We further analyzed which upstream kinases were more responsible for the ASP-mediated Nrf2/ARE activation, using specific inhibitors for each kinase: U0126 (MEK1/2 inhibitor), SP600125 (JNK inhibitor), SB202190 (p38 inhibitor) and LY294002 (PI3K inhibitor). Pretreatment with U0126 or LY294002 prior to ASP treatment completely blocked the ASP-induced Nrf2 expression to near basal level, whereas SP600125 and SB202190 were not as effective as U0126 or LY294002 in the blockade of the ASP-induced Nrf2 expression (Figure 5A). Similarly, the ASP-induced ARE-luciferase activity was more effectively suppressed by the inhibitors of ERK and Akt (Figure 5B). Taken together, these results indicate that the ASP-induced activation of Nrf2/ARE-pathway might be at least in part through the activation of ERK and PI3K/Akt pathways in HepG2 cells.

**Effects of ASP on Serum ALT and AST Levels in APAP-Treated Mice.** In the present study, APAP treatment (300 mg/kg) resulted in a dramatic increase in activity of serum ALT and AST, biomarkers of hepatotoxicity,[34] compared to vehicle treatment (Figure 6). Plasma ALT and AST levels increased 9- and 7-fold after an 8 h APAP challenge, respectively, suggesting a significant damage in the hepatocytes by APAP. Preadministrations with ASP at 1 mg/kg and 10 mg/kg, however, significantly attenuated the levels of the ALT and AST activity. Silymarin (50 mg/kg), reported to possess protective capacity against APAP-mediated liver necrosis, similarly inhibited the APAP-elevated activity of ALT and AST. The administration of ASP alone did not affect the basal activity of these transaminases.

**Induction of Nrf2 and Phase II Enzyme Expression by ASP in the Liver of APAP-Treated Mice.** The activation of Nrf2 and phase II enzyme NQO1 in the cell line was further evaluated in APAP-treated animal model. The injection of APAP dramatically lowered the expression of Nrf2 as well as that of NQO1; however, administrations of ASP at both 1 mg/kg and 10 mg/kg restored the reduced expression levels of Nrf2 by APAP to near basal level, whereas administration of ASP alone did not change the basal protein levels (Figure 7). Moreover, the level of NQO1 expression induced by ASP was higher than that induced by the positive control silymarin. Our study is the first in vivo report demonstrating that procyanidins from almond skins have hepatoprotective activity through activation of Nrf2 and Nrf2/ARE-mediated antioxidant defense mechanism.

**Effects of ASP on the Expression and Activity of Antioxidant Enzymes in the Liver of APAP-Treated Mice.** The expression and activity of antioxidant enzymes including SOD-2, GPx, and CAT by ASP were also determined in the APAP-treated mice. Similar to the data observed in Figure 7, the injection of APAP to mice resulted in significant reduction in the expressions of all three antioxidant enzymes. However,

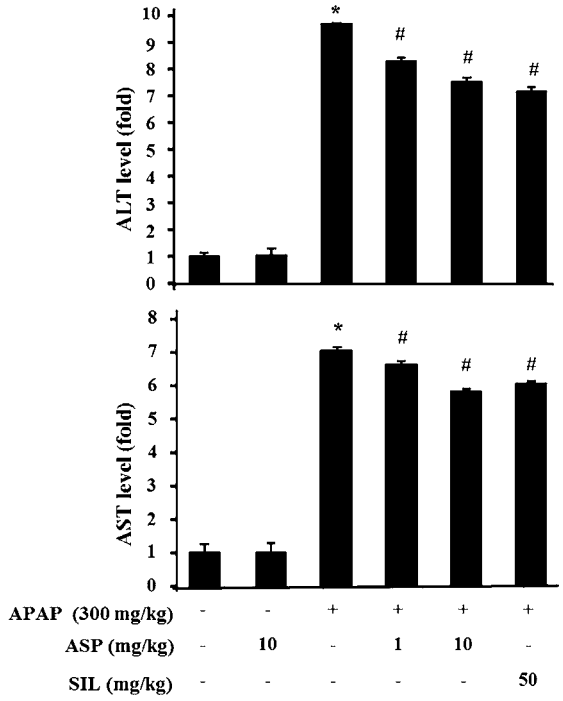

**Figure 6.** Effects of ASP administration on serum ALT and AST levels in APAP-treated mice. Vehicle or ASP (1 or 10 mg/kg) or silymarin (SIL, 50 mg/kg) was orally administered three times per week before intraperitoneal injection of APAP (300 mg/kg) injection. Activities of plasma ALT and AST were measured 8 h after the APAP injection, as described in the Materials and Methods. The data are expressed by means ± SD for five mice. (*) $p < 0.05$, significantly different from the vehicle control group. (#) $p < 0.05$, significantly different from the APAP-treated group.

dx.doi.org/10.1021/jf5027247 | J. Agric. Food Chem. 2014, 62, 8668−8678

ASP preadministration significantly restored the APAP-reduced protein levels of GPx and SOD-2 at doses of both 1 and 10 mg/kg, although the restoration of CAT expression by ASP was not statistically significant ($p < 0.05$) (Figure 8A). The activity of these antioxidant enzymes was also measured in the differentially treated mouse groups. Similar to the data of protein levels, APAP challenge caused reductions in the enzymes activities; however, only decreases in GPx and Mn-SOD activity were significant but not in CAT activity (Figure 8B). Restoration of GPx and Mn-SOD activity was observed only in ASP 10 mg/kg group. The positive control silymarin was not significantly effective in the restoration of antioxidant enzyme activity decreased by APAP treatment in this mouse model system. These data demonstrated that the enhancement of both expression and activity of hepatic antioxidant enzymes by ASP might contribute to attenuate the acute hepatotoxic effect caused by APAP in mice.

**Effects of ASP on Upstream Kinases in APAP-Treated Mice.** Based on the regulatory roles of ASP on MAPKS observed in cells, we further examined the modulation of MAPKs by ASP in APAP-treated mice. In the present study, exposure of mice to 300 mg/kg of APAP resulted in strong increases in the phosphorylation levels of ERK and JNK (2.3−2.7-fold) (Figure 9A). However, APAP treatment significantly downregulated the phosphorylation level of p38 in the mice. Preadministration of ASP (1 or 10 mg/kg) or silymarin (50 mg/kg) inhibited the APAP-induced phosphorylations of the hepatic ERK and JNK. However, the decreased p38 phosphorylations by APAP were significantly restored by ASP or silymarin preadministrations. The phosphorylation level of Akt was not significantly changed by APAP but significantly lowered in ASP treatment at 10 mg/kg (Figure 9B). Overdose of APAP-caused liver damage in rodents has been related to an early oxidative stress and the involvement of JNK activation.[11] The inhibitory effect on the JNK phosphorylation plays vital role in protection of cell/tissue against APAP toxicity. Saito et al. suggested that the JNK inhibitor SP600125 protects mice against APAP-induced liver injury mainly by preventing the mitochondrial oxidant stress and peroxynitrite formation.[35] A recent study also has demonstrated sustained activation of JNK and ERK by APAP in mice and possible protection by ROS scavenging antioxidant.[36] Additionally, PI3K/Akt pathway has been demonstrated to be involved in hepatotoxicity caused by toxicants such as carbon tetrachloride.[37] However, effects of APAP toxicity on the phosphorylation of Akt have not been fully understood yet.

## DISCUSSION

In the present study, various analytical tools confirmed the existence of procyanidins in almond skins with the average polymerization degree about 4.2. Although the exact structures of ASP still remain unclear due to the structural complexity as well as the variety differences. In spite of the efforts for the structural analyses on almond skin procyanidins, their biological roles and the underlying molecular mechanisms have been largely unknown. Our present study shows the cytoprotective activity of ASP in cells as well as in APAP-induced mice.

Protection of cells/tissues from endogenous and/or exogenous carcinogens has been regarded as a key defense mechanism of cancer chemoprevention by natural products. This can be mainly achieved by the induction of phase II detoxifying/antioxidant enzymes such as NQO1, GST, CAT, GPx, and SOD, which are capable of scavenging ROS, metabolizing and eliminating chemicals and their metabolites.[1,33] In this study, our results indicate that ASP possesses an ability to stimulate these phase II detoxifying and antioxidant enzymes in vitro and in vivo. The phase II detoxifying enzyme NQO1 catalyzes the two-electron reductive metabolism and detoxification of quinones and their derivatives resulting in protection of cells against chemical-oxidative stress and cancer.[38] Moffit et al. have shown enhanced levels of hepatic NQO1 may reduce the reactive NAPQI availability by converting it to the parent APAP compound.[39] Role of cellular defensive phytochemicals against oxidative stress can be roughly classified into two categories; direct scavenger of ROS/free radicals or indirect stimulator of cellular antioxidant defense systems including antioxidant enzymes. The major ROS in the mechanism of APAP-induced hepatotoxicity in mice has been superoxide anion radical ($O_2^-$), which dismutates to molecular oxygen and hydrogen peroxide or reacts with nitric oxide (NO) to form peroxynitrite ($ONOO^-$), a potent oxidant and nitrating species.[10] Our results clearly show that ASP significantly induces the expression and activity of SOD in cell and APAP-treated mice, indicating cytoprotection of liver cells/tissues from APAP damage by ASP-mediated SOD activation. Our findings suggest that ASP potentiates the cellular defense system through activation of phase II and antioxidant enzymes both in vitro and in vivo.

Induction of phase II/antioxidant enzymes has been positively associated with transcription factor Nrf2 expression and its nuclear translocation.[33] Therefore, we assume that the induction of the phase II/antioxidant enzymes and cytoprotection by ASP may be due to the activation of Nrf2/ARE pathway. Our previous study has also proclaimed that procyanidins from wild grape (*Vitis amuresis*) seed is a potential chemopreventive agent that activates the phase II enzymes through the regulation of Nrf2/ARE pathway.[40]

Stress-response kinases have been involved in the regulation of cellular signaling pathways in response to a variety of stresses from both external and internal environments.[1] Previous studies have shown that activation of PI3K/Akt and MAPKs including ERK, JNK and p38 MAPK has been shown to participate in the activation of Nrf2 and induction of ARE-mediated gene expressions in various in vitro and in *vivo* models.[41] Yu et al. have indicated that the induction of phase II detoxifying enzymes by SFN and *tert*-butyl hydroquinone is mediated by activation of ERK pathway.[25] Also, it has been shown that JNK implicates in the induction of phase II enzymes by phenethyl isothiocyanate, whereas p38 MAPK activates Nrf2 in response to quercetin in HepG2 cells.[42,43] Although we have found similar effects of ASP in the activation of Nrf2 and phase II/antioxidant genes both in vitro and in vivo models, however, the modulation of upstream kinases by ASP seems to be different between cell line and mouse model. In the HepG2 cell model, ASP potently upregulated the phosphorylations of all three upstream MAPKs and Akt. Moreover, blockade of ERK and Akt using the corresponding specific inhibitor resulted in the inhibition of ASP-induced Nrf2-ARE activation, indicating involvement of these kinases in ASP-mediated stimulation of cytoprotective mechanisms. However, data on upstream kinases from mice were quite different from those observed in cells. ASP administration did not alter the basal phosphorylation levels of these kinases in the liver of mice while overdose of APAP significantly changed the phosphorylation levels. In addition, APAP seemed to differentially regulate each MAPK in mice; it induced phosphorylation of ERK and JNK but

inhibited that of p38 and did not affect Akt phosphorylation. In any case, however, the pretreatment of ASP significantly changed the phosphorylation levels of these kinases toward basal levels. For example, ASP administration reduced the phosphorylations of ERK and JNK stimulated by overdose of APAP while it induced the phosphorylation of p38 reduced by APAP. The reason for this discrepancy in the regulation of the upstream kinases by ASP between cell line and mouse model is not clear at this moment. However, it might come from difference in bioavailability and/or pharmacokinetics between models in vitro and in vivo or the presence/absence of stimuli (APAP in this case).

Despite of abundant data on biological activities of procyanidins, the in vivo bioavailability and efficacy of procyanidins have been continuously questioned. Procyanidins up to tetramers but not higher degrees of polymer have been shown to be absorbed and present in blood circulation.[44−46] Therefore, ASP with average polymerization degree of 4.2 in our study might be able to be, at least in part, absorbed and exert its cytoprotective activity in the current mouse model. However, further studies on the exact molecular mechanisms and pharmacokinetics of ASP should be followed.

**ABSTRACT:** Slight variations in lipid composition of wine yeast membranes can alter some essential functions including selective nutrient transport and ion permeability. The absence of oxygen during alcoholic fermentation inhibits fatty acid desaturation and sterol biosynthesis, thereby reducing the stress resistance of yeast cells. In this work, membrane lipids in two commercial active dry yeast strains rehydrated in the presence of three activators (ergosterol, tetrahydrofolic acid, and manganese) were studied. Each was assayed at three different concentrations. The effect of these activators on the phospholipid, neutral lipid, and fatty acid contents in cell membranes was assessed. Also, cell viability and fermentation kinetics were determined. Ergosterol was found to shorten the lag phase and improve cell viability and membrane lipid composition; tetrahydrofolic acid raised neutral lipid levels; and manganese(II) increased cell viability and modified phospholipid composition and linoleic acid concentration. All activators interacted with yeasts in a strain-dependent way.

**KEYWORDS:** *Saccharomyces cerevisiae, membrane lipids, fatty acids, active dry yeasts, metabolic activators*

## INTRODUCTION

Wine yeasts suffer osmotic, thermal, nutritional, anaerobic, and toxic stress during alcoholic fermentation. Nutritional and osmotic stresses typically occur in high-sugar musts with poorly available nitrogen, whereas anaerobic−toxic stresses take place in the presence of ethanol and short- and medium-chain fatty acids. Those stressing conditions can lead to stuck or sluggish fermentations.

Inoculation with active dry yeasts (ADYs) is a common winemaking practice. On rehydration, ADYs recover their ability to ferment sugars in the must. The dehydration−rehydration process is cell-damaging; thus, cells lose nucleotides, ions, and most soluble cellular components.[1] However, most rehydrated cells keep their reproductive ability if they are grown under optimum conditions after rehydration.[2] ADY manufacturers address this problem by marketing "fermentation activators", including growth factors, which affect cell replication, and survival factors, molecules that yeasts are unable to produce under anaerobic conditions.[3]

The plasma membrane of *Saccharomyces cerevisiae* is about 7.5 nm thick and exhibits cytoplasmic invagination in some regions. The lipid composition of this membrane strongly influences its tolerance to various types and/or levels of stress, as well as its resistance to toxic compounds such as ethanol, acetic acid, acetaldehyde, and medium-chain fatty acids.[4] In addition, lipid composition of the plasma membrane plays a prominent role in the adaptive response of cells.[5] Small changes in it can alter some essential functions such as ion permeability or transport.[6,7]

Some environmental factors (e.g., temperature, oxygen availability), growth rate, and the presence of sterols can modify the lipid bilayer and/or unsaturated fatty acid composition of yeast cell membranes during alcoholic fermentation. The effect of these modifications includes reducing membrane fluidity and altering some essential functions (particularly selective transport of sugars and amino acids).[8]

Sterols take part in the construction and maintenance of eukaryotic membranes by regulating their permeability and fluidity in addition to their ethanol resistance and plasma $H^+$-ATPase activity.[9] It should be pointed out that ergosterol plays a different role depending on its concentration in the medium.[10] Thus, trace contents of this sterol help trigger cell replication, whereas high levels enable active growth and membrane synthesis. The remarkable enrichment of the plasma membrane in ergosterol parallels the preferential location of cholesterol in the plasma membrane of animal cells.[11] Secretory vesicles are second highest in ergosterol concentration, suggesting that these vesicles contribute to the flow of ergosterol from the endoplasmic reticulum to the plasma membrane.[12] On the other hand, Soubeyrand et al.[13] found the in situ addition of sterols during rehydration enhances the fermentation capacity of yeasts.

Several lipids, which have an important rol in membrane fluidity, exhibit dramatic differences in membrane concentration in a temperature-dependent manner.[14]

Phospholipids (particularly phosphatidylcholine, phosphatidylethanolamine, and, to a lesser extent, phosphatidylserine and phosphatidylglycerol) improve membrane fluidity.[15]

The unsaturation degree of fatty acids largely influences the physical properties of the cell membrane.[14,16] Oleic (C18:1), palmitoleic (C16:1), palmitic (C16:0), and stearic (C18:0) are

the main fatty acids in cell membranes.[17] Besides, fluidity is also governed by the packing degree of these fatty acids. Thus, the less unsaturated and long-chained a fatty acid is, the tighter it packs and the less disordered and fluid is the resulting structure. By contrast, the more unsaturated the fatty acid is, the greater is the fluidity of the membrane and the more easily it can adapt to adverse conditions such as a high ethanol concentration or low temperature during fermentation.[18] Consequently, the correlation of unsaturated fatty acid content with ethanol tolerance is potentially due to increased membrane fluidity. *S. cerevisiae* yields saturated and monounsaturated fatty acids of 16 and 18 carbon atoms, but it is unable to produce polyunsaturated acids (PUFAs).[19]

Nonpolar lipids such as triacylglycerides (TAGs) provide an energy pool for the synthesis of membrane lipids[20] and also serve as precursor pool for phospholipids.

The absence of oxygen during alcoholic fermentation suppresses fatty acid desaturation and sterol biosynthesis, thereby reducing the ability of cells to adapt to the dramatic environmental changes involved in the process.[21]

Díaz-Hellín et al.[22] found rehydration of some commercially available yeast strains with different metabolic activators, such as ergosterol or ascorbic acid, to increase their fermentation capacity and sugar consumption. Ergosterol is a cell membrane component that enhances membrane plasticity under hyperosmotic conditions and thus favors nutrient transport;[23] tetrahydrofolic acid plays a role in energy-generating reactions through the biochemical oxidation of carbohydrates, fats, and proteins; and finally manganese(II) is a component of certain ATP-dependent coenzymes and reactions.

The main purpose of this work was to study the membrane lipid composition of two commercial active dry wine yeast strains following rehydration in the presence of three metabolic activators: ergosterol, tetrahydrofolic acid ($FH_4$), and Mn. The last one was selected instead of other oxidation states because it is involved in specific metabolic cycles. To this end, phospholipid (PL), neutral lipid (NL), and fatty acid (FA) compositions of yeasts cell membranes were determined. Yeast viability and fermentation kinetics were also measured.

## MATERIALS AND METHODS

**Yeast Strains and Metabolic Activators.** Two different commercially available active *S. cerevisiae* ADYs designated L2 and L4 and three activators were selected because they improved the behavior of the studied yeasts.[22] Half a gram of each yeast strain was rehydrated in 4.5 mL of physiological solution (0.9% w/v) at 35 °C for 30 min in the presence of $4.5 \times 10^{-2}$ g/L ergosterol plus $3.0 \times 10^{-2}$ g/L Tween 80 (used as emulsifier), 0.56 g/L tetrahydrofolic acid ($FH_4$), or 1.51 g/L manganese(II) sulfate 1 Hidrate (Sigma). The activators were used at normal dose (N) in addition to half-dose (0.5N) and double dose (2N) for kinetics studies and viability. For lipid membrane assays, normal dose (N) and half-dose (0.5N) were used.

Rehydrated cells in the presence of Tween 80 or 0.9% (w/v) physiological solution were used as controls for each treatment.

**Flow Cytometry Analysis.** Following rehydration, viable cell counts were carried out in duplicate using flow cytometry on CyFlow SPACE equipment (Partec GmbH, Münster, Germany) fitted with a 22 mW ion laser for excitation (488 nm) while monitoring with a single emission channel (575 nm band-pass filter). FloMax software (Quantum Analysis GmbH, Münster, Germany) was used for instrument control, data acquisition, and data analysis. As control of full viabililty (99% by propidium iodide stain), an overnight YPD culture of each reference strain was used.

**Growth Kinetics.** Growth kinetics was examined using a sterile synthetic must (125 g/L glucose, 125 g/L fructose, 4.15 g/L YNB with amino acids, 3 g/L malic acid, 2 g/L tartaric acid, and 0.5 g/L citric acid, at pH 3.7). The initial concentration of viable cells was $5 \times 10^6$ cells/mL. A calibration curve was obtained for cell counts using a Thoma chamber versus optical density (OD) (absorbance at 600 nm) using a spectrophotometer (V-530, JASCO, Tokyo, Japan). Tests were performed in microtitration plates and involved reading the OD at 600 nm at 20 min intervals until stationary growth was reached. Plates were read with a Polar Star Omega ELISA instrument (BMG Labtech GmbH, Ortenberg, Germany). Each determination was performed in octuplicate.

**Lipid Extraction from Rehydrated Yeast Cells.** Prior to lipid extraction, a solution of 100 $\mu$L of methanol and 20 $\mu$L of 0.1 mM EDTA was added to the pellet of rehydrated yeast cells with 1 g of 0.5 mm glass beads (Biospec Products, Bartlesville, OK, USA) in Eppendorf tubes and then mixed for 5 min in a Mini-Beadbeater-8 (Qiagen, Hilden, Germany).[24] Lipid extraction was performed in four steps: The first one involved extracting the organic layer with 200 $\mu$L of methanol and 600 $\mu$L of chloroform under stirring on an Orbit M60 vortexer for 1 h, followed by centrifugation at 5000 rpm for 1 min. This procedure was repeated three times with different extractant combinations: 300 $\mu$L of methanol plus 600 $\mu$L of chloroform, 450 $\mu$L of methanol plus 450 $\mu$L of chloroform, and 600 $\mu$L of methanol plus 300 $\mu$L of chloroform. The volume of organic layer extracted in each run was placed in a glass tube that was cleaned with one-fourth of the total extract volume of an 0.88% (w/v) KCl solution. This was followed by vortexing, cooling at 4 °C for 10 min, and centrifugation at 3000 rpm for 5 min. The organic phase was collected and finally concentrated to dryness under a nitrogen stream in a Supelco solid-phase evaporator. The resulting residue was dissolved in a 2:1 (v/v) chloroform/methanol mixture and stored in an amber-colored vial with a glass insert.

**Separation and Quantification of Phospholipids (PLs) in Cell Membrane by High-Performance Thin Layer Chromatography (HPTLC).** Phospholipids (phosphatidic acid (PA), phosphatidylethanolamine (PE), phosphatidylcholine (PC), and phosphatidylinositol plus phosphatidylserine (PI + PS)) were separated by one-dimensional HPTLC on silica gel plates (10 × 20 cm, 200 $\mu$m) (Merck, Darmstadt, Germany) with chloroform, acetone, methanol, glacial acetic acid, and water (50:15:10:10:5, v/v/v/v/v). Samples were loaded by using a Linomat semiautomatic applicator, and the mobile phase was held in a Camag semiautomatic cell. After the plate had been charred with 10% $CuSO_4$ in 8% $H_3PO_4$ and heated at 180 °C for 4 min,[25] PLs were identified using known standards: phosphatidic acid, phosphatidylethanolamine, phosphatidylcholine, phosphatidylinositol, and phosphatidylserine (Sigma). Calibration curves using standards of every phospholipid at a concentration of 0.5, 1, 2, or 4 $\mu$g/ $\mu$L were constructed. An image of the plate was acquired with an image scanner from Amersham Biosciences (Piscataway, NJ, USA). Each spot of the image was quantified with the software ImageJ (National Institutes of Health, Bethesda, MD, USA). All phospholipids were determined in triplicate.

**Separation and Quantification of Neutral Lipids (NLs) in Cell Membrane by Thin Layer Chromatography (TLC).** NLs (squalene, sterol esters, lanosterol, ergosterol, and free fatty acids) were separated by one-dimensional TLC on silica gel plates (10 × 20 cm, 250 $\mu$m) from Merck. Each plate was developed in three steps with (1) 50:50 (v/v) methyl *tert*-butyl ether (MTBE)/glacial acetic acid, (2) 80:20:1 (v/v/v) hexane/MTBE/glacial acetic acid, and (3) pure hexane. Plates were processed as described in under Separation and Quantification of Phospholipids (PLs) in Cell Membrane by High-Performance Thin Layer Chromatography (HPTLC), and Sigma standards (squalene, cholesteryl oleate, diolein, triolein, lanosterol, ergosterol, and ethyl oleate) were used to quantify NLs: calibration curves were constructed from the application of standards to every plate at a concentration of 0.5, 1, 2, or 4 $\mu$g/ $\mu$L.

**Quantification of Fatty Acids (FAs) in Cell Membrane by Gas Chromatography (GC).** Following rehydration, saturated fatty acids (SFAs; C10:0, C12:0, C14:0, C16:0, and C18:0) and unsaturated fatty acids (UFAs; C14:1, C16:1, C18:1, C18:2. and C18:3) were measured. Also, mean fatty acid chain length (ChL) was determined to ease the interpretation of the results. ChL was calculated according to the

following equation: ChL = Σ $(C_i n_{C,i})/\Sigma C_i$, where $C_i$ corresponds to the "$i$" fatty acid concentration and $n_{C,i}$ is the number of carbon atoms in the mentioned acid.

Sedimented cells ($10^8$ cells/mL) in sealed tubes with a Teflon-lined screw cap were saponified using 1 mL of 5% NaOH in 50% methanol/water[26] and placed in a dry bath (100 °C) for 30 min. After that, the saponified material was cooled at room temperature, and 2 mL of 6 M HCl and 1 mL of $BCl_3$ were added to obtain methylated free fatty acids. Then, samples were heated at 80 °C in the water bath for 10 min. At that point, fatty acid methyl esters were extracted with 1 mL of hexane; samples were vortexed for 30 s, and the organic phase was collected after centrifugation (3000 rpm, 3 min). The extraction step was repeated again, and then the combined organic phase extract was washed with 5 mL of Milli-Q water to remove excess HCl. Finally, the organic extract was dried with anhydrous sodium sulfate ($Na_2SO_4$).

Fatty acid methyl esters were separated on a gas chromatograph model 6890 equipped with a 7863 autosampler (Agilent, Santa Clara, CA, USA), a split/splitless injector, and a flame ionization detector (FID). The capillary column used (50 m long × 0.25 mm i.d.) was coated with a 0.25 μm thick film of SGL-1000 (acidified polyethylene glycol) stationary phase, (Sugelabor, Madrid, Spain). The carrier gas was helium at 1 mL/min, the injection volume 3 μL, and the split ratio 8:1. The injector and detector temperatures were both 250 °C. The temperature program was as follows: 100 °C (held for 3 min), 15 °C/min ramp to 210 °C, and a hold for 20 min. Heptanoic acid (20 mg/mL) and heptadecanoic acid (40 mg/mL) were used as internal standards. The amounts of fatty acids found were related to cell dry weights and expressed as percentages of total fatty acids. The determinations were performed in triplicate.

**Statistical Analysis.** Changes in membrane lipid composition upon rehydration of the ADYs in the presence of the metabolic activators were checked by one-way analysis of variance (ANOVA) at the 95% significance level ($p \leq 0.05$), using Duncan's test (SPSS v. 17.0). Data were processed in triads (i.e., each sample was compared with its corresponding control).

## RESULTS AND DISCUSSION

**Cell Viability.** In a previous work, Díaz-Hellín et al.[22] found that rehydration of L2 in the presence of glutathione and glycerol increased cell viability in this yeast strain after 15 days of fermentation. Likewise, L4 exhibited an increase of viability after rehydration in the presence of tetrahydrofolic acid ($FH_4$) and ascorbic acid.

Some extrinsic variables in relation with the transport and conservation of the dry yeasts could influence this parameter. Dehydrated yeast can lose up to 30% of soluble cell compounds when rehydrated, which proves the nonfunctionality of the cell membrane.[1] A faster reduction in nucleotides and trehalose leakage are therefore beneficial for the vitality of rehydrated yeast cells.[2] As can be seen in Figure 1, L2 exhibited higher viability than L4 in all studied cases. This could be a consequence of a specific strain factor because viability percentages hardly vary compared with controls in both strains.

By exception, ergosterol and manganese increased L2 viability in a statistically significant manner, whereas L4 exhibited significantly increased viability when rehydrated in the presence of manganese irrespective of its dose, contrary to what happened with ergosterol, which produced a significant decrease.

**Growth Kinetics.** Besides the lag period and the asymptotic value, another valuable parameter of the growth curve is the maximum specific growth rate ($\mu_{max}$). Because the logarithm of the absorbance is used, $\mu_{max}$ is given by the slope of the line when the organisms grow exponentially.[27] In this work, the growth kinetics of the two yeast strains in terms of initial population ($N_0$), maximum population ($N_{max}$), specific growth rate ($\mu_{max}$), lag time (T-Lag), and duplication time (T-d) were examined.

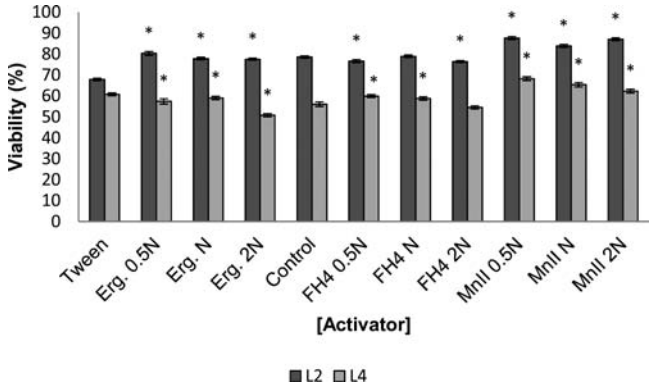

**Figure 1.** Percentage of viability of L2 (black bars) and L4 (gray bars) strains after rehydration with ergosterol (Erg.) + Tween 80, $FH_4$, and Mn(II) at half (0.5N), normal (N), and double (2N) doses. Controls: Tween 80 (rehydration with Tween 80) and control (rehydration with physiological solution). Values are means of $n = 2 \pm$ standard deviations. (*) Significantly different from each control ($p \leq 0.05$, $n = 2$).

L2 reached the stationary growth phase after 38 h of incubation and L4, after 83 h (data not shown). As viability, the lag time (T-Lag) was strain-dependent. Thus, L2 rehydrated in 0.5N ergosterol exhibited a shorter lag phase than both the control and the samples rehydrated with ergosterol at the other two doses (Table 1). It also affected the duplication rate, which was higher than the control and the other evaluated samples. Similar differences were observed in L4 rehydrated with a 0.5N or N dose of ergosterol. As can be seen from Table 1, $\mu_{max}$ and $N_{max}$ for L4 (0.44 $h^{-1}$ and 0.12, respectively) doubled the values for L2 (0.22 $h^{-1}$ and 0.06, respectively), and none of the activators succeeded in increasing them in either strain.

Rehydration in the presence of the tested activators had an effect on either $\mu_{max}$ or $N_{max}$; thus, the strain that started cell division later (L4) grew faster. This could be a result of the fact that the slower the yeast adaptation to the medium, the LAG phase, the better the fermentation kinetic in the LOG phase.

It is noticeable that double doses (2N) did not give remarkable results compared to the other dosages, so it was decided to reject them for further assays.

**Phospholipids and Neutral Lipids.** Overall, PL contents were higher in L2 than in L4 irrespective of the particular rehydration treatment (Figure 2). On the other hand, the NL content was invariably higher in L4 (Figure 3).

The ergosterol treatment significantly increased the content in phosphatidylcholine and phosphatidylinositol−phosphatidylserine in the L2 membrane (Figure 2A), as well as those in all neutral lipids except lanosterol (Figure 3A). Worthy of special note is the accumulation of ergosterol in L2 treated with this activator and also the increase in sterol esters resulting from esterification of sterols. On the contrary, ergosterol had no influence on either the composition or the concentration of the L4 strain phospholipids, except for PA at 0.5N dose, for which concentration diminished significantly (Figure 2B).

$FH_4$ increased the contents in phospholipids and some neutral lipids (squalene, sterol esters, and lanosterol) of L2. By contrast, it caused a slight decrease in the PL concentration of L4 at half-dose (0.5N) and increased it at the normal dose (N), but never overcoming significantly the value of the control.

Manganese(II) affected significantly neutral lipid content in L2 and FA, lanosterol, and squalene for L4. On the other hand, it decreased the contents in all PLs of L4 and only PA in L2 (Figures 2 and 3).

[a]Controls: Tween (rehydration with Tween 80) and control (rehydration with physiological solution). Values are means of $n = 3 \pm$ standard deviation. [b]Statistically significant differences of the treated sample with respect to its control (one-way ANOVA; $p \leq 0.05$; $n = 3$).

On the basis of the kinetic study results, T-Lag (Table 1), ergosterol (0.5N) was the most efficient activator. Therefore, its presence can have a beneficial effect on both yeasts. Ergosterol has been found to accumulate in cells during the initial fermentation stage;[28] also, it is added together with some amino acids and vitamins to some yeast preparations to accelerate fermentation.[29] As stated above, this compound was the most efficient activator for both yeast strains.

Tween 80 had an unexpected effect: whereas L2 was unaffected by its presence, L4 exhibited increased amounts of all neutral lipids (Figure 3).

**Fatty Acid Composition.** The composition of plasma membrane is especially relevant to the production of industrial

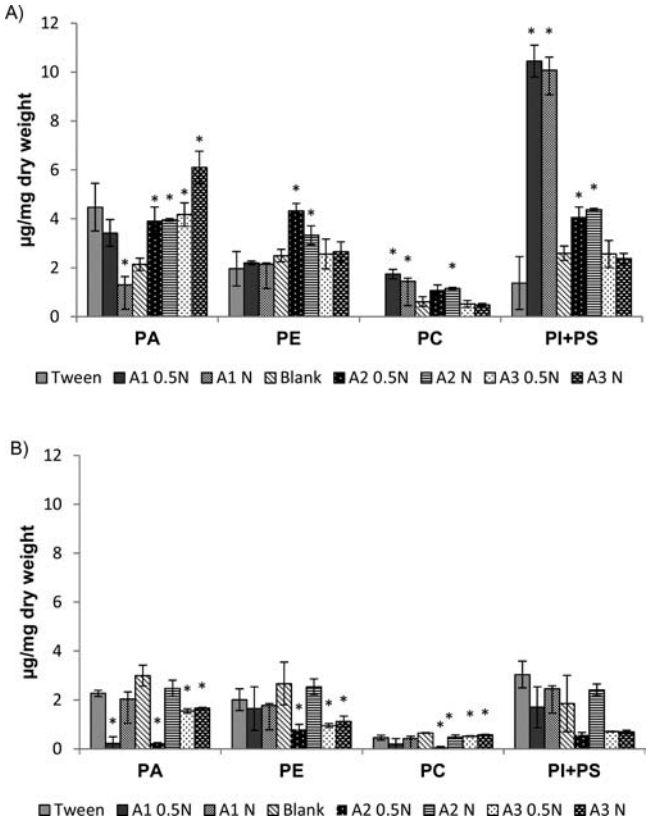

**Figure 2.** Concentrations ($\mu$g/mg dry weight) of phosphatidic acid (PA), phosphatidylethanolamine (PE), phosphatidylcholine (PC), and phosphatidylinositol + phosphatidylserine (PI + PS) determined by TLC in L2 (A) and L4 (B) strains. Treatments are defined in the legend. Controls: (black bars) Tween 80 (rehydration with Tween 80); (slashed bars) control (rehydration with physiological solution). Values are means of $n = 3 \pm$ standard deviations. (*) Significantly different from each control ($p \leq 0.05$, $n = 3$).

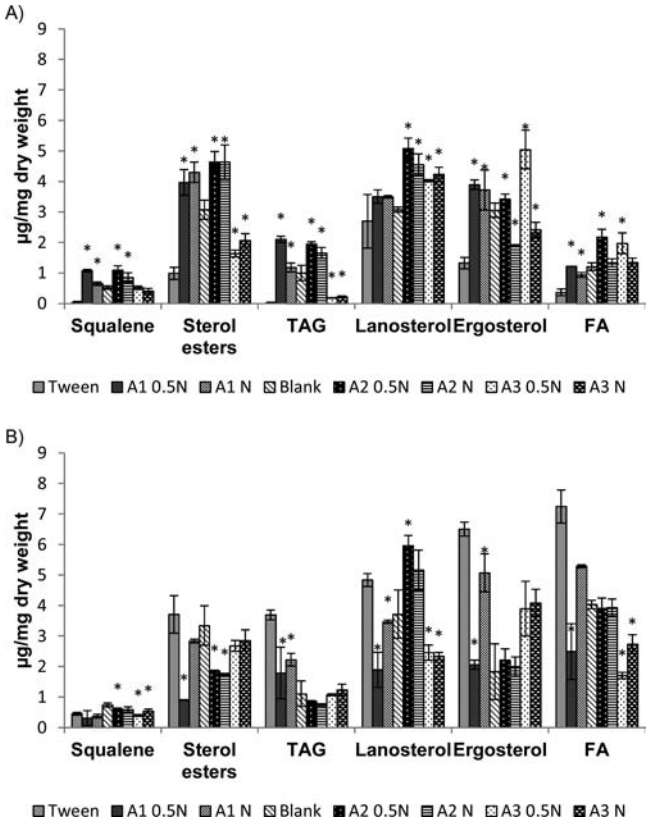

**Figure 3.** Concentration ($\mu$g/mg dry weight) of squalene, sterol esters, triacylglycerides (TAG), lanosterol, ergosterol, and fatty acids (FA) determined by TLC in L2 (A) and L4 (B) strains. Treatments are defined in the legend. Controls: (gray bars) Tween 80 (rehydration with Tween 80); (slashed bars) control (rehydration with physiological solution). Values are means of $n = 3 \pm$ standard deviations. (*) Significantly different from each control ($p \leq 0.05$, $n = 3$).

yeast strains in submerged stirred cultures; thus, enriching cell membranes with linoleic acid (C18:2) and ergosterol has been found to improve their ethanol tolerance.[30] Table 2 lists the proportions of membrane fatty acids in the yeasts after rehydration with the different activators. Overall, the activators had little impact on such proportions; nevertheless, L2 membranes had higher contents in C18 fatty acids (stearic, oleic, linoleic, and linolenic) than L4 membranes irrespective of the particular treatment; therefore, this variable is strain-dependent because already it is known. By contrast, L4 contained greater amounts of C16:0 and C16:1. Rehydrating with manganese(II) (N) or $FH_4$ at any dose significantly increased the content in C18:2 of L4. In the same manner, the N dose of $FH_4$ increased C14:1 of L2. By contrast, the presence of ergosterol decreased the content in C18:3 of L4.

As can be seen in Table 3, the contents in SFAs and UFAs were similar (i.e., treatment-independent) in all samples, with no significant differences among activators or doses. Nevertheless, L2 showed a lesser SFA and a higher UFA content than L4. Moreover, mean chain lengths (ChL) were similar in both strains. Besides, only ergosterol (N dose) caused a statistically significant change (a decrease) in ChL and exclusively in L2. In summary, metabolic activator treatment modified (increased or decreased) the production of fatty acids in both yeasts, but failed to alter their proportions.

Both strains showed different viabilities. L2 exhibited the highest viability in all cases. This could be a consequence of a specific strain factor. Numerous extrinsic variables in relation with the transport and conservation of the dry yeasts could influence this parameter, too.

In general, rehydration in the presence of the tested molecules caused no substantial change in cell viability, which suggests that maybe yeasts require a longer exposure time. Nevertheless, ergosterol was proved to be the most efficient of the three activators assayed. On the basis of the kinetic results, 0.5N dose reduced the lag time of both yeast strains. It also improved cell viability and membrane lipid composition; tetrahydrofolic acid raised neutral lipid levels, and manganese-(II) increased cell viability and modified phospholipid composition and linoleic acid concentration. All activators interacted with yeasts in a strain-dependent way.

As is already known, the content of membrane fatty acids is strain-dependent; the activators had little impact on such proportions. L2 cell membranes had higher contents in C18 fatty acids (stearic, oleic, linoleic, and linolenic) than L4 cell membranes.

Ergosterol treatment resulted in cellular accumulation of this lipid but only in L2. A quantitative lipid analysis revealed the presence of not only free but also esterified ergosterol (as sterol esters). This would make yeasts more robust and efficient in industrial processes under osmotic and hydric stress conditions than they are in alcoholic fermentation.[13]

It should be noted that the target parameters were assessed on freshly rehydrated yeasts. Taking into account that the

above-described changes occur within the first 24 h of cell growth, it would therefore be interesting to perform another subsequent sampling during lag phase to ensure the effect of the different treatments tested.

Supporting Information

**ABSTRACT:** Renewed interest in breeding for high anthocyanins in wheat (*Triticum* ssp.) is due to their antioxidant potential. A collection of different pigmented wheats was used to investigate the stability of anthocyanins over three crop years. The data show higher anthocyanins in blue-aleurone bread wheat (*Triticum aestivum* L.), followed by purple- and red-pericarp durum wheat (*Triticum turgidum* L. ssp. *turgidum* convar. *durum*), using cyanidin 3-*O*-glucoside as standard. HPLC of the anthocyanin components shows five to eight major anthocyanins for blue wheat extracts, compared to three anthocyanins for purple and red wheats. Delphinidin 3-*O*-rutinoside, delphinidin 3-*O*-glucoside, and malvidin 3-*O*-glucoside are predominant in blue wheat, with cyanidin 3-*O*-glucoside, peonidin 3-*O*-galactoside, and malvidin 3-*O*-glucoside in purple wheat. Of the total anthocyanins, 40−70% remain to be structurally identified. The findings confirm the high heritability for anthocyanins, with small genotype × year effects, which will be useful for breeding purposes, to improve the antioxidant potential of cereal-based foods.

**KEYWORDS:** *pigmented durum and bread wheats, total anthocyanin content, qualitative parameters, anthocyanin composition, genotype by environment interaction, minerals, total polyphenol, trolox equivalent antioxidant capacity*

## INTRODUCTION

Wheat (*Triticum* ssp.) is one of the most common human foods in the world, and recently the focus has been on the possibility of increasing the content of bioactive compounds to improve health and prevent disease.[1] Some bioactive compounds can be specific to certain cereals, for example, γ-oryzanol in rice, avenanthramides and saponins in oat, β-glucans in oat and barley, alkylresorcinols in rye, and anthocyanins and carotenoids in pigmented cereal grains.[1−3] In particular, there is extensive literature on anthocyanins in colored rice, corn, and to a lesser extent, in barley, buckwheat, sorghum, millet, bread (*Triticum aestivum* L.) and durum wheat (*Triticum turgidum* L. ssp. *turgidum* convar. *durum*).[2,4−9]

Anthocyanins are recognized as having the ability to scavenge free radicals that can cause oxidative stress in human cells.[10] For a long time, the accumulation of anthocyanins in wheat grain was not considered in breeding programs, except as a genetic marker for specific purposes (feed) to enable their distinction from that used for human consumption or in genetic studies, for example, when carrying out an indirect selection program.[11] Indeed, anthocyanin accumulation is an extremely rare trait, which is seen in some forms of tetraploid wheats, with its high frequency in Ethiopian wheat germplasm.[11] More recently, a series of blue wheats have been developed through intraspecies crosses from *Triticum boeticum*, *Triticum monococcum*, and related wheat species (*Agropyron* ssp.) with bread wheat.[11−13] Early studies confirmed that the purple pigment is localized to the grain pericarp (outer layer), whereas the blue pigment is localized to the grain aleurone layer.[11]

The anthocyanins were identified and quantified in various blue, purple, and red bread wheats by Abdel-Aal et al.[4] The total anthocyanin contents varied from 7.1 to 211.9 μg/g. These pigments normally exist as glycosides (bonded to a sugar moiety), as the anthocyanidin (or aglycon) component alone is extremely unstable. The most common anthocyanin in purple wheat is cyanidin 3-*O*-glucoside (Cy-3-Glc), followed by peonidin 3-*O*-glucoside (Pn-3-Glc), whereas delphinidin 3-*O*-glucoside (Dp-3-Glc) is the most abundant anthocyanin in blue wheat.[2,14]

Carotenoids are the most important natural pigments, and these compounds have a wide distribution, different structures, and numerous biological functions. In humans, the nutritional importance of carotenoids arises mainly from the pro-vitamin A activity of β-carotene. In addition to their role as precursors of vitamin A, carotenoids have been associated with reduced risk of cancer, decreased cardiovascular disease, protection of the macula region of the retina, prevention of cataracts, and increased iron absorption. The concentration of carotenoids is higher in durum wheat (1.50−4.00 μg/g) than in bread wheat (0.50−2.00 μg/g)[15,16] as a result of selection in durum wheat

breeding programs for high yellow pigment concentrations.[17] Inheritance of grain or semolina pigment concentrations is complex, although the overall heritability of pigment concentrations is relatively high, ranging from 0.78 to 0.96.[18]

Recent studies have shown genetic variability for both anthocyanin[4,8,19,20] and carotenoid[3,17] contents in wheat. For breeding programs, the availability of genetic variability is a key factor to consider, as well as the interaction of genotype × environment (G×E). Few studies have been conducted to evaluate the effects of the environment, defined as a combination of location (L), year (Y), and agronomic management of the crop (M), on the total content of anthocyanins in wheat[14] whereas up to now, no studies have been conducted to evaluate the technological performance of these genetic materials.

The objectives of the present study were to (i) explore the genetic variability of the total anthocyanin content (TAC) and other qualitative parameters [yellow pigment (YP), thousand-kernel weight (TKW), protein content (PC), sodium dodecyl sulfate (SDS) sedimentation volume, and ash content (ASH)] and nutritional parameters [minerals, total polyphenol (TPC), Trolox equivalent antioxidant capacity (TEAC)] in wheat grain; (ii) identify the main anthocyanin compounds in a collection of wheats that includes accessions of tetraploid and hexaploid wheats; and (iii) estimate the effects of G×Y over three growing seasons for all of the traits evaluated. This will thus provide information on the existing variability and genetic resources available to breeders to improve the nutritional value of pasta, bread, and other wheat-based end-products.

## MATERIALS AND METHODS

**Genotypes and Field Experiments.** In all, 76 pigmented wheat genotypes were analyzed in the present study. These included 70 (27 purple, 43 red) that were durum wheat (*T. turgidum* L. ssp. *turgidum* convar. *durum* Desf; $2n = 4x = 28$; tetraploid AABB genome) and three that were blue bread wheat (*T. aestivum* L.; $2n = 6x = 42$; hexaploid AABBDD genome) (Supporting Information Table S1). The collection also included two Italian durum wheat genotypes (Preco, PR22D89) and one Italian bread wheat genotype (Spada), which were used as commercial yellow controls, that is, nonpigmented. The 76 genotypes were grown in field trials during three consecutive growing seasons (2008−2009, 2009−2010, 2010−2011) at the CRA-CER in Foggia, Italy. The experimental design was a randomized complete block with three replications. Each experimental unit consisted of a 1 $m^2$ plot (two rows of 1 m length, with 0.5 m between rows).

During the growing season, standard cultivation practices were used. Table S2 (Supporting Information) reports the monthly precipitation and temperature ranges throughout the entire growth cycle of the durum wheat, from November to June.

Whole plots were harvested mechanically on June 13, 2009, June 15, 2010, and June 20, 2011, and the grains were kept at 4 °C until analysis. Approximately 100 g of grain was sampled from each plot shortly before analysis and used for the preparation of whole meal, using an experimental mill (Tecator Cyclotec 1093) with a 0.05 mm sieve.

**Chemicals and Reagents.** Sulfuric acid, hydrogen peroxide, SDS, lactic acid, potassium chloride, sodium acetate ($CH_3CO_2Na{\cdot}3H_2O$), formic acid, 6-hydroxy-2,5,7,8-tetramethylchroman-3-carboxylic acid (Trolox), sodium hydroxide, 2,2′-azinobis(3-ethylbenzothiazoline-6-sulfonic acid) diammonium salt (ABTS), potassium ferricyanide ($K_3Fe(CN)_6$), iron(III) chloride, the gum arabic and catechin standards were purchased from Sigma-Aldrich (Milan, Italy). Methanol, *n*-butanol, hydrogen chloride, acetonitrile, acetone, and acetic acid were purchased from Carlo Erba (Milan, Italy). All chemicals and solvents used in the present study were of high-pressure liquid chromatography (HPLC) grade. Eleven anthocyanin standards were purchased: Cy-3-Glc, cyanidin 3-*O*-galactoside (Cy-3-Gal), malvidin 3-*O*-glucoside (Mv-3-Glc), pelargonidin 3-*O*-glucoside (Pg-3-Glc), and Pn-3-Glc from Extrasynthese (Genay, France); and cyanidin 3-*O*-rutinoside (Cy-3-Rut), Dp-3-Glc, delphinidin 3-*O*-rutinoside (Dp-3-Rut), peonidin 3-*O*-arabinoside (Pn-3-Ara), peonidin 3-*O*-galactoside (Pn-3-Gal), and Pt-3-Glc from Polyphenols Laboratory (Sandnes, Norway).

**Quality Traits Assessment.** Thousand-kernel weight was calculated from the mean weight of three sets of 100 grains per plot. PC was assayed using the micro-Kjeldahl method, according to the AACC International,[21] which was then multiplied by 5.7. The SDS sedimentation volume was measured on 0.6 g of whole meal flour, according to the UNI 10277 method (*Ente Nazionale Italiano di Unificazione*[22]), expressed as a specific SDS sedimentation volume of whole meal flour (in mL/g). The ash content was determined according to the UNI 2171 method[23] for the determination of ash yield by complete combustion. These data are expressed as percentages. Yellow pigments were analyzed according to method 14-50 of AACC International,[24] as modified by in ref 25 for microsamples. The data were expressed as micrograms per gram on dry matter.

**Total Anthocyanin Content Using the pH Differential Method.** The extraction and purification of TAC was performed according to the mehtod of Hosseinian,[9] with slight modifications. A mixture of methanol acidified with 1 N HCl (85:15; v/v) (8 mL) was added to the whole meal samples (0.5 g) in 50 mL centrifuge tubes and sonicated for 18 min at room temperature in an ultrasonic bath (DT 510 Sonorex, DIGITEC). After centrifugation at 9000*g* for 15 min at room temperature, the supernatants were recovered into 15 mL centrifuge tubes. The pellets were extracted with a further 4 mL of the acidified methanol, and following the same centrifugation, the second supernatants were added to the first. These total supernatants were incubated at −20 °C in the dark for 48 h to facilitate macromolecule precipitation. After this incubation, the samples were centrifuged at 9000*g* for 15 min, and the supernatants were filtered using 0.45 μm regenerated cellulose syringe filters (Phenomenex, Torrance, CA, USA).

Total anthocyanin content was evaluated using a colorimetric method with different pH solutions. Two aliquots of the supernatants extracted (750 μL) were put into different tubes and diluted (1:2, v/v) with either potassium chloride buffer (0.03 M KCl), for pH 1.00, or sodium acetate buffer (0.4 M $CH_3CO_2Na{\cdot}3H_2O$), for pH 4.50. The resulting samples were incubated for 30 min at room temperature in the dark and then filtered with 0.45 μm regenerated cellulose syringe filters. The absorbances of the samples at 520 nm were measured against distilled water as the blank. Total anthocyanin content was corrected for the dry matter and is expressed as Cy-3-Glc equivalents as micrograms per gram dry matter.

**Anthocyanin Composition Using HPLC Analysis.** The anthocyanins were extracted according to the method described by Abdel-Aal and Hucl,[14] with slight modifications. Briefly, 500 mg of material was extracted twice by mixing 8 mL of acidified methanol with 1.0 N HCl (85:15; v/v), which was then left in an ultrasonic bath for 30 min, with nitrogen gas introduced into the tubes. The crude extracts were centrifugated at 3000*g* for 15 min at 10 °C and then stored at −80 °C to precipitate the large molecules. The extracts were recentrifuged at 3000*g* for 15 min at 10 °C and concentrated in centrifugal evaporators (JOUAN RC 1022, Thermo Electron Corp.). The concentrated extracts (5 mL) were filtered through 0.45 μm regenerated cellulose syringe filters (Phenomenex) before analysis by HPLC. The anthocyanins were separated and quantified with a 1200 series chromatography system (Agilent Technologies, Waldbron, Germany) equipped with a G1379B degasser, G1312B binary pump, G1367D temperature-controlled injector, G1330B temperature-controlled column thermostat, G1316B photodiode array detector, and Chemstation Rev. B03.02. A 100 mm × 4.6 mm, 2.6 μm, C18 Kinetex column (Phenomenex) was used for the anthocyanin separation. The column temperature was 40 °C, and the mobile phase consisted of (A) 5% formic acid and (B) methanol 22.5%,

[a]TAC, total anthocyanin content (μg/g); YP, yellow pigment (μg/g); TKW, thousand-kernel weight (g); PC, protein content (%); SDS, sodium dodecyl sulfate sedimentation volume (mL/g); ASH, ash content (%). [b]§, significant at $p \leq 0.001$.

acetonitrile 22.5%, and ultrapure water, at a flow rate of 0.5 mL/min. The gradient was programmed as follows: 0 → 12 min, 9% B; 12 → 25 min, 35% B; 25 → 30 min, 50% B; 30 → 35 min, 9% B. The anthocyanins were detected at 520 nm and identified according to their retention times, using UV−vis spectra authenticated standards. The stock standard solutions were prepared by weighing 1 mg of each standard and dissolving each in 1 mL of acidified methanol. The working standard solutions were prepared by diluting the stock solution, and then they were injected. The range of injected standard was from 0 to 40 ng. All of the coefficients ($R^2$) ranged from 0.99981 to 0.99998. Data are expressed as micrograms per gram dry matter.

**Mineral Element Analysis.** The mineral element concentrations (Fe, Mn, Cu, Zn) of the whole meal were determined using a Varian Vista-MPX simultaneous inductively coupled plasma optical emission spectrometer, with CCD detection, as described in detail by Ficco et al.[26]

All of the mineral determinations were compared to certified reference materials (NIST SRM 8436: durum wheat flour on dry weight). The moisture content was determined by oven-drying samples of each material at 60 °C for 24 h and then allowing the samples to cool in a desiccator for 4 h prior to reweighing. The data are expressed as milligrams per kilogram.

**Total Polyphenol Content.** Total polyphenol content was quantified using the Prussian blue assay,[27] as modified and described in detail by Finocchiaro et al.[5] The absorbance was measured at 700 nm using a DU-64 spectrophotometer (Beckman Instruments, Brea, CA, USA). Increasing concentrations of catechin standard (from 0.3 to 1.0 mmol/L, initial concentrations) were used to construct the calibration curve. To verify the linearity of the curve in the range in these samples, the assay was standardized against 0.001 M catechin, and the polyphenols were expressed as catechin equivalents as grams per kilogram dry matter.

**Trolox Equivalent Antioxidant Capacity.** Total antioxidant capacity was evaluated according to the Trolox equivalent antioxidant capacity method,[28] as described in detail by Finocchiaro et al.[5] The TEAC method is based on decoloration of the ABTS radical cation at 734 nm in the presence of antioxidants. The data are expressed in millimoles of Trolox (used as the antioxidant reference) per kilogram dry matter.

**Statistical Analysis.** The results of TAC, YP, TKW, PC, SDS, and ASH were subjected to a combined analysis of variance (ANOVA) using Statistica software (StatSoft version 7.1 StatSoft, Inc., Tulsa, OK, USA) (1), whereas the analysis of minerals, TPC, and TEAC were subject to one-way ANOVA (2), according to the following equations:

$$y_{ijk} = \mu + \alpha_i + \beta_j + (\alpha\beta)_{ij} + e_{ijk} \quad (1)$$

$$y_{ijk} = \mu + \alpha_i + e_{ik} \quad (2)$$

$\mu$ represents the overall mean of all plots in all years, $\alpha_i$ represents the effect of the $i$th genotype, $\beta_j$ represents the effect of $j$th year, and $\alpha\beta_{ij}$ represents the effect of interaction of genotype $i$ with year $j$, whereas $e$ represents the residual effect.

Means were identified as being significantly different on the basis of Fischer's protected least significant differences (LSD) at a probability level of 5%. The variance components were calculated from a mixed model (genotype and genotype by year random effects; year and block within year fixed effects), as analyzed using the restricted maximum likelihood procedure.

Narrow-sense heritability ($H^2_B$) was estimated from the resulting variance components on a genotype-mean basis. Pearson correlation coefficients ($r$) were used to study the relationship among the qualitative traits evaluated.

## RESULTS

**ANOVA and Year Effect.** The results of combined analysis of variance (ANOVA) made on data obtained from three growing seasons are given in Table 1. Highly significant year (Y), genotype (G), and G×Y effects were detected for each of the investigated traits. Component of variance ($\sigma^2_G$ and $\sigma^2_{GY}$) and narrow-sense heritability estimates on a genotype-mean basis were also evaluated (Table 1). Total anthocyanin content showed the highest $H^2_B$ (92.8%) value followed by YP (69.7%). The narrow-sense heritability estimates were small for all other traits, ranging from 16.1% (ASH) to 43.9% (TKW).

The three experimental years showed similar annual temperature ranges, whereas the variations in the total rainfall levels were more significant (Supporting Information Table S2). In particular, the growing seasons of 2009−2010 and 2010−2011 had analogous rainfall, as 435.8 mm and 470.2 mm, respectively. This rainfall was more concentrated in the winter months with respect to the 2008−2009 growing season, during which it was distributed over the entire cycle of the plants, with about 2-fold the rainfall considered as the seasonal average over the past 52 years. These data significantly influenced all of the parameters analyzed, and in particular the PC, SDS sedimentation volume, and ASH, for which the highest values were recorded in the third year (16.90%, 3.03 mL/g, and 2.39%, respectively; Table 2). The behavior observed for TAC, however, was completely the opposite. In this case, the values were higher for those recorded in the first two growing seasons (19.0 and 18.8 μg/g, in 2008−2009 and 2009−2010, respectively), whereas the lowest TAC (17.1 μg/g) was recorded in the third study year (2010−2011). The levels of YP did not follow any clear trend, with an increased accumulation of carotenoids observed in the second growing season (2009−2010), when the minimum value of TKW was also recorded (35.1 g).

**Table 2. Mean Values of TAC and Qualitative Traits of 76 Pigmented Wheat Genotypes Evaluated over Three Growing Seasons at Foggia, Italy[a]**

| year | TAC | YP | TKW | PC | SDS | ASH |
|---|---|---|---|---|---|---|
| 2008−2009 | 18.98 | 5.90 | 45.48 | 13.93 | 2.69 | 2.21 |
| 2009−2010 | 18.82 | 6.75 | 35.08 | 13.83 | 2.99 | 2.03 |
| 2010−2011 | 17.14 | 6.02 | 41.88 | 16.90 | 3.03 | 2.39 |

[a]TAC, total anthocyanin content (μg/g); YP, yellow pigment (μg/g); TKW, thousand-kernel weight (g); PC, protein content (%); SDS, sodium dodecyl sulfate sedimentation volume (mL/g); ASH, ash content (%).

**Qualitative Parameters among and within the Blue, Purple, and Red Wheat Groups.** The data reported in Table 3 subdivide the genotypes according to the color of the pericarp and their ploidy level, and these show higher values of TAC in the pigmented wheat than in the commercial varieties, with values close to zero. In particular, the blue wheat had a higher mean TAC (118.37 μg/g) than the purple (22.60 μg/g) and red (9.91 μg/g). This means that TAC in the blue wheat genotypes was 5-fold greater than for the purple and 12-fold greater than for the red tetraploid wheat.

The blue wheat was also characterized by the highest mean SDS sedimentation volume (4.40 mL/g). Compared to the bread and durum commercial varieties, the pigmented wheat also showed greater accumulation of ash in the grain than the commercial varieties (2.38, 2.21, and 2.22%, for blue, purple, and red wheats, respectively). Different behavior was seen for YP of the grain. In this case, the commercial varieties of durum wheat, which were genetically improved for this YP trait,[17,29] showed the highest YP (9.84 μg/g) compared to both the commercial control bread wheat variety Spada (4.49 μg/g) and the pigmented durum wheat (about 6 μg/g). A good level of variability was also seen for PC, for which the means were included in the range from 11.90 to 13.72% in the commercial wheat; among the pigmented wheats, the red had the highest PC (15.10%), followed by the purple (14.89%) and blue (13.54%). Contrary to what was observed for PC, the qualitative responses of the genetic materials in terms of SDS sedimentation volume were higher for the blue wheat (4.40 mL/g) with respect to the wheat with purple and red pericarp grain (2.80 mL/g each).

Thousand-kernel weight was significantly affected by the level of ploidy and the genetic improvements carried out with these two wheat species over the past decades.[30,31] Indeed, the tetraploid wheat, with particular reference to the durum wheat varieties used as references in the present study, showed higher mean TKW (49.18 g) as compared to pigmented blue wheat (35.46 g).

Considering the genotypic variability within each group (Supporting Information Table S1), among the blue wheat group, Sebesta Blue2 was the genotype with the highest TAC (174.27 μg/g), YP (7.01 μg/g), SDS sedimentation volume (4.90 mL/g), and ash (2.45%) but also the lowest TKW (32.05 g). Compared to the commercial bread wheat (Spada), the blue wheat showed good qualitative traits, in terms of both pigment content (anthocyanins and carotenoids) and technological traits (PC and SDS sedimentation volume).

The purple durum wheats were characterized by a wide range of values for all of the traits evaluated. Wide variations were seen for TAC, which ranged from 8.12 μg/g (Mog) to 50.22 μg/g (378b), for PC, which ranged from 12.47% (MP3) to 17.88% (ELS 6304-56), and for TKW, which ranged from 34.53 g (286b) to 49.70 g (ELS 6404-130-3). The 378b genotype showed the best performance in terms of TAC, PC, and SDS sedimentation volume.

The group of red durum wheats followed the same trend as the purple wheat, with the major differences being for TAC, which ranged from 1.20 μg/g (ELS 6404-139-3) to 24.57 μg/g (ELS 6304-71), for TKW, which ranged from 27.91 g (ELS 6404-114-2) to 49.75 g (ELS 6404-139-3), and for PC, which ranged from 13.02% (ELS 6404-116-3) to 18.38% (ELS 6404-159-2). Interestingly, the lower ash values ranged from 1.98% (337) to 2.06% (ELS 6404-85-2). Both of the durum pigmented groups are characterized by relatively variable YP and SDS sedimentation volume (from 5.26 to 7.34 μg/g and from 2.2 to 3.9 mL/g, respectively).

**Anthocyanin Composition of Pigmented Wheats.** The anthocyanin composition according to the HPLC analysis for the three different pigmented groups collected in the year 2010−2011 are reported in Table 4 and the Supporting Information (Table S3). These show different profiles for each of the groups in terms of the 11 standard compounds used as references for their identification (see Materials and Methods; Figure 1A). No anthocyanins were detected in the commercial wheats used as references (Figure 1C,F).

In the bread wheat, the blue aleurone was most represented by Dp-3-Rut (33.44 μg/g), Dp-3-Glc (13.68 μg/g), and Mv-3-Glc (12.04 μg/g), followed, with lower levels, by Cy-3-Rut (8.42 μg/g), Cy-3-Glu (3.07 μg/g), Pn-3-Ara (2.22 μg/g), Pn-3-Gal (1.94 μg/g), and Pn-3-Glc (0.88 μg/g) (Figure 1B). Among the genotypes belonging to this group, Sebesta Blue2

also showed the highest levels of anthocyanin compounds (85.36 μg/g) by HPLC, as compared to the spectrophotometric analysis.

The anthocyanin profile of the durum wheat genotypes with purple pericarp was simpler than that for the blue wheat. For the purple, HPLC analysis showed a total anthocyanin compound of 11.81 μg/g, with the most representative compound being Cy-3-Glc (10.34 μg/g), followed by Pn-3-Gal (0.58 μg/g) and Mv-3-Glc (0.48 μg/g) (Figure 1D). Within this group, the behavior of the individual genotypes was relatively diverse, especially for the content of Cy-3-Glc, which oscillated between 0.63 μg/g (ELS 6304-69) and 29.00 μg/g (T-1303). T-1303 is the genotype that also showed the highest Mv-3-Glc (2.35 μg/g). For all of the other compounds, extremely small quantities were detected.

A profile similar to that of the previous group was also seen for the red wheat (Figure 1E). In this case, the data confirm the presence of the same anthocyanin compounds, although in smaller quantities. Cy-3-Glc was also confirmed as the most representative compound for this group of wheat (4.02 μg/g), followed by Pn-3-Gal (0.33 μg/g) and Mv-3-Glc (0.22 μg/g). ELS 6404-117-4 was the genotype with the highest levels of anthocyanin compounds (11.39 μg/g), in agreement with its TAC (20.78 μg/g) detected with the spectrophotometric system. For 10 of the 43 wheat genotypes with red pericarp, these anthocyanins were not detected, probably because the amount is below the threshold of detectability of the instrument used.

To quantitatively analyze and confirm the relationships among anthocyanin components, TAC, YP, TKW, PC, SDS, and ASH, the Pearson correlation analysis was applied to the obtained data (Table 5). Higher TAC, but not TKW, was significantly associated with an increase in the concentration of almost all individual anthocyanin components, a finding suggesting that among the tested genotypes there was not a direct influence of the seed weight on the anthocyanin concentration. Positive associations were also recorded between SDS and the anthocyanin content in the grain. In contrast, YP and PC were correlated negatively with each other, but in relation to other characters, they did not show any association.

**Other Qualitative Parameters and Nutritional Properties of Pigmented Wheat.** To complete the characterization of the pigmented wheat, the 76 genotypes collected in the crop year 2010−2011 were also explored for the mineral content of their grain (Table 6 and Supporting Information Table S4). The highest levels of Fe were in blue wheat (46.13 mg/kg), whereas for the other pigmented groups, the means for Fe were lower. A similar trend was seen for Zn in the grain. The blue wheat showed the highest Zn (33.13 mg/kg), followed by the red and purple wheats (31.54 and 31.28 mg/kg, respectively). The other two elements analyzed, Mn and Cu, do not show a definite trend, and the commercial variety PR22D89 showed the highest concentrations of Mn (42.40 mg/kg) and Cu (9.50 mg/kg). Considering the genotypic variability within each group, the blue bread wheat did not show as wide a range as for the purple wheat. Indeed, the data show variations for Fe, from 30.10 mg/kg (286b) to 42.00 mg/kg (ELS 6304-56), for Mn, from 17.60 mg/kg (226) to 51.50 mg/kg (ELS 6304-56), for Cu, from 4.30 (286b) to 9.60 mg/kg (ELS 6404-75-3, ELS 6304-56), and for Zn, from 24.10 mg/kg (9503) to 40.40 mg/kg (ELS 6404-75-3).

Within the red group, for Fe, the range was from 30.80 mg/kg (377b) to 46.80 mg/kg (ELS 6404-159-4), for Mn, from 30.80 mg/kg (377b) to 51.70 mg/kg (ELS 6404-92-4), for Cu, from 3.80 mg/kg (ELS 6404-139-3) to 9.20 mg/kg (1842), and for Zn, from 22.90 mg/kg (377b) to 40.60 mg/kg (ELS 6404-92-4).

Table 7 shows the means for TPC and TEAC in relation to a selected number of genotypes, as representative of each group considered in the present study. These data show a significant correlation between the means of TPC and TEAC (0.97; $p \leq 0.001$). In particular, there was greater accumulation of TPC in the blue-pigmented wheat, as > purple, > red, which is reflected in the performance of the TEAC.

The commercial variety Preco appeared to show abnormal behavior, where a high TPC was seen (4.79 g/kg), and its TEAC was comparable to that for purple durum wheat (19.44 vs 20.08 mmol Trolox/kg).

Table 7. Mean Values of TPC and TEAC for a Subset of Pigmented Wheat Genotypes Collected during the 2010−2011 Growing Season at Foggia, Italy[a]

## DISCUSSION

Increasing attention has been paid to anthocyanins, due to their frequent presence in plants, particularly berry fruits, vegetables, grapes, and more recently in pigmented (black/blue/purple) cereal grains, for their health benefits as dietary antioxidants.[4,19] Most of the studies in the literature have been related to pigmented bread wheat and field trials conducted in a single growing season, and only rarely these investigations were carried out on tetraploid wheat genotypes. In the present study, the results are reported for a large collection of wheat genotypes. These are primarily represented by durum wheat genotypes, but also by bread wheat, with the aim being not only to evaluate the anthocyanin levels and composition in the grain but also to characterize other qualitative traits, which have not been investigated to date. The agronomic evaluation conducted for 3 years has also allowed estimation of the effect of growing season (Y) on the qualitative performance of these genetic materials.

**Total Anthocyanin Content, Qualitative Traits, and Nutritional Properties of Pigmented Wheats.** Our results confirm that blue wheat has, among wheat genetic resources, the highest TAC in the grain.[32−34] Recently, Syed Jaafar et al.[35] analyzed the TAC levels in a series of genotypes of wheat, including the same three Sebesta Blue genotypes analyzed in the present study. Although their mean TACs were relatively higher (159.8, 251.8, and 130.2 μg/g, for Sebesta Blue1, Sebesta Blue2, and Sebesta Blue3, respectively), the authors also confirm the graded list in the present study in which the Sebesta Blue2 genotype shows the highest TAC.

In particular, the TAC range observed in the present study, for the three Sebesta Blue genotypes throughout the entire study period (82.7−174.3 μg/g), was quite similar to that found in blue wheat by Abdel-Aal and Hucl[32] and Zofajova et al.[33] (157 and 193.3 μg/g, respectively).

However, sligthly lower were the values reported by Eticha et al.[34] and Knievel et al.,[19] between 39.9 and 106 μg/g. By contrast, higher values ranging from 76 to 286 μg/g were reported in refs 4, 7, and 19, although these other studies investigated different genotypes with respect to those considered in the present study.

Comparison with the literature of TAC in purple and red durum wheats is difficult, as most of the studies reported were conducted using hexaploid wheat varieties. The means recorded in the present study for purple durum wheat are comparable to

dx.doi.org/10.1021/jf5003683 | J. Agric. Food Chem. 2014, 62, 8686−8695

those reported in numerous other studies.[2,35] In these cases, TACs ranged from 27.0 μg/g[34] for the variety BVAL 258034 to 476.9 and 522.7 μg/g, recorded by Knievel et al.[19] for the breeding of a purple wheat line and by Hossenian et al.[9] in a stressed field trial, respectively. In the case of red wheat, the mean TACs in the present study were lower than for purple wheat, and in agreement with the means of 5, 5.2, and 5.76−7.97 μg/g observed by Escribano-Bailòn et al., Abdel-Aal et al., and Syed Jaafar et al.,[2,32,35] respectively.

The carotenoid pigments were lower than the anthocyanin pigments, which is in agreement with Abdel-Aal et al.,[32] who reported lower YP than TAC. Moreover, Eticha et al.[34] reported a range of YP from 2.6 to 7.6 μg/g for 13 blue and purple wheat genotypes. Here, no significant differences were observed among the three pigmented wheat groups, which suggests that for this character, there has been no selection, in contrast to the commercial varieties of durum wheat. For these latter, the present study indeed shows very high YP, which confirms the strong selective pressure that has been exerted by breeders to increase the content of the carotenoid pigments in the durum wheat grain.[17] The highest PC recorded in the present study is also comparable to the studies of Abdel-Aal et al.[32] and Eticha et al.[34] for both bread and durum wheats and the blue and purple wheats, whereas the red durum wheat shows values similar to those of the two commercial varieties used as controls.

Total polyphenol and TAC are also good indicators of antioxidant capacity, and some studies have reported high correlation between antioxidant capacity and TPC.[36,37] On a selected number of the genotypes chosen within each of the groups of the pigmented wheat in the present study, TPC and TEAC were determined. The positive association (0.64; $p < 0.001$) between TPC and the ability of these compounds to capture reactive oxygen species confirms previous studies on wheat[38−40] and on other crop species.[41] Our data confirm in part also the results obtained by Eticha et al.[34] relating to the antioxidant effects produced by TAC. Indeed, although it is less than that for TPC, the positive association between TAC and TEAC is significant (data not shown). However, the mean TEAC for durum wheat varieties (e.g., Preco) that are characterized by the absence of TAC and a high content of YP suggests that TEAC for some genotypes might be due to one or more other groups of pigments. This confirms the significant, but not exclusive, role that the anthocyanins appear to have in the control and capture of reactive oxygen species.[42]

For the mineral concentrations across the entire collection, the data in the present study are within the ranges defined previously by Ficco et al., Liu et al., and Ozkan et al.[26,43,44] on nonpigmented tetraploid wheat. With the exception of Cu, the concentrations of Mn, Zn, and Fe in purple wheat were higher than those of the commercial varieties (3.0, 5.8, and 3.9%, respectively). Interestingly, the mineral contents in the blue wheat analyzed in the present study are characterized by the highest Fe content (46.13 mg/kg), with a limited range of variation, whereas the red wheat is characterized by the highest Zn content, which is more variable. These data indicate that these variations can be exploited for breeding activities to improve the mineral availability in the final products.

**Effects of Year on Total Anthocyanin Content and Qualitative Parameters of Pigmented Wheats.** In our work we did not observe a strong effect of the growing season and of the G×Y effect on the TAC. Indeed, our results are similar to those obtained by Bustos et al.,[45] who analyzed the effect of crop management on TAC. Different from when a wider range of environmental conditions were explored, a larger effect associated with a significant G×E was observed. Moreover, the results of the G×E response on the accumulation of anthocyanins in wheat grain and their results appear to conflict. For instance, whereas water stress, as argued by Eticha et al.,[34] results in lower accumulation of TAC, Hossenian et al.[9] reported that this stress promotes accumulation of anthocyanin pigments in grain. Moreover, Abdel-Aal et al.[7] argued that in blue and purple wheats, the anthocyanin concentration is significantly influenced by growing conditions and that the environmental effect is much stronger in purple wheat, due to the pigment location in the outer pericarp. Probably, the intensity and duration of the stress may also produce substantialy different outcomes associated with the differences in environmental conditions not different from what is also occurring for complex traits such as grain yield.[29] Considering our results, the behavior of anthocyanin pigments appears similar to that of carotenoid pigments, for which there is a wide literature available that supports for this trait a strong genotypic component and a high heritability.[18,46,47] For the other traits evaluated (TKW, PC, ASH, and SDS), the data reveal that these are more influenced by genotype and G×Y, confirming a greater difficulty in obtaining a genetic progress as reported in refs 29 and 48.

**Anthocyanin Composition of Pigmented Wheat.** Compared to other cereals, such as maize and rice, the anthocyanin composition of pigmented wheat is not well characterized.[2,8] Moreover, the studies reported in the literature have almost always referred to a few selected genotypes of durum wheat. For these reasons, the present study appears to be the first that has examined a large number of purple/red tetraploid wheats. Our analysis was conducted using 11 standard compounds of the anthocyanins, with reference to bread wheat. Our data confirm delphinidin (Dp-3-Rut and Dp-3-Glc) as the main aglycone in blue wheat, as it represents 68.9% of the total anthocyanins,[4,7,8,19,49] followed by cyanidin, in the form of Cy-3-Glu and Cy-3-Rut. However, compared to previous studies, in all three Sebesta genotypes evaluated, relatively large levels of Mv-3-Glc were also found, whereas the peonidin aglycone is always present, and it is glycosylated with various sugars (glucoside, arabinoside, and galactoside) for each of the three genotypes.

To date, more than 15 types of anthocyanins have been identified in purple wheat,[35] which suggests greater complexity in the genetic control of purple durum wheat compared to blue bread wheat.[20] However, with the exception of the study of Hossenian et al.,[9] in which they identified and quantified 13 anthocyanin compounds using HPLC analysis, in all of the other studies, the number of compounds identified was limited to cyanidin in the form of Cy-3-Glc and Cy-3-Rut.[4,35] Although the chromatographic profiles of purple wheat appear more simple than those generated by blue wheat, the retention times overlapped only in part. In the purple and red tetraploid wheats in the present study, Cy-3-Glc was confirmed as the predominant anthocyanin, at 87.5 and 91.4% of TAC in purple and red wheats, respectively, followed by Pn-3-Gal (4.91−7.50%) and Mv-3-Glc (4.06−5.00%), which is consistent with previous results.[9,50] It must be emphasized, however, that with respect to blue wheat, purple and red wheats express lower levels of TAC, and although the chromatograms of wheat with purple and red pericarp appear simpler, this does not mean that other compounds are not present. It could be that the

extraction, identification, and quantification methods used have not allowed for the identification of all of the compounds examined. When the relationship between TAC determined by colorimetry and the sum of the individual anthocyanins determined by HPLC was examined, a significant positive correlation was obtained, with a correlation coefficient of 0.90 ($p < 0.05$). The difference might be due to the contribution of other pigments present in the grain that have an absorbance at 520 nm, and to be sure of this, there is the need to know more through more sensitive detection systems.

In conclusion, pigmented wheat genotypes exhibited large variations in quality and composition of anthocyanins as well as antioxidant activity. Cyanidin and delphinidin are the main anthocyanidins identified in the present collection of pigmented wheat and, although there is a need for more reliable and sensitive methods for their identification and quantification, the knowledge gained from the present study represents a very important aspect toward our better understanding of the genetic mechanisms that regulate the pathways of synthesis of anthocyanins in wheat.

For wheat, these genetic materials represent a source of genes/traits that will be very interesting for the improvement and development of new genotypes with enhanced nutritional properties. The high heritability values recorded for TAC and YP in wheat grain suggest that both traits can be combined, through specific crossing programs, in commercial wheat varieties with high technological grain quality to improve their nutritional value.

The characterization of these materials was also extended to the minerals content and, the higher contents of Fe and Zn make it even more attractive for the production of functional foods and also as added ingredients. In this way, the antioxidant activity of the wheat-derived products can be improved significantly.

However, to ensure a real effect of wheat grain pigments and minerals on human health, it is necessary to undertake further studies to evaluate the stability of these compounds during the manufacture of the final products (bread, pasta, and bakery products), milling, bread- and pasta-making, and cooking and to estimate the effects on human health through the evaluation of biomarkers of target functions and biological response.

Supporting Information

**ABSTRACT:** Epidemiological and toxicological studies have suggested Annonaceaeous acetogenins to be environmental neurotoxins responsible for sporadic atypical parkinsonism/dementia in tropical areas. These compounds are present in the tropical genus *Annona* (Annonaceae), known for its fruit-yielding cultivated species such as *Annona cherimolia*. This species is widely cultivated in South America, Spain, and Portugal and yields acetogenins in its seeds, stems, and roots. The presence of these compounds in the pulp of its fruit and in derived food products is unclear. An innovative and sensitive methodology by HPLC-ESI-LTQ-Orbitrap with postcolumn infusion of lithium iodide was used to identify the presence of low levels of acetogenins in an *A. cherimolia* Mill. fruit-based commercial alcoholic beverage. More than 80 representatives were detected, and the 31 most intense acetogenins were identified. All together these findings indicate that this species should be considered as a risk factor within the framework of a worldwide problem of food toxicity.

**KEYWORDS:** *acetogenins, Annona cherimolia Mill., Annonaceae, annonacin, dereplication, environmental neurotoxins, mass spectrometry, HPLC-MS/MS*

## INTRODUCTION

The tropical family Annonaceae has economic importance in the food-processing industry and fresh fruit local markets, mainly with members of the genus *Annona*. Species such as *Annona cherimolia* Mill. (annona, chirimoya), *Annona muricata* L. (soursop), and *Annona squamosa* L. (custard apple) are appreciated for their edible fruits and derived food products.[1] These plants are also widely used in traditional medicine.[2] Case-control studies[3−5] have suggested consumption of the fruits of Annonaceae and herbal infusions derived from these plants as the cause of the high prevalence of sporadic atypical Parkinsonism/dementia clusters reported in Guadeloupe (French West Indies)[6,7] and New Caledonia.[8] They might also be involved in atypical Parkinsonism observed in some communities in London[9] and on the island of Guam.[10] Phytochemical and toxicological studies have identified Annonaceous acetogenins (AAGs), a class of polyketides specific to the Annonaceae,[11,12] as candidate neurotoxins. The French food safety agency expressed its concern about this issue.[13]

AAGs constitute a chemically homogeneous class of polyketides with a common skeleton consisting of an $\alpha,\beta$-saturated or unsaturated $\gamma$-methyl-$\gamma$-lactone, optionally hydroxylated, substituted in position 2 by a long alkyl chain of 32 or 34 carbons. The aliphatic chain most often bears one or two tetrahydrofuranic cycles (THF) flanked by adjacent hydroxyls, free hydroxyls (possibly acetylated), ketones, epoxides, or double bonds. These compounds are potent inhibitors of mitochondrial complex I, with structure−activity relationships based on the above-mentioned structural features and global lipophilicity.[12,14] In agreement with clinical and anatomopathological observations, toxicological studies showed that these compounds induce hyperphosphorylation and redistribution of Tau and cell death in striatal and cortical neuronal primary cultures.[14−17] Annonacin, the major AAG of *A. muricata*, induces neurodegeneration after subchronic systemic intoxication in rats and Tau hyperphosphorylation in neurons of mice transfected with the human mutated Tau gene.[18−20] Chemical homogeneity among members of the Annonaceae family suggests that all edible species might be sources of AAGs. Indeed, phytochemical studies of *A. muricata*, *A. squamosa*, and *Asimina triloba* Dunnal. (paw paw) revealed significant quantities of AAGs in their fruits.[17,21−24] In addition, soursop processed nectars from different origins were also shown to contain AAGs.[21−23,25]

The fruit of *A. cherimolia* is cultivated and eaten in South America and Asia and also in southern Europe, with Spain as the main producer and an annual volume of 300 tons for the Portuguese island of Madeira only.[26] However, it is unclear whether the species is a dietary source of AAGs. Indeed, the chemical composition of this fruit is poorly known apart from essential oil and kaurane diterpenes.[27−29] According to the literature, 27 AAGs have been isolated from the seed, stem, and

root of this species, including 3 artifactual compounds.[12,30] Our previous study showed the absence of AAGs in fruits originating from Spain.[29] We recently developed an innovative approach for the detection of AAGs, using reversed-phase high-performance liquid chromatography coupled to a hybrid linear trap/Orbitrap mass spectrometer (LTQ-Orbitrap) with post-column infusion of lithium.[25] Under these conditions, intense lithium adducts of AAGs are preferably formed, with enhanced detection compared to other metabolites, providing useful fragment ions for structural studies. This technique was here used to investigate an industrial alcoholic beverage prepared with *A. cherimolia* originating from Madeira (Portugal). In the total ethyl acetate (EtOAc) extract, numerous AAGs could be detected, and those yielding the most intense $[M + Li]^+$ ions could be identified or structurally characterized.

## MATERIALS AND METHODS

**Chemical Reagents.** Ethyl acetate (EtOAc), methanol (MeOH, LC-MS grade), acetonitrile (HPLC grade), and $H_2SO_4$ were purchased from VWR-Prolabo (Fontenay-sous-Bois, France). Lithium iodide (LiI) and sodium sulfate ($Na_2SO_4$) were purchased from Sigma-Aldrich (Saint Quentin-Fallavier, France). Milli-Q water was prepared in house.

**Standards.** Diepomuricanin-B (**1**) ($C_{35}H_{62}O_4$; monoisotopic mass = 546.4648 Da), corossolin (**3**) ($C_{35}H_{64}O_6$; monoisotopic mass = 580.4703 Da), annonacin (**6**) and *cis*-annonacin (**7**) ($C_{35}H_{64}O_7$; monoisotopic mass = 596.4652 Da), *trans*-corossolone (**13**) and *cis*-corossolone (**14**) ($C_{35}H_{62}O_6$; monoisotopic mass = 585.4701 Da) were obtained as previously described.[12,31] Stock solutions were prepared in methanol at a concentration of 1 $\mu$M.

**Extracted Material.** *A. cherimolia* Mill. alcoholic beverage (brand Licor de Annona, J. Faria and Filhos, LDA; no batch number), packaged in a glass bottle (total volume = 0.7 L), was purchased in Madeira (Portugal). Its composition was "water, 20° alcohol, sugar and annona".

**Extraction.** The beverage (0.5 L) was acidified with $H_2SO_4$ (0.5 N) to pH 3 and then extracted (L/L) three times with EtOAc (3 × 300 mL) followed by centrifugation for 15 min at 4000 rpm to remove the emulsion produced by sugars. The organic phases were combined, dried over anhydric $Na_2SO_4$, and evaporated to dryness under reduced pressure to obtain a sample of 141 mg (yield = 4.7 × $10^{-2}$% w/v). The extract was kept at 4 °C. Aliquots were extemporaneously dissolved in MeOH (1 mg/mL) and filtered using an Acrodisc CR 4 mm syringe filter (0.45 $\mu$m PTFE membrane) before injection in the chromatographic system.

**High-Performance Liquid Chromatography with Tandem Mass Spectrometry (HPLC-MS/MS).** HPLC was performed on an HPLC Ultimate 3000 system (Dionex, Voisins-le-Bretonneux, France) consisting of a degasser, a quaternary pump, an autosampler, a column oven, and a photodiode array detector. Separation was achieved on an octadecyl column (Sunfire, 100 × 2.1 mm, 3.5 $\mu$m particle size; Waters, Guyancourt, France), equipped with a guard column. Column oven temperature was set at 30 °C. Elution was conducted with a mobile phase consisting of water (A) and acetonitrile (B), following the gradient 40 to 100% B in 25 min, then maintaining 100% B for 7 min at a flow rate of 0.3 mL/min. Injection volume was 10 $\mu$L (full loop) for standards and extract solutions. After LC separation, UV detection was operated at 210 nm. The HPLC system was interfaced to a hybrid linear trap/Orbitrap mass spectrometer (LTQ-XL Orbitrap, Thermo Scientific, Les Ulis, France) equipped with an electrospray (ESI) ionization source. Accessible ranges were $m/z$ 250−1200 for full-scan MS experiment and $m/z$ 160−700 for $MS^2$ experiments. Mass resolutions (fwhm) were fixed at 60000 and 30000 for MS and $MS^2$ experiments, respectively. The source parameters in the positive ion mode were as follows: spray voltage set at 5 kV, capillary temperature at 300 °C, capillary voltage at 45 V, and tube lens voltage at 165 V. The optimal collision energy was 50 au, and activation time was 33 ms. Postcolumn infusion of lithium iodide (2 mM in MeOH) was performed at a flow rate of 5 $\mu$L/min. Mass measurements were obtained with a mass precision below 3 ppm using an external calibration. The LOD (UV, MS) of purified annonacin (**6**) was evaluated in the same conditions, based on triplicate injection (10 $\mu$L) of the targeted concentration, with a signal-to-noise ratio above 3.

**AAGs Classification.** After structural identification, the AAGs contained in the extract were ranked using the classification established by Cavé et al.[11] The first rank classification type is based on the layout of the aliphatic chain: A-type (mono-THF), B-type (adjacent bis-THF), or C-type (nonadjacent bis-THF). These THF cycles are always flanked by two adjacent hydroxyl groups, except for a few representatives with one hydroxyl only, placed on the methyl-terminal end. E-type AAGs contain no THF, but epoxides and/or double bonds. The second rank classification is the subtype depending on the nature of the lactone ring. The most frequently referenced are subtype 1a ($\alpha,\beta$-unsaturated $\gamma$-methyl-$\gamma$-lactone) and subtype 1b ($\alpha,\beta$-unsaturated $\gamma$-methyl-$\gamma$-lactone with a hydroxyl on the C-4 position).

**Data Analyses.** The search for AAGs formulas corresponding to lithiated adducts was carefully achieved following the method described below. $[M + H]^+$, $[M + Na]^+$, and $[M + K]^+$ ions were excluded on the basis of the raw formulas assigned for each of these ions (precision better than 3 ppm). The characteristic structural fragments of lithiated adducts were sought according to the method established in our previous publication.[31] To validate that these compounds are AAGs, characteristic fragments of AAGs were first sought in the $MS^2$ spectra of C35 and C37 compounds corresponding to the AAGs: loss of CO (−27.9949 amu), $CO_2$ (−43.9898 amu), and cleavage on $\beta$ of the lactone.

Second, other characteristic structural fragments were searched, according to the classification established by Laprévote et al.: terminal $CH_3$-containing X-fragments, produced by an $\alpha$-cleavage of hydroxyl group; lactone-containing B-fragments for cleavage of a THF group; terminal $CH_3$-containing Y-fragments by breaking of bis-THF (B-type AAGs) and nonadjacent-THF groups (C-type AAGs); and finally lactone-containing c-fragments for the cleavage of an epoxide cycle.[25,31] Numeral subscripts used with these letters distinguish the different ions belonging to the same series (e.g., $X_1$ is the fragment produced by $\alpha$-cleavage to the first hydroxyl group, starting from the methyl end) (Figure 1). Fragments corresponding to successive water losses are not specific to the number of hydroxyls and therefore were not used. The relative intensity of the fragment corresponding to the $\beta$-cleavage of the lactone can differentiate subtype 1a (<100%) from subtype 1b (100%). However, no fragment allowed full characterization of the part between THF and terminal $CH_3$, the second epoxide, ketones, and double bonds.

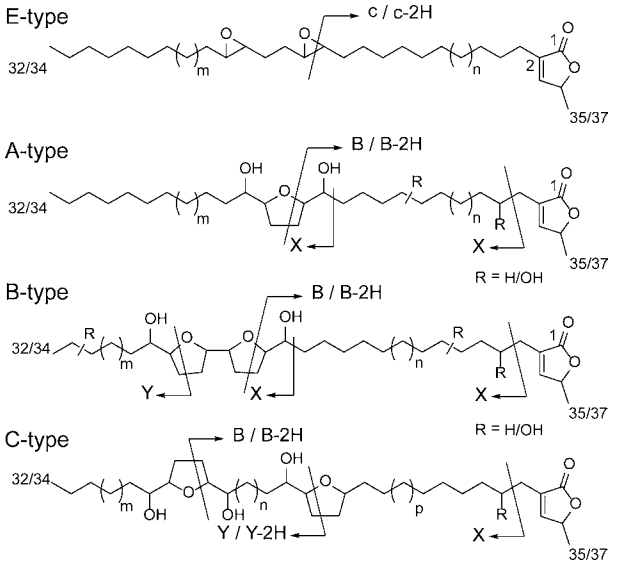

**Figure 1.** Fragmentation patterns for the $[M + Li]^+$ adduct ions of AAGs identified in the *Annona cherimolia* alcoholic beverage.

## RESULTS AND DISCUSSION

**Detection of AAGs.** Analysis of the EtOAc extract of the *A. cherimolia* fruit alcoholic beverage was performed by HPLC-UV-LTQ-Orbitrap with postcolumn infusion of lithium under previously described conditions.[25] Three major molecules at retention times Rt = 18.3, 20.0, and 26.0 min, respectively, are distinguishable by UV detection (Figure 2a). These compounds with respective formulas $C_{25}H_{38}O_5$, $C_{26}H_{40}O_5$, and $C_{24}H_{38}O_4$ do not match with AAGs structural definition (C35 or C37). $MS^2$ studies did not show the characteristic fragments of AAGs described in our previous publication (loss of CO, $CO_2$, and lactone). In the total ion current chromatogram (TIC) different peaks corresponding to mass-to-charge ratio of AAGs are however detected (Figure 2b). The low TIC intensity and the absence of detection of AAGs by UV, despite the high amount of extract injected (10 $\mu$g), show the little quantity of these compounds in our extract in comparison to *A. muricata* pulp

dx.doi.org/10.1021/jf501174j | J. Agric. Food Chem. 2014, 62, 8696−8704

extract.[25] Indeed, the LOD of annonacin (**6**) was $5.10^{-7}$ M in UV ($\lambda$ = 210 nm) and $2.10^{-10}$ M in MS with postcolumn lithium infusion.

**AAGs Profile.** More than 80 AAGs are detected as lithiated adducts, including 20 different formulas. These results offer new insight on the chemical composition of the species, in which 27 AAGs corresponding to 7 different raw formulas had been identified so far. Most of the chromatographic peaks corresponding to AAGs are observed between 10 and 22 min, with about 12 main representatives (Figure 2b). Thirty-one AAGs could be precisely and unambiguously characterized and classified into types and subtypes, among which 18 were identified.

**C35 AAGs.** Thirteen different nominal $m/z$ values were attributed to the $[M + Li]^+$ ions of AAGs bearing 35 carbon atoms. Eight of them correspond to AAGs already isolated from the Annonaceae family, whereas only four were known in the case of *A. cherimolia* ($C_{35}H_{60}O_7$; $C_{35}H_{62}O_7$; $C_{35}H_{64}O_7$; $C_{35}H_{66}O_7$).[12] The formula $C_{35}H_{60}O_8$ had never been described within the AAGs group. Over 55 different C35 AAGs were detected, that is, 66% of the total number of AAGs. Preferential biosynthesis of AAGs of such length was indeed suggested by previous isolation works and is observed in most *Annona* species studied so far.[11,12]

**E-Type: Aliphatic AAGs.** No E-type AAG has been described in *A. cherimolia* so far. Two species with the same formula $C_{35}H_{62}O_4$ are detected at very low intensity ($4 \times 10^4$) and closely eluted at retention times Rt = 30.5 (**1**) and 30.8 min (**2**) (Figure 2c). Their $MS^2$ spectra exhibit major fragment ions corresponding to the loss of water, CO, and $CO_2$, whereas cleavage in $\beta$ of the lactone ring is not noticeable, indicating that they belong to subtype 1a (i.e., no hydroxyl in C-4). However, the c and c-2H fragments are detected (Table 1), indicating the presence of an epoxide between C-17 and C-18 carbons (Figure 1). Finally, coelution with a standard of the bis-epoxydic diepomuricanin-B confirmed the identity of **1**. Structural knowledge of E-type AAGs designates **2** as its diastereoisomer (Figure 3), the second epoxide being located in the $\gamma$-position of the first.[11] E-type AAGs are considered as biosynthetic precursors of THF-bearing, biologically active AAGs and are minor compounds in Annonaceae.[12,32] Their low amount in the extract could thus be expected. However, only compounds **19**–**24** are possible biosynthetic derivatives of **1** and **2**, which cannot be proposed as precursors of any of the A-type AAG identified in the extract (see below).

**A-Type A: Mono-THF.** Three main compounds are attributed to the formula $C_{35}H_{64}O_6$, along with about five minor peaks. Two of them were partially separated, at retention times Rt = 23.5 min (**3**) and 23.8 min (**4**), respectively. Both showed low intensity ($1 \times 10^5$) (Figure 2d). The fragment resulting from the cleavage in $\beta$ of the lactone shows that they belong to subtype 1a ($[M - C_6H_8O_2 + Li]^+$, relative intensity $\leq$ 10%). In addition, for the first compound, in the $MS^2$ spectrum of $m/z$ 587.48–587.49 ion, a B-fragment is detected, allowing placement of a THF ring between C-16 and C-19 carbons ($B_1 - 2H$ fragment), flanked by hydroxyl groups (postulated for C-20) (Figure 1). According to coelution with a standard, these two molecules are unambiguously assigned to corossolin (**3**) and a stereoisomer (**4**) (Figures 2d and 3). Neither has ever been described in this species. The third compound (retention time Rt = 25.3 min) is an AAG of subtype 1b (i.e., hydroxylated in C-4), but no other fragment was detected.

The most intense peaks ($7.8 \times 10^6$) correspond to AAGs with the formula $C_{35}H_{64}O_7$ (Figure 2e). Along with four minor peaks, eight main molecules are detected in the chromatogram, all of them bearing a hydroxyl in position C-4 on the aliphatic chain (subtype 1b, $X_4$ fragment, relative intensity = 100%). The four most polar compounds have an $\alpha,\alpha'$-dihydroxylated THF system placed between the C-15 and C-20 carbons ($B_1$, $B_1 - 2H$, $B_1 - 2H - H_2O$, and $X_2$ fragments). Three of them (retention times Rt = 17.9, 18.9, and 19.2 min) have their last hydroxyl located at C-10 ($X_3$ fragment). Compared with standards, these molecules are identified as annonacin (i.e., *trans*-annonacin) at retention time Rt = 18.9 min (**6**), *cis*-annonacin at Rt = 19.2 min (**7**), and a diastereoisomer such as annonacin-A, which was previously described in the species (**5**, Rt = 17.9 min).[12] The last compound (**8**, Rt = 19.6 min), with the same THF pattern and position, bears a hydroxyl at C-8 ($X_3$ fragment) and corresponds to xylopianin (*Xylopia aromatica*) or one of its stereoisomers (Figures 1 and 2). The four slightly polar AAGs show an $\alpha,\alpha'$-dihydroxy-mono-THF system between carbons C-13 and C-18 (**9**, Rt = 20.2 min; **10**, Rt = 20.4 min; **11**, Rt = 20.7 min; **12**, Rt = 21.0 min), because the $MS^2$ spectra of compounds **9** and **10** exhibit a $B_1 - H_2O$ fragment at $m/z$ 315.2140, whereas the THF position could be established by comparison with the LC-MS profile previously published for *A. muricata* for compounds **11** and **12**.[25] The free hydroxyl position was confirmed at C-10 for compound **11** ($X_3$ fragment). These compounds could correspond to goniothalamicin (**11**), previously isolated from *A. muricata*,[12] and to different diastereoisomers (**9**–**12**; Figure 3).

Ten compounds with formula $C_{35}H_{62}O_6$ are detected in the extracted ion chromatogram at $m/z$ 585.47–585.49 (Figure 2f), with two major peaks (**13**, Rt = 24.2; and **14**, Rt = 24.5 min). The respective $MS^2$ spectra show that these major peaks correspond to subtype 1a AAGs (fragment similar to $X_3$, relative intensity $\leq$ 10%). The detection of typical fragments for the AAG **13** confirms that this compound corresponds to an A-type AAG, with a THF positioned between C-16 and C-19 carbons and flanked by adjacent hydroxyls ($B_1$; $B_1 - 2H$, and $X_2$ fragments). These $B_1$ and $B_1 - 2H$ fragments have a mass difference of 2 amu when compared to compounds **5**–**7** ($C_{35}H_{64}O_6$). A ketone replacing the hydroxyl between the THF and the lactone is a frequent feature among AAGs. Indeed, **13** and **14** respectively match the retention times and the fragments of the standards *trans*- and *cis*-corossolones, isolated from *A. muricata* (Figure 3).[12] Noteworthy, at least eight minor peaks with the same molecular mass are detected with retention times ranging between 19 and 28 min. The low intensity of the $MS^2$ fragment ion peaks did not allow their identification.

The $C_{35}H_{62}O_7$ formula represents one of the major AAGs groups on the chromatogram (intensity $3 \times 10^6$) (Figure 2g). In the extracted ion chromatogram, more than 10 partially coeluted AAGs are detected, corresponding to AAGs of heterogeneous structures (i.e., different types and subtypes), all regrouped by retention time. According to the $MS^2$ spectra, two compounds (**15**, Rt = 20.0; and **16**, Rt = 20.4 min) belong to A-type, with THF between their C-16 and C-19 carbons ($B_1$, $B_1 - 2H$, and $X_2$ fragments) and to subtype 1b ($X_3$ fragment, relative intensity = 100%). The mass difference of 2 amu with the formula $C_{35}H_{64}O_7$ can be attributed to a carbonyl group placed between the THF and the lactone instead of a hydroxyl. These compounds could therefore be annocherin, which is an AAG previously isolated from *A. cherimolia* and bearing a carbonyl at C-10, a favored decoration site as evidenced above and exemplified in the literature, or position isomers (Figure 3).[12]

**Table 1. $[M + Li]^+$ and Characteristic Fragment Ions of the AAGs Identified in the *Annona cherimolia* Alcoholic Beverage**

[a]All AAGs displayed loss of CO (−27.9949 amu) and $CO_2$ (−43.9898 amu). [b]Types: A (mono-THF), B (adjacent bis-THF), C (nonadjacent bis-THF); THP, tetrahydropyranic ring. Subtypes: 1a (unsaturated lactone without OH at C-4), 1b (unsaturated lactone with OH at C-4). Structures of **1**–**31** are depicted in Figure 3.

**B-Type: Adjacent Bis-THF.** Five other AAGs with the same molecular formula are also clearly distinguished in the extracted ion chromatogram of $m/z$ 601.46−601.47 ($C_{35}H_{62}O_7$) (Figure 2g). The $MS^2$ spectra show that three of them are of B-type and subtype 1a (fragment similar to $X_3$, relative intensity < 100%). The $MS^2$ spectra of the two most polar molecules (**17**, Rt = 16.1 min; and **18**, Rt = 16.7 min) showed the characteristic fragments of an adjacent bis-THF moiety between C-14 and C-21 carbons ($B_1$, $B_1$ − 2H, and $B_2$ fragments), with flanking hydroxyl groups (postulated for C-22) (Figure 1) and an additional hydroxyl between the THF and the $CH_3$ terminal part. For example, squamocin-B (*A. squamosa*)[12] corresponds to the structural features of these two compounds. The third AAG is detected at a retention time of 18.2 min (**19**). Its α,α′-dihydroxy-bis-THF system lies between C-13 and C-22 carbons ($B_1$ − 2H and $B_2$ fragments) Its third hydroxyl group is positioned between the lactone and the THF. Compound **19** could therefore be bullacin-B (*A. squamosa*)[12] or a position isomer (Figure 3). Finally, two other AAGs (**20**, Rt = 19.0 min; **21**, Rt = 19.7 min; Figure 2g) are of subtype 1b ($X_3$ fragment, relative intensity = 100%) and of B-type. According to the $MS^2$ spectra, their bis-THF is placed between the C-14 and C-21 carbons ($B_1$ − 2H and $B_2$ fragments). Therefore, they could correspond to molvizarin-1, already obtained from *A. cherimolia*,[12] and/or diastereoisomers (Figure 3). Interestingly, relationships between structures of AAGs and their retention times can be proposed: for the same molecular formula, AAGs of B-type are more polar than that of A-type bearing a ketone. Moreover, the presence of a hydroxyl between the THF and the lactone ring increases the retention times in comparison with a substitution on the methyl-terminal end.

Thirteen $C_{35}H_{62}O_8$ AAGs are detected in the extract (Figure 2h). The three most intense ones are evidenced as being of subtype 1b ($X_4$ fragment, relative intensity = 100%) and of B-type (THF between carbons C-14 and C-21: $B_1$, $B_1$ − $H_2O$, and $B_2$ fragments) (Figures 2h and 3). Two of them (**22**, Rt = 13.1 min; and **23**, Rt = 14.1 min) generate an $X_3$ fragment showing the presence of a fourth hydroxyl group at position C-8. This structure corresponds to that of annonisin, isolated from the species *A. atemoya* (a hybrid of *A. cherimolia* and *A. squamosa*)[12] and/or diastereoisomers (Figure 3). For the third major AAG of this group (**24**, Rt = 14.9 min), the lack of a fragment similar to $X_3$ suggests its free hydroxyl group lies in the methyl-terminal end. To our knowledge, such an AAG was never identified so far, despite a classical substitution pattern.

**C-Type: Nonadjacent Bis-THF.** No C-type AAG in C35 was observed in this study, which is consistent with literature data.

**Atypical C35 AAGs.** The $MS^2$ spectra of the three main peaks at $m/z$ 599.4494 ($C_{35}H_{60}O_7$; **25**, Rt = 21.7 min; **26**, Rt = 22.6 min; **27**, Rt = 23.0 min) were surprisingly different from the other spectra obtained during this study (Figure 2i). Similar compounds were identified in our previous study by LC-LTQ-Orbitrap performed with an *A. muricata* nectar[25] and were attributed, according to their fragmentation pattern, to AAGs bearing a THP ring between the C-4 and C-8 carbons (fragments at $m/z$ 487.3961 and $m/z$ 431.3703, see Table 1 and Supporting Information Figure S1) in addition to an α,α′-dihydroxylated mono-THF in C-15/C-20 ($B_1$ and $B_1$ − 2H fragments) and a ketone between C-6 and C-14 (Figure 3). Compounds **25**−**27**, displaying close retention times and identical $MS^2$ spectra, are proposed to be assigned to montanacin-D

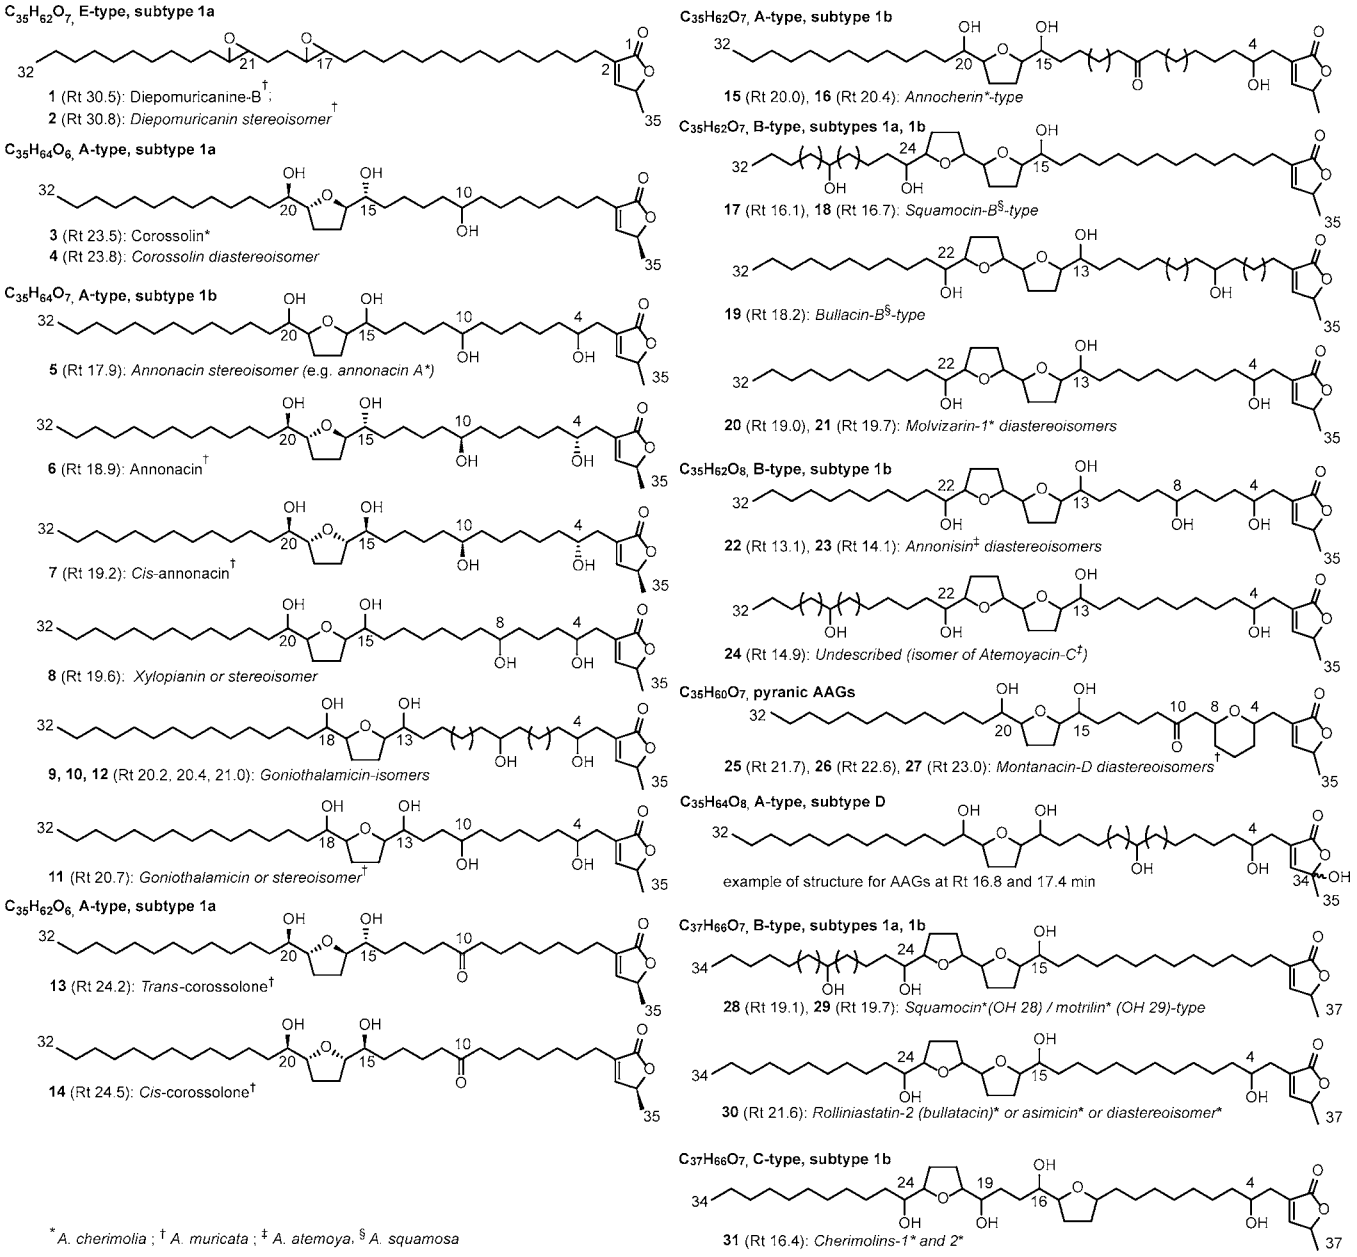

**Figure 3.** Structures of AAGs identified in the *Annona cherimolia* alcoholic beverage. Compounds were previously isolated from (*) *A. cherimolia*, (†) *A. muricata*, (‡) *A. atemoya* (*A. cherimolia* × *A. squamosa*), and (§) *A. squamosa*).

and/or diastereoisomers or position isomers for the carbonyl group (Figures 2i and 3). Interestingly, aromin-A ($C_{35}H_{60}O_7$), an AAG of close structural features except for a THF at C4−C-7, bearing a carbonyl group in C-9, was previously isolated from *A. cherimolia*.[12] The $MS^2$ spectra of minor peaks (Rt < 21 min) did not allow identification of typical fragments of this molecule.

AAGs with the formula $C_{35}H_{64}O_8Li$ are frequently encountered in *Annona* spp. At least eight peaks are detected in the extracted chromatogram of ion $m/z$ 619.44−619.45 (Figure 2j), all showing low intensity. Two original compounds are detected at Rt = 16.8 and 17.4 min. In the $MS^2$ spectra of $m/z$ 619, the cleavage in $\beta$ of the lactone shows a difference of 16 amu from the expected fragment ($C_{29}H_{56}O_5Li$, $m/z$ 491.4271, $\Delta_{m/z}$ = −2.3 ppm), corresponding to a hydroxylated unsaturated lactone, possibly in position C-34 (lactonic type L-D in the classification of Bermejo et al.;[12] Figure 3). Such AAGs are only scarcely distributed, but two ketonic analogues were already described in *A. cherimolia* (annomolons-A and -B, $C_{35}H_{62}O_7$ and $C_{35}H_{62}O_8$, respectively).[12]

Finally, no AAG of formula $C_{35}H_{60}O_8$ was identified so far, whereas at least five matching peaks are detected, as minor compounds (lowest signal intensity, $9.3 \times 10^4$) (Figure 2k). The two main peaks can be distinguished at Rt = 14.3 and 15.3 min in the extracted ion chromatogram. The $MS^2$ spectra show that these AAGs are of subtype 1b, but no other characteristic fragment is observed.

**C37 AAGs.** Extracted ion chromatogram analysis also shows the presence of C37 AAGs in the extract. Their intensities are lower than C35 AAGs (between $10^4$ and $10^6$), and the chromatographic profiles show that they are outnumbered by C35 AAGs. At least 27 C37 AAGs with 7 different formulas were detected here, whereas 13 were isolated from *A. cherimolia* so far. Most of their formulas were retrieved in our analysis

dx.doi.org/10.1021/jf501174j | J. Agric. Food Chem. 2014, 62, 8696−8704

($C_{37}H_{66}O_7$, Rt = 16−24 min; $C_{37}H_{66}O_8$, Rt = 11−20 min; $C_{37}H_{68}O_8$, Rt = 17−19 min). However, AAGs with the formula $C_{37}H_{68}O_8$ were not detected, although several representatives were identified in the species (asimicin, itrabin).[12] The other formulas identified in our analysis were $C_{37}H_{64}O_7$ (Rt = 13−25 min), $C_{37}H_{64}O_8$ (Rt = 13−22 min), $C_{37}H_{66}O_9$ (Rt = 7−14 min), and $C_{37}H_{68}O_9$ (Rt = 8−11 min). Due to numerous coeluting compounds and low ionic intensities, only AAGs with the formulas $C_{37}H_{66}O_7$ and $C_{37}H_{66}O_8$ could be structurally characterized. However, C37 AAGs belonging to E-, A-, and C-types were detected in the other most prominent groups.

**B-Type: Adjacent Bis-THF.** As for C35 AAGs, the C37 AAGs bearing seven oxygen atoms (here with three degrees of unsaturation; $C_{37}H_{66}O_7$) are those with the peaks of the highest intensity ($3.8 \times 10^6$). The extracted ion chromatogram shows at least seven peaks, with the major one at Rt = 19.7 min (**29**) (Figure 2l). The $MS^2$ spectrum of this compound is identical to that of the AAG at Rt = 19.1 min (**28**). Both compounds correspond to AAGs of subtype 1a ($X_4$ fragment, relative intensity <10%) and B-type with a THF located between the C-16 and C-23 carbons ($B_1 - 2H$, $B_2$ and $B_2 - 2H$ fragments). These two molecules are thus similar to motrilin and squamocin, both previously isolated from *A. cherimolia*.[11,12] A third AAG (**30**), detected at Rt = 21.6 min, is also of B-type but belongs to subtype 1b. Its $\alpha,\alpha'$-dihydroxy-bis-THF is located between C-15 and C-24 ($X_4$ fragment, relative intensity = 100%, $B_1 - 2H$, $B_2$). This AAG could possibly correspond to asimicin or rolliniastatin-2, both already isolated from *A. cherimolia*.[11]

**C-Type: Nonadjacent Bis-THF.** In the extracted ion chromatogram of *m/z* 645.45−645.55 ($C_{37}H_{66}O_8$; not shown), a prominent peak at Rt = 16.4 min displays an unusual $MS^2$ spectrum, evidencing an AAG (**31**) of subtype 1b ($X_4$ fragment, relative intensity = 100%), bearing two nonadjacent THF cycles (C-type). The first one is evidenced by a typical $Y_2 - 2H$ fragment indicating its location between C-12 and C-15, with a single hydroxyl flanking group, according to the typical structural features of this group of AAGs. The second one is visible between C-20 and C-23, with adjacent hydroxyl groups ($B_2$ and $B_2 - 2H$ fragments; Figure 1). Compound **31** therefore corresponds to cherimolin-1 or cherimolin-2 (both previously isolated from the species)[12] or to a stereoisomer (Figure 3). However, the presence of minor diastereoisomers of **31** in the extract cannot be excluded.

**Comparison with Literature, Human Exposure to AAGs.** Among the 80 AAGs detected here, the majority are constituted by C35 species. According to the $MS^2$ spectra of resolved or coeluted peaks, approximately 17 AAGs (21%) are of A-type, 17 (21%) of B-type, and 7 (9%) belong to other types. The structure of the THF moiety remains undetermined for 39 (50%) species. With regard to the lactone, 29 AAGs (36%) belong to subtype 1a and 48 (60%) to subtype 1b. Atypical hydroxylation of the lactone, which distinguishes *A. cherimolia* from other *Annona* spp.,[12] was observed. These structural features are in agreement with the compounds isolated from the plant.[11,12,30] The tandem mass spectrometry analyses of the ions corresponding to the major peaks allowed identification of 31 AAGs, of which 8 could be confirmed by comparison with isolated standards. The main AAGs belong to A-type and subtype 1b and have a 13 C alkyl spacer between the lactone and the THF moiety. Bearing these characteristics, annonacin (**6**), the main AAG in the species *A. muricata*, exhibited the most prominent AAG peak in this *A. cherimolia* sample, although it had surprisingly never been firmly identified in the species so far.[30] Given the LOD of our detection method, the amount of annonacin (**6**) per liter of beverage would be >35 ng. This is less than the concentrations measured in samples of *A. muricata* leaf herbal teas.[21] Moreover, this amount is negligible in comparison to the fruit pulps of *A. muricata* and *Asimina triloba*.[17,23,24]

This is the first evidence of the presence of AAGs in a dietary product derived from *A. cherimolia*. These results are not in agreement with our previous study made by MALDI-TOF MS (LOD ~ $1.5 \times 10^{-7}$ M for annonacin), which showed an absence of AAGs in the pulp of the fruit.[21,22,29] This might be due to the lower sensitivity of the method used here. However, this discrepancy could also be attributed to genetic or external factors. Indeed, 5-fold seasonal variations in AAGs content have been measured for the twigs of *Asimina triloba*.[33] Varieties and cultural conditions also are likely to influence secondary metabolites contents. Our previous study on *A. cherimolia* was performed with fruits harvested in southern Spain (Mediterranean climate, 38° N latitude), whereas the fruits used for preparation of the beverage studied here originated from Madeira (tropical climate, 32° N latitude). Nevertheless, a contamination of the beverage with seed fragments cannot be excluded. *A. cherimolia* thus appears as a minor source of exposure to environmental neurotoxins. Its consumption and that of derived products should, however, be considered as a risk factor in surveys about sporadic atypical Parkinsonism and dementia.

**ABSTRACT:** This study aimed at understanding the contribution of the fruit physicochemical parameters to *Musa* sp. diversity and plantain ripening stages. A discriminant analysis was first performed on a collection of 35 *Musa* sp. cultivars, organized in six groups based on the consumption mode (dessert or cooking banana) and the genomic constitution. A principal component analysis reinforced by a logistic regression on plantain cultivars was proposed as an analytical approach to describe the plantain ripening stages. The results of the discriminant analysis showed that edible fraction, peel pH, pulp water content, and pulp total phenolics were among the most contributing attributes for the discrimination of the cultivar groups. With mean values ranging from 65.4 to 247.3 mg of gallic acid equivalents/100 g of fresh weight, the pulp total phenolics strongly differed between interspecific and monospecific cultivars within dessert and nonplantain cooking bananas. The results of the logistic regression revealed that the best models according to fitting parameters involved more than one physicochemical attribute. Interestingly, pulp and peel total phenolic contents contributed in the building up of these models.

**KEYWORDS:** *Musa sp. fruits, physicochemical analysis, total phenolic compounds, ripening stage, discriminant analysis, principal component analysis, logistic regression*

## INTRODUCTION

With a world production of more than 138 million tons in 2010, bananas (*Musa* sp. fruits) are the seventh most important food crop after maize, rice, wheat, potato, soybean, and cassava.[1] Although Asia is the continent of origin of both wild and cultivated *Musa* sp., this crop is now also widely cultivated in Latin America, Caribbean countries, and Africa, where their fruits contribute to food security and socio-economical life. Studies have shown that bananas are good sources of starch, fibers, minerals (potassium, magnesium, phosphorus, manganese), and vitamin $B_6$ for consumers.[2] Furthermore, bananas are a source of natural dietary antioxidants such as carotenoids and phenolic compounds, which exhibit health-promoting effects including antioxidant, anti-inflammatory, antibacterial, and anticancer activities.[3,4] Our recent study revealed that bananas are good sources of phenolic compounds, hydroxycinnamic acids, particularly ferulic acid-hexoside, and flavonol glycosides e.g. rutin dominating in the plantain pulp and peels, respectively.[5] Information about the nutrient composition of bananas is of major importance for breeders and programs of varietal dissemination.

Edible *Musa* sp. are characterized by a large diversity, which constitutes one of the most interesting property for breeders. Several field collections exhibiting *Musa* sp. diversity are hosted in Latin America, India, Asia, and Africa countries where they are managed for breeding.[6] *Musa* sp. genotypes are generally classified according to the consumption mode of the fruits (dessert or cooking bananas) and the constitution of their genome.[7,8] The wild diploid bananas are characterized by the presence of seeds in their pulps and include two main species *Musa acuminata* Colla (AA) and *Musa balbisiana* Colla (BB), which contributed to the major groups of edible bananas. Intra- and interspecific hybridizations between these wild species in nature gave rise to many seedless cultivars whose reproduction occurs by vegetative multiplication (rationing or suckering). These cultivars are diploids or triploids with different genomic constitutions composed of genome A or genomes A and B. According to molecular and cytological studies, most of the edible cultivars have the genomic constitutions AA, AB, AAA, AAB, or ABB.[9,10] Their peels are mostly green at harvest.

[a]Abbreviations: cv, cultivar; ind, undetermined; D, dessert; NPC, nonplantain cooking; PC, plantain cooking. [b]A, B: genomic constitution of *Musa accuminata* and *Musa balbisiana* respectively. [c]French, Horn: agro-morphological character within plantain cooking indicating respectively the presence or the absence of the male bud at harvest.

Central Africa is considered as a secondary center of plantain (a type of cooking banana) diversity harboring a wide range of unique varieties.[11,12] In general, the presence or absence of the male bud at harvest is used to distinguish the two main types of plantain, namely, the French and the Horn plantains, respectively. There is also a wide diversity in fruit peel colors. Somatic mutations are likely to be responsible for the great morphological diversity observed in plantains.[13] Moreover, the breeders undertake crossings between *Musa* varieties including wild species and cultivars. This leads to the creation of hybrids with improved disease resistance such as CRBP 14, CRBP 39, FHIA 17, and FHIA 21, which contribute to the diversity observed in this group.[14]

Due to the large diversity of bananas, there is still a lack of information on the physicochemical characteristics of fruits of numerous varieties. Most of the studies focused on the export dessert banana "Grand Nain" (AAA). Investigations on plantain are often limited to their pulps. For instance, Gibert et al.[15] investigated the difference between dessert and cooking bananas based on some physicochemical characteristics of the

pulp and found that dry matter, edible fraction, pH, total ash, and total sugar can help to differentiate dessert, nonplantain cooking, and plantain cooking bananas. However, more information may emerge if the secondary metabolites as well as the overall physicochemical attributes of the fruit pulp and peel are also taken into account.

Edible *Musa* sp. are also characterized by the ripening process occurring during the storage. During ripening, the fruits undergo physicochemical changes associated with organoleptic and nutritional modifications. These changes have many implications on their uses in food processing. For instance, the quality of plantain banana chips and the functional properties of dessert banana flour vary according to the ripening stage of the raw material.[16−18] In field collections, postharvest characterization of the ripening stages are assessed on dessert and cooking bananas.[19] However, the identification of the fruit ripening stages is currently based on a subjective color scale, which is designated for dessert banana with green peels at harvest.[20] With regard to the large diversity of peel color among plantain cultivars, there is a need to predict the ripening stages of the fruits using quantitative attributes. A study on some physicochemical characteristics of plantain pulp and peel during ripening reported changes in edible fraction, pH, dry matter, and pulp soluble solids.[21] To our best knowledge, no attempt to predict the ripening stage from these postharvest physicochemical characteristics has been reported.

This study proposed multivariate analytical approaches to describe how some postharvest physicochemical characteristics can be used (i) to discriminate groups within the diverse *varieties* of *Musa* sp. and (ii) to predict the ripening stages in plantains.

## MATERIALS AND METHODS

**Plant Material.** The starting plant material consisted of 33 *Musa* genotypes from the germplasm collection of the African Research Centre on banana and plantain (CARBAP) in Njombe in the littoral region of Cameroon at 80 m above the sea level (Table 1).[22] This working collection was organized in six cultivar groups based on their consumption mode, genomic constitution and morphological characters. Each of the three consumption groups, which are dessert, nonplantain cooking, and plantain cooking bananas, were divided in two subgroups. For dessert and nonplantain cooking bananas, monospecific varieties were separated from interspecific varieties. The first group contained only the A genome (A group) whereas the other one was made of varieties containing both the A and B genomes (AB group). For the plantains, the two main phenotypic classes (French and Horn) were separated. In addition, two newly created plantain-like hybrids resistant to the black Sigatoka disease were also part of the study and constituted a separated group. Bunches were harvested at CARBAP in 2010 at physiological maturity according to the protocol described by Tchango, Achard and Ngalani.[23] For each genotype, two to three bunches from different plants were used.

At least 15 fruits were collected from the middle hands of each bunch and allowed to ripe at room temperature in cardboard containers. Dessert and plantain banana ripening stages have been defined on the basis of changes in peel colors according to the scale described by Soltani, Alimardani, and Omid.[20] The four ripening stages 1, 3, 5, and 7 assessed correspond to peel color being all green, greener than yellow, yellow with green ends, and yellow with brown speckles, respectively. For each ripening stage, 3 fruits were removed from the cardboard and weighted. Each fruit was cut on the length and across the width into four quarters. Diagonally opposite quarters were put together to form two groups. For each group, samples from the three fruits were pooled. The pulps and peels of one group were separately freeze-dried, ground, and then vacuum sealed in polypropylene plastic bags. The other group was used for the determination of color, edible fraction, peel thickness, total soluble solids, pH, and total ash content. The freeze-dried samples were transported to the laboratory (Louvain-La-Neuve, Belgium) and kept at −20 °C.

**Chemicals.** Gallic acid and Folin-Ciocalteu reagent (2 N) were purchased from Sigma (St Louis, MO). Pure acetone, glacial acetic acid, and sodium carbonate (purity ≥99.5) were respectively obtained from Prolabo (Fontenay-sous-bois, France), Fisher Scientific (Loughborough, U.K.), and Merck (Darmstadt, Germany).

**Physicochemical Analyses.** *Banana Peel and Pulp Color.* The color of peel and pulp was assessed at different ripening stages by a hand-held color reader (CR-14, Konica Minolta, Japan) displaying the CIE Yxy chromaticity coordinates. The recorded values were then transformed into C (chroma) and L (lightness) color indexes.[24]

*Edible Fraction and Peel Thickness.* Two quarters of each fruit were separately weighted, the peel was then separated from the pulp and weighted. Edible fraction (%) was calculated by dividing the pulp weight by the pulp and peel weight. Peel thickness was measured using a caliper, and the result was expressed in millimeters.

*Total Soluble Solids and pH.* Total soluble solids and pH were determined according to the methods described in the International Network of the Improvement of Banana and Plantain technical guidelines.[19] For each part of the fruit, a mixture of the sample in distilled water (1:3, w: w) was vigorously blended for 2 min. The mixture was filtered using a Whatman no. 1 paper and the refraction index was read using a visual hand-held refractometer. The total soluble solids were expressed in degrees Brix (°Bx). The pH was measured with a benchtop pH meter (Knick, Berlin, Germany).

*2.3.4. Water and Total Ash Contents.* The fresh samples of pulp and peel were separately analyzed for their water and ash contents according to the norms of AFNOR.[25] Water content was determined by oven drying for 24 h at 105 °C. The content of total ash composed of free minerals and mineral salts was determined by calcinating the dried samples at 550 °C during 24 h. The results were expressed in percentage of the fresh sample.

*Total Phenolic Content.* For each freeze-dried banana peel and pulp sample, 0.5 g were extracted with 10 mL of acetone/water/acetic acid (50:49:1). The mixture was vortexed for 1 min. and the extraction was carried out in a water bath under agitation at 40 °C for 1 h. The extract was centrifuged at 5000*g* for 20 min at 4 °C. The colorimetric method[26] for total phenolic content determination was then used as a measure of the reducing capacity of the sample.[27] For the calibration curve, 5 concentrations were prepared from a stock solution of gallic acid. The results were expressed in milligrams gallic acid equivalents (GAE)/100 g of fresh weight (FW).

**Statistical Analysis.** The statistical analysis of the data was performed by the JMP9.0 statistical discovery software from SAS and SAS entreprise guide 4.3.

*Discriminant Analysis.* A linear discriminant analysis[28] was performed to (i) compare the physicochemical profile of the six cultivar groups, and to (ii) assign each new hybrid fruit to one of the groups. To compare cultivar groups, the software displayed the scatterplot of the *Musa* sp. fruit scores and the loading plot of the physicochemical attributes. The loading plot reflected the relative contribution of physicochemical attributes to the separation of the groups. In order to identify to which cultivar group a new hybrid fruit sample is closest, classification functions were created for each group in the form

$$F = b_1x_1 + b_2x_2 + \ldots + b_nx_n + c \quad (1)$$

Each of the six classification functions were evaluated with the physicochemical attributes ($x$) of the hybrid fruit sample. This later was assigned to the group whose classification function yielded the highest value.

*Logistic Regression.* In order to predict the ripening stage of plantain cultivars according to physicochemical attributes, an ordinal logistic regression was performed. The ripening stage was considered as an ordinal response with 4 modalities. For each ripening stage, the software gave the cumulative logit($j$), which is the logarithmic function of the ratio between the cumulative probability $P(y \leq j)$ that a plantain

sample "$y$" is at a level less or equal to a given ripening stage "$j$" with $j$ = 1, 3, 5, or 7 and the probability that it is not $(1 - P(y \leq j))$. Its formula as adapted from Gillet, Brosteaux, and Palm[29] is written as follows:

$$\text{Logit}(j) = \ln \frac{P(y \leq j)}{1 - P(y \leq j)} = \beta_0 + \beta_1 X_1 + \beta_2 X_2 + \cdots + \beta_p X_p \quad (2)$$

In eq 2, $\beta_0$ is the constant, each of the $\beta_{(1\rightarrow p)}$ values stands for the coefficients related to each X physicochemical attribute. The model gives the coefficients for the first three ripening stages, the last one being used as the reference in the statistical procedure. The models were evaluated by the $R^2$ and the corrected Akaike information criterion (AICc), which measures the fit of the model.[30] Twelve plantain genotypes with a green peel color at stage 1 were used to build the models. Only models explaining at least 70% of the variability are presented. Three plantain genotypes (two with three biological replicates and one with two biological replicates) with green peel with chestnut pigments at stage 1 were used to investigate the abilities of the models to predict the ripening stages. To predict the ripening stage of a plantain sample $y$, the probability $P(y = j)$ for this sample to be at a ripening stage $j$ is estimated for each ripening stage and the sample is considered to be at the ripening stage that has the highest probability. For that, the cumulative probability $P(y \leq j)$ formula is first deduced from eq 2 as follows:

$$P(y \leq j) = \frac{e^{\text{logit}(j)}}{1 + e^{\text{logit}(j)}} \quad (3)$$

Cumulative probabilities are then calculated for ripening stages 1, 3, and 5 and probabilities $P(y = j)$ are deduced as follows:

$$P(y = 1) = P(y \leq 1) \quad (4)$$

$$P(y = 3) = P(y \leq 3) - P(y \leq 1) \quad (5)$$

$$P(y = 5) = P(y \leq 5) - P(y \leq 3) \quad (6)$$

$$P(y = 7) = 1 - P(y \leq 5) \quad (7)$$

## RESULTS AND DISCUSSION

**Physicochemical Composition of Cultivar Groups at Harvest.** *General Description.* Tables 2 and 3 present the results of the physicochemical composition of the seven groups of *Musa* sp. fruits. At harvest, the fruits were at the ripening stage 1.

Most of the physicochemical attributes studied varied according to the cultivar groups. Significant differences were observed for pulp color indexes L and C (chroma and lightness), edible fraction, peel thickness, pulp water content, pulp total soluble solids, pulp pH, and pulp total phenolic compounds. As regard the comparison between pulp and peel, the physicochemical attribute values were different except for total soluble solids and pH. The observations about the L index being lower in peel and the water content being higher in peel were also reported in the literature for dessert bananas.[31,32] The data showing that the total phenolic compounds were (1.5 to 2 times) higher in peel than in pulp also matched with a report published on total phenolic compounds in Malaysian bananas.[33]

Among the dessert bananas, the cultivar Yangambi km5 presented the highest content of pulp total phenolic compounds (306.4 mg GAE/100 g FW). The contents obtained for A dessert banana pulps were higher than the contents reported for the dessert banana Pisang Mas (35.9−72.2 mg GAE/100 g FW) by Alothman, Bhat, and Karim.[34] Peel total phenolic compound contents of A dessert bananas (252.1−383.5 mg GAE/100 g FW) were similar to those of the export dessert banana Grand Nain at a ripe stage (2.6−3.1 g GAE/100g dry weight ∼260−310 mg/100g FW) reported by González-Montelongo, Gloria Lobo, and González.[35] Surprisingly, the cultivar Pelipita from the AB nonplantain cooking banana group showed the highest pulp total phenolic compound values (319.5 ± 70.4 GAE/100 g FW) within our banana collection. A drastically lower value was reported by Ngoh Newilah et al.[36] for this genotype (46 μg GAE/100 g dry weight ∼0.02 mg GAE/100 g FW). This low value might have resulted from the fact that the samples were dried in oven, which might have provoked phenolic compound oxidation. The highest pulp total phenolic compound values of plantains were obtained for the French plantain Niangafelo (198.4 ± 28.9 mg GAE/100 g FW) and the Horn plantain Moto Ebanga (182.1 ± 27.4 mg GAE/100 g FW). These results show that bananas and plantains could be as important sources of phenolic compounds as other vegetables such as potato (3950 μg GAE/g dry weight ∼90.85 mg GAE/100 g FW),[37] bitter melon (143.6 ± 8.4 mg GAE/100 g FW), and beetroot (257.2 ± 0.7 mg GAE/100 g FW).[38]

*Discriminant Analysis.* A linear discriminant analysis was performed to point out the most relevant physicochemical attributes contributing to the differentiation between cultivar groups. Furthermore, this approach was also intended to help allocating each of the two new hybrids to one of the cultivar groups.

Figure 1 presents the scatterplot of the standardized discriminant scores (A) and the corresponding standardized scoring coefficients of the physicochemical attributes or loading plot (B). The 2 first discriminant functions (1 and 2) explain 79.23% of the variation between groups. These 2 first discriminant functions were found to be highly significant ($P$ < 0.0001). The matrix generated by the software indicated that the number of samples correctly classified in the groups accounted for 92.6% of the samples involved in this analysis. The scatterplot shows that the dessert banana groups are separated from the cooking banana groups along the function 1 axis. On this axis, peel pH, pulp water content, edible fraction and fruit mass have the higher scoring coefficients in absolute terms, meaning that they were mostly responsible for this differentiation. The two groups of dessert bananas (A and AB) are separated according to function 2 axis, where pulp total phenolic compounds have the highest scoring coefficient. Pulp total phenolic compounds appear therefore to have highly contributed to the differentiation between the dessert bananas containing only the A genome (247.3 ± 76.3 mg/100 g FW) and those containing both A and B genomes (103.7 ± 33.2 mg/100 g FW). The nonplantain cooking bananas also split on the second axis: the A nonplantain cooking group has considerably higher scores on the second axis than the AB nonplantain cooking group. Furthermore, the AB nonplantain cooking group partly overlaps with the French and Horn plantain cooking groups, suggesting close physicochemical characteristics.

The comparison of the loading and the score plots of Figure 1 indicates that dessert bananas had the highest values of peel pH, edible fraction, and pulp water content whereas AB nonplantain cooking bananas and plantain cooking bananas had the lowest values for these attributes. It also appears that AB dessert bananas had the highest edible fraction values and A dessert bananas had the highest pulp water content values. The fact that the pulp water content mean value of the A dessert

Table 2. Physicochemical Characteristics (L and C Indexes, Fruit Mass, Edible Fraction, Peel Thickness, and Water Content) of *Musa* sp. Fruits at Harvest[#]

[#]See Table 1 for the significance of the group names. FW: fresh weight. For each cultivar, the value is the mean of two (standard deviation not shown) to three biological replicates, each in duplicate. Superscript a, b, and c result from the comparison of groups using Tukey's test. Groups connected by the same letter are not significantly different.

[#]FW: fresh weight. For each cultivar, the value is the mean of two (standard deviation not shown) to three biological replicates, each in duplicate. Superscript a, b, and c result from the comparison of groups using Tukey's test. Groups connected by the same letter are not significantly different.

bananas (74. Two ±1.1% FW) was higher than those of the plantain cooking bananas (61.4 ± 1.9% FW and 60.8% ± 1.4 FW for French plantain and Horn plantain cooking bananas, respectively) Table 2 is in agreement with the results obtained by Gibert et al.[15] According to the direction of the fruit mass vector, AB nonplantain and plantain cooking banana groups had the heaviest fruits. In addition, the highest mean value of pulp total phenolic compounds was observed for the A dessert banana group (247.3 ± 76.3 mg/100 g FW) whereas the lowest mean value was registered for the A nonplantain cooking banana group (65.4 ± 23 mg GAE/100 g FW).

Interestingly, this study shows that the content in pulp total phenolic compounds is one of the most important attributes, which has made the difference between both genomic constitutions (A and AB) within nonplantain cooking bananas and within dessert bananas.

Table 4 presents the nonstandardized coefficients of the estimated classification functions for the six cultivar groups. The two hybrid banana plant under investigation can then be classified by simply multiplying the values of the physicochemical attributes of their fruits with these coefficients and then taking the sum. Table 5 shows the results obtained for the three

plants of each of these two hybrids. It can be observed that the highest values correspond to AB nonplantain cooking (NPC-AB) and French plantain cooking groups (PC-French), which means that the hybrids appear closer to those groups. Interestingly, the two hybrids had in their family tree, monospecific (AA) and interspecific (AB) cooking bananas. In fact, their parents are also hybrids, obtained following two different crossings, one between the A nonplantain cooking banana Tomolo (AA) and the A cooking hybrid Crbp060 (AA), and another between the French plantain cooking banana Red Yade (AAB) and the wild species Calcutta 4 (AA) (which was shown to be close to the A dessert banana group, data not shown). This shows that the interspecific cooking banana physicochemical characters were dominant. However, for the hybrid F568, the plants nos. 1 and 2 also appear to be close to the A dessert group (D-A) and to the A nonplantain cooking group (NPC-A), respectively.

**Physicochemical Changes during the Ripening Process of Plantains.** *Description.* In order to study the evolution of the physicochemical attributes of plantains during ripening, we performed a principal component analysis on three cultivars, namely Mbeta 1, Red Yade, and 3/4 Nain. Stages 1, 3, 5, and 7 were evaluated. The results are presented as a scatterplot of the scores of the different ripening stages, and a loading plot of the attributes (Figure 2).

On the scatterplot, four clusters corresponding to each ripening stage can be observed. The four groups are separated along the principal component 1 (PC1) axis in an ascending order from the left to the right (Figure 2A). A simultaneous analysis of the vector positions of the attributes in the loading plots (Figure 2B) shows that the physicochemical attributes are distributed in three groups. Two of them are correlated with the ripening stage and negatively correlated with each other. The first group is positively correlated with the ripening stage and includes pulp and peel total soluble solids, peel total ash content, edible fraction and pulp C index, suggesting that these parameters increased during the ripening. Peel total phenolic compounds, pulp water content, pulp total ash content, and peel pH also appear positively correlated with the ripening stage but to a lesser extent. The second group consists of peel thickness, peel water content, pulp L index, and pulp pH, which are, on the other hand, negatively correlated with the ripening stage. The third group including peel C and peel L indexes and to a lesser extent pulp total phenolic compounds separated the ripening stage group 5 from the other ripening stage groups on the PC2 axis. This suggests that the values of these three attributes reached a maximum at stage 5 and then decreased.

Peel and pulp color changes associated with the ripening process could be described by the evolution of L and C indexes. The increase of peel lightness and chroma to a maximum level at stage 5 could express the change from the green color to the yellow color due to the chlorophyll degradation and the accumulation of carotenoids.[39] Their subsequent decrease could be related to the apparition of black spots that might involve enzymatic browning due to the activity of the polyphenol oxidase and of other oxidative enzymes.[39,40] In pulp, the decrease of lightness and the increase of chroma reflect the decrease of whiteness and the increase of the color intensity.

Changes in fruit firmness can be considered as another means by which the ripening is perceived. Fruit firmness was not measured in this study but it has been reported that the softening of the fruit results from the disruption of cell walls and the hydrolysis of starch under the actions of amylase and other enzymes.[39] In general terms, the ripening process in the pulp results in the release of water-soluble solids, which include proteins, minerals, and predominantly soluble sugars from the starch hydrolysis and are evaluated by the total soluble solid measurement. The subsequent osmotic transfer of water from the peel into the pulp may have resulted in the increase of pulp water content and pulp edible fraction.[41,42] A transfer of water and other volatile compounds (carbon dioxide, ethylene, and aroma) from the peel to the environment[31] has probably also contributed to the decrease of peel water content and peel thickness. The decrease of peel water content might have resulted in the increase of the peel total ash concentration.

A decrease of pulp pH was registered upon ripening, which fits with an increase of acidic taste. The pH decrease is believed

Each observation represents one biological replicate of a cultivar, at one ripening stage. [d]Number of samples collected at each ripening stage according to the color scale.

to be associated with the accumulation of some organic acids such as malic acid.[43]

Pulp total phenolic compounds increased up to the ripening stage 5 and then decreased, whereas peel total phenolic compounds increased throughout the ripening process. This suggests a tissue specific regulation of the ripening process as mentioned by Bruno Bonnet et al.[44] and Inaba et al.[45] for *Musa* species. A different result was found by Ngoh Newilah et al.,[36] who obtained an increase in pulp total phenolic compounds of plantains from stage 1 to stage 7. During the ripening, it is generally reported that anthocyanin-rich fruits increase their content in total phenolic compounds, whereas many other fruits have their total phenolic compounds decreasing.[46]

The observed separation of the ripening stage groups suggests that, whatever the cultivar, a ripening stage could be characterized by a certain behavior of same physicochemical attributes. Under this hypothesis and considering the great importance of the identification of the ripening stage in food processing, physicochemical attributes were used to model the ripening stages.

*Modeling the Ripening Stages Using Logistic Regression.* Table 6 presents the proposed prediction equations in the form of the cumulative logit function as explained in the Materials and Methods section. The ability of those models to predict the ripening stages of three plantain genotypes are also presented. The number of well classified plantain samples over the total sample investigated at each ripening stage is reported. Each model presents the cumulative logit of each of the 3 first ripening stages, which have different constant values but the same coefficient per attribute. Lower AICc values indicate better fittings.

For each model, the involved attribute coefficients were found to be significant ($P < 0.05$) according to the likelihood-ratio $\chi$-square test. When performing stepwise regression control in the forward direction, pulp total soluble solids was the first attribute selected by the software and model 1 was proposed. This indicates that its contribution to the ripening was the most important. When the stepwise process ended, pulp pH, peel total ash content and peel C index were additionally selected. Model 2 was then proposed as the best model and was used as a reference. Its $R^2$ and AICc values were 0.92 and 38.78, respectively (Table 6).

We investigated many combinations of attributes to find other models with fitting parameters and prediction abilities similar to those of the reference model (model 2). Models 3 and 4 were found to be among the best. They had lower $R^2$ values (0.81 and 0.82, respectively) and higher AICc values (70.50 and 70.45, respectively) than model 2 but their

prediction abilities were close to those of model 2. They may offer an alternative when there is a lack of material needed to assess some attributes involved in model 2. Model 6, involving edible fraction, pulp pH, and pulp total phenolic compounds, had good fitting parameters when compared to models 3 and 4, and its prediction ability was almost similar to those of the model 1. Models 1 and 6 had acceptable prediction abilities up to stage 5 but were not effective to make the difference between stages 5 and 7.

All the models had ripening stage predictions below 100%. This supports the fact that the monitoring of the ripening stage based on the color scale and using a subjective assessment might lead to wrong classifications. Applying a model as a ripening stage control method, which uses objective parameters can increase the homogeneity within a ripening stage group and could be therefore relevant. Moreover, it is worth noting that the best models involved more than one physicochemical attribute, which stresses the importance of considering diverse attributes in the determination of the ripening stage of plantain.

## CONCLUSIONS

We aimed at investigating the involvement of some *Musa* sp. fruit postharvest physicochemical characteristics in the differentiation between diverse *Musa* sp. cultivars, as well as in the prediction of the plantain ripening stages. The discriminant analysis highlighted the importance of the edible fraction, the peel pH, the pulp water content, and the pulp total phenolic compounds in the distinction between cultivar groups at ripening stage 1. The great contribution of the pulp total phenolic compounds in the differentiation between interspecific and intraspecific groups within the dessert bananas and the nonplantain cooking bananas called for a deeper understanding of the specific phenolic composition. The physicochemical attributes considered in the present study did however not allow differentiating French and Horn plantain cooking bananas. They also showed that interspecific nonplantain cooking bananas are very close to plantain cooking bananas. The hybrids seemed to have physicochemical characteristics close to those of interspecific cooking bananas. This result seems to meet the breeder expectations who created these hybrids to be like plantain. It also emerged from this study that the use of logistic regression could be successfully applied in the control of the fruit ripening stages. The involvement of pulp total phenolic compounds in the model that had good evaluations according to $R^2$ and AICc criterion aroused the interest for monitoring the phenolic compound profiles during the ripening process. These results allow to consider applying the proposed analytical approaches to a whole collection such as that of the CARBAP. The genomic constitution in its entirety (ploidy level and composition in A and B genomes) will be thus taken into account for the characterization of *Musa* cultivars. This broadening of samples will also enhance the search of the ripening stage prediction models easily applicable to a wide range of cultivars.

# Influence of California-Style Black Ripe Olive Processing on the Formation of Acrylamide

Suthawan Charoenprasert and Alyson Mitchell*

Department of Food Science and Technology, University of California, Davis, California 95616, United States

**ABSTRACT:** Methods used in processing California-style black ripe olives generate acrylamide. California-style black ripe olives contain higher levels of acrylamide (409.67 ± 42.60−511.91 ± 34.08 $\mu$g kg$^{-1}$) as compared to California-style green ripe olives (44.02 ± 3.55−105.79 ± 22.01 $\mu$g kg$^{-1}$), Greek olives (<1.42 $\mu$g kg$^{-1}$), and Spanish olives (not detected), indicating that the higher temperatures used to sterilize the California-style green ripe and black ripe olives are required for acrylamide formation. Preprocessing brine storage influenced the formation of acrylamide in a time-dependent manner. Acrylamide increased during the first 30 days of storage. Longer brine storage times (>30 days) result in lower acrylamide levels in the finished product. The presence of calcium ions in the preprocessing brining solution results in higher levels of acrylamide in finished products. Air oxidation during lye processing and the neutralization of olives prior to sterilization significantly increase the formation of acrylamide in the finished products. Conversely, lye-processing decreases the levels of acrylamide in the final product. These results indicate that specific steps in the California-style black ripe olive processing may be manipulated to mitigate the formation of acrylamide in finished products.

**KEYWORDS:** *olive, Olea europaea, acrylamide, California-style black ripe olives*
